(*d*) Taking into account that (*i*) the solvent seems to affect complex stability mainly through its own solvating ability (see point *b* above), (*ii*) the concept of donor number (DN, which is defined (14) as $-\Delta H^0$ of association in an inert medium between the solvent molecule and $SbCl_5$ reference acceptor) was shown to be useful as a measure of solvating abilities of donor solvents; the conclusion can be drawn that, among all the properties proposed previously to justify the solvent influence on complex stability (i.e., polarity, dielectric constant, donor number, autoprotolysis constant, hydrogen-bond forming ability), donor number is probably the most important. At the same time ΔG^x_{non} (which was demonstrated to be determinant on the ΔG^x sequence, see point *a* above) is equal to ΔH_{non}, being zero the corresponding entropy contribution (1). Therefore, it results from the present discussion that the influence of the solvent on complex stability is due to solute–solvent enthalpy factors. Taking into account the above definition of donor number, the equivalence of the two concepts becomes evident.

(*e*) Donor number does not always seem sufficient to justify experimental data of stability. Inadequacy of DN can be summarized in the following points. (*i*) Steric properties of solvents are not taken into account by DN, as it refers to the reaction of only one molecule of solvent with one molecule of $SbCl_5$ (14). In reality, when solute particles are surrounded by the solvent, bulk properties of the latter are important in determining the number and strength of solute–solvent bonds

and, consequently, the actual solvating properties of the solvent. (*ii*) For reasons similar to the preceding ones, DN does not consider the highly ordered structure of certain solvents. Water is a typical example of this fact. Taking into account that a DN of 18.0 is usually assigned to water and of 19.0 to organic solvents such as methanol and dioxane (15), the conclusion should be drawn that the latter have a slightly higher capacity than water for opposing metal–ligand complex formation. But for the most part the experimental data are in contrast with this conclusion (see, as an example, the ΔG^x values of Table 1). To eliminate this inconsistency, a DN value referring to the bulk donation properties of water is used by some authors (16), the magnitude of which is far greater than 18.0. (*iii*) Inert media in which the reaction enthalpy of the solvent with $SbCl_5$ may be measured correctly appear difficult to find. Dichloroethylene, which is the usual medium, shows unusual solvating properties which can affect experimental enthalpies. $SbCl_5$ too was shown, in some cases, to be a poor reference acid for the quantitative determination of donor strength (17). (*iv*) Since DN is a conventional ΔH^0, it may be affected, in addition to short-range factors, by external electrostatic factors too. The latter have no relationship with solvation bonds (7), so they could have an undue influence on DN.

The problem of evaluation of solvating properties could be treated in a more correct way by using the nonelectrostatic part of enthalpy instead of conventional ΔH^0. Let us for instance consider an association reaction $M + L \rightleftarrows ML$ in the solvent S_1 and in another solvent S_2 taken as reference. In accord with the present discussion and previous considerations (7), ΔH_{non} for this reaction may be considered as determined by two main factors: covalent interactions between M and L [ΔH(M–L)] and solvating bonds [ΔH(solv.)]. The former are equal in both solvents, while the latter are different. Consequently the difference of ΔH_{non} for this reaction in the two solvents may be indicated as follows:

$$[1] \quad (\Delta H_{non})_{S_1} - (\Delta H_{non})_{S_2} = [\Delta H(\text{solv.})]_{S_1} - [\Delta H(\text{solv.})]_{S_2}$$

The quantity at the left-hand side of eq. [1] has the same enthalpy nature as usual DN but, unlike DN, is not affected by external electrostatic factors. Moreover, as it refers to the real case of a solute surrounded by solvent molecules, it seems to eliminate the above mentioned disadvantages of usual DN. Therefore the concept of ΔH_{non}, at least in principle, could give an improved means, other than the usual DN, to measure solvating abilities of solvents.

(*f*) ΔH_{el} and ΔS_{el} of Table 1 are generally positive. This fact is usually due to the prevalence of solvent-destructuring processes over other processes, such as the formation of solute–solute bonds (which should give exothermic values of enthalpy). It may also be observed that ΔH_{el} and ΔS_{el}, few cases excepted, become more positive (i.e., solvent-destructuring processes increase) with increasing amounts of organic cosolvent. This fact may be justified, at least for heteroelectric associations, considering that the solvent, before the association reaction, is ordered by the electric field of ions. While the polar structure of water remains ordered after the association too, other solvents such as dioxane and alcohols become less ordered (4). Therefore, a greater increase of disorder is expected in the association as the quantity of the organic cosolvent increases.

Measurement of some primary nuclear interferences in neutron activation analysis with a SLOWPOKE reactor

G. KENNEDY, J.-L. GALINIER, AND L. ZIKOVSKY
École Polytechnique, Montréal, Que., Canada H3C 3A7

Received April 15, 1985[1]

G. KENNEDY, J.-L. GALINIER, and L. ZIKOVSKY. Can. J. Chem. **64**, 790 (1986).

The interference factors were measured for 21 cases where the (n, p) and (n, α) reactions induced by fast neutrons produce the same radioisotopes as those used in the determination of F, Na, Mg, Al, S, Sc, Ti, V, Cr, Mn, Co, Ni, Cu, Ga, and As. The measured factors are compared with those calculated from data found in the literature.

G. KENNEDY, J.-L. GALINIER et L. ZIKOVSKY. Can. J. Chem. **64**, 790 (1986).

On a mesuré les facteurs d'interférence dans 21 cas pour lesquels les réactions (n, p) et (n, α) induites par des neutrons rapides produisent les mêmes radioisotopes que ceux utilisés lors de la détermination des éléments suivants: F, Na, Mg, Al, S, Sc, Ti, V, Cr, Mn, Co, Ni, Cu, Ga et As. On a comparé les facteurs mesurés avec ceux calculés sur la base des données que l'on peut retrouver dans la littérature.

[Traduit par la revue]

Introduction

In neutron activation analysis using reactors as a neutron source, it is usually assumed that each radioisotope detected is produced by the (n, γ) reaction on a stable isotope of the same element; however, in most irradiation sites, there is a significant component of fast neutrons which may produce the radioisotope of interest by (n, p) and (n, α) reactions on heavier elements. The analyst must be aware of which elements may be affected by these nuclear interferences and he may be able to correct them using an "interference factor" if the interfering element is also analysed.

In the case of the Canadian SLOWPOKE II reactor where the inner irradiation sites are located in the beryllium reflector, the fast neutron spectrum includes a component due to the (γ, n) reaction on beryllium as well as the fission neutrons. Using several (n, p) and (n, α) reactions of well-known cross section, this fast neutron flux has been determined (1) to be 0.21×10^{12} neutrons $cm^{-2} s^{-1}$ when the thermal neutron flux in these sites is 1.0×10^{12} neutrons $cm^{-2} s^{-1}$. With this significant fast neutron flux, it is estimated that the interferences from (n, p) and (n, α) reactions may be important for about 15 low- and medium-Z elements which are often analysed. The aim of this paper is to measure the "interference factors" for these elements with sufficient accuracy that they may be used to correct the interferences.

Several researchers have reported interference factors measured for interferences which occur with the analysis of sodium (2), aluminum (3, 4), sulfur (5), scandium (2), chromium (6), manganese (2, 5, 7), cobalt (2, 3, 7), and nickel (7). When the same factors were measured in several laboratories, the values measured varied by as much as several orders of magnitude, because of the widely varying ratios of fast to thermal neutron fluxes in the different reactors and irradiation sites used.

As a first approximation, the interference factors may be calculated using thermal neutron and fission neutron cross sections found in the literature as outlined by De Soete *et al.* (8). However, in a SLOWPOKE reactor the interference factors may be significantly different because of the influence of the beryllium reflector and other reactor components on the fast neutron spectrum. All the SLOWPOKE reactors currently in operation are of identical construction (including fuel, moderator, and reflector) and should, therefore, have identical neutron spectra. Any slight differences in the neutron spectra among these reactors would first be noticed as differences in the ratio of fast neutron flux to slow neutron flux. In the three reactors surveyed (1, 9)[2] this ratio has been measured as 0.21, 0.22, and 0.19, respectively, using various reactions for fast and thermal neutrons. These ratios appear to agree if one considers the uncertainties involved in their measurement. In addition, at the Montréal SLOWPOKE reactor this ratio was found to be constant, within the experimental error of 5%, over a period of seven years despite aging of the fuel and additions to the beryllium reflector. Thus, it is felt that a set of interference factors measured accurately with one SLOWPOKE II reactor will provide the data necessary for the accurate and reliable corrections of these interferences by analysts using any of the SLOWPOKE II reactors.

Experimental

In the analysis of an element with a given Z, the interference factor F for the (n, p) reaction is the weight, in micrograms, of element $(Z + 1)$ which produces the same activity of the radioisotope used for analysis as 1 μg of element Z via the (n, γ) reaction. For the (n, α) reaction, F is the weight of element $(Z + 2)$ which produces the same activity as 1 μg of element Z. Thus, the smaller the interference factor, the more severe is the interference.

The first step in determining the interference factors was to measure the activity produced by the (n, γ) reaction for each element under study. Known amounts of each element were sealed in 1.4 mL polyethylene vials and irradiated in an inner irradiation site and each was counted with a Ge(Li) detector in order to measure the area of the γ-ray peak per microgram of element. Elements $(Z + 1)$ or $(Z + 2)$ were irradiated in a similar manner to produce the same radioisotope by the (n, p) or (n, α) reaction. The peak area per microgram of interfering element was thus determined and the comparison with the peak area per microgram measured for element Z gives the interference factor.

The main difficulty in these measurements is that very small amounts of element Z in the standards of elements $(Z + 1)$ and $(Z + 2)$ produce a significant amount of the radioisotope under study since the (n, γ) cross sections are generally much larger than the (n, p) or (n, α) cross sections. In order to reduce this effect, only the purest compounds available were used for the standards of elements $(Z + 1)$ or $(Z + 2)$. In addition, all irradiations of elements $(Z + 1)$ or $(Z + 2)$ were performed with cadmium covers as well as in the normal manner. The presence of

element Z in these standards was indicated by a higher peak area from the sample irradiated without cadmium cover.

Results and discussion

The measured interference factors are presented in Table 1. For $^{54}Cr(n, \alpha)^{51}Ti$, no ^{51}Ti activity was observed even with the irradiation under cadmium cover because of the more intense ^{51}Cr activity produced by the (n, γ) reaction on chromium. Thus, for this case, only a lower limit for the interference factor is given. For $^{59}Co(n, \alpha)^{56}Mn$ and $^{72}Ge(n, p)^{72}Ga$, the ^{56}Mn and ^{72}Ga activities were measurable only with the irradiation performed under cadmium cover. Thus, in these two cases, a part of the measured activity may be due to $^{55}Mn(n, \gamma)^{56}Mn$ and $^{71}Ga(n, \gamma)^{72}Ga$, respectively. For this reason, no experimental uncertainty is given with these interference factors, and the true interference factors may be higher than the values given in Table 1 for these two cases. For the other 18 cases, the uncertainty given includes the measurement error in the activities produced by both the (n, γ) and the (n, p) or (n, α) reactions.

Also shown in Table 1 are the interference factors calculated (8) using published cross sections. For the (n, p) interferences they were calculated with the formula

$$[1] \quad F = \frac{\theta_Z(\sigma_\gamma + 0.06R_\gamma)M_{Z+1}}{0.21\theta_{Z+1}\sigma_p M_Z}$$

where θ is the isotopic abundance, σ_γ the thermal-neutron (n, γ) cross section, R_γ the resonance integral including the $1/v$ contribution (8), M the atomic mass, and σ_p the (n, p) cross section for fission neutrons. For (n, α) interferences. σ_p is of course replaced by σ_α, the (n, α) cross section, and M_{Z+1} and θ_{Z+1} by M_{Z+2} and θ_{Z+2}. The term $0.06R_\gamma$ is included because the neutron flux has been measured to have a 6% component of epithermal neutrons. The factor 0.21 accounts for the previously mentioned 21% component of fast neutrons. The values of θ, M, σ_γ, and R_γ were taken from the Chart of the nuclides (10) and the recommended values of σ_p and σ_α from the Handbook on nuclear activation cross sections (11). For $^{40}Ar(n, \alpha)^{37}S$, $^{54}Cr(n, \alpha)^{51}Ti$, and $^{76}Se(n, p)^{76}As$ no measured cross sections were available. In these three cases, values extrapolated by Calamand (11) from cross-section systematics were used. The uncertainties listed with the calculated interference factors are those of the σ_p or σ_α cross sections since all the other factors in eq. [1] are known with much greater accuracy than these cross sections. All these data are shown in Table 2.

For 12 of the interferences listed in Table 1, the interference factors have been calculated (12) for the Halifax SLOWPOKE reactor whose construction is identical to the one used here. In general, their calculated values agree well with the values calculated in this work, which is to be expected since the two reactors have similar fast-to-thermal neutron-flux ratios (1, 9).

As can be seen from Table 1, there is generally very good agreement between the interference factors measured here and those calculated from measured cross sections found in the literature. This would lead us to believe that the component of the neutron spectrum due to the (γ, n) reaction on the beryllium of the reflector does not alter significantly the relative reaction rates for the (n, p) and (n, α) reactions on the elements studied in this work. But in the cases $^{37}Cl(n, p)^{37}S$, $^{51}V(n, p)^{51}Ti$, $^{54}Fe(n, \alpha)^{51}Cr$, $^{66}Zn(n, p)^{66}Cu$, and $^{76}Se(n, p)^{76}As$, the differences between the measured and calculated interference factors are significant. There are several possible reasons for these differences. In the first four cases it is possible that the (n, p) and (n, α) cross sections used in calculating the interference factors

TABLE 2. Nuclear data used in calculations of interferences factors

Ga	Ge	40.0	69.7	4.70	31	27.5	72.6	0.022±0.006
As	Se	100	74.9	4.40	61	9	79.0	0.63±0.32

are erroneous since they are based on a single measurement which is not corroborated by other data. If the $^{67}Zn(n, d)^{66}Cu$ and $^{77}Se(n, d)^{76}As$ cross sections are high enough, this mode of production may be the reason why the measured interference factors are lower than those calculated from the (n, p) cross sections. Thus, in the five cases where a significant disagreement exists between the measured and the calculated interference factors, we prefer the present measurements because they are based on several individual determinations.

We recommend that the measured interference factors in Table 1 be used in the following manner. The sample is analysed for the element of interest and the interfering element, and the concentration of the interfering element is divided by the interference factor to yield the amount to be subtracted from the measured concentration of the element of interest. The accuracy of the corrected result thus depends on the accuracy of the determination of the interfering element and the uncertainty in the interference factor listed in Table 1. For $^{54}Cr(n, \alpha)^{51}Ti$, $^{59}Co(n, \alpha)^{56}Mn$, and $^{72}Ge(n, p)^{72}Ga$, for which only lower limits of the interference factors have been determined, the interferences will usually be negligible; their magnitude may be estimated from the calculated interference factors.

Conclusions

It is important to take into account interferences from (n, p) and (n, α) reactions in neutron activation analysis with reactors where the neutron flux has a significant fraction of fast neutrons. The interference factors measured in the present work make possible the accurate correction of these interferences. For any SLOWPOKE reactor, a verification of the ratio of fast-to-thermal neutron fluxes with one or two fast neutron reactions should be sufficient to permit the accurate correction of these 21 interferences with the factors measured here.

E,E- and *E,Z*-α-phenyl-α′-acetoxyorthoquinodimethanes have been prepared from the corresponding *cis*- and *trans*-1-acetoxy-3-phenyl-1,3-dihydrobenzo[*c*]thiophene-2,2-dioxides. The regio- and diastereoselectivity of the addition reactions with dimethyl fumarate, dimethyl maleate, maleic anhydride, and methyl crotonate have been determined. *Ab initio* calculations have been carried out on orthoquinodimethane and its α-phenyl and α-oxy derivatives. A correlation has been made between the steric and electronic properties of the orthoquinodimethanes and the regio- and diastereoselectivity of their Diels–Alder reactions.

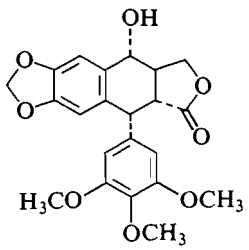
JAMES L. CHARLTON, MIAN M. ALAUDDIN et GLENN H. PENNER. Can. J. Chem. **64**, 793 (1986).

On a préparé les α-phényl α′-acétoxy *o*-quinodiméthanes-*E,E* et -*E,Z* à partir des acétoxy-1 phényl-3 dihydro-1,3 benzo[*c*]thiophènedioxydes-2,2-*cis* et -*trans*. On a déterminé les régio- et diastéréosélectivités de leurs réactions d'addition avec le fumarate de diméthyle, le maléate de diméthyle, l'anhydride maléique et le crotonate de méthyle. On a effectué des calculs *ab initio* sur l'*o*-quinodiméthane et sur ses dérivés α-phényle et α-oxy. On a établi une corrélation entre les propriétés stériques et électroniques des *o*-quinodiméthanes et les régio- et diastéréosélectivités de leurs réactions de Diels–Alder.

[Traduit par la revue]

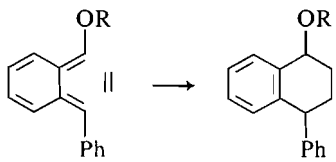
Introduction

Recently there has been an interest in the use of orthoquinodimethanes as intermediates in lignan synthesis (1–5). This work has been stimulated by a growing interest in podophyllotoxin **1** and its derivatives, which show promise as cancer chemotherapeutic agents (6).[2]



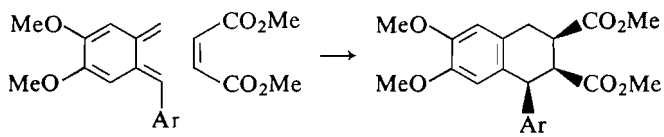
1

Our recent discovery of a simple route to α-oxy-α′-phenyl orthoquinodimethanes **2** (7, 8) has prompted us to investigate the reactions of these intermediates with dienophiles, to establish routes to the various diastereomers of the 1-aryl-4-oxy tetralin



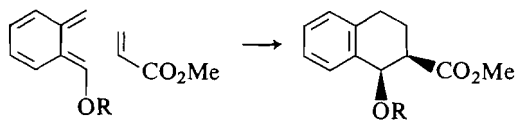
2

system. Previous work on the addition of oxy and phenyl substituted orthoquinodimethanes (*o*-QDMs) to alkenes (1, 2, 4, 7–9) indicated that the regio- and stereochemical course of the addition followed that expected for the Diels–Alder reaction of substituted dienes with alkenes. A *cis*-1,2 substituted pattern seemed to predominate, as shown by the following two examples (1, 9).



3 **4** 90%

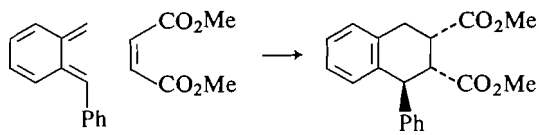
Ar = 3,4-dimethoxyphenyl



62%

R = —CHPh—CH(CH$_3$)—N(CH$_3$)$_2$

While the *cis*-1,2 substitution pattern is in accord with frontier molecular orbital predictions (10), there have been more recent claims of exceptions to the general pattern, which are in contrast to the previously observed directing effect of an aryl group as shown below (9, 11).



57%

To elucidate further the steric and electronic factors involved in these cycloadditions, we have carried out a study of the Diels–Alder reactions of both *E,E*- and *E,Z*-*o*-QDMs **6** and **16** (see Schemes 1 and 2) with the dienophiles dimethyl fumarate, dimethyl maleate, maleic anhydride, and methyl crotonate. Correlations have been drawn between the addition stereoselectivities and the steric and electronic properties of the *o*-QDMs.

Results

The acetoxyphenyl *o*-QDMs **6** and **16** were prepared by thermolysis of the *cis*- and *trans*-acetoxy sulfones **5** and **15** (5). We assume that **5** yields the *E,E*-*o*-QDM **6**, as it is much less

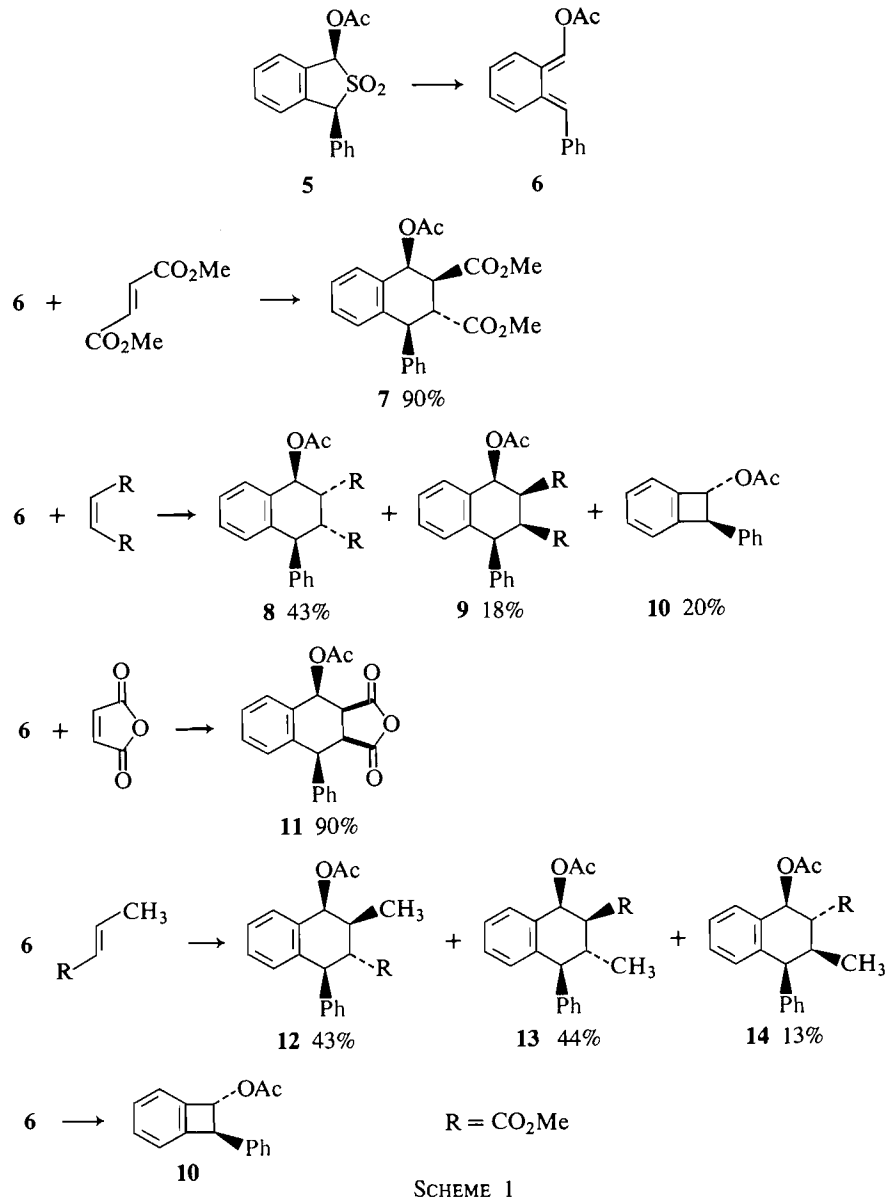
[2]See also references cited in ref. 3.



SCHEME 1

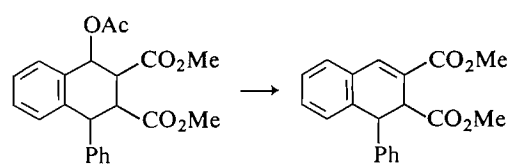
sterically hindered than the *Z,Z* configuration, which could have also formed by pericyclic extrusion of SO_2 from **5**. We also assume that **15** yields the *o*-QDM **16** with the *E*-acetoxy and *Z*-phenyl configuration, on the basis of arguments put forward by Sammes, who has noted a reluctance for oxy substituents to occupy the *Z*-position in *o*-QDMs (12).

TABLE 1. Reaction conditions for cycloadditions

Reactant	Diene[a]	Solvent	Temperature (°C)	Time (h)
5	DMF	T	140	5
5	DMM	T	180	5
5	MA	T	140	5
5	MC	T	140	10
5	—	T	140	15
16	DMF	T	180	5
16	DMM	T	180	18
16	MA	T	180	11
16	—	X	140	23

[a]Key: DMF = dimethylfumarate; DMM = dimethylmaleate; MA = maleic anhydride; MC = methyl crotonate; T = toluene; X = xylene.

The thermolysis conditions are given in Table 1. The product structures and yields are given in Schemes 1 and 2. The product structures were determined primarily on the basis of 300-MHz ^{1}H nmr spectra (see Table 2). The structures were further confirmed by elimination of acetic acid to form the 1-phenyl-2,3-dicarbomethoxy-1,2-dihydronaphthalenes.



7, 8, 9, 17, or **18** → *trans* **20**, *cis* **21**

Thus adducts **7**, **8**, **17**, and **18** were converted to the known *trans*-alkene **20** and adduct **9** was converted to the *cis*-alkene **21**. The structure of the maleic anhydride adduct **11** was determined by treatment with methanol and diazomethane, which converted it to adduct **9**. The benzocyclobutenyl acetate **10**, which is formed as a minor product from **6** and dimethyl maleate, and as a major product in the absence of dienophile,

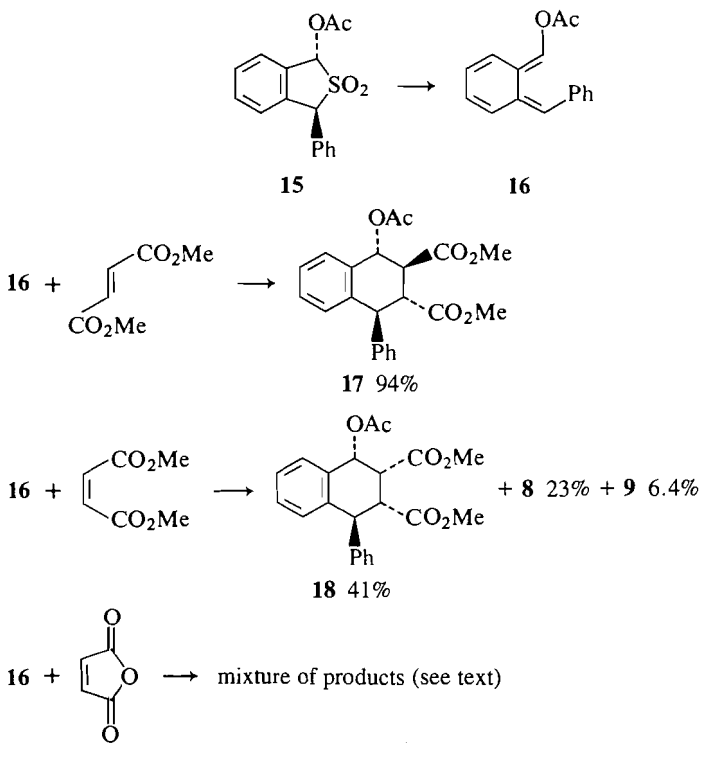


SCHEME 2

was identified by its ^1H nmr and ir spectra. It could also be converted to the adduct **7** by heating with dimethyl fumarate, which further confirmed its structure.

The adducts **12**, **13**, and **14** were not individually isolated. Their structures were deduced solely from ^1H nmr of the mixture using decoupling techniques to decipher the spectrum (see Table 2). Although the *E,Z-o*-QDM **16** plus maleic anhydride gave a mixture of products, the mixture could be converted to primarily the *trans*-alkene **20** by successive treatment with methanol (reflux) and diazomethane. This would indicate that the initial adduct of **16** and maleic anhydride was the *endo* adduct.

Discussion

The most notable feature of these cycloaddition reactions is the contrast between the stereoselectivity for addition of fumarate and maleate versus maleic anhydride. For fumarate and maleate the major products always have the phenyl and neighboring carbomethoxy group *trans*, irrespective of other factors. On the other hand, maleic anhydride added to both **6** and **16** to give predominantly the *cis*-1,2 stereochemistry via an *endo* transition state (assuming the acetoxy group is in the *E* configuration in both **6** and **16**).

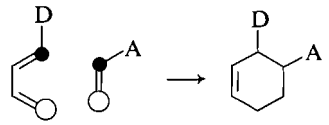
It should be noted that the formation of **16** requires a higher temperature than does **6**. Thus **5** could be converted to **10** at 110°C whereas **15** was unaffected at this temperature. At 140°C, both were converted to anthracene in high yield. At the higher temperature, **10** is in equilibrium with **6** but must also be able to form the *Z,Z* isomer, which intramolecularly closes to eventually form anthracene. We were unable to find a temperature at which the *E,Z-o*-QDM **16** formed the *cis*-acetoxyphenylbenzocyclobutene as a stable product.

The difficulty that others have encountered in preparing a substituted benzocyclobutenol similar to **10** has not gone unnoticed (3). We are currently attempting to extend the scope of the reaction **5** → **10**.

The formation of **8** and **9** from the attempted reaction of **15** plus dimethyl maleate is probably due to the isomerization of **15** to **5**. Although zinc oxide, added to the reaction mixture as an acid scavenger, is relatively neutral, it may catalyse the conversion of **15** to **5** at high temperature. We have observed that this interconversion is readily catalysed by K_3PO_4 in *tert*-butanol or triethylamine in benzene.

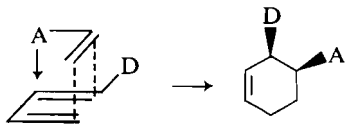
Frontier orbital, secondary orbital, and dipole effects

Frontier orbital theory has often been used to predict regioselectivity of Diels–Alder reactions (10, 13–15). Generally, regioselectivity can be predicted on the basis of the most favourable overlap of the HOMO (highest occupied molecular orbital) of the diene with the LUMO (lowest unoccupied molecular orbital) of the dienophile (10). The predicted product has the larger HOMO coefficient of carbons 1 or 4 of the diene interacting with the larger LUMO coefficient of the dienophile. Thus, dienes with electron-releasing substituents add head-to-head with dienophiles bearing electron-withdrawing substituents.



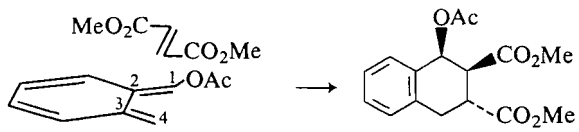
HOMO LUMO

Favourable secondary orbital overlap of the electron acceptor group of the dienophile with carbon 2 of the diene can lead to predominantly *endo* products (14–16).



In cases where the primary orbital effects (carbons 1 and 4 of the diene) are approximately equal, the secondary orbital effect may also affect the regioselectivity (14). In the absence of any strong orbital effects, dipolar interactions may come into play to direct regioselectivity.

In Appendix A we describe *ab initio* calculations that have been used to find the optimum geometry, charge distribution, and molecular orbital coefficients for *o*-QDM, α-phenyl-, α-hydroxy-, and α-phenyl-α′-hydroxy-*o*-QDM. The calculations indicate that an *E*-α-phenyl substituent is rotated out of the plane of the *o*-QDM and has little effect on the orbital coefficients relative to the unsubstituted *o*-QDM. The fact that previously studied α-phenyl-*o*-QDMs add head-to-head with monoactivated dienophiles (1, 8, 11) may thus be related to dipolar effects rather than orbital effects since the phenyl group in *E*-α-phenyl-*o*-QDM does decrease the electron density on the carbon bearing the phenyl group (see Appendix A). It may also be due to the fact that α-phenyl-*o*-QDMs exist in the *Z* configuration, where orbital factors may be larger and direct the regiochemistry of addition. In the case of α-oxy-*o*-QDMs there are both a polar effect and secondary and primary orbital effects, which all favour head-to-head addition. The secondary orbital interaction should be large (large coefficient on C_2) and should favour a *cis*-1,2 adduct stereochemistry when fumarate is added. The α-oxy-*o*-QDMs do indeed give *endo* head-to-head addition (8, 9) as predicted. An analogous case dealing specifically with fumarate addition to 1-substituted dienes has been provided by Kakushima (15). However, for α-phenyl- and α-phenyl-α′-oxy-*o*-QDMs, only maleic anhydride gives the *endo* addition while fumarate and maleate always give the *trans*-phenyl carbomethoxy stereochemistry. In view of the out-of-plane rotation of the α-phenyl group in *E*-α-phenyl-*o*-QDM, it is likely that the preference for *exo* addition of dienophiles other than maleic anhydride is rooted in steric factors.



It should be noted that Mann and Piper have reported a case (see **3** → **4**) in which maleate undergoes *endo* addition to an α-aryl-*o*-QDM (2). This could be rationalized on the basis of increased secondary orbital effects, since the methoxy substituents on the *o*-QDM will raise the energy of the HOMO and increase orbital interaction with the dienophile LUMO.

Finally, we note that addition of crotonate to **6** gave a mixture of head-to-head and head-to-tail adducts indicating that, in this case at least, the directive effects of the phenyl and acetoxy group on the regiochemistry of addition are about equal.

Experimental

Proton magnetic resonance spectra were recorded on a Bruker AM-300 using tetramethylsilane as internal standard. Infrared (ir) spectra were recorded on a Unicam 1000 spectrometer. Mass spectra were recorded on a Finnegan 1015 mass spectrometer and only the major peaks are reported. Merck Kieselgel 60 was used for all chromatography. Elemental analyses were performed by Guelph Chemical Laboratories Ltd., Guelph, Ontario, Canada.

1-Acetoxy-3-phenyl-1,3-dihydrobenzo[c]thiophene-2,2-dioxide

The *cis* and *trans* acetates **5** and **15** were prepared as described previously (8). They were separated by a combination of crystallization and chromatography using 2% ethyl acetate in benzene as eluant.

Cycloaddition reactions

A procedure different from that previously used (8) was employed in this work. A toluene solution of the acetoxy phenyl sulfone **5** or **15** (100–200 mg), 30 mg of anhydrous, powdered zinc oxide, and four equivalents of the dienophile were sealed in a pressure flask (200 mL) and heated as described in Table 1. The solution was then filtered through a short column of silica gel with methylene chloride (through only filter paper for the maleic anhydride adducts), evaporated, and then heated at 100°C under high vacuum to remove excess dienophile.

The cycloadducts were then purified by recrystallization, sometimes after chromatography, as described below.

7: Recrystallized from hexane – ethyl acetate, mp 109–110°C; for spectra properties see ref. 8.

8: Chromatography, 20% ethyl acetate – hexane; recrystallized from hexane–CH_2Cl_2; for properties see ref. 8.

9: Chromatography, 20% ethyl acetate – hexane; recrystallized from hexane–CH_2Cl_2, mp 150–153°C; ir (CH_2Cl_2): 1747 cm^{-1}; mass spectrum *m/e* (rel. %): 382 (10), 339 (33), 322 (40), 307 (40), 262 (43), 221 (43), 203 (47), 188 (100). *Anal.* calcd. for $C_{22}H_{22}O_6$: C 69.10, H 5.80; found: C 68.92, H 6.09.

11: Recrystallized from hexane – ethyl acetate, mp 168–170°C; ir (CH_2Cl_2): 1750, 1760, 1795 cm^{-1}; mass spectrum *m/e* (rel. %): 336 (12), 293 (12), 276 (21), 248 (38), 204 (35), 195 (44), 178 (100). *Anal.* calcd. for $C_{20}H_{16}O_5$: C 71.42, H 4.79; found: C 71.55, H 5.09.

12, **13**, and **14**: Chromatography, 10% ethyl acetate – hexane. Separation of the three isomers was not possible by chromatography. The identity of the three isomers is based solely on the 300-MHz nmr spectrum of the mixture, which was analysed using decoupling and COZY techniques. The nmr data are given in Table 2.

17: Recrystallized from hexane–CH_2Cl_2, mp 135–137°C; ir (CH_2Cl_2): 1742 cm^{-1}; mass spectrum *m/e* (rel. %): 322 (7), 262 (36), 176 (44), 131 (65), 117 (76), 91 (100). *Anal.* calcd. for $C_{22}H_{22}O_6$: C 69.10, H 5.80; found: C 68.82, H 6.02.

18: Chromatography 10% ethyl acetate – hexane; recrystallized from hexane–CH_2Cl_2, mp 128–132°C; ir (CH_2Cl_2): 1745 cm^{-1}; mass spectrum *m/e* (rel. %): 382 (1), 351 (1), 339 (1.5), 322 (31), 294 (28), 231 (20), 204 (25), 43 (100). *Anal.* calcd. for $C_{22}H_{22}O_6$: C 69.10, H 5.80; found: C 68.98, H 6.00.

The cycloaddition product from **15** and maleic anhydride appeared to be a mixture by ^1H nmr. The crude reaction mixture was refluxed in methanol for 1 h, evaporated to dryness, and then treated with excess

diazomethane in ether. The ^{1}H nmr analysis showed the resulting product to be a mixture of **20** (major), **18** (minor), and **21** (minor).

trans-*1-Acetoxy-2-phenylbenzocyclobutene* ***10***

This compound was first isolated as a minor product from the reaction of the *cis*-sulfone **5** with dimethyl maleate by chromatography using 20% ethyl acetate – hexane (20%). Refluxing **5** (101.5 mg) in toluene with ZnO (33 mg) gave, after chromatography (20% ethyl acetate – hexane), 42 mg of **10** and 32.5 mg of **5** for a corrected yield of 76%. Recrystallized from hexane, mp 50–53°C; ir (CH_2Cl_2): 1740 cm^{-1}; ^{1}H nmr ($CDCl_3$): 2.15 (s, 3H), 4.67 (d, 1H, J_{12} = 1.63), 5.67 (d, 1H), 7.2–7.5 (m, aromatics); mass spectrum *m/e* (rel. %): 196 (27), 195 (47), 178 (100), 167 (67). *Anal.* calcd. for $C_{16}H_{14}O_2$: C 80.65, H 5.92; found: C 80.40, H 6.19. Refluxing **5** with ZnO in xylene (138°C) gave only anthracene.

Treatment of ***11*** *with methanol and diazomethane*

Compound **11** (10 mg) was refluxed for 1.5 h in methanol, evaporated, and then treated with diazomethane in ether; ^{1}H nmr showed the product of the reaction to be mainly **9**.

Elimination reactions to form ***20*** *and* ***21***

The cycloadducts **7**, **8**, **17**, and **18** could all be converted to **20** by refluxing (20 mg) in toluene (10 mL) with *p*-toluene sulfonic acid (5 mg) for 2 h. The product mixture was filtered through a short silica gel column with CH_2Cl_2 and evaporated to give a nearly quantitative yield of the alkene in each case. For properties see ref. 8. The all-*cis* tetralin, **9**, treated in the same way, gave the *cis*-alkene **21** as an oil; ir (CH_2Cl_2): 1720, 1735 cm^{-1}; ^{1}H nmr ($CDCl_3$): 3.34 (s, 3H), 3.79 (s, 3H), 4.02 (d, 1H, $J_{1,2}$ = 8.15), 4.61 (d, 1H), 7.01 (m, 1H), 7.18–7.38 (m, aromatics), 7.73 (s, 1H); mass spectrum *m/e* (rel. %): 322 (28), 290 (50), 262 (57), 204 (95), 203 (98), 202 (93), 178 (64), 105 (100). When **21** was dissolved in 0.1 *M* NaOMe and left at room temperature for 15 h, it was converted quantitatively to the alkene **20**.

Appendix A

Ab initio molecular orbital calculations at the STO-3G level have been carried out on *o*-QDM **22**, α-hydroxy-*o*-QDM **23**, α-phenyl-*o*-QDM **24**, and α-hydroxy-α′-phenyl-*o*-QDM **25**. All bond lengths and bond angles were optimized with the constraint that the atoms of the *o*-QDM moiety remain planar. For the α-phenyl derivatives the benzene ring was held planar and the ring carbons were constrained to a hexagonal geometry.

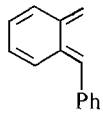
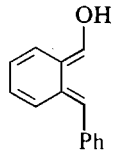
23



24



25

Calculations were performed on an Amdahl 470/V8 system using program MONSTERGAUSS (17).

Calculations on **25** were made for several different angles of the plane of the phenyl substituent relative to the plane of the *o*-QDM. The optimum angle appeared to be 60° with a small barrier (2.58 kJ/mol) at 90° and a prohibitive barrier at 0°. For comparison purposes, data given for **24** and **25** below are for calculations in which the phenyl group was held at 90°. Table 3 gives the HOMO and LUMO molecular orbital coefficients and the net atom charges for the four molecules studied.

Open chain nitrogen compounds. Part X.[1] Thermolysis of α-diazoacetanilides in methanol: a convenient synthesis of α-methoxyacetanilides from ethyl *N*-(arylazo)glycinate

α-Diazoacetanilides (**4**), which are readily available from the open-chain triazenes (**2**), undergo thermolysis in methanol solution to afford the α-methoxyacetanilides (**5**), an apparently rare type of ether/amide derivative. The methanolic thermolysis is inhibited by the presence of a tertiary amine in the solvent, suggesting that a carbocation, rather than a carbene, intermediate is involved in the conversion of the diazo-amide to the methyl ether. This hypothesis is supported by the retardation of the reaction in the presence of an electron-withdrawing group in the *para* position of the anilide. The conversion **4** → **5** was also observed, on a small scale, under photolytic conditions. It is suggested that the α-diazoacetanilide represents a useful synthetic equivalent for the synthon $ArNHCOCH_2^+$.

KUMUDINI U. K. GAMAGE NICHOLAS et KEITH VAUGHAN. Can. J. Chem. **64**, 799 (1986).

Les triazènes (**2**) aliphatiques conduisent facilement aux α-diazoacétanilides (**4**) qui, en solution dans le méthanol, subissent une thermolyse conduisant aux α-méthoxyacétanilides (**5**), un type apparemment rare de derivé éther/amide. Les thermolyses en solution méthanolique sont inhibées par la présence d'amines tertiaires dans le solvant; ceci suggère que l'intermédiaire dans la conversion du diazo-amide en éther méthylique est un carbocation plutôt qu'un carbène. Cette hypothèse est en accord avec le fait que la réaction est retardée par la présence de groupes électro-atrtracteurs en position *para* de l'anilide. Opérant sur une faible échelle et dans des conditions photolytiques, on a pu aussi observé la conversion de **4** → **5**. On croit que l'α-diazoacétanilide représente un équivalent de synthèse utile pour le synthon $ArNHCOCH_2^+$.

[Traduit par la revue]

In a previous report (1), we described the base-catalysed cyclization of the ethyl *N*-(arylazo)glycinates (**2**), which affords the 5-hydroxytriazoles (**3**). The triazoles undergo rearrangement with Lewis acid catalysis to afford the α-diazoacetanilides (**4**). The triazenes (**2**) are readily obtained by diazotization of the arylamine (**1**) and diazonium coupling with ethyl glycinate. The diazoacetanilides (**4**) offer an interesting range of possible synthetic opportunities, since loss of nitrogen under thermal or photolytic conditions might afford the reactive intermediate carbene, Ar.NH.CO.C̈H. This paper describes a study of the thermolysis and photolysis of these diazo compounds (**4**) in methanol and other alcohols, which afford moderate yields of the ethers (**5** and **6**), formally the carbene O—H insertion product.

While a great number of studies have been carried out on the thermo- and photo-chemistry of diazo compounds, only a little of this work has been devoted to the study of α-diazoamides (>N—C(=O)—C(—)=N_2) and most of these studies involve photolysis. For example, photolysis of the α-diazoacetamides ($CH_3NH.CO.CN_2.CO_2Et$) in *tert*-butanol generates the appropriate carbene, which undergoes O—H insertion to give the corresponding ether $CH_3NH.CO.CH(Ot\text{-}Bu)CO_2Et$ (2). Similarly, photolysis of *N*,*N*-diethyl-α-diazoacetamide ($Et_2N.CO.CHN_2$) in methanol gives the O—H insertion product ($Et_2N.CO.CH_2OCH_3$), together with rearrangement and the

intramolecular C—H insertion products (3). Graziano, Scarpati, and co-workers (4) have extensively studied the photochemistry of diazoamide acetals (R—NHC(OMe)$_2$—C(=N$_2$)—), which have also been studied under thermolysis (5) and were found to be surprisingly stable up to 160°C.

The α-diazoacetanilides (**4***a*, *c*, and *d*) were prepared according to the published method (1). Diazotization of *p*-bromoaniline (**16**) and coupling of the diazonium salt with ethyl glycinate gave a high yield of the triazene (**2***b*), which has not been reported previously. Structural identification of **2***b* was based on comparison of spectroscopic features with other triazenes in the series. Cyclization of **2***b* in alcoholic KOH proceeded as expected to give the hydroxytriazole (**3***b*), which in turn underwent rearrangement over alumina in chloroform to give the α-diazoacetanilide (**4***b*).

Thermolysis of the diazoacetanilides was carried out in refluxing methanol. The progress of reaction was followed both by thin-layer chromatography, and by observing the disappearance of the uv absorption maximum of the reactant diazo compound. (The λ_{max} for each substrate is given in Table 1.) The time of reaction required for complete conversion of reactant to products, shown in Table 1, varied significantly with the substituent in the aryl group of **4**; electron-withdrawing groups retard the reaction significantly. Indeed the *p*-nitro-α-diazoacetanilide (**4***d*) was recovered unchanged after 120 h in refluxing methanol, whereas reaction of the *p*-bromo analogue (**4***b*) was complete after 5.5 h in refluxing methanol.

Structural identification of the methyl esters (**5** *a*, *b*, and *c*) obtained from these reactions is based on spectroscopic (Table 1) and elemental analyses. The ir spectra show absorption from NH and amide-carbonyl groups, and the ^{1}H nmr spectra exhibit characteristic O—Me resonance at 3.5 ppm, a methylene signal at 4.0 ppm, and NH resonance at ca. 8.2–8.4 ppm. The ^{13}C spectra (Table 2) were obtained for the *p*-bromo- and *p*-chloro-α-methyoxyacetanilides (**5***a* and **5***b*) to corroborate the structural assignment. The structures of **5***a* and **5***b* were also confirmed by elemental analysis. Refluxing **4***b* in ethanol afforded the analogous ethyl ether (**6**), which was identified by ir and nmr spectroscopy; the reaction of **4***b* in ethanol required longer time than in methanol, which is consistent with a polar mechanism and with the lower dielectric constant of ethanol (24.3) compared to methanol (32.6).

A simple, but attractive, mechanism for the conversion **4** → **5** is that shown in Scheme 1, path (b), in which loss of N_2 from the free diazo compound generates the carbene (**7**), followed by O—H insertion during reaction with the solvent. Such O—H insertion of diarylcarbene Ar_2C:, generated thermally in methanol from diaryldiazomethanes Ar_2CN_2, has been observed to give the ethers $Ar_2CH.OMe$; the mechanism proposed for this reaction involves the intermediate formation of an ylide, Ar—C$^-$—O$^+$(R)(H), rather than a carbenium ion intermediate (6). However, the alternative route for **4** → **5** shown in the scheme, path (a), should also be considered. Protonation of the amide carbonyl group by the protic solvent gives intermediate **8**, which would undergo prototropic shift to the diazonium ion (**9**) followed by loss of N_2 to give the carbenium ion (**10**). Nucleophilic attack by the solvent at the carbocation centre of **10**, and loss of H^+, affords the observed product (**5**).

In order to distinguish which of these mechanisms might be

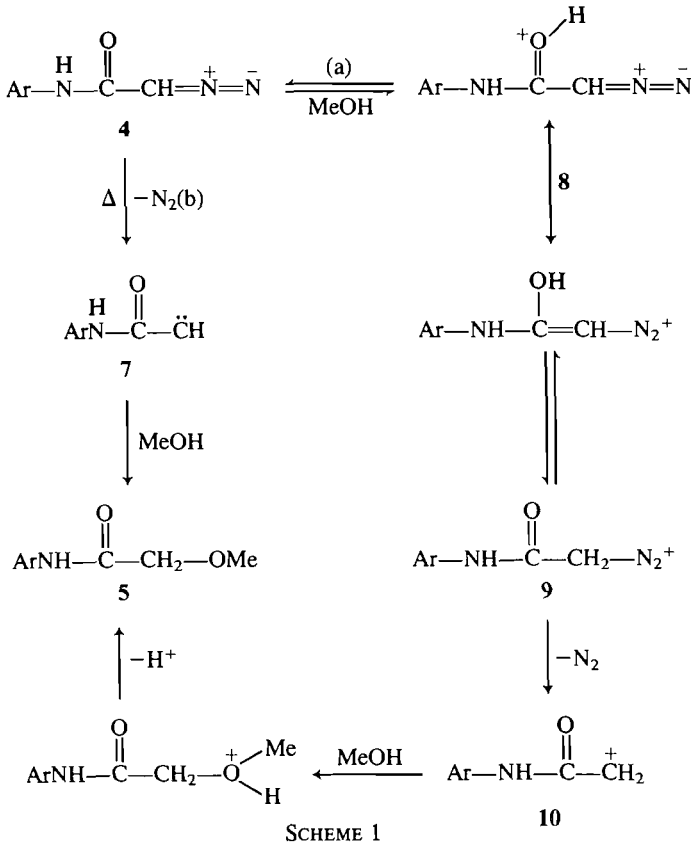
occurring, we investigated the effect of tertiary amines on the rate and course of the methanolysis of **4**. Accordingly, the *p*-bromo-α-diazoacetanilide (**4***b*) was refluxed in methanol containing 2% triethylamine. While the total time for the disappearance of the diazo compound was increased significantly, compared to the reaction in methanol alone, product analysis indicated the formation of a complex mixture not containing the expected ether (**5***b*). However, reaction of **4***b* in methanol containing 2% pyridine did afford the expected product (**5***b*) but the reaction time required for complete disappearance of the diazo compound was observed to be 2–3 times that in methanol alone. These observations support the suggestion that the methanolysis is acid catalysed and that path (a), Scheme 1, is the more likely route for the conversion **4** → **5**. Further support for the carbocation (**9**) pathway is the substituent effect described previously; electron-withdrawing substituents in Ar decrease the basicity of the amide group, thus shifting the equilibrium **4** ⇌ **8** away from the protonated form (**8**). (The effect of electron-withdrawing substituents on the rate of carbene generation by nitrogen loss from diazoalkanes is usually to accelerate the reaction (10).) Consequently, the lower concentration of **8** in the reaction mixture could be responsible for the lowering of the rate of reaction.



SCHEME 1

These arguments raise the question of the source and nature of the protic acid needed in part (a), Scheme 1. Normally the —OH group in an alcohol is not sufficiently acidic to react with a diazo-alkane (11); however, it has been observed that the reactivity of alcohols towards diphenylmethylene, generated by photolysis of diphenyldiazomethane, increases with increasing acidity of the hydroxy group (6*b*). Thus it is possible that the methanol functions as a weak acid, affording a low concentration of the highly reactive protonated species (**8**).

We also considered the possible intervention of a "Wolff" type rearrangement of the potential intermediate carbene (**7**). By analogy with the Wolff rearrangement of diazoacetyl esters (12), an expected product of the methanolysis of **4** would be the methyl α-anilinoacetate, $ArNH.CH_2CO_2Me$. However, spectroscopic analysis of the product mixtures from methanolysis of the diazo-amides (**4**) indicated the complete absence of any methyl esters.

It was also of interest to us to examine the behaviour of an α-diazoacetanilide when subjected to photolysis. Accordingly the *p*-bromo-α-diazoacetanilide (**4***b*) was photolyzed in methanol on a small scale using a low-power 254-nm uv lamp as the light source. The methyl ether (**5***b*) was observed to crystallize out of the solution during photolysis; the structures of this product was clearly evident from the nmr spectrum, which was identical with that of the thermolysis product from **4***b* in methanol. However, we have not pursued this reaction further to establish its preparative value.

A literature search of the substructure, —N(Ar)—CO.CH_2OR, revealed surprisingly few examples of this apparently simple type of molecule. Recent literature (7, 8) reports the investigation of the fungicidal and microbiocidal uses of *N*,*N*-disubstituted methoxyacetamides; the monosubstituted methoxyacetamides ($ArNHCO.CH_2OMe$) appear to have been ignored in this context. An earlier report (9) lists the *p*-bromo-α-methoxyacetanilide **5***b* as one of several anilides used in a study of their optical crystallography; the method of synthesis was acylation of the aniline by methoxyacetyl chloride, but no yield was reported. The method of synthesis reported here via the triazene **2** has an advantage over the aniline-acylation route for anilines with electron-withdrawing groups in the aryl moiety, which would have low reactivity as nucleophiles towards the acyl chloride. An electron-withdrawing group in Ar is a distinct advantage in the synthesis of the triazene **2**, which can only be obtained in good yield when Ar has an electron-withdrawing group attached. Accordingly, it appears that the synthesis of α-methyoxyacetanilides reported here is a new route to a seemingly rare group of simple amides.

In conclusion, it appears that α-diazoacetanilides of type **4** undergo thermal solvolysis in methanol by a carbenium ion, rather than by a carbene mechanism, and that the diazo compound $ArNH.CO.CHN_2$ is a convenient synthetic equivalent for the carbenium synthon ($Ar.NH.CO.CH_2^+$), which might be useful for other synthetic applications, presently being investigated in this laboratory.

Experimental

Melting points were measured with a Kofler hot-stage apparatus and are uncorrected. Infrared spectra were recorded in Nujol mulls with Perkin Elmer 1300 or 299 grating spectrometers, and uv spectra were obtained with a Unicam SP8-400 spectrophotometer. The nmr spectra were recorded with Varian EM360 (60 MHz) or Nicolet (360 MHz) spectrometers. Microanalyses were conducted by the Canadian Microanalytical Laboratory, Vancouver, B.C. Since the compounds were all prepared by the same sequence of reactions, and since the ^{1}Hmr and ^{13}Cmr spectra are so simple and consistent for the series, only representative compounds were analyzed.

Ethyl N-(p-*bromophenylazo)glycinate (***2***b)*

Diazotization of *p*-bromoaniline and coupling the diazonium salt with ethyl glycinate according to the published procedure (1) afforded the triazene (***2****b*), 90% yield, mp 69–70°C (hexanes); ir: 3395, 1734, 1580, and 840 cm^{-1}; nmr δ ($CDCl_3$): 1.35 (3H, t, Me), 4.25 (2H, q, CH_2), 4.36 (2H, s, CH_2), 7.16–7.5 (4H, AA′BB′, arom.), 8.4 (1H, br, s, NM).

*1-(*p*-Bromophenyl)-5-hydroxy-1,2,3-triazole (***3***b)*

The triazene (***2****b*) was treated with alcoholic potassium hydroxide according to the published method (1) and the resulting potassium triazolate dissolved in water and neutralized with acetic acid to give the triazole (***3****b*), 63% yield, mp 119–119.5°C (hexane); ir: 3150 and 1590 cm^{-1}; δ (DMSO-d_6); 7.06 (1H, s) and 7.75 (4H, s).

α-Diazoacetanilides ***4***

The α-diazoacetanilides (***4****a*, *c*, and *d*) were prepared as described previously (1) and had physical properties in agreement with those reported. *p*-Bromo-α-diazoacetanilide (***4****b*) was prepared from the triazole (***3****b*) by the same method. Yield of ***4****b* 70%, mp 130–135°C (yellow needles from benzene–nitromethane); λ_{max} (EtOH): 273 nm; ir: 2120, 1730, and 1630 cm^{-1}; nmr δ ($CDCl_3$): 5.5 (1H, s, C*H*N_2), 7.1 (4H, s, arom.), and 9.8 (1H, br s, NH; exchangeable with D_2O).

*α-Methoxyacetanilides (***5***). General procedure*

The α-diazoacetanilide (***4***) was dissolved in absolute methanol to a concentration 0.01 *M* (e.g. in the case of the *p*-bromo derivative ***4****b*, 60 mg of the diazoamide was dissolved in methanol (25 mL)). The methanolic solution was flushed with dry N_2 gas and then refluxed. Reaction was taken to completion by following the decrease of uv absorption of the diazo compound and by thin-layer chromatography; tlc of the final product mixtures showed only one major component. The methanolic solution was evaporated to dryness under vacuum and the residue recrystallized from an appropriate solvent (usually water) to afford the ether (***5***). Reaction times required for completion, product yields, and physical and spectroscopic characteristics are given in Tables 1 and 2.

Cyclic hydroboration of geraniol derivatives: a synthesis of the left-hand portion of X-14547A

RALPH ALLEN WHITNEY
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6
Received June 26, 1985

RALPH ALLEN WHITNEY. Can. J. Chem. **64**, 803 (1986).

The stereochemical consequences of the cyclic hydroboration–oxidation of geraniol derivatives have been examined; moderately high selectivity (85–88%) for the formation of one major diastereomer has been observed, presumably as a consequence of remote asymmetric induction in the cyclic hydroboration of these 1,5-dienes. An approach to the synthesis of the left-hand portion of the ionophore antibiotic X-14547A is described.

RALPH ALLEN WHITNEY. Can. J. Chem. **64**, 803 (1986).

On a évalué les conséquences stéréochimiques de l'hydroboration–oxydation cyclique de dérivés du géraniol. On a observé des séléctivités relativement élevées (85–88%) pour la formation du diastéréoisomère prépondérant; ce résultat est probablement la conséquence d'une induction asymétrique à distance qui se fait sentir lors de l'hydroboration cyclique de ces dienes-1,5. On décrit une approche à la synthèse de la portion de gauche de l'antibiotique ionophore X-14547A.

[Traduit par la revue]

One of the major objectives in the synthesis of complex natural products is to transform stereochemically simple compounds into topologically complex structures in the most efficient manner possible. In this regard, reactions that allow the formation and relative control of a number of asymmetric centres in one synthetic step are extremely important; intramolecular cycloaddition reactions have been particularly useful in achieving this objective, with the Diels–Alder reaction (for recent reviews, see ref. 1) having received notable attention. Other recent examples of specific reactions that generate multiple asymmetric centres are the permanganate oxidation of dienes (2), arene-olefin cycloadditions (3), and diene cyclic hydroboration–oxidation (4). In this last case, the hydroboration of 1,4- and 1,5-dienes was examined and moderate to high levels of stereochemical control were obtained in the formation of acyclic 1,4- and 1,5-diols containing two remote asymmetric centres.

X-14547A, **1**, is an ionophore antibiotic possessing interesting and unusual structural features (5); the left-hand portion of the molecule, **2**, contains a trisubstituted tetrahydropyran ring with *trans* substituents across the ring oxygen, while the right-hand portion, **3**, contains a *trans*-fused tetrahydroindan with an appended ketopyrrole unit, an unusual structural feature for this type of antibiotic. Several synthetic approaches to the left-hand (6) and right-hand (7) portions of X-14547A have been reported, as well as three total syntheses (8) of the compound. Interestingly, the intramolecular Diels–Alder route to the right-hand portion has allowed a high degree of relative stereochemical control in establishing four additional centres of asymmetry from one pre-existing asymmetric centre in the triene substrate. In considering the possibility of establishing four centres of relative asymmetry in one step from an achiral precursor through cyclic hydroboration, it was decided that the left-hand portion **2** of X-14547A was a suitable synthetic target upon which to test this notion.

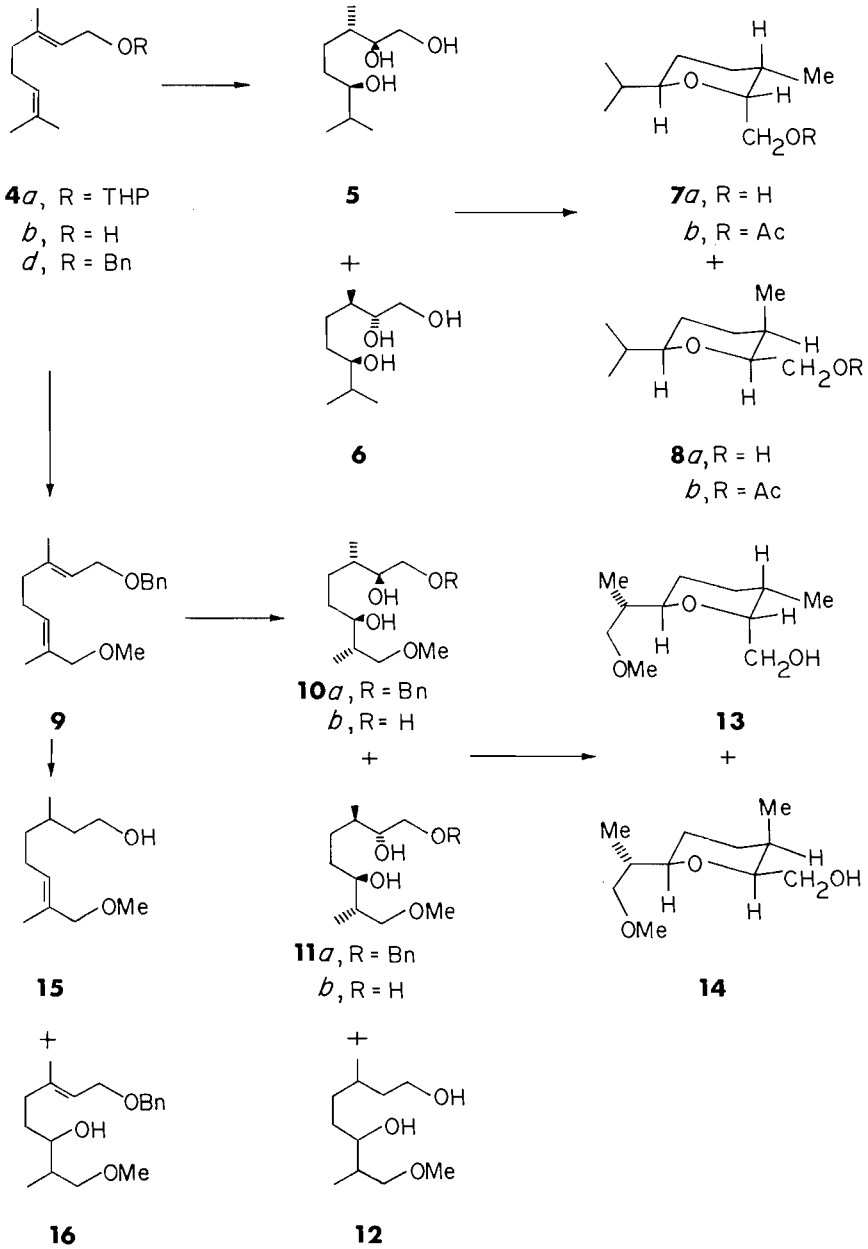
Results and discussion

Geraniol tetrahydropyranyl ether **14***a* was the first diene examined; hydroboration was performed with borane–tetrahydrofuran complex at low temperature to suppress elimination in the β-alkoxyalkyborane intermediate (13). Subsequent oxidation followed by alcoholysis of the tetrahydropyranyl group provided 3,7-dimethyl-1,2,6-octanetriol (9) as a mixture of the diastereomers **5** and **6** in a 73% yield. Examination of the proton decoupled ^{13}C nmr spectrum indicated the presence of the two diastereomers in approximately an 85:15 ratio, by integration, but gave no indication as to the stereochemistry of the major isomer. Elucidation of the stereochemistry of the major diastereomer was accomplished using a precedented sequence (6*a*,*b*; 8*d*) in which the configuration at C-2 of **5** and **6** was inverted during the formation of the tetrahydropyran ring in **7***a* and **8***a*. The triol was selectively sulfonated at the primary hydroxyl group with *p*-toluenesulfonyl chloride to give a β-hydroxytosylate that, on treatment with base, afforded an epoxide. Intramolecular alcoholysis of the epoxide under acidic conditions proceeded to give a mixture of tetrahydropyranyl alcohols **7***a* and **8***a* with precedented inversion of configuration at C-2 (6*a*,*b*; 8*d*). Proton nmr data on the corresponding acetate indicated the presence of predominantly one stereoisomer, **7***b* or **8***b*, but did not unambiguously indicate which one of the two was the predominant isomer; mass spectral data showed fragment ions arising from α-cleavage of the C-2 and C-6 substituents as is characteristic of tetrahydropyrans (14). The ^{13}C nmr data on the alcohols were, however, very informative; **7***a* and **8***a* differ only in the axial versus equatorial disposition of the hydroxymethyl group at C-2 and the equatorial versus axial disposition of the methyl group at C-3. In general, axial sub-



stituents in tetrahydropyranyl rings show a large upfield chemical shift compared to equatorial substituents (10); the nmr spectrum of the mixture of **7***a* and **8***a* showed the major isomer having chemical shifts of 64.7 and 12.1 ppm, respectively, for the C-2 hydroxymethyl and C-3 methyl groups, while the minor isomer had chemical shifts of 57.7 and 16.2 ppm, respectively. On this basis, **8***a* was the major diastereomer obtained and hence triol **6** was the major stereoisomer obtained from the cyclic hydroboration–oxidation of geraniol tetrahydropyranyl ether. Subsequent experiments showed that direct hydroboration of geraniol **4***b* with 2.5 molar equivalents of borane–tetrahydrofuran complex also gave triol **6** as the major diastereomer, obviating the need for an alcohol-protecting group during the hydroboration.

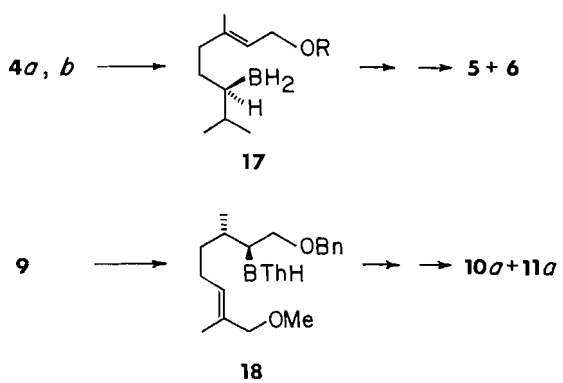
The use of thexylborane (13) as the reagent for hydroboration of **4***a* substantially altered the stereochemical outcome in that the mixture of triols obtained, on subsequent oxidation then alcoholysis of the tetrahydropyranyl group, showed a small predominance (60:40) of the diastereomer **5** over **6**, as evidenced by the proton decoupled ^{13}C nmr spectrum of the triol mixture. Conversion of this triol mixture to the mixture of tetrahydropyranylalcohols **7***a* and **8***a* showed the major isomer having chemical shifts of 57.7 and 16.2 ppm, respectively, for the C-2 hydroxymethyl and C-3 methyl groups, as expected for **7***a*.

Attention was next turned to diene **9**, prepared by selenium dioxide oxidation of *O*-benzylgeraniol (Sharpless catalytic procedure (11)) and subsequent methylation. The use of borane–tetrahydrofuran complex at low temperature as the cyclic hydroborating reagent led, on oxidation, to a mixture of nearly equal amounts of diols **10***a* and **11***a*, as determined by the proton decoupled ^{13}C nmr spectrum of the diol mixture. The use of thexylborane resulted in a substantial increase in diastereoselectivity (88:12 ratio of isomers) when the reaction was performed at $\leqq -10°C$; however, a competing β-elimination rehydroboration reaction led to the formation of a substantial amount of the diol **12** as well; we were unable to suppress the β-elimination without suppressing cyclic hydroboration. As a

consequence, the mixture of diastereomers **10***a* and **11***a* was obtained in only 31% yield upon chromatographic purification.

The mixture of diols was hydrogenolysed over palladium to give a mixture of triols **10***b* and **11***b*, which was converted to a mixture of the tetrahydropyranylalcohols **13** and **14** as described previously. The proton nmr spectrum did not readily identify the major diastereomer, while mass spectral data again showed typical fragment ions arising from α-cleavage of a tetrahydropyran. The ^{13}C nmr spectrum of the mixture of **13** and **14** showed the major diastereomer having a chemical shift of 57.4 ppm for the carbon of the hydroxymethyl group at C-2 and 16.3 ppm for the C-3 methyl group, clearly indicating (*vide supra*) **13** to be the major stereoisomer. The minor isomer **14** showed a hydroxymethyl group at 64.5 ppm and a C-3 methyl group at 12.1 ppm. That the stereochemistry of the major product was identical to that of the left-hand portion **2** of X-14547A was confirmed by oxidation of **13** to **2***b* with ruthenium tetroxide (Sharpless catalytic procedure (12)); treatment with ethereal diazomethane afforded the diester **2***c*. Both **2***b* and **3***c* have recently been reported (8*b*) as degradation products of X-14547A; comparison of the proton nmr spectra of our synthetic samples with spectra for samples obtained by degradation confirmed the structural assignment.

The difference in the stereoselectivities observed in the hydroboration–oxidation of dienes **4***a*/*b* and **9** can be rationalized as arising from opposite chemoselectivity in the initial site of hydroboration, followed subsequently by either an endocyclic or exocyclic intramolecular hydroboration step in which nonbonded interactions control the stereochemistry observed in the oxidation products. In the case of **4***a*/*b* it is well known that electrophilic reagents (e.g. ozone (15) and *N*-bromosuccinimide (16)) preferentially added to the C-6 double bond of geraniol; furthermore, recent studies by Nelson and Brown (17) have shown that an electronegative allylic heteroatom (chlorine) reduces the relative rate of reactivity of the alkene towards hydroboration. This strongly suggests that the first hydroboration of **4***a*/*b* is at the C-6 double bond, giving **17**, which undergoes an endocyclic hydroboration in a subsequent step that controls the stereochemical outcome. In the diene **9**, however, both double bonds are trisubstituted and have an allylic heteroatom substituent; again, the results of Nelson and Brown on allylic halogen substituent effects indicate that the relative rate of addition of boron to an alkene is slower when the site of boron addition is γ rather than β to the allylic heteroatom. This suggests that the initial site of hydroboration is reversed for diene **9**; that is, intermediate **18** is formed followed by an exocyclic ring-forming reaction. This latter case was verified experimentally by reacting diene **9** with 9-BBN (9-borobicyclo[3.3.1]nonane); the major hydroboration–oxidation product obtained was the alcohol **15** arising from hydroboration, β-elimination, then rehydroboration, prior to oxidation.



In summary, the cyclic hydroboration–oxidation of geraniol and certain of its derivatives has been shown to proceed to give moderately high levels of remote asymmetric induction in the formation of acyclic diols with the generation of up to four centres of relative asymmetry; the apparent importance of endocyclic versus exocyclic reaction pathways has been noted, as has the effect of electronegative allylic heteroatoms on relatives rates of alkene reactivity.

Experimental

General

Unless otherwise stated, sodium sulfate was used as the drying agent for organic solutions; organic solutions were concentrated by rotary evaporation at water aspirator pressure and temperatures below 40°C. All aqueous–organic partitioning was followed by a wash of the separated aqueous layer with an additional portion of the same organic solvent. Dry organic solvents were prepared by distillation from the following desiccants: magnesium (methanol), calcium hydride (pyridine, tetrahydrofuran). Column chromatography was performed with Merck silica gel 60 (70–230 mesh), while high performance liquid chromatography was performed on Merck Lobar columns. Melting points were determined on a Fisher–Johns or a Thomas Hoover melting point apparatus and are uncorrected. Infrared spectra were recorded on a Perkin–Elmer 528 instrument. Proton and carbon magnetic resonance spectra were recorded on Varian EM360, Bruker WH60, Bruker HX60, Bruker CXP200, or Bruker AM400 spectrometers; chemical shifts are recorded in δ values relative to tetramethylsilane, while coupling constants are generally reported to values of ±0.5 Hz. Mass spectra were recorded on an AEI MS12 at Trent University, Peterborough, Ontario, or on a V.G. 7070F at McMaster University, Hamilton, Ontario.

*(2RS,3RS,6RS)-3,7-Dimethyloctane-1,2,6-triol **6** and its diastereomer **5***

A solution of borane in tetrahydrofuran (1 *M*, 16 mL, 16 mmol) under a nitrogen atmosphere was cooled in a Dry Ice – isopropanol bath to −65°C, then geraniol tetrahydropyranyl ether (3 g, 12.6 mmol) was added neat by syringe. The resulting reaction mixture was allowed to warm to 0°C over 2 h, then aqueous sodium hydroxide (3 *M*, 16 mL), followed by 30% hydrogen peroxide (16 mL), was added. After stirring several hours the solution was extracted with methylene chloride (3 times) and the combined organic solutions were dried, filtered, then concentrated under reduced pressure. The residue obtained was dissolved in methanol (100 mL), a few crystals of *p*-toluenesulfonic acid were added, then the solution was stirred 24 h; addition of solid sodium carbonate, dilution with methylene chloride, filtration, and concentration under reduced pressure afforded an oil that was purified by kugelrohr distillation to give the triols **5** and **6** (bp 130°C/0.1 Torr; 1 Torr = 133.3 Pa) (lit. bp (9) 142°C/0.1 Torr) (1.73 g, 9.2 mmol, 73%); ^1H nmr ($CDCl_3/D_2O$): 3.8–3.3 (4H, m), 1.75–1.15 (6H, m), 0.91 (6H, d, J = 7 Hz); ^{13}C nmr ($CDCl_3$): 76.3, 76.1, 64.7, 35.3, 33.8, 30.3, 28.4, 18.8, 17.8, 15.5 (major isomer).

*(2SR,3RS,6RS)-2-Hydroxymethyl-3-methyl-6-methylethyltetrahydropyran **8**a and acetate **8**b, and their diastereomers **7**a and **7**b*

The mixture of triols (1.73 g, 9.2 mmol) was dissolved in methylene chloride (20 mL) and pyridine (8 mL) in a round-bottomed flask protected by a calcium chloride guard tube, then cooled in an ice–salt bath. *p*-Toluenesulfonyl chloride (2.0 g, 10.5 mmol) was added, and the reaction mixture was allowed to warm to room temperature and stirred overnight at room temperature. The reaction mixture was then partitioned between methylene chloride and dilute hydrochloric acid, with the organic layer being separated, dried, filtered, then concentrated under reduced pressure followed by high

vacuum to give the monotosylate: ^{1}H nmr ($CDCl_3$): 7.82 (2H, d, J = 9 Hz) 7.36 (2H, d, J = 9 Hz), 4.16 (1H, d of d, J = 10.5 and 3 Hz), 3.98 (1H, d of d, J = 10.5 and 7 Hz), 3.63 (1H, m), 3.32 (1H, m), 2.45 (3H, s), 1.9–1.2 (8H, m including OH), 0.88 (6H, d, J = 7 Hz), 0.84 (3H, d, J = 7 Hz); ^{13}C nmr ($CDCl_3$): 145.0, 133.3, 130.0, 128.0, 77.2, 73.5, 72.8, 35.6, 33.8, 30.9, 28.4, 21.6, 18.8, 17.4, 15.4 (major isomer).

The tosylate was dissolved in methanol, then freshly prepared sodium methoxide in methanol was added dropwise until the reaction mixture was basic. After stirring for an additional 15 min, the solution was concentrated under reduced pressure. The crude epoxide was dissolved in glacial acetic acid (8 mL), then stirred 2 days at room temperature. The reaction mixture was partitioned between ether and aqueous sodium carbonate, and the organic layer was separated, dried, filtered, then concentrated under reduced pressure. Purification by kugelrohr distillation (100°C/0.07 Torr) afforded a mixture of alcohols **7***a* and **8***a* (0.767 g, 4.5 mmol, 49%); ^{1}H nmr ($CDCl_3$): 3.75–3.4 (3H, m), 3.03 (1H, m), 1.99 (1H, br s), 1.81–1.31 (6H, m), 0.95 (3H, d, J = 7 Hz), 0.89 (6H, d, J = 7.5 Hz); ^{13}C nmr ($CDCl_3$): 83.4, 80.7, 64.7, 33.2, 31.3, 28.9, 22.9, 18.5, 18.3, 12.2 (major isomer); 76.7, 74.6, 57.7, 32.4, 31.7, 27.7, 27.7, 18.7, 18.5, 16.2 (minor isomer).

Treatment with acetyl chloride in pyridine gave the acetate **8***b* (bp 125°C/15 Torr); ^{1}H nmr ($CDCl_3$): 4.12 (1H, ABX, J = 12 and 8.7 Hz), 4.03 (1H, ABX, J = 12 and 4.5 Hz), 3.68 (1H, d of d of d, J = 8.7, 4.5, and 2 Hz, H-2), 3.06 (1H, m, H-6), 2.12 (3H, s), 1.9–1.3 (6H, m), 1.0 (6H, d, J = 7 Hz), 0.95 (3H, d, J = 7 Hz); ms *m/e*: 215 (M^+ +1) (23%), 214 (M^+) (12%), 213 (M^+ −1) (31%), 171 (73), 154 (91), 141 (52), 123 (67), 111 (72), 93 (60), 82 (98), 55 (100). Signals at 2.12 (s) and 4.58 (d of d) in the proton nmr spectrum were assigned to the acetate methyl group and one of the two diastereotopic hydrogens on the exocyclic methylene group, respectively, of the minor diastereomer **7***b*.

*(2*E*,6*E*)-1-Benzyloxy-8-methoxy-3,7-dimethylocta-2,6-diene* ***9***

Following the procedure of Umbreit and Sharpless (11), a solution of *tert*-butyl hydroperoxide (from 42 mL of 70% aqueous), salicylic acid (1.2 g, 8.7 mmol), and selenium dioxide (0.22 g, 2 mmol) in methylene chloride (54 mL) was prepared. To this solution was added slowly *O*-benzylgeraniol (18 g, 73.8 mmol), then the reaction mixture was stirred 2 days at room temperature after which time it was diluted with ether (200 mL), washed with aqueous sodium hydroxide (3 *M*, 30 mL, 3 times), dilute aqueous sodium bisulfite (twice), dried, filtered, then concentrated under reduced pressure. The crude product was dissolved in 95% ethanol (200 mL), then sodium borohydride (2 g) was added and the reaction mixture stirred overnight. After concentration under reduced pressure, the reaction mixture was partitioned between ether (350 mL) and water (100 mL). The ether layer was separated, dried, filtered, then concentrated under reduced pressure to give, after drying under high vacuum, an oil (16.3 g). The oil was dissolved in dry ether (100 mL) and then added to a stirred suspension of sodium hydride (7.5 g, 50% dispersion in oil, hexane washed, 156 mmol) in dry ether (150 mL). Methyl iodide (8 mL, 128 mmol) was added, then the reaction mixture was refluxed overnight under a calcium chloride guard tube. The organic solution was then washed with water, dried, filtered, and concentrated under reduced pressure. The crude product was purified by vacuum distillation to give the diether (bp 120–125°C/0.01 Torr, 8.3 g, 30.3 mmol, 41%); ir (neat): 2910, 2840, 1490, 1450, 1370, 1190, 1090 cm^{-1}; ^{1}H nmr ($CDCl_3$): 7.35 (5H, m), 5.45 (2H, m), 4.5 (2H, s), 4.05 (2H, d, J = 6 Hz), 3.8 (2H, s), 3.3 (3H, s), 2.4–1.4 (10H, m).

*(2*SR*,3*SR*,6*RS*,7*SR*)-1-Benzyloxy-8-methoxy-3,7-dimethyloctane-2,6-diol* ***10***a *and its diastereomer* ***11***a

The diether **9** (1.8 g, 6.57 mmol) was dissolved in dry tetrahydrofuran (10 mL) under a nitrogen atmosphere, then cooled in an ice–salt bath to −10 to −15°C. A solution of thexylborane (13) (1 *M*, 10 mL) was then added dropwise via a double-tipped cannula; the resulting reaction mixture was stirred for 2 h at −10°C. Aqueous NaOH (3 *M*, 20 mL) was added, followed by 50% aqueous hydrogen peroxide (10 mL); the resulting solution was stirred overnight, then partitioned between ether (100 mL) and water. The organic layer was separated, washed with aqueous sodium metabisulfite, dried, filtered, and concentrated under reduced pressure. Thin-layer chromatography (silica, ether) showed two major components, R_f 0.4 and 0.3. Chromatographic purification (Lobar, ether) gave a mixture of diols **10***a* and **11***a* (0.63 g, 31%) as the higher R_f component; ir ($CHCl_3$): 3600–3200, 2860, 1450, 1200, 1100 cm^{-1}; ^{1}H nmr ($CDCl_3$): 7.35 (5H, s), 4.58 (2H, s), 3.72–3.16 (9H, m including s at 3.36), 2.62 (1H, br s), 1.95–1.14 (7H, m), 0.90 (6H, d, J = 7 Hz); ^{13}C nmr ($CDCl_3$): 138.31, 128.41, 127.67, 77.22, 76.39, 74.31, 73.49, 72.82, 58.95, 38.35, 36.35, 32.35, 28.31, 15.62, 14.04 (major diastereomer).

The lower R_f component was the diol **12** (0.58 g, 44%) as an equal mixture of a pair of diastereomers, as evidenced by proton decoupled ^{13}C nmr; ir ($CHCl_3$): 3610, 3600–3100, 2920, 1450, 1090 cm^{-1}; ^{1}H nmr ($CDCl_3$): 3.75–2.85 (10H, m, including s at 3.34 and br —OH), 1.88–2.05 (8H, m) 0.98–0.82 (6H, m); ^{13}C nmr ($CDCl_3$): 77.5/77.45, 76.24/75.71, 60.63/60.58, 59.00, 39.99/39.64, 38.25/38.21, 32.54/32.07, 32.03/31.79, 29.78/29.17, 19.88/19.64, 13.93/13.85 (carbon chemical shifts have not been unambiguously assigned for each of the diastereomers).

*(2*SR*,3*SR*,6*RS*,7*SR*)-8-Methoxy-3,7-dimethyloctane-1,2,6-triol* ***10***b *and its diastereomer* ***11***b

The mixture of diols (0.490 g, 1.58 mmol) was dissolved in methanol (20 mL) containing glacial acetic acid (2 drops) and 5% palladium on charcoal (100 mg), then hydrogenolysed at atmospheric pressure until thin-layer chromatography (silica, ethyl acetate) showed no remaining starting material. The solution was then filtered through Celite, concentrated under reduced pressure, and dried under high vacuum to give the triol as a mixture of stereoisomers (0.338 g, 1.55 mmol, 98%); ir ($CHCl_3$): 3600–3100, 3000, 2930, 1450, 1190, 1090 cm^{-1}; ^{1}H nmr ($CDCl_3$): 3.82–3.30 (9H, m including s at 3.37), 3.3–1.9 (3H, br), 1.9–1.28 (6H, m), 0.9–0.8 (6H, pair of overlapping doublets); ms *m/e*: 201 (M^+ −H_3O) (7%), 187(17), 171(25), 139(48), 129(72), 103(95), 71(100). *Exact Mass* calcd. for $C_{11}H_{24}O_4$ − CH_5O: 187.1334; found: 187.1343.

*(2*RS*,3*SR*,6*RS*,1′*SR*)-6-(2-Methoxy-1-methylethyl)-2-hydroxymethyl-3-methyltetrahydropyran* ***13*** *and its diastereomer* ***14***

The mixture of triols (0.339 g, 1.55 mmol) was dissolved in dry pyridine (10 mL) under a nitrogen atmosphere, then cooled in an ice–salt bath to −10°C. *p*-Toluenesulfonyl chloride (0.325 g, 1.70 mmol) was added, then the reaction mixture was stirred 2 h at −10°C, followed by 2 h at room temperature. The solvent was then removed under high vacuum and the residue partitioned between methylene chloride (50 mL) and water (25 mL). The organic layer was separated, washed with dilute aqueous HCl, dried, filtered, and concentrated under reduced pressure to give the monotosylate; ir ($CHCl_3$): 3600–3300, 2960, 1450, 1350, 1160, 1085, 890 cm^{-1}; ^{1}H nmr ($CDCl_3$): 7.82 (2H, d, J = 6 Hz), 7.36 (2H, d, J = 6 Hz), 4.17–3.92 (2H, m, AB portion of ABX), 3.70–3.30 (7H, m including s at 3.36), 2.46 (3H, s), 2.4–2.00 (2H, br s), 1.86–1.20 (6H, m), 0.88 (3H, d, J = 7 Hz), 0.87 (2H, d, J = 7 Hz).

The tosylate was dissolved in dry methanol (25 mL), then freshly prepared sodium methoxide in methanol was added dropwise until thin-layer chromatography (silica, ether) showed complete consumption of the starting material. The reaction mixture was concentrated under reduced pressure, then partitioned between methylene chloride (50 mL) and water (25 mL). The organic layer was separated, dried, filtered, and concentrated under reduced pressure to give the epoxide, which was used without purification. The ^{1}H nmr spectrum showed multiplets centred at 2.73 and 2.48 δ in a 2:1 ratio, indicative of an epoxide structure.

The epoxide was dissolved in glacial acetic acid (4 mL), then stirred 3 days at room temperature, after which time the reaction mixture was partitioned between methylene chloride (50 mL) and aqueous NaOH (3 *M*, 25 mL). The organic layer was dried, filtered, then concentrated under reduced pressure to give the crude product. Purification by Lobar chromatography (ether–hexanes, 1:1; ether) gave a mixture of diastereomeric tetrahydropyrans with **13** as the major component and **14** as the minor component (0.13 g, 49%); ir ($CHCl_3$): 3650–3150, 2900, 1450, 1220, 1085, 1065, 1050, 900 cm^{-1}; ^{1}H nmr ($CDCl_3$): 4.0–3.84 (2H, m), 3.72 (1H, dd, J = 9 and 5 Hz), 3.51–3.26 (5H, m including s

at 3.34), 3.22 (1H, dd, J = 9, 3 Hz), 3.15 (1H, br OH), 2.06–1.18 (6H, m), 0.95 (3H, d, J = 7 Hz), 0.82 (3H, d, J = 7 Hz); doublets at 0.94 and 0.91 were attributed to the minor diastereomer; ^{13}C nmr ($CDCl_3$): 76.67, 75.24, 70.24, 58.93, 57.37, 38.13, 31.83, 28.54, 27.88, 16.27, 14.22 (major diastereomer); 80.88, 79.88, 75.16, 64.46, 58.78, 38.89, 31.32, 28.88, 22.92, 13.19, 12.09 (minor diastereomer); ms *m/e*: 203 (M^+ +1) (13%), 184 (11), 171(57), 139(53), 129(55), 111(53), 99(71), 93(60), 81(86), 69(97), 55(100). *Exact Mass* calcd. for $C_{11}H_{22}O_3 - CH_2OH$: 171.1385; found: 171.1385.

Methyl (2RS,5SR,6RS, αRS)-6-Carboxy-α,5-dimethyltetrahydropyran-2-acetate **2**b *and dimethyl ester* **2**c

Following the procedure of Sharpless and co-workers (12), to a solution of the alcohols **13** and **14** (30 mg, 0.15 mmol) in carbon tetrachloride (2 mL) and acetonitrile (2 mL) were added water (3 mL), ruthenium trichloride trihydrate (10 mg), and sodium periodate (360 mg, 1.68 mmol). The resulting reaction mixture was stirred 18 h at room temperature, then partitioned between methylene chloride (25 mL) and water (10 mL). The aqueous layer was separated, dried, filtered, and concentrated under reduced pressure to give the half-ester **2***b* (20 mg, 58%) on purification by Lobar chromatography (ether): ir ($CHCl_3$): 3700–3000, 2920, 1715 (br), 1450, 1430, 1310, 1200, 1170, 1080 cm^{-1}; ^{1}H nmr ($CDCl_3$): 8.25 (1H, br s, CO_2H), 4.35 (1H, d, J = 5 Hz, H-C6), 3.89 (1H, ddd, J = 11, 9 and 2.5 Hz, H-C2), 3.75 (3H, s, methyl ester), 2.65 (1H, d of q, J = 9 and 7 Hz, H-Cα), 2.18–0.9 (11H, m including doublets at 1.16 and 1.15 with J = 7 Hz); ^{13}C nmr ($CDCl_3$): 175.26, 172.16, 76.28, 75.07, 51.86, 43.95, 32.35, 27.02, 26.20, 16.09, 13.27; ms *m/e*: 231 (M^+ +1) (10%), 212 (21), 199(21), 185(45), 170(36), 153(54), 143(49), 125(72), 115(68), 97(75), 88(67), 69(78), 55(100). *Exact Mass* calcd. for $C_{11}H_{18}O_5 - CO_2H$: 185.1176; found: 185.1169.

Treatment of the half-ester **2***b* with ethereal diazomethane afforded the diester **2***c*; ir ($CHCl_3$): 2940, 1725, 1450, 1435, 1170, 1085 cm^{-1}; ^{1}H nmr ($CDCl_3$): 4.33 (1H, d, J = 5.6 Hz), 4.27 (1H, ddd, J = 2.9, 8.5, 10.8 Hz), 3.71 (3H, s), 3.68 (3H, s), 2.57 (1H, dq, J = 7.1, 8.2 Hz), 2.2–1.2 (5H, m), 1.11 (3H, d, J = 7 Hz), 0.92 (3H, d, J = 7 Hz).

Reaction of **9** *with 9-borabicyclo[3.3.1]nonane*

The diene **9** (0.36 g, 1.3 mmol) was dissolved in dry tetrahydrofuran (2 mL) under a dry nitrogen atmosphere in a round-bottomed flask. The flask was placed in a room-temperature bath, then 9-BBN (0.5 *M* in tetrahydrofuran, 5 mL) was added to the flask by syringe. After stirring the reaction mixture overnight, aqueous sodium hydroxide (3 *M*, 5 mL) was added, followed by hydrogen peroxide (30%, 5 mL). The resulting mixture was stirred several hours, then partitioned between methylene chloride and water. The organic layer was separated, dried, filtered, then concentrated under reduced pressure to give an oil that was chromatographed (Lobar; ether–hexanes, 1:1) to give recovered diene (0.19 g) and the alcohol **15** (0.054 g); ir ($CHCl_3$): 3610, 3600–3100, 2990, 2910, 1445, 1370, 1200, 1085 cm^{-1}; ^{1}H nmr ($CDCl_3$): 5.42 (1H, t, J = 7 Hz) 3.81 (2H, s), 3.68 (2H, m), 3.28 (3H, s), 2.55–1.13 (11H, m including s at 1.66), 0.92 (3H, d, J = 7 Hz); ^{13}C nmr ($CDCl_3$): 131.83, 128.63, 78.75, 60.88, 57.29, 39.84, 36.83, 29.24, 25.13, 19.52, 13.75. The alcohol **16** was detected by proton nmr as a minor and unquantifiable component in another fraction (5 mg).

This paper describes the synthesis, in ethereal solvents, of the complexes of 18-crown-6, the *cis–syn–cis* and the *cis–anti–cis* isomers of dicyclohexano-18-crown-6, and dibenzo-18-crown-6 with the potassium and sodium salts of phenoxide and thiocyanate (as well as some potassium oximate salts). In general, the macrocycles break down the aggregates of the potassium salts so that the complexes of the contact ion pairs are isolated. The complex of the *cis–anti–cis* isomer of dicyclohexano-18-crown-6, however, which has a low stability constant, complexes the dimer of potassium phenoxide to give a complex with a 1:2 host:guest ratio. This appears to be the first example of a 1:2 host:guest ratio of a potassium salt with an 18-crown-6 macrocycle. There is a greater tendency for the complexes of sodium salts to have host:guest ratios less than 1:1. Thus, 18-crown-6 gives complexes with sodium phenoxide and sodium thiocyanate which have 1:3 and 1:2 host:guest ratios, respectively. Host:guest ratios of 1:2 are also obtained for the two above-mentioned isomers of dicyclohexano-18-crown-6 and for dibenzo-18-crown-6 with sodium phenoxide. Sodium thiocyanate gives complexes with either 1:1 or 1:2 host:guest ratios depending on the macrocycle. With dibenzo-18-crown-6, sodium thiocyanate gives a 1:1 complex in which one molecule of the solvent used is incorporated into the complex. The infrared and ultraviolet spectra of the complexes are discussed.

ANDRÉ RODRIGUE, JOHN W. BOVENKAMP, BENOIT V. LACROIX, ROBERT A. B. BANNARD et GERALD W. BUCHANAN. Can. J. Chem. **64**, 808 (1986).

Dans cette communication, on décrit la synthèse, dans des solvants éthérés, des complexes de la 18-couronne-6, des isomères *cis–syn–cis* et *cis–anti–cis* de la dicyclohexano-18-couronne-6 et de la dibenzo-18-couronne-6 avec les phénolates et thiocyanates de potassium et de sodium (ainsi qu'avec quelques oximates de potassium). D'une façon générale, les macrocycles brisent les agrégats des sels de potassium et l'on peut donc isoler les complexes des paires d'ions de contact. Toutefois, la constante de stabilité du complexe de l'isomère *cis–anti–cis* de la dicyclohexano-18-couronne-6 est faible et il se complexe donc avec le dimère du phénolate de potassium pour donner un complexe dans le rapport 1:2. Il semble que ce soit le premier exemple d'un complexe dans le rapport 1:2 d'un sel de potassium avec un macrocycle 18-couronne-6. Dans le cas des complexes du sodium, il existe une grande tendance à avoir des complexes dans des rapports plus petits que 1:1. La 18-couronne-6 donne donc des complexes avec le phénolate de sodium et le thiocyanate de sodium dans des rapports respectifs de 1:3 et 1:2. On a aussi obtenu des rapports 1:2 lors de la formation de complexes entre le phénolate de sodium et les isomères mentionnés plus haute de la dicyclohexano-18-couronne-6 ainsi qu'avec la dibenzo-18-couronne-6. Dans le cas du thiocyanate de sodium, on obtient, suivant la nature des macrocycles, des complexes avec des rapports 1:1 ou 1:2. Avec la dibenzo-18-couronne-6, le thiocyanate de sodium donne un complexe 1:1 dans lequel une molécule du solvant utilisé est incorporée dans le complexe. On discute des spectres infrarouges et ultraviolets des complexes.

[Traduit par la revue]

Introduction

Since the pioneering paper by Pedersen (1) on the synthesis of cyclic polyethers and their complexes, there has been a great deal of interest in this area. Macrocyclic ether complexes have been shown to have 1:1 host:guest stoichiometry when the radius of the metal ion of the salt and the size of the cavity formed by the macrocycle are compatible (e.g. potassium salts with 18-crown-6 macrocycles (2)) but have 2:1 host:guest ratios when the metal ion radius is too large to fit into the cavity (e.g. (benzo-15-crown-5)$_2$·KNCS (3)). Alternatively, when the cavity of the cyclic polyether is large enough, two metal ions can be accommodated. Examples in this category are the 1:2 host:guest ratios exhibited by 18-crown-6·2LiNCS·2H$_2$O (4) and DB-24-crown-8·2KNCS (5).

Recently, we have carried out low temperature ^{13}C nmr stereochemical studies of the *cis–syn–cis* and *cis–anti–cis* isomers (isomers A and B, respectively) of dicyclohexano-18-crown-6 (6, 7). During our work with these compounds, it was found that on the addition of the commercial mixture of the two isomers to a 1,2-dimethoxyethane solution of potassium phenoxide, a solid precipitated. This solid had a narrow-range melting point and was shown by proton nmr to have a 1:2 host:guest ratio. Upon repeating the reaction with isomer B by itself, the same complex (**8** in Table 1) was obtained. It was apparent that an aggregate of potassium phenoxide, presumably a dimer, was being complexed by isomer B of DC-18-crown-6 instead of the contact ion pair that would have been expected.

The above result led to the present study in which the complexes of a series of sodium and potassium salts (mainly phenoxide and thiocyanate) were isolated from the ethereal solvents 1,2-dimethoxyethane (DME), tetrahydrofuran (THF), and diethyl ether. Whenever possible, a standard method was used, which involved reacting the macrocycle with an excess quantity of the sodium or potassium salt solubilized in anhydrous solvent (see experimental section). The complex that precipitated was then collected by filtration, washed with diethyl ether, and subjected to high vacuum. It was not possible to use this standard method with all of the complexes in Table 1

20	DB-18-C-6	Na^+OPh^-	1:2
21[b]	DB-18-C-6	Na^+NCS^- (in dimethoxyethane)	1:1:1
22[b]	DB-18-C-6	Na^+NCS^- (in tetrahydrofuran)	1:1:1
23[b]	DB-18-C-6	Na^+NCS^- (in 1,3-dioxolane)	1:1:1

[a]DC-18-C-6 (A) designates the *cis–syn–cis* isomer and DC-18-C-6 (B) the *cis–anti–cis* isomer of this macrocycle.

[b]One molecule of solvent adheres very strongly to the complex of DB-18-C-6 and NaSCN. Thus, **20**, **21**, and **22** are 1:1:1 complexes containing one molecule of the solvents indicated (see text).

since in some cases the potassium salts were not soluble in the solvents used and in other cases the complex was too soluble to precipitate from the solvent in which it was formed. Dry solvents were used and the complexations were carried out in an argon atmosphere.

Results and discussion

In ethereal solvents like DME, THF, and Et_2O, many alkali metal salts form aggregates, $(R^-M^+)_n$. Jackman and Szeverenyi (8) have shown that lithioisobutyrophenone forms tetramers and dimers in this type of solvent. The authors (8) state that there did not appear to be any compelling reason to postulate free ions or monomeric ion pairs in the exchange process between the tetramer and the dimer in DME.

The degree of association of ion pairs depends on the solvent and on the size, charge density, and hardness of both the cation and the anion (9, 10). Reichle (11) has found that the degree of aggregation of 0.08 *M* potassium phenoxide in THF at 37°C is 3.2. Sodium and potassium alkoxides have been shown to form associated ion pairs even in more polar solvents than those used in this study (10, 12). Ion pairs of *t*-BuOLi were found to be more associated than those of *t*-BuOK (12). In Jackman and Lange's review (9), solvents are separated into four classes with respect to the occurrence of free ions, ion pairs, and aggregates of ion pairs. Weakly polar solvents like the ethereal solvents used in this study were called class B solvents. Evidence is presented that indicates that in this class of solvent "the 'tightness' of ion pairing (either as monomers or aggregates) will be greatest for Li^+, the smallest alkali metal cation, and will decrease monotonically with increasing ion radius of the cation" (9).

TABLE 2. Stability constants for sodium and potassium salt complexes in water and methanol (ref. 16)

	Sodium salts		Potassium salts	
Macrocycle	Log *K* (Water)	Log *K* (Methanol)	Log *K* (Water)	Log *K* (Methanol)
Cryptand [2.2.2]	3.90	7.98[a]	5.40	10.41[a]
18-Crown-6	0.8	4.36	2.03	6.05
DC-18-Crown-6				
Isomer A	1.21	4.08	2.02	6.01
Isomer B	0.69	3.68	1.63	5.38
DB-18-Crown-6	1.16	4.5	1.67	5.1

[a]All values are taken from ref. 16*a* except those for cryptand [2.2.2] in methanol, which are from ref. 16*b*.

It has been generally accepted that when 18-crown-6 macrocycles are added to solutions of sodium or potassium salts in ethereal solvents, the aggregates are broken up and 1:1 complexes with either the contact ion pair or the separated ion pair are formed (13, 14). In fact, Thomassen *et al.* (14) present kinetic evidence in support of this behaviour in the reaction of potassium phenoxide with butyl bromide in the presence of DC-18-crown-6. The study of Cornelis *et al.* (15) using sodium-23 nmr, however, has shown that the sodium salt of ethyl acetoacetate exists in THF as an equilibrium of monomeric and dimeric ion pairs, both of which interact with 18-crown-6 or 15-crown-5.

This work shows that, in some cases, complexes of 18-crown-6 macrocyclic ethers with potassium and sodium salts can be obtained from ethereal solvents with host:guest ratios smaller than 1:1. As shown in Table 2, the macrocyclic ethers used in this study had varying complexing abilities. "Hard" anions, such as phenoxide and oximates, as well as the "soft" thiocyanate anion were utilized. Sodium, as well as potassium, salts were used, since sodium salts would tend to form stronger aggregates (*vide supra*) and at the same time the stability constants of 18-crown-6 macrocycles are significantly smaller with sodium salts than with potassium salts (see Table 2).

Table 3 gives the melting points and elemental analyses of the isolated complexes while Table 4 gives the solvents used and the yields of the complexes obtained.

As the host:guest ratios for the potassium salts in Table 1 show, the 18-crown-6 macrocycles, with a single exception, give isolated complexes which have 1:1 host:guest ratios. As expected, cryptand [2.2.2], the strongest complexer in the table, also gives a 1:1 complex (**13**) with potassium phenoxide. The complex of DB-18-crown-6 with KNCS (**12**) gave the same 1:1 ratio when precipitated from DME as that obtained by Pedersen (3) from methanol. Also, the complex of 18-crown-6 with KNCS (**5**) gave the same 1:1 ratio as obtained by Dale and Kristiansen (17) and Seiler *et al.* (18) from methylene dichloride under non-anhydrous conditions. The B isomer of DC-

[a]Literature (17) mp 190°C.

[b]Pedersen (1) has reported the synthesis of the potassium thiocyanate complex of the mixture of A and B isomers of DC-18-crown-6 (mp (1) of the mixture was 72–122°C).

[c]Literature (3) mp 245–246°C.

[d]Complex **13** is especially sensitive to the atmosphere and to light (see the experimental section). Even so, it was possible to obtain a reasonable elemental analysis (except for the value for carbon, which was 1.9% low).

[e]At 137°C for **15** and 178°C for **19**, the solid turns into a mixture of liquid and solid. The solid in the mixture does not melt even up to 250°C. It is apparent that the 1:2 complex is decomposed at 137°C for **15** and 178°C for **19**, possibly to the 1:1 complex and NaNCS.

18-crown-6, however, gives a complex with a host:guest ratio of 1:2 (**8**). The crystal structure of this complex has been determined by X-ray diffraction techniques (19). Essentially, it is a dimer of potassium phenoxide that is being complexed. The potassium ions are related by symmetry and each is located approximately halfway between the crown ether and two phenoxide anions. Each individual crown molecule complexes one of the potassium ions of two dimers, one above the approximate plane of the macrocyclic ring and one below. Thus, it appears that the complexing ability of isomer B, DC-18-crown-6, a weak complexer (see Table 2), is not sufficient to break up the dimer to the contact ion pair stage.

Other examples of the potassium cation being out of the plane of the macrocycle ring have been reported. For example, in the 1:1 complex of 18-crown-6·potassium ethyl acetoacetate enolate, the K^+ is displaced by 0.9 Å out of the mean plane of the crown towards the strongly chelating anion of ethyl acetoacetate (20). With the NCS^- anion, the K^+ is situated exactly in the mean plane of the crown (18). The explanation must involve the competition between the crown and the anion for the K^+. If the anion is "hard", then it is closely associated with the K^+ and the crown cannot take the K^+ all the way into the "pocket" because of the repulsion between the crown oxygens and the negatively charged anion.

From Table 1, it is evident that the sodium salts have a much greater tendency to form complexes with multiple host:guest ratios than the potassium salts. A number of interesting comparisons can be made between the host:guest ratios obtained with sodium and potassium thiocyanates. Sodium thiocyanate gives a complex with 18-crown-6 which has a 1:2 host:guest ratio (**15**). This ratio can be compared with the 1:1 complex (18-crown-6·NaNCS·H_2O) formed by allowing a methylene dichloride solution of 18-crown-6 and NaNCS to evaporate in an open beaker to near dryness (17, 21, 22). The complex of NaNCS with DC-18-crown-6 (A) (**17**), however, has a 1:1 host:guest ratio, even though its complexing ability is not appreciably different from that of 18-crown-6 (see Table 2). It is thought that the cyclohexane rings, which are on the same side in DC-18-crown-6 (A), play a role in the explanation for this behaviour. That is, 18-crown-6 and also DC-18-crown-6 (B) would find it easier to complex two "out-of-pocket" cations than DC-18-crown-6 (A). In contrast to isomer A, DC-18-crown-6 (B) gives a NaNCS complex with a 1:2 host:guest ratio (**19**). The complex of DB-18-crown-6 with NaNCS has a 1:1 host:guest ratio (**21**, **22** and **23**) but it is interesting to note that the complex isolated is a 1:1:1 host:guest:solvent complex. Thus, solvent adheres very strongly to this complex and, even after 17 h in a drying pistol at 56°C under high vacuum, only a fraction of the solvent is removed from the 1:1:1 complexes that are formed in DME, THF, and 1,3-dioxolane. Complexes of DB-18-crown-6 with 1:1:1 ratios have been reported previously. For example, Hilgenfeld and Saenger (23) report the 1:1:1 complex of DB-18-crown-6 with potassium iodide and thiourea and Pedersen (24) reports 1:1:1 complexes of DB-18-crown-6 with sodium or potassium thiocyanate and thiourea. In the crystal structure of DB-18-crown-6 with potassium iodide and

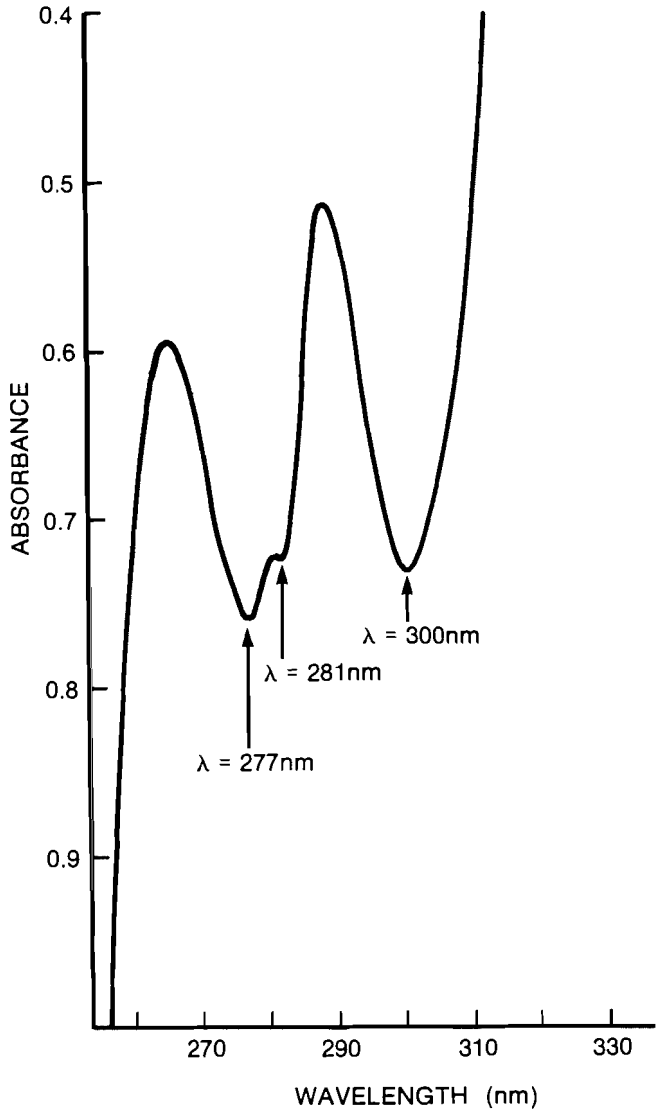

FIG. 1. The ultraviolet spectrum of DB-18-crown-6·2NaOPh in dimethoxyethane.

thiourea, the thiourea hydrogen bonds to the anion (23). This is not possible in **20**, **21**, and **22** and very likely the solvent molecule interacts with the Na^+. Solvent does not adhere as strongly to the 1:1 complex of DB-18-crown-6 with KNCS (12). This is in agreement with the work of Wong, Konizer, and Smid (25), who showed that THF is more strongly bonded to Na^+ than to K^+ in their system involving dimethyldibenzo-18-crown-6 and fluorenyl alkali salts.

Sodium phenoxide exhibits a greater propensity to form complexes with lower host:guest ratios than does KOPh (see Table 1). The reasons for this appear to be that Na^+ is not as strongly complexed by the crowns (see Table 2) and also that Na^+ is expected to form stronger associated ion pairs. Also, sodium phenoxide forms complexes with lower host:guest ratios than NaNCS. The proposed reason for this behaviour is that the "hard" phenoxide anion forms associated ion pairs more readily than the "soft" thiocyanate anion. Some support is obtained for this from the published crystal structure of 1:1 thiocyanate salt complexes. In the crystal structure of 18-crown-6·KNCS (18), the thiocyanate anions are disordered and interact only weakly with the K^+. Also, in 18-crown-6·NaNCS·H_2O, it is the water molecule that interacts with the Na^+ while the thiocyanate anion is hydrogen bonded to the water molecule (22).

18-Crown-6 forms a complex (**14**) with NaOPh that has a host:guest ratio of 1:3, the lowest ratio found in this study. It was readily precipitated using our standard method from a solution containing a 4:1 excess of salt to crown and has a melting point of 190.5–192.5°C. The reason why 18-crown-6 forms a complex with NaOPh with a 1:3 host:guest ratio, whereas the three substituted 18-crown-6 macrocycles give complexes with NaOPh with 1:2 ratios (**16**, **18**, and **20**), is not readily apparent. Attempts to grow suitable crystals of **14** for an X-ray diffraction structure determination have not yet been successful.

DC-18-crown-6 (A) forms a complex (**16**) with a 1:2 host:guest ratio with NaOPh as compared with the 1:1 ratio of its potassium analogue (**6**). The crystal structure of **16** has been determined (19) and differs considerably from that of DC-18-crown-6 (B)·2KOPh (**8**). The structure of **16** in the crystal form consists of a tetramer of NaOPh in which two macrocyclic ether molecules each complex two sodium ions. One sodium is coordinated to the six hexaether oxygens and to one of the phenoxide oxygens, while the other sodium is coordinated to only one of the crown oxygens and to three of the phenoxide oxygens. The crown adopts a highly irregular conformation. A full description of the structure of this interesting complex is given in ref. 19. The DC-18-crown-6 (B) complex with NaOPh (**18**) has the same host:guest ratio of 1:2 as its KOPh counterpart (**8**). However, DB-18-crown-6 gives a complex with NaOPh (**20**) with a host:guest ratio of 1:2, in contrast with its KOPh counterpart (**11**), which has a 1:1 ratio.

TABLE 5. λ_{max} from the ultraviolet spectra of the phenoxide anion in the complexes dissolved in dimethoxyethane

Free ion	2052	738	2052	738

[a]The solvent used was tetrahydrofuran except for the dimer of KNCS where dioxolane was used.

Ultraviolet spectra of the complexes

The ultraviolet spectrum of DB-18-crown-6·2NaOPh (**20**) in DME is shown in Fig. 1. Three peaks are present at λ_{max} 277, 281, and 300 nm. Only a single peak with a λ_{max} of 276 nm is present for DB-18-crown-6 in dimethoxyethane. The peak at λ_{max} 300 nm is that of the phenoxide anion. The appearance of a small peak like that at λ_{max} 281 nm has been shown by Pedersen (1) to be indicative of complex formation of DB-18-crown-6 with salts like KNCS, KI, and NaBr.

It is interesting to compare the λ_{max} values for the phenoxide anion for the applicable complexes. These are shown in Table 5 for DME solutions. The λ_{max} for potassium phenoxide itself, which is expected to exist as dimers and (or) higher aggregates of ion pairs, is 309 nm. The λ_{max} for phenoxide ion in the 1:1 complexes **1**, **6**, and **11** are shifted to 317, 318, and 316 nm, respectively. The phenoxide anion in these cases is expected to exist as a contact ion pair with the potassium ion. This ion pair is complexed by the crown ether. The λ_{max} for the phenoxide anion in the cryptand [2.2.2] complex (**13**) is shifted even further to 322 nm. In this case, the potassium ion is expected to be encased in the cryptand [2.2.2] molecule and contact between the cation and the phenoxide anion is expected to be greatly diminished (26). The λ_{max} value of the phenoxide ion in the complex formed by DC-18-crown-6 (B) with two KOPh salt molecules (**8**) is shifted to only 311 nm from the value of 309 nm for potassium phenoxide itself. Compound **8** in the crystalline state is essentially a complexed dimer of potassium phenoxide with the potassium ions above and below the plane formed by the ether rings (19) (*vide supra*). The small shift, compared to the larger ones for the 1:1 complexes in which contact ions pairs are expected, is evidence that this structure is maintained in solution.

In contrast, the λ_{max} values for the phenoxide anion in **14**, **16**, **18**, and **20**, which all have either 1:2 or 1:3 host:guest ratios, are essentially identical with that found for sodium phenoxide itself. This is a good indication that the Na^+ ions are not being complexed strongly and that the NaOPh salt molecules are associated more strongly with each other than with the macrocycles.

Ismail and El-Bayoumi (27) report that the λ_{max} of potassium *p*-methylphenoxide in THF increased from 317 to 326 nm when 18-crown-6 was added to the solution. This is similar to the magnitude of the shift difference found for potassium phenoxide and **1** (see Table 5). Thus, a 1:1 complex is probably formed in solution. On the other hand, for potassium *p*-methoxyphenoxide the λ_{max} of 334 nm did not change on the addition of 18-crown-6 (27). Also the λ_{max} of sodium *p*-methoxyphenoxide was found to be 323 nm by itself and 322 nm in the presence of 18-crown-6. These results would appear to indicate that 18-crown-6 complexes the dimer or higher aggregates of potassium and sodium *p*-methoxyphenoxide in THF. The sodium and potassium *p*-formyl phenoxide salts have λ_{max} shifts (27) in THF from 334 to 340 nm and from 347 to 357 nm, respectively, on the addition of 18-crown-6, indicative of 1:1 ion pair complexation.

Thus, single ion pairs are complexed more readily with substituted phenoxide in which the least charge is expected on the phenoxide oxygen (e.g. *p*-formyl) and associated ion pairs are complexed when the greatest amount of charge is expected on the phenoxide oxygen (e.g. *p*-methoxy). That is, the "harder" the anion, the stronger the associated ion pair aggregates and the more difficult it is for the crown to complex single ion pairs.

Infrared spectra of the complexes

Infrared spectra were obtained using the Nujol mull of the complexes. As noted by Pedersen (1) and others, for complexes that they studied, the infrared spectra of the complexes in Table 1 differ significantly from those of the macrocyclic ethers themselves, especially in the 700–1100 cm^{-1} region, which contains bands attributable to the wag, twist, and rock modes of vibration of the methylene groups of the macrocycle. Perhaps the most interesting aspect of the infrared spectra is the position and number of the ν_{CN} and ν_{CS} bands of the thiocyanate complexes.

Table 6 shows the position of these bands in the free anion, the contact ion pair, and the dimer, as determined by Chabanel and co-workers (28, 29) in tetrahydrofuran (dioxolane was used for $(KNCS)_2$). Table 7 shows the ν_{CN} and ν_{CS} frequencies

TABLE 7. ν_{CN} and ν_{CS} infrared frequencies (cm^{-1}) for the thiocyanate complexes[a]

Macrocycle	Sodium thiocyanate			Potassium thiocyanate		
	ν_{CN}	ν_{CS}	Host:guest ratio	ν_{CN}	ν_{CS}	Host:guest ratio
DC-18-C-6 (A)	2072	756	1:1 (**17**)	2057	749	1:1 (**7**)
DC-18-C-6 (B)	2050	767	1:2 (**19**)	2045	746	1:1 (**10**)
18-C-6	2067	756	1:2 (**15**)	2053	734	1:1 (**5**)
	2043	760				

[a]Obtained from the Nujol mull of the solid complexes.

obtained from the Nujol mulls of the solid complexes of Table 1. The thiocyanate complexes of DB-18-crown-6 are not included in Table 7 because the ν_{CS} peaks are masked by the peaks due to the aromatic carbon–hydrogen out-of-plane bending mode of vibration.

Although one must exercise caution in comparing the data in Table 6 for solutions of the thiocyanate salts with those in Table 7 for the Nujol mulls of the complexes, some speculation appears in order. The ν_{CS} frequency (734 cm^{-1}) found for the potassium thiocyanate complex of 18-crown-6 (**5**), is closest to that found for the free thiocyanate ion (738 cm^{-1}, see Table 6). The reason for this behaviour can be found in the published crystal structure of this compound (18), in which it was shown that the thiocyanate anion was disordered and interacted only weakly with the cation. The ν_{CS} frequencies of the 1:1 potassium thiocyanate complexes **7** and **10** (ν_{CS} = 749 and 746 cm^{-1}, respectively) are closest to that found for the contact ion pair of potassium thiocyanate in solution (752 cm^{-1}, see Table 6).

If it is assumed that the ν_{CS} and ν_{CN} frequencies of the 1:1 sodium thiocyanate complex of DC-18-crown-6 (A) (**17**) (see Table 7) are those for the contact ion pair (a not unreasonable assumption when these values are compared with those of Table 6), then some interesting comparisons can be made with **19** and **15**. For **19**, the ν_{CS} frequency increases by 11 cm^{-1} and the ν_{CN} frequency decreases by 22 cm^{-1} compared to the corresponding frequencies found for **17** (see Table 7). From Table 6, it can be seen that the ν_{CS} frequency of the dimer is higher by 9 cm^{-1} than that of the contact ion pair and the ν_{CN} frequency is lower by 14 cm^{-1}. Thus, it would be reasonable to expect that, in **19**, a dimer of sodium thiocyanate is being complexed. This would be a similar situation to that found in the crystal structure of **8**, in which the same macrocycle complexes a dimer of KOPh (19).

The ν_{CS} and ν_{CN} peaks for the 1:2 complex of 18-crown-6 with sodium thiocyanate (**15**) exist as doublets. Note that one set of ν_{CN} and ν_{CS} frequencies (2067 and 756 cm^{-1}, respectively) is close to that found for **17**, in which a contact ion pair was assumed, while the other set (ν_{CN} = 2043 and ν_{CS} = 760 cm^{-1}) has frequency values that are each 7 cm^{-1} less than those for **19** in which a dimer was postulated. Attempts are being made to prepare suitable crystals of **15** for an X-ray diffraction structure determination.

Experimental

Commercial anhydrous diethyl ether and toluene were dried over sodium wire. Reagent grade DME and THF were distilled from lithium aluminum hydride using a Stedman column and a variable take-off still head. Potassium and sodium thiocyanate were obtained commercially and were used after being subjected to high vacuum (<0.001 Torr; 1 Torr = 133.3 Pa) at 56°C for 18 h; mp 176–176.8 and >290°C, respectively (lit. (3) mp 173 and 287°C, respectively).

Isomers A and B of DC-18-crown-6 were separated from the commercial mixture by the method of Izatt *et al.* (30); mp 81.5–82.5°C (lit (30) mp 83–84°C) and 60.2–61.2°C (lit. (30) mp 61–62°C), respectively. DB-18-crown-6 was recrystallized from toluene; mp 161.5–163°C (lit. (3) mp 164°C and (31) mp 162.5–163.5°C). Commercial 18-crown-6 was precipitated as the acetonitrile complex (32) and the acetonitrile was removed under vacuum; mp 40.5–41.0°C (lit. (1) mp 39–40°C).

Preparation of the potassium salts of phenol, acetylacetone, E-acetophenone oxime (33), and 2,3-butanedione monoxime

These salts were obtained by reacting the starting material with powdered potassium in a nitrogen atmosphere. The safe handling procedures of Johnson and Schneider (34) were followed with potassium. Except in the case of the larger potassium salt preparations, where the initial filtration was carried out in the open air, the work-up of the reaction mixtures was conducted in a Dri-Lab (Vacuum Atmospheres) under an argon atmosphere. Purities of the potassium salts were checked by proton nmr and by potassium microanalyses. The procedure given below for potassium phenoxide is typical.

Potassium phenoxide

Potassium (9.21 g, 0.236 mol), freed of oxide crust, was added to a three-necked flask equipped with a reflux condenser, drying tube, stirring bar, and nitrogen gas inlet. Dry toluene (150 mL) was introduced and the potassium was powdered by heating the mixture to the boiling point while stirring vigorously. The mixture was allowed to cool and dry ether was added (150 mL). Phenol (25.00 g, 0.266 mol, sublimed under vacuum) dissolved in dry ether (150 mL) was added by dropping funnel. After being refluxed for 2 h, the mixture was filtered and the colourless solid was washed twice with dry ether. The salt was placed in a drying pistol under high vacuum (<0.001 Torr) at 56°C for 24 h. Yield, 28.2 g (91%); mp 285–289°C. *Anal.* calcd. for C_6H_5OK: K 29.57; found: K 29.17. Kornblum and Lurie (35) synthesized this salt by reacting phenol with potassium hydroxide in aqueous methanol.

Potassium acetylacetonate

A 9-day reflux period with powdered potassium was used; mp 210–215°C (dec.). *Anal.* calcd. for $C_5H_7O_2K$: K 28.33; found: K, 28.30. Carty *et al.* (36) report a potassium analysis for this salt which is 3.3% low.

Potassium 2,3-butanedione monoximate

The crude potassium salt obtained after a 1-week reflux period did not give a satisfactory potassium analysis. The solid was dissolved in warm ethanol, the solution was filtered while warm to remove undissolved material, and the salt was precipitated with dry ether; mp 224–226°C. *Anal.* calcd. for $C_4H_6NO_2K$: K 28.09; found: K 28.42.

E-*Potassium acetophenone oximate*

The crude potassium salt obtained after a 2-day reflux period was dispersed in a mixture of acetonitrile and dimethylsulfoxide (5:1 ratio). The mixture was heated to 70°C and filtered while hot. The solid that precipitated upon cooling had a mp of 267–270°C. *Anal.* calcd. for C_8H_8NOK: K 22.57; found: K 22.23.

Sodium phenoxide

Phenol and chunks of sodium metal in dry ether were refluxed under nitrogen for 3 days in a similar fashion to that described for the potassium

salt. The white salt was recrystallized from acetone. *Anal.* calcd. for C_6H_5ONa: Na 19.80; found: Na 19.74. Kornblum and Lurie (35) synthesized this salt using NaOH in methanol.

Synthesis of the macrocyclic ether complexes

It was possible to use a standard method for the synthesis of most of the complexes (see below). In this procedure, one equivalent of the macrocycle was added to a solution containing three equivalents of the salt. The complex was then allowed to precipitate from solution. The methods of synthesis of complexes for which the standard method was not used are given separately. Table 4 gives the solvent used, its volume, and the % yield (based on the macrocycle) for the complexes. All complexation reactions were carried out in a Dri-Lab (Vacuum Atmospheres) under an argon atmosphere. Table 3 gives the elemental analysis obtained for each complex.

*Standard synthetic method used for **1**, **5**, **8**, **10–12**, **16–23***

The sodium or potassium salt (5.1 mmol) was solubilized in anhydrous solvent. The crown was added (1.7 mmol) and the mixture was stirred for 1 h at room temperature. The precipitated complex was obtained by filtration, washed with diethyl ether, and subjected to high vacuum (<0.001 Torr) in a drying pistol (at 56°C) for approximately 17 h.

Solvents adhere very strongly to the complex between DB-18-crown-6 and NaNCS. One molecule of either dimethoxyethane, tetrahydrofuran, and 1,3-dioxolane is incorporated into the complex, when these are used as the complexing solvent (**21**, **22**, and **23**, respectively). Since only a fraction of this solvent was removed during the 17-h high vacuum treatment mentioned above, these complexes were only subjected to a 2-h period of high vacuum treatment. According to proton nmr and the elemental analyses, one molecule of solvent remained in the complexes in each case.

*Synthesis of **14** and **15***

The standard method was used except that 6.8 mmol of sodium phenoxide or sodium thiocyanate was used with 1.7 mmol of 18-crown-6.

*Synthesis of **7** and **10***

The complexes of isomers A and B of DC-18-crown-6 with potassium thiocyanate (**7** and **10**, respectively) were soluble in both dimethoxyethane and tetrahydrofuran and did not precipitate during the 1-h stirring period used in the standard method. Thus, the solvent was removed and methylene chloride (7 mL) was added. The insoluble solid was filtered off and washed with additional methylene chloride (3 mL). Diethyl ether (50 mL) was added to the combined methylene chloride filtrates to precipitate the complex.

*Synthesis of **6***

Isomer A of DC-18-crown-6 (1.7 mmol) was dissolved in diethyl ether (30 mL). Solid potassium phenoxide (1.7 mmol) was added. In about 4 min, only a trace of solid remained undissolved and this was filtered off. After several minutes, the complex began to precipitate from the filtrate and the mixture was filtered after being stirred for 30 min. After being washed with diethyl ether, the solid was subjected to high vacuum (<0.001 Torr) at 56°C for 17 h. The standard method could not be used to form this complex because the KOPh and the complex have similar solubilities in the solvents used. Both are very soluble in DME and the complex could not be precipitated without also precipitating the KOPh.

*Synthesis of **2** and **9***

The crown ether (1.7 mmol) and the potassium salt (5.1 mmol) were stirred in DME for 3 h. The excess potassium salt was filtered off. The solvent was removed from the filtrate and the residual complex was stirred for 30 min in diethyl ether. After being collected by filtration, the light-yellow salt was washed with diethyl ether and subjected to high vacuum (<0.001 Torr) at 56°C for 17 h.

*Synthesis of **3** and **4***

The potassium oximate (1.7 mmol) was dispersed in dimethoxyethane. Upon addition of the 18-crown-6 (1.8 mmol), the potassium salt dissolved and the complex soon precipitated. After the mixture was stirred for 1 h, the light-yellow solid was filtered off, washed with diethyl ether, and subjected to high vacuum (<0.001 Torr) at 56°C for 17 h.

*Synthesis of **13***

To potassium phenoxide (2.68 mmol) dissolved in DME (8 mL) was added cryptand [2.2.2] (2.66 mmol) in DME (6 mL). A clear light-yellow solution resulted. The beige precipitate that formed during the 18-h stirring period was collected by filtration and dried under high vacuum (<0.001 Torr) at 56°C for 9 h (0.687 g, 51%). Stirring the complex with fresh DME did not improve the elemental analysis (see Table 3), which was outside of the normally acceptable levels for carbon and hydrogen. In these experiments, flasks and sample bottles were covered with aluminum foil since cryptand [2.2.2] was stated to be light sensitive. Indeed, the complex (as a solid or in solution) turned purple when exposed to the atmosphere and to light.

Ultraviolet spectra of the phenoxide salt complexes

The complexes were dissolved in DME and a sample was inserted into the ultraviolet cells (0.1 cm) under an argon atmosphere. The ultraviolet spectra were obtained with a Varian Cary 2390 spectrophotometer. One of two methods was used to dissolve the complex in DME depending on its solubility. *Method A* (**6**, **13**, **14**, **16**, NaOPh, and KOPh): The complex (1 mmol) was weighed into a volumetric flask (50 mL) and anhydrous DME was added to the mark. A portion (5 mL) of this solution was diluted to 50 mL. The reference cell was filled with DME. *Method B* (**1**, **8**, **11**, **18**, **20**, and DB-18-crown-6): These materials were not soluble enough in DME to use Method A; however, about 0.05–0.1 mmol of each did dissolve in 50 mL of DME and this solubility was sufficient to give good ultraviolet spectra.

Intrared spectra of the thiocyanate salt complexes

A Perkin–Elmer infrared spectrophotometer (model 283) was used. Spectra were obtained on the Nujol mulls of the complexes using ZnSe optically flat windows (25 mm diameter × 2 mm thick).

Nuclear magnetic resonance studies of the complexes

^1H and ^{13}C studies of the complexes reported in this paper have been carried out. Some of this work has been published in refs. 6 and 7. Additional work will be reported in due course.

The crystal structures of the 1:2 host:guest complexes of dicyclohexano-18-crown-6 (isomer B) with potassium phenoxide and dicyclohexano-18-crown-6 (isomer A) with sodium phenoxide have been determined. The potassium phenoxide complex crystallizes in space group $P\bar{1}$ with a = 10.023(2), b = 11.238(2), c = 7.546(2) Å, α = 95.73(2), β = 103.04(2), γ = 92.03(2)°, and Z = 1. The sodium phenoxide complex crystallizes in space group $P2_1/n$ with a = 19.185(12), b = 13.266(5), c = 13.038(5) Å, β = 96.55(4)°, and Z = 4. Both structures were solved by direct methods and refined by full matrix least-squares calculations to a residual, R, of 0.035. The host conformation as well as the metal cation coordination differ considerably in the two structures. In the potassium phenoxide complex, the two cations are related by symmetry and have, consequently, the same chemical environment. Each potassium is located approximately halfway between the plane formed by the crown ether oxygens and the phenoxide anions and is coordinated to four of the crown oxygens and to two phenoxide oxygens. The oxygens of the crown are found to outline an elliptical cavity and to lie approximately in a plane. In the sodium phenoxide complex, the two sodiums have different crystallographic and chemical environments. One sodium is coordinated to the six hexaether oxygens, with distances ranging from 2.36 to 2.84 Å, and to one of the phenoxide oxygens. The other sodium is coordinated to only one of the crown oxygens and to three of the phenoxide oxygens. The hexaether adopts a highly irregular conformation.

MARIE E. FRASER, SUZANNE FORTIER, ANDRÉ RODRIGUE et JOHN W. BOVENKAMP. Can. J. Chem. **64**, 816 (1986).

On a déterminé les structures cristallines des complexes 1:2 de la dicyclohexano-18 couronne-6 (isomère B) avec le phénolate de potassium et de la dicyclohexano-18 couronne-6 (isomère A) avec le phénolate de sodium. Le complexe du phénolate de potassium cristallise dans le groupe d'espace $P\bar{1}$, avec a = 10,023(2), b = 11,238(2), c = 7,546(2) Å, α = 95,73(2), β = 103,04(2), γ = 92,03(2)° et Z = 1. Le complexe du phénolate de sodium cristallise dans le groupe d'espace $P2_1/n$, avec a = 19,185(12), b = 13,266(5), c = 13,038(5) Å, β = 96,55(4)° and Z = 4. On a résolu les deux structures par des méthodes directes et on les a affinées par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs résiduelles de R de 0,035. La conformation de la molécule hôte ainsi que la coordination du cation métallique diffèrent considérablement dans les deux structures. Dans le complexe du phénolate de potassium, les deux cations sont reliés par de la symétrie et ont donc des environnements chimiques semblables. Chaque potassium est situé approximativement à mi-chemin entre le plan formé par les oxygènes de la couronne et celui des anions phénolates et chacun est coordonné à quatre oxygènes de la couronne et à deux oxygènes des phénolates. On a trouvé que les oxygènes de la couronne forment le contour d'une cavité ellipsoïdale et qu'ils se retrouvent approximativement dans un plan. Dans le complexe du phénolate de sodium, les deux cations de sodium se trouvent dans des environnements cristallographiques ainsi que chimiques qui sont différents. Un des cations de sodium est coordonné aux six oxygènes de l'éther, avec des distances variant de 2,36 à 2,84 Å, et à l'un des oxygènes des phénolates. L'autre sodium est coordonné à un seul des oxygènes de la couronne et à trois oxygènes des phénolates. La conformation de la couronne est hautement irrégulière.

[Traduit par la revue]

Introduction

Of the crown ethers, 18-crown-6 is probably the most extensively characterized. Nuclear magnetic resonance (nmr), infrared (ir), X-ray diffraction studies, as well as thermodynamics and molecular mechanics, have provided a basis for the understanding of the complexation of 18-crown-6 and its analogues, dicyclohexano-18-crown-6 and dibenzo-18-crown-6, with various guests (1–4).

Several factors contribute to the structural characteristics of host–guest complexes. It is well known that both ligand and salt (both cation and anion) parameters play a role in the structural features of the host–guest complex. This is seen in the results of the several crystallographic studies of alkali-metal complexes with 18-crown-6. The crystal structure analyses of the alkali thiocyanate complexes with 18-crown-6, for example, clearly show how the structures of the complexes are affected by the size of the cation relative to the size of the crown ether cavity (5–10). The "hole-size" criterion is not, however, the only one to be considered, as shown by the crystallographic study of the 18-crown-6 complex with potassium ethyl acetoacetate (11), where the counterion is seen to have a marked effect on the resultant structure: in spite of the fact that the size of the potassium ion is ideally suited to that of the 18-crown-6 cavity, a "hard" anion such as ethyl acetoacetate can pull the cation out of its ideal nesting position.

During a study of the *cis–syn–cis* and *cis–anti–cis* isomers (isomers A and B, respectively) of dicyclohexano-18-crown-6 (12), it was found that on the addition of the commercial mixture of the two isomers to a 1,2-dimethoxyethane solution of potassium phenoxide, a solid precipitated. The solid had a narrow-range melting point and was shown by proton nmr to have a 1:2 host:guest ratio. Upon repeating the reaction with isomer B by itself, the same complex was obtained. It was apparent that an aggregate of potassium phenoxide, presumably a dimer, was being complexed by isomer B of DC-18-crown-6 instead of the contact ion pair that would have been expected. The 1:2 host:guest ratio was surprising in view of the compatibility between the cation and the hexaether cavity size. In fact, this appears to be the first example of a 1:2 host:guest ratio complex of a potassium salt with an 18-crown-6 macrocycle. Also, a 1:2

host:guest complex of sodium phenoxide with DC-18-crown-6 (isomer A) was obtained from ethereal solvents (12). It was clear that, in both cases, the nature of the solvent used and the nature of the counterion played a role in the unusual host:guest ratios. This crystallographic study was undertaken to determine how the DC-18-crown-6 ligands were complexing the two salt molecules in these unusual complexes.

Experimental

The synthetic method used for the preparation of the two complexes has been described in a previous publication (12). Suitable crystals of DC-18-crown-6 (isomer A)·2NaOPh were obtained by dissolving the complex in dry tetrahydrofuran in a Dri-Lab (Vacuum Atmospheres) under an argon atmosphere and allowing the solvent to evaporate completely at room temperature. Crystals of DC-18-crown-6 (isomer B)·2KOPh were similarly obtained, except that the complex was initially dissolved in warm, dry 1,3-dioxolane. Pertinent data about the crystals used and the measurement of diffraction intensities are summarized in Table 1. The crystals used in the diffraction experiments were mounted inside a glass capillary in an oxygen-free atmosphere. The intensity data were collected on an Enraf–Nonius CAD-4 diffractometer using graphite monochromated MoKα ($\lambda = 0.71073$ Å) radiation. In each case, intensities were collected by the $\omega/2\theta$ scanning procedure and three reflections were measured after every 7200 s of exposure time to check on the stability of the crystals; in neither case was any evidence of crystal decay detected. The data were corrected for Lorentz and polarization effects; absorption corrections were not considered necessary. The structures were solved by direct methods using the program MULTAN 80 (13). For the K^+ complex, the positions of all the hydrogen atoms were found in the difference Fourier map. For the Na^+ complex, 44 out of 46 hydrogens were located in the maps; the remaining two were calculated. The structures were refined by full matrix least-squares using all reflections with $I > 3\sigma(I)$. Anisotropic temperature factors were used for the non-hydrogen atoms and isotropic temperature factors for the hydrogen atoms. All the hydrogen atoms were included in the calculations and refined except for the two calculated hydrogen atoms in the Na^+ complex, which were held fixed. The function minimized was $\Sigma w||F_o| - |F_c||^2$, where $w = 1/\sigma^2(|F_o|)$. A correction for isotropic secondary extinction effect was included in each refinement. The scattering factors were taken from Cromer and Waber (14). All the calculations were done on a PDP 11/23 computer using the Enraf–Nonius SDP program package (15).

Results and discussion

The 1:2 host:guest complex of DC-18-crown-6 (isomer B) with potasium phenoxide

ORTEP (16) drawings of the ligand and of the complex itself showing the atom numbering scheme are given in Figs. 1 and 2, respectively. The fractional coordinates and equivalent isotropic temperature factors of the non-hydrogen atoms are presented in Table 2. Oxygen–potassium bond lengths and angles appear in Table 4, average and range in the bond lengths and angles of the host and of the phenoxide are given in Table 5, and macrocyclic ring torsion angles appear in Table 6.[2]

Host geometry and conformation

In the present crystal structure, the *cis–anti–cis* isomer of DC-18-crown-6 has a crystallographic centre of symmetry. The cavity outlined by the oxygens of the hexaether is elliptical, a feature also observed in the uncomplexed ligand (17) although more pronounced there than in the present case. In 1:1 host:guest complexes of 18-crown-6 macrocycles in which the guest cation size is equal to or larger than the size of the host cavity, the cavity is generally found to be circular, with the oxygens outlining a nearly regular hexagon. This was also found to be the case in the 1:1:1 complex of DC-18-crown-6 (isomer B) with potassium phenoxide and phenol, in which the

potassium ion is found in the ideal nesting position,[3] and other 1:1 complexes of DC-18-crown-6 as well (18, 19). Thus the elliptical shape of the cavity is not a result of substituent effects but rather of host–guest interactions. In fact, it can be seen in Fig. 2 that with the donor atoms of the hexaether arranged in an elliptical shape, optimal $K^+ \ldots O$ distances can be achieved while keeping sufficient $K^+ \ldots K^+$ separation. Figure 3 shows the cavity geometry of the uncomplexed form (17), of the 1:1:1 complex containing potassium phenoxide and phenol,[2] and of the 1:2 host:guest complex of DC-18-crown-6 (isomer B) with potassium phenoxide. In the two cases where an elliptical shape is found, elongations are along the lines joining opposite oxygens, located on either side of the cyclohexyls. In contrast to the uncomplexed form, in the 1:2 complex the oxygens all point towards the centre of the cavity. They form an approximate plane and are found alternately ≈0.15 Å above and below their mean plane.

[a] $B_{eq} = \frac{4}{3}\Sigma_i\Sigma_j\beta_{ij}\,(\boldsymbol{a}_i\cdot\boldsymbol{a}_j)$.

In the regular hexaether conformation, all torsion angles about C—C bonds are synclinal and those about C—O bonds are antiplanar. As can be seen from Table 6, these values are found in the present structure with the exception of the torsion angle about the C—$O_{equatorial}$ bond. This distortion is responsible for the elliptical shape of the host cavity and thus allows for optimal host-guest interactions. In other cases, it was also found that the deformation strain was preferentially accommodated in torsion angles about the C—O bonds, without affecting the *gauche* arrangement of the OCH_2CH_2O units (20). In the hexaether, the C—C bond lengths show the characteristic shortening with an average value of 1.498 Å. As has been previously observed, the C—C distances in the cyclohexyl substituent, on the other hand, are in the normal range with an average value of 1.520 Å. The C—O bond lengths have an average value of 1.426 Å and the O—C—C and C—O—C angles, in the hexaether, have average values of 109.0° and 112.9°, respectively. The cyclohexyl ring is found in the chair conformation with an average absolute torsion angle value of 55.9°. All of these values conform with those obtained in previous studies (20).

Host–guest interactions

The potassium ions are related by a centre of symmetry and each is located approximately halfway between the crown ether and two phenoxide anions, as depicted in Fig. 2. The distance between the K^+ ion and the approximate plane defined by the crown oxygens is 1.678 Å, while a distance of 1.467 Å is found between the K^+ and the plane of the phenoxides. The $K^+ \ldots K^+$ distance is 3.87 Å. This value is very close to the $K^+ \ldots K^+$ distance of 3.8 Å found in the dibenzo-24-crown-8·2KNCS complex, where the cavity formed by the eight oxygens is larger and both potassium ions are approximately in the cavity (21). Addition of translational symmetry to Fig. 2 would show

[a]The primed atoms are related to the unprimed atoms by the following symmetry operation: $-x, -y, -z$.

that each of the phenoxide oxygens is shared by two potassium ions and thus dimers of potassium phenoxide are formed. Each individual crown molecule complexes one of the potassium ions of two dimers, one above the approximate plane of the macrocyclic ring and one below. Each of the potassium ions is coordinated to four crown oxygens. The potassium–oxygen distance is somewhat closer for the oxygens attached to the cyclohexane rings (K^+ ... O(2) = 2.75 Å and K^+ ... O(8) = 2.84 Å) than for the oxygens in the middle of the macrocyclic ring (K^+ .... O(5) = 2.98 Å and K^+ ... O(5′) = 2.89 Å). The average of these K^+ ... O distances of 2.87 Å is only slightly larger than the value of 2.81 Å in the KNCS complex of 18-crown-6 (8), in which the K^+ is found in the ideal nesting position. Shorter distances are found between the K^+ ions and the oxygens of the two phenoxide goups, with an average value of 2.60 Å. This distance indicates that the potassium ions are strongly associated with the phenolate oxygens.

and 5, respectively. The fractional coordinates and equivalent isotropic temperature factors of the non-hydrogen atoms are presented in Table 3. Oxygen–sodium bond lengths and angles appear in Table 4, average and range in the bond lengths and angles of the host and of the phenoxides are given in Table 5, and macrocyclic ring torsion angles appear in Table 6.[2]

Host geometry and conformation

As can be seen from Fig. 4 and Table 6, the host conformation is highly irregular. The irregular part of the hexaether consists of seven atoms, from C(17) to C(5). The remaining atoms are found in the regular crown conformation. As in the case of the NaNCS complex of 18-crown-6 (7), the irregular fragment of the hexaether is folded out of the mean plane of the ring to partially envelop the cation guest. Thus, while four of the oxygens are found to lie in an approximate plane, the remaining two, O(3) and O(18), are at distances of 1.903 and 2.655 Å from that plane. The distortion observed in the present structure is more pronounced than that observed in the NaNCS complex of 18-crown-6, where the irregular fragment consisted of five atoms and where five of the oxygen atoms were found to lie in an approximate plane (7).

The average C—C bond length in the hexaether is 1.475 Å, while a value of 1.513 Å is found in the cyclohexyls. In the hexaether, the average O—C—C and C—O—C angles are 110.0 and 115.1°, respectively, and the average C—O distance is 1.420 Å. The cyclohexyl rings are in the chair conformation with average absolute torsion angle values of 54.5 and 56.0°.

Host–guest interactions

Figure 5 shows four sodium ions complexed by two crown ethers so that the 1:2 DC-18-crown-6 (A) sodium phenoxide complex has essentially a tetramer of sodium phenoxides. The two sodium ions are in different chemical environments. Na(1) is coordinated to only one of the hexaether oxygens, O(6), at a distance of 2.425 Å and to three of the phenoxide oxygens at an average distance of 2.23 Å. Na(2) lies in the plane defined by the four oxygens of the regular crown fragment. It is coordinated to all six oxygens of the hexaether at distances ranging from 2.358 to 2.842 Å with an average value of 2.55 Å. In addition, Na(2) is coordinated to one phenoxide oxygen, O(27), located at a distance of 2.323 Å. It is worth noting that the distances between the Na^+ and the phenolate oxygens are all significantly shorter than those between the Na^+ and the crown oxygens. Thus, stronger interactions exist between the Na ions and the phenolate oxygens of the tetramer than between the Na ions and the crown oxygens. The Na(1)—Na(1), Na(2)—Na(2), and Na(1)—Na(2) distances are 3.147, 6.107, and 3.392 Å, respectively. By comparison, the $Na^+ \ldots Na^+$ distance in the complex of dibenzo-24-crown-8 with two sodium *o*-nitrophenolate salt molecules is 3.383 Å (22). With this larger macrocycle, the polyether ring folds around a pair of sodium ions. The two halves of the complex are related by a two-fold symmetry axis which passes through a pair of aliphatic C—C bonds on

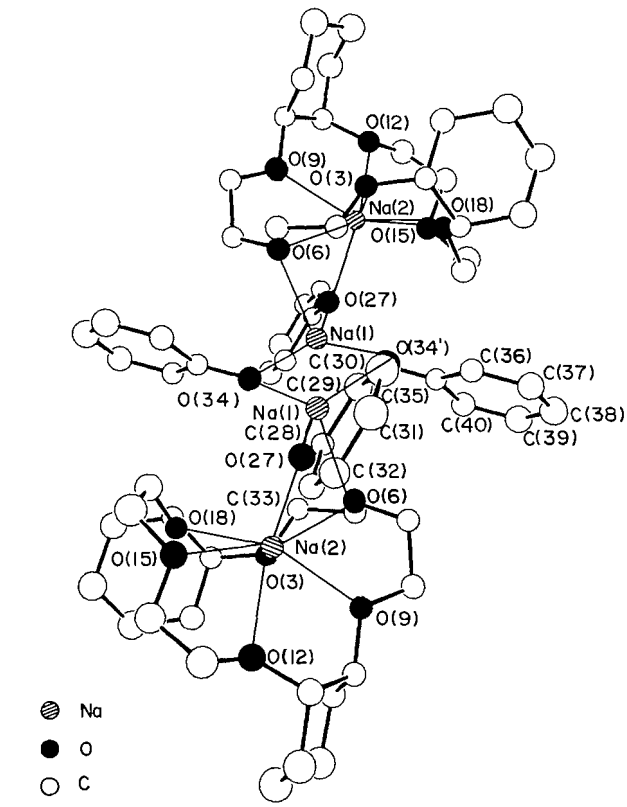

FIG. 5. ORTEP diagram and atom-numbering scheme for the sodium phenoxide complex.

opposite sides of the crown ring. The two phenolate oxygens, one on each side of the macrocyclic ring, bridge the pair of cations.

Conclusions

In this paper, the structures of two complexes of DC-18-crown-6 with unusual host:guest ratios were presented. Both complexes were obtained from relatively nonpolar ethereal solvents and in both cases, the "hard" phenoxide is the counterion. In the case of the K^+ complex, a dimer, and in the case of the Na^+ complex, a tetramer is being complexed instead of the contact ion pair that would have been expected for these 18-crown-6 macrocycles.

Further work on the structures of other unique complexes involving 18-crown-6 macrocycles is in progress and will be reported in due course.

Substitution régiosélective d'arènesulfonylhydrazones α,β-insaturées via la réaction de Shapiro

JEAN CLAUDE CAILLE, MICHEL FARNIER ET ROGER GUILARD[1]

Laboratoire de synthèse et d'électrosynthèse organométallique associé au Centre national de la recherche scientifique (UA 33), Faculté des sciences « Gabriel », 21100 Dijon, France

Reçu le 4 janvier 1985[2]

JEAN CLAUDE CAILLE, MICHEL FARNIER ET ROGER GUILARD. Can. J. Chem. **64**, 824 (1986).

Les arènesulfonylhydrazones de cyclopentanones α,β-insaturées de type isopropylidène et cyclopentylidène cyclopentanones, ont été soumises à l'action successive d'organolithiens à −78°C et de divers agents électrophiles. La réactivité des hydrazones dépend étroitement de la nature de l'électrophile dont le choix permet d'orienter régiosélectivement la substitution. La structure des produits est établie par analyse des spectres rmn ^1H et ^{13}C. Les hydrazones conservent leur configuration au cours de la réaction. Un mécanisme réactionnel faisant intervenir un intermédiaire a « six centres » est proposé. Par ailleurs, la réactivité de ces hydrazones est mise à profit pour élaborer une nouvelle stratégie de synthèse d'aldéhydes monoterpéniques.

JEAN CLAUDE CAILLE, MICHEL FARNIER, and ROGER GUILARD. Can. J. Chem. **64**, 824 (1986).

Arenesulfonylhydrazones of α,β-unsaturated cyclopentanones such as isopropylidene and cyclopentylidene cyclopentanones have been treated with alkyllithium reagents at −78°C followed by trapping with a variety of electrophiles. The reactivity of these hydrazones depends on the nature of electrophile that controls the regioselectivity of the reaction. The structure of all the products is established by ^1H and ^{13}C nmr. The reaction occurs with no inversion of configuration of the hydrazones. The formation of a "six centers" intermediate is discussed. Moreover, such a reactivity is used to prepare monoterpenic aldehydes.

Introduction

Opposés aux dérivés organolithiens, les tosylhydrazones présentent une réactivité singulière (1) mise à profit dans un grand nombre de synthèses (2). Les travaux de Lipton et Shapiro (3) démontrent de plus que l'action des alkyllithiens s'accompagne de la formation d'un *syn*-dianion réagissant très aisément avec de nombreux agents électrophiles pour conduire à une hydrazone substituée en α (voie A, fig. 1). Par ailleurs, la décomposition du dianion conduit à un lithien vinylique pouvant également réagir avec un électrophile (voie B, fig. 1). En outre la décomposition du dianion est plus aisée dans le cas d'hydrazones encombrées telles les trisylhydrazones (4), sans que la réactivité à l'égard des électrophiles soit altérée.

Cependant, peu de travaux ont été consacrés aux arènesulfonylhydrazones α,β-insaturées, depuis les études de Shapiro, Dauben et coll. (5). Dauben *et al.* ont toutefois montré le rôle déterminant de la stéréochimie de l'hydrazone et de la nature du solvant (6). Or nous avons rapporté dans une note préliminaire (7) qu'il était possible d'alkyler régiosélectivement la tosylhydrazone de la cyclopentylidène cyclopentanone. Dans ce travail nous nous sommes proposés de montrer l'influence de l'électrophile sur la régiospécificité de la réaction et d'étudier l'évolution de la stéréochimie des hydrazones. Dans ce but, nos travaux réalisés initialement au départ de la cyclopentylidène cyclopentanone ont été étendus à l'isopropylidène cyclopentanone, modèle plus proche de celui utilisé par Dauben *et al.* (6). De plus, nous avons tenté d'élaborer une voie d'accès à des aldéhydes monoterpéniques, applicable à la synthèse d'analogues naturels.

Résultats

Réactivité d'hydrazones α,β-insaturées vis-à-vis d'électrophiles

Les hydrazones **1** ont été soumises à l'action du butyllithium, puis de divers agents électrophiles, selon la voie A schématisée sur la figure 1. Les proportions des produits **2** et **3** obtenus (fig. 2) dépendent étroitement de la nature de l'électrophile, et l'ensemble de nos résultats est regroupé en tableau 1.

Au départ de l'hydrazone **1***b* de l'isopropylidène cyclopentanone, et après transformation en dianion correspondant, l'action de l'iodure de méthyle et du propionaldéhyde conduit uniquement et respectivement aux produits **2***c* et **2***d*, résultant de l'attaque de l'électrophile sur l'atome de carbone porteur du reste isopropényle. Dans le cas du sulfure de diméthyle, à côté de l'hydrazone **2***b* issue du même type d'attaque, il est possible d'isoler dans une faible proportion (5%) un mélange des isomères **3***d* correspondant à une attaque sur les sommets γ et γ′ du reste isopropylidène.

Dans la série des hydrazones de la cyclopentylidène cyclopentanone, l'action du sulfure de diméthyle est alors régiospécifique et ne conduit qu'à l'hydrazone **2***f*. Cette même régiospécificité est observée par action de l'iodure de méthoxy-2 éthyle : seules les hydrazones **2***e* et **2***g* sont isolées, ceci indépendamment de la nature du reste aryle, tosyl (—SO_2 *p*-tolyle) ou trisyl (—SO_2 triisopropyl-2,4,6 phényle), porté par l'hydrazone de départ. À l'opposé et, curieusement, lorsque l'on met en oeuvre le sulfure de diphényle, l'attaque ne porte jamais sur le carbone 2 de l'hydrazone de départ mais toujours sur les sommets γ et γ′ du reste alkylidène, quelle que soit la nature du reste alkylidène et celle du groupe aryle porté par l'hydrazone : dans tous les cas, seuls les mélanges d'hydrazones **3***a*, **3***c* et **3***f* sont obtenus. De plus, nous avons vérifié que l'introduction d'un groupe alkyle sur le sommet 5 de l'hydrazone **1** de départ ne modifie pas cette spécificité : à partir de l'hydrazone **1***c*, seul se forme le mélange **3***e*. Toutefois, la régiosélectivité n'est pas toujours aussi marquée puisque dans un cas, en utilisant le chloroformiate de méthyle, nous isolons conjointement les hydrazones **2***a* et **3***b* dans des proportions de 68 et 32%.

Ainsi la réactivité des hydrazones α,β-insaturées ne paraît dépendre ni de la nature du groupe alkylidène, ni de la nature du reste aryle porté par l'hydrazone. Par contre, le choix de l'agent électrophile est un facteur déterminant de la spécificité de la réaction.

Synthèse d'aldéhydes monoterpéniques

Selon le schéma réactionnel représenté en figure 1 (voie B), les hydrazones **1***b* et **1***c* sont traitées par le *sec*-butyllithium en excès dans le tétrahydrofuranne à −78°C. Le retour du milieu

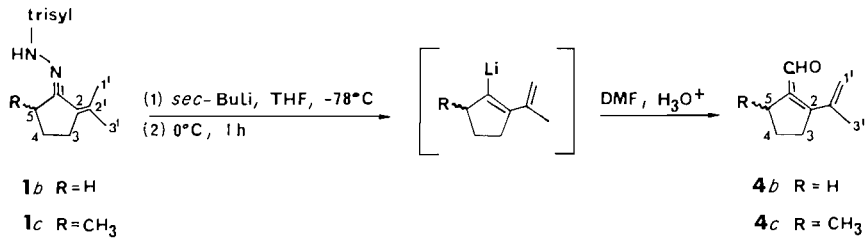

FIG. 3.

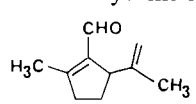
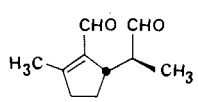
réactionnel à 0°C permet d'accéder aux lithiens vinyliques résultant de la déprotonation du sommet 1′ (fig. 3). La condensation du diméthylformamide (8) livre les aldéhydes correspondants **4***b* et **4***c* avec des rendements de l'ordre de 35%. Or, l'isomère **5** de l'aldéhyde **4***c* ainsi synthétisé est le précurseur du chrysomélidial (9).



5



chrysomélidial

Nous avons tenté de proposer une voie d'accès plus simple à ce précurseur en utilisant les deux types de réactivité des arènesulfonylhydrazones. En effet, l'introduction d'un groupement *à priori* facilement éliminable devait permettre la formation de la double liaison dans la position recherchée. Nos résultats sont schématisés en figure 4.

Comme nous l'avons déjà décrit, l'hydrazone **1***b* traitée par le *sec*-butyllithium puis le sulfure de diméthyle conduit régiosélectivement au dérivé **2***b*. L'alkylation de ce dernier par l'iodure de méthyle fournit l'hydrazone **6** avec un rendement de 40%. Il est à noter que l'obtention de cette hydrazone a été également envisagée en traitant directement l'hydrazone **1***c* par le sulfure de diméthyle, mais cette voie ne permet d'isoler le composé **6** qu'avec un très faible rendement (de l'ordre de 10%). L'hydrazone **6**, traitée comme décrit précédemment pour

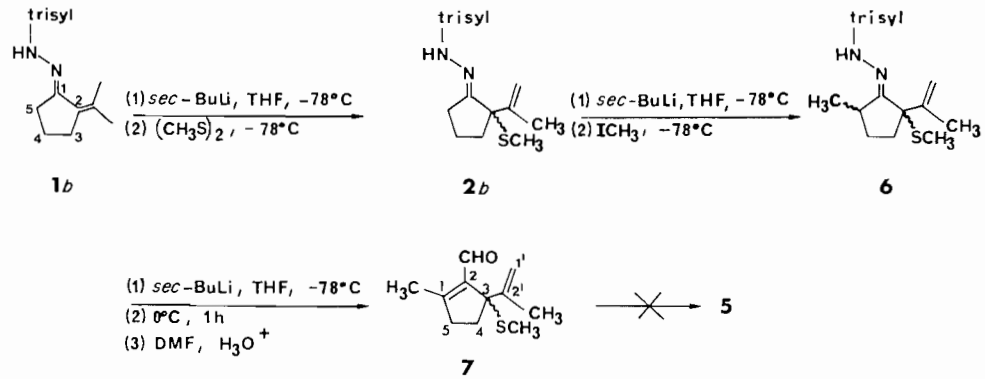

FIG. 4.

préparer les aldéhydes **4**, conduit à l'aldéhyde thiométhylé **7** (rendement : 38%).

Pour accéder à l'aldéhyde **5** recherché, la coupure du groupe thiométhyle a été tentée par action du lithium en présence d'éthylamine. En effet, cette méthode a déjà été utilisée avec succès (10) pour éliminer un groupe thiophényle en position allylique. Malheureusement, tous nos essais ont laissé inaltéré l'aldéhyde thiométhylé **7**. Par contre, dans le mémoire suivant, nous décrivons des exemples d'application de cette stratégie de synthèse permettant de proposer une nouvelle voie d'accès à des δ-lactones dont le squelette de base est celui des iridoïdes (11).

Établissement des structures

La structure de chacun des produits obtenus a pu être établie sur la base des données de l'analyse élémentaire et des résultats de rmn ^1H et ^{13}C. Nous avons regroupé dans le tableau 2 les caractéristiques de rmn protonique de la plupart des hydrazones d'alkylidène cyclopentanones **1** et **3**. Les caractéristiques rmn ^1H des autres hydrazones synthétisées et celles des aldéhydes **4***b*, **4***c* et **7** sont données dans la partie expérimentale où sont également reportées les caractéristiques rmn ^{13}C des hydrazones **2***c* et **3***d*. Dans le tableau 2 nous n'avons pas fait figurer les déplacements chimiques des protons du groupe aryle de la fonction hydrazone dont les caractéristiques sont en moyenne les suivantes : le reste tosyle donne un système AA′BB′ entre 7,2 et 7,9 ppm et un singulet vers 2,4 ppm; le reste trisyle, un singulet à 7,2 ppm pour les protons aromatiques, un doublet d'intensité 18 vers 1,3 ppm et deux heptuplets vers 2,9 et 4,2 ppm pour les protons des groupes isopropyle.

Comme il apparaît sur le tableau 2, les hydrazones **3** correspondent en fait à des mélanges des dérivés substitués respectivement en 1′ et 3′. Les deux isomères d'un mélange **3** n'ont pu être séparés, mais des caractéristiques rmn sont individualisables pour chacun de ces isomères : de façon générale, les protons du groupe méthyle en 1′ sont plus déblindés que ceux de groupe méthyle en 3′, ceci par analogie avec les résultats observés sur les hydrazones **1** de départ. Il en est de même pour les protons du reste (CH_2R). L'analyse des spectres de rmn ^1H montre également que les isomères des mélanges **3** se forment sensiblement dans les mêmes proportions. Une preuve supplémentaire de la présence d'un mélange pour les hydrazones **3** est apportée par l'examen du spectre rmn

^{13}C (écho de spin)[3] de **3***d*: des signaux distincts apparaissent pour les divers atomes de carbone des deux isomères. Nous avons de plus vérifié qu'après coupure de la fonction hydrazone (12) en cétone, ces dédoublements observés sur les spectres rmn ^{13}C persistent, ceci pour exclure l'existence éventuelle d'un mélange des deux configurations *syn* et *anti* d'hydrazones. D'autres arguments en faveur de la présence d'une seule configuration pour ces hydrazones sont discutés dans le paragraphe suivant.

Les spectres rmn ^1H de toutes les hydrazones **2** mettent en évidence des protons éthyléniques sous la forme de deux singulets entre 4,0 et 5,2 ppm pour un reste isopropényle, et d'un multiplet entre 5,1 et 5,7 ppm pour un reste cyclopentényle. De plus, la présence d'un carbone quaternaire en position 2 est confirmée dans un cas particulier par le relevé du spectre rmn ^{13}C (écho de spin) pour l'hydrazone **2***c*.

Enfin, il convient de souligner que l'hydrazone **6** correspond à un mélange de diastéréoisomères, ce qui se traduit sur le spectre rmn ^1H par la présence de deux doublets pour le groupe méthyle en position 5.

Stéréochimie des hydrazones

En opérant à température ambiante, il est classique (6) de n'obtenir que des hydrazones **1***a* (*E*) à partir des cétones correspondantes. Les caractéristiques rmn reportées au tableau 2 et dans la partie expérimentale pour les hydrazones **1**, correspondent toujours à la forme *E*, sauf dans le cas de l'hydrazone **1***a* où nous avons de plus préparé l'isomère *Z* aux fins de comparaison des données rmn ^1H. L'examen de ces données pour les hydrazones **1***a* (*E*) et **1***a* (*Z*) montre que les glissements chimiques des divers protons de la forme *E* sont toujours supérieurs à ceux de la forme *Z*. Les données rmn des autres hydrazones **1** synthétisées confirment la configuration *E* du produit obtenu sauf pour l'hydrazone **1***c*. Dans ce cas, nous obtenons en fait un mélange des configurations *E* et *Z* dans des proportions relatives de 80 et 20% : en effet, sur le spectre rmn ^1H, à côté des signaux relatifs aux groupes méthyle en 1′ et 3′ de la forme *E* respectivement à 1,89 et 1,74 ppm, apparaissent deux autres singulets à 1,61 et 1,54 ppm correspondant aux mêmes protons de la forme *Z*.

Nous avons voulu préciser si la configuration de l'hydrazone était conservée ou non au cours de la réaction conduisant aux hydrazones **2** et **3**. La stéréochimie des hydrazones d'alkénylcyclopentanones **2** est démontrée sur un cas particulier: par coupure de l'hydrazone **2***e*, on isole la cétone **8** à partir de laquelle l'hydrazone *E* est régénérée à température ambiante (2*g*) (fig. 5). Les caractéristiques physicochimiques et rmn ^1H du produit ainsi obtenu s'avèrent identiques à celles de l'hydrazone **2***e* mise en jeu qui doit donc être de configuration *E*.

La comparaison des glissements chimiques observés pour les protons des groupes méthyle en 1′ et 3′ des deux isomères **1***a* (*E*) et **1***a* (*Z*) et de ceux des mêmes groupes méthyle du mélange des hydrazones **3***a* issu de **1***a*(*E*) montre encore que la configuration de la fonction hydrazone est conservée lors de la transformation envisagée. L'examen des données rmn ^1H des autres hydrazones **3** permet de généraliser ce résultat. Un dernier argument confirme la stéréochimie *E* des hydrazones **2** et **3**: la protonation à −78°C du dianion issu de **1***b* de configuration *E* ne modifie pas la stéréochimie de cette hydrazone.

Le fait que la configuration *E* de l'hydrazone reste toujours inchangée lors de la préparation des composés **2** et **3** nous a conduit à proposer un mécanisme réactionnel précisant la nature du dianion intermédiaire.

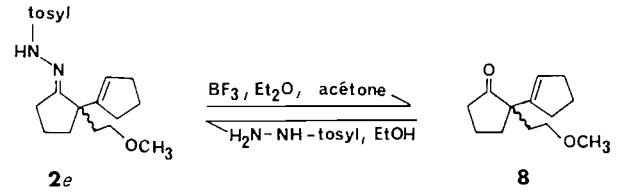

FIG. 5.

Mécanisme réactionnel

Lipton et Shapiro (3), puis Chamberlin et Bond (13), ont montré que l'alkylation d'hydrazones *E* en α procède par l'intermédiaire d'un *syn*-dianion (voie A, fig. 1). Le même mécanisme appliqué aux hydrazones α,β-insaturées **1** que nous avons étudiées, aurait dû conduire aux produits de substitution en position 5. Or, nous n'avons jamais pu isoler de tels composés, mais uniquement les hydrazones de type **2** et **3**. De plus, nous avons précisé dans le paragraphe précédent que la réaction s'effectue sans isomérisation de la fonction hydrazone *E*. Il n'est donc pas possible d'envisager un intermédiaire *syn*-dianion dans notre cas. L'hypothèse la plus plausible pour expliquer ces résultats paraît être l'intervention d'un intermédiaire à « six centres » qui se forme par déprotonation régiospécifique du sommet 1′. Le mécanisme réactionnel proposé est représenté en figure 6: l'intermédiaire à six centres (A) conduit au dianion allylique (B), précurseur des hydrazones **2** et **3**.

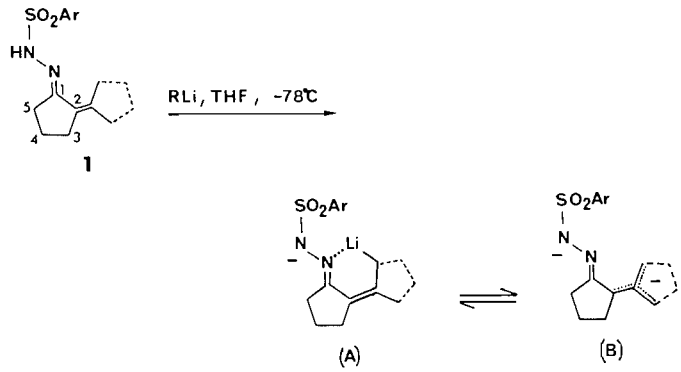

FIG. 6.

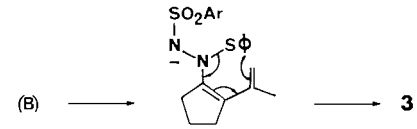
Il est à noter qu'un intermédiaire à six centres avait été évoqué par Bunnell et Fuchs (14) pour des hydrazones de β-céto ester. Une interprétation possible du changement de régiospécificité observé lors de l'emploi du sulfure de diphényle comme agent électrophile serait la suivante: à partir du dianion (B), il y aurait formation initiale d'une sulfimine conduisant ultérieurement aux hydrazones **3***a*, **3***c*, **3***e* et **3***f* selon



Conclusion

L'étude de la réactivité d'hydrazones α,β-insaturées vis-à-vis d'agents électrophiles montre que la déprotonation résultant de l'action de l'alkyllithien est régiospécifique et conduit à un

[3]Microprogramme d'écho de spin, « JMODXH.AU », Brüker.

intermédiaire à six centres. La configuration *E* des hydrazones est conservée au cours de la réaction. La formation d'un dianion allylique permet d'expliquer la formation concomitante ou non d'hydrazones d'alkényle et d'alkylidène cyclopentanones, la régiosélectivité de la réaction étant sous la dépendance essentielle de la nature de l'électrophile mis en jeu.

Cette réactivité particulière a été appliquée à la synthèse d'aldéhydes monoterpéniques et sera également mise en oeuvre dans l'article suivant pour proposer de nouvelles voies d'accès à des δ-lactones cyclopenténiques.

Partie expérimentale

Le déroulement des réactions est suivi par ccm (chromatographie sur couche mince) sur gel de silice (Kieselgel 60F254, Merck 5535). Les points de fusion mesurés sur banc Kofler ne sont pas corrigés. Les spectres infrarouges (ir) sont obtenus sur spectrophotomètre Perkin Elmer 580 B. Les spectres de résonance magnétique nucléaire (rmn) sont enregistrés à 400 MHz sur appareil Brüker WM 400. Les déplacements chimiques sont exprimés en ppm, le TMS étant pris comme référence interne (s, singulet; d, doublet; t, triplet; q, quintuplet; h, heptuplet; m, multiplet; M, massif). Les analyses sont effectuées par le Service central de microanalyses du Centre national de la recherche scientifique.

Le tétrahydrofuranne est distillé sur $LiAlH_4$, l'hexane et le tétraméthyléthylènediamine sur CaH_2. Les solutions d'alkyllithien sont commerciales. La lithiation des hydrazones est réalisée sous atmosphère d'argon.

Les produits de départ suivants sont préparés par les méthodes citées en référence : isopropylidène-2 cyclopentanone-1 (15); isopropylidène-2 méthyl-5 cyclopentanone-1 (16); tosylhydrazone de la cyclopentylidène-2 cyclopentanone-1, **1***d* (17).

Tosylhydrazones de l'isopropylidène-2 cyclopentanone-1 **1**a (E) *et* **1**a (Z)

(a) *Tosylhydrazone* **1**a (E)

On dissout au bain-marie 11,2 g (60 mmol) de tosylhydrazide dans 20 mL d'éthanol à reflux en présence d'une goutte d'acide chlorhydrique concentré, puis on ajoute, à température ambiante, l'isopropylidène-2 cyclopentanone-1 (7,5 g, 60 mmol). Après 12 h au réfrigérateur, puis filtration, on obtient 14 g (80%) d'un solide recristallisé dans l'éthanol; pf 216°C; R_f 0,27 (éther éthylique – hexane, 1 : 1); ν_{max}(KBr) : 3250 (NH), 1650 (C=C), 1600 aromatique, 1330 et 1150 (SO_2N) cm^{-1}. *Anal.* calc. pour $C_{15}H_{20}N_2O_2S$: C 61,63, H 6,90, N 9,58, O 10,95, S 10,95; trouvé : C 61,79, H 7,01, N 9,70, O 11,00, S 11,19.

(b) *Tosylhydrazone* **1**a (Z)

À une suspension de tosylhydrazide (5,0 g, 26,9 mmol) dans l'éthanol (50 mL), on ajoute l'isopropylidène-2 cyclopentanone-1 (3,33 g, 26,9 mmol) et 0,4 mL d'acide chlorhydrique concentré. Le mélange est porté à reflux pendant 3 h, puis évaporé sous pression réduite; l'huile brune obtenue est purifiée par chromatographie sur gel de silice (éluant : éther éthylique – hexane, 4 : 1). On recueille 4,7 g (60%) d'un solide recristallisé dans l'éthanol; pf 196°C; R_f 0,10 (éther éthylique – hexane, 1 : 1); ν_{max}(KBr) : 3200 (NH), 1640 (C=C), 1600 (aromatique), 1365 et 1160 (SO_2N) cm^{-1}. *Anal.* calc. pour $C_{15}H_{20}N_2O_2S$: C 61,63, H 6,90, O 10,95; trouvé : C 61,36, H 6,72, O 11,27.

Trisylhydrazones **1**b, **1**c *et* **1**e

Le même mode opératoire est utilisé pour préparer ces trois hydrazones : à une suspension de triisopropyl-2,4,6 benzènesulfonylhydrazide (29,8 g, 100 mmol) dans le méthanol (100 mL), on ajoute l'alkylidène cyclopentanone fraîchement distillée (100 mmol) et 1 mL d'acide chlorhydrique concentré. On agite vigoureusement jusqu'à formation d'un précipité abondant. Le mélange est ensuite déposé au réfrigérateur pendant la nuit. Le précipité obtenu est filtré, lavé au méthanol froid (3 × 50 mL), séché, puis recristallisé dans l'éthanol.

(a) *Trisylhydrazone de l'isopropylidène-2 cyclopentanone-1* **1**b

Rendement : 80%; pf 196°C; R_f 0,62 (éther éthylique – hexane, 1 : 1); ν_{max}(KBr) : 3250 (NH), 1655 (C=C), 1600 (aromatique), 1330 (SO_2N), 1160 et 1150 (SO_2N) cm^{-1}. *Anal.* calc. pour $C_{23}H_{36}N_2O_2S$: C 68,29, H 8,97, N 6,92; trouvé : C 68,21, H 8,98, N 6,81.

(b) *Trisylhydrazone de l'isopropylidène-2 méthyl-5 cyclopentanone-1* **1**c

Rendement : 40%; pf 158°C; R_f 0,69 (éther éthylique – hexane, 1 : 1); ν_{max}(KBr) : 3240 (NH), 1650 (C=C), 1600 (aromatique), 1330 (SO_2N), 1160 et 1150 (SO_2N) cm^{-1}. *Anal.* calc. pour $C_{24}H_{38}N_2O_2S$: C 68,87, H 9,15, N 6,69, S 7,64; trouvé : C 68,52, H 8,91, N 6,69, S 7,53.

(c) *Trisylhydrazone de la cyclopentylidène-2 cyclopentanone-1* **1**e

Rendement : 80%; pf 206°C; R_f 0,59 (éther éthylique – hexane, 1 : 1); ν_{max}(KBr) : 3240 (NH), 1665 (C=C), 1600 (aromatique), 1330 (SO_2N), 1160 et 1150 (SO_2N) cm^{-1}. *Anal.* calc. pour $C_{25}H_{38}N_2O_2S$: C 69,74, H 8,90, N 6,51, 0 7,43, S 7,43; trouvé : C 69,68, H 9,01, N 6,40, O 7,47, S 7,61.

Réactivité des tosylhydrazones **1**a (E) *et* **1**d *vis-à-vis d'agents électrophiles*

Le mode opératoire général est le suivant : à une solution de tosylhydrazone **1***a* ou **1***d* (6,84 mmol) dans le tétrahydrofuranne (30 mL) est ajoutée, à −78°C et goutte à goutte, une solution de *n*-butyllithium dans l'hexane (17,1 mmol). L'agitation est poursuivie pendant 20 min avant d'introduire goutte à goutte l'agent électrophile (10,26 mmol) en solution dans 5 mL de tétrahydrofuranne. À la fin de l'addition le milieu réactionnel est agité pendant 15 min à −78°C, puis 30 min à température ambiante. Après hydrolyse par NH_4Cl (50 mL), extraction par l'éther éthylique, lavage à l'eau et par une solution saturée en NaCl, puis évaporation du solvant, on obtient une huile éluée sur colonne de gel de silice par le mélange éther éthylique – hexane (1 : 1).

(a) *Action du sulfure de diphényle sur* **1**a (E)

Après recristallisation dans l'éthanol, on isole 0,87 g de tosylhydrazone de (phénylthio-1′(3′) isopropylidène)-2 cyclopentanone-1 **3***a*; pf 188–189°C; R_f 0,44 (éther éthylique – hexane, 1 : 1); ν_{max}(KBr) : 3200 (NH), 1650 (C=C), 1600 (aromatique), 1340 et 1170 (SO_2N) cm^{-1}. *Anal.* calc. pour $C_{21}H_{24}N_2O_2S_2$: C 62,98, H 6,04, 6,99, O 7,99, S 15,98; trouvé : C 63,27, H 5,89, N 6,85, O 8,53, S 15,69.

(b) *Action du chloroformiate de méthyle sur* **1**a (E)

Après recristallisation dans l'éthanol, on obtient successivement : 0,50 g de la tosylhydrazone de l'isopropényl-2 méthoxycarbonyl-2 cyclopentanone-1 **2***a*; pf 124°C; R_f 0,52 (éther éthylique – hexane, 3 : 2); ν_{max}(KBr) : 3200 (NH), 1725 (CO_2CH_3), 1640 (C=C), 1600 (aromatique), 1340 et 1170 (SO_2N) cm^{-1}; rmn ($CDCl_3$) δ : 7,82 et 7,29 (2d, 4H, —C_6H_4—), 4,93 et 4,64 (2s, 2H, —C=CH_2), 3,63 (s, 3H, —CO_2CH_3), 2,41 (s, 3H, —C_6H_4—CH_3), 2,31 (ddd, 1H, J_{3a3b} = 12,98, J_{3a4a} = 6,24 et J_{3a4b} = 9,83 Hz, H3a), 2,22 (dd, 2H, J_{4a5} = 6,11 et J_{4b5} = 8,81 Hz, (CH_2)-5), 2,04 (ddd, 1H, J_{3a3b} = 12,98, J_{3b4a} = 6,08, J_{3b4b} = 4,24 Hz, H3b), 1,80 (m, 1H, J_{4a5} = 6,11, J_{4a4b} = 12,15, J_{3a4a} = 6,24 et J_{3b4a} = 6,08 Hz, H4a), 1,73 (s, 3H, H_3C—C=C), 1,69 (m, 1H, J_{4b5} = 8,81, J_{4a4b} = 12,15, J_{3a4b} = 9,83 et J_{3b4b} = 4,24 Hz, H4b). *Anal.* calc. pour $C_{17}H_{22}N_2O_4S$: C 58,28, H 6,33, N 7,99, O 18,26, S 9,13; trouvé : C 58,13, H 6,24, N 8,24, O 18,11, S 9,02; et 0,24 g de la tosylhydrazone de (méthoxycarbonyl-1′(3′) isopropylidène)-2 cyclopentanone-1 **3***b*; pf (dec.) 90°C; R_f 0,36 (éther éthylique – hexane, 3 : 2); ν_{max}(KBr) : 3200 (NH), 1722 (CO_2CH_3), 1655 (C=C), 1600 (aromatique), 1340 et 1170 (SO_2N) cm^{-1}. *Anal.* calc. pour $C_{17}H_{22}N_2O_4S$: C 58,28, H 6,33, N 7,99, O 18,26, S 9,13; trouvé : C 58,46, H 6,28, N 7,96, O 17,92, S 9,05.

(c) *Action de l'iodo-1 méthoxy-2 éthane sur* **1**d

Après recristallisation dans le cyclohexane, on recueille 1,03 g de la tosylhydrazone de la cyclopentényl-2 (méthoxy-2 éthyl)-2 cyclopentanone-1 **2***e*; pf 127°C; R_f 0,23 (éther éthylique – hexane, 2 : 1); ν_{max}(KBr) : 3180 (NH), 1662 (C=C), 1600 (aromatique), 1360 et 1160 (SO_2N), 1120 (OCH_3) cm^{-1}; rmn ($CDCl_3$) δ : 7,86 et 7,25 (2d, 4H, —C_6H_4—), 5,10 (m, 1H, —C=CH—), 3,30 (m, 2H, —CH_2OCH_3), 3,23 (s, 3H, —OCH_3), 2,41 (s, 3H, —C_6H_4—CH_3), 2,00–1,60 (M, 14H, méthylènes cycliques et —$CH_2CH_2OCH_3$). *Anal.* calc. pour $C_{20}H_{28}N_2O_3S$: C 63,80, H 7,45, N 7,45, S 8,50; trouvé : C 64,17, H 7,52, N 7,38, S 8,33.

Réactivité des trisylhydrazones **1**b, **1**c *et* **1**e *vis-à-vis d'agents électrophiles*

Le mode opératoire général est le suivant: à une solution de trisylhydrazone (4,65 mmol) dans le tétrahydrofuranne (20 mL) à −78°C est ajoutée, goutte à goutte, une solution de *sec*-butyllithium dans le cyclohexane (11,62 mmol). Après agitation à −78°C pendant 1,5 h on ajoute lentement, et à cette même température, l'agent électrophile (7 mmol) en solution dans le tétrahydrofuranne (5 mL). On maintient le milieu réactionnel sous agitation pendant 7 h à −78°C. On réalise l'hydrolyse à l'aide d'une solution saturée de NH_4Cl, l'extraction par l'éther éthylique, puis on lave à l'eau et à l'aide d'une solution saturée de NaCl et l'on évapore les solvants organiques.

(a) *Action du sulfure de diphényle sur* **1**b

L'huile obtenue est éluée sur gel de silice, sous pression moyenne, par le mélange éther éthylique – hexane (1 : 2,5). Après recristallisation dans l'éthanol, on obtient 1,45 g de trisylhydrazone de (phénylthio-1′(3′) isopropylidène)-2 cyclopentanone-1 **3***c*; pf 120°C; R_f 0,55 (éther éthylique – hexane, 1 : 1); ν_{max}(KBr) : 3250 (NH), 1650 (C=C), 1600 et 1565 (aromatique), 1330 (SO_2N), 1165 et 1155 (SO_2N) cm^{-1}. *Anal.* calc. pour $C_{29}H_{40}N_2O_2S_2$: C 67,90, H 7,86, N 5,46, O 6,24, S 12,48; trouvé : C 67,89, H 7,86, N 5,34, O 6,17, S 12,39.

(b) *Action du sulfure de diméthyle sur* **1**b

Après chromatographie sur gel de silice (éluant : éther éthylique – hexane, 1 : 2,5), on recueille, après recristallisation dans l'éthanol, 1,15 g de trisylhydrazone de l'isopropényl-2 méthylthio-2 cyclopentanone-1 **2***b*; pf 140–141°C; R_f 0,63 (éther éthylique – hexane, 1 : 1); ν_{max}(KBr) : 3240 (NH), 1640 (C=C), 1600 et 1560 (aromatique), 1330 (SO_2N), 1165 et 1150 (SO_2N) cm^{-1}; rmn ($CDCl_3$) δ : 7,13 (s, 2H, aromatiques), 5,14 et 4,86 (2s, 2H, —C=CH_2), 4,19 (h, 2H, J = 6,80 Hz, *o*-*CH*(CH_3)$_2$), 2,88 (h, 1H, J = 6,80 Hz, *p*-*CH*(CH_3)$_2$), 2,47 et 2,33 (2m, 4H, (CH_2)-3 et (CH_2)-5), 1,77 (m, 2H, (CH_2)-4), 1,60 (s, 3H, H_3C—C=C), 1,37 (s, 3H, —SCH_3), 1,30 (d élargi, 18H, J = 6,80 Hz, —HC(*CH_3*)$_2$). *Anal.* calc. pour $C_{24}H_{38}N_2O_2S_2$: C 63,97, H 8,50, N 6,22, O 7,10, S 14,20; trouvé : C 63,90, H 8,69, N 6,09, O 7,27, S 14,20; et 0,062 g de trisylhydrazone de (méthylthio-1′(3′) isopropylidène)-2 cyclopentanone-1 **3***d*; pf 160°C; R_f 0,59 (éther éthylique – hexane, 1 : 1); ν_{max}(KBr) : 3250 (NH), 1650 (C=C), 1600 et 1565 (aromatique), 1335 (SO_2N), 1165 et 1150 (SO_2N) cm^{-1}; rmn ^{13}C ($CDCl_3$) δ : 160,3 et 160,2 (C-1), 153,9 et 153,8 puis 151,9 et 151,8 (2C, quaternaires aromatiques), 135,2 et 134,7 (C quaternaires aromatiques), 133,1 et 133,0 puis 131,9 et 131,8 (C-2 et C-2′), 41,2 et 35,6 (—*C*H_2SCH_3) ppm. *Anal.* calc. pour $C_{24}H_{38}N_2O_2S_2$: C 63,97, H 8,50, O 7,10, S 14,20; trouvé : C 63,90, H 8,69, O 7,27, S 14,20.

(c) *Action de l'iodure de méthyle sur* **1**b

L'huile obtenue traitée par le pentane abandonne 1,13 g de trisylhydrazone de l'isopropényl-2 méthyl-2 cyclopentanone-1 **2***c* recristallisée dans l'éthanol; pf 137°C; R_f 0,65 (éther éthylique – hexane, 1 : 1); ν_{max}(KBr) : 3240 (NH), 1635 (C=C), 1600 et 1560 (aromatique), 1330 (SO_2N), 1170 et 1155 (SO_2N) cm^{-1}; rmn ($CDCl_3$) δ : 7,12 (s, 2H, aromatiques), 4,55 et 4,31 (2s, 2H, —CH=CH_2), 4,19 (h, 2H, J = 6,80 Hz, *o*-*CH*(CH_3)$_2$), 2,88 (h, 1H, J = 6,80 Hz, *p*-*CH*(CH_3)$_2$), 2,20–1,60 (M, 6H, méthylènes cyclopentaniques), 1,45 (s, 3H, H_3C—C=C), 1,30 (d élargi, 18H, J = 6,80 Hz, —CH(*CH_3*)$_2$), 1,12 (s, 3H, C—CH_3); rmn ^{13}C ($CDCl_3$) δ : 162,9 (C-1), 153,9, 151,9 et 147,6 (3C, quaternaires aromatiques), 131,1 (C-2′), 124,3 (CH aromatique), 112,2 (C-1′), 52,8 (C-2 quaternaire), 38,2 (C-5), 34,9 (C-3′), 27,7 et 21,5 (C-3 et C-4) ppm. *Anal.* calc. pour $C_{24}H_{38}N_2O_2S$: C 68,87, H 9,15, N 6,69, O 7,64, S 7,64; trouvé : C 69,12, H 9,34, N 6,46, O 7,65, S 7,94.

(d) *Action du propionaldéhyde sur* **1**b

Après élution sur gel de silice, sous pression moyenne, par le mélange éther éthylique – hexane (1 : 1) et recristallisation dans l'éthanol, on isole 1,03 g de trisylhydrazone de 1′(hydroxy-1 propyl)-2 isopropényl-2 cyclopentanone-1 **2***d*; pf 150°C; R_f 0,33 (éther éthylique – hexane, 1 : 1); ν_{max}(KBr) : 3460 (OH), 3260 (NH), 1630 (C=C), 1600 et 1565 (aromatique), 1340 (SO_2N), 1170 et 1155 (SO_2N), 1110 (CHOH) cm^{-1}; rmn ($CDCl_3$) δ : 7,17 (s, 2H, aromatiques), 4,90 et 4,60 (2s, 2H, —C=CH_2), 4,15 (h, 2H, J = 6,80 Hz, *o*-*CH*(CH_3)$_2$), 3,73 (dd, 1H, J = 8,54 et 4,92 Hz, —*CH*OH—), 3,47 (d, 1H, J = 4,92 Hz, —CHO*H*—), 2,89 (h, 1H, J = 6,80 Hz, *p*-*CH*(CH_3)$_2$), 2,40 et 2,31 (2m, 4H, (CH_2)-3 et (CH_2)-5), 2,20–1,70 (M, 4H, (CH_2)-4 et (—CHOH*CH_2*CH_3)), 1,60 (s, 3H, H_3C—C=C), 1,30 (d élargi, 18H, J = 6,80 Hz, —CH(*CH_3*)$_2$), 0,83 (t, 3H, J = 7,32 Hz, —CH_2*CH_3*). *Anal.* calc. pour $C_{26}H_{42}N_2O_3S$: C 67,50, H 9,15, N 6,05, O 10,37, S 6,92; trouvé : C 67,59, H 9,22, N 6,00, O 10,51, S 7,20.

(e) *Action du sulfure de diphényle sur* **1**c

Après chromatographie sur gel de silice sous pression moyenne (éluant : éther éthylique – hexane, 1 : 5) et recristallisation dans l'éthanol, on recueille 1,27 g de trisylhydrazone de méthyl-5 (phénylthio-1′(3′) isopropylidène)-2 cyclopentanone-1 **3***e*; pf (dec.) 50°C; R_f 0,61 (éther éthylique – hexane, 1 : 1); ν_{max}(KBr) : 3200 (NH), 1650 (C=C), 1600 et 1570 (aromatique), 1330 (SO_2N), 1160 et 1150 (SO_2N) cm^{-1}. *Anal.* calc. pour $C_{30}H_{42}N_2O_2S_2$: C 68,42, H 8,04, S 12,15; trouvé : C 68,26, H 7,94, S 12,47.

(f) *Action du sulfure de diphényle sur* **1**e

Après élution sur gel de silice, sous pression moyenne, par le mélange éther éthylique – hexane (1 : 5) et recristallisation dans l'éthanol, on recueille 1,78 g de trisylhydrazone de (phénylthio-1′(3′) cyclopentylidène)-2 cyclopentanone-1 **3***f*; pf 140°C; R_f 0,55 (éther éthylique – hexane, 1 : 1); ν_{max}(KBr) : 3240 (NH), 1650 (C=C), 1600 et 1570 (aromatique), 1330 (SO_2N), 1165 et 1150 (SO_2N) cm^{-1}. *Anal.* calc. pour $C_{31}H_{42}N_2O_2S_2$: C 69,12, H 7,86, O 5,94, S 11,88; trouvé : C 69,01, H 7,94, O 5,75, S 12,11.

(g) *Action du sulfure de diméthyle sur* **1**e

L'huile obtenue abandonne dans le pentane 1,20 g de trisylhydrazone de la cyclopentényl-2 méthylthio-2 cyclopentanone-1 **2***f*, recristallisée dans l'éthanol; pf 163°C; R_f 0,65 (éther éthylique – hexane, 1 : 1); ν_{max}(KBr) : 3240 (NH), 1640 (C=C), 1600 et 1570 (aromatique), 1330 (SO_2N), 1170 et 1150 (SO_2N) cm^{-1}; rmn ($CDCl_3$) δ : 7,13 (s, 2H, aromatiques), 5,62 (m, 1H, —CH=C—), 4,20 (h, 2H, J = 6,80 Hz, *o*-*CH*(CH_3)$_2$), 2,88 (h, 1H, J = 6,80 Hz, *p*-*CH*(CH_3)$_2$), 2,40–1,50 (M, 12H, méthylènes cycliques), 1,37 (s, 3H, —SCH_3), 1,30 (d élargi, 18H, J = 6,80 Hz, —HC(*CH_3*)$_2$). *Anal.* calc. pour $C_{26}H_{40}N_2O_2S_2$: C 65,52, H 8,46, N 5,88, S 13,43; trouvé : C 65,44, H 8,52, N 5,87, S 13,07.

(h) *Action de l'iodo-1 méthoxy-2 éthane sur* **1**e

L'huile obtenue traitée par le pentane abandonne 1,50 g de trisylhydrazone de la cyclopentényl-2 (méthoxy-2 éthyl)-2 cyclopentanone-1 **2***g*, recristallisée dans l'éthanol; pf 144°C; R_f 0,48 (éther éthylique – hexane, 1 : 1); ν_{max}(KBr) : 3240 (NH), 1650 (C=C), 1600 et 1570 (aromatique), 1330 (SO_2N), 1165 et 1155 (SO_2N), 1114 (OCH_3) cm^{-1}; rmn ($CDCl_3$) δ : 7,13 (s, 2H, aromatiques), 5,11 (m, 1H, —C=CH—), 4,18 (h, 2H, J = 6,80 Hz, *o*-*CH*(CH_3)$_2$), 3,16 (m, 2H, —*CH_2*OCH_3), 3,14 (s, 3H, —OCH_3), 2,88 (h, 1H, J = 6,80 Hz, *p*-*CH*(CH_3)$_2$), 2,30–1,50 (M, 14H, méthylènes cycliques et —*$CH_2CH_2OCH_3$*), 1,30 (d élargi, 18H, J = 6,80 Hz, —CH(*CH_3*)$_2$). *Anal.* calc. pour $C_{28}H_{44}N_2O_3S$: C 68,82, H 9,07, N 5,73, O 9,82, S 6,55; trouvé : C 68,81, H 9,32, N 5,73, O 9,97, S 6,69.

Trisylhydrazone de l'isopropényl-2 méthyl-5 méthylthio-2 cyclopentanone-1 **6**

Selon le mode opératoire décrit pour préparer **2***c*, on obtient, à partir de 2,1 g (4,65 mmol) de **2***b* et 1,0 g d'iodure de méthyle, une huile éluée sur gel de silice, sous pression moyenne, par le mélange éther éthylique – hexane (1 : 5). Après recristallisation dans l'éthanol, on obtient 0,86 g (40%) d'un solide jaune pâle; pf 145°C; R_f 0,66 (éther éthylique – hexane, 1 : 1); ν_{max}(KBr) : 3172 (NH), 1635 (C=C), 1600 et 1560 (aromatique), 1380 (SO_2N), 1160 et 1154 (SO_2N) cm^{-1}; rmn ($CDCl_3$) δ : 7,13 (s, 2H, aromatiques), 5,07 et 4,83 (2s, —C=CH_2), 4,15 (h, 2H, J = 6,80 Hz, *o*-*CH*(CH_3)$_2$), 2,88 (h, 1H, J = 6,80 Hz, *p*-*CH*(CH_3)$_2$), 2,20–1,60 (M, 5H, protons cyclopentaniques), 1,66 (s, 3H, H_3C—C=C), 1,34 (s, 3H, —SCH_3), 1,30 (d élargi, 18H, J = 6,80 Hz, —CH(*CH_3*)$_2$, 1,29 et 1,14 (2d, $J_{5\text{-}CH_3}$ = 8,00 Hz, —CH*CH_3*). *Anal.* calc. pour $C_{25}H_{40}N_2O_2S_2$: C 64,63, H 8,68, N 6,03, O 6,88, S 13,77; trouvé : C 64,42, H 8,41, N 5,93, O 6,99, S 13,49.

Méthode générale de synthèse des aldéhydes **4**b, **4**c *et* **7**

À une solution de trisylhydrazone (10 mmol) dans le tétrahydrofuranne (20 mL) est ajoutée, à −78°C et goutte à goutte, une solution de *sec*-butyllithium dans le cyclohexane (35 mmol). À la fin de l'addition, le milieu réactionnel est agité pendant 1 h à −78°C, puis 1 h à 0°C. On ajoute alors le diméthylformamide (3,1 mL, 40 mmol) en solution dans le tétrahydrofuranne (5 mL). La solution obtenue est agitée à 0°C durant 1 h, hydrolysée par une solution saturée de NH_4Cl, puis extraite par l'éther éthylique. Les phases organiques sont lavées à l'eau et par une solution saturée en NaCl, puis évaporées. Après élution du résidu sur gel de silice (solvant : éther éthylique – hexane, 1 : 5), l'aldéhyde est isolé sous forme d'une huile jaune pâle.

(a) *Isopropényl-2 cyclopentènecarbaldéhyde-1* **4**b

À partir de **1***b*, on obtient 0,48 g (35%) de **4***b*; R_f 0,57 (éther éthylique – hexane, 1 : 4); ν_{max}(film) : 1661 (CHO), 1607 (C=C) cm^{-1}; rmn ($CDCl_3$) δ : 9,92 (s, 1H, —CHO), 5,20 et 5,08 (2s, 2H, —C=CH_2), 2,72 (tt, 2H, $J_{34\text{ ou }54}$ = 7,60 et J_{35} = 2,00 Hz, (CH_2)-3 ou -5), 2,63 (tt, 2H, $J_{54\text{ ou }34}$ = 7,60 et J_{35} = 2,00 Hz, (CH_2)-5 ou -3), 1,96 (s, 3H, CH_3—C=C), 1,90 (q, 2H, J_{43} et J_{45} = 7,60 Hz, (CH_2)-4). *Anal.* calc. pour $C_9H_{12}O$: C 79,37, H 8,88, O 11,75; trouvé : C 79,03, H 9,05, O 11,90.

(b) *Isopropényl-2 méthyl-5 cyclopentènecarbaldéhyde-1* **4**c

À partir de **1***c*, on obtient 0,55 g (37%) de l'aldéhyde **4***c*; R_f 0,60 (éther éthylique – hexane, 1 : 4); ν_{max}(film) : 1662 (CHO), 1605 (C=C) cm^{-1}; rmn ($CDCl_3$) δ : 9,88 (s, 1H, —CHO), 5,20 et 5,05 (2s, 2H, —C=CH_2), 3,14 (m, 1H, H-5), 2,75, 2,66, 2,09 et 1,51 (4m, 4H (CH_2)-3 et (CH_2)-4), 1,94 (s, 3H, H_3C—C=C), 1,13 (d, 3H, J = 6,89 Hz, —C—CH_3). *Anal.* calc. pour $C_{10}H_{14}O$: C 79,95, H 9,39, O 10,65; trouvé : C 80,20, H 9,01, O 11,12.

(c) *Isopropényl-3 méthyl-1 méthylthio-3 cyclopentènecarbaldéhyde-2* **7**

À partir de **6**, on obtient 0,74 g (38%) de l'aldéhyde **7**; R_f 0,33 (éther éthylique – hexane, 1 : 7); ν_{max}(film) : 1678 (CHO), 1615 (C=C) cm^{-1}; rmn ($CDCl_3$) δ : 9,76 (s, 1H, —CHO), 4,99 (m, 2H, —C=CH_2), 2,51–2,44 (M, 2H, (CH_2)-5), 2,23 (t, 3H, $J_{5\text{-}CH_3}$ = 1,10 Hz, H_3C—C=C—CHO), 2,20 (m, 2H, (CH_2)-4), 1,96 (s, 3H, —SCH_3), 1,83 (dd, $J_{1'a\text{-}CH_3}$ = 1,28 et $J_{1'b\text{-}CH_3}$ = 0,55 Hz, H_3C—C=C). *Anal.* calc. pour $C_{11}H_{16}OS$: C 67,32, H 8,22, O 8,15, S 16,31; trouvé : C 67,29, H 8,15, O 8,40, S 16,01.

Cyclopentényl-2 (méthoxy-2 éthyl)-2 cyclopentanone-1 **8**

À une solution d'hydrazone **2***e* (0,38 g, 1 mmol) dans le mélange acétone–eau (10 : 1, 11 mL) est ajouté l'éthérate de trifluorure de bore (0,63 mL, 5 mmol) (12). Le milieu réactionnel est agité pendant 48 à 72 h à température ambiante. Le solvant est évaporé puis le résidu repris par le pentane (3 × 20 mL). Les phases organiques sont réunies puis évaporées pour donner 0,13 g (61%) de cétone **8**; pé 135°C/3 Torr (1 Torr = 133,3 Pa); R_f 0,78 (éther éthylique – hexane, 1 : 1); ν_{max}(film) : 1735 (CO), 1638 (C=C), 1114 (OCH_3) cm^{-1}; rmn ($CDCl_3$) δ : 5,50 (m, 1H, —CH=C—), 3,33 (m, 2H, —CH_2OCH_3), 3,27 (s, 3H, —OCH_3), 2,30–1,83 (M, 14H, méthylènes cycliques et —$CH_2CH_2OCH_3$). *Anal.* calc. pour $C_{13}H_{20}O_2$: C 74,96, H 9,68, O 15,36; trouvé : C 74,89, H 9,76, O 15,37.

Reçu le 4 janvier 1985[2]

JEAN CLAUDE CAILLE, MICHEL FARNIER, ROGER GUILARD, ANDRÉ AUBRY et CLAUDE LECOMTE. Can. J. Chem. **64**, 831 (1986).

La synthèse de deux δ-lactones cyclopenténiques, l'hexahydro-1,3,4,4a,5,6 cyclopenta[*c*]pyrannone-1 et son analogue substitué en position 4a par un cyclopentényle, est décrite au départ de la cyclopentanone et de la cyclopentylidène-2 cyclopentanone. La réactivité singulière des tosylhydrazones permet la transformation de ces cyclopentanones en cyclopentènes fonctionnalisés en vue de leur cyclisation ultérieure en δ-lactone. Les conditions de cyclisation dépendent de la nature de la cyclopentanone. La structure des deux δ-lactones synthétisées est établie par analyse des spectres rmn ^1H, ^{13}C et de masse, et dans un cas, par analyse radiocristallographique.

JEAN CLAUDE CAILLE, MICHEL FARNIER, ROGER GUILARD, ANDRÉ AUBRY, and CLAUDE LECOMTE. Can. J. Chem. **64**, 831 (1986).

Synthesis of two cyclopentenic δ-lactones, 1,3,4,4a,5,6-hexahydrocyclopenta[*c*]pyran-1-one and its analogue possessing a cyclopentenyl group bonded to the carbon atom 4a is described, starting from the cyclopentanone or cyclopentylidene cyclopentanone. The remarkable reactivity of the tosylhydrazones allows transformation of these compounds into substituted cyclopentenes, which lead to δ-lactones by cyclization. The conditions of cyclization depend on the nature of the cyclopentanone. The structure of the two δ-lactones is established by ^1H and ^{13}C nmr data, mass spectrometry, and, in one case, by X-ray analysis.

Introduction

Dans le mémoire précédent (1), nous avons montré que la réaction de Shapiro (2) appliquée à des arènesulfonylhydrazones de cyclopentanones α,β-insaturées permet d'introduire régiospécifiquement un groupe alkyle sur l'atome de carbone substitué par un reste insaturé et situé en α de la fonction hydrazone. Le produit d'alkylation soumis à l'action d'un alkyllithien conduit à un dianion qui se décompose à température ambiante en un anion vinylique très réactif vis-à-vis d'électrophiles. En utilisant cette réactivité particulière et au départ d'hydrazones non cycliques, Adlington et Barrett (3) ont récemment mis au point une synthèse d'α-méthylène γ-butyrolactones. Nous nous sommes proposés d'utiliser des hydrazones de cyclopentanones pour accéder à des δ-lactones cyclopenténiques. En effet, ce motif δ-lactonique est fréquemment retrouvé dans un grand nombre de substances naturelles tels les monoterpènes bicycliques (4). Nous décrivons dans ce mémoire la synthèse de deux δ-lactones cyclopenténiques **1** et **2**, une partie de ce travail ayant déjà fait l'objet d'une note préliminaire (5).

2

Résultats et discussion

Les premières étapes de la synthèse des δ-lactones cyclopenténiques **1** et **2**, communes à ces deux dérivés, sont schématisées en figure 1.

Les tosylhydrazones **3** et **4**, préparées selon des modalités classiques à partir des cyclopentanones correspondantes, sont alkylées après traitement par le *n*-butyllithium dans le mélange THF (tétrahydrofuranne) – hexane à −78°C, par l'iodo-1 méthoxy-2 éthane. Les dérivés alkylés **5** et **6** sont obtenus avec des rendements respectifs de 64 et 45%.

Les hydrazones **5** et **6** sont à nouveau traitées à −78°C par une solution de *n*-butyllithium dans le mélange TMEDA (tétraméthyléthylènediamine) – hexane. Les anions vinyliques générés après retour du milieu réactionnel à température ambiante sont soumis à un courant de CO_2; les acides obtenus après hydrolyse acide sont directement transformés en chlorures **7** et **8** correspondants par traitement au chlorure d'oxalyle (rendements de l'ordre de 50%).

Les divers essais de lactonisation des chlorures **7** et **8** sont respectivement représentés sur les figures 2 et 3. À partir du chlorure d'acide **7**, les esters méthylique **9***a*, éthylique **9***b* et tertiobutylique **9***c* sont préparés classiquement avec des rendements de l'ordre de 90%. Le trichlorure et le tribromure de bore ont déjà été utilisés avec succès (6, 7) pour lactoniser des esters porteurs d'un groupe méthoxy. Aussi, nous avons tout d'abord tenté une lactonisation directe de l'ester **9***a* en le traitant par le tribromure de bore, mais dans notre cas, la proportion de lactone **1** recherchée n'a jamais atteint 5%. Par ailleurs, une tentative de cyclisation de l'acide **10** obtenu par saponification de l'ester **9***b* s'est également soldée par un échec. Nous avons alors cherché à utiliser avec profit les réactifs préconisés par Olah *et al.* (8, 9) pour régénérer des fonctions acide et alcool à partir d'ester ou d'éther. Au départ de l'ester éthylique **9***b* et par action à température ambiante de l'iodure de dichlorométhylsilyle, l'alcool **11** uniquement est formé. Par contre, l'utilisation de l'ester tertiobutylique **9***c* permet d'obtenir la lactone **1** selon deux voies : en opérant au reflux de l'acétonitrile en présence d'iodure de dichlorométhylsilyle, la lactonisation s'effectue

1. Auteur à qui adresser toute correspondance.

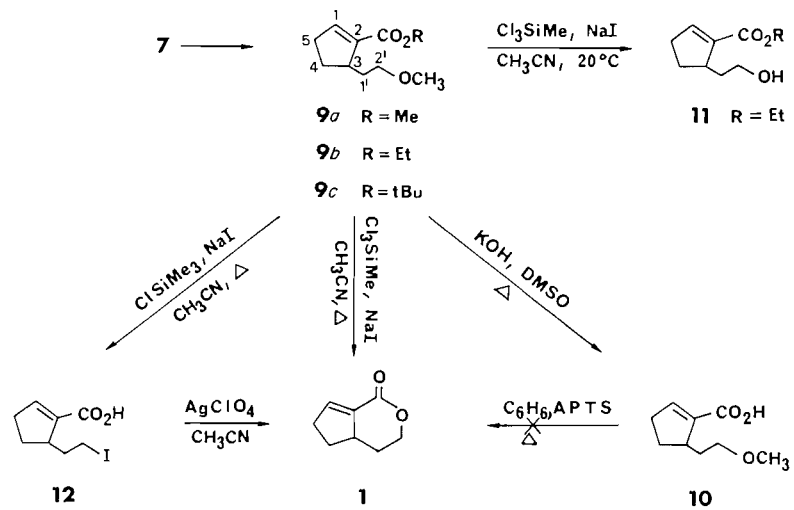

FIG. 2.

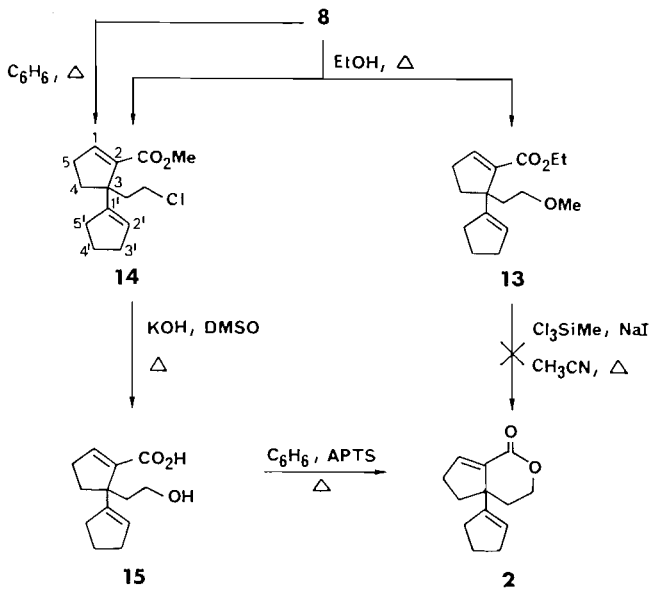

FIG. 3.

directement mais seulement avec un rendement de 44%; il est préférable d'employer l'iodure de triméthylsilyle, car celui-ci permet, via l'iodo-acide **12**, d'isoler la même lactone avec un rendement de 63%.

La même stratégie pouvait à priori être étendue à la synthèse de la lactone **2**. Lors de l'estérification du chlorure d'acide **8** par l'éthanol, outre l'ester **13** attendu, il y a formation de chloro-ester **14** dans une proportion d'environ 17% (fig. 3). Tous nos essais de lactonisation de l'ester **13** par l'iodure de dichloro-méthylsilyle se sont soldés par un échec. Pour accéder à la lactone **2** recherchée, nous avons utilisé le chloro-ester **14** qui peut par ailleurs être obtenu avec un rendement de 96% en chauffant le chlorure d'acide **8** au reflux du benzène. Le dérivé **14** traité par la potasse dans le DMSO (diméthyl-sulfoxyde) conduit à l'hydroxy-acide **15** avec un rendement de 80%. La cyclisation de ce dérivé est aisément réalisée par chauffage au reflux du benzène en présence d'acide *p*-toluènesulfonique et la lactone **2** est isolée avec un rendement de 80%.

Le chloro-ester **14** peut être également utilisé pour accéder au δ-lactame **17** correspondant (fig. 4), en le transformant en phtalimide **16** cyclisé en présence d'hydrate d'hydrazine.

Établissement des structures

La structure des divers produits synthétisés est établie par analyse des spectres de rmn (résonance magnétique nucléaire) protonique dont les données figurent dans la partie expérimentale. Dans le cas des lactones **1** et **2**, des informations structurales complémentaires sont apportées par la spectrométrie de masse et par la rmn ^{13}C et, pour l'une des deux lactones, **2**, une analyse radiocristallographique a été effectuée. Cette étude radiocristallographique montre la présence d'un cycle δ-lactonique accolé à un cyclopentène et porteur en 4a d'un reste cyclopenténylé, comme représenté en figure 5. L'angle formé par les plans moyens des cycles lactonique (C(4a)—C(7a)—C(1)—O(2)—C(3)—C(4)) et cyclopenténylé (C(4a)—C(5)—C(6)—C(7)—C(7a)) est égal à 17,9° et l'angle formé par le plan moyen du reste cyclopenténylé avec le plan moyen du bicycle lactonique est de 91,2°. Les valeurs des longueurs et angles de liaisons (tableau 1) confirment la

C(2')—C(3')—C(4')	102,0(4)	C(3')—C(4')—C(5')	110,0(5)
C(1')—C(5')—C(4')	103,7(4)		

présence de deux liaisons doubles C(7)—C(7a) et C(1')—C(2'). Enfin l'examen des distances intermoléculaires montre que la cohésion du cristal est assurée par des forces de type van der Waals.

Les données spectrales sont en accord avec cet arrangement structural : le spectre rmn ^{13}C du composé **2** montre effectivement la présence d'un carbone quaternaire C(4a) à 51 ppm; en rmn protonique, pour cette lactone, seuls les protons éthyléniques et ceux du méthylène en position 3 peuvent être individualisés. Par contre, en rmn protonique à 400 MHz et à l'aide d'expériences de corrélation homonucléaire (COSY), l'attribution de tous les signaux des protons est possible pour la lactone **1** et ses précurseurs.

Enfin, la configuration des hydrazones **5** et **6** est différente : en effet, de façon classique (2*b*), l'hydrazone **5** est *Z*, alors que nous avons montré dans l'article précédent (1) que la configuration *E* de l'hydrazone **4** est conservée lors de sa transformation en **6**.

Conclusion

L'application de la réaction de Shapiro à des hydrazones de cyclopentanones constitue une voie d'accès aisée à des cyclopentènes fonctionnalisés. La lactonisation ultérieure des cyclopentènes dépend étroitement de la nature des fonctions portées par le cycle. Les réactifs silylés de Olah ont permis une lactonisation uniquement lorsque la δ-lactone cyclopenténique recherchée n'est pas substituée par un reste cyclopentényle. Dans ce cas, la lactonisation a été réalisée via la cyclisation classique d'un acide alcool.

Les deux nouvelles δ-lactones que nous avons synthétisées renferment le motif de base de divers produits naturels de la famille des monoterpènes bicycliques. La fonctionnalisation ultérieure des δ-lactones obtenues devrait permettre la préparation d'analogues structuraux d'iridoïdes.

Partie expérimentale

Le déroulement des réactions est suivi par ccm (chromatographie sur

couche mince) sur gel de silice (Kieselgel 60F254, Merck 5535). Les points de fusion mesurés sur banc Kofler ne sont pas corrigés. Les spectres infrarouges (ir) sont enregistrés sur spectrophotomètre Perkin Elmer 580 B. Les spectres de masse sont obtenus par impact électronique (30–70 eV) sur appareil Finnigan 3300. Les spectres rmn sont enregistrés à 100 MHz sur spectromètre JEOL FX 100 et à 400 MHz sur appareil Brüker WM 400. Les déplacements chimiques sont exprimés en parties par million et le tétraméthylsilane est pris comme référence interne (s, singulet; d, doublet; t, triplet; q, quadruplet; m, multiplet; M, massif). Les analyses sont effectuées par le Service central de microanalyses du Centre national de la recherche scientifique.

Le tétrahydrofuranne est distillé sur $LiAlH_4$, l'hexane et le tétraméthyléthylènediamine sur CaH_2. Les solutions d'alkyllithien sont commerciales. La lithiation des hydrazones est réalisée sous atmosphère d'argon.

Matières premières

Les produits de départ suivants sont préparés par les méthodes citées en référence : tosylhydrazone de la cyclopentanone, **3** (2); tosylhydrazone de la cyclopentylidène-2 cyclopentanone-1, **4** (10). La synthèse de la tosylhydrazone **6** est décrite dans le mémoire précédent (1).

Tosylhydrazone de la (méthoxy-2 éthyl)-2 cyclopentanone-1 **5**

À une solution de tosylhydrazone **3** (2,52 g, 10 mmol) dans le THF (60 mL) est ajoutée, goutte à goutte et à −78°C, une solution de *n*-butyllithium dans l'hexane (20 mmol). L'addition terminée, on ajoute, goutte à goutte et à −78°C, de l'iodo-1 méthoxy-2 éthane (2,05 g, 11 mmol) (11) dans le THF (10 mL). À la fin de l'addition l'agitation est maintenue 15 min, puis on laisse le milieu réactionnel revenir à température ambiante et maintient 30 min l'agitation. Après hydrolyse par une solution saturée de NH_4Cl (40 mL), on extrait par l'éther éthylique (3 × 20 mL). La phase organique lavée à l'eau (30 mL), puis séchée et évaporée, abandonne 2 g (64%) d'hydrazone **5** sous forme d'une solide blanc recristallisé dans l'éther isopropylique; pf 115°C; R_f 0,14 (éther éthylique – hexane, 2:1); ν_{max}(KBr) : 3140 (NH), 1645 (C=N), 1170 (SO_2N), 1120 (OCH_3) cm^{-1}; rmn 100 MHz ($CDCl_3$) δ : 7,85 et 7,30 (2d, 4H, —C_6H_4—), 3,39 (t, 2H, J = 6,59 Hz, —CH_2OCH_3), 3,28 (s, 3H, OCH_3), 2,42 (s, 3H, —$C_6H_4CH_3$), 2,20–1,20 (M, 9H, protons cyclopentaniques et —$CH_2CH_2OCH_3$). *Anal.* calc. pour $C_{15}H_{22}N_2O_3S$: C 58,06, H 7,09, N 9,03, S 10,32; trouvé : C 58,13, H 7,07, N 9,30, S 10,39.

Préparation des chlorures d'acide **7** *et* **8**

À une suspension de tosylhydrazone **5** ou **6** (30 mmol) dans le mélange TMEDA – hexane (1:1; 100 mL) est ajoutée à −78°C une solution de *n*-butyllithium dans l'hexane (105 mmol). La solution obtenue est agitée pendant 15 min à −78°C, puis 8 h à température ambiante. Après avoir à nouveau refroidi à −78°C, la solution est traitée par un rapide courant de CO_2. Après retour à température ambiante, la solution est hydrolysée par l'eau (300 mL) puis extraite par l'éther éthylique (3 × 50 mL). La phase aqueuse est acidifiée par l'acide chlorhydrique concentré jusqu'à pH 1 et extraite par l'éther éthylique (3 × 100 mL). Cette dernière phase éthérée lavée à l'eau (5 × 40 mL), puis séchée, fournit par évaporation l'acide correspondant.

À une solution de cet acide dans le benzène anhydre (100 mL) est ajouté goutte à goutte, sous courant d'azote et à température ambiante, le chlorure d'oxalyle (15 mL, 171 mmol). Après 3 h d'agitation à cette température, puis évaporation du solvant et de l'excès de réactif, on recueille le chlorure d'acide **7** ou **8** sous forme d'une huile (rendement ≃ 50%) utilisée sans autre purification pour les synthèses ultérieures.

Préparation des esters **9**a, **9**b *et* **9**c

(a) *(Méthoxy-2 éthyl)-3 cyclopentènecarboxylate-2 de méthyle* **9**a

Une solution de 2,65 g (14 mmol) du chlorure d'acide **7** dans 200 mL de méthanol est portée à reflux pendant 1 h. Le solvant est évaporé et le résidu est purifié par chromatographie sur gel de silice dans le solvant éther éthylique – hexane (1:4). On obtient 2,32 g (89%) d'une huile jaune; pé 125°C/3 Torr (1 Torr = 133,3 Pa); R_f 0,39 (éther éthylique – hexane, 1:4); ν_{max}(film) : 1715 (CO_2Me), 1625 (C=C), 1120 (OCH_3) cm^{-1}; rmn 400 MHz ($CDCl_3$) δ : 6,78 (m, 1H, H-1), 3,73 (s, 3H, —CO_2CH_3), 3,43 (dd, 2H, J = 6,40 et 7,38 Hz, —CH_2OCH_3), 3,32 (s, 3H, —OCH_3), 3,01 (M, 1H, H-3), 2,49 et 2,41 (2m, 2H, (CH_2)-5), 2,10 (m, 2H, H-4a et H-1′a), 1,75 (m, 1H, H-4b), 1,51 (m, 1H, H-1′b). *Anal.* calc. pour $C_{10}H_{16}O_3$: C 65,20, H 8,75, O 26,05; trouvé : C 64,87, H 8,82, O 26,40.

(b) *(Méthoxy-2 éthyl)-3 cyclopentènecarboxylate-2 d'éthyle* **9**b

Le mode opératoire est identique à celui décrit pour **9***a*, et on isole l'ester **9***b* avec un rendement de 94%; pé 130°C/3 Torr; R_f 0,42 (éther éthylique – hexane, 1:4); ν_{max}(film) : 1715 (CO_2Et), 1625 (C=C), 1120 (OCH_3) cm^{-1}; rmn 400 MHz ($CDCl_3$) δ : 6,77 (m, 1H, H-1), 4,19 (m, 2H, —$CO_2CH_2CH_3$), 3,43 (dd, 2H, J = 6,89 Hz et 7,38 Hz, —CH_2OCH_3), 3,32 (s, 3H, OCH_3), 3,00 (M, 1H, H-3), 2,48 et 2,40 (2m, 2H, (CH_2)-5), 2,10 (m, 2H, H-4a et H-1′a), 1,74 (m, 1H, H-4b), 1,51 (m, 1H, H-1′b), 1,30 (t, 3H, J = 7,39 Hz, —$CO_2CH_2CH_3$). *Anal.* calc. pour $C_{11}H_{18}O_3$: C 66,64, H 9,15, O 24,21; trouvé : C 66,37, H 8,86, O 24,41.

(c) *(Méthoxy-2 éthyl)-3 cyclopentènecarboxylate-2 de tertiobutyle* **9**c

Cet ester a été préparé selon la méthode décrite par M. Yamaguchi et coll. (12).

À une solution de 2,65 g de chlorure d'acide **7** dans le benzène anhydre (50 mL) sont ajoutés, sous courant d'azote, le cyanure d'argent (3,75 g, 30 mmol) et l'alcool tertiobutylique (15 mL). Le mélange est porté à reflux pendant 1 h, puis filtré. Après évaporation du filtrat et élution sur gel de silice dans le mélange éther éthylique – hexane (1:4), on recueille 2,91 g (92%) d'ester **9***c* sous forme d'une huile jaune; pé 140°C/3 Torr; R_f 0,45 (éther éthylique – hexane, 1:4); ν_{max}(film) : 1710 (CO_2tBu), 1625 (C=C), 1120 (OCH_3) cm^{-1}; rmn 400 MHz ($CDCl_3$) δ : 6,67 (m, 1H, H-1), 3,42 (dd, 2H, J = 6,90 et 7,38 Hz, —CH_2OCH_3), 3,33 (s, 3H, —OCH_3), 2,94 (M, 1H, H-3), 2,49 et 2,41 (2m, 2H, (CH_2)-5), 2,08 (m, 2H, H-4a et H-1′a), 1,71 (m, 1H, H-4b), 1,54 (m, 1H, H-1′b), 1,49 (s, 9H, —$C(CH_3)_3$). *Anal.* calc. pour $C_{13}H_{22}O_3$: C 68,99, H 9,80, O 21,21; trouvé : C 68,62, H 9,50, O 21,44.

(Hydroxy-2 éthyl)-3 cyclopentènecarboxylate-2 d'éthyle **11**

À une suspension d'iodure de sodium (5,25 g, 35 mmol) dans l'acétonitrile (60 mL) sont ajoutés, sous courant d'azote, le trichlorométhylsilane (5,23 g, 35 mmol) et l'ester **9***b* (6 g, 30 mmol). Le mélange est agité à température ambiante pendant 8 h, puis hydrolysé par l'eau (60 mL). Après extraction par l'éther éthylique (3 × 50 mL), la phase organique est lavée par une solution saturée de thiosulfate de sodium (30 mL) puis par l'eau (30 mL), séchée et évaporée. Après élution sur gel de silice par le mélange éther éthylique – hexane (4:1), on obtient 4 g (72%) d'ester alcool **11** sous forme d'une huile incolore; pé 143°C/1 Torr; R_f 0,23 (éther éthylique – hexane, 1:1); ν_{max}(film) : 3420 (OH), 1715 (CO_2Et), 1620 (C=C) cm^{-1}; rmn 400 MHz ($CDCl_3$) δ : 6,81 (m, 1H, H-1), 4,20 (q, 2H, J = 6,90 Hz, —$CO_2CH_2CH_3$), 3,64 (m, 2H, —CH_2OH), 3,08 (M, 1H, H-3), 2,50 (m, 2H, (CH_2)-5), 2,17 (m, 2H, H-4a et H-1′a), 1,84 (m, 1H, H-4b), 1,65 (m, 1H, H-1′b), 1,30 (t, 3H, J = 6,90 Hz, —$CO_2CH_2CH_3$). *Anal.* calc. pour $C_{10}H_{16}O_3$: C 65,21, H 8,70, O 26,08; trouvé : C 65,43, H 8,73, O 25,84.

Acide (iodo-2 éthyl)-3 cyclopentènecarboxylique-2 **12**

À une suspension d'iodure de sodium (1,35 g, 9 mmol) dans l'acétonitrile (15 mL) sont ajoutés, sous courant d'azote, l'ester **9***c* (0,60 g, 3 mmol) puis le triméthylchlorosilane (0.98 g, 9 mmol). Le mélange est porté à reflux pendant 16 h, puis hydrolysé par 15 mL d'eau. Après extraction par l'éther éthylique (3 × 10 mL), la phase organique est lavée par une solution saturée de thiosulfate de sodium (10 mL) puis par l'eau (10 mL), séchée et évaporée. On recueille 0,56 g (70%) de l'iodo-acide **12** recristallisé dans le cyclohexane; pf 104°C; R_f 0,30 (éther éthylique – hexane, 1:1); ν_{max}(KBr) : 3240 (OH), 1670 (CO_2H), 1625 (C=C); rmn 400 MHz ($CDCl_3$) δ : 6,97 (m, 1H, H-1), 3,25 (td, 1H, J = 4,75 et 9,63 Hz, H-2′a), 3,12 (td, 1H, J = 7,52 et 9,63 Hz, H-2′b), 3,00 (M, 1H, H-3), 2,51 (m, 2H, (CH_2)-5), 2,43 (m, 1H, H-4a), 2,17 (m, 1H, H-1′a), 1,80 (m, 1H, H-4b), 1,70 (m, 1H, H-1′b). *Anal.* calc. pour $C_8H_{11}O_2I$: C 36,00, H 4,13, I 47,74; trouvé : C 36,47, H 4,18, I 47,68.

Acide (méthoxy-2 éthyl)-3 cyclopentènecarboxylique-2 ***10***

À une solution d'ester **9***b* (1,21 g, 6,1 mmol) dans le DMSO (50 mL) est ajoutée une solution de potasse 2 *N* (20 mL). On chauffe pendant 4 h à 100°C. La solution est ensuite hydrolysée par l'eau (50 mL), puis extraite par l'éther éthylique (3 × 15 mL). La phase aqueuse est alors acidifiée par HCl concentré, puis à nouveau extraite par l'éther éthylique (3 × 20 mL). Cette dernière phase organique lavée jusqu'à neutralité, séchée, puis évaporée, abandonne 0,83 g (80%) de l'acide **10** sous forme d'un liquide incolore; ν_{max}(film) : 3240 (OH), 1685 (CO_2H), 1620 (C=C), 1114 (OCH_3) cm^{-1}; rmn 400 MHz ($CDCl_3$) δ : 6,92 (m, 1H, H-1), 3,44 (dd, 2H, J = 6,40 et 7,38 Hz, $-CH_2OCH_3$), 3,33 (s, 3H, —OCH_3), 3,02 (M, 1H, H-3), 2,50 (m, 2H, (CH_2)-5), 2,13 (m, 2H, H-4a et H-1′a), 1,75 (m, 1H, H-4b), 1,53 (m, 1H, H-1′b). *Anal.* calc. pour $C_9H_{14}O_3$: C 63,51, H 8,29, O 28,20; trouvé : C 63,39, H 8,40, O 28,28.

Hexahydro-1,3,4,4a,5,6 cyclopenta[c]pyrannone-1 ***1***

Cette lactone a été isolée soit à partir de l'ester **9***c*, soit à partir de l'acide **12**.

(a) *Synthèse à partir de l'ester* **9**c

À une suspension d'iodure de sodium (12,1 g, 81 mmol) dans l'acétonitrile (60 mL) sont ajoutés, sous courant d'azote, le trichlorométhylsilane (12,1 g, 81 mmol) et l'ester **9***c* (7 g, 31 mmol). Le mélange est porté à reflux pendant 24 h. On ajoute 50 mL d'eau puis on extrait par l'éther éthylique (3 × 50 mL). La phase organique est lavée par une solution saturée de thiosulfate de sodium (30 mL) puis par l'eau (30 mL), séchée et évaporée. L'huile obtenue est purifiée par chromatographie sous pression moyenne sur gel de silice avec le mélange éther éthylique – hexane (1 : 1). On isole ainsi 1,9 g (44%) de lactone **1**, sous forme d'une huile; pé 130°C/0,1 Torr; R_f 0,30 (éther éthylique – hexane, 1 : 1); ν_{max}(film) : 1721 (CO_2—), 1630 (C=C) cm^{-1}; rmn 400 MHz ($CDCl_3$) δ : 6,99 (m, 1H, H-7), 4,46 et 4,31 (2m, 2H, $J_{3\alpha4\beta}$ = 4,65, $J_{3\alpha4\alpha}$ = 2,05, $J_{3\beta4\alpha}$ = 2,76, $J_{3\beta4\beta}$ = 12,37 et $J_{3\alpha3\beta}$ = 11,47 Hz, (CH_2)-3), 2,98 (M, 1H, H-4a), 2,46 (m, 2H, (CH_2)-6), 2,37 (m, 1H, H-5α), 2,11 (m, 1H, H-4α), 1,66 (m, 2H, H-5β et H-4β); spectre de masse : $M^{+\bullet}$ 138 (69%), 108 (34), 94 (40), 80 (100). *Anal.* calc. pour $C_8H_{10}O_2$: C 69,56, H 7,25, O 23,19; trouvé : C 69,30, H 7,38, O 23,32.

(b) *Synthèse à partir de l'acide* **12**

À une solution de l'acide **12** (0,2 g, 0,75 mmol) dans l'acétonitrile (10 mL) on ajoute, sous courant d'azote, le perchlorate d'argent monohydraté (0,31 g, 1,5 mmol). On agite durant 48 h à température ambiante; le précipité obtenu est filtré et la phase organique est lavée à l'eau (3 × 20 mL) puis par une solution saturée en NaCl, séchée et évaporée. On recueille ainsi 93 mg (90%) de lactone **1**.

Préparation des esters ***13*** *et* ***14***

(a) *Action de l'éthanol sur le chlorure d'acide* **8**

Une solution de 3,58 g de chlorure d'acide **8** dans 200 mL d'éthanol est portée à reflux pendant 1 h. Après évaporation de l'éthanol, le résidu est élué sur gel de silice par le mélange éther éthylique – hexane (1 : 4) et on recueille dans l'ordre : 0,64 g (15%) de (chloro-2 éthyl)-3 (cyclopentényl-1′)-3 cyclopentènecarboxylate-2 de méthyle, **14**; pé 130°C/0,05 Torr; R_f 0,58 (éther éthylique – hexane, 1 : 4); ν_{max}(film) : 1718 (CO_2Me), 1620 (C=C), 655 (C—Cl) cm^{-1}; rmn 100 MHz ($CDCl_3$) δ : 6,87 (m, 1H, H-1), 5,37 (m, 1H, H-2′), 3,69 (s, 3H, —CO_2CH_3), 3,43 (m, 2H, —CH_2Cl), 2,65–1,60 (M, 12H, méthylènes cyclopenténiques et —CH_2CH_2Cl). *Anal.* calc. pour $C_{14}H_{19}O_2Cl$: C 66,14, H 7,48, O 12,59; trouvé : C 66,41, H 7,60, O 12,86; et 2,77 g (75%) de (cyclopentényl-1′)-3 (méthoxy-2 éthyl)-3 cyclopentènecarboxylate-2 d'éthyle, **13**; pé 135°C/0,05 Torr; R_f 0,37 (éther éthylique – hexane, 1 : 4); ν_{max}(film) : 1718 (CO_2Et), 1625 (C=C), 1114 (OCH_3) cm^{-1}; rmn 100 MHz ($CDCl_3$) δ : 6,84 (m, 1H, H-1), 5,35 (m, 1H, H-2′), 4,11 (q, 2H, J = 7,20 Hz, —$CO_2CH_2CH_3$), 3,34 (m, 2H, —CH_2OCH_3), 3,27 (s, 2H, —OCH_3), 2,43–1,60 (M, 12H, méthylènes cyclopenténiques et —$CH_2CH_2OCH_3$), 1,25 (t, 3H, J = 7,20 Hz, —$CO_2CH_2CH_3$). *Anal.* calc. pour $C_{16}H_{24}O_3$: C 72,69, H 9,15, O 18,16; trouvé : C 72,98, H 9,03, O 18,26.

(b) *Chauffage du chlorure d'acide* **8** *au reflux du benzène*

Une solution de 3,58 g de chlorure d'acide **8** dans le benzène (100 mL) est portée à reflux pendant 12 h. Après évaporation du solvant et purification sur gel de silice dans le mélange éther éthylique – hexane (1 : 4), on obtient 3,43 g (96%) du chloro-ester **14**.

Acide (cyclopentényl-1′)-3 (hydroxy-2 éthyl)-3 cyclopentènecarboxylique-2 ***15***

À une solution du composé **14** (0,3 g, 1,18 mmol) dans le DMSO (20 mL) est ajoutée une solution de potasse 2 *N* (5 mL). On porte à 100°C durant 4 h, puis on hydrolyse par l'eau (40 mL). La phase aqueuse est extraite par l'éther éthylique (3 × 10 mL), puis acidifiée par l'acide chlorhydrique concentré et extraite à nouveau par l'éther éthylique (3 × 20 mL). Cette dernière phase organique est lavée à l'eau (4 × 15 mL), séchée et évaporée. On recueille 0,21 g (80%) d'acide alcool **15**, recristallisé dans le benzène; pf 130°C; ν_{max}(KBr) : 3400 (OH), 1688 (CO_2H), 1618 (C=C) cm^{-1}; rmn 100 MHz ($CDCl_3$) δ : 7,00 (m, 1H, H-1), 5,40 (m, 1H, H-2′), 4,49 (M, 1H, —OH), 3,66 (m, 2H, —CH_2OH), 2,53–1,75 (M, 12H, méthylènes cyclopenténiques et —CH_2CH_2OH). *Anal.* calc. pour $C_{13}H_{18}O_3$: C 70,24, H 8,16, O 21,59; trouvé : C 69,89, H 8,29, O 21,82.

(Cyclopentényl-1′)-4a hexahydro-1,3,4,4a,5,6 cyclopenta[c]pyrannone-1 ***2***

On porte à reflux pendant 3 h dans un appareil Dean–Stark l'hydroxy-acide **15** (2,6 g, 11,7 mmol) dissous dans le benzène anhydre (100 mL) en présence d'acide *p*-toluènesulfonique (0,05 g). Le mélange réactionnel est versé sur de l'eau glacée et extrait par l'éther éthylique (3 × 50 mL). La phase organique est lavée à l'eau, séchée et évaporée. Le résidu élué sur gel de silice par le mélange éther éthylique – hexane (1 : 1) fournit, après recristallisation dans l'hexane, 1,90 g (80%) de lactone **2**; pf 74°C; R_f 0,41 (éther éthylique – hexane, 1 : 1); ν_{max}(KBr) : 1709 (CO_2—), 1630 (C=C) cm^{-1}; rmn 400 MHz ($CDCl_3$) δ : 7,00 (m, 1H, H-1), 5,38 (m, 1H, H-2′), 4,29 et 4,16 (2m, 2H, $J_{3\alpha4\beta}$ = 4,89, $J_{3\alpha4\alpha}$ = 1,60, $J_{3\beta4\alpha}$ = 2,84, $J_{3\beta4\beta}$ = 13,06 et $J_{3\alpha3\beta}$ = 11,36 Hz, (CH_2)-3), 2,41–1,62 (M, 12H, méthylènes cyclopenténiques et —CH_2CH_2O—); spectre de masse : $M^{+\bullet}$ 204 (100%), 176 (43), 148 (40). *Anal.* calc. pour $C_{13}H_{16}O_2$: C 76,47, H 7,84, O 15,69; trouvé : C 76,89, H 7,68, O 15,54.

(Cyclopentényl-1′)-3 (phtalimido-2 éthyl)-3 cyclopentènecarboxylate-2 de méthyle ***16***

À une solution du composé **14** (0,5 g, 1,97 mmol) dans le DMF (diméthylformamide) anhydre (10 mL) sont ajoutés, sous courant d'argon, le phtalimide de potassium (0,46 g, 2,5 mmol) et l'iodure de sodium (0,45 g, 3 mmol). On chauffe à 100°C durant 24 h. On hydrolyse par l'eau (30 mL) et extrait la phase aqueuse par l'éther éthylique (3 × 15 mL). La phase organique est lavée à l'eau, séchée et évaporée. Après élution sur gel de silice par le mélange éther éthylique – hexane (1 : 1), on obtient 0,3 g (42%) du phtalimide **16** recristallisé dans l'éthanol; pf 118°C; R_f 0,42 (éther éthylique – hexane, 1 : 1); ν_{max}(KBr) : 1771 (imide), 1711 (CO_2Me), 1614 (C=C), 1608 (aromatique); rmn 100 MHz ($CDCl_3$) δ : 7,82 et 7,69 (2m, 4H, aromatiques), 6,88 (m, 1H, H-1), 5,45 (m, 1H, H-2′), 3,65 (s, 3H, —CO_2CH_3), 3,64 (m, 2H, —CH_2N—), 2,58–1,63 (M, 12H, méthylènes cyclopenténiques et —CH_2CH_2N—). *Anal.* calc. pour $C_{22}H_{23}NO_4$: C 72,33, H 6,30, N 3,83, O 17,53; trouvé : C 72,25, H 6,39, N 3,75, O 17,77.

(Cyclopentényl-1′)-4a hexahydro-1,3,4,4a,5,6 2H*-cyclopenta[c]-pyridinone-1* ***17***

À une solution du composé **16** (1,5 g, 4,1 mmol) dans le méthanol (20 mL) est ajoutée une solution aqueuse d'hydrate d'hydrazine (13,7 mmol). On agite pendant 3 h à température ambiante, puis on ajoute une solution de 6,9 mL d'acide acétique dans 30 mL de méthanol. On agite pendant 5 min à 20°C et filtre le précipité formé. Après évaporation du filtrat, on ajoute 40 mL de CH_2Cl_2. La phase organique est lavée par une solution saturée de $NaHCO_3$ puis par l'eau, séchée et évaporée. L'huile obtenue est purifiée par chromatographie sous pression moyenne sur gel de silice à l'aide du mélange éther éthylique – hexane (1 : 1). On isole, après recristallisation dans le benzène, 0,2 g (24%) de lactame **17**; pf 200°C; R_f 0,17 (éther éthylique – hexane, 4 : 1); ν_{max}(KBr) : 3200 (NH), 1656 et 1639 (CONH—)

cm^{-1}; rmn 400 MHz (acétone-d_6, D_2O) δ : 6,55 (m, 1H, H-1), 5,26 (m, 1H, H-2′), 3,24 (m, 1H, $J_{3\alpha3\beta}$ = 12,70, $J_{3\alpha4\alpha}$ = 5,30 et $J_{3\alpha4\beta}$ = 1,90 Hz, H-3α), 3,12 (m, 1H, $J_{3\alpha3\beta}$ = 12,70, $J_{3\beta4\alpha}$ = 12,70 et $J_{3\beta4\beta}$ = 3,69 Hz, H-3β), 2,33–1,64 (M, 12H, méthylènes cyclopenténiques et —CH_2CH_2NH—). *Anal.* calc. pour $C_{13}H_{17}NO$: C 76,81, H 8,43, N 6,89, O 7,87; trouvé : C 76,80, H 8,53, N 6,77, O 7,71.

Analyse radiocristallographique du composé **2**

$C_{13}H_{16}O_2$ M = 204

Monoclinique $I2/c$ ($h + k + l = 2n$; $h0l$, $l = 2n$); a = 17,144(7), b = 6,274(3), c = 20,977(7) Å; β = 98,66(3)°; V = 2231 Å^3; Z = 8; ρ_c = 1,21 g/cm^3; F (0, 0, 0) = 880; μ (MoKα) = 0,45 cm^{-1}.

Les cristaux du composé **2** ont été obtenus par recristallisation dans l'hexane. Après de multiples essais, un cristal de taille 0,2 × 0,4 × 0,1 mm a été utilisé pour enregistrer, sur un diffractomètre automatique CAD4 Enraf–Nonius, 2310 réflexions avec le rayonnement Kᾱ du molybdène monochromatisé au graphite ($1 < 2\theta < 60°$, largeur de balayage (0,90 + 0,35 tan θ)°). Seules 935 réflexions ont été conservées pour affiner la structure répondant au critère statistique $I > 3{,}3\sigma(I)$. Les intensités ont été corrigées des phénomènes de Lorentz et de polarisation, l'absorption a été négligée. L'ensemble des réflexions a été renormalisé par suite de la décomposition du cristal ($\Delta I_c/I_c$ = 0,25 à la fin de l'enregistrement) en ajustant une droite au sens des moindres carrés à l'intensité de deux réflexions de contrôle (312, 112). La structure a été résolue dans le groupe $I2/c$ (x, y, z; $\bar{x}, \bar{y}, \bar{z}$; $x, \bar{y}, 1/2 + z$; $\bar{x}, y, 1/2 - z$; $+1/2, 1/2, 1/2$) pour conserver un angle β proche de 90°. Les coordonnées fractionnaires des atomes de carbone et d'oxygène ont été déterminées à l'aide du programme MULTAN (13). Au cours de l'affinement (SHELX 76 (14)), chaque atome non-hydrogène a été affecté d'un coefficient d'agitation thermique anisotrope. L'ensemble des atomes d'hydrogène a été trouvé dans les sections de la différence de la densité électronique et affiné avec un facteur d'agitation thermique isotrope. L'affinement a convergé jusqu'aux indices suivants : $R(F)$ = 0,057; $R_w(F)$ = 0,051;[3] $R(F^2)$ = 0,058; S = 1,47;[3] N_p = 198; N_o = 935; $w = 1{,}7/[\sigma^2(F) + 0{,}0016\,F^2]$; max Δ/σ = 0,23 pour z de C(11); ρ résiduelle maximum = 0,2 ē/Å^3.

Les coordonnées fractionnaires des atomes autres que les atomes d'hydrogène sont rassemblées dans le tableau 2. La numérotation des atomes est visualisée en figure 5. Les coordonnées fractionnaires des atomes d'hydrogène, les facteurs d'agitation thermique et une liste des facteurs de structure ont été déposés sous forme de matériel supplémentaire.[4]

JIA-SEN LIU, YUAN-LONG ZHU, CHAO-MEI YU, YOU-ZUO ZHOU, YAN-YI HAN, FENG-WU WU, and BAO-FENG QI. Can. J. Chem. **64**, 837 (1986).

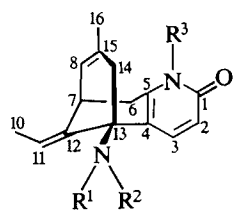
Huperzine A and B, two new Lycopodium alkaloids isolated from *Huperzia serrata* (Thunb.) Trev., are shown to possess structures **1** and **3**, respectively, on the basis of chemical and spectroscopic data.

JIA-SEN LIU, YUAN-LONG ZHU, CHAO-MEI YU, YOU-ZUO ZHOU, YAN-YI HAN, FENG-WU WU et BAO-FENG QI. Can. J. Chem. **64**, 837 (1986).

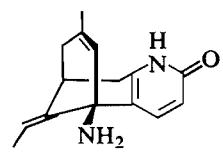
En se basant sur des données chimiques et spectroscopiques, on démontre que les deux nouveaux alkaloïdes du Lycopodium, les huperzines A et B, qui ont été isolés du *Huperzia serrata* (Thunb.) Trev., possèdent respectivement les structures **1** et **3**.
[Traduit par la revue]

Huperzine A (**1**) and B (**3**), two new Lycopodium alkaloids, were isolated from *Huperzia serrata* (Thunb.) Trev. = *Lycopodium serratum* Thunb., a Chinese folk medicine. They exhibit strong anticholinesterase activity in pharmacological studies (1) and markedly increase efficiency for learning and memory in animals.[3] Presently, the use of huperzine A in the treatment of myasthenia gravis (2), Alzheimer's dementia, and for the improvement of senile memory loss are under clinical investigation. In this paper we report chemical studies on the structures of huperzine A and B.

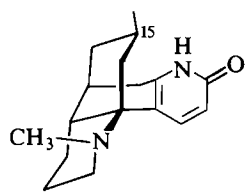
Huperzine A (**1**), $C_{15}H_{18}N_2O$ (M^+ 242.1426), mp 230°C, $[\alpha]_D^{24.5}$ −150.4° (*c* 0.498, MeOH), shows the characteristics of an α-pyridone in its uv spectrum (λ_{max} (EtOH) nm (log ε): 231 (4.01), 313 (3.89)), ir spectrum (3180, 1650, 1615, 1550 cm^{-1}), and ^1H nmr spectrum (see Table 1). Dehydrogenation of huperzine A over Pd/C at 300°C affords 6-methyl-2(1*H*)-pyridone, further attesting to the presence of an α-pyridone ring in the molecule. The presence of an endocyclic double bond and an exocyclic double bond as revealed in the ^1H and ^{13}C nmr spectra of huperzine A (Tables 1, 2), as well as the similarity of its mass spectrum with that of selagine (3), indicate that the structure of huperzine A (**1**) closely resembles that of the known alkaloid selagine (**2**) (4). The specific rotation (−99° in MeOH) of selagine (4) is much less than that of huperzine A. The olefinic proton of the endocyclic double bond in the ^1H nmr of 11,12-dihydroselagine appears as a singlet (4), while in the ^1H nmr of huperzine A (**1**) or in the ^1H nmr of 11,12-dihydrohuperzine A the olefinic proton appears as a doublet. This clearly accounts for the structural differences between **2** and **1** and



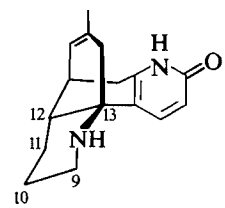
1 $R^1 = R^2 = R^3 = H$
1*a* R^1 = Me, $R^2 = R^3 = H$
1*b* $R^1 = R^2$ = Me, $R^3 = H$
1*c* $R^1 = R^2 = R^3$ = Me
1*d* R^1 = Ac, $= R^2 = R^3 = H$



2



4



3

indicates the presence of a vicinal methine coupled to the olefinic proton in compound **1**. This partial structure can be accommodated in the molecule if the endocyclic double bond is located at C-8,C-15 with the olefinic proton at C-8. Corroborative evidence for the proposed structure is available from ^1H–{^1H} decoupling experiments and nOe (nuclear Overhauser effect) measurements. Irradiation at H-7 leads to simultaneous decoupling of H-8 and H-6, while irradiation at H-14 produces a 12.2% nOe enhancement at H-3.

Methylation of huperzine A with methyl iodide, formic acid/formaldehyde, and dimethyl sulfate provides *N*-monomethylhuperzine A (**1***a*), mp 235–236°C; *N,N*-dimethylhuperzine A (**1***b*), mp 243–245°C; and *N,N,N*-trimethylhuperzine A (**1***c*), viscous oil, respectively. Acetylation of **1** in Ac_2O/Py furnishes *N*-acetylhuperzine A (**1***d*), mp 276–277°C. Catalytic hydrogenation of **1** with Pt/EtOH gives 11,12-dihydrohuperzine A,

[1]Presented in part at the International Symposium on Organic Chemistry of Medicinal Natural Products (IUPAC), Shanghai, China, November 1985. After submission of the manuscript to the symposium, we found that an analogous alkaloid named isoselagine had been reported (9). From the published data, we conclude that huperzine A is not identical with isoselagine and that the latter may be the *Z* isomer of huperzine A.

mp 269–270°C, while use of Pt/AcOH gives tetrahydrohuperzine A, mp 264–265°C.

Examination of the ^{1}H nmr of huperzine A and its derivatives shows a remarkable upfield shift of the signals for H-3 and H-11 of 0.30 and 0.11 ppm in *N*-monomethylhuperzine A (**1***a*) and of 0.44 and 0.14 ppm in *N*-acetylhuperzine A (**1***d*). The remaining protons do not show any significant shift relative to the corresponding protons of huperzine A. This information reveals a close spatial relationship between H-3, H-11 and the *N*-methyl or the *N*-acetyl group, i.e., the exocyclic double bond of huperzine A has an *E* configuration. This assignment was confirmed by nOe experiments. Enhancements at H-7 of 11.7% upon irradiation of H-10 and 8.3% upon irradiation of H-6 were observed. Selagine (**2**) (5) has a *Z* configuration of the exocyclic double bond.

Huperzine B (**3**), $C_{16}H_{20}N_2O$ (M^+ 256.1558), mp 270–271°C, $[\alpha]_D^{25}$ −54.2° (*c* 0.203, MeOH), also possesses an α-pyridone and a C-8,C-15 endocyclic double bond. It is characterized by its uv spectrum (λ_{max} (MeOH) nm (log ε): 231 (3.95), 312 (3.85)), ir spectrum (3100, 1670, 1620, 1610, 1560 cm^{-1}), and ^{1}H and ^{13}C nmr spectra (see Tables 1, 2). The notable difference between **1** and **3** is the absence of signals corresponding to an exocyclic double bond in the ^{1}H and ^{13}C nmr spectra of **3**. Methylation of **3** with formic acid/formaldehyde provides *N*-methylhuperzine B, mp 272–273°C, a compound the spectral characteristics of which closely resemble those of the known alkaloid β-obscurine **4** (6). Dehydrogenation of huperzine B with Pd/C at 300°C furnishes 7-methylquinoline and 6-methyl-2(1*H*)-pyridone, providing further evidence that huperzine B possesses structure **3**.

An attempt to transform *N*-methylhuperzine B to β-obscurine by hydrogenation was unsuccessful. Hydrogenation of an acetic acid solution of *N*-methylhuperzine B in the presence of Pt gave a single product in nearly quantitative yield. The product was identified as 15-epi-β-obscurine, mp 281–283°C, characterized by the high-field chemical shift (δ 0.60) of the C-15 methyl in its ^{1}H nmr (7). This result suggests that, in *N*-methylhuperzine B, H-12 is β since in this configuration hydrogen addition to the C-8,C-15 double bond should proceed to produce 15-epi-β-obscurine. The stereochemistry at C-12 is verified by nOe experiments. Irradiation at H-12, H-10β, and H-11α causes a 7.9, 7.4, and 10.6% enhancement at H-14$_{exo}$, H-12, and H-6α, respectively, indicating the close spatial relationship between H-12, H-14$_{exo}$, and H-10β, and between H-11α and H-6α. The ^{1}H nmr line-broadening effect (8) in chloroform-*d* containing a trace of acid, which causes signals of H-12, H-14$_{exo}$, and H-10β to broaden and to shift downfield 0.21, 0.27, and 0.19 ppm respectively, also leads to the conclusion about the configuration of the three protons spatially close to the nitrogen lone-pair electrons, i.e., that H-12 is β configuration.

The assignment of absolute configuration for the bridgehead carbons C-13 and C-7 rests on the comparison of cd (circular dichroism) curves of 15-epi-β-obscurine derived from huperzine B **3** with that of β-obscurine **4**, a compound of known configuration (6). The cd curve of 15-epi-β-obscurine closely resembles that of β-obscurine except in the amplitude of the first Cotton effect at 310 nm. This phenomenon is also observed when the cd of huperzine B and 11,12-dihydrohuperzine A are compared, demonstrating that the configurations of the bridgehead carbons in β-obscurine, huperzine B, and huperzine A are similar. Thus, the 7*R*,13*R*,11*E* configuration may be assigned to huperzine A, and 7*S*,13*R*,12*R* to huperzine B.

Acknowledgements

The authors are deeply grateful to Professor William A. Ayer for providing an authentic sample of β-obscurine and for helpful discussion.

The reduction of (1-(4-cyanophenyl)-3-hydroxy-2-buten-1-one-*N*)pentaamminecobalt(III) by chromium(II)

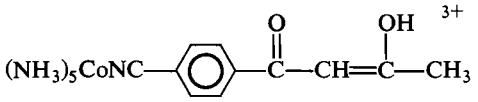
ROBERT J. BALAHURA[1] AND A. JOHNSTON

Guelph–Waterloo Centre for Graduate Work in Chemistry, Department of Chemistry and Biochemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received June 3, 1985[2]

ROBERT J. BALAHURA and A. JOHNSTON. Can. J. Chem. **64**, 841 (1986).

The reduction of the title compound,

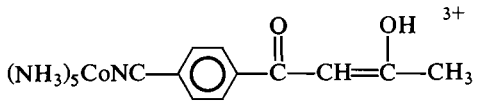


1

by chromium(II) is first order in Cr(II) and obeys the rate law $k_{obsd} = k_1K_a'/(K_a' + [H^+])$ at 25.0°C and $I = 1.0\,mol\,L^{-1}$ ($LiClO_4$) with $k_1 = (2.9 \pm 0.1) \times 10^4\,L\,mol^{-1}\,s^{-1}$ and $K_a' = 0.86 \pm 0.03\,mol\,L^{-1}$. In the rate law, k_1 refers to reduction of the 3+ ion above and the K_a' is the acid dissociation constant for the protonated form of **1**. The reduction occurs by a remote attack inner-sphere mechanism with complete transfer of the organic ligand to chromium.

ROBERT J. BALAHURA et A. JOHNSTON. Can. J. Chem. **64**, 841 (1986).

Le composé **1** mentionné dans le titre



1

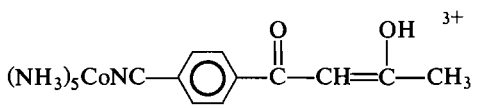
est réduit par le chrome(II); la réaction est du premier ordre en Cr(II) et, à 25,0°C, elle obéit à la loi de vitesse $k_{obs} = k_1K_a'/(K_a' + [H^+])$ alors que $I = 1,0\,mol\,L^{-1}$ ($LiClO_4$), $k_1 = (2,9 \pm 0,1) \times 10^4\,L\,mol^{-1}\,s^{-1}$ et $K_a' = 0,86 \pm 0,03\,mol\,L^{-1}$. Dans l'équation de vitesse, k_1 se rapporte à la réduction de l'ion 3+ mentionné plus haut alors que K_a' représente la constante de dissociation de la forme protonée du composé **1**. La réduction se produit par un mécanisme d'attaque à distance de la couche interne avec un transfert complet du ligand organique vers le chrome.

[Traduit par la revue]

Introduction

Electron transfer via "remote" substituents has been shown to occur in a wide variety of systems (1–5). For reduction of $(NH_3)_5CoNC—C_6H_4—R$ complexes by chromium(II), inner-sphere remote attack by the reductant takes place for R = CN (6), $C(O)CH_3$ (7), CHO (6), CO_2^- (8), and O^- (9). In all of these cases, the second-order rate constant determined is a composite of k_{et} (intramolecular electron transfer) and K_p (formation of precursor complex), which, in general, cannot be separated. However, for reduction of $(NH_3)_5CoNCacac^{2+}$, where NCacac = 3-cyano-2,4-pentanedionate, by chromium(II), saturation behaviour was observed with respect to the reductant concentration and individual values of k_{et} and K_p were obtained (10). This behaviour was attributed to three features of the remote β-diketonate group: (*1*) the large affinity of Cr^{2+} for hard oxygen donors, (*2*) the formation of a "stable" chelate with the reductant, and (*3*) a reduction of electrostatic repulsion by the presence of the delocalized negative charge.

In extending these studies, we attempted the synthesis of an analogous complex, $(NH_3)_5CoNC—C_6H_4—C(O)—acac^{2+}$. This preparation resulted in the isolation of **1**



1

where a $COCH_3$ fragment has been lost. In this paper we wish to report on the preparation, characterization, and chromium(II) reduction of **1**.

Experimental

All reagent solutions were prepared in water that was deionized and distilled from alkaline permanganate in an all-glass apparatus. All metal salts, solvents, and organic starting materials were of reagent grade and used without further purification. Chromium(II) solutions were prepared as previously described (11). All kinetic measurements were performed on a Dionex model D-100 stopped-flow spectrophotometer interfaced with a digital storage unit. Reactions were carried out under pseudo-first-order conditions with the ratio Cr(II)/Co(III) > 15 at 314 and 360 nm. Observed rate constants were obtained directly from the exponential decay traces by curve matching with a calibrated decay generator.

The pK_a of $[(NH_3)_5CoNC—C_6H_4—C(O)CH=C(OH)—CH_3]^{3+}$ was determined by potentiometric titration with $0.01\,mol\,L^{-1}$ KOH (12).

Reaction mixtures from kinetic runs were subjected to ion exchange chromatography using SP-Sephadex cation exchange resin and Dowex 50W 50X8-200 cation exchange resin and eluted with gradually increasing concentrations of $NaClO_4/HClO_4$ solutions. Chromium concentrations were determined by oxidation to CrO_4^{-2} and measurement of the absorbance at 372 nm ($\varepsilon = 4815\,L\,mol^{-1}\,cm^{-1}$) (13).

Proton magnetic resonance spectra were obtained using Varian A60 or Bruker WP60FT spectrometers. Ultraviolet–visible spectra were recorded on a Beckman Acta CIII spectrophotometer, and infrared spectra were recorded using KBr pellets on a Beckman IR12 infrared spectrophotometer. Measurements of pH were made using a Radiometer model PHM26 pH meter.

Syntheses

Preparation of 3-(4-cyanobenzoyl)-2,4-pentanedione

To a stirred solution of 5.0 g 4-cyanobenzoyl chloride in benzene was added 10.0 g thallium(I) 2,4-pentanedionate, and the reaction mixture was heated at 50°C for 30 min. The precipitate of thallous chloride was filtered off and the benzene solution reduced in volume under vacuum to yield a viscous oil. This oil was taken up in ethanol and a small amount of water added. Refrigeration of this solution yielded crystals of 3-(4-cyanobenzoyl)-2,4-pentanedione, which was washed with water and air-dried. The nitrile stretching frequency was observed at 2235 cm^{-1}; ^1H nmr spectrum (DMSO-d_6) δ: 8.20 (C_6H_4, 4H), 2.20 (CH_3, 6H), 17.2 (O—H, 1H). *Anal.* calcd. for $C_{13}H_{11}NO_3$: C 68.1, H 4.84, N 6.11; found: C 68.0, H 4.70, N 6.10.

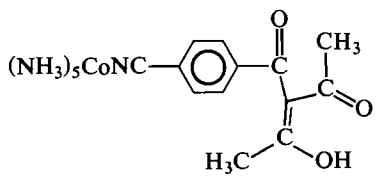
*Preparation of (1-(4-cyanophenyl)-3-hydroxy-2-buten-1-one-*N*)-pentaamminecobalt(III) perchlorate, [$(NH_3)_5CoNC—C_6H_4—C(=O)—CH=C(OH)—CH_3](ClO_4)_3$*

To a solution of 5.0 g $[(NH_3)_5Co(CF_3SO_3)](CF_3SO_3)_2$ (14) in 25 mL sulfolane was added 2.2 g 3-(4-cyanobenzoyl)-2,4-pentanedione. The red solution was stirred for 1 day at 40°C, and the resultant orange solution was poured into 500 mL diethyl ether. The orange semisolid was washed with several portions of ether, dried, and dissolved in 500 mL water. The filtered aqueous solution was charged onto a CM-Sephadex column and eluted with 0.1–0.5 mol L^{-1} NaCl solution. The required complex moved down the column as a yellow band, with the characteristics of a 3+ ion. The band was physically removed and the complex removed from the resin by addition of 5 mol L^{-1} NaCl. Addition of sodium perchlorate resulted in precipitation of a light yellow powder, which was filtered, washed with water, ethanol, and finally ether, and then air-dried.

The electronic spectrum of the complex in water exhibited peak maxima at 466 (ε = 105 L mol^{-1} cm^{-1}), 320 (1.31 × 10^4), and 255 (2.2 × 10^4) nm. The nitrile stretching frequency was observed at 2295 cm^{-1}; ^1H nmr spectrum in DMSO-d_6 δ: 8.20 (C_6H_4, 4H), 2.23 (CH_3, 3H), 6.65 (CH, 1H), 4.20 (*cis*-NH_3, 12H), 3.80 (*trans*-NH_3, 3H). *Anal.* calcd. for $CoC_{11}N_6O_{14}H_{24}Cl_3$: C 21.0, H 3.84, N 13.3; found: C 21.4, H 4.40, N 13.4.

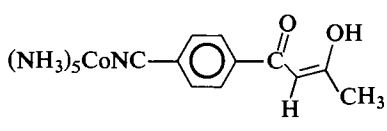
Results and discussion

Attempts to form the complex **2** by reaction of free ligand with $[(NH_3)_5Co(CF_3SO_3)](CF_3SO_3)_2$ in a noncoordinating solvent, sulfolane, resulted in isolation of a major species characteristic of a nitrile-bonded pentaamminecobalt(III) complex ($\nu(C\equiv N)$ = 2295 cm^{-1}) but which exhibited an nmr spectrum inconsistent with **2**. The ratio of phenyl protons to



2

methyl protons in the nmr spectrum was 4:3 rather than 4:6 as expected. This fact, combined with elemental analysis and reactions of the free ligand (*vide supra*), indicated that the major product has structure **1**, which results from loss of a $COCH_3$ fragment. The mechanism of this transformation was believed to involve reaction of the free ligand with traces of trifluoromethanesulfonic acid in the $[(NH_3)_5Co(CF_3SO_3)](CF_3SO_3)_2$–sulfolane solution. The nmr spectra of the free ligand in DMSO-d_6 showed a decrease in the methyl peaks with time upon addition of a drop of trifluoroacetic acid.



1

The pK_a for deprotonation of complex **1** was determined by potentiometric titration to be 6.92 ± 0.05. This value, as compared to that for the NCacac complex (10) (pK_a = 1.30) can be explained as being due to the change in position of the electronegative $(NH_3)_5CoNC$— group from the 3-position, which is directly adjacent to the β-diketone, to a more remote location in **1**, where the inductive effect is not nearly as great. Furthermore, small changes in the uv–vis spectrum of the complex **1** were observed in the acid range 0.10–1.0 mol L^{-1}, indicating a second equilibrium with pK_a value between 1 and 0. The changes were too small to allow a more accurate estimation of this equilibrium constant, which likely pertains to deprotonation of $[(NH_3)_5CoNC—C_6H_4—C(OH)=CH—C(OH)—CH_3]^{4+}$. Solutions of the complex in pure water were unstable and decomposition was evident after approximately 1 h.

Addition of Cr^{2+} to a solution of $[(NH_3)_5CoNC—C_6H_4—C(=O)—CH=C(OH)—CH_3]^{3+}$ resulted in a rapid decrease in absorbance at wavelengths corresponding to the maxima of the Co(III) complex. The stoichiometry of the reaction was determined to be 1:1 by reaction of the complex with excess Cr^{2+} followed by titrimetric determination of Cr^{2+} after the reaction.[3] Kinetic studies were limited to a rather narrow range of chromium(II) concentrations since runs at concentrations higher than 0.0122 mol L^{-1} resulted in rates too fast to be determined accurately by the stopped-flow method. Several runs were carried out at wavelengths corresponding to formation of product and in the ultraviolet region, and in all cases only one reaction was observed. At a constant acid concentration the rate of reduction was directly proportional to the chromium(II) concentration (Table 1). The variation of the observed rate constant with hydrogen ion concentration shows that the rate approaches a limiting value at low acid concentrations (Table 1). The data are consistent with a rate law of the general form [1] given below:

$$[1]\quad k_{obsd} = \frac{a}{b + [H^+]}$$

As predicted by eq. [1], a plot of k_{obsd}^{-1} vs. $[H^+]$ gives a straight line with intercept $(b/a) = (3.5 \pm 0.1) \times 10^{-5}$ *M* s and slope $(1/a) = (4.0 \pm 0.1) \times 10^{-5}$ s, yielding $a = (2.5 \pm 0.1) \times 10^4$ s^{-1} and $b = 0.86 \pm 0.03$ mol L^{-1}. A mechanism consistent with all the experimental results is given in Scheme 1. This mechanism leads to the rate law [2]:

$$[2]\quad k_{obsd} = \frac{k_1 K_a'}{[H^+] + K_a' + \dfrac{K_a K_a'}{[H^+]}}$$

If $K_aK_a'/[H^+] \ll ([H^+] + K_a')$, eq. [2] simplifies to eq. [3]:

$$[3]\quad k_{obsd} = \frac{k_1 K_a'}{[H^+] + K_a'}$$

which has the same form as eq. [1]. The analysis gives k_1 = (2.9

[3]Excess standard Fe^{3+} was added to the reaction mixtures and the excess Fe^{3+} determined by titration of liberated I_2 with standard sodium thiosulfate.

$\pm$ 0.1) $\times 10^4$ L mol^{-1} s^{-1} and $K'_a = 0.86 \pm 0.03$ mol L^{-1}. The large value of K'_a is consistent with deprotonation of the 4+ species given in Scheme 1. The plot of k_{obsd}^{-1} vs. $[H^+]$ did not show any signs of downward curvature at low $[H^+]$, thus eliminating **3** as a reactant (16).

Cation exchange separation of reaction mixtures at various acidities (0.05–0.20 mol L^{-1} H^+) indicated only one chromium(III) complex as the major product. This species eluted as a 2+ complex and the electronic spectral parameters are consistent with the assignment of the product as the chelate **4** (Table 2 and Scheme 1). Quantitative experiments at a Co(III):Cr(II) ratio of 1:1 showed that this product accounted for ~90% of the Cr(II) initially added. Experiments at 1.0 mol L^{-1} H^+ gave increased amounts of $Cr(OH_2)_6^{3+}$ but repeated analyses were

inconsistent. It is likely that **4** hydrolyzes on the cation exchange column at the higher acidities.

Scheme 1 indicates that the reductant attacks the remote carbonyl oxygen adjacent to the benzene ring. Following electron transfer, rapid ring closure and deprotonation give the observed product **4**. The value of k_1, 2.9×10^4 L mol^{-1} s^{-1}, is similar to rate constants obtained for reduction by Cr^{2+} of other $(NH_3)_5Co^{3+}$ complexes with ligands containing remote carbonyl groups (Table 3). For these complexes, Cr^{2+} has been shown to attack at the remote carbonyl oxygen. The product analyses show that ligand transfer is essentially quantitative. In this sytem, the protonated form of the complex, **3**, would be expected to react via an outer-sphere pathway. This is a less facile process for nitrile complexes where rate constants in the range 0.02–0.06 L mol^{-1} s^{-1} are observed for outer-sphere processes (6, 8) (Table 3). The value of the acid dissociation constant of 0.86 mol L^{-1} obtained from the kinetic data is not unreasonable for protonation of a carbonyl oxygen. Similar values have been obtained for the acetato- and propionatopentaamminecobalt(III) complexes (0.35 and 0.24 mol L^{-1}, respectively) at high ionic strength (18). The proposed mechanism also provides a rationale for the fact that **5** does not react with Cr^{2+} even though the delocalized β-diketonate chelate has been shown to be an excellent lead-in group (10). In both **5** and **1** the carbonyl oxygen adjacent to the benzene group is available as a lead-in group for Cr^{2+}, but **1** is the predominant species in the acidity range studied. Even though **5** contains a chelate function it is unlikely that this is sufficient to make **5** much more reactive than **1**.

S. G. Bertolotti, J. J. Cosa, H. E. Gsponer, M. Hamity, and C. M. Previtali. Can. J. Chem. **64**, 845 (1986).

The electron donor–acceptor (EDA) interaction between methyl viologen (MV^{2+}) and 1-naphthylamine (1NA), 2-naphthylamine (2NA), and *N*,*N*-dimethyl-1-naphthylamine (DMA) was studied in water and in aqueous sodium dodecyl sulphate (SDS). The experimental values of the association constants in water were 8.9, 9.8, and 2.8 M^{-1} for 1NA, 2NA, and DMA, respectively. In the presence of SDS the observed values were very much higher and strongly dependent upon the detergent concentration. The enhancement in the interaction is due to an increase in the local concentration of the partners in the micellar pseudophase. MV^{2+} itself was shown to strongly interact with the micelles. A new absorption is present at the red tail of the spectrum of MV^{2+} in the presence of SDS micelles. An association constant of 1700 M^{-1} was obtained from this absorption.

S. G. Bertolotti, J. J. Cosa, H. E. Gsponer, M. Hamity et C. M. Previtali. Can. J. Chem. **64**, 845 (1986).

Opérant dans l'eau et dans des solutions aqueuses de dodécylsulfate de sodium (DSS), on a étudié l'interaction de donneur–accepteur d'électrons (DAE) entre le viologène de méthyle (VM^{2+}) et la naphtylamine-1 (NA1), la naphtylamine-2 (NA2) et la *N*,*N* diméthyl naphtylamine-1 (DMA). Dans l'eau, les valeurs expérimentales pour les constantes d'association sont respectivement 8,9, 9,8 et 2,8 M^{-1} pour NA1, NA2 et DMA. En présence de DSS, les valeurs observées sont beaucoup plus élevées et elles dépendent beaucoup de la concentration du détergent. L'augmentation de l'interaction est due à une augmentation de la concentration locale des partenaires dans la pseudophase micellaire. On a démontré que le VM^{2+} lui-même interagit beaucoup avec les micelles. En présence de micelles de DSS, on a observé une nouvelle absorption à la fin de la région rouge du spectre du VM^{2+}. On a évalué à 1700 M^{-1} la constante d'association de cette absorption.

[Traduit par la revue]

Introduction

One of the key features responsible for the numerous current studies of micellar phenomena is the ability of charged micelles to solubilize and concentrate a wide variety of reagents, ranging from oppositely charged ions to hydrocarbons. Thus the formation of electron donor–acceptor (EDA) complexes between a hydrophobic donor solubilized within an anionic micelle and a cationic acceptor may proceed very efficiently (1, 2). It is known that methyl viologen cations (MV^{2+}) form EDA complexes with aromatic amines (3). In the present work we wish to report the effect of sodium dodecyl sulphate (SDS) concentration on the EDA equilibrium and charge transfer band between MV^{2+} and 1-naphthylamine (1NA), 2-naphthylamine (2NA), and *N*,*N*-dimethyl-1-naphthylamine (DMA).

Experimental

1NA and 2NA (Fluka, pure) were recrystallized at least three times from ethanol–water and subsequently vacuum sublimed. DMA (Fluka, pure) was purified by chromatography on an alumina column under nitrogen. Methyl viologen dichloride was obtained from a commercial solution and was recrystallized from methanol. Triply-distilled water was employed.

The uv–vis absorption measurements were recorded with a Cary 17 spectrophotometer.

The association of MV^{2+} with SDS was studied by means of the uv difference spectra between solutions containing MV^{2+} plus SDS versus MV^{2+}. In all cases the absorption measurements were corrected by the small absorption of SDS at the working wavelength. The concentration of MV^{2+} was held constant at 5×10^{-4} *M* and the SDS concentration was changed between 8×10^{-3} and 2×10^{-2} *M*.

Association of MV^{2+} and naphthylamines in SDS solutions was studied by absorption measurement on the charge transfer band. The reference cell always contained the same amount of MV^{2+} as that of the measuring cell in order to subtract the absorbance of the MV^{2+}–SDS complex. The concentration of MV^{2+} was changed between 2×10^{-4} and 2×10^{-3} *M*. In all cases the results were analyzed by a Benesi–Hildebrand (B–H) treatment or by a nonlinear regression analysis of the absorbance–concentration plots. Results in good agreement were obtained by both methods.

Results and discussion

Association of MV^{2+} with SDS micelles

The absorption spectra of $MVCl_2$ (10^{-4} *M*) in water, in the absence and in the presence of SDS 0.05 *M*, are shown in Fig. 1. The observed red shift of the absorption is typical of the EDA interaction of MV^{2+} with several anions (4, 5). The difference spectrum is shown in the inset in Fig. 1.

A B–H analysis of the difference band at 288 nm as a function of surfactant concentration yields a straight line. A value of 1700 M^{-1} is obtained for the apparent association constant (K_1) of MV^{2+} with SDS micelles, defined by eq. [1]

$$[1] \quad K_1 = \frac{[MV^{2+}]_m}{[MV^{2+}]_w[D]_m}$$

where $[MV^{2+}]_m$ and $[MV^{2+}]_w$ stand for the concentration of bound and free MV^{2+}, respectively, and $[D]_m$ is the micellized detergent concentration (D_{total} − cmc).

This result shows that MV^{2+} may be considered almost quantitatively bound to SDS under our working conditions. The same conclusion can be drawn from the earlier results of Schmehl and Whitten (6), who used an ionic exchange approach to study the binding of MV^{2+} to SDS micelles.

Interaction of naphthylamines with SDS micelles

When 1NA, 2NA, and DMA are dissolved in aqueous SDS a red shift is observed in the absorption spectra relative to water. The apparent association constants between the different naphthylamines and micelles can be obtained by employing an approach similar to that of Bunton *et al.* (7). The equilibrium constants (K_2) defined in the same way as eq. [1] were

determined using the equation:

$$[2] \quad (A - A_w)/[D]_m = K_2 A_m - K_2 A$$

where A is the observed absorbance, and A_w and A_m are the absorbances in the water and of the fully micellar-bound naphthylamine at a given wavelength. Equation [2] applies, provided that the concentration of bound amine is small compared with D_{total}. From a plot of $(A - A_w)/[D]_m$ vs. A, K_2 can be obtained. The values of the association constants are collected in Table 1.

Association of MV^{2+} with naphthylamines in the presence of SDS micelles

It is well known that MV^{2+} forms ground-state complexes of the EDA type with a variety of electron donors. These complexes are characterized by a broad charge transfer band, generally in the 400–500 nm region. These bands are red shifted and enhanced in intensity by the presence of anionic micelles (2). In Fig. 2 is shown the effect of SDS on the charge transfer band of the MV^{2+}–1NA system. Similar behaviour was found for the other naphthylamines.

From a B–H plot, the apparent equilibrium constant (K_{BH}) and the extinction coefficient for the EDA complex can be obtained. No deviation from linearity was observed in the plots

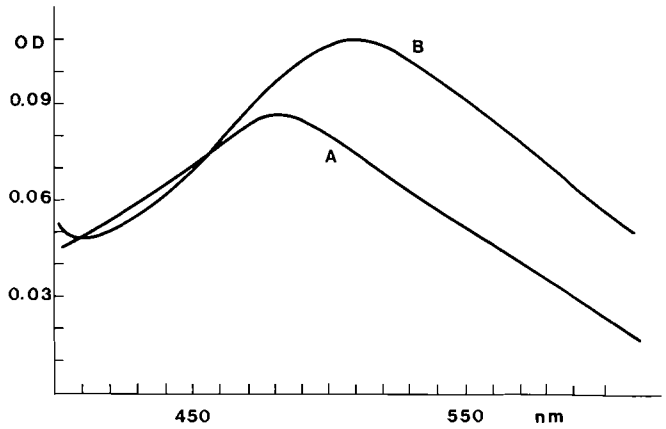

FIG. 2. Charge transfer absorption band of naphthylamine – methyl viologen complex. (A) 1NA 5×10^{-4} and MV^{2+} 0.1 *M* in aqueous solution. (B) 1NA 5×10^{-4} and MV^{2+} 0.1 *M* in SDS 0.1 *M*.

in the presence of micelles. The results are collected in Table 2. It can be seen that while the extinction coefficients are not much affected by the presence of the micelles, K_{BH} increases by two orders of magnitude with respect to pure water. From this it can be concluded that the enhancement is due to an increase in the local concentrations and not to a change in the electronic character of the transitions. Moreover, the red shift in the absorption maximum is indicative of the effect of a less polar medium on the charge transfer band (6). The absorption maximum in methanol for the system MV^{2+}–1NA was reported as 525 nm (3). This suggests that in our case the polarity of the region in which the transition takes place should be similar to that of methanol.

It is interesting to note that when cetyltrimethylammonium bromide (CTAB) was used as surfactant, the charge transfer band was suppressed.

Dependence of the association constant on surfactant concentration

According to the value of K_1, MV^{2+} can be considered almost quantitatively bound to SDS under our working conditions. Therefore the association of MV^{2+} and naphthylamines is taking place mainly in the micellar pseudophase and it is expected that changing the volume of the pseudophase would affect the equilibrium constants through a change in the local concentration of the reactants. The effect of detergent concentation on K_{BH} can be seen in Fig. 3 for the system MV^{2+}–1NA.

The behaviour of K_{BH} is similar to that observed for micelle catalyzed bimolecular reactions (7), where the observed rate constant generally goes through a maximum with increasing surfactant concentration. The sharp increase in K_{BH} with the SDS concentration before the critical micellar concentration may be due to several factors. The addition of MV^{2+} may induce change in the cmc and, in addition, it seems likely that some association is occurring in pre-micellar aggregates. The decrease in K_{BH} beyond the cmc can be fitted in all cases to a lienar plot of K_{BH}^{-1} versus micelle concentration, as shown in Fig. 4. From the association constants for the binding of reactants to micelle (Table 1), the fraction of reactants bound to the micelles can be calculated by eq. [3]

$$[3] \quad f = \frac{K[D]_m}{1 + K[D]_m}$$

where K is the observed binding constant.

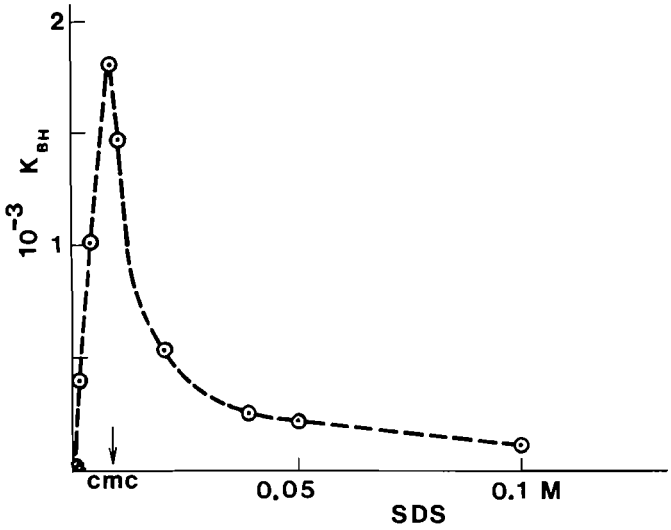

FIG. 3. Benesi–Hildebrand association constant (K_{BH}) of 1NA–MV^{2+} at different SDS concentrations.

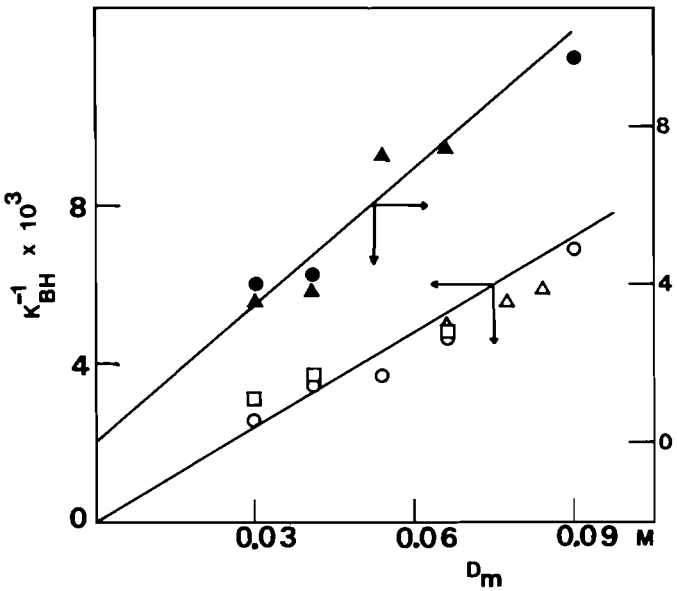

FIG. 4. Plots of the inverse of Benesi–Hildebrand constants versus micellized detergent. □, 2NA 1×10^{-4} *M*; ○, 2NA 5×10^{-4} *M*; △, 2NA 1×10^{-3} *M*; ▲, DMA 5×10^{-4} *M*; ●, 1NA 5×10^{-4} *M*.

For the detergent concentration range in Fig. 4, f is near unity for MV^{2+}, while for the naphthylamine, values between 0.75 and 0.97 are obtained. In these conditions the only equilibria to be considered are

$$[4] \quad A + M \overset{K_2}{\rightleftharpoons} (A)_m$$

$$[5] \quad (A)_m + (MV^{2+})_m \overset{K_3}{\rightleftharpoons} (AMV^{2+})_m$$

where A stands for any of the naphthylamines, M is the micelle, and $(AMV^{2+})_m$ is the EDA complex in the micellar pseudophase.

Equation [5] describes a reaction that occurs within the micelle and not an intermicellar reaction. From eq. [5], with the assumption that MV^{2+} is in excess over the amine,

$$[6] \quad \frac{[AMV^{2+}]_m}{f_A[A]_T - [AMV^{2+}]_m} = K_3 [MV^{2+}]_m$$

where $[A]_T$ is the total analytical concentration of the amine and f_A is the corresponding fraction incorporated with the micelles, eq. [3]. Rearranging, and assuming that Beer's law holds for the complex in the micellar phase, we obtain:

$$[7] \quad \frac{[A]_T}{OD} = \frac{1}{\varepsilon f_A} + \frac{1}{f_A \varepsilon K_3} \cdot \frac{1}{[MV^{2+}]_m}$$

where OD is the absorbance of the complex over 1 cm and ε the extinction coefficient. Now, the concentration of MV^{2+} in the micellar phase should be related to the analytical concentration

TABLE 3. Association constants in the micellar pseudophase

System	K_3 (M^{-1})
1NA–MV^{2+}	1.4
2NA–MV^{2+}	2.0
DMA–MV^{2+}	1.1

$[MV^{2+}]_0$ through:

$$[8] \quad [MV^{2+}]_m = \frac{[MV^{2+}]_0}{\bar{V}\,[D]_m}$$

where $\bar{V}$ is the molar volume of the micellized detergent. So, from the experimental B–H plots of $[A]_T/OD$ vs. $[MV^{2+}]_0$, the slope over intercept ratio gives

$$[9] \quad K_{BH}^{-1} = \frac{\bar{V}\,[D]_m}{K_3}$$

which predicts a linear relationship between K_{BH}^{-1} and $[D]_m$, as found in Fig. 4. From the slopes of these plots K_3 can be obtained, assuming a certain value for $\bar{V}$. Different opinions are sustained by several authors as to the correct value of $\bar{V}$. If it is assumed that the equilibrium takes place in the Stern region, a

value of $0.14\,L^{-1}$ (7) can be taken for $\bar{V}$. The equilibrium constants in the micellar phase calculated in this way are shown in Table 3. It can be seen that they are lower than in water but very similar to that found for MV^{2+} in methanol (3) when MV^{2+} is in excess of 1NA.

In summary, we have shown that the methyl viologen is strongly bound to SDS micelles. A charge transfer band appears in the difference spectrum, from which the association constant can be calculated. Naphthylamines are also incorporated with the micelles and the absorption of the EDA complex between the aromatic amines and MV^{2+} is enhanced by the presence of the surfactant. This can be explained as due to an increase in the local concentrations of the partners.

Preparation and X-ray crystal structures of the arsenic pentafluoride adducts of benzo-2,1,3-thiadiazole and benzo-1,2,3-thiadiazole

ALLEN APBLETT, TRISTRAM CHIVERS,[1] AND JOHN F. RICHARDSON
Department of Chemistry, University of Calgary, Calgary, Alberta, Canada T2N 1N4
Received October 23, 1985

ALLEN APBLETT, TRISTRAM CHIVERS, and JOHN F. RICHARDSON. Can. J. Chem. **64**, 849 (1986).

The reaction of arsenic pentafluoride with benzo-2,1,3-thiadiazole, **1**, or benzo-1,2,3-thiadiazole, **2**, in liquid SO_2 gave 1:1 adducts that were characterized spectroscopically (infrared and ^{13}C nmr) and by X-ray crystallography. Crystal data: for **1**·AsF_5, monoclinic, space group $P2_1/n$, $a = 6.932(1)$, $b = 9.113(1)$, $c = 15.136(2)$ Å, $\beta = 98.035(7)°$, $V = 946.8(2)$ Å^3, $Z = 4$; for **2**·AsF_5, monoclinic, space group $P2_1/a$, $a = 7.573(2)$, $b = 13.101(2)$, $c = 9.514(3)$ Å, $\beta = 90.95(2)°$, $V = 943.9(4)$ Å^3, $Z = 4$. The coordination of AsF_5 to one of the nitrogen atoms in **1** introduces asymmetry in the heterocyclic ring, with the longer bond lengths being associated with the coordinated nitrogen atom, d(S—N) = 1.633(5) and 1.577(6) Å, d(C—N) = 1.364(7) and 1.339(8) Å. The quinonoid character of the benzene ring is still apparent in the adduct. In **2**·AsF_5, the AsF_5 molecule is coordinated to the nitrogen atom that is bonded to carbon.

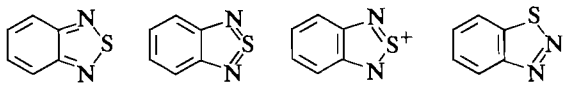
ALLEN APBLETT, TRISTRAM CHIVERS et JOHN F. RICHARDSON. Can. J. Chem. **64**, 849 (1986).

La réaction du pentafluorure d'arsenic avec le benzothiadiazole-1,2,3 (**1**) ou avec le benzothiadiazole-1,2,3 (**2**) dans le SO_2 liquide conduit à des adduits 1:1 que l'on a caractérisé par spectroscopie (infrarouge et rmn du ^{13}C) et par cristallographie des rayons-X. Les données cristallographiques sont les suivantes: le composé **1**·AsF_5 est monoclinique, groupe d'espace $P2_1/n$ avec $a = 6{,}932(1)$, $b = 9{,}113(1)$ et $c = 15{,}136(2)$ Å, $\beta = 98{,}035(7)°$, $V = 946{,}8(2)$ Å^3 et $Z = 4$ alors que le composé **2**·AsF_5 est monoclinique, groupe d'espace $P2_1/a$ avec $a = 7{,}573(2)$, $b = 13{,}101(2)$ et $c = 9{,}514(3)$ Å, $\beta = 90{,}95(2)°$, $V = 943{,}9(4)$ Å^3 et $Z = 4$. La coordination du AsF_5 à l'un des atomes d'azote du composé **1** introduit une asymétrie dans l'hétérocycle et les longueurs de liaison les plus longues sont associées avec l'atome d'azote coordonné, d(S—N) = 1,633(5) et 1,577(6) Å, d(C—N) = 1,364(7) et 1,339(8) Å. Le caractère quinonoïde du cycle benzénique est encore apparent dans l'adduit. Dans le composé **2**·AsF_5, la molécule de AsF_5 est coordonnée à l'atome d'azote qui est lié au carbone.

[Traduit par la revue]

Introduction

X-ray structural investigations of 2,1,3-benzothiadiazole **1** (1) and of numerous related 2,1,3-thiadiazoles (2) have indicated extensive π-delocalization in the heterocyclic ring and quinonoid character for the benzene ring, suggesting contributions from both resonance structures **1***a* and **1***b* to the overall structure of **1**. These conclusions are supported by ^1H nmr (3), microwave (4), and photoelectron spectra (5), and *ab initio* MO calculations (5) for **1**. The reactions of the parent 2,1,3-thiadiazole ring suggest that ionic forms such as **1***c* are also important contributors to the resonance hybrid (6).



1*a* **1***b* **1***c* **2**

It has been demonstrated by nmr spectroscopy that **1** may coordinate to metals such as Pt(II) (7), Cr(O), Mo(O), and W(O) (8, 9), via one nitrogen, and *N,N'* dicoordinated binuclear adducts of Cr(O), Mo(O), and W(O) have been prepared very recently (10). Complexes of Hg(II), Ag(II), Cu(II), Cd(II) (11), (Co(II), Ni(II), and Fe(III) (12) have also been reported, but the mode of bonding of the ligand to the metal was not discussed. No X-ray structural data are available for any of these complexes.

In order to determine the effect of coordination on the structure of **1** we have prepared the AsF_5 adduct and determined its structure by X-ray crystallography. A similar investigation was also carried out for the AsF_5 adduct of benzo-1,2,3-thiadiazole, **2**, in order to establish the site of coordination of this unsymmetrical isomer of **1** with Lewis acids.

Experimental

Reagents and general procedures

Benzo-2,1,3-thiadiazole (Eastman), benzo-1,2,3-thiadiazole (Fluka), and arsenic pentafluoride (Ozark–Mahoning) were obtained commercially and used without further purification. Liquid sulphur dioxide (Matheson) and $CFCl_3$ (Aldrich) were dried over P_2O_5 and transferred under vacuum into the reaction vessel, which consisted of two Pyrex bulbs separated by a medium porosity sintered glass frit and equipped with Kontes and J. Young Teflon-stemmed valves. Solid products were handled under a dry nitrogen atmosphere in a Vacuum Atmospheres dry box.

Instrumentation

Infrared spectra (4000–250 cm^{-1}) were recorded as Nujol mulls (CsI windows) on a Nicolet 5DX FT ir spectrometer. Mass spectra (EI/70 eV) were obtained on a Kratos MS80 RFA instrument. The nmr spectra were run on a Varian XL-200 spectrometer. Chemical shifts are reported in ppm downfield from Me_4Si.

Preparation of benzo-1,2,3-thiadiazole·AsF_5

Arsenic pentafluoride (1.01 g, 5.94 mmol) was condensed onto SO_2 (6.20 g) at −78°C in one bulb of the reaction vessel. The mixture was allowed to warm to room temperature and was then poured through the frit into the opposite bulb, which contained benzo-1,2,3-thiadiazole (0.80 g, 5.88 mmol) dissolved in SO_2 (4.10 g). Immediate reaction occurred to give a light tan solution and a white precipitate. After 18 h the solution was filtered through the frit into the empty bulb. The SO_2 was then slowly condensed into the opposite bulb by cooling it to 18°C in a thermostatted bath. This procedure produced colourless, rectangular crystals, which were used for the X-ray analysis after removal of solvent under vacuum. Infrared spectra indicated that the precipitate and the crystals were the same compound. The total yield of benzo-1,2,3-thiadiazole·AsF_5 was 1.79 g (5.85 mmol), mp 121°C (dec.). Infrared (major bands): 1533 (vs), 1482 (s), 1336 (s), 1280 (vs), 1247 (m), 1158 (s), 1135 (s), 949 (s), 906 (vs), 840 (s), 767 (vs), 754 (vs), 713 (vs), 661 (s), 647 (s), 592 (m), 541 (m), 533 (m), 422 (s), 388 (vs) cm^{-1}. The nmr data are given in Table 1.

[b]Data taken from ref. 19.
[c]The assignments of ^{13}C chemical shifts are based on those reported for 5,6-dimethyl-2,1,3-benzothiadiazole (19).
[d]In $CDCl_3$.
[e]In CD_3NO_2.
[f]The assignments for the inequivalent pairs of carbon atoms (C-1 and C-2, C-3 and C-6, C-4 and C-5) are made on the assumption that the carbon atom closest to AsF_5 in **1**·AsF_5 or to N(2) in **2** will have the higher downfield chemical shift in each pair.
[g]The accidental degeneracy for C-3 and C-6 and the closeness of the chemical shifts for C-1/C-2 and C-4/C-5 preclude an unambiguous assignment for these chemically inequivalent pairs of carbon atoms.

Preparation of benzo-2,1,3-thiadiazole·AsF$_5$

The reaction of arsenic pentafluoride (1.00 g, 5.87 mmol) in SO_2 (5.02 g) with benzo-2,1,3-thiadiazole (0.78 g, 5.69 mmol) in SO_2 (7.23 g) was carried out using the procedure described above to give benzo-2,1,3-thiadiazole·AsF_5 (1.74 g, 5.68 mmol), mp 191°C. Yellow, cubic crystals suitable for X-ray analysis were obtained by slow removal of solvent from a solution of the adduct in SO_2 containing a trace of $CFCl_3$ into a bulb thermostatted at 17°C. Infrared (major bands): 1556 (s), 1350 (m), 1297 (m), 1271 (s), 1243 (m), 970 (s), 835 (m), 769 (s), 717 (vs), 707 (vs), 646 (s), 590 (m), 549 (m), 433 (m), 382 (vs) cm^{-1}. The nmr data are given in Table 1.

X-ray crystallography

The crystals used for data collection were fragments of approximate dimensions of 0.3 × 0.3 × 0.5 mm for **1**·AsF_5 and 0.3 × 0.5 × 0.5 for **2**·AsF_5, cut from larger samples. They were mounted in a glass capillary under an inert atmosphere. Intensity data were collected on an Enraf–Nonius CAD4F automated diffractometer using graphite monochromated MoKα radiation. Details concerning space group determination and data collection procedures were as described previously (13) while crystal data and experimental conditions are summarized in Table 2. The intensities of 3 standard reflections showed deviations of less than 3% in each case, indicative of crystal stability. Data were corrected for Lorentz, polarization, and absorption effects (empirical method using the program DIFABS (14)).

With each structure the coordinates of the As atom were determined by Patterson techniques and the remaining atoms located by difference Fourier techniques. Full-matrix least-squares cycles were based on F

minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, where w is defined in Table 2. H atoms were located on a difference Fourier map and included in idealized positions but not refined for $\mathbf{1}\cdot AsF_5$, and were included in positions located with positional parameters refined for $\mathbf{2}\cdot AsF_5$. In each case thermal parameters were set to $1.1 \times B_{eq}$ of the C atom to which they are bonded, but not refined. In the final cycles of $\mathbf{1}\cdot AsF_5$, all non-H atoms were refined with anisotropic thermal parameters and the maximum shift/error was 0.05. An isotropic extinction parameter could not be refined. The highest peak in the final difference Fourier synthesis is 0.80 e Å^{-3} and is associated with the As atom. In the final cycles for $\mathbf{2}\cdot AsF_5$, all positional and non-H anisotropic thermal parameters were refined. The maximum shift/error was 0.14, the highest peak in the final difference Fourier synthesis is 0.94 e Å^{-3} and is associated with the As atom. All computations were done using the XRAY-76 system of programs (15) implemented on the Honeywell computer at the University of Calgary. Atomic scattering factors used for non-H atoms were those of Cromer and Mann (16) and were corrected for real and anomalous dispersion (17). Scattering factors for H atoms were from ref. 18. The final fractional atomic coordinates for $\mathbf{1}\cdot AsF_5$ and $\mathbf{2}\cdot AsF_5$ are given in Tables 3 and 4, respectively.[2]

Results and discussion

*Preparation and spectroscopic characterization of arsenic pentafluoride adducts of benzo-2,1,3-thiadiazole, **1**, and benzo-1,2,3-thiadiazole, **2***

The AsF_5 adducts of **1** and **2** were prepared in essentially quantitative yields as moisture-sensitive, colourless ($\mathbf{1}\cdot AsF_5$) or pale yellow ($\mathbf{2}\cdot AsF_5$) crystals by the reaction of the appropriate thiadiazole with the stoichiometric amount of AsF_5 in liquid sulphur dioxide. The adducts were characterized spectroscopically (mass, infrared, and ^{13}C nmr spectra) and by X-ray crystallography.

The base peak in the mass spectrum of $\mathbf{1}\cdot AsF_5$ at m/e 136 corresponds to the ion of the parent ligand, $\mathbf{1}^+$. The ion $\mathbf{2}^+$ (m/e 136, 70%) is also observed as a strong peak in the mass spectrum of $\mathbf{2}\cdot AsF_5$, but the base peak is at m/e 108 ($C_6H_4S^+$).

The ^{13}C nmr chemical shifts for the adducts $\mathbf{1}\cdot AsF_5$ and $\mathbf{2}\cdot AsF_5$ are compared with those of the parent ligands in Table 1. The symmetrically equivalent pairs of carbon atoms in **1** exhibit chemical shift differences of 5–7 ppm in $\mathbf{1}\cdot AsF_5$, indicating that coordination is via a nitrogen rather than the sulphur atom. In **2** all the carbon atoms are inequivalent and chemical shift differences are observed for those pairs of carbon atoms which are equivalent in the symmetrical isomer, **1**, the effect being most pronounced for the carbons bonded to the heteroatom. In the adduct $\mathbf{2}\cdot AsF_5$, however, these chemical shift differences are much smaller.

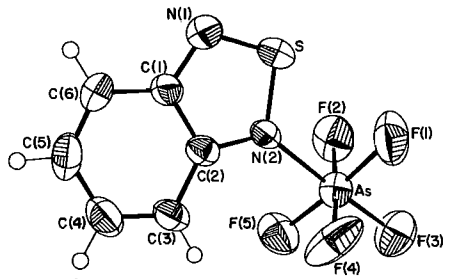

FIG. 1. An ORTEP drawing (50% probability ellipsoids) of $\mathbf{1}\cdot AsF_5$ showing the atomic numbering scheme. Hydrogen atoms are included as spheres of radius 0.1 Å.

Crystal and molecular structure of the AsF_5 adduct of benzo-2,1,3-thiadiazole

An ORTEP drawing of $\mathbf{1}\cdot AsF_5$ is depicted in Fig. 1. The bond lengths and bond angles are compared with those of the parent ligand **1** and $\mathbf{2}\cdot AsF_5$ in Table 5. The coordination site for the Lewis acid is, as expected, one of the nitrogen atoms. The X-ray structure of the parent ligand, **1**, was determined in 1951 (1), but the data are unreliable (the final R factor was 0.215). There is, however, a substantial bank of structural data for related thiadiazole ring systems (2), which can be used for comparison with the corresponding data for $\mathbf{1}\cdot AsF_5$. In summary the S—N and C—N bond lengths in 2,1,3-thiadiazoles are ca. 1.62 and 1.34 Å, respectively, and the angles at S and N are ca. 100 and 106°, respectively.

The coordination of AsF_5 to **1** does not distort the overall planarity of the heterocycle; the largest deviations are 0.02 Å for C(1) and S, which are on opposite sides of the molecular plane. As might be expected, however, adduct formation introduces asymmetry into the molecule so that bonds that were equivalent in **1** are no longer equal in the adduct. This effect is most

[a]Data taken from ref. 1.

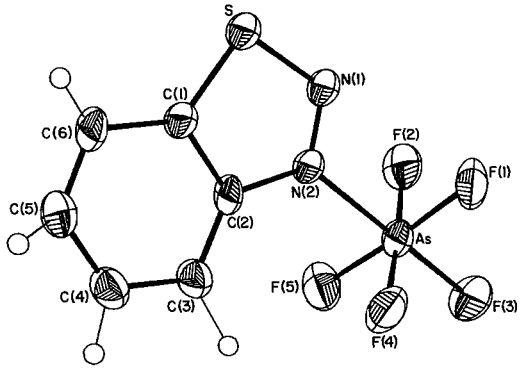

FIG. 2. An ORTEP drawing (50% probability ellipsoids) of **2**·AsF_5 showing the atomic numbering scheme. Hydrogen atoms are included as spheres of radius 0.1 Å.

pronounced for the S—N bonds, which now have lengths of 1.633(5) Å for the nitrogen bonded to AsF_5 and 1.577(6) Å for the uncoordinated nitrogen atom. The difference in the C—N bond lengths, 1.364(7) and 1.339(8), respectively, is on the borderline of the 3σ criterion of significance, but the longer bond also involves the coordinated nitrogen atom. The effect of coordination on the bond angles in the heterocyclic ring is small. The angle at sulphur is reduced to 98.1(3)°, whereas the average angle at nitrogen is increased to ca. 109° and there is no significant difference between the angles at the coordinated and uncoordinated nitrogen atoms. The most pronounced effect is for the carbon bonded to the coordinated nitrogen; the C(1)—C(2)—N(2) angle is reduced to 109.9(5)° from ca. 114° in **1** (1). In summary, the changes in the structural parameters of the heterocyclic ring in **1**, upon coordination, are small and indicate an increased contribution of the ionic resonance form **1***c* to the overall structure, consistent with removal of electron density from sulphur to nitrogen induced by the acceptor AsF_5 molecule.

Adduct formation also introduces some asymmetry in the C—C bond lengths of the aromatic ring. Nevertheless the quinonoid character is retained, albeit somewhat attenuated. Thus the average of the C(3)—C(4) and C(5)—C(6) distances is 1.345(10) Å, whereas the average of the other four C—C distances is 1.401(10) Å. The bond angles at C(3) and C(6) are 116.1(6) and 117.1(7)°, respectively, compared to 123.3(6) and 122.3(6)° for C(4) and C(5), respectively.

The As—N bond length of 1.958(5) Å is slightly longer and the mean As—F bond length of 1.685(5) Å is shorter than the corresponding distances in S_4N_4·AsF_5 (20) (d(As—N) = 1.910(5) and d(As—F) = 1.716(4) Å, cf. d(As—N) = 1.985(16) and d(As—F) = 1.695(10) Å in *N*-methyl-*S*,*S*-difluorosulphoximine·AsF_5 (21)).

Crystal and molecular structure of the AsF_5 adduct of benzo-1,2,3-thiadiazole

An ORTEP drawing of **2**·AsF_5 is shown in Fig. 2. Although the X-ray structure of **2** has not been determined, the following geometrical parameters were constructed on the basis of available structural data for related heterocycles and used for *ab initio* MO calculations (22): d(C—C) = 1.40, d(C—N) = 1.366, d(N—N) = 1.290, d(S—N) = 1.668, and d(C—S) = 1.724 Å. If these values can be taken as a reasonable guide to the structure of the parent ligand, it can be concluded that the effect of coordination on the bond lengths of the heterocyclic ring in **2**

is small. The C—N bond (1.400(6) Å) is slightly longer and the S—N bond (1.631(4) Å) is shorter in the adduct, whereas the N—N distance 1.300(6) Å is not changed significantly. The heterocyclic ligand in **2**·AsF_5 is planar within experimental error.

The trends in bond lengths and angles in the benzene ring of **2**·AsF_5 parallel closely those found for **1**·AsF_5, but the quinonoid character is less well developed (Table 5). The mean of the C(3)—C(4) and C(5)—C(6) distances is 1.370(9) Å compared to a mean value of 1.410(8) Å for the other four C—C bonds.

The As—N distance 1.986(4) Å is significantly longer than that in **1**·AsF_5, suggesting a slightly weaker interaction, but the mean As—F distance of 1.704(4) Å is longer.

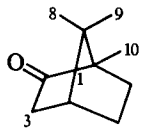
Base-promoted ring cleavage of 9,10- and 8,10-dibromocamphor provides chiral intermediates for natural product synthesis.

J. H. HUTCHINSON, T. MONEY et S. E. PIPER. Can. J. Chem. **64**, 854 (1986).
Sous l'action de bases, il se produit une rupture de cycle des dibromo-9,10 (ou -8,10) camphres qui fournit des intermédiaires chiraux utiles dans la synthèse de produits naturels.

[Traduit par la revue]

The use of camphor as a chiral starting material in natural product synthesis (1) is dependent on the availability of methods for the regiospecific and stereoretentive functionalization of (+)-camphor (**1**) or (−)-camphor at the C(8) (2), C(9) (3), and C(10) (4) positions. Methods are also available for the synthesis of 8,10- and 9,10-disubstituted camphor derivatives (5). In addition, ring cleavage of the C(1)—C(2) (6) or C(2)—C(3) (7) bonds in camphor and its derivatives can be achieved, with variable efficiency, by a variety of methods.



1

During our early investigations on the potential use of disubstituted camphor derivatives in steroid synthesis we attempted to synthesize 9,10-dicyanocamphor ethylene acetal (**3**) by treating (+)-9,10-dibromocamphor ethylene acetal (**2**) (Scheme 1) with sodium cyanide in dimethylsulphoxide (DMSO). The product of this reaction was a mixture of the required dinitrile (**3**) and, surprisingly, a monocyclic hydroxy-ethyl ester (**4**) whose structure was deduced from spectroscopic data (ir, nmr, and ms). It seemed reasonable to assume that the latter compound was produced by DMSO-promoted Grob-type cleavage (cf. Scheme 2) of the C(1)—C(2) bond in **2** and this was supported by the subsequent observation that treatment of **2** with DMSO alone resulted in a similar ring cleavage reaction to provide bromo-ester **5**. The extension of these investigations revealed that simple treatment of (+)-9,10-dibromocamphor (**6**) with KOH/THF/H_2O or NaOMe/MeOH for ~4 h at room temperature resulted in efficient ring cleavage and formation of bromo-acid **7** or the corresponding methyl ester (**8**) in 90–95% yield (8) (Scheme 3). Spectroscopic (nmr, ir) evidence indicated that the double bond in **7** and **8** was in the less stable (9), but synthetically useful, exocyclic position and this was confirmed by ozonolytic degradation to the corresponding cyclopentanone derivatives. Subsequent studies demonstrated that treatment of (+)-9,10-dibromocamphor (**6**) with KOH/DMSO–H_2O (5:1) for 12 h at 65°C provided hydroxy-acid **9** in ~90% yield (8*b*). The latter compound (**9**) can also be prepared by hydrolysis of the lactone **10** (8*a*) derived by cyclization of bromo-acid **7**, and tlc evidence indicated that lactone **10** is an intermediate in the "direct" conversion of 9,10-dibromo-camphor (**6**) to hydroxy-acid **9**.

As expected, (+)-8,10-dibromocamphor (**11**) (5) also undergoes ring cleavage when treated with NaOMe/MeOH to provide bromo-ester **12** (Scheme 4). However, in contrast, treatment with KOH/DMSO/H_2O provided a mixture (1:1) of lactone **13** and bicyclic acid **15**. The latter compound is presumably formed by initial formation of 10-bromo-3,8-cyclocamphor (**14**), followed by β-bromoketone cleavage in the usual way. Consistent with this explanation is our observation that (+)-8-bromocamphor (1, 2)[2] provides (+)-3,8-cyclo-camphor (1, 10) under the reaction conditions. Lactone **13** is obviously formed by spontaneous lactonization of the *cis* hydroxy-acid (Scheme 4) derived by ring cleavage of (+)-8,10-dibromocamphor (**11**) in the predicted fashion (cf. **6** → **7**).

The facile, efficient cleavage of the C(1)—C(2) bond in (+)-9,10-dibromocamphor (**6**) and (+)-8,10-dibromocamphor (**11**) are examples of a reaction that is characteristic of α,α-disubstituted β-bromoketones (11–22). Of particular relevance are reports in the early literature, by Forster (12) and Burgess (13), respectively, which claim that treatment of "β-bromocamphor" (**16**) (12) and "α,β-dibromocamphor" (**17**) (13) with refluxing KOH/EtOH for 5–8 h produces (+)-α-campholenic acid (**18**) (12) or the corresponding bromo-acid (**19**) (13). At that time (1900–1924) "β-bromocamphor" and "α,β-dibromocamphor" were assigned structures that, in modern nomenclature, would be named 6-bromocamphor (**16**) and 3,6-dibromocamphor (**17**), respectively, and their ring cleavage to (+)-α-campholenic acid (**18**) and its bromo derivative (**19**) were consistent with these structural assignments. However, the results of later investigations (24–26) indicated that "β-bromocamphor" (mp 78°C), derived from 1-hydroxy-camphene (**20**) (12), was identical to 10-bromocamphor (**21**), mp 78°C, prepared by thermolysis of 10-camphorsulfonyl bromide (**22**) (23) or camphor-10-mercurichloride (**23**) (26), and this structure assignment is now commonly accepted. It is interesting to realize, however, that a footnote in the paper by Burgess (13) refutes the suggestion by Lipp and Lausberg (25) that "α,β-dibromocamphor" has the 3,10-dibromocamphor structure (**24**), since this is inconsistent with its cleavage to bromo-α-campholenic acid (**19**). Despite these reservations it is now generally accepted that the early literature describes the conversion of 10-bromocamphor (**21**) and 3,10-dibromo-camphor (**24**) to (+)-α-campholenic acid (**18**) and its bromo derivative (**19**), respectively. These results, however, are inconsistent with our observations that ring cleavage of 9,10-dibromocamphor (**6**) provides unsaturated monocyclic compounds (**7**–**9**) in which the double bond is exclusively in the

exocyclic position.[3] As a result of these inconsistencies we treated 10-bromocamphor (**21**) under various conditions (cf. Scheme 2) used to cleave 9,10-dibromocamphor and found that the only major product formed was the exocyclic isomer (**25**) of (+)-α-campholenic acid (**18**). Since isomerization of these compounds does not seem to occur under basic conditions, the observed transformation of "β-bromocamphor" (i.e. 10-bromocamphor), to α-campholenic acid by the early workers is difficult to explain except in terms of their assumption (12, 13) that "α-bromocamphor" was 6-bromocamphor (**16**). As indicated above, however, this assumption is invalid.

As a footnote to the early literature it is interesting to note that treatment of authentic (−)-*endo*-6-bromocamphor (**30**)[4] with KOH/DMSO–H_2O (5:1) at 65°C for 36 h does indeed produce (+)-α-campholenic acid (**32**) as well as (+)-5,6-dehydrocamphor (**34**). In addition, more recent studies (27) indicate that treatment of (**30**) with KOBu^t/Bu^{t}OH followed by hydrolysis provides (−)-α-campholenic acid (**32**) as the major product in ~55% yield. Similarly, (−)-*endo*-6,9-dibromocamphor (**31**)

[3]10-Bromofenchone (**26**) also cleaves with base to provide an unsaturated monocyclic acid (**27**) with the double bond in the exocyclic position (14) (see Scheme 6).

[4](−)-*endo*-6-Bromocamphor (**30**) and (−)-*endo*-6,9-dibromocamphor (**31**) are readily prepared by acid-catalyzed arrangement of (+)-*endo*-3-bromocamphor (**28**) and (+)-*endo*-3,9-dibromocamphor (**29**), respectively. The mechanism of these fascinating rearrangements, in which the camphor configuration is inverted, will be described in a future report from our laboratory (cf. ref. 27).

can be converted to hydroxy-α-campholenic acid (**33**) and (+)-5,6-dehydro-9-bromocamphor (**35**).

Aside from these mechanistic considerations, the ease and efficiency with which the bromo-acid **7**, hydroxy-acid **9**, and lactone **10** can be obtained from (+)-9,10-dibromocamphor (**6**) and bromo-ester **12**[5] from (+)-8,10-dibromocamphor (**11**) has prompted us to assess the potential of these compounds as chiral synthons in terpenoid and steroid synthesis and the results of our initial investigations have been described in recent reports (1, 8)[6] from this laboratory.

Experimental

Melting points (mp) were determined on a Kofler micro heating stage and are uncorrected. Infrared spectra were recorded on a Perkin–Elmer 137 spectrophotometer and optical rotations were made on a Perkin–Elmer 141 polarimeter. The ^{1}H nmr spectra were recorded on Bruker WH-400, Bruker WP-80, or Nicolet-Oxford H-270 instruments. Signal positions are given in delta (δ) with tetramethylsilane (TMS) as internal reference. The integrated areas and signal multiplicities are indicated in parentheses. Low resolution mass spectra were determined on a MAT CH-4 spectrometer and high resolution spectra were recorded on a Kratos MS-50 spectrometer. Gas–liquid chromatography was performed on a Hewlett–Packard model 5830A gas chromatograph with a 6 ft × ⅛ in. column (3% OV-17) or a Hewlett–Packard model 5880A gas chromatograph using 50 or 12 m × 0.2 mm columns (Carbowax 10M). Column chromatography was done using Merck silica gel 60 (230–400 mesh) and thin-layer chromatography (tlc) utilizing silica gel 1B2-F (Baker-flex) sheets. Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia.

(+)-9,10-Dibromocamphor (6) (5)[7]

To (+)-*endo*-3-bromocamphor (**28**) (Aldrich Chemical Co.) (100 g, 0.433 mmol) in an ice bath was added chlorosulphonic acid (80 mL) and bromine (35 mL, 0.683 mmol). The ice bath was then removed and the reaction stirred for 1 h before being added to ice/sodium bisulphite (solid). Extraction with ether (3 × 450 mL), followed by treatment of the ether layer with sodium bicarbonate, water (×3), and removal of the dried solvent provided (+)-3,9-dibromocamphor (**29**) as a white crystalline solid (133 g, 84% pure by glc; OV-17, 190°C). This material was used without further purification.

To the crude *endo*-3,9-dibromocamphor (133 g) at 0°C was added chlorosulphonic acid (160 mL) and bromine (40 mL, 0.78 mmol). The ice bath was removed, the flask covered with aluminum foil, and the reaction stirred for 6 days. Further portions of chlorosulphonic acid and bromine (20 mL and 15 mL and 15 mL, respectively) were added after the second and third days. The mixture was worked up as before to yield crude (+)-*endo*-3,9,10-tribromocamphor as a viscous dark orange oil (132 g). This was immediately dissolved in ether (250 mL) and glacial acetic acid (100 mL) and treated with zinc (35 g, 0.54 mmol) at 0°C (**care!**) over 20 min. The reaction was stirred vigorously for 45 min and then poured into water, extracted with ether (×3), and the excess acetic acid removed with sodium bicarbonate. Work-up in the usual way provided a viscous oil (72 g), which was a mixture of (+)-9,10-dibromocamphor (**6**) (55%) 9-bromocamphor (30%), and (−)-*anti*-7,9-dibromofenchone (8%) as determined by glc (OV-17, 190°C). (+)-9,10-Dibromocamphor (**6**) (30 g, 22% overall) was crystallized from the crude oil with methanol/petroleum ether.

In a separate experiment, the by-products were isolated and identified. Column chromatography (silica gel; petroleum ether/ether 24:1) provided (−)-*anti*-7,9-dibromofenchone as a white crystalline solid, mp 70.5–72°C; $[\alpha]_D$ −225.3° (*c* 1.13, MeOH); ν_{max} $(CHCl)_3$: 1740 cm^{-1}; δ ($CDCl_3$, 270 MHz): 1.11 (3H, s), 1.23 (3H, s), 1.44 (1H, m), 1.87 (2H, m), 2.30 (1H m), 2.53 (1H, d, J = 3.5 Hz), 3.36 (1H, d, J = 10.5 Hz), 3.48 (1H, d, J = 10.5 Hz), 4.19 (1H, br, s); *m/e* (relative intensity): 312/310/308 (M^+, 0.7/1.5/0.7), 231/229 (8/8), 203/201 (14/14), 121 (28), 107 (13), 93 (17), 81 (100), 79 (19). *Mol. Wt.* calcd. for $C_{10}H_{14}OBr_2$: 311.9371/309.9391/307.9411; found (high resolution mass spectrometry: 311.9362/309.9394/307.9367. *Anal.* calcd. for $C_{10}H_{14}OBr_2$: C 38.74, H 4.55, Br 51.55; found: C 38.81, H 4.50, Br 51.36. The structure and absolute configuration of this compound was confirmed by X-ray analysis.[8] Further elution provided 9-bromocamphor as a white crystalline solid.

(+)-9,10-Dibromocamphor ethylene ketal (2)

(+)-9,10-Dibromocamphor (**6**) (5.0 g, 16.1 mmol), ethylene glycol (15 mL), *para*-toluenesulphonic acid (100 mg), and dry benzene (60 mL) were refluxed in a Dean–Stark trap containing 4A molecular sieves for 1 week. The sieves were replaced every 24 h. The solution was poured into brine and extracted with ether (3 times). The combined organic layers were washed twice with water, dried ($MgSO_4$), and filtered through a silica gel pad. Removal of the solvent provided a crude oil (5.40 g). Column chromatography (silica gel, petroleum ether/ether 50:1) gave starting material (1.0 g) and (+)-9,10-dibromocamphor ethylene ketal (**2**) (3.66 g; 64% yield; 76% based on recovered starting material) as a white crystalline solid, mp 38–42°C; δ ($CDCl_3$, 400 MHz): 1.27 (3H, d, J = 1 Hz), 1.37 (1H, m), 1.50 (1H, d, J = 14 Hz), 1.80 (1H, m), 1.89 (1H, m), 2.02 (1H, m), 2.18 (2H, m), 3.43 (1H, d, J = 10 Hz), 3.51 (d) and 3.53 (d) (2H, AB quartet, J = 12 Hz), 3.69 (1H, dd, J = 10 Hz, 1 Hz), 3.72–3.99 (4H, m, ketal protons); *m/e* (relative intensity): 275/273 (M^+ − Br, 98/100), 193 (47), 149 (18), 131 (24), 121 (26), 107 (79), 105 (26). *Anal.* calcd. for $C_{12}H_{18}O_2Br_2$: C 40.71, H 5.12, Br 45.13; found: C 40.96, H 5.17, Br 45.00.

9,10-Dicyanocamphor ethylene ketal (3) and cyanoester (4)

(+)-9,10-Dibromocamphor ethylene ketal (**2**) (2.1 g, 5.9 mmol), sodium cyanide (0.87 g, 17.8 mmol), and potassium iodide (50 mg) were stirred in dry dimethylsulphoxide (25 mL) at 110°C under argon for 6 days. The mixture was poured into brine, extracted three times with ether, and the combined organic layers washed twice with brine, dried, and the solvent removed. The residue (1.1 g) was shown by glc (OV-17, 210°C) to be a mixture (4:3) of cyanoester (**4**) and 9,10-dicyanocamphor ethylene ketal (**3**). A portion of this material was subjected to column chromatography (silica gel; petroleum ether/ether 1:1) to provide a sample of 9,10-dicyanocamphor ethylene ketal (**3**), which was recrystallized from ether/petroleum ether to yield colourless needles, mp 73.5–74.5°C; ν_{max} ($CHCl_3$): 2250 cm^{-1}; δ ($CDCl_3$, 400 MHz): 1.33 (3H, s), 1.49 (1H, m), 1.45 (1H, d, J = 13.5 Hz; C(3) *endo* proton), 1.68 (1H, m), 1.81 (1H, m), 2.06 (1H, ddd, J = 13.5 Hz, 5 Hz and 3 Hz; C(3) *exo* proton), 2.18 (1H, dd, J = 4.5 Hz, 4.5 Hz; C(4) proton), 2.32 (1H, ddd, J = 13 Hz, 9 Hz, 4 Hz), 2.38 (d) and 2.46 (d) (2H, AB quartet, J = 18 Hz), 2.38 (d) and 2.54 (d) (2H, AB quartet, J = 18 Hz), 3.75–4.0 (4H, m, ketal protons); *m/e* (relative intensity): 246 (M^+, 0.9), 231 (1.1), 206 (100), 120 (56), 87 (96). *Mol. Wt.* calcd. for $C_{14}H_{18}O_2N_2$: 246.1368; found (high resolution mass spectrometry): 246.1376.

Further elution using pure ether provided the cyanoester (**4**) as a colourless oil; ν_{max} ($CHCl_3$): 2375, 1730, 1660 and 900 cm^{-1}; δ ($CDCl_3$, 400 MHz): 1.06 (3H, s), 1.42 (1H, m), 2.00 (2H, m, one proton exchangeable with D_2O), 2.29 (1H, dd, J = 16 Hz, 8 Hz), 2.35–2.50 (3H, m), 2.50 (2H, s, CH_2CN), 2.55 (1H, dd, J = 16 Hz, 4 Hz), 3.84 (2H, br s; sharpens to a multiplet on addition of D_2O; CH_2OH), 4.24 (2H, m; CH_2CH_2OH), 4.94 (1H, t, J = 2 Hz), 5.03 (1H, t, J = 2 Hz); *m/e* (relative intensity): 237 (M^+, 4.5), 176 (46),

[5]The enantiomers of **7**, **9**, **10**, **12**, and **13** are of course available from (−)-9,10-dibromocamphor and (−)-8,10-dibromocamphor, which can be prepared (5) from commercially available (−)-camphor or (−)-borneol.

[6]Some of these results were described at the C.I.C. Conference, Montreal, June 3–6, 1984, and at the International Symposium on the Chemistry of Natural Products, Edmonton, June 23–26, 1985.

[7]This is a modification of the method used by Dadson *et al.* (5*b*).

Bromohydroxy-ester (5)

(+)-9,10-Dibromocamphor ethylene ketal (**2**) (180 mg) was dissolved in dry dimethylsulphoxide (10 mL) and heated to 110°C for 4 h. The solution was cooled, acidified with 1 *N* hydrochloric acid, and extracted three times with ether. The ethereal layers were washed with water (3 times), dried, and evaporated to yield a colourless oil (94 mg). Purification by column chromatography (silica gel; petroleum ether/ether 2:1) gave starting material (34 mg) and the bromohydroxy-ester (**5**) (36.4 mg); ν_{max} (film): 3420 (br), 1740, 1660, 890 cm^{-1}; δ ($CDCl_3$, 400 MHz): 1.08 (3H, s), 1.35 (1H, m), 1.90 (1H, br s, exchangeable with D_2O), 1.97 (1H, m), 2.22 (1H, m), 2.30–2.47 (2H, m), 2.53–2.64 (2H, m), 3.37 (1H, d, J = 10 Hz), 3.46 (1H, d, J = 10 Hz), 3.85 (2H, m), 4.24 (2H, m), 4.85 (1H, t, J = 2.5 Hz), 5.00 (1H, t, J = 2.0 Hz); *m/e* (relative intensity): 292/290 (M^+, 0.1/0.1), 275/273 (1.4/1.3), 197 (45), 107 (100).

Methyl (1'R,2'R)-2-(2'-bromoethyl-2'-methyl-3'-methylenecyclopentyl)ethanoate (8); bromo-ester (8)

Sodium metal (0.41 g, 17.8 mmol) was added to dry methanol (50 mL) under argon at 0°C. When all the sodium had reacted, 9,10-dibromocamphor (**6**) (3.68 g, 11.9 mmol) was added, and after 6 h the reaction was terminated by acidifying with 1 *N* hydrochloric acid and then extracting three times with ether. The organic phase was washed with brine, dried ($MgSO_4$), and the solvent removed to yield the bromo-ester (**8**) (3.08 g, 99%), ν_{max} ($CHCl_3$): 1730, 1660, 900 cm^{-1}; δ ($CDCl_3$, 270 MHz): 1.05 (3H, s), 1.35 (1H, m), 1.93 (1H, m), 2.10 (1H, dd, J = 13.5 Hz, 11.5 Hz), 2.25–2.41 (2H, m), 2.46–2.59 (2H, m), 3.36 (d) and 3.45 (d) (2H, AB quartet, J = 12 Hz), 3.67 (3H, s; OCH_3), 4.84 (1H, t, J = 2.5 Hz), 4.98 (1H, t, J = 2 Hz); *m/e* (relative intensity): 262/260 (M^+, 0.1/0.1), 231/229 (1/1), 167 (57), 121 (15), 107 (100), 93 (22), 91 (24). *Mol. Wt.* calcd. for $C_{11}H_{17}O_2Br - OCH_3$: 231.0208/229.0228; found (high resolution mass spectrometry): 231.0211/229.0216.

(1'R,2'R)-2-(2'-Bromomethyl-2'-methyl-3'-methylenecyclopentyl) ethanoic acid (7); (−)-bromo-acid (7)

Method A

To a solution of (+)-9,10-dibromocamphor (**6**) (1.5 g, 4.8 mmol) in dimethylsulphoxide (51 mL) was added potassium hydroxide (1.35 g, 24 mmol) in water (10 mL). After 1 h, the yellow solution was poured into water and extracted once with ether. The ether layer was washed once with water and the combined aqueous layers were then carefully acidified with 6 *N* hydrochloric acid. This was extracted three times with ether and the combined ethereal layers washed with brine (twice), dried ($MgSO_4$), and evaporated to yield the bromo-acid (**7**) (1.17 g, 98%) as a white crystalline solid, one spot on tlc. Recrystallization of a small amount of this material from petroleum ether afforded pure bromo-acid (**7**), mp 62–64°C; $[\alpha]_D$ −45.8° (*c* 0.4, MeOH); ν_{max} ($CHCl_3$): 2950 (br), 1705, 1640, 890 cm^{-1}; δ ($CDCl_3$, 400 MHz): 1.08 (3H, s; angular methyl group), 1.39 (1H, m), 2.01 (1H, m), 2.18 (1H, dd, J = 16 Hz, 10 Hz), 2.32–2.48 (2H, m; allylic protons), 2.55 (1H, m; methine proton), 263 (1H, dd, J = 16 Hz, 4 Hz), 3.39 (d) and 3.47 (2H, AB quartet, J = 10 Hz), 4.86 (1H, t, J = 2 Hz), 5.00 (1H, t, J = 2 Hz); *m/e* (relative intensity): 248/246 (M^+, 0.4/0.4), 188/186 (4/4), 167 (7), 166 (17), 153 (100), 111 (32), 107 (98). *Anal.* calcd. for $C_{10}H_{15}O_2Br$: C 48.58, H 6.12, Br 32.35; found: C 48.47, H 6.16, Br 32.20.

Method B

(+)-9,10-Dibromocamphor (**6**), (1.0 g, 3.2 mmol), 0.5 *N* potassium hydroxide (80 mL, 40 mmol), and tetrahydrofuran (80 mL) were stirred at room temperature for 4.5 h. Work-up as described above gave the bromoacid (**7**) (0.75 g, 94%) as a white solid.

(1'R,2'R)-2-(2'-Hydroxymethyl-2'-methyl-3'-methylenecyclopentyl)ethanoic acid (9); (−)-hydroxy-acid (9)

Method A: From (+)-9,10-dibromocamphor (6)

A solution of (+)-9,10-dibromocamphor (**6**) (1.5 g, 4.8 mmol), potassium hydroxide (1.35 g, 24 mmol), dimethylsulphoxide (51 mL), and water (9 mL) was stirred at room temperature for 1.5 h, then at 65°C for 20 h. This was poured into ice-cold water and worked up as before to yield the hydroxy-acid (**9**) (0.807 g, 91%) as a white crystalline solid. A pure sample of **9** was obtained by recrystallization of a portion from ethyl acetate/petroleum ether, mp 118–119°C; $[\alpha]_D$ −21.4° (*c* 0.35, MeOH); ν_{max} ($CHCl_3$): 2850 (br), 1705, 890 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.88 (3H, s), 1.39 (1H, m), 1.99 (1H, m), 2.22 (1H, dd, J = 14 Hz, 9 Hz), 2.34 (1H, m), 2.40–2.56 (3H, m), 3.42 (d) and 3.53 (d) (2H, AB quartet, J = 11 Hz), 4.82 (1H, t, J = 2.5 Hz), 5.02 (1H, t, J = 2.0 Hz); *m/e* (relative intensity): 184 (M^+, 2), 166 (8), 154 (32), 153 (34), 107 (97), 95 (85), 94 (100), 93 (65), 79 (52). *Mol. Wt.* calcd. for $C_{10}H_{16}O_3$: 184.1100; found (high resolution mass spectrometry): 184.1096. *Anal.* calcd. for $C_{10}H_{16}O_3$: C 65.19, H 8.75; found: C 64.97, H 8.61.

Method B: From (1R,6R)-1-methyl-9-methylene-3-oxa-4-oxobicyclo[4.3.0]nonane (10); ((−)-lactone (10))

(−)-Lactone (**10**) (49 mg, 0.3 mmol) was dissolved in tetrahydrofuran (5 mL) and treated with 0.5 *N* potassium hydroxide solution (5 mL, 2.5 mmol) for 30 min. The solution was partitioned between ether and 1 *N* hydrochloric acid. After the usual work-up, the hydroxy-acid **9** was obtained as a white crystalline solid (54 mg, 100%).

(1R,6R)-1-Methyl-9-methylene-3-oxa-4-oxobicyclo[4.3.0]nonane (10); (−)-lactone (10)

A solution of the bromo-acid (**7**) (1.67 g, 6.8 mmol), potassium hydroxide in dimethylsulphoxide/water 9:1 (0.277 *M*, 24.55 mL, 6.8 mmol), silver(I) oxide (0.35 g, 1.5 mmol), and dimethylsulphoxide (111 mL) was stirred at room temperature for 1 h and then at 70°C for 1 h.

The solution was poured into brine, extracted with ether (×3), and the ether extracts washed with brine and dried. Removal of the solvent provided a yellow solid (1.23 g), which on trituration with cold petroleum ether gave the lactone (**10**) (1.04 g, 92%; 96% pure by glc; 3% OV-17, 160°C) as a crystalline solid. Subsequent recrystallization from petroleum ether provided pure lactone (**10**), mp 96.5–98.5°C; $[\alpha]_D$ −27.3° (*c* 0.42, CH_2Cl_2); ν_{max} ($CHCl_3$): 1740, 1650, 890 cm^{-1}; δ ($CDCl_3$, 400 MHz): 1.05 (3H, s; angular methyl group), 1.45 (1H, 9-line multiplet), 1.87 (1H, m), 2.01 (1H, 7-line multiplet; methine proton), 2.43 (1H, dd, J = 18 Hz, 13.5 Hz; H_A), 2.43 (1H, m), 2.62 (1H, m), 2.78 (1H, dd, J = 18 Hz, 5.5 Hz; H_B), 4.23 (d) and 4.37 (d) (2H, AB quartet, J = 10 Hz), 4.63 (1H, t, J = 2.5 Hz), 4.83 (1H, t, J = 2 Hz); *m/e* (relative intensity): 166 (M^+, 15), 107 (23), 95 (18), 94 (100), 93 (24), 79 (70). *Mol. Wt.* calcd. for $C_{10}H_{14}O_2$: 166.0994; found (high resolution mass spectrometry): 166.0994. *Anal.* calcd. for $C_{10}H_{14}O_2$: C 72.26, H 8.49, O 19.25; found: C 72.12, H 8.68, O 19.13.

Cleavage of (+)-10-bromocamphor (21); (+)-isocampholenic acid (25)

(+)-10-Bromocamphor (**21**) (28), (234 mg, 1.0 mmol) and potassium hydroxide (284 mg, 5.0 mmol) were stirred in dimethylsulphoxide (11 mL) and water (1.5 mL) at 65°C for 1 h. The solution was cooled, poured into brine, and extracted with ether. The aqueous phase was then acidified with 6 *N* hydrochloric acid and further extracted with ethyl acetate (×3). After two washings with brine, the organic extracts were dried ($MgSO_4$) and evaporated to yield a yellow oil (180 mg). Column chromatography (silica gel; petroleum ether/ether 1:1) gave isocampholenic acid (**25**) as a colourless oil (130.2 mg, 77%); $[\alpha]_D$ +1.6° (*c* 0.5, CH_2Cl_2); ν_{max} (film): 3000 (br), 1710, 1660, 885 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.85 (3H, s), 1.09 (3H, s), 1.38 (1H, m), 1.98 (2H, m), 2.15 (1H, dd, J = 15 Hz, 10 Hz), 2.36 (1H, m), 2.46 (1H, m), 2.46 (1H, dd, J = 15 Hz, 3.5 Hz), 4.78 (1H, t, J = 2.5 Hz), 4.80 (1H, t, J = 2 Hz); *m/e* (relative intensity): 168 (M^+, 2), 153 (26), 108 (100), 93 (97), 91 (37), 79 (33). *Mol. Wt.* calcd. for $C_{10}H_{16}O_2$: 168.1150; found (high resolution mass spectrometry): 168.1152. *Anal.* calcd. for $C_{10}H_{16}O_2$: C 71.39, H 9.59; found: C 71.13, H 9.59.

Cleavage of (−)-endo-6-bromocamphor (30)

(−)-*endo*-6-Bromocamphor (**30**) (27) (6.5 g, 0.028 mol), potassium

hydroxide (7.89 g, 0.14 mol), dimethylsulphoxide (280 mL), and water (40 mL) were stirred at 70°C for 96 h. The solution was diluted with water, extracted with ether (3 × 100 mL), and worked up in the usual way to yield a yellow oil (2.2 g). Flash chromatography on silica gel (petroleum ether/ether 9:1) afforded a volatile white solid, (+)-dehydrocamphor (**34**) (2.0 g, 47%); $[\alpha]_D$ +756° (*c* 0.50, CH_2Cl_2) (lit. (30), for enantiomer, $[\alpha]_D$ −735° (*c* 1.0, EtOH), lit. (31) $[\alpha]_D$ −731° (EtOH)); ν_{max} ($CHCl_3$): 1735 cm^{-1}; δ ($CDCl_3$, 400 MHz) (cf. ref. 32): 0.91 (3H, s), 1.01 (3H, s), 1.07 (3H, s), 1.93 (1H, d, *J* = 16.5 Hz; C(3) *endo* proton), 2.22 (1H, ddd, *J* = 16.5 Hz, 3.5 Hz, 1.0 Hz; C(3) *exo* proton), 2.68 (1H, br s; C(4) proton), 5.58 (1H, br d, *J* = 5.5 Hz; C(6) proton), 6.71 (1H, dd, *J* = 5.5 Hz, 3 Hz; C(5) proton); *m/e* (relative intensity): 150 (M^+, 12), 93 (58), 85 (59), 71 (92), 69 (100). *Mol. Wt.* calcd. for $C_{10}H_{14}O$: 150.1045; found (high resolution mass spectrometry): 150.1049. Further elution provided starting material (65 mg).

The aqueous phases were acidified with 1 *N* hydrochloric acid, then extracted with ether (3 × 300 mL), and the combined extracts washed with brine. Removal of the solvent gave (−)-α-campholenic acid (**32**) (1.88 g, 40%); $[\alpha]_D$ −8.2° (*c* 2.25, CH_2Cl_2) (lit. (33) $[\alpha]_D$ −9.0° (*c* 1.1, $CHCl_3$)); ν_{max} (film): 2950 (br), 1710 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.80 (3H, s), 1.02 (3H, s), 1.62 (3H, br s), 1.94 (1H, m), 2.20–2.35 (2H, m), 2.40–2.52 (2H, m), 5.24 (1H, br s); *m/e* (relative intensity): 168 (M^+, 28), 153 (64), 135 (28), 108 (100), 107 (82), 93 (80), 91 (42).

Cleavage of (−)-endo-6,9-dibromocamphor (31)

(−)-*endo*-6,9-Dibromocamphor (**31**) (34) (423 mg, 1.36 mmol), potassium hydroxide (382 mg, 6.8 mmol), dimethylsulphoxide (13 mL), and water (2 mL) were stirred at 60°C for 24 h. Work-up as before provided (before acidification of the aqueous phase) a crude oil (136 mg). Chromatography (silica gel; petroleum ether/ether 25:1) gave (+)-9-bromodehydrocamphor (**35**) (68.2 mg, 22%) as a white crystalline solid, mp 46.5–48.5°C (sealed tube); $[\alpha]_D$ +377.2° (*c* 0.5, CH_2Cl_2); ν_{max} ($CHCl_3$): 1740 cm^{-1}; δ ($CDCl_3$, 400 MHz): 1.05 (3H, s), 1.08 (3H, d, *J* = 1 Hz; C(9) methyl), 2.01 (1H, d, *J* = 17 Hz; C(3) *endo* proton), 2.22 (1H, ddd, *J* = 17 Hz, 3.5 Hz, 1 Hz; C(3) *exo* proton), 3.00 (1H, br s; C(4) proton), 3.22 (1H, d, *J* = 10 Hz), 4.02 (1H, dd, *J* = 10 Hz, 1 Hz), 5.68 (1H, br d, *J* = 6 Hz; C(6) proton), 6.49 (1H, dd, *J* = 6 Hz, 3 Hz; C(5) proton); *m/e* (relative intensity): 230/228 (M^+, 2/2), 188/186 (19/19), 107 (100), 91 (29), 79 (21). *Mol. Wt.* calcd. for $C_{10}H_{13}OBr$: 230.0129/228.0150; found (high resolution mass spectrometry): 230.0135/228.0149. *Anal.* calcd. for $C_{10}H_{13}OBr$: C 52.42, H 4.72, Br 34.87; found: C 52.40, H 5.60, Br 34.77.

Acidification of the aqueous phase and work-up as before provided a crude solid (139 mg), which after chromatography (silica gel; petroleum ether/ether/acetic acid 150:50:1) gave the hydroxy-acid (**33**) (59 mg) as a white crystalline solid, mp 102–103.5°C; $[\alpha]_D$ −19.52° (*c* 0.21, CH_2Cl_2); ν_{max} ($CHCl_3$): 3000 (br), 1705 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.82 (3H, s), 1.65 (3H, br s), 1.97 (1H, m), 2.34 (1H, dd, *J* = 16 Hz, 9 Hz), 2.64 (1H, dd, *J* = 16 Hz, 5.5 Hz), 2.64 (1H, m), 2.70 (1H, m), 3.42 (1H, d, *J* = 11 Hz), 3.54 (1H, d, *J* = 11 Hz), 5.41 (1H, br s); *m/e* (relative intensity): 184 (M^+, 0.01), 166 (17), 151 (32), 107 (59), 94 (100), 93 (80), 91 (63), 79 (95). *Mol. Wt.* calcd. for $C_{10}H_{16}O_3$: 184.1100; found (high resolution mass spectrometry): 184.1102. *Anal.* calcd. for $C_{10}H_{16}O_3$: C 65.19, H 8.75; found: C 65.01, H 8.70.

Cleavage of (+)-8,10-dibromocamphor (11) (ref. 5b)

(a) *With potassium hydroxide*

(+)-8,10-Dibromocamphor (**11**) (159 mg, 0.51 mmol), potassium hydroxide (144 mg, 2.56 mmol), dimethylsulphoxide (6 mL), and water (0.75 mL) were stirred for 1 h at room temperature. The mixture was poured into water, extracted with ether, and the aqueous layer subsequently acidified (1 *N* hydrochloric acid) and extracted with ethyl acetate (×3). After two washings with brine, the ethyl acetate extract was evaporated to provide a crude oil (118 mg). Flash chromatography on silica gel (petroleum ether/ether 1:1) gave bicyclic acid (**15**) (66.2 mg; 78%), as an oil that crystallized on standing, mp 45–48°C; $[\alpha]_D$ +167.9° (*c* 0.14, CH_2Cl_2); ν_{max} (film): 2950 (br), 1700, 1660, 890 cm^{-1}; δ ($CDCl_3$, 400 MHz): 1.33 (3H, s), 1.76 (2H, m), 1.99 (1H, ddd, *J* = 12 Hz, 9 Hz, 2 Hz), 1.32 (1H, dd, *J* = 12 Hz, 9 Hz), 2.37 (1H, m), 2.71 (1H, m; H_D), 2.77 (1H, m), 3.38 (1H, ddd, *J* = 9 Hz, 9 Hz, 9 Hz), 4.63 (1H, br s), and 4.75 (1H, br s); irradiation at δ 3.38 causes the signal at δ 1.99 to collapse to a doublet of doublets (*J* = 12 Hz, 2 Hz), δ 1.32 to collapse to a doublet (*J* = 12 Hz), and δ 2.71 is simplified. Irradiation at 1.76 causes the signal at δ 2.37 to collapse to a broad doublet (*J* = 16 Hz), δ 2.77 becomes a broad doublet (*J* = 16 Hz), and δ 2.71 becomes a broad doublet (*J* = 9 Hz); *m/e* (relative intensity): 166 (M^+, 1), 151 (6), 121 (15), 105 (21), 94 (76), 93 (31), 91 (37), 79 (100), 77 (37). *Mol. Wt.* calcd. for $C_{10}H_{14}O_2$: 166.0994; found (high resolution mass spectrometry): 166.0992. *Anal.* calcd. for $C_{10}H_{14}O_2$: C 72.26, H 8.49; found: C 71.99, H 8.52.

Further elution provided the lactone (**13**) (17.5 mg, 20%) as a crystalline solid; mp 55–56.5°C; $[\alpha]_D$ +29.6° (*c* 0.23, CH_2Cl_2); ν_{max} ($CHCl_3$): 1740, 1660, 890 cm^{-1}; δ ($CDCl_3$, 400 MHz): 1.20 (3H, s), 1.40 (1H, 6-line multiplet), 2.03 (1H, 6-line multiplet), 2.19 (1H, dddd, *J* = 7 Hz, 7 Hz, 7 Hz, 7 Hz), 2.33 (1H, dd, *J* = 15 Hz, 7.5 Hz), 2.43 (2H, m), 2.64 (1H, dd, *J* = 15 Hz, 7 Hz), 3.96 (1H, d, *J* = 11.5 Hz), 4.07 (1H, d, *J* = 11.5 Hz), 4.82 (1H, t, *J* = 2 Hz), 5.02 (1H, t, *J* = 2 Hz); *m/e* (relative intensity): 166 (M^+, 1), 136 (21), 107 (25), 94 (100), 79 (82). *Mol. Wt.* calcd. for $C_{10}H_{14}O_2$: 166.0994; found (high resolution mass spectrometry): 166.0993. *Anal.* calcd. for $C_{10}H_{14}O_2$: C 72.26, H 8.49; found: C 72.10, H 8.50.

(b) *With sodium methoxide*

Sodium metal (17 mg, 0.74 mmol) was added to dry methanol (2.5 mL) and, when all the metal had reacted, (+)-8,10-dibromocamphor (**11**) (105 mg, 0.34 mmol) was added in one portion. The reaction was stirred at room temperature under an argon atmosphere for 20 h and then acidified with a few drops of saturated ammonium chloride solution. Removal of methanol followed by extraction with ether yielded bromo-ester **12** as a colourless oil (88 mg, 98% yield); ν_{max} ($CHCl_3$): 1740, 1660, 890 cm^{-1}; δ ($CDCl_3$, 80 MHz): 1.23 (3H, s), 1.3–2.7 (7H, m), 3.32 (2H, s; CH_2Br), 3.70 (3H, s; OCH_3), 4.85 (1H, t, *J* = 2.5 Hz), 4.98 (1H, t, *J* = 2 Hz); *m/e* (relative intensity): 262/260 (M^+, 0.1/0.1), 231/229 (1/1), 167 (27), 107 (100).

Conversion of (+)-8-bromocamphor to (+)-3,8-cyclocamphor

(+)-8-Bromocamphor (447 mg, 1.94 mmol) and potassium hydroxide (542 mg, 9.68 mmol) were stirred in dimethylsulphoxide (22 mL) and water (3 mL) at room temperature. After 20 min, the dark orange solution was diluted with water and extracted with ether (×3). Removal of the solvent under reduced pressure afforded (+)-3,8-cyclocamphor (240 mg, 83%; 98% pure by capillary glc; OV-101, 120°C), which was crystallized (low temperature) from petroleum ether, mp 148–151°C (sealed tube), (lit. (29) mp 151–152.5°C); $[\alpha]_D$ +194.2° (*c* 0.652, $CHCl_3$) (lit. (29), for enantiomer, $[\alpha]_D$ −232° ($CHCl_3$)); ν_{max} ($CHCl_3$): 1745 cm^{-1}; δ ($CDCl_3$, 400 MHz): 1.05 (3H, s), 1.06 (3H, s), 1.39 (1H, ddd, *J* = 14 Hz, 8 Hz, 8 Hz), 1.60 (1H, m; C(5) *exo* proton), 1.64 (1H, d, *J* = 8 Hz; C(8) proton), 1.80 (1H, ddd, *J* = 13 Hz, 9 Hz, 2.5 Hz), 1.90 (1H, m), 1.97 (1H, dd, *J* = 8 Hz, 3 Hz), 2.49 (1H, dd, *J* = 5 Hz, 2.5 Hz; C(4) proton), 2.86 (1H, dd, *J* = 3 Hz, 2.5 Hz; C(3) *endo* proton). Decoupling of the proton at δ 1.97 causes the doublet at δ 1.64 to collapse to a singlet and the signal at 2.86 to a doublet (*J* = 2.5 Hz). Decoupling the signal at δ 2.49 causes the proton at δ 2.86 to appear as a doublet (*J* = 3 Hz) and the signal at δ 1.60 is simplified; *m/e* (relative intensity): 150 (M^+, 11), 122 (22), 107 (61), 95 (100), 91 (54), 79 (93). *Exact Mass* calcd. for $C_{10}H_{14}O$: 150.1045; found: 150.1041.

The dilemma of estimating forms of sulfur in low-sulfur low rank coals

SUJIT K. CHAKRABARTTY AND ANGELO IACCHELLI

Coal Research Department, Alberta Research Council, Devon Coal Research Centre, P.O. Bag #1310, Devon, Alta., Canada T0C 1E0

Received August 23, 1985

S. K. CHAKRABARTTY and A. IACCHELLI. Can. J. Chem. **64**, 861 (1986).

The analytical methods for estimating forms of sulfur in coals are reviewed on the basis of sulfur analyses of Western Canadian low sulfur subbituminous coals. The reasons for the variance in analyses are examined, and a novel method of analysis is recommended for evaluation

S. K. CHAKRABARTTY et A. IACCHELLI. Can. J. Chem. **64**, 861 (1986).

On présente une revue des méthodes analytiques permettant qu'évaluer diverses formes de soufre dans des charbons; cette revue est basée sur des analyses de soufre dans des charbons subbitumineux de l'ouest canadien contenant de faibles niveaux de soufre. On examine les raisons qui expliquent pourquoi les analyses conduisent à des résultats variables et on recommande une nouvelle méthode d'analyse pour l'évaluation.

[Traduit par la revue]

Introduction

The importance of coal as boiler fuel in power plants, particularly in North America, and the development of new coal resources have resulted in a renewed interest in coal analytical techniques. Having experienced the effect of acid rains, it is imperative that the forms of sulfur in coal should be determine precisely before it is combusted in a large utility boiler.

Sulfur in coal is recognized as existing in three forms: (*1*) inorganic sulfate (S_s), as ferrous sulfate and gypsum; (*2*) inorganic sulfides (S_p), generally as pyrites, although sulfides of zinc and lead may occur in some coals; and (*3*) as organic sulfur compounds (S_o) (1, 2). Elemental sulfur is occasionally detected and may be formed by weathering of exposed deposits (1). Most of the inorganic sulfur can be extracted by sequential treatment with hydrochloric and nitric acids. ASTM methods prescribe meticulous extraction of ground coal with dilute hydrochloric acid to remove soluble iron compounds including $FeSO_4$ and other sulfates. The HCl-washed coal is then treated with nitric acid, which dissolves pyrites (FeS_2), and iron is determined in the extracts (3). In the absence of standard methods for determining organic sulfur, S_o, the differences $S_o = S_T - (S_s + S_p)$ is denoted as sulfur present in the organic matrix as organo-sulfur compounds. The cumulative errors in determining S_T, S_s, and S_p are reflected in the values of S_o.

Simultaneous determination of iron and sulfur in various forms using suitable methods is more reliable than relying on either iron or sulfur analyses alone, but multifarious problems are encountered. Pyrites in coal occur as ultrafine particles frequently coated with, or encapsulated in, organic matter or minerals such as kaoline. Complete extraction of pyritic iron thus becomes difficult. Though it is claimed that nitric acid extractions isolate pyritic iron quantitatively, some of the non-pyritic iron may also be extracted along with pyrites and would be counted as pyritic iron. On the other hand, a loss of sulfur by oxidation during nitric acid extraction is a distinct possibility, and non-stoichiometry of iron-to-sulfur ratios poses a problem in assigning the analyses as pyrites, S_p. Young and Zawadzki (4) provided a convenient method for S_p determination, using the iron content of hydrochloric acid-washed coal as a measure of pyrite when extracted from 750°C ash, but a fair amount of sulfur is lost during ashing and could not be directly measured by this method. It has been suggested that a low temperature ashing method (5) could be used for simultaneous estimation of iron and sulfur, but the presence of alkali and alkaline-earth metals in coal minerals and in the organic matrix (as cations corresponding to carboxylate anions) would allow organic sulfur to be captured in low temperature ash and to interfere in the apparent pyrite stoichiometry.

The magnitude of errors is intensified when the total sulfur is low and a microanalytical technique is employed for analysis of forms of sulfur. For example, the sulfur content of Canadian Cretaceous coals used in power plant boilers is less than 1%. To meet emission standards and other regulations, a sound knowledge of the forms of sulfur and the associated chemistry should be at hand to provide a reliable guide to anticipated technological and environmental problems. The purpose of this paper is to review various modifications of the ASTM methods to analyse forms of sulfur in low-sulfur low rank coals. This review illustrated the dilemma of estimating the forms of sulfur in coal, and suggests the problem be resolved through the development of a procedure for the direct determination of organic sulfur or, alternatively, a method that permits the accurate determination of the iron-to-sulfur stoichiometry in the pyrite present in coal.

Analytical methods: experimental

Coal samples

Representative specimens of coals from eight deposits in central Alberta were used for this study. The specimens belong to three geological formations, and the ASTM ranking of samples was subbituminous A, B, and C (6).

Total sulfur determination

Total combustible sulfur in coal specimens was determined according to ASTM D4239 using the Leco SC-32 model sulfur determinator wherein 250-mg samples of −200 mesh air-dried coal are combusted in a stream of oxygen at 1350°C. The combustion products are freed from entrained particles and moisture by passage through a magnesium perchlorate trap, and an equilibrium mixture of SO_2 and SO_3 in the gas stream is determined by infrared absorption.

Total iron determination

Similar coal samples (2.0 g) were combusted to 750°C in a Fisher programmable furnace according to the ASTM D3174-82 procedure. Freshly ignited ash (200 mg) was placed in a 125 ml Teflon bottle containing 3 mL aqua regia and 5 mL hydrofluoric acid, and heated in a steam bath for 2 h. The excess HF was neutralized with 50 mL saturated boric acid solution. The volume of the solution was then made up to 100 mL with deionized water and the iron content was determined using an ICP spectrometer, ARL-34000 model, at wavelength 259.94 nm.

TABLE 1. Sulfur and iron content of the coal specimens (g/100 g dry coal)

Specimen	Geological "formations"	Total S	Total Fe	Atomic ratio S/Fe

Blackfoot	Horseshoe Canyon	0.580	0.654	1.54

Forms of sulfur

Different procedures used for this purpose are described below.

1. *Standard procedure*: ASTM D2492, Method 1

Sequential extractions of a 3-g coal sample, air-dried and pulverized to −200 mesh, were undertaken first with 50 mL 2.3 *N* HCl and then with 50 mL 1.7 *N* HNO_3 under reflux conditions. The extracts were diluted to 200 mL and analysed for iron and sulfur content using an ICP spectrometer, ARL-34000.

2. *Modified procedure*: Janke *et al.* (7), Young and Zawadzki (4), Method 2

Coal samples were first extracted with HCl according to ASTM D2492. The HCl-treated sample was then combusted in a furnace at 750°C. The resulting ash was then extracted with 2.3 *N* HCl under reflux conditions. The iron and sulfur content in the HCl extracts was measured separately using an ICP spectrometer, ARL-34000.

3. *Low temperature ashing (LTA) procedure*: Method 3

Coal samples were first extracted with HCl according to ASTM D2492. The HCl-treated coal was dried at 110°C for 1 h, transferred onto a 10 cm id Pyrex petri dish, and placed on a four-chamber oxygen plasma asher (manufactured by International Plasma Corporation) for low temperature combustion. When the inorganic matter was totally oxidized (25 h), the residual ash was sequentially extracted with HCl and HNO_3 according to ASTM D2492. The iron and sulfur content in the extracts was measured separately using an ICP spectrometer.

4. *Alternate LTA of coal*: Method 4

Oven-dried −200 mesh coal samples were oxidized in the oxygen plasma as in 3. No attempt was made at complete combustion of carbon, so that oxidation of pyrites could be avoided (8). Following sequential extraction with HCl and HNO_3 of the so-called LTA residue, determinations of the iron and sulfur content in the extracts were undertaken as in 3.

5. *Second alternate LTA of coal*: Method 5

The procedure for LTA described under 4 was modified to include more efficient ashing with combined oxygen–fluorine plasma (9). Fluorine plasma was generated *in situ* by using a Teflon petri dish instead of a Pyrex glass dish. All other steps for the estimation of the forms of sulfur were the same as in 4.

Results and discussion

The following results are described to demonstrate the dilemma coal analysts face when reporting the results of analysis according to some standard procedures. The results in Table 1, describing the coal samples, their geology, and analysis with respect to total iron and total sulfur content are precise and pose no problem. The error ranges within ±1.0% between replicate analyses. The atomic ratio, S/Fe, however, varies randomly according to sample origin.

In Table 2 these single-step analyses are compared with multiple-step iron analyses according to Methods 2 and 3, respectively. The results of multiple-step analyses are 4–25% lower than the single-step procedure. The error may be due to incomplete extractions, but both high and low temperature ashing procedures gave comparable results. Alternately, lower values may be assigned to handling losses during transfer, filtration, etc., or there may be forms of iron in the coal that are HCl/HNO_3 insoluble (after ashing), but soluble in HF.

Similar comparisons could not be made between single and multiple-step analyses of sulfur. Table 3 summarizes the results of total sulfur determination by "Leco" and by the multiple steps of Methods 1–5. The recovery of sulfur varies widely between different procedures. Between 15 and 57% sulfur is recovered by the standard ASTM D2492 (Method 1) procedure; this portion should be assigned as a combination of sulfate and pyritic sulfur. Using high temperature ashing, Method 2, recovery was extremely poor. Not only the organic sulfur was lost, but the pyrites probably decomposed to Fe_2O_3 and SO_2. Low temperature ashing (Method 4), on the other hand, gave more than 85% recovery in 7 out of 8 cases. The high recovery in the LTA procedure may have been due to the fixation of organic sulfur in the inorganic matrix without loss of pyritic sulfur. This possibility was suspected from the fact that the recovery of sulfur using Method 3 procedures, where low temperature ashing was done after HCl leaching of coals, was not as high as 85%. HCl leaching would remove alkali and alkaline-earth ions, which are responsible for fixing sulfur during low temperature ashing.

S* = calculated sulfur as pyrite from Fe_p in Table 4.
S_o = organic sulfur; parenthetical number is dry ash-free basis.

This discussion leads one to conclude that neither sulfur nor iron analysis according to the standard procedure can be applied in a straightforward way to estimate the distribution of sulfur in various forms. The data are difficult to interpret on the basis of a mass balance of sulfur and iron in single- and multiple-step analyses.

The ASTM procedures calculate pyritic sulfur from the nitric acid-extracted portion of iron analysis, the precision of which depends on completion of extraction without contamination from other iron minerals. An alternate procedure for calculating the distribution of sulfur in different forms may be carried out as shown in Tables 4 and 5. Here the pyritic iron is calculated from the differences between total iron and iron extracted with HCl. Iron in the HCl extract is assumed to be present as ferric sulfate and other soluble but non-sulfate iron compounds. Estimation of other sulfates, particularly gypsum, should be carried out to validate this interpretation of the iron distribution.

Between 43 and 76% of total iron in these coals is presumed to be present in a non-sulfide (or sulfate) form, according to the results in Table 4. If the iron distribution figures are correct, one

TABLE 6. S_o, organic sulfur (% S_{total}) estimated by different methods

*Computed on the basis of sulfur analyses.

obtains the sulfur distribution results in Table 5. Here total and sulfate sulfur are analytical values and pyritic sulfur is calculated. These analyses suggest that the sulfur content of the organic matrix changes with the geology of the deposit; within the same formation a variation exists between deposits with respect to pyrite contents. This conclusion is based on the assumed distribution of the three types of sulfur compounds, and assumed association of sulfur with iron in coal (1, 3). Application of ASTM methods (3), however, gives contradictory results (Table 6) due to uncertainty regarding the validity of the assumptions and the estimation of pyrites.

The dilemma of correctly estimating organic sulfur depends on measuring pyritic sulfur accurately. Hyman and Rowe (10) have suggested a novel thermo-magneto-gravimetric analytical (TMGA) method that is based on the combined effects of temperature and a strong magnetic field on the apparent weight of a ferromagnetic material. TMGA results for 30 U.S. coals of various ranks were found highly reproducible with 0.09% standard deviation for pyrite measurement (11) and TMGA was recommended for routine application. The present discussion on the merit of standard procedures for estimating forms of sulfur in low-sulfur coals suggests that the TMGA approach may be more suitable for low-sulfur coals than these standard procedures.

S. N. LIMAYE and M. C. SAXENA. Can. J. Chem. **64**, 865 (1986).

Metal–ligand association constants of 1:1 binary (ML) and 1:1:1 ternary (MAL) complexes of the type M + A ⇌ MA; MA + L ⇌ MAL (where M = La^{3+}, Ce^{3+}, Pr^{3+}, Nd^{3+}, or Sm^{3+}; A = primary ligand = EDTA; L = secondary ligand = O—O, O—N, O—S donor aliphatic or aromatic ligand) have been determined potentiometrically by the Irving–Rossotti titration technique at ionic strength 0.2 (mol dm^{-3} $NaClO_4$) and 25°C. Differences between log K_{ML} and log K_{MAL} are negative; this may be chiefly due to electrostatic repulsion between the primary binary complex and the incoming secondary ligand during the formation of the mixed-ligand complexes. The relative complexing tendencies of various secondary ligands have been found to follow the sequence O—O donor (aromatic) > O—N donor > O—O donor (aliphatic) ≥ O—S donor.

S. N. LIMAYE et M. C. SAXENA. Can. J. Chem. **64**, 865 (1986).

Utilisant la méthode de titration potentiométrique de Irving–Rossotti et opérant à 25°C et à une force ionique de 0,2 mol dm^{-3} $NaClO_4$, on a déterminé les constantes d'association métal–ligand des complexes binaires 1:1 (ML) et ternaires 1:1:1 (MAL) du type M + A ⇌ MA ou MA + L ⇌ MAL (où M = La^{3+}, Ce^{3+}, Pr^{3+}, Nd^{3+} ou Sm^{3+}; A = ligand primaire = EDTA; L = ligand secondaire = ligand donneur aliphatique ou aromatique O—O, O—N ou O—S). Les différences entre log K_{ML} et log K_{MAL} sont négatives; ce résultat est principalment dû à une répulsion électrostatique entre le complexe binaire primaire et le ligand secondaire qui approche au cours de la formation des complexes avec ligands mixtes. On a observé que les tendances relatives à la complexation de divers ligands secondaires sont dans l'ordre suivant: donneur O—O aromatique > donneur O—N > donneur O—O aliphatique ≥ donneur O—S.

[Traduit par la revue]

Introduction

The lanthanide metal ions are reported to display little tendency to form complexes with π-bonding ligands as their 4*f*-orbitals do not seem to be available for bonding (1–3). They exhibit class "a" (or hard acid) character as acceptor metal ions. Although earlier literature reveals that their coordination chemistry is limited mainly to complexes with oxygen, or oxygen–nitrogen donors (4, 5) some investigations have been carried out recently on their complexes with oxygen–sulphur (6, 7) and nitrogen donors (8, 9). Some β-diketone chelates have also been studied (10, 11).

The present work is intended to report the relative complexing tendencies of O—O, O—N, and O—S donor (secondary) ligands in the formation of 1:1:1 mixed-ligand complexes of the type LN–EDTA–L (charges omitted), where LN = La^{3+}, Ce^{3+}, Pr^{3+}, Nd^{3+}, or Sm^{3+}; EDTA = primary ligand; and L = O—O, O—N, or O—S donor secondary ligand. Aspects dealing with the effect of ring size of the secondary ligand on the stability of the mixed-ligand complex (12*a*), and occurrence of the intramolecular hydrophobic interaction (12*b*), have been communicated elsewhere.

Experimental

The lanthanides were supplied by Indian Rare Earths Ltd. (99.99% purity). Other chemicals were of standard purity (BDH Analar; E. Merck G. R.; Fluka). Solutions of La^{3+}, Ce^{3+}, and Sm^{3+} were prepared by dissolving the requisite quantities of the nitrate salts in double distilled water, and those of Pr^{3+} and Nd^{3+} by dissolving the oxides in the minimum quantity of perchloric acid and removing the excess by evaporation. The solutions were standardized by means of complexometric titrations (13). EDTA was used as the disodium dihydrate; the remaining two protons were neutralized before use. The secondary ligands were used as purchased.

Usual titration sets (14) were prepared for each system by using the final metal and ligand concentrations as 1×10^{-3} mol dm^{-3}. The ionic strength, *I*, was maintained constant at 0.2 (mol dm^{-3}, $NaClO_4$). These sets were equilibrated and titrated potentiometrically at 25°C with 0.2 mol dm^{-3} (carbonate free) NaOH using an Elico digital (model LI-120) pH meter. Reproducible pH readings were used for calculations. In the cases of salicyclic, phthalic, and anthranilic acids a partial aqueous medium (40% v/v ethanol–water) was used and the experimental pH-meter readings were corrected by using the Van-Uitert technique (15). The Irving–Rossotti approach (16) and its extension as applicable to ternary systems (17) were used for computing the proton–ligand and metal–ligand association constants.

Results

A representative set of pH titration curves for the system La(III) – EDTA – malic acid is shown in Fig. 1. The primary complex, MA (i.e., metal ion – EDTA chelate), is formed at a lower pH (below pH ~ 4.2) and remains stable over a fairly long range of pH (up to about 6.5–7.0). The secondary ligand, L, combines with MA in the pH region 4.0–5.0. The formation of the 1:1:1 ternary complex, MAL, in the present work may be represented as (charges omitted),

[1] M + A ⇌ MA

and

[2] MA + L ⇌ MAL

Similarly the formation of the binary complex may be written as,

[3] M + L ⇌ ML

and the association of protons with the secondary ligand as,

[4] H + L ⇌ HL; H + HL ⇌ H_2L; etc.

In eqs. [1]–[4] A represents deprotonated primary ligand and L deprotonated secondary ligand. The equilibrium constants corresponding to these equilibria are the metal–ligand association constants, K^{M}_{MA}, K^{MA}_{MAL}, K^{M}_{ML} (eqs. [1]–[3], respectively), and

[1]Revision received December 16, 1985.

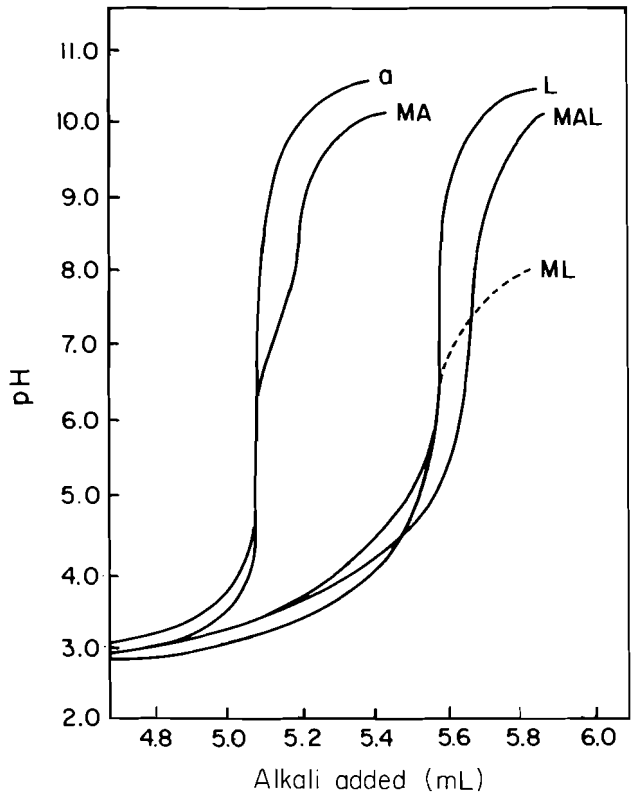

FIG. 1. Representative pH-titration plots for 1:1 binary (ML) and 1:1:1 ternary (MAL) La–EDTA–malic acid system.

proton–ligand association constants K^{H}_{HL}, $K^{HL}_{H_2L}$, etc. (or, K^{H}_{1}, K^{H}_{2}, etc.) (eq. [4]).

The quantity Δ log K used to quantify the stability of the ternary complex MAL (formed from MA) relative to that of the binary complex ML is defined as,

$$[5] \quad \Delta \log K = \log K^{MA}_{MAL} - \log K^{M}_{ML}$$

The formation functions of the protonated ligand, $\bar{n}_H$, and of the metal complex, $\bar{n}$, and the free-ligand exponent, pL, have been calculated from the titration curves in the usual manner (17).

The proton–ligand association constants have been calculated from the expression

$$[6] \quad \log K^{H}_{n} = B + \log \frac{\bar{n}_H}{1 - \bar{n}_H}$$

where B is the pH-meter reading. For a partially aqueous medium B was corrected (15) by means of the relationship

$$[7] \quad B = -\log [H] - [\log f + \log U_{H^0}]$$

where, f = activity coefficient of hydrogen ion in solution; U_{H^0} = correction at zero ionic strength.

In the case of amino acids it has been observed (see Fig. 2, for example) that the experimental curve MA diverges from curve A, indicating the formation of hydroxo species of the type $[MA(OH)_n]$; the secondary ligand L combines with MA in this higher pH region. The hydrolysis corrected values have been determined (18) in these cases and shown within square brackets in Table 3.

The values of log K^{M}_{ML}, log K^{MA}_{MAL}, and Δ log K have been reported in Tables 1–4. The quantities within parentheses are the standard deviations. The possibility of formation of species of the type MA_2 (including any disproportionation of MAL into MA_2 and ML_2) has been ignored in view of the hexadentate nature of EDTA. The use of sufficiently dilute solutions of metal ions and ligands (1×10^{-3} mol dm^{-3}) and smooth curves (not shown) between $\bar{n}$/[L] vs. [L] have been regarded as indicative of the absence of polynuclear species in the ternary systems.

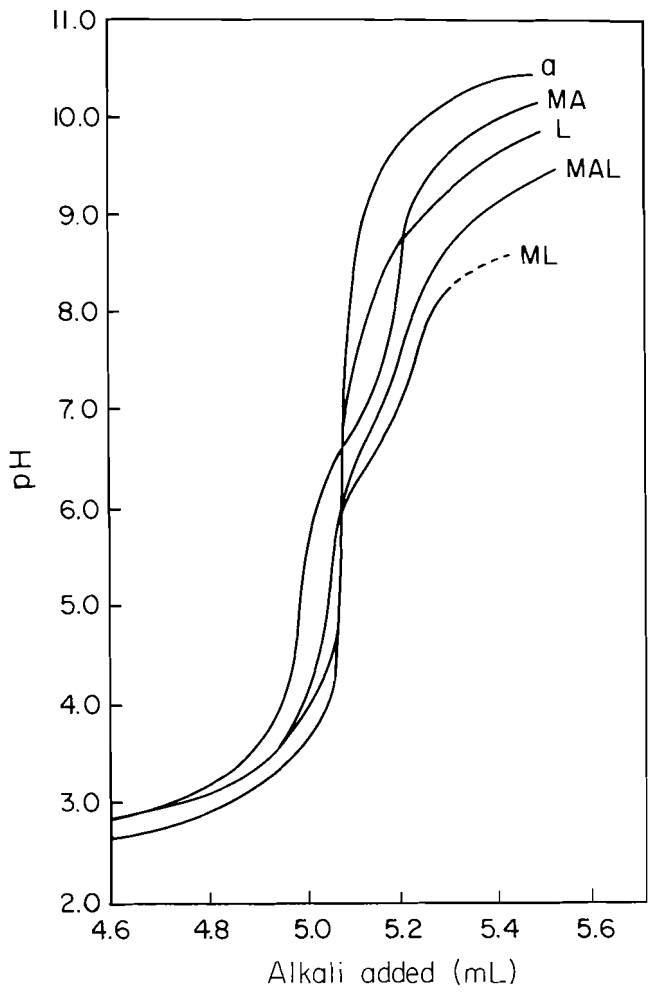

FIG. 2. Representative pH-titration plots for 1:1 binary (ML) and 1:1:1 ternary (MAL) La–EDTA–glycine system.

A representative figure (Fig. 3) has been incorporated to show the distribution of various species as a function of pH for the ternary system La(III)-EDTA-glycine. It may be seen that in this case the binary complex MA is formed (up to 90%) at pH 6.0 and the ternary complex MAL up to about 80% in the pH region 7.5 and above.

Discussion

A perusal of the data in Tables 1–4 reveals clearly that the association constants log K^{M}_{ML} and log K^{MA}_{MAL} follow the sequence $La^{3+} < Ce^{3+} < Pr^{3+} < Nd^{3+} < Sm^{3+}$ for all the O—O, O—N, and O—S donor ligands. This sequence is also of the order of increasing occupancy of the $4f$ orbitals of the lanthanides, and is accompanied by a regular decrease in ionic radii and hence a gradual increase in ionic potentials. Plots (not shown) of these metal–ligand association constants vs. r^{-1} (r = ionic radius of LN^{3+} ion), however, show some departure from linearity at Nd^{3+} and Sm^{3+} (electronic configuration: $4f^3$ and $4f^5$) which may well be due to a possible tetrad effect (19).

For related secondary ligands the association constants vary with ligand characteristics also. Thus, for the aliphatic hydroxy acids and the unsaturated carboxylic acids studied the trends are

TABLE 1. Association constants of 1:1 binary (log K^{M}_{ML}) and 1:1:1 ternary (log K^{MA}_{MAL}) lanthanide–EDTA complexes with O—O donor aliphatic ligands, and Δ log K values with I = 0.2 (mol dm^{-3}, $NaClO_4$) and a temperature of 25°C

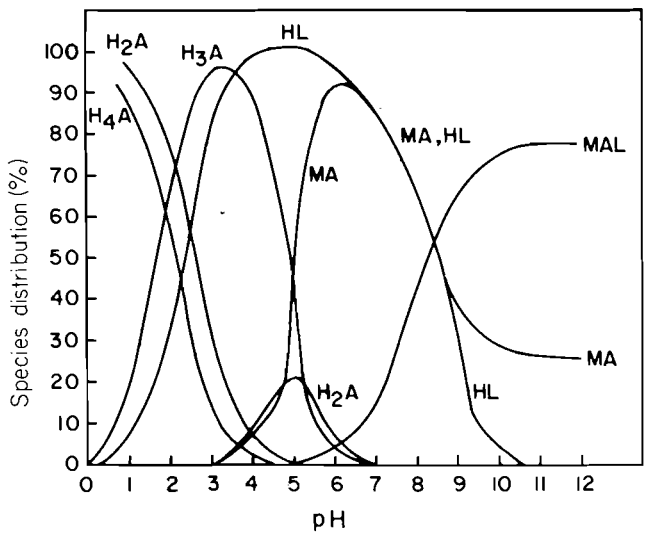

FIG. 3. Distribution of various species (%) as a function of pH in the La–EDTA–glycine ternary system.

malic acid > lactic acid > glycolic acid > gluconic acid (20) and citraconic acid > maleic acid > itaconic acid > crotonic acid, which are also the orders of ligand basicities. A similar sequence has been reported (21) for the ternary systems (LN-EDTA-L) where, LN = La^{3+}, Pr^{3+}, Nd^{3+}; L = malic acid, lactic acid, glycolic acid. For the saturated aliphatic dicarboxylic acids (12*a*) the order is malonic acid > succinic acid > glutaric acid, which may be due to a gradual increase in the size of the chelate ring formed by these ligands. In the case of O—N donors the sequence with respect to ligands has been found to be α-alanine < glycine < aspartic acid < leucine ≤ β-alanine < valine using the hydrolysis corrected values. For O—S donors thiomalic acid > thioglycolic acid is again the order of ligand basicities. A similar sequence has been observed for some 3*d* elements (22).

The Δ log K values are consistently negative for all the mixed-ligand complexes studied. This may be chiefly due to an electrostatic repulsion between the negatively charged primary complex and the incoming secondary ligand (also negatively charged) during the formation of mixed-ligand complexes.

$CH_2(SH)$ | COOH	log K^{MA}_{MAL}	3.32 (±0.03)	3.47 (±0.015)	3.53 (±0.02)	3.63 (±0.02)	3.68 (±0.03)
	−Δ log K	0.08	0.05	0.06	0.04	0.04

[8] $LN^{3+} + EDTA^{4-} \rightleftharpoons [LN\text{–}EDTA]^{-}$

$[LN\text{–}EDTA]^{-} + L^{n-} \rightleftharpoons [LN\text{–}EDTA\text{–}L]^{-(n+1)}$

The $-\Delta \log K$ values have been found to vary numerically from 0.04 to as much as 3.73; a general sequence in the $-\Delta \log K$ values has been observed to be

$$O\text{—}O_{(aromatic)} > O\text{—}N > O\text{—}O_{(aliphatic)} > O\text{—}S$$

for the different donor types, showing probably a discrimination of MA towards L. It is interesting to note that in the present case the highest $-\Delta \log K$ values have been obtained for catechol, resorcinol, and protocatechuic acid, which may be due to a greater electronic repulsion caused by a higher electron density associated with the π-electron cloud over the aromatic ring.

Sigel (23, 24) has observed a certain dependence of $-\Delta \log K$ on the proton–ligand association constants of the secondary ligands in complexes of the type M.Dipy.L. In the present work, a general parallel has also been noticed between the magnitudes of $-\Delta \log K$ and the proton–ligand association constants of the secondary ligands. A higher value of $\log K_n^H$ would imply that a relatively larger concentration of L^{n-} species exists in the ternary system, resulting in greater electronic repulsion during the formation of mixed-ligand complexes and a consequent enhancement in the magnitude of $-\Delta \log K$.

A significant conclusion that may be drawn from the experimental values of the association constants is that the $\log K_{MAL}^{MA}$ values lie in the sequence,

$$O\text{—}O_{(aromatic)} > O\text{—}N > O\text{—}O_{(aliphatic)} \geq O\text{—}S$$

with respect to the donor atoms of the secondary ligands. This trend is justified in view of the fact that the lanthanides are hard acids in terms of the "hard and soft" acid–base theory. The hard–hard interactions, being more facile, would result in more stable complexes with hard bases. It is also significant that the primary complex $(LN\text{–}EDTA)^{-}$ possesses enough hardness to show a preference towards O—O and O—N donors in the formation of the mixed-ligand complexes. The greater stability of the mixed-ligand complexes with O—O aromatic donors may result from the enhanced stabilizing capability of the aromatic ring due to resonance effects.

AHMAD S. SHAWALI and HASSAN A. ALBAR. Can. J. Chem. **64**, 871 (1986).

The kinetics of triethylamine (TEA) catalyzed deydrochlorination of a series of *N*-aryl-*C*-ethoxycarbonylformohydrazidoyl chlorides **1***a–m* have been studied under pseudo-first-order conditions in 4:1 (v/v) dioxane–water solution at 30°C. For all compounds studied, the kinetics followed the rate law: $k_{obs} = k_2$ (TEA). The values of the overall second-order rate constants for the studied compounds were correlated by the equation: $\log k_2 = 0.533\,\sigma^- - 0.218$. The results are compatible with a mechanism involving a fast reversible deprotonation step leading to the anion of **1**, followed by rate-determining step involving the loss of the chloride ion from the anion. The reaction constants of these two steps were estimated to be 0.845 and − 0.312, respectively.

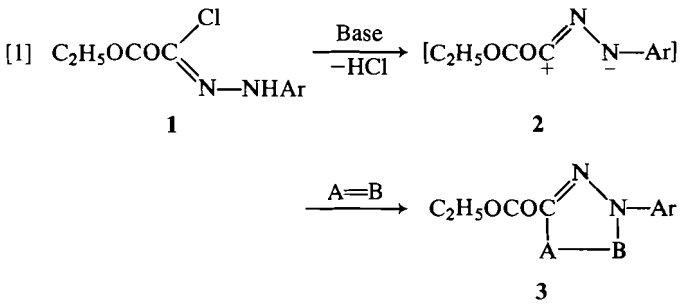
AHMAD S. SHAWALI et HASSAN A. ALBAR. Can. J. Chem. **64**, 871 (1986).

Opérant à 30°C et dans des solutions 4:1 (v/v) de dioxanne/eau, on a étudié les cinétiques du pseudo-premier ordre des réactions de déshydrochloruration catalysées par la triéthylamine (TEA) d'une série (**1***a–m*) de chlorures de *N*-aryl *C*-éthoxycarbonyl formohydrazidoyles. Dans tous les cas étudiés, l'équation de vitesse de la cinétique est la suivante: $k_{obs} = k_2$ (TEA). Pour tous les composés étudiés, on a établi une corrélation entre les constantes de vitesse globales du deuxième ordre qui est définie par l'équation suivante: $\log k_2 = 0{,}533\sigma^- - 0{,}218$. Les résultats sont compatibles avec un mécanisme impliquant une étape de déprotonation réversible rapide conduisant à l'anion de **1** qui serait suivie par une étape déterminante impliquant une perte de l'ion chlorure par l'anion. On a évalué les constantes de vitesses pour ces deux étapes à 0,845 et −0,312 respectivement.

[Traduit par la revue]

Introduction

The chemistry of *N*-aryl-*C*-ethoxycarbonylformohydrazidoyl chlorides **1** has been thoroughly investigated during the last decade (1–3). Due to their ease of preparation, such compounds have been extensively used in 1,3-dipolar cycloaddition reactions, where the intermediate nitrilimine **2**, formed *in situ* by the action of a base catalyst, reacts with a dipolarophile A=B, producing a cycloadduct **3**, eq. [1] (4,5).



[1]

1 **2**

3

However, no attention has yet been given to the mechanism of formation of **2** from **1**. We wish to report here the results of our kinetic study of the triethylamine catalyzed dehydrochlorination of a series of substituted *N*-phenyl-*C*-ethoxycarbonylformohydrazidoyl chlorides **1***a–m* in 4:1 (v/v) dioxane–water mixture at 30°C in an attempt to shed some light on the mechanism of this elimination reaction.

Results and discussion

The sequence followed in the preparation of **1***a–m* is outlined in Scheme 1. Some of these hydrazidoyl chlorides were reported and others, namely **1***b* and **1***e–h*, are new. The structures of these chlorides were evidenced by their elemental and spectral analyses. For example, the infrared spectra of all compounds reveal the presence of characteristic bands near 3280–3220 (hydrazone NH), 1725–1695 (ester, CO), 1665–1600 (C=N), and 1080–1060 (ester C—O—C) cm^{-1}. In their ^{1}Hmr spectra, they exhibit a triplet signal at δ 1.3–1.4 (3H, J = 7 Hz, CH_3CH_2O), a quartet at δ 4.4–4.3 (2H, J = 7 Hz, CH_3CH_2O), and a singlet near 9.5–8.32 (1H, NH), in addition to the aromatic proton multiplet signal in the region 7.0–8.0 ppm.

On standing for 3 days at 25°C in 80% (v/v) dioxane–water mixture, these hydrazidoyl chlorides were recovered unchanged. However, addition of triethylamine (TEA) to the solution of **1** in this same solvent mixture liberated the chloride ion. Accordingly, the dehydrochlorination kinetics were followed at 30°C in 80% (v/v) dioxane–water mixture in the presence of a large excess, at least 10-fold, of TEA by determining the chloride ion concentration with an ion selective electrode (see Experimental). In all kinetic runs, the ionic strength in the reaction mixture was maintained at 0.10 by the addition of the appropriate volume of 5 *M* sodium nitrate solution in the same solvent system (80:20 dioxane–water, v/v).

The pseudo-first-order rate constant of the dehydrochlorination of **1** was estimated from the plot of log (C_∞ and C_t are the concentrations of chloride ion liberated at infinite time and at time t, respectively. The values of k_{obs} determined for the series of compounds studied are listed in Table 1. The value of k_{obs} was, in each case, a linear function of the triethylamine concentration as shown in Fig. 1, where k_{obs} is plotted vs. amine concentration. The fact that such plots have zero intercepts indicates that the water-assisted (i.e. the uncatalyzed) reaction is negligible.

[a] $k_2 = k_{obs}/[(C_2H_5)_3N]$.

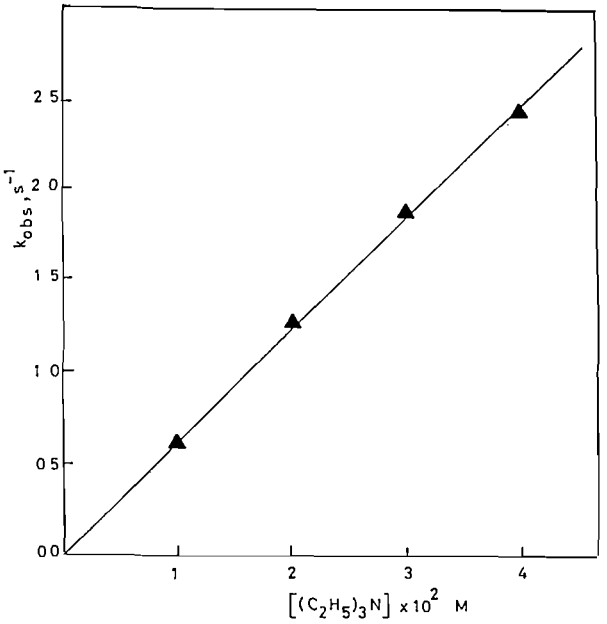

FIG. 1. Plot of the observed pseudo-first-order rate constants against triethylamine concentration for the dehydrochlorination of *N*-phenyl-*C*-ethoxycarbonylhydrazidoyl chloride in 4:1 dioxane–water at 30°C and μ = 0.1.

The plot of the log k_2 (where $k_2 = k_{obs} / [(C_2H_5)_3N]$) vs. the substituent constant σ_x^-, is linear (Fig. 2). The equation of the regression line is

$$[\log k_2 = 0.533\ \sigma_x^- - 0.218]$$

with correlation coefficient $t = 0.997$ and standard deviation $s = \pm 0.016$.

The most compatible mechanism that can account for the foregoing results is outlined in Scheme 2.

According to this sequence, it could be shown that,

$$\left[\log \frac{k_2}{k_2^0} = (\rho_1 - \rho_a)\sigma_x^- = \rho\ \sigma_x^-\right]$$

That is, the observed ρ value is the algebraic sum of the ρ values describing the separate stages.

For the reaction under study, it is expected that opposing effects will be operative in the 1,3-dipolar ion formation. That

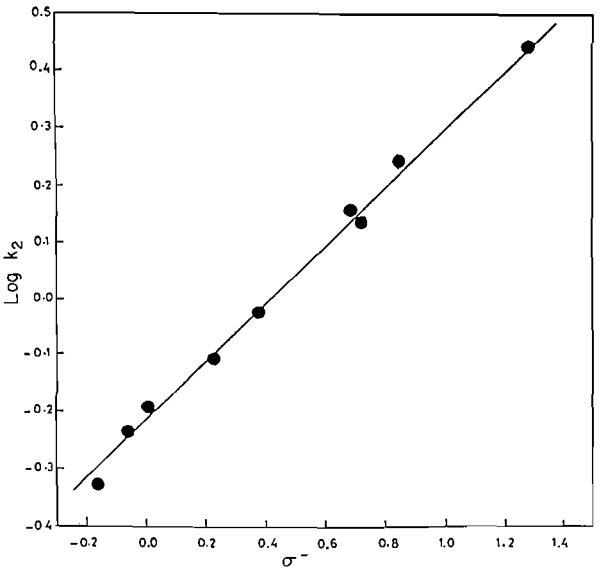

FIG. 2. Hammett plot of log k_2 versus σ^- constant for dehydrochlorination of the hydrazidoyl chlorides, $XC_6H_4NHN{:}C(Cl)COOC_2H_5$, in 4:1 dioxane–water at 30°C and μ = 0.1.

is, ρ_1 and ρ_a constants will have opposite signs, ρ_1 being negative whereas the value of ρ_a is positive. The positive sign of the ρ value obtained implies that $\rho_a < \rho_1$. To confirm this it was necessary to determine the acid dissociation constants K_a of the reaction series studied. However, the very high reactivity shown by these hydrazidoyl chlorides in basic solution made direct measurement of K_a difficult. Therefore, the rate of chloride ion loss from the hydrazidoyl chloride anion (k_2 in Scheme 2) could not be separated from the acidity constant K_a.

To overcome this difficulty, it was thought possible to estimate the value of ρ_a by determining the pK_a of the hydrazone series **4***a–h* in 80% (v/v) dioxane–water mixture at 30°C and ionic strength 0.1. The choice of **4** was based on the close similarity of the inductive effects of the CN and Cl groups. For example, the Taft σ constants of these two groups are σ^*_{CN} = 1.30 and σ^*_{Cl} = 1.05 (6). also, the values of σ_I of the CN and Cl groups were reported to be 0.60 and 0.47, respectively (6).

The compounds **4***a–h* required for such study were prepared by coupling ethyl cyanoacetate with diazotized arylamines in ethanol in the presence of sodium acetate. The structures of **4***a–n* were confirmed by their infrared and ^{1}Hmr spectra. Thus, the infrared spectra of all compounds reveal the presence of

c, X = 4-Cl *f*, X = 3-NO_2

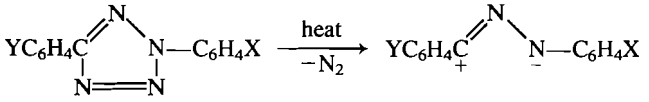
At pH < 8 each of the compounds **4***a–h* shows an intense π–π* absorption band near 360 nm. In alkaline medium, the corresponding anion shows π–π* band in the region 380–470 nm (Table 2). Spectra recorded at different pH values show an isobestic point near 380 nm. Typical spectra of an example of the series studied are reproduced in Fig. 3 and the values of λ_{max} of **4***a–h* in acid (pH < 3) and alkaline (pH > 11) media are summarized in Table 2. The absorbance of a freshly prepared solution measured at the wavelength of the absorption maximum of the anion plotted against pH shows a dependence in the shape of a dissociation curve of a monobasic acid. From the pH–absorbance data, the pK_a values of **4***a–h* were calculated. The results are summarized in Table 2.

A plot of pK_a vs. the substituent constant σ^- was linear (Fig. 4). The equation corresponding to this regression line is

$$[\log K_a = 0.845\ \sigma_x^- - 0.873]$$

with correction coefficient $r = 0.946$ and standard deviation $s = \pm 0.120$. As shown, the value of the slope (ρ_a) as expected is positive and has a value of 0.845. Since $\rho = \rho_i - \rho_a$ it follows that $\rho_i = -0.312$. This ρ_i value is negative, as expected for a reaction involving the generation of positive charge in the transition state.

These conclusions seem to be in agreement with literature data (7–9). Thus, for the thermolysis of 2,5-diaryltetrazoles **5**



5 **6**

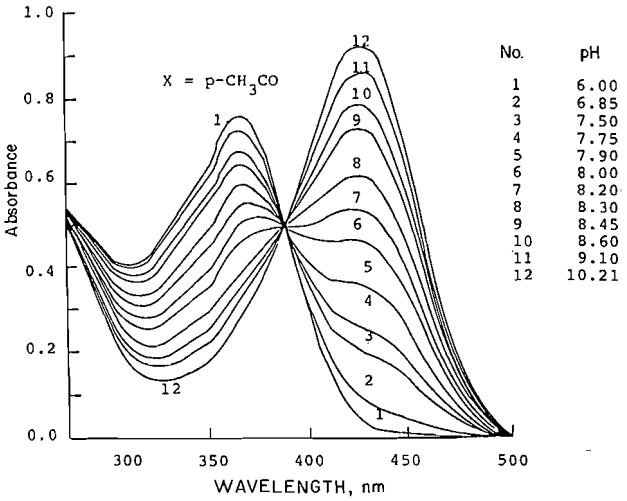


FIG. 3. Absorption spectra of ethyl α-cyanoglyoxalate arylhydrazones, $XC_6H_4NHN{:}C(CN)COOC_2H_5$, in 4:1 dioxane–water at 30°C and $\mu = 0.1$ at different pH values.

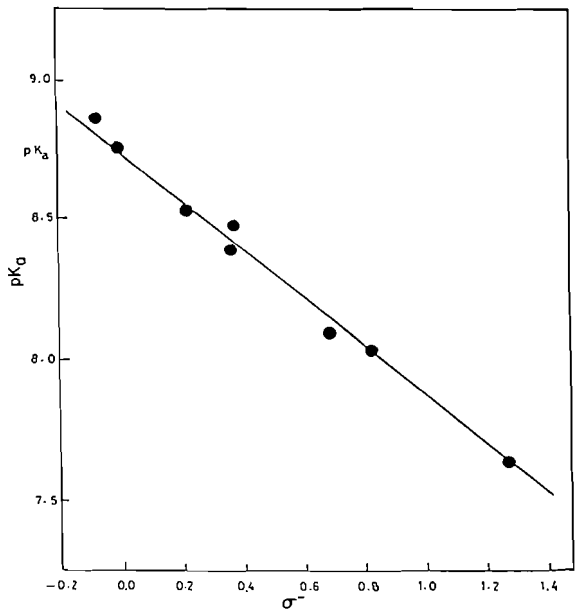

FIG. 4. Hammett plot of acid dissociation constant versus σ^- constant for ethyl α-cyanoglyoxalate aryl hydrazones, $XC_6H_4NHN{:}C(CN)COOC_2H_5$, in 4:1 dioxane–water at 30°C and $\mu = 0.1$.

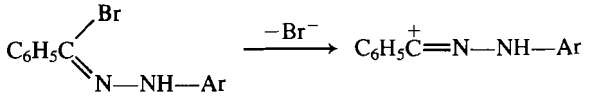
the values of ρ_Y and ρ_X were found to be 1.16 and −0.23, respectively (7). Furthermore, a Hammett ρ value of −0.63 was reported for the formation of the azocarbonium ion **8** from the hydrazidoyl bromides **7** (8,9).



7 **8**

Ar = 2—Br, 4—XC_6H_3

The small value of ρ (−0.312) observed for series **1** undoubtedly results from the compensation of the trivalent anionic nitrogen centre for the positive charge buildup, such that the effect of substitution was reduced.

Experimental

All melting points were measured on Bockmonoscop, Karlkolb Scientific Technical Supplies, West Germany, and are uncorrected. The infrared spectra were recorded in potassium bromide on a Zeiss infrared spectrophotometer model IMT16. The electronic absorption spectra were measured on a Pye–Unicam SP8000 spectrophotometer. The proton magnetic resonance spectra were obtained in deuterated chloroform with a Varian EM-390 90-MHz spectrometer. Microanalyses were performed on Perkin Elmer elemental analyzer model 240-B at the microanalytical laboratory of King Abdulaziz University. Ethyl 2-chloroacetoacetate was prepared by chlorination of ethyl acetoacetate with sulfuryl chloride in anhydrous ether as previously described (10).

Preparation of N-*aryl*-C-*ethoxycarbonylformohydrazidoyl chlorides* **1**a–i

A solution of ethyl 2-chloroacetoacetate (1.64 g, 0.01 mol) in ethanol (100 mL) was stirred for 15 min with 1.3 g sodium acetate trihydrate. The mixture was then chilled in an ice bath to 0.5°C. While the ester solution was cooling, the desired diazonium salt solution was prepared by diazotizing the appropriate arylamine (0.01 mol) in 6 *M* hydrochloric acid (6 mL) with cold 1 *M* sodium nitrite solution (10 mL) in the usual way. The diazonium salt solution was added to the cold ester solution over a period of 20 min while stirring and keeping the temperature below 5°C. The reaction mixture was then left in a refrigerator for 3 h. The precipitated solid was collected, washed with water, dried, and finally crystallized from ethanol. The compounds prepared, together with their physical constants, are listed in Table 3.

Preparation of ethyl cyanoglyoxalate arylhydrazones **4**a–h

These were prepared by coupling ethyl cyanoacetate with diazotized anilines following the same procedure described for **1***a–i*. The crude product, usually colored, was filtered, washed with water, and dried. Crystallization from acetic acid gave the corresponding ethyl cyanoglyoxalate arylhydrazone **4** in 70–85% yield. The compounds prepared are listed, together with their physical constants, in Table 4.

Kinetic studies

The kinetics of dehydrochlorination of the hydrazidoyl chlorides **1***a–i* were studied in dioxane–water (4:1, v/v) at 30°C(±0.1°C) and ionic strength μ = 0.1 ($NaNO_3$). The rates of dehydrochlorination were followed by recording the increase in the chloride ion concentration with time.

An Orion research microprocessor ion analyzer model 901 (Orion Research Incorporated, Mass., U.S.A.) with double junction reference electrode (90-02) and chloride ion electrode (94-17B) was used to record the chloride ion liberated during the dehydrochlorination of **1**.

Stock solutions of hydrazidoyl chlorides **1***a–i*, usually about 10^{-2} *M*, were prepared in 20% aqueous dioxane. A stock solution of triethylamine (1 *M*) was also prepared in the same solvent system. Appropriate concentrations of the amine and the hydrazidoyl chloride were prepared by dilution of the stock solutions and thermostated at 30°C in a constant temperature water bath.

Reactions were followed to 80% completion, with at least 15 readings taken. All kinetic runs were carried out in a double-wall cell, through which water at 30°C was circulated by means of a constant temperature MgW Louda circulating water pump.

In a typical kinetic run, the hydrazidoyl chloride solution (usually 2×10^{-3} *M*) was transferred to the cell. Then the appropriate volume of sodium nitrate stock solution (1.0 *M*) was added so that the ionic strength in the test solution was 0.1. The mixture was stirred with a magnetic stirrer. Then the chloride ion and the reference electrodes were introduced. The run was started by injecting the amine solution by means of a syringe and the stop watch was started at the moment of injection. the concentration of the chloride ion liberated was recorded at given intervals. In all kinetic runs, at least a tenfold excess of amine over the hydrazidoyl chloride was used in order to maintain pseudo-first-order kinetics. Duplicate or triplicate runs were performed for each concentration.

Good first-order plots of log ($C_\infty - C_t$) against time were obtained. The observed pseudo-first-order rate constants were calculated from the slopes of the straight lines obtained by the method of least squares (Table 1). The average deviation from the mean value of the rate constant in duplicate or triplicate experiments was ±5% or less.

Product analysis

A mixture of *N*-*p*-nitrophenyl-*C*-ethoxycarbonylformohydrazidoyl chloride **1***i* (0.71 g., 0.005 mol), triethylamine (0.71 mL, 0.005 mol), and sodium nitrate solution (5 *M*, 2 mL) in 100 mL 80% dioxane–water mixture was kept at the kinetic temperature 30°C until the chloride **1***i* disappeared, as evidenced by tlc (thin-layer chromatographic) analysis. The solvent in the mixture was distilled under reduced pressure and the residue was washed with water, dried, and subjected to preparative tlc separation using silica gel as adsorbent and the solvent system : toluene – ethyl acetate – acetic acid (12:4:0.5 by volume) as eluent.

Two products were separated and identified as 1,4-bis-*p*-nitrophenyl-3,6-diethoxycarbonyl-1,4-dihydotetrazine **8** and ethyl oxalate mono-*p*-nitrophenylhydrazide **9**, by comparison with authentic samples prepared by literature methods (11).

The tetrazine derivative **8** was obtained in 35% yield, mp 237°C (AcOH) (Lit. (11) mp 236–237.5°C); ir (KBr) $\bar{\nu}$: 1746 (ester CO), 1580 (C=N), 1520, 1330 (NO_2), 1290 (C—N), 1175 (C—O—C) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.2 (t, 6H, J = 7 Hz, $2CH_3$—CH_2), 4.3 (q, 4H, J = 7 Hz, $2CH_3$—CH_2O), 7.3 (d, 2H J = 9 Hz, 2 *p*-NO_2—ArH), 8.3 (d, 2H J = 9 Hz, 2 *p*-NO_2—ArH) ppm.

The hydrazide **9** was obtained in 60% yield, mp 170°C (ethanol); ir (KBr) $\bar{\nu}$: 3320 (NH), 1738 (ester CO), 1690 (anilide CO), 1505, 1320 (NO_2) cm^{-1} ^{1}Hmr ($CDCl_3$) δ: 1.43 (t, 3H, J = 7 Hz, CH_3—CH_2O), 4.52 (q, 2H, J = 7 Hz, CH_3—CH_2O), 7.06 (d, 2H, J = 9 Hz, *p*-NO_2—ArH), 8.26 (d, 2H, J = 9 Hz, *p*-NO_2—ArH), 8.7 (s, 1H, CONH), 10.90 (s, 1H, HNC_6H_4—NO_2-*p*) ppm. *Anal.* calcd. for $C_{10}H_{11}N_3O_5$: C 47.43, H 4.38, N 16.59; found: C 47.10, H 4.13, N 16.30%.

Determination of acid dissociation constants of **4**a–h

The acid dissociation constants of the compounds **4***a–h* were determined spectrophotometrically in 80% dioxane–water at 30 ± 0.1°C and an ionic strength of 0.1.

A Taccussel digital pH meter PHN 78 fitted with a glass electrode type C-285-725 and a reference electrode type TB/HS 286-506 was employed for the determination of pH. The instrument was accurate to ±0.01 pH unit. It was calibrated using two standard Beckman buffer solutions of pH 4.01 and 7.00. The pH meter readings (B) recorded in dioxane–water solutions were converted to hydrogen ion concentration [H^+] by means of the widely used relation of van Uitert and Hass (12), namely:

$$-\log [H^+] = B + \log U_H$$

where log U_H is the correction factor for the solvent composition and ionic strength used, for which B is read. For this purpose, readings were made on a series of solutions containing known amounts of hydrochloric acid and sodium chloride, such that the ionic strength was equal to 0.1 in 80% dioxane–water at 30.0 ± 0.1°C. The value of log U_H was found to be −0.55.

The experimental procedure in the determination of pK_a constants and their calculations from the absorbance–pH data were as described earlier (13). The pK_a values obtained were reproducible to within ±0.01 pK_a unit. The results are summarized in Table 2.

The crystal and molecular structure of *N*-(3,4,5-trimethoxycinnamoyl)-Δ^3-piperidine-2-one, an amide alkaloid (piperlongumine), $C_{17}H_{19}NO_5$

TAPATI BANERJEE AND SIDDHARTHA CHAUDHURI

Crystallography and Molecular Biology Division, Saha Institute of Nuclear Physics, Sector I, Block AF, Bidhannagar, Calcutta-700 064, India

Received March 15, 1985

TAPATI BANERJEE and SIDDHARTHA CHAUDHURI. Can. J. Chem. **64**, 876 (1986).

The crystals of $C_{17}H_{19}NO_5$ belong to the monoclinic space group $P2_1/n$ with $a = 15.793(3)$, $b = 4.089(4)$, $c = 24.649(5)$ Å, $\beta = 97.56(3)°$ $V = 1578(2)$ Å^3, and $Z = 4$. The structure was solved by MULTAN 78 and refined by full-matrix least-squares to a final R of 0.053 for 1863 observed reflections. X-ray crystallography has revealed that the molecule is the Δ^3 isomer and not the Δ^5 isomer suggested originally from nmr spectroscopy. The piperidyl nitrogen is sp^2 hybridized with its electron lone pair involved in conjugation with the carbonyl groups. The piperidone ring adopts a distorted boat conformation. An interesting feature of the structure is the formation of two C(ethylenic)—H...O(keto) intramolecular hydrogen bonds which stabilize the molecular conformation.

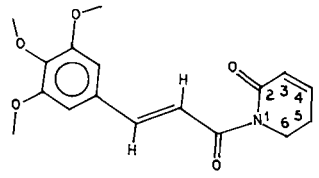
TAPATI BANERJEE et SIDDHARTHA CHAUDHURI. Can. J. Chem. **64**, 876 (1986).

Les cristaux du $C_{17}H_{19}NO_5$ appartiennent au groupe d'espace $P2_1/n$ avec $a = 15,793(3)$, $b = 4,089(4)$, et $c = 24,649(5)$ Å, $\beta = 97,56(3)°$, $V = 1578(2)$ Å^3, et $Z = 4$. On a résolu la structure par la méthode MULTAN 78 et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à une valeur finale de R de 0,053 pour 1863 réflexions observées. La cristallographie par diffraction des rayons X a permis de montrer qu'il s'agit de l'isomère Δ^3 et non pas de l'isomère Δ^5 qui avait été suggéré sur la base de la rmn. L'azote de la pipéridine est hybridée sp^2 et sa paire d'électrons libres est impliquée dans une conjugation avec les groupements carbonyles. Le cycle pipéridone adopte une conformation bateau déformé. Une caractéristique intéressante de la structure est la formation de deux liaisons hydrogènes intramoléculaires. C(éthylénique)—H...O(cétone) qui stabilisent la conformation moléculaire.

[Traduit par la revue]

Introduction

The amide alkaloid piperlongumine, **1**, isolated from the roots of the climbing plant *Piper Longum* L., is an effective drug in the treatment of asthma and chronic bronchitis (1). Earlier crystallographic (2–4) and spectroscopic (5) studies have shown that several alkaloids separated from *Piper* species, e.g., West African black or Ashanti pepper (3,4), contain the piperidine moiety; the amide alkaloids separated from the roots of *Piper Longum* L. are the exceptions (1). The present



1

structural study has revealed certain interesting features of the piperlongumine molecule which are discussed here.

Experimental

Crystal data:

$C_{17}H_{19}NO_5$ fw=317.34

Monoclinic, $P2_1/n$, systematic absences: $h0l$, $h+l$ odd, $0k0$, k odd; $a = 15.793(3)$, $b = 4.089(4)$, $c = 24.649(5)$ Å, $\beta = 97.56(3)°$, $V = 1578(2)$ Å^3, $Z = 4$, $\rho_o = 1.35$ (by flotation in KI solution), $\rho_c = 1.33$ g cm^{-1}, $\lambda(CuK_\alpha) = 1.5418$ Å, $\mu(CuK_\alpha) = 8.3$ cm^{-1}.

The compound was recrystallized from ethanol. Initial symmetry information and unit cell dimensions were derived from oscillation and Weissenberg photographs. The intensity data were collected at 22°C on an Enraf-Nonius CAD4 diffractometer, using graphite monochromatized radiation, with a crystal of dimensions 0.40 × 0.18 × 0.10 mm. The data were collected in the needle option in which the intensities were recorded in the minimum absorption position of the crystal. Accurate cell parameters were obtained from the least-squares fit of the setting angles of 25 well-centred reflections with 2θ values ranging from 32.8 to 55.8°. The $\omega/2\theta$ technique was used for data collection up to a limit of $2\theta = 120°$. The peaks were scanned at the take-off angle of 4° with a scan width of $(0.60 + 0.15 \tan\theta)°$ and a variable scan time extending up to a maximum of 60 s. Three orientation control reflections and three intensity control reflections were monitored every 50 reflections and every hour of X-ray exposure, respectively, to ensure the stability of the crystal position and the crystal quality.

Out of 2350 unique reflections measured, 1863 were considered to

be observed ($I \geq 3\,\sigma\,(I)$). The intensities were corrected for Lorentz and polarization factors but not for absorption. Corrections were also applied for the small variation (<2%) in the intensities of the control reflections.

The structure was determined by MULTAN (6) and refined by the full-matrix least-squares program ORFLS (7) to a final R of 0.053 (0.072 including unobserved reflections) and R_w of 0.066 ($w = 1/\sigma^2(|F_o|)$);[1] nine of the strongest reflections, namely $\bar{2}12$, $\bar{1}12$, 011, 012, $\bar{2}21$, $\bar{1}11$, $\bar{1}13$, 020, and 220, were removed from the least-squares refinement and marked as unobserved as their accuracy was doubtful because of the large differences between the intensity counts in the forward and reverse scans on the diffractometer. The hydrogen atoms, located from two successive difference electron density syntheses, were included in the refinement with isotropic thermal parameters. The maximum shift/error was less than 0.03 and peak heights ranging from −0.20 to 0.26 e Å^{-3} were found in a final difference synthesis computed at the end of the refinement.

The scattering factors for the non-hydrogen atoms were taken from Cromer and Waber (8) and those for the hydrogen atoms from Stewart, Davidson, and Simpson (9). The non-hydrogen scattering factors were corrected only for the real parts of the anomalous dispersion ($\Delta f'$ = 0.047, 0.029, and 0.017, for O, N, and C, respectively) from the International Tables for X-ray Crystallography (10). The geometrical parameters of the molecule were computed with the program PARST (11).

[1]Structure factor tables and the anisotropic thermal parameters may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Discussion

Figure 1 shows a perspective view of the piperlongumine molecule together with the atom labelling scheme. The coordinates for the non-hydrogen atoms together with their equivalent isotropic thermal parameters (12) are listed in Table 1. The interatomic bond distances and angles are given in Table 2, while Table 3 lists some selected torsion angles.

It is observed that the double bond in the piperidone ring is between C(3) and C(4); the compound is therefore the Δ^3 isomer rather than the Δ^5 isomer proposed from chemical and nmr spectroscopic studies (1). The N(1)—C(6) bond distance is in

good agreement with the values found in piperidine derivatives where C(6) is sp^3 hybridized (2–4,13–15).

As in other similarly substituted piperidine structures (2,3,13–16), the lone pair of electrons on the piperidyl nitrogen atom, N(1), is involved in conjugation with the carbonyl groups. This is indicated by the slight lengthening of the two C=O double bonds (1.216(3) and 1.218(3) Å) and the concomitant shortening of the two N—C(sp^2) single bonds (1.401(3) and 1.398(3) Å). Accordingly, the state of hybridization of the piperidyl nitrogen atom is sp^2 as shown by the sum (357.9(6)°) of the angles around it and the small deviation (−0.071(2) Å) of the atom from the plane of N(1), C(2), C(6), and C(8). The O(9)—C(8)—N(1)—C(6) torsion angle of 9.4(4)° is consistent with the partial double bond character of the N(1)—C(8) bond (17).

The bond distances and angles in the cinnamoyl moiety agree with those in other cinnamoyl derivatives (18,19). The progressive decrease in the C—C—C and C—C—N angles along the chain from the phenyl ring to the piperidone ring has also been observed in other cinnamoyl derivatives (2,3,16,18,19). This has been attributed to the steric repulsion between the hydrogen atoms of the chain (16).

The relative magnitudes of the C(phenyl)—O(methoxy) bond lengths C(14)—O(18), C(15)—O(20), and C(16)—O(22) (1.370(3), 1.381(3), and 1.365(4) Å) suggest considerable conjugation between the phenyl ring and the two methoxy groups substituted at C(14) and C(16). This conjugation appears to be favoured by the near coplanarity of these groups with the ring as indicated by the torsion angles C(13)—C(14)—O(18)—C(19) and C(17)—C(16)—O(22)—C(23) (Table 3). The extent of conjugation of the methoxy group at C(15) with the phenyl ring is comparatively smaller, possibly due to the accumulation of a considerable negative charge density at this carbon atom by the +R effects of the two adjacent methoxy groups. The noncoplanarity of the methoxy group at C(15) with the phenyl ring, indicated by the torsion angle C(16)—C(15)—O(20)—C(21), is obviously a result of the steric repulsion of the methoxy groups on either side of it.

The dissymmetry in the exocyclic angles at C(14) and C(16) may be attributed to the steric repulsive interaction between the

Piperx(2)	C(3)—H(3)...O(4)	0.87(1)	2.451(9)	1.72(1)	138.8(4)

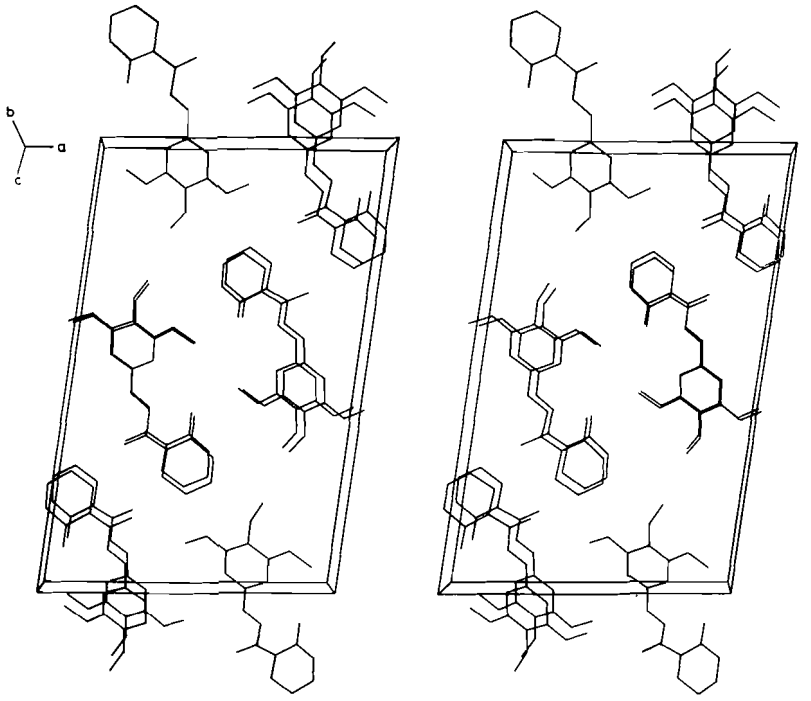

FIG. 2. A stereo view of the crystal structure.

corresponding methyl groups and the phenyl ring atoms.[2] A similar dissymmetry in th exocyclic angles has been observed in the structure of ethyl 3,4,5-dimethoxy-2-(3-methyl-2,2-pyridylsulphamoyl) phenyl propionate (20).

The torsion angles about the N(1)—C(8), C(8)—C(10), C(10)—C(11), and C(11)—C(12) bonds show that the molecule is nearly in the extended form. The acrylyl chain, O(9)—C(8)—C(10)—C(11)—C(12), makes dihedral angles of 18.7(2) and 24.3(1)° with the mean planes of the phenyl and piperidone rings, respectively.

The puckering parameters (21) for the different rings in the structure have been listed in Table 4. The piperidone ring is seen to have a distorted boat conformation. The piperidine ring, common in several amide alkaloids separated from *Piper* species (2–4) and in compounds containing piperidyl carbonyl groups (17), is found to be in the chair conformation.

The benzene ring is significantly nonplanar (11); the puckering parameters indicate a somewhat flattened distorted boat conformation for the ring (21).

The C—H groups that are near the electron withdrawing groups are capable of forming hydrogen bonds with a wide variety of acceptor atoms (22). The geometries of the intramolecular contacts C(10)—H(10)...O(7) and C(11)—H(11)...O(9), listed in Table 5, reveal that the ethylenic C—H groups in the present structure are indeed involved in such hydrogen bonds, leading to the formation of two hydrogen bonded rings. The six-membered ring, C(10)—H(10)—O(7)—C(2)—N(1)—C(8), is found to have a twist boat conformation while the five-membered ring, C(11)—H(11)—O(9)—C(8)—C(10), is in the twist form (Table 4) (21). In the course of the present study it has been found that a similar C—H...O bond, leading to the formation of a five-membered ring in the twist form, also exists in the structure of Piperx, *N*-piperidyl-5-(2-methoxy-4,5-methylenedioxyphenyl)-*trans*-2-*cis*-4-pentadienamide (2). Figure 2 shows a perspective view[3] of the crystal structure. The molecules are separated by unit cell translations along the *b* direction with translation related atoms superimposed. The unit vector along the *b* axis, 4.089(4) Å, is seen to be the sum of the van der Waals radii of the superimposing methyl groups.

[2]The C(13)—C(19), C(19)—H(13), C(17)—C(23), and C(23)—H(17) distances are 2.794(5), 2.51(3), 2.805(4), and 2.58(4) Å, respectively.

Acknowledgments

Transferts d'électrons assistés par les métaux de transition : influence de la nature du cation métallique sur la réduction de composés carbonylés en milieu aprotique

F. FOURNIER et M. FOURNIER. Can. J. Chem. **64**, 881 (1986).

L'électropinacolisation de cétones est favorisée en présence de cations des métaux de transition. C'est un phénomène général qui se produit avec Cr^{2+}, Mn^{2+}, Fe^{2+}, Co^{2+}, Zn^{2+}, mais pas avec Ni^{2+}. La réduction conduit aux α-glycols, avec un bon résultat, sans résinification et à un potentiel moins négatif que celui de la cétone de départ. La répartition des composés isolés dépend du caractère acide, au sens de Lewis, et du pouvoir complexant du cation métallique. Ainsi, la plus grande spécificité, en dimère généralement, est observée avec Fe^{2+}, sauf pour la chalcone, où Zn^{2+} conduit à la meilleure stéréosélectivité. Aucun complexe préexistant, entre le dérivé carbonylé et l'ion métallique, n'a pu être mis en évidence.

F. FOURNIER and M. FOURNIER. Can. J. Chem. **64**, 881 (1986).

The pinacolisation of ketones is enhanced when a bivalent transition metal cation is present. This phenomenon is general and occurs with Cr^{2+}, Mn^{2+}, Fe^{2+}, Co^{2+}, Zn^{2+} but not with Ni^{2+}. The cathodic reduction leads to α-glycols with a good yield, without any resin production, and at a less negative potential than that of the ketone itself. The distribution of all isolated compounds is dependent on the Lewis character-acidity and complexing power of the metallic cation. Thus, for the dimerization, the greatest specificity is generally observed when Fe^{2+} is present. For the chalcone, the better stereoselectivity is obtained with Zn^{2+}. No evidence of initial carbonyl complex of the metal ion was shown.

Les réactions catalysées par transferts d'électrons et plus particulièrement celles assistées par les complexes de métaux de transition, font l'objet d'études intensives (1).

Le cas des composés carbonylés, spécialement celui des cétones aromatiques, suscite depuis ces dernières années quelques controverses (2). En effet, le problème essentiel qui se pose dans l'interprétation du mécanisme de la réduction électrochimique duplicative de la fonction carbonyle est celui de l'étape de couplage. Ainsi après formation initiale de l'anion radical $A^{\bar{\cdot}}$, éventuellement suivie de sa protonation, trois types de couplage peuvent être envisagés : (*1*) radical–radical ; (*2*) radical–substrat ; (*3*) ion–substrat. Ce qui peut être résumé par le Schéma suivant :

Étape initiale $A + \bar{e} \rightleftharpoons A^{\bar{\cdot}}$ et $A^{\bar{\cdot}} + H^+ \rightleftharpoons AH^{\cdot}$

Mécanisme 1 $2\,A^{\bar{\cdot}} \rightleftharpoons D^{2-}$, $A^{\bar{\cdot}} + AH^{\cdot} \rightleftharpoons DH^-$, $2\,AH^{\cdot} \rightleftharpoons DH_2$

D = dimère
DH^- = dimère anion protoné
DH_2 = dimère

Mécanisme 2 $A + A^{\bar{\cdot}} \rightleftharpoons D^{\bar{\cdot}}$, $A + AH^{\cdot} \rightleftharpoons DH^{\cdot}$

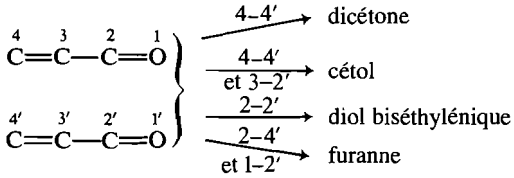
Puis éventuellement $D^{\bar{\cdot}} + \bar{e} \rightleftharpoons D^{2-}$, $DH^{\cdot} + \bar{e} \rightleftharpoons DH^-$

Mécanisme 3 $A^{\bar{\cdot}} + \bar{e} \rightleftharpoons A^{2-}$, $A^{2-} + H^+ \rightleftharpoons AH^-$

(fixation d'un 2ème $\bar{e}$) $A^{2-} + A \rightleftharpoons D^{2-}$, $AH^- + A \rightleftharpoons DH^-$
et éventuellement $A^{2-} + 2H^+ \rightleftharpoons AH_2$

ce qui se traduit sur le plan préparatif, par l'obtention de différents produits, monomères ou dimères.

Par exemple, avec les cétones aromatiques, on obtient uniquement des alcools (monoalcool ou diol). Par contre, avec les cétones α-β éthyléniques, les hydrodimères formés peuvent avoir des structures diverses, le radical anion créé existant sous plusieurs formes tautomères. Ainsi selon les liaison formées :



De plus, si le milieu est aprotique, DMF par exemple, l'électroréduction des cétones aromatiques conduit souvent à un fort pourcentage d'alcools par rapport à celui des glycols-α (3). Elle s'accompagne malheureusement d'une intense résinification. Le rapport monomère–dimère dépend de nombreux paramètres (4), et en particulier de la concentration d'éventuels donneurs de protons introduits en cours de réduction (2*b*, 2*c*). La résinification est souvent moins importante pour les cétones insaturées, les composés obtenus correspondant rarement à l'hydromérisation, mais à l'oligomérisation du réactif (dimérisation, trimérisation ...) (5, 6).

Des études polarographiques et voltampérométriques ont également montré que lors de l'électroréduction de quelques cétones aromatiques en présence de cations alcalins ou alcalino-terreux (2*e*, 7) (Na^+, Li^+, K^+, Ba^{2+}), il se forme des paires d'ions souvent instables qui disparaissent par dimérisation ou dismutation. Le schéma réactionnel couramment proposé est alors le suivant :

$$\left.\begin{array}{rl} 2\,R^{\bar{\cdot}} & \xrightarrow{k_1} \\ R^{\bar{\cdot}}....Me^+ + R^{\bar{\cdot}} & \xrightarrow{k_2} \\ 2R^{\bar{\cdot}}.....Me^+ & \xrightarrow{k_3} \end{array}\right\} \text{produits}$$

1. Auteur à qui adresser toute correspondance.
2. Révision reçu le 16 décembre 1985.

De notre côté, nous avions pu montrer qu'en présence d'un cation métallique de transition tel que Cr(III) ou Mn(II), la réduction électrochimique des cétones aromatiques (8, 9) ou α-β insaturées (5) conduisait préférentiellement aux hydrodimères avec inhibition totale des polymérisations, et ce, au potentiel même de réduction du métal(II) lorsque ce dernier a un potentiel de demi-vague plus positif que celui de la cétone.

Cet effet entraine un gain d'« énergie » pouvant atteindre 500 mV. L'interprétation de ce processus d'électroréduction assistée est complexe bien que certains auteurs pensent en avoir élucidé le mécanisme (10, 11). De plus, leurs études sont restées limitées au seul cas du chrome, alors que nous avons montré que le manganèse présente une action également bénéfique (9).

Il nous a paru indispensable d'établir la généralité du phénomène en variant la nature du cation métallique.

Notre choix, affecté par la solubilité dans le DMF du chlorure correspondant, a privilégié les éléments de la première série de transition (Cr, Mn, Fe, Co, Ni, Zn) pour étudier l'influence de la configuration électronique sur l'orientation du processus de réduction. Puisque nous avions suggéré antérieurement que le caractère acido-basique du cation métallique pouvait influer sur le mécanisme de l'hydrodimérisation (5), il nous a paru judicieux de pratiquer parallèlement l'étude électrochimique et les électrolyses préparatives en présence de Li^+, dont le caractère acide est bien connu dans ce milieu.

Pour éviter toute ambiguïté quant à la structure des composés formés et pour faciliter l'établissement des bilans réactionnels, notre étude s'est volontairement limitée à quelques cétones aromatiques, cycliquement ou linéairement encombrées, dont le potentiel de réduction diffère de, ou avoisine, celui du cation métallique, et à une cétone α-β éthylénique. Ces composés sont présentés dans la figure 1.

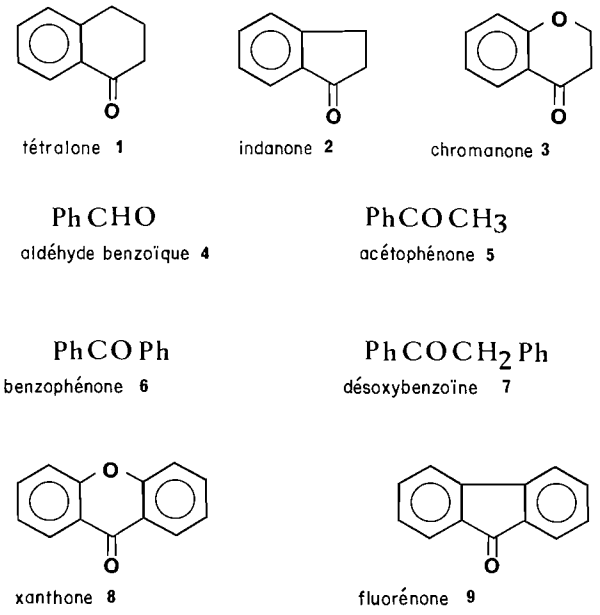


FIG. 1

A. *Analyse polarographique (tabl. 1) et voltammétrique (tabl. 2)*

I. Ions des métaux de transition

Les polarogrammes et voltammogrammes des espèces Cr(III) et Mn(II) dans le diméthylformamide (DMF) ont été précédemment décrits (8, 9). En ce qui concerne les autres cations, leur polarogramme, pour des solutions de concentration 10^{-3} *M* dans le DMF, présente, soit une seule vague de réduction biélectronique (cas de $FeCl_2 \cdot 4H_2O$ ou de $NiCl_2 \cdot 6H_2O$), soit deux vagues de réduction monoélectroniques de hauteurs sensiblement égales (cas de $CoCl_2 \cdot 6H_2O$).

L'analyse par voltamétrie cyclique de ces différents systèmes montre que les pics correspondants aux processus

$$\text{ou} \begin{cases} M^{II} + 2\bar{e} \longrightarrow M^0 \\ M^{II} + \bar{e} \longrightarrow M^I \\ M^I + \bar{e} \longrightarrow M^0 \end{cases}$$

sont de nature irréversible.

Sur électrode stationnaire, sans renouvellement de la goutte de mercure, les voltammogrammes se modifient à chaque cycle jusqu'à disparition complète du phénomène de réduction. Si l'on renouvelle la goutte après chaque balayage, et après agitation de la solution par barbottage d'argon, une variation linéaire du potentiel du premier pic de réduction E_{pc1} avec le logarithme de la vitesse de balayage (v) est observée. Ces résultats sont rassemblés dans le tableau 2.

La solution de $ZnCl_2$ anhydre ne présente pas de vague de réduction dans le domaine d'électroactivité accessible dans ces conditions.

Cette absence de réductibilité, surprenante au premier examen, méritait d'être confirmée. Des essais répétés en solvant anhydre nous ont permis d'établir ce résultat sans ambiguïté. Toutefois, l'addition de traces d'eau (1% en volume) ou l'utilisation de DMF insuffisamment déshydraté permet de révéler, vers −2 V, une vague de hauteur sensiblement égale à celle de Mn^{2+} lorsqu'on l'enregistre dans les mêmes conditions. Cette vague est très sensible à la présence d'eau et peut même se déplacer jusqu'à −1,8 V si le zinc est complètement hydraté.

Ce phénomène n'est pas affecté par la nature de l'anion du sel de fond puisque les résultats sont inchangés en présence de TBA ClO_4. Le cation Zn^{2+}, solvaté par le DMF, est donc non réductible dans ce domaine d'électroactivité (−0,4 V ; −3 V). Ce résultat fera l'objet d'une publication prochaine.[3]

II. *Cétones*

Elles présentent toutes une première vague de réduction polarographique qui correspond à l'échange d'un électron. En effet, leur hauteur est égale à moins de 10% près à celle de la vague de réduction du benzaldéhyde enregistrée dans les mêmes conditions et dont il est établi (12) qu'elle traduit un échange monoélectronique réversible.

Cette première vague est réversible, pour toute vitesse de balayage, dans le cas des cétones aromatiques (composés **1**–**9**). Par contre pour la chalcone **10**, si le balayage est inférieur à 0,5 V s^{-1}, la réduction devient irréversible.

Dans tous les cas, la seconde vague de réduction est, lorsqu'elle n'est pas masquée par la décharge de l'électrolyte support, irréversible et sensiblement monoélectronique.

III. *Mélanges cétone – cation métallique*

Dans un souci de simplicité évidente, nous n'avons considéré

3. Un des rapporteurs s'est étonné de la non réductibilité de Zn^{2+} dans ce milieu et suggère une intervention des anions halogénures introduits simultanément aux cations puisque les sels de départ sont des chlorures et le sel de fond un bromure. Il nous paraît, que la présence d'eau, même à l'état de traces, est le facteur essentiel, ce qui expliquerait nos divergences avec les résultats publiés antérieurement.

TABLEAU 1. Potentiels de demi-vague polarographique d'un mélange équimolaire 10^{-3} *M* de cation métallique et de cétone dans du DMF contenant TBABr 0,1 *M* (ECS)

que l'influence du cation métallique sur la première vague de réduction du composé carbonylé.

(a) *Cations non réductibles : Li^+, Zn^{2+}*

Quelle que soit la cétone, leur action est un simple abaissement du potentiel de réduction dans un effet rappelant celui des protons. En voltamétrie cyclique, le pic correspondant devient alors irréversible pour toute vitesse de balayage.

Ceci rappelle l'effet bien connu des ions alcalins ou alcalino-terreux, habituellement interprété par la formation de paires d'ions entre le radical anion et le cation. Toutefois, cette interaction est souvent plus importante sur l'espèce A^{2-} que sur le radical anion $A^{\cdot-}$, ce qui se traduit, sur les polarogrammes, par un rapprochement des deux étapes monoélectroniques, pouvant même conduire à leur confusion. Ceci est particulièrement bien mis en évidence dans le cas des quinones (7*c*). Dans notre cas, seule la première vague est très notablement affectée et le zinc présente un effet moindre que celui du lithium.

(b) *Cation beaucoup plus réductible que la cétone : Ni^{2+}*

On observe alors (polarographie et voltammétrie cyclique) la simple additivité des systèmes en présence, sans intéraction.

(c) *Cations de potentiel de réduction voisin de celui du composé carbonylé : Cr^{2+}, Mn^{2+}, Fe^{2+}*

Dans le cas où le potentiel de réduction du cation métallique est plus négatif que celui de la première vague de réduction de la cétone (fluorénone **9**, chalcone **10**), la vague de réduction du système M(II)/M(0) disparaît et la première vague de réduction de la cétone se trouve avancée vers des potentiels plus positifs (de 50 à 100 mV selon les cas), rappelant ainsi l'action des cations non réductibles. Il en est de même avec le cation zinc aquo, $Zn{\cdot}(H_2O)_4{}^{2+}$ lorsque sa vague de réduction peut être observée.

Si le potentiel de réduction du cation métallique est moins négatif que celui de la cétone (cétones aromatiques **1**–**8**), la vaque de réduction de cette dernière disparaît complètement

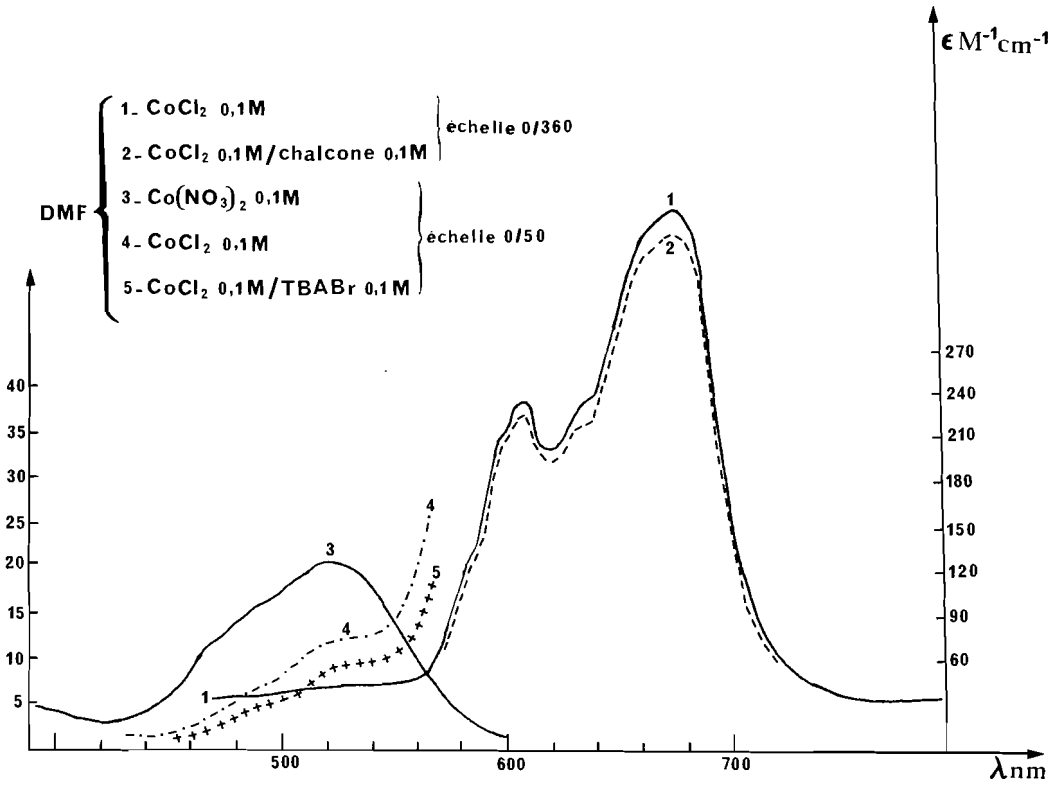

FIG. 2. Spectres d'absorption électronique des mélanges sel de cobalt – chalcone.

pour des quantités équimolaires de cétone et de sel métallique. La vague de réduction du métal M(II) → M(0) est très peu affectée et se déplace légèrement vers les potentiels positifs (de l'ordre de 10 mV).

La voltammétrie cyclique montre, pour toute vitesse de balayage supérieure à 5 mV s^{-1}, la simple additivité de systèmes en présence pour quasiment toutes les cétones aromatiques.

Par contre, pour la chalcone **10**, l'addition de quantités croissantes de cation métallique entraîne l'apparition d'un nouveau pic, irréversible, qui remplace progressivement le premier pic de réduction de la chalcone. Sa hauteur croit et le potentiel de pic E_{pc1} se déplace légèrement vers des potentiels moins négatifs. À l'équimolarité, ce nouveau pic, traduit une réaction monoélectronique. L'addition d'un excès de cation métallique n'affecte pas le potentiel de pic, mais augmente légèrement sa hauteur. Les pics de réduction propres au cation métallique ne réapparaissent jamais.

Le comportement des systèmes **6***d*, **7***c* et **8***b* est intermédiaire ; il dépend fortement de la vitesse de balayage, et nous verrons plus loin que dans ces cas le monoalcool est obtenu seul et quantitativement.

(d) *Cas du cobalt* Co^{2+}

Les vagues polarographiques sont mal définies en raison de la complexité du système $Co^{2+}/Co^{(0)}$. Toutefois, quelques effets marqués peuvent être observés. Pour les cétones dont la première vague de réduction est située entre les deux vagues de réduction $Co^{2+} \rightarrow Co^{+}$, $Co^{+} \rightarrow Co^{(0)}$ du cation métallique (cétone aromatiques **1**–**8**) la deuxième vague de réduction du cation métallique ($Co^{+} \rightarrow Co^{0}$) disparaît sans que la vague correspondant au système $Co^{2+} \rightarrow Co^{+}$ soit affectée. La vague de réduction de la cétone est alors légèrement déplacée vers des potentiels moins négatifs. Le phénomène est proche de celui observé dans le cas du chrome(III) et décrit antérieurement (5, 10, 11).

Pour les cétones dont la réduction se fait avant celle du système métallique (florénone **9** et chalcone **10**), les vagues du système Co^{2+}/Co disparaissent comme dans le cas précédent (III(c)) et la première vague de réduction de la cétone se déplace vers des potentiels moins négatifs.

En voltammétrie cyclique, le phénomène est analogue à celui décrit en III(c).

IV. *Discussion*

Dans tous les cas de cétones aromatiques, il apparaît que l'interaction composé carbonylé – espèce métallique est cinétiquement lente, puisqu'elle n'affecte les voltammogrammes que pour des vitesses de balayage inférieures à 5 mV s^{-1}, domaine où les processus de diffusion deviennent prépondérants. Aux vitesses supérieures, les systèmes cation métallique/métal – cétone/radical anion se comportent indépendamment, y compris en terme de réversibilité de la première étape du dérivé carbonylé. Les modifications observées aux faibles vitesses ne peuvent donc provenir que d'une réaction lente impliquant l'espèce métallique. Par contre, dans le cas d'insaturation (chalcone **10**) ou dans les cas **8***b*, **6***d* et **7***c*, l'interaction est soit très rapide, soit d'une autre nature ; puisque la disparition du pic de réduction du métal est observée même pour des vitesses supérieures à 5 mV s^{-1} et jusqu'à des vitesses égales à 500 mV s^{-1}, limite supérieure accessible avec notre appareillage. La variation du potentiel du premier pic de réduction du système cétone – cation métallique en fonction de log v^4 ($\delta E_{pc1}/\delta \log v$) est fortement dépendante du cation métallique présent comme le

4. Un des rapporteurs suggère de discuter plutôt de la dépendance de E_{pc} avec la concentration C_R du substrat, en considérant les valeurs des pentes $\delta E_{pc}/\delta \log C_R$. Cette remarque fondée nécessite toutefois de pouvoir explorer un domaine de concentration suffisamment étendu, ce qui nous était difficile compte tenu de la faible solubilité des halogénures utilisés.

montre le tableau 2, et ceci que cette première étape soit attribuée à la réduction du cation ou à la réduction du dérivé carbonylé.

Ceci suggère donc que l'échange électronique a lieu sur chaque espèce indépendamment, bien que suivi d'une interaction forte entre les espèces formées, interaction dont la cinétique peut être lente ou très rapide selon le cas.

B. *Étude spectrophotométrique*

Dans le but de mettre en évidence un éventuel complexe cétone – ion métallique préexistant dans la solution avant électrolyse et de déterminer l'influence des ions halogénures (chlorures et bromures) présents en concentration importante, nous avons choisi d'étudier l'influence du dérivé carbonylé sur le spectre d'absorption du cation métallique. Cette étude a été menée avec le cobalt, dont le spectre d'absorption électronique est caractéristique (fig. 2), dans les conditions de concentration des électrolyses préparatives.

Dans le DMF, pour l'ion cobalteux, si le contre ion n'est pas complexant (nitrate par exemple), le spectre est voisin de celui de l'ion hexa aquo (λ_{max} 520 nm, ϵ = 22,5). Par contre, à la même concentration, le chlorure cobalteux hexahydraté fournit un spectre caractéristique du complexe tétraédrique $CoCl_4^{2-}$ en présence de la quantité équivalente du complexe aquo. Si le sel est dissout en présence de TBABr 0,1 *M*, alors la proportion de cobalt cationique décroit au profit du mélange des complexes halogénés.

L'addition de benzophénone **6** à la solution dans le DMF du composé cationique aquo $Co{\cdot}(H_2O)_6^{2+}$ ne modifie pas le spectre du complexe cationique. Il en est de même dans le cas du complexe anionique. Aucune modification dans la répartition des deux espèces n'est perceptible. Ainsi, peut-on considérer qu'il n'y a pas d'interaction préexistante significative dans ce cas.

La même étude a été menée avec la chalcone **10**. Là encore, aucune interaction ne se manifeste sur le spectre de l'élément métallique. Il en est de même du spectre de la chalcone **10**, qui n'est pas influencé par la présence du cobalt. La même observation peut être faite pour une solution de chalcone dans LiCl 0,1 *M*.

C. *Électrolyses à potentiel contrôlé*

Les bilans réactionnels globaux, en produits effectivement isolés, pour chaque composé et chaque système métallique sont rassemblés dans le tableau 3. Les résultats des électrolyses préparatives confirment la différence de comportement des cétones aromatiques et d'un composé α-β insaturé, comme la chalcone, telle qu'elle est suggérée par la voltammétrie cyclique.

I. *Coulométries*

(a) *Chalcone **10***

Réalisées dans les conditions d'équimolarité cétone – cation métallique, au palier de la nouvelle vague de réduction de **10**, les coulométries confirment, pour tout métal, un échange monoélectronique (1–1,2 F/mol selon les cas).

(b) *Cétones aromatiques **1–9***

La proportion respective *R* de cation métallique et de cétone a été déterminée empiriquement par variation continue de telle sorte que ces conditions expérimentales permettent la conversion totale du composé carbonylé de départ.

Dans le cas où le cation métallique n'est pas réductible (Li^+, Zn^2), l'équimolarité (R = 1) des composants suffit pour transformer la totalité de la cétone par réduction au palier de sa première vague et après passage d'une quantité d'électricité Q variable selon le composé carbonylé et telle que

$$1{,}5\ \text{F} \leqslant Q \leqslant 2\ \text{F pour } Li^+$$

$$2\ \text{F} \leqslant Q \leqslant 3\ \text{F pour } Zn^{2+}$$

Lorsque le cation métallique est lui-même réductible (Cr^{3+}, Mn^{2+}, Fe^{2+}, Co^{2+}), mais de potentiel de réduction voisin de celui de la cétone, la réduction a été menée au potentiel du palier de la vague de réduction du cation métallique (système M^{II}/M^0) dans le cas des composés **1–8**. Dans le cas du composé **9**, c'est la première vague de réduction de la fluorénone qui est touchée et nous considérerons ce composé à part.

Pour un composé donné, les proportions respectives des constituants dépendent fortement du métal. Si l'équimolarité (R = 1) suffit pour Cr^{3+} et Mn^{2+}, il faut doubler la quantité du cation (R = 2) dans le cas où M = Fe ou Co. Ainsi, pour la tétralone **1** en présence de Fe^{2+}, l'électrolyse ne conduit après séparation qu'à un taux de conversion de 78% (60% de diol *d,l* et 18% de diol *méso*) si R = 1.

Ceci s'explique si l'on prend en compte les quantités respectives anion/cation dans ces deux cas précis (fig. 2) où l'étude spectrophotométrique indique une équipartition entre les complexes cationiques et anioniques, et si l'on admet que c'est l'espèce cationique qui intervient dans le phénomène d'électrocatalyse. Il en est vraisemblablement de même dans le cas du fer(II). Les quantités d'électricité sont telles que les taux de conversion de 100% ne sont obtenus que pour

$$Q = 4\ \text{F}\ (Cr^{3+});\ 3\ \text{F}\ (Mn^{2+})$$

$$3\ \text{F} \leqslant Q \leqslant 5\ \text{F}\ (Fe^{2+}, Co^{2+})$$

Si l'on considère (8) que le système $Cr^{3+} \rightarrow Cr^{2+}$ consomme 1 F sans intervenir dans le processus, ce qui est confirmé par l'utilisation de chrome(II), alors chrome et manganèse sont équivalents du simple point de vue de la coulométrie (3 F). Par contre, après prise en compte de l'excès d'espèce métallique, fer et cobalt induisent un échange tel que $1\ \text{F} \leqslant Q \leqslant 3\ \text{F}$ selon le cas; c'est-à-dire un comportement intermédiaire entre Li^+ et Cr^{2+} (Mn^{2+}). Si le cation métallique est beaucoup plus réductible que la cétone (Ni^{2+}), le taux de conversion T est toujours nul quel que soit R.

La fluorénone **9** se distingue des autres cétones aromatiques. Le taux de conversion est nul (T = 0) avec Li^+, Mn^{2+} et Ni^{2+} quel que soit R. Il est maximum (T = 100%) avec Cr^{3+}(R = 1, Q = 4 F); Co^{2+} (R = 2, Q = 1,7 F); (R = 2, Q = 1,2 F).

Dans ce cas encore, si le rapport fer/fluorénone est R = 1, le taux de conversion est T = 80% et après traitement le mélange comprend 80% de diol et 20% de fluorénone non transformée.

II. *Résultats et discussion*

L'influence de Ni^{2+} est nulle et les résultats des électrolyses préparatives confirment les prévisions qui pouvaient être faites de l'examen des polarogrammes et des voltammogrammes.

Par contre, comme le montre le tableau 3, la nature et la répartition des produits obtenus dépendent plus ou moins du cation présent selon la cétone étudiée.

(a) *Cétone α-β insaturée **10***

La structure des hydrodimères obtenus par électroréduction de la chalcone **10** a été résolue dans une publication antérieure (5). La prise en compte des facteurs orbitalaires et des données électrochimiques a permis de proposer, pour chaque hydrodimère, un mécanisme de formation. Dans ce mémoire (5), nous avions montré qu'en l'absence de cation métallique, la réduction électrochimique (DMF, TBABr 0,1 *M*) conduit, par une réaction d'oligomérisation radicalaire, à un trimère cétoni-

TABLEAU 3. Résultats des électrolyses préparatives

que cyclique avec un rendement de 60%, à côté de résines non séparables. Nous avions montré également qu'en présence d'un cation métallique, tel que Cr^{3+}, le taux de conversion et le rendement chimique sont toujours de 100%, le produit majoritaire étant toujours un β-cétol.

Qu'en est-il, en présence d'ions métalliques de polarisabilité différente, mais qui, dans ce cas, se réduisent toujours après le composé carbonylé, et dont les voltammogrammes suggèrent une interaction cétone–cation forte et rapide qui pourrait être de type paire d'ions?

(*i*) *Cations non réductibles*

En présence de Li^+, le β-cétol est obtenu de façon sélective, avec un rendement très élevé, sous ses deux formes *cis* (46%) et *trans* (46%).

En présence de Zn^{2+} anhydre, le même cétol est obtenu avec un rendement de 97%, mais uniquement sous sa forme *trans*. Dans ces deux cas, un seul produit est formé et la variation du potentiel de pic de réduction de la cétone avec la vitesse de balayage est une droite de pente −32 mV. La pente théorique pour un mécanisme de couplage radical anion – substrat est de 30 mV (13). Ceci suggère que le mécanisme de formation du β-cétol débute par l'attaque d'un radical anion sur une molécule neutre. Un tel couplage a d'ailleurs été proposé par Savéant dans le cas de milieux aprotiques très secs (14). Le radical anion serait stabilisé par formation d'une paire d'ions avec le cation métallique, ce qui est conséquent avec la variation du ptoentiel de demi-vague du composé carbonylé vers les potentiels positifs. De telles interactions sont fondamentales dans les processus biochimiques où l'ion Zn^{2+} est particulièrement efficace dans l'hydrolyse des chaines peptidiques. De la même façon, l'influence de l'ion Mg^{2+} a déjà été signalée lors de la réduction de composés carbonylés (15).

(*ii*) *Cations réductibles : Cr^{2+}, Fe^{2+}, Co^{2+}, Mn^{2+}*

Les composés obtenus sont les mêmes pour tous ces cations : cétone, dicétone, β-cétols, mais leur répartition dépend sensiblement du cation métallique antagoniste. La différence de comportement est maximum avec Co^{2+}. Avec Mn^{2+}, on note la présence d'un composé nouveau hydroxy-4 furannique en place de la dicétone. Ce nouveau composé est présent sous forme d'au moins trois diastéréoisomères.

L'ensemble de ces observations peut se relier au caractère acide de Lewis de ces cations si l'on se réfère à l'échelle de dureté au sens de Jorgensen (16):

$$\sigma_A = \frac{E^0 + 4{,}5}{z}$$

σ_A représentant la douceur, E^0 le potentiel standard du couple M^{z+}/M^0, z la charge de l'ion, et l'on suppose que les cations sont solvatés d'une manière équivalente.

Dans ces conditions, les ions se classent comme ci-dessous :

Li^+	Mn^{2+}	Cr^{2+}	Zn^{2+}	Fe^{2+}	Co^{2+}	
1,48	1,65	1,79	1,87	2,03	2,11	douceur

Il apparaît bien que le caractère acide de Mn, Fe, Cr, est de même nature, l'ion Co^{2+} étant un peu moins dur d'où une moindre proportion de cétol si l'on admet que c'est bien une interaction de nature acide qui favorise ce composé (5).

Le mécanisme primaire est complexe puisque la nature des produits obtenus est variée et l'examen des pentes $\delta E_{pc}/\delta \log v$ est d'un faible secours puisque la compétition entre plusieurs mécanismes est probable. Le cas de Cr^{2+} est peut être le plus simple puisque le système métallique seul n'interfère pas (pente nulle pour l'ion isolé).

Dans ce cas, une pente de 22 mV est obtenue en présence de chalcone, ce qui peut être interprêté comme une dimérisation primaire du radical anion conduisant à la dicétone, ce processus imposant sa vitesse. Le caractère électrophile du substrat dépendant de la force de l'interaction avec le métal de transition, un acide dur orientera préférentiellement la duplication vers une réaction de type radical anion – substrat; un acide mou défavorisera cette interaction d'autant plus qu'il est mou et la réaction radical anion – radical anion ne s'en exprimera que mieux.

(b) *Cétones aromatiques **1–9***

La plupart des cations se réduisent avant le composé carbonylé et c'est sur cette vague que nous conduisons l'électrolyse. Dans les quelques cas où le cation métallique se réduit après le composé carbonylé (Li^+, Zn^{2+}), on conduit l'électrolyse au potentiel de réduction de la cétone, valeur déplacée vers les potentiels moins négatifs, vraisemblablement par un effet de type paires d'ions comme en la réf. 7. Les résultats des électrolytes préparatives sont plus complexes à analyser, quel que soit le cation métallique.

Toutefois, dans le DMF, en présence de cation métallique, nous dégageons quelques points importants :

Les résinifications sont totalement supprimées.

Les cétones aromatiques encombrées sont réduites au potentiel de réduction du cation métallique, ce qui représente souvent un gain supérieur à 400 mV (**1**, **2**, **3**, **5**, **7**) par rapport au potentiel de réduction de la cétone seule.

La répartition des produits obtenus, diols ou alcools, dépend beaucoup du métal. Les différences les plus marquées sont obtenues dans le cas des composés **5**, **6**, **7**, **8** et **9**.

De tous les cations Fe^{2+} est le plus sélectif puisque dans presque tous les cas le diol est obtenu comme produit unique, sous forme *méso* ou *dl*, avec un rendement supérieur à 85%.

Le rendement faradique (exprimé comme le rapport entre la coulométrie théorique de réduction de la cétone (1 F/mol) et la coulométrie réelle) est toujours inférieur à 1. Il est même quelque fois très faible (0,2) contrairement au cas de la chalcone **10** où le rendement faradique est toujours voisin de 1.

Dans tous les cas où le monoalcool est obtenu seul (cas **8***b* avec Cr^{2+}, **7***c* avec Mn^{2+}, **6***d* avec Fe^{2+}), on n'observe, en voltammétrie cyclique, que le pic de réduction du composé carbonylé et ceci quelles que soient les vitesses de balayage. Le pic du cation métallique n'apparaît jamais. Au contraire, dans le cas où le diol est formé, la voltammétrie cyclique montre une simple additivité des systèmes ; il est logique de supposer que le système métallique est le premier touché.

Les taux de conversion ne sont en général pas proportionnels à la quantité d'électricité échangée. Ainsi lorsque le diol est le seul produit formé, on attend un rendement de 0,33 F puisque 2 F sont consommés dans la réaction $M^{II} \rightarrow M^0$ en sus d'une éventuelle réduction du composé carbonylé. C'est en particulier le cas de Cr^{2+} et Mn^{2+}. Un test simple permet de confirme cette observation. Dans le cas de la tétralone **1**, si l'électrolyse en présence de Mn^{2+} est arrêtée après 2,2 F, seulement 63% de diol se sont formés et 20% de **1** n'ont pas été transformés ; 0,8 F sont donc nécessaire à la transformation des 20% restants. Le même test mené avec Cr^{2+}, conduit après passage de 1,5 F à un mélange de 60% de produit de départ **1** et 29% de diol. Il faut donc 1,5 F pour transformer les 60% restants.

La présence simultanée du cation métallique et du composé

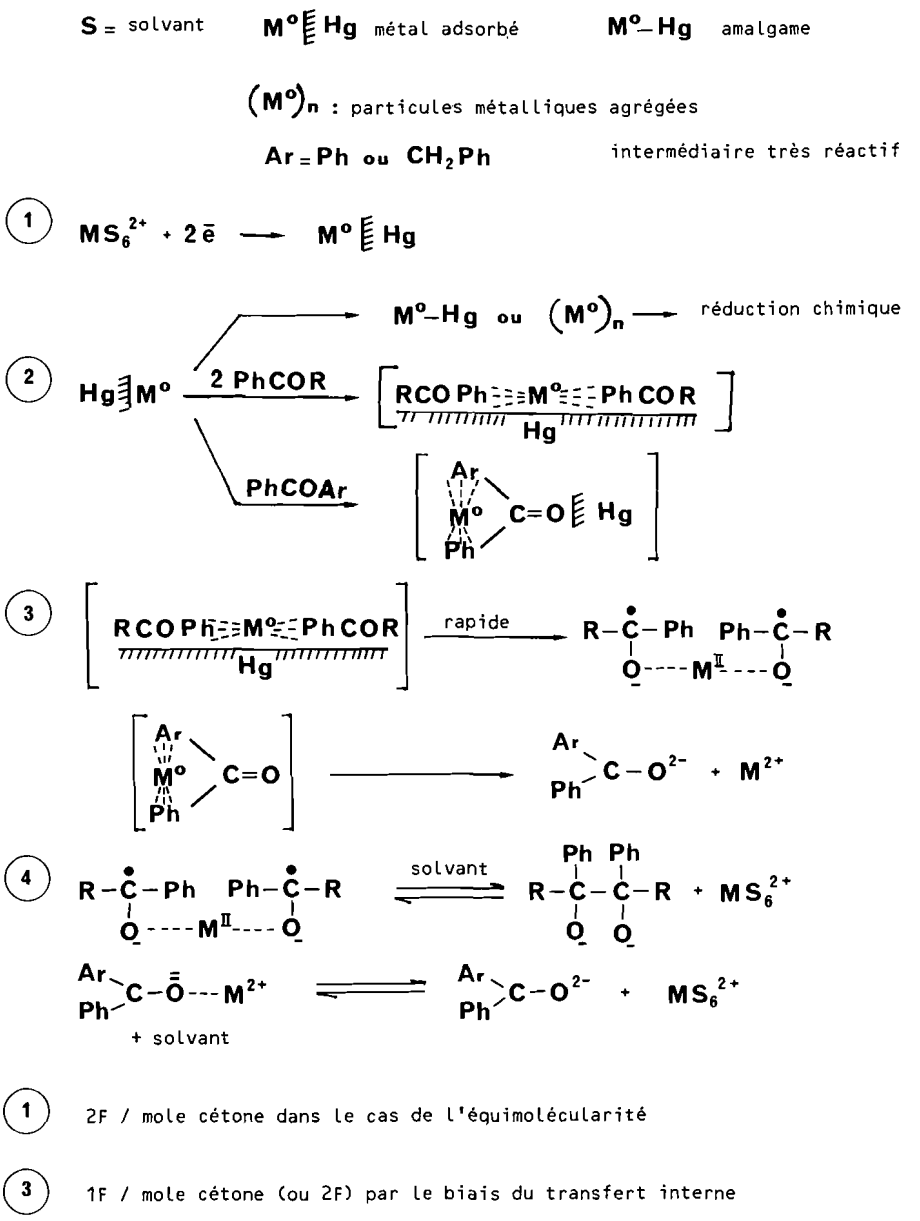

FIG. 3. Schéma réactionnel possible pour l'électroréduction catalysée de cétones aromatiques.

carbonylé est indispensable au processus d'électroréduction. Ainsi, un test de préélectrolyse du cation jusqu'à l'état métallique (2 F) suivi de l'introduction de la cétone **1** dans le compartiment cathodique en maintenant le potentiel du mercure au potentiel de réduction du métal ne conduit à aucune duplication (on récupère intégralement la cétone de départ si le cation est Mn^{2+} ; la résinification est totale avec Fe^{2+}).

Le rendement final dépend fortement de la quantité de cation présente. Ainsi si la préélectrolyse du cation n'est menée que jusqu'à 1,5 F (cas de $MnCl_2$) puis poursuivie normalement, après ajout de la cétone **1**, jusqu'à son terme (3 F), on récupère après séparation 50% de diol et 35% de résines. 25% de la quantité initiale de cation ont permis 50% de duplication.

D. *Interprétation*

L'ensemble de ces observations, bien que ne permettant pas d'élucider complètement et définitivement les mécanismes mis en jeu, suggère cependant quelques voies d'approche.

Dans les cas les plus simples (chalcone **10**, cations peu ou non réductibles), le composé carbonylé est le premier réduit et le radical anion formé interagit plus ou moins fortement avec le cation métallique dans une interaction de type paire d'ions $R^{\bar{\cdot}}$ ... M^+ ou $R^{\bar{\cdot}}$ ... M^{2+} ... $R^{\bar{\cdot}}$. Ceci est assez classique. Le radical ainsi stabilisé peut alors réagir sur une molécule neutre ou sur lui-même. Dans tous les cas, si le cation était réductible son potentiel de demi-vague devient plus négatif dans cette interaction et peut se trouver repoussé lors de la zone d'électroactivité.

L'interprétation des autres systèmes est plus délicate. La première étape de réduction doit être nécessairement le passage du cation à l'état métallique, le carbonyle n'étant pas touché ; une interaction de type paire d'ions entre le radical et l'ion métallique est impossible.

Comme l'étude spectrale, dans la zone des transferts électroniques du métal de transition, n'a mis en évidence aucune interaction préexistante importante, la présence nécessaire de la cétone en début d'électrolyse ne peut s'expliquer que par interaction entre des centres métalliques réduits à la surface du mercure et le système aromatique du composé carbonylé, avant que le métal ne puisse diffuser dans l'électrode (amalgame) ou

s'agréger en particules inertes (fig. 3). Cette participation du métal de la cathode (mercure) est suggérée par l'observation de la passivation d'une électrode à goutte de mercure déposée sur électrode d'or et polarisée au potentiel de réduction du cation métallique. Après un tel traitement l'électrode reste inactivé vis-à-vis du composé carbonylé même après lavage.

L'amalgame ou le métal divisé peut être réducteur et conduire à la formation de résines, comme dans une réduction classique.[5] La répartition des produits de réaction depend donc des cinétiques de toutes ces interactions. Le comportement de tous ces composés carbonylés peut, peut-être, s'expliquer par le passage progressif d'une interaction forte de type complexe à l'interaction faible de type « acide–base » selon la variation des facteurs orbitalaires, les deux types d'interaction pouvant se manifester conjointement. La force de l'interaction forte dépendrait essentiellement de l'aptitude de l'élément métallique à former des complexes intermédiaires de type π, donc du nombre d'électrons « *d* » du métal. Ainsi dans le cas du chrome (d^6) et lorsque le noyau benzénique (3 doublets π) n'est pas fortement conjugué avec le carbonyle (composés **1**, **2**, **3**, **4**, **5**), les composés type « sandwich » à 18 électrons sont sûrement favorisés. Dans le cas du manganèse, du fer et du cobalt, les complexes ainsi créés seraient à 19, 20 et 21 électrons, ce qui les rendrait particulièrement aptes au transfert électronique interne suivi de la dimérisation des radicaux anions formés et de la libération du métal dans son état d'oxydation 2+. Dans tous ces cas, ce modèle rend compte de la non réductibilité du ligand organique après interaction avec le métal.

Dans le cas où la conjugaison croit (**6**, **7**, **8**) à l'ensemble du système π, défavorisant le complexe « type sandwich » (20 ē pour Cr, puis 21, 22, 23 ē pour Mn, Fe, Co) au profit de l'interaction de type acidobasique au niveau du carbonyle, un échange biélectronique conduisant au monoalcool devient alors possible.

Toutefois trop de paramètres ne sont pas encore maîtrisés, rendant aléatoire une conclusion formelle. La répartition des produits obtenus dépend fortement du cation métallique pour un composé donné.[6] Retenons que, comme nous l'avions suspecté en considérant l'influence des ions Mn^{2+} (9), le phénomène de réduction duplicative observé en présence de Cr^{3+} n'est pas spécifique de ce cation métallique. Le phénomène est général pour toute la première série des éléments de transition et son mécanisme, malgré des indices nouveaux, reste encore à démontrer sans ambiguité.

Partie expérimenale

Les points de fusion ont été déterminés au banc de Köfler. Les spectres ir ont été obtenus avec un spectromètre Pye-Unicam SP 3-200, ceux de rmn ^{13}C avec un appareil Brüker WP 80 et ^1H avec un appareil Brüker SY 250. Les spectres uv ont été enregistrés sur Perkin–Elmer 555. Les spectres de masse ont été effectués sur un appareil AEI type MS 30. Les analyse élémentaires ont été effectuées au laboratoire de microanalyse de l'Université de Paris VI que nous tenons à remercier vivement. Les chromatographies sur couche mince ont été réalisées sur gel de silice fluorescente Merck PF-254 (plaque 20 × 20, e = 0,1 cm).

En électrochimie, tous les potentiels ont été mesurés par rapport à une électrode de référence au calomel – KCl saturé (ECS) munie d'une jonction remplie avec une solution de TBA Br 0,1 *M* dans le DMF (électrode Tacussel RDJ/C 10). Les polarogrammes ont été enregistrés sur une table traçante XY Iffelec IF 3802 couplée à un polarographe PAR 174 A. Les voltammogrammes ont été réalisés grâce à un potentiostat PAR 173 gouverné par un générateur de signaux PAR 175, sur goutte de mercure fournie par une électrode de Kémula à piston micrométrique (Tacussel).

Les électrolyses ont été réalisées en atmosphère d'argon, à température ambiante, avec un potentiostat PAR 173 muni d'un coulomètre PAR 179, sur une cathode de mercure de 26 cm^2 environ de surface et agitée avec un barreau aimanté. Les compartiments anodique et cathodique sont séparés par une pastille de verre fritté de porosité 4 et de 2,5 cm de diamètre. L'anode est un disque de platine de 2 cm de diamètre.

Le DMF utilisé est d'origine Merck; il est préalablement distillé sur P_2O_5. Il contient du bromure de tétrabutylammonium 0,1 *M* et un peu d'eau 2×10^{-2} *M* environ (dosage de Karl-Fischer). Ainsi pour les analyses voltammétriques avec des concentrations en $CrCl_3 \cdot 6H_2O$ ou $MnCl_2 \cdot 4H_2O$ de 10^{-3} *M*, la concentration d'eau est de l'ordre de $2–3 \times 10^{-2}$ *M*; pour les électrolyses où la concentration de sel métallique est en général de 7×10^{-2} *M* (5×10^{-3} moles dans 70 cm^3 de solvant), la concentration d'eau est de 0,45 *M* environ.

En fin de réaction (déterminée par analyse polarographique), le mélange obtenu est versé dans un grand volume d'eau (700 cm^3 au moins), extrait à l'éther et séché sur sulfate de sodium. Le solvant est chassé sous vide, le résidu séparé par chromatographie sur couche mince de silice.

Les produits résultants des électrolyses ont déjà été décrits (5, 17–20) et nous les avons identifiés par leurs caractéristiques physiques et spectroscopiques, par comparaison avec celles d'échantillons authentiques. Les particularités observés et les spectres de rmn des produits obtenus sont donnés dans les réfs. 5 et 21. Le pourcentage respectif des formes *méso* et *dl*, pour les diols de l'acétophénone **5** et du benzaldéhyde **4**, a été évalué par spectroscopie rmn (22, 23). Dans tous les autres cas, les deux isomères *méso* et *dl* ont pu être séparés.

Les halogénures métalliques hydratés sont des produits Prolabo, les composés anhydres étant fournis par Ventron. Dans le cas du chrome les mêmes résultats sont obtenus à partir de la solution de chlorure chromique électrolysée à l'état de chlorure chromeux ou à partir de chlorure chromeux anhydre.

5. Un des rapporteurs rappelle que la plupart des métaux étudiés sont peu solubles dans le mercure et qu'une adsorption du composé organique sur les cristallites métalliques est possible, modifiant le processus d'électroréduction. Ce phénomène est difficilement discernable d'une vraie complexation au sens organométallique comme nous le proposons.

6. Un des rapporteurs rappelle aussi l'influence des métaux de transition dans l'évolution de la réaction des réactifs organomagnésiens avec les fonctions carbonyles (24).

The electrochemical behaviour of the Zn(II)–Zn(Hg) system in aqueous ethylene glycol (EG) solutions containing 5.0×10^{-2} *M* $LiClO_4$ has been studied by polarography and cyclic voltammetry. The reversible half-wave potentials, the diffusion coefficients and the Walden products for Zn(II) have been polarographically determined. The standard free energies of transfer of 1 mol of Zn(II) ions from water to EG–water mixtures, ΔG_t^0, obtained from the reversible half-wave potentials vs. the ferrocene electrode scale, are always negative, indicating a greater stability of Zn(II) in EG–water mixtures than in pure water. The splitting of the ΔG_t^0 values into electrostatic and chemical contributions shows that the mixtures are more basic than water. The analysis of the variation of the Walden product with solvent composition indicates an enhancement of the solvent structure in the water-rich region. The diffusion coefficient for Zn in mercury, the transfer coefficients for Zn(II) electroreduction, and the apparent standard rate constants of the Zn(II)–Zn(Hg) system have been determined by cyclic voltammetry. The change in the kinetics with solvent composition is discussed in terms of existing models.

R. M. RODRÍGUEZ, E. BRILLAS, J. A. GARRIDO et J. DOMÉNECH. Can. J. Chem. **64**, 891 (1986).

Faisant appel à la polarographie et à la voltammétrie cyclique, on a étudié le comportement électrochimique du système Zn(II)–Zn(Hg) dans des solutions aqueuses d'éthylène glycol (EG) contenant $5{,}0 \times 10^{-2}$ *M* de $LiClO_4$. A l'aide de la polarographie, on a déterminé les potentiels réversibles de demi-vague, les coefficients de diffusion et les produits de Walden pour le Zn(II). On a déterminé que les énergies libres standards pour le transfert d'une mole d'ions Zn(II) de l'eau à des mélanges d'eau–EG, ΔG_t^0, qui ont été obtenues à partir des potentiels réversibles de demi-vague vs. l'échelle de l'électrode du ferrocène sont toujours négatives; ce résultat indique que le Zn(II) est plus stable dans des mélanges d'eau–EG que dans de l'eau pure. Le dédoublement des valeurs de ΔG_t^0 en contributions électrostatiques et chimiques permet d'établir que les mélanges sont plus basiques que l'eau. L'analyse de la variation du produit de Walden avec la composition du solvant indique qu'il se produit une augmentation de la structure du solvant dans la région riche en eau. Utilisant la voltammétrie cyclique, on a détermine le coefficient de diffusion du Zn dans le mercure, les coefficients de transferts pour l'électroréduction du Zn(II) et les constantes de vitesses apparentes standards du sytème Zn(II)–Zn(Hg). On discute du changement dans les cinétiques avec la composition du solvant en fonction de modèles existants.

[Traduit par la revue]

Introduction

The electrochemical behaviour of the Zn(II)–Zn(Hg) system has been studied in several organic solvent–water mixtures (1–5). The authors have shown that the kinetics of this system depend basically on the solvation energy which represents the main contribution to the activation energy, and on the adsorption of the organic solvent which modifies the structure of the double layer at the electrode surface. Two different changes in the rate constant with solvent composition have been found, depending on the organic solvent used. Thus, in mixtures of water with less basic organic solvents, the rate constants of the Zn(II)–Zn(Hg) system exhibit minima in the intermediate composition range (1–4). To explain this behaviour, Behr *et al.* (2) propose to determine the rate constant, k, in a given aqueous mixture by means of the expression

$$[1] \quad k = k_w P$$

where k_w is the rate constant in the pure aqueous solution and P a correction term which describes the surface concentration, c, of the reactant ion. This term can be regarded as the distribution coefficient of the reactant between the bulk (α) and surface (σ) phases and it has the following form:

$$[2] \quad P = c^\sigma / c^\alpha = \exp(-{}^\alpha\Delta^\sigma G_t / RT)$$

${}^\alpha\Delta^\sigma G_t$ being the change in the free energy of transfer of 1 mol of ions between both phases. These two phases differ in solvent composition due to adsorption of the organic solvent on the electrode.

On the other hand, in mixtures of water with more basic organic solvents, the rate constants of the Zn(II)–Zn(Hg) system change monotonically when the concentration of the organic component increases (4, 5). This behaviour has been explained using the model of Broda and Galus (6) who propose to calculate the value of k in a given aqueous mixture by the equation

$$[3] \quad k = k_w(1 - \theta_{sol}) + k_{sol}\theta_{sol}$$

where k_w and k_{sol} denote the rate constants in pure water and in pure organic solvent respectively, θ_{sol} is the surface coverage of the electrode by organic solvent molecules. This model considers that two parallel reactions take place due to reactant ions approaching the surface layer and reacting either with the surface organic solvent molecules or with the surface water molecules.

Ethylene glycol (EG) is a common solvent in electrochemistry. Some studies on the electroreduction of several cations with amalgam formation in this solvent and its aqueous mixtures have been reported in the literature dealing with the determination of the reversible half-wave potential and the diffusive properties of the species in solution (7–9). In this way, we have previously investigated (10) the polarographic reduction of Cd(II) in EG–water mixtures with $LiClO_4$ as supporting

electrolyte. Under these conditions, we have found that solvent structure is enhanced in the water-rich region, whereas the ion always has a greater stability in EG–water mixtures than in pure water, suggesting that the mixtures are more basic than pure water.

The purpose of this paper is to study the electrochemical behaviour of the Zn(II)–Zn(Hg) system in EG–water mixtures containing a concentration of 5.0×10^{-2} *M* of $LiClO_4$, to clarify the acid–base and structural properties of these mixtures, and to check the application of the existing models stated above to explain the changes in the kinetics under the influence of the organic solvent.

Experimental

Ethylene glycol (Fluka, A.R. grade) was dried over 3 Å molecular sieves; its water content determined by the Karl Fisher method was lower than 0.05%. Lithium perchlorate (Fluka, A.R. grade) was dried at 130°C under reduced pressure and kept dry afterwards. Zinc sulphate (Merck, A.R. grade) was used without further purification. All solutions were prepared by weight with water obtained using a Millipore Milli Q system.

The polarographic measurements were performed with an Amel model 471 multipolarograph. The cyclic voltammetric measurements were carried out with a P.A.R. model 175 universal programmer, connected to an Amel model 551 potentiostat. The cyclic voltammograms were done at scan rate *v*; values lower than 0.200 V s^{-1} were directly displayed on a Philips model 8043 X–Y recorder, whereas the measurements made at higher scan rates were previously recorded on a Nicolet model 3091 digital storage oscilloscope. The ohmic drop compensation of all voltammetric measurements was achieved with a positive feedback network of the same instruments.

All voltammetric experiments were conducted in a three-electrode cell under nitrogen presaturated with the solution to be investigated. The temperature was kept at 25.0°C. A satured calomel electrode (SCE), with aqueous solution of NaCl, was used as reference electrode and a Pt wire as counter electrode. The flow rate, *m*, of the dropping mercury electrode employed in polarography was 0.628 mg s^{-1} in 0.1 *M* KCl solution on open circuit at a mercury height of 50 cm. In cyclic voltammetry the working electrode was a hanging mercury drop electrode with an area, *A*, of 0.0222 cm^2.

Solutions of Zn(II) (5.0×10^{-4} *M*) in both water and EG–water mixtures of 0.10–0.70 EG mole fraction, containing a concentration of 5.0×10^{-2} *M* of $LiClO_4$ as background electrolyte, were studied. The polarograms of each solution were recorded using a mercury height of 50 cm and drop times, *t*, 0.5, 1.0, 2.0, and 3.0 s. Drop times were regulated with a Tacussel GCMS hammer. The cyclic voltammograms of each solution were recorded in a scan rate range between 0.020 and 20 V s^{-1}.

Results and discussion

Polarographic behaviour

The Zn(II) displayed a single, well defined, polarographic reduction wave in all solutions studied. The wave is always diffusion controlled since a good linear correlation between the logarithm of the limiting current, I_l, and the logarithm of *t*, with slopes close to 0.19, was obtained in all solutions. In each solution the half-wave potential, $E_{1/2}$, was found to be independent of the drop time. Moreover, as can be seen in Fig. 1, the plots of *E* (applied potential) vs. log $((I_l - I)/I)$ were always linear, with slopes of about 30 mV. These results indicate that, in all solutions, Zn(II) electroreduction is a two-electron reversible process (11).

Table 1 summarizes polarographic results obtained for Zn(II) under the experimental conditions tested. It can be observed that when the EG mole fraction increases, $E_{1/2}$ is shifted to more

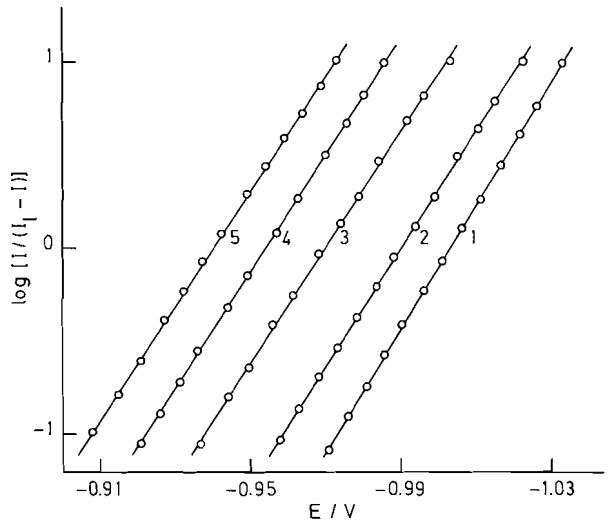

FIG. 1. Dependence of $\log (I/(I_l - I))$ on the applied potential for the polarographic reduction of Zn(II) in different aqueous EG solutions containing 5.0×10^{-2} *M* $LiClO_4$. EG mole fraction: (1) 0.00, (2) 0.10, (3) 0.30, (4) 0.50, (5) 0.70. Drop time 3.0 s and temperature 25.0°C.

positive values, whereas the value of the diffusion-current constant, I_d, gradually decreases. The diffusion coefficient of Zn(II), D_{ox}, also reported in Table 1, was calculated in each solution by substitution of the corresponding I_d value in the Ilkovič equation using a number of transferred electrons per reactant ion (*n* value) of 2.

To analyse the variation of $E_{1/2}$ with solvent composition, the liquid junction potential between the SCE (aqueous solution of NaCl) and each solution must be determined. In this way we have previously reported (10) that, in the EG–water media used, the liquid junction potentials can be estimated adopting the half-wave potentials of the ferrocene oxidation as internal reference. The half-wave potentials of Zn(II) expressed with respect to the half-wave potentials of ferrocene, $E_{1/2,Foc}$, are listed in Table 1. As can be seen, the $E_{1/2,Foc}$ values for Zn(II) become more negative as long as the EG mole fraction increases.

Taking into account these $E_{1/2,Foc}$ values, the standard free energies of transfer of one mole of Zn(II) ions from water to mixed solvents, ΔG_t^0, were calculated according to the following expression (2, 5, 6):

$$[4] \quad \Delta G_t^0 = 2F\,{}^{w}\Delta^{x}E^0$$

${}^{w}\Delta^{x}E^0$ being the difference between the standard potentials, E^0, of the Zn(II)–Zn(Hg) system in mixed solvent, x, and aqueous solution, w. Assuming that the diffusion coefficient of Zn in the amalgam formed by reduction of Zn(II) does not vary with solvent composition, as it has been confirmed from the cyclic voltammetric results which will be presented below, the differences ${}^{w}\Delta^{x}E^0$ were determined by means of the equation (12, 13):

$$[5] \quad {}^{w}\Delta^{x}E^0 = {}^{w}\Delta^{x}E_{1/2,Foc} + \frac{RT}{2F} \ln \frac{(\gamma_{ox})_w (D_{ox})_x^{1/2}}{(\gamma_{ox})_x (D_{ox})_w^{1/2}}$$

where γ_{ox} and D_{ox} are the activity coefficient and the diffusion coefficient, respectively, of Zn(II) in each solution. Then, to calculate ${}^{w}\Delta^{x}E^0$ a value of 0.570 was employed as activity coefficient $(\gamma_{ox})_w$ in the aqueous solution (14), whereas the

[f]Standard free energy of transfer of 1 mol of Zn(II) ions from water to mixed solvent.

values used as activity coefficients $(\gamma_{ox})_x$ in mixed solvents (see Table 1) were estimated by means of the expression (15):

$$[6] \quad \log (\gamma_{ox})_x = (\epsilon_w/\epsilon_x)^{3/2} \log (\gamma_{ox})_w$$

where ϵ_w and ϵ_x denote the dielectric constants of water and the mixed solvent, respectively. These latter values were determined from the dielectric constants provided for several EG–water mixtures in ref. 16.

The ΔG_t^0 values obtained following the procedure stated above are given in the last column of Table 1. As can be seen, these values are more negative as long as the EG content in the solvent increases. This fact indicates that the transfer of Zn(II) from water to mixed solvents is thermodynamically favoured and also, that this process becomes more spontaneous when more EG is added to the mixed solvent. A similar behaviour has been previously reported for the transfer of Cd(II) from water to EG–water mixtures (10). This same effect has been described for the transfer of several ions, as Cd(II), Zn(II), and Pb(II), from water to dimethylsulfoxide–water mixtures (5), being ascribed to a higher solvating power of the dimethylsulfoxide, probably due to its greater basicity.

To gain a better understanding of this behaviour in EG–water mixtures, the ΔG_t^0 values for Zn(II) were split into two contributions: (*i*) an electrostatic one, $\Delta G_{t,el}^0$, which arises from the change in the dielectric constant of the solvent and (*ii*) a chemical one, $\Delta G_{t,ch}^0$, which depends on the solvation and other specific ion–solvent interactions. The electrostatic contribution to the standard free energy of transfer was estimated by means of the Born equation (17),

$$[7] \quad \Delta G_{t,el}^0 = \frac{N(ze)^2}{2r}\left(\frac{1}{\epsilon_x} - \frac{1}{\epsilon_w}\right)$$

where r is the crystallographic radius of Zn(II) (= 0.74 Å (18)). So, the chemical contribution to the standard free energy of transfer was determined by subtracting the $\Delta G_{t,el}^0$ found in each EG–water mixture from the corresponding ΔG_t^0. The dependence of the resulting $\Delta G_{t,ch}^0$ on EG mole fraction is shown in Fig. 2. It can be observed that the $\Delta G_{t,ch}^0$ values are more negative with increasing the EG content in the solvent. A similar behaviour has also been reported by Kundu *et al.* (19) for alkali

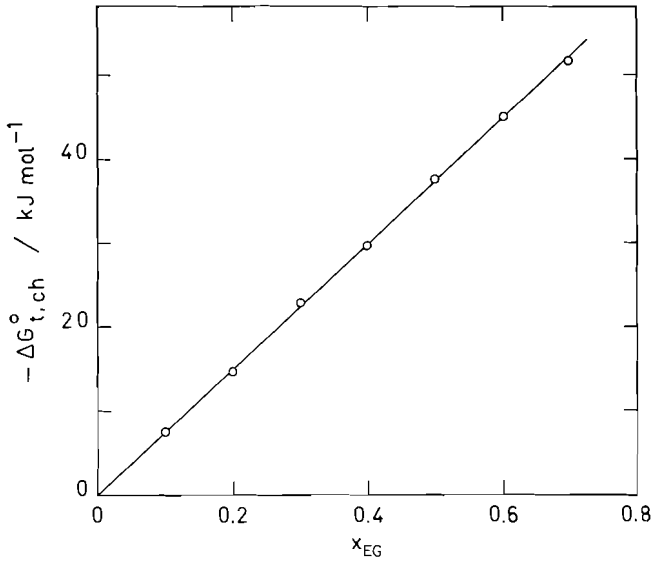

FIG. 2. Plot of the $\Delta G_{t,ch}^0$ for Zn(II) vs. EG mole fraction. Temperature 25.0°C.

cations in EG–water mixtures. According to these authors, the trend in the variation of $\Delta G_{t,ch}^0$ for Zn(II) with solvent composition could be explained considering the existence of specific acid–base interactions between the ion and solvent molecules. In this way these results indicate that the mixtures are more basic than water, increasing its basicity when EG is added to the solvent and hence, producing stronger ion–solvent interactions. In addition, the linear correlation found between $\Delta G_{t,ch}^0$ and x_{EG} (see Fig. 2) suggests a gradual increase in the Zn(II) solvation proportional to the EG mole fraction.

On the other hand, it should be noted that the gradual decrease in diffusion coefficient of Zn(II) when the EG content in the solvent increases (see Table 1) is mainly due to the progressive increase in viscosity, η, of the solution. The viscosities of the EG–water mixtures tested, containing 5.0×10^{-2} *M* $LiClO_4$, have been previously measured (10) and they are shown in Fig. 3*b*. Then, the change in the structure of the EG–water mixtures at different compositions can be analysed from the variation of

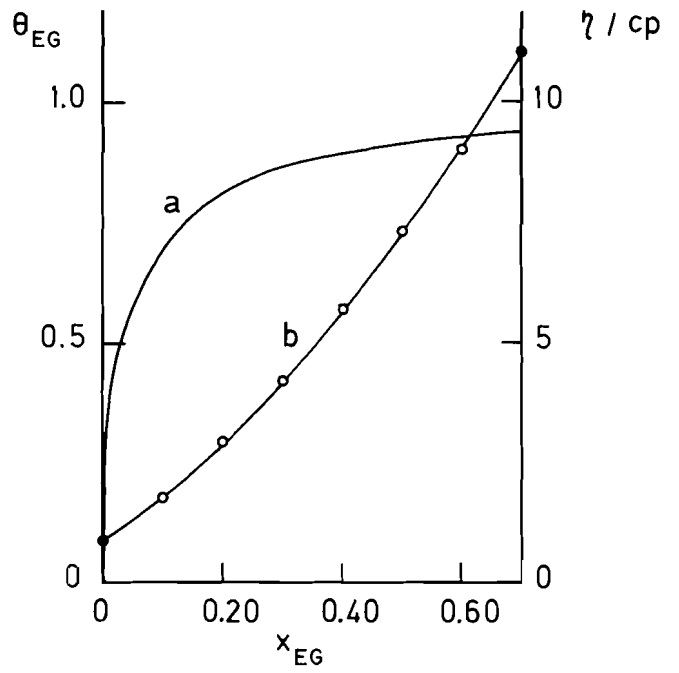

FIG. 3. (*a*) The surface coverage of the electrode by EG molecules in different EG–water mixtures at $E = -1.0$ V vs. SCE (aqueous solution of NaCl). Data estimated from refs. 25 and 26. (*b*) Viscosity of EG–water mixtures vs. EG mole fraction (10). Temperature 25.0°C.

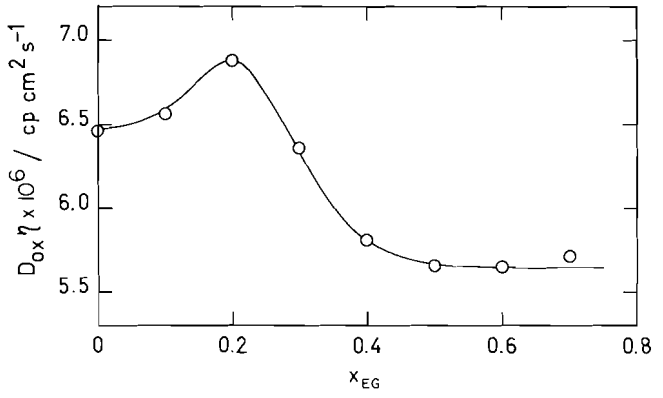

FIG. 4. Variation of the Walden product for Zn(II) with EG mole fraction. Temperature 25.0°C.

the Walden product, $D_{ox}\eta$, with solvent composition to avoid the effect of the bulk viscosity.

The dependence of $D_{ox}\eta$ for Zn(II) on EG mole fraction is shown in Fig. 4. As it can be seen, a maximum value of the Walden product is reached in the water-rich region, close to $x_{EG} = 0.2$. A similar behaviour for the Walden product of Cd(II) has also been previously described (10). This could be explained considering that in the water-rich region the solvent becomes more structured because small amounts of EG added to pure water promote the three-dimensional network building of the last solvent, as we have recently reported from viscosity measurements of several alkali cations.[1] Consequently, in the water-rich region, the Zn(II) ion, as well as the Cd(II) ion, become more structure breaking. This decreases local viscosity around the ion, leading to an increase in its mobility. At $x_{EG} > 0.2$, addition of EG to mixed solvent causes a decrease in solvent structure and hence, a loss in mobility of the Zn(II) ion, which partially causes the observed decrease in its Walden product. In addition, according to the Stokes–Einstein relation, the product $D_{ox}\eta$ is inversely proportional to the solvated radius of diffusive species. Thus, the gradual decrease in $D_{ox}\eta$ of Zn(II) at $x_{EG} > 0.2$ is also explained by an increase in the solvated radius of this ion due to the substitution of the more voluminous EG molecules by water ones. This fact is consistent with the progressive increase in the Zn(II) solvation, as stated above.

Cyclic voltammetric behaviour

The Zn(II)–Zn(Hg) system exhibits a redox couple under all the experimental conditions studied, which shows a different voltammetric behaviour depending on the EG content in the mixture and the scan rate. To determine the cyclic voltammetric parameters corresponding to this system in each tested solution, the cyclic voltammograms were carried out starting from −0.700 V and reversing the scan at −1.200 V.

Values of cathodic peak potential, E_p^c, cathodic half-peak potential, $E_{p/2}^c$, anodic peak potential, E_p^a, and cathodic peak current, I_p^c, obtained at a scan rate of 0.020 V s^{-1} are summarized in Table 2. It can be observed that E_p^c, $E_{p/2}^c$, and E_p^a are gradually shifted with increasing EG content in the mixture to less negative values. On the other hand, I_p^c progressively decreases as long as the EG mole fraction rises, in accordance with the gradual increase in viscosity of the reaction medium (see Fig. 3b). From the I_p^c values, the cathodic peak-current functions, ψ_p^c, were calculated employing an n value of 2 and the diffusion coefficients for Zn(II) previously determined by polarography (see Table 1). The ψ_p^c values thus obtained are also listed in Table 2. As can be seen, ψ_p^c is independent of the EG content in the mixture with a value of 0.46 ± 0.01, as is expected for a two-electron reversible reduction process (11, 20).

For a given solution and at scan rates lower than 0.150 V s^{-1}, the ratio of anodic to cathodic peak currents, I_p^a/I_p^c, is found to be higher than unity, its value dependent on the applied reversal potential, E_λ. This is due to the concentration effect of the Zn amalgam formed in the hanging mercury drop electrode because of the spherical diffusion and the limited volume of the electrode. Recently, Tokuda *et al.* (20) have studied theoretically, by cyclic voltammetry, this kind of process for a simple reversible system, such as

[8] $M^{n+} + ne^- \rightleftharpoons M(Hg)$

They established the following equations to calculate the diffusion coefficient, D_{red}, for metal M in mercury and the reversible half-wave potential, $E_{1/2}^r$, corresponding to the M^{n+} electroreduction:

$$[9] \quad D_{red} = [\{(I_p^a/I_p^c) - 1\}/4.130 D_{ox}^{0.172} r_0^{-1.273} \times (RT/nFv)^{0.637} \{(nF/RT)(E_p^c - E_\lambda)\}]^{0.719 - 0.469}$$

$$[10] \quad E_{1/2}^r = E_p^c + (RT/nF)[1.109 + 5.047 D_{ox}^{0.344} D_{red}^{0.168} \times r_0^{-1.024} (RT/nFv)^{0.512}]$$

r_0 being the electrode radius.

Because the Zn(II) electroreduction is reversible in all solutions at 0.020 V s^{-1}, as was pointed out above, it seems plausible to consider that the Zn(II)–Zn(Hg) system behaves as a simple reversible one at low v values and hence, D_{red} for Zn in mercury and $E_{1/2}^r$ for the Zn(II) electroreduction can be

TABLE 2. Cyclic voltammetric results of the Zn(II)–Zn(Hg) system in water and EG–water mixtures containing 5.0×10^{-2} *M* $LiClO_4$, at a scan rate of 0.020 V s^{-1} and at 25.0°C

determined by means of eqs. [9] and [10], respectively. To corroborate all these suppositions, several cyclic voltammograms were recorded for each studied solution at 0.020 and 0.050 V s^{-1}, with different values of $(E_p^c - E_\lambda)$ between 0.080 and 0.200 V. The I_p^a/I_p^c ratio for each redox couple was determined following the method described in ref. 11. The mean value of D_{red} obtained for each solution by using eq. [9] is given in Table 2. It can be observed that the diffusion coefficient for Zn in mercury remains practically constant in all experimental conditions, taking a value of $(1.40 \pm 0.09) \times 10^{-5}$ $cm^2\,s^{-1}$ which agrees with those reported in the literature from other reaction media (5, 21). This indicates that the Zn(II)–Zn(Hg) system is always reversible at low scan rates. On the other hand, the $E_{1/2}^r$ values calculated from the eq. [10] are listed in the last column of Table 2. It should be noted that these values are in accordance with those determined by polarography (see Table 1), with a maximum deviation of ±2 mV. From an inspection of Table 2 it can be seen that there is a difference between $E_{1/2}^r$ and E_p^c of 17 ± 1 mV in all solutions, i.e., a value slightly higher than the 14 mV expected for a two-electron reversible process (11). Then, the fact that the values of $(E_p^a - E_p^c)$ and $(E_{p/2}^c - E_p^c)$ for the Zn(II)–Zn(Hg) system under reversible conditions (see Table 2) slightly differ from the 28 mV established for a two-electron reversible system (11), can be attributed to the amalgam formation process.

For each studied solution and at scan rates higher than 0.150 V s^{-1}, the I_p^a/I_p^c ratio remains close to unity, although it slightly decreases as the scan rate rises. With increasing v, there is always a progressive decrease in ψ_p^c, whereas, simultaneously, E_p^c is shifted to more negative values and E_p^a to less negative ones; hence, a gradual increase in $(E_p^a - E_p^c)$, as well as in $(E_{p/2}^c - E_p^c)$, is also observed. All these results are indicative of a quasi-reversible behaviour of the Zn(II)–Zn(Hg) system under these conditions. Experimental efforts were then concentrated on the determination of the kinetic parameters of this system in each solution.

The apparent standard rate constant, k_s, of a simple quasi-reversible system can be calculated by means of the expression (22)

$$[11] \quad k_s = D_{red}^{\alpha/2} D_{ox}^{(1-\alpha)/2} (\pi nFv/RT)^{1/2}\,\psi$$

where ψ is a function of $(E_p^a - E_p^c)n$ and of the transfer coefficient, α, for the reduction process. According to Matsuda and Ayabe (23), this transfer coefficient can be determined when the process is quasi-reversible from a given v_o value, because in such conditions, a linear correlation between E_p^c and $-\log v$, with a slope of $(0.0296/\alpha n)$ V at 25.0°C, is expected. Thus, eq. [11] can only be used to obtain k_s at scan rates lower than v_o.

TABLE 3. Kinetic parameters of the Zn(II)–Zn(Hg) system in water and EG–water mixtures containing 5.0×10^{-2} *M* $LiClO_4$, at 25.0°C

0.70	3.7	0.27	8.9

[a]Apparent standard rate constant of the Zn(II)–Zn(Hg) system.
[b]Transfer coefficient for Zn(II) electroreduction.
[c]Apparent standard rate constant of the Zn(II)–Zn(Hg) system at $\gamma_{ox} = 1$.

For the cathodic peak of the Zn(II)–Zn(Hg) system under quasi-reversible conditions, good linear correlations between E_p^c and $-\log v$ were always obtained at v values higher than 3 V s^{-1}. Assuming that the slope of these plots was $(0.0296/\alpha n)$ V per decade and $n = 2$, the transfer coefficient for the Zn(II) electroreduction is always found to be close to 0.3, as can be seen in Table 3. Similar α values have also been reported for this reduction process in other reaction media (5, 24).

In the scan rate range between 0.2 and 2 V s^{-1} the difference $(E_p^a - E_p^c)$ gradually increases with rising v from 0.045 to 0.110 V, approximately. Under these conditions, the ψ parameter for each redox couple was determined from the ψ vs. $(E_p^a - E_p^c)n$ plot established by Nicholson (22) and then, the corresponding k_s of the Zn(II)–Zn(Hg) system was calculated by using eq. [11]. For each solution, at least seven cyclic

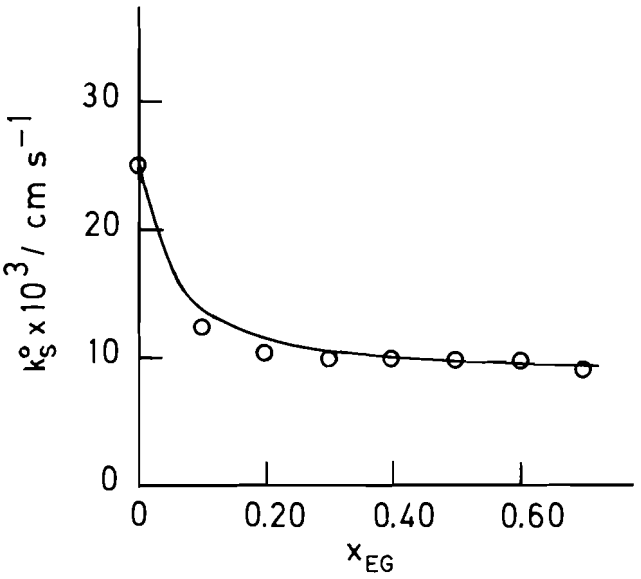

FIG. 5. Dependence of experimental values of k_s^0 for the Zn(II)–Zn(Hg) system on EG mole fraction. The solid line corresponds to the theoretical curve calculated from the model of Broda and Galus (6).

voltammograms with different scan rates were recorded to obtain a mean value of k_s. The resulting k_s values, with an accuracy of ±8%, are given in Table 3. A progressive decrease in k_s with increasing EG mole fraction can be observed.

A better insight into the variation of the apparent standard rate constant with the reaction medium can be gained taking into account that k_s depends on the activity coefficient, γ_{ox}, of Zn(II), according to the expression (23):

[12] $k_s = k_s^0 \gamma_{ox}^{1-\alpha}$

k_s^0 being the apparent standard rate constant at $\gamma_{ox} = 1$. The k_s^0 values were calculated using the γ_{ox} values reported in Table 1 and they are listed in the last column of Table 3. It was then tried to interpret the change in the kinetics of the Zn(II)–Zn(Hg) system with solvent composition in terms of existing models stated in the Introduction.

The monotonic decrease in k_s^0 as the EG mole fraction increases can only be explained by the model of Broda and Galus (6), which describes the change in kinetics by eq. [3]. This model seems plausible to use because the EG–water mixtures are more basic than water as was pointed out above.

To corroborate if eq. [3] can describe the change of k_s^0, the theoretical k_s^0 value for each solution was calculated. For this, the $k_{s,w}^0$ value was taken from Table 3, whereas the $k_{s,EG}^0$ value was obtained by extrapolation at $x_{EG} = 1$. On the other hand, the surface coverage of the electrode by EG molecules, θ_{EG}, at −1.000 V, i.e., at the potential of Zn(II) electroreduction, in the different EG–water mixtures studied was estimated from data reported in refs. 25 and 26. The variation of θ_{EG} with EG mole fraction is presented in Fig. 3*a*.

Figure 5 shows the dependence of the experimental k_s^0 values on EG mole fraction, as well as the corresponding theoretical curve (solid line) calculated by using eq. [3]. A very good agreement between the experimental and the calculated values is found, indicating that the model of Broda and Galus [6] explains the change of k_s^0 for the Zn(II)–Zn(Hg) system in EG–water mixtures.

Finally, according to the above-mentioned authors, a linear dependence of the activation energy on the surface coverage must be expected. This fact is difficult to interpret if the solvation energy (ΔG_t^0) is the main contribution to the activation energy, as it is usually considered, because ΔG_t^0 gradually increases with rising EG mole fraction (see Table 1), whereas most of the increase in activation enrgy should take place up to $x_{EG} = 0.4$, as can be deduced from Fig 3*a*. Then, the increase in activation energy could be ascribed to the activation energy needed for the reorganization of the solvation shell of the reactant ion entering the surface layer, as Jaenicke and Schweitzer (1) have suggested.

Synthetic routes to hydridoiridium(III) dimethylsulfoxide complexes via oxidative addition of HCl or H_2 to precursor *in situ* iridium(I) species are described. The complexes, *trans,mer*-$IrHCl_2(DMSO)_3$ (**1***a*) and *cis,mer*-$IrH_2Cl(DMSO)_3$ (**2**), have been characterized by ^1H nmr and ir, and contain only S-bonded sulphoxide, DMSO. Comparison is made with data for other isomers reported in the literature, and some discrepancies are discussed. The decomposition of **1***a* and **2** in chloroform leads to isomers of $IrCl_3(DMSO)_3$, while (**2**) with HCl generates *cis,cis*-$IrHCl_2(DMSO)_2(DMSO)$ with the O-bonded sulfoxide *trans* to hydride. The reaction of **1***a* in dichloromethane with dioxygen occurs with a 1:1 stoichiometry and generates two complexes tentatively formulated as $Ir(OH)Cl_2(DMSO)_2H_2O$ (**3**) and $IrCl_2(O_2)(DMSO)_2 \cdot DMSO$ (**4**); a hydroperoxide intermediate (Ir—OOH) initially formed from **1***a* is considered to react with further **1***a* in the rate-determining step. Oxidation of coordinated DMSO to the sulphone is not observed, implying that such a catalyzed O_2-oxidation reported earlier in aqueous 2-propanol proceeds via reaction of IrOOH with free DMSO, or else via free hydrogen peroxide.

BRIAN R. JAMES, ROBERT H. MORRIS, et PAL KVINTOVICS. Can. J. Chem. **64**, 897 (1986).

On décrit des voies de synthèses de complexes de l'hydroiridium(III) et du diméthylsulfoxyde qui impliquent l'addition de HCl ou de H_2 à des précurseurs d'iridium(I) préparés *in situ*. On a caractérisé les complexes, soit le $IrHCl_2(DMSO)_3$-*trans,mer* (**1***a*) et le $IrHCl_2(DMSO)_3$-*cis,mer* (**2**), en faisant appel à la rmn du ^1H et à la spectroscopie ir et ils ne contiennent que des sulfoxydes liés par le soufre, DMSO. On fait une comparaison avec les données publiées antérieurement pour d'autres complexes et on discute des divergences. La décomposition des composés **1***a* et **2** dans le chloroforme conduit à des isomères du $IrCl_3(DMSO)_3$ alors que la réaction du composé **2** avec du HCl conduit à la formation de $IrHCl_2(DMSO)_2(DMSO)$-*cis,cis* dans lequel le sulfoxyde est lié par l'oxygène en position *trans* par rapport à l'hydrure. Dans le dichlorométhane, le composé **1***a* réagit avec le dioxygène avec une stoïchiométrie 1:1 et conduit à deux complexes auxquels on a attribué, à titre d'essai, les formules $Ir(OH)Cl_2(DMSO)_2H_2O$ (**3**) et $IrCl_2(O_2)(DMSO)_2 \cdot DMSO$ (**4**); on a considère qu'un intermédiaire hydroperoxyde (Ir—OOH) qui se forme initialement à partir de **1***a* réagirait à nouveau avec le composé **1***a* dans l'étape déterminante. On n'a pas observé d'oxydation du DMSO coordonné en sulfone; ce résultat implique qu'une telle réaction catalysée d'oxydation par O_2, dont on a antérieurement suggéré l'existence pour des réactions dans le propanol-2 aqueux, se produirait soit par une réaction du IrOOH avec du DMSO libre soit via du peroxyde d'hydrogène libre.

[Traduit par la revue]

Introduction

We have become increasingly interested in transition-metal catalyzed oxygenations using O_2 in the presence of a co-reductant, for example (1–4),

$$[1] \quad O_2 + \text{substrate} + H^- \xrightarrow{H^+} \text{substrate(O)} + H_2O$$

In the particular case of a selective oxygenation of cyclooctene (X) to cyclooctanone using O_2–H_2 mixtures in the presence of an iridium catalyst (2), the suggested basic mechanism is outlined in eq. [2], a key feature being the formation of the iridium–hydroperoxide intermediate (Ir—OOH) by a net insertion of O_2 into the metal–hydride bond.

$$[2] \quad (X)IrH \xrightarrow{O_2} (X)Ir{-}OOH \longrightarrow Ir(OH) + XO$$

$$\uparrow \qquad\qquad +H_2, -H_2O \qquad\qquad \downarrow$$

Evidence was obtained for an Ir—OOH species and oxygen transfer to coordinated cyclooctene was considered to occur via a peroxometallocyclic intermediate. Other groups have reported on formation of Rh—OOH (5, 6) and Pt—OOH complexes (7) via reactivity of the platinum metal monohydride with O_2.

There is very intense interest generally in selective oxygenations utilizing O_2, (1, 3, 8–10). Those exemplified by eq. [1] resemble in stoichiometry those of cytochrome-P450, and here also, Fe(III)—OOH intermediates have been invoked but formed, in this case, via protonation of an Fe(III)peroxide (1, 2, 10, 11).

In addition, it is also known that "trace" O_2 can have marked effects on both stoichiometric and catalytic reactions of platinum metal complexes (12, 13). The catalytic reactions include hydrogenation of olefins and aromatics (13), and species formed from metal–hydrides with O_2 may play a role, although this was never suggested directly. Hydrogenolysis of O_2 to H_2O or H_2O_2 has been little studied using homogeneous catalysts (14, 15), but as the rate-determining step sometimes involves formation of a hydride from complex and H_2 (14), a subsequent step almost certainly involves metal–hydride plus O_2.

All of the above findings have encouraged us to pursue metal–hydride – O_2 chemistry. Previously, we had used the complex, *trans*-dichloro-*mer*-tris(dimethylsulfoxide)hydridoiridium(III), **1***a*, as a hydrogen transfer catalyst (16). This complex seemed a good candidate for a reactivity study

[1]Present address: Department of Chemistry and Scarborough Campus, University of Toronto, Toronto, Ont., Canada M5S 1A1.

[2]On leave at the University of British Columbia. 1981–1982.

toward O_2, particularly since Trocha-Grimshaw and Henbest (17) had used such a hydride (and one of Rh) in aqueous 2-propanol solutions for the air oxidation of DMSO to the sulphone, and we had discovered a similar rhodium-catalyzed oxygenation using O_2–H_2 mixture and had suggested a Rh—OOH intermediate (2, 18).

The communication describing the hydrogen transfer work (16) had noted differences with literature data (19) on various isomers of $IrHCl_2(DMSO)_3$.[3] A further interest in the hydrides themselves stems from their potential as catalysts (with chiral sulfoxides) for asymmetric hydrogenation of prochiral substrates. The present paper gives the details on the syntheses and full spectroscopic characterization of **1***a*, and other mono- and dihydrides of Ir(III), together with data on reactivity of **1***a* toward O_2.

Experimental

The iridium was obtained from Johnson, Matthey Ltd. as $IrCl_3 \cdot 3H_2O$ containing 51.76% of the metal, or as $IrCl_4$ from Platinum Chemicals; the cyclooctene precursor $[IrCl(C_8H_{14})_2]_2$ was prepared by a literature procedure (20). The sources of all the other materials used, the synthetic procedures, the procedure used for following gas (O_2) uptake at constant pressure, and the instrumentation for the spectroscopic methods and gc separations, can be traced largely through earlier papers (2, 21). The DMSO was dried with KOH and then vacuum distilled; CH_2Cl_2 was distilled from CaH_2. A Varian E-3 was used to record esr spectra, and the magnetic susceptibility was measured on a Faraday balance (22). Microanalyses were performed by Mr. P. Borda of this department.

Acid of cis-*tetrachlorobis(DMSO)iridate(III), [H(DMSO)$_2$][IrCl$_4$(DMSO)$_2$]*

To a red solution, formed by heating $IrCl_3 \cdot 3H_2O$ (0.3 g, 0.87 mmol) in aqueous HCl (1.1 mL, 2.4 *M*) at 80°C for 30 min, was added DMSO (0.52 mL, 7.5 mmol); heating was continued for 38 h in air in a closed, glass-stoppered Schlenk tube. When the tube was opened, the strong smell of Me_2S emanated from the orange solution; the solution was reduced to an oil by pumping, and the residue dissolved in 1 mL H_2O and extracted with CH_2Cl_2 (3 × 10 mL). Evaporation of the aqueous layer gave a syrup, to which addition of 2-propanol (5 mL) and DMSO (0.5 mL) yielded the acid as yellow needles (yield, 40%). Spectral data agree with those published (19). For example, nmr (D_2O): δ 3.52 (s, 12H, DM*S*O), 2.71 (s, 12H, free DMSO). The CH_2Cl_2 extracts yielded 20 mg of $IrCl_3(DMSO)_2(DMSO)$ (19).

Acid of trans-*tetrachlorobis(DMSO)iridate(III), [H(DMSO)$_2$][IrCl$_4$(DMSO)$_2$]*

After $IrCl_4$ (0.45 g, 1.3 mmol) had reacted with conc. HCl (0.3 mL, 4 mmol) in 5 mL 2-propanol for 4 h at 55°C, the resulting green-red solution was cooled to room temperature, and DMSO (2.5 mL, 35 mmol) added. The orange needles that crystallized overnight were filtered in air, washed with 2-propanol and ether, and dried *in vacuo* (yield, 52%, mp 152–154°C); ir (cm^{-1}): ν(SO) 1127(s), $\rho_r(CH_3)$ 1027(s), 980(s); ν(OHO) 1700–1100(m), 900–600(s), ν(Ir—Cl) 335(m), 326(s). nmr (D_2O): δ 3.50 (s, 12H, DM*S*O), 2.71 (s, 12H, free DMSO).

trans-*Dichloro*-mer-*tris(DMSO)hydridoiridium(III), IrHCl$_2$(DMSO)$_3$ (1a)*

(*a*) The precursor $[IrCl(C_8H_{14})_2]_2$ (0.1 g, 0.11 mmol) was dissolved in dry DMSO (0.4 mL, 5.6 mmol) and CH_2Cl_2 (3 mL) at 10°C under Ar to give a yellow solution. A few large crystals of DMA·HCl (27 mg, 0.22 mmol) were rapidly weighed and added,[4] and the resulting colourless solution reduced in volume to ~0.5 mL *in vacuo*; dry ether was added slowly until a turbidity appeared, the solution was then warmed until clear and left at 0°C to deposit white crystals. The product was filtered under Ar, washed with a little ether, and dried *in vacuo* (yield, 70%); the crystals, isolated as a mono-DMSO solvate (see nmr), were very hygroscopic (giving a yellow oil) and were also sometimes contaminated with a small amount of cyclooctene as evidenced by nmr (δ 5.5, 2.0, 1.4 ppm). Carbon content was typically high. For example, *Anal.* calcd. for $C_6H_{19}O_3S_3Cl_2Ir \cdot C_2H_6OS$: C 16.66, H 4.37; found: C 18.1, H 4.1. Infrared (cm^{-1}): ν(Ir—H) 2180(s), ν(SO) 1134(s), 1110(s), $\rho_r(CH_3)$+ν(SO) of solvate 1027(s), ν(Ir—Cl) 302(w); nmr ($CDCl_3$): δ 3.73 (s, 6H, DM*S*O), 3.57 (s, 12H, DM*S*O), 2.62 (s, 6H, free DMSO), −18.86 (s, 1H, IrH).

(*b*) The solvate-free complex may be obtained by adding DMA·HCl (68 mg, 0.56 mmol) to a degassed suspension of $[IrCl(C_8H_{14})_2]_2$ (0.25 g, 0.28 mmol) in 5 mL 2-propanol and 1.0 mL DMSO; the suspended compound turns from orange to white in 10 min at room temperature. The product was filtered, washed with ether, and recrystallized following dissolution in 1 mL DMSO and addition of 5 mL 2-propanol–ether, (1:2 v/v) (yield, 60%). The spectral data were essentially the same as above, but there were no free DMSO peaks; trace, free cyclooctene was always detected and resulted in high carbon content. *Anal.* calcd. for $C_6H_{19}O_3S_3Cl_2Ir$: C 14.46, H 3.81; found: C 15.5, H 4.2.

Several attempts starting with either the *cis* or *trans* acid complexes $[H(DMSO)_2][IrCl_4(DMSO)_2]$ (see above) failed to reproduce the published syntheses (19) of $IrHCl_2(DMSO)_3$, *trans*-Cl_2-*mer*$(DMSO)_3$, or *cis*-Cl_2-*mer*$(DMSO)_3$. A few milligrams of a yellow product could be realized, but this was a mixture of hydrides and other neutral complexes. Infrared (cm^{-1}): ν(Ir—H) 2180–2150(w), ν(SO) 1130–1100(s); nmr ($CDCl_3$): δ 3.51 (main DM*S*O peak), 3.73, 3.63, 3.57, 3.21 (minor DM*S*O peaks), 2.91 (minor DMS*O* peak), −18.85 (small amount of hydride **1***a*), −19.45 (main hydride).

Reaction of 1a *with* $CDCl_3$

On heating **1***a* at 40°C in $CDCl_3$ under Ar, the solution turned from colourless to yellow and contained $IrCl_3(DMSO)_2(DMSO)$ with equal intensity nmr peaks at δ 3.63, 3.52, 2.88 (19), and *mer*-$IrCl_3(DMSO)_3$ with peaks at δ 3.56 and 3.46 (ratio 1:2) (19), as well as $CHDCl_2$ (δ 5.2).

Reaction of 1a *with* O_2 *in* CH_2Cl_2

Complex **1***a* (0.1 g, 0.20 mmol) was dissolved in CH_2Cl_2 (10 mL) and the solution stirred under O_2. After about 1 h, a white solid was filtered off, washed with CH_2Cl_2 and dried *in vacuo* at room temperature (yield 35 mg; ~38% based on an "$Ir(OH)Cl_2(DMSO)_2H_2O$" formulation). Infrared (see text). Nmr (d_6-DMSO): δ 3.35, 3.2-(DM*S*O); see text. *Anal.* calcd. for $C_4H_{15}O_4S_2Cl_2Ir$: C 10.57, H 3.30, O 14.09, S 14.09, Cl 15.61; found: C 11.3, H 3.5, O 13.4, S 13.2, Cl 16.4.

Evaporation of the CH_2Cl_2 filtrate at room temperature yielded a yellow material. Addition of $CHCl_3$ (5 mL) dissolved all but a trace of material that was filtered off; addition of ether (~2 mL) to the filtrate led to slow deposition of a yellow compound (yield 60 mg; ~57% based on an "$IrCl_2(O_2)(DMSO)_3$" formulation). Infrared (see text), μ_{eff} = 1.28 BM; nmr ($CDCl_3$); δ 3.6–3.2(DM*S*O), 3.0–2.8(DMS*O*), 2.6(free DMSO); *Anal.* calcd. for $C_6H_{18}O_5S_3Cl_2Ir$: C 13.61, H 3.40, O 15.12, S 18.15, Cl 13.4; found: C 12.8, H 3.4, O 14.0, S 17.5, Cl 13.9.

[3]Abbreviations used: DMA = *N*,*N*′-dimethylacetamide; DMSO = dimethylsulfoxide (DM*S*O and DMS*O* imply S- and O-bonded, respectively); within structures, S = DM*S*O, and O = DMS*O*.

[4]We have found DMA·HCl a useful reagent for quantitative HCl additions; a crystal structure determination done here in 1976 (R. Ball, R. S. McMillan, B. R. James, and J. Trotter, unpublished) revealed protonation at the oxygen and essential planarity at the carbonyl carbon [—C(O$^-$)=$\overset{+}{\text{N}}$<]; the findings agree with those of a structural paper that has come to our attention recently (23).

*Chloro-*cis*-dihydrido-*mer*-tris(DMSO)iridium(III), $IrH_2Cl(DMSO)_3$ (2)*

The precursor $[IrCl(C_8H_{14})_2]_2$ (0.1 g, 0.11 mmol) was dissolved in dry DMSO (0.4 mL, 5.6 mmol) and CH_2Cl_2 (3 mL) under Ar. Upon introduction of 1 atm H_2 (1 atm = 101.3 kPa), the solution turned colourless; after 5 min, it was concentrated to ~0.5 mL under vacuum, when 1 mL of 2-propanol and sufficient ether were added to give a white, air-stable precipitate. The suspension was cooled for a few hours at −10°C, and then filtered. The product was washed with ether and dried *in vacuo* (yield 70%). Infrared (cm^{-1}): ν(Ir—H) 2177(s), 2087(s), ν(SO) 1128(s), 1120(sh), 1090(m), $\rho_r(CH_3)$ 1035(s), 978(w), ν(Ir—Cl) too weak; nmr ($CDCl_3$): δ 3.57 (s, 6H, DM*S*O), 3.53 (s, 6H, DM*S*O), 3.39 (s, 6H, DM*S*O), −16.3 (d, J = 6Hz, 1H, IrH), −19.5 (d, J = 6Hz, 1H, IrH); *Anal.* calcd. for $C_6H_{20}O_3S_3ClIr$: C 15.53, H 4.34; found: C 15.6, H 4.2.

Reaction of the dihydride with $CDCl_3$ and with DMA·HCl

On leaving the dihydride in $CDCl_3$ at room temperature for 20 h, small amounts of at least two decomposition products were observed: the only monohydride was **1***a* (δ 3.73, 3.57, −18.85); a peak at δ 3.45 may be due to *mer*-$IrCl_3(DMSO)_3$ (see above, **1***a* + $CDCl_3$) although the requisite second peak at δ 3.56 was hidden; $CHDCl_2$ was observed at δ 5.2.

A stoichiometric amount of DMA·HCl reacts rapidly with the dihydride in $CDCl_3$ to give the nmr spectrum shown in Fig. 1. The iridium product is considered to be $IrHCl_2(DMSO)_2(DMSO)$ with *cis*-chlorides, and DMS*O* *trans* to the hydride; nmr: δ 3.56 (s, 6H, DM*S*O), 3.51, (s, 6H, DM*S*O), 2.68 (s, 6H, DMS*O*), −20.60 (s, 1H, IrH); other *in situ* peaks are seen at: δ 2.63 (s, 1H, free DMSO), 3.01 (2, 6H, N—CH_3), 2.16 (s, 3H, C—CH_3). The equivalence of the N—CH_3 groups of DMA must result from proton exchange with unreacted DMA·HCl (the spectrum of DMA·HCl in $CDCl_3$ also shows a single peak for the *N*-methyl groups).

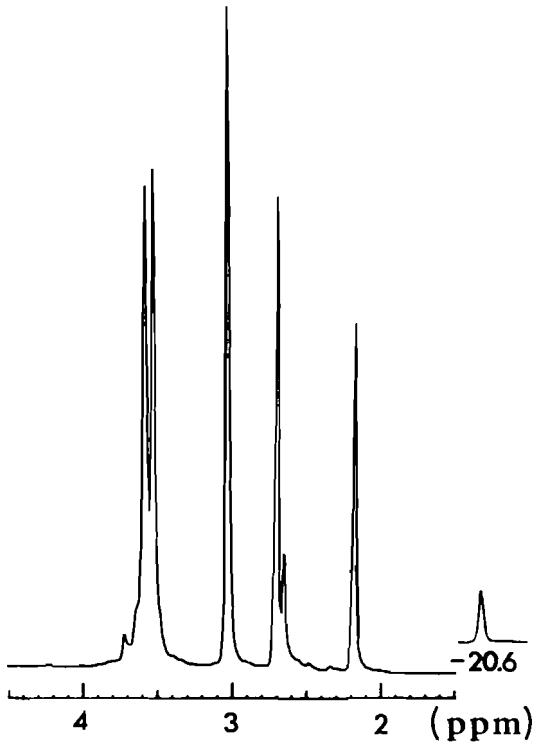

FIG. 1. ^1H nmr spectrum of a $CDCl_3$ solution containing *in situ* products from reaction of $IrH_2Cl(DMSO)_3$ (2) with HCl (added as DMA adduct) at room temperature and 100 MHz.

Results and discussion

Synthesis and characterization of the iridium(III) hydrides

It should be noted first that ^1H nmr and ir spectroscopy have been widely used to distinguish between O- and S-bonded sulfoxide ligands (21, 24), and we have extensively used such procedures in the present work.

The published routes (19) to $IrHCl_2(DMSO)_3$ isomers (**1**) via 2-propanol reduction of the acid complexes $[H(DMSO)_2][IrCl_4(DMSO)_2]$ were first investigated. The precursor *cis* and *trans* acids were readily synthesized from the available starting materials $IrCl_3·3H_2O$ or $IrCl_4$ by slightly modifying the methods of Haddad *et al.* (19). It is not clear whether these workers recognized the nature of the $[Me_2SO..H...OSMe_2]^+$ cation; the ir spectra show the typical broad ν_a(OHO) absorption (1700–600 cm^{-1}) of a symmetrically hydrogen-bonded system (25), with a region of decreased intensity at 1100–900 cm^{-1} and loss of ν(SO) of the cation, a phenomenon that we first encountered in the corresponding *trans*-$[H(DMSO)_2][RhCl_4(DMSO)_2]$ complex (26).

The spectroscopic data for the yellow *cis* and orange *trans* isomers of the Ir acids that we synthesized correspond closely to those given in the literature (19); the formulation of the yellow isomer as the *cis* acid seems reasonable based on its greater stability in polar solvents, and on the relative nmr shifts of the methyl protons (19). The Me_2S formed in our preparation of the *cis* acid may result from an acid-catalyzed decomposition of free or coordinated DMSO; formation and decomposition of hydridoiridium species is not a likely source of sulfide (as demonstrated for a corresponding Rh(III) system (18)), since no reducing agent was present. The only difference between our data and those in the literature (19) for the iridium acids is the melting point and colour of the *trans* isomer (mp 152–154°C, orange vs. 171.5–172°C, pink (19)), indicating different crystalline modifications. Our *trans* complex on warming at 65°C for 15 min in D_2O yielded the aquated species *trans*-$[IrCl_4(DMSO)(D_2O)]^-$, as evidenced by methyl peaks that grow in the ^1H nmr at δ 3.58. This reaction parallels that of the corresponding *trans* Rh acid (21), and supports the stereochemical assignment in view of the high kinetic *trans* effect of S-bonded sulfoxides (24, 27). Only minor amounts of the D_2O product from the *cis* acid were observed under corresponding conditions.

We were unable to generate significant amounts of $IrHCl_2(DMSO)_3$ isomers by the reported 2-propanol reduction of the *cis* or *trans* acids (19), and thus resorted to oxidative addition of HCl (added as the DMA adduct) to solutions containing Ir(I); see eq. [3] (written for a monomeric precursor).

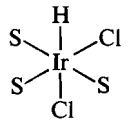
[3] $IrCl(C_8H_{14})_2 + HCl \xrightarrow[-2C_8H_{14}]{DMSO}$ 
1*a*

$\xrightarrow[-CHDCl_2]{CDCl_3}$ 
Excess DMSO is required to prevent formation of a mixed C_8H_{14}–DMSO complex that was obtained when a DMSO:Ir ratio of 3 was used; *in situ* ^1H nmr ($CDCl_3$) showed broad peaks of coordinated olefin (δ 4.7, 2.5, 1.5) along with a DMSO peak at δ 3.46. Use of excess HCl led to production of *trans*-

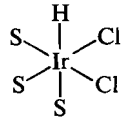
$[H(DMSO)_2][IrCl_4(DMSO)_2]$, presumably by protonation of a coordinated hydride with loss of H_2.

The stereochemistry shown in **1***a*, with *trans* chlorides and *mer*-DMSO ligands, is the only one consistent with the nmr data; other isomers should give three methyl peaks because the two methyl groups in some of the DMSO ligands become magnetically inequivalent. The isolated hydride (**1***a*, τ 28.86, 2180 cm^{-1}; ν(Ir—Cl) 302 cm^{-1}) was white, in contrast to two yellow isomers reported by Haddad *et al.* (19); one of these isomers was considered to be **1***a* by preliminary X-ray data[5], but the spectral data (τ 35.29, 2190 cm^{-1}; 334(s), 300(w) cm^{-1}) were quite different to those of our **1***a* complex. The methyl ^1H nmr resonances of the yellow **1***a* were said to be in the required 2:1 intensity ratio, but unfortunately the δ values were not reported. It is thus difficult to rationalize the differences; indeed, the brief mention of the X-ray work[5] does not specifically state that the DMSO ligands are all S-bonded. The yellow **1***a* had been made from *trans*-$[H(DMSO)_2][IrCl_4(DMSO)_2]$ (19); our efforts with this procedure (see Experimental) gave an *in situ* main hydride resonance at τ 29.45 and a minor one at τ 28.85, with no evidence for a hydride at τ 35.29.

To add to the confusion, the other yellow isomer reported by Haddad *et al.* (19), made by reduction of the *cis*-precursor acid, showed three equally intense methyl resonances in the ^1H nmr (again, δ values were not given), consistent with a *cis*-dichloro geometry; however, the spectral hydride data (τ 28.84, 2180 cm^{-1}) are identical to those for our white **1***a*, although the ν(Ir—Cl) region (335(s), 312(m), 282(m)) is different! Structure **1***b* was preferred over **1***c* for the *cis*-dichloro isomer, largely



1*b*



1*c*

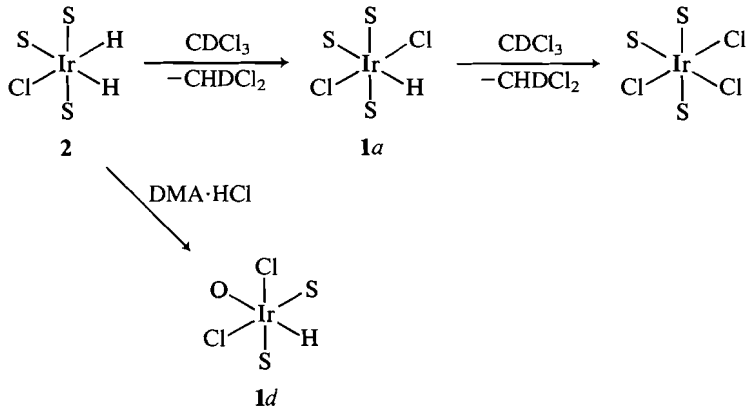
because reaction with HCl gave *mer*-$IrCl_3(DMSO)_3$, this assuming that reactions of Ir(III) hydrides with HCl proceed without rearrangement of other ligands (but see below); this has been suggested based on data from corresponding tertiary phosphine systems (29).

Like both the yellow hydrides (19), our white hydride reacts with chalcone (PhCH=CHCOPh) to give the chelated alkyl $Ir[CH(Ph)CH_2C(Ph)O]Cl_2(DMSO)_2$, that has been fully characterized crystallographically (28) and spectroscopically (30). The methyl groups are all inequivalent in the nmr (δ 3.92, 3.50, 3.38, 2.04), and it is worth noting the previously unmentioned large upfield shift of an S-bonded DMSO (δ 2.04), that must result from a ring current of a proximal phenyl group (28). The white hydride decomposes in $CDCl_3$ and generates the products shown in eq. [3]; the nmr data noted for the products in this and previous work (19) allow for a fairly confident assignment of the stereochemistries shown. The expected (31) generation of the *mer*-$IrCl_3(DMSO)_3$ compound provides further indirect evidence for the **1***a* geometry for our white hydride.

A white, *cis*-dihydride $IrH_2Cl(DMSO)_3$, **2**, was prepared in good yield by the oxidative addition of H_2 to the cyclooctene dimer in DMSO (see eq. [1]). The nmr data are consistent only with the stereochemistry shown (see eq. [4] below); the mutually *trans* DMSO ligands contain magnetically inequivalent methyl groups. Haddad *et al.* (19) synthesized a further white isomer of **2** by treating their yellow **1***a* monohydride with aqueous 2-propanol. Their dihydride corresponds to structure **2** but with the DMSO *trans* to hydride being O-bonded; this is reflected in the nmr (δ 2.78 vs. δ 3.39 observed for **2**) and ir (ν_{IrH} 2250, 2170 cm^{-1} vs. 2177, 2087 for **2**), while the nmr data for the DMSO ligands and metal hydride (δ and *J* values) are essentially identical to those for our dihydride. The presence of the O-bonded DMSO in the dihydride of Haddad *et al.* is of interest, considering that full evidence for having all S-bonded DMSO in the precursor yellow **1***a* is not available for evaluation.

The major products of the decomposition of dihydride **2** in $CDCl_3$, eq. [4], are consistent with the assigned stereochemistries, cf. eq. [3], (31).

[4]



2 **1***a* **1***d*

The reaction of **2** with DMA·HCl results in the quantitative formation of a new monohydride **1***d* that contains O-bonded DMS*O*, eq. [4]; the observed stereochemistry is not consistent with that predicted by the iridium(III) hydride plus HCl "rule" referred to above.

[5]Unpublished work noted in ref. 28.

Reaction of $IrHCl_2(DMSO)_3$ (1a) with O_2

The reaction of **1***a* with O_2 was initially monitored in DMA or CH_2Cl_2 solution using the constant pressure gas uptake apparatus. The stoichiometry (and rates) were followed conveniently at 30°C under 1 atm total pressure (Fig. 2); the uptake curves reveal autocatalytic behaviour, and limited preliminary data in DMA for the maximum rates (Table 1) suggest a second-order

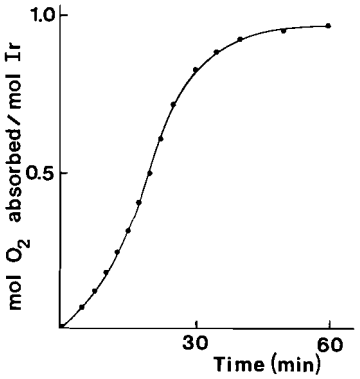


FIG. 2. Uptake of O_2 by DMA solution of $IrHCl_2(DMSO)_3$ (**1***a*) at 30°C, 1 atm O_2; [Ir] = 7.3×10^{-3} *M*.

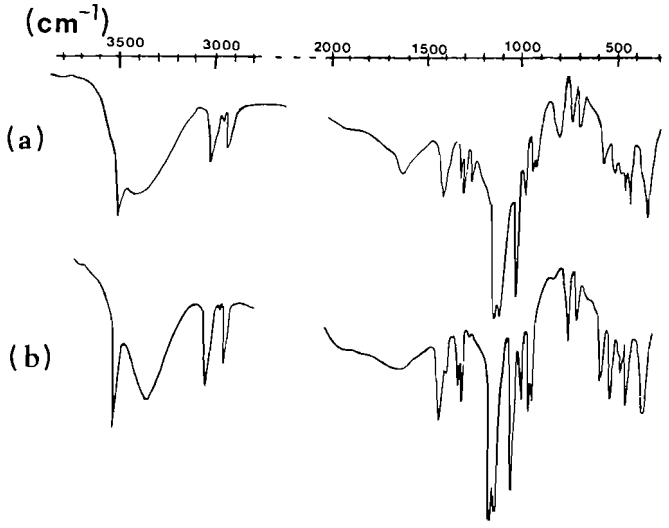

FIG. 3. Infrared spectrum (KBr) of complex **3**. (*a*) Sample dried *in vacuo*; (*b*) same sample, redissolved in DMSO and reprecipitated by addition of CH_2Cl_2.

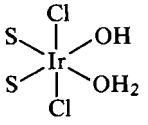
dependence on metal. The net stoichiometry was invariably 0.95 ± 0.02 mol O_2/mol Ir, which seemed a good harbinger for possible formation of an IrOOH species (cf. eq. [2]). During the reaction in CH_2Cl_2 the initially colourless solution turned yellow and, towards completion of the O_2 uptake, a white precipitate appeared. Samples of the solution or filtrate taken after ~1 h, and analyzed by Karl–Fischer titration, showed the absence of water. Analysis for free DMSO by glc revealed ~0.8 mol/mol Ir; no sulphone ($DMSO_2$), readily identified by ir and mp, and an expected oxidation product (see Introduction), was ever detected.

The white solid is considered to be $Ir(OH)Cl_2(DMSO)_2H_2O$, **3**, (see Experimental). The ir (Fig. 3) reveals ν(OH) at 3500 cm^{-1} and coordinated or lattice water (3600–3100, ~1600 cm^{-1}); bands at 560, 510 cm^{-1}, not present in the hydride precursor, could be water librational modes (32). We had difficulty in obtaining completely satisfactory elemental analyses for **3** because of variable water content. Redissolving a



3

sample in DMSO and reprecipitating by adding CH_2Cl_2 gave changes in the ir (Fig. 3) that indicate loss of some water (changes in the 3600–3100, 1600 cm^{-1} regions; the loss of the 800 cm^{-1} band could result from loss of rocking–wagging modes of coordinated water (32)). The strong peak at 310 cm^{-1} is attributed to ν(Ir—Cl).

The metal–hydride bond of **1***a* (ν, 2180 cm^{-1}) has clearly undergone reaction, while the ν(SO) region of **3** is very similar to that of **1***a* and shows DM*S*O ligands. The ^{1}H nmr also reveals the S-bonded sulfoxides (δ 3.35, 3.22); the relative intensities, although comparable, were difficult to estimate because of a variable broad resonance around δ 3.3–2.8 that resulted from the variable water content. In total, the data are most consistent with the geometry shown; the broad ir absorption in the 1700–600 cm^{-1} region is again typical of ν_a(OHO) (see above), and an intra- or intermolecular H-bonded network within **3** is easy to visualize. A noted solubility of **3** in hot DMSO only is in accord with a polymeric type structure.

The other major iridium product formed in the reaction of **1***a* with O_2 was isolated from the yellow CH_2Cl_2 filtrate following removal of **3**. The elemental analysis is reasonable for the formulation $IrCl_2(O_2)(DMSO)_3$, **4**. Of major importance, treatment of **4** with aqueous HCl yielded 6.8 ± 0.1 mol% of H_2O_2 estimated by iodometric titration (7); The O_2, bound as peroxide (within a formally Ir(IV) complex), would generate a theoretical 6.43% of H_2O_2. Comparison of the ir of **4** with that of the residue following HCl treatment shows loss of a band at 795 cm^{-1} (Fig. 4), consistent with loss of coordinated, side-on, η^2 peroxide (33). A Faraday measurement at room temperature gave μ_{eff}=1.28 BM, which is low for a single unpaired electron, but is not unreasonable (34) for a low-spin, pseudo-octahedral d^5 Ir(IV) system (with O_2 occupying 2 sites as peroxide, and one DMSO being a solvate, see below). Furthermore, at room temperature, solid state esr measurement yielded a signal with a sharp component at g=2.11 and a broad component centred at g~4.5; low-spin d^5 complexes in (pseudo)octahedral fields typically give esr signals with $g_\perp > 2.00$ and $g_\parallel < 2.00$ that are detectable more readily at low temperatures (35). The low μ_{eff} value could result from a high spin–orbit coupling constant, which is characteristic of the heaviest ions, and (or) antiferromagnetic interactions. More detailed studies, including temperature dependence data, are needed in order to explain the magnetic properties of **4**. The ir (Fig. 4) reveals S-bonded DM*S*O (1130 cm^{-1}); the 1015 cm^{-1} band could be O-bonded DM*S*O and (or) methyl rocking modes. In CH_2Cl_2 the ir reveals an extra band at 1055 cm^{-1}, attributed to free DMSO, implying perhaps O-bonded DM*S*O or DMSO solvate in the solid state. The ^{1}H nmr spectrum (Experimental) gives paramagnetically broadened signals and is not very satisfactory, but is consistent with the ir data. A broad ir band at ~330 cm^{-1} is assigned to ν(Ir—Cl). Some broad absorption in the 3600–3300 cm^{-1} region (KBr) was considerably reduced in CH_2Cl_2

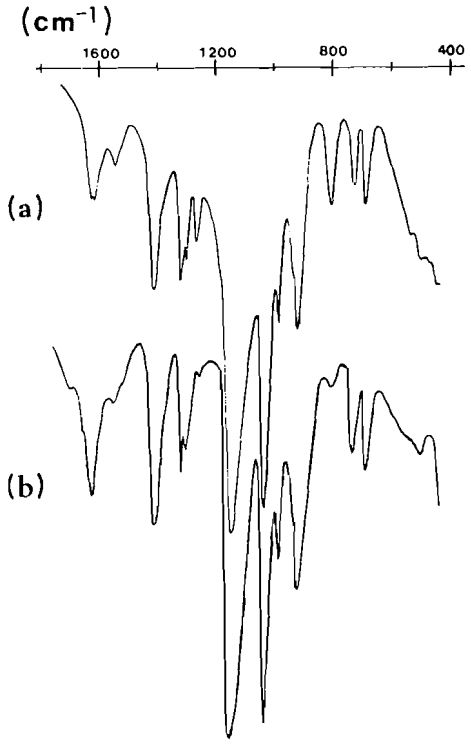


FIG. 4. Infrared spectrum (KBr) of complex **4** (*a*) before and (*b*) after treatment with HCl.

suggesting perhaps some H-bonding interactions in the solid state.

Thus, the favoured formulation of the yellow iridium oxidation product **4** is $IrCl_2(O_2)(DMSO)_2 \cdot DMSO$; its novelty, however, compels us to present this as a very tentative formulation. The possibility of a more realistic, diamagnetic Ir(III)–hydroperoxide formulation, $IrCl_2(OOH)(DMSO)_2 \cdot DMSO$ was considered, and such a species would similarly generate an equivalent of H_2O_2 (5), but the magnetic properties rule this out. An iridium(III) superoxide species would generate only 0.5 equivalents of peroxide, and would in any case be readily identified by esr (36).

Problems in distinguishing between peroxide and hydroperoxide have arisen before (5, 6, 37, 38), and key criteria of —OOH are certain ir bands: 3600–3500(w), ν(OO—H); 1260(w), δ(OO—H); 820(s), ν(O—OH). Sampling by ir the reacting CH_2Cl_2 solutions of $IrHCl_2(DMSO)_3$ under O_2 gave no firm evidence for such bands. It is worth noting that the ir changes in Fig. 3 ($a \rightarrow b$) reveal a loss of accompanying bands at 1260 and 800 cm^{-1}; we have attributed the loss of the 800 cm^{-1} band to removal of water, but presumably removal of some Ir—OOH species by the DMSO treatment could equally well explain the ir changes (including those in the 3500 cm^{-1} region).

It seems established that the final iridium products (**3** and **4**) are not hydroperoxides. Indeed, the overall reaction stoichiometry shown in eq. [5] is quite nicely established on consideration of all the data (no sulphone, no free H_2O, <1 free DMSO per Ir, ~38% of **3**, ~57% of **4**).

The autocatalytic nature of the O_2-uptake plot can be explained qualitatively by slow formation of an Ir(III)(OOH) intermediate that reacts subsequently with precursor **1***a*. The second-order dependence on Ir in the maximum rate region also accommodates such a suggestion, and resembles behaviour of

[5] $3\ IrHCl_2(DMSO)_3 + 3\ O_2 \longrightarrow Ir(OH)Cl_2(DMSO)_2H_2O + 2\ IrCl_2(O_2)(DMSO)_2 \cdot DMSO + DMSO$

1*a* **3** **4**

Co(II) systems that generate bridged-peroxo species via a corresponding $Co(II)O_2 + Co(II)$ pathway (39). In the present system, successive transfers of hydrogen from **1***a* to Ir(OOH) could formally result in **3** with concomitant generation of Ir(II), that subsequently binds O_2 to give the peroxide **4**. It is difficult not to invoke an Ir(OOH) intermediate for the reaction, and implies that the coordinated —OOH prefers to attack a metal–hydride rather than transfer an oxygen atom to coordinated DMSO. The observed catalyzed O_2-oxidation of DMSO to the sulphone via Ir(III) and Rh(III) hydrido(DMSO) complexes (17) thus almost certainly involves either oxygen transfer from M—OOH to free sulphoxide, or generation of free H_2O_2 (via protonation of M—OOH) that is known to effect the oxidation. The reported DMSO oxidation using the yellow **1***a* was effected using air in "hot" aqueous 2-propanol solutions containing excess DMSO.

An Ir—OOH moiety is considered to transfer an oxygen atom to a coordinated alkene via a peroxometallocyclic intermediate to give a ketone product (2); based on recent findings for some related Pt(II) systems (40), prior ionization of the moiety to Ir(III) and OOH^-, and external nucleophilic attack of the anion at the alkene would probably yield epoxide product. A coordinated alkene is more electrophilic than DMSO, and thus not surprisingly the nature of the substrate, and whether it is coordinated or not, will govern its susceptibility to, and mode of, oxidation via M—OOH species.

Concluding remarks

In summary, we have discovered efficient synthetic routes to hydridoiridium(III) species containing sulfoxide ligands via oxidative addition of a protonic acid to a labile, precursor iridium(I) complex in the presence of excess sulfoxide. Corresponding oxidative addition of H_2 yields dihydridoiridium(III) species. Some of the solution chemistry of the hydrides (decomposition in $CHCl_3$, and protonation) is briefly documented, while reactivity of an $IrHCl_2(DMSO)_3$ complex toward O_2 in solution has been studied in some detail. There is no oxidation of the coordinated sulfoxide, which has implications in catalysis utilizing metal–hydroperoxide species. The two iridium oxidation products are tentatively formulated as an aquo(hydroxy)iridium(III) species and a peroxoiridium(IV) species.

Metabolites formed in still culture by *Ceratocystis clavigera, C. ips*, and *C. huntii*, three of the four *Ceratocystis* species associated with the blue stain disease of pine, have been identified. In addition to the ubiquitous fungal metabolites ergosterol, ergosterol peroxide, and fatty acids we have isolated succinic acid, β-phenethyl alcohol (**1**), tryptophol (**2**), prolylleucyl anhydride (**3**), tyrosol (**4**), 3-phenylpropane-1,2-diol (**5**), 6,8-dihydroxy-3-methylisocoumarin (**8**), 6,8-dihydroxy-3-hydroxymethylisocoumarin (**9**), *p*-hydroxybenzaldehyde (**10**), phenylacetic acid (**11**), *p*-hydroxyphenylacetic acid (**12**), phenyllactic acid (**13**), *p*-hydroxyphenyllactic acid (**14**), and 2,3-dihydroxybenzoic acid (**15**). The complex formed by chelation of iron with 2,3-dihydroxybenzoic acid may be responsible, at least in part, for the blue staining of the sapwood of diseased pine.

WILLIAM A. AYER, LOIS M. BROWNE, MEOW-CHEN FENG, HELENA ORSZANSKA, et HOSSEIN SAEEDI-GHOMI. Can. J. Chem. **64**, 904 (1986).

On a identifié les métabolites qui se forment par culture à l'aide de *Ceratocystis clavigera, C. ips* et *C. huntii*, trois des quatre espèces de *Ceratocystis* associées avec la maladie des taches bleues des pins. En plus des métabolites de champignons que l'on retrouve partout, comme l'ergostérol, le peroxyde d'ergostérol et des acides gras, on a aussi isolé de l'acide succinique, de l'alcool β-phényléthylique (**1**), du tryptophol (**2**), de l'anhydride de prolylleucyle (**3**), du tyrosol (**4**), du phényl-3 propanediol-1,2 (**5**), de la dihydroxy-6,8 méthyl-3 isocoumarine (**8**), de la dihydroxy-6,8 hydroxyméthyl-3 isocoumarine (**9**), du *p*-hydroxybenzaldéhyde (**10**), de l'acide phénylacétique (**11**), de l'acide *p*-hydroxyphénylacétique (**12**), de l'acide phényllacétique (**13**), de l'acide *p*-hydroxyphényllacétique (**14**) et de l'acide dihydroxy-2,3 benzoïque (**15**). Le complexe qui se forme par chélation entre le fer et l'acide dihydroxy-2,3 benzoïque pourrait être responsable, au moins en partie, pour la couleur bleue qui se développe sur les pins malades.

[Traduit par la revue]

Fungi belonging to the genus *Ceratocystis* are important pathogens of forest trees, causing such problems as blue stain of conifers (1), oak wilt (2), and Dutch elm disease (3). In western Canada blue stain disease of conifers, so called because the sapwood of the diseased trees is stained a pronounced blue, currently causes death of about 40 million mature pines yearly (4). The disease is spread by the mountain pine beetle (*Dendroctonus ponderosae* Hopk.) (5), which lives symbiotically with a variety of microorganisms (6). The microflora associated with the mountain pine beetle has been the subject of several investigations (7*a–d*) and is reported to consist of yeasts and mycelial fungi including several species of blue stain fungi belonging to the genus *Ceratocystis*. Death of trees affected by blue stain disease results from the combined action of the bark beetle and its blue stain fungi. These organisms live in close mutualistic association. The bark beetle is the vector by which the disease spreads and the means by which the fungi gain access to the phloem and sapwood. The fungi kill the living host tissue, thus preventing resinosis (the production of copious amounts of resin and callus tissue), and this in turn facilitates beetle brood development (8). When the sapwood becomes girdled by blue stain fungi, the region above the infected area becomes water stressed; vital functions decline throughout the tree and it rapidly dies (8, 9*a–d*). The relationship, if any, of the characteristic blue stain in the sapwood to the etiology of the blue stain disease is a controversial question (10). Recently there have been several reports that, *concurrent with the development of blue stain* in the sapwood, the transpiration stream of bark beetle infected trees becomes restricted to the inner portions of sapwood and eventually transpiration fails completely (9, 11).

Currently we are engaged in a study of the metabolites produced by the various blue stain fungi thought to be involved in this disease in an attempt to determine the role that these metabolites may play in tree mortality and symptom expression. Since it has been inferred that water stress and the development of blue stain occur in the same time period (11), we have been especially interested in metabolites that may be responsible for the staining effect. Concurrently others have been reexamining the microflora associated with mountain pine beetle infested lodgepole pine (*Pinus contorta* Dougl. var *latifolia* Engelm.) at various stages of disease development.[2] Four species of blue stain fungi have consistently been isolated: *Ceratocystis clavigera* (Robins.-Jeff *et* Davison) Upadhyay, *Ceratocystis huntii* Robins.-Jeff., *Ceratocystis ips* (Rumb) Moreau, and *Ceratocystis minor* (Hedgc.) Hunt (12). As well, 15 other fungi (*Hormonema dematioides* Lagerb. and Melin, *Phialemonium dimorphosporum* Gams and Cooke, and *Rhinocladiella atrovirens* Nannf. have been positively identified) and ambrosial-like yeasts are frequently observed. In this paper we describe the metabolites produced on artificial medium by one strain of *C. clavigera*, two strains of *C. huntii*, and two strains of *C. ips*. *C. minor* was not included because its metabolites had been investigated previously.

Ceratocystis clavigera was grown in still culture for eight

weeks. A production study using various media including potato dextrose broth (2.1%), yeast-malt broth (malt extract broth (Difco) 2.5%, glucose 1.3%, yeast extract 0.4%, peptone 0.07%), and V-8 broth (clarified V-8 juice 10% and glucose 1%) was undertaken for this and for each species of *Ceratocystis*. For each species the thin-layer chromatography (tlc) of the 3 broth extracts and 3 mycelial extracts showed the same metabolite production. The media chosen for routine metabolite production were based upon the best yield of extract obtained. In the case of *C. clavigera* a medium consisting of dextrose, malt extract, peptone, and yeast extract gave the best yield of metabolites. The mycelium was separated from the broth and the broth was concentrated at reduced pressure to approximately 5% of its original volume and extracted with ethyl acetate. The mycelium was extracted with methanol and the ethyl acetate soluble portion of the methanol extract was subjected to chromatographic separation. It was found that the mycelial extract contained squalene, linoleic acid, lignoceric acid, palmitic acid, linoleic acid triglyceride, ergosterol, and ergosterol peroxide. Each of these compounds was identified using mass spectrometry (ms), nuclear magnetic resonance (nmr), and infrared (ir) spectroscopy. Identity was confirmed by comparison with authentic samples.

The concentrated broth extract was shown by tlc to be a complex mixture of compounds and was separated by chromatography over silica gel. Squalene and linoleic acid triglyceride were identified as the least polar components of the mixture. The next metabolite isolated, with molecular formula $C_8H_{10}O$, was shown to be β-phenethyl alcohol (**1**), by its spectroscopic characteristics and by comparison with an authentic sample. The mixture also contained a crystalline nitrogen-containing compound with the molecular formula of $C_{10}H_{11}NO$. The melting point (mp) and spectral data for this compound suggested that it was tryptophol (**2**). Its primary hydroxyl function was readily acetylated at room temperature with acetic anhydride in pyridine. The identity of **2** was firmly established by comparison with an authentic sample prepared by $LiAlH_4$ reduction of the methyl ester of indole-3-acetic acid. Tryptophol has been reported as a metabolite of several fungi (13) including *C. fagacearum*, one of the blue stain fungi responsible for oak wilt (2). A second nitrogen-containing compound was present in the broth extract in small amounts. High resolution ms indicated the molecular formula $C_{11}H_{18}N_2O_2$. The base peak in the ms corresponds to the loss of a butene molecule. The ^{13}C nmr spectrum shows amide carbonyls at δ 170.0 and 166.2 as well as peaks at δ 59.0, 53.6, and 45.6, indicating three sp^3 carbons directly bonded to nitrogen atoms. The ^1H nmr spectrum has a singlet at δ 5.94 for the proton of a secondary amide function, an apparent triplet at δ 4.16 for a proton α to both a nitrogen and a carbonyl group, and a double doublet at δ 4.05 for another proton in a similar situation. The spectrum also indicates the presence of three consecutive methylene groups and an isobutyl group. The ir spectrum shows N—H stretching at 3260 cm^{-1} and amide carbonyl absorptions at 1670 and 1635 cm^{-1}. The mp, ir spectrum, and optical rotation are identical with those reported for prolylleucyl anhydride (**3**) (14*a*,*b*). Compound **3** which has been identified as a bitter testing component of sake (15*a*), has also been isolated from cultures of *Nocardia restricta* (15*b*) and reported as one of several phytotoxins produced by *Guignardia laricina*, the fungus responsible for larch shoot blight (15*c*). The major component of the broth extract has the molecular formula $C_8H_{10}O_2$. Inspection of its mp and spectral characteristics suggested that it is tyrosol (**4**). Its phenolic and primary hydroxyl functions were readily acetylated. Tyrosol was prepared from *p*-hydroxyphenylacetic acid by esterification with diazomethane followed by reduction with $LiAlH_4$. Comparison of the synthetic material with the natural product confirmed its identity. Tyrosol has been reported to possess phytotoxic activity against rice and germination inhibitory activity against lettuce seeds (16). The most polar metabolite isolated from the broth extract has the molecular formula $C_9H_{12}O_2$. Its ir spectrum shows a strong hydroxyl absorption at 3370 cm^{-1}. The ^1H nmr spectrum shows a complex multiplet for 5 aromatic protons centered at δ 7.27. It also displays a multiplet at δ 3.97 and a pair of double doublets at δ 3.72 and 3.54, suggesting the presence of a 1,2-diol group. Benzylic protons appear as doublets at δ 2.82 and 2.79. The spectral evidence suggests that the compound is 3-phenyl-1,2-propanediol (**5**). The diacetyl derivative **5***a* was prepared and shows spectral properties consistent with the assigned structure. Confirmation of the structure was obtained by synthesis. Cinnamic acid was esterified with diazomethane and the resulting methyl cinnamate was transformed to the epoxide **6** by treatment with *m*-chloroperbenzoic acid. Reduction of **6** with

$LiAlH_4$, provided 3-phenyl-1,2-propanediol (**5**) as well as a small amount of 3-phenyl-1,3-propanediol (**7**). To the best of our knowledge, 3-phenyl-1,2-propanediol has not previously been reported as a fungal metabolite.

The metabolites of two strains of *C. ips* were investigated. The differences observed between isolates are detailed in the Experimental. *C. ips* was grown in still culture in potato dextrose broth for eight weeks. The mycelium was separated from the broth and each was extracted as previously described. The mycelial extract was fractionated by chromatography over silica gel. It was found to contain a mixture of fatty acids and ergosterol peroxide. The fatty acid mixture was esterified with ethereal diazomethane and subjected to gas chromatography – mass spectral analyses. Eight peaks were observed in the gas chromatogram and the methyl esters of the following acids were identified: lauric palmitic, oleic, pentadecanoic, stearic, linoleic, linolenic, and heptadecanoic acids.

The broth was separated into neutral and acidic fractions and each fraction was subjected to chromatography over silica gel. The acidic fraction consisted mainly of one crystalline compound, which was identified a succinic acid. The neutral fraction was found to contain tyrosol (**4**) and about eight other compounds. The least polar components, **A** ($C_{10}H_8O_4$, mp 240–242°C) and **B** ($C_{10}H_8O_5$, mp 223–226°C) showed similar fragmentation patterns in their ms. The ir spectrum of each compound showed the presence of hydroxyl and α,β-unsaturated carbonyl functionality. The ^1H nmr spectra of **A** and **B** are very similar and reveal that a vinylic methyl group in the spectrum of **A** is replaced by a vinylic hydroxymethyl group in **B**. The molecular formulas, melting points, and spectral characteristics of **A** and **B** indicated that they are the isocoumarins **8** and **9**, respectively, metabolites that have previously been isolated from *C. minor*, the blue stain fungus associated with the southern pine beetle (17). The more polar fractions consisted of several simple aromatic compounds. One component was identified as *p*-hydroxybenzaldehyde (**10**) by comparison with an authentic sample. Two other components, **C** ($C_8H_8O_2$, mp 75–77°C) and **D** ($C_8H_8O_3$, mp 148°C) show similar fragmentation pätterns in their ms. The ir spectra of **C** and **D** show absorption bands characteristic fo a carboxylic acid. The ^1H nmr spectra indicated that **C** was phenylacetic acid (**11**) and **D** was *p*-hydroxyphenylacetic acid (**12**). These structural assignments were confirmed by comparison with authentic samples. Very small quantities (1 mg of each) of two very polar aromatic compounds, $C_{11}H_{12}O_5$ and $C_{12}H_{14}O_5$, and a phenolic acid, $C_{10}H_{10}O_5$, were isolated but were not identified.

We employed a rapid qualitative test to measure stem water conductivity in lodgepole pine seedlings. The stems of lodgepole pine seedlings were cut under water and the cuttings were placed in vials containing either test solution or control solvent. When metabolites produced by the blue stain fungi were isolated in sufficient quantity, their effect on stem water conductivity was measured. Several sets of replicate tests using three different concentrations of test solution were carried out for each of the following: *C. clavigera* broth and mycelial extracts, *C. ips* broth and mycelial extracts, *C. huntii* broth and mycelial extracts, ergosterol. ergosterol peroxide, tryptophol (**2**), tyrosol (**4**), *p*-hydroxybenzaldehyde (**10**), and 4-hydroxyphenyllactic acid (**13**). None of the metabolites tested (except **10**, which gave a weakly positive test) caused any pronounced effect in the bioassay, although the crude broth extracts and the crude mycelial extracts showed weak to moderate inhibition of water uptake. The differences between the individual metabolites and crude extracts in the bioassay may be due to synergistic effects of the metabolites or to difficulties in resolubilizing the crude extracts.

At this stage in the chemical investigations we sought further leads from biological studies as to where to focus our attention. Because of the complex nature of the disease it has not yet been possible to determine which, if any, of the *Ceratocystis* species is principally responsible for the death of the trees. Aware that the correlation between blue stain and failing transpiration may be faulty, we decided to study further the fungi which most rapidly caused the blue staining of pine chip medium and of pine bolts (18) inoculated with the individual fungi. It was found that *C. minor* caused staining most rapidly, followed by *C. huntii*. *C. clavigera* causes staining only slowly, and *C. ips* not at all. Since the metabolites of *C. minor* had been reported previously (17), we turned our attention to *C. huntii*.

Two stains of *C. huntii* were examined. *C. huntii* was grown in still culture in potato dextrose broth for eight weeks and extracted as before. The mycelial extract was fractionated by chromatography over silica gel. It was found to contain sterols, mainly ergosterol peroxide, fatty acids, and small amounts of tyrosol (**4**). Concentration of the broth extract yielded a white crystalline precipitate and a gummy residue. The crystalline precipitate, recrystallized from chloroform, was identified as succinic acid. The gummy residue was separated into neutral and acidic fractions by acid–base extraction and each fraction was subjected to chromatography over silica gel. The neutral fraction contained mainly one component, which was purified by crystallization from benzene, and identified as *p*-hydroxybenzaldehyde (**10**). The acidic fraction yielded further succinic acid and a residue, which was subjected to flash chromatography over silica gel. Only partial separation was achieved since succinic acid co-elutes with the small quantities of the other acids present in the extract. Other chromatographic techniques were investigated but simplification of the mixture by chromatography was not achieved. Further separation was accomplished by fractional crystallization from benzene – Skellysolve B to give three acids, **A**, **B**, and **C**. Compounds **A**, $C_9H_{10}O_4$, and **B**, $C_9H_{10}O_3$, are closely related compounds, as indicated by their ms. The ir spectra of both compounds show the presence of a carboxylic acid group. Their ^1H nmr spectra reveal that **A** is a *p*-substituted aromatic acid whereas **B** is its unsubstituted analog. On this basis and by comparison with authentic samples **A** was identified as (+)4-hydroxyphenyllactic acid (**13**) and **B** was identified as (+)-phenylactic acid (**14**). Both **13** and **14** are known oxidative enzyme inhibitors (19). Compound **C**, $C_7H_6O_3$, was identified (ms, ir, nmr) as 2,3-dihydroxybenzoic acid (**15**). Identity was confirmed by comparison with an authentic sample.

2,3-Dihydroxybenzoic acid (**15**) is a known iron-chelating agent (20) and it gives a bright blue color in the presence of ferric chloride. 2,3-Dihydroxybenzoic acid derivatives are common metabolites of microbes that have developed iron transport systems involving iron chelating agents, and which are called siderophores (21). We feel that the blue stain of the sapwood of infected lodgepole pine may be due, at least in part, to the siderophore **16** formed by chelation of iron with compound **15**. We are able to artificially induce blue staining on lodgepole pine by treating shavings of sapwood with a methanol solution of **15** and then adjusting the pH to near neutrality. Compound **15** also forms a greenish-brown complex with cobalt ions in weakly acid or basic medium; thus other metal complexes may be involved in the color formation.

In this paper we have described the metabolites produced by three of the four species of *Ceratocystis* responsible for blue staining of sapwood in blue stain diseased pine. 2,3-Dihydroxybenzoic acid (**15**) is probably the compound responsible for the staining effect of *C. huntii* since **15** readily forms a blue-colored siderophore in the presence of iron. None of the metabolites previously reported from *C. minor* (17) possesses the structural features for siderophore formation. Compounds **8** and **9**, which we also isolated from *C. ips*, do not show any apparent staining in the presence of iron. We, therefore, decided to reexamine the metabolites produced by *C. minor* and these results will form the topic of a separate communication. In the accompanying paper we report the results of a study undertaken to test the hypothesis that chelating metabolites produced by *Ceratocystis* species affect the essential metal balance, especialy that of iron, in diseased lodgepole pine.

Experimental

High resolution mass spectra were recorded on an A.E.I. MS-50 mass spectrometer coupled to a DS 50 computer. Unless diagnostically significant, only peaks greater than 20% of the base peak are reported. Infrared spectra were recorded on a Nicolet 7199 FT spectrometer. High field ^{1}H nmr spectra were recorded on a Bruker WH-200 or WH-400 spectrometers with an Aspect 2000 computer system. Optical rotations were obtained on a Perkin Elmer 141 polarimeter. Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. E. Merck silica gel 60 (230–400 mesh) was used for flash column chromatography. Analytical thin-layer chromatography (tlc) was carried out on BDH precoated plates of silica gel 60 PF 254, with visualization by ultraviolet light or 5% phosphomolybdic acid in 5% sulfuric acid, followed by careful charring on a hot plate. All solvents were distilled prior to use. Skellysolve B refers to Skelly Oil Company light petroleum, bp 62–70°C.

Fungal strains

The blue stain fungi used in this study were obtained from Y. Hiratsuka, Northern Forest Research Center, Edmonton, and deposited with L. Sigler, Curator, The University of Alberta Microfungus Collection (UAMH).

C. clavigera: strain C837 (UAMH 4818) isolated by A. Tsuneda from *P. contorta* growing in southern Alberta in June 1983.

C. ips, formerly *C. montia*: strain C450 (UAMH 4910) isolated by R. C. Jeffrey from *P. contorta* growing in B.C. in August 1962 and strain C852 (UAMH 4838) isolated by A. Tsuneda from *P. contorta* growing in southern Alberta in June 1983.

C. huntii: strain C451 (UAMH 4997) isolated by R. C. Jeffrey from *P. contorta* growing in Alberta in August 1962, deposited at the Mycological Herbarium, Biosytematics Research Institute, Department of Agriculture, Ottawa, Canada (DAOM 90235) and C840 (UAMH 4825) isolated by A. Tsuneda from *P. contorta* growing in southern Alberta in June 1983.

Fungal strains were maintained at 4°C in slant tubes containing Difco potato dextrose agar. An aqueous suspension of mycelium was used to inoculate two potato dextrose agar plates. After 7–10 days at 17°C the culture was blended in a Waring blender with approximately 200 mL of sterile media and 20-mL aliquots were used to inoculate 10 × 1 L sterile media in 1-L Fernbach flasks. After inoculation the still cultures were kept at room temperature for 8 weeks. The culture broth was decanted from the mycelium, concentrated *in vacuo* to about 1 L, and continuously extracted with ethyl acetate for 24 h. The ethyl acetate extract was dried and concentrated to give crude broth extract. The mycelium was air-dried, pulverized, and subjected to Soxhlet extraction with ethyl acetate. The ethyl acetate extract was dried and concentrated to give crude mycelial extract.

Isolation of metabolites

The broth extract (1.8 g) was redissolved in ethyl acetate (150 mL) and extracted with saturated sodium bicarbonate (2 × 15 mL). The bicarbonate extract was washed with chloroform (2 × 10 mL), then cooled with ice and acidified to pH 3 with 6 *N* hydrochloric acid and extracted with chloroform (4 × 50 mL). The chloroform extract was dried (sodium sulfate) and evaporated to form a viscous oil (0.225 g). The ethyl acetate extract left after bicarbonate extraction was washed with water, brine, dried, and concentrated to give neutral material (0.480 g). The neutral material (0.470 g) was chromatographed using gradient elution (0–10% methanol in chloroform) to give, in order of increasing polarity, compounds **1**–**5**.

Phenethyl alcohol (1): Impure phenethyl alcohol obtained from the column was further purified by flash chromatography (eluent benzene – ethyl acetate 4:1) to give pure phenethyl alcohol (10 mg) as a colorless oil; ir(film): 3340, 1600, 1487, 1447, 1040 cm^{-1}; ^{1}H nmr ($CDCl_3$); identical with published spectrum (24); ms *m/z*: 122(M^+, 34), 92(62), 91(100).

Tryptophol (2): Flash chromatography of the impure tryptophol (eluant benzene – ethyl acetate 2:1) provided a crystalline sample of **2**, which was recrystallized from ether – Skellysolve B to give pure **2** (9 mg) as yellow needles, mp 57–58°C; ir(film): 3400, 3300, 1620, 1482, 1453, 1420, 1350, 1335 cm^{-1}; ^{1}H nmr ($CDCl_3$): identical with published spectrum (24); ms *m/z*: 161(M^+, 27), 131(11), 130(100)

Prolylleucyl anhydride (3): Crude anhydride **3** obtained from the original column was further purified by flash chromatography (eluent benzene – ethyl acetate, 1:1) to provide pure lactam **3** (5 mg) as white crystals, mp 147–150°C; $[\alpha]_D^{25}$ −102, (*c* 0.25, $CHCl_3$); ir (film): 3260, 1683, 1670, 1635, 1470, 1435, 1367, 1328, 1300 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 5.94 (s, 1H), 4.16 (t, *J* = 8 Hz, 1H), 4.05 (dd, *J* = 4, 10 Hz, 1H), 3.60 (m, 2H), 2.38 (m, 1H), 2.10 (m, 3H), 1.96 (m, 1H), 1.78 (m, 1H), 1.56 (m, 1H), 1.04 (d, *J* = 7 Hz, CH_3), 0.99 (d, *J* = 7 Hz, CH_3); ^{13}C nmr ($CDCl_3$) δ: 170.0, 166.2, 59.1, 53.5, 45.6, 38.8, 28.2, 24.8, 23.3, 22.8, 21.8; ms *m/z*: 210 (M^+, 0.1), 154(100), 86(24), 70(64).

Tyrosol (4): Tyrosol (**4**), mp 91–92°C, was identified by the following spectral properties, ir(film): 3380, 3140, 1590, 1505, 1440, 1350, 1335, 1225, 1097, 1043, 1006 cm^{-1}; ^{1}H nmr($CDCl_3$) δ: 7.12 (d, *J* = 8 Hz, 2H), 6.80 (d, *J* = 8 Hz, 2H), 6.80 (br, s, 1H), 3.84 (t, *J* = 8 Hz, 2H), 2.81 (t, *J* = 6 Hz, 2H); ms *m/z*: 138(M^+, 24), 107(100).

3-Phenyl-1,2-propanediol (5): Impure **5** was subjected to flash chromatography (eluent benzene – ethyl acetate, 1:2) to provide pure 3-phenyl-1,2-propanediol (4.5 mg) as a colorless oil; $[\alpha]_D^{25}$ 0; ir (film): 3370, 1603, 1498, 1455, 1090, 1068 and 1032 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 7.27 (5H), 3.97 (m, 1H), 3.72 (dd, *J* = 3.5, 11 Hz, 1H), 3.54 (dd, *J* = 7, 11 Hz, 1H), 2.82 (d, *J* = 1.5 Hz, 1H), 2.79 (d, *J* = 3 Hz, 1H), 2.05 (1H), 1.64 (1H); ms *m/z*: 152 (M^+, 4), 121, 103(19), 192(100), 91(44).

Acetylation of 5: Acetic anhydride (0.25 mL) was added to a solution of diol **5** (3.5 mg) in pyridine (0.5 mL). The reaction mixture was stirred at room temperature overnight. Toluene (5 mL) was added and the solvents were evaporated under reduced pressure. Flash chromatography of the residue (eluent ether – benzene 1:9) provided the diacetate **5***a* as a colorless oil (4 mg); ir (film): 1742, 1498, 1452, 1370, 1225, 1120, 1040 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 7.27 (5H), 5.27 (m, 1H), 4.25 (dd, *J* = 3.5, 12 Hz, 1H), 4.02 (dd, *J* = 6, 12 Hz, 1H), 2.10 (s, 3H), 2.06 (s, 3H); ms *m/z*: 177 (M^+, 7), 176(58), 134(100), 133(67), 116(49), 105(24), 92(37), 91(52).

Preparation of diol 5: Cinnamic acid (0.6 g, 4.05 mmol) was dissolved in a 9:1 mixture of ether–ethanol (20 mL). Ethereal diazomethane was added until the yellow color of diazomethane persisted. The solvents were removed at reduced pressure to provide methyl cinnamate (0.65 g) as a colorless oil, which was dissolved in dichloromethane (50 mL). The solution was cooled in an ice bath and *m*-chloroperbenzoic acid (0.84 g) was added. The mixture was stirred at room temperature for 4 days. The reaction mixture was diluted with ether (200 mL) and the solution was successively washed with saturated sodium bicarbonate, water, brine, and then dried (sodium sulfate) and concentrated. The oily residue was purified by flash chromatography (eluent ether – Skellysolve B 1:4) to provide epoxide **6** (0.456 g) and unreacted methyl cinnamate (0.120 g). Epoxide **6** (0.180 g) was dissolved in dry ether and $LiAlH_4$ (0.100 g) was added.

After stirring at room temperature, excess $LiAlH_4$ was destroyed by addition of ethyl acetate. Water (20 mL) was added and the aqueous phase was adjusted to pH 4 by adding 6 *N* HCl. The mixture was diluted with ethyl acetate and the organic phase was separated, washed with water, brine, dried (sodium sulfate), and concentrated. The residue was purified by flash chromatography (eluant ethyl acetate – benzene, 3:1) to give 3-phenyl-1,2-propanediol **5** (0.135 g, 88%). The spectra data obtained for synthetic **5** were identical with that obtained for natural **5**.

Two strains of *C. ips* were investigated. The metabolites isolated were present in both strains (tlc) but quantities of metabolites varied between strains.

A portion of the mycelial extract (1.3 g) was chromatographed over silica gel (180 g). Gradient elution with ethyl acetate – methanol gave two major fractions. The less polar fraction (0.09 g) was purified by rechromatography over silica gel (3 g) and elution with ethyl acetate. It contained one component, which was identified as ergosterol peroxide, mp 163–165°C, by comparison with an authentic sample. A portion of the more polar fraction (0.16 g) was chromatographed over silica gel (20 g) by elution with Skellysolve B – acetone – acetic acid, 150:1:1. A white crystalline component **B** with a wide mp range (50–80°C) was obtained. The tlc of **B** showed a single spot in several solvent systems (R_f 0.7, toluene–acetone – acetic acid 75:25:1; 0.5, ethyl acetate – Skellysolve B – acetic acid 300:1:1; 6.2, chloroform–methanol 1:10). Recrystallization of **B** did not improve the mp range. The ir and ms of the crystalline component suggested that it was a mixture of fatty acids. Thus a portion of the component (0.008 g) was treated with ethereal diazomethane. After evaporation of the ether, the residue was analyzed by gas chromatography (column: 1/8 in × 6 ft., Apiezon on Chromasorb W; carrier gas: N_2, 40 mL/min; column temperature; 200°C; injection port: 250°C; detector: 250°C). Eight peaks were exhibited in the gas chromatogram. This mixture was subjected to gc–ms analysis and the following methyl esters were identified on the basis of their known mass spectral fragmentation patterns: methyl laurate, methyl palmitate, methyl oleate, methyl pentadecanoate, methyl stearate, methyl linoleate, methyl linolenate, and methyl heptadecanoate.

The broth extract (0.130 g) was redissolved in ethyl acetate and separated into acidic (0.149 g) and neutral (0.370 g) fractions by extraction with sodium bicarbonate solution as described before. The acidic fraction was treated with ethyl acetate – chloroform (1:1) and a crystalline compound, mp 187–188°C, identified as succinic acid by comparison with an authentic sample, was removed by filtration. The tlc of the mother liquors showed components present in the neutral extract, thus this fraction was not separated further. The neutral fraction was subjected to chromatography over silica gel. Tyrosol (**4**), identified by comparison with an authentic sample, and eight other components, listed in order of increasing polarity, were separated and identified.

6,8-Dihydroxy-3-methylisocoumarin (8): R_f 0.4 (chloroform – Skellysolve B – methanol, 25:25:1); mp 242–244°C (lit. (17) mp 240–242°C); ir (methanol cast): 3250, 1679, 1629, 1570, 1253 cm^{-1}; ^1H nmr (DMSO-d_6) δ: 2.20 (s, 3H), 6.29 (d, J = 2 Hz, 1H), 6.34 (d, J = 2 Hz, 1H), 6.48 (s, 1H), 10.90 (s, 1H); ms m/z: 192 (M^+, 100), 177(50), 163(10), 121(37).

p-*Hydroxybenzaldehyde (10)*: R_f 0.3 (chloroform – Skellysolve B – methanol, 25:25:1) was identified by comparison with an authentic sample.

6,8-Dihydroxy-3-hydroxymethylisocoumarin (9): R_f 0.5 (chloroform–methanol – acetic acid, 100:3:3); mp 223–226°C (lit. (17) mp 220–225°C); ir (methanol cast): 3200, 1682, 1636, 1500 cm^{-1}; ^1H nmr (acetone-d_6) δ: 6.6 (s, 1H) 6.5 (dd, 2H), 4.6 (s, 1H, D_2O exchange), 11.1 (s, 1H D_2O exchange); ms m/z: 208 (M^+, 99), 177(100), 121(62).

Phenylacetic acid (11): mp 75–77°C, was identified by comparison with an authentic sample.

p-*Hydroxyphenylacetic acid (12)*: mp 148°C, was identified by comparison with an authentic sample.

Compound $C_{11}H_{12}O_5$: R_f 0.5 (ethyl acetate – Skellysolve B – acetic acid, 100:100:1); mp 82–85°C.

Compound $C_{12}H_{14}O_5$: R_f 0.42 (ethyl acetate – Skellysolve B – acetic acid, 100:100:1); mp 112–117°C.

Compound $C_{10}H_{10}O_5$: R_f 0.23 (chloroform – methanol – acetic acid, 100:3:4), mp 138–141°C.

The major metabolites in *C. ips* (UAMH 4910) were compounds **4**, **6**, **7**, **8**, **11**, **12**, and the unidentified metabolites, whereas *C. ips* (UAMH 4838) contained **4**, **6**, **9**, and **10** as its major metabolites.

C. huntii

Two strains of *C. huntii* were examined.

The mycelial extract (0.2 g) was separated by silica gel chromatography utilizing gradient elution with chloroform–methanol. Elution with chloroform gave a crystalline compound (0.039 g, mp 178–179°C), which was identified as ergosterol peroxide by comparison with an authentic sample. Elution with chloroform–methanol (99:1) gave a component (0.045 g) whose spectral properties suggested it was a carboxylic acid. The component was esterified with diazomethane, then purified by chromatography over silica gel (eluent: benzene–ether (95:5)). The methyl ester (0.018 g) was identified as methyl linoleate by comparison with an authentic sample. Finally, elution with $CHCl_3$–methanol (96:4) gave a crystalline compound (2 mg) that was identified as tyrosol (**4**).

The broth extract, which contained large quantities of water soluble compounds, was redissolved in ethyl acetate (50 mL) and set aside in the refrigerator for 24 h. A solid precipitate (1.8 g) separated from the mother liquors. A portion of the white precipitate was recrystallized from chloroform–methanol to give white crystals (mp 188–192°C) identified as succinic acid by comparison with an authentic sample. The mother liquors from the crystallization were concentrated and the residue (6.68 g) was suspended in ethyl acetate (500 mL). The ethyl acetate extract was washed with saturated aqueous sodium bicarbonate (5 × 100 mL). The organic fraction was dried (anhydrous magnesium sulfate) and concentrated to yield neutral and phenolic compounds (0.336 g). The aqueous, alkaline extracts were acidified with 5% hydrochloric acid, then extracted with ethyl acetate (5 × 100 mL), dried (anhydrous magnesium sulfate), and concentrated to yield crude acids (1.20 g). The neutral extract (0.191 g), which was shown by tlc to be a complex mixture, was subjected to flash chromatography over silica gel. Elution with $CHCl_3$ – ethyl acetate – acetic acid (97:2:1) gave a fraction that contained mainly one compound. This material could not be further purified by chromatography but yielded *p*-hydroxybenzaldehyde **10** (0.052 g) after recrystallization, first from benzene – Skellysolve B, then from benzene. Attempts to isolate additional components from this extract were unsuccessful.

The crude acidic extract (1.20 g) was dissolved in $CHCl_3$ – ethyl acetate (1:1) and allowed to stand in the cold for 24 h. A crystalline precipitate (0.105 g) was removed by filtration and identified as succinic acid. The mother liquors were concentrated and subjected to flash chromatography over silica gel eluting with $CHCl_3$ – ethyl acetate – acetic acid (97:2:1). The chromatography resulted in a partial separation; the fractions from the chromatography contained 3 compounds in addition to succinic acid, which co-eluted with the others. No further chromatographic separation could be effected. Fractions 10–20 were combined (0.5 g). Crystallization from benzene – Skellysolve B gave a crystalline compound (**13**) (5 mg). Further crystallization of the mother liquors from benzene – Skellysolve B gave a second crystalline compound (**14**) (3 mg). A final crystallization from benzene – Skellysolve B yielded compound **15** (5 mg). The mother liquors from the crystallizations contained further quantities of the 3 compounds and succinic acid but these could not be further separated. Attempted purification by reverse phase chromatography was unsuccessful.

p-*Hydroxybenzaldehyde (10)*: mp 117–118°C (lit. (22) mp 116°C), was identified by its spectral properties and by comparison with an authentic sample; ir ($CHCl_3$ cast): 3180, 2880, 1678, 1612 cm^{-1}: ^1H nmr ($CDCl_3$) δ: 9.87 (s, C*H*O, 1H), 7.82 (d, J = 9 Hz, 2H), 6.98 (d, J = 9 Hz, 2H), 6.50 (s, O*H* 1H); ms m/z: 122(90), 121(100), 93(42), 65(41).

(+)-4-Hydroxyphenyllactic acid (13): mp 173°C (lit. (23) mp

168°C) gave a positive ferric chloride test and showed $[\alpha]_D$ +8.8° (*c* 0.5, methanol) (lit. (23) $[\alpha]$ +20° (*c* 2.5, ethanol); ir(KBr): 3470, 3240, 3190, 1740, 1610, 1600, 1510 cm^{-1}; ^1H nmr (CD_3OD) δ: 7.40 (d, J = 9 Hz, 2H), 7.02 (d, J = 9 Hz, 2H), 4.46 (dd, J = 4.5, 9 Hz, 1H), 3.14 (dd, J = 4.5, 14 Hz, 1H), 2.93 (dd, J = 9, 14 Hz, 1H); ms m/z: 182(11), 107(100).

*Phenyllactic acid (**14**)*: mp 116°C, $[\alpha]$ +19°C (*c* 0.3, methanol), was identified by its spectral properties and comparison with an authentic sample; ir ($CHCl_3$ cast): 3450, 2896, 2956, 1734, 1610, 1590 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 5.74 (br, s, 2H), 4.78 (s, 1H), 3.38 (dd, J = 4, 8 Hz, 1H), 3.15 (dd, J = 8, 16 Hz, 1H); ms m/z: 166(6), 148(19), 91(100).

*2,3-Dihydroxybenzoic acid (**15**)*: mp 207–210°C, was identified by its spectral properties and by comparison with an authentic sample; ir (methanol cast): 3375, 3040, 2929, 1677, 1657, 1600 cm^{-1}; ^1H nmr (CD_3OD) δ: 7.46 (dd, J = 2, 8 Hz, 1H), 7.00 (dd, J = 2,8 Hz, 1H), 6.74 (t, J = 8 Hz, 1H); ms m/z: 137(9), 108(27), 80(23).

Water uptake bioassay

In this bioassay, the rate of water uptake depends upon the rate of transpiration and is meaningful when the rate of water uptake is relatively large. The seedling is washed free of soil, the root is removed by cutting under water, and the cutting is then immersed in the test solution. After a given time period (which varies according to seedling age), the test solution is replaced with acid fuschin dye for an equal time period. The degree of dye uptake in shoot cuttings that have been treated is measured (cm) and reflects the degree of inhibition of the tested compound on water conduction. Test solutions and control solvent were tested as described above and the measured water uptake is reported as a ratio, length of dye movement for test solution (cm)/length of shoot cutting (cm). In this assay three replicates per solution were tested on 1 and 2 year old lodgepole pine seedlings. The concentration of compound is expressed as fungal concentration, i.e., that isolated from 1 L of culture; 1/2 fungal concentration; and 10 times fungal concentration. In this assay the dye uptake for control solvent gave a ratio of 1. The ratio of dye uptake for metabolite treated seedlings (fungal concentration) divided by dye uptake for solvent treated seedlings: *C. clavigera* broth extract 1.0, mycelial extract 0.6; *C. ips* broth extract 0.5, mycelial extract 0.2; *C. huntii* broth extract 0.5, mycelial extract 0.5; ergosterol peroxide 0.98; succinic acid 1; tryptophol (**2**) 1; tyrosol (**4**) 1; *p*-hydroxybenzaldehyde (**10**) 0.7; 4-hydroxyphenyllactic acid 1; 2,3-dihydroxybenzoic acid (**15**) 1.

Acknowledgments

We wish to thank Dr. Y. Hiratsuka, Northern Forest Research Centre, Canadian Forestry Service, Edmonton for his interest and for cultures of *C. huntii*, *C. ips*, and *C. clavigera*, Anna Szenthe, Department of Chemistry, The University of Alberta, for growing the fungi, Dr. G. Lee, Department of Genetics, The University of Alberta, for helpful discussions, and the Alberta Forestry Service for plant materials. We gratefully acknowledge the financial support of the Natural Sciences and Engineering Research Council of Canada and the Alberta Forest Development Fund.

The concentrations of 13 trace elements were determined in the needles and wood of a closely grouped stand of lodgepole pine infected with blue stain disease. Over 100 samples each of needles and wood from both healthy and diseased trees were analyzed to assess possible correlation between metal levels and degree of infection. Statistical analysis showed no difference in the concentrations of essential trace elements in the wood at the 95% confidence level. Differences were observed at this confidence level in the needles, however, for calcium, iron, zinc, and chromium, calcium being lower and the other three elements higher in the diseased trees. Levels of aluminum, iron, manganese, and calcium in the needles increase 20–30% per year in both diseased and healthy trees.

WILLIAM A. AYER, BYRON KRATOCHVIL, ERIC ALLEN, LOIS M. BROWNE, CLAUDE DUFRESNE, DANIEL FIGUEROA, et ANNA SZENTHE. Can. J. Chem. **64**, 910 (1986).

On a déterminé les concentrations de 13 éléments présents à l'état de trace dans les aiguilles et dans le bois de pins bien regroupés infectés par le maladie des taches bleues. Dans le but d'essayer d'établir une corrélation possible entre les niveaux des métaux et le degré d'infection, on a effectué des analyses sur plus de 100 échantillons tant d'aiguilles que de bois provenant tant d'arbres malades que sains. À un niveau de confiance de 95%, on n'a pas pu noter de différence entre les concentrations des éléments essentiels à l'état de traces. Toutefois, à ce niveau de confiance, on a pu observé des différences dans les aiguilles pour le calcium, le fer, le zinc et le chrome; dans les arbres malades, le niveau de calcium est plus bas alors que les niveaux des trois autres éléments sont plus élevés que dans les arbres sains. Dans les aiguilles, tant des arbres sains que malades, les niveaux d'aluminium, de fer, de manganèse et de calcium augmentent 20–30% par année.

[Traduit par la revue]

Introduction

The disease of pine known as the blue stain disease currently causes the death of about 40 million trees each year in Western Canada (1). The disease is caused by a complex of fungi (2) that are spread by the mountain pine beetle (3). The fungi belong to the genus *Ceratocystis* and the name of the disease derives from the fact that the wood of the diseased trees is stained a pronounced blue color. As part of a collaborative research project with scientists at the Canadian Forestry Service, we have investigated the metabolites produced by these *Ceratocystis* species and this forms the topic of the accompanying paper. The blue coloration appears to be due to the iron chelate of 2,3-dihydroxybenzoic acid (4) and another siderophore isolated from *C. minor* (Hedgcock) Hunt, the structure of which forms the topic of a separate communication.

To test the hypothesis that the blue staining effect and subsequent blue stain disease symptoms (5) are related to metal ion levels, especially iron, we undertook a comparative study of micronutrient element levels of diseased and healthy lodgepole pine (*Pinus contorta* Loudon var *latifolia* Engelm) from one forest stand in southern Alberta. Our method of analyses allowed for the simultaneous determination of multiple element concentrations; thus the measurement of several physiologically important micronutrient metal concentrations, as well as those other elements accessible by the analytical method employed, was undertaken. Xylem sapwood and foliage samples were used in this analysis. Clement and Janin (6) have shown that metal concentrations vary significantly within different areas of the trunk in normal trees, with higher levels occurring in the central ring, then dropping rapidly across the heartwood to the sapwood. Within the sapwood, metal concentrations tend to remain constant. Since the staining of a diseased tree by the blue stain fungi occurs in the sapwood, our sampling of wood tissue was from this area. It is well documented that element concentrations on pine foliage vary with age and position along the crown (7*a*–*c*). For a single growing season nutrient levels are maximum during the summer months, stabilizing in the autumn. Yearly fluctuations arise from variations in moisture conditions and other environmental variables. Our sampling of pine tissue occurred during the summer and took into account tissue age and crown position. There have been few reported studies that compare trace element levels between healthy and diseased pine. On the other hand, several studies (8*a*–*d*) have tried to establish a relationship between environmental pollution and trace element levels observed in healthy and diseased trees. In most cases, however, fewer than three trees have been used for analysis. Because of the inherent tree-to-tree variability and the within-tree variability of element concentrations (7*b*), we chose to study a group of 20 trees, all located within a single stand a short distance from one another.

Experimental

Sample collection

Lodgepole pine (*P. contorta* Loudon var *latifolia* Engelm) located in an area of natural mountain pine beetle infestation near Blairmore, Alberta, were used for this study. The collection day was hot and sunny (25°C) with light winds blowing from the southeast. Samples from closely-grouped diseased (10 trees: tree number(base radius (cm)); 1(10), 2(10), 3(11), 4(11), 5(11), 6(10), 7(10), 8(8), 9(11), 10(9)) and healthy (10 trees: tree number(base radius (cm)); 11(8), 12(9), 13(9), 14(11), 15(11), 16(11), 17(10), 18(9.5), 19(6), 20(11)) trees were obtained.

Each tree was cut at its base. Four 5-cm cross-sections of wood were obtained: one section at the base of the trunk (for diseased trees the blue stain had often spread into the roots), two section about 3 m and 7 m

above the base (in diseased trees this is the area of bark beetle attack), and one section near the base of the crown (for diseased trees this section was just above the upper limit of the stained sapwood). The wood sections were labelled, placed in polyethylene bags, and taken to the laboratory, where three wedge-shaped sections of the sapwood, of about 5 g each, were collected at 120-degree intervals on the circumference of the sections. A total of 125 samples from healthy and 119 samples from diseased trees were obtained.

For each tree, needle samples were obtained from three positions in the crown (low, middle, and apex branches), and insofar as feasible from three ages of tissue (needles produced in 1984, 1983, and 1982 or older). A total of 89 samples from healthy and 53 samples from diseased trees were collected. The diseased trees did not have foliage from 1984, indicating that tree death occurred in the fall of 1983. The needle samples were placed in polyethylene bags, closed with twist ties, and labelled as to tree, position on the tree, and age of needles.

Sample preparation

The wood samples were placed on edge so that both faces of sapwood were exposed to the air for 7 days. Each sample was cut into small pieces (0.3 × 0.3 cm) using a stainless steel blade. The ends of each piece that had been in contact with the chain saw were removed and discarded. The wood pieces were ground to a coarse powder (20 mesh) in a tungsten carbide disk mill (Spex Shatterbox). The wood powder was dried at 85°C for 6 h, then allowed to cool to room temperature in a desiccator over anhydrous calcium sulfate. A sample (1.0 g) was accurately weighed, immediately placed in a dry Erlenmeyer flask (125 mL), and treated with concentrated HNO_3 (15 mL). The mixture was heated to boiling (glass boiling chips) and held at this temperature until it had concentrated to about 1/2 volume. Concentrated HNO_3 (10 mL) was added and the sample was digested and concentrated to a sample volume of 3.5–5 mL. The flask and contents were cooled to room temperature, 70% $HClO_4$ (5.5 mL) was added, and the mixture was heated in a stainless steel fume hood designed for perchloric acid use until dense, white fumes of $HClO_4$ evolved and the solution became colorless (maximum 10 min). The solution was cooled, diluted with doubly distilled water (10 mL), then transferred quantitatively to a volumetric flask (25 mL) and diluted to volume with water. A few clear particles, apparently mineral matter, could be seen in many of the flasks; therefore the solutions were filtered through low porosity, low ash filter paper (Whatman No. 42) into a polyethylene (50 mL) bottle.

The needle samples were dried in open plastic bags on the laboratory bench for 7 days. The dried needles were ground in a tungsten carbide disk mill to a coarse powder (20 mesh), then dried at 85°C for 2 h, and digested as described for the wood above. The digested needle samples contained an insoluble white precipitate of silica (1–3 mg), which was also removed by filtration.

To determine if the knives or grinding mill introduce metal contamination, two wood samples were frozen in liquid nitrogen, ground with a mortar and pestle, and the results compared with those obtained using stainless steel knives and the tungsten carbide disk mill. The only detectable differences observed were with Al, which was about 1 μg/g higher, and with Ni, which was about 0.1 μg/g higher when the knife and disk mill were used. It was concluded that the extent of contamination was sufficiently low that the knife–disk mill method could be used for all the samples.

Analysis

Samples were analyzed by inductively coupled plasma atomic emission spectroscopy (ICP-AE) on a direct reader instrument (Applied Research Laboratories, Model 16000). Plasma operating conditions and flow rates were as follows: frequency 27.12 MHz, forward power 1.25 kW, reflected power 0.05 kW, viewing zone 15 mm above load coil, coolant gas flow rate 10 L/min, auxilliary gas flow rate 0.65 L/min, nebulizer gas flow rate 0.5 L/min. All samples were introduced as aerosols using a standard concentric gas nebulizer. Measurements were made for all the elements listed below; several elements were at or below the detection limits; however, these are not included in the results section. Standard stock solutions (1 000 ppm) of metal salts were prepared by the method of Ward (9) employing the following salts: Al in 6 *M* HCl, $BaCl_2$ in H_2O, H_3BO_3 in H_2O, $CaCO_3$ in 0.5 *M* HNO_3, Cr in 4 *M* HCl, CuO in 4 *M* HNO_3, Fe in 4 *M* HCl, $MgCl_2.6H_2O$ in H_2O, Mn in 4 *M* HNO_3, $NiCl_2.6H_2O$ in H_2O, NaCl in H_2O, and Zn in 4 *M* HNO_3. The following standard solutions prepared from the above stocks were employed: standard 1, water; standard 2, Al, B, Cu, Fe, Mn, Mo, Ni, Zn, 3 ppm each; standard 3, Al, B, Cu, Fe, Mn, Mo, Ni, Zn, 30 ppm each; standard 4, Ba 1 ppm, Ca, Mg 10 ppm each; standard 5, Ba 10 ppm, Ca, Mg, 100 ppm each; standard 6, Na 3 ppm; standard 7, Na 30 ppm; standard 8, Cr 1 ppm; standard 9, Cr 10 ppm; standard 10, NBS pine needles standard reference material 1575, wet digested in the manner described above. Standard solutions of all the elements listed above were aspirated into the plasma at the beginning of data acquisition. These solutions were used to determine the concentration of the elements in the digested wood samples and the elements in the digested needle samples. Integration times were 10 s, and three replicate measurements were performed on each sample and standard solution.

Results and discussion

Results of the analyses are summarized in Table 1 for the needles and Table 2 for the wood. The values in general are similar to those reported by other workers on similar vegetation (7, 8). Because variations in the distribution of the elements also may provide useful information, the factors of needle age and needle and wood location were assessed using a MIDAS statistical package on the University of Alberta Amdahl 5860 computer. The conclusions can be summarized as follows.

No overall differences in the wood samples were observed between diseased and healthy trees by analysis of variance (ANOVA) at the 95% confidence level for any of the elements. Comparison of elements in the individual four wood sections of healthy vs. sick trees by the two sample t-test, however, showed calcium levels to be significantly higher in health sections A, B, and C (0.95 probability) but about the same in healthy and sick trees for section D. No significant trend was found for the other elements tested: B, Mg, Cu, Fe, Zn, Mn, and Ba. On the other hand, differences in the needles were found by ANOVA between diseased and healthy trees at the 95% confidence level for iron, zinc, magnesium, calcium, and chromium. The needles of diseased trees contained 12% less calcium, 15–20% greater levels of iron, zinc, and magnesium, and a four-fold increase in chromium. The magnitude of the differences does not indicate, however, that the blue stain fungi are causing a major perturbation in the levels of essential trace elements except perhaps for chromium.

The levels of aluminum, iron, manganese, and calcium in the needles increase at a rate of 20–30% a year as needle age increases. This trend is seen in both healthy and diseased trees. The accumulation of these trace elements in older foliage tissue has been observed by others (7*b*). The other eight elements studied did not show this trend.

The levels of aluminum and zinc in the needles increase from the base toward the crown of the tree (the overall increase amounting to about 50%), while the levels of calcium and possibly manganese decrease (calcium some 20–30% overall and manganese 15–20% for healthy, and variably for diseased, trees). The other elements showed no statistical change.

For the wood analyses, no trends in elemental composition with vertical location on the trunk were observed for any of the elements measured except magnesium, which shows an increase of 30–40% with height of the section from the ground in both healthy and diseased trees.

In addition to the above observations, an attempt was made to further reduce the effect of variability from highly localized parameters such as soil composition or drainage, by pairing diseased and healthy trees located near each other and performing statistical analysis on the pairs. Precision was not measurably improved, and so additional information could not be obtained by this approach. In fact, we found that trace element levels tended to differ significantly between adjoining healthy (or diseased) trees. It has been observed previously that tree-to-tree variability and within-tree variability of foliage are the main causes of deviation among foliar analyses for major and trace elements (8*b*,*c*). Statistically significant differences in trace element levels between healthy and diseased trees are thus difficult to detect, especially since reported trace element levels normally encompass a fairly wide range.

In conclusion, the magnitude of the natural variability of trace elemental composition of lodgepole pine is sufficiently great that within-tree differences in element levels that may be induced by fungal infection cannot be detected with a high degree of confidence. Previously we reported (4) that several species of blue stain fungi implicated in the blue stain disease of pine produce siderophores. Studies over the last several decades on the effects of chelating agents in plant nutrition have shown that the use of excess chelating agent can be toxic to plants (10*a*–*c*). Absorption of the chelator by the plant facilitates the movement of metals through the plant (11). Slight excesses of iron chelators produce increased iron uptake by plants as a result of an iron stress response (12). These studies are consistent with our findings: iron chelating agents are metabolites of blue stain fungi, and the foliage of blue stain diseased lodgepole pine shows increased levels of iron with respect to foliage of healthy lodgepole pine. It is interesting to note that other wilt diseases caused by microbes (13), e.g. *Fusarium*, produce wilt toxins that seem to chelate micronutritients and induce deficiencies and metal imbalances. Tree pathologists have observed that elms compartmentalize wood infected by the blue stain fungus that causes Dutch elm disease (14). In fact metal imbalances may serve as the "trigger" through which wilt diseases induce the tree to wall off and isolate (compartmentalize) wood infected by such fungi.

Acknowledgments

We wish to thank Mr. R. Miyigawa, Alberta Forestry Service, Edmonton, for help with plant material; Drs. I. Edwards and P. Addison, Northern Forest Research Center, Canadian Forestry Service, Edmonton, for helpful discussions; Mrs. L. Linarez for technical assistance in sample preparation; Mr. Y-B Shao for the ICP-AE analyses; Mrs. M. Duke for the analysis of the statistical data; and the Natural Sciences and Engineering Research Council of Canada for financial support.

Ab Initio SCF MO calculations on the reaction of hydroxyl radical with cytosine

BEVERLEY G. EATOCK, WILLIAM L. WALTZ, AND PAUL G. MEZEY

Department of Chemistry, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received September 5, 1985

BEVERLEY G. EATOCK, WILLIAM L. WALTZ, and PAUL G. MEZEY. Can. J. Chem. **64**, 914 (1986).

Ab initio calculations have been carried out on the relative stabilities of various possible products of the reaction between cytosine and the OH radical. These products are of importance in modelling radiation damage to living tissues. The preferred theoretical gas-phase addition site is the C6 ring atom according to these calculations. The analysis of a series of possible contributions to solvent effects strongly suggests the predominance of intermolecular H bonds in stabilizing the experimentally observed C5 adduct.

BEVERLEY G. EATOCK, WILLIAM L. WALTZ, et PAUL G. MEZEY. Can. J. Chem. **64**, 914 (1986).

On a effectué de calculs *ab initio* sur les stabilités relatives de divers produits possibles pour la réaction de la cytosine avec le radical OH. Ces produits sont importants dans l'élaboration d'un modèle pour les dommages dûs à la radiation dans les tissus vivants. D'après ces calculs théoriques, le site préféré pour l'addition en phase gazeuse est l'atome de carbone C6. L'analyse d'une série de contributions possibles aux effets de solvant suggère fortement la prédominance de liaisons hydrogènes intermoléculaires dans la stabilisation de l'adduit en C5 qui est observé expérimentalement.

[Traduit par la revue]

Introduction

Radiation damage to nitrogen heterocycles has attracted interest due to the relevance of such effects for biologically important systems. As an extension of studies on the reactions of OH radicals with N heterocyclic systems (pyridine, imidazole) (1, 2), we have investigated the attack of OH on the pyrimidine base cytosine. Experimental results on the reaction of OH with cytosine agree that ring addition occurs (3,4), but information on site preference for addition is obtained only by indirect methods (esr, pulse radiolysis) leaving results open to some controversy. *Ab initio* calculations, however, provide a direct aid to identification of favored product isomers, and have been shown to be useful in past studies, supplementing experimental results (1,2,5,6).

Radiation damage to cytosine is of interest because of its status as a component of DNA. Consideration of the N bases of DNA as subjects for *ab initio* studies favors the pyrimidines, both because of their greater susceptibility to OH attack (7) and the simpler problem that the electronic structure of the pyrimidines represents, as compared to the purine bases. Although more information exists regarding reactions of OH with thymine and uracil, the greater experimental controversy for site preference of OH addition to cytosine lent impetus to the choice of cytosine as a subject for these calculations. A recent paper (8) suggested that site selection of OH attack of cytosine is more discriminating than for the analogous reactions with thymine and uracil and that the major product, in opposition to expectations from the results of our previous studies on OH reactions with N heterocycles (1,2), was the species favored on account of electrophilic interactions rather than being the most electronically delocalized product. These factors contributed to the selection of cytosine as the subject for study. In particular, the following two types of processes are of interest:

[1] OH +  → H abstraction radicals + H_2O

[2] OH +  → OH adducts

Hydroxyl radicals are generally thought to add to the ring; however, some evidence also exists for the occurrence of H abstraction (3,4,9) either at the amino group or at N1 (10). Electron spin resonance spectra of the products arising from the reaction of OH with cytosine have yielded ambiguous results as line broadening occurs, obscuring finer splittings. However, all esr studies reported addition of OH at the C5—C6 bond (4,7,11–15). The conclusion by some authors that the C5 adduct is formed is not necessarily reliable as this is based on analogy with the reaction of OH with uracil (7,11,13–15). Both Joshi *et al.* (11) and Planinic (13) found evidence of the formation of two adducts. Planinic concluded that the preferred C5 adduct was kinetically favored by a ratio of 3:2 (13). Published pulse radiolysis work also supports the theory that two adducts are formed (9,16–18). Hissung and Von Sonntag used pulse radiolysis with both optical and conductimetric detection techniques to conclude that 55% of OH addition occurs at the C5 position (9). This preference for attack at the C5 site is supported by Hazra and Steenken who used pulse radiolysis and the oxidative–reductive characteristics of the nascent radicals (8). These authors however found a ratio of preference for the C5 adduct to the C6 adduct of 9:1.

In this paper, we present the results of *ab initio* calculations performed on the reaction of OH with cytosine. Both addition to the cytosine ring and H abstraction were considered as potential reactions. The products resulting from such reactions are depicted in Fig. 1; total energies and energy changes for the reactions [1] and [2] have been determined. Calculations were also performed on different tautometers as well as on various internally H-bonded forms of the adducts, and kinetic aspects of the reaction were investiated via the calculation of assumed reaction paths.

Computational methods

The total energies of reactants and possible products shown in Fig. 1 were calculated by *ab initio* SCF MO techniques using a version of the GAUSSIAN 76 program (19,20). Only the STO-3G minimal basis set was employed in the restricted Hartree–Fock (RHF) and unrestricted Hartree–Fock (UHF) calculations due to the prohibitively large number of functions required for extended basis set calculations. Due to the limitations on the basis set and the lack of the inclusion of correlation energy terms only large calculated energy differences can serve as basis for chemical conclusions. However, the

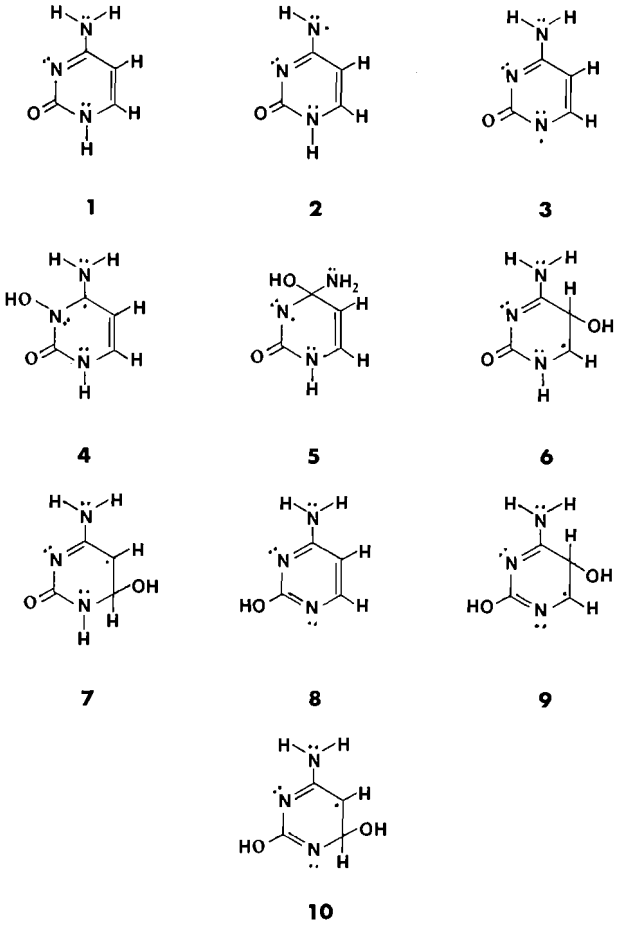

FIG. 1. Species studied and their designations.

high level of correlation between calculated 3G and 4-31G basis results of earlier model studies (2) on various imidazole + OH adducts suggests that an extension of the basis set would not overturn our conclusions. The geometry optimization for the most important species has been carried out to a uniform level of accuracy, higher than that routinely enforced in *ab initio* studies (*vide infra*).

Initial geometries for both cytosine and species **2–7** were obtained from X-ray diffraction data (21) with the local geometry of the OH addition site assumed to be tetrahedral (1,2,5,6). Initial geometries of species **9** and **10** were taken from modified optimized geometries of the analogous keto forms of the adducts. Geometry optimization was performed using the energy gradient method and continued until the average internal coordinate energy derivatives were less than or equal to 0.01 au. Optimization was not carried out as rigorously for species **3**, **4**, **9**, and **10** on the basis of the energetic unfavorability for formation of these species. Further refinement is not expected to change the relative energies of the products. The optimized geometries for all species calculated are reported in the appendix in Cartesian coordinate form. The energy of the OH radical was obtained from the study of OH with pyridines (1).

Quantitative aspects of the kinetics of the various reactions were obtained by calculating energy along assumed reaction paths. Points for each of the reaction path calculations were obtained by taking the mininum calculated energy of a choice of two different ring geometries: a geometry identical to that of the optimized adduct and a geometry intermediate between that of the optimized adduct and the starting reagent were used for the ring geometry with the C—OH bond length varied. There is some degree of arbitrariness in the choice of assumed reaction path. Note, however, that our purpose is to establish upper bounds for activation energies with the given basis set. Any optimization of the reaction path can lead only to an energy lowering, hence these assumed reaction paths provide upper bounds for the theoretical activation energies.

Results and discussion

Calculations were performed on potential products arising from the abstraction of H at N1 and at the amino group and from the addition of OH to the N3—C4 and C5—C6 double bonds.

Initially energies were calculated for the keto tautomeric forms of cytosine and the OH adducts. It is not within the scope of this paper to review the many articles published on the tautomerism of cytosine; here we refer only to some theoretical studies on the subject (22–29) including the first *ab initio* work (22), and a review by Kwiatkowski and Pullman (30) that gives an excellent perspective on this topic. The keto form of cytosine (species **1**) has been shown to be the form present in DNA and in solid crystals (30,31). Recent theoretical calculations (MINDO calculations and other calculations taking some components of solvation into account) (23–25, 29) concur with the results from the wide range of experimental techniques (30) supporting the general acceptance of the keto form as the predominant tautomer in aqueous solution despite the considerable controversy in earlier stages of research.

Tautomerism of the product of the OH reaction with cytosine (Cy) is an area where no direct experimental information exists. Hazra and Steenken (8) report that substitution at the N1 or N3 positions has little effect on site preference, thus implying a keto tautomeric form as shown in species **4–7** (Fig. 1).

Total and relative energies of the keto tautomers of potential products are presented in Table 1. Hydrogen abstraction at the N1 position and at the amino group and addition of OH at N3 are calculated to be unfavorable. The more extensively electron delocalized C6 adduct is calculated to be more stable relative to the C4 adduct and the experimentally found C5 adduct. In earlier theoretical studies (2,22,26–28), an arbitrary value of 40 kJ/mol was set as the limit of significant energy difference; thus, the small energy difference between the C4 and C5 adducts (5 kJ/mol) suggests similar stabilities, and no conclusive ordering in their relative stabilities can be made.

Hazra and Steenken's interpretation of their results (8) relies heavily on the assumption that the C4 and C6 adducts are oxidizing radicals while the C5 adduct has reducing properties. As a check on the veracity of these assumptions, *ab initio* calculations were performed on the optimized geometries of the adducts in question (species **5**, **6**, and **7**) with an electron added to each species. Energies (see Table 2) calculated for the addition of an electron to the adducts confirm that the C4 and C6 adducts are better oxidizing agents than the C5 adduct.

Because of the systematic disparity between the aqueous phase experimental results and the *ab initio* calculations involving heterocyclic compounds (2,22,23,29,30) it was decided to investigate the enol tautomers of the experimentally found C5 adduct and the theoretically preferred C6 adduct. This tautomeric form was chosen on the basis of the favorable relative energy of the enol tautomer of cytosine as suggested by various theoretical calculations (26–29). The results for these calculations, presented in Table 3, show that the enol tautomers are less stable than the corresponding keto forms for the adducts and that C6 is still the preferred addition site.

Energy was calculated for various geometry modifications to test the effect of internal H bonding. Figure 2 depicts the

TABLE 1. Calculated total energies for keto tautomeric forms and relative energies[a]

Species[b]	Molecule or radical	E(tot) (au)	ΔE(kJ/mol)
	OH	−74.3649

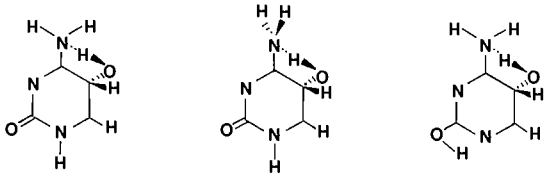
[b]The energy for species **8** is taken from ref. 22.
[c]The geometries for species **9** and **10** were not optimized to as high a degree as for other species (see text).



11 **12** **13**

FIG. 2. Modified geometries for the C5 adduct to test for internal hydrogen bonding.

modifications in geometry of the keto and enol forms of the C5 adduct used for the calculations. To increase the proximity between the hydroxyl protons and the lone electron pair of the N atom, both rotation of the amino group (species **12**) and displacement of the hydroxyl proton back into the plane of the ring (species **11** and **13**) were attempted in order to promote more internal H bonding with the N atoms. Results from these calculations show that these geometries destabilize the adducts

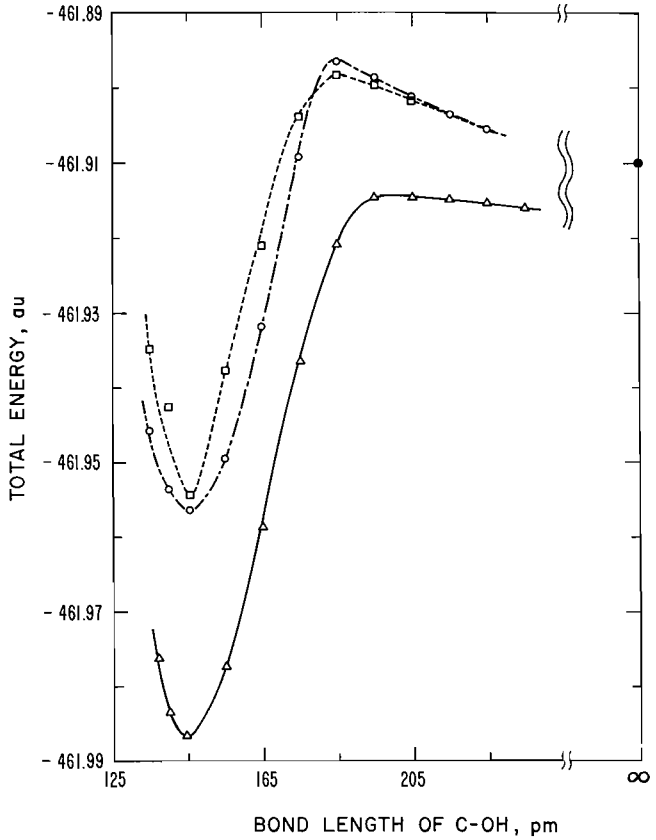


FIG. 3. Energy variation along approximate reaction paths calculated for addition of OH at the C4, C5, and C6 positions of cytosine. The reactions proceed from right to left. (——) C4—OH—Cy, (– – –) C5—OH—Cy, (———) C6—OH—Cy, (●) cytosine + OH at infinite separation.

TABLE 6. Energies corrected for electrostatic solute–water interaction

Species[b]	Molecule or radical	Dip. mom. D	Molec. polar. (Å^3)	Solute-H_2O interaction (kJ/mol)	Relative energy[a] (kJ/mol)	Corrected relative energy (kJ/mol)
2	H abs. NH_2	3.4	10.6	−13.1[b]	183.8	170.7
5	C4—OH—Cy	2.4	12.2	−7.0	−121.0	−128.0
6	C5—OH—Cy	3.8	11.6	−17.8	−116.0	−133.8
7	C6—OH—Cy	3.9	11.6	−18.4	−200.1	−218.5
9	C5—OH—Cy	3.6	11.5	−15.8	−1.1	−16.9
10	C6—OH—Cy	4.2	11.5	−21.4	−88.9	−110.3

[a]Energy is taken relative to eq. [1] for species **2** and eq. [2] for all other species. For species **9** and **10**, the enol form of cytosine (species **8**) was taken to be the starting reactant.

[b]Because species **2** is not an isomer of the other products, additional factors such as cavitation and van der Waal's forces are expected to contribute to a different extent to the solvation energy and hence should not be compared to the solvation energies of the other products.

(species **6** and **9**) by at least 50 kJ/mol, and hence the energy ordering of the OH adducts is unchanged.

To gain some insight into the kinetic aspects of the addition reactions, calculations were performed on assumed reaction paths for addition at the C4, C5, and C6 sites. Such assumed (not optimized) reaction paths, as shown in Fig. 3, are sufficient to give theoretical upper bounds for activation energies. As expected from the near diffusion-controlled rates of reaction (32), the upper bounds for the activation energies for OH addition, given in Table 4, are all small values. From these calculations, it can be seen that attack at the C6 position appears to lead to the kinetically as well as the thermodynamically favored product. No conclusions can be drawn regarding the relative kinetic preference for addition at the C4 vs. C5 positions due to the small difference in calculated approximate activation energies.

In Table 5, we have tabulated calculated spin eigenvalues for each of the radical species **2**–**10**. Comparing these values, S, to the expected value of 0.5 for doublets, it is evident that considerable spin contamination has occurred, as is common in UHF calculations. This likely results in lowered calculated energy values for the adducts while calculated energies for cytosine and OH are for the appropriate singlet and doublet states. Thus comparison of energies of the products to the energies of the starting reactants results in exaggerated low theoretical relative energies. The increase of calculated spins along the assumed reaction paths (shown in Table 5) suggests that the greatest degree of mixing of spin states occurs for the assumed reaction path of the C6 adduct, and thus this can possibly explain the apparent lack of an energy barrier for the addition of OH at C6.

An important aspect for consideration when comparing theoretical results of studies using isolated molecules with experimental results in solution is solvation. Hydrogen-bonding and electrostatic interactions between solute and solvent molecules are the main solvation features expected to modify the relative stabilities of the isomeric products (33, 34). Whereas in aqueous solution, H bonding is often the dominant effect, a direct, quantitative test of this effect with an *ab initio* model is prohibitively expensive. On the other hand, it is relatively simple to account for some electrostatic effects. In an attempt to explain the discrepancy between experimental results and calculated relative stabilities of tautomers of cytosine, Scanlan- and Hillier (23) corrected their calculated energies by including an estimate of electrostatic interaction. Despite the exclusion of consideration of H-bonding interactions, they were successful in showing the change in relative stabilities of tautomers in vapor phase as opposed to tautomers in solution.

Estimates of the water-adduct electrostatic interaction energy have been calculated using the reaction field continuum model (35) and are presented in Table 6. (Calculations are also presented for the product arising from H abstraction at the amino group, despite the nonisomeric nature of this product. Cavitation and van der Waals forces cannot be assumed to have the same effect as for the adduct products.) Molecular polarizabilities have been calculated using the method of Miller and Savchik (36) and the dipole moments have been obtained by *ab initio* STO-3G calculations. The dielectric constant of water was taken to be 78.54 and the radius of the spherical cavity assumed to be the same as for cytosine, 3.3 Å (23).

Although the small energy difference involved permits no definitive conclusions as to preference for attack between the C4 and C5 sites, the energies for electrostatic interaction with water show some reordering of relative stabilities of the adducts with the experimentally found C5 adduct now determined to be slightly more preferred than the C4 adduct. However, the small energy difference involved permits no conclusions as to preference of attack between C4 an C5.

Conclusions

Ab initio calculations have indicated that the preferred reaction of OH with cytosine is addition of OH to the C6 position, whereas the experimental results in aqueous solution indicate the preference for the formation of the C5 adduct. Interestingly, this experimental–theoretical discrepancy appears to be systematic for a number of N heterocyles (2,22,30). Various factors were considered as the basis for the disparity between experimental and theoretical results including tautomerism of the adducts, kinetic effects, mixing of higher order spin states in calculations of wave functions for doublet adducts, internal H bonding, and solvation aspects. Several plausible explanations have been excluded and using essentially a process of elimination, the results suggest that intermolecular hydrogen bonding is the major factor leading to the formation of the C5 adduct in solution as the predominant product.

A study has been performed on the extraction of alkaline-earth metal *ortho*- and *para*-nitrophenoxides, from aqueous medium into methylene chloride, in the presence of crown ether and cryptand complexing agents. The results are analyzed in terms of the various constituent complexation and extraction equilibria involved. Comparison is drawn with our previously reported study on extraction of potassium *p*-nitrophenoxide. The different anion stoichiometries in the two systems result in relatively more favorable extraction of M^+ systems at low anion concentrations. Furthermore, while extraction of MX (X = *o*- or *p*-nitrophenoxide) can be carried out in the presence of excess MOH, this is not possible in the case of MX_2 due to the limited solubility of $M(OH)_2$. The addition of excess MOH leads to more efficient extraction of M^+-phenoxides and prevents hydrolysis to free phenols. A noteworthy point in both MX and MX_2 systems is that at high concentrations of complexing agent a saturation effect occurs, which limits the overall extent of extraction achievable. Under these conditions the extraction is governed by the equilibrium constant, K_{dcs}, representing the partitioning of the complexed salt between the aqueous and organic phases, and is independent of the amount of ligand present.

On a réalisé une étude sur l'extraction des *ortho*- et *para*-nitrophénolates de métaux alcalino-terreux de milieux aqueux vers le chlorure de méthylène, en présence d'éthers couronnes et d'agents complexants cryptants. On analyse les résultats en fonctions des divers équlibres impliqués pour la complexation et l'extraction des constituants. On établit une comparaison avec l'étude que nous avons publiée antérieurement sur l'extraction du *p*-nitrophénolate de potassium. Les stoïchiométries anioniques différentes impliquées dans les deux systèmes font que les systèmes d'extraction de M^+ sont relativement plus favorables à des concentrations faibles d'anions. De plus, alors que l'extraction de MX (X = *o*- ou *p*-nitrophénolate) peut se faire en présence d'un excès de MOH, ceci n'est pas possible dans le cas de MX_2, à cause de la solubilité limitée du $M(OH)_2$. L'addition d'un excès de MOH conduit à une extraction plus efficace des phénolates de M^+ et élimine l'hydrolyse en phénols libres. On doit noter que, à des concentrations élevées d'agent complexant, tant de le système MX que MX_2, il se produit un effet de saturation qui limite les possibilités d'extraction. Dans ces conditions, l'extraction est gouvernée par la constante d'équilibre, K_{dcs}, qui représente la répartition du sel complexé entre les phases aqueuses et organiques, et elle est indépendante de la quantité de ligand qui est présente.

[Traduit par la revue]

Introduction

Efficient extraction of alkali-metal salts from aqueous media into organic solvents is often observed in the presence of macrocyclic complexing agents. This is especially true when the charge on the accompanying anion is highly delocalized as, for example, in the picrate anion (1–6).

Studies of extraction equilibria have considerable practical importance in relation to phase-transfer catalysis (7, 8) and analytical applications (9), and are also frequently used for comparative purposes in estimating the complexing capabilities of newly synthesized ligands (3, 10, 11). At a more fundamental level, a detailed analysis of the various equilibria involved in the overall extraction process is of some intrinsic interest, and is directly relevant to a better understanding of carrier-mediated ion transport in biological and synthetic membranes.

As part of a continuing investigation of the effect of macrocyclic complexing agents of cations on reaction rates and equilibria (12–14), we recently reported results of a comparative study on the extraction of potassium phenoxide, *p*-nitrophenoxide, and picrate from aqueous medium into methylene chloride in the presence of crown ether and cryptand complexing agents (5). In a parallel systematic study, the extraction of potassium phenoxide with macrocyclic ligands from aqueous medium into diverse organic solvents was investigated (6). In the present study we report the results of an investigation on the extraction of alkaline-earth *ortho*- and *para*-nitrophenoxides from aqueous medium into methylene chloride. The divalent cations could possibly serve in binding to two ligand sites in certain molecules of biological interest, which could be pertinent to studies concerning catalysis by metal cations and the effect of crown ethers and cryptands on such processes (14).

Experimental

Materials

The macrocyclic ligands (C) were purchased from BDH, Aldrich, Merck, or Parish Chemical Co., and used as received. Methylene chloride was dried and distilled. *o*-Nitrophenol and *p*-nitrophenol (Fisher, Reagent) were recrystallized from 2% v/v aqueous hydrochloric acid. The alkaline-earth salts of the *o*- and *p*-nitrophenols were prepared using the method of Poonia *et al.* (15, 16), from the alkaline-earth metal hydroxides (Mg^{2+}, BDH; Ca^{2+}, Anachemia;

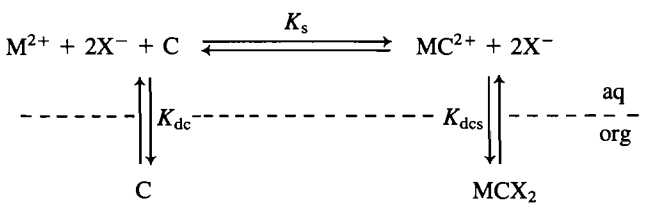
Ba^{2+}, Aldrich) and the *o*- and *p*-nitrophenols in the presence of ammonium hydroxide. As an example of the method, to a solution of *p*-nitrophenol (1.0 g, Fisher) in 95% ethanol (50 mL) was added concentrated ammonia (2 mL) followed by calcium hydroxide (0.27 g) in small portions. The reaction mixture was stirred for 3 h, filtered, and the filtrate was concentrated over a steam bath for 3 h to allow the ammonia to evaporate. The solution was further concentrated until crystallization started and was then allowed to cool. The yellow-orange needle-like crystals of calcium *p*-nitrophenoxide were filtered and dried *in vacuo* (0.10 g).

Extraction procedure

In the previous studies (5, 6) the potassium phenoxide salts were prepared *in situ* and used in the presence of excess hydroxide. The poor solubility of $M(OH)_2$ prevented this approach in the present series and this meant that, except where the basic cryptand ligands were involved, small amounts of the nitrophenoxides were extracted into the organic phase in the form of the free nitrophenol. All solutions (aqueous and organic), however, were analysed by uv, and any ArOH present was readily distinguished from ArO^- by virtue of its different absorption maxima. In other respects the extraction procedure was as previously described (5, 6). Control experiments showed that none of the nitrophenoxide salts were extracted in the absence of ligand. The initial concentrations of the complexing agent and the alkaline-earth nitrophenoxides used in the extraction experiments are listed in Table 1. The results are based on duplicate or triplicate determinations which usually agreed to ±2%.

Results

The equilibria involved in the extraction of the alkaline-earth nitrophenoxides MX_2 are represented in Scheme 1. The



SCHEME 1

extraction of MX_2 in the absence of C is negligible under the present conditions and has not been included in Scheme 1. The three equilibrium constants involved, representing partitioning of the ligand (K_{dc}) and complexed salt (K_{dcs}), and complex formation in the aqueous phase (K_s), are defined in eqs. [1]–[3].

$$[1] \qquad K_{dc} = \frac{[C]_{org}}{[C]_{aq}}$$

$$[2] \qquad K_{dcs} = \frac{[MCX_2]_{org}}{[MC^{2+}]_{aq}[X^-]^2_{aq}}$$

$$[3] \qquad K_s = \frac{[MC^{2+}]_{aq}}{[M^{2+}]_{aq}[C]_{aq}}$$

The equilibrium constant for extraction (by C) of salt MX_2 is defined by eq. [4].

$$[4] \qquad K_e = \frac{[MCX_2]_{org}}{[M^{2+}]_{aq}[X^-]^2_{aq}[C]_{org}}$$

[a]Equilibrium constants referred to zero ionic strength, see Appendix.

Calculation of K_{dcs} (eq. [2]) and K_e (eq. [4]) requries knowledge of the stability constant for complexation in the aqueous phase (K_s), and the extent of partitioning of the free ligand between the aqueous and organic phases (K_{dc}). However, in cases where the free ligand is confined essentially to the organic phase and only weak complexes are formed between M^{2+} and C, we have $[M^{2+}]_{aq} \approx [M^{2+}]'_{aq}$, where $[M^{2+}]'_{aq} = [M^{2+}]_{aq} + [MC^{2+}]_{aq}$, and $[C]_{org} \approx [C]'$, where $[C]'$ is the total concentration of C exclusive of $[MCX_2]_{org}$. Then we may consider an approximate equilibrium constant K'_e given by eq. [5].

$$[5] \qquad K'_e = \frac{[MCX_2]_{org}}{[M^{2+}]'_{aq}[X^-]^2_{aq}[C]'}$$

Calculation of the fraction of M^{2+} (or X^-) extracted into the organic phase via eqs. [4] and [5] is considered in the discussion.

The data in Table 1 yield directly $[M^{2+}]'_{aq}$ and $[C]'$. Thus calculation of K'_e values is quite straightforward and does not require knowledge of either the partition coefficient of the ligand or the stability constant of MC^{2+}. The concentrations required for calculation of K_e (eq. [4]) and K_{dcs} (eq. [2]) may be obtained by appropriate manipulations of the terms contained in the definitions of $[M^{2+}]'_{aq}$, $[C]'$, K_{dc}, and K_s, as described in the Appendix. The ligand partition coefficients, K_{dc} (5, 6), and relevant complex stability constants, K_s (17, 18), used in the calculations are listed in Table 2. The equilibrium constants K'_e, K_e, and K_{dcs}, corrected to infinite dilution (see Appendix), are listed in Table 3.

Individual comments on calculation of the equilibrium constants for the various systems in Table 3 are as follows.

Calcium p-*nitrophenoxide*

An upper limit only is available for the stability constant of the 18-C-6 complex ($\log K_s \leqq 0.5$) (17). However, even assuming the maximum value, at the concentrations used (Table 1) the extent of formation of MC^{2+} is negligible.

Barium o- *and* p-*nitrophenoxide*

Values of K_{dc} and K_s are not available for DC-24-C-8, but K_s should be lower than that for 18-C-6 (17, 19) ($\log K_s = 3.9$) and K_{dc} should be similar to that of DC-18-C-6 ($\log K_{dc} = 3.3$). For any reasonable choice of K_s and K_{dc} it may be shown that the fraction of C and MC^{2+} in the aqueous phase is negligible, and hence $K_e = K'_e$.

Magnesium o- *and* p-*nitrophenoxide*

Stability constants are not available for Mg^{2+} complexes but size considerations suggest that they will be significantly lower than the corresponding values for Ca^{2+} complexes (17–19).

Thus for (2,2,2) and 18-C-6, complex formation in the aqueous phase has been neglected in calculating K_e. The stability constant of $Mg(2,2,1)^{2+}$ may, however, be large, and calculated K_e values are very sensitive to K_s $Mg(2,2,1)^{2+}$ for $K_s \geqq 10^2 M^{-1}$. Thus it is not possible to calculate K_e for extraction of Mg^{2+} salts by cryptand (2,2,1) with any certainty.

Discussion

In considering the extraction of M^{2+} salts, compared with the corresponding M^+ salts investigated previously (5, 6), two important differences may be noted. The first is that for a given cation size the solvation energy of M^{2+} is considerably larger than that of M^+. This leads to the practical result that in the present systems no extraction of M^{2+} salts was observed in the absence of added complexing ligand. This in turn simplifies the calculation somewhat and obviates the need of an iteration procedure in analyzing the data.

More importantly, there is also a difference in the stoichiometry of the extraction reaction. This means that the relative efficiencies of extraction of M^+ and M^{2+} systems will depend not only upon the differences in solvation energies of the cations and the extent to which these are modified or overcome by complexation with the ligands, but also on the total salt concentration range investigated. Thus extraction of MX_2 will be much more sensitive to the concentration and nature of the anion X^- than in the corresponding MX system. This is discussed quantitatively below, but it is clear that at low $[X^-]$ extraction of MX will be favoured relative to MX_2, and that the extraction of MX_2 becomes increasingly favoured with increasing $[X^-]$, as the latter has a second-order dependence on $[X^-]$. Thus any simple comparison of extraction percentages of M^{2+} and M^+ salts will be valid only for the concentrations at which the measurements were carried out.

A feature common to both M^+ and M^{2+} systems is that the extent of complex formation in the aqueous phase has a very strong influence on the overall extraction behaviour, especially for ligands with a significant tendency to partition into the aqueous phase. This is because in such cases a considerable proportion of M^{2+} (or M^+) may remain in the aqueous phase as MC^{2+} (or MC^+). Thus in the limit of high ligand concentrations, although eq. [4] (correctly) predicts that $[M^{2+}]_{aq}$ will approach zero, the extent of extraction of M^{2+} (as MCX_2) into the organic phase will not increase indefinitely, but rather will be governed by eq. [2], i.e., the extent to which the *complexed ion* partitions between the two layers. For purely practical purposes the percentage of extraction of a salt into the organic phase may be required, and it follows from the above that K_e values are often not of *direct* use in this respect. This is illustrated and amplified below in some detail for the extraction of M^{2+} salts as investigated in this work, but corresponding equations for M^+ may be written down by inspection.

The ratio of M^{2+} in the organic and aqueous phases, $[MCX_2]_{org}/[M^{2+}]'_{aq}$, and hence the percentage extraction is given by eq. [6].

$$[6] \qquad \frac{[MCX_2]_{org}}{[M^{2+}]'_{aq}} = \frac{K_e[X^-]^2_{aq}[C]_{org}}{1 + [C]_{org}K_s/K_{dc}}$$

Equation [6] follows directly from eq. [4] and the definition of $[M^{2+}]'_{aq}$ (= $[M^{2+}]_{aq}$ + $[MC^{2+}]_{aq}$, i.e. the total concentration of M^{2+} in the aqueous phase), together with eqs. [1] and [2]. There are two limiting cases corresponding to eq. [6].

(*i*) $[C]_{org}K_s/K_{dc} \ll 1$. This will occur at sufficiently low $[C]_{org}$, when the stability constant for complex formation is very small, or when the ligand partitions almost exclusively into the organic phase. Equation [6] then reduces to eq. [7].

$$[7] \qquad \frac{[MCX_2]_{org}}{[M^{2+}]'_{aq}} = K_e[X^-]^2_{aq}[C]_{org}$$

and the concentration ratio of M^{2+} in the two phases depends directly upon $[C]_{org}$.

(*ii*) $[C]_{org}K_s/K_{dc} \gg 1$. This corresponds to limiting high concentrations of $[C]_{org}$, very stable MC^{2+}, or strong partitioning of C into the aqueous phase. Under these conditions, quantitative conversion of M^{2+} in the aqueous layer to MC^{2+} occurs and the concentration ratio is given by eq. [8].

$$[8] \qquad \frac{[MCX_2]_{org}}{[M^{2+}]'_{aq}} = \frac{K_eK_{dc}[X^-]^2_{aq}}{K_s} = K_{dcs}[X^-]^2_{aq}$$

It is clear from the above that the relative efficiencies of two different ligands as extracting agents will depend upon the concentration range employed. This is illustrated by the results in Table 4, in which the extraction of $Ba(p\text{-}NO_2PhO)_2$ with a ligand of very strong complexing ability (2,2,2) is compared with one of moderate complexing ability (18-C-6). It may be seen that even at very low (excess) levels (10^{-4} *M*) of (2,2,2) the maximum extent of extraction is obtained. For 18-C-6, significantly higher levels are required to achieve maximum extraction, but the limiting value is only slightly lower than that for (2,2,2). This latter observation, which follows from the similar K_{dcs} values (Table 3), contrasts sharply with the behaviour of the corresponding K^+ salt (5, 6), results for which are also included in Table 4. In this case, although similar trends with ligand concentration are observed, the limiting extraction percentage is very much lower for 18-C-6 than for (2,2,2).

TABLE 4. Extraction of $Ba(p\text{-}NO_2PhO)_2$ (0.1 *M*) and $K(p\text{-}NO_2\text{-}PhO)$ (0.01 *M*) from water to methylene chloride by 18-C-6 and (2,2,2)

[a]Equilibrium excess ligand concentration.

The difference in behaviour of (2,2,2) and 18-C-6 with respect to extraction of the two cations K^+ and Ba^{2+} (which have similar ionic radii) may result from structural differences of the two ligands. For the essentially planar 18-C-6 ligand, cation coordination sites perpendicular to the ligand plane remain free, whereas the spherical cavity of the cryptand ligand totally encapsulates the ions. This would tend to make extraction of the 18-C-6 complexes more difficult, as in aqueous solution the remaining coordination sites would be occupied by water molecules, conferring extra stability on the complex. However, for the Ba^{2+} crown complex in methylene chloride the two associated anions can presumably satisfy both remaining coordination sites so that there is little difference between the extraction of Ba^{2+} as the (2,2,2) or 18-C-6 complexes. In the case of the K^+ crown complex there is only one anion available for coordination to K^+ in the organic phase.

It is of course difficult to compare the *absolute* extents of

extraction of M^+ and M^{2+} cations in any meaningful thermodynamic way, as the ratio of cation concentration in the organic and aqueous phases varies with $[X^-]$ in the former case and $[X^-]^2$ in the latter case. This means that for low salt concentrations extraction of KX will be favoured relative to BaX_2 and vice versa. It may readily be shown from the K_{dcs} values for the 18-C-6 extraction of barium *p*-nitrophenoxide (Table 3) and potassium *p*-nitrophenoxide ($3.60\,M^{-1}$) (5, 6) that at limiting high ligand concentrations the two salts are extracted to an equal extent when the salt concentrations are $3 \times 10^{-3}\,M$; the corresponding figure for extraction by (2,2,2) is $1.25\,M$.

Comparing the present overall results with those reported previously (5, 6), in practice the efficiency of extraction of *p*-nitrophenoxide achieved for the K^+ salt by the macrocyclic ligands was much higher than the values reported here. This is because it was possible to carry out the extractions in the presence of excess potassium hydroxide, which has the effect of driving the equilibrium position towards more favourable anion extraction percentages. This is not possible for M^{2+} systems because the limited solubility of $M(OH)_2$ necessitated the use of the prepared phenoxide salts. This represents a practical limitation in the extraction of phenoxides as their alkaline earth salts and also means that the hydrolysis of phenoxide to generate small quantities of (readily extractable) phenol could not be suppressed by the addition of excess hydroxide.

While the present results refer to the extraction of nitrophenoxide salts of the alkaline-earth cations, it is known from earlier work on K^+ salts (5, 6) that the extent of extraction is very sensitive to the nature of the accompanying anion. Thus for several crown ether and cryptand complexing ligands in a variety of solvents the order of extraction of K^+ salts was always phenoxide $\ll$ *p*-nitrophenoxide $\ll$ picrate, and in a number of cases extraction of picrate salts was observed even in the absence of added ligand. The extraction of salts of simple, highly solvated ions such as Cl^-, OH^-, etc. should be even more difficult than that of the phenoxide salts (20). These general trends relating to the nature of the anion should also be observed for M^{2+} salts, but are expected to be considerably amplified because of the involvement of two anions in the extraction process.

The results for extraction of Ca^{2+} and Ba^{2+} salts by cryptand ligands show that the *complexed* Ca^{2+} salts (K_{dcs} values) are extracted slightly more readily than the corresponding complexed Ba^{2+} salts. This is a good illustration of the extent to which the bicyclic cryptand ligands are able to shield the enclosed cations from the surrounding solvent. It has been shown, for example, that the extent of extraction of simple uncomplexed uni–univalent electrolytes such as alkali metal halides from water to organic solvents such as nitrobenzene and 1,2-dichloroethane decreases dramatically with decreasing cation (or anion) size (21, 22); e.g., for transfer between water and nitrobenzene, $K_{ds}(NaBr)/K_{ds}(KBr) = 2 \times 10^{-3}$. This is in line with the increased hydration energies of the small ions, and even larger differences would be expected for uncomplexed Ca^{2+} and Ba^{2+} salts, because of the much higher hydration energies involved ($\Delta G_{hyd}(Ca^{2+}) - \Delta G_{hyd}(Ba^{2+}) = 274\,kJ\,mol^{-1}$; cf. $\Delta G_{hyd}(Na^+) - \Delta G_{hyd}(K^+) = 73.5\,kJ\,mol^{-1}$) (ref. 23).

Appendix

The total concentrations of M^{2+} and C exclusive of $(MCX_2)_{org}$, $[M^{2+}]_t'$, and $[C]_t'$, respectively, are defined by eqs. [A1] and [A2],

$$[A1] \quad [M^{2+}]_t' = [M^{2+}]_{aq} + [MC^{2+}]_{aq} = [M^{2+}]_t - [MCX_2]_{org}$$

$$[A2] \quad [C]_t' = [C]_{org} + [C]_{aq} + [MC^{2+}]_{aq} = [C]_t - [MCX_2]_{org}$$

where $[M^{2+}]_t$ and $[C]_t$ are the total concentrations of M^{2+} and C in the system.

By combining eqs. [A1] and [A2] with eq. [1] (K_{dc}) and eq. [3] (K_s) it is possible to calculate all of the concentrations required to evaluate K_e (eq. [4]) and K_{dcs} (eq. [2]) as follows. Substituting eq. [1] into [A2] gives eq. [A3],

$$[A3] \quad [C]_{aq} = \frac{[C]_t' - [MC^{2+}]_{aq}}{1 + K_{dc}}$$

which, upon substitution into eq. [3], leads to eq. [A4]:

$$[A4] \quad [MC^{2+}]_{aq} = \frac{K_s[M^{2+}]_{aq}[C]_t'}{1 + K_{dc} + K_s[M^{2+}]_{aq}}$$

Substitution of eq. [A4] into eq. [A1] gives eq. [A5]:

$$[A5] \quad [M^{2+}]_{aq} = \frac{-b \pm (b^2 - 4c)^{1/2}}{2}$$

where

$$b = \frac{1 + K_{dc} + K_s([C]_t' - [M^{2+}]_t')}{K_s}$$

and

$$c = \frac{-(1 + K_{dc})[M^{2+}]_t'}{K_s}$$

This value of $[M^{2+}]_{aq}$ may then be substituted into eq. [A1] to give $[MC^{2+}]_{aq}$, which with eq. [A3] gives $[C]_{aq}$, and hence, from eq. [1], $[C]_{org}$.

Calculations carried out in this manner give equilibrium constants referred to the ionic strengths at which the measurements were carried out. K_e (and hence K_e') and K_{dcs} values may be corrected to infinite dilution via eqs. [A6] and [A7], in which γ is the activity coefficient.

$$[A6] \quad K_e = \frac{[MCX_2]_{org}}{[M^{2+}]_{aq}[X^-]^2[C]_{org}\,\gamma_{M^{2+}}\gamma_{X^-}^2}$$

$$[A7] \quad K_{dcs} = \frac{[MCX_2]_{org}}{[MC^{2+}]_{aq}[X^-]_{aq}^2\,\gamma_{M^{2+}}\gamma_{X^-}^2}$$

The required activity coefficients were calculated using the Davies equation (eq. [A8]) (ref. 24),

$$[A8] \quad \log \gamma_{\pm} = \frac{-AZ^2 I}{1 + I^{1/2}} + \frac{AI}{3}$$

in which $A = 0.5$ is the Debye–Hückel parameter and I is the ionic strength. The ionic strengths involved were quite low (0.007–0.015 M) but the overall activity coefficient correction, $\gamma_{M^{2+}}\gamma_{X^-}^2$, is not negligible, varying between 0.697 and 0.611. It is assumed also that $\gamma_{MC^{2+}} = \gamma_{MC^{2+}}$ (see eqs. [A6], [A7]).

Apparent molar heat capacities and volumes of aqueous solutions of several 1:1 electrolytes at elevated temperatures[1]

Research Chemistry Branch, Atomic Energy of Canada Limited, Whiteshell Nuclear Research Establishment, Pinawa, Man., Canada R0E 1L0

Received November 20, 1985

PREET P. S. SALUJA, JACQUES C. LEBLANC, and HAROLD B. HUME. Can. J. Chem. **64**, 926 (1986).

The results of heat capacity (C_p) and density (d) measurements at 0.6 MPa and in the temperature range 298.15–373.15 K are presented for several 1:1 electrolytes in water. The flow microcalorimeter and densimeter used for these measurements were modificatons of the room-temperature designs. Data were obtained over concentrations ranging from 0.02 to 1.0 mol kg^{-1} (or to the solubility limit, whichever was lower). The heat capacity of a solution relative to that of water was measured with a precision of ± 0.1 mJ K^{-1} g^{-1} at all temperatures. The density of a solution relative to that of water was measured with a precision of ± 5 μg cm^{-3}. These C_p and d results were used to calculate the apparent molar heat capacities, ${}^{\phi}C_p$, and volumes, ${}^{\phi}V$, at 298.15, 323.15, 348.15, and 373.15 K, at a constant pressure of 0.6 MPa. These results are in good agreement with available literature data.

PREET P. S. SALUJA, JACQUES C. LEBLANC et HAROLD B. HUME. Can. J. Chem. **64**, 926 (1986).

Opérant à 0,6 MPa et à des températures allant de 298,15 à 373,15 K, on a mesuré les capacités calorifiques (C_p) et les densités (d) de plusieurs mélanges 1:1 d'électrolytes dans l'eau. Les densimètres et microcalorimètres à écoulement utilisés pour ces études étaient des appareils à température ambiante qui avaient été modifiés. On a obtenu des données à des concentrations allant de 0,02 à 1,0 mol kg^{-1} (ou, si elle était plus basse, jusqu'à la limite de solubilité). A toutes les températures, on a pu mesurer la capacité calorifique d'une solution relative à celle de l'eau avec une précision de $\pm 0,1$ mJ K^{-1} g^{-1}. On a mesuré la densité des solutions relative à celle de l'eau avec une précision de ± 5 μg cm^{-3}. On a utilisé ces résultats de C_p et de d pour calculer les capacités calorifiques, ${}^{\phi}C_p$, et les volumes, ${}^{\phi}V$, molaires apparents à des températures de 298,15, de 323,15, de 348,15 et de 373,15 K et à une pression constante de 0,6 MPa. Ces résultats sont en bon accord avec ceux disponibles dans la littérature.

[Traduit par la revue]

Introduction

Thermodynamic data for aqueous species at elevated temperatures are requried to understand, and model, various chemical processes in the vicinity of an underground nuclear fuel, waste disposal vault (1, 2), specifically the interactions of aqueous I^-, IO_3^-, Cs^+, and TcO_4^- with major constituents of groundwaters and mineral surfaces. Experimental heat capacities, C_p, are needed to determine partial molar heat capacities, $\bar{C}^0_{p,2}(T)$, and thereby standard Gibbs energies, $\bar{G}^0_2(T)$, for aqueous species as a function of temperature. Gibbs energies can then be used to calculate solubilities and chemical speciation in aqueous environments (2, 3).

The $\bar{G}^0_2(T)$ can be calculated at any temperature, T, using the following thermodynamic relation:

$$[1]\quad \bar{G}^0_2(T) = \bar{G}^0_2(T_R) - \bar{S}^0_2(T_R)(T - T_R) - T\int_{T_R}^{T} \frac{\bar{C}^0_{p,2}(T)}{T}\,dT + \int_{T_R}^{T} \bar{C}^0_{p,2}(T)\,dT$$

Standard Gibbs energy, $\bar{G}^0_2(T_R)$, and entropy, $\bar{S}^0_2(T_R)$, at room temperature (T_R) are usually available in the literature, in regularly updated compilations (4). To calculate Gibbs energies at elevated temperatures, we only need to determine $\bar{C}^0_{p,2}(T)$ as a function of temperature. The latter is identical to the apparent molar heat capacity, ${}^{\phi}C_p(T, m)$, extrapolated to infinite dilution ($m = 0$, m being the molality of solution in mol kg^{-1}) using a suitable ion-interaction approach for modelling ionic solutions (3, 5, 6). The ${}^{\phi}C_p(T, m)$ can be calculated directly from the heat capacity measurements, $C_p(T, m)$, over a wide range of concentrations and temperatures.

While $C_p(T, m)$, ${}^{\phi}C_p(T, m)$, and $\bar{C}^0_{p,2}(T)$ values for a few aqueous 1:1 species are available at room temperature (7–10), very few values (4, 11, 12) are available at higher temperatures. This is because both heat capacity and density measurements at elevated temperatures have been difficult. Consequently, the available data for aqueous species are often inconsistent. For example, the two $\bar{C}^0_{p,2}$ values for CsI in the literature agree only in the 300–323 K range. Data from adiabatic calorimetry (12) show a maximum, at about 353 K, in the $\bar{C}^0_{p,2}$ vs. temperature plot, whereas the data of Mitchell and Cobble (11) show no maximum in the 273–373 K range.

Recent advances in flow calorimeters (1, 5, 14, 15) and flow densimeters (1, 16, 17) allow determination of $C_p(T, m)$ and $d(T, m)$ data with improved precision, and make measurements in aqueous solutions at elevated temperatures easier. Thus, we have undertaken to measure heat capacities and densities of several 1:1 electrolytes, including fission product electrolytes (Cs, I). In this paper, we give measured heat capacities, calculated ${}^{\phi}C_p(T, m)$ values, measured densities, and calculated apparent molal volumes, ${}^{\phi}V(T, m)$, for nine 1:1 elctrolytes up to 373.15 K at a constant pressure of 0.6 MPa. In ref. 6, we apply Pitzer's ion-interaction model (1, 5) to our data to obtain $\bar{C}^0_{p,2}(T)$ and $\bar{V}^0_2(T)$ functions and to calculate thermodynamic properties of aqueous electrolytes at higher temperatures.

Experimental

(a) General approach

As discussed above, the $\bar{C}^0_{p,2}(T)$ and $\bar{V}^0_2(T)$ functions, two quantities of interest, are, respectively, identical to infinite-dilution ${}^{\phi}C^0_p(T)$ and ${}^{\phi}V^0(T)$ values, over a wide temperature range. Since ${}^{\phi}C_p(T, m)$ and ${}^{\phi}V(T, m)$ values can be experimentally determined only in finite concentration ranges, a theoretical ion-interaction approach (1, 5) is required to extrapolate these values to infinite dilution. To apply this model, a large number of $C_p(T, m)$ and $d(T, m)$ measurements are required, with a high degree of precision, for the parametric fit of the data to Pitzer's equations, to evaluate reliably the $\bar{C}^0_{p,2}(T)$ and $\bar{V}^0_2(T)$ functions and the temperature-dependent ion-

considering the uncertainties estimated in such measurements. This was expected, because the literature data were obtained recently with a room-temperature version of our flow microcalorimeter and flow densimeter system (1, 3).

For KIO_3, $CsIO_3$, and $KClO_4$, no room-temperature literature data are available for comparison. In the case of NaI and HCl, heat capacity and density measurements were not carried out at room temperature.

High-temperature values

Figure 2 shows a comparison of our data for CsCl, at 323.15

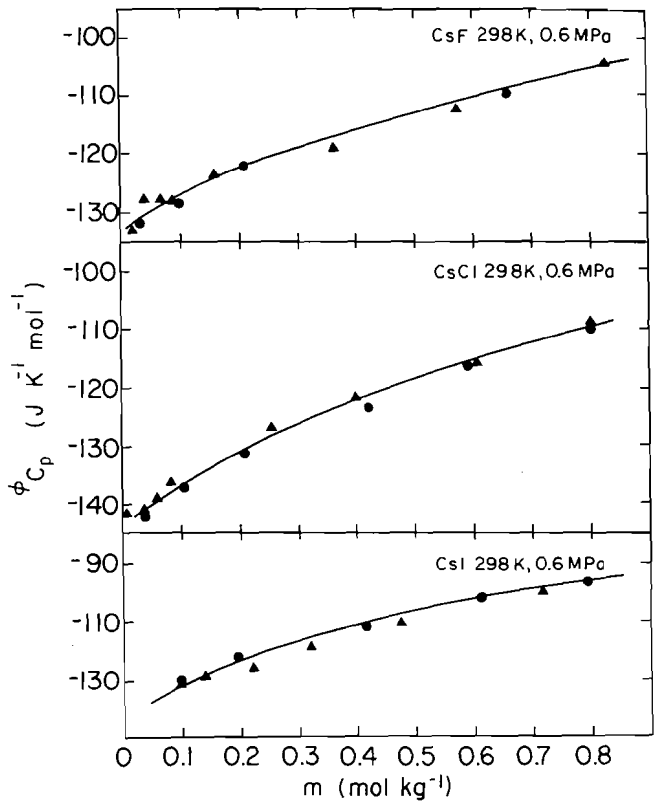

FIG. 1. Apparent molar heat capacities, $^\Phi C_p$, as a function of molality, m, for aqueous solutions of cesium halides; a comparison with 298.15 K data of Fortier *et al.* (7) and Desnoyers *et al.* (8). Present work, ●; data for refs. 7 and 8, ▲.

and 373.15 K, with existing data as a function of concentration (12). The literature data were obtained from adiabatic calorimetry measurements, and are based on only three, relatively high concentration (0.498, 1.084, and 1.606 mol kg^{-1}) of aqueous CsCl (12). The agreement is reasonable, but our $^\Phi C_p(T, m)$ values are about 5 J K^{-1} mol^{-1} less negative than the $^\Phi C_p(T, m)$ values of Rüterjans *et al.* (12). We believe the reason for the discrepancy at higher temperatures is that the adiabatic calorimetric measurements (12) require vaporization corrections, because both liquid and vapour phases of the sample coexist during the course of C_p measurement (12, 21). The large vaporization corrections at higher temperatures decrease the precision of the measured heat capacities and, consequently, of the $^\Phi C_p(T, m)$ values (12). The present flow calorimetric method does not require such vaporization corrections (1, 13).

Our $^\Phi C_p(T, m)$ values for CsI are about 13 J K^{-1} mol^{-1} less

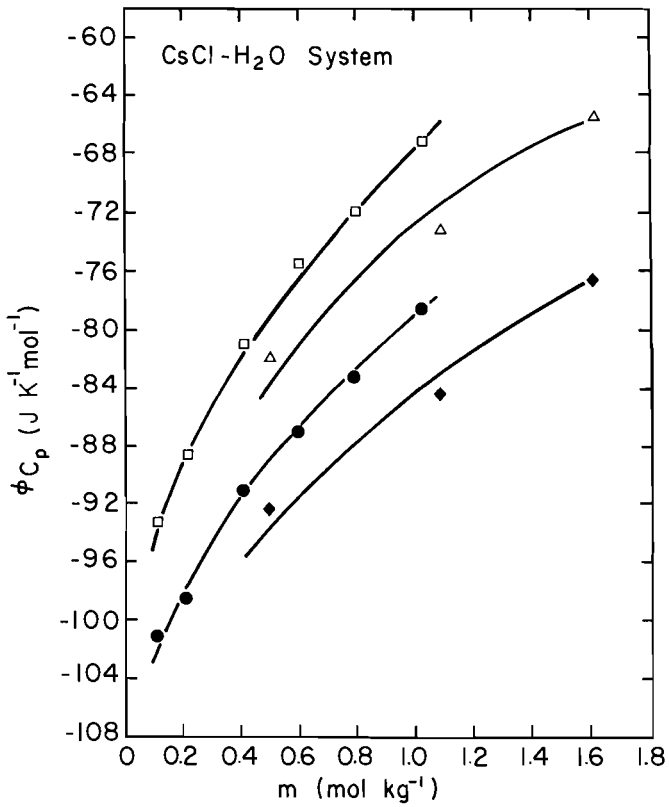

FIG. 2. Apparent molar heat capacities, ${}^{\phi}C_p$, as a function of molality, m, for aqueous CsCl solutions; a comparison with data of Rüterjans *et al.* (12) at 323.15 and 373.15 K. Data for 323.15 K: ◆, ref. 12; ●, present work. Data for 373.15 K: △, ref. 12; □, present work.

negative at 323.15 K and about 18 J K^{-1} mol^{-1} less negative at 373.15 K than the ${}^{\phi}C_p(T, m)$ values of Rüterjans *et al.* (12). We attribute the discrepancies between the two sets of data to uncertainties in the literature data associated with the vaporization corrections, as discussed above.

In the case of NaI, CsF, $NaIO_3$, KIO_3, $CsIO_3$, and $KClO_4$, no literature data at higher temperatures are available for comparison.

Conclusions

We have obtained the heat capacities (C_p and ${}^{\phi}C_p$), densities (d) and volumes (${}^{\phi}V$) of several 1:1 electrolytes in water, as a function of temperature and concentration. Our data are in good agreement with the sparse data available in the literature and determined by similar, or different, techniques. The present data are used in ref. 6 to determine reliable $\bar{C}^{o}_{p,2}(T)$ functions, which can then be used to calculate the thermodynamic properties of ions in water over an extended temperature range.

The chemistry of some methoxychlor derivatives

WILLIAM H. BAARSCHERS[1] AND JAMES P. VUKMANICH
Department of Chemistry, Lakehead University, Oliver Road, Thunder Bay, Ont., Canada P7B 5E1
Received May 21, 1985[2]

WILLIAM H. BAARSCHERS and JAMES P. VUKMANICH. Can. J. Chem. **64**, 932 (1986).

The preparation of 1-chloro-2,2-bis(*p*-methoxyphenyl)ethylene (**3***a*) and of 1-chloro-2,2-bis(*p*-hydroxyphenyl)ethylene (**3***b*), required for a study of the microbial degradation of methoxychlor (**1***a*) was reinvestigated. The methoxy compound (**3***a*) was readily obtained by alkaline dehydrohalogenation of 1,1-dichloro-2,2-bis(*p*-methoxyphenyl)ethane (**2***a*), but similar treatment of 1,1-dichloro-2,2-bis(*p*-hydroxyphenyl)ethane (**2***b*) gave a chlorine-free compound, characterized as the diethyl acetal of 2,2-bis(*p*-hydroxyphenylacetaldehyde (**5***a*) on the basis of spectroscopic evidence and comparison with a model compound. Also, 2,2-bis(*p*-methoxyphenyl)acetic acid (**4***a*) and 2,2-bis(*p*-hydroxyphenyl)acetic acid (**4***b*) were prepared and the solubility and *p*-values (ethyl acetate/water) of these acids were determined.

WILLIAM H. BAARSCHERS et JAMES P. VUKMANICH. Can. J. Chem. **64**, 932 (1986).

On a réétudié la préparation du chloro-1 bis(*p*-méthoxyphényl)-2,2 éthylène (**3***a*) et du chloro-1 bis(*p*-hydroxyphényl)-2,2 éthylène (**3***b*) qui nous étaient nécessaires pour une étude de la dégradation microbienne du méthoxychlor (**1***a*). On obtient facilement le composé méthoxylé (**3***a*) par une déhydrohalogénation alcaline du dichloro-1,1 bis(*p*-méthoxyphényl)-2,2 éthane (**2***a*); toutefois, si l'on traite le dichloro-1,1 bis(*p*-hydroxyphényl)-2,2 éthane (**2***b*) de la même manière, on obtient un composé ne contenant pas de chlore. Sur la base de données spectroscopiques et par comparaison avec un composé modèle, on a établi qu'il s'agissait du diéthyl acétal du bis(*p*-hydroxyphényl)-2,2 acétaldéhyde (**5***a*). De plus, on à préparé l'acide bis(*p*-méthoxyphényl)-2,2 acétique (**4***a*) et l'acide bis(*p*-hydroxyphényl)-2,2 acétique (**4***b*) et l'on a déterminé leurs solubilités ainsi que leurs valeurs *p* (acétate d'éthyle/eau).

[Traduit par la revue]

Introduction

It was shown (1) that methoxychlor (**1***a*) and its hydroxy analogue (**1***b*) are reductively dechlorinated by *Klebsiella pneumoniae*. The resulting dichloro compounds (**2**) appeared to be further degraded, possibly (2) via the monochloro-olefins (**3**) to the substituted phenylacetic acids (**4**). Better evaluation of these preliminary results (1) required the preparation of the monochloro-olefins (**3**) and the acids (**4**) and measurement of the water solubility and extractability of the latter.

Most of the required compounds could be synthesized by methods published in earlier literature (3–5) and need no further discussion. However, attempts to prepare the dihydroxymonochloro-olefin (**3***b*) by alkaline dehydrohalogenation led to an unusual substitution product. The elucidation of structure **5***a* for this product on the basis of its spectroscopic properties and a comparison with the model compound **5***b* constitute a major part of this report.

Results and discussion

The dehydrohalogenation of substituted 2,2-diarylchloroethanes, including methoxychlor (**1***a*), has been studied by Cristol *et al.* (6). These authors found the rate of this E2 reaction to be primarily dependent on the acidity of the benzylic hydrogen, which in turn is determined by the electronic effects of the *p*-substituents on the aromatic rings and the degree of chlorine substitution on the α-carbon. Thus, the dehydrohalogenation of methoxychloro (**1***a*), hydrochlor (**1***b*), and the dimethoxydichloro compound (**2***a*) was found to proceed smoothly in ethanolic potassium hydroxide. In the case of hydroxychlor (**1***b*), the decrease in acidity of the benzylic hydrogen caused by the formation of the dianion (in alkaline medium) is sufficiently offset by the presence of the trichloromethyl group to allow elimination to proceed.

For the dihydroxydichloro compound (**2***b*) it appears that the decrease in chlorine substitution, as compared to hydroxychlor (**1***b*), has attenuated the acidity of the benzylic hydrogen to a point where alkaline dehydrohalogenation is no longer possible. Thus, treatment of the dichloro compound (**2***b*) with ethanolic potassium hydroxide gave a crystalline. chlorine-free product, $C_{18}H_{22}O_4$, in nearly quantitative yield. The elucidation of structure **5***a* (Scheme 1) for this new compound is relevant to the understanding of the chemistry of the 2,2-diarylchloroethanes.

The proton nuclear magnetic resonance (^{1}H nmr) spectrum of this unexpected reaction product contained multiple signals centered at δ = 9.04 and 3.20 ppm, characteristic of two equivalent ethoxy groups. A single 2-proton signal at δ = 4.21 ppm was initially assigned to the methylene group in a benzoin type structure (**7**), which could mechanistically be rationalized in terms of a modified Fritsch–Buttenburg–Wiechell rearrangement (7). However, a symmetrical 4-line pattern (8H), centered at δ = 6.94 ppm in this spectrum, indicated the equivalence of the two aromatic rings, which is inconsistent with structure **7**.

Treatment of the ethoxy compound with *p*-toluenesulfonic acid in dry acetone (8) gave a crude mixture in which the aldehyde (**6***a*) was the major component. Although attempts to purify this aldehyde failed due to slow and continuing decomposition during handling, the impure aldehyde (ν_{max} = 1719 cm^{-1}) gave a ^{1}H nmr spectrum in which the benzylic proton (H_a, **6**) gave a signal at δ = 4.69 ppm coupled (J = 1.5 Hz.) with the aldehydic proton (H_b) at δ = 9.75 ppm. The instability of the aldehyde (**6***a*) must be attributed to the *p*-hydroxy groups, since the commercially available diphenyl acetaldehyde (**6***b*) is a stable compound.

The anomalous chemical shift of the protons H_a and H_b of the acetal **5***a* must also be attributed to the presence of the *p*-hydroxy groups. Hexadeuteroacetone, routinely used in this study for solubility reasons, could form hydrogen bonds with these hydroxy groups, causing the benzylic proton H_a and the α-proton H_b to have the same chemical shift, so that only the single two-proton signal at δ = 4.21 is observed. Attempts to

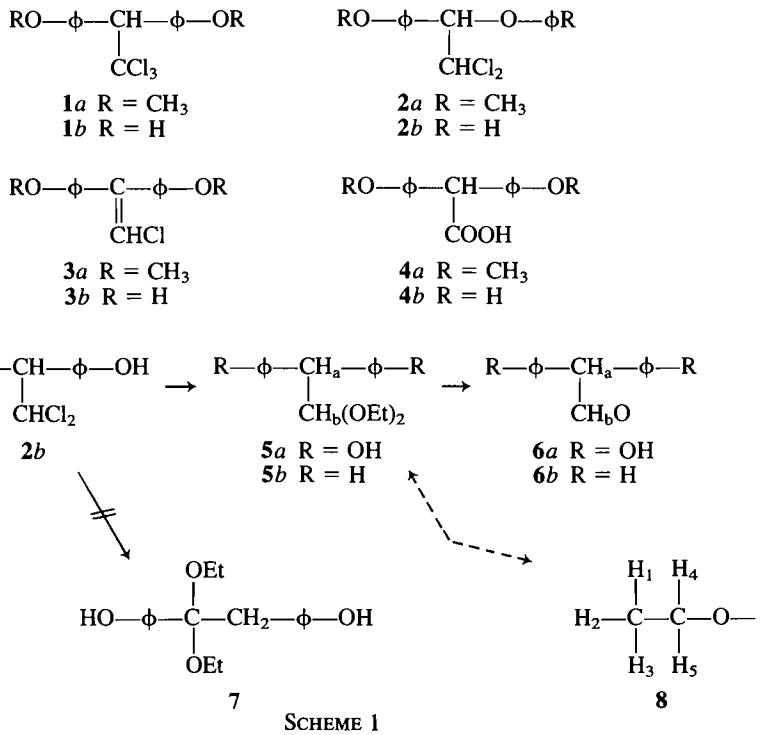
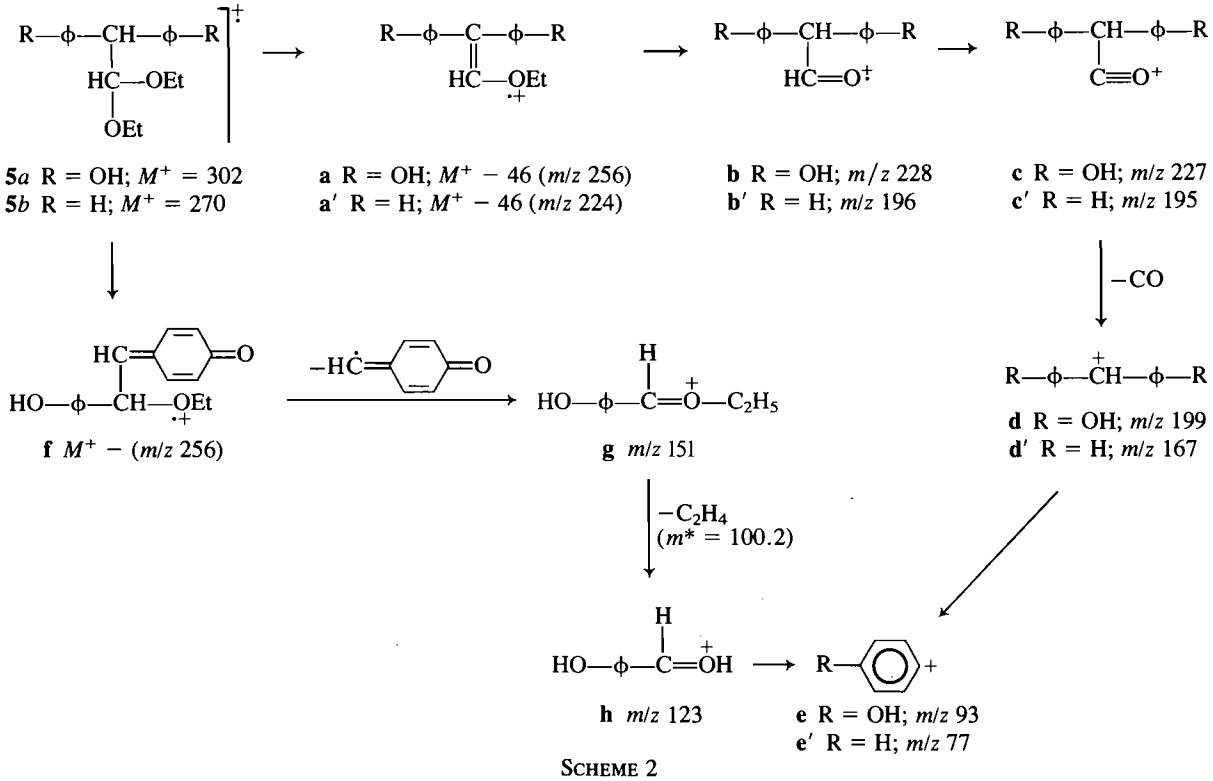


SCHEME 1



SCHEME 2

confirm this explanation by recording the ^{1}H nmr spectrum at 400 MHz were not successful.

Incidentally, the 400-MHz spectrum of the acetal (**5***a*) did provide the necessary resolution to show the considerable rigidity of this molecule in terms of the nonequivalence of the methylene protons of the ethoxy groups. A computer simulation of the observed 16-line signal was carried out using the ITRCAL program (9). Assignment of $\delta = 3.16$ and $\delta = 3.27$ ppm to protons H_4 and H_5 (**8**), respectively, and setting $J_{4,5} = 9.5$ Hz and $J_{1,4} = 7.27$ Hz gave a simulated spectrum identical to the observed pattern.

Final confirmation for the structure of the acetal (**5***a*) was obtained by comparison of its mass spectrum with that of the diethyl acetal (**5***b*) prepared from diphenyl acetaldehyde (**6***b*). The ions **a,a'** → **e'**, which result from fragmentations (see Scheme 2) that do not involve the *p*-hydroxy groups (of **5***a*), are

TABLE 1. Water solubility and *p*-values of the diarylacetic acids (**4**)

	Solubility (H_2O, ppm)	*p*-Value (EtOAc/H_2O)
Methoxy acid (**4***a*)	199	0.79
Hydroxy acid (**4***b*)	17 656	0.82

common to both spectra, and the ions **g**, **h**, and **e** are only found in the spectrum of **5***a*.

It may be noted that formation of acetals by direct substitution on a dichloromethyl group is not uncommon and, together with the analogous formation of aldehydes, is one of the standard routes for the preparation of these functional groups (10). However, such reactions usually involve substrates in which elimination is not a viable alternative. That this reaction has not been observed before with 2,2-diarylchloroethanes is probably because systematic studies of this group of compounds (5, 6, 11) have usually excluded compounds containing phenolic hydroxy groups.

For the preparation of the acids **4***a* and **4***b* by condensation of glyoxylic acid with anisole or phenol it was found that the use of glacial acetic acid with concentrated sulfuric acid substantially improved the yield of the methoxy acid (**4***a*) from 16% (12) to 80%, but this modification did not affect the yield of the hydroxy acid (**4***b*). The water solubilities of these acids were determined by gas chromatography and titration of carefully prepared, saturated solutions, and the *p*-values for the water/ethyl acetate system were determined according to Beroza *et al.* (13). The results of these measurements are presented in Table 1. It follows that, notwithstanding the relatively high water solubility of the hydroxy acid (**4***b*), the *p*-values of both acids are such that they may be expected to be recovered under conditions previously used for the extraction of *K. pneumoniae* cultures (1).

Experimental

General

Melting points are uncorrected. Infrared (ir) spectra were recorded on a Beckmann IR-12 spectrophotometer. Proton magnetic resonance (^{1}H nmr) spectra were recorded on a Bruker WP-80 and (or) a Bruker WP 400 spectrometer for hexadeuteroacetone solutions with tetramethylsilane as internal standard. Mass spectra (ms) were recorded on a Hitachi–Perkin–Elmer RMU-7 double focussing mass spectrometer. Combustion analyses were carried out with a Perkin Elmer Model 240 elemental analyser. A Perkin Elmer Model 3920 B gas chromatograph equipped with a flame ionization detector was used with silicone gum SE-30 (5%) on Gaschrom Q in a 1.8 × 6.4 mm column at 230–250°C. Nitrogen was the carrier gas at 25 mL/min.

1,1,1-Trichloro-2,2-bis(*p*-hydroxyphenyl)ethane ("Hydroxychlor", **1***b*), 1,1-dichloro-2,2-bis(*p*-methoxyphenyl)ethane (**2***a*), and 1,1-dichloro-2,2-bis(*p*-hydroxyphenyl)ethane (**2***b*) had been prepared earlier (1), according to Kapoor *et al.* (3). 1-Chloro-2,2-bis(*p*-methoxyphenyl)ethylene (**3***a*) was prepared according to Mendel *et al.* (4), and 1-chloro-2,2-bis-(*p*-hydroxyphenyl)ethylene (**3***b*) according to Davison *et al.* (5). All of these compounds had the required mp's, gave satisfactory elemental analysis results, and had spectral properties (^{1}H nmr and ms) in accordance with their structures.

*2,2-Bis(*p*-hydroxyphenyl)acetaldehyde diethyl acetal (**5**a)*

1,1-Dichloro-2,2-bis(*p*-hydroxyphenyl)ethane (**2***b*, 0.402 g) was added to a solution of potassium hydroxide (0.4 g) in ethanol (96%, 40 mL) and the mixture was refluxed for 1 h. The solvent was removed *in vacuo*, the residue dissolved in icewater (50 mL), and the resulting aqueous solution was acidified and extracted with ether (3 × 50 mL). The combined extract, after drying and removal of the solvent *in vacuo*, gave a crude product that, on recrystallization (chloroform–benzene – ethyl acetate), gave the pure acetal (**5***a*, 0.399 g, 93%); mp 190–192°C; ^{1}H nmr δ:0.94 (t, 6H, J = 7 Hz), 3.21 (m, 4H), 4.21 (s, 2H), 6.94 (q, 8H, arom.); ms: 302 (M^+, 1.5), 256 (30), 228 (11), 227 (14), 199 (40), 151 (100), 123 (80), 93 (22), 77 (18). *Anal.* calcd. for $C_{18}H_{22}O_4$: C 71.50, H 7.33; found: C 71.44, H 7.27.

*2,2-Bis(*p*-hydroxyphenyl)acetaldehyde (**6**a)*

To the diethylacetal (**5***a*, 0.902 g), in dry acetone (35 mL), was added *p*-toluenesulfonic acid (0.106 g) and the mixture was stirred at room temperature for 2 h. After removal of the solvent *in vacuo*, the residue was dissolved in water (80 mL) and sodium bicarbonate was added until pH = 7. Extraction with ether and removal of the solvent gave the crude aldehyde (**6***a*, 0.624 g). Thin-layer chromatography indicated the absence of starting material and the presence of minor impurities; ^{1}H nmr δ: 4.69 (d, 1H, J = 1.5 Hz), 6.90 (q, 8H, arom.), 9.75 (d, 1H, J = 1.5 Hz).

Attempts to purify the aldehyde (**6***a*), by recrystallization or by column or preparative thin-layer chromatography, led to increasingly impure products.

*2,2-Diphenylacetaldehyde diethyl acetal (**5**b)*

To a solution of diphenylacetaldehyde (**6***b*, 2.73 g) in ethanol (25 mL), was added concentrated sulfuric acid (0.5 mL), the mixture refluxed for 3 h, concentrated to small volume, and poured into icewater (50 mL) containing sodium carbonate (1 g). Extraction with ether gave a crude product (2.71 g) of which a small portion was purified by chromatography on silica gel. Elution with $CHCl_3$ gave the pure acetal (**5***b*) as a colourless oil; ^{1}H nmr δ: 0.99 (t, 6H, J = 7 Hz), 3.53 (m, 4H), 4.25 (d, 1H, J = 8 Hz), 5.20 (d, 1H, J = 8 Hz), 7.33 (m, 10H, arom.); ms: 270 (M^+, not observed), 224 (100), 196 (57), 195 (29), 167 (85), 77 (62).

*2,2-Bis(*p*-methoxyphenyl)acetic acid (**4**a) and 2,2-bis(*p*-hydroxyphenyl)acetic acid (**4**b)*

The acids were prepared by condensation of glyoxylic acid with anisole and phenol, respectively. The method of Hubacher (10) was modified by using glacial acetic acid as the solvent and concentrated sulfuric acid as the catalyst. The acid (**4***a*) was obtained in 80% yield and the yield of **4***b* was 42%. Both compounds were characterized by satisfactory combustion analysis results and had spectroscopic (^{1}H nmr, ms) properties in agreement with their structures.

Solubility measurements

(*i*) Methoxy acid **4***a* (25 mg) was added to water (50 mL) and the mixture stirred at room temperature for 48 h and filtered through a plug of glass wool. The first 20 mL of filtrate were discarded and, from the next 20 mL, triplicate 1-mL aliquots were transferred to 1-mL serum vials. After removal of the water with a stream of dry nitrogen, each sample was silylated (Tri-sil, 0.2 mL) and diluted with an internal standard solution (0.8 mL, DDT in benzene). Gas chromatographic analysis of these samples and of a series of similarly prepared standard solutions indicated the concentration of the acid **4***a* in water to be 199 ppm

(*ii*) Hydroxy acid **4***b* (2.0 g) was added to water (50 mL) and the mixture stirred and filtered as above. Triplicate 5.00-mL aliquots were titrated with sodium hydroxide solution to pH = 7.4. The average titer of 11.94 mL indicated the solubility of the acid to be 17 656 ppm.

p-Values

Stock solutions were prepared by dissolving the methoxy acid (45.51 mg) and the hydroxy acid (24.81 mg) in ethyl acetate (100 mL each). Aliquots (5.0 mL) of these stock solutions were transferred to 10-mL screw cap vials, containing distilled water (5.0 mL), previously equilibrated with ethyl acetate. The vials were shaken by hand, the layers allowed to separate, and 2-mL aliquots of the organic phase were withdrawn, placed in separate vials, and the solvent removed with a stream of dry nitrogen. Each dry residue was treated with Tri-sil reagent (Pierce, 0.2 mL) and made up to 1 mL with a DDT-containing internal standard solution. Gas chromatographic analysis of these

samples, as compared to a series of similarly prepared standard solutions, gave *p*-values (i.e., the ratio of the material in the organic phase to that originally present in the stock solution) as 0.79 for the methoxy acid (**4***a*) and 0.82 for the hydroxy acid (**4***b*).

Acknowledgments

The authors gratefully acknowledge financial support from the Natural Sciences and Engineering Research Council of Canada, and thank Dr. R. Lenkinski, Department of Chemistry, Guelph University, for recording the 400-MHz ^{1}H nmr spectra, and Dr. S. Maciaszek of this Department, for his help with the ITRCAL simulation.

FLORIAN PRUCHNIK, BRIAN R. JAMES, and PÁL KVINTOVICS. Can. J. Chem. **64**, 936 (1986).

The syntheses and characterization of some dimeric rhodium(II) complexes containing bridging mandelato ligands and a metal–metal bond are described. The compounds isolated are $Rh_2(O_2CR)_4(H_2O)_2$, previously described by Shchelokov and coworkers, and derivatives of the type $Rh_2(O_2CR)_2(N{-}N)_2X_2{\cdot}nH_2O$ (R = (*R*)—CH(OH)Ph, N—N = *o*-phenanthroline or 2,2′-dipyridyl, X = Cl, Br, I, and *n* is 4, 2, or 1). A mixture of species containing both bridged acetate and mandelate was isolated also. Infrared and electronic spectral data are reported. The chloride ligands of the dimers are displaced readily by alcohols, phosphines, phosphites, and amines; the metal centre also may be reduced by alcohols, $P(OEt)_3$, and $^nBu_2NH$. Preliminary studies point to the conditions necessary for the rhodium(II) mandelate and derivatives (phosphine or (N—N) substituted) to activate H_2 for catalytic hydrogenation of olefins and ketones, including prochiral substrates.

FLORIAN PRUCHNIK, BRIAN R. JAMES, et PÁL KVINTOVICS. Can. J. Chem. **64**, 936 (1986).

On décrit la synthèse et la caractérisation de quelques complexes dimères du rhodium(II) qui contiennent des ligands mandélato qui forment des ponts ainsi qu'une liaison métal–métal. Les composés isolés comportent le $Rh_2(O_2CR)_4(H_2O)_2$, qui a été décrit antérieurement par Shchelokov et ses collaborateurs, et des dérivés du type $Rh_2(O_2CR)_2(N{-}N)_2X_2{\cdot}nH_2O$ dans lesquels R = (*R*)—CH(OH)Ph, N—N = *o*-phénanthroline ou bipyridyle-2,2′, X = Cl, Br, ou I, et *n* = 4, 2, ou 1. On a aussi isolé des mélanges d'espèces contenant à la fois des ponts acétate et mandélate. On rapporte les données relatives aux spectres infrarouges et électroniques. Les ligands chlorures des dimères sont facilement déplacés par des alcools, des phosphines, des phosphites et des amines; le métal central peut aussi être réduit par les alcools, le $P(OEt)_3$, et $^nBu_2NH$. On a effectué des études préliminaires dans le but d'établir les conditions nécessaires pour que le mandélate de rhodium(II) et ses dérivés (substitués par des phosphines ou des N—N) puises activer le H_2 afin de réaliser une hydrogénation catalytique des oléfines et des cétones, y compris des substrates prochiraux.

[Traduit par la revue]

Introduction

Rhodium(II) carboxylato complexes such as $Rh_2(O_2CR)_4$ and bis-ligated adducts, $Rh_2(O_2CR)_2(N{-}N)_2X_2$ and $Rh_2(O_2CR)_2(L{-}L)_2$, where N—N = 2,2′-dipy, *o*-phen, X = halide, L—L = acac, dmgH, etc.,[3] have aroused considerable interest because of their interesting structures, catalytic properties, and anti-tumour activity (1,2). Our interests were based on the reported effectiveness of $Rh_2(O_2CR)_4$ (R = CH_3, C_3H_7) or $Rh_2(O_2CR)_2(dipy)_2Cl_2$ species for catalytic hydrogenation of olefins (3) and ketones (4), and cyclopropanation of substituted ethylenes (5,6). By using chiral carboxylates, we hope to develop catalytic systems for asymmetric hydrogenation of prochiral olefins and ketones, as well as for asymmetric cyclopropanation. Naturally occurring, inexpensive chiral ligands are especially attractive for use in asymmetric synthesis, and this paper describes the syntheses and characterization of some rhodium(II) complexes of the type $Rh_2(O_2CR)_2(N{-}N)_2X_2$ containing *R*- or *S*-mandelic acid. Reports on the synthesis and characterization of the *S*-mandelate complex $Rh_2(O_2CR)_4(H_2O)_2$, R = (*S*)—CH(OH)Ph, and a range of adducts formed with neutral ligands, have been published by Shchelokov *et al.* (7).

[1]On leave at the University of British Columbia, 1983.

[2]On leave from the University of Chemical Engineering, Veszprem, Hungary, 1981–1982.

[3]Ligand abbreviations used: 2,2′-dipy = 2,2′-dipyridyl, *o*-phen = 1,10-phenanthroline, Hacac = acetylacetone, $dmgH_2$ = dimethylglyoxime, py = pyridine, P(2-py)$_3$ = tris(2-pyridyl)phosphine.

Experimental

Rhodium(III) trichloride trihydrate (41.37% Rh) was supplied by Johnson, Matthey Ltd. The precursor rhodium complexes $Rh_2(O_2CCH_3)_4(MeOH)_2$ (8), $Na_4Rh_2(CO_3)_4{\cdot}2.5H_2O$ (9), and the 2-methylallyl complex $[RhCl_2(C_4H_7)]_2$ (10), were prepared by the literature methods. *R*- and *S*-Mandelic acid were used as supplied by Aldrich Chemical Co. Infrared spectra (KBr pellets) were measured on Perkin Elmer 283 and 598 instruments, uv–vis on Cary 15 and 17 instruments, and ^1H nmr on a Bruker WP-80 machine. Elemental analyses were carried out by Mr. P. Borda of the Chemistry Department at U.B.C. and at the Institute of Chemistry, University of Wroclaw. The procedures used to study the catalytic hydrogenation of the olefinic substrates have been described previously (11).

Diaquo-μ-tetrakis(R- *or* S-*mandelato)dirhodium(II), $Rh_2(O_2CR)_4(H_2O)_2$, **1**[4]*

The method used was similar to that given in the literature (7). The carbonate complex $Na_4Rh_2(CO_3)_4{\cdot}2.5H_2O$ (0.31 g, 5.3×10^{-4} mol) and (*R*)- or (*S*)-mandelic acid (0.685 g, 4.5×10^{-3} mol) in water (30 mL) were refluxed for 1 h. The blue colour of the carbonate faded and **1** precipitated as a green solid; the volume was reduced to 15 mL, and **1** was filtered off, washed with water, and recrystallized from CH_3OH–H_2O (1:1 v/v), yield 0.36 g (85%). *Anal.* calcd. for $C_{16}H_{16}O_7Rh$: C 45.41, H 3.81; found: C 45.9, H 4.1%. This method provides the simplest route to the tetrakis(mandelato) dimer; prior to the literature report of this synthesis (7), we had developed a procedure starting from $RhCl_3{\cdot}3H_2O$. Mandelic acid (0.46 g, 3×10^{-3} mol) was dissolved in EtOH (25 mL); freshly prepared ethoxide (3×10^{-3} mol Na/10 mL absolute EtOH) was then added under Ar, followed by $RhCl_3{\cdot}3H_2O$ (0.26 g, 1×10^{-3} mol), and the mixture refluxed for 1 h. Filtering

[4]R = (*R*) or (*S*)-CH(OH)Ph throughout this paper, unless stated otherwise.

yielded a green solution, which was concentrated to about 5 mL prior to addition of diethylether (10 mL) that precipitated out a green solid. This was dissolved in EtOH and loaded onto a silica-gel column; elution of the blue-green fraction with ethyl acetate gave $Rh_2(O_2CR)_4$, 0.20 g (50%). *Anal.* calcd. for $C_{16}H_{14}O_6Rh$: C 47.41, H 3.46; found: C 47.4, H 3.5. The ir data have been reported previously (7), but not the nmr data: ^{1}H nmr (DMSO-d_6), δ: PhC*H*(OH)— (4.88d, J_{HH} = 6 Hz, 1H); PhCH(O*H*)— (5.5d, J_{HH} = 6 Hz, 1H); C_6H_5 (7.1–7.3m, 5H); ^{13}C—{^{1}H} nmr(DMSO-d_6), δ: —*C*O_2 (193.3), *C*$_1$—CH(OH)CO_2 (140.8), Ph(C_2—C_6) (133–123), —*C*H(OH) (73.74).

Attempts to prepare pure mixed acetate–mandelate complexes were unsuccessful. Thus, for example, $Rh_2(O_2CCH_3)_4(MeOH)_2$ (5×10^{-4} mol) and (*S*)-mandelic acid (2×10^{-3} mol) were heated at 120°C for 4 h in 2-ethoxyethanol (7 mL); every hour ~1 mL of solvent was evaporated under vacuum to remove acetic acid. The remaining volume (~2 mL) was then filtered into diethylether (150 mL), and the mixture then refiltered. The filtrate was reduced in volume to 3–4 mL, when addition of toluene (5 mL) led to precipitation of a green solid. The precipitate was washed with toluene, dried, twice dissolved in dry diethylether and reprecipitated by adding hexane. A mixture of mixed-carboxylato ligand complexes containing both acetate and mandelate was obtained: ^{1}H nmr (CD_3COCD_3), δ: C*H*$_3CO_2$ 1.57 s, 1.62 s, 1.65 s, 1.70 s, 1.79 s; *H*$_2O$ + CH_3O*H* 2.89 s; C*H*$_3$OH 3.60 s; PhCH(O*H*)— 4.34 m; PhC*H*(OH)— 4.79 d, 4.87 m, 4.92 m; C_6H_5 7.1–7.3 m.

In $(CD_3)_2CO$ containing D_2O, the multiplets in the δ 4.79–4.92 region collapse to five singlets (loss of coupling to the mandelate–OH), the intensity ratios being the same as for the five acetate–CH_3 singlets. A mixture of $Rh_2[O_2CCH(OH)Ph]_n(O_2CMe)_{4-n}$ species, presumably with the possibility of *cis* and *trans* isomers for $n = 2$, is indicated, and an elemental analysis corresponded to $Rh_2[O_2CCH(OH)Ph]_{2.5}$-$(O_2CMe)_{1.5}\cdot 1.5H_2O\cdot 0.5CH_3OH$. *Anal.* calcd: C 39.46, H 3.80; found: C 39.5, H 4.0. Reaction of the rhodium acetate with mandelate in water gave mainly insoluble **1**; work up of the aqueous filtrate yielded water-soluble species with *n* being variable between 1 and 3.

Dichlorobis(phenanthroline)-μ-bis(S-mandelato)dirhodium(II)-tetrahydrate, $Rh_2(O_2CR)_2(phen)_2Cl_2\cdot 4H_2O$, 2

(*a*) Equimolar amounts (5×10^{-4} mol) of $[RhCl_2(C_4H_7)]_2$,phen, and (*S*)-mandelic acid, in 95% EtOH (15 ml) were refluxed for 5 h. A yellow-brown precipitate that formed was filtered off, and the red-brown filtrate left overnight under N_2 to yield red-brown crystals and a yellow powder that were separated by decantation. The red-brown compound was then recrystallized from 95% EtOH; yield 0.11 g (43%). *Anal.* calcd. for $C_{20}H_{19}O_5N_2ClRh$: C 47.50, H 3.79, O 15.82, N 5.54, Cl 7.01; found: C 47.2, H 3.8, O 15.6, N 5.6.

(*b*) A solution of $RhCl_3\cdot 3H_2O$ (10^{-3} mol), (*S*)-mandelic acid (5×10^{-3} mol) and NaOH (4×10^{-3} mol) in 95% EtOH (10 mL) were refluxed for 10 h. Some NaCl and Rh metal were filtered off to give a green solution thought to contain $[Rh_2(O_2CR)_4Cl_n]^{n-}$. Addition of 10^{-3} mol phen was followed by refluxing under N_2 for 4 h; a small quantity of a brownish-green precipitate was filtered off, and the filtrate left overnight to yield a red-brown precipitate that was recrystallized from 95% EtOH; yield 0.19 g (40%). *Anal.* found: C 47.8, H 4.0, N 5.4, Cl 7.1.

(*c*) A solution containing **1** (0.085 g, 10^{-4} mol), phen (0.040 g, 2×10^{-4} mol), and NaCl (0.013 g, 2.2×10^{-4} mol) in 75% EtOH (12 mL) was refluxed under N_2 for 2 h. The resulting dark green solution, on filtering hot in air to remove trace amounts of solid, became reddish-brown and yielded crystals of **2** on cooling; yield 70 mg (70%). *Anal.* found: C 47.5, H 3.5, N 5.7, Cl 7.4.

The bromo (3) and iodo (4) analogues of 2.

The bromo and iodo complexes were isolated in 70–80% yields as the tetra- and monohydrates, respectively, by the procedure described above in (*c*) but using NaBr or NaI. *Anal.* calcd. for $C_{20}H_{19}O_5N_2BrRh$: C 43.66, H 3.48, N 5.09, Br 14.52; found: C 43.3, H 3.2, N 4.8, Br 14.6. *Anal.* calcd. for $C_{40}H_{32}N_4I_2Rh_2$: C 42.13, H 2.83, N 4.91, I 22.26; found: C 41.7, H 2.5, N 4.6, I 22.5.

Dihalobis(dipyridine)-μ-bis(S-mandelato)dirhodium(II) dihydrate, $Rh_2(O_2CR)_2(dipy)_2X_2\cdot 2H_2O$; X = Cl (5), Br (6), I (7)

The procedure used was identical to that described in (*c*) but using dipy in place of phen, and the appropriate sodium halide; yields were 60%. *Anal.* calcd. for $C_{18}H_{17}O_4N_2ClRh$: C 46.62, H 3.70, N 6.04, Cl 7.65; found: C 46.4, H 3.4, N 6.2, Cl 7.9. *Anal.* calcd. for $C_{18}H_{17}O_4N_2BrRh$: C 42.55, H 3.37, N 5.51, Br 15.72; found: C 42.1, H 3.1, N 5.3, Br 15.4. *Anal.* calcd. for $C_{18}H_{17}O_4N_2IRh$: C 38.94, H 3.09, N 5.05, I 22.86; found: C 38.8, H 3.1, N 4.7, I 22.6.

Results and discussion

Although the metal–metal bonded μ-tetrakis(carboxylato)-dirhodium(II) species readily form adducts in which the axial sites are occupied by donor solvents or ligands (e.g., the mandelate species $Rh_2(O_2CR)_4$ readily and reversibly binds axial water ligands, and the nmr spectrum measured in DMSO-d_6 is certainly that of the bis(sulfoxide) adduct), the μ-carboxylates are thermally and substitutionally stable (1,2). The findings here confirm that substitution of the carboxylate ligands by other carboxylates, or chelating agents such as 2,2′-dipyridine or *o*-phenanthroline, is rather slow. Nevertheless, the best route that we found for the $Rh_2(O_2CR)_2(N—N)_2X_2$ complexes was via the precursor tetrakis-(mandelato) complex, rather than via $Rh_2Cl_4(C_4H_7)_2$ or $RhCl_3\cdot 3H_2O$ which gave more side products.

The extensive ir data in the literature for rhodium(II) carboxylates (1,2,12,13) allow for a fairly confident assignment of the bands listed in Table 1; ν_{asym}(RhO) almost certainly occurs at higher wavenumbers than ν_{sym}(RhO) (1). The relatively low ν(RhX) values indicate weakly held halide ligands as in the corresponding formate and acetate analogues (12,13), and ethanol solutions of the chloro and bromo complexes gave conductivities in the 140 ohm^{-1} cm^2 mol^{-1} range, while the iodo species gave about half this value; all the halide compounds show incomplete dissociation (see below). The tetrakis(mandelato) complex **1** has bands at 1380 and 1410 cm^{-1} in the $\nu_{sym}(CO_2)$ region, and a 1595 cm^{-1} band in the $\nu_{asym}(CO_2)$ region; the values are in the range given by Shchelokov *et al.* (7) for various tetrakis(mandelato) complexes, and are consistent with the familiar dimeric "lantern" structure with bridging carboxylates and a metal–metal bond. The free —OH group of the mandelate is seen at 3510 cm^{-1}. For complexes **2–7**, $\nu_{sym}(CO_2)$ and $\nu_{asym}(CO_2)$ are found in the ranges 1402–1410 and 1572–1577 cm^{-1}, respectively; the ir data, and electronic spectral data (see below), resemble very closely those of the formate and acetate $Rh_2(O_2CR)_2$-$(N—N)_2X_2$ analogues, and the type of structure, based on that determined for the formato-phenanthroline-chloro complex (12), is shown diagrammatically in Fig. 1.

The electronic spectra (Table 2) are typical of those of binuclear rhodium(II) complexes, and the lowest energy band (I) results from an allowed $\pi^*_{Rh—Rh} \rightarrow \sigma^*_{Rh—Rh}$ transition (1,7,12,14,15). The energy of this transition is higher for **2–7** than for **1**, and this we attribute to stabilization of the $\pi^*_{Rh—Rh}$ state by interaction with the π* orbitals of the unsaturated amine (12). The energy of band I has been shown previously to increase with increasing field strength of ligands coordinated along the Rh—Rh axis (1), and some limited data given in Tables 2 and 3 support further this claim. The aquo ligands of **1**, and the halide ligands of **2–7**, are readily displaced in ethanol solution and the data show an increase in energy within the series: L = ROH < RNH_2 ~ R_2NH ~ R_3N < PR_3 ~ $P(OR)_3$. A recent paper (16) has described formation of $Rh_2(O_2CCH_3)_2$-$(Ph_2P(C_6H_4))_2(CH_3CO_2H)_2$ from $Rh_2(O_2CCH_3)_4(MeOH)_2$ via

[e] Charge transfer, halide → Rh.

a refluxing procedure using PPh_3 in acetic acid, in which orthometallation has occurred at one phenyl ring on each phosphine; however, at the ambient conditions used in our work, simple ligand displacement to give $Rh_2(O_2CR)_4(EtOH)_{2-n}$ (phosphine)$_n$ from **1**, and $[Rh_2(O_2CR)_4(N{-}N)_2Cl_{2-n}(phosphine)_n]^{n+}$ from **2** and **5** (comparable to $Rh_2(O_2CCH_3)_2(dmg)_2(PPh_3)_2$ (17)), is considered to be occurring.

The electronic spectra of the bromo and iodo complexes (Table 2) show extra bands in 3.1–3.3 or 2.5–2.8 μm^{-1} regions, respectively, compared to the corresponding chloro complexes. The high extinction coefficients and relative positions of the peaks, based on differences between optical electronegativities of the metal and bromine and iodine (18), suggest they are halogen → Rh charge transfer bands; the halides probably remain partly coordinated in alcohol solutions. Assignment of the Cl → Rh bands, expected in the 3.6–4.0 μm^{-1} region, is difficult because of the presence of bands of the N—N ligands and phenyl groups.

The absorption occurring in the 2.2–2.35 μm^{-1} region (band II) (Tables 2, 3) arises from an allowed $\pi^*_{Rh-Rh} \rightarrow \sigma^*_{Rh-O}$ transition, with a weaker, forbidden $\delta_{Rh-Rh} \rightarrow \sigma^*_{Rh-Rh}$ component (1,7,14,15); without interference from charge transfer, the extinction coefficient of band II is less than that of band I. In the spectra of the phenanthroline and dipyridyl systems, band II is seen as a shoulder with much higher ϵ values because of charge transfer bands in the region (metal→ligand, or intraligand).

The $Rh_2(O_2CR)_2(N{-}N)_2X_2$ species on treatment with certain ligands in solution slowly undergo reduction. Thus, an ethanolic solution of **2** on treatment with a 100-fold excess of $P(OEt)_3$ under Ar at room temperature initially gives an electronic spectrum almost identical to that of the PPh_3 adduct (Table 3); on standing, the solution turns dark green ($t_{1/2} \sim 0.5$ h) with new, highly intense bands appearing at 1.49 and 1.66 μm^{-1} (670 and 602 nm), but on exposure to trace O_2, rapid reconversion to the Rh(II) species is observed. The intense, low energy bands are strongly indicative of Rh—Rh interactions within polynuclear $[Rh(I)]_n$ or $[Rh(I)Rh(II)]_n$ species (19); the bands result from metal to ligand charge transfer transitions ($d_{z^2} \rightarrow \pi^*$), the energies decreasing on increasing the number of interacting metal atoms. At refluxing temperatures, the ethanol solvent (or 2-propanol) can act as reductant, and air-sensitive green solutions again result. Green solutions formed by using $^nBu_2NH$ as reductant (Table 3) are somewhat more air-stable. Recent studies from one of our groups have revealed that reduction of Rh(III) to Rh(I) using alkyl amines occurs via a net dehydrogenation of the amine to give an enamine fragment (20); a similar redox process could be envisioned at two Rh(II) centres.

Preliminary studies show that complex **1** (or the unligated $Rh_2[O_2CCH(OH)Ph]_4$ species) in EtOH or dimethylacetamide solution will catalyze the H_2 hydrogenation of prochiral olefinic acids such as α-methylcinnamic or α-acetamidocinnamic under mild conditions (40°C, 1 atm H_2). A pretreatment of the complex with H_2 in the absence of substrate (30 min) is necessary for effective catalysis, during which time a color change from green to brown is observed: initial turnovers (mol H_2/mol Rh) for the catalysis at [Rh] = 2.5×10^{-3} M, [substrate] = 0.1 M, are about 1.0 min^{-1}, and final conversions are close to 100%. However, optical yields are close to zero, and the homogeneity of the systems is not established. Of interest, earlier work reporting on the ability of $Rh_2(O_2CCH_3)_4$ to catalyze the H_2 hydrogenation of terminal olefins in a range of solvents notes that the acetate dimer was unreactive toward H_2, although the hydride $HRh_2(O_2CCH_3)_3$ was postulated as a

catalytic intermediate (3). During the 30 min reaction of H_2 with **1**, ~0.65 mol gas/mol Rh_2 were taken up in solution, but reaction was still occurring slowly; no evidence for formation of a Rh hydride was obtained, and so presumably the H_2 reaction involves reduction to lower valent species. Addition of PPh_3 to solutions of **1** (PPh_3/Rh = 1) yields a catalyst system with *R*-mandelate effective for hydrogenation of E-α-methylcinnamic acid without the H_2 pretreatment; there is no darkening of colour, turnovers are now about 0.1 min^{-1}, and an enantiomeric excess of ~15% (*S*) was determined by rotation measurements on the $PhCH_2CH(CH_3)CO_2H$ product (21).

Complex **1** in the presence of phenanthroline or dipyridyl (N—N/Rh = 1) or complexes **2** and **5**, in basic alcoholic solutions, also catalyze the H_2 hydrogenation (at 30°C, 1 atm) of olefins. In the presence of excess of the chelating amines (5:1), **2** and **5** effect similar catalytic hydrogenation of ketones. Further studies are in progress on these systems, particularly with regard to use of prochiral substrates, and the relationship of the systems to other hydrogenations catalyzed by rhodium systems containing only the N—N ligands (22) or only carboxylate (3, 23), the latter sometimes utilizing hydrogen transfer from 2-propanol. Our preliminary findings on the catalytic hydrogenations suggest that π-acceptors (PPh_3, N—N) are necessary as ancillary ligands with the chiral carboxylates in order to effect any measurable asymmetric induction, and presumably this relates to stabilization of lower valent, most probably univalent, rhodium species. We have found recently that a trialkylphosphite is a required ancillary ligand for hydrogen transfer asymmetric hydrogenation of acetophenone using some iridium – chiral mandelate catalyst systems (24).

A simple, biogenetically modeled synthesis of 4-(methylthio)butyl thiocyanate: the reaction of thiocyanate anion with *S*-methyl-(1,*n*)-epithionium ions

M. H. Benn and Vinod K. Singh
Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4
Received October 21, 1985

M. H. Benn and Vinod K. Singh. Can. J. Chem. **64**, 940 (1986).

The reaction of *S*-methylthiolanium fluorosulphate with thiocyanate ion gives predominantly 4-(methylthio)butyl thiocyanate, a result which is in accord with a hypothesis for the biogenesis of this compound, and which has implications for the natural occurrence of analogous thiocyanates.

M. H. Benn et Vinod K. Singh. Can. J. Chem. **64**, 940 (1986).

La réaction du fluorosulfate du *S*-méthylthiolanium avec l'ion thiocyanate conduit principalement au thiocyanate de (méthylthio)-4 butyle; ce résultat est en accord avec une hypothèse relative à la biogénèse de ce composé et il a des implications relativement à l'existence à l'état naturel de thiocyanates analogues.

Introduction

Glucosinolates are naturally occurring anions, characterized by the general structure **1**. They are commonly, but not exclusively, encountered within plants of families that constitute the Capparales and their decomposition is a matter of considerable current interest, because the products are known to be important factors in determining the palatability and toxicity of these plants to man and other animals (see ref. 1, and references therein).

Of the nearly 100 glucosinolates that have been isolated, or inferred to exist, all can be catabolized to isothiocyanates or nitriles. These products are known to arise from the aglucones that are released from **1** by myrosinase (thioglucoside glucohydrolase EC 3:2:3:1) (Scheme 1) (1). In contrast with this generality, only three, the allyl (2), benzyl (2, 3), and 4-(methylthio)butyl (4) compounds are known to be capable of yielding the corresponding thiocyanates, and they do so under conditions that indicate that these conversions involve other, plant-specific, enzymes.

To account for this striking restriction it has been postulated (5) that the thiocyanates are formed from aglucones by a fragmentation process in which departure of sulphate, instead of being concerted with the [1,2]-shift of the substituent R that yields the isothiocyanates, results in fragmentation to thiocyanate anion and a cation corresponding to R. Recombination of this ion pair would then be expected to preferentially form the thiocyanate as a consequence of the high nucleophilicity of the *S*-terminus of the ambident thiocyanate anion. Also plausible is the possibility that the fragmentation process is a consequence of a $Z \rightarrow E$ isomerization that destroys the geometry required for the concerted isothiocyanate-forming reaction (Scheme 2) (5). (The aglucone intermediates are shown in Schemes 1 and 2 in their free, protonated, forms. It may well be that they are bound, through bivalent sulphur, to a metal ion: this would inhibit tautomerism and interconversion of *E* and *Z* isomeric forms.)

Fragmentation should be favoured for substrates that yield relatively stable cations. The allyl and benzyl systems are textbook examples of such ions, and we visualized 4-(methylthio)butyl glucosinolate (**2**) ($n = 4$) as yielding the even more stable *S*-methylthiolanium cation. In this latter case there is then a requirement that attack by thiocyanate ion on the cation should favour ring opening over demethylation (path (b) of Scheme 3 rather than (a)), as well as preferential formation of thiocyanate. We reasoned that the first of these requirements would be met as a consequence of the release of torsional strain, as well as entropy, and statistical factors. Examination of the literature reveals excellent precedent for this in the report of Eliel *et al.* (6) that the reaction of azide and thiolate anions with **3***a* gave predominantly the products of ring opening, **4** and **5**, respectively, but we decided to submit the matter to direct test.

The reaction of thiolane (**6**, $n = 4$) with methyl fluorosulphate in dichloromethane gave the *S*-methylthiolanium salt (**3***b*). When this salt was treated with potassium thiocyanate in ethanol, or DMF, and the reaction monitored by gc, a single major product was observed (ca. 80%), together with two minor products (each ca. 10%). The latter two substances cochromatographed with authentic thiolane and methyl thiocyanate. The identity of the major product as 4-(methylthio)butyl thiocyanate (**7**) was first indicated by the results of a gc–ms analysis, and then confirmed by its isolation. The distilled material had physical properties (ir and ^{1}H nmr spectra) in excellent agreement with those reported for **7**, and the ^{13}C nmr spectrum was also in complete accord with this structure.

In order to assess the extent of isothiocyanate formation, we utilized the reaction of **3***b* with azide ion to make **4**, reduced this to the amine (**8**), and prepared from that an authentic specimen of **9**. We then established capillary gc conditions under which it was possible to obtain a base-line resolution of the isomeric thiocyanate–isothiocyanate pair. When the crude reaction products from **3***b* and potassium thiocyanate were reanalysed under these conditions, a trace (ca. 2–3%) of material chromatographically indistinguishable from the isothiocyanate (**9**) was detected. Similarly an analysis of the 200-MHz ^{1}H nmr spectrum of these crude reaction products, based on the relative integrals of the α-methylene groups of **7** and **9**, indicated the presence of the same amount of isothiocyanate.

Thus the biogenetically patterned synthesis of 4-(methylthio)butyl thiocyanate worked well, and provided a simple route to this compound, which previously had only been synthesized from 4-chloro-1-butanol, in several steps, in less than 10% yield (4).

It may also be noted that while good evidence has accumulated from the existence of a series of ω-(methylthio)alkylglucosinolates (**2**) ($n = 3$–8) (7), only the 4-(methylthio)butyl compound has been found to yield a thiocyanate. Were the higher homologues to fragment to form *S*-methyl-[1,*n*]-epithionium ions (**10***a*), our expectation would be that these would lack the torsional strain present in the thiolanium ion, and that the pre-

SCHEME 3. The reaction of *S*-methyl-1,*n*-epithionium ions with nucleophiles

ferred reaction with thiocyanate anion would be demethylation rather than ring opening; i.e., we predict that the glucosinolates **2** ($n = 5$–8) may be catabolized via cyclic *S*-methyl sulphonium salts to yield cyclic sulphides, but little, if any, of the thiocyanates **11***a*. On the other hand, **2** ($n = 3$) might give the highly strained and reactive sulphonium ion **12***a*, which we would expect to undergo ring-opening reaction with thiocyanate ion; i.e. **12***a* might give the lower homologue **14** of **7**.

In line with the first of these predictions, Eliel *et al.* have shown that azide ion attack on the *S*-methylthianium iodide (**10***b*) gives thiane and methyl azide (6). We found that thiocyanate ion behaved similarly: reaction of **10***c* with potassium thiocyanate gives thiane and only ca. 3% of **11***a*. At the other extreme, we could not control the methylation of thietane with methyl fluorosulphate on account of the very reactive nature of **12***b*: oligomerization of the theitane, to form **13**, competed with *S*-methylation. However, the reaction of potassium thiocyanate with the crude *S*-methylation products did give 3-(methylthio)propyl thiocyanate (**14**), albeit in low yield and accompanied by compounds arising from the oligomeric methylation products (see Experimental). Despite this, we think that rather than form **12***a*, 3-(methylthio)propyl glucosinolate is most likely to fragment to nitrile and elemental sulphur; i.e., since **12***a* is so highly energetic, **2** ($n = 3$) is most likely to avoid its formation and, instead, to behave as a glucosinolate incapable of yielding an efficiently charge-delocalized cation and follow path (a) of Scheme 2. Consistent with this idea are observations of the rates of solvolysis of ω-haloalkyl sulphides: little, if any, anchimeric assistance (via intramolecular cyclization to sulphonium ions) was seen when a 4-membered ring would result, in sharp contrast to the accelerated rates observed when 3-, 5-, or 6-membered rings would be formed (8, and references therein).

Thus the reactions of thiocyanate anion with *S*-methyl-(1,*n*)-epithionium ions are in accord with the fragmentation ion-pair recombination model for the biogenesis of 4-(methylthio)butyl thiocyanate, and suggest why homologues of this compound have not been observed in nature.

Experimental

Instrumental and analytical methods were as described before (9), augmented by gc and gc–ms. Packed-column gc analyses were performed with a Shimadzu 9A chromatograph (with fid) and C-R24X data processor using 3% OV-17 in 2 m × 4 mm glass columns, with a N_2 flow rate of 20 mL/min, and a temperature programme of 60 (1 min) – 250°C at 20°C/min. Capillary gc was done on a Carlo Erba instrument, using a 30 m × 0.32 mm, 0.25-μm, DB-1 column, a He flow rate of 1 mL/min, 60–200°C at 10°C/min. The gc–ms analyses were performed either with a HP 5992A instrument using similar conditions to those employed for the packed column gc work (but He as carrier gas), or a Kratos MS-80 spectrometer – data system interfaced with the Carlo Erba chromatograph.

Preparation of S*-methylthiolanium fluorosulphate (3*b*)*

Typically, to a stirred solution of thiolane (250 mg, 2.84 mmol) in dry CH_2Cl_2 (3 mL) was added a solution of methyl fluorosulphate (325 mg, 2.85 mmol) in CH_2Cl_2 (5 mL). A mildly exothermic reaction

ensued and the flask was cooled (water bath) so as to maintain an internal temperature of 20–25°C. The turbid reaction mixture was stirred for 1 h at room temperature and then evaporated to dryness under reduced pressure, finally under high vacuum. The residual free-flowing white solid (545 mg, 95%) was hygroscopic and was normally used directly. It could be recrystallized from EtOH–Et_2O (dry-box) to give the salt **3***b*, mp 188°C (sealed capillary); ^1H nmr (DMSO-d_6) δ: 2.30 (4H, m), 2.90 (3H, s), 3.46 (2H, m), 3.63 (2H, m); ^{13}C nmr (DMSO-d_6) δ: 24.9 q, 27.6 t, 44.3 t.

*Preparation of 4-(methylthio)butyl isothiocyanate (**9**)*

Treatment of the salt **3***b* with sodium azide, essentially as described by Eliel (6) but using dry DMF as solvent and conducting the reaction at 40°C for 20 h, gave **4** isolated as a colourless oil, bp 80–85°C/ca. 10 Torr (1 Torr = 133.3 Pa) (68%); ir (film): 2097; ^1H nmr ($CDCl_3$) δ: 1.7 (4H, m), 2.10 (3H, s), 2.53 (2H, m), 3.31 (2H, m); ^{13}C nmr ($CDCl_3$) δ: 15.3 q, 26.0 t, 27.8 t, 33.6 t, 51.0 t; ms: 117 ($M-N_2$, 6), 89 (16), 74 (20), 61 (78), 43 (100) (lit. (6) bp 86–87°C/15 Torr; ^1H nmr ($CDCl_3$) δ: 1.67 (4H, m), 2.08 (3H, s), 2.50 (2H, distorted t), 3.28 (2H, distorted t)).

The azide **4** was reduced with LAH according to a literature procedure (10) to give the amine **8**, which was obtained after distillation as a colourless oil, bp 80–82°C/12 Torr (54%) (lit. (11) bp 78–78.5°C/12 Torr); ir (film): 3480, 3287; ^1H nmr ($CDCl_3$) δ: 1.19 (2H, s, disappears after adding D_2O), 1.45–1.72 (4H, m), 2.1 (3H, s), 2.51 (2H, t, J = 7 Hz), 2.71 (2H, t, J = 7 Hz); ^{13}C nmr ($CDCl_3$) δ: 15.5 q, 26.5 t, 32.9 t, 34.1 t, 41.9 t; ms: 121 (6), 120 (20), 119 (100), 104 (37), 87 (18), 72 (24), 61 (33).

Following a general procedure (12), **8** (1.5 g, 12 mmol) was added to a mixture of CS_2 (2.0 g, 26.3 mmol) and H_2O (1 mL), followed by a solution of NaOH (800 mg, 40 mmol). This mixture was boiled under reflux for 10 min, then cooled to 25°C. Ethyl chloroformate (13 g, 119 mmol) was added and the mixture stirred for 15. h, after which more NaOH (800 mg) in H_2O (1 mL) was added and stirring continued for a further 1.5 h. The supernatant was decanted from a residue of salts that were washed with Et_2O (3 × 10 mL).

The combined supernatant and Et_2O extracts were then washed successively with 10% aqueous NaOH, H_2O, and brine. Removal of solvent from the dried (Na_2SO_4) Et_2O phase left a residual oil (2.46 g) that was shown by gc analysis to consist of two major components, one of which was recovered ethyl chloroformate. Column chromatography of the oil over silica gel (45 g) gave an oil (1.6 g) eluted with EtOAc–hexanes (5:95 v/v), a portion of which was further purified by distillation to give **9** as a light yellow oil, bp 90–92°/0.6 Torr (lit. (13) bp 136°C/12 Torr); ir (film): 2185, 2110 (br vs); ^1H nmr ($CDCl_3$) δ: 1.8 (4H, m), 2.11 (3H, s), 2.54 (2H, t, J = 7 Hz), 3.56 (2H, t, J = 7 Hz); ^{13}C nmr ($CDCl_3$) δ: 15.4, 25.9, 29.0, 33.3, 44.8, 130.3.

The reaction of potassium thiocyanate with sulphonium salts

(a) With S-methylthiolanium fluorosulphate

A solution of potassium thiocyanate (1.0 g, 10.3 mmol) in dry DMF (15 mL) was added to a stirred solution of **3***b* (prepared from 500 mg (5.7 mmol) thiolane) in dry DMF (10 mL), followed by a solution of KSCN (1.0 g, 10.3 mmol) in the same solvent (15 mL). The reaction mixture was stirred vigorously, and kept at 70°C (bath) for 7 h. It was then cooled to room temperature, diluted with H_2O (50 mL), and extracted with Et_2O (3 × 15 mL). The Et_2O extracts were combined, washed with H_2O (3 × 15 mL) and brine (15 mL), and then dried (Na_2SO_4). Packed column gc and gc–ms analyses revealed a single major product (ca. 80%) corresponding to **7**, together with small amounts (ca. 8% each) of thiolane and methyl thiocyanate. The oil remaining after careful removal of solvent from the Et_2O extract was distilled to yield **7** as a near colourless oil, bp 105–110°C/0.5 Torr (410 mg, 45%) ir (film): 2155; ^1H nmr ($CDCl_3$) δ: 1.75 (2H, m), 1.96 (2H, m), 2.1 (3H, s), 2.53 (2H, t, J = 7 Hz), 2.97 (2H, t, J = 7 Hz); ^{13}C nmr ($CDCl_3$) δ: 15.3 q, 27.0 t, 28.6 t, 33.1 t, 33.5 t, and 112.0 s; ms: 163 (2), 162 (2), 161 (100) (lit. (4) ir ($CHCl_3$): 2165; ^1H nmr (60 MHz, $CDCl_3$) δ: 1.5–2.0 (4H, m), 2.1 (3H, s), 2.3–2.7 (2H, m), 2.75–3.1 (2H, m)).

Capillary gc–ms revealed our distilled product to be ca. 98% pure, accompanied by ca. 2% of the isothiocyanate **9**. A similar conclusion was reached upon reexamining the ^1H nmr spectrum of the distilled **7**: traces of **9** were detectable as an absorption at δ 3.56, with an integrated intensity corresponding to the presence of 2–3% of this compound.

*(b) With S-methylthianium fluorosulphate (**10**c)*

Thiane (250 mg, 2.45 mmol) was converted to the sulphonium salt **10***c* by treatment with methyl fluorosulphate (285 mg, 2.50 mmol) in CH_2Cl_2. This salt was then dissolved in dry DMF (10 mL) containing KSCN (485 mg, 4.5 mmol) and the mixture heated at 80°C for 5 h. Work-up as described for the equivalent reaction of **3***b* yielded an Et_2O extract that was shown by gc–ms analyses to contain thiane and methyl thiocyanate as major components and only a small amount (ca. 4%) of a substance with the expected retention time and ms (176 (6), 119 (3), 117 (63), 101 (23), 61 (100)) of **11** (n = 5).

*(c) With S-methylthianium fluorosulphate (**12**b)*

To a stirred solution of methyl fluorosulphate (155 mg, 1.36 mmol) in CH_2Cl_2 (2 mL), at −5°C, was slowly added a solution of thietane (100 mg, 1.35 mmol) in CH_2Cl_2 (2 mL), the internal temperature of the reaction mixture being held at room temperature by external cooling. A gummy solid separated from the reaction mixture. After removal of solvent under reduced pressure and drying under high vacuum a sticky white solid was obtained. This material was dissolved in dry DMF (5 mL) containing KSCN (200 mg) and heated at 60°C for 1.5 h, with continuous stirring. After the usual work-up the solution of reaction products in Et_2O was analysed by gc–ms: a multitude of components were detected, among which the major were CH_3SCN (R_T 1.2 min, ca. 20%), **14** (R_T 7.5 min, ca. 25%) (149 (6), 148 (4), 147 (54), 120 (53), 61 (100)), and $CH_3S(CH_2)_4S(CH_2)_4SCN$ (R_T 12.5 min, ca. 18%) (221 (32), 206 (2), 121 (100), 73 (29), 61 (20)). Also present was $(CH_3SCH_2CH_2)_2$, (R_T 5.5 min, ca. 7%) (136 (100), 121 (18), 61 (43)).

Fastigiatine, a lycopodium alkaloid with a new ring system

ROBERT V. GERARD, DAVID B. MACLEAN,[1] ROMOLO FAGIANNI, AND COLIN J. LOCK[1]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1
Received September 6, 1985

ROBERT V. GERARD, DAVID B. MACLEAN, ROMOLO FAGIANNI, and COLIN J. LOCK. Can. J. Chem. **64**, 943 (1986).

Fastigiatine, $C_{19}H_{28}N_2O$, is a minor component of the alkaloids of *Lycopodium fastigiatum* R. Br. collected in New Zealand. Its structure and relative configuration have been resolved by an X-ray analysis of the free base. The pentacyclic ring system of fastigiatine has not been previously observed in the Lycopodium family of alkaloids or elsewhere. A proposal is presented for its derivation from the tetracyclic flabellidane ring system that is widely distributed among Lycopodium species. The mass spectrum and the ^{13}C and ^1H nmr spectra of fastigiatine are discussed.

ROBERT V. GERARD, DAVID B. MACLEAN, ROMOLO FAGIANNI, et COLIN J. LOCK. Can. J. Chem. **64**, 943 (1986).

La fastigiatine, $C_{19}H_{28}N_2O$, est un constituant mineur des alcaloïdes du *Lycopodium fastigiatine* R. Br. récolté en Nouvelle Zélande. On a résolu sa structure et sa configuration relative par l'analyse aux rayons-X de la base libre. On n'avait pas encore observé le système pentacyclique de la fastigiatine dans la famille des alcaloïdes du Lycopodium ou ailleurs. On propose une méthode de préparation de la fastigiatine à partir du système tétracyclique de la flabellidane que l'on retrouve souvent dans les espèces du Lycopodium. On discute du spectre de masse et des spectres rmn du ^{13}C et du ^1H de la fastigiatine.
[Traduit par la revue]

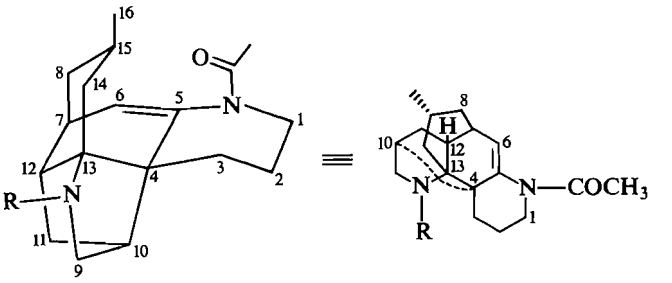
Introduction

The Lycopodium family of alkaloids comprises about 100 members of established structure distributed among some 20 different skeletal types (1). This surprisingly large number of alkaloids and ring systems has been derived from an estimated (2) 10% of the extant Lycopodium species. Recently, a number of species native to New Zealand have been investigated in this laboratory (3) and from one of them, *Lycopodium fastigiatum* R. Br., two new alkaloids, fastigiatine **1** ($C_{19}H_{28}N_2O$) and des-*N*-methylfastigiatine **2** ($C_{18}H_{26}N_2O$), have been isolated. We report here on the structure and on the nmr and mass spectra of **1**.

Fastigiatine and its lower homologue were initially detected in an extract of *L. fastigiatum* through examination by gas chromatography – mass spectrometry (gc–ms) (3). The alkaloids were then isolated from the extract by conventional liquid chromatographic procedures on alumina and silica columns. A detailed account of the isolation procedure is described elsewhere (3).

The initial examination of **1** by spectroscopic methods established its composition and the number and nature of its functional groups. An *N*-methyl, an *N*-acetyl group, a $CHCH_3$ group, and a trisubstituted double bond were evident from the nmr spectrum. The uv spectrum indicated that the double bond and the *N*-acetyl group were probably present in an enamide structure. However, the nmr spectrum and the mass spectrum of **1** did not lend themselves to simple interpretation and, because of the limited amount of compound available, an X-ray analysis was carried out. The structure derived from the X-ray study is shown in the accompanying formulas. The numbering system conforms with that commonly employed in this family of alkaloids (4).

The structure of fastigiatine is closely related to that of flabellidine **3** (1, 4) and one can envisage its formation from a derivative of *N*-methylflabellidine **4** through the iminium compound **5** by the route outlined in Scheme 1. It is noteworthy that lycopodane alkaloids functionalized at C-10 have recently been reported (5, 6), although flabellidanes similarly functionalized have not been found. The pentacyclic fastigiatine has a structural relationship to alkaloids of the tetracyclic flabellidane



1 fastigiatine, R = CH_3 ≡ **2** des-*N*-methylfastigiatine, R = H

group that is analogous to that between the pentacyclic alopecurane group of alkaloid (1, 4, 7), e.g., dehydrolycopecurine **6** (1, 4, 8), and the lycopodane group, e.g., lycopodine **7** (1, 4). In each series the pentacyclic ring system may be formally derived from the corresponding tetracyclic ring system through formation of a bond between C-4 and C-10.

Since fastigiatine represents a new skeleton among the Lycopodium alkaloids, its mass spectrum was investigated in detail in the expectation that the information gained might be useful to others who may encounter this ring system in the future. Besides the molecular ion peak at m/z 300 and the peaks at m/z 176 and 124, there are prominent peaks at m/z 285 ($M-15$) and m/z 257 ($M-43$) in the mass spectrum of **1**. The composition of the ions corresponding to these peaks is recorded in Table 1. A B/E linked scan (9) carried out on the molecular ion at m/z 300 revealed that the ions, m/z 285, 257, and 124, are formed directly from the molecular ion, but the ion of m/z 176 was not observed in the B/E spectrum. However, its absence from the B/E spectrum does not preclude its formation from the molecular ion so long as the fragmentation leading to it occurs only in the ion source.

7

The ions at m/z 124 and 176 appear to arise from the fragmentation of fastigiatine into two parts, each of which can carry the charge. In the case of the spectrum of des-*N*-methylfastigiatine (3), the ion occurring at m/z 124 in **1** is shifted by 14 mass units (CH_2) to m/z 110. Thus these ions arise from the portion of the molecule bearing the N—H group in the case of des-*N*-methylfastigiatine and bearing the N—CH_3 group in the case of fastigiatine. It is apparent from the structures of **1** and **2** that the ions of m/z 124 and 176 cannot form in a simple manner. A fragmentation scheme for fastigiatine is proposed in Scheme 2, which accounts for the formation of the two ions, and in which the fragmentation is considered to be initiated in a retro Diels–Alder reaction resulting in fission of the bond between C-12 and C-7 and the bond between C-13 and C-4. Subsequent to the retro Diels–Alder process, the rupture of the bonds between C-9 and C-10 and between C-8 and C-15 is postulated and is predicted to be followed by the formation of bonds between C-9 and C-15 and between C-8 and C-10. At this stage there may be two ions, on one of which the charge is localized on N_α and on the other on N_β. The ion with the charge localized on N_α is postulated to fragment in the source leading to the ion of m/z 176, for which a metastable transition was not observed. The second ion with the charge localized on N_β is postulated to fragment more slowly, and for this fragmentation a metastable transition was observed. The charge is more delocalized on the ion of m/z 176, which may account for its more rapid formation. A reviewer[2] has suggested that the ion of m/z 176 may form by an entirely different and faster process from that of m/z 124. While this is an attractive proposal to account for the metastable transition in one case and its absence in the other, it is very difficult to envisage a simple and rapid process leading to m/z 176.

The loss of a methyl group can arise from various locations on the molecular ion. The loss of CH_3CO is a well-recognized loss from the N—$COCH_3$ group and the loss of C_3H_7 could arise in the same way as the loss of the corresponding fragment from the bridge atoms in a lycopodane system (10).

An analysis of the ^{13}C nmr spectrum of **1** has been carried out through application of two-dimensional (2D) heteronuclear and homonuclear nmr methods (11) (See Figs. 1 and 2, respectively). Many of the chemical shifts of the protons in the ^1H nmr spectrum were also revealed in this way. Through off-resonance and spin-sorted experiments, the 19 signals in the ^{13}C spectrum could be separated into four groups, carbon atoms devoid of hydrogen (four), methine carbon atoms (five), methylene carbon atoms (seven), and methyl groups (three). These data are recorded in Table 2.

The assignment of the ^{13}C signals (Fig. 1) to the nonprotonated carbon atoms was relatively simple. On the basis of their chemical shifts, peak 1 (170.0 δ) was assigned to the carbonyl carbon (C-17), and peak 2 (139.2 δ) to the vinylic quaternary carbon (C-5). The two tetrahedral quaternary signals, peaks 4 (65.4 δ) and 6 (55.0 δ), have been assigned to C-4 and C-13,

[2]We thank the reviewer for this comment and for others which led us to reconsider our original discussion on the fragmentation of **1**.

TABLE 1. Masses of selected ions of fastigiatine

Composition	Mass	
	Calculated	Observed
$C_{19}H_{28}N_2O$	300.2202	300.2198
$C_{18}H_{25}N_2O$	285.1967	285.1960
$C_{16}H_{21}N_2O$	257.1654	257.1625
$C_{17}H_{25}N_2$	257.2018	257.2017

$C_8H_{14}N$	124.1126	124.1125

TABLE 2. Assignment of the signals in the ^{13}C spectrum of fastigiatine

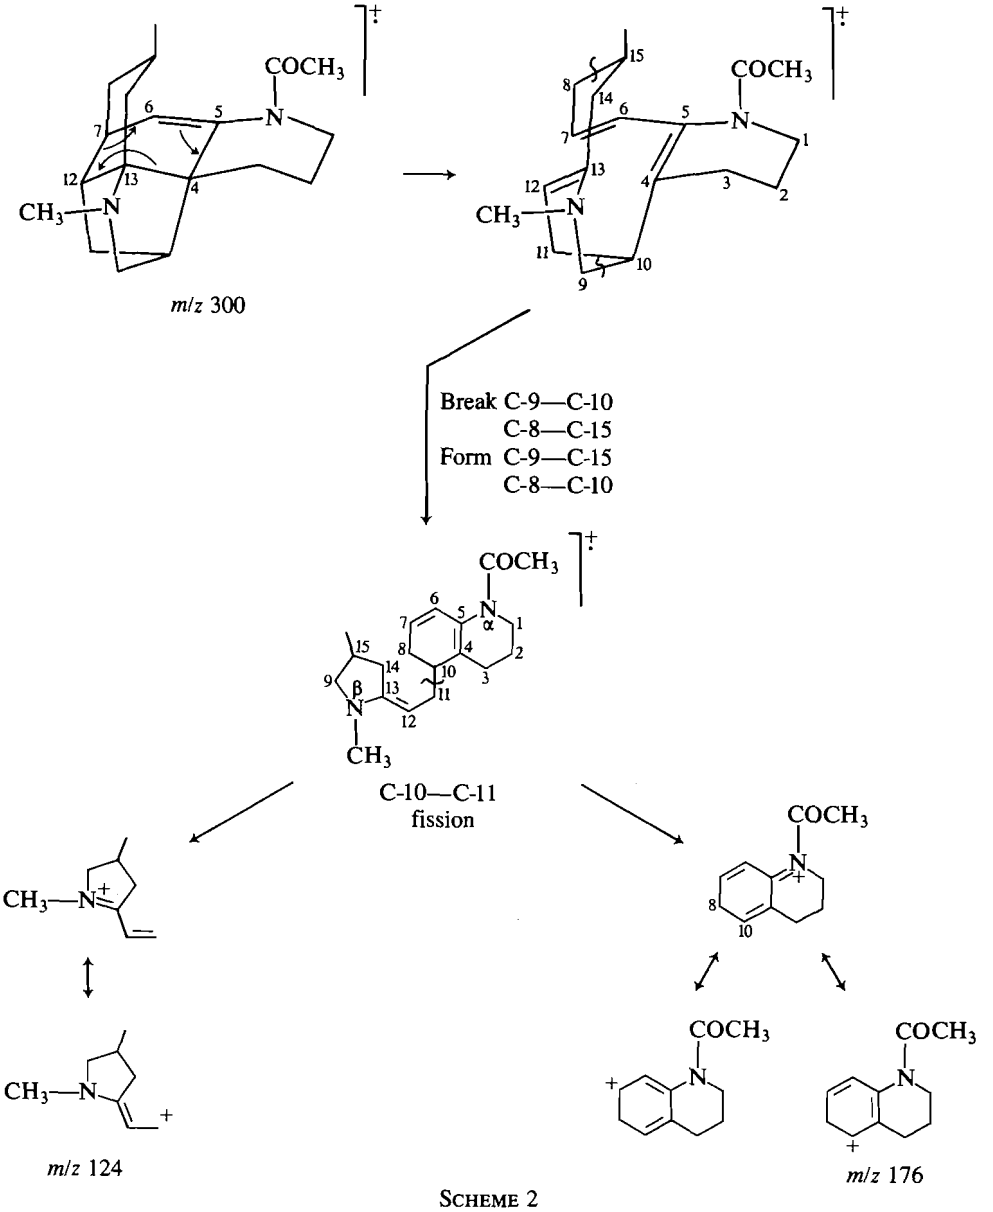
Peak number	δ	Carbon type[a]	Carbon atom of fastigiatine
1	170.0	>C=O	17
2	139.2	=C<	5
3	123.1	=C<H	6
4	65.4	C	4 or 13
5	59.6	CH_2	9
6	55.0	C	13 or 4
7	45.5	CH	10
8	45.3	CH_2	1
9	40.2	CH	7
10	38.3	CH	12
11	37.4	CH_2	8
12	35.0	CH_3	19 (NCH_3)
13	34.6	CH_2	14
14	33.9	CH_2	11
15	25.5	CH	15
16	23.0	CH_2	3
17	22.3	CH_3	16 ($CHCH_3$)
18	21.5	CH_3	18 ($NCOCH_3$)
19	21.1	CH_2	2

[a]C, CH, CH_2, and CH_3 represent quaternary, tertiary, secondary, and primary aliphatic carbon atoms, respectively.

respectively, on the basis of their chemical shifts; however, these assignments are not secure and may be reversed.

Except in a few obvious cases the assignment of the ^{13}C signals of the protonated carbon atoms was not as straightforward, and resort to more refined techniques had to be taken. Accordingly, $^1H/^{13}C$ heteronuclear and $^1H/^1H$ homonuclear correlated spectra of fastigiatine were recorded and analysed as discussed below.

The doublet at 0.92 δ (3H, J = 6.5 Hz) in the proton spectrum of fastigiatine (Fig. 1 or 2) can be assigned to the protons on C-16 on the basis of its chemical shift, integrated area, and multiplicity. Accordingly, by making use of the 2D $^1H/^{13}C$ spectrum (Fig. 1), peak 17 (22.3 δ) can be assigned to C-16 of fastigiatine. The protons on C-16 are coupled to the proton on C-15 to form a multiplet near 1.9 δ as seen in the $^1H/^1H$ spectrum. With the chemical shift of the C-15 proton established, and referring now to the $^1H/^{13}C$ spectrum, peak 15 (22.2 δ) of the ^{13}C spectrum can be assigned to C-15 of fastigiatine. From the proton spectrum the singlet at 2.34 δ was



SCHEME 2

assigned to the NCH_3 group and the singlet at 2.15 δ to the $NCOCH_3$ group. The $^1H/^{13}C$ spectrum was then used to assign the NCH_3 group to peak 12 (35.0 δ) and the methyl of the $NCOCH_3$ group to peak 18 (21.5 δ).

Peak 3 (123.1 δ) in the ^{13}C spectrum may be assigned to the vinylic carbon C-6 on the basis of its chemical shift and multiplicity. The proton on C-6 is coupled to the proton on C-7 and shows a long range coupling, presumably to the proton on C-12 (*W* coupling), to form a doublet of doublets, 5.2 δ (dd, 1H, J = 1.1 and 5.5 Hz). From the $^1H/^1H$ spectrum (Fig. 2), couplings between the protons on C-6 and C-7 and between those on C-6 and C-12 are observed that enable a chemical shift to be assigned to the protons on each of these carbon atoms. By reference to the $^1H/^{13}C$ spectrum, peak 9 (40.2) in the ^{13}C spectrum may now be assigned to C-7, and peak 10 (38.3) to C-12.

The protons on C-1 and C-9 should resonate downfield since they are adjacent to a nitrogen atom, and therefore the multiplets centred near 3.7, 3.3, and 2.3 δ in the ^1H spectrum can be attributed to them. The protons on C-9 in fastigiatine should couple to each other and to the proton on C-10, a tertiary carbon atom. By examining the $^1H/^1H$ spectrum it may be observed that the multiplet at 3.3 δ couples to the multiplets at 2.3 δ and at 1.9 δ, the latter being assigned to C-10. With the determination of the chemical shifts of both C-9 protons and the proton at C-10, it was now possible, by examining the $^1H/^{13}C$ spectrum, to assign peak 5 (59.6 δ) to C-9, and peak 9 (45.5 δ) to C-10. The other set of protons adjacent to nitrogen at C-1 in fastigiatine should couple to the protons of C-2. By examining the $^1H/^1H$ spectrum, it can be observed that the multiplets at 3.7 and 3.3 δ couple to each other and to the multiplets at 1.5 and 1.7 δ. With the ^1H chemical shifts known it was possible, using Fig. 1, to assign peak 8 (45.3 δ) to C-1 and peak 19 (21.1 δ) to C-2. Turning now to C-3, it is evident that the protons on C-2 will couple to the protons on C-3 and, from an examination of the $^1H/^1H$ spectrum and the $^1H/^{13}C$ spectrum, peak 16 (23.0 δ) was assigned to C-3.

The proton at C-7 couples to the protons at C-8, as seen from the $^1H/^1H$ spectrum, and the chemical shift of each C-8 proton could then be determined. Thus, by examining the $^1H/^{13}C$

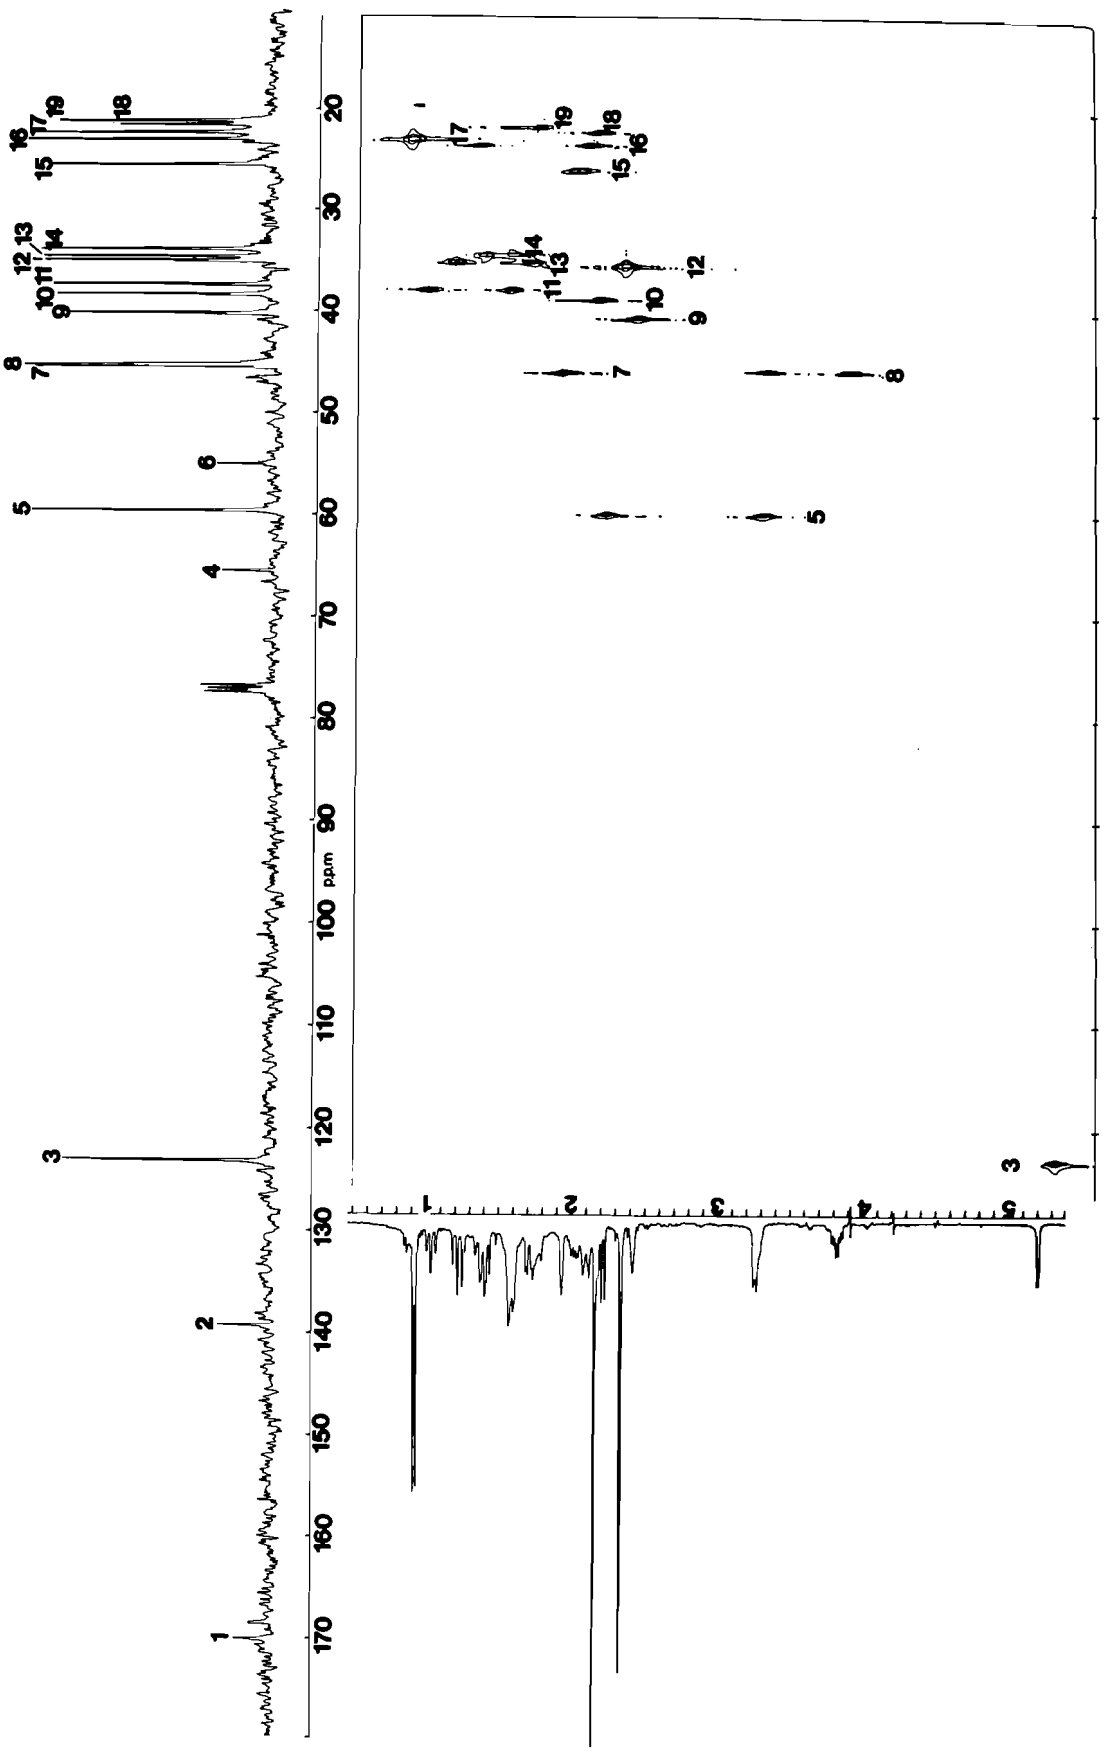


FIG 1. Heteronuclear (^1H,^{13}C) correlated spectrum of fastigiatine. N.B.: the ^{13}C spectrum is shown along the top of the figure and the ^1H spectrum at the side. The numbers assigned to the peaks are arbitrary but the assignment to specific carbon atoms may be found in Table 1.

spectrum, peak 11 (37.4 δ) can be assigned to C-8. The assignment of the two remaining resonances was resolved in the following manner. The proton on C-10 is coupled to the two protons on C-11 and, by analysing the $^1H/^1H$ spectrum and the $^1H/^{13}C$ spectrum, C-11 can be assigned to peak 14 (33.9 δ). In like manner the protons on C-14 should couple to the proton on C-15, and by examining a slice of the $^1H/^1H$ spectrum along 1.9 δ the chemical shifts of the protons on C-14 were determined. In this way peak 13 (34.6 δ) in the ^{13}C spectrum was assigned to C-14. All assignments and ^{13}C chemical shifts are recorded in Table 2.

The molecular structure of fastigiatine is shown in Fig. 3.

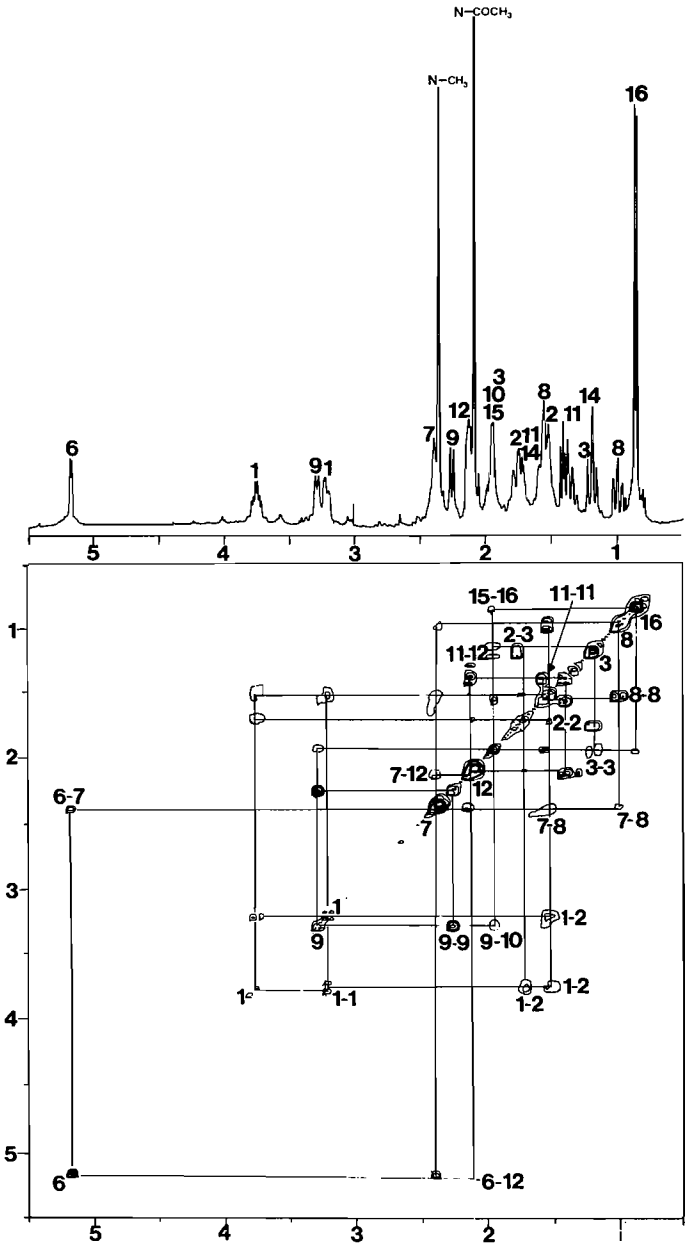

FIG. 2. Homonuclear (^1H,^1H) correlated spectrum of fastigiatine. N.B.: the numbers assigned to peaks in the ^1H spectrum refer to the position of the protons in the molecule.

Bond lengths and angles (Table 3) within the structure are normal when compared to similar structures. The *N*-acetyl features are like those in (−)-aspidospermine-*N*(b)-methiodide (12). Angles within the five-membered rings are considerably less than the tetrahedral angle and the averages are 99.6 and 100.5 for the respective rings C(10)C(4)C(13)C(12)C(11) and N(2)C(13)C(4)C(10)C(9). With the exception of C(10)—C(4)—C(13), 91.5(6)°, the range is similar to those observed in a keto lactam acid from lycoctonine (13) and the averages are only about 2° smaller. All rings are *cis*-joined, the two five-membered rings comprising an 2-aza-norbornane system. The six-membered rings have varying conformations, the N(1)C(1)C(2)C(3)C(4)C(5) ring being a twist boat, the C(4)C(5)C(6)C(7)C(12)C(13) ring being half-chair, and the third ring, C(7)C(8)C(15)C(14)C(13)C(12), a chair. Interactions between molecules in the cells are van der Waals and all intermolecular distances are equal to, or greater than, the van der Waals distances.

Experimental

Apparatus, methods, and materials

The $^1H/^1H$ and $^1H/^{13}C$ 2D spectra were recorded on a Brüker WH400 spectrometer at the Southwestern Ontario NMR Centre, University of Guelph, Guelph, Ontario.

Electron impact (EI) mass spectra were recorded on a VG Micromass 7070F mass spectrometer at 70 eV. The high resolution spectra and the linked scan experiments were carried out on a Kratos MS50 instrument at the University of California, San Francisco, at the Bio-organic, Biomedical Mass Spectrometry Resource (A. L. Burlingame, Director) supported by NIH Division of Research Resources Grant RR01614.

Lycopodium fastigiatum R.Br. was obtained in 1967 through the Department of Scientific and Industrial Research, Botany Division, Christchurch, New Zealand, and carefully stored in a dry cupboard. It was collected at Mt. Robert, Nelson Lakes National Park, South Island, New Zealand. Fastigiatine, mp 143–46°C, was isolated as described elsewhere (3). The specimen used in this investigation was prepared by recrystallization from ether.

Measurement of the X-ray data

A platelike colourless crystal was mounted along the longest axis and used for X-ray studies. Precession photographs revealed the orthorhombic symmetry, and unit cell parameters were obtained from least-squares fit of χ, ϕ, and 2θ for 15 reflections in the range $18.3° < 2\theta < 23.8°$ recorded on a Syntex $P2_1$ diffractometer with use of graphite-monochromatized Mo$K\alpha$, radiation (λ = 0.70926 Å). Crystal data and other numbers related to data collected are given in Table 4. The density was measured by flotation in aqueous KBr. Intensities were also measured with the Syntex $P2_1$ diffractometer with use of a coupled θ(crystal) − 2θ(counter) scan. The methods of selection of scan rates and initial data treatment have been described (14, 15). Corrections were made for Lorentz polarization effects but not for absorption. This will give a maximum error in F_o of <1.0%.

The phases were determined by direct methods with use of 242 reflections with $|E| > 1.54$ and 12 sets of starting phases. Fourteen of

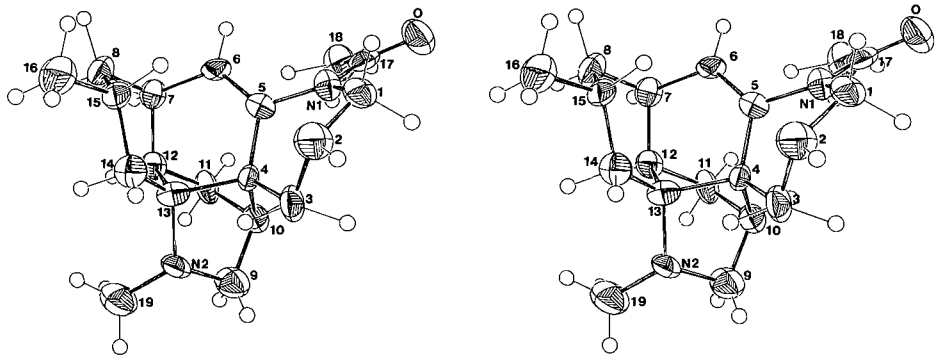

FIG. 3. The molecular structure of fastigiatine.

the non-hydrogen atoms were located on the *E* map and all atoms were located after refinement and subsequent difference syntheses. All non-hydrogen atoms were made anisotropic at this stage. In further refinement, which minimized $\Sigma\omega(|F_o| - |F_c|)^2$, hydrogen atoms were included but not refined. Corrections were made for secondary extinction (x(SHELX = 0.00429).[3] Scattering curves were taken from ref. 16. No attempt was made to determine the absolute configuration of the molecule. The configuration given here, to which all the data apply, is based on that commonly observed among the Lycopodium alkaloids (1). The atom parameters are listed in Table 5.[4]

Received December 23, 1985

NICK BURLINSON, STEVEN J. RETTIG, JAMES TROTTER, and BRUCE MCKAGUE. Can. J. Chem. **64**, 950 (1986).

A by-product formed in the preparation of tetrachloroguaiacol is shown to be a trimeric quinone. Derivatization of the quinone to a crystalline tetramethoxy derivative allowed X-ray determination of its crystal structure as 3,6-dichloro-4,5-dimethoxy-1,2-bis(2′-methoxy-3′,4′,5′,6′-tetrachlorophenoxy)benzene, **4**. Rarely observed long range J_{CH} coupling between ring carbons and methoxyl hydrogens as well as conformational isomerism were observed in ^1H and ^{13}C nmr studies of **4**. Crystals of **4** are triclinic, $a = 12.562$ (1), $b = 12.708(1)$, $c = 9.223(1)$ Å, $\alpha = 96.93(1)$, $\beta = 97.478(7)$, $\gamma = 101.285(8)°$, $Z = 2$, space group $P\bar{1}$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to $R = 0.056$ and $R_w = 0.056$ for 2946 reflections with $I \geq 1.5\sigma(I)$. The molecule contains a central six-membered dichloro-tetraoxo substituted aromatic ring, linked via oxygen bridges to two identical tetrachloro-dioxo substituted rings; intramolecular steric overcrowding causes significant deviations from a symmetrical conformation. Bond lengths, angles, and intermolecular distances are generally close to expected values.

NICK BURLINSON, STEVEN J. RETTIG, JAMES TROTTER, et BRUCE MCKAGUE. Can. J. Chem. **64**, 950 (1986).

Un sous produit obtenu lors de la préparation du tétrachloroguaïacol est en fait une quinone trimère. On a transormé cette quinone en un dérivé tétraméthoxylé dont l'analyse par cristallographie des rayons-X révèle que sa structure cristalline correspond à celle du dichloro-3,6 diméthoxy-4,5 bis(méthoxy,2′ tétrachloro-3′,4′,5′,6′ phénoxy)-1,2 benzène **4**. Des études par rmn du ^1H et du ^{13}C ont permis d'observer des constantes de couplage à longue distance. J_{CH}, assez rares entre les carbones du cycle et les hydrogènes des groupements méthoxyles, ainsi que de l'isomérie conformationnelle. Les cristaux appartiennent au groupe d'espace triclinique $P\bar{1}$ avec $a = 12{,}562(1)$, $b = 12{,}708(1)$, $c = 9{,}223(1)$ Å, $\alpha = 96{,}93(1)$, $\beta = 97{,}478(7)$, $\gamma = 101{,}285(8)°$, et $Z = 2$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs de $R = 0{,}056$ et de $R_w = 0{,}056$ pour 2946 réflexions avec $I \geq 1{,}5\sigma(I)$. La molécule contient un cycle aromatique central à 6 chaînons portant un substituant dichloro-tétraoxo qui est lié par l'intermédiaire de deux ponts oxygène, à deux cycles identiques portant un substituant tétrachloro-dioxo. Un encombrement stérique intramoléculaire provoque des déviations importantes par rapport à une conformation symétrique. Les longueurs de liaison, les angles et les distances intermoléculaires sont généralement très près des valeurs attendues.

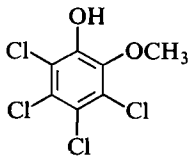
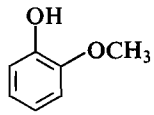
Introduction

Tetrachloroguaiacol, **1**, a compound formed during the bleaching of pulp and paper (1, 2), is readily prepared by the chlorination of guaiacol, **2**, in acetic acid (3).



1



2

In the preparation of **1**, we frequently observed the formation of a bright orange, highly insoluble by-product, **3**, which could be separated from **1** during crystallization.

This paper reports the structural determination of the by-product, **3**, as a trimeric quinone as evidenced by the crystallographic structure determination of its tetramethoxy derivative, **4**. Additionally, the ^1H and ^{13}C nmr spectra of **4** are presented to suggest conformational isomerism in solutions of **4** due to steric crowding.

Experimental

Melting points were taken n a Kofler Micro Hot Stage and are uncorrected. Infrared (ir) spectra were recorded on a Unicam SP1100 spectrophotometer; ultraviolet (uv) spectra on a Beckman DB-GT spectrophotometer. A Kratos MS50 mass spectrometer was used to obtain mass spectra. Liquid chromatography (lc) was performed on a Hewlett Packard Model 1084B high performance liquid chromatograph equipped with a variable wavelength detector set at 254 nm. Reverse phase partition chromatography was done on a 4.6 mm × 20 cm RP-8 column, 5-μm particle size, using isocratic elution with acetonitrile–water, 90:10 and a flow of 1 mL/min.

^{13}C and ^1H magnetic resonance (nmr) spectra were obtained on a Varian XL-300 FT spectrometer operating at 75.429 MHz for carbon and 299.943 MHz for hydrogen. A 5-mm broadband probe was used. Solutions of 100 mg of each compound in 0.5 mL of *d*-chloroform, to which a small amount of tetramethylsilane (TMS) was added, were prepared. For the ^1H spectra, narrow spectral widths (200–500 Hz) and resolution enhancement processing of the FID were employed to obtain good peak resolution. Using aquisition times of 4 or 5 s and repetition rates of 5 s allowed digitization of 8–10 points/Hz.

Isolation of the by-product

Tetrachloroguaiacol was prepared by the chlorination of guaiacol in acetic acid as described in the literature (3). The crude product was dissolved in hexane and the orange, insoluble by-product isolated by filtration. Two grams by-product was obtained from the chlorination of guaiacol on a 50-g scale. The orange compound, which was insoluble in common organic solvents, including dimethyl sulfoxide, had mp 250–255°C; ir (KBr): 1685, 1560 cm^{-1}; ms *m/e* (% relative intensity): 702 (25.6), 700 (42.8), 698 (51.4), 696 (38.2), 694 (13.6), 692 (5.8) M^+, 661 (42.9 M^+ −HCl), 247 (100). *Anal.* calcd. for $C_{20}H_6Cl_{10}O_6$: C 34.47, H 0.87; found: C 34.33, H 0.88.

Preparation of the tetramethoxy derivative

Sodium borohydride was added in small portions to a stirred suspension of the by-product (800 mg) in methanol (10 mL) until a clear solution formed (approximately 5 min). The product was poured into ice-water, acidified with sulphuric acid, and extracted thrice with ether. After washing the combined extracts with water, and drying with anhydrous magnesium sulfate, a few mL of the extract was evaporated with a stream of nitrogen to give a clear oil, ir (film): 3350 cm^{-1}, which rapidly turned orange in air. The remainder of the extract was methylated with diazomethane and evaporated to give a colourless white solid (700 mg). Extraction with hexane and concentration of the extract gave the product as a colourless solid (480 mg), mp 161.5–163°C. Three crystallizations from hexane gave the tetramethoxy derivative as colourless prisms (400 mg); mp 163–164°C; uv (ethanol), λ_{max}: 295 nm (ϵ 3900); ^1H nmr in $CDCl_3$, δ: 3.62 and 3.64 (singlets, total 3H), 3.93 (singlet, 3H); ^{13}C nmr in $CDCl_3$, δ: 61.46 and 61.74 (OCH_3), 119–128 (CCl), 140–150 (COR); ms *m/e* (% relative intensity): 730 (48.4), 728 (85.8), 726 (100), 724 (69.9), 722 (21.7)M^+. *Anal.* calcd. for $C_{22}H_{12}Cl_{10}O_6$: C 36.35, H 1.66; found: C 36.22, H 1.72.

X-ray crystallographic analysis of 3,6-dichloro-4,5-dimethoxy-1,2-bis(2'-methoxy-3',4',5',6'-tetrachlorophenoxy) benzene, 4

A crystal bounded by the 5 faces (followed by their distances in mm from a common origin): {1 $\bar{1}$ 0}, 0.104, (0 0 −1), 0.175, (1 1 0), 0.213, (−1 −1 1), 0.069 was mounted in a general orientation. Unit-cell parameters were refined by least squares on 2 sin θ/λ values for 25 reflections (2θ = 26–35°) measured on a diffractometer with Mo-$K\alpha$ radiation ($\lambda(K\alpha_1)$ = 0.70930, $\lambda(K\alpha_2)$ = 0.71359 Å). Crystal data at 22°C are:

$C_{22}H_{12}Cl_{10}O_6$ fw = 726.86

Triclinic, a = 12.562(1), b = 12.708(1), c = 9.223(1) Å, α = 96.93(1), β = 97.478(7), γ = 101.285(8)°, V = 1415.4(2) $Å^3$, Z = 2, = 1.705 Mg m^{-3}, $F(000)$ = 724, μ(Mo-$K\alpha$) = 10.28 cm^{-1}. Absent lections: none. Space group $P\bar{1}$ (C_i^1, No. 2, conventional reduced) from structure analysis.

ensities were measured with graphite-monochromated Mo-$K\alpha$ ion on an Enraf–Nonius CAD4-F diffractometer. An ω–2θ scan 5–10.06° min^{-1} over a range of (0.80 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of 3 check reflections, measured every 3600 s throughout the data collections, remained constant to within 4%. After data reduction,[2] an absorption correction was applied using the analytical method (4,5).

Transmission factors ranged from 0.697 to 0.822. Of the 6480 independent reflections measured, 2946 (45.5%) had intensities greater than or equal to 1.5σ(I) above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The structure solution was initiated in the centrosymmetric space group $P\bar{1}$ on the basis of the E-statistics. The structure was solved by direct methods, the coordinates of 36 of the 38 non-hydrogen atoms being determined from an E-map. The remaining atoms, including hydrogen, were positioned from subsequent difference maps. In the final stages of refinement the non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms were included as fixed contributors in idealized positions (based on observed peaks, C—H = 0.98 Å, U_H = 1.25 U_C $Å^2$). The scattering factors of ref. 6 were used for non-hydrogen atoms and those of ref. 7 for hydrogen atoms. Anomalous scattering factors from ref. 8 were used for the Cl atoms. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o|-|F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix refinement of 343 variables. Reflections with $I < 1.5\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.056 and R_w = 0.056 for 2946 reflections with $I \geq 1.5\sigma(I)$. For all 6480 reflections R = 0.156. The function minimized was $\Sigma w(|F_o|-|F_c|)^2$, $R = \Sigma \||F_o|-|F_c|\|/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts correspond to 0.002 and 0.03σ, respectively. The mean error in an observation of unit weight was 1.908. A final difference map showed maximum fluctuations of −1.51 to +0.55 e $Å^{-3}$ (near Cl(10) and C(14), respectively) and was essentially featureless elsewhere. The final positional and thermal parameters appear in Table 1. Bond lengths and angles appear in Tables 2 and 3, respectively. Calculated hydrogen coordinates and thermal parameters (Table 4), a complete listing of torsion angles (Table 5), and a listing of nonbonded distances (Table 6) are included as deposited material. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[3]

Results and discussion

The amorphous by-product, which normally comprised only a few percent of the product, had a melting point of 250–255°C and was insoluble in common organic solvents, including dimethyl sulfoxide. The material had infrared absorption at 1685 and 1560 cm^{-1} (KBr), suggesting the presence of a quinone group. No absorption was present in the hydroxyl region. Mass spectrometry indicated the compound was highly chlorinated and had a probable molecular weight of 692.

Addition of $NaBH_4$ to a methanol suspension of the by-product resulted in the immediate discharge of the orange colour and formation of a clear solution. The crude product had a large hydroxyl peak in the infrared spectrum (film) but no carbonyl absorption. Since it underwent air oxidation back to the starting

[2]The computer programs used include locally written programs for data processing and locally modified versions of the following: MULTAN 80, multisolution program by P. Main, S. J. Fiske, S. E. Hull, L. Lessinger, G. Germain, J. P. Declercq, and M. M. Woolfson; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin, and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

material rapidly, as evidenced by the formation of an orange colour on standing a few minutes, the methyl ether derivative was prepared by reaction with diazomethane in ether. After three recrystallizations from hexane, a colourless crystalline material with a melting point of 163–164°C was obtained in 50% overall yield.

Liquid chromatography indicated the methylated reduction product had a purity of 94%. The molecular weight from mass spectrometry was 722, consistent with the introduction of two methyl groups, and the intensities of the molecular ion isotope peaks were in agreement with a molecular formula of $C_{22}H_{12}O_6Cl_{10}$. The by-product was evidently a trimeric quinone **3**, which yielded the tetramethoxyderivative **4** on reduction and methylation.

The proton decoupled ^{13}C nmr spectrum of **4** revealed three groups of lines: one group has two resonances at δ 61.46 and 61.74, of integrated area 1:3, respectively, which are assigned to the four-methoxyl carbons; another group of resonances between δ 119 and 128 had 10 lines, consistent with 10 carbons each attached to chlorine; the third group of resonances had 6 lines in the region of δ 140–150, consistent with aromatic carbons attached to —OR groups. The 10 resonance lines in the C—Cl region would normally suggest an unsymmetrical structure for **4**; however, in light of the crystal structure, *vida infra*, the multiplicity of lines must be due to the presence of hindered rotations between rings as well as preferred methoxyl group orientations. The ring chlorines cause severe intramolecular steric crowding, and space filling models also suggest this.

A "coupled nOe" (nuclear Overhauser enhancement) ^{13}C nmr experiment resulted in collapse to quartets of the two resonances furthest downfield at δ 147.17 and δ 146.30 with 4.1 and 4.0 Hz coupling, respectively. This is indicative of long range $^3J_{CH}$ coupling between the ring carbons and the methoxyl hydrogens. This long range C—H coupling has been observed previously in anisole (9) but only as a broadening effect. To our knowledge these coupling values have not been reported. These $^3J_{CH} \cong$ 4 Hz are consistent with other $^3J_{CH}$ values, which in general are of the same order as $^3J_{HH}$ couplings of this geometry. Consequently, the resonance at δ 147.17 is assigned to three degenerate ring carbons containing a methoxyl group and the resonance at δ 146.30 to a fourth carbon with a methoxyl bonded. This assignment is also consistent with the above noted methyl carbon resonances, which gave two peaks but with integrated areas of 3:1.

The ^1H nmr spectrum of **4** has only three peaks (slightly broadened) all in the methoxy region at δ 3.62, 3.64, and 3.93. Scanning at a narrower sweep width to give 8 points/Hz digitization and using mathematical enhancement of the FID to improve resolution gave at least three resolved peaks of varying intensity for the broadened peak at δ 3.93 and two resolved peaks each for the lines at δ 3.64 and 3.62. This suggests the existence of more than one conformational isomer for each of the methoxyl groups in **4** and is in agreement with ^1H nmr work by T. Schaefer and R. Laatikainen (10) on 1,2-dimethoxybenzene, in which they suggest a predominance of a planar conformation in solution.

A similar multiplicity of chemical shifts for the ^1H resonance in tetrachloroveratrole (1,2-dimethoxytetrachlorobenzene) was also observed by us. The single peak at δ 3.91 upon enhanc

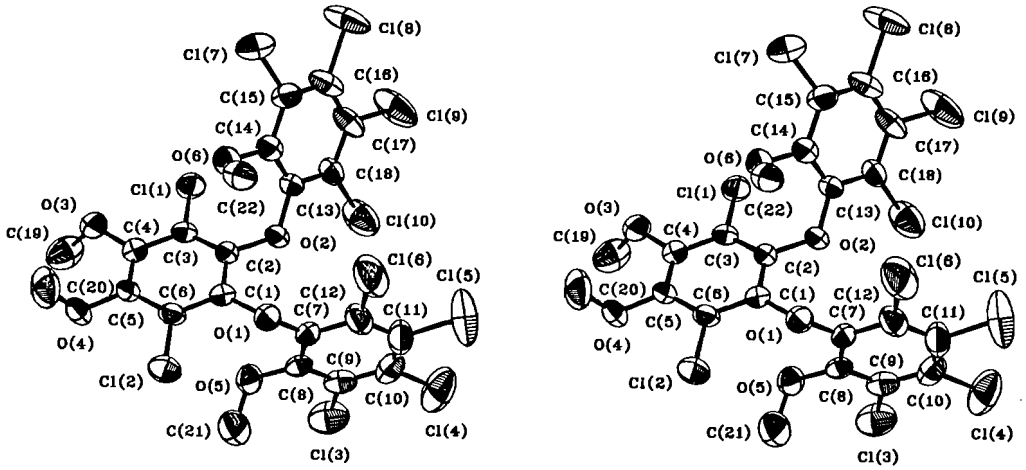

FIG. 1. Stereo view of **4**. 50% probability thermal ellipsoids are shown for the atoms.

resolution procedures split into two lines of area 2:1 with $\Delta\nu$ = 1.2 Hz, suggesting a *cis*:*trans* arrangement of methoxyl groups. The same long range $^3J_{CH}$ coupling referred to above was also observed for this model compound in a similar ^{13}C -"coupled NOe" experiment.

Formation of the trimer likely occurs during the final stage in the chlorination of guaiacol. The reaction progresses rapidly to tetrachloroguaiacol **5** under mild conditions, but introduction of the final chlorine is somewhat slower. Under forcing conditions, intermolecular reactions and oxidation may occur, possibly as shown, with the formation of condensation products such as the trimer **3**.

Discussion of crystal structure of ***4***

The molecule (Fig. 1) contains a central six-membered dichloro-tetraoxo substituted aromatic ring, linked via oxygen bridges to two identical tetrachloro-dioxo substituted rings. Although a structural formula has apparent C_{2v} symmetry, intramolecular steric interactions prevent the attainment of this symmetrical conformation. The observed molecular structure

has very rough C_2 symmetry, but with large deviations from exact symmetry; e.g. the outer-ring planes make angles of 91.5 and 68.3(5)° with the plane of the central ring (Fig. 1). Each six-membered ring is close to planar, with maximum displacements from the mean planes of 0.029(5) Å in the central ring, and 0.009(6) and 0.019(6) Å in the outer rings. The substituents are, however, more significantly displaced from the ring planes, presumably as a result of the steric overcrowding, by 0.005–0.137(2) Å for Cl and 0.005–0.092(4) Å for O atoms; the methoxy groups are oriented with the outer methyl carbon atoms displaced from the ring planes by 0.99–1.21(1) Å.

Some of the O—CH_3 bond distances seem anomalously short, particularly O(6)—C(22) at 1.202(6) Å, and to a lesser extent O(5)—C(21) at 1.344(7) Å. However, some of the thermal parameters of the atoms involved, particularly O(6), are quite large, although not physically unrealistic, and suggest possible librational or disorder errors in the positions of these outer atoms. Otherwise, the bond lengths in the molecule (Table 2) are generally close to expected values. Mean lengths (with standard deviations derived from rms deviations in parentheses) are C—Cl = 1.721(2), C—C = 1.382(3), C(sp^2)—O = 1.380(4), C(sp^3)—O = 1.415(13) Å. Bond angles (Table 3) are also close to normal values, relief of any steric strain apparently being accomplished by rotations and deviations from planarity, rather than bond angle distortions. Intermolecular distances are generally close to normal van der Waals separations; the shortest intermolecular Cl...Cl contacts of 3.481, 3.526, 3.604, 3.616(3) Å represent fairly strong interactions. Two C—H...Cl groupings (one intramoleclar, H...Cl = 2.89 Å, and one intermolecular, H...Cl = 2.80 Å) and one intramolecular C—H...O (H...O = 2.37 Å) may represent weak hydrogen-bond type interactions.

Kinetics of the interactions between dyes and micelles

VINCENT C. REINSBOROUGH[1] AND JOSEF F. HOLZWARTH
Fritz-Haber-Institut der Max-Planck-Gesellschaft, Faradayweg 4-6, D-1000 Berlin 33, West Germany

Received July 31, 1985[2]

VINCENT C. REINSBOROUGH and JOSEF F. HOLZWARTH. Can. J. Chem. **64**, 955 (1986).

The rates of association of three azo dyes, methyl red (MR), methyl orange (MO), and pyridine-2-azo-*p*-dimethylaniline (PADA), with sodium dodecylsulfate (SDS) and cetyltrimethylammonium bromide (CTAB) micelles in water were measured at 25°C over a wide pH range by the continuous flow method of integrating observation (CFMIO). The association was considered in 3 steps: bulk solution encounter, pH jump, and electrostatic and hydrophobic interactions. Either the first or third step is rate limiting depending on the charge of the dye. The rate constant of association of neutral PADA, MR, and MO with SDS micelles is approximately 2×10^6 dm^3 mol^{-1} s^{-1} while charging the dyes positively increases k to 10^9 dm^3 mol^{-1} s^{-1}. Increasing the hydrophobicity of dye or micelle increases k for the interaction with the neutral dye species. Changes in k with pH for the dye–CTAB association were less pronounced.

VINCENT C. REINSBOROUGH et JOSEF F. HOLZWARTH. Can. J. Chem. **64**, 955 (1986).

Opérant à 25°C, dans des solutions aqueuses à des pH très variés et faisant appel à une méthode d'écoulement continue d'intégration des observations, on a mesuré les vitesses d'association de trois colorants azo, le rouge de méthyle (RM), l'orange de méthyle (OM) et la pyridine-2-azo-*p*-diméthylaniline (PADA), avec des micelles de dodécylsulfate de sodium (DSS) ou du bromure de cétyltriméthylammonium (BCTA). On a considéré l'association en trois étapes : la rencontre globale des solutions, le changement rapide du pH et les interactions électrostatiques et hydrophobes. Suivant la charge du colorant, la première ou la troisième étape peuvent limiter la vitesse de la réaction. Les constantes d'association des entités neutres PADA, RM et OM avec les micelles de DSS sont de l'ordre de 2×10^6 dm^3 mol^{-1} s^{-1} alors que, si l'on charge les colorants positivement, la valeur de k augmente jusqu'à 10^9 dm^3 mol^{-1} s^{-1}. À cause de l'interaction avec les espèces colorantes neutres, une augmentation de l'hydrophobicité du colorant ou des micelles provoque une augmentation de k. Les variations de k avec le pH, pour l'association des colorants avec le BCTA, sont beaucoup moins prononcées.

[Traduit par la revue]

Introduction

Neutral molecules usually associate with ionic micelles in aqueous solution close to the diffusion-controlled limit, i.e., with a rate constant of 10^8–10^{10} dm^3 mol^{-1} s^{-1} (1–5). When the molecule and micelle are oppositely charged this should even more be the case, but when both have the same charge, it is not clear what effect the electrostatic repulsion has upon the solubilization process which, in this case, must proceed mainly through hydrophobic forces.

These three situations were examined in anionic micellar sodium dodecylsulfate (SDS) and cationic micellar cetyltrimethylammonium bromide (CTAB) solutions with azo dyes whose charges could be altered by altering the pH. The dye most extensively examined was methyl red (MR) which is positively charged, neutral (zwitterionic), or negatively charged depending upon the pH. Methyl orange (MO) came in for scrutiny also to confirm the trends noted with MR. The third dye, pyridine-2-azo-*p*-dimethylaniline (PADA), resembles the other two in structure but at ordinary pH values can only be neutral or positively charged. It was studied because it is widely used as an indicator reaction in its complexation with metal ions in micellar rate enhancement studies. It is usually assumed in these kinetics that the association step of PADA to the micelle is not rate limiting but it has never been measured.

Experimental

The continuous flow method of integrating observation (CFMIO) was used to obtain the rates of association of dye with micelle (6, 7). Solution A contained dye and surfactant at a concentration less than the critical micelle concentration (cmc) and solution B contained surfactant slightly higher than twice the cmc. As a result, the surfactant concentration after mixing was 25–50% higher than the cmc. No change in k_{obs} was noted within error when the final surfactant concentration did not greatly exceed twice the cmc, which took different values as the pH changed. Under these mixing conditions, both solutions contained surfactant monomer so that any dye–monomer interaction effects (8) in the mixing would be minimized. Micelle concentrations were calculated by subtracting the cmc from the final total surfactant concentration and dividing by the aggregation number. Values for the cmc and aggregation numbers as affected by ionic strength were taken from the literature (9, 10).

Pseudo-first-order conditions usually pertained with the micelles (10^{-5}–10^{-4} mol dm^{-3}) in at least 10-fold excess over the dye (10^{-6} mol dm^{-3}). For CFMIO to be effective, spectral differences on mixing must be at least 10–15%. This was not always possible when dye and micelle bore similar charges.

Three methods were used to calculate the rate constant of association of the dye with the micelles in the continuous flow method with integrating observation. If there are no interfering slower reactions, then the "constant speed" method is the most accurate. Most of the data could be collected by this technique. Solution absorbances of the reaction mixture at constant flow (E), the products (E_∞), and the two reactant solutions (averaged as E_0) are measured and combined in the ratio M defined as $(E - E_\infty)/(E_0 - E_\infty)$. The relationship between M and the rate constant takes different forms depending upon the order of the reaction (6). The error in k values determined by the constant speed method is usually 25–40%.

When more than one reaction occurs in the time it takes to register E_∞ (~0.1 s), then either one of two variants in approach can be used to eliminate E_∞ from the calculations. In the first, which could be called the "two speed" method, solution absorbances of the reaction mixture are obtained at two different mixing speeds (E_1, E_2) along with the absorbances of the reactants (E_0). The ratio M then takes the form $(E_1 - E_2)/(E_0 - E_2)$ where E_1 is associated with the faster flow rate (11). Then, for example, for a pseudo-first-order reaction

$$[1] \quad M = \frac{V_1[1 - \exp(-R/V_1)] - V_2[1 - \exp(-R/V_2)]}{R - V_2[1 - \exp(-R/V_2)]}$$

where $R = kc_0l$ in which k is the second order rate constant, c_0 is the

[1]On sabbatical leave from Mount Allison University, Sackville, N.B., Canada.

[2]Revision received January 14, 1986.

concentration of the reactant in excess, and l is the length of the observation tube. V_1 and V_2 are the two flow rates with $V_1 > V_2$.

The other variant in technique is the "three speed" method which eliminates E_0 and involves only the three solution absorbances (E_1, E_2, and E_3) of the reaction mixture at three different speeds (12). The ratio M is $(E_1 - E_3)/(E_2 - E_3)$ which for a pseudo-first-order reaction becomes

$$[2] \quad M = \frac{V_2[1 - \exp(-R/V_1)] - V_3[1 - \exp(-R/V_3)]}{V_2[1 - \exp(-R/V_2)] - V_3[1 - \exp(-R/V_3)]}$$

with V_1, V_2, and V_3 being the three flow rates and R having the same form as previously (12).

The difficulty with both these variants is that the absorbances E_1, E_2, and E_3 may not differ appreciably over the range of flow rates that are practical for the instrumentation. Errors in k thus usually lie in the 50–100% range. These two methods are often useful as a check only when one process is being viewed by the constant speed technique.

The surfactants and methyl red were obtained from Merck, methyl orange from Serva, PADA from ICN Pharmaceuticals, and 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol (bromo-PADAP) from Janssen. Solutions were made from triply distilled water and used within an hour or two of preparation. The appropriate pH was obtained by adding NaOH or HCl solution to both reactant solutions.

Results

Methyl red interactions with SDS and CATB micelles

The spectra for MR in nonmicellized and micellized SDS solutions reveal sufficient spectral differences for kinetic exploitation by CFMIO as long as the pH is less than 8 (Fig. 1). The second order rate constant for the association of MR with SDS micelles obtained by CFMIO is shown in Fig. 2 for the pH range 1–8. The rate constant rises sharply from 2×10^6 dm^3 mol^{-1} s^{-1} at pH 8 to a value 2×10^9 dm^3 mol^{-1} s^{-1} or greater at pH 4. From pH 3 to 4, k is too large to be measured by CFMIO ($k \geq 2 \times 10^9$ dm^3 mol^{-1} s^{-1}). From pH 2.5 to 1, k drops rapidly being only 4×10^6 dm^3 mol^{-1} s^{-1} at pH 1.2.

With CTAB micelles, the applicable pH range for CFMIO is wider extending from pH 11 to 2.5 but the k values do not show the same dramatic changes as with SDS micelles (Fig. 2). Although it is tempting to draw a curve through the data points to yield a maximum in k around pH 5–6, it is not justified in view of the experimental error associated with each point (see error bars in Fig. 2). The best that can be said is that the rate of interaction of MR with CTAB micelles rises slowly but perceptibly over the pH range 2.5–11.

Salt additions were made at pH 4.5 and 8 in the MR–SDS system to see whether the changes in k were consistent with the different MR species postulated at each pH. At pH 4.5, the rate of interaction between dye and micelle was noticeably lowered, in regular fashion, with NaCl additions (Fig. 3) but at pH 8 a slight increase from $(2.0 \pm 0.5) \times 10^6$ to $(4.1 \pm 1.0) \times 10^6$ dm^3 mol^{-1} s^{-1} was detectable with the salt addition being 0.20 mol dm^{-3} NaCl. The uncertainties from the measurements justify saying only that k remains constant with salt additions at pH 8.

Methyl orange interactions with SDS micelles

Methyl orange differs from MR in structural detail only in having a *para*-SO_3^- group instead of an *ortho*-COO^- group as a substituent on one of the benzene rings (Figs. 4, 5). The spectra in micellar and nonmicellar SDS solutions are similar except that pH 4.2 catches the titration transition zone for MO (pH 3.5–4.5) and the acid region for MR (transition zone

pH 5–6). For MO–SDS solutions above pH 6, there is no spectral difference from MO solutions without SDS (Fig. 6).

The k values for the MO–SDS system were measured by the less precise two speed CFMIO variant (see Experimental) because of an interfering secondary reaction. As with MR, the rate constant for the interaction between MO and SDS micelles rose from 2×10^6 to at least $5 \times 10^8\ dm^3\ mol^{-1}\ s^{-1}$ (Fig. 7) on decreasing pH in the acid region. Again, there was a short range at low pH (1.5–2.0 in pH) over which, the rate was too rapid to detect ($k \geq 5 \times 10^8\ dm^3\ mol^{-1}\ s^{-1}$). Below pH 1.5, k fell

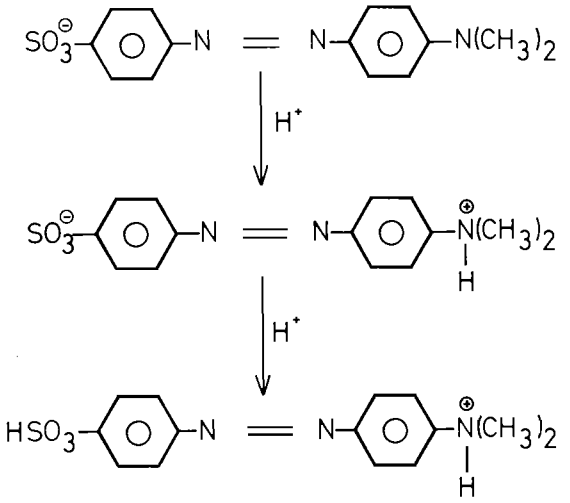

FIG. 5. Mechanism of protonation of methyl orange (MO).

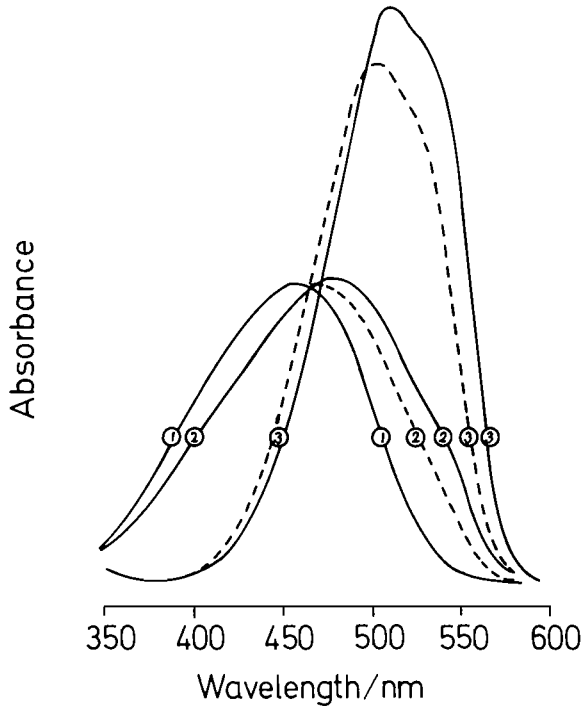

FIG. 6. Spectra for methyl orange in micellar (solid lines) and nonmicellar (dotted lines) SDS at pH 8.6 (1), pH 4.2 (2), and pH 1.0 (3). The two spectra at pH 8.6 are identical ($5 \times 10^{-3}\ dm^3\ mol^{-1}$ MO and $1 \times 10^{-4}\ dm^3\ mol^{-1}$ SDS micelles).

rapidly so that at pH 1.0 it was $2 \times 10^7\ dm^3\ mol^{-1}\ s^{-1}$ (Fig. 7). The identity of the interfering reaction was not pursued further since its effect could easily be eliminated by the two speed method.

Interactions of PADA with SDS and CTAB micelles

The pH dependence of the rate constant of interaction of PADA with micellar SDS solutions is shown in Fig. 8. Below pH 5.5, the reaction rate was too rapid to be observed without salt additions (Fig. 3) but dropped rapidly with increasing alkalinity to a constant value of $(2.0 \pm 0.5) \times 10^6\ dm^3\ mol^{-1}\ s^{-1}$ over the range pH 7–10.5. It should be noted that, unlike MO and MR associated with SDS micelles, with this diazo dye

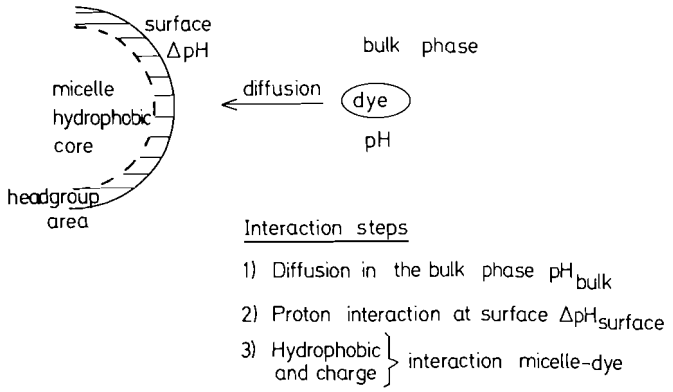

FIG. 10. Model of dye–micelle interactions.

sufficient spectral difference from the counterpart soapless solutions was maintained in the alkaline region (Fig. 9).

Discussion

The association of a dye molecule with a micelle may be divided into three stages corresponding to the three sites of interaction: the bulk solution, the micelle surface region, and the micelle interior (Fig. 10). In the first stage, the rate of interaction will be the bulk solution encounter rate which must be close to the diffusion-controlled limit of about 3×10^9 dm^3 mol^{-1} s^{-1} (13) especially when micelle and dye are oppositely charged. Dye protonation or deprotonation may occur in the second stage since the surface region pH will differ by approximately 2 pH units from the bulk solution value (14, 15). However, the rate of proton transfer in micellar media is also in the 10^9 dm^3 mol^{-1} s^{-1} range (16) so that this step should not ordinarily be rate-determining. The final stage of incorporation must be a complex interaction between electrostatic and hydrophobic forces as the dye settles into its binding site in the micelle core or surface or some intermediate position.

Methyl red and MO undergo protonation as depicted in Figs. 4 and 5. A more complete analysis would include quinoid forms (17, 18) but, for our purposes, a simplified scheme is sufficient. The *ortho* position of the COO^- group in MR as opposed to the *para* position of the SO_3^- substituent in MO affords stability to azo nitrogen protonation through the formation of a six-membered ring for MR. The pK_a values for MR in water are 4.9 and 2.4 while MO changes colour in the pH 3.1–4.1 range. The apparent pK_a for the dissociation of the neutral form of MR to the negative form is shifted to 6.7 in micellar SDS and to 3.55 in micellar decyltrimethylammonium bromide (15). Pyridine-2-azo-*p*-dimethylaniline is neutral in alkaline solution but positively charged in acid solution with its pK_a of 4.5 shifted to 6.7 in micellar SDS solutions (14).

Of the three dyes, only PADA gives rise to a spectral difference in alkaline SDS solutions. Only PADA is neutral above pH 7; MO and MR are negatively charged as are the SDS micelles. In acid solution, no spectral change results when positively charged PADA interacts with positively charged CTAB micelles. Apparently, when dye and micelle are similarly charged spectral differences are not found rendering CFMIO powerless to detect spectrophotometrically the kinetics of interaction between such species.

Thus, at pH 8 in the MR–SDS system (Fig. 2) where the observed rate of interaction is relatively slow at $2 \times$

10^6 dm^3 mol^{-1} s^{-1}, CFMIO senses only the association of the neutral MR species with negatively charged SDS micelles, even though negatively charged MR is the dominant species at this pH. Supporting evidence for this comes from salt additions to this system at pH 8. Even with 0.20 mol dm^{-3} NaCl, the rate constant remained unchanged. If the negative species were affecting the CFMIO-determined rate constants, they should have been dramatically affected by ionic strength changes of this order of magnitude.

As the pH is lowered from 8 to 4, negatively charged MR disappears, neutral MR waxes in concentration and then wanes as positively charged MR makes its appearance. The observed rate in this pH range is a blend of neutral MR and positively charged MR interactions with SDS micelles and rises sharply as a result. The increasing proportion of positively charged MR to neutral MR brings the rate close to the limit imposed by diffusion presumably due to the dominance of the electrostatic attractive forces as the hydrophobicity of the dye changes in character and strength with the charging of the dye. Salt additions at pH 4.5 depress k markedly (Fig. 3) as would be expected with Na^+ ions competing with positively charged MR for micelle surface sites. This same effect on k was noted in electron transfer reactions when salt was added (4).

In effect, this depression of k with salt addition explains why, at pH values lower than 4, the rate constant decreases markedly. The added H^+ ions act as added Na^+ ions in excluding positively charged MR from the micellar surface region. In fact, pH 2 and 10^{-2} mol Na^+/dm^3 are roughly equivalent in depressive power. The overall interpretation of the kinetic results for the MO–SDS system is similar.

For alkaline solutions in the PADA–SDS system where PADA is neutral, the rate constant of association is 2×10^6 dm^3 mol^{-1} s^{-1} for pH 7.5–10.5 (Fig. 8). Below pH 7, protonated PADA is formed and, as with MR, the sharp rise in k to the diffusion-controlled limit and the depressive effect upon k of salt additions reflect the strength of the electrostatic attractive forces.

Because cationic micelles shift the pK_a of dyes to lower pH, many of the protonation changes of these dyes are not available for study with CTAB micelles. Thus, in the MR–CTAB system, despite the wide pH range monitored, we see only the effect of the protonation of the negative species to the neutral form and it appears to have minimal effect on the rate constant of interaction. The hydrophobic force operative at intermediate pH values is relatively strong to yield a k value of 1×10^8 dm^3 mol^{-1} s^{-1}. At pH 11, k rises only to 2×10^8 dm^3 mol^{-1} s^{-1} with the electrostatic attractive contribution to the interaction but this contribution does not play the same dominant role as it did in the MR–SDS system.

This increase in the hydrophobic force of attraction with CTAB micelles is especially noticeable with PADA where the rate of interaction of neutral PADA with the micelles is so rapid as to be near or at the diffusion imposed limit. The longer carbon chain of CTAB as compared with SDS confers greater hydrophobicity to CTAB which is reflected also in its lower cmc. To test this further, the interaction rate constant was measured at pH 9 for neutral PADA associating with sodium tetradecylsulfate and sodium decylsulfate micelles. The k values thus determined were 2.4×10^8 and 1.6×10^5 dm^3 mol^{-1} s^{-1}, respectively, as compared with 2.0×10^6 dm^3 mol^{-1} s^{-1} for SDS. These data indicate that a two carbon increase in the chain length increases k by at least an order of magnitude in the C10–C14 range as the hydrophobic forces within the micelle are increased.

In summary, when the neutral dye species of MR, MO, and PADA interact with SDS and CTAB micelles the rate constants are 10^6 dm^3 mol^{-1} s^{-1} but when dye and micelle are oppositely charged k increases to 10^9 dm^3 mol^{-1} s^{-1}, the diffusion-controlled limit. Since even neutral molecules and micelles are thought to associate at this limit in solution (1–3), the slowness of the observed rate must be a consequence of the final stage of incorporation of the dye into the micelle when hydrophobic forces must chiefly be operative. The charging of the dye oppositely from the micelle must consequently affect the hydrophobicity of the dye and so the electrostatic forces now brought to bear upon the final interaction step are dominant. Increasing the hydrophobicity of the micelle by lengthening the carbon chain of the monomer serves to increase the rate of interaction. Increasing the hydrophobicity of the dye serves the same purpose. This was tested by investigating the association of the very hydrophobic dye, bromo-PADAP, in both SDS and CTAB and, even for neutral bromo-PADAP, k values were always too fast to be measured accurately by CFMIO despite sufficient spectral changes. With MR, MO, and PADA interacting with SDS and CTAB micelles, the hydrophobic forces responsible for the association are relatively weak causing the third stage of incorporation to be slow and rate-determining but this is not the case for bromo-PADAP associating with these same micelles.

Synthesis, structure, proton-nuclear magnetic resonance, and Fourier transform infrared spectroscopy of several transition and nontransition metal–adenosine-5-triphosphate complexes

H. A. TAJMIR-RIAHI, M. J. BERTRAND, AND T. THEOPHANIDES[1]

Department of Chemistry, Université de Montréal, Montréal, Que., Canada HC 3V1

Received September 20, 1985

H. A. TAJMIR-RIAHI, M. J. BERTRAND, and T. THEOPHANIDES. Can. J. Chem. **64**, 960 (1986).

Several complexes of adenosine-5-triphosphate disodium salt (Na_2H_2ATP) with the metal ions, Na^+, Mg^{2+}, Ca^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, and *cis*- and *trans*-$Pt(NH_3)_2Cl_2$ and K_2PtCl_4 at pH = 3.5 and 7.2 have been isolated, identified, and studied. Marked spectral similarities have been observed for the structurally known metal–phosphate bonded compounds, $[Cu(H_2ATP)(phen)]_2 \cdot 7H_2O$ and $[Zn(H_2ATP)(bipy)]_2 \cdot 4H_2O$ and all the metal–ATP complexes studied here, except the Pt–ATP complexes. The metal binding is through the α, β, and γ phosphate oxygen atoms when the N1-position of adenine is protonated. Spectral changes have also been observed for the Pt–ATP complexes in which there is a Pt–N7 and –N1 coordination. The sugar pucker in the $Na_2H_2ATP \cdot 3H_2O$ crystal dimers is C3′-*endo*–*anti* (in one) and C2′-*endo*–*anti* (in the other) with a characteristic infrared band at 818 cm^{-1}. In the corresponding Cu^{2+} and Zn^{2+} complexes the sugar has C3′-*endo*–*anti* conformation with the marker band at about 814 cm^{-1}. The C2′-*endo*–*anti* conformation is observed for all the metal–ATP complexes prepared here with a marker band at 825–822 cm^{-1}.

H. A. TAJMIR-RIAHI, M. J. BERTRAND et T. THEOPHANIDES. Can. J. Chem. **64**, 960 (1986).

Opérant à des pH de 3,5 et de 7,2, on a isolé, étudié et identifié plusieurs complexes du sel double de sodium du triphosphate-5 d'adénosine (Na_2H_2ATP) avec les ions métalliques Na^+, Mg^{2+}, Ca^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+} et avec les $Pt(NH_3)_2Cl_2$-*cis* et -*trans* ainsi que le K_2PtCl_4. On a remarqué des similarités spectrales marquées pour tous les composés structuraux connus comportant un phosphate lié à un métal, comme le $[Cu(H_2ATP)(phen)]_2 \cdot 7H_2O$, le $[Zn(H_2ATP)(bipy)]_2 \cdot 4H_2O$ et tous les complexes métal–ATP étudiés ici, excepté les complexes Pt–ATP. Lorsque la position N1 de l'adénine est protonée, la liaison du métal se fait par les atomes d'oxygène α, β et γ du phosphate. On a noté des changements spectraux dans les cas des complexes Pt–ATP dans lesquels il y a une cordination Pt–N7 et –N1. La conformation du sucre dans les cristaux dimères du $Na_2H_2ATP \cdot 3H_2O$ est C3′-*endo*–*anti* (dans l'un) et C2′-*endo*–*anti* (dans l'autre) et elle présente une bande infrarouge caractéristique à 818 cm^{-1}. Dans les complexes correspondants avec le Cu^{2+} et le Zn^{2+}, le sucre adopte une conformation C3′-*endo*–*anti* et il possède une bande caractéristique à 814 cm^{-1}. On observe une conformation C2′-*endo*–*anti* pour tous les complexes de métaux–ATP qui ont été préparés ici et ils sont tous caractérisés par une bande à 825–822 cm^{-1}.

Introduction

Of all metal–mononucleotide complexes those involving ATP have been the subject of extensive investigations (1, 2). This is mainly due to the important role of ATP as a mediator in maintaining the energy balance in living cells by hydrolysis of its phosphoryl groups and by transfer to various acceptors. Since most of the reactions responsible for phosphoryl group transfer are catalyzed by metal ions the study of metal–ATP interactions is biologically significant. Although various spectroscopic techniques have been used (3–6) to characterize the nature of metal–ATP interactions, until recently the metal ion binding to the various potential coordination sites of the ATP molecule was the subject of speculation. A recent X-ray structural analysis of ternary complexes $[Cu(H_2ATP)(phen)]_2 \cdot 7H_2O$ (7) and $[Zn(H_2ATP)(bipy)]_2 \cdot 4H_2O$ (8) and several other complexes of Mg^{2+}, Ca^{2+}, Mn^{2+}, and Co^{2+} with ATP and dipyridylamine (9, 10) showed that the metal–ATP binding is through the α, β, and γ, phosphate oxygen atoms and that there is no interaction between the metal ion and the base adenine.

In the present work, several binary complexes of ATP with Na^{2+}, Mg^{2+}, Ca^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, and Pt^{2+} have been isolated and studied by means of microanalysis, proton-nmr and Fourier transform infrared (FTir) spectroscopy. The spectroscopic results have been compared with those of the structurally known $[Cu(H_2ATP)(phen)]_2 \cdot 7H_2O$ and $[Zn(H_2ATP)(bipy)]_2 \cdot 4H_2O$ (8) complexes in order to detect the characteristic features of each structural type of complexes synthesized here and to establish a correlation between the spectral changes and the coordination sites involved. Furthermore, the marker bands of the sugar conformations C2′-*endo*–*anti* and C3′-*endo*–*anti* have been identified and tentative infrared assignments of the ATP absorption frequencies are reported. The molecular structure of the ATP anion (H_2ATP^{2-}) with the numbering of the atoms is shown below.

Experimental

Materials

Na_2H_2ATP was purchased from Raylo Chemicals Limited. K_2PtCl_4 was from Johnson Matthey Chemicals and was converted to *cis*- and *trans*-$Pt(NH_3)_2Cl_2$ as previously reported (11). These were purified according to a known procedure (12). D_2O (99.8%) was from Cambridge Isotope Laboratories. All the metal ion salts were reagent grade and were used as supplied.

Preparation of metal–ATP complexes

An aqueous solution of the metal ion salt (1 mmol) was added to a solution of Na_2H_2ATP (1 mmol) in H_2O (20 mL) and the pH was adjusted to 3.5 at room temperature. The solution was kept for 24 h and an ethanolic solution was added to precipitate the complex which was washed with ethanol several times and dried over $CaCl_2$. The analytical results agreed with the formula $M(H_2ATP) \cdot nH_2O$, where M = Mg^{2+}, Ca^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, and Zn^{2+} and n = 4–6. The platinum complexes were synthesized by addition of stoichiometric amounts of *cis*- or *trans*-$Pt(NH_3)_2Cl_2$ and K_2PtCl_4 to a solution of Na_2H_2ATP in H_2O (25 mL) in a similar fashion as stated for the other metal–ATP complexes. The complexes were isolated at pH = 3.5 and were analysed to give the composition of $[Pt(Na_2H_2ATP)_n]Cl_2 \cdot xH_2O$ and *cis*- and *trans*-$[Pt(NH_3)_2(Na_2H_2ATP)_2]Cl_2 \cdot 4H_2O$, where n = 1–4 and x = 2–6. The Mg^{2+}– and Pt^{2+}–ATP complexes were also prepared and isolated at pH = 7.2. The analytical data are given in Table 1.

[a]Structurally known.

Physical measurements

The solution pH values were measured on a Fisher Accumet Model 630 pH meter using 0.1 *N* NaOH or HCl solutions to control the pH. The ^{1}H-nmr spectra were recorded on a Varian EM 360–60 MHz. The solutions were in D_2O containing DSS as reference (δ = 0.00 ppm). The FTir spectra were recorded on a Digilab FTS-15C/D Fourier transform infrared interferometer equipped with a HgCdTe detector (Infrared Associates, New Brunswick, NJ), a KBr beam splitter, and a Globar source. The spectra were taken using KCl pellets and the resolution was 2–4 cm^{-1}. Previous procedures of data collecting and calculating the spectra were used (13). The compounds were analyzed for C, H, and N by Schwarzkopf Microanalytical Laboratory (U.S.A.) and the metal ions were determined complexometrically.

Results and discussion

Nuclear magnetic resonance spectra

The ^{1}H-nmr chemical shifts for Na_2H_2ATP and some of its metal adducts in D_2O solution are given in Table 2. Whereas the chemical shifts observed for H2 and H8 of ATP^{4-} are 8.03 and 8.43 ppm, those in Na_2H_2ATP are observed at 8.43 and 8.53 ppm, the downfield shifts of H2 and H8 protons are due to the protonation of the N1 position of the adenine ring, which is in agreement with the X-ray structural data for the Na_2H_2ATP compound (14). Complexation with the metal ions, Mg^{2+}, Ca^{2+}, and Zn^{2+} does not alter the chemical shifts of H2 and H8 considerably, while in Pt–ATP complexes drastic changes have been observed. It should be noted that the large downfield shifts of H8 in all the Pt–ATP complexes synthesized at pH = 3.5 and 7.2 are due to the direct Pt—N7 bonding (Table 2). The downfield shifts of H2 in all platinum–ATP compounds prepared at pH = 3.5 is attributed to the effect of Pt—N7

TABLE 2. The ^{1}H-nmr chemical shifts of 5′-ATP and its metal adducts in D_2O solution

bonding. Moreover, platinum–N1 interaction has also been observed in the Pt–ATP complexes isolated at pH = 7.2, where deprotonation of the N1 position takes place. Upon a comparison of the proton-nmr spectra of Pt–ATP complexes with those of the corresponding Mg^{2+}, Ca^{2+}, and Zn–ATP compounds (Table 2), one can conclude that the binding of platinum to ATP occurs through the N7 site of the adenine ring in all the Pt–ATP adducts prepared in acidic media. The Pt–N1 coordination as well as the Pt—N7 bonding is inferred from the spectra of the platinum complexes isolated at pH = 7.2. There is no metal–base interaction in the Mg^{2+}, Ca^{2+}, and Zn^{2+}–ATP complexes (only metal–phosphate bonding is indicated from the spectra). It is worth mentioning that the sugar H1′ proton showed a considerable downfield shift in the spectra of all Pt–ATP complexes and this is most likely due to the direct metal–N7 coordination (Table 2). More conclusive evidence regarding the nature of the metal–ATP interaction is obtained from infrared spectroscopic studies discussed in the following section.

Fourier transform infrared species

Analyses of the crystal structure by X-ray showed that $Na_2H_2ATP \cdot 3H_2O$ exists as a dimer in which two of the Na^+ ions are bonded to the α, β, γ phosphate oxygens and the N7 nitrogen of the adenine ring. The other Na^+ ions are phosphate and water coordinated (14). In the crystal structures of $[Cu(H_2ATP)(phen)]_2 \cdot 7H_2O$ and $[Zn(H_2ATP)(bipy)]_2 \cdot 4H_2O$ complexes the metal ions are bonded only to the phosphate oxygen atoms with no metal–purine interaction (7, 8). The infrared spectra of these structurally known complexes have been recorded in the region of 4000–500 cm^{-1} and compared with the corresponding complexes of Mg^{2+}, Ca^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, and Pt–ATP synthesized here. The results of the spectra analysis are described below in the two regions 3600–2700 cm^{-1} and 1800–500 cm^{-1}.

3600–2700 cm^{-1}

In this region, it is difficult to draw conclusions on the nature of metal–ligand bonding due to the presence of the strong hydrogen bonding network in the free Na_2H_2ATP and its metal adducts (7, 8, 14). The antisymmetric and symmetric stretching vibrations of NH_2, NH^+, H_2O sugar OH, CH_2, and CH groups are observed in this region and exhibit no major changes upon ATP–metal complexation.

1800–500 cm^{-1}

In this region of the spectra of the metal–ATP complexes, drastic changes occurred related to the base, phosphate and sugar vibrations and these are discussed below.

(a) Base vibrational frequencies. A strong and broad absorption band at 1705 cm^{-1} in the spectrum of Na_2H_2ATP, assigned to the protonated N1 position of the adenine base (3), showed shifting of about 10 cm^{-1} in the spectra of all the metal–ATP adducts synthesized at pH = 3.5 (Table 3). Upon deprotonation of the N1 position this absorption band disappeared and a new band was observed at 1656 cm^{-1} in the spectrum of the ATP^{4-} (Table 3 and Fig. 1). This absorption band is assigned to the NH_2 in-plane bending vibration (14). The small shifts of the

complexes in the region of 1800–500 cm^{-1} with possible assignments

bands at 1705–1695 cm^{-1} in the spectra of metal–ATP adducts are due to the rearrangement of the N1–H^+ hydrogen bonding system and are not due to the deprotonation or the participation of the N1 site in metal–ligand bonding. It should be noted that similar shifts of that absorption band were observed in the spectra of $[Cu(H_2ATP)(phen)]_2\cdot 7H_2O$ and $[Zn(Na_2H_2ATP)(bipy)]_2\cdot 4H_2O$ complexes where only metal–phosphate coordination has been reported (7, 8) (Fig. 1). It is worth mentioning that upon ionization of the N1–H^+ group and platination of the N1 position at a pH of 7.2, the absorption band at 1705 disappeared and a strong band at 1650 cm^{-1}, related to the NH_2 bending, was observed. This confirms the assignment of the band at 1705 cm^{-1} to the NH_2 bending upon protonation of the N1–H^+ group. The absorption band at 1612 cm^{-1} in the spectrum of the Na_2H_2ATP, attributed to the imidazol and pyrimidine ring skeletal vibrations, showed no changes in the spectra of the metal–ATP complexes (Table 3). A band with medium intensity appeared at about 1580 cm^{-1} in the spectra of deprotonated ATP^{4-}, $Mg_2(ATP)\cdot 6H_2O$, and $[Pt_2(Na_4ATP)_3Cl_4]\cdot 6H_2O$ complexes (Fig. 1 and Table 3) which is assigned to the pyrimidine ring vibration (14). This absorption is not present in the spectra of all the other metal–ATP complexes obtained in acidic media. A weak absorption band at 1500 cm^{-1}, in the free nucleotide spectrum, related to the pyrimidine ring vibration did not change upon ligand metalation. The two absorption bands with medium intensities at 1465 and 1414 cm^{-1} in the free ATP spectrum assigned to the purine N7—C8 stretching and C8—H bending vibrations (15), showed a small change in the spectra of all the metal–ATP compounds isolated from acidic solutions. Considerable shifting was observed in the spectra of platinum complexes (Table 3). Since the proton-nmr results indicated no direct N7–metal interaction, the small downfield shift of H8 (Table 2) and the infrared changes of the adenine ring vibrations are related to indirect metal–N7 interaction. This indirect interaction via H_2O molecules or the participation of the N7 atom in the base stacking interactions has been observed in the crystal structures of $[Cu(H_2ATP)(phen)]_2\cdot 7H_2O$, $[Zn(H_2ATP)(bipy)]_2\cdot 4H_2O$ (7, 8), and several other ternary Mg^{2+}– and Ca^{2+}–ATP complexes (9, 10). It should be noted that considerable changes ($\Delta\nu = 30\ cm^{-1}$) have been observed in the spectra of all the Pt–ATP compounds and they are, for the purine vibrational frequencies, caused by the direct Pt—N7 coordination. This is consistent with the major downfield shift of the H8 resonance in the platinum–ATP complexes described above (Table 2). Similar infrared spectral changes were observed for several platinum—N7 bonded mononucleotide complexes (15–19). A weak absorption band at 1330 cm^{-1} in the free nucleotide spectrum, assigned to the adenine ring vibration, exhibited considerable shifting and splitting in the spectra of Pt–ATP complexes (Table 3 and Fig. 1). The alteration observed for this absorption band is also related to the direct platinum—N7 bonding which is not observed in the spectra of the other metal–ATP complexes. Owing to the coupling of the vibrations, both in pyrimidine and imidazol rings, it is difficult to assign any individual absorption bands to the metal–N1 coordination and thus the Pt–N1 binding has been shown by the downfield shift of the H2 proton observed in aqueous solutions (Table 2).

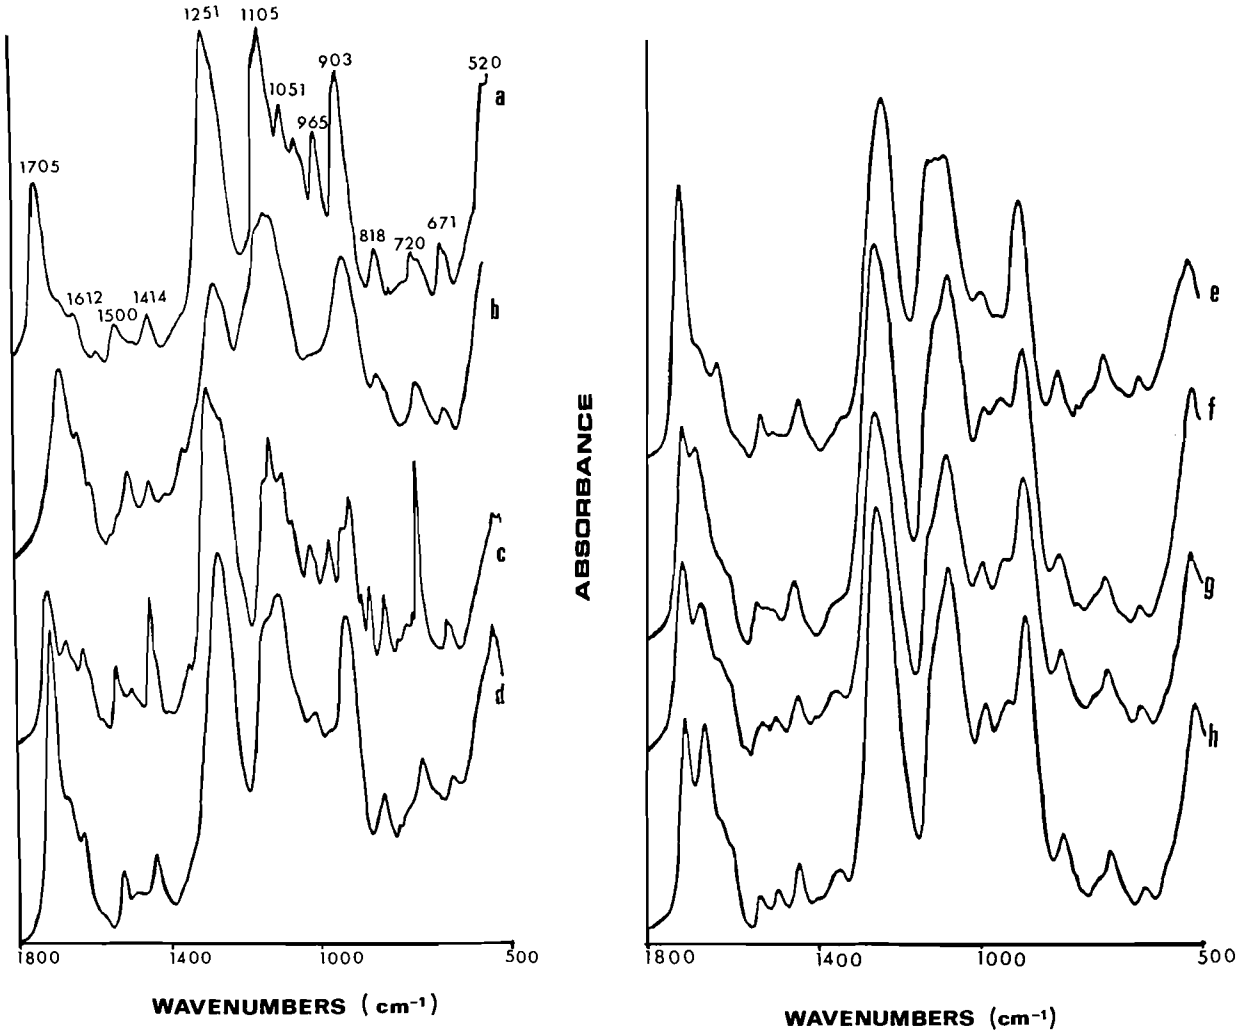

FIG. 1. The FTir spectra of $Na_2H_2ATP \cdot 3H_2O$ and metal–adducts in the region of 1800–500 cm^{-1} for (*a*) $Na_2H_2ATP \cdot 3H_2O$, (*b*) Na_4ATP, (*c*) $[Cu(H_2ATP)(phen)]_2 \cdot 7H_2O$, (*d*) $Mg(H_2ATP) \cdot 5H_2O$, (*e*) $Co(H_2ATP) \cdot 4H_2O$, (*f*) $Pt(Na_2H_2ATP)_2Cl_2 \cdot 6H_2O$, (*g*), *cis*-$[Pt(NH_3)_2(Na_2H_2ATP)_2]Cl_2 \cdot 4H_2O$, and (*h*) *trans*-$[Pt(NH_3)_2(Na_2H_2ATP)_2]Cl_2 \cdot 4H_2O$.

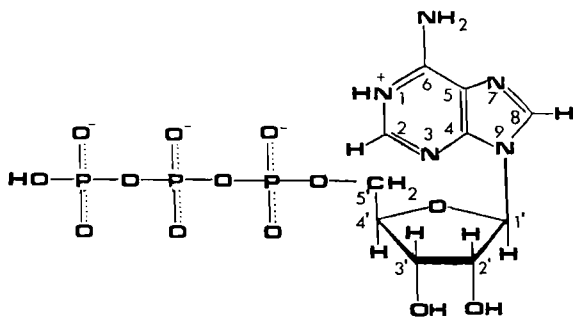
(b) Phosphate vibrational modes. The triphosphate chain in ATP is a potentially multidentate ligand, binding through the α, β, and γ phosphate oxygen atoms (7, 8). The phosphate group in H_2ATP^{2-} shows fundamental infrared vibrations in the region 1200–900 cm^{-1} which are assigned as follows: the two strong and broad absorption bands at 1252 and 1105 cm^{-1} are assigned to the PO_2^- antisymmetric and symmetric stretching vibrations, a strong band at 965 cm^{-1} is assigned to the P—O—H stretching, and the band at 903 cm^{-1} is assigned to the O—P—O stretching vibration (3). Upon dissociation of the H_2ATP^{2-} to ATP^{4-} at pH 7.2 the band at 965 cm^{-1} disappeared and two other strong absorption bands at 1120 and 1092 cm^{-1} were observed, which are assigned to the antisymmetric and symmetric stretching vibrations of the PO_3^{2-} (3) (Fig. 1). Upon phosphate coordination to the metals Cu^{2+} and Zn^{2+} in the ternary compounds $[Cu(H_2ATP)(phen))_2]_2 \cdot 7H_2O$ and $[Zn(H_2ATP)(bipy)]_2 \cdot 4H_2O$, the band at 1252 cm^{-1} shifted towards lower frequencies and the other phosphate band at 1105 cm^{-1} also showed shifting and splitting (Fig. 1). The band at 903 cm^{-1}, assigned to the O—P—O stretching, shifted towards higher frequencies. These spectral changes are due to the coordination of the α, β, and γ phosphate oxygen atoms to the metal cations which is in agreement with the X-ray structural



analysis (7, 8). Similar spectral changes were observed in the spectra of all the binary complexes synthesized here with the exception of the Pt–ATP compounds. This is indicative of a phosphate coordination mode in this series of metal–ATP complexes. The coordination of the α, β, and γ phosphate oxygen atoms in Mg^{2+} and Ca^{2+} in several other ternary metal–ATP complexes is known from X-ray crystallography (9, 10). In the spectra of the Pt–ATP complexes prepared here, the vibrations related to the phosphate group exhibited no major changes upon metal complexation (Fig. 1). This indicates that

TABLE 4. Sugar pucker in Na_2H_2ATP and in its metal adducts

cis-$[Pt(NH_3)_2(Na_2H_2ATP)_2]Cl_2 \cdot 4H_2O$	824	C2′-*endo–anti*
trans-$[Pt(NH_3)_2(Na_2H_2ATP)_2]Cl_2 \cdot 4H_2O$	823	C2′-*endo–anti*

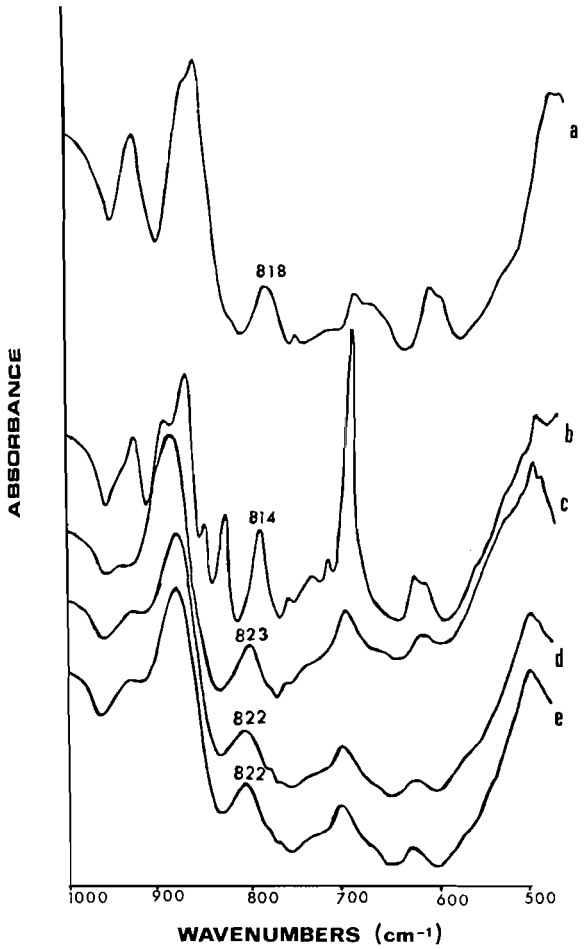

FIG. 2. The FTir spectra of $Na_2H_2ATP \cdot 3H_2O$ and metal–adducts in the region of 1000–500 cm^{-1} for (*a*) $Na_2H_2ATP \cdot 3H_2O$, (*b*) $[Cu(H_2ATP)(phen)]_2 \cdot 7H_2O$, (*c*) $Mg(H_2ATP) \cdot 5H_2O$, (*d*) *cis*-$[Pt(NH_3)_2(Na_2H_2ATP)_2]Cl_2 \cdot 4H_2O$, and (*e*) *trans*-$[Pt(NH_3)_2(Na_2H_2ATP)_2]Cl_2 \cdot 4H_2O$.

there is no direct Pt–phosphate interaction in the platinum–ATP complexes. However an indirect Pt–phosphate interaction via hydrogens of NH_3 or H_2O molecules can not be excluded.

(c) Characteristic sugar pucker bands. The OH stretching frequencies of the sugar are observed in the region 3500–3200 cm^{-1} and overlap with the base NH_2 and the water molecules bonded to the metal. The other absorption bands in the region 1400–600 cm^{-1} are masked by the strong and broad absorption bands of the phosphate group and the base (Fig. 1). A shoulder at 1120 cm^{-1} in the spectrum of Na_2H_2ATP is assigned to the sugar C—O stretching vibration which shows no changes upon nucleobase metalation (Table 3). However, a strong band at 818 cm^{-1} in the ligand spectra exhibited major changes upon sugar conformational transitions. The sugar pucker in $(Na_2H_2ATP \cdot 3H_2O)_2$ showed both C2′-*endo–anti* and C3′-*endo–anti* conformations (14) with a characteristic band at 818 cm^{-1}. This infrared band appeared at 814 cm^{-1} in the spectra of $[Cu(H_2ATP)(phen)]_2 \cdot 7H_2O$ and $[Zn(H_2ATP)(bipy)]_2 \cdot 4H_2O$ compounds which are known to contain only the C3′-*endo–anti* conformation (7, 8) (Fig. 3 and Table 4). In the spectra of the binary complexes of Mg^{2+}, Ca^{2+}, Zn^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, and Pt–ATP studied here, the sugar band appeared as a strong band at about 822 cm^{-1}, which corresponds to the C2′-*endo–anti* conformation (Fig. 2 and Table 4). A recent structural analysis of Mg^{2+} and Ca^{2+} complexes of ATP and dipyridineamine also exhibited the C2′-*endo–anti* sugar conformation in these metal complexes (10). It is interesting to note that in the ternary compounds of ATP with Cu^{2+} and Zn^{2+}, the sugar has C3′-*endo–anti* conformation (7, 8), whereas in the corresponding binary complexes the sugar showed the C2′-*endo–anti* conformation (Table 4). This could be due to the effect of the bulky ligands, 1,10-orthophenanthroline and 2,2′-bipyridyl on the sugar pucker.

Conclusions

Several new metal–ATP complexes have been prepared and comparison of the FTir spectra and X-ray structural information of the known compounds $[Cu(H_2ATP)(phen)]_2 \cdot 7H_2O$ and $[Zn(H_2ATP)(bipy)]_2 \cdot 4H_2O$ with that of the unknown binary M–ATP compounds (where M = M^{2+}, Ca^{2+}, Zn^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, and Pt^{2+}) leads to the following remarks: (1) All the binary metal–ATP complexes (except the Pt–ATP adducts) are bonded to the phosphate oxygen atoms with no direct metal–base interaction. (2) The Pt–ATP adducts synthesized in acidic media are N7-bonded, while the Pt–ATP complexes isolated here at pH = 7.2 are dimers $[Pt(Na_4ATP)_3Cl_4] \cdot 6H_2O$ having metal binding through the N1 and N7 atoms of the pyrimidine and imidazol rings. (3) The N1 atom of the pyrimidine ring is protoned in the acidic media and prevents metal–N1 coordination. (4) The phosphate spectral changes suggest that the metal coordination is via α, β, and γ phosphate oxygen atoms. (5) The sugar is not involved in metal complex formation and its conformation in $Na_2H_2ATP \cdot 3H_2O$ is both C2′-*endo–anti* and C3′-*endo–anti*. This changes to the C3′-*endo–anti* conformation in the ternary Cu^{2+}– and Zn^{2+}–ATP complexes. In all the other binary metal–ATP compounds studied here the sugar shows C2′-*endo–anti* conformation. The characteristic infrared band for C2′-*endo–anti* sugar pucker in ATP is at 822 cm^{-1} and the shift of this band to 814 cm^{-1} is a diagnostic of the transition to the C3′-*endo–anti* conformation.

The thermolysis and photolysis of malonic acid in the gas phase[1]

J.-R. CAO[2] AND R. A. BACK

Division of Chemistry, National Research Council of Canada, 100 Sussex Drive, Ottawa, Ont., Canada K1A 0R6

Received November 12, 1985

J.-R. CAO and R. A. BACK. Can. J. Chem. **64**, 967 (1986).

The thermolysis of malonic acid has been studied briefly in the gas phase at temperatures from 92 to 151°C at pressures around 0.1 Torr. Major products were CO_2 and acetic acid, while smaller amounts (< 5% of the CO_2) of CO, acetone, C_2H_6, and CH_4 were formed. Arrhenius parameters of E = 30.9 kcal/mol and log A (s^{-1}) = 13.27 were obtained, based on first-order rate constants for the formation of CO_2. It is suggested that the major products are formed by an internal hydrogen-atom transfer through a 4-centre transition state. The gas-phase photolysis was examined briefly using light of 228.8 nm, and gave products very similar to those of the thermolysis.

J.-R. CAO et R. A. BACK. Can. J. Chem. **64**, 967 (1986).

Opérant à des températures allant de 92 à 151°C et à des pressions d'environ 0,1 Torr, on a brièvement étudié la thermolyse de l'acide malonique en phase gazeuse. Les produits majoritaires sont le CO_2 et l'acide acétique qui se forment aux côtés de faibles quantités (< 5% par rapport aux quantités de CO_2) de CO, d'acétone, de C_2H_6 et de CH_4. En faisant l'hypothèse que les constantes de vitesse sont du premier ordre pour la formation du CO_2, on a déterminé les paramètres d'Arrhénius qui sont E = 30,9 kcal/mol et log A (s^{-1}) = 13,27. On suggère qu'un transfert interne d'hydrogène, par l'intermédiaire d'un état de transition à 4 centres, est responsable de la formation des produits majoritaires. On a examiné brièvement la photolyse en phase gazeuse, en utilisant une lumière de 228,8 nm; les produits obténus sont très semblables à ceux obtenus lors de la thermolyse.

[Traduit par la revue]

Introduction

Recent work in this laboratory has been concerned with the gas-phase photolysis and thermal decomposition of several carboxylic acids with adjacent carbonyl groups, including oxalic (1), pyruvic (2), and glyoxylic acids (3). Malonic acid, a β-dicarbonyl compound, is interesting for comparison. Its decomposition in the molten liquid and solid phase and in solution is well known, yielding CO_2 and acetic acid, but the gas-phase decomposition has not been reported. The present paper describes a brief study of the thermolysis and photolysis of malonic acid in the gas phase.

Experimental

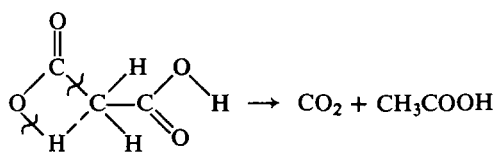
Apparatus and methods were similar to those used before with other slightly volatile acids (1–3). The same reaction vessel, a quartz cylinder 10 cm long and 5 cm in diameter, was used for both pyrolysis and photolysis and was contained in an air thermostat. A Philips Cd spectral lamp was used for the photolysis. Malonic acid (obtained from Aldrich) is marginally volatile enough to work with as a vapor, as a useful vapor pressure is barely attained before thermal decomposition becomes prohibitive. After prolonged degassing at lower temperatures, solid malonic acid was sublimed at 92°C until the desired presure was reached in the reaction vessel, which was then isolated and the experiment begun. To minimize the amounts of products from the decomposition of the solid during vaporization, which took some time, small samples were used (5–10 mg) and renewed before each experiment. Substantial amounts of products were still present in the reaction cell at the beginning of an experiment, and corrections had to be made for these.

Products were analysed by fractionation at −196, −78, and 0°C, collected, and measured with a Toepler pump and gas buret, and by gas chromatography.

Results and discussion

The thermal decomposition

Major products were CO_2 and acetic acid, in roughly equal amounts, as found previously from liquid-phase decomposition (4). Minor products were CO (5%), acetone (3%), C_2H_6 (0.4%), and CH_4 (0.2%), with their yields relative to CO_2 at 92°C shown in parentheses. Formation of CO_2 followed approximate first-order kinetics over a range of conversions (up to 50%) and pressures between about 0.7 and 0.12 Torr (1 Torr = 133.3 Pa). First-order rate constants based on CO_2 formation are shown in Table 1, and in an Arrhenius plot in Fig. 1 together with the data of Clark (4) obtained in molten malonic acid. Each rate constant in Table 1 is based on 5 or 6 experiments at different reaction times, and is derived from the slope of a plot of CO_2 product (corrected for depletion of malonic acid, assuming first-order kinetics) against reaction time. From Fig. 1, Arrhenius parameters of E = 30.9 kcal/mol and log A (s^{-1}) = 13.27 were obtained, closer to those found for oxalic acid than to those for glyoxylic and pyruvic acids, which showed unusually low frequency factors (2). Realistic confidence limits of ±2 kcal/mol for E and ±0.2 for log A can be rather arbitrarily estimated. Although surface dependence was not tested, the Arrhenius parameters suggest that the present data probably correspond to a gas-phase reaction, which is also probably partly in its pressure-dependent region so that the high-pressure Arrhenius parameters may be somewhat higher than the measured values. The similarity of E and A to those for oxalic acid suggests a similar mechanism, i.e., a hydrogen-atom transfer through a 4-membered transition state:



$\longrightarrow CO_2 + CH_3COOH$

TABLE 1. First-order rate constants for decomposition of malonic acid vapor

T (K)	k (s^{-1})
365.2	5.66×10^{-6}

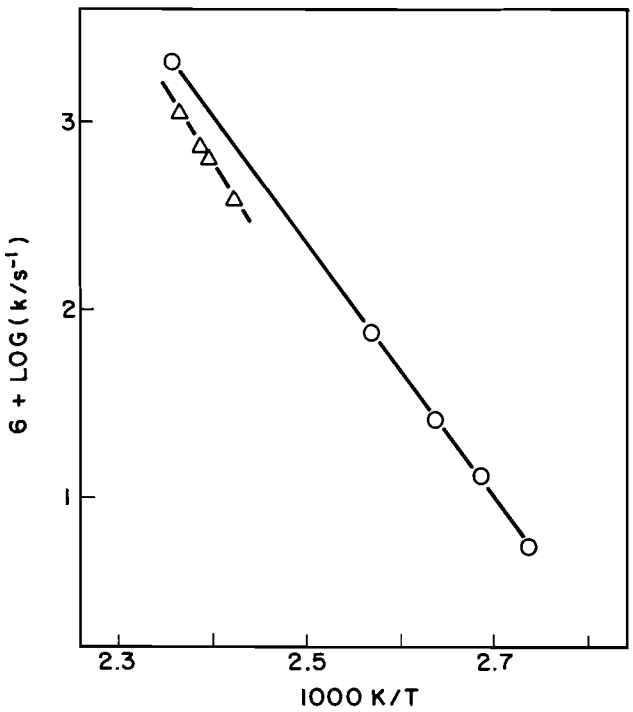

FIG. 1. Arrhenius plot for the thermal decomposition of malonic acid in the gas phase, based on first-order rate constants for the formation of CO_2. ○ = present data; △ = data for molten malonic acid (4).

The similarity of the rate constants for decomposition in the molten acid and in the gas phase indicates perhaps a similar mechanism in the former, although Clark suggested a biomolecular interaction (4) while Loudon *et al.* (5) preferred a unimolecular decomposition via a 6-centre transition state. The latter, yielding CO_2 and 1,1-ethylenediol (the enol form of acetic acid), is perhaps also a possibility for the gas-phase reaction, although it seems doubtful that the enol form would be energetically accessible in the gas phase in the absence of solvent stabilization.

The photolysis

Attempts to obtain an absorption spectrum of the vapor were unsuccessful, as no absorption significantly different from that of acetic acid was observed, and acetic acid was always present as a decomposition product. No structure was evident and no measurable absorption above about 250 nm. Under these circumstances, the radiation effective in the photolysis was almost entirely the 228.8-nm resonance line of the Cd lamp.

Major products at 92°C were again CO_2 and acetic acid in roughly equal yields, and minor products were also those found in the thermal reaction, with about the same product ratios. Sizeable corrections were made for the thermal decomposition in these experiments, but the rate of product formation was about 2.5 times larger with the light on than with the light off, and there is no doubt that a true gas-phase photolysis was taking place. It is interesting that the photolysis is so similar to the thermolysis despite the much higher energy of excitation (125 kcal/mol) available in the former. The mechanism of minor product formation in both systems is also curious. The nature of the products indicates formation of CH_3 and CH_3CO radicals, and while the energy in the photolysis is certainly high enough to generate such free radicals, their source in the thermal reaction at 92°C is not clear.

Oxidation of the mercurous ion by peroxidase

DONALD C. WIGFIELD AND SEASON TSE
The Ottawa–Carleton Institute for Research and Graduate Studies in Chemistry, Carleton University Campus, Ottawa, Ont., Canada K1S 5B6

Received July 2, 1985[1]

DONALD C. WIGFIELD and SEASON TSE. Can. J. Chem. **64**, 969 (1986).

The kinetics of oxidation of the mercurous ion by peroxidase have been measured by following the disappearance of mercurous ion using cold-vapour atomic absorption spectroscopy. Pseudo-first-order kinetics are observed with respect to mercurous ion, and the pseudo-first-order rate constants are linearly related to peroxidase concentration, showing first-order dependence on peroxidase. This behaviour is identical to oxidation of elemental mercury, and the second-order rate constant, $1.44 \times 10^4\ M^{-1}\ s^{-1}$ at 23°C, is also, within experimental error, the same as that for elemental mercury oxidation. The data are interpreted in terms of peroxidase-induced disproportionation of the mercurous dimer, followed by two-electron oxidation of zero-valent mercury.

DONALD C. WIGFIELD et SEASON TSE. Can. J. Chem. **64**, 969 (1986).

Faisant appel à la spectroscopie d'absorption atomique à vapeurs froides pour déterminer la disparition de l'ion mercureux, on a mesuré la cinétique de l'oxydation de l'ion mercureux par la peroxydase. Par rapport à l'ion mercureux, la réaction est d'un pseudo-premier ordre et on peut établir une corrélation linéaire entre les constantes de vitesse de pseudo-premier ordre et la concentration de peroxydase; ce résultat démontre que la réaction est aussi du premier ordre par rapport à la peroxydase. Ce comportement est identique à celui observé pour l'oxydation du mercure élémentaire et la constante de vitesse du deuxième ordre, $1{,}44 \times 10^4\ M^{-1}\ s^{-1}$ à 23°C, est aussi, à l'intérieur des limites expérimentales, la même que celle observée pour l'oxydation du mercure élémentaire. On interprète ces données en fonction d'une disproportionation du dimère mercureux qui est induite par la peroxydase et qui est suivie par une oxydation à deux électrons du mercure zéro-valent.

[Traduit par la revue]

Recently, in connection with the mechanism of toxicological action of elemental mercury, we have reported the kinetics of oxidation of elemental mercury by peroxidase, and proposed a mechanism for this transformation (1, 2). This, in combination with the powerful cold-vapour atomic absorption spectroscopy technique, which now allows analysis not only of total mercury (3) and zero-valent mercury (4), but also of the mercurous ion (5–7), leads to the possibility of studying the oxidation of the mercurous ion by peroxidase. We have completed this study and herein present the results.

Results

In our previous study on the oxidation of elemental mercury by peroxidase (1), in which pseudo-first-order behaviour with respect to elemental mercury was found, it was only possible to establish this first-order behaviour over a very limited concentration range. This resulted from the fact that the upper limit (solubility) and the lower limit (detection) differed only by one order of magnitude. A study of oxidation of a suitably soluble mercurous salt, such as nitrate, offered the possibility of a greater concentration range. In addition, it was of acute interest to investigate the oxidation of the mercurous ion, partly for its own sake, to compare its oxidation with that of elemental mercury, and partly because of the unknown role that the mercurous ion might play in the toxicological oxidation of elemental mercury.

Both elemental mercury and the mercurous ion give signals in cold-vapour atomic absorption analysis, whereas the mercuric ion does not, unless the analysis is carried out in the presence of a reducing agent (5). Thus the disappearance of the absorption signal represents a measure of formation of the mercuric ion, i.e. the oxidation of mercurous ion. We have previously investigated the size of the absorption signal from mercurous ion and found that, although the signal size can vary depending on experimental conditions, it does bear direct relationship to mercurous ion concentration under a particular set of reaction conditions and is therefore useful for following the reaction. Total mercury can also be determined (analysis in presence of a reducing agent) to ensure that one is indeed witnessing an interchange of mercury species, and not an absolute disappearance of mercury as a whole, e.g. by surface adsorption.

Figure 1 shows the disappearance of absorption signal when mercurous ion is in contact with horseradish peroxidase and its cofactor hydrogen peroxide, with various concentrations of the latter reagent. Two features are evident from this figure. The control points show that over the kinetic run more than 90% of the mercury is retained, showing that the potentially serious problem of mercury adsorption or evaporation at these trace levels is under control. Secondly, the change of hydrogen peroxide over several orders of magnitude makes no impact on the rate of mercurous ion oxidation. This was also observed in the oxidation of elemental mercury (1) and is consistent with the rapid and essentially irreversible formation of peroxidase Compound I (HRP-I) followed by slower oxidation of either form of mercury by HRP-I.

$$\text{HRP} + \text{H}_2\text{O}_2 \rightleftarrows \text{HRP-I} + \text{H}_2\text{O}$$

$$\text{HRP-I} + \text{mercury} \xrightarrow{\text{slow}} \text{oxidized mercury} + \text{HRP}$$

Under these circumstances, the rate of mercury oxidation is not dependent on hydrogen peroxide concentration.

In view of the finding that oxidation of elemental mercury by HRP-I obeyed normal chemical kinetics rather than Michaelis–Menten kinetics, over several half-lives of reaction(s),

$$\text{i.e. Rate} = k[\text{Hg}]^a[\text{HRP-I}]^b$$

where $a = b = 1$

we investigated the possibility that oxidation of the mercurous ion might show similar behaviour. Kinetic runs were therefore performed in which the rate of oxidation of the mercurous ion (disappearance of atomic absorption signal) was followed at

[1]Revision received January 27, 1986.

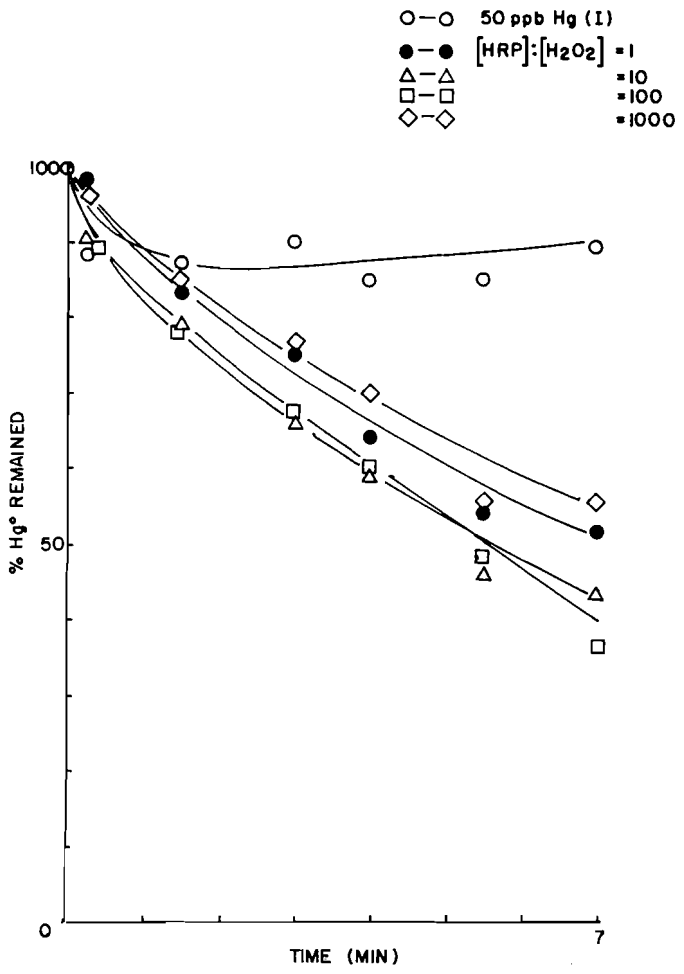

FIG. 1. Disappearance of mercurous ion in the presence of HRP and variable concentrations of H_2O_2.

various HRP-I concentrations. The logarithmic first-order test of these data is shown in Fig. 2, clearly establishing that, in common with oxidation of elemental mercury (1), oxidation of the mercurous ion is first order in mercury. In our previous paper (1) we have shown that the linearity of these plots, where the reaction is taken substantially to completion, requires that the enzyme is being constantly regenerated in the reaction, by re-oxidation to HRP-I with excess hydrogen peroxide; this in turn requires that, at least insofar as the enzyme is concerned, a two-electron oxidation is involved.[2]

Unlike the oxidation of elemental mercury, it is possible to study oxidation of the mercurous ion over a reasonable range of concentration. The pseudo-first-order rate constants summarized in Table 1 show that, consistent with the first-order process, these rate constant values are indeed independent of mercurous ion concentration. The rate constants are, however, heavily dependent on HRP-I concentration and a plot of these values as a function of each other is shown in Fig. 3, demonstrating that the reaction is first order with respect to HRP-I. The second-order rate constant that follows from these data is $1.44 \times 10^4\ M^{-1}\ s^{-1}$ at 23°C, and the overall rate equation is represented by:

$$\text{Rate} = k[Hg^{2+}{}_2][\text{HRP-I}]$$

[2]A one-electron process would cause formation of the species HRP-II, which cannot easily recycle either to HRP or HRP-I (1).

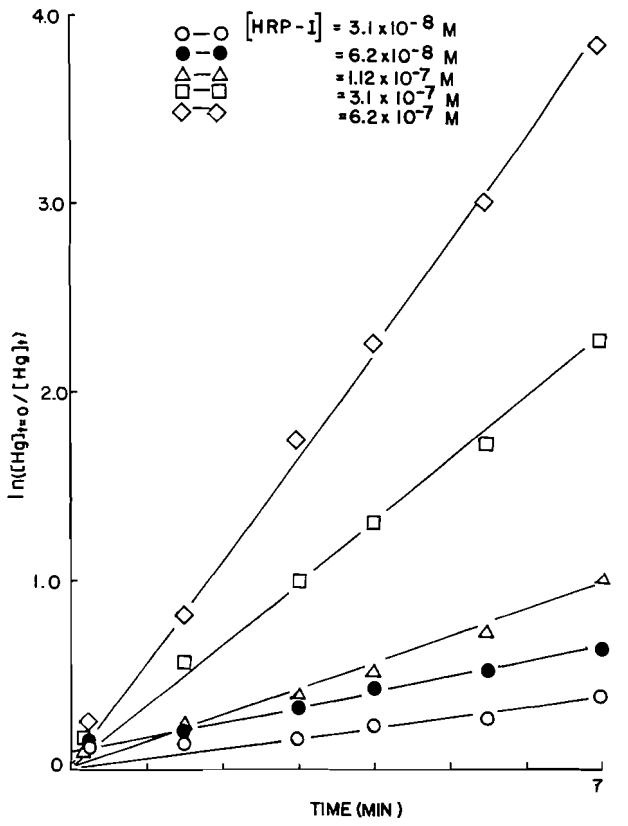

FIG. 2. First-order plot of the logarithm of remaining mercurous ion as a function of time ([Hg(I)] = 50 ppb initial).

TABLE 1. Pseudo-first-order rate constants for the oxidation of Hg(I) as a function of Hg(I) and HRP-I concentrations

[HRP-I] $\times 10^8$ (M)	[Hg(I)] (ppb)	$k^1 \times 10^3$ (min^{-1})	Correlation coefficient
3.10	50	0.6±0.2	0.927
6.20	50	1.0±0.2	0.980
12.4	50	2.0±0.2	0.996
12.4	100	2.1±0.2	0.993
12.4	250	2.0±0.1	0.995
12.4	500	2.0±0.1	0.993

Discussion

The striking feature about the results presented above is the extraordinary similarity to oxidation of elemental mercury. Indeed they are indistinguishable. Both involve a second-order rate process, first order both in mercury (either Hg^0 or $Hg^{2+}{}_2$) and in enzyme. Both involve a two-electron oxidation process and, within experimental error, the rate constants are the same ($1.43 \times 10^4\, M^{-1}\, s^{-1}$ vs. $1.44 \times 10^4\, M^{-1}\, s^{-1}$). Conceptually the simplest mechanism that would accommodate the data would be one in which HRP-I somehow would accept an electron from each half of the mercurous dimer, giving two mercuric ions.

$$\text{HRP-I} + Hg^{2+}{}_2 \rightarrow \text{HRP} + 2Hg^{2+} + O^{2-}$$

This mechanism is, however, highly unsatisfactory on several grounds. The bulky mercurous dimer would have to approach the heme centre of the enzyme; it would have to do so in a fashion to enable both mercury atoms to give up an electron, and presumably only one of the mercuric ions produced would end up bound to the oxide ion of which HRP-I must divest itself in the process. Furthermore, to give an identical rate constant, this process would have to occur with precisely equal ease to the incomparably simpler oxidation of a mercury atom. This mechanism can probably be rejected.

The identity of rate constants suggests very strongly that disproportionation of the mercurous dimer is involved in the process, followed by two-electron oxidation of the mercury atom produced, i.e.

$$Hg^{2+}{}_2 \overset{K}{\rightleftarrows} Hg^0 + Hg^{2+}$$

$$Hg^0 + \text{HRP-I} \xrightarrow[\text{determining}]{\text{rate}} Hg^{2+} + \text{HRP}$$
$$k$$

In this way the rate-determining step in the reaction is the same two-electron oxidation involved in the oxidation of elemental mercury, which will clearly proceed at a rate independent of the source of Hg^0.

This simple process is, however, not consistent with the kinetic data because of the pre-equilibrium involved. In the absence of externally added Hg^{2+}, the concentrations of Hg^0 and Hg^{2+} are the same; thus

$$[Hg^0] = K^{1/2}[Hg^{2+}{}_2]^{1/2}$$

In this case, since the rate equation is:

$$\text{Rate} = k[Hg^0][\text{HRP-I}],$$

the reaction should have an initial half-order dependence on the concentration of mercurous ion.[3]

The disproportionation of the mercurous ion, however, is one that is dramatically dependent on experimental conditions. Although, in the absence of other ions, the equilibrium is far to the side favouring mercurous ion ($K = 5.5 \times 10^{-9}$) (8), it is an equilibrium that may be moved completely to the other side by ions that complex with the mercuric ion. Thus several potential salts of the mercurous species, such as cyanide and sulfide, simply do not exist (9). It is noteworthy that sulfide from cysteine is also a component of peroxidase (10). If the disproportionation mechanism is thus disturbed, the half-order dependence on mercurous ion disappears and is replaced by simple first-order kinetics, as is experimentally observed. The peroxidase thus apparently acts not only as the precursor of HRP-I, but also as the agent for the displacement of the disproportionation reaction, then to be followed by the two-electron oxidation of Hg^0. This process would not only have the kinetic properties experimentally observed, but would also demand a rate constant identical to that for elemental mercury oxidation. This overall mechanism is shown below.

$$Hg^{2+}{}_2 \xrightarrow{\text{peroxidase}} Hg^0 + Hg^{2+} - \text{peroxidase}$$

$$\text{HRP} + H_2O_2 \rightarrow \text{HRP-I} + H_2O$$

$$\text{HRP-I} + Hg^0 \xrightarrow[\text{determining}]{\text{rate}} \text{HRP} + Hg^{2+}$$

We have already commented on the detailed mechanism of the rate-controlling oxidation of Hg^0 (1).

From the data obtained it appears likely that the mechanism of oxidation of mercurous ion by the peroxidase system is best represented by the three steps outlined above.[4] It is noteworthy that complexation of Hg^{2+} by peroxidase evidently does not significantly affect the reaction rate, thus reinforcing the idea that only the heme portion of the peroxidase is important in the reaction and that this is basically a chemical reaction between two species (HRP-I and Hg^0). This is in contrast to the usual situation involving enzyme catalysis in which substrate binding and Michaelis–Menten kinetics are involved.

Experimental

Reagents and solutions

Horseradish peroxidase (E.C.1.11.1.7, Type X)

Horseradish peroxidase was obtained as a $(NH_4)_2SO_4$ suspension (Sigma Chemical Co., St. Louis, Mo., C-100). Solutions were freshly prepared by dissolving the desired amount of the enzyme in phosphate buffer (pH = 7.00, 0.05 *M*). The subsequent enzyme concentration was determined by the absorbance at 403 nm and the corresponding extinction coefficient ($\epsilon = 1.02 \times 10^4\, M^{-1}\, cm^{-1}$). The R.Z. value, an indicator of purity, was determined as the ratio of the absorbances at 403 and 280 nm.

Mercurous solutions

Stock mercurous solutions were prepared monthly by dissolving 1.0000 g of mercurous nitrate (Fisher Scientific, Toronto, Canada, M-168) in 1 L of 0.1% V/V nitric acid (Canlab, McGraw Ltd.). Serial dilutions from this solution were freshly made for each experiment. The concentrations were determined by cold vapour atomic absorption, under reducing conditions (5).

Hydrogen peroxide

Hydrogen peroxide solutions were prepared daily from 30% stock solution (Anachemiz Ltd., Montreal, Canada).

Water

All glassware used for solution preparation were cleaned by soaking in 35% nitric acid solution for at least a period of 48 h, and were thoroughly rinsed with distilled deionized water prior to use. All solutions were prepared using distilled deionized water (Millipore Corporation, Bedford, Mass.).

Mercury analysis

Mercury analysis by cold vapour atomic absorption, with separate determinations for elemental mercury and mercuric ion, has been fully described previously (4). Analysis of mercurous ion using the same apparatus is also fully documented (5).

Kinetic experiments

To 10 mL of mercury solution were added peroxidase and H_2O_2

[3]A referee has pointed out that after the initial period $Hg^0 \neq Hg^{2+}$ and thus the half order will gradually change.

[4]The analytical method cannot distinguish between Hg^0 and $\frac{1}{2}\, Hg^{2+}{}_2$; thus there is no inconsistency between the original use of mercurous ion and its ultimate analysis.

or previously prepared HRP-I. Mixing was done by means of the sampling syringe, for 15 s. The flask was stoppered with a glass stopper, and sampling done by momentary removal of the stopper.

Preparation of HRP-I

Compound I was prepared by mixing (Vortex) 0.9 mL of phosphate buffer and the desired amount of HRP, and various equivalents of H_2O_2, in a 1.5-mL disposable micro test tube. Its presence was confirmed by obtaining the spectra prior to addition to mercury solutions (1).

A rate and equilibrium study of the addition of acetone enolate ion to the 2-methyl-5-nitroisoquinolinium cation in aqueous solution

JOHN W. BUNTING AND JAMES W. TAM[1]
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received December 3, 1985

JOHN W. BUNTING and JAMES W. TAM. Can. J. Chem. **64**, 973 (1986).

Rate and equilibrium constants for the reaction between acetone and the 2-methyl-5-nitroisoquinolinium cation to give 1-acetonyl-1,2-dihydro-2-methyl-5-nitroisoquinoline (**2**) have been evaluated over the pH range 10.0–11.3 in aqueous solutions at 25°C. This reaction is shown to occur under much milder conditions (temperature, pH) and in much shorter reaction times than previously used for the synthesis of this adduct. Analogous data for the reaction of hexadeuteroacetone with this heterocyclic cation are also presented. The formation of **2** is shown to be first order in each of acetone, isoquinolinium cation, and hydroxide ion, and is not catalyzed by carbonate buffer species. These data are consistent with the rate-determining attack of the acetone enolate anion upon the isoquinolinium cation. The microscopic reverse of this reaction is the uncatalyzed decomposition of **2**, which is consistent with the observed pH independence of the first-order rate constant for this process. Quantitative comparisons of rates and equilibria for the addition of hydroxide ion and acetone enolate ion to this isoquinolinium cation and to substituted benzaldehydes are now available.

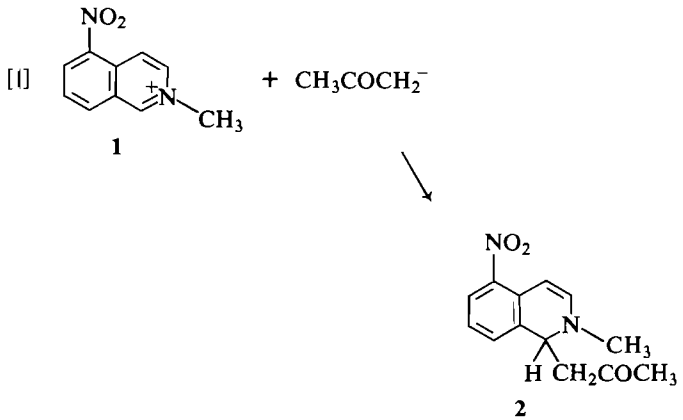
JOHN W. BUNTING et JAMES W. TAM. Can. J. Chem. **64**, 973 (1986).

Opérant en solutions aqueuses, à 25°C et dans un intervalle de pH allant de 10,0 à 11,3, on a évalué les constantes de vitesse et les constantes d'équilibre pour la réaction entre l'acétone et le cation méthyl-2 nitro-5 isoquinoléinium qui conduit à l'acétonyl-1 dihydro-1,2 méthyl-2 nitro-5 isoquinoléine (**2**). On a démontré que cette réaction s'effectue dans des conditions beaucoup plus douces (température, pH) et utilisant des temps de réaction beaucoup plus courts que ceux utilisés antérieurement dans la synthèse de cet adduit. On a également évalué les mêmes constantes pour la réaction de l'hexadeutéroacétone avec ce cation hétérocyclique. On a démontré que la réaction de formation du composé **2** est d'ordre un tant pour l'acétone que pour le cation isoquinoléinium et l'ion hydroxyde: toutefois, cette réaction n'est pas catalysée par des solutions tampon de carbonate. Ces données s'accordent avec un mécanisme impliquant une étape déterminante dans laquelle l'anion énolate de l'acétone attaque le cation isoquinoléinium. La réaction microscopiquement inverse est la décomposition non catalysée du composé **2**, ce qui s'accorde parfaitement avec les faits observés, à savoir que la constante de vitesse d'ordre un de cette réaction ne dépend pas du pH. Des comparaisons quantitatives de vitesses et des équilibres, dans le cas de l'addition de l'ion hydroxyde et ion énolate de l'acétone sur cet cation isoquinoléinium et sur des benzaldéhydes substitués, sont maintenant disponibles.

[Traduit par la revue]

Carbanion addition to heteroaromatic cations is a common route for the functionalization of heterocyclic rings (1–7).[2] These adducts can be reoxidized to the heteroaromatic system or, alternatively, can be employed as synthons for the further elaboration of the substitution pattern and (or) the extension of the ring system. Such adducts are particularly useful in isoquinoline chemistry, since the C-1 adducts derived from isoquinolinium cations are 1,2-dihydroisoquinolines that have enamine character. Such enamines have been shown to be useful intermediates for the introduction of sidechains by electrophilic attack at C-4 (3, 5, 10–13).

Despite the synthetic usefulness of such carbanion addition reactions, there do not appear to have been any quantitative studies of such processes. Quantitative information on the dependence of the rates and equilibria of such reactions upon the reactivity of the carbanion and the heterocyclic cation, and also upon other variables such as solution basicity, solvent, etc. would allow the straightforward prediction of the optimum conditions for the formation of such adducts. In an initial study in this area, we now report the rates and equilibria for the addition of the enolate ion of acetone to the 2-methyl-5-nitroisoquinolinium cation (eq. [1]), a reaction which has been found to be of synthetic use (5). In conjunction with literature information, this study also provides data that allow a quantitative comparison of nucleophilic addition to a heterocyclic cation and to the aldehyde carbonyl group.



Experimental

2-Methyl-5-nitroisoquinolinium iodide was prepared by refluxing 5-nitroisoquinoline with methyl iodide in ethanol. After addition of a drop of concentrated HI, the salt precipitated upon cooling, and was recrystallized from a mixture of methanol and ethanol containing a few drops of concentrated HI. The presence of the acid is required to shift the equilibrium from the alkoxide adducts towards the cation. This salt was pure by Vollhard titration of the iodide ion and ^{1}Hmr spectral analysis.

[2]To the best of our knowledge, there is no general review in this area. References given are to examples that come readily to mind, and are certainly not meant to be a complete survey of this area. The extensive studies (8, 9) based upon Reissert compound chemistry (cyanide adducts of heteroaromatic cations) also fall into this category. Analogous carbanion additions to electron-deficient neutral aromatic systems have recently been reviewed (23, 24).

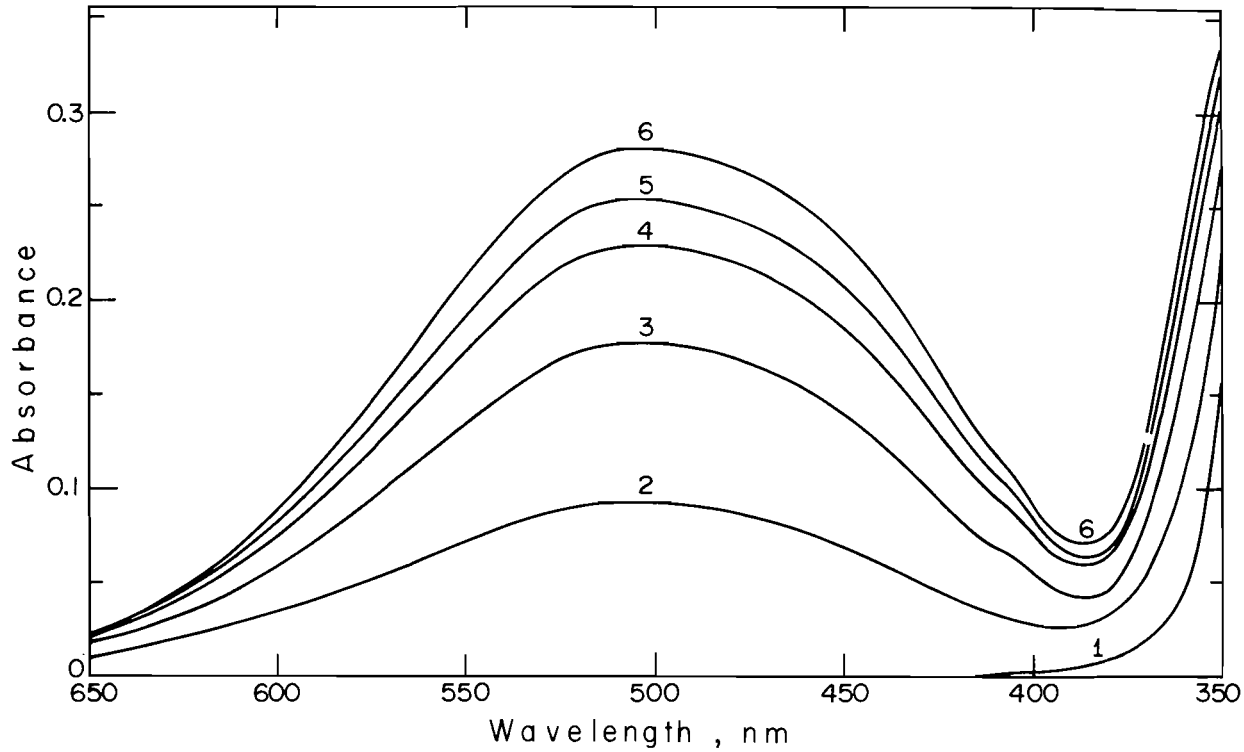

FIG. 1. Absorption spectra of solutions of the 2-methyl-5-nitroisoquinolinium cation (0.1 m*M*) equilibrated with various concentrations of acetone at pH 10.1 (25°C, ionic strength 0.1, 1-cm cell path length). Curve, [acetone]: 1, 0 *M*; 2, 0.226 *M*; 3, 0.452 *M*; 4, 0.678 *M*; 5, 0.904 *M*; 6, 1.356 *M*.

All kinetic studies employed spectral grade acetone or hexadeuteroacetone (99.9% D from MSD Isotopes, Montreal), and ACS Reagent grade KCl, KOH, HCl, and Na_2CO_3. Buffer solutions were prepared by the careful neutralization of a standard sodium carbonate solution with standard HCl solution to the appropriate pH, or by preparation of standard KOH solutions. All solutions for kinetic studies were adjusted to a final ionic strength of 0.1 by addition of the appropriate amount of KCl.

All kinetic data were obtained at 25°C by recording the time dependence of the increase in absorbance at 500 nm on a Unicam SP-1800 spectrophotometer equipped with an AR-125 linear recorder. Concentrations of the heterocyclic cation were in the range 0.05–0.2 m*M* (usually 0.1 m*M*), while acetone concentrations were in the range 7–500 m*M* depending upon the pH under study. The absorbance vs. time curves were digitized to give 15–20 data points covering approximately the first 90% of the reaction. These data points were fitted to the three-parameter first-order kinetic equation, $A = A_E + (A_0 - A_E)\exp(-k_{obs}t)$, where A is the absorbance at time t, A_0 and A_E are the initial and equilibrium absorbances respectively, and k_{obs} is the observed pseudo-first-order rate constant, by a computerized curve-fitting iteration procedure based upon the Marquardt algorithm. Replotting these data as $\ln(A_E - A)$ vs. t, gave plots that were strictly linear over at least the first 90% of the reaction, and slopes that were identical with the rate constants evaluated by the iterative fit.

The electronic absorption spectrum of the adduct **2** was observed to be unstable over extended periods of time, with the peak at 500 nm slowly disappearing in favour of a more intense absorption maximum in the vicinity of 435 nm. We have not investigated this very slow process (having a half-time of many hours), which did not interfere with the study of the much faster equilibration of the heterocyclic cation and its acetone adduct (half-time between 1 and 10 min under our experimental conditions).

A sample of the adduct for ^{1}Hmr spectral analysis was prepared by adjusting a solution containing 2-methyl-5-nitroisoquinolinium iodide (1 g) and acetone (1 mL) in water (10 mL) to pH 11.0 (pH meter) by the dropwise addition of 0.5 *M* NaOH. The dark red solution was extracted with several aliquots of chloroform and, after drying ($MgSO_4$), these extracts were evaporated to give a dark red oil, which was characterized by ^{1}Hmr spectroscopy.

Results

The electronic absorption spectrum of the 2-methyl-5-nitroisoquinolinium cation (**1**) after standing for 10 min at 25°C in aqueous solution at pH 10.1 in the presence of various concentrations of acetone is shown in Fig. 1. The appearance of a broad absorption maximum in the vicinity of 450–500 nm is characteristic of 1,2-dihydro-5-nitroisoquinoline derivatives (14, 15). Confirmation of the structure of the product of this reaction was obtained upon the isolation of a red oil from solutions containing higher concentrations of this cation. The ^{1}Hmr spectrum of this oil was identical to that previously reported by Somei *et al.* (5) for 1-acetonyl-1,2-dihydro-2-methyl-5-nitroisoquinoline (**2**).

The increase in absorbance at 500 nm proved to be cleanly kinetically first order in the 2-methyl-5-nitroisoquinolinium cation under all reaction conditions examined. However, the final absorbance at this wavelength displayed a pH dependence and also a dependence upon acetone concentration. This final absorbance increased with acetone concentration at constant pH (Fig. 1), and also increased with increasing pH at constant acetone concentration. These observations suggest a pH-dependent equilibrium between the 2-methyl-5-nitroisoquinolinium cation and the adduct **2**.

Since this isoquinolinium cation undergoes hydroxide ion addition to form the pseudobase **3** with pK_{R+} 11.7 (14), pseudobase formation competes with the formation of **2** in more basic aqueous solutions. Cation–pseudobase equilibration is essentially instantaneous (15), and is much faster than the reaction of the 2-methyl-5-nitroisoquinolinium cation with

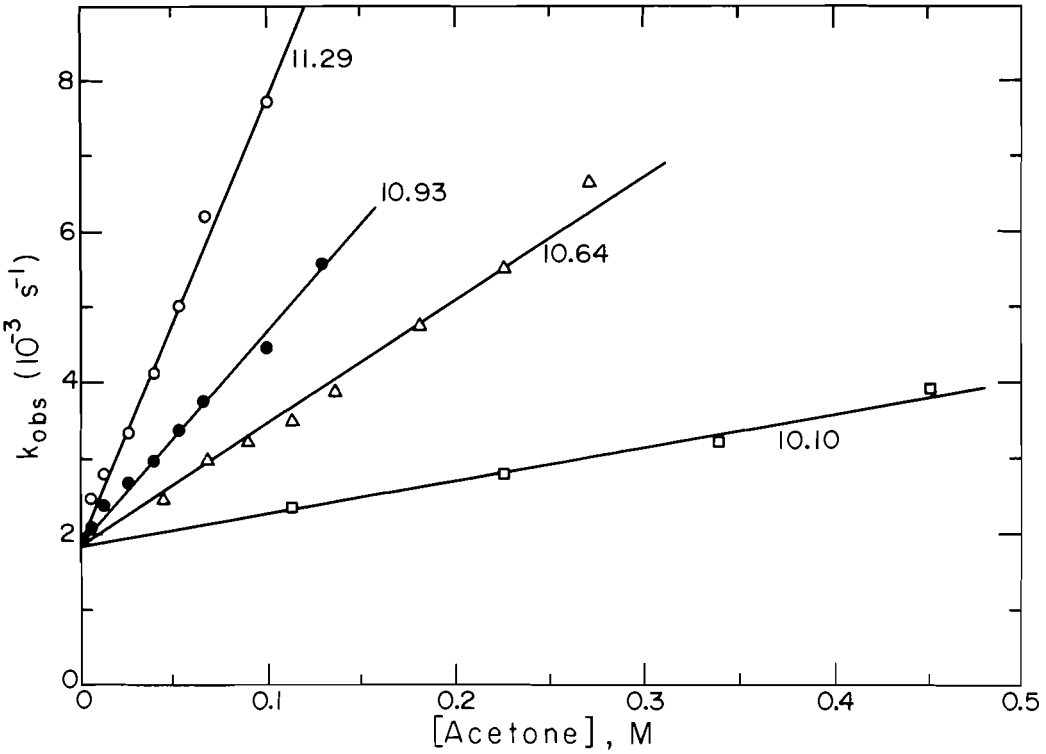

FIG. 2. Dependence of k_{obs} upon acetone concentration for the equilibration of **1** and **2** in solutions of various pH (as indicated on the figure).

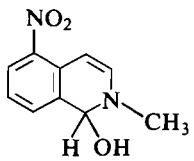
acetone; however, spectral observations of the formation of **2** in more basic solutions are complicated by the similarity in the absorption spectra of **2** and **3**. We have therefore limited our quantitative study of the formation of **2** to the range pH 10.0–11.3. The lower limit to this range is determined by the low equilibrium concentrations of **2** that are present in solutions of lower pH, at acetone concentrations that are sufficiently small that they do not induce significant solvent effects (see below).



3

Pseudo-first-order rate constants (k_{obs}) for the equilibration of the 2-methyl-5-nitroisoquinolinium cation with the adduct **2** were evaluated as a function of acetone concentration and pH. At constant pH, k_{obs} is linear in acetone concentration up to 0.5 *M* (Fig. 2). At higher acetone concentrations, the observed rate constants show increasingly positive deviations from these linear relationships. We attribute this phenomenon to solvent effects upon the reaction rates at higher acetone concentrations. This interpretation is supported by our observation that such deviations can also be induced at lower acetone concentrations by the addition of acetonitrile to these predominantly aqueous reaction solutions. We have therefore restricted our studies to a maximum acetone concentration of 0.5 *M* (i.e. 3.5% v/v acetone in water) to avoid such solvent effects.

Values of k_{obs} proved to be independent of carbonate buffer concentration at constant acetone concentration, pH, and ionic strength (Table 1). Thus catalysis by buffer species is not involved in these reactions. This is confirmed by the data in Table 2 for studies at approximately constant pH (10.59 and 10.64) but quite different carbonate buffer concentrations.

TABLE 1. Pseudo-first-order rate constants for the equilibration of the 2-methyl-5-nitroisoquinolinium cation and acetone[a]

pH	[Carbonate] (*M*)	k_{obs} (s^{-1})
10.60	0.0390	$3.77(\pm0.05) \times 10^{-3}$
10.60	0.0312	$3.82(\pm0.04) \times 10^{-3}$
10.60	0.0234	$3.75(\pm0.05) \times 10^{-3}$
10.60	0.0156	$3.60(\pm0.04) \times 10^{-3}$
10.60	0.0078	$3.65(\pm0.03) \times 10^{-3}$
10.60	0.0039	$3.79(\pm0.05) \times 10^{-3}$
		Mean = $3.73(\pm0.08) \times 10^{-3}$

[a]All data at [acetone] = 0.136 *M*, ionic strength 0.1 (KCl + $NaHCO_3$ + Na_2CO_3). Carbonate concentrations in the table refer to total concentrations of carbonate and bicarbonate buffer species.

The dependence of k_{obs} upon acetone concentration is consistent with:

[2] $k_{obs} = k_f[\text{acetone}] + k_d$

Values of k_f and k_d were evaluated by least-squares analysis according to eq. [2] at each pH, and are collected in Table 2. While k_d appears to be pH independent within experimental error, k_f increases with pH in a way that is consistent with an approximate first-order dependence upon [$^-$OH]. The ratio k_f/k_d, which represents the apparent equilibrium constant (K_{app}) for the addition of acetone to the isoquinolinium cation at constant pH, is included in Table 2 and is also almost proportional to [$^-$OH]. It is shown below that these minor deviations from strict linearity in [$^-$OH] arise from the presence of small amounts of the pseudobase **3** in the most basic solutions.

Values of K_{app} could also be evaluated from the dependence

[d]In carbonate buffer of ionic strength 0.05 + 0.05 *M* KCl.

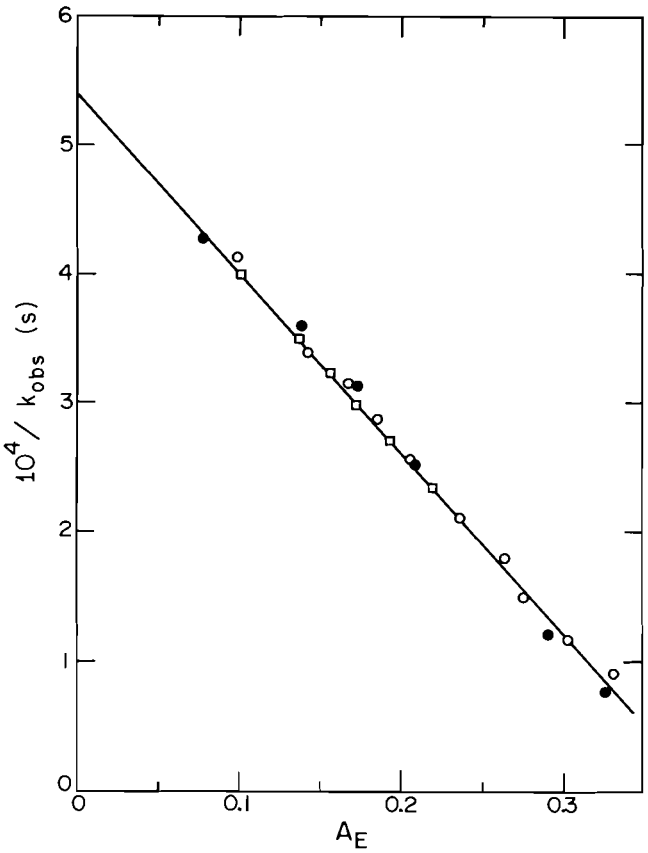

FIG. 3. Dependence of $1/k_{obs}$ on A_E according to eq. [5]. Data shown for pH 10.10 (●), pH 10.64 (○) (carbonate buffer $I = 0.1$), and pH 10.59 (□) (carbonate buffer $I = 0.05 + 0.05\ M$ KCl).

of the absorbance of equilibrated solutions upon acetone concentration. For an equilibrium of the form,

[3] $R^+ + CH \rightleftharpoons RC + H^+$

the apparent equilibrium constant at constant pH is given by $K_{app} = [RC]_E/[R^+]_E[CH]$ when [CH] (acetone) is in large excess over $[R^+]$ (isoquinolinium cation), as is the case in the current study. Since neither R^+ nor CH has significant absorbance at 500 nm, the observed absorbance at this wavelength is directly proportional to the concentration of the adduct (RC). If A_E is the equilibrium absorbance, then it follows that

[4] $A_E/[CH] = -K_{app}A_E + K_{app}\,\varepsilon_{RC}\,[R^+]_o$

where $[R^+]_o$ is the initial concentration of R^+. At pH 10.93 and 11.29, where there is a slight initial absorbance (A_o) at 500 nm because of the presence of small amounts of the hydroxide adduct of R^+, the left-hand side of eq. [4] must be modified to $(A_E - A_o)/[CH]$. Plots of this function were linear in A_E, and allowed the evaluation of K_{app} at each pH (Table 2), and the extinction coefficient of the adduct $\varepsilon_{RC} = 3900 \pm 200\ M^{-1}\,cm^{-1}$, which is pH independent.

Equations [2] and [4] may also be combined in the form:

[5] $1/k_{obs} = 1/k_d - A_E/(k_d\,\varepsilon_{RC}\,[R^+]_o)$

which predicts a linear dependence of $1/k_{obs}$ upon A_E (Fig. 3). The common line observed at the different pH and buffer concentrations in Fig. 3 further stresses the fact that k_d is independent of these variables. The data for pH 10.93 and 11.29 show small deviations from this line, but in a way that is consistent with the presence of minor amounts of hydroxide adduct in these more basic solutions.

	Mean = 1.3±0.1		

[a]At 25°C, in ionic strength 0.1 carbonate buffer.
[b]From $K_{app} = k_f/k_d$.

The reaction of hexadeuteroacetone with the 2-methyl-5-nitroisoquinolinium cation was also investigated. This reaction was significantly slower than for acetone itself, but displayed the same dependence upon ketone concentration and pH as described above. Parameters for the hexadeuteroacetone addition reaction are summarized in Table 3.

For eq. [3], we define a pH-independent equilibrium constant $K = [H^+][RC]/[R^+][CH]$ that is related to the pH-dependent K_{app} of Tables 2 and 3 by:

[6] $K = K_{app}[H^+](1 + K_{R+}/[H^+])$

Using $pK_{R+} = 11.7$ for the 2-methyl-5-nitroisoquinolinium cation (14), eq. [6] may be used to convert each value for K_{app} in Tables 2 and 3 into values for K. Values for K calculated in this way are listed in Table 4, and are clearly pH independent within experimental error.

The pseudo-first-order rate constants k_{obs} are defined in terms of the equilibrium mixture of the isoquinolinium cation and its

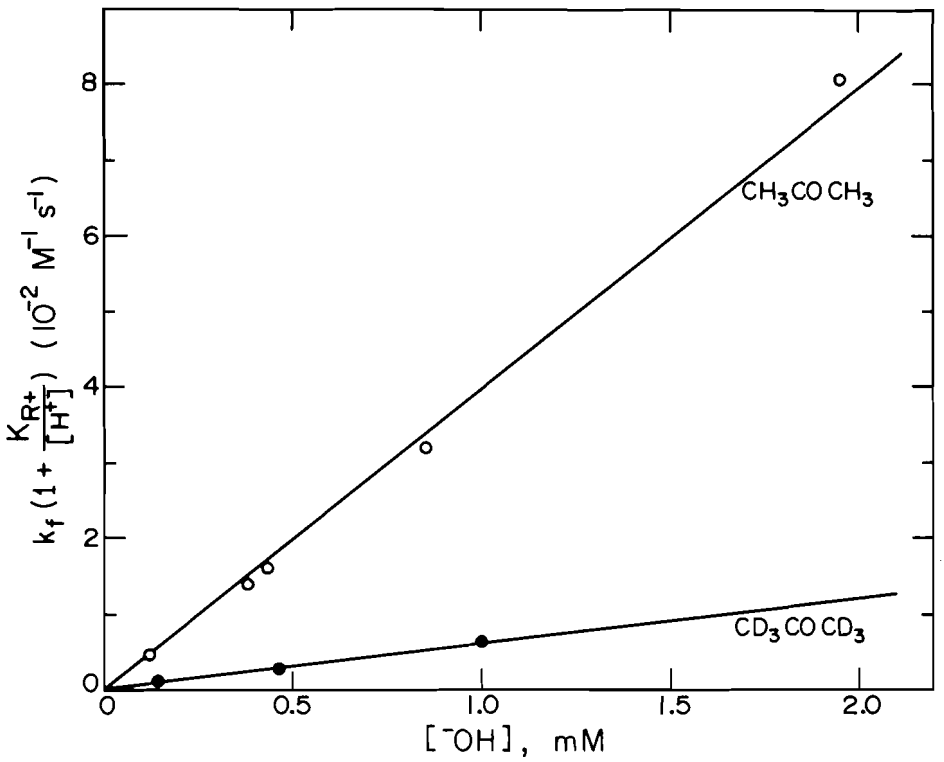

FIG. 4. Dependence of $k_f(1 + K_{R+}/[H^+])$ upon hydroxide ion concentration for acetone and hexadeuteroacetone addition to **1**.

TABLE 4. Values of K for the reaction of acetone and hexadeuteroacetone with the 2-methyl-5-nitroisoquinolinium cation[a]

	10.59	2.0	
	10.64	2.1	
	10.93	2.1	
	11.29	2.4	
		Mean $K = 2.1(\pm 0.2) \times 10^{-10}$	
			4.5
CD_3COCD_3	10.16	0.47	
	10.67	0.49	
	11.00	0.46	
		Mean $K = 4.7(\pm 0.2) \times 10^{-11}$	

[a]Defined by eq. [6], at 25°C, ionic strength 0.1.

pseudobase at each pH. Whereas k_d is pH independent, k_f is pH dependent and should be corrected for the small amount of pseudobase present at each pH in the form $k_f(1 + K_{R+}/[H^+])$. This latter function is strictly proportional to $[^-OH]$ for both acetone and hexadeuteroacetone (Fig. 4). The slopes of these lines define pseudo-third-order rate constants (k_3) of 38 ± 2 $M^{-2}\,s^{-1}$ for acetone and 6.1 ± 0.1 $M^{-2}\,s^{-1}$ for hexadeuteroacetone. Thus $k_3^H/k_3^D = 6.2$.

Discussion

Somei *et al.* (5) report the preparation of 1-acetonyl-1,2-dihydro-2-methyl-5-nitroisoquinoline (**2**) by refluxing the 2-methyl-5-nitroisoquinolinium cation (**1**) with acetone in 0.2 *M* aqueous sodium hydroxide for 4 h. In the current work we have shown that the equilibrium of eq. [1] is established rapidly at room temperature in solutions that are much less basic than 0.2 *M* NaOH. For instance, at pH 11 in the presence of 0.5 *M* acetone, this equilibrium favours the adduct **2** over the cation **1** by a 10:1 ratio, with equilibrium being established with a half-time of less than 1 min at 25°C. The use of higher acetone concentrations would further displace the equilibrium in favour of the adduct, and so allow the use of even less basic solutions if desired. Thus the synthesis of **2** can be efficiently performed under much milder conditions than previously reported: lower temperatures, shorter reaction times, and less basic reaction medium.

The yield and rate of formation of the adduct are expected to decrease above pH 11.7 as the cation is preferentially converted into its pseudobase **3**. In 0.2 *M* NaOH (pH 13.3), the pseudobase predominates over this cation by a 40:1 ratio. Although in this pH region the concentration of the acetone enolate ion nucleophile is proportional to $[^-OH]$, the concentration of the isoquinolinium cation is inversely proportional to $[^-OH]$ and so there is no net increase in rate of adduct formation with increasing pH. In these more basic solutions the yield of adduct also suffers because its formation must compete with the disproportionation of the pseudobase to 2-methyl-5-nitro-1-isoquinolinone and 1,2-dihydro-2-methyl-5-nitroisoquinoline (16). Since this disproportionation is an irreversible process, whereas adduct formation from the cation is reversible, extended reaction periods (especially at high temperatures) will result in reduced yields of adduct and increased amounts of disproportionation products.

Similar considerations also apply to other carbanion additions to heteroaromatic cations, and suggest that in all such reactions yields will be optimized by the use of shorter reaction times in pH regions just below the pK_{R+} for pseudobase formation. Such low basicity reaction media also minimize side reactions in which the carbanion species may be involved (aldol condensations, etc.).

TABLE 5. Comparison of the addition of hydroxide ion and acetone enolate anion to 2-methyl-5-nitroisoquinolinium cation and to 4-nitrobenzaldehyde

	2-Methyl-5-nitroisoquinolinium cation			4-Nitrobenzaldehyde		
Parameter	H_2O[a]	MeCOMe[b]	MeCOMe/H_2O	H_2O[c]	MeCOMe[d]	MeCOMe/H_2O

[e]Using $pK_a = 14.0$ for alkoxide ion formation from the neutral aldol, as estimated from a linear free energy relationship for alcohol ionization (22).

Kinetics

Adduct formation from acetone and the 2-methyl-5-nitroisoquinolinium cation is found to be kinetically third order; i.e. first order in each of acetone, isoquinolinium cation, and hydroxide ion. Such a process is kinetically equivalent in this pH range to the reaction of the acetone enolate anion (C^-) with the isoquinolinium cation with second-order rate constant $k_2 = k_3K_w/K_a$, where K_w is the ionic product of water, and K_a is the acid dissociation constant of acetone in aqueous solution:

$$k_3[^-OH][CH][R^+] = (k_3K_w/K_a)[C^-][R^+] = k_2[C^-][R^+]$$

Thus $k_2 = 5.5 \times 10^6\ M^{-1}\ s^{-1}$ can be evaluated for the attack of the acetone enolate ion on the 2-methyl-5-nitroisoquinolinium cation in aqueous solution at 25°C, by making use of k_3 as evaluated above, $pK_w = 14.00$, and $pK_a = 19.16$ for acetone, as recently reported by Kresge and co-workers (17).

The first-order dependence upon isoquinolinium cation concentration indicates that enolate ion formation from acetone is not the rate-determining step for adduct formation in the kinetic scheme described in eq. [7], where k_1 and k_{-1} are respectively the pseudo-first-order rate constants for deprotonation of acetone and protonation of the enolate ion for the experimental conditions under consideration:

$$[7] \quad CH \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} C^- \underset{k_{-2}}{\overset{k_2[R^+]}{\rightleftharpoons}} RC$$

This is confirmed by the fact that the rates of these reactions are not dependent upon the concentration of carbonate buffer species (Table 1).

We may therefore treat the enolate anion (C^-) as a steady-state intermediate according to the kinetic scheme of eq. [7]. We may readily evaluate k_1 and k_{-1} in eq. [7] for aqueous potassium hydroxide solutions using the reported second-order rate constant of $0.22\ M^{-1}\ s^{-1}$ for deprotonation of acetone by hydroxide ion and $pK_a = 19.16$ for this process at 25°C (17). Thus at pH 11, $k_1 = 2.2 \times 10^{-4}\ s^{-1}$ and $k_{-1} = 3.2 \times 10^4\ s^{-1}$. This value of k_{-1} is much larger than the maximum value of $k_2[R^+] = 5.5 \times 10^6 \times 1 \times 10^{-4} = 550\ s^{-1}$ for a reaction in which the initial concentration of isoquinolinium cation is 0.1 mM. This condition ($k_{-1} \gg k_2[R^+]$ holds over the entire pH region investigated in this work. Thus analysis of eq. [7], treating C^- as a steady-state intermediate, and with $[CH] \gg [R^+]$ and $k_{-1} \gg k_2[R^+]$, predicts the observed pseudo-first-order rate constant to be:

$$[8] \quad k_{obs} = k_2K_a[^-OH][CH]/K_w + k_{-2}$$

Equation [8] has the same form as the empirically deduced eq. [2], with k_f being proportional to $[^-OH]$ as is experimentally observed, and $k_d = k_{-2}$ being pH independent.

The values of k_2 and k_{-2} deduced in the current work may be combined with the extensive data available upon the rates of acetone – enolate ion equilibration (18, 19) to provide a complete description of the kinetics of eq. [7] for essentially any pH in any buffer solution at ionic strength 0.1 and 25°C.

The data in Tables 2 and 3 clearly indicate that there are significant kinetic and equilibrium isotope effects when the addition of the enolate ions of acetone and its hexadeutero derivative are compared. However, the interpretation of $K^H/K^D = 4.5$ and $k_3^H/k_3^D = 6.2$ is complicated by the fact that they contain contributions from the pK_a values of both acetone and hexadeuteroacetone. While the former value has been accurately measured as 19.16 (17), the latter value is not available, and strictly speaking is not simply definable for the reversible ionization of hexadeuteroacetone in H_2O. This latter point also applies to eq. [3], which for hexadeuteroacetone becomes:

$$[9] \quad R^+ + CD \rightleftharpoons RC + D^+$$

The reported K^D for eq. [9] can, strictly, only be considered as a pseudo-equilibrium constant in H_2O, since true equilibrium will only be achieved when essentially all deuterium in acetone molecules is exchanged for hydrogen, one atom at a time, via the equilibration of the adduct RC with R^+ and ketone.

The observed ratio $k_{-2}^H/k_{-2}^D = 1.5$ simply represents the relative first-order rate constants for the loss of the enolate ion and the pentadeutero-enolate ion of acetone from their respective adducts. This process should be influenced by only secondary isotope effects from replacement of two hydrogen atoms by two deuterium atoms on the methylene carbon atom of the adduct **2**. This secondary isotope effect will mainly reflect the change in hybridization of this carbon atom from sp^3 in the adduct to essentially sp^2 in the enolate anion. The observed isotope effect of 1.5 (for two deuterium atoms) is appropriate for a transition state in which enolate ion formation is well advanced. Such a product-like transition state is expected for an elementary reaction that generates the thermodynamically unstable enolate ion.

Comparison with related reactions

Analogous equilibria to eq. [1] can be written for essentially any nucleophilic addition to this heterocyclic cation. Such reactions can be summarized by eq. [10], [11], and [12].

[10] $HNu \overset{K_a}{\rightleftharpoons} H^+ + Nu^-$

[11] $R^+ + Nu^- \underset{k_{-Nu}}{\overset{k_{Nu}}{\rightleftharpoons}} RNu \qquad K_{Nu} = k_{Nu}/k_{-Nu}$

[12] $R^+ + HNu \overset{K_{HNu}}{\rightleftharpoons} RNu + H^+ \qquad K_{HNu} = K_{Nu}\,K_a$

To the best of our knowledge, the only analogous addition that has previously been quantitatively analyzed is the addition of hydroxide ion to give the pseudobase **3**. Rate and equilibrium constants for the addition of hydroxide ion and acetone enolate ion to the 2-methyl-5-nitroisoquinolinium cation are summarized in Table 5. This table also contains data from the literature for analogous addition reactions to the carbonyl group of 4-nitrobenzaldehyde, which was chosen since it is the most reactive substituted benzaldehyde for which quantitative data are available for both hydration (20) and acetone addition (mixed aldol condensation) (21). It can be readily seen that the relative rate and equilibrium constants for acetone and water addition to these two substrates are qualitatively similar. Quantitative agreement in such comparisons is unlikely since, in the case of the aldehyde, eqs. [11] and [12] represent addition to a neutral electrophile to give an anionic adduct rather than addition to a cationic electrophile to give a neutral adduct, as is the case for the heterocyclic cation. It should be noted that enolate addition to the carbonyl group is found to be the rate-determining step in the base-catalyzed addition of acetone to benzaldehydes (21). This is exactly analogous to the rate-determining addition of enolate ion to the isoquinolinium cation that is found in the current work.

The ^{125}Te Mössbauer and nmr spectra of the compounds $(R_3X)_2Te$ (R = Me, X = C, Si, Ge, and Sn; R = Ph, X = Ge and Sn), R_3MTePh (R = Me, X = Si, Ge, and Sn; R = Ph, X = Ge, Sn, Pb), $R_2Sn(TePh)_2$ (R = Me and *t*-Bu), and the cyclic compounds $(Me_2SnTe)_3$, $(Me_2Sn)_3Te_2$, and $(t\text{-}Bu_2SnTe)_2$ have been measured. The trends in the Mössbauer and nmr data are discussed. The Mössbauer quadrupole splittings increase as the nmr chemical shifts become more positive, corresponding to a decrease in the shielding at the tellurium nucleus. The ^{119}Sn Mössbauer and nmr parameters of the compounds $(R_3Sn)_2E$ and R_3SnEPh (R = Me and Ph), $(Me_2SnE)_3$, $(Me_2Sn)_2E_2$, $(t\text{-}Bu_2SnE)_2$, and $Me_2Sn(EPh)_2$ (E = S, Se, and Te) are discussed. The ^{119}Sn Mössbauer quadrupole splittings are again observed to increase as the nmr chemical shifts become more positive. The ^{125}Te and ^{119}Sn nmr and Mössbauer data provide evidence that there is little transmission of bonding effects through the tin–tellurium bond as the chemical environment about the tin or tellurium is changed.

C. H. W. JONES, R. D. SHARMA et S. P. TANEJA. Can. J. Chem. **64**, 980 (1986).

On a mesuré les spectres de Mössbauer et de rmn du ^{125}Te des composés suivants: $(R_3X)_2Te$ dans lesquels R = Me et X = C, Si, Ge et Sn ou R = Ph et X = Ge et Sn; R_3MTePh dans lesquels R = Me et X = Se, Ge et Sn ou R = Ph et X = Ge, Sn et Pb; $R_2Sn(TePh)_2$ dans lesquels R = Me et *t*-Bu ainsi que les composés cycliques $(Me_2SnTe)_3$, $(Me_2Sn)_3Te_2$ et $(t\text{-}Bu_2SnTe)_2$. On discute des tendances qui se manifestent dans les données relatives aux spectres de rmn et de Mössbauer. Les couplages quadrupolaires de Mössbauer augmentent lorsque les déplacements chimiques de la rmn deviennent plus positifs; ceci correspond à une diminution du blindage au niveau du noyau du tellure. On discute des paramètres de la rmn et des spectres de Mössbauer des composés $(R_3Sn)_2E$ et R_3SnEPh dans lesquels R = Me et Ph ainsi que dans les composés $(Me_2SnE)_3$, $(Me_2Sn)_2E_2$, $(t\text{-}Bu_2SnE)_2$ et $Me_2Sn(EPh)_2$ dans lesquels E = S, Se et Te. Encore une fois dans ces cas, on observe que les couplages quadrupolaires dans les spectres de Mössbauer du ^{119}Sn augmentent lorsque les déplacements chimiques de la rmn deviennent plus positifs. Les donnés de la spectroscopie de Mössbauer et de la rmn du ^{125}Te et du ^{119}Sn mettent en évidence que les effets de liaison ne sont que faiblement ou peu transmis à travers la liaison étain-tellure lorsque change l'environnement chimique autour de l'étain ou du tellure.

[Traduit par la revue]

Introduction

As part of an on-going study of the ^{125}Te Mössbauer spectroscopy of organotellurium compounds (1–3) it was of interest to study the organotellurides of the group IV elements. In earlier studies the alkyl and aryl tellurides have been extensively investigated (1, 2) and the present experiments extend this work to include compounds of silicon, germanium, tin, and lead. In many of the compounds investigated the group IV organo ligand is of the form R_3X— where X = Si, Ge, Sn, and Pb. For this reason, it was of interest to synthesize and characterize di-*tert*-butyl telluride, $(Me_3C)_2Te$, for comparison with its group IV analogues and this work has been described in another paper (4). As another off-shoot of this work, the crystal structure of $(Ph_3Sn)_2Te$ was determined and this structure is compared with that of the sulphur and selenium compounds in ref. 5.

For some of the compounds under investigation, ^{125}Te nmr spectra have been reported in the literature (6, 10) and were initially used to aid in characterizing and identifying the compounds studied. However, the ^{125}Te nmr parameters are of some interest in their own right and a correlation has been observed between the ^{125}Te Mössbauer quadrupole splittings in the solid state and the solution nmr chemical shifts for the organotellurides.

The ^{119}Sn Mössbauer spectra of the organotin tellurides have been measured to complement the ^{125}Te data. The ^{119}Sn nmr spectra were recorded where these had not previously been measured. These experiments were extended to include the organotin selenides and sulphides so that comparisons could be made with regard to the trends observed in the Mössbauer and nmr parameters on variation of the chalcogen within the organotin chalcogenides. An empirical correlation was again observed between the ^{119}Sn Mössbauer quadrupole splitting in the solid state and the solution nmr chemical shifts.

Discussion

^{125}Te Mössbauer and nmr data

The Mössbauer quadrupole splittings, Δ, of both tellurium and tin are generally assumed to derive from an imbalance in the 5*p*-orbital populations, the 5*d* orbitals not being considered to contribute significantly. The Mössbauer isomer shifts, δ, reflect the relative *s*-electron densities at the nucleus and these in turn are dependent on the population of the 5*s* and 5*p* orbitals of the tellurium and tin atoms (11, 12).

In the series $(R_3X)_2Te$ (R = Me, X = C, Si, Ge, and Sn; R = Ph, X = C, Ge, Sn) the ^{125}Te quadrupole splittings range from 6.3 mm s^{-1} for $(Me_3Sn)_2Te$ to 10.5 mm s^{-1} for *t*-Bu_2Te, while the ^{125}Te isomer shifts are all very similar and are small and positive with respect to the reference standard (^{125}I in copper). A sample spectrum is shown in Fig. 1.

The large quadrupole splitting observed for *t*-Bu_2Te reflects the considerable imbalance in the 5*p*-orbital populations on tellurium resulting from the different hybrid characters and electron populations of the bonding and nonbonding orbitals. It would be expected that, as the electronegativity of the ligand bonded to tellurium decreases, the *p*-orbital imbalance, and hence the quadrupole splitting, should decrease and this is indeed so (Table 1). The similarity in the Δ values for $(Me_3Si)_2Te$, $(Me_3Ge)_2Te$, and $(Me_3Sn)_2Te$ reflects the similar group electronegativities of the trimethylsilyl, germyl, and stannyl ligands.

The quadrupole splittings of the compounds Ph_2Te (11.0 mm

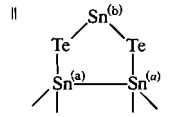
*δ ^{125}Te Mössbauer isomer shifts with respect to I/Cu, source and absorber at 4.2 K. Γ av. is the average linewidth.

†δ ^{125}Te nmr chemical shifts measured in $CDCl_3$ solution with respect to neat Me_2Te.

‡Except where noted these are $^1J(^{125}Te-^{119}Sn)$ values. For $Me_2Sn(TePh)_2$ and $(t$-$Bu_2SnTe)_2$ the signal-to-noise ratio at the tin side bands was poor. Values of $^1J(^{119}Sn-^{125}Te)$ were obtained from the ^{119}Sn spectra and are given in Table 3.

§C denotes this work and the measurements were made in $CDCl_3$ solution. Other referenced work is as shown.



**Value is $^1J(^{125}Te-^{207}Pb)$.

s^{-1}), $Ph_3SnTePh$ (9.0 mm s^{-1}), and $(Ph_3Sn)_2Te$ (6.6 mm s^{-1}) show a similar trend with the changing electronegativity of the ligand, as do the compounds $Me_3GeTePh$ (9.75 mm s^{-1}) and $(Me_3Ge)_2Te$ (6.7 mm s^{-1}).

With regard to the ^{125}Te Mössbauer isomer shifts the large errors in δ, coupled with the small magnitude of the shifts, make it difficult to discern any systematic trends in δ as the ligand is changed.

The ^{125}Te Mössbauer quadrupole splitting for tellurium in a given moiety remains relatively constant within a given series of compounds. Thus, the Sn—^{125}Te—Ph group in $Me_3SnTePh$, $Me_2Sn(TePh)_2$, and t-$Bu_2Sn(TePh)_2$ has a very similar Δ value. Similarly, the Sn—^{125}Te—Sn groups in $(Ph_3Sn)_2Te$, $(Me_2Sn)_2Te$, and in the cyclic species $(Me_2SnTe)_3$, $(Me_2Sn)_3Te_2$, and $(t$-$Bu_2SnTe)_2$ also have similar values. For these latter compounds $(Me_2SnTe)_3$ is a six-membered ring (13), $(Me_2Sn)_3Te_2$ a five-membered ring containing the >Sn—Te—Sn—Te—Sn< macrocycle and $(t$-$Bu_2SnTe)_2$ is a four-membered ring. The crystal structures of the latter two have not been reported but those for $(t$-$Bu_2SnSe)_2$ and $(t$-$Bu_2SnS)_2$ have and show Sn—E—Sn bond angles of 82.5–87.6° (14).

The constancy of the ^{125}Te Mössbauer quadrupole splittings for the Sn—Te—Sn group in these different compounds indicates that this parameter is relatively insensitive to changes in the number or the nature of the organic groups bonded to the tin ligands or of inserting the tellurium into a six-, five-, or four-membered ring. This point will be returned to later.

The ^{125}Te nmr chemical shifts listed in Table 1 can be seen to span a very wide range from +993 to −1310 ppm with respect to Me_2Te. While the present data for t-Bu_2Te, t-Bu_2Te, and $(Me_3Sn)_2Te$ are in good agreement with the literature values, the value for $(Me_3Si)Te$ does not agree with that reported earlier by du Mont and Kroth (8). The present result was confirmed on samples of $(Me_3Si)_2Te$ prepared by two independent routes and characterized by ^{29}Si and proton nmr as well as by mass spectrometry.

The nmr chemical shifts appear to fall into three groups, those that are large and positive (Ph_2Te, t-Bu_2Te, t-Bu_2Te_2), those that are small and positive or negative (R_3XTePh where X = Si, Ge, Sn, R = Me; and X = Ge, Sn, R = Ph), and finally, those

*$^1K^{RC}$ values are in N A^{-2} m^{-3} when J is in Hz and are to be multiplied by 10^{21}.

that are large and negative ($(R_3X)_2Te$, where X = Si, Ge, Sn, R = Me; X = Ge, Sn, R = Ph). The nmr shifts in heavy atoms are generally taken to be dominated by the Ramsey paramagnetic shielding term (15–17) and the above trend then corresponds to the smallest shielding at tellurium when two carbon atoms are bonded to tellurium and the largest shielding when two Si, Ge, or Sn atoms are bonded to tellurium.

We note that this trend also follows the trend in the Mössbauer quadrupole splittings since Ph_2Te and t-Bu_2Te have Δ values of 11.0 and 10.5 mm s^{-1}, the R_3XTePh compounds Δ values of 9.05–9.75 mm s^{-1} and $(R_3X)_2Te$ splittings of 6.27–7.23 mm s^{-1}. Thus there appears to be a rough correlation between these two parameters for tellurium-125. The existence of such a correlation between nmr chemical shifts and nuclear quadrupole coupling constants has been commented on previously for terminal halogen ligands (17–22). The origin of this correlation in ^{125}Te organotellurides in particular will be discussed elsewhere.

The only previous correlation observed between tellurium Mössbauer and nmr data is that of Chadha and Miller (23) who reported a linear relationship between ^{13}C chemical shifts and ^{125}Te isomer shifts for diaryltellurides and diaryltellurium dihalides.

Other features of the ^{125}Te nmr data that should be commented on include the couplings to Sn and Pb. The tellurium–tin coupling constants obtained from ^{125}Te spectra are reported in Table 1 and the complementary data obtained from ^{119}Sn spectra are given in Table 2. Where coupling constants were obtained from both ^{125}Te and ^{119}Sn nmr spectra on the same compound the agreement was good, e.g., $Ph_3SnTePh$ $^1J(^{125}Te–^{119}Sn)$ = 3245 Hz, $^1J(^{119}Sn–^{125}Te)$ = 3242 Hz. In some cases the coupling constants were abstracted only from the tellurium spectra ($Me_3SnTePh$ and $(Me_3Sn)_2Te$) or from the tin spectra ($Me_2Sn(TePh)_2$ and $(t\text{-}Bu_2SnTe)_2$). Sample spectra are shown in Fig. 2.

The $^1J(^{125}Te–^{119}Sn)$ values are generally in the range of 3100–3250 Hz although smaller values are observed for $(Me_3Sn)_2Te$, 2753 Hz; for $Me_3SnTePh$, 2614 Hz; and for $(t\text{-}Bu_2SnTe)_2$, 2117 Hz. The coupling constants are more consistent in magnitude with those reported by Mathiasch (24) than with that of McFarlane (25). The tellurium–tin bond appears to have relatively constant s character, as monitored by the coupling constants, in $(Ph_3Sn)_2Te$, $Ph_3SnTePh$, $Me_2Sn(TePh)_2$, $(Me_2SnTe)_3$, $(Me_2Sn)_3Te_2$, and t-$Bu_2Sn(TePh)_2$. For $(t\text{-}Bu_2SnTe)_2$ the Te–Sn coupling constant is a minimum, and this may reflect the peculiar stereochemical requirements of the four-membered ring.

The $^1J(^{125}Te–^{207}Pb)$ value in $Ph_3PbTePh$ was found to be 4058.7 Hz (Table 1) and this appears to be the only compound in which the Pb–Te coupling has been observed. In order to facilitate a comparison of this coupling constant with that of $^1J(^{125}Te–^{119}Sn)$ in $Ph_3SnTePh$ it is necessary to correct for the different magnetogyric ratios for the two pairs of nuclei, Pb–Te and Sn–Te, and also for the relativistic effects which are extremely important in spin–spin coupling constants of heavy-metal elements. The application of these corrections has been described in detail by Burns *et al.* (26). Thus, the reduced coupling constant $^nK_{AB}$, corrected for the magnetogyric ratios γ_A and γ_B, is related to $^nJ_{AB}$ by:

$$^nK_{AB} = \frac{4\pi^2}{h\gamma_A\gamma_B}{}^aJ_{AB}$$

The relativistic correction factors taken from ref. 27 lead to the relativistically corrected coupling constants ($^nK^{RC}_{AB}$):

$$^nK^{RC}_{PbTe} = {}^nK_{PbTe}\left(\frac{1}{3.079}\right)\left(\frac{1}{1.459}\right)$$

$$^nK^{RC}_{SnTe} = {}^nK_{SnTe}\left(\frac{1}{1.426}\right)\left(\frac{1}{1.459}\right)$$

$$^nK^{RC}_{SnSe} = {}^nK_{SnSe}\left(\frac{1}{1.426}\right)\left(\frac{1}{1.155}\right)$$

The values for the relativistically corrected coupling constants are given in Table 2, together with a number of values for Sn—Te and Sn—Se which will be discussed later.

The point of note is that the relativistically corrected reduced coupling constants for $Ph_3SnTePh$ and $Ph_3PbTePh$ indicate very similar s-electron densities in the Pb—Te and Sn—Te bonds

in these compounds, although this, of course, was not immediately obvious from the $^1J_{AB}$ values. This again bears out the similarity in the bonding to tellurium reflected in the similar ^{125}Te nmr chemical shifts and the similar ^{125}Te Mössbauer parameters. In particular, the ^{125}Te Mössbauer isomer shifts which monitor the *s*-electron densities at the tellurium nucleus are very similar in both cases.

^{119}Sn Mössbauer and nmr data

There is already a substantial body of ^{119}Sn nmr data in the literature for the compounds investigated and these data, together with those measured in the present work, are given in Table 2. The ^{119}Sn Mössbauer data in Table 3 were primarily obtained in the present investigation.

The Mössbauer parameters of the compounds $(Ph_3Sn)_2E$, Ph_3SnEPh, and $(Me_3Sn)_2E$, where E = S, Se, or Te, show a simple trend with the changing electronegativity of the chalcogen. An increase in the electronegativity of E results in an increased removal of tin electron density along the Sn—E bond in those tetrahedral molecules (5), an increase in the *p*-orbital imbalance about the tin, and hence in Δ, and a small net decrease in *s*-electron density at the nucleus.

The ^{119}Sn nmr chemical shifts within each series become more positive with decreasing size and increasing electronegativity of the chalcogen, corresponding to a decreased shielding of the tin nucleus. As can be seen from Table 3 there again appears to be a rough correlation between the ^{119}Sn nmr and Mössbauer parameters, the nmr shift becoming more positive as the quadrupole splitting increases in magnitude. For example, in the series $(Me_3Sn)_2E$, E = S, Se, Te, the ^{119}Sn quadrupole splittings decrease from 1.68 to 1.49 (±0.03) mm s^{-1} while the nmr chemical shifts decrease from 94 to −63 ppm and a similar trend holds for the series $(Ph_3Sn)_2E$ and Ph_3SnEPh. However, in $(Me_3Sn)_2E$ or Me_3SnEPh the Mössbauer quadrupole splittings of the Me_3SnEPh compounds are significantly greater than would have been expected on the basis of their solution nmr chemical shifts. It would appear that the coordination about tin is not tetrahedral in Me_3SnEPh in the solid state and that this results in much larger quadropole splittings than those observed for Ph_3SnEPh.

In the five-membered rings $(Me_2Sn)_3E_2$ only one tin site is observed in the Mössbauer spectra while two are clearly resolved in the nmr spectra. This reflects the different inherent resolutions of the two techniques.

For the two- and six-membered ring cyclic compounds, the tin quadrupole splittings are comparable to those of the $Me_2Sn(EPh)_2$ analogues. The $^1J(^{125}Te–^{119}Sn)$ values are also comparable for the tellurium compounds ranging from 3095 ($(Me_2SnTe)_3$) to 3164 Hz (t-$Bu_2Sn(TePh)_2$). In the four-membered rings (t-$Bu_2SnE)_2$, the ^{119}Sn quadrupole splittings are greater than those observed in the five- and six-membered rings, while the $^1J(^{119}Sn–^{125}Te)$ coupling constant in (t-$Bu_2SnTe)_2$ is significantly smaller (2117 Hz) than that in $(Me_2SnTe)_3$ or $(Me_2Sn)_3Te_2$, as noted above. Similar trends are also observed in the corresponding selenides.

As noted above, it is also possible to compare coupling constants between different nuclei in similar or differing structural types if relativistically corrected reduced coupling constants are calculated. In Table 2 the $^1K^{RC}$ values for Sn–Te and Sn—Se bonds in pairs of isostructural selenium and tellurium compounds are given. It can be seen that there are only small differences in the Sn—Te and Sn—Se bond *s* characters in these different compounds and that these differences remain reasonably constant from one compound to another, although the Sn—Te *s* character is somewhat less in the four-, five-, and six-membered rings in comparison with $Ph_3SnTePh$.

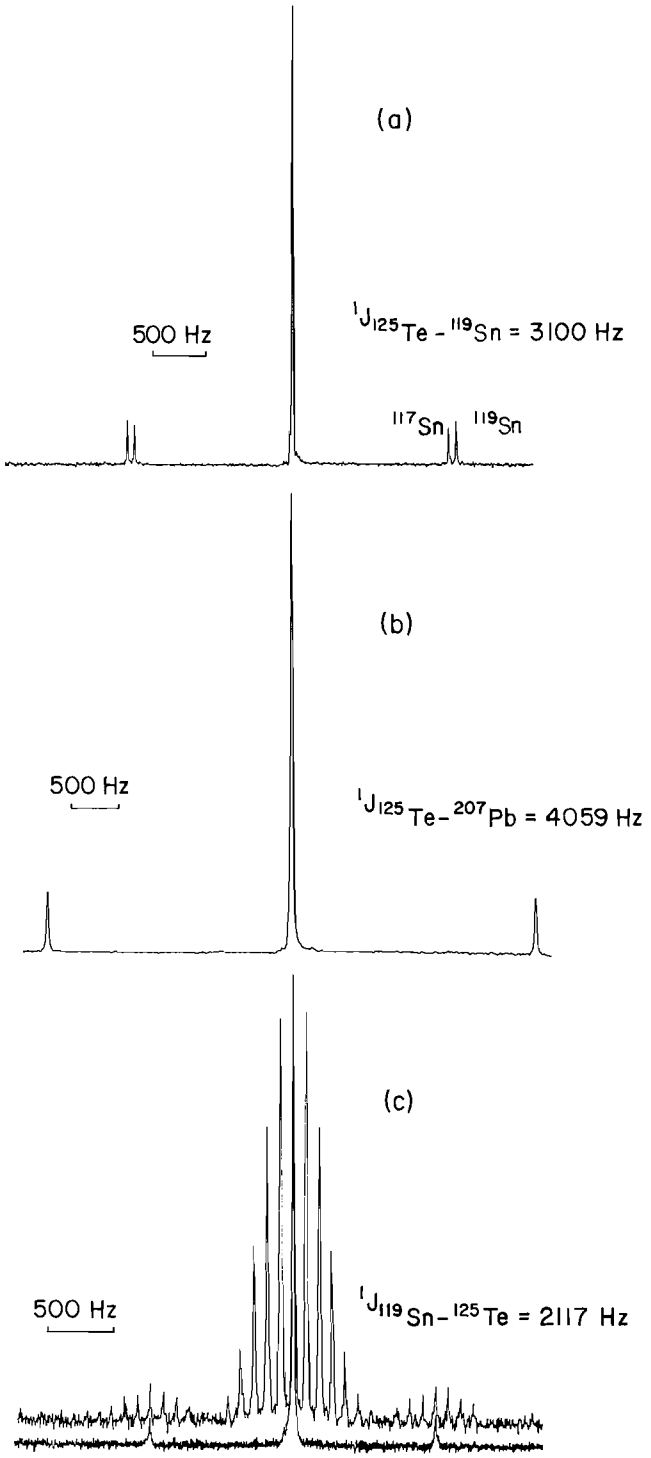

FIG. 2. Sample nmr spectra illustrating the couplings observed in the ^{125}Te spectra of (*a*) $(Me_2SnTe)_3$ and (*b*) $Ph_3PbTePh$, and in the ^{119}Sn spectrum of (*c*) (t-$Bu_2SnTe)_2$. In the latter the proton-coupled and -decoupled spectra are shown. The relative chemical shifts are not illustrated in this figure.

The $^1K^{RC}_{SnSe}$ value is always somewhat smaller than the $^1K^{RC}_{SnTe}$ value in a pair of isostructural compounds corresponding to somewhat less *s* character in the Sn—Se bonds than in the Sn—Te bonds. It is interesting that in all cases the ^{119}Sn Mössbauer isomer shift in the selenide is somewhat smaller than

in the corresponding telluride indicating a smaller *s* electron at the tin nucleus in the selenide than in the telluride.

A comparison of the tellurium and tin data in the tellurides

Finally it is of interest to bring together some of the above points and to compare and contrast trends in the ^{119}Sn and ^{125}Te data within a related series of compounds.

	$(Me_3Sn)_2Te$ (1)	$(Ph_3Sn)_2Te$ (2)	$Me_3SnTePh$ (3)	$Ph_3SnTePh$ (4)
$^{119}\Delta$ (mm s^{-1})	1.49	1.23	1.98	1.31
$^{125}\Delta$ (mm s^{-1})	6.3	6.6	9.5	9.1
$^{119}\delta$ nmr (ppm)	−62.7	−143.2	−29.6	−125.0
$^{125}\delta$ nmr (ppm)	−1225.9	−1310.0	−186.9	−205.8
^1J(Te–Sn) (Hz)	2753	3225	2614	3245

For compounds **1** and **2** the ^{119}Sn Mössbauer quadrupole splittings show a small but significant difference, and the ^{119}Sn nmr chemical shifts an appreciable difference, when the Me_3Sn— group is replaced by the Ph_3Sn— group. On the other hand, the ^{125}Te quadrupole splittings and nmr chemical shifts show very little change at all. The change in the electronic environment about the tin is not transmitted through the tin–tellurium bond to any great extent.

Compounds **3** and **4** show similar trends although, as noted above, the environment about tin does not appear to be tetrahedral in the solid state.

In compounds **2** and **4** it can be seen that changing one Ph_3Sn— ligand on the tellurium for a phenyl ligand has a dramatic effect on the ^{125}Te quadrupole splitting and nmr chemical shift. However, it does not have a very significant effect on the ^{119}Sn parameters of the second Ph_3Sn— ligand, nor does it greatly affect the $^1J(^{119}Sn-^{125}Te)$ coupling constant. Thus, changes in the electronic environment about the tellurium are not reflected at the tin. It is also apparent that the $^1J(^{119}Sn-^{125}Te)$ coupling constants appear to be dominated by the coordination about the tin rather than about tellurium.

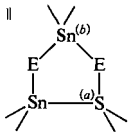
*δ Mössbauer isomer shift relative to $BaSnO_3$, source and absorber at 77 K, Γ av. is the average linewidth.

†δ nmr chemical shift relative to Me_4Sn.

‡Except where noted these are $^1J(^{119}Sn-^{125}Te)$ values. For $Me_3SnTePh$ and $(Me_3Sn)_2Te$ the signal-to-noise ratio at the tellurium side bands was poor and values for $^1J(^{125}Te-^{119}Sn)$ are quoted in Table 1. Similarly a value for $^1J(^{125}Te-^{77}Se)$ for $(Me_3Sn)_2Se$ was not obtained.

§C denotes this work and the measurements were made in $CDCl_3$ solution. Other referenced work is as shown.



**$^1J(^{119}Sn-^{125}Te)$ and $^{119}Sn-^{119}Sn$ couplings were assigned noting that the $^1J(^{125}Te-^{119}Se)$ value obtained from the ^{125}Te spectrum was 2630 Hz.

For the cyclic compounds, on going from **5** to **7** it can be seen that

	 **5**	 **6**	 7
$^{119}\Delta$ (mm s^{-1})	1.64	1.72	1.87
$^{125}\Delta$ (mm s^{-1})	1.64	6.23	1.87
$^{119}\delta$ nmr (ppm)	−197.3	−38.4(a)	−121.0
$^{125}\delta$ nmr (ppm)	−860	−1082	−1099
^1J(Sn–Te) (Hz)	3100	2630(a) 3170(b)	2117

$^{119}\Delta$ becomes larger, the $^{119}\delta$ nmr chemical shifts become more positive, and the coupling constants markedly decrease.

However, neither the ^{125}Te quadrupole splittings nor the $^{125}\delta$ values show as significant a change. The constraints imposed within the four-membered ring in compound **7** appear to be greater for the four-coordinate tin than the two-coordinate tellurium.

Experimental

The syntheses were carried out under dry oxygen-free nitrogen and solvents were freshly distilled and flushed with nitrogen. The desired compounds were purified by either vacuum distillation or recrystallization. The preparations generally followed those reported in the literature.

Bis-*tert*-butyl telluride was prepared by reacting $TeCl_4$ with *t*-BuMgCl in THF and the ditelluride, $t\text{-}Bu_2Te_2$ was obtained by treating *t*-BuMgCl with tellurium metal in the presence of hexamethylphosphorustriamide (HMPTA) (4). The compounds $(Me_3X)_2E$, where X = Si, Ge, E = Te; and X = Sn, E = S, Se, and Te, were synthesized by the reaction of Li_2E with Me_3XCl in THF (28), while as an adaptation of this method, LiTePh in THF was reacted with Me_3SnCl, Me_2SnCl_2, and $t\text{-}Bu_2SnCl_2$ to give $Me_3SnTePh$, $Me_2Se(TePh)_2$, and $t\text{-}Bu_2Sn(TePh)_2$, respectively.

The compounds Ph_3XTePh (X = Ge, Sn, and Pb) were prepared by

TABLE 4. $^2J^{119}Sn-^1H$ coupling constants for methyltin chalcogenides

	$^2J^{119}Sn-^1H$ (Hz)	
$(Me_3Sn)_2S$	57.1	
$(Me_3Sn)_2Se$	56.1

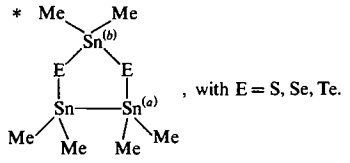
$(Me_2Sn)_3Te_2$*	55.0(*a*)	48.0(*b*)



the addition of Ph_3XCl to NaTePh in an ethanol benzene solution (29). The selenide and telluride $(Ph_3Sn)_2Se$ and $(Ph_3Sn)_2Te$ were obtained by reacting NaHSe NaHTe with Ph_3SnCl in the presence of NaOH (5).

The reaction of Me_2SnCl_2 with Na_2S, NaHSe, and NaHTe produced $(Me_2SnS)_3$, $(Me_2SnSe)_3$, and $(Me_2SnTe)_3$ respectively, whereas ether solutions of Me_2SnH_2 containing small amounts of DMF reacted with S and Te to form $(Me_2Sn)_3S_2$ and $(Me_2Sn)_3Te_2$, respectively (30). The reaction of Li_2E, E = S, Se, or Te, with t-Bu_2SnCl_2 gave the dimers $(t\text{-}Bu_2SnE)_2$ (14).

Mössbauer spectra (256 channels) were recorded at 4.2 (tellurium) and 77 K (tin) using a standard constant acceleration drive and using the general methods previously described (1–3). For ^{125}Te a 5 mCi $^{125}Sb/Cu$ (1 Ci = 37 GBq) source was used and for ^{119}Sn, a 1 mCi $Ba^{119}mSnO_3$ source, these being provided by New England Nuclear. The spectra were computer fitted to independent Lorentzians and the ^{125}Te spectra gave linewidths (full width at half maximum, FWHM) of 5.2–6.5 mm s^{-1} and the ^{119}Sn spectra 0.9–1.1 mm s^{-1}. The ψ-squared values divided by the number of degrees of freedom lay in the range of 0.95–1.10.

The nmr spectra were measured on a Bruker WM 400 nmr spectrometer at 126.24 (^{125}Te) and 149.1 MHz (^{119}Sn) at ambient temperature, the general methods used having been previously described (4). The ^{125}Te chemical shifts are referenced with respect to neat Me_2Te and the ^{119}Sn chemical shifts to Me_4Sn. Positive chemical shifts are downfield from the reference standard. The linewidths (FWHM) were of the order of 5–10 (^{125}Te) and 1–2 Hz (^{119}Sn).

The ^{125}Te Mössbauer spectra for $(CF_3)_2Te$ and $(C_6F_5)_2Te$ have been recorded and exhibit significantly larger quadrupole splittings (14.02 and 13.40 mm s^{-1} respectively) than those of Me_2Te (10.5 mm s^{-1}) and Ph_2Te (11.0 mm s^{-1}). The dihalides $(CF_3)_2TeX_2$ and $(C6_6F_5)_2TeX_2$ (X = F, Cl,Br) have consistently smaller quadrupole splittings than the dihalides Me_2Tex_2 and Ph_2TeX_2. These observations are consistent with the greater electronegativity of the CF_3 and C_6F_5 ligands. The ^{125}Te nmr chemical shifts of $(C_6F_5)Te$ and its dihalides show a consistent trend to more positive values (increased deshielding) as the electronegativity of the ligands attached to tellurium increases ($(C_6F_5)Te$, 297.6 ppm; $(C_6F_5)_2TeF_2$, 1060 ppm). However, for $(CF_3)_2Te$ and its dihalides a more complex pattern is observed which may be explained by changes in the mean electronic excitation term in the Ramsey paramagnetic shielding term.

C. H. W. JONES, R. D. SHARMA et D. NAUMANN. Can. J. Chem. **64**, 987 (1986).

On a enregistré les spectres Mössbauer du ^{125}Te des composés $(CF_3)_2Te$ et $(C_6F_5)_2Te$. Ces spectres comportent des couplages quadrupolaires nettement plus élevés (respectivement de 14,01 et de 13,40 mm s^{-1}) que ceux observés pour le Me_2Te et le Ph_2Te (10,5 et 11,0 mm s^{-1} respectivement). Les couplages quadrupolaires des dihalogénures $(CF_3)_2TeX_2$ et $(C6_6F_5)_2TeX_2$ dans lesquels X = F, Cl ou Br) sont toujours plus faibles que ceux des dihalogénures Me_2TeX_2 et Ph_2TeX_2. Ces observations reflètent la plus grande électronégativité des ligands CF_3 et C_6F_5. Les déplacements chimiques, en rmn ^{125}Te, du $(C_6F_5)Te$ et de son dihalogénure rélèvent une tendance marquée vers des valeurs plus positives (augmentation du déblindage) lorsque l'électronégativité des ligands attachés au tellure augmente ($(C_6F_5)_2Te$ 297,6 ppm, $(C_6F_5)_2TeF_2$ 1060 ppm)). Cependant, dans la cas du $(CF_3)_2Te$ et de son dihalogénure, on observe un spectre plus complexe qui peut être expliqué par des changements dans le terme d'excitation électronique moyen du terme de blindage parmagnétique de Ramsey.

[Traduit par la revue]

Introduction

In earlier papers (1–4), we have reported the ^{125}Te Mössbauer parameters of a wide range of organotellurium compounds. Of particular interest for the present discussion were the dialkyl- and diaryl-tellurides, R_2Te, and their dihalide derivatives, R_2TeX_2.

It was found that, for the tellurides R_2Te, varying the alkyl ligand from Me to *tert*-Bu, for example, or the aryl ligand from phenyl to *p*-MeOPh or *p*-EtOPh, did not have any very significant effect on the ^{125}Te Mössbauer parameters, the quadrupole splittings, Δ, lying in the range 10.5–11.0 ±0.1 mm s^{-1}, and the isomer shifts, δ, in the range 0.10–0.30 ±0.08 mm s^{-1}. Similarly, incorporation of the tellerium into a heterocyclic ring, as in dibenzotellurophene, also had little effect on the observed Δ and δ values.

The dihalides R_2TeX_2 showed a systematic trend in the quadrupole splittings with a change in the halogen, the difluorides having the largest Δ values and the diiodides the smallest, while the isomer shifts showed very little dependence on the halogen. On changing the organic ligand R for different substituted phenyl groups, relatively little effect was observed on the quadrupole splittings for a given dihalide, except for the bis(2,2′-biphenyl)tellurides where there was some evidence for steric crowding about the tellurium.

In light of the above, it was of some interest to measure the Mössbauer parameters for dialkyl- and diaryl-tellurides, and their dihalides for compounds containing a significantly more electronegative organic ligand. We report here the ^{125}Te Mössbauer data for the bis(trifluoromethyl)- and bis(pentafluorophenyl-tellurides and their difluorides, dichlorides, and dibromides. The bis(trifluoromethyl) compounds have been synthesized previously (5,6). However, the syntheses of the dihalides of bis(pentafluorophenyl)telluride are reported here for the first time.

The ^{125}Te nmr chemical shifts of the $(CF_3)_2Te$ and $(CF_3)_2TeX_2$ (X F, Cl, or Br) have been reported by Gombler (7). We have measured the ^{125}Te nmr spectra of $(C_6F_5)_2Te$ and $(C_6F_5)_2TeX_2$ (X = F, Cl, or Br) and the data for the two series are compared.

Results and discussion

Mössbauer data

The ^{125}Te Mössbauer parameters are shown in Table 1 and a sample spectrum in Fig. 1. It is immediately apparent that $(CF_3)_2Te$ and $(C_6F_5)_2Te$ have significantly larger quadrupole splittings than those of Me_2Te (10.5 mm s^{-1}) and Ph_2Te (11.0 mm s^{-1}). The large quadrupole splittings arise from a considerable *p*-orbital imbalance on the tellurium, reflecting the difference between the Te—C bonds on the one hand and the two tellerium lone pairs on the other. The very electronegative CF_3 and C_6F_5 ligands result in a substantial increase in the *p*-orbital imbalance at tellerium in comparison with that in Me_2Te or Ph_2Te.

The Mössbauer isomer shifts for $(CF_3)_2Te$ and $(C_6F_5)_2Te$, with respect to the I/Cu as a reference standard, are similar to those of Me_2Te (0.06 mm s^{-1}) and Ph_2Te (0.12 mm s^{-1}). The range of isomer shifts for ^{125}Te is known to be relatively small and the similarity in the δ values is not unexpected. Moreover,

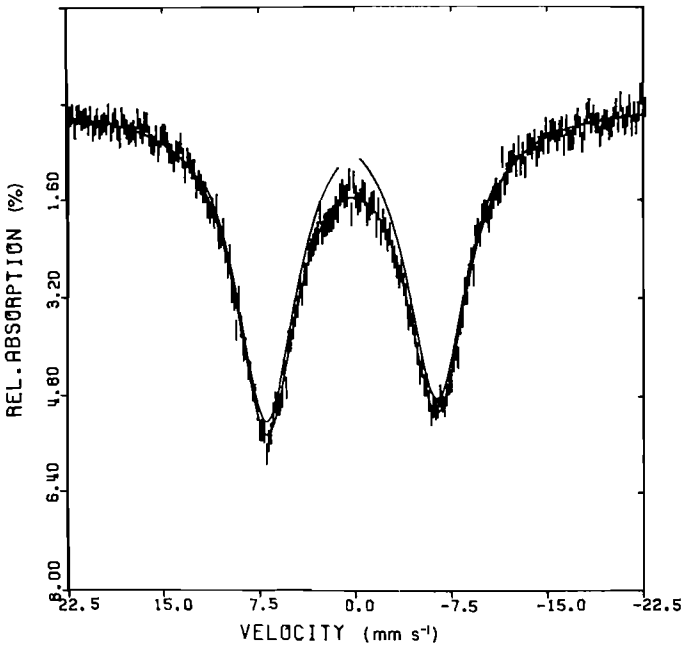

FIG. 1. Tellurium-125 Mössbauer spectrum of $(CF_3)_2Te$ at 4.2 K.

the Te—C bonds will have significant *s*–*p* hybrid character. The removal of *p*-electron density from tellurium in bonding will lead to an increase in the nuclear *s*-electron density, $|\psi_s(0)|^2$, through deshielding and hence to a more positive isomer shift, while the removal of *s*-electron density will decrease $|\psi_s(0)|^2$ and will make δ more negative. These off-setting factors appear to result in the similarity in the δ values observed.

The dihalides of $(CF_3)_2Te$ and $(C_6F_5)_2Te$ exhibit quadrupole splittings which are systematically smaller than those generally observed for dialkyl- and diaryl-tellurium dihalides. Thus, $(C_6F_5)_2TeF_2$ has a Δ value of only 8.8 mm s^{-1}, in comparison with 10.4 mm s^{-1} for Ph_2TeF_2; data for Me_2TeF_2 are not available. Similarly, $(C_6F_5)_2TeCl_2$ (6.9 mm s^{-1}) and $(CF_3)_2TeCl_2$ (6.9 mm s^{-1}) have significantly smaller splittings than those of Ph_2TeCl_2 (9.2 mm s^{-1}) and Me_2TeCl_2 (9.4 mm s^{-1}) while $(C_6F_5)_2TeBr_2$ (5.4 mm s^{-1}) and $(CF_3)_2TeBr_2$ (5.6 mm s^{-1}) have smaller splittings than Ph_2TeBr_2 (7.9 mm s^{-1}) and Me_2TeBr_2 (8.5 mm s^{-1}), respectively. Within each series of dihalides the quadrupole splittings follow a simple trend: F>Cl>Br.

The isomer shifts of the dihalides are all very similar and are more positive than those of the parent tellurides.

These trends in the Mössbauer parameters can be readily understood in terms of a simple valence–bond model for these compounds. The diphenyltellurium dihalides have crystal structures which show the tellurium to be in ψ-tbp environment, with the halogens occupying *trans*-axial positions and with the organic ligands and the presumed lone pair in the equatorial plane (8,9). The quadrupole splittings then reflect the *p*-orbital imbalance between the X—Te—X axial linkage and the Te—C bonds, and the lone pair in the equatorial plane. As the electronegativity of the organic ligand increases, this *p*-orbital imbalance might be expected to decrease, in agreement with the trend observed. Thus, $(C_6F_5)_2TeF_2$ has a significantly smaller quadrupole splitting than Ph_2TeF_2, consistent with a greater removal of electron density from the tellurium in the equatorial plane by the C_6F_5 ligand. A similar argument would apply to the chlorides and bromides. It is also of interest that consistent with this simple model, the difference in Δ between pairs of compounds in the CF_3 and Me series are all somewhat larger than those in the C_6F_5 and Ph series. Thus, the difference in Δ between $(CF_3)_2Te$ and Me_2Te is roughly reflected in the large difference in Δ between $(CF_3)_2TeBr_2$ and Me_2TeBr_2, while the smaller difference in Δ between $(C_6F_5)_2Te$ and Ph_2Te leads to a smaller difference in quadrupole splitting between $(C_6F_5)_2TeBr_2$ and Ph_2TeBr_2.

The isomer shifts for the dihalides reported in Table 1 are all more positive than those of the parent tellurides. This is consistent with the previous general observations on the R_2TeX_2 compounds. The bonding in the X—Te—X linkage appears to remove predominantly *p*-electron density from the tellurium, leading to a deshielding of the 5*s* electrons from the nucleus, an increase in $|\psi_s(0)|^2$, and a more positive isomer shift. The fact that isomer shifts are all similar again reflects the relative insensitivity of ^{125}Te isomer shifts to changes in the *s*- and *p*-orbital populations.

Nuclear magnetic resonance data

The ^{125}Te nmr chemical shifts are reported in Table 2 and the values for $(CF_3)_2Te$ and $(CF_3)_2TeX_2$ (X = Cl, Br) are in reasonable agreement with the literature values (7). To assist in an intercomparison of the data, we recorded the spectrum of $(CF_3)_2Te$ as a neat liquid and in solution in $CDCl_3$ and in CH_3CN. The ^{125}Te chemical shifts for $(C_6F_5)_2Te$ and $(C_6F_5)_2TeX_2$ (X = F, Cl, or Br) have not previously been measured.

The data for $(CF_3)_2Te$ and $(C_6F_5)_2Te$ and their dihalides are compared with those of Me_2Te and Ph_2Te and their dihalides in Fig. 2. It can be seen that $(CF_3)_2Te$ has a much more positive (downfield) shift than Me_2Te. The nmr chemical shifts for tellurium are generally assumed to be dominated by the paramagnetic shielding term. The increase in shift for $(CF_3)_2Te$, relative to Me_2Te, is consistent with a marked decrease in the shielding at the tellurium nucleus as a result of the greater electronegativity of the —CF_3 ligand. However, $(C_6F_5)_2Te$ has a less positive chemical shift than Ph_2Te, indicating that electronegativity is not the only factor involved.

It is of interest that in the dialkyltellurides and ditellurides, substitution of α-carbon protons by methyl groups leads to a more positive (downfield) shift, β-carbon proton substitution leads to a smaller negative (upfield) change in δ, and γ-substitution to a very small positive change in δ (4,10,11). An analogous situation is found in the phenyltellurides. As shown in Table 3, as the number of protons on the carbon atom bonded to tellurium decreases (*a*) δ becomes more positive; on *o*-substitution

m-MeOPhTeMe	341		—†
(*d*) PhTePh	688	−20	
p-MeOPhTePh	668		14

*Δ(δ) is the difference in successive ^{125}Te nmr chemical shifts.
†D. H. O'Brien. Private communication.

(*b*) there is a smaller negative change in δ; on *m*-substitution (*c*) the effect on δ is small and positive; and finally, on *p*-substitution (*d*) a small, negative change in δ is observed.

On the basis of the above, $(CF_3)_2Te$ would be expected to have a much more positive δ than Me_2Te since there are no α protons in $(CF_3)_2Te$.

In $(C_6F_5)_2Te$, all the above effects will be superimposed. However, the full *o*-substitution for four fluorine ligands should have the dominant effect and a substantial negative change in δ, with respect to Ph_2Te, would be expected and is indeed observed.

The chemical shifts for the C_6F_5, Ph, and Me series appear to roughly parallel one another (Fig. 2), although data for Me_2TeF_2 is not available. The halides all exhibit more positive chemical shifts than the parent tellurides, consistent with less shielding at the tellurium nucleus in the presence of the electronegative halogens. The chemical shifts for these dihalides lie in the order F>Cl>Br.

The trend for the CF_3 series is more complex and, not only does $(CF_3)_2Te$ have a very large positive shift, but the values for the dihalides do not follow the trend referred to above. Rather, they exhibit a minimum value at $(CF_3)_2TeCl_2$. This may be rationalized in terms of the Ramsey paramagnetic shielding in the expression for nmr chemical shifts.

$$\sigma_p\alpha - \frac{1}{\Delta E}[\langle r^{-3}_p\rangle Pu + \langle r^{-3}_d\rangle Du]$$

where ΔE is the mean electronic excitation, *Pu* and *Du* are the "unbalance" in the valence *p* and *d* orbital populations, and $\langle r^{-3}_p\rangle$ and $\langle r^{-3}_d\rangle$ are the expectation values of the radii of the *p* and *d* valence orbitals.

Nuclear quadrupole coupling constants are also dependent on the valence *p* and *d* orbital populations and hence we might anticipate some correlation between the nmr chemical shifts and the Mössbauer quadrupole splittings for molecules of similar coordination. For $(C_6F_5)_2Te$ and $(CF_3)_2Te$ the quadrupole splittings are similar, suggesting similar valence orbital populations on the tellurium in these two molecules. However, the nmr chemical shifts are significantly different. This can be explained by a much smaller value for ΔE in $(CF_3)_2Te$ than in $(C_6F_5)_2Te$.

It is interesting that the difluorides all have very similar chemical shifts despite the differences in the shifts of the parent tellurides themselves (Fig. 2). In the difluorides, the shielding at the tellurium nucleus appears to be primarily determined by the fluorine ligands rather than the organic ligands.

Experimental

Bis(trifluoromethyl)telluride and the dihalides $(CF_3)_2TeX_2$ (X = F, Cl, or Br) were prepared and characterized as previously described (5,6).

Bis(pentafluorophenyl)telluride was prepared by heating an equimolar mixture of $(C_6F_5)_2Hg$ and tellurium in a sealed, evacuated tube at 225°C for 24 h (16). The corresponding dichlorides and dibromides were prepared by reaction of $(C_6F_5)_2Te$ with the elemental halogen in CCl_4. The difluoride was synthesized by reacting an excess of NaF with $(C_6F_5)_2TeCl_2$ in acetonitrile. In a second preparation, $(C_6F_5)_2Te$ was heated with a mixture of HNO_3 and 40% HF in a Teflon beaker for 12 h. The solution was then heated to dryness and $(C_6F_5)_2TeF_2$ was isolated by $CHCl_3$ extraction of the solid. Attempts to prepare the diiodide, either by halogenation of $(C_6F_5)_2Te$ or by reaction of KI with $(C_6F_5)_2TeCl_2$, were unsuccessful. Diphenyltellurium difluoride, whose ^{125}Te nmr chemical shift had not previously been reported, was prepared by the method of Sadekov (17).

The compounds were characterized by carbon analyis and by mass

spectrometry on a Hewlett–Packard 598B mass spectrometer: *Anal.* calcd. for $C_{12}F_{10}Te$: 31.16; found: C 31.17; m/e (^{130}Te) 464; *Anal.* calcd. for $C_{12}F_{12}Te$: 28.80; found: C 28.63; m/e 502; *Anal.* calcd. for $C_{12}F_{10}Cl_2Te$: 27.01, found: C 27.29; m/e 534; *Anal.* calcd. for $C_{12}F_{10}Br_2Te$: 23.15, found: C 23.19; m/e 543, corresponding to $(C_6F_5)_2TeBr^+$.

Mössbauer spectra were recorded using a Harwell Instruments constant acceleration drive, based on a Harwell 200 series wave-form generator and amplifier. A 2 mCi $^{125}Sb/Cu$ source (New England Nuclear) was used. The source and absorbers were immersed in liquid helium in a Harwell Instruments dewar. The 35.5 keV Mössbauer γ-ray was monitored through the 6 keV escape beak in a Xe/CO_2 proportional counter. The spectra were accumulated in a Nuclear Data 66 analyzer as 256-channel spectra and were subsequently computer-fitted to Lorentzians using the Nuclear Data 66 as a computer terminal for transmitting data to, and for computation on, the University IBM 4341 main-frame computer. The spectrometer was routinely calibrated using a $^{57}Co/Rh$ source and an iron foil absorber. The ^{125}Te isomer shifts were reported with respect to $^{125}I/Cu$ as a reference standard and this entailed adding 0.15 mm s^{-1} to the shifts measured against $^{125}Sb/Cu$ as the source.

The ^{125}Te nmr spectra were obtained on a Brüker WM 400 spectrometer at 126.24 MHz, operating at ambient temperature. The resonances were found by utilizing 166 kHz sweep widths, 10 μs (25°C) pulse widths, and a 0.01 s delay between acquisitions. Final spectra were obtained at the appropriate frequency, generally using a 5 kHz sweep width and 90° pulse widths with no delay. No broadband decoupling was employed. Data acquisition consisted of 16 000 data points, which were zero filled to 32 000 data points for the Fourier transform. The linewidths were 6–12 Hz. The ^{125}Te chemical shifts are reported with reference to neat Me_2Te.

LYNN MIHICHUK, MONICA PIZZEY, BEVERLY ROBERTSON, and RICHARD BARTON. Can. J. Chem. **64**, 991 (1986).

$(L{-}L)W(CO)_4$ (L–L = $(CH_3AsC(CF_3){=}C(CF_3)As(CH_3)_2$) is oxidized by Br_2 to yield the seven-coordinate complex $(L{-}L)W(CO)_3Br_2$, which reacts with monodentate phosphines or phosphites to form $(L{-}L)W(CO)Br_2P_2$ (P = phosphine or phosphite). Crystals of $(L{-}L)W(CO)Br_2[P(OCH_3)_3]_2$ are monoclinic, space group $P2_1/c$, a = 19.110(5), b = 9.208(3), c = 17.845(6) Å, β = 108.93(2)° at 21°C with Z = 4. The structure was solved from a Patterson map and refined by least squares to a conventional R value of 0.092 using 2330 independent reflections. The crystal structure indicated the tungsten atom to be seven-coordinate with the geometry most closely approximated by a capped trigonal prismatic environment, the capping group being a bromine atom (W—Br, 2.686(5) Å). The capped face consists of the remaining bromine atom (W—Br, 2.695(5) Å), a phosphorus atom (W—P, 2.465(9) Å), and the two arsenic atoms from the bidentate ligand (W—As, 2.619(3) and 2.526(4) Å). The W—As bond *trans* to a phosphite is significantly longer (by 0.093 Å) than the W—As bond *trans* to a bromine. The ^1H nmr data indicate that the complex is stereochemically rigid at 25°C and nonrigid at higher temperatures; however, the data at 25°C are not consistent with the configuration found in the crystal.

LYNN MIHICHUK, MONICA PIZZEY, BEVERLY ROBERTSON et RICHARD BARTON. Can. J. Chem. **64**, 991 (1986).

L'oxydation du $(L{-}L)W(CO)_4$ (L–L = $(CH_3AsC(CF_3){=}C(CF_3)As(CH_3)_2$) par le Br_2 donne le complexe heptacoordonné $(L{-}L)W(CO)_2Br_2$ qui réagit avec les phosphines ou les phosphites monodentates pour donner le $(L{-}L)W(CO)Br_2P_2$ (P = phosphine ou phosphite). Les cristaux de $(L{-}L)W(CO)Br_2[P(OCH_3)_3]_2$ appartiennent au groupe d'espace monoclinique $P2_1/c$ avec a = 19,110(5), b = 9,208(3), c = 17,845(6) Å, β = 108,93(2)° à 21°C et Z = 4. On a résolu la structure à partir d'une carte de Patterson et on l'a affinée par la méthode des moindres carrés jusqu'à une valeur de R = 0,092 pour 2330 réflexions indépendantes. La structure cristalline indique que l'atome de tungstène est heptacoordonné avec une géométrie approximative très voisine d'un environnement prismatique trigonal cappé par un atome de brome (W—Br, 2,686(5) Å. La face cappée comprend l'atome de brome résiduel (W—Br, 2,695(5) Å), un atome de phosphore (W—P, 2,465(9) Å) et les deux atomes d'arsenic du ligand bidentate (W—As, 2,619(3) et 2,526(4) Å). La liaison W—As qui est en position *trans* par rapport au phosphite est nettement plus longue (0,093 Å de plus) que la liaison W—As en position *trans* par rapport au brome. Les donnés de la rmn du ^1H indiquent que, à 25°C, le complexe est stéréochimiquement rigide, mais que ce n'est pas le cas à des températures plus élevées. Cependant, les données obtenues à 25°C ne concordent pas avec la configuration trouvée dans le cristal.

[Traduit par la revue]

Introduction

Studies of seven-coordinate complexes of metal carbonyls have shown that they can be described by either a capped octahedral geometry (1, 2) or a capped trigonal prismatic geometry (3, 4). The actual structures seldom match ideal polyhedral arrangements and, if the deviations are large, the choice of the most appropriate description may not be obvious. Various methods have been proposed to aid in the assignment of the best reference polyhedron (5–7).

This paper reports on the assignment of the polyhedron for the seven-coordinate complex $(L{-}L)W(CO)Br_2[P(OCH_3)_3]_2$ where L–L is the fluorocarbon-bridged ligand $(CH_3)_2AsC(CF_3{=}C(CF_3)As(CH_3)_2$. Variable temperature ^1H nmr studies have shown the complex to be stereochemically nonrigid, a common phenomenon observed in seven coordination (8). In an attempt to elucidate the mechanism of the motion of the ligands, which is generally poorly understood in seven coordination, we have undertaken to determine the solid-state geometry of the tungsten monocarbonyl complex.

Experimental

$C_{15}H_{30}As_2Br_2F_6O_7P_2W$ Mol. wt. = 991.88

Monoclinic, space group $P2_1/c$, a = 19.110(5), b = 9.208(3), c = 17.845(6) Å, β = 108.93(2)°, T = 21°C, V = 2970 Å^3, Z = 4, D_x = 2.22 g cm^{-3}, D_m = 2.20(5) g cm^{-3}, μ(MoKα) = 95.0 cm^{-1}, F(000) = 1880.

Initially, attempts were made to prepare the molybdenum analog of the compound reported here. Crystals were obtained but they proved to be extremely unstable in the X-ray beam. Their deterioration in the beam was not significantly attenuated by lowering their temperatures. Furthermore, a complex phase transformation occurs slightly below room temperature in the Mo compound.

The tungsten compound was prepared according to a method similar to that previously reported by Cullen and Mihichuk (9). The synthesis of the ligand *cis*-2,3-bis(dimethylarsino)-1,1,1,4,4,4-hexafluorobut-2-ene (L–L), and the $(L{-}L)W(CO)_4$ complex has been previously reported (10, 11).

Slow addition of bromine (0.070 g, 0.45 mmol) in dichloromethane to a rigorously degassed dichloromethane solution of an equimolar amount of $(L{-}L)W(CO)_4$ afforded orange-coloured crystals of $(L{-}L)W(CO)_3Br_2$ (0.25 g, 69%).

$(L{-}L)W(CO)_3Br_2$ (0.25 g, 0.31 mmol) and trimethyl phosphite (0.091 g, 0.73 mmol) were refluxed under argon in degassed benzene (25 mL) for 48 h, after which time the ir spectrum of the solution indicated complete reaction of the tricarbonyl complex. The benzene was removed under reduced pressure and recrystallization of the residue from a degassed dichloromethane–hexane mixture at −5°C afforded yellow plates of $(L{-}L)W(CO)Br_2[P(OCH_3)_3]_2$ (0.15 g, 48%). Their density was determined by flotation in a chloroform–bromoform mixture.

Preliminary investigation of the tungsten compound also showed evidence of crystal deterioration in the X-ray beam. The deterioration was not significantly influenced by lowering the temperature of the crystal, by coating it with collodion, or by isolating it in a capillary. It was decided that all diffraction data should be collected as quickly as was reasonably possible. A crystal in the form of a yellow plate of dimensions 0.2 × 0.2 × 0.3 mm was chosen for study. Laue symmetry and systematic absences (l = 2n + 1 for $h0\,l$, k = 2n + 1 for $0k0$) indicated the monoclinic space group $P2_1/c$.

[1]Author to whom correspondence may be addressed.

Intensity data were collected on a modified Picker FACS-1 diffractometer with graphite-monochromated Mo$K\alpha$ radiation ($\lambda = 0.71069$ Å), using the NRCC diffractometer control system (12). Diffraction intensities were measured first in the range $3° \leq 2\theta \leq 40°$ and then in the range $40° < 2\theta \leq 45°$, using a scan speed of 2 deg min^{-1} and a scan width of $(0.9 + 0.692 \tan \theta)°$. Data were collected in the octants with hkl and $\bar{h}kl$.

Three standard reflections were measured after every 47 reflections. Over the total period of the data collection their intensities decreased 15%, 25%, and 50%, respectively. It was decided that the data collected last was not reliable and only that collected between 3 and 40° was used in the structure determination. The standard deviations of the intensities ($\sigma(I)$) were calculated from the counting statistics of the individual reflections with a term added based on the extent to which the scatter in the intensities of the standard reflections exceeded that predicted from their own counting statistics. The inclusion of the third standard (12,0,0) with its high decay rate in this calculation led to unrealistically large standard deviations for strong reflections. The rate of fall-off of intensity did not appear to be anisotropic and the behaviour of the 12,0,0 reflection was anomalous. It was decided to exclude that reflection from all calculations. The intensities of the 2776 individual reflections in the range $3° \leq 2\theta \leq 40°$ were corrected for the fall-off in the intensities of two remaining standard reflections. The decrease in the intensity of each reflection, relative to its initial value, was calculated from a five-point interpolation of the curve of the sum of the intensities of the two remaining standards (0,6,0 and 0,0,12) and adjusted to the initial value of the sums of these standards. The maximum correction was 17%. Of these, 2330 showed $I > 2.0\sigma(I)$ and were treated as observed.

At the end of the data collection, attempts were made to measure the centered position of strong reflections with $2\theta > 30°$. However, the crystal had deteriorated to an extent that this was not possible. The remaining material was recrystallized but the crystals that were obtained were not the same as that for which data had been collected. New crystals were synthesized from the starting materials. They showed the same space group and approximate lattice constants as the original. Cell dimensions were calculated from all of the centered settings of 31 reflections using one of the new crystals with $30° \leq 2\theta \leq 40°$.

The intensity data from the original crystal was corrected for the effects of absorption using the Gaussian method and the XTAL system of programs (13). Scattering factors were those assigned by XTAL. Dispersion corrections taken from ref. 14 were applied.

The structure was solved by applying the Patterson method to the heavy atoms, with subsequent use of electron density and difference Fourier maps. It was refined by full-matrix least squares applied to the structure amplitudes using anisotropic temperature factors for tungsten, arsenic, bromine, and phosphorus atoms and isotropic temperature factors for the carbon, oxygen, and fluorine atoms. When anisotropic refinement was extended to other atoms, unrealistic values were obtained for the anisotropic temperature factors and the variation in similar bond lengths increased. The hydrogen atoms were not located. The final values of R and wR were 0.092 and 0.118, using σ^{-2} weights. The standard deviation of an observation of unit weight was 1.50, and the maximum value of Δ/σ was 2.4×10^{-4}. The only significant residual electron density consisted of several peaks in the neighbourhood of the W atom, with an electron density of approximately 2.5 e $Å^{-3}$. The atomic coordinates and isotropic or equivalent thermal parameters are given in Table 1. The important bond lengths and angles are given in Table 2.[2] The atomic labelling is given in Fig. 1 and a stereoscopic view of the molecule with thermal ellipsoids represented at 50% probability is shown in Fig. 2. Torsional angles in the five-membered ring of the chelate ligand and their estimated standard deviations are shown in Fig. 3.

[2]Tables of observed and calculated structure factor amplitudes, anisotropic temperature factors, and additional bond lengths and angles may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[a]The numbers in parentheses refer to the estimated standard deviation in the last significant figure quoted.

[b]Thermal parameters are of the form $\exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{12}hka^*b^* + 2U_{13}hla^*c^* + 2U_{23}klb^*c)]$ and $U_{eq} = 1/3 \sum_{i=1}^{3}\sum_{j=1}^{3}[U_{ij}a_i^*a_j^*(\mathbf{a}_i.\mathbf{a}_j)]$.

Variable temperature ^1H nmr data were obtained using a Perkin–Elmer R12-B nmr spectrometer equipped with a variable-temperature probe. The variable-temperature controller was calibrated against standards and showed a maximum deviation of ±3 K in the temperature range investigated (233–373 K). Low temperature studies were done using $CDCl_3$ as solvent and high temperature studies using C_6H_6.

Discussion

The tungsten atom is seven-coordinate. Its coordination sphere includes the two arsenic atoms of the L–L ligand, two bromine atoms, two phosphorus atoms, and the carbon atom of the carbonyl group. The relevant seven-vertex polytopal polyhedra are the monocapped octahedron (C_{3v}), the quadrilaterally monocapped trigonal prism (C_{2v}) and the pentagonal prism (C_{5h}). Based on bond repulsion calculations, Kepert has shown that for identical ligands the capped trigonal prism is a transition state between two capped octahedral arrangements, reminiscent of the Berry rearrangement for five coordination (15). However, the barrier height in the seven-coordinate case is negligible, suggesting that facile rearrangement of the ligands is possible.

TABLE 2. Bond distances and angles with estimated standard deviations

(a) Bond	Distance (Å)
W—Br(1)	2.687 (5)
W—Br(2)	2.695 (5)
W—As(1)	2.619 (3)
W—As(2)	2.526 (4)

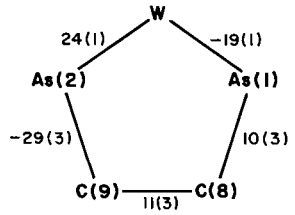

FIG. 3. Schematic diagram showing the torsional angles in the five-membered ring of the chelate ligand.

In order to describe the geometry of the observed polyhedron found here, we used the dihedral angles between the normals of adjacent faces of the polyhedron (δ angles) as suggested by Porai-Koshits and Aslanov (16). The δ angles for seven-coordinate polyhedra have been calculated by Muetterties and Guggenberger (5). It is convenient to focus attention on a subset of the δ angles for analysis of polyhedra. In this case the δ angles for three edges of the face, which is capped in the octahedral arrangement, are the relevant subset. In the capped octahedron their value is 24.2°. In the capped trigonal prism, two become zero as two quadrilateral faces are formed, and the third edge, which is also an edge at the base of the capped quadrilateral face of the trigonal prism, becomes 41.5° (5).

It has been suggested by Kouba and Wreford (17) that a preferable measure of polyhedral type is obtained if the polyhedron created by moving the vertices of the original polyhedron along their radii to the surface of a unit sphere is examined instead of the original polyhedron. One of us (18) has used this procedure for larger polyhedra and found that the use of the unit sphere provides superior discrimination among candidate ideal polyhedra.

The important δ parameters for $(L–L)W(CO)Br_2[P(OCH_3)_3]_2$, based on the unit sphere procedure, are 4°, 8°, and 30°, which are nearer those for the monocapped trigonal prism (0°, 0°, 41.5°) than the monocapped octahedron (24.2°, 24.2°, 24.2°). The capping atom is Br(1). The configuration is nevertheless on a plausible reaction path between a capped trigonal prism and a capped octahedron. If the polyhedron is described as an octa-

hedron, the capping atom is the carbon atom of the carbonyl group.

The structure of the closely related seven-coordinate compound (L–L)W(CO)$_3$I$_2$ has been reported by Mercer and Trotter (2). The configuration is similar but with δ angles (14°, 19°, 12°) that are closer to those of the capped octahedron. Based on an analysis of the edge lengths of the unit spheres, the small difference in configuration appears to be a direct consequence of the different spatial requirements of the two ligands that are carbonyl groups in the previously reported structure and phosphite groups in that reported here. The difference between the bonding radii of iodine and bromine seems less important in determining the small difference in configuration.

The bidentate ligand in both structures has a *bite* on the unit sphere ("normalized *bite*" in the terminology of Kepert (15)) of 1.23. According to the analysis by Kepert (15) of seven-coordinate polyhedra with one bidentate ligand and five unidentate ligands, all with equal metal–ligand bond lengths, such polyhedra may adopt, among others, a particular stereochemistry he labels as "D". In stereochemistry D in the capped trigonal prism, the bidentate ligand bridges an edge of the capped quadrilateral face that joins the trilateral faces of the prism. In the associated capped octahedron, the bidentate ligand joins the capped trilateral face to the trilateral face formed by the remaining three ligands. Keperts survey of seven-coordinate polyhedra suggests that for seven-coordinate polyhedra with a bidentate ligand having a normalized *bite* greater than 1.2, the D configuration is predominant.

The polyhedron in the compound reported here adopts stereochemistry D. Given the large variation in metal–ligand bond lengths in (L–L)W(CO)Br$_2$[P(OCH$_3$)$_3$]$_2$, we must conclude that the presence of the predicted stereochemistry D is either due to factors other than those considered by Kepert, or that the bond lengths are much less important than the normalized *bite* of the bidentate ligand in establishing stereochemistry.

The bidentate ligand forms a five-membered ring with the tungsten atom. The torsional angles for the ring are given in Fig. 3. The nature of the ring puckering was analyzed according to the method of Cremer and Pople (19). The relevant parameters are $q = 0.43$, $\phi = -13.2°$, indicating a highly puckered ring closer to the twist conformation than the envelope conformation. The W atom is above the plane of As(1), As(2), and C(9), and C(8) is below the plane. However, because of short bond lengths to C(8), the appearance of the ring in Fig. 1 is that of an envelope folded across the As–As line.

The parameters describing the ring in (L–L)W(CO)$_3$I$_2$ are essentially the same as in the present study. The fold about the As–As line is caused by the contact between the arsenic methyl groups and the carbonyl and the phosphite ligand containing P(2). The tetrahedral coordination of the arsenic atom is further distorted by these contacts. The reason that C(8) is also puckered out of the plane of the envelope is not clear. The fold may serve to optimize the *bite* of the ligand or it may be related by the packing requirements of the methyl and CF_3 groups.

Significant shortening of the W—As bonds from a predicted value of 2.73 Å (1) to the experimental values of 2.619(3) and 2.526(4) Å is thought to be due to some double-bond character in the W—As bonds caused by $d\pi$–$d\pi$ back donation from the tungsten atom. The two W—As bonds are also significantly different from each other, which can be explained by a consideration of their respective *trans* ligands. The Br(2) atom *trans* to As(2) is not as strong a $d\pi$ acceptor as P(1) *trans* to As(1), which should result in a greater back donation to As(2). This causes a shortening of the W—As(2) bond compared to the W—As(1) bond, the difference being 0.093 Å. Considerable back donation from W to the carbonyl group is evident from a comparison of the W—C(1) bond length of 1.86(3) Å to other carbonyl tungsten complexes. This in turn results in a longer C—O bond length (1, 2, 20). The two W—P bonds are significantly different from each other, which again can be explained on the basis of their respective *trans* ligands. Thus the W—P(2) bond, (P(2) *trans* to Br(1)) is shorter than the W—P(1) bond (P(1) *trans* to As(1)).

The geometry found in the solid state is not consistent with the structure in solution as deduced from ^{1}H nmr data. Two arsenic methyl resonances are observed at room temperature, which remained fairly sharp even at 233 K. However, as the temperature is increased the two resonances broaden, collapse, and coalesce into a single resonance line (coalescence temperature 343 K). The coalesced peak sharpened further in the range 343–373 K. The room temperature spectrum suggests a more symmetrical structure than observed in the solid state. The change in the ^{1}H nmr spectrum at higher temperature is indicative of stereochemical nonrigidity. The mechanism previously proposed for the related molybdenum complex (9), involving the migration of a capping CO group over faces of a more symmetrically capped octahedral polyhedron, is not consistent for the tungsten species in view of the geometry found in the solid state. A similar mechanism, as stated above, would explain the high temperature ^{1}H nmr results assuming the tungsten complex undergoes a rearrangement process to give a more symmetrical ligand arrangement, as stated for the Mo complex (9). Thus the ^{1}H nmr results suggest that there are two exchange processes occurring; a lower energy process which averages two sets of As—CH_3 groups (the spectrum recorded at 233 K is probably not the limiting spectrum) and a higher energy process which averages all four As—CH_3 groups.

If the reaction pathway between the octahedron capped by the carbonyl group and the trigonal prism capped by Br(1) is extended, another octahedron, capped by P(2), is obtained. None of these polyhedra show higher symmetry consistent with the room temperature nmr data, for which a pentagonal prism is required.

The δ angle for the edge P(1)–As(2) is smaller in both observed polyhedra than in the ideal polyhedron. This is consistent with a small distortion toward the geometry of the pentagonal bipyramid, unfortunately not a pentagonal bipyramid with higher symmetry required by the nmr results. A combination of concerted rearrangements of the ligands following pathways such as those discussed by King (21) would be required to generate a polyhedron (or time-averaged combination of polyhedra) with the required higher symmetry.

Interactions between cations and sugars. II. Enthalpies, heat capacities, and volumes of aqueous solutions of Ca^{2+}–D-ribose and Ca^{2+}–D-arabinose at 25°C

JEAN-PIERRE MOREL[1], CLAUDE LHERMET, AND NICOLE MOREL-DESROSIERS
Laboratoire d'Étude des Interactions Solutés–Solvants, U.A. au C.N.R.S. n° 434, Université Clermont 2, 63170 Aubière, France

Received November 7, 1985

JEAN-PIERRE MOREL, CLAUDE LHERMET, and NICOLE MOREL-DESROSIERS. Can. J. Chem. **64**, 996 (1986).

The thermodynamic parameters characterizing the interaction between Ca^{2+} and the suitably positioned sequences of hydroxyls of some sugar isomers have been determined. This was done by comparing the properties of D-ribose which bears such sequences of hydroxyls with the properties of D-arabinose chosen as an inactive reference. The enthalpies of solution and of dilution, the apparent molal heat capacities, and the apparent molal volumes of the two pentoses have been first measured in water at 25°C. The measurement of these properties for the transfer of the sugars from water to $CaCl_2$ solutions (and, conversely, for the transfer of $CaCl_2$ from water to the sugar solutions) directly gives access to the Ca^{2+}–hydroxyls pair interaction parameters. The thermodynamic properties of this reaction of association may then be estimated: $\Delta H^\theta \cong -24$ kJ mol^{-1}; $\Delta S^\theta \cong -83$ J K^{-1} mol^{-1}; $\Delta V^\theta \cong 5$ cm^3 mol^{-1}; $\Delta C_p^\theta \cong 40$ J K^{-1} mol^{-1}. The analysis of these data shows that the weak association constant results from a large compensation between the favourable enthalpy and the unfavourable entropy of reaction.

JEAN-PIERRE MOREL, CLAUDE LHERMET et NICOLE MOREL-DESROSIERS. Can. J. Chem. **64**, 996 (1986).

Les paramètres thermodynamiques caractéristiques de l'interaction entre l'ion Ca^{2+} et les séquences d'hydroxyles en position favorable qui existent dans certains isomères des sucres sont déterminés. Pour ceci, on compare les propriétés du D-ribose qui comporte de telles séquences et celles du D-arabinose choisi comme référence non active. Les enthalpies de dissolution et de dilution, les capacités calorifiques molaires apparentes et les volumes molaires apparents sont d'abord déterminés dans l'eau à 25°C. La mesure des mêmes grandeurs relatives au transfert des sucres de l'eau pure aux solutions de $CaCl_2$ (et, inversement, de $CaCl_2$ de l'eau aux solutions de sucre) permet d'accéder aux paramètres correspondants relatifs à l'interaction par paire Ca^{2+}–hydroxyles. On peut alors évaluer les grandeurs thermodynamiques de cette réaction d'association: $\Delta H^\theta \cong -24$ kJ mol^{-1}, $\Delta S^\theta \cong -83$ J K^{-1} mol^{-1}, $\Delta V^\theta \cong 5$ cm^3 mol^{-1}, $\Delta C_p^\theta \cong 40$ J K^{-1} mol^{-1}. Celles-ci sont discutées; on observe en particulier que la constante d'association faible est due à une large compensation entre l'enthalpie favorable et l'entropie défavorable du processus.

Introduction

The study of the thermodynamics of hydration of sugars and sugar derivatives has raised, for a long time, a great deal of interest (1, 2). Amongst the most recent work based on precise thermodynamic determinations, some are concerned with the properties at infinite dilution (3–5), whereas others are interested in the excess properties which reflect the solute–solute interactions (6–8). The interactions between sugars and metal cations in aqueous solution are of great importance in biochemistry and have been closely looked at since Angyal's pioneering studies (9). The primary aim of Angyal's work was to compare the complexing ability of various cations with some sugars through the determination of the stability constants, a subject which was analysed in our previous paper (10).

The study of the interactions between D-arabinose or D-ribose and calcium ion by a very sensitive potentiometric method, which can be applied to solutions dilute in the metal ion, has led us to analyse the characteristics of the free energy of interaction. More precisely, the comparison of these two pentoses gives access to a pair interaction parameter g_{RCa} which is characteristic of the couple Ca^{2-} – axial–equatorial–axial sequence of oxygen atoms of the ribose isomers present at equilibrium. The presence in solution of many sugar anomers is one of the great difficulties of the thermodynamic, hence global, approach to the problem. Yet, it is essential to get this thermodynamic picture of the phenomena since it completes the interpretation which can be elaborated from, for instance, the nmr data. Indeed, the nmr methods (11, 12) allow one to "isolate" the interactions between the cation and the various isomers of the sugar but they can be used only on solutions with high salt concentrations, hence the following drawbacks: importance of the anion effects and of the activity coefficients. The thermodynamic methods we use are, on the contrary, based on extrapolation to infinite dilution and reflect the interaction between the sugar and the metal ion in this particular condition. The parameter g_{RCa}, which is characteristic of the free energy of interaction between calcium and ribose, can be directly related to the association constant β_1 (10) if one prefers to speak in terms of chemical equilibria to describe these weak interactions.

It is interesting now to determine other thermodynamic parameters which will help us to better characterize this interaction. Studies of this kind have already been performed on various solutes involving either nonelectrolyte–nonelectrolyte or electrolyte–nonelectrolyte pairs. Our previous work regarding the interactions between electrolytes and alcohols (13) in aqueous solutions will serve as a basis for the method and the formalism used in the present paper. We shall determine enthalpies of solution, volumes, and heat capacities which give access to the corresponding sugar–electrolyte (SE) pair interaction parameters h_{SE}, v_{SE}, c_{SE}.

Theoretical relations

It is well known that the excess thermodynamic functions can be expressed as virial expansions in concentration. These expansions, which are based on McMillan–Mayer theory, relate the nonideal component of any total thermodynamic function to a series of pair, triplet, and higher order interaction parameters. It is possible to evaluate these parameters through the determination of transfer functions. We shall only give here the relations which are necessary to the understanding of the present work; the details of the theoretical analysis have been given in a previous paper (13) and in the references cited therein. In these expressions, we shall designate the components of the ternary system water–nonelectrolyte–electrolyte

[1]To whom all correspondence should be addressed.

by the following letters: W for water, S for sugar (A: arabinose, R: ribose), and E for electrolyte.

The transfer function X of a nonelectrolyte S at molality m_S from pure water to a solution of electrolyte E at molality m_E is given by

$$[1] \quad \Delta_t X_S = 2\nu x_{SE} m_E + 3\nu^2 x_{SEE} m_E^2 + 3\nu x_{SSE} m_E m_S + \ldots$$

where ν is the number of ions into which E dissociates and x_{SE}, x_{SEE}, x_{SSE} are the pair and triplet interaction parameters. In the same way, the transfer function of the electrolyte at molality m_E from water to the solution of nonelectrolyte at molality m_S is given by

$$[2] \quad \Delta_t X_E = 2\nu x_{SE} m_S + 3\nu x_{SSE} m_S^2 + 3\nu^2 x_{SEE} m_S m_E + \ldots$$

For a standard function ($m_S \rightarrow 0$ in the first case and $m_E \rightarrow 0$ in the second one) the higher order terms in m_S or m_E on the right-hand side of eqs. [1] and [2] vanish. It immediately follows that

$$[3] \quad \left(\frac{\partial \Delta_t X_S^\theta}{\partial m_E}\right)_{m_E=0} = \left(\frac{\partial \Delta_t X_E^\theta}{\partial m_S}\right)_{m_S=0} = 2\nu x_{SE}$$

The pair interaction parameter is then readily measurable for any thermodynamic function from each of the studied transfers. Let us note that for an electrolyte with ν ions, x_{SE} characterizes all the pair interactions between the nonelectrolyte S and the various ions of E. Here, for instance, E$\equiv$$CaCl_2$ and it follows that

$$[4] \quad x_{SE} = \frac{x_{SCa^{2+}} + 2x_{SCl^-}}{3}$$

We have recently studied the case where $X \equiv G$ (10) and have shown that the measurement of the emf of a cell using electrodes which are reversible to Ca^{2+} and Cl^- gives access to the standard free energy of transfer $\Delta_t G_E^\theta$ and, accordingly, to g_{SE}. We shall examine here other functions, namely the enthalpy, the heat capacity, and the volume.

The measurement of the enthalpy of solution of the pure solid sugar $\Delta_{sol}H_S$ in water and in the electrolyte solution at sufficiently low final concentration ($m_S < 0.1$ mol kg^{-1}) gives directly access to the transfer function at infinite dilution. In fact, we observe that the enthalpies of solution do not, considering the uncertainty of the measurements, vary significantly with m_S; they may, thus, be assumed to be standard values. The standard enthalpy of transfer of the sugar from water to the electrolyte solution may be written

$$[5] \quad \Delta_t H_S^\theta(m_E) = \Delta_{sol}H_S(m_E) - \Delta_{sol}H_S = 2\nu h_{SE} m_E + 3\nu^2 h_{SEE} m_E^2 + \ldots$$

There is another method which gives access to the standard enthalpy and we shall use it for the transfer of the electrolyte E from water to the solution of sugar. This method is very useful when it is difficult to handle the pure solute (gas, hygroscopic product) (14). It involves the dilution of a concentrated aqueous solution of electrolyte E in water and in the sugar solutions. In the case studied here, the final concentrations in electrolyte are relatively low and, provided they are identical in water and in the sugar solution we may write

$$[6] \quad \Delta_t H_E^\theta(m_S) = \Delta_{dil}H_E(m_E, m_S) - \Delta_{dil}H_E(m_E) = 2\nu h_{SE} m_S + 3\nu h_{SSE} m_S^2 + \ldots$$

Through the measurement of the density of the solutions we get the apparent molal volume of the solute. Hence, the apparent molal volume of the sugar in water ϕ_{VS} is given by

$$[7] \quad \phi_{VS}(m_S) = M_S\rho^{-1} + 1000(\rho^{-1} - \rho_0^{-1})m_S^{-1}$$

where M_S is the molecular weight of the sugar and ρ and ρ_0 the densities (g cm^{-3}) of the solution of molality m_S and of pure water, respectively. One may also define the apparent molal volume of the sugar S in a solution of electrolyte of molality m_E by using the densities $\rho(m_S, m_E)$ and $\rho(m_E)$ (15). At low m_S concentrations, the transfer function $\phi_{VS}(m_S, m_E) - \phi_{VS}(m_S)$ may be assumed to be a standard value (infinite dilution) and we may write

$$[8] \quad \phi_{VS}(m_S, m_E) - \phi_{VS}(m_S) = 2\nu v_{SE} m_E + 3\nu^2 v_{SEE} m_E^2 + \ldots$$

Similarly, by considering the transfer of the electrolyte from water to the sugar solutions we get

$$[9] \quad \phi_{VE}(m_E, m_S) - \phi_{VE}(m_E) = 2\nu v_{SE} m_S + 3\nu v_{SSE} m_S^2 + \ldots$$

The apparent molal heat capacities at constant pressure are obtained by measuring the specific heats (J K^{-1} g^{-1}) of the solutions, c, and of the solvent, c_0, respectively,

$$[10] \quad \phi_{CS}(m_S) = M_S c + 1000(c - c_0)m_S^{-1}$$

The study of the ternary systems gives access, as outlined above, to the transfer function $\phi_{CS}(m_S, m_E) - \phi_{CS}(m_S)$ which is assumed to be the standard molal heat capacity of transfer if m_S is small enough. Equations similar to [8] and [9] may then be written

$$[11] \quad \phi_{CS}(m_S, m_E) - \phi_{CS}(m_S) = 2\nu c_{SE} m_E + 3\nu^2 c_{SEE} m_E^2 + \ldots$$

$$[12] \quad \phi_{CE}(m_E, m_S) - \phi_{CE}(m_E) = 2\nu c_{SE} m_S + 3\nu c_{SSE} m_S^2 + \ldots$$

Experimental

The two studied pentoses, D-arabinose and D-ribose, (Fluka puriss.) were dried under vacuum (no significant weight loss was observed), stored in a desiccator and used as such. The solutions of $CaCl_2$ (Merck pro analysis) were titrated by EDTA. All solutions were prepared by weight from triply distilled water degassed prior to use.

The enthalpies of solution and of dilution were measured with an LKB 8700 calorimeter by using the classical ampoule breaking technique. The densities were measured with a Sodev flow densimeter with a precision of about $\pm 5 \times 10^{-6}$ g cm^{-3} (16). The heat capacities were measured with a Picker flow microcalorimeter (Setaram) with, in the present case, an uncertainty on $\Delta c = c - c_0$ of the order of 0.5% (17).

All the measurements were carried out at 25.00 ± 0.01°C.

Results

Properties of the aqueous solutions of ribose and arabinose

The enthalpies of solution of both sugars have been measured in water, the final concentration varying from 0.01 to 0.1 mol kg^{-1}. The measurements were repeated six times and shown to be, considering the experimental uncertainty, concentration independent. The mean values may thus be assumed to be the standard values at infinite dilution. It follows that, for ribose,

$$\Delta_{sol}H_R^\theta = 13.60 \pm 0.06 \text{ kJ mol}^{-1}$$

and, for arabinose,

$$\Delta_{sol}H_A^\theta = 14.20 \pm 0.08 \text{ kJ mol}^{-1}$$

0.8008	286.2		

The agreement with the values given in the literature (13.04 and 13.24 kJ mol^{-1}, respectively) (5) is not excellent.

We have reported in Table 1 the apparent molal volumes and heat capacities at various molalities. The variation with concentration is almost linear and the following relations may be proposed for ribose

$$\phi_{CR} = 284._5 + 2m_R \text{ J K}^{-1} \text{ mol}^{-1}$$
$$\phi_{VR} = 95.1 + 0.5m_R \text{ cm}^3 \text{ mol}^{-1}$$

and, for arabinose

$$\phi_{CA} = 282._5 + 4._5m_A \text{ J K}^{-1} \text{ mol}^{-1}$$
$$\phi_{VA} = 93.2 + 0.6m_A \text{ cm}^3 \text{ mol}^{-1}$$

The standard values at infinite dilution can be compared with those given in the literature: our ϕ_{VR}^θ is in good agreement with the value of 95.3 cm$^{3\ -1}$ given by Franks (18), but is slightly less than the value of 95.56 cm^3 mol^{-1} given by Jasra (5), the precision of the latter value being, however, overestimated. For ϕ_{VA}^θ, Jasra gives a value of 94.00 cm^3 mol^{-1} which is rather different from ours; as indicated above, we have also observed a large discrepancy between the enthalpy of solution of arabinose given by this author and our value. As regards the ϕ_{CR}^θ and ϕ_{CA}^θ values, we find two sets of data in the literature: on the one hand, 294 and 318 J K^{-1} mol^{-1} (5) and, on the other hand 271 and 278 J K^{-1} mol^{-1} (3) respectively. Jasra's data were determined from enthalpies of solution measured at 25 and 35°C and, obviously, their precision cannot be compared with that of heat capacities directly measured with the Picker flow microcalorimeter (17). The ϕ_C values given, at 30°C, by Kawaizumi (3) look more scattered as a function of m than ours but his values at infinite dilution, in particular that for arabinose, are in good agreement with those proposed here. Considering the precision of the methods used here and the low scattering of the results shown in Table 1, we believe that the ϕ_C and ϕ_V values we propose may be taken as reference values.

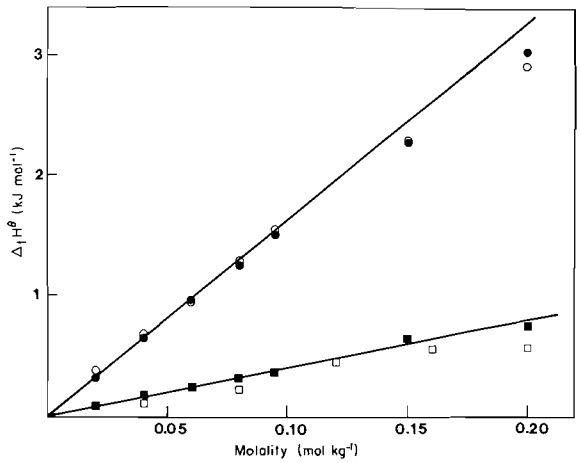

FIG. 1. Standard enthalpies of transfer of ribose (R) or arabinose (A) from water to aqueous solutions of $CaCl_2$ (E) and of transfer of $CaCl_2$ from water to aqueous solutions of ribose or arabinose. ●, $\Delta_t H_R^\theta$ versus m_E; ■, $\Delta_t H_A^\theta$ versus m_E; ○, $\Delta_t H_E^\theta$ versus m_R; □, $\Delta_t H_E^\theta$ versus m_A.

TABLE 2. Parameters characterizing the pair interaction between $CaCl_2$ and ribose or arabinose in water at 25°C

Parameters	Ribose	Arabinose
$2vg_{SE}$[a] (J mol^{-2} kg)	−2 200	−100
$2vh_{SE}$ (J mol^{-2} kg)	−16 500	−4000
$2vs_{SE}$ (J K^{-1} mol^{-2} kg)	−52	−10
$2vc_{SE}$ (J K^{-1} mol^{-2} kg)	350	80
$2vv_{SE}$ (cm^3 mol^{-2} kg)	5.0	2.5

[a]In ref. 10, the g_{SE} values are given in a molality scale which is relative to the aqueous sugar solution; here, the molality scale is relative to water. The difference between g_{RE} and g_{AE} is the same, i.e., −2100.

Transfer functions

Enthalpies

The dilution of a concentrated solution of $CaCl_2$ in water ($0.6948m$) is carried out into ribose and arabinose solutions of molality varying up to 0.2 mol kg^{-1}; the final $CaCl_2$ concentration is of the order of $0.0185m$. The enthalpies of dilution of transfer given by eq. [6] are reported in Fig. 1. Similarly, the dilution of concentrated solutions of ribose and arabinose ($0.6384m$) into $CaCl_2$ solutions of concentration varying up to $0.2m$ leads (by interchanging E for S in eq. [6]) to the transfer functions shown in Fig. 1. The extrapolation at $m = 0$ of the plots $\Delta_t H^\theta/m$ versus m gives (eqs. [5] and [6]) the parameters $2vh_{SE}$ shown in Table 2. The slope of the straight lines of Fig. 1 corresponds to $2vh_{RE}$ for ribose and $2vh_{AE}$ for arabinose; we see that relation [3] is verified.

Some transfer functions have been obtained by the solution method (relation [5]); these values are, although slightly less precise, in good agreement with those obtained by the dilution method.

Volumes

The apparent molal volumes of $CaCl_2$ have been measured at $0.1018m$ salt concentration in ribose and arabinose solutions of molality varying up to 0.8 mol kg^{-1}. Similarly, the apparent molal volumes of the sugars at $0.1000m$ have been measured in $CaCl_2$ solutions of molality varying up to 0.8 mol kg^{-1}. The transfer functions calculated from eqs. [8] and [9] are plotted in Fig. 2. Since the precision of the volumes of transfer is less than that of the enthalpies of transfer, it is necessary to work at higher

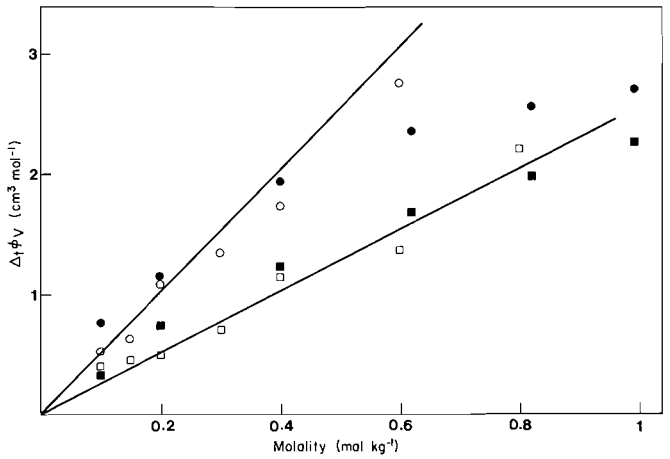

FIG. 2. Standard volumes of transfer of ribose (R) or arabinose (A) from water to aqueous solutions of $CaCl_2$ (E) and of transfer of $CaCl_2$ from water to aqueous solutions of ribose or arabinose. ●, $\Delta_t\phi_{VR}$ versus m_E; ■, $\Delta_t\phi_{VA}$ versus m_E; ○, $\Delta_t\phi_{VE}$ versus m_R; □, $\Delta_t\phi_{VE}$ versus m_A.

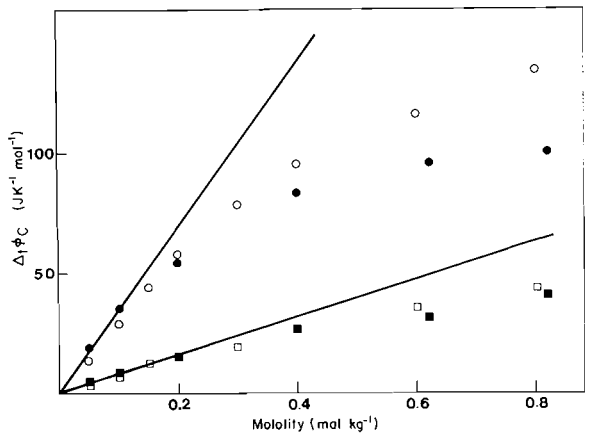

FIG. 3. Standard heat capacities of transfer of ribose (R) or arabinose (A) from water to aqueous solutions of $CaCl_2$ (E) and of transfer of $CaCl_2$ from water to aqueous solutions of ribose or arabinose. ●, $\Delta_t\phi_{CR}$ versus m_E; ■, $\Delta_t\phi_{CA}$ versus m_E; ○, $\Delta_t\phi_{CE}$ versus m_R; □, $\Delta_t\phi_{CE}$ versus m_A.

concentrations to be able to use a treatment similar to the one described above so as to get, after extrapolation at $m = 0$, the parameters $2\nu v_{SE}$ given in Table 2. These parameters of ribose and arabinose are represented by the straight lines of Fig. 2.

Heat capacities

The apparent molal heat capacities have been measured at the same concentrations as the volumes above. The transfer functions given by relations [11] and [12] are shown in Fig. 3. They give access to the pair parameters $2\nu c_{SE}$ which are reported in Table 2. Relation [3], again, is verified: the initial slopes are the same even if, in the case of ribose, both curves diverge rapidly. It thus looks as if the contribution of the triplet terms (relations [11] and [12]) is more important for ribose.

Discussion

In Table 2 are reported all the parameters which characterize the pair interactions between $CaCl_2$ and the two studied sugars, ribose and arabinose. These are mean values relative to both SCa^{2+} and SCl^- pairs, as shown by relation [4]. In our previous work (10), we have assumed that the difference observed between the interactions with each of the two isomeric pentoses was essentially due to some specific interaction between Ca^{2+} ion and the axial–equatorial–axial sequence of hydroxyls of ribose. This is analogous to say that the nonspecific interactions between Ca^{2+}, or Cl^-, and each of the two sugars are identical. We may then write (10)

[13] $2\nu g_{RE} - 2\nu g_{AE} = 2g_{RCa}$

as well as similar relations for the parameters corresponding to the other thermodynamic functions. It is then possible to evaluate by a simple subtraction all the parameters characteristic of the specific interaction between Ca^{2+} and ribose: $2g_{RCa} = -2100$ J mol^{-2} kg; $2h_{RCa} = -12\,500$ J mol^{-2} kg; $2s_{RCa} = -42$ J K^{-1} mol^{-2} kg; $2c_{RCa} = 270$ J K^{-1} mol^{-2} kg; $2v_{RCa} = 2.5$ cm^3 mol^{-2} kg. What do these parameters represent in a more familiar language? The chemical model which involves the following reaction of association (no R_2Ca^{2+} complex has been observed (10)) allows us to define the

[14] Ca^{2+} +  =

corresponding thermodynamic functions. We have shown in our previous work (10) that there is a coherence between the two languages by which we can express and estimate weak interactions. For instance, the association constant relative to reaction [14]

$$[15]\quad \beta = \frac{[RCa^{2+}]}{[Ca^{2+}][R]}$$

is directly related to the parameter g_{RCa} by the following good approximation

[16] $RT\beta = -2g_{RCa}$

It follows that $\beta = 0.85$. The pair interaction parameters x_{SE} defined by relations [1]–[3] correspond to the derivatives of the thermodynamic functions of transfer with respect to the concentration. It can readily be seen that the classical thermodynamic relations which exist between the various functions are also found between the x_{SE} parameters. Hence, we may write

$$\left(\frac{\partial g}{\partial T}\right)_P = -s; \quad \left(\frac{\partial (g/T)}{\partial T}\right)_P = -\frac{h}{T^2}; \quad \left(\frac{\partial g}{\partial P}\right)_T = v$$

and, also,

[17] $s = (h - g)/T$

with which we have calculated the s_{SE} parameters of Table 2. By integrating relation [17] we get the values of the g_{RCa} parameter at some characteristic temperatures and, as a result, the β values. We get, for instance,

[18] $\beta(0°C) = 1.44$; $\beta(25°C) = 0.85$; $\beta(37°C) = 0.63$

Each of the parameters characteristic of the pair interactions between Ca^{2+} and the suitably positioned hydroxyls is related in a simple way to each of the standard thermodynamic functions corresponding to the reaction of association (eq. [14]). Hence, the standard enthalpy of association can be calculated from the β constant by

$$[19]\quad \Delta H^\theta = RT^2\left(\frac{\partial \ln \beta}{\partial T}\right)_P$$

whence, from eq. [16],

[20] $2h_{RCa} = \beta\Delta H^{\theta}$

The meaning of this expression is obvious if we recall that the term $2h_{RCa}m_{Ca}$ corresponds to the enthalpy of transfer of ribose from water to an aqueous solution of Ca^{2+} of molality m_{Ca}; hence, if α which is the extent of association of the sugar is weak, as it is the case in the present conditions, we may write

$$[21]\quad \Delta_t H_R^{\theta}(m_{Ca}) = 2h_{RCa}m_{Ca} = \alpha\Delta H^{\theta} \cong \beta m_{Ca}\Delta H^{\theta}$$

Similarly, we may show that the relations corresponding to the entropy and the volume are given by

[22] $2s_{RCa} = \beta\Delta S^{\theta} - R\beta(\ln\beta - 1)$

[23] $2v_{RCa} = \beta\Delta V^{\theta}$

The interpretation of the heat capacity is, however, more complicated. We have shown (19) that the apparent molal heat capacity of transfer of a species which is involved in an association reaction (such as eq. [14]) contains a term equal to $(\partial\alpha/\partial T)\Delta H^{\theta}$ which corresponds to the equilibrium shift resulting from the temperature rise inherent in the heat capacity measurement. The apparent molal heat capacity of transfer is thus given by

$$[24]\quad \Delta_t\phi_{CR}(m_{Ca}) = 2c_{RCa}m_{Ca} = \alpha\Delta C_p^{\theta} + \left(\frac{\partial\alpha}{\partial T}\right)\Delta H^{\theta}$$

The case for which we have studied these problems into detail (19) is totally comparable to the present one except for the stability constants which were much higher. Relation [24] may thus be written

$$[25]\quad 2c_{RCa} = \beta\left(\Delta C_p^{\theta} + \frac{\Delta H^{\theta 2}}{RT^2}\right)$$

The equilibrium shift term is always positive; here, it is equal to 293 J K^{-1} and constitutes the major part of the $2c_{RCa}$ term. The ΔC_p^{θ} term is then obtained by subtraction. From eqs. [20], [22], [23], and [25] we get

$$\Delta H^{\theta} = -14.7 \text{ kJ mol}^{-1}$$

$$[26]\quad \Delta S^{\theta} = -51 \text{ J K}^{-1} \text{ mol}^{-1}$$

$$\Delta V^{\theta} = 3 \text{ cm}^3 \text{ mol}^{-1}$$

$$\Delta C_p^{\theta} = 24 \text{ J K}^{-1} \text{ mol}^{-1}$$

One must not forget that reaction [14] involves only the ribose isomers which bear a sequence of hydroxyls suitable for association: the β-pyranose 1C4 (~35%), the two α-pyranose conformers (~21%), and the α-furanose (~6%); percentages are given by Angyal at 31°C (9). The mean values given in eq. [26] characterize only the active isomers indicated above which represent about 60% of ribose. Hence, if we make the very crude approximation that all the isomers involved in an association process are characterized by identical thermodynamic functions of reaction, we may then propose the following values: $\Delta H^{\theta} \cong -24$ kJ mol^{-1}; $\Delta S^{\theta} \cong -83$ J K^{-1} mol^{-1}; $\Delta V^{\theta} \cong 5$ cm^3 mol^{-1}; $\Delta C_p^{\theta} \cong 40$ J K^{-1} mol^{-1}. But this is only, let us repeat it, a very crude estimation of the thermodynamic functions characterizing reaction [14]. As far as we know, these are the first values deduced from calorimetric measurements for the complex formation between a cation and a sugar. It is interesting to note that the ΔH^{θ} and ΔS^{θ} values proposed here are in good agreement with those determined by Lenkinski and Reuben (11) (−7 kcal mol^{-1} and −20 eu, respectively) for α-D-ribopyranose from nmr measurements at two temperatures. Even if our values are "mean" values, it is worthwhile underlining the fact that totally different methods lead to results in good agreement.

We thus notice that the enthalpic contribution to the cation–sugar association is favourable, and the weak value of the stability constant results from the very large unfavourable entropic term. Hence, as regards the energetic balance, the replacement of some water molecules in the hydration shell of Ca^{2+} by three hydroxyls of the ribose molecule results in a decrease of the enthalpy. Since the enthalpy of hydration of Ca^{2+} is large and the molecule of sugar has a hydrophilic character, the negative energetic balance for the association process indicates that the cation–sugar complex is itself strongly hydrated through the cation, which is probably largely accessible to the water molecules, and through the three lone pairs of the oxygen atoms of the hydroxyls involved in the complex formation with the cation. This complexation leads to a loss of degrees of freedom which gives a negative contribution to ΔS^{θ}, and to a partial dehydration of Ca^{2+} which gives a positive entropic contribution; the results given here show that the former is largely predominant. The three hydroxyls involved in the complex-formation process totally lose their rotational freedom: the lone pairs of the oxygen atoms cannot anymore be involved in the hydrogen bonds of the various hydration structures of the free sugar.

The positive value for the volume of reaction (~5 cm^3 mol^{-1}) may be logically explained through the classical "electrostriction" phenomena. The ion–solvent interaction gives a negative contribution to the partial molal volume of the cation and the replacement of part of the hydration shell of this cation by the sugar results in a positive ΔV^{θ} value.

The interpretation of the ΔC_p^{θ} of reaction is much more delicate, in particular because the values of the ionic heat capacities are unknown (19). We have shown that, as regards ΔS^{θ}, the negative contribution due to the loss by the sugar of internal and external degrees of freedom was predominant over the positive contribution due to the dehydration of the cation. Since the loss of internal degrees of freedom leads to a negative contribution to ΔC_p (19), it is obviously the balance of complicated hydration phenomena which is responsible for the positive ΔC_p^{θ} value observed here.

Conclusion

We have presented here the thermodynamic methods, in particular the calorimetric ones, which give access to the thermodynamic functions characterizing the reaction of weak association between an ion and a ligand through the determination of the pair interaction parameters.

The ΔH^{θ}, ΔS^{θ}, ΔV^{θ}, and ΔC_p^{θ} values have thus been estimated for the association between the complexing sequence of hydroxyls of the D-ribose molecule and the cation Ca^{2+} in aqueous solution. We have shown that the association constant is weak because of the large compensation between the favourable enthalpic term (~−25 kJ mol^{-1}) and the unfavourable entropic term (~−80 J K^{-1} mol^{-1}).

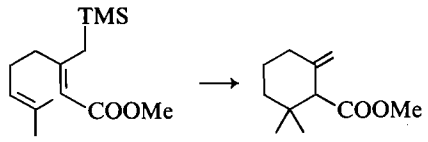
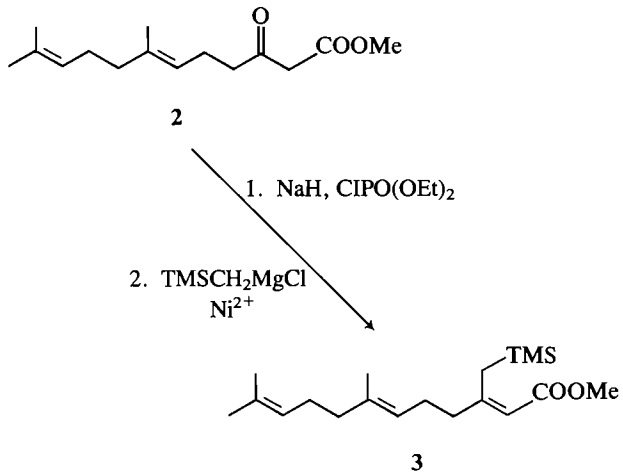
In 1976, Fleming *et al.* reported the first use of an allylsilane in an electrophilic cyclization (1). These results have been extended by Fleming and co-workers (2) and exploited by several other groups (3), including our own (4). In particular, we were able to show that the methyltrimethylsilyl group activated and controlled the regioselective alkene formation in the electrophilic cyclization of allylsilanes of α,β-unsaturated esters. This led to a method for the facile and efficient cyclization of epoxy alkenes (4*b*, 4*d*). Our initial efforts to cyclize olefinic allylsilanes involved a detailed study of the cyclization of the diene **1** to the exocyclic methylenecyclohexane shown below (4*c*). In this paper we report the details of the extension of this chemistry to the cyclization of trienes and the application of this cyclization in the synthesis of two drimane sesquiterpenes.[3]



1

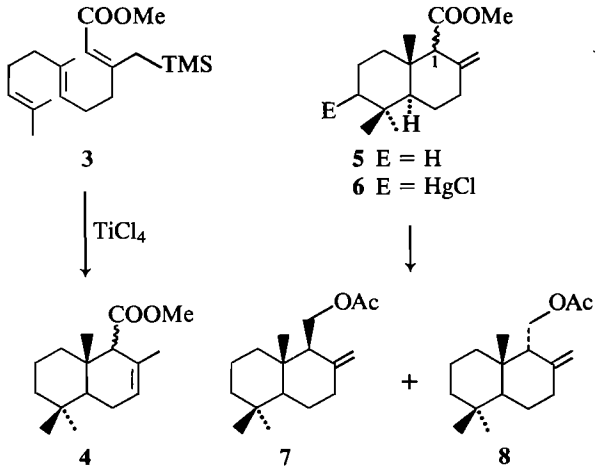
Synthesis of the (*E*,*Z*)-triene **3** is shown in eq. [1]. The β-keto ester **2** (5) was converted into the corresponding *Z*-enol phosphate (6) and coupled with trimethylsilymethylmagnesium chloride in the presence of nickel(II) bisacetylacetonate (7). The best yields of **3** were obtained by vigorous stirring of the reaction mixture, and by addition of fresh catalyst during the coupling reaction. The stereoselectivity in the formation of the conjugated alkene of **3** in this coupling reaction was greater than 95% as estimated from the ^{1}H nmr of the crude product.

[1]



2 **3**

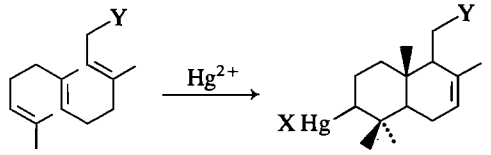
We carried out a study of the cyclization of triene **3** with a range of Lewis acids (4*c*) and determined the products by a combination of ^{1}H nmr spectroscopy and gas chromatography.[4] If titanium tetrachloride was used as the Lewis acid catalyst, the endocyclic compounds **4** were obtained in good yield. The ratio of the 1α:1β isomers was 1:1 and it was independent of the geometry of the terminal alkene in **3**.[5] It is interesting to note that the conjugated $\Delta^{1,2}$ alkene was not observed in any of our cyclization reactions. A number of Lewis acids, including boron trifluoride etherate, aluminum chloride, and stannic chloride, gave the exocyclic esters **5**. These reactions were quite solvent and temperature dependent. The optimum cyclization conditions for production of the exocyclic alkenes involved treating **3** with stannic chloride at −56°C in methylene chloride saturated with water. Under these conditions the esters **5** were obtained in 95% yield and the ratio of the 1α:1β isomers was 1:4. Under more vigorous conditions the exocyclic alkenes **5** isomerized to the more stable endocyclic compounds **4**. We were unable to separate the two epimers of **5** on preparative scale at this stage, nor were we able to epimerize either compound.



It was somewhat surprising to find that the cyclization of the allylsilane **3** gave an epimeric mixture of the products **5**. In accordance with the Stork–Eschenmoser hypothesis (9), cyclization of the triene **3** via the chair–chair conformation would be expected to yield the 1β isomer. The 1α epimer presumably arises via the chair–boat conformation. It seems that small steric interactions in the transition stage may play an important role in determining the product distribution (4*d*, 10).

Mercuric ion initiated cyclization (11) of the triene **3** was also investigated. Treatment of **3** with mercuric trifluoroacetate followed by a brine work-up gave the bicyclic products **6**, which were isolated, after chromatography, in 55–65% yield along with ca. 10% of a monocyclic product. We were unable to determine the number and structure of the stereoisomers of **6** present in the product. However, this problem was resolved in the subsequent reactions of **6**. The bicyclic product **6** was reduced with lithium aluminum hydride and acetylated to give the C-1 epimeric compounds **7** and **8** in good yield. The ratio of **7**:**8** was 3:1, which indicated that the energy difference between the chair–chair transition state and the chair–boat transition state for the Lewis acid cyclization and the mercuric trifluoroacetate cyclization must be very similar. Again, the crucial role of the trimethylsilyl group in controlling the high regioselectivity in the introduction of the exocyclic alkene cannot be underestimated (1–4). In a recent study of the mercuric cyclization of a range of trienes **9**, the $\Delta^{2,3}$-endocyclic compound was invariably the major product obtained (eq. [2]) (12).

[2]



(ref. 12)

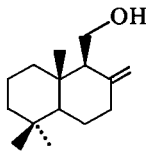
9

[3]A preliminary account of some of these results has been reported in ref. 4*a*.

[4]For details of this study see ref. 8.

[5]The *E* isomer of **3** was prepared from the *E*-enol phosphate of **2**; see ref. 15.

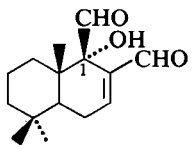
Recently the alcohol **10**, albicanol, and the corresponding acetate **7** have been isolated from a nudibranch (13). Albicanol (**10**) is also found in terrestrial sources (14). Albicanyl acetate (**7**) appears to have potent fish antifeedant activity and may well be of ecological importance in the marine environment. In the above sequence, we illustrated the conversion of the organomercurial compound **6** into albicanol (**10**) and its acetate **7**. This



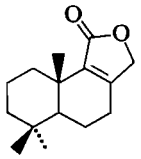
10

confirmed the expected *trans* ring fusion in the cyclized products from the triene **3**. In a similar fashion, the epimeric esters **5** were reduced to give albicanol (**10**) and *epi*-albicanol in high yield. These alcohols could be separated by column chromatography and albicanol (**10**) was obtained in 75% yield. Acetylation gave racemic albicanyl acetate (**7**) which had identical spectroscopic data to that of the natural product.[6] The racemic compound **7** from this synthesis was found to have antifeedant activity comparable to that of natural albicanol acetate, which is optically active.[7]

Warburganal (**11**) is another member of the drimane class of natural products that has attracted a great deal of interest recently. Much of this interest stems from the fact that warbuganal possesses potent insect antifeedant activity against the African army worms, *Spodoptera littoralis* and *S. exempta* (16). Difficulties are often encountered in the synthesis of the drimanic sesquiterpenes, including warbuganal, due to the variations in functionality at the C-1 and C-2 positions.[8] A similar problem has been encountered in some the syntheses of isodrimenin (**12**), which is an intermediate in one of the

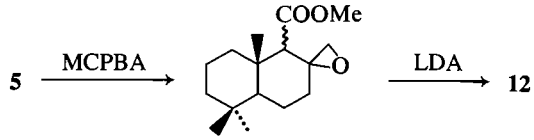


11



12

syntheses of warburganal (17). Several of the reported syntheses of isodrimenin have been characterized by a lack of regioselectivity in the introduction of the C-1 and C-2 substituents, by double bond isomerization to the $\Delta^{2,3}$ isomer, or by low yields (18).[9] A regioselective synthesis of isodrimenin (**12**) from the epimeric mixture of esters **5** is shown below. The exocyclic olefin in **5** was epoxidized using *m*-chloroperoxybenzoic acid (MCPBA) to give a mixture of all four isomers of **13** in 92% yield. The major isomer is thought to be the product obtained via α attack of MCPBA on the 1β isomer of **5**, since attack from the β direction would be hindered by the bridgehead methyl group. The epoxy esters **13** were then treated with 5 equivalents of lithium diisopropylamide in THF at −78°C, and allowed to stir at room temperature for 3 h. Isodrimenin (**12**) was isolated in 60% overall yield from **5**; the spectral data were in good agreement with that of an authentic sample.[10]



13

Experimental[11]

Methyl (2Z,6E)-7,11-dimethyl-3-[(trimethylsilyl)methyl]-2,6,10-dodecatrienoate (3)

The Grignard reagent was prepared from 1.05 g (0.080 mol) of magnesium turnings and 12.2 mL (0.088 mol) of trimethylsilylmethyl chloride in ether. To this solution was added 0.25–0.50 g (1.0–2.0 mmol) portions of anhydrous nickel(II) acetylacetonate 15.5 g (0.040 mol) of crude enol phosphate from **2** (6). The reaction mixture was heated at reflux for 4 h and further portions of 0.25–0.50 g (1.0–2.0 mmol) of catalyst were added after 0.5 and 1.5 h. Work-up of the reaction mixture gave 14.2 g of compound **3** as an orange oil. The crude product was purified by flash chromatography using petroleum ether – ethyl acetate (40:1) as eluant to yield 9.3 g (72%) of ester **3**. Preparative tlc of a small amount of this material using petroleum ether – ethyl acetate (20:1) gave **3** as a colourless liquid; bp (Kugelrohr distillation) 100°C/0.2 Torr (1 Torr = 133.3 Pa); ir ($CHCl_3$): 1700, 1620, 1435, 1245, 1160, and 855 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.05 (s, 9H), 1.60 (s, 6H), 1.70 (s, 3H), 1.97–2.25 (m, 8H), 2.41 (s, 2H), 3.65 (s, 3H), 5.00–5.22 (m, 2H), and 5.55 (s, 1H); mass spectrum, *m/z*: 322(M^+, 15), 307(19), 253(18), 186(14), 150(12), 149(87), 121(19), 119(11), 117(36), 115(10), 95(12), 93(21), 89(25), 82(46) 81(25), 79(17), 75(10), 74(10), 73(100), 69(59), 59(19), 55(14), and 53(19). *Anal.* calcd. for $C_{19}H_{34}O_2Si$: C 70.75, H 10.62; found: C 70.90, H 10.60.

Methyl trans*-decahydro-5,5,8aβ-trimethyl-2-methylene-1ξ-naphthalenecarboxylate (5)*

To a solution of 1.60 g (5.0 mmol) of the ester **3** in 120 mL of CH_2Cl_2 saturated with water at −56°C was slowly added to a solution of 1.46 mL (12.5 mmol) of $SnCl_4$ in 20 mL of CH_2Cl_2 saturated with water. The reaction mixture was stirred for 3 h at −56°C, then quenched with aqueous KF solution, and diluted with ether. The organic phase was washed four times with aqueous KF, twice with saturated $NaHCO_3$, once with saturated NaCl, and dried. The solvent was removed to give 1.40 g of crude bicyclic esters **5**. Purification of **5** by flash chromatography using petroleum ether – ethyl acetate (40:1) gave 0.76 g (61%) of a mixture of α and β isomers of **5** as a colourless liquid (1α:1β = 17:83, as determined by gc (T = 160°C)); bp Kugelrohr distillation) 108°C/0.1 Torr; ir ($CHCl_3$): 1730, 1645, and 1165 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.80 (s, 3H), 0.85 (s, 2.5H), 0.88 (s, 0.55H), 0.92 (s, 0.5H), 1.05 (s, 2.5H), 1.10–2.55 (m, 11H), 2.78 (bs, 1H), 3.65 (s, 3H), 4.63 (bs, 1H), and 4.81 (bs, 1H); mass spectrum, *m/z*: 250(M^+, 66), 235(25), 191(12), 175(24), 137(100), 136(17), 125(16), 124(23), 123(48), 121(24), 114(45), 109(30), 107(25), 105(19), 95(36), 93(20), 91(20), 82(22), 81(43), 79(22), 77(17), 69(49), 67(19), and 55(36). *Anal.* calcd. for $C_{16}H_{26}O_2$: C 76.75, H 10.47; found: C 76.58, H 10.41.

trans*-Decahydro-5,5,8aβ-trimethyl-2-methylene-1β-naphthalene-methanol (albicanol) (10)*

This compound was prepared using 0.190 g (5.0 mmol) of $LiAlH_4$ and 1.40 g of a mixture of esters **5** in ether. Work-up of the reaction

[6]We are grateful to Professor R. J. Andersen and J. Hellou for this data and for an authentic sample of albicanyl acetate.

[7]R. J. Anderson, S. W. Ayer, and M. E. LeBlanc. Unpublished observations, 1982.

[8]The numbering convention used in this paper is shown on structures **5** and **11**. This is not the usual convention for the drimane skeleton.

[9]For two recent syntheses of isodrimenin (**12**) that avoid these problems see ref. 19.

[10]We are grateful to Professor J. D. White for this data.

[11]For an outline of general procedures see ref. 4*c*.

mixture gave 1.11 g of compound **10** and the α isomer as a yellow oil (1α:1β = 17:83, as determined by gc (T = 170°C)). The crude product was purified by flash chromatography using petroleum ether – ether (2.5:1) as eluant. After six successive chromatographic separations of the mixture of isomers, 0.90 g of crude product gave 0.15 g (17%) of the α isomer and 0.67 g (75% from trimethylsilyl ester **3**) of alcohol **10**. The major alcohol **10** had spectral data identical to that of a sample of albicanol provided by Professor R. Andersen.

Methyl trans*-decahydro-6-chloromercurial-5,5,8aβ-trimethyl-2-methylene-1ξ-naphthalenecarboxylate (6)*

A sample of 0.363 g (1.13 mmol) of triene **3** was dissolved in 4 mL of dry nitromethane and cooled under N_2 to −20°C. A solution of 0.530 g (1.24 mmol) of mercuric trifluoroacetate in 1 mL of dry nitromethane was added dropwise to the above solution. The reaction mixture was stirred at −20°C for 1 h, then quenched with an aqueous solution of $NaHCO_3$ an NaCl. The mixture was extracted thoroughly with CH_2Cl_2. The combined organic extracts were washed, dried, and the solvent removed to yield 0.51 g of crude **6**. The crude product was purified by flash chromatography using petroleum ether – ether acetate (8:1) to give 0.33 g (60%) of **6** as a white solid that was characterized by its ^{1}H nmr spectrum and subsequent conversion to a mixture of **7** and **8**.

*Conversion of **6** to albicanol (**10**)*

Lithium aluminum hydride (33 mg, 0.87 mmol) was suspended in 3 mL of anhydrous ether. The above crude mercurial compound **6** (0.33 mg) was dissolved in 3 mL of anhydrous toluene and added to the hydride suspension. A second portion of 33 mg of $LiAlH_4$ was added and the mixture was refluxed for 3/4 h. Work-up of the reaction gave 0.14 g of crude product, which was purified by flash chromatography using petroleum ether – ether (3:1) to yield 95 mg of albicanol identical to that obtained above.

trans*-Decahydro-5,5,8aβ-trimethyl-2-methylene-1β-naphthalene-methyl acetate (albicanyl acetate) (7)*

A mixture of 0.16 mL (1.6 mmol) of acetic anhydride, 0.13 mL (1.6 mmol) of pyridine, and a catalytic amount of 4-dimethylaminopyridine was stirred in dry ether at room temperature. A solution of 0.33 g (1.5 mmol) of alcohol **10** in dry ether was added to the mixture, and the reaction was stirred for 2 h at room temperature. The reaction mixture was diluted with ether, washed three times with saturated $NaHCO_3$, three times with 1 *M* HCl, twice with saturated NaCl, dried, and concentrated to give 0.38 g (95%) of acetate **7**. Preparative tlc of this material using petroleum ether – ethyl acetate (10:1) gave **7** as a colourless liquid whose spectral data is in good agreement with that of an authentic sample of albicanyl acetate provided by Professor R. Andersen.

Methyl trans*-decahydro-5,5,8aβ-trimethyl-2-methylene-1ξ-naphthalenecarboxylate epoxide (13)*

To a solution of 0.678 g (2.7 mmol) of alkenes **5** in dry CH_2Cl_2 at 0°C was slowly added a solution of 0.56 g (3.4 mmol) of MCPBA in CH_2Cl_2. The reaction mixture was stirred for 2 h while allowing it to warm to room temperature, and was then diluted with ether. The organic layer was washed three times with saturated $NaHCO_3$, once with saturated NaCl, and dried. The solvent was removed to give 0.658 g of a mixture of crude epoxides, which was used without further purification in the preparation of isodrimenin. Preparative tlc of a small amount of this material using petroleum ether – ethyl acetate (20:1) gave a mixture of the four isomers of **13** as a colourless liquid; bp (Kugelrohr distillation) 100°C/0.1 Torr; ir ($CHCl_3$): 1730 and 1175 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 0.90 (s, ≈2.4H), 0.95 (s, ≈2.4H), 1.00 (s, ≈0.6H), 1.05 (s, ≈0.6H), 1.10 (s, ≈0.6H), 1.15 (s, ≈2.4H), 1.00–2.10 (m, 11H), 2.43–2.72 (m, 2H), 3.30–3.50 (bs, 1H), 3.61 (s, ≈2.1H), 3.63 (s, ≈0.35H), 3.67 (s, ≈0.35H), and 3.68 (s, ≈0.2H); mass spectrum, m/z: 266(M^+, 4), 251(12), 248(39), 236(37), 235(31), 143(28), 141(100), 137(50), 130(76), 129(43), 128(33), 123(40), 121(26), 112(25), 109(51), 107(26), 95(56), 93(30), 91(28), 82(34), 81(61), 79(33), 69(74), 67(38), 59(26), and 55(76). *Exact Mass* calcd. for $C_{16}H_{26}O_3$: 266.1882; found (ms): 266.1881.

(4,5,aα,6,7,8,9,9aβ)-Octahydro-6,6,9a-trimethyl-naphtho[1,2-c]-furan-1(3H)-one (isodrimenin) (12)

To a solution of 0.70 mL (5.0 mmol) of diisopropylamine in dry THF at 0°C was added 2.94 mL (5.0 mmol) of a 1.70 *M* solution of *n*-butyllithium in hexane. The pale yellow solution was stirred for 15 min at 0°C, cooled to −78°C, and a solution of 0.266 g (1.0 mmol) of epoxy esters **13** was added. The reaction was allowed to warm to room temperature over a period of 1 h, stirred at room temperature for 3 h, then quenched with 1 *M* HCl and diluted with ether. The organic phase was washed once with 1 *M* HCl, twice with saturated NaCl, dried, and concentrated to give 0.266 g of crude product. Purification by flash chromatography using petroleum ether – ethyl acetate (5:1) as eluant gave 0.141 g (60% from esters **5**) of **12** as a white solid. Preparative tlc of a small amount of this material using petroleum ether – ethyl acetate (6:1) gave **12** as a crystalline solid whose spectral data (^{1}H nmr, ir, ms) are in good agreement with those of the literature (19); mp 88.5–90.0°C (lit. (19) mp 89–90°C).

Acknowledgments

We are grateful to Professors Andersen and White for spectral data and to the Natural Sciences and Engineering Research Council of Canada for financial support. One of us (R. J. A.) is grateful to the Canadian Commonwealth Scholarship and Fellowship Plan for the award of a graduate scholarship.

Interdiffusion of acids and bases. HCl and NaOH in aqueous solution

DEREK G. LEAIST[1] AND BETTY WIENS
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received November 12, 1985

DEREK G. LEAIST and BETTY WIENS. Can. J. Chem. **64**, 1007 (1986).

Stokes magnetically stirred diaphragm cells have been used to measure interdiffusion of hydrochloric acid and sodium hydroxide in aqueous solution at 25°C. Expressions are developed to estimate ternary diffusion coefficients for these mixtures. The analysis reveals sharp discontinuities between the diffusion properties of HCl-rich and NaOH-rich mixtures. Although the diffusion coefficients are sensitive to concentration, accurate analytic approximations for rates of interdiffusion can be obtained by averaging coefficients along the diffusion path. When HCl and NaOH interdiffuse, proton-coupled and hydroxide-coupled diffusion operating simultaneously on opposite sides of the diffusion boundary lead to rapid diffusion of inert Na^+ and Cl^- species.

DEREK G. LEAIST and BETTY WIENS. Can. J. Chem. **64**, 1007 (1986).

On a utilisé des cellules à diaphragme de Stokes agitées d'une façon magnétique pour mesurer l'interdiffusion de l'acide chlorhydrique et de l'hydroxyde de sodium dans des solutions aqueuses à 25°C. On a développé des expressions mathématiques pour évaluer les coefficients de diffusion ternaire pour ces mélanges. L'analyse révèle l'existence de discontinuités marquées entre les propriétés de diffusion de mélanges riches soit en HCl ou en NaOH. Même si les coefficients de diffusion sont sensibles à la concentration, on peut obtenir des approximations analytiques assez précises pour les vitesses d'interdiffusion si l'on fait des moyennes des coefficients le long du chemin de diffusion. Lorsqu'il se produit de l'interdiffusion du HCl et du NaOH, des diffusions liées soit au proton ou à l'hydroxyde qui opèrent simultanément de chaque côté de la frontière de diffusion provoquent la diffusion rapide d'espèces Na^+ et Cl^- inertes.

[Traduit par la revue]

1. Introduction

Interdiffusion of acids and bases occurs in many important absorption, extraction, and leaching operations. Transport in these and other reactive electrolyte mixtures is usually described by solving the Nernst–Planck equations (1, 2).

$$[1] \qquad \partial c_i/\partial t = D_i\nabla^2 c_i - (F/RT)z_iD_i\nabla(c_iE) + r_i$$

for the concentrations c_i of each diffusing species. Reaction rates per unit volume, r_i, are included for species produced or consumed by chemical reactions. The diffusion-induced electric field (E) couples transport of charged species. As a result of these complications, Nernst–Planck equations are difficult to solve. Solutions are usually obtained numerically by finite difference approximations (3, 4).

This research was undertaken to test a simpler treatment of acid–base diffusion, multicomponent Fick equations (5, 6)

$$[2] \qquad \partial C_i/\partial t = \sum_{k=1}^{N} \nabla(D_{ik}\nabla C_k)$$

which are phrased in terms of total concentrations C_i of neutral electrolyte components (such as HCl and NaOH) rather than concentrations c_i of charged species (such as H^+, Cl^-, Na^+, and OH^-). This approach offers several advantages:

(*a*) Fewer differential equations are required.

(*b*) Because total (reacted plus unreacted) components are conserved, reaction rate terms r_i can be dropped.

(*c*) Since the components are electrically neutral, it is not necessary to evaluate the electric field. (The effects of E are included implicitly in the values of the multicomponent diffusion coefficients.)

(*d*) If the diffusion coefficients are constant, or if suitable average coefficients can be defined, eq. [2] simplifies to

$$[3] \qquad \partial C_i/\partial t = \sum_{k=1}^{N} D_{ik}\nabla^2 C_k$$

for which analytic solutions exist.

To illustrate these ideas, we develop expressions to estimate multicomponent diffusion coefficients for aqueous hydrochloric acid + sodium hydroxide mixtures. Rates of diffusion for these mixtures predicted by multicomponent diffusion equations are then compared with rates measured by diaphragm cell experiments.

2. Experimental

Diffusion was measured by the Stokes diaphragm cell method (7). In these experiments solute diffuses between upper and lower magnetically stirred cell compartments through the pores of a sintered glass disc. The rate of diffusion is determined from changes in solute concentration after the cells are run for a timed interval.

Fine porosity pyrex diaphragms (3 cm diameter, 0.2 cm thick, mean pore diameter 5×10^{-4} cm) were used in this work. Cell compartment volumes (25–35 cm^3) of each cell were matched to within 0.5%. Each compartment was fitted with a greaseless teflon stopcock and a glass-coated iron stirrer which was rotated once per second by external magnets. Each cell was calibrated at frequent intervals by diffusing 0.5 *M* KCl into pure water at 25°C. Cell constants β (0.16–0.20 cm^{-2}) were computed from the relation

$$[4] \qquad \Delta c(t) = \Delta c(0)\exp(-\beta\bar{D}t)$$

where $\Delta c(t)$ is the measured difference in KCl concentration between upper and lower compartments at time t. The integral diffusion coefficient of aqueous KCl ($\bar{D}$) was evaluated by interpolation of the data reported by Stokes (8).

At the start of each experiment the lower compartment was filled with a binary solution of aqueous HCl or NaOH, whichever was denser. The upper compartment was filled with a binary solution of the other component. The cells were placed in a thermostat at 25 ± 0.01°C and stirred for about 2 h to establish steady state diffusion through the diaphragms. The cell compartments were rinsed, refilled with fresh solution, then returned to the thermostat for the duration of the run (0.2–5 days). Initial and final solute concentrations were determined

[1]To whom all correspondence should be addressed.

by potentiometric titration against silver nitrate and standardized HCl or NaOH.

Chemical reaction of HCl and NaOH produces heat. To maintain isothermal conditions during a run, dilute solutions with small heats of reaction were used. The rate of heat production in each diaphragm was never more than 1 mW (considerably less near the end of a run). We estimate the maximum increase in diaphragm temperature was only 0.001°C.

3. Theory

What is the minimum number of solute flows that must be specified to give a complete macroscopic description of diffusion in an isothermal electrolyte mixture containing s different solute species which undergo e chemical reactions? Because electrolytic reactions are rapid, e chemical equilibria exist locally. Electroneutrality provides one additional restriction. Therefore, only $N = s - e - 1$ solute concentrations are independent (9). We may choose N neutral solute components and describe diffusion of these components by multicomponent Fick equation [2].

Multicomponent diffusion equations, though simpler than Nernst–Planck equations, are of little practical use unless values of multicomponent diffusion coefficients D_{ik} are known. Fortunately, values of D_{ik} can be estimated by taking weighted averages of the diffusion coefficients D_i of the various solute species (9–12). This well-established procedure is illustrated in the Appendix for aqueous hydrochloric acid + sodium hydroxide mixtures.

Hydrochloric acid(1) + sodium hydroxide(2) + water (s = 4, e = 1, N = 2)

Four different solute species (H^+, Cl^-, Na^+, OH^-) are transported in aqueous HCl + NaOH mixtures. However, the conditions of chemical equilibrium ($H_2O \rightleftharpoons H^+ + OH^-$) and electroneutrality reduce the number of independent solute flows to only two. Therefore, a concise but complete description of interdiffusion of HCl and NaOH is given by ternary diffusion equations

$$[5a] \quad \partial C_1/\partial t = \nabla(D_{11}\nabla C_1) + \nabla(D_{12}\nabla C_2)$$

$$[5b] \quad \partial C_2/\partial t = \nabla(D_{21}\nabla C_1) + \nabla(D_{22}\nabla C_2)$$

where C_1 and C_2 denote total concentrations of HCl(1) and NaOH(2) components in moles per unit volume. Molar flux densities of the components are given by

$$[6a] \quad -J_1 = D_{11}\nabla C_1 + D_{12}\nabla C_2$$

$$[6b] \quad -J_2 = D_{21}\nabla C_1 + D_{22}\nabla C_2$$

Expressions developed in the Appendix together with the species diffusion coefficients listed in Table 1 were used to calculate ternary diffusion coefficients for aqueous HCl + NaOH mixtures at 25°C. The results are plotted against solute fraction of HCl (designated by X_1) in Fig. 1.

When HCl and NaOH interdiffuse, proton-coupled transport and hydroxide-coupled transport operate simultaneously on opposite sides of the diffusion boundary. This leads to remarkable diffusion properties, such as rapidly varying diffusion coefficients, large cross terms, and sharp discontinuities in diffusion properties. As expected for a strong electrolyte mixture (12), values of D_{ik} are sensitive to the ratio of solute concentrations, but not to total solute concentration.

The diffusivity of HCl in aqueous NaOH solutions (D_{11}) takes values from 2.0×10^{-9} to 6.3×10^{-9} m^2 s^{-1}. As the solute fraction of HCl approaches unity, D_{11} approaches the binary diffusivity of aqueous HCl, about 3.0×10^{-9} m^2 s^{-1}. In pure aqueous HCl, Cl^- and highly mobile H^+ diffuse at the same speed; the diffusion-induced electric field slows down H^+ and speeds up Cl^-, thereby preventing charge separation. If NaOH is added, it reacts with HCl to form NaCl. In the resulting ternary mixture, H^+ can diffuse more rapidly than Cl^-. Charge separation is avoided because the electric field established by the HCl gradient generates counterflow of Na^+. This mechanism increases the diffusivity of HCl and leads to large negative values for D_{21}, the cross coefficient that measures coupled flow of NaOH along the HCl gradient. Because the HCl gradient is unable to generate flow of NaOH in solutions free of NaOH, $D_{21} \rightarrow 0$ as $X_1 \rightarrow 1$.

TABLE 1. Species diffusion coefficients at 25°C[a]

Species	D_i (10^{-9} m^2 s^{-1})
H^+	9.31
Cl^-	2.03
Na^+	1.33
OH^-	5.30

[a]Estimated from published limiting ionic molar conductances (13) λ^0_i using the relation $D_i = RT\lambda^0_i F^2$. F is the Faraday, 96 487 C mol^{-1}.

There are sharp spikes in the diffusion coefficients near $X_1 = 0.5$. For example, D_{11} reaches a maximum value of 6.3×10^{-9} m^2 s^{-1} at solute fractions of HCl slightly above 0.5 where all but a trace of HCl is neutralized by NaOH. At these compositions, transport of HCl corresponds to tracer diffusion of H^+ in supporting NaCl solutions. Therefore, the HCl gradient ∇C_1 produces flow $-D_{H^+}\nabla C_1$ of H^+ with tracer diffusivity $D_{H^+} = 9.3 \times 10^{-9}$ m^2 s^{-1}. The HCl gradient also drives co-current flow $-D_{11}\nabla C_1$ of Cl^- and counter-current flow $-D_{21}\nabla C_1$ of Na^+. Electroneutrality requires that $D_{11} - D_{21} = D_{H^+}$ at $X_1 = 0.5^+$.

At solute fractions of HCl below 0.5, HCl reacts completely with excess NaOH. The disappearance of free H^+ leads to a sudden drop in the diffusivity of the HCl component. In this region the HCl gradient ∇C_1 produces an equal but opposite gradient $-\nabla C_1$ in free OH^-. At HCl solute fractions just below 0.5, trace amounts of OH^- diffuse in supporting NaCl solutions. In this case the Cl^- flux $-D_{11}\nabla C_1$ and Na^+ flux $-D_{21}\nabla C_1$ are balanced by the tracer OH^- flux $D_{OH^-}\nabla C_1$. Hence $D_{11} - D_{21} = D_{OH^-} = 5.3 \times 10^{-9}$ m^2 at $X_1 = 0.5^-$. In the limiting case of a trace of HCl in aqueous NaOH, D_{11} approaches the tracer diffusion coefficient of Cl^-, about 2.0×10^{-9} m^2 s^{-1}.

The diffusivity of NaOH in aqueous HCl solutions, D_{22}, ranges from 1.3×10^{-9} to 4.3×10^{-9} m^2 s^{-1}. At low solute fractions of HCl, values of D_{22} are close to the binary diffusivity of aqueous NaOH, about 2.0×10^{-9} m^{-2} s^{-1}. As more HCl is added, D_{22} increases. It reaches the value 2.8×10^{-9} m^2 s^{-1} just below $X_1 = 0.5$. At $X_1 = 0.5^-$, electroneutrality requires that $D_{22} - D_{12} = D_{OH^-}$.

In HCl-rich mixtures, proton-coupled transport of Na^+ leads to D_{22} values as large as 4.3×10^{-9} m^2 s^{-1}. A gradient in concentration of NaOH in an otherwise uniform solution of excess HCl establishes an equal but opposite gradient in free H^+. As H^+ diffuses rapidly towards the zone of higher NaOH concentration, counterflow of Na^+ is generated to prevent

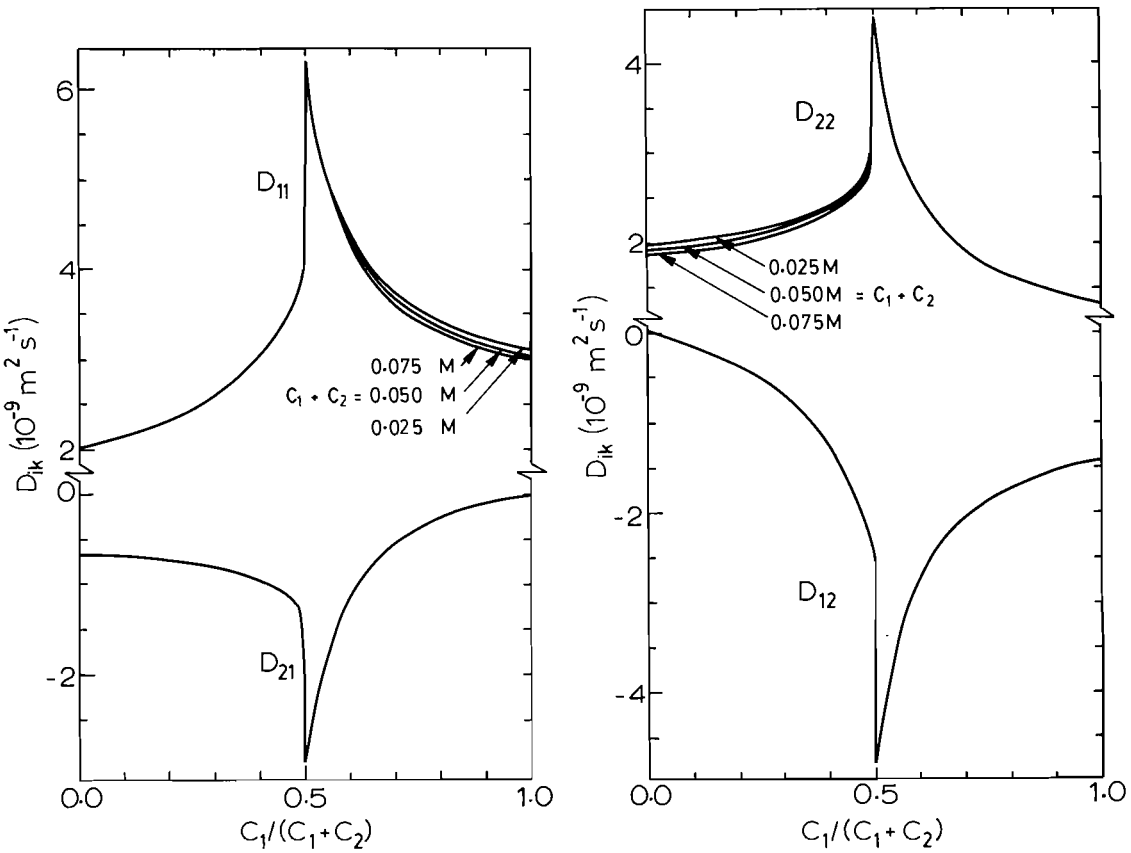

FIG. 1. Ternary diffusion coefficients at 25°C for aqueous HCl(1) + NaOH(2) plotted against HCl solute fraction $X_1 = C_1/(C_1 + C_2)$ for total solute concentrations $C_1 + C_2$ equal to 0.025, 0.050, and 0.075 M. Activity coefficient terms were included in the calculations.

charge separation. At $X_1 = 0.5^+$, $D_{22} - D_{12} = D_{H^+}$. In the limit $X_1 \rightarrow 1$, D_{22} equals the tracer diffusion coefficient of Na^+ in supporting HCl solutions, about $1.3 \times 10^{-9}\,m^2\,s^{-1}$.

4. Results and discussion

Figure 2 shows diaphragm cell results, for diffusion of 0.025, 0.050, and 0.075 M HCl into 0.075, 0.050, and 0.025 M NaOH, respectively. Component concentration differences across the cell diaphragms are plotted against βt.

The data shown in Fig. 2 can be used to calculate the apparent binary diffusion coefficients.

$$[7] \qquad D_{ai} = -\mathrm{d}\ln \Delta C_i/\mathrm{d}(\beta t)$$

for the HCl(1) and NaOH(2) components. When 0.075 M HCl diffuses into 0.025 M NaOH, for example, the initial slope of ΔC_1 versus βt corresponds to an apparent diffusivity of HCl equal to $8 \times 10^{-9}\ m^2\ s^{-1}$, an exceptionally large apparent diffusivity. In this case the HCl component diffuses rapidly because the main flow of HCl ($-D_{11}\nabla C_1$) is reinforced by a large co-current coupled flow of HCl ($-D_{12}\nabla C_2$) generated by the NaOH gradient. As further evidence for strongly coupled diffusion, note that the concentration difference for the HCl component can change sign. When this happens, the cell compartment that held no HCl at the start of the experiment now contains more HCl than the compartment which initially held all of the HCl. Thus HCl has diffused "up" its concentration gradient.

If the diffusion coefficients are constant, integration of the ternary diffusion equations gives simple analytic expressions (14)

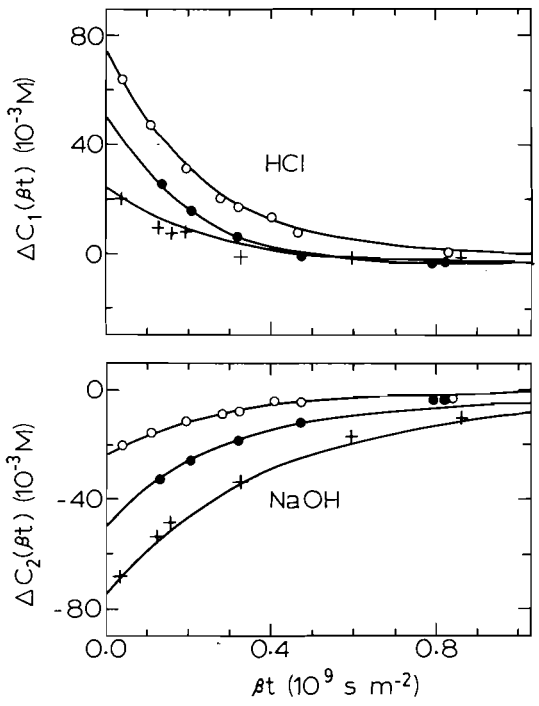

FIG. 2. Comparison of experimental and calculated concentration differences between upper and lower cell compartments for inter-diffusion of HCl(1) and NaOH(2) compartments: +, diffusion of 0.025 M HCl into 0.075 M NaOH; ●, 0.05 M HCl into 0.05 M NaOH; ○, 0.075 M HCl into 0.025 M NaOH. The plotted curves give concentration differences calculated from eqs. [8] using integral diffusion coefficients listed in Table 1.

TABLE 2. Integral diffusion coefficients for aqueous HCl(1) + NaOH(2)[a]

$\Delta C_1(0)$	$\Delta C_2(0)$	$\bar{X}_{1L}$	$\bar{X}_{1U}$	$\bar{D}_{11}$	$\bar{D}_{12}$	$\bar{D}_{21}$	$\bar{D}_{22}$
0.025	−0.075	0.50	0.10	2.59	−0.68	−0.83	2.19
0.050	−0.050	0.75	0.25	3.64	−1.93	−1.05	2.45
0.075	−0.025	0.10	0.50	3.75	−2.14	−0.63	2.00

[a] $\Delta C_i(0)$ and $\bar{D}_{ik}$ in units of M and 10^{-9} m^2 s^{-1}, respectively.

$$[8a] \quad \Delta C_1(t)/\Delta C_1(0) = A_1 \exp(-\beta D)^{(1)}t) + (1 - A_1)\exp(-\beta D^{(2)}t)$$

$$[8b] \quad \Delta C_2(t)/\Delta C_2(0) = (1 - A_2)\exp(-\beta D^{(1)}t) + A_2 \exp(-\beta D^{(2)}t)$$

for the concentration differences across the cell diaphragms. $D^{(1)}$ and $D^{(2)}$ denote eigenvalues of the diffusion coefficients matrix

$$[9a] \quad D^{(1)} = [D_{11} + D_{22} + (D_{11} - D_{22})(1 + 4D_{12}D_{21}/(D_{11} - D_{22})^2)^{1/2}]/2$$

$$[9b] \quad D^{(2)} = [D_{11} + D_{22} - (D_{11} - D_{22})(1 + 4D_{12}D_{21}/(D_{11} - D_{22})^2)^{1/2}]/2$$

Constants A_i are given by

$$[10a] \quad A_1 = [D_{11} - D^{(2)} + D_{12}\Delta C_2(0)/\Delta C_1(0)]/(D^{(1)} - D^{(2)})$$

$$[10b] \quad A_2 = [D_{22} - D^{(1)} + D_{21}\Delta C_1(0)/\Delta C_2(0)]/(D^{(2)} - D^{(1)})$$

Unhappily, diffusion coefficients for HCl + NaOH mixtures change by several hundred percent and pass through sharp discontinuities along the diffusion path. This rules out any hope of obtaining exact analytic descriptions of diffusion. However, it is helpful to define mean integral diffusion coefficients (15)

$$[11] \quad \bar{D}_{ik} = (\bar{X}_{1L} - \bar{X}_{1U})^{-1} \int_{\bar{X}_{1L}}^{\bar{X}_{1U}} D_{ik}\, dX_1$$

where $\bar{X}_{1L}$ and $\bar{X}_{1U}$ denote mean solute fractions in the lower (L) and upper (U) compartments, i.e., $\bar{X}_{1U} = [X_{1U}(t=0) + X_{1U}(t=\infty)]/2$. Values of $\bar{D}_{ik}$ calculated in this manner are listed in Table 2. Upon substitution of mean integral diffusion coefficients into eqs. [8], one obtains the calculated values for $\Delta C_1(t)$ and $\Delta C_2(t)$ given by the solid curves in Fig. 2. Experimental and calculated concentration differences are in close agreement. This comparison suggests that the calculated ternary diffusion coefficients correctly describe interdiffusion of HCl and NaOH. The calculated concentration differences corroborate negative experimental values for ΔC_1.

In conclusion, multicomponent diffusion equations provide accurate analytic descriptions of interdiffusion of acids and bases, a convenient alternative to finite difference approximations to the Nernst–Planck equations. The multicomponent analysis also provides direct information about the diffusivity of each electrolyte and the importance of coupled transport of other electrolytes in the mixture.

Appendix

The purpose of this appendix is to derive expressions for estimating ternary diffusion coefficients for aqueous HCl + NaOH mixtures. We will use the identity (5, 6)

$$[A1] \quad D_{ik} = \sum_{m=1}^{2} L_{im}\partial\mu_m/\partial C_k$$

where μ_m are the chemical potentials of the components. L_{im} are Onsager transport coefficients defined by flow equations for the components

$$[A2] \quad -J_i = \sum_{m=1}^{2} L_{im}\nabla\mu_m$$

According to the Nernst–Planck approximation, the flow of each species is proportional to the gradient in its electrochemical potential

$$[A3] \quad -j_i = l_{ii}\nabla\tilde{\mu}_i$$

where $l_{ii} = c_iD_i/RT$. R is the gas constant and T is the temperature. We number the solute species in aqueous HCl(1) + NaOH(2) as follows: $Cl^- = 1$, $Na^+ = 2$, $H^+ = 3$, and $OH^- = 4$.

The flux of the HCl component equals the flux of Cl^-. Also, the flux of the NaOH component equals the flux of Na^+.

$$[A4] \quad J_1(HCl) = j_1(Cl^-)$$

$$[A5] \quad J_2(NaOH) = j_2(Na^+)$$

The gradients in chemical potential of each component equals the sum of the gradients in electrochemical potential of the constituent species

$$[A6] \quad \nabla\mu_1(HCl) = \nabla\tilde{\mu}_1(Cl^-) + \nabla\tilde{\mu}_3(H^+)$$

$$[A7] \quad \nabla\mu_2(NaOH) = \nabla\tilde{\mu}_2(Na^+) + \nabla\tilde{\mu}_4(OH^-)$$

Electroneutrality and local chemical equilibrium of H^+ and OH^- provide the relations

$$[A8] \quad j_1(Cl^-) + j_4(OH^-) = j_2(Na^+) + j_3(H^+)$$

$$[A9] \quad \nabla\tilde{\mu}_3 + \nabla\tilde{\mu}_4 = 0$$

Substitution of eqs. [A3]–[A9] into eq. [A2] gives

[A10] $RTL_{11} = c_1D_1(c_2D_2 + c_3D_3 + c_4D_4)/A$

[A11] $RTL_{12} = RTL_{21} = c_1D_1c_2D_2/A$

[A12] $RTL_{22} = c_2D_2(c_1D_1 + c_3D_3 + c_4D_4)/A$

where A stands for

[A13] $A = c_1D_1 + c_2D_2 + c_3D_3 + c_4D_4$

The component chemical potentials are given by the expressions

[A14] $\mu_1(\mathrm{HCl}) = \mu_1^0(\mathrm{HCl}) + RT \ln [c_3(\mathrm{H^+})c_1(\mathrm{Cl^-})y_3y_1]$

[A15] $\mu_2(\mathrm{NaOH}) = \mu_2^0(\mathrm{NaOH}) + RT \ln [c_2(\mathrm{Na^+})c_4(\mathrm{OH^-})y_2y_4]$

in which y_i are ionic activity coefficients (molar concentration scale). Concentrations of H^+ and OH^- are related by

[A16] $K_w = c_3(\mathrm{H^+})c_4(\mathrm{OH^-})y_3y_4$

where K_w is the dissociation constant for water. We will assume that the activity coefficients are given by the Debye–Hückel equation (16)

[A17] $\ln y_i = -S_f z_i^2 I^{1/2}/(1 + I^{1/2})$

where I is the ionic strength and $S_f = 1.17$ for aqueous solutions at 25°C.

Excess HCl ($C_1 > C_2$)

For mixtures containing excess HCl: $c_1(\mathrm{Cl^-}) = C_1$, $c_2(\mathrm{Na^+}) = C_2$, $c_3(\mathrm{H^+}) = C_1 - C_2$ and $c_4(\mathrm{OH^-}) = K_w/(C_1 - C_2)y_3y_4 \cong 0$. Differentiation provides

[A18] $(RT)^{-1}\partial\mu_1/\partial C_1 = C_1^{-1} + (C_1 - C_2)^{-1} - S_f C_1^{1/2}/(1 + C_1^{1/2})^2$

[A19] $(RT)^{-1}\partial\mu_1/\partial C_2 = (RT)^{-1}\partial\mu_2/\partial C_1 = (C_2 - C_1)^{-1}$

[A20] $(RT)^{-1}\partial\mu_2/\partial C_2 = C_2^{-1} + (C_1 - C_2)^{-1}$

Finally, expressions for the ternary diffusion coefficients may be obtained by substituion of eqs. [A10]–[A12] and [A18]–[A20] into eq. [A1]. If activity coefficient terms are omitted, the expressions for D_{ik} simplify considerably,

[A21] $D_{11} = t_1D_3 + (1 - t_1)D_1$

[A22] $D_{12} = t_1(D_2 - D_3)$

[A23] $D_{21} = t_2(D_1 - D_3)$

[A24] $D_{22} = t_2D_3 + (1 - t_2)D_2$

Here t_i refers to the transference number of ion i defined by

[A25] $t_i = c_iz_i^2D_i \Big/ \sum_{k=1}^{4} c_kz_k^2D_k$

Excess NaOH ($C_2 > C_1$)

When excess NaOH is present, $c_1(\mathrm{Cl^-}) = C_1$, $c_2(\mathrm{Na^+}) = C_2$ as before, but $c_4(\mathrm{OH^-}) = C_2 - C_1$ and $c_3(\mathrm{H^+}) = K_w/(C_2 - C_1)y_3y_4 \cong 0$. Expressions for derivatives $\partial\mu_m/\partial C_k$ for these solutions can be obtained by interchanging subscripts 1 and 2 in eqs. [A18] and [A19].

If activity coefficient corrections are dropped, we obtain

[A26] $D_{11} = t_1D_4 + (1 - t_1)D_1$

[A27] $D_{12} = t_1(D_2 - D_4)$

[A28] $D_{21} = t_2(D_1 - D_4)$

[A29] $D_{22} = t_2D_4 + (1 - t_2)D_2$

Polarized overtone-combination bands in the near-infrared spectra of $K_2SnCl_4 \cdot H_2O$ and $KSnCl_3 \cdot H_2O$ at cryogenic temperatures

Received November 4, 1985

IAN M. WALKER and PAUL J. MCCARTHY. Can. J. Chem. **64**, 1012 (1986).

The near-infrared (nir) spectra of $K_2SnCl_4 \cdot H_2O$ and $KSnCl_3 \cdot H_2O$ contain many highly polarized absorptions, due largely, if not completely, to combinations of vibrations of the water molecules in the crystals. The polarization of the absorptions can be related to the site symmetry of the water molecule. In $K_2SnCl_4 \cdot H_2O$ combination bands based on rocking, wagging, and twisting librations are seen, from which it is possible to definitively identify the rocking libration. The librations are much less in evidence in the spectra of $KSnCl_3 \cdot H_2O$. Sets of normal mode anharmonicity constants have been calculated from the energies of the absorptions.

IAN M. WALKER et PAUL J. MCCARTHY. Can. J. Chem. **64**, 1012 (1986).

Les spectres du $K_2SnCl_4 \cdot H_2O$ et du $KSnCl_3 \cdot H_2O$ dans le proche infrarouge (pir) contiennent plusieurs absorptions hautement polarisées qui sont dues principalement, si non uniquement, à des combinaisons de vibrations de molécules d'eau dans les cristaux. La polarisation des absorptions peut être reliée au site de symétrie de la molécule d'eau. Dans le $K_2SnCl_4 \cdot H_2O$, on peut observer des bandes de combinaison qui sont basées sur des librations de rotation, de balancement et de torsion; parmi celles-ci, on peut identifier d'une façon définitive la libration de rotation. Les librations sont beaucoup moins évidentes dans le spectre de $KSnCl_3 \cdot H_2O$. En se basant sur les énergies des absorptions, on a calculé des ensembles de constantes d'anharmonicité pour le mode normal.

[Traduit par la revue]

Introduction

The near-infrared (nir) spectra of water, alcohols, amides, etc., have proved most useful in the study of hydrogen bonding (1–3). In many cases, however, the vibrational overtone-combination features which appear in this region show severe broadening and overlap. This is a consequence of extensive coupling between the individual oscillators in concentrated media. This is especially true in ice, even at liquid nitrogen temperature (4).

In a recent article (5) we have shown that water overtone-combination bands in $M_2[FeCl_5H_2O]$ (M = Cs, K) are quite sharp at cryogenic temperatures. Since these nir features are considerably weaker than the fundamental bands, relatively thick (0.5 mm), oriented, single crystal samples may be used. The use of polarized light in this region has also revealed that these overtone-combination bands are excited only when the electric vector of the radiation is oriented along specific crystal directions. So far, our observations in this region have confirmed the notion that water molecules in salt hydrates are isolated from one another, and that they interact only modestly with neighboring halide ions via hydrogen bonding.

In this report we consider two further instances of this kind of salt hydrate, $K_2SnCl_4 \cdot H_2O$ and $KSnCl_3 \cdot H_2O$. The unusually high energies of the stretch fundamentals in these salts indicate that hydrogen bonding is considerably weaker than that encountered in $Cs_2[FeCl_5H_2O]$ (5). The spectrum of $K_2SnCl_4 \cdot H_2O$ in particular is remarkable for the number, sharpness, and distinct polarization of its bands. These features have enabled us to show that there is a definite relationship between the site symmetry of the water and the polarization of the spectrum, and to determine, possibly for the first time, values for the anharmonicities involving the librational modes.

Experimental

Crystal preparation

$K_2SnCl_4 \cdot H_2O$

Large needles of this substance appear when a solution containing 1 mol $SnCl_2$ and 2.5 mol KCl in 1 *M* HCl is evaporated under a stream of nitrogen. The crystals are for the most part cloudy in appearance, and examination under a microscope reveals an opaque band concentrated near the center of the crystal running along the needle axis. To obtain single-crystal spectra the needles must be mounted so that light passes through the clearer regions near the crystal edges.

$KSnCl_3 \cdot H_2O$

Clear transparent needles of this substance are obtained when a solution containing 1 mol $SnCl_2$ and 0.8 mol KCl in 1 *M* HCl is evaporated under nitrogen.

Both substances were dried *in vacuo*, and were characterized by ir spectroscopy using the highly distinctive water stretching vibrations reported in the literature (6, 7) as the criterion of purity.

Spectral data

Single crystals were mounted on the optical probe of a Displex cryogenic refrigerator and cooled to 10 K. Spectra were obtained on a Varian 2300 spectrophotometer. Polarized light, provided by Glan-Thompson prisms, was oriented along the extinction directions, which lie parallel and perpendicular to the needle axis in both cases.

Results and discussion

Structural data

The structure of $K_2SnCl_4 \cdot H_2O$ was solved originally in the space group *Pbnm* (D_{2h}^{16}, #62) with four formula units per unit cell (8). Subsequent authors (6) have transformed the data to the standard setting, *Pnma*, which we will use in our discussion. All atoms except hydrogen appear in the X-ray structure; this consists of trigonal pyramidal $SnCl_3^-$ units, K^+ ions, Cl^- ions, and water. The water is not attached to tin, but

rather, is weakly coordinated to potassium. There is a crystallographic plane of symmetry normal to the b axis, and the oxygen of water, two of the four chloride ions, and the tin atom all lie in this plane. The proton positions have been located by nmr studies (9, 10). One proton, H(1), is involved in a normal quasi-linear hydrogen bond to chloride ion, Cl(3), lying in the symmetry plane, while the other proton, H(2), forms a bifurcated hydrogen bond to two chloride ions, Cl(2), lying an equal distance above and below this symmetry plane. Thus the water molecule as a whole lies in the symmetry plane, the site symmetry being C_s. Deuteration studies on the ir fundamentals of $K_2SnCl_4 \cdot H_2O$ are entirely consistent with the presence of only one type of water in the unit cell (6). A list of all atomic coordinates has been reported (6).

The growth habit of $K_2SnCl_4 \cdot H_2O$ is such that needle growth takes place preferentially along the crystal b direction. Therefore a spectrum with electric vector E parallel to the needle axis ($E \| b$) excites vibrations which are normal to the plane of the water molecule (symmetry A''). These are the twisting (ρ_t) and the wagging (ρ_w) vibrations. The $E \perp b$ spectrum will contain the vibrations which take place in the plane of the water molecule (symmetry A'). These are the two OH stretches, the HOH bend, and the rocking (ρ_r) vibration. Thus in the reduction from C_{2v} (the symmetry of free water) to C_s, A_1 and B_1 become A', while A_2 and B_2 become A''.

The details of the structure of $KSnCl_3 \cdot H_2O$ have not been fully elucidated. The crystals are known to be orthorhombic, with diffraction symmetry *mmm* (7). Deuteration studies on the ir fundamental bands indicate that there is more than one water site in this lattice (7). These differences also appear in the ir stretch fundamentals of the fully protiated materials at low temperatures. From the general similarity of the nir spectra of the two compounds, however, we can conclude that the waters in $KSnCl_3 \cdot H_2O$ also lie in planes perpendicular to the needle axis.

Infrared fundamental spectra

The ir fundamentals for both crystals are listed in Table 1. In these compounds there is no distinction between the symmetric and antisymmetric stretches. We will, however, use these as convenient labels in the ensuing discussion. Three libration bands are found in the ir spectrum of $K_2SnCl_4 \cdot H_2O$; in environments of higher symmetry the ir spectrum of water can show only two such bands.

Overtone-combination spectra

It is well known that when water is engaged in hydrogen bonding the OH stretches are lowered and the HOH bend is raised in frequency (11). The stronger the hydrogen bonding the greater the effect. The frequencies of the fundamentals in $K_2SnCl_4 \cdot H_2O$ and $KSnCl_3 \cdot H_2O$ indicate that hydrogen bonding is weak in both, but weaker in the latter. Therefore, since almost all the combination bands contain at least one stretch, comparable bands in the spectra of the two compounds will in general be at higher energy in $KSnCl_3 \cdot H_2O$.

If one lists the normal vibrations of a crystal such as $K_2SnCl_4 \cdot H_2O$, then calculates the energy of all combinations which fall in the region 3800 – 12 000 cm^{-1}, then compares this long list with the observed spectrum, one reaches the conclusion that only a small fraction of the possible bands have appreciable intensity. The following general guidelines are useful for assigning bands in the water overtone-combination region:

(*a*) Binary combinations are in general considerably more intense than ternary combinations, while quaternary combinations are rarely seen unambiguously.

(*b*) The intensities of binary combinations usually fall off with increasing energy. This suggests that combination bands steal intensity from the fundamentals. The intensity-stealing mechanism appears to obey a $1/\Delta E$ law, where ΔE is the separation of the combination level from the stretch fundamentals around 3500 cm^{-1}.

(*c*) The fundamentals which combine to give observable bands must involve some significant motion of the water molecule. The commonest features are built on stretches, bends, and librations of water. We have been unable to find evidence that metal–oxygen or skeletal vibrations of metal chromophores contribute to the nir spectra of water in complexes. Translational motion of noncoordinated water could contribute to combination bands. There are, however, no instances where water translations have been unambiguously identified.

(*d*) Factor group splittings do not appear to be a major consideration in crystals where the water molecules are isolated from one another by several bonds. Therefore, for the compounds described here, our analysis will be based on site symmetries alone.

(*e*) The energy of a combination band will be close to, but usually somewhat less than, the sum of the energies of the fundamentals involved in it. This lowering is due to the varying degrees of anharmonicity in the combination bands.

(*f*) Finally, the normal electric dipole selection rules apply to the nir bands. The symmetry of a combination state is simply the direct product of the symmetries of the fundamentals of which it is composed.

TABLE 1. Fundamental bands in the infrared spectra of $K_2SnCl_4 \cdot H_2O$ and $KSnCl_3 \cdot H_2O$ at 113 K[a]

Mode	$K_2SnCl_4 \cdot H_2O$[b]	$KSnCl_3 \cdot H_2O$[c]

ν_3 (ν_a)	3543	3632
ν_4 (L_1)	530	427
ν_5 (L_2)	458	—
ν_6 (L_3)	427	—

[a]All data are in cm^{-1}. Symbol L refers to libration.
[b]Data from ref. 6.
[c]Data from ref. 7.

The spectra of the two compounds in the nir region are shown in Figs. 1 and 2. The great range of intensities should be noted. The weakest features near 10 000 cm^{-1} (not shown in the figures) can barely be seen above the background in clear, thick crystals. These features are about 0.002–0.003 times as intense as the strongest bands near 4000 cm^{-1}.

For $KSnCl_3 \cdot H_2O$ the polarizations are labeled 1 and 2, since the structure of the crystal is not known. The similarity of the spectra with those of $K_2SnCl_4 \cdot H_2O$ strongly suggest, however, that polarizations (pol.) 1 and 2 are perpendicular and parallel, respectively, to a unique axis. A general difference between the two compounds is this: the nir bands containing one or more librational quanta are stronger, sharper, and more numerous in the spectra of $K_2SnCl_4 \cdot H_2O$. This is related in part to the fact that this compound shows three librational bands in its ir fundamental spectrum while $KSnCl_3 \cdot H_2O$ shows only one (Table 1). Bands involving only stretches and bends have

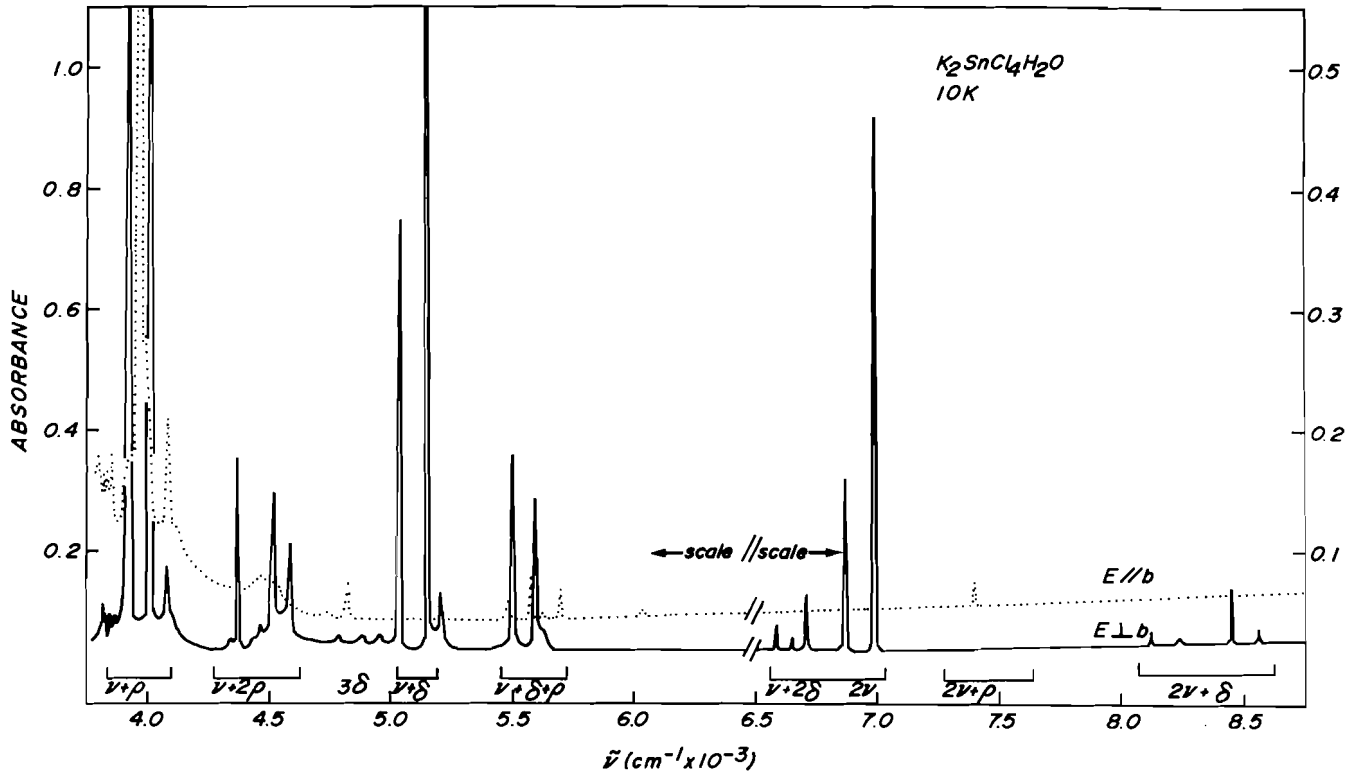

FIG. 1. Near-infrared spectra of single crystals of $K_2SnCl_4 \cdot H_2O$ at 10 K. The electric vector is oriented parallel (dotted line) and perpendicular (solid line) to the needle *b* axis. Rough assignments are shown beneath each band group. Band energies are listed in Table 2.

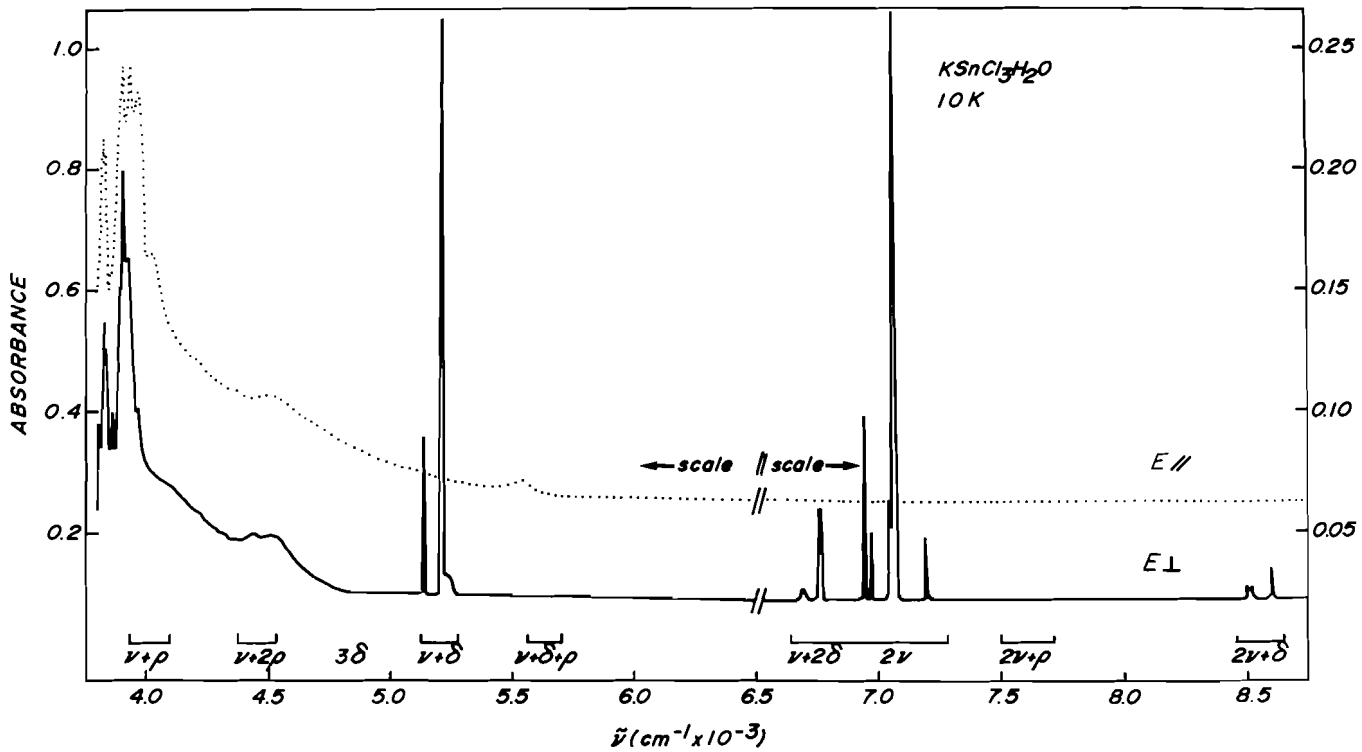

FIG. 2. Near-infrared spectra of single crystals of $KSnCl_3 \cdot H_2O$ at 10 K. The electric vector is oriented parallel (dotted line, pol. 2) and perpendicular (solid line, pol. 1) to the needle axis. Rough assignments are shown beneath each band group. Band energies are listed in Table 2.

similar intensity and sharpness in the two compounds. In Figs. 1 and 2 the general assignments for the various groups of bands are indicated. These are based on considerations of the symmetry, energy, and intensity of the bands. Table 2 lists the energies of all reproducible features of the spectra of both compounds (3800–9000 cm^{-1}) together with band assignments and calculated energies for most bands. The band positions are estimated to be accurate to $\pm 1\ cm^{-1}$. The method of energy calculation is discussed below.

To supplement the information contained in the figures and tables, we will make some comments on the various regions of the spectra.

Binary stretch–libration combinations (3800–4150 cm^{-1})

Since there are two OH stretches and three librations for $K_2SnCl_4 \cdot H_2O$, six possible binary states around 4000 cm^{-1} may arise. Two will have symmetry A' and should appear in the $E \perp b$ spectrum. The other four will be A'' and should appear in the $E \| b$ spectrum. Because of the high energy of the fundamental stretches in $K_2SnCl_4 \cdot H_2O$, almost all the expected features are actually seen in this region.

The $E \perp b$ spectrum shows two very strong bands at 3908 and 4010 cm^{-1}. Symmetry considerations indicate that these are the combinations of the two stretches with the rocking vibration. This analysis implies in turn that the middle of the three librations (458 cm^{-1}) must be the rocking vibration.

The $E \| b$ spectrum shows a very intense band whose peak (3959 cm^{-1}) could not be recorded even in a very thin crystal; it is flanked by two much weaker bands. The central band probably consists of two combinations which are expected to have almost the same energy, namely, $\nu_s + r_t$ and $\nu_a + \rho_w$. It is not clear why these combinations are so strong, while the other two ($\nu_s + \rho_w$ and $\nu_a + \rho_t$).

In this region the spectrum of $KSnCl_3 \cdot H_2O$ (pol. 1) shows two bands at 3823 and 3901 cm^{-1} (separation 78 cm^{-1}). These represent the combination of the OH stretches with a libration. The two OH stretches are separated by ca. 82 cm^{-1} in the ir spectrum, and the only libration observed there is at 427 cm^{-1} (7). The symmetry of this single libration is uncertain. The fact that nir bands appear around 3900 cm^{-1} in both polarizations with essentially the same energy may mean a near degeneracy of two librations of different symmetry. But, as in $K_2SnCl_4 \cdot H_2O$, the spectrum of pol. 2 in this region is somewhat more complex than that of the other polarization, an observation which suggests similar site symmetry for water in the two complexes. In addition to the two principal peaks (3826 and 3904 cm^{-1}), pol. 2 shows other features at higher energy which cannot, at present, be assigned.

Ternary stretch–libration combinations (4150–4700 cm^{-1})

At about 4500 cm^{-1} there is a series of bands in the spectra of $K_2SnCl_4 \cdot H_2O$. Combination of the two stretches with pairs of librations can give rise to 12 states. The $E \perp b$ spectrum is quite rich and seven absorptions of varying intensity and sharpness are seen, while the other spectrum is weaker and shows only three broad absorptions. The spectra agree with theory in that a larger number of bands (eight) is expected to occur in the A' ($E \perp b$) spectrum than in the A'' ($E \| b$) spectrum (four). Specific assignment of the bands in this region does not seem feasible at present.

The spectra of $KSnCl_3 \cdot H_2O$ in this region are poorer in detail, as is expected from the fact that only one libration is seen in the ir spectrum. Two principal bands in pol. 1 are separated by 80 cm^{-1}, the difference between the two fundamental stretches. The contrast of the sharpness of the bands in these spectra to those of $K_2SnCl_4 \cdot H_2O$ is worth noting.

(4700–5000 cm^{-1})

The polarized band at 4827 cm^{-1} in the $E \| b$ spectrum of $K_2SnCl_4 \cdot H_2O$ is totally absent at 292 K, and is barely visible above the background at 220 K. The crystal seems to go through a slight phase change at 202 K. This is seen as a sharp but noticeable rise in the baseline. On cooling the crystal from 160 to 10 K this band at 4827 cm^{-1} grows stronger with no change in baseline. It is not known what processes causes this absorption. No analogous band is found in $KSnCl_3 \cdot H_2O$.

The $E \perp b$ spectrum of $K_2SnCl_4 \cdot H_2O$ in this region contains three weak features, one of which (4782 cm^{-1}) is most likely the ternary $3\nu_2$ band. A similar very weak feature at 4716 cm^{-1} in pol. 1 of $KSnCl_3 \cdot H_2O$ is given the same assignment. The other features in both polarizations of $K_2SnCl_4 \cdot H_2O$ may be quaternary bands, several of which are calculated to appear in this region. They are of the type $\nu + 3\rho$.

Binary stretch–bend combinations (5000–5300 cm^{-1})

In this region both $K_2SnCl_4 \cdot H_2O$ and $KSnCl_3 \cdot H_2O$ show two intense, completely polarized bands, 5037, 5140 and 5137, 5213 cm^{-1}, respectively. These bands are readily assigned to the two stretch–bend combinations.

Since ν_1 of $KSnCl_3 \cdot H_2O$ is split into two components and ν_2 into three components, the band at 5137 cm^{-1} could have six components and the 5213 cm^{-1} band could have three components. This is, however, *not* seen. The sharp bands at 5137 and 5213 cm^{-1} are singlets with $\Delta\nu_{1/2} = 3.3$ and 4.4 cm^{-1}, respectively.

In $M_2[FeCl_5H_2O]$ (M = Cs, K) only one band is seen in this region (5), and it occurs in only one polarization. This transition was assigned in both cases to $\nu_a + \delta$, and in neither molecule was there any evidence for the corresponding $\nu_s + \delta$ transition. In $Cs_2[FeCl_5H_2O]$ the water lies on a C_{2v} site (5), while in $K_2[FeCl_5H_2O]$ there is evidence that a symmetry plane bisects the water molecule (12). Thus in these two crystals there is a symmetry distinction between the symmetric and antisymmetric stretching modes. The absence of the $\nu_s + \delta$ combination appears therefore to be a property of water in higher symmetry sites. In $K_2SnCl_4 \cdot H_2O$ the two stretches belong to the same symmetry species, and intensity transfer from one stretch–bend combination to the other can take place.

In $K_2SnCl_4 \cdot H_2O$ the weak band at 5209 cm^{-1} is assigned to the quaternary band $3\delta + \rho$ which appears to gain intensity from the nearby binary band $\nu_a + \delta$. The same assignment can be made for the double band at 5237, 5246 cm^{-1} in $KSnCl_3 \cdot H_2O$. The fit for the latter is poor because in the calculation x_{24} was set equal to zero. The splitting reflects the splitting in the fundamental bending vibration.

Stretch–bend–libration combinations (5300–6000 cm^{-1})

In $K_2SnCl_4 \cdot H_2O$ six such bands are expected some 500 cm^{-1} higher in energy than the stretched–bend combinations. They should show the same polarization as the binary stretch + libration modes. The A' spectrum of $K_2SnCl_4 \cdot H_2O$ contains two strong features which correspond to the two $\nu + \delta + L_2$ combinations. Each band is actually a closely spaced doublet, 5498 (sh) + 5504 cm^{-1}, and 5594 + 5606 cm^{-1} (sh). This may mean that at 10 K there are two slightly different sites for the

[a]Numbers in parentheses give the fundamentals used to calculate the energy. Fundamentals are listed in Table 1 and non-zero anharmonicities used in calculating the energies are shown in Table 3. Starred (*) combinations are those expected in the A'' spectrum.

[b]Symmetry of overtone containing a libration assumes L_2 (458 cm^{-1}) is ρ_r. A'' vibrations are ρ_w and ρ_t; rest are A'.

[c]Site symmetry of water assumed same as in $K_2SnCl_4 \cdot H_2O$; fundamentals used in calculations are $\nu_1 = 3550$, $\nu_2 = 1610$, $\nu_3 = 3632$, $\nu_4 = 427$ cm^{-1}.

[d]Pol. 1 and pol. 2 were recorded with the electric vector, E, perpendicular and parallel, respectively, to the needle axis.

water molecules. As noted above, a small phase change occurs at 202 K, and this could bring about such a situation. The A'' spectrum shows three principal peaks. Two of the four combinations expected here, $\nu_a + \delta + L_3$ and $\nu_s + \delta + L_1$ should have very nearly the same energy. This provides the basis for the assignments shown in Table 2. The nature of the other weak features seen in this region is unknown. No quaternary combinations are calculated to appear between 5400 and 5900 cm^{-1}.

In this region the pol. 2 spectrum of $KSnCl_3 \cdot H_2O$ shows one certain, broad band at 5547 cm^{-1} and possibly other bands at lower energy. The uncertainty arises from the fact that free water in the optical path of the spectrophotometer absorbs in this region and obscures weak absorptions that might occur here. The band(s) again represent $\nu + \delta + \rho$ combination(s).

Binary stretch and ternary strech–bend combinations (6000–7250 cm^{-1})

In both crystals these two sets of bands ($\nu + 2\delta$ and 2ν) are completely polarized, as expected. In $K_2SnCl_4 \cdot H_2O$ the two sets overlap, but in $KSnCl_3 \cdot H_2O$ they do not (see Table 2). For the $\nu + 2\delta$ set in each compound the separation is approximately the difference between the two fundamental stretches. In $KSnCl_3 \cdot H_2O$ the band at higher energy is a doublet of 9.5 cm^{-1} separation. Since the fundamental HOH bend is split into three components at 113 K (7), it is not surprising that some splitting of this overtone is observed. Perhaps more surprising is the fact that splitting of the lower-energy band is not observed, since the symmetrical stretch is also a doublet at 113 K.

For the 2ν combinations, $K_2SnCl_4 \cdot H_2O$ shows the expected three bands. They differ greatly in intensity, $2\nu_1$ being very weak, $2\nu_3$ strong, and $\nu_1 + \nu_3$ intermediate. But it is worth noting that the relative intensities of the three bands vary considerably as the face on which the light falls is changed. Such a change in crystal orientation can cause variation in the extent of mixing of the two stretches in the plane perpendicular to b and consequent variations in band intensity. The two $\nu + 2\delta$ bands show a similar variation in intensity upon change of crystal orientation, and in the various orientations $\nu_1 + 2\nu_2$ is weaker than $\nu_3 + 2\nu_2$.

The spectrum of $KSnCl_3 \cdot H_2O$ is considerably more complex in this region due to the splitting of the fundamentals. Reasonable assignments are listed in Table 2.

Other ternary combinations (7250–10 300 cm^{-1})

No clear example of the combination $2\nu + \rho$ is seen, with the possible exception of the weak 7398 cm^{-1} ($E \parallel b$) band in $K_2SnCl_4 \cdot H_2O$. Two possible assignments are shown in Table 2.

The set of bands at about 8500 cm^{-1} is in both compounds completely polarized, as expected for $2\nu + \delta$. The spectra of $K_2SnCl_4 \cdot H_2O$ contains four rather weak absorptions, three of them sharp and one quite diffuse. The three sharp bands, so alike in contour, are ascribed to the $2\nu + \delta$ absorptions. It seems most likely that the diffuse band is a quaternary combination, $\nu + 3\delta$. Fermi interaction of the various combinations may be the reason the fit between calculated and observed energies for the $2\nu_1 + \nu_2$ band is rather poor.

In $KSnCl_3 \cdot H_2O$ the lower energy band in this region is a doublet (16.0 cm^{-1} separation). This again seems to reflect the splitting of the fundamentals, ν_1 and ν_2. In the spectra we see no evidence of the $\nu_2 + 2\nu_3$ combination.

In the A' spectrum of $K_2SnCl_4 \cdot H_2O$ two very weak absorptions which may possibly be ascribed to 3ν are found at 9978 and 10 053 cm^{-1}. It is likely that an extremely weak absorption ca. 10 330 cm^{-1} in the analogous spectrum of $KSnCl_3 \cdot H_2O$ also represents this combination.

Calculation of band energies

For a molecule of more than three atoms without degenerate vibrations the combination and overtone bands will have energy (ref. 13, pp. 205–208)

$$[1] \quad G_0(v_1, v_2, \ldots) = \sum_i \omega^0{}_i v_i + \sum_i \sum_{k \geq i} x^0{}_{ik} v_i v_k$$

The energy is referred to the ground state and not to the minimum in the potential well. In this equation v_i is the vibrational quantum number of normal mode, i, $x^0{}_{ik}$ are the normal mode anharmonicity constants, and $\omega^0{}_i$ are the zero-order frequencies. The $\omega^0{}_i$ are related to the observed fundamentals, ν_i, as follows:

$$[2] \quad \omega^0{}_i = \omega_i + x_{ii} + \frac{1}{2}\sum_{k \neq i} x_{ik} + \ldots$$

$$[3] \quad \nu_i = \omega^0{}_i + x_{ii}$$

Here $x_{ik} = x_{ki}$ and, if higher powers are neglected, $x^0{}_{ik} = x_{ik}$.

Using the above equations and the observed absorptions we

[c]Reference 14.

have calculated sets of normal mode anharmonicities (Table 3) which reproduce most of the bands nicely, as can be seen in Table 2.

The method used to calculate the anharmonicities for $K_2SnCl_4 \cdot H_2O$ is as follows: from the ir overtone, $2\nu_2$, x_{22} was calculated; from the $\nu + \delta$ bands x_{12} and x_{23}, from the 2ν bands x_{11}, x_{33}, and x_{13}, from the $\nu + \rho$ region x_{ik} ($i = 1, 3$; $k = 4, 5, 6$), and from the $\nu + \delta + \rho$ region x_{2k} ($k = 4, 5, 6$) were determined. The set of bands in the 4300–4600 cm^{-1} range, due to $\nu + 2\rho$, should in theory provide the basis for the calculation of the interlibrational anharmonicities. The specific identity of most of the bands is, however, uncertain, and we have not been able to determine values for these constants. Accordingly, in the calculations they have been equated to zero.

What precision can be attached to the anharmonicities listed in Table 3? Let us again consider $K_2SnCl_4 \cdot H_2O$. The calculations depend on the energies of the overtone and of the fundamentals of which it is composed. If each is accurate to ± 1 cm^{-1}, then there is a built-in uncertainty of ± 3 cm^{-1} for x_{ik} determined from a binary combination and ± 4 cm^{-1} for one from a ternary combination. Since the librations are broad in the fundamental spectrum, a larger uncertainty is expected in combinations involving them. Most ternary and quaternary combinations involve two or more different x_{ik} and so the uncertainties will be cumulative. A further source of uncertainty is the possibility of Fermi interaction between bands of the same symmetry and like energy. The observed value of the overtone might depend strongly on such interaction and, if used in calculating an anharmonicity constant, could lead to a completely misleading value. We have tried to avoid this, but have not had the mathematical apparatus to evaluate possible Fermi interactions. The consistency of the results and their comparison with gaseous water suggest that the x_{ik} involving only ν_i ($i = 1$, 2, 3) are quite acceptable. The other values listed are, we believe, also acceptable, but probably contain a greater uncertainty than the first set.

In the case of $KSnCl_3 \cdot H_2O$ the calculated anharmonicities are of lower precision than those for $K_2SnCl_4 \cdot H_2O$. The reasons for this are the multiplicity of two of the ir fundamentals with the consequent use of average energies in the calculation of the anharmonicities, and the lack of exact knowledge of the crystal structure. In addition, the appearance of only one libration instead of the expected three in the ir spectrum results in less rich overtone spectra. This, in turn, has made it impossible to calculate anharmonicities involving the libration.

While the anharmonicities of $KSnCl_3 \cdot H_2O$ are less precise than those of $K_2SnCl_4 \cdot H_2O$, the corresponding values for the two compounds show similar trends. These in turn are much like those of gaseous water. For comparison, values for the latter are also listed in Table 3 with, however, less precision than given in the original reference (14).

Certain specific points may be noted: (*1*) The anharmonicities involving only ν_i ($i = 1, 2, 3$) are all negative, as is also true for gaseous water. (*2*) About half of the anharmonicities involving librations are positive. While this is less usual, positive values have been found in many small molecules, as for example, gaseous CO_2, N_2O, and HCN (ref. 13, pp. 272–280). (*3*). In $K_2SnCl_4 \cdot H_2O$, in which there is no symmetry distinction between the two OH stretches, the anharmonicities x_{11} and x_{13} have nearly the same value. This is not true of $KSnCl_3 \cdot H_2O$ nor of gaseous water. (*4*) Certain anharmonicities show distinct trends in going from gaseous water to water in crystals: x_{11} is larger and x_{13} is smaller in crystals than in gas; x_{12} and x_{23} are slightly larger in crystals; x_{22} and x_{33} appear to be less affected. The variations in the stretch–stretch anharmonicity constants may be due to variations in the Fermi interaction on going from gas to crystal phase. Therefore we cannot rule out the possibility that there may actually be no difference between these gas and crystal anharmonicities once they have been corrected for this effect.

Finally, we should point out that the normal mode description of overtone bands is no longer considered to be accurate. Its use in the above analysis was dictated by convenience in the comparison of the small differences between our crystal data and the data for gas phase water (14). Current theory holds that analysis in terms of local excitation of individual O—H oscillators (local mode model) is a better description of reality (15). The implications of this for the overtone spectra of water in crystals will be explored in detail in later communications.

Conclusions

In both compounds of this study most bands are highly polarized, and the polarizations are consistent with the plane of the water molecules being perpendicular to the needle axis.

We have shown that for $K_2SnCl_4 \cdot H_2O$ it is possible to assign and characterize the librations of bound water. This could not be done on the basis of the fundamental ir spectrum (6).

An extensive list of normal mode anharmonicities has been calculated for both molecules. Those involving librations appear to be the first reported for such vibrations.

In future articles we will show how the nir spectrum can be used to study cooperative excitation in oriented chains of water molecules.

Rate constants for the proton and deuteron transfer from 1-(4-nitrophenyl)-1-nitroethane to cesium *n*-propoxide in *n*-propanol have been measured under pseudo-first-order conditions with an excess of base for four temperatures between 5 and 35°C. Using literature values of the fraction of cesium *n*-propoxide ion pairs that are dissociated into free ions, separate second-order rate constants for the proton and deuteron transfer to the ion pair and to the free ion have been calculated. The cesium *n*-propoxide ion pair is about 2.8 times more reactive than the free *n*-propoxide ion. The primary kinetic isotope effects for the two reactions are the same (k_H/k_D = 6.1–6.3 at 25°C) within experimental error. The enthalpy of activation is smaller for the ion-pair reaction and the entropy of activation more negative than for the free-ion reaction. For proton transfer, $\Delta H^{\pm}_{\text{ion pair}}$ = 8.3±0.2 kcal mol^{-1}, $\Delta H^{\pm}_{\text{ion}}$ = 9.6±1.0 kcal mol^{-1}, $\Delta S^{\pm}_{\text{ion pair}}$ = −12.3±0.6 cal mol^{-1} deg^{-1}, $\Delta S^{\pm}_{\text{ion}}$ = −10.1±3.4 cal mol^{-1} deg^{-1}. The greater reactivity of the ion pair relative to the free ion is interpreted in terms of the weaker solvation shell of the ion pair in the initial state.

ARNOLD JARCZEWSKI, GRZEGORZ SCHROEDER, PRZEMYSLAW PRUSZYNSKI et KENNETH T. LEFFEK. Can. J. Chem. **64**, 1021 (1986).

Opérant dans l'alcool propylique, dans des conditions de réactions de pseudo premier ordre, en présence d'un excès de base et à quatre températures allant de 5 à 35°C, on a mesuré les constantes de vitesse de réactions de transfert de protons et de deutérons du (nitro-4 phényl)-1 nitro-1 éthane vers le propylate de césium. Utilisant les données de la littérature relatives à la fraction des paires d'ions du propylate de césium qui sont dissociées en ions libres, on a calculé des constantes séparées de vitesse du deuxième ordre pour les transferts de protons et de deutérons vers les paires d'ions et vers les ions libres. La paire d'ions du propylate de césium est environ 2,8 fois plus réactive que l'ion propylate libre. À l'intérieur des erreurs expérimentales, les effets isotopiques cinétiques primaires sont les mêmes pour les deux réactions (k_H/k_D = 6,1–6,3 à 25°C). Par comparaison avec les valeurs correspondantes pour la réaction de l'ion libre, l'enthalpie d'activation de la réaction de la paire d'ions est plus petite alors que son entropie d'activation est plus négative. Pour la réaction de transfert de proton, $\Delta H^{\pm}_{\text{paire d'ions}}$ = 8,3 ± 0,2 kcal mol^{-1}, $\Delta H^{\pm}_{\text{ion}}$ = 9,6 ± 1,0 kcal mol^{-1}, $\Delta S^{\pm}_{\text{paire d'ions}}$ = −12,3 ± 0,6 cal mol^{-1} deg^{-1}, et $\Delta S^{\pm}_{\text{ion}}$ = −10,1 ± 3,4 cal mol^{-1} deg^{-1}. On interprète la plus grande réactivité de la paire d'ions par rapport à l'ion libre en fonction de la couche de solvatation plus faible de la paire d'ions dand l'état initial.

[Traduit par la revue]

Introduction

The different reactivity of free ion and ion-pair reagents in solution is well known (1, 2). Different relative reactivities for the two types of reagent have been observed under different circumstances, but it has frequently been assumed that ion-pair reactivity is negligibly small compared to that of the free ion. In 1956, Bevan and Monk (3) showed that the differences in second-order rate constants for the reaction of sodium, potassium, magnesium, calcium, and strontium thiosulfates with *n*-propyl bromide in mixed ethanol–water solvent could be eliminated completely if the rate constant was calculated with respect to the free thiosulfate ion. They assumed that ion pairs made no contribution to the reaction velocity and the rate constants for the free thiosulfate ion were found not only to be independent of the cation present, but also independent of the ion strengths of the solution (3). Cram *et al.* (4) investigated the rates of the racemization and exchange of 1-phenylmethoxyethane-1-*d* in dimethyl sulfoxide (DMSO) –potassium *tert*-butoxide. The order of the reaction with potassium *tert*-butoxide and other kinetic observations led them to conclude that potassium *tert*-butoxide in DMSO is largely in the form of ion pairs, but that only the dissociated *tert*-butoxide ion is chemically active, with the reactivity of the ion pairs vanishingly small in comparison. Leffek and Suszka (5) measured the second-order rate constants for the reaction of 4,4′-bis(dimethylamino)triphenylmethyl tetrafluoroborate carbonium ion with sodium methoxide in methanol and sodium ethoxide in ethanol. The results were used to evaluate the ion-pair dissociation constants for the two alkoxides, assuming that the ion-pair reactivity was negligibly small compared to that of the free ion. The dissociation constants based on this assumption were in good agreement with those determined from conductance measurements.

A spectrophotometric study of fluorenyl alkali metal salts by Hogen-Esch and Smid (6, 7) provided direct evidence for the existence of two types of ion pair. Chan and Smid (8), in a study of the deprotonation of triphenylmethane by polystyryl anions, showed that even though the bulk of the base is in the form of ion pairs, the free ions are responsible for the deprotonation.

However, in some solvents the ion pairs did show a reactivity, leading to the suggestion that there were two forms of ion pairs, tight and loose, and that the latter were active reagents.

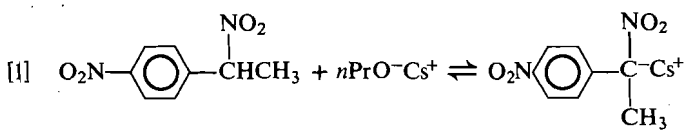
Proton transfer from 3,4-benzofluorene and 1,2-benzofluorene to various fluorenyl salts acting as bases showed (9) marked changes in second-order rate constant with concentration when the Li salt was used, but no such change when cesium or tetrabutylammonium salts were used. The latter reactions must be going via ion-pair reagents (1, 9) and it appears, therefore, that loose ion pairs in this system are much more reactive than tight ion pairs in the lithium salt reaction. Hogen-Esch and Smid (10) also found that aliphatic alcohols are relatively poor cation coordinators. Thus, in such a solvent a large ion pair would be expected to show considerable reactivity compared to the free ion.

These results suggest that it would be of interest to select a proton transfer reaction from a carbon acid to an alkoxide base, which might exist as free ions and also as loose ion pairs, and measure the rates of the two reactions to compare the primary isotope effects and activation parameters for the two transition states. Cesium *n*-propoxide was selected as the base since its large and poorly solvated cation should give its ion pair increased reactivity relative to ion pairs containing small cations such as lithium or sodium.

Results and discussion

In order to determine the individual rate constants and activation parameters for the proton transfer reaction between a carbon acid and alkoxide ions (k_i) and metal alkoxide ion pairs (k_{ip}) in the corresponding alcohol, independent and precise values of the ion association constants as a function of temperature are required. The necessary conductivity measurements for cesium *n*-propoxide in *n*-propyl alcohol were made by Barthel *et al.* (11, 12) at four temperatures between 5 and 35°C for a concentration range of $3.38 \times 10^{-4} - 32.12 \times 10^{-4}$ M propoxide, and the corresponding degrees of dissociation were calculated.

The reaction of 1-(4-nitrophenyl)-1-nitroethane with cesium *n*-propoxide in *n*-propyl alcohol solvent gives a single absorption peak, $\lambda_{max} = 410$ nm, identified (13, 14) as the carbanion ion-pair product of eq. [1].



The absorptivity was found to be constant over a cesium *n*-propoxide range of $9.6 \times 10^{-4} - 2.8 \times 10^{-2}$ M, indicating that the equilibrium constant for the reaction is large.

The cesium *n*-propoxide exists in *n*-propanol as free ions and ion pairs in proportions that depend upon the concentration and temperature (11). For the overall reaction, with the base pesent in large excess, the pseudo-first-order rate constant, k_{obs}, is given by eq. [2], in which [B] is the stoichiometric concentration of cesium *n*-propoxide and k_f and k_b are the rate constants for the forward and backward reactions of eq. [1].

$$[2] \quad k_{obs} = k_f[B] + k_b$$

Provided that the interconversion of ions and ion pairs is fast compared to the reaction of both species with the carbon acid, k_f

TABLE 2. Rate constants for the proton and deuteron transfer reactions to cesium *p*-propoxide ion pairs and to free *n*-propoxide ions from 1-(4-nitrophenyl)-1-nitroethane in *n*-propanol

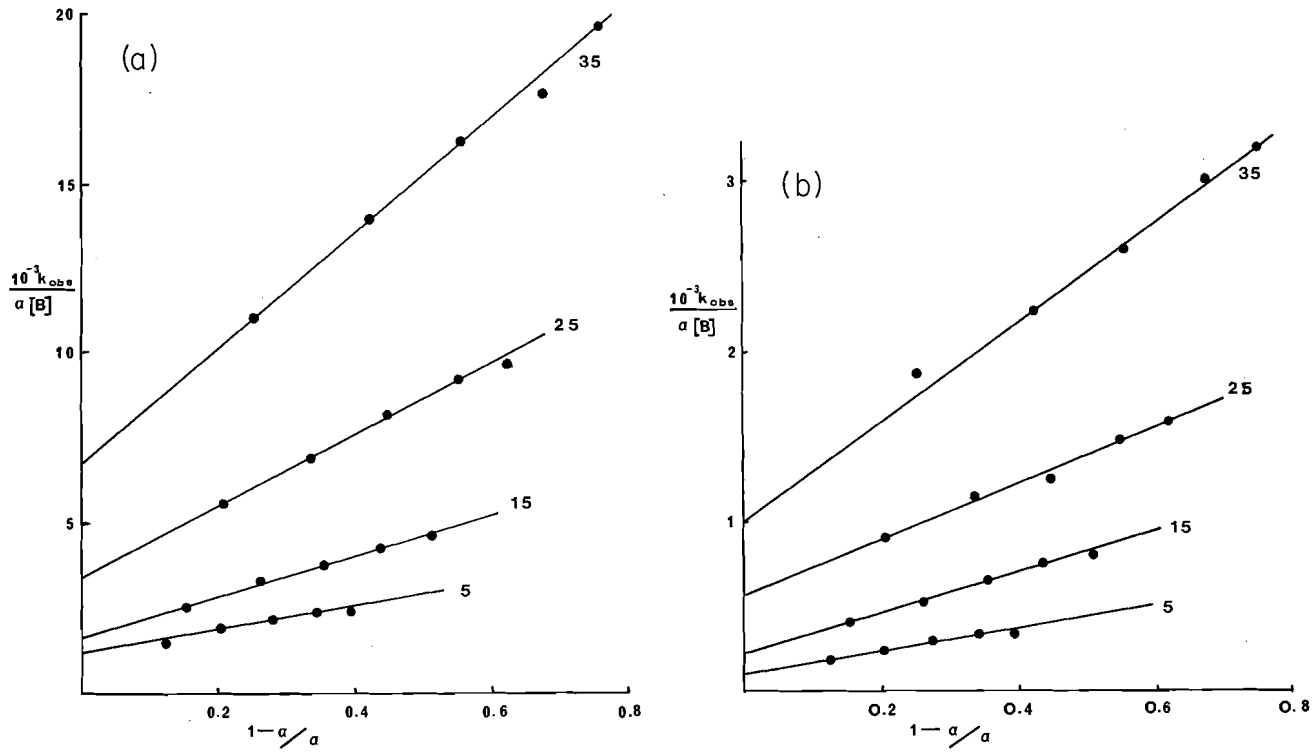

FIG. 1. Plots of 10^{-3} k_{obs}/α[base] vs. 1-α/α for (a) the proton and (b) the deuteron transfer from 1-(4-nitrophenyl)-1-nitroethane and its deuterated analogue to cesium *n*-propoxide in *n*-propanol.

is given by eq. [3]

[3] $k_f = \alpha\, k_i + (1\text{-}\alpha)\, k_{ip}$

in which α is the mole fraction of free ions, k_i is the first-order rate constant for the proton abstraction by free *n*-propoxide ions, and k_{ip} the first-order rate constant for proton abstraction in cesium *n*-propoxide ion pairs. Since k_b is essentially zero, k_{obs} is given by eq. [4], which may be rearranged to eq. [5].

[4] $k_{obs} = \alpha\, k_i[B] + (1 - \alpha)k_{ip}[B]$

[5] $k_{obs}/\alpha[B] = k_i + k_{ip}\,(1\text{-}\alpha/\alpha)$

Thus, from a plot of k_{obs}/α[B] vs. 1-α/α, k_{ip} is obtained as the slope and k_i as the intercept.

Table 1 shows the values of k_{obs} and the second-order rate constants k_f, calculated from the slopes of the plots of k_{obs} vs. base concentration, for the normal and 1-d_1 deuterated substrate at a series of temperatures between 5 and 35°C. Values of α at each of the cesium *n*-propoxide concentrations used in Table 1 were determined from plots of α vs. cesium *n*-propoxide concentration in *n*-propanol using the data of Barthel *et al.* (12), at the four temperatures shown in Table 2. Plots of k_{obs}/α[B] vs. 1-α/α are shown in Fig. 1 and k_i and k_{ip}, determined by a linear least-squares calculation, are recorded in Table 2, together with their standard deviations.

TABLE 4. Activation parameters for the reaction of cesium *n*-propoxide with 1-(4-nitrophenyl)-1-nitroethane in *n*-propanol

	Total base concentration		Ion pairs		Free ions	
Parameter	H-transfer	D-transfer	H-transfer	D-transfer	H-transfer	D-transfer
$\Delta H^{\neq}$ (kcal mol^{-1})	10.1±0.4	11.0±0.4	8.3±0.2	8.3±0.6	9.6±1.0	11.6±0.2
$\Delta S^{\neq}$ (cal mol^{-1} deg^{-1})	−7.3±1.2	−7.7±1.4	−12.3±0.6	−15.9±2.0	−10.1±3.4	−6.8±0.7
$\Delta G^{\neq}$ (kcal mol^{-1})	12.3	13.3	12.0	13.0	12.6	13.6

The primary kinetic isotope effects, k_H/k_D, for k_f, k_i, and k_{ip} are given in Table 3 together with their standard deviations. Of the eight isotopic rate ratios reported in Table 3 for the ion-pair reaction and free-ion reaction, seven are identical within the limits of plus or minus one standard deviation. The remaining isotope effect of 9.2 ± 1.6 for the free-ion reaction at 5°C is just outside this limit but well within plus or minus two standard deviations. It is concluded, therefore, that there is no significant difference in isotope effect between the reaction going via the free ion and that going via the ion pair. The same conclusion is reached if the isotope effects on the activation parameters for the two reactions, shown in Table 4, are compared: $(\Delta H_D^{\neq} - \Delta H_H^{\neq})_{ip} = 0.0 \pm 0.8$ kcal mol^{-1}, $(\Delta H_D^{\neq} - \Delta H_H^{\neq})_i = 2.0 \pm 1.2$ kcal mol^{-1}, $(\Delta S_D^{\neq} - \Delta S_H^{\neq})_{ip} = -3.6 \pm 2.6$ cal mol^{-1} deg^{-1}, $(\Delta S_D^{\neq} - \Delta S_H^{\neq})_i = 3.3 \pm 4.1$ cal mol^{-1} deg^{-1}. These values show the differences between the two reactions that are just on the limit of plus or minus one standard deviation. Thus, values of isotope effects and activation parameters previously reported for proton transfers to alkoxide bases (15–17) based on k_f values are meaningful. The magnitude of the isotope effects, between 6 and 7, is consistent with the theory for the loss of one C—H or C—D stretching vibration. The constancy of the isotope effects for the two reactions indicates that the transition states for the proton transfers must be very similar.

The k_f, k_i, and k_{ip} values from Tables 1 and 2 yield the activation parameters by a linear least-squares fit to the transition state theory equation. These are shown in Table 4, with their standard deviations. These are typical values for reactions of carbon acids with alkoxide bases (15–17) and also similar to the values obtained for proton transfers from this substrate to nitrogen bases in aprotic solvents (13, 14, 18). The differences between the free ion and the ion-pair reactions are again very small.

From Table 2, it can be seen that the reactivity of the alkoxide ion pair is about 2.8 times greater than that of the free ion, although this rate difference is not large enough to give a detectable curvature of the plots of k_{obs} vs. base concentration. The ion-pair reaction has a lower free energy of activation than the ion reaction by about 0.6 kcal mol^{-1}, which arises from a lower enthalpy of activation offset by a more negative entropy of activation. Since a large part of the energy barrier to reaction for proton transfers to alkoxide bases is considered to arise from the energy required to break up the initial state solvation shell (15, 19), it is probable that the reactivity of the cesium *n*-propoxide ion pair arises from the nature of its solvation shell. The large size of the cesium ion gives it a weaker solvation shell than a smaller ion such as sodium and this results in the cesium *n*-propoxide ion pair being less strongly solvated than the *n*-propoxide ion. This effect is sufficient to give rise to the observed rate constant and activation parameter differences found for the two reactions.

However, it has been suggested by Cram and Gosser (20) that the cation within the ion pair may stabilize the transition state by interaction with the developing negative charge on the carbon atom. The larger negative entropies of activation for the ion-pair reactions, in our case, are consistent with the more highly structured transition state required by cesium interaction with the developing negative charge. Similar electrostatic effects have been observed by Kresge and co-workers for the hydrolysis of vinyl ethers and also for proton transfer reactions (21, 22). In the present reactions, however, the lack of dependence of the primary isotope effect on the nature of the reagent suggests that the initial state desolvation effect is the major contributor to the difference in the rate constants and activation parameters.

It may be concluded that in small cation alkoxide systems the free ions are generally more reactive than ion pairs because the latter are tightly bound by electrostatic forces. Only with large poorly solvated metal alkoxide ion pairs will the free-ion reaction be slower than the ion-pair reaction. However, since the two reactions show very similar activation parameters and primary isotope effects, no significant error is introduced by the interpretation of these parameters for the overall reaction, although it must be remembered that such parameters may be averages of two similar but separate reaction paths.

Experimental

1-(4-Nitrophenyl)-1-nitroethane and its α-deuterated analogue were prepared as described by Boyle (23) and earlier workers (24, 25). Commercial *n*-propanol was fractionally distilled over potassium metal. The fraction boiling at 97.0°C was collected. Commercial cesium metal (Aldrich) was used to prepare the cesium propoxide solutions under an atmosphere of argon.

The kinetic measurements were carried out under pseudo-first-order conditions using an acid concentration of 3.02×10^{-5} and base concentrations ranging from 3.2×10^{-4} to 16.0×10^{-4} *M*. The stock solutions were always freshly prepared and protected from moisture and carbon dioxide under an argon atmosphere. The reaction rates were measured with a stopped-flow spectrophotometer using the standard technique previously described (15).

Mechanisms of elimination reactions. 40. Attempted study of stereochemistry of elimination from 2-(*p*-nitrophenyl)ethyltrimethylammonium ion. Base-promoted *cis–trans* isomerization of *p*-nitrostyrene-β-*d*[1]

BRENT R. DOHNER AND WILLIAM H. SAUNDERS, JR.[2]

Department of Chemistry, University of Rochester, Rochester, NY 14620, U.S.A.

Received September 20, 1985

This paper is dedicated to Professor Arthur N. Bourns

BRENT R. DOHNER and WILLIAM H. SAUNDERS, JR. Can. J. Chem. **64**, 1026 (1986).

Stereospecifically deuterated $ArCHDCHDNMe_3^+I^-$ and $ArCHDCHDNMe_2O$ have been prepared, where Ar=C_6H_5 and *p*-$NO_2C_6H_4$. When Ar=C_6H_5, the elimination reaction of the quaternary salt with ethoxide in ethanol goes with >98% *anti* stereochemistry, and the Cope elimination of the amine oxide with >98% *syn* stereochemistry. When Ar=*p*-$NO_2C_6H_4$, however, both reactions lead to apparent 50:50 *anti*/*syn* product. Subjection of (*E*)-*p*-nitrostyrene-β-*d* to the conditions of both the ethoxide-promoted and Cope eliminations results in complete *cis–trans* equilibration. No loss of deuterium from *p*-nitrostyrene-α-*d* occurs under either set of conditions, excluding isomerization via an α-arylvinyl carbanion. The most likely mechanism for isomerization is reversible addition of ethoxide under E2 conditions and $ArCHDCHDNMe_2O$ under Cope conditions to the β-carbon of *p*-nitrostyrene. The *cis–trans* isomerization of the *p*-nitrostyrene is sufficiently rapid to preclude determination of the stereochemistry of base-promoted eliminations leading to it.

BRENT R. DOHNER et WILLIAM H. SAUNDERS, JR. Can. J. Chem. **64**, 1026 (1986).

On a préparé des $ArCHDCHDNMe_3^+I^-$ et des $ArCHDCHDNMe_2O$ spécifiquement deutérés, dans lesquels Ar=C_6H_5 et *p*-$NO_2C_6H_4$. Lorsque Ar=C_6H_5, la réaction d'élimination du sel quaternaire, sous l'influence de l'éthylate dans l'éthanol, se produit à >98% par une stéréochimie *anti* alors que l'élimination de Cope de l'oxyde d'amine se fait à >98% par une stéréochimie *syn*. Toutefois, lorsque Ar=*p*-$NO_2C_6H_4$, les deux réactions conduisent à un produit qui est apparemment 50:50 *anti*/*syn*. Lorsqu'on soumet le *p*-nitrostyrène-β-*d*-(*E*) à des réactions d'élimination tant de Cope que sous l'influence de l'éthylate, on obtient toujours un équilibre complet entre les isomères *cis–trans*. Ni l'une ni l'autre des conditions d'élimination ne provoque la perte de deutérium du *p*-nitrostyrène-α-*d*; ce résultat exclut la possibilité d'une élimination par le biais d'un carbanion α-arylvinyle. Le mécanisme le plus probable pour l'isomérisation est l'addition réversible d'éthylate, sous les conditions E2, et de $ArCHDCHDNMe_2O$, sous les conditions de Cope, au carbone β du *p*-nitrostyrène. L'isomérisation *cis–trans* du *p*-nitrostyrène est suffisamment rapide pour éliminer la possibilité de déterminer la stéréochimie des réactions d'élimination, effectuées sous l'influence de bases, qui lui donnent naissance.

[Traduit par la revue]

The mechanisms of base-promoted elimination from 2-arylethyl derivatives have been subjected to intensive scrutiny. Most of these reactions have been found to proceed via the E2 mechanism (2, 3). In the one reported stereochemical study in this series, 2-phenylethyl-1,2-d_2-trimethylammonium ion was found to give entirely (>95%) *anti* elimination when treated with ethoxide ion in ethanol or *tert*-butoxide ion in *tert*-butyl alcohol (4). Only when there is a second group, alkyl or aryl, in the 2-position is there appreciable *syn* elimination (1, 5).

Recently, evidence has been presented that 2-(*p*-nitrophenyl)ethyl quaternary ammonium salts eliminate by the E1cB mechanism (6, 7). The evidence included exchange of the β-hydrogens with solvent protons, an inverse solvent isotope effect on initial rates, and markedly curved plots of rate vs. buffer concentration. Even under conditions where there was no evidence for exchange, the lack of coupling between proton removal and leaving-group departure suggested an $(E1cB)_I$ mechanism.

In the light of these findings, the 2-arylethyl system seemed to offer an excellent opportunity to compare the stereochemical courses of E2 and E1cB reactions of closely similar substrates. What is to be expected in an E1cB reaction is by no means clear. A long-lived carbanion, free to rotate and invert prior to loss of the leaving group, should result in 50:50 *syn*/*anti* elimination. It is possible, however, that stereochemical randomization of the carbanion would be slowed by a hyperconjugative interaction of the lone pair with the bond between the α-carbon and the leaving group (8), by ion pairing (9), or simply by a very short lifetime. In such cases, considerable stereoselectivity, or even stereospecificity, could result.

In order to study the stereochemistry of elimination, we prepared 2-phenylethyl-1,1-d_2-trimethylammonium (**6**) and 2-(*p*-nitrophenyl)ethyl-1,2-d_2-trimethylammonium (**7**) iodides by stereospecific reactions. The synthetic sequence is shown in Scheme 1. The corresponding amine oxides, **8**, and **9***a*, were also prepared to provide checks on the stereochemical integrity of **6** and **7**. The commercial β-bromostyrene (**1**) was not stereochemically pure. It was shown by nmr to be 78.6% *E* and 21.4% *Z*. We thus needed to know whether this composition was preserved through the transformations leading to **6** and **7**. In order to do this, **5** was converted to **8**, which in turn was subjected to a Cope elimination, a reaction known to proceed via a stereospecifically *syn* pathway (10, 11). The products expected from *anti* and *syn* elimination are shown in Scheme 2.

By this procedure, **5** was shown to be 79.5% *RS,SR*. As a double check, **2** was deuteroborated as in Scheme 1, but then treated with NH_2OSO_3H (12). The resulting primary amine was converted to **5** by treatment with formaldehyde and formic acid (13). This sample of **5** was treated with hydrogen peroxide and the product subjected to Cope elimination, which showed it to be 79.0% *RR,SS*. It is clear that the synthesis of **5** is stereospecific, and there is no reason to believe that conversion of **5** to **6** or **8** affects its stereochemistry. Neither should the nitration to give **9**, but Cope elimination of **9***a* gave unexpected results, which will be discussed below.

[1]For previous paper in this series, see ref. 1.

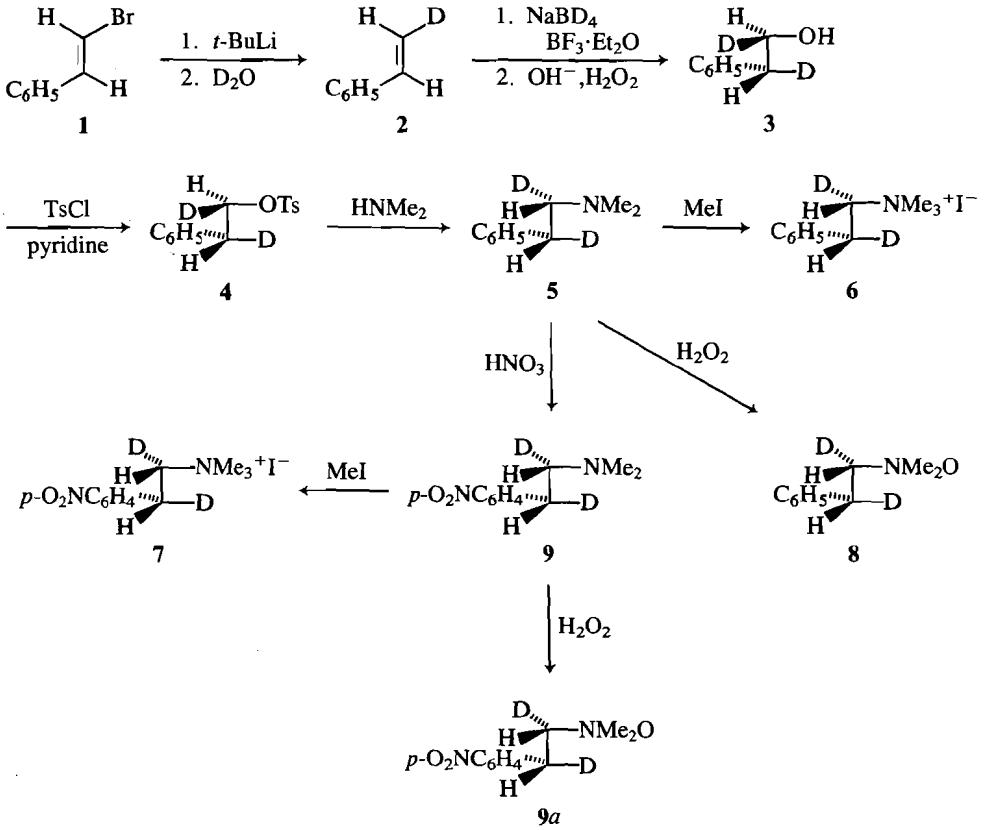


SCHEME 1. Synthesis of stereospecifically labeled 2-arylethyl-1,2-d_2-trimethylammonium salts and -dimethylamine oxides.

(*RS,SR*)-ArCHDCHDX

	10	**11**	**12**	**13**
Ar = C_6H_5:	5.80, d $J_{H,H}$ = 17.4 Hz	5.22, t $J_{H,D}$ = 1.4* Hz	5.23, d $J_{H,H}$ = 11.0 Hz	5.79, t $J_{H,D}$ = 2.8* Hz
Ar = *p*-$NO_2C_6H_4$:	5.94, d $J_{H,H}$ = 17.6 Hz	5.50, t $J_{H,D}$ = 1.5* Hz	5.50, d $J_{H,H}$ = 10.9 Hz	5.94, t $J_{H,D}$ = 2.5* Hz
	anti ⟶ **10** + **11**		*syn* ⟶ **12** + **13**	

*$J_{H,D}$ values are calculated from observed H,D splittings. Slightly different (and probably more accurate) values are obtained from the formula $J_{H,D} = J_{H,H}/6.5$ (2.7 Hz for *E* and 1.7 Hz for Z orientation of H and D)

SCHEME 2. Products expected in *anti* and *syn* elimination from ArCHDCHDX.

The two samples of **6**, which can be presumed to be 79.5% *RS,SR* and 79.0% *RR,SS*, respectively, permitted us to check the results of Bourns and Frosst (4). The high-field nmr spectrometers that we used permit more precise determination of the composition of the mixture of **10**–**13** than the 60-MHz nmr instrument available for the earlier work. On treatment with sodium ethoxide in ethanol at 80°C, the 79.5% *RS,SR* sample of **6** gave 78.7% **10** and **11**, while the 79.0% *RR,SS* sample gave 79.0% **12** and **13**. These results confirm that the elimination is entirely *anti* within experimental error. Any *syn* elimination must be less than 1–2% of the overall reaction.

Nitration of **5** with fuming nitric acid at −10°C (14) afforded a mixture that was 71% *para* and 29% *ortho*, from which the pure *para* isomer, **9**, was isolated by flash chromatography (15). **9** was converted to **7**, which was then treated with sodium ethoxide in ethanol at 60°C. Analysis of the mixture of deuterated *p*-nitrostyrenes gave 52.5% of **10** and **11** and 47.5% of **12** and **13**. Conversion of **9** to **9***a*, followed by Cope

elimination, gave 49.0% of **10** and **11** and 51% of **12** and **13**. This outcome indicates essentially complete loss of stereochemistry in *both* the base-promoted elimination of **7** and the Cope elimination of **9***a*. A random stereochemical outcome in the base-promoted elimination can be readily rationalized, but a nonstereospecific Cope elimination is, to the best of our knowledge, unprecedented. Consequently, we considered the possibility that stereochemistry was lost at some stage other than during the elimination reactions.

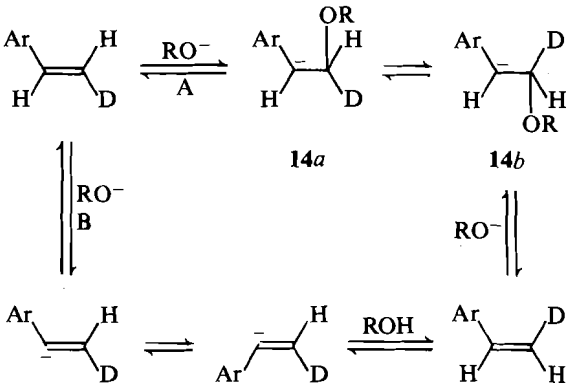
In principle, epimerization could occur during the nitration of **5** to **9**. The nmr spectra of **7** and **9** were too complex to give any information about proportions of stereoisomers, however, and the possibility of epimerization during nitration of **5** seemed farfetched in any case. A third possibility for loss of stereochemistry would be $E \rightleftharpoons Z$ isomerization of the deuterated nitrostyrenes under the conditions of the elimination reactions. This possibility was easiest to test experimentally, and was pursued first.

In order to obtain stereospecifically deuterium-labeled *p*-nitrostyrene, (*E*)-β-bromo-*p*-nitrostyrene was prepared by the method of Cristol and Norris (16), and converted to *p*-nitrophenylacetylene by treatment with sodium *tert*-butoxide in *tert*-butyl alcohol. Treatment of *p*-nitrophenylacetylene with 9-BBN (9-borabicyclo[3.3.1]nonane) (17) in tetrahydrofuran, followed by acetic-*O*-*d* acid, gave (*E*)-*p*-nitrostyrene-β-*d*. This *E* isomer showed a single nmr signal attributable to the β-proton at δ 6.01.

Treatment of the *E* isomer for 10 min with 0.1 *M* sodium ethoxide in ethanol led to a new vinyl proton nmr signal at δ 5.50, attributable to the *Z* isomer. The ratio of the signals at 6.01 and 5.50 was 47.7:52.2. Heating the *E* isomer at 80°C for 2.5 h in 80% Me_2SO – 20% H_2O containing 2-phenylethyldimethylamine oxide (Cope reaction conditions) led to a 50.0:50.0 mixture of the *E* and *Z* isomers. It is clear that complete equilibration between the *E* and *Z* isomers occurs under the conditions of both E2 and Cope eliminations.

Two possible mechanisms for the isomerization are outlined in Scheme 3. Here RO^- is EtO^- (base-promoted reaction) or $ArCH_2CH_2N^+Me_2O^-$ (Cope reaction). While path A seemed more likely than path B, we felt it necessary to distinguish between them, and chose an experiment which shed further light on path A as well. Reduction of *p*-nitroacetophenone by sodium borodeuteride, followed by tosylation and treatment of the resulting tosylate with sodium *tert*-butoxide in *tert*-butyl alcohol, afforded *p*-nitrostyrene-α-*d*. Neither under the E2 nor the Cope elimination conditions was there any observable loss of the α-deuterium, a fact which excludes path B. The method of synthesis also excludes path B for reaction with *tert*-butoxide in *tert*-butyl alcohol. Finally, the experiment excludes any significant *reversible* protonation of the carbanion **14**, resulting from addition of RO^- to *p*-nitrostyrene, for this, too, would lead to loss of α-deuterium. Irreversible protonation of **14** would give 2-(*p*-nitrophenyl)ethyl ethyl ether in the ethoxide-promoted isomerization, but no lines attributable to this compound appeared in the nmr spectrum of the isomerization product.

That nucleophilic addition to *p*-nitrostyrene occurs readily is not surprising, and there are literature precedents. Secondary amines give isolable adducts (18), and *N*-methyl-*C*-phenylnitrone (a model for the amine oxide) undergoes 1,3-dipolar addition, the nucleophilic oxygen going to the β-carbon of the *p*-nitrostyrene (19). Even more pertinent is the report of Alunni and Jencks that eliminations from 2-(*p*-nitrophenyl)ethyl quaternary ammonium salts are reversible (20), which means that tertiary amines as well can add to *p*-nitrostyrene.



SCHEME 3. Possible mechanisms for stereoisomerization of (*E*)-*p*-nitrostyrene-β-*d*.

The data of Alunni and Jencks provide a means of estimating this rate of addition. The overall equilibrium (eq. [1]) is the sum of the two reactions of eqs. [2] and [3].

[1] $ArCH{=}CH_2 + HNMe_3^+ \leftrightharpoons ArCH_2CH_2NMe_3^+$

[2] $ArCH{=}CH_2 + NMe_3 \leftrightharpoons ArCHCH_2NMe_3^+$

[3] $ArCHCH_2NMe_3^+ + HNMe_3^+ \leftrightharpoons ArCH_2CH_2NMe_3^+ + NMe_3$

The equilibrium constant K_1 is not given by Alunni and Jencks, but there is a good linear correlation between log K_1 and $pK_a(R_3NH^+)$ for the other quaternary salts, which permits estimation of K_1 as 0.05. The equilibrium constant for eq. [3] is given by the ionization constant of Me_3NH^+ divided by the ionization constant of $ArCH_2CH_2NMe_3^+$. The former is quoted by Alunni and Jencks as $10^{-9.85}$, and the latter estimated by Keeffe and Jencks (7) as $10^{-15.5}$. With these numbers in hand, we can estimate K_2 to be $10^{-4.35}$. In turn, $K_2 = k_{addn}/k_{elim}$, and Keeffe and Jencks estimate k_{elim} to be 15 s^{-1}, which makes k_{addn} 7×10^{-4} M^{-1} s^{-1}. This compares with an *overall* rate of elimination reaction of 10^{-3} M^{-1} s^{-1} at 25°C in water.

Thus, even the back addition of trimethylamine to *p*-nitrostyrene is comparable in rate to the overall elimination, and the addition of the stronger hydroxide ion can be expected to be faster still. These conclusions apply to aqueous solution at 25°C, of course, rather than to our conditions of ethanolic solution at 60°C. It is probably safe, however, to assume that the difference in solvent and temperature does not drastically change the qualitative picture. Definitive evidence would require determination of the rates of both elimination and stereoisomerization. We did not consider this practicable, because both reactions are complete in less than ten minutes under our conditions. The available evidence strongly suggests that it will be difficult if not impossible to determine the stereochemistry of elimination from 2-(*p*-nitrophenyl)ethyltrimethylammonium ion without interference from stereoisomerization of the product.

Experimental

Solvents

Ether and tetrahydrofuran were refluxed over sodium, with benzophenone used as an indicator of dryness (21). They were then distilled. Dimethyl sulfoxide was stirred over calcium hydride for 2 days. It was distilled under reduced pressure and the first 10% discarded. Distilled water was refluxed over potassium permanganate for 2 h and distilled. Absolute ethanol was refluxed over magnesium turnings for 8 h and distilled. The first 10% of distillate was discarded.

General

All melting and boiling points are uncorrected. Most of the nmr spectra were recorded on a Bruker WH-400 or a Nicolet QE 300 nmr spectrometer. In a few cases a Varian EM-390 instrument was used. Chloroform-*d* and dimethyl-d_6 sulfoxide were used as nmr solvents.

(E)-Styrene-β-d was obtained from β-bromostyrene (Aldrich: 78.6% *E*, 21.4% *Z*) by the procedure used to prepare (*E*)-1-phenyl-1-(*p*-methoxyphenyl)ethylene-2-*d* (5). The product was extracted into ether and kept in solution to minimize possible polymerization or isomerization.

(RR,SS)-2-Phenylethanol-1,2-d_2

Deuteroborane was generated by the addition of boron trifluoride etherate (0.029 mol) to a solution of sodium borodeuteride (0.022 mol) in 200 mL of tetrahydrofuran at 0°C. (*E*)-Styrene-β-*d* was then converted to the desired product by the procedure used to prepare (*RR,SS*)-3-methyl-2-phenyl-1-butanol-1-*d* (5), except that ether was used to extract the product and the extract washed with aqueous ferrous sulfate before drying over magnesium sulfate.

(RR,SS)-2-Phenylethyl-1,2-d_2 *tosylate* was prepared by a standard procedure (22) and used without recrystallization.

(RS,SR)-2-Phenylethyl-1,2-d_2*-dimethylamine* was obtained from (*RR,SS*)-2-phenylethyl-1,2-d_2 tosylate and dimethylamine by the procedure used to prepare (*RS,SR*)-3-methyl-2-phenyl-1-(butyl-1-*d*)dimethylamine (5). It was shown to be 78% *RS,SR* isomer by analysis of its Cope elimination products (see below); ^{1}H nmr δ: 2.31 (s, 6H), 2.52 (d, 1H), 2.80 (d, 1H), 7.2–7.4 (m, 5H).

(RS,SR)-2-Phenylethyl-1,2-d_2*-trimethylammonium iodide*

Treatment of the above product with methyl iodide (5) gave material of mp 230–233°C; ^{1}H nmr δ: 3.02 (d, 1H), 3.12 (s, 9H), 3.50 (d, 1H), 7.35 (m, 5H).

(RR,SS)-2-Phenylethyl-1,2-d_2*-amine*

Deuteroboration of (*E*)-styrene-β-*d* was carried out as in the preparation of (*RS,SR*)-2-phenylethanol-2,3-d_2 (above), but instead of treating the borane with hydrogen peroxide, NH_2OSO_3H (1.1 equiv.) was added slowly and the reaction mixture heated to 95°C for 4 h. The reaction mixture was treated with concentrated hydrochloric acid, made basic, and the amine extracted with ether. The crude product was obtained in 14% yield.

(RR,SS)-2-Phenylethyl-1,2-d_2*-dimethylamine* was obtained by methylation of the above amine with formaldehyde and formic acid (13) and was shown to be 79% *RR,SS* by analysis of its Cope elimination products (see below).

(RR,SS)-2-Phenylethyl-1,2-d_2*-trimethylammonium iodide* was prepared by the same procedure as for the *RS,SR* isomer (above) and had mp 228–232°C.

(RS,SR)-2-(p-Nitrophenyl)ethyl-1,2-d_2*-dimethylamine* was prepared by adding (*RS,SR*)-2-phenylethyl-1,2-d_2-dimethylamine dropwise to fuming nitric acid at −10°C (14). The reaction mixture was allowed to warm to 0°C, made basic with sodium hydroxide, and the product extracted into ether. After removal of the ether, it was shown by nmr to be 71% *para* and 29% *ortho*. Separation was effected by flash chromatography (15). The solvent consisted of 120 mL of pentane, 30 mL of trimethylamine, and 100 mL of ether. A 230–240 mesh silica gel 60 column was used. The *ortho* isomer (R_f=0.36) preceded the *para* isomer (R_f=0.28), which was obtained in 56% yield; ^{1}H nmr δ: 2.31 (s, 6H), 2.51 (d, 1H), 2.80 (d, 2H), 7.80 (dd, 4H).

(RS,SR)-2-(p-Nitrophenyl)ethyl-1,2-d_2*-trimethylammonium iodide* was obtained by treatment of the above product with methyl iodide (5) and had mp 207–208°C; ^{1}H nmr δ: 3.13 (s, 9H), 3.31 (d, 1H), 3.58 (d, 1H), 7.95 (dd, 4H).

(E)-β-Bromo-p-nitrostyrene was prepared by the procedure of Cristol and Norris (16). It had mp 155–157°C (lit. (16) mp 156–157°C); ^{1}H nmr δ: 6.69 (s, 1H), 7.03 (s, 1H), 7.70 (dd, 4H).

p-Nitrophenylacetylene

(*E*)-β-bromo-*p*-nitrostyrene (0.044 mol) was dissolved in 250 mL of 0.1 *M* sodium *tert*-butoxide in *tert*-butyl alcohol and stirred at 30°C for 35 h. The reaction mixture was poured into water and the product extracted with ether. The ether extract was dried over magnesium sulfate and the ether removed to give 88% of the crude product; ^{1}H nmr δ: 3.30 (s, 1H), 7.85 (dd, 4H).

(E)-p-Nitrostyrene-β-d

p-Nitrophenylacetylene (0.0034 mol) in anhydrous tetrahydrofuran was added to a solution of 9-BBN (17) (0.0017 mol) in tetrahydrofuran at 0°C. The mixture was stirred for 1 h at 0°C and 2 h at room temperature. Acetic-*O*-*d* acid (0.034 mol) was added and the mixture stirred for 2 h. The mixture was poured into water and the product extracted with ether. It was stored in ether solution to minimize possible polymerization or isomerization. ^{1}H nmr δ: 6.01 (d, 1H), 6.65 (d, 1H), 7.81 (dd, 4H).

1-(p-Nitrophenyl)ethanol-1-d

To 0.0055 mol of *p*-nitroacetophenone in ethanol was added 0.0055 mol of sodium borodeuteride and the mixture stirred for 1 h at room temperature. The reaction mixture was poured into water and the product extracted with ether. The ether solution was dried over magnesium sulfate and evaporated to give 58% of crude product; ^{1}H nmr δ: 1.50 (s, 3H), 3.44 (s, 1H), 7.80 (dd, 4H).

1-(p-Nitrophenyl)ethyl-1-d *tosylate* was obtained from 1-(*p*-nitrophenyl)ethanol-1-*d* by a standard procedure (22). The crude product was used in the next step; ^{1}H nmr δ: 1.49 (d, 3H), 2.49 (s, 3H), 4.99 (q, 1H), 7.60 (dd, 4H), 7.80 (dd, 4H).

p-Nitrostyrene-α-d was obtained by heating 1-(*p*-nitrophenyl)ethyl-1-*d* tosylate (0.0032 mol) in excess 0.1 *M* sodium *tert*-butoxide in *tert*-butyl alcohol at 60°C for 12 h. The mixture was cooled, poured into water, and the product extracted with ether. It was kept in ether solution to minimize possible polymerization; ^{1}H nmr δ: 5.53 (t, 1H), 6.09 (t, 1H), 7.81 (dd, 4H).

Cope elimination reactions (23) of 2-arylethyldimethylamine oxides

The amine (0.00051 mol) was dissolved in 10 mL of methanol, cooled at 0°C, and 30% hydrogen peroxide (0.0015 mol) added dropwise. The mixture was warmed to room temperature, stirred for 24 h, and the excess peroxide decomposed by adding 5 mg of 10% platinum on carbon and stirring for 5 h. The mixture was filtered, the solvent removed under reduced pressure, and the residue dissolved in 80% dimethyl sulfoxide – 20% water and heated for 2.5 h (>5 half lives for 2-phenylethyldimethylamine oxide (24)). The solvent was removed and the mixture of mono- and di-deuterated styrenes analyzed by 300- or 400-MHz nmr (see Discussion).

Stereochemistry of base-promoted reactions of 2-arylethyl-1,2-d_2*-trimethylammonium iodides with sodium ethoxide in ethanol*

The substrate (ca. 20 mg) was dissolved in 5 mL of 0.1 *M* sodium ethoxide in ethanol at 80°C (unsubstituted) or 60°C (*p*-nitro substituted). The reaction was followed to completion by tlc (thin-layer chromatography). The reaction mixture was poured into water and the product was extracted with petroleum ether. The petroleum ether solution was dried over magnesium sulfate, filtered, 2 mL of dimethyl-d_6 sulfoxide added, and the petroleum ether removed on a rotary evaporator. The mixture of mono- and di-deutero styrenes was analyzed by 300- or 400-MHz nmr.

This paper is dedicated to Professor Arthur N. Bourns

JAHANGIR, DAVID B. MACLEAN, and HERBERT L. HOLLAND. Can. J. Chem. **64**, 1031 (1986).

Anions derived from furo[3,4-*c*]pyridin-3(1*H*)-one, by treatment with lithium diisopropylamide, react with substituted, 3,4-dihydroisoquinolines and 2-methyl-3,4-dihydroisoquinolinium salts yielding nitrogen analogues of the protoberberine and phthalideisoquinoline alkaloids, respectively.

JAHANGIR, DAVID B. MACLEAN et HERBERT L. HOLLAND. Can. J. Chem. **64**, 1031 (1986).

Les anions formés par la réaction de la furo[3,4-*c*]pyridine-(1*H*) one-3 avec le diisopropylamidure de lithium réagissent avec les dihydro-3,4 isoquinoléines substituées et avec les sels de méthyl-2 dihydro-3,4 isoquinolinium pour conduire respectivement aux analogues azotés des alcaloïdes de la protoberbérine et de la phtalideisoquinoléine.

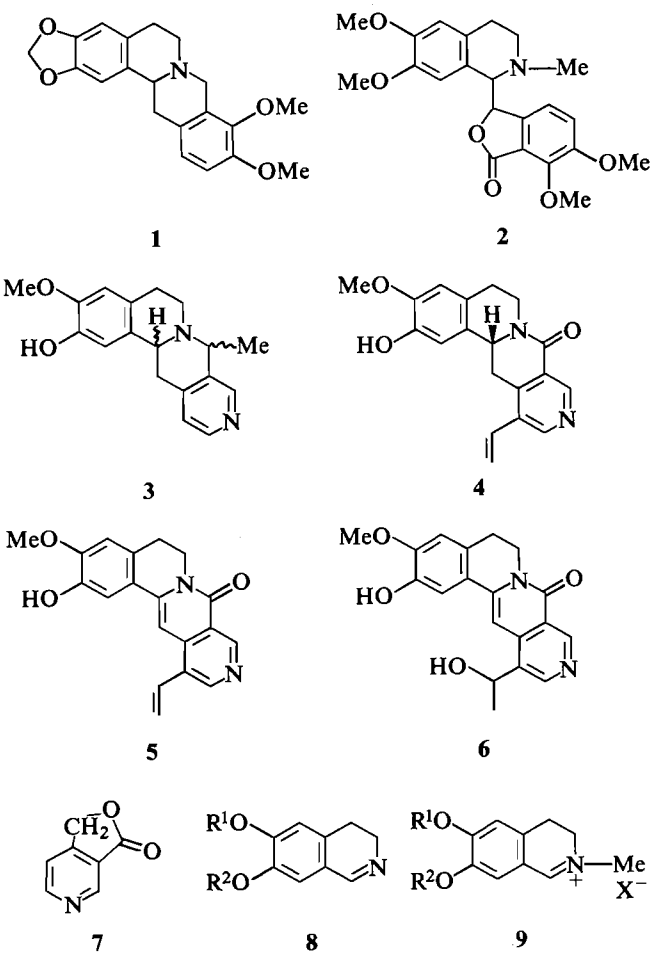
[Traduit par la revue]

In several recent publications from this laboratory we have reported (1–5) the reactions of phthalide anions with imines and iminium salts. These reactions provided convenient routes to protoberberine (e.g., canadine **1**) and phthalideisoquinoline alkaloids (e.g., cordrastine **2**), respectively, and to related compounds in each series. The recent discovery of pyridine analogues of the protoberberines such as **3**, **4**, **5**, and **6** in *Alangium* species (6, 7) prompted us to investigate their synthesis by a route similar to that used for the synthesis of the protoberberine alkaloids from phthalide precursors (1, 2). To this end we prepared the anion derived from furo[3,5-*c*]pyridin-3(1*H*)-one (azaphthalide **7**) and studied its reaction with 3,4-dihydroisoquinolines **8** and also with the corresponding 2-methyl-3,4-dihydroisoquinolinium salts **9**. These reactions, which are reported below, provided, in the case of the reaction with imines, a straightforward route to the ring system of the *Alangium* alkaloids and, in the case of the reaction with iminium salts, a new class of compounds, which are pyridine analogues of the phthalideisoquinolines.

The imines **8***a*–**8***c* were prepared by cyclization of substituted *N*-formylphenylethylamines with $POCl_3$ as condensing agent. This procedure gave better yields than the usual method in which mixtures of acetonitrile and $POCl_3$ were employed. The imines **8***a*–**8***c* were converted to their methiodides **9***a*–**9***c* by standard procedures.

The furo[3,4-*c*]pyridin-3(1*H*)-one used in this study was prepared by reduction of cinchomeronic acid anhydride with sodium borohydride as outlined in Scheme 1. This major isomer was separated by crystallization from the minor regioisomer **10**. This preparation, an adaptation of a method developed by Kayser and Morand (8) for reduction of other acid anhydrides, proved superior to the previously reported reductions of cinchomeronic acid anhydride with LAH (lithium aluminum hydride) (9) and of the half ester of cinchomeronic acid with LAH (10).

Reaction of the lithium salt of the azaphthalide **7** with the 3,4-dihydroisoquinolines **8***a*, **8***b*, and **8***c* is outlined in Scheme 2. The initial products of the reaction were assigned structures **11** on the basis of spectroscopic examination of the compounds and of their *O*-acetates **12** and in analogy with the previously studied products of the reaction of lithium phthalide and 3,4-dihydroisoquinolines (1, 2). The relative configuration at C-13 and C-14 could not be established with certainty by examination



[1]A part of this work was presented at the 14th IUPAC International Symposium on the Chemistry of Natural Products, Poznan, Poland (see ref. 5).

SCHEME 1

of the nmr spectra of compounds **11**, but their *O*-acetyl derivatives **12** showed that H-13 and H-14 were *trans* to one another, $J_{13,14}$ = 10.5 Hz (ref. 2, and references therein). The dehydration of **11***a*, **11***b*, and **11***c* was effected by treatment with $POCl_3$, yielding the isocarbostyril system found in compounds **13**. Again, these compounds showed the anticipated spectroscopic behaviour. Thus, the condensation of the azaphthalide with the imines provided a convenient route to the ring system found in the *Alangium* alkaloids.

Alternative routes to this ring system, which are not regiospecific, and which involve photochemical (11, 12) or thermal (12) cyclization of tricyclic enamides, have been described. Both methods have been applied successfully to the synthesis of the *Alangium* alkaloids, alamarine **6** and alangimarine **5** (13).

The mass spectral fragmentation of the compounds **11**(*a*–*c*) prepared in this study is analogous to that of the corresponding protoberberines examined in the previous study (2). The major fragmentation involves a retro-Diels–Alder opening of ring C of the azaberberine system. Ions corresponding to the isoquinoline moiety plus a hydrogen are observed in the three compounds at *m/z* 192, 176, and 268, respectively, and an ion derived from rings C and D is present in all three compounds at *m/z* 135.

We recently described the synthesis of phthalideisoquinoline alkaloids and related compounds by treatment of lithium phthalides with 2-methyl-3,4-dihydroisoquinolinium salts (3). Here we report that the lithium salt of furo[3,4-*c*]pyridin-3(*H*)-one behaves in an exactly analogous fashion to lithium phthalide in its reaction with isoquinolinium salts, as shown in Scheme 3, yielding mixtures of the racemic *threo* **14** and *erythro* **15** diastereomers. The yields reported for the two isomers refer to crystalline product isolated from the reaction system and should not be used as a measure of the *threo*:*erythro* ratio present in the crude reaction product, which is expected to be nearly 1:1.

The assignment of configuration to the *threo* and *erythro* isomers is based on a comparison of the properties of the isomeric compounds prepared in this study with those of phthalideisoquinoline alkaloids where the configurational assignments are secure (14, 15). In the *threo* compounds examined in this work, the proton at C-7′ is always deshielded relative to the corresponding proton in the *erythro* series. This situation is similar to that observed for the phthalideisoquinoline alkaloids themselves (16, 17), indicating that the isoquinoline–azaphthalide system in compounds **14** and **15** adopts the same preferred conformation as the corresponding rings in the alkaloids. In the *erythro* systems, the preferred conformation places the hydrogen at C-7′ in the shielding cone of the aromatic ring of the isoquinoline moiety, whereas in the preferred *threo* conformation this hydrogen is not in a position where it can be similarly affected. There is also consistency with respect to the coupling constants between the hydrogens at C-1 and C-1′. In each series the *threo* isomer has a smaller coupling constant than the *erythro* isomer. Moreover, the *erythro* and *threo* isomers also exhibit a similar chromatographic behaviour in each series. The *threo* isomer is less polar than the *erythro* on silica columns and shows a higher R_f value on tlc plates.

Experimental

Apparatus, materials, and methods

Unless otherwise stated, the ^1H nmr spectra were continuous wave, run at 90 MHz on a Varian EM 390 spectrometer. The samples were dissolved in $CDCl_3$ using tetramethylsilane (TMS) as the internal standard. Chemical shifts, quoted as δ values, were measured in relation to TMS. The symbols s, singlet, d, doublet, t, triplet, q, quartet, and m, multiplet are used in reporting spectra. The Fourier transform spectra were run on either a Bruker WP80 (80 MHz) or WM250 (250 MHz) spectrometer. The ^{13}C nmr spectra were run at 62.9 MHz on a Bruker WM250 FT spectrometer or at 20.115 MHz on a Bruker WP80 FT spectrometer, both at ambient temperature.

EI (electron impact) mass spectra were recorded on a V.G. Micromass 7070 F mass spectrometer at 70 eV and CI (chemical ionization) spectra on the same instrument using NH_3 at ca. 1 Torr (1 Torr = 133.3 Pa) as reagent gas. Infrared spectra were recorded on a Perkin–Elmer 283 spectrometer in $CHCl_3$ solution. Melting points were determined using a Gallenkamp apparatus and are uncorrected. The microanalyses were performed by the Guelph Chemical Laboratories Ltd., Guelph, Ontario.

Thin-layer chromatography (tlc) was performed using Polygram Sil G/UV_{254} or Polygram Aloxn/UV_{254} plates. Flash column chromatography (18) was employed using Kieselgel 60 (230–400 mesh).

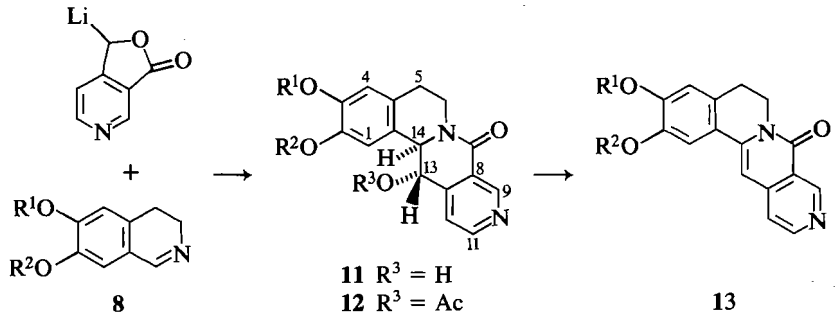
All reactions involving lithiation steps were carried out in flame-dried apparatus under a blanket of argon, using septa and syringes for transfer of reagents. Diisopropylamine was refluxed over calcium hydride and distilled onto molecular sieves (4A). THF (tetrahydrofuran) was dried by distillation from Na/benzophenone under a nitrogen atmosphere just prior to use. The following compounds were obtained commercially or prepared according to literature procedures: cinchomeronic acid, cinchomeronic acid anhydride (19, 20); *N*-formyl-3,4-methylenedioxyphenylethyl amine (2); *N*-formyl-3,4-demethoxyphenylethyl amine (16); 6,7-methylenedioxy-2-methyl-3,4-dihydroisoquinolinium iodide (21); 6,7-dimethoxy-2-methyl-3,4-dihydroisoquinolinium iodide (22).

Preparation of 3,4-dihydroisoquinolines **8**a–**8**c

The appropriate formamides, *N*-formyl-3,4-dimethoxyphenylethyl amine, *N*-formyl-3,4-methylenedioxyphenylethyl amine, and *N*-formyl 3-methoxy-4-benzyloxyphenylethyl amine (25.0 g), were treated slowly and carefully at ice bath temperature with freshly distilled $POCl_3$ (60 mL) in a flask protected with a $CaCl_2$ tube. When the vigorous initial reaction subsided, the mixture was warmed to room temperature over a period of 10–20 min, then heated to 40°C for 5 min, and finally kept at room temperature for 2 h. The excess $POCl_3$ was destroyed by addition of the reaction mixture to crushed ice and the resulting solution made basic with concentrated aqueous NH_3. The mixture was extracted with $CHCl_3$, the $CHCl_3$ extract dried and evaporated, and the residue purified by bulb-to-bulb distillation. Compounds **8***a*–**8***c* were obtained in 80–90% yield; their spectroscopic properties were in accord with those reported in the literature: **8***a* (2), **8***b* (2), and **8***c* (23).

Reduction of cinchomeronic acid anhydride

A suspension of $NaBH_4$ (1.9 g, 0.05 mol) in freshly distilled THF (100 mL) and dry DMF (10 mL) was heated under reflux in a 2-necked, flame-dried, round-bottom flask under an argon atmosphere for 20 min. The reaction mixture was then cooled to 0°C in an ice bath and finely powdered cinchomeronic acid anhydride (7.48 g, 0.05 mol) was added in one portion. The mixture, which turned faintly pink, was stirred for 1 h at 0°C, the ice bath was removed, and stirring continued for a further 3 h. Excess $NaBH_4$ was destroyed by careful addition of a few drops of concentrated aqueous HCl at 0°C. The solvent was then evaporated, the residue taken up in 30 mL of 10 *M* HCl (aq) and the mixture heated under reflux for 1 h. The solution was then cooled and carefully neutralized to pH 8–9 with solid K_2CO_3. The neutral solution was extracted with $CHCl_3$, the extract washed with brine, and then dried over Na_2SO_4. The residue obtained on evaporation of the dried $CHCl_3$ extract was a mixture of azaphthalides 7 and **10** in a 4:1 ratio as estimated by ^1H nmr. The crude yields in a number of reactions ranged



8 **11** R^3 = H; **12** R^3 = Ac **13**

Note: For compounds 8, 11, 12, and 13 in the (*a*) series, $R^1 = R^2 = CH_3$; in the (*b*) series $R^1 + R^2 = CH_2$, and in the (*c*) series $R^1 = CH_3$, $R^2 = C_6H_5CH_2$

SCHEME 3

from 40–65%. The azaphthalides **7** and **10** were purified by fractional sublimation and by fractional crystallization from $CHCl_3$–Et_2O; azaphthalide (**7**), mp 142–143°C (lit. (10) mp 130–135°C; lit. (24) mp 145°C); azaphthalide (**10**), mp 116–118°C (lit. (23) mp 118°C). The spectroscopic properties of **7** and **10** were in agreement with literature values (10, 24).

Reaction of imine (8a) with the lithium salt of azaphthalide (7)

A solution of *n*-BuLi (2.44 mmol) in hexane 1.6 *M* was added dropwise with stirring to a solution of diisopropylamine (2.44 mmol) in THF at −20°C under an argon atmosphere. The LDA solution was stirred for an additional 5 min at the same temperature. After the addition was complete, the temperature of the reaction mixture was then lowered to −60°C and a solution of azaphthalide **7** (300 mg, 2.22 mmol) in THF (2 mL) was added dropwise to the LDA solution. The solution of the red anion so generated was stirred for a further 15 min at −60°C. Imine **8***a* (439 mg, 2.22 mmol) in 3 mL THF was then added dropwise and, when addition was complete, stirring of the solution was continued another 2 h. The temperature was raised to 20°C and the reaction mixture kept at this temperature for ca. 12 h. The mixture was worked up in the usual manner (1, 2) affording the condensation product **11***a* (590 mg, 81%), mp 230–235°C (dec.) ($CHCl_3$, acetone): R_f 0.22 (alumina, EtOAc); ir ($CHCl_3$), ν_{max}: 1645 cm^{-1}; ^1H nmr (90 MHz) δ: 2.8–3.0 (3H, m, C-5 H's and C-6 H_{ax}), 3.87 (3H, s, OCH_3), 3.90 (3H, s, OCH_3), 4.57–4.75 (2H, m, C-13 H and C-14 H), 4.85–5.05 (1H, m, C-6 H_{eq}), 6.75 (1H, s, C-4 H), 7.03 (1H, s, C-1 H), 7.70 (1H, d, J = 5.5 Hz, C-12 H), 8.74 (1H, d, J = 5.5 Hz, C-11 H), 9.13 (1H, s, C-9 H); ^{13}C nmr (62.9 MHz) δ: 30.3 (C-5), 39.3 (C-6); 56.3, 56.5, (2 × OCH_3); 61.4 (C-14), 71.3 (C-13); 112.4, 118.5, 123.3, 123.9, 129.2, 147.9, 149.1, 149.6, 149.7, 153.0 (aromatic carbon atoms);[3] 162.8 (C=O); ms (EI), *m*/*z* (%): 326 (26.5) $M^{+\cdot}$, 309 (4.5), 192 (100), 135 (10), 134 (6.5), 106 (18). *Anal.* calcd. for $C_{18}H_{18}N_2O_4$: C 66.26, H 5.52, N 8.59; found: C 66.11, H 5.59, N 8.58%. *Exact Mass* (hrms) calcd. for $C_{18}H_{18}N_2O_4$: 326.127; found: 326.127.

Reaction of imine (8b) with the lithium salt of azaphthalide (7)

This reaction was carried out in exactly the same manner as that described above. The condensation product **11***b* was separated as an oil but crystallized from ethyl acetate (420 mg, 61%), mp 230–231°C; R_f 0.46 (alumina, EtOAc); ir ($CHCl_3$), ν_{max}: 1640 cm^{-1}; ^1H nmr (90 MHz), δ: 2.80–3.13 (3H, m, C-5 H's and C-6 H_{ax}), 4.53–4.73 (2H, m, C-13 H and C-14 H), 4.83–5.03 (1H, m, C-6 H_{eq}), 5.97 (2H, s, OCH_2O), 6.73 (1H, s, C-4 H), 6.97 (1H, s, C-1 H), 7.67 (1H, d, J = 5.5 Hz, C-12 H), 8.77 (1H, d, J = 5.5 Hz, C-11 H), 9.20 (1H, s, C-9 H); ^{13}C nmr ($CDCl_3$ + DMSO-d_6) δ: 30.0 (C-5), 38.9 (C-6), 60.7 (C-14), 69.8 (C-13), 100.8 (OCH_2O); 108.1, 109.9, 119.0, 122.8, 125.4, 129.5, 145.4, 146.5, 148.6, 151.2, 152.4 (11 aromatic carbons); 162.0 (C=O); ms (EI), *m*/*z* (%): 310 (23) $M^{+\cdot}$, 176 (96.5), 135 (20.9), 106 (100). *Anal.* calcd. for $C_{17}H_{14}N_2O_4$: C 65.80, H 4.52, N 9.03; found: C 65.70, H 4.71, N 9.23%. *Exact Mass* for $C_{17}H_{14}N_2O_4$: 310.095; found: 310.094.

Reaction of imine (8c) with the lithium salt of azaphthalide (7)

The reaction was carried out in the manner described for the reaction between **8***a* and **7** except that 1.85 mmol of **8***c* was used and other quantities adjusted accordingly. The product (**11***c*) was recrystallized from $CHCl_3$–acetone (317 mg, 43%), mp 222–223°C; R_f 0.56 (alumina, EtOAc); ir ($CHCl_3$), ν_{max}: 1650 cm^{-1}; ^1H nmr (90 MHz), δ: 2.67–3.00 (3H, m, C-5 H's and C-6 H_{ax}), 3.97 (3H, s, OCH_3), 4.47–4.67 (2H, m, C-13 H and C-14 H), 4.87–5.03 (1H, m, C-6 H_{eq}), 6.70 (1H, s, C-4 H), 6.95 (1H, s, C-1 H), 7.30–7.53 (5H, m, C_6H_5), 7.60 (1H, d, J = 5.5 Hz, C-12 H), 8.75 (1H, d, J = 5.5 Hz, C-11 H), 9.20 (1H, s, C-9 H); ^{13}C nmr, δ: 29.8 (C-5), 39.0 (C-6), 55.9 (OMe), 60.6 (C-14), 70.2 (C-13 or OCH_2Ar), 71.0 (C-13 or OCH_2Ar); 111.7, 115.7, 119.0, 123.0, 124.4, 127.4, 127.5, 127.8, 128.4, 129.0, 137.0, 146.1, 148.8, 148.9, 151.1, 152.6 (aromatic carbons);[4] 162.5

[3]Ten signals were observed for 11 carbon atoms.

[4]16 signals observed for 17 aromatic carbon atoms.

(C=O); ms (EI), *m/z* (%): 402 (24.1) $M^{+\cdot}$, 268 (12.0), 177 (10.2), 135 (100), 134 (26.2), 106 (75), 91 (68.4). *Anal.* calcd. for $C_{24}H_{22}N_2O_4$: C 71.64, H 5.47, N 6.97; found: 71.98, H 5.76, N 7.14%.

O-*Acetyl derivative of* ***11***a

Compound **11***a* (50 mg) was dissolved in pyridine (0.5 mL) and treated with an excess of acetic anhydride (1.5 mL). The mixture was kept in a stoppered flask for ca. 12 h, the excess reagent removed under vacuum, and water (5 mL) added to the residue. The aqueous suspension was extracted with chloroform, and the chloroform extract washed with brine, dried over Na_2SO_4, and evaporated to dryness. The *O*-acetate (**12***a*) crystallized from methanol (47 mg, 83%), mp 249–250°C (dec.) (MeOH); R_f 0.36 (alumina, EtOAc); ir ($CHCl_3$), ν_{max}: 1645, 1745 cm^{-1}; ^1H nmr (250 MHz), δ: 2.23 (3H, s, $OCOCH_3$), 2.78–3.10 (3H, m, C-5 H's and C-6 H_{ax}), 3.88 (3H, s, OCH_3), 3.90 (3H, s, OCH_3), 4.92 (1H, d, *J* = 10.7 Hz, C-14 H), 4.90–5.00 (1H, m, C-6 H_{eq}), 6.05 (1H, d, *J* = 10.7 Hz, C-13 H), 6.72 (1H, s, C-4 H), 6.76 (1H, s, C-1 H), 7.15 (1H, d, *J* = 5.20 Hz, C-12 H), 8.76 (1H, d, *J* = 5.2 Hz, C-11 H), 9.27 (1H, s, C-9 H); ^{13}C nmr (62.9 MHz), δ: 21.0 (*CH*$_3$CO), 30.0 (C-5), 39.8 (C-6); 56.0, 56.4 (2 × OCH_3); 59.1 (C-14), 71.3 (C-13); 111.7, 111.8, 118.0, 120.8, 122.3, 125.5, 129.5, 146.2, 150.2, 153.0 (aromatic carbon atoms);[5] 160.57 (lactam C=O), 172.9 (CH_3*CO*); ms (EI), *m/z* (%): 368 (0.8) $M^{+\cdot}$, 325 (22.7), 308 (100), 293 (38.6), 135 (19.3), 134 (65.8). *Exact Mass* (hrms) calcd. for $C_{18}H_{17}N_2O_4$ ($M-C_2H_3O$): 325.119; found: 325.121; calcd. for $C_{18}H_{16}N_2O_3$ ($M-C_2H_4O_2$): 308.116; found: 308.121.

O-*Acetyl derivative of* ***11***b

This compound was prepared from 50 mg of **11***b* under the conditions used to prepare **12***a*. The product **12***b* crystallized from methanol (55 mg, 97%), mp 232–233°C (MeOH); R_f 0.63 (Al_2O_3, EtOAc); ir ($CHCl_3$), ν_{max}: 1650, 1750 cm^{-1}; ^1H nmr (250 MHz), δ: 2.23 (3H, s, *CH*$_3$CO), 2.76–3.05 (3H, m, C-5 H's and C-6 H_{ax}), 4.87 (1H, d, *J* = 10.7 Hz, C-14 H), 4.90–4.96 (1H, m, C-6 H_{eq}), 5.96 (2H, s, OCH_2O), 5.97 (1H, d, *J* = 10.7 Hz, C-13 H), 6.69 (1H, s, C-4 or C-1 H), 6.71 (1H, s, C-1 or C-4 H), 7.16 (1H, d, *J* = 5.2 Hz, C-12 H), 8.76 (1H, d, *J* = 5.2 Hz, C-11 H), 9.26 (1H, s, C-9 H); ms (EI), *m/z* (%): 352 (<1.0%) $M^{+\cdot}$, 2.09 (7.6), 292 (57.2), 277 (29.7), 176 (14.3), 135 (11.3), 134 (33). *Anal.* calcd. for $C_{19}H_{16}N_2O_5$: C 64.77, H 4.55, N 7.95; found: C 64.42, H 4.62, N 7.86. *Exact Mass* (hrms) calcd. for $C_{19}H_{13}N_2O_4$ ($M-C_2H_3O$): 309.088; found: 309.082.

O-*Acetyl derivative of* ***11***c

This compound was prepared from 25 mg of **11***c* under the conditions used to prepare **12***a*. The product **12***c* crystallized from chloroform–ether (23 mg, 83%), mp 182–185°C; R_f 0.80 (alumina, EtOAc), 0.52 (silica, EtOAc); ir ($CHCl_3$), ν_{max}: 1760, 1655 cm^{-1}; ^1H nmr (250 MHz), δ: 2.08 (3H, s, CH_3CO), 2.80–3.10 (3H, m, C-6 H's and C-5 H_{ax}), 3.88 (3H, s, —OCH_3), 4.80–5.00 (2H, m, C-14 H, C-5 H_{eq}), 5.08 (2H, s, CH_2Ar), 5.95 (1H, d, *J*=10.3 Hz, C-13 H), 6.72 (1H, s, C-1 or C-4 H), 6.80 (1H, s, C-1 or C-4 H), 7.09 (1H, d, *J* = 5.0 Hz, C-12 H), 7.30–7.50 (5H, m, C_6H_5), 8.72 (1H, d, *J* = 5.0 Hz, C-11 H), 9.24 (1H, s, C-9 H); ms (EI), *m/z* (%): 444 (3.1) $M^{+\cdot}$, 384 (44), 293 (20), 134 (20), 91 (100). *Exact Mass* (hrms) calcd. for $C_{24}H_{20}N_2O_3$ $(M-C_2H_4O_2)^{+\cdot}$: 384.147; found: 384.147.

Dehydration of alcohol ***11***a

To a solution of alcohol **11***a* (100 mg) in dry pyridine (5 mL) was added freshly distilled $POCl_3$ (1 mL) and the reaction mixture was left at ~20°C for 3 h. The excess of the reagent was evaporated *in vacuo* and the residue dissolved in water (10 mL), made basic with concentrated aqueous NH_3, and thoroughly extracted into chloroform. The combined chloroform extracts were washed with brine, dried over anhydrous Na_2SO_4, and evaporated *in vacuo*. The last traces of pyridine were removed by codistillation using benzene. The crude material on crystallization from MeOH gave product **13***a* (62 mg, 65.6%), mp 185–186°C (MeOH) (lit. (11) mp 169–172°C; R_f 0.37 (alumina, EtOAc); ir ($CHCl_3$), ν_{max}: 1650 cm^{-1}; ^1H nmr (250 MHz), δ: 2.97 (3H, t, *J* = 6.1 Hz, C-5 H's), 3.96 (3H, s, OCH_3), 4.00 (3H, s, OCH_3), 4.33 (2H, t, *J* = 6.1 Hz, C-6 H's), 6.77 (1H, s, C-1 or C-4 H), 7.27 (1H, s, C-13 H), 7.37 (1H, d, *J* = 5.5 Hz, C-12 H), 8.67 (1H, d, *J* = 5.5 Hz, C-11 H), 9.58 (1H, s, C-9 H); ^{13}C nmr, δ: 27.7 (C-5), 39.4 (C-6), 56.0, 56.3 (2 × OMe); 99.1, 108.5, 110.6, 118.9, 120.2, 129.5, 141.7, 142.9, 148.6, 150.4, 151.1, 151.2 (vinylic and aromatic carbons);[6] 161.6 (C=O); ms (EI), *m/z* (%): 308 (100) $M^{+\cdot}$, 307 (17), 294 (13.3), 293 (67.9), 291 (5.0), 277 (3.6), 265 (4.8). *Exact Mass* (hrms) calcd. for $C_{18}H_{16}N_2O_4$: 308.117, found: 308.116.

Dehydration of alcohol ***11***b

This reaction was carried out under the same conditions used for the preparation of **13***a*. The product **13***b* was obtained in 77% yield, mp 288–290° (dec.); R_f 0.58 (alumina, EtOAc); ir ($CHCl_3$), ν_{max}: 1650 cm^{-1}; ^1H nmr (250 MHz), δ: 2.94 (2H, t, *J* = 6.2 Hz, C-5 H's, 4.33 (2H, t, *J* = 6.2 Hz, C-6 H's), 6.05 (2H, s, OCH_2O), 6.75 (2H, s, C-1 and C-4 H's), 7.26 (1H, s, C-13 H), 7.34 (1H, d, *J* = 5.3 Hz, C-12 H), 8.67 (1H, d, *J* = 5.3 Hz, C-11 H), 9.58 (1H, s, C-9 H); ms (EI), *m/z* (%): 292 (97) $M^{+\cdot}$, 291 (34.3), 277 (100), 233 (26.3), 205 (23.6). *Exact Mass* (hrms) calcd. for $C_{17}H_{12}N_2O_3$: 292.085; found: 292.082.

Dehydration of alcohol ***11***c

This reaction was carried out in the same manner used for the dehydration of **11***a*. The product **13***c* was obtained in 95% yield, mp 180–182°C (EtOAc–hexane); R_f 0.68 (alumina, EtOac); ir ($CHCl_3$), ν_{max}: 1655 cm^{-1}; ^1H nmr (90 MHz), δ: 3.05 (2H, t, *J* = 6.2 Hz, C-5 H's), 4.05 (3H, s, OCH_3), 4.40 (2H, t, *J* = 6.2 Hz, C-6 H's), 5.34 (2H, s, OCH_2Ar), 6.73 (1H, s, C-1 H or C-4 H), 6.90 (1H, s, C-4 H or C-1 H), 7.30–7.67 (7H, m, C_6H_5, C-12 H and C-13 H), 8.87 (1H, d, *J* = 5.5 Hz, C-11 H), 9.58 (1H, s, C-9 H); ^{13}C nmr, δ: 29.9 (C-5), 41.5 (C-6), 58.1 (OMe), 74.0 (*OCH*$_2$Ar); 101.1, 113.1, 114.1, 120.7, 123.5, 129.6, 130.2, 130.7, 132.4, 138.9, 143.9, 149.8, 152.6, 153.6, 154.4 (vinylic and aromatic carbons);[7] 163.1 (C=O); ms (EI), *m/z* (%): 384 (74.3) $M^{+\cdot}$, 383 (8.8), 293 (29.0), 265 (7.2), 91 (100). *Exact Mass* (hrms) calcd. for $C_{24}H_{20}N_2O_3$: 384.147; found: 384.148.

*Reaction of iminium salt (****9***a*) *with the anion of azaphthalide (****7***)

n-BuLi (2.56 mmol) in hexane (1.6 *M*) was added to a stirred solution of disopropylamine (2.56 mmol) in dry THF (5 mL) at −78°C under an argon atmosphere. The temperature of the LDA solution was raised to 0°C for 10–15 min and then cooled again to −78°C before proceeding with the dropwise addition of a solution of the azaphthalide **7** (2.2 mmol in THF, 3 mL). Towards the end of the addition the initially formed red solution became turbid but became homogeneous again on raising the temperature to −40°C. The temperature was kept at −40°C during the remainder of the addition and for an additional 20 min. The solution was then transferred through a syringe tube into a flask fitted with a magnetic stirrer containing a suspension of 6,7-dimethoxy-2-methyl-3,4-dihydroisoquinolinium iodide (**9***a*) (740 mg, 2.2 mmol) in dry THF (3 mL). The mixture was stirred at −40°C for 3–4 h and then at ambient temperature overnight. The solvent was evaporated from the reaction mixture and the crude residue passed through a column of neutral alumina (activity I) using EtOAc as eluant. The residue obtained upon evaporation of the EtOAc was taken up in EtOH and from this solution the crystalline *threo* isomer **14***a* was obtained. The mother liquors were taken to dryness and the residue, dissolved in EtOAc, was separated into *threo* (**14***a*) and *erthryo* (**15***a*) components by flash chromatography.

Threo, **14***a* (213 mg, 25.6%); mp 198°C (from EtOH); R_f 0.48 (SiO_2, EtOAc); ir ($CHCl_3$), ν_{max}: 1762 cm^{-1}; ^1H nmr (250 MHz), δ: 2.4–3.2 (4H, m, C-3 H's, and C-4 H's), 2.71 (3H, s, —NCH_3); 3.71 (3H, s, OCH_3), 3.80 (3H, s, OCH_3), 4.19 (1H, d, *J* = 3.7 Hz, C-1 H), 5.75 (1H, d, *J* = 3.7 Hz, C-1′ H), 6.31 (1H, s, C-5 H), 6.66 (1H, s, C-8 H), 7.72 (1H, d, *J* = 5.1 Hz, C-7′ H), 8.63 (1H, d, *J* = 5.1 Hz,

The quantum theory of atoms in molecules defines structures for and determines the properties of the atoms and bonds in the series of carbocations $[(CH_3)_nCH_{3-n}]^+$ with $n = 0$–3, and their parent hydrocarbons. In this theory, an atom in a molecule and its properties are defined by quantum mechanics. The quantum condition defining the atom is given in terms of a property derived from the charge density, as are the other concepts of the molecular structure hypothesis. In terms of the amount of electronic charge density accumulated between the carbon nuclei and its spatial distribution, a C—C bond of the carbocations exhibits an order greater than one. There is a transfer of charge from the hydrogens of methyl to the central carbon that destroys the axial symmetry of these C—C bonds and concentrates the charge in a plane perpendicular to the plane of substitution, in a manner consistent with the hyperconjugative mechanism of electron transfer. The positive charge of a carbocation is thus delocalized over all the atoms in the molecule, and the extent of this delocalization increases with increased methyl substitution. The electron population of each atom in a carbocation increases with this increase in the delocalization of positive charge and its energy is correspondingly decreased (the atom becomes more stable). These effects are most pronounced for the carbon atom bearing the methyl groups and they account for the observed increase in the relative stabilities of the carbocations with increasing methyl substitution. The electron populations and energies of the atoms in saturated hydrocarbons are also determined. The group additivity scheme for the energy in the homologous series of normal alkanes is predicted and explained in terms of the properties of the quantum atoms. It is the possibility of such transferability of the quantum atoms and their properties between systems that identifies them with the atoms of chemistry.

R. F. W. BADER. Can. J. Chem. **64**, 1036 (1986).

La théorie quantique des atomes dans les molécules définit les structures et détermine les properiétés des atomes et des liaisons dans une série de carbocations $[(CH_3)_nCH_{3-n}]^+$, dans lesquels $n = 0$–3, ainsi que dans leurs hydrocarbures de base. Dans cette théorie, la condition quantique qui définit l'atome ainsi que les autres concepts de l'hypothèse relative à la structure moléculaire sont définies en fonction d'une propriété dérivée de la densité de charge. En termes de la densité de la charge électronique qui est accumulée entre les noyaux de carbone et de leur distribution spatiale, une liaison C—C des carbocations présente un ordre qui est plus grand que un. Il se produit un transfert de charge des hydrogènes du méthyle vers le carbone central et ceci détruit la symétrie axiale de ces liaisons C—C et concentre la charge dans un plan perpendiculaire au plan de la substitution, d'une manière qui est en accord avec le mécanisme d'hyperconjugaison de transfert électronique. La charge positive d'un carbocation est donc délocalisée sur tous les atomes de la molécule et le degré de cette délocalisation augmente avec la substitution par des groupements méthyles. La population électronique de chaque atome d'un carbocation augmente avec cette augmentation dans la délocalisation de la charge positive et son énergie diminue d'une manière correspondante (l'atome devient plus stable). Ces effets se font sentir le plus sur l'atome de carbone qui porte les groupements méthyles et ils expliquent le fait que les stabilités relatives des carbocations augmentent avec une augmentation de la substitution par des groupements méthyles. On a aussi déterminé les populations électroniques et les énergies des atomes dans des hydrocarbures saturés. Le schéma d'additivité des groupements pour déterminer l'énergie dans des séries homologues d'alcanes normaux est prédit et expliqué en fonction des propriétés des atomes quantiques. C'est cette possibilité de tels transferts d'atomes quantiques et des leurs propriétés entre atomes qui les identifie avec les atomes de la chimie.

[Traduit par la revue]

Introduction

This paper relates the chemistry of carbocations and their parent hydrocarbons to the properties of their charge distributions. The molecules considered are the cations $[H_{3-n}C(Me)_n]^+$, $n = 0$–3, their parent hydrocarbons, and the additional hydrocarbons *n*-butane and *n*- and neo-pentane. The atoms, their properties, and the networks of bonds in these molecules are defined in terms of the quantum theory of atoms in molecules (1, 2). Trends in the properties of the atoms are determined within each set and compared between the sets. The primary static properties considered are the net charges and the energies of the atoms (3). The characters of the carbon–carbon bonds are summarized in terms of a bond order as determined by the value of the charge density ρ, at the bond saddle point, and a bond ellipticity as determined by the relative magnitudes of the two curvatures of ρ perpendicular to the bond path at the saddle point (4). The ellipticity of a bond measures its departure from radial symmetry and determines the plane in which charge density is preferentially accumulated. The atomic charges together with the orders and ellipticities of the bonds enable one to distinguish between the inductive and hyperconjugative electron release of charge to the carbon atom bearing the formal positive charge in the carbocations. The dominant factor determining the increasing stability of the carbocations with increasing methyl substitution is the corresponding increase in their ability to disperse the positive charge over the hydrogens of the methyl groups by both mechanisms of electron release.

The Laplacian of the charge density, the quantity $\nabla^2\rho$, determines the points within a molecule where electronic charge is locally concentrated and depleted (5, 6). The susceptibility of the carbocations to the addition of a nucleophile is related to the properties of their Laplacian distributions, and the relative inertness of the hydrocarbons to either nucleophilic or electrophilic attack is accounted for in the same manner.

Approximate single determinant state functions were obtained for all molecules using the 6-31G** basis set at 6-31G*

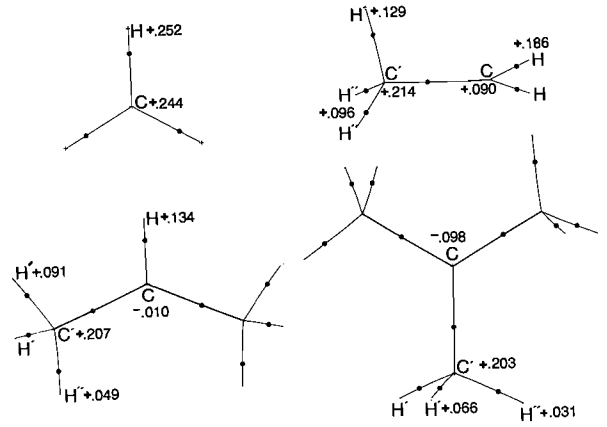

FIG. 1. Molecular graphs illustrating the structures of carbocations calculated from the charge distributions obtained in 6-31G**/6-31G* calculations. The dots indicate the positions of bond critical points. The existence of such a critical point in the charge distribution implies that the two neighbouring nuclei are linked by a line along which the charge density is a maximum with respect to any neighbouring line. In an equilibrium geometry, such a line is called a bond path. The bond paths between carbon nuclei are drawn in heavy line. A bond critical point lies in the interatomic surface denoting the common boundary shared by neighbouring atoms. Note that this surface is not equally placed between the carbon nuclei but is displaced from the midpoint in a direction away from the carbon bearing the methyl substituents. The numbers indicate the net charges on the atoms in atomic units.

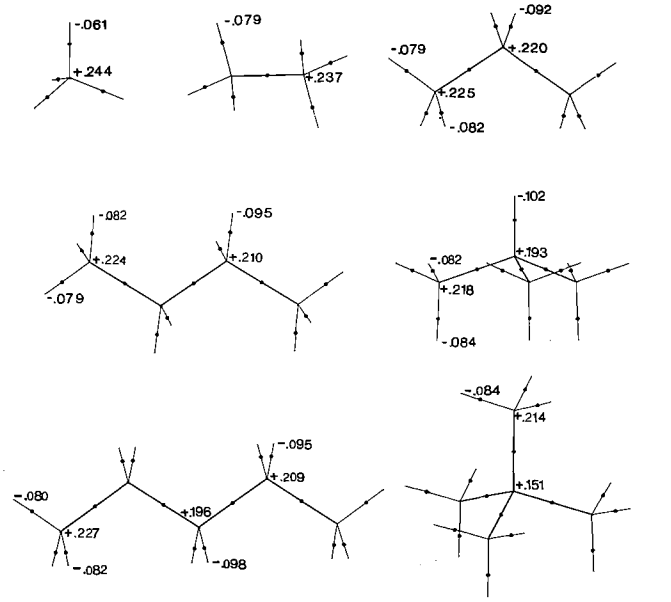

FIG. 2. Molecular graphs illustrating the structures of saturated hydrocarbons calculated from charge densities obtained in 6-31G**/6-31G* wave functions. See the caption for Fig. 1 for details.

optimized geometries, calculations denoted by 6-31G**/6-31G*.[1] The methyl cation is predicted to be of D_{3h} symmetry. The C_s structure reported for the ethyl cation (Fig. 1) is predicted to be most stable for all basis sets below 6-31G**. Using this larger basis a hydrogen bridged structure is found to be marginally more stable (7). The classical C_s structure is retained here for the purpose of comparing the abilities of hydrogen atoms and methyl groups to disperse the net positive charge of the cationic species. The C_{2v} structure for the 2-propyl cation is the most stable one for all basis sets that have been studied (7). The structure of the *tert*-butyl cation is found to be of C_{3h} symmetry. The structures of the saturated hydrocarbons are given in Fig. 2 from 6-31G* geometries determined by Wiberg and Wendoloski (8). In what follows, the carbon atom bearing the formal positive charge in a cation is denoted by C, as is the most substituted carbon in the neutral branched hydrocarbons. The carbon atom of a methyl group is denoted by C′. The properties of the atoms are calculated using the program PROAIM (9).

Atomic and bond properties

The principal differences between the distribution of charge in a hydrocarbon and in its corresponding carbocation are illustrated by comparing displays of their charge densities and associated gradient vector fields, as is done for the CH_4/CH_3^+ system in Fig. 3. The properties of a charge distribution are summarized by the properties of ρ at its critical points, points where the gradient vector field vanishes, i.e., where $\nabla\rho = 0$. For the molecules of interest here, which do not possess ring or cage structures, only two types of critical points are found, those where ρ is a local maximum (all three curvatures of ρ at the critical point are negative) and others, called bond critical points, where ρ possesses one positive and two negative curvatures (ρ at the critical point is a minimum along one direction and a maximum along the other two orthogonal directions). When the charge density is viewed in a plane containing one of the negative curvatures and the single positive curvature as in Fig. 3, a bond critical point has the appearance of a saddle.

The gradient vector of ρ points in the direction of maximum increase in ρ. One can follow the path of maximum increase in the charge density starting from some arbitrary point by following the path traced out by the gradient vector of ρ starting at that point. Every such gradient path originates and terminates at a critical point. The elements of molecular structure as embodied in the topology of the charge density are made evident in the flow of these gradient vectors, as shown in Fig. 3. The nuclear–electron attractive force dominates the interactions present in a molecule and, as a consequence, ρ exhibits a local maximum only at the position of a nucleus (Fig. 3). Because of this property, all of the paths traced out by the gradient vectors of ρ in the vicinity of a given nucleus terminate at that nucleus. The nucleus acts as an attractor in the gradient vector field and the region of space traversed by all the paths that terminate at a given attractor is called the basin of the attractor. Thus, as a result of the single dominant property that ρ exhibits a local maximum only at the position of a nucleus, all of space is partitioned into basins and associated with each basin is a single attractor or nucleus. An atom is defined as the union of an attractor and its basin, the basin being the region of space dominated by that nucleus.

Reference to Fig. 3 indicates that ρ exhibits a saddle point

[1]The total energies of all the molecules, quantities that are considered later, are given in Tables 2 and 3. The 6-31G* optimized geometries of the carbocations are as follows: CH_3^+, R(C—H) = 1.078 Å; $C_2H_5^+$, R(C—C) = 1.431 Å; R(C—H) = 1.079 Å, R(C—H′) = 1.117 Å, R(C—H″) = 1.081 Å, ∠(CCH) = 121.37°, ∠(CCH′) = 97.60°, ∠(CCH″) = 114.89°; $C_3H_7^+$, R(C—C) = 1.456 Å, R(C—H) = 1.080 Å, R(C—H′) = 1.093 Å, R(C—H″) = 1.079 Å, ∠(CCH) = 116.75°, ∠(CCH′) = 107.77°, ∠(CCH″) = 114.23°; $C_4H_9^+$, R(C—C) = 1.473 Å, R(C—H′) = 1.090 Å, R(C—H″) = 1.079 Å, ∠(CCH′) = 108.20°, ∠(CCH″) = 113.74°.

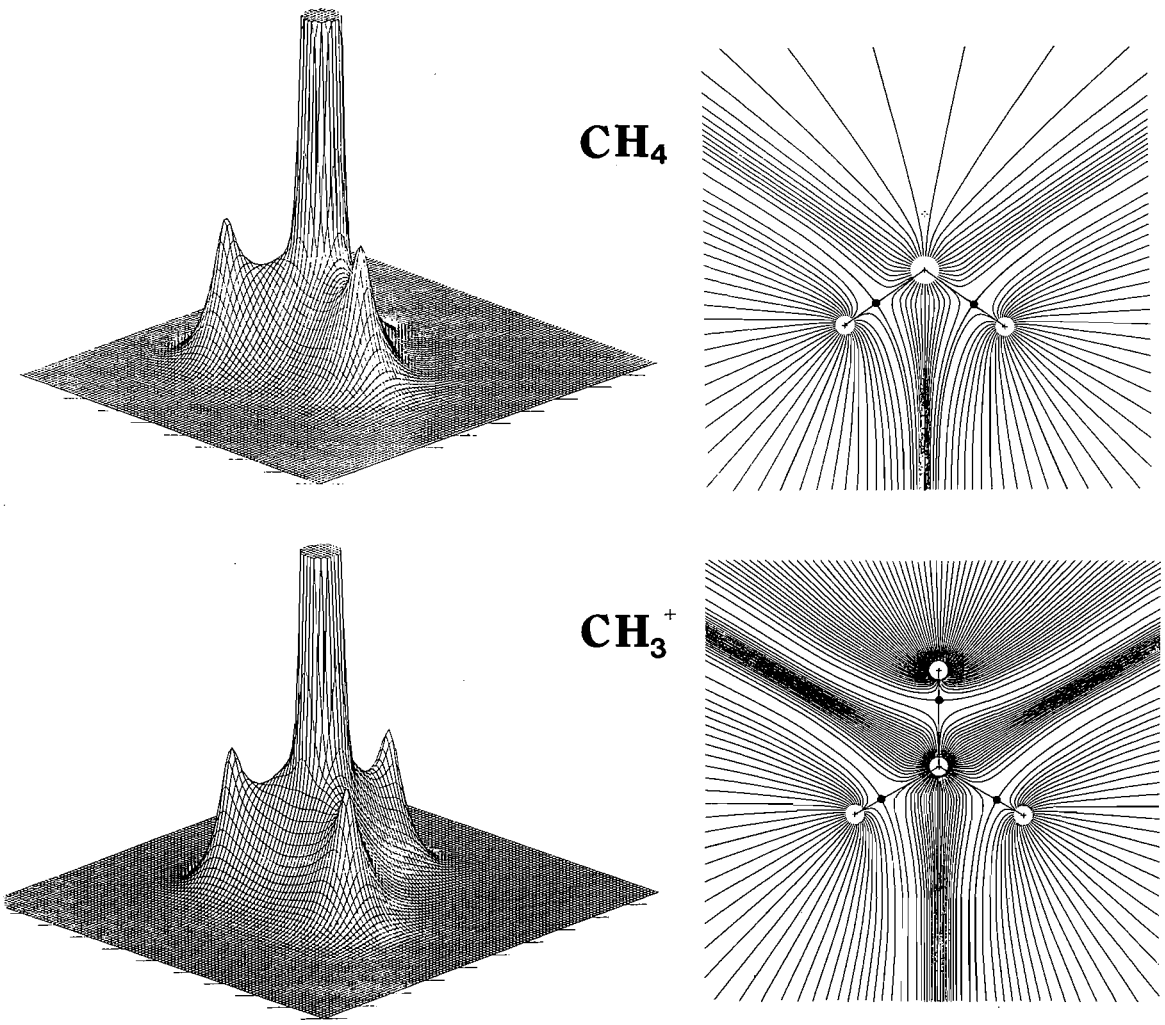

FIG. 3. Displays of the total electronic charge distributions of methane, in a plane containing the carbon nucleus and two protons, and of methyl cation, in a plane containing the carbon nucleus and three protons. Also shown are the gradient vector fields of the charge distributions for the same planes. These latter functions are displayed in terms of the trajectories traced out by the gradient vectors of the charge density. Most trajectories terminate at the local maxima in ρ located at the positions of the nuclei. The region of space traversed by all the trajectories that terminate at a given nucleus is called the basin of the atom. In these symmetry planes, two trajectories of ρ terminate at each of the bond critical points indicated by black dots. These pairs of paths indicate the intersection of the interatomic surface with the plane of the diagram. Two trajectories also originate at each of the bond critical points and terminate at the maxima on the neighbouring nuclei. The resulting lines define the bond paths.

between certain pairs of atoms. Such a critical point indicates that electronic charge is accumulated between the corresponding pairs of nuclei and for molecules in equilibrium geometries it is called a bond critical point. Two trajectories of $\nabla\rho$ originate at such a critical point and terminate at the neighbouring nuclei. They define a path along which the charge density is a maximum with respect to any neighbouring line, a bond path (see Fig. 3). While ρ is a minimum at a bond critical point in the direction of the bond path, it is a maximum with respect to all perpendicular directions and thus it serves as a terminus for gradient paths which form and define an interatomic surface (see Fig. 3). The network of bond paths defines a molecular graph and the structure of a molecule. The structures shown in Figs. 1 and 2 are representations of the molecular graphs as determined by the properties of the molecular charge distributions.

The value of ρ at the position of the proton is less in CH_3^+ than it is in CH_4, 2.79 compared to 2.90 e/Å^3. Its value at the carbon nucleus is greater in the cation than in the neutral molecule, 800.0 compared to 796.6 e/Å^3. The position of the bond critical point is shifted 0.09 Å closer to the proton and 0.08 Å away from the carbon nucleus in the cation, the difference in these two values representing the small difference in bond length between CH_4 and CH_3^+. These observations make quantitative what is qualitatively evident in Fig. 3: the removal of H^- from CH_4 to form the cation is accompanied by a general contraction of the charge density towards the carbon nucleus and by a transfer of charge from the hydrogen atoms to carbon. This result is typical of the systems studied here. As illustrated below, the positive charge of a carbocation is delocalized over all the hydrogens in the molecule and the extent of this delocalization increases with methyl substitution.

The average electron population of each atom Ω in a molecule is obtained by integrating $\rho(\boldsymbol{r})$ over the basin of the atom, eq. [1]

$$[1] \quad N(\Omega) = \int_{\Omega} \rho(\boldsymbol{r}) d\tau$$

The net charge on an atom, denoted by $q(\Omega)$, is obtained by subtracting this average number of electrons from the nuclear charge Z_Ω. The net charges obtained in this manner, with the use of charge densities obtained from the 6-31G**/6-31G* calculations, are indicated in Figs. 1 and 2.

The hydrogens in saturated hydrocarbons bear net negative charges (3). Since H is more electronegative than C in these molecules, the methyl group withdraws charge from the methylene group. In the normal paraffins, propane, butane, and pentane, the methyl groups have net charges of -0.018 ± 0.001 e, the charge being withdrawn from the methylenic groups. In propane this charge is withdrawn from a single CH_2 group, in butane, from two such groups, and the methylenic charges are +0.036 and +0.020 e, respectively. In pentane the charge is withdrawn only from the CH_2 groups linked to the methyl groups (they have the same net charge as they do in butane) and the central methylene group in this molecule has a zero net charge—the charge transfer is damped by a single methylene group. In the branched series $Me_nCH_{(4-n)}$ starting with methane, the magnitude of the negative charge on H increases with n from 0.06 e in methane to 0.10 e in isobutane. The charge on a methyl group is +0.06 e in methane and becomes more negative as n increases, equalling 0.00, −0.018, −0.029, and −0.038 in ethane, propane, isobutane, and neopentane, respectively. As a consequence of hydrogen being more electronegative than carbon, the relative electron-withdrawing ability of the functional groups in saturated hydrocarbons is H > CH_3 > CH_2 > CH > C. The positive charge on carbon C in the branched series decreases with increasing methyl substitution since Me withdraws fewer electrons than does H. The charge on this carbon atom exhibits the greatest dependence on structure.

The variation in atomic charges in the series of cations $[Me_nCH_{(3-n)}]^+$ is much greater than is found in the corresponding neutral series of molecules. In CH_3^+ the positive charge is almost equally delocalized over the C and H atoms. An increasing amount of electronic charge is transferred to C with increasing methyl substitution, and in the *tert*-butyl cation this atom bears a net negative charge. While the electron population of carbon atom C increases with increasing n, the net positive charges of the H atoms and methyl groups decrease with increasing n. That is, as more methyl groups are added, the total amount of electronic charge transferred to C is increased but, because of the increasing number of atoms able to donate charge, the net charges on these atoms are decreased. Thus the net charges on the methyl groups decrease through the series ethyl, 2-propyl, and *tert*-butyl. The values are respectively, +0.535, +0.438, and +0.366 e. Next to carbon atom C, the greatest variation in charge is found for the hydrogens, both the methyl hydrogens and those bonded directly to carbon atom C. In summary, increased methyl substitution at a carbon bearing a formal positive charge leads to an increase in the transfer of electronic charge to that atom and to an increase in the extent of delocalization of the positive charge over the methyl hydrogens.

The stabilities of the carbocations in the gas phase increase in the order of $CH_3^+ < CH_3CH_2^+ < (CH_3)_2CH^+ < (CH_3)_3C^+$. The energy changes underlying this ordering are discussed in a following section. Here we wish to note that the increase in stability parallels the increase in the dispersal of charge over the methyl hydrogens. A similar delocalization of charge over the methyl hydrogens has been found by Stutchbury and Cooper (10) to occur in protonated amines, thereby accounting for the observed order of increasing gas phase basicity, $NH_3 < CH_3NH_2 < (CH_3)_2NH < (CH_3)_3N$, and in alkoxide ions, thereby accounting for the observed order of increasing gas phase acidity, $H_2O < CH_3OH < CH_3CH_2OH < (CH_3)_2CHOH < (CH_3)_3COH$. In the alkoxide ions the methyl groups bear net negative charges (nearly all of which are located on the hydrogens) of −0.215, −0.191, and −0.184 e, respectively, in ethyl, isopropyl, and *tert*-butyl. In the protonated amines the methyl groups bear net positive charges of +0.569, +0.541, and +0.519 e, respectively, for the mono-, di-, and tri-metyl cations. Stutchbury and Cooper also observed that methyl substitution in the corresponding neutral molecules does not cause significant changes in the atomic populations, the variations in the net charges on the atoms in the saturated alcohols and amines being of the same order as the small variations reported here for the saturated hydrocarbons. The behaviour of the atomic charges in all three systems of molecules supports the following general conclusions: (a) In neutral, saturated molecules, replacement of hydrogen by methyl causes only small changes in atomic populations, the largest change being found for the atom at which the replacement occurs. (b) In corresponding anionic and cationic species, the replacement of hydrogen by a methyl group causes significant changes in the atomic popualtions, changes that correspond to a dispersal of the net charge over the methyl hydrogens. The variation in charge with the extent of methyl substitution is greatest for a system in which the site of substitution has an orbital vacancy. (c) The hydrogens of a methyl group may act effectively as either a sink or source of electronic charge (10).

Within the orbital model of electronic structure one differentiates between the inductive and hyperconjugative mechanisms of electron release from a methyl group to an unsaturated carbon or to a carbon with an orbital vacancy. If the hyperconjugative mechanism is operative, then the C—CH_3 bond should possess a bond order greater than one and exhibit some degree of π character. In addition, this mechanism can lead to differing extents of charge release from the methyl hydrogen atoms. The theory of atoms in molecules enables one to test for the presence of these anticipated consequences of hyperconjugation. Previous studies of hyperconjugation in these molecules employed the methods of a Mulliken population analysis (11).

The data in Table 1 characterize the properties of the C—C bonds in terms of the properties of ρ at the bond critical points. The value of ρ at a bond critical point, the quantity ρ_b, can be used to define a C—C bond order n (n = 1.0, 1.6, 2.0, 3.0, respectively, for ethane, benzene, ethylene, and acetylene) that provides a measure of the extent to which electronic charge is accumulated between the bonded nuclei (4). The C—C bonds in the saturated hydrocarbons are all of order 1.0. The values of ρ_b and of the bond ordr n increase slightly with methyl substitution and with chain length in the saturated hydrocarbons, notwithstanding small corresponding increases in the carbon–carbon bond lengths. In the carbocations, however, the C—CH_3 bond orders are all greater than unity, being largest in the ethyl cation. The observation of bond orders greater than unity for the C—CH_3 bonds in the cations correlates with the presence of partial double bond character.

In a bond with cylindrical symmetry the two negative curvatures of ρ at the bond critical point are of equal magnitude. However, if electronic charge is preferentially accumulated in a given plane (as it is for a bond with π character), then the rate of falloff in ρ, from its maximum value ρ_b at the bond critical point in the interatomic surface is less in this plane than in the one perpendicular to it and the magnitude of the corresponding

TABLE 1. Properties of C—C bonds (6-31G**/6-31G*)

A. In hydrocarbons

Molecule	Bond length R_e (Å)	$\rho(r_C)$ (e/Å^3)	Order n	Ellipticity ϵ	$\nabla^2\rho(r_c)$ (e/Å^5)	λ_3 (e/Å^5)
CH_3—CH_3	1.527	1.707	1.00	0.000	−16.04	7.15
CH_3—CH_2CH_3	1.528	1.718	1.01	0.008	−16.20	7.21
CH_3—$CH(CH_3)_2$	1.530	1.725	1.02	0.007	−16.28	7.24
CH_3—$CH_2CH_2CH_3$	1.528	1.719	1.01	0.007	−16.21	7.20
CH_3CH_2—CH_2CH_3	1.530	1.727	1.02	0.016	−16.29	7.28
CH_3—$CH_2(CH_2)_2CH_3$	1.527	1.722	1.01	0.006	−16.26	7.21
CH_3CH_2—$CH_2CH_2CH_3$	1.528	1.734	1.03	0.014	−16.42	7.27
CH_3—$C(CH_3)_3$	1.533	1.725	1.02	0.000	−16.25	7.25

B. In carbocations

Molecule	Bond length R_e (Å)	$\rho(r_C)$ (e/Å^3)	Order n	Ellipticity ϵ	$\nabla^2\rho(r_c)$ (e/Å^5)	λ_3 (e/Å^5)
CH_3—CH_2^+	1.431	2.028	1.37	0.091	−24.37	3.72
CH_3—$CH(CH_3)^+$	1.456	1.958	1.28	0.051	−22.50	4.86
CH_3—$C(CH_3)_2^+$	1.473	1.918	1.22	0.038	−21.21	5.69

curvature of ρ is smaller. If the two negative curvatures of ρ at a bond critical point are denoted by λ_1 and λ_2 with λ_2 being the curvature of smallest magnitude, the quantity $\epsilon = \lambda_1/\lambda_2 - 1$, the ellipticity of the bond, provides a measure of the extent to which charge is preferentially accumulated in a given plane (4). Thus, for example, the ellipticity of the C—C bond in ethane is zero, greater than zero for benzene, and greater still for ethylene (and equal to 0.45 in the 6-31G** basis). In the latter two molecules the curvature of smallest magnitude is directed perpendicular to the plane of the nuclei, as anticipated for bonds with π character. The C—C bonds in the saturated hydrocarbons are close to being axially symmetric and their ellipticities are in general close to zero. The ellipticities in the cations are significantly greater than zero and the trend in their values is the same as that found for the bond orders, being greatest in $C_2H_5^+$ and smallest in $C_4H_9^+$. In all three of these cations the major axis of the ellipticity is perpendicular to the plane containing the nuclei bonded to the C nucleus. That is, the charge density in the C—CH_3 bonds of the carbocations is preferentially delocalized in a direction parallel to the axis of the vacant $p\pi$ orbital on carbon atom C.

The final quantity listed in Table 1 is $\nabla^2\rho(r_c)$, the sum of the three curvatures of ρ at the bond critical point. The charge density is a maximum in an interatomic surface at the bond critical point. The two curvatures of ρ perpendicular to the bond path are, therefore, negative and charge is locally concentrated in the surface at this point. Since $\rho(r)$ is a minimum at r_c along the bond path, the third or parallel curvature of ρ at the bond critical point is positive. Charge is locally depleted at r_c with respect to neighbouring points along the bond path. Thus the formation of an interatomic surface and a chemical bond is a result of a competition between the perpendicular contractions of ρ, leading to a concentration or compression of electronic charge along the bond path, and the parallel expansion of ρ, leading to a depletion of charge in the interatomic surface and to its separate concentration in the basins of neighbouring nuclei. When $\nabla^2\rho < 0$, the perpendicular curvatures dominate the interaction and electronic charge is concentrated along the bond path. The result is a sharing of electronic charge between the nuclei as found in covalent or polar interactions. As one would anticipate, $\nabla^2\rho(r_C) < 0$ for all of the bonds in the hydrocarbon molecules. Its values for a C—C bond in the saturated molecules exhibits only small variations throughout the series, its magnitude being slightly larger in the branched systems and for the interior bonds linking methylene groups. To a first approximation, the C—C bonds in the saturated hydrocarbons exhibit autonomous behaviour. The small variations in the bond indices that are present indicate a slight increase in order and degree of binding as the extent of branching is increased or as the chain length is increased.

The values of $\nabla^2\rho$ for the C—CH_3 bonds in the cations become less negative through the series from ethyl to *tert*-butyl and are all greater in magnitude than the value for a C—C bond in the neutral molecules. Thus the greater the release of charge from methyl to carbon C, the greater is the bond order, the greater is the ellipticity and the more negative is the value of $\nabla^2\rho$. The value of $\nabla^2\rho(r_C)$ becomes more negative with an increase in bond order n as a consequence of two effects: (i) as n increases, charge is increasingly concentrated along the bond path, as reflected in an increase in magnitude of the perpendicular curvatures of ρ; (ii) the increase in the accumulation of charge in the internuclear region that accompanies an increase in n results in a decrease of λ_3, the (positive) curvature of ρ along the bond path. The C—CH_3 bonds of the carbocations all possess λ_3 values smaller than those for the neutral molecules, the smallest value being found for the ethyl cation for which the value of $\nabla^2\rho$ approaches that for a C—C double bond, −28.7 e/Å.

In terms of the amount of electronic charge accumulated between the carbon nuclei as measured by ρ_b, its mode of accumulation as measured by $\nabla^2\rho$, and its spatial distribution as measured by ε, the C—CH_3 bonds of the carbocations exhibit characteristics intermediate between those of a single and a double bond. It is clear that the transfer of charge from the hydrogens of methyl to carbon atom C occurs via a mechanism that destroys the axial symmetry of the C—CH_3 bond and concentrates the charge in a plane aligned with the direction of a $p\pi$ orbital on atom C. This alignment of the charge transfer is

reflected in the differing extents of charge removal from the hydrogen atoms of the methyl groups. There is no large differentiation between the charges on the methyl hydrogens in the saturated hydrocarbons. This is not the case in the carbocations. One notes that the net positive charge on a methyl carbon is not much changed from its value in the neutral precursor. The methyl hydrogens, however, bear net negative charges in the neutral molecules and net positive charges in the cations. Furthermore, the magnitude of this positive charge depends upon the orientation of H relative to the axis perpendicular to the plane of substitution at carbon C. In the ethyl cation the hydrogens of the methyl group are aligned such that the combination of orbitals depicted in **a** will be in-phase with the $p\pi$ orbital on carbon C. The loss of electronic charge is greater for the hydrogen labelled H′ (see Fig. 1) than it is for those labelled H″ and this is in line with the weighting of the coefficients of the atomic orbitals in **a**. This difference in extent of charge loss is reflected in the bond lengths as well, the values being 2.099 and 2.044 Å for the bonds to H′ and H″, respectively. In the 2-propyl and *tert*-butyl cations the methyl hydrogens are aligned such that the combination of orbitals depicted in **b** provides the overlap with the $p\pi$ orbital on carbon

a **b**

C. In both these molecules the hydrogens labelled H′ (Fig. 1) have approximately twice the net charge and slightly longer bond lengths than do the hydrogens labelled H″. If one accepts the simple orbital model of hyperconjugation, then the hydrogen atom populations of methyl may be used to determine what fraction of the charge loss from these atoms is caused by this mechanism. In the *tert*-butyl and 2-propyl cations the atoms H″ (see Fig. 1) cannot donate charge by the hyperconjugative mechanism and their net charges determine the inductive charge losses, which are 0.03 and 0.05 e, respectively. The 0.04 e lost in excess of this amount by the atoms H′ in these two molecules thus represents the charge released by the hyperconjugative mechanism. According to the model, the hyperconjugative release from H′ is twice that from H″ in the ethyl cation and, if the inductive loss is taken as 0.05 e, then the populations indeed yield hyperconjugative losses of 0.08 e from H′ and 0.04 e from H″.

Moments other than the monopole (the net charge) may be determined for an atom in a molecule. Of particular interest for the cations is the quadrupole moment of carbon atom C. The z^2 component of the traceless quadrupole moment tensor is (12)

$$[2] \quad Q_{zz}(\Omega) = -e\int_{\Omega} \rho(3z^2 - r^2)d\tau$$

with corresponding expressions for x^2 and y^2. For a spherical distribution all three components are zero. If the sphere is flattened at its poles to yield an oblate spheroid, then (taking the polar axis along z) $Q_{zz}(\Omega) > 0$ and $Q_{xx}(\Omega) = Q_{yy}(\Omega) = -\frac{1}{2}Q_{zz}(\Omega)$, reflecting the accumulation of negative charge in the xy-plane. The orbital model assigns a vacant $2p\pi$ orbital to atom C in CH_3^+ and one anticipates the charge distribution of this atom to exhibit the moments characteristic of an oblate spheroid. The magnitudes of these moments should be smaller for carbon C in *tert*-butyl cation, as some part of the charge transferred to this atom preferentially populates its $2p\pi$ orbital. These conjectures are borne out. Both methyl and *tert*-butyl cations possess a three-fold symmetry axis and the principal moments lie along the three cartesian axes. For CH_3^+ the value of $Q_{zz}(\Omega)$ is +1.22 au while for the *tert*-butyl cation its value is reduced to +0.43 au. The oblate nature of the C atom charge distribution is also reflected in the distribution of charge in the C—H bonds. These bonds exhibit significant ellipticities ranging from 0.054 in CH_3^+ to 0.050 in $C_3H_7^+$ and their major axes are in the same plane as that in which the sphere is flattened.

Reactivity

The susceptibility of a carbocation to nucleophilic addition can be predicted and understood in terms of the properties of the Laplacian of its charge distribution. The Laplacian of ρ is the sum of the three principal curvatures of ρ at each point in space:

$$[3] \quad \nabla^2\rho(\boldsymbol{r}) = \partial^2\rho/\partial x^2 + \partial^2\rho/\partial y^2 + \partial^2\rho/\partial z^2$$

When $\nabla^2\rho(\boldsymbol{r}) < 0$ the value of the charge density at $\boldsymbol{r}$ is greater than the value of $\rho(\boldsymbol{r})$ averaged over all the neighbouring points in space, and when $\nabla^2\rho(\boldsymbol{r}) > 0$, then $\rho(\boldsymbol{r})$ is less than this averaged value. These statements follow directly from the definition of the second derivative of a scaler function such as ρ (5, 6). The Laplacian distribution recovers the shell model of electronic structure by exhibiting a corresponding number of alternating pairs of shells of charge concentration and charge depletion. For an isolated atom with a complete outer shell, the valence shell of charge concentration (VSCC) possesses a sphere on whose surface charge is maximally concentrated. In general, this sphere of maximum charge concentration persists for an atom in chemical combination, but the charge is not uniformly concentrated over its surface. Instead, a number of local maxima are present on this surface and, in terms of their number, relative position, and size, they yield a faithful replica of the Lewis model of bonded and nonbonded electron pairs. A carbon atom in a saturated hydrocarbon possesses four bonded charge concentrations (see Fig. 4). Each of these maxima is linked to the other three by unique pairs of trajectories of the gradient of the Laplacian of ρ, which originate at intervening saddle points on the surface of charge concentration. These lines are the analogues of the bond paths defined by corresponding trajectories of the gradient of the charge density. This network of lines, called the atomic graph, partitions the surface of charge concentration into four segments and the basic structure is that of a tetrahedron with curved faces. In the centre of each face there is a local minimum in the surface of the VSCC. The uniform spherical surface of charge concentration of a free (sphericalized) carbon atom is transformed in methane, for example, into one with four tetrahedrally arranged concentrations of charge with charge depletions in the centre of each of the resulting faces. The surface of maximum charge concentration in the molecule is no longer perfectly spherical, the maxima and minima lying at slightly different distances from the nucleus, but all within the range of 0.54–0.55 Å.

It is well documented (6, 13, 14) that centres of charge concentration in the VSCC serve as sites of electrophilic attack, while the centres of charge depletion play the corresponding role in nucleophilic attack. The localized charge concentrations in the VSCC of carbon in a saturated hydrocarbon are, of course, all bonded concentrations and as such are relatively unreactive towards electrophiles. Because of the relatively small extent of charge transfer between atoms in saturated

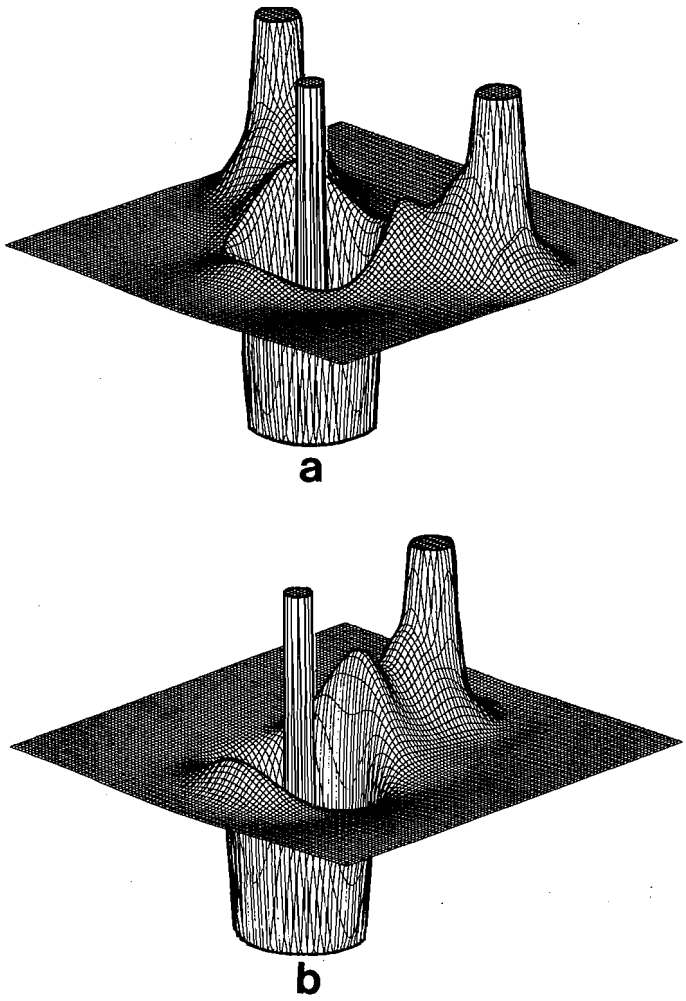

FIG. 4. Displays of the negative of the Laplacian of the charge distributions of (a) methane, in a plane containing the carbon and two hydrogen nuclei, and (b) of methyl cation in a plane containing the carbon nucleus and a single proton. A maximum (minimum) in $-\nabla^2\rho$ indicates a local concentration (depletion) of electronic charge. There is a local maximum at the position of each nucleus, which has been terminated at some arbitrary value. For carbon, this maximum and its neighbouring region of charge depletion denote the presence of an inner shell. Both drawings are to the same vertical scale. Note that the bonded maxima in the valence shell of carbon are larger in the cation than in the neutral molecule, a reflection of the contraction of charge towards the carbon nucleus in the former molecule. Most important is the absence of a "lip" separating the core region of the carbon in the cation from its valence region of charge removal. This puncturing of the valence shell of charge concentration (a shell which totally envelopes the carbon core in methane) is found in all of the cations and it gives approaching nucleophiles direct access to the region of charge removal in the carbon core.

hydrocarbons, the regions of charge depletion in the VSCC of a carbon atom are not pronounced and these atoms are also relatively unreactive towards nucleophilic attack. Substitution of a hydrogen in methane by fluorine greatly increases the extent of charge depletion in the VSCC of carbon in the face opposite the fluorine atom, thereby increasing the susceptibility of the carbon to nucleophilic attack (14).

The carbon atom in the methyl cation exemplifies the VSCC of a Lewis acid. The surface of maximum charge concentration of this atom is punctured on either side of the plane containing the nuclei, reducing the VSCC to an equatorial belt of charge concentration, the three bonded maxima being linked to form a ring by intervening saddle points. This behaviour is made evident in the relief map of the Laplacian (Fig. 4) by the absence of a "lip" at the corresponding positions of the core. Thus an incomplete valence shell of the Lewis model or a $p\pi$ orbital vacancy of the orbital model appears in the Laplacian distribution as two holes in the valence shell of charge concentration. These holes provide direct access to the region of charge depletion in the core of the atom, making it very susceptible to nucleophilic attack. The boron atom in trivalent systems exhibits similar behaviour, as does the carbon bearing the formal positive charge in the classical structure of the norbornyl cation (1). The two equivalent classical structures of this ion as determined by their charge distributions are separated by, and differ little in energy from, the symmetrical bridged or nonclassical structure. The Laplacian of this latter structure exhibits holes only on the *exo* side of the two carbons, which are alternately three-bonded in the two classical structures. On vibrational averaging, the most pronounced holes in the valence shells of these two atoms are those which, when combined with the charge concentration of a nucleophile, yield the mirror-image *exo*-norbornyl product, as is observed.

If purely electrostatic effects determined the reactivity of these systems, both the net charge and the quadrupole moment of carbon C would indicate that the reactivity should decrease through the series from methyl to *tert*-butyl. However, the very pronounced positive character of the Laplacian of the core as exposed by the holes in the VSCC of carbon atom C ensures the susceptibility of all these cations to nucleophilic attack, even though carbon C is essentially neutral in one, and bears a small negative charge in another, member of the series. Because of the ability of the methyl hydrogens to act as sinks as well as sources of electronic charge, the charge distribution of the carbon bearing the methyl groups is very polarizable, charge leaving the atom and migrating back to the methyl hydrogens with the approach of the negatively charged nucleophile.

Atomic energies

The topological atoms are quantum subsystems and, therefore, all of the theorems derivable from the Heisenberg equation of motion for any operator A apply to an atom in a molecule (2). In particular, the virial theorem applies (the operator A is set equal to $\boldsymbol{r}\cdot\boldsymbol{p}$) and one may define $E(\Omega)$, the energy of atom Ω in a molecule. These energies are additive and their summation over a molecule in an equilibrium geometry equals E, the total energy of the molecule,

$$[4] \quad E = \sum_{\Omega} E(\Omega)$$

It is important to realize that this partitioning of the total energy into atomic contributions includes a nontrivial partitioning of the nuclear–nuclear potential energy of repulsion.[2]

The viral theorem gives the following relationships between

[2]The partitioning of the nuclear–nuclear repulsive energy is obtained as a consequence of the potential energy being defined as the virial of the (Ehrenfest) forces exerted on the electrons. The virial of the forces that results from the electron–nuclear potential energy operator yields the electron–nuclear potential energy plus the virial of the Hellmann–Feynman forces exerted by the nuclei on the electrons. For an equilibrium geometry this latter contribution equals the nuclear–nuclear potential energy.

TABLE 2. Atomic energies in saturated hydrocarbons (6-31G**/6-31G*)

RH	E (au) and $\gamma = -V/T$	$E(CH_3)$ - A^a (kcal/mol)	$E(CH_2)$ - B^a (kcal/mol)	$\Delta E(C)^b$ of CH_3 (kcal/mol)	$\Delta E(C)^b$ of CH_2 (kcal/mol)	$E - \Sigma_\Omega E(\Omega)$ (kcal/mol)

[a] Energies of atoms in CH_3^+ are: E(C) = −37.6824 au; E(H) = −0.5183 au.
[b] Energy change for reaction $CH_3^+ + RH \rightleftarrows CH_4 + R^+$.
[c] Experimental data for cations taken from ref. 18. The experimental values of ΔE^+ are calculated from $\Delta H_f^\circ(298)$ values.

the kinetic ($T(\Omega)$), potential ($V(\Omega)$) and total ($E(\Omega)$) energies of an atom in a molecule that is in an equilibrium geometry:

$$[5] \quad E(\Omega) = -T(\Omega), \quad 2T(\Omega) = -V(\Omega), \quad E(\Omega) = \tfrac{1}{2}V(\Omega)$$

where $E(\Omega) = T(\Omega) + V(\Omega)$. The kinetic energy of an atom in a molecule is easily obtained by integration of a corresponding density over the basin of the atom and the first of the relationships given in [5] is then used to obtain the total energy of the atom, $E(\Omega)$. The virial theorem is not exactly satisfied at the 6-31G** level of calculation and the ratio $-V/T$ for each molecule differs slightly from the correct value of two for an equilibrium geometry. This can be seen from the data in Tables 2 and 3, where this ratio is given under the heading γ. To correct for the small error in the virial, each atomic kinetic energy is multiplied by the factor $(\gamma - 1)$ to obtain a set of atomic energies that correctly sum to the total energy of the molecule. The nuber $(\gamma - 1)$ is in every case close to unity, the value it should equal at equilibrium. An atomic kinetic energy is obtained by numerical integration over the basin of an atom. As a test of the numerical methods, Tables 2 and 3 compare the sums of the atomic energies with the total energies (eq. [4]). The integration error is never greater than 2.0 kcal/mol. The relative precision of each integration may be determined[3] and, when the error in eq. [4] exceeds 0.5 kcal/mol, the results for the atom with the smallest precision are adjusted to yield the correct sum.

The most interesting property of the energies of the saturated hydrocarbons is that they obey an additivity relation wherein one assigns fixed energies to the CH_3, CH_2, CH, and C groups (15). The most important property of the topological atom is that its properties, including its energy, are determined by its spatial distribution of charge, that is, by its form in real space. Thus when two atoms or two functional groupings of atoms "look the same", i.e., when they have the same spatial distribution of charge, they have the same properties and they contribute identical amounts to the total energies of the systems in which they occur. This possibility of transferability in real space, together with the additivity of the atomic energies over a given

[3] As a consequence of the quantum condition of zero flux in the gradient vector of ρ through the surface of an atom, the integration of the Laplacian of the charge density over an atom must vanish (1, 2). The smallness of the value of this intergral may thus be used to judge the quality of an integration. Its value is a direct measure of the difference in the values of the two methods of calculating the average kinetic energy of an atom and normally it equals 0.1 kcal/mol or less.

molecule as expressed in eq. [4], are both necessary to account for additivity schemes in homologous series of molecules.

It is possible to fit the experimental heats of formation of the homologous series $CH_3(CH_2)_mCH_3$, starting with $m = 0$, with the expression $2A + mB$, where A is the contribution from the methyl group and B that from the methylene group. The generally accepted value for B at 25°C is -4.93 kcal/mol, while $A = -10.12$ kcal/mol. Wiberg has shown that the correlation energy correction, the zero point energies, and the change in H_f on going from 298 to 0 K are reasonably well represented by group equivalents (16*a*).[4] This is indeed the case, for the calculated 6-31G**/6-31G* energies (for the vibrationless molecules at 0 K) may also be fitted by the relationship $E = 2A + mB$, with $A = -39.61912$ au and $B = -39.03775$ au. Those constants reproduce the calculated energies with a maximum error of 0.13 kcal/mol, which is slightly smaller than the experimental errors in the measurements at 25°C. This means that the calculated state functions, energies, and charge distributions contain the necessary information to account for the additivity observed in this homologous series of molecules.

It is clear from the populations already considered that the methyl group in ethane is not identical to those found in the other members of the series and, similarly, the methylene group is different in the three molecules of the series considered here. The small differences found for these groups are to be expected, as their environments change by corresponding small amounts from molecule to molecule. In ethane, methyl is bonded to methyl, while in the other systems it is bonded to methylene, from which it withdraws charge. Table 2 lists the energies of the methyl groups relative to the constant A, the energy of a methyl group in ethane. To within the accuracy of the integrations, the population and energy of methyl are constant when it is bonded to methylene. That is, the methyl group is the same in all members of the homologous series past ethane. The methyl group in these molecules, relative to methyl in ethane, is more stable by an amount $\Delta E = -10.5 \pm 0.5$ kcal/mol and its electron population is greater by an amount $\Delta N = 0.018 \pm 0.001$ e. The charge and energy gained by the methyl groups are taken from the methylene groups. What is remarkable and what accounts for the additivity of energy in this series of molecules is that the energy gained by the methyl groups is equal to the energy lost by the methylene groups. Table 2 lists the energies of the methylene groups relative to the energy increment B and one finds that, in propane, the energy of the methylene group is $B - 2\Delta E$ and its charge is $+2\Delta N$. In butane, each methylene is bonded to a single methyl and their energies are given by $B - \Delta E$ and their charges by $+\Delta N$. The corresponding CH_2 groups in pentane, those bonded to a methyl group, have the same properties, implying that the central methylene in pentane, which is bonded only to methylene groups, should have an energy equal to B and a zero net charge. This is what is found, to within the uncertainties of the integrated values. Thus methylene groups bonded only to other methylenes, as found in pentane and all succeeding members of the series, possess zero net charges and contribute the standard increment B to the total energy. Also listed in Table 2 are the energies of the carbon atoms in the methyl and methylene groups relative to the corresponding energies in ethane and propane, respectively. These data show that essentially all of the increase in stability of CH_3 relative to its value in ethane, and of CH_2 relative to its value in propane, comes from the increase in the electron population of the carbon atom in these groups. The populations as well as the energies of the carbon of methyl are also remarkably constant after ethane, the net charge on a carbon of methyl in propane, butane, and pentane varying by only ± 0.002 e from the value 0.225 e.

Thus the additivity scheme for the energy in the hydrocarbons is not the result of the methyl and methylene groups having the same energies in every molecule in spite of small changes in their environments. Instead, their properties do change with changes in environment but the effect is damped by a single methylene group and, most important, the change in energy for a change in population, the quantity $\Delta E/\Delta N$, is the same for both the methylene and methyl groups. It is also necessary that the change in correlation energy for a change in population be the same for both groups to within the experimental uncertainty of ± 0.2 kcal/mol.

The branched molecules, isobutane and neopentane, are more stable than their normal isomers by 1.9 and 5.1 kcal/mol in terms of their ΔH_f values at 25°C and by 1.6 and 3.8 kcal/mol in their vibrationless states at 0 K (17). The 6-31G**/6-31G* calculated energies predict increased stabilities of only 0.4 and 0.5 kcal/mol, respectively, indicating that the change in correlation energy for a change in population for the CH and C groups is different from that for the CH_3 and CH_2 groups. As noted above, the relative electron-withdrawing abilities of the hydrocarbon groups are in the order $C < CH < CH_2 < CH_3$. Thus the charges on the methyl groups in the branched isomers are greater than those found in the normal alkanes, and they are correspondingly more stable. Relative to methyl in ethane, the ΔE and ΔN values for methyl in isobutane are 20.3 kcal/mol and 0.029 e and in neopentane they are 28.8 kcal/mol and 0.036 e, respectively, and the actual energies of the CH and C groups are less than the values assigned to them in the additivity scheme. Essentially all of the increase in stability of the methyl groups in the branched hydrocarbons resides in the carbon of the methyl group (see Table 2). Thus the ratio $\Delta E/\Delta N$ is greater for the branched isomers, where it equals 1.12 for isobutane and 1.27 au/e for neopentane, than it is for the normal alkanes for which it equals 0.88 au/e. The carbon exhibiting the greatest increase in stability is the one at which the branching occurs. In isobutane this atom is 26.6 kcal/mol more stable than the carbon atom in ethane, and in neopentane the corresponding increase in stability is 46.2 kcal/mol.

Table 3 lists the atomic and group energies for the carbocations, all relative to the values in CH_3^+. The final set of entries are the energy changes for the reaction of a carbocation R^+ with methane.

$$CH_3^+ + RH \rightarrow CH_4 + R^+ \qquad \Delta E^+$$

The experimental values for this energy change are also listed, calculated from heat of formation data at 298 K. The calculated values clearly reproduce the experimental increase in the stability of the cation with increased methyl substitution. The difference between the two sets of values is an almost constant 11 kcal/mol. As noted above, increasing methyl substitution leads to an increase in electron population of the carbon atom at which substitution occurs (carbon atom C in Fig. 1). There is also an increase in the extent of delocalization of the positive charge over the methyl hydrogens. This leads to an increase in the electron population of every atom with increased methyl substitution and to a corresponding increase in their stabilities, as indicated by the values of the relative energies listed in Table 3. The effect is most pronounced for carbon atom C because of

[4]For an extension of this work to other systems, see ref. 16*b*.

the transfer of charge to this atom, a transfer brought about by both inductive and hyperconjugative mechanisms of charge release. It is to be recalled that in the *tert*-butyl cation, the most stable of these cations, this carbon actually bears a net negative charge. While the branched neutral hydrocarbons also increase in stability with methyl substitution, the changes between members are less pronounced than between corresponding members of the cationic series and hence $\Delta E^{+} < 0$ and decreases through the series.

Acknowledgments

We thank Professor Wiberg for sending the optimized geometries and wavefunctions of the saturated hydrocarbons and for useful comments on the discussion of hyperconjugation. This paper is dedicated to Professor A. N. Bourns, the man who introduced me to organic chemistry, to scientific research, and to the art of teaching.

Gas-phase reactions of the hydroperoxide and peroxyformate anions

JOHN H. BOWIE,[1] CHARLES H. DEPUY,[2] SALLY A. SULLIVAN, AND VERONICA M. BIERBAUM
Department of Chemistry and Biochemistry, University of Colorado, Boulder, CO 80309, U.S.A.

Received October 23, 1985

JOHN H. BOWIE, CHARLES H. DEPUY, SALLY A. SULLIVAN, and VERONICA M. BIERBAUM. Can. J. Chem. **64**, 1046 (1986).

The flowing afterglow technique has been used to study the reactions of HO_2^- and HCO_3^- in the gas phase. The hydroperoxide ion reacts slowly with CO to form HO^-, and oxidizes CO_2, OCS, CS_2, NO, SO_2, CH_3NCO, and CH_3NCS in fast reactions to form CO_3^-, CO_2S^-, COS_2^-, NO_2^-, SO_3^-, $CH_3NCO_2^-$, and CH_3NCOS^-, respectively. Reactions of HO_2^- with certain amides and esters provide synthetic routes for a number of interesting peracyl anions. One of these, the peroxyformate ion, HCO_3^-, reacts with CO and NO in slow oxidation reactions to form the formate ion HCO_2^-. It also forms HCO_2^- upon reaction with acetone and pivalaldehyde, perhaps by Baeyer–Villiger oxidation.

JOHN H. BOWIE, CHARLES H. DEPUY, SALLY A. SULLIVAN et VERONICA M. BIERBAUM. Can. J. Chem. **64**, 1046 (1986).

Faisant appel à la technique de la phosphorescence dynamique, on a étudié les réactions des ions HO_2^- et HCO_3^- en phase gazeuse. L'ion hydroperoxyde réagit lentement avec le CO pour former du HO^- et il oxyde rapidement les substances suivantes: CO_2, OCS, CS_2, NO, SO_2, CH_3NCO et CH_3NCS pour former respectivement les ions suivants: CO_3^-, CO_2S^-, COS_2^-, NO_2^-, SO_3^-, $CH_3NCO_2^-$ et CH_3NCOS^-. Les réactions du HO_2^- avec certains amides ou esters s'avèrent des routes de synthèses intéressantes pour un certain nombre d'anions peracyles. Un d'eux, l'ion peroxyformate, HCO_3^-, oxyde lentement le CO et le NO pour donner l'ion formate HCO_2^-. Il forme aussi du HCO_2^- par réaction avec l'acétone et le pivalaldéhyde et cette réaction implique peut-être une oxydation de Baeyer–Villiger.

[Traduit par la revue]

Introduction

The gas phase ion chemistry of the hydroperoxy anion, HO_2^-, has been only sparsely investigated. The ion may be prepared in a flowing afterglow apparatus by sequential reactions involving hydride ion transfer to oxygen, for example from the cyclohexadienyl anion (1) or, better, from the anion derived by proton abstraction from 2,3-dimethyl-1-butene (eqs. [1] and [2]) (2).

[1] $NH_2^- +$  $\rightarrow$  $+ NH_3$

[2]  $+ O_2 \rightarrow HO_2^- +$ 
Certain physical parameters related to HO_2^- have been determined. The electron affinity (E.A.) of the hydroperoxy radical ($HO_2^- \rightarrow HO_2 + e^-$, ΔH = E.A.(HO_2)) is 1.078 ± 0.017 eV, and the gas-phase acidity of hydrogen peroxide ($H_2O_2 \rightarrow H^+ + HO_2^-$, $\Delta H = \Delta H^0_{acid}$ (H_2O_2)) is 376.4 ± 0.6 kcal mol^{-1} (2, 3). In a previous paper (1) we reported briefly that HO_2^- is a powerful oxidant, donating an oxygen atom to a number of substrates, and that it also can serve as a gas-phase base, reacting by proton abstraction with acidic organic molecules. In this paper we describe the chemistry of HO_2^- in its reactions as both oxidant and base in more detail, including its reaction rates with a variety of neutral substrates. In this context, HO_2^- reacts with certain amides to form peracyl anions. Dimethyl formamide, for example, reacts with HO_2^- to form the peroxyformate ion, HCO_3^-, and we describe some of the gas-phase reactions of this interesting ion.

Experimental

Experiments were performed at 300 K in a flowing afterglow (FA) system, which has been described previously (4). The system consists of a 100 cm × 7.6 cm id flow reactor affixed to a quadrupole mass spectrometer. A fast flow (80 m s^{-1}) and relatively high pressure (0.4 Torr; 1 Torr = 133.3 Pa) of helium buffer gas is maintained in the flow tube by a Roots blower. The HO_2^- ion was generated as follows. Amide ion was produced by electron impact on NH_3 (2×10^{-3} Torr) and 2,3-dimethyl-1-butene was added 10 cm downstream until no NH_2^- signal remained. Oxygen was then added at the same position until the signal corresponding to the anion of 2,3-dimethyl-1-butene disappeared. Care must be taken not to add too much oxygen as this causes the formation of O_4^-; subsequent reactions of this ion complicate the determination of branching ratios. The reaction sequence produces HO_2^- and O_2^- (normally in a 4:1 ratio), but the O_2^- has little or no effect on further reactions. The neutral reagent to be reacted with HCO_2^- was added through the movable inlet at least 10 cm downstream from the initial point of HCO_2^- generation.

In order to observe the reactions of the peroxyformate ion, HCO_3^-, dimethylformamide was introduced through a fixed inlet 10 cm downstream of HO_2^- formation. Since HCO_3^- reacts at a much slower rate than HO_2^- it is desirable that all HO_2^- ions be removed; therefore excess dimethylformamide is added. Nevertheless some experiments (see Table 2) show products formed by trace amounts of HO_2^-. The neutral reagent to be reacted with HCO_3^- was introduced through the movable inlet at a distance at least 10 cm downstream from the region of HCO_3^- generation.

Flow rates were determined by monitoring the pressure increase with time in a calibrated volume. Rate coefficients were measured by following reactant ion counts as a function of reaction distance. Measurements were made at several neutral flow rates, and reported values are averages of three measurements. The experimental precision of each rate constant is better than ±10%; the overall accuracy of the rate constants is estimated to be ±25%. Theoretical rates were calculated using the method of Su and Bowers (5). Branching ratios were measured as described previously (6).

All neutral reagents were obtained from commercial sources. Gases were of the following purities: He (99.997%), NH_3 (99.999%), O_2 (99.98%), N_2O (99.99%), NO (99.2%), CO (99.9%), CO_2 (99.5%), OCS (97.7%), and SO_2 (99.98%). Liquids were commercial reagent grade.

Results and discussion

Reactions of HO_2^-

The hydroperoxy anion reacts with many substrates by oxygen atom transfer and (or) proton abstraction. Those reactions for which we have determined rate constants are listed in Table 1. These data demonstrate that HO_2^- is a moderately

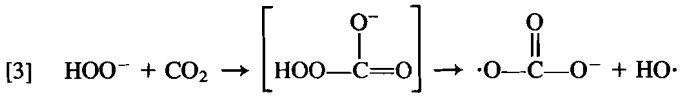
$HCON(CH_3)_2$	$HCO_3^- + (CH_3)_2NH$	1.0	7.3×10^{-10}	0.23
$CH_3CO_2CH_3$	$^-CH_2CO_2CH_3 + H_2O_2$	0.52	1.9×10^{-9}	0.98
	$CH_3CO_3^- + CH_3OH$	0.48		

[a] In cm^3 $molecule^{-1}$ s^{-1}.
[b] Reaction efficiency. ADO rate constant calculated by the method of Su and Bowers (5).
[c] Since HS^- and HO_2^- are both m/z 33, the small buildup in HS^- makes the rate measurement inaccurate. The rate is less than that observed for the reaction: $HO_2^- + CO_2 \rightarrow CO_3^- + HO$.
[d] Some may come from O_2^-.
[e] Structure of the neutral product is not known.

strong base and a powerful oxidizing agent. Its basicity is demonstrated by the deprotonation of acetone (ΔH^0_{acid} = 368.8 kcal mol^{-1}) (7), which occurs at almost every collision, and of methyl acetate (ΔH^0_{acid} = 371.0 kcal mol^{-1}) (7), which occurs, on average, every second collision. These results are consistent with our previous determination of the acidity of H_2O_2 (*vide supra*).

The most interesting feature of the reactivity of HO_2^- is its power as an oxidizing agent. It readily oxidizes carbonyl compounds by donation of an oxygen atom, as exemplified by its reaction with CO_2, which we formulate as written in eq. [3].



[3] $HOO^- + CO_2 \rightarrow [HOO{-}C(O^-){=}O] \rightarrow {\cdot}O{-}C(=O){-}O^- + HO{\cdot}$

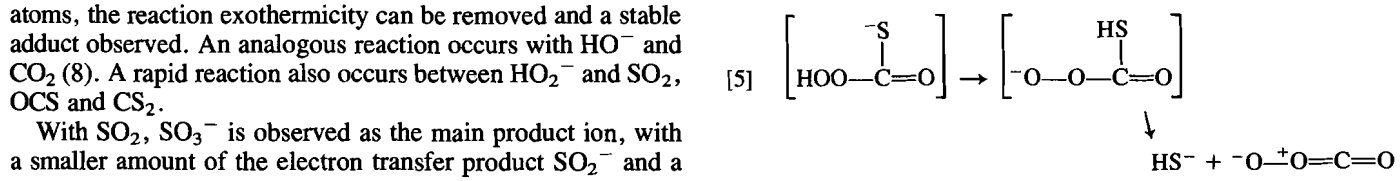
This reaction occurs, within the experimental uncertainty, at every collision, and this rapid rate is consistent with other addition reactions to CO_2, which we reported in an earlier paper (8). A small amount of the adduct, $HOOCO_2^-$, is also formed. The exact amount formed is dependent upon the helium pressure since the reaction is termolecular. Provided that the adduct lives long enough ($\sim 10^{-7}$ s) to collide with one or more helium atoms, the reaction exothermicity can be removed and a stable adduct observed. An analogous reaction occurs with HO^- and CO_2 (8). A rapid reaction also occurs between HO_2^- and SO_2, OCS and CS_2.

With SO_2, SO_3^- is observed as the main product ion, with a smaller amount of the electron transfer product SO_2^- and a trace of adduct. Both OCS and CS_2 give mainly (>95%) the corresponding oxygen transfer products CO_2S^- and COS_2^-, respectively, but in both cases HS^- is produced in small amounts. Since HS^- and HO_2^- have the same mass, the determination of rate constants for these reactions is complicated; kinetic plots are curved because of buildup of a product ion of the same mass as that of the reactant whose intensity is being monitored. Qualitatively, however, both OCS and CS_2 react rapidly, but somewhat less so than do CO_2 or SO_2. The formation of HS^- must arise from proton transfer within the initial adduct, followed by fragmentation (eq. [4*b*]).

[4*a*] $HOO^- + OCS \xrightarrow{>0.95} CO_2S^- + HO$

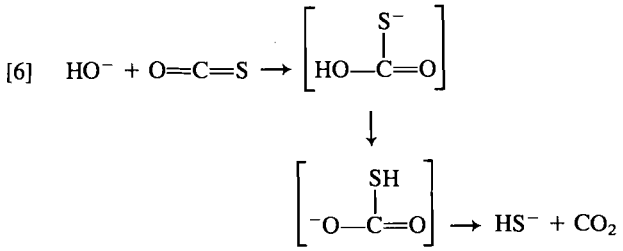
[4*b*] $\xrightarrow{<0.05} HS^- + CO_3$

Since the electron affinity of the carbonate radical (2.69 eV) (9) is higher than that of HS· (2.32 eV) (9) and no CO_3^- is seen among the products, it is unlikely that CO_3 has the carbonate structure. We suggest instead that the following reaction occurs (eq. [5]).



[5] $[HOO{-}C(S^-){=}O] \rightarrow [{}^-O{-}O{-}C(SH){=}O] \rightarrow HS^- + {}^-O{-}{}^+O{=}C{=}O$

The overall reaction would then be analogous to that which occurs between hydroxide ion and COS (eq. [6]) (8).

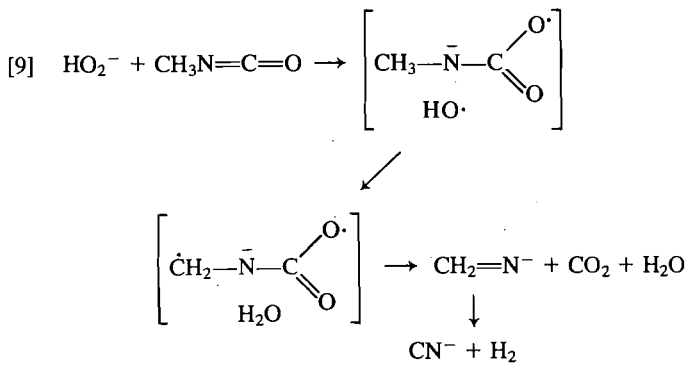


Reactions between HO_2^- and methylisocyanate and methylisothiocyanate offer an opportunity to compare substitution and oxidation reactions within the same molecule (eqs. [7] and [8]).

[7] $HO_2^- + CH_3NCO \rightarrow NCO^- + CH_3O_2H$
$\rightarrow CH_3NCO_2^- + HO$

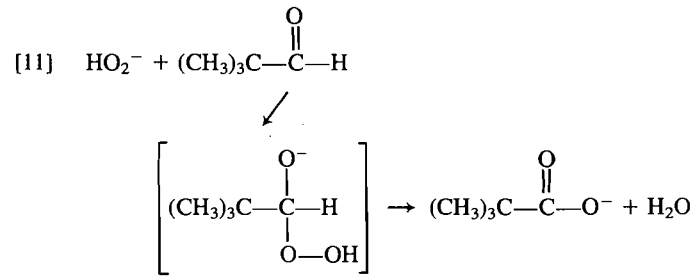
[8] $HO_2^- + CH_3NCS \rightarrow NCS^- + CH_3O_2H$
$\rightarrow CH_3NCOS^- + HO$

For methylisocyanate only a trace (2%) of substitution, which generates NCO^-, is observed while with methylisothiocyanate NCS^- is the major product (82%). This is consistent with the fact that NCS^- is expected to be a better leaving group than NCO^- due to its lesser basicity (8). A more surprising product is cyanide ion (14%) from reaction of methylisocyanate with HO_2^-. A possible pathway for the formation of this ion is that shown in eq. [9].

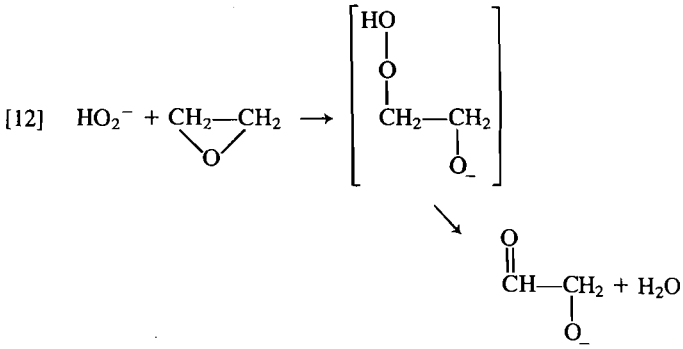


We have shown previously (10) that CN^- is formed readily when the formimine anion is produced in an exothermic reaction (eq. [10]).

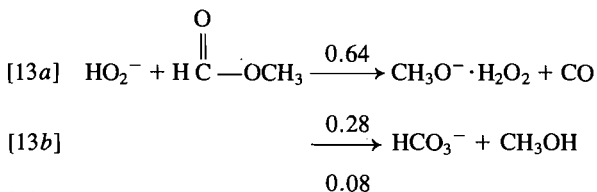
The gas-phase hydroperoxy anion also oxidizes aldehydes to carboxylate ions, just as it does in solution. To avoid proton transfer reactions, which compete effectively, aldehydes without α-hydrogens must be used (eq. [11]).



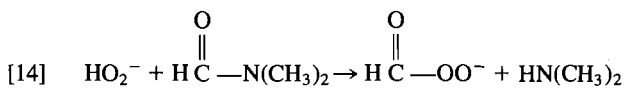
The mechanism by which water is eliminated from the adduct remains uncertain. The addition step should be only slightly exothermic, so that the adduct will not be energized sufficiently to promote even oxygen–oxygen bond cleavage. A seemingly related loss of water across a carbon–oxygen bond is observed upon addition of HO_2^- to ethylene oxide (eq. [12]).



We reported previously (11) the reaction of HO_2^- with methyl formate, where proton abstraction resulting in the Riveros reaction ([13*a*]) gives rise to the major product ions, accompanied by smaller amounts of carbonyl addition ([13*b*]) and nucleophilic substitution products ([13*c*]).



With methyl acetate as the substrate, a 50:50 mixture of products arising from proton abstraction and from carbonyl addition is observed. When dimethyl formamide is used, however, the peroxyformate ion is the exclusive ionic product (eq. [14]).



This reaction is somewhat slower than the others but still occurs at approximately one in four encounters. The chemistry of the peroxyformate ion will be considered briefly in a later section.

The reactions of HO_2^- with CO and NO are also appreciably slower than the encounter rates; the former produces hydroxide ion (eq. [15]), and the latter, NO_2^- (eq. [16]).

[15] $HOO^- + CO \rightarrow [HO—O—\bar{C}=O] \rightarrow HO^- + CO_2$

[16] $HOO^- + NO \rightarrow [HO—O—\dot{N}—O^-] \rightarrow NO_2^- + HO$

In either case the initial adduct is of higher energy than that, for example, from CO_2, and the difficulty in its formation probably presents a barrier along the reaction pathway and accounts for the slower rates. In the case of reaction with carbon monoxide, for example, the initial adduct is a formyl-type anion, a relatively high energy species. Subsequent decomposition gives HO^- and CO_2. Analogous decomposition of an adduct between HO_2^- and NO would be expected to form HO and NO_2^-, since NO_2 has a higher electron affinity (2.275 eV) (9) than does HO (1.83 eV) (9).

TABLE 2. Reactions of $H—\overset{O}{\overset{\|}{C}}—O_2^-$. Products, branching ratios, rate constants, and efficiencies

Neutral reactant	Products	Branching ratios	k_{expt}[a]	k_{expt}/k_{ADO}[b]
CO	$HCO_2^- + CO_2$	1.0	5.2×10^{-11}	0.07
CO_2		>0.95[c]	1.1×10^{-27} [d]	
	$HCO_2^- + CO_3$	0.02		
NO	$HCO_2^- + NO_2$	1.0[e]	7.0×10^{-11}	0.11
SO_2	$SO_2^- + HCO_3$	1.0	1.4×10^{-9}	1.1
CH_3COCH_3	$HCO_2^- + C_3H_6O_2$	1.0[f]	3.0×10^{-10}	0.13
$(CH_3)_3CCHO$	$HCO_2^- + C_5H_{10}O_2$	1.0[g]	8.4×10^{-10}	0.42

[a]In cm^3 $molecule^{-1}$ s^{-1}, unless otherwise noted.
[b]Reaction efficiency. ADO rate constant calculated by the method of Su and Bowers (5).
[c]This adduct is formed by a termolecular reaction; branching ratio is given for the pressure = 0.385 Torr.
[d]In cm^6 $molecule^{-2}$ s^{-1}.
[e]A small amount of NO_2^- is present (10% of HCO_2^- peak). The intensity of the signal increases markedly as the distance between the NO and DMF inlets is decreased. We believe NO_2^- is formed from residual HO_2^-.
[f]A small amount of $CH_3COCH_2^-$ is present (15% of HCO_2^- peak) but we believe this arises from residual HO_2^-.
[g]A small amount of $(CH_3)_3CCO_2^-$ is present (5% of HCO_2^- peak) but we believe this arises from residual HO_2^-. We cannot exclude the possibility that some $(CH_3)_3CCO_2^-$ is produced in the HCO_3^- reaction.

Reactions of HCO_3^-

Since the peroxyformate ion[3] can be formed readily from the reaction of HO_2^- with dimethylformamide, we have made a brief study of its chemistry and the results are summarized in Table 2. It is clear that the peroxyformate ion is significantly less reactive than the hydroperoxy anion. For example, it reacts with carbon monoxide at only a quarter of the rate at which HO_2^- reacts. This is consistent with HCO_3^- being a weaker base than is HO_2^-, as is shown by the fact that it does not deprotonate acetone, as HO_2^- does. To the extent, then, that a formyl-type anion is involved in the oxidation of CO, the peroxyformate ion should react more slowly (eq. [17]).

[17] 
HCO_3^- also oxidizes NO more slowly than does HO_2^-. Since the formoxyl radical has a greater electron affinity (3.5–4 eV) than does NO_2, the formate ion is observed rather than NO_2^-.

Since HCO_3^- is not a strong enough base to abstract a proton from aldehydes and ketones, we were able to examine other, slower reactions of these neutrals. In particular we noted that acetone reacts rather slowly (eff. = 0.13) with HCO_3^- to produce HCO_2^-, and other carbonyl compounds react similarly. Obviously oxygen atom transfer has occurred to acetone, but the formate ion is such a weak base that it is the only ionic product. We suggest that when the peroxyformate ion reacts with aldehydes and ketones a gas-phase Baeyer–Villiger reaction occurs. For example, methyl acetate would be the neutral product from reaction with acetone as given in eq. [18].

[18] 
Pivalaldehyde reacts somewhat more rapidly (eff. = 0.42), also to form the formate ion.

Carbon dioxide reacts slowly with HCO_3^- in a termolecular reaction to form an adduct; only a small amount of the oxidation product is observed.

[3]There are two structures for an ion of molecular formula HCO_3^- that we must consider, namely the bicarbonate ion $HOCO_2^-$ and the peroxyformate ion HCO_3^-. We have prepared the bicarbonate ion by the termolecular process $HO^- + CO_2 + He \rightarrow HOCO_2^- + He$ (12). The bicarbonate ion undergoes ready exchange with (for example) D_2O or MeOD to form $DOCO_2^-$. The ion formed from HO_2^- and dimethylformamide does not exchange with either D_2O or MeOD; instead, it undergoes slow clustering reactions. Other reactions of the bicarbonate ion will be described in a subsequent publication.

Received October 18, 1985

This paper is dedicated to Professor Arthur N. Bourns

ALEX G. HARRISON. Can. J. Chem. **64**, 1051 (1986).

The $[C_2D_5]^+$ species forms an adduct in the gas phase with ethyl acetate, ethylbenzene, and *p*-ethyltoluene, which subsequently unimolecularly eliminates C_2H_4 and C_2D_4 in approximately a 2:1 ratio. These results indicate that the adduct is not a weakly bound ion–molecule complex but a bonded species in which the C_2D_5 group has become equivalent to the C_2H_5 group present in the molecule; the preference for elimination of C_2H_4 is due to an isotope effect. From observations of the relative loss of C_2H_4 and C_2D_4 from $[C_2D_5]^+$ adducts with other molecules containing a C_2H_5 group, it is concluded that the $[C_2D_5]^+$ species attaches to the carboxyl group in ethyl benzoate, primarily to the ring in substituted phenetoles and in ethylphenols, primarily to the nitrogen in ethylpyridines, and primarily to the ring for *N*-ethyl- and *p*-ethyl-aniline.

ALEX G. HARRISON. Can. J. Chem. **64**, 1051 (1986).

En phase gazeuse, les espèces $[C_2D_5]^+$ forment des adduits avec l'acétate d'éthyle, l'éthylbenzène et le *p*-éthylbenzène qui, par le biais d'une réaction unimoléculaire, éliminent par la suite du C_2H_4 et du C_2D_4 dans un rapport de 2:1. Ces résultats indiquent que l'adduit n'est pas uniquement un complexe ion–molécule faiblement relié mais plutôt une espèce comportant une liaison et dans laquelle le groupement C_2D_5 est devenu équivalent au groupement C_2H_5 qui est présent dans la molécule; l'élimination préférentielle du C_2H_4 serait due à un effet isotopique. Sur la base des observations concernant les pertes relatives de C_2H_4 et de C_2D_4 à partir d'adduits du $[C_2D_5]^+$ avec d'autres molécules contenant un groupement C_2H_5, on en conclut que les espèces $[C_2D_5]^+$ s'attachent soit au groupement carboxyle du benzoate d'éthyle soit principalement au cycle aromatique des phénétoles substitués, des éthylphénols ou des anilines *N*- ou *p*-éthylées.

[Traduit par la revue]

There is considerable interest as to the site of protonation and alkylation of organic molecules in the gas phase; this interest is prompted not only by questions of intrinsic molecular properties such as proton affinities but also by the question of the effect of the site of attack on ionic fragmentation reactions under chemical ionization conditions. In considering the site of protonation/alkylation it is important to distinguish between conditions of thermodynamic control that apply when equilibrium proton affinities are measured and kinetic control that characterizes protonation and alkylation under chemical ionization conditions.

There now is a large body of equilibrium gas-phase proton affinity data (for a summary of data and methods of measurement, see ref. 1) including many bifunctional molecules. Although the thermodynamically favoured site of protonation has been elucidated from an investigation of substituent effects (2), for most bifunctional molecules, the site of protonation has been determined from correlations of gas-phase proton affinities with core binding energies. Thus, from correlations of the measured proton affinities of carboxylic acids and derivatives with O(1*s*) binding energies it has been established (3–5) that these compounds are protonated on the carbonyl oxygen. A similar study (6) has established that in the gas phase amides are protonated on the oxygen, which is in agreement with solution phase results (7). The correlation of proton affinity data of substituted pyridines with N(1*s*) binding energies (8) shows that protonation occurs on the nitrogen, while a similar correlation for substituted anilines (9) reveals a more complex behaviour where protonation on either the ring or a nitrogen depends on the substituent.

The position of proton or cation attack under the conditions of chemical ionization is much less clear. Much of the evidence has arisen from collision-induced dissociation (CID) studies (10) of the protonated and cationized products. Thus, Maquestiau *et al.* (11) found that the CID mass spectra of ethylated pyrrole and protonated *N*-ethylpyrrole showed substantial differences and they concluded that neither ethylation nor protonation occurred at the nitrogen. From similar studies of the ethylation of pyridine and the protonation of ethylpyridines they concluded that ethylation and protonation both occurred at the nitrogen. In the case of aniline they concluded from the similarity of the CID spectra of protonated 2-, 3-, and 4-ethylaniline with the CID spectrum of ethylated aniline that ring protonation and ethylation occurred. In contrast to these results, in a similar CID study Cooks and co-workers (12) concluded that aniline was both methylated and ethylated predominantly at the nitrogen, although in the ethylation reaction they concluded that 20% ring attack occurred. At the considerably higher pressures involved in radiolytic studies Attina and Cacace (13) observed ~20% nitrogen and ~80% ring ethylation of aniline. More recently, Burinsky and Campana (14) have studied the site of attachment of H^+, $[CH_3]^+$, and $[C_2H_5]^+$ to morpholine, thiomorpholine, and 1,4-thioxane by CID studies of the adducts. They concluded that the site of protonation followed the predicted trends in proton affinities of the heteroatoms (N > S > O) but that alkyl ion reactivities followed differences in electronegativity or electrophilicity (S > N > O).

Cooks and co-workers (12) observed that the ethyl ion adducts that they studied showed a strong tendency to eliminate ethylene in unimolecular (metastable) fragmentation reactions. They suggested that this arose because the adduct fragmenting in this way existed as a weakly bound ion–molecule complex such as a proton bound dimer of the substrate and ethylene, which would be expected to lose ethylene readily. To investigate this possibility we have reacted $[C_2D_5]^+$ with a number of substrates containing unlabelled ethyl groups. We have found that the adduct ion that fragments unimolecularly cannot be explained in terms of a weakly bound ion–molecule complex but rather that, in many cases, the labelled ethyl group added has become equivalent with the unlabelled ethyl group originally

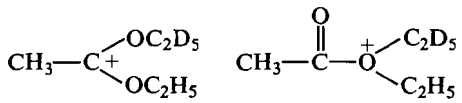
present in the substrate molecule. As is indicated below, these studies also provide information on the site of attack when more than one site is possible.

In our initial studies we examined the unimolecular fragmentation of the $[C_2D_5]^+$ ethylbenzene and *p*-ethyltoluene adducts. In both cases we observed loss of both C_2H_4 and C_2D_4 in the ratio 2.3_9:1.0 (ethylbenzene) and 2.1_5:1.0 (*p*-ethyltoluene), favouring C_2H_4 loss. These results indicate that those adducts that are fragmenting unimolecularly cannot be described in terms of a weakly bound ion–molecule complex but rather that they are chemically bound species in which the C_2D_5 group has become equivalent with the C_2H_5 group originally present in the substrate molecule, i.e.

[1] $[C_2D_5]^+$ +  $-C_2H_4$, $-C_2D_4$

Fragmentation of protonated ethylbenzenes is known to involve elimination of ethylene (15). The preferred elimination of C_2H_4 compared to elimination of C_2D_4 undoubtedly arises from an isotope effect favouring H transfer over D transfer; isotope effects of this magnitude are observed frequently (16). The present experiment provides no information as to the exact position of attack, and attack at the *para* position as shown in reaction [1] is for illustrative purposes only.

Reaction of $[C_2D_5]^+$ with ethyl acetate leads to an adduct that subsequently loses C_2H_4 and C_2D_4 in the ratio 2.3_3:1.0. Again this indicates equivalence of the two ethyl groups, with elimination of C_2H_4 favoured by an isotope effect. We cannot distinguish between the two alternative sites of $[C_2D_5]^+$ attack exemplified by **1** and **2**, although the thermodynamically



1 **2**

favoured product is **1** (3–5). The adduct formed between $[C_2D_5]^+$ and ethyl benzoate lost C_2H_4 and C_2D_4 unimolecularly in the ratio 2.1_5:1.0. This result indicates equivalence of the two ethyl groups and thus formation of an adduct similar to **1** or **2** rather than $[C_2D_5]^+$ addition to the aromatic ring.

Protonated and ethylated phenyl *n*-propyl ethers have been shown (17) to eliminate propylene, and a similar reaction would be expected for substituted phenetoles. Accordingly, we have studied the unimolecular fragmentation of the adduct of $[C_2D_5]^+$ with three substituted phenetoles, with the results summarized in Table 1. In all cases the observed ratio of C_2H_4 loss to C_2D_4 loss is greater than that expected for equivalence of the two ethyl groups, based on the results presented above. We interpret this result in terms of $[C_2D_5]^+$ addition at both the oxygen and the aromatic ring, viz.

[2] $[C_2D_5]^+$ + X–  –OC_2H_5

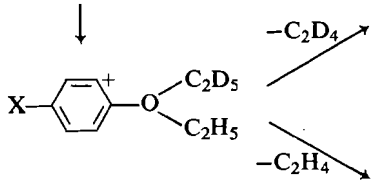


TABLE 1. Fragmentation of $[C_2D_5]^+$ adducts of substituted phenetoles

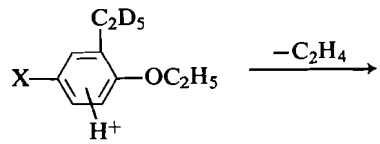
Phenetole	Fractional loss of C_2H_4	Fractional loss of C_2D_4	$-C_2H_4/-C_2H_4$
p-F	0.78_1	0.21_9	3.5_7
p-CH_3	0.85_4	0.14_6	5.8_5
p-Cl	0.92_1	0.07_9	11.6

[3] $C_2H_5^+$ + X–  –OC_2H_5



We can present no evidence concerning the exact position of attack on the ring; *ortho* attack is used for illustrative purposes only. If we assume that addition to oxygen (reaction [2]) will subsequently lead to C_2H_4 and C_2D_4 loss in the ratio 2.2:1.0 (see above) and that addition at the ring (reaction [3]) leads to loss of C_2H_4 only, we calculate that the percent of ring addition is 30% (*p*-F) 53% (*p*-CH_3), and 75% (*p*-Cl). The thermodynamically favoured site of protonation of the substituted phenetoles is not known, although it is known (2, 5) that the thermodynamically favoured site of protonation of anisole is the aromatic ring. It should be emphasized that the above results refer only to those ions that undergo fragmentation in the second field-free region of the mass spectrometer.

The $[C_2D_5]^+$ adducts with 2-ethylphenol and 3-ethylphenol showed unimolecular loss of C_2H_4 and C_2D_4 in the ratios 1.7_5(2-ethyl) and 2.0_1(3-ethyl). Again, the extensive loss of C_2H_4 is not consistent with a weakly bound ion–molecule complex between $[C_2D_5]^+$ and the phenol; such a complex would be expected to eliminate C_2D_4. Nor are the results consistent with addition of $[C_2D_5]^+$ to the hydroxyl group because, by analogy with the fragmentation of protonated phenetole (17), such a species also would eliminate C_2D_4. The results can be rationalized readily in terms of dominant addition to the ring, leading to equivalence of the labelled and unlabelled ethyl groups. Assuming that in such an intermediate C_2H_4 and C_2D_4 would be lost in the ratio 2.2:1.0, we estimate 79% ring ethylation of 2-ethylphenol and 92% ring ethylation of 3-ethylphenol. From CID studies, Cooks and co-workers (12) have concluded that phenol undergoes ring ethylation about 90% of the time. The ring is known (2) to be the thermodynamically favoured site of protonation.

Table 2 summarizes the results obtained for the $[C_2D_5]^+$ adducts with the isomeric ethylpyridines. The predominant loss of C_2D_4 in metastable ion fragmentation reactions clearly indicates that the added C_2D_5 has not become equivalent with the C_2H_5 group present in the molecule. While this might be taken as indicating that only a weakly bound ion–molecule complex is formed, we favour the alternative interpretation that the $[C_2D_5]^+$ species attacks the nitrogen, the thermodynamically favoured site of protonation (8). The fact that some loss of C_2H_4 is observed indicates a minor extent of ring ethylation. An unusual fragmentation is loss of CH_3 and CD_3 from the adduct ions. In other studies we have noted that protonated ethylpyri-

TABLE 2. Fragmentation of $[C_2D_5]^+$ adducts with ethylpyridines

p-Ethyl	0.44_8	0.34_8	0	0.20_4

dines lose CH_3 unimolecularly. The loss of CH_3 and CD_3 from the adducts also implies some ring ethylation. The conclusion that ethylation occurs predominantly at nitrogen is in agreement with the conclusion reached by Maquestiau *et al.* (11).

Table 3 summarizes the results obtained for the unimolecular fragmentation of the $[C_2D_5]^+$ adducts with *N*-ethylaniline and *p*-ethylaniline. For the adduct with *N*-ethylaniline, metastable ion fragmentation involves primarily loss of C_2D_4 and C_2D_5 with only minor loss of C_2H_4 and C_2H_5. Clearly the C_2D_5 group added has not become equivalent with the C_2H_5 attached to the nitrogen. While this might be explained in terms of formation of a weakly bound ion–molecule complex, we prefer the conclusion that ethylation has occurred predominantly on the ring. This conclusion is supported by the results for the adduct with *p*-ethylaniline where elimination of C_2H_4 exceeds elimination of C_2D_4, indicating a significant extent of ring ethylation. An unusual observation is that only C_2D_5 loss, and no C_2H_5 loss, is observed for the adduct with *p*-ethylaniline, while for the adduct with *N*-ethylaniline predominant loss of C_2D_5 is observed. These results suggest that C_2H_5 loss may be occurring from a weakly bound ion–molecule complex rather than from the σ-bonded adduct that leads to subsequent ethylation loss. The overall reaction is, of course, a charge transfer reaction and is not surprising, since the ionization energy of C_2H_5 (8.38 eV (18)) is greater than that of either of the ethylanilines (7.6 eV (18)). In any event, the present results are in agreement with the conclusions of Maquestiau *et al.* (11), that ethylation of anilines occurs primarily on the ring rather than at the nitrogen, even though, for the ethylanilines, the nitrogen is the thermodynamically favoured site of protonation (9).

In summary, ethylphenols and substituted phenetoles undergo ethyl ion addition primarily on the aromatic ring, the thermodynamically favoured site, while pyridines undergo ethyl ion addition primarily at the nitrogen, again the thermodynamically favoured site. By contrast, ethylanilines undergo attack primarily at the ring even though the nitrogen is the thermodynamically favoured site of attack. It is clear that the site of attack under conditions of kinetic control cannot always be predicted from the site of attack under thermodynamic control.

Experimental

The $[C_2D_5]^+$ adducts were prepared in the chemical ionization source of a VG Analytical ZAB-2FQ mass spectrometer by using CD_4 as reagent gas. Under chemical ionization conditions the CD_4 reagent gas gives a large yield of $[C_2D_5]^+$, which, in part, reacts by adduct formation with a variety of molecules. Source pressures were not measured directly but, from the extent of conversion of the methane primary ions to product ions, the pressure was estimated to be greater than 0.3 Torr (1 Torr = 133.3 Pa). The $M.C_2D_5^+$ adduct was mass selected by the magnetic sector of the reverse-geometry double-focussing mass spectrometer and underwent unimolecular fragmentation in the drift region between the magnetic and electric sector, with the ionic products of fragmentation being established from their kinetic energy by scanning the electric sector in the usual MIKES technique (19). Source temperatures were approximately 200°C with the electron energy 50 eV and the filament emission 500 μA. The ion accelerating voltage was 8 keV. Samples were admitted through a heated inlet system. All compounds were obtained commercially and they showed no detectable impurities in their mass spectra. The CD_4 was obtained from Merck, Sharp and Dohme, Montreal.

When alkenes are oxidized by quaternary ammonium or phosphonium permanganates in polar organic solvents, such as acetone, the structures of the cations have little or no effect on the rates of reaction. In less polar solvents, such as methylene chloride or toluene, the rates of reaction are, however, dependent on the identity of the quaternary ammonium or phosphonium ions. It thus appears as if the reacting species may exist as solvent-separated ion pairs in polar solvents and as intimate ion pairs in nonpolar solvents. The rates of reaction are also very sensitive to substituent effects, a nonlinear (concave upward) Hammett plot being obtained for the oxidation of substituted β-bromo and β-methoxystyrenes. The mechanism is best visualized as proceeding by way of a continuum of transition states that can vary from electron rich to electron poor depending on the capacity of the substrate structures to accommodate either negative or positive charges.

DONALD G. LEE, KEITH C. BROWN et HASAN KARAMAN. Can. J. Chem. **64**, 1054 (1986).

Lorsque des alcènes sont oxydés par des permanganates d'ammonium ou de phosphonium quaternaires, dans des solvants organiques polaires comme l'acétone, les structures des cations n'ont pas ou peu d'effet sur les vitesses des réactions. Dans des solvants moins polaires, comme le chlorure de méthylène ou le toluène, les vitesses dépendent toutefois de l'identité des ions quaternaires. Il semble donc que les entités qui réagissent peuvent exister sous la forme de paires d'ions solvatés dans les solvants polaires et de paires d'ions intimes dans les solvants non-polaires. Les vitesses de réaction sont aussi très sensibles aux effets de substituants: on obtient une courbe de Hammett qui n'est pas linéaire (concave vers le haut) lors de l'oxydation de β-bromo et de β-méthoxystyrènes substitués. La meilleure représentation du mécanisme de la réaction implique des états de transition continus qui varient suivant leur nature riche ou pauvre en électrons, qui dépend elle-même de la capacité des structures des substrats d'accommoder soit des charges positives ou négatives.

[Traduit par la revue]

Introduction

Recent studies have shown that a wide variety of organic functional groups may be oxidized by quaternary ammonium and phosphonium permanganates under mild, nonpolar conditions (1). For example, this reaction has been used for the oxidation of aliphatic hydrocarbons (2), arenes (2, 3), alcohols (4, 5), aldehydes (5, 6), ethers (7), sulfides (8), amines (9), and alkenes (10).

Because these reactions appear to have considerable synthetic potential and because they present an interesting example of electron transfer processes under nonaqueous conditions, we have undertaken a study of the oxidation of a number of styrene derivatives in three solvents, methylene chloride, toluene, and acetone. Our purpose was to investigate the reaction mechanism and to achieve a better understanding of the role that solvents play in these reactions.

Experimental

Reactants and solvents

The quaternary ammonium and phosphonium permanganates were prepared as previously described (11). The substituted methyl cinnamates were prepared by methylation of the corresponding cinnamic acids and purified by distillation or recrystallization (12). The physical properties of the esters corresponded well with those reported in the literature (Table 1). The substituted β-bromostyrenes were prepared, as described in the literature (12), by treating the corresponding cinnamic acids with bromine in hot chloroform, isolating the product (a substituted 2,3-dibromo-3-phenylpropanoic acid), and refluxing it in aqueous sodium bicarbonate. β-Bromostyrene was isolated by vacuum distillation and purified by prepartive glc using a 7-ft 15% Apiezon L on Chromosorb P column. The other substituted β-bromostyrenes, being volatile solids, were purified by vacuum sublimation. The physical properties of these compounds are summarized in Table 1. The substituted β-methoxystyrenes were prepared, as described in the literature (13), by treatment of the corresponding phenylacetylenes with potassium hydroxide in absolute methanol. The products were isolated from the reaction mixture by vacuum distillation and purified by radial chromatography, using a Harrison Research model 7924 chromatotron. The physical properties of these compounds are summarized in Table 1.

Proton magnetic spectra were recorded using a Perkin–Elmer 60-MHz R12B spectrophotometer.

The solvents (methylene chloride, toluene, and acetone) were purified by treatment with tetrabutylammonium permanganate for several hours, followed by fractional distillation from the solution.

Kinetics

Solutions of the substrate (0.8 M) and quaternary ammonium permanganate (4×10^{-4} M) were prepared in a particular solvent and thermostated for 15 min. Then an aliquot (3.0 mL) of the oxidant solution was transferred to a 10-mm cuvette in the thermostated cell compartment of a Hewlett–Packard 8450A spectrophotometer. A small portion of the reductant solution was injected from a syringe, and the absorbance was recorded at intervals. Plots of $\ln (A - A_\infty)$ against time were linear (10), thus indicating that the reaction is first order in permanganate. The pseudo-first-order rate constants, obtained from the slopes of these plots, were found to be directly proportional to the concentration of the reductant, thereby confirming that the reaction is also first order in reductant concentration (10).

Stoichiometry

The stoichiometry of the reaction was determined by adding small portions of a reductant solution to a standardized solution of permanganate and recording the spectrum of the product. A calculation of the number of moles of permanganate reduced, per mole of reductant added, indicated a 1:1 stoichiometry.

Products

The brown-yellow solution remaining after all of the permanganate had been reduced in methylene chloride by a typical alkene, 1-phenyl-1-

pentene, was found by iodometric analysis (18) to contain manganese in the +4 oxidation state. Although no organic products could be detected in this solution when it was analyzed by glc, the corresponding diol, 1-phenyl-1,2-dihydroxypentane, could be isolated after treatment with base. On the other hand, when the yellow-brown methylene chloride solution was treated with aqueous acid, benzaldehyde was found to be a major product. similar results for other compounds have previously been reported (19).

The oxidation state of the manganese remained at +4 after treatment with aqueous base, but decreased to about +3 after treatment with aqueous acid. Thus, it appears that the organic product (diol) may be complexed to a manganese(IV) compound (MnO_2?) in organic solvents, and released only by hydrolysis. Under basic conditions no further redox reactions occur during hydrolysis, but under acidic conditions the diol is oxidatively cleaved with concurrent reduction of the manganese, as in eq. [1].

$$[1]\quad \text{Alkene} + MnO_4^- \xrightarrow{CH_2Cl_2} \text{Manganese(IV) complex}$$

$$\text{Manganese(IV) complex} \xrightarrow{OH^-/H_2O} \text{Diol} + MnO_2$$

$$\text{Manganese(IV) complex} \xrightarrow{H^+/H_2O} \text{cleavage products} + \text{Mn(III)}$$

Results and discussion

Although most salts exist as discrete ions in aqueous solutions, quaternary ammonium compounds when dissolved in organic solvents are more likely to form ion pairs (11). Brandstrom has shown that the probability of salts existing as ion pairs is inversely dependent on the distance between the centres of the two ions and the dielectric constants of the solvents (20). Using his method of calculation, we have previously shown that most quaternary ammonium permanganates would be expected to exist as ion pairs in all solvents except water (1). This can be demonstrated by examining the ^1H nmr spectrum of tetraethylammonium permanganate in three solvents, D_2O, acetone-d_6, and methylene chloride-d_2 (Fig. 1). In water a distinct triplet and quartet is apparent, while in acetone and methylene chloride the resolution is dramatically reduced, with the spectrum becoming two broad multiplets in the latter solvent. Assuming that the lack of resolution in the organic solvents is due to close association of the quaternary ammonium ion with the permanganate ion (11), it would appear that $Et_4N^+MnO_4^-$ exists as separate ions in water, as a loose ion pair in acetone, and as a tight ion pair in methylene chloride.

The data sumarized in Table 2 are also in agreement with this

TABLE 2. Second-order rate constants for the oxidation of methyl cinnamate by $Q^+MnO_4^-$ in three solvents[a]

Q^+	Acetone	Methylene chloride	Toluene[b]
Tetra-*n*-butylammonium	0.32±0.01	1.15±0.02	
Tetra-*n*-octylammonium	0.31±0.01	0.91±0.02	1.31±0.05
Methyltri-*n*-octylammonium	0.33±0.01	1.54±0.05	2.17±0.04
Methyltri-*n*-butylammonium		1.54±0.02	
Methyltriphenylphosphonium	0.34±0.02	1.35±0.02	
n-Butyltriphenylphosphonium	0.27±0.01	0.99±0.02	
Benzyltriphenylphosphonium	0.30±0.01	1.53±0.04	
18-Crown-6-K^+	0.27±0.01	1.64±0.01	

[a]Temperature = 22.0°C. $[Q^+MnO_4] = 4 \times 10^{-4}$ *M*. [Methyl cinnamate] = 8×10^{-3} *M*. Units are $M^{-1}\,s^{-1}$.
[b]Studies in toluene were limited by the insolubility of most quaternary ammonium and phosphonium salts in solvents of low polarity (11).

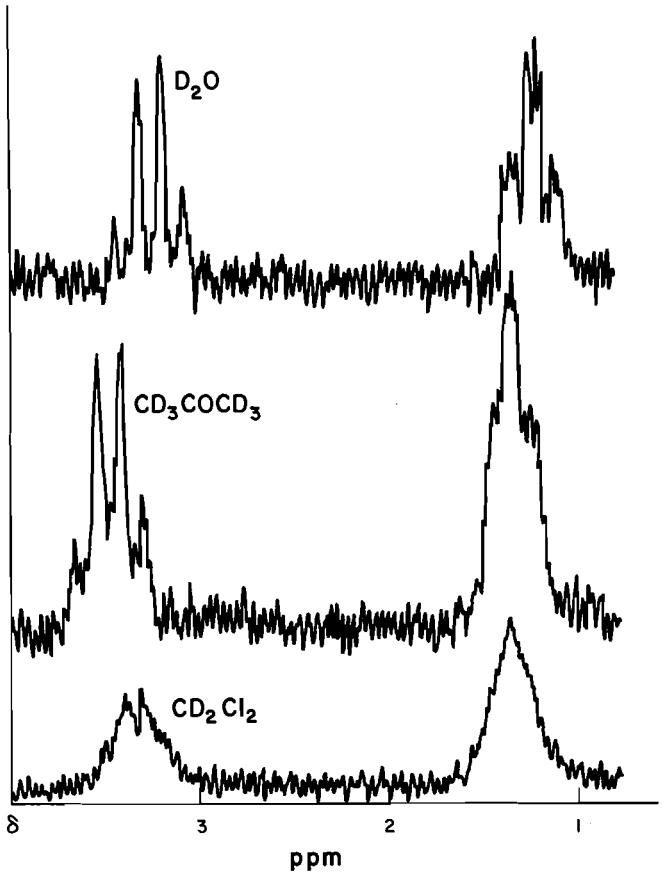

FIG. 1. Proton magnetic resonance spectra of tetraethylammonium permanganate in water-d_2, acetone-d_6, and methylene chloride-d_2.

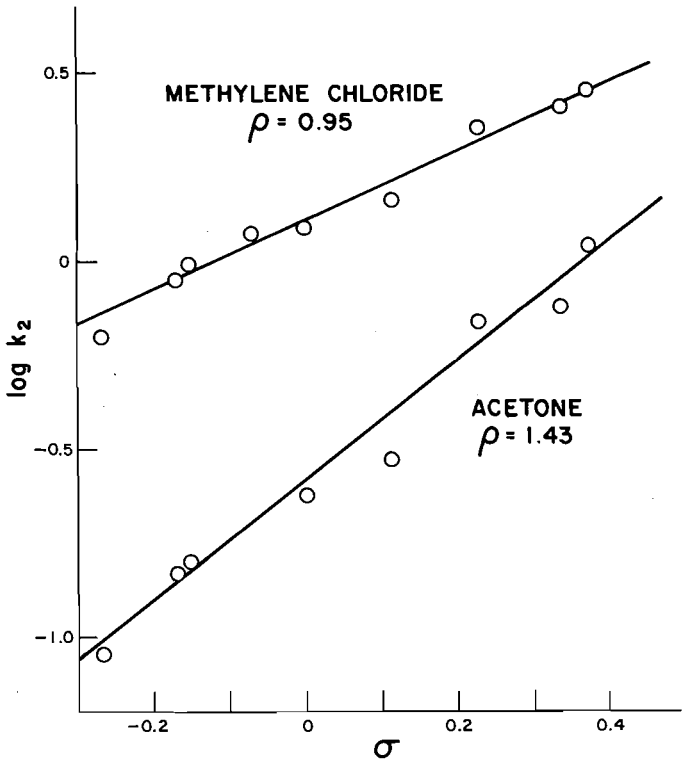

FIG. 2. Hammett plot for the oxidation of substituted methyl cinnamates by tetrabutylammonium permanganate in methylene chloride and acetone. $[QMnO_4] = 3.7 \times 10^{-4}$ *M*. [Methyl cinnamates] = 7.5×10^{-3} *M*. Temperature = 20.0 ± 0.1°C. For upper plot, slope = 0.95 ± 0.12, $r = 0.989$. For lower plot, slope = 1.43 ± 0.18, $r = 0.99$.

interpretation; the rate constants for the oxidation of methyl cinnamate in acetone are not dependent on the nature of the quaternary ammonium ion, whereas substantial variations in rates are found in the less polar solvents, methylene chloride and toluene. It thus appears as if the ion pairing in acetone is sufficiently loose to not affect the relative energies of the ground and transition states. However, in less polar solvents, where theory predicts tighter ion pairs (20), the ions must be intimately associated in either (or both) the ground state and the transition state. Furthermore, close contact within the ion pair seems to increase the rate of reaction. For example, the rate constants for oxidation of methyl cinnamate by methyltri-*n*-octylammonium permanganate are greater (in toluene and methylene chloride) than for tetra-*n*-octylammonium permanganate, presumably because the former allows for greater penetration of the anion into the structure of the cation (11, 21). Hence it appears as if quaternary ammonium permanganates may exist as solvent-separated ion pairs in acetone, but as intimate ion pairs in toluene and methylene chloride (22).

Additional evidence in support of this conclusion is obtained from a consideration of the effect of substituents on the rates of reaction. The Hammett ρ value for the oxidation of substituted methyl cinnamates by tetrabutylammonium permanganate is greater in acetone (ρ = 1.43) than it is in methylene chloride (ρ = 0.95). See Fig. 2. Since the ρ values are positive in both solvents, it is apparent that the transition state bears a greater

TABLE 3. Activation parameters for the oxidation of methyl cinnamate by methyltri-*n*-octylammonium permanganate[a]

Solvent	$\Delta H^{\ddagger}$ (kcal/mol)	$\Delta S^{\ddagger}$ (eu)	$\Delta G^{\ddagger}$ (kcal/mol)[b]
Acetone	8.06±0.50	−33.3±1.8	18.0±1.0
Methylene chloride	5.34±0.28	−39.2±1.0	17.0±0.6
Toluene	3.69±0.74	−44.1±0.3	16.8±0.8

[a]Temperature range from 0 to 30°C.
[b]At 25°C.

electron density than the ground state. However, the lower sensitivity of the reaction to substituent effects in methylene chloride suggests that, in this solvent, some of the increased negative charge is shared by the quaternary ammonium ions. In acetone, where the ion pair is much looser, the effect of substituents is greater because of a greater net charge developed in the transition state.

The thermodynamic parameters observed when different solvents are used could also be a consequence of ion pairing (Table 3). Since these reactions are clearly second order in all three solvents, the values of $\Delta H^{\ddagger}$ must reflect the differences in potential energies between the ground and transition states, while the relative magnitudes of $\Delta S^{\ddagger}$ must be associated with the different amounts of structure (or organization) in the ground and transition states. On this basis, the increase in organization on going from ground state to transition state is least in acetone ($\Delta S^{\ddagger} = -33.3 \pm 1.8$ eu) and greatest in toluene ($\Delta S^{\ddagger} = -44.1 \pm 0.3$ eu), with the value in methylene chloride being intermediate ($\Delta S^{\ddagger} = -39.2 \pm 1.0$ eu). Despite the fact that the reaction in toluene exhibits the least favorable entropy of activation, its rate of reaction is greatest because of the relatively low enthalpy of activation ($\Delta H^{\ddagger} = 3.69 \pm 0.74$ kcal/mol), the converse observation being true for the reaction in acetone ($\Delta H^{\ddagger} = 8.06 \pm 0.50$ kcal/mol). It therefore appears as if the formation of an intimate ion pair provides relatively greater organization and stability to the transition state than to the ground state during the oxidation of methyl cinnamate.

Current theory (23, 24) suggests that these reactions are initiated by formation of a π-complex between the alkene and manganese, as in eq. [2]. It is believed that this complex, **1**, can rapidly transform into a metallocyclooxetane, **2**, which then rearranges into a cyclic manganese(V) diester, **3**, long known to be an intermediate in these reactions (25). The latter is an example of a well-known group of reactions in which carbon migrates from metal to oxygen (23).

[2] 
It is not possible to specify where, in this reaction sequence, the transition state is located. However, it may be noted that the formation of both **1** and **2** involves bond making, whereas conversion of **2** into **3** requires cleavage of the C—Mn bond. Hence it is not unreasonable, to assume, in the absence of other compelling evidence, that the last step in eq. [2] is likely to be rate limiting.

Since the effect of substituents indicates an electron-rich transition state when methyl cinnamate is oxidized, it seems reasonable to suggest that this rate-limiting step may involve heterolytic cleavage of the carbon–manganese bond to give an enolate-like transition state, as in eq. [3].

[3] 
In this picture of the reaction, it is assumed that the proximity of the quaternary ammonium ion would increase the stability of the transition state in nonpolar solvents, but that this effect would be less in more polar solvents (such as acetone) where the cation could be surrounded by a sheath of solvent molecules.

Although the Hammett ρ value is observed to be positive for the oxidation of methyl cinnamates, previous work has shown that this observation is not universally true. For example, Toyoshima *et al.* (26) have reported that the oxidation of vinyl ethers by potassium permanganate in aqueous THF exhibited a negative ρ value (10), while Brownridge found that the ρ value for the oxidation of substituted cinnamic acids in aqueous acetic acid/$HClO_4$ solutions is essentially zero (27). Since some substituted alkenes (such as methyl cinnamates) that are capable of delocalizing negative charges exhibit positive ρ values, while other alkenes (such as vinyl ethers) that are able to stabilize positive charges exhibit negative ρ values, it is not surprising that for certain reactions, the sign of ρ actually changes when different substituents are present. The oxidation of substituted stilbenes, which has been studied by Henbest *et al.* (28), is one example of this phenomenon; the rate of reaction is accelerated by both electron-donating and electron-withdrawing substituents (10). The oxidation of substituted β-methoxy and β-bromostyrenes also gives Hammett plots with a distinctive

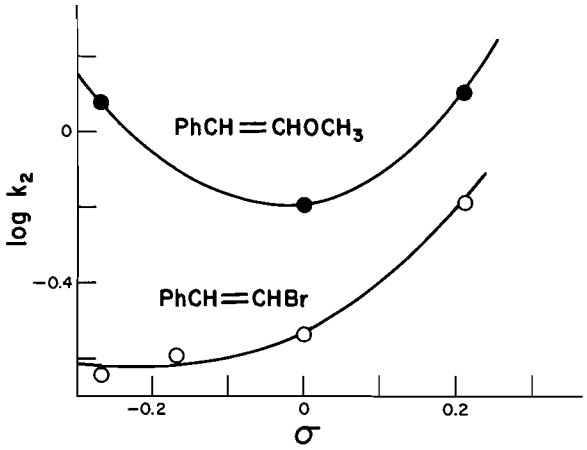

FIG. 3. Hammett plot for the oxidation of substituted β-bromostyrenes and β-methoxystyrenes by tetrabutylammonium permanganate in methylene chloride at 20.0°C.

upward curvature, as demonstrated in Fig. 3. Concave upward plots of this type are obtained only when the variation in substituents causes a change in mechanism (29). In other words, when substituents that are capable of stabilizing a positive charge are present, the reaction must be capable of selecting a pathway in which the transition state is electron deficient (eq. [3]), while the converse must be true when substituents that could stabilize a negative charge are present (eq. [4]).

[4] 
2 3

Since the mechanism chosen by the reaction can be altered from an electron-rich to an electron-deficient path merely by a change in substituents, it follows that the two transition states must be of similar energy and suggests that the reaction could best be visualized by use of a potential energy surface diagram (Fig. 4). According to transition state theory (30), the reaction would select the lowest energy pathway from **2** to **3**. When the substrate is capable of accommodating a negative charge, the reaction pathway would be shifted toward the lower right hand side of the surface, whereas the use of substrates capable of bearing positive charges would shift the reaction pathway toward the upper left hand corner of the diagram.

Although there is an overwhelming amount of evidence that **3** is an intermediate in these reactions, the yellow-brown product solution contains manganese in the +4 *not* the +5 oxidation state. Hence, it appears as if **3** may be a very reactive compound that rapidly undergoes a one-electron reduction, possibly by abstraction of a hydrogen atom from a molecule of solvent, as in [5].

[5] 
3 4 5

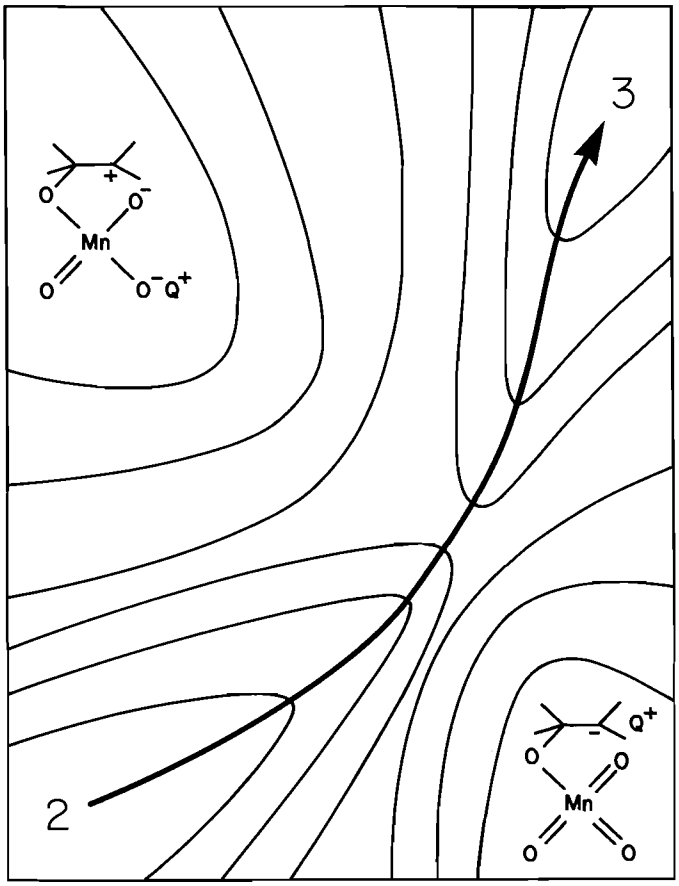

FIG. 4. Potential energy surface diagram for the rearrangement of structure **2** into structure **3**.

The product of this reaction would be a manganese(IV) cyclic diester, **4**, which could decompose to a diol anion, **5**, and manganese dioxide (31). Treatment of this product with aqueous base would release diol plus MnO_2, while addition of aqueous acid causes a further redox reaction in which the diol is oxidatively cleaved and manganese reduced to a lower oxidation state. The latter reaction is consistent with the higher reduction potential of manganese dioxide under acidic conditions (32).

Summary

1. A study of the effect of solvents on the rate of oxidation of methyl cinnamate by quaternary ammonium and phosphonium permanganates indicates that the cations are intimately associated with the transition state in nonpolar solvents, such as methylene chloride and toluene. In more polar solvents, such as acetone, the structure of the quaternary ammonium and phosphonium ions has no observable effect on the rate of reaction, presumably because they form solvent-separated ion pairs in both the ground state and the transition state.

2. A study of substituent effects on the rates of these reactions leads to the conclusion that they can proceed by way of continuum of transition states ranging from electron rich to electron poor. Although the mechanism is best visualized by use of a potential energy surface diagram (Fig. 4), the two extremes may be summarized as in Scheme 1.

3. The initial product of this reaction, **3**, is very reactive and rapidly undergoes a one-electron reduction to a manganese(IV) compound (or complex) that can be hydrolyzed under basic conditions to liberate a diol, or under acid conditions to produce cleavage products.

This paper is dedicated to Professor Arthur N. Bourns

PETER JAMES SMITH and JYOTSNA PRADHAN. Can. J. Chem. **64**, 1060 (1986).

The solvolytic reaction of several 9-(*ortho*-substituted phenylmethyl)fluoren-9-yltrimethylammonium salts has been investigated in several different solvents. Substitution and elimination products were found for the reactions in all the solvents studied, with the exceptions that reaction in both *tert*-butyl alcohol and chloroform led exclusively to the alkene product. The observed rate constants for alkene formation and the percent alkene were measured and it was found that the di-*ortho* compounds reacted at a faster rate but produced less alkene than the reaction of the corresponding mono-*ortho* salts. Hydrogen–deuterium isotope effects were also determined for the various reactions. The results are discussed in terms of the reaction proceeding by way of the E1 mechanism, where steric acceleration promotes the loss of the bulky ammonium leaving group to give the carbocation intermediate.

PETER JAMES SMITH et JYOTSNA PRADHAN. Can. J. Chem. **64**, 1060 (1986).

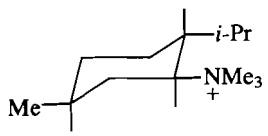
Opérant dans plusieurs solvants, on a étudié la réaction solvolytique de plusieurs sels triméthylammonium des ⟨phénylméthyles substitués en *ortho*)-9 fluorène-9 yles. À l'exception des réactions dans l'alcool *tert*-butylique ou dans le chloroforme, toutes les réactions étudiées dans les autres solvants ont conduit à la formation de produits de substitution ainsi que d'élimination. On a mesuré les constantes de vitesse pour la formation des alcènes ainsi que les pourcentages d'alcènes formés; on a trouvé que les composés doublement substitués en *ortho* réagissent plus rapidement mais qu'ils produisent moins d'alcènes que les réactions des sels correspondants qui ne portent qu'un substituant en *ortho*. On a déterminé les effets cinétiques hydrogène–deutérium pour diverses réactions. On discute des résultats en fonction d'une réaction qui se produirait par le biais d'un mécanisme E1 et dans lequel l'accélération stérique favoriserait le perte du nucléofuge ammonium encombrant au profit de la formation d'un carbocation intermédiaire.

[Traduit par la revue]

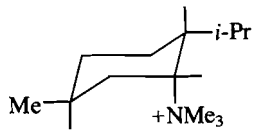
Introduction

Studies on the base-promoted 1,2 elimination reaction of quaternary ammonium salts have received considerable attention both from the experimental (1–6) and theoretical approaches (7, 8). Such substrates generally react with alkoxide bases by way of the one-step concerted E2 mechanism (9, 10) although reaction proceeding by the ylide mechanism (α', β) has been demonstrated by Cope and Mehta (11) for a substrate where approach of base to the β-hydrogen is unfavourable for steric reasons.

Generally, quaternary ammonium salts do not undergo elimination via a carbocation intermediate under solvolytic conditions and, hence, amines have been classified as "poor leaving groups" (poor nucleofuges (2, 12)). However, in a study on the degradation of ax-7-cholestanyltrimethylammonium iodide in boiling ethanol it was reported (13) that the reaction undoubtedly proceeded via an E1 process. Similarly, Hughes and Wilby (14) proposed that menthyltrimethyl- and neomenthyltrimethylammonium hydroxides, **1** and **2**, underwent reaction in water by the unimolecular E1 pathway. Since the neomenthyltrimethylammonium ion, where the $-\overset{+}{N}(CH_3)_3$ group is *cis* to the isopropyl substituent, showed a much larger propensity for reaction via the E1 mechanism than the menthyl substrate, the authors considered that carbocation formation is made favourable due to a relief in steric strain in the molecule.



1



2

The effect of *para* substituents on the aryl ring on the nature of the E2 transition state was examined (2) for the reaction of 2-arylethyltrimethylammonium salts with ethoxide ion in ethanol, eq. [1]. It was found that when the *para* substituent was made more electron withdrawing the reaction rate *increased*. Also, measurements (2) and calculations (8) of both the primary hydrogen–deuterium and nitrogen (leaving group) isotope effects indicated that an increase in the electron-withdrawing power of the ring substituent leads to a corresponding transition state with *both decreased* C—H and C—$\overset{+}{N}$ bond weakening. This substituent effect on transition state geometry (a Hammond effect) was considered to be consistent with the theories of Thornton (15, 16), More O'Ferrall (17) and Jencks (18).

[1] 
In an investigation (19) on the E2 reaction of 9-(4-substituted phenylmethyl)fluoren-9-yltrimethylammonium bromides, **3**, with ethoxide in ethanol, however, it was found that the

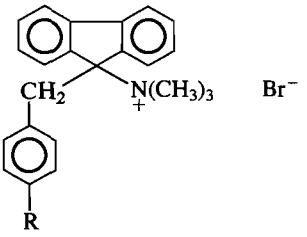
[2]Present address: Department of Chemisty, University of Iowa, Iowa City, IA 52242, U.S.A.

variation of both the primary hydrogen–deuterium and nitrogen isotope effects with changes of the 4-substituent (R) on the phenyl ring were the *opposite* to those found in the earlier studies on the 2-arylethyl system. As well, the Hammett ρ value of +1.33 found for the reaction of **3** was very much less than the value of +3.77 found for the reaction of the 2-arylethyl salts with ethoxide (2), in spite of the fact that in both cases a benzylic hydrogen was being removed with ethoxide ion. It was concluded (19) that for reaction of **3** where the 4-substituent (R) is an electron withdrawer, which leads to an *increase* in the rate of reaction, the extent of both the β-carbon–hydrogen and the α-carbon–nitrogen bond rupture at the transition state is *more* advanced.[3] This apparent variance with the conclusions reached in the earlier studies (2) was discussed in the light of possible steric effects between the *ortho* hydrogens on the phenyl ring and the 1,8 hydrogens on the fluorene nucleus in the reactant and in the transition state.

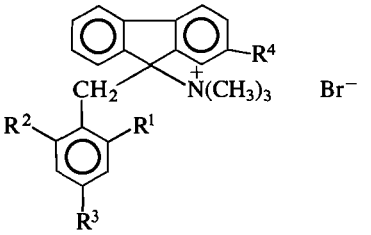


The effect of the nature of the leaving group has been extensively studied (20–30) for several elimination reactions in terms of mechanism as well as in transition-state structure. In all cases, nucleofugality was considered essentially as being entirely due to "electronic factors" (basicity, polarizability, etc). In order to test the proposal (19) that steric interactions might affect leaving group ability and, hence, are responsible for the unexpected results obtained from the study of the reaction of **3** in terms of transition-state geometry, several 9-(*ortho*-substituted phenylmethyl)fluoren-9-yltrimethylammonium salts have been prepared in order to investigate the possible effect of the *ortho* substituents on the phenyl ring in terms of mechanism and (or) transition-state structure. An examination of Dreiding models of the *para*-substituted salts, **3**, suggests that there is a possible steric interaction between the *ortho* hydrogens on the phenyl ring and the fluorenyl 1,8 hydrogens. Consequently, replacing the *ortho* hydrogens with bulkier groups should enhance the "steric effect".

In the present study,[4] the rate of reaction of a series of 2-substituted-9-(*ortho*-substituted phenylmethyl)fluoren-9-yltrimethylammonium salts, and their β-d_2 analogues, have been measured in a variety of protic solvents as well as in the aprotic solvent chloroform, and the product composition determined. Also, the effect of externally added trimethylamine and, as well, the effect of the addition of the strong base, sodium ethoxide, on both the rate of reaction and the product ratios have been examined for reaction of the *ortho*-substituted compounds in ethanol. Secondary β-hydrogen–deuterium isotope effects on carbocation formation have been measured and, as well, an estimate of the primary β-hydrogen–deuterium isotope effect for proton loss from the carbocation has been made by determining the product ratios. Activation parameters for the reaction of several 9-(*ortho*-substituted) salts in both absolute ethanol and 2-propanol were also determined.

Results

The compounds investigated in the present study are shown below:



4, $R^1 = R^2 = CH_3$; $R^3 = R^4 = H$
5, $R^1 = R^2 = Cl$; $R^3 = R^4 = H$
6, $R^1 = CH_3$; $R^2 = R^3 = R^4 = H$
7, $R^1 = R^3 = CH_3$; $R^2 = R^4 = H$
8, $R^1 = R^2 = R^3 = CH_3$; $R^4 = H$
9, $R^1 = R^2 = CH_3$; $R^3 = H$; $R^4 = Br$

The observed rate constants for alkene formation, k_1, for reaction of the *ortho*-substituted salts, **4–9**, and their β-dideuterated analogues in absolute ethanol at 57.3°C are shown in Table 1. The secondary β-hydrogen–deuterium isotope effects, k_1^H/k_1^D, as well as the primary β-hydrogen–deuterium isotope effects,[5] k_E^H/k_E^D, determined from the product ratio data, are also given in this table. A comparison of the observed rate constant for alkene formation, k_1, for reaction of the bromine-substituted fluorenyl ring salt, **9**, with that for reaction of **4** at 68.4°C in absolute ethanol, $120 \pm 3.0 \times 10^{-5}$ (s^{-1}) and $109 \pm 0.5 \times 10^{-4}$ (s^{-1}), gives a Hammett ρ value of −2.5 for reaction of the 2,6-diMe substrate in ethanol.

The effect of externally added trimethylamine on the observed rate of alkene formation, k_1, and, as well, on the percent alkene product, was determined for the reaction of the 2-Me, **6**, and 2,4,6-triMe, **8**, salts in ethanol at approximately[6] 57°C, Table 2. The effect of the addition of a strong abstracting base, sodium ethoxide, on the observed rate constant for alkene formation, k_1, and on the percent alkene formed, was investigated for the reaction of the 2,4,6-triMe salt, **8**, in ethanol at the same temperature as used for the trimethylamine experiments, Table 2.

The effect of a change in solvent on the observed rate constant for alkene formation, k_1, the percent alkene, the secondary β-deuterium isotope effect, k_1^H/k_1^D, and the primary β-deuterium isotope effect, k_E^H/k_E^D, for the reaction of the 2-Me, 2,6-diMe, and 2,4,6-triMe salts, **6**, **4**, and **8**, respectively, were examined for reaction in a series of alcohol solvents as well as in two alcohol–water mixtures at 57.3°C, and the results are given in Table 3. The thermodynamic activation parameters were determined for the reaction of the 2-Me (**6**), 2,6-diMe (**4**), and 2,6-diCl (**5**) substrates in absolute ethanol and also for the reaction of the 2,6-diMe salt in 2-propanol. The observed rate constants for alkene formation, k_1, together with the per-

[3]This apparent "anti-Hammond" behavior on E2 transition state geometry can be accounted for by the More O'Ferrall theory (17) and will be discussed in a manuscript currently under preparation.

[4]A preliminary account of some of the studies has been published (31, 32).

[5]The method used for the determination of this effect will be given in the discussion section.

[6]The temperature was not exactly 57.3°C as used in the previous experiments and, hence, the rate constants differ slightly from those shown in Table 1.

cent alkene values determined at three diferent temperatures for reaction of the three substrates, **4**, **5**, and **6**, are given in Table 4 alone with the values for E_A, $\Delta H^{\ddagger}$ (60°C), and $\Delta S^{\ddagger}$ (60°C).

The effect of an aprotic solvent, chloroform, on the observed rate constant for alkene formation, k_1, for reaction of the 2,6-diMe (**4**), 2,4,6-triMe (**8**), and 2-Me (**6**) salts and their β-dideuterated analogues was determined by both the uv (ultraviolet) spectroscopic method, used in all the preceding studies, and a nuclear magnetic resonance procedure (see the experimental section for details). The results are shown in Table 5 along with the secondary β-hydrogen–deuterium isotope effects, k_1^H/k_1^D. In all cases, the alkene was formed in 100 ± 5% yield. The rate constant for the bromine-substituted fluorene ring substituted salt, **9**, of 16.6 ± 0.2 × 10^{-5} (s^{-1}) can be compared with that of 128 ± 3 × 10^{-5} (s^{-1}) for reaction of **4** to give a ρ value for reaction of the 2,6-diMe salt in chloroform of −2.3 at 50°C.

Discussion

*Reaction of 2-substituted-9-(*ortho*-substituted phenylmethyl)-fluorene-9-yltrimethylammonium ions in absolute ethanol at 57.3°C*

In order to investigate the elimination reaction of the *ortho*-substituted quaternary ammonium salts **4–9** with ethoxide they were first dissolved in dry absolute ethanol and a uv spectrum was obtained for each solution. Surprisingly, it was found that the uv spectra of all the substrate solutions changed with time, indicating that reaction was taking place in the *absence* of base. It must be noted that the *para*-substituted analogues **3** (with hydrogens at the *ortho* positions) were completely stable in ethanol in the absence of ethoxide ion.

The products of the reaction of the *ortho*-substituted salts **4–9** in dry ethanol were found to be the corresponding alkene **10** as well as the ethyl ether, 9-ethoxy-9-(*ortho*-substituted phenylmethyl)fluorene, **11**, eq. [2]. The rate of reaction of the

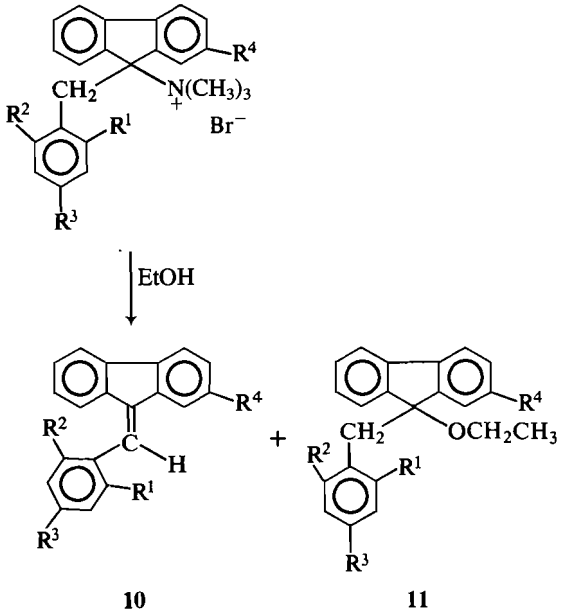
ortho-substituted salts in ethanol was determined by measuring the formation of the alkene product at 320 nm since the uv spectrum of the ether does not show any absorption at this wavelength. The percent alkene formed in the reaction was calculated from the absorbance reading at infinite time (see the experimental section for details).

[2]



10 **11**

A consideration of the data in Table 1 indicates that the mono-*ortho*-substituted substrates react in ethanol to give a greater amount of alkene product, as compared with the reaction of the di-*ortho*-substituted salts; i.e., reaction of the undeuterated 2-Me and 2,4-diMe compounds give 55 and 57% alkene, respectively, while reaction of the 2,6-diMe salt gives approximately 28% alkene.

It can also be seen that the rate of reaction of the mono-*ortho*-substituted compounds is considerably slower than the rate of reaction of the di-*ortho*-substituted substrates. The observed rate constants for alkene formation, k_1, for reaction of the undeuterated 2-Me and 2,4-diMe salts in ethanol at 57.3°C are 2.35 and 2.85 × 10^{-5} (s^{-1}), respectively, while the corresponding rate constants for reaction of the 2,6-diCl, 2,6-diMe, and 2,4,6-triMe compounds are 9.59, 294, and 297 × 10^{-5} (s^{-1}), respectively. The compounds with only one *ortho* substituent react at a slower rate but give a greater yield of alkene product.

It is noteworthy that a 4-methyl substituent does not change significantly the observed rate constant for alkene formation, k_1, or the percent alkene, as compared to the reaction of compounds with only *ortho* substituents. The observed rate constants for alkene formation, k_1, together with the percent alkene for reaction of the undeuterated 2-Me and 2,4-diMe substrates are 2.35 × 10^{-5} (s^{-1}) (55%) and 2.85 × 10^{-5} (s^{-1}) (57%), respectively, while the corresponding values for reaction of the 2,6-diMe and 2,4,6-triMe compounds are 294 × 10^{-5} (s^{-1}) (28%) and 297 × 10^{-5} (s^{-1}) (30%), respectively.

The only mechanism that is consistent with the above results for reaction of the *ortho*-substituted salts in ethanol in the absence of a strong abstracting base is the E1 process involving carbocation formation. In principle, the formation of this carbocation can be a reversible process, eq. [3], and conse-

quently the rate of alkene formation and the percent alkene were determined for reaction of both the 2-Me and 2,4,6-triMe substrates in absolute ethanol, both in the absence and presence of added trimethylamine, Table 2.

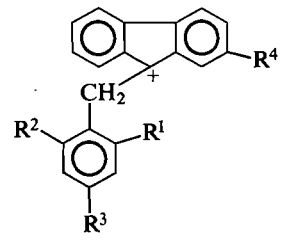
The results in Table 2 indicate that the rate of alkene formation, k_1, and the amount of alkene formed do not change for reaction of either the 2-Me or the 2,4,6-triMe compounds in ethanol when trimethylamine is added. Hence the formation of the carbocation in the system under study is irreversible, i.e. $k_2 >> k_1$ eq. [3].

The proton removal step to give the alkene product, k_E in eq. [4], was investigated for the reaction of the 2,4,6-triMe salt

[4] *ortho*-Substituted salts $\xrightarrow{k_1\ (\text{slow})}$ carbocation $\xrightarrow{k_E}$ alkene; carbocation $\xrightarrow{k_S}$ ether

when the strong base, sodium ethoxide, was added to the reaction solution, Table 2. It is seen that the observed rate constant for alkene formation, k_1, and the percent alkene were essentially unaffected when the concentration of the added ethoxide ion was either a factor of two or ten times as great as the substrate concentration. The loss of the proton from the carbocation must, therefore, not be rate determining, i.e. $k_1 \ll (k_E + k_S)$. Furthermore, the failure of the addition of ethoxide to change the alkene : ether ratio suggests that the solvent ethanol, and not ethoxide, is involved in the removal of the proton to give the alkene in the k_E step, as it is unlikely that ethoxide ion would affect the rate of alkene and ether formation in an identical fashion. The failure of ethoxide to affect the reaction can possibly be due to electrostatic control of the approach of $^-$OEt to a non-reacting site of the substrate, which leaves the β-proton and α-carbon open to attack by solvent.

The rate-determining formation of the 9-fluorenyl carbocation **12** is consistent with the observation of a Hammett ρ of −2.5, calculated from the k_1 values determined for the reaction of the 2,6-diMe salt **4** and the 2,6-diMe salt with a 2-bromo substituent on the 9-fluorenyl ring, **9**. Several groups of workers have prepared the 9-substituted 9-fluorenyl carbocations by reaction of the corresponding alcohol in acid media for spectroscopic (33, 34) and kinetic studies (35). As well, in spite of their "antiaromaticity", the 9-fluorenyl and the 9-methyl-9-fluorenyl carbocations have been proposed as intermediates in the solvolytic reaction of the 9-chloro (36) and 9-(3,5-dinitrobenzoate) (37) derivatives, respectively.



12

Reaction proceeding via the E1 mechanism where formation of the carbocation is rate determining, eq. [4], should give rise mainly to a secondary β-deuterium kinetic isotope effect (38) since rupture of the β-hydrogen bond occurs in a subsequent fast step. Applying the steady-state treatment to the reaction scheme

shown in eq. [4] leads to the expression for the rate of formation of the alkene product,

$$\frac{\mathrm{d[alkene]}}{\mathrm{d}t} = \left(\frac{k_1 k_E}{k_E + k_S}\right) A$$

where A represents the substrate concentration.

Setting E and S as the concentration of the alkene and ether products, respectively, it follows that the quaternary ammonium salt concentration, A, at a time T is given by

$$A_T = E_\infty - E_T + S_\infty - S_T$$

and since $k_E/k_S = E/S$ then

$$A_T = E_\infty - E_T + E_\infty\left(\frac{k_S}{k_E}\right) - E_T\left(\frac{k_S}{k_E}\right)$$

which becomes

$$A_T = (E_\infty - E_T)\left(\frac{k_E + k_S}{k_E}\right)$$

therefore

$$\frac{\mathrm{d}E}{\mathrm{d}T} = \frac{k_1 k_E}{(k_E + k_S)}\left(\frac{k_E + k_S}{k_E}\right)(E_\infty - E_T)$$

which reduces to

$$\frac{\mathrm{d}E}{E_\infty - E_T} = k_1 \mathrm{d}T$$

which integrates to $-\ln(E_\infty - E_T) = k_1 T + \text{constant}$. Since the alkene is the only absorbing species, then $\mathrm{OD}_\infty = \epsilon_E E l$ (OD is optical density), and the equation can be rewritten as

$$-\ln(\mathrm{OD}_\infty - \mathrm{OD}_E) = k_1 T + \text{constant}$$

Consequently the observed rate constant for alkene formation is, in fact, k_1 and the secondary β-deuterium isotope effect for carbocation formation is given by k_1^H/k_1^D.

The primary β-hydrogen–deuterium isotope effect for proton loss from the carbocation to give the alkene, k_E^H/k_E^D, can be determined from the product ratios. since

$$\frac{k_E^H}{k_S^H} = \frac{E^H}{S^H}$$

and

$$\frac{k_E^D}{k_S^D} = \frac{E^D}{S^D}$$

then

$$\frac{k_E^H}{k_E^D} = \frac{(\%E/\%S)_H}{(\%E/\%S)_D}$$

if the valid assumption is made that $k_S^H = k_S^D$.

It is seen that k_1^H/k_1^D varies between 1.16 ± 0.01 and 1.62 ± 0.03, while values for k_E^H/k_E^D vary between 1.6 ± 0.2 and 4.9 ± 2.0. In all cases the amount of alkene formed was decreased as a result of deuterium substitution at C_β; i.e. percent alkene was 55 ± 1.0 and 43 ± 1.0 for reaction of the 2-Me salt and its 2,2-d_2 analogue, respectively, while reaction of the 2,6-diMe compound and its 2,2-d_2 analogue led to values of percent alkene of 28 ± 1.0 and 11 ± 2.0, respectively. It is apparent, therefore, that a primary hydrogen–deuterium isotope effect is operative in the fast proton removal step. The values for the secondary β-deuterium isotope effects are consistent with literature values (38) for reactions proceeding by way of a slow rate-determining step involving carbocation formation, while the primary effects are reasonable in terms of the proposed mechanism where proton loss occurs in a fast step.

It appears from the data in Table 1 that the k_1^H/k_1^D values are significantly lower when the substrate has only one *ortho* substituent as compared to two, i.e. k_1^H/k_1^D = 1.22 ± 0.05 and 1.62 ± 0.03 found for reaction of the 2-Me and 2,6-diMe salts, respectively. As well, the magnitude of the primary β-hydrogen–deuterium isotope effect also is lower when the reactant has only one *ortho* substituent as compared to two, i.e. k_E^H/k_E^D = 1.6 ± 0.2 and 3.1 ± 1.0 found for reaction of the 2-Me and 2,6-diMe substrates, respectively. Although a comparison of the primary isotope effects, which are similar within experimental error, is difficult due to the error involved in the determination of the % alkene when elimination is a minor process, it may be concluded that the increase in the magnitude of the secondary β-deuterium effect is due to an increase in carbocation character at the transition state.

Secondary β-deuterium isotope effects of approximately 1.3 (for two hydrogens (deuteriums)) found in the present study are in accord with literature values found for other solvolytic reactions leading to carbocation formation (38–41). It is generally considered (38) that secondary β-deuterium isotope effects arise due to hyperconjugative assistance by the β-hydrogens to the formation of the carbocation. The magnitude of this isotope effect, in the absence of competing reactions, participation, ion-pairing, etc., depends on the ability of the β-CH(D) bond to overlap with the developing vacant orbital of an incipient carbocation at C_α. When they are orthogonal, a kinetic isotope effect of unity is expected (42, 43). Consequently, for the reaction under study where a normal secondary β-deuterium isotope effect is found, it appears that rotation is sufficiently free about the C_α—C_β bond to allow the required overlap.

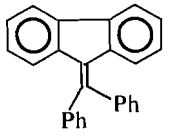
As indicated earlier in the discussion section, the salts with only one *ortho* substituent react at a slower rate in ethanol but give a greater yield of elimination product, as compared to the reaction of the *ortho*-disubstituted compounds. As well, it was noted that a *para* substituent had a negligible effect on the solvolytic process, indicating the absence of a significant polar effect due to the alkyl groups. It appears, therefore, that the reaction of the ammonium salts in ethanol in the present investigation is promoted by "steric acceleration" due to the bulky trimethylammonium group (14, 44), leading to the favourable conversion of a tetrahedral carbon to a less crowded trigonal carbon. Dreiding stereomodels indicate considerable interaction between the *ortho* substituents and the 1,8 hydrogens on the fluorene ring as well as with the onium group. This supports the observation, Table 1, that the 2,6-diCl salt is less reactive than the 2,6-diMe compound but more reactive than the 2,4-diMe substrate since chlorine is "smaller" than methyl (Taft E_S steric substituent scale).

The accelerating effect of the relief of steric strain has been investigated by a series of workers for a variety of reactions (45–49). To our knowledge, however, the accelerating effect observed in the present study is only the second example (14) where a trialkylammonium salt (poor leaving group) undergoes solvolysis to give an alkene in an E1 process.

The observed variation of the alkene:ether ratio (% alkene) with the number of *ortho* substituents indicates that the alkene forming step (k_E) becomes less favourable relative to the competing ether forming step (k_S) for reaction of the di-*ortho*-

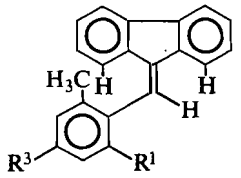
substituted compounds as compared to the reaction of the mono-*ortho*-substituted substrates. It is generally considered that, for reactions proceeding by way of a carbocation intermediate, the most important factor that determines the relative amount of elimination and substitution products is the stability of the alkene. The more stable the alkene the greater the amount of alkene product relative to the substitution product.

Extensive studies have been carried out on both the static and dynamic stereochemistry of "crowded" ethylenes (50–55) and it is now clear that bulky groups attached to the ethylenic carbons can lead to a twisting about the ethylene bond. Furthermore, it has been concluded (56, 57) that both 1,1-diphenylethylene and 9-diphenylmethylenefluorene **13**, which is related to the alkenes



13

formed in the present study, have a phenyl group twisted out of the plane of the molecule due to steric interactions between the groups attached to the double bond. This is illustrated in **14** for the alkenes formed in the present study where the *ortho* methyl group "interacts" with the 1,8 hydrogens of the fluorene nucleus. The addition of a second *ortho* group to **14** (R^1 = CH_3) will lead to a further decrease in the planarity of the alkene, leading to decreased stability and hence a decrease in the percent alkene formed as observed.



14

The proposal that the interaction between the *ortho* methyl groups with the 1,8 hydrogens on the fluorene nucleus leads to a decrease in the stability of the alkene receives support from uv spectroscopic data (see the experimental section). The λ_{max} values for the solutions of the *ortho*-substituted alkenes (obtained from compounds **4**–**9**) are the same within experimental error but are significantly lower[7] than those of the corresponding *para*-substituted alkenes where the *ortho* groups are hydrogens. The twisting of the aryl groups out of the plane of the double bond and the fluorenyl ring will lead to a decrease in the extent of conjugation and hence to higher energy electronic transitions. Such steric inhibition to effective conjugation has been observed in other systems (59, 60), where it was found that the conjugated 1,3 diene **15** did not have a uv maximum down to 200 nm whereas the structurally related conjugated diene **16** exhibited a more normal uv maximum at 232 nm.

16

[7]P. J. Smith, D. S. K. Tsui, and G. S. Dyson. Unpublished results.

An alternative explanation for the changes in alkene:ether ratios effected by *ortho* substitution can be considered since it has been proposed that reaction to give the carbocation is induced by significant steric interactions in the substrate. The solvated carbocation can be neutralized by either proton loss from C_β with solvent acting as the base or by direct substitution of solvent to give the ether. Steric access of solvent to the carbocationic centre and the β-hydrogen could play a role in determining the relative amounts of the two products. This possibility will be discussed in the following section where the effect of solvent changes on both the rate of alkene formation and on product ratios is considered.

*Reaction of 9-(*ortho*-substituted phenylmethyl)fluoren-9-yltrimethylammonium ions in various solvents at 57.3°C*

A test for the carbocation mechanism proposed for the reaction of the *ortho*-substituted salts in ethanol, eq. [4], is determination of the effect of a change in the reaction medium on both reaction rate and product composition. Accordingly, the k_1 values for alkene formation as well as the percent alkene were determined for the reaction of three representative compounds, 2-Me, 2,6-diMe, and 2,4,6-triMe salts, in a variety of solvents, Table 3. The hydrogen–deuterium isotope effects, k_1^H/k_1^D and k_E^H/k_E^D, are also included.

It is seen that for reaction of all three substrates the amount of elimination product, % alkene, varies significantly when the alcohol solvent is changed; i.e. the percent alkene formed for reaction of the 2,6-diMe salt in ethanol, 2-propanol, and *tert*-butyl alcohol was 28, 52, and 100, respectively, while reaction of the 2-Me compound gave 43, 55, and 100% alkene for reaction in methanol, ethanol and *tert*-butyl alcohol, respectively. For reaction in all of the solvents studied, with the exception of the *tert*-butyl alcohol solvent where all the compounds gave exclusively the alkene product, the mono-*ortho* salt gave a greater percentage of alkene than the di-*ortho*-substituted compounds, in agreement with the results obtained for reactions in ethanol.

The increase in the amount of alkene formed when the solvent is varied from methanol to ethanol, 2-propanol, and *tert*-butyl alcohol can be attributed to an increase in the rate of proton abstraction as compared to the direct attack of solvent at the carbocationic centre. As the "size" of the alcohol molecule increases (primary < secondary < tertiary), the transition state for reaction proceeding to the ether products becomes more sterically crowded and, hence, of higher energy. This leads to a decrease in the amount of substitution relative to elimination.

Brown and Fletcher (61) were the first to suggest that steric effects are mainly responsible for the increase in olefin yields in reactions proceeding by way of a carbocation intermediate. They considered that since the trigonal carbocation is less strained than both the tetrahedral reactant and substitution product, an increase in the size of the groups attached to the reaction centre carbon would lower the rate of the substitution reaction relative to the elimination process.

With the *exception* of the results obtained for reaction in *tert*-butyl alcohol, the k_1 values for the reaction of the three compounds (**4**, **6**, and **8**) increased when the polarity of the alcohol solvent (as given by both *Y* and *Z* values) decreased. The k_1 values for reaction of the 2,6-diMe salt in 95% ethanol, ethanol, and 2-propanol were 212×10^{-5}, 294×10^{-5}, and 337×10^{-5} (s^{-1}), respectively. Similarly, the 2,4,6-triMe compound produced the alkene with rate constants of 245×10^{-5} and 297×10^{-5} (s^{-1}) for reaction in methanol and ethanol,

respectively. A study of the reaction of the 2-Me salt in 70% ethanol, 95% ethanol, methanol, and ethanol gave rate constants of 0.93×10^{-5}, 1.58×10^{-5}, 2.18×10^{-5}, and 2.35×10^{-5} (s^{-1}), respectively.

The observed trends in rate constants when the solvent is changed from methanol to the aqueous ethanol solutions, ethanol, and 2-propanol are predictable since the charged substrates, which will be solvated in the polar media, react via a transition state where there is charge dispersal. Consequently, reaction of a charged substrate proceeding via the rate-determining formation of a carbocation will proceed at a faster rate in a less polar solvent.

It was anticipated that the reaction of both the 2-Me and 2,6-diMe salts would proceed at the greatest rate in *t*-BuOH, the least polar solvent studied. However, the k_1 values were found to be the lowest in this solvent for reaction of both the 2-Me and 2,6-diMe compounds, Table 3. This unexpected effect of *tert*-butyl alcohol on the rate of reaction can perhaps be attributed to solvation effects. It has been suggested (8) that direct solvation of the positive nitrogen of the trimethylammonium group is unlikely, and that the interactions occur between solvent and the C—H dipoles induced by the positive nitogen. While *t*-BuOH and the other alcohol solvents can participate in this solvation, perhaps *t*-BuOH is less able to solvate the carbocationic intermediate for steric reasons.

In order to gain additional information concerning the reaction of the *ortho*-substituted salts, the thermodynamic activation parameters were determined for the reaction of the 2-Me, 2,6-diCl, and 2,6-diMe compounds in ethanol and also for the reaction of the 2,6-diMe substrate in 2-propanol. The appropriate rate constants and the percent alkene determined for reaction at three different temperatures along with values for E_A, $\Delta H^{\ddagger}$(60°C), and $\Delta S^{\ddagger}$(60°C) are given in Table 4. The Arrhenius plots all gave correlation coefficients better than 0.99.

The data in Table 4 indicate that the magnitude of $\Delta H^{\ddagger}$ decreases when a second *ortho* substituent is placed on the phenyl ring; $\Delta H^{\ddagger}$(60°C) = 36.2 and 29.6 kcal mol^{-1} for reaction of the 2-Me and 2,6-diMe substrates, respectively. As well, it is seen that the reaction of the 2,6-diMe salt (a charged substrate) has a lower enthalpy of activation when carried out in a solvent of decreased polarity; $\Delta H^{\ddagger}$(60°C) = 29.6 and 27.7 kcal mol^{-1} for reaction in absolute ethanol and 2-propanol, respectively. These results are consistent with the suggestion of steric acceleration promoting the ionization process via a charge-dispersed transition state.

The positive values for $\Delta S^{\ddagger}$ found for the reactions is consistent with reduced solvation at the transition state as compared with the initial state. A trend in $\Delta S^{\ddagger}$ is noted when the substrate is changed from 2-Me to 2,6-diCl to the 2,6-diMe compound for reaction in ethanol; $\Delta S^{\ddagger}$(60°C) = 29.9, 26.2, and 19.4 cal K^{-1} mol^{-1}, respectively. It may be concluded that reaction of the di-*ortho*-substituted compounds in ethanol are less entropically favoured due to decreased solvation of the ammonium ion for steric reasons. The change in the value $\Delta S^{\ddagger}$ when the solvent for the reaction of the 2,6-diMe compound is changed from ethanol to 2-propanol can be rationalized similarly, since 2-propanol will solvate the onium group to a lesser extent ($\Delta S^{\ddagger}$(60°C) = 13.7 and 19.4 cal K^{-1} mol^{-1} for the reaction of the 2,6-diMe salt in 2-propanol and ethanol, respectively).

The observed isotope effects, k_1^H/k_1^D, for reaction of the 2-Me, 2,6-diMe, and 2,4,6-triMe salts in the various solvents fall in the range between 1.1 and 1.7, Table 3. These values are consistent with the expected values for a secondary β-deuterium isotope effect associated with rate-determining carbocation formation. There does not appear to be a trend in the magnitude of these isotope effects for reaction of the three salts when the solvent is varied. The values for k_E^H/k_E^D lie in the range between 1.2 and 5.1. The error involved in the determination of these values does not allow a detailed discussion on the observed variations when the three substrates are reacted in the different solvents. It has been pointed out (62) that α- and β-deuterium effects in solvolytic reactions generally do not strongly depend on solvent changes.

As noted earlier, reaction of both the 2-Me and 2,6-diMe compounds in *tert*-butyl alcohol gave the alkene product in 100% yield. Consequently the values of k_1^H/k_1^D (the secondary β-deuterium isotope effect for slow rate-determining carbocation formation) of 1.24 and 1.57, for reaction of the 2-Me and 2,6-diMe compounds, appear to be significantly different. The difference between these two values indicates that the respective transition states for carbocation formation differ in the extent of positive charge developed at the 9-fluorenyl carbon and (or) that the extent to which the β-hydrogens can stabilize the developing charge by hyperconjugation is different (presumably for steric reasons).

*Reaction of 2-substituted-9-(*ortho*-substituted phenylmethyl)-fluoren-9-yltrimethylammonium ions in the aprotic solvent chloroform*

In order to further investigate the solvolytic reaction of the *ortho*-substituted compounds, it was decided to measure the rate of alkene formation for reaction of several substrates in the nonpolar aprotic solvent chlorform. It was reasoned that reaction in this nonpolar solvent would be favourable due to charge dispersal at the transition state for carbocation formation. Furthermore, reaction cannot proceed with solvent acting as either the base or nucleophile, and only the counterion, bromide, is capable of abstracting the β-hydrogen.

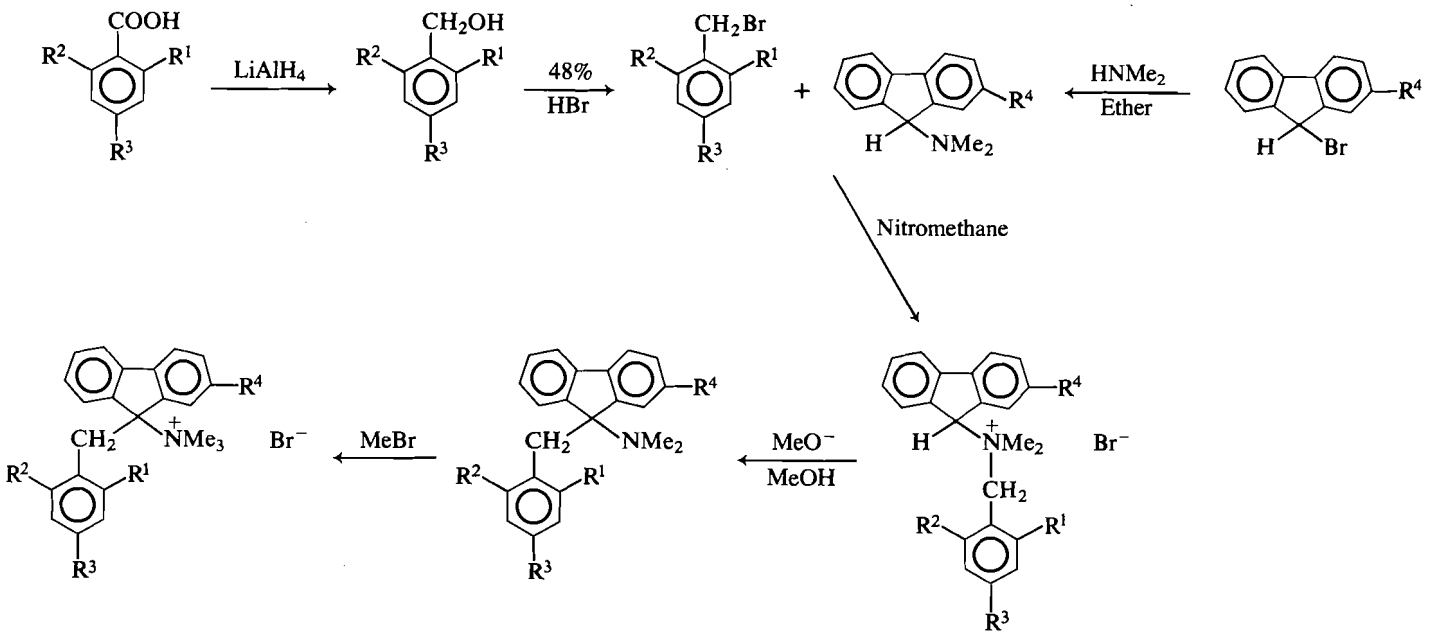
The rate of alkene formation, k_1, for reaction of the 2-Me, 2,6-diMe, and 2,4,6-triMe compounds was determined at 50°C in chloroform, Table 5, as well as the secondary β-deuterium isotope effects, k_1^H/k_1^D. In all cases the alkene was formed in 100 ± 5% yield. The present results are in contrast to earlier studies (63)[8] on the reaction of quaternary ammonium salts in chloroform, where substitution products were formed exclusively.

Reaction of the three salts in chloroform appears also, as in the other solvents, to proceed via the E1 mechanism. The observed ρ value of −2.3 and values of k_1^H/k_1^D = 1.47–1.88, which are unlikely to be primary effects, are consistent with reaction proceeding via a carbocation intermediate.

The variation in the k_1 values with changes in the *ortho* substituents follows the same trend for reactions of the salts in chloroform as in the other solvents. The observed rate constants for reaction of the di-*ortho*-substituted salts, 2,6-diMe and 2,4,6-triMe, at 50°C are 88.9×10^{-5} and 108×10^{-5} (s^{-1}), respectively, while the rate constant for reaction of the mono-*ortho*-substituted compound, 2-Me, is 0.76×10^{-5} (s^{-1}). Presumably, reaction in chloroform, as in the other solvents, is promoted by steric relief.

Reaction of the *ortho*-substituted salts in chloroform appears to be similar to that in the poorly solvating *tert*-butyl alcohol

[8]K. C. Westaway and H. Joly. Private communication.



SCHEME 1. Synthetic route to 9-(*ortho*-substituted phenylmethyl)fluoren-9-yltrimethylammonium bromides.

solvent. This is reasonable since the onium group of the reactant and the developing carbocationic centre will be very poorly solvated in both solvents. Perhaps in chloroform the quaternary ammonium halides exist to a significant extent as ion pairs.

Experimental

Melting points are uncorrected. The ^1H nmr spectra were determined on a Varian T60 spectrometer. Mass spectra were obtained on an AEI M-12 mass spectrometer. Elemental analyses were carried out by the Guelph Chemical Laboratories, Guelph, Ontario, Canada. All reagents and solvents were reagent grade and were dried and purified by the usual procedures.

The synthetic pathways for most of the compounds in this study were similar and are outlined in Scheme 1. The deuterated substrates were all better than 95% deuterated since nmr and mass spectrometric analyses indicate complete deuteration.

Benzyl alcohols which were not commercially available and the α,α-dideuterated analogues of the benzyl alcohols were prepared by reduction of the corresponding benzoic acid or the methyl ester (65, 66).

2,6-Dimethylbenzyl alcohol

A solution of 2,6-dimethylbenzoic acid (80 g, 0.53 mol) in 500 mL of anhydrous diethyl ether was added to a slurry of $LiAlH_4$ (30 g, 0.79 mol) in 350 mL ether. After refluxing for 108 h the excess lithium aluminum hydride was destroyed using 30 mL water and 150 mL 10% sulphuric acid. The organic layer was separated and the aqueous layer washed three times with ether. The combined organic extracts were dried and evaporated to give 2,6-dimethylbenzyl alcohol, which was recrystallized from absolute ethanol; 77% yield, mp 80.5–81°C (lit. (67) mp 81–82°C).

2,6-Dimethylbenzyl bromide

2,6-Dimethylbenzyl alcohol (27.2 g, 0.2 mol) was refluxed with 48% HBr (105 g, 1.3 mol) for 5 h (58). After work-up, 35.9 g (0.18 mol) of 2,6-dimethylbenzyl bromide was obtained (90% yield). Since the nmr mass spectra showed no impurities and because of the extreme lachrymatory nature of the compound, it was used without further purification.

9-Fluorenyldimethylamine

Anhydrous dimethylamine gas was passed into an ice-cold solution of 49.4 g (0.2 mol) of 9-bromofluorene dissolved in 500 mL of anhydrous diethyl ether for 0.5 h. This mixture was stirred for a further 2 h and the resulting white precipitate was filtered off. The solvent was removed from the yellow filtrate using a rotary evaporator to give a solid, which on crystallization from *n*-hexane afforded pale yellow crystals (35.3 g, 0.17 mol) in 84% yield; mp 47.5–48°C; nmr and mass spectra confirmed the structure.

2,6-Dimethylphenylmethyl-9-fluorenyldimethylammonium bromide

A 10-mL solution of 18.5 g (0.093 mol) of 2,6-dimethylbenzyl bromide in nitromethane was added to a solution of 21 g (0.01 mol) of *N,N*-dimethylfluoren-9-ylamine in 20 mL of nitromethane. This mixture was stirred for 15 h and 200 mL of anhydrous diethyl ether was added to precipitate the salt. The white precipitate was filtered and dried and then recrystallized from ethanol–ether to give 29.3 g (0.072 mol) of pure compound in 78% yield, mp 169–170°C. The melting points of the various analogues of this compound are given in Table 6.

N,N-*Dimethyl-9-(2,6-dimethylphenylmethyl)fluoren-9-ylamine*

2,6-Dimethylphenylmethyl-9-fluorenyldimethylammonium bromide, 22.6 g (0.055 mol), was dissolved in 40 mL of methanol. Freshly cut metallic sodium, 4.6 g (0.2 mol), dissolved in 40 mL of methanol was added to the ammonium salt solution. This reaction mixture was stirred for 10 h at room temperature and then poured into 100 mL of water. This was extracted four times with 50-mL portions of chloroform. The combined organic extracts were dried over anhydrous $MgSO_4$ and rotary evaporated to give the crude amine, 17.2 g (0.053 mol) in 96% yield, mp 105–105.5°C. Repeated crystallization from 95% ethanol gave a pure white compound with satisfactory C, H, N analysis. The nmr and mass spectra confirmed the structure. The other *ortho*-substituted amines were similarly prepared by the Steven's rearrangement and the pertinent data is given in Table 7.

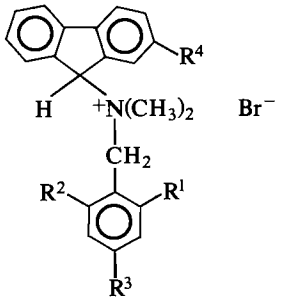
9,(2,6-Dimethylphenylmethyl)fluoren-9-yltrimethylammonium bromide

Pure *N,N*-dimethyl-9-(2,6-dimethylphenylmethyl)fluoren-9-ylamine, 2 g (0.0061 mol), was dissolved in 10 mL of sodium-dried benzene. This was refluxed with 20 mL of bromomethane at 0°C till turbidity was observed. The mixture was maintained at 5°C for a few days and the pure white solid was filtered off using a sintered glass funnel and washed three times with sodium-dried benzene (16% yield). Mass spectra and elemental analysis, Table 8, confirmed the structure.

2,6-Dimethylphenyldibenzofulvene

2,4-Dimethylbenzyltriphenylphosphonium bromide, 9.5 g (0.021 mol), prepared by Wittig's method (64), in 20 mL of dry benzene was

TABLE 6. The melting points of 2-substituted-9-fluorenyl-(*ortho*-substituted)-phenylmethyldimethylammonium bromides



Compound		Melting point (°C)

stirred under nitrogen for 2 h with 3 g of sodium *tert*-butoxide. After the addition of 4 g (0.022 mol) of fluorenone in 50 mL of dry benzene the solution was stirred for another 2 h. The crude alkene obtained after work-up was separated on an alumina column (2 cm × 40 cm) using hexane as a solvent. The product was further purified by recrystallization from 95% ethanol, mp 165–165.5°C. The elemental analysis data for the above alkene and the related dibenzofulvenes are given in Table 9.

Kinetic measurements

The reactions were carried out in cuvettes with gas-tight covers inside a Bausch and Lomb Spectronic 710 instrument. The cuvette holder was linked to an external Haake FS circulator. The temperature of the water in the circulator was maintained at ±0.02°C. The temperature at which kinetic measurements were made was the actual temperature inside the cuvette, measured using a thermocouple attached to a digital thermometer. The fluctuations in the temperature in the cuvette were less than ±0.05°C.

Since the absorbance of the sample under study had to be directly measurable, the concentrations of the quaternary ammonium salt solution had to be appropriately adjusted. A stock solution of the compound under study was made using the dry ethanol (or the other solvents) at room temperature. These solutions were stored in the refrigerator and it was found that, except for the very reactive 2,6-diMe and the 2,4,6-triMe substrates, the storage did not affect the initial absorbance readings over a period of months.

Just before a kinetic run was initiated, the solution of the quaternary salt was brought to room temperature. A small amount was poured into a uv cell that had been rinsed with the solution. The tightly stoppered cuvette was fitted into the cuvette holder of the uv spectrometer and the timer started. A matched reference cell containing only the solvent was used to zero the absorbance before a reading was noted. In most cases the first reading was taken after at least 3 min so that the reaction mixture was in thermal equilibrium with the surroundings. The absorbance values were then taken at the appropriate time intervals. The reactions were generally followed up to 40–80% completion and at least three runs were made for each compound. Since it was not possible to measure more than one kinetic run at a time, the rates of reaction of the hydrogen and the deuterium substrates had to be measured consecutively within the least possible time.

The wavelength of the uv light used was fixed at 320 nm. It was determined that at this wavelength the product of the substitution reaction, the ether, did not have any significant absorption. Therefore, the change in the optical density that was monitored was due only to the increasing concentration of the alkene products.

The infinity readings were obtained by taking 5-mL aliquots of the initial salt solution in 10-mL volumetric flasks and filling to the mark. This was done in triplicate. These flasks were then lowered into an oil bath, which was maintained at the temperature of the reaction, and allowed to stand for at least 8–10 half-lives. These flasks were then withdrawn at different times and allowed to reach room temperature. If any solvent loss had occurred it was made up by addition of the pure solvent to the volumetric flask. A sample of this solution was used to measure the absorbance, which was the value at infinite time. This was repeated with the other two flasks. The infinity reading was taken as the average of the three readings. Using this average value of absorbance at infinite time, $\ln (A_\infty - A_t)$ was plotted versus time to obtain good linear first-order plots. At least three such plots for each compound were obtained. The experimentally obtained data were treated by least-squares analysis to determine the first-order rate constants using a HP 200A computer.

The *ortho*-substituted phenyldibenzofulvene solutions in the various solvents were used to determine values of the extinction coefficients at various wavelengths, Table 10. These extinction coefficients and the absorbance at infinite time were used to calculate the percent alkene formed in the reaction.

Kinetic measurements by nuclear magnetic resonance method

The rates of reaction of the 2-Me, 2,6-diMe, and the 2,4,6-triMe substrates and the β-d_2 analogues of the 2,6-diMe and the 2,4,6-triMe compounds in chloroform at 50°C were determined by following the disappearance of appropriate hydrogen signals using a nmr spectrometer.

A dilute solution of the ammonium salt in $CDCl_3$ was prepared at room temperature and immediately placed in the probe of a Brüker WP-80 spectrometer maintained at 50°C. Several peaks in the spectrum (usually the peaks due to the hydrogen of the $—N^+(CH_3)_3$ and the ring methyl groups) were integrated at suitable times using chloroform as an internal standard. The slope of the plot of log (integral of the appropriate peak) against time was determined by least squares. The rate constants determined by monitoring the disappearance of several different hydrogen signals agreed to within 5% in all cases.

Preparation of deuterium labelled styrenes and divinylbenzenes

NICK HENRY WERSTIUK AND GEORGE TIMMINS
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1
Received October 18, 1985
This paper is dedicated to Professor Arthur N. Bourns

NICK HENRY WERSTIUK and GEORGE TIMMINS. Can. J. Chem. **64**, 1072 (1986).

Specifically deuteriated styrenes (1-*d*, 2,2′-d_2, and ring labelled), perdeuteriostyrene, and specifically deuteriated divinylbenzenes (1,1′-d_2, 2,2,2′,2′-d_4, and ring labelled) have been prepared by transforming suitably labelled phenylacetic (hydride or deuteride reduction and dehydration by solid KOH) and phenylenediacetic acids (esterification, hydride or deuteride reduction, and dehydration by solid KOH), respectively.

NICK HENRY WERSTIUK et GEORGE TIMMINS. Can. J. Chem. **64**, 1072 (1986).

On a préparé des styrènes deutérés d'une façon spécifique (*d*-1, d_2-2,2′ et marqué sur le cycle), du perdeutérostyrène et des divinylbenzènes deutérés d'une façon spécifique (d_2-1,1′,d_4-2,2,2′,2′ et marqué sur le cycle) en transformant respectivement d'acides phénylacétiques (réduction par l'hydrure ou le deutérure et déshydratation par le KOH solide) ou phénylènediacétiques (estérification, réduction par l'hydrure ou le deutérure et déshydratation par le KOH solide) marqués d'une façon appropriée.
[Traduit par la revue]

Introduction

The high temperature – dilute acid (HTDA) method has been used to prepare a wide range of deuteriated and tritiated organic compunds (1–8). In this paper we document its application to the preparation of deuteriated styrenes and divinylbenzenes (DVB's) that were required for solid-state ^{2}Hmr studies of cross-linked styrene polymers (9). Although initial studies established that styrene can be labelled directly at the 2-position under HTDA conditions (*vide infra*), it is not a viable route due to production of dimers and oligomers. Consequently, a general route to the specifically labelled styrenes was developed based on the H–D exchange of phenylacetic acid (PAA). To prepare specifically labelled divinylbenzenes (DVB's), phenylenediacetic acid (PDA) was used as a substrate.

Results and discussion

Attempted direct exchange of styrene and divinylbenzene

When styrene was reacted under HTDA conditions at 165°C, it was found that full equilibration of the C-2 hydrogens with the deuterium pool could be achieved. Unfortunately, although small amounts of styrene-2,2-d_2 (**1***b*) could be isolated by preparative gas chromatography (gc), it appeared that most of the styrene was lost as dimers and oligomers, making this route viable only for preparing **1***b* in relatively small amounts. Treatment of DVB under HTDA conditions resulted in rapid production of polymer, as expected, and this direction was pursued no further.

Preparation of deuteriated styrenes

Since direct deuteriation of styrene and DVB[1] was inefficient, PAA and PDA were selected as precursors. Labelled PAA **1***f* (1.90 excess D per molecule) was prepared from **1***e* by refluxing it twice in 1.3 *M* DCl/D_2O. Reduction of this product by LAH, followed by elimination of water by KOH, gave styrene-1-*d* (**1***a*) that contained 0.75 excess D atoms over natural abundance. The ^{2}Hmr spectrum of **1***a* showed signals at 6.6 and 2.7 ppm (<1%), the latter peak indicating that <0.5% of starting material was present. That **1***a* contined substantially less deuterium than expected (1.90/2), based on the deuterium content of the precursor PPA **1***f*, indicates that D–H exchange

competes with elimination. Nevertheless, back exchange can be minimized by using KOD and the O–D labelled alcohol.

When PAA was heated at 260°C in 0.26 *M* HCl/D_2O and recycled in 0.26 *M* DCl/D_2O, perlabelled acid **1***g* was obtained. Back exchange at the 2-position by KOH/H_2O (11) yielded ring-deuteriated acid **1***h*. LAH reduction, followed by elimination of water, gave **1***c* that contained 4.75 excess D atoms per molecule. The ^{2}Hmr spectrum of **1***c* exhibited a signal at 7.2 ppm and it was ascertained that <5% of starting alcohol was present.

Reduction of perlabelled PAA **1***g* by LAD, followed by elimination of water from **1***l*, yielded **1***d* (7.17 excess D atoms per molecule). It is evident from the ^{2}Hmr spectrum of **1***d* (Fig. 1) that a substantial amount (~25%) of D–H exchange occurred at the 1-position, as was observed in the preparation of **1***a*.

Reduction of PAA by LAD, followed by elimination of water, gave **1***b* (1.99 excess D atoms per molecule). The ^{2}Hmr spectrum of **1***b* exhibited signals at 5.1 and 5.6 ppm and no signals due to starting alcohol.

Preparation of deuteriated divinylbenzenes

Treatment of PDA **2**d with KOH/D_2O at 160°C yielded PDA-1,1,1′,1′-d_4 (**2***e*), and ^{1}Hmr analysis established that

[1]The commercially available material was a mixture of DVB, diethylbenzene, and the half-dehydrogenated compound.

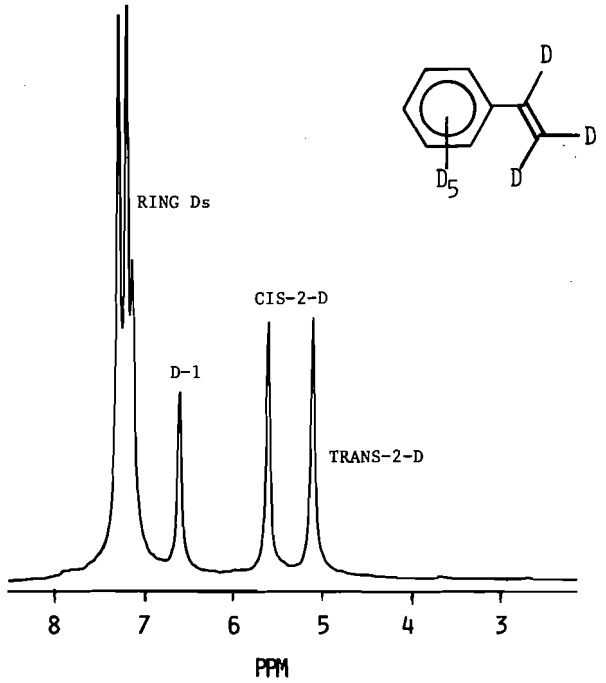

FIG. 1. The ^{2}Hmr (38.4 MHz) spectrum of styrene-d_8 in $CHCl_3$.

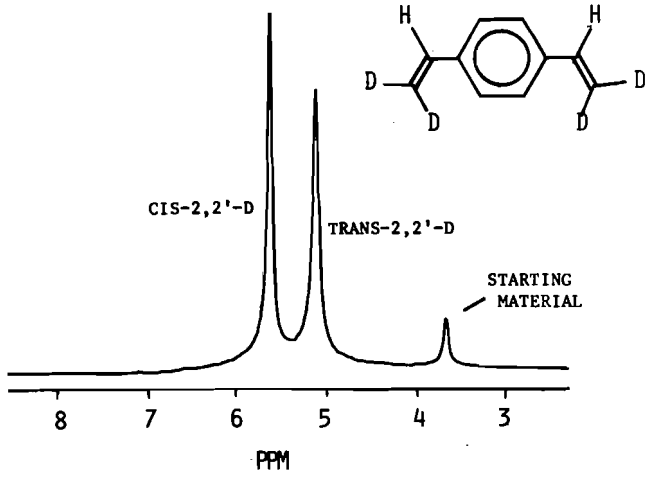

FIG. 2. The ^{2}Hmr (38.4 MHz) spectrum of divinylbenzene-2,2,2′, 2′-d_4 in $CHCl_3$.

exchange was >95% complete. Since direct reduction of the diacid proved to be unsatisfactory, the diethyl ester was prepared and reduced to **2***k* by LAH. KOH-promoted elimination of water from **2***k* gave DVB-1,1′-d_2 (**2***a*) (1.39 excess D per molecule). As observed in the preparation of styrene-1-*d*, **2***k* contained less deuterium (1.39 D) than expected (1.90 D) on the basis of the labelled PDA **2***e* (~3.8 D). As in the case of 2-phenylethanol, D–H exchange competes with elimination of water from **2***k*. The ^{2}Hmr spectrum of **2***a* exhibited signals at 6.6 and 2.8 ppm (6%), the latter establishing that the product contained 3% starting material.

At 260°C in 0.26 *M* DCl/D_2O **2***d* was perlabelled. Following back-exchange in aqueous KOH, the acid was converted, as described above, to DVB **2***c* (3.62 excess D atoms per molecule). The ^{2}Hmr spectrum of **2***c* showed, in addition to an intense signal at 7.4 ppm, weak signals at 7.2 (<5%) and 2.7 (<1%) due to starting material. A weak signal (<1%) at 6.7 indicated that a small amount of deuterium was located at the 1,1′-positions of **2***c*.

DVB-2,2,2′,2′-d_4 (**2***b*) (3.89 excess D atoms per molecule) was prepared by reducing diethyl ester **2***h* by LAD and eliminating water from **2***l* in the usual manner. The ^{2}Hmr spectrum (Fig. 2) of **2***b* indicates (signal at 3.7 ppm) that the product contains approximately 6% of **2***l*. The presence of 3–6% of starting material in the DVB's is due to the fact that it was necessary to carry out the elimination reactions at reduced pressure to minimize polymerization.

Conclusions

This study establishes that phenylacetic acid and phenylenediacetic acid are convenient starting materials for the preparation of specifically deuteriated styrenes and *p*-divinylbenzenes as well as the perlabelled compounds, even though the yields of the dehydration steps are modest as a consequence of the reactivity of the compounds. Although styrene-1,2,2′-d_3 was not prepared, its synthesis from PAA would be a simple matter. It should be possible to prepare a wide range of deuteriated substituted styrenes and the isomeric divinylbenzenes using the methodology documented in this paper. Furthermore, the corresponding tritiated compounds can be prepared using this approach as well.

In conclusion, we wish to comment on the facile elimination of water from the alcohols by solid KOH. Although base-promoted dehydration of alcohols is not discussed in general organic chemistry texts, it appears that it may be a very useful method for dehydrating fairly high-boiling alcohols that have an acidic hydrogen β to the hydroxyl group.

Experimental

Mass spectral deuterium analyses were carried out with a VG Micromass 7070F spectrometer at low ionizing voltage (12–15 eV) to minimize fragmentation. The nmr spectra were obtained on Varian EM-390 and Brüker WM-250 spectrometers; gc analyses were performed on a Tracor Model 560 gas chromatograph with a Varian Model 485 electronic integrator using a 6 ft × 4 mm id 3% OV-1 on 100–120 mesh Supelcoport column. For preparative gc a Varian A-700 gas chromatograph fitted with a 5 ft × 1/4 in. 15% SE-30 on 80–100 mesh Chromosorb W column was used. Ether for the hydride reductions was dried by distillation from LAH.

H–D exchange of styrene

Styrene (0.20 g), decalin (2 mL), and 0.26 *M* DCl/D_2O (5 mL) were sealed under vacuum in a medium-walled glass tube after degassing by three freeze–pump–thaw cycles. The tube was sealed in a Parr high pressure apparatus containing water to equalize pressure, and was heated at 165°C for 12 h. The organic solution was decanted from the frozen aqueous layer and styrene collected by preparative gc (5 ft × 1/4 in. 15% SE-30 on 80–100 mesh Chromosorb W). Mass spectral analysis indicated the incorporation of 1.94 excess D atoms per molecule (0.7% d_0, 4.3% d_1, 95.1% d_2); ^{1}Hmr ($CDCl_3$) showed that the C-2 Hs had been fully exchanged (δ:6.72 (m, H-1), 7.2–7.5 (m, aromatic Hs)). Gas chromatographic analysis indicated the presence of substantial amounts (~35%) of dimeric products; gc analysis of styrene was found to be inconsistent and unreliable, presumably due to reactivity of styrene on the column and injector block.

An attempt to distill styrene from a large-scale reaction (4.2 g styrene) resulted in the collection of no styrene. Using decalin as an internal standard, gc analysis indicated that only ~20% of the styrene was left in the product with dimeric material comprising ~10% more.

Phenylacetic acid-1,1-d_2 (**1***f*)

Phenylacetic acid (12.0 g) was refluxed for 142 h in 2.6 *M* HCl/D_2O (50 mL), the product was extracted with ether (50 mL, 3 × 20 mL), dried over anhydrous Na_2SO_4, and solvent removed on a roto-

evaporator to yield 11.8 g of **1***f* (97%, 1.57 excess D per molecule). This product (11.8 g) was then refluxed with 1.3 *M* DCl/D_2O (50 mL) for 72 h and extracted as above (yield 11.6 g, 98%; 1.90 excess D atoms per molecule).

Phenylethanol-2,2-d_2 (**1**i)

Phenylacetic acid-2,2′-d_2 (11.6 g) in dry ether (100 mL) was slowly added to a magnetically stirred slurry of LAH (3.0 g) in dry ether (100 mL) and refluxed for 2 h. More LAH (0.5 g) was added and reflux continued for 3 h. The reaction was quenched by careful addition of water (75 mL), then was acidified with concentrated HCl until most of the solid dissolved. The aqueous layer was saturated with NaCl and extracted with ether (4 × 40 mL) after removal of the organic layer. The extracts were washed with saturated aqueous $NaHCO_3$, dried over anhydrous Na_2SO_4, and filtered. The ether was removed by distillation through a 25-cm glass helices column and the last traces were removed under rotatory-pump vacuum to yield 9.9 g (95%) of **1***i*.

*Styrene-1-*d (**1**a)

Phenylethanol-2,2-d_2 (9.9 g) was heated with KOH pellets (4.3 g) (10) and styrene was rapidly distilled through a 15-cm Vigreux column into a Dry Ice – acetone cooled flask. Styrene-1-*d* was separated from water and dried over anhydrous Na_2SO_4 (yield 2.9 g, 35%). A considerable amount of polymer was produced. Mass spectral analysis indicated incorporation of 0.75 excess D atoms per molecule (27.5% d_0, 70.2% d_1, and 2.0% d_4 species) and ^{2}Hmr ($CHCl_3$) showed two resonances at 6.6 and 2.7 ppm (<1%). This analysis was confirmed by ^{1}Hmr ($CDCl_3$), δ:5.21 (m, *trans*-H-2), 5.72 (m, *cis*-H-2), 6.69 (q, H-1, po.3H), 7.1–7.5 (m, aromatic Hs).

Phenylacetic acid-d_7 (**1**g)

Phenylacetic acid (13.5 g) was heated at 260°C with 0.26 *M* HCl/D_2O (100 mL) for 72 h in a 600-mL Parr high pressure apparatus containing a glass liner. The product was extracted with ether (100 mL, 4 × 50 mL), the extracts were washed with saturated aqueous NaCl (25 mL), ether was removed on a roto-evaporator, and the remaining solvent was removed under vacuum to yield 11.2 g (83%) of **1***g*. The partially deuterated phenylacetic acid (10.9 g) was reacted with 0.26 *M* DCl/D_2O (100 mL) using the same procedure (yield 9.5 g, 87%). Mass spectral analysis showed the presence of 6.81 excess D atoms per molecule (0.5% d_4, 4.0% d_5, 20.2% d_6, 64.3% d_7, 11.0% d_8). The results indicate that not all of the carboxyl deuterons were exchanged during the work-up procedure.

Phenylacetic acid-d_5 (**1**h)

The deuteriated phenylacetic acid obtained above (9.2 g) was back-exchanged (11) by heating with H_2O (50 mL) and KOH (4.1 g) in a 600-mL Parr high pressure apparatus at 160°C for 24 h. The solution was acidified with concentrated HCl and extracted with ether (100 mL, 4 × 25 mL). The extracts were washed with saturated aqueous NaCl (25 mL), dried over anhydrous Na_2SO_4, decolorized with carbon, and the ether was stripped on a roto-evaporator and pumped off under vacuum to yield 9.0 g (98%) of **1***h*. Mass spectral analysis indicated that 4.9 excess D atoms per molecule remained (1.5% d_3, 16.6% D_4, 72.5% d_5, 7.9% d_6, 1.5% d_7); ^{1}Hmr ($CDCl_3$) confirmed that back exchange was essentially complete (δ:3.62 (2, H-2), 7.3–7.4 (residual aromatic Hs), 11.8 (s, —O—H).

Phenylethanol-d_5 (**1**k)

Phenylacetic acid-d_5 (8.9 g) in dry ether (150 mL) was added slowly to a magnetically stirred suspension of LAH (1.2 g) in dry ether (50 mL) and the mixture was refluxed for 5 h. The reaction was quenched by careful addition of water (75 mL), then acidified with concentrated HCl until the precipitates were disolved. After separation of the ether, the solution was further extracted with ether (5 × 20 mL), and the extracts were dried over anhydrous Na_2SO_4 and decolorized with carbon. The ether was stripped on a roto-evaporator and the remainder was removed under vacuum to yield 6.5 g (81%) of **1***k*; ^{1}Hmr ($CDCl_3$), δ:2.80 (t, H-1), 3.60 (s, —O—H), 3.80 (t, H-2), 7.3 (residual aromatic Hs).

Styurene-d_5 (**1**c)

Phenylethanol-d_5 (5.7 g) was heated with KOH (3.2 g, pellets) and styrene rapidly distilled through a 15-cm Vigreux column into a flask cooled in Dry Ice – acetone. The styrene was separated from water and dried over anhydrous Na_2SO_4 to yield 3.2 g (65%) of **1***c*. Mass spectral analysis indicated the presence of 4.75 excess D atoms per molecule (0.6% d_2, 4.0% d_3, 19.4% d_4, 72.1% d_5, 3.8% d_6, 0.1% d_7); ^{2}Hmr ($CHCl_3$) showed a resonance at 7.2 ppm; ^{1}Hmr ($CDCl_3$), δ:5.21 (d, *trans*-H-2), 5.72 (d, *cis*-H-2), 6.73 (q, H-1), 7.3 (residual aromatic Hs).

Phenylethanol-d_9 (**1**l)

To a slurry of LAD (3.0 g) in dry ether (100 mL) was slowly added perdeuteriated phenylacetic acid (10.2 g) in dry ether (100 mL). After refluxing for 2 h a further portion of LAD (0.5 g) was added and reflux continued for 6 h. After careful quenching of the reaction with wet ether (25 mL) and water (50 mL) and acidification with concentrated HCl, the aqueous layer was saturated with NaCl and extracted with ether (5 × 30 mL). The combined extracts were washed with saturated aqueous $NaHCO_3$ (30 mL), dried over anhydrous Na_2SO_4, decolorized with carbon, filtered, and solvent was removed by distillation through a 15-cm glass helices column. Traces of ether were removed under vacuum to yield 8.3 g (88.5%) of **1***l*.

Styrene-d_8 (**1**d)

Phenylethanol-d_9 from the previous reaction (8.2 g) was heated with KOH (3.7 g) and the styrene was distilled through a 15-cm Vigreux column into a Dry Ice cooled receiver as it was produced. After separation from water, the product was dried over anhydrous Na_2SO_4 and distilled through a 15-cm Vigreux column at reduced pressure (~10 Torr; 1 Torr = 133.3 Pa) to yield 5.4 g (77%) of **1***d*.

Mass spectral analysis indicated the incorporation of 7.17 excess D atoms per molecule (0.5% d_4, 6.0% d_5, 12.6% d_6, 37.0% d_7, 44.0% d_8); ^{2}Hmr ($CHCl_3$) (Fig. 1), δ:5.1 (*trans*-D-2), 5.6 (*cis*-D-2) 6.6 (D-1) 7.1–7.4 (aromatic Ds). Electronic integration established the following deuterium distribution; 1.88 D at C-2, 0.73 D at C-1, and 4.56 D in the aromatic ring.

Phenylethanol-2,3-d_2 (**1**j)

Phenylacetic acid (5.0 g) in dry ether (100 mL) was slowly added to a magnetically stirred slurry of LAD in dry ether (100 mL) and the mixture was refluxed for 4 h. The reaction mixture was carefully quenched with water, then acidified with concentrated HCl until precipitates were dissolved. The ether layer was separated, and the aqueous layer was saturated with NaCl and extracted with ether (4 × 15 mL). The combined extracts were dried over anhydrous Na_2SO_4, ether was stripped on a roto-evaporator, and the last traces were removed under vacuum to yield 4.2 g (95%) of **1***j*; ^{1}Hmr (CCl_4), δ:2.69 (s, H-1) 4.15 (s, —O—H), 7.0–7.3 (m, aromatic H5).

Styrene-2,2-d_2 (**1**b)

Phenylethanol-2,2-d_2 (3.6 g) was heated with KOH (2.0 g, pellets) and the styrene rapidly distilled through a 15-cm Vigreux column into a Dry Ice – acetone cooled receiver. The styrene was separated from water and dried over anhydrous Na_2SO_4 to yield 2.6 g (84%) of **1***b*. Mass spectral analysis indicated that 1.99 excess D atoms per molecule (2.5% d_1, 96.0% d_2, 1.5% d_3) were incorporated in the styrene; ^{2}Hmr, δ:5.1 (*trans*-D-2), 5.6 (*cis*-D-2).

Attempted H–D exchange of divinylbenzene

Divinylbenzene (0.20 g), decalin (2 mL), and 0.26 *M* DCl/D_2O (5 mL) in a medium-walled glass tube were degassed via three freeze–pump–thaw cycles and the tube was sealed under vacuum. Reaction was carried out at 160°C for 19 h in a Parr high pressure apparatus containing water to equalize pressure. A solid mass of polymer was formed and this deuteration approach was abandoned.

Phenylenediacetic acid-2,2,2′,2′-d_4 (**2**e)

The potassium salt of phenylenediacetic acid (9.6 g) was prepared by reaction with KOH (3.0 g) in water (20 mL). Water was removed with heating on a roto-evaporator and the salt was reacted with D_2O (50 mL)

and KOH (1.0 g) in a 600-ML Parr high pressure apparatus with a glass liner at 160°C for 28 h. The solution was acidified with concentrated HCl and the solid removed by filtration to yield 9.3 g (95%) of **1***e*; ^{1}Hmr (DMSO-d_6), δ:7.25 (s, aromatic Hs), 11.8 (s, —O—H), 3.53 (residual H-2).

Phenylenediacetic acid diethyl ester-2,2,2′,2′-d_4 *(2*i*)*

Phenylenediacetic acid **2***e* (8.9 g) was refluxed with absolute ethanol (38 mL), benzene (63 mL), and concentrated H_2SO_4(10 mL) with magnetic stirring in a Dean–Stark apparatus. After 12 h reaction, saturated aqueous NaCl (75 mL) was added and the mixture extracted with ether (50 mL, 3 × 20 mL). the combined extracts were washed with saturated aqueous $NaHCO_3$ (2 × 10 mL), dried over anhydrous Na_2SO_4, decolorized with carbon, and the ether was removed on a roto-evaporator, then with heating under vacuum. Removal of all the ethanol was difficult, to yield 9.6 g (84%) of **2***i*; ^{1}Hmr (CCl_4), δ:1.18 (t, CH_3), 4.07 (q, ethyl CH_2), 7.20 (s, aromatic Hs), 3.47 (residual 2,2′ Hs).

Benzenediethanol-2,2,2′,2′-d_4 *(2*k*)*

Phenylenediacetic acid diethyl ester (9.2 g) from the above reaction in dry ether (100 mL) was slowly added to a magnetically stirred suspension of LAH (1.9 g) in dry ether (50 mL). After a 6-h reflux, the reaction mixture was quenched by careful addition of water (50 mL) and acidified with concentrated HCl to dissolve the precipitate. Extraction with ether (9 × 50 mL) yielded 5.1 g (83%) of **2***k*; ^{1}Hmr (CDCl), δ:1.87 (s, —O—H), 2.82 (m, 1,1′ Hs), 3.97 (s, residual 2,2′ Hs), 7.20 (s, aromatic Hs).

Divinylbenzene-1,1′-d_2 *(2*a*)*

Benzenediethanol **2***k* (4.9 g) was heated rapidly with KOH pellets (2.5 g) and divinylbenzene (2.3 g, 62%) was quickly distilled through a 15-cm Vigreux column at ~60 Torr. Mass spectral analysis indicated the presence of 1.39 excess D atoms per molecule (11.6% d_0, 41.2% d_1, 45.0% d_2, 1.4% d_3, 0.9% d_4); ^{2}Hmr ($CHCl_3$), δ:6.6 (D-1), 2.8 (6%) (2,2,2′,2′-Ds) of **2***k*; ^{1}Hmr (CCl_4), δ:5.17 (m, *trans*-2,2′ Hs), 5.63 (m, *cis*-2,2′ Hs), 6.63 (residual 1,1′ Hs, 0.64H), 7.30 (s, aromatic Hs).

Phenylenediacetic acid-d_8 *(2*f*)*

Phenylenediacetic acid (10.0 g) was reacted with 0.26 *M* DCl/D_2O (100 mL) in a 600-mL Parr high pressure apparatus fitted with a glass liner at 260°C for 88 h. The solid was filtered off, washed with water (2 × 15 mL), and dried to yield 9.35 g (89.9%) of **2***f*. Mass spectral analysis disclosed the presence of 8.29 excess D atoms per molecule (0.9% d_5, 4.5% d_6, 16.2% d_7, 34.3% d_8, 31.2% d_9, 12.8% d_{10}); apparently not all of the carboxyl deuterons were washed out during isolation.

Phenylenediacetic acid-d_4 *(2*g*)*

Phenylenediacetic acid **2***f* (7.9 g) was reacted with KOH (5.0 g) in water (50 mL) to form the salt, and the water was removed on a roto-evaporator with heating and then with heating under vacuum. The salt was reacted in a glass-lined 600-mL Parr high pressure apparatus with KOH (1.0 g) and water (50 mL) at 160°C for 24 h. The reaction mixture was acidified, the precipitate filtered off, washed with water (4 × 15 mL), and dried by heating under vacuum to yield 7.4 g (96%) of **2***g*; ^{1}Hmr (DMSO-d_6), δ:3.56 (s, H-2,2′), 7.24 (s, residual aromatic Hs), 11.7 (s, —O—H).

Phenylenediacetic acid diethyl ester-d_4 *(2*j*)*

Phenylenediacetic acid **2***g* (7.2 g) was refluxed with magnetic stirring with absolute ethanol (35 mL), benzene (65 mL), and concentrated H_2SO_4 (12 mL) in a Dean–Stark apparatus for 18 h. To the reaction mixture was added ether (50 mL) and saturated aqueous NaCl and the organic solution separated. The aqueous layer was further extracted with ether (5 × 30 mL) and the combined extracts were washed with saturated aqueous $NaHCO_3$ (2 × 20 mL) and saturated aqueous NaCl (20 mL). After drying over anhydrous Na_2SO_4 and decolorizing with carbon, ether was stripped on a roto-evaporator, then with heating under vacuum, to yield 8.3 g (90%) of **2***j*. Mass spectral analysis demonstrated the presence of 3.75 excess D atoms per molecule (3.7% d_2, 23.5% d_3, 66.5% d_4, 5.9% d_5, 0.4% d_6); ^{1}Hmr ($CDCl_3$), δ:1.20 (t, CH_3), 3.60 (s, 2,2′ Hs) 4.18 (q, ethyl CH_2), 7.30 (s, residual aromatic Hs).

Benzenediethanol-d_4 *(2*m*)*

A solution of **2***j* (8.0 g) in dry ether (100 mL) was added slowly to a magnetically stirred suspension of LAH (1.3 g) in dry ether (50 mL) and the mixture refluxed overnight. The reaction was quenched by careful addition of water (50 mL) and then acidified by addition of concentrated HCl to dissolve the precipitate. The organic layer was separated, the aqueous phase extracted with ether (10 × 30 mL), and the combined extracts were washed with saturated aqueous NaCl (20 mL), dried over anhydrous Na_2SO_4, and decolorized with carbon. Ether was stripped on a roto-evaporator, then under vacuum, to yield 5.2 g (97%) of **2***m*; ^{1}Hmr ($CDCl_3$) δ:1.89 (s, O Hs), 2.81 (dt, 2,2′ Hs), 3.82 (t, 1,1′ Hs), 7.20 (s, residual aromatic Hs).

Divinylbenzene-d_4 *(2*c*)*

Benzenediethanol-d_4 **2***m* (5.0 g) was heated with KOH pellets (2.5 g) and the divinylbenzene (1.0 g, 26%) quickly distilled through a 15-cm Vigreux column at ~60 Torr. In this reaction the divinylbenzene polymerized very rapidly in the reaction flask. Mass spectral analysis indicated 3.62 excess D atoms per molecule (0.5%, d_0, 0.9% d_1, 5.7% d_2, 26.1% d_3, 63.0% d_4, 3.5% d_5, 0.3% d_6). The ^{2}Hmr spectrum showed, in addition to an intense peak at 7.4 ppm, weak signals at 7.2 (<5%) and 2.7 (<1%) due to starting material. A weak signal at 6.7 (<1%) indicated that a small amount of the deuterium was located at the 1,1′-positions of **2***c*. ^{1}Hmr (CCl_4), δ:5.11 (d, *trans*-2,2′ Hs), 5.59 (d, *cis*-2,2′ Hs), 6.66 (q, 1,1′ Hs), 7.30 (s, residual aromatic Hs, 0.35H).

Benezenediethanol-1,1,1′,1′-d_4 *(2*l*)*

The diester of PDA (11.0 g) in dry ether (150 mL) was slowly added to a magnetically stirred suspension of LAD (2.2 g) in dry ether (50 mL). After refluxing for 5 h, the reaction mixture was carefully quenched with water (50 mL) and acidified with concentrated HCl to dissolve the precipitate. After separation of the organic layer, the aqueous solution was extracted with ether (10 × 50 mL), and the combined extracts were washed with saturated aqueous NaCl (20 mL) and dried over anhydrous Na_2SO_4. Ether was stripped on a roto-evaporator, then the last traces were removed under vacuum to yield 7.5 g (88%) of **2***l*; ^{1}Hmr ($CDCl_3$), δ:1.58 (s, O Hs), 2.84 (s, 2,2′ Hs), 7.20 (s, aromatic Hs).

Divinylbenzene-2,2,2′,2′-d_4 *(2*b*)*

Benzenediethanol **2***l* (7.2 g) was heated with KOH pellets (2.6 g) and the divinylbenzene (2.5 g, 46%) was quickly distilled through a 15-cm Vigreux column at ~65 Torr. Mass spectral analysis showed that the product contained 3.89 excess D atoms per molecule (2.9% d_2, 6.6% d_3, 89.3% d_4, 1.1% d_5, 0.1% d_6 species). The ^{2}Hmr ($CHCl_3$) (Fig. 2) showed signals at 5.10 and 5.60 ppm corresponding to the 2,2′ deuterons and a signal at 3.7 pm that was due to starting material; ^{1}Hmr ($CDCl_3$), δ:6.67 (br s, 1,1′ Hs), 7.35 (s, aromatic Hs). Only a very small signal (<1%) was present for the 2,2 protons.

Bridged polycyclic compounds. 88. Multiple intermediates in solvolysis of certain bridged bicyclic and tricyclic compounds[1]

STANLEY J. CRISTOL,[2] GEORGE C. SCHLOEMER, DIETER BRAUN, AND GWENDOLYN O. MAYO
Department of Chemistry, University of Colorado, Boulder, CO 80309, U.S.A.
Received August 26, 1985

This paper is dedicated to Professor Arthur N. Bourns

STANLEY J. CRISTOL, GEORGE C. SCHLOEMER, DIETER BRAUN, and GWENDOLYN O. MAYO. Can. J. Chem. **64**, 1077 (1986).

Acetolyses of 7-chloromethyl- and 7-bromomethyldibenzobicyclo[2.2.2]octatrienes, 8-chloro- and 8-bromo-7-methylenedibenzobicyclo[2.2.2]octa-2,5-dienes, 4-bromo-8-methylenedibenzobicyclo[3.2.1]octa-2,6-diene, and 2-chlorodibenzotricyclo-[3.2.2.$0^{2,4}$]nonadiene were carried out. The results observed were consistent with the involvement of two carbocations interconverting by a Wagner–Meerwein rearrangement, and with the absence of the 1-dibenzosemibullvalenylcarbinyl cation, which is the cyclopropylcarbinyl isomer of one of the cations produced. The preparations of the reactants and products are described.

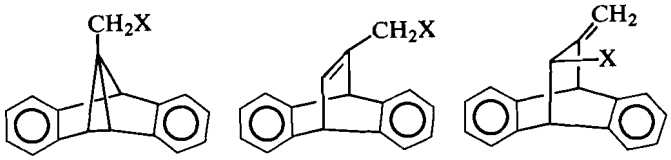
STANLEY J. CRISTOL, GEORGE C. SCHLOEMER, DIETER BRAUN et GWENDOLYN O. MAYO. Can. J. Chem. **64**, 1077 (1986).

On a effectué les acétolyses des composés suivants: les chloromethyl-7 et bromomethyl-7 dibenzobicyclo[2.2.2]octatriènes, les chloro-8 et bromo-8 méthylène-7 dibenzobicyclo[2.2.2]octatriènes-2,5, le bromo-4 méthylène-8 dibenzobicyclo[3.2.1]octadiène-2,6 et le chloro-2 dibenzotricyclo[3.2.2.$0^{2,4}$]nonadiène. Les résultats observés sont en accord avec un mécanisme impliquant la présence de deux carbocations qui s'interconvertissent par une transposition de Wagner–Meerwein et l'absence du cation dibenzosemibullvalénylcarbinyle-1 qui est l'isomère cyclopropylcarbinyle de l'un des cations produits. On décrit les préparations des réactifs et des produits.

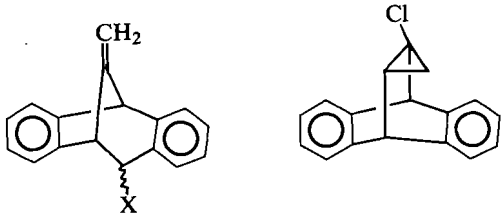
[Traduit par la revue]

Introduction

Some years ago (2), the solvolysis of **1**-Br (1-bromomethyldibenzosemibullvalene) and the solvolytic deamination of **1**-NH_2 were described and the nature of the intermediates involved in the formation of the solvolytic products was discussed. The purpose of this paper is to describe silver-ion assisted acetolyses of the corresponding allylic isomers (**2** and **3**, X = Cl, Br), the homoallylic bromide **4**-Br, and the cyclopropyl chloride **5**, all of which might be expected to share in the manifold of carbocations available to **1**. We were particularly interested in the nature of the products of these ground-state solvolyses, in order to compare them with those of ground-state solvolysis of **1** and those of photosolvolyses of similar or identical compounds.



1 **2** **3**



4 **5**

Silver-ion induced acetolysis (2) of **1**-Br gave, in addition to a small amount of 3,4-benzofluorene,[3] a mixture of the acetates **2**, **3**, and **4** (X = OAc). The ratios of the acetate products (rationalized to 100) are given in Table 1, as are corresponding results for **2**-Br, **3**-Br, and **4**-Br. The latter compounds gave no benzofluorene, consistent with the idea[3] that the progenitor of this hydrocarbon is a species not reached in the carbocation manifold from **2**-Br, **3**-Br, or **4**-Br. The ratios of products are, within experimental error, identical for the isomeric allylic compounds **2**-Br and **3**-Br. It was first assumed that the experiments conducted at 100°C for approximately an hour were kinetically controlled ones involving silver acetate. However, experiments on corresponding chlorides (see below) made clear that the experiments, which involved addition of silver acetate after the solution had been brought to temperature, allowed for substantial acetolysis and epimerization before solvolysis, and allowed for partial acid-catalyzed *exo–endo* transformation of the benzylic acetates **4** and for a partial conversion of **4**-OAc to the more stable **2**-OAc and **3**-OAc isomers.

When the acetate mixtures were allowed to stand in acetic acid containing 0.5 *M* perchloric acid for 90 h, conversion to **3**-OAc was substantially complete (95% could be isolated) (2).

It seems possible to conclude from these experiments that the carbocations **6** and **7** are involved, **6** leading to *exo* and *endo*-**4** acetates and **7** to **2**- and **3**-acetates. Reproducibility of conditions is not precise enough, in our opinion, to allow confidence in the assumption (2) that **6** and **7** are interconvertible at a rate substantially slower than capture, as this assumption would lead to substantially different mixtures from the benzylic and the allylic isomers, although the slightly greater amount of **4**-OAc

[3]Plausible reaction paths for the formation of this hydrocarbon were discussed earlier (2), as were results on the deamination of **1**-NH_2.

TABLE 1. Silver-ion induced acetolysis of certain bromides

Substrate	Temperature, °C	Time, min	Order of AgOAc addition[a]	Composition of acetate product, % 2-OAc	3-OAc	4-OAc[c]
1-Br	100	65	Last	28	29	43
	90	45	Last	26	29	43
2-Br	100	45	Last	35	37	28
3-Br	100	45	Last	39	32	29
	97	840	Last	32	44	24
	23	300	Last	34	30	36
	100	1[d]	First	23	30	47
4-Br[b]	90	45	Last	21	23	56

[a]For those samples marked "last," the solutions of alkyl bromide were brought to temperature and silver acetate was then added; for that marked "first," the alkyl halide was added to a solution of silver acetate already at temperature.
[b]Composition of product computed from that of a reactant mixture of 72% **4**-Br, 10% **2**-Br, and 18% **3**-Br.
[c]The major portion of these product mixtures was *exo*; the fraction of *endo* epimer increased with increasing time and (or) severity.
[d]Time of heating after RBr added.

TABLE 2. Solvolyses of certain bicyclic and tricyclic chlorides in acetic acid at reflux

Substrate	Time	Order of AgOAc addition	RCl recovered	Composition of acetate product, % 2-OAc	3-OAc	4-OAc
2-Cl	2 h	None	32% **2**-Cl, 28% **3**-Cl	27	43	30
	35 min[a]	Last	0	26	43	31
	<1 min[a]	Last	19% **2**-Cl, 18% **3**-Cl	29	41	30
	1 min[b]	First	8% **3**-Cl	20	39	42

	9 d	Last	—	23	53	24

[a]Time of heating after AgOAc added.
[b]Time of heating after RCl added.

from **4**-Br suggests this. It is clear, however, from the absence of **1**-OAc and benzofluorene, that interconversion with **8** (homoallyl → cyclopropylcarbinyl isomerization) is not important in these experiments.

The chlorides **2**-Cl, **3**-Cl, and **5**-Cl were also subjected to acetolysis (Table 2). With **2**-Cl, in the absence of silver acetate (or when silver acetate was added after the solution had been brought to reflux and reaction was terminated by pouring into cold water as soon as possible after the addition), there was substantial conversion to the more stable allylic isomer **3**-Cl, along with solvolysis. On the other hand, solvolysis of **3**-Cl, which was significantly less reactive than **2**-Cl, was accompanied by, at most, trace rearrangement to **2**-Cl. Thus, like the acetates, **3**-Cl is thermodynamically more stable than its allylic isomer **2**-Cl.

In the experiments where the alkyl chlorides were added to a refluxing solution of silver acetate in acetic acid, and the reaction was terminated after a few minutes (presumably kinetic control) with **2**-Cl, **3**-Cl, and **3**-Br, the reaction mixture was somewhat richer in **4**-OAc (42–47%) and poorer in **2**-OAc than those prepared under more severe conditions. These results make it clear that **4**-OAc is converted to both **2**-OAc and **3**-OAc and, when previous work (2) on these acetates is considered, that, considerably less rapidly, **2**-OAc is converted to **3**-OAc. This same phenomenon can be noted in the silver-ion promoted acetolysis of **5**-Cl, which gives mixtures comparable to those from the other isomers at shorter times, and, at longer times, shows the tendency to give mixtures richer in **3**-OAc, consonant with its stability (2). The low reactivity of **5** is obviously a function of its being a chlorocyclopropane (3), and the products are consistent with those of other bridged systems (see, for example, ref. 4), and with the intervention of ions **6** and **7** as the reactive intermediates in the process.

Photochemical results are recorded in the accompanying paper (5), and discussions of the differences between the photoreactions and ground-state reactions are also given there.

Reagents and products

Compound **2**-Br was prepared, essentially as described by Shenoy (6), by treatment of **2**-OH (2, 6) with phosphorus

tribromide in pyridine. The other allylic isomer, **3**-Br, was prepared by a sequence in which allyl chloride was added to anthracene, elimination of hydrogen chloride gave the olefin **3**-H, and bromination with *N*-bromosuccinimide gave largely **3**-Br. The preparation of **4**-Br was carried out by heating **1**-Br (2) in xylene; a mixture containing 18% of **3**-Br, 10% of **2**-Br, and 72% of **4**-Br was produced. The lability of **4**-Br made purification difficult, hence this mixture was used in the reactions. The acetates **1**-OAc, **2**-OAc, **3**-OAc, and **4**-OAc have already been reported (2). **2**-Cl was prepared from **2**-OH using the method of Young *et al.* (7), for the conversion of primary allylic alcohols into the corresponding chlorides, without allylic rearrangement. We were unable to convert **2**-OH or **3**-OH into mixtures of allylic chlorides from which pure samples of **3**-Cl could be obtained (although it is now clear (see above) that thermolysis of these mixtures would have given **3**-Cl). We therefore prepared **3**-Cl by treatment of 7-chloro-8-chloromethyldibenzobicyclo[2.2.2]octa-2,5-diene (prepared from anthracene and 1,3-dichloropropene) with base, following the concept of Jarvis (8) regarding elimination in such systems. **5**-Cl was prepared by triplet-sensitized irradiation of **2**-Cl or **3**-Cl (5).

Experimental

The ^{1}H nmr spectra were determined with a Varian A-60A 60-MHz instrument (bromide work) and a Varian EM-390 (90-MHz) instrument (chloride work). Analyses were by Galbraith Laboratories, Inc., Knoxville, TN.

Preparation of 7-bromomethyldibenzobicyclo[2.2.2]octatriene (2-Br)

A mixture of 250 mg (1.07 mmol) of **2**-OH (2), 2.8 g (10.5 mmol) of PBr_3, 1 mL of pyridine, and 25 mL of reagent-grade benzene was heated and stirred for 20 min at 60°C, following the procedure of Shenoy (6). After being cooled, the mixture was extracted several times with water, aqueous $NaHCO_3$, and water. The benzene solution was dried ($MgSO_4$); evaporation of the solvent left an oil that crystallized from petroleum ether (bp 40–60°C) to give 282 mg (92%) of **2**-Br, mp 132–135°C (lit. (6) mp 142–144°C); ^{1}H nmr ($CDCl_3$), δ: 7.0 (dt, 1H, H-8, $J_{4,8}$ = 6.5 Hz, $J_{8,9}$ = 0.5 Hz), 5.28 (s, 1H, H-1), 5.22 (d, 1H, H-4, $J_{4,8}$ = 6.5 Hz), 4.40 (d, 2H, H-9, $J_{8,9}$ = 0.5 Hz).

Preparation of 7-methylene-8-bromodibenzobicyclo[2.2.2]octadiene (3-Br)

A solution of 7.73 g (35.4 mmol) of 7-methylenedibenzobicyclo-[2.2.2]octadiene (9), 7.9 g (35 mmol) of *N*-bromosuccinimide, and a catalytic amount of azobisisobutyronitrile in 90 mL of reagent-grade carbon tetrachloride was irradiated with a 100-W unfrosted tungsten lamp for 3½ h. The heat from the lamp caused the solution to reflux gently. The mixture was cooled and the insoluble succinimide was filtered. The filtrate was evaporated *in vacuo*. The resulting oil was chromatographed on Merck 71707 alumina and eluted rapidly with petroleum ether, bp 40–60°C. The major fraction was collected. Several recrystallizations from petroleum ether (bp 40–60°C) produced 6.2 g (60%) of **3**-Br, mp 121–122°C; ^{1}H nmr ($CDCl_3$), δ: 5.40 (d, 1H, H-9, $J_{8,9}$ = 1.5 Hz), 5.23 (d, 1H, H-9, $J_{8,9}$ = 2.0 Hz), 5.90 (m, 1H, H-8, $J_{4,8}$ = 3.0, $J_{8,9}$ = 2.0, 1.5 Hz), 4.72 (s, 1H, H-1), 4.54 (d, 1H, H-4, $J_{4,8}$ = 3.0 Hz).

Anal. calcd. for $C_{17}H_{13}Br$: C 68.70, H 4.41; found: C 68.75, H 4.57.

Thermal isomerization of 1-bromomethyldibenzotricyclo[3.3.0.0^{2,8}]octadiene (1-Br)

A solution of 70 mg (0.24 mmol) of **1**-Br in 50 mL of *m*-xylene was heated at reflux for 15 h. The *m*-xylene was removed *in vacuo* to give a yellow oily residue; ^{1}H nmr analysis showed 46% of *exo*-**4**-Br, 26% of *endo*-**4**-Br, 18% of **3**-Br, and 10% of **2**-Br. The mixture was analysed from the area of the following absorptions in the ^{1}H nmr spectrum: H-4, d, δ 5.90 of *endo*-**4**-Br; H-4, d, δ 5.65 of *exo*-**4**-Br; H-9, d, δ 4.40 of **2**-Br; H-1, s, δ 4.72 and H-4, d, δ 4.54 of **3**-Br. This mixture resisted attempts at separation and purification by either chromatography or crystallization due to the lability of the compounds. The yield of rearranged products was quantitative. The ^{1}H nmr spectra of *exo*- and *endo*-**4**-Br reported are those provided by analysis of the spectrum of the mixture: *exo*-**4**-Br: ^{1}H nmr ($CDCl_3$), δ: 5.65 (d, 1H, H-4, $J_{4,5}$ = 2.2 Hz), 5.07, 5.03 (2s, 2H, H-9), 4.40 (s, 1H, H-1); *endo*-**4**-Br: ^{1}H nmr ($CDCl_3$), δ: 5.90 (d, 1H, H-4, $J_{4,5}$ = 5.5 Hz), 4.98, 4.92 (2s, 2H, H-9), 4.40 (s, 1H, H-1), 4.05 (d, 1H, H-5, $J_{4,5}$ = 5.5 Hz).

Silver-assisted solvolysis of 7-bromomethyldibenzobicyclo[2.2.2]octatriene (2-Br)

To a solution of 500 mg (1.68 mmol) of **2**-Br in 15 mL of acetic acid at 100°C was added, with stirring, 300 mg (1.8 mmol) of solid silver acetate. The reaction mixture was stirred for 45 min, cooled, and filtered. Dilution of the filtrate with 150 mL of cold water produced a cloudy precipitate, which was extracted with several 50-mL portions of ether. The combined ether layers were washed with water and saturated sodium bicarbonate solution until neutral, then dried ($MgSO_4$). Evaporation of the solvent *in vacuo* produced 460 mg (98%) of an oil whose ^{1}H nmr spectrum[4] indicated it contained 35% of **2**-OAc, 37% of **3**-OAc, 22% of *endo*-**4**-OAc, and 6% of *exo*-**4**-OAc. This analysis was confirmed, as was that of all other solvolyses of the bromides, by reduction with $LiAlH_4$ to the corresponding alcohols and analysis of the ^{1}H nmr spectra of that mixture.

Silver-assisted solvolysis of 4-bromo-8-methylenedibenzobicyclo-[3.2.1]octadiene (4-Br)

To a solution of 70 mg (0.24 mmol) of the mixture of bromides from the thermolysis of **1**-Br described above, in 30 mL of acetic acid heated at 90°C, was added 100 mg (0.6 mmol) of silver acetate. The reaction was stirred at 90°C for 45 min, cooled, and filtered. The clear filtrate was diluted with 150 mL of water and extracted with several portions of ether. The combined ether layers were washed with water and saturated sodium bicarbonate solution until neutral, and dried ($MgSO_4$). Evaporation of the solvent gave 66 mg of an oil (100%) whose ^{1}H nmr spectrum[4] indicated a composition of 56% **4**-OAc, 23% of **3**-OAc, and 21% of **2**-OAc.

Silver-assisted solvolysis of 7-methylene-8-bromodibenzobicyclo [2.2.2]octadiene (3-Br)

A suspension of 1.24 g (4.18 mmol) of **3**-Br in 33 mL of acetic acid was heated to 100°C, after which silver acetate (0.70 g, 4.18 mmol) was added. The reaction mixture was heated at 100°C for 45 min, cooled, and filtered. Dilution of the filtrate with 150 mL of cold water resulted in a white precipitate, which was extracted with several 50-mL portions of ether. The combined ether portions were washed with water and saturated sodium bicarbonate solution. The ether was then dried ($MgSO_4$) and evaporated *in vacuo* to yield 1.65 g (97%) of an oil. The ^{1}H nmr spectrum of the mixture indicated the formation of 24% of *exo*-**4**-OAc, 5% of *endo*-**4**-OAc, 32% of **3**-OAc, and 39% of **2**-OAc.

Preparation of 8-chloro-7-methylenedibenzobicyclo[2.2.2]octadiene (3-Cl)

To a solution of 4.0 g (14 mmol) of 7-chloro-8-chloromethyldibenzobicyclo[2.2.2]octadiene (10) in 100 mL of dry dimethyl sulfoxide was added 2.3 g (21 mmol) of potassium *tert*-butoxide. The reaction mixture was stirred for 12 h at room temperature, and was then quenched by additon of 500 mL of water. The resulting suspension was extracted with several portions of ether. The combined ether layers were washed with 1 *M* hydrochloric acid and with water, then dried ($MgSO_4$). Evaporation of the solvent produced a yellow solid. Recrystallization from water–acetone yielded 2.5 g (71%) of crystalline **3**-Cl, mp 132 – 133°C; ^{1}H nmr ($CDCl_3$), δ: 5.35 (d, 1H, H-9, $J_{8,9}$ = 2.0 Hz), 5.17 (d, 1H, H-9, $J_{8,9}$ = 1.8 Hz), 4.71 (s, 1H, H-1), 4.70 (m, 1H, H-8, $J_{4,8}$ = 3.0, $J_{8,9}$ = 2.0, 1.8 Hz), 4.48 (d, 1H, H-4, $J_{4,8}$ = 3.0 Hz). *Anal.* calcd. for $C_{17}H_{13}Cl$: C 80.79, H 5.19; found: C 80.91, H 5.01.

[4]The properties of the acetate products and of the corresponding alcohols as well have already been reported (2).

Preparation of 7-chloromethyldibenzobicyclo[2.2.2]octatriene (2-Cl)

To a solution of 3.5 g (15 mmol) of 7-hydroxymethyldibenzobicyclo[2.2.2]octatriene **2**-OH (2) and 1.5 g (19 mmol) of pyridine in 200 mL of anhydrous ethyl ether was added (dropwise) a solution of 2.0 g (17 mmol) of thionyl chloride dissolved in 50 mL of anhydrous ether. After stirring overnight, the reaction mixture was poured into 350 mL of cold water. The ether layer was separated, and the water layer extracted twice with ether. The combined ether extracts were washed twice with sodium bicarbonate solution and twice with water. After the solution was dried ($MgSO_4$), removal of the solvent by distillation left a solid residue (3.8 g, 100%). Recrystallization from petroleum ether (bp 40–60°C) produced more than 90% of **2**-Cl, mp 147–148°C; ^{1}H nmr, δ: 7.41–6.91 (m, 8H, aromatic H), 6.80 (dt, 1H, H-8, $J_{4,8}$ = 6 Hz, $J_{8,9}$ = 1 Hz), 5.10 (s, 1H, H-1), 5.03 (d, 1H, H-4, $J_{4,8}$ = 6 Hz), 4.22 (d, 2H, H-9, $J_{8,9}$ = 1 Hz). *Anal.* calcd. for $C_{17}H_{13}Cl$: C 80.79, H 5.19; found: C 80.70, H 5.35.

Preparation of 2-chlorodibenzotricyclo[3.2.2.0^{2,4}]nonadiene (5)

A solution of 1.9 g (7.5 mmol) of **2**-Cl and 12 mL of acetophenone in 65 mL of acetonitrile in a Pyrex tube was deoxygenated by nitrogen bubbling for 20 min. It was then irradiated at 300 nm for 4 days with an Hanovia 500-W lamp (pyrex filter). The solvent was distilled off and the residual oil was chromatographed on 600 mL of a 60–200 mesh silica gel column. Elution with 10% benzene in petroleum ether (bp 40–60°C) gave **5**, contaminated with acetophenone. Steam distillation removed most of the acetophenone. The residue (1.2 g, 63%) contained 80% product and 20% acetophenone. Recrystallization from hexane gave pure **5**, mp 121–122°C; ^{1}H nmr ($CDCl_3$), δ: 7.40–7.00 (m, 8H, aromatic protons), 4.51 (s, 1H, H-1), 4.37 (d, 1H, H-5, $J_{4,5}$ = 5 Hz), 1.80 (dt, 1H, H-4, $J_{4,5}$ = 5 Hz, $J_{3anti,4}$ = 9 Hz, $J_{3syn,4}$ = 5 Hz), 1.17 (dd, 1H, H-3$_{anti}$, $J_{3anti,4}$ = 9 Hz, $J_{3anti,3syn}$ = 7 Hz), 0.55 (dd, 1H, H-3$_{syn}$, $J_{3anti,3syn}$ = 7, $J_{3syn,4}$ = 5 Hz). *Anal.* calcd. for $C_{17}H_{13}Cl$: C 80.79, H 5.19; found: C 80.59, H 5.13.

Thermal rearrangement of 2-Cl to 3-Cl

A solution of 66 mg (0.26 mmol) of **2**-Cl and 31 mg of anhydrous ferric chloride in 10 mL of carbon tetrachloride was heated at reflux for 2 h. After dilution with more carbon tetrachloride, the solution was washed with water, then chromatographed on a cold short silica-gel column to remove traces of ferric chloride. Elution with hexane gave a solution that, upon removal of the solvent by distillation, left a residue whose ^{1}H nmr spectrum was essentially that of **3**-Cl.

Acetolysis of 2-Cl in acetic acid

A solution of 18 mg (0.07 mmol) of **2**-Cl in 10 mL of acetic acid was heated at reflux for 2 h. After work-up similar to that described above for the bromides, ^{1}H nmr analysis indicated 32% of **2**-Cl remaining, 28% had been isomerized to **3**-Cl, while acetolysis was also seen (17% of **3**-OAc, 11% of **2**-OAc, and 12% of **4**-OAc).

Silver-assisted solvolyses of 2-Cl, 3-Cl, and 5-Cl

These experiments were generally conducted with about 0.01–0.04 *M* alkyl chloride in glacial acetic acid, and with 1.5–10 times the equivalent amount of silver acetate. Recoveries were close to quantitative. Conditions and results are tabulated in Table 2. When silver acetate is described as added "last," the alkyl chloride solution was heated to reflux before addition of silver acetate. In the "first" cases, a solution or suspension of silver acetate in acetic acid was brought to reflux before addition of solid alkyl chloride.

Photochemical transformations. 42.[1] Photoreactions of certain bridged bicyclic and tricyclic chlorides and bromides containing aromatic chromophores

STANLEY J. CRISTOL,[2] DIETER BRAUN, GEORGE C. SCHLOEMER, AND BART J. VANDEN PLAS
Department of Chemistry, University of Colorado, Boulder, CO 80309, U.S.A.

Received August 26, 1985

This paper is dedicated to Professor Arthur N. Bourns

STANLEY J. CRISTOL, DIETER BRAUN, GEORGE C. SCHLOEMER, and BART J. VANDEN PLAS. Can. J. Chem. **64**, 1081 (1986).

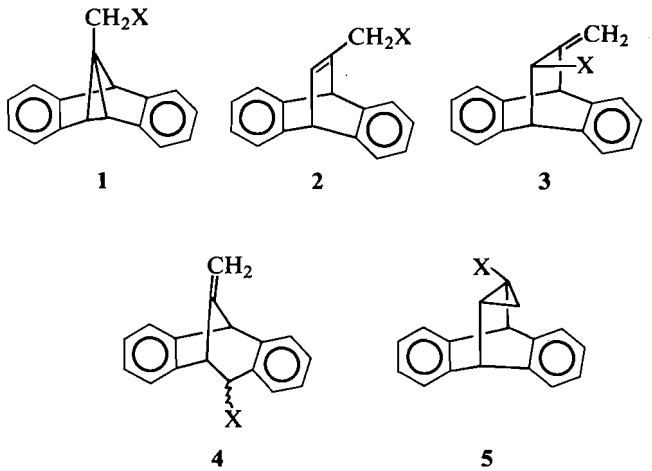
Irradiations of a number of bicyclic and tricyclic bromides and chlorides containing aromatic rings have been carried out. With the allylic chlorides **2**-Cl and **3**-Cl, triplet-sensitized photoreactions in acetone (or in acetonitrile with acetophenone sensitizer) lead to allylic scrambling and allyl-to-cyclopropyl isomerization to **5**-Cl, while the corresponding bromides, under similar conditions, give allylic scrambling, photo-Wagner–Meerwein rearrangement, and photosolvolysis, but no allyl-to-cyclopropyl isomerization. The differences in reaction types are ascribed to the requirement for intramolecular electron transfer for the "ionic" reactions, which may be exothermic in the triplet states of the bromides, but not in those of the chlorides. In direct irradiations in acetic acid with 254-nm light, the singlet state of the chloride **2**-Cl is photoactive in the "ionic" sense, giving a mixture of acetates, benzofluorenes, and 1-methylfluoranthene. The latter hydrocarbon is the major product in the direct irradiation of **5**-Cl in acetic acid, along with a mixture of acetates. The photochemical results are contrasted with ground-state solvolyses of these compounds.

STANLEY J. CRISTOL, DIETER BRAUN, GEORGE C. SCHLOEMER et BART J. VANDEN PLAS. Can. J. Chem. **64**, 1081 (1986).

On a effectué des irradiations sur un certain nombre de bromures et de chlorures bicycliques et tricycliques contenant des noyaux aromatiques. Dans les cas des chlorures allyliques **2**-Cl et **3**-Cl, les photoréactions sensibilisées par un triplet et effectuées dans l'acétone (ou dans l'acétonitrile en utilisant l'acétophénone comme sensibilisateur) conduisent à des transpositions allyliques aléatoires et à une isomérisation de l'allyle en cyclopropyle au niveau du **5**-Cl. Par ailleurs, lorsqu'on soumet les bromures correspondants à des conditions semblables, il se produit des transpositions allyliques aléatoires, une photo-transposition de Wagner–Meerwein ainsi que de la photolyse; toutefois, il ne se produit pas d'isomérisation de l'allyle en cyclopropyle. On attribue les différences dans les types de réactions aux conditions requises pour que les réactions "ioniques" puissent procéder par un transfert électronique intramoléculaire qui peut être exothermique dans le cas des états triplets des bromures, mais pas dans le cas des chlorures. Lors d'irradiations directes par de la lumière à 254 nm dans de l'acide acétique, l'état singulet des chlorures **2**-Cl est photoréactif au sens "ionique" et il conduit à des mélange d'acétates, de benzfluorènes et de méthyl-1 fluoranthène. Lors des irradiations directes du **5**-Cl dans de l'acide acétique, ce dernier hydrocarbure est le produit principal aux côtés d'un mélange d'acétates. Les résultats photochimiques sont en opposition avec ceux observés lors des solvolyses de ces composés dans leur état fondamental.

[Traduit par la revue]

In connection with our continuing interest in photosolvolyses and photo-Wagner–Meerwein rearrangements (2), as well as in the photoreactions of allylic halides (3), we undertook a study of the photoreactions of certain chlorides and bromides of structures **1**–**5**, whose ground-state acetolyses have been reported in the accompanying paper (4), both upon direct irradiation and upon photosensitization.



Triplet-sensitized reactions

Our initial interest in these compounds arose in connection with studies of allylic systems (3), and focussed on the allylic chlorides **2** and **3**, under triplet-sensitized conditions. When **2**-Cl was irradiated in acetone-d_6 in a Pyrex tube with a 450-W Hanovia lamp (Corex filter sleeve) or in an acetonitrile solution with acetophenone as sensitizer, it was rapidly converted to a roughly 1:6 mixture of **2**-Cl and **3**-Cl. Somewhat more slowly, this mixture was converted to **5**-Cl. A similar result occurred with **3**-Cl in acetonitrile, with either acetophenone or acetone as sensitizer. No evidence for photo-Wagner–Meerwein isomerization to **4**-Cl, for rearrangement to **1**-Cl, or for photosolvolysis was noted, although recovered chemical yields, when isomerization to **5**-Cl was carried out to completion, were only about 50%. Thus the results were comparable to those of other allylic chlorides (3), that is, allylic isomerization, with ultimate allyl-to-cyclopropyl rearrangement.

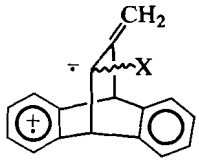
Irradiation of the corresponding allylic bromides gave rise to distinctly different results. While irradiation, in acetone, of allyl bromide itself gives cyclopropyl bromide (3*a*), no **5**-Br was produced when either **2**-Br or **3**-Br was irradiated through Pyrex in acetone-d_6. Instead, a steady-state ratio of **2**-Br to **3**-Br of 1.1:1.0 was set up, and the reaction mixture contained, in addition, significant amounts of the Wagner–Meerwein rearranged, less thermodynamically stable (4), bromide **4**-Br (largely the *endo* isomer) and the rearranged alcohol **4**-OH. The presence of **2**-OH and **3**-OH was not certain, as ^{1}H nmr data

[1]For preceding paper in series see ref. 1.
[2]Author to whom correspondence may be addressed.

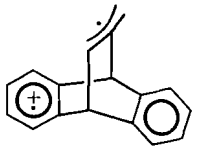
were indistinct, but, when an experiment was conducted in a 1:3 mixture of acetone and methanol, evidence for **2**, **3**, and **4** methyl ethers was adduced. Whether the alcohol comes, in part at least, directly from the allylic bromides or via the benzylic bromides **4**-Br was not ascertained, but we did find that *exo*-**4**-Br was substantially more photoactive (solvolysis in acetone to **4**-OH) than its *endo* epimer. Wagner–Meerwein products were also formed in acetonitrile with acetophenone sensitizer, and **5**-Br was again absent.

These results are quite different from those (5) with the 1-halomethylnaphthalenes, which undergo, in addition to solvolysis under direct irradiation, sensitized photosolvolysis from triplet states when the halogen is either chlorine or bromine. The authors (5) believe that the triplet reactions occur via exciplex formation, while results on benzyl and substituted benzyl chlorides (6), which also undergo sensitized photosolvolysis, are well interpreted by the involvement of an upper triplet state.

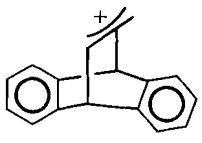
While the disparity between the chloride and bromide results was at first puzzling, recent ideas (7) regarding photosolvolyses of β-arylethyl derivatives rationalize the results well. For some time (8) it has been proposed that there is a key requirement for these "ionic" reactions resulting in photo-Wagner–Meerwein rearrangements of β-arylethyl derivatives and (or) photosolvolysis. The requirement is that electron transfer of the photoexcited π^* electron to the σ^* orbital of the carbon–nucleofuge bond occurs to give a zwitterionic species. Thus, for example, **3** would give the zwitterionic biradical **6**. A variety of modes of fragmentation of **6** was proposed, all involving cleavage of the carbon—X bond. If that cleavage occurred prior to ring migration the biradical cation **7** (paired with X^-) would be produced, which could lead, by reverse electron transfer, to **8** or, by rearrangement followed by decay, to **9**. On the other hand, rearrangement concerted with cleavage would give a biradical cation excited-state precursor of **9**, which could decay to **9** and consequently to its equilibration (4) with **8**.



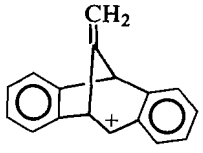
6



7



8



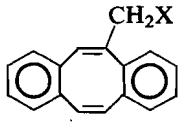
9

We have noted (7) that electron transfer from the π,π^* excited state to give a zwitterionic biradical may only be important when it is fast (and thus only when it is exothermic) and that the exothermicity may be judged from the Weller equation (9). A consequence of this requirement is that excited triplet states are less apt to be reactive than corresponding singlet states, as they are generally lower lying in energy (7*c*). In general, electron transfer from an excited benzene ring in its triplet state to a β carbon–chlorine bond is apt to be endothermic (7*c*). Thus, lacking the capability for ready electron transfer, the triplet of **3**-Cl (and that of its allylic isomer) undergoes the alternative allylic and allyl-to-cyclopropyl rearrangements.

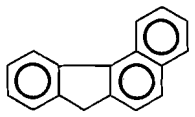
Carbon–bromine bonds may be estimated to be at least 0.5 V more readily reducible than corresponding carbon–chlorine bonds (10). This energy difference is reflected in an equivalent lowering in energy requirement for electron transfer in **3**-Br vs. **3**-Cl (or to the allylic bromide system (11)) and thus, with the bromides, the "ionic" process is favored. In the dipolar aprotic solvent acetone, it is reasonable that tight ion pairs would be formed and that ion-pair return would be an important phenomenon. This, in fact, is the case, as allylic isomerization and rearrangement return to **4**-Br occur more rapidly than solvolysis. The latter undoubtedly involves capture of cation **9** by acetone (6), followed by hydrolysis of the resulting oxonium ion, enol ether, or hemiacetal by adventitious water or during work-up.

Direct irradiations

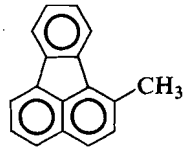
As the singlet energy of the aromatic ring is about 16 kcal/mol greater than its triplet energy (7*c*, 12) it might be anticipated (7, 9) that **2**-Cl and (or) **3**-Cl might be photoactive in the "ionic" sense upon direct irradiation. Accordingly, a solution of **2**-Cl in acetic acid was subjected to 254-nm irradiation. It disappeared rapidly, giving rise to a melange of hydrocarbon and acetate products including about 65% of a mixture of **3**-OAc, *exo*-**4**-OAc, and **10**-OAc, 15% of 3,4-benzofluorene (**11**), 10% of 1-methylfluoranthene (**12**), and small amounts of **1**-OAc and of



10



11



12

what is tentatively identified as 2,3-benzofluorene. (When the irradiation was interrupted before complete disappearance of alkyl chloride, **3**-Cl was also present.) In a separate experiment, it was shown that direct (254-nm) irradiation of **2**-OAc in acetic acid or in benzene led to a 4:1 mixture of **10**-OAc and **1**-OAc (so that **2**-OAc is undoubtedly the source of the **10**-OAc and the **1**-OAc), that **3**-OAc is photochemically inert, and that **4**-OAc is slightly active (with no identifiable products seen).

As discussed below, irradiation of **5**-Cl leads to **12**, so that the primary products of direct irradiation of **2**-Cl in acetic acid are undoubtedly **2**-OAc, **3**-OAc, **4**-OAc, **3**-Cl, **5**-Cl, and the benzofluorenes. Of these, one might speculate that **5**-Cl arises via intersystem crossing to the triplet of **2**-Cl and (or) **3**-Cl and that the others are the result of excited singlet reactions.

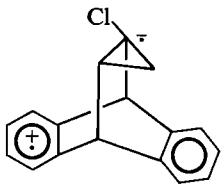
As the composition of the acetate mixture changed with irradiation time, an experiment was conducted in which the extent of acetate production from **2**-Cl was less than 15%. This led to a mixture of acetates containing approximately 50% of **4**-OAc, 28% of **3**-OAc, 13% of **2**-OAc, and 8% of **10**-OAc. The absorbance for **1**-OAc was too small to integrate. These ratios are not substantially different from those produced in the ground-state silver acetate induced acetolysis of **2**, **3**, and **4** chlorides (4). It therefore seems reasonable to assume that the acetates are formed by capture of the mixture of cations **8** and **9**, as in the ground-state system. It is generally true (1) that photosolvolysis products in systems such as these arise from thermally relaxed, that is, normal, cations, and this seems to be true here as well. As described above, it has been proposed (7, 8) that, following photoexcitation, β-arylethyl halides suffer electron transfer to give zwitterionic biradicals that may fragment to biradical cations and halide ion, and it is not unreasonable to

propose a similar initial course for **2**-Cl and **3**-Cl photoreactions. Where the branching to give benzofluorenes occurs is completely obscure.

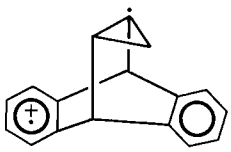
It is of interest that benzofluorenes are not produced in observable amounts in the ground-state solvolysis of **2**, **3**, or **4** bromides or chlorides (4), but that **11** is produced (13) in small amounts by silver acetate promoted solvolysis of **1**-Br or by deamination of **1**-NH_2. No 2,3-benzofluorene was reported by these workers. As the process for the formation of **11** from **1**-Br is not clear, and as labelling experiments have not been done in either the ground-state work or the photoreactions, it seems wise to defer speculation at this time.

While **5**-Cl is stable under sensitization conditions (it, of course, is the product of triplet sensitization of **2**-Cl and **3**-Cl), irradiation with 254-nm light led to the formation of 1-methylfluoranthene (**12**) in about 50% yield, along with about 25% of a mixture of acetates. **12** was identified by its mass spectrum, its ^1H and ^{13}C nmr spectra, its ultraviolet spectrum, and its melting point (14). **12** is not observed in silver ion promoted acetolysis of **5**-Cl (4).

The acetate mixture produced in the irradiation of **5**-Cl was substantially identical with those produced by kinetic control in the ground-state reactions (4) or **2**-Cl, **3**-Cl, and **5**-Cl, comprising 43% of **4**-OAc, 36% of **3**-OAc, 11% of **2**-OAc, 8.5% of **10**-OAc, and 1.5% of **1**-OAc, if it is assumed that the latter two compounds are derived by photoreaction of **2**-OAc. It seems reasonable to assume that **4**-OAc, **3**-OAc, and **2**-OAc are derived by electron transfer from the π,π^* state to give the zwitterionic biradical **13**, or an isomeric species in which electron transfer has occurred from the other ring, which loses chloride ion to give the biradical cation **14**. Reverse electron transfer from **14** followed by, or concomitant with, ring opening would give the allylic cation **8** whose equilibration with **9** is discussed above.



13



14

We are considering a number of possibilities for this remarkable rearrangement of **5**-Cl to **12**. It is known that irradiation of dibenzonorbornadienes (15), triptycenes (16), and dibenzohomobarrelenes, e.g., **5**-H (17), leads to products whose formation can be rationalized by an initial π,π bridging between two aromatic rings, followed by extrusion of a carbene from the frustrated di-π-methane biradical intermediate. It is possible to devise mechanisms for the reaction involving carbene intermediates. It is also possible to conceive of reaction paths involving an early electron-transfer process (1, 7, 8), consistent with the accompanying formation of acetolysis products. We are presently continuing work on this reaction and hope that experiments in progress or in prospect will allow us to choose among the various possibilities.

Experimental

General

The ^1H nmr spectra were determined with Varian A-60-A (60 MHz) (bromides), and EM-390 (90 MHz) and Brüker WM-250 (250 MHz) (chlorides) instruments. The preparation and properties of all compounds have been described (4). Solvents used were spectrograde quality. Irradiations in acetone with the Hanovia lamps were carried out in Pyrex tubes and the lamp had a Corex filter. Irradiations in acetic acid were carried out in a Srinivasan–Griffin Rayonet reactor with 254-nm lamps in quartz vessels.

Irradiation of 7-chloromethyl-2,3;5,6-dibenzobicyclo[2.2.2]octa-2,5,7-triene (2-Cl) in acetone

A solution of 100 mg (0.40 mmol) of **2**-Cl in 0.8 mL of acetone-d_6 in a Pyrex nmr tube was deoxygenated by bubbling nitrogen through the solution for 1 h while it was being cooled. Irradiation was conducted with a 450-W Hanovia lamp for 24 h, at which time the tube had become frosted with polymer. The ^1H nmr analysis showed a composition of approximately 65% of **5**-Cl, 30% of **3**-Cl, and 5% of **2**-Cl. The product ratios were obtained by integration of the following absorptions: H-8 (*exo*), 1H, dd, δ 1.30 (J = 7.0, 8.8 Hz) and H-8 (*endo*), 1H, dd, δ 0.55 (J = 7.0, 4.9 Hz) of **5**-Cl; H-9, 2H, d, δ 4.45 (J = 1.2 Hz) of **2**-Cl; H-9, 1H, d, δ 5.25 (J = 1.8 Hz) and H-9, 1H, d, δ 5.35 (J = 2 Hz) of **3**-Cl. Evaporation of the solvent under reduced pressure and chromatography of the residue on alumina (Merck 71707) gave **5**-Cl as the first fraction when eluted with petroleum ether – 10% benzene. The isolated yield of **5**-Cl was 41% (41 mg, 0.16 mmol), mp 116–117°C (lit. (4) mp 121–122°C). The reaction on a preparative scale in acetonitrile sensitized by acetophenone is described in the accompanying paper (4).

Irradiation of 8-chloro-7-methylene-2,3;5,6-dibenzobicyclo[2.2.2]-octa-2,5-diene (3-Cl) in acetone–acetonitrile

A solution of 100 mg (0.40 mmol) of **3**-Cl in 0.6 mL of acetonitrile-d_3 and 0.3 mL of acetone-d_6 in a Pyrex nmr tube was deoxygenated as above. The sample was then irradiated with a 450-W Hanovia lamp for 72 h, at which time ^1H nmr analysis indicated a composition of approximately 48% each of **5**-Cl and **3**-Cl and 4% of **2**-Cl.

Acetophenone-sensitized irradiation of 3-Cl

A solution of 150 mg (0.59 mmol) of **3**-Cl and 0.2 mL (205 mg, 1.67 mmol) of acetophenone dissolved in 0.7 mL of acetonitrile-d_3 in a Pyrex nmr tube was deoxygenated as above and was irradiated with a 450-W Hanovia lamp for three days, after which time the ^1H spectrum indicated a ratio of **5**-Cl to **3**-Cl of about 20:1. The contents were subjected to chromatography on silica gel and eluted with 10% benzene in petroleum ether (bp 40–60°C). The first fraction was collected. This contained 70 mg (47%) of **5**-Cl.

When biphenyl was attempted as sensitizer, no reaction ensued.

The ^1H nmr analysis of product mixtures of bromides

The areas of the following absorptions were used to calculate the ratios given in the following irradiation experiments (acetone-d_6): 4-*endo*-bromo-8-methylene-2,3;5,6-dibenzobicyclo[3.2.1]octadiene (*endo*-**4**-Br), H-4, 1H, d, δ 5.80, J = 5.5 Hz; 4-*exo*-bromo-8-methylene-2,3;5,6-dibenzobicyclo[3.2.1]octadiene (*exo*-**4**-Br), H-4, 1H, d, δ 5.52, J = 1.8 Hz; 8-bromo-7-methylene-2,3;5,6-dibenzobicyclo[2.2.2]octadiene (**3**-Br), H-9, 2H, d, δ 4.20, J = 1.2 Hz; 8-methylene-2,3;5,6-dibenzobicyclo[3.2.1]octadiene-4-ol (**4**-OH), H-4, 1H, d, δ 3.8–3.9, J = 2 Hz (*exo*-OH) and J = 5 Hz (*endo*-OH).

The experiments were conducted substantially as described above for the chlorides (through Pyrex). Compound **2**-Br gave a product mixture of approximately 17% of **4**-OH, 7% of **4**-Br, 40% of **2**-Br, and 37% of **3**-Br, and **3**-Br gave one of 14% of **4**-OH, 4% of **4**-Br, 43% of **2**-Br, and 38% of **3**-Br upon irradiation until the solutions turned brown. The ratio of solvolysis to isomerization was not affected by addition of small amounts of water. No peaks attributable to **5**-Br were noted.

Irradiation of 1-bromomethyl-3,4;6,7-dibenzotricyclo[3.3.0.$0^{2,8}$]-octa-3,6-diene (1-Br) in acetone

A solution of 80 mg (0.27 mmol) of **1**-Br in 0.6 mL of acetone-d_6 in a Pyrex nmr tube was deoxygenated as above for 1 h, and irradiated with a 250-W Hanovia lamp for 5 d; ^1H nmr analysis showed that no significant reaction had occurred.

Irradiation of 4-bromo-8-methylene-(2,3;6,7)dibenzobicyclo[3.2.1]-octa-2,6-diene (4-Br)

In a Pyrex nmr tube was placed a mixture of 80 mg (0.27 mmol) of 52% of *exo*-**4**-Br, 30% of *endo*-**4**-Br, 6% of **2**-Br, 9% of **3**-Br, and 3% of **1**-Br dissolved in 0.6 mL of acetone-d_6. The solution was degassed as above and the sample was irradiated with a 450-W Hanovia lamp. After 17 h of irradiation, ^{1}H nmr analysis showed a ratio of 31 of *endo*-**4**-Br/15 of *exo*-**4**-Br/12 of **3**-Br/13 of **2**-Br/10 of **1**-Br/20 of **4**-OH.

Direct irradiation of 2-Cl in acetic acid

In a typical experiment, a solution of 108 mg (0.43 mmol) of **2**-Cl in 30 mL of HOAc in a quartz tube, after 20 min of nitrogen bubbling, was irradiated in a Rayonet reactor at 254 nm for 20 h. The solution was poured into a mixture of water and ether. The water layer was extracted with ether and the combined ethereal solutions were neutralized with aqueous sodium bicarbonate, washed three times with water, and dried (Na_2SO_4). Evaporation of the solvent left 130 mg of a dark oil, which was separated into polar acetate fractions and nonpolar hydrocarbon fractions by thick-layer chromatography on silica gel. The hydrocarbon fractions moved with hexane and the acetates were extracted with ether. Analysis was by 250-MHz ^{1}H nmr spectroscopy, using peaks (4) at δ 5.51, 5.30, 5.00, 4.77, and 4.60 for **3**-OAc, at δ 5.95, 5.05, 4.93, 4.32, and 3.88 for *exo*-**4**-OAc, at δ 4.44 and 3.10 for **1**-OAc, at δ 4.87 for **10**-OAc, at δ 8.79, 8.42, and 4.02 for 3,4-benzofluorene (**11**) (18), at δ 8.21 and 4.09 for 2,3-benzofluorene (18), and at δ 2.90 for 1-methylfluoranthene (14*c*,*d*). The results averaged for several experiments are given in the discussion section.

In an experiment designed to measure initial products, a solution of 117 mg (0.46 mmol) of **2**-Cl in 65 mL of HOAc was irradiated for 30 min. Chromatographic separation gave 92 mg of less polar material containing largely **3**-Cl (major) and **2**-Cl (minor) and 16 mg of polar material; ^{1}H nmr analysis (250 MHz) with "cut-and-weigh" determination of the carbinyl proton(s) gave 51% of **4**-OAc, 28% of **3**-OAc, 13% of **2**-OAc, and 8% of **10**-OAc. **1**-OAc could not be measured accurately.

Direct irradiation of 7-acetoxymethyl-2,3;5,6-dibenzobicyclo[2.2.2]-octa-2,5,7-triene (2-OAc) in acetic acid

A solution of 10 mg of **2**-OAc in 1 mL of acetic acid-d_4 was deoxygenated and irradiated with 254-nm light for 17 h. The ^{1}H nmr analysis indicated that the mixture contained 80% of **10**-OAc and 20% of **1**-OAc. A larger scale reaction, carried out in benzene,[3] gave similar results: **10**-OAC, bp 90°C (1 Torr); ^{1}H nmr ($CDCl_3$), δ: 6.74 (s, 2H, H-7, H-8), 4.87 (d, 2H, CH_2, $J_{CH_2,4}$ = 1 Hz), 1.94 (acetate CH_3). *Anal.* calcd. for $C_{19}H_{16}O_2$: C 82.58, H 5.84; found: C 82.71, H 5.99.

Direct irradiation of 2-chloro-6,7;8,9-dibenzotricyclo[3.2.2.0^{2,4}]-nona-6,7-diene (5-Cl) in acetic acid

A solution of 168 mg (0.66 mmol) in 60 mL of HOAc in a quartz tube was deoxygenated (N_2 bubbling) for 25 min. After 3.4 h irradiation at 254 nm, the solvent was rotovapped off; ^{1}H nmr analysis of the residual oil indicated about 40% reaction using integration of H-1 and H-5 proton absorbances for **5**-Cl, that of the methyl group of 1-methylfluoranthene at δ 2.79, and the acetate methyl peaks (δ 1.9–2.3). Column chromatography and silica gel with methylene chloride – hexanes gave three fractions. The first fraction was **5**-Cl (72 mg, 43% of recovery).

The second fraction was 1-methylfluoranthene. It was identified by melting point, 67–72°C (lit. (14*a*,*b*) mp 72–73°C); its uv spectrum (λ_{max}: 275, 282, 285, 310, 325, 347, 362 nm); its mass spectrum (parent peak, 216); its ^{1}H nmr spectrum (14*c*,*d*), δ: 8.00–7.27 (m, 9H, aromatic H), 2.80 (s, 3H, CH_3). A ^{13}C nmr spectrum showed 16 carbon atoms in the range δ 140.0–119.8 (aromatic) and one at 20.1 (CH_3).

[3]This reaction was carried out by Dr. G. O. Mayo.

This fraction weighed 41 mg (50% yield based upon unrecovered **5**-Cl).

The third fraction was a mixture of five acetates and weighed 37 mg (26% yield based upon unrecovered **5**-Cl). The composition of this mixture was determined by ^{1}H nmr analysis (250-MHz nmr as described above for the irradiation of **2**-Cl, but using a cut-and-weigh procedure). It contained 43% of **4**-OAc, 36% of **3**-OAc, 11% of **2**-OAc, 8.5% of **10**-OAc, and 1.5% of **1**-OAc.

Steric activation in prototropic reactions of pyrazine derivatives. I. Polar and conformational effects

T. W. S. LEE AND ROSS STEWART[1]
Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6
Received September 13, 1985
This paper is dedicated to Professor Arthur N Bourns

T. W. S. LEE and ROSS STEWART. Can. J. Chem. **64**, 1085 (1986).

The rates of proton loss from methyl groups in a number of pyrazine derivatives have been measured in D_2O by monitoring the replacement of protium by deuterium at the acidic sites of the substrates; they include the reaction of four methylpyrazines with $NaOD/D_2O$ and nine alkylpyrazinium ions with D_2O/DCl. The reactive site, which is a methyl group conjugated to the aza or azonium group of the substrate, is in all cases activated by an adjacent alkyl group, with the greatest effect, a factor of about 30, occurring when a proton on nitrogen is replaced by a methyl group. The phenomenon is analysed in terms of polar effects, ring strain and inter-alkyl interactions (including gear effects), and hybridization changes at nitrogen.

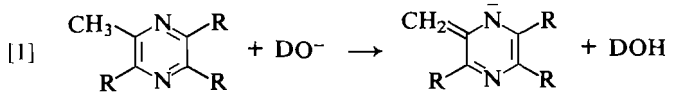
T. W. S. LEE et ROSS STEWART. Can. J. Chem. **64**, 1085 (1986).

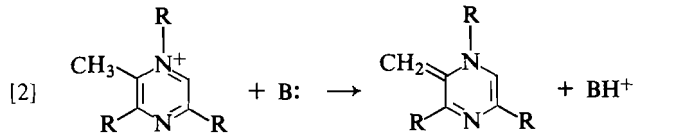
Opérant dans le D_2O et observant le taux de remplacement des protons par des deutérium au niveau des sites acides des substrats, on a mesuré les vitesses de perte de protons des groupements méthyles d'un certain nombre de dérivés de la pyrazine; les systèmes étudiés comportent les réactions de quatre méthylpyrazines avec le $NaOD/D_2O$ et de neuf ions alkylpyrazinium avec le D_2O/DCl. Dans tous les cas, le site réactif, qui est le groupement méthyle qui est conjugué avec le groupement azo ou azonium du substrat, doit sa réactivé à un groupement alkyle voisin et l'effet est maximal, par un facteur de 30, est obtenu lorsqu'on remplace un proton de l'azote par un groupement méthyle. On analyse le phénomène en fonction d'effets polaires, de tensions de cycles, d'interactions inter-alkyles et de changements d'hybridation au niveau de l'azote.

[Traduit par la revue]

Introduction

We have previously shown that alkyl groups adjacent to an acidic methyl group in a number of heterocyclic systems activate the methyl group with respect to proton loss. These systems include lumazines and 5-deazalumazines (1–3), 2-pyrimidones (4, 5), iminopyrimidines (4), and pyrimidonium salts (6).[2] We now report the results of a study of alkyl substituted pyrazines and their protonated or quaternized salts (eqs. [1] and [2]), where again activation by adjacent alkyl groups and





deactivation by more distant alkyl groups is observed. In the accompanying paper we have scrutinized the bases used to remove the proton from the reactive methyl group of one of the cationic substrates (eq. [2]). Using the Brønsted relationship we find that steric acceleration is present there also, but only with carboxylate bases; sterically hindered amines react more slowly than would be expected on the basis of their equilibrium base strengths.

Results and discussion

Pyrazines

The effect of methyl substitution on the reaction between pyrazines and hydroxide ion (eq. [1]) can be seen from the results in Table 1. The reaction of **1**, 2,3-dimethylpyrazine, with hydroxide ion is first order in substrate (highly linear first-order plots were obtained in all cases) and is also first order in hydroxide ion, as can be seen from the results in the table. Whereas the 2,3-dimethyl compound reacts faster than the 2-methyl compound, the 2,5- and 2,6-dimethyl compounds react more slowly. (Since all the methyl groups in the compounds in Table 1 are reactive, the comparisons are made on a per methyl basis.) The direction of this effect is consonant with those observed earlier. Though the magnitude is smaller than that observed in some of the earlier reactions, the deactivating effect of remote methyl is nonetheless quite substantial. A Hammett plot for compounds **2**, **3**, and **4**, using **2** as the parent and the σ values for *m*-methyl and *p*-methyl for **3** and **4**, gives a slope of +6.2. The magnitude of the latter shows that there is a strong electronic effect operating in this reaction and that it is in the conventional direction. That is, nonadjacent alkyl groups are substantially deactivating.

The electronic effect of an *ortho* group in aromatic systems is believed to be greater than that of the same group in the *meta* and *para* positions, though this may not always apply to alkyl groups (8–10).

Work with other heterocyclic systems had shown that a methyl group in a position "*meta*" to a reactive methyl centre is strongly deactivating, with effects that are generally considerably greater than that observed in this instance. It was suspected that the effects should be even greater for methyl at a "*para*" position and from the present results that appears to be so. (Such an arrangement could be achieved in only a few instances in the systems studied previously and then only when the "*para*" methyl was attached to nitrogen rather than to carbon. Since the geometrical changes that accompany those prototropic reactions are much greater at nitrogen than at carbon, *vide infra*, the significance of the observed effects was less clear than in the present case.) Similar effects of alkyl groups on the acidities of substituted benzenes have been observed previously (11, 12).

Pyrazinium ions

In order to compare the effect of hydrogen with alkyl at the cationic nitrogen centre, experiments were conducted in two

different acidic media, 2.13 *M* DCl in D_2O and 2.0 *M* CF_3CO_2D in D_2O, where the neutral bases **1**, **2**, and **4** are highly protonated (13). It can be seen from the results in Table 2 that similar trends are observed when the rate constants of the protonated and alkylated species are compared in the two media. The observed rates are slightly higher in the CF_3CO_2D/D_2O solution than in the DCl/D_2O solution, presumably because the trifluoroacetate ion makes a contribution to the proton abstraction process.

In the cases of **8**, **10**, and **11**, slow exchange was also observed at the C-3 methyl groups (~1/25th of the rate at the C-2 methyl) but we cannot be certain that this is not due to the presence of low concentrations of the protonated form of the quaternary salts. The pK_2 values of methylpyrazines, which would correspond to pK_1 of the quaternary salts, are in the region of −4.0 (13) but the higher prototropic reactivity expected for the dications might well compensate in part for their low concentrations and allow observation of exchange at the C-3 methyl groups.

In comparing the protonated and alkylated species one should note first that the difference in rate between the fast and slow isomers, those having a 1,2 and a 1,4 dimethyl arrangement, is much more striking in both of these cationic forms than in the neutral compounds **1** and **4**. The rate ratio for the latter reacting with hydroxide ion is 14 (Table 1), with the 1,2 compound being the more reactive. In the case of the protonated isomers **6** and **7** reacting with water the ratio is 78 and in the case of the pairs of alkylated isomers **8** and **12** and **10** and **13** the values are 109 and 120, again with the adjacent arrangement of methyl groups being the more reactive one.

The rate constant shown in Table 2 for methylpyrazinium ion, **5**, has been statistically corrected in an attempt to put it on the same basis as the other ions. In the other cases the exchanging methyl group is flanked at all times by cationic nitrogen, whereas **5** is in equilibrium with the other protonated form in which the methyl group and the cationic nitrogen are out of conjugation. Since **5** is expected to be present in larger amount than its isomer the correction factor should be less than two, leading to the estimated value given in the table.

Alkylation site

We recently examined the effect of neighbouring methyl on the prototropic reactivity of lumazines and deazalumazines and showed that the effect was greater when the neighbouring group was on nitrogen than when it was on carbon (1). The effect was as large as two orders of magnitude in one case, although for various reasons the precision of the measurements was less than in the present work.

In the present work the effect of replacing a proton on a neighbouring nitrogen atom with a methyl group can be seen by comparing the rate constants for **6** and **8**, the rate ratios being 29 in DCl/D_2O and 26 in D_2O/CF_3CO_2D. A similar result is seen when the values in DCl/D_2O of **7** and **12** are compared; here the rate ratio is 21.

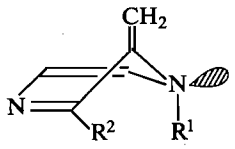
How does the size of the alkyl group affect the degree of activation? It can be seen by comparing the rate constants for **8**, **10**, and **11** that going from methyl to ethyl to isopropyl causes the effect to subside. The rate ratio for hydrogen, methyl, ethyl, and isopropyl is 1:29:26:20 in the DCl/D_2O medium, with the drop-off being somewhat greater in D_2O/CF_3CO_2D. A similar effect is observed in the series **8** and **9** and in the series **7**, **12**, and **13**, where the ratio of rate constants for hydrogen, methyl, and ethyl is 1:21:17. As with the earlier system, the effect of alkyl at a neighbouring carbon is less, the rate ratio for **5** and **6** being 1:6.

It is clear that alkylation at nitrogen has a large effect on the adjacent reactive group; the size of the alkyl group is not critical, the effect being largest for methyl. (In 2-iminopyrimidinium ions, where the flanking alkyl groups are attached to carbon, the size of the alkyl group is again not critical, though in this case the isopropyl group has the largest effect (4).)

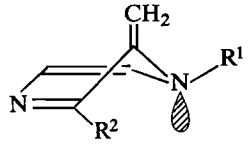
The large effect of *N*-alkylation is probably a result of relief of methyl–alkyl strain that accompanies conversion of the cation to the neutral intermediate **15** in eq. [3].

[3] 
14 **15**

Each atom in the pyrazinium ring has sp^2 bonding and the ring can be assumed to be planar (14) or as close to planarity as the steric effect of the neighbouring substituents will allow; the intermediate **15**, however, has an sp^3 arrangement at nitrogen and it can adopt nonplanar conformations such as those shown in **16** and **17**. (See refs. 15*a* and *b* (p.75) for a description of the conformations of the analogous 1,3-cyclohexadiene and dihydropyrimidine systems.)



16



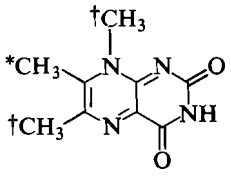
17

Molecular models of **15** show that the *N*-alkyl group R^1 can swing well away from the adjacent methylene group if it adopts the pseudoaxial conformation shown in **16**. As we have seen, the size of the alkyl group is not critical here though the effect is biggest in the present instance with methyl, the smallest alkyl group. Presumably the conventional steric effects that would be expected to be present in the transition state of any bimolecular reaction are present here and come into play with the larger groups.

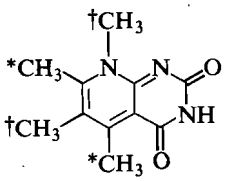
When the neighbouring alkyl group is attached to carbon rather than to nitrogen the effect is smaller since here no hybridization change accompanies proton loss from the reactive site. Nonetheless, the bonds that join R^2 and methylene to the ring in the intermediate **16/17** make a significant dihedral angle, whereas in the starting materials the aromaticity of the ring ensures that these angles will be close to zero, at least in the absence of major strain. Accordingly, whatever strain accompanies the positioning of, say, two methyl groups at adjacent sites on an aromatic ring should be relieved to some extent by conversion to a nonaromatic system.

Can this explanation be applied to the heterocyclic systems studied previously, which all show activation by neighbouring methyl groups? Their structures are shown below, with the active site marked by an asterisk and the activating methyl groups marked by a dagger.

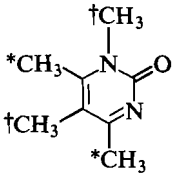
In the cases of **18–20** the alkylated nitrogen is formally sp^3 but in each case there is conjugation with a powerful electron sink, which will tend to make the ring planar. Indeed, in the case of **18** the geometry of the ring containing the exchanging groups



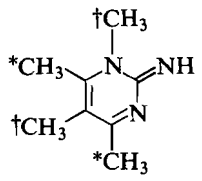
18



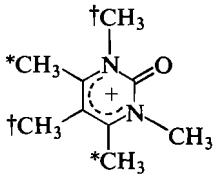
19



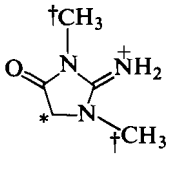
20



21



22

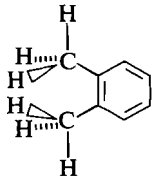


23

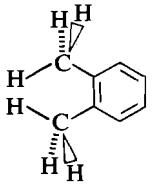
may closely resemble the quaternary pyrazine salts described herein. In the cases of **21** and **22** the rings will also tend toward a planar arrangement and will also form nonplanar intermediates when proton loss occurs. The creatinium salts, **23**, are an enigma. Here, methyl groups are slighly activating when present on endocyclic nitrogen and slightly deactivating when present on exocyclic nitrogen. The deprotonated intermediate in this case is mesoionic and it is difficult to assess the geometrical changes that accompany the loss of a proton from the activated methylene group in the ring.

Gear effects

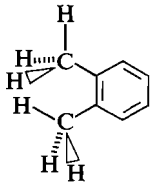
It is known that *o*-xylene prefers the gear-clashed conformation **24** rather than the other gear-clashed form **25**, or the gear-meshed form **26** (16, 17).



24



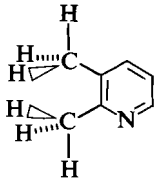
25



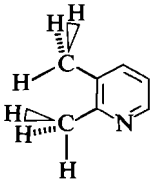
26

Roussel and co-workers (17, 18) have recently examined the interplay between alkyl groups attached to aromatic rings and have rationalized reactivity differences in a number of systems on the basis that adjacent methyl and similar alkyl groups prefer to avoid the interactions shown in **25** and **26**. Moreover, Schug and Viers (19) have calculated the energies of the rotational conformers of 2,3-lutidine and found that the gear-clashed rotamer **27** is more stable than the two gear-meshed rotamers **28** and **29** by 0.36 and 0.59 kcal mol^{-1}, respectively; it is more stable than the gear-clashed rotamer **30**, which has a frontal interaction of hydrogens, by 1.00 kcal mol^{-1}.

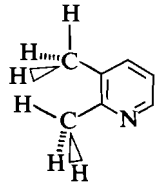
In an attempt to determine the extent of ring strain on rates of prototropic reactivity we have previously determined the geometry of a number of pyrimidonium salts, **22**, by means of X-ray crystallography. Although adjacent alkyl groups caused the ring to depart significantly from planarity in most cases, this did not always produce the higher reactivity that might have been expected. In addition to the matter of ring strain, bond deformations and inter-methyl conformational effects such as gearing may have significance. We showed that the inter-methyl distances were short in a number of the pyrimidonium ions but, as with ring strain, there was not a particularly good correspondence with high reactivity. The situation can be illustrated with



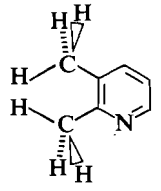
27



28



29

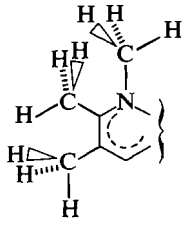


30

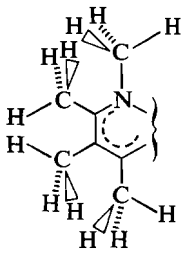
the three ions **31**–**33**, where the methyl group that undergoes proton loss is marked with an asterisk (Table 3).

The lower reactivity of **33** compared to **32** can be partly explained by the polar effect of the additional methyl group but it would be surprising if this alone were sufficiently large to overwhelm the effects of higher ring strain and lower inter-methyl distances.

In all three ions the adjacent methyl groups at positions 1 and 6 adopt the gear-clashed conformation shown in **24** and **27**. In **32** the methyl groups at positions 5 and 6 are close to being gear-meshed, as shown in **34**. In **33** the stable arrangement (at least in the crystal lattice) is that shown in **35**, where only gear-clashed arrangements are present (two favourable, one unfavourable).



34



35

It is not certain what would be the favoured geometry of adjacent methyl and methylene groups in the intermediate species formed as a consequence of proton loss from the C-5 methyl group. However, it is clear that the unfavourable inter-hydrogen interaction between the central methyl groups in **35** (at C-5 and C-6) will be retained to a considerable extent in the intermediate since the methyl pair at C-4 and C-5 will presumably maintain their gear-clashed arrangement. The intermediate formed from **34**, on the other hand, will be free to adopt whatever conformation is most satisfactory, since there is now no buttressing methyl group present at C-4.

The energy difference calculated by Schug and Viers for the two gear-clashed rotamers of 2,3-lutidine is 1.0 kcal mol^{-1}. In the case of the isomeric pyrimidonium ions **31** and **32** the rate difference corresponds to an energy of some 1.8 kcal mol^{-1}, indicating that gear effects are large enough to be significant contributors to the rate effects we have observed.

In summary, the phenomenon of adjacent alkyl groups activating and remote methyl groups deactivating prototropic

methyl sites in nitrogen heterocyclic systems has been rationalized on the basis of combinations of the following effects: (*a*) the polar effect of alkyl (deactivating), (*b*) ring strain in the starting materials (activating), (*c*) hybridization changes at nitrogen, which lead to less hindrance in the intermediate species than in the starting materials (activating), and (*d*) gear effects, which influence the energies of species containing alkyl groups (activating or deactivating).

Experimental

Compounds **1**–**4** are commercially available; the preparation of the iodide salts of **8**, **10**, **11**, and **13** has been described elsewhere (13).

The iodide salt of **12** was prepared by alkylation of 2,5-dimethylpyrazine with methyl iodide, essentially as previously described (13). Upon recrystallization from ethanol – ethyl acetate, yellow needles were obtained, mp 239–240°C. *Anal.* calcd. for $C_7H_{11}N_2I$: C 33.62, H, 4.43, N 11.20, I 50.75; found: C 33.51, H 4.56, N 11.15, I 50.60.

The iodide salt of **9** was prepared by alkylating 2-methyl-3-ethylpyrazine with methyl iodide. Analysis of the reaction mixture by nmr showed it to be a 3:1 mixture of **9** and the 2-ethyl isomer. Repeated recrystallization from ethanol – ethyl acetate gave **9**, as iodide, mp 186–188°C. *Anal.* calcd. for $C_8H_{13}N_2I$: C 36.24, H 5.34, N 10.56; found: C 36.51, H 5.20, N 10.60.

The rate measurements were made by following the exchange of deuterium for protium by nmr as previously described (4). In virtually all cases the reproducibility of the rate constants was ±5%.

Steric activation in prototropic reactions of pyrazine derivatives. II. The Brønsted relation

K. NAGARAJAN, T. W. S. LEE, R. R. PERKINS, AND ROSS STEWART[1]
Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6
Received September 13, 1985

This paper is dedicated to Professor Arthur N. Bourns

K. NAGARAJAN, T. W. S. LEE, R. R. PERKINS, and ROSS STEWART. Can. J. Chem. **64**, 1090 (1986).

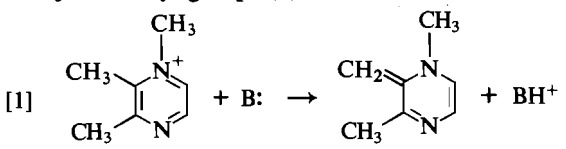
The rate of deprotonation of the 2-methyl group in 1,2,3-trimethylpyrazinium ion by carboxylate, aniline, and pyridine bases has been measured in D_2O. Carboxylate ions containing bulky groups near the reaction centre, e.g. *ortho* benzoates, react faster than predicted by the Brønsted equation that correlates the reactions of unhindered carboxylates. Anilines and pyridines, on the other hand, show conventional steric effects. A tentative explanation for the activation engendered by groups adjacent to the carboxylate centre is based on the known effect that high concentrations of organic electrolytes have on the strengths of carboxylic acids but not of amines. Since *ortho* carboxylate ions have their relative basicities increased by an alkyl-rich environment, it is argued that the reactive methyl groups of the substrate might provide such an interaction in the transition state.

K. NAGARAJAN, T. W. S. LEE, R. R. PERKINS et ROSS STEWART. Can. J. Chem. **64**, 1090 (1986).

Opérant dans le D_2O, on a mesuré la vitesse de déprotonation du groupement méthyle de l'ion triméthyl-1,2,3 pyrazinium par les bases carboxylate, aniline et pyridine. Les vitesses de réaction des ions carboxylates qui comportent des groupements encombrants près du centre réactionnel, comme les *ortho* benzoates, sont plus rapide que celles prévues par l'équation de Brønsted qui établit une corrélation pour les réactions des carboxylates qui ne sont pas encombrés. Par ailleurs, on observe les effets stériques conventionnels avec les anilines et les pyridines. Comme explication préliminaire de l'activation engendrée par les groupements encombrants adjacents au centre réactionnel du carboxylate, on peut faire appel à l'effet connu des concentrations élevées d'électrolytes organiques sur les forces des acides carboxyliques qui n'influence pas les amines. Puisque les basicités relatives des ions *ortho* carboxylates sont augmentées par une environnement riche en groupements alkyles, on suggère que les groupements méthyles réactifs des substrats doivent fournir une telle interaction dans l'état de transition.
[Traduit par la revue]

Introduction

The role of steric effects in proton transfer reactions has been the subject of numerous publications from this laboratory (1–5). In particular, the accompanying paper deals with the increases in rate of proton removal from the activated methyl group of pyrazinium ions (eq. [1]) that are brought about by the presence of adjacent alkyl groups (1).



1

We turn our attention here to the matter of steric effects in the other component of the reaction, that is, the base. We report herein the results of a study of the reaction of carboxylate ions, anilines, and pyridines with 1,2,3-trimethylpyrazinium ion (**1**).

Results

Carboxylate ions

Reported in Table 1 are the rate constants for deprotonation of **1** by 35 different carboxylate bases. The latter can be subdivided into three categories: aliphatic, *meta*- and *para*-substituted benzoates, and *ortho*-substituted benzoates. The only one of these groups that gives a good Brønsted relation is that comprising the *meta*- and *para*-substituted benzoates, for which a coefficient of 0.447, (corr. coeff. 0.9913) is obtained. Considerable scatter is found in Brønsted plots of the other two groups, with the deviations being most apparent for those bases containing bulky substituents, e.g. diphenylacetate or 2,6-dimethoxybenzoate. The overall effect of bulk in the base can be seen in Fig. 1, where data for all the carboxylate ions appear. The straight line has been drawn for those carboxylates that have only monosubstitution at the α-carbon atom (included here are formate and acetate). The Brønsted coefficient for these points is 0.639, corr. coeff. 0.9987. All the other bases show positive deviations from this line, that is, they are more effective in abstracting a proton from **1** than would be expected on the basis of their equilibrium base strengths. It should be noted that over the years there have been isolated reports of other positive deviations from the Brønsted relation involving carboxylate ions, for example, in the anion catalyzed halogenation of certain ketones and esters (6) and the ionization of creatininium salts (7).[2]

Anilines and pyridines

Reported in Table 2 are the rate constants for the reaction of **1** with a series of anilines and a series of pyridines. The Brønsted plots for these two series are shown in Fig. 2. It can be seen that substitution at the 2-position gives rise to a conventional steric effect, that is, the bases are less effective kinetically than would be suggested by their equilibrium base strengths. Although the effect is small in the case of the anilines it is quite substantial in the case of the pyridines. There are many examples of this sort of behaviour in the literature (see, for examples, refs. 8–10). The Brønsted slope for the anilines is 0.707, corr. coeff. 0.9875, and for the pyridines is 0.566, corr. coeff. 0.9972, excluding in each case the 2-substituted compounds.

[1]Author to whom correspondence may be addressed.

[2]We have been informed by Dr. Brian Cox that analogous effects have recently been observed in his laboratory in the protonation of cryptands by *ortho*-substituted benzoic acids (B. G. Cox and N. van Truong, personal communication).

Discussion

It is clear from the results shown in Figs. 1 and 2 that steric hindrance in the base can have quite different effects on the rate of proton abstraction from **1**. Carboxylate ions that contain groups near the basic centre are more reactive than predicted by the Brønsted equation that correlates the reactivities of their unhindered analogues. A quite different situation is found in the case of anilines and pyridines, particularly the latter, where conventional steric effects appear to be operating.

In the accompanying paper we examined the effect of alkyl groups adjacent to the reactive site of the substrate; such groups invariably increase the rate of proton transfer, the effects being quite large when account is taken of the deactivating polar effect that more distant alkyl has on the acidic site.

Since amine bases are shown here to have conventional (deactivating) steric effects, we are not obliged to seek a universal explanation for what otherwise would have appeared to be a general (and surprising) phenomenon, viz. that groups adjacent to the reactive sites in both the acidic and basic components of the reaction accelerate the rate of proton transfer. Accordingly, we shall focus our attention on the carboxylate group in attempting to rationalize the present results.

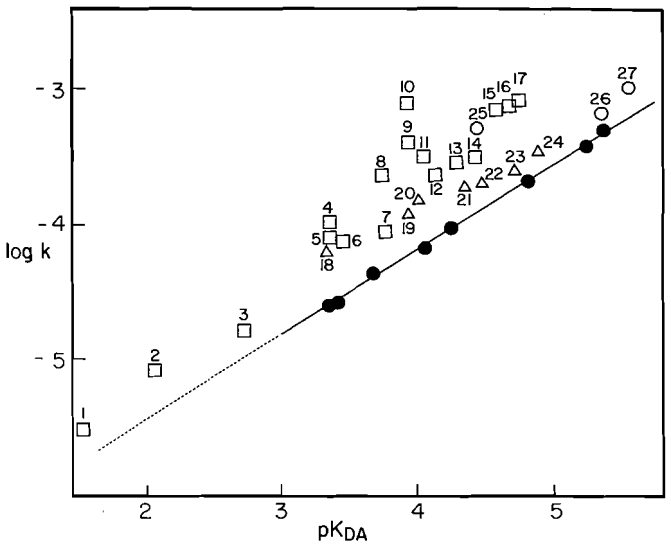

FIG. 1. Brønsted plot for the reaction of eq. [1] using carboxylate bases; numbers correspond to the carboxylic acids of Table 1; aliphatic acids (circles), *m*- and *p*-benzoic acids (triangles), *o*-benzoic acids (squares). The solid circles, which were used to determine the line, are the acids **28–35** in the table; Brønsted coefficient 0.639.

[a]Values from ref. 18 corrected to 30°C and D_2O according to ref. 7.

Although all the deviating points in Fig. 1 are on the positive side of the line, it must be pointed out that in most cases these do not correspond to absolute rate increases. For example, an *ortho* halo benzoate ion is less reactive than benzoate or, indeed, than the corresponding *meta* or *para* ions. The positive deviation

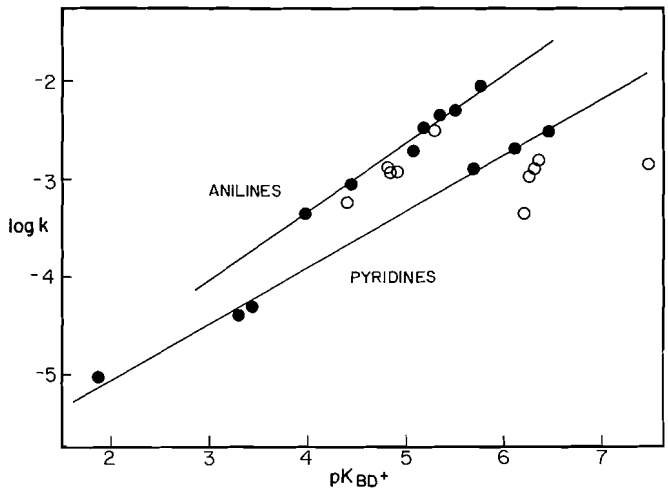

FIG. 2. Brønsted plots for the reaction of eq. [1] using aniline and pyridine bases (Table 2). The open circles represent compounds containing a substituent in the 2-position. The Brønsted coefficients are 0.707 (anilines) and 0.566 (pyridines).

arises to a great extent from the unusually low basicity of the *ortho* ions. Thus, as in all case of deviations from Brønsted relationships, it is necessary to examine the factors that affect both variables, that is, the reaction rate *and* the degree of the equilibrium ionization. The generally accepted explanation for *ortho* benzoates being weaker bases than their *para* counterparts is that there is hindrance to conjugation between the carboxyl group and the ring in the neutral acid, thus raising the energy of the latter and shifting the equilibrium toward the carboxylate ion. The moderately large Brønsted coefficient (0.639) and the fact that the proton transfer reaction is endergonic (uphill) suggests that the transition state should have a considerable amount of the character of the carboxylic acid (11, 12). It might be argued that the proton in the transition state is associated with both oxygen atoms, neither one of which would have significant carbonyl character, and in this case the deviation of the *ortho* compounds could be said to arise simply from anomalies in pK_{HA} rather than anomalies in rate. Since we have no grounds for believing that this situation obtains, and since it would not apply to the three aliphatic cases (**25**–**27**), we seek an explanation in other terms.

It was shown some time ago by Steigman and Sussman (13) that a high concentration of organic electrolyte, e.g. tetra-*n*-butylammonium bromide, has a profound effect on the pK of carboxylic acids. They become weaker acids and this change was found to be particularly marked in the case of *ortho*-substituted benzoic acids, which, in 7.75 molal $(n\text{-Bu})_4N^+Br^-$, become essentially equal in strength to their *para* isomers. Inorganic salts do not have this effect, and its was argued that the high concentration of alkyl units induces a high degree of structure in the water and that this has a greater effect on the *ortho* compounds than on their *meta* or *para* isomers. (There are indications that the effect is also present in aliphatic systems.)

Regardless of the precise origins of the pK changes, it is apparent that *ortho* carboxylate ions become relatively better proton acceptors (compared to their *meta* or *para* counterparts) in an environment that is alkyl rich. The transition state of the reactions under consideration here must have some of this character since the proton source is, in fact, an alkyl group and, indeed, adjacent alkyl groups in the substrate may also contribute to this sort of interaction when carboxylate bases are used. Accordingly, we tentatively ascribe the positive deviations from the Brønsted line for hindered carboxylates to an increase in effective basicity of the carboxylate group caused by the propinquity in the transition state of the carboxylate ion and the alkyl group(s) of the substrate. In the case of amine bases it is known that there is no increase in base strength in the presence of high concentrations of organic electrolyte and, indeed, in some cases, the base strength decreases. Conventional steric effects would thus be expected for amine bases, which is found to be the case.

Since polarizability effects can be important in acid–base reactions (see, for example, refs. 14 and 15) we consider briefly here the four *ortho* halo benzoates. If a high degree of polarizability in the nearby substituent helps stabilize the transition state, the deviations from the Brønsted (or Hammett) line should be in the order I > Br > Cl > F. This is, indeed, what is found, although it should be remembered that this is also the order of group size and, since *tert*-butyl has a larger deviation than the other *ortho* alkyl groups, the halogen order may simply reflect size rather than polarizability, although, of course, the two parameters are not unrelated. The use of thio substituents should clarify this point.

Experimental

The carboxylic acids, anilines, and pyridines were either obtained from commercial sources or were prepared by standard synthetic procedures.

The measurements of the rate of exchange for 1,2,3-trimethylpyrazinium iodide in D_2O were made using nmr spectroscopy, essentially as previously described (1, 4). For each compound two to four kinetic runs were performed at a given pH; in most cases the reproducibility of the derived second-order rate constants was ±10%.

Solvolysis of 1,4-dimethyl-4-nitrocyclohexa-2,5-dien-1-ol in mixed aqueous organic solvents gives the diastereomers of 1,4-dimethylcyclohexa-2,5-diene-1,4-diol, 1,4-dimethylcyclohexa-3,5-diene-1,2-diol, 2-nitro-*p*-xylene, 2,4-dimethylphenol (all derived from the title cation, itself formed by ionization of the nitro group as nitrite), and 2,5-dimethylphenol. In aqueous methanol the diastereomers of 4-methoxy-1,4-dimethylcyclohexa-2,5-dienol are also obtained. Significant yields of 2,5-dimethylphenol are only obtained on the acid-catalysed further reaction of the dienediol (or the methoxydienol) and involve the intermediate formation of 1,4-dimethylcyclohexa-3,5-diene-1,2-diol. In the absence of added base the acid released in the solvolysis catalyses this reaction and leads to the aromatization of the dienes.

ALFRED FISCHER, GEORGE N. HENDERSON et TREVOR A. SMYTH. Can. J. Chem. **64**, 1093 (1986).

La solvolyse du diméthyl-1,4 nitro-4 cyclohexadiène-2,5 ol-1 dans des mélanges de solvants organiques aqueux conduit aux diastéréoisomères du diméthyl-1,4 cyclohexadiène-2,5 diol-1,4 et du diméthyl-1,4 cyclohexadiène-3,5 diol-1,2 ainsi qu'au nitro-2 *p*-xylène et au diméthyl-2,4 phénol (tous dérivés du cation mentionné dans le titre qui est lui-même formé par ionisation du groupement nitro sous forme de nitrite) et au diméthyl-2,5 phénol. Dans le méthanol aqueux, on obtient aussi les diastéréoisomères du méthoxy-4 diméthyl-1,4 cyclohexadiène-2,5 ol-1. On n'obtient des rendements importants de diméthyl-2,5 phénol que lors d'une réaction subséquente, catalysée par les acides, du dièndiol (ou du méthoxydiènol) et celle-ci implique la formation du diméthyl-1,4 cyclohexadiène-3,5 diol-1,2. Lorsqu'on n'ajoute pas de base, l'acide qui est formée lors de la solvolyse catalyse cette réaction qui conduit à l'aromatisation des dienes.

[Traduit par la revue]

Introduction

The adducts obtained on nitration of arenes in acetic anhydride, typically derivatives of 4-methyl-4-nitrocyclohexa-2,5-dienyl acetate, are labile and readily undergo rearomatization reactions in solution (1–6). A variety of rearomatization products have been obtained but the pathways to many of these appear to have one or other of two competitive initial steps, each of which involves the formation of a cyclohexadienyl cation (6, 7). For these routes rearomatization is initiated by unimolecular ionization of the nitro group as nitrite, forming a 1-acetoxy-4-methylcyclohexadienyl cation, or by acid-catalysed loss of the acetate function as acetic acid ($A_{Al}1$), forming a 4-methyl-4-nitrocyclohexadienyl cation. Formation of various substituted 4-methyl-4-nitrocyclohexadienyl cations and, more generally, substituted 4-alkyl-4-nitrocyclohexadienyl cations has been demonstrated by trapping experiments, e.g. both diastereomers of 4-ethyl-1-methyl-4-nitrocyclohexa-2,5-dienol were obtained when (*Z*)-4-ethyl-1-methyl-4-nitrocyclohexa-2,5-dienyl acetate was hydrolysed in acidified aqueous acetone (2). In the present paper we are concerned with the fate of the cyclohexadienyl cation obtained on solvolysis of the nitro group. We have investigated the solvolysis of 1,4-dimethyl-4-nitrocyclohexadienyl acetate (**1***a*), the corresponding dienol **1***b*, and the methyl ether **1***c*, and thus the formation and reactions of the 1-acetoxy-1,4-dimethylcyclohexadienyl cation (**2***a*) and its 1-hydroxy and 1-methoxy analogues **2***b* and **2***c*, respectively. Studies of the 1,4-dimethyl-4-nitrocyclohexa-2,5-dienyl acetate system have been reported by Moodie, Schofield, *et al.* (6), by Myhre and co-workers (7), and by Fischer and Ramsay (8). The 1-hydroxy-1,4-dimethylcyclohexadienyl cation and its 2-hydroxy isomer are simultaneously-formed intermediates in the acid-catalysed ring opening of 1,4-dimethylbenzene oxide (9, 10). In the present work the individual chemistries of the two cations can be distinguished since they are not formed simultaneously, and the 1-hydroxy cation can be studied in the absence of its isomer.

[1]In this paper enumeration of the cyclohexadienyl cations follows that of the parent cyclohexadienes.

Results and discussion

Configurations of 1,4-substituted cyclohexadienes

The configuration of (*E*)-1,4-dimethyl-4-nitrocyclohexa-2,5-dienol has been established by X-ray crystallography and those of the corresponding nitrodienyl acetates and methyl ethers by stereospecific interconversion reactions (11). Addition of methyllithium to 4-methyl-4-nitrocyclohexa-2,5-dienone gives preferentially the (*Z*)-dienol (12). Applying a similar argument, the major product isomer of the dienediol **3***bn* obtained on addition of methyllithium to 4-hydroxy-4-methylcyclohexa-2,5-dienone has been assigned the (*Z*) configuration (13). As would be expected, the (*E*)-dienediol has the higher melting point. The assignment is also supported by our shift reagent studies. There is only a small difference in the gradients of the shifts of the 4-CH_3 protons of the diastereomers produced on the addition of *tris*-(1,1,1,2,2,3,3-heptafluoro-7,7-[$^2H_6$]dimethyl-4,6[$^2H_3$]octanedionato)europium(III) (Eu([$^2H_9$]fod)$_3$). However, in accord with expectation, the (*E*) isomer, with the 4-CH_3 *cis* to the europium complexed at 1-OH, has the larger slope, 0.34 versus 0.31.

In the methylation reactions the stereochemistry at the asymmetric centres is not disturbed. Thus the configurations of the methoxydienols and the dimethoxydienes follow from the partial methylation of (*Z*)-**3***bn* to a mixture of (*Z*)-**3***bo* and (*Z*)-**3***co*, the methylation of (*Z*)-**3***bo* to (*Z*)-**3***co*, the partial methylation of (*E*)-**3***bn* to (*E*)-**3***bo*, and the methylation of (*E*)-**3***bo* to (*E*)-**3***co*.

Solvolysis reactions

Strongly ionizing solvents and low acidity are the conditions that favour the ionization of the nitro group over the competing

loss of the hydroxyl, acetate, or methoxyl group in the solvolysis of the nitrocyclohexadienols, their acetates, or methyl ethers (2, 5, 6). Accordingly, we studied initially the solvolysis of *E*-**1***b* in 50% aqueous methanol (Tables 1 and 2). Experiments 101–106, 201, 202, and 206 were carried out either in the absence of base or in the presence of the very weak base urea. For reaction times of up to ten solvolysis half-lives (i.e. up to 1 h at 40°C), dienes, including the methoxydienol **3***bo* and the diol **3***bn*, were obtained, as well as aromatic products, which were mainly phenols (expts. 102, 103, 201, 202, 206). However, after a longer reaction time (expt. 104) the diene components decreased and the aromatic components increased, and at very long reaction times only aromatic products were obtained as the initially formed dienes were aromatized (expts. 105 and 106). Except in the case of the shortest reaction time (expt. 101) the dienes obtained also included the dimethoxy compound **3***co* and the aromatic component also included dimethylanisoles, suggesting that these are secondary reaction products. In these reactions in the absence of base only minor amounts of 2-nitro-*p*-xylene (**6***p*) were formed and the amount did not increase with extended reaction times, which otherwise resulted in an increase in the total amount of aromatic product. Solvolysis in acidified aqueous methanol (pH 3.2) gave **3***co* (12%) and a complex mixture of aromatic products (88%) that included dimethylanisole(s).

When the solvolysis of (*E*)-**1***b* was carried out in the presence of base, formation of the dimethoxydienes and anisoles was suppressed and the methoxydienol **3***bo* and dienediol **3***bn* were either not subject to rearomatization or the rate of rearomatization was greatly reduced (compare expts. 104–106 with 107 and 108). The product distribution then was **3***bo* (44%), **3***bn* (22%), **6***p* (20%), 2,4-dimethylphenol (**7***b*, 11%), and 2,5-dimethylphenol (**6***n*, 2%) (expts. 209–211, 214, 215), both diastereomers of **3***bo* and **3***bn* being formed from the single diastereomer of the substrate. In the presence of potassium nitrite (in addition to potassium acetate) the yield of 2-nitro-*p*-xylene was greatly enhanced and that of the diene and phenol components correspondingly reduced (compare expts. 216 and 217). Solvolysis in methanol containing *N,N*-diisopropylethylamine gave **3***bo* (47%), **6***p* (36%), and **7***b* and **6***n* (17%). Solvolysis in the presence of base in aqueous acetone, aqueous tetrahydrofuran, and in ether–water mixtures gave both diastereomers of dienol **3***bn*, 2-nitro-*p*-xylene, and the 2,4- and 2,5-dimethylphenols (Table 3). Solvolysis in aqueous dioxan at pH 3.2 gave a complex mixture of aromatic products including nitrodimethylphenol(s).

Solvolysis of (*E*)-**1***c* in aqueous methanol containing *N,N*-diisopropylethylamine gave **3***co* (21%), **3***cn* (≡ **3***bo*, 34%), **6***p* (4%), and dimethylanisoles plus dimethylphenols (41%).

Solvolysis of (*E*)-**1***a* in aqueous methanol gave 2,5-dimethylphenyl acetate (**8***a*) as the sole product. In the presence of base, **8***a* was the very dominant (initial) product but partial solvolysis of **8***a* to **8***b* ensued. Solvolysis of 4-methyl-4-nitrocyclohexa-2,5-dien-1-ol in the presence of base gave *p*-cresol (90%) and unidentified diene (10%).

Reaction of (*E*)-**3***bn* with trifluoroacetic acid gave **7***b* (98%) and **6***n* (2%). In aqueous methanol at pH 3.2 **7***b* (68%) and **6***n* (32%) were obtained, although in a reaction carried out at a lower temperature, and which was therefore incomplete, some methoxydienes (12%) and dimethylanisoles (10%) were

[a]Analyses by ^1H nmr. The conjugated dienol **5***bn* was probably present in all of the reactions.

[b]Organic component and its percentage specified; the other component was water. The diethyl ether mixtures were heterogeneous.

[c]The mole ratio of base to (*E*)-**1***b* was 1.1 except for expts. 301 (2.2) and 304 (1.3).

[d](*E*)-**1***b* (14%).

[e]**5***bn* (8%).

[f]**5***bn* (6%), unidentified components with ^1H nmr peaks at 1.95 ppm (6%) and 2.25 ppm (4%).

[g]The 1.95-ppm (15%) and 2.25-ppm (9%) components.

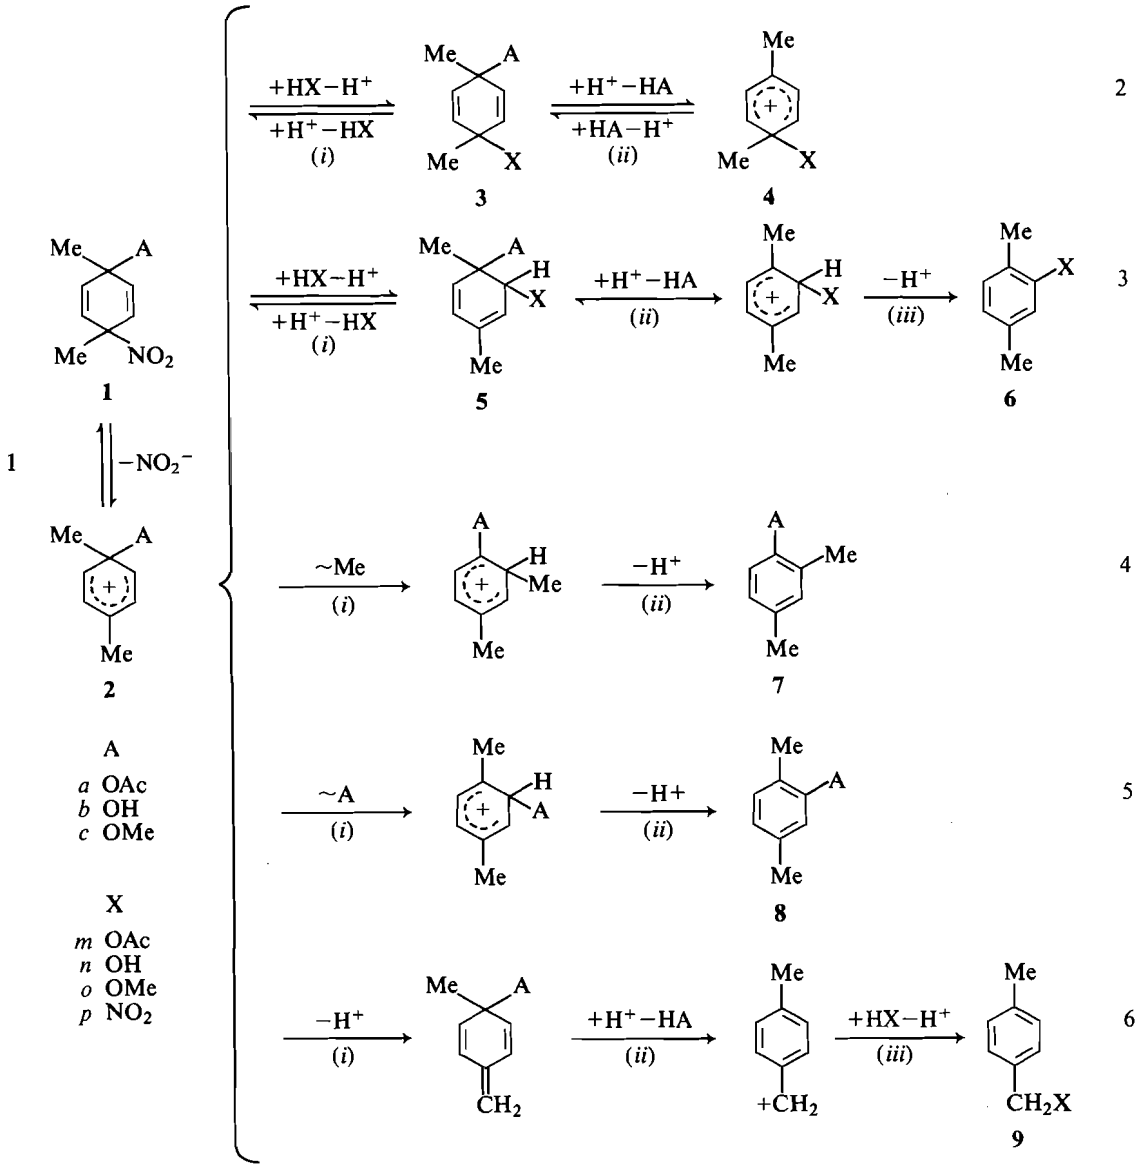
[h]Tetrahydrofuran.

[i]Tris(hydroxymethyl)aminomethane.

[j](*E*)-**1***b* (72%).

[k](*E*)-**1***b* (59%).

[l](*E*)-**1***b* (51%).

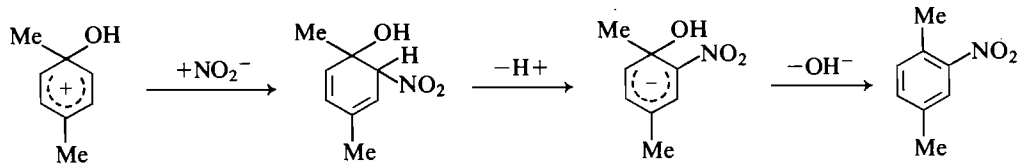


SCHEME 1

present in addition to the xylenols. In aqueous dioxan at pH 3.2 **7***b* and **6***n* were obtained in the 2:1 ratio. Reaction of (*Z*)-**3***co* with trifluoroacetic acid gave **7***c*.

We account for the solvolysis reaction products in terms of the formation and further reactions of a 1-A-1,4-dimethylcyclohexadienyl cation (**2**), as illustrated in Scheme 1, an elaboration of earlier schemes (2, 6, 7). Reactions 2(*i*) and 3(*i*) represent additions of a nucleophile to the electrophilic centre that is in a 1,4 or 1,2 relationship to the tetrahedral centre of the cation, respectively. As shown, these reactions may be followed by further reactions of the new cyclohexadienes. Reactions 4 and 5 in their initial steps (*i*) involve competing 1,2 migrations of the methyl and substituent A groups at the tetrahedral centre of the cation. Reaction 6 involves deprotonation of the cation to a triene followed by S_N1' substitution to form a benzylic derivative.

Unimolecular ionization of the nitro group in (*E*)-**1***b* leads to the hydroxycyclohexadienyl cation **2***b* (Scheme 1, reaction 1, A = OH). The methoxydienol **3***bo* and the dienediol **3***bn* are formed by solvent methanol or water, respectively, trapping **2***b* (reaction 2(*i*), A = OH and HX = HOMe or HOH). Reaction 2(*i*) is the dominant reaction of **2***b* since some 65% of the product consisted of **3***bn* and **3***bo*. The fact that both diastereomers of **3***bo* and **3***bn* are formed from a single diastereomer of **1***b* confirms the S_N1 substitution mechanism. 2-Nitro-*p*-xylene (**6***p*) was obtained in 19% yield. Addition of the nitrite ion, released in the ionization step, to the *ortho* position of **2***b* would give the nitrodiene **5***bp*, which, on elimination of water, would give the nitroarene. The addition–elimination would more likely follow the base-catalysed sequence depicted in Scheme 2 than the acid-catalysed sequence of reaction 3, Scheme 1. This is shown by the fact that only small amounts of **6***p* were formed in the reactions carried out in the absence of base, when the liberated nitrite would be present as the less nucleophilic nitrous acid. Our previous study of the methanolysis of 1-ethyl-4-methyl-4-nitrocyclohexadienol, which gave 4-ethyl-3-nitrotoluene in addition to 2-ethyl-4-methylphenol and the diastereomers of 1-ethyl-4-methoxy-4-methylcyclohexadien-1-ol, confirms that the nitro group is added at the position *meta* to its original position (2). The nitrite anion might also be expected to add to the *para* position of **2***b*. This reaction (2(*i*), X = NO_2) is just the reverse of the ionization reaction (reaction 1) and Myhre and



SCHEME 2

co-workers have argued that such return from the ion-pair is facile (7). The fact that in the presence of external nitrite the yield of 2-nitro-*p*-xylene from *E*-**1***b* increased to over 50% indicates that nitrite is a very effective competitor for cation **2***b* and establishes the intermolecular pathway of the formation of **6***p*. A 36% yield of **6***p* was obtained when the solvolysis reaction was carried out in methanol (containing diisopropylethylamine). This increased yield is presumably attributable to the effect of the lower dielectric constant solvent increasing the rate of the reaction between carbonium ion and nitrite anion, involving charge annihilation, relative to the rates of the other reactions of the carbonium ion, in which charge is preserved.

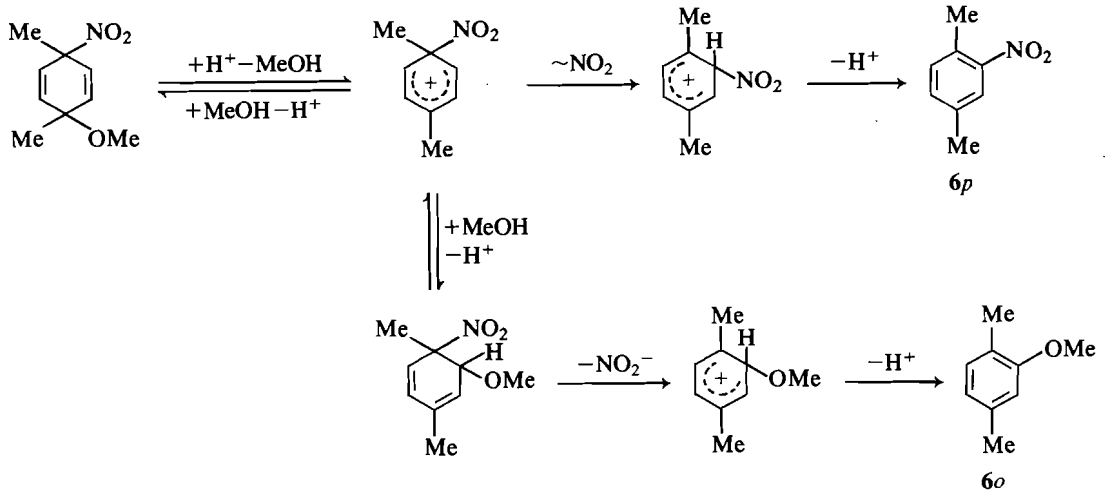
The 2,4-dimethylphenol (**7***b*), formed in 13% yield in the aqueous methanol solvolysis, arises via reaction 4. Since 2,5-dimethylphenol was formed in much lower yield (3%), it is evident that in cation **2***b* the methyl is much more prone to migrate (reaction 4(*i*)) than the hydroxyl (reaction 5(*i*)). This preference is even more marked than it appears since 2,5-dimethylphenol is also formed (and likely only formed) via reaction 3. The reaction of diol **3***bn* with trifluoroacetic acid, which gave 98% of 2,4-dimethylphenol, indicates that the relative migratory aptitude of methyl to hydroxyl in **2***b* is at least 50:1. The preference for methyl migration over migration of hydroxyl (or methoxyl) in cyclohexadienyl cations is well established in dienone–phenol rearrangement studies (14–16). Reaction of solvent at the position adjacent to the tetrahedral centre of **2***b* (reaction 3(*i*): S_N1') is slower than reaction at the *para* position (reaction 2(*i*): S_N1). On separation of the product of a large-scale reaction we obtained a small amount of the 1,2-diol (**5***bn*). It was difficult to establish the presence of **5***bn* and (or) **5***bo* in the solvolysis reaction mixtures because of the overlap of the methyl peaks with those of (*E*)-**1***b* (at 1.77 ppm) and of the products **3***bn* and **3***bo* (at 1.29 ppm). However, in a few reactions carried out in aqueous acetone and in aqueous tetrahydrofuran it was possible to establish from the absence of the quartet centred at 6.0 ppm that all of the reactant was consumed. The peak at 1.77 ppm could then be attributed to **5***bn*. In these reactions **5***bn* was present to the extent of 20% of the amount of **3***bn*, about 7% of the total reaction product. A further indication of the formation of **5***bn* was provided by the observation that in weakly acid solution (pH 3.2) the dienediol **3***bn* gave ca. 33% of **6***n*, presumably by the sequence **3***bn* → **2***b* → **5***bn* → → **6***n*. We conclude that the conjugated dienediol **5***bn* is a necessary intermediate between **2***b* and **6***n*. In dilute acid conditions the conversion of **5***bn* to **6***n* must be relatively efficient, since the extent of formation of **6***n* is half that of **7***b* although **5***bn* is only 20% of **3***bn*.

The formation of dienediol and (or) methoxydienol as intermediates in the solvolysis of the nitrocyclohexadienol has been inferred from kinetics studies (7). Our study of the products of solvolysis of 1-ethyl-4-methyl-4-nitrocyclohexa-2,5-dienol (2) and the present investigation provide the first reports of the positive identification of the dienediols and the methoxydienols as nitrocyclohexadienol solvolysis products and, in the case of the 1,2-diol, the first direct evidence of its formation in any reaction. The intermediate formation of **3***bn* in the second of two acid-catalysed mechanisms of ring opening of 1,4-dimethylbenzene oxide and its aromatization to **7***b* and **6***n* has been conclusively demonstrated by Bruice, Jerina, and co-workers (9). They proposed alternative pathways for the conversion of the diol to **7***b* and **6***n*, one being that depicted in Scheme 1 (**3***bn* → **2***b* → **5***bn* → → **6***n* and **3***bn* → **2***b* → → **7***b*), and the other, re-formation of the protonated oxide and its direct conversion to **7***b* and **6***n*. They preferred the second path. Our results, which demonstrate the intermediate formation of the 1,2-diol **5***bn* and the fact that **6***n* is not formed when **2***b* cannot be trapped by water (e.g. in trifluoroacetic acid), are in accord with the first. Our results also show that reversible formation of protonated oxide from cation **2***b* cannot occur since this would lead to a ratio **7***b*:**6***n* from the nitrodienol solvolysis reaction in the acid region (2:1), and from the reaction of the dienediol with acid, identical to that observed in reaction of the oxide with acid. However, the oxide reaction gives more **6***n* than **7***b* at pH 3.5 and **6***n* is even more favoured in stronger acid (9, 17).

No benzylic compounds were obtained in the solvolysis of (*E*)-**1***b* and thus the deprotonation of **2***b* (reaction 6(*i*)) must be slower than reactions 2(*i*), 3(*i*), or 4(*i*). Examples of reaction type 6 are known for nitrocyclohexadienyl cations, e.g. the nitrodimethylcyclohexadienyl cation formed by protonation of **1** at A and loss of HA (7, 8). However, there have been no reports of benzylic products being formed via cations such as **2***a*, **2***b*, or **2***c*.

The solvolysis reaction generates nitrous acid. In the absence of added base the solution becomes acidic and the initially formed dienes **3***bo* and **3***bn* can reform the cation **2***b* by acid-catalysed loss of methoxy or hydroxyl, respectively (reverse of reaction 2(*i*)), as discussed above. However, **3***bo* can also undergo acid-catalysed loss of hydroxyl (reaction 2) to generate the methoxycyclohexadienyl cation **4***o*. This, on reaction with methanol, would generate the dimethoxydiene **3***co*. Prolonged exposure to the acid conditions would lead to complete formation of aromatic products (phenols and anisoles) via reactions 3 and 4, and this was demonstrated by the results of solvolysis reactions carried out at pH 3.2 in which (*i*) little or no diene was obtained; (*ii*) in the case of the reaction in aqueous methanol, the small amount of diene obtained was largely **3***co*, reflecting the (acid-catalysed) exchange of the original hydroxyl group, and the aromatic compounds included anisoles, also indicative of this exchange; (*iii*) the phenols were nitrated under the acid conditions. We can thus understand why, in the aqueous methanol solvolyses of (*E*)-**1***b*, anisoles were significant components of the aromatic products and dimethoxydienes were formed only in the absence of added base and why these products were not obtained, even in the absence of added base, when the reaction time was very short.

Solvolysis of (*E*)-**1***c* in aqueous methanol follows analogous pathways to those described for (*E*)-**1***b* and does not require additional comment. Reaction of (*E*)-**1***c* with 50% trifluoroacetic acid in methanol gave **6***p*, **7***c*, and **6***o*. At such acidity this reaction presumably involves, at least in part, the nitrocyclohexa-



SCHEME 3

dienyl cation as shown in Scheme 3. However, the formation of **7***c* under these conditions must involve the methoxycyclohexadienyl cation **2***c*. Thus in this solvent mixture ionization of nitrite and the acid-catalysed loss of methanol are competitive. The reaction of (*Z*)-**3***co* with trifluoroacetic acid, which gave **7***c*, demonstrates the preferential migration of methyl rather than methoxyl in cation **2***c*.

Solvolysis of (*E*)-**1***a* differed from solvolysis of (*E*)-**1***b* and (*E*)-**1***c* in that essentially a single product (**8***a*) was obtained. The 1,2 shift of the acetate group in ion **2***a* should be facilitated by the formation of a bond to the carbonyl oxygen so that rearrangement (reaction 5) can occur via a cyclic transition state. We investigated the possibility that rearrangement of the acetate was concerted with the ionization of the nitro group by measuring the rates of solvolysis of (*E*)-**1***a* and (*E*)-**1***b*. Although (*E*)-**1***a* reacts faster than (*E*)-**1***b*, the rate ratio was only 2:1. The enhancement seems too small to require a concerted transition state, although it should be noted that formation of **2***a* should be slower than **2***b* since the acetoxy group is more electron withdrawing than the hydroxy group. Thus the true rate enhancement must be greater than is apparent. In any event, since cation **2***a* was not effectively trapped by nucleophiles, in contrast to **2***b* and **2***c*, the rearrangement of the acetate must occur very soon after **2***a* is formed if it is not synchronous with the ionization step.

Experimental

Infrared spectra were obtained on a Perkin–Elmer 283 spectrometer. The ^{1}H nmr spectra, at 90 MHz, were determined using a Perkin–Elmer R32 spectrometer. The ^{13}C nmr spectra, at 15.1 MHz, were obtained with a Nicolet TT-14 spectrometer. Mass spectra were determined on a Hitachi Perkin–Elmer RMU7 spectrometer. High pressure liquid chromatography (hplc) was carried out with a Waters system 500 (preparative) and on a Varian model 5000 (analytical) chromatograph. The gas–liquid chromatograph used was a Varian Aerograph model 2400.

2,4-Dimethylphenol, 2,4-dimethylanisole, 2,5-dimethylanisole, *N,N*-diisopropylethylamine, chlorotrimethylsilane, iodotrimethylsilane, bis(trimethylsilyl)acetamide, and 2,6-lutidine were from Aldrich. 2,5-Dimethylphenol, from Eastman, was recrystallized twice from *n*-heptane. Methyl iodide was from Mallinckrodt, trifluoroacetic acid was from Matheson, Coleman and Bell, and the Eu([^{2}H$_9$]fod)$_3$ shift reagent was from Merck, Sharp and Dohme. 2,5-Dimethylphenyl acetate was prepared by acetylation of the phenol with acetic anhydride (18).

1,4-Disubstituted cyclohexa-2,5-dienes

(*E*)-1,4-Dimethyl-4-nitrocyclohexa-2,5-dienyl acetate ((*E*)-**1***a*) was obtained by nitration of *p*-xylene (8, 11). Reaction of (*E*)-**1***a* with aluminum hydride gave (*E*)-1,4-dimethyl-4-nitrocyclohexa-2,5-dienol (*E*))-**1***b*) (11). Methylation of (*E*)-**1***b* gave (*E*)-**1***c* (11). Reduction of 4-methyl-4-nitrocyclohexa-2,5-dienone with sodium borohydride gave 4-methyl-4-nitrocyclohexa-2,5-dien-1-ol (12). Both diastereomers of 1,4-dimethylcyclohexa-2,5-diene-1,4-diol (**3***bn*) were obtained by addition of methyllithium to *p*-benzoquinone (13). Addition of methyllithium to 4-methoxy-4-methylcyclohexa-2,5-dienone (itself prepared from the chlorodienone by reaction with silver nitrate in methanol, cf. ref. 19) gave both isomers of 4-methoxy-1,4-dimethylcyclohexa-2,5-dienol (**3***bo*) in a 1:3 ratio. The isomers were separated by hplc. The minor isomer (*E*)-**3***bo* had mp 95–96°C (lit. (9) mp 94–95°C); ir (Nujol): 3415 (OH), 2820 (OCH_3), 1120, 1065 (C—O), 800 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.30 (s, 3), 1.33 (s, 3), 1.80 (s, 1, O*H*), 3.02 (s, 3, OC*H*$_3$), 5.57 (d, 2, *J* = 10 Hz, 3-*H* and 5-*H*), 6.02 (d, 2, *J* = 10 Hz, 2-*H* and 6-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_C: 27.9 (1-*C*H$_3$ and 4-*C*H$_3$), 51.5 (O*C*H$_3$), 65.4 (*C*-1), 71.0 (*C*-4), 130.4 (*C*-3 and *C*-5), 136.4 (*C*-2 and *C*-6) ppm. The major isomer (*Z*)-**3***bo* was obtained as oil; ir (film): 3410 (OH), 2830 (OCH_3), 1135, 1085 (C—O), 780 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.22 (s, 3), 1.28 (s, 3), 2.35 (s, 1, O*H*), 3.10 (s, 3, OC*H*$_3$), 5.59 (d, 2, *J* = 10 Hz, 3-*H* and 5-*H*), 5.95 (d, 2, *J* = 10 Hz, 2-*H* and 6-*H*) ppm; ^{13}C nmr δ_C: 28.0 and 29.0 (1-*C*H$_3$ and 4-*C*H$_3$), 51.9 (O*C*H$_3$), 65.4 (*C*-1), 71.0 (*C*-4), 130.3 (*C*-3 and *C*-5), 135.7 (*C*-2 and *C*-6) ppm.

(*E*)-3,6-Dimethoxy-3,6-dimethylcyclohexa-1,4-diene ((*E*)-**3***co*) was obtained by methylation of the methoxydienol (*E*)-**3***bo*. A mixture of freshly precipitated silver oxide (1.2 g), methyl iodide (4.5 cm^3), potassium hydroxide (0.03 g), and (*E*)-**3***bo* (0.30 g) was stirred at ambient temperature. The disappearance of the dienol (*E*)-**3***bo* was monitored by ^{1}H nmr and after 18 h, when none remained, the reaction mixture was filtered and the residue washed with ether (3 × 10 cm^3). The combined filtrate and washings were dried ($MgSO_4$) and the solvent evaporated at 30°C; ^{1}H nmr indicated that the solid residue (0.22 g) was essentially pure (*E*)-**3***co*. Crystals were obtained from pentane and a sample was sublimed at 40–60°C and had ir (KBr): 2820 (OCH_3), 1080 (C—O), 780 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.29 (s, 6, 3-C*H*$_3$ and 6-C*H*$_3$), 3.03 (s, 6, 3-OC*H*$_3$ and 6-OC*H*$_3$), 5.75 (s, 4, 1-*H*, 2-*H*, 4-*H*, 5-*H*) ppm; ^{13}C nmr ($CDCl_3$, −10°C) δ_C: 27.6 (3-*C*H$_3$ and 6-*C*H$_3$), 51.6 (3-O*C*H$_3$ and 6-O*C*H$_3$), 71.0 (*C*-3 and *C*-6), 134.1 (*C*-1, *C*-2, *C*-4, *C*-5) ppm; ms (70 eV) *m/e* (relative intensity): 168 (0.5, *M*), 153.085 (100, M_r $^{12}C_9{}^1H_{13}{}^{16}O_2$: 153.092, *M* − CH_3), 137 (94), 122 (62), 121 (13), 105 (19), 91 (46), 79 (22), 78 (12), 77 (39), 65 (16), 53 (13), 51 (20), 43 (38). *Anal.* calcd. for $C_{10}H_{16}O_2$: C 71.39, H 9.59; found: C 71.20, H 9.61.

Similar methylation of the dienol (*Z*)-**3***bo* for 34 h gave (*Z*)-3,6-dimethoxy-3,6-dimethylcyclohexa-1,4-diene ((*Z*)-**3***co*) in essentially quantitative yield. The dimethoxydiene was also prepared by methyla-

tion of the dienediol (*Z*)-**3***bn* (0.8 g) by stirring with a mixture of methyl iodide (27 cm^3), potassium hydroxide (0.165 g), and silver oxide (14 g added in 1–3 g portions over the reaction period) for 8 days. After work-up, ^1H nmr showed that the residue consisted of (*Z*)-**3***co* (92%) and (*Z*)-**3***bo* (8%). Sublimation at 60–70°C gave colourless plates of (*Z*)-**3***co*, mp 56°C (with sublimation); ir (KBr): 2820 (OCH_3), 1090 (C—O), 800 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.23 (s, 6, 3-CH_3 and 6-CH_3), 3.15 (s, 6, 3-OCH_3 and 6-OCH_3), 5.82 (s, 4, 1-*H*, 2-*H*, 4-*H*, 5-*H*) ppm; ^{13}C nmr ($CDCl_3$, −10°C) δ_C: 28.4 (3-*C*H_3 and 6-*C*H_3), 52.3 (3-O*C*H_3 and 6-O*C*H_3), 70.9 (*C*-3 and *C*-6), 134.0 (*C*-1, *C*-2, *C*-4 and *C*-5) ppm; ms (70 eV) *m/e* (relative intensity): 168 (0.3), 153.091 (100, M_r $^{12}C_9{}^1H_{13}{}^{16}O_2$: 153.092, $M - CH_3$), 138 (31), 137 (97), 123 (13), 122 (51), 121 (13), 107 (10), 106 (16), 105 (17), 91 (41), 79 (26), 78 (14), 77 (43), 65 (19), 53 (19), 52 (13), 51 (25), 43 (63), 41 (25). *Anal.* calcd. for $C_{10}H_{16}O_2$: C 71.39, H 9.59; found: C 70.93, H 9.47.

*Shift reagent studies on the diastereomers of 4-methoxy-1,4-dimethylcyclohexa-2,5-dienol (***3**bo*)*

A solution of Eu($[^2H_9]$fod)$_3$ (150 mg) in [^{2}H]chloroform (450 mm^3) was prepared and measured volumes were added, at 0°C, to solutions of the methoxydienols (*E*)-**3***bo* and (*Z*)-**3***bo* (30 mg) in [^{2}H]chloroform (300 mm^3) containing tetramethylsilane (20 mm^3). The ^1H nmr of each solution was measured at 0°C after addition of the shift reagent. Plots of the chemical shifts of the other protons against that of the 1-CH_3 protons gave relative shift gradients (gradient 1-CH_3 = 1.00) as follows: (*E*)-**3***bo*: 0.34 (4-CH_3), 0.35 (4-OCH_3), 0.45 (3-*H* and 5-*H*), 1.06 (2-*H* and 6-*H*); (*Z*)-**3***bo*: 0.31 (4-CH_3), 0.35 (4-OCH_3), 0.43 (3-*H* and 5-*H*), 1.02 (2-*H* and 6-*H*).

*Solvolysis of (*E*)-1,4-dimethyl-4-nitrocyclohexadienol ((*E*)-**1**b) in aqueous methanol*

Initial experiments (101–118) were carried out using (*E*)-**1***b* (100 mg, 0.6 mmol) in aqueous methanol (1:1 v/v, 8 cm^3), in both the presence and absence of a weak base, and at both ambient temperature and 40°C. These reactions were not stirred, as the nitrodienol appeared to dissolve completely. The products were worked up by first saturating the reaction mixture with sodium chloride, extracting with ether (3 × 20 cm^3), and washing the combined ether layers with saturated brine (3 × 10 cm^3). The ethereal solution was dried ($MgSO_4$) and the ether evaporated; ^1H nmr analysis ($CDCl_3$; 0°C) gave the results listed in Table 1.

Generally, integration of characteristic methyl peaks was the preferred means of determining the product ratios. The methyl peaks of 2-nitro-*p*-xylene were clearly separated from those of the dimethylphenols and the product dienes **3***bn* and **3***bo*. The C-CH_3 peaks of **3***bn* and **3***bo* overlapped but the total integral could be subdivided using the O-CH_3 peak to measure the amount of **3***bo*. In some cases, e.g. when *N*,*N*-diisopropylethylamine was used, the methyl region was partially obscured and the ratio of (**3***bn* + **3***bo*):**6***p*:(**7***b* + **6***n*) was determined from the integral of the vinyl and aromatic regions of the ^1H nmr spectrum. In subsequent experiments (below) the ratio of **7***b* to **6***n* was determined by analytical hplc. Careful examination of the aromatic phenol region of the ^1H nmr of mixtures of known phenol composition showed that it was possible to determine the ratio of **7***b*:**6***n* by ^1H nmr using solutions of known composition for standardization. The (*E*) isomer of the dienediol **3***bn* was not completely soluble in $CDCl_3$ and in later experiments [$^2H_6$]dimethylsulfoxide was the preferred solvent for ^1H nmr.

In the second set of experiments (201–205) a solution of (*E*)-**1***b* (1.0 g, 5.9 mmol) in aqueous methanol (1:1 v/v, 80 cm^3) was stirred at 40°C for 1 h. In most reactions a weak base was added. Each reaction mixture was worked up by cooling to 0°C, saturating the solution with sodium chloride, and extracting with cold ether (3 × 100 cm^3). The combined ethereal extracts were washed with brine (3 × 50 cm^3) and dried ($MgSO_4$). The ether was evaporated at 30°C and final traces of ether were removed under reduced pressure. Analysis was carried out by ^1H nmr using $(CD_3)_2CO$, $(CD_3)_2SO$, or $CDCl_3$ as solvent. The ratio of 2,4- to 2,5-dimethylphenol was determined by hplc. The peaks of the phenols overlapped and the amounts of each were determined by cutting and weighing the peaks, having first calibrated the system using solutions of known phenol ratios prepared from pure phenols. Results are listed in Table 2 (expts. 201–205).

In the third set of experiments (206–217) a solution of (*E*)-**1***b* (100 mg, 0.6 mmol) in aqueous methanol (1:1 v/v, 2 cm^3), also containing added reagent, was maintained at 40°C in an ultrasonic bath for 20 min. Ether (50 cm^3) was added and the solution dried, first over sodium sulfate and then over magnesium sulfate. The drying agents were washed with ether and the combined ether solution evaporated at 30°C. Analysis was carried out by ^1H nmr. The ratio of 2,4- to 2,5-dimethylphenol was determined by analytical hplc, or by nmr using the nmr of reaction mixtures in which the phenol ratio had previously been determined by analytical hplc as standards. Results are given in Table 2. Experiments 206–216 were carried out under the most carefully controlled conditions and using refined methods of product analysis. Of the reactions carried out in the presence of base, expts. 209–211, 214, and 215 were without complication and the results may be regarded as particularly reliable. Experiments 208, 212, and 216 are of less, but acceptable, reliability. Reaction 207 was complicated by the insolubility of the base disodium hydrogen phosphate and reaction 213 did not go to completion. The mean product distribution from the particularly reliable set of experiments is **3***bo* (44%), **3***bn* (22%), **6***p* (20%), **7***b* (11%), and **6***n* (2%) and from the particularly reliable plus reliable sets is **3***bo* (43%), **3***bn* (21%), **6***p* (18%), **7***b* (15%), and **6***n* (3%).[2]

A solvolysis reaction was also carried out under acid conditions. (*E*)-**1***b* (0.07 g, 0.4 mmol) was added to aqueous methanol (1:1 v/v, 10 cm^3) containing potassium chloride (7.5 mg, 1 mmol) after the pH of the solution had been adjusted to 3.2 by the addition of hydrochloric acid. The solution was stirred at ambient temperature for 22 h. The product, obtained after work-up as described above for expts. 101–118, contained (^1H nmr) dimethoxydienes (12%) and a mixture of aromatic compounds (88%) including dimethylanisoles, dimethylphenols, and, tentatively, dimethylnitrophenol(s).

In a larger-scale reaction (*E*)-**1***b* (3 g, 0.018 mol) was dissolved in aqueous methanol (1:1 v/v, 240 cm^3) and potassium acetate (1.9 g, 0.02 mol) was added. The solution was stirred at 40°C and then chilled. A sample (8 cm^3) was worked up to confirm completion of the solvolysis. The main reaction mixture was then saturated with salt, stirred for 5 min, and extracted with ether (3 × 200 cm^3). The combined ether layers were washed with brine (3 × 100 cm^3) and dried, first over sodium sulfate and then over magnesium sulfate. Evaporation of the ether at 30°C and removal of the final traces under reduced pressure gave an oil (2.4 g) that contained (by nmr) the methoxydienols **3***bo* (60%), dienediols **3***bn* (12%), dimethylphenols plus dimethylanisoles (16%), and 2-nitro-*p*-xylene (12%). Preparative hplc on silica and elution with ether gave four fractions, the first containing the aromatic compounds, the second was methoxydienol (*E*)-**3***bo*, the third its isomer (*Z*)-**3***bo* containing some (*E*)-**3***bo* (7%), and the fourth a mixture of (*Z*)-**3***bo* and the dienediols **3***bn*. Recrystallization of the second fraction from ether–pentane gave colourless crystals, mp 95–97°C (lit. (9) mp 94–95°C) with ^1H nmr identical to that of an authentic sample of (*E*)-**3***bo*. The ^1H nmr of the major component of the third fraction was identical to that of an authentic sample of (*Z*)-**3***bo*. Some crystals separated from the fourth fraction on standing. They were washed free of the oil with ether, dissolved in [$^2H_6$]acetone, and then had ^1H nmr identical to that of authentic (*E*)-**3***bn*.

*Solvolysis of (*E*)-**1**b in methanol*

A solution of (*E*)-**1***b* (70 mg, 0.41 mmol) and *N*,*N*-diisopropylethylamine (82 mm^3, 0.45 mmol) in CD_3OD (0.6 cm^3) was observed by nmr. Little or no reaction occurred over 1 h at 40°C. After 6 min at

[2]We have ignored the fact that the product distribution may be a function of the particular base used. The product distributions for reactions in which the same base was used are more closely similar than the product distributions for experiments involving different bases. However, such differences are small compared to those between reactions carried out with and without base. We have also ignored the likely presence of a small amount of **5***bn* and (or) **5***bo*.

60°C, formation of the two diastereomers of the methoxydienol **3***bo* was apparent. The reaction half-life at 60°C was 75 min and after 5.3 h the reaction mixture was worked up to give (^{1}H nmr) a mixture of **3***bo* (47%), dimethylphenols (17%), and 2-nitro-*p*-xylene (36%). A small amount of the dimethoxydiene **3***co* or dienediol **3***bn* was observed in the reaction mixture prior to work-up.

Solvolysis of (E)-**1**b *in aqueous tetrahydrofuran, aqueous ether, aqueous acetone, and aqueous dioxan*

The nitrodienol (100 mg, 0.59 mmol) was dissolved in the organic solvent, the requisite amount of water and the base were then added, and the solution stirred at the chosen temperature for the specified time. Work-up and ^{1}H nmr analysis gave the results summarized in Table 3.

Solvolysis was also carried out under acidic conditions in aqueous dioxan. The pH of the dioxan solution (1:1 v/v) containing potassium chloride was adjusted to 3.2 by the addition of hydrochloric acid. (*E*)-**1***b* was added and the mixture was stirred for 22 h at ambient temperature. After work-up, ^{1}H nmr indicated that aromatization was essentially complete and ^{1}H nmr and gc–ms indicated that the two major products were 2-nitro-*p*-xylene and dimethylnitrophenol.

In a larger-scale reaction a solution of (*E*)-**1***b* (10 g, 0.059 mol) in acetone (200 cm^3) and water (400 cm^3) containing *N*,*N*-diisopropylethylamine (11.7 cm^3, 0.065 mol) was stirred at 40°C for 1 h. The reaction mixture was saturated with salt, extracted with ether, and the combined ethereal extracts washed with brine, dried ($MgSO_4$), and the ether evaporated. The ^{1}H nmr analysis indicated that the mixture consisted of dienediol **3***bn* (35%), dimethylphenols (56%), and 2-nitro-*p*-xylene (10%). Addition of carbon tetrachloride gave colourless crystals of (*E*)-**3***bn* (0.7 g), which after recrystallization from acetone had mp 158–159°C; ir (KBr): 3370, 3330, 1125, and 1070 (OH), 1410 (C—CH_3), 780 (*cis* vinyl) cm^{-1}; ^{1}H nmr ($(CD_3)_2CO$, 0°C) δ: 1.18 (s, 6, 1-C*H*$_3$ and 4-C*H*$_3$), 3.02 (s, 2, 1-O*H* and 4-O*H*), 5.67 (s, 4, 2-*H*, 3-*H*, 5-*H*, and 6-*H*) ppm; ^{13}C nmr ($(CD_3)_2CO$) δ_C: 29.3 (1-*C*H$_3$ and 4-*C*H$_3$), 65.4 (*C*-1 and *C*-4), 133.9 (*C*-2, *C*-3, *C*-5, and *C*-6) ppm; ms (70 eV) *m/e* (relative intensity): 140 (1), 126 (17), 125.059 (100, M_r $^{12}C_7{}^1H_9{}^{16}O_2$: 125.060, $M - CH_3$), 124 (8), 122 (7), 111 (8), 110 (30), 108 (6), 107 (20), 106 (13), 105 (7), 97 (12), 91 (20), 79 (14), 77 (15). *Anal.* calcd. for $C_8H_{12}O_2$: C 68.55, H 8.63; found: C 68.62, H 8.61.

The carbon tetrachloride soluble extract contained 21% of dienes. After evaporation of the solvent a sample (5.5 g) of the residue was subjected to hplc on silica using ether eluant. The initial fraction (4.9 g) was a mixture of 2-nitro-*p*-xylene and dimethylphenols. The next fraction (0.19 g) was (*Z*)-**3***bn* containing a small amount of its (*E*) isomer and the final fraction (0.35 g) was a mixture containing **5***bn*. Purification by short-path distillation below 50°C at 50 Pa in a sublimator gave **5***bn* as an oil; ^{1}H nmr ($CDCl_3$, 270 MHz) δ: 1.29 (s, 3, 1-C*H*$_3$), 1.77 (t, 3, 4-C*H*$_3$), 2.81 (b, O*H*), 3.85 (bd, 1, 2-*H*), 5.61 (bd, 1, 3-*H*), 5.70 (dd, 1, J = 2, 10 Hz, 5-*H*), 5.75 (d, 1, J = 10 Hz, 6-*H*) ppm. In the 90-MHz spectrum, irradiation at 1.77 ppm collapsed the peaks at 3.85 and 5.61 to the doublets of an AB quartet (J = 4 Hz); irradiation at 3.85 collapsed the peak at 1.77 ppm to a doublet (J = 1.8 Hz) and sharpened the peak at 5.61 to an incompletely resolved quartet; irradiation at 5.61 collapsed the peak at 1.77 to an uneven doublet (J = 1.6 Hz) and sharpened the peak at 3.85 ppm to an incompletely resolved quartet.

Solvolysis of (E)-*3-methoxy-3,6-dimethyl-6-nitrocyclohexa-1,4-diene* ((E)-**1**c)

Solvolysis of (*E*)-**1***c* (100 mg, 0.55 mmol) was carried out for 5 h at 56°C in aqueous methanol (1:1 v/v, 8 cm^3) containing diisopropylethylamine (108 mm^3, 0.61 mmol). The substrate was not completely soluble. After work-up as described for expts. 101–118, the products obtained were (*E*)- and (*Z*)-**3***co* (21%), (*E*)- and (*Z*)-**3***cn* (34%), dimethylanisoles and dimethylphenols (41%), and 2-nitro-*p*-xylene (4%). The reaction was repeated at 40°C and at 25°C in the absence of added base. The reaction did not go to completion but a similar product distribution was obtained.

Reaction of (E)-**1**c *with methanol – trifluoroacetic acid*

Diene (*E*)-**1***c* (100 mg, 0.55 mmol) was dissolved in a mixture of methanol (250 mm^3) and trifluoroacetic acid (250 mm^3) at 0°C. After 16 h at 35°C aromatization was complete (^{1}H nmr). The solvent was evaporated and the residue was dissolved in ether (20 cm^3) and washed with aqueous sodium bicarbonate (3 × 10 cm^3) and water (10 cm^3). After drying ($MgSO_4$) the ether was evaporated to give an oil (55 mg) containing 2,4-dimethylanisole (16%), 2,5-dimethylanisole (34%), and 2-nitro-*p*-xylene (50%). Analysis by glc (10% FFAP) confirmed the presence of dimethylanisoles (single peak) and the 2-nitro-*p*-xylene. Similar results were obtained when the reaction was repeated at ambient temperature for 100 h.

Solvolysis of (E)-*1,4-dimethyl-4-nitrocyclohexa-2,5-dienyl acetate* ((E-**1**a)

Acetate (*E*)-**1***a* (100 mg, 0.47 mmol) was dissolved in aqueous methanol (1:1 v/v, 8 cm^3) and the mixture stirred at ambient temperature for 2 h. The reaction was worked up as described for expts. 101–118. 2,5-Dimethylphenyl acetate (47 mg) was the sole product (^{1}H nmr). The same result was obtained when the reaction was carried out for 1 h at 40°C. The reaction was also carried out in the presence of added base (diisopropylethylamine, potassium acetate) when partial solvolysis of the 2,5-dimethylphenyl acetate to 2,5-dimethylphenol occurred. A control experiment showed that 2,5-dimethylphenyl acetate was solvolysed to the phenol under these conditions. Any acetoxydienol formation could not have exceeded 3% of the product.

Solvolysis of 4-methyl-4-nitrocyclohexa-2,5-dien-1-ol

The nitrodienol (100 mg, 0.65 mmol) was weighed into a chilled flask and aqueous methanol (1:1 v/v, 2 cm^3), at −10°C, and sodium bicarbonate (57 mg, 0.68 mmol) were added. The mixture was heated in an ultrasonic bath at 40°C for 20 min. Ether (50 cm^3) was added, the solution dried over Na_2SO_4 and then over $MgSO_4$, and the solvent evaporated to give an oil (51 mg) consisting of *p*-cresol (90%) and unidentified dienes (δ: 1.57 and 5.95 ppm, 10%). Solvolysis was also carried out on a 0.16-mmol scale in D_2O–CD_3OD (1:1) containing C_5D_5N (0.18 mmol) and the reaction monitored by ^{1}H nmr. Again *p*-cresol (90%) and unidentified dienes (10%) were obtained. The half-life of **10** was 50 min at −10°C and 10 min at 0°C. When the solvolysis was carried out in acetone–water (1:2 v/v) containing sodium bicarbonate, *p*-cresol (90%) and unidentified diene (10%) were formed.

Rates of solvolysis of (E)-**1**a *and* (E)-**1**b

The diene (0.3 mmol) was dissolved in CD_3OD (1 cm^3) at 0°C, and cold D_2O (1 cm^3) and C_5D_5N (27 mm^3, 0.33 mmol) were added. A sample of the solution was quickly transferred to a nmr tube and the FT ^{1}H nmr spectrum observed (50 scans per spectrum) at the desired temperature. The time taken for the integral of the aliphatic methyl region to decrease to half of the original intensity was determined from a first-order plot. For (*E*)-**1***a*, $t_{1/2}$ = 2.5 min at 40°C and 75 min at 27°C. For (*E*)-**1***b*, $t_{1/2}$ = 5.5 min at 40°C and 210 min at 27°C.

Reaction of (E)-*1,4-dimethylcyclohexa-2,5-diene-1,4-diol* ((E)-**3**bn) *with trifluoroacetic acid*

The dienediol (*E*)-**3***bn* (40 mg) was dissolved in trifluoroacetic acid (0.5 cm^3) at 0°C in an nmr tube. After 15 min at 0°C and 10 min at 38°C, ^{1}H nmr indicated that aromatization was complete and that the product was largely 2,4-dimethylphenol. The same result was obtained when the experiment was repeated using (*E*)-**3***bn* (50 mg) in trifluoroacetic acid (1 cm^3) and allowing the solution to stand at ambient temperature for 1.5 h. The product phenol was isolated by neutralization of the trifluoroacetic acid with sodium bicarbonate solution and extraction with ether. The ^{1}H nmr of the isolated products from the two reactions confirmed that 2,4-dimethylphenol was the predominant product. Each reaction product was treated with bistrimethylsilylacetamide and the resulting mixtures of trimethylsilyloxydimethylbenzenes analysed by glc: the product from each reaction was determined to be trimethylsilyloxy-2,4-dimethylbenzene (98%) and trimethylsilyloxy-2,5-dimethylbenzene (2%).

Reaction of (E)-**3**bn *with dilute acid*

(*E*)-**3***bn* was solvolysed at 50°C for 5 h and at ambient temperature for 72 h, in aqueous methanol at pH 3.2, as described for (*E*)-**1***b*. After

work-up and ^{1}H nmr measurement, the ratio of dimethylphenols was determined by addition of bistrimethylsilylacetamide and analysis by glc: 2,4- (68%) and 2,5-dimethylphenol (32%) were the only products. In a second experiment, in which the mixture was heated for 21 h at 40°C, aromatization was not complete; ^{1}H nmr and glc–ms confirmed the presence of (*E*)-**3***co* (4%), (*Z*)-**3***co* (4%), (*E*)- and (*Z*)-**3***bo* (4%), **7***b* (55%), **6***n* (22.5%), and **6***o* plus **7***o* (10.5%). Solvolysis of (*E*)-**3***bn*, at ambient temperature for 26 h, was also carried out in aqueous dioxane at pH 3.2. Silylation and glc analysis gave the product distributions **7***b* (68.5%), **6***n* (31.5%) and **7***b* (64.4%), **6***n* (35.6%) in duplicate experiments.

Reaction of (Z)-3,6-dimethoxy-3,6-dimethylcyclohexa-1,4-diene ((Z)-3co) with trifluoroacetic acid

The ether (*Z*)-**3***co* (31 mg) was dissolved in trifluoroacetic acid (0.5 cm^3) and the reaction was monitored by ^{1}H nmr over 1 h, after which time rearomatization was complete. The nmr spectrum showed that 2,4-dimethylanisole was formed.

Mechanism of azo coupling reactions. Part 34.[1] Reactivity of five-membered ring heteroaromatic diazonium ions

HEINZ DIENER AND HEINRICH ZOLLINGER
Technisch-Chemisches Laboratorium, Eidgenössische Technische Hochschule, CH-8092 Zurich, Switzerland
Received October 15, 1985

This paper is dedicated to Professor Arthur N. Bourns

HEINZ DIENER and HEINRICH ZOLLINGER. Can. J. Chem. **64**, 1102 (1986).

The azo coupling reactions of six five-membered ring heteroaromatic diazonium ions with 2-naphthol-3,6-disulfonic acid are investigated kinetically at various pH values. The dependence of the measured rate constants on the acidity of the aqueous reaction system is evaluated. It can be shown that the 2-naphtholate-3,6-disulfonate trianion reacts $4 \times 10^8 - 8 \times 10^8$ times faster than the 2-naphthol-3,6-disulfonate dianion. The rate constants of the six diazonium ions vary by more than four orders of magnitude. The logarithms of the rate constants of all comparable diazonium ions correlate linearly with ^{1}H nmr chemical shifts of the respective unsubstituted heteroaromatic parent compounds. An analogous correlation was found for azo couplings with substituted benzenediazonium ions. Diazotization of heteroaromatic amines does not go to completion, rather to an equilibrium. It is shown therefore that in acidic coupling systems the azo compound is only the kinetically controlled product. The thermodynamic products are 1-nitroso-2-naphthol-3,6-disulfonic acid and the heteroaromatic amine.

HEINZ DIENER et HEINRICH ZOLLINGER. Can. J. Chem. **64**, 1102 (1986).

Opérant à divers pH, on a étudié la cinétique de réactions de couplage azo entre six ions diazonium d'hétérocycles aromatiques à cinq chaînons et l'acide naphtol-2 disulfonique-3,6. On a évalué la dépendance des constantes de vitesses mesurées sur l'acidité du système aqueux de la réaction. On peut démontrer que le trianion naphtolate-2 disulfonate-3,6 réagit de 4×10^8 à 8×10^8 plus rapidement que le dianion naphtol-2 disulfonate-3,6. Les constantes de vitesse pour les six ions diazonium varient par plus de quatre ordres de grandeurs. Il existe une corrélation linéaire entre les constantes de vitesse de tous les ions diazonium comparables et les déplacements chimiques en rmn du ^{1}H des composés hétéroaromatiques de base qui ne sont pas substitués. On a pu établir une corrélation analogue pour les couplages azo avec des ions benzènediazonium substitués. La réaction de diazotation des amines hétéroaromatiques n'est pas complète; il s'agit plutôt d'un équilibre. On démontre alors que, dans les systèmes de couplages acides, les composés azo ne sont que les produits de contrôle cinétique. Les produits de contrôle thermodynamique sont l'acide nitroso-1 naphtol-2 disulfonique-3,6 et l'amine hétéroaromatique.

[Traduit par la revue]

Introduction

In contrast to the large number of investigations of the reactivity of carboaromatic diazonium ions in general and of the mechanism of their azo coupling reactions, very few comparable investigations have been made with heteroaromatic diazonium ions. Goerdeler and Haubrich (2) have made a semiquantitative comparison of the reactivity of 3-phenyl-1,2,4-thiadiazole-5-diazonium ion with 2-naphthol and the respective reaction with 2,4-dinitrobenzenediazonium ion. Sawaguchi *et al.* (3) have measured the rate of azo coupling of various heteroaromatic diazonium ions with 2-naphthol-3,6-disulfonic acid. There exists an extensive patent literature on azo dyes synthesized with heteroaromatic diazonium ions since Dickey and Towne realized in the early 1950s that industrially interesting disperse dyes can be obtained on this basis. Weaver and Shuttleworth (4) have reviewed that subject, but give no information on reactivities and yields.

Relations between the structure of heteroaromatic parent compounds and the reactivity of the respective diazonium ions have not been investigated in the past. The goal of this investigation is the measurement of the rates of azo coupling reactions of a series of five-membered ring heteroaromatic diazonium ions with the tri- and, if possible, the di-basic anion of 2-naphthol-3,6-disulfonic acid, and the correlation of the kinetic results with the chemical shift in ^{1}H nmr of the heteroaromatic compound that contains a hydrogen atom instead of the diazonio group. In addition, 1-nitroso-2-naphthol-3,6-disulfonic acid was identified as a by-product, as it is known that the yields of azo coupling reactions with heteroaromatic diazonium ions are in most cases significantly lower than those with carboaromatic diazonium ions.

The diazonium ions of the following amines were included in this investigation: thiazole-2-, -4-, and -5-diazonium ions (**1**, **2** and **3**), 1,2,4-thiadiazole-5-diazonium ion (**4**), 1,3,4-thiadiazole-2-diazonium ion (**5**), and 1,3,4-triazole-2-diazonium ion (**6**).

4 **5** **6**

Experimental and kinetic results

The diazonium ions **1**–**6** were obtained by diazotization of the respective amines. For *2-aminothiazole* the synthesis of Traumann (5) was used.

4-Aminothiazole was synthesized from chloroacetonitrile and sodium thiocyanate, which form cyanomethylthiocyanate (NC—CH_2—S—CN). This compound was cyclized to 2-bromo-4-aminothiazole hydrobromide with HBr following a procedure described by Johnson and Nasutavicus (6). For the debromination of 2-bromo-4-aminothiazole the amino group has to be protected by acylation. Johnson and Nasutavicus used acetic anhydride for this purpose. We obtained

[1]Part 33: Kaminski *et al.* (1).

insufficient yields by using their procedure. Therefore we acylated with trifluoroacetanhydride: 28.6 g (0.11 mol) 2-bromo-4-aminothiazole hydrobromide was added in four batches to 75 g (0.36 mol) trifluoroacetanhydride. After 1 h at room temperature the solution was evaporated *in vacuo*. Yield: 34,75 g (81%) of the 1:1 addition product of 2-bromo-4-trifluoroacetamidothiazole with trifluoroacetic acid. Of this, 31.0 g were dissolved in 125 mL EtOH and purified on 80 g Amberlite IRC-50 (pretreated with 2 *M* NaOH and washed with 2 L water and afterwards with 200 mL ethanol). Afterwards, the EtOH solution was extracted with 150 mL hexane and treated at the boiling temperature with 0.5 g charcoal. After filtration and cooling, colorless needles precipitated, 16.78 g (76.6%) 2-bromo-4-trifluoroacetamidothiazole, mp 58°C; 16.78 g (61 mmol) of this product was debrominated with H_2 at normal pressure in a solution of 7.30 g (89 mmol) NaOAc in 500 mL absolute EtOH in the presence of 3 g Pd on coal (10%). After 6 h the filtrate was evaporated. The residue was extracted with warm CH_2Cl_2 and recrystallized from EtOH, 8.11 g (67.8%) 4-trifluoroacetamidothiazole, mp 139°C. *Anal.* calcd. for $C_5H_3N_2OSF_3$ (196.15): C 30.62, H 1.54, N 14.28%; found: C 30.57, H 1.65, N 14.31%. Then 392 mg (2 mmol) 4-trifluoroacetamidothiazole was dissolved in 3 mL water and 0.25 mL 50% NaOH. After 6 h at 35°C under Ar the solution was cooled in an ice bath and glacial acetic acid was added to pH 8. Water was evaporated under rotation at 40°C in an Ar atmosphere. The residue was distilled at 0.01 Torr/85°C (1 Torr = 133.3 Pa). We obtained a colorless oil that crystallized out at deep-freezer temperatures, 42 mg (21%). The melting point was not determined because the product rapidly became black. *Anal.* calcd. for $C_3H_4N_2S$ (100.14): C 35.98, H 4.03, N 27.97%; found: c 35.69, H 4.01, N 27.74%.

5-Aminothiazole was synthesized from aminoacetonitrile. Reaction with formic acid ethyl ester gave *N*-cyanomethylacetamide, as described by Sekiya and Osaki (7). As we were not successful in following the procedure of these authors for the next step, namely the addition of H_2S at the cyano group in order to form 2-formamido-thioacetamide, we used the method described by Sen *et al.* (8), in which gaseous H_2S was introduced into a pyridine solution of the substrate. As we did not obtain the desired product, rather again the substrate after evaporation at normal pressure, we evaporated the solvent *in vacuo* and did not purify the residue, but made the cyclocondensation to 5-aminothiazole directly with the help of $POCl_3$ as described by Masui and Tamura (9): 18.79 g raw 2-formamidothioacetamide gave 1.32 g 5-aminothiazole, which was chromatographed ($CHCl_3/CH_3OH$ 9:1, Kieselgel) and recrystallized from isopropanol under Ar, 0.537 g (3.5%) colorless crystals, mp 81°C (dec.). *Anal.* calcd. for $C_3H_4N_2S$ (100.14): C 35.98, H 4.03, N 27.97%; found: C 35.80, H 4.13, N 27.74%.

5-Amino-1,2,4- and *2-amino-1,3,4-thiadiazole* were synthesized by the methods of Goerdeler (10) and Stolle and Fehrenbach (11), respectively.

2-Amino-1,3,4-triazole: Fluka product, puriss; mp 154–155°C. *Anal.* calcd. for $C_2H_4N_4$ (84.08): C 28.57, H 4.80, N 66.63%; found: C 28.62, H 4.82, N 66.48%.

Methods of diazotization and azo coupling

After comparative studies of various methods, we used the following two procedures, which gave the best results with our amines **1–6**.

Method A: 1.0 mmol amine was dissolved in 5 mL 72% H_2SO_4 and diazotized by addition of 1.0 mmol powdered $NaNO_2$ at −10°C. After 1 h the solution was diluted to 50 mL with 72% H_2SO_4. For preparative azo coupling reactions 1 mmol of 2-naphthol-3,6-disulfonic acid (disodium salt, purified, containing 9% crystal water) was added. After 1 h the solution was carefully neutralized with Na_2CO_3. The precipitate consisted of a mixture of the azo compound, Na_2SO_4, and the products of decomposition, which were separated by preparative paper chromatography (*n*-butanol/ethanol/water 4:3:3). The colored zone on the paper was cut out and the azo compond extracted with water. Yields were low (1 to 5% pure azo compound). For kinetic measurements a 5-μL droplet of the diazo solution was put on the Teflon stopper of an uv cell that contained 3.0 mL buffer solution and 50 μL 0.211 *M* solution of 2-naphthol-3,6-disulfonic acid. The reaction was started by the shaking of the cell. Initial concentrations: 2-naphthol-3,6-disulfonic acid, 3.52×10^{-3} *M*; diazonium salt, 3.33×10^{-5} *M* (or lower).

Mean value (μ)		1.37±0.18[c]	

[a]Diazotization method A in 72% H_2SO_4; λ_{max} of azo compound: 486 nm.
[b]30% H_2SO_4 ($H_0 = -1.72$).
[c]95% confidence limits: $1.19 \times 10^8 < \mu < 1.55 \times 10^8$.

Method B: 1.0 mmol amine was dissolved in 1.0 mL 50% or 90% H_2SO_4 and diazotized at −10°C with 1.0 mL 1 *M* nitrosyl sulfuric acid (50% or 90% H_2SO_4). This solution was used directly for reactions on a preparative scale as described for method A. For kinetic measurements a 50-mL volumetric flask was filled with buffer and 100 μL of a 0.25 *M* solution of 2-naphthol-3,6-disulfonic acid and thermostatted. The diazo solution (5–20 μL) was dropped on the stopper. The volumetric flask was sealed with the stopper and the reaction was started by shaking. Afterwards a sample of the reacting solution was transferred into a quartz cell for spectrophotometric analysis. Initial concentrations: 2-naphthol-3,6-disulfonic acid, 5.00×10^{-4} *M*; diazo solution, $1.25–5.00 \times 10^{-5}$ *M*.

Method C: Due to the very low stability of 4-aminothiazole, the following procedure was used for diazotization: 0.196 g (1 mmol) 4-trifluoroacetamidothiazole was dissolved in 1.5 mL water by adding 0.125 mL 50% NaOH. The solution was stirred under Ar at room temperature for 24 h. After cooling to −10°C we added dropwise 2.5 mL (4.59) 96% H_2SO_4. This yielded a solution of 4-aminothiazole in 72% H_2SO_4. It was diazotized by adding 1.0 mL of 1 *M* nitrosylsulfuric acid (72% H_2SO_4) at −10°C.

Kinetic measurements were made in thermostatted 1.0-cm cells at 20.0 ± 0.1°C. Based on eq. [1], pseudo-first-order rate constants (k_{ps}) were obtained by linear regression from plots of $-\ln(A_\infty - A_t)$ against time (A_∞, A_t = optical density at the visible absorption maximum λ_{max} of the azo compound formed at times $t = \infty$, i.e. at least 10 half-life times, and t). All rate constants are mean values of the rate constants determined in three independent runs. Buffer solutions were made on the basis of the CRC Handbook (12).

$$[1] \quad -\ln(A_\infty - A_t) = k_{ps}t + C$$

Equation [1] has the advantage that k_{ps} can be determined without knowing the molar extinction coefficient of the azo compound at λ_{max}. The second-order rate constant is calculated as usual (13). Due to the high reactivity of the diazonium ions used and the relatively low pH values of the reacting solution (pH 1.72–5.97, see Results), the reaction rate consists of the sum of two independent reactions, namely that of the 2-naphtholate-3,6-disulfonate trianion RO^- (k_1) and that of the 2-naphthol-3,6-disulfonate dianion ROH (k_2). Equation [2] shows that by plotting log k_{ps} against pH, a straight line with a slope of 1.0 ± 0.1 is obtained if the reaction with RO^- is dominant. If $k_2[ROH] \gg k_1[RO^-]$ the overall rate is independent of pH.

$$[2] \quad \frac{d[Azo]}{dt} = k_{ps}[D] = k_1[RO^-][D] + k_2[ROH][D]$$

where D = diazonium ion. $[RO^-]$ and [ROH] were calculated as usual with the help of the acidity constant of the OH group of the coupling component: $pK_3 = 9.76$. This constant was calculated from data of Hashida *et al.* (14) for the ionic strength ($I = 0.08–0.10$) used in our experiments except for azo couplings of thiazole-2-diazonium (Table 1), which were run at $I = 0.20–0.25$. We determined $pK_3 = 9.40$ at this ionic strength. Results are given in Tables 1–6.

50	(2.62±0.32) × 10^{-3}	5.25±0.65

[a]Diazotization method B in 90% H_2SO_4; λ_{max} of azo compound: 541 nm.
[b]$k_2 = k_{sp}/[ROH]$; $k_1[RO^-] \ll k_2[ROH]$. Štěrba and co-workers (19) and we (this paper) found ratios of reactivities of 2-naphtholate-3,6-disulfonate dianion $k_1/k_2 = 5.69 \times 10^8 - 7.94 \times 10^8$. Therefore we can calculate approximately k_1 for the azo coupling reaction of 1,2,4-thiadiazole-5-diazonium ion, based on k_2 in 30% H_2SO_4: $k_1 \cong 5.4 \times 10^9\ L\ mol^{-1}\ s^{-1}$.

TABLE 5. Azo couplings of 1,3,4-thiazole-2-diazonium ion[a]

% H_2SO_4	k_{ps}[b] (s^{-1})	k_2[c] ($L\,mol^{-1}\,s^{-1}$)
30	(1.87±0.13) × 10^{-3}	3.74±0.26
50	(5.33±0.85) × 10^{-4}	1.07±0.17

[a]Diazotization method B in 50% H_2SO_4; λ_{max} of azo compound: 544 nm.
[b]Calculated on the basis of initial rates.
[c]See footnote *b* of Table 4, $k_1 \cong 2.7 \times 10^9\ L\ mol^{-1}\ s^{-1}$.

In the azo coupling of the 1,3,4-thiadiazole-2-diazonium ion in 50% H_2SO_4 one observes that the absorption at $\lambda_{max} = 544$ nm goes through a maximum at approximately 1 h and decreases asymptotically thereafter (Fig. 1). Simultaneously, the optical density at 380 nm increases. This secondary band corresponds to the absortion maximum of 1-nitroso-2-naphthol-3,6-disulfonic acid. Pure 1-(1′,3′,4′-thiazolyl-2′-diazo)-2-naphthol-3,6-disulfonic acid in 50% H_2SO_4 solution shows the same

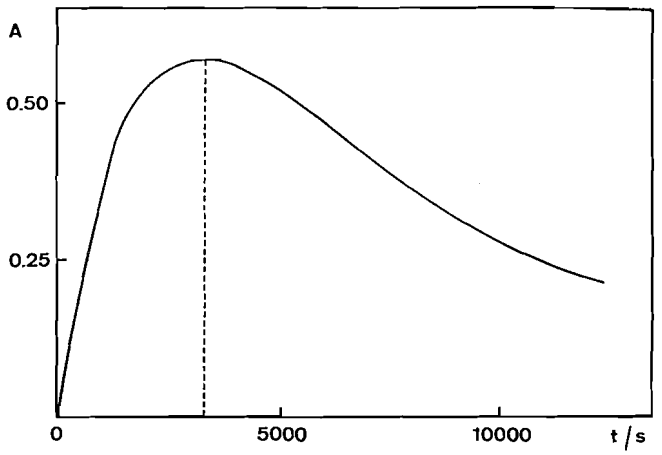

FIG. 1. Absorption of a mixture of the 1,3,4-thiadiazole-5-diazonium ion and 2-naphthol-3,6-disulfonic acid in 50% H_2SO_4 at 544 nm as a function of time.

decrease and increase, respectively, at the 544-nm and 380-nm bands, respectively. From such an experiment the rate of the retro-azo coupling reaction, i.e. the substitution of the heteroaryldiazo group by a proton, can be calculated: $k = (1.03 \pm 0.10) \times 10^{-4}\ s^{-1}$ (mean value of 3 measurements), 95% confidence limits; $0.92 \times 10^{-4} < \mu < 1.14 \times 10^{-4}\ s^{-1}$.

Discussion

The pseudo-first-order rate constants (k_{ps}) of the azo coupling reactions of the diazonium ions of six five-membered ring heteroaromatic amines with 2-naphthol-3,6-disulfonic acid show the typical dependence on the acidity of the aqueous solvent system that is known from respective investigations of carboaromatic diazonium ions with naphthols. The classical case is shown in Fig. 2 for the azo coupling of the thiazole-5-diazonium ion for the pH range 4–6: the measured values for log k_{ps} increase proportionally to pH, i.e. the rate is linearly dependent on the concentration of hydroxyl ions and therefore also linearly dependent on the concentration of the naphtholate ion (RO^-). It is the naphtholate ion that reacts with the diazonium ion (see ref. 13 and reviews (15, 16)).

Figure 3 demonstrates that the pH dependence of the azo coupling reaction of the thiazole-2-diazonium ion is in part different from that of the 5-isomer: the logarithm of the rate constant k_{ps} shows a linear dependence on pH with a slope of 1 only above pH 1. At lower pH values the curve gradually becomes horizontal. A similar figure results if our results with the 4-isomer are plotted. This is consistent with a dominant reaction of the naphthol relative to that of the naphtholate in the pH range below 0.5 ($k_2[ROH] > k_1[RO^-]$, because $[ROH] \gg [RO^-]$): in eq. [2] the first term can be neglected due to the ex-

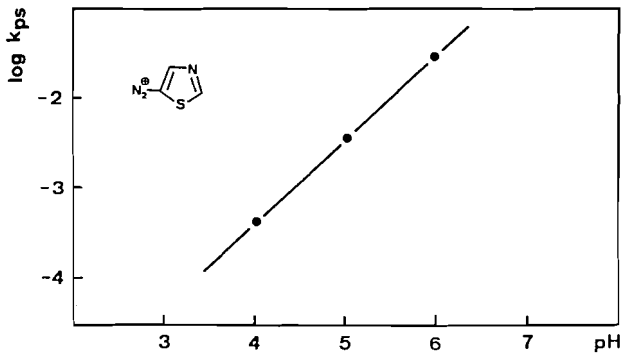

FIG. 2. Rate of azo coupling of the thiazole-5-diazonium ion with 2-naphthol-3,6-disulfonic acid as a function of acidity.

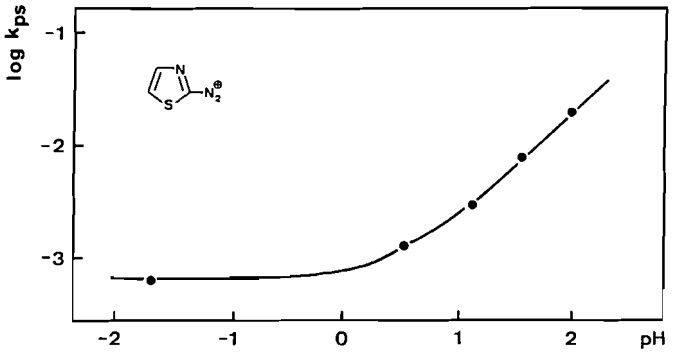

FIG. 3. Rate of azo coupling of a mixture of the thiazole-5-diazonium ion and 2-naphthol-3,6-disulfonic acid as a function of acidity.

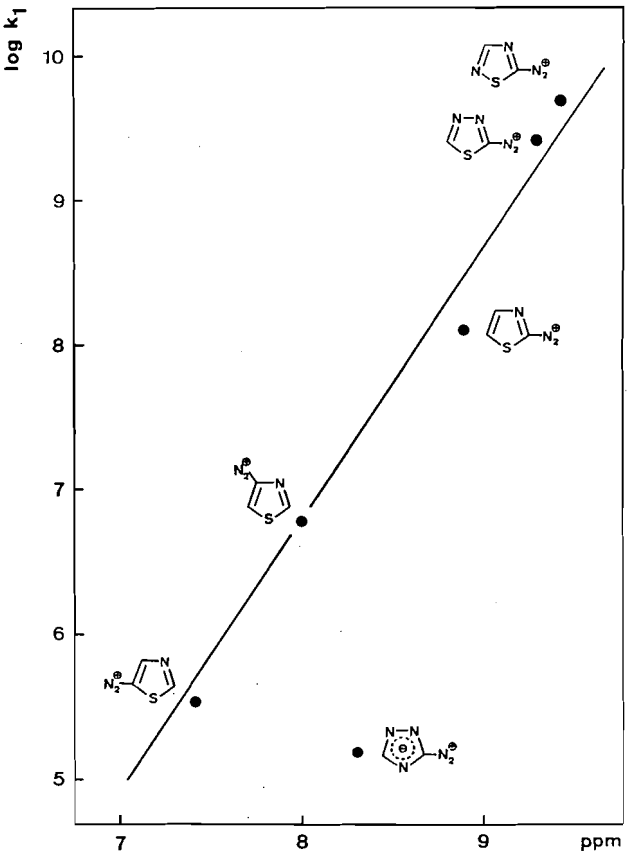

FIG. 4. Correlation between azo coupling rates of heteroaromatic diazonium ions with 2-naphtholate-3,6-disulfonate trianion and the chemical shifts of protons at the position of the diazonio group in ^{1}H nmr spectra of the respective heteroaromatic parent compound (nmr data from refs. 20 and 21).

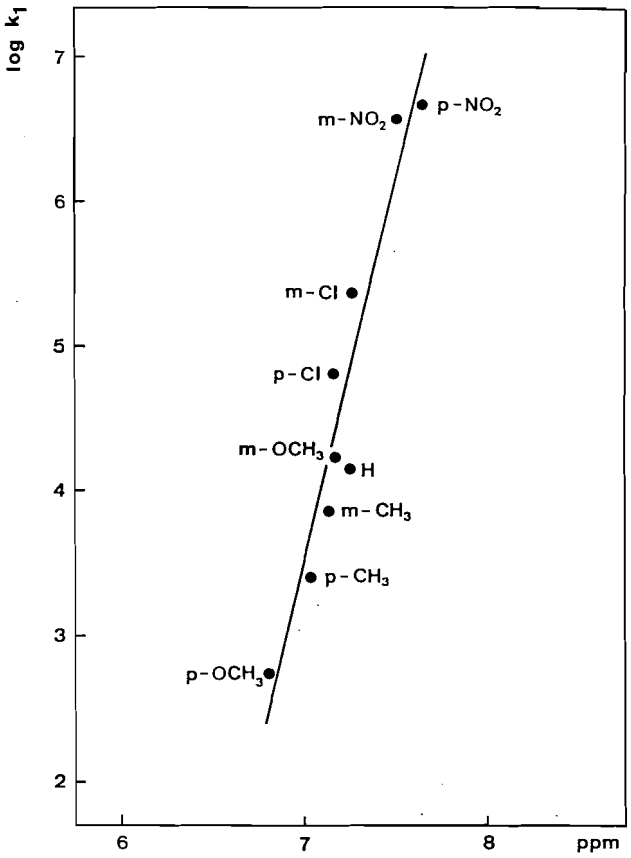

FIG. 5. Correlation between azo coupling rates of substituted benzenediazonium ions with the 2-naphtholate-3,6-disulfonate trianion (from ref. 15, p. 241) and the chemical shifts of protons at the position of the diazonio group in ^{1}H nmr spectra of the respective monosubstituted benzenes (nmr data from ref. 20).

tremely low numerical value of [RO^-]. For example, at pH 0, the equilibrium concentration of the naphtholate is $10^{9.76}$ times lower than that of the naphthol. An analogous pH dependence is expected for the thiazole-2-diazonium ion at lower pH values. Rates at pH < -2 are, however, too small to be measured accurately.

Semiquantitative work carried out in the fifties (17) suggests that undissociated naphthols and phenols do react with carboaromatic diazonium ions, but at rates that are several orders of magnitude lower than those of the respective naphtholates and phenolates. Quantitative evaluations of kinetic measurements carried out by Štěrba and co-workers (18, 19) in the seventies demonstrate that the naphtholates are 10^8–10^9 times more reactive than the naphthols.

The evaluation of the rate constants k_{ps} of the azo couplings of thiazole-2- and -4-diazonium ions with eq. [2] gives k_1 and k_2, i.e. the rate constants for reaction with the naphtholate and the naphthol, respectively (Tables 1 and 2). The ratios k_1/k_2 are 7.65×10^8 and 5.69×10^8. Very good agreement exists with the ratio k_1/k_2 of the reaction of the 3-nitrobenzenediazonium ion with 2-naphthol-3,6-disulfonic acid reported by Štěrba and co-workers (19): $k_1/k_2 = 7.94 \times 10^8$. This indicates strongly that, in this respect, azo coupling reactions of the heteroaromatic diazonium ion are mechanistically similar to those of carboaromatic analogs.

An interesting problem is the influence of the structure of the heteroaromatic ring on the reactivity of the respective diazonium ions. The results in Tables 1–6 show that the reactivities of the

six diazonium ions with the naphtholate ion (k_1) cover a range of more than 4 orders of magnitude ($1.76 \times 10^5 - 5.4 \times 10^9$ L mol^{-1} s^{-1}).

Is there a rationale behind the sequence of reactivities that we found? One may consider checking the results from MO calculations made with heteroaromatic compounds of the types used for this study. Literature data which we found could, however, not be compared because they were either not obtained with the same type of MO treatment or obtained with outdated methods. We preferred, therefore, a comparison with an experimental probe for the reactivity of heteroaromatic compounds, namely the ^{1}H nmr chemical shifts of the heteroaromatic compounds on which our six diazonium ions are based. In Fig. 4 we plotted the logarithms of our azo coupling rate constants k_1 against the chemical shift of that proton in the respective heteroaromatic parent compound which is substituted by the diazonio group in our diazonium ions. We found a surprisingly good linear relationship for all but one rate. This results should, in fact, not be astonishing: a change of the chemical shifts to lower field indicates lower nucleophilicity (i.e. higher electrophilicity) of a heteroaromatic compound, which is reflected in the higher electrophilicity of the diazonio group. More astonishing, in our opinion, is the fact that, to our knowledge, such a correlation between chemical shifts and a series of comparable electrophilic aromatic substitutions has not yet been reported in the literature.

It was therefore imperative to check if the same type of correlation also exists for azo coupling reactions of substituted benzenediazonium ions with 2-naphthol-3,6-disulfonic acid. This is indeed the case, as shown in Fig. 5.

The only heteroaromatic diazonium ion whose rate of azo coupling does not follow the linear relationship with the ^{1}H nmr data in Fig. 4 is the 1,3,4-triazole-2-diazonium ion. This apparent discrepancy is most likely based on the fact that the ion is easily deprotonated at the heterocyclic nitrogen atom in the 1-position. Under our azo coupling conditions (pH 4.01–5.97) the equilibrium is almost completely on the side of the zwitterion **7** in eq. [3]. The mesomeric structure **7***b* demonstrates

[3] 
6 **7***a* **7***b*

that the reactivity of **7** is expected to be lower than that of **6** and the diazonium ions **1**–**5** used in this study. In Fig. 4 the chemical shift of 1,3,4-triazole is plotted (8.31 ppm). For the corresponding anion of 1,3,4-triazole a chemical shift of 8.10 ppm is reported (21). This value hardly improves the position of this diazo compound relative to the five others.

A comparison of Figs. 4 and 5 also offers an explanation for the deviation of the 1,3,4-triazole-2-diazonium zwitterion (**7**) in Fig. 4. The straight lines have different slopes. This is obviously due to the fact that the aromatic ring current is influenced by the type of aromatic systems involved, namely benzene (Fig. 5) and various heteroaromatic five-membered ring compounds (Fig. 4). It seems that the number and type of heteroatoms in these rings is of minor importance except for a (formally) anionic nitrogen as present in **7**.[2]

[2]A referee suggested that 1,3,4-triazole is the only compound in which the proton in question resides between two nitrogen atoms. This may be the cause for the deviation.

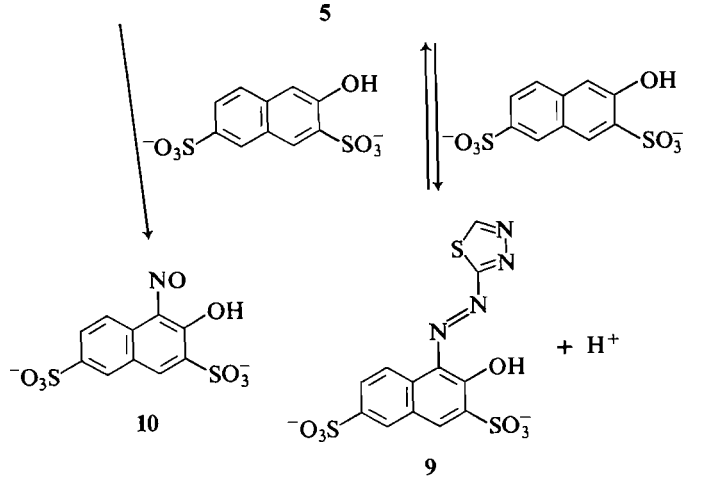
An additional factor for a decreased reactivity may be the addition (equilibrium [4]) of water to the diazo compound **7** to

[4] 
7*a* **8**

form the diazohydroxide **8**, which is probably not electrophilic at all. This possibility was, however, not investigated in more detail because of the low stability of solutions of this diazo compound.[3]

We explain the spectral change in kinetic runs of the azo coupling of the 1,3,4-thiadiazole-2-diazonium ion with time (Fig. 1) by the mechanism [5]. The diazonium ion **5** is present in

[5] 
5



10 **9**

equilibrium with the nitrosating reagent[4] and forms the azo compound **9** as a kinetically controlled reaction product, whereas 1-nitroso-2-naphthol-3,6-disulfonic acid (**10**) is the thermodynamically controlled product. The back reaction of the azo coupling reaction **9** → **5** has been described in various cases involving carboaromatic diazonium ions.[5] Our results confirm that heteroaromatic diazonium ions also show the same behavior in this respect.

We will report on the mechanism of diazotization of heteroaromatic amines later (see ref. 22). In contrast to the diazotization of carboaromatic amines, which give quantitative yields of diazonium ions under the usual conditions, heteroaromatic amines are in equilibrium with the respective diazonium ions in the presence of nitrosating reagents. The formation of 1-nitroso-2-naphthol-3,6-disulfonic acid in reaction [5] is a consequence of that equilibrium.

[3]Note added Dec. 19, 1985: We only now became aware of the recent paper of Macháček *et al.* (23), who investigated the azo coupling mechanism of 5-methyl- and 5-phenyl-1,2,4-triazole-3-diazonium ions with phenols. In the context of diazo acid–base equilibria, they discuss structures analogous to **8** as potential intermediates.

[4]The formulation of the nitrosating reagent does not imply that it is not an ionic species.

The photo-rearrangement of mixtures of azoxybenzene **4** and, successively, [^{15}N,^{15}N′]**4**, [^{18}O]**4**, and [2-^{14}C]**4** were carried out. Kinetic isotope effects (KIE) were calculated from measurements of isotopic ratios in both recovered **4** and the product, 2-hydroxyazobenzene (**6**). Analogous rearrangement of mixtures of 2,2′-azoxynaphthalene (**8**) with [^{15}N,^{15}N′]**8** and [1,1′-$^{13}C_2$]**8** were carried out and KIE were calculated from isotope ratios in the product. The results (particularly the lack of nitrogen KIE) collectively indicate that if an oxadiazole-like intermediate is involved in these rearrangements, an activation barrier exists in its formation rather than its decomposition.

HENRY J. SHINE, WITOLD SUBOTKOWSKI et EWA GRUSZECKA. Can. J. Chem. **64**, 1108 (1986).

On a réalisé des photo-transpositions sur des mélanges d'azoxybenzène (**4**) et successivement de composés **4** marqués au [^{15}N,^{15}N′], au [^{18}O] ou au [2-^{14}C]. On a calculé les effets isotopiques cinétiques (EIC) à partir de mesures des rapports isotopiques, tant dans le produit **4** qui était récupéré que dans le produit de la réaction, l'hydroxy-2 azobenzène (**6**). On a aussi réalisé des transpositions analogues sur des mélanges d'azoxynaphtalène-2,2′ (**8**) et de dérivés marqués au [^{15}N,^{15}N′] ou au [$^{13}C_2$-1,1′] et l'on a calculé les EIC en se basant sur les rapports isotopiques dans le produit. L'ensemble des résultats (et particulièrement le fait qu'il n'y a pas d'EIC de l'azote) indique que, si un intermédiaire ressemblant à un oxadiazole est impliqué dans ces transpositions, la barrière à l'activation existe plutôt dans sa formation que dans sa déomposition.

[Traduit par la revue]

Introduction

In recent years sporadic attempts have been made to detect intermediates in photochemical reactions in solution by measuring heavy-atom (other than hydrogen isotopes) kinetic isotope effects (KIE). The basis for this approach was expressed by Schutte and Havinga in 1967, who used the photo-Fries rearrangement to try to answer "the question that has been raised whether photochemical reactions after electron excitation pass through a transition state of appreciable energy of activation" (1). Schutte and Havinga used 4-methoxyphenyl-[^{14}C]acetate for measuring the carbon KIE in the photorearrangement of the ester into 2-acetyl-4-methoxyphenol, and found that within experimental error the rearrangement did not exhibit an isotope effect. They concluded, therefore, that rearrangement began in the electronically excited state (singlet) and proceeded very rapidly through vibrationally excited states in a process that required no thermal energy of activation.

The quest was later pursued by Kwart and co-workers (2), who sought evidence for a vibrationally excited ground state intermediate in the photochemical rearrangement of the ylide **1** into the diazepine **3**. In this case an inverse carbon KIE was found with the use of specifically labeled [^{13}C]**1**, and the result was attributed to the formation of the intermediate **2** in the pathway from excited **1** to product (**3**) (reaction [1]). To our knowledge this is the first time in which a heavy-atom KIE has been found in a photochemical rearrangement.

[1] 
1 **2** **3**

We have been attracted to the idea of using heavy-atom KIE measurements in seeking evidence for activation barriers in photochemical rearrangements in solution. Such a barrier can exist in the electronically excited state (3). If we accept Ullman's view (4) and Kwart's conclusion, an activation barrier may also exist in a vibrationally excited ground state, reached by internal conversion from an electronically excited state. Internal conversion of this kind is known from photophysics studies to occur in the gas phase (3), but there is considerable doubt, because of rapid collisional deactivation, that a vibrationally excited ground state intermediate could exist long enough for detection in reactions in solution (5, 6).

Nevertheless, we have thought it worthwhile to continue the search for heavy-atom KIE in photochemical reactions, and have chosen the photo-Wallach rearrangement for study.

The photo-Wallach rearrangement is the intramolecular converison of an azoxyarene into a hydroxyazoarene (7). It is a singlet-state reaction (8), and does not involve radical pairs. Hence, in the use of ^{13}C labeling, it is not subject to the magnetic isotope effects associated with radical-pair reactions (9).

The photo-Wallach rearrangement is exemplified by the conversion of azoxybenzene (**4**) into 2-hydroxyazobenzene (**6**). The hydroxy group is known, from studies of substituent effects and nitrogen and carbon labeling, to migrate to the distant ring

(7). It is now generally accepted that an intermediate is formed in the rearrangement, represented as **5** (eq. [2]) and attributed usually, but erroneously, to Badger and Buttery, in their finding and studies of the rearrangement's intramolecularity (10).[3]

Circumstantial evidence for the probable validity of **5** as an intermediate has been presented by Gegiou (13). That is, irradiation of 2,2′-azoxytoluene in solution at −70°C led to an absorption spectrum having a new band at approximately 436 nm. This was attributed to the dimethyl analog of **5** since it was thought to be the region in which an intermediate, similar to **5**, would absorb. This species was converted into the rearrangement product either by irradiation at 436 nm at −70°C or by warming the solution to room temperature without further irradiation. Although the corresponding band (i.e., for **5**) in the irradiation of **4** could not be detected, it was possible to irradiate **4** at temperatures in the range of −70 to −60°C and measure the rate of formation of **6** after irradiation was stopped. In this way an activation barrier for the formation of **6** of 12 kcal/mol was obtained and this was assigned to the decomposition of **5**. The several pieces of data when fitted together, then, showed that a ground-state intermediate is formed, consistent with the expectations for **5**, and that there is an activation barrier for its conversion into **6**. Noteworthy, also, is an additional report by the same authors that the formation of the ground-state intermediate appeared also to be temperature dependent; definitive supporting data for this report were not given, however (13).

The reports in the literature concerning rearrangement of **4** which we have briefly summarized suggested to us that we might be able to find heavy-atom KIE consistent with the formation and decay of an intermediate such as **5**. Our plan was to label **4** at its nitrogen, oxygen, and 2-carbon atoms and to measure the effects of labeling on the rate of rearrangement, seeking evidence thereby for bond-forming or bond-breaking steps in the conversion of **4** into **6**. Furthermore, because labeled precursors were available from earlier but unrelated work, we included the rearrangement of 2,2′-azoxynaphthalene (**8**) into 1-hydroxy-2,2′-azonaphthalene (**10**) in our plans, seeking evidence for the participation of the corresponding intermediate (**9**). The rearrangement of **8** into **10** had already been reported by Badger and Buttery (10).

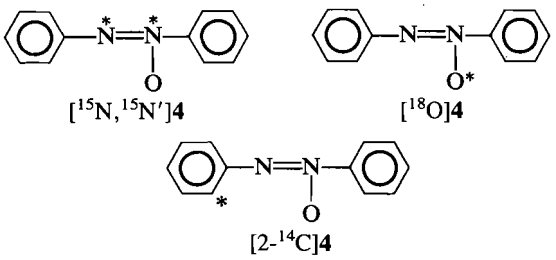
Results and discussion

Preparation of labeled substrates

The labeled isomers of **4** which were prepared are designated as [^{15}N,^{15}N′]**4**, [^{18}O]**4**, and [2-^{14}C]**4**. Each of these was prepared by the reduction of the appropriately labeled nitrobenzene by heating with sodium hydroxide in methanol (14).



[^{15}N,^{15}N′]**4** [^{18}O]**4** [2-^{14}C]**4**

Labeled isomers of **4** have been prepared earlier in tracing the orientation and intramolecularity of the photorearrangement. The syntheses have been summarized by Dolenko and Buncel (15). These syntheses include singly labeled [^{15}N]**4** and [1-^{14}C]**4**. In our case we chose to use doubly labeled [^{15}N,^{15}N′]**4** and also [^{14}C]**4** which was a mixture of [2-^{14}C]**4** and [2′-^{14}C]**4**. The choice was made for convenience in preparation and also to avoid the raising of any question of ambiguity in our measurements from the possibility of isomerization of the azoxy group via an oxadiaziridine (16), prior to the photo-Wallach rearrangement. Such a possibility would appear to be ruled out by studies of orientation in the photo-Wallach rearrangement (10, 17), but isomerization of 4′- into 4-methoxyazoxybenzene has been reported, implicating the participation of an oxadiaziridine intermediate (17, 18), while the possible formation of diphenyloxadiaziridine as an initial side reaction in the photorearrangement of **4** has been proposed (19). Furthermore, Oae and co-workers found that a small amount of scrambling did, in fact, occur in the photo-rearrangement of [1-^{14}C]**4**. In that case the cause of the scrambling was attributed, however, to direct migrations to each *o*-position of **4** rather than to the initial involvement of a symmetrical oxadiaziridine ring (20).

[^{15}N,^{15}N′]**4** has been prepared earlier in our laboratory by the oxidation of [^{15}N,^{15}N′]azobenzene (21). In the present work it was more convenient to reduce [^{15}N]nitrobenzene containing 99 atom% of ^{15}N. In this way [^{15}N,^{15}N′]**4** was obtained containing

---

[3]It is curious that Badger and Buttery did not, in fact, claim that an intermediate with structure **5** was formed. Instead they concluded, from their studies with unsymmetrical azoxyarenes, that "an intramolecular mechanism is probably involved" and they represented this clearly as what we would now call a concerted process, as shown in reaction [3]

[3] **4** →  → **6**

7

Structure **7** is described by Badger and Buttery as "the quinonoid transition state," but whether they really meant transition state in its modern sense rather than (as is more likely) an intermediate is not now known. Lewis and Reiss (11), as has been reported by Buncel (12), proposed in 1966 that **5** is the intermediate in the rearrangement. Spence, Taylor, and Buchardt (7) although reproducing the scheme of Lewis and Reiss, represent **5** as an intermediate in what they describe as a *reformation* of the mechanism of Badger and Buttery. It may be, in this way, that the mechanism first set out by Lewis and Reiss is now attributed to Badger and Buttery, in whose work, however, no suggestion of an oxadiazole-like intermediate is made at all.

approximately 98% of doubly labeled **4**. This was diluted with ordinary **4** to give 10 mol% of [^{15}N,^{15}N′]**4** for rearrangement.

In the case of ^{14}C-labeling we began with [2-^{14}C]nitrobenzene which had been prepared earlier from 2-nitro-[1-^{14}C]aniline (22). This necessarily gave us a mixture of [2-^{14}C]**4** and [2′-^{14}C]**4**, which for convenience we designate here as solely [2-^{14}C]**4**. The final product had a radioactivity of approximately 16 mCi/mol.

In preparing [^{18}O]**4**, we found that the condensation of [^{18}O]phenylhydroxylamine with nitrosobenzene (23, 24), was inconvenient because of difficulties in preparing the labeled phenylhydroxylamine in reasonable yield and the loss of almost half of the initial ^{18}O content by this method. The method of choice, therefore, was by the reduction of [^{18}O]nitrobenzene (23) prepared by the nitration of benzene with [^{18}O]H_2O/NO_2BF_4 (25). After starting with [^{18}O]H_2O containing approximately 20 atom% of ^{18}O the **4** obtained had approximately 7 mol% of [^{18}O]**4**.

The compounds [^{15}N,^{15}N′]**8** and [1,1′-$^{13}C_2$]**8** were prepared from the corresponding 2,2′-azonaphthalene (26), by oxidation with *m*-chloroperbenzoic acid. Each labeled starting material contained approximately 10 mol% of the doubly labeled isomer.

Rearrangements and KIE measurements

Rearrangements were carried out by broad-band irradiation with 350-nm lamps in a Rayonet reactor. Solutions of **4** in 95% ethanol and, because of solubility problems, of **8** in dimethoxyethane (DME), contained in a cyclindrical quartz flask were irradiated for pre-determined times so as to bring about either partial (5–20%) or complete conversion into product. Times for these conversions were obtained by monitoring the rearrangement of unenriched azoxy compound, at 410 nm for **4** and 505 nm for **8**. However, the extents of conversion used in calculating KIE were measured also by separation and isolation of unrearranged azoxy compound and product. The two measures of conversion (uv and isolation) were in good agreement in the work with **4**. We found that the planned complete conversion of **4** was never quite complete. Small amounts of **4** remained and were isolated. The data on conversions are given in Tables 1 and 2. The data in Table 1 concern calculations of KIE from isotopic abundances in isolated product (**6**). Table 2 concerns calculations of KIE from isotopic abundances in the starting material (substrate). In that table, therefore, only data for high conversions are given, which, in the calculations, are related to the isotopic abundances in the starting substrate.

The separations of unconverted substrate from product by column chromatography in the rearrangements of **8** were not as sharp as those in the rearrangements of **4**. Eluted fractions containing small amounts of both **8** and **10** were always obtained. Therefore, the amount of product isolated at low conversions was always 1–2% less than anticipated from absorption spectroscopy. Because of this, the extent of low conversion (i.e., F) used in calculating KIE is the spectroscopic conversion. We have used the spectroscopic measure also for 100% conversion of **8**. In this case, also, the amount of product after chromatography and crystallization was only about 75–80% of the expected yield. Lengthy irradiation of **10** itself caused the formation of a small amount of another, unidentified substance. Therefore, the low, isolated yield of **10** is attributable, not only to losses on separation and crystallization but also to a small amount of photochemical loss.

We measured isotopic abundances in the product (**6**) for rearrangements of [^{18}O]**4** and [^{15}N,^{15}N′]**4**, and in the substrate (**4**) for rearrangements of [2-^{14}C]**4** and [^{15}N,^{15}N′]**4**. In the rearrangements of **8** isotopic abundances only in the product **10** were measured.

Calculations of the oxygen and nitrogen KIE from isotopic abundances in the product (**6**) were made in two ways, A and B. It is important in calculating KIE from isotope ratios in products to know that complete conversion is indeed complete. If the isotope ratio is measured in a product at less than complete conversion but with the impression that conversion was complete ($F = 1.0$) the KIE calculated (eq. [5]) (27) will be smaller than the true KIE. This is to say, KIE both greater than or smaller than 1.000 will appear deceptively to be closer to 1.000. In that case eq. [6] is used for calculating KIE. In these equations R_0, R_p, and R'_p are the ratios of normalized abundances $(M + 2)/M$ in the product at molar conversions 1.0, F, and F', while k_2/k_1 is the KIE (k_H/k_L) for the reaction. The method of calculating KIE from low and almost 100% conversions with the use of eq. [6] and an iteration procedure has been described earlier (27). The columns A and B in Table 1 list KIE (k_1/k_2) calculated (A) on the assumption that complete conversion reached 100% and (B) with the use of real conversions based on isolations of unused **4**. The results of the two methods do not differ greatly, but are important particularly insofar as the ^{18}O KIE is concerned. The ^{18}O KIE is seen to be, within experimental error, an inverse one. On the other hand, there does not appear to be a nitrogen KIE. These data (Table 1) are averaged and listed in Table 3.

$$[5] \quad R_p/R_0 = [1 - (1 - F)^{k_2/k_1}]/F$$

$$[6] \quad R_p/R'_p = \frac{F'[1 - (1 - F)^{k_2/k_1}]}{F[1 - (1 - F')^{k_2/k_1}]}$$

In Table 2 are listed ^{14}C and ^{15}N KIE (k_1/k_2) obtained with recovered substrate in the rearrangement of **4**. It was necessary for these determinations to hydrogenolyze the substrate to aniline first, and to prepare the trifluoroacetyl derivative for ^{14}C and ^{15}N analyses. In the case of ^{14}C, both **4** and **6** are themselves unsuitable for scintillation counting because, being colored, each causes quenching. Hydrogenolysis of **4** goes quantitatively to aniline, and the colorless trifluoroacetyl derivative, also obtained quantitatively, can be purified by repeated sublimation. In the case of ^{15}N, the substrate itself is unsuitable for whole-molecule mass spectrometry. The abundance of the parent ion is low and the fragmentation pattern is unsuitable for use. Therefore, hydrogenolysis and trifluoroacetylation are again most useful. The mass spectrum of the trifluoroacetyl derivative is highly suitable for whole-molecule mass spectrometry. The results are summarized in Table 2 and averaged in Table 3. They show, again, that there is no nitrogen KIE and that there is a small ^{14}C KIE, averaging 1.0145.

Kinetic isotope effects (k_1/k_2) for the rearrangement of **8** are listed in Table 4. These were calculated on the assumption that 100% conversion was reached, as indicated spectroscopically. In the event that, like the rearrangement of **4**, the final conversion was a few percent short of 100% the results in Table 4 are minima. Our conclusion is that the rearrangement of **8**, like that of **4**, does not exhibit a nitrogen KIE. On the other hand there is a small, positive carbon KIE, averaging 1.07%.

The meaning of the KIE

The absence of a nitrogen KIE in the rearrangements of both **4** and **8** indicates that if there is a step in the photo-Wallach rearrangement having a significant activation barrier, breaking of the N—O bond is not part of that step. The results are, then, not consistent with the barrier-less formation of an intermediate like **5** (and **9**) followed by its conversion over an activation barrier into product. The inverse oxygen KIE in the rearrangement of **4** and the positive, small carbon KIE in the formation of **6** and **10** suggest the surprising property of the rearrangement that it is in the formation of the intermediate that an activation barrier exists. The small size of the carbon KIE in the rearrangements of **4** and **8** is not inconsistent with the change in bonding which occurs at the aromatic position in a bond-forming reaction (27).

Bunce and co-workers (17) found that when an electron-donating group (CH_3) is placed in the ring which receives the migrating atom the quantum yield of rearrangement is greater than that when an electron-attracting group (CF_3) occupies the same position. For this reason it was proposed that the attack of the oxygen atom on the distant ring is an electrophilic rather than, as thought earlier, a nucleophilic reaction. This, in itself, suggests that the bonding of the oxygen atom with the ring is a ground-state reaction. Electrophilic attack was represented by Bunce and co-workers as in eq. [7]. This interesting proposal invites further analysis. Bunce noted that the photorearrangement involves an n,π^* singlet excitation, and proposed that excitation occurs from an *n* orbital on oxygen to an antibonding N—N oribital. If this is correct the oxygen atom has radical

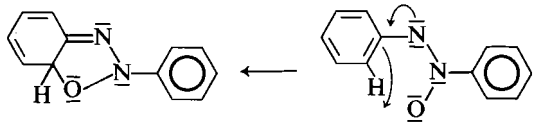
character rather than positive-charge character in the excited state, and only after electronic reorganization can the intermediate **11**, with its electron-deficient oxygen atom, be formed.[4] Again, this likelihood suggests that the formation of **5** is a ground state rather than an electronically excited state reaction, the intermediate **11** being formed by demotion from the electronically excited state to a ground excited state. Our KIE results are in harmony with this description. An inverse (here, for oxygen) or a small positive (here, for carbon) KIE is consistent with the forming of a new bond in the transition state (29). The result is, by coincidence, similar to that found by Kwart and co-workers in the photo-rearrangement of **1** (reaction [1]) (2).

[7] 
4 **11**



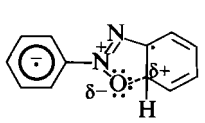
5 **12**

The photo-Wallach rearrangement then, appears to involve the formation, after excitation, of a ground-state intermediate in a step having an activation barrier. Collectively, the known information now indicates that this step is between ground-state intermediates.

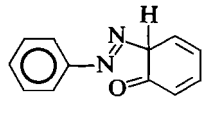
Among Bunce's results on the effect of substituents on quantum yields it is seen that the greatest relative increases in quantum yield occur not when the methyl groups are in the acceptor ring but when the CF_3 groups are in the ring nearer to the N—O bond (17). For example, the quantum yields for rearrangement of 4′-CH_3-**4** and 4′-CF_3-**4** were, respectively, 0.37 and 1.70; the values for 3′,5′-$(CH_3)_2$-**4** and 3′,5′-$(CF_3)_2$-**4** were, respectively, 0.80 and 2.5. These results show that electron-attracting CF_3 groups in the nearby ring enhance rearrangement, and suggest that the n,π^* excitation may, in fact, be surprisingly from a nonbonding orbital on oxygen to a π^* orbital of the nearby ring. Thereafter electron reorganization to an intermediate such as **11** would follow.

If these representations are incorrect, we are left with the alternative possibility that bonding to form an intermediate such as **5** may occur in the electronically excited state between the electrophilic oxygen radical and the electron-rich distant ring. In other words, the closure is a radical reaction, albeit with electrophilic character in the transition state. The transition state, in that case, might have the character of **13**.

We might now ask about the fate of **5**. Our results indicate that the conversion of **5** into **6** does not have an activation barrier large enough to show up in the KIE measurements. We would anticipate that, in spite of changes which occur in bond orders (e.g., a single bond is broken and a double one is formed at nitrogen), we should have found significant positive KIE for nitrogen and oxygen if opening of the heterocyclic ring in **5** was the rate-determining process in the sequence of ground-state reactions. If then, **5** is to proceed on toward the final product (**6**) without isotopic fractionation, the reverting of **5** to **4** must no



13



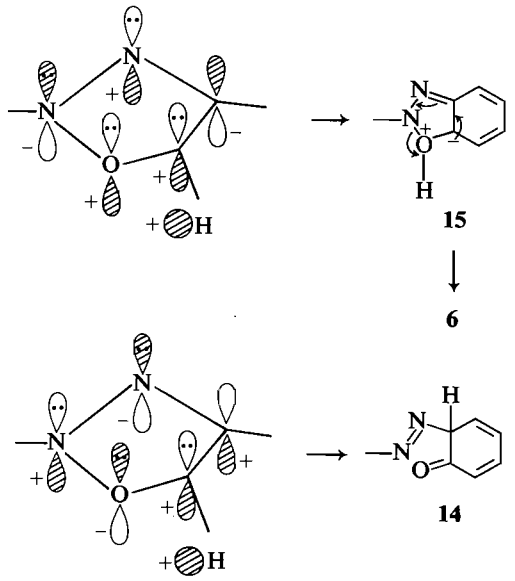
14

longer be possible. That is, return of **5** to **4** must be an unfavorable process as compared with going on completely to **6**, and the low quantum yield (13) for forming **6** from **4** is decided in one of the paths toward forming **5**. The way in which formation of **6** from **5** occurs is not known, but some possibilities are open to conjecture. One of them is, simply, ring opening accompanying deprotonation by basic solvents, in the present cases of ethanol or DME (reaction [8]), such as was proposed in the early work of Lewis and Reiss (11).

[8] 
6

Another possibility arises as follows. Bunce has shown that diazonium ions are formed (and trapped by added 2-naphthol) during irradiations of **4** and other azoxyarenes in benzene solution. Diazonium ion formation was suppressed to very low amounts by the use of moderately basic solvents such as ethanol and diethyl ether (30). The origin of the diazonium ion was attributed by Bunce to an intermediate (**14**), obtained from **5** by

[4]An analogy can be drawn here with the electron distribution in an n,π^*-excited carbonyl group. This has been represented by Zimmerman (28) as having in one of its two resonance structures a positively charged, electrophilic oxygen atom in which two single electrons remain in separate orbitals. n,π^*-Excitation of the *N*-oxide group could be viewed similarly, that is as having positive charge character on the oxygen atom in the electronically excited state. But, we take structure **11** to represent a new, ground state, formed in Zimmerman's terminology, by electron demotion after excitation.



SCHEME 1

an intramolecular 1,2-hydrogen-atom shift, and undergoing either scission to give the diazonium ion or prototropy to form **6**. This proposal in itself could also account for the conversion of **5** into **6** in basic solvents. In connection with the intramolecularity of the H-migration, Bunce noted that *m*-cresol, obtained as the side product of irradiation of 2,2′-azoxytoluene in ethanol-*O*-*d*, contained no deuterium. We pose another possibility for intramolecular H-migration which may lead both to **6** and diazonium-ion formation, and this is a [1,5]-sigmatropic migration of hydrogen across the face of the heterocyclic ring, brought about by continuous broad-band irradiation. Suprafacial, solvent-dependent migration of the LUMO of the H atom across the HOMO of the excited eight-electron ring system could bring the H atom either to the *O*-terminus (**15**) or *C*-terminus (**14**), the former leading to **6** and the latter either to **6** by prototropy or diazonium ion by scission (Scheme 1). Perhaps these speculations may be related to the observations by Gegiou *et al.* that an intermediate was formed from 2,2′-azoxytoluene which, by continued irradiation (436 nm) at −70°C, went on to the rearrangement product (13).

Experimental

Preparation of labeled azoxybenzene (4)

Each labeled **4** was prepared from the reduction of the appropriately labeled nitrobenzene by heating with sodium hydroxide in methanol (14). Commercial (Merck, Sharpe and Dohme) [^{15}N]nitrobenzene, 99 atom% ^{15}N, was used for making [^{15}N,^{15}N′]**4**. [2-^{14}C]Nitrobenzene, previously prepared from 2-nitro-[1-^{14}C]aniline (22), was used for making [2-^{14}C]**4**. The product had an activity of approximately 16 mCi/mol. For making [^{18}O]**4** it was necessary first to prepare [^{18}O]nitrobenzene by the method of Høg (25) using $H_2{}^{18}O$ containing 20.3 atom% ^{18}O (Prochem BOC, Ltd.). The **4** finally obtained was found by mass spectrometry to contain approximately 7 mol% of [^{18}O]**4**. An example of the preparation of labeled **4** follows.

[^{15}N]Nitrobenzene (2.0 g, 16.3 mmol) was added during 50 min to a well-stirred solution of 3 g of sodium hydroxide in 8 mL of methanol at 75–80°C. The mixture was stirred at that temperature for 2.5 h and then diluted with crushed ice. After standing 12 h the yellow product was filtered, washed with water, and dried in air. The crude product was purified on a column of neutral alumina with benzene elution. Removal of the benzene left a liquid product (1.6 g, 8.0 mmol, 98%) which crystallized on standing overnight; mp 34.5°C. The solid was mixed with ordinary **4** and the mixture was crystallized from benzene, giving **4** containing 10 mol% of [^{15}N,^{15}N′]**4**.

Photo-rearrangements

Rearrangements were carried out in a Rayonet reactor with eight 350-nm U-tube lamps. Solutions to be irradiated were placed in a cylindrical quartz vessel and stirred gently during irradiation with a current of nitrogen. In order to specify particular extents of conversion, the disappearance of azoxy compound and the formation of product were first monitored spectroscopically with irradiations of unlabeled substrate. The formation of 2-hydroxyazobenzene (**6**) was monitored at 410 nm, while the formation of 1-hydroxy-2,2′-azonaphthalene (**10**) was monitored at 505 nm. Solvents for photo-rearrangement were 95% ethanol for **4** and 1,2-dimethoxyethane (DME) for **8**. Specific examples of rearrangement and workup follow.

Rearrangement of 4

(A) For product KIE measurement

A solution of 198 mg (1.0 mmol) of [^{18}O]**4** in 1.0 L of 95% ethanol was irradiated for 20 min. The solution was then divided into two parts. The larger part (750 mL) was evaporated at reduced pressure. The residue was dissolved in 20 mL of benzene and placed on a column of neutral alumina (Matheson, Coleman, Bell, AX0612-3, 80-200 mesh). Unrearranged **4** (130.2 mg 87.7%), mp 34.0–34.5°C, was eluted with benzene, while product, [^{18}O]**6**, was eluted with methanol. The crude product was dissolved in 80 mL of 10% aqueous sodium hydroxide, and the solution was acidified, after filtration, with hydrochloric acid. The product was then extracted with 3 × 50 mL of ether, giving 14.6 mg (9.6%) of [^{18}O]**6**. This was sublimed at low pressure to give [^{18}O]**6**, mp 81–82°C, for mass spectrometry.

The smaller part (250 mL) of the ethanol solution was irradiated again for 20 h to effect complete conversion of **4**. Workup as above then gave 3.2 mg (6.5%) of **4** and, for mass spectrometry, 41.4 mg (83.8%) of **6**. For the purpose of calculating KIE the extents of conversion of **4** were based on recovered **4**, namely 12% and 93.5% conversions.

Rearrangements of [^{15}N,^{15}N′]**4** designed for mass spectrometry of the product were carried out identically.

Results for all runs are listed in Table 1.

(B) For substrate KIE measurement

A solution of 297 mg (1.5 mmol) of [^{15}N,^{15}N′]**4** in 1 L of ethanol was irradiated for 12.2 h, the time calculated for 81% conversion. The solution was worked up as described above and gave 55.6 mg (18.7%) of recovered [^{15}N,^{15}N′]**4** and 226 mg (76.1%) of product. A portion (38.8 mg, 0.196 mmol) of recovered [^{15}N,^{15}N′]**4** was dissolved in 5 mL of absolute ethanol and was hydrogenolyzed over 5% Pd/charcoal at atmospheric pressure for 3 h. The ethanol solution was filtered and evaporated at 25°C, and the residue was dissolved in 15 mL of benzene. To this solution was added 2 mL of trifluoroacetic anhydride and the mixture was heated under reflux for 15 min. Evaporation gave crude product which was sublimed at low pressure to give 51.7 mg (0.27 mmol, 70%) of *N*-trifluoroacetyl[^{15}N]aniline, mp 87.5–88°C (lit. (31) mp 88.5–90°C). This was sublimed twice again for mass spectrometry.

A sample of unirradiated [^{15}N,^{15}N′]**4** was hydrogenolyzed and worked up in the same way to produce *N*-trifluoroacetyl[^{15}N]aniline for mass specrometry "at zero conversion".

Results are listed in Table 2.

(C) For scintillation counting and substrate KIE measurement

A solution of 400 mg (2.02 mmol) of [2-^{14}C]**4** in 1.0 L of ethanol was irradiated for 12 h, a time calculated for 70% conversion. Unrearranged substrate and product were separated on alumina as usual. The benzene eluate was evaporated at reduced pressure to give crystalline, unrearranged [2-^{14}C]**4**. This was again chromatographed on neutral alumina, crystallized, and hydrogenolyzed as described above, to give *N*-trifluoroacetyl-[2-^{14}C]aniline which was sublimed successively six times for scintillation counting. The final product had mp 87.6°C.

Preparation of labeled 2,2′-azoxynaphthalene (8)

Labeled **8** was prepared from [^{15}N,^{15}N′]- and [1,1′-$^{13}C_2$]-2,2′-azonaphthalene which had been synthesized earlier (26). Each of the

azonaphthalenes contained approximately 10 mol% of the doubly labeled isomer.

A solution of 1.06 g (3.76 mmol) of labeled 2,2′-azonaphthalene in 190 mL of benzene was kept at 27°C in a thermostated bath. To this solution was added a freshly prepared solution of 3.24 g (18.8 mmol) of *m*-chloroperbenzoic acid in 55 mL of benzene. The mixture was kept at 27°C for 17 h, during which time the reaction was monitored periodically by TLC. After oxidation was complete the solution was washed with dilute sodium bicarbonate solution and water, and then was dried and evaporated. The residue was chromatographed on a column of silica gel, eluting with cyclohexane, and the product was crsytallized from ethanol giving 1.01 g (3.38 mmol, 90%) of labeled **8**, mp 167–168°C (lit. (10) mp 166°C).

Rearrangement of 8 for product KIE measurements

A solution of 149 mg (0.50 mmol) of **8** containing approximately 10 mol% of labeled **8** in 1.0 L of DME was irradiated for 40 min, a time calculated to result in approximately 8% conversion. The solvent was removed in a rotary evaporator and the residue was separated by flash chromatography on silica gel (E. T. Baker) into recovered **8** and product **10**. The eluent was a mixture of cyclohexane, benzene, and piperidine (91:5:4 by volume). The recovered **8** was crystallized from ethanol giving 121 mg (81%). The crude **10** was dissolved in a small amount of chloroform and streaked on preparative-scale TLC plates (EM silica gel). Development with a mixture of cyclohexane, benzene, and piperidine (80:15:5) separated **10** from a small amount of another, unidentified, substance. After removal from the plate material, **10** was crystallized from ethanol giving 10.5 mg (7%) of labeled **10** for mass spectrometry.

For complete conversion of **8** a solution of 75.5 mg (0.25 mmol) of labeled **8** in 50 mL of DME was irradiated for 32 h. Workup as described gave 54 mg (72.5%) of **10** for mass spectrometry and 3 mg (4.0%) of recovered **8**.

These experiments were repeated three times for each of the [^{15}N,^{15}N′]**8** and [1,1′-$^{13}C_2$]**8**, with similar results. It is seen that the total recovery of material from the low-conversion irradiation was 88%. Losses occurred in the flash chromatography in which some fractions containing both **8** and **10** were discarded. The amount of **10** recovered (7%) was pleasingly close to that anticipated. The total recovery of material from 100% conversion (76.5%) was rather low, particularly **10** itself. Irradiation of **10** (14.9 mg in 100 mL of DME) for 10 h showed, by TLC, that a very small amount of a new compound having lower R_f was formed. Possibly, therefore, the lengthy irradiations needed for complete conversion of **8** may have also caused loss of some of the product **10**. The lengthy irradiations are taken as having achieved 100% conversion. Results are listed in Table 4.

KIE measurements

(A) Whole-molecule – ion mass ratios were measured with Hewlett–Packard mass spectrometers, Model 5985B (Rutgers University)[5] and 5995 (Texas Tech University). In the latter case multiple scanning was carried out in the selected-ion-monitoring (SIM) mode and the data were analyzed in blocks (27) with the aid of a program kindly supplied by Professor San Filippo. The number of scans made with the Model 5995 instrument was in the order of 5000 per run. The handling of samples was as described earlier (27).

Ions monitored, at 50 ms/ion dwell times, were M and $(M + 2)$ in the products (**6** and **10**) of rearrangement of [^{15}N,^{15}N′]**4**, [^{18}O]**4**, [^{15}N,^{15}N′]**8**, and [1,1′-$^{13}C_2$]**8**. Ions monitored when substrate was recovered and hydrogenolyzed in the rearrangement of [^{15}N,^{15}N′]**4** were the M and $(M + 1)$ of *N*-trifluoroacetylaniline.

(B) Scintillation counting was carried out with a Beckman Model LS 7000 liquid scintillation counter. The sample (approximately 5 mg) was dissolved in 10 mL of cocktail (Parkard, SCINT-0, No. 6103183) and counted ten times. Three separately weighed samples were counted for each conversion. Samples were weighed precisely (±0.001 mg) on a Cahn balance. Finally, the average of ten counts was expressed in counts per 1.000 mg and the results for the three samples were averaged for KIE calculations.

In making these calculations, it was assumed that equal amounts of [2-^{14}C]**4** and [2′-^{14}C]**4** were available for rearrangement. Therefore, in the labeled molecules, rearrangements to one labeled and three unlabeled *o*-position were possible, among which an intramolecular KIE existed and was assumed to have the same magnitude as the sought-after intermolecular KIE.

All KIE calculations were made as described earlier (27).

[5]We thank Dr. J. San Filippo, Jr. and Mrs. Marilyn Brownawell for these measurements, Table 4. Information on the way of making measurements has been given (27).

Acid-catalyzed hydrolysis of 2-methylene-1,3-dithiolane. 2.[1] Remarkable effects of β substitution on reversibility of the carbon protonation

TADASHI OKUYAMA,[2] MASAYOSHI TOYODA, AND TAKAYUKI FUENO
Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560, Japan
Received October 25, 1985

This paper is dedicated to Professor Arthur N. Bourns

TADASHI OKUYAMA, MASAYOSHI TOYODA, and TAKAYUKI FUENO. Can. J. Chem. **64**, 1116 (1986).

Hydrolyses of 2-ethylidene- (**1***b*), 2-isopropylidene- (**1***c*), and 2-benzylidene-1,3-dithiolane (**1***d*) were kinetically investigated in aqueous solution. All the individual rate constants involved in this three-step reaction were evaluated. Initial carbon protonation is only partially reversible (k_2/k_{-1} = 1.33, 0.68, and 1.02 for **1***b*, **1***c*, and **1***d*, respectively) at higher pH, while the protonation becomes completely reversible below pH 2 where the third step is rate determining. Complete H–D isotope exchange at the β-carbon of **1***b* and **1***d* was observed in deuterium media before appreciable hydrolysis took place. It was demonstrated that reversion from the tetrahedral intermediate **3** to **1** occurs extensively during the reaction in the latter acidity range. Relative stabilities and reactivities of the olefinic substrates **1** are discussed.

TADASHI OKUYAMA, MASAYOSHI TOYODA et TAKAYUKI FUENO. Can. J. Chem. **64**, 1116 (1986).

Opérant en solutions aqueuses, on a examiné la cinétique des réactions d'hydrolyse des éthylidène-2 (**1***b*), isopropylidène-2 (**1***c*) et benzylidène-2 dithiolanes-1,3 (**1***d*). On a évalué toutes les constantes de vitesse individuelles de cette réaction en trois étapes. À des pH élevés, la réaction de protonation initiale du carbone n'est que partiellement réversible (k_2/k_{-1} = 1,33, 0,68 et 1,02 respectivement pour les composés **1***b*, **1***c* et **1***d*) alors que, à des pH inférieurs à 2, la protonation devient complètement réversible et que la troisième étape devient l'étape déterminante. Dans des milieux deutérés, on observe un échange complet des isotopes H/D au niveau du carbone β des composés **1***b* et **1***d* avant qu'une hydrolyse appréciable ne se produise. On a démontré que, au cours de la réaction, la transformation de l'intermédiaire tétraédrique **3** en **1** ne se produit que dans le dernier intervalle de pH. On discute des stabilités et des réactivités relatives des substrats oléfiniques **1**.

[Traduit par la revue]

Introduction

We recently accomplished complete kinetic analysis of a three-stage reaction process of the acid-catalyzed hydrolysis of 2-methylene-1,3-dithiolane, **1***a* (1). Main features of this reaction are: (*1*) Both steps 1 and 2 are partially rate determining above pH 2.5 (k_2/k_{-1} = 7.2) while step 3 becomes the slow step at higher acidities. (*2*) The equilibrium concentration of the tetrahedral intermediate (**3***a*) is greater than that of **1***a* (**3***a*/**1***a* = 27.5), and **3***a* builds up at the higher acidities.

In our continuing interest in this reaction, hydrolyses of the β-methyl and phenyl derivatives, 2-ethylidene- (**1***b*), 2-isopropylidene- (**1***c*), and 2-benzylidene-1,3-dithiolanes (**1***d*), have been examined in detail. The reactions follow essentially the same mechanism as that of the parent substrate **1***a* (eq. [1]). However, apparent kinetic behavior is much different from that of **1***a*. Buildup of the intermediate **3** was not observed because the equilibrium concentration of **1** (as compared with **3**) is greatly increased by the β substituent. A very rapid H–D isotope exchange at the β-carbon was found to precede the hydrolysis of **1***b* and **1***d* in deuterium media. The complete kinetic analysis enables us to make interesting comparisons of stabilities of olefinic substrates **1**, carbocations **2**, and tetrahedral intermediates **3**.

Results

Acid-catalyzed hydrolysis of β-substituted 2-methylene-1,3-dithiolane (**1***b*, **1***c*, and **1***d*) proceeds stepwise in the same way as that of other ketene dithioacetals (eq. [1]) (1–5). At high acidities was observed rapid formation of the absorption (λ_{max} 330 nm) of the carbocation intermediate **2**, which disappears slowly to give the thiolester product **4**. In less acidic solutions, however, the decay of **1** seems to occur with simultaneous formation of **4**. In the intermediate pH region 0–3, the decrease in the absorption of **1** was accompanied by a short induction period.

Reaction of the isolated salts of **2** was also examined independently. The spectral changes observed by the conventional uv spectroscopy were essentially the same as those observed by starting with **1** in the whole acidity range examined. Only the decay of **2** could be observed at higher acidities, while the reaction of **1** was observed at low acidities even when the reaction was started with **2**. That is, the initial rapid breakdown

TABLE 1. Summary of the sigmoid correlations of the absorbances with the H_C and H_R acidity functions[a]

Substrate (conc. 10^4 M)	Absorbance	No. of data	pK_R[b]	Limiting absorbances at high and low acidities[b]	
1*b* (1.14)	A^0_{330}	8	−0.567(0.015)	0.887(0.011)	0.025(0.013)
1*b* (1.14)[b]	A^0_{235}	9	−0.609(0.020)	0.232(0.008)	0.736(0.008)
2*b* (1.12)	A^0_{330}	14	−0.609(0.010)	0.880(0.007)	0.005(0.008)
2*b* (1.12)	A^∞_{330}	11	−3.518(0.034)	0.898(0.006)	0.004(0.005)
1*c* (0.95)	A^0_{330}	7	−2.023(0.024)	0.688(0.011)	0.058(0.016)
1*c* (1.09)[c]	A^0_{230}	8	−1.957(0.013)	0.323(0.004)	0.841(0.008)
1*c* (0.95)	A^∞_{330}	7	−3.485(0.030)	0.662(0.013)	0.043(0.008)
1*d* (1.2)	A^0_{340}	7	−2.588(0.035)	0.855(0.021)	0.082(0.026)
1*d* (0.55)[d]	A^0_{304}	7	−2.665(0.033)	0.202(0.024)	1.101(0.025)
1*d* (1.2)	A^∞_{340}	7	−4.389(0.024)	0.814(0.010)	0.049(0.013)

[a]A^0 and A^∞ are correlated with the H_C and H_R acidity functions, respectively.
[b]Standard deviations are given in parentheses.
[c]Absorbance of **1***b* in H_2O was 0.846 at 235 nm.
[d]Absorbance of **1***c* in H_2O was 0.848 at 230 nm.
[e]Absorbance of **1***d* in H_2O was 1.034 at 304 nm.

of **2** largely results in the formation of **1** in less acidic solutions. This behavior of the carbocation is in contrast to that observed with the parent substrate **2***a* (1) and other dithio carbocations (3), which break down mainly to form **3** without any appreciable uv absorption, and slower formation of **4** follows.

The uv absorbance in acid solution was quantitatively examined on a conventional spectrophotometer. The "initial" absorbances A^0_{330} at 330 nm (λ_{max} of **2**)[3] as well as those at λ_{max} of **1** (**1***b*, 235; **1***c*, 230; **1***d*, 304 nm) were determined by rapidly introducing an aliquot of the stock solution of **1** into various acid solutions and extrapolating the absorbances to the time of mixing. The former absorbances increase and the latter decrease with increasing acidity. The decay of **2** was not complete in strong acid, leaving an equilibrium amount of **2**. The ultimate absorbances A^∞_{330} at 330 nm were also recorded. Results are given in Table S1 (supplementary material).[4] The initial absorbances are correlated with the H_C acidity function (6), which was obtained from protonation of the unsaturated carbon to give carbocations. The reason for the choice of the acidity function is given under Discussion. The correlations seem to be better than those with the H_R acidity function (7, 8). The initial absorbances at 330 nm and at λ_{max} of **1** respectively follow the sigmoid curves of the same midpoint (pK_R) as summarized in Table 1. The ultimate absorbances A^∞_{330} are correlated with H_R to give sigmoid curves with more negative pK_R (defined as pK_T in Table 5). Similar examinations were also carried out with the cation **2***b* and the results are the same as those obtained with **1***b* (Tables S1 and 1). The constant pK_T corresponds to the equilibrium between **2** and **4** (1, 9).

Pseudo-first-order rate constants k_0 were measured at 25°C by monitoring the decrease in the absorption of **1** in HCl solutions (<1 M) and that of **2** (330 nm) in $HClO_4$ solutions of higher acidities. The k_0 values determined at these two wavelengths coincide with each other as measured in some moderately strong acids. Rate constants obtained by starting with **2***b* were close to those obtained from the reaction of **1***b*. For some runs in the intermediate pH region where an induction period was observed, k_0 were determined from the later part of the first-order plots. Observed rate constants k_0 are summarized in Table S2[4] and plotted logarithmically against pH or the H_0 function (7) in Fig. 1. All the acidity–rate profiles are complicated with a maximum at pH 2–3 and a minimum around pH 1. That is, two acid-catalyzed regions were observed. In the case of **1***b* another maximum was observed at $H_0 \simeq -0.5$.

Reactions of **1** were also examined in deuterium solutions at both high and low DCl concentrations corresponding to the two different acid-catalyzed regions. The results are summarized in Table 2. Observed behavior is much different in the two acidity regions. First-order plots for **1***b* and **1***d* curved downward at the lower acidities while the plots were linear at the high acidities. In the former case, approximate initial and ultimate rate constants were determined from the slopes of the initial and later parts of the plots, respectively. Both of the rate constants are smaller than those obtained in the HCl solutions; the kinetic isotope effects are normal. By contrast, the rate constants obtained in DCl for the high acidity region are essentially identical with those found in HCl. The curvature of the first-order plots was not found with **1***c* but the kinetic isotope effects observed are similar to those found with **1***b* and **1***d*: normal at the low acidity and none at the high acidity.

Products from reactions of **1***b* and **1***d* in deuterium media were found to be deuterated extensively at the β position. Isotope exchange of **1***d* was kinetically examined in 80 vol% CH_3CN–D_2O at [DCl] = 0.1 and 0.002 M. Hydrolysis rates under these conditions were very small as measured spectrophotometrically (Table 3). Deuterium solvent isotope effects on the hydrolysis rate of **1***b* were negligibly small at 0.1 M but were normal at 0.002 M. The nmr analysis of the residues from the ether extract of the reaction mixture showed loss of the β-hydrogen of the substrates **1***b* and **1***d*. The intensity of the β-hydrogen relative to that of the phenyl group of **1***d* was calculated from the integration curves of the nmr spectra, and the rate constant k_{ex} for the isotope exchange was evaluated by the first-order plots as shown in Fig. 2. Values of k_{ex} are given in Table 3. The rate of the exchange is greater than that of the hydrolysis by factors of 10^3 and 60 at 0.1 and 0.002 M DCl, respectively.

Curved buffer dependences were observed in the hydrolyses of **1** in carboxylate buffers in the low acidity region as before

[3]The absorbances at 340 nm were measured for **2***d* rather than at 330 nm (λ_{max}) because absorption due to **1***d* is still large at 330 nm.

[4]Tables S1, S2, and S3 have been deposited as supplementary material and may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

(1–5). The rate increase Δk ($= k_{obsd} - k_0$) induced by the buffer ($[B]_t$) follows the saturation curve according to eq. [2]. Parameters, K_{app} and Δk_{max}, were calculated by the least-

$$[2] \quad \Delta k = \Delta k_{max}[B]_t/(K_{app} + [B]_t)$$

squares treatments of $1/\Delta k$ vs. $1/[B]_t$, where k_0 ($k_{H^+}[H^+]$) was calculated from the results obtained in HCl solutions, and are given in Table 4.

Discussion

Low acidity region

The reaction concerned here involves three consecutive steps (eq. [1]) as was the case with the parent substrate **1***a* (1). In the high pH region (pH > 3 for **1***b* and **1***c* and pH > 2 for **1***d*) where the reaction is catalyzed by acid, the third step must be rapid and the first and second steps are both rate determining (eq. [3]). The rate constants k_0 observed in HCl solutions are given by eq. [4] (1).

$$[3] \quad 1 \underset{k_{-1}\ \ k'_{-1}[B]}{\overset{k_1[H^+]\ \ k'_1[BH^+]}{\rightleftharpoons}} 2 \xrightarrow{k_2} 3 \xrightarrow{\text{rapid}} 4$$

$$[4] \quad k_0 = k_{H^+}[H^+] = k_1k_2[H^+]/(k_{-1} + k_2)$$

Kinetic behavior is very similar to that of **1***a* in this pH region (1). Reactivity of **1***a* (k_{H^+}) is, however, greatly reduced by the β substitution as summarized in Table 5.

Curved buffer dependence observed in this pH region must arise from the fact that the buffer accelerates the first step but not the second step. The limiting rate constant k_{max} is described by eq. [5] (1).

$$[5] \quad k_{max} = k_1k_2[H^+]/k_{-1}$$

From the values of k_0 and k_{max}, the rate constant k_1 and the ratio k_2/k_{-1} ($= \Delta k_{max}/k_0$) can be evaluated (1). The results given in Table 4 show that the β substituent reduces this ratio. In other words, the substitution increases the reversibility of the carbon protonation in a kinetic sense.

The curvature of the pseudo-first-order plot for the reaction of **1***b* and **1***d* in deuterium media at higher pH must come from the isotope exchange occurring during the reaction (eq. [6]). The

[6] 
deuterated substrate is more reactive owing to the secondary kinetic isotope effects and for some other reasons (2). The disubstituted substrate **1***c*, which has no hydrogen capable of exchange, showed linear first-order behavior. Normal kinetic isotope effects observed are consistent with the carbon protonation involved in the rate-determining steps. The isotope effects k_{H_2O}/k_{D_2O} decrease in the order **1***b* > **1***c* > **1***d*, in agreement with the diminishing contribution from the first step to the rate (i.e., decreasing k_2/k_{-1}).

High acidity region

As the pH is lowered, the rate of the reverse of the second step ($k_{-2}[H^+]$) increases and the third step becomes rate determining. This occurs because the third step (k_3) is catalyzed by both acid and base and the acid-catalyzed reversion (k_{-2}) is faster than the acid-catalyzed decay of **3**. This situation will be seen below in Fig. 4 and is the same as that for the parent substrate **1***a*. However, the apparent kinetic behavior observed with the derivatives is much different from that found with **1***a*. In the latter case, the rate of decay of **1***a* increases with acidity beyond the pH at which $k_{-2}[H^+]$ exceeds k_3, but appearance of the product **4***a* becomes slower with increasing acidity. The intermediate **3***a* accumulates. By contrast, in the cases of the β-substituted derivatives, the rate of decay of **1** decreases and the decay seems to occur with simultaneous formation of **4**. The rate increases again with acidity beyond the minimum near pH 1. These differences found between **1***a* and its derivatives in this acidity region can be explained by the same mechanism but different equilibrium behavior involving the first and second steps. At equilibrium, **3***a* is favored over **1***a* (1), while the β-substituted derivatives of **1***a* are much favored over the corresponding **3**. Another decrease in the rate of reaction of **1***b* in strong acid will also be rationalized by this mechanism.

Equilibrium involving cation 2

The equilibrium involving the first and second steps was examined by the conventional uv method in the higher acidity range where the third step is slow enough. The "initial"

absorbances due to **2** and **1** changed sigmoidally with acidity. Choice of the acidity functions is a problem here. If the equilibrium reflected mainly the second step, as was found with **1a** (1), the H_R acidity function defined by dehydration of alcohols (7) would be appropriate. On the other hand, if the first step is a main contributor, the H_C acidity function, which was defined by protonation of the unsaturated carbon bases (6), may be more suited for the correlation. The latter was found to be the case for all the β-substituted derivatives as analyzed below. Thus, the initial absorbances were correlated with H_C to give pK_R as listed in Table 1. The pK_R values obtained from the different wavelengths agree well and appropriate values are given in Table 5.

The equilibrium constant K_R is a composite of the two constants K_1 and K_2 for the first and second steps (eq. [7]).

$$[7] \quad K_R = 1/K_1 + K_2$$

Relative concentrations [**1**]/[**3**] in equilibrium would be found at the lower acidity limit where the contribution from **2** becomes negligibly small. Since **3** may absorb little light at wavelengths longer than 230 nm, the limiting absorbance at the absorption maximum of **1** at lower acidity must result from the absorption of **1**. The limiting absorbances for **1b**, **1c**, and **1d** are 86.9 (±1.0), 99.2 (±1.0), and 106.5 (±2.5)% of the absorbance of **1** for the same concentration in unbuffered water (no reactions), respectively.[5] Since the reactions of **1** are rapid enough and the equilibrium should be attained within a second in the acidity range examined, as evaluated from the rate constants obtained,

[5]Quenching of the isolated salt of **2d** in weakly acidic solutions revealed that (*1*) the initial absorbances at 304 nm in 1.2–2.4 *M* $HClO_4$ correspond to 100% formation of **1d**, and (*2*) the absorbance in HCl solutions decreases with decreasing concentration of acid below 1 *M*, limiting absorbance showing about 65% formation of **1d**. The limiting value should reflect the partitioning ratio k_{-1}/k_2 but the value was somewhat too high as compared with that calculated from the rate constants. Insufficient mixing may in part be responsible for this discrepancy.

[g]Free energy change on going from **3** to **1**.

the limiting absorbances no doubt correspond to the equilibrium concentrations of **1**. The results indicate that **1** is much more stable than **3**. The first step mainly contributes to the observed equilibrium. This must be responsible for the more negative pK_R values obtained as compared with that of **1***a*, which comes mainly from the second step (1).

We have to mention here that the conventional uv analyses of the initial absorbances successfully gave the equilibrium values in the present cases although the same analysis of the parent substrate **1***a* was unsuccessful, probably owing to some mixing problems (1). The present equilibrium reflects the first step and the very rapid equilibration may adjust the initial failure by insufficient mixing, if any, before any measurable decay of **3** takes place. By contrast, the second step is mostly responsible for the equilibrium **1***a* ⇌ **2***a* ⇌ **3***a* and the ensuing reaction of **3***a* may occur appreciably before initial mixing errors are corrected. This would have resulted in the poor reproducibility of the experiments with **1***a*.

The relative concentrations [**1**]/[**3**] in equilibrium should be equal to $1/K_1K_2$. In the case of **1***b*, $K_1 = 0.29$ and $K_2 = 0.52$ can be calculated from the observed values, $1/K_1K_2 = 86.9/13.1 = 6.63$ and $K_R = 3.98$. Since we also know values of k_1 and k_2/k_{-1}, all rate constants for the first two steps can be evaluated as listed in Table 5. For **1***c* and **1***d*, however, $K_R \simeq 1/K_1$ and we cannot evaluate reasonably the values of K_2. We now know k_{-2} values for **2***a*, **2***b*, and unsubstituted 1,3-dithiolanylium ion and the 2-*tert*-butyl derivative (9), and they correlated well with the σ* substituent constants (10) as shown in Fig. 3 (ρ* = −2.0). From this correlation, k_{-2} for **2***c* and **2***d* are estimated to be 100 and 15 $M^{-1}\,s^{-1}$, respectively. However, this correlation could be fortuitous, because it may not be well rationalized that the effects of alkyl substitution in the carbocation-

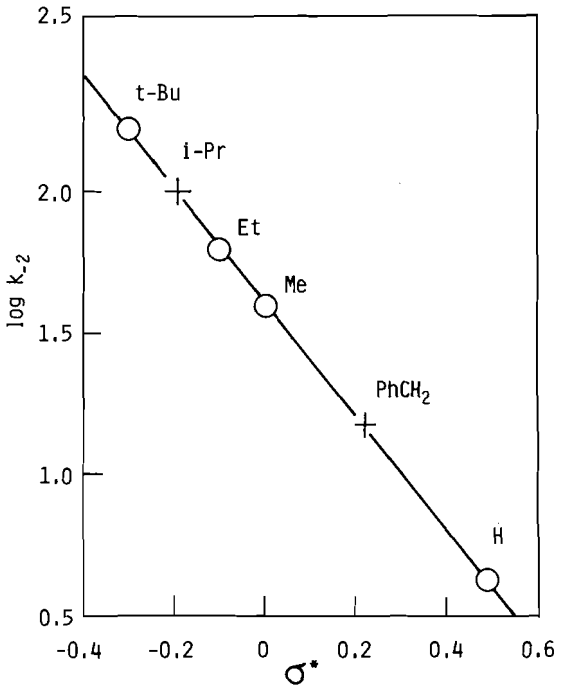

FIG. 3. Correlation of log k_{-2} with σ* of the 2-alkyl substituents of 2-hydroxy-1,3-dithiolane. Crosses indicate the estimated values.

forming reaction conform to the σ* constants, which refer mainly to the inductive effects. This reaction must be accelerated by the steric strain, which is relieved on going from the tetrahedral intermediate **3** to the planar cation **2**. The observed rate may be a compromise of the steric and electronic effects, and the σ* constants happen to be a good measure of the reactivity. Rate constants for another related reaction (eq. [8]) were determined before (4).

$$[8]\quad RC(SCH_3)_3 + H^+ \xrightarrow{k_{H^+}} RC^+(SCH_3)_2 + CH_3SH$$

The rate constants k_{H^+} (in $M^{-1}\,s^{-1}$) obtained at 30°C are: R = CH_3, 6.0×10^{-3}; C_2H_5, 1.8×10^{-2}; $(CH_3)_2CH$, 0.14; $C_6H_5CH_2$, 2.1×10^{-3}. With these limited number of data, the linear free-energy relationship between k_{H^+} and k_{-2} gives 140 and 25 $M^{-1}\,s^{-1}$ for k_{-2} of **2***c* and **2***d*, respectively. From these estimations, k_{-2} values for **2***c* and **2***d* of 120 and 20 $M^{-1}\,s^{-1}$ are used for the evaluation of other rate and equilibrium constants, as summarized in Table 5.

Decay of tetrahedral intermediate

Having K_1 and K_2 values at hand, we can calculate the fraction of tetrahedral intermediate **3** and the rate constant k_3 for its decay by eq. [9].

$$[9]\quad k_3 = (K_R + h_C)k_0/K_2$$

The k_3 values calculated in this way are logarithmically plotted against pH or the H_S acidity function[6] in Fig. 4. The profiles show that the k_3 process is catalyzed by both acid and base (eq. [10]).

$$[10]\quad k_3 = k_aH_S + k_b[OH^-]$$

Probable values of k_a and k_b are given in Table 5.

[6]The H_S acidity function is defined by $H_S = 1.3H_0 + 0.3$ (log $[H^+]$) for sulfur protonation (1, 9).

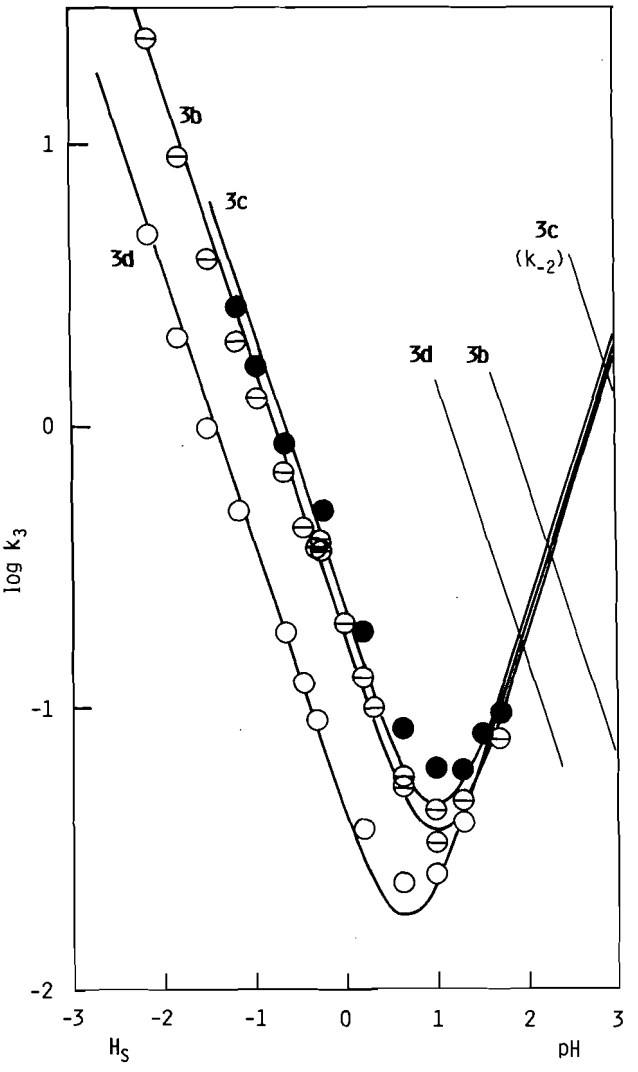

FIG. 4. Acidity – log k_3 correlations for the decay of the tetrahedral intermediates **3***b* (⊖), **3***c* (●), and **3***d* (○). Solid curves are calculated with the rate constants given in Table 5. Straight lines indicate rates of the reversion from **3** to **2** ($k_{-2}[H^+]$).

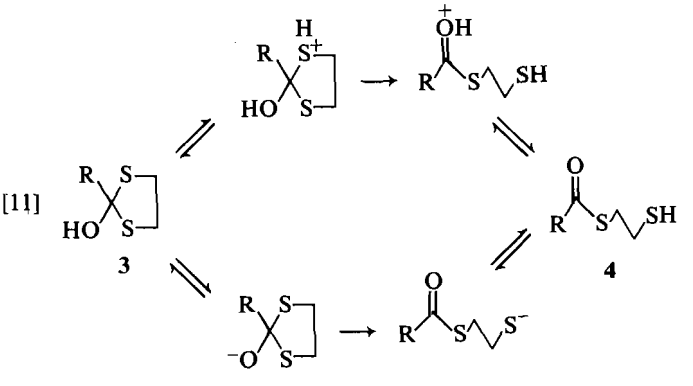
The acid-catalyzed reaction conforms to the H_S acidity function defined for sulfur protonation. This may be rationalized by a mechanism presented in eq. [11]. The rate-determining step would be opening of the ring. Kinetic solvent isotope effects were found to be very small at 0.1–1.0 *M* HCl (DCl), where the reactions involved are the pre-equilibrium formation of **3** and the acid-catalyzed decay of **3**. The observed isotope effects are not inconsistent with this mechanism (1).



The values of k_b obtained here may be those when the deprotonation of **3** is a rapid equilibrium, although the proton transfer step was found to be involved in the rate-determining step of the base-catalyzed decay of **3** at higher pH when R = *tert*-butyl (9). We could not examine the present reaction at higher pH. The rate constants k_a and k_b are not much influenced by the substituent. This is understandable because the reaction center is remote from the substituent.

Isotope exchange

The nmr spectra of the extracted mixtures from the reaction of **1***b* and **1***d* in acidic acetonitrile–D_2O solutions showed that extensive loss of the β-hydrogen occurred before the hydrolysis proceeded. The loss is due to the isotope exchange with solvent deuterium. The doublet for the methyl group of **1***b* changed to a poorly separated triplet (coupled with the deuterium) as the quartet for the β-hydrogen disappeared. Quantitative evaluation of the rate constant k_{ex} for the isotope exchange of **1***d* in 80 vol% CH_3CN–D_2O showed that the exchange is much faster than the hydrolysis (10^3- and 60-fold at 0.1 and 0.002 *M* of DCl, respectively), as seen from the data of Table 3. This is consistent with the mechanism involving the pre-equilibrium steps and the conclusion that the pre-equilibrium is more complete at higher acidities. With the acyclic analogue $PhCH{=}C(SMe)_2$, the exchange was only 3-fold as rapid as the hydrolysis under similar conditions, although the kinetic reversibility of the protonation in terms of k_2/k_{-1} (0.36) was greater in mostly aqueous solutions (2). The isotope exchange of **1***d* occurs largely through reversion from the tetrahedral intermediate **3**, while that of the acyclic analogue takes place from the carbocation intermediate (eqs. [12] and [13]).

[12] 
[13] 

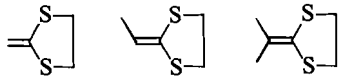
Stability and reactivity

The equilibrium constants K_1 for protonation of the double bond refer to carbon basicity. Similar determinations of which we are aware are those with 1,1-diarylethylenes (6, 11) and enamines of propiophenone (12). The most basic is the enamine ($\log K_1 \simeq 10$) (12). The dithioolefins ($\log K_1 = 1.7$ to -2.9 for **1***a*–**1***d*) are more basic than diarylethylenes ($\log K_1 = -4.4$ for $(p\text{-}CH_3OC_6H_4)_2C{=}CH_2$ and -9.4 for $(C_6H_5)_2C{=}CH_2$) (6).

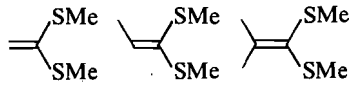
The equilibrium constants K_2 for hydration of the 2-alkyl-1,3-dithiolanylium ions **2** are only slightly influenced by the change in alkyl structure. The stability of **2** (relative to **3**) increases in the order R = $C_6H_5CH_2 < CH_3 \simeq C_2H_5 < (CH_3)_2CH < (CH_3)_3C$ (9). This order is opposite to the electron-donating ability of the alkyl group to the cationic center as deduced from, e.g., the σ_p^+ substituent constants. The steric strain in the tetrahedral form **3** is larger than that in the planar form **2** and this may contribute to the apparent stability of **2**. If we examine the rate constants k_2 and k_{-2}, the alkyl structure greatly influences k_{-2} but k_2 only slightly. The transition state for the second step may be closer to the state of the cationic intermediate **2**. A similar trend is also seen for the first step by comparing the magnitudes of k_1 and k_{-1}; the transition state for this step may also be close to the state of **2**.

Stability of the olefinic substrate **1** relative to the tetrahedral intermediate **3** is given by $1/K_1K_2$ as listed in Table 5. These values can be transformed to free energy differences ΔG_1 between **1** and **3** (Table 5). The unsubstituted **1***a* is less stable than **3***a* by 2 kcal/mol but the β-substituted derivatives **1** are a few kcal/mol more stable than the corresponding **3**. The β substitution would not affect appreciably the total energy of saturated compounds **3** but stabilizes the olefinic linkage of **1**. That is, the methyl, dimethyl, and phenyl groups stabilized the double bond by 3.1, 5.7, and 5.0 kcal/mol, respectively. These amounts of stabilization (in free energy) are close to those found in alkene stabilization (in enthalpy terms) (13, 14).

Effects of monomethyl and phenyl substitutions on the reactivity of **1***a* in protonation (k_1) are similar to those observed with the acyclic analogue $CH_2{=}C(SCH_3)_2$ (2–4), vinyl ethers (15–18), and vinyl sulfides (19). A second methyl group of **1***c* reduces the reactivity of **1***b* by nearly the same factor as the first (**1***a*/**1***b*), as shown below.



1 : 1/21 : 1/400



1 : 1/23 : $1/(8.8 \times 10^5)$

By contrast, a large reduction in the reactivity of the acyclic derivative was previously observed by dimethyl substitution (4). This was ascribed to a steric factor (4), but we suspected that a change in rate-determining step had been overlooked. Reexamination revealed, however, that the rates of hydrolysis of dimethylketene dimethyldithioacetal in 1 *M* and 0.1 *M* HCl nearly coincide with the extrapolation of those obtained in strong acid, and deuterium kinetic solvent isotope effects are normal ($k_{H_2O}/k_{D_2O} = 2.7$–3.0). That is, the largely reduced reactivity of the dimethyl derivative in protonation is real, and some steric factor that cannot operate in the dithiolane system should be the cause for this reduction in the acyclic system.

Summary

The carbon protonation of the β-substituted 2-methylene-1,3-dithiolanes was found to be completely reversible at higher acidities but only partially reversible at lower acidities during the hydrolysis. This is rationalized by the change in the rate-determining step and the stability of the olefinic substrates.

Experimental

Materials

2-Ethylidene- (**1***b*), 2-isopropylidene- (**1***c*), and 2-benzylidene-1,3-dithiolane (**1***d*) were obtained by deprotonation of the corresponding dithiolanylium perchlorates **2**, which were prepared from the reaction of the acyl chlorides with 1,2-ethanedithiol in the presence of perchloric acid as described elsewhere (20).

Equilibrium measurements

Initial (A^0) and equilibrium absorbances (A^∞) of the substrates in acid were measured on a Shimadzu UV-200 spectrophotometer at 25.0 ± 0.1°C. A sample of 30 μL of a stock solution of the substrate in dry acetonitrile was introduced from a microsyringe into 3.0 mL of acid solution, which was thermally equilibrated in a quartz cuvette, and time-dependent absorbance change was recorded. The absorbance was extrapolated to the time of mixing by a pseudo-first-order plot to obtain A^0, and A^∞ was read after 6 half-lives. The absorbances were plotted

against the H_C or H_R acidity function (6, 8) and pK_R was calculated by linear least-squares treatment according to the literature (21).

Kinetic measurements

Kinetic measurements were made in the same way as before (1). Reactions were carried out in aqueous solutions containing 0.5–1.0 vol% of CH_3CN at 25.0 ± 0.1°C and the ionic strength of the solutions of low acidity was maintained at 0.50 *M* by adding KCl. Reactions were followed spectrophotometrically on a Shimadu UV-200 or UV-140 spectrophotometer. The values of pH were determined with a Hitachi–Horiba F-7 pH meter.

Product analysis

In a 0.1 *M* HCl solution in 80 vol% CH_3CN–H_2O (20–30 mL) was dissolved 50 mg of the substrate **1** and the solution was kept at 25°C for about 5 half-lives. The products were taken up in ether after quenching with 10% $NaHCO_3$, washed with saturated NaCl, and dried over $MgSO_4$. The ether was removed under reduced pressure and the residues were subjected to nmr analysis by a JNM-C-60HL spectrometer. The spectra were consistent with the thiolester structure **4**; nmr (CCl_4) δ: **4***b*, 1.17 (t, 3H), 1.47 (t, 1H), 2.2–3.2 (m, 6H including q at 2.54 ppm); **4***d*, 1.42 (t, 1H), 2.3–3.4 (m, 4H), 3.70 (s, 2H), 7.2 (br s, 5H).

Isotope exchange

Reactions were carried out in 80 vol% CH_3CN–D_2O containing DCl. The DCl solutions were prepared by bringing 20 parts by volume of an appropriate DCl solution in D_2O (Merck, 99.75%) to 100 parts with dry acetonitrile in a volumetric flask. In a typical reaction, about 150 mg of **1***b* or **1***d* was dissolved in 100 mL of the DCl solution equilibrated thermally at 25°C. The mixture was shaken and left standing at 25°C. After appropriate reaction time, a 25-mL aliquot of the mixture was taken by a syringe, quenched with 10% $NaHCO_3$, extracted with ether, washed with saturated NaCl, and dried over $MgSO_4$. The ether was removed under vacuum and the residues dissolved in CCl_4 were subjected to nmr analysis. During the reaction of **1***b* in 0.1 *M* DCl, the quartet due to the β-hydrogen (5.4 ppm) was mostly (ca. 80%) lost in 10 min and the doublet due to the methyl group (1.7 ppm) changed to a broad singlet (or a poorly separated triplet). A similar change was also observed at 0.002 *M* of DCl. In the case of **1***d*, the intensity of the singlet at 6.5 ppm (β-hydrogen) was quantitatively evaluated in reference to that of the phenyl group. The rate of isotope exchange was calculated from the first-order plots of the intensity (Fig. 3). Kinetic analysis of the hydrolysis in this medium as well as in the corresponding HCl solution was also undertaken by uv spectrophotometry in the same way as above.

The acid-catalysed rearrangements of 2,6-dichloro-*N*-nitroaniline and 2,6-dibromo-*N*-nitroaniline to give the corresponding 4-nitro derivatives have been followed by ^{1}H and ^{15}N nmr spectroscopy in deuteriochloroform at 30°C. When $^{15}NO_2$-labelled nitramines are used, the ^{15}N nmr signals for both the substrate and product show enhanced absorption during reaction. When one labelled nitramine and one unlabelled nitramine are rearranged together, isotopic exchange occurs and ^{15}N nmr signals are seen for both substrates and both products. For the initially unlabelled nitramine and its product, these signals are in emission. The change in the enhancement of the signals during reaction shows that the nuclear polarization arises from the rearrangement, not from a preliminary equilibrium.

Opérant à 30°C, dans des solutions de deutérochloroforme et faisant appel à la rmn du ^{1}H et du ^{15}N, on a pu suivre l'évolution des transpositions acido-catalysées des dichloro-2,6 et dibromo-2,6 *N*-nitroanilines en dérivés nitro-4 correspondants. Lorsqu'on utilise des nitramines marquées avec des $^{15}NO_2$ et que l'on suit l'évolution de la réaction par rmn du ^{15}N, on observe une augmentation de l'absorption tant pour le substrat que pour le produit. Quand on effectue une transposition entre une nitramine marquée et une autre qui ne l'est pas, il se produit des échanges isotopiques et les signaux de la rmn du ^{15}N sont observés tant dans les substrats que dans les produits. Pour la nitramine qui n'était initialement pas marquée, ces signaux correspondent à des émissions. Les changements qui se manifestent par une augmentation des signaux au cours de la réaction indiquent que la polarisation nucléaire provient de la transposition et non pas d'un équilibre préliminaire.

Introduction

Although a number of mechanisms have been put forward for the nitramine rearrangement (1), that most generally accepted, at least for nitramines from the more basic amines, is the radical pair interpretation first put forward by W. N. White *et al.* (2). On this interpretation the protonated nitramine undergoes homolysis to form the cation radical of the amine and nitrogen dioxide. One weakness of this mechanism is the lack of direct evidence for the intermediate radicals (3) and a related problem is the ill-defined borderline between the radical mechanism and the heterolytic processes expected for the rearrangement of nitramines containing strongly electron-withdrawing groups (1).

In our preliminary communication on this work (4), we showed that the rearrangement of $^{15}NO_2$-labelled 2,6-dibromo-*N*-nitroaniline gave strongly enhanced ^{15}N nmr signals during reaction for both the substrate and the 4-nitro product. This evidence for nuclear polarization shows that a radical pair is involved in some way in the reaction. However, since strong nuclear polarization was present in both the substrate and the product, it was recognised that this work did not provide unambiguous evidence for the radical pair interpretation of the rearrangement. The nuclear polarization could have been generated by a preliminary equilibrium involving the nitramine and then carried over into the product by a non-radical process. This complication has been rendered less likely by the recent work of Shine *et al.* (5), for these authors have used heavy element isotope effects to show that the rearrangement is not a concerted process. The present work was carried out to provide more direct evidence for the involvement of radical pairs in the rearrangement reaction.

2,6-Dibromo-*N*-nitroaniline and 2,6-dichloro-*N*-nitroaniline were chosen as the substrates partly because of the ease with which these compounds can be prepared from nitric acid (the source of the isotopic label) and partly because of the relative cleanliness of the corresponding rearrangements. The early work of Orton and Pearson (6) has, however, shown that the rearrangement of the bromo compound is accompanied by the formation of some 2,4-dibromo-6-nitroaniline.

Results

For this work, it was necessary to obtain conditions in which a relatively high concentration of the nitramine would rearrange smoothly in solution with a half-life of ca. 10 min. The conditions chosen involved reaction in deuteriochloroform at 30°C with trifluoroacetic acid as the catalyst. The reaction was studied first by ^{1}H nmr spectroscopy with nitromesitylene present as an inert standard.

The spectrum of 2,6-dibromo-*N*-nitroaniline in deuteriochloroform is as expected (δ: 7.19(t, 4-H, J = 8.14), 7.65(d, 3, 5-H), 9.62(s, N-H)). As reaction proceeds, the signal for the product appears at δ 8.34. The progress of the reaction was followed from the height of this peak and from the larger of the two peaks for the reactant at δ 7.65, both measured relative to the height of the peak for nitromesitylene (δ 6.92). A similar procedure was used for following the rearrangement of 2,6-dichloro-*N*-nitroaniline. In this compound, the aromatic protons give rise to a multiplet (δ: 7.44(m, 3, 4, 5-H), 9.44(s,

N-H), and the product signal is at δ 8.15. The dichloro compound gave reasonable first-order kinetics when followed from either the disappearance of the starting material or the appearance of the products: the conditions of the reactions and the rate coefficients obtained are shown in Table 1. The spectra for the rearrangement of the dichloro compound in the first series of Fig. 1 show the separation of the peaks and the cleanliness of the overall reaction. Some very small additional peaks can be seen in the final spectrum coming from the by-products formed. The results with the dibromo compound were less reproducible (see Discussion).

The runs with the $^{15}NO_2$-nitramines were carried out in a similar way and were followed by ^{15}N nmr spectroscopy using ^{15}N-nitrobenzene as an internal standard. For the dibromo compounds, the nitramine signal was 24.7 ppm to high field of the standard and the product signal was 5.1 ppm to high field of the standard. For the dichloro compounds, the corresponding values are 24.2 and 4.7. These slight differences in the positions of absorption of the dibromo and dichloro compounds made possible the observation of crossover experiments.

The changes in the heights of these nmr signals for the separate rearrangement of the two nitramines are shown in Table 2. It is immediately obvious that the intensity of the signals depends more on the nuclear polarization present than on the concentrations of the species concerned. Thus, the intensity of the peak for the nitramines rises over the first five minutes of reaction and remains above the initial intensity over almost all of the period studied (several half-lives). The intensity of the peak for the product also rises rapidly over the first five minutes and then decreases more slowly. The form of these spectra is illustrated for the dichloro compound in the second series of Fig. 1.

Studies have also been carried out on the simultaneous rearrangement of the two nitramines in the same solution, but with only one of the nitramines labelled with ^{15}N. The dichloro and dibromo nitramines used here are very suitable for this kind of experiment since they rearrange at similar rates (Table 1). If no isotopic exchange occurs then, when the reaction mixture is studied by ^{15}N nmr spectroscopy, only the rearrangement of the labelled nitramine should be seen. However, in these experiments, peaks were seen for both nitramines and both products. The peaks could be clearly distinguished since those for the initially unlabelled nitramine and the corresponding product were in emission. The heights of the peaks relative to the

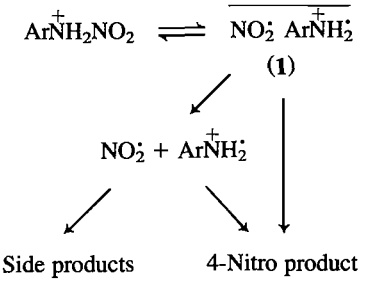
Discussion

The rearrangement will be discussed in terms of the radical pair mechanism originally proposed by White *et al.* (2) and shown in Scheme 1. The reverse reaction of the radical pair (**1**) to reform the nitramine has been added to the original mechanism to explain the polarization of the substrate observed in the present work.



SCHEME 1

The present results provide support for this mechanism in several ways. First, the presence of nuclear polarization in the product of rearrangement is clear evidence for the involvement of radical pairs at some stage on the reaction path. If the radical pair is considered to be formed from the cation radical of the amine and nitrogen dioxide (as implied by the scheme), then Kaptein's rules (7) permit the phase of the polarization to be calculated from the sign of the difference between the g-values of the amine cation radicals ($g > 2.00249$) (8) and nitrogen dioxide ($g = 2.0000$) (9).[2] The application of Kaptein's rules also requires the sign of the hyperfine coupling constant (a_N) for the nitrogen atom in nitrogen dioxide; this should be negative because of the negative magnetogyric ratio of the ^{15}N nucleus (10). The negative magnetogyric ratio also has the consequence

[2]Several values exist for this quantity; the reasons for selecting g = 2.0000 are given in ref. 10.

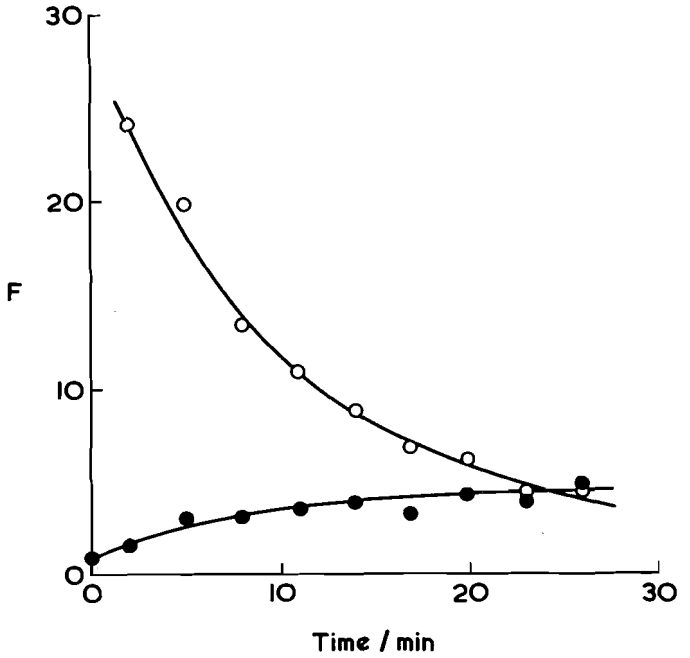


FIG. 3. The variation in the enhancement of the ^{15}N nmr signals during the rearrangement of 2,6-dichloro-*N*-nitroaniline: dots, nitramine; open circles, 4-nitro product.

that an additional negative sign should be added to the normal equation expressing Kaptein's rule for net polarization (11). The rule then takes the form of eq. [1], where the sign of Γ is positive for absorption and negative for emission. The sign of μ is positive when the radical pair is formed by the diffusion together of the radicals and negative when the radicals are formed from a singlet precursor (e.g., by homolysis of the protonated nitramine). The sign of ε is positive for cage products and negative for products formed from radicals that have escaped from the cage.

$$[1] \quad \Gamma = -\mu\varepsilon a_N(g_{NO_2} - g_{ArH+\cdot})$$

When the signs appropriate for the present reaction are inserted in this equation, it is clear that the recombination of the radical pair within the cage either to reform the nitramine or to form the rearranged product should lead to enhanced absorption, as observed (Fig. 1). Most of the radicals that separate should eventually diffuse together to form the same products but some of the polarization of the free nitrogen dioxide radicals should be lost through nuclear relaxation; the overall polarization should therefore be that for the recombination reaction within the cage.

This picture of the reaction also accords with the polarization observed when one labelled nitramine and one unlabelled nitramine are rearranged together, for the signals for the initially unlabelled nitramine and the corresponding rearranged product appear in emission (Fig. 2 and Table 3). These signals derive from species that have undergone isotopic exchange and it is reasonable, therefore, that they should reflect the polarization of the nitrogen dioxide molecules that have escaped from the original cage. This is of opposite phase to that of the cage products because the CIDNP (chemically induced dynamic nuclear polarization) effects derive from a degree of partitioning of the nitrogen dioxide molecules according to the ^{15}N nuclear spin.

The enhanced absorption signals observed in the rearrangement of a labelled substrate and the emission signals seen during the crossover experiments could also be explained by a reaction scheme in which the protonated nitramine dissociates reversibly to form the radical pair (1) but undergoes the nitramine rearrangement by a separate non-radical process. To eliminate this possibility, it is necessary to consider the relative polarization of the nitramine and the rearranged product. From the magnitude of the ^{15}N signals in Table 2 and the concentrations of the nitramine and rearranged product calculated from the rate coefficients in Table 1, it is possible to calculate the changes in the enhancement factor (F) of the ^{15}N signals during reaction (see experimental section). Such enhancement factors are plotted for the rearrangement of the 2,6-dichloronitramine in Fig. 3; the results for the rearrangement of the 2,6-dibromonitramine are very similar. The results show that, at the start of reaction, the enhancement factor for the product is much greater than that for the reactant; the greater part of the polarization of the product must therefore be generated in the rearrangement stage.

There are several possible complications in the above argument that require consideration. One is the possibility that the ^1H nmr measurements are distorted by nuclear polarization and so do not provide a true measure of the extent of reaction. When Kaptein's rules (7) are applied to the ^1H nmr spectra, the predicted result at the 3,5-position is emission, since calculations[3] suggest that the sign of the hyperfine coupling constant is positive at this position in the cation radical of dichloroaniline. A contribution from such nuclear polarization would therefore give an apparent increase in the rate of disappearance of the nitramine and a decrease in the rate of appearance of the rearranged product. The rate coefficients calculated from the heights of the peaks for the substrate and product are not identical (Table 1), but the discrepancy is in the opposite direction to that expected. However, in a number of runs, a curious variation exceeding the expected experimental error was observed in the height of the peaks for the dibromonitramine at the start of reaction; the above argument concerning the enhancement factors is therefore based on the results for dichloro compound (Fig. 3).

The discrepancy in the values of k_N and k_P (Table 1) could arise from the side reactions present. A concurrent first-order process would not interfere with the calculation of k_P but the presence of any subsequent reaction would decrease the height of the signal for the product at the end of reaction and thus cause the extent of reaction at earlier times to be overestimated. In this connection, it is interesting that some deamination does appear to occur in the reaction (see experimental section). Fortunately, the difference between the enhancement factors for the nitramine and product (Fig. 3) is far too great for the conclusions to be affected by such small uncertainties in the rate coefficients.

The relative enhancement factors for the nitramine and the rearranged product are also affected by the relaxation times of the ^{15}N nucleus in these compounds. The relaxation time of this nucleus in the N-$^{15}NO_2$ position of the dichloronitramine has therefore been measured (152 s). The result is slightly less than that found for an aromatic C-$^{15}NO_2$ group (170 s in nitrobenzene (12), 182 s for the 2-nitro group of 2,4-dinitrophenol (13)). This difference is insufficient to require any change in the above argument concerning the generation of the polarization in the rearrangement stage.

[3] J. Courtneidge, personal communication of results of MNDO calculation.

Because of this similarity in the relaxation times, the greater polarization found for the product in the exchange experiments (Fig. 2) implies that the radical pairs (**1**), at least when formed by diffusion, react mainly at the 4-position rather than at the nitrogen atom. What happens when the radical pair is formed by the homolysis of the protonated nitramine is less clear because the extent of nuclear polarization depends on the lifetime of the radical pair. If the initial orientation of the radical pair favours rapid recombination at the nitrogen atom, the contribution of this to the nuclear polarization could be slight because of the short lifetime involved. For a more complete discussion of this, it would be necessary to distinguish between different types of radical pairs, including solvent-separated pairs (14).

The extent of isotopic exchange during the concurrent rearrangements (Table 3) can be estimated from the relative heights of the ^{15}N peaks for the two rearranged products at the end of reaction. The results are not very accurate because, in the absence of nuclear polarization, the signal-to-noise ratio is low. However, the extent of exchange is clearly very considerable, for the peak height of the product formed by exchange is 70% of that formed from the initially labelled substrate when the initial label is in the dichloronitramine. The corresponding figure is 60% when the initial label is in the dibromo compound. These results accord with the extensive exchange observed by White and Golden (15) in the concurrent rearrangement of *N*-nitro-*N*-methylaniline and 4-fluoro-*N*-nitro(^{15}N)-*N*-methylaniline. Thus, the complete set of results are in full agreement with the mechanism proposed by White (2) (with the addition of some return of the radical pairs to the nitramine). The generation of nuclear polarization in the rearrangement stage provides unequivocal evidence for the involvement of radical pairs in the rearrangement.

Experimental

Materials

The nitramines were prepared by a modification of the method used by Orton and Smith (16) for the preparation of 2,6-dibromo-*N*-nitroaniline. The modifications were to facilitate the preparation of the labelled compounds. Nitric acid (2.8 mL, 40%) was added to a solution of the amine (0.014 mol) in glacial acetic acid (31 mL) followed, after cooling to 12°C, by the addition of acetic anhydride (2.1 mL). The reaction mixture was maintained below 20°C for 9 min and then poured into ice-water (51 g). After extraction with $CHCl_3$ (100 mL) and washing with water (3 × 100 mL), the chloroform solution was extracted with sodium carbonate (2 × 50 mL, 4%) and the extract was cautiously neutralized with hydrochloric acid. The precipitated nitramines were washed with water and dried under vacuum. 2,6-Dibromo-*N*-nitroaniline was formed in a yield of 71% and had mp 107°C (lit. (16) mp 108°C). *Anal.* for $C_6H_4N_2O_2Br_2$: C 24.4, H 1.4, N 9.5; found: C 24.2, H 1.4, N 9.5. 2,6-Dichloro-*N*-nitroaniline was formed in a yield of 80% and had mp 94–95°C (lit. (17) mp 102–103°C(dec.)). *Anal.* for $C_6H_4N_2O_2Cl_2$: C 34.8, H 2.0, N 13.5; found: C 34.5, H 1.9, N 13.7. The ^{15}N-labelled nitramines were prepared in the same way using nitric acid (95–99% ^{15}N, 40%) from B.O.C. Prochem. The trifluoroacetic acid was prepared by the addition of D_2O or H_2O to trifluoroacetic anhydride and standardized by titration with sodium hydroxide. The $CDCl_3$ used in the kinetic studies was from Aldrich (Gold Label).

Products

The ^1H nmr spectrum of the products of rearrangement of 2,6-dichloro-*N*-nitroaniline includes a number of small peaks with a total height of ca. 10% of the peak for the 4-nitro product (Fig. 1). The rearrangement of this nitramine (0.2828 g) followed by separation of the products by hplc gives 2,6-dichloro-4-nitroaniline (0.2135 g) together with other fractions (0.0336 g). The yield of the main product is therefore 86% of the isolated material or 75.5% overall. The other products have not been investigated in detail but an analysis by glc–ms indicated a complex mixture including some *meta*-dichlorobenzene and 3,5-dichloronitrobenzene. The results with the 2,6-dibromonitramine were very similar. Separation by hplc showed that the 4-nitro product was 89% of the isolated material.

Kinetics

The kinetic studies followed by ^1H and ^{15}N nmr spectroscopy were carried out on a Varian XL-200 FT spectrometer; the measurement of the relaxation time was made on a Jeol FX 90Q FT spectrometer using the fast inversion recovery method (18).

The nitramine or mixture of nitramines (usually 0.15 mmol) and an equivalent amount of the standard (nitromesitylene or ^{15}N-nitrobenzene) were dissolved in $CDCl_3$ (usually 1 or 2 mL) and brought to the required temperature (usually 30°C). The nmr spectrum was measured and the reaction was started by the addition of CF_3CO_2D or CF_3CO_2H (usually 0.1 mL); nmr spectra were then taken every 2 or 3 min for ca. 2 half-lives using 50 pulses, delay time 2 or 3 s. More acid was then added (0.1 mL) and the final spectrum was taken after ca. 10 half-lives.

For the runs followed by ^1H nmr spectroscopy, the rate coefficients obtained from the concentration of the nitramine were calculated from a plot of $\ln(h_n/h_s)$ against time, where h_n and h_s are the heights of the peaks for the aromatic protons in the nitramine and in nitromesitylene respectively (for the dibromo compound, the larger of the two peaks for the 3,5-protons was used). As expected, the height of the peak for nitromesitylene was almost constant throughout the run.

The rate coefficients for the runs followed from the concentration of the rearranged product were calculated from a plot of $\ln((h_p/h_s)_{t=\infty} - (h_p/h_s)_t)$ against time, where h_p is the height of the peak for the 3,5-protons in the product. Ten points were usually taken over about 2 half-lives but, in some runs, the first one or two points were neglected since these seemed subject to greater error. Regression coefficients were 0.99 ± 0.01.

The enhancement factors (F) for the nitramine plotted in Fig. 3 were calculated from eq. [2] and those for the product were calculated from eq. [3].

$$[2] \quad F = \frac{(h_n/h_s)_t a}{(h_n/h_s)_{t=0}(a - x)}$$

$$[2] \quad F = \frac{(h_p/h_s)_t a}{(h_p/h_s)_{t=\infty} x}$$

In these equations, the heights (h_n, h_p, h_s) refer to the peaks in the ^{15}N nmr spectra for the nitramine, product, and standard. The initial concentration of the nitramine is a and the concentration of the product (x) is calculated from the mean rate coefficient ($k = 9.6 \times 10^{-4}\ s^{-1}$) for the appropriate kinetic run.

The rates of triplet decay of a series of β-aryl-(4-alkoxypropiophenone)s in the smectic, nematic, and isotropic phases of 4′-butyl- and 4′-ethylbicyclohexyl-4-carbonitrile (BCCN and ECCN, respectively) have been measured over the 30–95°C temperature range by nanosecond laser flash photolysis. The rates of triplet decay for these probe molecules in fluid solution are governed by the rates of Cα—Cβ bond rotation, which allows intramolecular quenching of the carbonyl triplet state by the β-aryl ring. The ketones are substituted with alkyl groups of varying length, shape, and flexibility in the *para* positions of the β-phenyl (H, n-hexyl, cyclohexyl) and benzoyl (meth-, n-pent-, and n-octoxy) rings. With the exception of β-phenyl-(4-methoxypropiophenone), for each ketone the Arrhenius parameters for triplet decay in the smectic phase of BCCN are similar to those in the nematic phase of the same solvent, and in all cases, the Arrhenius plots exhibit perfect continuity at the S—N transition temperature. A solvation model is tentatively advanced to explain these results. In the nematic phase of BCCN, the Arrhenius activation energy and entropy are significantly more positive than those in isotropic ECCN for all the ketones studied, but variations in the energetics of triplet decay in the nematic phase as a function of solute structure are parallelled in the isotropic solvent. Thus, the inhibiting effect of the nematic solvent on the bond rotations leading to intramolecular triplet quenching in these probes is attributed to the predominant influence of microviscosity (viscous drag) effects; the presence of solvent orientational order appears to have little or no effect on the intramolecular mobility of these ketones. The results and conclusions of earlier studies of unimolecular reactions in nematic solvents are discussed in light of these results.

WILLIAM J. LEIGH. Can. J. Chem. **64**, 1130 (1986).

Faisant appel à la photolyse flash au laser dans le domaine des nanosecondes et opérant à des températures allant de 30 à 95°C, on a mesuré les taux de dégénérescence des triplets d'une série de β-aryl alkoxy-4 propiophénones dans des phases smectiques, nématiques et isotropes des butyl-4′ et éthyl-4′ bicyclohexylcarbonitriles-4 (BCCN et ECCN). Les taux de dégénérescence de ces molécules sondes dans des solutions fluides sont gouvernées par les vitesses de la rotation autour de la liaison Cα—Cβ qui permet un piégeage intramoléculaire de l'état triplet du carbonyle par le cycle β-arylique. Les positions *para* des groupements phényle (H, n-hexyle, cyclohexyle) ou benzoyle (méthoxy, n-pentoxy ou n-octoxy) des cétones sont substitués par les groupements alkyles indiqués qui ont diverses longueurs, formes et flexibilités. A l'exception de la β-phényl méthoxy-4 propiophénone, les paramètres d'Arrhénius de chacune des cétones, pour la dégénérescence de l'état triplet dans la phase smectique du BCCN, sont les mêmes que ceux mesurés dans la phase nématique du même solvant; de plus, dans tous les cas, les courbes d'Arrhénius présentent toutes une continuité parfaite à la température de transition S—N. Sur une base préliminaire, on suggère un modèle de solvatation pour expliquer ces résultats. Pour toutes les cétones étudiées dans la phase nématique du BCCN, les énergies et les entropies d'activation d'Arrhénius sont toutes beaucoup plus positives que celles mesurées dans la phase isotrope du ECCN; toutefois, les variations dans les facteurs énergétiques de la dégénérescence de l'état triplet dans la phase nématique, en fonction de la structure soluté, sont parrallèlles à celles observées dans le solvant isotrope. Ainsi, l'effet inhibiteur du solvant nématique sur les rotations des liaisons, qui conduit à un piégeage intramoléculaire du triplet dans ces sondes, est attribué à l'effet prédominant des effets de microviscosité (attraction visqueuse); l'influence de l'ordre orientationnel du solvant semble n'avoir que peu ou pas d'effet sur la mobilité intramoléculaire de ces cétones. A la lumière de ces résultats, on discute des résultats et des conclusions d'études antérieures sur des réactions unimoléculaires dans des solvants nématiques.

[Traduit par la revue]

Introduction

The effects of liquid crystalline order on the dynamics of uni- and bimolecular reactions of dissolved solutes is an area of increasing interest. Several investigations have examined the possible effects of these media on cyclization reactions, both thermally (2) and photochemically (3) induced. The premise behind these investigations is that the conformational mobility of a reactive molecule dissolved in an orientationally ordered solvent might be restricted in favour of those conformations which "fit" the best into the surrounding solvent framework. Nematic and smectic liquid crystals are formed by compounds whose molecular shape is rod-like,[2] and the dominant feature of the ordering in these materials is that the long molecular axes of the constituent molecules are oriented parallel to one another, on the average. Thus, cyclization of a similarly oriented, rod-like solute molecule is expected to be inhibited in a liquid crystal, to the extent that extended or rod-like conformations are favoured over those which are more globular (or less rod-like) in shape, and that formation of the globular conformer and subsequent transition state for cyclization involves some local disruption of liquid crystalline order.

With a couple of exceptions (*2e*, *3e*, *f*), the investigations reported to date have established only small or negligible effects of liquid crystalline solvents on the energetics of cyclization reactions. Several factors may be contributing to these results. The first (and most obvious) relates to the degree and rigidity of the orientational ordering in the various types of liquid crystals employed in these studies. Most have examined the effects of nematic or cholesteric liquid crystals on solute cyclization (*2a–d*, *3a–d*). These are the most fluid types of liquid crystalline phase, and their relatively low degree of orientational

[1]Natural Sciences and Engineering Research Council (Canada) University Research Fellow, 1983–1986.

[2]For comprehensive descriptions of the nature and properties of liquid crystals and leading references, see ref. 4.

ordering and rigidity is apparently insufficient to significantly inhibit the conformational mobility of solutes. On the other hand, the smectic types are more crystalline in character (4), with the result that substantial effects on cyclization energetics can be observed in these types of mesophase (2*e*, *f*, 3*e*, *f*).

The second factor which presumably contributes to the ability of liquid crystals to affect solute cyclization is the structure of the solute itself (5). Bulky, globular solutes have a more disruptive effect on macroscopic liquid crystalline order (as measured by mesophase transition temperatures) than do rod-like solutes (2*e*, 3*d*, 5, 6), an effect which is presumably the result of microscopic (in the vicinity of the solute) disruption of solvent order (3*e*, 5). This local isotropization of the solute's environment effectively truncates the potential effects of the ordered solvent on the solute's conformational (3*e*) or configurational (5) mobility. Recent results from our laboratory suggest that for smectic phases, the molecular length of the solute in relation to the smectic layer thickness may be an important factor in determining the extent to which solvent order inhibits the conformational mobility of the solute (7). In general, it appears that liquid crystalline effects on solute intramolecular motions are greatest for solutes whose sizes and shapes are similar to that of the solvent molecules (3*c*–*f*, 7).

While it is clear that solute mobility can be affected to some extent in nematic and cholesteric liquid crystals, it is difficult to ascertain the nature of the effect. Considering the rather high bulk viscosities of these mesophases (8), the magnitude of the effect which is generally observed (<3 kcal/mol in E_a; <5 eu in $\Delta S^{\ddagger}$) might just as reasonably be attributed to microviscosity (viscous drag) effects as to the presence of solvent order. In principle, a distinction between the two effects should be possible by comparing the conformational mobilities of a series of probes of varying molecular lengths in isotropic and liquid crystalline solvents. For a suitable series of probes, microviscosity effects should be revealed by parallel behaviour of the probes in the two solvents, while solvent order effects should be revealed by varying changes in probe dynamics in the two solvents depending on the structures of the probes.

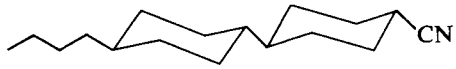
A number of techniques have been used to investigate solute molecular mobility in liquid crystals, including nmr (9), esr (10), fluorescence decay (3*c*–*e*, 11), and nanosecond laser flash photolysis (3*f*, 7) methods. In particular, the latter two techniques are the most useful for investigating *intramolecular* solute motions, since such motions can be monitored directly by examining the dynamics of intramolecular excited state quenching processes, such as intramolecular excimer or exciplex formation (3*c*–*e*) or triplet quenching (7). These experiments involve measuring the competition between normal, unimolecular decay of the initially excited end of a probe molecule and its quenching by a moiety at the other end. As long as the quenching step occurs irreversibly, and at a rate which exceeds both those of collapse of the quenching geometry prior to quenching and the competing unimolecular decay process, then the observed rate of excited state decay reflects the rate(s) of the conformational changes which are required in order for quenching to occur.

The time scale over which a particular probe system is useful depends primarily on the excited state lifetime of the isolated chromophore in the absence of quencher. For fluorescence decay methods, this limits the usable time range to 1–250 ns. While this appears to be adequate for nematic and cholesteric phases, difficulties arise in smectic solvents, where bond rotations occur on a time scale which is apparently of the same order of magnitude (or perhaps longer) than the isolated lumophoric lifetime (3*e*). Nanosecond laser flash photolysis techniques allow the investigation of intrinsically longer-lived species, such as aromatic ketone triplet states, which affords more flexibility for monitoring the much slower rates of intramolecular quenching which may obtain in smectic phases.

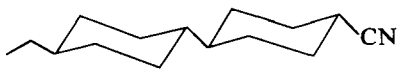
Recently, we reported preliminary results of a nanosecond laser flash photolysis study of the effects of nematic and smectic solvent order on the triplet lifetime of β-phenyl-(4-methoxypropiophenone) (**1***a*) (7). β-Phenyl ketones such as **1***a* owe their photoinertness (12, 13) and unusually short triplet lifetimes (13, 14) to intramolecular quenching of the carbonyl triplet state via exciplex interactions between the β-phenyl ring and the carbonyl group (reaction [1]) (13–15).

[1] 
1*a*

Attainment of the quenching geometry, which requires rotation about the Cα—Cβ bond (13–17), is severely inhibited in the smectic phase of *trans*,*trans*-4′-butylbicyclohexyl-4-carbonitrile (BCCN); the activation energy and entropy for triplet decay of **1***a* are 12 kcal/mol higher and 35 eu more positive, respectively, relative to their values in a model isotropic solvent (*trans*,*trans*-4′-ethylbicyclohexyl-4-carbonitrile, ECCN). In the nematic phase of BCCN, E_a and $\Delta S^{\ddagger}$ were found to be 1.5 kcal/mol and 4 eu more positive, respectively, than their values in isotropic ECCN.



BCCN



ECCN

The similarity between the molecular shapes of **1***a* (in its *trans*-conformation) and BCCN-type analogues, and the ease with which solute structural features can be altered via appropriate substitution, make this system a seemingly ideal probe with which to examine how the conformational mobility of solutes in liquid crystals depends on solute length and substituent shape and flexibility. To this end, we have synthesized a series of β-aryl-(4-alkoxypropiophenone)s (**1**–**3**) and measured their triplet lifetimes as a function of temperature in the smectic, nematic, and isotropic phases of BCCN and ECCN by nanosecond laser flash photolysis. The results of this study are reported below.

Results

The substituted β-phenylpropiophenones (**1**–**3**) were prepared by condensation of 4-hydroxy- or 4-methoxyacetophenone with the appropriate *para*-substituted benzaldehyde (18), hydrogenation of the resulting α,β-unsaturated ketones over Raney nickel, and alkylation of the β-aryl-(4-hydroxypropio-

phenone) with the appropriate alkyl bromide or dialkyl sulfate. The ultraviolet absorption and phosphorescence emission spectra of each of these compounds are similar to those of the parent compound **1***a*.

Transition temperatures for BCCN, ECCN, and mixtures ca. 0.04 molal (1 mol%) in each of the ketones studied were measured by thermal microscopy and are listed in Table 1.

The ultraviolet absorption spectra of **1***a* in methylcyclohexane, acetonitrile, and isotropic BCCN are shown in Fig. 1. The spectra of this compound as non-oriented solutions in the nematic and smectic phases of BCCN (prepared by simple cooling of the isotropic melt) were indistinguishable from that in the isotropic phase.

Laser flash photolysis experiments were carried out using the pulses (337.1 nm, <10 mJ, ~8 ns) from a nitrogen laser for excitation, and monitoring transient absorptions using a system with nanosecond time response (19). Samples for these experiments were ~1.0 mol% solutions of the ketones in BCCN and ECCN, and were contained in Pyrex cells of 0.7 mm pathlength. Optical densities of the isotropic solutions were in the range of 0.15–0.20 at the excitation wavelength. Liquid crystalline samples were prepared by normal cooling from the isotropic melts. Smectic samples prepared in this way were typically somewhat opaque and caused considerable scattering of the monitoring light, which necessitated more extensive signal averaging (compared to nematic and isotropic samples) in order to obtain reproducible decay traces. Annealing these samples at 40°C for 2–7 days results in homeotropically aligned samples, which are much more suitable for transient absorption measurements within a limited temperature range (40 ± 6°C). Above and below this temperature range, the glassy samples develop imperfections and turn opaque. Triplet lifetimes from annealed samples were identical to those obtained from unannealed ones, within experimental error. The former yield pseudoisotropic nematic phases upon warming; the characteristic turbid appearance of the nematic phase could be obtained by simple agitation of the sample cell.

Transient absorption spectra, recorded for **1***b* and **3***a* in the nematic phase of BCCN (~60°C), are shown in Fig. 2. These

spectra, as well as those of the other ketones studied (**1***a*, *c*, **2**, and **3***b*, *c*) agree well with that previously reported for the triplet state of **1***a* (17*a*, 20).

The triplet states of **1–3**, monitored at 390 nm, decayed with clean first-order kinetics in every case. Representative decay traces, recorded for **1***b* and **3***a* in nematic BCCN (60°C), are included as inserts in Fig. 2. Generally, the transient absorptions decayed completely to baseline, although residual absorption did occur occasionally in the smectic phases. These absorptions were irreproducible and resulted in slightly larger errors in the calculated decay rates.

For each ketone, the triplet decay was monitored at several temperatures between 30 and 95°C in both BCCN and ECCN. Arrhenius plots of $-\log \tau_T$ versus $1/T$ in the two solvents are shown in Figs. 3 and 4 for **1***c* and **3***a*, respectively. With the exception of **1***a* in BCCN (7), and possibly **3***c* in the same solvent, the data appear to fit to a single line in each case. Arrhenius parameters for triplet decay in the nematic and smectic phases of BCCN and the isotropic phase of ECCN,

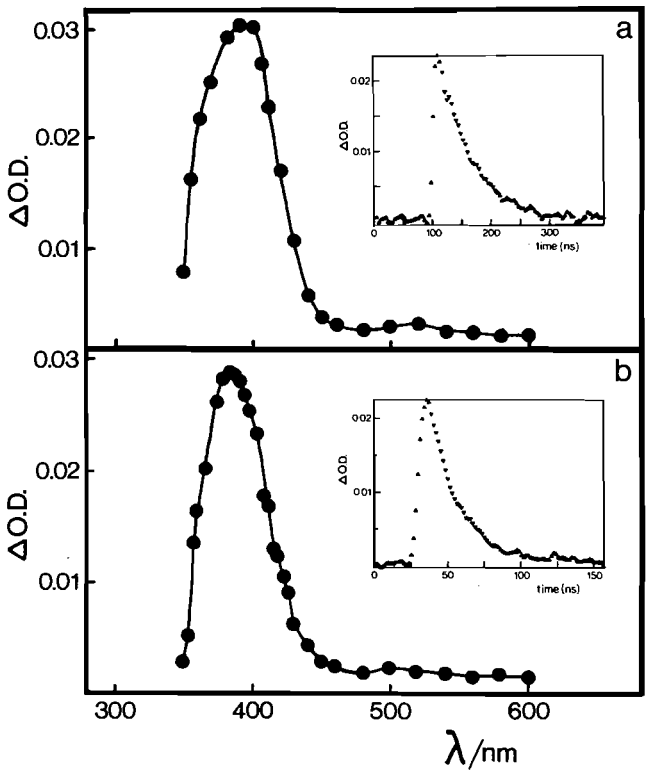

FIG. 2. Triplet–triplet absorption spectra of (*a*) **1***b* and (*b*) **3***a* in nematic BCCN, recorded at 58°C. Inserts: Representative decay traces, monitored at 390 nm for (*a*) **1***b* at 57°C and (*b*) **3***a* at 61°C.

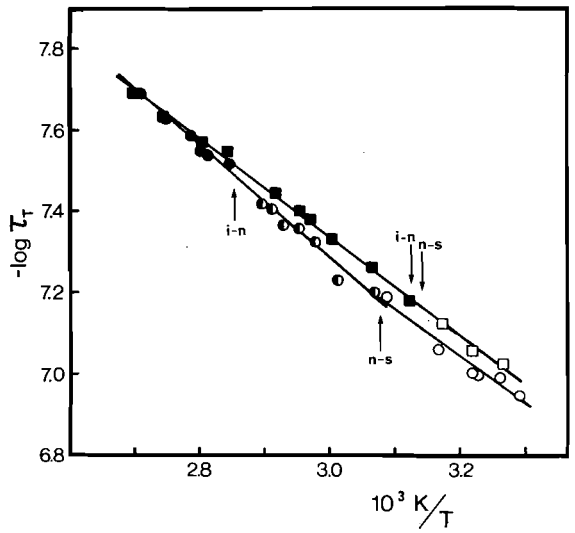

FIG. 3. Arrhenius plot ($-\log \tau_T$ vs. $1/T$) for triplet decay of **1***c*, monitored at 390 nm, in the nematic and smectic phases of BCCN (●) and the isotropic and smectic phases of ECCN (■). Open symbols denote smectic phase, half-symbols denote nematic phase, and closed symbols denote isotropic phase results. Transition temperatures for the mixtures are indicated.

obtained from least squares analysis of the data for each ketone, are summarized in Table 2. Entropies of activation, $\Delta S^{\ddagger}$, were obtained from standard Eyring plots of the same data. The errors listed in Table 2 for E_a, log A, and $\Delta S^{\ddagger}$ are listed as $\pm 2\sigma$ (i.e. 95% confidence limits), as obtained from the least squares analyses. Table 2 also includes triplet lifetimes for each ketone

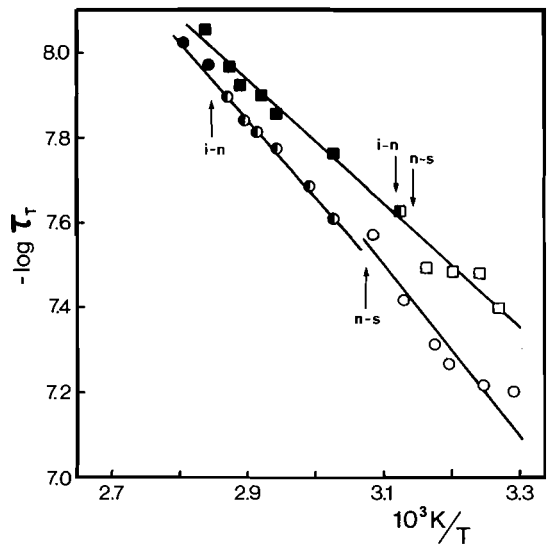

FIG. 4. Arrhenius plot ($-\log \tau_T$ vs. $1/T$) for triplet decay of **3***a*, monitored at 390 nm, in the nematic and smectic phases of BCCN (●) and the isotropic and smectic phases of ECCN (■). Open symbols denote smectic phase, half-symbols denote nematic phase, and closed symbols denote isotropic phase results. Transition temperatures for the mixtures are indicated.

in nematic and smectic BCCN and isotropic ECCN at 30 and 50°C, calculated from the corresponding Arrhenius parameters.

Owing to the limited temperature range over which we are able to obtain data in the isotropic phase of BCCN, we have employed ECCN as the model isotropic solvent with which to compare the behaviour of **1**–**3** in nematic and smectic BCCN. While ECCN is isotropic only above 48°C, the isotropic phase Arrhenius parameters reported in Table 2 were obtained from analysis of the ECCN data *over the full temperature range studied* (30–90°C). This treatment is justified on the basis that separate analysis of the smectic and isotropic phase data for this solvent yields identical Arrhenius parameters for each of the ketones studied. Similarly, the limited number of data points obtained in isotropic BCCN are indistinguishable from the nematic phase data in each case, and thus the two sets were combined and analysed as one to obtain the nematic phase Arrhenius parameters. For BCCN, separate calculations were performed for nematic and smectic phase data, even though in most cases (**1***b*, *c*, **2**, and **3***a*, *b*) triplet behaviour appears to be phase independent. This apparent phase independence *may* be the result of the somewhat greater scatter in the smectic phase data, caused by the usual semi-opaque nature of these samples.

Triplet lifetimes were also measured for 4-methoxyacetophenone (MAP) in the smectic, nematic, and isotropic phases of BCCN and ECCN by laser flash photolysis, and the results are plotted in Fig. 5. The factor of ca. 10 shorter lifetime of MAP in the isotropic and nematic phases of these solvents compared to those in smectic BCCN is presumably the result of more efficient impurity quenching in the former phases, reflecting their considerably lower viscosities relative to those of smectic BCCN (8).

Discussion

The triplet lifetime of β-phenylpropiophenone in fluid solution at room temperature is exceedingly short (ca. 1 ns (14)), and it is now reasonably well established that this is the result of efficient intramolecular deactivation via exciplex interactions

[c]Analyses performed using the combined data for all phases of this solvent.
[d]Calculated from standard Eyring plots.

between the carbonyl group and the β-phenyl ring (14–16) (see reaction [1]). The activation energy for triplet decay of this molecule in fluid solution (2.3 kcal/mol (14)) is approximately that for rotation about the Cα—Cβ bond (14, 21); that these bond rotations are necessary for intramolecular quenching to occur is demonstrated by the fact that when the molecule is incorporated in zeolites (of such dimensions that the solute can reside in the channels only when it assumes the *trans*-conformation), the triplet lifetime is extended to ca. 2 ms at room temperature and phosphorescence is observed (16).

Ketones such as **1–3** have lowest π,π* triplet states (17*a*, 20), and the somewhat longer triplet lifetime and higher activation energy for triplet decay of **1***a* relative to that observed for β-phenylpropiophenone in fluid solution has lead to the conclusion that like the Norrish Type I and Type II reactions (22), β-phenyl quenching *requires* the proximity of the n,π* state (17*a*). This introduces an extra energy requirement for the process in addition to that of the bond rotations involved in assuming the correct quenching geometry, viz., thermal population of the n,π* triplet state. Accordingly, the activation energy for triplet decay of **1***a* in fluid solution (4.4 kcal/mol in toluene) and that of β-phenylpropiophenone in the same solvent (2.3 kcal/mol) corresponds roughly to the energy difference between the π,π* and n,π* triplet states of **1***a* (17*a*).

The triplet lifetime of 4-methoxyacetophenone (MAP) in BCCN and ECCN is 50–80 times greater than that of **1***a* under the same conditions of temperature and solvent phase, as comparison of the lifetime data in Table 2 and Fig. 5 shows. Furthermore, the fact that samples of **1***a* have been subjected to prolonged irradiation in these solvents with no apparent change in the appearance of the triplet decay profile or lifetime attests to the expected (14, 17*b*) photoinertness of these compounds.

These results indicate that the observed triplet decay rates for **1–3** in liquid crystalline as well as isotropic solution are dominated by unimolecular decay processes, and that bimolecular quenching by adventitious impurities or hydrogen abstraction from the solvent is unimportant. As well, these results demonstrate that the observed Arrhenius parameters for triplet decay of **1–3** in the various phases of BCCN and ECCN reflect the energetics of those molecular motions which must occur in order for the correct geometry for β-phenyl quenching to be attained. These motions are, presumably, Cα—Cβ bond rotation (interconverting *trans*- and *gauche*-conformers) and Cβ—C_{phenyl} bond rotation (which brings the β-phenyl group into a position such that its π-system overlaps with the carbonyl n-orbital).

Solvent properties

The dominant feature of the molecular ordering in liquid crystals is that the long molecular axes of the constituent molecules are oriented parallel to one another, on the average.[2,3] In nematic phases, this is the only type of ordering present, and hence these are the most fluid type of liquid crystalline phase. While molecular tumbling is on the whole anisotropic in these phases, the constituent molecules undergo nearly free rotation about their long molecular axes (24). In smectic phases, the constituent molecules are further arranged in layers in which the orientational vector is at some angle, or perpendicular, to the plane of the layer. Several types of smectic phases are known, and these are characterized according to the

[3]For the sake of brevity, we confine our discussion to smectic, nematic, and cholesteric phases of rod-like mesogens. The molecular ordering in discotic liquid crystals is quite different. For a review of this type of liquid crystal, see ref. 23.

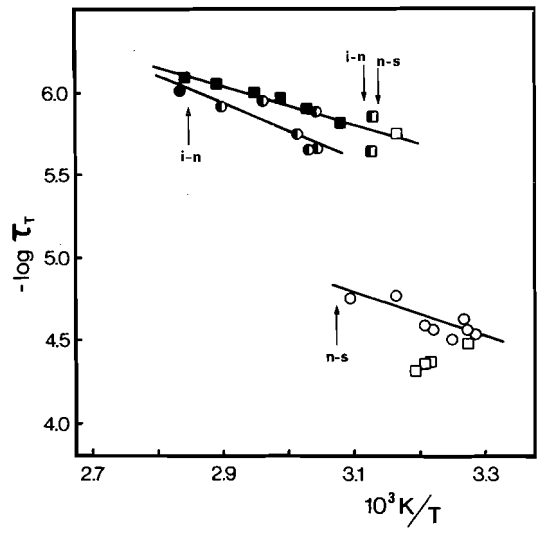

FIG. 5. Arrhenius plot ($-\log \tau_T$ vs. $1/T$) for triplet decay of MAP, monitored at 390 nm, in the nematic and smectic phases of BCCN (●) and the isotropic and smectic phases of ECCN (■). Open symbols denote smectic phase, half-symbols denote nematic phase, and closed symbols denote isotropic phase results. Transition temperatures for the mixtures are indicated.

nature of the molecular packing within the layers (25). In smectic A phases for example, the packing within the layers is nematic-like; thus, this type of smectic phase might be expected to resemble a nematic phase with respect to its effects on the motions and unimolecular reactivity of dissolved solutes. The smectic B phase is more crystalline in nature; within the layers, the constituent molecules are hexagonally close-packed (25).

BCCN forms a single smectic phase between 29–54°C and a nematic phase between 54–79°C, while ECCN is smectic between 28–44°C, nematic between 44–48°C, and is an isotropic liquid at temperatures above 48°C (26). The smectic phases of these two compounds have not yet been conclusively assigned with respect to mesomorphic type. X-ray diffraction studies have been carried out with the homologous *trans,trans*-4′-propylbicyclohexyl-4-carbonitrile (PCCN), a polymorphic smectic (26), from which it has been established that the high temperature smectic modification of this compound is Sm B (27). Thermal microscopy (28, 29) and DSC investigations with mixtures of BCCN/PCCN and BCCN/ECCN indicate that BCCN forms a smectic phase of similar but higher order than the SmB phase of PCCN, and that the smectic phase of ECCN is of even higher order than that of BCCN (28).

Incorporation of a solute in a liquid crystal results in some degree of disruption of solvent order in the vicinity of the solute (2*e*, 3*d*, 5, 6), the extent of which depends on the structure of the solute in relation to that of the mesogen (6), and is reflected in the transition temperatures of the liquid crystalline mixture (6, 30). Rigid, rod-like solutes tend to be oriented in a liquid crystal with their long axes parallel to those of the solvent (31). Flexible molecules cause more disruption of local order, and may be oriented to a lesser extent than rigid solutes (9*g*). Nevertheless, while such solutes retain a high degree of conformational mobility in liquid crystals, the conformational distribution is altered relative to that in isotropic solvents in favour of those conformers which are most compatible with solvent ordering (9*g*).

The transition temperatures listed in Table 1 for the ketone-doped samples of BCCN and ECCN indicate that incorporation of 1 mol% of each of the ketones studied has pronounced effects on both the Sm → N and N → I transition temperatures of the two mesogens. n-Alkyl substituents at either end of **1***a* (compare **1***a* with **1***b*, *c* and **2**) apparently result in somewhat greater disruption of local solvent order than a cyclohexyl substituent (cf. **1***a* and **3***a*) does. This is to be expected (6) considering the conformational motions available to the flexible alkyl chains compared to the relatively rigid cyclohexyl group, and the fact that the size and shape of the β-(4-cyclohexylphenyl) group in **3***a–c* is very similar to that of the solvent molecules.

The ultraviolet absorption spectra of **1***a* shown in Fig. 1 reveal that chromophore solvation in BCCN and ECCN is more like that in acetonitrile than in methylcyclohexane. Presumably, the fact that the position of the π,π* absorption is shifted to longer wavelengths in acetonitrile from its position in methylcyclohexane while the n,π* band is unaffected suggests that solvation in the nitrile solvents is such that there are strong interactions between the CN-group of the solvent and the benzoyl π-system.

The behaviour of 1–3 in nematic BCCN

Variation in the length and flexibility of the alkoxy substituent (**1***a–c*) has no effect on the Arrhenius parameters for triplet decay in either the nematic phase of BCCN or in isotropic ECCN, although the activation energy for decay in the nematic solvent (E_a^{nem}) is consistently higher than that in the isotropic solvent (E_a^{isot}). The same trend is observed in the nematic and isotropic phase data for the homologous series **3***a–c*. This indicates that increasing the length of the alkoxy group with flexible substituents has no effect on the ability (albeit slight) of the nematic solvent to impede the bond rotations leading to β-phenyl quenching. Averaging the differences between E_a^{nem} and E_a^{isot} and between $\Delta S^{\ddagger}$ values in the nematic and isotropic solvents over all the ketones studied yields $\Delta E_a = 1.4 \pm 0.5$ kcal/mol and $\Delta(\Delta S^{\ddagger}) = 3.9 \pm 1$ eu.

On the other hand, increasing the size of the β-aryl group within the series of 4-methoxy ketones **1***a*, **2**, and **3***a* results in continuous increases in both E_a^{nem} and E_a^{isot}, and similar trends are observed in $\Delta S^{\ddagger}$ (to more positive values). Along with the trends in the Arrhenius parameters observed for **1***a–c* and **3***a–c*, this suggests that solvation of the probes in these two solvents is such that solvent–solute interactions are strongest at the benzoyl end. This conclusion is supported by comparison of the uv absorption spectra of **1***a* in BCCN, acetonitrile, and methylcyclohexane. Thus, the benzoyl end of the ketone is apparently "anchored", and the β-aryl group constitutes the more mobile portion of the molecule. As the size of the mobile portion increases, the activation energy and entropy for intramolecular quenching tend to more positive values. This appears to be the case in both isotropic and nematic phases.

An explanation for the substituent effect on the energetics of β-phenyl quenching observed for **1***a*, **2**, and **3***a* which is based on a substituent effect on the quenching step (i.e. that which occurs after the correct geometry has been attained) can be discounted. Substitution on the β-phenyl ring by electron-donating substituents might be expected to increase the rate of intramolecular quenching of the electron-deficient n,π* triplet state. While the somewhat shorter triplet lifetimes of **2** and **3** compared to that of **1** in the isotropic solvent appear to be consistent with this, examination of the trends in E_a and $\Delta S^{\ddagger}$ show that this cannot be the origin of the observed substituent effect on τ_T. It is known that an increase in the activation energy

for an endothermic quenching process is accompanied by a *decrease* in the entropy of activation (a higher enthalpic requirement for quenching demands a tighter activated complex) (32). The trend to more positive $\Delta S^{\ddagger}$ values as E_a^{isot} increases which is observed for **1***a*, **2**, and **3***a* is clearly consistent with Cα—Cβ and Cβ—C_{phenyl} bond rotations being rate determining, since both will tend to more positive values as the viscous drag of the solvent on intramolecular motion increases. This provides further support for the explanation of the lack of a clear trend in the τ_T values for a series of β-arylpropiophenones with lowest n,π* triplet states (17*a*), from which it was concluded that bond rotations, and not the actual quenching process, form the rate determining step for β-phenyl quenching.

The effect of an ordered environment such as that found in liquid crystals on the intramolecular and diffusive mobility of solutes can be the result of microviscosity (viscous drag) effects or orientational ordering effects, or some combination of the two. Ultimately, the effects of high microviscosity and solvent orientational order on the Arrhenius parameters for solute motions are the same; E_a will increase and $\Delta S^{\ddagger}$ will become more positive as molecular motions become more difficult and require greater displacement of the surrounding solvent matrix, whether it is ordered or not. Solvent microviscosity will heighten the barrier to conformational interconversions only as a result of effects on the transition state energy; it should have little or no effect on the relative energies of the ground state conformers. On the other hand, solvent orientational order will affect the energies of both the ground state conformers (9*g*) and the transition state for their interconversion (2*e*, 3*c*–*e*, 5, 6). In the present case, the presence of solvent order should stabilize the rod-like *trans*-conformer and destabilize the transition state for formation of the quenching (*gauche*-like) geometry.

It is important to note that the Arrhenius parameters for triplet decay of **1**–**3** obtained by the present method represent average values over all conformations present in solution. If microviscosity alone is responsible for the observed effects on the triplet decay of **1**–**3** in nematic BCCN, then parallel changes in activation parameters in the nematic and isotropic solvents with changes in solute structure should be observed. On the other hand, if solvent order plays the dominant role, then the difference between the activation parameters for triplet decay in nematic and isotropic phases should vary depending on solute structure, if the difference in conformational distribution between nematic and isotropic phases varies with solute structure. Clearly, the results obtained for **1**–**3** in nematic BCCN and isotropic ECCN indicate that microviscosity effects are almost entirely responsible for the slightly higher E_a and more positive $\Delta S^{\ddagger}$ for solute bond rotations in the nematic phase. Either solute conformational energies are not altered enough in the nematic relative to isotropic phase to significantly contribute to the increase in activation parameters, or the changes do not vary appreciably throughout the series **1**–**3**.

The behaviour of ***1***–***3*** *in smectic BCCN*

The ability of the smectic phase of BCCN to inhibit β-phenyl quenching is strongly dependent on the structure of the probe (7). Inhibition is strong for probes which are shorter than (i.e. **1***a*) (7) or of a similar length to BCCN (28). For probes such as **1***b* and **1***c*, which are longer than BCCN, triplet decay is phase-independent (or almost so); this demands that the nature of the solvation of such probes in this smectic phase is much different than that experienced by **1***a*. The results imply that the environment experienced by **1***b* and **1***c* in smectic BCCN is essentially isotropic (or perhaps nematic; *vide infra*) with respect to its effects on the conformational mobility of the solute, although *bulk* smectic order is preserved in the samples.

Other workers have observed analogous variations in solute behaviour in smectic solvents as a function of solute structure. The product distribution from the Norrish Type II reaction of phenylalkyl ketones in smectic n-butyl stearate varies quite dramatically with reactant length; the effect of smectic solvent order in this case is greatest when the reactive solute is similar in length to the mesogen, and falls off as the solute increases or decreases from this optimal length (3*f*). Electron spin resonance investigations of nitroxide spin probes in smectic phases have led to the suggestion that, depending on solute/solvent structural relationships, solutes can reside in either the relatively rigid, core portion of the layers or the more fluid, hydrocarbon interlayer region (10*c*, *f*), or be partitioned between the two (10*b*). Solute mobility is very different in these two regions. For small solutes, mobility can apparently be greater in Sm B phases than in the lower order Sm A types (10*b*). This has been attributed to the solute residing in cavities in the hydrocarbon interlayer region, which become better-defined and afford less restriction to solute motion as the region increases in its overall rigidity.

BCCN is not a typical smectogen, in that the relatively short n-butyl end-chain does not allow for as much fluidity in the interlayer region as is usually the case in smectic phases (4). The Sm B phase of PCCN is regarded as being more crystalline in character than typical Sm B phases (27). This is the result of intercalation of the short n-propyl end-chains of one layer with nitrile groups in the next. For smectic BCCN, it thus seems unlikely that a solute which is unable to be incorporated unobtrusively *within* a smectic layer might reside instead in the interlayer region; there is simply just not enough room.

The perfect continuity in the Arrhenius plots for triplet decay of **1**–**3** at the S–N transition temperature may offer a clue as to the nature of the solvation of these probes in the smectic phases of both BCCN and ECCN, and allow a tentative explanation for the behaviour of **1**–**3** in these solvents. Normally, properties affected by diffusive mobility or viscosity are substantially altered at the S–N transition (4, 8*b*). The drastic change in the triplet lifetime of MAP at this transition (Fig. 5) is a perfect example of this behaviour; since the lifetime in this case is determined by impurity (e.g., oxygen) quenching, the large difference in the viscosities of the nematic and smectic phases (8) results in substantial differences in triplet lifetime in the two phases. The similar lifetimes above and below the bulk S–N transition temperature observed for **1**–**3** indicate that the microviscosity of the probes' *local* environment does not change detectably at the phase transition.

For all the probes studied except **1***a*, the results suggest that in the smectic phases of BCCN and ECCN, the local probe environment retains the order that was present in the nematic phase. Thus, the solvation shell for **1***b*–**3***c* in these smectic phases might be viewed as a small, isotropized nematic "pool" surrounded by the bulk smectic phase. In each case, the effective microviscosity in the solvation shell depends on probe structural features. Probes with long, flexible substituents create more disorder and a less compact solvation shell, with microviscosity similar to that in the bulk nematic phase. Elongated probes with inflexible, solvent-like substituents (**3**) experience a slightly greater microviscosity since the overall shape change in proceeding to the quenching geometry is more pronounced.

In the smectic phase of ECCN, these solvation pools may be intrinsically larger or better-defined than in BCCN, because the more crystalline-like interlayer packing renders the bulk smectic phase less miscible with the disordered regions surrounding the solute molecules. We note that the disordered microenvironment in a probe molecule's vicinity can only involve a few solvent molecules (certainly less than about ten) in order to maintain bulk smectic order at the high probe concentrations employed. The above description is essentially that of a mixed phase system, consisting of a ketone-rich nematic phase in coexistence with the smectic phase of the pure solvent.

In the case of **1***a* in BCCN, there is clearly a microscopic change in solvent phase which accompanies the bulk N → S phase transition, but the difference in local microviscosity just below the transition is apparently negligible. This is surprising, considering the very much higher degree of order and rigidity present in the smectic phase of pure BCCN relative to the nematic (27, 28). Further experiments are clearly necessary in order to conclusively define the nature of the solvation of **1** in this phase.[4]

Summary and conclusions

The Arrhenius parameters for triplet decay of a series of β-aryl-(4-alkoxypropiophenone)s reflect those of the simple conformational motions which allow intramolecular quenching of the carbonyl triplet state, and are significantly affected in the smectic and nematic phases of BCCN relative to their values in the isotropic phase of ECCN. The probes vary in the size and flexibility of substituents, and in their completely extended conformations, vary over a factor of two in length. Smectic solvent order results in large increases in E_a and $\Delta S^{\ddagger}$ for small, relatively compact probes, small increases for probes bearing a large inflexible substituent, and has no effect on the Arrhenius parameters for triplet decay of probes with flexible, long-chain alkyl substituents. The perfect continuity in the Arrhenius plots at the S–N transition temperature of BCCN suggests that for probes longer than the smectic layer thickness, their microenvironment in the smectic phase is similar to that in the nematic phase.

In the nematic phase, E_a and $\Delta S^{\ddagger}$ are consistently ca. 1.5 kcal/mol and 4 eu higher, respectively, than the corresponding values in the isotropic solvent. Variation of the alkoxy substituent has no effect on the Arrhenius parameters, while variation of the β-aryl substituent results in systematic increases with substituent size and rigidity. Parallel effects are observed in the isotropic phase, which leads to the conclusion that higher microviscosity, and not an orientational ordering effect, is responsible for the slight inhibition to solute conformational motion in the nematic phase relative to that in isotropic solvents.

From the present results, and previous studies of unimolecular reactions in nematic and cholesteric phases (2, 3), several conclusions can be derived with respect to the ability of these types of liquid crystals to inhibit intramolecular motion. It appears that the most one can expect in the way of an effect on the activation energy for such a process is about 3 kcal/mol, and it is likely that this is almost solely the result of microviscosity effects. Furthermore, an effect can only be expected when substantial changes in the *overall* shape of the molecule occur on the way to the transition state for reaction. The result that nematic solvents have no effect on the energetics of the Claisen rearrangement of cinnamyl phenyl ether (2*c*), for example, can be readily explained in this context; examination of molecular models shows that the bond rotations which interconvert the fully extended conformation of this molecule and that in the transition state for cyclization do not in fact alter the overall rod-like shape of the molecule appreciably. This same explanation can rationalize the small effects of cholesteric and compensated nematic solvents on the Norrish Type II reaction of α-diketones (3*a*).

Further investigation of the balance between solute/solvent structural features and the ability of smectic phases to inhibit the intramolecular mobility of solutes is in progress and will be reported in the near future.

Experimental

Melting points and transition temperatures were measured on a Reichert micro-hot stage microscope with polarizing lenses and are corrected. ^{1}H nmr spectra were recorded in deuterochloroform solution on a Varian EM390 nmr spectrometer, and are reported in parts per million downfield from TMS. Infrared spectra were recorded on a Perkin-Elmer Model 283 infrared spectrometer, and are reported in wavenumbers, calibrated against the 1601.8 cm^{-1} polystyrene absorption. Mass spectra were recorded on a VG Micromass 70-70F mass spectrometer, and exact masses have been calculated using an atomic mass of 12.00000 for carbon. Ultraviolet absorption spectra were recorded on a Hewlett Packard HP-8451 spectrometer.

Laser flash photolysis experiments employed the computerized facility which has been described in detail elsewhere (19), and the pulses (337.1 nm, ~8 ns, <10 mJ) of a nitrogen laser for excitation. Sample temperatures were recorded using a calibrated platinum thermometer, and are considered accurate to ±0.5°C. Samples of **1–3** as ~1.0 mol% solutions in BCCN and ECCN were contained in 0.7 mm × 7 mm rectangular Pyrex (Vitro Dynamics) sample cells. They were prepared by adding an aliquot of a standard solution of the ketone in dichloromethane to a cell by microlitre syringe, evaporating off the solvent with a stream of nitrogen, and then weighing the required amount of the mesogen into the cell. The samples were then either sealed with rubber septa and deoxygenated by bubbling dry nitrogen through the isotropic melts or subjected to three freeze–pump–thaw degassing cycles followed by sealing on a high vacuum line (10^{-3} Torr). Decay of laser-generated transients was monitored by uv absorption. The optical densities of the isotropic solutions were in the range 0.15–0.20 at 337 nm. While the isotropic solutions were optically clear at the transient monitoring wavelength (390–395 nm), and the nematic solutions almost so, the smectic samples generally had optical densities in the range 0.6–1.3 as a result of light scattering. For the smectic samples, decay traces represent the average of 40–60 shots, each corrected for background scattering from the excitation pulse. Annealing the smectic samples at 40°C for 2–7 days results in homeotropically aligned (i.e. glassy) samples, which have considerably better light transmission characteristics. The triplet lifetimes obtained using these samples do not differ significantly from the lifetimes obtained from the samples used immediately after cooling from the isotropic melts.

Methylcyclohexane (BDH Omnisolv), acetonitrile (Caledon HPLC), and dichloromethane (Caledon HPLC) were used as received. 4′-Butylbicyclohexyl-4-carbonitrile (BCCN; EM Licristal ZLI1538) and 4′-ethylbicyclohexyl-4-carbonitrile (ECCN; EM Licristal ZLI1537) were used as received from E. Merck, Co. 4-Methoxyacetophenone (Aldrich) used for laser flash photolysis experiments was recrystallized twice from methanol.

4-(n-Hexyl)benzaldehyde (bp 118–119°C, 3 mm Hg) and 4-cyclo-

[4]NOTE ADDED IN PROOF: The 4-ethoxy and 4-propoxy derivatives of **1** also show phase dependent behaviour in BCCN. However, the break in the Arrhenius plot does not occur at the bulk N → S transition temperature; rather it moves to progressively lower temperatures with increasing alkoxy chain length. The behaviour of the 4-^{n}butoxy derivative is phase independent (27).

hexylbenzaldehyde were prepared by formylation of 1-phenylhexane and cyclohexylbenzene (Aldrich), respectively, with hexamethylenetetramine in trifluoroacetic acid (33). The 4-cyclohexylbenzaldehyde that was obtained as a yellow oil after column chromatography of the crude reaction mixture on silica gel exhibited ^{1}H nmr, infrared, and mass spectra that were consistent with its structure. It was used without further purification or characterization.

The β-phenyl ketones **1***a* and **3***a* were prepared by condensing 4-methoxyacetophenone with benzaldehyde and 4-cyclohexylbenzaldehyde, respectively (18*a*), and hydrogenation of the resulting chalcone derivative over Raney nickel in ethyl acetate. Ketones **1***b*, *c*, **2**, and **3***b*, *c* were prepared by condensing 4-hydroxyacetophenone with the appropriate 4-alkylbenzaldehyde (18*b*), hydrogenation of the resulting chalcone over Raney nickel in 10% sodium hydroxide, and finally alkylation of the β-aryl-4′-hydroxypropiophenone with 1-bromopentane, 1-bromooctane, or dimethyl sulfate and potassium carbonate in refluxing acetone (34). 3-(4-Methoxyphenyl)-1-phenylpropen-3-one (**5***a*) had mp 105–106°C (lit. 101–103°C (1), 3-(4-hydroxyphenyl)-1-phenylpropen-3-one (**4***a*) had mp 171–172°C (lit. 177.5°C (18*b*), 1-(4-methoxyphenyl)-3-phenylpropan-1-one (**1***a*) had mp 96–97°C (lit. 96–97°C (18*b*)), and 1-(4-hydroxyphenyl)-3-phenylpropan-1-one (**6***a*) had mp 104–105°C (lit. 104°C (18*b*)). Spectral data for the other ketones which were synthesized as precursors to **1–3** are as follows:

*3-(4-Hydroxyphenyl)-1-(4-^{n}hexylphenyl)propen-3-one (**4**b)* (from 4-hydroxyacetophenone and 4-^{n}hexylbenzaldehyde) was recrystallized once from aqueous ethanol to afford light yellow needles, mp 108–112°C. ^{1}H nmr: δ 0.88(t, 3H), 1.32(m, 6H), 1.61(m, 2H), 2.65(t, 2H), 6.89(br s, 1H), 7.00(d, 2H), 7.34(d, 2H), 7.53(d, 1H), 7.59(d, 2H), 7.87(d, 1H), 8.04(d, 2H). Ir (CCl_4): 3608(w), 3415(m, br), 2960(w), 2925(m), 2855(w), 1667(m), 1653(m), 1598(s, sh), 1530(s, br), 1329(m), 1209(m), 1161(m), 980(m), 705(s, br). Mass: calcd. for $C_{21}H_{24}O_2$, 308.1776; found, 308.1754.

*1-(4-Cyclohexylphenyl)-3-(4-hydroxyphenyl)propen-3-one (**4**c)* (from 4-hydroxyacetophenone and 4-cyclohexylbenzaldehyde) was recrystallized once from 95% ethanol to afford light yellow plates, mp 190–192°C. ^{1}H nmr: δ 1.40(m, 5H), 1.83(m, 5H), 2.46(m, 1H), 6.41(br s, 1H), 6.95(d, 2H), 7.27(d, 2H), 7.48(d, 1H), 7.58(d, 2H), 7.84(d, 1H), 8.03(d, 2H). Ir (KBr): 3100(br, s), 2918(m), 2840(m), 1646(m), 1595(s), 1552(s, sh), 1405(m), 1328(s), 1296(m), 1218(s), 1161(s), 1022(m), 980(m), 810(m), 579(w), 538(w). Mass: calcd. for $C_{21}H_{22}O_2$, 306.1620; found, 306.1630.

*1-(4-Cyclohexylphenyl)-3-(4-methoxyphenyl)propen-3-one (**5**c)* (from 4-methoxyacetophenone and 4-cyclohexylbenzaldehyde) was chromatographed on silica gel (hexane/dichloromethane mixtures), and recrystallized once from 95% ethanol to afford light yellow plates, mp 95–96°C. ^{1}H nmr: δ 1.40(m, 5H), 1.83(m, 5H), 2.52(m, 1H), 3.89(s, 3H), 6.98(d, 2H), 7.37(d, 2H), 7.50(d, 1H), 7.59(d, 2H), 7.83(d, 1H), 8.07(d, 2H). Ir (CCl_4): 3006(w), 2927(s), 2847(m), 1666(s), 1604(s, br), 1418(w), 1329(m), 1252(m), 1167(s), 1022(m). Mass: calcd. for $C_{22}H_{24}O_2$, 320.1776; found, 320.1792.

*3-(4-^{n}hexylphenyl)-1-(4-hydroxyphenyl)propan-1-one (**6**b)* (from **4***b*) was recrystallized from aqueous ethanol to yield a colourless solid, mp 94–95°C. ^{1}H nmr: δ 0.87(t, 3H), 1.30(m, 6H), 1.56(m, 2H), 2.57(t, 2H), 3.13(m, 4H), 6.33(br s, 1H), 6.90(d, 2H), 7.15(s, 4H), 7.94(d, 2H). Ir (CCl_4): 3603(m), 3366(m, br), 3016(w), 2949(m), 2928(s), 2850(m), 1687(s), 1663(s), 1602(s, br), 1435(m), 1362(m), 1286(m), 1266(m), 1166(s). Mass: calcd. for $C_{21}H_{26}O_2$, 310.1933; found, 310.1930.

*3-(4-Cyclohexylphenyl)-1-(4-hydroxyphenyl)propan-1-one (**6**c)* (from **4***c*) was recrystallized from aqueous ethanol to yield a colourless solid, mp 147–150°C. ^{1}H nmr: δ 1.37(m, 5H), 1.81(m, 5H), 2.42(m, 1H), 3.11(m, 4H), 6.31(s, 1H), 6.90(d, 2H), 7.16(s, 4H), 7.95(d, 2H). Ir (CCl_4): 3608(m), 3372(m, br), 3010(w), 2928(s), 2850(m), 1688(s), 1667(m, sh), 1602(s, br), 1458(m), 1262(m), 1166(s). Mass: calcd. for $C_{21}H_{24}O_2$, 308.1776; found, 308.1759.

Substituted β-phenylpropiophenones 1–3

*1-(4-Pentoxyphenyl)-3-phenylpropan-1-one (**1**b)* (from **6***a* and 1-bromopentane) was recrystallized twice from methanol to yield colourless plates, mp 63–64°C. ^{1}H nmr: δ 0.91(t, 3H), 1.42(m, 4H), 1.80(m, 2H), 3.15(m, 4H), 4.02(t, 2H), 6.94(d, 2H), 7.31(s, 5H), 7.99(d, 2H). Ir (CCl_4): 3024(w), 2948(m), 2928(m), 2867(w), 1683(s), 1595(s, sh), 1532(s, br), 1303(m), 1338(m, br), 1306(w, sh), 1168(s), 978(m, br), 709(s, br). Mass: calcd. for $C_{20}H_{24}O_2$, 296.1776; found, 296.1759.

*1-(4-Octoxyphenyl)-3-phenylpropan-1-one (**1**c)* (from **6***a* and 1-bromooctane) was recrystallized twice from methanol to yield colourless plates, mp 48–49°C. ^{1}H nmr: δ 0.87(t, 3H), 1.31(m, 10H), 1.78(m, 2H), 3.13(m, 4H), 4.00(t, 2H), 6.90(d, 2H), 7.28(s, 5H), 7.94(d, 2H). The ir spectrum was similar to that of **1***b* except for minor differences in the C—H stretching region. Mass: calcd. for $C_{23}H_{30}O_2$, 338.2246; found, 338.2289.

*3-(4-^{n}hexylphenyl)-1-(4-methoxyphenyl)propan-1-one (**2**)* (from **6***b* and dimethylsulfate) was recrystallized twice from ethanol to yield colourless plates, mp 56–57°C. ^{1}H nmr: δ 0.87(t, 3H), 1.31(m, 6H), 1.53(m, 2H), 2.58(t, 2H), 3.12(m, 4H), 3.85(s, 3H), 6.92(d, 2H), 7.15(s, 4H), 7.97(d, 2H). Ir (CCl_4): 3003(w), 2948(m), 2920(s), 2846(m), 1685(s), 1594(s, sh), 1535(s, br), 1462(w), 1416(w), 1357(w), 1302(m), 1244(s), 1165(s), 1030(m), 966(w), 706(s, br). Mass: calcd. for $C_{22}H_{28}O_2$, 324.2090; found, 324.2067.

*3-(4-Cyclohexylphenyl)-1-(4-methoxyphenyl)propan-1-one (**3**a)* (from catalytic hydrogenation of **5***c*) was recrystallized twice from ethanol to yield colourless needles, mp 89–90°C. ^{1}H nmr: δ 1.40(m, 5H), 1.84(m, 5H), 2.43(m, 1H), 3.12(m, 4H), 3.84(s, 3H), 6.91(d, 2H), 7.17(s, 4H), 7.96(d, 2H). Ir (CCl_4): 3080(w), 2925(s), 2851(s), 1683(s), 1594(m, sh), 1530(s, br), 1241(s), 1201(w), 1165(s), 1300(m), 966(w), 709(s, br). Mass: calcd. for $C_{22}H_{26}O_2$, 322.1933; found, 322.1918.

*3-(4-Cyclohexylphenyl)-1-(4-pentoxyphenyl)propan-1-one (**3**b)* (from **6***c* and 1-bromopentane) was recrystallized twice from ethanol to yield colourless plates, mp 70–71°C. ^{1}H nmr: δ 0.92(t, 3H), 1.38(m, 9H), 1.81(m, 7H), 2.43(m, 1H), 3.13(m, 4H), 4.01(t, 2H), 6.92(d, 2H), 7.17(s, 4H), 7.94(d, 2H). The ir spectrum was similar to that of **3***a* except for minor differences in the 2800–3100 and 950–1050 cm^{-1} regions. Mass: calcd. for $C_{26}H_{34}O_2$, 378.2558; found, 378.2560.

*3-(4-Cyclohexylphenyl)-1-(4-octoxyphenyl)propan-1-one (**3**c)* (from **6***c* and 1-bromooctane) was recrystallized twice from ethanol to yield colourless plates, mp 63–64°C. ^{1}H nmr: δ 0.90(t, 3H), 1.32(m, 15H), 1.84(m, 7H), 2.47(m, 1H), 3.13(m, 4H), 4.02(t, 2H), 6.92(d, 2H), 7.18(s, 4H), 7.94(d, 2H). The ir spectrum was similar to those of **3***a*, *b* except for minor differences in the 2800–3100 and 950–1050 cm^{-1} regions. Mass: calcd. for $C_{29}H_{40}O_2$, 420.3028; found, 420.3037.

Acknowledgements

I wish to express my gratitude to Dr. J. C. Scaiano and the National Research Council of Canada for the use of the laser flash photolysis facility, Mr. H. Ladendorff, BDH Canada, for generous gifts of BCCN and ECCN, Dr. J. J. McCullough for the use of the thermal microscope, and Mr. J. Chan for technical assistance. Financial support of this work by the Natural Sciences and Engineering Research Council of Canada and the Research Corporation is gratefully acknowledged.

Activation volumes for ester hydrolysis via elimination–addition

NEIL S. ISAACS[1] AND TARIQ S. NAJEM
Department of Chemistry, University of Reading, Whiteknights, Reading, Berks, England

Received October 29, 1985

This paper is dedicated to Professor Arthur N. Bourns

NEIL S. ISAACS and TARIQ S. NAJEM. Can. J. Chem. **64**, 1140 (1986).

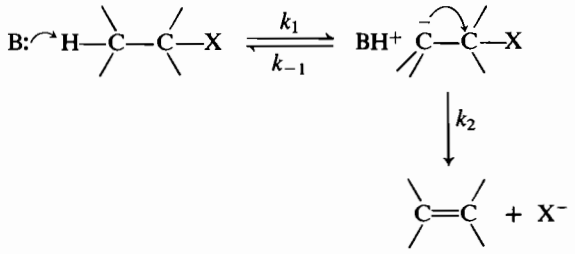
Esters that have an acidic proton α to the carboxyl group (or in a vinylogous situation) and a good leaving group may undergo hydrolysis by elimination to an intermediate ketene, which rapidly hydrates. Examples are found in *p*-hydroxybenzoate, malonate, and acetoacetate esters of nitrophenols. The evidence for this mechanism (E1cb type) includes the independence of rate with pH in the region of dissociation of the acidic proton and, in particular, positive volumes of activation that contrast sharply with negative values typical of the more usual $B_{Ac}2$ mechanism of hydrolysis.

NEIL S. ISAACS et TARIQ S. NAJEM. Can. J. Chem. **64**, 1140 (1986).

Les esters qui possèdent un proton acide dans la position en α du groupement carbonyle (ou dans une position vinylique) et un bon groupement nucléofuge peuvent subir une hydrolyse impliquant une élimination conduisant à un cétène intermédiaire qui s'hydrate rapidement. Les *p*-hydroxybenzoate, malonate et acétoacétate des nitrophénols constituent de bons exemples de ce type de réaction. Les données qui laissent croire en ce mécanisme (du type E1cb) impliquent le fait que la vitesse de réaction est indépendante du pH, dans la région de dissociation du proton acide, et, en particulier, sur le fait que les volumes d'activation positifs contrastent nettement avec les valeurs négatives qui sont caractéristiques du mécanisme plus courant d'hydrolyse du type $B_{Ac}2$.

[Traduit par la revue]

Alkene-forming eliminations via the conjugate base of the substrate, the E1cb mechanism, have been conclusively demonstrated to take place in competition with the synchronous E2 route when the α-proton is of high acidity and the leaving group has a rather low nucleofugacity:

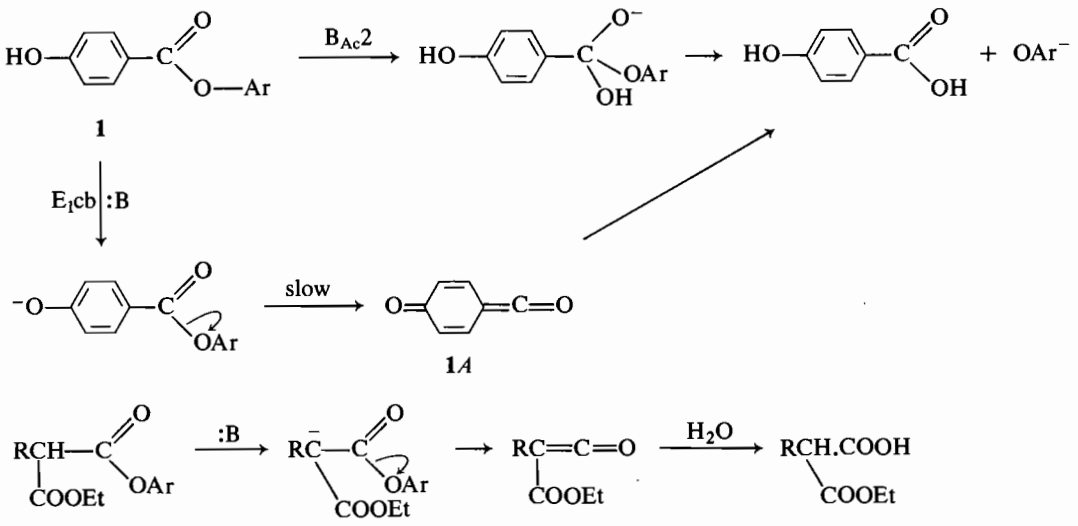


Several variants of this mechanism have been identified according to whether step 1 is reversible or not and whether k_1 or k_2 is rate determining ($E1cb_{re}$, $E1cb_{irr}$, $E1cb_{anion}$, respectively).

The E1cb mechanism of hydrolysis of esters, Scheme 1, was proposed by Holmquist and Bruice in 1969 (1, 2) to account for the kinetics of hydrolysis of certain malonate esters possessing at least one acidic α-hydrogen. Since that study, many esters have been inferred to hydrolyse in an analogous manner, the structural requirement in all cases being the availability of a stabilized carbanion or oxyanion α to the carboxyl group or in a vinylogous position such that $pK_A < pK_w$. Usually, a leaving group of high nucleofugacity such as a nitrophenolate is also required so that the more usual $B_{Ac}2$ mechanism should not supervene. In addition to the obvious candidates such as malonate and β-ketoesters (3) (and their thio-analogues (4, 5)), Williams, Thea, and co-workers (6–8) have supplied evidence that the hydrolyses of *p*-hydroxybenzoates and of *p*-hydroxybenzenesulphonates also occur by an E1cb route. In all the cases cited, the main body of evidence leading to these mechanistic proposals was the observation of anomalous pH–rate profiles. Typically, rates of hydrolysis in buffered solution were found to be abnormally high in the region of dissociation of the acidic hydrogen and to exhibit a plateau indicative of rate-determining proton removal by general base catalysis with a sharp discontinuity indicative of a mechanistic change. At a pH below the plateau, the mechanism is $B_{Ac}2$ since the substrate is not appreciably dissociated, and similarly above, where $[OH^-]$ is high enough for $B_{Ac}2$ hydrolysis of the conjugate base to compete with the E1cb pathway. In each of these regions, a linear relationship between log *k* and pOH (or a suitable acidity function at high basicity) is required and is observed. Also, deviations from linear free energy relationships have been observed, rates of hydrolysis of *o*-nitrophenyl malonates being 10^2–10^3 times greater than predicted from those of other substituted acetates with less acidic α-hydrogens. We considered it likely that there would be a significant difference between volumes of activation for $B_{Ac}2$ and E1cb routes. The former are known to have small, negative values ($\Delta V^{\ddagger}$ −10 to −20 $cm^3\ mol^{-1}$ (9)), rates being mildly increased by pressure, consistent with an associative activation step. E1cb mechanisms in olefin formation have been found (10) to be characterized by positive values of $\Delta V^{\ddagger}$ (the rate diminished by pressure), which would be expected for an activation step in which an intermediate carbanion dissociates into two fragments, i.e. k_2. This would apply to the E1cb (anion) mechanism for which k_2 is rate-determining and $\Delta V^{\ddagger}_{obs} = \Delta V^{\ddagger}_2$. Predictions concerning the other variants of the mechanism may depend upon the charge state of the base. If neutral, then $\Delta V^{\ddagger}_1$ will be strongly negative due to solvent electrostriction around the developing charges and $\Delta V^{\ddagger}_2$ correspondingly positive, making the reaction volume for the pre-equilibrium, ΔV_e ($= \Delta V^{\ddagger}_1/\Delta V^{\ddagger}_2$) large and positive. If the base is an anion such that there is no net change in charge during the pre-equilibrium, then $\Delta V^{\ddagger}_1$ and ΔV_e will be small and probably negative. The following mechanistic relationships with observed activation volumes may be made:

[1]Author to whom correspondence may be addressed.

Printed in Canada / Imprimé au Canada



SCHEME 1

	E1cb type				
	Anion	Reversible		Irreversible	
$\Delta V^{\ddagger}_{obs}$	$\Delta V^{\ddagger}_2$	$\Delta V^{\ddagger}_e + \Delta V^{\ddagger}_2$		$\Delta V^{\ddagger}_1$	
Base charge	0 or −	0	−	0	−
Magnitude of $\Delta V^{\ddagger}_{obs}$	Moderate positive	Large negative	Moderate positive	Large negative	Small

Similar predictions may be made for ester hydrolyses by this group of mechanisms. The examples that we have studied are of the E1cb (anion) or possibly E1cb (rev) with an anionic base and therefore we would expect to have an especially favourable situation for the application of high pressures to this mechanistic problem, since the two possible pathways to be considered, E1cb or $B_{Ac}2$, would be characterized by activation volumes of opposite sign. This paper reports that this expectation has been borne out and concludes that the measurement of activation volumes is diagnostically appropriate to distinguish between these mechanisms.

Experimental

Nitrophenyl esters of aromatic carboxylic acids were prepared by the following general method (11); carboxylic acid (100 mmol) and nitrophenol (100 mmol) were dissolved in dry ether or tetrahydrofuran and dicyclohexylcarbodiimide (110 mmol) was added. The mixture was stirred at room temperature for several hours or until the precipitation of dicyclohexylurea was complete. After filtration, the product was isolated by evaporation of the solvent and purified by recrystallization.

Nitrophenyl esters of malonic acids were prepared by an analogous method, starting with the potassium salt of ethyl hydrogen malonate (methylmalonate or dimethylmalonate), while nitrophenyl acetoacetates were prepared by reaction between the nitrophenol and diketene in dichloromethane (12).

Melting points in all cases corresponded with published values and nmr spectra were in accordance with the expected structures, as follows.

2,4-Dinitrophenyl 4-hydroxybenzoate: mp 160–161°C. *Anal.* calcd. for $C_{13}H_8N_2O_7$: C 51.3, H 2.65, N 9.2%; found: C 51.5, H 2.63, N 9.52%.

2,4-Dinitrophenyl 3-hydroxybenzoate: mp 180°C. *Anal.* calcd. for $C_{13}H_8N_2O_7$: C 51.3, H 2.65, N 9.2%; found: C 51.27, H 2.51, N 9.4%.

2,4-Dinitrophenyl 4-methoxybenzoate: mp 134°C. *Anal.* calcd. for $C_{14}H_{10}N_2O_7$: C 52.8, H 3.14, N 8.8%; found: C 54.2, H 3.3, N 8.8%.

2,4-Dinitrophenyl 4-acetamidobenzoate: mp 170°C. *Anal.* calcd. for $C_{15}H_{11}N_3O_8$: C 52.2, H 3.21, N 12.1%; found: C 51.9, H 3.03, N 12.1%.

4-Nitrophenyl benzoate: mp 142°C. *Anal.* calcd. for $C_{13}H_9NO_4$: C 64.5, H 3.3, N 5.7%; found: C 63.5, H 3.51, N 5.7%.

Ethyl 4-nitrophenyl malonate: mp 62°C. *Anal.* calcd. for $C_{10}H_9NO_5$: C 52.2, H 4.4, N 5.5%; found: C 52.2, H 4.4, N 5.5%.

2-Nitrophenyl acetoacetate: mp 73°C. *Anal.* calcd. for $C_{10}H_9NO_5$: C 53.8, H 4.1, N 6.3%; found: C 53.9, H 4.3, N 6.3%.

Kinetic measurements were carried out in water or in aqueous acetone or methanol, buffered between pH 7 and 12, at concentrations around 10^{-4} *M*. The particular choice of conditions was governed by the reactivities of the substrates but the pH at which measurements were made corresponded to the plateau region for E1cb reactions. The reaction solution was placed within a 1-cm cuvette ("Spectrosil"), closed with a stopper fitted with a rubber bulb for equalization of pressure and enclosed within a high pressure optical cell, thermostatted to ±0.5°C in a spectrophotometer as previously described (13). The progress of reaction was monitored by following the absorption of the nitrophenol produced at wavelengths around 400 nm. Reactions were all of first order and rate constants were evaluated using the Guggenheim procedure. Volumes of activation were calculated from eq. [1], the constant *B* being calculated by a computed fit to a plot of ln *k* against pressure.

$$[1] \quad RT\,\mathrm{d}\ln k/\mathrm{d}p = -\Delta V^{\ddagger} = RT(A + Bp + Cp^2)$$
$$B = -\Delta V^{\ddagger}/RT$$

Results are summarized in Tables 1 and 2 and Figs. 1–3.

Discussion

Volumes of activation for nitrophenyl esters of *p*-nitrophenylacetic acid were, as expected, negative, as were those for hydrolyses of the *p*-methoxybenzoate. This is a consequence of the $B_{Ac}2$ mechanism and the rate-determining association between ester and base, in this case water. The values of the activation volumes, −21 and −19 $cm^3\,mol^{-1}$, respectively, are comparable with that for uncatalysed hydrolysis of ethyl acetate

in aqueous ethanol (-31 cm^3 mol^{-1} (12)), the difference being attributable to the less polar solvent in the latter case and the greater degree of electrostriction. These activation volumes are considerably more negative than those for hydrolyses promoted by either H^+ or OH^-, for both of which $\Delta V^{\neq}$ is around -5 to -10 cm^3 mol^{-1}.

The *p*-hydroxybenzoate ester, in contrast, hydrolyses at around pH 8, where the phenolic group is substantially dissociated, at a rate which decreases with pressure and in consequence has a positive volume of activation, $+16$ cm^3 mol^{-1}. This points to the operation of a different mechanism and is in accordance with a rate-determining fission of the conjugate base of the ester, the E1cb process. As a reactive intermediate, the ketenoid species, **1***A*, is presumed to be formed, which would rapidly hydrolyse to *p*-hydroxybenzoic acid. This interpretation is given more force by the observation that $\Delta V^{\neq}$ changes with increasing pH, becoming $+7$ at pH 10.1, in the intermediate region, and finally negative, -18 at pH 12.5, where the $B_{Ac}2$ pathway is reestablished due to the increase in $[OH^-]$. The behaviour of *p*-methoxybenzoate and *m*-hydroxybenzoate, neither of which are capable of producing an intermediate analogous to **1***A*, is understandable: hydrolyses of these esters are characterized by the negative volumes of activation typical of the $B_{Ac}2$ mechanism.

10	−20.7	—
11	—	+8.7
12	−19.7	—

[a]The esters correspond to the numbering in Table 1.

Malonate esters with at least one α-hydrogen are also potentially able to partake of the E1cb mechanism and accordingly it was observed that hydrolyses of both the malonate and monomethylmalonate esters had positive volumes of activation, as also had nitrophenyl acetoacetate. The dimethylmalonate with no remaining acidic protons must of necessity hydrolyse by the $B_{Ac}2$ route and is indeed found to have $\Delta V^{\neq}$ negative.

The examples studied therefore show a clear distinction in their response to pressure between, on the one hand, those esters which possess a proton on the α-carbon or a vinylogous position that has $pK <$ ca. 10 and those which do not, and we take this as convincing evidence of the availability of the E1cb mechanism in the former case and the $B_{Ac}2$ mechanism in the latter.

This paper is dedicated to Professor Arthur N. Bourns

D. C. NEWBURY, I. ISHII, and A. P. HITCHCOCK. Can. J. Chem. **64**, 1145 (1986).

The carbon K-shell spectra of gaseous furan, pyrrole, tetrahydrofuran, pyrrolidine, tetrahydropyran, and piperidine have been recorded by electron energy loss spectroscopy (ISEELS) under electric dipole scattering conditions (2.5 keV impact, small angle). The spectra are dominated by transitions to unoccupied valence states of π and σ symmetry. Features attributed to transitions to $\pi^*(CH_2)$ levels are consistently observed below the ionization threshold in the spectra of the saturated species. The positions of continuum features are generally in agreement with a previously documented correlation with bond lengths. Additional weak continuum features are observed in the smaller saturated heterocyclic species which are ascribed to delocalized σ^* states.

D. C. NEWBURY, I. ISHII et A. P. HITCHCOCK. Can. J. Chem. **64**, 1145 (1986).

Faisant appel à la spectroscopie par perte d'énergie électronique (ISEELS) dans des conditions de diffusion des dipôles électriques (impact de 2,5 keV, petit angle), on a déterminé les spectres de la couche K du carbone du furanne, du pyrrole, du tétrahydrofuranne, de la pyrrolidine, du tétrahydropyranne et de la pipéridine à l'état gazeux. Les spectres sont dominés par des transitions vers des états de valence non-occupés de symétrie π ou σ. Dans les spectres des espèces saturées, on observe d'une façon systématique que les caractéristiques attribuables aux transitions vers les niveaux $\pi^*(CH_2)$ apparaissent à des niveaux inférieurs à ceux du seuil d'ionisation. Les caractéristiques continues apparaissent généralement à des positions qui sont en accord avec les relations qui ont été observées antérieurement avec les longueurs des liaisons. Dans les espèces hétérocycliques saturées plus petites, on a observé des caractéristiques additionnelles continues faibles que l'on attribue à des états σ^* délocalisés.
[Traduit par la revue]

Introduction

Over the last few years K-shell excitation studies by Inner Shell Electron Energy Loss (ISEELS) spectroscopy have proven to be particularly useful in examining the unoccupied energy levels of molecules containing the second row elements C, N, O, and F (1). The features present in the K-shell spectra of free molecules can be classified as transitions either to Rydberg orbitals or to unoccupied molecular orbitals of σ^* or π^* character. In contrast to valence shell excitation spectroscopy the latter dominate when the highly localized K-shell electrons are excited. An intriguing development in K-shell excitation is the evidence recently presented for an empirical relationship between bond length and σ shape resonance position (2, 3). According to this simple picture the K-shell spectrum of a molecule containing 2 or more second row atoms will exhibit a σ shape resonance associated with each bond. The position of this resonance relative to the core ionisation potential (IP) can be related to the bond length through a correlation among all bonds of the same class defined by a parameter Z, the sum of the atomic numbers of the two bonded atoms. The correlation was developed from the spectra of diatomic and "pseudo-diatomic" molecules (e.g. C_2H_2, C_2H_4, HCN, H_2CO etc.). A general goal of our research is to test the utility of the empirical relationship in larger molecules, both for bond length determination and spectral interpretation.

Recently studies have been reported on K-shell excitation in gas phase non-cyclic aliphatic hydrocarbons (2–4), cyclic aliphatics (5), and cyclic aromatics (6). In order to provide further understanding of inner shell excitation in different environments we have carried out an investigation of some saturated and unsaturated heterocyclic hydrocarbons, in particular furan (C_4H_4O), pyrrole (C_4H_4NH), tetrahydrofuran (C_4H_8O or THF), pyrrolidine (C_4H_8NH), tetrahydropyran ($C_5H_{10}O$ or THP), and piperidine ($C_5H_{10}NH$). Heterocyclic molecules such as these are important in many organic and biochemical reactions. Furan and pyrrole in particular, have been the topics of extensive study (7). The ISEELS spectra of all of these molecules are compared to their cyclic hydrocarbon analogs (5) to explore the effect of the heteroatom on the electronic structure of the ring. The continuum features are interpreted in comparison with the results predicted from the previously documented correlation between the position of σ shape resonances and bond lengths (3).

Experimental

The experimental apparatus and techniques used to acquire the ISEELS spectra have been described in detail elsewhere (2, 5). Briefly, the spectra are produced by inelastic scattering of energetic electrons by gases at ca. 10^{-4} Torr (10^{-2} Pa). The spectrometer is operated with scattering angles of 1–2° and a final electron energy (2) of 2.5 keV. The spectral resolution is limited to 0.7 eV, largely determined by the thermal spread of electron energies in the unmonochromated incident electron beam. The gases used were obtained from the vapours of high purity liquid samples, which, except for the THF and THP, were obtained commercially and used without further purification. THF was vacuum distilled to remove impurities (probably peroxides) detected in spectra recorded prior to distillation. A distilled THP sample was also studied to check for possible peroxide contamination. No changes were observed between the spectra of the distilled and undistilled THP samples. Air and volatile impurities in the liquids were removed by a series of freeze–pump–thaw cycles. The absolute energy scales were determined by calibrating the spectra relative to the C $1s \rightarrow \pi^*$ transition in CO (287.40(2) eV (8)), C_2H_4 (284.7(1) eV (4)) or CO_2 (290.7(1) eV (9)); the N $1s \rightarrow \pi^*$ transition in N_2 (401.10(2) eV (8)); or the O $1s \rightarrow \pi^*$ transition in CO (534.21(9) eV (8)). The calibrant gas was chosen for minimum overlap between the calibrant feature and the sharpest feature in the heterocyclic spectrum. In all cases the spectrum of a mixture of the two gases was recorded with each gas being let into the collision region through a separate leak vale to ensure a constant composition mixture. This approach is desirable since the spectrometer energy scale shifts slightly with changes in sample gas pressure or composition because of changes in the work function of the electron emitting surface and of surface potentials throughout the spectrometer.

Results and discussion

Knowledge of the core ionization threshold (IP) aids spectral analysis both through identification of Rydberg states through term values (10) and alignment of corresponding features in

different core edge spectra. In addition the correlation between shape resonance position and bond length (3) uses the IP as a reference level. Where available (11), gas phase ionization potentials measured by X-ray photoelectron spectroscopy (XPS) have been used for the carbon and heteroatom 1*s* IP's. However, XPS data was not available for the C 1*s* and O 1*s* IP's of THF and tetrahydropyran (THP) and the C 1*s* IP's of pyrrolidine and piperidine. For these molecules the IP's were estimated from literature values of similar molecules. For THF and THP the IP's were estimated from the gas phase XPS IP's of furan, dimethyl ether, and ethanol. The 1*s* IP's of the carbon nearest the oxygen in these molecules are 291.6, 292.3, and 292.5 eV, respectively (11), while the more distant carbons of furan and ethanol have IP's of 290.4 and 291.1 eV. The values of THF should be similar to these and thus the C 1*s* IP's for the two distinguishable C 1*s* environments in THF and THP are estimated to be 292.0 and 290.8 eV. (Note that all carbons more than one position away from the heteroatom are expected to have IP's within 0.5 eV of each other and are essentially indistinguishable in unmonochromated XPS and in ISEELS with the present resolution. For this reason in all of the molecules studied carbons more than one position away from the heteroatom are labelled C_1 while those adjacent to the heteroatom are labelled C_2.) The O 1*s* IP of furan is 540.0 eV while that of both dimethyl ether and ethanol is 538.6 eV (11). The O 1*s* IP of THF is estimated to be 539.0(5) eV, closer to the value for the non-aromatic species. The gas phase C 1*s* IP's were also unavailable for both pyrrolidine and piperidine. The C 1*s* IP's of CH_3NH_2 and $N(CH_3)_3$ are 291.6 and 291.3 eV while that of pyrrole is 290.8 eV. The C_2 IP of pyrrolidine and piperidine is expected to be similar to these and is given a value of 291.0 eV. The effect of the nitrogen is expected to disturb the ring less than the oxygen in THF so the C_1 IP is estimated to be 290.3 eV, close to that for cyclic hydrocarbons. In all cases the deviation between the estimated and actual IP's is expected to be less than 0.5 eV.

1.1. Carbon K-shell spectrum of furan

Furan, an aromatic five-membered ring with C_{2v} symmetry, is isoelectronic with the cyclopentadienyl anion. Since the carbon K-shell spectrum of the cyclopentadienyl anion has not been studied yet a direct comparison between furan and its closest hydrocarbon analog is not possible. However, comparisons to benzene or pyridine are appropriate. The carbon K-shell electron energy loss spectrum of furan is shown in Fig. 1 while the energies and assignments of the features in the spectra are listed in Table 1.

The first four features in the carbon K-shell electron energy loss spectrum of furan are attributed to $1s \rightarrow \pi^*$ transitions. There are two distinguishable carbon 1*s* environments and two unoccupied π^* levels which leads to four possible C $1s \rightarrow \pi^*$ transitions, all of which are electric-dipole allowed. The 0.86(6) eV separation of features 1 and 2 and the 0.80(4) eV separation of features 3 and 4 could represent the separation of either the C 1*s* levels (1.2 eV (11)) or that of the $3b_1$ and $2a_2$ π^* levels. Optical and valence electron energy loss spectra (7, 12) and a number of theoretical calculations (13, 14) indicate that the two π^* levels are separated by about 1.8 eV with the $3b_1$ orbital at lower energy. This suggests that the separation of features 1 and 2 reflects the separation of the core levels rather than the π^* levels. Thus the first shoulder (#1) is assigned to the C_1 $1s \rightarrow \pi^*(3b_1)$ transition while the more intense feature 2 is attributed to the C_2 $1s \rightarrow \pi^*(3b_1)$ transition. Features 3 and 4

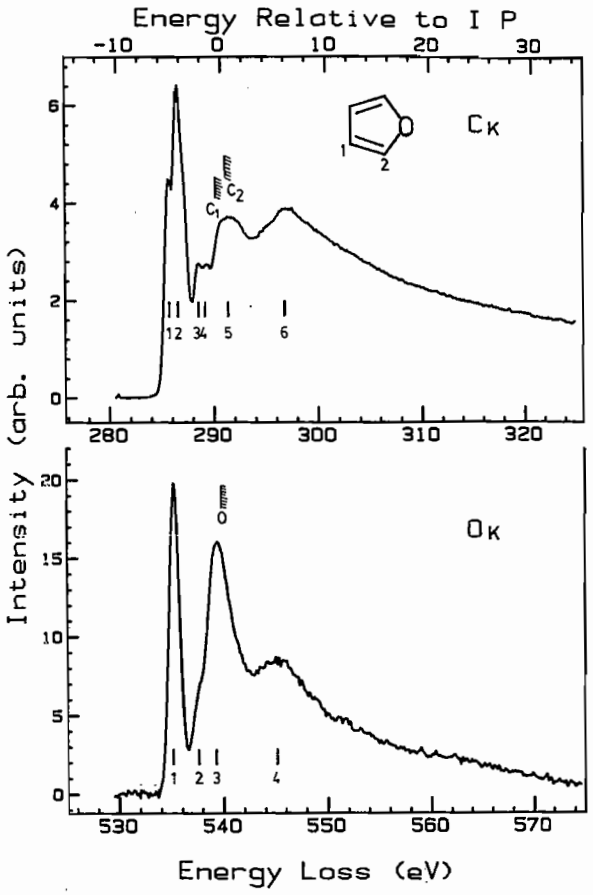

FIG. 1. The carbon and oxygen K-shell ISEELS spectra of gaseous furan recorded at 0.7 eV FWHM resolution by electron energy loss with 2.5 keV final electron energy. The hatched lines indicate the locations of the IP's as determined by XPS. A (linear) background following the shape of the underlying continuum was subtracted prior to plotting each of the spectra.

are then assigned to the C_1 $1s \rightarrow \pi^*(2a_2)$ and C_2 $1s \rightarrow \pi^*(2a_2)$ transitions. These assignments are consistent with the similarity of the 1–2 and 3–4 separations. The average separation (0.83(5) eV) is an ISEELS measure of the difference in the IP's of the two distinguishable carbon environments. This estimate is significantly lower than the measured C_1—C_2 splitting reported by two independent XPS measurements (15, 16). We have re-examined the published XPS spectrum (16) and measure a separation of 1.0 ± 0.2 eV, somewhat lower than the reported values and in better agreement with our results. If there is a smaller C_1—C_2 separation in excitation (ISEELS) rather than ionization (XPS), the electron in the π^*(C=C) level is having a different influence on the (C_1^{-1}, π^*) than on the (C_2^{-1}, π^*) state. Previously the carbon 1*s* core level separation in the monohalobenzenes was found to be essentially the same whether measured directly by XPS or indirectly by ISEELS in terms of the separation of transitions from the different core levels to the same π^* level (17).

The relative intensities of features 1 to 4 in furan provide strong support for our assignments since the $3b_1$ orbital has greater density on the C_1 and O atoms while the $2a_2$ orbital has roughly equal density on the C_1 and C_2 atoms (18). This matches the experimental observations of greatly differing intensities of the transitions from C_1 and C_2 to the $3b_1$ (#1 and #2) but very similar intensities to the $2a_2$ level (#3 and #4). The possibility that features 3 and 4 are 3*p* Rydberg transitions

TABLE 1. Energies, term values, and proposed assignments for features observed in the K-shell spectra of furan

(*a*) Carbon 1*s*

Feature	Energy (±0.1 eV)	Term value (eV) C_1	Term value (eV) C_2	Assignment[a] C_1	Assignment[a] C_2

4	545.3	−5.3	σ*(C—C)

[a]Transitions occur from the indicated core level to the final orbital listed.
[b]This feature is located 4.3(1) eV below the C $1s \rightarrow \pi^*$ transition in CO_2 (290.7 eV (9)).
[c]Average of two XPS determinations (15, 16).
[d]Determined relative to the average C 1*s* IP.
[e]This feature is located 1.1(1) eV above the O $1s \rightarrow \pi^*$ transition in CO (534.21(9) eV (8)).

was also considered but the indicated assignments are preferred because of the relative intensity evidence and also because the transitions to the second π^* level in benzene and pyridine (6) have appreciable intensity and similar term values to those of features 3 and 4 in the carbon K-shell spectrum of furan. The presence of these features at similar intensity in the spectrum of condensed furan would confirm our assignment.

The two remaining features (5 and 6) present an interesting dilemma. They are assigned to C $1s \rightarrow \sigma^*$ transitions or σ shape resonances which should correlate with bond lengths according to the empirical analysis of σ shape resonances by Sette *et al.* (3). Furan contains two different carbon–carbon bond lengths (136.1 and 143.1 pm) and one carbon–oxygen bond length (136.2 pm) (19). Thus the bond length correlation predicts three resonances in the carbon K-shell spectrum of furan around 10.6, 6.8, and 2.5 eV above the IP, corresponding to the three different bond lengths. However, only two continuum resonances are observed and they are located 0.4 and 6.0 eV above the average C 1*s* IP, not in the positions predicted by the simple correlation. The aromatic character of furan suggests that its resonances should be treated in a manner similar to those of benzene and pyridine (6). Further discussion of the continuum resonances (features 5 and 6) is given in section 7 in comparison to analogous features in the spectra of the other heterocyclic molecules studied.

1.2. Oxygen K-shell spectrum of furan

The oxygen K-shell electron energy loss spectrum of furan is shown in the lower panel of Fig. 1 while the energies and assignments of the observed features are listed in Table 1. Four features can be distinguished in the oxygen K-shell spectrum of furan. The first feature is assigned to the O $1s(a_1) \rightarrow \pi^*(3b_1)$ transition. This feature is appreciably narrower than the corresponding C $1s \rightarrow \pi^*(3b_1)$ features (1 and 2) in the upper panel of Fig. 1. It is clearly a single transition. In general excitations from different core levels in a molecule occur to the same set of valence antibonding orbitals with the intensities determined by dipole selection rules and overlap considerations. In oxygen 1*s* excitation the symmetry of furan remains C_{2v} and only the O $1s \rightarrow \pi^*(3b_1)$ transition is allowed by dipole selection rules. Thus only one O $1s \rightarrow \pi^*$ feature is expected. The shoulder (#2) on the low energy side of feature 3 is assigned to a $3p$ Rydberg transition based on its term value of 2.4 eV (10). It is possible that this feature is the O $1s \rightarrow \pi^*(2a_2)$ transition observed either because of vibronic coupling or as a quadrupole transition due to the finite momentum transfer under our experimental conditions. The X-ray photoabsorption spectrum of gaseous or solid furan would clarify the origin of this feature. Peaks 3 and 4 are analogous to features 5 and 6 in the carbon K-shell spectrum and are also assigned to σ shape resonances. Within the simple bond length correlation (3) only a single resonance associated with the C—O bond is expected while transitions to σ* states associated with carbon–carbon bonds should not be observed. The presence of an additional σ resonance in the oxygen K-shell spectrum suggests that there are interacting σ* levels in furan which produce delocalized σ* states similar to those in benzene and pyridine (6).

2.1. Carbon K-shell spectrum of pyrrole

Pyrrole is an aromatic five-membered ring, isoelectronic with furan with the oxygen replaced by an NH group. The spectrum of pyrrole might then be expected to resemble those of furan and pyridine. The carbon K-shell electron energy loss spectrum of pyrrole and the energies and proposed assignments of the observed features are presented in Fig. 2 and Table 2 respectively. As with furan there are four possible dipole-allowed $1s \rightarrow \pi^*$ transitions. According to XPS (15, 16) the carbon 1*s* IP's are separated by 1.0 eV. Valence shell studies (20) and *ab initio* calculations (21) indicate that the $3b_1$ and $2a_2$ π^* levels are separated by about 0.9 eV. The splittings of both the carbon 1*s* and π^* levels are considerably smaller in pyrrole than in furan so the four separate transitions will not be as well resolved as in furan. The fwhm of the broad feature centered at 286.3 is 1.8 eV, considerably greater than the instrumental resolution (0.7 eV as measured on the C $1s \rightarrow \pi^*$ transition in CO or on the main beam). Close inspection of its lineshape (see insert to Fig. 2) shows a shoulder on the low energy side around 285.6 eV. Thus the low energy shoulder (#1) is assigned to the C_1 $1s \rightarrow \pi^*(3b_1)$ transition and the main intensity of the peak (#2) to the C_2 $1s \rightarrow \pi^*(3b_1)$ transition. As with furan the C_1 $1s \rightarrow \pi^*(3b_1)$ transition is weaker than the C_2 $1s \rightarrow \pi^*(3b_1)$, consistent with the lower density of the $3b_1$ orbital on the carbons farthest from the nitrogen (18). A shoulder is not observed on feature 3, which is not unexpected at our experimental resolution from two equal intensity transitions to the $\pi^*(2a_2)$ level. Higher resolution spectra would be very desirable to confirm our spectral interpretation and to provide more accurate transition energies.

Peaks 4, 5, and 6 in the carbon K-shell spectrum of pyrrole are assigned to σ shape resonances similar to those in furan and pyridine. Again, as in furan, the simple relationship (3) predicts three resonances at 3.9, 7.4, and 9.6 eV above the IP in the carbon K-shell spectrum corresponding to the carbon–nitrogen (137 pm) and carbon–carbon (142, 138 pm) bond lengths (19).

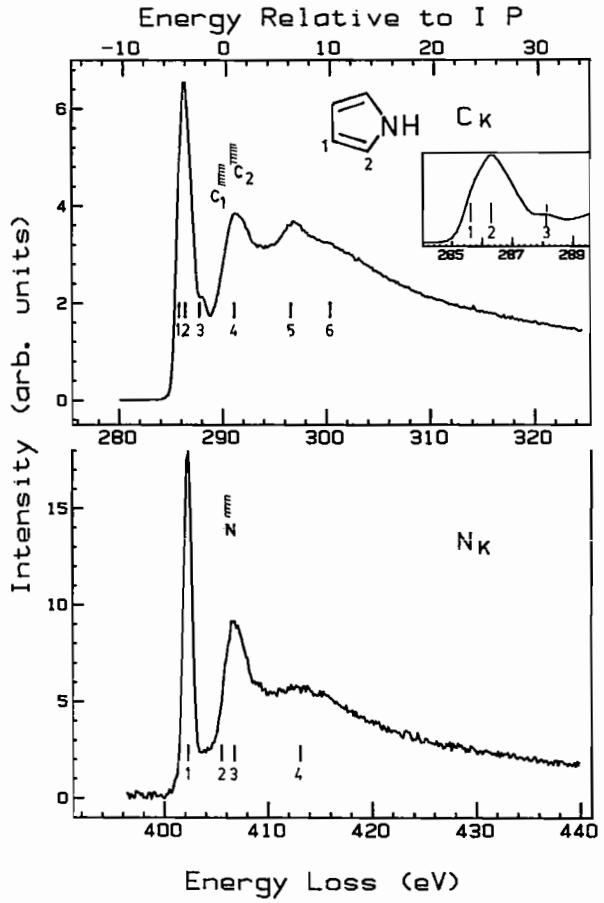

FIG. 2. The carbon and nitrogen K-shell ISEELS spectra of gaseous pyrrole recorded by electron energy loss. The hatched lines indicate the locations of the IP's as determined by XPS. The insert in the upper panel is an expansion of the spectrum in the region of the first three features.

Three resonances are observed at 1, 6.5, and 11 eV above the average C 1*s* IP. In contrast to furan the simple predictions seem to be in fair agreement with the experimental spectrum. However, the highest energy continuum feature is very broad and weak relative to the other two. While this feature may be a σ shape resonance, its absence in the furan spectrum suggests an alternate assignment such as a multielectron process (shake-up). The XPS satellite spectrum shows a prominent feature 7.6 eV above the main line (16) which is in reasonable agreement with the onset of feature 6 at 298 eV, about 8 eV above threshold. K-shell excitation features previously identified as shake-up onsets (22) have generally been weaker and more rapidly damped than feature 6 in pyrrole. Another possibility is a weak splitting of the σ shape resonances as suggested by MSXα calculations for benzene (6). From the studies of benzene and pyridine (6) one expects greatest deviation from the simple correlation in delocalized aromatic molecules. Since pyrrole is more aromatic than furan (23) we have also considered the intensity weighted average interpretation for the pyrrole continuum features (see section 7).

2.2. *Nitrogen K-shell spectrum of pyrrole*

The nitrogen K-shell electron energy loss spectrum of pyrrole is presented in the lower panel of Fig. 2 while the energies of the features and proposed assignments are listed in Table 2. To an even greater extent than the carbon K-shell spectra, the heteroatom core spectra of pyrrole and furan are similar. As

4	413.4	−7.3	σ*(C—C)

[a]Transitions occur from the indicated core level to the final orbital listed.
[b]This feature is located 4.4(1) eV below the C 1*s* → π* transition in CO_2 (290.7 eV (9)).
[c]Determined relative to the average C 1*s* IP.
[d]Not resolved as separate features.
[e]From XPS (11).
[f]This feature is located 1.2(1) eV above the N 1*s* → π* transition in N_2 (401.1(1) eV (8)).

with furan, dipole selection rules identify the first feature as the N $1s(a_1) \rightarrow \pi^*(3b_1)$ transition. A peak attributable to the N $1s \rightarrow \pi^*(2a_2)$ transition is not observed, as expected from its dipole-forbidden character. However, the valley between the first and second features is not baseline resolved suggesting some transition intensity which could be the dipole-forbidden $2a_2$ transition. Feature 2, a shoulder on #3, probably arises from Rydberg transitions. The two continuum features (3 and 4) are similar in appearance to those found in the oxygen K-shell spectrum of furan and are assigned correspondingly to σ shape resonances with the one at lower energy being closely associated with the C—N bond. The higher energy feature (#4) could arise from shake-up. However shake-up satellites are observed only at 8.7 and 15.1 eV above the N 1*s* IP in pyrrole (16), neither of which correlate with the onset of feature 4 around 411 eV, about 5 eV above threshold. The presence of two resonances where only the σ*(C—N) feature might be expected indicates that the σ*(C—C) levels are delocalized and have some density at the nitrogen atom.

3.1. *Carbon K-shell spectrum of tetrahydrofuran*

The carbon K-shell electron energy loss spectrum of tetrahydrofuran (THF) is shown in Fig. 3 while the energies and proposed assignments of the observed features are listed in Table 3. Tetrahydrofuran is the oxygen heterocyclic analog of cyclopentane and thus the carbon K shell spectrum of THF might be expected to be similar to that of cyclopentane (5). While the spectra are not precisely the same, some similarities can be noted. In cyclopentane, as in cyclohexane, a sharp

3	541.4	−2.4	σ^*(in-ring)

[a]Transitions occur from the indicated core level to the final orbital listed.
[b]Estimated from the XPS IP's of furan and ethanol (11).
[c]This feature is located 3.6(1) eV below the C 1*s* → π^* transition in CO (287.40 eV (8)).
[d]Determined relative to the average C 1*s* IP.
[e]This feature is located 3.2(1) eV above the O 1*s* → π^* transition in CO (534.2 eV (8)).

feature below the IP has been assigned to transitions to a $\pi^*(CH_2)$ level (5). This assignment was based on the observation of a corresponding feature in the C 1*s* spectra of both solid and chemisorbed cyclohexane recorded by partial photoelectron yield (near edge X-ray absorption fine structure, NEXAFS). A strong polarization dependence of the NEXAFS feature was observed, consistent with transitions to a state of π symmetry with respect to the C—H bond. Both its observation in the condensed phase spectrum and the strong polarisation dependence rule out a Rydberg assignment for this feature. The existence of unoccupied $\pi^*(CH_2)$ levels, their spatial distribution and their importance in descriptions of the electronic structure of saturated organic molecules has been noted by Jorgensen and Salem (18). Based on comparison to cyclopentane and cyclohexane features 1 and 2 in THF are also assigned to $\pi^*(CH_2)$ states corresponding to transitions from the C_1 and C_2 levels, respectively.

The third feature in the C 1*s* spectrum of THF is a σ shape resonance associated with the carbon–carbon and carbon–oxygen bonds. All of the carbon–carbon bond lengths in THF are very similar (19) and therefore only one σ(C—C) resonance is expected at 1.1 eV above the IP. In addition the bond length correlation predicts a σ shape resonance for the C—O bond at 0.6 eV above the IP which should be roughly 40% as intense as the σ(C—C) feature. Close examination of feature 3 in Fig. 3 reveals indications of two maxima (at 290.7 and 291.2 eV) at the top of this broad peak. The 0.5 eV separation of these maxima is in good agreement with the predicted separation of the σ(C—O) and σ(C—C) resonances. Feature 3 is significantly broader than the σ(C—O) resonance in the O 1*s* spectrum (feature 2 in the lower panel of Fig. 3). The increased width of this feature in the C 1*s* spectrum is likely associated with the overlap of the lower energy σ(C—O) resonance with two σ^*(C—C) features at higher energy separated by the 1.2 eV spacing of the two C 1*s* levels. According to the simple correlation (3) feature 4 is too high in energy to correlate directly with any of the bond lengths in THF. A continuum feature similar to peak 4 in THF was also observed in cyclopentane (5) and was assigned to transitions to a second σ^* state, possibly arising from the overlap of in-ring orbitals. A similar assignment is proposed for feature 4 in THF (see section 7 for further discussion).

3.2. Oxygen K-shell spectrum of tetrahydrofuran

The oxygen K-shell electron energy loss spectrum for THF is shown in the lower panel of Fig. 3 while the energies and proposed assignments of the observed features are listed in Table 3. The oxygen K-shell spectrum is quite similar to the carbon K-shell spectrum, indicating that the unoccupied levels are substantially delocalized. A weak peak, observed at 531 eV, is attributed to residual peroxide since a much more intense peak was observed at exactly the same energy in the undistilled sample. The first THF feature, which appears only as a shoulder, is assigned to transitions to the $\pi^*(CH_2)$ level as in the carbon K-shell spectrum. This indicates that these levels are not localized on the carbon atoms but can be reached by a 1*s* excitation from any atom provided it is dipole-allowed. The second feature is assigned to a σ shape resonance associated with the C—O bond. The final feature in the oxygen K-shell

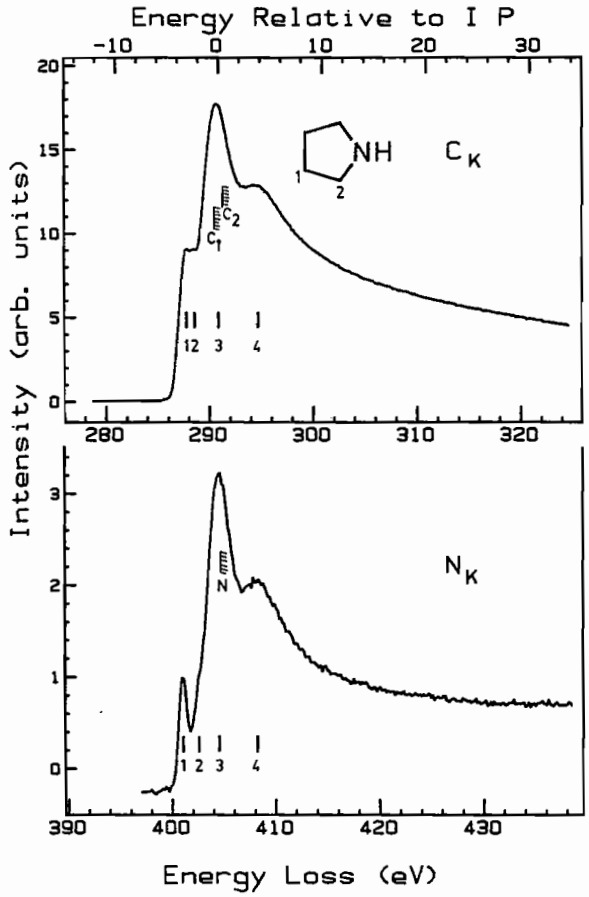

FIG. 4. The carbon and nitrogen K-shell ISEELS spectra of gaseous pyrrolidine recorded by electron energy loss. The hatched lines indicate the locations of the IP's as determined either by XPS (N_K) or by estimates from the IP's of similar compounds.

spectrum is a transition to a second σ shape resonance analogous to feature 4 in the carbon K-shell spectrum.

4.1. Carbon K-shell spectrum of pyrrolidine

Pyrrolidine, C_4H_8NH, is the nitrogen heterocyclic analog of cyclopentane. Since nitrogen is not as electronegative as oxygen, the perturbation of the ring electronic structure is expected to be less and the carbon K-shell spectrum of pyrrolidine, shown in Fig. 4, should and does resemble that of cyclopentane more closely than does that of THF. The energies and assignments of spectral features are listed in Table 4. There are four identifiable features in the spectrum. The first and second features occur at an energy and intensity similar to the features assigned to the C 1*s* → $\pi^*(CH_2)$ transitions in cyclopentane and THF (see Fig. 7). The two C 1*s* → $\pi^*(CH_2)$ transitions in pyrrolidine are closely spaced because of the small separation of the C_1 and C_2 carbon 1*s* levels. The separation of features 1 and 2 (0.7(1) eV) is in good agreement with that of the two C 1*s* IP's estimated from the IP's of similar molecules. The $\pi^*(CH_2)$ transitions in pyrrolidine are less distinct than those in THF because the separation of the two C 1*s* levels is considerably smaller.

The major feature (#3) is assigned to the σ shape resonance associated with the carbon–carbon bond. There should also be a resonance associated with the carbon–nitrogen bond. However, the σ(C—N) transition does not appear as a distinct feature because of overlap with the σ(C—C) resonance. Feature 4 is assigned to a second σ transition, possibly associated with an in-ring σ* state, similar to those seen in cyclopentane and THF. These features are discussed in more detail in section 7.

4.2. Nitrogen K-shell spectrum of pyrrolidine

The nitrogen K-shell spectrum of pyrrolidine is shown in the lower panel of Fig. 4 while the energies and proposed assignments of the observed features are listed in Table 4. The nitrogen K-shell spectrum shows four features and bears a strong resemblance to the carbon K-shell spectrum of pyrrolidine. The first feature is at essentially the same energy as the intense N 1*s* → π* transition in N_2 and was originally suspected to arise from nitrogen impurity or an air leak. However, the absence of signal in the oxygen K-shell region eliminated the air leak explanation. Extensive degassing was done to remove any N_2 trapped in the liquid. The intensity of feature 1 with respect to the rest of the spectrum remained constant throughout successive degassings. Thus we are convinced that this is a true spectral feature of pyrrolidine. In analogy with features 1 and 2 in the C 1*s* spectrum it is assigned to transitions to a delocalized $\pi^*(CH_2)$ level. The shoulder 2, on the low energy side of the third feature, is assigned to a 3*p* Rydberg transition based on its term value of 2.1 eV. The largest feature in the spectrum is the σ shape resonance associated with the carbon–nitrogen bond. Feature 4 is assigned to a second σ shape resonance analogous to that observed in the C 1*s* spectra of pyrrolidine, THF, and cyclopentane (see Fig. 7). The $\pi^*(CH_2)$ and continuum features are discussed further in section 7.

5.1. Carbon K-shell spectrum of tetrahydropyran

The carbon K-shell spectrum of tetrahydropyran (THP) is

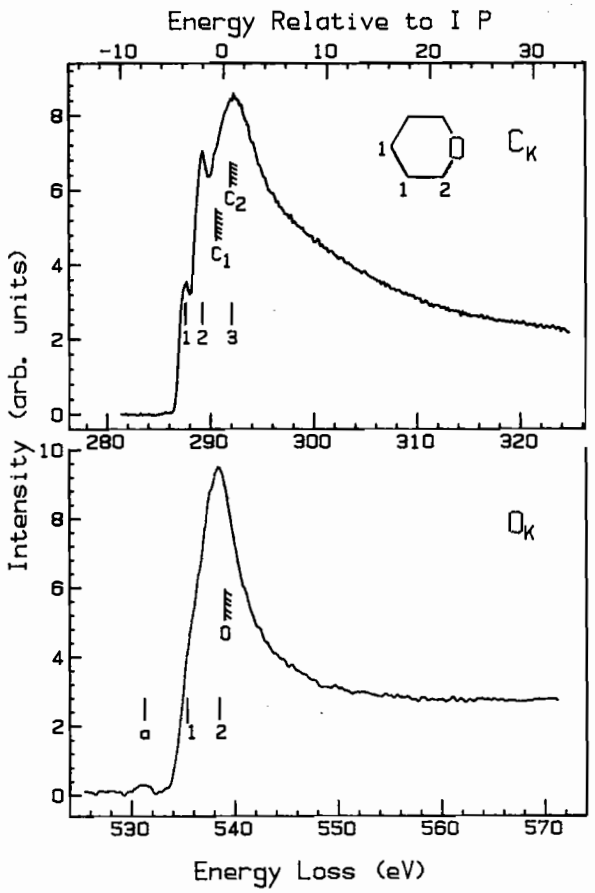

FIG. 5. The carbon and oxygen K-shell ISEELS spectra of gaseous tetrahydropyran recorded by electron energy loss. The hatched lines indicate the estimated locations of the IP's.

TABLE 5. Energies, term values, and proposed assignments for features observed in the K-shell spectra of tetrahydropyran

(*a*) Carbon 1*s*

Feature	Energy (±0.1 eV)	Term value (eV) C_1	Term value (eV) C_2	Assignment[a] C_1	Assignment[a] C_2

(*b*) Oxygen 1*s*

Feature	Energy (±0.1 eV)	Term value (eV)	Assignment[a]
a	531		π^*(in O_2)[e]
1 (sh)	536.6	3.4	$\pi^*(CH_2)$
O IP	539.0(5)[c]		
2	538.3[f]	0.7	σ^*(C—O)

[a]Transitions occur from the indicated core level to the final orbital listed.
[b]This feature is located 4.6(1) eV above the C 1*s* → π^* transition in C_2H_4 (284.7(1) eV (4)).
[c]Estimated from the XPS IP's of furan and ethanol (11).
[d]Determined relative to the average C 1*s* IP.
[e]The O 1*s* → π^* transition in O_2 occurs at 530.6 eV (25).
[f]This feature is located 4.1(1) eV above the O 1*s* → π^* transition in CO (534.2(1) eV (8)).

presented in Fig. 5 while the energies and proposed assignments are listed in Table 5. The spectrum is similar to those of cyclohexane (5) and piperidine (section 6.1) and resembles that of THF. According to our estimates the C 1*s* IP's of the two distinguishable carbon environments differ by about 1.2(7) eV. Thus transitions from these two levels to a common unoccupied level should be clearly resolved with our apparatus. On this basis the first two features are assigned to C_1 1*s* → $\pi^*(CH_2)$ and C_2 1*s* → $\pi^*(CH_2)$ transitions, respectively, analogous to the assignments of the first features in the carbon K-shell spectra of both cyclohexane and piperidine. The measured separation of features 1 and 2 (1.64(1) eV) suggests that the separation of the estimated C 1*s* IP's of THP may be too small. The total intensity of the C 1*s* → $\pi^*(CH_2)$ transitions increases as heavier heteroatoms are substituted for carbon (see Fig. 7). The explanation for this is not clear although the shift in intensity from C_1 to C_2 excitation in the CH_2 → NH → O sequence indicates that the electron density in the $\pi^*(CH_2)$ orbital shifts systematically towards the heteroatom end of the molecule. Further discussion of the $\pi^*(CH_2)$ transitions is given in section 7.

The third feature is assigned to the σ(C—C) shape resonance. There is no distinguishable feature from the σ(C—O) presumably since it overlaps the σ(C—C) resonance. The predicted σ(C—C) and σ(C—O) resonance positions are 0.9 and 0.5 eV above the edge while feature 3 has a width of at least 4 eV. This is noticeably wider than the continuum resonance in the oxygen K-shell spectrum of THP (feature 2 in the lower panel of Fig. 5) because of overlapping transitions from the C_1 and C_2 levels to both the σ(C—C) and σ(C—O) levels. As with piperidine (section 6.1) the σ resonance region is in good accord with the expectations from the simple correlation, in contrast to the situation in the spectra of the five-membered ring heterocyclics.

5.2. *Oxygen K-shell spectrum of tetrahydropyran*

The oxygen K-shell spectrum of THP is shown in the lower panel of Fig. 5 while the energies and proposed assignments are listed in Table 5. A weak feature is observed around 531 eV from the O 1*s* → π^* transition in impurity O_2 or possibly peroxide contamination. The THP oxygen K-shell spectrum is dominated by one intense broad feature which is attributed to the σ shape resonance associated with the C—O bond. There is a relatively intense shoulder on the low energy side of the σ^*(C—O) feature which likely arises from transitions to the $\sigma^*(CH_2)$ level. As with the nitrogen K-shell spectrum of piperidine (section 6.2) the simple one bond, one resonance picture (3) is in good agreement with the observed spectrum.

6.1. *Carbon K-shell spectrum of piperidine*

The carbon K-shell electron energy loss spectrum of piperidine, $C_5H_{10}NH$, is shown in Fig. 6 while the energies and proposed assignments of the observed features are listed in Table 6. The carbon K-shell spectrum of piperidine should and does closely resemble that of cyclohexane since the replacement of a CH_2 with an NH group should have even less effect in a six- than a five-membered ring. The first and second features in the carbon K-shell spectrum of piperidine are assigned to the C_1 1*s* → $\pi^*(CH_2)$ and C_2 1*s* → $\pi^*(CH_2)$ transitions, respectively. The separation of 0.82(4) eV between these two features is an ISEELS estimate of the splitting of the C_1 and C_2 levels. In

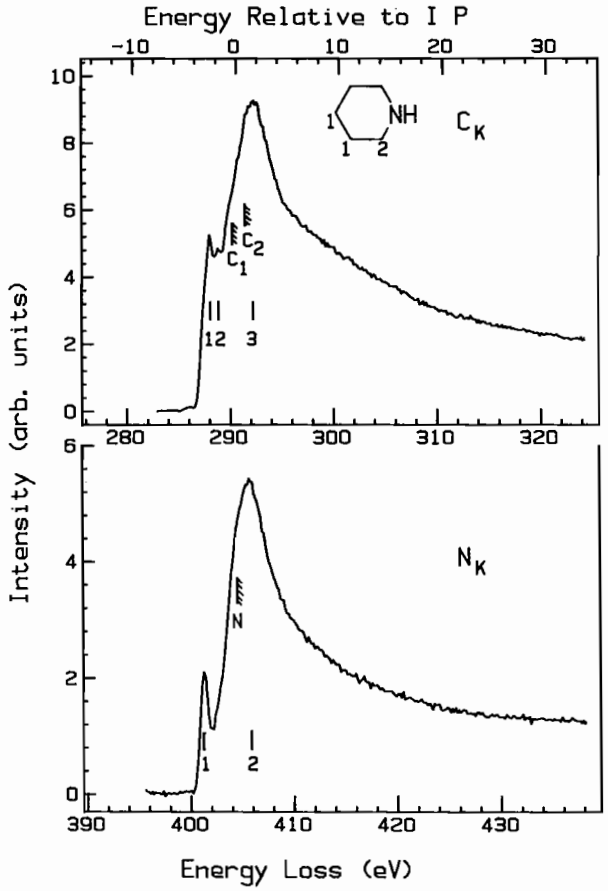

FIG. 6. The carbon and nitrogen K-shell ISEELS spectra of gaseous piperidine recorded by electron energy loss. The hatched lines indicate the locations of the IP's as determined either by XPS (N_K) or by estimates from the IP's of similar compounds.

contrast to the C_1—C_2 separation of the π^*(C=C) transitions in furan and pyrrole, it is in good agreement with that of the estimated C 1*s* IP's.

The third feature is assigned to overlapping σ(C—C) and σ(C—N) shape resonances. Interestingly a peak analogous to peak 4 in the carbon K-shell spectrum of pyrrolidine is not observed in piperidine. This feature was also less intense in cyclohexane than in cyclopentane (5). This suggests that the positions and intensities of continuum excitations depend on ring geometry as well as on the type of heteroatom and the bond lengths (see section 7).

6.2. *Nitrogen K-shell spectrum of piperidine*

The nitrogen K-shell electron energy loss spectrum of piperidine is shown in the lower panel of Fig. 6 while the energies and proposed assignments of the observed features are listed in Table 6. The N 1*s* and C 1*s* spectra of piperidine are very similar indicating that transitions are occurring to a common set of delocalized levels. The first feature, a sharp, well-resolved peak, is quite intense and is likely due to a N $1s \rightarrow \pi^*(CH_2)$ transition as in pyrrolidine. Observation of an unchanging intensity with successive degassings ruled out the possibility of impurity N_2 in the sample. The presence of this transition in the heteroatom core edge spectrum of each of the saturated heterocyclic molecules is an indication that the $\pi^*(CH_2)$ orbital is not highly localized on the carbon atoms. The second feature is the σ shape resonance from the carbon–nitrogen bond. There are no features beyond this peak again

TABLE 6. Energies, term values, and proposed assignments for features observed in the K-shell spectra of piperidine

[f]This feature is located 4.5(1) eV above the N $1s \rightarrow \pi^*$ transition in N_2 (401.1(1) eV (8)).

suggesting that the intensity of the second σ shape resonance which was present in the five-membered saturated rings is strongly geometry dependent. Since the feature is present at a low intensity in cyclohexane but absent in piperidine, a dependence on the heteroatom also exists.

7. *Systematics of π^* intensities and the positions of K-shell continuum resonances*

A comparison of the carbon K-shell spectra of the CH_2, NH, and O five- and six-membered rings is presented in Fig. 7. There are interesting trends in the intensities of the discrete features attributed to the $\pi^*(CH_2)$ states. The NH and O heterocyclics each have two distinguishable C 1*s* environments and a splitting of the $\pi^*(CH_2)$ features is observed, as expected. Because of the 50% increase in number of C_1 carbons one might expect a large increase in the $C_1 \rightarrow \pi^*(CH_2)$ transition relative to that from C_2 as the ring size increases from 5 to 6. Although an increase is observed it is much smaller than expected. A more dramatic effect is observed in the comparison of the NH and O species. The $C_2 \rightarrow \pi^*(CH_2)$ feature is substantially more intense in THF or THP than it is in pyrrolidine or piperidine. This suggests that the $\pi^*(CH_2)$ level has considerably greater density at the heteroatom end of the molecule and that the electron density shifts towards the heteroatom as the heteroatom electronegativity increases. This is also consistent with the increased intensity of the $\pi^*(CH_2)$ features in the O K-shell spectra of THF and THP relative to those in the N K-shell spectra of pyrrolidine or piperidine (see Figs. 3–6) (although the shift to higher energy caused by the more electronegative O results in greater overlap with higher energy features in the O 1*s* spectra). Finally there is an obvious increase in the width of the first *continuum* feature through the $CH_2 \rightarrow NH \rightarrow O$ sequence in both the five- and six-membered ring series. This increased width is partially due to overlap of the σ(C—C) and σ(C—O)

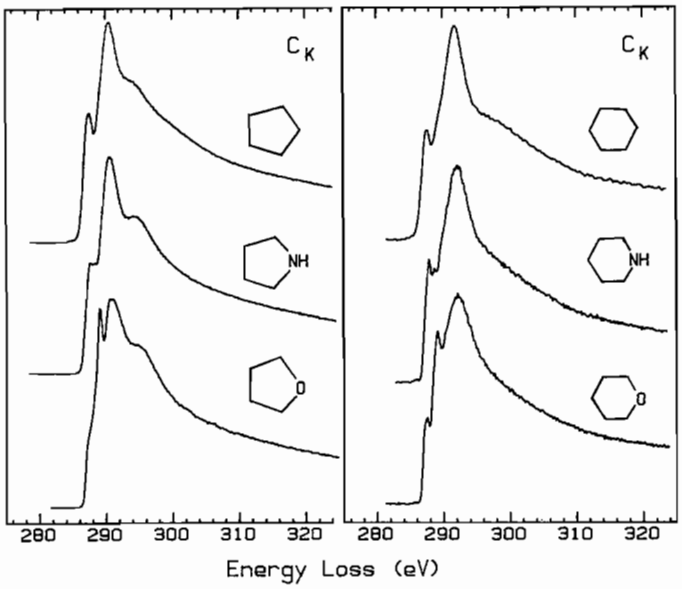

FIG. 7. Comparison of the carbon K-shell spectra of the five- and six-membered (CH_2, NH, O) saturated rings.

resonances in the heterocyclics but it is also indicative of the occurrence of transitions to both σ* levels from each of the two distinguishable C 1*s* levels which are separated by increasing amounts in the NH (0.7 eV) and O (1.2 eV) cases. This same trend of increasing widths of σ resonances is apparent also in the series cyclopentene (5), pyrrole (Fig. 2), and furan (Fig. 1), again in good agreement with contributions of transitions from two separate C 1*s* levels.

Turning now to the positions of continuum features, the correlation between δ, the shape resonance position relative to the IP, and *R*, the bond length, gives reasonable results for the ISEELS spectra of many molecules (2, 3, 5). Among the heterocyclic molecules studied in this work, those with simple bonding generally show good agreement between predicted and experimental results. However, although there is a continuum feature in each of the saturated molecules which correlates well with bond length, an additional continuum feature is also observed, in some cases with appreciable intensity. The second continuum feature in THF and pyrrolidine is similar to that seen in cyclopentane (5) and is similarly assigned to in-ring σ* states. This feature appears to decrease in intensity from THF to pyrrolidine and then to cyclopentane (see Fig. 7). This is consistent with shorter C—O and C—N bonds. The more constrained geometry should increase the overlap of the in-ring σ* orbitals and thus the splitting of the derived states. It is interesting to note that compared to the five-membered rings, the spectra of the six-membered rings are all in much better agreement with the one bond, one resonance picture. A second continuum feature is observed weakly only in the spectrum of cyclohexane (see Fig. 7). This suggests that the overlap of σ* states is less in the larger rings so that delocalization and splittings are greatly reduced compared to smaller rings. Note however that the continuum resonances in the C 1*s* spectra of the six-membered rings are significantly wider than the first continuum resonances in the corresponding five-membered ring. The increased width suggests that there may be overlap with a second resonance.

In the two aromatic molecules, furan and pyrrole, the number and positions of the observed resonance features are not fully

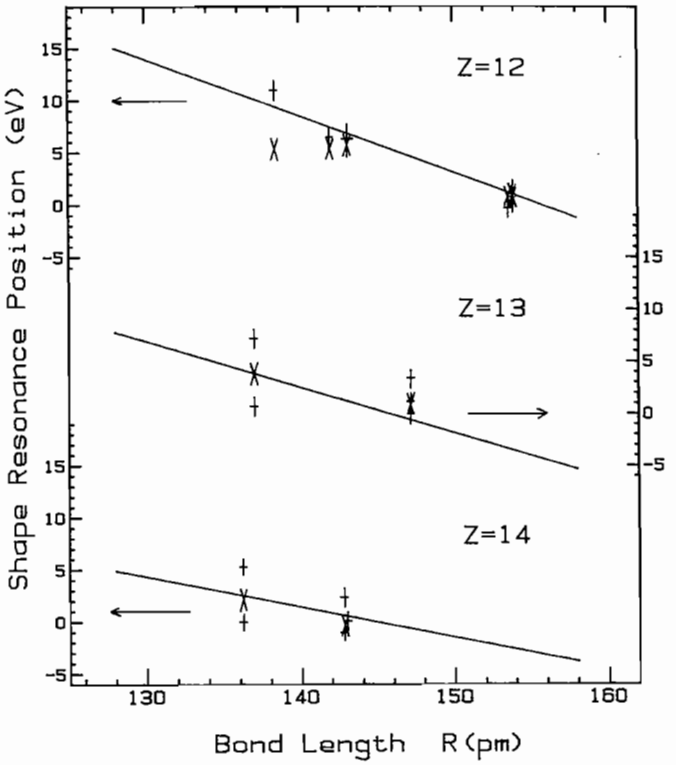

FIG. 8. Plots of the bond length versus resonance position for Z = 12 (C—C), Z = 13 (C—N), and Z = 14 (C—O) bonds in the heterocyclic molecules studied in this work. The daggers indicate the positions of individual spectral features while the X's indicate intensity weighted average positions of several continuum features. The straight lines are the correlation lines derived earlier from the spectra of other molecules (3). The data used for this figure are listed in Table 7.

consistent with the simple correlation suggesting that a different interpretation may be required. In the K-shell continua of benzene, pyridine (6), and borazine (24) two resonances are observed whereas only one is expected (2, 3). Based on the correlation derived from smaller molecules the intensity-weighted average (IWA) positions of the experimentally observed resonances give much better estimates of the C—C, C—N, and B—N bond lengths than the positions of any single resonance feature (6, 24). The merits of a similar approach for the spectra of furan and pyrrole have been investigated. The intensity weighted average positions were determined by first subtracting an estimation of the smooth continuum upon which the resonances are located. The position and area of each background-subtracted peak were then measured and the IWA calculated. The relevant data for all of the molecules studied in this work are listed in Table 7 while the observed resonance positions and their intensity weighted averages are plotted against bond length in Fig. 8. For both furan and pyrrole, the intensity weighted averages of the two heteroatom continuum resonances gives better agreement with the correlation than does the position of either of the individual features. The continuum resonances in the carbon K-shell spectrum of pyrrole are well interpreted within the simple correlation. For the carbon–carbon distances in furan, if peak 5 is assigned to overlapping σ(C—O) and σ(C—C) and peak 6 to σ(C=C), the IWA improves the situation relative to this one-bond one-resonance assignment although the fit is not spectacular. This may be a reflection of the lesser degree of aromaticity in pyrrole or furan with respect to benzene and pyridine. The decrease in π delocalization appears

TABLE 7. Bond lengths and continuum resonance positions for heterocyclic molecules

[a]From XPS (11) except where noted. For those core edges with distinguishable environments the average of the two C 1*s* IP's has been used.

[b]Determined as $\delta = E_\sigma - IP$ from the values listed. For the $Z = 13$ and $Z = 14$ data the average of the δ values from the carbon and heteroatom spectra is listed.

[c]Position (±0.8 eV) determined from the intensity weighted average of the continuum features observed in the same core edge spectrum. The IWA was determined by subtracting an estimated background representing the underlying non-resonant continuum, measuring the position (E) and area (A) and calculating: $IWA = (E_1A_1 + E_2A_2)/(A_1 + A_2)$.

[d]Predicted from the previously reported correlation (3) according to the linear relationship: $\delta = m - n \times R$, with [m (eV), n (eV pm^{-1})] values of: (84.73, 0.5445) for $Z = 12$; (64.15, 0.4401) for $Z = 13$; and (42.19, 0.2913) for $Z = 14$.

[e]Bond lengths (pm) are from (19) except where noted.

[f]Estimated from the IP's of similar molecules (11) (see text).

[g]Estimated from Stoicheff rules (26).

[h]Estimated from average C—N and C—O bond lengths (27).

to be accompanied by a decrease in σ delocalization which results in a situation intermediate between benzene and the more localized aliphatic molecules. An alternate assignment of furan gives good agreement with the bond length correlation within the simple one bond one-resonance picture. This occurs if peak 5 in the C K-shell spectrum of furan is assigned to σ(C—O) and peak 6 to σ(C—C), with no feature in the spectrum being explicitly associated with σ(C=C). A high energy tail on peak 6 can be discerned by comparison to the O K-shell spectrum which may be how the σ(C=C) intensity appears in furan. This interpretation is the one presented in Tables 1 and 7. Calculations of the continuum cross-sections in furan and pyrrole would be helpful in evaluating these alternate interpretations.

For all of the heterocyclic molecules the heteroatom core spectrum resembled the C 1*s* spectrum of the same molecule quite closely. This indicates that the unoccupied levels in these molecules are extensively delocalized so that, within symmetry restrictions, transitions to all antibonding orbitals occur from any site with finite intensity. In the heteroatom spectra of furan and pyrrole, the first σ shape resonance is more intense, relative to the higher energy resonance, than it is in the corresponding carbon 1*s* spectrum. This resonance is approximately where the σ(C—O) or σ(C—N) shape resonances would be expected in a localized picture. The increased intensity of this feature, relative to its counterpart in the carbon spectrum, appears to be a further reflection of the decrease in aromaticity of furan and pyrrole relative to pyridine and benzene, where the two continuum resonances are more similar in intensity (6).

Conclusions

The core excitation spectra of furan, pyrrole, tetrahydrofuran, pyrrolidine, tetrahydropyran, and piperidine have been recorded by gas phase ISEELS spectroscopy and assignments have been proposed for all observed features. To our knowledge none of these spectra have been reported previously. The spectra of the saturated heterocyclic molecules are similar to those of their cyclic hydrocarbon analogs. In all cases the carbon and heteroatom K-shell spectra are generally similar indicating that transitions occur to a common set of extensively delocalized unoccupied levels. Features attributed to a $\pi^*(CH_2)$ state were observed about 3 eV below the IP in both the carbon and heteroatom spectra of all of the saturated heterocyclics studied.

The correlation of experimental σ shape resonance positions with bond lengths shows reasonable agreement with earlier results. This is further indication that the empirical approach developed by Sette *et al.* (3) can be useful for a wide variety of molecules. However the complications of additional continuum features and the somewhat greater scatter in the correlation for more complex molecules appears to limit the accuracy of the structural information obtainable. The greatest accuracy is expected from shifts in resonance position in the same molecule in different environments, as in geometry changes of a surface adsorbed molecule. From the viewpoint of gas phase K-shell spectroscopy the correlation between resonance position and bond length provides a useful framework for spectral interpretation.

Alkoxyphosphonium ions. 5. Kinetics of the Michaelis–Arbuzov intermediate

EDWARD S. LEWIS AND BRIDGET A. MCCORTNEY[1]

Department of Chemistry, Rice University, P.O. Box 1892, Houston, TX 77251, U.S.A.

Received October 21, 1985

This paper is dedicated to Professor Arthur N. Bourns

EDWARD S. LEWIS and BRIDGET A. MCCORTNEY. Can. J. Chem. **64**, 1156 (1986).

Rates of formation and destruction of the alkoxyphosphonium ion, the intermediate in the Michaelis–Arbuzov reactions of some methyl esters of trivalent phosphorus acids with methyl iodide, are followed by a conductivity method in the solvent propylene carbonate. Specific conductances of the unstable intermediates are well estimated through stable model salts. Rate constants for both the alkylation of the reagent and the dealkylation of the intermediate are obtained. The conductivity time curves are simulated by adjusting rate constants for two sequential second order reactions, assuming no ion pairing at the concentrations used. In these measurements of the intermediate only, there is no rate-determining step; for the overall reaction the first step is in most cases rate-determining.

EDWARD S. LEWIS et BRIDGET A. MCCORTNEY. Can. J. Chem. **64**, 1156 (1986).

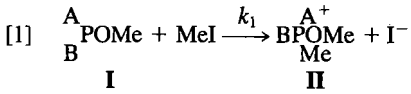
Opérant dans le carbonate de propylène comme solvant et faisant appel à une méthode de conductivité, on a déterminé les vitesses de formation et de destruction de l'ion alkylphosphonium, l'intermédiaire dans les réactions de Michaelis–Arbuzov de quelques esters méthyliques d'acides phosphoreux trivalents avec l'iodure de méthyle. En se basant sur des sels modèles stables, on a pu bien évalué les conductivités spécifiques des intermédiaires instables. On a pu déterminer les constantes de vitesse tant de l'alkylation du réactif que de la déalkylation de l'intermédiaire. Faisant l'hypothèse qu'il n'y a pas de couplage d'ions ux concentrations utilisées, on a simulé les courbes de conductivité vs. temps en ajustant les constantes de vitesse pour deux réactions du deuxième ordre qui se suivent. Dans ces mesures qui n'impliquent que l'intermédiaire, il n'y a pas d'étape déterminante; pour l'ensemble de la réaction, la première étape est généralement l'étape qui détermine la vitesse.

[Traduit par la revue]

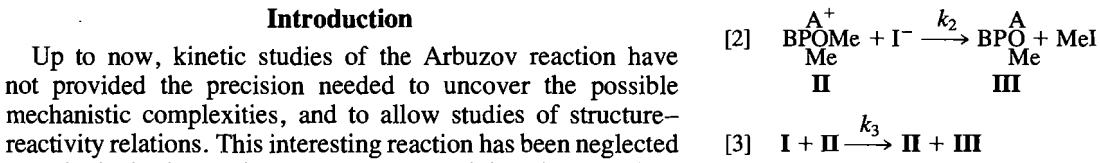
Introduction

Up to now, kinetic studies of the Arbuzov reaction have not provided the precision needed to uncover the possible mechanistic complexities, and to allow studies of structure–reactivity relations. This interesting reaction has been neglected quantitatively, in part because many potential analyses such as absorption or titration for the reagents or products are inapplicable or undeveloped.

The first reasonably successful method, by Aksnes and Aksnes (1), used an infrared analysis based upon the formation of the characteristic P=O bond in the product, leading to the still accepted conclusion that in that case the first alkylation step was rate-determining. This analysis is cumbersome, slow, and of limited precision; we have not found it attractive for our studies. Our attempts to substitute a gas chromatographic analysis did not overcome these problems, but a nmr method showed promise as a highly compound-specific method. This was in fact successful at the level of seeing compounds at fairly high concentrations and it allowed the observation of the intermediate alkoxyphosphonium salt and rough rate studies using both proton and phosphorus nmr (2). Studies of structure reactivity relations were unconvincing. Nevertheless, the mechanisms were clearly delineated as a combination of reactions [1] and [2], with in some cases a contribution of reaction [3]. Reaction [3] was not identified as an important contributor in the case of the iodide counter ion; it was observed only with less nucleophilic anions.



[1] $\underset{\mathbf{I}}{\overset{A}{\underset{B}{P}}OMe} + MeI \xrightarrow{k_1} \underset{\mathbf{II}}{BP^{+}(A)OMe} + I^-$



[2] $\underset{\mathbf{II}}{BP^{+}(A)OMe} + I^- \xrightarrow{k_2} \underset{\mathbf{III}}{BP(A)O} + MeI$

[3] $\mathbf{I} + \mathbf{II} \xrightarrow{k_3} \mathbf{II} + \mathbf{III}$

Earlier studies (3, 4), in which the intermediate salt is detected quantitatively by its electrical conductivity tempted us to revive this method. Although these earlier studies succeeded in detecting the intermediate and observing its concentration rise and fall, they failed to establish the relation between conductivity and concentration and were led into some incorrect assumptions and hence unjustifiable mechanistic conclusions. The further conclusion that in acetonitrile there is extensive ion pairing is now suspect.

Results

The alkoxyphosphonium iodides are unstable; it is thus not possible to measure directly the conductivities of solutions of known concentration. Alkoxyphosphonium trifluoromethanesulfonates are stable, as are ordinary phosphonium iodides. The strategy was therefore to substitute for the methoxy groups of the unstable salts ethyl groups which have a similar size. The results of these measurements are shown in Table 1. The conductivity data are presented as the slopes of the conductivity–concentration plots corrected for the cell constant. Conductivities of triflate salts with ethyl groups substituted for the methoxy groups showed that indeed this substitution had only a minor effect on the conductivity, as shown by the last two entries in Table 1. It was then assumed that the concentration of the methoxyphosphonium iodide was the same as that of the corresponding ethylphosphonium iodide of the same conductivity.

The same measurements showed that, for the stable salts, the conductivity was with good precision proportional to the

[1]National Science Foundation Predoctoral Fellow.

TABLE 1. Concentration dependence of the conductivity of salts $ABCP^+Me\ X^-$ at 25°C in propylene carbonate

A	B	C	X	Specific conductance (mho cm^{-1})/M^a	Melting point (°C)
OCH_3	OCH_3	OCH_3	OTf	0.0229 ± 0.0009	49–50[c]
CH_3CH_2	CH_3CH_2	CH_3CH_2	OTf	0.0238 ± 0.0001	87–90
CH_3CH_2	CH_3CH_2	CH_3CH_2	I	0.0296 ± 0.0002	307–311 (lit.[d] 300–302)
CH_3CH_2	CH_3CH_2	Ph	I	0.0248 ± 0.0003	110–112 (lit.[e] 110)
CH_3CH_2	Ph	Ph	I	0.0256 ± 0.0003	188–190 (lit.[f] 183)
CH_3CH_2	Ph	Ph	OTf	0.0237 ± 0.0005	~22
OCH_3	Ph	Ph	OTf	0.0244 ± 0.0005	34–36 (lit.[g] 34–37)

[a]Values reported are the slope ± s.d. of the specific conductivity vs. concentration plot.
[b]Data on this compound were much more scattered than with the other compounds. The salt is very sensitive and possible water contamination may be the source of error.
[c]This melting point was taken in a capillary sealed under N_2. The earlier reported value (28–32°C), ref. 7, did not take this precaution.
[d]Reference 11.
[e]Reference 12.
[f]Reference 13.
[g]Reference 7.

concentration. This gave assurance that there was no significant ion pairing or covalent phosphorane formation, at least in the concentration range (up to about 0.01 *M*). The data for concentration vs. conductivity were subject to a linear least-square fit, and in every case the calculated intercept at zero concentration was so small that assuming it to be zero introduced no significant error, as long as concentrations in the kinetic runs did not exceed those in these calibrations. Parenthetically, we may note that very little error in concentrations would have resulted if we had assumed that the slopes of all these plots had been the same.

The experiments on reacting systems showed usually an initial rise followed by a slow fall in conductivity. These data, converted to concentration time dependencies using Table 1, were then compared to the computed values of the salt concentration from the numerical integration of eqs. [4], [5], and [6], with plausibly guessed values of k_1 and k_2.

$$[4]\quad -\mathrm{d(ABPOMe)}/\mathrm{d}t = k_1(\mathrm{ABPOMe})(\mathrm{MeI})$$

$$[5]\quad \mathrm{d(MeABPO)}/\mathrm{d}t = k_2(\mathrm{MeABPOMe^+})(\mathrm{I^-})$$

$$[6]\quad \mathrm{d(MeABPOMe^+)}/\mathrm{d}t = k_1(\mathrm{ABPOMe})(\mathrm{MeI}) - k_2(\mathrm{MeABPOMe^+})(\mathrm{I^-})$$

Then the two rate constants were adjusted for a good fit to the experimental data. Figure 1 shows this plot for trimethyl phosphite, the only case where the rise in conductivity was too fast to follow by our manual conductivity bridge. For methyl diethylphosphinite, the curve could not be even remotely well fitted by adjustment of only two rate constants. The inclusion of reaction [3] resulted in the fit shown in Fig. 2.[2] There is a wide variation in the maximum concentration of the salt, with the two extremes shown in Figs. 1 and 2, about 0.2% of the starting ester concentration in the first case and about 60% in the second.

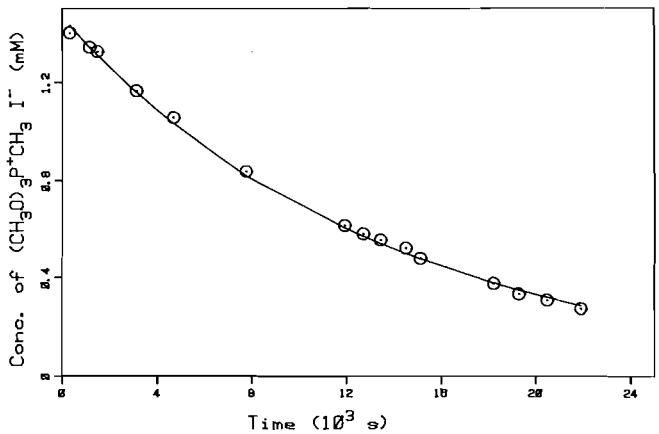


FIG. 1. Plot of methyltrimethoxyphosphonium iodide concentration vs. time with initial concentrations for this run of 0.7119 molar in trimethyl phosphite and 2.068 molar in methyl iodide. The circles represent experimental data points; the solid curve is that calculated from numerical integration of the rate law.

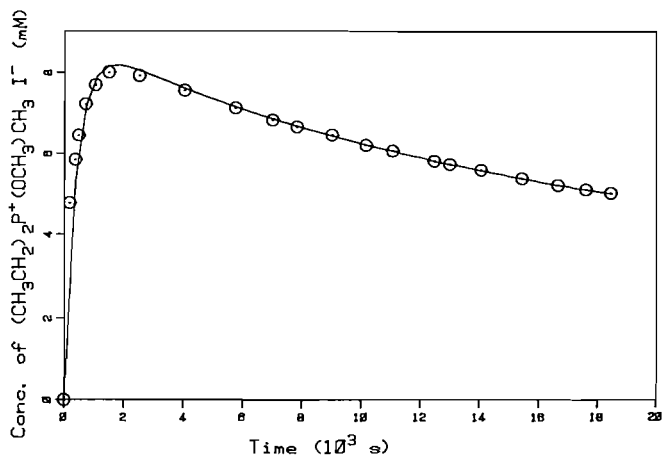

FIG. 2. Plot of diethylmethoxymethylphosphonium iodide concentration vs. time with initial concentrations for this run of 1.28×10^{-2} molar in methyl diethylphosphinite and 2.165×10^{-2} molar in methyl iodide. The circles represent experimental data points; every third point up to 12 000 s and every point thereafter is shown. The solid curve is that calculated from numerical integration of the rate law.

[2]ADDED IN PROOF: Later direct measurement of k_3 has shown that the value given here in Table 2 is more than an order of magnitude too large. The fit in Fig. 2 is at least as good with only k_1 and k_2, having the values 1.75×10^{-1} and 4.7×10^{-3}, respectively. The discrepancy arises from loss of some of the reagent by oxidation prior to conductivity measurements, which makes the apparent extent of conversion of the reagent to the intermediate salt far too small. In fact, in this case the conversion is almost quantitative before much decay has occurred.

TABLE 2. Rate constants for reactions [1], [2], and [3] of $ABPOCH_3$ at 25°C in propylene carbonate

A	B	k_1, M^{-1} s^{-1} [a]	k_2, M^{-1} s^{-1} [a]	k_3, M^{-1} s^{-1} [a,b]
OCH_3	OCH_3	$(8.25 \pm 2.32) \times 10^{-5}$ [c]	52.5 ± 6.7	—
OCH_3	Ph	$(1.86 \pm 0.10) \times 10^{-3}$	4.17 ± 0.25	—
Ph	Ph	$(5.68 \pm 0.36) \times 10^{-3}$	0.217 ± 0.008	—
CH_3CH_2	CH_3CH_2	$(6.61 \pm 1.77) \times 10^{-2}$	$(4.62 \pm 0.30) \times 10^{-3}$	0.142 ± 0.004

[a]Values reported are the mean ± s.d. for three independent runs of the same reaction. The effect of ionic strength variations is neglected.

[b]Not required for fit except in last compound. The value is presumed small enough in the other cases that its contribution is unimportant. However, see footnote 2 for more details.

[c]^{31}P nmr kinetic result: $1.18 \pm 0.04 \times 10^{-4}$ M^{-1} s^{-1} at 26.4°C. A few other less satisfactory nmr runs scattered badly, but agreed within their own rather large error limits.

The rate constants determined are presented in Table 2. A rate constant measured by observing the loss of trimethyl phosphite as shown by its ^{31}P nmr signal at an estimated temperature of 26.4°C is also included to show that within that rather substantial experimental error, especially of the nmr rate, the rate constant k_1 calculated by fitting procedure is indeed the rate of the first and rate determining step (Table 3). It is note-worthy that the intermediate treated quantitatively by the conductivity studies in this case is completely invisible in the nmr.

Discussion

In a case such as this in which neither the reagents nor the products of a reaction are observed, it is absolutely necessary to show that the reaction being followed is in fact the correct one. The fact that the reagents are those well known to undergo the Arbuzov reaction is useful. The identification of the reaction products by nmr as the only detected phosphorus containing material adds further evidence. The accepted mechanism requires the intermediacy of an electrolyte, which is detected. Finally, the similarity of the rate constants postulated to account for the conductivity and that measured by an nmr method, which observes the reagent and the product, but not the intermediate, makes the identification of the two processes very convincing.

The identification of the conducting species as the alkoxyphosphonium iodide rests not only on the mechanism, but also on the isolation of such salts in related reactions where the lower reactivity is understood; examples are phenyl esters (5), neopentyl esters (6), many of these alkoxyphosphonium salts as their triflates (7) and fluoborates (8), and even one quite unstable iodide salt of a methyl ester (7, 9). The concentrations of the salts are determined plausibly by the relation to the stable salts described above. These concentration determinations probably do not have errors exceeding a few percent, but also are not much more precise than that either. The assumption of linearity of the concentration–conductivity plots cannot be correct (10), but concentration errors of this sort are very small, as are random errors in the conductivity measurements, because the conductivity–time curves are very smooth.

This method still does not answer the question of a highly precise method for following the Arbuzov kinetics. Almost certainly, this is due to the fact that only the small difference between the rates of the two important steps is measured, the actual rate constants are subject to an amplification of errors more or less related to the concentration ratio of the major species to the measured intermediate, a factor between 2 and 500. It appears to provide data of an extremely exacting nature that, when the good analysis becomes available, will have to be fitted.

We can check on the plausibility of the results by looking at the substituent effects on the rate. If log k_1 is plotted in a Taft plot against $\Sigma\sigma_1$, a rather poor line results ($\rho_1 = -4.1$, $r = 0.97$), a line which includes a rate for the methylation of triphenylphosphine, measured independently in this solvent by conductivity.[3] The sign is reasonable; the less than perfect fit is expected for a reaction so close to the substituents.

The same plot for k_2 is much better ($\rho_1 = +6.4$, $r = 0.99$), again with the expected sign of ρ_1. The greater distance from the site of substitution is probably the reason for the better fit; there is no reason to expect one rate constant to be better than another.

In the previous nmr study no intermediate was observed even with methyl dialkylphosphinite, although here it builds up to as high as 60% of the starting material concentration, which should be conspicuous by nmr. The discrepancy is probably a solvent effect; the salt should be formed less rapidly and be decomposed more rapidly in chloroform than in propylene carbonate.

These results differ greatly from those of Buck and Yoke (3) and of Cachaza, Casado, and Varela (4). The major difference is that they all assumed that the intermediate was formed quantitatively; thus the rise in concentration was interpreted as a measured k_1 and the subsequent fall as a measure only of k_2.

In fact, the two rate constants are combined in both the rise and the fall; the fall does nearly follow a first order course, as observed by Buck and Yoke, but the apparent rate constant is closer to k_1 than to k_2! A manifestation of this aspect is that the fastest rise to the maximum was observed with trimethyl phosphite, which has the smallest value of k_1. Both the conductivities and the rate measurements show that in this solvent ion-pairs are insignificant.

In conclusion, the kinetics of the Arbuzov reaction are followed in a consistent way by measuring the conductivity of the alkoxyphosphonium iodide intermediate. The fallacies of earlier measurements by this method are now understood. Rather precise determination of the time dependence of the concentration of the intermediate provides new kinetic data of good precision, but translates into much less precise rates for the overall reaction. Nevertheless, significant new structure reactivity data on the formation and destruction of the intermediate are presented, and the previously confusing conduc-

tivity measurements are explained. A precise measurement of overall rates of this reaction is not yet available. The substituent dependence of the autocatalytic rate constant is small, as observed before (2), but there is no evidence even on the sign of ρ_I for this reaction.

Experimental section

Materials

Methyl diethylphosphinite, methyl diphenylphosphinite, and dimethyl phenylphosphonite were obtained commercially (Strem Chemical) and used without further purification. The identity and purity of each was checked by ^{31}P nmr before use. Trimethyl phosphite (Aldrich) was treated with sodium followed by distillation under nitrogen: bp 112°C. Propylene carbonate (99% from Aldrich Chemical Co.) was twice vacuum distilled at 8–10 Torr and stored under nitrogen until used. This procedure was sufficient to give propylene carbonate with undetectable conductivity on the system described below. Methyl iodide was distilled under nitrogen from P_2O_5. The methoxyphosphonium trifluoromethanesulfonate (triflate) salts were prepared following the procedure of Lewis and Colle (7). The four triflate salts prepared were oils which, after removal of the solvent under vacuum, solidified upon storage at 0°C. The phosphonium iodides (triethylmethyl, diethylmethylphenyl, diphenylethylmethyl) were prepared by methylation of the commercial phosphines with methyl iodide in the same manner as the triflates. These salts were obtained as fine white precipitates which were recrystallized from EtOH/Ether (diphenylethylmethylphosphonium iodide, diethylmethylphenylphosphonium iodide) or isopropanol (methyltriethylphosphonium iodide). The purity of the phosphonium salts was determined by their melting points and ^{31}P nmr spectra. The ^{31}P chemical shifts of the reagents, intermediates, and products of the reactions studied are reported in Table 3.

Conductivity measurements

Conductivities were measured using a Fisher brand enclosed conductivity cell with platinized electrodes (cell constant 0.250 ± 0.003 cm^{-1}), a General Radio conductivity bridge (Model 1603-A), an oscillator operated at 1000 Hz with an applied voltage of 0.50 V across the bridge with the bridge imbalance detected with an oscilloscope. The cell was immersed in a 25.0°C thermostat; all conductivity measurements were taken at this temperature. Propylene carbonate was chosen as a solvent only because it is the solvent we found with minimal reaction with methyl iodide, a reaction which turned out to be a consequence of using too high a voltage and too low a frequency on a different bridge, and not a property of the solvent. Thus, there is no reason to believe that several other aprotic solvents rejected earlier would not have worked well with the proper bridge. The electrodes also were platinized during this preliminary bridge problem; there is no reason to believe that it is necessary. To obtain the concentration dependence of the conductivity for the phosphonium iodides and triflates, an approximately 0.01 *M* solution of each salt in propylene carbonate was prepared; this was diluted to obtain solutions of approximately 0.001, 0.003, 0.005, 0.007, and 0.009 molar concentration. The conductivities of the solutions were measured and plotted as a function of the concentration.

Kinetic experiments

The reaction mixtures were prepared at room temperature by mixing the two reagents (either as stock solutions in propylene carbonate or by addition of the neat compounds) in propylene carbonate in a 25 mL volumetric flask. After mixing, approximately 15 mL of the solution were transferred to the conductivity cell. All transfers were performed under nitrogen, and the cell was kept under nitrogen and away from light during the course of the experiments. Measurements were made at frequent intervals. The possibility of a reaction occurring at the cell electrodes was ruled out by adding a few millilitres of the starting reaction solution to the conductivity cell after the reaction was nearly complete. In all cases, the conductivity changed by a negligible amount. Each reaction solution was allowed to remain in the cell until the conductivity no longer changed (in each case the final conductivity was less than 10% of the maximum conductivity for that run, except in the case of trimethyl phosphite which had a very low conductivity), and at that point a ^{31}P nmr was taken. In each case, only one phosphorus-containing compound was detected. It had an appropriate chemical shift for the product.

Two programs were used to integrate the concentration as a function of time data for chosen rate constants, one that was used by Lewis and Hamp (2), and one kindly provided by Professor David Stanbury of Rice University (used only for trimethyl phosphite, except on a few other runs to show that the results are the same). The iteration to find the best rate constant to fit the experimental data was done by hand (manually adjusting the guessed rate constants and evaluating the resulting fit); the least-squares method described by Lewis and Hamp was time consuming and did not always converge. The error of the rate constants is mostly derived from agreement between different runs; the sensitivity of the fit to the chosen rate constants was usually somewhat better than the reproducibility.

^{31}P nmr kinetics

All ^{31}P FT nmr spectra were obtained on a Jeolco FX-90Q instrument. The reaction solution was prepared at room temperature under nitrogen by addition of trimethyl phosphite and methyl iodide to propylene carbonate in a 10 mL volumetric flask. The solution was transferred under nitrogen to a 10 mm nmr tube containing a concentric capillary tube containing $(CH_3O)_3P(O)$ (as an external reference and standard for concentration determination) in *d*-6 acetone (as an external deuterium lock). A total of 15 spectra were obtained at intervals of 2000 s between the first six and 2500 s between the remaining nine. Each spectra contains 15 pulses (interpulse delay of 5 s). The reaction was followed by observing the increase in the dimethyl methyl phosphonate(III) peak with time. The second order rate constant for reaction [1] of trimethyl phosphite was obtained by dividing the slope of the plot of $\ln[(\mathbf{III})_\infty - (\mathbf{III})_t]$ vs. time by the methyl iodide concentration which remains essentially constant.

Kinetics and mechanism of nucleophilic displacements with heterocycles as leaving groups. Part 23.[1] Studies at the borderlines between reactions proceeding (*i*) via free carbocations, (*ii*) via rate-determining formation of ion–molecule pairs, and (*iii*) via rate-determining nucleophilic attack on ion–molecule pairs

Evidence is presented to demonstrate that at the borderline between first-order reaction via nucleophilic trapping of intimate ion–molecule pairs and first-order reaction via the formation of free carbocations, both mechanisms proceed independently, without merging. Similarly at the borderline between first-order (rate-determining formation) and second-order (rate-determining nucleophilic attack) reactions of intimate ion–molecule pairs, both reactions again proceed independently.

ALAN R. KATRITZKY et BOGUMIL BRYCKI. Can. J. Chem. **64**, 1161 (1986).

On présente des données qui démontrent que, à la limite entre la réaction du premier ordre se produisant par le piégeage nucléophile de paires intimes ion–molécule et la réaction du premier ordre se produisant par le biais de la formation de carbocations libres, les deux mécanismes se produisent d'une façon indépendante, sans se confondre. De la même manière, à la limite entre les réactions du premier ordre (la formation est l'étape déterminante) et du deuxième ordre (l'attaque nucléophile est l'étape déterminante) des paires intimes ion–molécule, chacune des réactions se produit encore une fois d'une façon indépendante.

[Traduit par la revue]

Introduction

Nucleophilic displacements of the N-substituents in pyridinium cations have been shown to proceed by each of the five mechanisms of Scheme 1 (1). In solvents of low nucleophilicity solvolyses of *N*-(primary alkyl)pyridiniums occur via ion-pair intermediates formed without anchimeric assistance by synchronous rate-enhancing H^+ or R^+ migration (2). Nucleophilic displacement of *N*-(secondary alkyl)pyridiniums can occur by the classical S_N2 reaction, by rate-determining ion-pair formation, or by rate-determining ion-pair dissociation, depending on the conditions (3). In particular, no evidence was found in these systems for any "merging" of S_N1–S_N2 reaction type or for the "S_N2 intermediate" mechanism which has been advocated by Bentley and Schleyer (4). We have recently confirmed that the nature of the gegen ion, or the presence of small quantities of water, have no significant effect on the rate.[3]

Studies of tertiary alkyl halides and sulfonates have usually been interpreted to demonstrate that nucleophilic displacement occurs exclusively by unimolecular S_N1 type mechanism: with (5) or without (6) the intermediacy of ion-pairs. Although Bentley and co-workers have recently advocated nucleophilic solvent assistance in the solvolysis reactions of such *t*-alkyl substrates (7, 8) our own detailed studies of *N*-(*t*-alkyl)pyridinium salts[4] have shown solvolysis rates almost independent of solvent, and with less variation with the substrate structure than found for analogs with anionic leaving groups: specifically, no evidence was found for nucleophilic assistance by solvent.

The use of positively charged substrates and neutral leaving groups has several advantages for the study of nucleophilic substitution mechanisms (1). Unimolecular reactions of a neutral substrate involve charge creation: such reactions require media of high dielectric constant, where the role of the medium as solvent and as nucleophile is not easily disentangled. Substrates with neutral leaving groups can undergo unimolecular reactions in media of low dielectric constant. Furthermore, the reaction scheme is less complex in that the distinction (caused by strong electrostatic attraction) between a solvent-separated ion pair and a free carbocation disappears: for positively charged substrates we simply have intimate ion–molecular pairs and free carbocations.

To better understand the detailed mechanism of nucleophilic substitution at sp^3-hybridised carbon atoms, we wished to investigate four mechanistic borderlines utilizing pyridines as leaving groups (Scheme 1). These borderlines comprise: (*1*) that between first-order reactions involving ion-molecule pairs and first-order reactions proceeding via dissociation into free carbocations; (*2*) that between first-order and second-order reactions of nucleophiles with ion–molecule pairs; (*3*) that between second-order attack on ion–molecule pairs and second-order mechanism proceeding by direct displacement; (*4*) that between classical second-order displacements and second-order displacements involving previous electron transfer.

The present paper describes the results of investigations aimed at the further clarification of borderlines (*1*) and (*2*). In particular, we wished to investigate whether it was possible to explain the results at the borderlines by the simultaneous operation of the two appropriate independent reaction mechanisms, or whether "merging" occurred between them so that a reaction occurred by a single mechanism of intermediate type. In other words, do the two mechanisms remain distinct and competitive with dominance passing gradually from one to the other or does a single mechanism always operate with gradual change over?[5]

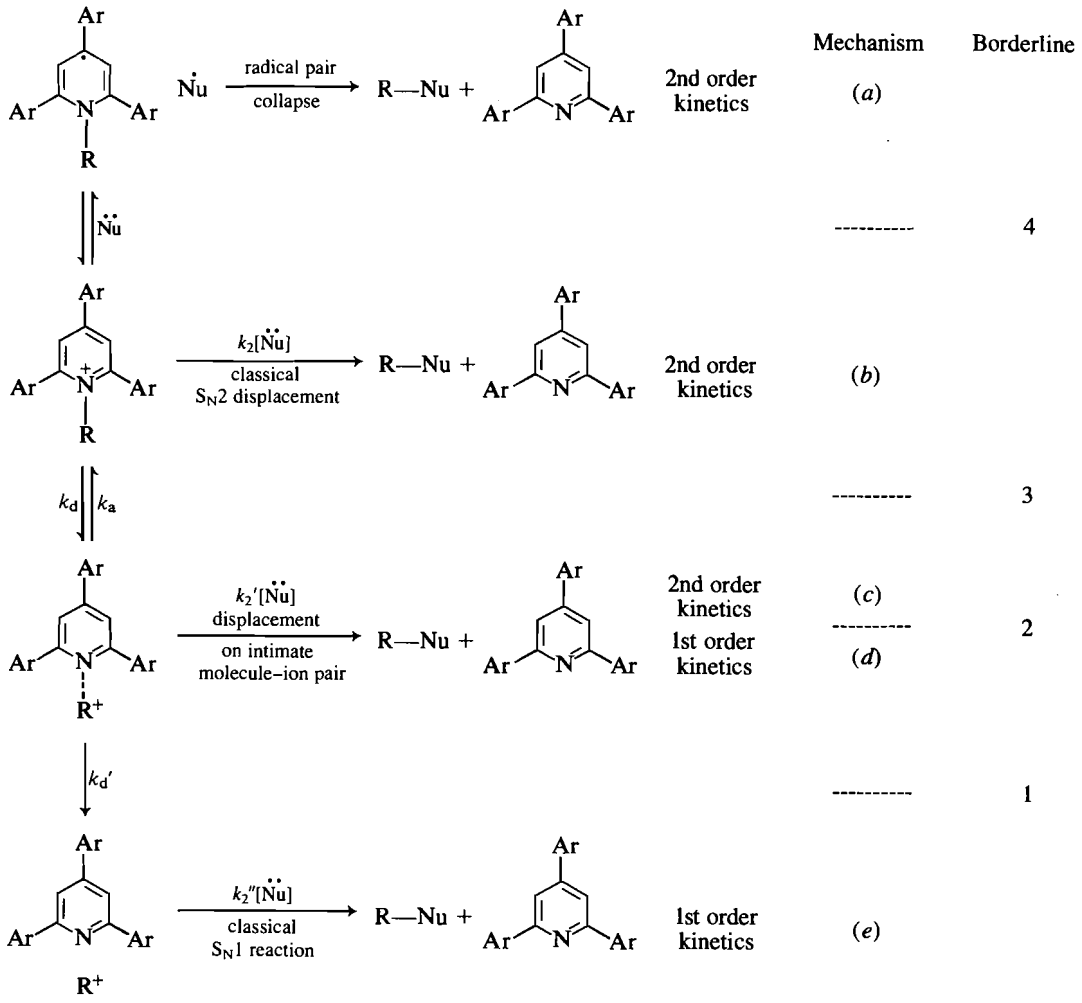

SCHEME 1. Nucleophilic substitutions with pyridine-leaving group

Borderline (*1*) between classical S_N1 and S_N1 by nucleophilic capture of an ion–molecule pair

In the region of this borderline, competition between two alternative first-order reactions occurs: (*i*) mechanism *d*; capture by solvent or nucleophile at the ion–molecule pair stage (i.e. rate-determining formation of the ion–molecule pair) and (*ii*) mechanism *e*; dissociation of the ion–molecule pair to give a free carbocation followed by further reactions with solvent or nucleophile (here the rate-determining step could be either formation of a ion–molecule pair or its dissociation to a carbocation).

Some results for solvolyses of secondary alkyl substrates indicating that reaction can occur either via free carbocations or via solvent capture of an ion–molecule pair (the first borderline region) have already been reported (3). The present experiments were based on the expectation that secondary substrates in non- or very weakly nucleophilic solvents with small amounts of strong nucleophiles (piperidine or morpholine) should give first-order kinetics (no dependence of nucleophile concentration) but undergo reaction via ion–molecule pairs, i.e. without any rearrangement of the secondary substrates. By contrast, weak nucleophiles such as 1,1,1,3,3,3-hexafluoropropan-2-ol or trifluoroacetic acid should give classical unimolecular reaction via free carbocations, and carbocation rearrangements should occur.

Solvolyses[6] of 1-(2-pentyl)-5,6-dihydro-2,4-diphenylbenzo[*h*]quinolinium trifluoromethanesulphonate (**2***c*) and 1-(3-pentyl)-5,6-dihydro-2,4-diphenylbenzo[*h*]quinolinium tetrafluoroborate (**2***e*) in chlorobenzene occur at convenient rates at 65.0°C. The kinetics of these solvolyses were followed spectrophotometrically at 345 nm. In pure, unbuffered solvent an initial decrease in absorption followed by an increase is due to acid–base equilibria (cf. footnote 4). These equilibria were suppressed *either* by carrying out the reaction in the presence of triethylamine, *or* by diluting the kinetic solutions with chlorobenzene containing trifluoroacetic acid prior to measurement of the absorbance. With this precaution, all reactions showed good pseudo-first-order behaviour. Reactions carried out in the presence of a nucleophile (piperidine, morpholine, pyridine, lutidine, anisole, *p*-chlorophenol, acetic acid, or trifluoroacetic acid) were measured under pseudo-first-order conditions: good straight lines were obtained to at least 70% completion. The observed rate constants (k_{obs}) (Tables 1 and 2) plotted against

[6]Here and elsewhere the word "solvolysis" is used to denote a reaction which is induced by the fact that a substrate is dissolved in a solvent. In a solvolysis, a solvent molecule need not be involved in the rate-determining stage. Solvolyses of some of the present and other similar substrates, in the absence of added nucleophiles has been shown to give various products of carbocation attack on solvent or product molecules (unpublished work) when elimination is not possible.

[a]Concentration of pyridinium salt 2.8×10^{-5} (mol L^{-1}); measured at 345 nm.
[b]Solvent contained triethylamine, 2.8×10^{-4} (mol L^{-1}).
[c]Kinetic solutions of pyridinium salt (1.4×10^{-4} mol L^{-1}) were diluted to uv concentration (2.8×10^{-5} mol L^{-1}) using 5% (v/v) solution of triethylamine in chlorobenzene; measured at 345 nm.

concentration of nucleophile gave straight lines (Figs. 1 and 2). The derived first order rate constants (intercepts) are given in Table 3. Weak nucleophiles such as *p*-chlorophenol, anisole, or acetic acid have negligible effects on the rate: strong nucleophiles (piperidine, morpholine) show only small rate accelerations, i.e. first-order predominates over second-order reaction. Similar results were previously obtained (3*b*) for the solvolyses of a series of 1-(s-alkyl)pyridinium cations in $CHCl_3$, CH_3CN, TFE, and $(CF_3)_2CHOH$ as solvents, and with pyridine, piperidine, or morpholine as added nucleophiles.

Product analyses were carried out by gc/ms. The solvolysis of 2-pentyl derivative **2***c*, in chlorobenzene at 65°C containing morpholine (0.1 *M*) (i.e. under conditions where over 91% of the reaction is kinetically of first-order) gave: pentene (14%) and *N*-2-pentylmorpholine (86%) (Table 7).[7] The mass spectrum of pentene shows three peaks at *m/z* 70 (M^+), 55 ($C_4H_7^+$, the base peak), and 42 ($C_3H_6^+$), the two latter correspond to $M^+ - CH_3$ and to $M^+ - CH_2{=}CH_2$, respectively (9), and clearly show the pent-2-ene structure (10). *N*-2-Pentylmorpholine shows three major peaks at *m/z* 157, 142, and 114 which correspond to molecular ion, to $M^+ - CH_3$, and to $M^+ - C_3H_7$, respectively (Table 7). In tertiary amines, loss of the largest branch from the α-C atom is preferred. Since the peak at *m/z* 114 is the base peak, the fragmentation pattern corresponds to the *N*-(2-pentyl)morpholine structure. Thus, the solvolysis of **2***c* in chlorobenzene in the presence of morpholine gave mixtures of pent-2-ene (14.4 ± 2.0%; elimination product) and *N*-2-pentylmorpholine (85.6 ± 2.0%; nonrearrangement product): specifically no *N*-3-pentylmorpholine could be detected. Similarly, solvolysis of **2***c* in the presence of acetic acid (1 *M*) gave only 2-pentyl acetate, the fragmentation pattern of which exhibited a characteristic fragment ion at *m/z* 87 corresponding to $M^+ - 43$. No peak at *m/z* 101 for 3-pentyl acetate (rearranged product) was found.

Gas chromatography/mass spectral analysis of the products from solvolyses of the 2-pentyl derivative **2***c* in chlorobenzene in the presence of *p*-chlorophenol gave pent-2-ene (72.7%) and *p*-chlorophenyl-2-pentyl ether (27.3%) which showed five significant peaks (Table 9). The structure of the ether is supported by the base peak at *m/z* 128 and the peak at *m/z* 111 corresponding respectively to cleavage β and α to the ring, with hydrogen migration. β-Cleavage of aromatic ethers is dominant; therefore the peak at *m/z* 128 is the base peak. The peaks at *m/z* 155 ($M^+ - 43$) and *m/z* 43 ($C_3H_7^+$) prove the 2-pentyl structure. Solvolysis of 2-pentyl derivative **2***c* in chlorobenzene in the presence of anisole gave only pent-2-ene.

The fact that the rate constants, and specifically the inter-

[7]Tables 7 to 9 have been deposited. Complete set of material may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

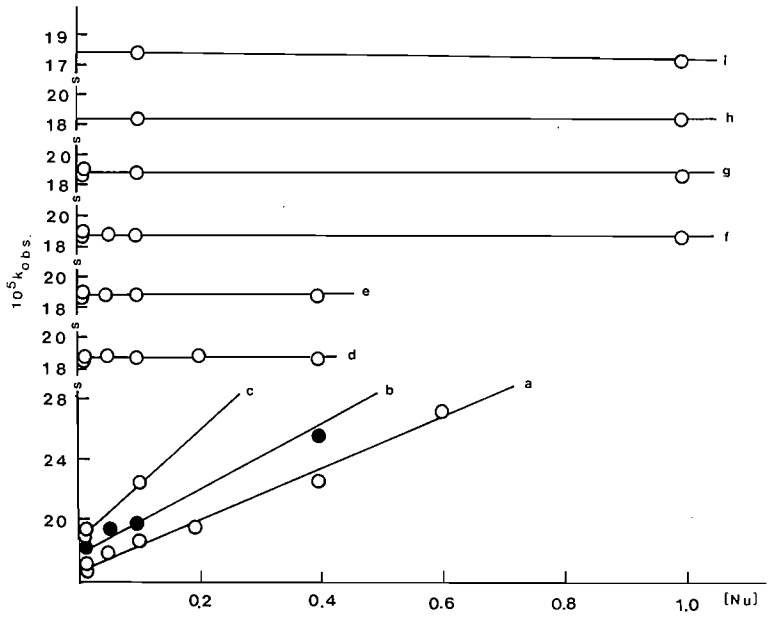

FIG. 1. Plots of observed rate constants for the solvolyses of 1-(2-pentyl)-5,6-dihydro-2,4-diphenylbenzo[*h*]quinolinium trifluoromethanesulphonate **2***c* in chlorobenzene at 65.0°C vs. nucleophilic concentration; *a*, morpholine; *b*, isopropylamine; *c*, piperidine; *d*, pyridine; *e*, 2,6-lutidine; *f*, *p*-chlorophenol; *g*, anisole; *h*, acetic acid; *i*, trifluoroacetic acid.

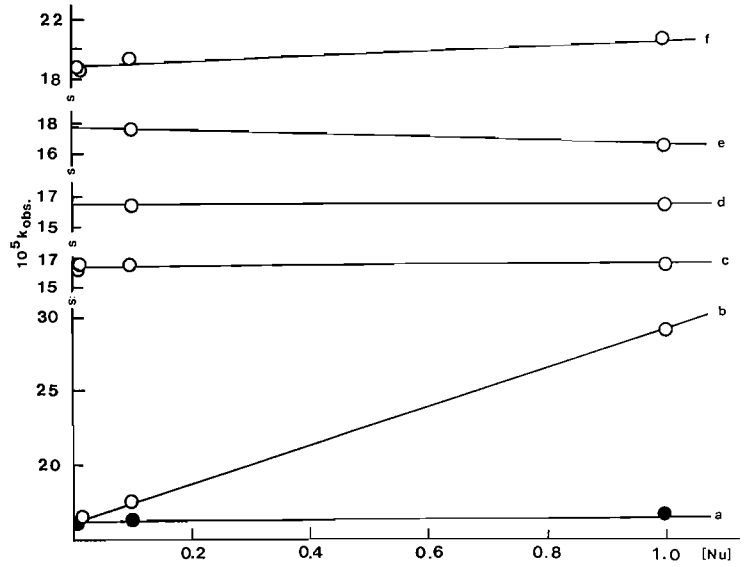

FIG. 2. Plots of observed rate constants for the solvolyses of 1-(3-pentyl)-5,6-dihydro-2,4-diphenylbenzo[*h*]quinolinium tetrafluoroborate **2***e* in chlorobenzene at 65.0°C vs. nucleophilic concentration; *a*, 2,6-lutidine; *b*, morpholine; *c*, pyridine; *d*, acetic acid; *e*, trifluoroacetic acid; *f*, anisole.

cepts, for the reaction of the 2-pentyl derivative **2***c* in chlorobenzene containing morpholine, *p*-chlorophenol, and anisole are so similar, whereas the proportion of elimination varies from 14–100%, confirms that the rate-determining step occurs before elimination.

Solvolysis of 3-pentyl derivative **2***e* in chlorobenzene containing morpholine (0.1 *M*) gave 2-pentene (88%) (identified as above) and *N*-3-pentylmorpholine (12%) (Table 8) for which the only two peaks above *m/z* 100 at *m/z* 157 (1.67%) and *m/z* 128 (100%) correspond to M^+ and to $M^+ - C_2H_5$, respectively, and prove the structure. No *N*-2-pentylmorpholine was detected. Likewise solvolysis of **3***a* in chlorobenzene containing acetic acid gave only the 3-pentyl acetate which showed a fragment ion at *m/z* 101 which corresponds to $M^+ - 29$, and no peak at *m/z* 87 (for rearranged 2-pentyl acetate) was detected.

The kinetic results discussed above show that there is no large rate acceleration in the reactions of **2***c* and **2***e* when 0.1 *M* morpholine or 1 *M* acetic acid is added to chlorobenzene. However, morpholine or acetic acid is able to intercept the incipient 2- or 3-pentyl carbocations before rearrangement to give only the 2-pentyl or only the 3-pentyl products, respectively, which strongly suggests that the solvolyses of **2***c* and **2***e* occur through intimate ion–molecule pairs. This supports the conclusions drawn from our earlier work with 1,1,1,3,3,3-hexafluoropropan-2-ol (3): solvolyses of **2***c* and **2***e* in this solvent gave identical mixtures of rearranged and non-rearranged ether

products, evidently by a carbocation mechanism; however, solvolysis of **2***c* and **2***e* in 1,1,1,3,3,3-hexafluoropropan-2-ol in the presence of morpholine as nucleophile, gave the non-rearranged *N*-(2-pentyl)- and *N*-(3-pentyl)-morpholine products, respectively, just as we have now observed (3*b*).

We showed previously (3*b*) that both the 2-pentyl and the 3-pentyl substrates underwent solvolysis in trifluoroacetic acid to give the same mixture of 2-pentyl and 3-pentyl trifluoroacetates. We have now carried out solvolysis of **2***c* and **2***e* in chlorobenzene in the presence of trifluoroacetic acid (1 *M*): in further confirmation of our previous work, in each case a mixture of *both* the 2-pentyl and 3-pentyl trifluoroacetates was obtained. Although the trifluoroacetates were not separable under gc condition used,[8] the fragmentation pattern of the isomeric mixture obtained from the solvolysis of the 2-pentyl derivative **2***c* on gc/ms analysis exhibited characteristic fragment ions for both *m/z* 155 and 141, which correspond to the rearranged product (3-pentyl trifluoroacetate *m/z* 155, i.e. $M^+ - 29$) and the non-rearranged product (2-pentyl trifluoroacetate *m/z* 141, i.e. $M^+ - 43$, respectively). The same fragmentation pattern was obtained on analysis of the mixture obtained from the 3-pentyl derivative.

Borderline (*2*): reactions by rate-determining formation of an ion–molecule pair and by rate-determining attack by nucleophile

In this region, reactions proceed by capture of an ion–molecule pair by the solvent or added nucleophile, and competition occurs between two different mechanisms: (*i*) mechanism *d* or *e*; rate-determining formation of the ion–molecule pair, or of the free carbocation, i.e. unimolecular reaction mode and (*ii*) mechanism *b* or *c*; rate-determining nucleophilic attack, i.e. bimolecular reaction mode. Here, we have studied the behaviour of the *N*-benzylpentacyclic pyridinium cation in chlorobenzene containing small amounts of nucleophiles, i.e. under conditions where both mechanisms should be of comparable importance.

Solvolyses of 1-benzyl-5,6,8,9-tetrahydro-7-phenyldibenzo[*c*,*h*]acridinium trifluoromethanesulphonate (**3***b*) and 1-(*p*-methoxybenzyl)-2,4,6-triphenylpyridinium tetrafluoroborate **1***b* in chlorobenzene occur at convenient rates at 65.0°C and were followed spectrophotometrically at 399 and 312 nm, respectively. In pure solvent an initial decrease in absorption is followed by an increase due to acid–base equilibria; this was avoided by the addition of small amounts of NEt_3 (see experimental section). Reactions carried out in the presence of morpholine, pyridine, lutidine, isopropylamine, and anisole, measured under pseudo-first-order conditions, gave good straight lines to at least 62% completion. The observed rate constants (k_{obs}) (Tables 4 and 5) for these reactions plotted against concentration of nucleophile gave straight lines (Fig. 3). The first order rate constants (intercepts) are given in Table 6.

[8]Conditions: 3% SP 2100 on 100/120 Supelcoport, flow rate 30 mL/min, helium carrier gas, 40–200 deg at 10 deg/min.

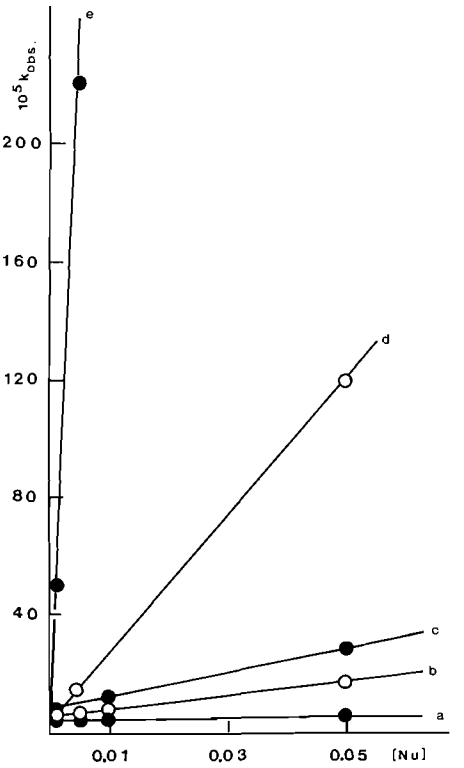

FIG. 3. Plots of observed rate constants for the solvolyses of 1-benzyl-5,6,8,8-tetrahydro-7-phenyldibenzo[*c*,*h*]acridiniumtrifluoromethanesulphonate **3***b* in chlorobenzene vs. nucleophilic concentration; *a*, 2,6-lutidine (60°C); *b*, pyridine (60°C); *c*, pyridine (65.0°C); *d*, isopropylamine (60°C); *e*, morpholine.

The *N*-benzylpentacyclic derivative **3***b* reacts with morpholine almost exclusively via a bimolecular route (Table 6). Dramatically different is the reaction of **3***b* with lutidine; for this much less powerful nucleophile the second-order component is insignificant and the substrate undergoes solvolysis almost entirely via a unimolecular route. For solvolysis in the presence of pyridine, the percentage reaction by the unimolecular route is found to be 15% at 65.0°C and 13% at 60.0°C for 0.1 *M* nucleophile. It has been demonstrated that *N*-benzylpentacyclic derivative **3***b* reacts with piperidine predominantly through the second-order reaction of the intimate ion–molecule pair with the nucleophile at normal and fairly low pressures, but that at higher pressures reaction by the classical S_N2 process takes over (11). We therefore believe that at normal pressures the dominant second-order reaction of **3***b* with morpholine is also via the intimate ion–molecule pair. The first-order rates at 65°C for the *N*-benzylpentacyclic derivative **3***b* do not change appreciably on changing the nucleophile: morpholine $6.38 \times 10^{-2}\ s^{-1}$, pyridine $7.33 \times 10^{-5}\ s^{-1}$. Similarly, first-order rates for **3***b* at 60°C are likewise constant: pyridine $4.01 \times 10^{-5}\ s^{-1}$, lutidine $4.03 \times 10^{-5}\ s^{-1}$, isopropylamine $3.53 \times 10^{-5}\ s^{-1}$. The solvolysis rate of **3***b* in the absence of nucleophile is $(3.98 \pm 0.09) \times 10^{-5}\ s^{-1}$ at 60.0°C. We interpret this invariance as evidence that there is no merging of the unimolecular (S_N1 type) and bimolecular (S_N2 type) mechanisms; rather two mechanisms can and do proceed independently. If the bimolecular mode is the reaction of nucleophile with the ion–molecular

TABLE 6. First-order (k_1) and second-order (k_2) rate constants for the reactions of 1-substituted pyridinium salts with nucleophiles in chlorobenzene

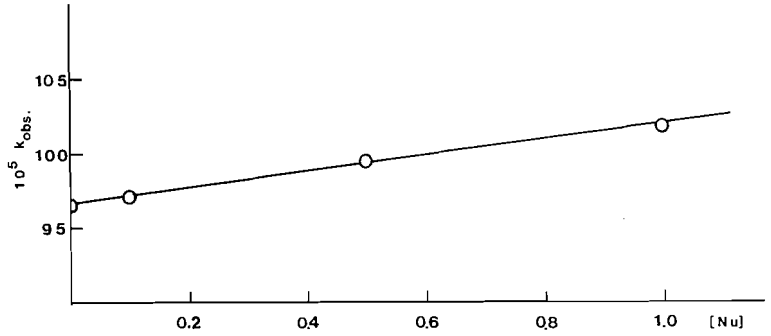

FIG. 4. Plot of observed rate constants for the solvolyses of 1-(*p*-methoxybenzyl)-2,4,6-triphenylpyridinium tetrafluoroborate **1***b* in chlorobenzene at 65.0°C vs. anisole concentration.

pair (mechanism *c*), then the unimolecular modes must in this case be the dissociation of the ion-molecular pair to the free carbocation (mechanism *e*).

Solvolysis of 1-(*p*-methoxybenzyl)-2,4,6-triphenylpyridinium tetrafluoroborate **1***b* was carried out at 65.0°C in chlorobenzene with anisole as nucleophile. As can be seen from Table 6 nucleophilic displacement in this case occurs almost exclusively by an unimolecular S_N1 type mechanism. There is no large rate acceleration when some anisole is added to chlorobenzene solvent. The calculated first-order component (k_1) is the same as that observed for the reaction without the nucleophile.

Conclusions

From Scheme 1, rates for mechanisms (*c*) and (*d*) are proportional to $k'_2[Nu]k_d/(k'_2[Nu] + k_a)$. For mechanism (*c*), $k_a \gg k'_2[Nu]$ and thus the rate is proportional to $k'_2[Nu]k_a/k_d$. For mechanism (*d*), $k'_2[Nu] \gg k_a$ and thus the rate is proportional to k_d. For mechanism (*e*), k''_2 is fast and the rate is proportional to $k_d k'_d/(k_a + k'_d)$. The results presented in this paper are entirely consistent with this scheme and with the operation of two distinct mechanisms at the appropriate borderlines.

Experimental

Ultraviolet spectra of reactants and products were measured on Pye Unicam PU 8800 and Pye Unicam SP6-550 uv–visible spectrophotometers. ^1H nmr spectra were obtained with a Varian Model EM 3604 spectrometer (Me_4Si as internal standard). Infrared spectra were recorded with a Perkin-Elmer Model 283 B spectrophotometer. Melting points (mp) were determined with a Reichart hot stage microscope.

Gas chromatography/mass spectra analysis utilized an AEI MS-30 mass spectrometer (using a Kratos DS-55 data system) interfaced to a Pye 104 gas chromatograph. The column packings employed were 3% SP2100 on 100/120 Supelcoport, 10% Carbowax — 20M/2%KOH (5 or 6 ft × 4 mm) in glass columns, 30 mL/min helium as the carrier gas at flow rates and temperatures specified (Tables 7, 8, 9).

Preparation of compounds

The following were prepared by the literature method quoted: 2,4,6-triphenylpyrylium tetrafluoroborate **1***a*, mp 257°C (lit. (12): 251–257°C); 5,6-dihydro-2,4-diphenylnaphtho[1,2-*b*]pyrylium trifluoromethanesulphonate **2***a*, mp 276°C (lit. (13): 276°C); 5,6-dihydro-2,4-diphenylnaphtho[1,2-*b*]pyrylium tetrafluoroborate **2***b*, mp 268–271°C (lit. (14): 270°C); 5,6,8,9-tetrahydro-7-phenyldibenzo[*c*,*h*]xanthylium trifluoromethanesulphonate **3***a*, mp 304 (lit. (15): 304°C).

General procedure for preparation of pyridinium salts (Scheme 2)

Equimolar quantities of the pyrylium salt, the amine and triethylamine were stirred in dichloromethane (5 mL/g of pyrylium salt) for 2 h. Glacial acetic acid (double molar quantity) was added and the mixture stirred for 24 h. After washing the solution with water, precipitation with ethyl ether gave the products: 1-(*p*-methoxybenzyl)-2,4,6-triphenylpyridinium tetrafluoroborate **1***b*, mp 138–139°C; 1-(2-pentyl)-5,6-dihydro-2,4-diphenylbenzo[*h*]quinolinium trifluoromethanesulphonate **2***c*, mp 141–144°C; 1-(3-pentyl)-5,6-dihydro-2,4-diphenylbenzo[*h*]quinolinium tetrafluoroborate **2***e*, mp 153–154°C (lit. (3*a*): 147–150°C); 1-benzyl-5,6,8,9-tetrahydro-7-phenyldibenzo[*c*,*h*]acridinium trifluoromethanesulphonate **3***b*, mp 170–171°C (lit. (16): 170–171°C).

Kinetic measurements

Kinetics were followed by uv spectrophotometry by monitoring the decrease or the increase of absorbance of the pyridinium salts at fixed wavelengths using the procedure already described (17). Ultraviolet

SCHEME 2. Pyrylium and pyridinium salts

cells and sealed glass tubes of 28 cm × 14 mm diameter were used as reaction vessels. Ultraviolet cells were controlled to ±0.5°C in a cell basket inside the uv spectrophotometer by the Pye Unicam Cell Temperature Controller. Glass tubes were controlled to ±1°C in hot blocks (Statim Model 252). For kinetic runs in which the solvent did not contain a basic nucleophile, either small amounts of Et_3N (1×10^{-3} mol L^{-1}) were added, or the kinetic solutions of the pyridinium compounds were diluted to uv concentration (1.4×10^{-5} mol L^{-1}) using an 8% solution of trifluoroacetic acid in chlorobenzene before uv measurement. For solvolyses in the presence of acetic acid and trifluoroacetic acid as nucleophiles, the kinetic solutions of the pyridiniums (1.4×10^{-4} mol L^{-1}) were diluted to uv concentration (2.8×10^{-5} m L^{-1}) using 5% (v/v) solution of triethylamine in chlorobenzene before uv measurement. These procedures converted acid–base equilibrium mixtures into free base or protonated pyridine, respectively (see footnotes to Tables). Pseudo-first-order rate constants were calculated from the slopes of conventional plots of ln $(\epsilon - \epsilon_2)/(\epsilon - \epsilon_2)$ vs. time (18). Such plots were linear to at least 70% completion, and k_{obs} values were reproducible to ca. 2%.

Solvolysis procedure for gc/ms study

The pyridinium salt in 1.0 mL of solvent was heated with the nucleophile in a sealed glass tube at 65°C for 24 h. The tube was opened immediately before the gc/ms study.

The hydrolysis of $(\pi\text{-}C_6H_6)Cr(\pi\text{-}C_6F_5CO_2C_2H_5)$: an unexpected decarboxylation

MICHAEL J. MCGLINCHEY AND HAO NGUYEN
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received November 5, 1985

This paper is dedicated to Professor Arthur N. Bourns

MICHAEL J. MCGLINCHEY and HAO NGUYEN. Can. J. Chem. **64**, 1170 (1986).

The attempted basic hydrolysis of the ester sandwich compound $(C_6H_6)Cr(C_6F_5CO_2Et)$ did not yield the expected carboxylic acid but instead produced $(C_6H_6)Cr(C_6F_5H)$ in good yield together with traces of $(C_6H_6)Cr(C_6HF_4OMe)$. Attempts to trap a benzyne intermediate were unsuccessful and the mechanism of decarboxylation is discussed in terms of internal chelation at the chromium centre.

MICHAEL J. MCGLINCHEY et HAO NGUYEN. Can. J. Chem. **64**, 1170 (1986).

On a tenté une hydrolysé en milieu basique de composé ester sandwinch $(C_6H_6)Cr(C_6F_5CO_2Et)$; toutefois, au lieu d'obtenir l'acide carboxylique attendu, il y a eu formation du $(C_6H_6)Cr(C_6F_5H)$, avec un bon rendement, ainsi que des traces du $(C_6H_6)Cr(C_6HF_4OMe)$. On a tenté sans succès de piéger l'intermédiaire benzynique et on discute du mécanisme de décarboxylation en fonction d'une chélation interne au niveau du chrome central.

Introduction

While the ferrocenyl moiety has now become a standard organic functional group (1) and the $(C_5H_5)Fe$ fragment has been exploited for synthetic purposes (2, 3), the chemistry of the analogous bis(arene)chromium complexes (chromarenes) (4) is much less understood. Initially, the problems were synthetic in that the Friedel–Crafts route (5) to $(C_6H_6)_2Cr$ — viz., $CrCl_3/C_6H_6/AlCl_3/Al$ — would not tolerate functional groups on the arene. Thus, arenes such as chlorobenzene or anisole, which possess non-bonding electron pairs, react with the Lewis acid catalyst ($AlCl_3$) and undergo side reactions which do not yield the desired sandwich compounds (6). This problem has been largely circumvented by the metal atom vapour technique (7–10) whereby the gaseous metal and the ligand vapour are cocondensed onto a cold (77 K) surface and direct combination occurs to give the required products. By this means, a wide variety of organic functional groups can be incorporated into the chromarene system (11).

A further development was the discovery that in the mixed sandwich compound 1,2,3,4,5-pentafluorochromarene, **1**, the unique hydrogen was readily removable using an alkyl lithium (12) and the corresponding anion **2** reacted with a variety of electrophiles (4). In particular, one can produce the ester **3** in high yields (13). It therefore seemed not unreasonable that one could hydrolyze the ester to the corresponding carboxylic acid **4**; subsequent measurement of the pK_a of **4** and also of $C_6F_5CO_2H$ should allow a direct evaluation of the electronic effect of the $(C_6H_6)Cr$ moiety on another arene ring.

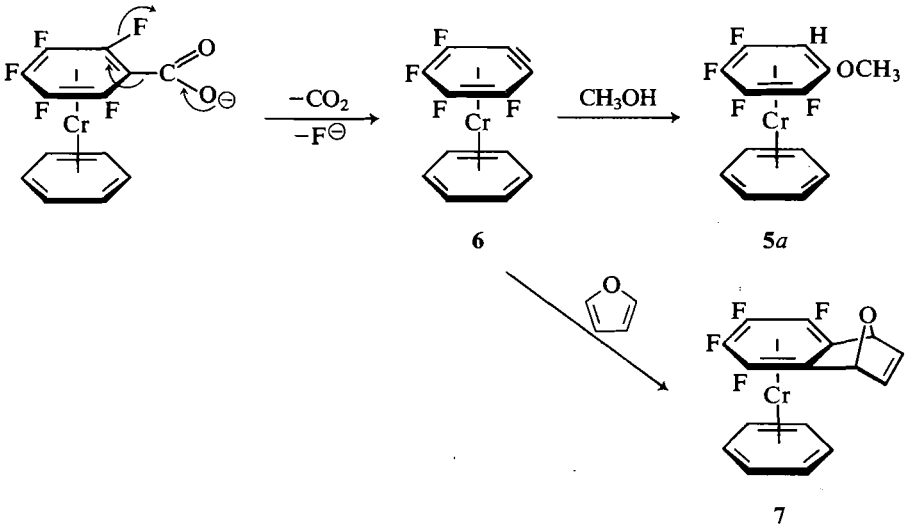
Results and discussion

The electronic effect of an organometallic fragment on an organic molecule was probably first studied by Nicholls and Whiting (14) who noted that the pK_a of $(C_6H_5CO_2H)Cr(CO)_3$ was similar to that of *para*-nitrobenzoic acid. He proposed that the tricarbonylchromium moiety was strongly electron-withdrawing and should hence facilitate nucleophilic attack on aromatic rings. This perceptive prediction has since been amply verified and much elegant chemistry has resulted (15). Owing to the non-availability of chromarenyl carboxylic acids, such an approach has not been possible and so more indirect probes have been used. Typically, a comparison of the ν_{CO} values for $C_6F_5M(CO)_x$ and the corresponding chromarenes $(C_6H_6)Cr(C_6F_5M(CO)_x)$ indicated that the $(C_6H_6)Cr$ moiety was a net donor of electron density to the fluorinated ring (4).

For these reasons, we attempted a standard basic hydrolysis of **3** using methanolic KOH. To our surprise, the product after neutralization and extraction was not the anticipated acid but rather pentafluorochromarene, **1**, with traces of a methoxytetrafluorochromarene, **5**, which was identified mass spectroscopically.

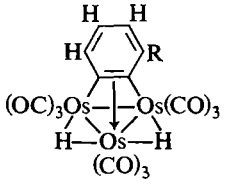
Our initial thoughts focussed on the possibility of a benzyne intermediate, **6**, produced via decarboxylation and elimination of fluoride ion. Subsequent attack by methanol should then yield the ortho isomer **5***a*, as in Scheme 1. Indeed, it is well established that pentafluorophenyl lithium is an excellent precursor for tetrafluorobenzyne (16) which undergoes Diels–Alder reactions with thiophene and benzene (17, 18). However, in our hands, repeated attempts to trap **6** as its furan adduct **7** were unsuccessful and we are not of the opinion that a benzyne intermediate is formed. We note that other attempts to detect π-complexed arynes have not been successful (19–21) except where the aryne binds to a metal triangle as in **8** (22). In these latter molecules the ligand functions as a cycloalkyne rather than as an aryne. Recently, however, it has been shown that a benzyne–zirconocene adduct has a transient existence (23) and can be used in synthesis (24).

Eventually, after numerous reactions, the available quantities of **5** were such as to allow the measurement of its ^{19}F nmr spectrum which showed only two fluorine environments. We thus assign **5** as the *para* isomer since the other possibilities would exhibit four fluorine resonances. As we have noted previously (25–27), the fluorine chemical shifts of π-complexed fluoroarenes are very markedly shielded relative to those of the free arenes themselves. It seems most likely that **5** arises via a nucleophilic attack on the complexed fluoroarene and is probably unrelated to the mechanism of decarboxylation. As



SCHEME 1

with their non-complexed analogues (28), nucleophilic attack to displace fluoride from pentafluorochromarenes occurs predominantly at the *para* position (29).



8

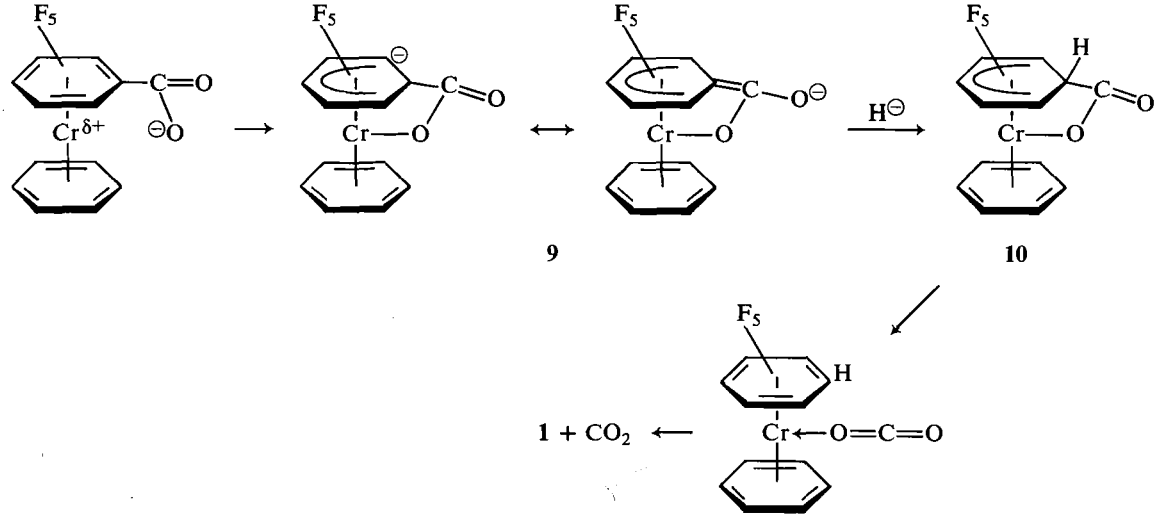
Finally, one might speculate as to the reason for the unexpectedly facile decarboxylation during ester hydrolysis. Clearly, since this process is not observed with the free arene, the metal must be implicated either directly or indirectly in the elimination of carbon dioxide. We note that decarboxylation processes are sometimes catalyzed by the presence of transition metal ions, such as Cu^+ or Mn^{2+}, and chelate formation is almost invariably invoked (30). In fluorochromarene sandwiches, such as those discussed here, the chromium is generally considered to be rather more positive than its formal zero oxidation state would indicate. Thus, the relative difficulty of oxidizing the chromium (31), the decreased infrared frequency of the ring-breathing mode of the fluorinated ring (32), as well as ESCA data (unpublished data from this laboratory), all indicate that there is a net transfer of electron density into the fluorinated ring and that the chromium atom bears a partial positive charge. It is then reasonable to visualize chelation by the carboxylate oxygen, thus placing a formal negative charge on the fluorinated ring as in **9**. Subsequent protonation and elimination of CO_2 from the cyclohexadienyl complex **10** would lead directly to the observed product. A tentative mechanism is presented in Scheme 2.

To conclude, complexation of $C_6F_5CO_2Et$ to a π-$(C_6H_6)Cr$ moiety reduces its susceptibility towards nucleophilic displacement of fluoride. However, upon hydrolysis to the corresponding carboxylate, loss of CO_2 is greatly facilitated. There is no evidence in favour of a π-complexed benzyne intermediate.

Experimental section

All reactions were carried out under an atomosphere of nitrogen. Mass spectra were obtained using a VG-7070F mass spectrometer fitted with a VG 2035 data system. ^{19}F nmr spectra were obtained on a Bruker WH90 spectrometer operating at 84.66 MHz using $CFCl_3$ as an external reference.

Using the metal atom vapour apparatus previously described (25), pentafluorobenzene, benzene and chromium vapour were cocondensed at −196°C to yield **1** which was purified by repeated sublimations.



SCHEME 2

As described elsewhere (4), treatment of **1** with *tert*-butyl lithium at −78°C and subsequently with an excess of ethyl chloroformate yielded ethyl pentafluorochromarenoate, **3**. Attempted hydrolysis of **3** (500 mg, 1.35 mmol) with a six-fold excess of KOH in methanol gave a slightly greenish coloured solution. After neutralisation with HCl, filtration and ether extraction, the products were chromatographed on alumina and eluted with benzene to give **1** (221 mg, 0.76 mmol; 55%), identical in all respects with an authentic sample, and traces of a yellow compound **5** showing mass spectral peaks at m/z 310, $C_{13}H_{10}F_4OCr^+$; 279, $C_{12}H_7F_4Cr^+$; 261, $C_{12}H_8F_3Cr^+$; 242, $C_{12}H_8F_2Cr^+$; 180, $C_7H_4F_4O^+$; 149, $C_6HF_4^+$; 131, $C_6H_2F_3^+$; 130, $C_6H_6Cr^+$; 78, $C_6H_6^+$; 52, Cr^+. The accumulated samples of **5** from six experiments gave multiplets in the ^{19}F nmr spectrum at −173 and −178 ppm (i.e., to high field of $CFCl_3$).

When the hydrolysis was repeated in a ten-fold excess of furan, the same products were obtained and no evidence for the production of **7** could be obtained.

This paper is dedicated to Professor Arthur N. Bourns

BO ANHEDE, NILS-ÅKE BERGMAN, and A. JERRY KRESGE. Can. J. Chem. **64**, 1173 (1986).

Proton exchange between β-fluorinated ethanols and ethoxide ions has been studied using the MNDO SCF-MO method. Calculations were performed on reactions of ethoxide ion with ethanols substituted in the β-position with 0, 1, 2, and 3 fluorine atoms as well as on reactions where both the ethanol and the ethoxide ion were substituted with the same number (1, 2, 3) of fluorine atoms in the β-position. The energies obtained for the ion–molecule reactant complexes and the transition states from these reactions have been analyzed using the Marcus equation. Through the calculated force-constant matrices of reactants and transition states we also calculated the kinetic isotope effects for the proton-transfer reactions. The semiclassical isotopic rate constant ratios $(k_H/k_D)_s$ were found to be of rather normal magnitude and showed a variation with the energy of reaction. The calculated ratios of tunnel correction factors, Q_{tH}/Q_{tD}, proved to be unrealistically high. These factors were also calculated with the frequencies scaled down by 10% and this was found to reduce the Q_{tH}/Q_{tD} ratios to more realistic values.

BO ANHEDE, NILS-ÅKE BERGMAN et A. JERRY KRESGE. Can. J. Chem. **64**, 1173 (1986).

Utilisant la méthode MNDO d'orbitales moléculaires en champ auto-cohérent, on a étudié l'échange protonique entre des éthanols β-fluorés et des ions éthylates. On a effectué des calculs sur les réactions de l'ion éthylate avec des éthanols substitués par 0, 1, 2 et 3 atomes de fluor en position β ainsi que sur les réactions dans lesquelles tant l'éthanol que l'éthylate étaient substitués par le même nombre (1, 2 ou 3) d'atomes de fluor en positions β. Faisant appel à l'équation de Marcus, on a analysé les énergies obtenues pour les complexes ion–molécule qui réagit ainsi que pour les états de transition de ces réactions. À l'aide des matrices des constantes de force calculées pour les réactifs et pour les états de transition, on a aussi calculé les effets isotopiques cinétiques pour les réactions de transfert de protons. On a trouvé que les rapports (k_H/k_D) des constantes de vitesse isotopiques semi-classiques sont d'une amplitude assez normale et on a trouvé qu'elles varient avec l'énergie de la réaction. Il appert que les rapports calculés pour les facteurs de correction pour l'effet tunnel, Q_{tH}/Q_{tD}, sont trop élevés et non réalistes. On a aussi calculé ces facteurs en se basant sur les fréquences réduites par 10% et on a ainsi trouvé que les valeurs des rapports Q_{tH}/Q_{tD} sont beaucoup plus réalistes.

[Traduit par la revue]

Proton-transfer reactions have been extensively studied from an experimental point of view (1). In such investigations isotope effects and linear free-energy relationships have often been employed. These methods have generated parameters that the investigators have interpreted in terms of the transition-state theory. This approach has proved successful in gaining knowledge usable in predicting the behaviour of many reactions. However, in order to use the transition-state theory one has to make assumptions regarding the reaction step studied, not always easily done in an unambiguous way.

Modern quantum-mechanical methods and powerful computers have made it possible to calculate the stationary points on the potential-energy surface for simple reactions, and thus calculated quantities, e.g., isotope effects, can be compared with experimental data. Even though other assumptions are introduced by the quantum-mechanical methods the two approaches may complement each other. A successful application of this to proton-transfer reactions would contribute to our understanding of such reactions.

In an earlier study we investigated the proton transfers between some carbon acids (CH_3CN and HCCH) and bases (OH^-, CH_3O^-, and CH_2CN^-), utilizing MNDO computations (2). We have now extended our tests of this method and have investigated a series of proton-transfer systems where the immediate vicinity of the reaction centre is unchanged while a perturbation is introduced at some distance from the proton to be transferred. Our choice of system fell on ethanols fluorinated in the β position with 0, 1, 2, and 3 fluorine atoms. This series shows an increasing gas-phase acidity, according to ion cyclotron resonance spectroscopy (3). We employed ethoxide as the base in our simulation of proton abstraction from these substances. In order to have the symmetrical reaction parameters available we also made calculations on the proton transfers with β-fluorinated ethoxides as bases.

Method

The calculations were performed according to the semiempirical scheme devised by Dewar and Thiel (4). During the present investigation different versions of the MNDO computer program have been used. In the first preliminary computations we used the MNDO program by Thiel (5), installed on an IBM 3030 N computer at the Gothenburg University Computing Centre. This program was later transferred and adapted to the VAX 11/730 computer at the Department of Organic Chemistry, University of Gothenburg and Chalmers University of Technology. Later the VAX version of the program package, MOPAC (6), was acquired and used for most of the calculations.

Computational aspects

The energy of each stable species was computed separately with optimization of all geometric parameters (bond lengths, bond angles, and dihedral angles). The species considered as reactants and products on our energy profiles were the stable ion–molecule complexes found by complete optimization of an alcohol molecule and alkoxide ion. See for example, Fig. 1.

The transition states were located as described earlier (2). The

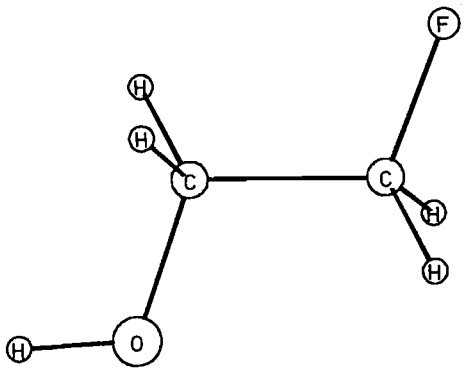

FIG. 3. Optimized geometry for 2-fluoroethanol when the calculation was started from a *trans* geometry with O—H pointing away from C—C.

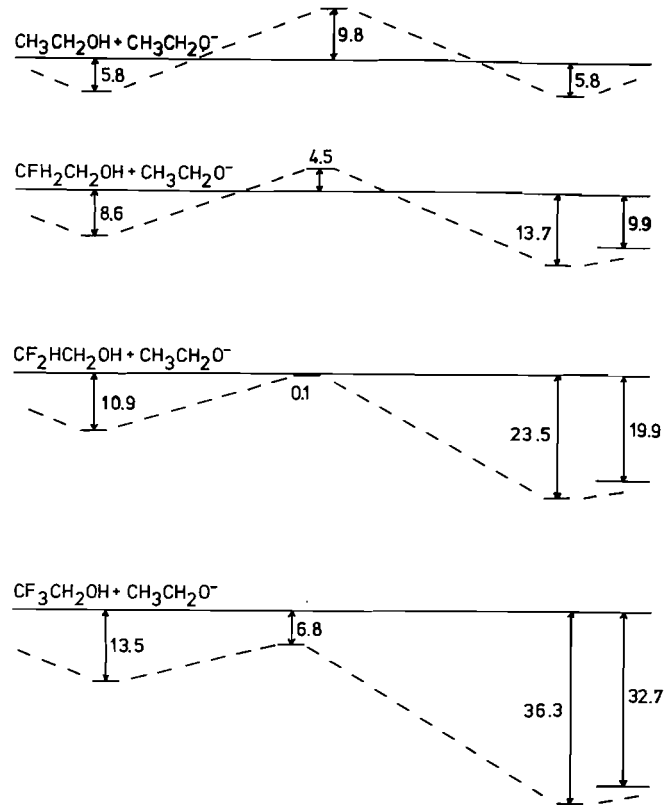

FIG. 4. Energy profiles for some proton-transfer reactions calculated by the MNDO method. Energies in kcal/mol.

semiclassical isotopic rate constant ratios were calculated according to ref. 7*a* using frequencies taken from a FORCE calculation within MOPAC. The tunnel correction factors were calculated from the Bell formula (7*b*). The summation was carried out until Q_t changed by less than 10^{-6} when adding a new term.

Conformational aspects

A number of investigations (microwave, ir, and *ab initio* calculations) (8) have revealed the most stable conformers of the 2-fluoroalcohols to be the *gauche* (G'g), with an intramolecular hydrogen bond between the alcohol hydrogen and a fluorine atom (Fig. 2).

If we started our calculations with a *gauche*-type geometry, the MNDO optimization facility ended up with a minimum-energy geometry for a *gauche* conformer. However, if the starting geometry was given as a conformer close to one with the O—H bond pointing away from the atoms on carbon 2, the optimization resulted in a geometry that retained this feature (Fig. 3). This latter conformer showed a little higher energy (ca. 0.6 kcal/mol) than the one obtained in the preceding procedure.
