Conformational energies were computed relative to the energy of the α-helix structures considered as the global minima. The α-helix conformational energies were obtained by the procedure described above, keeping an α-helix backbone constant and varying the side-chain orientations. The conformational energies of 200 randomly generated orientations of the side chains were energy-minimized.

The calculations were done on CRAY X-MP (The Ontario Center for Large Scale Computation, Toronto, Ont.) and on an IBM 4381, VM/CMS operating system (Computing Center, Université de Sherbrooke, Québec). The SYBYL molecular modeling system was used for the display, plotting, and fitting of the molecular structures (28). Dihedral angles are given according to the IUPAC–IUB Commission on Biochemical Nomenclature (29).

Results

Table 2 presents the values of the conformational energies[3] obtained for the 20 most stable conformers. The corresponding conformations have been coded in accordance with the conventional letter-coded partition of the [ϕ, ψ] maps (30).

The differences observed between the three peptides reflect the influence of the substitution of residue 6(7) on the global conformations: for each peptide, the same 1000 random conformers were used as starting points, and the minimization processes converged in different ways for each peptide, depending on the nature of residue 6(7), to reach the conformers given in Table 2.

It is worth noting that relatively high energy values of 5.32, 6.16, and 6.86 kcal/mol correspond to the 20 most stable conformers. This observation reflects highly restricted conformations. Many substructures are common to the three sequences, like DCC* for SP(5–11) no. 5, no. 10, EL(7–11) no. 12, NK(6–10) no. 13, no. 17; AAA observed for SP(7–11) no. 1, no. 2, EL(7–11) no. 1, no. 8, NK(6–10) no. 1, no. 5, no. 7; EAA for SP(7–11) no. 3, EL(7–11) no. 19, NK(6–10) no. 14; AEC*A for SP(7–11) no. 13, EL(7–11) no. 6 and NK(6–10) no. 8. The last three residues of SP(7–11) no. 20, EL(7–11) no. 4 (Fig. 1a), and NK(6–10) no. 18 adopt the C*CC structure. Relatively few structures share the same conformation for the five residues: SP(7–11) no. 6, no. 13, and NK(6–10) no. 2, no. 8, SP(7–11) no. 5 and EL(7–11) no. 2, no. 15, NK(6–10) no. 5, no. 14, no. 18, and EL(7–11) no. 8, no. 19, no. 4.

Many characteristic structures are found within those stable conformers. C_7 hydrogen bonds are present in many structures, as shown in Table 2. Most of the residues coded C adopt the C_7^{eq} and C* the C_7^{ax} inducing a γ-turn in the sequence. SP(7–11) no. 20, EL(7–11) no. 4 (Fig. 1a), and NK(6–10) no. 18 adopt the C_7 helix for the terminal tripeptide. Figure 1b shows the C_7 conformation for Gly in SP(7–11) no. 19 while Fig. 1c shows the same conformation observed for Leu in EL(7–11) no. 13. Moreover, C_{10} hydrogen bonds are common as shown in Table 2. Among those, many β turns have been found in the most

[2]The nomenclature for the receptors is in accordance with the recommendations of the committee for the Substance P and Neurokinin Symposium (July, 1986, Montréal, Canada.)

[3]Conformational energies are relative to the value calculated for the α-helix structure, following a procedure described in Methods.

[a]Codes have been determined as defined in ref. 24.

[b]Energies are conformational energies relative to the α helix and expressed in kcal/mol. C C* indicates residues involved in a C_{10} structure. C indicates residues involved in a C_7 structure.

stable structures: SP(7–11) no. 1, no. 2, no. 4, EL(7–11) no. 1, no. 15, no. 17, NK(6–10) no. 1, no. 4, no. 7, no. 12. This conformation is illustrated by NK(6–10) no. 4 on Fig. 1d.

Other types of hydrogen bonds have been observed, inducing non-classical U-turns, like SP(7–11) no. 3, no. 6, no. 7, no. 9, no. 10, no. 13, EL(7–11) no. 11, no. 16, no. 19, and in NK(6–10) no. 2, no. 3, no. 14 (Fig. 1e) the structure of EL(7–11) no. 19 illustrates such folded structures. Hydrogen bonds have been located with SYBYL (28) using the geometrical constraints of 1.8 Å ≤ d(CO--NH) ≤ 2.5 Å and the angle N—H—O ≥ 120°.

Discussion

Examining Table 2 and comparing the series of conformers obtained for the three pentapeptides, it appears that the substitution differentiating the three sequences generates very different populations of conformers. The trend to create intramolecular hydrogen bonds is reflected in the three peptides, generating rigidified structures. A large predominance of conformations where the Gly residue adopts a structure with positive ϕ's (* code) is observed for all the structures. Nevertheless, structure–activity studies (9) have shown that the substitution of Gly by D-Ala seriously affected the activities. The observation would suggest that we reject star-coded conformations. Our results diverge from this conclusion, suggesting that the substitution of Gly by D-Ala affects the activity for other reasons than conformational modifications.

Folded structures have been postulated by most of the NMR studies (11, 12, 14, 16). Particularly, the NH group of Phe^7 in SP analogues has been shown to form hydrogen bonds with a carbonyl group close to the C-terminal end (12). Some of our structures support this observation: mainly SP(7–11) no. 11, no. 12, EL(7–11) no.3, no. 19 (Fig. 1e), NK(6–10) no. 3, no. 14, no. 20 form hydrogen bonds between NH of $Phe^{7(6)}$ and the carbonyl of Met. Another possibility, compatible with NMR results, is SP(7–11) no. 3, involving the carbonyl group of Leu. Table 2 reveals that many conformers are in agreement with the possibility of forming a C_7 hydrogen bond between the carbonyl group of Gly and the NH of Met, as postulated by other NMR (500 MHz) results (11, 16). This situation is illustrated in Fig. 1c.

Very few structures corroborate the hypothesis of an extended structure, even for the last three residues, as proposed by structure–activity relationship studies (7) and NMR results (16). This might be attributed to the low value of the dielectric constant used in the calculations, favoring the formation of intramolecular interactions.

A very NK3-selective analogue [Pro^7]NKB (7) was also studied by NMR at 500 MHz (16) and possible values for torsional angles were suggested. Examining our results, we found that the structure of NK(6–10) no. 4 (Fig. 1d) was compatible with these results. Furthermore, Val^7 of NK(6–10) no. 4 was substituted by Pro(down), and the conformational energy minimized. The resultant structure shown in Fig. 2 in superposition with NK(6–10) no. 4 adopts a conformation in agreement with the NMR results (16), preferring a C_7 hydrogen bond between the carbonyl group of Pro and the NH of Leu, instead of the β turn originally present in NK(6–10) no. 4 (Fig. 1d). Other structure–activity relationship studies emphasized the importance of a rigidification at residue 7, increasing the

selectivity by N-methylation, introducing an unusual Sarcosin (Sar) residue (1).

Consequently, the structure of NK(6–10) no. 4 appears to be a good model for further designs of very selective substrates of the NK3 receptor.

Pharmacological studies have shown that highly selective compounds to the NK1 receptor have a geometrically constrained residue in position 9 (1, 7). Particularly, the presence of a Pro^9 in [pGlu^6]SP(6–11) and Sar^9 in other SP active fragments induced very high degrees of specificity to the NK1 receptor (1, 8). Examining our results, it appeared that the geometrical requirements for compatibility with a Pro substitution are achieved by the structure EL(7–11) no. 13. We substituted Gly^9 by a Pro^9(flat structure: $\phi = -57.6°$) in this structure. The resulting structure after energy minimization is presented in Fig. 3, in superposition with EL(7–11) no. 13. Again, the rigidity is assumed by a C_7 hydrogen bond between the carbonyl group of Gly^9 and the NH of Met^{11}. The structure presented in Fig. 2 accommodates the substitution by a Sar^9 residue. Consequently, EL(7–11) no. 13 appears to possess the structural requirements for NK1 receptor selectivity.

In conclusion, the strategy based on random generation of peptidic structures, followed by energy minimization, has been shown to generate populations of pertinent conformers, compatible with NMR results. The method appears to be an excellent alternative when a systematic conformational search of conformations is prohibitive. It has been demonstrated that the conformational properties of the C-terminal pentapeptides in Neurokinins, Substance P, and Eledoisin contain the structural requirements for molecular recognition by the NK1 and NK3 receptors. Model compounds have also been described, suggesting further synthesis of more selective compounds.

This paper is dedicated to Professor Arthur S. Perlin on the occasion of his 67th birthday

R. H. MARCHESSAULT, M. G. TAYLOR, and W. T. WINTER. Can. J. Chem. **68**, 1192 (1990).

^{13}C solid-state NMR spectra (CP/MAS) were recorded for mannan polymorphs: mannan I ("ivory nut") and mannan II (*Codium fragile*). These pure mannans, poly-β-(1→4) mannopyranose, show a single resonance for each carbon of the chemical repeat unit. This is the expected result based on the crystalline $P2_12_12_1$ and $I222$ symmetries. The T_1 values were also recorded and the results are compared to those for cellulose obtained from the literature. The much lower mobility of C-6, even in noncrystalline mannan, compared to native cellulose is attributed to the epimeric difference at C-2 between cellulose and mannan allowing intramolecular hydrogen bonding in the former but not the latter.

Key words: mannan, solid state NMR, T_1 relaxation, polysaccharide, ivory nut.

R. H. MARCHESSAULT, M. G. TAYLOR et W. T. WINTER. Can. J. Chem. **68**, 1192 (1990).

On a déterminé les spectres RMN du ^{13}C à l'état solide (CP/MAS) de mannanes polymorphes : le mannane I («noix d'ivoire») et le mannane II (*Codium fragile*). Ces mannanes purs, des poly-β-(1→4)mannopyranoses, ne présentent qu'une raie pour chaque atome de carbone de l'unité chimique de base. Ce résultat est en accord avec des symétries cristallines $P2_12_12_1$ et $I222$. On a aussi mesuré les valeurs T_1 et on les a comparées avec celles rapportées dans la littérature pour la cellulose. La mobilité du C-6, même dans du mannane qui n'est pas cristallin, est beaucoup plus faible que celle observée dans la cellulose; cette différence est attribuée au fait que l'épimère en C-2 de la cellulose permet une laison hydrogène intramolécuaire ce qui n'est pas le cas avec l'épimère présent dans le mannane.

Mots clés : mannane, RMN à l'état solide, relaxation T_1, polysaccharide, noix d'ivoire.

[Traduit par la revue]

Cellulose and mannan are often compared because they are both β(1→4) linked carbohydrate polymers based on D-glucose and D-mannose respectively, i.e., they differ only in configuration at C-2. They are frequently found together in plant cell walls and both show polymorphism (1). In the native state both may act as skeletal material, cellulose mostly in land plants and mannan in certain green algae.

In gymnosperm cells, mannans, in the form of the copolysaccharides glucomannans and galactoglucomannans, occur concurrently with cellulose microfibrils. It has been shown that these so-called hemicelluloses are oriented parallel to the microfibrils (2) but there is no evidence of mannan crystallization in this natural occurrence. Nevertheless, cellulose microfibrils can be made to serve as a crystallization template for mannan, producing an epitaxial crystallization of the mannan chains with their fibre axes parallel to that of cellulose (3).

In addition to its structural role, mannan also functions as a reserve substance in seeds. In this form it is found either as pure mannan, e.g., in the endosperms of palm, date, and coffee beans, or as galactomannan, e.g., in the endosperms of legumes such as locust bean or guar. In the latter, galactose residues occur as single substituents linked α(1→6) to the mannan backbone in an irregular fashion. Depending on the plant species, galactomannans have ratios of galactose to mannose ranging from zero to unity. The endosperm of date palm, commonly called "ivory nut", has no galactose while the endosperm of "fenugreek" seeds has almost one galactose per mannose residue in the backbone (4).

In this study we have used the cross-polarization and magic-angle spinning (CP/MAS) technique to acquire ^{13}C NMR spectra of the insoluble, crystalline mannans from ivory nut (mannan I) and *Codium fragile* (mannan II) in order to enrich the solid-state structure models derived from diffraction methods.

Fibre diagrams for mannan I were first recorded by Frei and Preston (5). Their unit cell parameters and three-dimensional structure models were further refined by Nieduszynsky and Marchessault (6). The proposed space group for the orthorhombic unit cell was $P2_12_12_1$. As in cellulose, the fiber repeat of 10.3 Å corresponds to an extended disaccharide residue with a twofold screw axis relating contiguous mannosyl residues. Thanks to the high quality electron diffraction data from lamellar single crystals of mannan I, the required systematic absences of the baseplane reciprocal lattice net are unequivocal (3, 7), resulting in a two-chain unit cell with anti-parallel chains, as required by the $P2_12_12_1$ space group. Accordingly, a single anhydromannose residue is the asymmetric unit. The occurrence of anti-parallel chains in the native crystalline form of mannan is in direct contrast with proposed models of cellulose (8, 9).

While the X-ray analysis for mannan II is not nearly as advanced, the proposed space group, $I222$ (personal communication, S. Arnott, St. Andrews University), also implies a single anhydromannose residue as the asymmetric unit. As in the mannan I structure, this naturally occurring polymorph involves an anti-parallel packing of regular twofold helices although the arrangement is less dense than in mannan I and is thought to involve a hydrated form of the polymer.

Experimental

Two samples of mannan were studied: ivory nut mannan powder from ground nuts of *Phytelephas macrocarpa* and algal mannan from *Codium fragile*. The first sample is a pure mannan I as shown by X-ray powder diffraction and has been used in previous work (3, 7). Additionally, a whole ivory nut was mounted on a lathe and turned down into a cylinder for direct insertion in the rotor. The second sample, which is predominantly mannan II, was prepared by Dr. H. Chanzy of the CERMAV/CNRS, Grenoble, and was purified in the manner described by Preston (1). X-ray diffraction analysis has shown that while this sample is predominantly mannan II, it has a minor mannan I component.

^{13}C NMR spectra were acquired at ambient temperature on a Bruker CXP200 spectrometer operating at an observation frequency of 50.3 MHz. Spectra were acquired using polarization transfer from ^{1}H to ^{13}C with Hartmann–Hahn matching radiofrequency fields of 60 MHz and a recycling time of 5 s. Samples were rotated at the magic angle at rates of 2.5–3.5 kHz. Chemical shift values were assigned by reference to the resonance at 32.9 ppm (10) relative to TMS arising from a small piece of crystalline polyethylene (NBS/1475) included with the samples. Spin lattice (T_1) relaxation times were measured using the pulse sequence of Torchia (11) with delay times between 10 and 400 s, acquiring 224 scans at each value of the delay time. Intensities in the transformed spectra were measured both as peak heights and by peak integration.

Discussion

The CP/MAS spectra of mannan I and II are shown in Fig. 1. The most notable feature of both spectra is that they both show exactly six resonances corresponding to the six carbons in the anhydromannan asymmetric unit. The breadth of the resonances is greater for mannan II in keeping with the lower level of crystalline perfection of this sample, as evidenced by X-ray line broadening.[3] It is noteworthy that C-1 and C-4 resonances are distinctly different from those of cotton cellulose, provided the assignments are the same (cf. Table 1). Assuming the correlation between chemical shift and the glycosidic dihedral angles is the same as for cellulose, this implies a distinctly different set of conformational angles (ϕ, ψ) as defined in ref. 7. The angles ϕ, ψ, which define the conformational relation of successive anhydromannopyranose residues, are reported as $-93°$ and $-147°$ for cellulose (8) and $-81°$ and $-161°$ for mannan I (7). These values are based on the atom sequence (O-5, C-1, O-1, C-4′, C-5′). Additionally, the differing C-2 epimers of cellulose and mannan may contribute to these chemical shift differences. Assuming that the C-2 epimer difference does not have an influence on the correlation data of Horii *et al.* (13), the observed chemical shift for C-6 in Fig. 1 corresponds to the O-6 oxygen in the *gt* arrangement (i.e., O-6 is *gauche* with respect to O-5 and *trans* with respect to C-4), supporting the diffraction-based modeling for mannan I. A similar refinement for mannan II (S. Arnott, private communication) also proposes a *gt* O-6 conformer.

Comparison of the CP/MAS spectra of native celluloses whose lateral order is known to differ (*Valonia* vs. cotton) has been helpful in furthering the interpretation of their spectra. *Valonia* cellulose with near 100% crystallinity has well-defined C-1 and C-4 multiplets and lacks so-called amorphous phase resonances. By contrast, cotton shows less-resolved multiplets and displays well-defined noncrystalline resonances, in keeping with its lower perfection in lateral order. While there has been considerable controversy (14) in the interpretation of the multiplets for cellulose, the two-chain unit cell with a $P2_1$ space group and the screw axis parallel to the chain direction leads one to expect that the asymmetric unit in cotton involves two glucose residues.

[3]The subsidiary maxima for mannan II at ~80 and 60 ppm probably reflect a well-defined, hydrogen-bonded, noncrystalline component as in CP-MAS spectra of cellulose I and II (18).

TABLE 1. ^{13}C chemical shifts (ppm relative to TMS) from the 50.3 MHz CP/MAS spectra of mannan and cotton

	C-1	C-4	C-2, C-3, C-5	C-6
Mannan I	102.0	81.4	76.3 72.5 70.3	62.4
Mannan II	102.4	83.0	75.0 72.5 70.9	62.9
Cotton	106–104	89	75.3–71.6	65.5

A simplification develops when a $P2_12_12_1$ space group is operative, as is the case for the ivory nut mannan; here the well-resolved single resonances at C-1 and C-4 are in sharp contrast to the multiplets observed for C-1 and C-4 resonances in the cotton and *Valonia* cellulose spectra (14). The narrowness of the resonances leaves little doubt concerning the good lateral order in ivory nut, especially in contrast with the broader resonances in *Codium fragile* (mannan II). The latter, in keeping with its $I222$ space group, does not display multiplets. The greater breadth of the resonances for the *Codium* polymer is indicative of lower lateral order, compared to mannan I, reminiscent of a similar difference between cellulose I and II.

Spin lattice relaxation times

Figure 2 shows partially relaxed spectra for ivory nut mannan acquired with relaxation delays of 10 s (A) and 150 s (B) as well as their difference spectrum (C). The difference between the spectra indicates there are at least two components in the sample with different spin lattice relaxation times. The difference spectrum, which is the spectrum of the component with the shorter relaxation time, presumably represents the noncrystalline fraction of the mannan. For short relaxation delays or under the normal CP pulse sequence, the observed spectra are superpositions of the spectra representative of both the crystalline and noncrystalline fractions of the mannan. The spectrum of the crystalline material can be extracted by allowing a longer relaxation delay during which the signals due to the more rapidly relaxing component decay. As seen in Fig. 2B, the resulting spectrum shows excellent resolution of all six peaks with linewidths much smaller than those observed in the spectrum of the noncrystalline fraction (Fig. 2C).

It was necessary to consider the composite nature of the spectra in calculating T_1 values from the relaxation data. Intensity data were measured from peak integrals rather than peak heights because of the large difference in line widths for the two components. The use of integrals does introduce errors where broad peaks are strongly overlapping, i.e., in the region from 70 to 80 ppm. T_1 values and relative contributions for each of the two components were calculated by fitting the integrated intensity vs. relaxation delay data to two-component exponential decays using nonlinear regression. The T_1 values for both components along with their relative fractions for each line in the mannan I spectrum are tabulated in Table 2.

These data can be compared with relaxation measurements for cotton cellulose (12, 16). Two-phase behavior was also noted for the ^{13}C T_1 relaxation in cellulose with the two components assigned to the crystalline and amorphous region. The values of the relaxation times determined for mannan are uniformly longer than those measured for cotton cellulose (12, 16). The most striking difference is noted for the short T_1 values

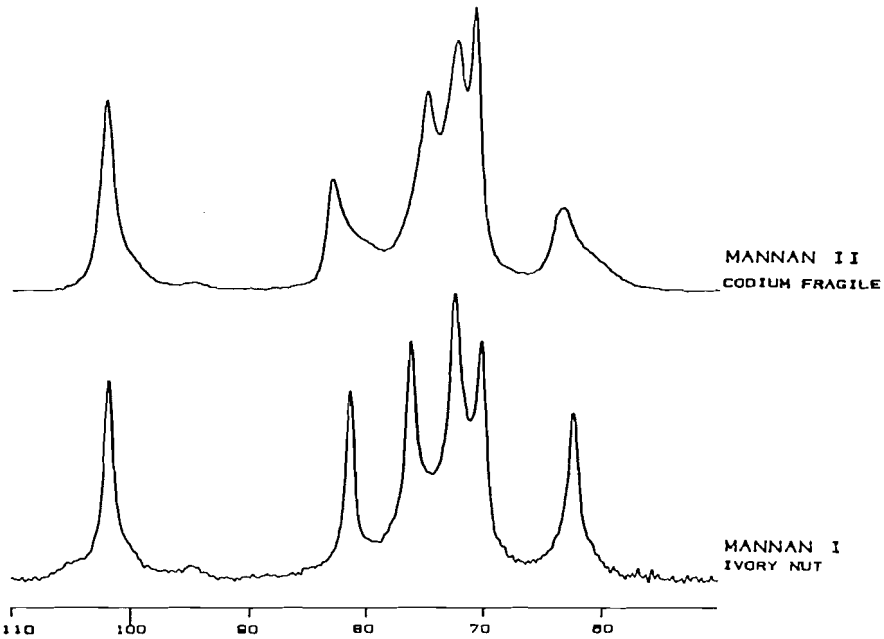

FIG. 1. ^{13}C CP/MAS NMR spectra of ivory nut and *Codium fragile* mannans. The samples are polymorphic and the unit cells are referred to as mannan I and mannan II, respectively.

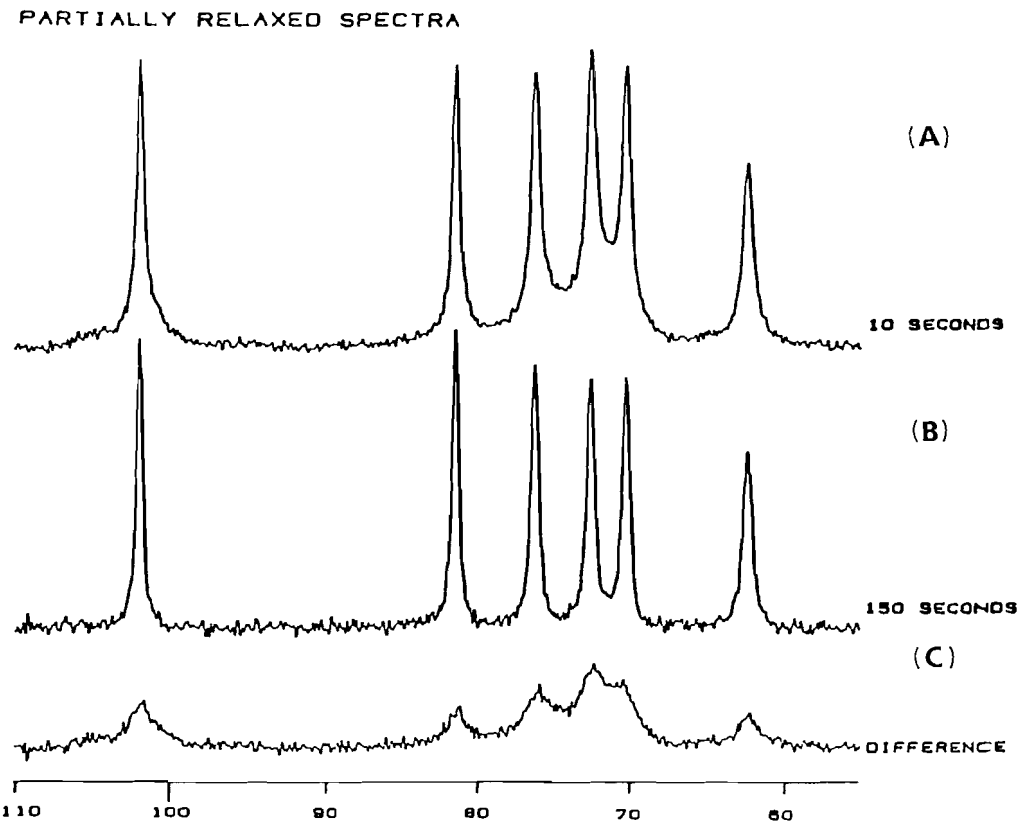

FIG. 2. ^{13}C CP/MAS NMR spectra of ivory nut mannan acquired with relaxation delays of 10 s (A), 150 s (B), and their difference (C).

assigned to the amorphous component in each polysaccharide. The T_1 values for the amorphous component of mannan are similar for all of the carbon resonances, while a large variation is observed in the case of amorphous cellulose. In particular, the observed T_1 for C-6 in amorphous cellulose is much shorter than the T_1's found for the other carbons, in contrast to the present data for mannan where the C-6 carbon T_1 is the second largest observed. This difference probably reflects greater restriction of the motional freedom of the hydroxymethyl group in amorphous mannan relative to cellulose. Such a conclusion would be expected on the basis of an intramolecular H-bond for O-6 in native cellulose vs. an intermolecular H-bond for O-6 in mannan (6, 7), an inevitable consequence of the configurational differences at C-2. In addition, cellulose hydrogen bonds into a

TABLE 2. ^{13}C T_1 relaxation times and parameters for mannan I from ivory nut

	C-1	C-4	C-2, C-3, C-5			C-6
Integral range (ppm)	107–97	85–79	79–74.5	74.5–71.5	71.5–68.5	65.5–59.5
Crystalline T_1 (s)	406	423	375	336	373	386
Noncrystalline T_1 (s)	26	39	23	21	24	33
Crystalline fraction (percent)	57	68	53	50	39	22

sheet-like structure whereas mannan hydrogen bonds into a three-dimensional network (6, 7).

Decomposition of the relaxation decay into two components should yield an estimate of the relative amounts of the crystalline and amorphous fractions in the sample. As seen inTable 2, a wide variation is noted in the relative crystalline fraction for the individual carbon resonances. Each of the resonances should in principle provide the same estimate of the degree of crystallinity of the sample. The discrepancy may result from the use of cross polarization for the generation of ^{13}C magnetization in the T_1 measurement. If the cross-polarization efficiencies for the two components of a particular line are not equal, the two components are not proportionally represented in the total initial ^{13}C magnetization. The subsequent relaxation decay faithfully represents the biased initial magnetization, leading to an incorrect estimate of the relative fractions of the two components. This difficulty could be circumvented by generating the ^{13}C magnetization by the normal single pulse method; however, it would be necessary to allow relaxation delays on the order of five times the longest T_1 value between pulses, leading to a prohibitively lengthy acquisition.

Conclusions

This study supports the concept that space group symmetry is an essential component of the interpretation of ^{13}C CP/MAS spectra of crystalline polymers. One signal for each carbon in the asymmetric unit provides a rational basis for understanding the differences between the multiplet-dominated cotton spectrum compared to the singlet resonances in the mannan spectrum. The observed differences in C-1 and C-4 chemical shifts between cellulose and mannan certainly derive from the ϕ, ψ dihedral differences for these two polysaccharides, but unfortunately it is not possible to partition the differences in chemical shifts between intra- (conformational) and inter-molecular influences. X-ray and electron diffraction data on crystalline fibers (6) and lamellar single crystals (7) are consistent with this conclusion.

In the case of the α-D-(1→4) glucans a linear correlation between crystallographic ϕ, ψ values and the C-1 and C-4 chemical shifts for the crystalline cyclomaltose hydrates has been shown (15, 17). Horii *et al.* (13) have proposed a similar correlation for the β-D-(1→4) glucans and the data for cellulose and mannan fit reasonably well on their plot. This kind of correlation is valuable to support diffraction-based modelling for crystalline polysaccharides. The agreement for the O-6 rotamer position (based on chemical shift correlation) between the X-ray fiber diffraction analysis and this study is very satisfying. Of equal significance is the striking difference in relaxation behaviour of C-6 in cotton vs. mannan. This observation, for samples of equal crystallinity, has structural implications. With the test of time, it appears more and more that the unique feature of native cellulose is the O-2...O-6 intramolecular H-bond. Because of the axial vs. equatorial orientation of O-2 in mannan compared to cellulose, such an intramolecular H-bond is not possible in mannan. Intramolecular H-bonds can be considered to allow greater translational and rotational freedom of individual chains; hence C-6 in cellulose would be expected to have a shorter T_1 than for mannan, especially in the noncrystalline regions.

This paper is dedicated to Professor Arthur S. Perlin on the occasion of his 67th birthday

STEVEN M. BARNETT, FRANÇOIS DICAIRE, and ASHRAF A. ISMAIL. Can. J. Chem. **68**, 1196 (1990).

The study of colored organometallic complexes by dispersive Raman spectroscopy has been limited due to fluorescence or photodecomposition caused by the visible laser used as the excitation source. As a solution to this problem, FT-Raman spectroscopy with a near-infrared laser source has been useful in lowering fluorescence or photolysis in these samples. To investigate the utility of this technique, we have obtained and assigned the FT-Raman spectra of a series of arene chromium tricarbonyl complexes and of cyclopentadienyl manganese tricarbonyl. Some bands previously unobserved by dispersive Raman spectroscopy were seen, including a band assigned to a ^{13}CO satellite in the spectrum of methylbenzoate chromium tricarbonyl. In addition, FT-Raman data for bovine serum albumin (BSA) and Protein-A are presented.

Key words: FT-Raman spectroscopy, metal carbonyl, proteins, organometallics, near infrared.

STEVEN M. BARNETT, FRANÇOIS DICAIRE et ASHRAF A. ISMAIL. Can. J. Chem. **68**, 1196 (1990).

L'étude des complexes organométalliques colorés par la spectroscopie Raman de dispersion a été limitée par la fluorescence ou la photodécomposition causées par les lasers visibles utilisés comme sources d'excitation. Pour solutionner ce problème, la spectroscopie Raman par transformée de Fourier à l'aide d'une source laser proche infrarouge s'est avérée utile pour diminuer la fluorescence ou la photolyse dans ces échantillons. Dans le but de définir l'utilité de cette technique, on a déterminé les spectres FT-Raman d'une série de complexes d'arènes chrome tricarbonyle et de cyclopentadiényl manganèse tricarbonyle. On a pu observé un certain nombre de bandes qui n'avaient pas été observées antérieurement par spectroscopie Raman de dispersion, y compris une bande attribuée à un satellite ^{13}CO du spectre du benzoate de méthyle chrome tricarbonyle. De plus, on présente des données de FT-Raman relatives au sérum d'albumine de bovins (SAB) et à la protéine-A.

Mots clés : spectroscopie FT-Raman, métal carbonyle, protéines, organométalliques, proche infrarouge.

[Traduit par la revue]

Introduction

Since the first synthesis of arene chromium tricarbonyl complexes in 1957, the chemical reactivities of this class of complexes have been extensively investigated (1, 2). Recently, we have employed certain arene chromium tricarbonyl derivatives as probes of enzyme binding sites (3) and as markers in infrared immunoassay (IRIA), a new assay technique employing FT-IR spectroscopy as the method of detection (4). The infrared characterization of these compounds has been undertaken by several groups (5, 6) but Raman studies have been limited to date due to the rapid thermal or photolytic decomposition of a large number of arene chromium tricarbonyl complexes under visible laser irradiation.

One approach to circumventing fluorescence and photodecomposition in Raman experiments is through the use of a near-infrared (NIR) laser in place of a visible laser as the excitation source. For samples containing molecules with low-lying electronic states, visible laser excitation puts the molecules in a virtual energy state that couples readily to adjacent electronic states, resulting in fluorescent de-excitation or photodecomposition. Irradiation of such samples with a NIR laser puts the molecules in a virtual energy state that lies between the electronic ground state and the first excited electronic state, thus avoiding both fluorescence and photodecomposition. However, the use of NIR lasers results in reduced sensitivity of the Raman measurements for two reasons. First, scattering efficiency decreases as the fourth power of the wavelength of excitation. Therefore, the intensity of the scattered signal using a NIR laser is 10 to 20 times lower than that using a visible laser. Second, the detectors suitable for near-IR measurements are not as sensitive as the ultrasensitive photomultiplier detectors used in the visible region. A successful approach to overcoming these problems has involved the use of interferometry and Fourier transform (FT) techniques for signal processing.

The use of the FT spectrometer has had a considerable impact on infrared spectroscopy in recent years. This is due to the three principal advantages of FT spectrometry: high throughput, wavelength accuracy, and multiplexing, that is, the simultaneous detection of all wavelengths. The first FT-Raman experiment was performed by Chandry *et al.* in 1964 (7) but went largely unnoticed until Hirschfeld and Chase (8, 9) and Murphy and co-workers (10) reintroduced FT-Raman spectroscopy in 1986. Several manufacturers of FT-IR instrumentation have recently adapted their spectrometers to perform FT-Raman measurements. As a result, IR and Raman spectra can be recorded using the same optical bench with two different sources and detectors. In addition, Raman data can be processed using the FT-IR software.

FT-Raman spectroscopy has proved very successful in a variety of applications, especially in the study of dyes (9, 11) and polymers (12, 13). In this paper, we will present some examples of the application of FT-Raman spectroscopy to the study of organometallic complexes, as well as the FT-Raman spectra of two proteins employed in our laboratory in the synthesis of protein-organometallic conjugates.

Experimental

The arene chromium tricarbonyl complexes were prepared from chromium hexacarbonyl by a previously described method (14).

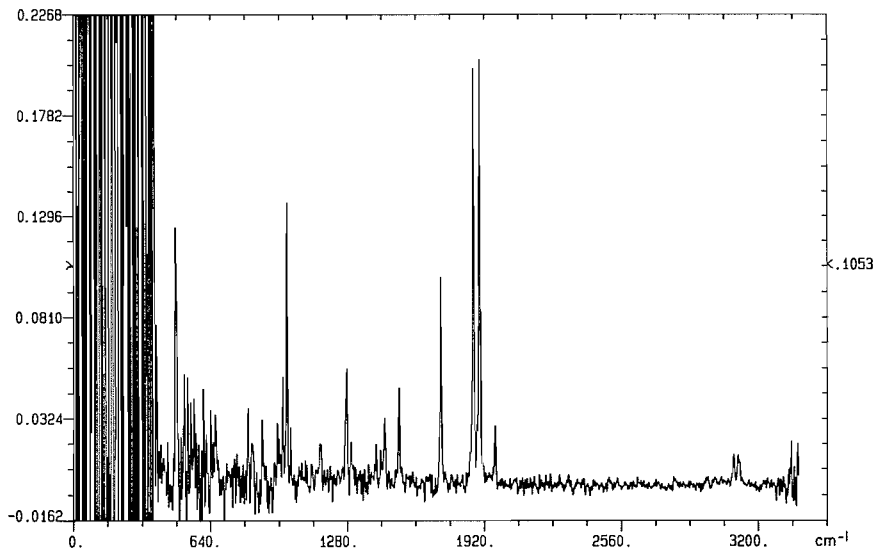

FIG. 2. FT-Raman spectrum of methylbenzoate chromium tricarbonyl ratioed against instrument response curve.

Bovine serum albumin (BSA) and Protein-A were used without purification (Sigma).

FT-Raman spectra were obtained using a Bomem DA-3 or Michelson spectrometer equipped with an indium–gallium–arsenide detector and configured to collect back-scattered radiation at a 180° angle. The excitation source was a Nd:YAG laser operating at 1064 nm. The laser power was typically 0.5 W for solids and 1 W for solution samples.

Solid samples were analyzed in 1-mm id glass capillary tubes. Saturated solutions of methylbenzoate chromium tricarbonyl and cyclopentadienyl manganese tricarbonyl in carbon tetrachloride were prepared in 10-mm glass vials. Protein samples were dissolved in phosphate buffered saline (0.01 M phosphate, 0.15 M NaCl), pH 7.2, in the concentration range of 1–5 mg/mL. The temperature of solution samples was monitored with a Fluke 2170A digital thermometer.

Results

The FT-Raman spectrum of methylbenzoate chromium tricarbonyl in the solid phase is shown in Fig. 1. As a result of the multiplexing advantage of FT-Raman spectroscopy, the complete spectral region can be covered at 4 cm^{-1} resolution in a matter of seconds. The ν(CO) peaks are clearly discernible in this spectrum at 1870, 1898, and 1970 cm^{-1}. However, the low-energy vibrations are missing due to the use of filters necessary to reduce the intensity of the Rayleigh line. The loss of information content in the low-frequency region can be best appreciated by ratioing the spectrum of methylbenzoate chromium tricarbonyl against the instrument response, as shown in Fig. 2. FT-Raman spectroscopy also allows for the recording of solution spectra of transition metal carbonyl complexes whereas photodecomposition of these complexes under visible-laser irradiation is often a particularly severe problem. Figure 3 shows the FT-Raman spectrum of cyclopentadienyl manganese tricarbonyl in carbon tetrachloride. After irradiation of 1 mL of solution with 1 W of power for 15 min, the sample temperature increased from 23 to 28°C.

The band positions from the FT-Raman spectra of a number of arene chromium tricarbonyl complexes, together with band assignments based on previous assignments in the literature (5, 6), are listed in Table 1. The corresponding data for cyclo-

pentadienyl manganese tricarbonyl (15) are presented in Table 2. It should be pointed out that the total measurement time for the acquisition of all these spectra was approximately one hour, which is less than the time required to record a comparable spectral region for a single sample using a conventional Raman spectrometer with the same signal-to-noise ratio at $4\,cm^{-1}$ resolution.

The advantage of using FT-IR software to treat FT-Raman data is illustrated by the example shown in Fig. 4, where the broad CH stretching peak in the FT-Raman spectrum of cyclopentadienyl manganese tricarbonyl is deconvoluted to show weak CH stretching bands at 3146, 3118, 3106, and $3098\,cm^{-1}$ in addition to the strong CH stretching band at $3130\,cm^{-1}$. Fourier deconvolution was also used in the case of methylbenzoate chromium tricarbonyl to isolate a weak shoulder on the $1870\,cm^{-1}$ peak, which is assigned to a ^{13}C satellite of the $1898\,cm^{-1}$ peak.

The FT-Raman spectrum of BSA in the solid state is shown in Fig. 5. The Raman spectrum of BSA has been previously obtained by dispersive methods (16, 17), and the results of the

earlier work have been used in assigning the peaks in the FT-Raman spectrum. The FT-Raman spectrum of Protein-A has also been obtained, and some assignments have been made by comparison of the spectrum with that of BSA. The data for these two proteins are shown in Table 3. Attempts to obtain the FT-Raman spectrum of BSA in solution were unsuccessful at 1 and 2 W of laser power. When the power was increased to 4 W, sample heating became significant; after 15 min of laser irradiation, the sample temperature was 47°C, at which temperature BSA is subject to denaturation.

Discussion

FT-Raman spectroscopy offers many advantages with respect to traditional Raman spectroscopy. It is particularly useful for samples where fluorescence or photolysis by visible laser

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12

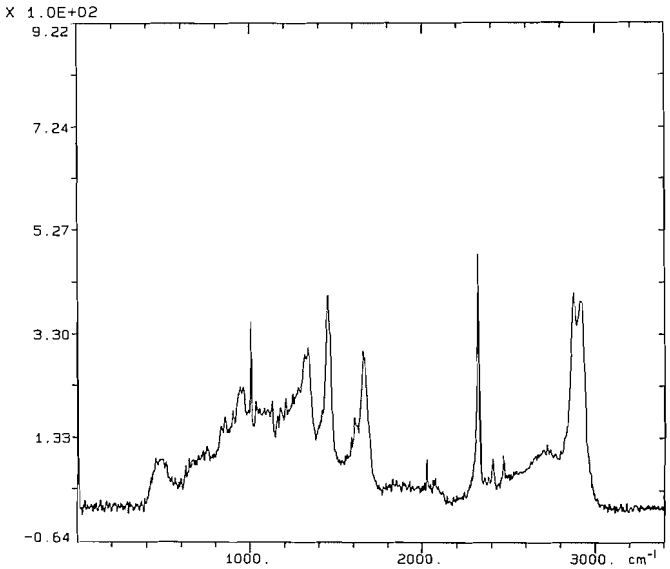

FIG. 5. FT-Raman spectrum of bovine serum albumin in the solid state.

irradiation is a problem. In addition, the entire Raman spectrum can be scanned in a much shorter time than with traditional Raman spectroscopy. Finally, the adaptation of FT-IR spectrometers for FT-Raman measurements allows the extensive FT-IR data handling capabilities to be applied to FT-Raman spectroscopy. As a result of these features, the development of FT-Raman spectroscopy should vastly extend the applicability of Raman spectroscopy.

In the present study FT-Raman spectroscopy has proved useful in obtaining the Raman spectra of colored organometallic complexes in both the solid and the solution phase without photolytic dissociation of the complexes. It has also provided a means for acquisition of protein spectra free of fluorescent background. Denaturation of protein samples has not been found under the conditions employed in our work. Lin and Koenig (17) determined that the Raman band at 934 cm^{-1} in the spectrum of BSA, due to skeletal stretching, was indicative of BSA in an α-helical conformation and that upon heat denaturation, this peak became very weak or disappeared. This peak was strong in the FT-Raman spectra of BSA and Protein-A, indicating that no significant denaturation occurred under NIR-laser irradiation with the laser powers employed (0.5–1 W). However, from the studies described above, it appears that the application of FT-Raman spectroscopy in the study of proteins in solutions is, at present, limited due to several factors: the weak scattering efficiency as a result of the use of a NIR laser for irradiation; the low concentrations of the proteins in solution that must be maintained in order to mimic physiological conditions and avoid formation of aggregated species; and the susceptibility of proteins to denaturation upon heating, limiting the laser power that can be employed. Sample heating could be alleviated through the use of the same cooling accessories as employed in traditional Raman experiments, such as spinning sample cells.

Acknowledgement

We would like to thank Dr. Henry Buijs for use of the FT-Raman facilities at Bomem Inc. One of us (F.D.) is grateful for a Pestcon Graduate Scholarship. This work was sponsored in part by an FCAR grant and a grant from Bomem Inc.

The title complex crystallizes in the space group *Pcab* with a = 16.019(7), b = 19.62(1), c = 15.847(5) Å, and Z = 8. The structure was solved by direct methods and refined by full matrix least-quares calculations to a residual, R, of 0.083. The monomeric structure lacks a true centre of symmetry although the two lithiums have similar chemical environments. Each lithium cation is coordinated to three different oxygens of the hexaether and to both phenoxide oxygens. The hexaether is slightly elongated allowing both Li(1) and Li(2) to lie in the cavity formed by the crown with values of −0.077 and 0.074 Å, respectively, out of the plane approximated by the six oxygens. Both cations are strongly associated with the phenol moieties. The distances between the lithium and the phenoxide oxygens range from 1.859–1.893 Å, while distances of 1.940–2.420 Å are found with the ether oxygens. The Li(1)—Li(2) distance is found to be relatively short at 2.35 (2) Å.

Evidence for motion in the 18-crown-6 portion of the solid complex has been obtained from ^{13}C CPMAS NMR spectroscopy. At 298 K, a dipolar washout phenomenon occurs since the motional correlation times are of the order of the inverse of the ^{1}H decoupling field amplitude. At lower temperatures, the motion becomes slow enough to permit resolution of the chemical shift differences of unique carbon sites of the crown ether. Consistent with the X-ray analysis, only five resonances are evident for the phenoxide carbons, indicating that the two aromatic rings are nearly equivalent in their crystallographic environment. The solution ^{13}C spectrum shows only five resonances in total down to 188 K indicative of rapid conformational averaging of all the 18-crown-6 carbon resonances and rapid rotation about the O-phenyl bond.

Key words: crown ethers, NMR, stereochemistry, dynamics, X-ray.

KIMBERLY A. WATSON, SUZANNE FORTIER, MICHAEL P. MURCHIE, JOHN W. BOVENKAMP, ANDRE RODRIGUE, GERALD W. BUCHANAN et CHRISTOPHER I. RATCLIFFE. Can. J. Chem. **68**, 1201 (1990).

Le composé mentionné dans le titre cristallise dans le groupe d'espace *Pcab* avec a = 16.019(7), b = 19,62(1) et c = 15,847(5) Å et Z = 8. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés jusqu'à une valeur de R = 0,083. La structure monomère ne possède pas de vrai centre de symétrie même si les deux atomes de lithium se trouvent dans des environnement chimiques semblables. Chaque cation lithium est coordonné à trois oxygènes différents de l'hexaéther et aux deux groupements phénolates. L'hexaéther est partiellement allongé et les deux Li(1) et Li(2) se trouvent respectivement à −0,077 et à +0,074 Å du plan approximatif formé par les six oxygènes dans la cavité formée par la couronne. Les deux cations sont fortement associés aux oxygènes des phénols. Les distances entre le lithium et les oxygènes des phénols varient de 1,859 à 1,893 Å alors que les distances entre les lithium et les oxygènes des éthers varient de 1,940 à 2,420 Å. On a trouvé que la distance Li(1)—Li(2) est relativement courte à 2,35(2) Å.

En se basant sur des données de spectroscopie rmn CPMAS due ^{13}C, on a pu mettre en évidence un mouvement de l'éther 18-couronne-6. A 298 K, il se produit un phénomène d'annulation dipolaire qui résulte du fait que les temps de corrélation des mouvements sont du même ordre de grandeur que l'inverse de l'amplitude du champ de découplage du ^{1}H. A des températures plus basses, le mouvement devient suffisamment lent pour permettre la résolution des différences dans les déplacements chimiques des sites uniques des carbones de l'éther couronne. En accord avec l'analyse des rayons-X, on n'observe que cinq bandes de résonance pour les carbones du phénolate; ces résultats indiquent que les deux cycles aromatiques sont pratiquement équivalents dans leur environnement cristallographique. Au total, le spectre du ^{13}C ne présente que cinq raies jusqu'à 188 K; ces résultats indiquent qu'il s'opère un équilibre conformationnel rapide de toutes les résonances des carbones de la 18-couronne-6 et une rotation rapide autour de la liaison O-phényle.

Mots clés: éthers couronniques, RMN, stéréochimie, dynamiques, rayons-X.

Introduction

Since Pedersen (1) reported the first synthesis of crown ether complexes, over four hundred crystal structure analyses of crown ether complexes have been carried out and it is now well understood that several factors, such as host–guest size compatibility, ligand substituents, anion and solvent effects, have an influence on the resulting structure and stoichiometry of these complexes.

Over the last few years, we have studied crown ether complexes with unusual host:guest ratios, that is ratios that would not be expected on the basis of the host:guest size compatibility criterion. For example, several 1:2 and 1:3 host:guest complexes of 18-crown-6 macrocyclic ethers with potassium and sodium salts (2) and 1:2 host-guest complexes of 15-crown-5 macrocyclic ethers with sodium and lithium salts (3) were synthesized. Crystal structure analyses were carried out on several of these complexes (3, 4) and in each case it was clear that the structural characteristics and stoichiometry were a result of concerted host, guest, anion, and solvent effects.

In the present work, we report the synthesis, solution and solid state NMR study, and X-ray crystal structure determination of the 1:2 host:guest complex of 18-crown-6 with lithium phenoxide. Few lithium complexes of 18-crown-6 have been reported to date and this study was undertaken to characterize the complexation of the lithium ions by this host. We were also interested in comparing these results with those of several complexes of alkali metal phenoxide salts with macrocyclic ethers, obtained from similar solvents, and exhibiting unusual host: guest ratios.

Experimental

Commercial anhydrous diethyl ether was dried over sodium wire. Hexane was dried over molecular sieves. Reagent grade tetrahydrofuran was distilled from lithium aluminum hydride using a Stedman column and a variable take-off still head. Commercial 18-crown-6 was precipitated as the acetonitrile complex (5) and the acetonitrile was removed under vacuum; mp 40.5–41.0°C (lit. (6) mp 39–40°C). Lithium phenoxide was prepared as described in ref. 7.

The complexation reactions, the preparation of samples for elemental analysis and the preparation of melting point and NMR spectroscopic samples were carried out in a Dri-Lab (Vacuum Atmospheres Corp.) under an argon atmosphere.

Synthesis of 18-crown-6·2LiOPh

In a typical reaction, LiOPh (6.49 mmol) was dissolved in a mixture of diethyl ether (40 mL) hexane (20 mL). The 18-crown-6 (2.17 mmol), dissolved in hexane (15 mL), was added to the LiOPh solution. A white precipitate was formed after less than 5 min. The reaction mixture was stirred overnight at room temperature. The precipitate was isolated by suction filtration and then dried under vacuum (<0.001 Torr) in a drying pistol at 56°C for 15 h. The white solid had a melting point of 143.5–146.0°C and was identified by proton NMR spectroscopy and elemental analysis of 18-crown-6·2LiOPh. *Anal.* calcd.: C 62.06, O 7.38, Li 2.99; found: C 61.73, O 7.16, Li 3.27. The yield of 18-crown-6·2LiOPh was 1.88 mmol which corresponds to an 87% yield based on 18-crown-6.

Preparation of a crystalline sample of 18-crown-6·2LiOPh

Suitable crystals of 18-crown-6·2LiOPh were obtained from a solution of the complex (0.19 g) in anhydrous tetrahydrofuran (10 mL). The solution was slowly evaporated to dryness in an argon atmosphere.

X-ray crystal structure analysis of 18-crown-6·2LiOPh

Pertinent data about the crystal used and the measurement of diffraction intensities are summarized in Table 1. The crystal used in the diffraction experiment was mounted inside a glass capillary in a moisture-free environment. The intensity data were collected on an Enraf-Nonius CAD-4 diffractometer using CuKα (λ = 1.5418 Å) radiation. The intensities were collected by the ω/2θ scanning procedure and two reflections were measured after every 7200 s of exposure time to check on the stability of the crystal. No evidence of crystal decay was detected. The data were corrected for Lorentz and polarization effects; absorption corrections were not considered necessary. The structure was solved routinely by direct methods using the program MULTAN 80 (8). The positions of sixteen of the total of thirty four hydrogen atoms were found in the difference Fourier map, the remaining eighteen were calculated. The structure was refined by full-matrix least squares using all reflections with $I > 3\sigma(I)$. Anisotropic temperature factors were used for the non-hydrogen atoms. The hydrogen atoms were assigned isotropic temperature factors equal in magnitude to the equivalent isotropic temperature factors of their parent atoms. They were included in the calculations but they were not refined. The function minimized was $\Sigma w||F_o| - |F_c||^2$, where $w = 1/\sigma^2(|F_o|)$. A correction for isotropic secondary extinction effect was included in the refinement. The scattering factors were taken from Cromer and Waber (9). All calculations were done on a PDP 11/23 computer using the Enfra-Nonius SDP program package (10).

TABLE 1. Crystal data[a]

Parameter	Crystal data

Standard deviation of an observation of unit weight, σ	2.635

[a]Estimated standard deviations are shown in parentheses.

Nuclear magnetic resonance spectra

The ^{13}C CPMAS spectra were recorded at 45.3 MHz using a Bruker CXP-180 NMR spectrometer and a Doty Scientific variable temperature probe. Cross polarization time was 0.5 ms with the rf field amplitude being ca. 60 kHz. The number of transients was 1000 at room temperature and 72 at 210 K. The sweep width was 20 kHz and the recycle times were 60 s at room temperature and 80 s at 210 K. Normally 2K data points were collected with zero filling to 8 K before Fourier transformation. At room temperature the magic angle spinning rate was 41.1 kHz and at 210 K the rate was 3.8 kHz. The chemical shifts were measured relative to external solid hexamethylbenzene (HMB) and converted to the TMS scale via the factor of 16.9 ppm which is the chemical shift of the CH_3 group of HMB.

The solution phase ^{13}C NMR spectra were obtained using a Varian

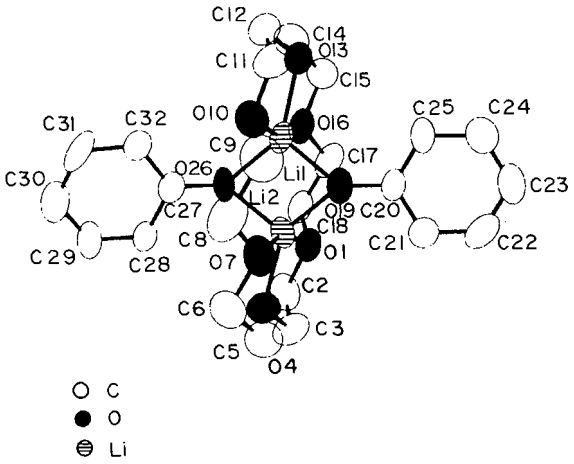

FIG. 1. ORTEP diagram of 18-crown-6·2LiOPh

XL-200 spectrometer operating at 50.3 MHz. Normal sweep width was 10 kHz with 32K data points and complete ^1H noise decoupling. Samples were ca. 0.2 M in 5 mm tubes using dimethoxyethane-d_{10} as solvent. Normally a 45° observing pulse was applied with delays of 1 s. Temperatures were calibrated using a copper–constantan thermocouple and are deemed accurate to within 2°C.

Results and discussion

Crystal structure of 18-crown-6·LiOPh

An ORTEP (11) drawing of the complex showing the atom numbering scheme is given in Fig. 1. The fractional coordinates and equivalent isotropic temperature factors of the non-hydrogen atoms are presented in Table 2. Lithium–oxygen bond distances and angles appear in Table 3; average and range of bond distances and angles of the macrocycle and of the phenoxides are given in Table 4; and macrocyclic ring torsion angles are presented in Table 5.

Host geometry and conformation

The cavity outlined by the oxygens of the hexaether is slightly elongated, with values of 5.454(6), 6.202(6), and 5.366(7) Å for O(1)---O(10), O(4)---O(13), and O(7)---O(16), respectively. The elliptical arrangement of the oxygens of the hexaether allows both Li^+ cations to be accommodated in the crown cavity while keeping a sufficient Li^+—Li^+ separation of 2.35(2) Å. The ether oxygens form an approximate plane with all oxygens pointing toward the centre of the cavity. They are found alternately, ca. 0.026 Å above and below their mean plane.

In a regular hexaether conformation all torsion angles about C—C bonds are synclinal and those about C—O bonds are antiperiplanar (12). From Table 5 is is evident that these values are present in some portions of the structure, but substantial deviations are present in other regions. For example, two of the six O—C—C—O networks have torsional angles which are >25° larger than the "regular" value of 60°. These deviations, combined with some lesser contractions of C—C—O—C angles result in an elliptical cavity shape for the 18-membered ring.

The C—C bond lengths in the macrocycle exhibit the characteristic (13, 14) shortening with an average value of 1.498 Å. The C—O bond lengths have an average value of 1.427 Å and the O—C—C and C—O—C angles have average values of 109.3° AND 113.5°, respectively, which are consistent with previous studies on related systems (13, 14).

Host–guest interactions

Although the two lithium cations are not related by crystallo-

graphic symmetry, they have nearly identical chemical environments. Both Li^+ cations lie in the approximate plane defined by the donor ether oxygens, with distances of −0.077 and 0.074 Å for Li(1) and Li(2), respectively, out of the mean plane. The lithium cations are located along the direction of elongation of the elliptically shaped cavity and are colinear with O(4) and O(13). Each lithium is coordinated to three diffferent oxygens of the crown ether and to both oxygens of the phenoxide moieties.

In their study of the environments of alkali cations complexed to ethers, Chakrabarti and Dunitz (15) found that the cations always lie close to the bisecting plane through the oxygen atom. They predicated that, for optimal complexation with lithium, a polyether ligand should have a cavity (M---O distances) of approximately 2 Å and should also have the C—O—C bisectors of the ether groups converging to one point. With a polyether ligand accommodating two lithium guests, we expect to see some deviations from these predictions and indeed we find some lengthening of the Li---O distances. The lithium cations are found, nevertheless, as predicted, near the C—O—C bisector planes of the ether groups. Li(1) is at distances of 0.35, 0.05, and 0.43 Å from the C(9)—O(10)—C(11), C(12)—O(13)—C(14), and C(15)—O(16)—C(17) bisector planes, respectively. Li(2) is at distances of 0.31, 0.05, and 0.57 Å from the C(18)—O(1)—C(2), C(3)—O(4)—C(5), and C(6)—O(7)—C(8) bisector planes, respectively. In each case the three bisector planes intersect approximately in a line such that each lithium is near this line of intersection and also in the plane defined by the ether–oxygens.

The lithium ether–oxygen distances range from 1.934–2.416 Å with an average value of 2.146 Å. The lithium phenoxide–oxygen distances range from 1.853–1.890 Å, with an average value of 1.875 Å. Thus, stronger interactions exist between the Li^+ ions and the phenoxide oxygens than between the Li^+ ions and the ether oxygens. The range in lithium ether–oxygen distances reported to date is 1.950–2.531 Å (16). Although the two lithium cations interact strongly with the phenoxide–oxygens to form an aggregate, as expected for these ions in ethereal solvents (3), the relatively large cavity of the 18-crown-6 host allows both lithium cations to coordinate to the regular hexaether host with all the oxygens participating in the coordination of the lithium guests. This is in contrast to the lithium ether–oxygen interaction observed in 18-crown-6·2LiSCN·$2H_2O$ (17), where it was believed that the hydrogen bonding of the water molecules to the ether–oxygen atoms was necessary for coordination of the lithium cations to the crown host. Clearly, in our structure, the two lithium cations are accommodated by the crown ether without the aid of hydrogen bonding.

The 18-crown-6-·2LiOPh complex contains an Li_2O_2 four membered ring defined by Li(1), O(19), Li(2), and O(26). The Li(1)---Li(2) distance is short, with a value of 2.35(2) Å. A search of all the entries in the Cambridge Structural Data Base (16) for Li^+---Li^+ separations revealed a range of distances between 2.299 and 2.759 Å with a mean value of 2.565 Å, based on 46 observations.

In our study of macrocyclic complexes with alkali metal–phenoxide salts, we have observed that the competition between the hard anion and the macrocyclic ligand can give rise to unusual host:guest stoichiometry and unexpected structural characteristics. For example, in both the 15-crown-5·2LiOPh (3) and the dicyclohexano-18-crown-6 (isomer A)·2NaOPh (4) complexes, the formation of the phenoxide aggregate predominates and the cations are pulled out of the host cavity. In the 15-crown-5·2LiOPh complex the aggregate consists of a dimer containing an Li_2O_2 four-membered ring, also observed in our structure. In dicyclohexano-18-crown-6 (isomer A)·2NaOPh it is a tetramer of sodium phenoxides that is formed. Similarly, in the dicyclohexano-18-crown-6 (isomer B)·2KOPh complex (4), the potassium ions are pulled out of the host cavity and a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12
For personal use only.

potassium phenoxide dimer is observed. However, the tendency to form aggregates in ethereal solutions does not preclude the possibility of obtaining an optimal host:guest coordination geometry. The present, 18-crown-6·2LiOPh, complex exhibits a strong phenoxide aggregate formation, in addition to a host:guest geometry where both lithium cations lie in the cavity outlined by the 18-crown-6.

The ability of a crown host to accommodate more than one guest in a nested position has been observed in complexes where the host cavity is large compared to the size of the guest ions. For example, in dibenzo-24-crown-8·2KNCS (18) the crown ring surrounds both potassium cations in a nearly planar geometry and all the ether–oxygens interact with the potassium cations, analogous to what is observed for the present complex.

Solid state and solution NMR spectra of 18-crown-6·2LiOPh

^{13}C CPMAS spectrum

The solid phase ^{13}C NMR spectra of this material as a function of temperature are presented in Fig. 2. At 298 K, a broad crown ether resonance containing no discernable fine structure is observed centered at *ca.* 70 ppm. At 310 K this resonance is considerably more broadened so that essentially no crown ether carbon signal was observed. Further temperature increases caused sample melting. Lowering the sample temperature sharpens this resonance and some discernable fine structure is apparent at 210 K. Before discussing the origin of the fine structure at low temperature however, the high temperature broadening phenomenon merits clarification.

Similar broadening has been observed recently in other 18-crown-6 complexes (19, 20) and can be attributed to a "dipolar washout" phenomenon. Under conditions where molecular motion has a correlation time of the order of the inverse of the decoupling field amplitude, the incoherent field generated by the motion destructively interferes with the coherent ^1H decoupling field. As a result, the ^1H decoupling field is rendered ineffective and hence a broad dipolar ^1H coupled ^{13}C resonance is observed (21, 22). In the presence of a decoupling field of amplitude 60 Hz, this broadening is maximal for $\tau_C = (1/2)\pi\gamma H_1 = (1/2)\mu \times 60\ \text{Hz} = 2.7 \times 10^{-6}$ S. At temperatures below 298 K, the crown ether resonance sharpens since the correlation time for molecular motion becomes too slow for the above conditions to be met.

With regard to the type of motion involved here, a model is required which allows a large amplitude motion consistent with the NMR data while at the same time preserving the X-ray crystallographic conformation of the 18-crown-6 moiety. The motion must be sufficient to cause an averaging of ^1H—^{13}C dipolar coupling. From other evidence on related 18-crown-6 complexes (20), the motion must also be sufficient to average the ^1H—^1H dipolar couplings and reduce the width and change the sign of the ^{13}C chemical shift anisotropy. The model proposed for the present complex and related systems (20) is one where the entire macrocycle reorients such that the O—CH_2—CH_2—O units exchange positions around the ring. Each unit must simultaneously readjust to fit the local conformation of each site visited, thereby keeping the crystallographic structure unchanged. This type of motion is analogous to a small cyclic molecule undergoing simultaneous reorientation and ring puckering.

A more subtle broadening of the crown ether line near 70 ppm occurs when the correlation time for motion becomes of the same order as the inverse of the chemical shift difference (in Hz). In the slow motional limit, separate resonances will be discernable for each unique carbon type should the chemical shift differences be sufficiently large.

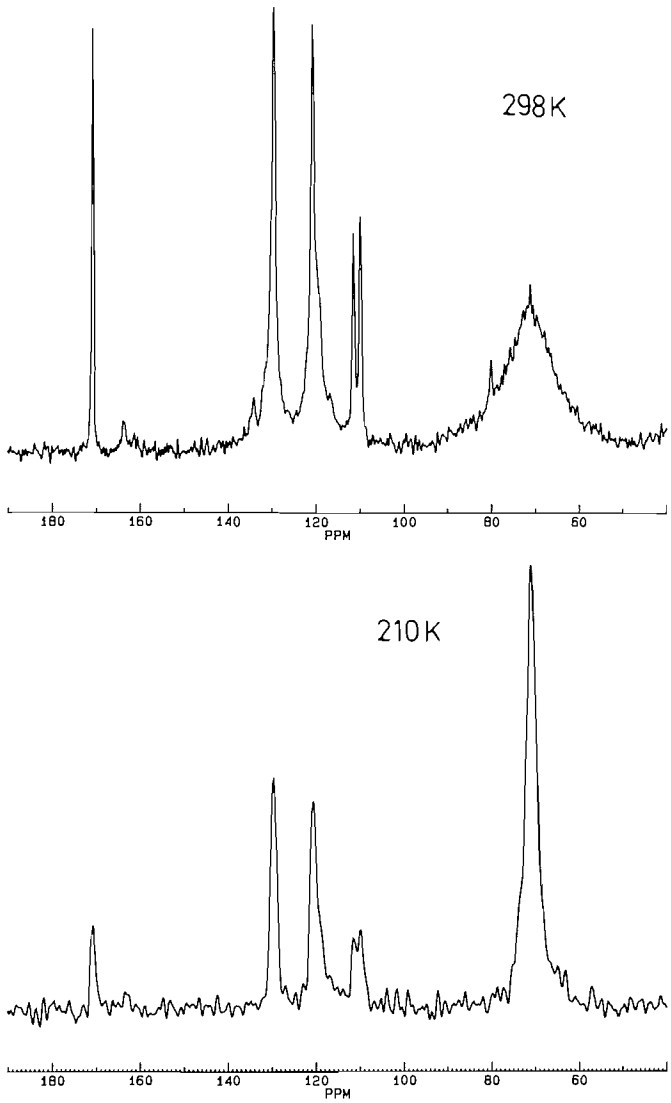

FIG. 2. 45.3 MHz ^{13}C solid phase NMR spectra at 298 and 210 K.

The X-ray results indicate that there are no elements of symmetry in the structure, so that in principle, one anticipates twelve unique ^{13}C resonances in the solid phase spectrum. In fact considerably less than this number are observed due to nearly equivalent chemical shifts and the inherently low resolution (*ca.* 20 Hz linewidth) of solid state ^{13}C spectra. The expanded spectrum showing the crown ether region at 210 K is depicted in Fig. 3. From spectral deconvolution techniques, four overlapping resonances appear to be present, at $\partial_C = 70.2$, 71.4, 72.5, and 73.3 ppm with relative intensities of *ca.* 8:2:1:1.

It is of interest to examine the above results in terms of the torsional environments of each of the twelve unique carbon atoms of the macrocycle. If hydrogens are ignored, then each carbon is present in four torsional networks, either as a central or a terminal atom as indicated in Table 6.

Although the dihedral angle dependence of ^{13}C chemical shifts in these particular types of networks has not been delineated, the effects are well documented experimentally for both central and terminal atoms of related C—C—C—C and C—C—C—O arrangements (23–25). In every instance carbons experiencing *gauche* interactions are shielded by *ca.* 5 ppm rela-

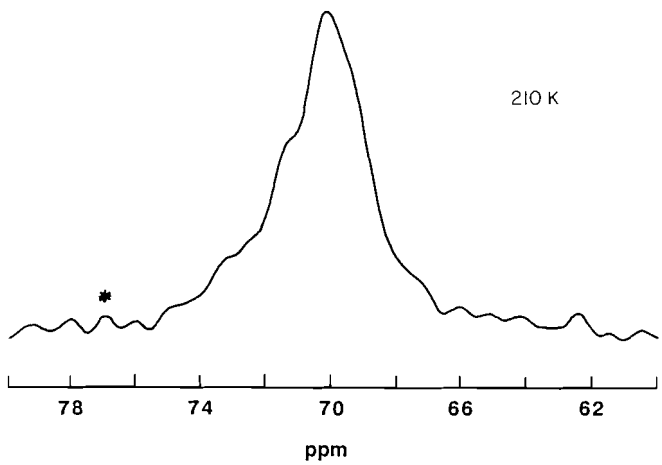

FIG. 3. Expanded crown ether carbon region of ^{13}C spectrum at 210 K.

tive to their counterparts in *trans* orientations. In view of the similarities in the bond angles for sp^3 hybridized carbon and oxygen atoms, it is reasonable to assume a qualitatively similar angular dependence of ^{13}C chemical shifts in O—C—C—O and C—C—O—C networks.

Examination of data in Table 6 shows that eight of the twelve carbons are in rather similar environments, namely they have O—C—C—O angles near 60° and three transoid interactions in the C—C—O—C fragment. Hence the broad resonance centered near 70.2 ppm is deemed to contain unresolved resonances due to C-2,3,5,6,11,12,14, and 15.

For C-8,9,17, and 18 expansion of the O—C—C—O angles to values near 85° is expected to lead to deshielding of the ^{13}C resonances (26). Based on a consideration of the torsional angles, identical chemical shifts are predicted for C-8 and 9, so that the intensity two line at 71.4 ppm is attributed to these carbons. Finally, C-17 and C-18 will likely be the most deshielded and the resonances at 72.5 and 73.2 ppm can be attributed to these sites.

It must be pointed out that in the interpretation of these data, one cannot rule out other contributions to the ^{13}C shifts of the macrocycle such as anisotropic and steric effects of the aromatic rings of the guest LiOPh species, however such influences probably play a lesser role than do the dihedral angle factors.

The solid phase ^{13}C shifts of the phenoxide carbons are also of interest. Since there are no true symmetry elements in the crystal structure, one anticipates twelve resonances in the range of chemical shifts from 100–175 p.p.m. (27). In fact only five are clearly evident. The low intensity signals at ∂_C = 110.0 and 111.9 arise from C-23 and C-30 *i.e.* those sites which are *para* to the carbon-bearing oxygen. At 120.5 is found the resonance for the *ortho* carbons C-21, 25, 28, and C-32, while the *meta* sites resonate near 130.0 ppm. Finally the phenoxide carbons appear at 170.9 ppm. This pattern of chemical shifts suggests that the two aromatic rings are very nearly equivalent in their crystallographic environment. There is, however, non-equivalence between each aromatic moiety as evidenced by the two observed *para* carbon resonances.

For comparison, the ^{13}C CPMAS spectrum of lithium phenoxide itself shows four resonances at ∂_C = 114, 119, 132, and 164. The relative intensities of these lines are 1:2:2:1 as expected on the basis of the above assignments.

From the temperature dependence of these solid state spectra and the dipolar washout temperature, it is also possible to estimate the activation energy for the macrocyclic motion using methods described in our previous work (19, 20). In the present case E_a is ca. 48 kJ/mol.

Solution ^{13}C NMR studies

In dimethoxyethane-d_{10} at 298 K the ^{13}C spectrum of this complex exhibits only five resonances at ∂_C = 167.9, 129.6, 120.1, 114.2, and 71.4 ppm. This is indicative of rapid conformational averaging of all the 18-crown-6 resonances on the NMR timescale as well as rapid rotation about the O—phenyl bond. Upon lowering the temperature to 188 K, the ^{13}C spectra undergo no appreciable changes other than minor temperature-dependent chemical shifts. Thus the aforementioned stereochemical phenomena remain rapid on the NMR timescale at this temperature in solution.

A further point concerns the state of aggregation of these species in solution. The solid phase ^{13}C shifts for the para carbon of the phenoxide moiety are consistent with a phenoxide dimer (7, 28). In solution, however, it has been shown (28) for lithium phenoxide itself that the species present in dimethoxyethane is the tetramer. This possibility cannot be ruled out unambiguously in the present work.

To conclude, a limitation exists in the analysis as presented for the solid phase ^{13}C spectra and their correlation with torsional angles. The X-ray data were obtained at 300 K and these data are employed in an attempt to interpret ^{13}C CPMAS spectra at

temperatures that are nearly 100° lower. Ideally, only X-ray data obtained at comparable temperatures should be utilized, however in the present instance the quality of the crystals prevents this from being carried out.

The liquid chromatographic retention behaviour of 16 diaromatic phenols and chlorophenols (PCB metabolic analogues) on a β-cyclodextrin bonded-phase column was investigated with respect to mobile-phase composition, pH, temperature, and ionic strength. The mechanistic aspects of retention of these compounds on the β-cyclodextrin column were studied and compared to other reversed-phase columns. Comparison is also made to the liquid chromatographic retention behaviour and separation of monoaromatic chlorophenols on the same column. The size, shape, and spatial geometry of each substrate appears to affect retention and selectivity. Most of the evidence suggests that inclusion complex formation, which involves hydrophobic interactions with the interior of the cavity and/or van der Waals interactions of the chlorine substituents with the backbone of the cavity, provides the physical basis for the resolution of these positional isomers. Under certain chromatographic conditions, however, it appears that, for certain congeners, all or part of the molecule is excluded from the cyclodextrin cavity; in such cases a normal-phase or mixed chromatographic mechanism is postulated based on the interaction of the substrates with the secondary hydroxyls on the periphery of the cyclodextrin moieties. The gradient–elution separation of 14 out of 16 of this type of compound on a single chromatogram is also reported and discussed.

Key words: biphenylols, chlorobiphenylols, biphenyldiols, liquid chromatographic retention behaviour, gradient-elution separation, β-cyclodextrin bonded-phase column.

MICHAEL PALEOLOGOU, SONG LI et WILLIAM C. PURDY. Can. J. Chem. **68**, 1208 (1990).

Faisant varier la composition de la phase mobile, le pH, la température et la force ionique, on a étudié le comportement de seize phénols et chlorophénols diaromatiques (analogues de métabolites de BPC) lors de leur chromatographie liquide de rétention dans une colonne remplie d'une phase liée à de la β-cyclodextrine. On a étudié les aspects mécanistiques de la rétention de ces composés sur la colonne de β-cyclodextrine et on les a comparés à ceux d'autres colonnes de phase inversée. On a aussi effectué une comparaison avec le comportement et la séparation par chromatographie liquide de chlorophénols monoaromatiques sur la même colonne. Il semble que la rétention et la sélectivité soient affectées par la grosseur, la forme et la géométrie spatiale de chaque substrat. La plupart des données obtenues suggère que la formation d'un complexe d'inclusion, qui implique les interactions hydrophobes avec l'intérieur de la cavité et/ou des interactions de van der Waals des substituants chlore avec le squelette de la cavité, fournisse la base physique pour la résolution de ces isomères de position. Toutefois, dans certaines conditions chromatographiques, il semble que, pour certains congénères, l'ensemble ou une partie de la molécule est exclu de la cavité de la cyclodextrine; dans de telles conditions, on envisage un mécanisme chromatographique de phase normale ou mixte qui serait basé sur l'interaction du substrat avec les groupements hydroxyles secondaires à la périphérie de la portion cyclodextriné. On rapporte aussi la séparation, sur un seul chromatogramme et en faisant appel à un gradient d'élution, de quatorze des seize composés de ce type et on discute ce résultat.

Mots clés : biphénols, chlorobiphénols, biphényldiols, comportement lors de la chromatographie liquide de rétention, séparation par gradient d'élution, colonne remplie d'une phase liée à la β-cyclodextrine.

[Traduit par la revue]

Introduction

In two previous publications (1, 2) we discussed the liquid chromatographic (LC) retention behaviour and separation of monoaromatic chlorophenols on a β-cyclodextrin (CD) bonded-phase column. It is the purpose of this paper to extend these investigations to diaromatic chlorophenols of a biphenyl-type structure (see Fig. 1). Stable CD bonded phases were first described in the literature in 1984 (3). These packings consist of chiral CD molecules linked to silica gel via a 6- to 10-atom non-nitrogen-containing spacer arm. Both the linkage and the CD are hydrolytically stable under standard LC conditions. The attachment is such that the CD molecules remain physically intact.

Cyclodextrins are torus-shaped cyclic oligosaccharides formed by the action of *Bacillus macerans* amylase on starch. These molecules contain six to twelve glucose units bonded through

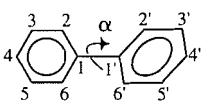

FIG. 1. Biphenyl structure. The numbers indicate the positions of substistituents. α indicates the relative angle between the phenyl rings.

α-(1, 4)-glycosidic linkages. The physical shape of the molecule is that of a truncated cone, with an internal cavity whose dimensions are determined by the number of glucose units. Due to the orientation of the glucose units, there are no hydroxyls on the interior of the cavity thus rendering it hydrophobic.

When using aqueous-organic mobile phases in LC employing CD bonded-phase stationary phases, retention is thought to be predominantly due to inclusion complex formation. The stability of the CD adducts varies markedly with the size of the CD cavity and/or with the structure of the substrate. Hydrogen bonding (4), van der Waals interactions (5, 6), hydrophobic interactions (6, 7), release of high-energy water (5), and com-

binations of these have been proposed to explain inclusion phenomena.

CD-bonded phases were demonstrated to be particularly adept in resolving structural isomers (8) such as the *ortho-*, *meta-*, and *para-* forms of many monoaromatic compounds. We have previously reviewed the LC retention behaviour and separation of monoaromatic chlorophenols (1, 2). A few researchers have investigated the interactions of diaromatic compounds with CD-bonded stationary phases; Fujimura *et al.* (9) and Kawaguchi *et al.* (10) have extensively reported on the retention behaviour and separation of napthalene and substituted napthalenes on diamino-β-CD and ethylenediamine-β-CD bonded-phase columns, respectively. Armstrong *et al.* (11) have described the separation of 80 compounds, including a number of diaromatic analogues, from their isomers using hydrolytically stable β-CD bonded-phase columns obtained from Advanced Separation Technologies, Inc., Whippany, NJ (12). Issaq *et al.* (13), using the same type of column, have examined the effect of mobile-phase composition, temperature, and pH on the retention of a selected group of compounds including napthalene and biphenyl. Finally, Weaver and van Lier (14) have reported the separation of 2-, 3- and 4-hydroxybiphenyls on a β-CD bonded-phase column.

All studies discussed to this point dealt with the LC retention behaviour and/or separation, on a CD bonded-phase column, of structural isomers of relatively small diaromatic molecules with one or two substituents. Here we extend these investigations to structural isomers with more than one or two substituents on the benzene rings. A class of compounds that we found particularly suited for the study of diaromatic phenols and chlorophenols is the chlorinated and non-chlorinated biphenylols and biphenyldiols (PCB metabolic analogues). Sixteen commercially available members of this family of compounds were chosen for our studies (see Table 1). These compounds were chosen because they present a number of distinct features: (*1*) Biphenyl is non-planar in solution (15, 16) and the angle between the two benzene rings is affected by the nature and the position of the substituents (17) (see Fig. 1). Wide stereochemical diversity can exist in biphenyl as a result of its three-dimensional structure, especially when seen in combination with the diversity arising from the degree of substitution and spatial geometry of the substituents on either or both of the benzene rings. (*2*) The largest possible diameter of a chloro-substituted biphenylol is about 7.1 Å which is very close to the diameter of the β-CD cavity (7.8 Å). One would, therefore, expect a close fit for many of these compounds into the cavity. The length of unsubstituted biphenyl is 9.1 Å as compared to 7.8 Å for the length of the cavity. This would allow for maximum interaction with the cavity and possibly hydrogen bonding with the hydroxyls in the periphery of the cavity. (*3*) The pK_a's of the various biphenylol isomers vary depending on the position of the substituents and the number of substituents (see Table 1). Thus by varying the pH of the mobile phase one can examine both the chromatographic behaviour of both the neutral and anionic forms of these compounds. (*4*) There exists a large variation in the solubility of the various biphenylols in common reversed phase mobile phases. This difference is quite substantial between biphenylols and biphenyldiols.

This paper investigates the LC retention behaviour of chlorinated and non-chlorinated biphenylols and biphenyldiols on a β-CD column with respect to mobile-phase composition, pH, temperature and ionic strength. This behaviour is compared with the results previously obtained with the structurally simpler monoaromatic chlorophenols (1). Based on the findings of this study conditions were chosen for the isocratic and gradient-elution separation of these compounds.

Experimental

The LC system consisted of a Waters Model 590 pump, a Rheodyne Model 7125 injector with a 10-μL loop, and a Model Spectroflow 773 variable wavelength uv–vis detector equipped with a 8-μL cell. For the gradient-elution separations an additional Waters Model M-6000 pump was used along with a Waters Model 660 solvent programmer. The chromatograms were obtained by using a Microohm Model SE 120 strip-chart recorder. The column temperature was controlled through a Heto Model 623 water bath.

A Cyclobond I, 250 × 4.6 mm column was obtained from Advanced Separation Technologies (Whippany, NJ). The Cyclobond I column has β-CD chemically bonded to a spherical silica gel support through a five-atom, non-nitrogen-containing spacer arm. The preparation and characterization of this column was fully described elsewhere (12). When not in use, the column was stored in 100% methanol. The column performance appeared to be unchanged for a period of about 3 months.

The effect of pH on the retention time of biphenylols was investigated by changing the pH of the aqueous part of the mobile phase from 4 to 6 using triethylamine–acetate buffers (0.01M). The effect of ionic strength on retention time was examined by varying the concentration of triethylamine buffer (pH = 4.0) in the aqueous part of the mobile phase from 0.01 to 0.1 M. The ionic strength study was performed at pH = 4.0 since at this pH all biphenylols are likely to be in their neutral form. The pK_a of all compounds, was determined from plots of retention time vs. pH on a PRP-1 prepacked analytical column obtained from Hamilton (18), in 60:40 (v/v) methanol:water.

The mobile phase was degassed by bubbling helium into it before use. The flow rate was 1.0 mL/min and the column back-pressures at this flow rate ranged from 1600 to 2200 psi. All compounds were dissolved in methanol to give concentrations of 0.02–0.1 mM. Typically 2 μL of these standard reference compounds were injected. The retention times and elution order were established from consecutive injections of the individual standards. The precision associated with the measured retention times for the various standards ranged from 5–10%. The wavelength utilized for detection was 290 nm. Since almost all ions and molecules, including the typical volume indicators, such as Cl^-, Br^-, I^- etc., partially bind to β-CD, they cannot be directly employed to determine column void volumes or times. For this reason, a special procedure by Hinze *et al.* (19) was used to estimate the void volume of the column which was found to be 3.1 mL at a flow rate of 1 mL/min.

HPLC grade methanol was obtained from Fisher Scientific Co., triethylamine from Aldrich and acetic acid from J. J. Baker Chemical Co. Water was deionized by passing distilled water through a Barnstead Water purification system. Biphenylol, biphenyldiol, chlorobiphenylol, and chlorobiphenyldiol standards were purchased from Chem Service.

Discussion

Effect of mobile-phase composition

The effect of mobile-phase composition on the capacity factor of biphenylols, chlorobiphenylols, and biphenyldiols was investigated by changing the methanol–water ratio in the mobile phase from 40/60 to 100/0 (v/v). In this set of experiments the mobile phase contained no buffer.

It was previously shown that a linear relationship exists between the log of the capacity factor, k, and the volume fraction of methanol in methanol/water mixtures used as mobile phases in reversed-phase chromatography (20–22). The shapes of plots such as these are assumed to be due to structural variations in the solvent system as the concentration of the organic modifier is changed. The fact that in the case of metha-

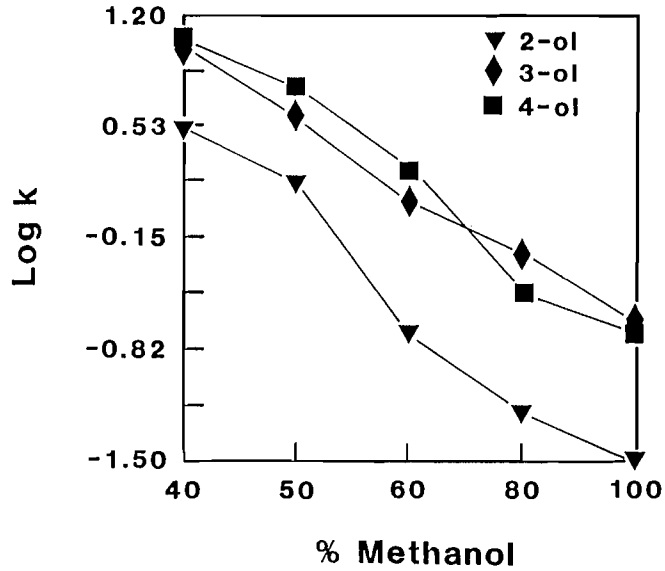

FIG. 2. Effect of mobile-phase composition on the logarithm of the capacity factor for biphenylols. Conditions: column, Cyclobond I (β-cyclodextrin bonded-phase); no buffer was used in the mobile phase; flow rate 1 mL/min; t_o = 3.1 min; ambient temperature.

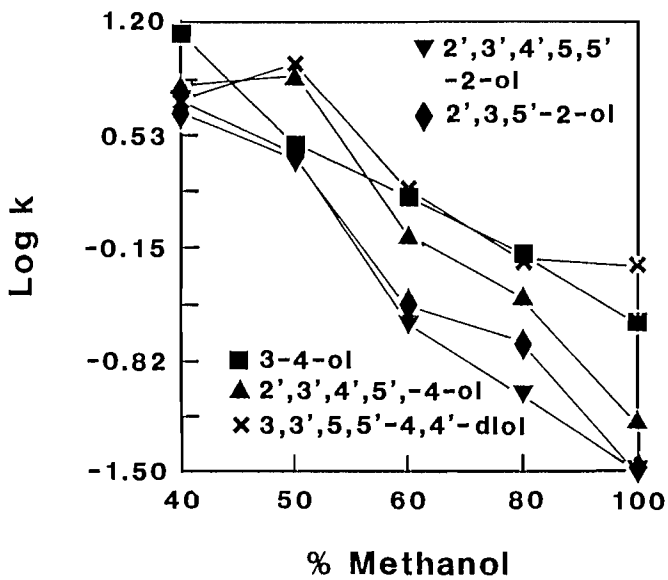

FIG. 3. Effect of mobile-phase composition on the logarithm of the capacity factor for chlorinated biphenylols. Conditions as in Fig. 2.

nol–water mixtures a linear relationship exists over almost the whole composition range was explained in terms of the ability of methanol to act as both a proton donor and acceptor (21).

By plotting log k vs. methanol content in the mobile phase for the various biphenylols, chlorobiphenylols, and biphenyldiols we found that the curves obtained are mostly linear (see Figs. 2–4) as would be expected if a reversed mechanism of retention was in operation. This is not the case, however, for 3,3′,5,5′-tetrachloro-4,4′-biphenyldiol, and 2′,3′,4′,5′ tetrachloro-4-biphenylol (see Fig. 3) which present local maxima at around 50% methanol. These maxima may be taken as suggestive evidence that in CD-bonded-phase chromatography one or more mechanisms of retention, in addition to the reversed-phase mechanism encountered with hydrocarbonaceous bonded-phases (hydrophobic interactions), may be in operation (e.g. van der

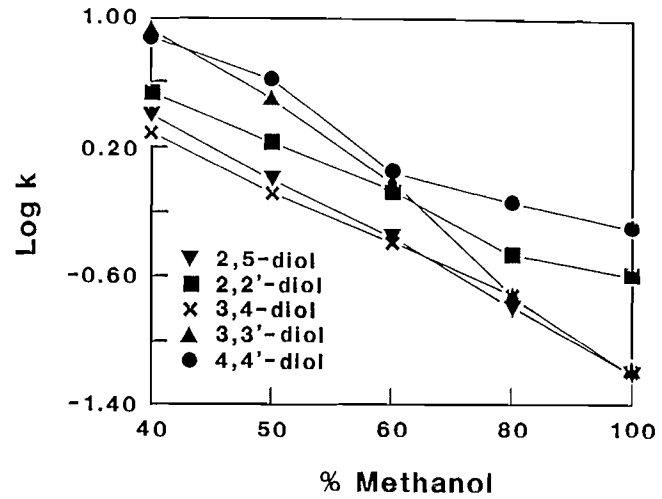

FIG. 4. Effect of mobile-phase composition on the logarithm of the capacity factor for biphenyldiols. Conditions as in Fig. 2.

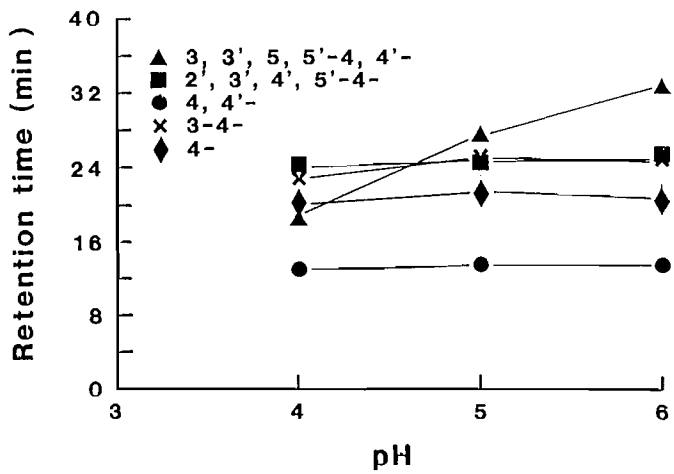

FIG. 5. Effect of pH on the retention time of diaromatic chlorophenols. Conditions: column, Cyclobond I (β-cyclodextrin bonded-phase); mobile phase, 50:50 methanol:water (0.01 M in triethylamine acetate buffer); flow rate: 1 mL/min; t_o = 3.1 mL; ambient temperature.

Waals interactions of the chlorine subtituents with the backbone of the cavity). Similar behaviour was observed by Chang and Wu (23) with nitrophenols, on a γ-CD column, with 2-propanol as the organic modifier and Paleologou *et al.* (1) with highly chlorinated monoaromatic chlorophenols, on a β-cyclodextrin column, with methanol as the organic modifier.

It should also be noted that for all biphenylols and particularly the more highly chlorinated ones, the shape of the peaks was affected by the mobile-phase composition; peaks became sharper (smaller width) as well as more symmetrical as the methanol content increased.

Effect of pH

The effect of pH on the retention time of biphenylols, chlorobiphenylols, and biphenyldiols was investigated by changing the pH of the aqueous part of the mobile phase (50/50: methanol/water) from 4 to 6 using triethylamine buffers (0.01 M). From plots of retention time vs. pH (e.g. see Fig. 5) it appears that for all compounds, except one, there is no change in retention time with pH in the range examined. This situation can be rationalized in terms of the pK_a's of these compounds (see Table 1). It should be pointed here that one can expect marked

effects on the retention as long as the pH of the mobile phase is within one unit of the pK_a of a given compound.

All compounds examined, except one, have pK_a values which exceed the maximum of the pH range examined by more than one pH unit and therefore are expected to remain in their neutral form throughout this range. In the case of 3,3′,5,5′-tetrachloro-4,4′-biphenyldiol, however (see Fig. 5), an increase in retention time is observed with increasing pH. This change can also be rationalized on the basis of the pK_a of this compound (see Table 1) which is quite a bit lower than the rest of the chlorophenols (pK_a = 6.0). It should be remembered at this point that binding to the CD lowers the pK_a's of chlorophenols (24) and therefore brings them closer to the pH range examined. Furthermore, since the mobile phase contains methanol, the apparent pH of the mobile phase is actually higher than that of the aqueous phase (25); these two effects are likely to position the pK_a of 3,3′,5,5′-tetrachloro-4,4′-biphenyldiol well within the limits of the pH range examined; this is probably the reason that the effect of pH on retention begins quite early on (see Fig. 5). The increase in retention time with increasing pH for 3,3′,5,5′-tetrachloro-4,4′-biphenyldiol confirms an earlier observation (1) that the chlorophenolate anions bind to the CD more tightly than the corresponding neutral forms. No reasonable explanation has yet been provided in the literature concerning this unusual phenomenon.

At pH = 4.0 all diaromatic phenols and chlorophenols are expected to be in their neutral form and therefore, valid comparisons can be made between these and the monoaromatic chlorophenols (1), under the same conditions, regarding the extent of their participation in the inclusion process. Table 1 presents the retention times of all diaromatic phenols under these conditions.

The biphenylols elute in the order 4- >3- >2- analogous to the monochlorophenols which also elute in this same order (1). This is likely to be due to the linear geometry of the 4-substituted analogs which allows full penetration into the CD cavity both ways along the axis of symmetry of the molecule (assuming that the aromatic C—OH bond lies on this axis). In such a case the β-CD cavity sees a diameter (projected width) of 4.3 Å and therefore this molecule can very easily enter this cavity from end to end. The 3-substituted analogs, on the other hand, can penetrate the cavity to a limited extent because of the phenyl substituent at the 3-position; in this case the CD cavity sees a diameter of 7.9 Å which is slightly larger than the diameter of the opening of the CD cavity itself. The 2-substituted analogs limit penetration even further because of the closeness of the phenyl substituent to the —OH group since the cavity still sees a diameter of 7.9 Å We previously showed that monoaromatic chlorophenols which have a substituent in the 2- or 6-position, and especially both these positions, present low retention times as compared to 4-substituted monoaromatic chlorophenols (1). Similar behaviour was also observed by Chang *et al.* (26) for the positional isomers of cresol and chlorophenol regardless of mobile phase composition and for nitrophenols when the methanol content in the mobile phase is less than 30%. The validity of these assumptions was confirmed by Armstrong (27) who used X-ray crystal structures (28–30) for the production of computer projected images of inclusion complexes of *o*-, *m*-, and *p*-nitrophenol and other isomers with α-CD as well as β-CD.

The retention time for 4-biphenylol is significantly higher than that of 4-chlorophenol (20.1 vs. 6.5 min). This can be rationalized in terms of the whole molecule (both benzene rings) entering the CD cavity and interacting with it. Since, in fact, one ring is at a slight angle with respect to the other (15, 16), it is likely that the two rings interact differently with the cavity and probably in a complementary fashion. The retention time for 3-biphenylol is also significantly higher than that of 3-chlorophenol (16.3 vs. 6.2 min). If this molecule were to be entering the cavity with the —OH group first, at all times, then one would expect a retention time similar to 3-chlorophenol since only one of the two benzene rings would have entered the CD cavity and this only partially. It, therefore, appears that the cavity can also be entered by way of the unsubstituted benzene ring. The high retention time of 2-biphenylol as compared to 2-chlorophenol (9.4 vs. to 5.8 min) can be rationalized using a similar argument.

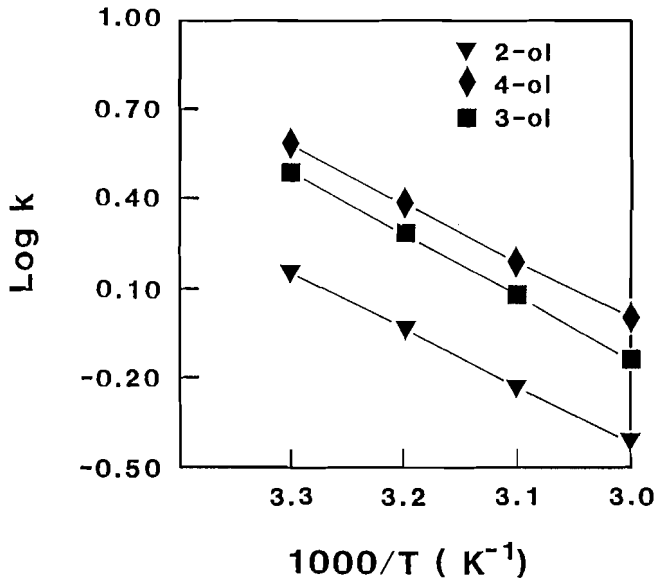

FIG. 6. van't Hoff plot for the retention of biphenylols in the 30–60°C temperature range. Conditions: column, Cyclobond I (β-cyclodextrin bonded-phase); mobile phase, 50:50 methanol:water (no buffer was used in the mobile phase); flow rate, 1 mL/min; t_o = 3.1 mL.

In the case of chloro-substituted biphenylols the following observations can be made regarding their retention behaviour. For 3-chloro-4-biphenylol, for example, the retention time is very similar to 4-biphenylol (22.7 vs. 20.1 min); this may be ascribed to the linear geometry of both these molecules which can allow full penetration into the cavity as illustrated above. The retention time is slightly higher in the former case because of the closer fit of one of the two benzene rings into the CD cavity as a result of the chlorine substituent; the cavity in the latter case sees a diameter of 5.64 Å as compared to 4.26 Å in the former case. Chlorine, as well as other substituents, are also known to affect the angle between the two benzene rings in biphenyl-type compounds (17), thereby leading to a three-dimensional interaction with the cavity. For 2′,3′,4′,5′-tetrachloro-4-biphenylol the retention time is even higher (24.1 min) probably due to the increased interactions between the second benzene ring and the cavity because of its numerous chlorine substituents; the cavity sees a diameter of 7.03 Å in this case, suggesting an almost perfect fit in the cyclodextrin cavity. A similar argument can be made to justify the greater retentions times of 2′,3′,4′,5′-tetrachloro-3-biphenylol (d = 7.03 Å for that part of the molecule that can enter the CD cavity, t_R = 20.5 min) as compared to 3 biphenylol (d = 4.26 Å, t_R = 16.3 min) and 2′,3,5′-trichloro-2-biphenylol (d = 7.03 Å, t_R = 10.7 min) and 2′,3′,4,5,5′-pentachloro-2-biphenylol (d = 7.03 Å, t_R = 12.1 min) as compared to 2-biphenylol (d = 4.26 Å, t_R = 9.4 min). In the case of biphenyls hydroxylated in the 2-position, only one benzene ring is likely to enter the cavity at a time and therefore, these retention times are likely to reflect, to some extent, weighted averages of the retention times of the corresponding monoaromatic chlorophenols and chlorobenzenes.

Effect of temperature

The effect of temperature on the retention time of biphenylols, chlorobiphenylols, and biphenyldiols was investigated in the temperature range 20–60°C with a mobile phase that was 50/50 (v/v) methanol:water. In this set of experiments the mobile phase contained no buffer. In all cases a decline in retention time with increasing temperature is observed (e.g. see Fig. 6 for biphenylols). This is likely to follow the decrease in the binding constant to the β-CD with increasing temperature. The temperature effect appears to increase in the order biphenyldiols<biphenylols<chlorobiphenylols. Moreover, the decline in retention with temperature is quite regular suggesting the same mechanism of retention at different temperatures for any given compound. An exception to this trend is 3,3′,5,5′-tetrachloro-4,4′-biphenyldiol that presents very high retention times for temperatures below 40°C.

The effect of temperature on retention is largely determined by the enthalpy of eluite interaction with the stationary phase. The enthalpy can be evaluated from the slope of van't Hoff plots, that is plots of log k versus the reciprocal of the absolute temperature (31, 32). When the equilibrium for eluite binding by the stationary phase can be written in terms of a single eluite species and a single bound species, then the enthalpy of this particular binding process is easily obtained. Figure 6 presents van't Hoff plots for the three biphenylols. Since all three of these compounds as well as all other diaromatic chlorophenols, except one, present pK_a's significantly above the pH of the mobile phase, a single eluite species and a single bound species is likely to exist. In addition, since these plots are quite linear, it is possible to determine the enthalpy of binding from the slope of the van't Hoff plots. These values are given in Table 1. From the intercept of van't Hoff plots it is theoretically possible to calculate the change in the corresponding entropy as well. This is difficult, however, because with bonded phases the phase ratio cannot be clearly defined (31). Given the relative bulkiness of biphenylols (4.26 Å projected diameter, assuming that one ring enters the cavity) and especially substituted biphenylols (5.64 to 7.03 Å depending on number and position of substituents) in comparison to the diameter of the β-CD cavity (7.8 Å at the front and 6 Å at the back) it is likely that the complexation is mostly governed by enthalpy and not entropy (33). This is because of the increased contribution or van der Waals interactions ($\Delta H<0$, $\Delta S<0$) in the binding process. Among the binding forces proposed for inclusion phenomena only hydrophobic interactions are governed by entropy. These would be of significance only in the case of relatively small substrates. Evidence supporting this hypothesis is also provided by gas chromatography using β-CD as the stationary phase (34) and di- and tri-substituted benzenes as the substrates; the retention and selectivity are quite appreciable despite the complete absence of hydrophobic interactions.

Deviations from linearity do exist for some of these compounds (e.g. 2,5-biphenyldiol, 2′,5′-dichloro-2-biphenylol, 4,4′-biphenyldiol, 4,4′-dichloro-3,3′-biphenyldiol and 3,3′,5,5′-4,4′-biphenyldiol). Non-linear van't Hoff plots in RPC can be expected whenever one of the following three conditions hold (31): (*1*) the eluite exists in two or more forms having different capacity factors; (*2*) the eluite is retained by two or more mechanisms due to the heterogeneity of the stationary phase surface containing more than one type of binding site; (*3*) eluite exists in more than one form and the surface is heterogeneous.

In the case of 2,5-biphenyldiol, for example, the non-linear van't Hoff plot is likely to be due to condition (*2*) being in effect. At T = 40°C ($10^3/T$ = 3.20) a break is observed in its van't Hoff plot. This break is likely to correspond to the dissociation of the CD-2,5-biphenyldiol complex at this temperature. 2,5-Biphenyldiol is not likely to fully enter the cavity because it has a phenyl substituent *ortho*- to one of the hydroxyl groups. Other biphenyldiols (e.g. 4,4′-) present breaks at a higher temperature (50°C) while the remaining ones present quite linear behaviour throughout the temperature range exam-

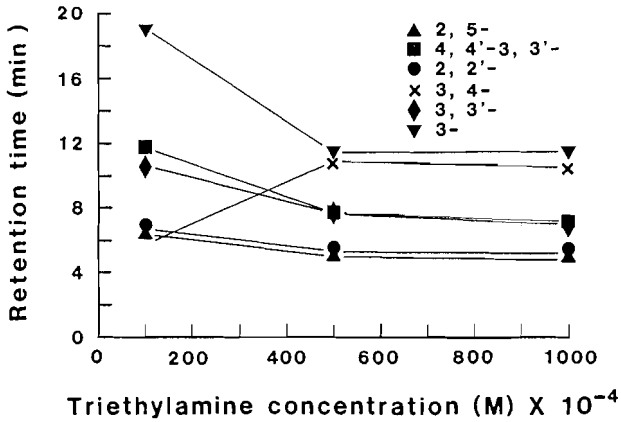

FIG. 7. Effect of ionic strength on the retention time of diaromatic chlorophenols. Conditions: column, Cyclobond I (β-cyclodextrin bonded-phase); mobile phase, 50:50 methanol:water (buffered to pH = 4.0 with triethylamine acetate); flow rate, 1 mL/min; t_o = 3.1 mL; ambient temperature.

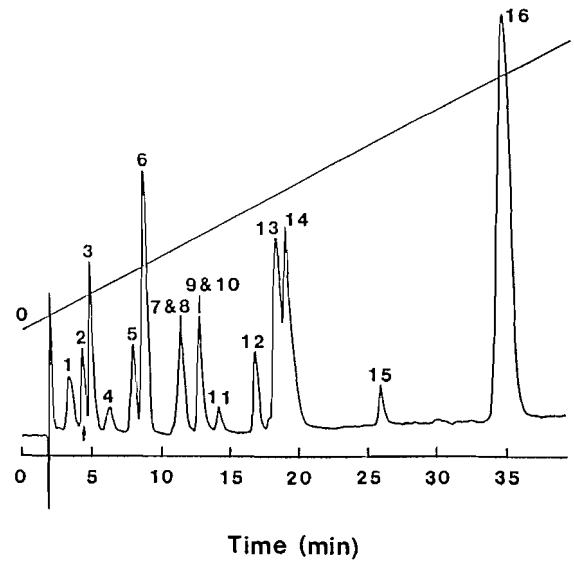

FIG. 8. Gradient elution separation of diaromatic chlorophenols. Bands are identified in Table 1. Conditions: column, Cyclobond I (β-cyclodextrin bonded-phase); mobile phase gradient, 27–73% methanol/aqueous buffer (0.01 M triethylamine acetate, pH = 4.0); flow rate, 1.0 mL/min; T: 50°C; detector, UV at 280 nm.

ined. From the above observations it appears that the inclusion mechanism of retention in CD-bonded phase RPC, affects the shape of van't Hoff plots. Non-linear van't Hoff plots on a β-CD column were also obtained by Issaq *et al.* (13) with various amino acids and Paleologou *et al.* (1) with some monoaromatic chlorophenols.

In the case of 3,3',5,5'-tetrachloro-4,4'-biphenyldiol the van't Hoff plot is also non-linear. The curvature in this plot is likely to be due to condition (3) being in effect since the pK_a of this compound is close to the pH of the mobile phase; this means that the eluite species is likely to exist in two forms (non-ionized and ionized). Since in the case of this compound there was more than one kind of eluite species, the van't Hoff plot yielded the overall retention enthalpy which is a weighted average of the enthalpies for the binding of the species. Similar behaviour was previously observed in the case of most monoaromatic tri-, tetra-, and pentachlorophenols with pK_a's close to the pH of the mobile phase (1). No enthalpies of binding were calculated for those compounds whose van't Hoff plots did not present any appreciable degree of linearity. Selectivity is affected very slightly, if at all, by changing the temperature. In this regard β-CD columns appear to behave like other reversed-phase columns (35).

Effect of ionic strength

The effect of ionic strength on the retention time of biphenylols and chlorobiphenylols was investigated in the concentration range of 0.01 to 0.1 M triethylamine–acetate (for aqueous part of mobile phase pH = 4.0) in a 50/50 methanol:water mobile phase. In the case of biphenyldiols (see Fig. 7) an initial decline in retention is observed in the electrolyte concentration range between 0–0.05 M followed by a plateau in the 0.05–0.1 M range. The effect of ionic strength on biphenylols and chlorobiphenylols is similar to that observed; in the case biphenyldiols, it is, however, more pronounced. An exception to the above behaviour is presented by 3,4-biphenyldiol whose retention increases in the 0.01–0.05 M ionic strength range while stabilizing in the 0.05–0.10M range. This phenomenon is likely to be due to the disruption of intramolecular hydrogen bonding in this compound by increasing ionic strength and the resulting increased interaction of its hydroxyls with the secondary hydroxyls at the periphery of the cavity; as a result of their electrical charge, both the triethylammonium cation and the acetate anion can be expected to be involved in the formation of more powerful hydrogen bonds with a given aromatic hydroxyl as compared to such a bond with an adjacent neutral hydroxyl (36).

Resolution is also affected by ionic strength. The peak shapes of chlorophenols and especially the most chlorinated ones, become sharper (shorter width) and more symmetrical with increasing buffer concentration. The selectivity of the separation of chlorophenols is affected very slightly, if at all, by the ionic strength as evidenced by the absence of any changes in the elution order of chlorophenols with increasing ionic strength. Since the presence of an electrolyte in the mobile phase does not affect the selectivity. it is possible to couple the β-CD bonded-phase column with an electrochemical detector (2).

Horvath *et al.* (37) showed that in RPC employing hydrocarbonaceous bonded phases, increasing ionic strength augments the capacity factors of neutral solutes. This effect has been ascribed to the increasing surface tension of the eluent and the concomitant increase in the energy required for cavity formation (38). As seen in Fig. 7, however, exactly the opposite behaviour is observed in the case of a CD-bonded silica stationary phase. This type of behaviour was previously encountered with monoaromatic chlorophenols as well and was rationalized in terms of the triethylamine cations including into the cavity thus competing with the substrate molecules (1).

Separation

After studying the liquid chromatographic retention behaviour of diaromatic chlorophenols with respect to mobile-phase composition, pH, temperature and ionic strength conditions were chosen for the isocratic separation of these compounds. Even though each category of chlorobiphenylols (2-, 3-, 4-) could be separated into its member components with reasonable resolution and selectivity, significant overlaps existed between the retention time ranges of the various categories which prevented the isocratic separation of all chlorophenols on the same chromatogram. A gradient-elution separation was, therefore, attempted.

Table 1 and Fig. 8 present the retention times and the gradient-elution separation, respectively, of 14 out of the 16 diaromatic chlorophenols within 35 minutes of injection of the mixture.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12
For personal use only.

This separation was achieved with a linear mobile phase gradient of 1%/min increase in methanol (solvent B) beginning with a 27:73 methanol/water (solvent A) mobile phase. The temperature was 50°C, the buffer concentration 0.01 M triethylamine acetate (TEAA) and the pH = 4.0. The design of this gradient was based on our previous experience with the gradient elution separation of monoaromatic chlorophenols on a β-CD column (2). We have thus established in this paper that the well-known selectivity of CD columns can be extended to polysubstituted and non-substituted diaromatic phenols such as the chlorinated and non-chlorinated biphenylols and biphenyldiols.

Received January 18, 1990

This paper is dedicated to Professor Arthur S. Perlin on the occasion of his 67th birthday

JOHN A. FINDLAY, ZHENG-QUEN HE, and BARBARA BLACKWELL. Can. J. Chem. **68**, 1215 (1990).

The structures of three new saponins from the starfish *Asterias forbesi* have been elucidated by spectroscopic means. Forbeside F is the hydrate of the monosodium salt of 6α-*O*-{β-D-fucopyranosyl(1→4)-*O*-[β-D-quinovopyranosyl(1→2)]-*O*-β-D-quinovopyranosyl(1→3)-*O*-6-deoxy-β-D-xylo-hexos-4-ulopyranosyl}-20*S*-hydroxy-3β-sulfo-oxy-5α-cholest-9(11)-en-23-one. Forbeside G is the hydrate of the monosodium salt of 6α-*O*-{[β-D-quinovopyranosyl(1→2)]-*O*-β-D-quinovopyranosyl(1→3)-*O*-6-deoxy-β-D-xylo-hexos-4-ulopyranosyl}-20*S*-hydroxy-3β-sulfo-oxy-5α-cholest-9(11)-en-23-one. Forbeside H is the monosodium salt of 6α-*O*-{[β-D-quinovopyranosyl(1→2)]-β-D-xylopyranosyl(1→3)-β-D-quinovopyranosyl}-20*S*-hydroxy-3β-sulfo-oxy-5α-cholest-9(11)-en-23-one.

Key words: *Asterias forbesi*; forbesides F, G, and H; starfish saponins; sterol glycosides.

JOHN A. FINDLAY, ZHENG-QUEN HE et BARBARA BLACKWELL. Can. J. Chem. **68**, 1215 (1990).

En se basant sur des méthodes spectroscopiques, on a élucidé les structures des trois nouvelles saponines isolées de l'étoile de mer *Asterias forbesi*. Le forbeside F est l'hydrate du sel de monosodium de la 6α-*O*- (β-D-fucopyranosyl(1→4)-*O*-[β-D-quinovopyranosyl(1 → 2)]-*O*-β-D-quinovopyranosyl(1 → 3)-*O*-6-désoxy-β-D-xylo-hexos-4-ulopyranosyl)-20*S*-hydroxy-3β-sulfo-oxy-5α-cholest-9(11)-èn-23-one. Le forbeside G est l'hydrate du sel de monosodium de la 6α-*O*([β-D-quinovopyranosyl(1→2)]-*O*-β-quinovo pyranosyl(1 → 3)-*O*-6-désoxy-β-D-hexos-4-ulopyranosyl}-20*S*-hydroxy-3β-sulfo-oxy-5α- cholest-9(11)-èn-23-one. Le forbeside H est le sel de monosodium de la 6α-*O*([β-D-quinovopyranosyl(1→2)]-β-D-xylopyranosyl(1→3)-β-D-quinovopyranosyl)-20*S*-hydroxy-3β-sulfo-oxy-5α-cholest-9(11)-èn-23-one.

Mots clés : *Asterias forbesi*; forbesides F, G et H; saponines de l'étoile de mer; stérol glycosides.

[Traduit par la revue]

Recently we reported (1, 2) the structures of three major saponins, designated forbesides A, B, and C, from the starfish *Asterias forbesi* (Desor). These were deduced totally by spectroscopic means. We now report the isolation from the same source of three new saponins, two of which, F and G, are structurally related to forbeside C, **1**, and the third, H, to forbeside A, **4**.

The FAB^+ mass spectrum of forbeside F, **2**, displays a prominent pseudomolecular ion at m/z 1159 corresponding to M^+ ($C_{51}H_{83}O_{24}SNa$) + 2H + Na and major fragments at m/z 1039 ($M^+ - NaSO_4 + Na + H$) and 623 (M^+ − aglycone − H + Na). Substantial fragments at m/z 477 (623−146), 331 (477−146), and 185 (331−146) attest to the attachment of three deoxyhexose units. The ^{13}C nmr spectrum indicates a total of 51 carbons, 27 of which were readily assigned to the thornasterol-3-*O*-sulfate aglycone by comparison of chemical shift and multiplicity with those of forbeside C (see Table 1). In addition to featuring four anomeric carbon signals, the downfield region displays signals at δ 90.4 and 92.7 ppm, the unusual chemical shifts associated with carbons 3 and 4, respectively, of the unique hydrated form of the 6-deoxy-xylo-4-hexulose unit as found in forbeside C. A comparison of the remaining chemical shifts shows a remarkably close correspondence of all the carbohydrate carbon signals with those of forbeside C, **1**, except for the signals assigned to the terminal fucose and the signal at δ 81.6 ppm assigned to the glycosidic linked C2 of the non-terminal fucose unit of the latter. Instead, forbeside F displays a signal at δ 73.7 ppm appropriate for C2 of a β-linked fucose unit. Hence we tentatively formulated forbeside F as **2**. Corroboration of this conclusion was obtained from 500 MHz 2D ^1H–^1H COSY and 2D hydrogen carbon correlation (HETCOR)

[a]From ref. 2.
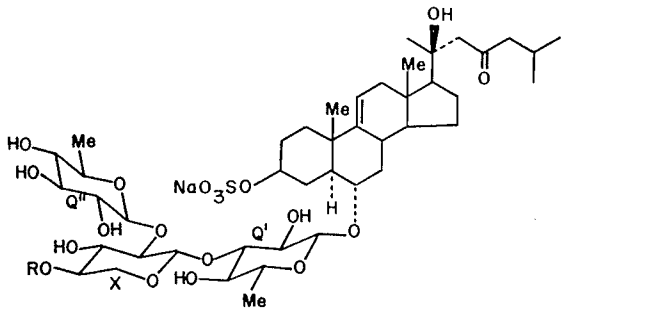
[b]Assignments from 500 MHz ^1H–^1H COSY data.
[c]From ref. 1.

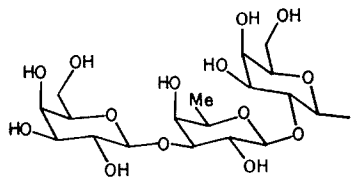
experiments, which permitted rigorous assignment of ^1H chemical shifts for the tetrasaccharide side chain that are in excellent agreement with those assigned to the first four sugars of forbeside C, **1** (Table 2). The assignments and connectivity of the latter were determined by nOe difference experiments in conjunction with ^1H–^1H COSY and 2D relayed coherence transfer (2D-RCT) experiments. Thus forbeside F is the hydrate of the monosodium salt of 6α-*O*-(β-D-fucopyranosyl(1→4)-*O*-[β-D-quinovopyranosyl(1→2)]-*O*-β-D-quinovopyranosyl-(1→3)-*O*-6-deoxy-β-D-xylo-hexos-4-ulopyranosyl)-20*S*-hydroxy-3β-sulfo-oxy-5α-cholest-9(11)-en-23-one, **2**.

Forbeside G displays a weak ion (3%) *m/z* 987 corresponding to M^- ($C_{45}H_{73}O_{20}SNa$) − H and a prominent *m/z* 965 (82%) ion corresponding to M^- − Na in the FAB^- mass spectrum. Other prominent ions at *m/z* 947 (965 − H_2O), 865 (965 − $C_6H_{12}O$ side chain by reverse aldol), 847 (865 − H_2O), 511 (aglycone + H − Na), 493 (511 − H_2O), 411 (511 − $C_6H_{12}O$), and 393 (411 − H_2O) are consistent with formulation **3**. The ^{13}C nmr spectrum revealed the presence of 45 carbons, 27 of which were assignable to the thornasterol-3-*O*-sulfate aglycone and the remaining 18 to the oligosaccharide moiety. As in the case of forbesides C and F, two distinctive signals could be assigned to C3 (δ 90.0 ppm) and C4 (δ 92.7 ppm) of the hydrated form of a 6-deoxy-xylo-4-hexulose unit Z. Examination of the ^1H–^1H COSY spectrum of forbeside G permitted assignment of ^1H signals for each of the quinovose units Q', Q'' and unit Z. HETCOR data allowed assignment of the ^{13}C signals for the trisaccharide side chain. The close correlation of ^{13}C and ^1H signals with their counterparts in forbesides C and F except for Q'4 leaves no doubt that forbeside G possesses structure **3**, the hydrate of the monosodium salt of 6α-*O*-{[β-D-quinovopyranosyl(1→2)]-*O*-β-D-quinovopyranosyl(1→3)-*O*-6-deoxy-β-D-xylo-hexos-4-ulopyranosyl}-20*S*-hydroxy-3β-sulfo-oxy-5α-cholest-9(11)-en-23-one.

The base peak of the FAB^- mass spectrum of forbeside H is at *m/z* 935, corresponding to M^- ($C_{44}H_{71}O_{19}SNa$) − Na. Significant ions also appear at *m/z* 957 (M^- − H), 835 (935 − $C_6H_{12}O$), 917 (935 − H_2O), 511 (aglycone + H − Na), 411 (511 − $C_6H_{12}O$), and 393 (411 − H_2O) showing parallel fragmentation to that of forbeside G. Inspection of the ^{13}C nmr



4, FORBESIDE A R =



5, FORBESIDE H R = H

spectrum showed the high field region to be identical to that of forbeside G (see Table 1); thus they must share the same aglycone. Confirmation of a trisaccharide side chain in forbeside H was confirmed by the presence of signals for three anomeric protons plus signals appropriate for two 6-deoxy hexose units and a pentapyranose in addition to those assigned to the aglycone. The 500 MHz ^1H–^1H COSY data allowed assignment of ^1H chemical shifts for each sugar unit and allowed their identification as two quinovose units and a xylose moiety from signal multiplicity and J values. A HETCOR experiment permitted assignment of ^{13}C signals in the trisaccharide chain and revealed the location of interglycosidic linkages via glycosylation shifts. Comparison of ^{13}C chemical shifts with those assigned to forbeside A showed a close correlation for all signals due to the aglycone and the first three sugars except for the X4 signal, which appears at δ 79.4 ppm in the latter since it is a site of interglycosidic linkage and at δ 69.5 ppm in forbeside H. Thus we conclude that forbeside H has structure **5**, the monosodium salt of 6α-*O*-{[β-D-quinovopyranosyl(1 → 2)]-β-D-xylopyranosyl(1→3)-β-D-quinovopyranosyl}-20*S*-hydroxy-3β-sulfo-oxy-5α-cholest-9(11)-en-23-one.

We are not aware of any previous reports of asterosaponins possessing a tetrasaccharide side chain and the only previously reported steroidal trisaccharides of starfish origin appear to be the sepositoides A, B, C, and D from *Echinaster sepositus*, which feature a three-sugar chain cyclized between C3 and C6 and lack sulfate moieties (3).

Experimental

The nmr spectra were recorded on Varian 200 and Bruker AM-500 NMR spectrometers using tetramethylsilane as internal reference. $^1H/^1H$ correlation (COSY) spectra were acquired as 512 FLO's of 2K data points and 3.3 kHz spectral window, using a 90° pulse of 22 μs and a recycle time of 3.3 s. Spectra were processed using sine-bell squared functions shifted π/4 in F1 and were zero-filled in F1 for a final digital resolution of 3.2 Hz/pt. $^1H/^{13}C$ correlation (HETCOR) spectra were acquired as 256 F10's of 4K data points with a 3 s recycle time and 14 kHz and 2.8 kHz spectral windows in F2 (^{13}C) and F1 (^1H), respectively. The data matrix was zero-filled in F1, processed using sine-bell squared functions shifted π/2 in F2 and π/4 in F1, and plotted as power spectra. FAB mass spectra were recorded on a Kratos MS50 instrument using Xenon as ionizing gas. Optical rotations were measured on a Perkin Elmer 241 polarimeter. Preparative tlc was performed with precoated silica gel F254 (1 mm) and KC18F reverse phase (0.25 mm) plates.

Isolation of forbesides F, G, and H

The starfish, *Asterias forbesi*, were collected at Indian Point, Bay of Fundy, Canada, on September 26, 1988, and frozen. The frozen animals (20 kg, wet wt) were defrosted and cut into small pieces and extracted with cold methanol (40 L). The total aqueous methanolic extract was filtered and the filtrate was concentrated on a rotary evaporator at 30°C. The aqueous extract thus obtained (4 L) was passed through a column of Amberlite XAD-2 (1 kg, 30–50 mesh). The column was washed with distilled water (2 L) and then eluted with methanol (4 L). The methanol eluate was concentrated to small volume (250 mL) and then treated with cold acetone (2.5 L) to give the crude glycoside mixture (12 g, yellow powder).

The crude glycoside mixture (10 g) was dissolved in $CHCl_3/CH_3OH/H_2O$ (66:44:5), filtered, and the filtrate was chromatographed on a silica gel (500 g, 230–400 mesh) column and eluted with the same solvent system, yielding 15 fractions. Fraction 3 afforded the previously reported (4) forbesides E1, E2, and E3. Fraction 4 (248 mg) was rechromatographed on ptlc plates (1 mm, 50 mg/plate) using the solvent system *n*-BuOH/EtOAc/H_2O (5:1:1) to yield forbeside F (36 mg) and a mixture of forbesides G and H (62 mg). By similar treatment, fraction 5 (300 mg) yielded forbeside E (30 mg) (6), forbeside F (50 mg), and a mixture of forbesides G and H (50 mg). The pure forbesides G (50 mg) and H (40 mg) were finally obtained by successive column chromotography over a Merck Lichroprep RP-18 reverse phase column (20 g) using CH_3OH/H_2O (7:3) as solvent, followed by purification on reverse phase ptlc using the same solvent system. Forbeside A (600 mg) was obtained from fraction 13 by repeated silica gel column chromatography.

The electrocatalytic hydrogenation (ECH) of phenanthrene, anthracene, and naphthalene has been investigated under constant current at Raney nickel electrodes in a mixed aqueous organic medium. The influence of various parameters on the efficiency of the process determined by the current efficiency (a measure of the competition between hydrogenation and hydrogen evolution, the only two electrochemical processes occurring), the extent of hydrogenation (yield of octahydro-derivatives), and the conversion rate was studied with phenanthrene. The best conditions were ethylene glycol or propylene glycol as cosolvent containing between 1.5 to 5% of water, a neutral or slightly acidic medium containing boric acid (0.1 M) as buffer (initial pH of 2.6, final pH of 6.0–6.2), sodium chloride or tetrabutylammonium chloride as supporting electrolyte, a temperature of 80°C, and a current density of 42 to 84 mA/cm^2. The most active electrodes (consisting of Raney Ni particles dispersed in a nickel matrix and surrounded by a layer of porous nickel) were obtained by leaching the dispersed alloy particles at 75°C for 7 h in 30% aqueous sodium hydroxide. The electrohydrogenation stopped at derivatives with a single aromatic ring, namely the octahydrophenanthrenes, octahydroanthracenes, and tetralin. In a non-buffered medium, tetrahydrophenanthrene could be obtained with selectivities of 80% or better.

Key words: electrocatalytic hydrogenation, Raney nickel electrodes, phenanthrene, anthracene, naphthalene.

On a étudié l'hydrogénation électrocatalytique (HEC) du phénanthrène, de l'anthracène et du naphtalène à courant constant sur des électrodes de nickel de Raney en milieu eau-solvant organique. L'étude de l'influence de divers paramètres sur l'efficacité de l'électrohydrogénation du phénanthrène déterminée par l'efficacité de courant (une mesure de la compétition entre hydrogénation et dégagement d'hydrogène, les deux seuls processus électrochimiques observés), le degré d'hydrogénation (rendement en octahydrophénanthrènes) et le taux de conversion, a conduit à définir les meilleurs conditions, soit : l'éthylène glycol ou le propylène glycol contenant entre 1,5 et 5% d'eau comme solvant, un milieu neutre ou légèrement acide contenant de l'acide borique (0,1 M) comme tampon (pH initial de 2,6–2,7 et pH final de 6,0–6,2), le chlorure de sodium ou de tétrabutylammonium comme électrolyte-support, une température de 80°C et une densité de courant de 42 à 84 mA/dm^2. Les électrodes sont faites de particules de nickel de Raney dispersées dans une matrice de nickel et entourées d'une couche de nickel poreux. Les plus actives provenaient d'une lixiviation des particules d'alliage précurseur à 75°C pendant 7 h dans de l'hydroxyde de sodium à 30%. L'électrohydrogénation s'est arrêtée aux dérivés possédant un seul noyau aromatique, soit les octahydrophénanthrènes, les octahydroanthracènes et la tétraline. En solution non tamponnée, on a obtenu le tétrahydrophénanthrène avec des sélectivités égales ou supérieures à 80%.

Mots clés : hydrogénation électrocatalytique, électrodes de nickel Raney, phénanthrène, anthracène, naphtalène.

Introduction

The electrocatalytic hydrogenation (ECH) of an unsaturated organic molecule in aqueous or mixed aqueous-organic media involves first the formation of chemisorbed hydrogen at a cathode with a low hydrogen overvoltage (transition metal) by reduction of water or hydronium ion (reaction [1] where M is the metallic surface and (H)M chemisorbed hydrogen). Hydrogenation then proceeds as in catalytic hydrogenation, that is by reaction of the adsorbed substrate (Y=Z)M, with chemisorbed hydrogen (reactions [3] and [4]).

[1] $2H_2O(H_3O^+) + 2e^- + M \rightarrow 2(H)M + 2OH^-(H_2O)$

[2] $Y{=}Z + M \rightarrow (Y{=}Z)M$

[3] $(Y{=}Z)M + (H)M \rightarrow (\dot{Y}{-}ZH)M$

[4] $(\dot{Y}{-}ZH)M + (H)M \rightarrow (YH{-}ZH)M$

[5] $(YH{-}ZH)M \rightarrow YH{-}ZH + M$

Electrocatalytic hydrogenations have been carried out since the beginning of the century (4–7). It has been suggested quite early that electrochemical reductions in aqueous media, on cathodes of spongy transition metals, might involve reaction of the unsaturated substance with adsorbed hydrogen (8). This has been confirmed in a number of mechanistic studies of ECH at Raney nickel (9–11), at nickel black (12, 13), at platinized platinum (Pt/Pt) (10, 12–21), at PTFE-bound platinum black (22, 23), at smooth platinum (24, 25), at Raney platinum iridium (26), at PTFE-bound palladium black (27), and at Raney ruthenium–iridium (28).

ECH has the following advantages over catalytic hydrogenation. Firstly, the kinetic barrier due to the splitting of the hydrogen molecule is completely bypassed, as is the mass transport of the poorly soluble hydrogen molecule. Thus the use of hydrogen gas, elevated temperatures and pressures can be avoided. Secondly, the fact that a cathodic potential is applied to the catalyst in ECH can in some cases diminish or even prevent the adsorption of poisons (3, 10, 11). A limitation of the ECH method with substrates that are difficult to hydrogenate comes from the competition between hydrogenation (steps [3]

[1]Part IV in the series "Electrocatalytic hydrogenation of organic compounds". For parts I, II, and III, see refs. 1, 2, and 3.

and [4]) and the formation of molecular hydrogen from chemisorbed hydrogen (reactions [6] and/or [7], respectively the Heyrovský and Tafel steps of the hydrogen evolution reaction (29)) (9, 10, 30).

[6] $H(M) + H_2O + e^- \rightarrow H_2 + M + OH^-$

[7] $H(M) + (H)M \rightarrow H_2 + M$

When compared to electrohydrogenation by the electronation–protonation (EP) process (reactions [8] to [11]), ECH has the

[8] $Y{=}Z + e^- \rightarrow [Y{=}Z]^{\cdot -}$

[9] $[Y{=}Z]^{\cdot -} + H_2O \rightarrow \dot{Y}{-}ZH + OH^-$

[10] $\dot{Y}{-}ZH + e^- \rightarrow \ddot{\overline{Y}}{-}ZH$

[11] $\ddot{\overline{Y}}{-}ZH + H_2O \rightarrow YH{-}ZH + OH^-$

advantage of requiring less energy. Indeed the formation of chemisorbed hydrogen by reduction of water on a low hydrogen overvoltage cathode (reaction [1]) requires a less negative potential than the electronation (reaction [8]) of most functional groups of organic chemistry (at the exception of the nitro group family).

The advantages of ECH over catalytic hydrogenation and direct electrochemical reduction (EP process)[3] make it a method of general interest for the hydrogenation of functional groups in organic molecules. For example, electrohydrogenations of interest in synthesis have been reported at various high area catalytic electrodes: nickel (1–3, 7, 9–11, 33–44), platinum (4, 6, 10, 21, 30, 44–51), palladium (4, 5, 30, 34, 35, 44, 50), and rhodium (30, 44). The functional groups electrohydrogenated include triple bonds (33, 37, 38), double bonds (4, 7, 34, 37, 41, 42), aromatic rings (1, 5, 6, 21, 30, 45–48), carbonyl groups (1, 9, 10, 16, 37, 40, 44, 49–51), imines (1, 37, 44), oximes (37), nitriles (35, 37, 44), heterocycles (36, 40), nitro groups (hydroxylamines) (1–3, 37), hydrazines (2), and bromides (42).

The efficiency of electrocatalytic hydrogenations is determined by the competition between hydrogenation (reactions [3] and [4]) and hydrogen evolution (reactions [6] and/or [7]). The relative rates of these two processes are affected by the strength of the bond to be hydrogenated and by a number of factors which influence the adsorption of the organic substrate, the coverage of the electrode by chemisorbed hydrogen, and/or the activity of chemisorbed hydrogen such as the electrode material (17, 30, 44), the electrode surface and, for a given electrode, the current density (polarization of the electrode) (44), the concentration of the substrate (9–11, 30), the pH of the solution (9, 31), the organic cosolvent (30) and the presence of any molecule that can be adsorbed on the electrode (11), the supporting electrolyte, and the temperature (36).

In this paper, we report the results of a study of the influence of the electrode activation and electrolysis conditions (pH, buffer, supporting electrolyte, solvent, temperature, current density) on the ECH of phenanthrene at a Raney Ni cathode. Anthracene and naphthalene were also electrohydrogenated under the best conditions found with phenanthrene.

Results and discussion

The electrohydrogenations were carried out on a 1 mmol scale, at constant current, on electrodes consisting of Raney Ni particles embedded in a Ni matrix (see below), and were stopped after the passage of the charge required for complete hydrogenation of the substrate. The catholyte was analysed by vapour phase chromatography (vpc). The 100% mass balance obtained in the vast majority of experiments show that the sole process competing with hydrogenation (reactions [3] and [4]) was hydrogen evolution (reactions [6] and/or [7]). The current efficiency is then a measure of the relative importance of the two processes. The current efficiency diminished gradually as the electrolysis proceeded due to the diminution of the rate of hydrogenation with the concentration of the substrate (9–11, 30). Because the freshly activated Raney Ni electrodes were filled with adsorbed-hydrogen, generally between 0.7 to 1.1 mmol of active hydrogen depending on the amount of catalyst as shown by open-circuit (catalytic) hydrogenations (see below), the current efficiency was usually higher than 100% up to a charge of 3 F/mol under the best conditions. The potential of the working electrode was measured at a current density of 84 mA/dm^2 (geometric area) in ethylene glycol – water 98.5:1.5 (v/v). It corresponds to the potential for reduction of the medium to hydrogen and varied with the pH and temperature as expected. Thus, it was less negative (reduction of water easier) at pH 2.6 (0.1 M H_3BO_3), −0.7 V against the saturated calomel electrode (SCE), than in alkaline medium (0.3 M (n-Bu)$_4$NOH), −1.0 V vs. SCE (T = 80°C). And it was less negative at higher temperatures, −0.7 V at 80°C and −0.85 V vs. SCE at 50°C (pH 2.6).

The working electrodes were prepared in the following way. First, particles of Raney alloy were suspended in a nickel bath and electroplating was carried out on a stainless steel grid to give a coating consisting of particles of alloy embedded in deposited nickel (1, 52). The Raney nickel electrode was then obtained by leaching out the aluminum in aqueous sodium hydroxide according to procedures described for the different preparations of Raney Ni (53). Scanning electron microscopic studies before and after leaching have shown that the particles of Raney alloy, and of Raney nickel after leaching, are held in a nickel matrix, each particle being surrounded by a layer of nickel (54). This nickel layer must be porous since leaching of the alloy did occur through it as shown by analysis of Ni and Al by X-ray powder diffraction (XRPD) before and after leaching (54).

ECH of phenanthrene

We studied the influence of the cathode activation, the pH of the solution, the buffer, the supporting electrolyte, the solvent, the temperature, and the current density on the efficiency of the ECH of phenanthrene (**1**). The products observed were 9,10-dihydrophenanthrene (**2**), tetrahydrophenanthrene (**3**), and the octahydrophenanthrenes **4** (asymmetric) and **5** (symmetric). The efficiency of electrohydrogenation was evaluated from the

[a]Electrolysis conditions: 1.1 mmol of phen (9 mM); 0.29 M $NaBF_4$; pH = 6 (initial) to 8 (final); T = 80°C; J = 42 mA/dm^2 (geometric area); charge passed (Q) = 7–8 F/mol.

[b]Amount of Raney alloy 0.7–0.8 g (58–62% of alloy in the matrix).

[c]The conversion rate and yield of products were determined by glc analysis. The yields are based on converted phenanthrene. Material balance ≥99%.

[d]By X-ray fluorescence.

[e]The Raney alloy electrode was immersed in the NaOH bath at 25°C then the bath was heated to 75°C on a hot plate.

[f]The electrode (0.6 g of alloy, 54%) was rinsed under an atmosphere of H_2 after leaching.

current efficiency, the extent of hydrogenation (the yield of octahydrophenanthrenes), and the conversion rate. The best conditions should give the highest current efficiency together with the best yield of octahydrophenanthrenes at high conversion (~100%).

The cathode

The effect of the particle size of the precursory alloy, of the quantity of Raney Ni (proportional to the quantity of deposited alloy), and of the conditions of leaching on the efficiency of electrohydrogenation of phenanthrene was investigated. Changing the range of the size of particles from 38–125 μm, to 53–106 μm, then to 45–75 μm had no detectable effect.

Increasing the quantity of Raney alloy from 0.71 g (55% of alloy in the matrix) to 1.2 g (69%)[4] caused an increase of the current efficiency from 40 to 47% and of the yield of octahydrophenanthrenes from 43% to 65%. The charge passed was 14 F/mol and the conversion of phenanthrene was 97–100% under the conditions used (ethylene glycol – water 98.5:1.5 (v/v); 0.1 M NaCl; 0.1 M H_3BO_3; pH = 2.7 (initial) to 6.0 (final), T = 80°C; J = 84 mA/dm^2 (geometrical area)). By increasing the surface of the support, for instance by using a reticulated vitreous carbon support, it was possible to increase the amount of alloy to 3 to 4 g (60 to 68% of alloy in the matrix). This resulted in a further increase of the current efficiency to 50–56% after complete conversion of phenanthrene (Q = 14 F/mol) and of the yield of octahydrophenanthrenes to 100% (**4**/**5** = 0.8 to 0.9). However, the material balance dropped to 70% due to loss of material by adsorption on the catalyst. The latter type of electrodes was not used for the studies reported below. With the first type of electrodes (stainless steel grid support), the electrohydrogenations were quite reproducible. For instance, four electrolyses on electrodes containing similar amounts of Raney Ni (from 0.75 to 0.85 g of deposited alloy (58–60%)) gave current efficiencies in the range of 42–44% and yields of octahydrophenanthrenes varying from 55 to 58%.

[4]On a given support, the percentage of alloy in the nickel matrix was usually higher, the larger the amount of deposited alloy, but not always.

Table 1 reports the results of a study of the influence of leaching on the efficiency of the electrohydrogenation of phenanthrene. Because the particles of alloy are covered with a layer of porous nickel, leaching required more forceful conditions (longer reaction time and/or higher temperature) than those reported for the preparations of Raney Ni from powdered Raney alloy (53). At an unactivated (unleached) electrode, hydrogen evolution was the sole process observed (Table 1, entry 1). Leaching at 50°C for 1 h in 30% aqueous NaOH (w/v) led to very little hydrogenation (entry 2). Immersing the electrode in the NaOH solution at 25°C then digesting at 75°C for 17 h (entry 4) produced an electrode with the same efficiency as one prepared by immersion at 75°C then digested at that temperature for 7 h (entry 5). A shorter leaching time (entry 3) or a higher temperature of leaching (entries 6 and 7) gave less efficient electrodes. The most efficient electrodes had the smallest content of aluminum together with a specific area of 20–21 m^2/g (entry 5). The decrease of efficiency at higher temperatures of leaching (entries 6 and 7) appears related mainly to a decrease in the specific area. Indeed, Freel *et al.* (55) have shown that the specific area of powdered Raney Ni decreases upon increasing the temperature of leaching above 100°C due to an increase of the size of the pores. The least active Raney nickel catalysts (W1 and W8) are obtained by leaching at temperatures above 100°C (53).

The most active form of powdered Raney Ni (W6) is prepared by leaching at 50°C followed by washing under H_2 atmosphere (53). However, an electrode rinsed under H_2 after leaching and immediately immersed into the cell showed no improvement of efficiency (entry 8). The smaller conversion rate, current efficiency, and percentage of octahydrophenanthrenes in entry 8 as compared to entry 5 probably reflects the smaller quantity of Raney Ni on the electrode.

We studied the effect of passing a charge of 400 coulombs (hydrogen evolution) before adding the substrate and found that there was practically no effect on the efficiency. Open-circuit hydrogenation (catalytic hydrogenation) of phenanthrene showed that an electrode (0.76 g of alloy, 57%) on which hydrogen was evolved contained about 0.48 mmol of active hydrogen

and an electrode (0.68 g of alloy, 59%) used without evolving hydrogen contained a little more, 0.66 mmol.

A Raney Ni electrode stored in dilute aqueous sodium hydroxide (0.1 to 1 M) for a month was almost as efficient as an electrode used immediately after leaching. The loss of efficiency was important, however, when the electrode was kept in absolute ethanol. The Raney Ni catalysts are usually stored in 0.1 M aqueous sodium hydroxide or in absolute ethanol. Loss of catalytic activity was observed when powdered Raney Ni was kept in absolute alcohol (56).

Although repeated use of the same electrode does lead to some loss of efficiency, the lifetime of electrodes made of Raney Ni particles embedded in a nickel matrix is much longer than that of an electrode made of powdered Raney Ni (37, 39–44).[5] A rapid loss of activity was reported for the latter type of Raney Ni electrodes and it was attributed to the agglomeration of the finely divided (dark) powder into larger size particles (lighter in colour) (58). In catalytic hydrogenation, agglomeration of powdered metal catalysts is a well known deactivation process (59). The agglomeration of catalyst particles dispersed in a metallic matrix, if not prevented completely, is considerably slowed down (2).

pH and buffer

As shown in reaction [1], the ECH process produces hydroxide ions at the surface of the cathode so the pH near the surface is most probably higher than in the bulk solution and the pH of an unbuffered electrolysis medium increases as the electrolysis proceeds. The effect of pH of the bulk solution on the efficiency of ECH of phenanthrene was investigated and the results are reported in Table 2. In an alkaline medium (0.3 M (n-$Bu)_4NOH$ as supporting electrolyte, entry 1), the efficiency was very poor even after the passage of only 4 F/mol.[6] At pH 10–12, the results were better (entry 2). The efficiency was improved further by commencing the electrolysis at lower pH values (entries 3 to 5). Thus, contrary to catalytic hydrogenations over Raney Ni (60) and to ECH of acetone at Raney Ni (9), ECH of phenanthrene becomes less efficient as the basicity increases. The addition of a weak acid at concentrations of 0.05 to 0.1 M allowed to keep the pH below 10 up to a charge of 14 F/mol (entries 5 to 12). The use of a carboxylic acid had a detrimental effect on the efficiency of ECH as shown by the lower conversion rates and current efficiencies in entries 6 to 9 as compared to entry 5, acetic acid (entry 9) being the least detrimental. However, the uses of boric acid to buffer the solution (entries 10 to 13) led to an appreciable improvement of the efficiency of the hydrogenation process as seen from the high conversion of phenanthrene, the higher current efficiencies, and better yields of octahydrophenanthrenes. The optimum concentration of boric acid was in the range of 0.05–0.1 M (entries 10 and 11). At higher concentrations, the hydrogenation efficiency did diminish (entries 12 and 13). The concentration of boric acid had also an effect on the ratio of asymmetric-to-symmetric octahydrophenanthrenes (see entries 10 to 13).

The negative influence of organic carboxylic acids can be explained by their adsorption on Raney Ni, adsorption strong enough to displace phenanthrene. A decrease in the concentration of adsorped phenanthrene would thus lead to a decrease in the rate of hydrogenation (reactions [3] and [4]) and to a lower

[5]Under continuous operation conditions (flow cell), there was no significant loss of activity after 200 h of electrolysis for the ECH of various organic substrates (2, 57).

[6]Better results were reported for the ECH of phenanthrene in ethanol–water 67:33 (v/v) containing (n-$Bu)_4NOH$ at room temperature for a charge of 6 F/mol (1): 94% conversion; 36% of **2**, 44% of **3**, and 6% of **4** + **5**; current efficiency of 46%.

[c]Taken from Table 2, entry 11.

[d]pH = 4.3–6.5. Phosphoric acid was added to bring down the initial pH to 4.3.

[e]No H_3BO_3 present since Na_2SO_4 was not soluble enough in 98.5:1.5 (v/v) ethylene glycol – water containing H_3BO_3: pH = 3.0–11.8; J = 43 mA/dm^2.

efficiency of the ECH process. The positive influence of boric acid could be related to an activation of the hydrogenation process (reactions [3] and [4]) and/or to an inhibition of hydrogen evolution (reactions [6] and/or [7]) due to a pH effect or to other effects which have to be investigated. At concentrations higher than 0.1 M, adsorption of boric acid could become important enough to slow down the hydrogenation process.

Supporting electrolyte

As shown in Table 3 for the NaX series (entries 1 to 4), the efficiency of ECH of phenanthrene depends on the anion of the supporting electrolyte and decreases in the order NaCl > NaBr >> NaH_2PO_4 >> NaI. This order most probably reflects the increasing strength of adsorption of the anions on Raney Ni, that is the increasing tendency to poison the catalyst. Chloride ions have been reported to poison Raney Ni in the catalytic hydrogenation of styrene (61). Furthermore, the rate of catalytic hydrogenation of organic halides on Raney Ni has been shown to decrease in the order chlorides > bromides >> iodides (61) and this could be due to poisoning of the catalysts by the halide ions produced in the hydrogenolysis (62), the poisoning effect of the soft iodide ions being much greater than that of the bromide or chloride ions. Open circuit experiments under the same conditions as those used for the electrolyses of phenanthrene confirmed the inhibiting effect of chloride ions in catalytic hydrogenation and showed the strong inhibiting effect of iodide ions. In the absence of halide ions, of the 1.1 mmol of phenanthrene initially present, 33% was hydrogenated and 1.15 mmol of active hydrogen was consumed to give 5% of **2** and 28% of **3**. In the presence of 0.1 M sodium chloride, 15% of phenanthrene was hydrogenated and only 0.5 mmol of hydrogen was used to give 3% of **2** and 14% of **3**. In the presence of 0.1 M sodium iodide, no hydrogenation occurred at all. Sulfate anions are probably not adsorbed on Raney nickel and the fact that sodium chloride (entry 1) was as efficient as sodium sulfate (entry 8) as supporting electrolyte shows that the application of a cathodic potential to the catalyst must diminish considerably or even prevent the adsorption of chloride ions, and in general the adsorption of poisons that are not too strongly adsorbed (3, 10, 11). This constitutes an advantage of ECH over catalytic hydrogenation as pointed out in the Introduction. The lower efficiency of ECH in entry 8 as compared to entry 1 probably reflects the absence of boric acid. Sodium sulfate was not soluble enough in the electrolysis medium containing 0.1 M boric acid.

The cation of the supporting electrolyte appears to have little effect on the efficiency of ECH as seen from entry 1 and entries 5 to 7 of Table 3. The efficiency decreases slightly in the order (n-Bu)$_4$NCl ≥ NaCl ≥ KCl > Me_4NCl.

For the electrolyses of Table 1, sodium tetrafluoroborate (0.29 M) was used as supporting electrolyte. Under the electrolysis conditions, it was rapidly hydrolysed to boric acid and hydrofluoric acid (reaction [2]) as shown by potentiometric titration. This explains why the pH varied little (between 6 and 8) during the electrolyses (Q = 7–8 F/mol). The supporting electrolyte was then sodium fluoride. The ECH was quite efficient (see entry 5 of Table 1) since boric acid was present and fluoride ions should not be adsorbed strongly on Raney Ni (even in the absence of a negative potential).

[12] $NaBF_4 + 3H_2O \rightarrow B(OH)_3 + 3HF + NaF$

Solvent

The best organic cosolvents are those that are less organic as found also for the ECH of phenol at a Pt/C or Rh/C cathode (30). For instance, very little hydrogenation of phenanthrene was observed with THF as cosolvent (current efficiency ~5% after Q = 4 F/mol) and little hydrogenation was observed with tertiobutanol (current efficiency ≤15%). This is most probably due to the adsorption of the organic solvent competing with the adsorption of the organic substrate as found with organic acids (see above). The effect is to diminish the effective concentration of adsorbed substrate and thus to inhibit the hydrogenation process (reactions [3] and [4]). The results of Table 4 show that ethylene glycol is superior to methanol as cosolvent (entries 1 and 2). Propylene glycol is as good as ethylene glycol (entries 4 and 5) whereas diethylene glycol is less good (entry 3) probably because it is more strongly adsorbed on Raney Ni and/or more viscous. The results of entries 5 to 8 also show the influence of

the amount of water. Larger quantities of water appear to favor the formation of octahydrophenanthrenes (entry 6). However, increasing the percentage of water beyond 5% caused material losses as shown by the lower material balance of entries 7 and 8. We were not able to account fully for these losses. Small amounts of diphenic acid resulting from the oxidation of phenanthrene were found in the anodic compartment for the electrolyses of entries 7 and 8. There was no loss due to sublimation or evaporation of phenanthrene or its derivatives. Only very small amounts of organic products were recovered by washing thoroughly the electrodes recovered from the electrolyses with organic solvents or by heating them under vacuum.

Temperature

The effect of temperature on the ECH of phenanthrene was studied, from 25°C to 56°C, in methanol–water 98.5:1.5 (v/v) containing 0.3 M lithium perchlorate as supporting electrolyte (pH = 7–8). The current efficiency after 4 F/mol increased from 30 to 61%. In ethylene glycol – water 98.5:1.5 (v/v) under the usual conditions (see Table 5 entries 1 to 4), an increase of temperature from 50 to 80°C caused an increase of the current efficiency at Q = 14 F/mol from 32 to about 44%. The current efficiency dropped slightly at 90°C (entry 5). A significant drop of current efficiency and conversion rate occurred at 100°C (compare entries 6 and 7 where the charge passed was 3.8 F/mol only). Thus, upon increasing the temperature up to 80–90°C, the rate of hydrogenation increases more rapidly than that of hydrogen evolution. At temperatures above 90°C, the situation appears to be reversed. The rate of ECH of pyridine at Raney Ni was reported to be influenced by the temperature between 20 and 50°C (36). In that paper, there is no indication of the direction of the effect but it can probably be assumed that an increase in rate was observed.

Current density

The effect of increasing the current density from 21 to 104 mA/dm^2 (geometric area) on the current efficiency after 14 F/mol is shown in Table 5. From 21 (entry 8) to 42 mA/dm^2 (entry 9), the small increase in cathodic polarization associated

[a]Electrolysis conditions: 1.1 mmol of substrate (1.6 mmol for naphthalene); 0.1 M NaCl; 0.1 M H_3BO_3; pH = 2.6–2.7 to 6.6.4; T = 80°C.
[b]See footnote *c* of Table 1.
[c]Taken from Table 2, entry 11.

with the increase of current density favors hydrogenation over hydrogen evolution which leads to an increase of both current efficiency and extent of hydrogenation (yield of octahydrophenanthrenes). There is little change between 42 (entry 9) and 84 mA/dm^2 (entry 5). Further increase favors hydrogen evolution over hydrogenation as shown by the diminution of the current efficiency and of the extent of hydrogenation in entry 10. For the ECH of acetone, De Hemptinne and Jungers (9) reported that beyond a certain current density, the rate of hydrogen evolution increased with the current density while the rate of hydrogenation remained constant. This would be translated by a drop in current efficiency as observed in this work and others (30).

A current density of 84 mA/dm^2 (42 mA/dm^2 in a few cases) was used throughout this work to evaluate the influence of the various parameters on the efficiency of ECH of phenanthrene. Such low current density reflects the low concentration of substrate (9–11) together with the difficulty of hydrogenation of aromatic rings.

ECH of hydrogenated derivatives of phenanthrene

In catalytic hydrogenation, the initial rate of hydrogenation, that is the ease of hydrogenation of fused polycyclic aromatics increases with the number of rings (benzene < naphthalene < phenanthrene) and only one ring is saturated at a time (63). In ECH, under the best conditions defined above (ethylene glycol – water 98.5:1.5 (v/v); 0.1 M NaCl; 0.1 M H_3BO_3; T = 80°C; J = 84 mA/dm^2), the octahydrophenanthrenes are not electrohydrogenated at all. The strength of the π bond of a single aromatic ring is such that hydrogen evolution becomes much faster than hydrogenation and is the sole electrochemical process occurring. The ECH of tetrahydrophenanthrene was more difficult than that of phenanthrene as expected. This is shown by the lower conversion rate and much lower current efficiency of entry 3, Table 6, as compared to entry 1. Thus it was possible, under basic conditions, to electrohydrogenate phenanthrene to tetrahydrophenanthrene with interesting selectivities and good conversions (see Table 2, entries 3 to 5). Long ago, Breteau (5) reported the ECH of phenanthrene to tetrahydrophenanthrene in acid medium at Pd/Pt—Ir. No yield was given but the tetrahydro derivative was the sole product identified. Catalytic hydrogenation of phenanthrene over Raney Ni in dry ethanol under more vigorous conditions (100°C, 127 atm) using a limited quantity of hydrogen is less selective, giving some 55% of tetrahydro derivative together with 28% of 9,10-dihydro derivative (and 8% of octahydrophenanthrenes) at 53% conversion (64).

Catalytic hydrogenation of phenanthrene results in the initial saturation of the 9,10 positions and can be stopped at the dihydro stage if the catalyst is not too active (65). In ECH at Raney Ni, the difference in the rate of hydrogenation of phenanthrene and dihydrophenanthrene is not sufficient to allow the selective formation of the dihydro derivative even below 50% conversion.

The highest proportion of dihydrophenanthrene was obtained in basic aqueous ethanol at room temperature (1). The conversion of 9,10-dihydrophenanthrene to tetrahydrophenanthrene cannot occur directly. Disproportionation to phenanthrene and tetrahydrophenanthrene over Raney Ni was shown to occur to an extent of 40% after 6 h at 150°C under pressure (100–140 atm of N_2) (64). We cannot exclude the possibility that some disproportionation does take place under the conditions of ECH, that is at temperatures of 25 to 80°C and at atmospheric pressure. However, the conversion of 9,10-dihydrophenanthrene to tetrahydrophenanthrene (Table 6, entries 2 and 3) probably involves either dehydrogenation to phenanthrene followed by hydrogenation to readily hydrogenated dihydro derivatives or isomerization of 9,10-dihydrophenanthrene to those same dihydroderivatives through partial dehydrogenation and double bond migration. Dihydrophenanthrenes with a double bond in a terminal ring should be readily hydrogenated. That dehydrogenation could occur under the electrolysis conditions was suggested by the fact that small amounts of 9,10-dihydrophenanthrene (2 to 4%) were detected in the attempts to electrohydrogenate the octahydrophenanthrenes (uncontaminated by the dihydroderivative). Surprisingly, no tetrahydrophenanthrene was detected. Dihydrophenanthrene was also detected in the ECH of uncontaminated tetrahydrophenanthrene (Table 6, entry 4).

ECH of anthracene (6) and naphthalene (11)

They were electrohydrogenated under the best conditions found with phenanthrene and the results are recorded in Table 6, entries 5 to 8. The electrohydrogenation of anthracene (entry 5) was somewhat less efficient than that of phenanthrene (entry 1) as shown by the lower current efficiency and lower yield of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12
For personal use only.

octahydro derivatives. The proportion of symmetric and asymmetric isomers differ in the two series. The electrohydrogenation of naphthalene was quite selective, giving tetralin (**12**) in a high chemical yield and with a good current efficiency (entry 7). As with phenanthrene, the derivatives with a single aromatic ring could not be hydrogenated further, hydrogen evolution being much faster and the sole electrochemical process observed. Entries 2 and 3, and entries 6 to 8 illustrate clearly the decrease of current efficiency (the decrease in the rate of hydrogenation with respect to that of hydrogen evolution) as the number of coulombs is increased (as the concentration of the organic substrate decreases).

Conclusion

In ECH of organic compounds, the efficiency of electrohydrogenation is determined by the relative rates of two competing processes, namely the addition of chemisorbed hydrogen to the organic substrate (hydrogenation: reactions [3] and [4]) and the formation of molecular hydrogen from chemisorbed hydrogen (hydrogen evolution: reactions [6] and/or [7]). In this paper, using phenanthrene as substrate and a Raney nickel cathode consisting of particles of Raney nickel embedded on a nickel matrix, we have shown that the relative rate of the two processes is influenced by a number of factors: the activation of the cathode, the pH of the solution, the buffer, the supporting electrolyte, the cosolvent, the amount of water, the temperature, and the current density. The best conditions with the most active electrode (leaching at 75°C for 7 h) were a pH of 2.6–6.2 with boric acid as buffer, sodium chloride or tetrabutylammonium chloride as supporting electrolyte, ethylene glycol or propylene glycol containing between 1.5 to 5% (v/v) of water as solvent, a temperature of 80°C, and a current density of 42 to 84 mA/dm^2. A weak organic acid as buffer had a detrimental effect probably because its adsorption displaced some of the adsorbed phenanthrene and thus caused a decrease in the rate of hydrogenation. For the same reason, the more organic the cosolvent, the less efficient was the electrohydrogenation as found also by Miller and Christensen (30) for the ECH of phenol on a Pt/Pt cathode. An alkaline medium did favor hydrogen evolution over electrohydrogenation and the ECH was quite inefficient at pH > 13 contrarily to what was reported for the ECH of acetone at Raney Ni (10). The hydrogenation to hydrogen evolution ratio increased upon increasing the temperature from 25 to 80°C and when increasing the current density from 21 to 42 mA/dm^2 and started to decrease at temperatures above 90°C and current densities higher than 84 mA/dm^2. Poisoning of Raney Ni by chloride ions, which was observed in catalytic hydrogenation (61), is prevented or at least significantly diminished by cathodic polarization of the catalyst in ECH.

Under the best conditions, a charge equivalent to the full saturation of the aromatic compound led to complete conversion. With phenanthrene and anthracene, a mixture of octahydro derivatives (60% with phenanthrene, 36% with anthracene) and tetrahydro derivatives (34% with phenanthrene, 52% with anthracene) was obtained with current efficiencies of 45% and 36%, respectively. With naphthalene, the yield of tetralin was 99% and the current efficiency 50%. Complete conversion of phenanthrene or anthracene to octahydro derivatives could be achieved either by increasing the charge to about 30 F/mol with concomitant diminution of current efficiency (15–20%) or by increasing the amount of catalyst with concomitant loss of material due to adsorption. Tetrahydrophenanthrene was obtained with very good selectivities (≥80%) in the absence of boric acid. Full saturation of the aromatics could not be achieved. A single aromatic ring has a stronger π bond than that of fused polycyclic aromatics and the rate of hydrogenation of octahydro derivatives of phenanthrene and anthracene, and of tetralin is then much slower than hydrogen evolution. ECH of compounds with a single aromatic ring has been achieved at room temperature and atmospheric pressure at platinum cathodes in acidic solutions (6, 21, 30, 45, 46).

Compared to catalytic hydrogenation, the advantages of the ECH process are real due to the prevention or the minimization of poisoning and due to milder conditions of temperature and pressure as illustrated in the ECH of anthracene, phenanthrene, and naphthalene to tetrahydro or octahydro derivatives (see refs. 63–65 for catalytic hydrogenation of these substrates). It is also possible that polarization of the catalyst increases the rate of catalytic hydrogenation (11).

Finally, it is noteworthy that the electrohydrogenation of the polycyclic aromatics studied in this work by the ECH method can be accomplished at potentials of −0.7 to −1.0 V vs. SCE depending on the pH, and thus requires much less energy than electrohydrogenation by the electronation–protonation process. The electronation of these molecules necessitates potentials of −1.9 V (anthracene) to −2.5 V (phenanthrene, naphthalene) vs. SCE (66), which requires 23 to 40 kcal more energy than the ECH process.

Experimental

Vapor phase chromatographic (vpc) analyses were performed on a Hewlett Packard (HP) 5710A chromatograph equipped with a flame ionization detector and an HP 3390A integrator, using a DB-5 (dimethyldiphenylpolysiloxane) fused capillary column 30 m long at 160°C.

The following aromatic compounds were commercially available: phenanthrene from BDH (95%); 9,10-dihydrophenanthrene (≥97%), anthracene and tetralin (99%) from Aldrich Chemical, and naphthalene (>99%) from Fisher Scientific. Tetrahydrophenanthrene (>99%) was prepared from naphthalene according to the method described by Haworth (67). Asymmetric octahydrophenanthrene (100%) was synthesized from cyclohexanone and 1-bromo-1-ethylcyclohexane according to the method described by Perlman *et al.* (68). Symmetric octahydrophenanthrene (95.5%) was obtained by catalytic hydrogenation over Raney Ni as described by Durland and Atkins (64) followed by flash chromatographic separation on Merck silica gel 60 (230–400 mesh) and contained 4.5% of 9,10-dihydrophenanthrene. The authentic samples were characterized by their ir, ^{1}H nmr, and mass spectra.

Methanol, 2-propanol, and THF were distilled before use. Ethylene glycol (ACS, Anachemia), propylene glycol (USP, Baker), and diethylene glycol (Reagent, Fisher Scientific) were used without purification. Tetraethylammonium hydroxide (40% aqueous solution) was purchased from Aldrich Chemical, sodium tetrafluoroborate (pract.) from Fluka, boric acid (ACS) from Analar, and the Raney alloy particles (Ni–Al 50:50 (w/w)) from Aldrich Chemical (38–125 μm), BDH (45–125 μm), or Fluka (38–75 μm).

Raney Ni electrodes (1, 53)

A 60 mesh stainless steel grid (3 cm × 4 cm) to which was fixed a copper or stainless steel wire was heated at 80°C for 30 min in a bath containing NaOH (30 g/L), K_3PO_4 (30 g/L), and K_2SiO_3 (10 g/L). After washing thoroughly with distilled water and drying at 150°C, it was immersed in a 1 L beaker containing 550 mL of a plating solution made of 28% aqueous NH_4OH (200 mL/L), $NiCl_2.6H_2O$ (213 g/L), and NH_4Cl (30 g/L), pH = 8–9, with the stainless steel grid as the cathode and a cotton bag containing nickel beads (nickel shots (99%), Anachemia or BDH) (300 g) surrounding a graphite rod as the anode. Nickel was plated at 500 mA with a McKee-Pederson mp-1026 or a Sorrensen SRL 20-25 power supply. The current efficiency for Ni deposition varied between 94 and 96%. For the codeposition of Ni and alloy particles, Raney alloy particles (7 to 10 g) were added to the above plating bath and maintained in suspension by magnetic stirring. Plating was carried out at 500 mA for 60 min. In order to obtain about the same amount of particles on both faces of the cathode, the latter was turned around twice, after 8 min then after 33 min. The grid was placed at an angle of about 20° with respect to the vertical lead (held in a glass tube) to ensure a better contact with the flowing particles. The electrode was washed thoroughly with distilled water, dried in air, and weighed after removing the loosed particles by gentle brushing. The quantity of deposited Ni evaluated from the charge passed (95% current efficiency) was 0.53 g. The amount of deposited alloy particles varied between 0.7 and 1.2 g and the percentage of deposited alloy from 55 to 69%. The same bath could be used for many platings provided 0.9 g of alloy was added after each plating and concentrated NH_4OH was added to maintain the pH between 8 and 9. The electrode was activated by immersing it in a 125 mL Nalgene beaker containing a 30% (w/v) NaOH solution (80 mL) heated to the desired temperature. The most active electrodes were obtained by digesting at 75 ± 5°C for 7 h. The electrode was then washed thoroughly with distilled water and used immediately or kept in a 4% (w/v) NaOH solution until used.

Electrolyses

The electrolyses were carried out with a Princeton Applied Research (PAR) 173 or an Electrosynthesis Company (ESC) 410 or a G. Bank Electronic Wenking potentiostat having an ESC 640 or a PAR 379 coulometer and an ammeter connected to the auxiliary circuit. A two compartment jacketed glass H-cell (volume of each compartment: 150 mL) having a Nafion-324 (E.I. du Pont de Nemours & Co) membrane (~5 cm^2) as separator was connected to a Haake F423 constant temperature circulating bath filled with water (25–50°C) or ethylene glycol (60–100°C). The counter electrode was a graphite rod (7 mm) or a platinum grid (~10 cm^2) or plate (~5 cm^2). The cell voltages varied between 20 and 40 V for i = 20 mA. A Cole Parmer saturated calomel electrode, placed in a compartment separated from the working electrode by a fritted glass disc positioned near the surface of the electrode facing the counter electrode, was used to monitor the cathode potential.

The supporting electrolyte (generally 25 mmol) and a weak acid (generally 25 mmol) were dissolved in 250 mL of an organic solvent containing water in the required volumic proportions (generally 246 mL of ethylene glycol and 3.8 mL of water). The pH of the solution was measured at ca. 25°C with a Sargent Welch 6000 pH meter and a Cole Parmer glass electrode which was calibrated using aqueous solutions of commercial buffers. The solution was then poured in the cell (125 mL in each compartment), heated to the required temperature while deaerated (N_2 or Ar). The activated cathode and the counter electrode were immersed in the cell, the organic substrate (1.12 mmol, 9 mM solution) was added, and a constant current was immediately circulated. The cathodic solution was stirred magnetically. Aliquots (0.5 mL) were extracted with ether after the addition of a saturated NaCl solution (1 mL) and analysed by vpc. In the case of phenanthrene and naphthalene, the products were identified by comparison of retention times with those of authentic samples. The yields and mass balance were determined by comparison of peak areas with those of standard solutions of authentic samples using bibenzyl (phenanthrene) or biphenyl (naphthalene) as internal standard. In the case of anthracene, the products were identified by gc–ms (system NSB HP5970 with a quadrupolar filter)[7] and the proportions of starting material and products were evaluated by comparison of peak areas assuming a similar response to the detector. The mass balance was determined by extracting the cathodic solution with ether followed by the usual work-up and weighing the residue. For phenanthrene and naphthalene, the mass balance determined by isolation of the crude product was similar to that determined by vpc. For most electrolyses, the anodic compartment was also extracted with ether and the residue was weighed (2 to 8 mg) and analysed by vpc.

Vinylpyridinium ionomers. III. Influence of the matrix glass transition temperature on the dynamic mechanical properties of random acrylate-based systems[1]

DENIS DUCHESNE[2] AND ADI EISENBERG[3]

Department of Chemistry, McGill University, 801 Sherbrooke St. W., Montreal, Que., Canada H3A 2K6

Received November 27, 1989

This paper is dedicated to Professor Arthur S. Perlin on the occasion of his 67th birthday

DENIS DUCHESNE and ADI EISENBERG. Can. J. Chem. **68**, 1228 (1990).

The thermal and dynamic mechanical properties of random butyl acrylate- and plasticized ethyl acrylate-based vinylpyridinium ionomers have been investigated. The properties of the ionomers were found to be dependent on the glass transition temperature of the matrix material. Ionomers having a glass transition temperature lower than ca. 25°C exhibited all the features associated with the presence of phase-separated microdomains or clusters while the materials with higher glass transition temperatures were not. It was also observed that the dispersion associated with the vinylpyridinium clusters for a butyl acrylate-based ionomer with 12 mol% of ionic units occurs at ca. 25°C. This value is very close to that observed previously by Otocka and Eirich in their study of a butadiene-based vinylpyridinium ionomer with the same ion content.

Key words: ionomers, plasticization, clustering, glass transition, dynamic mechanical properties.

DENIS DUCHESNE et ADI EISENBERG. Can. J. Chem. **68**, 1228 (1990).

On a examiné les propriétés dynamiques et mécaniques d'ionomères du vinylpyridinium basés sur de l'acrylate de butyle et de l'acrylate d'éthyle plastifié. On a trouvé que les propriétés des ionomères dépendent de la température de transition vitreuse du matériel de la matrice. Les ionomères possédant une température de transition vitreuse inférieure à environ 25°C présentent toutes les caractéristiques associées à la présence des microdomaines ou des agrégats séparés par des phases; ce n'est pas le cas avec les matériaux dont les températures de transition vitreuse sont plus élevées. On a aussi observé que la dispersion associée aux agrégats de vinylpyridinium d'un ionomère basé sur l'acrylate de butyle et contenant 12 mol% d'unités ioniques se produit à environ 25°C. Cette valeur est très semblable de celle observée antérieurement par Otocka et Eirich dans leur étude d'un ionomère de vinylpyridinium basé sur le butadiène et contenant la même quantité d'ion.

Mots clés : ionomères, plastification, agrégation, transition vitreuse, propriétés dynamiques et mécaniques.

[Traduit par la revue]

Introduction

In other publications of this series (1, 2), rheological evidence was presented to support the hypothesis that the formation of phase-separated microdomains or clusters does not occur in ethyl acrylate- and styrene-based vinylpyridinium ionomers. Indeed, the investigation of their dynamic mechanical properties has shown that the properties of the materials, aside from an increase in the glass transition temperature with increasing ion content, were unaltered by the incorporation of up to 24.2 mol% of vinylpyridinium units. This is in contrast with the results obtained by Otocka and Eirich (3, 4), for butadiene-based vinylpyridinium ionomers. Not only did they observe a large increase in the glass transition temperature of the materials with increasing ion concentrations, they also observed the appearance of a second inflexion point in the Young's modulus versus temperature curves and a decrease in the slope of the same curves in the transition regions. They concluded that all these modifications in the rheological properties of the butadiene–vinylpyridinium ionomers were most probably due to the formation of ionic aggregates and that these, according to their stress relaxation data, had a decomposition temperature of ca. 25°C.

A comparison of all these data suggests that while the butadiene–vinylpyridinium ionomers appear to be clustered, cluster formation in the ethyl acrylate- and styrene-based vinylpyridinium ionomers does not occur, possibly because their glass transition temperatures are higher than the vinylpyridinium cluster decomposition temperature previously reported by Otocka and Eirich, or because no clusters exist in these styrene or ethyl acrylate ionomers.

Another factor that could be invoked to explain the absence of clusters in the ethyl acrylate-based ionomers is the dielectric constant of the matrix, which is higher than that for the butadiene-based system. Eisenberg and co-workers (5) have compared the stress–relaxation behaviour of ethyl acrylate–sodium acrylate copolymers with that of styrene–sodium methacrylate copolymers and concluded that clusters become rheologically significant at higher ion contents in the former system. The threshold concentration values above which the clusters start to dominate the rheological behaviour were found to be 6 mol% and 12 mol% for the styrenic system and the acrylic system, respectively. Neppel *et al.* (6, 7), using Raman spectroscopy techniques, showed that the degree of solubility of multiplets is higher in the acrylates than in styrene. Hence, both the glass transition temperature and the dielectric constant of the matrix material seem to be parameters of utmost importance for cluster formation.

Many studies, reviewed elsewhere (8–10), have dealt with the influence of the ion structure as well as the dielectric constant of the matrix material on the formation of clusters. None, as yet, has specifically tried to establish the effect of the matrix glass transition temperature alone on cluster formation. In order to do this, the viscoelastic properties of the low glass transition temperature butyl acrylate-based vinylpyridinium ionomers as well as those of plasticized ethyl acrylate-based ionomers were investigated. The plasticizer, dimethyl malonate, was chosen to match the dielectric constant of the ethyl acrylate matrix so as to allow for the examination of the effect of one parameter alone, i.e., the glass transition. The results of

this investigation will be compared with the results that already exist on butadiene- (3, 4), styrene- (1), and ethyl acrylate-based (2) vinylpyridinium ionomers to obtain a better understanding of the effect of the matrix glass transition on cluster formation in vinylpyridinium ionomers.

Experimental

Materials

Ethyl acrylate (Aldrich, 98%, inhibited with 200 ppm of monoethylether hydroquinone) and butyl acrylate (Aldrich, 98%, inhibited with 10–50 ppm of monoethylether hydroquinone) were fractionally distilled under reduced pressure, discarding the first and last 10% of the distillate. The monomers were then stored under a nitrogen atmosphere at −20°C prior to use. 4-Vinylpyridine (Aldrich, 98%) was treated the same way.

Benzoyl peroxide (Baker, 99%) benzene (Fisher, reagent grade), hexanes (A&C, technical grade), and methanol (A&C, technical grade) were used without further purification.

Polymerization

The copolymers were prepared by the free radical copolymerization in solution. The amount of initiator necessary to get the required polymerization rate and molecular weight was assumed to be the same as that for the monomer constituting the major part of the copolymer.

For each mixture, the monomers were transferred through a double-tipped needle under flowing nitrogen into an ampoule and kept under nitrogen. Next, the solvent was weighed and the calculated amount of benzoyl peroxide (to get the desired molecular weight) was added and dissolved in the solvent. Once the catalyst was dissolved completely, the solvent–catalyst mixture was transferred through a double-tipped needle under flowing nitrogen into the ampoule already containing the monomers, and again kept under a nitrogen atmosphere.

Each ampoule was immediately degassed by several freeze–thaw cycles under vacuum (10^{-2} mm Hg), sealed off under vacuum, and immersed in a thermostatted bath preset to 56°C or 60°C. The polymerization time varied with the nature of the comonomers and the composition of the mixtures. The conversions were kept low to give less than 30% compositional heterogeneity in the copolymers. Subsequently, the ampoules were opened and the copolymers isolated by precipitation in a 10 volume excess of hexanes.

The gel-forming copolymers were soaked overnight in fresh non-solvent. Following this step, they were removed from the non-solvent. To insure total dryness, all the copolymers were placed in a drying oven at 60°C under reduced pressure (1 mm Hg) until constant weight was reached. The details of the copolymerization runs are given in Tables 1, 2, and 3.

Analysis

The vinylpyridine content was determined by potentiometric titration using a solution of perchloric acid in glacial acetic acid according to the procedures described by Burleigh *et al.* (11). These results were further verified for the series of ethyl acrylate-4-vinylpyridine copolymers by elemental analysis. Variations between the different techniques were less than 0.2 mol%.

Molecular weight determination

An approximate molecular weight for at least one copolymer of each series was obtained by measuring their intrinsic viscosities, [η], in acetone solutions. The determinations were made at 25°C (BuA) and 30°C (EA) using a Ubbelhode viscometer. The values of K and a were taken as $K = 6.8 \times 10^{-5}$ dl/g and $a = 0.75$ for the BuA (12) copolymers and 20×10^{-5} dl/g and $a = 0.66$ for the EA copolymers (13). The intrinsic viscosities ranged from 0.7 to 1.5 dl/g corresponding to molecular weights of $2–6 \times 10^5$ g-mol^{-1}.

Copolymer modification

Materials

Methyl iodide (A&C, reagent grade) was fractionally distilled under nitrogen and in the absence of light a few hours before use.

Tetrahydrofuran (THF) was dried by refluxing over potassium metal and benzophenone until the deep purple colour characteristic of the potassium–benzophenone complex persisted. It was then distilled directly into the flask containing the polymer. Absolute ethanol (100%, Consolidated Alcohols Ltd.) and hexanes (A&C, technical grade) were used without further purification.

Quaternization

The vinylpyridinium copolymers were obtained by the reaction of the vinylpyridine copolymers with methyl iodide. The procedure given below is a combination of those described by Otocka and Eirich (3, 4), Selb and Gallot (14), and Gauthier and Eisenberg (15).

The 4-vinylpyridine copolymers were quaternized by adding a five-fold excess of methyl iodide to a boiling 3% copolymer solution. The mixture was then refluxed under nitrogen for 2 h. The final products had a yellow colouration most probably due to the presence of triiodide ions. The solvents in which the reactions were conducted, ethanol for the EA copolymers and THF for the BuA copolymers were chosen to avoid the precipitation of quaternized material during the reaction.

The ionomers were recovered by precipitation into 10 volumes of stirred hexanes. The gel-forming materials were soaked overnight in the non-solvent and then dried in a vacuum over at 60°C for at least 24 h.

Analysis

The extent of quaternization of the ethyl acrylate- and butyl acrylate-based vinylpyridinium ionomers was determined by NMR

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12
For personal use only.

spectroscopy (Varian XL-200, Varian T-60). The ionomers were found to be at least 80% quaternized. This value was obtained by taking the ratio of the peak intensity for the PY+CH_3I^- protons (*N*-methyl-4-vinylpyridinium iodide (4-VPQ): 4.65 ppm) to the peak intensity for some of the protons on the pendant ethyl or butyl acrylate groups.

Plasticization

The plasticized ethyl acrylate-4-vinylpyridium iodide (EA-4-VPQ) 10.5 mol% samples were prepared by mixing pieces of the previously dried rubbery material with dimethyl malonate (Aldrich, 99%) in a compression mold. The mixtures were then molded at pressures no higher than 2000 psi at 70°C for 1 h and were used without further treatment. The plasticizer content was determined by measuring the difference in weight for the samples before performing the dynamic mechanical testing and after that, once the samples had been heated at 80°C under reduced pressures until a constant weight was reached. It is assumed that no loss of plasticizer occurred during the testing since dimethyl malonate has a boiling point of 182°C (19).

Calorimetry

The glass transition temperatures of the non-quaternized copolymers and the ionomers were determined using a Perkin and Elmer Differential Scanning Calorimeter (D.S.C.-II). The determinations were done on samples weighing about 10 mg. Indium and n-octane were used to calibrate the instrument. The calibration and experimental runs were carried out at a heating rate of 20°C min^{-1}. Prior to the determination of their glass transition temperatures, all the samples were dried for at least 48 h in a vacuum oven at 60°C.

The non-ionic copolymers were annealed at Tg+20°C for 5 min and quenched before each scan. Three scans were usually made to ensure reproducibility, the last one being retained.

The alkyl acrylate ionomers were annealed at Tg+10°C for 5 min, quenched, and then scanned. Three runs were also made, the last one being retained.

In all cases the values obtained for the glass transition temperature were reproducible within 2°C.

Dynamic mechanical measurements

The dynamic mechanical properties were investigated with a torsional pendulum which is described elsewhere (17). The frequency varied from ca. 3 Hz in the glassy region to ca. 0.03 Hz in the low modulus region. Rectangular samples obtained by compression molding of 0.7 to 0.9 g of polymer at a temperature of Tg+20°C and at pressures no higher than 2000 psi were used in this study. All samples were subjected to the same drying procedures as those adopted for the calorimetry study.

The experiments were performed under a nitrogen atmosphere. Heating rates of 1–2°C min^{-1} were employed and the temperature was controlled to ±1°C. The values of the shear storage modulus (G′), the shear loss modulus (G″), and the loss tangent (tan delta) acquired and calculated by a computerized system, were obtained directly.

Results

*Butyl acrylate-*N*-methyl-4-vinylpyridinium iodide ionomers*

The variation of the shear storage modulus (G′) with the temperature for a series of butyl acrylate ionomers with 4.6 to 18.3 mol% of 4-VPQ ions (BuA-4-VPQ) is plotted in Fig. 1. It can be seen that as the ion content increases, the curves shift upward in temperature, and the shapes of the curves are modified extensively in the glass to rubber transition region with noticeable broadening.

The loss tangent curves, shown in Fig. 2, display two distinct relaxations. The high temperature relaxation is seen to gain in intensity as more ions are incorporated and, at high levels, to become the dominant one. The position of both relaxations depends to a different degree on the ion content, as can be seen in Fig. 3. The low temperature relaxation moves progessively upward in temperature at a rate of about 1°/mol% while the high temperature relaxation is shifted at a rate of about 4.3°/mol%.

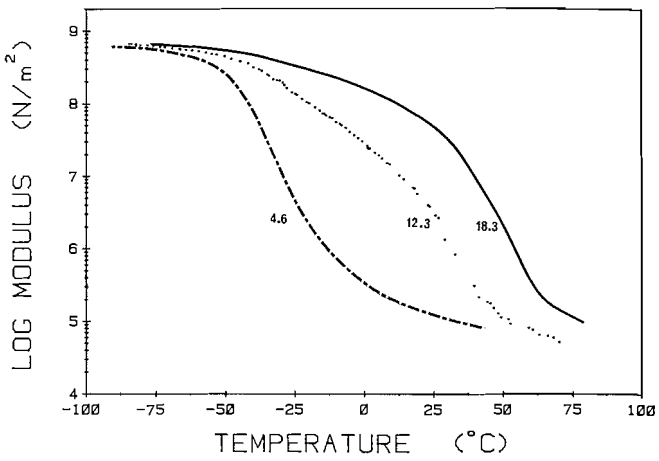

FIG. 1. Shear storage modulus as a function of temperature for butyl acrylate-*N*-methyl-4-vinylpyridinium iodide ionomers.

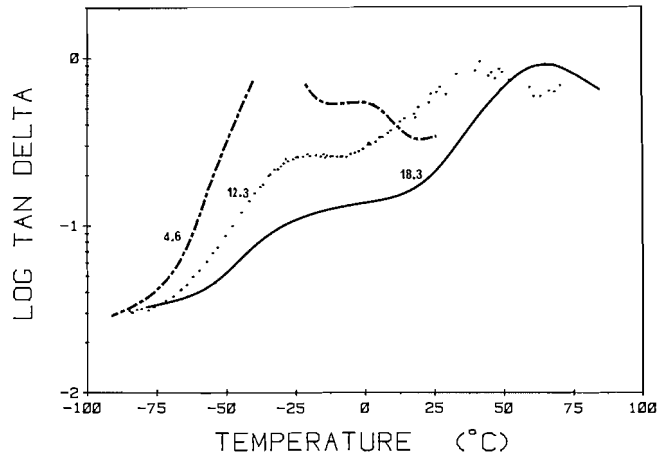

FIG. 2. Loss tangent as a function of temperature for butyl acrylate-*N*-methyl-4-vinylpyridinium iodide ionomers

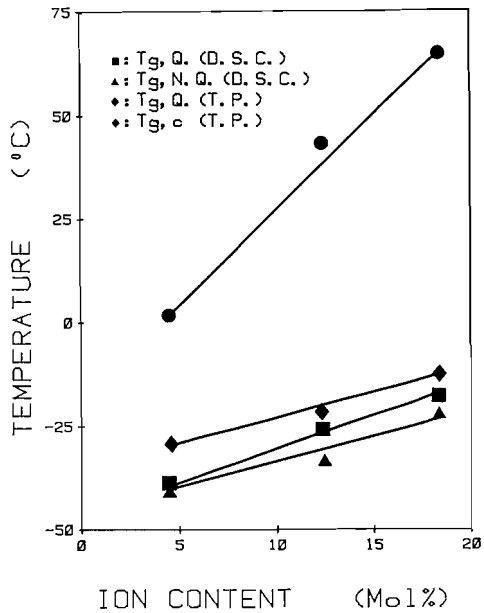

FIG. 3. Glass transition temperature (Tg) as a function of ion content as determined by D.S.C. and dynamic mechanical measurements (T.P.) for the non-quaternized (N.Q.) and quaternized (Q.) poly(butyl acrylate-co-4-vinylpyridine) copolymers, and high temperature peak position (Tg, c) as a function of ion content for the quaternized copolymers.

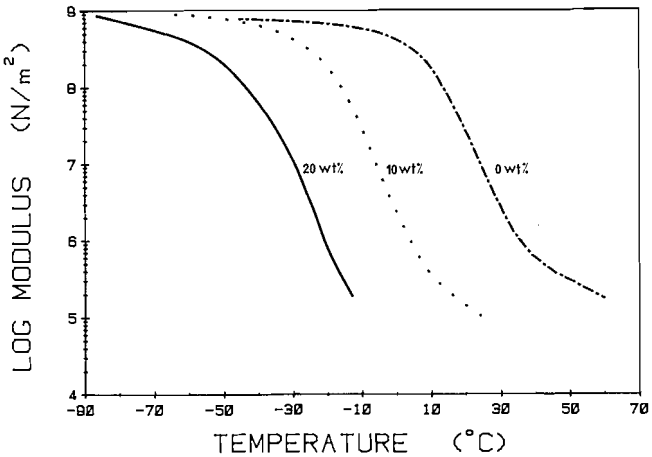

FIG. 4. Shear storage modulus as a function of temperature for ethyl acrylate-*N*-methyl-4-vinylpyridinium iodide ionomers plasticized with dimethyl malonate (DMM).

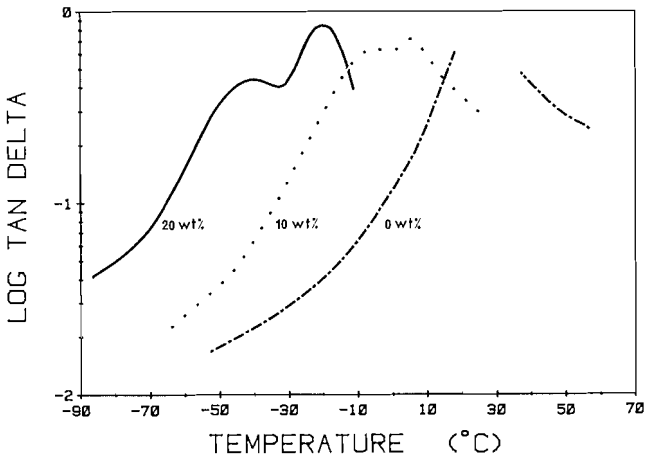

FIG. 5. Loss tangent as a function of temperature for ethyl acrylate-*N*-methyl-4-vinylpyridinium iodide ionomers plasticized with dimethyl malonate (DMM).

Only one transition is detected by calorimetry. Its position, also plotted in Fig. 3, is influenced by the ion concentration in the same way as the low temperature relaxation detected by dynamic mechanical measurements. For the sake of comparison, results obtained for the non-quaternized copolymers (N.Q.) are also presented.

*Plasticized ethyl acrylate-*N*-methyl-4-vinylpyridinium iodide ionomers*

The dynamic mechanical properties of an ethyl acrylate-based vinylpyridinium ionomer (EA-4-VPQ) 10.5 mol% plasticized with dimethyl malonate (DMM) were investigated. Figure 4 shows the variation of the shear storage modulus with temperature for samples of poly(ethyl acrylate) with 0, 10, 20 wt% of dimethyl malonate which was used as a plasticizer. A marked shift downward in temperature is observed as the amount of plasticizer increases. Along with this shift, the 20 wt% sample also exhibits some broadening in the glass to rubber transition region.

Similarly, the loss tangent curves, Fig. 5, move progressively downward in temperature indicating, as expected, a severe depression of the glass transition temperature with increasing plasticizer content. More importantly, the 10 and 20 wt% sample display two relaxations. The significance of this second relaxation will be discussed in detail in the next section.

Discussion

The damping behaviour of BuA-4-VPQ ionomers indicates that these materials are phase-separated. Indeed, the appearance of a high temperature relaxation can easily be related to the formation of clusters. As can be seen in Fig. 2, the high temperature relaxation gains substantially in intensity relative to the low temperature relaxation as the ion concentration increases.

In the light of these results, it is believed that the low temperature relaxation is due to microbrownian segmental motions associated with the glass transition of the ion-poor region, while the high temperature relaxation is associated with the same phenomenon in the ion-rich phase. Thus, the BuA-4-VPQ ionomers fall in the same category of ionomeric material as, among others, styrene – sodium methacrylate (18), styrene – sodium-*p*-styrene sulfonate (19), ethyl acrylate – sodium acrylate copolymers, sulfonated ethylene – propylene rubbers (EPDM) (20), and carboxylated polypentenamers (9).

The plot for the unplasticized EA ionomer in Fig. 5, along with results for a more extensive ion concentration range reported in ref. 2, tend to indicate that the EA ionomers are not clustered. By contrast, it is clear that ionomers based on BuA are clustered. The question of whether clustering takes place because the butyl acrylate matrix has a lower glass transition temperature or a lower dielectric constant than the ethyl acrylate matrix will now be addressed. The plasticization experiments provide the answer.

The results in Figs. 4 and 5 suggest that phase separation is induced and progressively enhanced as the glass transition is depressed by the addition of the plasticizer. As the plasticizer content increases, clusters are formed which have observable mechanical properties of their own. It should be noted that the plasticizer mimics the backbone: therefore, the clustering cannot be ascribed to changes in the dielectric constant, but only to changes in Tg. Thus, vinylpyridinium ionomers with a low glass transition temperature should be clustered while those with high glass transition temperature should not. Similar observations have been made in a parallel study for the poly(styrene-co-4-vinyl pyridine) system (21). Furthermore, while the dielectric constant of the matrix increases the solubility limit of the multiplets, it will not prevent cluster formation by itself unless it has a very high value, as in the case of the polyphosphates (22).

In the light of these results, it now seems surprising that the low concentration (<10 mol%) EA-4-VPQ ionomers did not show any sign of phase separation. It appears that these materials are a borderline case, and would probably be clustered if their glass transition temperatures were a few degrees lower.

Conclusions

The BuA-4-VPQ ionomers were shown to behave like clustered materials. In addition, the investigation of the viscoelastic properties of EA-4-VPQ 10.5 mol% samples plasticized with DMM suggest that while the EA ionomers are not clustered, in the absence of plasticizer, the plasticized samples are clustered, and that the essential condition for vinyl pyridinium ions to form clusters in this material is a lowering of the matrix glass transition temperature.

This paper is dedicated to Professor Arthur S. Perlin on the occasion of his 67th birthday

E. C. VAUTHIER, V. BARONE, C. MINICHINO, and S. FLISZÁR. Can. J. Chem. **68**, 1233 (1990).

The dissociation energies of the 1:1 hydrogen-bonded complexes formed by NH_3, H_2O, and HF were computed in the LCGTO-Xα local spin density approximation using extended basis sets. Attention was given to the appropriate selection of α. The order of stability of the various complexes reflects well their acid–base properties, in general agreement with experimental data and refined post Hartree–Fock computations.

Key words: hydrogen bonds, Xα method, local spin density method.

E. C. VAUTHIER, V. BARONE, C. MINICHINO et S. FLISZÁR. Can. J. Chem. **68**, 1233 (1990).

Les énergies de dissociation des complexes à liaison hydrogène formés par NH_3, H_2O et HF ont été calculées dans l'approximation LCGTO-Xα à densité de spin locale, à l'aide de bases étendues. La sélection de la valeur appropriée de α a été analysée. L'ordre de stabilité de ces complexes traduit bien leurs propriétés acide–base, en bon accord avec résultats expérimentaux et les meilleurs calculs post Hartre–Fock.

Mots clés : liaisons d'hydrogène, méthode Xα, methode à densité spin locale.

Introduction

The importance of hydrogen bonding has long been recognized. This study considers the various possible 1:1 complexes formed by water, ammonia, and hydrogen fluoride on two counts, namely for the physics underlying hydrogen bond formation and as an illustration of applications of density functional theory (DFT) in energy calculations involving the Xα approximation (1) for solving the equations of the local spin density (LSD) approach (2).

The merits of DFT, by far the most useful non-empirical alternative to configuration interaction calculations, are well demonstrated by applications to inorganic chemistry (3), i.e, in an area where the familiar wave function methods meet with formidable computational demands. LSD is presently the method of choice for the more complex systems involving several "heavier" atoms, namely transition metals. In the LCGTO approach, where the molecular orbitals are expanded as linear combinations of Gaussian type orbitals, full advantage is taken from the standard techniques of traditional *ab initio* calculations, namely as regards optimizations of basis sets (4). In short, thanks to these developments, the LCGTO-Xα(LSD) form of DFT now represents a manageable tool for the study of inorganic systems.

As regards organic molecules, the LCGTO-Xα(LSD) method was recently tested (5) in calculations of their total (kinetic + potential) energies, using the computational technology developed by Dunlap, Connolly, and Sabin (6). The attempt was a successful one: calculated energies were generally well within experimental uncertainties. The tentative hypothesis was that the LCGTO-Xα(LSD) method effectively mimics correlated calculations, although there is presently no formal justification for this contention. Briefly, it was assumed in this brute force approach that the energy should be right if α is properly selected. Here we proceed with the same philosophy, building on the quality of the results obtained in this fashion, and offer simple didactic examples. This work should be regarded as a first exploration in the field of intermolecular interactions, with special reference to the energetics of hydrogen bond formation. Our motivation rests with the suspicion that, in spite of its acknowledged merits in the description of electronic properties (e.g., multipole moments, ionization potentials, and transition energies), the Xα approach still suffers from difficulties in coping with subtle energy differences. The emphasis is on the general aspects regarding the proper use of Xα(LSD) theory in the field of "non-bonded" interactions. Possible further numerical improvements are left to future considerations.

The selection of α

Ever since the appearance of the Xα method, the way of selecting α has been a fundamental problem (1, 7). This is where we stand with our projected calculations of dimerization energies. Our results indicate that the "correct" α values — i.e., the α's corresponding to experimental energies — of monomeric H_2O and NH_3 differ from one another by as much as ~0.005; approximately the same difference is found between HF and H_2O and, finally, the difference between NH_3 and HF is as high as ~0.01. Under these circumstances, how can we pick the appropriate α values for the various possible hydrogen-bonded complexes involving H_2O, NH_3, and HF? In the Xα approach, the total energy is linear in α, i.e., if $E^0 = E^0(\alpha^0)$ is the energy

obtained for α^0, that deduced for $\alpha = \alpha^\circ + \Delta\alpha$ is

$$[1] \quad E = E^0 + (\alpha - \alpha^0)(\partial E/\partial\alpha)$$

Clearly, a relatively small uncertainty in the estimate of α rapidly translates into a large error for E. For example, $\Delta\alpha = 0.001$ and $\partial E/\partial\alpha$ values ranging from -20.86 to -28.59 au for the complexes considered here correspond to errors of $\sim$13–18 kcal mol^{-1} in dimerization energy and would put a stop to our hopes of doing thermochemistry using Xα(LSD) calculations.

Now we focus attention on the selection of $\alpha = \alpha_{AB}$ for the complex AB formed from monomers A and B with α values α_B, respectively. We tentatively select a common α value, α^0, and calculate the energies E^0_A, E^0_B, and E^0_{AB} for the monomers (A and B) and the complex AB, respectively. The corresponding *correct* energies are, from eq. [1],

$$E_A = E^0_A + (\alpha_A - \alpha^0)(\partial E_A/\partial\alpha)$$

$$E_B = E^0_B + (\alpha_B - \alpha^0)(\partial E_B/\partial\alpha)$$

$$E_{AB} = E^0_{AB} + (\alpha_{AB} - \alpha^0)(\partial E_{AB}/\partial\alpha)$$

The dimerization energy $\Delta E = E_{AB} - E_A - E_B$ is thus

$$\Delta E = [E^0_{AB} - E^0_A - E^0_B] + (\alpha_{AB} - \alpha^0)(\partial E_{AB}/\partial\alpha) - (\alpha_A - \alpha^0)(\partial E_A/\partial\alpha) - (\alpha_B - \alpha^0)(\partial E_B/\partial\alpha)$$

The term in square brackets would represent the correct answer if, instead of α^0, we had used the correct α's throughout our calculations, namely, the appropriate α_A and α_B for the monomers and the correct α_{AB} for the complex. As things are, the term in square brackets differs in principle from the true ΔE, and the error is

$$(\alpha_{AB} - \alpha^0)(\partial E_{AB}/\partial\alpha) - (\alpha_A - \alpha^0)(\partial E_A/\partial\alpha) - (\alpha_B - \alpha^0)(\partial E_B/\partial\alpha)$$

Here we inquire under what conditions this error vanishes. The answer is the dimerization energy, $E^0_{AB} - E^0_A - E^0_B$, calculated for a common α^0 minimizes the error if we use $\alpha^0 = \alpha_{AB}$, with α_{AB} given by eq. [2]:

$$[2] \quad \alpha_{AB} = \frac{\alpha_A(\partial E_A/\partial\alpha) + \alpha_B(\partial E_B/\partial\alpha)}{(\partial E_A/\partial\alpha) + (\partial E_B/\partial\alpha)}$$

Of course, the same reasoning also holds for the formation of higher polymers, i.e.

$$[3] \quad \alpha = \frac{\Sigma_i n_i\alpha_i(\partial E_i/\partial\alpha)}{\Sigma_i n_i(\partial E_i/\partial\alpha)}$$

for a complex containing n_A, n_B, ... n_i molecules with α values α_A, α_B, ... α_i and derivatives $\partial E_A/\partial\alpha$, $\partial E_B/\partial\alpha$, ..., $\partial E_i/\partial\alpha$, respectively. Equation [3] is the same as that used earlier for molecules containing n_A, n_B, ..., n_i atoms A, B, etc., in which case α_i and $\partial E_i/\partial\alpha$ represent atomic parameters (5). Note that eqs. [2] and [3] follow from the linearity of E in α, eq. [1], which is an integral part of the Xα theory, in an approximation which neglects higher order terms due to wave function variations. In actual practice, the α's obtained from a match of Xα computations with experimental energies also reflect the approximations involved in the present form of Xα(LSD) theory, including the treatment of correlation, not to mention the orbital and auxiliary basis set limitations. Nevertheless, this analysis also indicates — and this is an important point — that any reasonable common α° ($\neq \alpha_{AB}$) will do for the computation of ΔE. Indeed, the residual error

$$(\alpha_{AB} - \alpha^0)[(\partial E_{AB}/\partial\alpha) - (\partial E_A/\partial\alpha) - (\partial E_B/\partial\alpha)]$$

is small because $(\partial E_{AB}/\partial\alpha) \simeq (\partial E_A/\partial\alpha) + (\partial E_B/\partial\alpha)$. This point has been verified by detailed calculations which indicate that the computed ΔE's are almost independent of α^0. The results reported in this work were obtained using eq. [2] and the α's corresponding to the experimental atomization energies of the monomers, a strategy which minimizes the errors and gives the atomization energies of the complexes with reference to the experimental energies of the atoms.

Thermochemical data

All Xα(LSD) calculations are made for molecules at 0 K when all the atoms are stationary in their equilibrium positions. The total ground-estate energy of a molecule is then

$$[4] \quad E = \Sigma_i E_i^{atom} - \Delta E_a^*$$

where E_i^{atom} is the ground-state energy of the isolated atom i and ΔE_a^* the atomization energy of that molecule. Let us first examine the data required for comparisons with experiment, namely, with dimerization enthalpies.

The energy of an isolated atom, E^{atom}, is taken (with the appropriate change in sign) as the sum of its ionization potentials. With the conversion factor 1 hartree = 27.2106 eV, we obtain from the tabulation given by Moore (8) $E_N^{atom} = -54.6121$, $E_O^{atom} = -75.1102$, $E_F^{atom} = -99.8065$, and $E_H^{atom} = -0.5$ hartree. These energies are used in calculations of E, eq. [4], together with the appropriate experimental ΔE_a^* results. The latter are deduced from eq. [5].

$$[5] \quad \Delta E_a^* = \Sigma_i n_i[\Delta H_f^0(A_i) - \frac{5}{2}RT] + \text{ZPE} + (H_T - H_0) - \Delta H_f^0$$

where ΔH_f^0 is the standard enthalpy of formation of the molecule in the gas phase and $\Delta H_f^0(A_i)$ that of the isolated atom A_i, with n_i = number of atoms A_i found in the molecule. We have used (9) $\Delta H_f^0(H) = 52.09$, $\Delta H_f^0(N) = 113.0$, $\Delta H_f^0(O) = 59.54$, and $\Delta H_f^0(F) = 18.86$ kcal mol^{-1} for the atoms and (10) $\Delta H_f^0(H_2O) = -57.80$, $\Delta H_f^0(NH_3) = -10.97$, and $\Delta H_f^0(HF) = -65.14$ (9) kcal mol^{-1} for the molecules. ZPE is the zero point energy (evaluated in the harmonic oscillator approximation) and $(H_T - H_0)$ the heat content. ZPE + $H_T - H_0$ values of 15.25 (H_2O), 22.94 (NH_3), and 7.99 kcal mol^{-1} (HF) were deduced from the vibrational frequencies given in ref. 11*a* (for H_2O and NH_3) and ref 11*b*, (for HF). Finally, we obtain from eqs. [4] and [5] the experimental energies $E = -76.4804$ (H_2O), -56.5858 (NH_3), and -100.5314 hartree (HF), with 1 hartree = 627.51 kcal mol^{-1}.

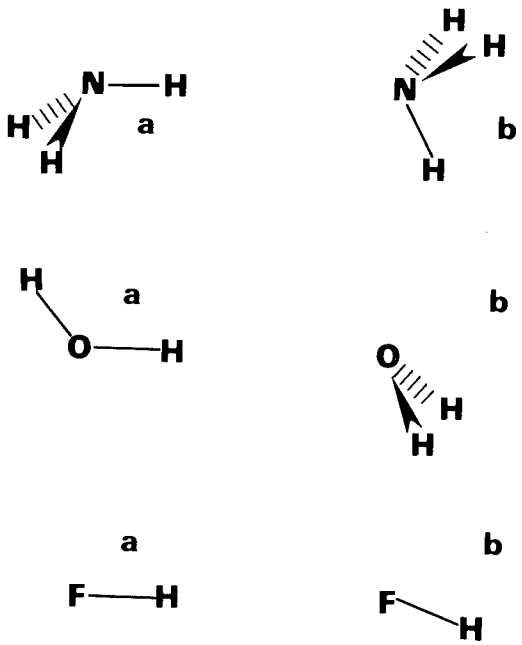
The dimerization energy ΔE_{dim} for the reaction A + B → AB is defined as follows

$$[6] \quad \Delta E_{dim} = E_{AB} - E_A - E_B$$

and the corresponding enthalpy change is, in the gas phase,

$$[7] \quad \Delta H_{298} = \Delta E_{dim} + \Delta(\text{ZPE} + H_T - H_0)$$

where $\Delta(\text{ZPE} + H_T - H_0)$ represents the value of the complex AB minus the values of the monomers A and B. We have used $\Delta(\text{ZPE} + H_T - H_0) = 1.663$ (water), 1.035 (ammonia), and 0.443 kcal mol^{-1} (hydrogen fluoride) (12). For the H_2O,HF complex we have deduced $\Delta(\text{ZPE} + H_T - H_0) = 1.72$ kcal mol^{-1} from the frequencies reported in ref. 13. Finally, for the H_2O,NH_3 and HF,NH_3 complexes, we have used frequencies calculated at the Hartree–Fock level in the basis described below for the geometries. Comparisons between calculated and observed frequencies of H_2O, NH_3, and HF indicated that (as usual) calculated frequencies should be reduced by $\sim$10%. A



SCHEME 1. Positioning of the monomers as they occur in the complexes. The $H_2NH\cdots NH_3$, $H_2NH\cdots OH_2$, $HOH\cdots NH_3$, $HOH\cdots OH_2$, $HOH\cdots FH$, $FH\cdots NH_3$, $FH\cdots OH_2$, and $FH\cdots FH$ complexes are combinations of (*a*) and (*b*), where (*a*) always refers to the first molecule indicated in these formulas.

balanced evaluation led to $\Delta(ZPE + H_T - H_0) \simeq 1.84$ and 1.87 kcal mol^{-1} for the H_2O,NH_3 and HF,NH_3 complexes, respectively.

The stage is set. All we need now are the energies E_{AB} of the complexes. They are the target of our Xα(LSD) calculations.

Outline of LCGTO-Xα(LSD) calculations

The calculations were performed using the program developed by Dunlap, Connolly, and Sabin (6), which includes the fitting methods for the charge density and the Xα exchange potentials to sets of auxiliary Hermite gaussian functions and the use of two *s*-type bond-centered auxiliary functions. No bond-centered functions were used for the hydrogen bonds because tests indicated that they have no effect on the results. The sampling points for the exchange potentials were determined by taking each tenth point of the Herman–Skillman radial mesh (14) and an angular mesh consisting of the twelve vertices of a regular icosahedron (15) — a procedure which may require future attention for the reasons indicated below.

It is now well-known that the quantitative description of hydrogen bonds by HF + CI methods requires at least double ζ bases augmented by two sets of polarization functions and one set of diffuse functions. Since basis sets optimized at the HF level are generally also adequate for LSD computations (4) provided, of course, that reasonably extended, flexible bases are used, we have selected the following two orbital basis sets. For nitrogen and oxygen we started with Dunning's $(9s5p) \rightarrow [4s2p]$ set (16). For N we added one uncontracted *s* (ζ = 0.0639), one uncontracted *p* (ζ = 0.0639) (17), and two uncontracted *d* primitives (ζ = 0.90 and 0.13) (18). For oxygen, on the other hand, we added one *s* (ζ = 0.0845), one *p* (ζ = 0.0845), and two *d* functions (ζ = 1.04 and 0.14) (18). Fluorine was described using Dunning's $(10s6p) \rightarrow [10s4p]$ set (19) to which we added one uncontracted *s* (ζ = 0.1076), one uncontracted *p* (ζ = 0.1076) (17), and two *d* functions (ζ = 1.06 and 0.18) (18). For hydrogen we have used Dunning's $(5s) \rightarrow [3s]$ set (19), to which two *p* functions were added with ζ = 1.0 and 0.08 (18). This concludes the description of basis 1. Our basis 2 is the same as above, with the addition of one set of diffuse *p* functions on N (ζ = 0.048), on O (ζ = 0.059), and on F (ζ = 0.074) (20). The selected auxiliary functions were $(9s5p3d)$ for N and O, $(11s4p4d)$ for F, and $(5s5p)$ for H (5).

TABLE 1. α and $\partial E/\partial\alpha$ values for monomers[a]

Molecule		Basis 1 α	Basis 1 $\partial E/\partial\alpha$, au	Basis 2 α	Basis 2 $\partial E/\partial\alpha$, au
NH_3	(a)	0.774578	−10.426	0.774563	−10.426
	(b)	0.774182	−10.432	0.774154	−10.432
H_2O	(a)	0.769162	−12.234	0.769164	−12.233
	(b)	0.769469	−12.229	0.769464	−12.229
HF	(a)	0.764424	−14.291	0.764388	−14.290
	(b)	0.764420	−14.291	0.764423	−14.290

[a]Basis 1: $(9,5,2/5,2) \rightarrow [4,2,2/3,2]$ plus diffuse (*sp*) functions for H_2O and NH_3; $(10,6,2/5,2) \rightarrow [6,4,2/3,2]$ plus diffuse (*sp*) function for HF. Basis 2: the same, plus additional diffuse *p* functions for N, O, and F.

Although we have not performed a comprehensive study of basis set effects, test computations indicated that they are quite similar in HF + CI and in Xα(LSD) computations. For example, with the addition of two sets of polarization functions and one set of diffuse functions to a double ζ basis set, the computed Xα and MP2 dimerization energies of water decrease from 13 to 6.5 and from 12.7 to 5.4 kcal mol^{-1}, respectively.

Results

The equilibrium geometries of the monomers and the various complexes were fully optimized by means of conventional Hartree–Fock calculations using Dunning's double ζ basis (16) augmented with single polarization functions (20).[1] The corresponding dimerization energies fall in the usual range of HF results obtained from medium size basis sets, e.g. −5.0 (water), −2.4 (ammonia), and −5.1 kcal mol^{-1} (hydrogen fluoride). The structure of the water dimer resembles that deduced by Dannenberg (21) at the MP2/6-31G* level, with a slightly bent hydrogen bond. Now we can proceed with Xα(LSD) calculations.

The first step consists in an evaluation of the appropriate α and $\partial E/\partial\alpha$ parameters corresponding to the experimental energies of the monomers, for use in eq. [2]. This was easily done using an initial guess, α^0, for α, which yields an approximate value of $E^0 = E^0(\alpha^0)$. Next, we estimated an improved value, $\alpha = \alpha^0 + \Delta\alpha$, using the experimental energy and eq. [1], and repeated the procedure until convergence was attained. In prac-

[1]Hartree–Fock geometries were used here for practical convenience because they are presently easier to obtain via a simultaneous optimization of all geometrical parameters than in the Xα approach. It should be added that Xα equilibrium geometries of diatomic molecules are in general good agreement with their experimental counterparts, e.g., 1.74 (calcd.) vs. 1.73 bohr (exptl.) for HF. Hartree–Fock bond distances, on the other hand, are systematically too short, by ~0.02 bohr, both in the dimers and in the monomers. As a result, we benefit here from error cancellations in the computation of Xα dimerization energies, a point which was carefully tested for the HF dimer, using both Hartree–Fock and Xα bond distances, as well as available experimental data. The uncertainties associated with the present selection of geometries should not exceed ~0.15 kcal mol^{-1} in dimerization energy.

[a]Results of Umeyama and Morokuma (23).
[b]The experimental results are extracted from ref. 24 ($H_2NH\cdots HN_3$); ref. 25 ($HOH\cdots OH_2$); ref. 26 ($FH\cdots OH_2$), and ref. 27 ($FH\cdots FH$).

tice, with a little experience as regards the initial guess, two calculations suffice. However, at this stage we met with a minor but disturbing computational imperfection — which is not there to stay — linked to the numerical fittings of the Xα exchange potentials: it turned out that the results slightly depend (≤0.3 kcal mol^{-1}) on how the reference axes are defined. To get around this difficulty, we positioned each monomer (with its own optimized geometry) as closely as possible as it is found in the complex. This simply means that each monomer had to be computed twice in order to determine the appropriate α and $\partial E/\partial\alpha$ parameters. The relative positions of the monomers are indicated in Scheme 1 and the results are given in Table 1. It is clear that, at this level, the enrichment of the basis set has little influence on the results. (The use of Huzinaga's (9*s*5*p*) orbital basis (22), which has proven adequate for the study of organic molecules, yield slightly higher α values (5)).

It is now straightforward to deduce the appropriate α's for the complexes from eq. [2] by means of the results given in Table 1. These are the α values which were used in our Xα(LSD) energy calculations for the complexes. The results are indicated in Table 2. Finally, with the help of the appropriate experimental energies of the monomers, the energies thus calculated for the complexes lead to the energies, eq. [6], and enthalpies, eq. [7], of dimerization indicated in Table 3.

In closing, our curiosity was attracted by the following point. The exchange-correlation energies $\alpha(\partial E/\partial\alpha)$, which are easily back-calculated from the data reported in Table 1 for the monomers and Table 2 for the complexes, change in going from the monomers to the corresponding complexes. Here we inquired about these changes by subtracting the $\alpha(\partial E/\partial\alpha)$ values of the monomers from those of the complexes: they appear to follow the pattern exhibited by the complexation energies (Table 4). These results are offered for what they are — namely, an observation which may, or may not, lend itself to future interpretations.

TABLE 4. Variation of exchange-correlation energies upon complex formation

Complex	ΔE_{xc}, kcal mol^{-1}	
	Basis 1	Basis 2
$H_2NH\cdots NH_3$	−1.9	−2.4
$H_2NH\cdots OH_2$	−2.9	−2.9
$HOH\cdots NH_3$	−4.8	−4.8
$HOH\cdots OH_2$	−3.9	−4.4

$FH\cdots NH_3$	−12.5	−12.5
$FH\cdots OH_2$	−10.1	−10.6
$FH\cdots FH$	−4.3	−5.3

Discussion

The calculated dimerization enthalpies of ammonia, water, and hydrogen fluoride nicely agree with their experimental counterparts (Table 3). There is some controversy, however, regarding the reported experimental values. For example, the result quoted for water (25) was obtained from infrared spectroscopy and is in line with experiments exploited in terms of the second virial coefficient, leading to $\Delta H_{298} = -5.5$ kcal mol^{-1} (28). The latter results were challenged (29) on the grounds of new measurements, suggesting $\Delta H_{298} = -3.6 \pm 0.5$ kcal mol^{-1}. We feel it is not our role to discuss the experimental aspects involved in the admittedly difficult measurements of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12
For personal use only.

dimerization enthalpies. In the main, the experimental results can be classified as either "high" or "low", e.g. −5.2 vs. −3.7 for water and −7.0 vs. −4.6 kcal mol^{-1} for hydrogen fluoride (30). Our present Xα results consistently support the more negative values (Table 3). The theoretical results of Umeyama and Morokuma (23) also point in that direction. In contrast, the most recent Hartree–Fock + CI calculations favor the less negative results (31, 32). The difference between the present Xα and the HF + CI calculations using comparable basis sets is nearly constant for the dimers of NH_3, H_2O, and HF. As regards the $FH\cdots OH_2$ complex, in spite of the present differences between the two theoretical approaches and without engaging into any final assessment on the accuracy of our results, it seems clear that the experimental value quoted for the formation of this complex probably requires revision.

The questions concerning dimerization energies are not yet quite settled, neither on the experimental nor on the theoretical side. As regards the Xα approach, additional investigations are certainly in order. On the whole, however, even in this first brute force attempt, Xα(LSD) theory has revealed its promising potential, perhaps beyond expectation. In any case, our results consistently reflect the trends in the complexation energy which would be anticipated from a consideration of the basicities and/or acidities of the species involved.

Conclusions

The use of the Xα approximation for solving the LSD equations raises the notorious problem concerning the appropriate selection of α. It now appears that the α to be used in energy calculations of a molecular complex is the weighted average of the α's of the individual molecules entering the composition of that complex. This result is a direct consequence of the linear dependence of the energy on α, which is an integral part of Xα(LSD) theory, and does not involve the introduction of any new hypothesis. The results thus obtained mirror the genuine qualities of the Xα(LSD) method. The formation of hydrogen bonded complexes — an example where small errors in the evaluation of α rapidly translate into important errors in computed dimerization energies — illustrates the merits of the present LCGTO-Xα(LSD) approach. Calculated complexation energies are of the quality of conventional post Hartree–Fock computations, thus suggesting that, in its present form, correlation has been effectively (though not explicitly) incorporated in our applications of Xα(LSD) theory. Beyond the absolute numerical values, the point is that this theory is adequate both in systems consisting of light atoms (in which case correlation is only a perturbation to the HF treatment) and in situations involving heavy atoms, i.e., systems still lying outside the reach of conventional HF + CI computations because of the huge amount of many-body effects.

^1H and ^{13}C NMR spectra have been recorded and the nuclear Overhauser enhancements (in D_2O), after pre-irradiation of the anomeric protons, have been measured for tri- and tetrasaccharides containing 2,3-disubstituted residues of α-L-rhamnose and the corresponding disaccharides. The proximity of the conformational states of the disaccharide units in these branched oligosaccharides and in the corresponding disaccharides has been shown, on the basis of both the nOe experimental data and theoretical conformational analysis. This conclusion is also confirmed by data for glycosylation effects in the ^{13}C NMR spectra of the oligosaccharides.

Key words: branched oligosaccharides, ^1H and ^{13}C NMR spectra, conformations.

GRIGORY M. LIPKIND, NIKOLAY E. NIFANT'EV, ALEXANDER S. SHASHKOV et NIKOLAY K. KOCHETKOV. Can. J. Chem. **68**, 1238 (1990).

On a déterminé les spectres RMN du ^1H et du ^{13}C et on a évalué les eOn (dans le D_2O, après irradiation des protons anomériques) de tri- et de tétrasaccharides contenant des résidues 2,3-disubstitués du α-L-rhamnose ainsi que des disaccharides correspondants. En se basant sur les données expérimentales relatives aux eOn ainsi que sur les résultats d'une analyse conformationnelle théorique, on a montré que les états conformationnels des unités disaccharides de ces oligosaccharides ramifiés ressemblent à ceux des disaccharides correspondants. Cette conclusion est confirmée par les données relatives aux effets de glycosylation sur les spectres RMN de ^{13}C des oligosaccharides.

Mots clés : oligosaccharides ramifiés, spectres RMN du ^1H et du ^{13}C, conformations.

Introduction

The spatial shape of branched polysaccharides depends mainly on the conformational features of the branch points. The branch points with vicinal substitution are the most conformationally rigid, because in this case the chemically nonbonded monosaccharide residues are in close proximity and interact with one another. The conformational properties of such branched oligosaccharides may cause considerable anomalies in chemical shift values in the NMR spectra, as is clear from the spectral data for both the branch points and the corresponding disaccharide fragments (1). The analysis of such differences in chemical shifts is important both for study of the spatial structure of branched oligosaccharide chains and for the extension of computer analysis of natural polysaccharide structures (on the basis of ^{13}C NMR data (2)) to the case of branched polysaccharides.

We earlier studied ^1H and ^{13}C NMR spectra and carried out the conformational analysis for several branched trisaccharides containing the galactose residue bis-glycosylated both at O3,O4 (3) and O2,O3 (4). These ^{13}C NMR data allowed us to carry out the primary structure analysis of branched polysaccharides containing a galactose residue at the branch point (5).

The present work deals with conformational analysis, on the basis of both NMR and theoretical calculations, for α-methylglycosides of branched trisaccharides with vicinal substitution at positions 2 and 3 of the α-L-rhamnopyranose residue. Such an investigation allows us to examine the stereochemical case when one of the vicinal substituents is equatorial and the other one axial, with neighbouring positions (1 and 4 in our case) lacking bulky substituents, i.e., a hydroxymethyl group.

The trisaccharides **1–4** of common formula:

X(1–2([Y(1–3)] αLRha-*O*Me

1 X = Y = αLRha

2 X = Y = βDGlc

3 X = Y = αDMan

4 X = Y = βLFuc

have been examined. The trisaccharides **1–4** differ from each other either by the absolute configuration of the substituents (D, L) or by the configuration of their anomeric centres (α, β). At the same time each separate trisaccharide has the same glycosyl residue.

It is important to mention that the anomeric centre of the rhamnose residue in the branch point has the α configuration in all examples. This choice is due to the α configuration of (1–2)-linked mannose and rhamnose residues in the overwhelming majority of natural polysaccharides (6).

Besides the trisaccharides **1–4**, we examined the tetrasaccharide **5** containing the same branched trirhamnose fragment as **1**:

αLRha(1–2)[αLRha(1–3)]αLRha(1–2)αLRha-OMe

5

as well as the trisaccharide **6** of the main chain of this tetrasaccharide:

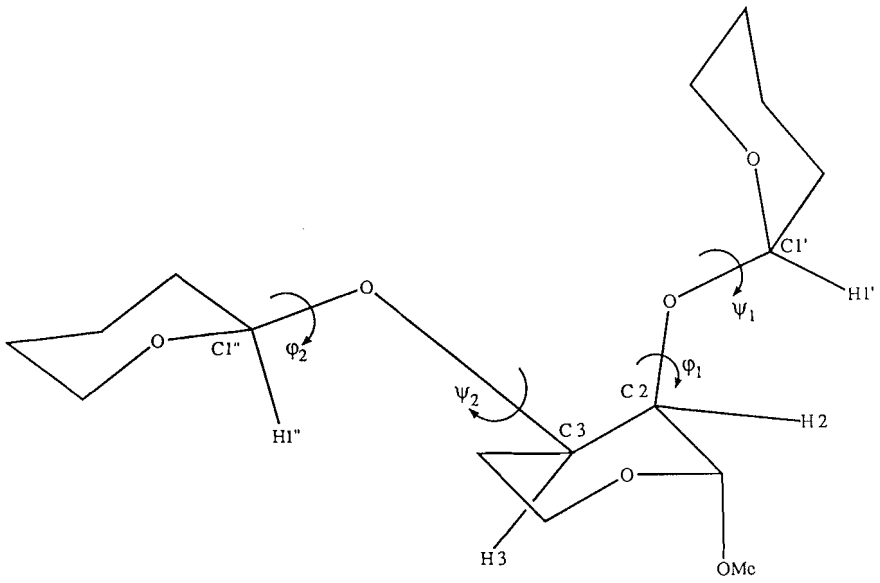
αLRha(1–2)αLRha(1–2)αLRha-OMe

6

The comparison of the spectral and conformational properties of oligosaccharides **1**, **5**, and **6** was made to prove the competence of "trisaccharide approximation" for the branch points in oligo- and polysaccharides.

We need data concerning model disaccharides of the following type:

Printed in Canada / Imprimé au Canada



SCHEME 1

X(1–2)αLRha-OMe and Y(1–3)αLRha-OMe

7 X = αLRha	**8** Y = αLRha
9 X = βDGlc	**10** Y = βDGlc
11 X = αDMan	**12** Y = αDMan
13 X = βLFuc	**14** Y = βLFuc

Since the disaccharides **7–10** were investigated previously (7, 8), we present the new data only for the disaccharides **11–14**.

It is well known that the experimental data essential for conformational analysis, and which could be obtained from ^{1}H NMR spectra, are the values of the nOe's, which reflect the spatial proximity of different protons in the molecule. Thus the nOe values caused by pre-irradiation of the anomeric protons in oligosaccharides **1–6** and **11–14** have been measured. As far as concerns ^{1}H NMR spectra recorded for solutions in D_2O, the nOe parameters reflect the conformational states of the oligosaccharides in aqueous solution. Here we also pay attention to the glycosylation effects in ^{13}C NMR spectra of oligosaccharides **1–14**, which are sensitive to conformations of the glycosidic linkages.

Theoretical conformational analysis of the oligosaccharides was carried out on the basis of molecular mechanics using atom – atomic potential functions.

The angles of rotation around the interunit glycosidic linkage are the conformational parameters of oligosaccharide chains. For the trisaccharides **1–4** these angles are given in Scheme 1. The angles of rotation around the C1′—O and O—C2 bonds of the X(1–2)αLRha units are designated respectively as φ_1 and ψ_1. For units Y(1–3)αLRha the angles of rotation around the C1″—O and O—C3 bonds are respectively φ_2 and ψ_2. The primed numbers refer to the X residue and the double primed numbers to the residue Y. All four angles are zero for the *cis* orientation of the corresponding C—H and C—O bonds.

Results and discussion

The nOe data obtained by pre-irradiation of H-1′ and H-1″ residues X and Y in **1–4** are given in Table 1. The nOe data for the tetrasaccharide **5** and the linear trisaccharide **6** are given in Table 2. The data in Tables 1 and 2 show that the nOe's were observed not only for the resonances of protons related to the pre-irradiated monosaccharide or glycosylated moiety but also for those of protons of the other monosaccharide moiety (e.g., Y, after pre-irradiation of H-1′ of X in the trisaccharide **1**).

For purposes of comparison of the nOe values for disaccharide units in branched trisaccharides with those for the corresponding disaccharides, the nOe data for **7–14** are listed in Table 3.

Calculation of the optimal conformations of **1–6** was based on minimization of the potential energies of the molecules by variation of φ_1, ψ_1, φ_2 and ψ_2, using, as initial approximations, the data on the optimal conformations for the disaccharide units of **1–6** (7, 8).

After determination of the lowest-energy conformer of the trisaccharide, the cross section of its potential surface was drawn (conformational maps), φ_1–ψ_1 (with φ_2 and ψ_2 fixed at their optimal values) and φ_2–ψ_2 (with φ_1 and ψ_1 at the optimal values). Such conformational maps demonstrate the range of admissible values of the rotation angles in the trisaccharide being studied.

The parametrization of the force field for calculations of branched trisaccharide conformations is given in ref. 3. It was shown that the energy of nonbonded interactions for the disaccharide units of trisaccharides was best calculated using the Scott and Scheraga function (9), and interactions of the nonbonded carbohydrate residues, using the Momany *et al.* (10) or Zhurkin *et al.* (11) potentials, suggested for the calculation of molecular packing in crystals. As was shown (12), the potentials in the calculations of the conformations of oligosaccharides in aqueous solution are those of "medium force". The parametrization of other minor components of the energy is also dealt with in ref. 8. The data on the structures of the anomers of Glc, Man, Rha residues for conformational calculations were taken from neutron diffraction studies (13–15). The coordinates of the βLFuc residue were obtained by mirror reflection of the βDGal residue coordinates (16). The valency angle of the glycoside-bond oxygen (17) was an average value (116.7°).

The conformational analysis of **1–4** allowed both calculation of the nOe's and comparison with the experimental values. The variation of signal intensity f_s^d for a proton d on pre-irradiation of a proton s can be calculated using the formula reported by

TABLE 1. The nOe (%) observed upon pre-irradiation of anomeric protons of the trisaccharides **1–4**

Trisaccharide	Observed nOe			
	Pre-irradiation of H-1′		Pre-irradiation of H-1″	
αLRha(1–2)αLRha-OMe αLRha(1–3)αLRha-OMe **1**	H-2,2′	14.6(1)	H-2″	8.0(0.8)
	H-1	0.5	H-3	10.6(1)[a]
	H-3″,5″	5.1(0.3)	H-2	2.2(0.2)
βDGlc(1–2)αLRha-OMe βDGlc(1–3)αLRha-OMe **2**	H-3′,5′	17.0(1.7)	H-3″,5″	19.0(2.0)
	H-2	9.6(1)	H-3	9.3(1.0)
αDMan(1–2)αLRha-OMe αDMan(1–3)αLRha-OMe **3**	H-2′	7.8(1.3)	H-2″,3	19.2(2.0)
	H-2	5.8(1.0)	H-2	9.8(1.0)
	H-1	7.2(1.2)	H-5′	3.8(0.4)
βLFuc(1–2)αLRha-OMe βLFuc(1–3)αLRha-OMe **4**	H-2′[b]		H-2″[b]	
	H-3′	6.4(1.0)	H-3″	7.7(0.8)
	H-5′	9.5(1.4)	H-5″	8.5(0.9)
	H-1	6.2(1.0)	H-2	3.2(0.3)
	H-2	6.4(1.0)	H-3	9.3(1.0)

[a]The relative nOe values are given in parentheses. The nOe value for the α-proton of the aglycon was accepted as unity.

[b]The nOe was not determined due to a "pseudo-indor" effect, as a consequence of the close location of the H-1′ and H-1″ signals.

TABLE 2. The nOe (%) observed upon pre-irradiation of anomeric protons of the oligosaccharides **5** and **6**

Oligosaccharide	Observed nOe					
	Pre-irradiation of H-1′[a,b]		Pre-irradiation of H-1″		Pre-irradiation of H-1	
5	H-2′	7.5	H-2″	7.5	H-2	6.1
	H-2	10.8	H-3	11.5	H-5′	5.0
	H-3″,5″	6.5	H-2	1.1	H-2‴	13.4
6	[c]		[c]		H-2	5.8
					H-5′	6.2
					H-2‴	12.3
					H-1‴	0.3

[a]Numeration of the protons H-1, H-1′ and H-1″ is the same as in the trisaccharides **1–4**; H-1‴ is the anomeric proton of the "reducing" rhamnopyranose residue.

[b]Protons with one, two, and three primes and without primes correspond to terminal non-reducing, reducing, and middle rhamnopyranose residues respectively.

[c]The nOe values upon pre-irradiation of H-1′ and H-1″ are not determined because of the overlap of H-1′ and H-1″ signals.

Shirmer *et al.* (18), taking into account the influence of adjacent protons on the nOe for proton d. For the comparison with the experimental data, the average values of the nOe $\langle f_s^d \rangle$ (s = H-1, H-1′, H-1″) were calculated and Boltzmann probabilities were considered for all possible conformations of each trisaccharide:

$$\langle f_s^d \rangle = \frac{\sum_{\varphi_1}\sum_{\psi_1}\sum_{\varphi_2}\sum_{\psi_2} (f_s^d)_{\varphi_1,\psi_1,\varphi_2,\psi_2} \exp(-\Delta U_{\varphi_1,\psi_1,\varphi_2,\psi_2}/kT)}{\sum_{\varphi_1}\sum_{\psi_1}\sum_{\varphi_2}\sum_{\psi_2} \exp(-\Delta U_{\varphi_1,\psi_1,\varphi_2,\psi_2}/kT)}$$

To minimize the time on the computer, only those values of φ and ψ that correspond to conformations with relative energy ≤3 kcal/mol on cross sections of the potential surface were considered. Each step in the accepted range was 10°.

The optimal values of φ_1, ψ_1, φ_2, and ψ_2 in the lowest-energy conformations of **1–4** are listed in Table 4, as well as calculated values of the nOe f_s^d for the optimal conformers. Table 5 contains the calculated values of the nOe $\langle f_s^d \rangle$ and their relative values used for comparison with the corresponding observed values. The deviations from additivity in the ^{13}C NMR spectra of **1–4** are given in Table 6. Tables 7 and 8 contain ^1H and ^{13}C NMR spectral data for **1–14** (see Experimental).

αLRha(1–2)[αLRha(1–3)]αLRha-OMe (*1*)

As well as for the disaccharides **7** and **8** (Table 3), pre-irradiation of H-1′ and H-1″ in **1** caused considerable nOe, first of all on the protons of the carbon atoms forming the glycosidic linkages, H-2 and H-3 (Table 1). At the same time the considerable nOe between protons of the nonbonded rhamnose residues in **1** has been observed. The pre-irradiation of H-1′ of the X residue caused an nOe for the resonances of H-3″ and H-5″ of Y to have a total value of 5.1% (Table 1). This effect is clearly seen in the nOe spectrum of the trisaccharide **1** (Fig. 1) obtained upon pre-irradiation of H-1′. This result demonstrates the close proximity of the X and Y rhamnose residues, first of all in the region of H-1′ and H-3″, H-5″.

After minimization of the potential energy, two low-energy conformers of the trisaccharide **1** have been found, in which units with (1–2) and (1–3) bonds with equal conformational states are presented, AA in one case and BB in the other (Table 4). The symbols A and B correspond to optimal conformations with the rotation angles φ and ψ (50, 20° and 40, −30° respectively) for the disaccharides **7** and **8** (see Table 3 in refs. 7 and 8). The molecular model of the optimal conformation BB of the trisaccharide **1** is presented in Fig. 2.

Conformations AB and BA for the trisaccharide **1** have high energy, shown in the cross section of the potential surface of the trisaccharide **1** (Fig. 3). If the (1–3)-bonded unit has conformation B with $\psi_2 < 0°$ (Fig. 3b), then the (1–2)-bonded unit may also have only negative values of ψ_1 (conformation B). In this case the region of positive values of ψ_1, which corresponds to

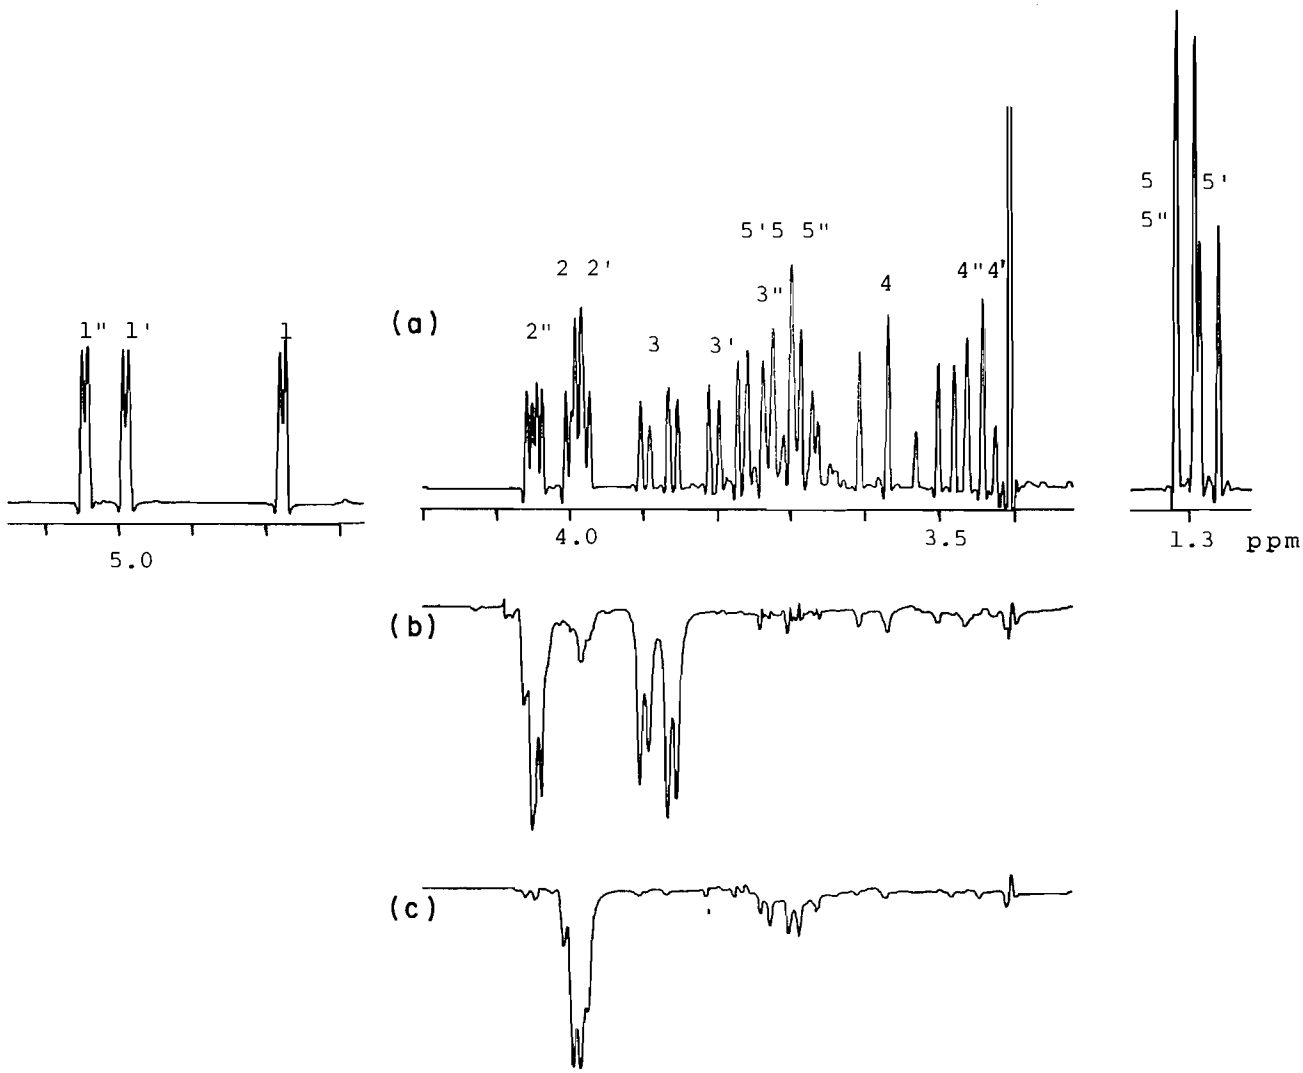

FIG. 1. (a) The ^{1}H NMR spectrum of the trisaccharide **1** αLRha(1–2)[αLRha(1–3)]αLRha-OMe. The nOe spectra obtained by pre-irradiation of (b) H-1″ and (c) H-1′.

state A, becomes energetically forbidden (Fig. 3a) for inadmissible proximity of X and Y residues. However, if the (1–3)-bonded unit has conformation A, then the (1–2)-bonded unit strives for state A as well (Fig. 3c), because in this case the optimal packing of the two nonbonded rhamnose residues X and Y is possible. At the same time, in each unit of the trisaccharide **1**, both preferred conformers A and B for the disaccharides **7** and **8** are possible.

As for conformers C (φ, ψ −40, −20°) of the disaccharides **7** and **8** (7, 8) with a *trans* orientation of the aglycon along the

TABLE 6. Deviations from additivity Δ^a (ppm) in ^{13}C NMR spectra of the trisaccharides **1–4** for C-1–C-6, C-1′, and C-1″ atoms

Trisaccharide	C1	C2	C3	C4	C5	C6	C1′	C1″
1	0.6	−0.2	0.2	0.5	0.3	0.6	−0.4	0.3
2	0.6	−0.5	−0.2	−0.4	0.1	0.0	−0.2	0.1
3	0.2	0.5	0.2	0.1	0.0	0.1	0.0	0.4
4	0.1	−0.8	0.4	−0.6	−0.2	0.0	−0.3	0.6

[a] $\Delta = \delta_{exp.} - \delta_{calc.}$; $\delta_{calc.} = \delta_1 + \delta_2 - \delta_{MR}$, where $\delta_{exp.}$ and $\delta_{calc.}$ are observed and calculated chemical shifts of carbon atoms in the trisaccharides; δ_1 and δ_2 in the (1–2)- and (1–3)-linked disaccharides; δ_{MR} in methyl-α-L-rhamnopyranoside.

C1′—O5′ bond (thought to be unfavorable due to the *exo*-anomeric effect (19)), these are not stabilized in the case of the trisaccharide **1** by additional dispersion interactions of the X and Y residues; that is why the corresponding conformers (AC, CC etc.) have high energy.

The results of conformational analysis for the trisaccharide **1** are in accordance with the observed nOe values. If in the conformation AA protons H-1′ and H-3″ are in close proximity (r(H-1′–H-3″) = 2.4 Å), then in the conformation BB (Fig. 2) the protons H-1′ and H-5″ become close (r(H-1′–H-5″) = 2.4 Å). The equilibrium of the two forms causes the nOe's for the resonances on both H-3″ and H-5″ protons upon pre-irradiation of H-1′. In fact the calculated value of $f_{H\text{-}1'}^{H\text{-}3''}$ in the AA conformation is 15% ($f_{H\text{-}1'}^{H\text{-}5''}$ = 0%), while the value $f_{H\text{-}1'}^{H\text{-}5''}$ in the BB conformation is 6% ($f_{H\text{-}1'}^{H\text{-}3''}$ = 0%, Table 4). The calculated average values of $\langle f_{H\text{-}1'}^{H\text{-}3''} \rangle$ and $\langle f_{H\text{-}1'}^{H\text{-}5''} \rangle$ turn out to be almost equal (4 and 5% respectively, Table 5). We also note that, in accordance with experimental data (Table 1), the ratio of sums of the average values $(\langle f_{H\text{-}1'}^{H\text{-}3''} \rangle + \langle f_{H\text{-}1'}^{H\text{-}5''} \rangle)/(\langle f_{H\text{-}1'}^{H\text{-}2'} \rangle + \langle f_{H\text{-}1'}^{H\text{-}2'} \rangle)$ is approximately 1:3 (Table 5).

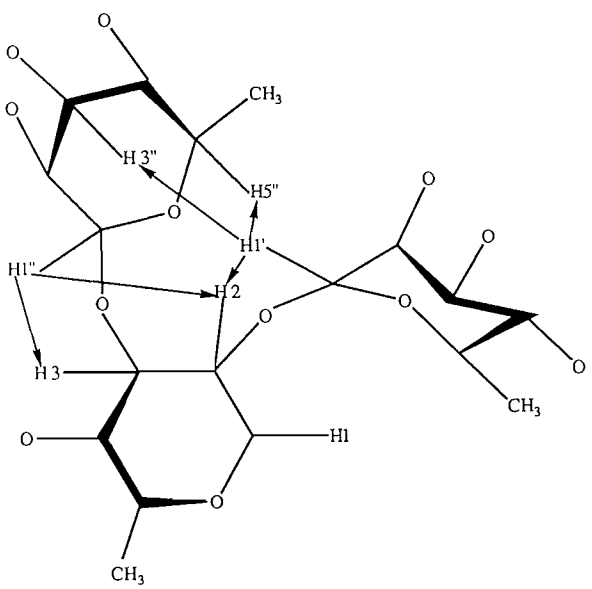

FIG. 2. Molecular model of low-energy conformer BB of the trisaccharide **1** αLRha(1–2) [αLRha(1–3)]αLRha-OMe. The optimal rotation angles are given in Table 4. Arrows show the protons with the fixed nOe's.

The conformers A ($\varphi \sim 60°$, $\psi \sim 15°$) in the αLRha(1–2)αLRha and αLRha(1–3)αLRha units are optimal, while the conformers B with $\varphi > 0°$ and $\psi < 0°$ ($\psi \sim -40°$) turn out to be of high energy according to the HSEA method (19). At the same time the reality of the ψ_2 value in the region between -30 and $-60°$ (see Fig. 2b) is proved by the presence of the nOe (2.2%, Table 1) for the H-2 proton upon pre-irradiation of H-1″ (as well as with the strong nOe for H-3). Within the range of ψ_2 values mentioned, the protons H-1″ and H-2 may be in close proximity and cause the nOe. Observation of the small nOe for the resonance of H-1 upon pre-irradiation of H-1′ (Table 1) also indicates the possibility of ψ_1 values near $-40°$. Thus, the conformer BB is actually present in aqueous solution of **1**. This conclusion also follows from the observed nOe for the resonance H-5″. The theoretical ratio of average values $\langle f^{H\text{-}2}_{H\text{-}1''}\rangle/\langle f^{H\text{-}3}_{H\text{-}1''}\rangle$ in the (1–3)-linked unit, as well as the $\langle f^{H\text{-}2}_{H\text{-}1'}\rangle/\langle f^{H\text{-}2}_{H\text{-}1'}\rangle$ ratio in the (1–2)-linked unit, is 1:10 (Table 5).

To summarize the conformational analysis for the trisaccharide **1**, one could mention that, in spite of some decrease of conformational freedom in its disaccharide units, the conformational freedom does not differ much from that in the corresponding free disaccharides **7** and **8**. Thus, in conformer BB the deviations of φ_2 and ψ_2 are considerable and approximately the same as in the disaccharide **8** (compare contours of relative

energy Δ 3 kcal/mol in Fig. 2b in this paper, and Fig. 2 in ref. 8). On the contrary, in conformer AA there is considerable conformational freedom in the (1–2)-linked unit, which is close to that in the disaccharide **7** (compare Fig. 2c in this paper and Fig. 3 in ref. 7). The closeness of the conformational states of the disaccharide units in the trisaccharide **1** as well as in the free disaccharides **7** and **8** is apparent in the nOe data: the ratio values of the nOe for H-2′ and H-2 upon pre-irradiation of H-1′, and that for H-2″ and H-3 upon pre-irradiation of H-1′ in the units of the trisaccharide **1** coincide well with the ratio values observed in the case of the corresponding disaccharides **7** and **8** (Tables 1, 3, and 5).

Our study of the tetrasaccharide **5** shows that the presence of aglycon for the bis-glycosylated α-L-rhamnopyranose residue does not cause any significant conformational deviations of the branch point. This becomes clear from the fact that, upon pre-irradiation of H-1′ for the αLRha(1–2)αLRha unit of **5** (here we use the same plots for protons as in **1**), strong nOe's are observed for the resonances H-3″ and H-5″ of the residue Y. In this case as well as in the trisaccharide **1**, the sum of the nOe's on H-2′ and H-2 is 3-fold higher than that for the resonances of H-3″ and H-5″ (Tables 1 and 2). As well, in **5** and in **1**, upon pre-irradiation of H-1″ the ratio of the nOe's for H-2″ and H-3 is 0.7/0.8 (Tables 1 and 2).

In fact, in the tetrasaccharide **5**, the aglycon in the form of the α-methylrhamnoside residue and the substituents X and Z are placed on opposite sides of the best four-atom plane of the branched rhamnose residue and do not interact with each other. The molecular model of the optimal conformation of **5** with rotation angles φ_1, 40; ψ_1, −31; φ_2, 49; ψ_2, −25; φ_3, 51; and ψ_3, 15° (the latter two angles correspond to αLRha(1–2)αLRha-OMe) is shown in Fig. 4.

The nOe data for the (1–2)-linked rhamnotriose core chain of the tetrasaccharide **1** and for the trisaccharide **6** are equal. For

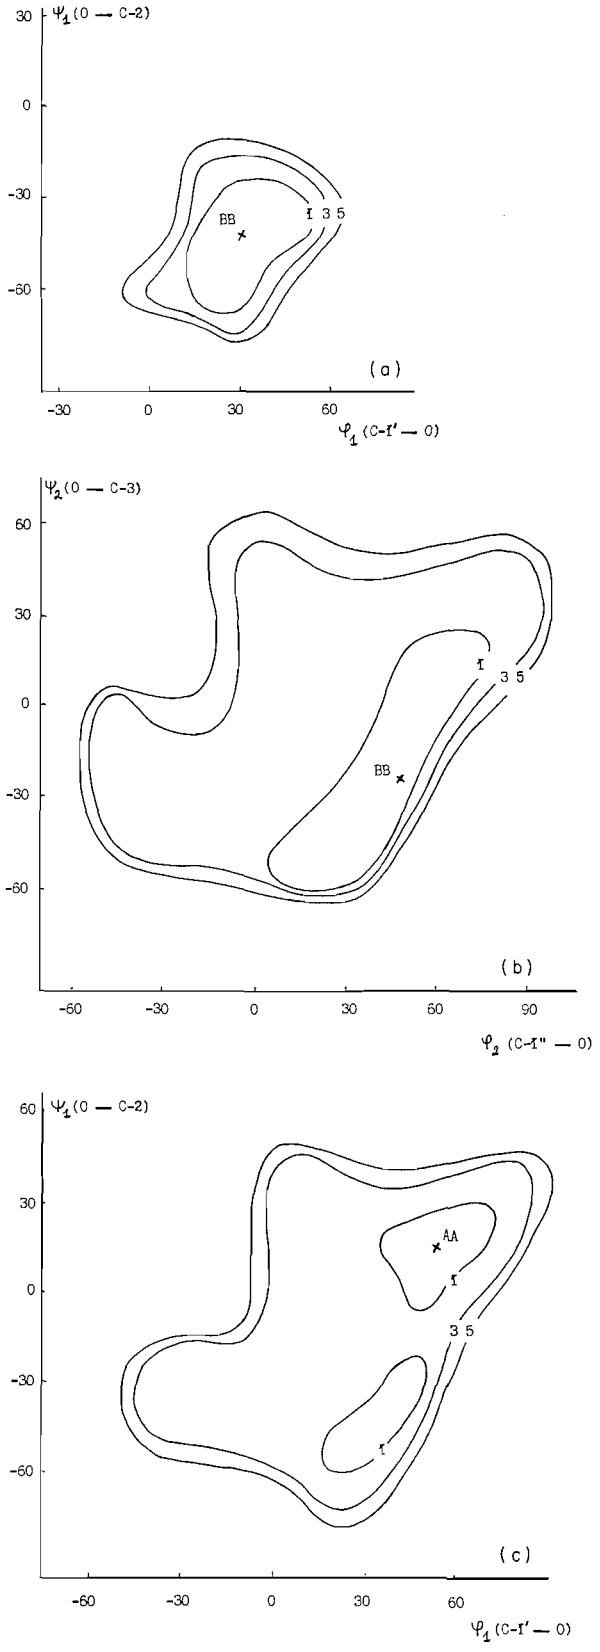

FIG. 3. Cross sections of potential surface for the trisaccharide **1** αLRha(1–2) [αLRha(1–3)]αLRha-OMe. (a) $\varphi_1 - \psi_1$ ($\varphi_2 = 49.2$, $\psi_2 = -25.1°$, Table 4); (b) $\varphi_2 - \psi_2$ ($\varphi_1 = 39.0$, $\psi_1 = -37.1°$); (c) $\varphi_1 - \psi_1$ ($\varphi_2 = 60.3$, $\psi_2 = 15.1°$);

The equipotentials of relative energy of Δ 1, Δ 3, and Δ 5 kcal/mol are given, × denotes the positions of local minima.

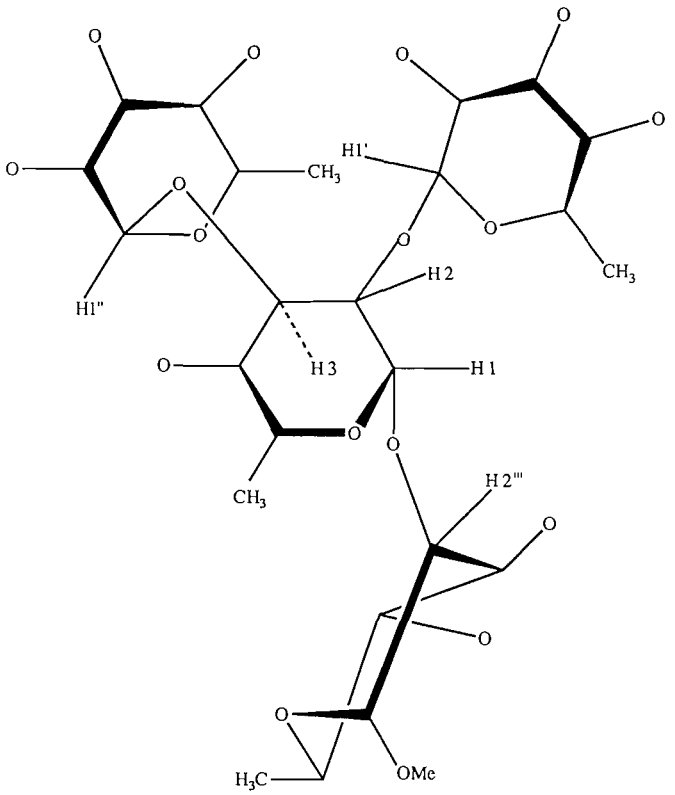

FIG. 4. Molecular model of the predominant conformer for the tetrasaccharide **5** αLRha(1–2)[αLRha(1–3)]αLRha(1–2)αLRha-OMe (see text).

example, in both cases, upon pre-irradiation of H-1 of the central L-rhamnose residue, the observed nOe's for the protons H-2, H-5′, and H-2‴ are almost equal (H-2‴ corresponds to the "reducing residue" of rhamnose Z), Table 2.

Thus, the conformational properties of branched trisaccharides with a 2,3-disubstituted α-rhamnose (or α-mannose) residue are preserved in the polysaccharide chain.

βDGlc(1–2)[βDGlc(1–3)]αLRha-OMe (2)

After pre-irradiation of H-1′ in the (1–2)-linked unit of **2** the nOe is observed only for H-2 of the rhamnose residue, and it is 40% less than the sum of nOe's for H-3′ and H-5′ of the irradiated residue βDGlc. Analogously, in the (1–3)-linked unit the nOe for H-3 after pre-irradiation of H-1″ is 50% less than the sum of nOe's for H-3″ and H-5″ (Table 1).

Both βDGlc substituents of the rhamnose residue in the trisaccharide **2** are separated and do not interact with each other in the majority of the admissible conformations; that is why the conformational possibilities for the disaccharide units are almost the same as for the free disaccharides **9** and **10** (7). This is clear from comparison of cross section $\varphi_2 - \psi_2$ (Fig. 5) and the conformational map of the disaccharide **10** (Fig. 5 (7)). Therefore, all four possible conformers AA, AB, BA, and BB in the trisaccharide **2** do exist (A and B are the optimal conformational states of the disaccharide units, see Table 3 (7)). Among the listed conformers the AB one is of lowest energy (Table 4). This conformer is additionally stabilized by means of dispersional interactions of two glucose residues (their energy is −2 kcal/mol). The molecular model of the AB conformer is presented in Fig. 6.

According to calculations for all conformers of the trisaccharide **2**, after pre-irradiation of the anomeric protons, the nOe's are possible only on the protons at the carbon atoms of the

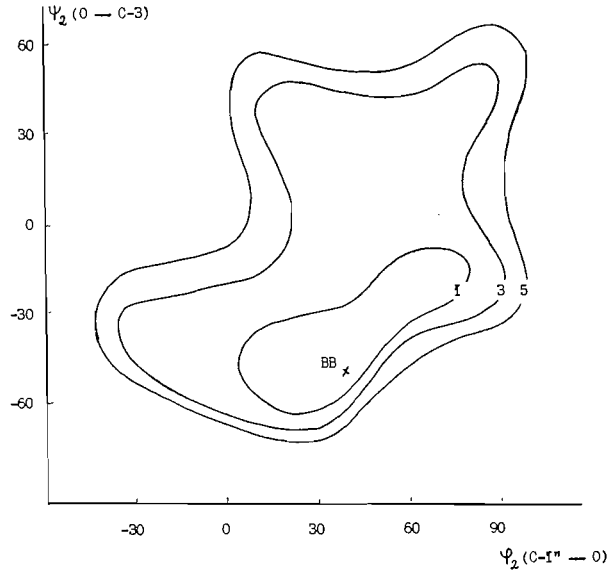

FIG. 5. Cross sections of potential surface for the trisaccharide **2** βDGlc(1–2)[βDGlc(1–3)]αLRha-OMe. $\varphi_2 - \psi_2$ ($\varphi_1 = 40.6$, $\psi_1 = -24.1°$); see legend to Fig. 3.

rhamnose residue forming the glycosidic linkages: for H-2 on pre-irradiation of H-1′ and for H-3 on pre-irradiation of H-1″ (Table 5). However, H-1′ and H-2″ in the AB conformation are in spatial proximity as well (Fig. 6); we failed to determine the corresponding effects on pre-irradiation of H-1′ because the positions of the H-1′ and H-1″ signals are too close to each other. The data for the statistical calculation of the nOe's are listed in Table 5. As well as in the (1–2)- and (1–3)-linked units, the ratio of average values $(\langle f^{H\text{-}3'}_{H\text{-}1'}\rangle + \langle f^{H\text{-}5'}_{H\text{-}1'}\rangle)/\langle f^{H\text{-}2}_{H\text{-}1'}\rangle$ and $(\langle f^{H\text{-}3''}_{H\text{-}1''}\rangle + \langle f^{H\text{-}5''}_{H\text{-}1''}\rangle)/f^{H\text{-}3}_{H\text{-}1''}\rangle$ is equal to 1.8/1.9. The same ratio of the nOe's under discussion is experimentally observed (Table 1). It should

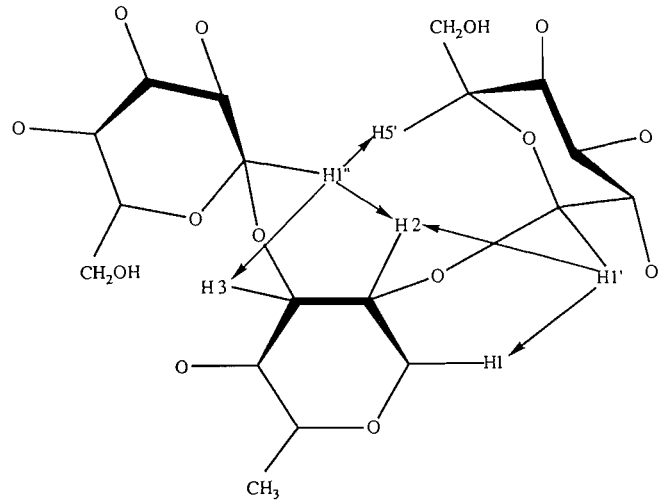

FIG. 7. Molecular model of preferred conformer AA of the trisaccharide **3** αDMan(1–2)[αDMan(1–3)]αLRha-OMe; see legend to Fig. 2.

be noted that similar values of the nOe's are observed for the disaccharides **9** and **10** (Table 3). This means that the conformational states of both disaccharide units in the trisaccharide **2** and in the disaccharides **9** and **10** are similar.

αDMan(1–2)[αDMan(1–3)]αLRha-OMe (3)

Trisaccharide **3** differs from trisaccharide **1** by the absolute configuration of the X and Y substituents at the rhamnopyranose residue. Due to this fact (see ref. 20), upon pre-irradiation of the anomeric proton in each disaccharide unit significant nOe is observed not only for the proton linked to the α-carbon atom of the aglycon (i.e., for H-2 and H-1 in the (1–2)-linked unit and for H-3 and H-2 in the (1–3)-linked unit, Table 1). The same situation exists for the disaccharides **11** and **12** (Table 3). The change of absolute configuration of the X and Y substituents in the trisaccharide **3** relative to the trisaccharide **1** causes a turn in the average planes of the X and Y residues of ≃180° and proton H-1″ in **3** is located in the region between the X and Y residues (Fig. 2). Indeed, the pre-irradiation of H-1″ causes the nOe for the resonance of H-5′ (3.8%, Table 1).

One preferred conformer is localized on the potential surface of **3** with rotation angles listed in Table 4. The molecular model of this conformer is drawn in Fig. 7. Two disaccharide units of this structure have the conformation A ($\varphi \simeq -60°$, $\psi \simeq -40°$) of the corresponding disaccharides **11** and **12** (see Table 2, ref. 7), i.e., it has the AA designation. In the optimal conformation found, the protons H-1″ and H-5′ are in close proximity (r(H-1″–H-5′) = 2.4 Å). The existence of the nOe for H-5′ after pre-irradiation of H-1″ (Table 1) indicates the significant statistical weight of the proposed AA conformation of **3**. We should point out that, in the AA conformation of **3**, not only the protons H-1″ and H-5′ are within the distance of van der Waals contacts, but also H-1″ and H-2 on one side and H-2″ and H-6′ on the other (Fig. 7). Thus this conformation is stabilized by effective dispersion interactions of the X and Y residues, with an energy of ca. −2 kcal/mol. This circumstance determines, in **3**, the location of the lowest energy contour Δ 1 kcal/mol for the cross sections on the potential energy surface φ_1–ψ_1 and φ_2–ψ_2 (Fig. 8) at values for the rotation angles of $\varphi < -30°$ and $\psi < -30°$. At other allowable values of φ and ψ of **3**, the residues X and Y are separated and do not interact with each other. Therefore the

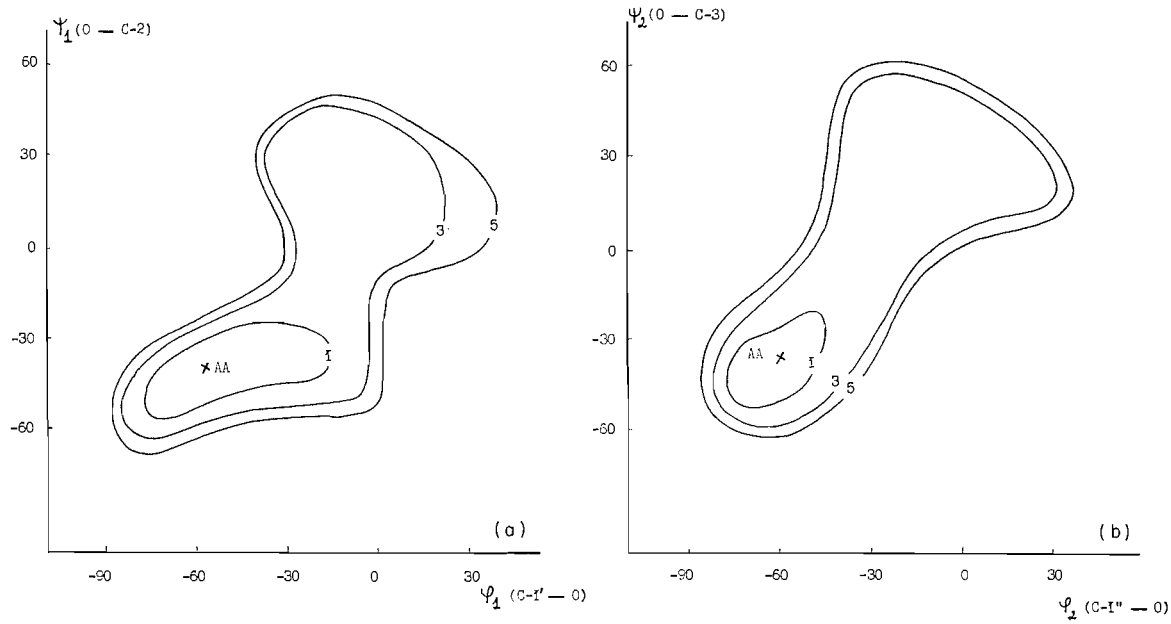

FIG. 8. Cross sections of potential surface for the trisaccharide **3** αDMan(1–2)[αDMan(1–3)]αLRha-OMe. (a) $\varphi_1 - \psi_1$ ($\varphi_2 = -61.5, \psi_2 = -35.1°$); (b) $\varphi_2 - \psi_2$ ($\varphi_1 = -59.0, \psi_1 = -37.6°$); see legend to Fig. 3.

contour forms of relative energy Δ 3 kcal/mol on cross sections (Fig. 8) and conformational maps of the free disaccharides **11** and **12** are equal.

Thus conformational state A of the disaccharide units (which in the free disaccharides **11** and **12** are assigned the statistical weight of 75% (7)) are additionally stabilized in the trisaccharide **3** by nonbonded interactions between two α-D-mannose residues, so that conformer AA is preferable for **3**.

The nOe value between H-1″ and H-5′ of the nonbonded mannose residues depends mainly on conformational possibilities of the disaccharide units in **3**. In this calculation they are determined by the φ_1–ψ_1 and φ_2–ψ_2 cross sections (in Fig. 8). The fact that the ratio of the nOe's for H-5′ and H-2 after pre-irradiation of H-1″ is 0.4 according to the experimental data (Table 1), while the calculated value is 0.3 (Table 5), indicates an acceptable description of the conformational flexibility of **3**.

In optimal conformation AA of **3**, for the (1–2)-linked unit the calculated value $f_{H\text{-}1'}^{H\text{-}1}$ is several times higher than $f_{H\text{-}1'}^{H\text{-}2}$ (Table 4). Similarly, for the (1–3)-linked unit the value of $f_{H\text{-}1''}^{H\text{-}2}$ is much higher than $f_{H\text{-}1''}^{H\text{-}3}$ (Table 4), but in statistical calculations the average value $\langle f_{H\text{-}1'}^{H\text{-}1} \rangle$ is higher than $\langle f_{H\text{-}1'}^{H\text{-}2} \rangle$ by only 1.4-fold (Table 5). The experimental ratio is 1.3 (Table 1). The values $\langle f_{H\text{-}1''}^{H\text{-}2} \rangle$ and $\langle f_{H\text{-}1''}^{H\text{-}3} \rangle$, taking into account the possible deviations of φ and ψ, are equal (Table 5). Due to overlapping of the H-2″ and H-3 signals, we failed to determine exactly the experimental nOe values for H-3 after pre-irradiation of H-1″ (Table 1). At the same time both the ratio of the sum of the observed nOe for the H-2″, H-3 protons and the nOe for H-2, as well as the ratio of the above-mentioned average values $(\langle f_{H\text{-}1''}^{H\text{-}3} \rangle + \langle f_{H\text{-}1''}^{H\text{-}2} \rangle)/\langle f_{H\text{-}1''}^{H\text{-}2} \rangle$, is 2:1 (Tables 1 and 5).

It should be noted that the calculated nOe values for H-2 and H-3 protons on pre-irradiation of H-1″ are equal (Table 5), whereas the observed nOe for H-2 of **12** is 2-fold higher than that for H-3 (Table 3). This fact may indicate the possibility of considerable differences in the conformational states of the αDMan(1–3)αLRha unit in the trisaccharide **3** and in the disaccharide **12**. But this is not the case. The decrease of the relative nOe value on H-2 in **3** is caused by additional spatial proximity (up to 2.6 Å) of this proton with H-1′ of the mannose residue of the (1–2)-linked unit, which is absent in the disaccharide **12**. In accordance with the conformational analysis, the conformer A (φ,ψ −60,−40°) of **12** remains predominant for the corresponding unit of **3**.

βLFuc(1–2)[βLFuc(1–3)]αLRha-OMe (4)

The X and Y residues in **4** differ from those in **3** by two-configuration parameters: absolute and anomeric configurations. That is why the observed regularities in spectra of these trisaccharides should be almost the same (20). Actually the commensurable nOe's are observed on pre-irradiation of H-1′ for H-1 and H-2 in the trisaccharide **3** as well as in **4** and on pre-irradiation of H-1″ for H-2 and H-3 of the rhamnose residue (Table 1). However, upon pre-irradiation of H-1′ as well as H-1″ of **4**, the nOe's on the protons of the nonbonded residues (Y for H-1′ and X for H-1″) were not observed.

The β configuration of the fucopyranosyl residues leads to increased conformational freedom of the disaccharides **13** and **14** in comparison with the disaccharides **11** and **12** (see refs. 7 and 8), which is preserved in the disaccharide units of the trisaccharide **4**; as before, the limit of admissible values for angles ψ_1 and ψ_2 ranges from −60 to +60°. This means that for the above-mentioned rotation angles the inadmissible van der Waals contacts between two nonbonded fucose residues do not appear. The molecular model of the lowest-energy conformation AA of **4**, in which the predominant conformers A (φ,ψ −50,−30°) of the disaccharide units are presented, is shown in Fig. 9. The spatial structure of **4** (Fig. 9) explains the relative decrease of the nOe value on H-2 on pre-irradiation of either H-1′ or H-1″ in this trisaccharide, in comparison with the disaccharides **13** and **14** (see the data in Tables 1 and 3). As for the trisaccharide **3**, this result for **4** is caused by the spatial proximity of H-2 to a greater number of protons than in the selected disaccharides **13** and **14**. It should be noted that the calculations present only a qualitative picture of the observed nOe's because of the absence of the definite X-ray structure of the β-L-fucopyranose residue (compare Tables 1 and 5).

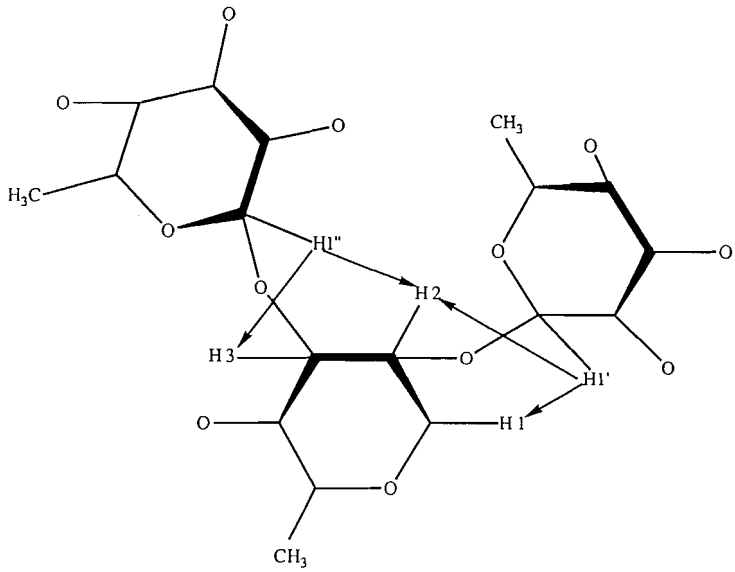

FIG. 9. Molecular model of low-energy conformer AA of the trisaccharide **4** βLFuc(1–2)[βLFuc(1–3)]αLRha-OMe; see legend to Fig. 2.

Glycosylation effects

The changes in chemical shifts of the carbon atom signals in the ^{13}C NMR spectra while transferring from mono- to disaccharides (the glycosylation effects) are directly connected with the spatial structure of the disaccharides formed. It was shown earlier that there is a distinct dependence between glycosylation effect values and nonbonded interactions of glycon and aglycon protons placed near a glycosidic linkage (20–22). Thus for "γ-*gauche*" interactions between anomeric proton H-1′ and the equatorial proton at the β position of the aglycon (which could be realized in (1–3)-linked glycosylgalactosides and glycosylmannosides (glycosylrhamnosides)), the glycosylation effects for C-β (C-4 in the first case and C-2 in the second one) could be −3 to −5 ppm (23), i.e., chemical shifts for the above-mentioned atoms are observed at a higher field. At the same time the glycosylation-effect values for linear oligo- and polysaccharides are preserved (24), so their ^{13}C NMR spectra could be calculated according to an additive scheme.

Upon investigation of branched oligosaccharides, a question arises — whether there is a similar correlation between glycosylation effects and spatial proximity of protons (as well as other atoms) for the different monosaccharide residues.

The analysis of a series of methyl-β-D-galactopyranoside derivatives glycosylated at neighbouring OH-3 and OH-4 or at OH-2 and OH-3 (1) showed that chemical shifts of the carbon atoms in branched trisaccharides, calculated with the use of an additive scheme on the basis of the spectra of the corresponding disaccharides and methyl-β-D-galactopyranoside, definitely differ from experimental data. It was found that deviations (about −3 ppm) of chemical shift values calculated by the additive scheme from the experimental values do correlate with the conformational changes that take place in disaccharide units of branched trisaccharides, in comparison with the corresponding free disaccharides.

The aim of this paper is the investigation of the dependence of the glycosylation effect on spatial structure for branched trisaccharides having vicinal substitution at axial OH-2 and equatorial OH-3 of the α-L-rhamnopyranose residue.

^{13}C NMR spectral data both for the disaccharides **7**–**14**, corresponding to disaccharide units of trisaccharides, and the trisaccharides **1**–**4** (see Tables 7 and 8 in Experimental), allow us to calculate the deviation from additivity Δ (ppm), which represents the difference between the observed ^{13}C chemical shifts of the trisaccharide and the shift calculated according to the additive scheme, $\Delta = \delta_{exp} - \delta_{calc.}$ (see Table 6).

The deviations from additivity Δ in the ^{13}C NMR spectra of **1**–**4** for all the carbon atoms of the α-L-rhamnopyranose residue at branch points and C-1′, C-1″ of the X and Y residues (for the other atoms of the X and Y groups, Δ-values are equal to 0) are presented in Table 6. It is obvious that in all cases the Δ-values are in the −0.6 to +0.6 ppm range, i.e., they practically correlate with the ordinary deviations of chemical shifts in the ^{13}C NMR spectra of oligosaccharides (experimental error is near ±0.5 ppm).

Thus the chemical shift values for the ^{13}C NMR spectra of the branched oligosaccharides **1**–**4** represent additive values related to the chemical shifts of the corresponding disaccharides. This means that the conformational states of disaccharide units in the trisaccharides **1**–**4** are close to the conformational states of free disaccharides. This conclusion was reached previously on the basis of the nOe data and conformational calculations for **1**–**4**.

It should be noted that chemical shifts of carbon atoms at the branch point (2,3-disubstituted α-L-rhamnopyranose residue) in the tetrasaccharide **5** are close to the chemical shift values of the carbon atoms (without prime) of the corresponding trisaccharides **1** and **6**. Thus the positions of C-3 and C-4 signals in **1** and **5** practically coincide; the same is true for the C-1 signals in **5** and **6** (Table 8).

The data obtained for **1**–**4** mean that chemical shifts of branch points having vicinal substituents at OH-2 and OH-3 of the α-rhamnopyranose (or α-mannopyranose) residue could be calculated according to an additive scheme.

Experimental

1D and 2D NMR experiments were performed on samples dissolved in D_2O at 40–55°C using Bruker WM-250 (for ^1H) and AM-300 (for ^{13}C) spectrometers. The reference for the ^1H and ^{13}C NMR spectra was acetone (2.225 and 31.45 ppm, respectively). Assignments of the ^1H NMR spectra (Table 7) were accomplished using COSY and RCT 2D experiments (COSY RCT of the standard Bruker software for

For personal use only.

ASPECT-2000). The HDO signal suppressing upon the relaxation delay (1 s) D_2 was 33 ms ($1/4J$; J = 7.5 Hz). Spectral windows were ca. 500 Hz (the region of the pyranose ring protons only). Data sets consisting of 256 t_1 experiments each with 512 data points were zero-filled to 512 data points. Prior to Fourier transformation the FIDs were multiplied with a sine-bell window function (not shifted). Typical COSY RCT contour plots are represented in Fig. 10.

The nOe experiments were performed in the difference mode within the tOe technique (25) with D_1 (pre-irradiation time) 0.5 s and D_2 (the relaxation delay) 0.8 s using the NOEMULT program of the standard Bruker software. The pre-irradiated signal area in the difference spectra was taken as 100%. The nOe's are expressed as the ratio of integrated intensities of the observed and saturated proton resonances.

In cases where, upon pre-irradiation of the anomeric proton of one residue, significant pre-irradiation of the anomeric proton of the other residue occurs, both irradiations might cause the nOe on the same proton d; for example, due to the close position of H-1′ and H-1″ signals in the H NMR spectrum of **2** (Table 7), during pre-irradiation of H-1″, proton H-1′ was also affected. Thus the registered value of nOe on the H-2 ("proton d") is a result of the pre-irradiation not only of H-1″, but H-1′ as well. The nOe values x and y on the d proton caused by the first and second irradiation were calculated from the solution of the equilibrium system:

$$I'_d = x\,I'_{H\text{-}1'} + y\,I'_{H\text{-}1''}$$

$$I''_d = x\,I''_{H\text{-}1'} + y\,I''_{H\text{-}1''}$$

where I'_d, $I'_{H\text{-}11'}$, and $I'_{H\text{-}1''}$ are the integral intensities of the differential nOe spectra signals of protons d, H-1′, and H-1″ on pre-irradiation of H-1′; I''_d, $I''_{H\text{-}1'}$, and $I''_{H\text{-}1''}$ are the same on pre-irradiation of H-1″.

The assignments of the ^{13}C NMR spectra (Table 8) were made in a straightforward manner by using 2D ^1H–^{13}C correlated spectroscopy (XHCORRD program of the Bruker software for ASPECT-3000). The typical spectral window was 500 Hz for ^1H and 5000 for ^{13}C (the region, respectively, of pyranose ring protons or carbon atoms only). Data sets consisting of 256 t_1 experiments each with 2K data points were zero-filled to 512 data points. For detection of ^1J correlations D_3 was set to 3.2 ms and D_4 to 1.6 ms ($1/2J$ and $1/4J$, respectively; J = 155 Hz). FIDs were multiplied with a square sine-bell window function (not shifted) in both directions, prior to Fourier transformation. A typical spectrum is represented in Fig. 11. The syntheses of **1**–**6** and **11**–**14** will be published elsewhere.

Photocyclisations de cétoacétals aromatiques en vue d'une approche synthétique de la crombénine

FRANÇOISE COTTET, LOUIS COTTIER ET GÉRARD DESCOTES

Laboratoire de chimie organique II, Université Lyon I, Unité associée n° 463 du Centre national de la recherche scientifique, 69622 Villeurbanne, France

Reçu le 8 août 1989

Cet article est dédié au Professeur Arthur S. Perlin à l'occasion de son 67e anniversaire

FRANÇOISE COTTET, LOUIS COTTIER et GÉRARD DESCOTES. Can. J. Chem. **68**, 1251 (1990).

La crombénine **1** est un spiropeltogynoïde présentant une structure spiroacétalique. Une approche de sa synthèse a été entreprise à partir d'orthocarbonylphénoxyisochromanne avec pour étape clef une réaction de photocyclisation de type Norrish II. En série isochromannique, le cycle aromatique induit une réaction secondaire de cyclisation sur le radical benzylique compétitive avec la réaction de spirocyclisation. Cependant, la présence de substituant électroattracteur ou encombrant en C-4′ diminue la formation du dérivé bicyclique de type [4.3.1] et oriente la photolyse vers le produit de structure spirannique.

Mots clés : acétals, isochromène, photocyclisation, spiroacétals.

FRANÇOISE COTTET, LOUIS COTTIER and GÉRARD DESCOTES. Can. J. Chem. **68**, 1251 (1990).

Crombenin **1** is a spiropeltogynoid compound with a spiroacetal moiety. A similar structure was synthesized starting from an orthocarbonylphenoxyisochroman by a Norrish type II photocyclisation. With an isochroman compound, the aromatic ring induces benzyl radical formation to give chiefly a bicyclic [4.3.1] derivative. However, with the introduction of electron-withdrawing or bulky substituents at C-4′, this side reaction is limited and the spiranic product becomes preponderant.

Key words: acetals, isochroman, photocyclisation, spiroacetals.

La crombénine **1** (R = OH) (1, 2) est une substance isolée en très faible quantité de l'«Acacia crombei». Sa structure, identifiée à partir de l'un de ses dérivés tétra-*O*-méthylé **1** (R = OMe) (3), possède un motif spiroacétalique (figure 1) présent dans de nombreuses substances biologiquement actives (4–8). Ayant étudié différentes réactions de spirocyclisation par voie photochimique de systèmes cétoacétaliques, une approche de la synthèse de la crombénine a été entreprise ayant pour étape clef une réaction de photocyclisation de type Norrish II.

En effet, les résultats obtenus en série glycosidique (9, 10) et en série tétrahydropyrannique (11–13) permettent d'envisager la synthèse de la crombénine ou de ses analogues selon un schéma rétrosynthétique en quatre étapes (Schéma 1). La condensation d'un phénol orthocarbonylé **A** avec un isochromène **B** ou un dérivé, devrait donner un acétal **C** qui, par photolyse, serait transformé en produit spirannique **D**. Selon la nature de la fonction hydroxyle sur le cycle furannique, une simple oxydation ou une déshydratation suivie d'une oxydation conduirait au composé **E** possédant la fonction cétone souhaitée. Ainsi, compte tenu des résultats obtenus avec les phénylglucosides orthocarbonylés (9), cette séquence réactionnelle a d'abord été étudiée en série tétrahydropyrannique puis elle a été étendue à des substrats isochromanniques.

Résultats

Synthèse des acétals

La fonction aldéhydique a été choisie comme groupe chromophore, car elle aurait permis d'accéder à un alcool secondaire en C-3 directement oxydable. La condensation directe entre l'aldéhyde salicylique et le dihydropyranne n'ayant pu être réalisée, le tétrahydropyrannyloxy-2 benzaldéhyde **6** a été synthétisé à partir de l'alcool *o*-hydroxy-benzylique **2**. L'estérification sélective de la fonction alcool primaire selon Nagao *et al.* (14), suivie de l'acétalisation avec le dihydropyranne, d'une saponification et d'une oxydation ménagée, permet d'obtenir l'aldéhyde **6** recherché (Schéma 2).

La synthèse des différents cétoacétals aromatiques **7** (tableau 1) a été récemment publiée en série hétérocyclique (15). En série isochromannique, l'acétal **10** a été obtenu par condensation en milieu alcalin de la chlorhydrine **9** issue de l'isochromène **8** (16) avec l'*ortho*-hydroxy-acétophénone selon la méthode décrite par Bakassian *et al.* (17) (Schéma 3).

En effet, l'isochromène, comme le dihydropyranne, réagit avec une solution d'eau de javel (18) pour donner un mélange *cis* + *trans* de chlorhydrines **9** isomères instables à température ambiante. L'attribution de la configuration a été réalisée à partir des dérivés acétylés **11** par comparaison en rmn ^{1}H des constantes de couplage entre les protons H-3 et H-4 avec celles des hydroxy-5 méthoxy-6 dihydro-5,6 [2*H*] pyrannes décrites par Chmielewski et Zamojski (19); l'isomère *trans* présente une constante de couplage inférieure à celle de l'isomère *cis* (pour **16** : *cis*, J_{3-4} = 3,1 Hz; *trans*, J_{3-4} = 2,6 Hz). Les dérivés **9** instables sont soumis à l'état brut à l'action de l'*ortho*-hydroxy-acétophénone qui sert de solvant et de réactif. Le produit de condensation obtenu **10**, de configuration *trans*, est alors estérifié par le *N*-acétylimidazole en **12** (20) ou silylé en **13** (Schéma 3).

*Photolyse des acétals **6**, **7**, **10**, **12** et **13***

Contrairement aux résultats antérieurs (9, 13), la photolyse de l'aldéhyde **6** donne un mélange complexe subissant une dégradation importante lors de la séparation sur une colonne de silice. En conséquence, le groupe chromophore aldéhydique a été remplacé par un groupe acétyle.

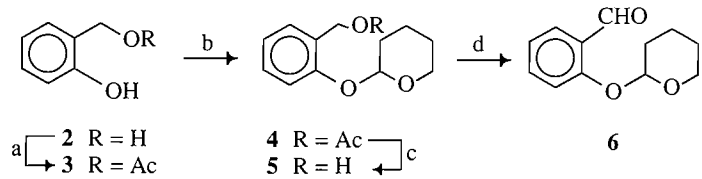
SCHÉMA 1. Schéma rétrosynthétique de la synthèse de la crombénine.

Avec les acétals cétoniques **7**, la réaction de cyclisation en composés spiranniques **14** dépend de la nature des substituants sur le cycle aromatique (tableau 1). La photolyse de **7***a* non substitué donne un mélange de quatre diastéréoisomères **14***a* détectés en rmn ^1H par la présence de quatre singulets pour les groupes méthyles quaternaires. Ces alcools isomères **14***a* sont déshydratés ($POCl_3$ + pyridine) afin d'établir la structure et le pourcentage des seuls isomères *cis–trans* au niveau du cycle tétrahydropyrannique. La structure des produits insaturés **15***a* (conformation avec la liaison C2—O1 axiale, isomère *cis–trans*) a été déterminée selon les méthodes spectrales précédemment signalées en série hétérocyclique (11, 12, 21) et en série glucosidique (9, 10, 22). La position axiale de la liaison C2—O1 résulte de la comparaison des déplacements chimiques des carbones C-2, C-3′, C-5′ entre les composés **15***a* et les dérivés spiranniques (11, 12) non aromatiques, compte tenu des effets d'un groupement acétate en C-3′ (23). Ainsi, en rmn ^{13}C, les déplacements chimiques observés et calculés pour les



a : Ac_2O, BF_3OEt_2 (84%)
b : DHP, PPTS (32%)
c : NaOH, EtOH (94%)
d : PCC (69%)

SCHÉMA 2. Synthèse du tétrahydropyrannyloxy-2 benzaldéhyde **6**.

carbones C-2, C-3′, C-5′ sont voisins à 2 ppm près (**15***a*, δ C-*i* (obs.–calc.) : *cis*, C-2 (107,5–106,9), C-3′ (71–72,7), C-5′ (24,7–22,7); *trans*, C-2 (105,9–105,3), C-3′ (69,7–68,5), C-5′ (19,0–18,9)). En rmn ^1H, la multiplicité des signaux du proton H-3′ permet d'attribuer respectivement aux isomères **15***a* la configuration *cis* et *trans* (**15***a* *cis*, δ : 5,5 (dd, J = 6 et 10 Hz); *trans*, δ : 5,05 (t, J = 3 Hz)). Enfin, le rapport de l'intégrale de ces signaux (5,5 et 5,05 ppm) montre pour ce mélange d'isomères *cis–trans*, une proportion égale à 78 : 22. Comme la déshydratation de **4***a* a été faite en milieu basique, la cyclisation radicalaire du produit **7***a* conduit au même mélange d'isomères *cis–trans*.

L'introduction de deux substituants méthoxy **7***c* sur le cycle aromatique modifie fortement la formation des produits spiranniques (tableau 1). Cette diminution de réactivité photochimique pour **7***c*, a déjà été observée pour d'autres cétones aromatiques (24, 25). Différents auteurs (24, 25) ont montré qu'avec un groupement méthoxy, l'état triplet de plus basse énergie prend un caractère $\pi\pi^*$ défavorisant une réaction de type Norrish II. De plus, Scaiano et coll. (26) ont relié la constante de vitesse d'abstraction d'un atome d'hydrogène à la valeur du paramètre σ d'Hammett. Des valeurs négatives (pour CH_3O-, $\sigma = -0{,}12$) (27) favorisent un état triplet $\pi\pi^*$ et entrainent une baisse de réactivité qui n'a pu être compensée par la présence d'un nouveau groupe chromophore éthoxalyle (COCOOEt) ayant un coefficient d'absorption plus élevé (28, 29). Une valeur positive de σ correspond à une augmentation de la population de l'état triplet $n\pi^*$ et permet ainsi d'expliquer le faible pourcentage de composé spirannique **14***b* obtenu avec des substituants acétoxy (pour CH_3COO-, $\sigma = +0{,}31$) (27) sur le cycle aromatique carbonylé.

L'irradiation des acétals isochromanniques **10**, **12** et **13** conduit à des composés spiranniques **16** ou bicycliques **17** (Schéma 4) dont les proportions varient avec la nature du substituant en position 4′. L'alcool **10** donne préférentiellement le dérivé bicyclique [4.3.1] **17***a* avec un rendement de 41%. La structure a été établie par rmn et confirmée par l'analyse cristallographique (figure 2). Le spectre rmn ^1H montre un seul singulet pour le méthyle quaternaire en C-2 et deux singulets pour les protons H-1 et H-6. L'absence de constante de couplage entre H-6 et H-7 résulte de la valeur de l'angle dièdre H-6—C-6—C-7—H-7 voisin de 90°. Par contre, le signal correspondant à H-7 est un doublet (J = 9 Hz) résultant du couplage avec l'hydrogène de l'hydroxyle secondaire. L'irradiation de l'ester **12** permet l'isolement, après purification, d'isomères spiranniques **16***b* (10%) et du régioisomère **17***b* (24%).

La présence de quatre stéréoisomères **16***b* est décelée par le nombre de singulets (huit) en rmn ^1H correspondant au méthyle quaternaire et à celui du groupe acétate. Le rapport des

*Pourcentage calculé par rmn ^{1}H.

intégrales de ces singulets indique que les quatre diastéréoisomères **16***b* sont dans des proportions pratiquement équivalentes (3 : 3 : 2 : 2).

Enfin, la photolyse du dérivé silylé **13** semble produire majoritairement le composé spirannique **16***c* (70%). En effet, si la purification du photolysat obtenu par chromatographie sur silice conduit à la dégradation des produits, le spectre rmn ^{1}H (350 MHz) du produit brut révèle la présence du mélange des isomères spiranniques **16***c* et du composé **17***c*.

Discussion des résultats

La photolyse des acétals aromatiques de type **C** comportant un groupe chromophore acétyle conduit à des composés de structure spirannique **D** en série hétérocyclique. En série isochromannique, la présence d'un second noyau aromatique induit une réaction secondaire de cyclisation sur le radical benzylique, compétitive avec la réaction de spirocyclisation.

Cette photocyclisation conduisant à des dérivés bicycliques de type [4.3.1] peut résulter d'une proximité plus grande du groupe carbonyle avec un des atomes d'hydrogène benzylique par rapport à l'atome d'hydrogène acétalique car un tel facteur peut intervenir dans la régiosélectivité d'une telle réaction radicalaire (30). De plus, la formation du dérivé bicyclique **17***a* peut s'expliquer en supposant une vitesse d'homolyse plus grande pour l'hydrogène benzylique étant donné la faible valeur de l'angle dièdre ($\theta_1 = 30°$) formé par la liaison C-1′—H-1′ et

‡Rendement estimé d'après le spectre rmn.

l'orbitale *p* non liante de l'atome d'oxygène (Schéma 5) (31–33). En outre, selon Leroy (34), l'énergie de stabilisation SE d'un radical benzylique (45,19 kJ mol^{-1}) est supérieure à celle d'un radical acétalique (−8,11 kJ mol^{-1}) alors que l'enthalpie de clivage de liaison (BDE) est inférieure de 52,7 kJ mol^{-1} (367,5 au lieu de 420,2). Ainsi, l'ensemble de ces facteurs stériques et énergétiques justifierait la formation du composé bicyclique **17**.

Ayant précédemment constaté l'influence favorable d'un groupement acétate en C-2 sur le processus de photocyclisation des glycosides (10, 22), il nous a semblé utile d'acétyler la fonction alcool. La présence d'un tel groupement modifie sensiblement la conformation de la partie tétrahydropyrannique (**10** *trans*, R = H, J_{3-4} = 2,6 Hz; **12**, R = Ac, J_{3-4} = 0) et probablement la valeur des angles θ_1 et θ_2. En outre, il est vraisemblable d'envisager selon Giese et coll. (35) une interaction stabilisante entre l'orbitale *p* occupée par un électron isolé (SOMO) et l'orbitale σ* (LUMO) de la liaison C-4—OAc.

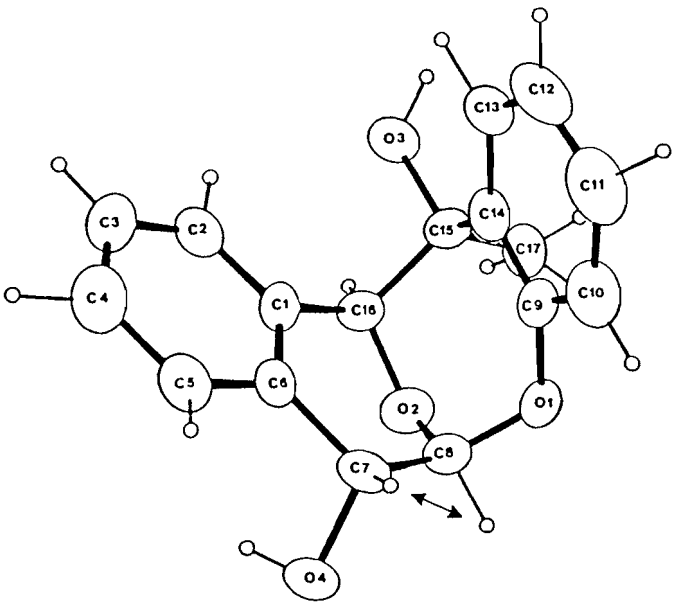

FIG 2. Analyse cristallographique de **17***a*. (La numérotation des atomes de **17***a* dans ce schéma est différente de celle du schéma 5.)

SCHÉMA 5. Représentation des acétals isochromanniques.

Enfin, les résultats avec le composé **13** montrent que l'introduction du groupe *tert*-butyldiméthylsilyle oriente la photolyse vers la spirocyclisation. La présence d'un tel groupement encombrant doit vraisemblablement modifier la conformation de la partie hétérocyclique (**13**, R = SiTBDM, J_{3-4} = 2 Hz) éloignant le groupe carbonyle des hydrogènes benzyliques.

En conséquence, l'application de ces résultats initiaux en série tétrahydropyrannique et en série isochromannique au diméthoxy-6,7 isochromène devrait être envisagée pour la synthèse ultérieure de la tétra-*O*-méthyl crombénine **1** (R = OMe) et de la crombénine **1** (R = OH).

Partie expérimentale

Les points de fusion non corrigés ont été déterminés sur un appareil Buchi. Les spectres rmn ^1H (60, 80 et 350 MHz) et masse, ont été tracés à température ambiante respectivement avec les spectromètres suivants : Varian EM 360, Cameca, Bruker WP.80 CW, Varian série 634 et Varian Match 5 à 70 eV. Les chromatographies «flash» ont été réalisées avec de la silice Merck (230–400 mesh).

Synthèse des acétals tétrahydropyranniques et isochromanniques

Synthèse de l'acétate de salicyle ***3***

À 50 g (0,4 mol) d'alcool *o*-hydroxybenzylique **2** dissous dans 300 mL d'éther et refroidis à 0°C, sont ajoutés goutte à goutte 48 mL (0,5 mol) d'anhydride acétique puis 1 mL d'éthérate de trifluorure de bore. Le mélange, agité pendant 4 h à 15°C, est neutralisé avec 44 g d'hydrogénocarbonate de sodium dissous dans 100 mL d'eau glacée. Après extraction avec 200 mL d'éther, lavage à l'eau et séchage sur sulfate de sodium, l'évaporation du solvant donne 65 g de produit **3** brut. Le composé **3** (4,8 g) est purifié par chromatographie (hexane/acétate d'éthyle, 3 : 2) donnant 4,16 g (0,025 mol) de **3** (rendement 84%); liquide; rmn ^1H 60 MHz ($CDCl_3$) δ : 7,6 (large s, 1H, OH), 7,1 (m, 4H, arom.), 5,05 (s, 2H, CH_2O), 2,0 (s, 3H, CH_3COO) ppm. Anal. calc. pour $C_9H_{10}O_3$: C 65,05, H 6,07; tr. : C 64,95, H 6,05.

Synthèse de l'acétate de tétrahydropyrannyloxy-2-benzyle ***4***

Le composé **4** a été préparé selon la méthode décrite par Miyashita *et al.* (36) à partir de 1,9 g (0,011 mol) de **3**, 1,5 mL (0,017 mol) de dihydropyranne et 0,3 g de paratoluène sulfonate de pyridinium. Le produit brut (1,4 g) est purifié par deux chromatographies successives (hexane/acétate d'éthyle, 4 : 1, puis dichlorométhane) donnant 0,915 g (3,6 mmol) de **4** (rendement 32%) et 1 g (6 mmol) d'alcool **3**; solide; *F* 48–49°C; rmn ^1H 60 MHz ($CDCl_3$) δ : 7,2 (m, 4H, arom.), 5,5 (m, 1H, OCHO), 5,2 (s, 2H, CH_2OCO), 3,8 (m, 2H, CH_2O), 2,05 (s, 3H, CH_3COO), 1,9 (m, 6H, $(CH_2)_3$) ppm. Anal. calc. pour $C_{14}H_{18}O_4$: C 67,18, H 7,25; tr. : C 67,10, H 7,23.

Synthèse de l'alcool tétrahydropyrannyloxy-2 benzylique ***5***

L'acétate **4** (2,5 g, 0,01 mol) dilué dans 20 mL d'éthanol est saponifié à 18°C pendant 1 h par une solution éthanolique de soude (10 mL de soude 2 N et 10 mL d'éthanol). Après évaporation de l'éthanol, le résidu est repris avec 50 mL d'éther. Après lavage à l'eau, séchage, filtration et évaporation, le produit brut (2 g) est chromatographié (hexane/acétate d'éthyle, 4 : 1) donnant 1,95 g (9,4 mmol) d'alcool **5** (rendement 94%); liquide; rmn ^1H 60 MHz ($CDCl_3$) δ : 7,2 (m, 4H, arom.), 5,35 (s, 1H, OCHO), 4,6 (s, 2H, CH_2OH), 3,9 (m, 2H, CH_2O), 2,55 (large s, 1H, OH), 1,8 (m, 6H, $(CH_2)_3$). Anal. calc. pour $C_{12}H_{16}O_3$: C 69,21, H 7,74; tr. : C 69,17, H 7,73.

Synthèse du tétrahydropyrannyloxy-2 benzaldéhyde ***6***

À la solution de 1,75 g (8 mmol) de chlorochromate de pyridinium dans 16 mL de dichlorométhane, sont ajoutés 0,1 g d'acétate de sodium anhydre puis 1,13 g (54 mmol) d'alcool **5** dilué dans 8 mL de dichlorométhane. Après 3 h d'agitation à température ambiante, le mélange est filtré sur Célite, dilué avec 20 mL d'éther, lavé à l'eau puis séché sur sulfate de sodium. Après filtration et évaporation, la chromatographie (hexane/acétate d'éthyle, 9 : 1) du produit brut (1 g) donne 0,78 g (38 mmol) d'aldéhyde **6** (rendement 69%); liquide; rmn ^1H 60 MHz ($CDCl_3$) δ : 10,4 (s, 1H, CH=O), 7,5 (m, 4H, arom.), 5,4 (s, 1H, OCHO), 3,8 (m, 2H, CH_2O), 1,8 (m, 6H, $(CH_2)_3$) ppm. Anal. calc. pour $C_{12}H_{14}O_3$: C 69,88, H 6,84; tr. : C 69,66, H 6,63.

Synthèse du chloro-4-isochromannol-3 ***9***

Une solution de 1,87 g (14,2 mmol) d'isochromène (16) dans 3 mL de tétrahydrofuranne est ajoutée à l'abri de la lumière et sous azote à 2,5 g de phosphate de potassium monopotassique solubilisé dans 3,4 mL d'eau distillée. Puis 7,9 mL d'une solution aqueuse d'hypochlorite de sodium (48° chlorométriques) sont ajoutés à 0°C goutte à goutte pendant 40 min. La solution, revenue à température ambiante, est évaporée puis extraite à l'éther. Après lavage à l'eau, séchage et évaporation, le produit **9** instable (2,1 g, rendement 80%) est utilisé à l'état brut; produit huileux; rmn ^1H 60 MHz ($CDCl_3$) δ : 7,35 (m, 4H, arom.), 5,5 (m, 1H, CHCl), 5,1 (m, 1H, CHOH), 4,9 (s, 2H, CH_2), 2,5 (large s, 1H, OH) ppm.

Synthèse de l'acétoxy-3-chloro-4- isochromanne ***11***

Sous azote et à l'abri de la lumière, on mélange 0,5 g (2,7 mmol) de chlorhydrine **9** avec 6,5 mL de pyridine anhydre, 16 mg de diméthylamino-4-pyridine et 5,1 mL (54 mmol) d'anhydride acétique. Après 3 h d'agitation à température ambiante, le mélange est concentré, repris avec 30 mL d'éther, neutralisé avec une solution aqueuse d'hydrogénocarbonate de sodium, puis lavé à l'eau. Après séchage, filtration et évaporation, le résidu (588 mg) est purifié par chromatographie (hexane/acétate d'éthyle, 7 : 3) donnant 350 mg (1,5 mmol) d'ester instable **11** (rendement 57%); solide; *F* 46–51°C; rmn ^1H 250 MHz ($CDCl_3$) δ : 7,35 (m, 4H, arom.), 4,96 (s, 1H, H-1), 6,38 (d, J = 2,6 Hz, H-3 *trans*), 6,37 (d, J = 3,1 Hz, H-3 *cis*), 5,13 (d, J = 3,1 Hz, H-4 *cis*), 4,94 (d, J = 2,6 Hz, H-4 *trans*), 2,15 (s, CH_3COO, *cis*), 2,08 (s, CH_3COO, *trans*) ppm. Anal. calc. pour $C_{11}H_{11}ClO_3$: C 58,29, H 4,89, Cl 15,64; tr. : C 58,60, H 4,70, Cl 15,60.

Synthèse de l'(acétyl-2'-phénoxy)3-isochromannol-4 ***10***

À une suspension de 0,874 g d'hydrure de sodium dans 20 mL d'éther anhydre sont additionnés sous azote et goutte à goutte 5 mL (41,5 mmol) d'*o*-hydroxy-acétophénone. Après l'arrêt du dégagement d'hydrogène, le mélange est dilué avec 60 mL d'*o*-hydroxy-acétophénone. Puis on ajoute 2,8 g (15 mmol) de chlorhydrine **9** solubilisée dans 10 mL d'*o*-hydroxy-acétophénone. Après 2 h d'agitation à température ambiante, le milieu est dilué avec 200 mL d'éther puis refroidi à 0°C avant l'addition de 52 mL d'une solution de soude à 5%. Après décantation, la phase organique est lavée avec cette solution basique pour éliminer l'*o*-hydroxy-acétophénone résiduelle. Après lavage à l'eau, séchage sur sulfate de magnésium et évaporation, le produit brut (2 g) est chromatographié (dichlorométhane/acétate d'éthyle, 85 : 15, plus 1% de pyridine) donnant 0,952 g (3,35 mmol) d'acétal **10** (rendement 22%); solide; *F* 73–74°C; rmn ^1H 80 MHz ($CDCl_3$) δ : 7,3 (m, 8H, arom.), 5,7 (d, J = 2,6 Hz, 1H, OCHO), 4,81 (s, 2H, CH_2O), 4,7 (d, J = 2,6 Hz, 1H, CHOH), 2,75 (large s, 1H, OH), 2,2 (s, 3H, $COCH_3$). Anal. calc. pour $C_{17}H_{16}O_4$: C 71,81, H 5,67; tr. : C 71,78, H 5,65.

Synthèse de l'(acétyl-2'-phénoxy)-3 acétoxy-4-isochromanne ***12***

Une solution d'alcool **10** (0,916 g, 3,2 mmol) dans 5 mL de tétrahydrofuranne est ajoutée, sous azote et goutte à goutte, à une suspension de 0,169 g d'hydrure de sodium (3,9 mmol) dans 3 mL de tétrahydrofuranne. Après 30 min d'agitation à température ambiante, 1,278 g de *N*-acétylimidazole (11,6 mmol) dilué dans 3 mL de tétrahydrofuranne sont ajoutés. Après 12 h d'agitation, le mélange est évaporé, repris avec 30 mL d'éther, lavé à l'eau puis séché sur sulfate de sodium. Après filtration et évaporation, le produit brut est chromatographié (dichlorométhane) donnant 0,875 g (2,6 mmol) d'acétate **12** (rendement 80%); solide; *F* 106–107°C; rmn ^1H 80 MHz ($CDCl_3$) δ : 7,4 (m, 8H, arom.), 5,9 (s, 2H, OCHO et CH—$OCOCH_3$), 4,9 (s, 2H, OCH_2), 2,15 (s, 3H, CH_3COO), 2,1 (s, 3H, $COCH_3$) ppm. Anal. calc. pour $C_{19}H_{18}O_5$: C 69,93, H 5,56; tr. : C 69,92, H 5,36.

Synthèse de l'(acétyl-2'-phénoxy)-3-tertiobutyldiméthylsilyloxy-4-isochromanne ***13***

De l'imidazole (0,874 g, 12,8 mmol) puis 0,968 g de chlorure de tertiobutyldiméthylsilyle (6,4 mmol) sont ajoutés à température ambiante à une solution de 0,912 g d'alcool **10** (3,2 mmol) dans 3,2 mL de diméthylformamide. Après 3 h d'agitation, le milieu réactionnel est dilué à 25 mL d'éther de pétrole. La phase inférieure est extraite trois fois avec 20 mL d'éther de pétrole. Les phases organiques sont lavées 2 fois avec 5 mL d'eau et séchées sur sulfate de sodium. Après filtration et évaporation, le produit brut (1,456 g) est chromatographié (hexane/acétate d'éthyle, 9 : 1) donnant 0,910 g (2,3 mmol) de produit silylé **13** (rendement 71%); solide; *F* 99–100°C; rmn ^1H 80 MHz ($CDCl_3$) δ : 7,35 (m, 8H, arom.), 5,8 (d, J = 2 Hz, 1H, OCHO), 4,9 (s déformé, 3H, OCH_2 et CHOSi), 2,2 (s, 3H, $COCH_3$), 0,9 (s, 9H, $SiC(CH_3)_3$), 0,13 et 0,1 (2s, 6H, $Si(CH_3)_2$). Anal. calc. pour $C_{23}H_{30}O_4Si$: C 69,31, H 7,59; tr. : C 68,84, H 7,59.

Photolyse des cétoacétals

Les irradiations ont été réalisées dans les conditions opératoires déjà décrites (22). La lampe est munie d'un filtre Vycor. Le solvant utilisé est l'acétonitrile ou le benzène.

7*a* : 7,2 g (26 mmol) de **7***a* dissous dans 600 mL d'acétonitrile ont été irradiés pendant 5 h. Après évaporation du solvant, le produit brut (7,4 g) est chromatographié (hexane/acétate d'éthyle, 3 : 2) donnant 6,28 g du mélange des stéréoisomères **14***a* (rendement 87%); liquide visqueux qui cristallise en partie lentement; rmn ^{1}H, 60 MHz (C_6D_6) δ : 7,15 (m, 4H, arom.), 5,5 et 5,05 (m, 1H, CH—OCOCH$_3$), 4,05 et 3,5 (m, 2H, CH_2O), 3,3 (s, 1H, OH), 1,9 et 1,7 (2s, 3H, CH_3COO), 1,5 (m, 4H, $(CH_2)_2$), 1,3 et 1,1 (2s, 3H, C—CH_3) ppm; rmn ^{13}C ($CDCl_3$) δ : 1,81, 1,80, 1,73 et 1,71 (4s, 3H, C—CH_3) ppm. Anal. calc. pour $C_{15}H_{18}O_5$: C 64,73, H 6,52; tr. : C 64,68, H 6,46.

Déshydratation des alcools isomères ***14***a

Selon la méthode décrite par Bernasconi *et al.* (9) 2 g (7,2 mmol) d'alcools **14***a* dans 15 mL de pyridine sont traités avec une solution d'oxychlorure de phosphore (2,1 mL, 23 mmol) dans 3,5 mL de pyridine. Le produit brut obtenu (1,76 g) est chromatographié (dichlorométhane/hexane/éther, 30 : 20 : 2) donnant 1,35 g (5,2 mmol) des isomères **15***a* (rendement 72%); liquide; rmn ^{1}H 60 MHz (C_6D_6) δ : 7,5–6,8 (m, 4H, arom.), 5,5 (dd, J = 6 et 10,4 Hz, 1H, CHOCOCH$_3$ *trans*), 5,05 (t, J = 3 Hz, 1H, CHOCOCH$_3$ *cis*), 4,8 (2 dd, J = 2,2 Hz, C=CH_2), 4,35–3 (m, 2H, -CH_2O), 2,2–0,8 (m, 4H, $(CH_2)_2$), 1,7–1,3 (2s, 3H, CH_3COO) ppm; rmn ^{13}C ($CDCl_3$) **15***a cis*, δ : 169,1 (C=O), 158,5 (C-3), 138,9, 134,1 (carbones quaternaires aromatiques), 129,6 (C-4), 129,03 (C-6), 122,1 (C-7), 119,8 (C-5), 107,5 (C-2), 80,8 (=CH_2), 71 (C-3′), 62,85 (C-6′), 25,2 (C-4′), 24,7 (C-5′), 20,2 (CH_3) ppm; **15***a trans*, δ : 169,3 (C=O), 157,9 (C-3), 139,6, 133,6 (carbones quaternaires aromatiques), 129,6 (C-4), 128,4 (C-6), 123,8 (C-7), 120,3 (C-5), 105,9 (C-2), 80,9 (=CH_2), 69,7 (C-3′), 63,4 (C-6′), 24,1 (C-4′), 21 (CH_3), 19 (C-5′) ppm. Anal. calc. pour $C_{15}H_{16}O_4$: C 67,73, H 6,50; tr. : C 67,71, H 6,46.

7*b* : 0,947 g (2,4 mmol) de **7***b* dissous dans 50 mL de benzène est irradié pendant 8 h. Le produit brut (0,940 g) obtenu après évaporation est chromatographié (hexane/acétate d'éthyle, 3 : 2) donnant 0,264 g (0,6 mmol) de produit initial **7***b* et 0,153 g (0,4 mmol) de composé spirannique **14***b* (rendement 20%); liquide; rmn ^{1}H 60 MHz ($CDCl_3$) δ : 7 (s, 2H, arom.), 5,8–5,4 (m, 1H, CHOCOCH$_3$), 4,4–3,5 (m, 2H, OCH_2), 2,3 et 2,28 (2s, 9H, CH_3COO), 1,85 (large s, 3H, CH_3), 2,9–1,6 (m, 5H, $(CH_2)_2$ et OH) ppm.

7*c* : 2,3 g (2,6 mmol) de **7***c* dissous dans 52 mL d'acétonitrile sont irradiés pendant 10 h. Après évaporation, 0,810 g de photoproduits sont déshydratés comme **14***a*. Le produit brut (0,619 g) obtenu, est chromatographié (hexane/acétate d'éthyle, 3 : 2) donnant des traces (19 mg) de produit insaturé **15***c*; liquide; rmn ^{1}H 60 MHz ($CDCl_3$) δ : 6,3 (m, 2H, arom.), 5,75 et 5,2 (2s, 2 × 2H, C=CH_2), 5,1 (m, 1H, CH—OCOCH$_3$), 4,1 (m, 2H, OCH_2), 3,9 et 3,85 (2s, 2 × 3H, OCH_3), 2,0 (m, 4H, $(CH_2)_2$), 2,15 et 1,9 (2s, 2 × 3H, CH_3COO) ppm.

10 (R = H) : 0,66 g (2,3 mmol) de produit **10** solubilisé dans 46 mL d'acétonitrile est irradié pendant 4 h. Après évaporation, le produit brut est purifié par deux chromatographies successives (dichlorométhane/acétate d'éthyle, 4 : 1, puis hexane/acétate d'éthyle, 1 : 1) donnant 0,167 g (0,6 mmol) de **10** et 0,204 g (0,7 mmol) de dérivé bicyclique **17***a* (rendement 41%); solide; F 149–150°C; rmn ^{1}H 80 MHz ($CDCl_3$) δ : 7,05 (m, 8H, arom.), 5,6 (s, 1H, OCHO), 4,75 (s, 1H, C-1—H), 4,35 (d, J = 9 Hz, 1H, C-7—H), 2,1 (d, J = 9 Hz, C-7—OH), 2,08 (s, 1H, C-2—OH), 1,8 (s, 3H, CH_3) ppm. Anal. calc. pour $C_{17}H_{16}O_4$: C 71,82, H 5,67; tr. : C 71,50, H 5,68.

12 (R = Ac) : 0,602 g (1,8 mmol) d'acétal acétylé **12** dans 37 mL de benzène est irradié pendant 12 h. Après évaporation, le produit brut est chromatographié (dichlorométhane/acétate d'éthyle, 9,5 : 0,5) donnant 0,060 g (0,18 mmol) d'acétate spirannique **16***b* (R = OAc) et 0,145 g (0,43 mmol) d'isomères bicycliques **17***b* (R = OAc); composé **16***b* (rendement 10%); solide; F 146–151°C; rmn ^{1}H 350 MHz ($CDCl_3$) δ : 7,3 (m, 4 × 8H, arom.), 6,6–6,5–5,9–5,8 (4s, 4 × 1H, CHOCOCH$_3$), 5,29–5,26–4,98–4,89 (4d, J = 15 Hz, 4 × 2H, C-1′—H_2), 3,2 (large s, 1H, OH), 2,13–2,10–1,95–1,92 (4s, 4 × 3H, CH_3COO), 1,83–1,79–1,77–1,74 (4s, 4 × 3H, C-3—CH_3) ppm; pour les CH_2 benzyliques deux isomères sur quatre sont observés; composé **17***b* (rendement 24%); solide; F 158–159°C; rmn ^{1}H 80 MHz ($CDCl_3$) δ : 7,1 (m, 8H, arom.), 5,8 (s, 1H, OCHO), 5,7 (s, 1H, CH—OCOCH$_3$), 4,95 (s, 1H, C-1—H), 2,3 (s, 1H, OH), 2,1 (s, 3H, CH_3COO), 1,9 (s, 3H, CH_3—C-2) ppm. Anal. calc. pour $C_{19}H_{18}O_5$: C 69,93, H 5,56; tr. : C 69,72, H 5,65.

13 (R = SiTBDM) : 0,5 g (1,3 mmol) d'acétal silylé **13** est irradié pendant 6 h. Après évaporation, le produit brut est analysé par rmn sans purification; rendement en produit spirannique **16***c* d'après le rapport des intégrales en rmn : 70%; rmn ^{1}H 350 MHz ($CDCl_3$) δ : 7,2 (m, 8H, arom.), 5,30–5,22–4,98–4,88 (4d, J = 15 Hz, 4 × 1H, C-1′—H), 5,30–5,29–5,25–5,21 (4s, 4 × 1H, C-4′—H), 1,84–1,79–1,77–1,75 (4s, 4 × 3H, C-3—CH_3), 0,8 (m, 9H, $C(CH_3)_3$), 0,1 (m, 6H, $Si(CH_3)_2$) ppm; **17***c* (rendement estimé d'après la rmn : 14%); rmn ^{1}H 350 MHz ($CDCl_3$) δ : 7,2 (m, 8H, arom.), 5,95 (s, 1H, C-6—H), 5,84 (s, 1H, C-7—H), 4,95 (s, 1H, C-1—H), 1,92 (s, 3H, C-2—CH_3) ppm.

Analyse cristallographique du composé ***17***a

Les données cristallographiques[1] sont :

$C_{17}H_{16}O_4$ PM = 284,30

Monoclinique, groupe d'espace Pc, a = 8,987(1), b = 8,784(1), c = 17,279(2) Å, β = 92,31(1)°, V = 1362,9(5) Å^3, F_{000} = 600, μ = 7,7 cm^{-1}, z = 4, ρ_c = 1,38 Mg m^{-3}.

Le cristal (prisme 0,10 × 0,10 × 0,20 mm) est étudié sur un diffractomètre automatique Enraf–Nonius (λ(Mo-Kα) = 0,71073 Å, scan ω/2θ = 1, t_{max} = 60 s); l'enregistrement donne 3010 reflections dont 2727 uniques (R_{int} = 0,045) et 2436 avec $I > \sigma(I)$. La structure est résolue à l'aide des méthodes directes. Après affinements en isotrope puis en anisotrope (R = 0,061) des atomes non-hydrogènes, les atomes d'hydrogène sont localisés dans la même différence de Fourier (entre 0,52 et 0,24 e Å^{-3}). Le meilleur affinement par matrice complète de la structure donne : $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0,055$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2} = 0,053$, $w = 1/\sigma^2|F_o|^2 = [\sigma^2(I) + (0,04F_o^2)^2]^{-1/2}$, S_w = 1,10, NV = 474. Les tableaux des différentes valeurs sont confiés au «Dépôt de données non publiées».[2]

Dodecylammonium-glutamate Schiff bases of retinal

ANIL K. SINGH, CAMILLE SANDORFY, AND JANOS H. FENDLER

Département de chimie, Université de Montréal, C.P. 6128, Succursale A, Montréal (Québec), Canada H3C 3J7

Received December 22, 1989

This paper is dedicated to Professor Arthur S. Perlin on the occasion of his 67th birthday

ANIL K. SINGH, CAMILLE SANDORFY, and JANOS H. FENDLER. Can. J. Chem. **68**, 1258 (1990).

Dodecylammonium glutamate (**4**) has been prepared from dodecylamine (**2**) and *l*-glutamic acid (**3**) in ethanol and in aqueous ethanol. The obtained crystalline glutamic acid salt of dodecylamine (**4**) has been characterized by absorption, FTIR, ^{1}H NMR, ^{13}C NMR, and mass spectroscopy. Reaction of all-*trans* retinal (**5**) with the α-amino group of **4** gave a Schiff base (**6**), which was protonated by the α-COOH group of the glutamyl residue. However, the protonated Schiff base underwent acid-catalyzed hydrolysis to **2** + **3** + **5**. Some of **5** reacted with **2** to give the corresponding Schiff base. The proposed structures have been substantiated by *in situ* absorption, FTIR, and ^{1}H NMR spectroscopy.

Key words: retinal Schiff base, retinal, rhodopsin model, dodecylammonium glutamate, Schiff-base protonation.

ANIL K. SINGH, CAMILLE SANDORFY et JANOS H. FENDLER. Can. J. Chem. **68**, 1258 (1990).

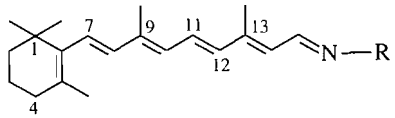
On a préparé le glutamate de dodécylammonium (**4**) en faisant réagir la dodécylamine (**2**) avec l'acide *l*-glutamique, dans l'éthanol et dans l'éthanol aqueux. On a caractérisé le sel cristallin **4** à l'aide des spectroscopies infrarouge par transformation de Fourier, RMN du ^{1}H et du ^{13}C, d'absorption et de masse. La réaction du rétinal complètement *trans* (**5**) avec le groupement α-amino du produit **4** conduit à la base de Schiff **6**. Le produit **6** se protone sous l'action du groupement α-COOH du résidu glutamyle. Toutefois, la base de Schiff protonée subit une hydrolyse catalysée par les acides qui fournit les produits **2**, **3**, et **5**. Une partie du produit **5** a réagi avec le produit **2** pour donner la base de Schiff correspondante. Les structures proposées sont proposées sur la base des spectres RMN du ^{1}H, d'absorption et infrarouge par transformation de Fourier qui ont été déterminés *in situ*.

Mots clés : base de Schiff rétinal, rétinal, modèle de rhodopsine, glutamate de dodécylammonium, protonation de la base de Schiff.

[Traduit par la revue]

Introduction

A major class of biological pigments contain the polyene aldehyde retinal attached to the apo-protein via a Schiff base linkage (Fig. 1) (1–3). The imine linkage is formed by the reaction of the aldehyde group of retinal and the ε-amino group of a lysine residue in the protein. It is believed that the imine nitrogen in rhodopsins is protonated, though the exact mechanism of their protonation is not known (4). To provide chemical clarification to several striking structural and functional features of rhodopsins, bio-organic models involving retinylidene Schiff bases (**1**) have been used extensively. In most of the model



1*a*: R = *n*-butyl
1*b*: R = *n*-propyl
1*c*: R = *tert*-butyl
1*d*: R = peptide

compounds of rhodopsin, an alkyl amine (mostly *n*-butyl, *n*-propyl, and *tert*-butyl amine) has been used to prepare the retinylidene Schiff base (4, 5), although a few models involving polymeric amino compounds (6, 7) and amino esters and acids (8) have also been reported. These model compounds have not shown, however, a red shift of the absorption spectra comparable to that observed in vivo for the Schiff base chromophore in rhodopsin. Protonation of the imine group, hydrogen bonding, and electrostatic perturbations of the chromophore by charged protein residues have been proposed to be responsible for shifting the absorption maximum of rhodopsins (4, 9, 10). This postulate has prompted the use of model Schiff bases that have negative charges in their vicinity (11).

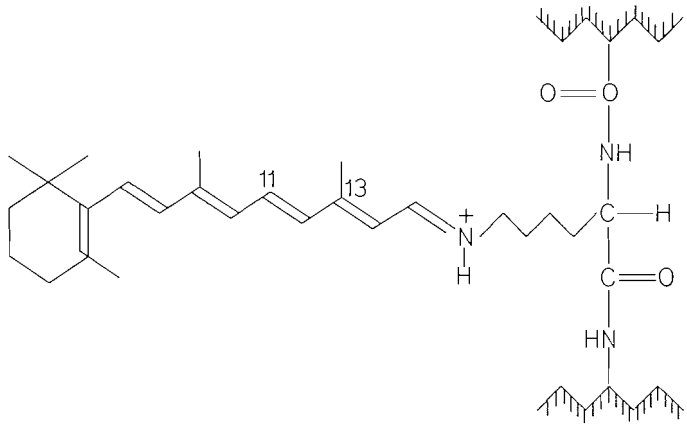


FIG. 1. Retinal attached to lysine via a protonated Schiff base linkage (11-*cis*, visual pigments, all-*trans* and 13-*cis*, bacteriorhodopsin).

A retinylidene Schiff base incorporating an amino acid residue provides a better model since it possesses a potentially intrinsic negative charge. The relative insolubility of amino acids in organic solvents and the instability of the retinylidene Schiff bases in the presence of hydrophobic carboxylates (e.g., CF_3COO^-) and water have hampered the development of a practical methodology for the preparation of retinylidene – amino acid Schiff bases. We have overcome these difficulties by taking advantage of reversed micelles. Recently, we reported that amino acids incorporated into sodium bis(2-ethylhexyl)sulfosuccinate- (AOT) solubilized water pools in heptane reacted with retinal to give Schiff bases (12). The small amounts of amino acids that could be incorporated into reversed micelles have, however, limited the preparative utility of this approach. Advantage has been taken of alkylammonium surfactants that contained amino acid counterions to form Schiff bases in orga-

nic solvents. The present report describes the formation of retinylidene Schiff bases of dodecylammonium glutamate and their protonation in methanol.

Experimental

All experiments using retinal and its derivatives were performed in the dark with dim red illumination. Dodecylamine (**2**), *l*-glutamic acid (**3**), and all-*trans* retinal (**5**) were obtained from the Aldrich Chemical Company. The solvents (Aldrich, spectral grade) were stored over a 4 Å Linde type molecular sieve and were freshly distilled under N_2 before use. UV–VIS absorption spectra were measured on a Varian Carey 16 spectrophotometer. NMR spectra were recorded on either a 300 or a 400 MHz Bruker NMR spectrometer. FTIR spectra were measured on a Nicolet 5 DXB FTIR spectrophotometer with a 2 cm^{-1} resolution. Mass spectra were recorded on a MS 50 TATC (Cratos) spectrometer. Thin-layer chromatographic analyses were done on silanized Si-60 reverse phase plates (Merck RP-2) using anhydrous and freshly distilled methanol as a solvent.

Dodecylammonium glutamate (4)

Two methods were used to prepare **4**:

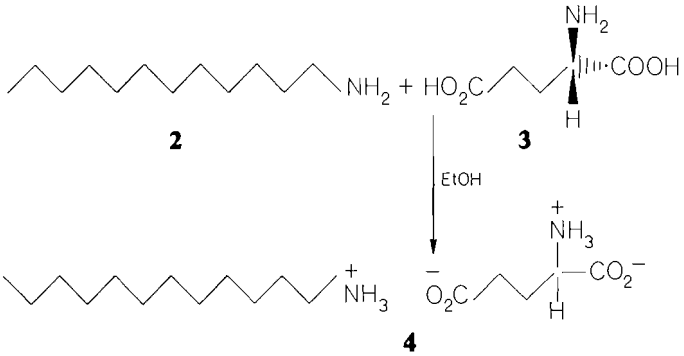
1. An ethanolic (97%) solution (5 mL) of dodecylamine (**2**, 0.63 g, 3.4 mmol) was added to *l*-glutamic acid (**3**, 0.50 g, 3.4 mmol) in a round-bottom flask. The white suspension was stirred (Teflon) at ambient temperature. A very thick white creamy mass appeared after 20 min of vigorous stirring. The white mass was washed with 100 mL ethanol–water (1:1) and benzene. The white powder (**4**, 1 g) was dried under vacuum.

2. *l*-Glutamic acid (**3**, 0.50 g) was suspended in 6 mL water and the mixture was stirred (Teflon) to dissolve the maximum amount of the acid. An ethanolic solution (5 mL) of dodecylamine (**2**, 0.70 g) was then slowly added to the glutamic acid suspension in water, which resulted in complete dissolution of the contents of the flask, giving a clear solution. The solution was further stirred for 2 h at ambient temperature. Benzene (10 mL) was added to the reaction mixture and the solvent was removed on a rotary evaporator. The white crystalline material (**4**), obtained in quantitative yield, was dried over P_2O_5 under vacuum; mp 168–169°C; IR (Nujol) ν: 3040, 3022, 2982, 2972, 2878, 2848, 2540, 2498, 2437, 2086, 1664, 1604, 1529, 1518, 1508, 1403, 1364, 1328, 1298, 1220, 1150, 974, 931, 681 cm^{-1}; ^1H NMR (D_2O, 400 MHz) δ: 0.844 (3H, t, CH_3), 1.260 (18H, br s, CH_2), 1.638 (2H, m, -CH_2), 2.0–2.16 (2H, m, glu-C_α-CH_2-), 2.29–2.40 (2H, m, glu-C_α-C-CH_2-), 2.927 (2H, t, -CH_2-N^+H_3), 3.727 (1H, t, glu-C_α-H); ^{13}C NMR (D_2O, 100.62 MHz) δ: 14.56 (CH_3), 23.32–29.71 (-CH_2), 33.72 (-CH_2COO^-), 40.24 (-$CH_2N^+H_3$), 55.35 (C_α), 175.17 (C_α-COO^-), 181.13 (glu-C_γ-COO^-); mass, *m/e* (% rel. int.): 186 (50), 130 (100).

*Reactions of all-*trans *retinal (5) with dodecylammonium glutamate (4)*

1. A solution of all-*trans* retinal (**5**, 4×10^{-5} M) in dodecylammonium glutamate (**4**, 1×10^{-2} M in anhydrous MeOH) was kept in the dark at ambient temperature. The progress of the reaction was monitored by UV–VIS absorption measurements. The reaction mixture had faint yellow coloration in the beginning and exhibited a UV–VIS absorption band at 371 nm due to retinal. After 30 min of reaction, an intense UV–VIS band appeared at 361 nm and a small band appeared at 457 nm. On further standing, the reaction mixture showed a decrease in the absorbance of the 361-nm band and an increase in the 457-nm band. The reaction mixture acquired a deep yellow color after 1 h.

2. Dodecylammonium glutamate (**4**, 0.0166 g, 0.05 mmol) and all-*trans* retinal (**5**, 0.0142 g, 0.05 mmol) were dissolved in CD_3OD. The dark brown solution was allowed to stand in the dark at 4°C overnight before NMR analyses: **6**: ^1H NMR (300 MHz, CD_3OD) δ: 0.89 (3H, t, -CH_3-CH_2-), 1.04 (6H, s, C_1-Me_2), 1.28 (18H, s, -$(CH_2)_9$), 1.49 (2H, m, -CH_2-), 1.64 (2H, m, -CH_2-CH_2-CH_2), 1.71 (3H, s, C_5-Me), 2.02 (3H, s, C_9-Me), 2.05 (2H, m, DO_2C-CH_2-CH_2-), 2.18 (3H, s, C_{13}-Me), 2.46 (2H, m, DO_2C-CH_2-CH_2-), 2.90 (2H, t, D_3N^+-CH_2-CH_2-), 3.54 (1H, m, C_α-H), 6.08 (1H, d, $J_{14,15}$ = 10 Hz, H_{14}), 6.16 (1H, d, $J_{7,8}$ = 16 Hz, H_8), 6.21 (1H, d, $J_{10,11}$ = 11.9 Hz), 6.30 (1H, d, J = 16 Hz, H_7), 6.45 (1H, d, $J_{11,12}$ = 15 Hz, H_{12}), 7.01 (1H, d,d, $J_{11,12}$ = 15 Hz, $J_{10,11}$ = 11.6 Hz, H_{11}), 8.48 (1H, d, $J_{14,15}$ = 10 Hz, H_{15}).



SCHEME 1

Results and discussion

Reaction of dodecylamine (2) with l*-glutamic (3) acid*

Dodecylamine (**2**) can react with the two carboxyl groups of *l*-glutamic acid (**3**) (Scheme 1). The chemical reaction leading to amide formation between dodecylamine and the -COOH group of glutamic acid is not considered, as the reaction is unlikely to be feasible at ambient temperature in the absence of a catalyst. It has been found (13) that amide bonds betwen amine and acid are formed at elevated temperatures.

Glutamic acid (**3**) is insoluble in ethanol and sparingly soluble in water. However, when an alcoholic solution of dodecylamine (**2**) was added to a water suspension of glutamic acid, the reaction mixture became completely transparent, indicating the modification of the molecular forces present in glutamic acid and dodecylamine. The properties of glutamic acid were changed by dodecylamine, even in the presence of relatively small amounts of water when the solid glutamic acid reacted with dodecylamine in 97% ethanol. Removal of solvent afforded a crystalline material that showed melting (168°C) behavior different from glutamic acid, as well as dodecylamine. The white crystalline solid was soluble only in alcohols and water, in which it foamed. It showed UV absorption bands at 204 and 275 nm. IR spectra of the solid showed a complex band with sharp peaks between 2950 and 2850 cm^{-1}, with major strong peaks located at 2851, 2918, 2953, and 2994 cm^{-1}. A continuous absorption with several small and broad peaks at 2731, 2598, 2543, 2496, and 2430 cm^{-1} was indicative of the presence of the ammonium group. Very intense IR absorption at 1640, 1604, and 1526 cm^{-1} indicated the presence of the COO^- group. A medium intensity (relative to the COO^- band at 1604 cm^{-1}) IR band at 1664 was also present. The IR data indicated the compound to be a salt of dodecylamine and glutamic acid.

A comparison of the ^1H NMR spectra of the reaction product with those of glutamic acid and dodecylamine confirmed the mono-salt structure **4**. The methylene group adjacent to the -NH_2 group in **2** resonates at δ 2.62 as a broad triplet, but this signal was absent in the product, and a new broad triplet appeared at δ 2.93. In glutamic acid (**3**), the two methylene groups of the side chain resonate as a complex multiplet between δ 1.50 and 2.50. However, in the product, the two side-chain methylene groups showed two complex multiplets centered at δ 2.33 and 2.07. The two multiplets are separated by a width of 1 δ. The C_α-*H* showed a triplet at δ 3.73 as against a multiplet at

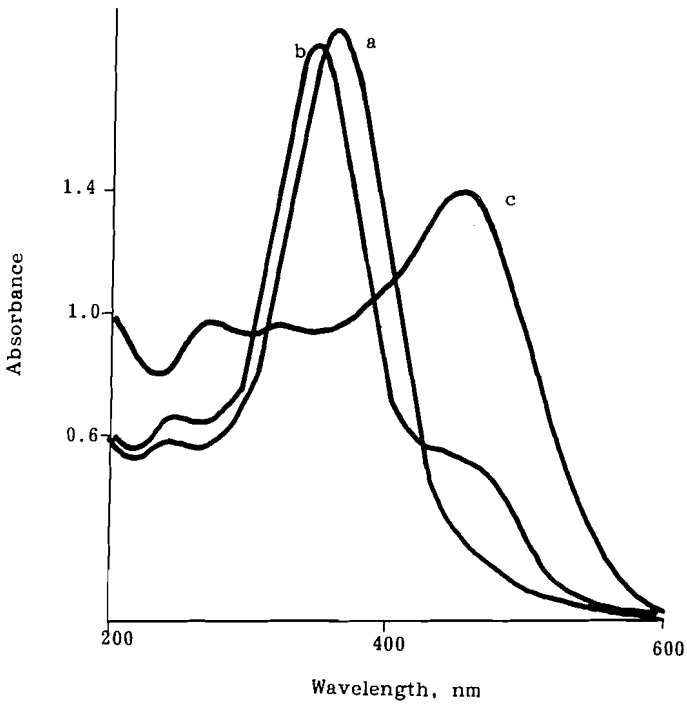

FIG. 2. Absorption spectra of a reaction mixture containing 4.5×10^{-5} M all-*trans* retinal (**5**) and dodecylammonium glutamate (**4**) in MeOH: (a) 0 h, (b) after 1 h, and (c) after 40 h.

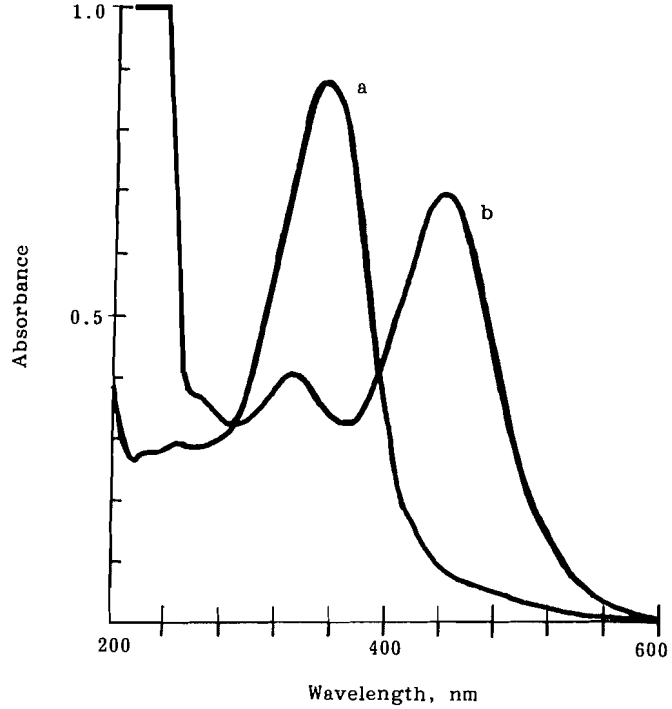

FIG. 3. Absorption spectra showing protonation of methanolic 5.9×10^{-5} M Schiff base **6** by excess CF_3COOH: (a) Schiff base formed between retinal (**5**) and dodecylammonium glutamate (**4**) in MeOH and (b) red shift after addition of CF_3COOH.

δ 3.25 in glutamic acid. The fact that the resonance frequency of the side-chain methylene group is perturbed shows that it is the side-chain carboxyl which reacted with the dodecylamine (**2**).

Further confirmation of structure **4** was obtained by ^{13}C NMR spectral analysis. Thus, the signal for the C_α-COO^- group of glutamic acid was seen unperturbed in the product resonating at δ 175.17. Similarly, the C_α carbon was seen at δ 55.35. Any change in chemical polarity around the C_α carbon is expected to influence its resonance frequency. Resonance frequency at δ 55.35 in the product was similar to the resonance frequency of C_α in glutamic acid (**3**).

Mass spectral analysis of **4** showed prominent peaks at *m/e* 186 (50%) due to $[C_{12}H_{28}N]^+$ and at *m/e* 130 (100%, base peak) due to $[C_5H_6O_4]^+$, which could readily be formed by breaking away NH_3 from the glutamic part of the molecule.

*Reaction of dodecylamine-glutamate (4) with all-*trans *retinal (5)*

Reaction of all-*trans* retinal (**5**) and dodecylammonium glutamate (**4**) was first studied by following absorption changes in a mixture of **5** (4×10^{-5} M) and **4** (10^{-2} M) in methanol. All of the retinal reacted with **5** within 30 min. Two UV–VIS bands were present in the absorption spectrum of the mixture (Fig. 2). The major band at 361 nm and a minor band at 457 nm accounted for ca. 90% and 10% of the retinylidene chromophore, respectively. Keeping the reaction mixture at ambient temperature in the dark resulted in the formation of a major band at 462 nm and a minor band at 327 nm (Fig. 2c).

The band at 361 nm is most likely to be due to a Schiff base formed from retinal. The Schiff base may undergo protonation by the glutamic acid part of **4** in methanolic solution, giving a protonated Schiff base with an absorption band at 457 nm. In due course, most of the Schiff base underwent protonation and gave a major band at 462 nm. However, the protonated Schiff base accounted for only ca. 59% of the retinylidene (assuming

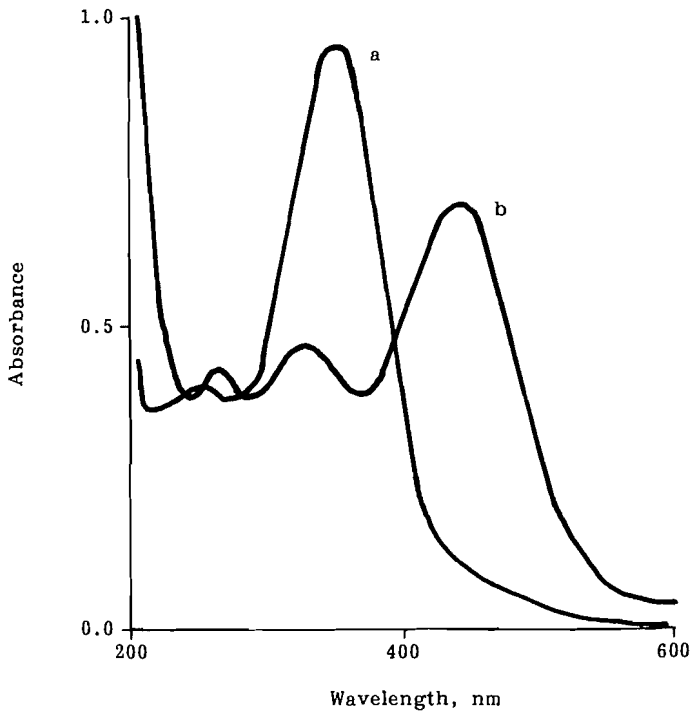

FIG. 4. Absorption spectra showing protonation of 5.9×10^{-5} M methanolic Schiff base **6** by excess 3-chloropropionic acid (CPA): (a) Schiff base **6** before addition of CPA and (b) after addition of CPA.

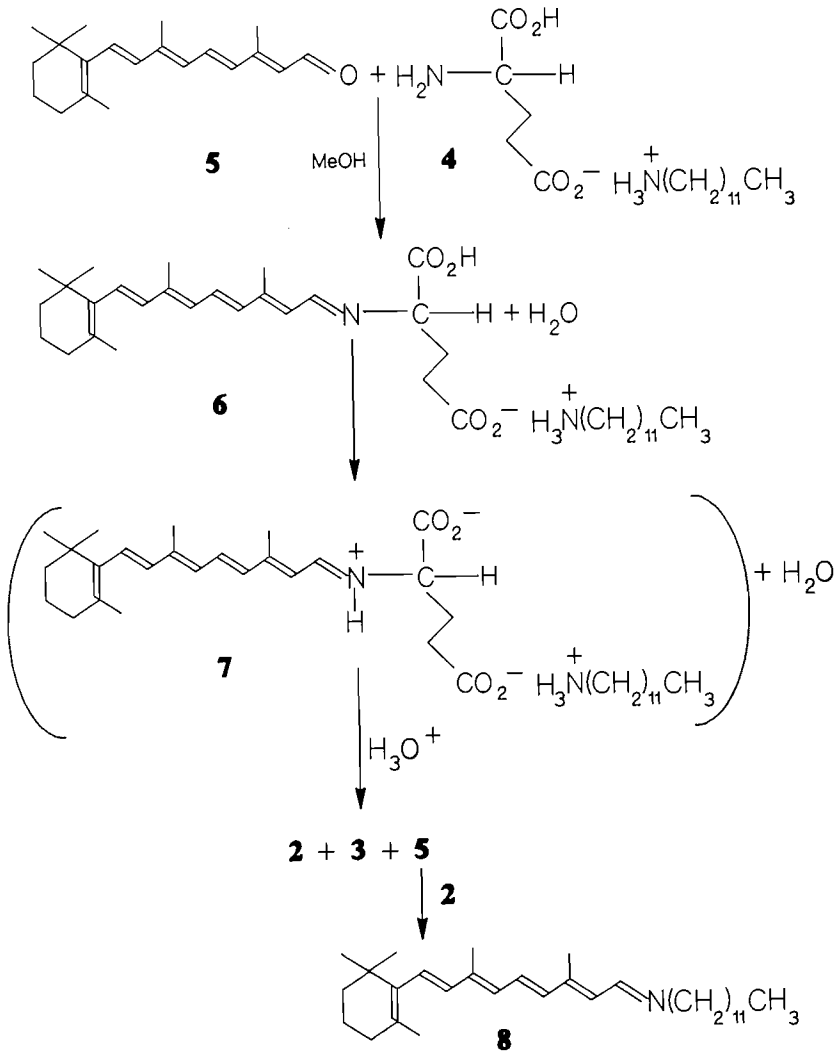
its absorbance to be 51 800 M^{-1} cm^{-1}) (14) chromophore. Thus, ca. 41% of the chromophore was lost in the synthetic mixture. That a Schiff base of retinal was formed in methanolic **4** could be confirmed by the fact that addition of CF_3COOH or 3-chloropropionic acid caused the 361-nm band to red shift to 440 nm (Figs. 3 and 4).



SCHEME 2

To further characterize the Schiff base formed, the reaction of **4** and retinal was studied by ^{1}H NMR spectroscopy. **4** and **5** were dissolved in CD_3OD in equimolar amounts and allowed to react at 4°C overnight. The proton ^{1}H NMR of the reaction mixture showed no signal corresponding to the aldehyde proton (δ 10.12; *J*, 8 Hz) (15) of retinal, indicating that most of the retinal had reacted. The NMR spectrum was characterized by the signals that were indicative of the presence of retinylidene, glutamic, and dodecyl moieties. Thus, a triplet at δ 0.89 was due to the CH_3 group of the dodecyl radical. The 18 methylene protons of the dodecyl group showed up as a broad singlet at δ 1.28. A sharp triplet at δ 2.89 was due to the -CH_2 group adjacent to the N^+H_3 group of the dodecylammonium residue. A multiplet at δ 1.64 corresponded to β-CH_2 of the dodecylammonium part. The α- and β-methylenes (H_3N^+-C_α-H_2-$C_\beta H_2$-) in the dodecylammonium part of **4** appeared as a sharp triplet at δ 2.92 and multiplet at δ 1.64 respectively. Hence, the dodecylammonium part of **4** remained unchanged after reaction with retinal. Therefore, it is the glutamic part which reacted with retinal. The most likely functional group of glutamic acid that can react with retinal is its amino function. The nucleophilic amino group can react with the electrophilic aldehyde group of retinal to give the corresponding Schiff base. That such reaction does occur is clear from the ^{1}H NMR spectrum of the reaction product. A doublet at δ 8.48 with coupling constant of 10 Hz is due to the C_{15} retinylidene proton. The C_{15} aldehyde proton of retinal is expected to show up as a doublet at δ 10.12. Other signals due to the retinylidene moiety were seen as expected. The protons of the glutamic side chain were seen as very complex multiplets centered at δ 2.05 and δ 2.47. The C_α-H of the glutamyl residue was seen at δ 3.54 as a multiplet. Appearance of minor doublets in δ 8.60–8.70 indicated the presence of an isomeric retinylidene group; however, the doublet at δ 8.48 was the major component (>80%). Proton decoupling experiments established that the dd at δ 7.01 and doublets at δ 6.42 and δ 6.21 are due to C_{11}, C_{12}, and C_{10} of the retinylidene unit, respectively, as irradiation at δ 7.01 caused the doublets at δ 6.42 and δ 6.21 to become singlets. Irradiation of the multiplet at δ 1.63 caused the triplet at δ 2.90 to become singlet. Hence, the t at 2.90 was due to the C_α-H_2 group of the dodecylammonium part. Irradiation at δ 2.40 caused simplification of the multiplet between δ 1.96 and 2.18 (except the intense, merged singlet at δ 2.02 due to the C_9-Me group of retinylidene). There was no change, however, in the multiplet at δ 3.55. Therefore, the complex multiplets belong to the methylene groups in the glutamyl side chain. Thus, the α-amino group of the glutamic acid part of **4** reacted with retinal to give Schiff base **4**. Reversed phase preparative TLC (silica gel 60-silanized, Merck RP-2, MeOH) of a 24-h reaction mixture gave two yellow bands with R_f values of 0.73 and 0.13. Further analysis (RP TLC) of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12
For personal use only.

band with R_f 0.73 showed it to be a mixture of two components with close R_f values (0.72 and 0.75). ^{1}H NMR of the front fraction showed it to be a mixture of retinal (13%) and all-*trans*-*N*-retinylidene-*n*-dodecylamine (87%, estimated from the integral intensity of doublets at δ 10.05, -CHO, and δ 8.36, -CH=N-). The lower fraction was found to contain the Schiff base of retinal and glutamic acid as the major components and minor amounts of dodecylamine. The 400 MHz, ^{1}H NMR spectrum of this fraction showed the doublet due to Schiff base proton (C_{15}-H=N-) at δ 8.30, as against δ 8.47 for the Schiff base proton of **6**. The olefinic region was too complex to be due to one isomer.

It appears that the α-amino group of **4** reacts with retinal to give the corresponding Schiff base **6**. The alkylammonium ion pair remains intact. The polarity of the $-N^+H_3$ group of dodecylamine is not reversed, hence there is no reaction with the electrophilic -CHO group of retinal (**5**). The Schiff base **6** undergoes protonation by the α-COOH group of the glutamyl residue. However, the Schiff base is not stable and the ion pairs get separated. The Schiff base may then undergo acid-catalyzed hydrolysis, giving retinal and **4** or dodecylamine and glutamic acid. Some of the dodecylamine reacts with retinal, giving the corresponding Schiff base **8** (Scheme 2).

In the Schiff base formation between retinal and alkylamine, a dehydrating agent (often anhydrous Na_2SO_4 or molecular sieves) is added to the reaction mixture in order to shift the equilibrium of the reaction towards the imine. However, in the reaction of retinal with **4**, in spite of the formation of H_2O, the equilibrium is completely shifted towards the formation of **6**. Though Schiff base **6** is formed in solution, it is not feasible to isolate and keep it at room temperature. In solution, the stability of **6** is limited, but it remains intact at −10°C for a day. The color of the solution indicates the nature of the products formed: the imine solution is generally yellow, whereas the imminium ion solution is characteristically deep orange to deep brown. Black residues appeared in the synthetic solutions kept for a few days even in the freezer.

It is important to comment on the absorption spectral characteristics of the synthetic solution in which **4** is present in 250 mole excess over retinal. There is a band at 457 nm corresponding to the protonated form **7**. It is believed that the protonation of an imine linkage in **6** is caused intramolecularly by the proton of the adjacent C_α-COOH group. The contribution of intermolecular protonation is not significant, as the amount of the protonated form of **6** is no more than 10% in the beginning.

The preparation of compound **4** was undertaken in the hope that it would form reversed micelles (16) in hydrocarbon solvents. A retinylidene Schiff base incorporated in a reversed micellar system containing glutamic acid would be a very attractive model because glutamic or aspartic acids are believed to be responsible for the protonation of rhodopsin's chromophore (17–20). Unfortunately, alkylammonium carboxylate **4** did not dissolve in hydrocarbon solvents, obviating the possibility of forming its reversed micelles. Nevertheless, the results obtained here present a new methodology for the preparation of biologically important Schiff bases between hydrophobic aldehydes and relatively insoluble amino acids. Further, they demonstrate that intramolecular association of the imine nitrogen with nearby H atoms can cause a bathochromic shift in the absorption spectra of rhodopsins. The imine bond may be protonated by the labile protons of the apo-protein and further stabilized by H-bonded counterions involving a few water molecules. It has recently been shown that there are, indeed, a few water molecules present in the vicinity of the chromophore of rhodopsins (21). Compound **6** serves as a good model for rhodopsins as far as through-space influence (11) of ion pairs and negatively charged (e.g., -COOH side chain) groups of the apo-protein are concerned.

Conformational analysis and complete assignment of the proton and carbon NMR spectra of ouabain and ouabagenin

DEANE D. MCINTYRE, MARKUS W. GERMANN, AND HANS J. VOGEL[1]

Division of Biochemistry, Department of Biological Sciences, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received June 12, 1989[2]

DEANE D. MCINTYRE, MARKUS W. GERMANN, and HANS J. VOGEL. Can. J. Chem. **68**, 1263 (1990).

The ^1H and ^{13}C NMR spectra of the cardenolide ouabain and its aglycon ouabagenin have been completely assigned by two-dimensional NMR techniques, including phase-sensitive COSY and carbon–proton correlation (HETCOR, HMQC, and COLOC) spectra. The major conformer of these two compounds in solution is all-chair as determined from proton–proton coupling constants and is similar to that in the crystal lattice as previously determined by X-ray diffraction. The conformations of the A and D rings of ouabain in water are somewhat different than in DMSO/$CDCl_3$ (2:1). At lower temperatures (−20°C) signals from two conformers in slow exchange were readily observed in the ^{13}C spectra, with an approximate ratio of 1:7. Molecular mechanics and dynamics calculations indicate that the conformational process responsible for this involves a chair/twist-boat interconversion of the A ring, with the all-chair conformer highly preferred.

Key words: ouabain, conformational analysis, 2-D NMR, molecular mechanics, molecular dynamics.

DEANE D. MCINTYRE, MARKUS W. GERMANN et HANS J. VOGEL. Can. J. Chem. **68**, 1263 (1990).

En se basant sur des techniques de RMN bidimensionnelles, y compris des spectres COSY sensibles aux phases ainsi que des corrélations (HETCOR, HMQC et COLOC) de spectres carbone–proton, on a pu attribuer toutes les bandes des spectres RMN du ^1H et du ^{13}C du cardénolide ouabaine et de son aglycone ouabagénine. En se basant sur les constantes de couplage proton–proton, on a démontré que ces deux composés en solution n'existent que sous des conformations chaises semblables à celles qu'on a observées antérieurement, á l'aide de la diffraction des rayons-X, dans la structure cristalline. En solution dans l'eau, les conformations des cycles A et D sont légèrement différentes de celles que l'on peut observer dans le DMSO/$CDCl_3$ (2:1). Dans les spectres du ^{13}C, mesurés à des températures plus basses (−20°C), on a observé les signaux des deux conformères en équilibre lent et présents dans un rapport approximatif de 1 : 7. Des calculs dynamiques et de mécanique moléculaire indiquent que le processus conformationnel responsable pour ces observations implique une interconversion chaise/bateau-croisé du cycle A; toutefois, le conformère préféré n'implique que des chaises.

Mots clés : ouabaïne, analyse conformationnnelle, RMN 2-D, mécanique moléculaire, dynamique moléculaire.

[Traduit par la revue]

Introduction

The cardenolide ouabain **1** (3-[(6-deoxy-α-L-mannopyranosyl) oxy]1,5,11α,14,19-pentahydroxycard-20(22)enolide) is obtained from the seeds of *Strophanthus gratus*. Upon acid hydrolysis, it yields its aglycon ouabagenin **2** (1,3,5,11,14,19- hexahydroxycard-20(22)enolide) and rhamnose (1). The cardenolides are of importance in the treatment of heart disease (2) and, in the case of ouabain, also for the treatment of cancer (3). In studies involving the interactions of ouabain and ouabagenin with Na^+, K^+-adenosine triphosphatase, it has been observed that ouabagenin is a reversible inhibitor while the interaction with ouabain is pseudo-irreversible (4, 5).

NMR spectroscopy has been the method of choice for the determination of the chemical structure of natural products (6, 7). However, obtaining the complete proton spectral assignments of cardenolides and steroids in general has been difficult due to severe signal overlap in the 1.0–2.5 ppm chemical shift range, even at high (>10 T) magnetic fields (6). The carbon-13 NMR spectra of steroids generally do not suffer from this problem as the signals are dispersed over a much larger chemical shift range, and they have consequently been used to assign NMR spectra of steroids by making comparisons with appropriate model compounds (7). However, the recent introduction of a variety of two-dimensional NMR techniques has made it possible to assign the ^1H NMR spectra of steroids without a need for model compounds. Once the task of assignment has been completed the solution conformation of the molecule can be determined from the dihedral angles between vicinal protons as deduced from the coupling constants obtained via the Karplus relationship. If necessary this can be supplemented by internuclear distances determined from nOe data (6).

2, R =

In this work, we report the complete assignment of both the proton and ^{13}C NMR spectra of ouabain and ouabagenin. For ouabain, the conformation was determined in two solvent systems, a 2:1 mixture of dimethylsulphoxide–chloroform, and in water. Molecular dynamics and molecular mechanics calculations were also used to further explore the nature of conformational processes. Some carbon-13 NMR assignments have been reported previously (8), and the solution conformation of the E

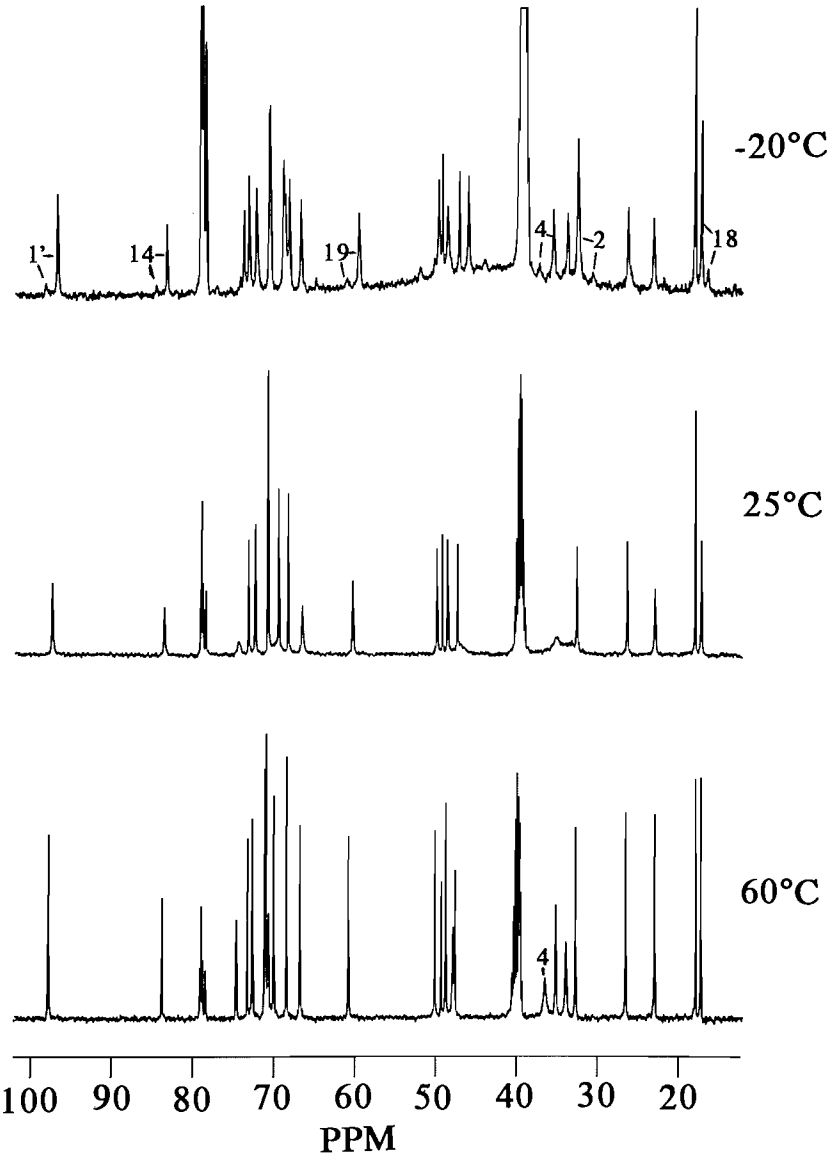

FIG. 1. Carbon-13 NMR spectra (proton decoupled) of ouabain in DMSO/$CDCl_3$ (2:1) solution at −20°C, 25°C, and 60°C. Representative signals in slow exchange at −20°C are indicated. At 25°C, a number of signals are broad, indicating that they are in intermediate exchange. The spectrum obtained at 60°C indicates that all signals, with the exception of C-4 (labelled), are in fast exchange.

ring relative to the D ring of various cardenolides has been determined by ^{1}H NMR (9).

Experimental

Ouabain (as the octahydrate) and ouabagenin were both obtained from Sigma Chemical Co., St Louis, Missouri, U.S.A., and were used as received. The samples for NMR were prepared by dissolving 40 mg of ouabain or 25 mg of ouabagenin in 0.5 mL of a 2:1 dimethylsulphoxide-d_6/chloroform-d mixture with tetramethylsilane added as an internal reference for both ^{1}H and ^{13}C. This solvent mixture is the same as that used previously in the assignment of the ^{13}C spectrum of ouabain (8). For the HMQC (heteronuclear multiple quantum coherence) experiment, ouabain was twice exchanged with D_2O in order to eliminate the signal from the water of hydration. A saturated solution of ouabain in D_2O was also prepared with 2,2-dimethyl-2-silapentane-5-sulphonate added as an internal standard.

All NMR spectra were obtained on a Bruker AM-400 spectrometer operating in the FT mode at a frequency of 400.1 MHz for ^{1}H and 100.6 MHz for ^{13}C. All two-dimensional NMR spectra were obtained using standard Bruker software. Phase-sensitive COSY spectra were obtained using a spectral width of 2500 Hz, 16 scans per t_1 increment, a 1.4 s recycle time, and a data matrix of 1024 ($F1$) × 2048 ($F2$) that was zero-filled once in each dimension prior to apodization with a standard sine bell function and transformation. HETCOR spectra, optimized for ^1J C–H = 130 Hz (10), and COLOC (correlation by long-range coupling) spectra, optimized for ^{2}J C–H = 5 Hz (11), were obtained using a spectral width of 11 000 Hz in $F2$ (carbon) and 2500 Hz in $F1$ (proton) with decoupling in both dimensions, using a 128 ($F1$) × 2048 ($F2$) matrix that was zero-filled to 512 × 4096 prior to apodization with a Lorentz–Gauss function and transformation. The resulting spectra were background subtracted, and are presented in the magnitude mode. HMQC spectra were obtained in the phase-sensitive mode without decoupling using a bilinear (BIRD) pulse (12) and a 128 ($F1$) (carbon) × 256 ($F2$) (proton) matrix that was zero-filled to 512 × 1024 prior to apodization with a Lorentz–Gauss function and transformation. A delay of 0.4 s was inserted between the BIRD and HMQC pulses.

Relaxation times were determined by using the standard inversion–recovery technique, with composite pulse decoupling and cycling of the delay times. The resulting data were fitted to an exponential function using standard Bruker software. The attached proton test (APT) spectra (13) were obtained with a delay time of 7.4 ms (ca. $1/J$).

Molecular mechanics and dynamics calculations were carried out on a Silicon Graphics Iris 4D/25G workstation using the Quanta software package (Polygen, Waltham, MA), which employs the CharmM force field (14). A dielectric constant of 1 was used for most simulations, but separate mechanics calculations with higher dielectric constants did not influence the results. Typically, molecular structures were energy-minimized using 200 steps of conjugate gradient minimization. In the calculation of root-mean-square (RMS) values only heteroatoms were considered. For the molecular dynamics simulations (Verlet dynamics), energy-minimized molecules were heated to 300 K over 5 ps, followed by a 10 ps equilibration at 300 K. Simulations were then run for 1000 ps using 10^{-3} ps time steps. Shake constraints were applied to all bonds containing a hydrogen atom (15).

Results

Carbon-13 NMR spectroscopy of ouabain

The carbon-13 NMR spectrum of ouabain obtained in DMSO/$CDCl_3$ at 25°C (Fig. 1) showed several broad signals, suggesting that an intermediate exchange process was occurring at this temperature. All signals were in fast exchange at 60°C, and therefore most experiments were performed at this temperature. The number of protons attached to each carbon was determined by means of an attached proton test (APT). In addition a spectrum was recorded without decoupling during acquisition, from which the carbon–proton coupling constants were obtained. The T_1 relaxation times were determined at both 25 and 60°C. From these data, initial tentative assignments were made. Upon cooling the sample to −20°C a large number of signals split into two components (approximate ratio 7:1) and the system is clearly in slow chemical exchange at this temperature (*vide supra*).

A proton–carbon correlation spectrum (HETCOR spectrum) (Fig. 2) was obtained at 60°C and all expected cross peaks were observed. A number of cross peaks, corresponding to those carbons in intermediate exchange, were missing in a HETCOR spectrum obtained at 25°C. To assign the quaternary carbon atoms, a COLOC spectrum, optimized for a 5-Hz long-range coupling constant, was obtained. From these carbon–proton correlation spectra, it was possible to obtain ^{13}C assignments (Table 1) for all carbon atoms with the exception of C-2, C-4, and C-6. These ^{13}C resonances were later assigned from the HETCOR and HMQC spectra using ^1H assignments, as will be discussed later.

As indicated in Table 1, the chemical shifts of some carbons, notably those in the A and B rings, were quite temperature dependent, and a pronounced upfield shift was observed with increasing temperature. The ^{13}C relaxation times (Table 1) are unexceptional for a molecule of this nature, and are considerably shorter at 25°C than at 60°C due to the combined effects of chemical exchange and longer correlation times in the reasonably viscous solvent system employed.

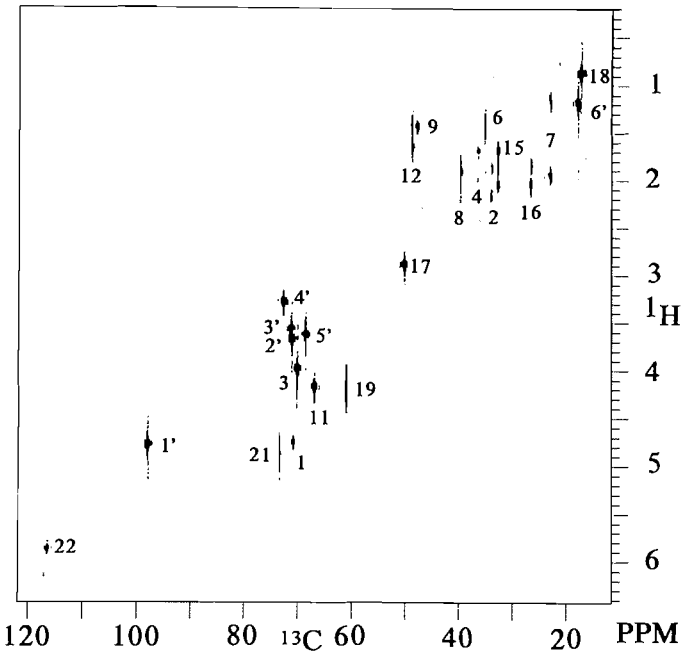

FIG. 2. Proton-decoupled HETCOR spectrum of ouabain, obtained at 60°C.

Proton NMR spectroscopy of ouabain

Approximate chemical shifts for all ouabain protons in DMSO/$CDCl_3$ were obtained in the first instance by inspection of the HETCOR spectrum; however, at this juncture, due to the uncertain assignments of C-2, C-4, and C-6 as indicated above, the assignments of the corresponding protons could only be considered tentative. In addition, due to the fact that the decoupled HETCOR spectrum does not decouple vicinal diastereomeric protons of methylene groups from each other, it is not possible to obtain accurate chemical shifts of such protons from a HETCOR spectrum alone. This unfavourable situation is made even more complex by the frequent occurrence of an artifact located between the two methylene doublets (16). Inspection of the HMQC spectrum (Fig. 3), in which this artifact does not occur, and which generally gives narrower cross peaks in the proton dimension than the HETCOR spectra, gave more accurate chemical shifts in this case.

To obtain proton chemical shifts of ouabain accurate to 0.01 ppm and to furthermore obtain the proton–proton coupling constants, a phase-sensitive COSY spectrum was obtained at fairly high digital resolution (1.2 Hz in $F2$). From this spectrum (Fig. 4), the proton assignments were straightforward. Beginning with the rhamnose moiety, the anomeric proton at 4.75 ppm was readily identified on the basis of its chemical shift. The remaining rhamnose protons were assigned from the COSY connectivity, ending with the 6′ methyl group at 1.16 ppm. All proton assignments, along with proton–proton coupling constants, are tabulated in Table 2. The coupling constants that could not be obtained directly from the one-dimensional spectra were obtained by measurement of the active coupling in expanded plots of the phase-sensitive COSY spectrum. Under the experimental conditions, the rhamnose hydroxyl protons were in slow exchange, and thus they were readily assignable from the COSY spectrum.

The steroid protons were assigned in an analogous fashion. Starting from H-1 (4.72 ppm), the connectivity between all A-ring protons was traced out. The B- and C-ring protons form

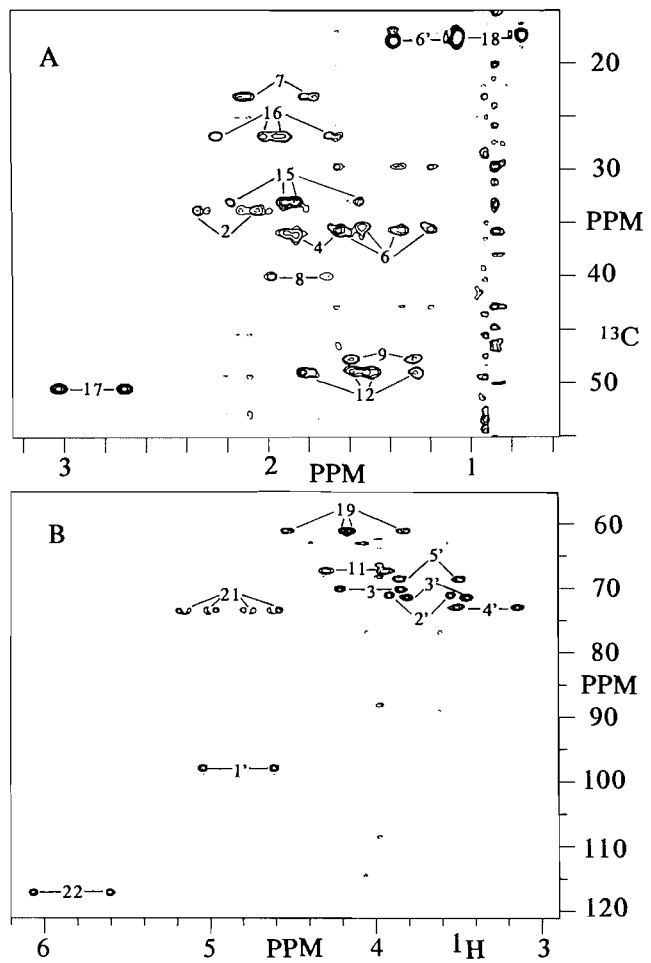

FIG. 3. Carbon-coupled HMQC spectra of ouabain, obtained in the phase-sensitive mode at 60°C. Panel (A) shows the upfield region of the spectrum, and panel (B) the downfield region. Each proton appears as a characteristic doublet parallel to the $F2$ axis; note the cross-peak shape, which is better defined compared to the HETCOR spectrum.

one extended spin system, which was assigned starting from H-11 at 4.15 ppm. The D-ring protons were assigned starting from H-17 at 2.86 ppm. Assignment of the remaining protons, including the methyl protons on C-18 as well as H-21 and H-22, was obvious from inspection of the one-dimensional spectrum. A NOESY spectrum, obtained at −20°C using a 250-ms mixing time, showed a fairly intense cross peak between the anomeric proton and H-3 of the steroid. This observation confirms the point of attachment of the sugar to the steroid moiety. In the solvent system used, the hydroxyl groups attached to the steroid are in fast or intermediate exchange with the remaining water peak at 3.20 ppm, and thus could not be assigned.

With the unambiguous proton assignments now in hand, it then became possible to complete and cross-check the assignment of the ^{13}C spectrum, as indicated in Table 1. It is noteworthy from the data in Table 1 that the previously reported ^{13}C assignments (8), which were based mainly on comparisons with model compounds, are partly in error.

To define the conformation of the ouabain molecule in solution, the proton–proton coupling constants, accurate to 1 Hz, were obtained from the appropriate cross sections of the phase sensitive COSY spectrum, measured parallel to the $F2$ axis. These are also included in Table 2. The conformation of ouabain in water was also studied by recording a phase-sensitive

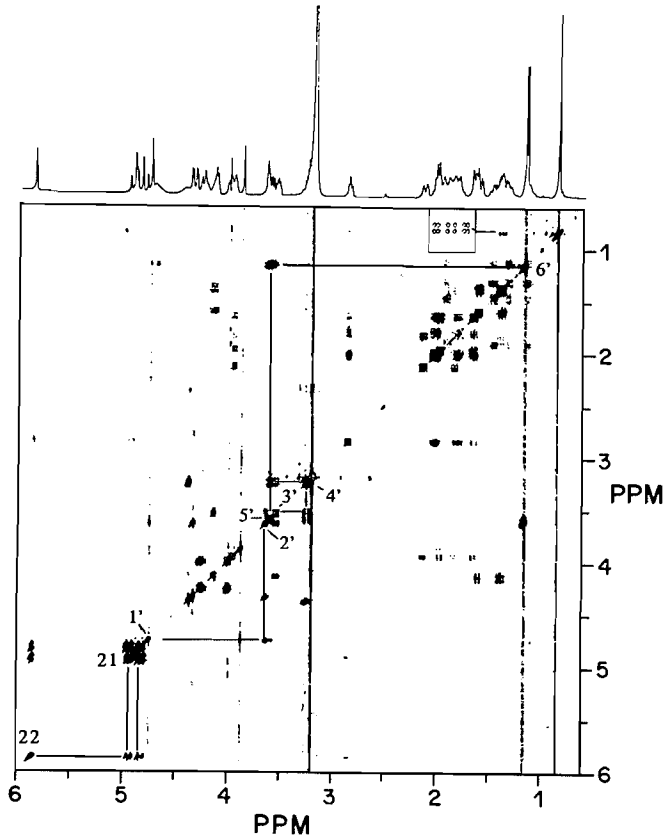

FIG. 4. Phase-sensitive COSY spectrum of ouabain obtained at 60°C. Representative connectivities are indicated by lines joining the diagonal and cross peaks arising from the carbohydrate and steroid H-21–H-22 protons. The insert shows an expansion of the 12β–18 cross peak, illustrating its fine structure; these were used to obtain the proton–proton coupling constants. The one-dimensional ^1H spectrum is shown above the *F2* axis.

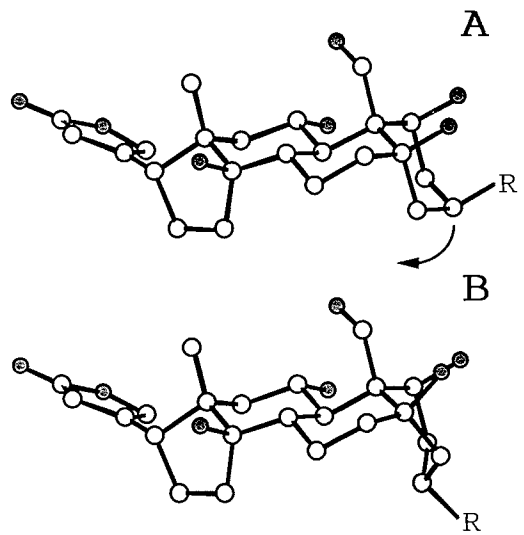

FIG. 5. Structures of ouabagenin (R = H) and ouabain (R = Rha) of the two conformers, observed in the MM calculations. (A) A ring in chair conformation; (B) A ring in twist conformation.

COSY spectrum at 60°C. This was assigned and analyzed as described above, and the resulting chemical shifts and coupling constants are included in Table 2. One-dimensional proton spectra were obtained in DMSO/$CDCl_3$ at temperatures between 60°C and −20°C. However, due to broadening resulting from high solvent viscosity, it was not possible to resolve signals arising from the minor conformer. Attempts to clarify this matter by using two-dimensional nOe/exchange spectroscopy at −20°C (slow exchange domain) and at 25°C (intermediate exchange domain) with a variety of mixing times were not successful. This has prevented us from determining the conformation of the minor form. Attempts at obtaining spectra in other solvents were hampered by low solubility.

Carbon-13 and proton NMR spectroscopy of ouabagenin

Carbon-13 NMR spectra of ouabagenin were obtained at temperatures ranging from 60°C to −20°C. As expected, most of the chemical shifts, with the exception of those near the point of attachment of the rhamnose in ouabain, namely C-2, C-3, and C-4, were within 0.5 ppm of the values observed in ouabain. They are tabulated in Table 1 for three different temperatures, 60°C, 25°C, and −20°C. Upon cooling of the sample, a number of signals broadened, and finally split into two signals in a manner analogous to that observed in ouabain. The approximate ratio of the components was again 7:1.

Following the same procedure as used for ouabain, the proton spectrum of ouabagenin was assigned from a phase-sensitive COSY spectrum obtained in DMSO/$CDCl_3$ at 60°C, a temperature at which the molecule is in fast chemical exchange. The resulting chemical shifts and coupling constants are tabulated in Table 2. As expected, most of the chemical shifts were close (within 0.03 ppm) to the values observed in ouabain, with the exception of the methylene protons attached to C-2 and C-4. No change was observed in the shift of H-3 despite the fact that this proton is vicinal to the rhamnose ring in ouabain.

Discussion

The chemical shifts and proton–proton coupling constants obtained in DMSO/$CDCl_3$ were almost identical in both compounds studied, which indicates that their conformations are similar. Hence the conformation of the steroid is not affected to a great extent by the presence of the rhamnose ring in ouabain. From the coupling constants the approximate dihedral angles were determined via the Karplus relationship. Molecular models were then constructed which would satisfy the calculated dihedral angles without imposing unrealistic steric crowding or strained bonds. One unique conformation was obtained, which therefore reasonably represents the conformation of the molecule in solution. All six-membered rings of the steroid portions of both ouabain and ouabagenin were found to be in the chair conformation, in complete agreement with the data from X-ray studies of both molecules (17–19). Thus, the extensive intermolecular hydrogen bonding that was observed in the crystal lattice did not influence the conformation of these compounds.

Ouabain in water has a conformation that is very similar to that in DMSO/$CDCl_3$; however, one significant difference is that the A-ring chair is less flat, as could be deduced from the observation that the H-1, H-2 coupling constants are approximately equal in DMSO/$CDCl_3$ (7 and 6 Hz), but are quite different in D_2O (8 and 3 Hz). Minor differences also occur in the conformation of the D ring, with this five-membered ring being flatter in DMSO/$CDCl_3$ than in D_2O. Moreover, in the latter solvent the D-ring conformation is closer to the 16β envelope than the 14β envelope found in DMSO/$CDCl_3$ and in the crystal lattice (17). The rhamnose ring of ouabain was found to be in the chair conformation, which is in agreement with the

TABLE 2. Proton chemical shifts (δ, ppm from TMS) and proton–proton coupling constants (Hz) for ouabain and ouabagenin at 60°C in DMSO-d_6/$CDCl_3$ (2:1) solution, and ouabain at 60°C in D_2O solution (DSS reference)

crystal structure. The fact that the aglycon of ouabain exists in solution in the same conformation as that of ouabagenin supports the notion that the irreversible inhibition of the Na^+, K^+-adenosine triphosphatase by ouabain is probably associated with the rhamnose ring (4, 5).

The nature of the conformational processes that affect these two molecules does not depend on the rhamnose moiety: similar behaviour was observed for both ouabain and ouabagenin. In fact, in ouabain, the exchange process was also observed for the anomeric carbon of the rhammose ring. As all the carbons that are bound to, or are directly attached to, the A ring (with the exception of C-3) exhibited chemical exchange, it appears reasonable to presume that the major conformational process that causes the observed temperature-dependent effects involves this ring. However, C-14 and C-18 also exhibited similar behaviour. It is possible, but not likely in view of the similar ratios of signal intensity, that this represents a distinct chemical exchange process. In principle, all carbons, regardless of their distance from the A ring, should exhibit separate signals. In practice, due to accidental chemical shift equivalence, this is not always the case. From the populations and the chemical shift differences between the two conformers, it can be calculated (20) that the free energy difference $\Delta G°$ and the free energy of activation (major → minor) $\Delta G°^{\ddagger}$ are approximately 4.6 and 58 kJ/mol, respectively. These values are reasonable for ring reversion of cyclohexane rings with annelated substituents (21). Thus, we hypothesize that the conformational process that is responsible for the observed chemical exchange involves interconversion of the chair form of the A ring with a higher energy conformer (see below). The major conformation at −20°C corresponds to that determined in the fast exchange regime at 60°C. However, in the absence of information about the proton–proton coupling constants for the minor conformer it is not possible to deduce its conformation unambiguously.

Molecular dynamics (MD) and molecular mechanics (MM) simulations can be used to obtain additional insight into conformational processes that have been detected by NMR studies (22). To help define the nature of the minor conformer, calculations were performed for ouabagenin with the E ring removed. One initial structure, corresponding to the major conformer, was constructed in which all six-membered rings of the steroid portion are in the chair conformation and subsequently energy minimized (see Fig. 5A). The observation of the minor NMR resonances at low temperatures for both ouabagenin and ouabain, combined with model building studies, prompted us to construct two additional conformers in which the

A ring assumes two different boat conformations. Upon energy minimization both boat conformers converged to the same twist structure, which is intermediate between the two boat conformers (see Fig. 5B) with an RMS deviation of 0.014 Å and an energy difference of 0.04 kJ/mol. A comparison of the twist and chair conformation (RMS deviation 0.27 Å) demonstrates that the all-chair conformation is energetically favoured by 32.6 kJ/mol. We have also investigated the conformational changes in the A ring (using a boat conformation as the starting structure) in molecular dynamics simulations by monitoring the C10-C1-C2-C3 torsion angle. This calculation demonstrated a rapid interconversion of the two boat forms on the picosecond time scale (0.5–1 ps). This considerable conformational freedom of the A ring indicates the presence of only relatively small energy barriers between the two boat conformations. In this MD simulation we also observed the conversion of the boat forms to the all-chair conformer, which occurs only infrequently (200–300 ps). No changes in the conformations of the other steroid rings were observed. Using the chair conformer as the starting structure, the boat conformers were not obtained over a 1000-ps simulation. Thus, both MM and MD calculations indicate that the all-chair conformation is the preferred structure for the A ring, corresponding to the major conformer observed in the NMR studies. In addition, the MD simulations suggest that the NMR-observed minor conformation may correspond to two rapidly interconverting boat forms of ring A that are in fast exchange on the NMR time scale.

Synthèse d'isoxazoles substitués en α de l'azote par une chaine alkyle ou alcényle

JEAN-CLAUDE CHERTON, MARC LANSON,[1] DAÏF LADJAMA, YVETTE GUICHON ET JEAN-JACQUES BASSELIER

Laboratoire de chimie organique structurale, Unité Associée n° 455, Université Pierre et Marie Curie, 8 Rue Cuvier, Bat. F, 7ème étage, Paris CEDEX 05, 75005, France

Reçu le 14 février 1989[2]

JEAN-CLAUDE CHERTON, MARC LANSON, DAÏF LADJAMA, YVETTE GUICHON et JEAN-JACQUES BASSELIER. Can. J. Chem. **68**, 1271 (1990).

Diverses synthèses d'isoxazoles particuliers et d'accès difficile : les isoxazoles dits « α-*N* substitués » portant en α de l'azote une longue chaîne alkyle ou alcényle, sont présentées. La classique cycloaddition dipolaire-1,3 est la méthode de choix dans le cas de substituants alkyles. Comme méthode compatible avec des chaînes alcényles, l'action de l'hydroxylamine sur les époxy-énones constitue une nouvelle voie univoque. Si l'on dispose d'« isoxazoles α-*O* substitués » d'accès plus facile, leur isomérisation est une voie rapide et générale. Enfin, l'action des magnésiens sur le bromométhyl-3 méthyl-5 isoxazole est une méthode originale et efficace.

Mots clés : isoxazoles, substitution en α de l'azote.

JEAN-CLAUDE CHERTON, MARC LANSON, DAÏF LADJAMA, YVETTE GUICHON, and JEAN-JACQUES BASSELIER. Can. J. Chem. **68**, 1271 (1990).

Several syntheses of special isoxazoles bearing a long alkyl or alkenyl side chain in the α position of the nitrogen are presented. A very convenient route in the case of an alkyl side chain is the classical 1,3-dipolar cycloaddition of a nitrile-oxide to a vinyl acetate. Although it is a rather long approach, the reaction of hydroxylamine with enone-epoxides represents a new and unequivocal method compatible with alkenyl side chains. The isomerisation of the easily synthesized isoxazoles bearing such substitutents α to the oxygen, by the reaction of their isoxazolium salts with hydroxylamine, is a fast and general method. Another very convenient access to "α-*N* substituted" isoxazoles is the coupling of magnesium compounds with 3-bromomethyl 5-methyl isoxazole.

Key words: isoxazoles, substitution in the α position of nitrogen.

Nous nous intéressons dans la perspective de leurs activités biocides à des isoxazoles substitués en α des hétéroatomes par une ou deux longues chaînes alkyle ou alcényle (1).[3] L'accès à des isoxazoles 3,5 disubstitués par ces groupements, de même qu'à des isoxazoles simplement « α-*O* substitués » est aisément réalisable (1[3] et 2–7). En revanche, les isoxazoles du type « α-*N* substitués » (cf. schéma 1), sont connus pour être beaucoup moins accessibles, même pour des substituants simples, et très peu sont décrits (8–10). Le substituant alcényle, dans le cas présent, peut entraîner une difficulté de synthèse supplémentaire. Nous présentons ici différents accès à de tels isoxazoles particuliers.

Résultats et discussion

Pour l'élaboration des isoxazoles α-*N* substitués, nous avons soit adapté des méthodes connues, soit développé de nouvelles voies de synthèse.

Voie A : cycloadditions dipolaires-1,3 d'oxydes de nitriles sur des alcynes (réf. 4) ou des alcènes (réf. 5)

1. *Isoxazoles* **4** α-N *monosubstitués*

Un accès univoque peut s'envisager par addition dipolaire-1,3 d'oxydes de nitriles **1** sur l'acétylène (4) et nous avons utilisé l'acétate de vinyle **2***a* comme équivalent synthétique de ce dipolarophile dans une méthode indirecte (11). Sa condensation avec des oxydes de nitrile à groupe alkyle ou alcényle, conduit régiosélectivement aux isoxazolines **3** (isolées ou non selon les cas), qui sont aromatisées en isoxazoles α-*N* par chauffage en milieu acide (cf. schéma 2 et tableau 1). Cette méthode[4] a l'avantage d'impliquer des matières premières et des précurseurs commerciaux ou d'accès facile : acétate de vinyl, bromure d'alkyle ou d'alcényle, aldéhydes.

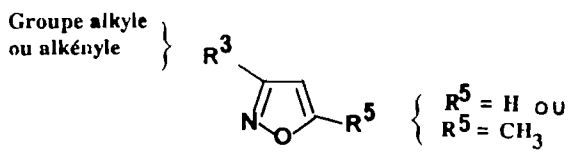

SCHÉMA 1. Isoxazoles α-*N* substitués.

2. *Isoxazoles* α-N **6** *méthylés en position 5*

Nous avons employé l'acétate d'isopropényle **2***b* comme équivalent synthétique du dipolarophile propyne dans la méthode indirecte via les isoxazolines **5** (cf. schéma 2). Le (décène-9 yl)-3 méthyl-5 isoxazole (**6***c*) est ainsi obtenu, mais en faible rendement (~20%) car il se forme une quantité importante (~40%) de furoxanne **1**′ (13) lors de la préparation de l'isoxazoline **5***c*.

Voie B : action de l'hydroxylamine sur des composés carbonylés

Nous avons d'abord retenu les énones[5] comme précurseurs carbonylés des isoxazoles α-*N*. En effet, une transformation *énone* → *isoxazole* a été obtenue par Büchi et Vederas (14) dans le cas des β-ionones, par action de l'hydroxylamine suivie d'une oxydation. Nous avons donc synthétisé des énones telles

[1]Partie de thèse soutenue a l'Université Pierre et Marie Curie, Paris, 1987.

[2]Révision reçue le 9 mars 1990.

[3]Synthèse d'« isoxazoles α-*O* substitués » soumis au Can. J. Chem., J. C. Cherton, M. Lanson, D. Ladjama, N. Lefèvre et J. J. Basselier.

[4]La déprotonation par les bases, du méthyle du méthyl-3 isoxazole, suivie d'une alkylation (voie de type C) n'est pas une voie d'accès aux isoazoles **4** puisque ce synthon, fragile en milieu basique, est de plus d'obtention difficile. L'action de l'hydroxylamine sur les β-cétoaldéhydes est hautement régiosélective mais conduirait dans notre cas aux isomères α-*O* substitués (12).

[5]L'action de l'hydroxylamine sur les β-dicétones (10, 18) et les ynones (19) conduit à des mélanges d'isoxazoles de types α-*N* et α-*O* substitués (9, 20).

SCHÉMA 3. Voie des époxy-énones **9** (voie B).

que **8** par action du magnésien approprié sur le crotonal suivie d'une oxydation de l'alcool allylique **7** résultant selon la méthode de Ratcliffe (15). Toutefois, la transposition de la méthode de Büchi aux énones **8** s'est avérée décevante dès la première étape (1), (cf. schéma 3). Ceci provient de la difficulté d'obtention des oximes d'énones (16). Aussi avons nous procédé par action de l'hydroxylamine non pas sur les énones **8** mais sur les époxy-énones **9**. Ces dernières sont obtenues par époxydation sélective de la double liaison de l'énone avec l'eau oxygénée en milieu alcalin. Leur conversion en isoxazoles **6** a nécessité une mise au point de chacune des étapes. L'action de l'hydroxylamine en l'absence de solvant supprime la coupure en α du carbonyle masqué qui se produit en présence de pyridine (17). La cyclisation des oximes d'époxy-énones **10** a été effectuée en milieu acide doux (BF_3/Et_2O), pour éviter l'hydrolyse des oximes et éventuellement l'isomérisation des doubles liaisons terminales (cf. schéma 3 et tableau 2).

Cette synthèse partant d'époxy-énones a un rendement global faible. C'est néanmoins une méthode sûre, univoque et compatible avec des chaînes alcényles.

Voies C : partant d'isoxazoles

1. *Isomérisation des isoxazoles* α-O *substitués* (Voie C_1)

Nous avons appliqué *à l'échelle préparative* la méthode d'isomérisation des isoxazoles de Kashima et al. (21)[6] en quaternarisant les isoxazoles α-*O* **11** (1), (cf. schéma 4). Les méthyl-2 isoxazoliums **12** cristallisent parfois difficilement à cause de la présence d'une longue chaîne lipophile, et nous avons dû, pour chaque cas, rechercher l'anion le plus favorable (cf. schéma 4 et tableau 3). Nous nous sommes volontairement limités aux cas les plus simples où les isoxazoliums cristallisent. Néanmoins, même dans le cas contraire, cette méthode semble être une voie d'accès très intéressante aux isoxazoles α-*N* substitués.

[6]La difficulté de synthèse des isoxazoles de type α-*N*-substitués est bien connue (8–10) et les tentatives négatives concernant le simple *tert*-butyl-3 méthyl-5 isoxazole ont incité Kashima à rechercher une méthode générale d'accès à ces isoxazoles α-*N*. Cette synthèse fait appel aux sels de methyl-2 isoxazoliums (21, 22). L'action de l'hydroxylamine (sous forme $NHOH^-$) se traduit finalement par une inversion des hétéroatomes du cycle.

*Cristallise au bout d'une semaine.

mise au point. La bromation fournit l'isoxazole bromé **6***g* dont le couplage avec le magnésien approprié s'est effectué sans difficulté (cf. schéma 5). Cette nouvelle méthode générale semble la plus efficace de celles que nous avons jusqu'ici testées pour produire des isoxazoles α-*N* substitués.

Ces isoxazoles α-*N* substitués dont les propriétés biologiques seront présentées indépendamment ont servi de synthons dans l'élaboration d'isoxazoles substitués de part et d'autre des hétéroatomes (1).[3]

Partie expérimentale

Les spectres d'absorption infrarouge ont été enregistrés sur un appareil Pye Unicam modèle SP3-200 (film liquide entre pastilles de NaCl, ou en pastilles de KBr, bandes d'absorption exprimées en cm^{-1} avec les abréviations suivantes : L, large; F, forte; m, moyenne; f, faible). Les spectres de rmn ^1H et de rmn ^{13}C ont été enregistrés sur des appareils Bruker WP 80, WM 250 et WM 500. Sauf indication contraire tous les spectres ont été effectués dans le $CDCl_3$. Les déplacements chimiques sont exprimés en ppm par rapport au TMS pour les spectres de rmn ^1H et par rapport au pic central du $CDCl_3$ choisi comme référence (77,1 ppm) pour les spectres de rmn ^{13}C (avec les abréviations suivantes : s, singulet; d, doublet; t, triplet; q, quadruplet; m, multiplet; M, massif). Les spectres de masse et de masse exacte ont été enregistrés sur des spectrographes MS 30 et MS 50 sous impact électronique à 70 eV par M^lle^ J. Mercier que nous remercions. Les pics sont exprimés en *m/z* avec, entre parenthèses, leur intensité relative. Les analyses élémentaires ont été executées au service de microanalyse de l'Université Pierre et Marie Curie ou au service de microanalyse du CNRS à Vernaison. Les points de fusion non corrigés ont été déterminés de façon instantanée au banc de Kofler.

Pour les composés intermédiaires tels que les isoxazoles **3** ou encore les énones **8**, les époxy-énones **9**, les oximes d'époxy-énones **10** et les sels d'isoxazolium **12**, les caractéristiques structurales sont souvent plus succintes en raison d'éventuelles instabilités. Ces composés sont alors utilisés directement sans purification.

Voie A (tableau 1)

2. *Synthèse de l'isoxazole* **6***c via l'isoxazoline* **5***c*

La méthode de Larsen est appliquée à un mélange équimoléculaire de 11 mmol de l'oxime de l'undécénal (2 g) et d'acétate d'isopropényle (1,1 g). Après évaporation du solvant (chloroforme), l'addition de 100 mL d'heptane au milieu réactionnel provoque la précipitation du furoxanne correspondant **1′** (1,46 g, 37%), *F* 96–97°C; ir (KBr) : 2880(F), 1610(m), 1410(m), 1360(m), 1000(f), 820(m); rmn ^{1}H : 5,75 (M, 2H), 5,0 (M, 4H), 1,25 (M, 32H).

La distillation sous vide du filtrat renfermant l'isoxazoline brute **5***c* conduit à l'isoxazole **6***c* (512 mg, 20% par rapport à l'oxime), $Eb_{0,05}$ 110–112°C. Ce composé présente les mêmes caractéristiques spectroscopiques que l'isoxazole **6***c* obtenu par la voie B.

Voie B (tableau 2)

1. *Synthèse des précurseurs*

Enones **8**a–d. Elles sont obtenues selon la réf. 14 à partir des alcools allyliques **7** eux mêmes synthétisés selon la réf. 27. *Octadiène-2,7 one-4* (**8***a*) : (54%), Eb_{12} 70°C (litt. (28) Eb_{15} 72°C). *Nonadiène-2,8 one-4* (**8***b*) : (57%), Eb_{14} 94°C (litt. (28) Eb_{17} 98°C). *Tétradecadiène-2,13 one-4* (**8***c*) : (86%), $Eb_{0,5}$ 106°C; ir : 2920(F), 2860(m), 1690(f), 1670(m), 1640(m), 1440(m), 990(f), 970(m), 910(F), 740(F); rmn ^{1}H : 6,85 (1H, qd, 16 Hz, 7 Hz), 6,12 (1H, qd, 16 Hz, 1 Hz), 5,8 (1H, m) 4,9 (2H, m), 2,5(2H, t, 7,5 Hz), 2,05 (2H, m), 1,90 (3H, dd, 6,9 Hz, 1,25 Hz), 1,60 (2H, m), 1,30 (10H, M); rmn ^{13}C : 200,6, 142,2, 139,2, 132, 114, 40,1, 33,8, 29,7, 29,4, 29,1, 24,3, 18,2; masse : M^+ 208, 193(20), 123(40), 84(50), 69(100), 55(20), 41(50). Anal. calc. pour $C_{14}H_{24}O$: C 80,71, H 11,61, O 7,68; tr. : C 80,88, H 11,65, O 7,47. *Pentadécadiène-2,14 one-4* (**8***d*) : (84%), $Eb_{0,3}$ 123°C; ir : 3080(f), 2920(F), 2860(F), 1695(m), 1670(F), 1630(F), 1460(m), 995(f), 970(m), 910(m); rmn ^{1}H : 6,65 (1H, qd, 16 Hz, 6 Hz), 5,7 (2H, m), 4,6 (2H, m), 2,4 (2H, t, 7 Hz), 2,2–1 (19H, M); rmn ^{13}C : 200,5, 141,9, 139,2, 132,2, 114,2, 40,2, 33,8, 29,4, 29,1, 29,0, 24,3, 18,0. Voie C_1 : *Isomérisations des isoxazoles* α-O *substitués* ***11*** (tableau 3)

Isoxazoliums ***12***

Les iodures d'isoxazoliums **12***a* et **12***b* sont préparés selon la méthode de Lampe et Smolinska (22) à partir des isoxazoles α-*O* substitués **11** correspondants (1).[3] *Iodure de (butène-3 yl)-5 diméthyl-2,3 isoxazolium* (**12***a*) : (45%), *F* <50°C (éther diéthylique); ir : 1640(f), 1600(m), 1540(m), 1480(m), 1420(m), 1000(m), 900(f); rmn ^{1}H : 7,1 (s, 1H), 5,8 (m, 1H), 5,0 (m, 2H), 4,5 (s, 3H), 3 (t, 7,4 Hz, 2H), 2,6 (s, 3H), 2,4 (m, 2H); rmn ^{13}C : 172,8, 158,2, 133,7, 114,8, 105,8, 36,6, 27,7, 23,1, 10,0. *Iodure de diméthyl-2,3 (pentène-4 yl)-5 isoxazolium* (**12***b*) : (72%), *F* <50°C (acétate d'éthyle); ir : 1640(f), 1610(f), 1550(f), 1050(f), 1000(f), 980(f), 930(m), 860(f), 650(m); rmn ^{1}H : 7,1 (s, 1H), 5,8 (m, 1H), 5,1 (m, 2H), 4,5 (s, 3H), 3 (t, 7,4 Hz, 2H), 2,9 (s, 3H), 2,2 (m, 2H), 1,8 (m, 2H); rmn ^{13}C : 176,1, 160,2, 136,2, 116,4, 108,6, 40,9, 32,4, 26,0, 25,5, 14,2. *Perchlorate de diméthyl-2,3 (undécène-10 yl)-5 isoxazolium* (**12***d*) : il est obtenu selon la méthode de Woodward et Olofson (30) (47%), *F* <50°C (acétone); rmn ^{1}H : 6,6 (s, 1H), 5,8 (m, 1H), 4,9 (m, 2H), 4,2 (s, 3H), 2,8 (t, 7,4 Hz, 2H), 2,6 (s, 3H), 2,0 (m, 2H), 1,7 (m, 2H), 1,4–1 (M, 12H); rmn ^{13}C : 176,8, 160,8, 139,2, 114,2, 107,8, 38,6, 33,8, 26,8, 26,6, 12,4.

Action de l'hydroxylamine sur les isoxazoliums ***12***

Les isoxazoles α-*N* **6***a*, **6***b* et **6***d* ont été préparés à partir des isoxazoliums correspondants selon la méthode de Kashima *et al.* (21). (*Butène-4 yl)-3 méthyl-5 isoxazole* (**6***a*) : (25%), Eb_{15} 82°C; rmn ^{1}H : 5,80 (M, 2H), 5,0 (m, 2H), 2,7 (t, 2H), 2,4 (m, 2H), 2,36 (s, 3H); rmn ^{13}C : 169,1, 163,6, 137,1, 115,7, 101,3, 32,2, 25,6, 12,2; masse : M^+ 137, 55(55), 43(100), 41(40). Anal. calc. pour $C_8H_{11}NO$: C 70,04, H 8,08, N 10,21; tr. : C 70,00, H 8,26, N 10,30. *Méthyl-5 (pentényl-4 yl)-3 isoxazole* (**6***b*) : (54%). *Méthyl-5 (undécène-10 yl)-3 isoxazole* (**6***d*) : (27%). Les composés **6***b* et **6***d* présentent les mêmes caractéristiques physiques que ceux obtenus par la voie B.

Voie C_2 : *À partir du bromomèthyl-3 méthyl-5 isoxazole* (**6***g*)

Méthyl-5 isoxazole carboxylate-3 d'éthyle (**6***e*) : On utilise la méthode de Baraldi *et al.* (23) (69%), Eb_{20} 124°C (litt. (23) Eb_{18} 112°C). *Hydroxyméthyl-3 méthyl-5 isoxazole* (**6***f*) : Afin d'éviter les problèmes d'extraction, nous avons modifié la méthode de Baraldi *et al.* (23). À une solution de 6,2 g (0.04 mol) de méthyl-5 isoxazole carboxylate-3 d'éthyle **6***e* dissous dans 84 mL d'éthanol absolu refroidi par un bain de glace, on ajoute 3,3 g (0,087 mol) de borohydrure de sodium par petites quantités. On laisse sous agitation à température ambiante pendant 3 h puis on neutralise le milieu réactionnel avec une solution concentrée de HCl. Le solvant est chassé sous vide, puis le résidu est saturé par du sulfate d'ammonium et extrait à l'éther. La phase éthérée est séchée sur sulfate de magnésium, évaporée au rotovapor, puis distillée sous vide (75%), Eb_{15} 120°C (litt. (23) Eb_{15} 120°C). *Bromométhyl-3 méthyl-5 isoxazole* (**6***g*) : À une solution de 25 mL be benzène anhydre refroidie à −10°C et contenant 2,9 g (0,01 mol) de PBr_3 et 0,6 mL de pyridine, on ajoute un mélange de 0,4 mL pyridine et de 5,6 g (0,05 mol) d'hydroxyméthyl-3 méthyl-5 isoxazole (**6***f*) en maintenant la température à −5°C durant l'addition. On agite ensuite pendant 1 h à −10°C, puis à température ambiante pendant 24 h. Le mélange est distillé, le distillat est étendu d'éther et lavé à l'eau, séché sur sulfate de magnésium. L'éther est chassé sous vide (59%), Eb_{15} 105°C; ir : 3150(m), 1610(F), 1480(F), 1450(F), 1270(F), 1230(F), 1150(F), 1020(F), 920(F), 810(F), 760(F), 710(F), 620(m); rmn ^{1}H : 5,9 (s, 1H), 4,2 (s, 2H), 2,3 (s, 3H); rmn ^{13}C : 170,3, 160,8, 101,5, 20,7, 12,1; masse : M^+ 177–175, 96(60), 43(100).

Attaque du bromométhyl-3 méthyl-5 isoxazole par les magnésiens

Butène-4 yl)-3 méthyl-5 isoxazole (**6***a*): À 17 mL (0,01 mol) du magnésien du bromure d'allyle refroidi par un bain de glace, on ajoute goutte à goutte 1,87 g (0,01 mol) du bromométhyl-3 méthyl-5 isoxazole (**6***g*) dilué dans 2 mL d'éther anhydre. Après 12 h d'agitation, le mélange réactionnel est traité par une solution de HCl concentré jusqu'à neutralité, puis extrait à l'éther. L'éther est chassé sous vide et l'huile obtenue est distillée (64%), et présente les mêmes caractéristiques physiques et spectroscopiques que l'isoxazole obtenu par la voie des isoxazoliums.

Tetrakis(*p*-methylsulphonylphenyl)tin(IV) and tetrakis(*p*-methylsulphinylphenyl)tin(IV) *n*-hydrate have been prepared and their spectra (ir 1350–400 cm^{-1}; nmr, ^1H, ^{13}C, ^{119}Sn) and X-ray crystal structures are reported. The first compound is monoclinic, space group $C2/c$, $Z = 4$, with $a = 21.589(6)$, $b = 6.207(3)$, $c = 22.861(11)$ Å, $\beta = 93.80(3)°$ (22°C); the structure was solved by the direct method and refined by full-matrix least squares calculations to $R = 0.043$ for 2755 observed reflections. It has 2 molecular symmetry with the methyl group and one oxygen atom completely disordered in both $CH_3S(O_2)$ groups in the asymmetric unit. The second compound is tetragonal, space group $P4_2/n$, $Z = 2$, with $a = b = 15.408(6)$, $c = 6.379(2)$ Å (−100°C); the structure was solved by the Patterson method and refined by full-matrix least squares calculations to $R = 0.060$ for 1209 observed reflections. It has $\bar{4}$ molecular symmetry with the whole asymmetric unit disordered. Water molecules occupy positions on parallel 4_2 axes but molecular packing requirements prevent all sites having 100% occupancy giving $n \sim 1$ for the hydrate.

Key words: Tetra-aryltins, crystal structures, sulphone, sulphoxide, hydrogen-bonding.

IVOR WHARF, MICHEL G. SIMARD et HENRY LAMPARSKI. Can. J. Chem. **68**, 1277 (1990).

On a préparé le tétrakis(*p*-méthylsulfonylphényl)étain(IV) et le *n*-hydrate du tétrakis(*p*-méthylsulfinylphényl)étain(IV) et on a déterminé leurs spectres ir (de 1350 à 400 cm^{-1}) et rmn du ^1H, du ^{13}C et du ^{119}Sn ainsi que leurs structures cristallines par diffraction des rayons-X. Le premier composé est monoclinique, groupe d'espace $C2/c$, $Z = 4$, avec $a = 21,589(6)$, $b = 6,207(3)$ et $c = 22,861(11)$ Å et $\beta = 93,80(3)°$ (22°C); on a affiné la structure par la méthode directe et on l'a affinée par la méthode des moindres carrés jusqu'à une valeur de $R = 0,043$ pour 2755 réflexions observées. Il possède symétrie moléculaire 2 alors que le groupement méthyle ainsi que l'atome d'oxygène sont complètement désordonnés dans les deux groupements $CH_3S(O_2)$ de l'unité asymétrique. Le second composé est tétragonal, groupe d'espace $P4_2/n$, $Z = 2$, avec $a = b = 15,408(6)$ et $c = 6,379(2)$ Å (−100°C); on a résolu la structure par la méthode de Patterson et on l'a affinée par la méthode des moindres carrés jusqu'à une valeur de $R = 0,060$ pour 1209 réflexions observées. Il possède une symétrie moléculaire $\bar{4}$ et l'unité asymétrique dans son ensemble est désordonnée. Les molécules d'eau occupent des positions parallèles aux axes 4_2; toutefois, l'empilement moléculaire ne permet pas à tous les sites d'être occupés à 100% et l'hydrate est à $n \sim 1$.

Mots clés : tétra-arylétains; structures cristallines; sulfone; sulfoxyde; liaison hydrogène.

[Traduit par la revue]

Introduction

Although the eight tetra-aryltin structures reported to date (2, 3) have $\bar{4}$ molecular symmetry, the specific tetragonal space group adopted depends on the phenyl ring substituents present. Usually substituted tetra-aryltins are prepared from the appropriate aryl bromide but if the substituent is itself a functional group, this can react further, yielding other tetra-aryltins. Here we report two new Ar_4Sn obtained by oxidation of the methylthio groups of $(p\text{-}CH_3SC_6H_4)_4Sn$ (**1**) to $CH_3S(O)$ or $CH_3S(O_2)$.

Oxidation of a sulphide to a sulphone is readily accomplished at room temperature with several oxidants (4*a*), including that used here, *m*-chloroperbenzoic acid (*m*-CPBA). Since crystal structures of compounds with an —$S(O_2)$— unit joined to aryl and alkyl groups concurrently (5–10) including two with the $CH_3S(O_2)$— moiety (11, 12), show no example where the C—S—C_{ar} unit and phenyl ring are coplanar, we undertook an X-ray diffraction study of $(p\text{-}CH_3S(O_2)C_6H_4)_4Sn$ (**2**), to determine the effect of this large unsymmetric *para*-substituent on the choice of space group for the compound.

Partial oxidation of (**1**) to give $(p\text{-}CH_3S(O)C_6H_4)_4Sn$ (**3**) using *m*-CPBA is unpredictable (4*b*) requiring careful temperature control (13) to prevent formation of sulphone groups whose presence can be detected from the infrared spectra of the products. Since **1** has the CH_3—S bond coplanar with the phenyl ring, equal numbers of *R* or *S* configuration $CH_3S(O)$— groups will be formed, enabling **3** with this disorder to have effective fourfold symmetry. However, infrared spectra show authentic samples of **3** also contain hydrogen-bonded lattice water, another potential cause of disorder. An X-ray diffraction study of **3** was therefore carried out to determine the nature of the disorder at each sulphur atom, as well as hydrogen bonding and the amount of lattice water in the crystal.

Experimental

Tetra(*p*-methylthiophenyl)tin (**1**) was a previous preparation (2) while *m*-CPBA (Aldrich) was used as received. All solvents were

stored over molecular sieves except anhydrous ether (Fisher). Other experimental details, e.g. micro-analyses and infrared (Nujol mull) 1350–500 cm^{-1} and nmr (^{13}C, ^{119}Sn) spectra were as described elsewhere (1, 14); proton nmr spectra ($CDCl_3$ solution) were obtained using a Varian T-60 instrument.

Preparations

*Tetra(*p*-methylsulphonylphenyl)tin (2)*

Solid *m*-CPBA (85%; 11.08 g) was added over 1½ h to a well-stirred dichloromethane (20 mL) solution of **1** (3.34 g) kept at −8°C. Further CH_2Cl_2 (75 mL) was added to the mixture which was then stirred for 2½ h at room temperature. Dissolving the white suspension with (1/1) CH_2Cl_2/ether (200 mL) followed by adding ether (300 mL) to the clear filtrate gave the *product* as a white powder. This was redissolved in CH_2Cl_2 (300 mL), then reprecipitated with ether (300 mL), and dried in vacuum overnight; yield 67%; dec. > 355°C; ir data, (1308, 1305)*vs($\nu_{as}(SO_2)$), 1296s, 1290sh, 1281sh, 1266wm, 1195wmsp, 1189wmsp, (1153, 1151)*vs($\nu_s(SO_2)$), 1117w, 1094sh, 1091m, 1061wmsp, 1013msp, 975sh, 967sm, 960s, 949sh, 824msp, 821sh, 814msp, 775*s($\nu(CH_3—S)$), 733wbr, 715wm, 708w, 554sh, 551*vs, 543*s, (534, 530)*vs; ^{1}H nmr δ: 3.07 (s, 3H), 7.67–8.05 (q, 4H). *Anal.* calcd. for $C_{28}H_{28}O_8S_4Sn$: C 45.5, H 3.8; found: C 45.0, H 3.8.

*Tetra(*p*-methylsulphinylphenyl)tin* n*-hydrate (3)*

A solution of *m*-CPBA (85%; 4.20 g) in CH_2Cl_2 (100 mL) was added dropwise over 1½ h to a well-stirred CH_2Cl_2 (20 mL) solution of (**1**) (3.05 g) kept at −12°C. The stirred mixture was allowed to slowly warm to room temperature (4 h) and the clear solution obtained washed with saturated aqueous solutions of $NaHCO_3$ (4 × 80 mL) and NaCl (100 mL). The organic layer was dried over anhydrous $MgSO_4$ (2 days) and then evaporated under vacuum to a clear glassy solid. This was recrystallised from much acetone (~1 L) to yield a fine white powder which was dried in a vacuum for 2 days; yield 55%; mp 265–267°C; ir data, 3440s, vbr (ν(OH)); 1298m, 1262w, 1189w, 1107w, 1088vs,sp, 1060m,sp, (1052vs, (1036, 1033, 1029)vs)*(ν(SO)), 1011vs,sp, 952s, 938m, 859w, 813s, 720w, 681wm ($\nu(CH_3—S)$), 629w,sp, 509s, 487sm; ^{1}H nmr δ: 2.23 (s, 1H), 2.79 (s, 3H), 7.73 (s, 4H); ^{13}C nmr δ: 43.76 (CH_3), 123.82 (*m*-C, J = 53.6 Hz, ^{119}Sn—C), 137.68 (*o*-C, J = 40.4 Hz, ^{119}Sn—C), 139.91 (*i*-C, J = 534.5 Hz, ^{119}Sn—C), 147.79 (*p*-C, J = 11.9 Hz, ^{119}Sn—C); ^{119}Sn nmr: −129.10 ppm (ext. $Sn(CH_3)_4$). Anal. calcd. for $C_{28}H_{28}O_4S_4Sn.nH_2O$: ($n$ = 1) C 48.5, H 4.4; (n = 2) C 47.3, H 4.5; found: C 47.5, H 4.5.

X-ray structure analysis

Data collection for both compounds followed previous procedures (2, 15); the specific parameters are given in Table 1. The structures were solved using MULTAN (**2**) or the Patterson method (**3**), followed by difference Fourier calculations. Final cycles introduced H-atoms at fixed positions (d(C—H) = 1.08 Å) followed by anisotropic refinement of all non-hydrogen atoms.

For **2**, the disordered solutions for the *para*-substituents obtained in both space groups (Cc and $C2/c$) showed the symmetry from the disorder was not imposed by the centrosymmetric $C2/c$ space group. This space group was retained for the final refinements with methyl group and oxygen atom positions related by disorder, treated together. Individual weights based on counting statistics applied in the last cycles ($w = 1/\sigma^2(F) + 0.0002F^2$), and isotropic temperature factors of the hydrogen atoms fixed at U(phenyl H) = 0.07 Å^2 and U(methyl H) = 0.10 Å^2, gave the refinement indicators presented in Table 1.

In the case of **3**, a high residual peak beside the initial sulphur atom in the second ΔF map which showed disorder existed was assigned to a second sulfur atom position. The model including Sn and the two sulphur atoms (occupancy = 0.65/0.35) revealed nearly all the disorder associated with the *para*-thiophenyl group, there being two

orientations using C(1) and Sn as a common pivot. The disorder involving the $CH_3S(O)$— groups was considered next. Only one methyl group could be localised for each sulphur atom, indicating that the disorder involved the oxygen atoms. For the major occupancy model (**A**, 0.70(2)) two oxygen positions on each side of the C(4)—S—CH_3 plane were introduced at first, from the computed ΔF map, but on refinement that giving local *S*-chirality at the sulphur was further divided to account for large anisotropic temperature factors. In contrast, for the minor occupancy model (**B**, 0.30(2)) only one oxygen position (local *R*-chirality) could be found. Oxygen atoms corresponding to water molecules were found distributed over three special positions ($4f$) along the 4_2 screw axis with an occupancy ratio of 1:3:1, and the total occupancy giving $H_2O/Sn = 1.24 \pm 0.40$. In the final cycles, ten reflections suffering extinction were rejected and individual weights ($w = 1/\sigma^2(F)$) based on counting statistics were applied. Fixed hydrogen isotropic temperature factors at U(phenyl H) = 0.05 Å^2 and U(methyl H) = 0.07 Å^2 gave refinement indicators presented in Table 1.

Refined coordinates for all non-hydrogen atoms for both compounds are listed in Table 2 while selected bond lengths and angles are listed in Tables 3. The remaining data are on deposit.[3]

Results

The compounds reported here are best identified by their infrared spectra which may be compared with the spectrum of the starting material (**1**).[4] Even though complete assignments for $CH_3S(O_n)C_6H_5$ (n = 0, 1, 2) have been made (16) and the infrared spectrum of *p*-bromothioanisole was assigned earlier (17), enabling $CH_3SO(O_n)$— group absorptions to be readily identified, the oxidation states of sulphur atoms in the various products of *m*-CPBA oxidation were monitored empirically using the strong peaks labelled (⊕), (*), and (≠) in the spectra of **1**, **2**, and **3**, respectively. Only two of the many attempted preparations of **3** had infrared spectra with no peaks characteristic of CH_3S— or $CH_3S(O_2)$— groups. The NMR spectra (^1H, ^{13}C, ^{119}Sn; $CDCl_3$ solution) of both samples also showed that only *p*-methylsulphinyl groups were present in each case.

[p-$CH_3S(O_2)C_6H_4]_4Sn$ (2)

This is the first fully characterised tetra-aryltin with less than fourfold symmetry. However, the deviation is small with $I4_1/a$ being the related minimal non-isomorphic supergroup for the $C2/c$ space group (18). The two *p*-$CH_3S(O_2)C_6H_4$— parts of the asymmetric unit (Fig. 1) differ principally in the orientation of the ordered S=O bond of each *para*-substituent with respect to the adjacent phenyl ring (Table S5). The rings themselves show fewer changes from ideal benzene ring values (Table S6) than other phenylmetal systems (19). While intramolecular interactions involving ring *meta*-H atoms and adjacent methylsulphonyl group are significant, it is more likely that intermolecular interactions cause the differing geometries of the two $CH_3S(O_2)$— moieties. Molecules pack in the crystal by interleaving *p*-$CH_3S(O_2)C_6H_4$ groups attached to tins on parallel 2 axes (Fig. S2). With each *para*-substituent disordered (interchange of CH_3 with an O atom) each group may be characterised as *exo-* or *endo-* depending on the orientation of its methyl radical with respect the inversion centre relating neighbouring groups of different Ar_4Sn (Fig. S3). Many of the interatomic distances between the possible *exo–exo*, *endo–endo*, and *exo–endo* pairs of asymmetric units from adjacent molecules are less than van der Waals indicating considerable strain in the crystal lattice but most are still allowed (Table S7). The few which are clearly unrealistically short suggest complete disorder does not occur at these points in the crystal. However, any ordering is localised at each position and does not give rise to any long range order in the lattice which remains for all practical purposes completely disordered.

[p-$CH_3S(O)C_6H_4]_4Sn.n$-H_2O (3)

Compound **3** has the usual $\bar{4}$ molecular symmetry for tetraorganotins although a new space group, $P4_2/n$, is used. The asymmetric unit (Fig. 2) is almost completely disordered with only the Sn—C_{ipso} bond ordered. The phenyl ring of model (**A**) shows the elongation expected when attached to a metal atom (19) (Table S12) but the phenyl ring of the minor occupancy model (**B**) is not well defined. Thus the large distortions observed may simply be artefacts from the solution of the structure. In contrast the four well-defined $CH_3S(O)$— groups of the asymmetric unit agree with the infrared data (ν(S=O)) for **3** with the peak at 1052 cm^{-1} assigned to the shorter non-hydrogen bonded $\rangle$S=O moiety of model **B** (20, 21) while the three lower frequencies may be assigned to the three longer possibly hydrogen-bonded S=O bonds in model **A** (22–24). It must be noted, however, that lattice effects could account for the splitting of ν(S=O) seen here.

The hydrogen bonding noted above — the distinctive feature of this Ar_4Sn structure — involves water molecules lying on 4_2 axes parallel to the Ar_4Sn columns in the unit cell (Fig. S5). The water molecules occupy sites grouped in threes, although only one site in each group at a time can be occupied, giving $n \simeq 2$ with full occupancy. Since the sites are surrounded by pairs of methylsulphoxide groups (Fig. S6), inspection of shorter intermolecular distances (Table S14) shows that the methyl radical from a model **B** $CH_3S(O)$— group clearly prevents the occupation of these sites by water molecules. With each $CH_3S(O)$— group in the structure described by the orientation of the sulphoxide oxygen with respect to the adjacent water column as *exo-* (O(1A) or O(1B) or *endo-* (O(2A) or O(3A)), the possible H-bonding environments of the lattice water molecules (Table S15) include a water molecule held in place by (*a*) four, (*b*) two, or (*c*) one oxygen(s) from *endo*-sulphoxide groups. However, since neighbouring water molecules can also hydrogen-bond in the column, we may assume that if *both* surrounding $CH_3S(O)$— groups are described by model **A**, each group of three sites will be occupied by a water molecule giving an occupancy of 0.46–0.52 and $n = 0.98 \pm 0.06$. Whether an asymmetric unit is assigned to model **A** or **B** depends on the packing of pairs of units related by inversion centres in the unit cell. If both such $CH_3S(O_2)$— units are *exo-* conformation then only the d(O---O) value (2.73 Å) when *both* oxygens belong to the minor model **B** is physically reasonable, although this value still implies considerable intermolecular strain, which may account for the distortion of the phenyl ring of model **B**. If the two groups are *exo-* *endo-* then both may belong to model **A**, giving predicted occupancy factrns, model **A**, 0.75, and model **B**, 0.25, with $n = 1.125$, a value close to that given by water molecule occupancy factors. However, the occupancy factors

for the two models of the asymmetric unit are better defined and on this basis we consider compound **3** is best described as a mono-hydrate.

Discussion

Empirical force field calculations (25) indicate that ground state isolated Ar_4Sn molecules will have $\bar{4}$ symmetry while Kitaigorodsky earlier proposed (26*a*) that the most efficient close packing of such quasi-spherical $\bar{4}$ molecules requires the use of tetragonal space groups with $I\bar{4}$, $P42_1c$, and $P4_2/n$ preferred. In addition, he predicted that as larger and more complex *para*-substituents make the Ar_4Sn less spherical, less

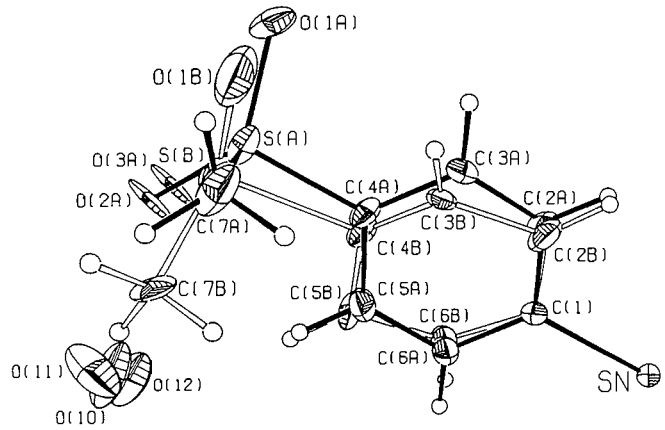

FIG. 2. The asymmetric unit, with numbering scheme, for (p-$CH_3S(O)C_6H_4)_4Sn.nH_2O$; darkened bonds stand for the major occupancy model **A**.

symmetric space groups would be favoured with a concomitant lowering of molecular symmetry. The structure of **2** is consistent with those predictions. Furthermore, since the molecule with the disorder seen here could easily have $\bar{4}$ symmetry, it is presumably the need for efficient crystal packing which determines the choice of space group.

In contrast, compound **3** with *para*-groups of similar size and complexity crystallises in the previously unused close-packed tetragonal space group, $P4_2/n$, and retains $\bar{4}$ molecular symmetry. Presumably the hydrogen bonding network promotes dense packing in the lattice even though when neighbouring *exo*-$CH_3S(O)$— groups interact, the considerable steric strain has to be relieved by distorting the full asymmetric unit. The exact amount of H-bonding (and degree of hydration) is therefore a balance between the increased lattice energy it creates and the unfavourable energy changes due to the larger intermolecular repulsions and phenyl ring distortions required. The importance of bulky *para*-substituents is shown also by the crystal data for (p-$EtOC_6H_4)_4Sn$ (26*b*, 27). However, the space group ($P2_1/a$) is not related to any tetragonal space group, and since tin atoms lie on general positions, a more detailed analysis of this structure is clearly necessary.

Electrochemical preparation and properties of the mixed-crystalline hexavanadates $M_xM'_{4-x}V_6O_{16}$, M, M' = NH_4, K, Rb, Cs

E. ANDRUKAITIS, P. W. M. JACOBS, AND J. W. LORIMER[1]

Department of Chemistry, The University of Western Ontario, London, Ont., Canada N6A 5B7

Received December 21, 1989

E. ANDRUKAITIS, P. W. M. JACOBS, and J. W. LORIMER. Can. J. Chem. **68**, 1283 (1990).

Coherent deposits of oriented, crystalline $M_xM'_{4-x}V_6O_{16+\delta}$, with M, M' = K, Rb, Cs, or NH_4, $0.0 \leq x \leq 4.0$ and $0.00 \leq \delta \leq 0.13$, have been prepared electrochemically on various conducting substrates from metavanadate solutions containing ammonium or alkali metal cations, singly or in combination. Chemical analysis and X-ray diffraction show that the deposits consist of a continuous series of mixed crystals based on the isomorphic end members $M_4V_6O_{16}$ and $M'_4V_6O_{16}$.

The deposits can be oxidized electrochemically, with removal of M and M' atoms, and the products can be used as cathodes for insertion of lithium, with the largest capacity achieved about 1.0 mol% of total vanadium. Cycling of the electrodes improves capacity, with insertion of lithium reaching 25 mol% of total vanadium. This gain in capacity results from further removal of alkali metal or ammonium ions from the electrode during the oxidation step of the cycling process.

The results extend the range of composition of homogeneous phases in the system $(NH_4)_2O$–K_2O–V_2O_4–V_2O_5.

Key words: alkali metal hexavanadates, electrochemical preparation.

E. ANDRUKAITIS, P. W. M. JACOBS et J. W. LORIMER. Can. J. Chem. **68**, 1283 (1990).

On a préparé des dépôts cohérents qui contiennent des cristaux orientés de $M_xM'_{4-x}V_6O_{16+\delta}$, avec M, M' = K, Rb, Cs ou NH_4, $0{,}0 \leq x \leq 4{,}0$ et $0{,}00 \leq \delta \leq 0{,}13$, par la méthode de voltammétrie cyclique sur des substrats divers et dans des solutions de metavanadates qui contiennent des cations des métaux alcalins ou d'ammonium seuls ou des combinations de tels ions. L'analyse chimique et la diffraction des rayons X ont démontré que les dépôts comprennent une série continue de cristaux mixtes basée sur les membres terminaux $M_4V_6O_{16}$ et $M'_4V_6O_{16}$.

L'oxydation électrochimique mène à une perte d'atomes M, et la réduction suivante rend possible l'insertion de lithium, avec une capacité maximum de 1 mol% du vanadium total. La voltammétrie cyclique a réussi à agrandir la capacité jusqu'à 25 mol% du vanadium total. Cet agrandissement résulte de la perte supplémentaire de M^+ et de NH_4^+ de l'électrode pendant l'étape d'oxydation.

Les résultats prolongent le domaine de composition des phases homogènes dans le système $(NH_4)_2O$–K_2O–V_2O_4–V_2O_5.

Mots clés : hexavanadates de métaux alcalins, préparation électrochimique.

Introduction

Vanadium oxides are useful materials for use as cathodes in lithium batteries (1); lithium ions can be inserted into the oxides during discharge, and removed during charge. Previous work from this laboratory (2–4) has been concerned with preparation of pure vanadium oxides via electrochemical deposition to form coherent deposits which can be used directly as electrodes. This method of preparation has potential advantages over other methods for both fundamental and practical studies: the electrodes are free of the customary, but extraneous, polymeric binders and materials to enhance conductivity. The route of preparation involves electrodeposition of diammonium (2) or tetraammonium hexavanadates (3) or vanadium pentoxide gels (4).

Mixed-valence alkali metal hexavanadates have been made by melting metal oxide and a vanadium oxide at high temperature (5, 6), and the corresponding ammonium compounds have been prepared by controlled precipitation and oxidation in solution (7). Regions of existence have also been established in part for the system $M_2O \cdot VO_2 \cdot V_2O_5$, where M = K or NH_4 (5–7). As an alternate route to synthesis of similar compounds, Goncharenko and Suvorova (8) deposited a mixed-valence vanadium oxide hydrate with approximate formula $3K_2O \cdot 2VO_2 \cdot 5V_2O_5 \cdot 15H_2O$ on a platinum cathode at room temperature. The electrochemical properrties of this material, especially as an insertion cathode for lithium, have not been investigated. The anodic deposition of diammonium hexavanadate near room temperature and its use in insertion electrodes (2) led to a reinvestigation of the work of Goncharenko, and it was found that the cathodic deposits actually consisted of $M_4V_6O_{16}$, where M = NH_4 or K (3). Either the diammonium or tetraammonium hexavanadates, prepared at or near room temperature, can be decomposed by controlled heating to V_2O_5 and to other oxides in which vanadium has mixed oxidation states, but maintain their coherence on the substrate.

In the course of investigation of the cathodic deposits (3), it was found possible to prepare, by electrochemical methods, new mixed-crystal hexavanadates of general formula $M_xM'_{4-x}V_6O_{16}$, with M, M' = K, Rb, Cs, or NH_4. This paper gives detailed chemical and X-ray analyses of several members of the mixed crystalline series, including the new Rb and Cs end members, and also gives some results on their electrochemical properties, especially those relating to ion insertion.

Experimental

The materials and methods of analysis were as described previously (2, 3). Solutions of K, Rb, or Cs metavanadates were prepared by adding stock 1 mol/L RbOH or CsOH to a saturated aqueous solution of NH_4VO_3, followed by boiling to remove ammonia. Solutions of RbOH or CsOH were prepared by passing a solution of RbCl or CsCl through an ion exchange column (in hydroxide form) or from commercial aqueous RbOH or CsOH solutions (50 mass%). Solutions containing both K^+ and NH_4^+ were made by saturating a solution with NH_4VO_3 at 40°C and adding K_2SO_4 to various concentrations of 0.0, 0.05, 0.10, and 0.5 mol/L. Mixtures of various combinations of Cs^+ with NH_4^+, Rb^+ or K^+, and Rb^+ with K^+ were made by combining these vanadate solutions in the desired proportions.

Electrochemical depositions used a cell operated at 40°C with platinum electrodes and one of the above solutions as electrolyte. Both constant current, density 0.1 mA/cm^2, or cyclic voltammetry, at scan rate 50 mV/s between potentials 0.0 and −0.7 V (SCE) for about 2000 cycles, were used to prepare deposits. Potentials and currents

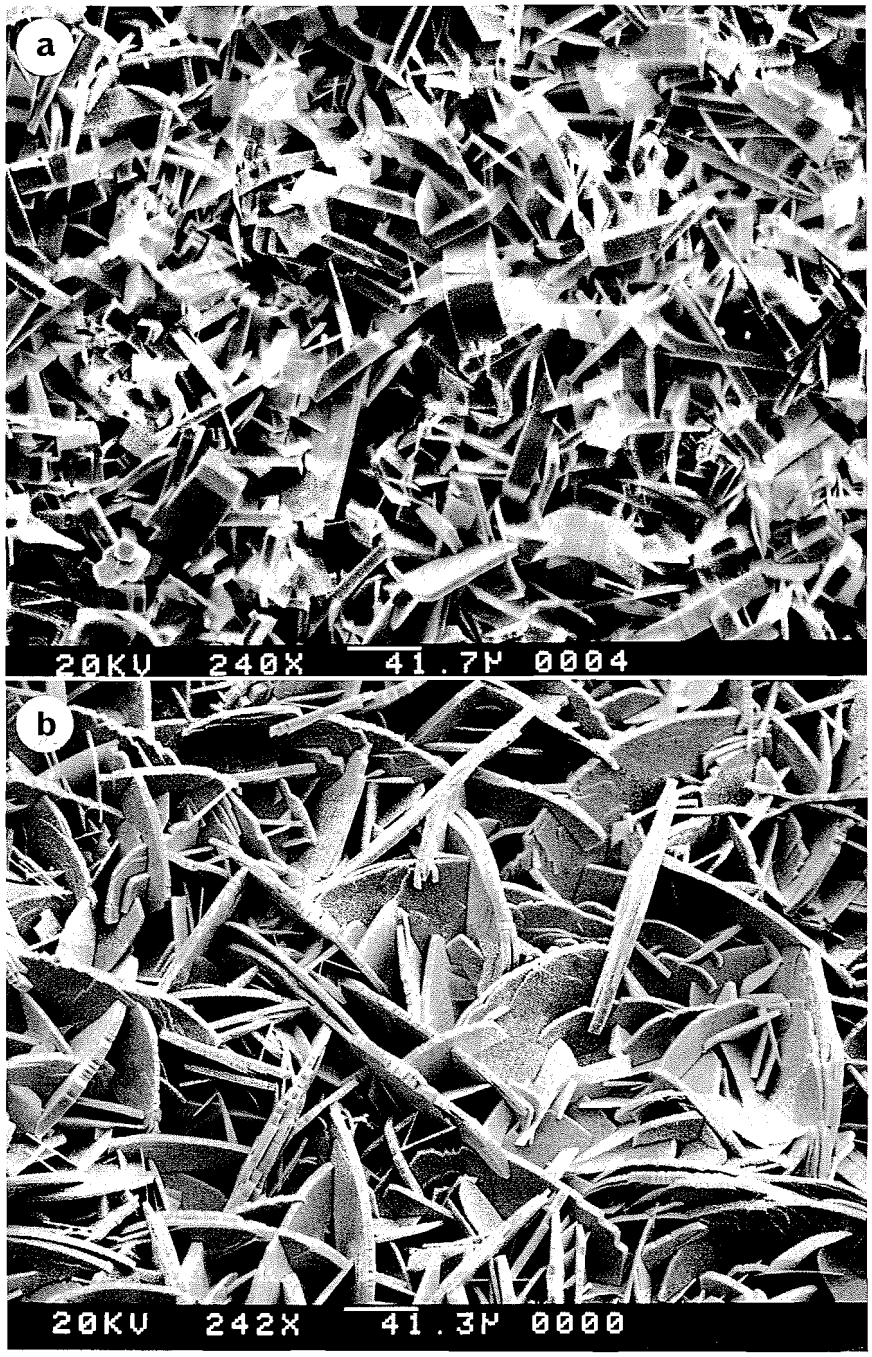

FIG. 1. SEM photographs of cathodic electrodeposits. (*a*) $Rb_4V_6O_{16}$ from $RbVO_3$ solution. Magnification ×240, bar length 41.7 μm. (*b*) $Cs_4V_6O_{16}$ from $CsVO_3$ solution, ×380, bar 26.3 μm.

were applied using a PAR Model 273 potentiostat interfaced to a microcomputer and graphics plotter.

The deposits were analyzed by scanning electron microscopy (SEM), with simultaneous energy-dispersive X-ray analysis (EDX). Direct X-ray diffraction of the deposits on their substrates was performed on a Rigaku rotation anode diffractometer (Bragg-Brentano focussing, curved graphite single crystal monochromator) using Cu $K\alpha_1$ radiation, $\lambda = 0.15405$ nm. Diffraction patterns were analyzed by iterative least squares to obtain refined values of the lattice parameters. Chemical analyses (2, 3) were done for NH_4 by the Kjeldahl method, for NH_4, K, Rb, and Cs by the gravimetric tetraphenylborate method, and for total vanadium, V(IV) and V(V) by redox titration (2). Densities were measured using a Berman density balance, with toluene as the buoyancy liquid, to which a drop of Triton X-100 was added to improve wetting.

All ion insertions were performed at constant current. Open circuit measurements of the potential were made for the insertion of lithium into the deposits and for cycles of oxidation–reduction to study insertion of lithium after an oxidation step; here a solution of 0.1 mol/L $LiClO_4$ in dry propylene carbonate was used, with a Ag–AgCl reference electrode (potential 3.550 V vs. Li^+/Li). The following sequence was controlled by computer. Constant current, density between 0.1 to 1 mA/cm^2, was passed for a measured time. The current was then turned off, the cell was allowed to equilibrate under

stirring for 1 min, then the open circuit potential was measured after stirring was stopped. Current was again passed, and the procedure was repeated until the maximum insertion of lithium had occurred.

Results and discussion

Formation and nature of deposits

(a) Phases containing a single alkali metal or ammonium cation

Details of the formation and morphology of cathodic deposits of the single phases tetraammonium and tetrapotassium hexavanadate, $(NH_4)_4V_6O_{16+\delta}$ and $K_4V_6O_{16+\delta}$, have been described elsewhere (3). The black deposits formed on platinum were usually grown to thicknesses up to 100 μm, with a surface density up to about 10 mg/cm^2. SEM photographs of the deposit made in solutions of KVO_3 and NH_4VO_3 have been given in ref. 3; the deposits made from solutions of $RbVO_3$ and $CsVO_3$ are shown in Figs. 1(*a*) and (*b*). SEM shows the crystals to have a preferred orientation with length about 50 μm and thickness about 5–10 μm. From NH_4VO_3 solution (3), the crystals are uniform in size (about 50 × 5 μm) and shape, with form and orientation the same as for anodic electrodeposits (2) with respect to their faces, but with a higher packing density. From KVO_3 solutions (3), densely-packed deposits are also formed; rosette-shaped crystalline masses, which appear to arise from secondary nucleation and growth at long electrolysis times, overlie a finer-grained deposit. $RbVO_3$ solutions tend to give much thicker crystals, Fig. 1(*a*), which vary in size from about 5 × 50 μm to 50 × 50 μm square, with a range of 5–50 μm in thickness. For $CsVO_3$ solutions, the deposit is shown in Fig. 1(*b*); the crystals are uniform in size (about 100 × 5 μm).

Chemical analyses after air drying are given in Table 1. The tetrarubidium and tetracesium hexavanadates have not been reported previously. While gravimetric analysis cannot distinguish between the alkali metal ions K, Rb, or Cs, EDX confirmed that only one type of alkali metal ion was present in each case. The general formula can therefore be written $M_aV(IV)_bV(V)_cO_d$, where M = K, NH_4, Rb, or Cs. The analytical data for the NH_4, K, and Rb compounds permit calculation of the ratios a/c, b/c, and d/c, and these values (normalized to $b + c = 6$) are given in Table 1. The ratio of total vanadium to metal or ammonium is stoichiometric for $M_4V_6O_{16}$ (*i.e.*, 1.5) within the experimental error of about 0.3%. Charge balance ($2d/c = a/c + 4b/c + 5$) is also satisfied to 0.5% or better. However, the mole ratio V(IV)/V(V) is variable, and is therefore the only source of non-stoichiometry. In the case of the Cs compound, samples of only about 15 mg were available, so the analysis for vanadium is inaccurate. The values in Table 1 for Cs have therefore been found by assuming charge balance. The formula can thus be written $M_4V(IV)_bV(V)_{6-b}(V)O_d$, with $(b + c)/a = 6$ and again normalized to $b + c = 6$, as above, which gives $d = 17 - b/2 = 16 + \delta$. The data in Table 1 and from other experiments give $-0.05 \leq \delta \leq 0.13$, so that departures from ideal stoichiometry are small.

(b) Mixed crystal phases containing two alkali metal or ammonium cations

Only minor differences in packing and crystal morphology are found in deposits made from solutions containing either single alkali metal or ammonium vanadates or their mixtures. Chemical analyses of several deposits formed at varying ratios of K^+ to NH_4^+ are given in Table 2 and of Cs^+ to NH_4^+ in Table 3. Varying the concentration of K^+ in solution produces a continuous series of mixed crystals of formula

[a]Assuming $x = 0$ for deposit from $CsVO_3$ solution for comparison with chemical analysis (see text).

$(NH_4)_xM_{4-x}V_6O_{16+\delta}$, where M = K or Cs, $0.00 \leq \delta \leq 0.13$ and $0.0 \leq x \leq 4.0$. Similar phases $M_xM'_{4-x}V_6O_{16+\delta}$, with $M \neq M' = K$, Rb, Cs, NH_4 can also be made from appropriate combinations of starting solutions. If only NH_4VO_3 is present, tetraammonium hexavanadate is formed, but as the amount of $M' = K^+$, Rb^+, or Cs^+ increases in solution, the value of x decreases continuously until in an $M'VO_3$ solution $x = 0$ is reached, corresponding to $M'_4V_6O_{16}$. Again δ varies over the small range 0.00 to 0.13, with a mean value for all analyses of 0.08. The amounts of K, Rb, and Cs were not determined because of interference of NH_4^+, which is always present to some extent as an unavoidable contaminant; their values $4 - x$ were found by difference from the amount of ammonium (x). However, semi-quantitative estimation of the mole ratio of alkali metal ion to total vanadium can be obtained from EDX. In $(NH_4)_xK_{4-x}V_6O_{16+\delta}$, the absolute error is large (>10%), but the presence of K^+ is confirmed. If the value $x = 0$ is assigned to the deposit from KVO_3 solution (*i.e.*, $K_4V_6O_{16}$), the EDX values show the same trend as the chemical analyses with better than 2% agreement for the three intermediate mixed cation phases analyzed, Table 2. For the two phases $(NH_4)_xCs_{4-x}V_6O_{16+\delta}$ in Table 3, EDX confirms the presence of Cs^+, but the agreement for the mole ratios is poorer; the large atomic weight of Cs makes analysis of NH_4^+ and V less accurate for a given sample size.

In SEM photographs of deposits containing both K and NH_4 (6), a large amount of secondary nucleation and growth was apparent as overlying rosette-shaped crystalline masses. The underlying layer was similar to that for the corresponding phases containing only a single type of ion. For deposits containing both K and Rb, a change in the mole ratio K/Rb from 1/2 to 2, Fig. 2(*a*), causes no perceptible change in overall crystal morphology. However, for deposits containing both K and Cs, Fig. 2(*b*,*c*), a mole ratio K/Cs of 1 produces rod-shaped crystals, while a ratio of 1/2 produces compact stacks of thin sheets.

(c) X-ray analyses of phases containing alkali metal or ammonium cations

X-ray diffraction data are given in Table 4 for the new compounds $Rb_4V_6O_{16}$ and $Cs_4V_6O_{16}$. The assumption that the unit cell is tetragonal, as in the corresponding K and NH_4 compounds, leads to successful indexing by iterative least squares. Of 35 observed lines, there are 19 matches between the Rb and Cs compounds; note the interchange in *d*-spacing between the (312) and (411) reflections. Table 5 summarizes the unit cell dimensions and densities, the latter showing that there are always two formula units in the unit cell. The measured densities tend to be somewhat less than those calculated from the unit cell dimensions because of the difficulty in wetting the very small crystals in the buoyancy liquid.

The ionic radii of Cs^+, Rb^+, NH_4^+, and K^+ are 0.166, 0.149, 0.146, and 0.134 nm, respectively, obtained (for consistency) by subtracting the Pauling radius for Cl^- (0.181 nm) from the interionic distances in alkali metal or ammonium chloride crystals with the NaCl structure (9). Plots of the a lattice dimension and the volume a^2c of the unit cell are linear in the ionic radius, as shown in Fig. 4, but the dimension c (the V—O layers lie in the [001] plane) increases more rapidly at smaller ionic radii. For comparison, the lattice dimensions a, b, c and volume for the monoclinic dimetal and diammonium hexavanadates, $M_2V_6O_{16}$, are given; for these, the V—O layers lie in the [100] plane and the monoclinic angle $\beta = 96.75°$ is constant (10). Thus, as expected, the expansion on adding larger cations is mainly in a direction perpendicular to the interplanar spacing between sheets of V and O atoms for both di- and tetrametalhexavanadates. Also as expected, for a particular insertion cation, the volumes of the unit cells for $M_4V_6O_{16}$ are larger than those for $M_2V_6O_{16}$, the difference increasing slightly as the cation becomes larger.

The vanadate phases containing a mixture of pairs of K, Rb, Cs, and NH_4 have not been described before. Because x varies continuously, only a few X-ray patterns with accompanying chemical analyses will be given. Table 5 gives lattice parameters for phases that have been analyzed by EDX and by chemical methods; the experimental diffraction patterns for $(NH_4)_xK_{4-x}V_6O_{16}$, with $x = 0.000$, 0.744, 2.114, 2.820, and 3.990, are given in Fig. 3. The progression from one pure phase to the other as NH_4^+ is replaced by K^+ is apparent: all major peaks in the one phase can be seen in the other, with minor shifts in their diffraction angles.

Plots of the lattice parameters and volume are almost linear in x in $M_{4-x}K_xV_6O_{16}$, Fig. 5, which is to be expected for completely random mixing of the two different ions on their lattice sites. The width of the diffraction peaks is greatest near $x = 2$, *i.e.*, equal proportions of M and M′ atoms, indicating a diminution of long-range order when two cations are present.

Sodium or lithium metavanadate solutions do not yield electrodeposits containing these two ions. Some reasons for this behaviour have been discussed elsewhere (2).

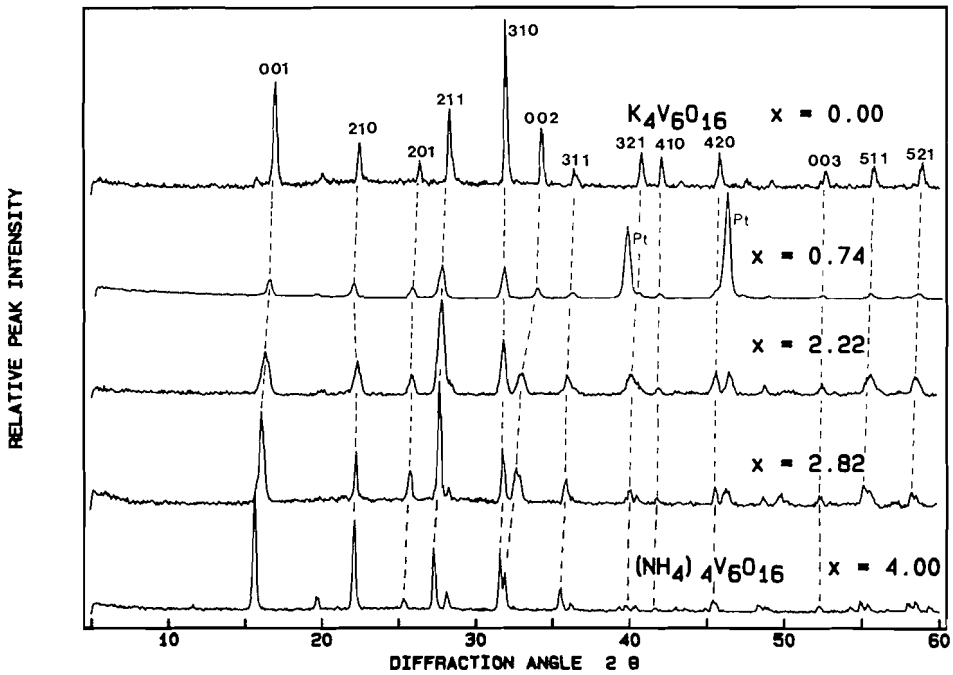

FIG. 3. X-ray diffraction for $(NH_4)_xK_{4-x}V_6O_{16}$, with principal reflections identified. The large shifts with x of the 00 l reflections are apparent. For $x = 0.74$, sample is sufficiently thin to show lines from the Pt substrate. All intensities are relative to the most intense line in each pattern.

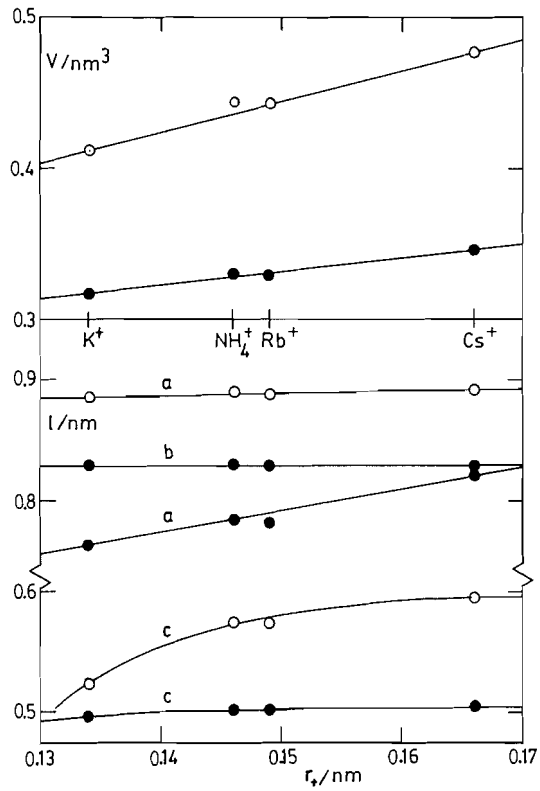

FIG. 4. Dependence of lattice parameter l and volume V of unit cells on ionic radius r_+ in $M_2V_6O_{16}$ (8) (closed circles; parameters a, b, c) and in $M_4V_6O_{16}$ (open circles; a, c).

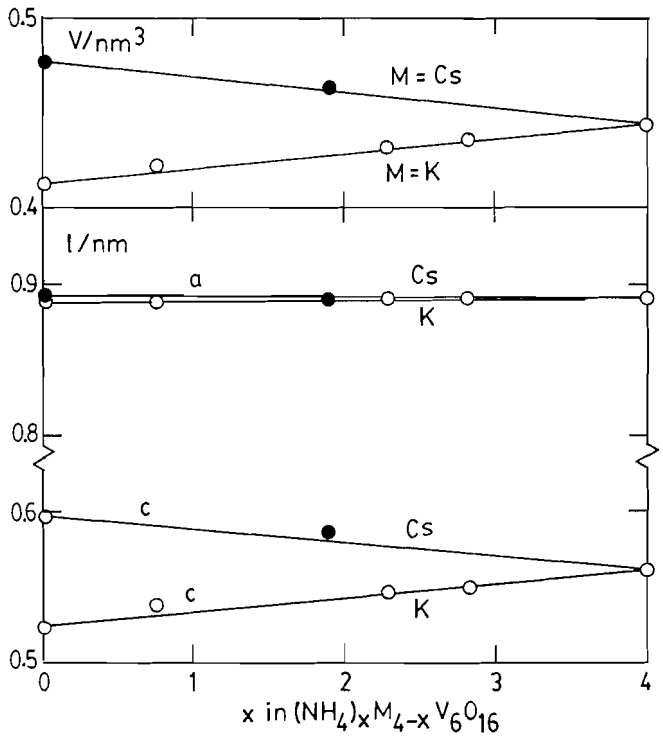

FIG. 5. Dependence of lattice parameter l and volume V of unit cells in $(NH_4)_xM_{4-x}V_6O_{16}$ on x for M = K (open circles), M = Cs (closed circles).

Insertion of alkali cations and protons

Only limited insertion of lithium occurs in unheated deposits of $(NH_4)_4V_6O_{16}$, corresponding to the α phase for lithium vanadium bronzes; the value of x in $Li_x(NH_4)_4V_6O_{16}$ is 0.05 (Fig. 6). Similarly, very little lithium can be inserted into the deposits containing K^+, with $x = 0.085$ for $K_{3.852}V_6O_{16}$ and $x = 0.025$ for $K_4V_6O_{16}$ (Fig. 7). Repetitive electrochemical oxidation and reduction of the deposit leads, as shown by chemical analysis and EDX, to cumulative loss of small amounts of K and NH_4 and a corresponding loss of V(IV). The K or NH_4 can be replaced by Li. After only a few such cycles, plateaus can be seen which indicate phase changes as lithium is inserted (Figs. 6, 7). The analyses show, again, that non-stoichiometry arises from a change in the V(IV)/V(V) ratio to

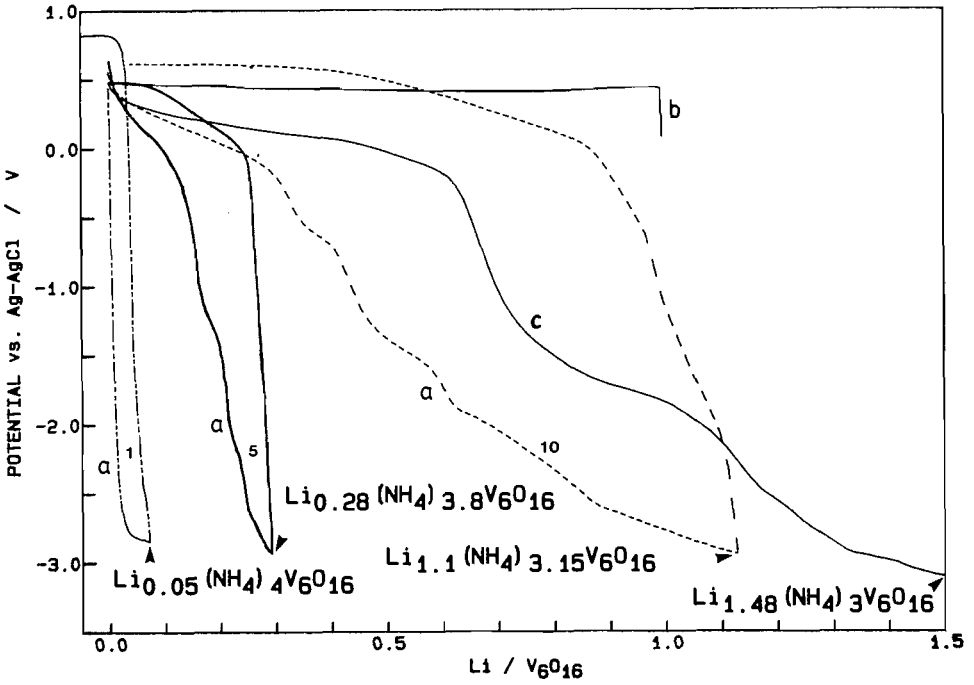

FIG. 6. Open circuit potentials for insertion of lithium into $(NH_4)_4V_6O_{16}$; (*a*) not oxidized; (*b*) after electro-oxidation by 6.7 C of charge; (*c*) subsequent insertion of Li. Numbers are cycles of insertion and removal. Compositions given for end of insertion process (arrows).

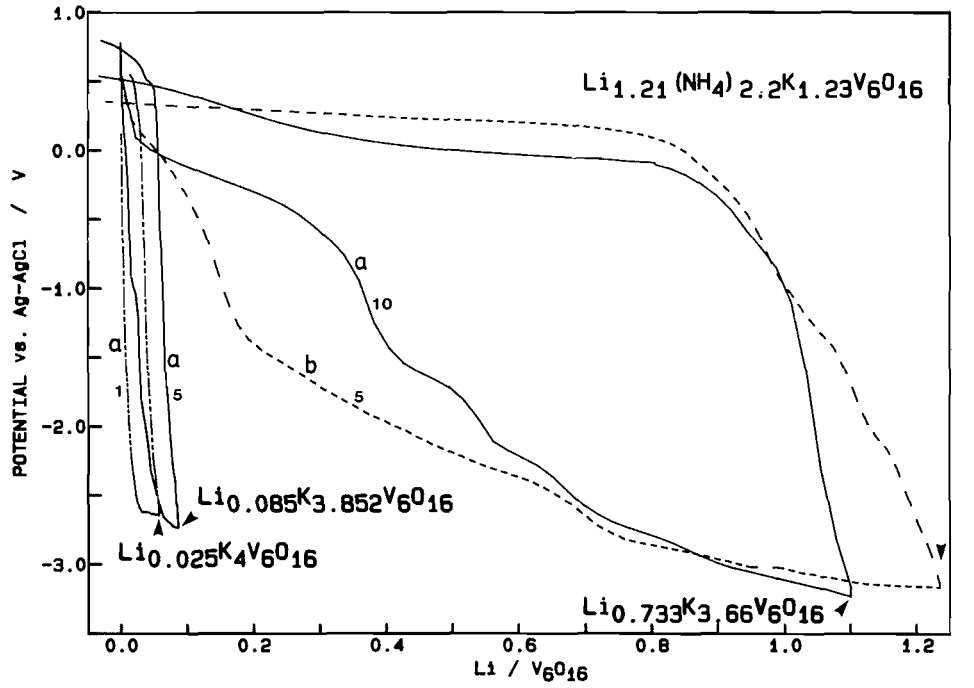

FIG. 7. Open circuit potentials for insertion of lithium into (*a*) $K_4V_6O_{16}$; (*b*) $(NH_4)_{2.67}K_{1.33}V_6O_{16}$. Numbers are cycles of insertion and removal. Compositions given for end of insertion process (arrows).

compensate for removal of M^+, but that the ratio O/V(total) remains unchanged. The formula consistent with the data is thus $(2 - x)M_2O \cdot (2 + x)V_2O_5 \cdot (1 - x)V_2O_4 = M_{4-2x}V_6O_{16}$, and loss of 1 M^+ is accompanied by loss of 1 V^{4+} and gain of a V^{5+}. Subsequent electrochemical insertion of lithium then takes place in two steps, the first involving replacement of the $M^+ = Cs^+$, Rb^+, NH_4^+, or K^+ lost during the previous oxidation, and decrease of the V(V)/V(IV) ratio to its initial value of 2. The second step is accompanied by a large drop in potential and involves insertion of sufficient lithium to reduce the V(V)/V(IV) ratio to less than 2. These processes can be summarized, using salt formulas, as:

$$M_{4-2x}V_6O_{16} \xrightarrow{+\,2xLi^+ + 2xe^-} M_{4-2x}Li_{2x}V(IV)_2V(V)_4O_{16}$$

$$\xrightarrow{+\,2yLi^+ + 2ye^-} M_{4-2x}Li_{2(x+y)}V(IV)_{2(2+y)}V(V)_{2(2-y)}O_{16}$$

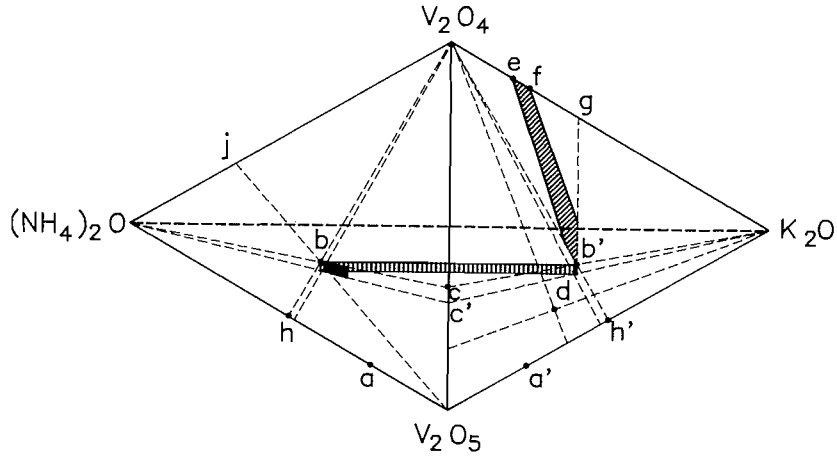

FIG. 8. Compositions of homogeneous phases in the quaternary system $(NH_4)_2O$–V_2O_4–K_2O–V_2O_5. a, a': $(NH_4)_2V_6O_{16}$, $K_2V_6O_{16}$ (6); b, b': $(NH_4)_4V_6O_{16}$, $K_4V_6O_{16}$ (7); c: V_3O_7; d: $3K_2O \cdot 5V_2O_5 \cdot V_2O_4$ (4); e: $K_2V_8O_{17}$; f: $K_2V_6O_{13}$; g: $K_4V_3O_7$; h, h': NH_4VO_3, KVO_3; j: $(NH_4)_2V_3O_7$. Diagonal hatching: results of ref. 5; solid shading: results of ref. 7; vertical hatching: this paper.

The compositions at various stages of cycling are given for a few electrode deposits in Figs. 6 and 7. The $K_2V_3O_8$ electrodes are the most resistant to oxidation–reduction processes, probably because removal of the smaller K^+ from between the V—O layers is more difficult than removal of the larger cations.

In an attempt to remove K^+ or NH_4^+ and insert lithium from other hexavanadate electrodes, similar reduction–oxidation experiments were performed in propylene carbonate solutions containing 0.5 mol/L $LiClO_4$. The results of these experiments are also given in Fig. 7. The initial low amount of insertion of Li^+ is to be expected because of the presence of K^+ or NH_4^+ between the V—O layers. Previously, anodic deposits of $(NH_4)_2V_6O_{16}$ were found to insert Li up to $x = 1.44$ in $Li_x(NH_4)_2V_6O_{16}$. The anodic deposits contain only half as much NH_4^+ as the cathodic deposits, although both yield V_2O_5 on thermal decomposition (2, 3).

Relation to other vanadate phases

Pouchard *et al.* (5) plotted a composition diagram showing the ranges of existence of homogeneous solid phases, named by them Φ-phases, of the form $K_{4-x}V_{6+2x}O_{16+2x\pm k}$, in the ternary system V_2O_5–V_2O_4–K_2O, and prepared by them by synthesis at high temperatures. They interpreted precision density measurements on a series of compounds in terms of the above formula, and claimed that it implied a double non-stoichiometry involving replacement of K^+ with $(VO)_2$ units, starting with the phase $K_4V_6O_{16}$ ($x = 0$), which has the minimum density for the system. Their formula is equivalent to $(2 - x/2)K_2O \cdot (2 - 3x/2 \pm k)V_2O_5 \cdot (1 + 5x/2 \mp k)V_2O_4$, which shows clearly that removal of 1 K^+ is accompanied by a net gain of 5/2 O^{2-} + 5 V^{4+} and a loss of 3 V^{5+}, *i.e.*, a net reduction of vanadium. Bernard *et al.* (7) extended this diagram to include the isomorphous compounds $(NH_4)_xV_6O_{16}$ made by precipitation near room temperature, and which also contained variable proportions of V(IV) and V(V). In their compounds, removal of NH_4^+ is accompanied by an increase in V^{5+}, as in our experiments. Figure 8 contains a further extension of this diagram to include the mixed crystals described in this paper, which are prepared electrochemically and contain both NH_4^+ and K^+. The quaternary system is plotted on a tetrahedral diagram with vertices $(NH_4)_2O$, V_2O_4, K_2O, V_2O_5. The mixed crystals are stoichiometric in the M/V(total) ratio, but not in the V(IV)/V(V) ratio, and thus exhibit a different type of non-stoichiometry than the compounds of Pouchard *et al.* (5), but are similar to those of Bernard *et al.* (7). Their compositions lie on a narrow surface bounded by the line bb' (on the plane $(NH_4)_2O$–c–K_2O) and a corresponding line on the plane $(NH_4)_2O$–c'–K_2O, where $b = (NH_4)_4V_6O_{16}$, $b' = K_4V_6O_{16}$, $c = V_6O_{14} = 2V_2O_5 \cdot V_2O_4$ and $c' = V_6O_{14+d} = (2 + d)V_2O_4$, with $d = 0.13$ the maximum observed value corresponding to non-stoichiometry. All other observed data lie on the two front faces of the tetrahedron. The V(V) hexavanadates a, a' (5), the Φ-phases of Pouchard *et al.* (5), the phases of Bernard *et al.* (7), and the single phase d reported by Goncharenko and Suvorova (8) are also shown, along with a number of characteristic compositions for the system. The phase reported in ref. 8 probably contains ammonium, so that its position is questionable. Several other phases which exist over small composition ranges in the V_2O_5-rich part of the K_2O–V_2O_5–V_2O_4 system (see ref. 6) have not been included in Fig. 6.

Extensive data on the products of electrochemical oxidation described above are not available, and therefore have not been included on the diagram. For hexavanadates containing only one type of M atom, these products are located in the same area as the products of Bernard *et al.* (7) for NH_4^+, and a corresponding area on the K_2O–V_2O_4–V_2O_5 part of the diagram. Products containing two types of M atom are located inside the volume defined by the plane $bb'c$ and the similar plane through point c'.

Conclusions

The compounds $Rb_4V_6O_{16+d}$ and $Cs_4V_6O_{16+d}$ and the mixed crystal phases $M_xM'_{4-x}V_6O_{16+\delta}$, with M, M' = K, Rb, Cs, NH_4, described in this paper, extend the range of known homogeneous solid phases in the general system M_2O–M'_2O–V_2O_5–V_2O_4. The non-stoichiometry of these compounds relative to the ideal stoichiometry of mixed crystals arises from varying ratios of V_2O_4 to V_2O_5, but with constant ratio of oxygen to total vanadium. Non-stoichiometry can be produced during preparation by excess reduction at a cathode, or by subsequent electro-oxidation. The series of tetrametal or tetraammonium hexavanadates, with average oxidation state for vanadium 14/3, is analogous to the series of dimetal hexavanadates with oxidation state 5. The unit cells of the tetragonal tetrametal (or ammonium) hexavanadates are larger than those of the corresponding monoclinic dimetal hexavanadates, but the differences in volume are more than those required to accom-

modate two more ions, indicating that the presence of V(IV) results in an expanded and less distorted lattice with higher symmetry. The tetrametal hexavanadate lattice is sufficiently open to permit limited replacement of one of the ions K^+, Rb^+, Cs^+, or NH_4^+ with Li^+, but at a very slow rate, unless the lattice is subjected to severe cyclic oxidation and reduction.

Self-association of caffeine in aqueous solution: an FT-IR study[1]

MICHAEL FALK, MANUEL GIL,[2] AND NEREA IZA[2]

Atlantic Research Laboratory, National Research Council of Canada, Halifax, N.S., Canada B3H 3Z1

Received November 10, 1989

MICHAEL FALK, MANUEL GIL, and NEREA IZA. Can. J. Chem. **68**, 1293 (1990).

Spectra of caffeine in D_2O solution (0.003 to 0.129 M) were studied by Fourier-transform infrared spectroscopy. Spectral changes in the carbonyl stretching region were interpreted in terms of the self-association equilibria resulting from the stacking of caffeine molecules. Absence of isosbestic points indicated the occurrence of more than two spectroscopically distinct caffeine species. A simple monomer–dimer–polymer model was employed, in which the successive equilibria are governed by two association constants, K_d for the formation of dimers and K_p for the formation of trimers and larger polymers. The value K_d = 158.1 L mol^{-1} was taken from a recent ultraviolet study by Iza *et al.* and the value K_p = 27 L mol^{-1} was derived from the analysis of infrared band profiles sharpened by Fourier self-deconvolution. From these values of K_d and K_p, the weight fractions of monomers, dimers, and polymers were calculated for every caffeine concentration and their individual molar absorptivity spectra were derived. In agreement with the earlier work of Maevsky and Sukhorukov, it was found that stacking association causes shifts of both C=O stretching fundamentals to higher wavenumbers. The monomer-dimer shifts are smaller than the dimer-polymer shifts. Analogous shifts were observed for the stacking self-association of 1,3-dimethyluracil in D_2O. The shifts to higher wavenumbers are probably caused by the diminished hydrogen bonding of water to C=O groups of the stacked bases.

Key words: caffeine, self association, infrared spectroscopy, base stacking.

MICHAEL FALK, MANUEL GIL et NEREA IZA. Can. J. Chem. **68**, 1293 (1990).

Nous avons étudié les spectres de la caféine dans des solutions de D_2O (0.003 à 0.129 M) par la spectroscopie infrarouge à transformée de Fourier. La variation des spectres dans la region de vibration de valence des groupes C=O a été interpreté en termes des équilibres impliquant l'auto-association par empilage de molécules de caféine. L'absence de points isosbestiques a indiqué l'existence d'au moins trois espèces distinctes de caféine. Nous avons employé un modèle monomère–dimère–polymère, dans lequel les équilibres successifs sont controlés par deux constantes d'association, K_d pour la dimérization et K_p pour la formation de trimères et de polymères plus grands. La valeur K_d = 158.1 L mol^{-1} a été prise de l'étude récente faite par Iza et al., tandis que la valeur K_p = 27 L mol^{-1} a été derivée de l'analyse des profiles de bandes infrarouges obtenues par auto-déconvolution. A partir des valeurs de K_d et K_p, nous avons calculé la fraction en poids des monomères, dimères et polymères pour chaque concentration de caféine, ce qui nous a permis de calculer leurs spectres individuels. En accord avec les travaux antérieurs de Maevsky et Sukhorukov, nous avons trouvé que l'association par empilage cause des déplacements de vibrations de valence des groupes C=O vers les hautes fréquences. Les déplacements monomère–dimère sont moins grands que les déplacements dimère–polymère. Nous avons aussi observé des déplacements analogues pour l'auto-association du 1,3-dimethyluracil dans du D_2O. Des tels déplacements vers les hautes fréquences semblent avoir comme origine la diminution des formations de liaisons hydrogène entre l'eau et les groupes C=O des bases empilées.

Mots clés : caféine, auto-association, spectroscopie infrarouge, empilage de bases.

Introduction

Like other purine bases, caffeine molecules in aqueous solution aggregate by plane-to-plane stacking (1–3). This type of molecular self-association is recognized as a key biophysical process, responsible for the stacking of purine–pyrimidine base pairs and hence for the double-helix structure of nucleic acids (4). Stacking interactions are also important in connection with the pharmacological action of caffeine (5) and the interaction between caffeine and nucleic acids (6).

Stacking of purine and pyrimidine bases is accompanied by major changes in the electronic spectrum. Particularly striking is the characteristic diminution of the intensity of absorption near 260 nm (the so-called hypochromic effect), well documented experimentally and understood theoretically (7–10).

In contrast to the electronic spectrum, the effect of base stacking on the vibrational spectrum has not been studied theoretically and was not clearly demonstrated until the recent work of Maevsky and Sukhorukov (11). These workers recorded spectra in the carbonyl stretching region for caffeine and for several other purine and pyrimidine bases in D_2O solution. In spite of the relatively low accuracy of their experimental data, obtained by dispersive spectroscopy, they detected shifts of peak position with solute concentration and succeeded in separating the observed spectra mathematically into contributions from monomeric molecules and stacked molecules.

We believe that vibrational spectra can offer information regarding the molecular details of base-stacking interactions, which is potentially as valuable as that obtained from the electronic spectras. Therefore, we have repeated the work of Maevsky and Sukhorukov using Fourier-transform infrared spectroscopy. The higher quality of FT-IR spectral data permitted us to use Fourier self-deconvolution, which demonstrated directly the occurrence of component bands in the experimental spectra. The data were of sufficient quality to permit an analysis in terms of a three-component model, which yielded the individual spectra of caffeine monomers, dimers, and higher polymers.

Experimental

Caffeine solutions. Solutions of caffeine (from Sigma Chemical company) in D_2O (from MSD Isotopes, Division of Merck Frosst Canada, Inc) were prepared gravimetrically. The lower concentration limit was 0.003 M, imposed by the photometric accuracy of the interferometer system. The upper concentration limit was 0.129 M, imposed by the solubility of caffeine in D_2O. The spectral accuracy increased with caffeine concentration.

Spectroscopy. Absorption spectra were recorded on a Bomem model

[1]NRCC No. 31522.

[2]On leave of absence, February–July 1989, from Departamento de Quimica Fisica, Facultad de Ciencias Quimicas, Universidad Complutense, 28040 Madrid, Spain.

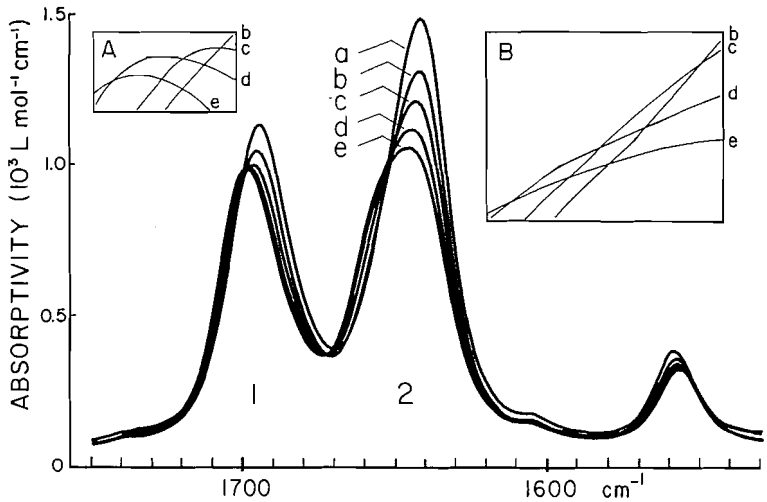

FIG. 1. Apparent molar absorptivity of caffeine in D_2O at the following concentrations: 0.010 M (*a*), 0.025 M (*b*), 0.050 M (*c*), 0.090 M (*d*), and 0.129 M (*e*). Inserts A and B: enlarged regions of intersections near 1699 and 1651 cm^{-1}, respectively.

DA3.02 FT-IR spectrometer, used with a potassium bromide beamsplitter and a mercury cadmium telluride detector, at a resultion of 2 cm^{-1} with 2500 interferograms co-added for each spectrum. The spectral range was 2000–1000 cm^{-1} and a detailed study was made of the carbonyl stretching region, 1750–1530 cm^{-1}. The temperature was 25°C.

Cells and experimental procedure. The spectra were recorded using a sealed liquid cell with CaF_2 windows and an optical path $b = 0.00289$ cm, calculated from the interference fringes recorded with the empty cell. The raw spectra were recorded in the sequence S_1 (cell with pure D_2O), S_2 (cell with one of the caffeine solutions), S_3 (empty beam). The transmittance of the solvent, T_1, and that of the solution, T_2, were obtained by ratioing the raw spectra:

[1a] $$T_1 = S_1/S_3$$

[1b] $$T_2 = S_2/S_3$$

The corresponding absorbances were obtained from $A_1 = \log(1/T_1)$ and $A_2 = \log(1/T_2)$. The absorbance of caffeine, A, at each concentration C (mol/L) was obtained from

[2] $$A = A_2 - A_1$$

and the apparent molar absorptivity of caffeine, ϵ, was determined from

[3] $$\epsilon = A/(b.C)$$

(The term "apparent" is used to indicate that ϵ is a function of C, as Beer's law is not obeyed).

Procedure and Results

Experimental spectra

Figure 1 shows the apparent molar absorptivity spectra for concentrations from 0.010 to 0.129 M, each of them the average of two to four individual measurements. The spectrum of caffeine in the region of the carbonyl stretching fundamentals consists of two major absorption bands: band 1 at 1692 to 1700 cm^{-1}, due to the stretching of the isolated carbonyl, C=O(2), and band 2 at 1641 to 1647 cm^{-1}, due to the stretching of the conjugated carbonyl, C=O(6) (see Fig. 2). A less intense third band, at about 1560 cm^{-1}, is due to C=N and C=C stretching vibrations of the purine ring and will not be discussed further. These vibrational band assignments for caffeine are well established (12). Changes of peak position, peak absorptivity, and halfwidth with concentration are recorded in Table 1. At increasing concentrations of caffeine, bands 1 and 2 shift to higher frequencies and increase their halfwidth. At the same time, their peak intensities are diminished, but in quite a different manner for the two bands. The intensity of band 1 undergoes an initial diminution with increasing caffeine concentration and then becomes concentration-independent. The intensity of band 2, on the other hand, undergoes a larger diminution which continues all the way to the highest concentrations.

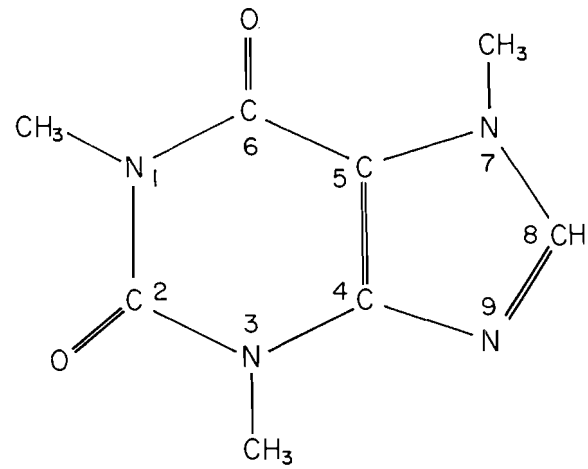

FIG. 2. Molecular structure of caffeine.

In our analysis of the spectra in terms of the self-association equilibria, we have assumed that each absorption band is a composite of contributions from several absorbing molecular species. Band 1 has an approximately Lorentzian shape at all concentrations and reveals its composite nature only indirectly, by the shift of its peak position and by slight broadening with increasing concentration. Band 2 also shifts and broadens, but, in addition, it also reveals the presence of underlying components more directly, by the appearance of a high-wavenumber shoulder at higher concentrations.

Absence of isosbestic points

In choosing the appropriate model to represent the spectral changes due to caffeine association, an important observation is that the apparent absorptivity curves in Fig. 1 intersect over a range of points and not over a single point. This has been

*Numbers following the ± symbol are standard deviations for the observed spectra and estimated standard errors for the calculated spectra.

verified by the examination of the points of intersection of the four most accurate absorptivity curves (corresponding to the four highest concentrations). The points of intersection form a regular pattern (inserts, Fig. 1), unlikely to arise from spectroscopic inaccuracy. The absence of a single isosbestic point indicates that aqueous caffeine solutions contain more than two distinct molecular species in equilibrium. Therefore, the analysis of the spectral data should be based on a model recognizing the existence of at least three molecular species. We have consequently adopted a simple three-species model, described below.

The monomer–dimer–polymer model

Our model, which follows that used by several earlier workers (13, 14) assumes that monomeric caffeine molecules (M) associate in aqueous solution to form dimers (M_2), trimers (M_3), etc., in a series of successive association equilibria:

[4*a*] $M + M = M_2$

[4*b*] $M + M_2 = M_3$

[4*c*] $M + M_3 = M_4, \ldots$ etc.

In general, each polymeric species of caffeine should possess a distinct spectrum, but as the size of the polymer increases, these spectra should converge. In the present model, we have assumed that monomers, dimers, and trimers possess distinct spectra, but that the spectrum of trimers is already the same as that of all the higher polymers. If the concentrations of the molecular species are defined as C_1, C_2, C_3, etc., then mass balance requires

[5] $$C = C_1 + 2C_2 + 3C_3 + 4C_4 + \ldots$$

If we also assume that ratios of activity coefficients are nearly unity, concentrations may be used instead of activities. In general, the association process must be governed by an infinite set of equilibrium association constants,

[6a] $$K_2 = C_2/(C_1.C_1)$$

[6b] $$K_3 = C_3/(C_2.C_1)$$

[6c] $$K_4 = C_4/(C_3.C_1) \ldots \text{ etc.}$$

The numerical values of the constants in the Series K_2, K_3, K_4, ... are likely to converge. We have assumed that the convergence already occurs at the second term, so that the association constants take only two distinct values, which we will call K_d (for the dimerization step) and K_p (for all the following polymerization steps), i.e.:

[7a] $$K_d = K_2$$

[7b] $$K_p = K_3 = K_4 = K_5 = \ldots$$

We will also introduce for the concentrations of caffeine species the symbols $C_m = C_1$, $C_d = C_2$, and $C_p = C_3 + C_4 + C_5 + \ldots$, appropriate to our model. Equations [5]–[7] lead to the following relation between the equilibrium constants, K_d and K_p, and the monomer concentration, C_m:

[8] $$C = C_m + \frac{K_d.C_m^2}{1 - K_p.C_m} + \frac{K_d.C_m^2}{(1 - K_p.C_m)^2}$$

For any values of K_d, K_p, and C, eq. [8] can be solved for C_m by iteration. Once C_m is known, the dimer concentration can be calculated from $C_d = K_d.C_m^2$ (eq. [6*a*]) and the weight fractions of the three components can be obtained as follows:

[9a] $$\text{Monomer fraction: } F_m = C_m/C$$

[9b] $$\text{Dimer fraction: } F_d = 2.C_d/C = 2.K_d.C_m^2/C$$

[9c] $$\text{Polymer fraction: } F_p = N_p.C_p/C = 1 - F_m - F_d$$

(where N_p is the average size of polymers larger than the dimer at caffeine concentration C.)

At low concentrations of caffeine, 0.25×10^{-3} to 1×10^{-3} M, the association equilibrium is mainly between monomers and dimers and the dimerization constant, K_d = 160 L mol^{-1}, has been determined with good accuracy from ultraviolet spectra (15, 16). At higher caffeine concentrations, trimers and higher polymers are also present and the isodesmic model (1, 17, 18) has been used to calculate an apparent single association constant, K, from various physico-chemical measurements (19–24). The values of K calculated under the isodesmic model tend to be in the range 8–12 L mol^{-1} and appear to be concentration-dependent (1). A two-constant monomer–dimer–polymer mod-

el, identical with the one described here, was used by Iza *et al.* (15, 16) to obtain the values $K_d = 158.1$ L mol^{-1} and $K_p = 18.1$ L mol^{-1} from the ultraviolet spectra of caffeine in the concentration range 1×10^{-3} to 5×10^{-3} M. We have adopted their value of K_d derived from ultraviolet data as the best available, but for K_p we have used a value estimated from the results of Fourier deconvolution of the infrared spectra, as explained below.

Fourier self-deconvolution

The object of Fourier self-deconvolution of a spectrum is to reduce the effect of natural broadening of absorption bands and to reveal band structure that could not be originally observed (25). The main problem is that as one increases the resolution by decreasing the halfwidth parameter HW and by increasing the narrowing factor NF, the side-lobes also increase, until they become difficult to distinguish from real features. We have followed the usual criteria for choosing HW and NF to minimize the possibility of error (26), but in addition we have used the following criterion to distinguish real band components from artifacts of deconvolution: The former should exhibit gradual and regular changes as a function of caffeine concentration, and their position and intensity should be relatively insensitive to small changes of deconvolution parameters.

The software for Fourier self-deconvolution was provided by Bomem, Inc. and is based on the method of ref. 25. Using the criteria of ref. 26 and the additional criterion stated above, we were led to the following optimal choice of deconvolution parameters: Lorentzian lineshape function, HW = 35 and NH = 2.8. This choice of parameters resulted in the series of deconvolved spectra shown in Fig. 3. Under these conditions band 1 did not resolve, but band 2 resolved into two components, the high-frequency component H at about 1657 cm^{-1} and a low-frequency component L at about 1640 cm^{-1}. The positions of H and L were constant to within 1 cm^{-1} and their relative intensities varied in a regular manner, that of H increasing and that of L decreasing with increasing caffeine concentration. Peak positions and fractional intensities of H and L are recorded in Table 2. Fractional intensities were calculated respectively as $H/(H + L)$ and $L/(H + L)$, where H and L are the peak heights of the two components, measured above a baseline traced through the peaks of the surrounding small bands, which are artifacts of deconvolution. Peaks H and L have the same bandshape and halfwidth (imposed by the deconvolution procedure), so that peak heights are a fair measure of relative band areas.

It is clear from the concentration behaviour of the deconvolved components H and L, that they represent respectively polymers and monomers, but as no distinct intermediate feature

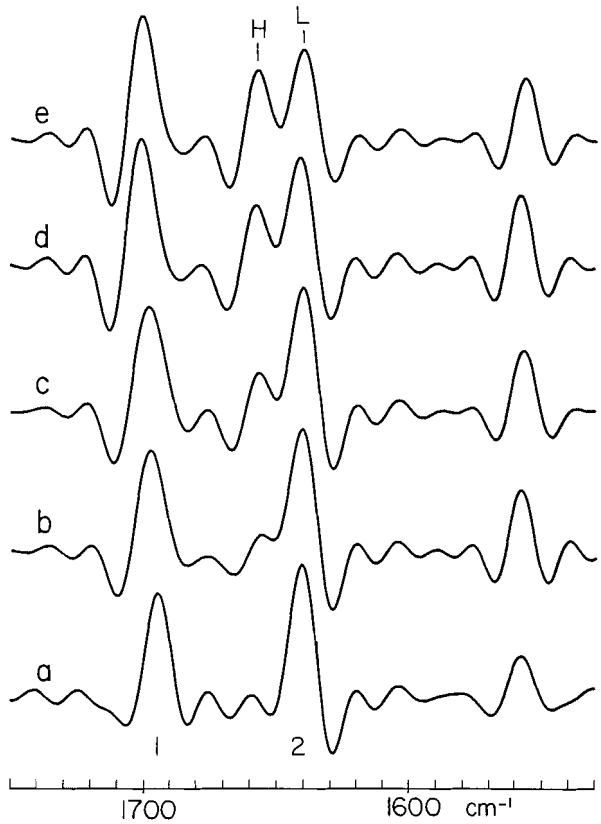

FIG. 3. Spectra obtained by self-deconvolution of the spectra in Fig. 1.

is observed, either H or L must include the dimer contribution. The ambiguity is resolved by the plots, shown in Fig. 4, of the polymer fraction, F_p, versus the caffeine concentration. F_p was calculated from eqs. [8] and [9], assuming $K_d = 158.1$ L mol^{-1} and a wide range of values of K_p. Similarly calculated values of the dimer fraction plus polymer fraction, $F_d + F_p$, are also plotted.

The rectangles in Fig. 4 represent the fractional intensity of H from Table 2. It is immediately apparent that the approximately linear increase of the fractional intensity of H with caffeine concentration is inconsistent with this band representing dimers *and* polymers, but plausible for a band representing only polymers. This finding is in agreement with other indications that the monomer–dimer wavenumber shift is much smaller than the monomer–polymer shift (see below), which makes it likely that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12
For personal use only.

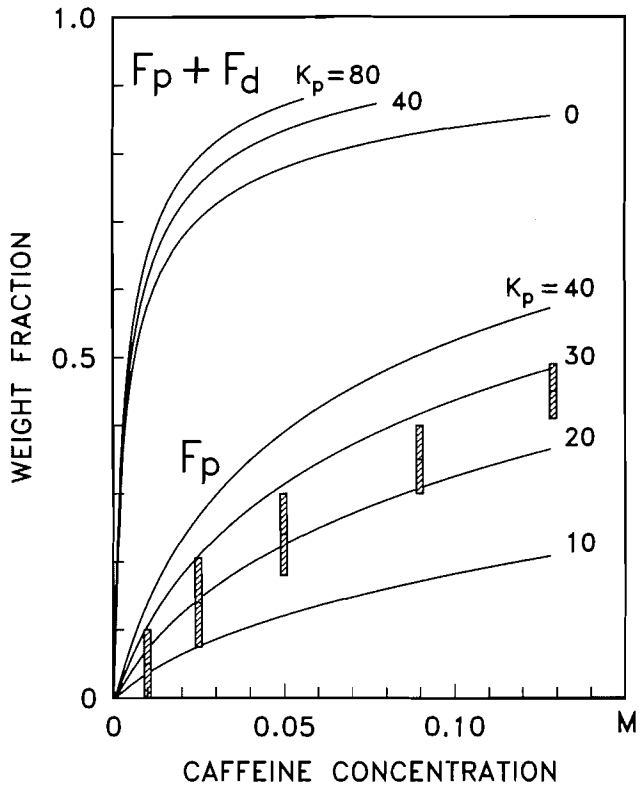

FIG. 4. Lower curves: Polymer weight fraction, F_p, calculated for K_d = 158.1 L mol^{-1} and different values of K_p. Upper curves: Similar plots for the sum of polymer and dimer weight fractions, $F_p + F_d$. Rectangles: Experimental values of the intensity fraction $H/(H + L)$ for the deconvolved components H and L of band 2.

the monomer and dimer absorptions remain unresolved by the deconvolution.

Analysis of the data in Fig. 4 allowed us to bracket the value of K_p as 27 ± 10 L mol^{-1}. This value agrees reasonably well with the value of 18.1 L mol^{-1} derived from ultraviolet spectra (19, 20). In addition, an analysis of the dependence of peak position of bands 1 and 2 with caffeine concentration (Table 1) yielded independent estimates of the polymer fraction, F_p, consistent with K_p = 158 L mol^{-1} and K_p = 27 L mol^{-1}. This gave us confidence in the above values, which we have adopted in subsequent calculations.

Weight fractions

Given the values of K_d and K_p, the weight fractions of the monomers, dimers, and polymers can be calculated by eqs. [8] and [9] for the caffeine concentrations employed in the present study (Table 3). Subject to the correctness of our model, it can be seen that between C = 0.003 M and C = 0.129 M, the dimer contribution changes relatively little, while the contribution of polymers increases and that of monomers decreases. The value of the parameter N_p, the average size of polymers larger than the dimer, varies only from 3.0 to 3.5. Therefore, in our concentration range, the contribution of polymers greater than the trimer is not very great, and the spectrum of "polymers" that we shall compute will be largely based on that of trimers.

Spectra of monomers, dimers, and polymers

The key assumption of the monomer–dimer–polymer model is that at each spectral point the total absorbance of caffeine in water, A, can be expressed as a sum of absorbance contributions from monomers, A_m, dimers, A_d, and "polymers", A_p:

TABLE 3. Molecular composition of caffeine solutions in the concentration range investigated in the present work. Calculated from eq. [9] for K_d = 158.1 L mol^{-1} and K_p = 27 L mol^{-1}

Caffeine concentration fraction C	Average polymer size N_p	Monomer weight fraction F_m	Dimer weight fraction F_d	Polymer weight F_p
0.003	3.052	0.614	0.357	0.029
0.005	3.075	0.521	0.429	0.050
0.010	3.121	0.400	0.505	0.095
0.025	3.216	0.263	0.547	0.190
0.050	3.327	0.183	0.529	0.288
0.090	3.463	0.130	0.483	0.387
0.100	3.492	0.122	0.472	0.406
0.129	3.571	0.104	0.444	0.452

[10] $$A = A_m + A_d + A_p.$$

Dividing eq. [10] by the optical path, b, and the total concentration of caffeine, C, we get:

[11] $$\epsilon = A/(b.C) = A_m/(b.C) + A_d/(b.C) + A_p/(b.C)$$

where ϵ is the apparent absorptivity of caffeine at concentration C, an experimentally derived quantity. Using the following definitions of the molar absorptivities of monomers, dimers, and polymers (per caffeine unit),

[12a] $$\epsilon_m = A_m/(b.C_m)$$

[12b] $$\epsilon_d = A_d/(b.2.C_d)$$

[12c] $$\epsilon_p = A_p/(b.N_p.C_p)$$

and introducing the definitions of weight-fractions, F_m, F_d, and F_p, from eq. [9] we obtain:

[13] $$\epsilon = F_m.\epsilon_m + F_d.\epsilon_d + F_p.\epsilon_p,$$

which holds at every spectral point.

Equation [13] contains one known quantity, ϵ, three parameters, F_m, F_d, F_p, calculable from K_d and K_p, and three unknown quantities, ϵ_m, ϵ_d, ϵ_p, to be calculated. To solve for the three unknowns, we require three equations and these are provided by using eq [13] three times, with experimental ϵ data for three caffeine concentrations. For this purpose we chose the absorptivity data for C = 0.01, 0.05, and 0.09 M, henceforth designated $\epsilon(1)$, $\epsilon(2)$, $\epsilon(3)$, respectively. This leads to a system of three simultaneous equations,

[14a] $$\epsilon(1) = F_m(1).\epsilon_m + F_d(1).\epsilon_d + F_p(1).\epsilon_p$$

[14b] $$\epsilon(2) = F_m(2).\epsilon_m + F_d(2).\epsilon_d + F_p(2).\epsilon_p$$

[14c] $$\epsilon(3) = F_m(3).\epsilon_m + F_d(3).\epsilon_d + F_p(3).\epsilon_p$$

which contains three experimental quantities, $\epsilon(1)$, $\epsilon(2)$, $\epsilon(3)$, three unknown quantities, ϵ_m, ϵ_d, ϵ_p, and nine weight fractions, forming 3 × 3 matrix [**F**]. Designating the observed quantities as the vector $[\epsilon_{obs}]$ and the quantities to be calculated as the vector $[\epsilon_{calc}]$, the above three equations can be expressed in matrix form as

[15] $$[\epsilon_{obs}] = [\mathbf{F}].[\epsilon_{calc}]$$

so that

[16] $$[\epsilon_{calc}] = [\mathbf{F}^{-1}].[\epsilon_{obs}]$$

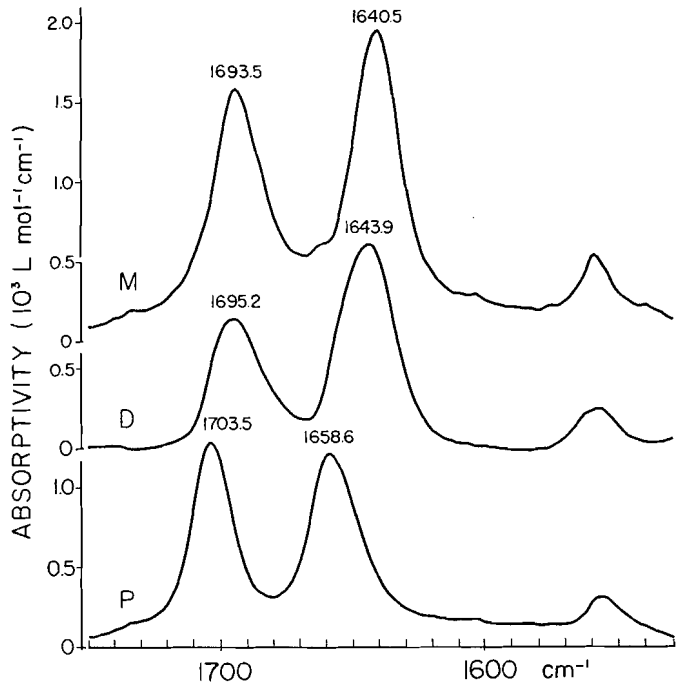

FIG. 5. Molar absorptivity of caffeine monomers (M), dimers (D), and polymers (P), calculated from eq. [16].

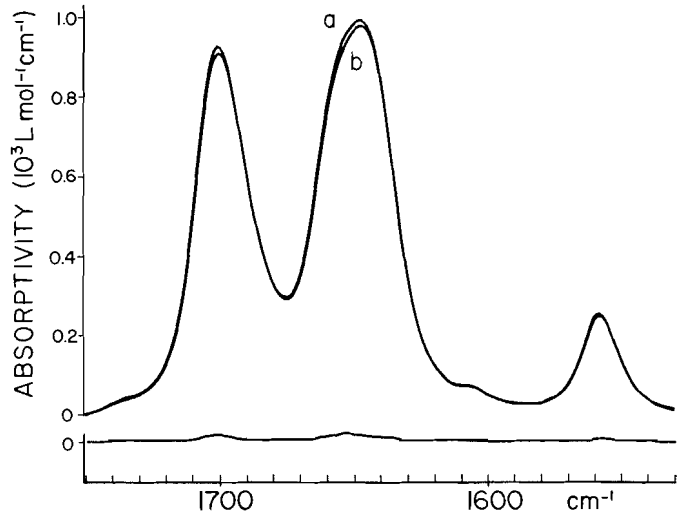

FIG. 6. Comparison of calculated (*a*) and observed (*b*) spectra for caffeine concentration 0.129 mol L^{-1}. Bottom: Difference (*a*) − (*b*).

where the matrix $[\mathbf{F}^{-1}]$ is the inverse of $[\mathbf{F}]$. In our procedure, we have calculated the nine components of the matrix $[\mathbf{F}]$ and inverted it to obtain $[\mathbf{F}^{-1}]$. The nine components of $\mathbf{F}^{-1}$ yielded the nine coefficients used to derive the calculated spectra, at each spectral point, from the observed spectra via eq. [16]. The calculations were performed on a personal computer.

The calculated absorptivity spectra of monomers, dimers and polymers are shown in Fig. 5; their peak positions, peak absorptivities, and halfwidths are recorded in the lower part of Table 1. The standard errors on these spectral parameters were estimated from their variation when K_p is changed from 27 to 18 L mol^{-1}. The derived absorptivity spectra of monomers, dimers, and polymers are physically reasonable, with good band shapes and smaller halfwidths than in the original spectra. Figure 6 shows the agreement between the observed ϵ spectrum for 0.129 M caffeine solution and the corresponding spectrum calculated by eq. [14], (using our values of ϵ_m, ϵ_d, and ϵ_p derived from spectra of 0.01, 0.05, and 0.09 M caffeine solutions). The maximum disagreement is about 2.0%, which is reasonable, as the standard deviation of individual measurements of the experimental spectra is of the order of 1%.

When the numerical parameters of the monomer–dimer–polymer model, K_d and K_p, are varied away from the values 158.1 and 27 L mcl^{-1}, respectively, the quality of the fit remains nearly equally good mathematically, but the derived spectra of monomers, dimers, and polymers display increasing negative regions, larger halfwidths and complex band shapes. We conclude that within the monomer–dimer–polymer model the above values of the association parameters are optimal.

The monomer–dimer wavenumber shifts turned out to be quite small: $+1.7 \pm 1.0$ cm^{-1} and $+3.4 \pm 3$ cm^{-1}, respectively, for bands 1 and 2. As the halfwidths of these bands are 20 to 25 cm^{-1}, it is not surprising that the monomer and dimer contributions remain unresolved, either in the original spectra or upon self-deconvolution.

The monomer–polymer shifts are considerably larger: $+10.2 \pm 0.8$ cm^{-1} and $+18.1 \pm 0.6$ cm^{-1}, respectively, for bands 1 and 2. These spectral differences are large enough to allow two spectral components to be easily resolved by deconvolution (and nearly resolved in the original spectra) for band 2 but not for band 1.

The intensity of the dimer bands is lower by 40–50% than that of the monomer bands. For band 2 the intensity of the polymers is about the same as that of the dimers, but for band 1 it is about half-way between that of the monomers and that of the dimers. The origin of these complex intensity changes due to stacking is not understood at the present.

General discussion

The model. The decomposition of the vibrational spectrum into contributions of three distinct species seems well warranted by the superior photometric and wavenumber accuracy of the FT-IR data. The use of a three-species model leads to more detailed information on the effect of base stacking on the spectrum than could be obtained from a two-component model, such as that used in ref. 11.

Values of the association constants. The association constant for the formation of the dimer, K_d, appears to be considerably larger than that for the formation of the larger aggregates, K_p. This implies a larger negative free energy for the dimerization step. It seems likely that the enthalpy change is the same for each association step, but that the entropy change is greater for the formation of the larger aggregates, because of their greater stiffness. The importance of the entropy contribution in the formation of stacking complexes has been emphasized by Gill *et al.* (2). The diminution of K with the degree of association of purine has been noted by Ts'o (1).

Spectroscopic effects of stacking. We have confirmed the observation of Maevsky and Sukhorukov (11) that base stacking causes shifts of carbonyl stretching fundamentals to higher wavenumbers. The direction and magnitude of the monomer–polymer shifts we have found are in almost exact agreement with those reported in ref. 11. The new and somewhat unexpected finding is that only about 20% of the overall shift due to stacking occurs in the first association step (dimer formation)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12
For personal use only.

and about 80% occurs in the subsequent step (trimer formation). This is an important clue to the origin of the shift, which appears to be due to diminished hydration of the carbonyl groups upon stacking.

The C=O groups of monomeric caffeine molecules in D_2O solution can be assumed to be fully hydrated. In the stacked dimer, steric hindrance may prevent full hydration of C=O groups, but due to the relative flexibility of the dimer structure, the resulting "dehydration" effect is likely to be relatively small. Already with the trimer, however, the structure may be much more rigid so that the extent of carbonyl dehydration may approach that encountered in an infinitely long stack.

Full hydration of carbonyl groups typically brings about a wavenumber lowering of C=O stretching fundamentals by about 20 cm^{-1}. For example, the wavenumber of the C=O stretching fundamental of acetone dissolved in a large excess of D_2O is lowered by 22 cm^{-1} with respect to pure liquid acetone (27) and by 18 cm^{-1} with respect to acetone dissolved in dioxane (28). Thus the magnitude of the monomer–polymer shifts for the carbonyl stretching fundamentals of caffeine is consistent with partial dehydration of C=O groups upon stacking.

Related systems. We have also recorded spectra of 1,3-dimethyluracil in D_2O. Our results show that C=O stretching fundamentals shift to higher wavenumbers with increasing concentration, similarly to what had been reported by Maevsky and Sukhorukov (11). We have not made a detailed analysis of these shifts, but qualitatively the spectral behaviour of dimethyluracil upon stacking resembles that of caffeine. The shifts of carbonyl fundamentals of purine and pyrimidine bases upon stacking in solution appear to be universal and are analogous to those observed in the spectra of nucleic acids and polynucleotides upon helix-coil transition (11).

Identification of some L-numbered *Lycopodium* alkaloids

WILLIAM A. AYER,[1] LOIS M. BROWNE, A. WARREN ELGERSMA, AND PETER P. SINGER
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received February 22, 1990

WILLIAM A. AYER, LOIS M. BROWNE, A. WARREN ELGERSMA, and PETER P. SINGER. Can. J. Chem. **68**, 1300 (1990).

The pioneering research on Lycopodium alkaloids carried out by R. H. F. Manske and L. Marion led to the characterization of a large number of alkaloids. Many of these alkaloids were designated by numbers preceded by an L (e.g., L1, which has since been shown to be dihydrolycopodine). While the identity of many of these alkaloids has now been established, several remain unreported. We have examined samples of alkaloids L15, L16, L17, L18, L22, L24, L25, L26, L28, L29, L31, and L35, obtained from Marion's collection, by GC–MS and GC–IR, and report herein the identity of these alkaloids and alkaloid mixtures. Most of the samples proved to be mixtures of known alkaloids. Acetylannofoline (**5**), a component of alkaloid L17, and 5,15-oxidolycopodane (**9**), a component of alkaloids L28 and L31, are identified for the first time as natural products. A complete listing of the L-numbered alkaloids is provided.

Key words: Lycopodium alkaloids, alkaloids, acetylannofoline, oxidolycopodane.

WILLIAM A. AYER, LOIS M. BROWNE, A. WARREN ELGERSMA et PETER P. SINGER. Can. J. Chem. **68**, 1300 (1990).

Les travaux de pionniers réalisés par R. H. F. Manske et par L. Marion sur les alcaloïdes du Lycopodium ont conduit à la caractérisation d'un grand nombre d'alcaloïdes. Plusieurs de ces alcaloïdes ont été désignés par des chiffres précédés de la lettre L (par example, L1; il a depuis été établi qu'il s'agit de la dihydrolycopodine). Même si l'identité de plusieurs de ces alcaloïdes a maintenant été établie, plusieurs n'ont pas été réétudiés. Faisant appel à la SM/CPG et à l'IR/CPG, on a donc réexaminé des échantillons des alcaloïdes L15, L16, L17, L18, L22, L24, L25, L26, L28, L29, L31 et L35 qui ont été obtenus de la collection de Marion et on rapporte ici l'identité de ces alcaloïdes et de ces mélanges d'alcaloïdes. L'acétylannofoline (**5**), un composant de l'alcaloïde L17, et le 5,15-oxidolycopodane (**9**), un composant des alcaloïdes L28 et L31, n'avaient jamais été identifiés antérieurement comme produits naturels. On fournit une liste complète des alcaloïdes désignés par L et un numéro.

Mots clés : alcaloïdes du Lycopodium, alcaloïdes, acétylannofoline, oxidolycopodane.

[Traduit par la revue]

Introduction

The presence of alkaloids in the genus *Lycopodium* (family Lycopodiaceae) was first noted in 1881. An extensive investigation of these compounds did not commence until the 1940's, and it was not until the late 1950's and early 1960's that the structures of these alkaloids began to be clarified. In Canada the study of the chemistry of the *Lycopodium* alkaloids was pioneered by R. H. F. Manske and L. Marion, who isolated and characterized a large number of alkaloids from various species of the club moss. Since that time the structures of about 100 alkaloids classified into 16 structure types have been established and their chemistry has been the subject of several reviews (1–4). However, the structures of a number of alkaloids originally characterized by Manske and Marion remain unreported (4). In the past few years we have been fortunate to come into possession of many of the original *Lycopodium* samples of Manske and Marion. Several of the alkaloids that were isolated over 40 years ago and whose structure or identity remain to be resolved were found in their sample collection. We have reexamined the samples of alkaloids L15 (*L. tristachyum*), L16 and L17 (*L. obscurum*), L18 (*L. clavatum*), L22, L24, and L25 (*L. lucidulum*), L26 (*L. sabinaefolium*), L28, L29, and L31 (*L. annotinum*), and L35 (*L. densum*) and report herein their identity.

Results and discussion

The alkaloid identification was based on GC/MS (5) examination coupled with GC/IR (6) examination of the sample to rapidly establish the structure. A reference library of MS and IR spectra of known alkaloids was prepared from over 35 authentic samples available to us. In each GC/MS and GC/IR analysis a library search algorithm program was used to search the sample spectrum against the data base to find the best match to a sample spectrum. When the sample was found to be a mixture of alkaloids and sufficient sample was available, the components were separated and the identity of the alkaloids was verified by spectral analysis including high resolution MS and NMR and by comparison with authentic samples.

In the early 1940's Marion and Manske began their chemical investigation of the genus *Lycopodium* with the hypothesis that similarities of alkaloid constituents were indicative of botanical similarities and that this information could form the basis of a chemotaxonomical classification of the genus. Accordingly, several *Lycopodium* species were investigated, their alkaloids isolated, characterized, and designated with an L number. In early 1944 examination of the alkaloids of *L. tristachyum* Pursh led to the isolation of nicotine, lycopodine, L13 (later found to be identical with lycopodine), L14 (subsequently identified as anhydrodihydrolycopodine (7)), and L15. Alkaloid L15 (reported as $C_{20}H_{31}NO_4$) (8) was analyzed by GC/MS and found to comprise one major and one minor component with molecular ions of m/z 247 and 263, respectively. Analysis of the sample by GC/IR confirmed the presence of two components and identified lycopodine (**1**) as the major alkaloid in the mixture. Since the components of the mixture eluted almost simultaneously from the GC column, it was not possible to identify unambiguously the minor alkaloid of L15. Thus alkaloid L15 was separated by chromatography into its components. The least polar compound from the mixture was found to be identical with an authentic sample of lycopodine. The more polar compound was identified as flabelliformine (**2**) (9) by spectral analysis and by comparison with an authentic sample.

The chemical investigation in 1944 of the alkaloids of *L. obscurum* var. *dendroideum* (10) yielded lycopodine, L13, obscurine, and two new alkaloids: L16 and L17. Alkaloid L16 ($C_{16}H_{25}NO$) was reported by these authors to be isomeric with

lycopodine and L13. Analysis of alkaloid L16 by GC/MS revealed that it is a 1:1 mixture of two compounds with molecular ions of m/z 247 and 231. Subsequent examination of L16 by GC/IR confirmed the presence of two alkaloids and identified these as lycopodine (**1**) and anhydrodihydrolycopodine (**3**). Alkaloid L17 was examined by GC/MS and GC/IR and found to be a 2:1 mixture of alkaloids. The minor component was identical with acetylacrifoline (**4**) (11). The major alkaloid was shown to be acetylannofoline (**5**) (12).

Later in 1944 *L. clavatum* L. of North American origin was examined and found to contain nicotine, lycopodine, L19 (subsequently found to be identical with L34 and shown to be clavolonine) (13, 14), and L18 (reported as $C_{11}H_{19}NO$ and isolated as its picrate) (15). Alkaloid L18 was examined by GC/MS and found to contain two alkaloids (ratio 3:1) each with a molecular ion at m/z 278 ($C_{18}H_{34}N_2$, HRMS) and with very similar fragmentation patterns. GC/IR confirmed that alkaloid L18 was a mixture and that each of the component alkaloids contained *N*-methyl functionality (2780 cm^{-1}). Attempted separation of the sample by chromatography was unsuccessful. Analysis of the ^1H NMR spectrum of the mixture revealed the structural similarity of each component. Each component contains two *N*-methyl groups (δ 2.16, 2.28 (major); 2.25, 2.26 (minor)) and a secondary methyl (δ 0.84 (major); 0.92 (minor)). The spectral properties of the minor component are identical with those of *N,N*-dimethylphlegmarine[2] (**6**) (16). We believe that the major component is an isomer of this compound.

[2]We thank Dr. J. C. Braekman for copies of the spectra of this compound.

A total of nine alkaloids were isolated from *L. lucidulum* Michx. by Manske and Marion in 1946 (17). Besides nicotine, lycopodine, and L13, the remaining alkaloids include L20 (18), L21 (later shown to be luciduline) (19), L22 (reported as $C_{16}H_{27}NO$), L23 (subsequently found to be isolycodoline (**7**)) (20), L24 (reported as $C_{16}H_{25}NO$), and L25 (reported as $C_{16}H_{25}NO_2$). We examined alkaloid L22 by GC/MS and GC/IR. Each analysis revealed that it was a mixture of two alkaloids (ratio 3:2), one of which was lycopodine (**1**). The other component of the mixture shows a molecular ion at m/z 263 ($C_{16}H_{25}NO_2$) and was found to closely match isolycopodine (**7**) in the GC/IR library. Separation of the sample by chromatography led to the isolation of lycopodine and isolycopodine, identical in all respects with authentic samples. Analysis of alkaloids L24 and L25 by GC/MS and GC/IR revealed that each was a single compound. Alkaloid L24 was identified as lycopodine (**1**) while alkaloid L25 was found to be identical with isolycopodine (**7**) (L23).

In a continuation of their studies, Manske and Marion reported that *L. sabinaefolium* Willd. contained four alkaloids: nicotine, lycopodine, alkaloid L13, and alkaloid L26 (reported as $C_{15}H_{25}NO$) (21). Alkaloid L26 was analyzed by GC/MS and GC/IR. It was found to be a pure compound with a molecular formula of $C_{16}H_{27}NO$ (HRMS) and its IR spectrum matched perfectly with that of dihydrolycopodine (22) from the library of known alkaloids. Further analysis of the sample was not undertaken due to the small sample size.

In 1947 it was reported that *L. annotinum* var. *acrifolium* contained a different alkaloid spectrum than other varieties of *L. annotinum*. In addition to annotinine and acrifoline (L27), four

TABLE 1. Lycopodium alkaloids: the "L" numbers

L no.	Molecular weight	Molecular formula	Name (reference)
L1	249	$C_{16}H_{27}NO$	Dihydrolycopodine (complanatine, L26) (22)
L2	291	$C_{18}H_{31}NO_2$	*O*-Acetyldihydrolycopodine (1)
L3	291	$C_{18}H_{31}NO_2$	*O*-Acetyldihydrolycopodine (1)
L4	231	$C_{16}H_{25}N$	Anhydrodihydrolycopodine (7)[a]
L5	288	$C_{18}H_{28}N_2O$	Flabellidine (30)
L6			Mixture: α- and β-obscurine (31)
L7	275	$C_{16}H_{21}NO_3$	Annotinine (32)
L8	263	$C_{16}H_{25}NO_2$	Lycodoline (L30) (24)
L9			Mixture: lycopodine and acetyllofoline
L10			Structure not reported and sample unavailable
L11	288	$C_{16}H_{21}NO_3$	Annotine (33)
L12	305	$C_{18}H_{25}NO_3$	*O*-Acetylacrifoline (11)
L13	247	$C_{16}H_{25}NO$	Lycopodine[b]
L14	231	$C_{16}H_{25}N$	Anhydrodihydrolycopodine (7)[a]
L15*			Mixture: lycopodine and flabelliformine (9)
L16*			Mixture: lycopodine and anhydrodihydrolycopodine (7)
L17*			Mixture: acetylannofoline (12) and acetylacrifoline (33)
L18*			Mixture: *N,N*-dimethylphlegmarine and isomer
L19	263	$C_{16}H_{25}NO_2$	(L34), clavolonine (13, 14)
L20	263	$C_{16}H_{25}NO_2$	6α-Hydroxylycopodine (18)
L21	207	$C_{13}H_{21}NO$	Luciduline (19)
L22*			Mixture: lycopodine and isolycodoline (L23) (20)
L23	263	$C_{16}H_{25}NO_2$	Isolycodoline (epilycodoline, pseudoselagine) (20)
L24*	247	$C_{16}H_{25}NO$	Lycopodine
L25*	263	$C_{16}H_{25}NO_2$	Isolycodoline (epilycodoline, pseudoselagine) (20)
L26*	249	$C_{16}H_{27}NO$	Dihydrolycopodine (L1) (22)
L27	261	$C_{16}H_{23}NO_2$	Acrifoline (26, 27)
L28*			Mixture: lycopodine and oxidolycopodane (**1**)
L29*	261	$C_{16}H_{23}NO_2$	Acrifoline (26, 27)[c]
L30	263	$C_{16}H_{25}NO_2$	Lycodoline (L8) (24)
L31*			Mixture: *O*-acetyllofoline and oxidolycopodane (**1**)
L32	262	$C_{16}H_{26}N_2O$	Cernuine (34)
L33	278	$C_{16}H_{26}N_2O_2$	Lycocernuine (34)
L34	263	$C_{16}H_{25}NO_2$	Clavolonine (L19) (13, 14)
L35*			Mixture: lycopodine, flabelliformine (9), and lycodoline (24)

*Alkaloids identified recently in this or other studies in our laboratories.

[a]Identical with L14, identified as anhydrodihydrolycopodine by Marion and Manske (Dr. Marion's laboratory notebook 698, p. 15). This identity was confirmed by GC/MS and GC/IR.

[b]Identified as lycopodine by Marion and Manske (Dr. Marion's laboratory notebook 698, p. 57). Eleven samples of L13 isolated from several *Lycopodium* species were found to be composed mainly of lycopodine by GC/MS and GC/IR.

[c]We thank T. Chua, Alberta Heritage Undergraduate Summer Research Assistant, 1986, for this identification.

previously unreported alkaloids were isolated and designated numbers L28–L31 (23). Subsequent investigations revealed that L30 was identical with L8, which has been shown to possess structure **8** and has been named lycodoline (24). The structures of L28, L29, and L31 have not been reported to date. L28 (reported as $C_{17}H_{27}NO_2$) was analyzed by GC/MS. It was shown to be a mixture of two compounds, each of which has a molecular weight of 247 with similar but not identical mass spectral fragmentation patterns. Analysis by GC/IR confirmed the presence of two components and revealed that one of the components was lycopodine (**1**). The mixture was separated by chromatography over alumina. The less polar component, L28-1, was identified as lycopodine by comparison of its spectral properties with those of an authentic sample. The more polar component, L28-2, was isolated as an optically active, air-sensitive oil. The HRMS confirmed its molecular weight as m/z 247 and established the molecular formula as $C_{16}H_{25}NO$. The base peak at m/z 174 ($M^+ - C_4H_9O$) is consistent with oxygen functionality on the "bridge atoms" (C-8, C-14, C-15). Examination of the IR spectrum of L28-2 revealed the absence of hydroxyl or carbonyl functional groups and thus the oxygen of L28-2 must be present as an ether. This was corroborated by its ^{13}C NMR spectrum, which showed oxygenated carbons at δ 74.3 (CH) and 72.3 (C). The ^1H NMR spectrum of L28-2 revealed a methyl singlet (δ 1.15) and this suggested that L28-2 may have structure **9**. 5,15-Oxidolycopodane (**9**) has not been isolated previously from natural sources although it has been prepared synthetically in a series of reactions from lycopodine (25). To confirm the identity of **9**, we oxidized dihydrolycopodine with lead tetraacetate. The oxidation product obtained was identical in all respects (MS, IR, ^1H and ^{13}C NMR) with L28-2. In earlier studies in these laboratories alkaloid L29 was identified as acrifoline (26, 27) by comparison (TLC, IR, MS) with an authentic sample.

Another unidentified alkaloid isolated from *L. annotinum*, L31 (reported as $C_{20}H_{29}NO_4$), was also found to be a mixture of two components by GC/MS: $C_{16}H_{25}NO$ (m/z 247) and $C_{20}H_{31}NO_4$ (m/z 359). The presence of two components in

TABLE 2. Compounds in the GC/MS and GC/IR library*

Molecular weight	Molecular formula	Name	Molecular weight	Molecular formula	Name
207	$C_{13}H_{21}NO$	Luciduline	274	$C_{17}H_{26}N_2$	Dihydroobscurinine
231	$C_{16}H_{25}N$	Anhydrodihydrolycopodine*	274	$C_{17}H_{26}N_2O$	Sauroxine
242	$C_{16}H_{22}N_2$	Lycodine	275	$C_{16}H_{21}NO_3$	Annotine
242	$C_{15}H_{18}N_2O$	Huperzine A (selagine)	275	$C_{16}H_{21}NO_3$	Annotinine
245	$C_{16}H_{23}NO$	Fawcettidine	278	$C_{16}H_{26}N_2O_2$	Lycocernuine
247	$C_{16}H_{25}NO$	Lycopodine	279	$C_{16}H_{25}NO_3$	Alopecuridine
248	$C_{16}H_{28}N_2$	Dihydrodeoxycernuine	291	$C_{18}H_{29}NO_3$	Clavine
249	$C_{16}H_{27}NO$	Dihydrolycopodine	291	$C_{17}H_{25}NO_3$	Lyconnotine
258	$C_{16}H_{22}N_2O$	Des-*N*-methyl-β-obscurine	303	$C_{18}H_{25}NO_3$	Acetylacrifoline
260	$C_{16}H_{24}N_2O$	Des-*N*-methyl-α-obscurine	305	$C_{18}H_{27}NO_3$	Acetylannofoline*
261	$C_{16}H_{23}NO_2$	Acrifoline	305	$C_{18}H_{27}NO_3$	Dehydro-α-lofoline
261	$C_{16}H_{23}NO_2$	Serratidine	305	$C_{18}H_{27}NO_3$	Dehydrofawcettiine
262	$C_{16}H_{26}N_2O$	Cernuine	305	$C_{18}H_{27}NO_3$	Dihydro-*O*-acetylacrifoline
263	$C_{16}H_{25}NO_2$	Clavolonine	307	$C_{18}H_{29}NO_3$	α-Lofoline
263	$C_{16}H_{25}NO_2$	Flabelliformine	307	$C_{18}H_{29}NO_3$	Fawcettiine (β-lofoline)
263	$C_{16}H_{25}NO_2$	Isolycodoline	307	$C_{18}H_{29}NO_3$	Lycoclavine
263	$C_{16}H_{25}NO_2$	Lucidioline	320	$C_{18}H_{28}N_2O_3$	Acetyllycocernuine*
263	$C_{16}H_{25}NO_2$	Lycodoline	321	$C_{18}H_{28}NO_4$	*N*-Acetylalopecuridine
263	$C_{16}H_{25}NO_2$	Lycofoline	323	$C_{18}H_{29}NO_4$	Lycofawcine
264	$C_{16}H_{28}N_2O$	Dihydrodeoxylycocernuine	333	$C_{19}H_{27}NO_5$	Acetylannopodine
265	$C_{16}H_{27}NO_3$	Dihydroclavolonine	349	$C_{20}H_{31}NO_4$	Acetyllofoline
272	$C_{17}H_{24}N_2$	Isoobscurinine*	349	$C_{20}H_{31}NO_4$	Acetylfawcettiine
272	$C_{17}H_{24}N_2$	Obscurinine	349	$C_{20}H_{31}NO_4$	Acetyllycoclavine
274	$C_{16}H_{26}N_2O$	α-Obscurine	367	$C_{23}H_{29}NO_3$	Alopecurine

*Alkaloids not present in the GC/MS library.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12

L31 was confirmed by GC/IR analysis, which indicated the presence of compound **9** and acetyllofoline. The components were separated by chromatography over alumina to give L31-1, identified as oxidolycopodane (**9**) by comparison with an authentic sample, and L31-2, identified as acetyllofoline (**10**) by comparison with an authentic sample (28).

The last species of *Lycopodium* investigated by these workers was a species indigenous to New Zealand, *L. densum* Labill. This plant, which has a lower than usual total alkaloid content, contains lycopodine, L34 (identified as clavolonine) (12, 13), and alkaloid L35 (reported as $C_{14}H_{21}NO_2$) (29). GC/MS analysis revealed that alkaloid L35 is a mixture of three components (ratio 5:1:2) with molecular ions of m/z 247 ($C_{16}H_{25}NO$), 263 ($C_{16}H_{25}NO_2$), and 263 ($C_{16}H_{25}NO_2$). Examination of the mixture by GC/IR indicated that these alkaloids were lycopodine (**1**), flabelliformine (**2**) (9), and lycodoline (L8) (**8**) (24), respectively. Alkaloid L35 was separated by chromatography. Comparison of the spectral data of each compound isolated with those of authentic samples confirmed their identity.

The Lycopodium alkaloids have proven to be a rich source of chemically interesting compounds. In total there were 35 alkaloids designated with an L number by Manske and Marion. The structures or identity of the majority of these alkaloids were determined previously. Table 1 presents a complete list of all of the L-numbered alkaloids. They are presented in order of increasing L number, and the table includes their molecular weight, molecular formula, name, and reference to their structure determination.

Experimental

Materials and methods

The alkaloids used in compiling the library of spectra are listed in order of increasing molecular weight in Table 2.

GC/MS and GC/IR

Alkaloid samples were prescreened by GC using the conditions described below. Initially retention indices were calculated with respect to lycopodine. Over the time period for this study, however, the retention index of some standards changed enough to warrant this data unacceptable for identification purposes. Analysis of the alkaloid sample by GC/MS was performed on a HP5985 MS system using an HP5840A gas chromatograph with a 18835 splitless capillary inlet. The samples (1–2 μL, c = 1 mg/mL) were injected onto a fused silica capillary column (12 m × 0.32 mm i.d.) coated with an SE-54 equivalent. (Conditions: flow rate 4 mL/min; carrier gas He; temperatures: injector 280°C, detector 300°C, oven 80°C (1 min), 80–300°C at 20°/min, 300°C (5 min).) The gas chromatograph was connected to the mass spectrometer by an open split interface (MS: positive ion mode; ionizing beam 70 eV; temperatures: source 200°C, transfer line 300°C; mass range 35–500; 50 scans/min). The MS of authentic samples of alkaloids were entered into a GC/MS library and test samples identified by computer match when possible (5). Analysis of the alkaloids by GC/IR was performed on a HP5965A IRD system. The samples (1–2 μL, c = 1 mg/mL) were injected onto an Ultra 2 capillary column (conditions: carrier gas He; temperature: injector 200°C, oven 80°C (1 min), 80–290°C at 20°/min, 290°C (5 min)). The gas phase IR spectra of known alkaloids were entered into the GC/IR library. The gas phase IR spectra of the unknown alkaloids were compared to library spectra by computer using a library search algorithm. The spectrum search parameters were developed and the accuracy of the match between the sample spectrum and known spectrum was assessed and a match quality number assigned. Match quality numbers greater than 950 (maximum 1000) were considered to be identical with an authentic sample. The best match was visually inspected for confirmation of identity.

5,15-Oxidolycopodane (9)

Alkaloid L28 (*L. annotinum*) was chromatographed over alumina (eluant: CH_2Cl_2–CH_3OH (2%) gradient) to give two compounds. The less polar constituent was identified as lycopodine by comparison with an authentic sample. The more polar component was identified as

oxidolycopodane (**9**) (25): $[\alpha]_D$ 51° (*c* 0.019, CH_3OH); FTIR: 2964, 2925, 2860, 1442, 1132, 1110 cm^{-1}; ^1H NMR (360 MHz, $CDCl_3$) δ: 3.63 (1H, m, H-5), 3.36 (1H, td, *J* = 3.5, 14.5 Hz, H-1e), 3.19 (1H, td, *J* = 3.5, 12.0 Hz, H-9e), 2.64 (1H, dd, *J* = 2.0, 12.0 Hz, H-14a), 2.53 (1H, dm, *J* = 2.0, 12.5 Hz, H-1a), 2.05 (1H, m, H-4), 1.97 (1H, m, H-2a), 1.89 (2H, m, H-3a, H-6a), 1.78 (1H, m, H-10e), 1.73 (1H, ddd, *J* = 2.5, 2.5, 12.0 Hz, H-11), 1.70 (2H, m), 1.67 (1H, m, H-10), 1.63 (1H, m), 1.60 (1H, m), 1.55 (1H, ddd, *J* = 2.0, 4.0, 12.0 Hz, H-8a), 1.47 (1H, m, H-3e), 1.40 (1H, m), 1.27 (1H, dm, *J* = 13 Hz, H-2a), 1.15 (3H, s, H-16), 1.06 (1H, d, *J* = 12.0 Hz, H-14e); ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 74.3 (d, C-5), 72.3 (s, C-15), 54.3 (s, C-13), 46.8 (d, C-12), 47.4 (t, C-9), 47.0 (t, C-1), 43.9 (t, C-14), 42.1 (t, C-8), 33.9 (d, C-7), 31.4 (d, C-4), 31.0 (t, C-6), 29.2 (q, C-16), 26.5 (t, C-10), 25.6 (t, C-11), 24.6 (t, C-3), 18.6 (t, C-2); HREIMS (probe) 70 eV, *m/z* (rel. int.) calcd. for $C_{16}H_{25}NO$: 247.1936; found: 247.1944; (47), 191 (10), 190 (60), 176 (10), 175 (15), 174 ($C_{12}H_{16}N$, 100), 163 (17), 146 (10).

Transformation of dihydrolycopodine to compound ***9***

$Pb(OA)_4$ (100 mg) and I_2 (catalytic amount) were added to a solution of dihydrolycopodine (26 mg) in CH_2Cl_2 (5 mL). The reaction mixture was irradiated for 16 h using a 75-W light bulb. H_2O (10 mL) was added and the layers separated. The aqueous fraction was extracted several times with CH_2Cl_2, then basified (aq. NH_3) and extracted exhaustively with CH_2Cl_2. The CH_2Cl_2 layer was subjected to acid–base work-up in the usual way. The resultant CH_2Cl_2 fraction was concentrated to give an oil (14.5 mg) that was shown to be a mixture of 3 components (TLC). Chromatography over Al_2O_3 gave dihydrolycopodine (5.4 mg) and 5,15-oxidolycopodane (8.0 mg). The third component decomposed before it was fully characterized.

Acknowledgements

We thank T. Chua (Alberta Heritage Undergraduate Summer Research Assistant) for the earlier identification of alkaloid L29, Dr. J. C. Braekman for spectra of *N*,*N*-dimethylphlegmarine, J. Hoyle for the GC/IR analyses, and the Natural Sciences and Engineering Research Council of Canada for financial support. Special thanks are due to Dr. O. E. Edwards, formerly of the National Research Council, Ottawa, for providing us with Dr. Marion's collection of Lycopodium alkaloids and the lab books describing their isolation, and Prof. D. B. MacLean for providing many reference samples over the years.

α-(Dialkylamino)-α-pyrrolylacetonitriles. A potpourri of useful synthetic transformations[1]

BRIAN L. BRAY[2] AND JOSEPH M. MUCHOWSKI[3]

Syntex Research, Institute of Organic Chemistry, 3401 Hillview Avenue, Palo Alto, CA 94304, U.S.A.

Received February 27, 1990

BRIAN L. BRAY and JOSEPH M. MUCHOWSKI. Can. J. Chem. **68**, 1305 (1990).

α-(Dialkylamino)-α-(pyrrol-2-yl)acetonitriles (**3**) are versatile intermediates that are readily converted into regiochemically pure 2-bromo-6-dialkylamino-1-azafulvenes and 5-bromo-2-acylpyrroles (acyl = CHO, COR). In addition, **3** (R^1 = H), **4** (R^1 = H), and the β-substituted compound **9** are transformed easily and under mild conditions, via the corresponding α-methylthio compounds (e.g., **7***a*), into the methyl pyrrole carboxylates **8***a*, **8***b*, and **10**, respectively.

Key words: α-(dialkylamino)-α-(pyrrol-2-yl)acetonitriles, 5-bromo-2-acylpyrroles, methyl pyrrole carboxylates.

BRIAN L. BRAY et JOSEPH M. MUCHOWSKI. Can. J. Chem. **68**, 1305 (1990).

Les α-(dialkylamino)-α-(pyrrol-2-yl)acétonitriles (**3**) sont des intermédiaires versatiles qui peuvent facilement être transformés en 2-bromo-6-dialkylamino-1-azafulvènes et en 5-bromo-2-acylpyrroles (acyle = CHO, COR) qui sont régiochimiquement purs. De plus, utilisant des conditions douces impliquant un passage par les composés α-méthylthio correspondants (comme le produit **7***a*), on a pu facilement transformer les composés **3** (R^1 = H), **4** (R^1 = H) ainsi que le composé β-substitué (**9**) dans les pyrrolecarboxylates de méthyle respectifs, **8***a*, **8***b* et **10**.

Mots clés : α-(dialkylamino)-α-(pyrrol-2-yl)acétonitriles, 5-bromo-2-acylpyrroles, pyrrolecarboxylates de méthyle.

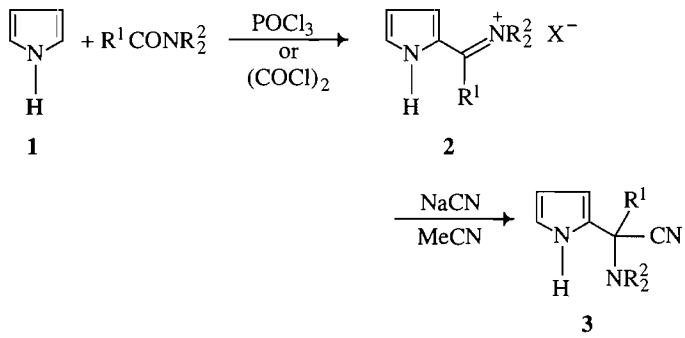
It was recently reported (1) that α-(dimethylamino)-α-pyrrolylacetonitriles were useful precursors of alkyl pyrrolyl ketones and were particularly valuable for the synthesis of 3-alkanoylpyrroles. This publication shows that these "Strecker type" nitriles undergo a number of other synthetically important transformations, some of which are uniquely characteristic of α-(dialkylamino)-α-pyrrolylacetonitriles.

The previously unreported α-dialkylamino nitriles **3***b* and **3***c* (Scheme 1) were synthesized by the reaction of excess sodium cyanide with the iminium salts **2***b* and **2***c*, which in turn were obtained from pyrrole and the appropriate dialkylamide under Vilsmeier–Haack (2) conditions. This process is analogous to that which has been used (1) to synthesize **3***a*.

The bromination of the α-dialkylamino nitriles **3***a–d* with *N*-bromosuccinimide in tetrahydrofuran (THF) occurred rapidly at −78°C to give predominantly, if not exclusively, the corresponding 5-bromo compounds **4***a–d* (Scheme 2). These substances, though isolable, were unstable, and were used without purification in subsequent reactions. For example, hydrolysis of **4***b–d* (see Experimental) gave 5-bromopyrrole-2-carboxaldehyde (**6***b*), 2-benzoyl-5-bromopyrrole (**6***c*), and 2-*n*-nonanoyl-5-bromopyrrole (**6***d*), respectively. These hydrolyses proceeded via intermediate 1-azafulvenes, which, in the case of **5***b* and **5***c* were easily isolable, stable entities. Compound **5***b* has recently been shown to be a valuable precursor of a wide variety of 5-substituted pyrrole-2-carboxaldehydes (3).

The bromination of **3** at C-5 is an important observation because it demonstrates that the α-dialkylaminoacetonitrile group is an activating substituent, even though formally at the aldehyde or ketone level of oxidation. This is of obvious synthetic significance since the direct bromination of 2-acylpyrroles occurs to give a mixture of the 4-bromo (kinetic product) and the 5-bromo compounds in which the latter is usually the minor product (4).

The dianions corresponding to **3***a* and **4***a*, which were generated with lithium diisopropylamide at low temperature,



1 **2** **3**

a, R^1 = H, R^2 = Me
b, R^1 = H, R^2 = *i*-Pr
c, R^1 = Ph, R^2 = Me

SCHEME 1

upon reaction with dimethyl disulfide gave the isolable but unstable methylthio compounds **7***a* and **7***b* (Scheme 3). On brief treatment with aqueous methanolic sodium hydroxide, these compounds gave the methyl esters **8***a* or **8***b* in ca. 60% yield. Methyl pyrrole-3-carboxylate (**10**) was obtained in an analogous manner from the known (1) α-dimethylaminoacetonitrile derivative **9**.

The formation of the above esters presumably takes place by addition of hydroxide ion to the *anti* thioimidate salts (**11**, Scheme 4) and subsequent stereoelectronically controlled fragmentation (5) of the tetrahedral intermediate **12** to the thiol ester **13**. Base-catalysed methanolysis of the thiol ester would provide the observed methyl esters.

The above process constitutes an exceedingly mild means of oxidation of pyrrole carboxaldehydes to the corresponding carboxylic acid esters. It has precedent in the work of Jonczyk *et al.* (6) who have reported that α-methylthio-α-dialkylaminoacetonitriles can be hydrolytically converted into *N*,*N*-dialkylamides or alkyl acetic acids. In addition, Boche and co-workers (7) have shown that *N*,*N*-dialkylamides are generated on acidic hydrolysis of α-trimethylsilyloxy-α-dimethylaminoacetonitriles.

In summary, α-(dialkylamino)-α-pyrrolylacetonitriles are not only useful precursors of alkanoylpyrroles (1) but, in

addition, can be converted with ease into 5-bromo-6-dialkylamino-1-azafulvenes, methyl pyrrolyl carboxylates, and 5-bromo-2-acylpyrroles. Because the α-(dialkylamino)-α-pyrrolylacetonitrile substituent is activating, at least when at C-2 of the pyrrole nucleus, such compounds are likely to find considerable utility in the synthesis of regiochemically pure 5-substituted-2-acylpyrroles.

Experimental

The melting points were determined in a Mel-Temp melting point apparatus and are not corrected. The infrared spectra were measured as dispersions in potassium bromide with a Nicolet 5 PC FT infrared spectrophotometer. The ^{1}H nmr spectra were measured with a Varian EM-360 or a Bruker WM 300 nmr spectrometer in deuteriochloroform and are expressed as parts per million (δ) from internal tetramethylsilane. When exchangeable protons were present, the data are given for deuterium oxide exchanged spectra.

The terms "worked up in the usual manner" or the "usual work-up" signify that the extract was dried over anhydrous magnesium sulfate and evaporated *in vacuo*.

The α-(dimethylamino)-α-pyrrolylacetonitriles **3***a*, **3***d*, and **9** were prepared by the method of Bray and Muchowski (1).

Tetrahydrofuran was distilled from benzophenone ketyl before use.

N,N-*Diisopropylpyrrole-2-formiminium chloride* **2**b

A solution of *N*,*N*-diisopropylformamide (28.9 g, 224 mmol) in anhydrous dichloromethane (50 mL) was added dropwise at 0°C to a stirred solution of oxalyl chloride (28.4 g, 224 mmol) in the same solvent (500 mL) over a 0.25 h period. After 0.33 h at 0°C, a solution of pyrrole (15.0 g, 224 mmol) in dichloromethane (50 mL) was added dropwise with stirring over a 0.25 h period. The reaction mixture was then stirred at room temperature for 0.33 h. The solvent was removed *in vacuo* and the resulting solid was washed with dry acetone and then dried *in vacuo* to provide the hygroscopic salt **2***b* (48 g, 100% yield), which was pure as judged by nmr spectroscopy. Three recrystallizations of the salt from dry ethyl acetate gave an analytical specimen, mp 212–213°C; ir: 3441, 1644 cm^{-1}; nmr (300) δ: 1.52 (d, 6H, J = 6.9 Hz, CH*Me*$_2$), 1.62 (d, 6H, J = 6.6 Hz, CH*Me*$_2$), 4.13 (sept, 1H, J = 6.9 Hz, *CH*Me$_2$), 4.79 (sept, 1H, J = 6.6 Hz, *CH*Me$_2$), 6.61 (m, 1H, $J_{3,4}$ = 4.4 Hz, $J_{4,5}$ ≈ 2.2 Hz, H-4),[4] 7.24 (bd, 1H, H-3), 7.54 (dd, 1H, $J_{4,5}$ ≈ 2.2 Hz, $J_{3,5}$ ≈ 1.0 Hz, H-5), 9.83 (bs, 1H, CH=N). Anal. calcd. for $C_{11}H_{19}ClN_2$: C 61.53, H 8.92, N 13.04; found: C 61.60, H 8.73, N 12.82.

*α-(Diisopropylamino)-α-(pyrrol-2-yl)-acetonitrile (3*b)

A slurry of the nmr pure iminium salt **26** (23 g, 108 mmol) and sodium cyanide (26.5 g, 540 mmol) in acetonitrile (750 mL) was stirred

[4]H-4 is coupled to the iminium proton by ~0.5 Hz.

at 23°C for 12 h. About 75% of the solvent was removed *in vacuo* and then ether (300 mL) was added. The organic solution was washed successively with water and saturated sodium chloride solution and then it was dried over anhydrous potassium carbonate. The solvent was removed *in vacuo* and the solid so obtained was recrystallized from hexane–ether to provide pure **3***b*, mp 113–115°C; ir: 3331, 2234 cm^{-1}; nmr (300) δ: 1.07 (d, 6H, J = 6.67 Hz, CH*Me*$_2$), 1.26 (d, 6H, J = 6.67 Hz, CH*Me*$_2$), 3.23 (sept, 2H, J = 6.67 Hz, *CH*Me$_2$), 4.96 (bs, 1H, CHN),[5] 6.19 (m, 1H, $J_{3,4}$ = 3.57 Hz, $J_{4,5}$ = 2.68 Hz, H-4), 6.37 (m, 1H, $J_{3,4}$ = 3.57 Hz, $J_{3,5}$ = 1.52 H, H-3),[6] 6.77 (m, 1H, $J_{4,5}$ = 2.68 Hz, $J_{3,5}$ = 1.52 Hz, H-5).[6] Anal. calcd. for $C_{12}H_{19}N_3$: C 70.20, H 9.33, N 20.46; found: C 70.31, H 9.41, N 20.70.

*α-(Dimethylamino)-α-phenyl-α-(pyrrol-2-yl)acetonitrile (**3**c)*

A solution of *N*,*N*-dimethylbenzamide (10.0 g, 67 mmol) in phosphorus oxychloride (10.0 g, 67 mmol) was left at room temperature, with protection from moisture, for 2 h. A solution of pyrrole (4.5 g, 67 mmol) in dry dichloromethane (200 mL) was added to the crystalline iminimum salt and the mixture was stirred for 20 h at 23°C. The resulting solution was concentrated *in vacuo* and the iminium salt **2***c* was dissolved in acetonitrile (400 mL). Powdered anhydrous potassium cyanide (65 g, 1.0 mol) was added with stirring. The light yellow colored reaction mixture rapidly became black. Stirring at 23°C was continued for 3.5 h and then the solvent was removed *in vacuo*. The black colored solid was partitioned between ether and water. The ether phase was separated, combined with an ether extract of the aqueous phase, and then it was washed successively with water and saturated salt solution. The ether solution was dried over anhydrous potassium carbonate and the deeply colored solution was stirred with activated charcoal (35 g). Filtration of the mixture and evaporation of the filtrate to dryness *in vacuo* gave **3***c* as a solid (11.7 g, 78%) that was pure as judged by nmr spectroscopy. Recrystallization of this material from hexane–ether gave the analytically pure material (9.1 g, 61% yield), mp 84–85°C; ir: 2234 cm^{-1}; nmr (300) δ: 2.26 (s, 6H, NMe$_2$), 6.07 (dd, 1H, $J_{3,4}$ = 3.52 Hz, $J_{4,5}$ = 2.81 Hz, H-4), 6.39 (dd, 1H, $J_{3,4}$ = 3.52 Hz, $J_{3,5}$ = 1.54 Hz, H-3), 6.70 (dd, 1H, $J_{3,5}$ = 1.54 Hz, $J_{4,5}$ = 2.81 Hz, H-5), 7.31–7.40 (m, 3H, H-3′,4′,5′), 7.69 (2H, H-2′,6′). Anal. calcd. for $C_{14}H_{15}N_3$: C 74.63, H 6.71, N 18.65; found: C 74.70, H 6.87, N 18.40.

*2-Bromo-6-diisopropylamino-1-azafulvene (**5**a)*

N-Bromosuccinimide (2.23 g, 12.5 mmol) was added to a stirred solution of **3***b* (2.57 g, 12.5 mmol) in dry THF (100 mL) at −78°C. The reaction mixture was stirred at this temperature for 4 h, removed from the cooling bath and, when the reaction temperature had reached ambient, the solvent was removed *in vacuo*. The residue (**4***b*) was dissolved in methanol (50 mL), 0.5 M HCl (50 mL) was added, and after 0.33 h at room temperature the deeply colored solution was poured into water. After extraction with ether (discarded) the aqueous phase was adjusted to pH 12 with 10 wt.% sodium hydroxide solution. The azafulvene precipitated out of solution. The mixture was extracted with ether, the extract was washed with saturated salt solution, and then it was dried over sodium sulfate. The solvent was removed *in vacuo* and the residual solid was crystallized from hexane–ether to give pure **5***a* (2.57 g, 80% yield), mp 110–112°C; ir: 1616 cm^{-1}; nmr (300) δ: 1.31 (d, 6H, J = 6.73 Hz, CH*Me*$_2$), 1.35 (d, 6H, J = 6.73 Hz, CH*Me*$_2$), 3.81 (sept, 1H, J = 6.73 Hz, *CH*Me$_2$), 6.31 (d, 1H, $J_{3,4}$ = 3.78 Hz, H-3), 6.40 (sept, 1H, J = 6.73 Hz, *CH*Me$_2$), 6.89 (d, 1H, $J_{3,4}$ = 3.78 Hz, H-4), 7.01 (s, 1H, H-6).[7] Anal. calcd. for $C_{11}H_{17}BrN_2$: C 51.37, H 6.66, N 10.89; found: C 51.45, H 6.71, N 10.85.

*2-Bromo-6-phenyl-6-dimethylamino-1-azafulvene (**5**c)*

N-Bromosuccinimide (1.46 g, 8.22 mmol) was added to a stirred solution of **3***c* (1.85 g, 8.22 mmol) in dry THF (50 mL) at −78°C. The solution was stirred at −78°C for 3 h and then warmed to 23°C over a 0.5 h period. The solvent was removed *in vacuo* and the solid residue (**4***c*) was dissolved in methanol (75 mL). Sodium hydroxide solution (10 wt.%, 20 mL) was added and the reaction mixture was stirred at room temperature for 5 min. The slurry was poured into an HCl (1 M, 150 mL) – ice (100 g) mixture and the resulting solution was extracted with ether. The aqueous phase was adjusted to pH 12 by the addition of 10 wt.% sodium hydroxide solution (the azafulvene precipitates). The mixture was shaken with ether and the azafulvene solution was processed as described for **5***a*. The solid produced in this way (1.96 g, 86%) was pure as judged by its nmr spectrum. Recrystallization from hexane–ether gave the analytically pure material (1.79 g, 78% yield), mp 160–162°C; ir: 1592 cm^{-1}; nmr (300) δ: 2.97 (s, 3H, NMe), 3.99 (s, 3H, NMe), 6.20 (q, 2H, $J_{3,4}$ = 3.95 Hz, H-3,4), 7.32 (m, 2H), 7.47 (m, 3H). Anal. calcd. for $C_{13}H_{13}BrN_2$: C 56.33, H 4.72, N 10.10; found: C 56.04, H 4.78, N 9.87.

*5-Bromopyrrole-2-carboxaldehyde (**6**a)*

A solution of the azafulvene **5***a* (0.100 g, 0.389 mmol) in methanol (20 mL) containing 10 wt.% sodium hydroxide solution (10 mL) was stirred at room temperature for 5 h. The reaction mixture was poured into 1 N HCl (50 mL) and the product was extracted into dichloromethane solution. After the usual work-up the aldehyde **6***a* was obtained as a pure crystalline solid (0.060 g, 88% yield), mp 94–96°C (lit. (8) mp 93–94°C).

*5-Bromo-2-benzoylpyrrole (**6**c)*

A solution of the azafulvene **5***c* (0.40 g, 1.4 mmol) in methanol (25 mL) containing sodium acetate (0.60 g, 7.2 mmol) and water (10 mL) was heated at reflux temperature for 22 h. The cooled solution was poured into saturated sodium chloride solution and the product was extracted into ether. After the usual work-up, the solid that was obtained was recrystallized from hexane – ethyl acetate to give pure **6***c* (0.33 g, 92% yield), mp 137–138°C; ir: 3430, 1632 cm^{-1}; nmr (300) δ: 6.30 (d, 1H, $J_{3,4}$ = 3.99 Hz, H-4), 6.79 (d, 1H, $J_{3,4}$ = 3.99 Hz, H-3), 7.54 (m, 3H), 7.87 (m, 2H). This substance tenaciously retained water of crystallization (exchangeable nmr absorption at δ 1.62). Anal. calcd. for $C_{11}H_8BrNO \cdot 0.1H_2O$: C 52.44, H 3.28, N 5.56; found: C 52.31, H 3.33, N 5.61.

*5-Bromo-2-n-nonanoylpyrrole (**6**d)*

N-Bromosuccinimide (0.33 g, 1.8 mmol) was added, at −78°C, to a stirred solution of the α-aminonitrile **3***d* (0.48 g, 1.8 mmol, purified just prior to use by passing through a column of Act II neutral alumina (25 g/g nitrile) with 4:1 hexane – ethyl acetate) in dry THF (35 mL) and after 2 h at this temperature it was left to reach ambient conditions over a 0.5 h period. The solvent was removed *in vacuo*, the residue (**4***d*) was dissolved in methanol (10 mL), and 10 wt.% sodium hydroxide solution (10 mL) was added. After agitation for 0.5 h, 0.05 M HCl (50 mL) was added and the product was extracted into ether. The crude product was purified by flash chromatography on silica gel using hexane – ethyl acetate (4:1) as the eluting solvent. The solid (0.30 g, 58% yield), which was pure as judged by nmr spectroscopy, was recrystallized from pentane to give analytically pure **6***d*, mp 66–67°C; ir: 3441, 3231, 1645 cm^{-1}; nmr (300) δ: 0.87 (t, 3H, J = 7.0 Hz, Me), 1.26–1.40 (m, 10H, $(CH_2)_5$), 1.70 (m, 2H, CH_2), 2.71 (t, 2H, J = 7.5 Hz, $COCH_2$), 6.23 (d, 1H, $J_{3,4}$ = 3.92 Hz, H-4), 6.80 (d, 1H, $J_{3,4}$ = 3.92 Hz, H-3). Anal. calcd. for $C_{13}H_{20}BrNO$: C 54.55, H 7.04, N 4.89; found: C 54.21, H 7.04, N 4.55.

*Methyl pyrrole-2-carboxylate (**8**a)*

A solution of *n*-butyllithium in hexane (1.6 M, 17.6 mL, 28.1 mmol) was added to a stirred solution of diisopropylamine (2.97 g, 29.3 mmol) in anhydrous THF (100 mL) maintained at −78°C in a nitrogen atmosphere. After 10 min, a solution of the α-dimethylamino nitrile **3***a* (1.82 g, 12.2 mmol) in dry THF (10 mL) was added. Stirring was continued at −78°C for 0.5 h and then at −40°C for a further 0.5 h. A solution of dimethyl disulfide (1.27 g, 13.4 mmol) in dry THF (10 mL) was added at −40°C and stirring was continued at this temperature for 0.25 h and then at 0°C for 0.5 h. The reaction mixture

[5]This proton is coupled to H-3 and H-5 by ca. 0.5–1 Hz.

[6]These coupling constants obtained after decoupling from the absorption at δ 4.96.

[7]The diisopropylamino group is *syn* to the azafulvene nitrogen atom. The one-proton absorptions at 3.81 and 6.40 were assigned to the *i*-Pr CH groups, which were proximal and distal to the azafulvene nitrogen atom. The basis for this assignment will be discussed in a future publication.

was poured into saturated aqueous ammonium chloride solution and the product was extracted with ether. After the usual work-up, a light colored crystalline solid (**7***a*, 2.5 g), which rapidly darkened, was obtained; nmr (60) δ: 1.98 (s, 3H, SMe), 2.35 (s, 6H, NMe_2), 6.03 (t, 1H, H-4), 6.42 (dd, 1H, $J_{3,4}$ = 3.6 Hz, $J_{3,5}$ = 1.4 Hz, H-3), 6.78 (dd, 1H, $J_{3,5}$ = 1.4 Hz, $J_{4,5}$ = 1.9 Hz, H-5). Crude **7***a* from above, in methanol (30 mL) and 5 wt.% sodium hydroxide (15 mL), was stirred at room temperature for 0.33 h and the reaction mixture was poured into water. The pH of the solution was adjusted to 6 with sodium dihydrogen phosphate and the product was extracted into dichloromethane. After the usual work-up, the crude product was taken up in ether (75 mL) and treated with activated charcoal. Removal of the solvent and purification of the solid by flash chromatography on silica gel using hexane – ethyl acetate as the eluting solvent gave pure **8***a* (0.96 g, 63% yield) as a white solid, mp 73–75°C (lit. (9) mp 69–70°C).

*Methyl 5-bromopyrrole-2-carboxylate (**8**b)*

Compound **3***a* was monobrominated in the same manner as described for **4***b* (see preparation of **5***a*). The monobromo compound **4***a* was converted into **8***b* in the same manner as described above for **8***a* except that the reaction with dimethyl disulfide was conducted for 1 h at −78°C and that the elution solvent for the chromatographic purification was hexane – ethyl acetate (7:1). Compound **8***b* (pure by nmr spectroscopy) was obtained as a solid (56% yield), which on recrystallization from hexane had mp 105–106°C (lit. (8) 102–103°C).

*Methyl pyrrole-3-carboxylate (**10**)*

The compound was prepared from **9** in exactly the same manner as described for **8***a* except that chromatographic purification was not required. The ester **10** (pure by nmr spectroscopy) was produced as a solid (74% yield), which on recrystallization from hexane–ether gave a pure sample (60% yield), mp 88–90°C (lit. (10) mp 86–87°C).

Received July 28, 1989[1]

A. C. HOPKINSON, C. F. RODRIQUEZ, and M. H. LIEN. Can. J. Chem. **68**, 1309 (1990).

Structures for trivalent silyl anions $SiH_nF_{(3-n)}^-$ and $SiH_nCl_{(3-n)}^-$, where n takes values from 0 to 3, have been optimized at the HF/6-31++G* level and single point calculations made at the MP2/6-31++G* level (core included). SiH_3^- and ions containing one halogen invert by the vertex mechanism in which the lone-pair has π-symmetry, and the monosubstituted ions have high barriers (SiH_2F^- 45.2 kcal/mol and SiH_2Cl^- 44.0 kcal/mol). Further substitution by halogens results in a change to the edge inversion mechanism involving a T-shaped transition structure with the lone-pair coplanar with the ligands. Barriers (kcal/mol) at the MP2/6-31++G* level including ZPE are lower than for the monosubstituted ions and are $SiHF_2^-$ 35.0, SiF_3^- 35.9, $SiHCl_2^-$ 28.4, and $SiCl_3^-$ 32.5. In $SiLi_3^-$ edge inversion is preferred, but the surface is much flatter and the barrier is low (9.8 kcal/mol). Trivalent silyl radicals $SiH_nF_{(3-n)}$, $SiH_nCl_{(3-n)}$ and $SiF_nCl_{(3-n)}$ (with n having values 0 to 3) have also been examined with the 6-31++G* basis set, with optimization at the UHF level and single point calculations at the UMP2 level. Radicals SiH_3, SiH_2F, SiH_2Cl, and $SiHCl_2$ all invert by the vertex mechanism. Increased halogenation results in a change of mechanism and SiF_3, $SiCl_3$, SiF_2Cl, and $SiFCl_2$ invert by the edge mechanism. For radical $SiHF_2$ the calculated barriers for the two mechanisms are almost identical with the higher level of theory slightly favouring edge inversion.

Key words: inversion mechanism, halogenated silyl radicals and anions.

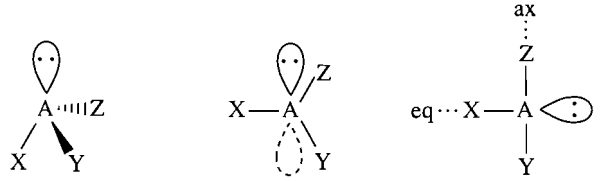
A. C. HOPKINSON, C. F. RODRIQUEZ et M. H. LIEN. Can. J. Chem. **68**, 1309 (1990).

Opérant au niveau HF/6-31++G*, on a optimisé les structures des anions silyles trivalents $SiH_nF_{(3-n)}^-$ et $SiH_nCl_{(3-n)}^-$ dans lesquels n varie de 0 à 3 et on a effectué des calculs ponctuels au niveau MP2/6-31++G* (y compris le noyau). L'inversion des ions SiH_3^- et ceux contenant un halogène se produit par un mécanisme de sommet dans lequel la paire libre possède une symétrie π et les ions monosubstitués possèdent des barrières élevées (SiH_2F^-, 45,2 kcal/mol; SiH_2Cl^-, 44,0 kcal/mol). La substitution par d'autres halogènes provoque un changement vers un mécanisme d'inversion des arêtes impliquant une structure de transition en forme de T et une paire libre coplanaire avec les ligands. Au niveau MP2/6-31++G*, incluant l'EPZ, les barrières (kcal/mole) des ions monosubstitués sont plus faibles, soit 35,0 pour le $SiHF_2^-$, 35,9 pour le SiF_3^-, 28,4 pour le $SiHCl_2^-$ et 32,5 pour le $SiCl_3^-$. Pour le $SiLi_3^-$, le mécanisme d'inversion des arêtes est le préfére; toutefois, la surface est beaucoup plus plane et la barrière est faible (9,8 kcal/mol). On a aussi étudié les radicaux silyles trivalents $SiH_nF_{(3-n)}$, $SiH_nCl_{(3-n)}$ et $SiF_nCl_{(3-n)}$ (dans lesquels n peut prendre des valeurs allant de 0 à 3) à l'aide de l'ensemble de base 6-31++G*, d'une optimisation au niveau UHF et de calculs ponctuels au niveau UMP2. Les radicaux SiH_3, SiH_2F, SiH_2Cl et $SiHCl_2$ s'inversent tous par un mécanisme de sommet. Une augmentation de l'halogénation provoque un changement de mécanisme et les radicaux SiF_3, $SiCl_3$, SiF_2Cl et $SiFCl_2$ s'inversent par un mécanisme d'arête. Pour le radical $SiHF_2$, les barrières calculées pour les deux mécanismes sont pratiquement identiques; le niveau de théorie le plus élevé favorise légèrement l'inversion d'arête.

Mots clés : mécanisme d'inversion, les radicaux et les anions silyles trivalents.

[Traduit par la revue]

Inversion of a pyramidal molecule AX_3 (**1**, X = Y = Z. C_{3v} point group) usually proceeds through a planar trigonal structure **2** which has D_{3h} symmetry. When X = Y = Z = H, the magnitude of the barrier to inversion increases as A becomes more electropositive due to the greater stabilization of the pyramidal structure through HOMO-LUMO interactions (1).



1 **2** **3**

The barriers to inversion of hydrides from the second row, then, are larger than those for analogous molecules from the first row and the silyl anion SiH_3^- has a much larger barrier than the methyl anion CH_3^- (26 kcal/mol (2) compared with 0.5 kcal/mol (3)). Replacing the hydrogens with atoms which are π-donors or σ-acceptors raises the barrier to inversion (2–7) and halogens, which have both these properties, are particularly effective (calculated barriers of CH_2F^- and SiH_2F^- are 24 and 58 kcal/mol, respectively). Increasing the number of halogen substituents should further increase the barrier to inversion by this vertex mechanism, but recent studies (8) have shown that inversion at phosphorus surrounded by electronegative substituents occurs by a different mechanism involving edge-inversion through the T-shaped transition structure, **3**. In **2** the lone-pair on the central atom is destabilised by π-interaction with lone-pairs on the halogens, while in **3** the lone-pair on the central atom is coplanar with the ligands and is available for σ-donation to the halogens.

Previously we reported barriers to inversion for monosubstituted silyl anions (9) and the discovery that increasing halogen substitution in the isolelectronic phosphines results in a change in the inversion mechanism stimulated us to extend our work to polyhalogenated silyl anions.

The parent silyl radical, SiH_3, is pyramidal (10) and the barrier to inversion in radicals R_3Si are sufficiently large that optically active silanes react via the radical with retention of

[1]Revision received March 7, 1990.

configuration (11), i.e., bimolecular reactions of the radicals are faster than unimolecular inversion. Radical $SiCl_3$ is bent further out of plane than $Si(CH_3)_3$ (12) and it appears that, as in the methyl radical (13), halogens will increase the barrier to inversion of silyl radicals. For a radical, where the out-of-plane orbital at the radical centre formally contains only one electron, there is less π-repulsion with lone-pairs on the substituents in transition structure **4** than in the corresponding structure **2** for the anion. Nevertheless, it seemed possible that even in silyl radicals structure **5**, with the unpaired electron in an orbital coplanar with the ligands, might be preferred over structure **4**. We therefore optimized structures **4** and **5** for radicals $SiH_nF_{(3-n)}$, $SiH_nCl_{(3-n)}$, and $SiF_nCl_{(3-n)}$ where n has values from 0 to 3.

4 **5**

Previous *ab initio* molecular orbital studies on polyhalogenated silyl radicals have focussed on calculating heats of formation (14, 15) or inversion (16) via transition structure **5**, but while this work was in progress Garrison and Goddard (17) predicted, on the basis of a theoretical study, that SiF_3 undergoes inversion through the T-shaped transition structure, **5**.

Computational method

Structures **1–5** and the pyramidal radicals were initially optimized at the HF/6-31+G* level of theory (3, 18) and then subsequently at the HF/6-31++G* level, using gradient methods in the Monstergauss (19) and Gaussian 82 (20) programs. The 6-31+G* basis set has diffuse *s*- and *p*-functions on only the silicon and halogen atoms whereas the 6-31++G* basis set also has diffuse *s*-functions on hydrogen. The results from the two basis sets are very similar with the larger basis set giving better energies by as much as 0.8 kcal/mol for SiH_3^-. Structures from the two basis sets are almost identical and only for the axial bonds in anions **3** are there significant differences (by up to 0.03 Å). Only the results from the larger basis set are included in this work.

Single point calculations on the optimised structures at the MP2/6-31++G* level (21) (including inner shells) were used to assess the effect of correlation energy. Total energies at both levels of calculation are given in Table 1. Harmonic frequency calculations on the optimised geometries provided zero-point energies and the number of imaginary frequencies was used to characterize the critical points as being either minima or transition structures.

Results and discussion

(A) Silyl anions

(I) Structural details and barriers to inversion

Pyramidal SiH_3^- has a bond angle of 96.7° (Table 2) and the HOMO, which formally holds the lone-pair on silicon, has a_1 symmetry with the largest contribution coming from the valence shell *s*-functions on silicon. The Si—H bonds then have little *s*-character and a large amount of *p*-character. Distortion of the pyramidal anion to form trigonal transition structure **2** imposes sp^2 character on the silicon atom with the lone-pair in the out-of-plane non-bonding π-orbital. This increase in *s*-character on vertex inversion results in a shortening of the Si—H bond by 0.062 Å and localization of more negative charge on the silicon atom (−0.668 compared with −0.202). By contrast, in transition structure **3** the axial Si—H bonds are longer than in the pyramidal ion by 0.352 Å while the equatorial bond is shorter by 0.032 Å. Also in **3** most of the negative charge resides on the axial hydrogens (−0.736) and the silicon has a large positive charge (+0.663). Transition structures **2** and **3** then have opposite characteristics; **2** concentrates the negative charge on silicon and **3** has a decrease in negative charge on silicon.

[c]Harmonic frequency calculations showed all structures to be minima.
[d]Calculations on $SiLi_3^-$ use the 6-31+G* basis set.

In pyramidal SiX_3^- where X is Cl and F, the bond angles (100.5° and 96.5°, respectively) are also considerably less than tetrahedral. On inversion similar structural changes to those found for SiH_3^- occur. Halogens are powerful σ-withdrawing substituents but they also function as π-donors. In pyramidal $SiCl_3^-$ σ-withdrawal dominates and the population analysis shows the silicon to be positively charged (+0.347). Inversion by the vertex mechanism leads to a dramatic charge reversal with the silicon in **2** (X = Y = Z = Cl) having a charge of −0.406. Much of this charge results from π-donation from Cl to Si, and examination of the gross orbital populations of valence shell functions of π-symmetry (3*p*, 4*p*, *d* and diffuse *p*-function) showed silicon to have a valence shell π-population of 2.3 e and the chlorines to have a population of 1.9 e, i.e., the silicon functions as a π-acceptor although it formally has a lone pair of π-symmetry. On vertex inversion of $SiCl_3^-$ then electron density is taken away from the electronegative chlorine atoms and placed on the electropositive silicon. The change in electron density is more pronounced than in the parent SiH_3^- with the results that halogen substitution increases the barrier to inversion by the vertex mechanism.

The π-crowding in transition structures **2** results in a rapid increase in the barriers to vertex inversion as the number of halide substituents increases. In ions $SiH_nF_{(3-n)}^-$ structures **2** are not always bound despite the inclusion of diffuse functions and we illustrate the effect of increasing numbers of halide substituents by using ions containing chlorine. The barriers to

inversion (in kcal/mol) via structure **2** are SiH_3^-, 26.5; SiH_2Cl^-, 44.0; $SiHCl_2^-$, 67.7; and $SiCl_3^-$, 99.8 (Table 3).

The T-shaped structure **3** has axial bonds which are markedly longer than those of **1**, while the equatorial bonds are slightly shorter. For all ions, except $SiCl_3^-$, the bond angles are smaller than 90°, leaving all the ligands on the opposite side of the central atom from the lone-pair. In ions with both hydrogen and halogen atoms, the halogens always occupy the axial position. For SiH_2F^- both T-shaped ions are transition structures to inversion (one imaginary frequency) but the structure with F in the axial position (C_s symmetry) is 14.6 kcal/mol below the other structure (C_{2v}). For $SiHF_2^-$ the T-shaped isomer with both fluorines axial (C_{2v}) is 14.3 kcal/mol lower in energy than the unsymmetrical isomer (C_s). For $SiHCl_2^-$ the isomer with both chlorines axial is stable while the unsymmetrical isomer loses the axial chlorine to form Cl^- solvated by SiHCl (this combination is 14 kcal/mol higher in energy than the structure with C_{2v} symmetry).

Structure **3** for $SiCl_3^-$ has a larger positive charge on Si than in the pyramidal ion (+0.559 compared with +0.347) and the π-population of the formally vacant $3p$-orbital on silicon is only 0.19, ie., there is less π-donation to silicon than in structure **2**. In structure **3**, then, the negative charge is on the more electronegative element, chlorine. The overall effect of substitution by halogens in **3** then is to transfer negative charge onto the halogens and to stabilize **3** relative to **1**. The effect is largest in the fluorinated ions where the barriers to edge inversion (in kcal/mol) via structure **3** are SiH_3^-, 83.6; SiH_2F^-, 52.9; $SiHF_2^-$, 35.0; and SiF_3^-, 35.9. In both the chloro- and fluoro-substituted ions substitution by the third halogen (in the equatorial position) results in little change.

The unusual bond lengths in the T-shaped transition structures, **3**, can be rationalised qualitatively by analysing the occupied valence shell molecular orbitals of SiH_3^-. The molecular orbitals have major contributions from s, p_y, and p_z-functions on silicon and the s-functions on the hydrogen atoms, with minimal contributions from the d-orbitals on silicon (from a 6-31++G*($5d$) basis set calculation the largest gross orbital population from the d-orbital is 0.07 from the d_{z^2} orbital). The occupied valence shell molecular orbitals, 6, 7, 8, and 9, have symmetries a_1 (eigenvalue −0.47 hartree), b_2 (−0.22 hartree), a_1 (−0.21 hartree), and a_1 (−0.04 hartree). The major atomic orbital contributions to these molecular orbitals are sketched in Fig. 1.

The most tightly bound molecular orbital, **6**, has largest coefficients on the two s-functions describing the $3s$ atomic orbital of silicon, with smaller coefficients on the s-functions of the equatorial hydrogen and almost zero contributions from the axial hydrogens. This molecular orbital then is largely localised on silicon, considerably more tightly bound than the other valence shell orbitals, and essentially represents the $3s$ electrons on silicon which are not significantly involved in the bonding. The major contributors to molecular orbital **7** (b_2 symmetry) are the p_y functions on silicon and the s-functions on the axial hydrogens, providing bonding between silicon and the axial hydrogens. Similarly molecular orbital **8** consists of the p_z-functions on silicon in phase with the s-functions on the equatorial hydrogen and this orbital describes the Si—H equatorial bond. Molecular orbital **9** is the most delocalised with major coefficients on the diffuse functions of the axial hydrogen (−ve) and the diffuse s-function on the silicon (+ve). Smaller contributions from the p_z-functions on silicon and the diffuse s-function on the equatorial hydrogen are also antibonding.

The unusual bond lengths of structure **3** for SiH_3^- are easily understood in terms of these valence shell molecular orbitals. The equatorial Si—H bond is a normal bond resulting mainly from the bonding interaction in molecular orbital **8**, with small offsetting bonding and antibonding contributions from molecular orbitals **6** and **9**. The bonds from silicon to the axial hydrogens result from interactions in molecular orbitals **7** (strongly bonding) and **9** (weakly antibonding) and these two bonds are weak and long. Orbitals **7** and **9** are essentially the

bonding and non-bonding molecular orbitals of a three-centre 4-electron system (22), a system which is known to result in weak bonds. In a three-centre 4-electron system the terminal atoms carry the majority of the electron density and such structures are favoured when the terminal atoms are more electronegative than the central atom. In SiH_3^- the axial hydrogens carry a large negative charge (−0.7357), much larger than that on the equatorial hydrogen (−0.1918). When a halogen replaces a hydrogen atom in structure **3** it occupies the axial position since this is the position in which it can obtain the largest amount of negative charge.

(II) Reactions in competition with inversion

The high inversion barriers in silyl anions could make alternative reactions competitive. Halogens stabilize singlet silylenes (by π-donation) and also support negative charges, and the dissociation reaction in eq. [1] is likely to occur, particularly in solution where X^- can be solvated.

[1] $SiH_nX^-_{(3-n)} \rightarrow SiH_nX_{(2-n)} + X^-$

In the gas phase negative ions lose electrons at relatively low energies ([2]).

[2] $SiH_nX^-_{(3-n)} \rightarrow SiH_nX_{(3-n)} + e$

The Si—H bond is considerably weaker than the Si—halogen bonds and homolysis of this bond yields radical anion $SiH_{(n-1)}X^-_{(3-n)}$ plus hydrogen atom

[3] $SiH_nX^-_{(3-n)} \dashrightarrow SiH_{(n-1)}X^-_{(3-n)} + H$

Energies for reactions [1] to [3] at the MP2/6-31++G* level are included in Table 3.

In eq. [1] all species are closed shell and molecular orbital calculations should give reliable estimates. Here it should be noted that attempts to optimize structure **3** for SiH_2Cl^- and also for $SiHCl_2^-$ (with one chlorine in the equatorial position) led to silylenes and the chloride anion. In reactions [2] and [3] the reactant anions have one more electron pair than the products and inclusion of correlation energy is important to describe

these processes. The calculated electron affinities of radicals $SiH_nX_{(3-n)}$ and the Si—H dissociation energies of the anions then are expected to be underestimated. Some estimate of the errors incurred here are provided by comparison of the calculated electron affinity of SiH_2 (19.3 kcal/mol) with the experimental value of 33.2 kcal/mol (23). Indeed the electron affinity of SiH_2 cannot be calculated satisfactorily even at much higher levels of theory (24).

From the data in Table 3 only one ion, SiH_2Cl^-, has a dissociation energy lower than the inversion barrier and the energy difference is small. For all other anions inversion occurs at considerably lower energy than dissociation. The calculated energies for electron loss from anions SiH_3^-, $SiHF_2^-$, and SiH_2Cl^- are all lower than the calculated barriers to inversion, but it must be remembered that the electron affinities are all underestimated due to errors inherent in the method. It therefore seems likely that both SiH_3^- and $SiHF_2^-$ will invert at lower energies than that required for electron loss. On a more definitive note, anions SiF_3^-, $SiHCl_2^-$, and $SiCl_3^-$ all undergo inversion at energies lower than those calculated for reactions [1] and [2]. For each of these anions the transition structure for inversion has the T-shaped structure **3**. The barrier to inversion in SiF_3^- of 35.9 kcal/mol compares with barriers of 53.8 and 64.6 kcal/mol for PF_3 and SF_3^+, i.e., as the central atom becomes more electropositive the barrier to edge inversion decreases. A similar trend was found for inversion by the vertex mechanism (1).

(III) $SiLi_3^-$

Electropositive substituents are stabilising in carbanions (3, 25) and failure to include polarisation functions in the basis set leads to an overemphasis on π-stabilization and an overestimation of the stabilization energy (3). At the 4-31+G level both H_2CBeH^- and $H_2CBH_2^-$ are planar, but singlet CH_2Li^- is pyramidal with a low barrier to inversion (3.2 kcal/mol) (3). By contrast preliminary calculations on $SiLi_3^-$ show the pyramidal structure (C_{3v}) to be at a minimum and this anion has the smallest XSiX bond angle (81.8°) of all the silyl anions. These small angles are consistent with a recent study on $SiLi_4$ where the global minimum on a rather flat surface was found to have bond angles of ~84° and to have C_{2v} symmetry rather than the expected tetrahedral structure (26). Our study of lithiated silyl anions is incomplete but the initial calculations at the 6-31+G* level show the inversion barrier of $SiLi_3^-$ to be low, 9.8 kcal/mol through the T-shaped structure, **3**, and 15.9 kcal/mol through **2**.

(B) Silyl radicals

(I) Structural details

The pyramidal silyl radicals all have bond angles close to the ideal tetrahedral angle. The parent SiH_3 is slightly flatter than the ideal angle but halogen substitution leads to an increase in the pyramidality and in SiF_3 the bond angle is 107.8° (Table 4). For $SiH_nF_{(3-n)}$ the bond lengths are similar to those reported previously (14) and show the same trend, a shortening of both

[a]Barriers in kcal/mol, include correction for zero-point energy.

Si—H and Si—X bonds as the number of halogens attached to silicon increases. When all three ligands are identical, structure **4** was assumed to have bond angles of 120°, but in the unsymmetrically substituted planar π-radicals the bond angles involving the more electronegative substituents are smaller than 120°, e.g. in SiH_2X, $\angle HSiX < \angle HSiH$; in $SiHX_2$, $\angle XSiX < \angle XSiH$; in $SiFCl_2$, $\angle ClSiF < \angle ClSiCl$; and in SiF_2Cl, $\angle FSiF < \angle ClSiF$. The bond lengths in **4** are slightly shorter than in the pyramidal radicals, consistent with a change to higher *s*-character in the bonding in planar radicals.

In structure **5** the ax—Si—eq angle is slightly larger than 90° and increases with the size of the atoms to a maximum value of 100.6° in $SiCl_3$. The axial bonds are markedly longer than in the pyramidal radicals (by ~0.03 Å for Si—F, ~0.1 Å for Si—H and ~0.085 Å for Si—Cl) while the equatorial bonds are almost unchanged. These are similar but less pronounced structural changes than those found in the T-shaped transition structures for the silyl anions and also for PF_3 (8*b*). In the T-shaped radicals SiX_3 the HOMO has a_1 symmetry and, as in the anions, is antibonding between silicon and each of the ligands. The largest contributors to this orbital are the diffuse and valence *s*-functions on Si and functions on the axial atoms (*s* for X = H, the *p*-functions directed toward silicon for X = F and Cl). This orbital, then, is largely responsible for the longer Si-axial bond lengths. Addition of another electron to this molecular orbital forms the anions SiH_3^-, SiF_3^-, and $SiCl_3^-$ and results in further elongation of the axial bond lengths (to 1.886, 1.747, and 2.506 Å, respectively, compared to 1.600, 1.609, and 2.149 Å in the radicals). By comparison the equatorial bonds are only slightly longer in the anions than in the radicals (for X = H, 1.502 Å compared with 1.492 Å; for X = Cl, 2.116 Å compared with 2.039 Å; and for X = F, 1.656 Å compared with 1.583 Å).

In T-shaped silyl radicals containing both halogens and hydrogen atoms the halogens always occupy the axial position. For SiH_2F structure **5** with C_s symmetry is better than the C_{2v} structure by 7.6 kcal/mol; for $SiHF_2$ the isomer with both fluorines in the axial position (C_{2v} symmetry) is better than the equatorially substituted isomer (C_s) by 3.0 kcal/mol; for SiH_2Cl the C_s structure is better than the C_{2v} one by 1.3 kcal/mol; and for $SiHCl_2$ the C_{2v} structure is the better one by 7.2 kcal/mol. For radicals containing both halogens, structures with fluorine in the equatorial position are the best. For SiF_2Cl and $SiFCl_2$ the differences are 2.5 and 2.6 kcal/mol, respectively.

(II) Barriers to inversion in radicals

For SiH_3, **4** is a transition structure, only 4.9 kcal/mol above the pyramidal structure. The T-shaped structure **5** is at a high minimum, 66.3 kcal/mol above **5**, and is clearly of no importance to the inversion process.

The barriers to inversion for silyl radicals in Table 5 show that, as for both silyl anions (9) and phosphines $PH_nF_{(3-n)}$ (7, 8*a*), inclusion of halogens greatly increases the barrier to inversion. Fluorine is more effective than chlorine and, assuming inversion occurs through transition structure **4**, each additional fluorine atom increases the barrier by approximately twice the increase resulting from addition of the previous fluorine, i.e. SiH_2F has a barrier 9.9 kcal/mol higher than SiH_3, $SiHF_2$ 20.6 kcal/mol higher than SiH_2F, and SiF_3 39.1 kcal/mol higher than $SiHF_2$. As with SiH_3, the π-radicals SiF_3 and $SiCl_3$ are both at high minima, 74.5 and 38.5 kcal/mol, respectively, above the pyramidal structures. However, for both $SiCl_3$ and SiF_3 the D_{3h} structures, in which the unpaired electron is in the σ-system (in an orbital of a_1 symmetry), are

lower in energy than the π-radicals. These latter structures have more than one imaginary frequency, i.e. they are not transition structures to inversion, and relaxing the requirement that all bond angles are 120° leads to collapse into the lower energy T-shaped structures **5**.

For all T-shaped structures **5**, with the exception of the parent SiH_3, there is one imaginary vibrational frequency involving out-of-plane motion, i.e., **5** is a transition structure for inversion. *In polyhalogenated radicals $SiF_nCl_{(3-n)}$ and for $SiHF_2$ **5** is lower than **4** and inversion will occur through edge inversion.* Halogen substitution at silicon then increases the barrier to inversion, but the effect is less drastic than suggested by using **4** as the model for the transition structure since for heavily substituted radicals the alternative edge inversion mechanism becomes operative.

The effect of halogen substituents on the relative energy of **5** can be understood by comparison with square-planar silanes and methanes. Square-planar SiH_4 is much closer in energy to the tetrahedral structure than for CH_4 (95 kcal/mol at the HF/3-21G* level compared with 170 kcal/mol at HF/3-21G*) (27, 28), and the stabilization is largely attributed to interaction between the hydrogen atoms and a silicon *d*-orbital of b_{1g} symmetry. The situation in the T-shaped SiH_3 is somewhat similar, with the three hydrogens occupying three vertices of the square and the unpaired electron the fourth. Here the energy difference of 66.3 kcal/mol between the pyramidal and T-shaped structures is somewhat smaller than in SiH_4, although comparison is difficult since the levels of theory used here are considerably higher. In square-planar SiH_4 all the valence electrons are in σ-orbitals leaving an empty *p*-orbital of π-symmetry on silicon and π-donating ligands are strongly stabilising. At the 3-21G* level the tetrahedral/square-planar difference is reduced to 75 kcal/mol. Similarly in T-shaped silyl radicals both fluorine and chlorine are π-donors and their inclusion reduces the pyramidal/T-shaped difference from 67 kcal/mol in SiH_3 to as low as 31.9 kcal/mol in $SiFCl_2$.

(III) Dissociation reactions in silyl radicals

The barriers to inversion in silyl radicals are substantial and it is possible that dissociation may occur at lower energies. In general, dissociation of a bond leads to breaking an electron pair and the products have less correlation energy than the reactant, making it impossible to obtain accurate dissociation energies from Hartree–Fock calculations. However, singlet silylenes are lower in energy than the triplets (27) and the isogyric

[4] SiXYZ (doublet) → SiXY (singlet) + Z (doublet)

reaction given in eq. [4] then gives a lower limit to the dissociation energy of the radical.

Dissociation energies at 0 K, calculated by taking the difference in electronic and zero-point energies and using eq. [3] are given in Table 6. We did not attempt to correct these energies to room temperature since Ho *et al.* (15) have shown that empirical corrections, considerably larger than the small thermal energies, have to be *added* in order to duplicate the experimental heats of atomisation of SiH_n, $SiCl_n$, and SiH_nCl_n. The values given in Table 6 then are expected to be *underestimates* of the dissociation energies. Only for one radical, $SiHF_2$, is the dissociation energy lower than the calculated inversion barrier but even here the difference is small (3.9 kcal/mol) and at an even higher level of theory the calculated dissociation energy of 42.7 kcal/mol (14) is higher than the inversion barrier of 34.8 kcal/mol. We conclude then that all halogenated silyl radicals undergo inversion at lower energies than that required for dissociation.

From Table 6 the relative bond strengths are Si—H < Si—Cl < Si—F. For any given type of dissociation, e.g., Si—H, the total dissociation energy is determined mainly by the kind of bond being broken but also depends on the stability of the silylene being produced. Fluorine (29) and, to a lesser extent, chlorine both stabilise singlet silylenes by π-donation and consequently dissociation reactions in which SiF_2 and $SiCl_2$ are products require less energy than reactions producing SiHF and SiHCl, while those producing SiH_2 are the least favourable.

Conclusions

The barrier to inversion in SiH_3 (4.9 kcal/mol) is much smaller than that in the silyl anion, SiH_3^- (26.5 kcal/mol) and both species invert through the trigonal structure with the non-bonding electron(s) in the out-of-plane *p*-orbital, i.e., they undergo vertex inversion. Replacement of one hydrogen by a fluorine results in an increase in the barrier by 9.9 kcal/mol for the radical and 18.7 kcal/mol in the anion, but the vertex inversion mechanism is preferred. A second fluorine substitution further destabilizes the transition structure for vertex inversion and both $SiHF_2$ and $SiHF_2^-$ invert by the edge inversion mechanism and have similar barrier (~35.0 kcal/mol) at the MP2/6-31++G* level. A third fluorine substituent destabilises the transition structure for vertex inversion even further but has little effect on inversion by the edge inversion mechanism. Similar, less pronounced, trends are found with chlorine substitution and all triply halogenated silyl anions and radicals invert by the edge inversion mechanism.

Thermal diffusion of weak electrolytes: aqueous phosphoric and iodic acids

LÜ HUI AND DEREK G. LEAIST[1]

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received October 27, 1989

LÜ HUI and DEREK G. LEAIST. Can. J. Chem. **68**, 1317 (1990).

Soret coefficients of aqueous phosphoric acid and aqueous iodic acid are determined conductimetrically at 25°C. As the molality of phosphoric acid drops from 0.05 toward 0.00 mol kg^{-1}, the enthalpy of transport jumps from 2 to 15 kJ mol^{-1}. For iodic acid, a stronger electrolyte, the corresponding increase is smaller, from 12 to 17 kJ mol^{-1}. Equations are developed for the enthalpy of transport of 1:1 weak electrolytes. The equations are used to evaluate the reactive enthalpy of transport and the intrinsic enthalpies of transport of the ionized and molecular forms of phosphoric and iodic acids. Equating the enthalpies of transport of the acid molecules and the acid anions provides estimates of single-ion enthalpies of transport. Thermal diffusion measurements are reported for potassium dihydrogen phosphate and potassium iodate to help interpret the results.

Key words: thermal diffusion, enthalpy of transport, Soret coefficients, weak electrolytes, phosphoric acid, iodic acid.

LÜ HUI et DEREK G. LEAIST. Can. J. Chem. **68**, 1317 (1990).

Opérant à 25°C et faisant appel à une méthode conductimétrique, on a déterminé les coefficients de Soret des acides phosphorique et iodique aqueux. Lorsque la molalité de l'acide phosphorique diminue de 0,05 vers 0,00 mol kg^{-1}, l'enthalpie de transport passe rapidement de 2 à 15 kJ mol^{-1}. Pour l'acide iodique, qui est un électrolyte plus fort, l'augmentation correspondante est plus faible et elle passe de 12 à 17 kJ mol^{-1}. On a développé des équations pour l'enthalpie de transport d'électrolytes faibles 1:1. On a utilisé les équations pour évaluer l'enthalpie de transport réactive ainsi que les enthalpies intrinsèques de transport des formes ionisées et moléculaires des acides phosphorique et iodique. Lorsqu'on établit une équation entre les enthalpies de transport des molécules d'acide et les anions d'acide, on obtient une bonne évaluation des enthalpies de transport des ions uniques. Afin d'aider dans l'interprétation des résultats, on rapporte aussi des mesures de diffusion thermique pour le phosphate diacide de potassium ainsi que l'iodate de potassium.

Mots clés : diffusion thermique, enthalpie de transport, coefficients de Soret, électrolytes faibles, acide phosphorique, acide iodique.

1. Introduction

A temperature gradient applied to an electrolyte solution causes the dissolved ions to diffuse relative to the solvent (1, 2). The thermally-driven diffusion of strong electrolytes has been the subject of a number of studies (1–11). In the work reported here, thermal diffusion measurements are reported for aqueous phosphoric acid ($pK_a = 2.15$), a "weak" electrolyte (12), and aqueous iodic acid ($pK_a = 0.80$), an "almost strong" electrolyte (13–15).

In contrast to a strong electrolyte, a weak electrolyte can diffuse in different chemical forms, e.g. $HA \rightleftharpoons H^+ + A^-$. The enthalpy of transport of a solute that exists as a mixture of rapidly-equilibrating species consists of a contribution from the intrinsic enthalpies of transport of the species and another, usually smaller, contribution from the enthalpy change of the chemical reaction (16–18). The treatment developed in the present study is used to estimate the intrinsic enthalpies of transport of the molecular and ionized forms of iodic and phosphoric acids and the reactive component of the total enthalpy of transport. To help interpret the results, thermal diffusion measurements are also reported for the potassium salts of the acids. No thermal diffusion data appear to have been reported previously for iodates or phosphates (11).

2. Experimental

The solutions were prepared from BDH reagent grade materials and distilled deionized water. The phosphoric acid solutions were analyzed by potentiometric titration against standard alkali.

Conductance methods for the determination of the Soret coefficients of electrolytes are well developed (1–8). The cells used in the present study were of the pattern described by Agar and Turner (3). The cells held short columns of solutions (height 0.9–1.2 cm) between copper thermostat blocks maintained at 20 or 30°C. Thermal diffusion of the ions was followed by measuring changes in electrical resistance across pairs of small platinum electrodes at fixed levels near the top and bottom of the solution column. Details of the equipment and procedure have been reported (19).

Published densities (20, 21), conductances (13, 15, 20–23), and isothermal diffusion data (24–27) were used to evaluate the Soret coefficients from the measured resistance changes. Since no diffusion coefficients appear to have reported for aqueous HIO_3 or KIO_3, a few isothermal diffusion measurements were made on these electrolytes. A simplified version of Harned's conductimetric procedure was employed (24).

3. Results

Thermal diffusion in a convection-free solution leads to a steady state in which the diffusion of solute driven by the temperature gradient is balanced by ordinary diffusion back down the thermally-induced concentration gradient. The Soret coefficient defined by (1, 2)

$$[1] \quad \sigma = -(1/m)(\mathrm{d}m/\mathrm{d}T)_{\text{steady-state}}$$

gives the relative change in solute molality per degree at steady state. Positive σ values indicate thermal diffusion to the colder parts of the solution.

The enthalpy of transport of an electrolyte is related to its Soret coefficient by the following identity (1, 2)

$$[2] \quad H^* = (\nu_+ + \nu_-)RT^2\sigma(1 + m\,\mathrm{d}\ln\gamma_\pm/\mathrm{d}m)_T$$

ν_+ and ν_- give the number of moles of cations and anions per mole of fully dissociated electrolyte, m is the total electrolyte molality, and $\gamma_\pm$ is the stoichiometric mean ionic activity coefficient. The enthalpy of transport may be interpreted as the heat absorbed to keep the solution at constant temperature when solute diffuses out of a volume element of solution (1, 2).

Soret coefficients were determined conductimetrically at molalities from 0.001 to 0.2 mol kg^{-1} at the mean cell temperature 25°C. The results are given in Tables 1–5. The reported σ values represent average values from two or three runs at each composition. The values of σ were reproducible within 2–4%, except at the lowest molalities where the reproducibility was poorer, about 5%. Published activity coefficient data (12, 13, 28–33) were used to calculate enthalpies of transport (H^*) from the measured Soret coefficients, as listed in Tables 1–5 and plotted against the square root of the ionic strength I in Fig. 1.

KH_2PO_4

A short extrapolation to zero ionic strength gives 4.3 kJ mol^{-1} for the limiting enthalpy of transport of aqueous KH_2PO_4. If Cl^- is arbitrarily assigned conventional enthalpy of transport 0 kJ mol^{-1} at ionic strength 0.01 mol kg^{-1}, the conventional (1, 4–6, 11) ionic enthalpies of transport of K^+ and $H_2PO_4^-$ are, respectively, 2.0 and 1.4 kJ mol^{-1}.

In addition to K^+ and $H_2PO_4^-$ ions, aqueous KH_2PO_4 solutions contain traces of H^+, HPO_4^{2-}, and molecular H_3PO_4 species due to the equilibria $H_2PO_4^- \rightleftharpoons H^+ + HPO_4^{2-}$ ($K_2 = 6.2 \times 10^{-8}$) (34, 35) and $H_3PO_4 \rightleftharpoons H^+ + H_2PO_4^-$ ($K_1 = 7.14 \times 10^{-3}$) (12). These minor species may be neglected here because their concentrations are very small. This simplification is supported by the observation that the limiting slope $dH^*/dI^{1/2}$ agrees qualitatively with the value -10.8 kJ $kg^{1/2}$ $mol^{-3/2}$ expected for a simple 1:1 electrolyte (11). Moreover, previously measured (27) isothermal diffusion coefficients of aqueous KH_2PO_4 extrapolate correctly to the limiting Nernst value for a strong 1:1 electrolyte.

K_2HPO_4

Thermal diffusion measurements were made on aqueous K_2HPO_4 solutions to provide additional information about aqueous phosphates. As the molality drops to 0.001 mol kg^{-1}, the slope of H^* against $I^{1/2}$ is increasing, and it exceeds the limiting value -32.4 kJ $kg^{1/2}$ $mol^{-3/2}$ suggested by theory for a 1:2 strong electrolyte (11). This behaviour may be due to the dissociation of $KHPO_4^-$ ion pairs, or to the hydrolysis reaction $HPO_4^{2-} + H_2O \rightleftharpoons H_2PO_4^- + OH^-$ ($K_h = 1.6 \times 10^{-7}$). It was not possible to estimate the limiting value of H^* reliably.

No attempts were made to measure thermal diffusion of K_3PO_4. Since this salt hydrolyzes extensively, its diffusion is a complicated ternary process involving coupled transport of $K^+ + OH^-$ (26).

KIO_3

Table 3 gives the Soret coefficients for the potassium salt of iodic acid. Extrapolation leads to the value 6.2 kJ mol^{-1} for the salt's limiting enthalpy of transport. The conventional enthalpy of transport of the IO_3^- ion has the value 4.2 kJ mol^{-1}. For comparison, the conventional enthalpies of transport of the ions IO_4^- and ClO_4^- are 1.5 and -0.8 kJ mol^{-1}, respectively (11). Table 3 includes the values of the isothermal diffusion coefficient D that were obtained for aqueous KIO_3 solutions. The limiting value of D, 1.393×10^{-9} m^2 s^{-1}, was calculated by using the Nernst relation $D^0 = 2D_+D_-/(D_+ + D_-)$ and the limiting ionic diffusion coefficients $D_+(K^+) = 1.958 \times 10^{-9}$ and $D_-(IO_3^-) = 1.081 \times 10^{-9}$ m^2 s^{-1}. The ionic diffusion coefficients were calculated from the limiting ionic conductances (15) $\Lambda_+^0 = 0.007354$ and $\Lambda_-^0 = 0.004060$ S m^{-2} mol^{-1} by using the identity $D_i = RT\Lambda_i^0/F^2z_i^2$.

H_3PO_4

The results of the experiments and calculations on aqueous phosphoric acid are given in Table 4. Both the Soret coefficient and the enthalpy of transport of the acid increase sharply as the concentration drops toward zero. This behavior is not surprising in view of the large intrinsic enthalpy of transport of the H^+ ions (11) that are produced by dissociation of the dilute acid.

The sharp curvature of the plot of H^* against $I^{1/2}$ (Fig. 1) makes the direct extrapolation of H^* highly unreliable. (Similar difficulties are encountered in the extrapolation of the acid's molar conductivity to the limiting value.) A better approach is to estimate the limiting enthalpy of transport of the dissociated acid by appealing to the additivity rule (1–6), and extrapolating the enthalpy of transport of the hypothetical fully dissociated electrolyte $H^+ + H_2PO_4^-$ estimated from strong electrolyte data as follows: $H^*(H^+ + H_2PO_4^-) = H^*(KH_2PO_4) + H^*(HCl) - H^*(KCl)$. The extrapolation of $H^*(H^+ + H_2PO_4^-)$ estimated from the measured enthalpies of transport of KH_2PO_4, HCl (10), and KCl (6) is shown in Fig. 1 (lower dashed curve). This procedure gives 15.4 kJ mol^{-1} for the limiting enthalpy of transport of phosphoric acid. This value is based on neglect of the second and third stages of dissociation of the acid.

HIO_3

The Soret coefficient and enthalpy of transport of HIO_3 (Table 5) are less sensitive to changes in concentration than for H_3PO_4 because the former is almost fully ionized at the concentrations used in the present study. As the molality of the acid drops from 0.05 toward 0.00 mol kg^{-1}, for example, the degree of dissociation, α, of HIO_3 increases from about 0.83 to 1.00 (13), whereas α for H_3PO_4 changes from 0.35 to 1.00 (12). Extrapolation of $H^*(HCl) + H^*(KIO_3) - H^*(KCl)$ (upper dashed curve in Fig. 1) leads to the value 17.3 kJ mol^{-1} for the limiting enthalpy of transport of HIO_3.

The values of the isothermal diffusion coefficients for aqueous HIO_3 are listed in Table 5. The limiting value of D was calculated according to Nernst's equation using $D(H^+) =$

9.317×10^{-9} and $D(IO_3^-) = 1.081 \times 10^{-9}$ m^2 s^{-1} (15). Previous studies (25, 36–39) have shown that diffusion data for dilute weak acids can be analyzed to estimate the diffusion coefficient of the molecular form of the acid, D_0. But in this case, only a small portion of dilute aqueous iodic acid diffuses in molecular form. As a result, it was not possible to obtain a reliable value of D_0. It is likely, however, that the value of D_0 for the molecular HIO_3 species is close to 1.081×10^{-9} m^2 s^{-1}, the diffusion coefficient of IO_3^-. (The diffusion coefficients of $H_2PO_4^-$ and the structurally similar molecular H_3PO_4 species, for example, are 0.86×10^{-9} and 0.87×10^{-9} m^2 s^{-1} (25, 40).)

4. Discussion

Polymeric species, such as $H(H_2PO_4)^-$ or $H(IO_3)_2^-$, complicate the properties of concentrated solutions of phosphoric and iodic acids in water (12, 13). But a negligible proportion of the total acid exists as these secondary species provided the acid molality is kept below about 0.05 mol kg^{-1}. For the purposes of the present study, dilute aqueous solutions of phosphoric acid or iodic acid will be treated as simple weak electrolytes subject to the single equilibrium reaction $HA \rightleftharpoons H^+ + A^-$.

Recently, Agar and Lin (18) developed the thermodynamic theory for thermal diffusion of a solute that exists in two

rapidly-equilibrating forms: $nA \rightleftharpoons A_n$. Adapting their results to the problem under discussion leads to the exact expression

[3] $$H^* = t_0 H_0^* + t_\pm H_\pm^* + H_r^*$$

for the enthalpy of transport of a 1:1 weak electrolyte. H_0^* and $H_\pm^*$ stand for the intrinsic enthalpies of transport per mole of the molecular (HA) and ionized ($H^+ + A^-$) forms of the electrolyte. t_0 and $t_\pm$ are transport numbers which give the fractions of the total electrolyte transported as HA or $H^+ + A^-$ (by definition, $t_0 + t_\pm = 1$). H_r^*, the reactive contribution to the enthalpy of transport, is given by

[4] $$H_r^* = [t_\pm - (dm_\pm/dm)]\Delta_r H$$

where $\Delta_r H$ is the enthalpy change of the dissociation reaction $HA = H^+ + A^-$, $m_\pm = \alpha m$ is the molality of the ionized portion of the electrolyte, and $dm_\pm/dm$ measures the change in the ionized electrolyte molality with the total electrolyte molality, under equilibrium conditions. If $t_\pm$ is greater than $dm_\pm/dm$, diffusion tends to remove ions faster than they are produced by dissociation; the subsequent dissociation required to maintain local equilibrium then makes a contribution to the enthalpy of transport of the same sign as the enthalpy of dissociation. Conversely, H^* and H_r^* will have opposite signs if $t_\pm < dm_\pm/dm$.

The generally accepted value of the enthalpy of dissociation of dilute aqueous phosphoric acid is -7.9 kJ mol^{-1} at 25°C (41). The value of $\Delta_r H$ for iodic acid is somewhat uncertain; calorimetric (14), conductance (15), and solubility measurements (42) lead to the discordant values -2.8, -4.6, and -10.0 kJ mol^{-1}, respectively. Without obvious reasons to dismiss any of these careful determinations, the simple arithmetic mean value -5.8 kJ mol^{-1} will be naively adopted.

Values of $t_\pm$ and $dm_\pm/dm$ are also required to estimate the reactive enthalpy of transport. $dm_\pm/dm$ was calculated from the extents of dissociation recommended by Pitzer and Silvester (12) (for phosphoric acid) and by Pethybridge and Prue (13) (for iodic acid). The transport numbers were evaluated by using the dilute-solution transport equations (43–45)

[5] $$j_i = -(c_i D_i/RT)\nabla \tilde{\mu}_i$$

for the flux densities of H^+, A^-, and molecular HA species (designated by subscripts +, −, and 0 respectively). c_i and $\nabla\tilde{\mu}_i$ are the concentrations (in moles per unit volume) and the gradients in the electrochemical potential of the species. The conditions of electroneutrality ($j_+ = j_-$) and local chemical equilibrium ($\tilde{\mu}_0 = \tilde{\mu}_+ + \tilde{\mu}_-$) may be used to show that the fraction of electrolyte transported in ionic form is given by

[6] $$t_\pm = \frac{j_-}{j_- + j_0} = \frac{\alpha D_+ D_-/(D_+ + D_-)}{(1-\alpha)D_0 + \alpha[D_+ D_-/(D_+ + D_-]}$$

(An approach similar to the one used here has been used to analyze the reactive enthalpy of transport of aqueous sulfuric acid (19) subject to the bisulfate/sulfate equilibrium.)

Tables 6 and 7 list the estimates of the reactive enthalpy of transport together with the supplementary values of $t_\pm$, $dm_\pm/dm$, and α. The calculations indicate negative reactive enthalpies for both phosphoric and iodic acids. Iodic acid has larger reactive enthalpies of transport because its enthalpy of dissociation is larger. The magnitude of H_r^* for each acid passes through a maximum at a molality near K^{-1}, where similar amounts of the associated and dissociated forms of the acid are present (18).

Study of Tables 6 and 7 indicates that the fraction of acid transported in the ionized form is less than the fraction of total acid that is dissociated, i.e. $t_\pm < \alpha$. This behavior stems from the relatively low mobility of the dissociated electrolyte: the motion of H^+ and A^- through the solvent meets greater frictional resistance than the motion of the single associated species HA (25, 36–39).

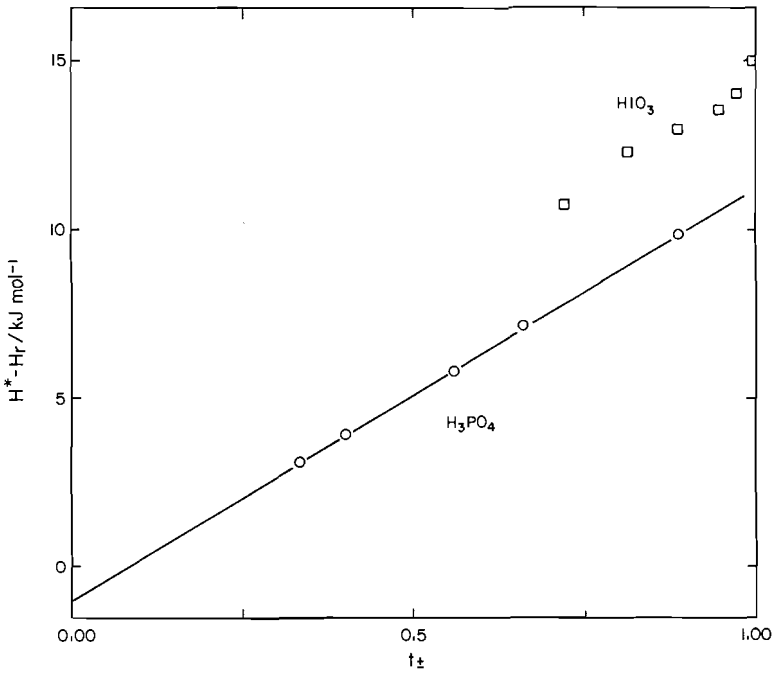

FIG. 2. Intrinsic enthalpy of transport of aqueous phosphoric acid and iodic acid plotted against the transport number of the ionized form of the acid.

The intrinsic enthalpy of transport can be evaluated by subtracting the reactive enthalpy of transport from the measured total enthalpy of transport: $t_0H_0^* + t_\pm H_\pm^* = H^* - H_r^*$. In Fig. 2, the intrinsic enthalpies of transport obtained in this manner are plotted against $t_\pm$, the transport number of the dissociated form of the acids. A linear extrapolation to $t_\pm = 0$ for phosphoric acid gives the value -1.0 kJ mol^{-1} for H_0^*, the enthalpy of transport of the molecular H_3PO_4 species. The corresponding extrapolation for iodic acid is long and unreliable due to the larger values of $t_\pm$ for this "almost strong" acid. It appears, however, that the extrapolation for iodic acid runs parallel to the extrapolation for phosphoric acid, but is shifted upwards by 2–4 kJ mol^{-1}. This observation leads to the tentative value 2 ± 1 kJ mol^{-1} for the enthalpy of transport of the molecular HIO_3 species.

It is intriguing that the difference between the enthalpies of transport of the H_3PO_4 and HIO_3 molecules appears to mirror the difference in the enthalpies of transport of the $H_2PO_4^-$ and IO_3^- ions [$H^*(H_2PO_4^-) - H^*(IO_3^-) = H^*(KH_2PO_4) - H^*(KIO_3)$ at low ionic strength (see Fig. 1)].

The comparison provides circumstantial evidence, but not proof, that the enthalpies of transport of the anion/molecule pairs $H_2PO_4^-/H_3PO_4$ and IO_3^-/HIO_3 are nearly identical. This suggestion is not unreasonable on physical grounds since the acid anions and the acid molecules are structurally very similar. Moreover, the relatively low charge densities of the $H_2PO_4^-$ and IO_3^- anions would tend to reduce the distortion of the structure of the nearby solvent.

If the enthalpies of transport of the acid molecules and anions are indeed nearly identical, it is then possible to evaluate single-ion enthalpies of transport. Adopting -1.0 kJ mol^{-1} for the enthalpy of transport of $H_2PO_4^-$ and molecular H_3PO_4 species, for example, leads to the corresponding values 16.4, 5.3, and 0.9 kJ mol^{-1} for the limiting enthalpies of transport of the ions H^+, K^+, and IO_3^-.

The quoted single-ion enthalpies of transport are speculative and remain to be checked by thermal diffusion measurements on other ion/molecule pairs. Nevertheless, progress along these lines may provide a practical scale of single-ion enthalpies of transport that is acceptably close to the true value of these elusive but theoretically-important quantities.

Synthesis and multinuclear magnetic resonance study of some tin(IV) complexes of pyridine-2-thiolate and related ligands, and the X-ray structural analysis of $Sn(C_5H_4NS)_4 \cdot C_5H_5NS$[1]

LESLIE C. DAMUDE, PHILIP A. W. DEAN,[2] VEERAGATHY MANIVANNAN, RADHEY S. SRIVASTAVA,[3] AND JAGADESE J. VITTAL[2]

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received January 16, 1990

LESLIE C. DAMUDE, PHILIP A. W. DEAN, VEERAGATHY MANIVANNAN, RADHEY S. SRIVASTAVA, and JAGADESE J. VITTAL. Can. J. Chem. **68**, 1323 (1990).

Tin metal reacts with 2,2′-dithiobis (pyridine) in refluxing toluene to give the pyridine-2-thiolate complex $Sn(C_5H_4NS)_4$, **1***a*. Multinuclear (^{77}Se, ^{119}Sn) magnetic resonance shows that ligand redistribution occurs in **1***a*:$Sn(EPh)_4$ (E = S or Se) mixtures to give $Sn(EPh)_{4-x}(C_5H_4NS)_x$. From the pattern of the ^{119}Sn chemical shifts of these series, compared with that of $Sn(EPh)_{4-x}(SR)_x$ (R = simple alkyl or aryl group), the complexes are shown to be five-coordinate $Sn(EPh)_3(C_5H_4NS\text{-}N,S)$ when x = 1 and six-coordinate $Sn(EPh)_{4-x}(C_4H_4NS\text{-}S)_{x-2}(C_5H_4NS\text{-}N,S)_2$ when x = 2–4. Reaction of $Sn(SPh)_2$ and $(C_5H_4NS)_2$ yields pure $Sn(SPh)_2(C_5H_4NS)_2$. The ^{13}C NMR spectrum of $Sn(C_5H_4NS\text{-}S)_2$ $(C_5H_4NS\text{-}N,S)_2$ is an exchange average down to 178 K, probably as a result of fluxionality. The series $Sn(EPh)_{4-x}(L')_x$ (E = Se, L′ = 5-nitropyridine- or quinoline-2-thiolate, x = 0–4; E = S or Se, L′ = pyridine-2-thiolate-*N*-oxide, x = 0–2) can be prepared *in situ* by redox between $Sn(EPh)_4$ and the disulfide $(L')_2$. Treatment of **1***a* with X_2 (X = Br or E- gives $SnX_{4-x}(C_5H_4NS\text{-}N,S)_x$ (x = 2 or 3), which have been characterized by NMR, and provides a new synthesis of the known dihalo complexes.

In a recrystallization of **1***a* from CH_2Cl_2:hexane $Sn(C_5H_4NS)_4 \cdot C_5H_5NS$, **2**, was obtained, probably as a result of hydrolysis. The structure of **2** has been solved by single crystal X-ray diffraction techniques. The compound crystallizes in the orthorhombic space group *Pbca* (No. 61) with a unit cell of dimensions a = 17.132(2) Å, b = 15.337(2) Å, c = 21.268(3) Å, and Z = 8. Full-matrix least-squares on F led to agreement factors R = 0.0439 and R_w = 0.0426 for 3145 independent reflections with $F_o > 2.5\sigma$ (F_o) and 206 variables. The molecule $Sn(C_5H_4NS\text{-}S)_2(C_5H_4NS\text{-}N,S)_2$ has highly distorted octahedral coordination about the tin atom, with the monodentate ligands in *cis* positions and the bidentate ligands attached with mutually *cis* nitrogen atoms. The Sn—S distances are 2.463(2)–2.542(2) Å and the Sn—N distances are 2.332(2) and 2.324(2) Å. The N—Sn—S angles in the chelate rings are 64.2(2) and 65.1(1)°. The molecule of pyridine-2-thione in the lattice is hydrogen-bonded to the N atom of one of the monodentate ligands in the tin complex, with a N—H···N hydrogen bond distance of 1.92(7) Å.

Key words: pyridine-2-thiolate, selenium-77 NMR, tin-119 NMR, tin(IV) complexes, X-ray analysis.

LESLIE C. DAMUDE, PHILIP A. W. DEAN, VEERAGATHY MANIVANNAN, RADHEY S. SRIVASTAVA, et JAGADESE J. VITTAL. Can. J. Chem. **68**, 1323 (1990).

L'étain métallique réagit avec la 2,2′-dithiobis (pyridine), dans le toluène au reflux, pour donner le complexe pyridine-2-thiolate, $Sn(C_5H_4NS)_4$, **1***a*. La résonance magnétique multi-noyaux (^{77}Se, ^{119}Sn) démontre que, dans des mélanges de **1***a*: $Sn(EPh)_4$ où E = S ou Se, il se produit une redistribution des ligands et la formation de composés du type $Sn(EPh)_{4-x}(C_5H_4NS)_x$. En se basant sur une comparaison des déplacements chimiques du ^{119}Sn dans les composés de cette série avec ceux observés dans les produits $Sn(EPh)_{4-x}(SR)_x$ où R = groupements aryles ou alkyles simples, on a démontré que, si x = 1, les complexes sont les entités penta-coordonnées $Sn(EPh)_3(C_5H_4NS\text{-}N,S)$ alors que, si x = 2–4, les complexes sont les entités hexa-coordonnées $Sn(EPh)_{4-x}(C_5H_4NS\text{-}S)_2$. La réaction du $Sn(SPh)_2$ avec le $(C_5H_4NS)_2$ fournit du $Sn(SPh)_2(C_5H_4NS)_2$ à l'état pur. Même lorsqu'on abaisse la température jusqu'à 178 K, le spectre rmn du ^{13}C du $Sn(C_5H_4NS\text{-}S)_2(C_5H_4NS\text{-}N,S)_2$ est un spectre moyen résultant probablement d'un mécanisme de fluxion. Faisant appel à une réaction redox *in situ* entre le $Sn(EPh)_4$, et le disulfure $(L')_2$, on peut préparer les produits de la série $Sn(EPh)_{4-x}(L')_x$ (E = Se, L′ = 5-nitropyridine- ou quinoléine-2-thiolate, x = 0–4; E = S ou Se, ′ L′ = pyridine-2-thiolate N-oxyde, x = 0–2). Le traitement du produit **1***a* par du X_2 (X = Br ou I) fournit les complexes $SnX_{4-x}(C_5H_4NS\text{-}N,S)_x$ (x = 2 ou 3) que l'on a caractérisés par rmn; ces réactions fournissent une nouvelle synthèse de ces complexes dihalogénés connus.

Lors de la recristallisation du produit **1***a* dans un mélange de CH_2Cl_2 : hexane, on obtient le $Sn(C_5H_4NS)_4 \cdot C_5H_4NS$, **2**, qui provient probablement d'une hydrolyse. On a déterminé la structure du composé **2** par des techniques de diffraction des rayons-X effectuées sur des cristaux uniques. Le composé donne des cristaux orthorhombiques qui appartiennent au groupe d'espace *Pbca* (No. 61) avec une maille unitaire dont les dimensions sont a = 17,132(2), b = 15,337(2) et c = 21,268(3) Å et Z = 8. On a affiné la structure par la méthode des moindres carrés jusqu'à des valeurs respectives de R = 0,0439 et R_w = 0,0426 pour 3145 réflexions indépendantes avec $F_o > 2{,}5\sigma(F_o)$ et 206 variables. La molécule de $Sn(C_5H_4NS\text{-}N,S)_2(C_5H_4NS\text{-}N,S)_2$ est caractérisée par une coordination octaédrique très déformée autour de l'atome d'étain; les ligands monodentates sont attachés aux positions *cis* et lis ligands bidentates sont attachés aux atomes d'azote qui sont mutuellement *cis*. Les distance Sn—S varient de 2,463(2) à 2,542(2) Å alors que les distances Sn—N sont égales à 2,332(2) et 2,324(2) Å. Les angles N—Sn—S des cycles chélates sont égaux à 64,2(2) et 65,1(1)°. La molécule de pyridine-2-thione présente dans le réseau est reliées par une liaison hydrogène avec l'atome d'azote de l'un des ligands du complexe d'étain; la longueur de la liaison hydrogène N—H···N est égale à 1,92(7) Å.

Mots clés : pyridine-2-thiolate, ^{77}Se RMN, ^{119}Sn RMN, complexes d'étain, analyses des rayons-X.

Introduction

In previous work from this laboratory (1), multinuclear magnetic resonance was used to characterize several new species of the type $Sn(EPh)_{4-x}(E'Ph)_x$ (E, E' = S, Se, Te). The probe nuclei were ^{119}Sn, ^{77}Se, and ^{125}Te,[4] and equilibrium mixtures of the species with mixed phenylchalcogenates were produced either by oxidation of $Sn(EPh)_2$ with $Ph_2E'_2$ (for E = S or Se; E' = S, Se or Te) or by ligand redistribution between $Sn(SPh)_4$ and $Sn(SePh)_4$.

In an extension of the earlier work, we present here a multinuclear magnetic resonance study of species of the type $Sn(EPh)_{4-x}(pyt)_x$ (E = S or Se;[5] pyt = pyridine-2-thiolate or related ligand). Pyridine-2-thiolates are known to be versatile ligands. Modes of attachment that have been established include monodentate terminal bonding through S with (e.g. refs. 3–5) or without (e.g. ref. 6) weak intramolecular M···N interaction, monodentate bridging through S, with weak M···N interaction (7), N,S-chelation, with various degrees of distortion caused by the small bite of the ligand (e.g. refs. 6, 8–11), and bidentate N,S-bridging (e.g. refs. 7, 12–15). Of particular relevance to the present work, chelation has been established in *cis*-$SnCl_2(C_5H_4NS\text{-}N,S)_2$ by X-ray analysis (9). The compound was found to be monomeric in methylisobutylketone (16), but no evidence seems to be available regarding the exact nature of the Sn(IV)–pyt^- interaction for this or related (16) dihalo tin complexes in solution. Tin-119 NMR is very senstitive to changes in the coordination number of tin(IV) (17) and so should be of use for determining the denticity of pyt^- in Sn(IV)-pyt^- complexes. Using ^{119}Sn NMR, we show here that in the series $Sn(EPh)_{4-x}(pyt)_x$ the pyt^- behaves as a chelate when $x = 1$ or 2, while both bidentate and monodentate pyt^- ligands occur when $x = 3$ or 4. The result for $x = 4$ is supported by an X-ray analysis of $Sn(C_5H_4NS)_4 \cdot C_5H_5NS$.

Experimental

Materials

The disulfides R_2S_2 (R = Et, Pr^n, $PhCH_2$, 4-C_6H_4Me, 4-$C_6H_4NO_2$, 2-pyridyl, 2-(5-nitropyridyl), or 2-pyridyl-*N*-oxide), and 2-mercaptopyridine (all from Aldrich), as well as diphenyldiselenide (from Aldrich or Strem) showed no significant impurities by NMR (^1H, ^{13}C, ^{77}Se, as appropriate), and were used as received.

Literature syntheses were used for $Sn(SPh)_2$ (18), and $Sn(EPh)_4$ (E = S or Se) (19). Standard methods (20) were used for the synthesis of Ar_2S_2 (Ar = Ph, 2-MeC_6H_4, 4-ClC_6H_4, or 2-quinolinyl) from the corresponding thiols. The purity of these disulfides was checked using ^{13}C NMR.

Tin(IV) thiolates or selenolates, and 2,2′-dithiobis(pyridine-*N*-oxide) were handled under an atmosphere of Ar or N_2. Solvents for use in synthesis or in the preparation of NMR samples were dried over 3 Å molecular sieves and sparged with Ar before use.

Synthesis

$Sn(SPh)_2(C_5H_4NS)_2$. This was synthesized by the oxidative addition of 2,2′-dithiobis(pyridine) to $Sn(SPh)_2$. The tin(II) compound (0.205 g, 0.608 mol) and $(C_5H_4NS)_2$ (0.134 g, 0.608 mmol) were stirred together in ca. 20 mL of CH_2Cl_2 under nitrogen for 48 h. After this time, the mixture was filtered and the filtrate was concentrated in vacuo then left at 5°C for crystallization to occur. The yellow product was separated by filtration, washed with an ice-cold mixture of CH_2Cl_2 and hexane (1:10 v:v), and dried *in vacuo*. Yield 0.210 g (62%). Mp 142–143°C. *Anal.* calcd. for $C_{22}H_{18}N_2S_4Sn$ (mol. wt. 557.34): C 47.41, H 3.25, N 5.02; found: C 47.37, H 3.20, N 5.04.

*$Sn(C_5H_4NS)_4$, 1*a. Following ref. 19, this compound was prepared from tin powder and 2,2′-dithiobis(pyridine) in refluxing toluene. In a typical reaction, tin powder 1.50 g (12.6 mmol) was refluxed with 4.18 g (19.0 mmol) of 2,2′-dithiobis(pyridine) in ca. 75 mL of toluene for ca. 18 h under N_2. The yellow supernatant liquid was separated by decantation. The excess tin was washed with toluene then CH_2Cl_2 and these washings were combined with the initial decantate. Removal of the solvent on a rotary evaporator gave the crude material. This was dissolved in CH_2Cl_2 and the yellow product was precipitated with hexane and separated by filtration. A second crop resulted from keeping the filtrate at 5°C overnight. Yield 4.88 g (92%). Mp 137–138°C. *Anal.* calcd. for $C_{20}H_{16}N_4S_4Sn$ (mol. wt. 559.30): C 42.95, H 2.88; found: C 43.33, H 3.20. Carbon-13 NMR ($CDCl_3$, 294 K): 162.5, 145.5, 137.6, 125.8, 118.9.

Conversion of $Sn(C_5H_4NS)_4$ to $Sn(C_5H_4NS)_4 \cdot C_5H_5NS$, 2. In attempting to obtain single crystals of $Sn(C_5H_4NS)_4$ for X-ray analysis, solvents that had not been dried were used. Yellow crystals, which proved to be $Sn(C_5H_4NS)_4 \cdot C_5H_5NS$, were grown by layering hexane onto a filtered solution of $Sn(C_5H_4NS)_4$ in CH_2Cl_2 then refrigerating the mixture overnight. *Anal.* calcd. for $C_{25}H_{21}N_5S_5Sn$ (mol. wt. 670.49): C 44.79, H 3.16, N 10.45; found: C 45.03, H 2.95, N 10.21. Carbon-13 NMR ($CDCl_3$, 213 K): 175.5, 138.5, 133.5, 114.1 (C_5H_5NS); 161.1, 146.0, 138.5, 126.4 ($J(^{119}Sn—^{13}C) \approx 35$ Hz), 120.0 ($Sn(C_5H_4NS)_4$). At 294 K, the ^{13}C NMR spectrum is similar but noticeably broader.

Reaction of $Sn(C_5H_4NS)_4$ with I_2 and Br_2. Reaction of $Sn(C_5H_4NS)_4$ with ≥ 1 mol. equiv. of I_2 or Br_2 in CH_2Cl_2 caused formation of poorly soluble $Sn(C_5H_4NS)_2X_2$, which are known compounds (16). For example, when a solution of 1.03 g (1.83 mmol) of $Sn(C_5H_4NS)_4$ in 10 mL of CH_2Cl_2 was mixed with a solution of 0.473 g (1.86 mmol) of I_2 in 20 mL of CH_2Cl_2, yellow $Sn(C_5H_4NS)_2I_2$ was precipitated. The yellow iodo complex was separated by filtration, washed with a little cold CH_2Cl_2, and dried under vacuum. Yield 0.83 g (76%). Mp 281–283°C (lit. (16) mp 271–273°C). *Anal.* calcd. for $C_{10}H_8I_2N_2S_2Sn$ (mol. wt. 592.79): C 20.26, H 1.36; found: C 20.02, H 1.28. Synthesis of $Sn(C_5H_4NS)_2X_2$ from $Sn(C_5H_4NS)_4$ avoids the use of air-sensitive SnX_2.

Nuclear magnetic resonance spectra

NMR samples were prepared and NMR spectra measured and referenced as reported in earlier papers from these laboratories (1, 21). Typically, the number of mol of solute per litre of solvent was 0.1–0.2 for $Sn(SPh)_4$ or $Sn(C_5H_4NS)_4$ and ca. 0.05–0.1 for $Sn(SePh)_4$. Spectra were obtained from samples at ambient probe temperature unless noted otherwise. Linewidths in the ^{77}Se NMR spectra were below 10 Hz, and those in the ^{119}Sn NMR spectra in the range 10–70 Hz, except as noted.

Collection and reduction of X-ray data

A well-developed, light yellow crystal of **2** of suitable quality was mounted on a glass fibre in air. A preliminary photographic examination indicated the unique orthorhombic space group *Pbca* (No. 61) (22). The crystal density was determined to be 1.61(5) g cm^{-3} by flotation in mixtures of carbon tetrachloride and bromoform.

The data collection was carried out on an Enraf-Nonius CAD4F diffractometer using an incident-beam monochromator and Mo Kα (0.71073 Å) radiation (23). Cell constants and an orientation matrix were determined and refined by using the angular settings for 20 high angle reflections with $28.2 < 2\theta < 35.82$. Intensity data were recorded at variable scan speeds chosen to optimize counting statistics within a maximum time per datum of 60 s. Background estimates were made by extending the scan by 25% on each side. Standard reflections 043, 600, 040, 006 were monitored every 120 min of X-ray exposure time and showed −2.5% decay over the total period of 109.2 h. In all, 5329 observations and 172 standards were recorded. Corrections were applied for Lorentz, monochromator and crystal polarization, background radiation effects and crystal decay, using the Structure Determination Package (24) running on a PDP11/23+ computer. The absorption coefficient was 13.0 cm^{-1} and a Gaussian absorption correction was applied (25). The transmission factors ranged from

[4]The natural abundances of ^{119}Sn, ^{77}Se, ^{125}Te, and ^{13}C are 8.58, 7.58, 6.99, and 1.108, respectively; their relative receptivities, D^C, are 25.6, 3.01, 12.7, and 1, respectively (2).

[5]To date, neither $Sn(TePh)_2$ nor $Sn(TePh)_4$ has been isolated pure.

0.8217 to 0.7373. Equivalent reflections were averaged before and after the absorption correction.

Crystal data and the experimental conditions are shown in Table 1.

Solution and refinement of the structure

The tin atom was located by Patterson heavy atom methods using SDP programs running on a PDP11/23+ computer (26). All the remaining non-hydrogen atoms, including those of a molecule of C_5H_5NS, were located in subsequent difference Fourier syntheses and refined by full-matrix least-squares techniques on F using the SHELX-76 software (27). Scattering factors for neutral, non-hydrogen atoms were taken from ref. 28. All the non-carbon atoms were assigned anisotropic thermal parameters. Refinement converged at R = 0.0580 and R_w = 0.0700. At this stage, all the 20 hydrogen atoms attached to the carbon atoms were successfully located in a difference Fourier syntheses, with electron density ranging from 0.259 to 0.777 e Å^{-3}. An electron density of 0.533 e Å^{-3} was found near the N atom of the free C_5H_5NS showing that this molecule is present in the thione rather than the thiol form. The 20 hydrogen positions were calculated (C—H = 0.95 Å) while a common isotropic thermal parameter was refined in the least squares cycles. The positional and the isotropic thermal parameters of the N—H proton were refined in the least square cycles at later stages.

An inspection of F_o and F_c suggested that an extinction parameter should be refined. With the use of 3145 observations with $F_o > 2.5\sigma(F_o)$, and a weighting scheme utilizing weights of the form $w = 1/\text{sig}^2(F_o) + g(F_o)^2$, where g = 0.000135, refinement of 206 variables converged at agreement factors R = 0.0439 R_w = 0.0426 where $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = [\Sigma w(|F_o| - |F_c|)^2/wF_o^2]^{1/2}$. The final least-square cycles had a maximum shift/esd of 0.0820 on U of C(22). In the analysis of a total difference Fourier synthesis, there were seven peaks with electron density greater than 0.510 e Å^{-3}; of these, the largest one was associated with C(33) at a distance of 0.68 Å and the remainder were of no chemical significance. An analysis of the data as a function of F_o, 2θ, and Miller indices showed no unusual trends. The extinction parameter refined to 0.000233 (14).

Positional and U(equiv) thermal parameters for the refined atoms are given in Table 2. Tables of hydrogen atom parameters, anisotropic thermal parameters, root-mean-square amplitudes of vibration, weighted least-squares planes, torsion angles, and structure factors have been deposited as supplementary material.[6]

Elemental microanalysis

Microanalyses for C, H, and N were carried out by Guelph Chemical Laboratories, Ltd.

Results and discussion

Synthesis

Tin metal reacts with 2,2′-dithiobis(pyridine), **3***a*, in refluxing toluene to produce yellow $Sn(C_5H_4NS)_4$, **1***a*:

[1] $Sn + 2(C_5H_4NS)_2 \rightarrow Sn(C_5H_4NS)_4$

This preparation parallels the straightforward synthesis of $Sn(SPh)_4$ that was reported recently (19). Under the conditions used to produce **1***a*, tin metal does not react with either 2,2′-dithiobis(5-nitropyridine), **3***b*, or 2,2′-dithiobis(quinoline), **3***c*. We note, however, that Sn(IV) species containing 5-nitropyridine-2-thiolate and quinoline-2-thiolate are well established, e.g. the dichlorotin(IV) complexes (16). We were able to obtain ^{119}Sn NMR spectroscopic evidence for $Sn(5\text{-}NO_2\text{—}C_5H_3NS)_4$, **1***b*, and $Sn(C_9H_6NS)_4$, **1***c* in reaction mixtures containing $Sn(SePh)_4$ and the appropriate dithio compound, **3***b* or **3***c* (see below).

When **1***a* was crystallized from CH_2Cl_2–hexane that had not been dried, hydrolysis apparently occurred and the product was yellow $Sn(C_5H_4NS)_4\cdot C_5H_5NS$, **2**. This compound has been fully characterized by X-ray analysis (see below).

Reaction of **1***a* with one or more mole equivalents of Br_2 or I_2

in CH_2Cl_2 gives clean conversion to $Sn(C_5H_4NS)_2X_2$ (X = Br or I) (reaction [2], $x = 2$). The dihalo complexes are already known (16).

[2] $Sn(C_5H_4NS)_4 + (x/2)\,X_2 \rightarrow Sn(C_5H_4NS)_{4-x}X_x + (x/2)\,(C_5H_4NS)_2$

The replacement of only two of the four $C_5H_4NS^-$ ligands of **1***a* in this experiment suggests that there are inequivalent bonding modes for $C_5H_4NS^-$ in $Sn(C_5H_4NS)_4$. For comparison, $Sn(EPh)_4$ (E = S or Se) can be converted to SnX_4 (via $Sn(EPh)_{4-x}X_x$) by addition of X_2 (X = Br or I).[7]

Nuclear magnetic resonance studies

The ^{13}C NMR spectrum of **1***a* in $CDCl_3$ or CH_2Cl_2 consists of only five resonances from room temperature to 178 K. Therefore in solution, the $C_5H_4NS^-$ ligands either are equivalent or are made equivalent by an averaging process. Clearly the ^{13}C NMR spectrum does not allow a distinction between four-coordinate $Sn(C_5H_4NS\text{-}S)_4$ and a higher coordinate species. The ^{119}Sn NMR spectrum of **1***a* in CH_2Cl_2 at ambient probe temperature consists of a singlet with $\delta_{Sn} = -516$, shielded by over 560 ppm relative to the resonance of $Sn(SPh)_4$ (Table 3). This change is very much larger than the difference between $\delta_{Sn}(Sn(SPh)_4)$ and δ_{Sn} for other simple $Sn(SR)_4$, as shown by data for several representative series $Sn(SPh)_{4-x}(SR)_x$ (Table 4). Equilibrium mixtures containing all members of these series are most easily produced by the reaction of R_2S_2 with $Sn(SPh)_2$:

[3] $Sn(SPh)_2 + R_2S_2 \rightarrow Sn(SPh)_{4-x}(SR)_x$ (equilibrium mixture)

Thus δ_{Sn} for **1***a* is apparently inconsistent with a structure containing only monodentate S-bonded $C_5H_4NS^-$. Monodentate bonding of $C_5H_4NS^-$ through nitrogen would be expected to result in shielding of the tin nucleus, but there do not appear to be any cases in which the ligand binds in this manner, so we discard this possibility.[8] Increase of the coordination number of tin from four to five or six is known to result in a significant increase in nuclear shielding at tin (17). Accordingly δ_{Sn} for **1***a* points to a coordination number of greater than four at tin. This possibility is supported strongly by the NMR data for $Sn(EPh)_4$ (E = S or Se): **1***a* mixtures and related systems, and is confirmed by an X-ray analysis of **2**.

The ^{13}C NMR spectrum of **2** in $CDCl_3$ exhibits signals from both $Sn(C_5H_4NS)_4$ and free C_5H_5NS, which is known to exist mainly as the thione tautomer in solution (31). Separate signals for the two components can be observed at ambient probe temperature, but the overall spectrum is sharper at reduced temperatures. Evidently there is slow intermolecular exchange of $C_5H_4NS^-$ between the tin complex and the free thione at ambient probe temperature which can be stopped at lower temperatures.

(i) $Sn(SePh)_{4-x}(C_5H_4NS)_x$

As the ratio of the two components is changed in $Sn(SePh)_4$: **1***a* mixtures, a total of five ^{119}Sn NMR signals and four ^{77}Se NMR signals is observed. Evidently the redistribution shown in reaction [4] (E = Se) occurs. Typically, several ^{119}Sn and

[4] $[(4-x)/4]\,Sn(EPh)_4 + (x/4)\,Sn(C_5H_4NS)_4 \rightleftharpoons Sn(EPh)_{4-x}(C_5H_4NS)_x$ (equilibrium mixture)

^{77}Se signals are observed for each sample, showing that multiple species coexist at equilibrium, as is frequently found in ligand scrambling processes. From their order of appearance, the signals are readily assignable to individual members of the series $Sn(SePh)_{4-x}(C_5H_4NS)_x$ (Table 3). Of particular significance is the pattern of the sequential differential ^{119}Sn chemical shifts, $\delta_{Sn}[Sn(EPh)_{4-x}(L')_x] - \delta_{Sn}[Sn(EPh)_{4-x+1}(L')_{x-1}]$ (or, more generally, $\delta_{Sn}[SnL_{4-x}L'_x] - \delta_{Sn}[SnL_{4-x+1}L'_{x-1}]$), hereinafter abbreviated $\Delta\delta_{Sn,x}$, which is quite unlike that found in the simple series $Sn(SePh)_{4-x}(SPh)_x$ (1). For $x = 1$, 2, 3, and 4, $\Delta\delta_{Sn,x} = -216$, -302, 51, and 84, respectively. The large negative values for $x = 1$ and 2 we attribute to substitution of $SePh^-$ by bidentate $C_5H_4NS^-$, with changes from four coordination to five coordination, and from five coordination to six coordination, respectively. Thus the complexes with $x = 1$ and 2 are $Sn(SePh)_3(C_5H_4NS\text{-}N,S)$, with kernel $SnSe_3NS$, and $Sn(SePh)_2(C_5H_4NS\text{-}N,S)_2$, with kernel $SnSe_2N_2S_2$, respectively. The values of $\Delta\delta_{Sn,x}$ for $x = 3$ and 4 are positive and of smaller magnitude. We associate these with the replacement of $SePh^-$ by a monodentate S-bonded $C_5H_4NS^-$. In the series $Sn(SePh)_{4-x}(SPh)_x$, replacement of $SePh^-$ by SPh^- leads to a diminution of ^{119}Sn shielding by ca. 45 ppm per substitution (1). Thus it is evident that the $C_5H_4NS^-$ complex with

[a]In 1:1 mixtures of $Sn(SPh)_2$ and R_2S_2.
[b]Estimated error in differential chemical shifts ±0.2 ppm; reproducibility of individual chemical shifts is probably poorer.
[c]From ref. 1.
[d]δ_{Sn} = 165 for neat $Sn(SMe)_4$ (29).
[e]δ_{Sn} = 138 for neat $Sn(SEt)_4$ (29).
[f]Could not be observed with certainty: probably isochronous with the signal of $Sn(SPh)(S\{4\text{-}C_6H_4NO_2\})_3$.

$x = 3$ is $Sn(SePh)(C_5H_4NS\text{-}S)(C_5H_4NS\text{-}N,S)_2$, with the kernel $SnSeS_3N_2$, while that with $x = 4$ is $Sn(C_5H_4NS\text{-}S)_2$ $C_5H_4NS\text{-}N,S)_2$, with the kernel SnS_4N_2. The last conclusion is in accord with the chemical evidence from halogen oxidation of **1***a* (see above), and also means that the five-line ^{13}C NMR spectrum observed for $Sn(C_5H_4NS)_4$ down to 178 K (see above) must be an exchange average.[9] The observation of separate ^{77}Se NMR spectra, with ^{119}Sn satellites, for the individual species $Sn(SePh)_{4-x}(C_5H_4NS)_x$ at 293 K shows that intermolecular exchange of $SePh^-$ is slow on the timescales of $^1J(^{119}Sn—^{77}Se)$ and $\Delta\delta_{Se}$, and therefore, presumably, of $\Delta\delta_{Sn}$ also, under these conditions. As a result, it is not possible to conclude from the observation of separate ^{119}Sn signals for this series that intermolecular exchange of $C_5H_4NS^-$ must also be slow here. However, exchange of the chelate ligands is evidently slow on the timescale of $\Delta\delta_{Sn}$ for the series $Sn(SPh)_2(C_5H_4NS\text{-}N,S)_2$-$(C_5H_4SNO\text{-}O,S)_n$ at 293 K (see (*iv*) below). Therefore we believe that it is rapid intramolecular (rather than intermolecular) exchange that simplifies the ^{13}C NMR spectrum of **1***a* at 293 K. The observation of ^{119}Sn satellites ($J(^{119}Sn—^{13}C)$ ≈ 35 Hz) about the 126.4 ppm resonance in the ^{13}C NMR spectra of **1***a* and **2** at 213 K shows that the exchange is certainly intramolecular at this temperature.

The ^{119}Sn and ^{77}Se NMR data are insufficient to allow the deduction of finer detail about the coordination kernel of tin in the complexes with mixed ligands, such as the coordination geometry and geometrical isomeric form. Undoubtedly the six-coordinate species are distorted octahedral, as reported for $SnCl_2(C_5H_4NS\text{-}N,S)_2$ (9). Either trigonal bipyramidal or square pyramidal geometry is possible for $Sn(SePh)_3(C_5H_4NS\text{-}N,S)$, but in any case this molecule must be fluxional to account for the occurrence of only one ^{77}Se NMR signal. With regard to the ^{77}Se NMR data, it is also interesting to note that $^1J(^{119}Sn—^{77}Se)$ shows only a 10% reduction in magnitude on changing from four-coordinate $Sn(SePh)_4$ to six-coordinate $Sn(SePh)_2$-$(C_5H_4NS\text{-}N,S)_2$. On the basis of a change from sp^3 to sp^3d^2 hybridization, a larger reduction might have been anticipated. Most likely the effects of substitution and change in hybridization almost cancel. Consistent with the existence of competing effects, both ^1J and δ_{Se} vary irregularly across the whole series (Table 3).

The series $Sn(SePh)_{4-x}(C_5H_4NS)_x$ can be generated in $Sn(SePh)_4$: **3***a* mixtures also (reaction [5], E = Se). However, the redox

[5] $Sn(EPh)_4 + (x/2)\,(C_5H_4NS)_2 \rightleftharpoons Sn(EPh)_{4-x}(C_5H_4NS)_x + (x/2)\,Ph_2E_2$ (equilibrium mixture)

reaction is very slow to reach equilibrium at room temperature. For example a 1:2 mixture was still changing slowly after one week. At that time a mixture of the species with x = 2–4 existed.

(ii) $Sn(SPh)_{4-x}(C_5H_4NS)_x$

This series is generated most easily from $Sn(SPh)_4$: **1***a* mixtures in CH_2Cl_2 (reaction [4], E = S). The same species can be generated over a matter of hours-days in $Sn(SPh)_4$: **3***a* or **1***a*: Ph_2S_2 mixtures (c.f. reaction [5]). As expected, a total of five species exists in the series. The ^{119}Sn NMR chemical shifts are given in Table 3. By comparison with data for simple complexes of the type $Sn(SPh)_{4-x}(SR)_x$ (Table 4), which can be accounted for on the basis of first or second order additivity models (37), the chemical shifts of $Sn(SPh)_{4-x}(C_5H_4NS)_x$ show irregular behaviour. For this latter series, $\Delta\delta_{Sn,x} = -201$ and -274 for $x = 1$ and 2, respectively, significantly larger than the values of -51 and -40 for $x = 3$ and 4, respectively. On this basis the pyridine-2-thiolate complexes are five-coordinate $Sn(SPh)_3$-$(C_5H_4NS\text{-}N,S)$ and six-coordinate $Sn(SPh)_{4-x}(C_5H_4NS\text{-}S)_{x-2}$-$(C_5H_4NS\text{-}N,S)_2$ (x = 2–4).

According to ^{119}Sn NMR measurements, $Sn(SPh)_2(C_5H_4NS)_2$ is the only species present at equilibrium when $Sn(SPh)_4$ and **1***a* or **3***a* are mixed in a 1:1 ratio in CH_2Cl_2. (The reaction of **1***a* with Ph_2S_2 is too slow to be useful.) Consistent with this observation, $Sn(SPh)_2(C_5H_4NS)_2$ can be isolated pure from a 1:1 mixture of $Sn(SPh)_2$ and **3***a* (see Experimental section).

When a solution of $Sn(SPh)_2(C_5H_4NS\text{-}N,S)_2$ is mixed with a solution containing $Sn(SePh)_2(C_5H_4NS\text{-}N,S)_2$ as the main component,[10] a major new ^{119}Sn NMR signal appears together with a corresponding new ^{77}Se NMR signal. The chemical shift of the new ^{119}Sn resonance is close to the midpoint of those of the $Sn(EPh)_2(C_5H_4NS\text{-}N,S)_2$ parents, and it is evident that scrambling of EPh^- anions has occurred to give $Sn(SPh)$-$(SePh)(C_5H_4NS\text{-}N,S)_2$.

(iii) $Sn(SePh)_{4-x}(SR')_x$ (R' = 5-nitro-2-pyridyl or 2-quinolinyl)

Although the parent compounds **1***b* and **1***c* were not isolated, these two series of complexes could be prepared in CH_2Cl_2 by the reaction of $Sn(SePh)_4$ with the appropriate $(R'S)_2$ (**3***b* or **3***c*). These redox reactions parallel [5]. The reactions are slow at ambient probe temperature, e.g. 1:1 mixtures had not reached equilibrium after a week. Nevertheless, it was possible to characterize all members of both series by ^{77}Se and/or ^{119}Sn NMR, and these data are given in Table 3. The similarity with

[9]Similarly, tin(IV) dialkyldithiocarbamates, with the solid-state structure $Sn(dtc\text{-}S)_2$ $(dtc\text{-}S,S')_2$ (32, 33), show equivalencing of dtc groups by ^{13}C NMR at ambient probe temperature (34). Tin(IV) xanthates, of analogous structure in the solid state (35), show equivalencing of ligands by ^{13}C NMR down to 183 K (36).

[10]Unlike $Sn(SPh)_2(C_5H_4NS)_2$, $Sn(SePh)_2(C_5H_4NS)_2$ always occurs as one component of an equilibrium mixture.

data for the series $Sn(SePh)_{4-x}(C_5H_4NS)_x$ is obvious, and the data can be accounted for in a like manner.

(iv) $SnX_{4-x}(C_5H_4NS)_x$ (X = Br or I or a mixture of these)

For $x = 2$ or 3, these complexes can be prepared *in situ* in CH_2Cl_2 according to reaction [2]. Their ^{119}Sn NMR spectra are readily assigned on the basis of the order of appearance of the signals, and the assignments are given in Table 3. As expected from the chemical shifts reported for $SnBr_6^{2-}$,[11] δ_{Sn} for $SnBr_{4-x}(C_5H_4NS\text{-}N,S)_x$ decreases with decreasing x. The iodo analogues are even more shielded as anticipated on the basis of the normal halogen dependence, which is observed for tin(IV).[12] A mixture of $SnBr_2(C_5H_4NS\text{-}N,S)_2$ and $SnI_2(C_5H_4NS\text{-}N,S)_2$ provides evidence for $SnBrI(C_5H_4NS\text{-}N,S)_2$. Overall, the pattern of ^{119}Sn chemical shifts for the halo complexes is very similar to those of various analogous halo-substituted xanthates of Sn(IV) (36).

Extension of $SnX_{4-x}(C_5H_4NS)_x$ to include the species with $x = 1$ can be made using **1***a* or $SnX_2(C_5H_4NS)_2$:SnX_4 mixtures. For instance, the complex with $x = 1$, X = I, gives a resonance at −1583 ppm, between those of $SnI_2(C_5H_4NS\text{-}N,S)_2$ and SnI_4. The signal of the trioiodo complex is significantly more shielded than that of $SnI_3(SPh)$ (−935 ppm).[7] This indicates a five-coordinate structure for $SnI_3(C_5H_4NS\text{-}N,S)$.

(iv) $Sn(EPh)_{4-x}(C_5H_4SNO)_x$

2,2′-Dithiobis (pyridine-*N*-oxide), $(C_5H_4SNO)_2$, is poorly soluble in CH_2Cl_2, but at the concentration used here dissolves over a period of ca. 1 h in the presence of 2 mol. equiv. of $Sn(SPh)_4$. When this reaction is followed by ^{119}Sn NMR, the first new signal to appear is at −161 ppm. This can be assigned to $Sn(SPh)_3(C_5H_4SNO)$. At equilibrium a second, significantly broader, new signal is observed at −352 ppm and can be attributed to $Sn(SPh)_2(C_5H_4SNO)_2$. The equilibrium mixture is far from statistical: $Sn(SPh)_3(C_5H_4SNO)$ is present in minor amount relative to $Sn(SPh)_4$ and $Sn(SPh)_2(C_5H_4SNO)_2$. A 1:1 $Sn(SPh)_4$:$(C_5H_4SNO)_2$ mixture at equilibrium contains only $Sn(SPh)_2(C_5H_4SNO)_2$. The large values of $\Delta\delta_{Sn,x}$, −211 and −191 ppm for $x = 1$ and 2, respectively, point to chelation by the $C_5H_4SNO^-$ ligand, which is a well-established feature of its coordination behaviour (e.g. refs. 40–42). Accordingly, the species with $x = 1$ and 2 must have the chelated structures $Sn(SPh)_3(C_5H_4SNO\text{-}O,S)$ and $Sn(SPh)_2(C_5H_4SNO\text{-}O,S)_2$, respectively.

Mixtures of $Sn(SePh)_4$ and $(C_5H_4SNO)_2$ behave very much like those containing $Sn(SPh)_4$. The species $Sn(SePh)_{4-x}(C_5H_4SNO\text{—}O,S)_x$ ($x = 1$ or 2) have been characterized by ^{77}Se and ^{119}Sn NMR (Table 3).

When a solution of $Sn(SPh)_2(C_5H_4SNO\text{-}O,S)_2$ is mixed with a solution of $Sn(SPh)_2(C_5H_4NS\text{-}N,S)_2$ a new species occurs in equilibrium with the two component complexes. This new species has a ^{119}Sn resonance at −389 ppm, between the signals of the two parent complexes, and is clearly the redistribution product $Sn(SPh)_2(C_5H_4NS\text{-}N,S)(C_5H_4SNO\text{-}O,S)$. Similarly, $Sn(SPh)(SePh)(C_5H_4SNO\text{-}O,S)_2$ may be detected by ^{77}Se and ^{119}Sn NMR in mixtures of $Sn(SPh)_2(C_5H_4SNO\text{-}O,S)_2$ and $Sn(SePh)_2(C_5H_4SNO\text{-}O,S)_2$.

Crystal structure of $Sn(C_5H_4NS)_4 \cdot C_5H_5NS$, 2

The crystal structure of **2** consists of $Sn(C_5H_4NS)_4$ molecules and pyridine-2-thione molecules. The N—H proton of the thione is hydrogen bonded to an uncoordinated N atom of one of the ligands attached to Sn(IV), with an N(5)—H···N(4) hydrogen bond distance of 1.92(7) Å. There are close nonbonded contacts of 2.71(6) Å between H(5) and H(45), 2.75(7) Å between H(5) and C(45) and 2.935(9) Å between N(4) and N(5). Figure 1 gives a perspective view of the $Sn(C_5H_4NS)_4$ molecule. A view of the lattice thione has been deposited.[6] The bond distances and angles for $Sn(C_5H_4NS)_4$ are given in Table 2. Those for the thione have been deposited.[6]

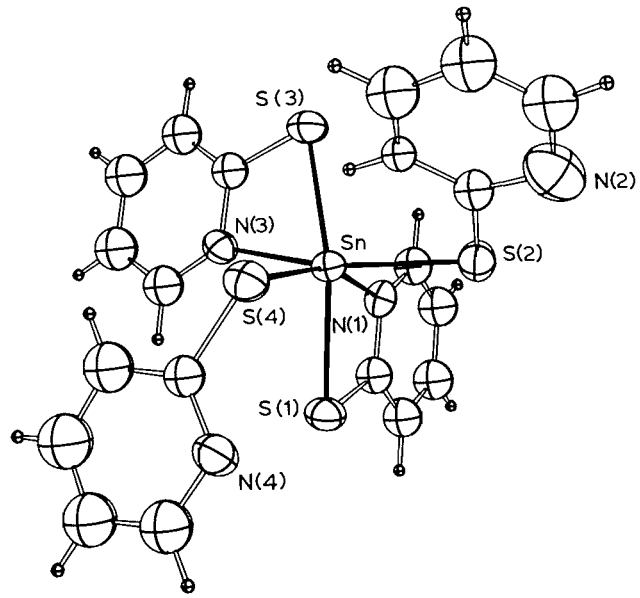

FIG. 1. Perspective view of the molecule $Sn(C_5H_4NS\text{-}S)_2(C_5H_4NS\text{-}N,S)_2$ in **2**.

As can be seen in Fig. 1, the monomeric $Sn(C_5H_4NS)_4$ has highly distorted octahedral coordination about Sn(IV). Of the four $C_5H_4NS^-$ ligands, two are monodentate and S-bonded with the two sulphur atoms in mutually *cis* positions, while the other two are bidentate, coordinating through their N and S atoms such that the two S atoms are *trans* and the two N atoms are *cis*. The configuration of $Sn(C_5H_4NS\text{-}S)_2(C_5H_4NS\text{-}N,S)_2$ is very similar to that reported for $Sn(C_5H_4NS\text{-}N,S)_2Cl_2$, **4** (9).

The Sn—S bond distances are 2.542(2) and 2.483(2) Å for the chelated ligands and 2.475(2) and 2.463(2) Å for the monodentate ligands. The distances from Sn to the S of the monodentate ligands are slightly lower than those of $Sn(SPh)_4$bpy, which are in the range of 2.502(1)–2.497(1) Å (43). In the chelate rings, the Sn—S bond distances are slightly lower than those found in $Sn(S_2CNEt_2)_4$ (32), $Sn(S_2CNMe_2)_4$ (33), or $Sn(S_2COEt)_4$ (35). The Sn—N bond distances (2.332(5) and 2.324(5) Å) and the Sn—S bond distances in the chelate rings are all higher than the corresponding distances observed in **4** and, consistent with these increased bond lengths, the chelate bite angles are 64.2(2) and 65.1(1)° in $Sn(C_5H_4NS)_4$ compared to 66.2(3) and 66.0(3)° in **4**. These differences may be due to either electronegativity differences between the Cl and S donor atoms, or crowding effects of phenyl rings, or both. The C—S bond distances of the coordinated ligands ranges from 1.740(7) to 1.779(7) Å with an average of 1.754(2) Å. For the chelating ligands, the C—S bond distances are shorter than for the monodentate ligands (Table 5). The C—N and C—C bond distances of the ligands are normal and warrant no further discussion.

The angle S(1)—Sn—S(3) between the mutually *trans* sulfur

[11] δ_{Sn} for $(Bu_4N)_2[SnBr_6]$ in CH_2Cl_2 is −2064 at 243 K (38), −2074 ppm at 307 K (39).

[12] The ^{119}Sn resonance of SnI_6^{2-} has not yet been observed (38, 39).

TABLE 5. Bond distances and angles for $Sn(C_5H_4NS\text{-}S)_2(C_5H_4NS\text{-}N,S)_2$ in **2**

C(33)	C(32)	C(31)	117.9(7)	C(34)	C(33)	C(32)	120.9(8)	C(35)	C(34)	C(33)	119.9(8)
C(34)	C(35)	N(3)	120.2(7)	C(41)	S(4)	Sn	101.7(2)	C(45)	N(4)	C(41)	116.9(6)
N(4)	C(41)	S(4)	117.5(5)	C(42)	C(41)	S(4)	119.6(6)	C(42)	C(41)	N(4)	122.9(6)
C(43)	C(42)	C(41)	116.5(8)	C(44)	C(43)	C(42)	122.6(9)	C(45)	C(44)	C(43)	117.2(9)
C(44)	C(45)	N(4)	123.9(8)								

atoms is 148.22(6)°, while the angle N(1)—Sn—N(3) between the mutually *cis* nitrogen atoms is 80.0(2)°. The angles N(1)—Sn—S(3) and N(3)—Sn—S(1) are 91.8(1) and 89.3(1)°, respectively. To our knowledge, *trans* S atoms and *cis* N atoms are a feature of all the other structurally characterized octahedral complexes having two chelated $C_5H_4NS^-$ ligands (6, 8, 44).

Each of the ligands is planar within experimental error. The tin atom is practically in the same plane as three of the ligands, but is out of the plane of one of the monodentate ligands probably due to hydrogen bonding. The Sn—S(4)—C(41)—N(4) and the Sn—S(4)—C(41)—C(42) torsional angles are 94.7(5) and −86.7(6)°, respectively. Between the two bidentate ligands, the interplanar angle is 96.2(2)°. The relative position of these two ligands is very similar to that observed for **4**.

The successful location and refinement of a hydrogen atom 1.04 Å from N(5) of the lattice C_5H_5NS confirms that this species is pyridine-2-thione. The thionic C—S bond distance of 1.667(8) is shorter than the average C—S bond distance (1.754(2) Å) observed here for the ligands attached to Sn(IV) and this can be attributed to multiple bonding occurring in the thione. Overall, the dimensions of C_5H_5NS in **2** are very similar to those found in the pure thione (45), as well as to those of the lattice thione in $[Cu(C_5H_5NS)_4](ClO_4)\cdot 2C_5H_5NS$ (46), and therefore they are not discussed further.

Acknowledgments

This work was made possible by funding from the Natural Sciences and Engineering Research Council of Canada. We are grateful to V. M. Richardson and S. England of this Department for expert technical assistance in obtaining some of the NMR spectra. One of us (J.J.V.) would like to thank Professor N. C. Payne of this Department, for providing the X-ray diffraction and computer facilities and computer programs, as well as for his keen interest and support.

Analysis of the kinetics of the thermal decomposition of pentafluoroethane

VIKTORYA AVIYENTE AND YÜKSEL INEL[1]
Chemistry Department, Bogaziçi University, Bebek 80815, Istanbul, Turkey
Received, July 19, 1989[2]

VIKTORYA AVIYENTE and YÜKSEL INEL. Can. J. Chem. **68**, 1332 (1990).

The thermal decomposition of pentafluoroethane has been studied experimentally over the temperature range 1180–1470 K under 3500 torr pressure by Tschuikow-Roux and co-workers (1). Although the principal process which occurred at around 1200 K was the elimination of hydrogen fluoride, the formation of radicals by carbon–carbon bond scission is suggested at around 1400 K. In this article the C_2HF_5 molecule has been submitted to a treatment in terms of the RRKM theory to test plausible activated complex models and to explain the formation of different products at different temperatures. The hydrogen fluoride elimination reaction is modeled after a four-membered ring for the activated complex whereas two different approaches (Gorin model and the criterion of minimum state density) have been used to explain the C—C bond rupture. In this work it is confirmed satisfactorily by calculation of the rate energy dependences for the different mechanisms that, at around 1200 K, the alkene (C_2F_4) is the dominant product; as the temperature approaches 1400 K carbon–carbon bond rupture becomes feasible.

Key words: RRKM, bond rupture, HF elimination, pyrolysis, rate coefficient.

VIKTORYA AVIYENTE et YÜKSEL INEL. Can. J. Chem. **68**, 1332 (1990).

La décomposition thérmale du pentafluorure d'éthane a été étudiée sous une pression de 3500 torr au laboratoire à des temperatures allant de 1180 à 1470 K par Tschuikow-Roux et ses collaborateurs (1). Le produit principal obtenu dans les conditions mentionnées, C_2F_4. résulte de l'élimination du fluorure d'hydrogène. Des produits secondaires ont aussi été obtenus par la scission de la liaison C—C au fur et à mesure que la temperature augmente. Dans cet article la molecule C_2HF_5 a été soumise à un traitement théorique, RRKM, dans l'intention de tester des modèles pour le complexe activé, formé pendant l'état de transition. La reaction d'élimination du fluorure d'hydrogène est expliquée en se servant d'un cycle à quatre chatnons comme modèle pour l'état de transition; deux modèles différents sont utilisés afin de rationaliser la rupture de la liaison carbonique.

Mot clés : RRKM, rupture de liaison, élimination du fluorure d'hydrogène, pyrolyse, constante de vitesse.

Introduction

The thermal decomposition of simple alkyl fluorides has received considerable attention in the seventies. The experimental investigations have shown that at temperatures where first product formation occurs, the principal mode of decomposition is via molecular elimination of hydrogen fluoride. Data on the experimental thermal decomposition of pentafluoroethane, C_2HF_5, in a single pulse shock tube, over the temperature range 1180–1470 K under 3500 torr pressure has been reported by Tschuikow-Roux *et al.* (1). As is claimed in that article the principal primary process in the pyrolysis of pentafluoroethane is the molecular elimination of hydrogen fluoride

[1] $C_2HF_5 \rightarrow C_2F_4 + HF$

The first order rate constant k_1 is given by

[2] $k_1/s^{-1} = 10^{13.6\pm0.4} \exp(-71.600 \pm 2.400 \text{ kcal mol}^{-1})/2.303RT$

From the knowledge of k_1 it was possible to evaluate the rate constant k_2 for the reaction

[3] $C_2HF_5 \rightarrow CHF_2^{\cdot} + CF_3^{\cdot}$

as

[4] $k_2/s^{-1} = 10^{16.6\pm0.6} \exp(-93.500 \pm 5.200 \text{ kcal mol}^{-1})/2.303RT$

The purpose of our work is to subject the thermal decomposition of C_2HF_5 to a theoretical treatment in terms of RRKM theory with the intent to test plausible activated complex models which would explain the experimental results.

[5a] $C_2HF_5 + M \rightarrow C_2HF_5^* + M \xrightarrow{k_{a1}(E^*)} [C_2HF_5^+] \rightarrow C_2F_4 + HF$

[5b] $C_2HF_5 + M \rightarrow C_2HF_5^* + M \xrightarrow{k_{a2}(E^*)} [C_2HF_5^+] \rightarrow CHF_2^{\cdot} + CF_3^{\cdot}$

First, the hydrogen fluoride elimination reaction is considered using a four-membered ring for the activated complex; next, the C—C bond scission reaction is analyzed. Two different models are employed for the second step. In the first model the activated complex is treated as a decomposing diatomic molecule in which the atoms have the masses of the actual fragments; in the second model the critical configuration has a value of the reaction coordinate such that the density of accessible internal states of the molecule is minimized. The significance of the centrifugal contributions to the loose activated complexes is also discussed.

Computational section

As is already known, to carry out the calculations mentioned above one needs to know the geometries as well as the vibrational frequencies of the energized molecule and the activated complex. In this study it has been assumed that the energized molecule has the same parameters as the molecule itself (2); these are given in Table 1. Besides, the molecule has

TABLE 1. The parameters of pentafluoroethane

Parameter	Value
Vibrational frequencies[a] (cm^{-1})	1218, 1198, 1111, 867, 725, 654, 523, 361, 3008, 217, 1393, 1309, 1145, 577, 413, 1359, 247, 74[b]
Moments of inertia[c] (amu Å^2)	147.86, 211.04, 243.76
Moment of inertia for internal rotation[c] (amu Å^2)	37.05
Symmetry number for internal rotation[d]	3
Collision diameter[e] (Å)	4.39

[a]Reference 2*a*.
[b]This vibrational frequency is included if the molecule is considered a vibrator.
[c]The moments of inertia have been calculated using the molecular structure given in ref. 2*b*.
[d]The symmetry number for internal rotation is taken into account if the molecule is considered a rotor.
[e]Reference 3.

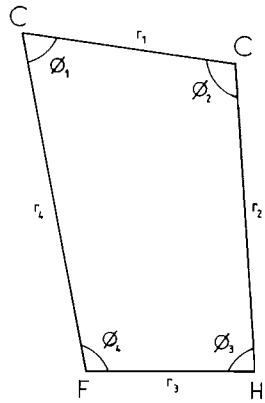

FIG. 1. The transition state for HF elimination.

TABLE 2. The parameters of the activated complex for H—F elimination reaction

Bond orders[a]: 1.5, 0.0259, 0.5, 0.0259
Bond lengths[a] (Å): 1.42, 2.04, 0.9, 2.28
Moments of inertia (amu Å^2): 171.39, 192.90, 341.11
Vibrational frequencies:
(*a*) The out-of-ring vibrational frequencies (cm^{-1}): 1218, 1198, 1111, 725, 654, 361, 1393, 1145, 577, 413, 1359, 523
(*b*) The in-plane ring frequencies (cm^{-1}): 2927, 1062, 484, 211
(*c*) The out-of-plane ring vibrational frequency (cm^{-1}): 50
$\delta = 0.4741$
$\phi_1 = 71°$
$\phi_2 = 101.58°$
$\phi_3 = 86.47°$
$\phi_4 = 100.95°$
Critical energy (kcal mol^{-1}): $E_0 = 70.72$
Entropy of activation (eu) $\Delta S^{\ddagger}_{1400\,K} = -1.94$[c]
$\Delta S^{\ddagger}_{1400\,K} = -1.94$[c]

[a]Bond orders and bond lengths are given in the following order: C—C, C—H, H—F, C—F.
[b]The molecule is treated as a rotor.
[c]The molecule is treated as a vibrator.

been treated as a vibrator as well as a rotor with an internal rotation around the C—C bond to see how this would affect the results. The parameters of the activated complex have been described using semi-empirical relationships.

I. HF elimination

HF elimination from pentafluoroethane is considered the reverse of HF addition to C_2F_4. The transition state for the reaction under consideration is characterized by six parameters. The first four parameters are bond orders of the four bonds involved in the reaction, the fifth parameter is the partial formal charge separation along the breaking bonds, and the sixth parameter is any one of the interior angles of the quadrilateral formed by the interacting bonds. In the model used by Maltman *et al.* (4), it is assumed that if the approach of the reactants is relatively unhindered their intermolecular interaction can be roughly described by the Kihara potential for interaction of linear core systems. The shortest distance between the two breaking bonds is maximized. By applying these principles the partial formal charge separation δ has been calculated to be 0.4741 and the angle ϕ_1 71°. Using the analytical expressions given by these workers the angles ϕ_2, ϕ_3 and ϕ_4 have been evaluated as $\phi_2 = 101.58°$, $\phi_3 = 86.47°$, $\phi_4 = 100.95°$. As seen from Fig. 1, the activated complex does not have any internal rotation, so σ^+, the symmetry number for internal rotation is taken as 1. The vibrational frequencies of the complex have been classified as described below and shown in Table 2.

(1) The out-of-ring vibrational frequencies: These are the C—F stretches and the CF_2 group bendings, a total of 12 frequencies.

(2) The in-plane ring vibrational frequencies: The values of the bond orders for the forming bonds were calculated assuming generalized bond order conservation, i.e., the sum of the transition state bond orders plus the partial formal charge separation equals the sum of the initial bond orders. The description of the transition state geometry was completed using Pauling's rule (5), which correlates bond lengths to bond orders. Finally, the vibrational frequencies were calculated from the partial bonds by means of Badger's rule (6).

(3) The out-of-plane ring vibrational frequency: The out-of-plane ring vibration is separable (by symmetry (7)) from the other ring modes. Its value was treated as an adjustable parameter; it was adjusted to best fit the experimental $\Delta S^{\ddagger}$ value.

II. The C—C bond rupture reaction

The experimentally observed high pre-exponential factor suggests a loose transition state. Two models which satisfy this condition have been used:

1. Model I (Gorin Model)

In this approach the critical configuration is located at the maximum of the potential energy surface separating reactants from products. The reaction coordinate is treated by considering the complex as a decomposing diatomic molecule in which the atoms have the masses of the actual fragments. The distance $\langle R_c \rangle$, the average value of the critical bond length, is large enough to validate the assumption mentioned above, the basic assumption in the Gorin theory (8). $\langle R_c \rangle$ was given by Tschuikow-Roux (9) as

$$[6] \quad \langle R_c \rangle = 1.3092(2a/kT)^{1/6}$$

where a is the constant in the attractive potential energy expression $V = -a/R^6$ and has been calculated by taking into account the electrostatic, inductive, and dispersion contribution from the two radicals. The fragments formed by the dissociation

of the molecule are assumed to have the same geometry and vibrational frequencies as the free radicals. There are five active internal rotational degrees of freedom which include the figure axis rotation plus two doubly degenerate tumblings of the $CHF_2^{\cdot}$ and $CF_3^{\cdot}$ groups about their own axis. The 12 vibrational frequencies of the complex are the frequencies of the $CHF_2^{\cdot}$ and $CF_3^{\cdot}$ radicals as shown in Table 3 (10).

2. Model II (Bunker and Pattengill Model)

The proposal was to locate the critical configuration where the density of states along the reaction coordinate is minimized and to predict that this bottleneck should represent the critical configuration or dividing surface of the RRKM theory (11). In studies where the potential energy of the reaction coordinate is represented by a Morse function, the criterion of minimum state density gives a value of r^+ at the critical configuration less than the value of r^+ at the rotational barrier. In this study where the reaction coordinate is assumed to be the C—C bond extension, $V(r^+)$, the potential energy is given by

$$[7] \quad V(r^+) = D\{1 - \exp[-\beta(r^+ - r_e)]\}^2 + E_z^+ - E_z^m$$

where

$$[8] \quad D = \Delta H^0_0 + E_z^m - E_z^p$$

$$[9] \quad \beta = (f/2D)^{1/2}$$

In [7], [8], [9] ΔH^0_0 is the bond dissociation energy at 0 K, E_z^m is the zero point energy of the reactant molecule, E_z^p is the zero point energy of the radicals produced, and f is the C—C stretching force constant. The rocking motions of the $CF_3^{\cdot}$ and $CHF_2^{\cdot}$ groups lower the frequencies of the molecule according to

$$[10] \quad \nu = \nu_i \exp[-\alpha(r^+ - r_e)] \qquad (i = 1, \ldots 4)$$

where ν_i represents the rocking vibrational frequencies and α is an adjustable parameter. The parameters for this model are given in Table 4.

Results and discussion

Collisions between molecules at a given temperature produce energized molecules with an equilibrium distribution of energy (the Maxwell–Boltzmann distribution which enables the fraction of molecules energized in the range E to $E + \delta E$ to be calculated as

$$[11] \quad K(E)\delta E = \frac{N(E)\exp(-E/kT)\delta E}{Q_2}$$

where $N(E)$ is the density of states of the molecule at energy E and Q_2 is the partition function for active degrees of freedom. On the other hand, the fraction of molecules reacting in the range E to $E + \delta E$ is expressed as

$$[12] \quad \frac{k_a(E)}{k_a(E) + w} K(E)\delta E$$

which under high pressure transforms into

$$[13] \quad \frac{k_a(E)}{w} K(E)\delta E$$

In eqs. [12] and [13] w is the rate constant for the backward reaction of the energized molecule,

$$[14] \quad C_2HF_5^* + M \xrightarrow{w} C_2HF_5 + M$$

Substitution of [11] in [13] will yield the final form for the fraction of molecules reacting in the energy range E to $E + \delta E$:

$$[13] \quad \frac{k_a(E)}{w} \times \frac{N(E)\exp(-E/kT)\delta E}{Q_2}$$

The fact that the ratio of the products formed via paths [5*a*] to [5*b*] is given by the ratio of the microcanonical rate coefficients $k_{a1}(E^*)$ to $k_{a2}(E^*)$ is confirmed when this ratio is evaluated using expression [15]. Figures 2 to 5 tend to rationalize the experimental results by comparing the rate coefficients for HF elimination with the ones for C—C bond breaking reactions. The RRKM calculation was carried out by using the equation

$$[16] \quad k_a(E^*) = L^+ W^+(E^* - E_0)/hN(E^*)$$

in which L^+ is a statistical factor given by $\alpha\sigma/\sigma^+$ (α is the number of optical isomers of the complex and is taken to be 1 for reactions [5*a*] and [5*b*]; σ and σ^+ are the symmetry numbers for the molecule and the complex respectively), W^+ is the sum of the transition state energy levels from 0 to $E^* - E_0$, E_0 is the activation energy.

An explanation of the calculated results has been given in what follows. The average energy a molecule needs to react is given by the classical value as $E_0 + skT$, where s is the number

[b]The molecule is treated as a rotor.

of degrees of freedom. At 1400 K, for HF elimination, this value is around 118 kcal mol^{-1}, whereas for C—C rupture, it is 144 kcal mol^{-1} (Model I) and 132.15 kcal mol^{-1} (Model II), respectively. In Fig. 2 the curves for the rate coefficients versus total energy cross at 116 kcal mol^{-1}. At this point, the rate for reaction [5*b*] starts to overcome the rate for reaction [5*a*]; although molecules would prefer to give products with low activation energy, the microcanonical rate constants favor radical formation so that products from both channels are observed. At 1200 K (Fig. 3) the crossing point at 113 kcal mol^{-1}. Under these conditions, the average energy possessed by molecules undergoing HF elimination is also 113 kcal mol^{-1}. When the rate coefficient for reaction [5*b*] starts to dominate, the excited molecules will already have reacted producing the alkene and HF. The contribution of the centrifugal effects to the rate coefficients supports the experimental results quite well. At 1400 K, the crossing point shifts to 110 kcal mol^{-1} (Fig. 4), at 1200 K it shifts to 109 kcal mol^{-1} (Fig. 5) so that C—C cleavage is observed only at high temperatures. The Waage–Rabinovitch approximation which has been used for this purpose has the form

$$[17] \quad k'_a(E^*) = k_a(E^*)/F$$

and

$$[18] \quad F = \{1 + [s + (r/2) - 1](I^+/I - 1)RT/(E_0 + a'E_z)\}^{-1}$$

where $k'_a(E^*)$ is the corrected rate coefficient, s and r are the number of active vibrational and rotational degrees of freedom, I^+ and I are the moments of inertia of the complex and the molecule, respectively, E_z is the zero point energy of the molecule, and a' is a parameter which can be calculated from the properties of the molecule. Table 5 compares the average experimental and calculated values for the unimolecular rate constants at high pressures. Consideration of these values favors Model II over Model I for the C—C bond rupture reaction. This is in agreement with Hase's proposal (11) which suggests that the unimolecular rate is overestimated by Gorin since the energized reactant molecules and critical configurations are not in kinematic equilibrium.

Another minor contribution of this work was the decision on whether the molecule should be treated as a rotor or as a vibrator. The entropy of activation was found experimentally to be $\Delta S^{\ddagger}_{1400\,K} = -1.37 \pm 1.8$ eu for HF elimination and $\Delta S^{\ddagger}_{1400\,K} = 12.35 \pm 2.8$ eu for C—C bond rupture reaction. These values support the treatment of the molecule as a vibrator when compared with the calculated results in Tables 2, 3, and 4.

Our future objective is to use Model II together with variational RRKM theory (14) to rationalize the experimental results for other fluoroethanes.

Polycarboxylate diaza crown ethers derived from *R,R*-(+)-tartaric acid: synthesis and complexation of metal ions

ASHOK ANANTANARAYAN AND THOMAS M. FYLES

Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received November 21, 1989

ASHOK ANANTANARAYAN and THOMAS M. FYLES. Can. J. Chem. **68**, 1338 (1990).

The synthesis and complexation properties of polycarboxylate diaza crown ethers based on *R,R*-(+)-tartaric acid are described. Cesium carbonate mediated macrocyclization of a bis-tosylamide precursor with a bis-tosylate precursor provided the protected crown ethers. Photochemical deprotection of the tosylamides and hydrolysis of the carboxamides yielded dicarboxylic and tetracarboxylic acid derivatives of 1,10-diaza-18-crown-6. *N*-Methylenecarboxylate (*N*-acetate) derivatives were prepared by *N*-alkylation with bromoacetic acid. The synthetic and purification procedures developed provide samples of the ligands in a metal-free form. Acidity and stability constants for complexation of alkali metal, alkaline earth, late- and post-transition metal cations were determined by potentiometric titration. The ligands form complexes which show enhancement of stability by charge–charge and chelate interaction with the carboxylates. In comparison with crown ether polycarboxylates these aza crown ethers showed a selectivity for softer metal ions relative to alkali and alkaline earth metal ions. *N*-Methylenecarboxylate chelate ligands were found to bind almost all types of metal ions, due to a highly co-operative array of charge–charge, chelate and crown ether interactions.

Key words: aza crown ether synthesis, tartaric acid, potentiometric titration, cation complexation, aminocarboxylate complexone.

ASHOK ANANTANARAYAN et THOMAS M. FYLES. Can. J. Chem. **68**, 1338 (1990).

On décrit la synthèse et les propriétés de complexation d'éthers couronnes diaza polycarboxyliques préparées à partir de l'acide *R,R*-(+)-tartrique. Le carbonate de césium permet de réaliser une macrocyclisation d'un précurseur bis-tosylamide avec un autre précurseur bis-tosylate et d'obtenir des éthers couronnes protégés. La déprotection photochimique des tosylamides et l'hydrolyse des carboxamides fournit les dérivés dicarboxylique et tétracarboxylique de la 1,10-diaza-18-couronne-6. On a préparé des dérivés *N*-méthylènecarboxylates (*N*-acétates) par le biais d'une *N*-alkylation avec de l'acide bromoacétique. Les méthodes de synthèse et de purification développées fournissent des échantillons des ligands qui sont exempts de métal. Faisant appel à une titration potentiométrique, on a déterminé l'acidité et les constantes de stabilité pour la complexation des cations des métaux alcalins, alcalino-terreux ainsi que des métaux de la fin de (ou qui suivent) la période de transition. Les ligands forment des complexes qui présentent une augmentation de la stabilité par des interactions charge–charge et de chélate avec les groupements carboxylates. Par comparaison avec les éthers couronnes portant des groupements carboxylates, les éthers couronnes diaza présentent une sélectivité pour les ions des métaux mous par rapport aux ions des métaux alcalins ou alcalino-terreux. On a trouvé que les ligands chélates *N*-méthylènecarboxylates se lient à pratiquement tous les types d'ions métalliques; cette caractéristique est due à un arrangement très coopératif d'interactions charge–charge, de chélate et d'éthers couronnes.

Mots clés : synthèse d'éthers couronnes aza, acide tartrique, titration potentiométrique, complexation des cations, complexion par un aminopolycarboxylate.

[Traduit par la revue]

Metal ion recognition by synthetic and naturally occurring ligands is a complex process involving a cooperative match of the complementary properties of the host and the guest. A key factor in the design of new ligands with unique complexation behaviors is the choice of ligand donor sites (1). Within a class of ligands, such as the crown ethers or cryptands, clear changes in selectivity of cation binding are provoked by substitution of the oxygen donors of a parent ring system for nitrogen or sulfur donor sites (2). Such substitutions alter the primary character of the donor (Lewis basicity) as well as the geometrical and conformational properties of the ligand (3). Thus in a system involving highly cooperative binding interactions, donor atom substitution can profoundly influence binding selectivity.

Our interest in ligand design has centered on crown ethers derived from *R,R*-(+)-tartaric acid: the di-, tetra-, and hexa-acids illustrated at the top of Fig. 1 (4–6). The tartarate derived units impart rigidity to the ligands, leading to well defined conformations, and the carboxylates, when ionized, provide a strong electrostatic field which greatly enhances complex stability for alkali metal and alkaline earth cations. Despite the favorable Coulombic interactions, binding of heavy metal cations occurs only to a limited extent due to a mismatch of the hard oxygen donor set and the softer guest cations (6). An obvious ligand modification which might lead to stabilized crown ether type complexes of heavier cations would be the substitution of some of the donor atoms for N or S. We have previously reported dithia crown ethers bearing four carboxylates (7); the purpose of this report is to describe the chemistry of the diaza polycarboxylate crown ethers illustrated in the lower part of Fig. 1. The ligands are derivatives of 1,10-diaza-18-crown-6 (**2.2**); the trivial names assigned (6) reflect the parent crown ether and the number of carboxylic acid groups from tartaric acid ($\mathbf{A_n}$) and *N*-methylene acetic acid units ($\mathbf{D_n}$).

The synthesis of aza crown ethers has been recently reviewed (8, 9) and the core methods have been successfully exploited by many groups. Of the two "classic" approaches, macrocyclization of a diamine with a diacid chloride to give a diamide which is reduced to the amine (10) was not suitable due to the presence of other reducible groups. The other "classic" route due to Richman and Atkins involves cyclization of a bis-tosylamide precursor with a suitable bis-alkylating agent (11). We have previously used a related approach to prepare dithia polycarboxylate crown ethers (7) following the procedure of Kellogg and co-workers in the use of cesium carbonate to generate a nucleophile (12). These workers also report the use of the same base system for the synthesis of protected diaza

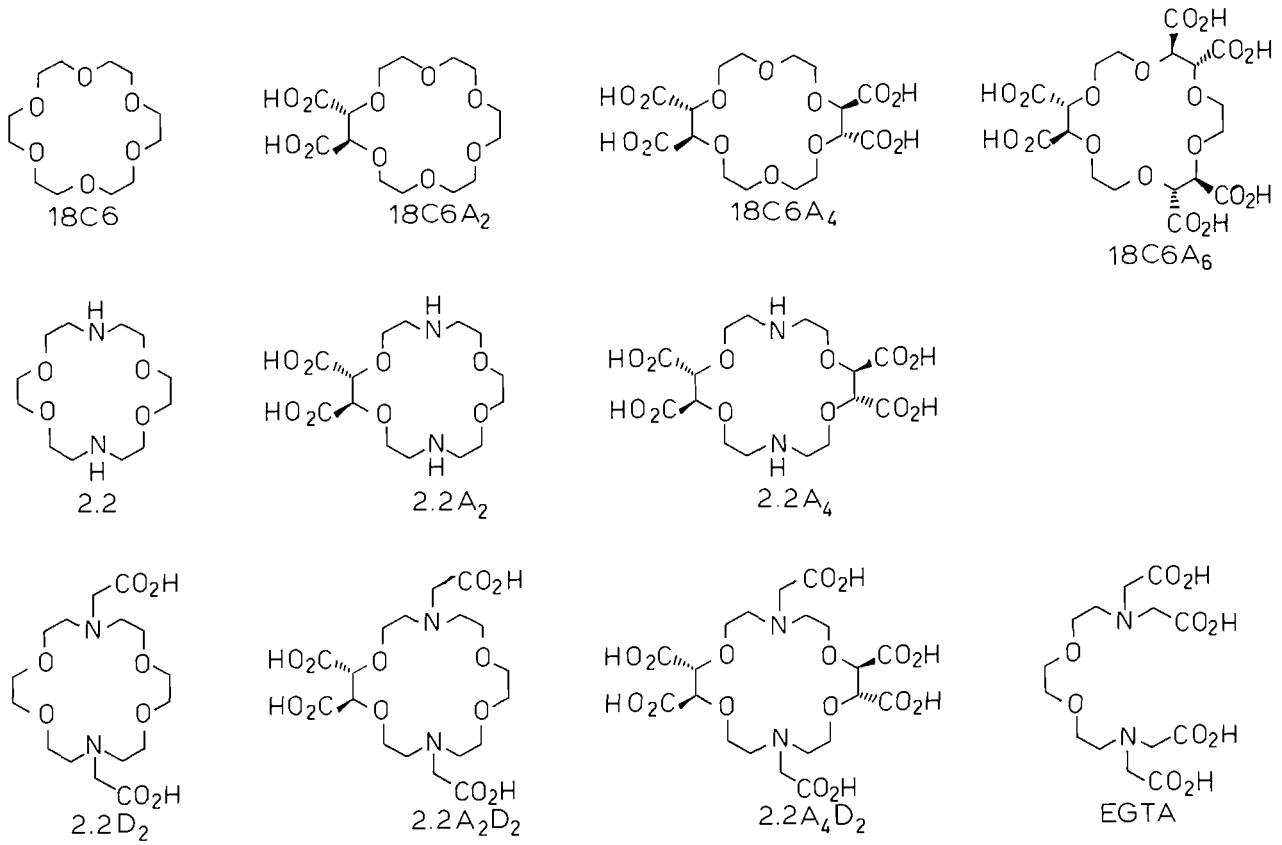

FIG. 1. Structures of oxa and aza crown ethers derived from tartaric acid showing incremental structural variations. Names are derived from 18-crown-6 (**18C6**) or 1,10-diaza-18-crown-6 (**2.2**) by addition of carboxylic acid units from tartaric acid ($\mathbf{A_n}$) (4–6), or *N*-methylene acetic acid ($\mathbf{D_n}$).

macrocycles (13, 14). A recent report provides further evidence of the general utility of the Kellogg modified Richman–Atkins cyclization using a metal carbonate as the base (15).

Despite all this excellent precedent, the synthesis of these ligands presented an additional challenge in that the neutral forms illustrated in Fig. 1 cannot exist at any pH. Zwitterionic and multiply charged forms of these amino acids ensure that they will be water soluble at all pH values, will resist extraction into organic solvents, and will bind to conventional chromatographic supports. Moreover, we expected that the ligands would show some affinity for most types of cations. The situation is exacerbated for the *N*-methylene carboxylates **2.2A$_2$D$_2$** and **2.2A$_4$D$_2$** as most procedures for the direct production of related complexones such as EDTA give the product in a vast excess of salt (16). For EDTA, the excess of NaCl may be ignored as the stability constant for complexation of Na^+ is only $50\,M^{-1}$ (16). This is negligibly small for many applications of the ligand and does not impede crystallization of the metal free ligand or a complexed form (17).

The diaza polycarboxylate crown ethers bear superficial similarity to aminopolycarboxylate complexones, particularly EGTA (Fig. 1). The ligands share a similar set of donors and bear similar negative charges in basic solution. At least one of the parent ligands, **2.2D$_2$**, is capable of achieving a chelate geometry similar to that found in simple aminopolycarboxylate complexones. The crystal structures of two copper complexes of **2.2D$_2$** (18–20) show encapsulated Cu^{2+} held in a geometry similar to a glycinate or EDTA complex. The ligand is relatively undistorted and the majority of the torsion angles are close to normal values for crown ether complexes. Moreover, the units which would be occupied by carboxylates from the tartaric acid residues are in open positions about the complex. The steric demands might therefore be modest. Unfortunately, all attempts to crystallize the aza crowns of Fig. 1 or their metal ion complexes have so far been fruitless. This report therefore examines the complexation chemistry of the ligands in solution only from the perspective of stability constants.

Results and discussion

Ligand synthesis

Our synthetic approach based on macrocyclization of a bis-sulfonamide is outlined in Fig. 3; the synthesis of the required precursors is sketched in Fig. 2. The diol **3** and the bis-toluenesulfonate **4** were prepared for related syntheses (7) via thallous ethoxide mediated alkylation of **1** followed by hydrolysis of the bis-tetrahydropyranyl ether **2**. A somewhat simplified procedure suitable for large scale is given in the Experimental section. The bis-toluenesulfonate **4** was converted into the bis-phthalimide derivative **5** in 92% purified yield, and was then subjected to hydrazinolysis to obtain the crude diamine **6** in 70% yield as a yellow oil. Attempted purification by distillation or salt formation was not successful and hence **6** was used as such for the next step. The bis-sulfonamide **7** was obtained as a white solid in 75% yield from **6** using a modified Schotten–Baumann technique.

Although the average yield per step was high, the overall

yield was not. It was thus desirable to explore other shorter routes leading to **7**. Direct conversion of **4** to **7** using *p*-toluenesulfonamide salts was unfortunately not feasible. A model study using octyl bromide as the alkylating agent showed that dialkylation was a major reaction pathway. Subsequently, other workers have reported a macrocyclization method based on bis-alkylation of *p*-toluenesulfonamide (21); we did not observe any **8** in our attempts to convert **4** directly to **7**. A more direct route leading to **7** directly from **1** using tosylaziridine (22) was similarly unsuccessful. Tosylaziridine polymerized under strongly basic conditions (the dianion of **1**) and was unreactive under neutral conditions (**1** alone).

Figure 3 sketches the macrocyclization reactions leading to protected crown ethers **8**, **10**, and **12**. The macrocyclization was performed using cesium carbonate according to the method of Vriesema *et al.* (13), at a concentration of 0.05 M in the sulfonamide **7** with excess solid cesium carbonate. The bis-toluenesulfonate (**3** or **9** (23)) was added over 2–3 h and the reaction was essentially complete in 12–15 h at room temperature. The crown ether products had a high affinity for alumina, hence chromatographic losses were sometimes high. Deactivated alumina (Brockmann III) gave consistent results; overall yields of purified product from the cyclization were 75% on average. As Fig. 3 also shows, K_2CO_3 could be substituted for Cs_2CO_3 in the synthesis of **12** from **9** and **11** (11), with no significant loss in yield. K_2CO_3, however, requires a higher temperature (40–50°C) in keeping with its lower solubility in DMF (14, 15).

In principle, hydrolysis of **8** and **10** should lead to the parent aza crown ethers $\mathbf{2.2A_4}$ and $\mathbf{2.2A_2}$ respectively. The sulfonamides are, however, known to require vigorous conditions for their removal (11). As expected, hydrochloric acid was found to be insufficient. The tetraacid **17** was, however, obtained in good yield (Fig. 4). Prolonged reflux in HCl was of no avail; the

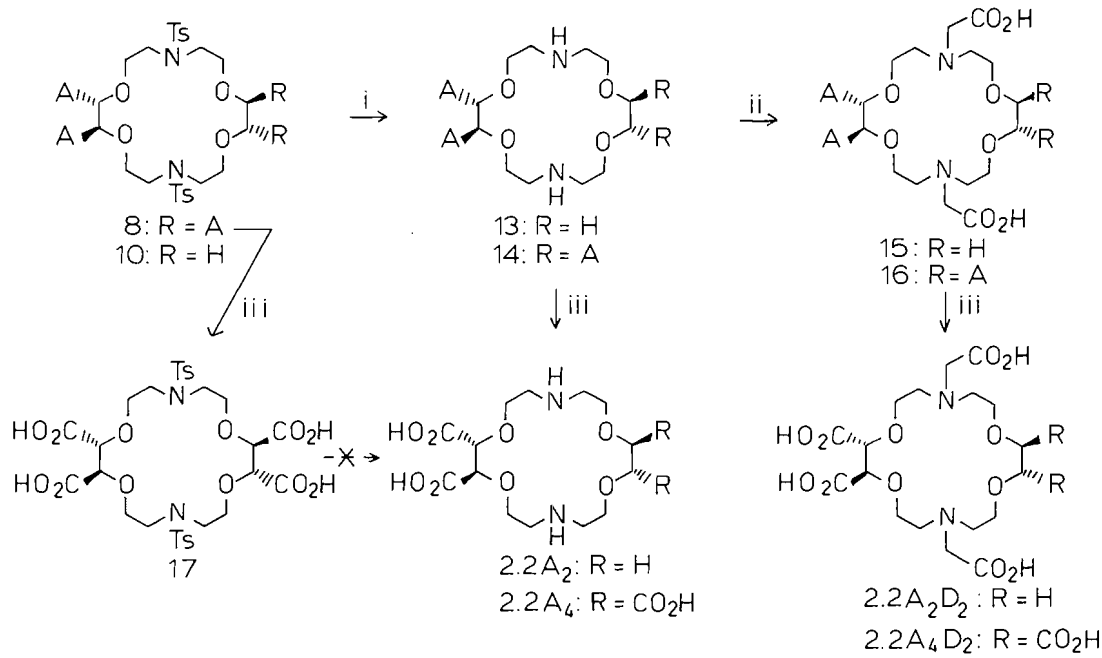

FIG. 4. Deprotections and *N*-alkylation of aza crown ether carboxylic acids. Conditions: (*i*) hν/dimethoxybenzene/hydrazine; (*ii*) HO_2CCH_2Br/Li_2CO_3; (*iii*) H_3O^+ (see text). Abbreviations as in Fig. 2.

tetraacid was recovered unchanged. Concentrated H_2SO_4 (11) at 100°C completely charred the reaction mixture, and no organic product could be isolated. HBr/AcOH/phenol (24) is the other common reagent for sulfonamide cleavage; some diethanolamine (from crown ether cleavage) and phenol (from the reagent) were the only products isolated from an attempt to deprotect **8**.

Lithium aluminum hydride is reported to be an effective reagent for sulfonamide removal (25), but it is inappropriate for **8** or **10** as the carboxamides would undergo reduction as well. Dissolving metal reductions using sodium amalgam (15, 21, 26), or Li or Ca (21) in liquid ammonia, are other reductive cleavage reagents. Since carboxylates are known to be relatively resistant to dissolving metal reductions, the tetraacid **17** was chosen as the starting material. Reductive methods typically require a large excess of metal to be used. For the tetraacid **17**, the first four equivalents form the tetra-salt, hence stoichiometry required at least 8 equiv. of metal. On workup, the ^1H NMR of an aqueous extract showed that the crown ether **2.2A$_4$** was indeed present. However, separation of the charged, water soluble crown ether from an eight-fold excess of salt (Li^+ or Ca^{2+}), to obtain "metal free" ligands, proved to be impossible. Attempted precipitation of Ca^{2+} with oxalate or carbonate was not successful, probably due to binding of Ca^{2+} by the ligand. Similarly, direct crystallization of the product was not possible. Ion exchange chromatography also did not succeed as the ligand could not be recovered from the resin.

Direct photochemical deprotection of arylsulfonamides is known (27), but the low reported yields give the reaction little practical unity. Attempted photolysis of **8** at 254 nm as a dilute solution in isopropanol produced the deprotected crown tetraamide **14** in poor yields (<25%) as a mixture that was difficult to separate. An improved photochemical procedure, exploiting the photosensitized electron transfer reactions of arylsulfonamides (28), finally achieved the required cleavage and left a product which could be purified. In our hands the most successful conditions utilized a ten-fold molar excess of *p*-dimethoxybenzene as sensitizer and hydrazine as the reducing agent. The crude diamines were purified to ^1H NMR "purity" by a tedious sequence of extractions and ion exchange chromatography.

The carboxamides of **13** and **14** are readily hydrolyzed in aqueous acids to give the desired crown ethers in an excess of dimethylammonium salt. In order to separate the crown ether from this inevitable byproduct, it was most convenient to manipulate a mixture of salts which was soluble in organic solvent. To this end, hydrolysis of the carboxamides (**13** or **14**) was achieved using a stoichiometric amount of *p*-toluenesulfonic acid in water. The reaction mixture was evaporated to dryness, dissolved in chloroform/methanol (1:1), and chromatographed using Sephadex LH-20. Fractions were collected and analyzed by ^{13}C NMR; the crown ethers **2.2A$_2$** or **2.2A$_4$** eluted near the void volume as their bis-toluenesulfonate salts. These were further purified by re-chromatography using a small amount of additional *p*-toluenesulfonic acid to ensure complete protonation of the ligands.

The ^{13}C NMR spectra of **2.2A$_4$** showed a pH dependence whereby "extra" resonances appeared at intermediate pH (3–6). At the extremes of pH (2 or 12), the expected four line spectra were observed for the ligand (plus signals for the counterion). The purified samples had the expected spectral properties (^1H and ^{13}C NMR, IR) but resisted reproducible elemental analysis. No constant level of hydration could be achieved, and the anhydrous samples were extremely moisture sensitive. The homogeneity of the anhydrous ligands was established by potentiometric titration using the pronounced end-point between pH 5 and 8 to indicate the formation of the bis-zwitterion (addition of base; 2 equiv. for **2.2A$_2$** and 4 equiv. for **2.2A$_4$**). In both cases the calculated equivalent weights were within 2% of the expectation values.

Reagents for the introduction of N—CH_2CO_2H side chains on amines are haloacetic acids (17) or their esters (29). Ethyl bromoacetate could not be used as the alkylating agent, probably due to competing amination of the esters. Alkylation

of crown ether **2.2A$_2$** or **2.2A$_4$** with bromoacetic acid in a buffered medium gave the expected alkylated product as judged by ^{13}C NMR. As before, the large excess of buffer required (either as alkali metal carbonate or tertiary ammonium chloride) made separation of the crown ether from the reaction mixture an extremely difficult task. Ultimately, bromoacetic acid in stoichiometric aqueous Li_2CO_3 proved to be the reagent of choice. The intermediate amides **15** and **16** were not purified, but were directly hydrolysed with stoichiometric amounts of *p*-toluenesulfonic acid to give samples of the N—CH_2CO_2H derivatives in excess lithium toluenesulfonate. Repeated gel permeation chromatography on LH20 as before gave **2.2A$_2$D$_2$** and **2.2A$_4$D$_2$** (as water soluble deliquescent solids) in 55–60% yields as their *p*-toluenesulfonate salts. An elemental analysis of **2.2A$_2$D$_2$** dihydrate was obtained and the same sample showed the expected equivalent weight. Alternatively, an anhydrous sample gave the expected equivalent weight. However, despite extensive gel permeation, **2.2A$_4$D$_2$** failed to give a satisfactory titrimetric equivalent weight. The presence of a substoichiometric amount of Li^+ was determined by atomic absorbance measurement. Presumably a lithium complex is formed which resists the separation as a lithium toluenesulfonate salt during chromatography. Consequently, the structure proof for **2.2A$_4$D$_2$** rests entirely on the spectra obtained. Unfortunately, our inability to purify this ligand has prevented the successful determination of acidity and stability constants for complexation.

Complexation of cations

Complex formation in solution can be described in terms of a cumulative formation constant β_{lmh} defined by the equilibrium between l ligands of charge $z-$, m cations of charge $y+$, and h protons (reaction [1])

$$[1]\quad lL^{z-} + mM^{y+} + hH^+ \rightleftharpoons lL^{z-}mM^{y+}hH^+$$

$$[2]\quad \beta_{lmh} = \frac{[lL^{z-}mM^{y+}hH^+]}{[L^{z-}]^l[M^{y+}]^m[H^+]^h}$$

Since ligand and complex activity coefficients are unknown, the β_{lmh} values are typically defined in terms of concentrations. The errors introduced are minimized by the use of a constant ionic strength, low ligand concentration, and corrections to the calibration of the pH electrode (below). Stepwise formation constants as would apply to the association of a partly protonated ligand with a metal ion can be derived from the β_{lmh} for the system (4, 6).

To render the cumulative formation constants entirely in terms of concentrations, it is necessary to convert from the pH meter reading (pH_m) to the concentration of H^+ (pC_{H^+}). A linear relationship is assumed (30–34):

$$[3]\quad pH_m = (s)^*(pC_{H^+}) + b$$

where "s" is a slope, typically very close to 1 and "b" an intercept. Both parameters, and the effective value of pK_w for the supporting electrolyte can be determined from a strong acid – strong base titration. We follow the procedure of Jameson and Wilson in the definitions (34),

$$[4]\quad \log K_w = (pH_{m1} + pC_{HO^-}) + pC_{H^+} - pH_{m2}$$

where pH_{m1} refers to the pH meter reading in the alkaline region and pH_{m2} to the pH meter reading in the acidic region of a strong acid/strong base titration. At every point in the titration, it is possible to calculate stoichiometric H^+ and HO^- concentrations corrected for dilution. In the strong acid buffer region (up to pH 2.5) the average value of $pC_{H^+} - pH_{m2}$ is $-b$. In the strong base buffer (>pH 11.5) an average value for $pH_{m1} + pC_{HO^-}$ when added to $-b$ gives $-pK_w$. The measured pH_m can thus be used to calculate the hydrogen ion concentration and using these values, the β values obtained will be true concentration constants containing no activity terms. The thermodynamic values may be obtained by calculating an activity correction using a modified Debye–Huckel expression (35, 36).

General trends

Table 1 presents the acidity and stability constant data for the ligands. The numbers tabulated are all cumulative constants; stepwise formation constants for the association of the metal ion with partially protonated forms of the ligand are given in parentheses. The values of l, m, and h serve to define the complex stoichiometry. The value of $h = -1$ indicates an hydroxo complex (see below). The value of r in square brackets is a "goodness-of-fit" parameter derived from the standard deviation in titer given by the program (37) divided by the experimental titer increment (usually 3 μL to give 18 points per equivalent of ligand titrated). Table 2 gives an abbreviated summary of the primary (β_{110}) complexes of the ligands, together with data on other ligands for comparison purposes.

The acidity constants follow expected trends consistent with the basic protonations occurring on nitrogen, and the acidic protonations occurring on carboxylate oxygen. As the ligands become progressively more negatively charged, the amines become more basic. For example, in the case of **2.2A$_2$**, the amines are deprotonated from a species that has a formal charge of −2. Compared to **2.2**, this causes a +0.3 increment in the first pK_a. The increment can be seen for the second amino group as well. The amino groups of **2.2A$_2$D$_2$** are less basic than **2.2A$_4$**, although both are tetraanionic ligands. This trend is in line with expectations, since the nitrogen on **2.2A$_2$D$_2$** is tertiary.

Most of the carboxylic acid groups in these ligands are strongly acidic (6). Only one weakly acidic carboxyl ($pK_a > 3$) was detected in every case. The other carboxyls were all more strongly acidic (<2.5) and outside the range of the pH-metric technique. These values are again in the expected range, compared for example with EGTA or **18C6A$_4$**.

An inspection of the data for the aza ligands with Group I or II cations reveals that they are quite unselective. For example, the Na^+, K^+, and Cs^+ complexes of **2.2A$_4$** have stability constants around $\log \beta = 3$. Thus metal ion size makes little difference in stability. As noted previously the "cation size – ligand cavity match" concept holds less well for charged oxa crown ethers (6), and this is confirmed in the aza series. Although larger and more polarizable ions like Cs^+ should be favored by the nitrogen donors, this effect is probably overwhelmed by the electrostatic effects.

The role of the nitrogen donors is more clearly seen in the complexes of the transition metal ions, Cd^{2+} and Pb^{2+}. Even with the neutral parent **2.2**, these ions form stronger complexes than do the harder alkali metals, and this tendency is retained and enhanced as the ligand charge increases. The ligand selectivities do not change in order (apparently the Irving–Williams order for the limited set available), nor in magnitude as the ligand charge increases. Along the sequence **2.2**, **2.2A$_2$**, **2.2A$_4$** the complex stability does increase in a regular manner.

Electrostatic ion binding and chelate interactions

One of the rationales for this study was the expectation that an anionic ligand environment would act to stabilize the

complexes. A number of points bear out this expectation. Firstly, divalent and trivalent ions are bound more strongly than monovalent ions. Secondly, the complexes of the fully deprotonated ligands with divalent ions show a regular increase in stability with increasing charge. For example, the Ca^{2+}, Cd^{2+}, and Cu^{2+} triad all experience 10^2–10^3 fold enhancement in stability for every two carboxylates added. Trivalent metal ions, like La^{3+}, experience an even larger increase (10^4) for every two additional carboxylates. Thirdly, most complexes undergo significant destabilization on ligand protonation. This effect was also observed in the oxa series, as were complexes of multiply protonated ligands (6). No diprotonated complexes were detected in the aza series.

There are two structural possibilities for the monoprotonated aza crown complexes; (*1*) *N* protonation, with loss of a donor site and creation of a positive charge in the macrocyclic binding site, or (*2*) carboxylate protonation with loss of remote electrostatic stabilization only. The latter possibility is supported by similar magnitudes of destabilization for the oxa and aza series: **2.2A$_2$** and **2.2A$_4$** with alkaline earth cations destabilized by log β_{110} − log β_{111} = 1.31 on average compared with 1.35 for the same cations and **18C6A$_2$**, **18C6A$_4$**, and **18C6A$_6$** (Table 2). In addition, the parent crown ethers **2.2** and **2.2D$_2$**, which lack these extra carboxylates, do not show protonated complexes.

To an extent therefore, the expectation of electrostatic stabilization appears to be fulfilled. However, there are a number of other features of the data that argue for an insignificant role for the ligand charge *per se*. Chief among these is the substantial difference in stability between **2.2A$_4$** and **2.2A$_2$D$_2$**; the divalent ion complexes of the latter are on average a thousand-fold more stable than the former yet the overall charges are identical (4−). The differences are even more pronounced for the 2− charged ligands **2.2A$_2$** and **2.2D$_2$** (4.7 in log β). Furthermore, there is a relatively modest difference between the divalent ion complexes of **2.2D$_2$** and **2.2A$_2$D$_2$** (1.3 in log β for an increase in charge from 2− to 4− compared with 2.1 in log β for the same ions and charge increment in the oxa series). There can be little doubt that a chelate interaction involving the *N*-acetate unit (N—CH_2—CO_2^-) is much more stabilizing than a remote charge, or an equivalent interaction involving a O—CH—CO_2^- unit. From the difference in log β for **2.2A$_2$** and **2.2D$_2$** (averaged over divalent ions) this stabilization can be estimated to be of the order of 20 kJ per chelate interaction at constant charge. Viewed from another perspective, introduction of two charges to **2.2** to generate **2.2A$_2$** gives a stabilization of the order of 8 kJ per charge, while the introduction of two *N*-acetates to **2.2** to generate **2.2D$_2$** gives a stabilization of 25 kJ per chelate and charge introduced. Either way the *N*-acetates bring substantial stability to the complexes of divalent ions. The same is apparently true for Tl^+, but not for the alkali metals.

We have previously analyzed the data for the oxa series to show that carboxylate participation in a chelate interaction is a recurring feature of the complexation process. A similar treatment of the data for the aza crown ether series yields substantially the same conclusions. The method involves a division of the complexation free energy into a "crown ether" part plus an electrostatic part which is scaled by the extent of protonation of the ligand (6, 39). In terms of log β values,

$$[5]\quad (\log \beta_{obs})^2 = (\log \beta_C)^2 + 2\Phi \log \beta_C \log \beta_E + (\Phi \log \beta_E)^2$$

where log β_{obs} is the formation constant for the complex, log β_C is the formation constant for a neutral reference compound (**2.2** in this case), and Φ is the scaling factor which takes values from zero for a neutral ligand form to 1 for a maximally deprotonated form. The unknown in [5] is log β_E, the electrostatic component of the binding. The three terms on the right hand side of [5] are proportional to the interaction of the macrocycle alone, the cooperative or chelating interaction of the carboxylates acting on a cation in the macrocycle and the purely electrostatic interaction, respectively. Expressed as percentages, the three terms describe the apparent cooperativity of the binding. The results are given in Table 3. In all cases, and as found in the oxa series as well, about 40–50% of the interaction energy can be ascribed to cooperative or chelating interactions. The donors are both tartro and *N*-acetate derived, yet this distinction cannot be found in the data. This implies that the ion binding process ignores whether the donor comes from the tartro units or the *N*-acetates.

Cooperative chelate interactions are also a dominant feature in the solid state chemistry of the oxa crown ethers (38), and can be seen in the published structures of **2.2D$_2$** copper complexes (18–20). We are therefore tempted to ascribe the energy differences noted above to the difference between five-membered chelate rings containing O vs. N as donors in the unit X—C—CO_2^-.

In summary, a generalized electrostatic effect is of minor importance in these crown ethers. The more important interactions are chelation of the ion, presumably located within the macrocyclic cavity, by donor carboxylates appended to the periphery. The tartro units provide one mode of coordination, while the *N*-acetates provide a more effective mode.

Hydroxo complexes

Many of the metals studied have important hydroxo complexes in alkaline media and the hydroxide ion is thus a competing ligand. On the other hand, cationic hydroxo complexes (e.g. $NiOH^+$) can still bind with the ligands of this study (Table 1). The complexes thus formed can be described as a sum of formation equilibria [6] and [7] (where the subscript −1 refers to addition of one OH^-):

[6] $MOH^+ \rightleftharpoons M^{2+} + HO^-$ $\quad 1/\beta_{01\text{-}1}$

[7] $L + M^{2+} + OH^- \rightleftharpoons LMOH^+$ $\quad \beta_{11\text{-}1}$

The reaction of interest is the stepwise association of the metal hydroxide with the ligand,

[8] $MOH^+ + L \rightleftharpoons LMOH^+$

whence the stepwise log K for the LMOH complex would be given by log $\beta_{11\text{-}1}$ − log $\beta_{01\text{-}1}$.

A few such complexes were detected, especially with ligands of lower charge and lower donor number (**2.2A$_2$**) (Table 1). A striking feature regarding these complexes is that they are almost as stable as, or in some cases more stable than, the primary 110 complexes. In the case of Group II complexes with **2.2A$_2$**, the $\beta_{11\text{-}1}$ complexes are more stable than the β_{110} complexes by a factor of 10^3. Alkaline earth cations are expected to bind weakly to the nitrogen and strongly to a hard ligating site. Addition of hydroxide would provide an additional

[a]%CE = crown ether alone; %CO = co-operative interaction, %EL = electrostatics alone; calculated using **2.2** as a reference point.

[b]—, inappropriate, since the protonated complex is less stable compared to the parent crown **2.2**.

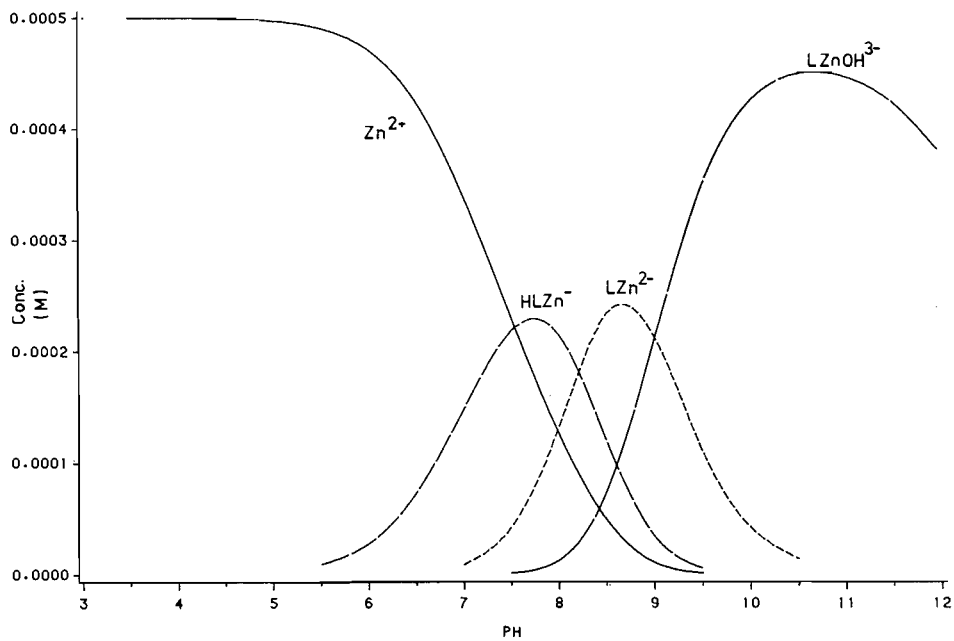

FIG. 5. Species concentration as a function of pH calculated for an equimolar mixture of Zn^{2+} and **2.2A$_4$** at 5×10^{-4} M.

hard donor, while maintaining a potentially high coordination number. In the higher charged ligands (**2.2A$_4$**) the statistical factor (four carboxylate donors) and the high charge acts to displace the hydroxide. Very few hydroxo complexes were detected in this case. Similarly in the case of **2.2A$_2$D$_2$**, the strong chelate donors completely prevent hydroxide ligation.

Speciation plots for **2.2A$_4$** in the presence of an equivalent of zinc are shown in Fig. 5. The binding occurs in the alkaline regions (pH > 7) as can be seen by a sharp drop in free Zn^{2+} concentration. Both the "primary" complex of the deprotonated ligand and the monoprotonated complex play a relatively minor role in the solution compared to the dominant role played by the hydroxo complex. Similar hydroxo complexes of aminopolycarboxylate complexones are known (16), but they

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12

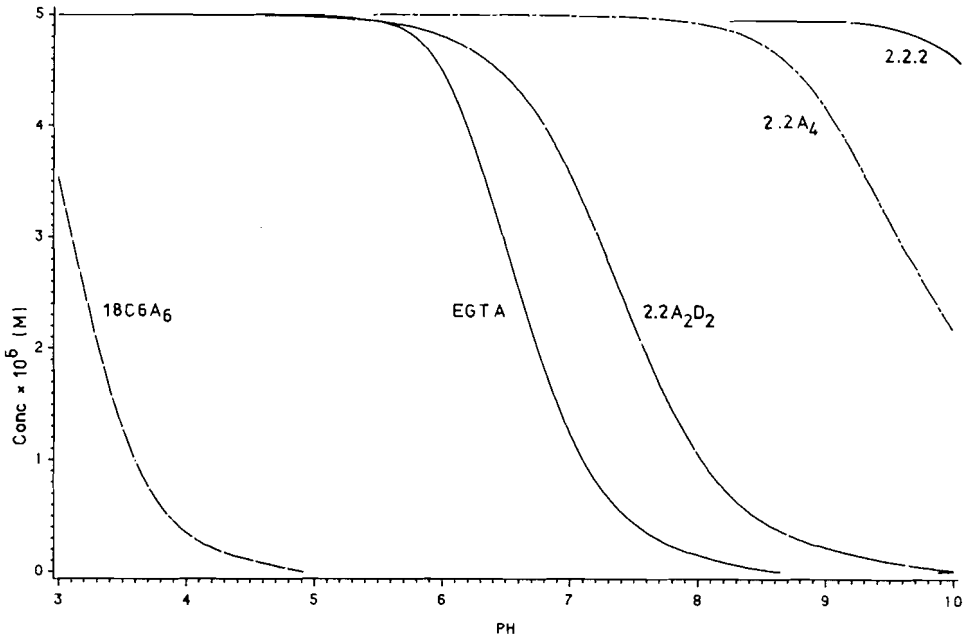

FIG. 6. Free calcium concentration as a function of pH calculated for an equimolar mixture of various ligands and Ca^{2+} at 5×10^{-6} M.

play only a minor role in solutions dominated by the "primary" 1:1 complexes.

Interligand comparisons

The polycarboxylate crown ethers, both oxa and aza, are effective cation complexing agents and compare favorably with neutral ligands, such as the cryptands, and with charged aminopolycarboxylates, such as EDTA. Table 2 provides an overview for comparisons between the ligands.

As noted previously, the oxa crown carboxylates form a number of protonated complexes (6). Protonation on carboxylate reduces complex stability but the metal ion remains effectively bound even in acidic solutions. In contrast, *N*-protonation results in significant destabilization in the aza crowns and EGTA and catastrophic destabilization in cryptand **2.2.2**. Comparisons are readily made in Fig. 6, where free Ca^{2+} concentrations have been calculated for an equimolar mixture of metal ion and ligand at 5×10^{-6} M. The relative concentrations at high pH reflect the relative stability constants for Ca^{2+} complexation. The persistence of the Ca^{2+} complex to pH 7 and below reflects the ability of the ligand to bind metal ions despite protonation. Clearly, the oxa crowns achieve this most effectively.

The close similarities, and significant differences due to donor atom substitution between the oxa and aza crowns have been examined above. Equally close similarities exist between the aza crowns and aminopolycarboxylate complexones such as EDTA and EGTA. With some exceptions, the formation constants of **2.2A$_2$D$_2$** are closely similar to EGTA as might be expected from the charge, donor set and the appropriate dimensions of EGTA (a rearranged "isomer" of **2.2A$_2$D$_2$** lacking a triethylene glycol bridge). The differences between EDTA and EGTA have been ascribed to a pre-organization effect in which the entropy term for the latter would be larger (40). Since the entropy associated with EGTA and **2.2A$_2$D$_2$** complexation must be significantly different in its detail, our results suggest that there is also a "cavity size" component as well. Relative to EDTA, EGTA or **2.2A$_2$D$_2$** apparently have difficulty bringing in all the available donor interactions. That the **2.2** cavity is too large for transition metal cations has been noted previously (41, 42); potentially this could result in a decrease in the number of coordinated donors.

We attempted to approach this question from the view point of the linear free energy relationships which had been described by Hancock and co-workers for the estimation of the stability constants for complexation by aminopolycarboxylates (41, 42). The approach seeks to relate unidentate binding constants for complexation of a cation by acetate and ammonia to the overall formation constant for the aminopolycarboxylate (43–45). Statistical or steric correction factors based on the number of each donor type are included. We envisaged using the available correlations, which work reasonably well for simple cases, and by simple variation of the donor number terms, derive a "best-fit" to the aza crown data. The results were considerably more scattered than for simple complexones, but "best-fits" were typically achieved using only one nitrogen donor site. Whether this is an artifact or reflects some underlying chemistry is not known.

An alternative linear free energy approach to the characterization of ligands is the use of the stability index, Q, and related derived parameters (46). As above, the results were considerably more scattered than for simple ligands but consistently indicated that the aza crowns of this study were more typical of class b behaviors. This is in general agreement with the size of the macrocycle which would favor larger cations.

Taken together, all the trends point to a close relationship of the aza crown series to crown ethers, and a somewhat more distant relationship to aminopolycarboxylates. The complex stabilities approach similar values but the ligand characteristic of a cavity maintained by its periphery and providing a flexible, but defined donor array are evident. As in all productive binding events, the strong complexes arise from a strong cooperativity of the various cavity, electrostatic, and chelate interactions. At the same time however, the relatively weak complexes of the alkali metals still represent significant enhancement over the neutral parent. One result is that the aza crowns described here,

and in particular **2.2A$_2$D$_2$**, have significant affinity for all types of cations and could serve as a general purpose cation binding agent. It remains to be seen if this molecular promiscuity can be turned to any chemical advantage.

Experimental

Melting points were taken on a Riechardt hot stage microscope (uncorrected). Proton NMR spectra were recorded with a Perkin-Elmer R32 (90 MHz, CW) or Bruker WM 250 (250 MHz, FT) spectrometer in $CDCl_3$ solvent with Me_4Si as internal standard or in D_2O with external Me_4Si in $CDCl_3$ as reference. Carbon NMR spectra were recorded at 62.8 MHz (WM 250) in $CDCl_3$ with the central solvent line as standard (77.0 ppm relative to Me_4SI) or in D_2O with a frequency reference for this solvent previously calibrated against external Me_4Si in $CDCl_3$. The mass spectra were recorded with a Finnegan 3300 GC-MS instrument with methane chemical ionization. IR spectra were recorded on a Perkin Elmer 283. Optical rotations were recorded on a Perkin Elmer 141 instrument; concentrations were in g/mL. Elemental analyses were performed by Canadian Microanalytical Services, New Westminster, B.C., and are quoted in percentages.

(2R,3R)-N,N,N′,N′-*Tetramethyl-2,3-bis(2-(tetrahydropyranyloxy)-ethoxy]succinamide (2)*

Thallous ethoxide (126 g, 0.5 mol) was added dropwise via syringe to a solution of (2*R*,3*R*)-*N*,*N*,*N*′,*N*′-tetramethyltartaramide **1** (48.6 g, 0.24 mol) in 3.5 L of dry dimethylformamide (DMF). The resultant slurry was mechanically stirred under an inert atmosphere and warmed to 50°C, whereupon 2-(2-bromoethoxy)tetrahydropyran (7) (130 g, 0.62 mol) was added in one portion. The mixture was heated at 65°C for a further 14 h and cooled. The thallous bromide was removed by filtration, and the solvent was removed by evaporation at reduced pressure. The oily product was dissolved in CH_2Cl_2 and filtered through a pad of Celite, the eluent evaporated, and the final traces of DMF removed by evaporation at high vacuum. The crude sample (100.5 g, 92%, predominantly **2** by ^{1}H NMR) could be used without further purification. Spectral data are given in Table 4.

Alternatively, crude **2** was purified by chromatography on neutral alumina (1 kg/100 g of **2**, column diameter 80 mm) using 1% MeOH/CH_2Cl_2. Fractions (400 mL) were collected and **2** eluted first. The appropriate fractions were combined and evaporated to yield **2** as a light yellow oil, in ca. 60% yield.

(2R,3R)-N,N,N′,N′-*Tetramethyl-2,3-bis(2-hydroxyethyl)succinamide (3)*

The crude bis(tetrahydropyranyl) ether **2** (92 g, 0.2 mol) was dissolved in 250 mL of methanol, 2 drops of concentrated HCl was added, and the mixture was stirred at reflux for 1 h, cooled, and evaporated. The oil was dissolved in water and extracted with 2 × 100 mL portions of ether, and the water layer was evaporated at high vacuum until a solid was obtained. Trituration using a minimum volume of ether/THF (1:9) gave **3** (42.5 g, 73%) as a white solid, mp 100–102°C. Spectral data are given in Table 4.

When pure **2** was subjected to hydrolysis as described, the diol **3** was obtained as a white solid in nearly quantitative yield. Infrared (KBr) 3500 br 1650 cm^{-1}. Anal. calcd. for $C_{12}H_{24}N_2O_6$: C 49.28, H 8.28, N 9.58; found: C 48.94, H 8.04, N 9.45.

(2R,3R)-N,N,N′,N′-*Tetramethyl-2,3-bis(2-(tosyloxy)ethoxy)succinamide (4)*

The diol **3** (23 g, 78 mmol) was dissolved in CH_2Cl_2 (200 mL) and triethylamine (20 mL) at 10°C, and solid *p*-toluenesulfonyl chloride (30.5 g, 160 mmol) was added. The mixture was stirred at ambient temperature for 24 h, diluted with a further 200 mL of CH_2Cl_2, extracted with 3 × 100 mL portions of cold 1 M HCl, followed by 5 × 100 mL portions of ice-cold water, dried over Na_2SO_4, and evaporated to a solid gum. The gum was triturated to a solid with a minimum of ether. This purity was sufficient for the subsequent steps (yield = 35.8 g, 78%). An analytical sample was obtained by recrystallization from ether/THF, mp 105–107°C. Spectral data are given in Table 4. Anal. calcd. for $C_{26}H_{36}N_2O_{10}S_2$: C 51.96, H 6.04, N 4.66, S 10.68; found: C 51.74, H 6.06, N 4.65, S 10.72.

(2R,3R)-N,N,N′,N′-*Tetramethyl-2,3-bis(2-(phthalimidoethoxy))-succinamide (5)*

The ditosylate **4** (20 g, 33 mmol) and potassium phthalimide (13 g, 70 mmol) were mixed in 400 mL of dry DMF. Distilled diethylamine (2 mL) was added as a solid–liquid phase transfer catalyst. The mixture was stirred at 50–60°C for 8 h under an inert atmosphere. The clear solution obtained was evaporated under reduced pressure and then evaporated at high vacuum overnight. The gummy product obtained was suspended in CH_2Cl_2 (500 mL) and the slurry stirred for 30 min. The precipitated solids were removed by filtration and the CH_2Cl_2 evaporated to give the crude diphthalimide **5** in quantitative yield (18.3 g). Recrystallization from 95% ethanol gave pure **5** as a white solid (16.7 g, 92%), mp 204–205°C. $[\alpha]_D = +46°$ ($c = 1.05$, CH_2Cl_2) $M^{+\cdot} = 550$. ^{1}H and ^{13}C spectral data are listed in Table 4. Anal. calcd. for $C_{28}H_{30}N_4O_8$: C 61.06, H 5.49, N 10.17; found: C 60.98, H 5.46, N 10.19.

(2R,3R)-N,N,N′,N′-*Tetramethyl-2,3-bis(2-aminoethyl)succinamide (6)*

The diphthalimide **5** (16.6 g, 30 mmol) was suspended in 300 mL of ethanol. Hydrazine hydrate (3.5 g, 70 mmol) was added and the mixture heated to 50°C with mechanical stirring. A thick precipitate formed over 3 h. This was stirred for a further 2 h and cooled. Most of the precipitated phthalhydrazide was removed by filtration. The filtrate was then concentrated and brought to pH 3–4 by cautious addition of cold 1 M HCl. Any remaining phthalhydrazide was thus precipitated and removed by filtration. The filtrate was cautiously concentrated and passed through a strongly basic (IRA 400) anion exchange resin. The alkaline fractions were combined and evaporated to yield the diamine **6** as a yellow oil (6.2 g, 70%, predominantly **6** by ^{1}H NMR) which was used without further purification (^{1}H NMR in Table 4).

(2R,3R)-N,N,N′,N′-*Tetramethyl-2,3-bis(2-tosylamidoethoxy)succinamide (7)*

The diamine **6** (6.2 g, 21 mmol) was dissolved in 100 mL of water. Potassium carbonate (5.5 g, 40 mmol) and *p*-toluenesulfonyl chloride (8.0 g, 42 mmol) were added in portions at room temperature over an hour. The reaction mixture was then stirred at 50°C for a further 4 h. It was then cooled and neutralized with 1 M HCl to pH 6–7. Crushed ice was added to complete precipitation. The solid was filtered and recrystallized from aqueous methanol to yield **7** as a white solid (9.4 g, 75%) mp 82–84°C. $[\alpha]_D = +41°$ ($c = 0.98$, CH_2Cl_2); $M^{+\cdot} = 598$. Spectral data are given in Table 4. Anal. calcd. for $C_{26}H_{38}O_8S_2N_4 \cdot 2H_2O$: C 49.17, H 6.67, N 8.82, S 10.11; found: C 49.09, H 6.62, N 8.83, S 10.15.

(2R,3R,11R,12R)-N,N,N′,N′,N″,N″,N‴,N‴-*Octamethyl-1,4,10,13-tetraoxa-7,16-ditosylazacyclooctadecane-2,3,11,12-tetracarboxamide (8)*

The bis-sulfonamide **7** (5.98 g, 10 mmol) and cesium carbonate (9.8 g, 30 mmol) were mixed in 200 mL of dry DMF and stirred for 1.5 h at ambient temperature under an inert atmosphere. The ditosylate **4** (6.0 g, 10 mmol) in 100 mL of DMF was added dropwise over a period of 2 to 3 h. The mixture was stirred for a further 20 h at ambient temperature. The solvent was removed under reduced pressure to obtain a solid paste. This was suspended in 200 mL of CH_2Cl_2 and stirred for 30 min. The precipitated solids were filtered and the solvent and the residual DMF were removed by evaporation at high vacuum. The resulting solid (predominantly **8** by ^{1}H NMR) was chromatographed on neutral alumina (Brockmann III, 180 g) using CH_2Cl_2 as eluent. The crown eluted after 6 or 7 column volumes of solvent had passed through. The appropriate fractions were combined and evaporated to yield **8** as a white solid (6.7 g, 79%). This could be further purified by recrystallization from 95% methanol: mp = 194–196°C; $[\alpha]_D = +74°$ ($c = 1$, CH_2Cl_2); $M^{+\cdot} = 854$; IR (KBr) 1655 cm^{-1}. Spectral data are given in Table 4. Anal. calcd. for

*(2R,3R)-N,N,N',N'-Tetramethyl-1,4,10,13-tetraoxa-7,16-ditosyl-azacyclooctadecane-2,3-dicarboxamide (**10**)*

The preparation of **10** was identical to **8** except that the bis-sulfonamide **9** (23) was used in place of **7**. Amounts: **9**, 4.5 g (10 mmol); Cs_2CO_3, 9.75 g (30 mmol); **4**, 6.0 g (10 mmol). Yield: 5.8 g (81%); mp = 62–64°C; $[\alpha]_D$ = +46° (c = 1, CH_2Cl_2); $M^{+\cdot}$ = 712; IR (KBr) cm^{-1} 1650. Spectral data are given in Table 4. Anal. calcd. for $C_{32}H_{48}N_4S_2O_{10}$: C 53.89, H 6.79, N 7.86, S 8.99; found: C 53.71, H 6.81, N 7.54, S 9.11.

*Preparation of 1,10-ditosylaza-4,7,13,16-tetraoxacyclooctadecane (**12**)*

The bis-sulfonamide **9** (2.2 g, 4.9 mmol) was mixed with finely powdered, oven-dried K_2CO_3 (2.0 g, 14.8 mmol) in 125 mL of dry DMF under nitrogen. The mixture was heated at 50°C for 2 h. Triethylene glycol ditosylate **11** (11) (2.25 g, 4.9 mmol) in 75 mL of DMF was added dropwise over 3 h. The mixture was stirred under

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12
For personal use only.

nitrogen at 50°C for a further 24 h. The reaction mixture was then concentrated and the last traces of DMF removed by evaporation at high vacuum. The solid mass obtained was suspended in CH_2Cl_2 and the solids were removed by filtration. The solvent was then evaporated to afford crude **12**. This could be purified by direct crystallization, albeit with difficulty, from aqueous methanol. Yield = 1.95 g, 70%. The spectral properties were in accord with expectations, mp = 161°C; Lit. (11) mp = 163–164°C.

(2R,3R,11R,12R)-1,4,10,13-tetraoxa-7,16-ditosylazacyclooctadecane-2,3,11,12-tetracarboxylic acid (17)

The tetraamide crown **8** (4.0 g, 4.7 mmol) was dissolved in 75 mL of 50% methanol. Concentrated HCl (15 mL) was added and the solution stirred at reflux for 4 h. The reaction mixture was cooled and passed through a column of strongly acidic cation exchange resin. The acidic fractions were combined and evaporated to give a pasty solid. Recrystallization from water/methanol (4:1) afforded **17** (2.4 g, 71%). This was used without further purification. Spectral data are listed in Table 4.

(2R,3R,11R,12R)-N,N,N′,N′,N″,N″,N‴,N‴-*Octamethyl-1,4,10,13-tetraoxa-7,16-diazacyclooctadecane-2,3,11,12-tetracarboxamide (14)*

The tetraamide bis-sulfonamide crown **8** (2 g, 2.3 mmol), hydrazine hydrate (2.3 g, 46 mmol), and *p*-dimethoxybenzene (3.1 g, 23 mmol) were dissolved in 500 mL of 80% EtOH. The solution was degassed by bubbling Ar through for half an hour. The mixture was photolysed in a preparative photoreactor using a high pressure Hannovia lamp for 1.5 h. The solvent was then evaporated to dryness to obtain a yellow pasty mass. This was taken up in deionized water (100 mL) and washed with 4 × 100 mL portions of ether. The aqueous layer was then passed through a strongly basic ion exchange resin (previously activated with Me_4NOH and washed well with deionized water). The alkaline fractions were combined and evaporated. The last traces of remnant hydrazine were removed by evaporation at high vacuum. The resulting yellow oil was partly decolorized by stirring an aqueous solution with 10% Pd–charcoal followed by saturation with SO_2 gas. *p*-Toluenesulfonic acid (0.95 g, 5 mmol) was then added, followed by filtration to remove the charcoal. The aqueous filtrate was washed with ether (4 × 50 mL) and rechromatographed on a basic resin as before, to yield **14** as a light yellow brittle foam. The product had to be stored under inert atmosphere in the absence of light. Yield = 0.77 g, 60%; $M^{+\cdot}$ = 546. Spectral data are given in Table 4.

(2R,3R)-N,N,N′,N′-*Tetramethyl-1,4,10,13-tetraoxa-7,16-diazacyclooctadecane-2,3-dicarboxamide (13)*

The experimental procedure for photodeprotection of **10** to **13** was identical to the one described for the preparation of **14**. Amounts: **10**, 2.0 g (2.8 mmol); *p*-dimethoxybenzene, 3.1 g (23 mmol); hydrazine hydrate, 2.3 g (46 mmol); 80% EtOH, 500 mL; photolysis time, 1.5 h. Yield: 0.66 g, 58%. Spectral data are listed in Table 4.

(2R,3R,11R,12R)-1,4,10,13-Tetraoxa-7,16-diazacyclooctadecane-2,3,11,12-tetracarboxylic acid bis(hydrogen toluenesulfonate) (2.2A$_4$)

The tetraamide diaza crown **14** (0.55 g, 1 mmol) and *p*-toluenesulfonic acid (1.2 g, 6.3 mmol) were dissolved in 10 mL of distilled deionized water and stirred at reflux for 24 h. The water was evaporated and the residue was examined by ^{13}C NMR. The two *N*-methyl resonances of the carboxamides had collapsed into a single peak at 37 ppm, thus indicating completion of hydrolysis. The reaction mixture was then evaporated under high vacuum to a brown powder. This was dissolved in a minimum of $CHCl_3$/MeOH (1:1) and loaded onto a 5 cm by 45 cm column of LH-20 Sephadex (ca. 250 mg of compound per 100 g of Sephadex). The column was eluted with the same solvent as above and fractions (10 mL) were collected. These were examined by ^{13}C NMR. The early fractions contained the crown ether **2.2A$_4$** and these were concentrated and rechromatographed as before to yield **2.2A$_4$** (0.57 g, 74%) as its bis-toluenesulfonate salt as a light brown deliquescent solid, mp >200 (dec.); $[\alpha]_D$ = +62° (*c* = 1.0, H_2O); IR (KBr) 3500–2500 (br), 1720 cm^{-1}. Spectral data are listed in Table 4. Equivalent weight: calcd. for 4 equiv. to pH 7 end-point: 195.5 g/equiv.; found: 193.5 g/equiv.

(2R,3R)-1,4,10,13-Tetraoxa-7,16-diazacyclooctadecane-2,3-dicarboxylic acid bis(hydrogen toluenesulfonate) (2.2A$_2$)

The preparation of **2.2A$_2$** from **13** was identical to the preparation of **2.2A$_4$**. Amounts: **13**, 0.5 g (1.2 mmol); *p*-toluenesulfonic acid, 0.95 g (5 mmol). Yield: 0.64 g (77%), mp 180°C (dec.); $[\alpha]_D$ = +39° (*c* = 0.9, H_2O), IR (KBr) 3500–2600 (br), 1730 cm^{-1}. Spectral data are listed in Table 4. Equivalent weight: calcd. for 2 equivalents to a pH 7 end-point: 347 g/equiv.; found: 340.4 g/equiv.

(2R,3R)-1,4,10,13-Tetraoxa-7,16-diazacyclooctadecane-2,3-dicarboxylic acid N,N′-*diacetic acid bis(hydrogen toluenesulfonate) (2.2A$_2$D$_2$)*

Crown ether **13** (0.25 g, 0.618 mmol) was mixed in 20 mL of aqueous methanol (1:2) containing suspended Li_2CO_3 (0.275 g, 3.72 mmol). Purified bromoacetic acid (0.173 g, 1.24 mmol) was added in portions with stirring. After the CO_2 evolution had ceased, the mixture was stirred at reflux for 4 h. Examination by ^{13}C NMR showed new peaks at ca. 178 and 51 ppm. (CO and NCH_2CO_2). The CH_2—Br resonance at 20 ppm had also disappeared. The mixture was now taken up in 5 mL deionized of water and purified *p*-toluenesulfonic acid (0.71 g, 3.7 mmol) was added. A minimum amount of water was added to homogenize the mixture. This was then heated at reflux for 24 h. A ^{13}C NMR of the crude mixture revealed that the carboxamides had hydrolyzed (collapse of *N*-methyls). The desired crown ether **2.2A$_2$D$_2$** was isolated from the reaction mixture by repeated gel permeation chromatography on LH-20 Sephadex as described for the preparation of **2.2A$_2$** and **2.2A$_4$** to obtain **2.2A$_2$D$_2$** as a light yellow deliquescent solid. Yield: 0.29 g (60%); mp 195°C (dec.) $[\alpha]_D$ = +32° (*c* = 0.5, H_2O). Spectral data are listed in Table 4. Anal. calcd. for $C_{32}H_{44}O_{18}N_2S_2.2H_2O$: C 45.47, H 5.73, N 3.32; found: C 45.32, H 5.86, N 3.96. Equivalent weight: calcd. for 2 equivalents to a pH 7 end-point: 422 g/equiv.; found: 415.6 g/equiv.

(2R,3R,11R,12R)-1,4,10,13-Tetraoxa-7,16-diazacyclooctadecane-2,3,11,12-tetracarboxylic acid N,N′-*diacetic acid bis(hydrogen toluenesulfonate) (2.2A$_4$D$_2$)*

The preparation of **2.2A$_4$D$_2$** from **14** was identical to that described for **2.2A$_2$D$_2$**. Amounts: **14**, 0.2 g (0.36 mmol); bromoacetic acid, 0.10 g (1.46 mmol); Li_2CO_3, 0.17 g (2.9 mmol); *p*-toluenesulfonic acid.H_2O, 0.56 g (2.9 mmol). Yield: 0.17 g (51%); mp 188°C (dec.). Spectral data given in Table 4. Neither a satisfactory elemental analysis, nor a titrimetric equivalent weight could be obtained. All samples were contaminated with 0.5–0.8 equiv. of Li^+.

Stability constant determination

Solutions of acid (0.05 M HNO_3) and base (0.05 M tetramethylammonium hydroxide (TMAOH)) were prepared and standardized against the primary standards TRIS (tris-hydroxymethylaminomethane) for HNO_3 or potassium acid phthalate for TMAOH. A constant ionic strength was maintained (0.1 M) by the addition of tetramethylammonium nitrate (TMAN) to both the standard acid and base, as well as by using a 0.1 M TMAN medium for titrations. Standard metal ion solutions (0.05 M) were made from the corresponding nitrates. All reagents were analytical grade or better and were dried before use. Standard ligand solutions (approximately 2×10^{-2} M) were made from thoroughly evacuated samples of the ligand bis-toluenesulfonate salts. The equivalent weight was determined from the average of several titrations and was used to establish ligand homogeneity and purity before the stability constant determinations.

The general procedures and apparatus have been described previously (4, 6). The following is an abbreviated outline which incorporates some recent modifications and controls. The electrode system was calibrated using commercially available buffers at pH 2.00 and pH 9.18 and linearity was confirmed at pH 6.86 and 4.01. For pK_a determinations, a 4 mL solution of the ligand (approximately 4×10^{-4} M) in 0.1 M TMAN was titrated with standardized Me_4NOH

containing 0.1 M TMAN to beyond the strong acid – strong base end point (60 μL per ligand equivalent with 0.05 M base) in 2–4 μL aliquots (minimum 18 points per ligand equivalent). The data file was processed using SCOGS (37) to yield β_{l0h} for the ligand.

Other checks and controls were as follows:

(*a*) The carbonate content in the base was determined by a strong acid – strong base titration against standardized HNO_3 (I = 0.1 with Me_4NNO_3). The effective pK_a's of CO_3^{2-} were determined to be log β_{110} = 9.73 and log β_{111} = 16.73. These, together with the concentration of carbonate, were included in the calculations.

(*b*) Slope and intercept corrections (34) for the pH meter as discussed in the text were also used in the calculations. The slope correction was found to be very small and was ignored (i.e., s = 1) but an intercept correction of −0.23 was determined and used.

(*c*) The pK_{medium} (13.78) was determined (34) using the same strong acid – strong base curve.

(*d*) The validity of the above procedure was checked by determining pK_a and log β (Ca^{2+}) values of EDTA and EGTA. Satisfactory agreement with the literature was obtained in all cases (better than ±0.2 in log β).

For stability constant determinations, two procedures were used. One followed the procedure for pK_a determination directly, with the addition of an equivalent of metal nitrate solution to the free acid before titration with the base. The other used the solution resulting from the pK_a titration by addition of an equivalent of metal nitrate to the basic solution. This mixture was then back titrated with standardized 0.05 M HNO_3 (containing 0.1 M TMAN) to the starting acidic pH. The second method, however, is inappropriate for metals which form insoluble hydroxo complexes. Both methods gave comparable β_{lmh} values. The hydroxo complexes for the relevant metal ions were chosen from the literature (47). These values had been determined under similar conditions to the present study (nitrate salts at 25°C and I = 0.1 M). The values for the various metal ions were as follows: log β (species): 0.7 [$CaOH^+$, $SrOH^+$, $BaOH^+$]; 4.7 [$LaOH^{2+}$]; 4.3 [$NiOH^+$]; 5.7 [$CuOH^+$]; 13.1 [$Cu(OH)_2$]; 16.9 [$Cu_2(OH)_2^{2+}$]; 33.7 [$Cu_3(OH)_4^{2+}$]; 4.7 [$ZnOH^+$]; 9.86 [$Zn(OH)_2$]; 5.7 [$Zn(OH)_3^-$]; 3.8 [$CdOH^+$]; 6.9 [$PbOH^+$]; 10.8 [$Pb(OH)_2$]; 13.3 [$Pb(OH)_3^-$].

All computations utilized the program SCOGS (37) adapted for the corrections to the pH. The standard deviation in titer reported by the program was divided by the titer increment from the experiment to yield a composite goodness-of-fit parameter, r, reported in Table 1. Since all the titrations were done under closely similar conditions, r reflects the quality of the modeling done by SCOGS. The reliability of the values, assessed from reproducibility between duplicate solution preparations from salts is ±0.1 in pK_a and ±0.2 in log β. Computations of species distribution as a function of pH was done using the algorithm COMPLEX (48) adapted for use on a microcomputer.

Received August 16, 1989[3]

WALTER ABRIEL, ANDRÉ DU BOIS, MAREK ZAKRZEWSKI, and MARY ANNE WHITE. Can. J. Chem. **68**, 1352 (1990).

The crystal structure of the title compound has been determined by single crystal X-ray diffraction data collected at 293 K, and refined to a final R_w of 0.057. The crystals are rhombohedral, space group $R\bar{3}$, with a = 27.134(8) Å, c = 10.933(2) Å, and Z = 18. The mole ratio of Dianin's compound (4-*p*-hydroxyphenyl-2,2,4-trimethylchroman) to CCl_4 is 6:1. The guest molecules are disordered. X-ray powder diffraction was carried out in the temperature range from 10 to 300 K. From this, the thermal expansion coefficients for the ***a***- and ***c***-axes and the volume have been determined.

Key words: thermal expansion, crystal structure, clathrate.

WALTER ABRIEL, ANDRÉ DU BOIS, MAREK ZAKRZEWSKI et MARY ANNE WHITE. Can. J. Chem. **68**, 1352 (1990).

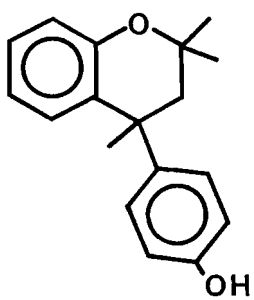
La structure cristalline du composé mentionné dans le titre a été déterminée par diffraction des rayons-X sur un cristal unique, à l'aide données recueillies à 293 K et affinées jusqu'à une valeur finale de R_w de 0,057. Les cristaux sont rhomboédriques, groupe d'espace $R\bar{3}$ avec a = 27,134(8) et c = 10,933(2) Å et Z = 18. Le rapport molaire entre le composé de Dianin (4-*p*-hydroxyphényl-2,2,4-triméthylchromane) et le CCl_4 est de 6 : 1. Les molécules hôtes sont désordonnées. La diffraction des rayons-X sur les poudres a été réalisée à des températures allant de 10 à 300 K. A partir de ces données, on a pu déterminer les coefficients d'expansion thermique pour les axes ***a*** et ***c*** ainsi que pour le volume.

Mots clés : coefficients d'expansion thermique, structure cristalline, clathrate.

[Traduit par la revue]

Introduction

4-*p*-Hydroxyphenyl-2,2,4-trimethylchroman, **1**, also known as Dianin's compound (1), forms clathrates by crystallization with many solvents (2, 3). In all reported adducts, it crystallizes in the space group $R\bar{3}$ (4, 5). The general structure of the host lattice consists of the hexamers of **1**, held together by a ring of hydrogen bonds involving the phenolic hydroxy groups. The monomeric units of the hexamers alternately point up and down from this ring, and groups of hexamers form chains of hourglass shaped cages. The upper half of each cage consists of three molecules of **1** from one hexamer, and the lower half is three molecules of **1** from another hexamer. The cage is held together at the roof and floor by the hydrogen-bond network, and at the waist by van der Waals forces between the molecules. The cages are quite large, free volume about 180 Å^3, and can accommodate even bulky molecules (2).



1

Clathrates can be used to investigate many interesting properties of matter, and one of the purposes of our ongoing clathrate studies is to examine the effect of guest molecules on the properties of the host lattice. The Dianin clathrate system is particularly interesting because it has the rare feature of a stable empty host lattice (5). The structure of the CCl_4 clathrate has not been reported previously, and knowledge of the structure, and particularly the guest occupancy, was required for the analysis of our recent calorimetric results (6). We are also interested in the effect of the number and type of guests in the host lattice on the cavity itself. We report here the structure of the CCl_4 adduct of **1**, as determined by single crystal X-ray diffraction at T = 293 K.

The effect of anharmonic interactions within clathrates has been proposed as the origin of the unusual thermal conductivities of clathrate hydrates (7) and in order to test the generality of this effect in other clathrates, we have recently measured the thermal conductivities (White and Zakrzewski, unpublished results) and thermal expansion of the empty and ethanol adducts of Dianin's compound. For comparison, we report here the thermal expansion coefficients for all significant lattice parameters for the CCl_4 adduct of Dianin's compound, based on X-ray powder diffraction determinations of the lattice parameters in the temperature range from 10 to 300 K.

Experimental

Dianin's compound (**1**) was prepared from phenol and mesityl oxide according to the method of Baker *et al.* (2), and isolated as the ethanol adduct. This was converted to the unsolvated form of **1** by bubbling CO_2 gas through a basic solution of the ethanol adduct in H_2O (2). The resultant white powder was dissolved in carbon tetrachloride to produce the CCl_4 adduct of **1** (2). Single crystals were obtained by slow evaporation; samples for the X-ray powder diffraction were obtained by rapid recrystallization. The observed melting point was 159–160°C, in agreement with the literature value (2). Chemical analysis gave the following composition in mass % (theoretical composition for host to

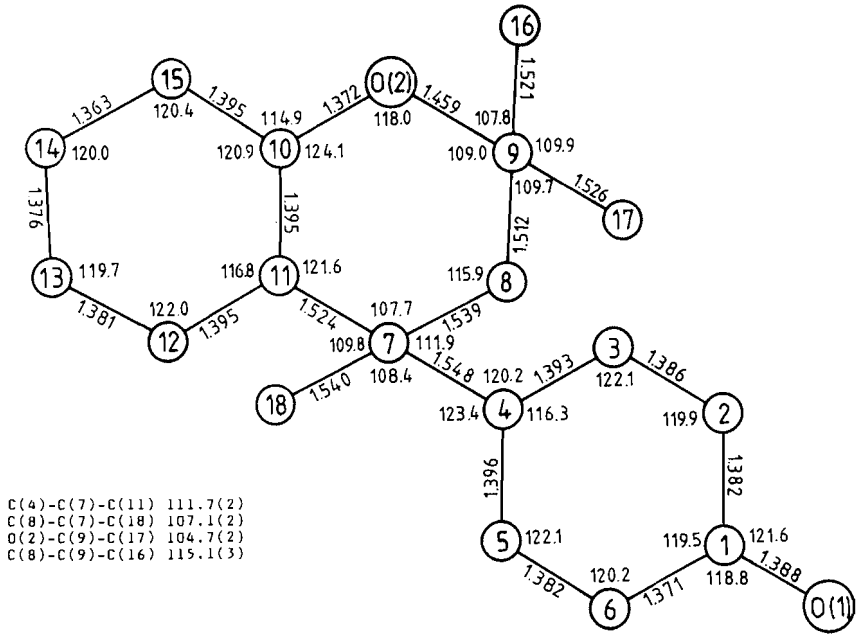

FIG. 1. Bond distances (Å) and angles (deg) for 4-*p*-hydroxyphenyl-2,2,4-trimethylchroman. The hydrogens are not shown.

guest ratio of 6:1 given in parentheses): C, 73.45 ± 0.2 (74.2); H, 7.1 ± 0.1 (6.86); Cl, 9.5 ± 0.1 (8.04). The errors quoted are precisions not accuracies.

Weissenberg photographs (CuKα) of a needle-shaped crystal showed Laue symmetry $\bar{3}$ with systematically absent reflections indicating a rhombohedral lattice. The crystal faces were: (2$\bar{1}$0), ($\bar{2}$10), (1$\bar{2}$0), ($\bar{1}$20), (110), ($\bar{1}\bar{1}$0), {001}. The crystal volume was 4.8×10^{-2} mm^3 with diameter of 0.68 mm in [001]. The X-ray data collection at 293 K was performed with a SIEMENS AED2 diffractometer using graphite monochromatized MoKα radiation. Accurate cell parameters from 33 reflections in the θ range 7.3 to 21.5° gave a = 27.134(8) Å, c = 10.933(2) Å. Intensity data collection: maximum $\sin\theta/\lambda = 0.704$ Å^{-1}; range of hkl 35, $\bar{1}$8, 0 to 35, 38, 15 in the ω-scan mode (minimum scan angle 1.2°, scan time maximum 36 s). Reflections $\bar{5}$55, 555, and $\bar{6}$82 were used for standard intensity measurements; intensity variation was less than 1%. 8374 measured reflections yielded 4259 unique reflections (R_{int} = 0.064); 2498 reflections with $F > 3\sigma(F)$ were regarded as observed. Numerical absorption correction (μ = 1.5 cm^{-1}) was applied with a min./max. transmission of 0.96/0.97.

X-ray powder diffraction experiments in the temperature range from 10 to 300 K were performed with a recently developed Guinier-diffractometer using Ge-monochromatized CuKα_1 radiation. A detailed description of the set up is given elsewhere (8). The powder sample was sieved to use the particles less than 50 μm in size. This procedure was chosen because grinding larger crystals produced structural defects and decomposition, as shown by the high background scattering and line broadening in the diffraction diagram. The diffractograms were recorded with a step width of 0.01° and a counter time of 4 s per step in the range $4° < \theta < 24°$.

Results[4]

Single crystal diffraction

The structural calculations were carried out in the space group $R\bar{3}$ (#148), *i.e.* that found by Flippen *et al.* (4) for other clathrates of Dianin's compounds, starting with refinement of the atomic parameters of the host structure. A subsequent ΔF synthesis yielded the positions of the CCl_4 guest molecules.

The refinement of the site occupancy factors for the atoms of the guest CCl_4 molecules yielded the values 0.514(9) for C(19), 0.983(5) for Cl(1), and 0.489(2) for Cl(2), indicating a 6:1 ratio of host-to-guest species. This contradicts the results of ref. 2 in which it is stated that two CCl_4 molecules occupy each cage. However, the theoretical atomic composition is also given incorrectly in ref. 2, and a 6:1 ratio is much closer to what one would expect on the basis of the chemical analysis of our sample (*e.g.* the theoretical mass % of Cl would be 8.04 for 6:1). Furthermore, we have measured the densities of single crystals of our sample using a calibrated pycnometer and found ρ = 1.262 ± 0.005 g cm^{-3} at T = 296 K. Using the lattice constants and thermal expansion determined here (*vide infra*), this gives a ratio of host-to-guest molecules of (5.94 ± 0.05):1.

For the final refinement of all structural parameters (on F) the site occupancy parameters for CCl_4 were fixed with the values 1.0 and 0.5 for Cl(1) and Cl(2), respectively. The hydrogen atoms were refined with geometrical constraints together with the adjacent C or O atom. The final refinement's results are R = 0.084, $R_w = \Sigma\Delta F\sqrt{W}/\Sigma F_o\sqrt{W}$ = 0.057 (with $W = 1/\sigma^2(F)$), S(GOF) = 3.92, maximum shift/esd 0.001 in the last cycle of refinement (195 parameters), $0.14 \geq \Delta \geq -0.2$ e/Å^3 from final ΔF synthesis. Neutral atom scattering factors were taken from International tables (9). The program used was STRUCSY from the diffractometer software package. A complete listing of the refined structural parameters is given in Table 1.

For the structure of the host compound, the previously reported atomic positions (4) were confirmed with only small deviations of the bond geometry (see Fig. 1).

The CCl_4 guest molecule is two-fold disordered in the cage (Fig. 2). The atom Cl(1) occupies the centre of the waist in the cage, consequently this position belongs to both guest molecules with a site occupancy factor of 100%. The CCl_4 molecule is almost a regular tetrahedron with the following bond distances (not corrected for libration) and bond angles: C(19)—Cl(1), 1.67(1) Å; C(19)—Cl(2), 1.702(4) Å; Cl(1)—C(19)—Cl(2), 108.5(1)°; and Cl(2)—C(19)—Cl(2), 110.5(2)°. We assumed

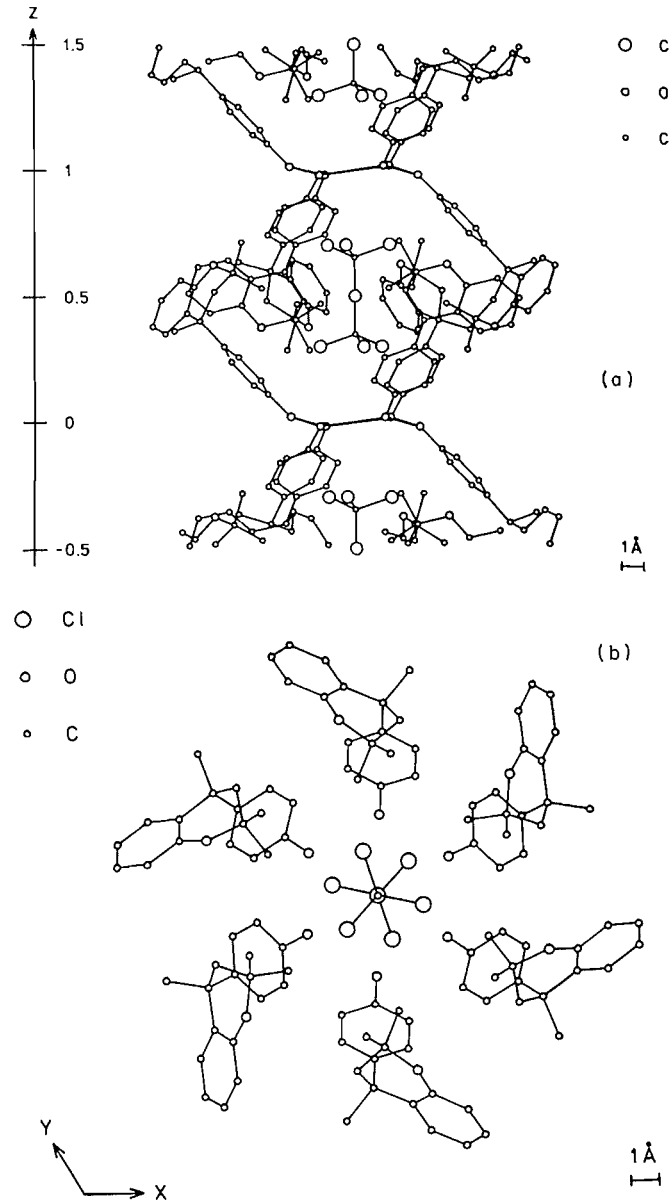

FIG. 2. The crystal structure of the CCl_4 adduct of Dianin's compound (plot program SCHAKAL (10)): (*a*) the stacking of the host lattice along the *c* axis; two cages per translation unit contain one CCl_4 molecule, (*b*) the crystal structure viewed along [001].

that the rigid CCl_4 molecule is librating about its centre of mass, and checked this model by calculating a generalized R-index for the agreement of observed and calculated U_{ij} (11). With the anisotropic displacement parameters from our structure determination we calculated for CCl_4 an R-factor of 0.058, indicating consistency of the model. The angular displacement of the libration is shown by the librational tensor L, where the values given are in degrees^2 for orthogonal axes:

$$\Lambda = \begin{vmatrix} 51.8 & 0 & 0 \\ 0 & 51.8 & 0 \\ 0 & 0 & 113.6 \end{vmatrix}$$

and the centre of gravity for the librational movement is at 0.0004, 0.0005, 0.3401 according to the T tensor (in Å^2):

$$T = \begin{vmatrix} 0.0379 & 0.0 & 0.0 \\ 0.0 & 0.0379 & -0.0002 \\ 0.0 & -0.0002 & 0.0690 \end{vmatrix}$$

The closest host–guest distances found were Cl(1)—H(163) (H(163) bonded to C(16)), 3.91 Å; Cl(2)—H(161) (H(161) bonded to C(16)), 3.09 Å; Cl(2)—C(1), 3.13 Å.

Powder diffraction

The lattice parameters were determined by least-squares fit to the 11 most intense reflections unambiguously assignable. As no change of symmetry occurred down to 10 K the space group $R\bar{3}$ was assumed for all diagrams.

The unit cell dimensions along the ***a*** and ***c*** axes, and the unit cell volume are shown in Fig. 3 as functions of temperature.

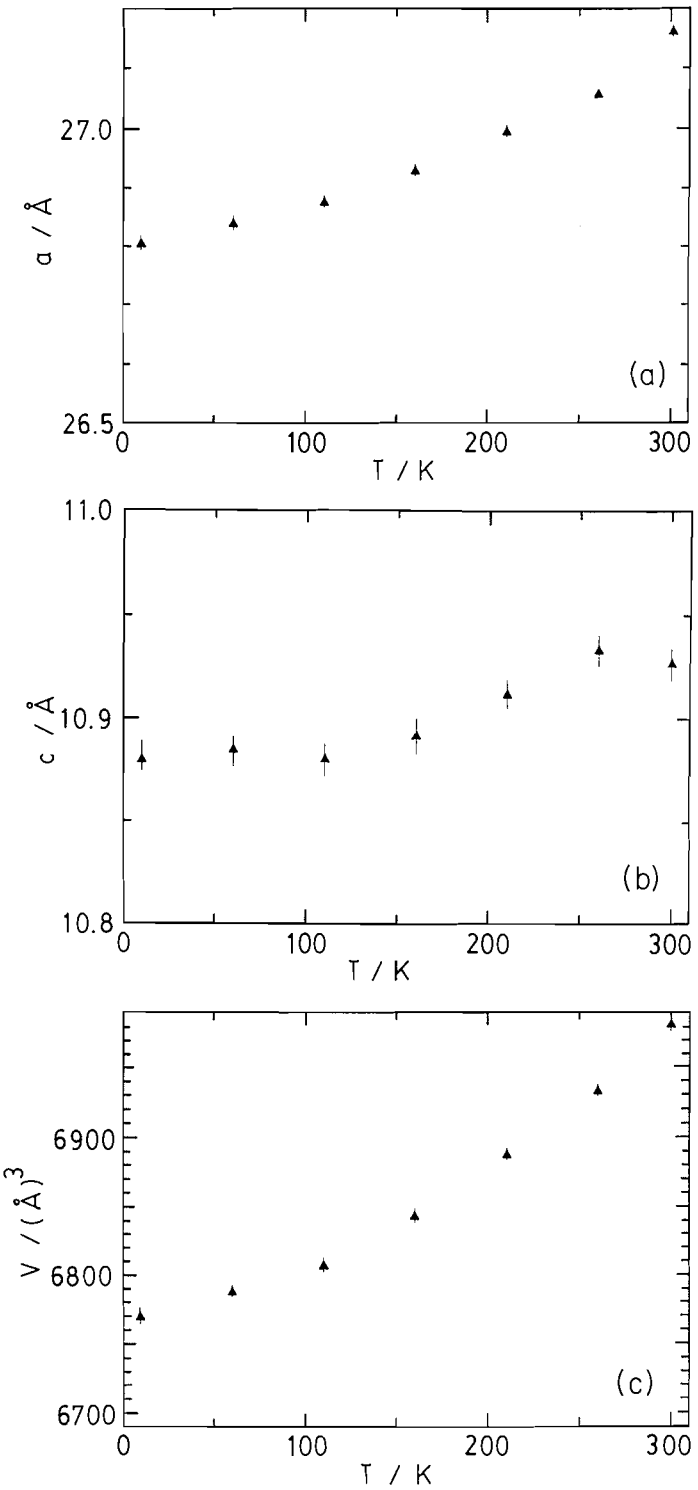

FIG. 3. Lattice parameters and unit cell volume of the CCl_4 adduct of Dianin's compound as a function of temperature: (*a*) along the ***a*** axis, (*b*) along the ***c*** axis, (*c*) unit cell volume.

Interpolation of the powder data to $T = 293$ K gives lattice parameters $a = 27.143(9)$ Å, $c = 10.928(8)$ Å in excellent agreement with those from the single crystal work, $a = 27.134(8)$ Å, $c = 10.933(2)$ Å.

Discussion

From the crystallographic results we find that the CCl_4 guest molecules are librating in the cage. The librational tensor (*vide supra*) reveals that the guest molecule is experiencing root-mean-squared amplitudes of vibration of 10.7° with respect to the ***c***-axis, and 7.2° with respect to two orthogonal axes in the ***ab*** plane. Using the method of Cruickshank (13), and moments of inertia corresponding to our determination of the bond lengths and angles ($I_x = I_y = 4.457 \times 10^{-38}$ g cm^2, $I_z = 4.601 \times 10^{-38}$ g cm^2), we determine the average librational frequencies of the CCl_4 molecules to be 40 cm^{-1} about the ***x*** and ***y*** axes, and 27 cm^{-1} about the *z* axis. From ^{35}Cl NQR studies of CCl_4 in ***1***, these librational frequencies have been determined to be 47 and 37 cm^{-1}, respectively (14).

Throughout the temperature range from 10 to 300 K the CCl_4 guest causes an increase in *a* of about 0.6%, and insignificant change in *c*, in comparison with the lattice parameters (15) for the empty host lattice. This can be contrasted with the ethanol adduct (15) in which the presence of the guest decreases *a* at low temperatures, but increases it above about 200 K. In the ethanol adduct, *c* is increased by about 0.5% at all temperatures. One of the differences between the CCl_4 adduct and the ethanol adduct is that the latter has a dimer guest in the cage. As we have shown with the single crystal work here, CCl_4 has only one guest per cage. The lack of expansion along the ***c*** axis in the CCl_4 adduct, relative to the expansion caused by the ethanol guest dimer, may be due to "free" space in the unoccupied half of the cage of the host lattice in the CCl_4 adduct.

The Dianin host lattice is, as stated above, held together predominantly by hydrogen bonds. In the region of the ring of hydrogen-bonded phenolic groups, we find the O····O distance in the CCl_4 adduct of **1** to be 2.857(3) Å, which is very similar to that found in the ethanol adduct of **1**, 2.85(1) Å (4). This is a longer distance than is found in the CCl_4 adduct of 4-*p*-hydroxyphenyl-2,4-dimethylchroman, 2.77 Å (16), which shows the appreciable role of the second methyl group at carbon-2 in **1**. In general, O····O bond distances in hydrogen-bonded systems such as ices, hydrates, and hydroxy compounds range from 2.7 to 2.9 Å (16); we are at the upper end of this range. Although we are unable to determine the true position of the hydrogen in this hydrogen bond, we expect that it will be unsymmetric with respect to the neighbouring oxygens, and possibly dynamically disordered at room temperature. This effect has been observed recently by solid state ^{2}H nmr (17).

We now turn our attention to the coefficients of thermal expansion, α_i ($= i^{-1}\, \mathrm{d}i/\mathrm{d}T$, $i = a, c, V$) for the CCl_4 adduct of **1**. These were calculated from polynomials fit to the appropriate lattice constant data. The thermal expansions, α_a and α_V, are shown in Fig. 4; the points shown were calculated directly from lattice parameter changes at neighbouring temperatures. The thermal expansion along the ***c*** axis, α_c, is given in Table 2.

The overall thermal expansion, α_V, is positive throughout the investigated temperature range, as is α_a. The thermal expansion along the ***c*** axis is very small especially at low temperatures; this was noticed also for the unsolvated Dianin's compound and the ethanol adduct.

In comparison with the empty host lattice, α_a is larger for the CCl_4 adduct only for $T < 100$ K and $T > 200$ K; in the intermediate temperature region α_a is essentially the same with and without the CCl_4 guest. The thermal expansion along ***c*** is virtually unchanged by the presence of the CCl_4 guest. Since α_V is dominated by α_a ($\alpha_V = 2\alpha_a + \alpha_c$), it shows the same trends as α_a with respect to the presence of the CCl_4 guest. α_a and α_V for the CCl_4 adduct of **1** are smaller than for the ethanol adduct

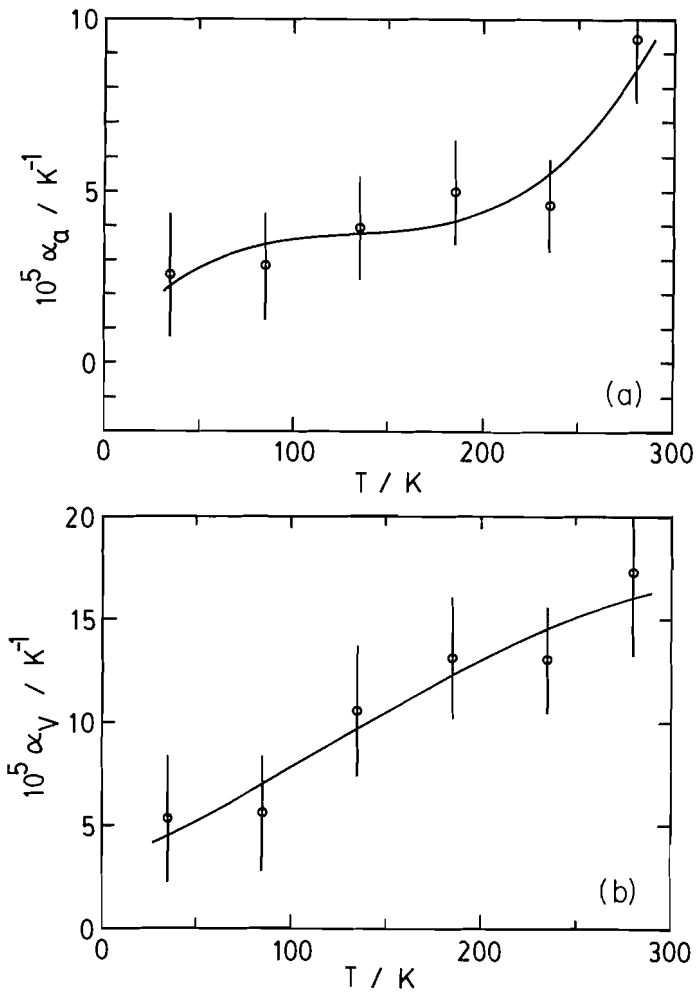

FIG. 4. Thermal expansion coefficient of CCl_4 adduct of Dianin's compound as a function of temperature: (*a*) along the ***a*** axis, (*b*) for the unit cell volume.

throughout the temperature region examined, *i.e.* the CCl_4 adduct is intermediate in thermal expansion between the empty host lattice and the ethanol adduct.

The origin of the unusual thermal conductivities of some clathrates has been attributed to the interactions of the low-frequency optic modes of the guest molecules with the acoustic modes of the host lattice (7). These interactions are due to anharmonicity in the interaction potential, and they should be manifest in other physical properties such as increased thermal expansion. We have recently shown (White and Zakrzewski, unpublished results) that the thermal expansion correlates with the thermal conductivity of the empty and ethanol adducts of Dianin's compound as one would expect for this model. A further test of the importance of guest–host interactions will be the measurement of the thermal conductivity of the CCl_4 adduct of **1**; if this hypothesis is correct, the intermediate thermal expansion of the CCl_4 adduct shoud lead to a thermal resistivity higher than that of the empty clathrate and lower than that of the ethanol adduct.

TABLE 2. Thermal expansion along the ***c*** axis, α_c, for the CCl_4 adduct of Dianin's compound

T/K	$10^5\ \alpha_c/K^{-1}$
50	0.7±0.5
100	1.2±0.5
150	1.8±0.8
200	2.3±0.8
250	2.8±0.8
300	3.3±0.8

Received December 14, 1989

C. Robert Lucas, Shuang Liu, Michael J. Newlands, and Eric J. Gabe. Can. J. Chem. **68**, 1357 (1990).

Preparations of the thiophenophane and open chain thioether complexes $MX_2 \cdot$BBTE (M = Pd; X = Cl, I) (M = Pt; X = Cl) (BBTE = 1,2-bis(benzylthio)ethane) and $MX_2 \cdot$L (M = Pd; X = Cl, Br, I, SCN) (M = Pt; X = Cl) (L = 2,5,8-trithia[9](2,5)thiophenophane) are described. The molecular structure of $PdBr_2 \cdot$L which contains a weak thiophene-sulfur-to-palladium interaction has been determined: space group $P2_1/n$, a = 8.3569(3), b = 16.3254(15), c = 11.1462(3) Å, β = 92.833(4)°, Z = 4, R_f = 0.060, R_w = 0.058. The electronic, low frequency ir, and ^{13}C nmr spectra are described. Variable temperature ^1H nmr spectra are discussed and it is concluded that the open chain complexes undergo rapid conformational exchange at room temperature but are configurationally rigid unless the temperature is increased. In contrast, the macrocyclic complexes undergo very limited conformational and no configurational exchange up to their decomposition temperatures. They are also nonfluxional in the same temperature range. Chemical exchange of acidic ligand hydrogens and a metal–ligand dissociative equilibrium were also detected when X = SCN.

Key words: thiophene, thioether, macrocyclic metal complexes.

C. Robert Lucas, Shuang Liu, Michael J. Newlands et Eric J. Gabe. Can. J. Chem. **68**, 1357 (1990).

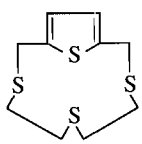
On décrit les préparations de complexes du thiophénophane et de thioéthers en chaîne ouverte de formule $MX_2 \cdot$BBTE (M = Pd; X = Cl ou I) (M = Pt; X = Cl) (BBTE = 1,2-bis(benzylthio)éthane) et $MX_2 \cdot$L (M = Pd; X = Cl, Br, I ou SCN) (M = Pt; X = Cl) (L = 2,5,8-trithia[9](2,5)thiophénophane). On a déterminé la structure du $PdBr_2 \cdot$L qui contient une interaction faible entre le soufre du thiophène et le palladium : groupe d'espace $P2_1/n$, a = 8,3569(3), b = 16,3254(15) et c = 11,1462(3) Å, β = 92,833(4)°, Z = 4, R_f = 0,060 et R_w = 0,058. On décrit les spectres électroniques, ir à basse fréquence et rmn du ^{13}C. On discute des spectres rmn du ^1H à température variable et on en conclut que, à la température ambiante, les complexes avec des chaînes ouvertes subissent des échanges conformationnels rapides; toutefois, ils sont rigides d'un point de vue configurationnel, à moins que l'on augmente la température. Par ailleurs, lorsqu'on soumet les complexes avec des macrocycles à des températures allant jusqu'à leurs températures de décomposition, ils ne subissent que des échanges conformationnels et configurationnels très limités. Dans le cas où X = SCN, on a aussi détecté un échange chimique impliquant les hydrogènes acides agissant comme ligands ainsi qu'un équilibre métal ligand impliquant une dissociation.

Mots clés : thiophène, thioéther, complexes métalliques de macrocycles.

[Traduit par la revue]

Introduction

As part of our continuing interest in the effects of structural constraint in sulfur-donor ligands (1) we have prepared several Pd and Pt derivatives of the ligand L and of BBTE (1,2-bis(benzylthio)ethane).



L

Structures and properties of complexes formed by sulfur-donor ligands in general and by sulfur-donor macrocycles in particular are of interest because they are often unusual (2). Their unusual nature derives from a combination of the electronic properties of thioether sulfur (3), the flexibility of polythioether chains (4), the conformational preferences of polythioether macrocycles (5), and the ability of polythioether ligands to be involved in fluxional processes (6). In order to assess the extent to which the unusual properties are controlled by stereochemical aspects in the ligand, we have carried out a variety of studies, some of which are described in this report.

Since rigidity associated with the aromatic thiophene ring is the structural constraint we have imposed on ligand L, we are able, in this study to explore at the same time the possibility of thiophene coordination. Conventionally, thiophene is considered to coordinate poorly to transition metals although there are several recent examples in which M—S(thiophene) distances have been found that are roughly equal to the sum of the covalent radii of divalent sulfur and the metal involved (7–15). In addition, there are compounds in which weaker interactions occur that can be detected spectroscopically and for which the M—S distance is much longer (16). Thus, it seems that the metal—S(thiophene) interaction is not inherently weak but rather that the conditions under which strong M—S(thiophene) interactions can be formed are not yet fully understood. Since hydrodesulfurization of thiophenes is a major industrial process that may involve M—S(thiophene) coordination, it is important to understand the controlling factors.

In our complexes, chelation by L using adjacent thioether sulfurs places the thiophene ring near the metal. Once there, its sulfur atom may choose whether or not to coordinate by rotating the plane of the thiophene ring about the bonds to substituents in its 2- and 5-positions so that the metal–sulfur distance varies. Part of our objective in this study was to see whether the M—S(thiophene) distance will be long or short under these conditions. This report also describes the unexpected rigidity

of these macrocyclic complexes, the nmr spectra of which clearly show several consequences of structural constraint. Interpretation of these spectra owes much to earlier work by Abel and co-workers (2, 17), Cross *et al.* (18, 19), and Hunter and Massey (19, 20) and as a point of departure from their studies we began by examining spectra of complexes formed by 1,2-bis(benzylthio)ethane, BBTE, an open chain dithioether which lacks some of the constraints we later found in the macrocyclic ligand, L.

Experimental

Commercially available reagents were obtained from the Aldrich Chemical Co. Inc., or from Morton Thiokol Alfa Products Inc., and were used without further purification. We have previously described the preparation of L (21). Spectroscopic data were obtained using the following instruments: ir, Perkin Elmer Model 283; uv/vis, Cary Model 17; nmr General Electric 300-NB; mass spectra, V.G. micromass 7070 HS. X-ray data were collected using an Enraf Nonius CAD-4 diffractometer. Analyses were performed by Canadian Microanalytical Services Ltd.

Preparative

(a) $C_{16}H_{18}S_2$ (BBTE)

Sodium metal (2.3 g, 0.10 mol) was dissolved in commercial absolute ethanol (300 mL) under an atmosphere of dry nitrogen and 1,2-ethanedithiol (4.7 g, 0.050 mol) added. The solution was refluxed for 5 min and then benzyl bromide (17.1 g, 0.100 mol) in dry benzene (150 mL) was added dropwise. The mixture was refluxed for 1 h, volatiles removed on a rotary evaporator, and the residue extracted with $CHCl_3$. The extract was washed, dried over anhydrous $MgSO_4$, and evaporated to give an oil that was crystallized from ethanol at 0°C as white crystals. mp 32–34°C. Yield 11.5 g (84%). Mass spectrum: parent ion 274 $[C_{16}H_{18}S_2]^+$. Nuclear magnetic resonance ($CDCl_3$, ppm from TMS int. std.), ^{1}H: 2.53 (s, 4H) —CH_2CH_2—, 3.52 (s, 4H) $PhCH_2$, 7.23 (m, 10H) C_6H_5.

(b) $PdCl_2$·BBTE

Solutions of *cis*-$PdCl_2(PhCN)_2$ (153 mg, 0.400 mmol) in acetone (20 mL) and BBTE (110 mg, 0.400 mmol) in CH_2Cl_2 (10 mL) were mixed and the solvents allowed to evaporate at room temperature until orange crystals had formed. The solid was separated, washed with acetone and then ether, and dried in vacuum. mp 184–185°C (dec). Yield 229 mg (79%). *Anal.* calcd. for $C_{16}H_{18}Cl_2PdS_2$: C 42.54, H 4.02, Cl 15.70, Pd 23.55; found: C 42.77, H 4.01, Cl 15.60, Pd 22.60.

(c) PdI_2·BBTE

A solution of *cis*-$PdCl_2(PhCN)_2$ (153 mg, 0.400 mmol) in acetone (20 mL) was treated with a solution of $AgCF_3SO_3$ (205 mg, 0.800 mmol) in acetone (30 mL). The resulting precipitate was removed and discarded and to the filtrate solutions of KI (133 mg, 0.800 mmol) in H_2O (5 mL) and BBTE (110 mg, 0.400 mmol) in CH_2Cl_2 (10 mL) were added in that order. The purple solution was filtered quickly and the solvent allowed to evaporate slowly at room temperature until a purple solid appeared. The solid was separated, washed, and dried in vacuum. mp 179–180°C (dec). Yield 190 mg (75%). *Anal.* calcd. for $C_{16}H_{18}I_2PdS_2$: C 30.26, H 2.86, Pd 16.76; found: C 30.39, H 2.87, Pd 15.90.

(d) $PtCl_2$·BBTE

Potassium trichloro(ethylene)platinate(II) (74 mg, 0.20 mmol) was dissolved in acetone (15 mL) and the solution filtered. BBTE (60 mg, 0.22 mmol) in CH_2Cl_2 (10 mL) was added and the mixture filtered. The filtrate was allowed to evaporate at room temperature until yellow crystals formed. The solid was separated, washed with acetone and then ether, and dried in vacuum. mp 180–186°C (dec). Yield 86 mg (80%). *Anal.* calcd. for $C_{16}H_{18}Cl_2PtS_2$: C 35.54, H 3.36, Cl 13.12; found: C 35.99, H 3.56, Cl 12.93.

(e) PdX_2·L (X = Cl, Br, I, SCN)

Preparations of these complexes were analogous to those containing BBTE. Thus, the chloro complex was prepared directly from *cis*-$PdCl_2(PhCN)_2$ but for X = Br, I, or SCN, chloride was first removed using $AgCF_3SO_3$ and the appropriate halide or pseudohalide added as its potassium salt KX before the ligand solution was added.

$PdCl_2$·L: orange, mp 223–226°C (dec). Yield 85%. *Anal.* calcd. for $C_{10}H_{14}Cl_2PdS_4$: C 27.31, H 3.21, Cl 16.13, Pd 24.19; found: C 27.21, H 3.20, Cl 16.29, Pd 22.90.

$PdBr_2$·L: red, mp 210–213°C (dec). Yield 85%. *Anal.* calcd. for $C_{10}H_{14}Br_2PdS_4$: C 22.72, H 2.67, Br 30.23, Pd 20.12; found: C 21.96, H 2.58, Br 29.71, Pd 17.60.

PdI_2·L: purple, mp 237–240°C (dec). Yield 83%. *Anal.* calcd. for $C_{10}H_{14}I_2PdS_4$: C 19.28, H 2.27, I 40.76, Pd 17.09; found: C 19.43, H 2.28, I 37.74, Pd 15.50.

$Pd(SCN)_2$·L: red, mp 169–170°C (dec). Yield 77%. *Anal.* calcd. for $C_{12}H_{14}N_2PdS_6$: C 29.72, H 2.91, Pd 21.94; found: C 29.71, H 2.91, Pd 22.50.

(f) $PtCl_2$·L

This yellow complex was prepared in the same way as its BBTE analogue. mp 235–240°C (dec). Yield 79%. *Anal.* calcd. for $C_{10}H_{14}Cl_2PtS_4$: C 22.73, H 2.67, Pt 36.91; found: C 23.00, H 2.75, Pt 36.40.

X-ray

A summary of the crystal data for $PdBr_2$·L is in Table 1. The diffraction intensities were collected at 295 K using the $\theta/2\theta$ scan technique with profile analysis (22) at a scan speed of 4°/min. Three standards were measured after every 100 reflections and no significant crystal decay was detected. Space groups were determined by systematic absences. Unit cell parameters in Table 2 were obtained by a least-squares refinement of the setting angles for 46 reflections ($35° \leq 2\theta \leq 45°$). Lorentz and polarization factors were applied and corrections were made for absorption.

The structure was solved with MULTAN (23) plus a difference Fourier map and refined by full matrix least-squares with counting statistics weights. H-atom positions were calculated but their parameters were not refined. All heavier atoms were refined anisotropically. All calculations were performed with the NRCVAX Crystal Structure programs (24). Scattering factors were taken from the usual source (25). The final atomic positional parameters, the equivalent isotropic temperature factors and important bond lengths and angles are listed in Tables 2 and 4. Anisotropic thermal parameters, a full listing of bond lengths and angles and final structure factors are available as supplementary data.[3] Figure 1 shows a view of the molecule and its atomic numbering scheme.

Results and discussion

The infrared and electronic spectra (Table 3) are consistent with *cis*-planar arrangements of donor atoms (26, 27) and the X-ray results (Fig. 1) confirm that structure for $PdBr_2$·L. In addition, however, there is a weak thiophene-sulfur-to-palladium interaction, revealed by the X-ray study which probably occurs in the other PdX_2·L complexes (X = Cl, Br, I, SCN) as well.

Complexes such as these are known (28) to exhibit *d–d* transitions, ligand-to-metal charge transfer (LMCT), and metal-to-ligand charge transfer (MLCT) bands all of which overlap in the same region of the spectrum. Therefore, no specific assignments have been made although it should be noted that the lowest energy band in each case moves to higher energy in the sequence I < Br < Cl and Pd < Pt as would be expected for LMCT. Furthermore, the highest energy band ($\sim$40 000 cm^{-1} in solution or $\sim$28 000 cm^{-1} in mull spectra) moves very little as X changes in MX_2·L or MX_2·BBTE but rises in energy when M changes from Pd to Pt, again as expected for LMCT. It is

therefore tempting to suggest the former to be X → M LMCT and the latter to be S → M LMCT.

The conformation of the ligand in solid $PdBr_2 \cdot L$ (Fig. 1) is the same as that in $[CuL_2]^+$ (21) and $(CuCl_2 \cdot L)_2$ (16) and as in the case of the copper(II) complex of L, there is a weak apical thiophene-sulfur-to-metal interaction in $PdBr_2 \cdot L$. Apical bonds in five or six coordinate palladium complexes tend to be longer than their equatorial counterparts. For example, the axial and average equatorial lengths in the five coordinate $PdBr_2$ complex of 1,4,7-trithiacyclononane are 3.125 and 2.266 Å, respectively (29), while the corresponding lengths in the six coordinate Pd(II) complex of 1,4,7,10,13,16-hexathiacyclooctadecane are 3.273 and 2.309 Å (30). In comparison, the apical (thiophene) and average basal Pd—S distances in $PdBr_2 \cdot L$ are 3.1817(3) and 2.279 Å, respectively. The apical distance to the thiophene-sulfur of $PdBr_2 \cdot L$ is significantly less than the sum (3.40 Å) (31) of the van der Waals' radii of Pd and S. The palladium atom lies in the plane defined by the two coordinated thioether sulfurs and the two bromines and the bond angles at Pd deviate no more than 3.38° and on average only 1.78° from ideal values. Bond lengths, angles and other details of the $PdBr_2 \cdot L$ structure are in Tables 1, 2, and 4.

Although not common, bonds between thiophene-sulfur and Re, Fe, Ru, Rh, Cu(I), Ag, and B have been identified using X-ray techniques (7–15). These bonds have lengths that are more or less equal to the sum of the covalent radii of M and S although establishment of an appropriate covalent radius for calculation of apical bond lengths for metals such as Pd, Cu(I), Cu(II), or Ag(I) that form apical bonds reluctantly or whose complexes are subject to Jahn–Teller distortion is problematical. Other weaker interactions that involve bond lengths greater

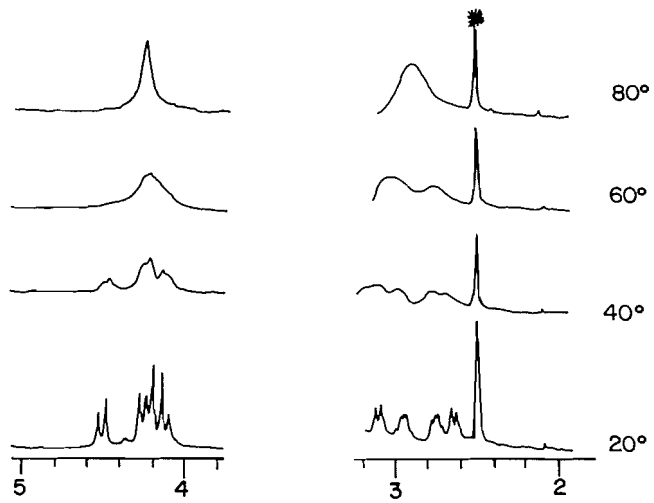

FIG. 2. ^1H nmr spectra of $PdCl_2 \cdot BBTE$ (* is d_6-DMSO).

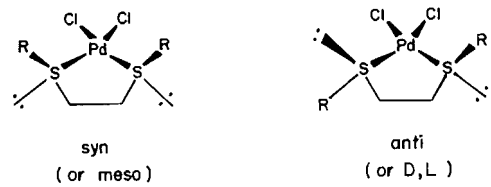

FIG. 3. Isomers of $PdCl_2 \cdot BBTE$ (R = $PhCH_2$).

than the sum of the usual covalent radii but less than the sum of the van der Waals' radii are also known such as that involving ligand L and Cu(II) (16). These interactions are analogous to the long apical M—S distances of 3.12 and 3.27 Å in macrocyclic polythioether complexes (29, 30) (*vide supra*) in the sense that they influence spectroscopic and other properties of the complexes but are weaker than other shorter M—S bonds in those molecules. The palladium bromide and related complexes of ligand L, described herein may be considered part of this latter group since the presence of the M—S(thiophene) interaction influences the rigidity of the molecules as observed by nmr (*vide infra*) even through the M—S(thiophene) distance is greater than the sum of the usual covalent radii of M and S.

The 300 MHz nmr spectra of all the BBTE complexes are similar and for the sake of brevity only that of $PdCl_2 \cdot BBTE$ (Fig. 2) will be discussed. At room temperature in d_6-dimethylsulfoxide it consists of a typical phenyl multiplet at 7.4 ppm from internal tetramethylsilane, a pair of partially overlapped AB quartets near 4.3 ppm due to benzylic methylenes and four distinct multiplets of equal intensity near 2.8 ppm due to $—CH_2CH_2—$ of the chelate ring. The integrated intensities of these three regions are in the ratio 10:4:4 as required. The occurrence of two sets of quartets near 4.3 ppm suggests two isomers (Fig. 3) are present in solution in the ratio 42%:58%. That which is present in the smaller amount has more de-shielded benzylic methylenes and is probably the *syn* isomer (19). The fact that only two AB quartets are seen may be attributed to conformational averaging of the axial and equatorial environments of the benzylic methylene hydrogens in each isomer so that only one averaged benzyl group is detected per isomer.

For analysis of the $—CH_2CH_2—$ portion of the spectrum near 2.8 ppm, the arguments applied by Hunter and Massey (20) to spectra of $PdCl_2 \cdot BISE$ (BISE = 1,2-bis(isopropylseleno)ethane) are appropriate. Thus, the observation at room temperature of two AA'BB' multiplets, one with widely separated components (~0.45 ppm) and another with narrowly separated ones (~0.2 ppm), all of which are of similar intensity, is consistent with the presence of nearly equal amounts of two isomers, both of which are undergoing reversal of their ring conformations that is rapid on the nmr time scale. This is the same conclusion already reached by examination of the benzylic methylene portion of the spectrum.

As the temperature of the solution is increased, the signals

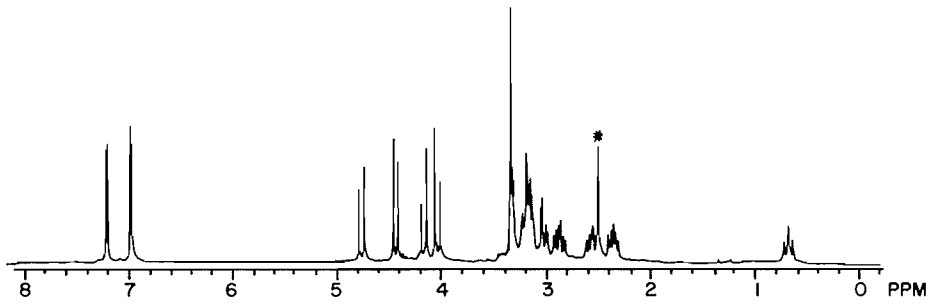

FIG. 4. ^{1}H nmr spectrum of $PdBr_2 \cdot L$ at room temperature.

near 4.3 ppm begin to coalesce as do those near 2.8 ppm until both become broad singlets at 353 K. These observations are consistent with the onset of rapid interconversion of the two isomers by either simultaneous or consecutive inversions at the two coordinated S-atoms (17, 20). Coalescence at 353 K for $PdCl_2 \cdot$BBTE may be compared to coalescences at 400 K (20) for $PdCl_2 \cdot$BISE or 240 K for $Mo(CO)_4 \cdot$BBTE (19). These are in accordance with the known trends in kinetic barriers to inversion as one changes either the identity of the inverting atom or the electropositive character of the metal to which the inverting atom is bound.

Thus, we may conclude that at room temperature the Pd and Pt complexes of BBTE are undergoing rapid exchange of the chelate ring conformations and of the axial and equatorial orientations of the lone pairs on the sulfurs. The complexes remain configurationally rigid, however, until the temperature is raised several tens of degrees when inversions at coordinated sulfurs interconvert the *syn* and *anti* isomers.

The 300 MHz ^{1}H nmr spectra of the complexes $MX_2 \cdot L$ (M = Pd, Pt; X = Cl, Br, I, SCN; L = 2,5,8-trithia[9](2,5)thiophenophane) are all similar (Table 5) and we shall therefore discuss in detail only that of $PdBr_2 \cdot L$ (Fig. 4) for which we also have X-ray structural data (Fig. 1). Subsequently, we will discuss the two differences between spectra of $PdBr_2 \cdot L$ and $Pd(SCN)_2 \cdot L$, the latter being the only member of the series for which significant differences occur. Spectral assignments are in Table 5.

At room temperature, H2 and H3, the two aromatic hydrogens give signals that are doublets near 7.2 and 7.0 ppm, respectively. These hydrogens are chemically non-equivalent as a result of the asymmetric way in which palladium is bound to the macrocycle. The non-equivalence of these hydrogens indicates the absence of a 1,4-heteroatom fluxionality involving S2, S3, and S4 similar to that reported for the nitrogen donor complex $Pd(non)_2^{2+}$ (non = 1,4,7-triazacyclononane) (6). This conclusion is supported by the ^{13}C spectrum (Table 6) which shows nine signals assigned by ^{13}C—^{1}H COSY and Attached Proton Test to all but one of the ten carbons in the molecule. The missing signal is due to C7 and is expected to be obscured by the solvent signal. Were the molecule fluxional only five signals would be expected.

This molecule is rigid in another respect as well. The hydrogens of every —CH_2— in the molecule are non-equivalent up to at least 120°C which indicates that inversions at S2 and S3 are not occurring. In the case of $PdCl_2 \cdot$BBTE, coalescence of the room temperature methylene signals to broad singlets has already occurred at 80°C and for $PdBr_2 \cdot L$ an even lower coalescence temperature, might be expected (17). Clearly, however, the rigidity of $PdBr_2 \cdot L$ is such that non-dissociative inversions at S2 and S3 are prevented even at 120°C.

[a] ^1H decoupled; in d_6-dmso.
[b] Obscured by solvent.
[c] Due to Pd species produced by ligand dissociation; cf $Pd(SCN)_4^{2-}$ at 119.0 ppm (34).

Unlike $PdCl_2 \cdot$BBTE, the two quartets near 4.5 ppm in the spectrum of $PdCl_2 \cdot L$ are due not to the presence of two isomers but rather to two different CH_2 groups in the same molecule. In fact, because S2 and S3 are part of a macrocyclic ring in which a third sulfur (S1) is also interacting with the metal, the only configuration possible for the five-membered chelate ring formed by L corresponds to the *syn* isomer of $PdCl_2 \cdot$BBTE. The remainder of the spectrum of $PdCl_2 \cdot L$ involves separate signals for each of the eight hydrogens comprising the two $-CH_2CH_2-$ units. One of these hydrogens is in a unique environment that is evidently much more shielded than the others since its signal is at comparatively high field (0.67 ppm). This is designated as H8A and is the hydrogen on C8 that lies over the center of the thiophene ring (Fig. 1) and is therefore subjected to the shielding effect of the induced ring current in the aromatic π-system. Because of the rigidity of the molecule, the conformations available to the chelate ring, $PdS2CH_2CH_2S3$, are strictly limited. For example, the envelope conformation which requires both sulphur lone-pairs to be simultaneously axial or simultaneously equatorial is not possible. It is this envelope conformation that is usually the transition state between two half-chair conformations and in its absence a pseudo-librational route between the two half-chair conformations is likely to be of sufficiently low kinetic barrier as to be undetectable by nmr (32). In either half-chair conformation, the $-CH_2CH_2-$ unit will be an ABCD spin system and the two such systems are unrelated by any symmetry element. Therefore, two ABCD spectra would be expected if conformational exchange is slow or one averaged ABCD spectrum if it is rapid. In view of the predicted low barrier to conformational exchange and our earlier observation of rapid conformational exchange in $PdX_2 \cdot$BBTE we would anticipate just one ABCD pattern at room temperature as is observed (Fig. 4). This interpretation is supported by the absence of change in these signals up to at least 120°C by which temperature any barrier to this conformational exchange must surely have been overcome.

The other $-CH_2CH_2-$ unit is also an ABCD system. As a result of steric crowding, due at least in part to the Pd–S1 interaction, conformational possibilities in this region of the molecule are also strictly limited and the spectrum observed at room temperature is consistent with the rigid structure in Fig. 1.

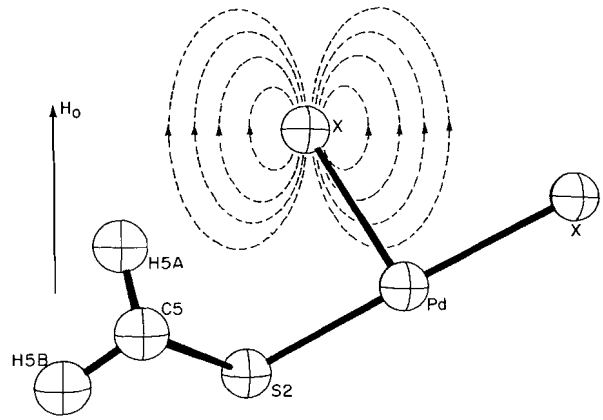

FIG. 5. Neighbour effects at H5A and H5B from X in $PdX_2 \cdot L$.

As the solution is warmed to 120°C, the two pairs of peaks that comprise the H5A–H5B quartet at ~4.5 ppm *move away* from each other with, however, no change in the coupling. The total movement is 0.02 ppm for the more shielded pair and 0.06 ppm for the lower field pair. There is no other change in the entire system. This curious behaviour is observed to a greater or lesser extent for all members of the $MX_2 \cdot L$ series and is a neighbour anisotropic effect made possible by the rigid orientations of H5A and H5B with respect to the atom X (Fig. 5).

As the temperature is raised, thermal enhancement of the bending vibration of H5A—C5—H5B occurs. In this vibrational mode, movement of one of the hydrogens is at a nearly constant radius from X whereas the other's motion is along a radius from X. Therefore, the extent of deshielding by this neighbour anisotropic contribution of X will vary with temperature for the nearer, more deshielded hydrogen but will remain more or less constant for the more distant and less deshielded hydrogen.

There is a second manifestation of this neighbour effect made possible by stereochemical rigidity. The quartet due to H5A and H5B moves to lower field as X changes from Cl to Br to I but the shift is in the wrong direction for an electronegativity effect. However, it can be attributed to a deshielding neighbour effect in which larger, more polarizable I will experience induced circulation of its electrons more readily than Cl. The induced field which is deshielding at H5A and H5B will therefore be larger for I than for Cl. This explanation is supported by the fact that the chemical shift difference between H5A and H5B is essentially the same for all X (i.e. both hydrogens are affected proportionally the same as X is varied) and J_{gem} is the same in all cases.

The spectrum of $Pd(SCN)_2 \cdot L$ shows two major differences from those of all other complexes in this series. The first difference is that free ligand peaks are present and grow in intensity as the temperature is raised. This indicates that formation of $Pd(SCN)_2 \cdot L$ is an equilibrium process and that the formation is exothermic. The second striking difference is that the H5A—H5B signal is a singlet. The only way this can occur while maintaining all other hydrogens distinctive is by dissociative interchange of H5A and H5B. It is known (33) that M—SCN systems are usually bent (~110°) and that the N atom is appreciably basic (34). The pK_a's (35) of DMSO (35.1), $PhCH_3$ (44.0), and $PhCH_2SPh$ (30.8) suggest that H5A and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12
For personal use only.

H5B should be significantly acidic and may therefore interchange by a process involving intermediate residence on the basic nitrogen of thiocyanate either in the same or a different molecule. Why the thiocyanate complex should dissociate its ligand so readily when none of the other complexes in this study show any sign of dissociation until they reach their decomposition temperatures may be due to the fact that S-bonded SCN is a better π-acid than halide and its presence weakens the *trans* M—S bond.

In conclusion the complexes $MX_2 \cdot L$ have been shown to involve pseudo-square pyramidal coordination with a weak interaction between the metal and a thiophene-sulfur in the apical position. This interaction contributes to an unexpected rigidity in these complexes which do not undergo either fluxional processes or sulfur inversions up to at least 120°. These results are in contrast with the behaviour of complexes formed by tridentate N-donor macrocycles and simple chelating dithioethers, respectively. Furthermore, unexpected effects on the nmr spectra of $MX_2 \cdot L$ species as X or temperature are varied have been identified as consequences of this rigidity and an uncommon acid–base reaction between a C—H bond and the nitrogen of a coordinated thiocyanate has been observed. The complexes $MX_2 \cdot L$ have been shown to be surprisingly robust and rigid except when X = SCN. These findings are of interest for a variety of reasons not the least of which involves an improved understanding of the behaviour in solution of these or related substances that may be used as chemotherapeutic agents or catalysts.

Received March 22, 1989[3]

VÉRONIQUE BELLOSTA, STANISLAS CZERNECKI, DANIÈLE AVENEL, SAÏD EL BAHIJ, and HÉLÈNE GILLIER-PANDRAUD. Can. J. Chem. **68**, 1364 (1990).

Reinvestigation of the structure of (4,6-di-*O*-acetyl-2,3-dideoxy-α-D-*erythro*-hex-2-enopyranosyl)benzene, obtained by the title reaction, is described. The α anomeric configuration was clearly established by X-ray diffraction methods on the deacetylated compound. The sugar moiety exhibits a distorted half-chair $^0H_5$ conformation. Circular dichroism data are included. These new data demonstrate the stereospecificity of intermediate arylpalladium *syn* addition on the α face of the glycal. The resulting adduct collapses in two different ways: *syn* elimination of acetatohydridopalladium leading to **3**, *trans* elimination of palladium acetate affording **5**.

Key words: *C*-glycosides, palladium, X-ray diffraction.

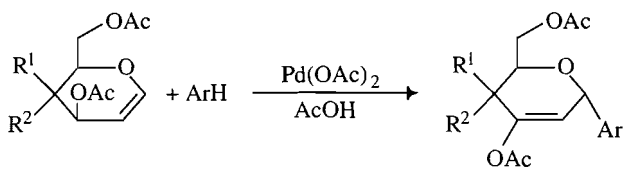
VÉRONIQUE BELLOSTA, STANISLAS CZERNECKI, DANIÈLE AVENEL, SAÏD EL BAHIJ et HÉLÈNE GILLIER-PANDRAUD. Can. J. Chem. **68**, 1364 (1990).

La structure du (di-*O*-acétyl-4,6-didésoxy-2,3-α-D-*érythro*-hexéno-2-pyrannosyl) benzène, obtenu par la réaction du titre, est réétudiée. La configuration anomérique est clairement établie comme étant α par diffraction des rayons X sur le composé déacétylé. La conformation du cycle glucidique est demi-chaise $^0H_5$ déformée. Des données de dichroïsme circulaire sont fournies. Ces nouvelles données démontrent la stéréospécificité de la *syn*-addition de l'arylpalladium intermédiaire sur la face α du glycal. L'adduit formé conduit ensuite à **3** par *syn*-élimination d'acétatohydruropalladium ou à **5** par *trans*-élimination d'acétate de palladium.

Mots clés : *C*-glycosides, palladium, diffraction des rayons-X.

Introduction

We previously demonstrated that the title reaction constitutes a new synthesis of *C*-glycosides (1). When 3,4,6-tri-*O*-acetyl-1,5-anhydro-2-deoxy-D-*arabino*-hex-1-enitol (tri-*O*-acetyl-D-glucal **1**) and its D-*lyxo* isomer (tri-*O*-acetyl-D-galactal **2**) were reacted with an aromatic compound in the presence of acetic acid and palladium acetate, 2,3-unsaturated α-D-*C*-glycopyranosides **3** and **4** were obtained in acceptable yields (43–67%).



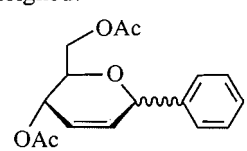
1 R^1 = H, R^2 = OAc
2 R^1 = OAc, R^2 = H

3 R^1 = H, R^2 = OAc
4 R^1 = OAc, R^2 = H

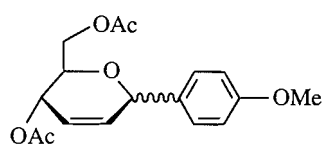
Unambiguous determination of the anomeric structures of **3** and **4** was rather difficult because only one anomer was obtained, thus methods using comparisons such as the γ-effect rule in ^{13}C nmr (2), which assigns the less shielded C-1 or C-5 signals to the *cis* anomer (β-D) (3, 4), were precluded. Furthermore, due to the presence of a double bond between C-2 and C-3, the values of the coupling constants $^3J_{1-2}$ (2.5–3.9 Hz) (1) were compatible with both configurations.

The structures of these compounds were finally determined unambiguously by X-ray diffraction for **4** (5) and by 250 MHz ^1H nmr for **3** and **4** after transformation of the enol-ester function into the parent oxime (6).

From tri-*O*-acetyl-D-glucal **1** and benzene a by-product **5** was isolated (≅10%), to which the β configuration was initially assigned.



5



6

Comparison of the specific rotation of **5** ($[\alpha]_D^{20}$ +3.3° (*c* 1.34, $CHCl_3$)) with the sole example of 2,3-dideoxy-2,3-unsaturated aryl-*C*-glycoside described in the literature at that time, **6** (7) ($[\alpha]_D^{20}$ +250° (*c* ≅ 1, CH_2Cl_2)), clearly indicated that the anomeric configurations were different. Since **6** was claimed (7) to be the α anomer,[4] the β configuration was

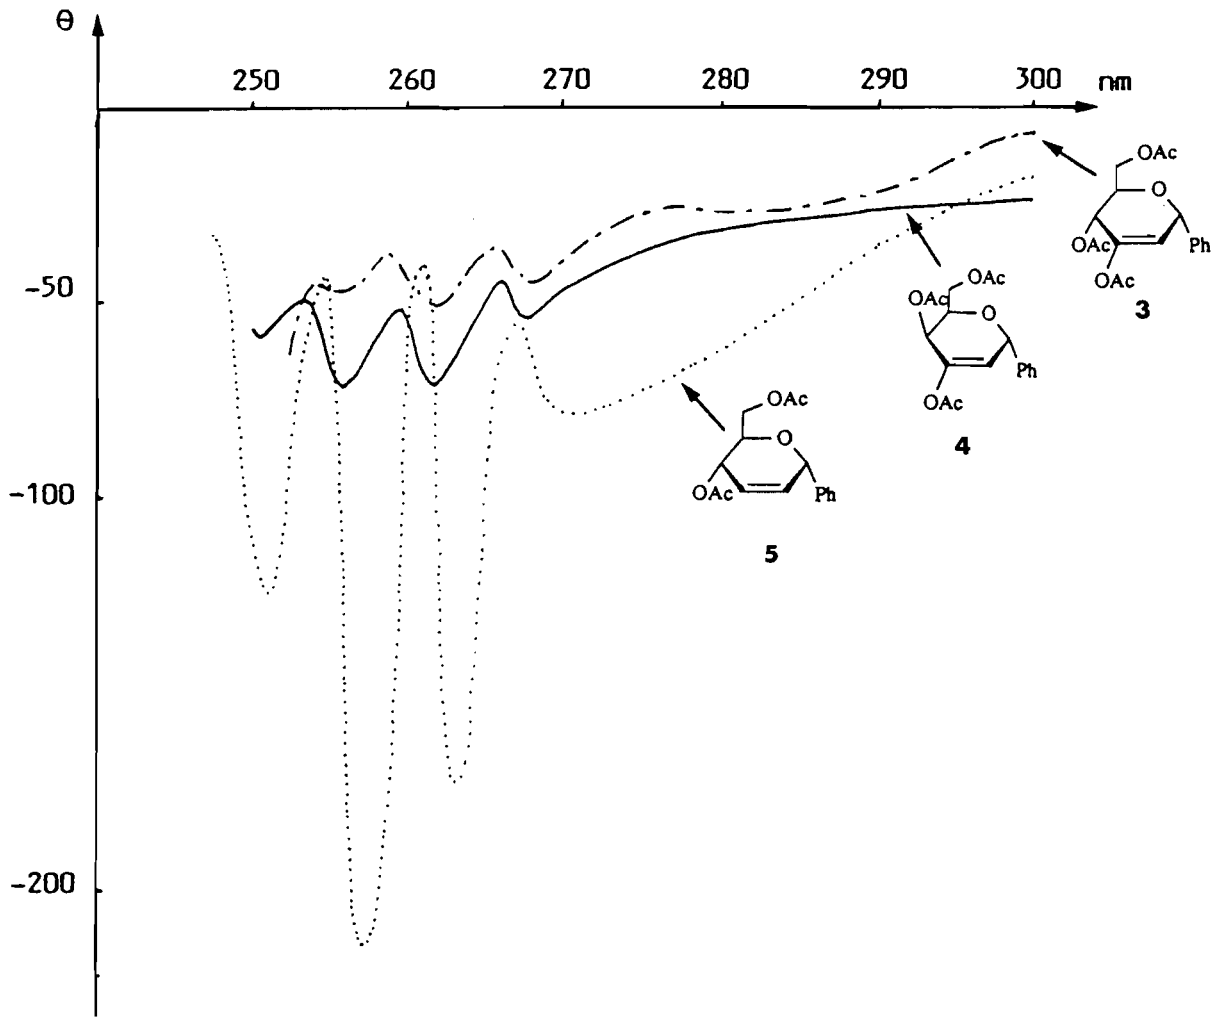

FIG. 1. Circular dichroism spectra of *C*-glycosides **3**, **4**, **5** recorded in 95% ethanol.

assigned to **5**. Rigorously, the aromatic ring was not the same in **5** and **6**, but we observed, in the series of aryl 2,3-unsaturated α-D-*C*-glycopyranosides derived from tri-*O*-acetyl-D-galactal, that the specific rotation was weakly influenced by the nature of this group (1).

We were not very confident in this assignment because several exceptions to Hudson's rules of isorotation were observed by different authors (9) for alkyl-2,3-dideoxy-hex-2-enopyranosides. Moreover the $^3J_{4-5}$ value observed for **5** (6.8 Hz in $CDCl_3$, 7 Hz in C_6D_6) appeared to us a little too small for a quasi-axial–axial relationship between H-4 and H-5. Meanwhile, several anomeric pairs of 2,3-unsaturated D-*C*-glycosides (3, 10–12) and *C*-nucleosides (13) appeared in the literature. Generally the coupling constant $^3J_{4-5}$ for the conformationally stable β-D anomer with all groups in the quasi-equatorial or equatorial position is high (8.7–9.4 Hz). For the conformationally more flexible α-D anomer this value is usually smaller (3.3–7 Hz). When the specific rotations were given (3, 10, 11), it was found that these compounds do not obey Hudson's rules of isorotation.

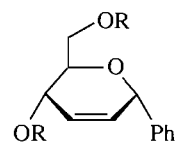
All these data prompted us to reinvestigate the structure assignment of compound **5**.

Results and discussion

Circular dichroism

Since compound **5** was not crystalline, we decided to examine its circular dichroism (cd) curves and to compare them with those of compounds **3** and **4** of known anomeric configuration. We have observed for a variety of aryl-*C*-glycosides that the sign of the Cotton effect is determined by the anomeric configuration and is not influenced by changes in conformation or by different substitutions at C-2, C-3, or C-4 (14).

Figure 1 shows that all three compounds give very similar curves, indicating the same spatial arrangement of the two chromophores present in the molecule (15). Consequently the α configuration should be assigned to compound **5**.



5 R = Ac
5' R = H

Furthermore, it has to be noticed that for these α-D anomers a negative Cotton effect is observed, whereas a positive one is observed for α-D-*C*-glycosides with no 2,3-unsaturation (11).

X-ray diffraction

Finally we were able to obtain crystals suitable for X-ray diffraction from the deacetylated derivative **5'**. The crystal-

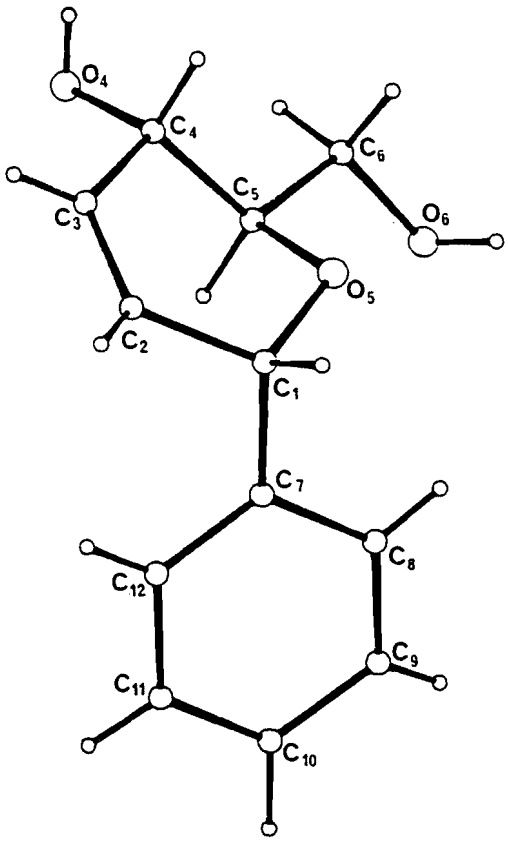

FIG. 2. ORTEP (16) representation of the molecule and atomic numbering.

lographically observed structure (ORTEP (16)) and atomic numbering are shown in Fig. 2. Coordinates and isotropic thermal parameters for carbon and oxygen atoms are listed in Table 1. Interatomic distances and bond angles are given in Tables 2 and 3.

Although the X-ray data determined only the relative position of the atoms, the certainty with respect to the chirality of C(4) and C(5) unambiguously established the α configuration of C(1). The enopyranoid ring of **5′** exhibits a distorted half-chair $^{0}H_{5}$ conformation in which C(1), C(2), C(3), C(4) are coplanar (π), C(5) and O(5) deviating disymmetrically by 0.53 and 0.25 Å respectively on both sides of this π plane. The ring deformation is related to the torsion angles listed in Table 4.

The dihedral angle between the π and benzene planes is 57.3°. This deviation from perpendicularity is related to the distortion of the $^{0}H_{5}$ enopyranoid ring. The values of the exocyclic torsion angles O(5)C(1)C(7)C(8) (−142.1(6)°) and O(5)C(1)C(7)C(12) (41.1(4)°) indicate that the conformation around the C(1)—C(7) bond approaches the energetic minimum of the "axial perpendicular" conformation of phenylcyclohexane (17).

Twelve molecules related to **5′** have already been characterized by X-ray diffraction (5, 18). Among these 13 enopyranoid rings, the ideal $^{0}H_{5}$ conformation was adopted by three of them (18*a–c*); in five others, this conformation was slightly distorted (8, 18*d–g*); in the remaining five (compound **5′** and refs. 18*e*, *h*, and *i*) a significant deformation towards the E_5 conformation was observed and C(5) deviates from the π plane at least 0.2 Å more than O(5). This deformation could be related neither to the size of the enopyranoid ring substituents nor to the conformation

change at C(4). It could rather be ascribed to the crystal field constraints.

Mechanistic implications

The better knowledge of the stereochemical outcome of the reaction affords a new insight into its mechanism, as exemplified for **1** in Scheme 1.

As proposed in our previous paper (1), the main product (**3**) is formed by a *syn* addition of an arylpalladium (ArPdOAc) from the α face of the glycal followed by a *syn* elimination of hydridoacetatopalladium.

Since the anomeric configuration of **5** was initially incorrectly assigned, a *syn* addition of ArPdOAc from the β face of the glucal followed by a *syn* elimination of $Pd(OAc)_2$ was initially evoked (1) to explain its formation. At that time, the stereochemistry of HPdOAc elimination was well documented (19), whereas that of $Pd(OAc)_2$ loss was not known.

Finally the *stereospecificity* of the initial attack of ArPdOAc to the glucal is demonstrated by the fact that **3** and **5** have the same anomeric configuration. Consequently, only one σ-alkyl palladium intermediate is generated from which **3** is formed by the usual *syn* elimination of HPdOAc and **5** by *anti* elimination of $Pd(OAc)_2$ after conformational change. It has been recently demonstrated (13) with rigid structures that the steric requirements for an *anti* elimination of palladium acetate is a *trans*-diaxial arrangement of palladium and β-acetate.

It is unclear why attack of the organopalladium reagent on the pyranoid glycal double bond for π-complex and σ-adduct formation should be stereospecific. Daves and co-workers also observed (13) that the Pd-mediated reactions of various pyranoid glycals with (1,3-dimethyl-2,4-dioxo 1,2,3,4-tetrahydropyrimidin-5-yl)mercuric acetate occurred regio- and stereospecifically to form, in each case, a single σ-alkylpalladium intermediate. The same stereospecificity was observed in our laboratory in the Pd-mediated arylation of three enones derived from glycals (20).

Experimental

General procedures are the same as indicated before (1).

*(4,6-Di-O-acetyl-2,3-dideoxy-α-D-*erythro*-hex-2-enopyranosyl)-benzene* **5** was prepared as previously reported (1) and characterized as follows: oil; R_f 0.59 (pet. ether:ether, 1:2); $[\alpha]_D^{20}$ +3.3° (*c* 1.34, $CHCl_3$); ν_{max} (film): 1735 (ester), 1690 (C=C), 730 (*cis*-alkene) cm^{-1}; uv (95% ethanol) ε_{257} = 553; ^1H nmr δ ($CDCl_3$; 250 MHz): 2.07 (s, 3H, $OCOCH_3$), 2.09 (s, 3H, $OCOCH_3$), 3.85 (ddd, 1H, H-5, J_{4-5} = 6.8 Hz), 4.10 (dd, 1H, H-6, J_{5-6} = 5.9 Hz and $|J_{6-6'}|$ = 12 Hz, 4.27 (dd, 1H, H-6′, $J_{5-6'}$ = 3.1 Hz), 5.32 (m, 1H, H-4), 5.33 (m, 1H, H-1), 5.99 (ddd, 1H, H-2 or H-3), 6.19 (ddd, 1H, H-2 or H-3), 7.27–7.45 (m, 5H, Ph); δ (C_6D_6; 250 MHz): 1.67 (s, 3H, $OCOCH_3$), 1.69 (s, 3H, $OCOCH_3$), 3.93 (ddd, 1H, H-5, J_{4-5} = 7 Hz), 4.12 (dd, 1H, H-6′, $J_{5-6'}$ = 3.2 Hz), 4.28 (dd, 1H, H-6, J_{5-6} = 6 Hz and $|J_{6-6'}|$ = 12 Hz), 5.13 (dd, 1H, H-1, J_{1-4} = 2.4 Hz), 5.44 (ddd, 1H, H-4), 5.76 (ddd, 1H, H-2, J_{2-3} = 10.3 Hz, J_{2-1} = 2.9 Hz, and J_{2-4} = 1.5 Hz), 5.88 (ddd, 1H, H-3, J_{3-1} = 2 Hz and J_{3-4} = 2.5 Hz), 6.87–7.20 (m, 5H, Ph); ^{13}C nmr δ ($CDCl_3$, 77.05 60 MHz): 20.62 and 20.90 (2 × $OCOCH_3$), 62.9 (C-6), 65.11 (C-4), 69.51 (C-5), 73.6 (C-1), 124.9 (C-3), 131.5 (C-2), 127.8, 128.11, 128.4, 138.97 (C phenyl); mass spectrum (70 eV) *m/e*: 290 (M^+) 105 (100%) (Ph-C≡O^+). Anal. calcd. for $C_{16}H_{18}O_5$ (290.3): C 66.19, H 6.25; found: C 66.16, H 6.17.

*(2,3-Dideoxy-α-D-*erythro*-hex-2-enopyranosyl)benzene* **5′**

A solution of **5** (100 mg, 0.34 mmol) in MeOH (4 mL) was stirred in the presence of 15 mg of Amberlite IRN-78 (OH^-) for 16 h at room temperature. After completion of the reaction was indicated by tlc (pet. ether:ether, 1:2) the reaction mixture was filtered. Removal of solvent gave a crude product, which was purified by flash column chromatography (silica gel; $CHCl_3$:MeOH, 98:2) to give **5′** (54 mg, 77%); mp 101–102°C (cyclohexane, diethyl ether, absolute ethanol); R_f 0.55 ($CHCl_3$:MeOH, 9:1); $[\alpha]_D^{20}$ −52° (*c* 0.97, MeOH). Anal. calcd. for $C_{12}H_{14}O_3$ (206): C 69.90, H 6.80; found: C 68.79, H 6.90.

Circular dichroism spectra were recorded on a Jobin et Yvon dicrograph III at room temperature with 1- or 2-cm cells. The compounds were dissolved in 95% EtOH to a concentration of ca. 0.6 mg/mL.

X-ray diffraction

A thin elongated plate (0.08 × 0.2 × 0.6 mm), obtained by

crystallization from a (cyclohexane, diethyl ether, absolute ethanol) solution, was mounted on an automatic Philips PW 1100 diffractometer. The orthorhombic cell parameters were obtained by least-squares refinement with the 2θ values of 25 reflections ($20 < \theta < 50°$) for monochromatized CuK_α radiation: $a = 21.338(5)$, $b = 8.161(2)$, $c = 6.209(1)$ Å, $V = 1081.2(6)$ Å^3, space group $P2_12_12_1$, $Z = 4$, $\rho_c = 1.27$ g cm^{-3}. Intensities were collected in the following conditions: room temperature, $2\theta_{max} = 138°$; $-24 < h < 24$, $-9 < k < 9$, $0 \leq l < 7$; θ–2θ scan mode; $\mu = 6.57$ cm^{-1}. Of the 4386 collected intensities, 1193 were independent and, on the criterion $I > 2.5\sigma(I)$, 1112 were considered observed above background.

The carbon and oxygen atom positions, obtained by multisolution direct methods (DEVIN program (21)), were refined by a full-matrix least-squares procedure (SHELX (22)). The H atoms were located on difference electron-density maps calculated at intermediate stages of the refinement. In the final cycles, positional parameters for all atoms were refined. Anisotropic thermal parameters were varied only for the carbon and oxygen atoms. The final values of the residuals $R(F)$ $(\Sigma(|F_o| - |F_c|)/\Sigma|F_o|)$ and $R(WF)$ $(\Sigma(|F_o| - |F_c|) \times W^{1/2}/\Sigma|F_o| \times W^{1/2})$ with $W = 1/\sigma^2(F)$ were respectively 0.08 and 0.066. The highest residual electron density on the difference map was 0.4 e Å^{-3}. Tables of anisotropic thermal parameters, hydrogen atom coordinates, and a listing of structure factor amplitudes have been deposited.[5]

Ozonolyses of 1,4-disubstituted 1,3-cyclohexadienes and of related compounds in methanol

KARL GRIESBAUM,[1] HENRI MERTENS, AND IN CHAN JUNG
Engler-Bunte-Institut, Bereich Petrochemie, Universität Karlsruhe (TH), D-7500 Karlsruhe, Germany

Received November 10, 1989

KARL GRIESBAUM, HENRI MERTENS, and IN CHAN JUNG. Can. J. Chem. **68**, 1369 (1990).

Ozonolyses of 1,4-dimethyl- (**5***a*) and of 1-methyl-4-isopropyl-1,3-cyclohexadiene (**5***b*) in methanol occur stepwise by sequential cleavage of the two double bonds. Monoozonolysis products are the corresponding compounds **6** and **7**, and diozonolysis products are the corresponding cyclic peroxides **19, 20**, and **21**. By contrast, ozonolysis of the non-conjugated diene 2,5-dimethyl-1,5-hexadiene (**13**) in methanol occurs by simultaneous mono- and diozonolysis to give **14, 16***a*, **18***a*, and **20***a*.

Key words: ozonolysis, 1,3-cyclohexadienes, 3-hydroperoxy-1,2-dioxanes, 2,5-bis-hydroperoxy-2,5-dimethoxyhexane, 3-hydroxy-1,2-dioxanes, 3,6-dimethoxy-1,2-dioxanes.

KARL GRIESBAUM, HENRI MERTENS et IN CHAN JUNG. Can. J. Chem. **68**, 1369 (1990).

L'ozonolyse, dans le méthanol, des 1,4-diméthyl- (**5***a*) et 1-méthyl-4-isopropyl-cyclohexa-1,3-diène (**5***b*) se produit par des clivages par étape des deux doubles liaisons. Les produits de monoozonolyse sont les composés **6** et **7** alors que les produits de diozonolyse sont les peroxydes cycliques correspondants **19, 20** et **21**. Par opposition, l'ozonolyse dans le méthanol d'un diène non-conjugué, comme le 2,5-diméthyl-hexa-1,5-diène (**13**), provoque des mono- et des di-ozonolyses simultanées qui fournissent les produits **14, 16***a*, **18***a* et **20***a*.

Mots clés : ozonolyse, cyclohexa-1,3-dièns, 3-hydroperoxy-1,2-dioxanes, 2,5-bis-hydroperoxy-2,5-diméthoxyhexane, 3-hydroxy-1,2-dioxanes, 3,6-diméthoxy-1,2-dioxanes.

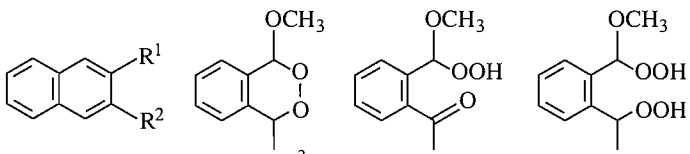
Introduction

Ozonolysis reactions of conjugated cyclic diolefins in participating solvents have not been studied extensively, and essential details concerning the course of events are unknown. Ozonolysis of 1,3-cyclohexadiene gave a mixture of oxalic acid and succinic acid (1); ozonolysis of 1-methyl-4-isopropyl-1,3-cyclohexadiene in methanol, followed by reduction with sodium iodide in acetic acid, gave 2-methyl-3,6-dioxoheptane (2). Ozonolysis of naphthalene (**1***a*) and of the substituted naphthalenes **1***b*–*d* in methanol afforded in each case the hemiperacetal **2***a*, and **1***d* gave, additionally, the peracetal **2***d* (3). Compounds **3** and **4** have been postulated, yet not proven, as intermediates for **2***a* and **2***d*, respectively. Similar results were reported for the ozonolysis of 1-methylnaphthalene (4) and of substituted 2-methoxynaphthalenes (5) in methanol.



1 **2** **3** **4**

	R^1	R^2	R^3
a	H	H	H
b	CH_3	CH_3	H
c	OH	H	H
d	OCH_3	H	CH_3

The results of these ozonolysis reactions did not reveal (a) whether ozone attack at the two double bonds of the diene systems occurred simultaneously or consecutively, (b) the direction of cleavage, and (c) the nature of the primary cleavage products. In line with our continued interest in the ozonolysis of conjugated dienes (6), we have now studied the ozonolysis of the cyclodienes **5***a* and **5***b*, and of the acyclic substrates **13** and **15** in methanol at ca. −75°C.

Results and discussion

Monoozonolyses of the dienes 5a, 5b, *and 13*

Treatment of **5***a* with 0.7 molar equivalents of ozone gave the two monoozonolysis products **6***a* and **7***a* in a ratio of 3:2, as shown by ^{1}H nmr analysis of the fresh ozonolysis product. Compound **7***a* could be isolated and structurally assigned by spectroscopic methods. At room temperature it decomposed slowly to give a mixture of **8***a* and **9***a*. Compound **6***a* was less stable and decomposed when we tried to isolate it. Hence its structural assignment is based only on its ^{1}H nmr data, which were obtained from the mixture of **6***a* and **7***a* in the crude reaction product, and on the fact that reduction of this mixture with dimethyl sulfide gave *Z*-**8***a* and *E*-**8***a* (ratio 1:2) as the sole products.

Treatment of **5***b* with ca. 0.8 molar equivalents of ozone afforded a peroxidic product mixture from which ca. 3% of **7***b*, 5% of **7***c*, 6% OF **8***b* (unknown stereochemistry), 2% of *E*-**8***c*, 2% of *Z*-**8***c*, 1% of **10***b*, and 0.1% of **10***c* have been isolated. While **6***b* and **6***c* could not be positively identified in the product mixture, there is indirect evidence for their transient existence from the results of the diozonolysis of **5***b* as reported below. We assume, by analogy with **6***a*, that **6***b* and **6***c* are labile and undergo rapid decomposition, possibly in part by oxygen transfer to the double bonds of **8***b* and **8***c* to give epoxides **10***b* and **10***c*, respectively.

The isolated hydroperoxides **7***b* and **7***c* decomposed spontaneously in $CDCl_3$, and within ca. 18 h as neat samples at room temperature, to give **8***b* and **8***c*, respectively. In $CDCl_3$/pyridine they were stable for several hours. Reductions of **7***b* and **7***c* with dimethyl sulfide also afforded **8***b* and **8***c*, respectively. Compound **8***b* of unknown geometry as well as *Z*-**8***c* and *E*-**8***c* have been identified by comparison of their ^{1}H nmr and mass spectral data with those published in the literature (7). Epoxides **10***b* and **10***c* have been tentatively identified based on their ^{1}H nmr data.

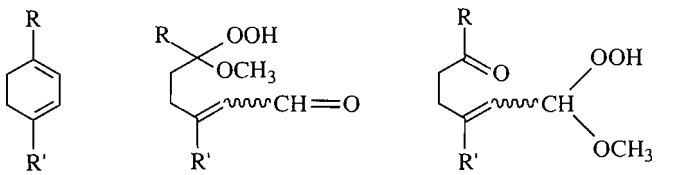
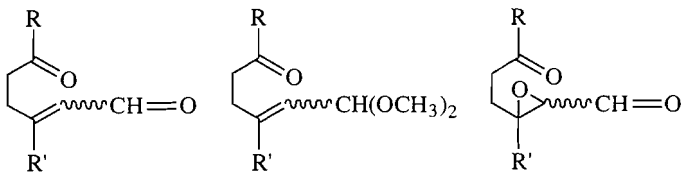
The relative proportions of the ozonolysis products in the crude reaction mixture could not be determined by glc analysis due to the thermal instability of **7***b* and of **7***c*, nor by ^{1}H nmr analysis due to overlap of diagnostic signals. Immediate reduction of a fresh ozonolysis product mixture with dimethyl sulfide afforded **8***b* and **8***c* in relative amounts of 70 and 30%.

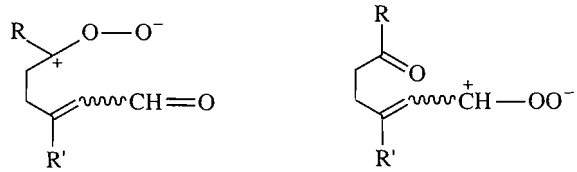
The above results show that ozone attack at the conjugated diene systems of **5***a* and **5***b* occurs stepwise and that, probably for steric reasons, attack at the methyl substituted double bond of **5***b* is approximately 2.3 times faster than attack at the isopropyl substituted double bond. The direction of cleavage in the monoozonolysis of **5***a*, which gave **11***a* and **12***a* in approximately equal amounts as primary cleavage products, is not in line with the experience that trialkyl substituted double bonds are almost exclusively cleaved to give the higher substituted carbonyl oxide. We believe that the stepwise attack of ozone at **5***a* and **5***b* is due to the fact that the oxygenated functional groups that are formed in allylic positions to the remaining double bonds of the monoozonolysis products **6** and **7** deactivate these double bonds against further ozone attack. Similarly, the relatively high proportion of **7***a* formed in the ozonolysis of **5***a* can be ascribed to resonance stabilization of the positive centre of the carbonyl oxide moiety in **12***a* by the neighbouring double bond.



5 **6** **7**



8 **9** **10**

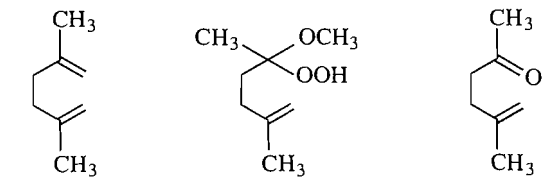


11 **12**

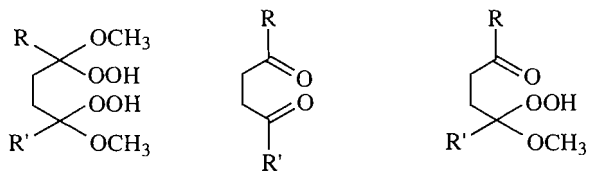
a: R = R' = CH_3
b: R = CH_3, R' = $(CH_3)_2CH$
c: R = $(CH_3)_2CH$, R' = CH_3

To test the above hypotheses concerning the reasons for the stepwise ozone attack and for the direction of cleavage, we investigated the monoozonolysis of the non-conjugated diene **13**. Treatment of **13** with 0.7 molar equivalents of ozone gave a mixture of **14** (52%),[2] **16***a* (23%), **19***a* (7%), *cis*-**20***a* (10%), and *trans*-**20***a* (8%), as shown by ^{1}H nmr analysis. Hydroperoxides **14** and **16***a* have been isolated and characterized by their ^{1}H nmr spectra as well as by reduction with triphenyl phosphine to give **15** and **17***a*, respectively. Monoozonolysis of **13** followed by immediate reduction with triphenyl phosphine afforded **15** and **17***a* in a ratio of 54:46.

From these results it can be concluded that, in contrast to the conjugated diene **5***a*, the two double bonds in **13** are almost simultaneously attacked by ozone to give approximately equal amounts of mono- and diozonolysis products. This is ascribed to the fact that the functional groups introduced by monoozonolysis are so remote from the remaining double bond that they do not decrease its reactivity towards ozone attack. It can be further concluded that ozone cleavage of the double bonds in **13** occurs predominantly in one direction only, with formation of the higher substituted carbonyl oxides, since there was no indication for the presence of either **15** or **17***a* in the product mixture.



13 **14** **15**



16 **17** **18**

a: R = R' = CH_3
b: R = CH_3, R' = $(CH_3)_2CH$

Diozonolyses of 5a, 5b, *and* **13** *and ozonolysis of some model compounds*

Diozonolysis of **5***a* gave 70–80% of **16***a* along with small amounts, each, of **19***a*, *cis*- and *trans*-**20***a*, and *cis*- and *trans*-**21***a*. After warm-up to room temperature and evaporation of the solvent, the contents of **19***a* (33%),[3] *cis*-**20***a* (12%), *trans*-**20***a* (19%), *cis*-**21***a* (11%), and *trans*-**21***a* (24%) had considerably increased at the expense of that of **16***a*, which had virtually disappeared.

Diozonolysis of **13** and oznonolysis of **14** gave similar results: Immediately after completion of the reaction, **16***a* was the major product in selectivities of 65% and 85%, respectively, but after warm-up to room temperature **16***a* had again disappeared. Thus, the aged product mixture derived from the ozonolysis of **13** contained **19***a* (12%), *cis*-**20***a* (12%), *trans*-**20***a* (11%), *cis*-**21***a* (20%), and *trans*-**21***a* (45%), yet none of **16***a*. From such mixtures, *cis*-**20***a* (in admixture with 30% of the *trans* isomer), *trans*-**20***a* (in admixture with 10% of the *cis* isomer), *cis*-**21***a*, and *trans*-**21***a* have been isolated.

Ozonolysis of **15** gave a mixture of **17***a* (27%)[2] and **19***a* (73%), from which **19***a* has been isolated. There was no indication for the presence of **18***a*.

Diozonolysis of **5***b* and subsequent warm-up to room temperature gave a product mixture from which **19***b*, **19***c*, and **21***b*, each of unknown stereochemistry, as well as *cis*-**20***b*, *trans*-**20***b*, *cis*-**20***c*, *trans*-**20***c*, and a mixture of **17***b* and **22**

[2]Relative product distribution. The products derived from the $=CH_2$ moiety are not included in the material balance.

[3]Relative product distribution. The products derived from the =CH—CH= moiety are not included in the material balance.

have been isolated. Due to overlap of diagnostic signals, the relative amounts of these compounds in the product mixture could not be determined by ^1H nmr spectroscopy. Ozonolyses of **8***b* and of **8***c* gave mixtures of **17***b* (58%), **19***b* (31%), **22** (11%), and of **17***b* (41%), **19***c* (32%), **22** (27%), respectively.

a: R = R' = CH_3
b: R = CH_3, R' = $(CH_3)_2CH$
c: R = $(CH_3)_2CH$, R' = CH_3

The hemiperacetals **19***a*, **19***b*, and **19***c* of unknown stereochemisty have been characterized by their ^1H and ^{13}C nmr spectra, by elemental analysis, and by reduction with dimethyl sulfide to give the corresponding diketones of structure **17**. Their formation is explained by ozone cleavage of monoozonolysis products **14** and **6, 7, 8**, respectively, to give γ-keto hydroperoxides of structure **18**, which subsequently undergo intramolecular acetalization. In the latter reaction, the equilibrium is apparently completely shifted towards the side of the hemiperacetal, since **19***a*, **19***b*, and **19***c* showed no positive hydroperoxide test with lead tetraacetate (8).

The hydroperoxyperoxides **20***a*, **20***b*, and **20***c* have been characterized by their ^1H and ^{13}C nmr spectra, by positive hydroperoxide tests with lead tetraacetate (8), and by reduction with dimethyl sulfide to give the corresponding diketones of structure **17** and dimethyl sulfoxide in molar ratios of 1:2. The stereochemical assignments are based on the assumptions (a) that in **20***a* the methyl group at the hydroperoxy substituted carbon atom and in **20***b* and **20***c* the isopropyl groups assume equatorial positions in the preferred conformations owing to the relatively high *A* values (9*a*), and (b) that, by analogy with results obtained for other substituted 6-membered rings (9*b*), the signals of the CH_3O groups in the equatorial position of *cis*-**20***a* (δ = 3.39), and of *cis*-**20***c* (δ = 3.40) as well as the signal of the axial CH_3 group of *cis*-**20***b* (δ = 1.50) appear downfield from the corresponding signals of *trans*-**20***a* (δ = 3.36) *trans*-**20***c* (δ = 3.36) and *trans*-**20***b* (δ = 1.37).

The formation of compounds **20***b* and **20***b,c* can be rationalized by further ozone cleavage of the monoozonolysis products **14** and **6**, respectively, to give intermediates of structure **23**. In the latter, the carbonyl oxide moiety can react either intramolecularly with the hydroperoxide group of **23** to give **20** or intermolecularly with methanol to give **16**, which subsequently forms **20** by intramolecular displacement of methanol. We could not find experimental evidence for the first reaction path, i.e., the intramolecular reaction of **23** to give **20**, and to our knowledge trapping of a carbonyl oxide by a hydroperoxide is hitherto unknown. The second reaction path via a bis-hydroperoxide of structure **16** is obviously responsible for the formation of **20***a* following the diozonolysis of **5***a* and of **13** since, as reported above, **20***a* was in each case formed at the expense of the precursor **16***a* upon warm-up of the fresh ozonolysis mixture. In support of this reasoning, it was found that authentic **16***a* in $CDCl_3$ was converted into a mixture containing 30% of *cis*-**20***a*, 30% of *trans*-**20***a*, 22% of cis-**21***a*, and 18% of *trans*-**21***a* when it was kept at room temperature overnight.

A priori, one had also to consider a third mode of formation for compounds **20**, viz. hydrolysis of methoxy hydroperoxides of types **6, 14, 16**, or **18** by trace amounts of water to give hydrogen peroxide, which in turn reacts with hemiperacetals of structure **19** to give **20**. If this were truely an alternative, one should also expect the formation of **20***a* in the ozonolysis of **15**. It should provide **18***a* as the primary product. This could undergo partial hydrolysis to give H_2O_2, which in turn could react with **19***a* to give **20***a*, whereas none of the intermediates **16***a* or **23***a*, required for the formation of **20***a* by the alternate routes, can be derived from **15**. As reported above, ozonolysis of **15** gave **17***a* and **19***a*, yet not detectable amounts of **20***a*, thus ruling out the third potential mode of formation for compounds **20**.

The cyclic peroxides **21***a* and **21***b* were characterized by their ^1H and ^{13}C nmr spectra, by elemental analysis, and by reduction with triphenyl phosphine to give the corresponding diketones of structure **17**. Both **21***a* and **21***b* are remarkably stable, as evidenced by the fact that reduction with sodium iodide or with triphenyl phosphine did not occur at room temperature but had to be performed at ca. 60°C. The stereochemical assignments of *cis*- and *trans*-**21***a* are again based on the assumptions (a) that due to the larger *A* value (9*a*), the methyl groups in *trans*-**21***a* assume equatorial positions in the preferred conformation, and (b) that the signals of the resulting axial CH_3O groups appear upfield (9*b*) (δ = 3.34) from those of the axial and equatorial CH_3O groups (δ = 3.38) in *cis*-**21***a*. The stereochemistry of isolated **21***b* could not be assigned on the basis of the above arguments, since only one isomer was obtained.

The formation of the cyclic peroxides **21** can be rationalized by reaction of compounds **19** or **20** with methanol. This view is supported by the fact that the yield of isolated **21***b* from the diozonolysis of **5***b* could be increased to 31% when the crude product mixture was treated with *p*-toluenesulfonic acid for 20 h, i.e., when the acetalization of **19***b* and **20***b* was catalyzed by acid.

The structure of ozonide **22** was proven through the independent preparation of **22** by the ozonolysis of a mixture of **8***b* and **8***c* in pentane and by reduction of **22** with triphenyl phosphine to give **17***b*. The formation of **22** from **5***b* is rationalized by intramolecular cycloaddition of the carbonyl oxide moieties with the carbonyl groups of intermediates **24***b* and **24***c*. The fact that **22** is obtained even in methanol as a solvent indicates that this cycloaddition competes favourably with the trapping of the carbonyl oxide by methanol.

In summary, the work described in this paper has shown that the course of the ozonolysis of conjugated dienes deviates considerably from that of similarly structured non-conjugated dienes both in the sequence of ozone attack and in the direction of cleavage of the two double bonds. Furthermore, the previously postulated (4, 5) intermediacy of 1,4-bis-methoxyhydroperoxides like **4** has now been proven by the isolation of **16***a*, and it was shown that they serve not only as precursors for compounds like **2***d* or **21**, but that they react also to give the hitherto unknown class of compounds **20**.

Experimental

General methods

The ^{1}H nmr and ^{13}C nmr spectra were recorded on a Bruker WM 250 and, only where it is specifically mentioned, on a Bruker WP 60 or on a Bruker WH 300; ir spectra on a Beckman Acculab 1; and gc/ms spectra on a Hewlett–Packard 5985 B instrument. The glc analyses were carried out on a Shimadzu model 6A using a glass column 0.3 × 300 cm, 5% Nitrilesiliconoil XE 60 on Chromosorb G.

Monoozonolysis of **5**a

A solution of 0.3 g (2.8 mmol) of **5***a* (10) in 10 mL of methanol was treated with 0.7 molar equivalents of ozone at −75°C. The mixture was flushed with nitrogen and evaporated at room temperature with a water aspirator to leave 0.51 g of a colourless liquid residue; ^{1}H nmr analysis ($CDCl_3$, Me_4Si) showed the presence of **6***a* (δ: 1.36 (s, 3H), 2.00 (s, 3H), 3.34 (s, 3H), 5.91 (d, J = 7.7 Hz, 1H), 7.88 (br s, 1H), 9.94 (d, J = 7.7 Hz, 1H)) and of **7***a* (data, see below) in a ratio of 3:2. From 0.5 g of the residue 72 mg (13% yield) of **7***a* were isolated by flash chromatography (11) (column 2.5 × 50 cm; 60 g Florisil; 1 L of pentane and diethyl ether, 7:3; fractions of 50 mL) in fractions 7–9.

1-Hydroperoxy-1-methoxy-3-methyl-6-oxo-2-heptene (**7***a*):[4] Colourless liquid; ir (film), ν: 3400 (OOH), 1715 (C=O), 1680 (C=C) cm^{-1}; ^{1}H nmr ($CDCl_3$, Me_4Si), δ: 1.75 (d, J = 0.8 Hz, 3H), 2.19 (s, 3H), 2.26–2.65 (m, 4H), 3.52 (s, 3H), 5.27 (dd, J = 6.3 Hz and 0.8 Hz, 1H), 5.44 (d, J = 6.3 Hz, 1H), 9.28 (s, 1H); ^{13}C nmr ($CDCl_3$, Me_4Si), δ: 22.88 q, 26.78 t, 29.98 q, 41.52 t, 55.12 q, 104.67 d, 120.88 d, 142.51 s, 208.33 s.

Decomposition of **7**a

A sample of 0.3 g of neat **7***a* was kept at room temperature for 16 days; ^{1}H nmr analysis ($CDCl_3$, Me_4Si) showed the presence of 8% of *Z*-**8***a* (δ: 1.97 (d, J = 1.3 Hz, 3H), 2.19 (s, 3H), 5.88 (dd, J = 7.9 and 1.3 Hz, 1H), 9.97 (d, J = 7.9 Hz, 1H)); of 4% of *E*-**8***a* (δ: 2.19 (s, 6H), 5.83 (d, J = 7.8 Hz, 1H), 9.99 (d, J = 7.8 Hz, 1H)); 43% of *Z*-**9***a* (δ: 1.75 (s, 3H), 2.16 (s, 3H), 3.31 (s, 6H), 5.02 (d, J = 6.2 Hz, 1H), 5.30 (d, J = 6.2 Hz, 1H)); and 43% of *E*-**9***a* (δ: 1.73 (s, 3H), 2.16 (s, 3H), 3.30 (s, 6H), 5.02 (d, J = 6.4 Hz, 1H), 5.22 (d, J = 6.4 Hz, 1H)).

Monoozonolysis of **5**a *followed by reduction with dimethyl sulfide*

A solution of 0.3 g (2.8 mmol) **5***a* in 10 mL of methanol was ozonized with 0.7 molar equivalents of ozone at −75°C. The reaction product was flushed with nitrogen, admixed with 0.16 g (2.6 mmol) of dimethyl sulfide, kept at room temperature for 18 h, and then evaporated at room temperature with a water aspirator to leave 0.7 g of a colourless liquid residue. Gas–liquid chromatographic analysis (60–180°C at 10°C/min) with the help of authentic samples showed the presence of *Z*-**8***a* (t_R = 20.46 min) and of *E*-**8***a* (t_R = 22.77 min) in a ratio of 1:2.

Monoozonolysis of **5**b

A solution of 1.07 g (7.9 mmol) of **5***b* in 25 mL of methanol was ozonized with 0.8 molar equivalents of ozone at −78°C. The reaction product was flushed with nitrogen and evaporated, at room temperature and 18 Torr (1 Torr = 133.3 Pa), to leave 1.81 g of a liquid residue. By flash chromatography (11) (column 2 × 100 cm; 100 g of Florisil; 2 L of pentane/diethyl ether, 7:3; fractions of 50 mL), 79 mg (3.3%) of **7***b* (fractions 20–27) and 119 mg (5.0%) of **7***c* (fractions 11–16) were isolated. Flash chromatography of a second sample (column 2 × 100 cm; 123 g of silica gel; 2 L of pentane/diethyl ether, 7:3, followed by 1 L of diethyl ether: fractions of 50 mL) provided 637 mg of a mixture of **8***b* (51%), **8***c* (37%), **10***b* (11%), and **10***c* (1%). Separation of this mixture by the hplc method (column 1.6 × 25 cm; Lichrosorb Si 100; 10 bar (1 bar = 100 kPa); pentane/diethyl ether, 3:7) gave 110 mg (6%) of **8***b*, 34 mg (1.8%) of *E*-**8***c*, 45 mg (2.4%) of *Z*-**8***c*, 24 mg (1.1%) of **10***b*, and 1.8 mg (0.1%) of **10***c*.

1-Hydroperoxy-1-methoxy-3-isopropyl-6-oxo-2-heptene (**7***b*):[4] Colourless, viscous liquid; ir (film), ν: 3350 (OOH), 1710 (C=O), 1663 (C=C) cm^{-1}; ^{1}H nmr ($CDCl_3$/pyridine-d_5, Me_4Si), δ: 1.03 (dd, J = 6.8 and 0.7 Hz, 6H), 2.16 (s, 3H), 2.21–2.63 (m, 5H), 3.51 (s, 3H), 5.27 (dd, J = 6.3 and 0.7 Hz, 1H), 5.42 (d, J = 6.3 Hz, 1H).

1-Hydroperoxy-1-methoxy-3,7-dimethyl-6-oxo-2-octene (**7***c*):[4] Colourless, viscous liquid; ir (film), ν: 3370 (OOH), 1710 (C=O), 1665 (C=C) cm^{-1}; ^{1}H nmr ($CDCl_3$/pyridine-d_5, Me_4Si), δ: 1.10 (d, J = 6.9 Hz, 6H), 1.74 (d, J = 1.1 Hz, 3H), 2.15–2.72 (m, 5H), 3.51 (s, 3H), 5.28 (dd, J = 6.0 and 1.2 Hz, 1H), 5.44 (d, J = 6.0 Hz, 1H).

3-Isopropyl-6-oxo-2-heptenal (**8***b*; unknown stereochemistry): Colourless, viscous liquid; glc (60–160°C at 4°C/min), t_R = 50.16 min; ^{1}H nmr (60 MHz, $CDCl_3$, Me_4Si), δ: 1.11 (d, J = 6.8 Hz, 6H), 2.19 (s, 3H), 2.29–2.76 (m, 5H), 5.89 (d, J = 7.7 Hz, 1H), 10.00 (d, J = 7.7 Hz, 1H). The data are identical with those reported for **8***b* in the literature (7).

E-*3,7-Dimethyl-6-oxo-2-octenal* (*E*-**8***c*): Colourless, viscous liquid; glc (60–160°C at 4°C/min), t_R = 55.23 min; ^{1}H nmr (60 MHz, $CDCl_3$, Me_4Si), δ: 1.11 (d, J = 6.8 Hz, 6H), 2.19 (d, J = 1.3 Hz, 3H), 2.41–2.80 (m, 5H), 5.83 (dq, J = 8.0 and 1.3 Hz, 1H), 10.00 (d, J = 8.0 Hz, 1H). The data are identical with those reported for *E*-**8***c* in the literature (7).

E-*3,7-Dimethyl-6-oxo-2-octenal* (*Z*-**8***c*): Colourless, viscous liquid; glc (60–160°C at 4°C/min), t_R = 47.33 min; ^{1}H nmr (60 MHz, $CDCl_3$, Me_4Si), δ: 1.11 (d, J = 6.9 Hz, 6H), 1.97 (d, J = 1.5 Hz, 3H), 2.50–2.84 (m, 5H), 5.88 (dq, J = 8.0 and 1.5 Hz, 1H), 9.99 (d, J = 7.9 Hz, 1H). The data are identical with those reported for *Z*-**8***c* in the literature (7).

2-Isopropyl-2-(3-oxo)-butyl-3-formyl-oxirane (**10***b*): Slightly yellow liquid; ^{1}H nmr (60 MHz, $CDCl_3$, Me_4Si), δ: 0.90 (d, J = 6.6 Hz, 3H), 1.01 (d, J = 6.6 Hz, 3H), 2.17 (s, 3H), 1.56–2.83 (m, 5H), 3.35 (d, J = 4.6 Hz, 1H), 9.54 (d, J = 4.6 Hz, 1H); ei-ms (rel. intensity, %), *m/e*: 184 (0.5) $(M)^+$, 155 (51) $(M - CHO)^+$, 141 (77) $(M - CH_3CO)^+$, 71 (23) $((CH_3)_2CHCO)^+$, 43 (100) $(CH_3CO)^+$; ci-ms (rel. intensity, %), *m/e*: 185 (27) $(M + 1)^+$. Since the compound was not pure (yellow), no elemental analysis was performed.

2-Methyl-2-(3-oxo-4-methyl)-pentyl-3-formyl-oxirane (**10***c*): ^{1}H nmr (60 MHz, $CDCl_3$, Me_4Si), δ: 0.96 (d, J = 6.8 Hz, 6H), 1.73 (s, 3H), 3.93 (d, J = 4.4 Hz, 1H), 9.44 (d, J = 4.4 Hz, 1H). Insufficient amount for elemental analysis.

Reduction of **7**b

To a solution of 23 mg (0.1 mmol) of **7***b* in C_6D_6, 13 mg (0.21 mmol) of dimethyl sulfide was added and the mixture was kept at room temperature for 17 h; ^{1}H nmr analysis (60 MHz, $CDCl_3$, Me_4Si) showed the signals of *E*- and *Z*-**8***b*, methanol (δ = 3.26), dimethyl sulfide (δ = 1.75), and dimethyl sulfoxide (δ = 1.79).

Reduction of **7**c

In the same way, 17 mg (0.08 mmol) of **7***c* was reduced with 5.6 mg (0.09 mmol) of dimethyl sulfide to give *E*- and *Z*-**8***c*, methanol, and dimethyl sulfoxide.

Monoozonolysis of **5**b *followed by reduction with dimethyl sulfide*

A solution of 1.04 g (7.6 mmol) of **5***b* in 20 mL of methanol was ozonized with 0.7 molar equivalents of ozone at −78°C. The mixture was flushed with nitrogen and admixed with 0.71 g (11.5 mmol) of precooled (−20°C) dimethyl sulfide. The mixture was briefly agitated, allowed to warm up to room temperature overnight, kept at room temperature for 5 h, and then evaporated at 20°C and 18 Torr to leave 2.44 g of a colourless liquid; glc analysis (60–160°C at 4°C/min) showed the peaks of **8***b* (t_R = 50.13 min), *E*-**8***c* (t_R = 55.04 min), and *Z*-**8***c* (t_R = 47.30 min). The relative peak areas of **8***b* and of *E*-**8***c* + *Z*-**8***c* were 70% and 30%, respectively. By flash chromatography (column 2 × 10 cm; 8 g silica gel; 250 mL of pentane/diethyl ether, 99:1, 250 mL pentane/diethyl ether, 3:2), 581 mg (3.46 mmol) of a mixture containing **8***b* and of **8***c* was isolated.

Monoozonolysis of ***13***

A solution of 0.95 g (8.7 mmol) of **13** in 20 mL of methanol was ozonized with 0.7 molar equivalents of ozone at −78°C.

A sample of the crude reaction product was immediately analyzed by ^{1}H nmr ($CDCl_3$, Me_4Si), to show the presence of **14** (52%),[2] **16***a* (23%), **19***a* (7%), *cis*-**20***a* (10%), and *trans*-**20***a* (8%). Then triphenyl

[4]Due to decomposition of the neat substance no elemental analysis has been performed.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12
For personal use only.

phosphine was added to the sample and the mixture was kept at room temperature for 10 min; ^{1}H nmr analysis showed the presence of **15** (δ: 1.72 (s, 3H), 2.14 (s, 3H), 1.84–2.59 (m, 4H), 4.65 (s, 1H), 4.73 (s, 1H)) and of **17***a* (δ: 2.19 (s, 6H), 2.72 (s, 4H)) in a molar ratio of 54:46.

The remainder of the crude ozonolysis product was warmed up to room temperature and evaporated at 18 Torr to leave 1.3 g of a peroxidic liquid residue. By flash chromatography (column 2.5 × 50 cm; 80 g silica gel; 2 L of pentane/diethyl ether, 75:25; fractions of 50 mL), 560 mg (35%) of **14** (fractions 4 and 5) and 30 mg (1.6%) of **16***a* (fractions 28–33) were isolated.

2-Methyl-5-hydroperoxy-5-methoxy-1-hexene (**14**):[4] Colourless liquid; ir (film), ν: 3320 (OOH), 1645 (C=C) cm^{-1}; ^{1}H nmr ($CDCl_3$, Me_4Si), δ: 1.36 (s, 3H), 1.75 (s, 3H), 1.80–188 (m, 2H), 2.04–2.13 (m, 2H), 3.32 (s, 3H), 4.70 (s, 2H), 7.74 (s, 1H); ^{13}C nmr ($CDCl_3$, Me_4Si), δ: 18.97, 22.51, 32.04, 33.24, 48.92, 107.04, 109.84, 145.27.

2,5-Bis-hydroperoxy-2,5-dimethoxyhexane (**16***a*;[4] probably a mixture of *meso*- and *rac*-**16***a* in nearly equal amounts): Colourless liquid; ^{1}H nmr ($CDCl_3$, Me_4Si), δ: 1.29 and 1.32 (s, each, CH_3) 1.50–2.05 (m, CH_2CH_2), 3.34 (s, CH_3O), 8.54 and 8.82 (s, each, OOH); ^{13}C nmr ($CDCl_3$, Me_4Si), δ: 18.37, and 18.67, 29.72 and 29.84, 48.93 and 48.97, 106.70 and 106.75.

Reduction of ***14***

Triphenyl phosphine was added to a solution of one drop of **14** in 0.6 mL of $CDCl_3$ and the mixture was kept at room temperature for 10 min; ^{1}H nmr analysis (Me_4Si) showed the presence of **15**.

Reduction of ***16***a

16*a* was completely converted into **17***a* by the above method, as shown by ^{1}H nmr analysis.

Diozonolysis of ***5***a

A solution of 0.3 g (2.8 mmol) of **5***a* in 10 mL of methanol was ozonized at −78°C until it turned blue, and excess ozone was removed by flushing with nitrogen. A sample of the crude reaction product was immediately analyzed by ^{1}H nmr ($CDCl_3$, Me_4Si) which showed the presence of ca. 75% of **16***a* (δ = 1.29, 1.32) and small amounts, each, of **19***a* (δ = 1.40), *cis*-**20***a* (δ = 1.51), *trans*-**20***a* (δ = 1.46), *cis*-**21***a* (δ = 1.41), and *trans*-**21***a* (δ = 1.30).

The remainder of the crude reaction product was warmed up to room temperature and evaporated at ca. 20 Torr to leave 0.49 g of a liquid residue; ^{1}H nmr analysis ($CDCl_3$, Me_4Si) showed the presence of **19***a* (33%), *cis*-**20***a* (12%), *trans*-**20***a* (19%), *cis*-**21***a* (11%), and *trans*-**21***a* (24%), whereas the signals of **16***a* had disappeared.

Diozonolysis of ***13***

(*a*) *Determination of the product distribution*

A solution of 0.1 g (0.90 mmol) of **13** in 10 mL of methanol was ozonized at −78°C until it turned blue. The excess of ozone was removed by flushing with nitrogen and the solution was evaporated at room temperature and 18 Torr to leave 1.39 g of a liquid residue. Immediate ^{1}H nmr analysis ($CDCl_3$, Me_4Si) showed the presence of **16***a* (65%, δ = 1.29, 1.32), **19***a* (12%, δ = 1.40), *cis*-**20***a*(10%, δ = 1.51), *trans*-**20***a* (8%, δ = 1.46), and *cis*-**21***a* (5%, δ = 1.41); ^{1}H nmr analysis of a sample that was kept at room temperature overnight showed the presence of **19***a* (12%), *cis*-**20***a* (12%), *trans*-**20***a* (11%), *cis*-**21***a* (20%), and *trans*-**21***a* (45%, δ = 1.30), whereas the signals of **16***a* had disappeared.

(*b*) *Isolation of stereoisomers of* ***20***a *and* ***21***a

A solution of 1.90 g (17.3 mmol) of **13** in 30 mL of methanol was ozonized at −78°C until the solution turned blue, and excess ozone was removed by flushing with nitrogen. The crude reaction product was warmed up to room temperature and evaporated at 20°C and 18 Torr to leave 2.43 g of a yellow liquid residue. Flash chromatography of the residue (column 2 × 100 cm; 122 g of silica gel; 2 L of pentane/diethyl ether, 4:1, and 0.5 L of diethyl ether; fractions of 50 mL) gave 830 mg of a mixture of *cis*- and *trans*-**21***a* in fractions 10 and 11 and 630 mg of a mixture of *cis*- and *trans*-**20***a* and *cis*-**21***a* in fractions 12–20. From fractions 10 and 11, 143 mg (5%) of *cis*-**21***a* and 531 mg (17.5%) of *trans*-**21***a* were isolated by hplc separation (column 3 × 10 cm; Lichrosorb Si 60; 10 bar; pentane/diethyl ether, 9:1). Fractions 12–20 were again submitted to flash chromatography under the same conditions to give 473 mg of a 1:1 mixture of *cis*- and *trans*-**20***a*. From the latter mixture, *cis*- and *trans*-**20***a* could be enriched, yet not completely separated from each other, by hplc separation (conditions as above).

cis-*3-Hydroperoxy-6-methoxy-3,6-dimethyl-1,2-dioxane* (*cis*-**20***a*; in admixture with 30% of *trans*-**20***a*): Colourless liquid; ir (film), ν: 3400 (OOH) cm^{-1}; ^{1}H nmr (60 MHz, $CDCl_3$, Me_4Si), δ: 1.44 (s, 3H), 1.51 (s, 3H), 1.60–2.16 (m, 4H), 3.39 (s, 3H), 8.59 (s, 1H); ^{13}C nmr ($CDCl_3$, Me_4Si), δ: 19.33, 19.60, 26.62, 29.75, 49.19, 102.64, 107.13. Anal. calcd. for $C_7H_{14}O_5$: C 47.18, H 7.92; found: C 47.10, H 7.81. Addition of a drop of *cis*-**20***a* to lead tetraacetate in benzene resulted in the spontaneous development of gas bubbles.

trans-*3-Hydroperoxy-6-methoxy-3,6-dimethyl-1,2-dioxane* (*trans*-**20***a*; in admixture with 10% of *cis*-**20***a*): Colourless solid; ir (film), ν: 3400 (OOH) cm^{-1}; ^{1}H nmr (60 MHz, $CDCl_3$, Me_4Si), δ: 1.31 (s, 3H), 1.46 (s, 3H), 1.53–2.16 (m, 4H), 3.36 (s, 3H), 8.36 (s, 1H); ^{13}C nmr ($CDCl_3$, Me_4Si), δ: 19.71, 19.81, 28.23, 31.00, 49.98, 103.37, 107.58. Addition of *trans*-**20***a* to lead tetraacetate in benzene resulted in the spontaneous development of gas bubbles.

cis-*3,6-Dimethyl-3,6-dimethoxy-1,2-dioxane* (*cis*-**21***a*): Colourless liquid; ^{1}H nmr ($CDCl_3$, Me_4Si), δ: 1.41 (s, 6H), 1.60–210 (m, 4H), 3.38 (s, 6H); ^{13}C nmr ($CDCl_3$, Me_4Si), δ: 19.70 (q, J = 29.9 Hz), 30.90 (t, J = 32.0 Hz), 49.71 (q, J = 44.0 Hz), 102.31 (s).

trans-*3,6-Dimethyl-3,6-dimethoxy-1,2-dioxane* (*trans*-**21***a*): Colourless liquid; ^{1}H nmr ($CDCl_3$, Me_4Si), δ: 1.30 (s, 6H), 1.50–2.10 (m, 4H), 3.34 (s, 6H); ^{13}C nmr ($CDCl_3$, Me_4Si), δ: 19.92, 29.69, 49.01, 101.72. Anal. calcd. for $C_6H_{16}O_4$: C 54.53, H 9.15; found: C 54.52, H 8.97.

Ozonolysis of ***14***

A solution of 0.1 g (0.63 mmol) of **14** in 10 mL of methanol was ozonized at −78°C until it turned blue. Excess ozone was removed by flushing with nitrogen and the solvent was evaporated at room temperature and ca. 20 Torr to leave 0.13 g of a liquid residue. Immediate ^{1}H nmr analysis ($CDCl_3$, Me_4Si) showed the presence of **16***a* (85%; δ = 1.29, 1.32), **19***a* (5%; δ = 1.40), *cis*-**20***a* (7%; δ = 1.51), and *trans*-**20***a* (3%, δ = 1.46).

Ozonolysis of ***15*** *and isolation of* ***19***a

A solution of 1.51 g (13.4 mmol) of **15** in 25 mL of methanol was ozonized at −74°C until it turned blue, and excess ozone was removed by flushing with nitrogen. A small sample was immediately analyzed by ^{1}H nmr ($CDCl_3$, Me_4Si) to show the presence of **17***a* (27%,[2] δ = 2.19 and 2.72) and of **19***a* (73%, δ = 1.32, 1,39, 3,34). The remainder of the product mixture was evaporated at 20°C and 20 Torr to leave 1.8 g of a liquid residue. By flash chromatography (column 2 × 100 cm; 120 g of silica gel; 1 L of pentane/diethyl ether, 4:1, fractions of 50 mL), 433 mg (20%) of **19***a* was isolated in fractions 14–23.

3-Hydroxy-6-methoxy-3,5-dimethyl-1,2-dioxane (**19***a*, unknown stereochemistry): Colourless solid, mp 68°C; ir (CCl_4), ν: 3620, 3480 cm^{-1}; ^{1}H nmr ($CDCl_3$, Me_4Si), δ: 1.32 (s, 3H), 1.40 (s, 3H), 1.60–2.10 (m, 4H), 3.03 (s, 1H), 3.35 (s, 3H); ^{13}C nmr ($CDCl_3$, Me_4Si), δ: 19.89, 25.13, 29.63, 29.95, 49.16, 99.43, 101.76. Anal. calcd. for $C_7H_{14}O_4$: C 51.84, H 8.70; found: C 51.88, H 8.37.

Diozonolysis of ***5****b*

(*a*) *Isolation of* ***19***b, ***19***c, cis-***20***b, trans-***20***b, cis-***20***c, and trans-***20***c

A solution of 3.07 g (22.6 mmol) of **5***b* in 50 mL of methanol was ozonized at −75°C until it turned blue. Excess ozone was removed by flushing with nitrogen and the reaction mixture was immediately evaporated at 20°C and 18 Torr to leave 5.42 g of a liquid residue. Immediate separation of the residue by flash chromatography (column 2 × 100 cm; 125 g of silica gel; 0.5 L of pentane/diethyl ether, 9:1, 2 L of pentane/diethyl ether, 4:1, 1 L of pentane/diethyl ether, 2:1, 0.5 L of diethyl ether; fractions of 50 mL) gave 45 mg of a 1:1 mixture of **21***b* and **22** in fractions 7–9, 1.15 g of a 1:2 mixture of **20***b* (*cis* + *trans*), and of **20***c* (*cis* + *trans*) in fractions 16–40, and 1.84 g of a mixture of **17***b*, **19***b*, **19***c*, and formic acid in fractions 50–63. Fractions 16–40 were further separated by the hplc method (column 1.6 × 25 cm;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12
For personal use only.

Lichrosorb Si 100; 11 bar; pentane/diethyl ether, 4:1) to give 192 mg of mixture A, containing *cis*- and *trans*-**20***b* and *trans*-**20***c*, 516 mg of mixture B containing *cis*-**20***b* and *trans*-**20***c* and 402 mg of mixture C, containing *cis*-**20***b* and *cis*- and *trans*-**20***c*. Further hplc separation under the same conditions gave 42 mg (0.9%) of *trans*-**20***b* from mixture A, 125 mg (2.7%) of *cis*-**20***c* from mixture C, as well as 74 mg (1.6%) of *cis*-**20***b* and 573 mg (12.3%) of *trans*-**20***c* from a combination of mixture B and the by-products obtained from the separation of mixtures A and C. The hplc separation of fractions 50–63 from the flash chromatography gave 42 mg (1%) of **19***b* and 137 mg (3.2%) of **19***c*.

3-Hydroxy-3-methyl-6-methoxy-6-isopropyl-1,2-dioxane (**19***b*): Colourless solid, mp 31°C; ^{1}H nmr ($CDCl_3$, Me_4Si), δ: 0.92 (d, J = 7.0 Hz, 3H), 0.97 (d, J = 7.0 Hz, 3H), 1,39 (s, 3H), 1.45–2.30 (m, 5H), 3.30 (s, 3H); ^{13}C nmr ($CDCl_3$, Me_4Si), δ: 16.50, 17.40, 21.15, 25.65, 28.82, 29.89, 48.19, 99.00, 104.38.

3-Hydroxy-3-isopropyl-6-methyl-6-methoxy-1,2-dioxane (**19***c*): Colourless viscous liquid; ^{1}H nmr ($CDCl_3$, Me_4Si), δ: 0.97 (d, J = 6.9 Hz, 3H), 0.98 (d, J = 6.9 Hz, 3H), 1.31 (s, 3H), 1.20–2.10 (m, 5H), 2.95 (s, 1H), 3.34 (s, 3H); ^{13}C nmr ($CDCl_3$, Me_4Si), δ: 15.94, 16.81, 20.22, 24.81, 29.52, 35.80, 49.05, 101.30, 101.51. Anal. (of a 1:1 mixture of **19***b* and **19***c*) calcd. for $C_9H_{18}O_4$: C 56.82, H 9.54; found: C 56.46, H 9.31.

cis-*3-Hydroperoxy-3-methyl-6-methoxy-6-isopropyl-1,2-dioxane* (*cis*-**20***b*): Colourless solid, mp 77°C; ir (CCl_4), ν: 3460 (OOH) cm^{-1}; ^{1}H nmr (300 MHz, $CDCl_3$, Me_4Si), δ: 0.94 (d, J = 6.8 Hz, 3H), 0.95 (d, J = 6.8 Hz, 3H), 1.50 (s, 3H), 1.67–2.16 (m, 4H), 2.19 (sept, J = 6.9 Hz, 1H), 3.35 (s, 3H), 8.42 (s, 1H); ^{13}C nmr ($CDCl_3$, Me_4Si), δ: 16.19, 16.48, 19.48, 24.53, 27.69, 31.90, 49.61, 106.27, 108.13. Addition of *cis*-**20***b* to lead tetraacetate in benzene resulted in the spontaneous development of gas bubbles.

trans-*3-Hydroperoxy-3-methyl-6-methoxy-6-isopropyl-1,2-dioxane* (*trans*-**20***b*): Colourless solid, mp 68°C; ir (CCl_4), ν: 3500 (OOH) cm^{-1}; ^{1}H nmr ($CDCl_3$, Me_4Si), δ: 0.91 (d, J = 6.8 Hz, 3H), 0.96 (d, J = 6.8 Hz, 3H), 1.37 (s, 3H), 1.53–2.02 (m, 4H), 2.03 (sept, J = 6.8 Hz, 1H), 3.31 (s, 3H), 8.15 (s, 1H); ^{13}C nmr ($CDCl_3$, Me_4Si), δ: 16.44, 17.40, 20.19, 21.83, 26.34, 30.04, 48.30, 104.98, 106.46. Addition of *trans*-**20***b* to lead tetraacetate in benzene resulted in the spontaneous development of gas bubbles.

cis-*3-Hydroperoxy-3-isopropyl-6-methyl-6-methoxy-1,2-dioxane* (*cis*-**20***c*): Colourless, viscous liquid; ir (CCl_4), ν: 3380 (OOH) cm^{-1}; ^{1}H nmr ($CDCl_3$, Me_4Si), δ: 0.98 (d, J = 7.0 Hz, 3H), 0.99 (d, J = 6.9 Hz, 3H), 1.44 (s, 3H), 1.65–2.20 (m, 4H), 2.36 (sept, J = 7.0 Hz, 1H), 3.40 (s, 3H), 8.43 (s, 1H); ^{13}C nmr ($CDCl_3$, Me_4Si), δ: 16.58, 16.81, 19.78, 23.23, 30.51, 31.53, 50.13, 103.83, 110.48. Addition of *cis*-**20***c* to lead tetraacetate in benzene resulted in the spontaneous development of gas bubbles.

trans-*3-Hydroperoxy-3-isopropyl-6-methyl-6-methoxy-1,2-dioxane* (*trans*-**20***c*): Colourless, viscous liquid; ir (film), ν: 3510 (OOH) cm^{-1}; ^{1}H nmr ($CDCl_3$, Me_4Si), δ: 0.97 (d, J = 6.8 Hz, 3H), 0.99 (d, J = 6.8 Hz, 3H), 1.29 (s, 3H), 1.34–2.10 (m, 4H), 2.39 (sept, J = 6.9 Hz, 1H), 3.36 (s, 3H), 7.92 (s, 1H); ^{13}C nmr ($CDCl_3$, Me_4Si), δ: 16.62, 17.41, 19.15, 19.93, 29.41, 30.32, 49.03, 101.93, 109.75. Anal. calcd. for $C_9H_{18}O_5$: C 52.41, H 8.80; found: 52.70, H 8.68. Addition of *trans*-**20***c* to lead tetraacetate in benzene resulted in the spontaneous development of gas bubbles.

(*b*) *Isolation of* ***21***b

Ozonolysis of **5***b* was repeated as described above for (a), but the crude reaction product was kept at room temperature for 27 h before it was evaporated. By flash chromatography (column 2 × 100 cm; 119 g of silica gel; pentane/diethyl ether, 9:1, fractions of 50 mL), 340 mg (7.3%) of **21***b* was obtained in fractions 6–9.

3-Methyl-6-isopropyl-3,6-dimethoxy-1,2-dioxane (**21***b*): Colourless liquid; ^{1}H nmr (300 MHz, $CDCl_3$, Me_4Si), δ: 0.90(d, J = 6.8 Hz, 3H), 0.95 (d, J = 6.8 Hz, 3H), 1.28 (s, 3H), 1.35–2.17 (m, 5H), 3.29 (s, 3H), 3.33 (s, 3H); ^{13}C nmr ($CDCl_3$, Me_4Si), δ: 16.49, 17.42, 20.43, 20.91, 29.03, 29.93, 47.94, 48.78, 100.96, 104.08. Anal. calcd. for $C_{10}H_{20}O_4$: C 58.80, H 9.87; found: C 58.95, H 9.66.

Reductions of hemiperacetals of structure ***19***

(*a*) *Reduction of* ***19***a: A solution of 23 mg (0.14 mmol) of **19***a* and 19 mg (0.30 mmol) of dimethyl sulfide in $CDCl_3$ was kept at room temperature for 5 days; ^{1}H nmr analysis (Me_4Si) showed the presence of **17***a* and of dimethyl sulfoxide (δ = 2.64) in a ratio of 1:1.

(*b*) *Reduction of* ***19***b *and* ***19***c: A solution containing 31 mg (0.16 mmol) of a 1:1 mixture of **19***b* and **19***c* and 32 mg (0.5 mmol) of dimethyl sulfide in $CDCl_3$ was kept at room temperature for 6 days; ^{1}H nmr analysis (Me_4Si) showed the presence of **17***b* (δ = 1.11, 2.19, 2.72) and of dimethyl sulfoxide (δ = 2.63) in a ratio of 1:1.

Reductions of hydroperoxyperoxides of structure ***20***

(*a*) *Reduction of* ***20***a: A solution containing 15 mg (0.08 mmol) of a 1:1 mixture of *cis*- and *trans*-**20***a*, and 25 mg (0.4 mmol) of dimethyl sulfide in 0.5 mL of $CDCl_3$ was kept at room temperature for 2 weeks; ^{1}H nmr analysis (Me_4Si) showed the presence of **17***a* (δ = 2.19, 2.71) and of dimethyl sulfoxide (δ = 2.63) in a ratio of 1:2.

(*b*) *Reduction of* ***20***b *and* ***20***c: Solutions containing dimethyl sulfide and *cis*-**20***b*, *trans*-**20***b*, *cis*-**20***c*, and *trans*-**20***c*, respectively, in $CDCl_3$ were kept at room temperature for ca. 1 week, each; ^{1}H nmr analysis (Me_4Si) showed in each case the presence of **17***b* and of dimethyl sulfoxide (δ = 2.62) in a ratio of 1:2.

Reductions of the cyclic peracetals of structure ***21***

(*a*) *Reduction of* cis- *and* trans-***21***a: A solution of **21***a* (*cis*:*trans* = 1:1) and triphenyl phosphine in $CDCl_3$ was heated to 60°C for 6 days; ^{1}H nmr analysis (Me_4Si) showed the presence of **17***a* (δ = 2.19 and 2.71).

(*b*) *Reduction of* ***21***b: A solution of 18.5 mg (0.09 mmol) of **21***b* and 47.5 mg (0.18 mmol) of triphenyl phosphine in 0.6 mL of $CDCl_3$ was kept at room temperature for 3 days; ^{1}H nmr analysis (Me_4Si) showed no change in the composition. The solution was heated to 60°C for 4 days; ^{1}H nmr analysis showed the presence of **17***b* and of the remaining **21***b* in a ratio of 2:1.

Ozonolysis of ***5***b *followed by acid catalysis*

A solution of 1.95 g (13.6 mmol) of **5***b* in 50 mL of methanol was ozonized at −74°C until it turned blue. Excess ozone was removed by flushing with nitrogen, the mixture was warmed up to room temperature, admixed with 50 mg of *p*-toluenesulfonic acid monohydrate, and stirred at room temperature for 20 h. Then 10 mg of potassium carbonate was added, stirring was continued for 1 h, and the solvent was evaporated at 20°C and 18 Torr. From the residue, 861 mg (31%) of **21***b* was isolated by flash chromatography in fractions 8–12 (column 2 × 100 cm; 120 g of silica gel; 1 L of pentane/diethyl ether, 9:1, fractions of 50 mL).

Preparation of ***22*** *by ozonolysis of* ***8***b *and* ***8***c *in pentane*

A solution of 581 mg (3.46 mmol) of a mixture of **8***b* and **8***c* in 50 mL of pentane was ozonized at −60°C until it turned blue. Excess ozone was flushed off with nitrogen, the mixture was warmed up to room temperature, pentane was largely evaporated, and the residue was submitted to flash chromatography (column 2 × 100 cm; 60 g of silica gel; 2 L of pentane/diethyl ether, 49:1; fractions of 50 mL) to give 93 mg (17%) of **22** in fractions 8–16.

1-Methyl-4-isopropyl-2,3,7-trioxabicyclo[2.2.1]heptane (**22**): Colourless liquid; ^{1}H nmr ($CDCl_3$, Me_4Si), δ: 1.06 (d, J = 6.9 Hz, 3H), 1.09 (d, J = 7.0 Hz, 3H), 1.67 (s, 3H), 1.76–2.41 (m, 5H); ^{13}C nmr ($CDCl_3$, Me_4Si), δ: 14.96, 17.35, 17.76, 28.99, 30.83, 34.92, 110.66, 115.37. Anal. calcd. for $C_8H_{14}O_3$: C 60.74, H 8.92; found: C 60.46, H 8.74.

Reduction of ***22***

A solution of 31 mg (0.20 mmol) of **22** and 154 mg (0.59 mmol) of triphenyl phosphine in 0.3 mL of $CDCl_3$ was kept at room temperature for 3 days; ^{1}H nmr analysis (Me_4Si) showed the presence of **17***b*.

Received December 8, 1989

MANOHAR LAL and H. S. MAHAL. Can. J. Chem. **68**, 1376 (1990).

Reaction rate constants of thiyl radicals with phenothiazines, promethazine (PMZ), chlorpromazine (CPZ), prochlorperazine (PPZ), trimeperazine tarterate (TPZ), and other antioxidants, e.g., ascorbic acid and 2,2-azinobis(3-ethyl benzthiazoline-6 sulphonate) (ABTS) have been estimated using pulse radiolysis technique. In general they are quite high (10^8–10^9 M^{-1} s^{-1}). The *k* values for cysteine, cysteamine, mercaptoethanol, and mercaptopropionic acid with similar structures and molecular weights are more or less similar for PMZ, CPZ, and PPZ.

Rate constants are lower in value for PenṠ, DṪT, DṪE and GuṠ radicals of phenothiazines showing that they are dependent upon the structure and the molecular weight of the compound.

Rate constants are the same whether the thiyl radicals are generated from thiols or their corresponding disulphides. The *k* values for chlorine-containing phenothiazines, chlorpromazine, and prochlorperazine are higher than those of promothazine

Key words: pulse radiolysis, thiyl radicals, phenothiazines, ABTS, ascorbic acid.

MANOHAR LAL et H. S. MAHAL. Can. J. Chem. **68**, 1376 (1990).

Faisant appel à la technique de la radiolyse pulsée, on a évalué les constantes de vitesse de réaction du radical thiyle avec les phénothiazines, prométhazine (PMZ), chlorpromazine (CPZ), prochlorpérazine, (PPZ) et tartrate de trimépérazine (TPZ) ainsi que d'autres antioxydants comme l'acide ascorbique et le 2,2-azinobis(3-éthylbenzothiazoline-6-sulfonate) (ABTS). Généralement, les constantes de vitesse sont très élevées (10^8–10^9 M^{-1} s^{-1}). Les valeurs de *k* pour la cystéine, la cystéinemaine, le mercaptoéthanol et l'acide mercaptopropanoïque qui possèdent des structures et des poids moléculaires semblables ressemblent aux valeurs obtenues pour la PMZ, la CPZ et la PPZ.

Les valeurs des constantes de vitesse de réaction des radicaux PenṠ, DṪT, DṪE et GuṠ avec les phénothiazines sont plus faibles; ces résultats démontrent que les valeurs de *k* dépendent de la structure et du poids moléculaire du composé.

Les constantes de vitesse des réactions des radicaux thiyles sont constantes quelles que soient les sources, thiols ou disulfures, de ces radicaux. Les valeurs de *k* pour les phénothiazines contenant du chlore, comme la chlorpromazine et la prochlorpérazine, sont plus élevées que celle pour la prométhazine.

Mots clés : radiolyse pulsée, radicaux thiyles, phénothiazines, ABTS, acide ascorbique.

[Traduit par la revue]

Introduction

Radiation protection of DNA, enzymes bacteriophage and mammals by thiols has been the subject of considerable interest in the past (1–3). The protective effect is known to be due to (*i*) the scavenging of potentially damaging primary species and (*ii*) the repair of the biological molecules by hydrogen transfer:

[1] $RH + \dot{H}, \dot{O}H \rightarrow \dot{R} + H_2, H_2O$

[2] $\dot{R} + RSH \rightarrow RH + R\dot{S}$

Thiyl radicals thus formed are very reactive (4). Their fate and reations with other molecules are of considerable importance in biological and biochemical processes.

Reactions of thiyl radicals with two phenothiazines and other antioxidants have been reported earlier (4*a*, 8, 12).

We have extended these studies to thiyl radicals generated from a variety of thiols and their corresponding disulphides to see if there is any difference in reactivity. In the earlier studies (4*a*) reactions of dithiothreitol radical with the phenothiazines could not be investigated because of their low signals. This prompted us to investigate the reactions of DṪT, DṪE radicals and radical anions with phenothiazines and other antioxidants. Phenothiazines are being used in psychiatric and anti-inflammatory treatment. Recent studies have shown that chlorpromazine HCl (CPZ), promethazine HCl (PMZ), prochlorperazine (PPZ), and trimeprazine tartrate (TPZ) are effective in the radiosensitization of hypoxic bacterial and mammalian cells *in vitro* and in mouse solid tumour *in vivo* (5–7). In addition to the first two phenothiazines we have also investigated the reactions of thiyl radicals with the last two phenothiazines. Effect of pH on the reaction of DṪT, DṪE, and GuṠ radicals with phenothiazines has been studied.

The metabolism, pharmacology, and toxicology of these compounds have been studied earlier and it has been suggested that free radicals are generated and expected to play an important role in the mechanism of toxic action of these compounds. In view of this, the fact that thiols are radiation protective agents and that variety of enzymes and proteins in biological systems contain the thiol group and disulphide bridges from which thiyl radicals may be generated, it is important and of interest to explore the reactions of thiyl radicals with phenothiazines and antioxidants and the reactions of phemothiazine radicals with other molecules.

Experimental

2,2-Azinobis(3-ethylbenzthiazoline-6 sulphonate) (ABTS), ascorbic acid, and other reagents were of A grade from Sigma Chemical Co. Prochlorperazine (PPZ) and trimeprazine tartrate (TPZ) were of pharmaceutical grade from May and Baker and were supplied to us by courtesy Dr. B. B. Singh of Biology Group, BARC, Bombay. Promethazine HCl (PMZ) and chlorpromazine (CPZ) were a gift from May and Baker Ltd., England. These two compounds were later procured from Sigma. Similar results were obtained with compounds from the two sources.

The pulse radiolysis set up (9) used in these investigations employs 25 ns pulses of 7 MeV electrons from a linear accelerator. Typical dose per pulse is ~13 Gy as evaluated by thiocyanate dosimetry. All solutions were prepared in Nano pure water of conductivity ~0.06 μS. Phosphate buffers of pH ~3.6 and 6.4 (total phosphate concentration

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12
For personal use only.

10 mM) were used in experiments with ABTS or ascorbic acid/thiol or disulphide solution. In the case of phenothiazines, however, some turbidity was observed when phenothiazine and thiol or disulphide were dissolved in the buffer. The signal obtained in these mixtures was too weak to be analyzed properly. Weak signals had also been reported earlier (4*a*) when similar experiments were carried out with dithiol DTT. The pH of the reaction mixtures viz. 3.5–3.7 and 6.4–6.7 used in these studies was adjusted using $HClO_4$ and NaOH. These pH values were chosen because we wanted to study the reactions of neutral DTT or DTE radicals and DTT or DTE radical anions which are formed in equilibrium [3] with a pk ~5.3 (10, 11) (see later).

It can be seen that at pH ~3.5 the majority of the radicals would be in the neutral form **I** and at pH ~6.7 they would be in the radical anion form **II**. For each experiment fresh solutions were prepared. In the case of mercaptoethanol (βME) and mercaptopropionic acid (βMPA) the aqueous solutions of phenothiazines or antioxidants were saturated with N_2O in a glass irradiation cell with rubber septum. After saturating, small amount of the liquid (βME or βMPA) was added to the cell via the septum. It is assumed that contribution from the oxygen content in the few μlitres of βME or βMPA is negligible.

Results and discussion

(I) N_2O-saturated thiol or disulphide – ABTS solutions

On pulse radiolysis of N_2O-saturated solutions containing ABTS a characteristic absorption immediately after the pulse was observed at 415 nm. This is known to be due to the $ABTS^{+}$ radical cation (12) formed according to reaction [4]

[4] $ABTS + \dot{O}H \rightarrow ABTS^{+} + OH^{-}$

Similar absoprtion was observed at 415 nm when N_2O-saturated aqueous solutions containing thiol or disulphide (2.5 mM) and ABTS (5–20 × 10^{-5} M) were pulse radiolysed. At these concentrations and with known $k_{\dot{O}H + \text{thiols/djsulphide}}$ and $k_{\dot{O}H + ABTS}$ it can be shown that the majority of $\dot{O}H$ radicals react with thiol/disulphide to give thiyl radicals according to reactions [5] and [6]. Reaction [6] is known to give ~50% of $R\dot{S}$ radicals when compared with other modes of reactions of $\dot{O}H$ with disulphides (11*b*).

[5] $RSH + \dot{O}H \rightarrow R\dot{S} + H_2O$

[6] $RSSR + \dot{O}H \rightarrow R\dot{S} + RSOH$

$R\dot{S}$ radical can then react with ABTS according to reaction [7] and can dimerise according to reaction [7*a*].

[7] $R\dot{S} + ABTS \rightarrow RS^- + ABTS^{+}$

[7*a*] $R\dot{S} + R\dot{S} \rightarrow RSSR$

The formation of $ABTS^{+}$ at 415 nm was exponential with time for all thiols and disulphides. The first order rate constants when plotted against [ABTS] gave straight lines. The small intercept observed on the Y-axis in few cases appears to be due to reaction [7*a*]. Bimolecular rate constants have been evaluated from the slopes of these plots and are presented in Table 1. Bimolecular rate constants obtained earlier (12) in the case of a few thiols are also given in Table 1 for comparison.

(II) N_2O-saturated thiols/disulphides – ascorbic acid solutions

On pulse radiolysis of N_2O-saturated ascorbic acid solutions at pH ~6.4 a characteristic absorption at 360 nm due to $A^{\cdot}$ formed via reaction [8] was observed (13)

[8] $AH^- + \dot{O}H \rightarrow A^{\cdot} + H^+ + OH^-$

Very similar absorption at 360 nm was observed in N_2O-saturated solutions containing thiol/disulphide (2.5 mM) and ascorbic acid 5–20 × 10^{-5} M at pH 6.4. The absorption spectrum is similar to the one observed in the absence of thiol/disulphide. This is attributed to $A^{\cdot}$ formed according to reactions [5], [6], and [9].

[9] $AH^- + R\dot{S} \rightarrow A^{\cdot} + H^+ + RS^-$

The absorption grows exponentially and is first order in AH^- concentration. Bimolecular rate constants for reaction [9] as evaluated from the slopes of the respective plots of first order rate constant versus $[AH^-]$ are presented in Table 1. The small intercept on *Y*- axis appears to be due to reaction [7*a*]. Table 1 also show the rate constants for a few thiols evaluated earlier (4*a*).

(III) N_2O-Saturated thiol/disulphide and phenothiazine solutions

On pulse radiolysis of N_2O-saturated aqueous solutions containing thiol/disulphide and phenothiazines at pH 3.6 and 6.5, a characteristic absorption between 510–525 nm due to phenothiazine radical cations was observed. The concentrations of sulphur compounds and phenothiazines were chosen in such a way that most of the $\dot{O}H$ radicals in N_2O-saturated solutions react with thiol/disulphide to give thiyl radical according to

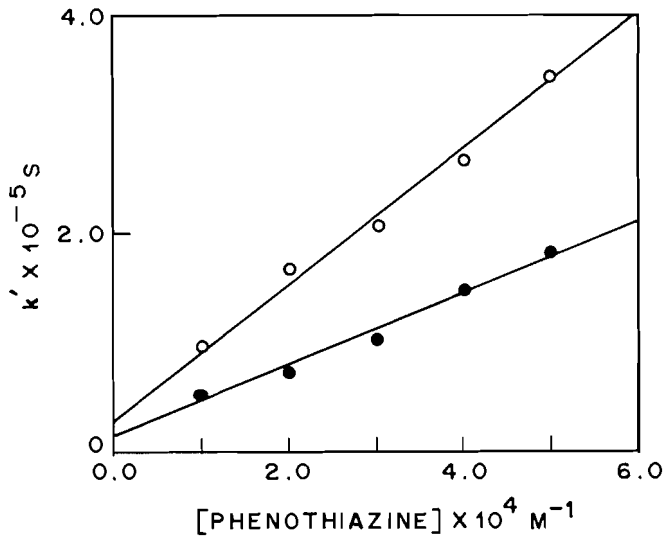

FIG. 1. Plot of first order rate constant (k') for the formation of absorption in N_2O-saturated solutions of PPZ^+ and cysteine ○; PMZ^+ and cysteine ●. Cysteine concentrations ~5 × 10^{-3} M.

reactions [5] and [6]. Thiyl radicals thus formed react with phenothiazines under investigation to give radical cations of the latter absorbing between 510 and 525 nm. Besides promethazine (PMZ^+) and chlorpromazine (CPZ^+) on which some work has been reported earlier (4*a*, 14), we have now studied two other phenothiazines viz. prochlorperazine (PPZ^+) and trimeprazine tartrate (TPZ^+). As the pk_a values for the side chain nitrogen atom of promethazine and chlorpromazine is 9.3 (15), it is expected that the phenothiazines would exist in the cationic form at the experimental pH values. The reactions of a variety of thiyl radicals have been investigated with the four drugs (reactions [10]–[13]).

[10] $R\dot{S} + PMZ^+ \rightarrow PMZ^{2+} + RS^-$

[11] $R\dot{S} + CPZ^+ \rightarrow CPZ^{2+} + RS^-$

[12] $R\dot{S} + PPZ^+ \rightarrow PPZ^{2+} + RS^-$

[13] $R\dot{S} + TPZ^+ \rightarrow TPZ^{2+} + RS^-$

Transient spectra of the radical cations formed in reactions [10]–[13] revealed maxima at 510, 525, 515, and 510 nm,

respectively, for PMZ^{2+}, CPZ^{2+}, PPZ^{2+}, and TPZ^{2+}. Our λ_{max} for PMZ^{2+} and CPZ^{2+} differed only slightly from those reported earlier (4*a*, 14). The *k* values for reactions [10]–[13] have been evaluated from the data obtained at the above wavelengths. Formation of radical cations in all four phenothiazines at the two pH's were found to be exponential with time and first order in phenothiazine concentration for all thiols and disulphides. The first order rate constants when plotted against phenothiazine concentrations gave straight lines. A typical plot of *k'* in the case of cysteine against $[PPZ^+]$ and cysteine against $[PMZ^+]$ is shown in Fig. 1. Bimolecular rate constants are derived from the slopes of these plots. It can be seen that there is an intercept on the *y* axis which appears to be due to reaction [7*a*].

In view of the complex nature of our system it is rather difficult to eliminate the intercept. To keep the ratio $k_{\dot{O}H + RSH}[RSH]/k_{\dot{O}H + phenothiazine}$ [phenothiazine] high, the thiol concentration is to be kept high. On the other hand, in order that the majority of the e^-_{aq} are converted to $\dot{O}H$ radicals the ratio $k_{e^-_{aq} + N_2O}[N_2O]/k_{e^-_{aq} + RSH}[RSH]$ should be high and therefore the thiol concentration has to be kept low. We have used 5×10^{-3} M thiol in these experiments. Taking the saturation concentration of N_2O as 2.5×10^{-2} M, $k_{e^-_{aq} + N_2O} \sim 9 \times 10^9\ M^{-1}\ s^{-1}$ and $k_{e^-_{aq} + RSH} \sim 1 \times 10^{10}\ M^{-1}\ s^{-1}$ for most thiols and disulphides except GuSH, it can be seen that about 82% of electrons are converted to $\dot{O}H$ radicals which would give $G(R\dot{S}) \sim 5.0$. Even though reduction in $\dot{O}H$ radicals would reduce the concentration of $R\dot{S}$ radicals in the system it wold not have any effect on the reactions of $R\dot{S}$ radicals with the phenothiazines and on the kinetics. In some cases the signal was low at low phenothiazine concentrations because of the competing reaction [7*a*]. High concentrations of both phenothiazines (4×10^{-4} M) and thiols (5×10^{-3} M) were taken and the rate constant evaluated by the average of four such experiments. Even at these concentrations reaction [7*a*] would occur to some extent (~5%). Rate constants thus obtained agreed to within 10% of the *k* values evaluated from straight line plots.

The results of Tables 1 and 2 demonstrate certain important common features.

(*i*) In general the rate constants are quite high (10^8–$10^9\ M^{-1}\ s^{-1}$), and seem to depend upon the individual thiyl radical, the antioxidant, and the phenothiazine. Minor differences with earlier reported results for ABTS and AH^- are within the limits of experimental error.

(*ii*) Rate constants increase with decreasing size of the thiyl radical. Rate constants for cysteine, cysteamine, mercaptoethanol, and mercaptoproprionic acid which have quite similar structure and molecular weight, however are more or less similar for PPZ^+, CPZ^+, and PMZ^+.

(*iii*) Rate constants are lower for the radicals PenṠ and GuṠ. The low value for PenṠ could be due to steric hindrance caused by the two methyl groups attached to the carbon atom that is close to the sulphur atom. The somewhat lower *k* value for GuS could be ascribed to its bulkiness.

(*iv*) Rate constants are the same whether the thiyl radicals are generated from thiol or the corresponding disulphide. This confirms the earlier finding that thiyl radicals are formed in both reactions [5] and [6].

(*v*) Rate constants are higher for chlorpromazine and prochlorperazine as compared to promethazine, which can be explained on the basis of the higher oxidation potential of the PMZ^{2+}/PMZ^+ couple as compared to that of CPZ^{2+}/CPZ^+ (14, 16). The oxidation reaction of phenothiazines by $\dot{O}H$ radicals takes place by a number of processes (14). The high rate constants for various processes in the two systems suggest the same explanation for all competing reactions.

TABLE 2. Rate constant of reaction between thiyl radicals and phenothiazines[a]

		$k_{R\dot{S} + Phenothiazines} \times 10^{-8}$ M s [b]			
	pH	PPZ^+	CPZ^+	PMZ^+	TPZ^+

GuSSGu	6.5	4.9	13	1.0	8.1
Cysteamine	6.5	9.1	19.0(1.7)	3.5(0.67)	8.8
Cystamine	6.5	8.6	11.0	2.2	9.0
PenSH	6.5	2.9	9.0(1.2)	1.6(0.27)	4.8
PenSSPen	6.5	3.4	7.5	1.9	4.0
ME	6.5	8.0	19.0	2.9	7.7
MPA	6.5	6.0	17.0	2.2	4.2

[a]Values in parentheses are from ref. 4*a*; values in Table 2 are an average of at least four independent determinations.
[b]Error within ±20%.

Even though we have not evaluated the rate constants for individual processes in our system, similar reactions may be involved in the reactions of thiyl radicals with the phenothiazines and higher oxidation potential for PMZ^+ as compared to CPZ^+ may be the cause for the low rate constant in the case of promethazine.

(*vi*) In general our rate constants are higher than those reported earlier (4*a*). The experimental conditions used in this study are very much similar to those in ref. 4*a*. (The dosage ~10 Gy and concentrations of reactants were more or less same. The pH used was 3.0.) The difference in pH as compared to ours should not affect the results, as the thiyl radicals will be neutral radicals in the pH range 3.0–6.5. In view of this it is rather difficult to explain the differences in *k* values in the two cases.

(IV) (a) N_2O-saturated DTT/DTE–phenothiazine solutions

As mentioned earlier, the authors of ref. 4*a* were not able to get good signals for the phenothiazine radical cation in dithiothreitol/phenothiazine mixtures. On the other hand, we have been able to get good formation signals with all four phenothiazines. A typical signal is shown in Fig. 2. The inset in Fig. 2 gives a straight line from which the first order rate constant (*k'*) is calculated. The pseudo first order rate constant (*k'*) versus phenothiazine concentrations are straight lines. The bimolecular rate constants are derived from the slope of these straight lines and are presented in Table 3. The low rate constants for DṪT and DṪE radicals appear to be due to the cyclic structure of DṪT and DṪE radicals (see **I** and **II** in reaction [3]) which may sterically hinder the approach towards the phenothiazines. The reason of very low signals in 4*a* in DTT/phenothiazines in N_2O-saturated aqueous solutions is not clearly known.

(b) Effect of pH on $k_{DṪT/DṪE + phenothiazines}$

Experiments have been carried out in N_2O-saturated aqueous solutions for DTT, DTE, and GuSH/phenothiazine mixtures. Thiyl radicals are generated in reaction of $\dot{O}H$ radicals with thiols. DṪT and DṪE radicals are known to exist in equilibrium (reaction [3]) with a p*k* value of 5.3 (10, 11). The pH's chosen were 3.6 and 6.4 with a view to investigate the reactions of

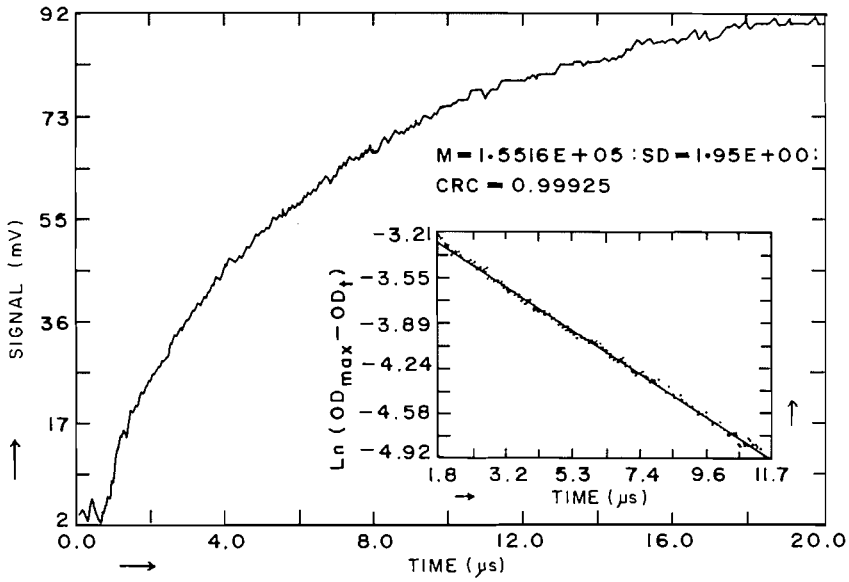

FIG. 2. Formation trace of the radical cation TPZ^{2+} observed at 515 nm after a 25 ns pulse (13 GY) on a N_2O-saturated trimeprazine tartrate (4×10^{-4} M) and dithiothreitol (5×10^{-3} M); aqueous solutions at pH ~6.5. Inset shows the straight line plot of ln ($OD_{max} - OD_t$) vs. time. Points derived from the formation trace and the straight line is the least square fit.

TABLE 3. Effect of pH on the rate constants

[a]Error within ±20%.

neutral DṪT or DṪE radical and DTT or DTE radical anion with phenothiazines. It can be seen that at pH 3.6, DṪT and DṪE radicals would exist almost entirely in the neutral form **I** and at pH 6.4 they would exist in the radical anion form **II**. The results of this study are shown in Table 3. The results of GuSH and GuSSGu at pH 3.6 and 6.4 are also shown in Table 3 for comparison.

As can be seen, there is no difference in rate constants for GuṠ radical at the two pH's. The rate constants for neutral DṪT and DṪE species **I** is about ½ that of the DTT and DTE radical anion species **II** for all phenothiazines. This might be explained as follows:

At pH ~3.6 and 6.4 all drugs chlorpromazine, promethazine, prochlorperazine, and trimeprazine tartrate are present in cationic forms $CPZH^+$, $PPZH^+$, $PMZH^+$, and $TPZH^+$, respectively (pk_a ~9.3). Thus the reactions of DTT and DTE radical anions at pH 6.4 with phenothiazine cations would be expected to be faster than the reactions of neutral DṪT and DṪE radicals at pH 3.6 with phenothiazine cations. The fact that there is no variation in the rate constants of GuṠ radicals with phenothiazine radical cation at the two pH's suggest that GuṠ radicals at either pH remain a neutral species.

The results of this study demonstrate that thiyl radicals are strong oxidizing species. Each thiyl radical generated from all thiols and disulphides can take up one electron from the four phenothiazines, ABTS, and ascorbic acid with considerable ease. The rate constants range between ~10^8–10^9 M^{-1} s^{-1} depending on the nature of the thiyl radicals and the reactants. In view of the complex nature of the systems under investigations no attempt has been made to correlate the rate constants with redox properties of thiyl radicals.

The radicals formed thus are quite reactive and may be responsible for cell damage and other biological problems. Our studies should therefore be relevant.

^{1}H and ^{19}F NMR conformational studies of the monofluorostyrenes in solution. Comparison with theory and vapor phase behavior

TED SCHAEFER AND RUDY SEBASTIAN
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received January 16, 1990

TED SCHAEFER and RUDY SEBASTIAN. Can. J. Chem. **68**, 1383 (1990).

The parameters for the high resolution ^{1}H and ^{19}F NMR spectra of 2-, 3-, and 4-fluorostyrene are reported for solutions in CS_2 and acetone-d_6 at 300 K. The populations of the planar *cis* and *trans* conformers of 2- and 3-fluorostyrene are deduced from the long-range coupling constants involving the *meta* and α protons. These populations are insensitive to solvent and appear to be in reasonable agreement with previous 6-31G MO computations for the free molecule; they are also compared with populations deduced from recent rotational and vibronic spectra. The long-range coupling constants for the protons of 4-fluorostyrene imply an internal barrier to rotation about the exocyclic carbon–carbon bond very similar to that in styrene, in agreement with the 6-31G results. The signs of the coupling constants involving ^{19}F and the protons in the side chain are reported and discussed in terms of coupling mechanisms for the three molecules. An earlier surmise, of a positive σ electron contribution to the coupling constant over six bonds in an all-*trans* arrangement, is confirmed for the *meta* and *trans*-β protons in 3-fluorostyrene.

Key words: monofluorostyrenes, ^{1}H and ^{19}F NMR, conformations, long-range coupling mechanisms, MO calculations of internal barriers.

TED SCHAEFER et RUDY SEBASTIAN. Can. J. Chem. **68**, 1383 (1990).

On a déterminé les paramètres pour les spectres RMN à haute résolution du ^{1}H et du ^{19}F des 2-, 3- et 4-fluorostyrènes, en solutions dans le CS_2 et dans l'acétone-d_6, à 300 K. On a déduit les populations des conformères plans *cis* et *trans* présents dans les 2- et 3-fluorostyrènes en se basant sur les constantes de couplage à longue distance impliquant les protons *méta* et α. Ces populations sont insensibles à la nature des solvants et elles semblent en bon accord avec des prévisions faites antérieurement en se basant sur des calculs d'OM effectués au niveau 6-31G, sur la molécule libre; on a aussi comparé ces résultats avec les populations qui ont récemment été déduites de spectres de rotation et de vibration. Les constantes de couplage à longue distance qui sont observées dans le 4-fluorostyrène impliquent que la barrière interne à la rotation autour de la liaison carbone–carbone exocyclique est très semblable à celle qui est observée dans le styrène; cette conclusion est en accord avec les prédictions faites à l'aide de calculs au niveau 6-31G. On rapporte aussi les signes des constantes de couplage entre le ^{19}F et les protons de la chaine latérale et on en discute en fonction de mécanismes de couplage opérant dans ces trois molécules. Pour les protons *méta* et *trans*-β du 3-fluorostyrène, on confirme la prédiction antérieure à l'effet que, dans un arrangement complètement *trans*, il existe une contribution σ électronique positive à la constante de couplage à travers six liaisons.

Mots clés : monofluorostyrènes, RMN du ^{1}H et du ^{19}F, conformations, mécanismes de couplage à longue distance, calculs d'OM des barrières internes.

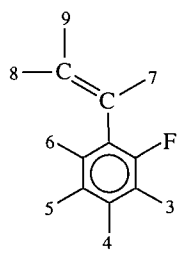
[Traduit par la revue]

Introduction

Recent microwave and electronic spectroscopic studies of 2-fluorostyrene (2FS) and 3-fluororstyrene (3FS) in the vapor phase disagree in some respects as to the internal rotational potentials and, again, with parts of the predictions from 6-31G MO computations (1–6). The present NMR studies of these molecules in polar and nonpolar solvents provide conformational information relevant to these discrepancies. In addition, the work reported here includes a conformational study of 4-fluorostyrene (4FS), meant to assess the change in the internal rotational potential of styrene caused by the substituent. It turns out that the solvent dependence of the conformational populations is weak for 2FS and 3FS. These populations for 3FS agree reasonably well with microwave and theoretical data but not with the jet spectroscopic results. For 2FS, the solution and theoretical data are moderately compatible, but disagree with the gas phase spectoscopic results.

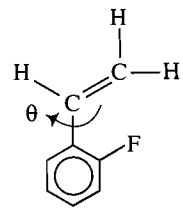
In the vapor phase at 260 K, the microwave spectrum (5) provides no evidence for the presence of **2**, the *cis* conformer of 2FS. The absence of this conformer is also noted in the single vibronic level fluorescence spectra of a supersonic jet (1). By way of contrast, 6-31G MO computations for the two conformations suggest a ratio of near 2:1 for the *trans*/*cis* populations at 300 K (6).

The spectra of 3FS in a supersonic jet (2) imply a *cis*/*trans* ratio of 3:1, apparently (3) that found at room temperature with



θ = 180°

1



θ = 0°

2

the high resolution electronic absorption spectrum. Yet the microwave spectrum of 3FS, while detecting both conformers, **3** and **4**, has this ratio as $1.15^{+0.34}_{-0.21}$ at 260 K (4), in rather better agreement with *ab initio* molecular orbital calculations with a

[a]5.0 mol% in a solution of CS_2, containing also 10.0 mol% C_6D_{12}, 0.5 mol% TMS, and 0.25 mol% of C_6F_6.
[b]5.0 mol%, containing also 0.5 mol% TMS and 0.25 mol% of C_6F_6.
[c]In Hz at 300.135$_2$ MHZ to high frequency of internal TMS.
[d]In Hz at 282.369 MHz to high frequency of internal C_6F_6; note that on the δ scale, C_6F_6 has a δ of −163 ppm (relative to $CFCl_3$ and therefore more shielded).
[e]Numbers in parentheses are standard deviations in the last significant figure.
[f]The marked solvent dependence of ^nJ (H,F) within the benzene ring is well known (46).
[g]Signs assumed on the basis that ^5J (H,F) in fluorobenzene derivatives becomes algebraically larger in more polar solvents, as experienced in this laboratory. Note also that ^5J (H,F) is positive in 3-fluorobenzaldehyde (47) and in 3-fluorotoluene (41), but is negative in 2-fluorobenzaldehyde (47) and in 2-fluorotoluene (43).

minimal basis set (7) and also with 6-31G MO computations (6). In solution (see below) the *cis* conformer is only slightly the more abundant at 300 K. In early work (8–10) the internal rotational barriers in 4FS and 3FS are discussed in terms of twofold symmetry; in view of recent experimental work on styrene (11, 12) and of theoretical work on styrene (13, 14) and 4FS (6), these terms are inappropriate.

Experimental

The three fluorostyrenes were prepared as 5.0 mol% solutions in CS_2/C_6D_{12} and acetone-d_6 (see Table 1 for details). These solutions were filtered into 5 mm o.d. NMR sample tubes, were degassed by five cycles of the freeze–pump–thaw procedure, and were then flame-sealed under vacuum to produce symmetrical tops. The ^1H and ^{19} NMR spectra were accumulated on a Bruker AM 300 spectrometer in a manner described before (15). Certain relative signs of $^1H,^{19}F$ coupling constants were also found (see below).

INDO and CNDO MO FPT computations (16, 17) were performed on a Amdahl 5870 system; *ab initio* molecular orbital computations, with geometry optimization (see the caption to Fig. 2), utilized the same computer and the program GAUSSIAN 86 (18).

Results and discussion

Spectral analyses

The ^1H and ^{19}F NMR spectra were analyzed with the program NUMARIT (19), extensively modified in this laboratory. The spectral parameters are to be found in Tables 1 and 2. Figure 1 shows parts of the ^1H NMR spectra of the α proton in the three compounds, together with their theoretical simulations. We discuss interring $^1H,^1H$ couplings first, most being known about their θ dependence.

The conformational equilibria based on $^5J_{37}$ and $^5J_{57}$

(i) 2-Fluorostyrene

The coupling constant between the α and *meta* protons in styrene has been examined theoretically (20–23), one study (23) strongly implying a predominant σ electron mechanism. In other words, $^5J_{37}$, analogous to that in **1**, is expected to be small whereas $^5J_{57}$ should be large for the all-*trans* arrangement of the five intervening bonds. Furthermore, it has been argued (24) that $^5J_{57}$ is proportional to $\sin^2(\theta/2)$, therefore vanishing in **2** when $\theta = 0°$ and attaining its maximum value in **1**, when $\theta = 180°$. The argument is based on the insensitivity of $^5J_{37}$ or $^5J_{57}$ to nonplanarity of the molecule, in 2,6-dichlorostyrene (20), for example, among others (24), and also that $^5J_{37}$ in 2,5-dichlorostyrene (20) is very small, corresponding to predominance of conformer **1** above. The argument implies that $^5J_{37}$ in styrene behaves like the analogous coupling constant in benzaldehyde (25) but not like that in toluene (26, 27).

[a]For the solutions described in Table 1.
[b]Note that H-7 is the α proton of the vinyl group and that H-9 is the *trans*-β proton.
[c]Numbers in parentheses are the standard deviations in the last significant figure.
[d]The sign is an accidental by-product of the double resonance experiments.
[e]These numbers are obtained from assessments of peak shapes and are not optimized.

In 4-methylstyrene in acetone-d_6 solution, $^5J_{37} = {}^5J_{57} =$ 0.377 (1) Hz (24), the same as that in 4-fluorostyrene (Table 2). For evenfold barriers to internal rotation about the C_{sp^2}—C_{sp^2} bond, the expectation value of $<\sin^2(\theta/2)>$ is 0.5 (see caption to Fig. 2). Hence $^5J_{180}$ is 2 (0.376_5) or 0.753 (3) Hz for 4FS, taking the average values of $^5J_{37}$ in the two solutions of Table 1. This result is now applied to the conformational equilibria for 2FS and 3FS.

The sum of $^5J_{37}$ and $^5J_{57}$ in 2FS is 0.757 (2) and 0.758 (4) Hz in CS_2/C_6D_{12} and acetone-d_6 solutions, respectively, equal to that in 4FS, within experimental error. On the assumption that the fluorine substituent in 2FS does not alter significantly the intrinisic magnitude of $^5J_{37}$, the population of the *trans* conformer, **1**, follows as 0.71 (1) in the nonpolar and as 0.72 (1) in the polar solvent at 300 K. This result implies that the conformational equilibrium is independent of solvent and, indeed, the STO-3G and 6-31G MO computations (6) suggest that the dipole moment of **1** is larger that that of **2** by only 0.01 D. The former computations have the *trans* form as 1.91 kJ/mol more stable, corresponding to a fractional *trans* population of 0.68, if differences in zero point energy between **1** and **2** are ignored; the latter basis gives the same population. These energy differences imply a population of about 0.30 for the *cis* conformer at 260 K, the temperature of the microwave experiments. Yet no spectral lines due to this conformer could be found (5). The same statement applies to the $S_1 \leftarrow S_0$ fluorescence excitation spectra in a supersonic jet (1). The gas phase experiments yield a barrier to planarity for the *trans* form of 0.19 (2) and 0.18 (5) kJ/mol (1, 5) while the 6.31G basis has the energy of the nonplanar as 0.04 kJ/mol lower than the planar *trans* form. The potential function given by this basis yields an average value of 16° for the dihedral angle between the vinyl and benzene planes at 300 K; the microwave data fit an angle of about 14° at 260 K. One might speculate that the density of vibrational and rotational states for the *trans* form is much larger for the *cis* form, which, according to the MO computations (6), is planar and has a barrier of 0.7 kJ/mol to rotation by 15° about the C_{sp^2}—C_{sp^2} bond. If this speculation were correct, then it would follow that entropy effects cause the very low abundance of the *cis* conformer in the vapor but also that the solvent molecules damp out these states in the NMR experiment.

The populations of **1** and **2** for 2FS in solution were based on a two-site analysis. The internal rotational potential given by the 6-31G basis yields $<\sin^2(\theta/2)>$ as 0.735 at 300 K, contributions from nonplanar conformations now being included. Hence $^5J_{37}$ follows as 0.735 (0.758) or 0.557 Hz, whereas $^5J_{57}$ becomes 0.201 Hz. The corresponding STO-3G potential has $<\sin^2(\theta/2)>$ as 0.675 at 300 K, suggesting $^5J_{37}$ as 0.512 Hz and $^5J_{57}$ as 0.246 hz. The differences in the coupling constants reflect the differences in the barrier heights predicted by the two bases; the minimal basis set has this height as 16.0 kJ/mol at $\theta = 90°$, some 2.4 kJ/mol larger than found with the split-valence basis. The means of the coupling constants obtained from the two theoretical potentials are rather near those found in solution.

For styrene itself, the 6-31G potential agrees quite closely with experiment (14) but the STO-3G potential (13) overestimates the barrier height by about 3.5 kJ/mol. It is conceivable that the solvent raises the barrier height in styrene. Quadrupolar splittings in the high resolution NMR spectra of deuterated styrene, in solvents of low polarity, are used (28) to deduce a twofold internal barrier of 16.7 ± 1.6 kJ/mol, close to the twofold component of 16.3 ± 0.1 kJ/mol given by the minimal basis (13); the free molecule, however, has a substantial fourfold component in the barrier (11). The temperature dependence of $^6J_{47}$ in 3,5-dichlorostyrene in acetone-d_6 and CD_2Cl_2 solutions (22) is interpreted to mean that the fourfold component is quite different than for styrene, that the barrier height in the former solvent is the same as in gaseous styrene, and that the height increases by 2.3 ± 1.5 kJ/mol in the chlorinated solvent. The nonpolar molecule, ethylbenzene, displays no solvent dependence of the barrier to rotation about the exocyclic C_{sp^2}—C_{sp^3} bond (29).

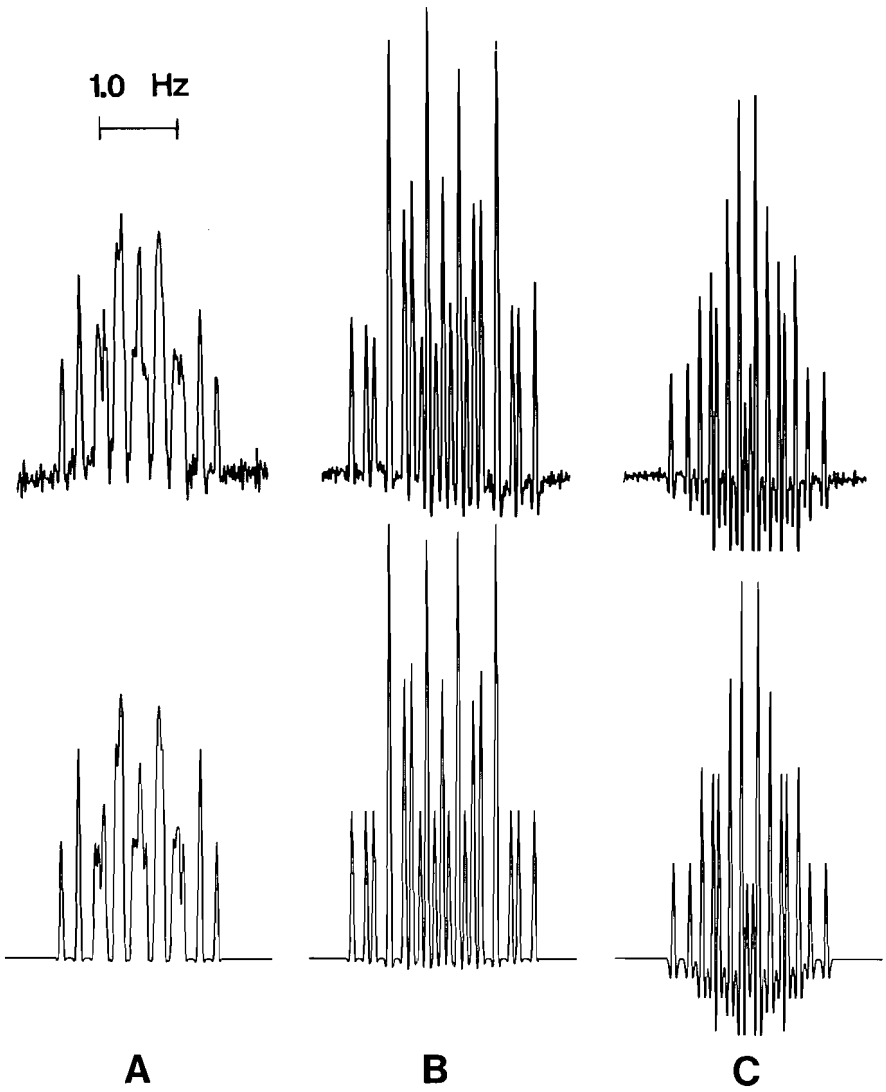

FIG. 1. The bands at lowest frequency of the ^{1}H NMR spectra at 300.135 MHz of the α protons in 2-, 3-, and 4-fluorostyrene are shown in A, B, and C, respectively, for 5.0 mol% solutions in acetone-d_6 and a probe temperature of 300 K. The splittings arise from long-range coupling interactions with all the ^{1}H and ^{19}F nuclei in the benzene ring. The theoretical spectra are produced with the spectral parameters in Tables 1 and 2 and each transition has a linewidth at half height of 0.04 Hz. The digital resolution is 0.005 Hz per point; the smallest spacings in B, for example, are about 0.07 Hz.

In summary, in both polar and nonpolar solutions at 300 K, the *cis* conformer of 2FS has an abundance of near 30%. In the gas phase, this conformer appears to be absent.

(ii) 3-Fluorostyrene

$^5J_{57}$ is 0.310 (1) and 0.314 (1) Hz in the CS_2 and acetone-d_6 solutions, respectively, implying that the conformational equilibrium is essentially independent of solvent polarity. The computed dipole moments of the *cis* and *trans* conformers, **3** and **4**, differ by less than 0.01 D (6). If $^5J_{180}$ is 0.753 (3) Hz, as in 4FS,[1] then a two-site analysis indicates that the fractional abundance of the *trans* form is 0.312 (3) /0.753 (3) or 0.41 (1) in both solvents.

The 6-31G energy of this form is 0.53 kJ/mol higher than that of the *cis* form, corresponding to a fractional population of 0.45 at 300 K if the computed energies are identified with free energies. The STO-3G computations have the *cis* form favored by only 0.20 kJ/mol. The gas phase electronic absorption spectrum at room temperature has an intensity ratio favoring the *cis* conformer by 3:1, or by 2.7 kJ/mol in free energy (3). However, the microwave spectra imply a free energy difference of only 0.3 ± 0.5 kJ/mol at 260 K, the *cis* form predominating (4). All methods agree that the *cis* conformer is most stable. The solution data imply a solvent independence of the conformational equilibrium. Table 3 summarizes the conformational populations suggested by the various methods.

$^6J_{47}$ as an indicator of the internal rotational barriers

$^6J_{47}$ in Hz for styrene has been written (24) as $-0.448 \sin^2\theta - 0.149$ on the assumption that the internal rotational barrier in the gas phase (11, 12) is the same as in acetone-d_6 solution. For 3,5-dichlorostyrene, $^6J_{47}$ is taken as $-0.670 \sin^2\theta - 0.130$, based on its temperature dependence in acetone-d_6 and CD_2Cl_2 solutions (22). The values of $^6J_{47}$ of 2FS and 3FS do not display a marked solvent dependence (Table 2). At 300 K,

[1]In unpublished work in this laboratory, it was shown that ^5J(H,CHO) in 4-fluorobenzaldehyde is essentially unchanged from its value in benzaldehyde, this coupling being a purely σ electron mediated interaction.

TABLE 3. Populations of *cis* conformers of 2-fluorostyrene and 3-fluorostyrene in various states by different methods

[a]Vibronic fluoresence spectra of a jet, suggested (1, 2) to have a room temperature conformer distribution.
[b]Based on long-range coupling constants between ring and vinylic protons in CS_2/C_6D_{12} and acetone-d_6 solutions.
[c]Based on the computed energy differences between the *cis* and *trans* conformers, uncorrected for zero point energy differences.

the STO 3G and 6-31G MO potentials (6) have $<\sin^2\theta>$ as 0.108 and 0.157, respectively, for 2FS and are 0.118 and 0.170 for 3FS. The smaller values of $<\sin^2\theta>$ from the minimal basis set reflect the higher computed internal barriers. The ensuing $^6J_{47}$ numbers obtained from these $<\sin^2\theta>$ values and the relationships above can be summarized as follows. For 2FS, the 6-31G potential yields $^6J_{47}$ as −0.219 and −0.235 Hz, the observed value being −0.238 (1) Hz in acetone-d_6 solution, whereas the STO-3G potential yields −0.197 and −0.202 Hz from the two relationships above. By way of contrast, for 3FS the 6-31G potential has $^6J_{47}$ as −0.225 and −0.244 Hz, rather larger in magnitude than the measured value of −0.199 (1) Hz, while the STO-3G potential has $^6J_{47}$ as −0.201 and −0.209 Hz.

Now, the 6-31G potential agrees best with the experimental potential for styrene in the gas phase. If this agreement holds true for 3FS in the gas phase, as is consistent with the microwave data (4), then $^6J_{47}$ implies a barrier in solution larger by about 3 kJ/mol than in the gas phase; this follows from the STO-3G potential (6), which has the barrier height as 3.4 kJ/mol larger than that from the 6-31G basis. Both parameterizations of ^6J imply such an increase.

However, a variety of potentials probably would be consistent with the $^6J_{47}$ numbers in Table 2. Hence it is best to conclude that the internal rotational potential may be somewhat larger for 3-fluorostyrene in acetone-d_6 solution, where $^6J_{47}$ is −0.199 (1) Hz, than it is for styrene in the same solution, where $^6J_{47}$ is −0.227 (3) Hz. This conclusion follows simply from the $\sin^2\theta$ dependence of $^6J_{47}$. The internal barrier in 3,5-dichlorostyrene is also higher than in styrene, based on the same comparison.

A caveat concerns the intrinsic substituent dependence of the predominantly σ−π coupling constant, $^6J_{47}$. The somewhat analogous coupling constant in 3-fluorotoluene, at −0.593 (2) Hz (30), is indeed slightly smaller in magnitude than the −0.602 (2) Hz for toluene (27) in the same solvent. Furthermore, in 3-fluorobenzaldehyde, $^6J_{47}$ is +0.045 (1) Hz (25), whereas it cannot be detected in benzaldehyde. In view of the detailed discussion of the coupling mechanisms in toluene (26, 27) and styrene (21) it seems possible that the fluorine substituent in 3FS causes a small intrinsic positive change in $^6J_{47}$. If so, then the increased barrier relative to styrene in solution is not established.

The long-range $^1H,^1H$ coupling constants for the β-olefinic protons

(i) Five-bond coupling constants

$^5J_{28}$ and $^5J_{68}$ were not detected for styrene (31) but occur as ±0.045 (1) Hz in 4-methylstyrene (24) and as ±0.048 (1) Hz in 4FS in both solvents of Table 2. Both the valence bond and molecular orbital models probably overestimate their positive magnitudes (20) for θ = 180°, that is, for J_{28} in **4**, for example. For $^5J_{68}$ in **4**, the latter model predicts a very small, negative value, probably arising from a direct or proximate coupling mechanism. Indeed, $^5J_{68}$ is −0.15 (4) Hz in 2,5-dichlorostyrene (20); if the latter exists entirely as one planar conformer, then ^5J is about −0.15 Hz for H-8 and H-*ortho* in a *cis* orientation. $^5J_{28}$ and $^5J_{68}$ are less than 0.1 Hz in magnitude for 2FS and 3FS and, since their signs are unknown, will not be further discussed.

The negative, proximate contribution to $^5J_{28}$ is not present in $^5J_{29}$ and $^5J_{69}$. Hence the latter have larger magnitudes, at about 0.17 Hz in styrene (31) as well as in 4FS and 3FS. $^5J_{69}$ is slightly larger than $^5J_{29}$ in 3FS, suggesting a small σ electron contribution, largest for an all-*trans* orientation of the intervening bonds. Such a contribution is also consistent with the small $^5J_{69}$ of 0.085 Hz in 2FS, for which the all-*trans* orientation is less prevalent (conformational bias) than in 4FS and 3FS.

(ii) Six-bond coupling constants

$^6J_{38}$ and $^6J_{58}$, computed as negative by both valence bond and molecular orbital methods (20), have not been detected in styrene (31) and are clearly very small in 4FS, as is $^6J_{58}$ in 3FS and 2FS (Table 2).

For the all-*trans* coupling path, $^6J_{39}$ and $^6J_{59}$ are predicted as positive (20), presumably due to a positive σ electron component. Again, these coupling constants have not been observed for styrene and are small in 4FS. However, the ^7J (H-3,CH_3) in β-methylstyrene (24) implies a π electron contribution of −0.08 Hz to these coupling constants for nearly planar conformations. Hence the very small values of $^6J_{39}$ and $^6J_{59}$ in 4FS may well arise from cancellation of the two components. Our INDO MO FPT computations give −0.12 and 0.09 Hz for $^6J_{39}$ in the two planar conformers, suggesting -0.01_5 Hz in 4FS; this result is consistent with observation (Table 2). For 3FS, our INDO MO FPT calculations give $^6J_{59}$ as 0.15 Hz in the *cis* conformer, **3**, and as −0.08 Hz in the *trans* conformer, **4**; the latter has an abundance of 41%, according to the discussion in a previous section. Accordingly, $^6J_{59}$ follows as 0.06 Hz, consistent with the measured value of +0.06 Hz.

(iii) Seven-bond coupling constants

$^7J_{48}$ and $^7J_{49}$ are attributed to π electron coupling mechanisms (20). In 4-methylstyrene, ^8J (H-8,CH_3) and ^8J (H-9,CH_3) are 0.26 Hz in magnitude (24), giving a measure of the π electron contributions to $^7J_{48}$ and $^7J_{49}$. In styrene itself, $^7J_{48}$ is 0.24 Hz, whereas $^7J_{49}$ is 0.28 Hz (31). The difference in mag-

[a]The number of formal intervening bonds, n, varies from 4 to 7, of course. See the text for the numbering of the protons in the olefinic group.
[b]The planar molecule has the angle, θ, as zero and, for 2FS and 3FS, the double bond of the side chain is then oriented *cis* to the fluorine substitutents.
[c]This block refers to the INDO MO FPT results.
[d]This block refers to the CNDO/2 MO FPT results.
[e]The computation did not converge for this number.

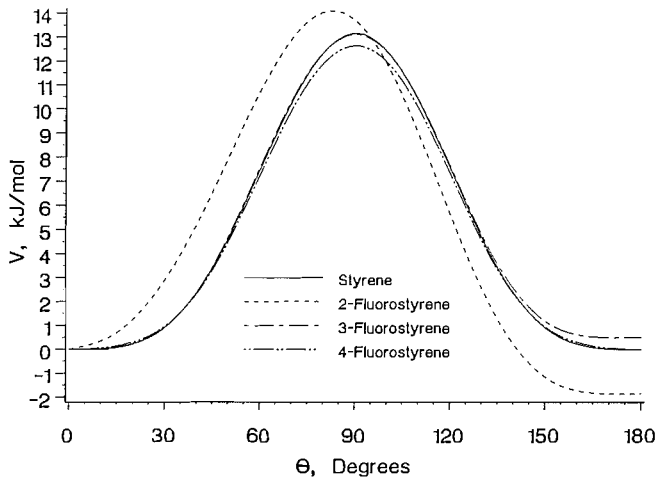

FIG. 2. The 6-31G MO potentials for rotation about the exocyclic carbon–carbon bond are displayed for styrene and the three monofluorostyrenes. A conformational angle, θ, of 180° corresponds to a *trans* orientation of the C—F and C=C bonds in 2-fluoro and 3-fluorostyrene. The curves result from a fit of the computed energies at intervals of 15° in θ. For styrene, the curve represents the internal potential (all energies in kJ/mol), $V = 13.19\ (15)\ \sin^2\theta - 3.18\ (15)\ \sin^2 2\theta$, the number in parentheses being the standard error in the fit of the computed energies (14) to twofold, in $\sin^2\theta$, and fourfold, in $\sin^2 2\theta$, components. This potential agrees to within combined experimental error with the components deduced from vibronic fluoresence data (11). For 4-fluorostyrene, the computed energies (6) are fit by twofold and fourfold components of 12.67 (3) and −3.02 (3), respectively, if an eightfold term of 0.08 (3) is included. The theoretical curves essentially coincide for the θ values accessible to the molecule at ambient temperatures. For 3-fluorostyrene, the theoretical potential is $V = 0.33\ \sin^2(\theta/2) + 12.97\ \sin^2\theta + 0.19\ \sin^2(3\theta/2) - 3.19\ \sin^2 2\theta - 0.09\ \sin^2 3\theta + 0.03\ \sin^2 4\theta$, the standard error in the fit of the energies (6) being 0.03. The presence of the onefold (0.33) and threefold (0.19) terms accounts for greater stability of the *cis* conformer. The computed potential for 2-fluorostyrene is $V = -4.66\ \sin^2(\theta/2) + 14.63\ \sin^2\theta + 2.82\ \sin^2(3\theta/2) - 2.84\ \sin^2 2\theta$, the standard error in each component being 0.04. The onefold and threefold components oppose each other in establishing the stability of the *trans* conformer.

nitude between $^7J_{48}$ and $^7J_{49}$ rises to 0.06 Hz in 2FS and 3FS. The difference is not reproduced by our INDO MO FPT computations. However, the magnitudes themselves are not drastically different from those in styrene, as is reasonable in terms of the internal rotational potentials sketched in Fig. 2.

The long-range $^1H,^{19}F$ coupling constants

The signs of the H,F coupling constants for the vinylic protons, all of which are 0.2 Hz or larger in magnitude, were determined by $^1H\{^1H\}$ experiments (32, 33) in the normal way and were based on the positive values of ^4J (H,F) and ^3J (H,F) within the aromatic ring. The signs are given in Table 2. Table 4 contains theoretical values for these coupling constants for planar and perpendicular conformations of the three molecules in question. Figure 3 shows an example of a sign determination.

(i) 4-Fluorostyrene

To a reasonable approximation (23), the CNDO/2 numbers for ^nJ (H,F) in Table 4 represent transmission of nuclear spin state information via the σ electron framework, while the INDO numbers also include contributions from π electrons and from σ–π interactions. Comparison of the theoretical results for 4FS indicates than $^6J_{47}$, $^7J_{48}$, and $^7J_{49}$ are dominated by π electron mechanisms, the CNDO/2 values being very small or zero. This indication is expected on the basis of previous theoretical data for the corresponding H,H interactions (20). Because the composite hyperfine interaction parameter, Q^F_{CF}, is positive, however, unlike Q^H_{CH}, the computed values of $^6J_{47}$, $^7J_{48}$, and $^7J_{49}$ are of opposite sign to the corresponding coupling constants in the parent molecule, styrene.

$^6J_{47}$ ia a σ–π coupling constant, predominantly, and accordingly has its largest value, 1.20 Hz, at θ = 90°. A pure σ–π coupling constant is proportional to $\sin^2\theta$. For 4FS, the 6-31 G potential has $<\sin^2\theta>$ as 0.171 at 300 K. If this potential were to apply to 4FS in CS_2 solution, $^6J_{47}$ would follow as 0.171 (1.20) or 0.205 Hz. The experimental value of 0.235 (1) Hz is somewhat larger than this, perhaps because a small term in $\cos^2\theta$, apparently present for $^6J_{47}$ in styrene (20, 22), is neglected. In our opinion, however, the rather good agreement between experiment and theory above is coincidental.

One might argue as follows. The long-range coupling

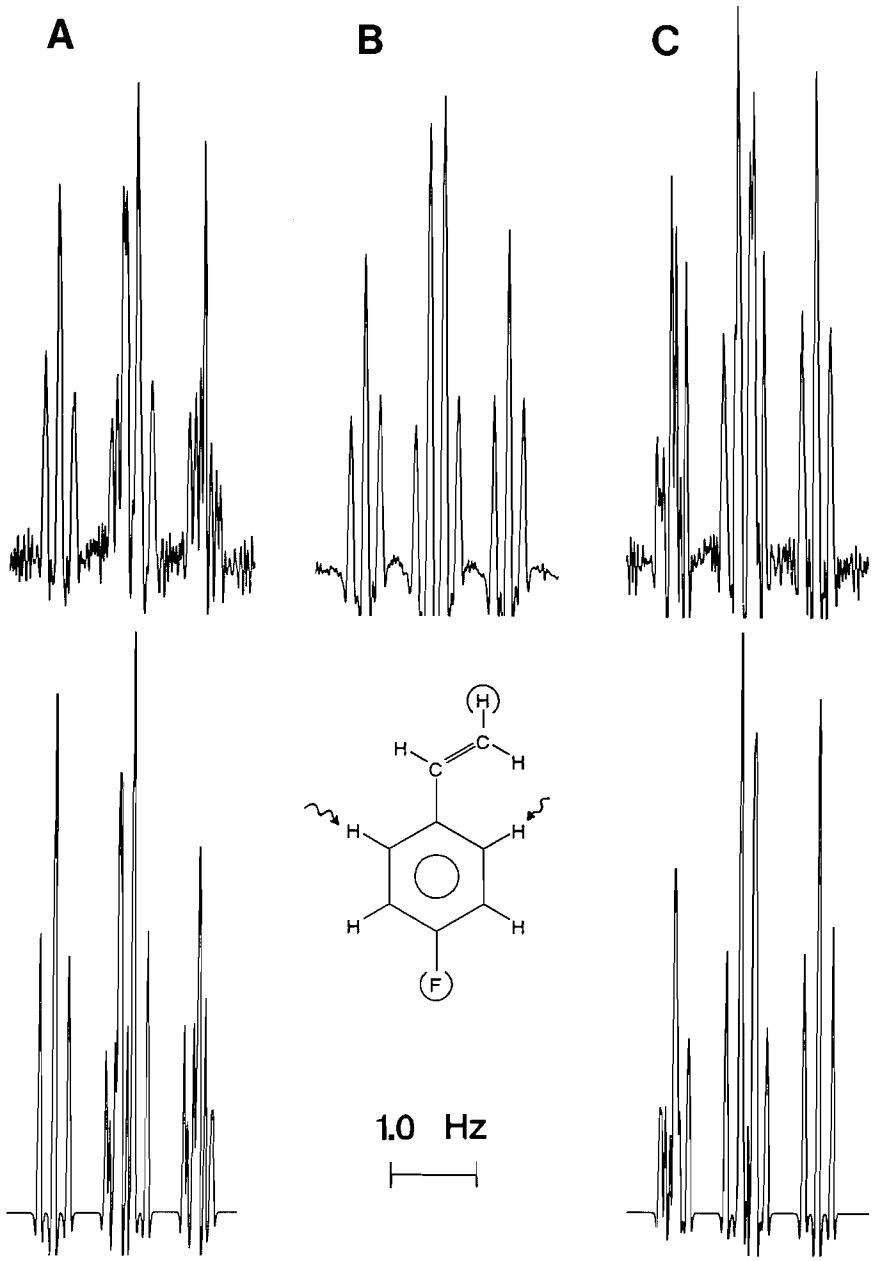

FIG. 3. The band at lowest frequency of H-9 in the ^{1}H NMR spectrum of 4-fluorostyrene in acetone-d_6 solution is shown in B. A geminal coupling of 0.90 Hz (Table 1), a ^7J (H, F) of ± 0.76 Hz, and a ^5J (H, F) of 0.17 Hz to H-2 and H-6 account for the structure of the band. In A this band has the given appearance when a second radiofrequency field of an amplitude roughly equal to 1 Hz is centered at 2255.48 Hz to high frequency of internal TMS, corresponding to irradiation of peaks due to H-2 and H-6. For these peaks the spin states of H-3 and F-4 are the same if $^3J_{23}$ and $^4J_{24}$ have the same sign, as they do (48–52). Qualitatively, it is clear in A that ^7J (H-9, F)/^4J (H,F) < 0 simply because the peaks in the multiplet at low frequency are perturbed in intensity or split when the peaks in the H-2 region are irradiated to high frequency of the shift position of H-2. The theoretical spectrum below the experimental one in A was computed with the program DOR (53), as modified in this laboratory to accommodate eight spins. The agreement between theory and experiment is not exact, depending as it does on the theoretical intensity of the irradiating field, but is sufficiently close to show that ^7J (H-9,F) is negative, ^4J (H,F) being positive (51, 52). A check is provided by the experimental and theoretical bands in C, corresponding to irradiation at 2241.04 Hz. Note that a positive sign of ^7J would have resulted in marked perturbations of that "triplet" in A and C, which was not, in fact, strongly altered in the double resonance experiment.

constants involving fluorine in 4FS should be proportional to Q^F_{CF} for the C—F bond. In toluene and 4-fluorotoluene, ^6J (H,CH_3) and ^6J (F,CH_3) are a measure of Q^H_{CH} and the composite (34, 36) Q^F_{CF} at the position *para* to the methyl group (26, 35). The former coupling constant is -0.602 (2) Hz (27), the latter 1.15 (2) Hz (35). Hence Q^H_{CH}/Q^F_{CF} is -0.52_3. In styrene $^7J_{48}$ is 0.237 (3) Hz (31), so that $^7J_{48}$ in 4FS should be 0.237 (3)/-0.52_3 or -0.45 Hz. However, $^7J_{48}$ in 4FS is measured as -0.59 Hz, implying a larger magnitude of Q^F_{CF} in 4FS than in 4-fluorotoluene. The methyl group is a π electron donor, whereas the vinyl group is electronically neutral (37). Hence the former will act to repress somewhat the π electron donation of the fluorine substituent, with the consequence that the double-bond character of the C—F bond in 4FS is larger

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12
For personal use only.

than in 4-fluorotoluene. The larger double-bond character increases Q^{F}_{CF} because it facilitates the transmission of electron spin density into the $2p_z$ orbital on fluorine (38). Given this interpretation, it still follows that $^6J_{47}$ in styrene, at −0.227 (3) Hz, should be much smaller in magnitude than $^6J_{47}$ in 4FS, measured, however, as 0.235 Hz in CS_2 solution. This is so, whatever the effect (21, 22) of the $=CH_2$ moiety on the spin polarizability of the π system of the olefinic group.

The theoretical calculations (Table 4) give $^6J_{48}$ as only about half as large as measured, but of correct sign. $^7J_{49}$ is even larger in magnitude, at −0.76 Hz (Table 2), whereas theory has $^7J_{49}$ almost equal to $^7J_{48}$ for a planar molecule, just as for the analogous coupling parameters in styrene itself. The larger magnitude measured for $^7J_{49}$ is reminiscent of the hyperfine splitting constants in the allyl radical (39, 40), these being somewhat different for the two protons bonded to the carbon atom of the methylene group; the larger Q^{H}_{CH} occurs for the C—H bond placed *cis* to the central C—H bond, just as in 4FS. A similar remark applies to the corresponding coupling constants in styrene.

It is also noted that the ratio of the $^7J_{48}$ values of styrene and 4FS is 0.40 whereas for $^7J_{49}$ it is 0.37, all values applying to the acetone-d_6 solutions.

The present discussion illustrates the difficulties involved in the use of ^nJ (H,F) in the conformational analysis of 4FS. The signs are understood but not their magnitudes, unlike their counterparts in styrene. Note, further, that $^6J_{47}$ is sensitive to solvent, intrinsically so, as strongly implied by the solvent independence of the (conformationally dependent) long-range H,H coupling parameters of 4FS (Table 2). The intrinsic solvent dependence of the H,F couplings of the olefinic protons is also present for 2FS and 3FS.

(ii) 3-Fluorostyrene

As expected, $^5J_{37}$ is calculated as strongly stereospecific by both CNDO/2 and INDO MO methods (Table 2). Comparison with similar computations for 3-fluorotoluene (41) suggests that the magnitudes will be overestimated, as is borne out by the measured value, near 0.9 Hz (Table 1). Furthermore, the INDO numbers imply a negative $^5J_{37}$ for θ values near 90°. That a coupling like $^5J_{37}$ is positive for planar conformations, defined by θ = 0° and 180°, and negative for certain intermediate conformations, has been shown for 3,5-difluoro derivatives of toluene, ethylbenzene, and isopropyl benzene (42). In the toluene derivative it is small and negative, all θ values being sampled equally at 300 K, whereas in the isopropyl compound $^5J_{37}$ is larger and positive as a consequence of the predominance of conformations described by θ values near 0° and 180°. The latter description also applies to 3FS, so that the large and positive $^5J_{37}$ is qualitatively reasonable.

Unlike the corresponding H,H coupling constants, it is not clear whether $^5J_{37}$ in 3FS vanishes for θ = 0°. A coupling constant as large as 0.1 Hz may well exist for such a conformation in the alkyl compounds above (42). Were this coupling constant to vanish, then the populations of 0.59 for the *cis* form of 3FS, deduced in a previous section, together with the measured value of 0.87 Hz in CS_2 solution, would imply a value near 1.5 Hz for $^5J_{37}$ at θ = 180° in 3FS, not far from the value of about 1.7 Hz suggested (42) for the alkyl compounds. In other words, the measured values of $^5J_{37}$ for 3FS can be said to be reasonably consistent with its conformational behaviour but are no more than that.

$^6J_{38}$ and $^6J_{39}$ are striking because they are so large compared to the apparently vanishing analogous coupling constants in styrene (31) or 4FS, for example. Theory (Table 1) reproduces their positive sign and also has $^6J_{39} > {}^6J_{38}$, as measured. In fact, for a two-site analysis, the INDO values and the experimental populations of the planar conformers together yield $^6J_{39}$ as 0.61 Hz, in good agreement with the measured values of 0.57 and 0.59 Hz in the two solutions. A similar treatment of the INDO numbers for $^6J_{38}$ gives a value of 0.21 Hz, substantially lower than the 0.30 Hz found by experiment.

The large theoretical values of $^6J_{39}$ for the all-*trans* conformation (θ = 180°) imply a substantial positive σ electron contribution over six bonds for this conformation, therefore accounting at least partly for the larger magnitude of $^6J_{39}$ relative to $^6J_{38}$. The σ-electron contribution to $^6J_{39}$ in styrene for such a conformation is also computed (20) as positive (the π electron contributions are of course of opposite sign for the long-range H,H and H,F coupling constants under consideration); note that $^6J_{59}$ in 3FS is positive (Table 2) and has been discussed in a previous section.

(iii) 2-Fluorostyrene

Because the *trans* conformer of 2FS is about 70% abundant in both solvents, the available theoretical data in Table 4 imply a negative $^4J_{27}$; its value is actually near 0.5 Hz (Table 2). The disagreement is reminiscent of 2-fluorotoluene (43), where negative values of ^4J are also found by INDO MO FPT computations for θ = 0° and 180° and are attributed to a faulty estimate of the proximate component of the coupling constant for a *cis* orientation of the bonds carrying the coupled nuclei. The use of model compounds (43) showed that ^4J must be positive for a *cis* arrangement of the C—F and C—H bonds, that is, for a conformation analogous to the *trans* form of 2FS. The large positive value of 1.24 Hz computed at θ = 90° for 2FS arises from the σ–π mechanism, of course. It is probable that, as for 2-fluorotoluene (43), the computations give values algebraically too small for $^4J_{27}$ for all θ values. That $^6J_{47}$ in 2FS differs by only 0.01 Hz or less from its magnitude in styrene is a strong indication that conformers with large θ values are not heavily populated at 300 K. The 6-31G potential for 2FS has $<\sin^2\theta>$ as less than 0.2 at this temperature, so that only a part of the observed value of 0.5 Hz for $^4J_{27}$ comes from this source.

Turning to $^5J_{28}$, the large and negative value computed for the *cis* form is again a consequence of the proximity of the C—H and C—F bonds and, in this semiempirical formulation that estimates only the contact interactions, of the overlap of the 1*s* orbital on hydrogen with the 2*s* orbital on fluorine, as previously discussed (43). The measured value is 0.298 (1) Hz in CS_2 solution and, although only about 30% of the molecules are in the *cis* form, this number indicates too large a magnitude for the computed proximate and negative component of $^5J_{28}$. That such a component is present, however, is suggested by the increase of 0.05 Hz, or 16%, in $^5J_{28}$ when 2FS is transferred to the acetone-d_6 medium. According to $^5J_{57}$, the *trans* form is more stable in this solvent and hence the negative, proximate component of $^5J_{28}$ should decrease in importance. While the intrinsic solvent dependence may account for part of the increase in $^5J_{28}$, the relative magnitude of the change is much larger for $^5J_{28}$ than for the other long-range H,F coupling constants in Table 2. A measurement of $^5J_{28}$ and its signs in 2,5-difluorostyrene and, say, 2-fluoro-6-chlorostyrene, might allow an assessment of the proximate coupling mechanism.

Note that proximate interactions also give rise to negative $^5J_{28}$ in styrene itself, that is, for the corresponding H,H coupling constant (20).

According to theory, $^5J_{29}$ is again negative in the less abundant *cis* conformer of 2FS, unlike the theoretical result for the analogous coupling constant in styrene (20), implying a relayed, proximity pathway. However that may be, the measured $^5J_{29}$ is near 0.3 Hz, implying that $^5J_{29}$ is positive and sizeable for the *trans* conformer.

(iv) A comparison of long-range $^1H,^1H$ and $^1H,^{19}F$ coupling constants

Because Q^F_{CF} and Q^H_{CH} are of opposite sign, it is expected that the $\sigma-\pi$, dependent on $\sin^2\theta$, and the π, dependent on $\cos^2\theta$, electron contributions to ^nJ (H,F) and ^nJ(H,H) are also of opposite sign. This is true for styrene and 4FS. When coupling between ^{19}F on the ring and protons on the side chain occurs predominantly via the σ electron system, experience has it that ^nJ (H,F) and ^nJ (H,H) usually have the same sign. This is borne out by $^5J_{37}$ in styrene and $^5J_{37}$ in 3FS, presumably also by the corresponding $^5J_{29}$ values in 2FS and styrene. Again, $^6J_{39}$ in 3FS is positive, as is $^6J_{59}$; the conformational bias ensures a positive σ electron contribution to the latter H,H coupling constant, but the former coupling constant has significant σ and π electron contributions of the same sign, positive.

A number of the long-range H,H coupling constants in styrene and its derivatives have π and σ electron contributions of opposite sign, $^6J_{38}$ and $^6J_{39}$ being examples (20, 31), and hence are often very small; these contributions often reinforce each other for the H,F coupling constants, leading to larger magnitudes. However, the stereospecificty of the latter may not be as strong as for the former; for example, $^5J_{37}$ in 3FS may not be zero in **4** while this is very likely true for the analogous H,H coupling constant.

The intra group spectral parameters

The chemical shifts of the olefinic protons in Table 1 in principle could be discussed in terms of the models developed by Reynolds and co-workers (37) for a series of 4-substituted styrenes, including 4FS. Fluorine is apparently an anomaly in these models (37), so that the shifts will not be discussed further, except to note that the differences between the chemical shifts of the β-protons, for example, in CS_2 solutions are 0.435, 0.449, and 0.452 ppm for 4FS, 3FS, and 2FS, respectively. In acetone-d_6 solution, these differences are 0.533, 0.556, and 0.500, as compared to 0.570 ppm in styrene (31). It has been shown (44) that solvent shifts for 4-substituted styrene derivatives are inconsistent with the reaction field model. It is apparent, from the numbers above and from Table 1, that a similar remark applies to 2FS and 3FS.

The geminal coupling constants in 4-substituted styrenes are sensitive to field and resonance effects from the substituent (37). In styrene, ^2J is 1.05 Hz in acetone-d_6 solution (31). In 2FS, ^2J rises to 1.22 Hz (Table 1), not much more than the 1.11 Hz found for 4-methylstyrene (24), but considerablly smaller than the 1.66 Hz in 2-vinylpyridine (45). A perusal of the θ dependent long-range coupling constants for these molecules shows that ^2J is not obviously related to θ in 2FS. The well-known solvent dependence of ^nJ (H,F) within a fluorophenyl group is documented in the references to Table 1. The generally somewhat larger values of ^nJ (H,H) within a phenyl group for more polar solvents is a common observation in this laboratory and is not an artifact of the spectral analyses. The vicinal coupling constants within the vinyl group behave in a similar manner (Table 1).

^{1}H and ^{13}C NMR studies of the conformational mobility of 1,2-dimethoxybenzene in solution

TED SCHAEFER, RUDY SEBASTIAN, ALBERTA LEMIRE,[1] AND GLENN H. PENNER[2]
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received January 24, 1990

TED SCHAEFER, RUDY SEBASTIAN, ALBERTA LEMIRE, and GLENN H. PENNER. Can. J. Chem. **68**, 1393 (1990).

^{1}H NMR and ^{13}C NMR spectral data are presented for 1,2-dimethoxybenzene-α,α'-^{13}C, as well as for a number of other anisole derivatives. For the title molecule, the coupling constants between the ^{13}C nucleus in the side chain and the *para* ring proton or ^{13}C nucleus in the benzene ring show that the expectation value of $\sin^2\theta$ is very near 0.2 at 300 K, where θ is the angle by which the methoxy groups twist out of the aromatic plane. This value of $\langle\sin^2\theta\rangle$ is much larger than that of 0.05 for anisole in solution, emphasizing the greater conformational mobility of the methoxy groups in 1,2-dimethoxybenzene (DMB). Long-range coupling constants between the methyl and ring protons in DMB are also discussed and compared with those in anisole and some of its derivatives. The preponderance of conformations with large values of θ, thought to occur in the vapor, disappears in solution at ambient temperatures. Under these conditions, the molecule is perhaps best described as preferring a planar conformation in which, however, the methoxy groups undergo excursions in θ whose average value is near 25°.

Key words: 1,2-dimethoxybenzene, conformational behaviour, internal mobility, long-range coupling constants, ^{1}H and ^{13}C NMR.

TED SCHAEFER, RUDY SEBASTIAN, ALBERTA LEMIRE et GLENN H. PENNER. Can. J. Chem. **68**, 1393 (1990).

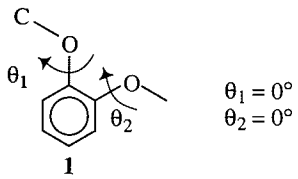
On présente des données relatives aux spectres RMN du ^{1}H et du ^{13}C pour des 1,2-diméthoxybenzène-α,α'-^{13}C ainsi que pour un certain nombre d'autres dérivés de l'anisole. Pour la molécule mentionnée dans le titre, les constantes de couplage entre le noyau ^{13}C de la chaîne latérale et le proton attaché en position *para* du cycle ou avec le noyau ^{13}C du noyau benzénique montrent que, à 300 K, la valeur attendue pour le $\sin^2\theta$ (où θ est l'angle de torsion du groupement méthoxyle par rapport au plan du noyau aromatique) se situe très près de 0,2. Cette valeur de $\langle\sin^2\theta\rangle$ est beaucoup plus importante que la valeur de 0,05 observée pour l'anisole en solution et elle démontre que les groupements méthoxyles du 1,2-diméthoxybenzène possèdent une mobilité conformationnelle beaucoup plus grande. On discute aussi des constantes de couplage à longue distance entre les protons des groupements méthyles du DMB et ceux du cycle et on les compare à celles observées dans l'anisole et dans quelques-uns de ses dérivés. Les conformations caractérisées par des valeurs élevées de θ, qui existeraient d'une façon prépondérante en phase gazeuse, disparaîtraient en solution, à la température ambiante. Dans ces conditions, la molécule semble exister dans une conformation plane dans laquelle les valeurs moyennes des angles θ des groupements méthoxyles sont de l'ordre de 25°.

Mots clés : 1,2-diméthoxybenzène, comportement conformationnel, mobilité interne, constantes de couplage à longue distance, RMN du ^{1}H et du ^{13}C.

[Traduit par la revue]

Introduction

The conformational behaviour of 1,2-dimethoxybenzene (DMB), veratrole, has been studied extensively with somewhat mixed results. Early STO-3G MO computations, with geometries based on calculations for anisole, have the 0°,90° (see **1**)



1

as 0.1 kJ/mol more stable than the planar or 0°,0° conformation, for example (1). The nonplanar conformations have a fourfold statistical weight, of course, so that they are expected to be predominant in the gas phase. The photoelectron spectrum of DMB in this phase is indeed in much better agreement with that expected for the 0°,90° than for the planar conformer (1). In the crystalline solid state, however, the planar conformation is prevalent for DMB derivatives (1–4), very likely caused by crystal packing forces. In solution, therefore, an intermediate situation may well prevail.

Nonplanarity of DMB in solution is indicated by partition coefficients (1), the temperature dependence of the dipole moment (5), dielectric relaxation times (6), ^{1}H and ^{13}C NMR chemical shifts (7–9), and by the energetics of charge-transfer complexes formed by its derivatives (10).

More recently, the vibrational spectra of crystalline DMB (11, 12) have been interpreted (11) in terms of the coexistence of planar and nonplanar conformers. The methoxy torsional frequencies do not distinguish between the two planar conformers, those characterized by 0°,0° and 0°,180° (11). The barrier to rotation about the C_{sp^2}—O bond was assessed at about 60 kJ/mol in the solid (11). In this connection, STO-3G MO computations, extensively geometry-optimized, find the 0°,0° conformer as most stable, whereas the 0°,90° conformation is higher in energy by about 2 kJ/mol and the 0°,180° is even higher at 12 kJ/mol (11, 13). It is stated that solvation or packing forces in condensed media can overcome these energy differences (11), perhaps accounting for the long-range proton–proton coupling constants (14), ^{13}C NMR chemical shifts, and ^{13}C spin-lattice relaxation times (15) for DMB in solution, all of which are interpreted as consistent with a predominantly planar conformer. However, ^{17}O NMR chemical shifts, measured at 348 K in acetonitrile solution (16), indicate that the methoxy groups of DMB rotate out of the benzene plane by an amount larger than does the methoxy group in 2-methylanisole.

The dipole moment of DMB in benzene solution at 303 K is 1.32 D (5) and is consistent (17) with a conformational mixture of planar conformers, namely, 0°,0° (70%) and 0°,180° (30%).

A more detailed investigation (18) of the dipole moments of DMB and some of its derivatives in benzene solution at 298 K shows that the measured values are compatible with a variety of conformational mixtures; the most likely appear (18) to be 0°,0° (40%) and 0°,90° (60%). Molecular mechanics computations (19) imply the coexistence of the conformers specified by 0°,0°; 0°,180°; 0°,90°; 90°,90°; they also imply an increase in the dipole moment as the temperature rises. It is noted that the dipole moment of DMB depends on the solvent in which it is measured, that it increases monotonically with temperature in benzene solution and for the liquid, and that it levels off at 363 K in decalin or paraffin oil (5).

Finally, phosphorescence spectroscopy of DMB in various organic solvents at 1.4 K indicates the existence of three conformers, depending on the solvent, and probably assignable to 0°,0°; 0°,180°; and 0°,90° (20). Furthermore, a photoinduced conversion between two conformers, very likely the planar ones, is observed.

Consideration of all these data suggests that DMB is conformationally mobile at ambient temperatures, that the mobility depends on the solvent, and that too small a number of conformations has been taken into account in the interpretation of at least some of the measurements. Ideally, a reliable calculation of the internal rotational potential surface for the free molecule should be combined with a reliable intermolecular force field, appropriate to each solution or state, in order to reproduce the experimental data in a satisfactory manner. This procedure is beyond our ability at present.

In this report we present new ^{1}H NMR and ^{13}C NMR data for DMB and some of its derivatives in solution and these are used to provide some conformational information.

While this work was in progress, Konschin (13) presented STO-3G MO computations on DMB, gave an extensive justification of the utility of such computations, and used geometry optimization procedures. We had done similar computations. Although our optimizations were somewhat more complete, we noted that there was good agreement with his energy for the most stable conformer of DMB. In the original version of this paper, the computations were used to discuss conformational populations and dipole moments in the various states of DMB. One referee objected to this discussion and it is now absent. The interested reader may ask for a copy.

Experimental

The 2-bromo and 2-fluoroanisole-α-^{13}C were prepared from the corresponding phenol derivatives as described previously for other anisoles (21). The 1,2-dimethoxybenzene-α,α′-^{13}C was made as follows. Catechol, 0.26 g, was dissolved in 2 mL of DMSO, to which was added 0.55 g of powdered KOH. After addition of 0.68 g of $^{13}CH_3I$ (95 at.%, MSD Isotopes), the mixture was stirred overnight. It was then diluted with 20 mL of water and stirred for 0.5 h. Extraction with CH_2Cl_2 (4 × 25 mL) and washing with water (3 × 25 mL) was followed by drying with anhydrous $MgSO_4$. Filtration and rotary evaporation gave 0.30 g of the desired product.

The 4,5-dibromo-1,2-dimethoxybenzene was synthesized as follows. In 50 mL of ethanol there was dissolved 15 g of DMB. Also, 12.5 g of Br_2 was added to 50 mL of ethanol, considerable heating occurring during the addition. The bromine solution was then added to the solution of DMB and the mixture was stirred for 2 h. On addition of 200 mL of water, an oil precipitated and 7.7 g of this oil was removed with a dropper. The oil was dissolved in 1 mL of methanol and stored in a refrigerator overnight. A few long needles of crystal formed. Addition of two drops of water caused a separation into two layers. Cooling in a refrigerator for several hours yielded crystals, which were isolated by filtration and washed with 1 mL of cold hexane. The yield was 0.25 g, mp 90°C (lit. (33) mp 91°C). The mass spectrum was consistent with the desired product. The ^{1}H NMR spectrum in benzene solution was also characteristic but showed a small amount of what was very likely the monobromo compound. All other compounds came from Aldrich.

Samples for NMR analysis were prepared in various solvents and at concentrations given in the tables below. These solutions were transferred to 5 mm o.d. NMR sample tubes by filtration through cotton wool. The tubes were degassed by several cycles of the freeze–pump–thaw procedure and were then flame-sealed.

^{1}H NMR and ^{13}C NMR spectra were obtained on an AM300 Bruker spectrometer at a probe temperature of 300 K by procedures previously described (see tables). The ^{1}H NMR spectrum of 1,2-dimethoxybenzene-α,α′-^{13}C was measured on a WH90 Bruker spectrometer, modified to allow clean decoupling (two frequencies of irradiation) of the two bands of the methyl protons arising from $^1J(^1H,^{13}C)$.

Results and discussion

The NMR spectral data

^{1}H NMR spectra were analyzed with the computer program NUMARIT (22). The ^{1}H NMR spectra were of a quality very similar to those previously illustrated for anisole and some of its derivatives (23–25). $^nJ(^{13}C,^{13}C)$ values were found from $^{13}C\{^1H\}$ NMR spectra by inspection. Figure 1 displays the proton-decoupled ^{13}C NMR spectrum of the aromatic carbon nuclei for 1,2-dimethoxybenzene-α,α′-^{13}C, demonstrating the resolution of the smallest coupling constant of 0.17_5 Hz. Tables 1–5 present the spectral parameters for the various molecules.

Conformational deductions from $^6J(^1H,^{13}CH_3)$ and $^5J(^{13}C,^{13}C)$

The important number in Table 1 is the coupling over six bonds between the ^{13}C nucleus and the ring proton in 1,2-DMB-α,α′-^{13}C. Its value is -0.13 ± 0.01 Hz. $^6J(H,^{13}C)$ is a σ–π coupling (21, 24, 26) and is therefore proportional to the expectation value, $\langle \sin^2 \theta \rangle$, θ being the angle by which the methoxy group twists out of the benzene plane. At θ = 90° this coupling is -0.63 ± 0.01 Hz (21, 24, 26). Consequently, $\langle \sin^2 \theta \rangle$ for DMB in benzene-d_6 solution is 0.21 ± 0.02 at 300 K. For anisole in CS_2, $^6J(H,^{13}C)$ is $\pm 0.030 \pm 0.005$ Hz (24), emphasizing the larger conformational mobility in DMB.

A similar mobility in acetone-d_6 is indicated by $^5J(^{13}C,^{13}C)$ for DMB in Table 2, given as $0.17_5 \pm 0.01$ Hz. This coupling also depends on $\langle \sin^2 \theta \rangle$ and, from a detailed discussion (21), can be assessed as 0.95 ± 0.03 Hz at θ = 90°. Hence $\langle \sin^2 \theta \rangle$ is 0.18 ± 0.02 at 300 K. The *weak* indication that DMB is somewhat less conformationally mobile in the polar acetone-d_6 solution than in benzene-d_6 solution is supported by the lower dipole moment of DMB in polar than in nonpolar solvents.

$^5J(^{13}C,^{13}C)$ for 2-bromoanisole-α-^{13}C was not apparent in the spectrum, suggesting a conformation in which the methoxy group is much more strongly confined to the benzene plane than is DMB. In 2-fluoroanisole-α-^{13}C this coupling (Table 1) has a value, 0.08 ± 0.02 Hz, intermediate between those in DMB and 2-bromoanisole, implying also an intermediate conformational mobility of the methoxy group in 2-fluoroanisole. When the methyl group of the methoxy moiety lies *trans* to the *ortho* substituent, the steric interaction occurs via the oxygen atom and should then be similar for DMB and 2-fluoroanisole. Accordingly, the larger conformational mobility in DMB is quite likely a consequence of the greater π electron donation by oxygen, thereby decreasing the mobile bond order of the other C_{sp^2}—O bond.

The trends in $^{2,3,4}J(^{13}C,^{13}C)$ for the three compounds in Table 2 are consistent with the relative conformational mobilities deduced from $^5J(^{13}C,^{13}C)$. This statement follows from

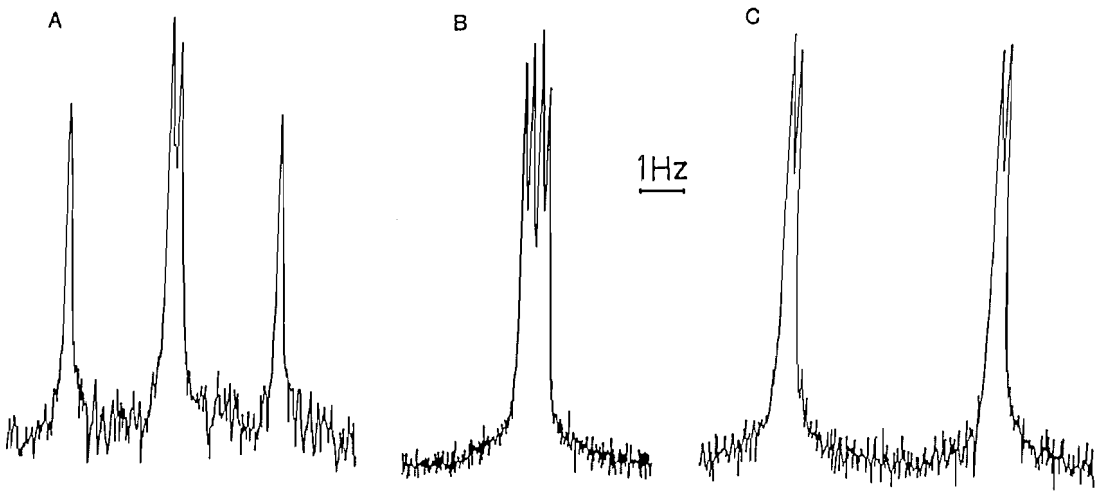

FIG. 1. The proton-decoupled ^{13}C NMR spectra at 75.486 MHz and 300 K of the aromatic nuclei of a 4 mol% solution of 1,2-dimethoxybenzene-α,α′-^{13}C in acetone-d_6 are displayed. The experimental conditions for spectral accumulation are given in great detail in ref. 21. In A, the doublet of doublets arises from C-1 and C-2, in B the four peaks come from C-4 and C-5, and in C they are due to C-3 and C-6. The important coupling constant (see text), $^5J(C\text{-}4,OCH_3) \equiv {}^5J(C\text{-}5,OCH_3)$, is cleanly resolved and has a magnitude of $0.17_5 \pm 0.01$ Hz, as shown by repeated experimental runs.

TABLE 1. ^1H NMR spectral parameters[a] for a 5 mol% solution in benzene-d_6 of 1,2-dimethoxybenzene-α,α′-^{13}C at 90.02 MHz and 298 K

Parameter	Value	Parameter	Value
$\nu(CH_3)$	148.3[b]	^5J(H-3,^{13}C)	0.277(6)
$\nu_3 = \nu_6$	439.307(4)	^6J(H-4,^{13}C)	−0.133(10)
$\nu_4 = \nu_5$	454.258(4)[c]	$^5J(^{13}C,^{13}C)$	0.000(7)
$^3J_{34}$	7.989(4)	Calcd. transitions	128.
$^3J_{45}$	7.589(6)	Assigned transitions	80.
$^4J_{35}$	1.571(5)	Peaks observed	36.
$^5J_{36}$	0.253(6)	Largest difference	0.039
^4J(H-3,^{13}C)	−0.050(8)	RMS deviation	0.021
^5J(H-4,^{13}C)	0.128(6)		

[a]The methyl protons are being decoupled.
[b]In Hz at 90.020 MHz to high frequency of an arbitrary frequency; ^1J(H,^{13}C) is 143.56 Hz.
[c]Numbers in parentheses are standard deviations in the last significant figure.

the observations on $^{2,3,4}J(^{13}C,^{13}C)$ for a variety of anisole derivatives (21).

Long-range $^1H,^1H$ coupling constants

$^5J(H,CH_3) \equiv {}^5J$ is −0.152(0) and −0.155(0) Hz for anisole in CS_2/C_6D_{12} and acetone-d_6 solutions, respectively (23). This proximate coupling constant is highly stereospecific (14, 25, 27, 28), all the available evidence being that it vanishes for the proton in the *ortho* C—H bond lying *trans* to the methyl group; hence ^5J is a precise indicator of methoxy group orientations in *meta*-substituted anisole derivatives, for example (25). As a proximate coupling constant, ^5J is very sensitive to the distance between the methyl protons and the proton in the ring C—H bond placed *cis* to the methyl group (14, 27). INDO MO FPT computations imply an approximate $\cos^4\theta$ dependence of ^5J, where θ is zero for the *cis* orientation, but also that ^5J increases in magnitude by, for example, about 0.04 Hz when θ is zero and the COC angle decreases by 1° (14, 27). The theoretical indications, therefore, are that substituents placed *ortho* to the methoxy group may enhance the magnitude of ^5J simply by compression of the angles at the methoxy moiety so as to decrease the average distance between the bonds carrying the coupled protons.

Table 3 presents precise analyses of the ^1H NMR spectra of 2-bromoanisole in CS_2/C_6D_{12} and acetone-d_6 solutions. The magnitudes of ^5J, at 0.322(1) and 0.329(0) Hz in the two solutions, are indeed rather larger than those, expected as 0.304(0) and 0.310(0) Hz, from the corresponding values for anisole in the two solvents. Based on $^5J(^{13}C,^{13}C)$ for 2-bromoanisole-α-^{13}C (Table 2) and anisole-α-^{13}C (21), in both of which this coupling constant is very small, if indeed present, the increased magnitude of $^5J(H,CH_3)$ in the former compound is reasonably attributed to bond-angle compression.

Table 4 contains the ^1H NMR spectral parameters of DMB in CS_2/C_6D_{12} and in C_6D_6 solutions. ^5J is smaller by 0.03 Hz in magnitude than for 2-bromoanisole in CS_2 solution but only 0.01 Hz smaller in magnitude than expected for a *cis* conformer of anisole in the same solution. $^6J(H,^{13}C)$ and $^5J(^{13}C,^{13}C)$ for anisole and DMB, as discussed in the previous section, both indicate much larger deviations from planarity for DMB than for anisole. Hence, the rather similar values of ^5J for the two molecules in CS_2/C_6D_{12} most likely arise from a partial compensation by two phenomena present in DMB: the decrease in magnitude of ^5J caused by larger out-of-plane excursions of the methoxy groups is counteracted by an increase due to bond-angle compression. Evidence for the latter comes from our own STO-3G MO computations as well as from published calculations of this kind (see Figs. 2 and 3 of ref. 11); the COC angle in planar DMB is computed as 0.7° smaller than in planar anisole and the CCH angle at the *ortho* C—H bond is also decreased by 0.6°, bringing the *ortho* proton nearer the methyl group. The subtle interplay of the two phenomena, together with the extreme distance dependence of ^5J, renders moot a further disentanglement.

A final point concerns the accuracy of ^5J. The ^1H NMR spectrum of DMB arises from an $AA'BB'X_3X_3'$ spin system, the ring protons being rather tightly coupled. The symmetry of the spin system, together with the presence of other small long-range coupling constants, entailed a correlation of ^5J of as large as 0.12 with another spectral parameter. Consequently, the ^1H NMR spectrum of 4-bromo-1,2-dimethoxybenzene in

CS_2/C_6D_{12} was also analyzed (Table 5). Here the symmetry is broken and the two ^5J values in fact are not very different from those in DMB. It may be significant that ^5J for the methoxy group placed *para* to the bromine substituent is nearly 0.01 Hz smaller in magnitude than the other ^5J because the dipole moment of this molecule has been interpreted (18) to mean that this methoxy group is conformationally more mobile than the one situated *meta* to bromine. The remote bromine substituent is nevertheless a minor perturber of the methoxy conformations and the data in Table 5 are taken as a confirmation of the accuracy of ^5J in Table 4. Furthermore, a 10 mol% solution of 4,5-dibromo-1,2-dimethoxybenzene in C_6D_6 solution gave a simple spectrum from which ^5J was deduced as 0.30(1) Hz, again very similar to the data in Tables 4 and 5.

Turning to ^6J(H,CH_3) and ^7J(H,CH_3), these coupling constants are interpretable as follows. The latter is −0.043(0) Hz for anisole in a CS_2/C_6D_{12} solvent (23) and arises via (23) an attractive nonbonded interaction in which a group orbital of π symmetry for the methyl group is used to form an aromatic cycle in the planar conformer. The transmission of nuclear spin state information via this cycle is interrupted in a perpendicular orientation of the methoxy group (23) and it might be expected that a twist of 45° would markedly reduce the efficacy of the external aromatic cycle. In DMB, ^7J is −0.043(0) Hz in CS_2/C_6D_{12} and implies that, on average, θ is rather less than 45°. Because $\langle\sin^2\theta\rangle$ is near 0.2, arc sin $\langle\sin^2\theta\rangle^{1/2}$ is near 25°, substantially larger than that of 13°, following for anisole from its $\langle\sin^2\theta\rangle$ of 0.05 at 300 K (25). A vanishing ^7J in DMB, or one greatly reduced in magnitude, would have indicated very large excursions in θ, on average. The ^7J in 2-bromoanisole cannot be used in this discussion because it correlates significantly with other spectral parameters (footnote to Table 5) and in consequence is not known accurately.

^6J(H,CH_3) also vanishes for perpendicular conformations of the methoxy group (23) and has a significant magnitude only for the *meta* C—H bond oriented *cis* to the methyl group. In anisole it is 0.049(0) Hz in CS_2/C_6D_{12} (23), being an average of two values, one essentially zero and the other near 0.1 Hz in magnitude. For DMB, ^6J in CS_2/C_6D_{12} is 0.087(1) Hz for the favored orientation, consistent with somewhat greater average θ values than in anisole (see discussion of ^6J in ref. 23). ^6J for the nonfavored bond orientations is indeed small but not zero; according to the proposed coupling mechanism (23), this coupling constant arises from a five-bond pathway involving the aromatic cycle, the other ^6J from a three-bond pathway. In 4-bromo-1,2-dimethoxybenzene (Table 5), ^6J is 0.090(1) Hz, roughly as expected.

In summary, the long-range coupling constants involving the ^{13}C nucleus and the protons of the methyl group in DMB are consistent with a description in which the methoxy groups move out of the ring plane with rather greater facility than does the methoxy group in anisole; the average deviation from planarity in solution is roughly twice as large in DMB. The spectral data are consistent with the planar being the conformation of lowest energy for DMB in solution, as previously suggested from other NMR data (14, 15). The most simple description then is that the methoxy groups undergo large excursions from planarity, of varying amplitudes but with an average value near 25° for the

[e]There are large correlations with other parameters, in particular one of 0.32 with $\nu(CH_3$-2).

twist angle, θ, at 300 K. This description, for liquid solutions of DMB, is possibly preferable to those in which equilibria between conformers with rather definite values of θ_1 and θ_2 (see **1**) have been postulated. The chemical shifts, discussed below, are consistent with this description.

Some chemical shift comparisons

A recent interpretation of ^{17}O and aromatic ^{13}C NMR chemical shifts (29) in some series of anisole derivatives can be taken to imply that these shifts in DMB in solution provide no evidence for conformations in which the methoxy groups take on large θ values of the kind implied by the photoelectron spectra in the vapor (1) or by the STO-3G MO calculations below. The ^{13}C NMR chemical shifts of the methoxy groups and the spin-lattice relaxation times of the ^{13}C nuclei of DMB (15) are consistent with this implication.

Again, the ^{1}H NMR chemical shifts of benzene (30), anisole (24), and DMB (Table 4) for 2.5 mol% solutions in CS_2/C_6D_{12} show that $\delta_{3,6}$ and $\delta_{4,5}$ are 0.055 and 0.048 larger at 300 K than expected on the basis of additivity of substituent effects. In other words, the ring protons are less shielded than expected from additivity. It has been argued (31) that H-6 in 2-X-anisoles is deshielded by steric crowding arising from the coplanar methoxy group buttressed by X as small as chlorine. This proximity shift is estimated as twice the deviation from the additivity shift. For DMB, therefore, its value is 0.11 ppm, about one third of the value of 0.32 ppm estimated (31) for 2-chloroanisole. Now, steric crowding is very sensitive to interatomic distances and hence the steric crowding in planar DMB, with an effective X of oxygen in the planar 0°,0° conformer, is anticipated as much smaller than for an X of chlorine. Furthermore, H-4 and H-5 are deshielded, relative to additivity expectations, by nearly as much as H-3 and H-6 in DMB. The simple explanation is that one methoxy group hinders the π electron donation of the other somewhat, leading to less shielding of the ring protons than calculated from additivity; then the methyl protons in DMB should be more shielded in DMB than in anisole, as should the ^{17}O nuclei, as observed (16, 24, 29). Consequently, the ^{1}H NMR chemical shifts of DMB are consistent with other NMR data. Large populations of, for example, the 0°,90° conformer would presumably cause much larger deviations for H-4 and H-5, the *para* proton in anisole being shielded by 0.436 ppm relative to benzene in CS_2/C_6D_{12} (25, 30).

From the viewpoint of the conformational behaviour of DMB in solution, perhaps the most interesting chemical shifts are those of C-6 in a series of *ortho*-substituted anisoles (32). These are shown (32) to contain a screening term due to steric compression by the planar *cis* conformation of the methoxy group. The striking result is that, while 2-fluoroanisole and DMB display somewhat smaller steric compression than, say, 2-bromoanisole, the conclusion must be (Tables 1 and 3 of ref. 32) that DMB in solution does not evince large populations of conformers with θ magnitudes such as are implied by experiment and theory for the vapor.

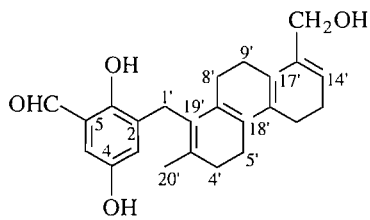
Introduction

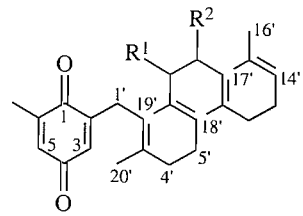
Brown algae belonging to the families *Sargassaceae* and *Cystoseiraceae* are known to produce diterpenes of mixed biogenesis, which are believed to be employed in chemical defence against predators (1). In fact, these families of seaweeds are characterized as offering more resistance than other algae to their potent predators, sea urchins, and some of these metabolites are inhibitors of the mitotic cell division in the fertilized sea urchin egg assay (2). On the other hand, few data on secondary metabolites of the brown algae belonging to the family *Desmarestiaceae* have been published, previous studies being limited to the hormonal secretions of its eggs (3). The only study we know was that done on *Desmarestia aculeata*, which reports the presence of plastoquinone-9 and a new C-27 sterol (4).

In this paper we report the isolation and structural elucidation of two new diterpenes of mixed biogenesis from the brown alga *Desmarestia menziesii* (J. Agardt), collected near the Antarctic peninsula (Chilean Base Arturo Prat), in January 1985. The air-dried alga was extracted with acetone and the resulting extract was partitioned between diethyl ether and water. After evaporation to dryness of the ether layer, the compounds were obtained by standard silica gel and Sephadex LH-20 chromatographies.

Desmarestial **1** had a molecular formula of $C_{27}H_{38}O_4$ (HRMS m/z: 426.2820; calcd.: 426.2825). The IR absorptions at 3600 cm^{-1} (hydroxyl group) and the UV band at λ = 266 nm (ϵ = 2170) were indicative of the presence of a quinol moiety. The NMR spectra exhibited signals for a dialkylated quinol ring: ^{13}C NMR δ: 153.8 (s), 127.0 (s), 115.4 (d), 148.8 (s), 125.4 (d), and 137.6 (s); ^1H NMR, two *meta* coupled (J = 2.9 Hz) proton resonances at δ 6.96 and 6.82. The presence of a formyl group at C-6 instead of the usual methyl group at this position, characteristic of this type of compound, was established as follows. The IR of **1** showed an absorption at 1650 cm^{-1} together with a band in the UV spectrum at λ 232 nm characteristic of an α,β-unsaturated carbonyl group. It was confirmed by the deshielded chemical shifts of the aromatic protons described above and also



1



2 : R^1 = H, R^2 = OH
3 : R^1 = R^2 = OH

by the MS fragmentation, which showed a peak at m/z 151 due to the fragment $C_8H_7O_3^+$.

The acyclic nature of the diterpene component was evident since the NMR spectrum showed the presence of four olefinic protons and four vinylic methyl groups, implying four unsaturations with *E* geometry in accordance with their chemical shifts (Table 1). The absence of one methyl group in the last isoprene unit in the diterpenic side chain was evident from its carbon NMR spectrum. It was replaced by an isolated allylic alcohol (^1H: δ 4.03 (s); ^{13}C: δ 69.2 (t)), which was long-range correlated in the homonuclear COSY experiment with the olefinic protons at δ 5.40 (H-14′) and also with the vinylic methyl group at δ 1.69 (Me-17′). The proton and carbon NMR chemical shifts of **1** were fully assigned by using homo- and heteronuclear COSY experiments (Table 1).

Compound **2**, oil, $[\alpha]_D$ +2.01 (*c* 0.9, $CHCl_3$), had a molecular formula of $C_{27}H_{38}O_3$ (HRMS m/z: 410.2816; calcd.: 410.2821). This compound possesses a 6-methyl-2-propenyl-1,4-benzoquinone system in accordance with its spectroscopic data: IR: 1650 cm^{-1}; UV, λ: 251 nm (ϵ = 21 000); ^1H NMR δ: 6.47 and 6.54 (each 1H, br m); ^{13}C NMR δ: 188.1 (s), 146.0 (s), 132.5 (d), 188.2 (s), 133.3 (d), 146.0 (s), 16.2 (q); MS m/z: 175.0.

The diterpenic part of this molecule was characterized as a (2′*E*, 6′*E*, 10′*E*, 14′*E*) hydroxygeranyl geranyl derivative. The methine from the hydroxy group, which appeared in the ^1H NMR spectrum at δ 4.44, was correlated on a COSY (^1H–^1H) map with the olefinic proton centered at δ 5.16 and also with

the methylene centered at δ 2.12. This type of correlation established that the possible positions for the OH group in the diterpenic side chain were the carbons C-5′, C-9′, or C-13′. Its actual location was impossible to deduce from the correlation observed in the homonuclear COSY map or by decoupling experiments because the signals from the olefin and from the methylene protons overlapped in both cases.

However, a choice was made on the basis of the mass spectrum fragmentations. Thus, the C(8′)—C(9′) bond cleavage divided the molecule into two fragments at m/z 257 $(C_{17}H_{21}O_2)^+$ and at m/z 153 $(C_{10}H_{17}O)^+$, the hydroxyl being placed in the latter. Furthermore, the fragment at m/z 69 $(C_5H_9)^+$ precludes its location at C-13′ and, consequently, the hydroxyl group must be at C-9′.

Together with these compounds we also isolated another diterpene that has physical and spectroscopic data identical with those reported for compound **3** (5). In the experimental part we give the ^{13}C NMR chemical shifts, which have not been previously reported.

Experimental

IR and UV spectra were recorded on a Perkin–Elmer model 257 and model 402 spectrophotometer, respectively. Optical rotations were determined for solution in $CHCl_3$ with a Perkin–Elmer model 241 polarimeter. NMR spectra were recorded on a Bruker WP-200 SY spectrometer (200 MHz), chemical shifts are reported relative to Me_4Si (δ = 0), and coupling constants are given in hertz. The 2D-NMR spectra were obtained using Bruker microprograms. Low and high resolution mass spectra were obtained from a VG Micromass ZAB-2F spectrometer. Silica gel column chromatography, TLC, and preparative layer chromatography (PLC) were performed on silica gel 60 G, from Merck. The TLC plates were developed by spraying with 6 N sulphuric acid and heating. Sephadex LH-20 obtained from Pharmacia was used for gel filtration chromatography. All solvents were purified by standard techniques. Anhydrous sodium sulfate was used for drying solutions.

The air-dried and ground alga (1.2 kg), collected in January 1985 near the Chilean base Arturo Prat in the Antarctic peninsula, was extracted three times with acetone. Evaporation of the solvent afforded a dark-green oil (60 g), which was chromatographed on Si gel (5 × 100 cm; increasing concentrations of ethyl acetate in *n*-hexane as the eluent).

Fractions of 200 mL were collected and those exhibiting similar TLC profiles were combined. Compounds **1** and **2** eluted in the 20% fraction and **3** in the 30% fraction. All the products were purified and the chlorophyll removed by successive chromatographies on a Sephadex LH-20 column with $CHCl_3$: MeOH: *n*-hexane (1:1:2), to afford pure **1** (40 mg), **2** (30 mg), **3** (30 mg), and demosterol (≈3 g). Their structures were established on the basis of the following spectroscopic data.

*Compound **1**: (2′E, 6′E, 10′E, 14′E)-2-(15′hydroxymethylgeranylgeranyl)-6-formylquinol*

Amorphous solid, mp 98–100°C; IR ν_{max} $CHCl_3$: 3600, 3500–3100, 3030, 1700, 1600, and 1450 cm^{-1}; UV λ_{max}: 232, 266 nm (ε = 2170, 4300); HRMS, m/z calcd. for $C_{27}H_{38}O_4$: 426.2825; found: 426.2820; MS m/z (rel. int. %): 426.30 (1), 175.00 (69), 151.00 (99), 135.02 (100), 93.05 (95), 68.98 (91), 68.00 (57), 67.05 (77). For NMR spectral data see Table 1.

*Compound **2**: (2′E, 6′E, 10′E)-2-(9′-hydroxygeranylgeranyl)-6-methyl-1,4-benzoquinone*

Yellow oil; $[\alpha]_D$ +2.0 (*c* 0.94, $CHCl_3$); UV λ_{max}: 250 nm (ε = 21 000); IR ν_{max} $CHCl_3$: 3650, 3550–3100, 3020, 3000, 2940, 2920, 1650, 1640, and 1600 cm^{-1}; HRMS, m/z calcd. for $C_{27}H_{38}O_3$: 410.2821; found: 410.2816; MS m/z (rel. int. %): 410.25 (3), 392.25 (4), 175.05 (100), 151.10 (4), 68.95 (77). For NMR spectral data see Table 1.

*Compound **3**: (2′E, 6′E, 10′E)-2-(8′,9′-dihydroxygeranylgeranyl)-6-methyl-1,4-benzoquinone*

Yellow oil; $[\alpha]_D$ −15.0 (*c* 0.40, $CHCl_3$). Physical and spectroscopic data were identical with those published for one of the benzoquinone constituents of *Sargassum tortile*. We add the ^{13}C NMR spectral data (50 MHz, $CDCl_3$), δ: 12.27 (q), 16.1 (q), 16.2 (q), 17.0 (q). 17.8 (q), 25.8 (q), 26.6 (t), 27.6 (t), 39.2 (t), 39.8 (t), 70.3 (d), 80.9 (d), 118.5 (d), 123.7 (d), 124.1 (d), 128.0 (d), 131.8 (d), 132.4 (d), 133.3 (s), 134.7 (s), 139.7 (s), 141.1 (s), 146.4 (s), 148.8 (s), 188.0 (s), and 188.5 (s).

The homogeneous thermal conversion of methane to higher hydrocarbons in the presence of ethylene

ALAIN R. BOSSARD AND MARGARET H. BACK
Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 6N5

Received February 9, 1990

ALAIN R. BOSSARD and MARGARET H. BACK. Can. J. Chem. **68**, 1401 (1990).

The pyrolysis of mixtures of methane and ethylene has been studied over the temperature range 774–853 K at total pressures below atmospheric to explore the effectiveness of ethylene as a catalyst for conversion of methane to higher hydrocarbons. Pyrolysis of ethylene alone at these temperatures yields ethane, propylene, butene-1, and butadiene as the major volatile products. In the lower temperature region the addition of methane increased the rate of production of ethane through the chain propagation reaction,

$$C_2H_5 + CH_4 \rightarrow C_2H_6 + CH_3$$

thus effecting the conversion of methane to ethane. The rates of formation of butene-1 and butadiene were not appreciably altered and that of propylene was increased only at low pressures of ethylene. At higher temperatures methane caused a substantial increase in the rate of production of propylene, the result of the increasing importance of the methyl radical in the propagation reactions. Thus ethylene can efficiently convert methane to ethane or to propylene depending on the temperature of the reaction. Addition of small quantities of butene-1, which acted as a secondary initiator, to the mixtures increased considerably the overall rate of the conversion of methane. A mechanism is discussed which accounts for the main features of the reactions.

Key words: methane, ethylene, kinetics, pyrolysis, catalysis.

ALAIN R. BOSSARD et MARGARET H. BACK. Can. J. Chem. **68**, 1401 (1990).

Dans le but de déterminer l'efficacité de l'éthylène comme catalyseur pour la conversion du méthane en hydrocarbures de masses plus élevées, on a étudié la pyrolyse de mélanges de méthane et d'éthylène, à des températures allant de 774 à 853 K, à des pressions totales inférieures à la pression atmosphérique. À ces températures, la pyrolyse de l'éthylène seul fournit de l'éthane, du propylène, du but-1-ène et du butadiène comme produits volatils majeurs. Dans la région de températures plus basses, l'addition de méthane provoque une augmentation de la vitesse de production de l'éthane par le biais d'une réaction de propagation en chaîne,

$$C_2H_5 + CH_4 \rightarrow C_2H_6 + CH_3$$

qui affecte ainsi la conversion du méthane en éthane. Les vitesses de formation du but-1-ène et du butadiène ne sont pas beaucoup modifiées et celle du propylène n'est augmentée qu'à des basses pressions d'éthylène. Aux températures plus élevées, l'addition de méthane provoque une augmentation importante de la vitesse de production du propylène; ce résultat est dû à l'augmentation de l'importance du radical méthyle dans les réactions de propagation. L'éthylène peut donc transformer le méthane en éthane ou en propylène, dépendant de la température de la réaction. Lorsqu'on ajoute aux mélanges de faibles quantités de but-1-ène qui agit comme initiateur secondaire, les mélanges augmentent considérablement les vitesses globales de conversion du méthane. On discute d'un mécanisme qui tient compte des principales caractéristiques des réactions.

Mots clés : méthane, éthylène, cinétique, pyrolyse, catalyse.

[Traduit par la revue]

Introduction

In the search for simple and efficient mechanisms for conversion of methane into fuels of higher carbon number, the major research effort has been directed to the development and improvement of catalytic processes (1–3). Homogeneous reactions have received less attention, mainly because the high temperatures necessary to induce decomposition of methane also lead to rapid conversion to carbon (4, 5). To interrupt the process at the stage where a reasonable yield of higher hydrocarbon is produced has proved difficult.

One approach to this problem is the use of a sensitizer that induces the decomposition of methane at lower temperatures where carbon is not so rapidly formed. A system has been described using small quantities of oxygen, which gives good yields of methanol (6). For production of hydrocarbon fuels, however, the sensitizer must be a hydrocarbon and must not only provide radicals for the attack on methane but also induce a chain reaction mechanism for the formation of products. A sensitizer that fulfills these requirements is ethylene and the present paper describes the results of the use of this reactant in the conversion of methane to higher hydrocarbons over the temperature range 774–853 K at pressures below atmospheric.

Description of the system

At temperatures in the neighborhood of 800 K ethylene reacts by a chain reaction mechanism, initiated by the bimolecular reaction of ethylene,

[1] $$2C_2H_4 \rightarrow C_2H_3 + C_2H_5$$

and followed by addition, abstraction, decomposition, and isomerization reactions of the ethyl, vinyl, and other radicals (7). The four major products, methane, ethane, propylene, and 1-butene, constitute about 80% of the products volatile at room temperature. Methane and ethane, the only saturated products, are formed by hydrogen abstraction by the corresponding radical,

[2] $$CH_3 + C_2H_4 \rightarrow CH_4 + C_2H_3$$

[3] $$C_2H_5 + C_2H_4 \rightarrow C_2H_6 + C_2H_3$$

Products formed from radical combination reactions, for example, propane and butane, are formed in minute amounts (7–9), indicating that the chain length is long. Thus ethane formed by combination of methyl radicals would be negligible compared to that formed by reaction [3]. Similarly, the only important source of methane is reaction [2]. Methyl and ethyl radicals are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12
For personal use only.

the most stable radicals in this system and are the only radicals for which abstraction competes with addition or decomposition. Propylene and butene-1 are formed by addition of radicals to ethylene followed by isomerization and decomposition reactions.

When methane is added to the system the additional reaction forming ethane may occur

[4] $C_2H_5 + CH_4 \rightarrow C_2H_6 + CH_3$

Direct dissociation of methane will be negligible at these temperatures. Thus methane enters the propagation reactions in the chain mechanism and is converted to ethane. If the amount of methane is small so that the actual and the relative concentrations of the radicals in the system are not altered, the relative initial rates of formation of ethane in the presence and absence of methane may be expressed as follows (10):

$$[5] \quad \frac{(R^0_{C_2H_6})_a}{R^0_{C_2H_6}} = 1 + \frac{k_4[CH_4]}{k_3[C_2H_4]}$$

The efficiency of the conversion of methane to ethane in this system depends on the ratio of rate constants k_4/k_3, and the relative concentration of methane and ethylene. The rate constants k_4 and k_3 have similar values (11) so that increasing the ratio of methane to ethylene should enhance the conversion of methane to ethane. As the concentration of methane is increased, however, and reaction [4] becomes the dominant source of ethane, ethyl radicals are converted to methyl radicals and the characteristics of the chain mechanism of the ethylene reaction are altered. The products formed from reactions of methyl radicals will become more important while the relative rate of formation of ethane will be reduced. The ratio CH_4/C_2H_4 is therefore an important factor in the efficiency of the conversion of methane to ethane.

Equally important is the absolute concentration of ethylene. As the initiator, ethylene controls the overall rate of the reaction, and a reduction in its concentration to allow a high ratio of CH_4/C_2H_4 inevitably reduces the rate of conversion of methane. Thus the high ratio CH_4/C_2H_4 favouring reaction [4] must be balanced by sufficient sensitizer to provide a reasonable rate. The purpose of the present study was to search for conditions where pyrolysis of mixtures of methane and ethylene would give a maximum efficiency for conversion of methane to ethane.

Experimental

The experiments were performed in a static pyrolysis system using a cylindrical quartz reaction cell of 0.21 L. The cell was placed in the center of a three-zone furnace, Lindberg model no. 54457, which controlled the temperature to within ±2 K. Mixtures were admitted to the reactor by expansion from calibrated volumes and samples were removed for analysis at the end of an experiment.

Mixtures of the reactants were prepared using spherical mixing flasks designed with a minimum of connecting tubing. The reactant present in lower concentration was introduced first. Rapid admission of a higher pressure of the second reactant caused convection currents that provided rapid mixing. Tests of the mixtures showed that homogeneous mixtures were achieved in less than one hour.

Products were analyzed using a Hewlett Packard gas chromatograph model 5710A with flame detector. Two columns were required for separation of the products from the large quantities of reactants. A silica gel column (40/60 mesh, 1.5 m × 6.5 mm) at 30°C separated the small quantities of the product ethane from the large amounts of methane and ethylene. A Durapak column (phenylisocyanate/Porasil C, 80/100 mesh, 6 m × 6.5 mm) maintained at 25°C was used for the products propylene and butene-1. Both columns were calibrated with a certified mixture, ethane 450 ppm, propylene 109 ppm, and butene-1 53 ppm, in ethylene, obtained from Matheson Gas Products, Whitby, Ont.

TABLE 1. Initial pressure of ethylene and ratios of methane to ethylene in the experiments

Temperature (K)	Pressure of C_2H_4 (Torr)	$\frac{CH_4}{C_2H_4}$
774	200	0.1, 0.5, 1.0
	100	1.0, 2.0, 3.0
	50	1.0, 3.0, 5.0, 8.0
	25	1.0, 3.0, 5.0, 8.0
	14	13.2, 20
824	50	4.0, 7.0
	25	4.0, 7.0
	12.5	4.0, 7.0
853	50	4.0, 7.0
	25	4.0, 7.0
	12.5	4.0, 7.0

Research grade ethylene (99.99%), research grade butene-1 (99.9%), and research grade methane (99.99%) were obtained from Matheson Gas Products, Whitby, Ont. and, except for rigorous degassing, were used without further purification. Impurities in the reactants were too small to affect the kinetics of the reaction, but correction to the yield of ethane, due to this impurity in the ethylene and the methane, was made where necessary.

Results

Ethylene and mixtures of methane and ethylene were pyrolyzed at 774, 824, and 853 K. A summary of the conditions for the experiments at each temperature is given in Table 1. In addition, experiments with small quantities (~4%) of butene-1 added to the mixtures of ethylene and methane were performed at 774 and 853 K.

A. Pyrolysis of ethylene

As reported in previous studies (12), propylene was the major product followed by butene-1 and ethane in comparable amounts. 1,3-Butadiene was of lesser importance. Methane was also a product but was not of course measurable in the presence of added methane. At these temperatures auto-acceleration of the rate was observed at all pressures, as illustrated in Figs. 1 and 2, which also show yields in the presence of methane, and initial rates were obtained by extrapolation of the ratio

$$\frac{(\text{yield product})_t}{t}$$

to zero time. This function was usually linear and the uncertainty in the initial rate was about ±30%. Auto-acceleration is caused by secondary initiation by products, principally butene-1, and is observed at conversions as low as 0.01% (12).

For each pressure of ethylene the rate of product formation was determined as a function of the initial pressure of ethylene. The order of the initial rate of formation of the three major products over the pressure range 25–200 Torr (1 Torr = 133.3 Pa) was for ethane, 2.0, for propylene, 2.7, and for butene-1, 2.3, in good agreement with previous measurements.

The thermal reactions of ethylene at these temperatures involve a complex set of parallel and interacting chain propagation reactions of the ethyl and vinyl radicals, following initiation by reaction [1]. The mechanism proposed by Back and Martin

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12
For personal use only.

(7) is based on the original suggestion by Kossiakoff and Rice (13) and substantiated by Quinn (14) that isomerization and decomposition of the normal radicals formed by addition of radicals to ethylene is not important until the chain has reached C_6 or possibly C_5. For these radicals isomerization can compete with further addition and the isomerized radical readily decomposes to give the products propylene and butene-1, regenerating the ethyl or methyl radicals. Thus methane and ethane are the result of radical abstraction from ethylene while propylene and butene-1 are the result of radical addition to ethylene. The vinyl radical undergoes similar reactions (although the abstraction is a simple exchange and hence unobservable) leading to butadiene and other products more unsaturated than propylene and butene-1. Since the measurement of such products was not the purpose of this study, reactions of the vinyl radical will not be considered further.

The following series of reactions represents a simplified scheme for the formation of methane, ethane, propylene, and butene-1 for which only the reactions of the methyl, ethyl, and higher saturated radicals need be considered.

[1] $2C_2H_4 \rightarrow C_2H_3 + C_2H_5$

[2] $CH_3 + C_2H_4 \rightarrow CH_4 + C_2H_3$

[3] $C_2H_5 + C_2H_4 \rightarrow C_2H_6 + C_2H_3$

[6] $C_2H_5 + C_2H_4 \leftrightarrows C_4H_9$

[7] $C_4H_9 + C_2H_4 \rightarrow 1\text{-}C_6H_{13}$

[8] $1\text{-}C_6H_{13} \rightarrow 2\text{-}C_6H_{13}$

[9] $2\text{-}C_6H_{13} \rightarrow C_3H_6 + 1\text{-}C_3H_7$

[10] $1\text{-}C_3H_7 + C_2H_4 \rightarrow 1\text{-}C_5H_{11}$

[11] $1\text{-}C_5H_{11} \rightarrow 2\text{-}C_5H_{11}$

[12] $2\text{-}C_5H_{11} \rightarrow C_3H_6 + C_2H_5$

[13] $1\text{-}C_6H_{13} \rightarrow 3\text{-}C_6H_{13}$

[14] $3\text{-}C_6H_{13} \rightarrow C_4H_8 + C_2H_5$

[15] $3\text{-}C_6H_{13} \rightarrow C_5H_{10} + CH_3$

[16] $CH_3 + C_2H_4 \rightleftarrows C_3H_7$

[t] $2C_2H_5 \rightarrow C_4H_{10}$

where [t] indicates the termination reaction.

Although several radicals are important in the mechanism, initiation and termination reactions of the ethyl radical probably control the total radical concentration. Assuming a steady-state concentration of radicals, the concentration of ethyl radicals may be expressed as follows:

$$[17] \quad [C_2H_5] = \left(\frac{k_1}{k_t}\right)^{1/2}[C_2H_4]$$

As discussed earlier, ethane is formed entirely by reaction [2] and the rate of formation of ethane is, therefore,

$$[18] \quad R_{C_2H_6} = k_3[C_2H_5][C_2H_4] = k_3\left(\frac{k_1}{k_t}\right)^{1/2}[C_2H_4]^2$$

The rate of formation of ethane was observed to be second order, in accord with this expression.

Butene-1 is formed by decomposition of the 3-hexyl radical, reaction [14], and its rate of formation may be expressed as follows:

$$[19] \quad R_{C_4H_8} = (1 - a)b\frac{k_6[C_2H_4]}{k_{-6} + k_7[C_2H_4]} \cdot k_7[C_2H_5][C_2H_4]$$

where a and b are the fractions $k_8/(k_8 + k_{13})$ and $k_{14}/(k_{14} + k_{15})$ respectively. Since the order of the rate of formation of butene-1 was observed to be slightly greater than two, the term in the denominator, $k_7[C_2H_4]$, makes a significant contribution. In other words, reaction [6] is not completely equilibrated under the conditions of these experiments.

Propylene is formed through reactions [9] and [12] and its rate of formation therefore involves two terms, as follows:

$$[20] \quad R_{C_3H_6} = a \cdot \frac{k_6[C_2H_4]}{k_{-6} + k_7[C_2H_4]} \cdot k_7[C_2H_5][C_2H_4] + k_{10}K_{16}[CH_3][C_2H_4]^2$$

or, expressing the concentration of methyl radicals in terms of the concentration of ethyl radicals:

$$[CH_3] = (1 - b)(1 - a) \cdot \frac{k_6[C_2H_4]}{k_{-6} + k_7[C_2H_4]} \cdot \frac{k_7}{k_2}[C_2H_5]$$

eq. [20] becomes

$$[21] \quad R_{C_3H_6} = a \cdot \frac{k_6[C_2H_4]}{k_{-6} + k_7[C_2H_4]} \cdot k_7[C_2H_5][C_2H_4] + (1 - b)(1 - a) \cdot \frac{k_6[C_2H_4]}{k_{-6} + k_7[C_2H_4]} \cdot \frac{k_{10}K_{16}k_7}{k_2}[C_2H_5][C_2H_4]^2$$

assuming equilibration of the propyl radicals by reaction [16]. The first term will give an order of the rate similar to that of butene-1 while the second term will lead to a higher order, due to the formation of the propyl radical by reaction [16]. Since the observed order for the rate of formation of propylene was 2.7, and in previous studies has always been observed to be greater than that for butene-1, formation through the reaction of propyl radicals must make a significant contribution.

The different orders for the rates of formation of these products are illustrated by the change in the ratios of the rates, $R_{C_3H_6}/R_{C_2H_6}$ and $R_{C_3H_6}/R_{C_4H_8}$, with increasing pressure of ethylene, shown in Fig. 3.

$$[22] \quad \frac{R_{C_3H_6}}{R_{C_2H_6}} = a \cdot \frac{k_6[C_2H_4]}{k_{-6} + k_7[C_2H_4]} \cdot \frac{k_7}{k_3} + (1 - b)(1 - a)\frac{k_6[C_2H_4]}{k_{-6} + k_7[C_2H_4]} \cdot \frac{k_{10}K_{16}k_7}{k_3k_2}[C_2H_4]$$

$$[23] \quad \frac{R_{C_3H_6}}{R_{C_4H_8}} = \frac{a}{b(1 - a)} + \frac{(1 - b)}{b} \cdot \frac{k_{10}K_{16}}{k_2}[C_2H_4]$$

Equation [22] predicts a dependence on ethylene pressure slightly greater than linear, because of the ratio $k_6[C_2H_4]/(k_{-6} + k_7[C_2H_4])$, while eq. [23] predicts a linear dependence. Both predictions are supported by the experimental data. Although this mechanism is greatly oversimplified it gives a general picture of the reactions leading to the three main products, ethane, propylene, and butene-1, which are used as the main indicators of changes in the mechanism that occur on addition of methane to the system.

Butadiene was also measured in the presence and absence of methane. It is most probably formed through a similar series of reactions involving the vinyl radical. Reactions of these unsaturated radicals are, however, not as well understood as those of the saturated radicals and the development of an expression for the rate of formation of butadiene would involve too many approximations and assumptions to allow reasonable credibility. The effect of methane on the rate of formation of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12
For personal use only.

butadiene and other more unsaturated products will therefore not be discussed further.

B. Pyrolysis of mixtures of ethylene and methane

Addition of methane to ethylene increased the rate of formation of ethane at all temperatures and pressures of ethylene. At 774 K the rate of formation of propylene was unaffected at 100 and 200 Torr of ethylene but was significantly increased at 25 and 50 Torr. These effects are shown in Figs. 1 and 2. At 774 K the rate of formation of butene-1 was slightly decreased at the two lowest pressures while the rate of formation of butadiene was not appreciably altered at any pressure of ethylene. At the highest temperature the reduction in the rate of formation of butene-1 was more pronounced but the rate of formation of butadiene was not much affected.

The fact that at 100 and 200 Torr of ethylene ethane was the only product whose rate of formation was increased by the addition of methane is strong indication that the only new propagation reaction introduced under these conditions is the abstraction of hydrogen from methane by ethyl radicals, reaction [4], and that the contribution by this reaction is not sufficient to alter appreciably the relative concentrations of radicals in the system. Under these conditions, as discussed earlier, the relative initial rates of formation of ethane may be described by eq. [5]. With the limited data available the function was linear up to a ratio of methane/ethylene of about two and from the slope of the linear portion a value of k_4/k_3 of 1.0 was obtained. This value is consistent with other values of this ratio measured with different additives at the same temperature by the same method, as shown in Table 2.

At the lower pressures of ethylene at 774 K and at all pressures at the higher temperatures, addition of methane enhanced considerably the rate of formation of propylene, and also altered the rate of formation of butene-1. Under these conditions, where the distribution of radicals in the chain mechanism is changed, the relative rates of formation of ethane cannot be expressed by the simple eq. [5]. When the relative concentration of radicals in the system changes, the main chain-carrying radical may change, with consequent changes in the termination steps and even in the total radical concentration. Nevertheless changes in the distribution of products may be examined as qualitative indication of changes in the mechanism induced by the presence of methane.

At the fractional conversions used in the present experiments the ratios of the products were unchanged during the course of the reaction. Therefore, secondary reactions of the products are not perturbing the chain propagation reactions and changes in the ratios of the products are due to the presence of methane.

In the presence of methane the two new reactions of most importance will be the following abstraction reactions:

[4] $C_2H_5 + CH_4 \rightarrow C_2H_6 + CH_3$

[24] $C_2H_3 + CH_4 \rightarrow C_2H_4 + CH_3$

As mentioned earlier, only for the methyl, ethyl, and vinyl radicals is abstraction from ethylene or methane sufficiently fast to compete with decomposition or addition to ethylene. For example, the products propane and butane are always very minor and no evidence was observed for increasing importance in the presence of methane. There is also no direct evidence for the occurrence of reaction [24] and the expressions for the rates of formation of the products presented later will not include this reaction. These expressions will therefore be qualitative and have not been used to estimate values for ratios of rate constants involved in the mechanism.

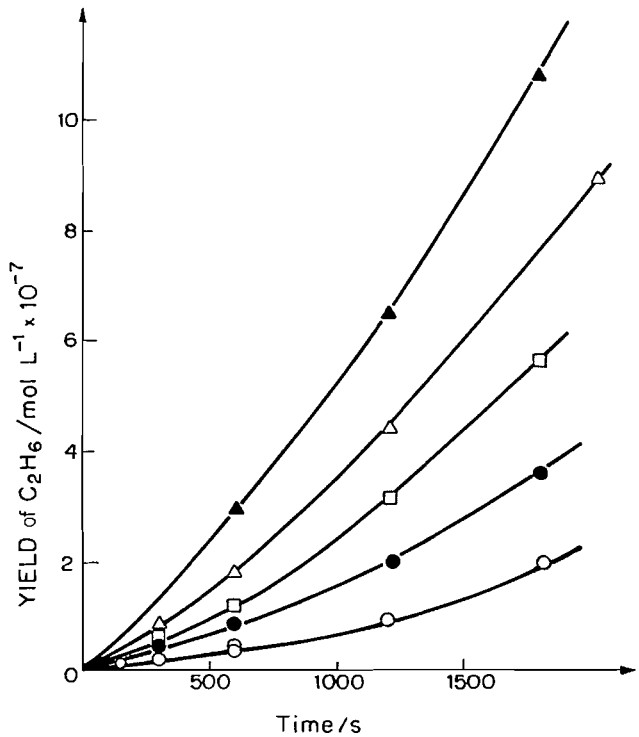

FIG. 1. Yield of ethane as a function of time at 774 K with an initial pressure of ethylene of 50 Torr. Pressure of CH_4 (Torr), ○: 0; ●: 50; □: 150; △: 250; ▲: 400.

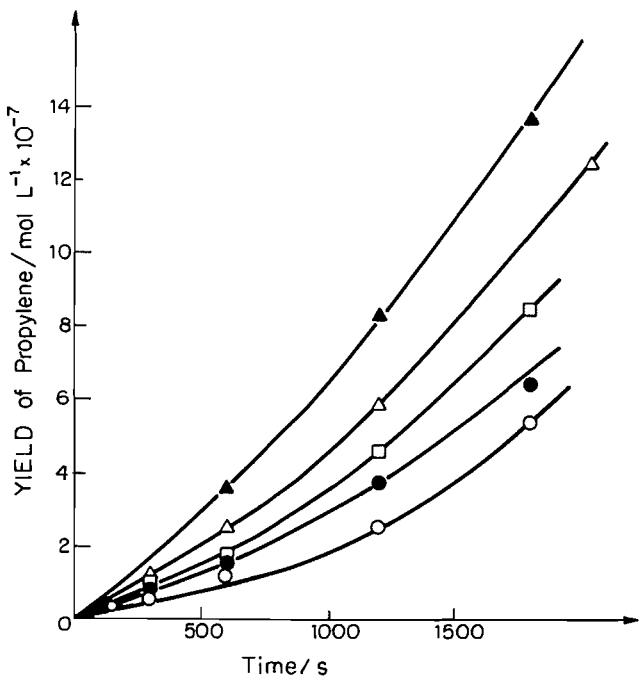

FIG. 2. Yield of propylene as a function of time at 774 K with an initial pressure of ethylene of 50 Torr. Pressure of CH_4 (Torr), ○: 0; ●: 50; □: 150; △: 250; ▲: 400.

As a first approximation we assume that the concentration of ethyl radicals is unchanged in the presence of methane and given, as before, by eq. [17]. Under these conditions the rate of formation of butene-1 will be unchanged, as expressed by eq. [19]. The rates of formation of ethane and propylene will be given as follows, still assuming equilibration of the propyl radical.

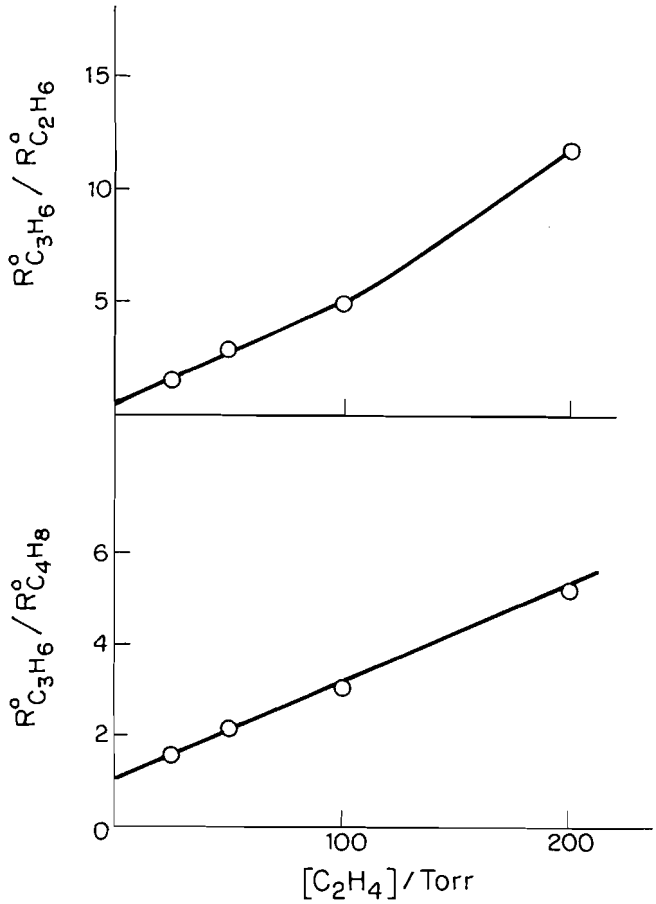

FIG. 3. The ratios $R^0_{C_3H_6}/R^0_{C_2H_6}$ and $R^0_{C_3H_6}/R^0_{C_4H_8}$ as a function of the initial pressure of ethylene obtained in the pyrolysis of ethylene at 774 K.

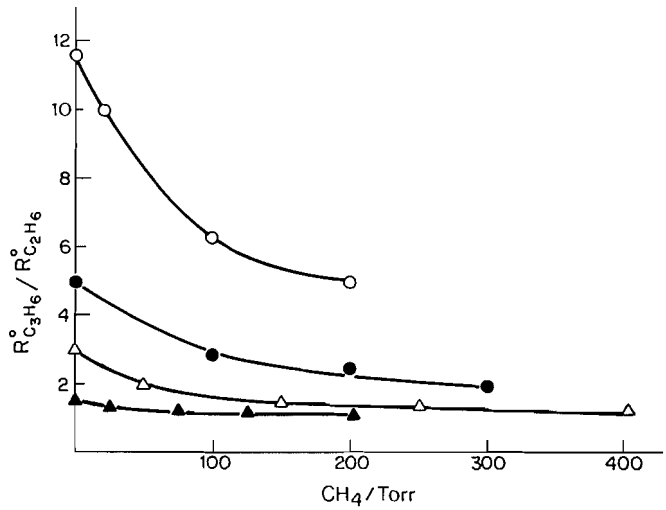

FIG. 4. The ratio $R^0_{C_3H_6}/R^0_{C_2H_6}$ as a function of the pressure of methane from the pyrolysis of the mixtures at 774 K. Initial pressure of ethylene (Torr), ○: 200; ●: 100; △: 50; ▲: 25.

$$[25]\quad R_{C_2H_6} = [C_2H_5](k_3[C_2H_4] + k_4[CH_4])$$

$$[26]\quad R_{C_3H_6} = [C_2H_5]\left\{a\cdot\frac{k_6[C_2H_4]}{k_{-6} + k_7[C_2H_4]}\cdot k_7[C_2H_4] + (1-b)(1-a)\cdot\frac{k_6[C_2H_4]}{k_{-6} + k_7[C_2H_4]}\cdot\frac{k_{10}K_{16}k_7}{k_2}[C_2H_4]^2 + \frac{k_{10}K_{16}}{k_2}[C_2H_4][CH_4]\right\}$$

In the presence of methane the rate of formation of ethane is increased directly through reaction [4] while the rate of formation of propylene is increased through the increasing importance of the methyl radical, the consequent formation of the propyl radical, and the sequence of reactions [10]–[12].

Letting the fraction $k_6[C_2H_4]/(k_{-6} + k_7[C_2H_4]) = X$, the expression for the ratios of rates $R_{C_3H_6}/R_{C_2H_6}$ and $R_{C_3H_6}/R_{C_4H_8}$ are given as follows:

$$[27]\quad \frac{R_{C_3H_6}}{R_{C_2H_6}} = \frac{a.X.k_7[C_2H_4] + (1-b)(1-a)X\dfrac{k_{10}K_{16}k_7[C_2H_4]^2}{k_2} + \dfrac{k_{10}K_{16}}{k_2}[C_2H_4][CH_4]}{k_3[C_2H_4] + k_4[CH_4]}$$

$$[28]\quad \frac{R_{C_3H_6}}{R_{C_4H_8}} = \frac{a}{b(1-a)} + \frac{(1-b)}{b}\cdot\frac{k_{10}K_{16}}{k_2}[C_2H_4] + \frac{1}{b(1-a)}\frac{k_{10}K_{16}[CH_4]}{k_2k_7X}$$

These ratios are shown as a function of the pressure of methane in Figs. 4 and 5. The changes in these ratios can be understood on the basis of the changes in the relative concentrations of the ethyl and methyl radicals. The ratio $R_{C_3H_6}/R_{C_2H_6}$ at first decreases with added methane due to the importance of reaction [4], before the concentration of the ethyl radical is significantly altered. As the balance of the two radicals gradually shifts toward the methyl radical, the final term in the numerator will eventually dominate the route to propylene and as a result the influence of methane on the two rates will tend to cancel. As illustrated in Fig. 4 the ratio approached a constant value at high pressures of methane.

The importance of the final term in the rate of formation of propylene is also illustrated by the ratio $R_{C_3H_6}/R_{C_4H_8}$. When this term is not important this ratio will be independent of the concentration of methane. This was the case for the experiments

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12
For personal use only.

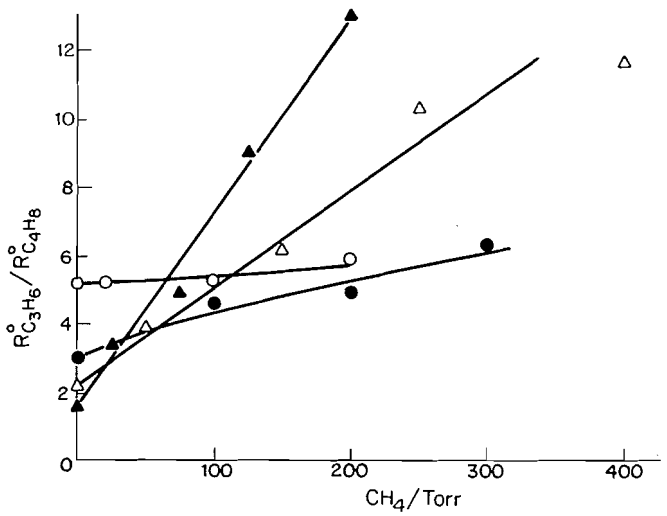

FIG. 5. The ratio $R^0_{C_3H_6}/R^0_{C_4H_8}$ as a function of the pressure of methane from the pyrolysis of the mixtures at 774 K. Initial pressure of ethylene (Torr), ○: 200; ●: 100; △: 50; ▲: 25.

with the highest pressure of ethylene, 200 Torr, and is consistent with the observed decrease in the ratio $R_{C_3H_6}/R_{C_2H_6}$ under the same conditions. At lower pressures of ethylene the final term becomes more important and the ratio $R_{C_3H_6}/R_{C_4H_8}$ increases linearly with increasing concentration of methane. Both ratios show that this term assumes increasing importance as the pressure of ethylene is lowered and is the dominant source of propylene at the lowest pressure of ethylene. Moreover, as predicted by eq. [28], the value of the ratio $R_{C_3H_6}/R_{C_4H_8}$ in the absence of methane is greatest for the highest pressure of ethylene. The results show therefore that the simple mechanism outlined earlier accounts satisfactorily for the effects observed on the rate of product formation by the addition of methane.

As discussed at the beginning of this section, the interpretation of the relative rates of formation of ethane in the presence and absence of methane in terms of eq. [5] was possible only for the experiments at the two highest pressures of ethylene. It is nevertheless useful to examine the magnitude of the increase in the rates of both products ethane and propylene in the presence of methane under the other conditions of the experiments, mainly as a means of assessing the efficiency of the conversion of methane. The relative rates of formation of ethane and propylene in the presence and absence of methane R^0_a/R^0, are shown as a function of the ratio CH_4/C_2H_4 for the three temperatures of the reaction in Fig. 6. At 774 K ethane is the product most affected by the addition of methane but by 824 K the increase in the rate of formation of propylene is significantly greater than the increase in the rate of formation of ethane, particularly at the lowest pressure. At the highest temperature, however, the effect of methane on the rates of formation of both products had diminished and no longer appears to increase linearly with the ratio CH_4/C_2H_4.

Probably of more significance than the relative rates is the actual rate of conversion of methane into higher molecular weight products. Since the conversion of both ethylene and methane was kept low in these experiments, in order to obtain measurements of the initial rates, the rate of conversion of methane must be estimated from the rate of formation of products. The two reactions that consume methane are [4] and [24]. The increase in rate of formation of ethane, which is the difference between the rate in the presence of methane, R^0, and

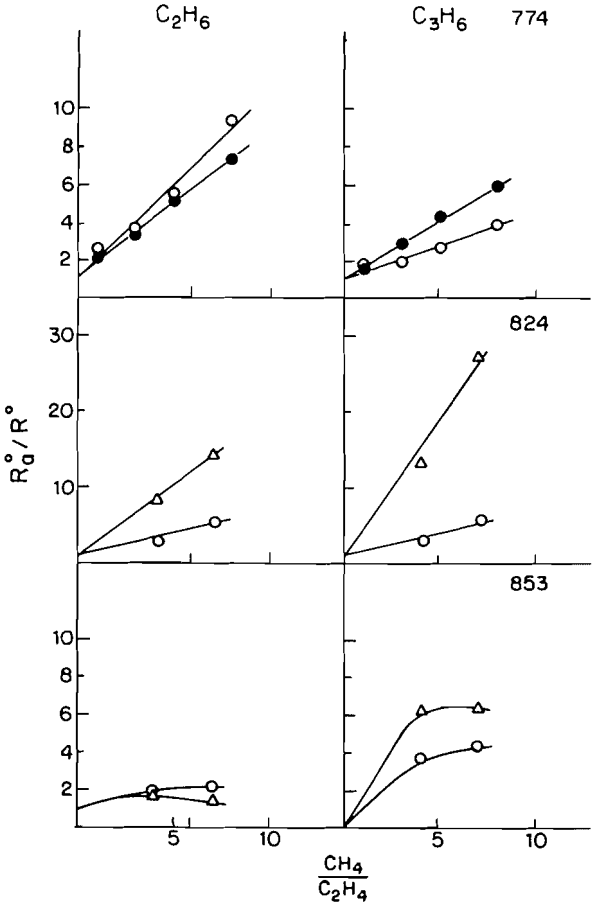

FIG. 6. Relative rates of formation in the presence and absence of methane, R^0_a/R^0, of the products ethane and propylene at the three temperatures of the reaction as a function of CH_4/C_2H_4. Initial pressure of ethylene (Torr), ○: 50; ●: 25; △: 12.5.

in the absence of methane, R^0_a, may be equated to a rate of loss of methane,

$$R^0_a - R^0 = \text{rate loss methane}$$

The conversion of methane was calculated from the measurements of the initial rates for all the experiments at each temperature. The highest rate of conversion was 2×10^{-5} percent·s^{-1}, measured at the highest temperature, 853 K, with 50 Torr ethylene and 200 Torr methane. This rate was actually not very different over the whole range of temperature because of the compensating effects of temperature, pressure, and relative rates.

C. Pyrolysis of mixtures of ethylene, methane, and butene-1

A rate of conversion of this magnitude is not likely to find application in industrial processing operations. Even though this estimate is a lower limit, the actual rate is probably no more than two or three times greater. An improved rate of conversion could be achieved only through an increase in the rate of the overall reaction of ethylene. At higher tempratures the rate of the reaction was greatly increased but experiments under these conditions showed that the mechanism was significantly different, leading to changes in the interpretation. These results will be reported separately. In the region of temperature of the present experiments the rate of the reaction could be increased only by the addition of a new source of initiation of radicals.

The rate of the thermal reaction of ethylene at these

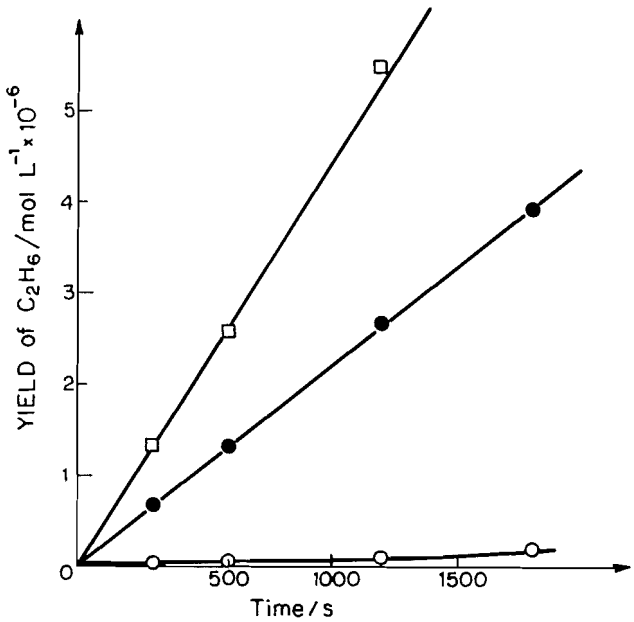

FIG. 7. Yield of ethane as a function of time from the pyrolysis of mixtures of ethylene, methane and butene-1 at 774 K. Initial pressures (Torr), ○: 50 (C_2H_4), 0 (CH_4), 0 (1-C_4H_8); ●: 50 (C_2H_4), 0 (CH_4), 2 (1-C_4H_8); □: 50 (C_2H_4), 400 (CH_4), 2 (1-C_4H_8).

temperatures is strongly auto-accelerated, as illustrated in Figs. 1 and 2, due to secondary initiation by the product butene-1. Furthermore, previous studies had shown that addition of butene-1 to thermally reacting ethylene caused an increase in the rate of the reaction, and, if the quantities of butene-1 were not too large, the products of the reaction were unchanged (12). Small quantities of butene-1 were therefore added to the mixtures of ethylene and methane in order to increase the overall rate of the reaction and the conversion of methane. Experiments were done at 774 and 853 K with mixtures of ethylene containing about 4% butene-1 in the presence and absence of methane. In the absence of methane the rate of formation of all products from the reaction of ethylene was substantially increased, as observed in previous studies. In the presence of methane the rate of formation of ethane was increased while the rates of formation of propylene and butene-1 were unaffected. The results are summarized in Table 3 and illustrated in Fig. 7.

The result clearly showed that butene-1 acted as a new initiator for the chain reaction of ethylene, through rapid thermal dissociation, increasing the rate of the overall reaction.

$$C_4H_8 \rightarrow CH_3 + C_3H_5$$

The extent of the conversion of methane in these experiments may be estimated from the difference between the rate of formation of ethane in the presence of methane and in the absence of methane, as in the experiments without butene-1. At 853 K with 400 Torr of methane the percentage conversion of methane per second was 5×10^{-4}. The addition of butene-1 therefore gave considerable improvement in the rate of conversion of methane.

Conclusions

The pyrolysis of mixtures of methane and ethylene leads to the direct conversion of methane to ethane and propylene, through participation of methane in the chain propagation reactions of the ethylene pyrolysis. The overall rate of the conversion may be enhanced by the addition of compounds that provide an increased rate of initiation. An advantage of the system is that methane is converted exclusively to hydrocarbon product.

Approaches to the tetracyclic eudistomins: the synthesis of N(10)-acetyleudistomin L[1]

IAN W. J. STILL[2] AND JURIS R. STRAUTMANIS

J. Tuzo Wilson Research Laboratories, Erindale Campus, University of Toronto, Mississauga, Ont., Canada L5L 1C6

Received August 24, 1989

IAN W. J. STILL and JURIS R. STRAUTMANIS. Can. J. Chem. **68**, 1408 (1990).

The successful synthesis of the tetracyclic ring system present in eudistomins C, E, K, and L involves a convergent approach to N(10)-acetyleudistomin L from 5-bromo-*N'*-hydroxytryptamine and a suitably protected cysteinal derivative. Ring C in the eudistomin was constructed by a modified Pictet–Spengler reaction and the unique 1,3,7-oxathiazepine ring (ring D) by an unprecedented intramolecular sila-Pummerer reaction. An interesting diastereoselectivity is observed in the former process. The formation of an alternative seven-membered ring cyclization product under certain conditions in the sila-Pummerer reaction is also described.

Key words: eudistomins, 1,3,7-oxathiazepine, Pictet–Spengler, sila-Pummerer.

IAN W. J. STILL et JURIS R. STRAUTMANIS. Can. J. Chem. **68**, 1408 (1990).

Une bonne synthèse du système tétracyclique présent dans les eudistomines C, E, K et L implique une approche convergente vers la N(10)-acétyleudistomine L, à partir de la 5-bromo-*N'*-hydroxytryptamine et d'un dérivé cystéinal protégé d'une façon appropriée. On a construit le cycle C de l'eudistomine en faisant appel à une réaction modifiée de Pictet–Spengler et on est parvenu à former le cycle unique de la 1,3,7-oxathiazépine (cycle D) en effectuant une réaction intramoléculaire de sila-Pummerer qui n'avait jamais été réalisée antérieurement. On décrit que, dans certaines conditions de la réaction de sila-Pummerer, il y a une formation alternative d'un cycle à sept chaînons.

Mots clés : eudistomines, 1,3,7-oxathiazépine, Pictet–Spengler, sila-Pummerer.

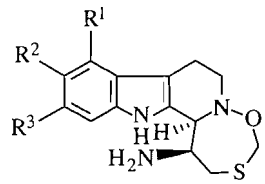
Introduction

In 1984, Rinehart and co-workers (1) reported the structure determination of 15 indole alkaloids, collectively termed eudistomins, which had been isolated from the tunicate (ascidian) organism *Eudistoma olivaceum*. Several reports of additional eudistomins, and the related compound eudistomidin A, have since appeared (2–5). Eudistomins C, E, K, and L (**1***a–d*,



1*a*, R^1 = H, R^2 = OH, R^3 = Br
b, R^1 = Br, R^2 = OH, R^3 = H
c, R^1 = R^2 = H, R^3 = Br
d, R^1 = R^3 = H, R^2 = Br

respectively) have been shown to contain the unique 1,3,7-oxathiazepine ring as ring D of the tetracyclic system. These compounds have been shown to possess strong antiviral activity against the *Herpes simplex* virus (HSV-1) as well as certain types of in vivo antitumour activity (5*d*). Several early attempts towards the synthesis of this class of compound have appeared (6–8). Since our earlier preliminary communication (9), Nakagawa *et al.* have reported a second successful approach (10).[3] We present here a detailed account of our synthesis of N(10)-acetyleudistomin L **2**, a simple analogue of eudistomins of the 1,3,7-oxathiazepine type.

Our general approach to the synthesis of **2** is outlined in Scheme 1. At the time this work was initiated, not only was there no literature precedent for the synthesis of the 1,3,7-oxathiazepine ring present in **2**, but there also existed no literature precedents for the N(2)-hydroxylated tetrahydro-β-carbolines such as **3**. We envisaged the construction of ring D in **2** as being carried out by a Pummerer-type reaction strategy (11), or perhaps the sila-Pummerer modification (12), while the construction of ring C in **3** might best be accomplished by a modification of the classical Pictet–Spengler reaction, via an intermediate nitrone (6). The details of the synthesis of the key intermediates **4** and **5** and the convergent synthesis of **2** are described in the following section.

Results and discussion

According to the plan we had established by our retrosynthetic analysis (Scheme 1), we first set out to prepare 5-bromo-*N'*-hydroxytryptamine **4**. 5-Bromoindole **6** is commercially available and may also be prepared from indole, using a procedure originally reported by Thesing *et al.* (13). The known 5-bromotryptamine **10** (14) is prepared via the intermediacy of the 3-carboxaldehyde **8** (15) and nitro-olefin **9** (14) (Scheme 2). We have been able to devise a modification to the reduction of **9** that allows us to prepare **4** by a two-stage reduction procedure, in 65–70% overall yield (Scheme 3).

The first reduction step (**9** → **11**) is based upon a procedure reported by Varma and Kabalka (16), our earlier attempt to achieve the reduction of **9** to the hydroxylamine **4** directly, based upon another procedure of Kabalka and co-workers (17) and using a BH_3·THF complex catalyzed by $NaBH_4$, having been completely unsuccessful. We feel that an important factor in the success of this nitro-olefin reduction is the necessity for the hydroxylic solvent. Under our conditions, the active reducing agent is likely a trimethoxyborohydride formed by reaction of borohydride anion with excess methanol. The nitronate anion initially formed from **9** has thus only trimethoxyborane with which to complex, and further reduction does not occur, in the absence of an electrophilic reducing agent (e.g., borane) or a more powerful hydride reducing agent (e.g., $LiAlH_4$). Interestingly, no protection of the indole N-H proton is necessary during this reduction, as observed independently by others (18).

Finally, the preparation of 5-bromo-*N'*-hydroxytryptamine **4** was readily achieved by aluminum amalgam reduction of the saturated nitro compound **11**. Aluminum amalgam reduction of nitro compounds to hydroxylamines is well established and, indeed, this was the route taken by Cava and co-workers (6) in their preparation of an analogous (non-brominated) *N'*-hydroxytryptamine. The zinc reduction of saturated nitro compounds to hydroxylamines, in the presence of a mild proton source and in a variety of solvents, is also well established in the literature (19). Due mainly to the more convenient preparation of the reducing agent, we preferred to use the zinc reduction for the preparation of 5-bromo-*N'*-hydroxytryptamine. Besides the work of Cava (6) and the present work, the only other preparation of *N'*-hydroxytryptamines was reported by Cohen and Heath-Brown (20), using zinc/ammonium chloride reduction of the corresponding nitro compounds in 95% ethanol.

We obtained **4** as a pale beige, sticky and sometimes foamy, substance, identified primarily on the basis of its ^{1}H NMR spectrum, in which the *NHOH* protons were characteristically observed as a broad singlet (2H) at δ 5.5 ppm, exchangeable by treatment with D_2O. In sharp contrast, the NH_2 protons in the corresponding tryptamine **10** appeared as a broad singlet (2H) at δ 1.7. The indole N-H proton in **10** appeared at δ 9.8, again in sharp contrast with **4**, where the corresponding proton appears at δ 8.2, an exceptionally shielded position for indole N-H protons in our series of compounds. We were never able to crystallize 5-bromo-*N'*-hydroxytryptamine nor achieve its purification in any other way. Hydroxylamines have often been characterized as their hydrogen oxalate salts (21). Treatment of the crude hydroxylamine, however, in dry ether with dried oxalic acid gave a beige precipitate, with a broad melting point, which we were unable to recrystallize. Neither a satisfactory ^{1}H NMR spectrum nor a satisfactory mass spectrum could be obtained for this material. Attempts to prepare the hydrochloride salt of **4** likewise led to intractable products. We decided to proceed with the hydroxylamine and to use the freshly prepared, crude free base in the subsequent reactions. Subsequently, the presence of the hydroxylamine was amply verified by irrefutable evidence for the identity of the reaction products derived from it.

The next phase of our strategy involved the construction of a suitable cysteine-derived moiety. The desired aldehyde **5** was chosen as the key intermediate because the aldehyde functionality is required for the modified Pictet–Spengler reaction (6)

SCHEME 4

with the *N'*-hydroxytryptamine **4** above to construct ring C (Scheme 1). For the purposes of our sila-Pummerer ring closure strategy for ring D (Scheme 1) we first converted the -SH group in **7** into the trimethylsilylmethyl analogue **13**, using a procedure modified from that reported by Shimizu and Ogata (22).

Protection of the amino group is also essential to avoid the well-known dimerization of α-amino acid esters or aldehydes. We initially discarded the idea of using the more common Boc and Cbz groups frequently used for this purpose, on the grounds that compounds of type **1** would likely be sensitive to both acid hydrolysis and to hydrogenolysis because of the (expected) labile nature of ring D. The first of these assumptions has now been found to be erroneous and we will return to this point later. In the event, *N*-acetylation, to give **14**, was employed in this step, immediately following the *S*-alkylation step.

The methyl ester **12** (23) was thought to be the most convenient derivative of L-cysteine to serve as a precursor of the required aldehyde **5**. Diisobutylaluminum hydride (DIBAL) reduction of esters to the corresponding aldehyde is well established in the literature (24), including recent applications in which protected α-amino aldehydes are prepared from the corresponding protected α-amino esters (25). The synthesis of **5** is outlined in Scheme 4.

With the exception of the final aldehyde **5**, all the products in Scheme 4 were obtained in optically active form. Attempts to purify **5** by chromatography on silica gel led to optically inactive material, as has been noted previously for α-amino aldehydes (26). Subsequent work on the ring C closure (q.v.) was to reveal, however, that use of the unpurified aldehyde **5** was justified, in terms of a satisfactory diastereomeric outcome. The yield in the reduction step (40–50%) was also disappointing, although significantly better than for the corresponding ethyl ester analogue. In spite of these problems, we were able to obtain **5** conveniently by the route outlined and the chemical purity of the crude aldehyde was adequately demonstrated by its IR and ^{1}H NMR spectra, notably the peaks at 2727 and 1736 cm^{-1} in the former and the singlet at δ 9.6 in the latter showing the expected integration.

With the key intermediates **4** and **5** in hand, we next turned our attention to the closure of ring C of the eudistomin skeleton, by the modified Pictet–Spengler strategy. Before proceeding to this, however, we wish to briefly present the results of some preliminary experiments, by an alternative approach.

We reasoned initially that an intermediate such as **15** would be useful as a means not only for introducing an α-thio substituent at the methyl site, by standard methodology, but also for later introduction of the C-10 amino group by reductive amination, probably in a stereoselective fashion. Attempts to carry out a classical Pictet–Spengler reaction with pyruvic aldehyde **16** (or its dimethyl acetal) and 5-bromotryptamine **10**, however, were completely without success. We have also synthesized 6-bromo-1,2,3,4-tetrahydro-β-carboline **17**, by adapting the procedure used by Ho and Walker (27) for the parent tetrahydro-β-carboline, and were able to oxidize it by sodium tungstate-catalyzed oxidation with H_2O_2 (28) to the cyclic nitrone **18**, which we had also considered as a potential intermediate in our synthesis, through addition of a suitable 2-carbon nucleophile at C-1. The yield of **18** that we obtained, however, was less than 20% and this approach was not pursued.

Returning to our modified Pictet–Spengler strategy using **4**, a chance discovery, using acetone in the presence of silica gel and subsequently duplicated with acetaldehyde, enabled us to demonstrate not only the intermediacy of the nitrone intermediates **19***a*,*b* but also the fact that these were stable, isolable compounds. It was subsequently found that nitrone formation was more effectively catalyzed by anhydrous magnesium sulfate. Subsequent cyclization with trifluoroacetic acid, also at 25°C, readily produced the model 2-hydroxy-1,2,3,4-tetrahydro-β-carbolines **20***a*,*b*. With our original preparation of **15** in mind, we have also successfully employed 2-methyl-1,3-dithiane-2-carbaldehyde **21** (29) in this two-step sequence, to produce **23**, via **22**, in 42% overall yield. This has established **21** as a viable alternative to pyruvic aldehyde and its derivatives for such Pictet–Spengler reactions. Because of our successful application of the cysteinal derivative **5** in this sequence, however, no attempt to hydrolyze the dithioacetal unit in **23** or to proceed further with this approach was made.

The intermediate aldonitrones, **19***b* and **22**, were very easily distinguished by the characteristic one-proton signal at δ ~6.4 ppm in the ^{1}H NMR spectrum. The comparable protons (at C-1) in the cyclized products **20***b* and **23**, on the other hand, appeared much further upfield at δ ~4.1 ppm. Compounds **20***b* and **23** were also easily distinguished by showing the presence of three, rather than four, aromatic protons and, additionally, by the presence of two exchangeable hydrogens (indole N-H and N-OH). The assignment of the *Z* configuration to the single isomer obtained in each case for **19***b* and **22** is based on numerous literature precedents. The mass spectral breakdown of **19***b* versus that of **20***b* is also very diagnostic, a Cope-type *syn*-elimination of a β-hydrogen being characteristic of the

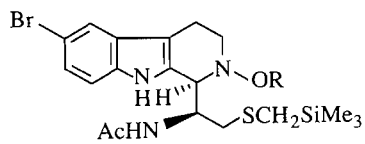
former, whereas a *retro*-Diels–Alder fragmentation, already well documented for simpler 1,2,3,4-tetrahydro-β-carbolines (30), is the major pathway in **20***b*. Both processes originate with initial electron ejection from the indole nitrogen atom. The model compound **20***b* was further characterized by the formation of its *O*-trimethylsilyl and *O*-acetyl derivatives **24***a*,*b*.

Having firmly established the generality of the modified Pictet–Spengler reaction with the *N'*-hydroxytryptamine **4**, we next carried out the reaction of **4** with the desired cysteinal **5**. This time the intermediate nitrone was cyclized immediately, without purification, under the conditions described above for the model compounds, to afford the desired 2-hydroxy-1,2,3,4-tetrahydro-β-carboline **25***a* in 24% yield, after recrystallization. Compound **25***a* has been fully characterized by IR, (400 MHz) ^1H and ^{13}C NMR, mass spectral, and elemental analyses.

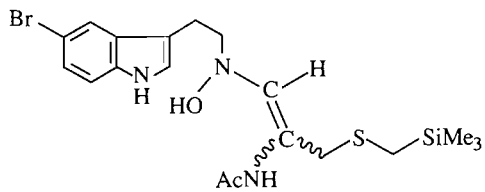
An attempt was made to purify the intermediate nitrone but this was not entirely successful as some contaminants were still present after column chromatography on alumina. The impure nitrone, however, did show certain characteristic spectroscopic features, which we have discussed above for the previously described nitrones (**19***b* and **22**), including the characteristic aldonitrone proton in the ^1H NMR at δ 6.6 ppm and the Cope-type mass spectral fragmentation.

Our preparation of the N(2)-hydroxy-1,2,3,4-tetrahydro-β-carboline **25***a* by the modified Pictet–Spengler reaction led to its isolation as a single diastereoisomer that was optically inactive. Since, as discussed above, the diisobutylaluminum hydride reduction of the optically active α-acetamido ester **14** led to crude, unpurified intermediate **5**, concurrent racemization at the α-carbon of this cysteine derivative, even without subjection to the potentially racemizing conditions of silica gel chromatography, cannot be ruled out. Alternatively, it is possible that the observed racemization occurred subsequently to give the compound presently under scrutiny, the ring C cyclized compound **25***a*. It was reported, however, by Nakagawa *et al.* (10) that *both* nitrone formation *and* the Pictet–Spengler cyclization, carried out under similar but not identical conditions to our own, proceeded with retention of enantiomeric purity.

In our case, nitrone formation in dichloromethane, in the presence of magnesium sulfate, would appear less likely to cause racemization than the more acidic conditions of the modified Pictet–Spengler reaction, in the presence of trifluoroacetic acid. Under the latter conditions, O-protonation of the nitrone, followed by deprotonation at the chiral carbon, might be expected to give the *N*-hydroxyenamine **26**. Chirality is thus lost and, upon reprotonation of **26**, the racemic ring C cyclized compound is obtained.



25*a* R = H
b R = $SiMe_3$



26

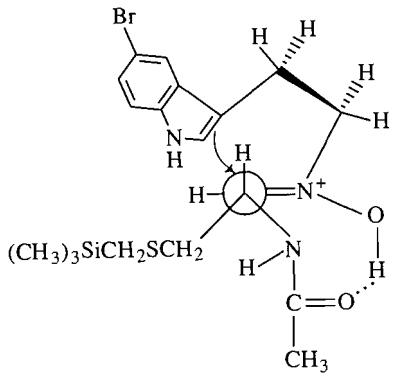
The correct explanation for this disappointing stereochemical outcome must remain conjectural for the present. More encouragingly, the observation of but a single set of signals in either the ^{13}C NMR spectrum or the (400 MHz) ^1H NMR spectrum of **25***a* verified that the ring C cyclized compound is a single diastereomer. The chiral centre at C(10) originates in L-cysteine and is racemized as described above, while the other centre, at C(1), is formed by what apparently is a diastereoselective process during the modified Pictet–Spengler cyclization. In our investigation of this reaction, we have found no evidence for a second diastereomeric compound being formed, a result essentially similar to that reported very recently by Nakagawa *et al.* (10), who reported preferred formation of one diastereomer (8:1 to 41:1 preference) at −78°C in trifluoroacetic acid.

In related literature examples, Ottenheijm and co-workers (7) obtained mixtures of diastereomers (with respect to the stereochemistry at C(1) and C(10)) in the modified Pictet–Spengler cyclization, using cysteine aldehydes in their work towards the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

eudistomins. This result is complicated, however, by their use, in the cyclization, of a hydroxylamine derived from the ethyl ester of tryptophan, although the reaction conditions for the cyclization were otherwise similar to ours. It is also noteworthy that carbamate groups were used for the cysteine amino group protection in both the other approaches cited (7, 10), whereas we used an amide protecting group.

We were able to determine the relative stereochemistry at C(1) and C(10) only after formation of the oxathiazepine ring (q.v.). As it turned out, we had fortuitously obtained the correct diastereomer of the N(2)-hydroxy-1,2,3,4-tetrahydro-β-carboline **25***a*, bearing the substituents at C(1) and C(10) in the same relative orientation as in the naturally occurring eudistomin L (**1***d*). We interpret this observation by proposing a model **27** for the modified Pictet–Spengler cyclization[4] similar



27

to that suggested by Czarnocki, MacLean, and Szarek (31) to explain the diastereoselectivity observed by these authors in the classical Pictet–Spengler reaction of β-phenylethylamines and aldehydes derived from carbohydrates, in the synthesis of isoquinoline alkaloids. This can be regarded as a variant of the model proposed by Cram and Elhafez (32) for nucleophilic attack at a double bond adjacent to a chiral centre. A related case of asymmetric induction in the 1,3-addition of Grignard reagents to nitrones has been very recently reported by Jenkins and co-workers (33).

In keeping with the above model structure, the amide carbonyl stretching vibration of **25***a* is observed in the IR at 1632 cm^{-1}, indicative of a very pronounced hydrogen bonded character. Interestingly, in the mass spectrum of **25***a* no evidence for a *retro*-Diels–Alder fragmentation was observed. As the model compound **23** has revealed, however, 2-hydroxy-1,2,3,4-tetrahydro-β-carbolines with relatively complex substituents at C(1) may prefer to undergo fragmentation by cleavage of the C(1)—C(10) bond, as in the present case. Compounds **20***a*, **20***b*, **23**, and **25***a* are amongst the first members of a new subclass of C(1)-substituted, N(2)-hydroxylated 1,2,3,4-tetrahydro-β-carbolines, which promise to be of considerable synthetic potential.

We were now in a position to complete our construction of the tetracyclic eudistomin skeleton in **1** by proceeding to the closure of ring D, using the sila-Pummerer intramolecular cyclization alluded to earlier. For this it was necessary to form the corresponding sulfoxide from **25***a*. Before proceeding to this, however, we reacted **25***a* by standard methodology to obtain the *O*-trimethylsilyl analogue **25***b* (for reasons which we will return to later) in 90% yield. Treatment of the sulfide **25***a* with *m*-chloroperbenzoic acid in THF, under the conditions shown (Scheme 5), gave the sulfoxide **28***a* as a pale yellow solid, in 67% yield. Compound **28***a* displayed a strong sulfoxide band at 1007 cm^{-1} (KBr) in its IR spectrum. This vibration is at a much lower value than that usually observed for sulfoxide bands, and two possible explanations are suggested. The sulfoxide oxygen may hydrogen-bond to either the indole N—*H* or the hydroxylamine N—O—*H* group in a manner similar to that suggested to account for the low value of the amide C=O band (1632 cm^{-1}) in sulfide **25***a*. (Significantly, the C=O band in **28***a* is found at 1661 cm^{-1} (KBr)). Alternatively, the low value of the sulfoxide band in **28***a* may be a manifestation of the β-effect of the trimethylsilyl group (34), which increases the contribution of the dipolar sulfoxide resonance structure. Based upon its (400 MHz) ^1H NMR spectrum, sulfoxide **28***a* appeared to be, as expected, a mixture of diastereomers. No further purification of the diastereomeric mixture was attempted as it was not anticipated that this would pose any problems in the next step. After a number of unsuccessful cyclization attempts in hot THF, benzene, or toluene, heating a 0.02 M solution of sulfoxide **28***a* in either acetonitrile or dimethylformamide (Scheme 5) was found to give the desired N(10)-acetyleudistomin L **2** in 20% yield, after chromatography on alumina. Compound **2** could be recrystallized from benzene and has been fully characterized by IR, ^{13}C NMR and ^1H NMR (Tables 1 and 2), and mass spectral analysis. The proposed structure has further been verified by a single crystal X-ray structure determination.[5,6]

This novel ring closure is assumed to proceed via an initial (concerted or stepwise) elimination of trimethylsilanolate ion, followed by attack on the dicoordinate sulfonium ion unit in **29** by the hydroxylamino oxygen atom, as shown. Besides the hydroxylamino oxygen, there are a number of potential nucleophiles present to intercept **29**, including both the indole nitrogen and C(3) sites, the acetamide nitrogen and oxygen atoms, and the hydroxylamine nitrogen atom, as well as the DMF or acetonitrile present, any water formed by condensation of two molecules of trimethylsilanol, and trimethylsilanolate ion itself. Such alternative pathways likely occur to some extent because, as noted above, the desired cyclization product **2** is obtained in relatively low yield. The use of a solvent of high dielectric constant, to minimize ion-pair formation in **29**, appears to be essential. None of the possible side products could be identified from the complex mixture remaining after separation of **2**.

While it is not known from the above cyclization whether the free hydroxyl group in **29**, or its anion, carries out the final nucleophilic 7-*endo*-trig (35) ring closure, we reasoned that the reaction might be facilitated by the use of the sulfoxide derived from the *O*-trimethylsilylated analogue **25***b* referred to above. Desilylation *in situ* by the trimethylsilanolate ion (to form hexamethyldisiloxane) might be expected to generate the

[4]This model shows only formation of the 1*S*,10*S* enantiomer. An equal amount of the 1*R*,10*R* enantiomer is also formed because of the racemization discussed above.

[5]Crystals of (±)-N(10)-acetyleudistomin L **2** were obtained by recrystallization from benzene as slightly discolored blocks. All work was performed on an Enraf–Nonius CAD4 diffractometer (graphite monochromatized MoK$\bar{\alpha}$ radiation, λ = 0.71069 Å; hexagonal plate of overall dimensions 0.212 × 0.237 × 0.375 mm) and gave the following crystal data: $C_{16}H_{18}BrN_3O_2S \cdot \frac{1}{2}C_6H_6$, M_r = 435.4, monoclinic, space group $C2/c$ with a = 15.492(2) Å, b = 21.425(6) Å, c = 12.184(2) Å, β = 100.87(1)°, V = 3971 Å^3, D_x = 1.456 g cm^{-1} for Z = 8, μ(MoK$\bar{\alpha}$) = 21.7 cm^{-1}, F(000) = 1784, T = 298 K.

[6]Full details of the crystallographic structure will be published elsewhere.

[a]The spectroscopic assignments in Tables 1 and 2 for these spectra recorded on a Varian XL-400 spectrometer were made on the basis of analysis of data obtained in the individual ^{13}C and ^{1}H NMR spectra, ^{1}H/^{13}C HETCOR (two-dimensional correlation spectroscopy), and homonuclear proton spin decoupling experiments. A comparison with data contained in a recent review of ^{13}C NMR data for indole alkaloids (44) also proved useful in assigning the quaternary carbon signals in **25***a*.
[b]In DMSO-d_6.
[c]In $CDCl_3$.

oxy-anion analogue of **29** and thus enable the ring closure to proceed more efficiently. Accordingly, we converted **25***b* into **28***b*, under conditions identical to those used for the formation of **28***a*, in 93% yield. This type of *in situ* generation of oxy-anions has been used recently by Eguchi and co-workers (36) and by Harpp and Gingras (37), and appeared, in our case, to have the additional advantage of avoiding the generation of water from the self-condensation of trimethylsilanol formed during the reaction of **28***a*.

After a number of unsuccessful attempts in refluxing solvents of low polarity, in which we obtained no identifiable products, heating sulfoxide **28***b* in acetonitrile at 80°C for 1 h gave the unexpected tetracyclic compound **30**, containing the 1,3-thiazepine ring shown, as the only identifiable product,[7] in 17% yield. Compound **30** was characterized by IR, ^{13}C and ^{1}H NMR (Tables 1 and 2), and mass spectral analysis. The formation of **30** may be viewed as involving initial deprotonation at the indole N—*H* by the (eliminated) trimethylsilanolate ion, followed by ring closure at the nucleophilic site so generated. A faint spot on TLC analysis indicated the presence of only a trace of the desired eudistomin **2**. It is possible that future work with an indole N-protected derivative would be instructive in

[7]The I.U.P.A.C. name for **30** is 10-acetamido-6-bromo-2-trimethylsilyloxy-1,2,3,4,10,11-hexahydro-13*H*-1,3-thiazepino[3,4,5-*l*,*m*]-β-carboline.

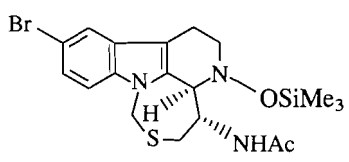
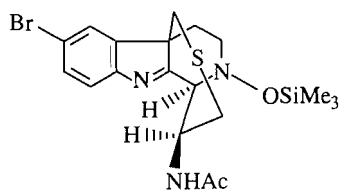
[c]In $CDCl_3$.

attempting to steer the ring closure in the desired direction of initial disiloxane, and subsequent oxathiazepine (eudistomin L) ring, formation.

The structure determination of the thiazepino-β-carboline **30** was essentially an exercise in determining the site of closure for the fourth ring formed in this competing sila-Pummerer reaction. The various possible sites for ring closure by nucleophilic attack on the sulfonium ion intermediate **29** have already been enumerated. The presence of IR bands at 3260 (NH) and 1646 (C=O) cm^{-1} in **30** eliminated the amide group of **28***b* as the intramolecular nucleophile. The base peak at m/z = 75 (C_2H_7OSi) in the mass spectrum indicated retention of the N—$OSiMe_3$ unit and hence ruled out six-membered ring closure involving the hydroxylamino nitrogen atom. It remained to distinguish between **30**, formed by ring closure at the indole nitrogen atom, and the spiroindolenine **31**, formed by alterna-



30



31

tive ring closure at C-3 of the indole unit. Firstly, the signal pattern for the protons on the benzene ring in the ^{1}H NMR spectrum of **30** was very similar to that found in all of our previous indoles and did not suggest an indolenine. The absence in the ^{13}C NMR spectrum of a signal for an imine carbon also tended to discount the indolenine. A third factor in allowing us to eliminate structure **31** was the observation of a fragmentation pattern in the mass spectrum of **30** which included a major (93%) *retro*-Diels–Alder reaction, clearly unlikely in the spiroindolenine **31** because of the quaternary carbon atom at the indole 3-position.

The stereochemistry at C(1) and C(10) in the earlier modified Pictet–Spengler cyclization of ring C is retained in the molecule during the alternative sila-Pummerer reaction producing **30**. However, instead of the H(1) axial – H(10) equatorial relationship found in N(10)-acetyleudistomin L **2**, compound **30** displays an H(1) axial – H(10) axial stereochemical relationship. This is because the fused 1,3-thiazepine ring has necessarily closed in the opposite direction to that for the oxathiazepine ring in the formation of **2**. These two processes require internal rotation of the substituent at C(1) in opposite directions and thus give the different relative stereochemistry observed at C(1) and C(10) as a result of this conformational change. The assignment of the H(1),H(10) *trans*-diaxial relationship in **30** is supported by the signal assigned to H(1) in the ^{1}H NMR spectrum, which appears as a doublet at δ 3.92 ppm, with a coupling constant $^{3}J_{H(1),H(10)}$ = 10.3 Hz. This should be contrasted with the signal assigned to H(1) in **2**, which appears as a broad singlet at δ 4.13 ppm, with a width at half height ($W_{1/2}$) of 5.2 Hz, indicating a small H(1),H(10) coupling constant and, therefore, according to the Karplus relationship, a *cis* relationship of H(1) and H(10). The stereochemistry of the racemic **30**, therefore, we believe to be as shown.

A number of unsuccessful attempts have been made to effect the removal of the N(10)-acetyl protecting group in **2** and to generate the free amine. Attempted ammonolysis of **2**, or hydrazinolysis in refluxing ethanol, returned largely the starting acetamide. Treatment with lithium hydroxide, potassium hydroxide, or sodium methoxide was without effect at 25°C but caused extensive decomposition of the molecule at higher temperatures (60–100°C). Interestingly, similar efforts under acidic conditions were also unsuccessful, treatment with 0.5 M hydrochloric acid in tetrahydrofuran–water (3:1) returning compound **2** even after 16 h at 50°C. This may indicate effective protection of the O,S mixed acetal functionality in the molecule by preferred protonation at the adjacent nitrogen atom. Clearly, the use of an amine protecting group that is acid-labile, in contrast to our initial concerns, is likely to prove more viable.

The preparation of N(10)-acetyleudistomin L **2** and the novel, 1,3,7-oxathiazepine ring system it contains had never been reported until recently (9, 10). Additionally, the present work represents the first successful example of a ring closure by an application of the sila-Pummerer reaction. In spite of the difficulty described in removing the *N*-acetyl protecting group, we believe the general synthetic strategy employed provides a versatile approach to the synthesis of eudistomins of this structural type and to the novel 1,3,7-oxathiazepine ring system in general. Further synthetic studies in this area and an investigation of the potentially interesting thiazepine-fused product **30** are continuing.

Experimental

Most of the intermediates and reagents used in this study were obtained from commercial suppliers and were used without further purification. 1,3-Dithiane, however, was freshly sublimed prior to use. Solutions of hydrogen peroxide (30% solution in water) and *n*-butyllithium (1.8 M and 2.5 M in hexanes) were titrated before use. Dry DMF, nitromethane, and dichloromethane were obtained by distillation from P_2O_5 and stored over 3 Å molecular sieves. Methanol was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

distilled from magnesium methoxide and acetonitrile and triethylamine were distilled from calcium hydride and stored over 3 Å molecular sieves. Absolute ethanol, pyridine (Analar^R grade), and benzene (ACS grade) were used without further purification. THF, diethyl ether, and toluene were freshly distilled from sodium/benzophenone immediately before use.

The silica gel (Merck) used in flash chromatography or chromatography was grade 60, 230–400 mesh, 60 Å. The R_f values used in several chromatographic separations are taken from the corresponding analytical TLC separations on plastic sheets coated with silica gel 60 F_{254} (Merck) or aluminum sheets coated with aluminum oxide 60 F_{254} (Merck), run under the solvent conditions specified. The neutral alumina (BDH) used was deactivated by long storage (>5 years). Preparative thin-layer chromatographic plates were from Merck; silica gel code: 13792; alumina code: Typ T.

Short-path (molecular) distillations were carried out on a Kugelrohr apparatus. Melting points were determined in open-ended glass capillary tubes on an Electrothermal melting point apparatus and are uncorrected.

Infrared spectra were run as KBr pellets or neat films on NaCl discs, as indicated, on a Nicolet 5DXB Fourier transform infrared spectrometer. ^{1}H NMR spectra were routinely run at 60 MHz on a Varian EM360-L spectrometer in $CDCl_3$, DMSO-d_6, and acetone-d_6, using tetramethylsilane as internal standard, or in D_2O, using sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) as internal standard. Additionally, ^{13}C and 400 MHz ^{1}H NMR spectra were run on a Varian XL 400 instrument. Mass spectra were routinely run under electron impact conditions on a VG11-250S instrument at 70 eV, unless otherwise stated. Optical rotations were measured on an Optical Activity Ltd polarimeter, model AA-10, path length 2 dm. Elemental analyses were performed by the Scandinavian Microanalytical Laboratory, Box 25, DK-2730 Herlev, Denmark.

*5-Bromoindole-3-carbaldehyde, **8***

Following the procedure of Smith (15), phosphorus oxychloride (13.5 mL, 0.147 mol) was added to dry DMF (110 mL) stirring at 10°C under nitrogen, dropwise during 15 min. To the solution at 15–20°C was added 5-bromoindole **6** (21.1 g, 0.108 mol), dissolved in dry DMF (125 mL), dropwise during 15 min. The reaction mixture was warmed to 35–40°C during 1.5 h; it turned to a yellow paste and, after 2 h at 35–40°C, was cooled to 25°C during 1.5 h, poured onto crushed ice (1850 g), and allowed to warm to 25°C during 3 h, giving a clear pink solution. Sodium hydroxide (26.0 g), dissolved in water (95 mL), was added dropwise to give a yellow solution containing a white precipitate. This was quickly brought to boiling for 2 min, and allowed to stand at 25°C overnight. The beige solid was collected by filtration, washed with water (4 L), and dried to give **8** (23.45 g, 97%), mp 202–203.5°C. Compound **8** obtained in this manner was suitable for use in subsequent reactions. Recrystallization from 35% ethanol (90% recovery) gave **8**, mp 204.5–205°C (lit. (38) mp 205°C); IR (KBr) ν: 3211, 2837, 1642 cm^{-1}; ^{1}H NMR (DMSO-d_6) δ: 11.2 (br s, 1H, exch, *ind-NH*), 9.9 (s, 1H, *CHO*), 8.3 (s, 1H, *H-2*), 8.2 (m, 1H, *H-4*), 7.4 (m, 2H, *H-6*, *H-7*) ppm; MS *m/z* (%): 225 (95), 224 (80), 223 (100), 222 (85), 196 (14), 194 (15), 169 (10), 167 (9), 143 (18).

*2-(5′-Bromo-3′-indolyl)-1-nitroethene, **9***

Following the procedure of Young (39), nitromethane (110 mL) was added to the aldehyde **8** (9.20 g, 41.1 mmol) and ammonium acetate (1.05 g, 13.3 mmol) under nitrogen. The reaction mixture was refluxed (oil bath, 110–120°C) for 2 h. The dark solution was allowed to stand at 25°C overnight, forming red crystals that were collected by suction filtration. The crystals were washed with toluene (2 × 50 mL) and dried to give **9** (7.80 g, 71%), mp 196.5–198.5°C. Recrystallization from methanol (70% recovery) did not raise the melting point (lit. (14) mp 192–193.5°C); IR (KBr) ν: 3454, 1602, 1522, 1477, 1310, 1295, 1272, 1203, 1117 cm^{-1}; ^{1}H NMR (DMSO-d_6) δ: 12.0 (br s, 1H, exch, *ind-NH*), 8.4 (d, J = 14 Hz, 1H, *vinylic H*), 8.3 (s, 1H, *H-2*), 8.2 (m, 1H, *H-4*), 8.1 (d, J = 14 Hz, 1H, *vinylic H*), 7.3 (m, 2H, *H-6*, *H-7*) ppm; MS *m/z* (%): 268 (90), 266 (95), 221 (60), 219 (55), 141 (100).

*5-Bromotryptamine, **10***

Following a general procedure by Ho *et al.* (14), dry THF (25 mL) was added to lithium aluminum hydride (1.00 g, 26.6 mmol) under nitrogen at 0–5°C dropwise, to give a grey slurry, followed by the nitroolefin **9** (1.25 g, 4.68 mmol), dissolved in dry THF (20 mL), during 20 min. The reaction mixture was refluxed for 4 h and stirred at 25°C for a further 18 h, before adding cold water (30 mL) dropwise at 0–5°C, followed by diethyl ether (50 mL). Filtration through Celite was followed by extraction of the aqueous layer with ether. The combined extracts were washed with 2 M HCl (3 × 40 mL). The combined aqueous extracts were rewashed with ether (2 × 25 mL), basified with concentrated NaOH, and extracted thoroughly with ether (3 × 40 mL). The ether layer was dried (Na_2SO_4) and concentrated to give **10** (0.93 g, 83%) as an amber oil. IR (CH_2Cl_2) ν: 3469, 3375, 3140, 3055, 2936, 2863, 1610, 1590, 1568, 1460, 1420, 1095 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 9.8 (br s, 1H, exch, *ind-NH*), 7.7 (d, J = 1.5 Hz, 1H, *H-4*), 7.2 (m, 2H, *H-7*, *H-8*), 6.9 (s, 1H, *H-2*), 3.0 (m, 4H, -CH_2CH_2-), 1.7 (br s, 2H, exch, NH_2) ppm; ^{13}C NMR (DMSO-d_6)[8] δ: 22.8 (*ind-CH_2*), 39.3 (*CH_2-N*), 109.5 (*C-3*), 111.2 (*C-5*), 113.6 (*C-7*), 120.5 (*C-4*), 123.6 (*C-6*), 125.2 (*C-2*), 128.8 (*C-3a*), 135.0 (*C-7a*) ppm; MS *m/z* (%): 240 (15), 238 (15), 211 (60), 210 (60), 209 (60), 208 (60), 130 (25), 129 (35).

*2-(5′-Bromo-3′-indolyl)-1-nitroethane, **11***

To the nitroolefin **9** (4.6 g, 17.2 mmol) dissolved in dry THF (80 mL) and methanol (10.3 mL) was added, portionwise during 10 min, sodium borohydride (0.92 g, 24.3 mmol). On being stirred at 25°C for 1 h, the reaction mixture foamed and became lighter in colour. Cold water (170 mL) and cold 1 M HCl (50 mL) were added and the THF and methanol were evaporated at a bath temperature of 30–35°C. The dark-brown, oily residue was taken into dichloromethane (100 mL), the aqueous layer was extracted with dichloromethane (2 × 25 mL), the combined organic layers were washed (5% $NaHCO_3$ aq., saturated NaCl), dried (Na_2SO_4), and concentrated to give **11** (4.62 g, 100%), as a dark-brown, thick oil. Column chromatography on silica gel, eluting with dichloromethane, gave **11** (3.65 g, 79%) (R_f 0.40) as a beige solid. Recrystallization from hexanes–chloroform (3:1) (78% recovery) gave pure **11** (2.83 g) as golden yellow needles, mp 91–92.5°C. (Concentration of the mother liquor gave **11** (0.80 g), which, combined with similar concentrates from other preparations and rechromatographed, gave **11** suitable for use in subsequent reactions.) IR (KBr) ν: 3411, 3133, 2968, 1551, 1543, 1385, 1095, 801 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 8.1 (br s, 1H, *ind-NH*), 7.6 (s, 1H, *H-4*), 7.2 (s, 2H, *H-6*, *H-7*), 6.9 (d, J = 3 Hz, 1H, *H-2*), 4.6 (t, J = 7 Hz, 2H, *CH_2NO_2*), 3.3 (t, J = 7 Hz, 2H, *ind-CH_2*) ppm; MS *m/z* (%): 270 (50), 268 (50), 224 (35), 223 (80), 222 (35), 221 (80), 210 (20), 208 (20), 143 (100). Anal. calcd. for $C_{10}H_9BrN_3O_2$: C 44.63, H 3.37, Br 29.70, N 10.41; found: C 44.59, H 3.40, Br 29.87, N 10.30.

*5-Bromo-N′-hydroxytryptamine, **4***

Method A: Following a procedure similar to that reported by Fieser and Fieser (40) for the preparation of aluminum amalgam, and by Shin *et al.* (41) for the aluminum amalgam reduction of saturated nitro compounds to hydroxylamines, aluminum powder (0.52 g, 19.3 mmol), washed with 1 M NaOH (50 mL), then with water (25 mL), swirled in 0.5% $HgCl_2$ (90 mL) for 1.25 min, and washed successively with water (30 mL), 95% ethanol (30 mL), and diethyl ether (2 × 25 mL), was covered with ether (15 mL), under nitrogen. The saturated nitro compound **11** (0.60 g, 2.23 mmol) in ether (30 mL) was added dropwise during 0.5 h. Water (2 × 5 drops) was added, effervesence was observed at the metal surface, and the reaction mixture was stirred at 25°C for 2.5 h with water (25 drops total) added periodically. Ether (50 mL) was added, the solids removed by suction filtration through Celite and washed with ether (2 × 25 mL), and the combined organic extracts washed with saturated NaCl (75 mL), dried (Na_2SO_4), and concentrated to give **4** (0.45 g, 79%) as a light yellow oil. The IR and NMR spectra of **4** prepared in this manner were essentially identical to those obtained using Method B (see below).

[8]This spectrum was recorded for the hydrochloride salt.

For personal use only.

Method B: Following a procedure by Corey and Estreicher (42), zinc dust (0.36 g, 5.51 mmol) was washed with 17.5% ammonium chloride solution (10 mL) for 1–2 min and with water (2 × 10 mL), and was added to the saturated nitro compound **11** (0.25 g, 0.93 mmol), dissolved in THF (10 mL) and water (5 mL) containing ammonium chloride (0.10 g, 1.87 mmol), under nitrogen. Unwashed zinc dust (0.10 g, 1.53 mmol) was added and the reaction mixture stirred at 25°C for 2.5 h. Diethyl ether (50 mL) was added, the solids were removed by filtration through Celite and washed with ether (2 × 25 mL), and the clear, colourless filtrate concentrated. The residue was dissolved in dichloromethane (50 mL), washed with saturated NaCl (25 mL), dried (Na_2SO_4), and concentrated to give **4** (0.22 g, 93%), as a pale beige, resinous material. Compound **4** obtained in this manner was used in subsequent reactions without further purification. IR (film) ν: 3428, 3264, 2921, 2858, 1617, 1566, 1460, 1422, 1266, 1097, 1051, 883, 793 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 8.2 (br s, 1H exch, *ind-NH*), 7.7 (s, 1H, *H-4*), 7.2 (m, 2H, *H-6*, *H-7*), 6.9 (m, 1H, *H-2*), 5.5 (br s, 2H, exch, *NHOH*), 3.1 (m, 4H, CH_2CH_2) ppm; ^{13}C NMR (DMSO-d_6)[9] δ: 23.0 (*ind-*CH_2), 51.9 (CH_2-*N*), 109.5 (*C-3*), 111.1 (*C-5*), 113.5 (*C-7*), 120.5 (*C-4*), 123.5 (*C-6*), 125.0 (*C-2*), 128.9 (*C-3a*), 135.0 (*C-7a*) ppm; MS *m/z* (%): 256 (6), 254 (11), 252 (6), 240 (14), 238 (25), 236 (19), 234 (9), 211 (87), 210 (100), 209 (90), 208 (93), 129 (50); MS (CI) *m/z* (%): 266 (22), 264 (28), 257 (22), 255 (30), 241 (83), 240 (26), 239 (100), 238 (100), 237 (17), 224 (66), 222 (67), 211 (31), 210 (32), 209 (32), 208 (25).

L-Cysteine methyl ester hydrochloride, 12

L-Cysteine (18.3 g, 0.151 mol) was slurried in dry methanol (350 mL) and hydrogen chloride was bubbled into the reaction mixture for 5 min at 25°C, accompanied by periodic cooling (ice bath). The reaction mixture was stirred at 25°C for 21 h, before concentrating to a volume of 100 mL. Diethyl ether (250–300 mL) and isopropyl alcohol (25–50 mL) were added and a white precipitate began to form. After standing overnight at 25°C, the white solid was collected by filtration, washed with isopropyl alcohol (2 × 25 mL) and ether (2 × 50 mL), and dried to give **12** (18.80 g, 73%), mp 134–138°C (lit. (23) mp 143°C); $[\alpha]_D^{25}$ −2.5° (*c* 10.0, MeOH) (lit. (23) $[\alpha]_D^{32}$ −3.0° (*c* 10, MeOH)). Storage of the filtrate at −15°C for 24 h gave a second crop of **12** (2.88 g, 11%), mp 136–139°C; IR (KBr) ν: 2990, 2843, 2642, 1747 cm^{-1}; ^1H NMR (D_2O) δ: 4.2 (t, *J* = 5 Hz, 1H, *CH*), 3.6 (s, 3H, CH_3), 2.9 (d, *J* = 5 Hz, 2H, CH_2) ppm.

L-Cysteine methyl ester, 12a

The hydrochloride **12** (11.2 g, 0.0653 mol) was dissolved in water (85 mL) containing sodium bicarbonate (9.70 g, 0.115 mol). The solution was saturated with sodium chloride and extracted thoroughly with dichloromethane. The combined organic extracts were washed (saturated NaCl), dried (Na_2SO_4), and concentrated to give the free base, **12***a* (7.50 g, 85%), as a slightly purple-tinged oil. IR (film) ν: 3380, 3311, 3000, 2954, 2846, 2568, 1738 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 3.8 (s, 3H, CH_3), 3.7 (t, *J* = 5 Hz, 1H, *CH*), 2.8 (d, *J* = 5 Hz, 2H, CH_2), 1.8 (br s, 3H, exch, NH_2, *SH*) ppm.

S-*(Trimethylsilylmethyl)-L-cysteine methyl ester, 13*

To the free base **12***a* (7.45 g, 0.0551 mol), dissolved in dry DMF (250 mL) under nitrogen, was added potassium carbonate (15.9 g, 0.115 mol) and chloromethyltrimethylsilane (10.0 mL, 0.0688 mol) and the reaction mixture was stirred at 25°C for 16 h. The pale yellow, cloudy reaction mixture was concentrated *in vacuo* (bath temperature 40°C) and the orange paste so obtained was partitioned between water (200 mL) and diethyl ether (250 mL). The aqueous layer was extracted with ether (2 × 50 mL) and the combined ether extracts washed (saturated NaCl) and concentrated. The residual oil was taken into dichloromethane (125 mL), washed (saturated NaCl), dried (Na_2SO_4), and concentrated to give a yellow oil. Kugelrohr distillation gave **13** (9.52 g, 78%), bath temperature 120–125°C/0.20 Torr (1 Torr = 133.3 Pa), $[\alpha]_D^{25}$ +16.5° (*c* 7.0, CH_2Cl_2), as a colorless, mobile liquid. IR (film) ν: 3380, 3311, 2956, 2895, 1738, 1679, 1248, 844 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 3.7 (s, 3H, CH_3), 3.6 (m, 1H, *CH*), 2.8 (m, 2H, CH_2S), 1.8 (s, 2H, SCH_2Si), 1.7 (br s, 2H, exch, NH_2), 0.1 (s, 9H, $Si(CH_3)_3$) ppm. Compound **13** was used in subsequent reactions immediately after distillation, as storage at room temperature for several hours caused considerable darkening.

N-*Acetyl-S-(trimethylsilylmethyl)-L-cysteine methyl ester, 14*

To the free base **13** (9.52 g, 0.0430 mol) in dry dichloromethane (350 mL) were added triethylamine (28.0 mL, 0.201 mol) and acetic anhydride (7.5 mL, 0.0795 mol) and the reaction mixture was stirred under nitrogen at 25°C for 22 h. The beige mixture was diluted with dichloromethane (50 mL), washed with water (100 mL), 1 M HCl (2 × 100 mL), 10% $NaHCO_3$ solution (2 × 50 mL), water (100 mL), and saturated NaCl (100 mL), dried (Na_2SO_4), and concentrated to give a thick oil. Kugelrohr distillation gave **14** (10.69 g, 94%), bath temperature 180–190°C/0.20 Torr, $[\alpha]_D^{25}$ +35.0° (*c* 5.0, toluene), as a beige-tinged oil. IR (film) ν: 3286, 3065, 2954, 2898, 2847, 1749, 1658, 1250, 848 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 6.4 (br d, 1H, *NH*), 4.8 (m, 1H, *CH*), 3.7 (s, 3H, OCH_3), 3.0 (d, *J* = 6 Hz, 2H, CH_2S), 2.1 (s, 3H, $COCH_3$), 1.8 (s, 2H, SCH_2Si), 0.1 (s, 9H, $Si(CH_3)_3$) ppm; MS *m/z* (%): 263 (12), 217 (19), 216 (14), 204 (48), 173 (21), 158 (33), 133 (28), 100 (62), 73 (100); HRMS observed: 263.1006; calcd. for $C_{10}H_{21}NO_3SSi$: 263.1011. Anal. calcd. for $C_{10}H_{21}NO_3SSi$: C 45.59, H 8.04, N 5.32, S 12.17; found: C 45.34, H 8.03, N 5.47, S 12.22.

N-*Acetyl-S-(trimethylsilylmethyl)-L-cysteine aldehyde, 5*

To compound **14** (2.15 g, 8.13 mmol), dissolved in dry toluene (81 mL) under nitrogen, was added a 1.0 M solution of diisobutylaluminum hydride in toluene (21.0 mL, 0.021 mol) at −60°C during 20 min. Some effervesence was observed and the colorless reaction mixture was stirred at −60°C for 2.5 h. Methanol (2.2 mL), followed by sodium potassium tartrate (22 g) dissolved in water (100 mL), was added dropwise at −60°C and the reaction mixture was allowed to warm to room temperature. Diethyl ether (100 mL) was added, the organic layer was separated, the aqueous layer extracted with ether (100 mL), and the combined organic extracts washed (saturated NaCl), dried (Na_2SO_4), and concentrated to give a yellow, very viscous oil. Flash chromatography on silica gel, eluting with dichloromethane – ethyl acetate (1:1), gave **5** (1.04 g, 55%) (R_f 0.25), as a clear oil; IR (film) ν: 3286, 3065, 2957, 2897, 2825, 2727, 1736, 1654, 1249, 847 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 9.6 (s, 1H, *CHO*), 6.4 (br s, 1H, *NH*), 4.7 (m, 1H, *CH*), 3.0 (d, *J* = 6 Hz, 2H, CH_2S), 2.1 (s, 3H, $COCH_3$), 1.8 (s, 2H, SCH_2Si), 0.1 (s, 9H, $Si(CH_3)_3$) ppm; MS *m/z* (%): 233 (5), 204 (16), 174 (40), 173 (28), 159 (37), 158 (55), 133 (52), 105 (41), 73 (100). Compound **5** was normally used in the subsequent reactions in the crude form, without purification, immediately after preparation.

6-Bromo-1,2,3,4-tetrahydro-β-carboline, 17

5-Bromotryptamine (**10**) hydrochloride (1.43 g, 5.19 mmol) in water (19.0 mL) was heated at 90°C (water bath). Glyoxylic acid monohydrate (0.52 g, 5.62 mmol) in water (1.0 mL) was added dropwise during 1 min, and the reaction mixture was adjusted to pH 3.5 by the addition of KOH (0.31 g, 5.52 mmol) in water (1.5 mL) and several drops of concentrated HCl. A beige precipitate formed, the reaction mixture was stirred at 25°C for 2 h, and a green-beige solid was collected by filtration and washed with water (2 × 5 mL). The solid was resuspended in water (10 mL) containing concentrated HCl (1.5 mL) and brought to the boil. Concentrated HCl (1.5 mL) was added; the reaction mixture was boiled for 0.5 h and then allowed to cool to room temperature. A grey solid was collected by filtration and washed with water (2 × 5 mL). The solid was resuspended in water (10 mL) and the mixture was adjusted to pH 12 with a concentrated solution of KOH. After 1 h at 40°C, a beige solid was collected by filtration, washed with water (3 × 5 mL) and dried to give crude **17** (0.92 g, 71%), mp 225–227°C. Recrystallization from methanol (65% recovery, 2 crops) gave **17**, mp 234–237°C; IR (KBr) ν: 3444, 3302, 3131, 3027, 2909, 2840, 2727, 1436, 798 cm^{-1}; ^1H NMR (DMSO-d_6) δ: 11.0 (s, 1H, exch, *ind-NH*), 7.6 (m, 1H, *H-5*), 7.2 (m, 2H, *H-7*, *H-8*), 3.9 (s, 2H, *H-1*), 3.2 (m, 3H, N(2)-H, exch, *H-3*),

[9]This spectrum was recorded for the hydrogen oxalate salt.

2.6 (m, 2H, *H-4*) ppm; MS *m/z* (%): 252 (25), 251 (10), 250 (30), 249 (10), 223 (95), 222 (10), 221 (100), 220 (15). Anal. calcd. for $C_{11}H_{11}BrN_2$: C 52.61, H 4.42, Br 31.82, N 11.16; found: C 52.79, H 4.63, Br 31.65, N 11.06.

6-Bromo-3,4-dihydro-β-carboline 2-oxide, ***18***

Following the procedure of Murahashi and co-workers (28), to compound **17** (0.46 g, 1.83 mmol), dissolved in 95% ethanol (46 mL) at 0–5°C, was rapidly added sodium tungstate dihydrate (0.05 g, 0.152 mmol). A 30% aqueous solution of hydrogen peroxide (0.65 mL, 5.73 mmol) in 95% ethanol was added dropwise during 15 min and the reaction mixture was stirred at 0–5°C for 1.5 h. Water (20 mL) was added, the reaction mixture stirred at 25°C for 2 h, dichloromethane (100 mL) was added, and the organic layer washed (dilute $NaHSO_3$ (2 × 25 mL), saturated NaCl (50 mL)), and concentrated. Column chromatography on neutral alumina, eluting with dichloromethane–methanol (85:15), gave **18** (0.08 g, 17%), as a beige amorphous solid that was not recrystallized. ^{1}H NMR (DMSO-d_6) δ: 11.4 (br s, 1H, exch, *ind-NH*), 7.8 (s, 1H, *H-1*), 7.7 (m, 1H, *H-5*), 7.3 (m, 2H, *H-7, H-8*), 4.2 (t, *J* = 8 Hz, 2H, *H-3*), 3.2 (t, *J* = 8 Hz, 2H, *H-4*) ppm.

N-*[2′-(5″-Bromo-3″-indolyl)ethyl]-2-propanimine* N-*oxide,* ***19****a*

Acetone (7 mL) was added to a solution of **4** (0.275 g, 1.1 mmol) in dry dichloromethane (16 mL). The reaction mixture was stirred in the presence of silica gel for 3 h, during which time the colour went from light yellow to deep brown. After removal of the solvent the residue was dissolved in dichloromethane and the resulting solution washed (5% $NaHCO_3$, saturated NaCl), dried (Na_2SO_4), and concentrated to give 0.29 g of material. Chromatography on a preparative TLC plate using CH_2Cl_2:MeOH = 9:1 gave **19***a* (0.26 g, 80%), mp 65–70°C, used in the subsequent reaction without further purification. ^{1}H NMR ($CDCl_3$) δ: 9.3 (s, 1H, exch, *NH*), 7.7 (s, 1H, *H-4″*), 7.3 (s, 2H, *H-6″, H-7″*), 7.0 (d, 1H, *H-2″*), 4.1 (t, 2H, *H-1′*), 3.3 (t, 2H, *H-2′*), 2.2 (s, 3H, CH_3), 1.7 (s, 3H, CH_3) ppm; MS *m/z* (%): 296 (4), 278 (16), 223 (65), 209 (40), 70 (100).

N-*[2′-(5″-Bromo-3″-indolyl)ethyl] acetaldimine* N-*oxide,* ***19****b*

To **4** (1.28 g, 5.02 mmol) in dry dichloromethane (115 mL), under nitrogen and cooled to 0–5°C, was added acetaldehyde (1.0 mL, 17.7 mmol) and anhydrous magnesium sulfate (5.15 g, 42.8 mmol). The reaction mixture was stirred for 8 h and allowed to warm to 25°C during 1 h. The pink-tinged reaction mixture was filtered and concentrated to give a beige solid. Column chromatography on neutral alumina, eluting with dichloromethane–methanol (96:4), gave **19***b* (0.65 g, 46%) (R_f 0.50), as a beige foam, mp 60–70°C; IR (KBr) *ν*: 3553, 3483, 3417, 3239, 2925, 1618, 1457, 1385, 1166, 1103 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 9.4 (br s, 1H, *ind-NH*), 7.8 (s, 1H, *H-4″*), 7.3 (m, 2H, *H-6″, H-7″*), 7.1 (d, *J* = 2 Hz, 1H, *H-2″*), 6.6 (q, *J* = 6 Hz, 1H, *HC*=*N*), 4.1 (t, *J* = 7 Hz, 2H, *H-1′*), 3.4 (t, *J* = 7 Hz, 2H, *H-2′*), 1.9 (d, *J* = 6 Hz, 3H, CH_3) ppm; MS *m/z* (%): 223 (90), 221 (100), 210 (18), 208 (17). Compound **19***b* could be used in subsequent reactions without prior chromatographic purification.

6-Bromo-1,1-dimethyl-2-hydroxy-1,2,3,4-tetrahydro-β-carboline, ***20****a*

The nitrone **19***a* (0.07 g, 2.3 mmol) was stirred briefly in a solution of CH_2Cl_2 (10 mL) with trifluoroacetic acid (0.5 mL) and the solution was refluxed for 6 h. Solvent was evaporated and the residue (0.06 g) taken up in CH_2Cl_2. The CH_2Cl_2 solution was washed (5% $NaHCO_3$), dried (Na_2SO_4), and concentrated to give 0.04 g of residue. Recrystallization ($CHCl_3$/*n*-hexane) gave 10 mg (15%) of **20***a*, mp 158–160°C; ^{1}H NMR ($CDCl_3$) δ: 7.8 (s, 1H, exch, *N-H*), 7.5 (s, 1H, *H-5*), 7.2 (s, 2H, *H-7, H-8*), 3.2 (t, 2H, *H-3*), 2.7 (t, 2H, *H-4*), 1.5 (s, 6H, CH_3) ppm.

6-Bromo-2-hydroxy-1-methyl-1,2,3,4-tetrahydro-β-carboline, ***20****b*

To the chromatographed nitrone **19***b* (0.10 g, 0.36 mmol) in dry dichloromethane (10 mL), under nitrogen at 25°C, was added trifluoroacetic acid (0.3 mL, 0.40 mmol). The reaction mixture darkened and was stirred at 25°C for 20 h. Dichloromethane (25 mL) was added and the reaction mixture washed (5% $NaHCO_3$ solution (2 × 25 mL), saturated NaCl (25 mL)), dried (Na_2SO_4), and concentrated to give crude **20***b* (0.09 g, 90%), as a beige solid, mp 175–180°C. Compound **20***b* could not be further purified. (Later preparations gave **20***b*, mp 190–193°C.) IR (KBr) *ν*: 3551, 3413, 3346, 3237, 2974, 2921, 2901, 2848, 2826, 1639, 1616, 1440, 1305 cm^{-1}; ^{1}H NMR (acetone-d_6)[10] δ: 10.4 (br s, 1H, exch, *ind-NH*), 7.6 (s, 1H, *H-5*), 7.5 (br s, 1H, exch, *N-OH*), 7.4 (m, 2H, *H-7, H-8*), 4.2 (q, *J* = 7 Hz, 1H, *H-1*), 3.0 (m, 4H, *H-3, H-4*), 1.6 (d, *J* = 7 Hz, 3H, CH_3) ppm; MS *m/z* (%): 282 (27), 280 (29), 265 (16), 264 (19), 263 (19), 262 (24), 261 (15), 260 (14), 237 (95), 235 (100); HRMS observed: 280.0204, 282.0206; calcd. for $C_{12}H_{13}BrN_2O$: 280.0197, 282.0221.

6-Bromo-1-methyl-2-trimethylsilyloxy-1,2,3,4-tetrahydro-β-carboline, ***24****a*

To crude **20***b* (0.27 g, 0.96 mmol) in dry dichloromethane (48 mL) under nitrogen at 0–5°C was added *N*-(trimethylsilyl)imidazole (0.20 mL, 1.36 mmol) at once, and the reaction mixture was stirred at 0–5°C for 1.5 h. The ice-bath was removed, dichloromethane (50 mL) was added, and the amber-coloured reaction mixture was washed (water (3 × 75 mL), saturated NaCl (50 mL)), dried (Na_2SO_4), and concentrated to give a brown solid. Flash chromatography on silica gel, eluting with dichloromethane–acetone (96:4), gave **24***a* (0.08 g, 24%) (R_f 0.40) as a colourless glassy solid, mp 47–67°C; IR (KBr) *ν*: 3420, 3322, 2962, 2933, 2905, 2846, 1439, 1250, 842 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 7.7 (br s, 1H, *ind-NH*), 7.5 (s, 1H, *H-5*), 7.1 (m, 2H, *H-7, H-8*), 3.9 (br q, 1H, *H-1*), 3.2 (m, 2H, *H-3*), 2.8 (m, 2H, *H-4*), 1.4 (d, *J* = 7 Hz, 3H, CH_3), 0.2 (s, 9H, $Si(CH_3)_3$) ppm; MS *m/z* (%): 354 (37), 352 (34), 339 (33), 337 (32), 238 (16), 237 (100), 236 (35), 235 (98), 234 (20), 75 (20), 73 (28).

2-Acetoxy-6-bromo-1-methyl-1,2,3,4-tetrahydro-β-carboline, ***24****b*

To compound **20***b* (0.10 g, 0.36 mmol), slurried in dry dichloromethane (7 mL) under nitrogen at 25°C, was added triethylamine (0.25 mL, 1.88 mmol). Acetic anhydride (0.05 mL, 0.53 mmol) was added and the reaction mixture stirred at 25°C for 5 h. Dichloromethane (50 mL) was added and the organic phase was washed (water (4 × 50 mL), saturated NaCl (50 mL)), dried (Na_2SO_4), and concentrated to give a brown oil. Column chromatography on silica gel, eluting with dichloromethane–acetone (90:10), gave **24***b* (0.06 g, 55%) (R_f 0.25) as a beige solid, mp 151–153°C. Recrystallization from ethyl acetate – hexane (1:1) gave **24***b* as beige crystals, mp 155–156.5°C; IR (KBr) *ν*: 3370, 3068, 2968, 2920, 2844, 1732, 1242, 1009 cm^{-1}; ^{1}H NMR ($CDCl_3$–acetone-d_6) δ: 9.1 (br s, 1H, *ind-NH*), 7.6 (d, *J* = 2 Hz, 1H, *H-5*), 7.2 (s, 2H, *H-7, H-8*), 4.4 (q, *J* = 7 Hz, 1H, *H-1*), 3.5 (m, 2H, *H-3*), 2.8 (t, *J* = 7 Hz, 2H, *H-4*), 2.1 (s, 3H, $COCH_3$), 1.5 (d, *J* = 7 Hz, 3H, CH_3) ppm; HRMS observed: 322.0310, 324.0294; calcd. for $C_{14}H_{15}BrN_2O_2$: 322.0304, 324.0292.

2-Methyl-1,3-dithiane-2-carbaldehyde, ***21***

This was prepared by the procedure of Seebach (29) from 2-methyl-1,3-dithiane, in turn prepared by methylation of 1,3-dithiane (29). Kugelrohr distillation gave **21** (2.30 g, 60%), bath temperature 140–150°C/7.0 Torr (lit. (29) bp 60°C/0.06 Torr), as a pale yellow liquid; IR (film) *ν*: 2962, 2924, 2865, 2814, 2702, 1717 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 9.0 (s, 1H, *CHO*), 3.2–1.8 (complex m, 6H, *H-4, H-5, H-6*), 1.5 (s, 3H, CH_3) ppm.

N-*[2′-(5″-bromo-3″-indolyl)ethyl]-2-methyl-1,3-dithiane-2-carbaldimine* N-*oxide,* ***22***

To 5-bromo-*N′*-hydroxytryptamine **4** (0.50 g, 1.96 mmol) in dry dichloromethane (40 mL) under nitrogen and at 0–5°C, was added **21** (0.40 g, 2.46 mmol), in dry dichloromethane (20 mL), followed by anhydrous magnesium sulfate (1.90 g, 15.8 mmol). The reaction mixture was stirred at 0–5°C for 8 h and allowed to warm to 25°C during 1 h before filtering and concentrating to give a white solid. Column chromatography on neutral alumina, eluting with dichloromethane–methanol (97.5:2.5), gave **22** (0.65 g, 83%) (R_f 0.50). Recrystallization from dichloromethane gave white, granular crystals, mp 182–184°C; IR (KBr) *ν*: 3230, 3081, 2935, 2901, 2825, 1584,

[10]Compound **20***b* was not very soluble in this solvent, hindering complete interpretation of the spectrum.

1-[1′-Acetamido-2′-(trimethylsilylmethylthio)ethyl]-6-bromo-2-trimethylsilyloxy-1,2,3,4-tetrahydro-β-carboline, ***25***b

To **25***a* (0.56 g, 1.19 mmol), slurried in dry dichloromethane (50 mL) under nitrogen and at 0–5°C, was added *N*-(trimethylsilyl)imidazole (0.25 mL, 1.70 mmol). The reaction mixture was stirred at 0–5°C until all the solids dissolved. Dichloromethane (50 mL) was added and the reaction mixture washed (water (3 × 100 mL), saturated NaCl (100 mL)), dried (Na_2SO_4), and concentrated, to give **25***b* as a pale yellow solid (0.60 g, 90%), mp 85–100°C; IR (KBr) *ν*: 3312, 3076, 2957, 2909, 2844, 1656, 1248, 844 cm^{-1}; ^1H NMR ($CDCl_3$)[11] δ: 8.9 (br s, 1H, *ind-NH*), 7.6 (s, 1H, *H-5*), 7.2 (m, 2H, *H-7*, *H-8*), 6.4 (br s, 1H, *NH-Ac*), 4.5 (m, 2H, *H-1*, *H-10*), 3.5–2.6 (m, 6H, *H-3*, *H-4*, *H-11*), 2.0 (s, 3H, CH_3), 1.8 (s, 2H, *H-13*), 0.2 (s, 9H, $OSi(CH_3)_3$), 0.1 (s, 9H, $Si(CH_3)_3$) ppm; MS *m/z* (%): 544 (0.2), 543 (0.2), 542 (0.2), 541 (0.19), 528 (2), 526 (2), 340 (21), 339 (100), 338 (20), 337 (95), 249 (19), 247 (17), 75 (12), 73 (35).

1-[1′-Acetamido-2′-(trimethylsilylmethylsulfinyl)ethyl]-6-bromo-2-hydroxy-1,2,3,4-tetrahydro-β-carboline, ***28***a

To compound **25***a* (0.94 g, 2.0 mmol) in dry THF (60 mL) under nitrogen was added sodium bicarbonate (0.60 g, 7.13 mmol). At 0–5°C *m*-chloroperoxybenzoic acid (80%, 0.60 g, 2.78 mmol) in dry THF (40 mL) was added dropwise during 20 min. The reaction mixture was stirred at 0–5°C for 2 h, dichloromethane (125 mL) was added, and the solution was washed (2.5% $Na_2S_2O_3$ (2 × 100 mL), saturated NaCl (100 mL)), dried (Na_2SO_4), and concentrated to give a yellow solid. This residue was taken into dichloromethane (25 mL) at reflux, cooled to room temperature, and allowed to stand at 25°C overnight. A pale yellow solid was collected by filtration and washed with dichloromethane (2 × 5 mL) to give **28***a* (0.65 g, 67%), mp 170–175°C; IR (KBr) *ν*: 3352, 3271, 2952, 2920, 2842, 1661, 1507, 1251, 1006, 848 cm^{-1}; ^1H NMR (DMSO-d_6)[11] δ: 10.7 (br s, 1H, exch, *ind-NH*), 8.3 (s, 1H, exch, *N-OH*), 7.8 (br d, 1H, *NH-Ac*), 7.6 (s, 1H, *H-5*), 7.3 (m, 2H, *H-7*, *H-8*), 4.8 (br m, 1H, *H-10*), 4.1 (br s, 1H, *H-1*), 3.2–2.5 (br m, 6H, *H-3*, *H-4*, *H-11*), 2.3 (s, 2H, *H-13*), 1.9 (s, 3H, CH_3), 0.15 (s, 9H, $Si(CH_3)_3$) ppm; MS *m/z* (%): 487 (3), 485 (3), 470 (16), 468 (16); HRMS observed: 466.0601, 468.0602; calcd. for $C_{19}H_{25}BrN_3O_2SSi$ ($M^+ - H, H_2O$): 466.0582, 468.0604.

N(10)-Acetyleudistomin L, ***2***

To sulfoxide **28***a* (0.34 g, 0.70 mmol) was added dry acetonitrile (34 mL) under nitrogen. The reaction mixture was brought to reflux (oil bath temperature 100°C) during 0.5 h. During this time the solid dissolved and the light yellow reaction mixture was heated at reflux for a further 1 h. The solvent was removed and the residue chromatographed on neutral alumina, eluting with dichloromethane–methanol (98.5:1.5), to give N(10)-acetyleudistomin L **2** (0.045 g, 20%) (R_f 0.70) as a white solid, mp 193.5–195.5°C, after trituration with diethyl ether. Recrystallization from benzene gave crystals suitable for X-ray crystal structure determination (q.v.). IR (KBr) *ν*: 3410, 3229, 3100, 2920, 2847, 1653, 1510, 1446, 1309, 1041, 793 cm^{-1}; ^1H NMR ($CDCl_3$): see Table 1; ^{13}C NMR ($CDCl_3$): see Table 2; MS *m/z* (%): 397 (17), 395 (17), 312 (24), 310 (24), 282 (15), 280 (17), 267 (23), 266 (99), 265 (2), 264 (100), 250 (13), 249 (26), 248 (15), 247 (25), 186 (11), 185 (17), 168 (24); HRMS, observed: 395.0303; calcd. for $C_{16}H_{18}BrN_3O_2S$: 395.0301.

1-[1′-Acetamido-2′-(trimethylsilylmethylsulfinyl)ethyl]-6-bromo-2-trimethylsilyloxy-1,2,3,4-tetrahydro-β-carboline, ***28***b

To compound **25***b* (0.27 g, 0.50 mmol) in dry dichloromethane (25 mL) under nitrogen at 0–5°C was added sodium bicarbonate (0.20 g, 2.38 mmol), followed by *m*-chloroperoxybenzoic acid (80%, 0.12 g, 0.56 mmol) in dry dichloromethane (10 mL) dropwise during 10 min. The reaction mixture was stirred at 0–5°C for 1 h, dichloromethane (50 mL) was added, and the organic phase washed (2% $Na_2S_2O_3$ (2 × 40 mL), 5% $NaHCO_3$ (2 × 40 mL), saturated NaCl (25 mL)), dried (Na_2SO_4), and concentrated to give crude **28***b* (0.26 g, 93%) as a pale yellow–beige solid, mp 95–105°C. Compound **28***b* was used without further purification in the subsequent reaction. IR (KBr) *ν*: 3412, 3083, 2958, 2905, 2847, 1654, 1252, 1015, 844 cm^{-1}; ^1H NMR ($CDCl_3$)[11] δ: 10.2 (s, 1H, *ind-NH*), 7.6 (s, 1H, *H-5*), 7.1 (s, 2H, *H-7*, *H-8*), 6.7 (br s, 1H, *NH-Ac*), 4.3 (br s, 2H, *H-1*, *H-10*), 3.3–2.5 (m, 6H, *H-3*, *H-4*, *H-11*), 2.3–2.1 (2s, 2H, *H-13*), 2.0 (s, 3H, CH_3), 0.2 (s, 18H, $Si(CH_3)_3$, $OSi(CH_3)_3$) ppm.

[11]For ease of reference, we have retained the eudistomin numbering in these NMR spectral assignments.

*10-Acetamido-6-bromo-2-trimethylsilyloxy-1,2,3,4,10,11-hexahydro 13*H*-1,3-thiazepino[3,4,5-1,*m*]-β-carboline, **30***

The sulfoxide **28***b* (0.24 g, 0.43 mmol) was slurried in dry acetonitrile (27 mL) under nitrogen, and the solution brought to reflux during 0.5 h (oil bath temperature 100°C). All the solids dissolved and the reaction mixture was refluxed for 1 h. The solvent was removed and the yellow residue chromatographed on a preparative thin-layer (neutral) alumina plate, eluting with dichloromethane–methanol (98:2), to give **30** (0.035 g, 17%) (R_f 0.85) as a white solid. Recrystallization from 95% ethanol (35% recovery) gave pure **30** as white leaflets, mp 230–234.5°C; IR (KBr) ν: 3551, 3475, 3417, 3260, 3081, 2959, 2935, 2895, 2841, 1646, 1618, 1570, 1249, 935, 889, 844 cm^{-1}; ^1H NMR ($CDCl_3$):[11] see Table 1; ^{13}C NMR ($CDCl_3$):[11] see Table 2; MS *m/z* (%): 469 (0.5), 467 (0.5), 454 (7), 452 (7), 384 (24), 382 (24), 380 (9), 378 (8), 338 (8), 336 (9), 268 (18), 267 (94), 266 (30), 265 (93), 264 (13), 77 (22), 75 (100), 73 (25).

X-ray crystallography[6]

Unit cell dimensions were based upon 25 reflections ($11.2 < \theta < 16.9°$). Intensity data collection (ω–2θ scans over scan ranges ($0.65 + 0.35 \tan\theta$)°, max. scan time = 60 s, octants h, k, $\pm l$ with $2\theta \leq 55°$, and an additional 1762 symmetry related data with negative h and k indices and $2\theta \leq 30°$) gave a total of 6752 data. Scan rates were conditional on information collected in prescans. Three standards collected every 7500 s suffered small (~6%) losses in intensity.

Lorentz, polarization, and crystal decay corrections applied to all reflections. Exclusion of 906 systematically absent or zero F_{obs} data and averaging 1764 symmetry equivalent reflections ($R_{merge}(F) = 0.031$) gave a final data set of 3872 reflections. Structure solution: Patterson function (Br), followed by standard least-squares and Fourier calculations. Hydrogen atoms located in ΔF maps have been allowed to refine. Full matrix least-squares refinements minimizing $\Sigma_i w\Delta F^2$ converged (max. $\Delta/\sigma = 0.26$) to final residuals $R(wR) = 0.044(0.047)$ for 1967 observed data with $I \geq 3\sigma(I)$. Weights: $w = 4F^2[\sigma^2(I) + ((0.033)F^2)^2]^{-1}$, and a final ΔF Fourier contains residual peaks up to 0.74 e $Å^{-3}$ close to Br and the solvent molecule in the lattice.

A ^{19}F magic angle spinning nuclear magnetic resonance and infrared analysis of the adsorption of alkali metal fluorides onto montmorillonite clay

FATHI M. ASSEID, CATHERINE V. A. DUKE, AND JACK M. MILLER[1]

Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received June 26, 1989[2]

FATHI M. ASSEID, CATHERINE V. A. DUKE, and JACK M. MILLER. Can. J. Chem. **68**, 1420 (1990).

Alkali metal fluorides have been adsorbed onto montmorillonite clay K10, and the resulting reagents analysed by ^{19}F magic angle spinning nuclear magnetic resonance and infrared spectroscopy. The complexes M_3SiF_6, $MAlF_4$, and M_3AlF_6 are readily formed, the particular complex depending on M, the loading, and the drying temperature employed. Chemisorption of fluoride to give surface -Si-F groups also occurs under certain conditions.

Key words: MAS NMR, alkali metal fluorides, adsorption, montmorillonite clay, infrared.

FATHI M. ASSEID, CATHERINE V. A. DUKE et JACK M. MILLER. Can. J. Chem. **68**, 1420 (1990).

On a fait adsorber des fluorures des métaux alcalins sur de la glaise montmorillonite K10 et on a analysé les réactifs qui en résultent par le biais de l'angle magique en résonance magnétique nucléaire du ^{19}F et par la spectroscopie infra-rouge. Il se forme facilement des complexes de M_3SiF_6, $MAlF_4$ et M_3AlF_6; la nature des complexes formés dépend de M, de la charge ainsi que de la température utilisée pour le séchage. Dans certaines conditions, il se produit aussi de la chemisorption des fluorures pour donner des groupements -Si-F superficiels.

Mots clés : MAS RMN, fluorures des métaux alcalins, adsorption, glaise montmorillonite, infra-rouge.

Introduction

The fluorination of oxide catalysts causes changes in catalytic activity. Fluorinated alumina has been studied extensively, and fluorination generally leads to significant increases in reactivity (1), but much less has been done on fluorinated aluminosilicates, since these materials already have high catalytic activity, and fluorination often reduces their reactivity (2). Fluorinated oxides are typically studied by IR spectroscopy of adsorbed model compounds (3). Other techniques such as X-ray photoelectron spectroscopy and X-ray diffraction have been used as well, and there are also a few examples of the use of ^{19}F NMR spectroscopy, the most recent of these being the papers by Schlup and Vaughan (4, 5).

We are currently studying fluorinated oxides using ^{19}F magic angle spinning (MAS) NMR spectroscopy. MAS is a line narrowing technique that significantly improves the resolution of peaks in the spectrum of a solid, and allows direct determination of the isotropic chemical shift, whereas without MAS the isotropic shift can only be found indirectly. ^{29}Si MAS NMR has been extensively used to analyse zeolites and silicates because silicon has a low chemical shift anisotropy (CSA), and therefore the line broadening can be removed at easily achievable spinning rates. ^{19}F MAS NMR has received much less attention, however; two recently described applications are in the analysis of fluorinated polymers (6), and of fluorohydroxyapatite (7). We have found ^{19}F MAS to be a very effective tool in the analysis of inorganic fluorides (8), and have applied the technique to MF-alumina (9) and MF-silica (16) reagents. In these reagents, the complexes M_3AlF_6 and M_3SiF_6 are readily formed on the alumina or silica surface at temperatures of 100–200°C. We are now extending our study to look at MF-montmorillonite K10 clay.

Experimental

NH_4F (Aldrich), NaF and KF (BDH), and RbF and CsF (Alfa) were used without further purification. Montmorillonite K10 clay (surface area 220–270 $m^2 g^{-1}$) was obtained from Fluka. K10 is a commercial support material prepared by acid washing. Our samples had an extractable iron content of between 0.3 and 1.3%. On removing iron by five successive extractions with 50 mL of 3 M HNO_3, we extracted a total of 1.3% iron, after which no significant additional iron could be removed. (The material contained about 3% iron, according to Fluka spec sheets, so the difference is presumably tightly bonded iron.) We could not detect a change in either our IR or ^{19}F results if we extracted iron and other soluble ions, so further work was carried on with the material as purchased. XRD powder patterns do not show detectable levels of quartz. Sodium, potassium, and calcium are all below 0.1% extractable, with additional found in lattice sites. The silica gel was Merck Kieselgel 100, 70–230 mesh.

The MF-K10 reagents were prepared at loadings of 0.5, 2.0, 3.5, 5.0, and 10.0 mmol MF per g K10 by dissolving the appropriate quantity of MF in water and adding the solution to K10 clay to form a slurry. The water was removed on a rotary evaporator until the reagent had caked to the wall of the flask, and the reagents were then dried in air at various temperatures. RbF-silica and CsF-silica were also prepared, at a loading of 5.0 mmol g^{-1}. In a typical preparation, KF-K10 (3.5 mmol g^{-1}) was prepared by dissolving 2.03 g of KF in 25 cm^3 of water, and adding 10.0 g of K10 to form a slurry. The water was then removed until the clay had caked onto the side of the flask, and the resulting reagent was dried in air.

IR spectra were obtained on an Analect FX6260 Fourier transform spectrometer, attached to a MAP-66 data system. Samples were prepared as KBr discs, using a KBr/reagent ratio of about 20:1 by weight.

NMR spectra were obtained on a Bruker AC200 instrument at 188.3 MHz, using our home-built ^{19}F MAS probe. Samples were spun in Delrin rotors at about 3300 Hz. Since this spinning rate is considerably less than the CSA of fluorine (the CSA of KF is 323 ppm, which is equivalent to 65 kHz in a 200-MHz field, for example (10)), spinning side bands are seen in most of the spectra. Some of the spectra, especially those of the NaF-K10 reagents, showed broad unresolved peaks, probably because of the low spinning rate. Peaks were referenced to external $CFCl_3$, using the usual convention that upfield peaks are more negative.

Results and discussion

Each of the MF-K10 reagents was prepared at several loadings and dried over a range of temperatures. The loadings

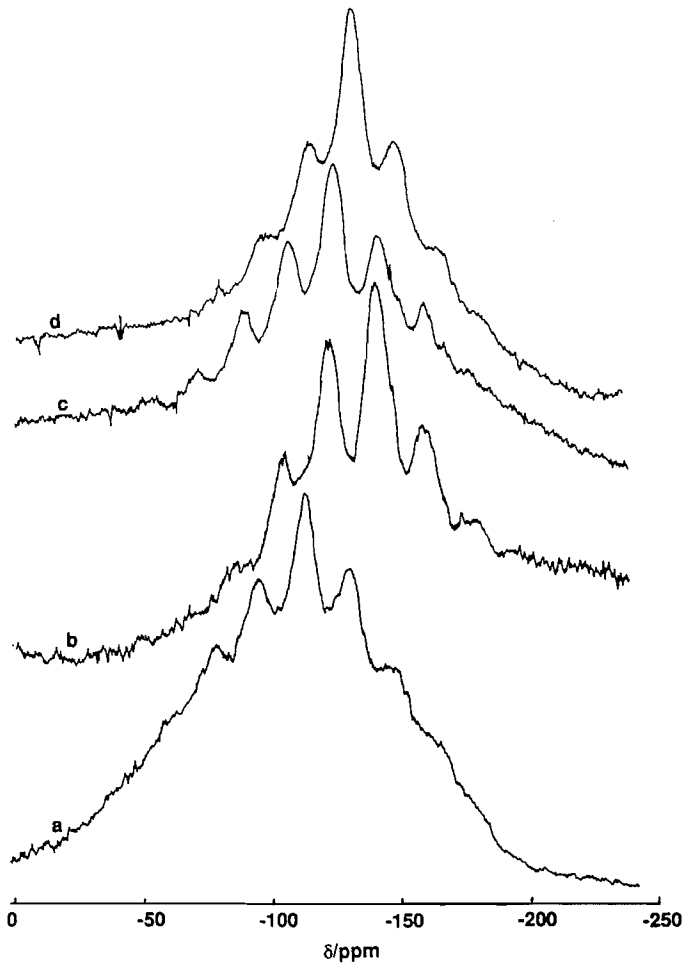

FIG. 1. ^{19}F MAS NMR spectra of (a) CsF-K10, (b) RbF-K10, (c) KF-K10, and (d) NH_4F-K10. Reagent loading is 5.0 mmol g^{-1}; reagents dried at 100°C.

range from 0.5 mmol g^{-1}, which is less than monolayer coverage, to 10.0 mmol g^{-1}, which should be well above the level of monolayer coverage. As the reagents were analysed, certain trends became apparent. The ^{19}F MAS NMR spectra of the reagents at a loading of 5.0 mmol g^{-1} and dried at 100°C are shown in Figs. 1 and 2 together with the spectrum of a mixed sample of $KAlF_4$ and K_3AlF_6. The corresponding IR spectra are shown in Figs. 3 and 4. The IR spectra of all the reagents except NaF-K10 show a band at about 740 cm^{-1}, which coincides with the position of the AlF_4^- band (lit. value for ν_3 for AlF_4^- is 760 cm^{-1} in the molten phase (11)). This suggests that either AlF_4^- or SiF_6^{2-} (or both) is being formed (lit. value for ν_3 for SiF_6^{2-} is 740 cm^{-1} (12)). The ^{19}F NMR spectrum of KF-K10 shows that SiF_6^{2-} is present, rather than AlF_4^-, with a peak at −129 ppm; the literature value for the ν_3 band of K_2SiF_6 is −129 ppm in the solid state (13), whereas the $KAlF_4$ sample has a peak at −155 ppm. SiF_6^{2-} is also formed on NH_4F-K10 in preference to AlF_4^-, the sample having an NMR peak at −136 ppm (lit. value (14) for NH_4AlF_4 is −147 ppm). On RbF-K10 both species are formed: the NMR spectrum shows two strong bands, at −123 and at −141 ppm, and although there is superposition of spinning side bands, two species are clearly present. RbF-silica shows a peak at −122 ppm, with an IR band at 740 cm^{-1}, and the chemical shift in RbF-alumina is −139 ppm, IR evidence indicating that the species present on

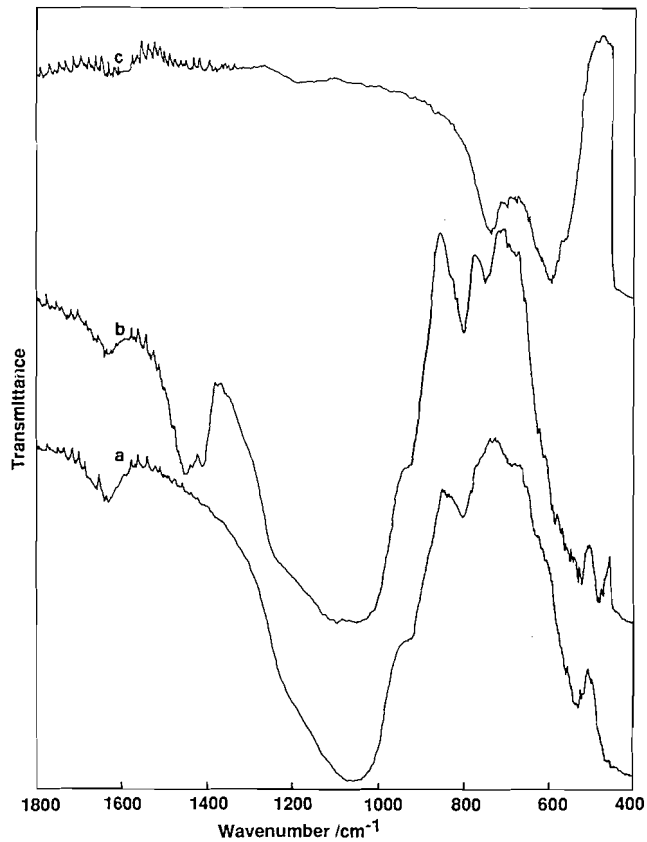

FIG. 4. IR spectra of (a) K10, (b) NH_4F-K10 (5.0 mmol g^{-1}, dried at 100°C), and (c) $KAlF_4/K_3AlF_6$.

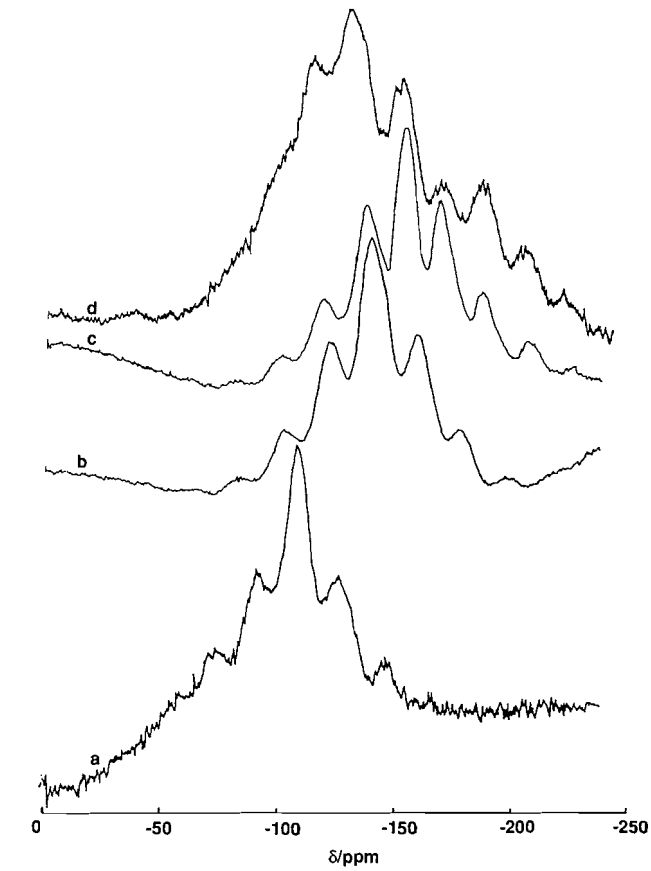

FIG. 5. ^{19}F MAS NMR spectra of (a) CsF-K10, (b) RbF-K10, (c) KF-K10, and (d) NH_4F-K10. Reagent loading is 5.0 mmol g^{-1}; reagents dried at 600°C.

this reagent is Rb_3AlF_6. The chemical shifts for $RbAlF_4$ and Rb_3AlF_6 should be close, since the chemical shifts for K_3AlF_6 and $KAlF_4$ are the same (the $KAlF_4$ and K_3AlF_6 peaks are not resolvable in these spectra because of their broadness). The IR spectrum of CsF-K10 also shows a band at 740 cm^{-1}, but this is probably due only to AlF_4^- with no SiF_6^{2-}. The ^{19}F MAS spectrum of CsF-K10 shows a peak at −113 ppm; CsF-alumina shows a peak at −115 ppm, which is due to Cs_3AlF_6 (IR band at 570 cm^{-1}; lit. value for AlF_6^{3-} (15), 568 cm^{-1}), whereas CsF-silica has an NMR peak at −92 ppm with an IR band at 740 cm^{-1}. The downfield shift of 37 ppm from −129 ppm for K_2SiF_6 to −92 ppm for Cs_2SiF_6 compares to a downfield shift of 42 ppm from −155 ppm for $KAlF_4$ to the −113 ppm peak found for CsF-K10. The NMR spectrum of NaF-K10 shows only a broad, unresolved peak, probably due to large dipolar interactions and (or) high CSA. In this case, a much higher spinning speed than is possible in our setup would be required to obtain a decent spectrum. The IR spectrum of the NaF-K10 reagent shows that there has been no formation of complex fluoride. It is possible instead that chemisorption has occurred to give -Si-F groups, or that F^- is dispersed over the surface.

The ^{19}F MAS spectra of the reagents dried at 600°C are shown in Fig. 5, and it can be seen that various changes have occurred on heating the reagents in air. As we found with NH_4F-silica, $(NH_4F)_2SiF_6$ on K10 readily decomposes at temperatures of 200°C and above, giving off, presumably, NH_3 and SiF_4. The HF that is formed then chemisorbs to the surface; the ^{19}F NMR spectrum of NH_4F-K10 shows a set of asymmetrical peaks, which indicates that the fluorine is no longer in a symmetrical environment, and is probably in the form of -Si-F surface groups as in NH_4F-silica (16). K_2SiF_6 is stable up to 400°C, depending on the loading of KF, with decomposition occurring at around 500°C (lower at lower loadings), but whereas F^- remains after the decomposition of K_2SiF_6 on KF-silica, AlF_4^- and (at high loadings) AlF_6^{3-} are formed when K_2SiF_6 decomposes on KF-K10. RbF-K10 behaves similarly: at 600°C Rb_2SiF_6 decomposes, forming some AlF_6^{3-} and leaving AlF_4^- intact. Cs_2SiF_6 does not form on CsF-K10, and CsF-K10 appears to be unchanged on heating. The ^{19}F MAS spectra of KF-K10 (3.5 mmol g^{-1}) dried at temperatures of 200°C, 400°C, and 600°C are given in Fig. 6, and clearly show the transition from SiF_6^{2-} to AlF_4^-; the IR band at 740 cm^{-1} becomes very much weaker in intensity as SiF_4 is given off, and is now only present as a shoulder. The IR spectra of RbF-K10 (5.0 mmol g^{-1}) dried at several temperatures are given in Fig. 7, and these show the loss in intensity of the 740 cm^{-1} band as SiF_4 is given off, and the appearance of a new band at 570 cm^{-1} due to Rb_3AlF_6. The IR spectrum of NaF-K10 at 600°C shows bands forming at 740 and 580 cm^{-1}, which suggests that the complexes Na_3AlF_6 and $NaAlF_4$ are forming, although the ^{19}F NMR still consists of an unresolvable broad peak. The 740 cm^{-1} peak is probably not due to Na_2SiF_6, as we would expect this to decompose, as on KF-K10. Therefore, on NaF-K10 dried at 100°C, F^- is probably dispersed over the surface rather than chemisorbed.

The ^{19}F MAS spectra of all the reagents (except NaF-K10) at the low loading of 0.5 mmol g^{-1}, which is rather less than monolayer coverage, are very similar and show a peak with nonsymmetrical spinning side bands, which is superimposed on a very broad underlying peak (Fig. 8). None of the reagents

shows a 740 cm^{-1} band in its IR spectra and hence no SiF_6^{2-} or AlF_4^- is forming. Presumably then, chemisorption is occurring, with -Si-F groups forming on the surface. Chemisorbed fluorine is present on NH_4F-alumina at fluorine concentrations

TABLE 1. Ionic radii of the M^+ ions

Ion	Radius/pm[a]
Na^+	97
K^+	133
NH_4^+	143
Rb^+	147
Cs^+	167

[a]CRC Handbook of Chemistry and Physics.

of less than about 5% by weight, which is equivalent to a loading of 2.6 mmol g^{-1} of MF, but at higher concentrations $(NH_4)_3AlF_6$ is formed. Most of the reagents, at the higher loading of 2.0 mmol g^{-1}, form a complex fluoride species. An exception is CsF-K10, which forms $CsAlF_4$ at the still higher loading of 5.0 mmol g^{-1}.

The varying behaviour of the MF-K10 reagents can probably be attributed to the different cation size of M^+ (see Table 1). NH_4F-K10, KF-K10, and RbF-K10 all behave similarly in initially forming M_2SiF_6, and these cations are similar in size, whereas NaF (Na^+ much smaller) appears to be dispersed over the K10 surface, and CsF (Cs^+ much larger) forms $CsAlF_4$ and Cs_3AlF_6. It is possible that Na^+ diffuses right through the open aluminosilicate structure, and that it only migrates to the external surface on heating; the local concentration of NaF will then become high enough to form Na_3AlF_6 and $NaAlF_4$. Cs^+ is large and less strongly polarizing (i.e., softer) than the other M^+ cations, and will therefore be attracted to the more polarizable (softer) AlO_4^{5-} tetrahedra rather than to the SiO_4^{4-} tetrahedra.

To conclude, complex fluorides form when MF is adsorbed onto montmorillonite K10, the particular species formed depending on the loading of MF, the drying temperatures, and the cation employed.

Received November 30, 1989

OLIVER E. EDWARDS and WERNER RANK. Can. J. Chem. **68**, 1425 (1990).

Photolysis of 2-alkyl-2-azido-3-oxobutanoic esters and amides gave products resulting from alkyl or acyl migration onto nitrogen. The resulting ketimimes could be isolated in moderate purity, but the *N*-acyl imines were rapidly converted into solvation products or enamides (*N*-acetyl dehydroamino acid esters) resulting from double bond migration. Mechanisms for formation of these products are discussed. The *N*-(2-azido-2-methyl-3-oxobutanoyl) derivative of the diketopiperazine from L-valyl-L-proline gave a stereoisomer of the cyclol tripeptide unit of ergovaline.

Key words: *N*-acyl imines, mechanism of 2-azido-3-keto ester photolysis, cyclol tripeptide synthesis, ergovaline.

OLIVER E. EDWARDS et WERNER RANK. Can. J. Chem. **68**, 1425 (1990).

La photolyse des esters et des amides des acides 2-alkyl-2-azido-3-oxobutanoïques fournit des produits qui proviennent de migrations d'alkyles ou d'acyles vers l'azote. L'état de pureté des cétimines qui en résultent est correct; toutefois, les imines *N*-acylées se transforment rapidement en produits de solvatation ou en ènamides (esters des *N*-acétyl déhydroamino acides) qui résultent d'une migration de double liaison. On discute des mécanismes de formation de ces produits. La dérivé *N*-(2-azido-2-méthyl-3-oxobutanoyle) de la dicétopipérazine provenant de la L-valyl-L-proline fournit un stéréoisomère de l'unité tripeptide cyclol de l'ergovaline.

Mots clés : imines *N*-acylées, mécanisme de photolyse des esters 2-azido-2-céto, synthèse de l'unité tripeptide cyclol, ergovaline.

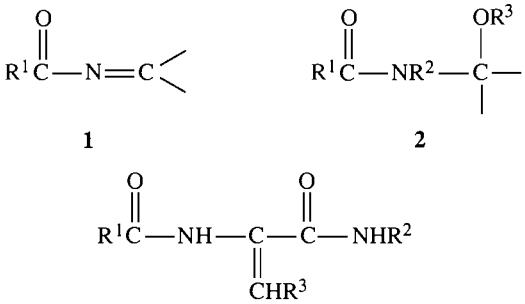
A number of biologically active molecules contain units derivable from *N*-acyl imines (**1**), such as carbinolamides (**2**, R^3 = H), carbinolamide ethers (**2**, R^3 = alkyl), and peptides containing dehydroamino acid units as in **3**. These include the 6-



1 **2**

3

methoxy β-lactam antibiotics (1), pederin (2), maytansine (3), bicyclomycin (4), and many ergot alkaloids (5). A review of natural dehydroamino acid derivatives was presented by Bycroft (6*a*) and more recent examples were cited by Steglich and co-workers (6*b*).

Interest in the mechanism of the photochemical formation of *N*-acyl imines and enamides from α-azido carbonyl compounds (7), possible extension of the reaction to α-azido-β-keto esters and amides, and the potential of the reaction for the synthesis of natural products and agents for chemotherapy prompted us to examine the photolysis of 2-alkyl-2-azido-3-oxobutanoic esters and amides.

[1]Issued as NRCC No. 31519. Presented in part at the 63rd Canadian Chemical Conference, Ottawa, June 3–6, 1980.

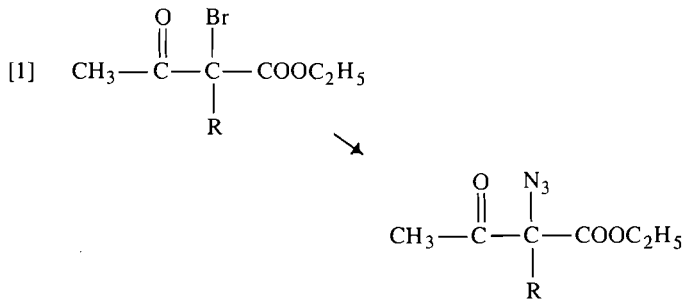
[3]NRCC research associate 1974–1976.

Results

The preparation of 2-alkyl-2-azido derivatives of 3-oxobutanoic esters was carried out using apparent S_N2 displacement on the corresponding bromides (eq. [1]). The mechanism of this



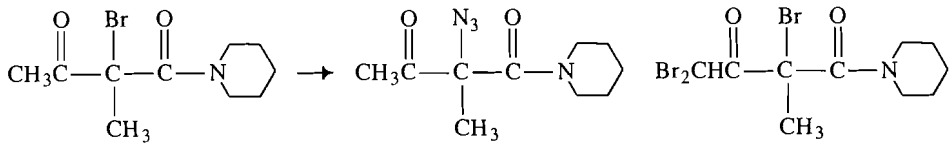
displacement has been studied in these laboratories (8). Good yields of azides **4***a* and **4***b* were obtained.

As a model for subsequent peptide work, the α-azidoketo amide **7** was prepared as shown in eq. [2]. A by-product of the bromination of **5** with pyridinium perbromide was the crystalline tribromide **8**.

The only primary products characterized from the photolysis of azides **4***a* and **4***b* in dichloromethane were the imines **10** (27%) (Scheme 1) and **16** (30%) (Scheme 3). The former was relatively stable, surviving heating in pyridine or distillation at 100°C *in vacuo*. However, **16** isomerized readily to the benzaldimine **18**. This was not isolated, but its hydrolysis product, benzaldehyde, appeared on handling of **16**.

The *N*-acyl imine primary products **9** and **15** formed in the photolysis of azides **4a** and **4b**, respectively, were not isolated as such, since they readily converted into the enamides **11** (27%)

[2] 
5



6 7 8

and **17** (21%), even on rapid chromatography on neutral silica gel, heating in dry pyridine, or distillation *in vacuo*. The presence and yields of **9** and **15** were also deduced from the isolation of derivatives (Schemes 1 and 3). *N*-Acyl imines **9** and **15** were trapped efficiently upon irradiation of the azides using 254-nm lamps in methanol (Schemes 2 and 4) or ethanol, or by the use of 300-nm lamps and an acid catalyst such as *p*-toluenesulfonic acid or trifluoroacetic acid. The resulting carbinolamide ethers **12**, **14** (44%), and **19** (26%) were well characterized. Finally, **14** was converted into the 2,4-dinitrophenylhydrazone of ethyl 2-oxobutanoate, confirming the skeleton.

Photolysis of the α-azidoketo amide **7** was only studied in methanol. The products characterized were *N*-(2-acetamido-2-methoxypropanoyl) piperidine **20** (26%) and *N*-(2-methoxy-2-methylamino-3-oxobutanoyl) piperidine **21** (11%).

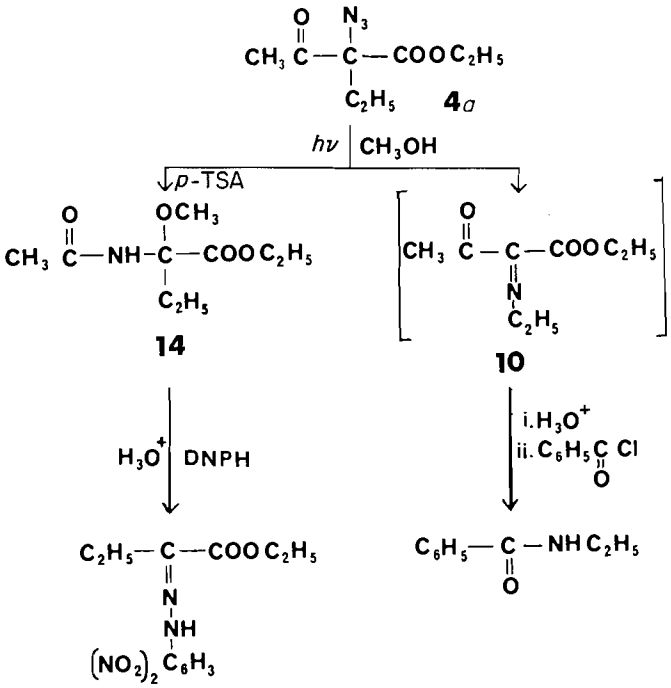
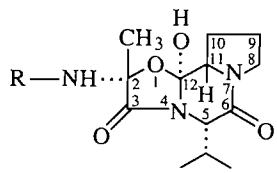
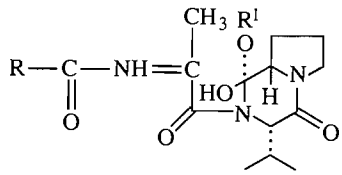


SCHEME 2

One objective of our research was to explore an *N*-acyl imine route for the synthesis of a cycloltripeptide unit found in therapeutically valuable ergot alkaloids. The only syntheses of these appear to be those of Hofmann and co-workers (9, 15). The cycloltripeptide portion in ergovaline (**22**, R = lysergyl) can be envisioned to arise from the hydrated diketopiperazine appropriately substituted with an *N*-acyl imine function (**23***a*). Thus the photochemical generation of such a unit seemed attractive.



22



23*a* $R^1 = H$
23*b* $R^1 = CH_3$

The preparation of the α-azidoketo lactam **28** from the diketopiperazine L-prolyl-L-valyl lactam **24** (9) was achieved as outlined in Scheme 5. Mixtures were obtained at each stage. The main *N*-(2-methyl-3-oxobutanoyl) diketopiperazine **26** was converted to a mixture of crystalline and amorphous bromo compounds **27**. No well-characterized products were obtained when the amorphous bromo compound(s) were subjected to azide exchange and subsequent photolysis. However, the crys-

32

talline isomer **27** was converted to the α-azidoketo lactam **28**, which according to its ^{1}Hmr spectrum was a mixture of two isomers. Photolysis of the mixture in methanol followed by treatment with acidic methanol and subsequent chromatography of the products on alumina gave 17% of a crystalline methyl ether **29** related to the *N*-acetyl derivative of the cycloltripeptide unit of ergovaline (9). An X-ray crystallographic analysis by Przybylska and Ahmed (10) confirmed the structural assignment and established the stereochemistry of the product as being 2*S*,5*S*,11*R*,12*S*-acetamido-3,6-dioxo-5-isopropyl-10b-methoxy-2-methyl-perhydro-8-*H*-oxazolo[3,2-*a*]pyrrolo[2,1-*c*]-pyrazine. It was thus a D-proline derivative with the configuration at C-2 opposite to that of the natural ergot alkaloid tripeptides.

Discussion

The longest wavelengths of light used for the above photolyses (centered at 300 nm) could excite either the azido group or the ketone carbonyl and thus three mechanisms seem plausible: The first (eq. [3]) involves a Norrish type 1 fission after $n \rightarrow \pi^*$ excitation of the ketone. The other two mechanisms in eqs. [4] and [5] involve the well-known photochemical cleavage of an azide to nitrogen and a singlet nitrene.

The mechanism described in eq. [3] seems unlikely. To produce the *N*-acyl imine the two radicals would have to combine before diffusing apart and before decarbonylation of the acetyl radical. In addition, the formation of the imines **10** and **16** cannot be explained readily.[4]

The singlet nitrene mechanism in eq. [4] can account for both acyl (route "a") and alkyl (route "b") migration. However, singlet nitrenes react with alcohols to give *N*-alkoxy compounds (11*b*), none of which were observed. A possible alternative mechanism is that the zwitterion **31** shown in eq. [5] forms very rapidly and, in its turn, rearranges rapidly to the main primary products. The zwitterion is internally neutralized, hence not very nucleophilic.[5] Some support for the zwitterion **31** comes from the failure to observe ethoxy carbonyl migration. According to Saunders *et al.* (12), lowering of the electron density on groups retarded their migration onto singlet nitrenes. Thus if the

[4]A referee suggested that $n \rightarrow \pi^*$ photoexcitation of the carbonyl would lead to rapid internal energy transfer to the azide group. We consider that this would likely result in formation of a triplet nitrene (11*a*), which would abstract hydrogen instead of rearranging.

[5]A referee pointed out that the nitrene may simply rearrange much faster than it can undergo bimolecular reaction.

singlet nitrene mechanism (eq [4]) were operative, one would expect a significant migration of the ethoxycarbonyl group, which has a higher electron density on its carbonyl carbon than that on the ketone carbonyl.[6] In contrast, the same electron density differential should favor formation of zwitterion **31** over the alternative **32**, thus leading to the products actually observed. We thus favor the mechanism in eq. [5], with the assumption that the initial nitrene has such a short lifetime that its reaction with solvent is negligible.

The facile isomerization of *N*-acyl imines, when the appropriate hydrogen is available, to the thermodynamically more stable enamides was also observed in our work on photolysis of a 9α-azido-11-keto steroid (unpublished work with T. Sano). Two other photochemical studies have reported production of *N*-acyl imines as very reactive intermediates (13, 14).

The moderately good yields of *N*-acyl imine derived products from the α-azido-β-keto esters and amides encouraged us to attempt a cycloltripeptide synthesis. However, the lack of stereochemical control in the reaction sequence in Scheme 5 was disappointing. The pure lactam **24** gave a mixture of two ketal lactams (**25**). These may have been diastereoisomers at C-2′. However, inversion of the asymmetric center of proline cannot be excluded since facile inversion of this center has previously been observed as a base-catalysed or thermal reaction of diketopiperazines derived from this amino acid (5, 9, 15). This facile isomerization at the proline center obviously occurred at one of the steps in Scheme 5. In addition, acid-catalysed isomerization of the cycloltripeptide units of the ergot alkaloids had been shown (16) to involve inversion at C-2, so the formation of the unwanted isomer **29** is not too surprising. Of course the cyclization of a solvated diketopiperazine such as **23*b*** could lead to a mixture of isomers at the new asymmetric centers C-2 and C-12.

Because of the isolation in this case of a modest yield of only one isomer, the method may be of limited utility for the preparation of other ergot peptides. Nevertheless, this study provided in principle another example of the potential of *N*-acyl imines as intermediates in synthetic sequences. Furthermore, the establishment of the structure of the cycloltripeptide **29** by X-ray analysis is noteworthy, since only two other related structures have been determined by X-ray methods (16, 17). Considering that in less complex α-azidoketo systems such as **4*a*** the yield of *N*-acyl imine derived products is around 45%, this method might prove useful for the generation of carbinolamide ether or dehydro-amino acid (enamide) units of natural products less prone to isomerizations than the diketopiperazine derivatives reported in this paper.

Experimental

Infrared (ir) spectra were obtained with a Perkin–Elmer grating spectrometer, model 257, using dichloromethane as solvent. Proton magnetic resonance (^{1}Hmr) and ^{13}C magnetic resonance (^{13}Cmr) spectra were recorded with a Bruker WP-80 FT spectrometer. The ^{1}H chemical shift data are quoted in δ units and refer to solutions in deuterochloroform using tetramethylsilane as internal reference. Optical rotations were measured with a Perkin–Elmer polarimeter. Mass spectral data were recorded on a VG 707E instrument. The photolytic experiments were carried out using a Rayonet photochemical reactor with lamps giving peak emission at 254 or 300 nm. Preparative layer chromatography (plc) was carried out on 20 × 20 cm glass plates precoated with silica. Neutralized "flash" silica gel refers to silica gel (230–400 mesh) that has been neutralized by treatment with pyridine in ethyl acetate. Unless otherwise stated, anhydrous sodium sulfate was used for drying organic solutions. Solvents were usually removed on a rotary evaporator using a water aspirator and bath temperatures of 30–40°C. Melting points and boiling points are uncorrected.

*Ethyl 2-azido-2-ethyl-3-oxobutanoate (**4**a)*

Alkylation of ethyl acetoacetate with bromoethane in the presence of sodium ethoxide gave ethyl 2-ethyl-3-oxobutanoate (18), bp 92–98°C at 24 Torr (1 Torr = 133.3 Pa), in a yield of 78%. Dropwise addition of bromine to an aqueous suspension of this material furnished ethyl 2-bromo-2-ethyl-3-oxobutanoate (18), bp 110–115°C at 20 Torr, in a yield of 91%. To a solution of 19.32 g of ethyl 2-bromo-2-ethyl-3-oxobutanoate in 40 mL of dimethylformamide was added portionwise 5.83 g of sodium azide over 20 min, during which time the temperature was kept below 30°C by cooling. After continued stirring for 6 h at room temperature the crude azide was isolated by extractive work-up with ether. Fractional distillation gave 73% of pure azide **4*a*** boiling at 60–63°C at 0.8 Torr. Spectral and analytical data supported the structural assignment; ir ν_{max}: 2110, 1740, 1725 cm^{-1}; ^{1}Hmr: 4.37 (2H, q, J = 7 Hz), 2.3 (3H, s), 2.07 (2H, q, J = 7 Hz), 1.35 (3H, t, J = 7 Hz), 0.93 (3H, t, J = 7 Hz). Anal. calcd. for $C_8H_{13}N_3O_3$: C 48.23, H 6.58, N 21.10; found: C 48.46, H 6.73, N 21.31.

*Ethyl 2-azido-2-benzyl-3-oxobutanoate (**4**b)*

Alkylation of ethyl acetoacetate with benzyl bromide in the presence of sodium ethoxide gave ethyl 2-benzyl-3-oxobutanoate (18), bp 103–105°C at 0.3 Torr, in a yield of 83%. Dropwise addition of bromine to an aqueous suspension of this material furnished ethyl 2-benzyl-2-bromo-3-oxobutanoate (18), bp 98–101°C at 0.1 Torr, in a yield of 76%. To a solution of 10.76 g of ethyl 2-benzyl-2-bromo-3-oxobutanoate in 20 mL of dimethylformamide was added portionwise 2.57 g of sodium azide while the temperature was maintained below 30°C by cooling. After continued stirring for 6 h at room temperature the crude azide was isolated by extractive work-up with ether. Fractional distillation gave 68% of pure azide **4*b*** boiling at 106–108°C at 0.3 Torr. Spectral and analytical data supported the structural assignment; ir ν_{max}: 2120, 1740, 1725 cm^{-1}; ^{1}Hmr: 7.38 (5H, s), 4.33 (2H, q, J = 7 Hz), 3.33 (2H, s), 2.22 (3H, s), 1.30 (3H, t, J = 7 Hz). Anal. calcd. for $C_{13}H_{15}N_3O_3$: C 59.76, H 5.79, N 16.08; found: C 59.90, H 5.88, N 16.21.

*Photolysis of ethyl 2-azido-2-ethyl-3-oxobutanoate (**4**a)*

1. In dichloromethane

(*a*) A solution of 690 mg of azide **4*a*** in 75 mL of dry dichloromethane was flushed with argon, then irradiated in a Vycor flask for 6.5 h at 10°C using 254-nm lamps. After distilling off the dichloromethane the residue had ir absorptions at ν_{max}: 3400, 2120 (residual azide), 1737, 1702, and 1679 cm^{-1}. Its ^{1}Hmr spectrum showed no enamide to be present. The residue was taken up in hexane/benzene (1:1, v/v) and adsorbed on a column of 4 g of neutralized flash silica gel. The same solvent eluted 268 mg of a material that was rich in imine **10** but contained some azide **4*a***. Elution with benzene, and then dichloromethane, gave 39 mg of unidentified products. Further elution with dichloromethane containing methanol (5%, v/v) yielded 247 mg of a material rich in enamide **11**. The azide-containing material was irradiated for another 2 h in 50 mL of dry dichloromethane and purified again by chromatography on 1.9 g of neutralized flash silica gel. Elution with hexane/benzene (1:1, v/v) gave 202 mg of a material that consisted of approximately 80% (by ^{1}Hmr ratios) of imine **10**, corresponding to a yield of 27%.

(*b*) A comparable photolysis of 450 mg of **4*a*** gave 457 mg of crude material. This was heated in 0.5 mL of dry pyridine for 1 h in a bath at 124°C. After removal of the pyridine *in vacuo* the remaining brown liquid was distilled in a Kugelrohr at a pressure of 0.3 Torr. Three fractions were collected: 94 mg boiling up to 75°C; 142 mg boiling at 75–130°C, and 49 mg boiling at 130–140°C. The middle fraction of 142 mg contained most of the enamide **11**. Purification by plc on silica

[6]The ^{13}Cmr shift of the ketone carbonyl (>200 ppm) relative to an ester carbonyl (ca. 170 ppm) is in accord with this electron density.

For personal use only.

gel (two plates of 1000 μm) using chloroform containing (5% v/v) methanol as solvent gave 49 mg (14%) of enamide **11***a* (R_f 0.39) followed closely by 45 mg (13%) of enamide **11***b*. (The yields are adjusted for unreacted azide.)

(*c*) In some of the photolyses in dichloromethane, crystalline ethylamine hydrochloride separated. This must have arisen from the hydrolysis of **10**, presumably a result of moisture accidentally present in the photolysate. The maximum yield obtained was 7%.

2. In methanol

(*a*) A solution of 323 mg of azide **4***a* in 40 mL of methanol was irradiated at 10°C for 3 h using 300-nm lamps. After irradiation, 200 mg of *p*-toluenesulfonic acid hydrate was added and the solution was left for 3 h at room temperature. It was then evaporated at 25°C *in vacuo* and the residue distributed between dichloromethane and aqueous sodium carbonate. The dichloromethane extracts yielded 255 mg of an oil, which was distilled in a Kugelrohr apparatus at 0.1 Torr. After a forerun of 28 mg (below 90°C) a main fraction of 124 mg was collected between 90 and 125°C. The main fraction was nearly pure methoxy compound **14**, some of which was also present in the forerun. The estimated yield of **14** was 44%, representing a minimum yield of *N*-acyl imine **9** as a primary product.

(*b*) The material from a comparable photolysis of 606 mg of azide **4***a* was hydrolyzed (60 mL methanol, 0.3 mL conc. hydrochloric acid, 0.5 mL water) for 1 h at room temperature. The methanol was removed *in vacuo* and the residue was distributed between water and dichloromethane. The water layers were concentrated to a volume of 2 mL and then treated for 1 h under Schotten–Baumann conditions with 300 mg of benzoyl chloride and 20% of aqueous sodium hydroxide. Extraction with dichloromethane gave 194 mg of a crude material. Purification by plc on silica gel (1 plate of 1000 μm) using chloroform containing ethanol (5%, v/v) furnished 132 mg (27%) of pure *N*-ethyl benzamide with a melting point of 69°C. This material was identical to an authentic sample. This represents a minimum yield of the imine **10** in this photolysis.

3. In ethanol

A solution of 430 mg of azide **4***a* in 80 mL of absolute ethanol was irradiated in a Vycor vessel for 2.5 h at 8°C using 254-nm lamps. The photolysate was then treated with 446 mg of *p*-toluenesulfonic acid hydrate for 1 h at 30°C. Concentration at 40°C *in vacuo* gave a material that was distributed between dichloromethane and aqueous sodium bicarbonate. The organic layers gave 323 mg of a crude oil that was purified by plc using silica gel (3 plates of 1000 μm) and chloroform containing ethanol (10% v/v). Zone extraction (R_f 0.5) gave 124 mg (26%) of ethoxy compound **12**.

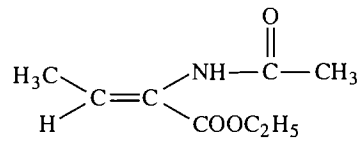
Characterization and derivatization of the photolysis products from azide **4**a

Ethyl 2-acetamido-2-butenoate (11)

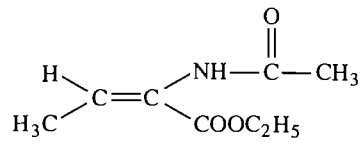
The enamide isomers **11** were further purified by plc, short path distillation at 100°C and 0.3 Torr, and recrystallization.

trans *Isomer (Z isomer) 11*a: The isomer with the higher R_f value crystallized from ethyl acetate/hexane upon cooling. The long flat needles had a melting point of 44–45°C. The spectral data supported the structural assignment; ir ν_{max}: 3400 (m), 1725 (m), 1680 (s) cm^{-1}; ^{1}Hmr: 7.7 (1H, br) 6.99 (1H, q, J = 8 Hz), 4.30 (2H, q, J = 7 Hz), 2.08 (3H, s), 2.07 (3H, d, J = 8 Hz), 1.35 (3H, t, J = 7 Hz); ^{13}Cmr: 169.1 (s), 164.7 (s), 127.7 (d), 126.3 (s), 61.5 (d), 24.2 (t), 14.3 (t). Reference 19 described this compound as an oil and assigned it the *Z* geometry illustrated below.

cis *Isomer (E isomer) 11*b: The isomer with the lower R_f value crystallized from ethyl acetate/hexane as sheaves of needles with a melting point of 64–65°C. Its spectral data supported the structural assignment; ν_{max}: ir 3405, 1692 cm^{-1}; ^{1}Hmr: 7.29 (1H, br), 6.80 (1H, q, J = 7 Hz), 4.23 (2H, q, J = 7 Hz), 2.13 (3H, s), 1.77 (2H, d, J = 7 Hz), 1.30 (3H, s). Reference 22 reported a melting point of 66.5°C while ref. 20 reported a melting point of 61°C for a mixture rich in this isomer. In ref. 22 the *E* geometry was assigned to this isomer as illustrated below:



11*a* *Z* isomer



11*b* *E* isomer

Ethyl 2-ethylimino-3-oxobutanoate (10)

The imine **10** was further purified by repeated plc on neutralized flash silica gel using hexane/benzene (1:1, v/v) as developing system. The nearly pure material so obtained was an oil with the following spectral data: ir ν_{max}: 1737, 1702 cm^{-1}; ^{1}Hmr: 4.55 (2H, q, J = 7 Hz), 3.61 (2H, q, J = 7 Hz), 2.45 (3H, s), 1.35 (6H, t, J = 7 Hz; at 60 MHz the two methyl triplets were separated by approx. 2 Hz); ^{13}Cmr: 197.0, 163.8, 159.4, 61.6, 50.0, 24.3, 15.3, 14.2. EI-MS: 171 (0.6), 156 (2.2), 144 (3.3), 128 (20), 101 (3), 98 (8.6), 56 (100). Mol. wt. calcd. for $C_8H_{13}NO_3$: 171 (the fragments with e/z 128 and 98 correspond to a loss of $CH_3CO\cdot$ and $\cdot COOC_2H_5$ respectively, while the base peak at 56 probably corresponds to the ion $CH_3CH_2N^+{=}CH\cdot$).

Imine **10** was further characterized by its conversion to the bis-4-nitrophenylhydrazone derivative. For this purpose a solution of 100 mg of **10** in 1 mL of ethanol and 0.05 mL of concentrated hydrochloric acid was left at room temperature for 1 h. After addition of 50 mg of sodium acetate, 200 mg of 4-nitrophenylhydrazine, and 1 mL of ethanol the mixture was heated under reflux for 20 min. A crystalline material separated, and was removed by filtration. Then 0.1 mL of acetic acid was added to the filtrate. This mixture was heated under reflux for 1 h to give a second bath of crystals. The combined solids were washed with water to remove salts, leaving 123 mg (51%) of a sparingly soluble product with a melting point of 290°C (dec.). Recrystallization from chloroform/ethanol gave pure ethyl 2,3-dioxobutanoate bis-hydrazone **13** melting at 292–294°C (dec.). It gave ^{1}Hmr signals in pyridine-d_5 at 8.5–7.0 (pyridine + Ar H), 4.90 (4H, s, 2NH + H_2O), 4.13 (2H, q, J = 7 Hz), 2.25 (3H, s), 1.24 (3H, t, J = 7 Hz). Anal. calcd. for $C_{18}H_{18}N_6O_6$: C 52.17, H 4.38, N 20.28; found (sample dried for 5 h at 140°C and 0.1 Torr): C 51.01, H 4.26, N 20.38.

Ethyl 2-acetamido-2-methoxybutanoate (14)

The methoxy compound **14** was further purified by plc on silica gel using chloroform containing methanol (5%, v/v). The material so obtained (R_f 0.5) was distilled over a short path at 90°C and 0.05 Torr. It crystallized from ethyl acetate and melted at 71.5–72.5°C. The reported melting point (19) is 80–81°C, but their ^{1}Hmr data were identical to ours. Spectral and analytical data supported the structure assigned to **14**; ir ($CHCl_3$) ν_{max}: 3410, 1730, 1688 cm^{-1}; ^{1}Hmr: 6.73 (1H, b), 4.30 (2H, q, J = 7 Hz), 3.25 (3H, s), 2.45–1.9 (2H, m), 2.06 (3H, s), 1.30 (3H, t, J = 7 Hz), 0.80 (3H, t, J = 7 Hz); ^{13}Cmr: 170.2, 169.5, 88.4, 62.1, 51.3, 28.3, 23.6, 14.1, 7.7. Anal. calcd. for $C_9H_{17}NO_4$: C 53.19, H 8.43, N 6.89; found: C 52.96, H 8.47, N 6.87.

Methoxy compound **14** was further characterized by its conversion to the 2,4-dinitrophenyldrazone derivative. For this purpose a solution of 64 mg of **14** in 3 mL of ethanol containing 108 mg of 2,4-dinitrophenylhydrazine in suspension was heated gently while concentrated hydrochloric acid was added dropwise. After a clear reddish solution was obtained, 0.5 mL of water was added and the solution was cooled. Crystalline ethyl 2-oxobutanoate 2,4-dinitrophenylhydrazone separated, melting at 135°C. Recrystallization from ethanol gave a 2,4-dinitrophenylhydrazone melting at 139–141°C (lit. (23) mp

142°C). It gave ^{1}Hmr signals at 9.20 (1H, d, J = 2 Hz), 8.6–7.8 (2H, m), 4.49 (2H, q, J = 7 Hz), 2.78 (2H, q, J = 7 Hz), 1.45 (3H, t, J = 7 Hz), 1.27 (3H, t, J = 7 Hz).

Ethyl 2-acetamido-2-ethoxybutanoate (12)

The ethoxy compound **12** was characterized by crystallization from ether/hexane, giving a product with a melting point of 78–79°C. The melting point reported in the literature (19) was 102–104°C. The structural assignment of the product was supported by its spectral and analytical data; ir ν_{max}: 3415, 1730, 1685 cm^{-1}; ^{1}Hmr: 6.85 (1H, s), 4.33 (2H, q), 3.1–3.7 (2H, m), 1.8–2.7 (2H, m), 2.08 (3H, s), 1.31 (3H, t, J = 7 Hz), 1.20 (3H, t, J = 7 Hz), 0.80 (3H, t, J = 7 Hz). Anal. calcd. for $C_{10}H_{19}NO_4$: C 5.28, H 8.82, N 6.45; found: C 55.49, H 8.82, N 6.40.

Photolysis of ethyl 2-azido-2-benzyl-3-oxobutanoate (4b)

1. In dichloromethane

(*a*) A solution of 618 mg of the azide **4***b* in 80 mL of dry dichloromethane was placed in a Vycor vessel and flushed with dry argon. It was then irradiated at 15°C for 4 h using 300-nm lamps. The yellow photolysate was then concentrated *in vacuo* to give 605 mg of an oil with ir signals at ν_{max} 3400, 1737, 1702, and 1681 cm^{-1} and ^{1}Hmr signals at 2.15 (weak singlet) and at 4.75, 3.85, 2.40, 2.20, and 1.95 (strong to medium singlets). The oil was taken up in a benzene/hexane mixture (1:1, v/v) and adsorbed onto a column (1.4 × 11 cm) of neutralized flash silica gel. Elution with a mixture of benzene/hexane (3:7, v/v) gave 228 mg of an oil very rich in the imine **16**. Further elution with the same solvent, then benzene, gave 94 mg of a mixture of unidentified products. Elution with dichloromethane gave another 44 mg of a mixture of unidentified products. Finally, elution with dichloromethane containing methanol (5%, v/v) gave 241 mg of an orange oil rich in enamide **17**. This oil was further purified by plc on silica gel (2 plates of 1000 μm) using chloroform containing ethanol (3%, v/v) as developing system. Zone extraction (R_f 0.2) furnished 146 mg (26%) or nearly pure enamide **17**.

(*b*) In a comparable experiment at 5°C crystalline benzylamine hydrochloride (25%) separated during the photolysis. Formation of this product presumably arose by hydrolysis of imine **16**, a result of moisture being present in the photolysate.

2. In methanol

(*a*) A solution of 300 mg of azide **4***b* in 60 mL of dry methanol was purged with nitrogen and then irradiated using a 100-W Hanovia lamp in an immersion well of Vycor glass cooled with circulating methanol at ca. −55°C. The outer vessel was immersed in a Dry Ice – acetone bath. Monitoring by ir spectroscopy showed that the azide signal at 2120 cm^{-1} diminished in intensity while new peaks at 1705 and 1680 cm^{-1} apeared. After 2 h of irradiation only a little amount of azide remained. Evaporation of the photolysate at 30°C *in vacuo* gave 242 mg of an oil that showed four main spots on tlc (CCl_4/EtOAc = 4:3). The oil showed ir absorptions at 3410 (w), 2120 (w), 1735 (s), 1705 (s), 1685 (s), 1645 (w), 1605 (w), and 1585 (w) cm^{-1}. The ^{1}Hmr spectrum showed two pairs of signals at 4.8 and 2.5 and at 4.0 and 2.2 consistent with the presence of the imine **16** and the *N*-acyl imine **15**. These two major components were present in nearly equal amounts (ca. 25% each). The ^{1}Hmr spectrum showed only weak methoxy signals at 3.30 and 3.35.

(*b*) A solution of 1.13 g of azide **4***b* in 170 mL of methanol was irradiated in two portions in a Vycor vessel at 10°C using 254-nm lamps. After 3 h only a small amount of azide remained (ir). Removal of the methanol *in vacuo* gave a material that was adsorbed from benzene onto 200 g of neutral alumina, activity III. Elution with benzene gave an early eluate of 203 mg of a mixture. Further elution with benzene and with benzene/dichloromethane (1:1, v/v) gave a second eluate of 405 mg, which was rich in the methoxy compound **19**. Chloroform and methanolic chloroform eluted another 181 mg of a mixture. The early eluate was further purified by plc on silica gel (2 plates of 1000 μm) using chloroform containing methanol (5%, v/v) as developing system. Extraction of the fastest zone (R_f 0.8) gave 65 mg of a material that contained roughly 40% of benzaldehyde accompanied by a number of other components. The second eluate yielded a total of 299 mg (26%) of crystalline methoxy compound **19**.

(*c*) A solution of 77 mg of azide **4***b* in 80 mL of methanol was irradiated in a Vycor vessel for 5 h at 10°C using 300-nm lamps. After concentration of the photolysate to a volume of 3 mL the remainder was treated with 1 mL of 6 N sulfuric acid for 1 h at room temperature and 0.5 h at 55°C. The remaining methanol was then removed *in vacuo*. After addition of 5 mL of water, extraction with dichloromethane removed the neutral and acidic products. The dichloromethane extracts were washed with aqueous sodium carbonate. Evaporative work-up gave 481 mg of neutral oil that was rich in the methoxy compound **19**. The acidic aqueous fraction was made strongly basic with sodium hydroxide. Extraction with dichloromethane, and evaporative work-up of the extracts, gave 108 mg of basic products. This material was acetylated to furnish 116 mg (26%) of nearly pure *N*-benzylacetamide, thus indicating that the photolysis produced a minimum yield of 26% of imine **16**.

Characterization and derivatization of the photolysis products from azide 4b

Ethyl 2-acetamido-3-phenylpropenoate (ethyl 2-acetamidocinnamate) (17)

Enamide **17** was further purified by plc on silica gel (plate of 1000 μm) using chloroform containing methanol (5%, v/v) as developing system. The material obtained by zone extraction (R_f 0.5) was distilled in a Kugelrohr apparatus at 145°C and 0.05 Torr to give pure **17** as characterized by the following spectral and analytical data: ir ($CHCl_3$) ν_{max}: 3350, 1680 cm^{-1}; ^{1}Hmr: 7.96 (1H, br s), 7.70 (1H, s), 7.25 (5H, s), 4.13 (2H, q, J = 7 Hz), 2.13 (3H, s), 1.02 (3H, t, J = 7 Hz); ^{13}Cmr: 169.0 (s), 164.9 (s), 135.3 (s), 128.5–126.8, 125.0 (d), 61.6 (t), 23.9 (q), 13.4 (q). Anal. calcd. for $C_{13}H_{15}NO_3$: C 66.93, H 6.48, N 6.01; found: C 66.81, H 6.44, N 5.95. According to its spectral data, **17** was mainly one geometric isomer, different from the one described by Hersheid *et al.* (21), which had a melting point of 98°C.

Ethyl 2-acetamido-2-methoxy-3-phenylpropanoate (19)

The methoxy compound **19** was recrystallized from acetone/hexane to give pure **19** melting at 100–101°C (lit. (19) mp 98°C). The spectral and analytical data supported the assigned structure; ir ($CHCl_3$)ν_{max}: 3415, 1730, 1690 cm^{-1}; ^{1}Hmr: 7.03 (5H, s), 6.47 (1H, br s), 4.31 (2H, q, J = 7 Hz), 3.95 (1H, d, J = 13 Hz), 3.25 (1H, d, J = 13 Hz), 3.30 (3H, s), 2.06 (3H, s), 1.32 (3H, t, J = 7 Hz); ^{13}Cmr: 169.8 (s), 134.7 (d), 130.2, 128.3 and 127.3 (d), 88.6 (s), 62.4 (t), 51.7 (q), 41.0 (t), 24.0 %q), 14.2 (q). Anal. calcd. for $C_{14}H_{19}NO_4$: C 63.38, H 7.22, N 5.28; found: C 63.53, H 7.30, N 5.16.

Methoxy compound **19** was further characterized by its conversion to the 2,4-dinitrophenylhydrazone derivative. For this purpose 40 mg of **19** was dissolved in 1 mL of ethanol. Then a hot solution of 77 mg of 2,4-dinitrophenylhydrazine in 3 mL of ethanol and 0.5 mL of concentrated hydrochloric acid was added. After 1.5 h, 0.5 mL of water was added and the mixture was allowed to stand for 2 h at room temperature. Concentration *in vacuo* gave a residue that was distributed between dichloromethane and 4 N sulfuric acid. The dichloromethane extracts were washed first with 3 N sulfuric acid and then with water. After drying, the solution was concentrated *in vacuo* to yield 57 mg of an orange coloured gum. Purification by plc on silica gel (2 plates of 500 μm) using chloroform containing ethanol (2%, v/v) gave 3 mg of a fast moving (R_f 0.6) crystalline material, followed closely by 13 mg of an amorphous material. Crystals combined from several runs were recrystallized from dichloromethane/ether to give the pure ethyl 3-phenyl-2-oxopropanoate 2,4-dinitrophenylhydrazone with a melting point of 132°C. Its spectral and analytical data supported the assigned structure; ^{1}Hmr: 9.12–8.10 (3H, m), 7.28 (5H, s), 4.36 (2H, q, J = 7 Hz), 3.95 (2H, s), 1.32 (3H, t, J = 7 Hz). Anal calcd. for $C_{17}H_{16}N_4O_6$: C 54.84, H 4.33, N 15.05; found: C 54.62, H 4.24, N 15.04. The amorphous material had an ^{1}Hmr spectrum nearly identical to that of the crystalline hydrazone, except for the benzyl methylene signal at 4.10 (2H, s). Thus the two materials must be the *syn* and *anti* isomers of the 2,4-dinitrophenylhydrazone.

Ethyl 2-benzylimino-3-oxobutanoate (16)

The crude imine **16** was estimated to be 75% pure but contained some benzaldehyde and a variety of minor impurities (^{1}Hmr). Although the sample could not be obtained pure, its structural identity was confirmed by the following spectral data: ir ν_{max}: 1737, 1702 cm^{-1}; ^{1}Hmr: 7.38 (5H, s), 4.75 (2H, s), 4.39 (2H, q, J = 7 Hz), 2.44 (3H, s), 1.36 (3H, t, J = 7 Hz); ^{13}Cmr: 196.7(s), 163.3(s), 159.3(s), 128.3, 127.7 and 127.2(d), 61.6(d), 58.5(d), 24.2(q), 13.8(q). The presence of benzaldehyde in most samples was confirmed by the ^{1}Hmr signal at δ 10.0 and ^{13}Cmr signals at 192.2 and 134.4 ppm. The benzaldehyde impurity was also confirmed by its conversion to a 4-nitrophenylhydrazone that had a melting point of 190°C and a mixture melting point with an authentic sample of 191°C.

Imine **16** was further characterized by its hydrolysis and subsequent derivatization with 4-nitrophenylhydrazine. For this purpose a solution of 75 mg of the best sample of imine **16** in 1 mL of ethanol (95%) and 0.1 mL of concentrated hydrochloric acid was left for 2 h at room temperature. Concentration *in vacuo* gave a residue that was taken up in dichloromethane. After washing with sodium bicarbonate solution, the dichloromethane was evaporated and 2 mL of ethanol and 207 mg of 4-nitrophenylhydrazine were added. The mixture was heated to boiling for 5 min and left overnight under argon. Evaporation of the ethanol *in vacuo* gave a residue that was partially soluble in chloroform. The insoluble material was filtered off and consisted of 26 mg of high melting crystals. The chloroform filtrate was washed with 3 N sulfuric acid and water. Evaporation of the chloroform gave a material that was purified by plc on silica gel (one plate of 1000 μm) using chloroform containing methanol (10%, v/v) as developing system. Zone extraction gave 2 mg of high melting crystals and 12 mg of benzaldehyde 4-nitrophenylhydrazone. The high melting crystals were sparingly soluble in hot chloroform or diglyme but could be recrystallized from dry pyridine to give a material melting at 292–294°C. This material showed no melting point depression with ethyl 2,3-dioxobutanoate bis-4-nitrophenylhydrazone **13** prepared from the imine **10**. However, its ^{1}Hmr spectrum showed no signals corresponding to an ethyl ester group. Therefore, the high melting crystals are most probably the pyrazolone **33**, formed also upon heating of the hydrazone **13**.

Preparation and photolysis of azide 7

Ethyl 3,3-ethylenedioxy-2-methylbutanoate

To a solution of 35 g of ethyl 2-methyl-3-oxobutanoate (Aldrich) in 40 mL of chloroform (ethanol-free) was added 35 g of ethylene glycol and 1 g of *p*-toluenesulfonic acid. The mixture was heated to gentle boiling to remove the chloroform and water (approximately 3.5 mL) during a period of 6 h. Fractional distillation of the residue gave 37 g (80%) of the ketal ester boiling at 58°C at a pressure of 0.1 Torr. The material showed ^{1}Hmr signals at 4.20 (2H, q, J = 7 Hz), 4.02 (4H, s), 2.81 (1H, q, J = 7 Hz), 1.43 (3H, s), and 1.29 (6H, t, J = 7 Hz).

3,3-Ethylenedioxy-2-methylbutanoic acid

To a solution of 4.35 g of ethyl 3,3-ethylenedioxy-2-methylbutanoate in 50 mL of dioxane–water (1:1 v/v) was added 5 g of potassium hydroxide. The initial two-phase mixture was stirred at 35°C and became homogeneous after 6 h. Stirring was continued for another hour, then the bulk of the solvents was removed under reduced pressure. The residue was dissolved in 30 mL of water and washed with dichloromethane. The aqueous solution was then acidified and extracted with chloroform. Evaporation of the solvent gave 3.0 g (81%) of the ketal acid, with the following ^{1}Hmr data: 9.8 (1H, br s), 4.03 (4H, s), 2.83 (1H, q, J = 7 Hz), 1.45 (3H, s), 1.33 (3H, d, J = 7 Hz).

3,3-Ethylenedioxy-2-methylbutanoyl chloride

A solution of 1.18 g of 3,3-ethylenedioxy-2-methylbutanoic acid in 10 mL of dry dichloromethane was cooled to 0°C under dry argon. Then a solution of 2.15 g of oxalyl chloride in 4 mL of dry dichloromethane was added. After 5 min at 0°C the mixture was allowed to warm and then was kept at room temperature. Gas evolution ceased after 30 min, and after another 30 min the solvent and excess oxalyl chloride were removed under reduced pressure. The residual oil was distilled over a short path to give 1.1 g of the ketal acid chloride boiling at 65°C at a pressure of 0.3 Torr.

N-*(3,3-Ethylenedioxy-2-methylbutanoyl)-piperidine*

To a solution of 376 mg of 3,3-ethylenedioxy-2-methylbutanoyl chloride in 5 mL of pentane was added slowly with stirring a solution of 400 mg of piperidine in 5 mL of dichloromethane. After complete addition the reaction mixture was washed with dilute sulfuric acid, followed by a washing with dilute sodium carbonate solution. Evaporation under reduced pressure gave 433 mg (66%) of crude ketal amide **8**. Distillation over a short path of 0.5 Torr and 100°C gave pure amide **8**. Spectral and analytical data were in agreement with the structural assignment; ir ν_{max}: 3410 (br), 1625 cm^{-1}; ^{1}Hmr: 3.93 (4H, s), 3.53 (4H, br s), 3.07 (1H, q, J = 7 Hz), 1.60 (6H, br s), 1.37 (3H, s), 1.20 (3H, d, J = 7 Hz). Anal. calcd. for $C_{12}H_{21}NO_3$: C 63.41, H 9.31, N 6.16; found: C 63.19, H 9.41, N 6.28.

N-*(2-Methyl-3-oxobutanoyl)-piperidine (5)*

To a solution of 111 mg of *p*-toluenesulfonic acid hydrate in 5 mL of water was added 79 mg of *N*-(3,3-ethylenedioxy-2-methylbutanoyl)-piperidine. After stirring for 10 h at room temperature the reaction mixture was made alkaline by adding sodium carbonate. Extraction with dichloromethane gave 647 mg (100%) of the keto amide **5** with the correct spectral data; ir ν_{max}: 3450 (br), 1725, 1645, 1635 cm^{-1}; ^{1}Hmr: 3.70 (1H, q, J = 7 Hz), 3.87–3.35 (4H, br s), 2.23 (3H, s), 1.67 (6H, br s), 1.37 (3H, d, J = 7 Hz).

N-*(2-Bromo-2-methyl-3-oxobutanoyl)-piperidine (6)*

(a) Bromination with bromine: To a stirred solution of 1.49 g of keto amide **5** and 100 mg of *p*-toluenesulfonic acid hydrate in 4 mL of dichloromethane was added slowly a solution of 800 mg of bromine in 4 mL of dichloromethane. After initial rapid uptake of bromine an excess persisted for 10 min. The reaction mixture was washed with a dilute solution of sodium carbonate and then concentrated under reduced pressure to give a crude residue of 1.85 g. According to its ^{1}Hmr spectrum, this residue still contained starting keto amide **9**. Therefore this residue was subjected to a repeat bromination and work-up to give a crude product weighing 1.98 g. This material was absorbed from benzene onto 40 g of neutral alumina (activity II). Elution with benzene gave 1.08 (50%) of nearly pure bromoketo amide **6**.

(b) Bromination with pyridinium bromide perbromide: To a solution of 560 mg of the keto amide **5** in 2 mL of dry pyridine was added 1.5 g of pyridinium bromide perbromide. The reaction mixture was stirred for 6 h at room temperature, during which time some hydrobromide crystallized. Removal of the pyridine *in vacuo* at 35°C left a residue that was taken up in dichloromethane (10 mL) and washed with dilute sulfuric acid (3 mL). The dichloromethane solution was then washed with a dilute solution of sodium thiosulfate and dried. Evaporation under reduced pressure gave a residue that contained much starting material (^{1}Hmr). The bromination was repeated with 3 mL of pyridine and 2 g of pyridinium bromide perbromide. A reaction time of 17 h at room temperature in the dark, followed by the above work-up, gave a residue that was extracted with dry ether. The ether-soluble component was 715 mg of a pale yellow gum. A crude purification by adsorption onto 20 g of neutral alumina (activity II) and elution with ether gave 585 mg of products followed by 84 mg of starting material. The product mixture was separated by plc on silica gel (4 plates of 100 μm) using a mixture of ethyl acetate/hexane (6:4, v/v) as eluent. Extraction of the front zone (R_f 0.8) gave 202 mg of an almost pure, fast moving solid material. A second zone yielded 245 mg of a pure, slower moving oily material.

The slower moving material proved to be the desired *N*-(2-bromo-2-methyl-3-oxobutanoyl)-piperidine **6** (30%) with correct spectra data: ir ν_{max}: 1720, 1710, 1640 cm^{-1}; ^{1}Hmr: 3.52 (4H, br s), 2.48 (3H, s), 2.04 (3H, s), 1.65 (6H, br s).

The fast moving material was further purified by filtering of a dichloromethane solution through a short column of neutral alumina (activity IV). Evaporation of the solvent gave a material that crystallized as prisms from ethyl acetate/hexane. This material proved to be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12
For personal use only.

N-(2,4,4-tribromo-2-methyl-3-oxobutanoyl)-piperidine (**8**) melting at 82–83°C. Spectral and analytical data corroborated the structural assignment; ir ν_{max}: 1741, 1651, 1619 cm^{-1}; uv (95% ethanol) λ_{max}: 269 nm (ϵ 1000); ^{1}Hmr: 6.52 (1H, s), 3.67 (4H, br), 2.18 (3H, s), 1.63 (6H, br); ^{13}Cmr: 190.4, 164.5, 59.7, 48.1 (br), 45.0 (br), 36.2, 27.2, 25.4, 24.1 (at −30°C the broad signals at 48.1 and 45.0 sharpened to singlets at 48.6 and 44.6, with small shift changes in other signals). Anal. calcd. for $C_{10}H_{14}Br_3NO_2$: C 28.60, H 3.36, N 3.34, Br 57.09; found: C 28.69, H 3.58, N 3.70, Br 56.10.

N-*(2-Azido-2-methyl-3-oxobutanoyl)-piperidine (7)*

Lithium azide (570 mg) was dissolved in 5 mL of dry dimethylformamide by heating. After cooling to 10°C a solution of 875 mg of bromoketo amide **6** in 5 mL of dry dimethylformamide was added. After 20 min at room temperature the main portion of the solvent was removed under reduced pressure and a bath temperature of 60°C. The residue was dissolved in dichloromethane, then the solution was washed with water, dried, and concentrated. The residue of 838 mg, containing a little dimethylformamide, was distilled over a short path. At a pressure of 0.1 Torr and a temperature of 130°C a colourless oil (657 mg, 88%) was obtained, which proved to be the desired azidoketo amide **7**. It had ir ν_{max}: 2105, 1721, 1651 cm^{-1}; ^{1}Hmr: 3.47 (4H, br s), 2.30 (3H, s), 1.73 (3H, s), 1.63 (6H, br s). Anal calcd. for $C_{10}H_{16}N_4O_2$: C 53.55, H 7.19, N 24.99; found: C 53.43, H 7.26, N 24.87.

Photolysis of N-*(2-azido-2-methyl-3-oxobutanoyl)-piperidine 7*

A solution of 310 mg of azidoketo amide **7** in 80 mL of dry methanol under argon was irradiated for 4 h at 10°C in a Vycor vessel using lamps with a peak emission at 254 nm. After addition of 130 mg of *p*-toluenesulfonic acid hydrate, the photolysate was warmed to 40°C and then left at room temperature for another hour. The photolysate was neutralized with a saturated aqueous solution of sodium bicarbonate and then concentrated under reduced pressure to a volume of 5 mL. After addition of 5 mL of water, extraction with dichloromethane (3 × 15 mL) and chloroform (10 mL) led to the isolation of 286 mg of an oily material. Separation of the products by plc using silica gel (2 plates of 1000 μm) and methanol/chloroform (1:9, v/v) gave 165 mg of a fast moving material (R_f 0.6) and 36 mg of a slower moving material (R_f 0.4). According to its ^{1}Hmr spectrum, the fast moving material was mainly methoxy compound **20**. Further purification by plc using methanol-washed alumina and ethanol-free chloroform gave a material isolated from the main zone (R_f 0.36), which was once more purified by plc using silica gel and methanol/chloroform (1:9, v/v). Zone extraction gave a faintly coloured oil (83 mg, 26%), which proved to be almost pure[7] *N*-(2-acetamido-2-methoxypropionyl)-piperidine (**20**) according to its spectral data; ir ν_{max}: 3375, 1677, 1617 cm^{-1}; ^{1}Hmr: 7.7 (1H, br), 4.0–3.4 (5H, m), 3.21 (3H, s), 2.07 (3H, s), 1.93 (3H, s), 1.69 (6H, br m); ^{13}Cmr: 168.9, 168.0, 87.0, 51.6, 47.0, 45.0, 26.4, 26.0, 25.7, 24.4, 23.0. CI-MS: 229 (94.5), 197 (100), 170 (17), 155 (50). Mol. wt. calcd. for $C_{11}H_{20}N_2O_3$: 228.

The slower moving pure material, which crystallized on standing, proved to be *N*-(2-methoxy-2-methylamino-3-oxobutanoyl)-piperidine (**21**) (36 mg, 11%) with a melting point of 121–123°C (needles from ethyl acetate/hexane). Spectral data, ir ν_{max}: 3450, 3420, 1722, 1653 cm^{-1}; ^{1}Hmr: 5.7 (1H, br), 3.5–3.2 (4H, br m), 3.18 (3H, s), 2.30 (3H, s), 1.61 (6H, br s); ^{13}Cmr: 207.8, 155.1, 87.8, 50.2, 45.0, 25.7, 24.3, 23.9, 21.8. CI-MS: 229 (94.5), 197 (100), 185 (7), 149 (75), 112 (35). Mol. wt. calcd. for $C_{11}H_{20}N_2O_3$: 228.

A second photolysis under comparable conditions was carried out with 274 mg of azidoketo amide **7** in 40 mL of methanol containing 159 mg of trifluoroacetic acid. After irradiation for 2.5 h the photolysate was concentrated under reduced pressure and the residue was dissolved in dichloromethane. This solution was washed with a saturated solution of sodium bicarbonate, and concentrated under reduced pressure to yield 250 mg of an oily product exhibiting only weak azide absorption. Purification of this material by plc using alumina (2 plates of 1000 μm) and chloroform gave 15 mg of a fast moving material that proved to be the starting azidoketo amide **7**. Zone extraction of a slower moving material (R_f 0.7) gave 79 mg (30% based on unrecovered **7**) of the 2-acetamido-2-methoxy compound **20**.

Preparation and photolysis of azido lactam 28

L-Prolyl-L-valyl lactam (24)

The diketopiperazine **24** was prepared from L-prolyl-L-valine methyl ester (an oil with $[\alpha]_D$ −55° (*c* 0.95, ethanol)), which in turn was prepared from benzyloxycarbonyl-L-prolyl-L-valine methyl ester (an oil with $[\alpha]_D$ −60° (*c* 1.01, ethanol) by hydrogenolysis over 30% Pd on charcoal in ethanol. The L-prolyl-L-valine methyl ester (3.49 g) was placed in a small flask equipped with a short air condenser. The ester was then cyclized by heating for 3 h in a bath at 110°C and at a pressure of 12 Torr. The residue was triturated with ethyl acetate/hexane, leaving a crystalline solid that was filtered off. The soluble material was heated again as above leading to the isolation of a second batch of crystals. After a third heating a total of 1.23 g (41%) of crystalline diketopiperazine **24** was collected. After recrystallization from ethyl acetate/hexane this material had a melting point of 190°C and $[\alpha]_D$ −156° (*c* 1.0, ethanol) (lit. (9) mp 192°C; $[\alpha]_D$ −159°).

N-*(3,3-Ethylenedioxy-2-methylbutanoyl)-prolyl-valyl lactam (25)*

A solution of 2.75 g of 3,3-ethylenedioxy-2-methylbutanoyl chloride in 3 mL of dry chloroform was added to a cooled solution of 2.67 g of diketopiperazine **24** and 1.66 g of 4-dimethylaminopyridine in 5 mL of dry chloroform. The resulting mixture was heated to reflux for 6.5 h and then left at room temperature for 9 h. After dilution with chloroform the solution was washed with dilute sulfuric acid and a saturated solution of sodium bicarbonate. Evaporation of the solvent followed by oil pump evacuation (40°C, 0.5 Torr) gave 4.5 g of an oily residue. This residue was dissolved in ethyl acetate/hexane (1:1, v/v) whereby a precipitate of 403 mg of unreacted diketopiperazine **24** was formed. Concentration of the filtrate led to the isolation of 3.6 g of a material that was rich in isomeric *N*-acylated diketopiperazines (ketal lactams) **25**. This material was dissolved in benzene and adsorbed onto 30 g of neutral alumina (activity III). Elution with benzene and dichloromethane gave 3.0 g of a principal eluate, which proved to be a mixure of isomers of the desired ketal lactam **25** and esters of ethylene glycol (^{1}Hmr). Further elution with dichloromethane and chloroform containing ethanol (0.75%, v/v) gave 207 mg of material rich in L-prolyl-L-valyl lactam **24**, followed by an isomer of **24**.

Spectral analysis of the principal eluate indicated that it consisted of similar amount of two isomeric ketal lactams **25** with the following ^{1}Hmr data: two doublets at 4.93 (J = 4 Hz) and 4.70 (J = 5 Hz), two singlets at 3.90 and 3.77, three major methyl signals at 1.25, 1.13, and 1.02, and a set of weaker methyl signals. In addition the ^{1}Hmr spectrum indicated the presence of minor impurities with signals at 4.33 and 2.0 and 1.92, suggesting the presence of a glycol ester and acetates or methyl ketones. These minor impurities could be removed at 90°C and 0.1 Torr.

N-*(2-Methyl-3-oxobutanoyl)-prolyl-valyl lactam (26)*

A mixture of 5.7 g of the isomeric ketal lactams **25** and 1 mL of tetrahydrofuran gave a syrup, which was stirred for 4 min at room temperature with 80% (v/v) aqueous trifluoroacetic acid. The reaction mixture was then concentrated by evaporation at 25°C and a pressure of 0.1 Torr (25 min). The residue was dissolved in 15 mL dichloromethane and the solution was washed with water followed by 5 mL of a saturated solution of sodium bicarbonate. The aqueous phases were extracted again with dichloromethane. Removal of the solvent from the combined dichloromethane extracts gave 4.39 g of an oily residue. When this residue was dissolved in ether a first crop of 878 mg of crystals separated. Addition of hexane to the mother liquor gave a second crop of 1.1 g of crystals. The combined crystalline material was recrystallized from acetone/hexane to give 1.54 g of a mixture of isomeric keto lactams **26** with a melting point of 150°C. Upon evaporation the mother liquors gave 2.4 g of an amorphous material, which was adsorbed from benzene onto 20 g of neutral alumina (activity III). The first eluates upon evaporation gave 1.1 g of a material that upon dissolution in ether gave another 303 mg of the keto lactam **26** melting at 150°C. The mother liquor contained more keto lactams and a glycol

[7]All the spectra showed evidence of contaminants.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12
For personal use only.

ester, which could be distilled at 90°C and 2×10^{-3} Torr. Later eluates contained crystals of prolyl-valyl lactam **24** and an isomeric keto lactam. The crystalline keto lactam mixture **26** (1.54 g) was separated by fractional crystallization from acetone/hexane. The main component **26*a*** crystallized as blades with a melting point of 155°C, while the minor component **26*b*** formed complex prisms with a melting point of 109°C.

The major keto lactam **26*a*** was further purified by plc on silica gel using chloroform containing methanol (5%, v/v). The prisms so obtained had a melting point of 158–160°C (dec.) and $[\alpha]_D$ +41° (*c* 0.8, ethanol). The spectral and analytical data supported the structural assignment as *N*-(2-methyl-3-oxobutanoyl)-prolyl-valyl lactam; ir ν_{max}: 1722, 1668, cm^{-1}; ^{1}Hmr: 4.96 (1H, d, J = 9 Hz), 4.3 (2H, m), 3.55 (2H, m), 2.29 (3H, s) 1.40 (3H, d, J = 7 Hz), 1.08 (6H, d, J = 6 Hz); ^{13}Cmr: 205.0, 170.9, 170.7, 165.3, 63.7, 59.9, 56.5, 45.5, 31.4, 29.6, 28.2, 22.8, 19.6, 13.1. Anal. calcd. for $C_{15}H_{22}N_2O_4$: C 61.20, H 7.53, N 9.52; found: C 61.02, H 7.50, N 9.35.

The minor keto lactam **26*b*** was recrystallized from acetone/hexane to give pure **26*b*** with a melting point of 108–109°C and $[\alpha]_D$ +174° (*c* 0.9, ethanol). The spectral and analytical data suported the structural assignment; ^{1}Hmr: 4.98 (1H, d, J = 9 Hz), 4.55 (1H, q, J = 15, J_2 = 7 Hz), 4.3 (1H, t, J = 7 Hz), 3.6 (2H, m), 2.25 (3H, 5), 1.39 (3H, d, J = 7 Hz), 1.09 (3H, d, J = 7 Hz), 0.98 (3H, d, J = 7 Hz). Anal. calcd. for $C_{15}H_{22}N_2O_4$: C 61.20, H 7.53, N 9.52; found: C 61.06, H 7.60, N 9.48.

N-(2-Bromo-2-methyl-3-oxobutanoyl)-prolyl-valyl lactam (27)

Bromination of keto lactams **26** using *N*-bromosuccinimide in THF or using bromine in the presence of trifluoroacetic acid in CH_2Cl_2 gave bad mixtures of products. Using bromine in dry pyridine gave reasonable yields of isomeric monobromoketo lactams. However, the best and most convenient procedure employed the pyridinium bromide perbromide complex.

A solution of 211 mg of quite pure keto lactam **26*a*** (mp 153°C) in 1 mL of dry pyridine was cooled in ice. After addition of 269 mg of pyridinium bromide perbromide the mixture was stirred in the dark at room temperature for 5 h. Concentration under reduced pressure at 30°C gave a residue that was dissolved in 15 mL of dichloromethane and then washed with 5 n sulfuric acid followed by a dilute solution of sodium thiosulfate. Concentration of the dichloromethane solution gave 251 mg of a frothy material from which, upon treatment with ether, a flocculent solid separated. Concentration of the filtrate and treatment of the residue with hexane gave a first crop of 114 mg of nearly pure bromoketo lactam **27** and a second crop of 52 mg of a mixture contining bromoketo lactam **27** and ca. 40% of the parent keto lactam **26*a***. The mixture of **27** and **26*a*** could be separated by chromatography using neutral alumina (activity III) and benzene. The total yield of crystalline bromoketo lactam **27** based on unrecovered **26*a*** was 60%. Recrystallization from dichloromethane gave colourless short needles of bromoketo lactam **27** with a melting point of 107°C and $[\alpha]_D$ 42° (*c* 0.5, ethanol). The spectral and analytical data supported the structural assignment; ir ν_{max}: 1733, 1669 cm^{-1}; ^{1}Hmr: 4.92 (1H, d, J = 9.5 Hz), 4.29 (1H, t, J = 8 Hz), 3.55 (2H m), 2.52 (3H, s), 2.00 (3H, s), 1.10 (3H, d, J = 6.5 Hz), 1.05 (3H, d, J = 6.5 Hz). Anal. calcd. for $C_{15}H_{21}BrN_2O_4$: C 48.26, H 5.63, N 7.50; found: C 48.49, H 5.80, N 7.44.

The mother liquor from the bromination contained mainly material giving ^{1}Hmr signals at 2.0 and 2.5 characteristic of the bromoketo lactam. However, the characteristic doublet at 4.9 arising from the lactam moiety was replaced by a complex multiplet, suggesting the presence of a mixture of isomers. Attempts to use this material in subsequent reactions led to bad mixtures.

N-(2-Azido-2-methyl-3-oxobutanoyl)-prolyl-valyl lactams (28)

To replace the bromo group of **27** by the azide function, "neutralized" lithium azide was prepared from commercial lithium azide. For this purpose lithium azide was dissolved in methanol and the pH of the solution adjusted to a value of 7.5 by addition of a dilute solution of perchloric acid in methanol. The neutralized solution was evaporated to dryness and the solid residue was dried at 100°C *in vacuo*. A solution of 75 mg of bromoketo lactam **27** in 0.5 mL of hot dimethylformamide was cooled to room temperature. A solution of 100 mg of neutralized lithium azide in 0.5 mL of dimethylformamide was added and the mixture was stirred at room temperature for 15 min. Concentration at 25°C and 0.3 Torr gave a residue that was taken up in 10 mL of dichloromethane. After washing twice with 5 mL of water and extraction of the aqueous washings with dichloromethane, the combined extracts of dichloromethane were concentrated to give 59 mg of an oil. This oil was purified through a short column of neutral alumina (0.3 g, activity III) using dichloromethane as solvent. The first eluates yielded 48 mg (71%) of the azidoketo lactams **28** free of bromoketo lactam **27**. The spectral data of this material suggested that there were at least two isomers present: It had ir signals at ν_{max} 2110, 1720, and 1670 cm^{-1}, and ^{1}Hmr signals at 1.03 and 1.13 (superimposed on other partially resolved signals), 1.60 (weak), 1.69 (less than half the intensity expected for a methyl group), and at 2.30 (a singlet integrating to approximately 3H). In comparable experiments it was observed that the ^{1}Hmr signal at 1.60 was nearly as intense as the one at 1.69. The factor influencing the signal ratio was not determined. Attempts to separate the isomers on alumina led to major loss of material without success. Therefore, the isometric mixture of azidoketo lactams **28** was used as such for the photolytic studies.

Photolysis of N-(2-azido-2-methyl-3-oxobutanoyl)-prolyl-valyl lactams 28

A solution of 72 mg of isomeric azidoketo lactams **28** in 12 mL of pure methanol was irradiated for 5 h at 10°C in a Vycor vessel using lamps with a peak emission at 300 nm. Most of the azido group had disappeared (ir) after 4 h. The photolysate was concentrated to give a material that exhibited only a very weak methoxy signal in the ^{1}Hmr spectrum. Therefore the material was dissolved in 3 mL of methanol containing 55 mg of trifluoroacetic acid and stirred at room temperature for 1.5 h. Then the mixture was neutralized using a few drops of a saturated solution of sodium bicarbonate and evaporated to dryness. The residue was taken up in dichloromethane and washed with a saturated solution of sodium bicarbonate. Evaporation of the solvent gave 49 mg of a gum, which was dissolved in ether. After addition of hexane, 16 mg of a gum separated. An ether solution of this gum led to the isolation of 5 mg of slowly crystallizing methoxy cycloltripeptide **29**. The soluble material was recycled through the methanol/trifluoroacetic acid treatment to give another 4 mg for a total of 9 mg (12%) of the methoxy cycloltripeptide **29**.

In comparable experiments the total product from the photolysis was adsorbed from dichloromethane onto a 40-fold weight ratio of neutral alumina (activity III). Elution with dichloromethane and chloroform removed undesired products, while elution with chloroform containing methanol (10%, v/v) eluted the methoxy cycloltripeptide **29** in a maximum yield of 17% The methoxy cycloltripeptide **29** crystallized from acetone/dichloromethane to give square plates or rods with a melting point of 176–178°C and $[\alpha]_D$ +60° (*c* 1.0, methanol). The spectral and analytical data supported the structural assignment; ^{1}Hmr: 6.30 (1H, s), 3.34 (3H, s), 1.90 (3H, s), 1.68 (3H, s), 1.08 (3H, d, J = 7 Hz), 1.03 (3H, d, J = 6 Hz); ^{13}Cmr: 186.0, 185.0, 179.0, 86.2, 63.4, 62.1, 49.9, 28.4, 23.6, 22.9, 20.2, 19.4. Anal. calcd for $C_{16}H_{25}N_2O_5$: C 56.62, H 7.43, N 12.38; found: C 56.73, H 7.52, N 12.48.

An X-ray crystallographic analysis (10) confirmed the gross structural assignment and established the stereochemistry of the product as being 2*S*,5*S*,11*R*,12*S* - acetamido - 3,6-dioxo-5 - isopropyl-10b-methoxy-2-methyl-perhydro-8*H*-oxazolo[3,2-*a*]pyrrolo[2, 1-*c*]-pyrazine.

Received February 19, 1990

J. W. GOODALE, D. K. EVANS, M. IVANCO, and ROBERT D. MCALPINE. Can. J. Chem. **68**, 1437 (1990).

The infrared laser induced multiphoton decomposition of ethyl alcohol has been studied in experiments with iodine as a radical scavenger and the deuterium substituted form CH_3CD_2OH of the alcohol. These experiments show that the principal product, C_2H_4, arises from a concerted molecular elimination, as do most of the CH_4 and CH_3CHO. The C_2H_6 product results from recombination of the nascent methyl radicals formed in the minor bond breaking channel.

Key words: ethyl alcohol, multiphoton decomposition.

J. W. GOODALE, D. K. EVANS, M. IVANCO et ROBERT D. MCALPINE. Can. J. Chem. **68**, 1437 (1990).

Par le biais d'expériences réalisées à l'aide de la forme deutérée CH_3CD_2OH de l'alcool et utilisant l'iode comme piège à radical, on a étudié la décomposition multiphotonique induite par un laser infrarouge de l'alcool éthylique. Ces expériences démontrent que le produit principal, le C_2H_4, se forme par une élimination moléculaire concertée, comme c'est aussi le cas pour la majeure partie du CH_4 et du CH_3CHO. Le C_2H_6 qui se forme provient d'une recombinaison des radicaux méthyles naissants qui se forment par une voie mineure de bris de liaison.

Mots clés : alcool éthylique, décomposition multiphotonique.

Introduction

There have been a number of studies of the infrared laser induced multiphoton decomposition (MPD) of ethyl alcohol over the past few years (1–13), and several reaction channels have been proposed to explain the product mix observed. In those papers, the channel ratios as a function of conditions such as fluence or pressure have been well documented. In this study, we are interested in the route to the products and have not been concerned with the channel ratios. The following three molecular reactions [1*a*,*b*,*c*] and the simple radical cleavage reaction [1*d*] have been deduced as the major decomposition channels for the MPD of ethyl alcohol:

$$[1a] \quad C_2H_5OH \rightarrow C_2H_4 + H_2O$$

$$[1b] \quad \rightarrow CH_3CHO + H_2$$

$$[1c] \quad \rightarrow CH_4 + H_2CO$$

$$[1d] \quad \rightarrow CH_3\cdot + H_2COH\cdot$$

The identification of the major channels suggested above is primarily based on final stable product analysis. For MPD, the molecular channel [1*a*] is believed to predominate but, in pyrolysis studies, other free radical channels, which lead to the products CH_3CHO and H_2, are reported to be most important (14). One recent report discusses the relative importance of molecular and radical channels for several alcohols (13).

In the present work, we have performed two types of experiments in an effort to clarify the mechanism of the decomposition: (i) experiments using iodine as a free radical scavenger and (ii) decomposition of the selected deuterium substituted form, CH_3CD_2OH, of ethyl alcohol. In the latter, the location of the deuterium atoms in the product molecules allows determination of the mechanism leading to several of the decomposition products.

We find that, at moderate fluences, the product C_2H_6 arises only via a radical channel involving combination of two methyl radicals, while the products C_2H_4 and CH_3CHO are produced through molecular channels. CH_4 is found to come mainly from a molecular elimination with little arising from abstraction by a methyl radical, generated through reaction [1*d*].

Experimental

A temporally smooth CO_2 laser operating at 2 Hz with a pulse duration of about 60 ns was used in all of the experiments reported here. The undeuterated alcohol was irradiated with the 9P(16) line (9.250 μm) while the deuterated species were irradiated with the 10P(14) line (10.532 μm). The beam was focused with a 54 cm focal length lens to an area of 0.005 cm^2 into a 12.6 cm path length Pyrex cell onto which NaCl windows were sealed with an epoxy. The focusing geometry was used to avoid damage to the windows at the fluences used for decomposition. The pressures of the ethyl alcohol vapour ranged from 0.067 to 1.33 kPa.

The protiated alcohol was dried as reported in ref. 12, while the deuterated alcohols (M.S.D. Isotopes) were used with only vacuum degassing. FTIR and mass spectrometric analyses were done to confirm the locations of the deuterium atoms.

Measurements of ethyl alcohol depletion and product formation, following MPD, were performed using a Hewlett–Packard 5995 GC/MS system in the Single-Ion-Monitor (SIM) mode. The cracking patterns of the isotopically labelled decomposition products were characteristic of the labelled site and thus accurate determinations of the location of the deuterium atoms in the parent ethyl alcohols and in the products of decomposition were possible. By judiciously choosing the sites of deuteration of the ethyl alcohol, we were able to use this procedure to help in determining the mechanism of multiphoton decomposition. While experiments were performed with several deuterated forms of ethyl alcohol, the majority of this deuterium atom location work was done using the CH_3CD_2OH form, for which the ion masses selected for identification of the products are at 15–20, 26–34, and 41–48 amu. The CH_3CD_2OH form provided definitive comments on the decomposition mechanism and only results from experiments with that isotopic form are discussed. The masses chosen identified both protiated and deuterated species of the major decomposition products (ethene, ethane, ethyne, ethenal, methane, and carbon dioxide). These products, and ethyl alcohol, were also measured quantitatively by comparing their peak areas against standards.

The gas chromatographic column (Porapac P, 2.44 m long × 3.2 mm outside diameter stainless steel) separates ethyl alcohol and product molecules effectively under the following column conditions. With a helium carrier gas flow rate of approximately 25 cm^3/min, the column temperature was initially set to 60°C and held at that temperature for 4 min, then raised at a rate of 16°/min to 140°C where

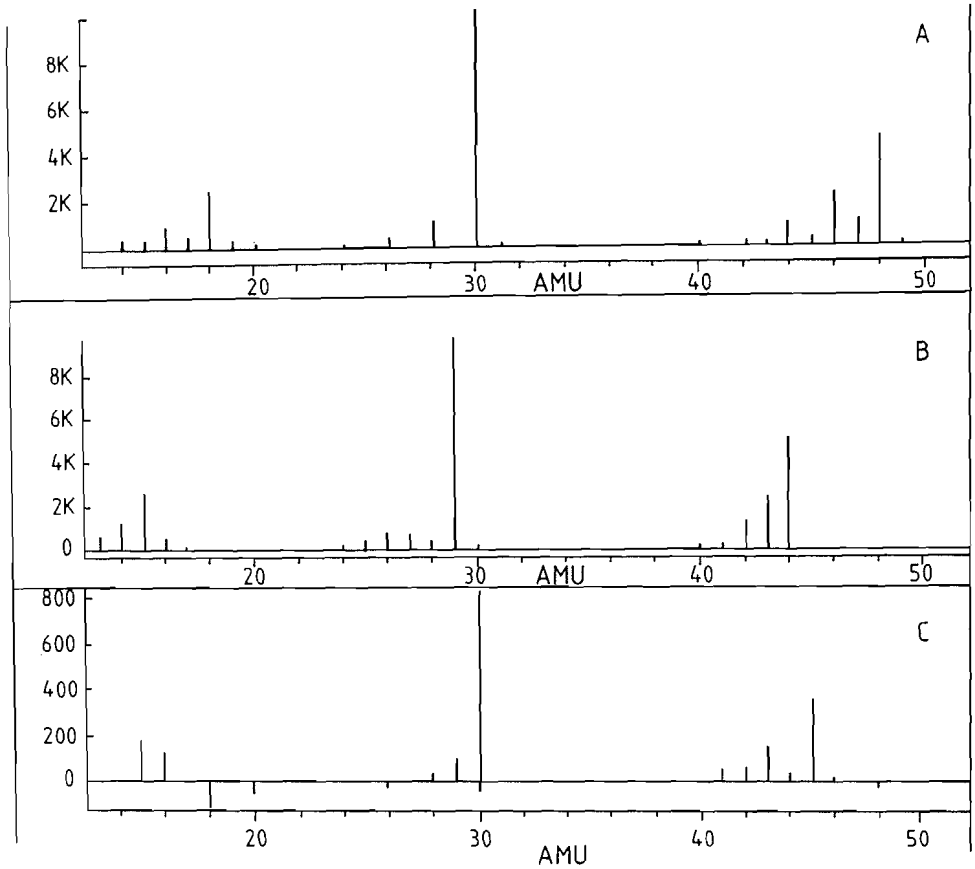

FIG. 1. The mass spectra of reference compounds (A and B) and of gas chromatographically separated products of MPD of CH_3CD_2OH (C). The location of the deuterium atoms is unique, and allows a clear interpretation of the decomposition mechanism as discussed in the text.

it was held for 25 min. The same GC/MS system was used in the quantitative analysis of the $C_2H_5OH + I_2$ irradiations, although the column temperature program was changed slightly (60°C for 10 min, then 10°C/min to 150°C where it was held for 30 min).

In some of the experiments, significant amounts of diethoxymethane were found. This only occurred after the cell had been used with iodine and is a result of reaction among the iodine, adsorbed ethyl alcohol, and the epoxy used to glue on the sodium chloride windows. This reaction was shown to be the source of the diethoxymethane both through atom balance calculations and by irradiating ethyl alcohol in a newly prepared cell. No diethoxymethane was found immediately after irradiation in the cell that had never been exposed to iodine. Iodine was added to the mixture of ethyl alcohol and decomposition products and the cell allowed to sit for 3 days. At the end of this time, another analysis was performed and diethoxymethane was found. This showed that the diethoxymethane was not a MPD product but its appearance was an artifact of a reaction not related to the photochemistry.

Results and discussion

Ethyl alcohol plus iodine

As reported earlier (12), the addition of O_2 as a radical scavenger had no effect on the molecular elimination reactions [1*a*], [1*b*], or [1*c*]; however, it completely suppressed the production of ethane. This indicated that ethane is produced following the radical reaction [1*d*], which produces $CH_3\cdot$ radicals. Our experiments with I_2 as a radical scavenger support the proposition that ethane results from radical combination, as methyl iodide is a new product and essentially no C_2H_6 is found when I_2 is present. Similarly, iodine additions had no effect on the other reaction products, indicating reactions [1*a*], [1*b*], and [1*c*] are molecular and only [1*d*] produces significant quantities of free radicals ($CH_3\cdot$). The lack of an effect on the quantity of methane produced indicates that the principle after-pulse reaction of the $CH_3\cdot$ radicals is for two to combine, and very little, if any, abstraction to form methane occurs. Also, unlike the mechanism suggested for pyrolysis (14), the CH_3CHO is produced by a molecular channel in the laser induced process.

Labelled ethyl alcohol

An example of determining the location of the deuterium atom(s) in acetaldehyde is shown in Fig. 1. Figure 1(A) and 1(B) show the mass spectra of fully deuterated (with up to about 10% protiated as purchased) and fully protiated acetaldehyde. The spectra are presented with the background subtracted from the signal of the GC peak. By examining Fig. 1(C) we can determine the number of deuterium atoms present and their location in the acetaldehyde product molecule. The major mass at *m/e* 45, CH_3CDO, shows there is exactly one deuterium atom in the molecule (*m/e* 44, CH_3CHO, has a small signal and *m/e* 48, CD_3CDO, has no signal). The mass at *m/e* 30 shows the presence of the CDO^+ ion, while the mass at *m/e* 15 shows that of the CH_3^+ ion. The molecule is thus CH_3CDO. Similar methods are used for the other product molecules.

In this report, information on the reaction mechanism has been determined by the IRMPD of deuterated species of ethyl alcohol and by analyzing the mass spectra of the reaction products. The following scheme is proposed.

$$[2] \quad CH_3CD_2OH \rightarrow H_2C{=}CD_2 + H_2O$$

$$[3] \quad \rightarrow CH_3CDO + HD$$

$$[4a] \quad \rightarrow CH_4 + D_2CO$$

$$[4b] \quad CH_3D + DCOH$$

$$[5] \quad \rightarrow CH_3\cdot + \cdot D_2COH$$

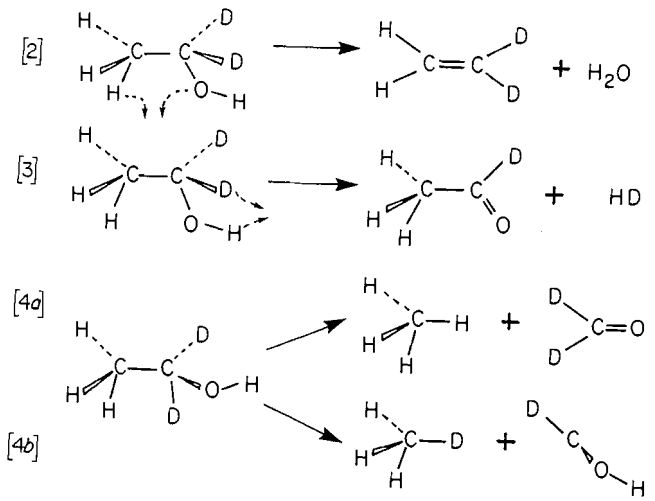

FIG. 2. The probable pathway for the decomposition mechanism producing the major products is indicated by the arrows. The molecular fragments leave by a concerted molecular process where the bonds of the products are formed while the reactant bonds are broken. Equation numbers are the same as in the text.

In ethyl alcohol MPD experiments, the major decomposition product was C_2H_4 with about 10–15% as much C_2H_6, slightly more than 5% as much CH_3CHO, and about 5% as much CH_4. The channel ratios were in agreement with previous reports. In this work, the interest was in how the products arise, not in their relative proportions.

Reactions [2]–[4] are shown pictorially in Fig. 2, where the mechanistic details can be more clearly seen. Molecular models were useful in visualizing the channels suggested as credible combinations of the normal modes of vibration of ethyl alcohol.

In reaction [2] the only isotopic form of ethene produced throughout the pressure range of 0.067–0.8 kPa, at a fluence of 25 J/cm^2, is CH_2=CD_2, indicating the reaction involves the removal of a C2 hydrogen and the -OH group to form water. No measurement of the water formed was made. Similarly, in reaction [3], the only isotopic form of acetaldehyde observed was CH_3CDO, consistent with a concerted elimination of HD across the CO bond. The gas chromatograph system used is not able to measure $m/e < 10$, so that no determination of the HD was possible here. There appears to be no involvement of the methyl hydrogens in this reaction. From product analysis, there are approximately equal quantities of CH_4 and CH_3D found after irradiation and their ratio is independent of starting pressure. A ratio near unity and the fact that there are two deuterium atoms on the α carbon of the starting ethyl alcohol, compared to the single hydrogen atom in the hydroxyl group, suggests a preference for reaction [4*a*], that is, a concerted molecular elimination of the methyl group with the hydrogen of the hydroxyl group. A physical model of the ethyl alcohol molecule shows that this is a possible mechanism. Reaction [5], at low pressure, produces only CH_3—CH_3; however, as the ethyl alcohol pressure increases, there appears to be a change in the mechanism and, by 1.33 kPa, equal quantities of CH_3—CH_3 and CH_3—CH_2D are produced. The experiments done for this study did not provide any further information on the changes resulting from increased pressure.

Conclusions

The infrared laser induced decomposition of ethyl alcohol leading to the products ethene, acetaldehyde, and methane has been shown to proceed mainly through molecular channels. Ethane is formed by efficient bimolecular recombination of methyl radicals (formed by a minor free radical channel) to the exclusion of abstractions to form methane. The preponderance of molecular eliminations is contrary to what was deduced for pyrolysis studies where products are formed largely by free radical channels (14).

Average local ionization energies on the molecular surfaces of aromatic systems as guides to chemical reactivity

PER SJOBERG
Nobel Chemicals, Nobel Industries Sweden, S-691 85 Karlskoga, Sweden
AND
JANE S. MURRAY, TORE BRINCK, AND PETER POLITZER[1]
Department of Chemistry, University of New Orleans, New Orleans, LA 70148, U.S.A.

Received January 3, 1990

PER SJOBERG, JANE S. MURRAY, TORE BRINCK, and PETER POLITZER. Can. J. Chem. **68**, 1440 (1990).

The average ionization energy, $\bar{I}(r)$, is introduced and is demonstrated to be useful as a guide to chemical reactivity in aromatic systems. $\bar{I}(r)$ is rigorously defined within the framework of self-consistent-field molecular orbital (SCF-MO) theory and can be interpreted as the average energy needed to ionize an electron at any point in the space of a molecule. An *ab initio* SCF-MO approach has been used to calculate $\bar{I}(r)$ at the 6-31G* level, using STO-3G optimized geometries. $\bar{I}(r)$ has been computed on molecular surfaces defined by the contour of constant electronic density equal to 0.002 electrons/bohr^3, for a series of aromatic systems. This surface $\bar{I}(r)$ provides site specific predictions for preferred positions of electrophilic aromatic substitution. Relative reactivity toward electrophiles increases as the magnitudes of the smallest $\bar{I}(r)$ values ($\bar{I}_{min}$) for these systems decrease. An excellent relationship, with a correlation coefficient of 0.99, has been found between the Hammett constants and $\bar{I}_{min}$; this allowed us to predict the values of these constants for the substituents NHF and NF_2, for which they were previously not known.

Key words: average local ionizations energy, chemical reactivity, electrophilic aromatic substitution, molecular surfaces, Hammett constants.

PER SJOBERG, JANE S. MURRAY, TORE BRINCK et PETER POLITZER. Can. J. Chem. **68**, 1440 (1990).

On introduit le concept d'énergie moyenne d'ionisation locale, $\bar{I}(r)$, et on démontre qu'il est un guide utile pour prédire la réactivité chimique dans les systèmes aromatiques. On définit $\bar{I}(r)$ d'une façon rigoureuse dans le cadre de la théorie des orbitales moléculaires en champ auto-cohérent (OM-CAC) et on peut l'interpréter comme l'énergie moyenne nécessaire pour ioniser un électron dans un point quelconque de l'espace d'une molécule. On a utilisé une approche *ab initio* d'OM-CAC pour calculer $\bar{I}(r)$ au niveau 6-31G*, en utilisant des géométries optimisées au niveau STO-3G. Pour une série de systèmes aromatiques, on a aussi calculé $\bar{I}(r)$ sur les surfaces moléculaires définies par le contour d'une densité électronique constante de 0,002 électrons/bohr^3. Cette $\bar{I}(r)$ de surface fournit des prédictions spécifiques au site pour les positions préférées par les substitutions aromatiques électrophiles. La réactivité relative vis-à-vis des électrophiles augmente avec une diminution des amplitudes des valeurs $\bar{I}(r)$ les plus faibles $\bar{I}_{min}$ de ces systèmes. On a obtenu une excellente corrélation, avec un coefficient de corrélation de 0,99, entre les constantes de Hammett et les valeurs de $\bar{I}_{min}$; cette corrélation nous permet de prédire les valeurs de ces constantes pour les substituants NHF et NF_2 pour lesquels ils n'étaient pas encore connus.

Mots clés : énergie moyenne d'ionisation locale, réactivité chimique, substitution aromatique électrophile, surfaces moléculaires, constantes de Hammett.

[Traduit par la revue]

Introduction

The interpretation and prediction of molecular reactive behavior is a continuing focus of our computational studies (1–5). In this work we introduce the average local ionization energy, $\bar{I}(r)$, and show its applicability in predicting sites and relative reactivities for electrophilic attack in aromatic systems.

$\bar{I}(r)$ is rigorously defined within the framework of self- consistent-field molecular orbital (SCF-MO) theory, as given by eq. [1]:

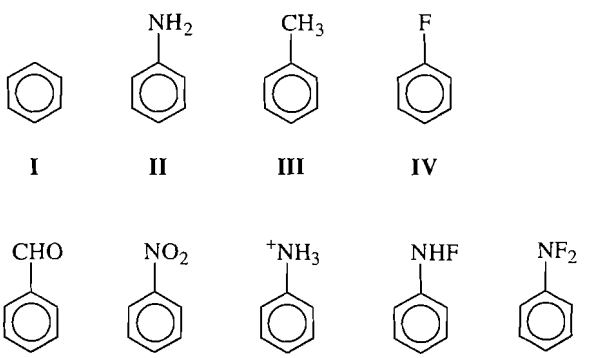
$$[1] \quad \bar{I}(r) = \sum_i \frac{\rho_i(r)|\epsilon_i|}{\rho(r)}$$

$\rho_i(r)$ is the electronic density of the ith molecular orbital at the point r, ϵ_i is the orbital energy, and $\rho(r)$ is the total electronic density. Since Koopmans' theorem justifies regarding the orbital energies as good approximations to the ionization potentials of the respective electrons (6), $\bar{I}(r)$ can be interpreted as the average energy needed to ionize an electron at any particular point in the space of the molecule. Thus, the positions where $\bar{I}(r)$ has its lowest values are the points at which are found, on the average, the highest energy electrons.

In this study, we have computed $\bar{I}(r)$ for a series of benzene derivatives, **I–IX**, on three-dimensional surfaces encompassing the molecules. These results will be discussed in relation to the experimentally observed reactive behavior of the repective molecules. Understanding and predicting the effects of substituents on electrophilic aromatic substitution reactions has long been an objective of both fundamental and practical interests (7, 8).

Methods and procedure

An *ab initio* SCF-MO approach (GAUSSIAN 82 (9)) has been used to compute 6-31G* wave functions for systems **I–IX**



I **II** **III** **IV**

V **VI** **VII** **VIII** **IX**

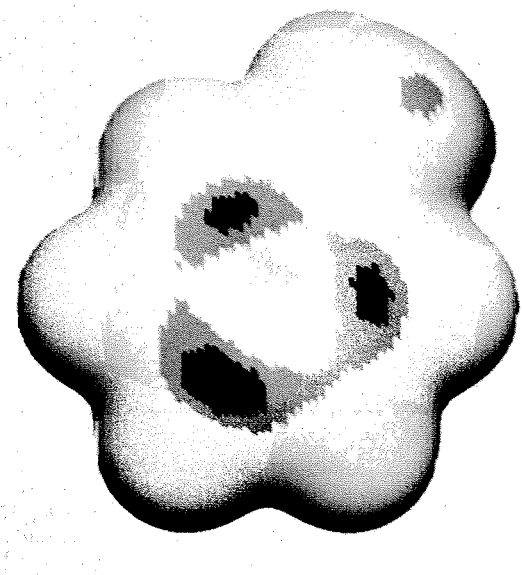

FIG. 1. Calculated $\bar{I}(r)$ on the molecular surface of aniline (**II**). Black is for $\bar{I}(r) < 11.84$ eV; gray is for $11.84 \text{ eV} < \bar{I}(r) < 12.11$ eV.

using STO-3G optimized geometries. These wave functions have then been used to calculate $\bar{I}(r)$ (eq. [1]) on the three-dimensional surfaces corresponding to the contour of constant electronic density equal to 0.002 electron/bohr^3. It has been shown, for a group of diatomic molecules and for methane, that this contour gives physically reasonable molecular dimensions, and encompasses at least 95% of the electronic charge (10–12). This surface is defined in terms of a molecular property, the electronic density function $\rho(r)$, and therefore reflects features such as bond formation, lone pairs, etc. that are unique to a molecule. This means of designating a molecular surface is in contrast to earlier methods in which it has been defined as the outer surface of a set of intersecting spheres centered on the nuclei of the molecule (12–22); such surfaces cannot take into account the very properties that are characteristic of a molecule. (This point has also been discussed by Bader *et al.* (23).) We have recently shown that the molecular electrostatic potential computed on the surface defined by the 0.002 contour is useful in studies of recognition interactions (24), and also permits predictions of sites for nucleophilic attack (25); the latter poses problems when two-dimensional plots are used.

Results

Figure 1 shows $\bar{I}(r)$ plotted on the molecular surface of aniline, **II**. The lowest average ionization energies are found above the *ortho* and *para* positions; slightly higher ones are associated with the amine lone pair.

In Table 1 are presented the locations and magnitudes of the smallest $\bar{I}(r)$ values, $\bar{I}_{min}$, for molecules **I**–**IX**. These are the points at which the least amount of energy is required to remove an electron from the surface; thus these sites are expected to be the most reactive toward electrophiles. (We have verified that there is no significant change in the magnitude of the surface $\bar{I}_{min}$ (less than 1% decrease) when the surface is defined by the 0.001 electrons/bohr^3 contour instead of the 0.002.) Also included in Table 1 is the energy of the highest occupied molecular orbital (HOMO) in each molecule. According to Koopmans' theorem (6), this should represent a good estimate of its ionization potential.

TABLE 1. Calculated 6-31G* $\bar{I}_{min}$ values, HOMO energies and Hammett constants[a] for **I**–**VIII**

Molecule	$\bar{I}_{min}$ (eV)	HOMO energy (eV)	Hammett constants[a] for substituent	
			σ_p	σ_m
 II	11.51 (*para*) 11.69 (*ortho*) 11.71 (*ortho*) 12.08 (amine N)	−7.87	−0.57	−0.09
III	11.93 (*ortho*) 11.96 (*ortho*) 11.96 (*para*) 12.08 (*meta*) 12.10 (*meta*)	−8.68	−0.14	−0.06
I	12.12 (C)	−9.00	0.00	0.00
 IV	12.31 (*para*) 12.44 (*ortho*) 12.45 (*ortho*)	−9.11	0.06	0.34
 V	12.55 (*meta*) 12.59 (*meta*)	−9.44	0.47	0.41
 VI	13.03 (*meta*) 13.04 (*meta*)	−9.97	0.81	0.71
 VII	16.58 (*para*) 16.59 (*meta*)	−13.59	[b]	[b]

The minimum values of $\bar{I}(r)$ on the surface of unsubstituted benzene are located above the carbons and have magnitudes of 12.12 eV. The magnitude of the HOMO energy is considerably less, 9.00 eV, and is in good agreement with the experimentally-determined ionization potential of benzene, 9.24 eV (26). This difference between the magnitude of $\bar{I}_{min}$ and the HOMO energy brings out the interesting point that there is quite a significant likelihood of finding inner, more tightly-bound electrons on the molecular surface. Comparison of the magnitude of $\bar{I}_{min}$ and the HOMO energies in Table 1 shows that this is true as well for the other molecules that have been studied.

$\bar{I}_{min}$ values of **II–IV** are found over the *ortho* and *para* positions (Table 1), consistent with the observed *ortho-* and *para*-directing tendencies of NH_2, CH_3, and F (7, 8). In the case of toluene (**III**), there are also minima in $\bar{I}(r)$ above the *meta* positions. These are larger than the *ortho* and *para* values, suggesting a lesser tendency for *meta* substitution. The magnitudes of $\bar{I}_{min}$ relative to that of benzene indicate whether the respective substituents activate or deactivate the benzene ring toward electrophilic attack. Aniline and toluene have $\bar{I}_{min}$ values lower than that of benzene, while those of fluorobenzene are higher. These results are in agreement with the well-known activating effects of NH_2 and CH_3 and the deactivating tendency of F (7, 8).

The surface $\bar{I}_{min}$ of **V** and **VI** are greater than those of benzene, and are above the *meta* positions. These findings reflect the established deactivating and *meta*-directing tendencies of the CHO and NO_2 groups (7, 8).

The substituent NH_3^+ is known to have the interesting property of being a *meta–para* director and to strongly deactivate the benzene ring toward electrophilic substitution (7, 8). Our calculated $\bar{I}_{min}$ for **VII** are fully consistent with these observations, being the largest in Table 1 and located over the *meta* and *para* positions.

Experimental reactivity data are not available for the NHF and NF_2 derivatives of benzene; accordingly our findings for **VIII** and **IX** constitute predictions for the effects of these substituents. The $\bar{I}_{min}$ values of **VIII** are found over the *ortho* and *para* positions, while **IX** shows the feature of having an $\bar{I}_{min}$ over all three types of positions: *ortho*, *meta*, and *para*, as was found for toluene. Our results suggest that the NF_2 group is less specific than the substituents in **II** and **IV–VIII** in directing electrophilic aromatic substitution. The $\bar{I}_{min}$ values of **VIII** are only slightly larger than those of benzene, while those of **IX** are intermediate between those of benzaldehyde (**V**) and nitrobenzene (**VI**) (see Table 1.) These data indicate that NF_2 is a significantly stronger deactivator of the aromatic ring than NHF.

Discussion

Our $\bar{I}(r)$ computations provide position specific predictions for preferred sites of aromatic electrophilic substitution. In addition, the magnitudes of the $\bar{I}_{min}$ values for each molecule (Table 1) are indicative of the relative activating and deactivating tendencies of the various substituents (relative to benzene itself).

The ability of $\bar{I}(r)$ to order the reactivities of **I–VII** led us to investigate the possibility of $\bar{I}(r)$ correlating with the Hammett constants, σ_p and σ_m (27, 28). The latter are established measures of the electron-withdrawing and -donating tendencies of substituents on aromatic rings, with reference to the *para* and *meta* positions. σ_p and σ_m are listed in Table 1 for the substituents in **I–VI**.

We have found an excellent correlation between the Hammett constant σ_p or σ_m and the corresponding $\bar{I}_{min}$. The relationship is shown in Fig. 2; the linear correlation coefficient is 0.99. This correlation strongly suggests tht our calculated $\bar{I}_{min}$ values are good indices of the relative electron-withdrawing and -donating effects of substituents on benzene rings.

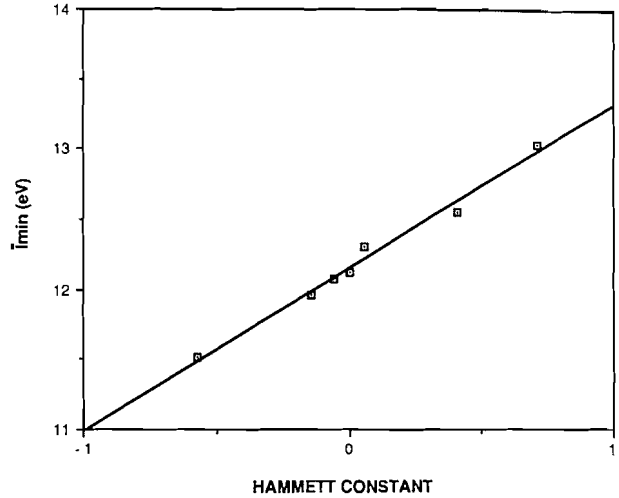

FIG. 2. Correlation between $\bar{I}_{min}$ and Hammett constants for six aromatic systems. Data are from Table 1. The least squares equation of the line is $y = 12.1547 + 1.1643x$, with a correlation coefficient of 0.99.

The correlation shown in Fig. 2 allows us to predict Hammett constants that have not yet been determined. For example, we predict σ_p for NHF to be 0.06 and σ_p and σ_m for NF_2 to be 0.49 and 0.54, respectively. Thus, NF_2 is expected to be a relatively strongly electron-withdrawing substituent, intermediate between CHO and the more powerful electron-attracting CN and NO_2 groups, whereas NHF is apparently, overall, a very weak attracter of electronic charge. (In view of the fact that Hammett's treatment did not include charge substituents, we have not estimated values for NH_3^+.)

We have recently presented a procedure that allows the inductive constant σ_I of a substituent X to be estimated from the calculated molecular electrostatic potential of X—NH_2 (29). For X = NF_2, we find σ_I to be 0.53. Since $\sigma_p \approx \sigma_I + \sigma_R$ (28), where σ_R describes resonance effects, then we can also predict that $\sigma_R \approx -0.04$ for NF_2. Our estimated σ_I for NHF is 0.43; a corresponding σ_R value of -0.37 is predicted [σ_R(NHF) $\approx$ 0.06–0.43]. These σ_R predictions for NHF and NF_2 are indicative of NHF being a significantly stronger resonance donor of charge than NF_2; presumably the nitrogen lone pair can more readily be delocalized to the ring when this is opposed by only one fluorine rather than two.

We also investigated $\bar{I}(r)$ at the 3-21G level (using STO-3G geometries) and obtained results generally similar to the 6-31G*. However, the latter basis set provides smoother surface $\bar{I}(r)$ representations and yields a better correlation with the Hammett constants. (The correlation coefficient between $\bar{I}_{min}$ computed at the 3-21G level and the Hammett constants is 0.94, compared to 0.99 for the 6-31G*.) This improvement in our $\bar{I}(r)$ data at the 6-31G* level reflects the nature of the property; $\bar{I}(r)$ depends on the goodness of the densities $\rho_i(r)$ and $\rho(r)$ at any specific point r and therefore improves with a larger, more flexible basis set.

Summary

In this study, we have introduced a new molecular property, $\bar{I}(r)$, the average local ionization energy, and have demonstrated

its usefulness as a guide to chemical reactivity in aromatic systems. $\bar{I}(r)$ is rigorously defined within the framework of self-consistent-field molecular orbital theory and can be interpreted as the average energy needed to remove an electron at any point in space r. Thus those regions where $\bar{I}(r)$ has its smallest values can be viewed as having, on the average, the highest energy electrons, most reactive toward electrophiles.

For a series of aromatic systems, we have computed $\bar{I}(r)$ on molecular surfaces defined by the contour of constant electronic density equal to 0.002 electrons/bohr^3. This surface $\bar{I}(r)$ provides site specific predictions of preferred positions for electrophilic aromatic substitution. The relative reactivities of these systems toward electrophiles increase as the magnitudes of the smallest $\bar{I}(r)$ values ($\bar{I}_{min}$) decrease. An excellent relationship, with a correlation coefficient of 0.99, is found between the Hammett constant σ_p or σ_m and the corresponding $\bar{I}_{min}$. This has allowed us to predict the σ_p and/or σ_m values for the substituents NHF and NF_2.

Synthesis and X-ray crystal structure of the 3,5-dimethylpyrazolato copper(I) trimer, [Cu (pz″)]$_3$

MARTIN K. EHLERT, STEVEN J. RETTIG, ALAN STORR, ROBERT C. THOMPSON, and JAMES TROTTER
Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received December 19, 1989

MARTIN K. EHLERT, STEVEN J. RETTIG, ALAN STORR, ROBERT C. THOMPSON, and JAMES TROTTER. Can. J. Chem. **68**, 1444 (1990).

A moderately high-yield, high temperature synthesis of the title compound is reported. Crystals of tris[(3,5-dimethylpyrazolato-N^1,N^2)copper(I)] are triclinic, a = 12.360(4), b = 14.637(4), c = 12.358(4) Å, α = 105.29(2), β = 119.83(2), γ = 93.99(3)°, Z = 4 (trimers, two per asymmetric unit), space group $P\bar{1}$. The structure was solved by heavy atom methods and was refined by full-matrix least-squares procedures to R = 0.034 and R_w = 0.038 for 3877 reflections with $I \geq 3\sigma(I)$. The structure consists of trimeric molecules with an unusually short average Cu—N distance of 1.852 Å. The central Cu_3N_6 nine-membered rings are planar to within 0.07 Å. The trimer units are linked in pairs about centres of symmetry by weak Cu···Cu interactions averaging 2.946 Å.

Key words: pyrazolato copper (I) timer, copper (I) pyrazolate.

MARTIN K. EHLERT, STEVEN J. RETTIG, ALAN STORR, ROBERT C. THOMPSON et JAMES TROTTER. Can. J. Chem. **68**, 1444 (1990).

Faisant appel à une méthode de synthèse impliquant une température élevée, on a préparé le produit mentionné dans le titre avec un assez bon rendement. Les cristaux du tris[(3,5-diméthylpyrazolato-N^1,N^2)cuivre(I)] sont tricliniques et ils appartiennent au groupe d'espace $P\bar{1}$, avec a = 12,360(4), b = 14,637(4) et c = 12,358(4) Å, α = 105,29(2), β = 119,83(2) et γ = 93,99(3)° et Z = 4 (deux trimères par unité asymétrique). On a affiné la structure par la méthode des atomes lourds et on l'a affinée par la méthode des moindres carrés jusqu'à des valeurs respectives de R = 0,034 et R_w = 0,038 pour 3877 reflexions avec $I \geq 3\sigma(I)$. La structure est formée de molécules trimères dans lesquelles la distance moyenne Cu—N, 1,852 Å, est anormalement courte. Les cycles centraux à neuf chaînons de Cu_3N_6 sont plans à moins de 0,07 Å. Des interactions Cu···Cu faibles, de distance moyenne 2,946 Å, retiennent les unités de trimère par paires autour de centres de symétrie.

Mots clés : trimère pyrazolato-cuivre (I), pyrazolat de cuivre (I).

[Traduit par la revue]

Introduction

A novel and efficient synthesis of the title compound has resulted unexpectedly from an attempt to prepare the polymetric copper(II) 3,5-dimethylpyrazolato species [Cu(pz″)$_2$]$_x$. Our interest in the latter material stems from the magnetic exchange properities exhibited by such infinite-chain polymers, with the pyrazolate ligands acting as propagating pathways between the interacting Cu centres (1). The trimeric copper(I) compound, [Cu(pz″)]$_3$, reported here was obtained as colorless crystals which provided excellent samples for data collection in an X-ray structure determination. The central nine-membered ring structure, Cu_3N_6, is qualitatively planar and the rings are arranged in pairs in the crystal lattice. The structure is discussed in relation to similar M(I) pyrazolate species (M = Cu, Ag, or Au) (2–4).

Experimental

Synthesis of [Cu(pz″)]$_3$, **1**

A mixture of $Cu(OH)_2$ (~0.3 g) and 3,5-dimethylpyrazole (Hpz″) (~4.0 g) was heated under a nitrogen atmosphere at 130°C for 10 days. The reaction mixture turned dark brown within a few minutes and within a day large colorless cyrstals could be seen forming on the sides of the reaction flask. At the end of the reaction period the mixture was allowed to cool to room temperature and was then extracted with acetone to remove excess Hpz″. This procedure also allowed the separation of the insoluble colorless crystals of [Cu(pz″)]$_3$ from a fine reddish-brown powder, chracterized as the [Cu(pz″)$_2$]$_x$ polymer, which was also produced in the reaction. Thus most of the reddish-brown powder was separated by suspending in acetone and decanting from the colorless crystals. Final separation of pure samples of the colorless crystals was achieved by manual separation under a microscope. The yields of the copper containing products were estimated at ~70% for [Cu(pz″)]$_3$ and ~30% for [Cu(pz″)$_2$]$_x$. *Anal.* calcd. for $C_{15}H_{21}Cu_3N_6$: C 37.85, H 4.45, N 17.66; found: C 38.00, H 4.43, N 17.45.

Physical characterization

[Cu(pz″)]$_3$ was found to be insoluble in both polar and non-polar organic solvents. It is indefinitely stable towards air and moisture. Differential scanning calorimetry (Mettler DSC 20 cell and TC 10 TA processor) shows the compound to be thermally stable to ~300°C at which temperature it decomposes without melting. The infrared spectrum (4000–250 cm^{-1}) was obtained as a Nujol mull on a Perkin-Elmer Model 598 spectrophotometer. Frequencies (cm^{-1}): 3120 w, 2734 w, 2720 w, 2283 w, 2122 w, 1535 wsh, 1524 s, 1509 wsh, 1438 s, 1421 s, 1358 wsh, 1345 s, 1150 s, 1125 wsh, 1059 s, 1043 w, 1029 wsh, 979 w, 769 s, 662 w, 659 m, 601 w, 464 m, 428 m (Nujol bands omitted, s = strong, m = medium, w = weak, sh = shoulder).

X-ray crystallographic analysis

A crystal *ca* 0.10 × 0.20 × 0.20 mm in size was mounted in a general orientation. Unit-cell parameters were refined by least-squares on setting angles for 25 reflections (2θ = 26.6–33.8°) measured on a diffractometer with Mo-$K\alpha$ radiation (λ = 0.71069 Å). Crystal data at 21°C are as follows:

$C_{15}H_{21}Cu_3N_6$ fw = 476.01

Triclinic, a = 12.360(4), b = 14.637(4), c = 12.358(4) Å, α = 105.29(2), β = 119.83(2), γ = 93.99(3)°, V = 1816(3) Å^3, Z = 4, ρ_c = 1.741 Mg m^{-3}, F(000) = 960, μ(Mo-$K\alpha$) = 35.0 cm^{-1}. Absent reflections: none, space group $P\bar{1}$ (reduced cell, Donnay convention) from structure analysis. Since the a and c axes are nearly equal in length and the β angle is close to 120° there was a possibility that the crystal lattice was actually hexagonal. No lattice transformations to a true hexagonal unit cell were found.

Intensities were measured with graphite-monochromated Mo-$K\alpha$ radiation on a Rigaku AFC6S diffractometer. An ω–2θ scan at 32° min^{-1} over a range of (1.31 + 0.35 tan θ) degrees in ω (with up to eight

[a]Primed and double-primed atoms have coordinates related to those in Table 1 by the symmetry operations: $1 - x, -y, -z$; and $2 - x, 1 - y, 2 - z$; respectively.

rescans, background/scan time ratio = 0.5) was employed. Data were measured to $2\theta = 55°$. The intensities of three check reflections, measured every 150 reflections throughout the data collection, showed only small random fluctuations. After data reduction,[1] an empirical absorption correction, based on azimuthal scans for four reflections, was applied which resulted in relative transmission factors ranging from 0.84 to 1.00. Of the 8714 reflections measured, 8329 were unique ($R_{int} = 0.026$) and 3877 (46.5%) of these had intensities greater than or equal to $3\sigma(F^2)$ above background where $\sigma^2(F^2) = (S^2(C + 4B) + (0.03(F_o^2))^2)/Lp^2$ with S = scan rate, C = scan count, B = total background count, and Lp = Lorentz-polarization factors.

The structure was solved by conventional heavy atom methods, the six crystallographically independent copper atoms being positioned from the Patterson map and the remaining non-hydrogen atoms from subsequent difference Fourier syntheses. All non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms were fixed in idealized positions (methyl group orientations based on difference map peaks, C—H = 0.98 Å, $U_H = 1.2U_{bonded\ atom}$). Scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from ref. 5. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(F)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and $\sin\theta/\lambda$ and was employed in the final stages of full-matrix refinement of 433 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at $R = 0.034$ and $R_w = 0.038$ for 3877 reflections with $I \geq 3\sigma(I)$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma\,||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the maximum parameter shift corresponded to 0.002σ. The mean error in an observation of unit weight was 1.45. The final difference map showed maximum fluctuations of −0.42 to 0.43 e Å^{-3}. The final positional and equivalent isotropic thermal parameters for the non-hydrogen atoms appear in Table 1. Bond lengths and angles are listed in Tables 2 and 3. Hydrogen

[1]All computations performed using the TEXSAN–TEXRAY Structure Analysis Package which includes versions of the following: AGNOST, absorption corrections, by J. A. Ibers; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin and H. A. Levy; DIRDIF, phase extension and refinement of difference structures, by P. T. Beurskens; ORTEP II, illustrations, by C. K. Johnson.

parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, least-squares planes, and structure factors have been deposited.[2]

Results and discussion

The first report of a coinage metal pyrazolate compound (silver(I) pyrazolate) appeared 100 years ago (6). It was not until more recently that Singh *et al.* reported the isolation of a gray diamagnetic Cu(I) pyrazolate material from the reaction of $Cu(acac)_2$ with hydrazine (7). To this they assigned the formulation [Cu(pz″)] although the calculated and found analytical data provided do not agree with this composition. At the same time Okkerson *et al.* reported the [Cu(pz)] and [Cu(5-Mepz)] species to be at least trimeric on the basis of mass spectrometric data (8). Since these reports a low yield synthesis and crystal structure of the trimer $[Cu(3,5\text{-}Ph_2pz)]_3$ (where 3,5-Ph_2pz = 3,5-diphenylpyrazolate) has been reported (4) and [Cu(pz)] and [Cu(pz″)] have been isolated as insoluble white polymeric materials (9). We report here a moderately high-yield, high temperature synthesis of crystalline $[Cu(pz'')]_3$ via the reaction of $Cu(OH)_2$ with molten Hpz″:

$$\text{excess Hpz}'' + Cu(OH)_2 \xrightarrow[130°C]{N_2} \underset{\text{colorless}}{[Cu(pz'')]_3} + \underset{\text{reddish-brown}}{[Cu(pz'')_2]_x} + ?$$

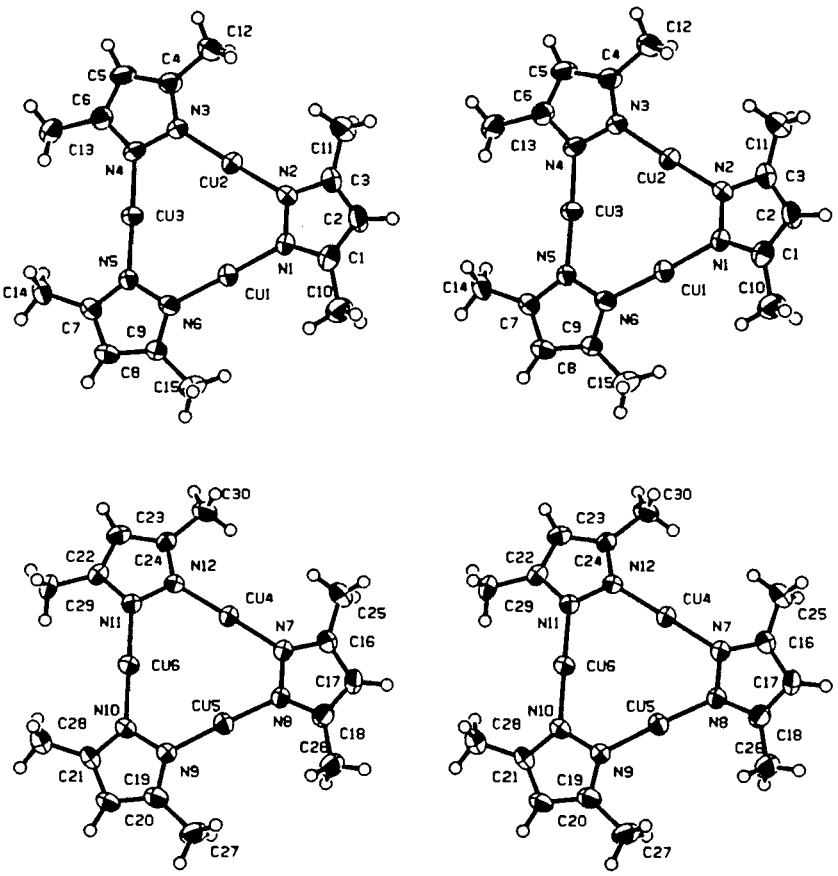

FIG. 1. Stereoscopic views of the two crystallographically independent molecules of tris[(3,5-dimethyl-pyrazolato-N',N^2)copper(I)]; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

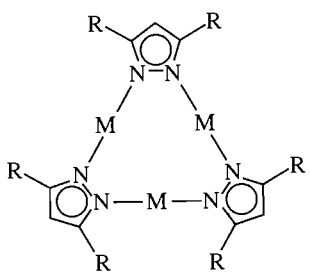
Obviously the Cu(II) reactant is being partially reduced in this reaction and consequently the pyrazole reactant must be oxidized. Oxidation of pyrazoles, albeit with more common oxidants, has been documented (10). The structure of the title compound consists of trimeric molecules (Fig. 1) linked in pairs (Fig. 2) by weak Cu...Cu interactions.

Related Ag(I) and Au(I) pyrazolate compounds have been recorded in the literature (2, 3) and an unusual Cu(II) complex, $[Cu_3(\mu_3\text{-}OH)(\mu\text{-}pz)_3(Hpz)_2(NO_3)_2]\cdot H_2O$, containing as a central feature a nine-membered metallocycle, common to all the $[M(3,5\text{-}R_2pz)]_3$ (M = Cu, Ag, or Au) structures, has also been reported (11). Selected structural parameters for $[M(3,5\text{-}R_2pz)]_3$ complexes are collected in Table 4 and relate to the general trimetallocycle formulation:



Of the five compounds listed in Table 4, compounds **1** and **4** exhibit essentially planar nine-membered M_3N_6 rings (those in **1** are planar to within 0.07 Å) whereas compounds **2**, **3**, and **5** show a marked puckering in the molecular arrangements. Interestingly the Cu(II) complex mentioned above (11) contains an almost planar Cu_3N_6 ring with Cu—N bond lengths ranging 1.917–1.972 (average 1.945 Å) and Cu···Cu intramolecular distances of 3.324–3.365 (average 3.351 Å). The same molecular arrangement as depicted above was also found in the structure of 3,5-dimethylpyrazole (Hpz″) itself (12). The structure of Hpz″ consists of planar trimeric units with strongly H-bonded hydrogen atoms between the three pyrazole molecules replacing the M atoms of the $[M(3,5\text{-}R_2pz)]_3$ metallocycles.

The present structure (Figs. 1 and 2) displays two strikingly unique features when compared with the structures of compounds **2**–**5**. The first is the shortening by ~0.2 Å of the Cu—N bonds relative to a standard Cu(I)—N single bond length. (The average Cu—N distance in the Cu(I) complex $[HBpz_3]Cu(CO)$ is 2.046 Å (13)). This observation would indicate that a considerable Cu($d\pi$)–pz″(π^*) interaction is augmenting the σ-bonding between the Cu and N atoms. Evidence for this interaction can be seen in the lengthening of the distances within the pyrazole rings, particularly the N—N bond (1.381–1.385, average 1.383 Å), when compared to the corresponding distances (average 1.334 Å) observed in the structure of $[Hpz'']_3$ (12). In the latter compound the hydrogen bonds linking the molecules into trimer units cannot interact with the π^* orbitals of the pz″ rings. The infrared spectra of the two compounds provide additional evidence in that the band attributed primarily to a $\nu_{C=N}$ mode is shifted from ~1599 cm^{-1} in $[Hpz'']_3$ to ~1524 cm^{-1} in

$[Cu(pz'')]_3$, consistent with a weakening of the bonds in the pz″ rings of the Cu trimer. The second unique feature is the arrangement of the trimer units within the crystal lattice. Only in the present structure is there an intermolecular (between trimers) M···M separation shorter than the intramolecular M···M distance. In compounds **2**–**4** the individual trimer units are clearly non-interacting whereas in the present example the trimers are arranged in pairs about crystallographic inversion centres with two Cu atoms from one M_3N_6 metallocycle being positioned close to two Cu atoms from the second unit (see Fig. 2). The mean intertrimer Cu—Cu distance of 2.946 Å is close to the sum of van der Waals radii (2.86 Å) (14) and thus the interaction holding the trimers together must necessarily be weak. Interestingly only two of the Cu atoms in each trimer are involved in these weak Cu···Cu interactions, the third Cu atom being positioned above the centre of a pz″ ring at the opposite end of the inversion-related trimer unit (average Cu···pz″ ring mean plane = 3.272 Å). The only related trimeric structure to show similar intermolecular interactions is the $[AuC(OEt)=N(p\text{-tolyl})]_3$ complex (15). In this structure the intramolecular Au···Au distances are reported at 3.224, 3.288, and 3.299 Å with one intermolecular Au···Au distance of 3.244 Å responsible for joining the trimers in pairs. In this example the nature of the interaction is not specified but again is likely to be weak since the distance observed is of the same order as the sum of van der Waals radii (~3.22 Å) (14).

JAMES CLAYTON BAUM, JIMAT BOLHASSAN, RICHARD FRANCIS LANGLER, PAUL JOSEPH PUJOL, and RAJ KUMAR RAHEJA. Can. J. Chem. **68**, 1450 (1990).

An attempt to explore aromatic sulfonate esters as agents for the condensation of alcohols with mercaptans revealed an unusual process for sulfonate esters: CS bond rupture. Two mechanistic possibilities for CS bond rupture are explored: (i) radical anion intermediacy via single electron transfer and (ii) nucleophilic aromatic substitution. Both experiments and molecular orbital computations are presented to support the conclusion that nucleophilic aromatic substitutions are occurring.

Key words: sulfonyl esters, nitrobenzenesulfonates, CS bond rupture.

JAMES CLAYTON BAUM, JIMAT BOLHASSAN, RICHARD FRANCIS LANGLER, PAUL JOSEPH PUJOL et RAJ KUMAR RAHEJA. Can. J. Chem. **68**, 1450 (1990).

Lorsqu'on a essayé d'utiliser les esters d'acides sulfoniques aromatiques comme agents de condensation des alcools avec les mercaptans, on a observé une réaction inusitée pour ce type de composé, à savoir une rupture de la liaison CS. On a exploré deux possibilités mécanistiques pour expliquer ces scissions : (i) un intermédiaire radical-anion se formant par le transfert d'un seul électron et (ii) une réaction de substitution aromatique nucléophile aromatique. On présente des expériences ainsi que des calculs d'orbitales moléculaires qui suggèrent que les réactions se produisent par le biais de substitutions aromatiques nucléophiles.

Mots clés : esters d'acides sulfoniques, nitrobenzènesulfonates, rupture de la liaison CS.

[Traduit par la revue]

Introduction

We recently reported (1) that phenyl methanesulfonate induces the condensation of *p*-tolyl mercaptan with primary alcohols, as shown in eq. [1]. Further study of this chemistry led to the observation that *p*-nitrophenyl methanesulfonate condensed with the mercaptan leaving the alcohol largely unused (eq. [2]).

[1] $PhOSO_2CH_3 + CH_3C_6H_4SH + CH_3CH_2OH \xrightarrow[HMPA]{2\ NaH} CH_3C_6H_4SCH_2CH_3$

[2] $O_2NC_6H_4OSO_2CH_3 + CH_3C_6H_4SH + CH_3CH_2OH \xrightarrow[HMPA]{2\ NaH} CH_3C_6H_4SC_6H_4NO_2$

1

In an attempt to examine nitro-substituted sulfonates that might induce alcohol–mercaptan condensation, a study of the chemistry of a linkage isomeric nitrophenyl sulfonate **2** was undertaken.

Results and discussion

Reaction of **2** with ethanol and *p*-tolyl mercaptan furnished the surprising results shown in eq. [3]. There appears to be only one example of a sulfonate ester substitution reaction leading to CS bond rupture (2) (see eq. [4]). There are, however, several known examples of CS bond rupture in reactions of related

[3] $O_2NC_6H_4SO_2OPh + CH_3C_6H_4SH + CH_3CH_2OH \xrightarrow[HMPA]{2\ NaH} O_2NC_6H_4SC_6H_4CH_3$

1 (63%)

[4] $Ph_2CHSO_2OAr \longrightarrow Ph_2CHOAr + SO_2$

[5] $O_2NC_6H_4SO_2OPh + CH_3C_6H_4SH \xrightarrow[HMPA]{NaH} \mathbf{1}\ (67\%) + CH_3C_6H_4SC_6H_4SO_2OPh\ \mathbf{3}\ (16\%)$

sulfonyl-containing structures (3, 4). Repetition of the eq. [3] reaction in the absence of ethanol permitted the isolation of **1** in the same yield, along with a modest yield of **3**. Thus a role for ethanol in the formation of **1** can be dismissed from consideration.

The unexpected CS rupture in the reactions of **2** with mercaptide anions prompted us to examine nitroaryl sulfonates to establish the relative propensities for CS and CO rupture. The behaviour of the ideal dinitrosulfonate ester **4** was modelled with the aid of the linkage isomeric dinitrosulfonates **5***a* and **5***b*.

The reactions of these dinitrosulfonate esters with *p*-tolyl mercaptide anions in HMPA are depicted below.

Assuming that methyl substitution diverts *x*% of product formation to the other ring, a simple calculation on the results in eqs. [6] and [7] leads to the conclusion that the ratio of the yields of **1** formed by CS rupture to the yields of **1** formed by CO rupture would be ca. 19:1 in the hypothetical reaction of **4** with *p*-tolyl mercaptide anions!

Two reasonable mechanisms may be advanced to account

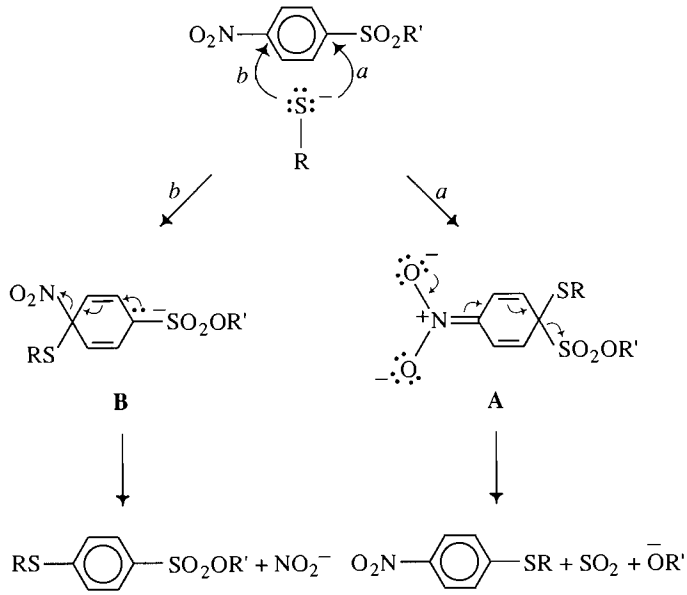

SCHEME 1

for the surprisingly facile CS bond rupture observed for the reactions of the bis(nitroaryl) sulfonates **5***a*, **5***b*. Reaction might proceed through a Meisenheimer complex (**A**) as shown in Scheme 1. Alternatively, the mercaptide anion could transfer an electron to the sulfonate ester, converting it into the corresponding radical anion as depicted in Scheme 2.

To explore Scheme 1, semi-empirical molecular orbital computations were carried out on the linkage isomers **5***a* and **5***b*. The ZINDO calculated LUMOs, presented in Fig. 1, indicate that nucleophilic attack should occur preferentially on the sulfonyl-substituted phenyl ring in accord with experiment.

Given that hard–soft acid–base arguments (5) militate against nucleophilic attack by mercaptide anions (soft) at nitrogen or sulfur (hard), the computations suggest a straightforward choice between soft acid sites: nitro-bearing carbon and sulfonyl-bearing carbon. Sulfonyl-bearing carbon has the larger LUMO coefficient, indicating that attack there will lead to a more strongly stabilized transition state (5). This analysis should also satisfactorily rationalize the results portrayed in eq. [5].

In contrast to the reaction of **5***a*, **5***b* undergoes a modest amount of nucleophilic attack on the nitrophenoxy ring. This may be rationalized by an examination of the NLUMO of **5***b* (6). The preferred soft acid site on that ring is the oxygen-bearing carbon (NLUMO coefficient: −0.319) rather than the nitro-bearing carbon (NLUMO coefficient: −0.176). The computed difference in energies between the NLUMO and the LUMO for **5***a* is 0.443 eV. The corresponding value for **5***b* is 0.279 eV, suggesting a relative enhancement for the role of the NLUMO in the chemistry of **5***b*.

ZINDO calculations were performed on **4** and its radical anion **4**$^{\cdot-}$. These computations were intended to reveal the nature and propensities of the radical anion in order to assess the viability of the Scheme 2 mechanism. Figure 2 presents selected bond length changes computed for the conversion **4** → **4**$^{\cdot-}$. The greatest *contractions* in bond length are computed for those bonds which are actually ruptured during one or more of the reactions reported herein. On this basis the Scheme 2 mechanism seems improbable.

It is our view that the substitution reactions reported in eqs. [3], [6], and [7] proceed through Meisenheimer complexes as portrayed in the Scheme 1 mechanism. However, aryl sulfonates can be drawn into electron transfer reactions (7, 8).

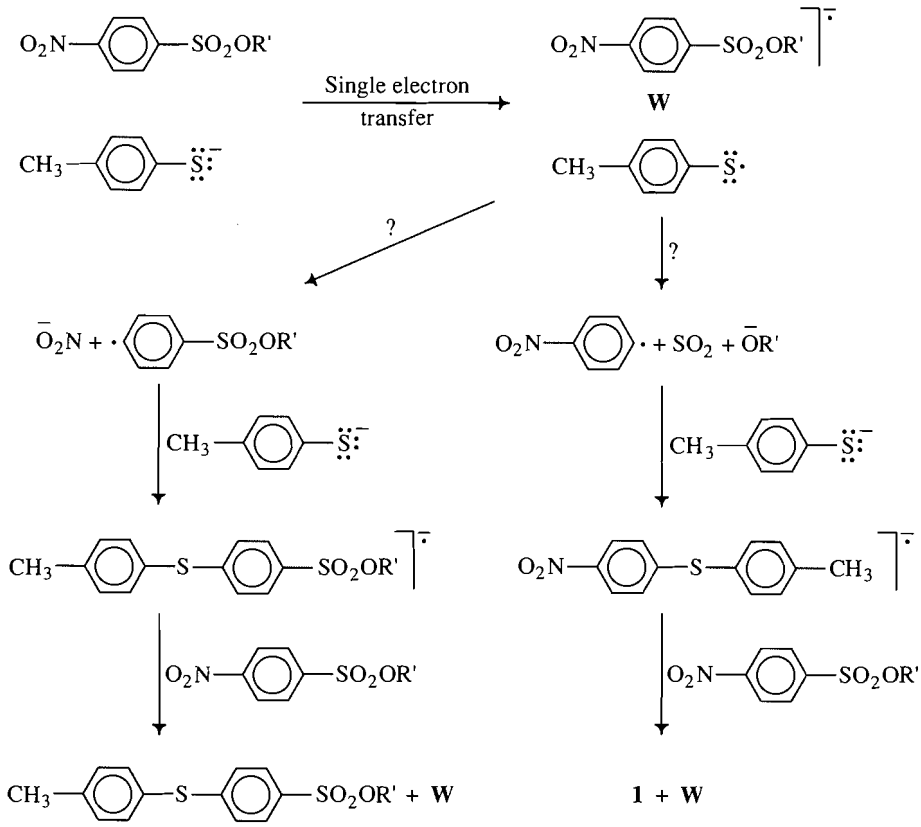

SCHEME 2

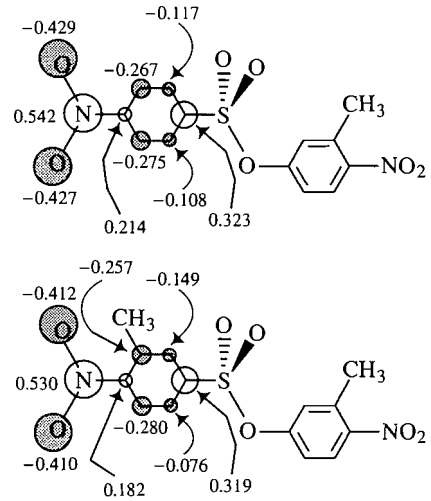

FIG. 1. ZINDO calculated lowest unoccupied molecular orbitals for **5***a* and **5***b*.

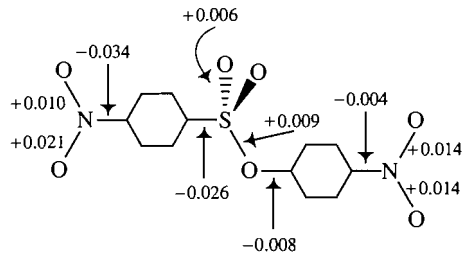

FIG. 2. Some calculated bond length changes (Å) induced by conversion of **4** into **4**$^{\cdot-}$.

Equation [8] presents a final nitroaryl sulfonate ester – mercaptide anion reaction.[3]

In the eq. [8] reaction, it seems extremely likely that the mesylate group is replaced first so that both products arise via the intermediacy of **10**. The formation of **9** is an appropriate reaction for a SET mechanism similar to the one outlined in Scheme 2.

In conclusion, it appears that nitroaromatic compounds may be involved in reactions proceeding through radical anions or in reactions proceeding through Meisenheimer complexes. Introduction of a sulfonate linkage onto a nitro-bearing phenyl ring appears to shift pathway preference toward nucleophilic aromatic substitution.

Computational methods

All computations were performed using the ZINDO molecular orbital method (9). The ZINDO program is available as part of the QUIPU molecular modelling package from the Quantum Theory Project, University of Florida.

The ground state geometries were obtained at the INDO/1 level, including *d*-orbitals on sulfur and using a BFGS updated Hessian search with Newton–Raphson optimization. The restricted Hartree–Fock method was used for the closed shell neutral molecule. For the radical anion (open shell) system, an unrestricted Hartree–Fock calculation with annihilation was employed. The INDO/S option was employed to determine the HOMO and LUMO eigenvalues and eigenvectors using Matago–Nishimoto repulsion integrals and fixed ground state geometries.

[3]Since this reaction was conducted early in our research program, an equivalent of ethanol was present to check for *p*-tolyl ethyl sulfide formation.

ZINDO calculated structural parameters for dimethyl sulfone are closer to experimental values than those obtained by 3-21G computations (10). ZINDO spectroscopic predictions agree well with experimentally determined ultraviolet spectra on a series of five substituted phenyl methanesulfonates. ZINDO spectroscopic predictions were systematically superior to those obtained by CNDO/UV computations.

Experimental

General

The ir spectra were recorded on a Perkin–Elmer 237B grating spectrophotometer. Ultraviolet spectra were run on a Beckman DU-2 spectrophotometer. The nmr spectra were obtained on a Varian EM360A instrument using TMS as the internal standard. Melting points were determined on a Gallenkamp MFB-595 capillary melting point apparatus and are uncorrected.

Preparation of phenyl p*-nitrobenzenesulfonate* **2**

A solution of phenol (0.43 g, 4.5 mmol) and triethylamine (0.45 g, 4.5 mmol) in pyridine (50 mL) was cooled with an ice/water bath. *p*-Nitrobenzenesulfonyl chloride (1.0 g, 4.5 mmol) was added in small portions. The ice/water bath was removed and the reaction mixture stirred overnight.

Chloroform extraction followed by acid washing gave crude sulfonate ester (0.98 g). The crude was recrystallized from methanol affording colorless crystals (0.67 g, 2.4 mmol, 54%, mp 118.1–118.6°C). The product had R_f 0.66 on analytical tlc plates when developed with chloroform; ir ($CHCl_3$): 1540, 1390, 1355, and 1150 cm^{-1}; nmr ($CDCl_3$) δ: 8.36 (2H, d, J = 8 Hz), 8.06 (2H, d, J = 8 Hz), 7.30 (3H, m), and 6.96 (2H, m). Anal. calcd. for $C_{12}H_9NO_5S$: C 51.60, H 3.24; found: C 51.58, H 3.22.

Reaction of **2** *with ethoxide and* p*-tolyl mercaptide anions*

Sodium hydride (0.65 g, 27 mmol) was suspended in HMPA[4] (30 mL). A solution of absolute ethanol (0.63 g, 13 mmol) in HMPA (10 mL) was added dropwise over 5 min. The reaction mixture was stirred at ambient temperature for 5 min. A solution of *p*-tolyl mercaptan (1.71 g, 13 mmol) in HMPA (10 mL) was added dropwise over 10 min. The reaction mixture was stirred at ambient temperature for 5 min. The nitrosulfonate **2** (3.82 g, 13 mmol) was added and the reaction mixture stirred at ambient temperature for 2 h. After about 10 min the homogeneous reaction mixture was rust colored.

The reaction mixture was poured into water (400 mL) containing 10% HCl (5 mL). The resultant mixture was extracted with diethyl ether (three 100-mL aliquots). The wet organic layer was concentrated. The residue was added to water (100 mL) and the resultant mixture washed with diethyl ether (three 100-mL aliquots). The combined ether layers were extracted with 2.5% NaOH (two 100-mL portions). The organic layer was dried ($MgSO_4$) and concentrated, yielding crude *p*-nitrophenyl *p*-tolyl sulfide **1** (3.79 g).

The crude was recrystallized from methanol, affording impure nitrosulfide **1** (2.71 g). The recrystallized nitrosulfide was chromatographed on silica gel (250 g) employing carbon tetrachloride elution (100-mL fractions). Fractions 11–18 were combined and concentrated, furnishing clean nitrosulfide **1** (2.130 g, 8.6 mmol, 63%). After recrystallization from methanol, the chromatographed nitrosulfide was shown to be identical to previously obtained material (2) by ir, nmr, tlc, mp, and mixture mp.

Reaction of **2** *with* p*-tolyl mercaptide anions*

Sodium hydride (0.36 g, 15 mmol), *p*-tolyl mercaptan (1.73 g, 13 mmol), and the nitrosulfonate **2** (3.82 g, 13 mmol) were reacted in HMPA (40 mL) as above.

The crude was subjected to column chromatography on silica gel (400 g) employing hexanes, carbon tetrachloride, and chloroform as sequential eluants. Nitrosulfide **1** (2.23 g, 9.1 mmol, 66.7%) was obtained along with a sulfonate ester mixture (1.67 g). The mixture was chromatographed on silica gel (200 g) employing 1:1 carbon tetrachloride/chloroform elution. Sulfide–sulfonate ester **3** (0.78 g, 2.1 mmol, 16%) was obtained. After recrystallization from methanol, the product had mp 52.3–53.5°C, R_f, 0.75 upon development with 1:1 chloroform/carbon tetrachloride; ir ($CHCl_3$); 1380 and 1180 cm^{-1}; nmr ($CDCl_3$) δ: 7.6 (2H, d, J = 9 Hz), 7.25 (6H, m), and 2.40 (3H, s); ms m/e: 356 (M, 33.9%), 263 (26%), 199 (100%), and 184 (64%). Anal. calcd. for $C_{19}H_{16}O_3S_2$: C 64.02, H 4.52; found: C 64.15, H 4.36. Fractions 13–19 were combined and concentrated, giving unchanged nitrosulfonate **2** (0.47 g).

Preparation of the dinitrosulfonate ester **5**a

p-Nitro-*m*-methylphenol (0.69 g, 4.5 mmol), triethylamine (0.45 g, 4.5 mmol), and *p*-nitrobenzenesulfonyl chloride (0.99 g, 4.5 mmol) in pyridine (50 mL), reacted as above, gave recrystallized **5***a* (0.85 g, 2.5 mmol, 56%, mp 131.4–132.2°C). The product had R_f 0.25 on analytical tlc plates when developed with 1:1 carbon tetrachloride/chloroform; ir ($CHCl_3$): 1540, 1395, 1350, and 1190 cm^{-1}; nmr ($CDCl_3$) δ: 8.40 (2H, d, J = 8 Hz), 8.06 (2H, d, J = 8 Hz), 7.90 (1H, d, J = 8 Hz), 6.96 (2H), and 2.35 (3H, s); ms m/e: 338 (M^+, 3.2%), 321 (31.8%), and 122 (100%). Anal. calcd. for $C_{13}H_{10}N_2O_7S$: C 46.15, H 2.97; found: C 46.10, H 2.81.

Preparation of p*-nitro-*m*-methylphenyl benzenesulfonate*

p-Nitro-*m*-methylphenol (5.00 g, 32 mmol), triethylamine (3.30 g, 32 mmol), and benzenesulfonyl chloride (5.75 g, 32 mmol) were reacted in pyridine (50 mL) following the procedure outlined for the preparation of phenyl *p*-nitrobenzenesulfonate **2**.

[4]HMPA is hexamethylphosphoramide $[(CH_3)_2N]_3PO$. HMPA is toxic and carcinogenic (11).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12
For personal use only.

The crude nitrosulfonate was recrystallized from methanol, affording nitrosulfonate (6.85 g, 23 mmol, 71%, mp 75–76°C). The product had R_f 0.67 on analytical tlc plates developed with 1:1 chloroform/carbon tetrachloride; ir ($CHCl_3$): 1525, 1382, 1348, and 1190 cm^{-1}; nmr ($CDCl_3$) δ: 7.40 (8H, m), 2.53 (3H, s); ms *m/e*: 293 ($M^{\ddagger}$, 0.35%) and 77 (100%). Anal. calcd. for $C_{13}H_{11}NO_5S$: C 53.23, H 3.78; found: C 53.21, H 3.72.

Preparation of p-*nitro*-m-*methylphenyl benzyl sulfide*

Sodium hydride (0.41 g, 17 mmol) was added to HMPA (30 mL). A solution of benzyl thiol (2.1 mL, 16 mmol) in HMPA (10 mL) was added dropwise over 5 min. *p*-Nitro-*m*-methyl-phenyl benzenesulfonate (5.00 g, 17 mmol) was added and the reaction mixture stirred at ambient temperature for 2 h.

The reaction mixture was subjected to the extraction procedure outlined under "Reaction of **2** with ethoxide and *p*-tolyl mercaptide anions".

Crude product was chromatographed on silica gel (400 g) employing carbon tetrachloride elution followed by chloroform elution. Dibenzyl disulfide (0.63 g) was isolated. The *p*-nitro-*m*-methylphenyl benzyl sulfide so obtained was recrystallized from methanol, furnishing clean yellow needles (0.85 g, 3.3 mmol, 20%, mp 58.3–59.2°C). The nitrosulfide had R_f 0.51 on analytical tlc plates developed with carbon tetrachloride; ir ($CHCl_3$): 1525 and 1340 cm^{-1}; nmr ($CDCl_3$) δ: 7.86 (1H, d), 7.20 (7H, m), 4.16 (2H, s), and 2.53 (3H, s); ms *m/e*: 259 ($M^{\ddagger}$, 10%) and 91 (100%). Anal. calcd. for $C_{14}H_{13}NO_2S$: C 64.84, H 5.05; found: C 64.77, H 4.96.

Preparation of p-*nitro*-m-*methyl benzenesulfonyl chloride*

p-Nitro-*m*-methylphenyl benzyl sulfide (3.99 g, 15 mmol) was suspended in a solution of glacial acetic acid (25 mL) and water (3 mL). Chlorine (ca. 200 mL/min) was bubbled through the mixture for 9.75 g. Ice/water cooling was used as required to maintain the reaction temperature below 30°C.

Chloroform extraction followed by base washing gave a crude residue. The residue was rectified at reduced pressure, yielding *p*-nitro-*m*-methyl benzenesulfonyl chloride (2.73 g, 11 mmol, 75%, bp 142–148°C/1.6 Torr) (1 Torr = 133.3 Pa). *p*-Nitro-*m*-methyl benzenesulfonyl chloride had ir ($CHCl_3$): 1540, 1385, 1355, and 1175 cm^{-1}; nmr ($CDCl_3$) δ: 8.10 (3H, s) and 2.70 (3H, s).

Preparation of **5** b

p-Nitrophenol (0.61 g, 4.3 mmol), triethylamine (0.47 g, 4.6 mmol), and *p*-nitro-*m*-methylbenzene sulfonyl chloride (1.03 g, 4.3 mmol) were reacted in pyridine (50 mL). Procedure and work-up were the same as those outlined for the preparation of the dinitrosulfonate ester **5***a*.

Recrystallized **5***b* (0.69 g, 2.0 mmol, 46%, mp 120–121°C) had R_f 0.34 on analytical tlc plates developed with 3:2 carbon tetrachloride/methylene chloride; ir ($CHCl_3$): 1530, 1400, 1350, and 1175 cm^{-1}; nmr ($CDCl_3$) δ: 8.30 (2H, d), 7.96 (3H, m), 7.23 (2H, d), and 2.66 (3H, s); ms *m/e*: 338 ($M^{\ddagger}$, 27%), 200 (100%), and 136 (78%). Anal. calcd. for $C_{13}H_{10}N_2O_7S$: C 46.15, H 2.97; found: C 46.21, H 2.68.

Reaction of dinitrosulfonate **5** a *with* p-*tolyl mercaptide anions*

Sodium hydride (0.05 g, 2.2 mmol) was added to HMPA (10 mL). A solution of *p*-tolyl mercaptan (0.29 g, 2.3 mmol) in HMPA (5 mL) was added dropwise. The dinitrosulfonate **5***a* (0.75 g, 2.2 mmol) was added and the reaction mixture stirred for 2 h. The reaction mixture was subjected to the extraction procedure outlined under "Reaction of **2** with ethoxide and *p*-tolyl mercaptide anions".

Crude product was chromatographed on silica gel (30 g), affording a mixture of *p*-tolyl disulfide and the nitrosulfide **1** (0.21 g). The mixture was rechromatographed on silica gel (25 g), furnishing clean nitrosulfide **1** (0.11 g).

Preparation of p-*nitro*-m-*methylphenyl* p-*tolyl sulfide* **6**

Sodium hydride (0.32 g, 13 mmol) was suspended in HMPA (30 mL). *p*-Tolyl mercaptan (1.69 g, 13.7 mmol) in HMPA (10 mL) was added dropwise over 5 min. *p*-Nitro-*m*-methylphenyl benzenesulfonate (4.00 g, 13.6 mmol) was added and the reaction mixture stirred at ambient temperature for 2 h.

The reaction mixture was subjected to the same extraction procedure as the **5***a* mixture.

Crude product was chromatographed on silica gel (400 g), affording *p*-tolyl disulfide (0.80 g, 3.2 mmol) and the nitrosulfide **6** (1.51 g, 5.8 mmol, 43%, mp 45.6–45.9°C). The nitrosulfide **6** had R_f 0.63 on analytical tlc plates developed with carbon tetrachloride; ir ($CHCl_3$): 1510 and 1340 cm^{-1}; nmr ($CDCl_3$) δ: 7.86 (1H, d), 7.16 (6H, m), 2.50 (3H, s), and 2.33 (3H, s); ms *m/e*: 259 ($M^{\ddagger}$, 100%), 198 (29%), and 123 (14%). Anal. calcd. for $C_{14}H_{13}NO_2S$: C 64.84, H 5.05; found: C 64.71, H 4.98.

Reaction of dinitrosulfonate **5** b *with* p-*tolyl mercaptide anions*

Sodium hydride (0.05 g, 2.3 mmol) was suspended in HMPA (10 mL). A solution of *p*-tolyl mercaptan (0.26 g, 2.1 mmol) in HMPA (5 mL) was added dropwise over 1 min. The dinitrosulfonate ester **5***b* (0.70 g, 2.0 mmol) was added and the reaction mixture stirred at ambient temperature for 2 h.

The reaction mixture was subjected to the same extraction procedure as the **5***a* and **6** mixtures.

The crude product was chromatographed on silica gel (70 g), affording *p*-tolyl disulfide (0.13 g, 0.5 mmol) and a mixture containing *p*-nitro-*m*-methylphenyl *p*-tolyl sulfide **6** (0.07 g) and *p*-nitrophenyl *p*-tolyl sulfide **1** (0.009 g). The sulfide mixture was homogeneous on tlc. The sample was split in half. The presence of each sulfide was confirmed by the addition of 15-mg aliquots of each sulfide, which induced the expected changes for appropriate signals in the nmr spectra of the mixtures.

Preparation of o-*dibromo*-p-*nitrophenyl methanesulfonate* **7**

o-Dibromo-*p*-nitrophenol (4.98 g, 16 mmol), triethylamine (1.70 g, 16 mmol), and methanesulfonyl chloride (1.93 g, 16 mmol) were reacted in dry pyridine (25 mL). Procedure and work-up were the same as those outlined under "Preparation of the dinitrosulfonate ester **5***a*". Recrystallized *o*-dibromo-*p*-nitrophenyl methanesulfonate (3.83 g, 10 mmol, 61%, mp 135–136°C) had R_f 0.77 on analytical tlc plates developed with chloroform; ir ($CHCl_3$): 1540, 1390, 1355, and 1190 cm^{-1}; uv (CH_3OH) λ_{max}: 385 (s, ε 172), 270 (ε 7352), and 224 (ε 16 176) nm; nmr ($CDCl_3$) δ: 8.46 (2H, s) and 3.56 (3H, s). Anal. calcd. for $C_7H_5Br_2NO_5S$: C 22.42, H 1.34; found: C 22.44, H 1.30.

Reaction of **7** *with ethoxide and* p-*tolyl mercaptide anions*

Sodium hydride (0.66 g, 27 mmol) was added to HMPA (30 mL). A solution of ethanol (0.62 g, 13 mmol) in HMPA (10 mL) was added dropwise over 5 min. Upon completion of the addition, a solution of *p*-tolyl mercaptan (1.71 g, 13 mmol) in HMPA (10 mL) was added dropwise over 5 min. The nitrodibromomesylate (5.24 g, 14 mmol) was added and the reaction mixture stirred at ambient temperature for 2 h. The reaction color changed from khaki to red, then to yellow, and finally orange within the first 15 min. The orange color persisted until the end of the reaction.

The reaction mixture was subjected to the extraction procedure outlined under "Reaction of **2** with ethoxide and *p*-tolyl mercaptide anions".

The crude residue was twice chromatographed on silica gel, affording pale yellow crystals of 3,4,5-tris(thio-*p*-tolyl) nitrobenzene **8** (0.73 g, 1.4 mmol, 32%). Upon recrystallization from methanol the product had mp 144–144.5°C, R_f 0.40 on analytical tlc plates developed with carbon tetrachloride; ir ($CHCl_3$): 1520 and 1340 cm^{-1}; uv (CH_3OH) λ_{max}: 395 (s, ε 2060), 375 (ε 2681), 253 (ε 56 666), and 207 (ε 157 575); nmr ($CDCl_3$) δ: 7.2 (14H, m), 2.43 (6H, s), and 2.36 (3H, s). Anal. calcd. for $C_{27}H_{23}NO_2S_3$: C 66.22, H 4.73; found: C 66.30, H 4.60.

In addition, colorless crystals of 2,6-dibromo-1,4-bis(thio-*p*-tolyl) benzene **9** (0.76 g, 1.5 mmol, 23%) were obtained. Upon recrystallization from methanol the product had mp 93.5–94°C, R_f 0.35 on analytical tlc plates developed with hexanes; ir ($CHCl_3$): 1560 and 1500 cm^{-1}; uv (CH_3OH) λ_{max}: 300 (ε 9070), 275 (ε 18 500), and

220 (ε 31 111); nmr ($CDCl_3$) δ: 7.20 (10H, m), 2.33 (3H, s), and 2.23 (3H, s). Anal. calcd. for $C_{20}H_{16}Br_2S_2$: C 50.01, H 3.35; found: C 49.95, H 3.33.

The structure of the antigenic lipopolysaccharide O-chain produced by *Escherichia hermannii* ATCC 33650 and 33652[1]

LINDA M. BEYNON, DAVID R. BUNDLE, AND MALCOLM B. PERRY
Institute for Biological Sciences, National Research Council, Ottawa, Ont., Canada K1A 0R6

Received February 20, 1990

LINDA M. BEYNON, DAVID R. BUNDLE, and MALCOLM B. PERRY. Can. J. Chem. **68**, 1456 (1990).

High resolution two-dimensional ^{1}H and ^{13}C nuclear magnetic resonance at 500 MHz was used in combination with molecular modelling to solve the structures of the antigenic O-polysaccharides produced by *Escherichia hermannii* strains ATCC 33650 and 33652. Classical structural methods such as methylation analysis, selective and partial hydrolysis, and periodate oxidations confirmed that the O-polysaccharides had a branched tetrasaccharide repeating unit with the structure:

$$\begin{array}{l}\rightarrow 4)\text{-}\beta\text{-D-Glc}p\text{-}(1\rightarrow 2)\text{-}\alpha\text{-D-Rha}p\text{-}(1\rightarrow 3)\text{-}\beta\text{-D-Rha}p\text{-}(1\rightarrow \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad 3 \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad \uparrow \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad 1 \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad \alpha\text{-D-Gal}p\end{array}$$

Key words: *Escherichia hermannii*, lipopolysaccharide, magnetic resonance, polysaccharide.

Faisant appel à une combinaison de résonance magnétique nucléaire du ^{1}H et ^{13}C bidimensionnelle à haute résolution (500 MHz) et de modelage moléculaire, on a résolu les structures des O-polysaccharides antigéniques produits par les souches ATCC 33650 et 33652 d'*Escherichia hermannii*. Les méthodes classiques de détermination de structure, comme l'analyse des méthylations, les hydrolyses sélectives et partielles ainsi que les oxydations par le periodate, ont permis de confirmer que l'unité de base qui se répète dans les O-polysaccharides est un tétrasaccharide ramifié possédant la structure :

$$\begin{array}{l}\rightarrow 4)\text{-}\beta\text{-D-Glc}p\text{-}(1\rightarrow 2)\text{-}\alpha\text{-D-Rha}p\text{-}(1\rightarrow 3)\text{-}\beta\text{-D-Rha}p\text{-}(1\rightarrow \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad 3 \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad \uparrow \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad 1 \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad \alpha\text{-D-Gal}p\end{array}$$

Mots clés : *Escherichia hermannii*, lipopolysaccharide, résonance magnétique, polysaccharide.

[Traduit par la revue]

Introduction

Escherichia hermannii is described as an atypical biogroup of *Escherichia coli*. Wounds, sputum, lungs, and stools account for the source of human isolates; however, the incidence and clinical significance of the organism has not been investigated (1). Our interest in *E. hermannii* arose from the fact that some strains of the organism were falsely identified by cross-serological reactions as the important human pathogen *E. coli* O157:H7 (2). Subsequent investigations in our laboratory revealed that the structural chemical basis for this cross-serological activity resided in the presence of common epitopes involving 1,2-linked 4-acetamido-4,6-dideoxy-α-D-mannopyranosyl residues contained in their respective lipopolysaccharide O-chains (3, 4). The LPS O-chains of the cross-reacting strains of *E. hermannii* were found to be composed of repeating pentasaccharide units in linear unbranched homopolymers containing 1,2- and 1,3-linked 4-acetamido-4,6-dideoxy-α-D-mannopyranosyl residues (5), having a very close structural similarity to the M antigen found in the LPS O-chains of *Brucella melitensis* (6).

Since no chemical analyses have been reported on *E. hermannii* species it was of interest to determine if all strains of *E. hermannii* were of one serotype, showing serological cross-reaction with *Brucella* or *E. coli* O157 polysaccharide antigens. The findings in this paper record that two of the three strains of *E. hermannii* (ATCC 33650 and 33652) carried in the American Type Culture Collection have identical LPS O-chains composed of tetrasaccharide repeating units containing D-galactose, D-glucose, and D-rhamnose (1:1:2), totally unrelated to the *Brucella* and *E. coli* O157 LPS O-chains, which contain *N*-acylated common 4-amino-4,6-dideoxy-D-mannose residues. The third *E. hermannii* ATCC strain (ATCC 33651) has been found to have a unique LPS antigenic O-chain of an unbranched polymer containing only 1,3-linked β-D-rhamnopyranosyl residues (7).

Results and discussion

Extraction of *E. hermannii* (ATCC 33650) cells by a modified lysozyme phenol–water extraction procedure (8), followed by ultracentrifugation (105 000 × *g*) of the concentrated dialyzed aqueous phase, afforded LPS (ca. 5% yield based on dry cell weight). The LPS was treated with hot dilute acetic acid to yield an insoluble lipid A (15%) and Sephadex G-50 gel filtration of the concentrated water soluble products afforded polysaccharide O-chain (K_{av} 0.03, 43%), core oligosaccharide (K_{av} 0.77, 11%), and a fraction containing phosphate and 3-deoxy-D-*manno*-octulosonic acid (K_{av} 0.99, 9%).

The lyophilized O-polysaccharide had $[\alpha]_D$ +55.4° (*c* 0.54, water). Anal. found: C 40.61, H 6.01, N nil, ash, nil%. Preparative paper chromatography of the polysaccharide hydrolyzate afforded (a) D-galactose (R_{Gal} 1.00), which had [α] +78° (*c* 0.3, water) and which on reduction and acetylation gave galactitol hexaacetate having mp and mixture mp 166°C, and on GLC (program A) it gave a single peak with T_{GA} 1.01; (b) D-glucose (R_{Gal} 1.20) having $[\alpha]_D$ +52° (*c* 0.04, water), which on reduction and acetylation gave D-glucitol hexaacetate, mp and mixture mp 99°C and $[\alpha]_D$ +10° (*c* 0.2, $CHCl_3$), and which

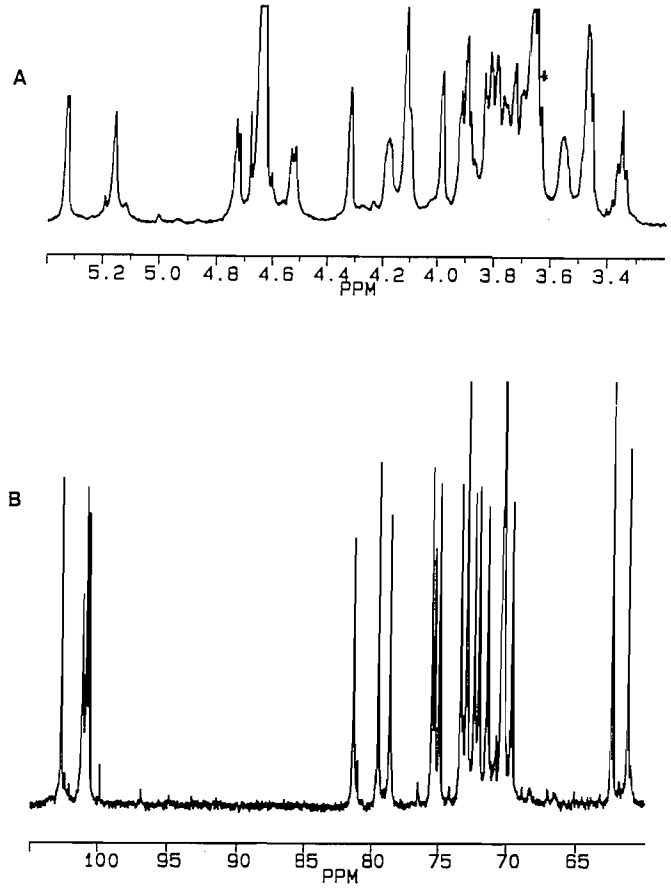

FIG. 1. (A) The 500 MHz ^{1}H NMR spectrum of the chromatographically purified *E. hermannii* O-polysaccharide. The spectral window covers the region δ 5.4–3.2 ppm, which includes the ring proton resonances. (B) The 125 MHz ^{13}C NMR spectrum of the O-polysaccharide. The ^{13}C resonances occurring in the displayed spectral region δ 105.0–60 ppm correspond to carbon atoms directly bonded to the protons displayed in A.

on GLC (program A) gave a single peak with T_{GA} 1.00; and (c) D-rhamnose (R_{Gal} 1.97) having $[\alpha]_D$ −8° (*c* 0.4, water), which on methanolysis afforded crystalline methyl α-D-rhamnopyranoside having mp and mixture mp 106°C, and $[\alpha]_D$ +62° (*c* 0.4, water), and the derived rhamnitol pentaacetate gave a single peak on GLC (program A) with T_{GA} 0.61. The assigned configurations were confirmed from the GLC analysis of the acetate and trimethylsilyl derivatives of derived 2-(+)-butyl glycosides (9, 10). Quantitative analysis of the polysaccharide constituent sugars by GLC (program A) of the derived alditol acetates of the hydrolysis products (11) showed D-galactose, D-glucose, and D-rhamnose to be present in the exact molar ratios of 1:1:2.

Four anomeric resonances were observed in both the ^{1}H and ^{13}C NMR spectra of the O-polysaccharide (Figs. 1A and 1B), suggesting a repeating unit based on a tetrasaccharide structure. The ^{1}H NMR spectrum of the O-antigen showed four equal intensity anomeric proton signals at δ 5.32 (d, 1H, $J_{1,2}$ 3.5 Hz), 5.16 (bs, 1H), 4.72 (bs, 1H), and 4.54 (d, 1H, $J_{1,2}$ 8 Hz) (Fig. 1). Consistent with the ^{1}H NMR spectrum, the ^{13}C NMR spectrum showed four distinct anomeric carbon resonances, δ 102.7, 101.1, 100.8, and 100.7, having $^1J_{C,H}$ values of 162, 170, 171, and 160 Hz respectively (Fig. 1B). Proton resonances at δ 1.32 with corresponding ^{13}C signals at δ 17.5 confirmed the presence of 6-deoxyhexose residues, while the heteronuclear

TABLE 1. ^{1}H NMR chemical shifts[a] of O-polysaccharide

Monosaccharide residue	H-1	H-2	H-3	H-4	H-5	H-6

d	102.69 (163)	73.35	74.92	79.50	75.49

[a]Chemical shifts were measured for solutions in D_2O at 37°C as expressed relative to 1% (v/v) internal acetone (δ 31.07 ppm).
[b]Value in parentheses: one-bond heteronuclear coupling constant in hertz.

coupling constants indicated the presence of two α- and two β-linked hexopyranose residues in the O-polysaccharide repeating unit.

Both ^{1}H and ^{13}C NMR spectra suggested that the structure of the polysaccharide repeating unit was based on a tetrasaccharide element, and detailed two-dimensional NMR experiments were used to unambiguously assign the structure of the polysaccharide using the absolute configuration of the component monosaccharides as the only non-spectroscopic technique. Homonuclear correlated (COSY) (12) and relayed coherence transfer (relayed COSY) (13) two-dimensional experiments allowed an almost complete assignment of the 26 proton resonances (Table 1), since the ^{1}H NMR spectrum showed very good dispersion (Fig. 2). In combination with ^{13}C/^{1}H correlation (14), the residual ^{1}H resonances were assigned, together with a complete assignment of the ^{13}C NMR spectrum (Table 2). Based upon the ^{1}H and ^{13}C chemical shifts (15–17) and the heteronuclear ^1J values (18), the polysaccharide contained α-D-galactopyranosyl, α-D-rhamnopyranosyl, β-D-rhamnopyranosyl, and β-D-glucopyranosyl residues. These four hexopyranose residues were labelled **a**–**d** based upon the chemical shift ordering of the ^{1}H anomeric resonances. This designation was used to track the dipolar coupling and residue sequence subsequently revealed by nOe experiments.

Phase sensitive NOESY (19) experiments (Fig. 3) served to establish the sequence of the monosaccharide residues in the polysaccharide and, in the case of the β-linked hexopyranose units (β-D-Glc*p* and β-D-Rha*p*), intra-residue nOe's that result from 1,3 diaxial relaxation between H-1, H-3, and H-5 atoms also confirmed the anomeric configuration. Monosaccharide **a** (α-D-Gal*p*) exhibits strong nOe's between H1**a**, H2**a**, and H3**b**, suggesting that residue **a** was α1,3 linked to **b**. The absence

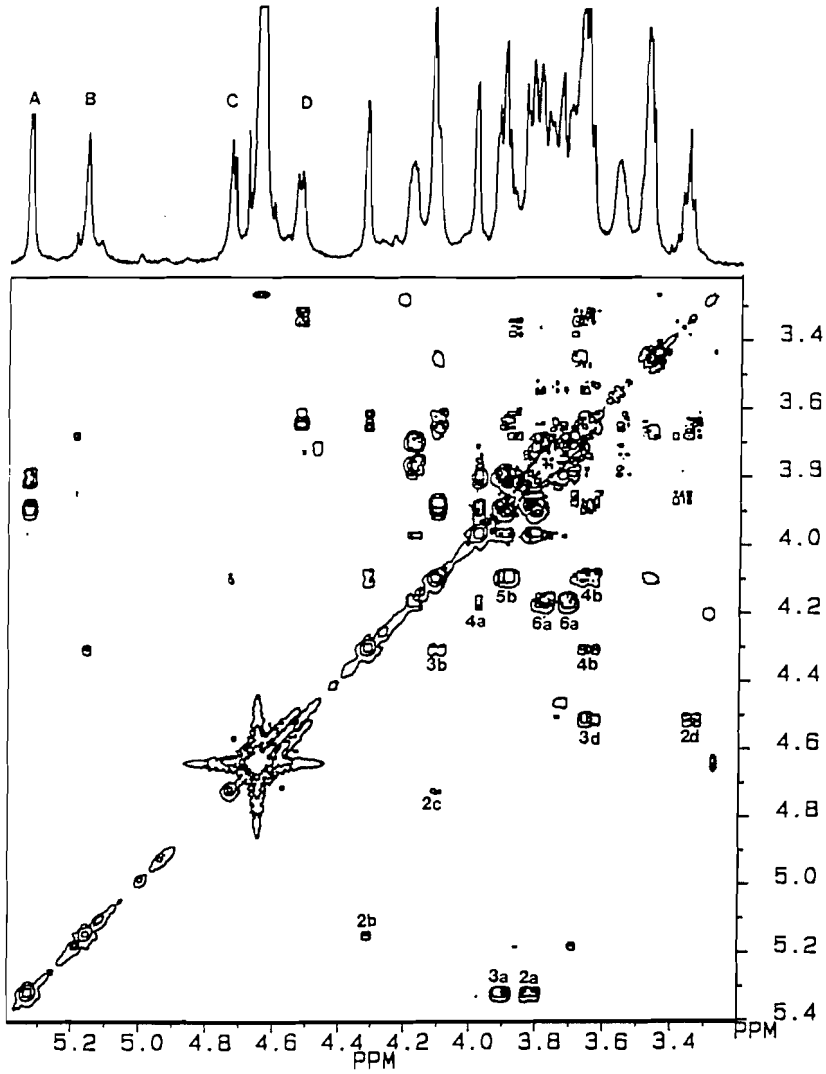

FIG. 2. Relayed coherence transfer experiment. The anomeric resonances 1a → 1d provide a point of entry for assignment of other ring protons. Magnetization transfer occurred during a fixed delay of 30 ms, which emphasizes spin networks with $^3J \approx 10$ Hz.

of any other nOe connectivities between **a** and either **d** or **c** suggests that **a** is a terminal unsubstituted residue. In comparison, residue **b** was correlated to residues **d** or **c** by an extensive network of inter-residue nOe cross peaks. These involved H1**b**, H2**b**, H1**c**, H1**d**, H2**c**, and either or both of H3**c**/H4**d**, resonances that are virtually coincident. Weaker cross peaks to H5**d** and H5**c**/H4**c** were also observed (Table 3). Thus it was not immediately clear whether unit **b** was glycosidically linked to residue **d** or **c**. The latter β-D-Rha*p* possessed nOe's between H1**c**, H3**c**, and H5**c**, and the magnitude of the cross peak between H1**c**/H3**c** suggested an additional nOe involving the coincident resonance H4**d**. Finally, residue **d** (β-D-Glc*p*) was concluded to be β1,2 linked to the α-D-Rha*p* unit **b**, since H1**d** showed strong cross peaks to H2**b**, H3**d**, and H5*d*. Based upon this data (Table 3, Fig. 4) the simplest linkage sequence was **d** → **b** → **c** with residue **a** as a branch point on **b**. The $^{13}C/^{1}H$ correlation map was consistent with this since it indicated that positions C4**d** and C3**c** were glycosylated as each carbon resonance experienced characteristic glycosylation shifts (Table 2) (17). Combining the ^{13}C NMR chemical shift with ^{1}H nOe data, the basic repeating unit structure was concluded to be

(**d**) (**b**) (**c**)

→4)-β-D-Glc*p*-(1→2)-α-D-Rha*p*-(1→3)-β-D-Rha*p*-(1→

α-D-Gal*p*

(**a**)

Inter- and intra-residue nOe's extracted from the NOESY experiment (Fig. 3) agree with predicated nOe's (Table 3). These were calculated from a molecular model of the proposed polysaccharide repeating unit using the GESA algorithm (20) adapted to take account of motional averaging about the glycosidic linkages. Ensemble averaged nOe's were also calculated by the full matrix treatment (21). The overlap of crucial proton resonances H3**c**/H4**d** and H3**d**/H4**b** introduces a degree of uncertainty into the assignment of sequence linkage position for residues **c** and **d**. To place the NMR structural assignment upon a rigorous basis, classical chemical methods that included specific degradation and methylation analysis were used (Scheme 1).

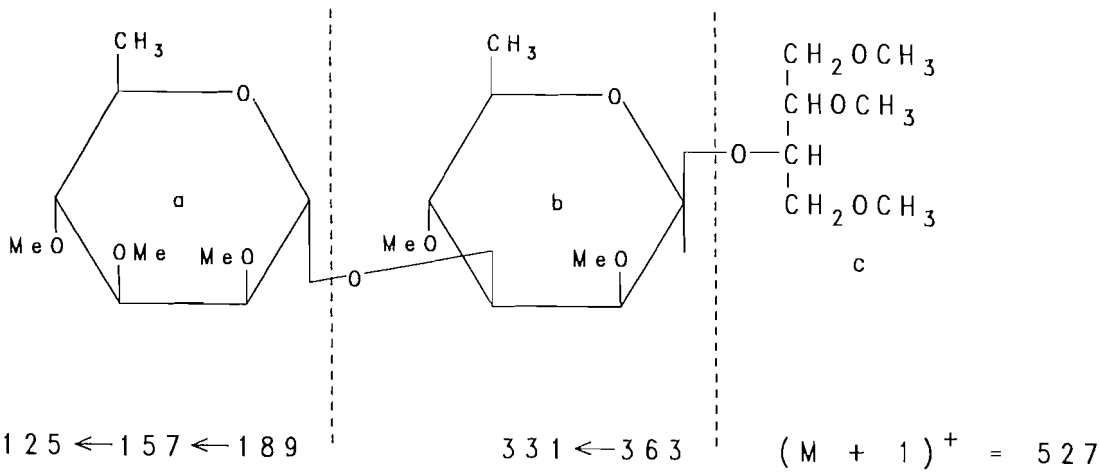
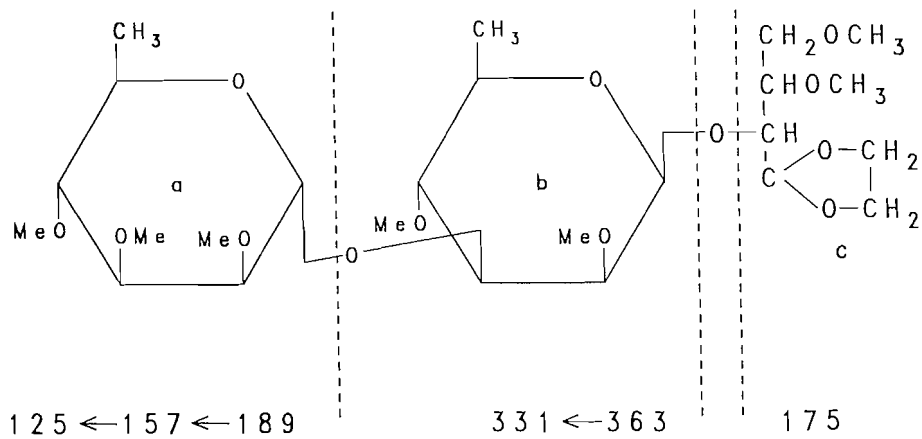
GLC–MS analysis of the reduced ($NaBD_4$) and acetylated products of the hydrolyzed methylated O-polysaccharide (Table 4) indicated the repeating unit to be a branched tetrasaccharide consisting of non-reducing D-galactopyranose end groups, 3-*O*-substituted D-rhamnopyranosyl units, 4-*O*-substituted D-glucopyranosyl units, and branch points of D-rhamnopyranose substituted at the *O*-2 and *O*-3 positions. The glycose sequence and anomeric configurations of the linkages in the O-chain were determined by degradation methods.

Selected acid hydrolysis (0.5 M trifluoroacetic acid, 1 h, 100°C) followed by Sephadex G-50 gel filtration chromatography of the concentrated hydrolyzate gave a major high molecular weight product (**1**) (K_{av} 0.06) composed of D-glucose and D-rhamnose (1:2). Methylation analysis (Table 4) of **1** gave 3,4-di-*O*-methyl-D-rhamnose, 2,4-di-*O*-methyl-D-rhamnose, and 2,3,6-tri-*O*-methyl-D-glucose (1:1:1.1). The new appearance of 3,4-di-*O*-methyl-D-rhamnose shows that the non-reducing D-galactopyranose end group was the single side substituent attached to the 2-*O*-glycosidically substituted D-rhamnopyranosyl residue contained in the unbranched linear backbone of the O-chain. The ^1H and ^{13}C spectra (Table 5) of the degraded O-chain are consistent with the proposed trisaccharide repeating unit present in the backbone structure and to assignment in the native O-chain of the α and β configurations to the D-galactopyranosyl and D-glucopyranosyl residues respectively.

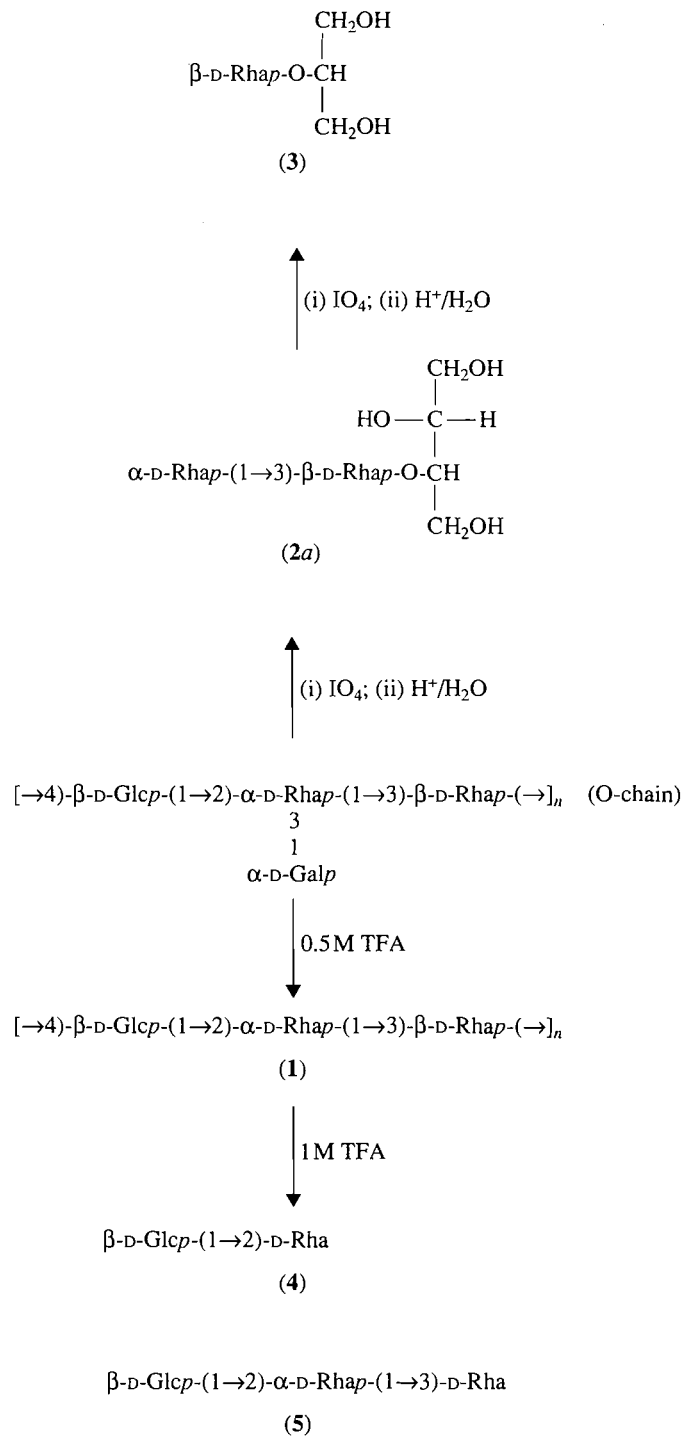
The sequence of the three glycose residues in the O-chain backbone was established through periodate oxidation studies. The periodate oxidized and reduced ($NaBH_4$) O-chain, on Smith type hydrolysis (22) and subsequent Bio-Gel P2 gel chromatographic separation of the hydrolyzate, gave a major product (**2**) (K_{av} 0.65), which on TLC exhibited two spots having R_f 0.48 and 0.42 (ca. 1:2.5). GLC–MS (program C) analysis of the methylated mixed product **2** gave two peaks for derivatives **2***a* and **2***b* having T_{MS} 1.58 and 2.45 (ca. 2.3:1). The GLC–CI-MS of **2***a* (Table 6) gave a fragmentation pattern consistent with the structure:



The GLC–CI-MS fragmentation pattern of **2***b* (Table 6) suggested that it was an artifact produced during the Smith-type hydrolysis and has the possible structure:



GLC–MS analysis of the reduced ($NaBD_4$) and acetylated hydrolysis products of methylated **2** (Table 4) showed it to give 2,3,4-tri-*O*-methyl-D-rhamnose and 2,4-di-*O*-methyl-D-rhamnose (1.2:1) consistent with the proposed structure **2***a* and of the linkage sequence →2)-D-Rha*p*-(1→3)-D-Rha*p*-(1→4)-D-Glc*p*-(1→ in the backbone of the O-chain. Periodate oxidation of **2** followed by Smith-type hydrolysis and preparative paper chromatography afforded a major product **3** (R_{Gal} 1.75), having $[\alpha]_D$ −110° (*c* 0.2, water), composed of D-rhamnose and glycerol (1:1) and identified as β-D-rhamnopyranosyl-(1→2)-glycerol by methylation analysis and from its ^{13}C NMR spectrum, which showed an anomeric carbon signal (δ 100.19)



SCHEME 1. Degradation of *E. hermannii* LPS O-chain by hydrolytic and periodate oxidation methods.

having a $J_{C,H}$ coupling of 159 Hz. The identification of **3**, considered in connection with the identified presence of an α and a β configuration present in its precursor **2***a* (Table 5), indicates that the backbone structure of the O-chain contains the sequence →4)-β-D-Glc*p*-(1→2)-α-D-Rha*p*-(1→3)-β-D-Rha*p*-(1→.

Further confirmation of the structure of the O-chain was obtained by partial hydrolysis of the native O-chain (1 M trifluoroacetic acid, 95°C, 45 min) followed by Bio-Gel P2 gel filtration chromatography of the products, affording a disaccharide **4** (23%) (K_{av} 0.82) and a trisaccharide **5** (12%) (K_{av} 0.61). Both products were chromatographically pure by TLC and had R_f 0.34 and 0.27 respectively.

Oligosaccharide **4** was composed of D-glucose and D-rhamnose (1:1) and GLC–MS (program C) of methylated **4** showed two peaks (T_{MS} 0.89 and 0.91) giving identical mass spectral fragmentation patterns (Table 6) consistent with the structure:

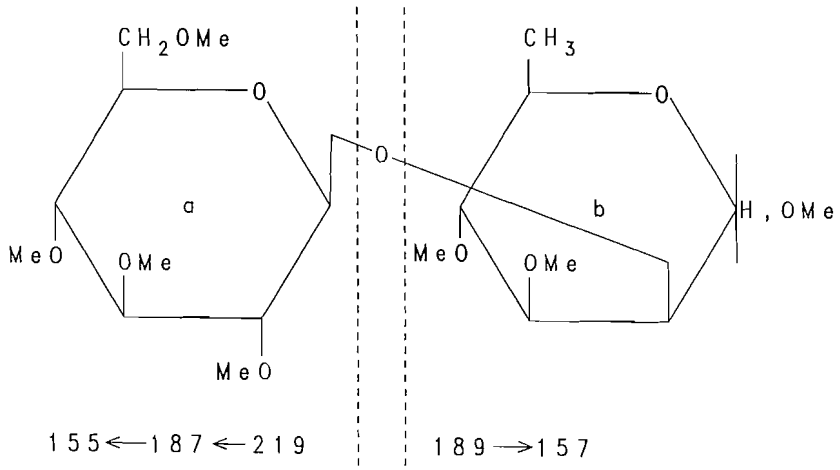
1,5-Di-*O*-acetyl-2,3,4,6-tetra-*O*-methyl-D-galactitol	1.06	0.7	—	—	—	—	—
1,2,3,5-Tetra-*O*-acetyl-4-*O*-methyl-D-rhamnitol	1.12	1.0	—	—	—	—	—
1,4,5-Tri-*O*-acetyl-2,3,6-tri-*O*-methyl-D-glucitol	1.31	1.0	1.1	—	—	—	—

[a]GLC (program B) retention time relative to 1,5-di-*O*-acetyl-2,3,4,6-tetra-*O*-methyl-D-glucitol = 1.00.

[b]Degradation products: **1**, degraded O-chain from selective hydrolysis; **2**, periodate oxidation product D-Rha*p*-(1→3)-D-Rha*p*-(1→2)-erythritol; **3**, periodate oxidation product D-Rha*p*-(1→2)-glycerol; **4**, partial hydrolysis product D-Glu*p*-(1→2)-D-Rha; **5**, partial hydrolysis product D-Glu*p*-(1→2)-D-Rha*p*-(1→3)-D-Rha.



Hydrolysis of methylated **4** gave 2,3,4,6-tetra-*O*-methyl-D-glucose and 3,4-di-*O*-methyl-D-rhamnose (1.2:1). The ^{1}H NMR spectrum (Table 5) of **4** showed the anomeric proton signal of the D-glucopyranosyl residue at δ 4.50 (d, 1H, $J_{1,2}$ = 8 Hz), allowing **4** to be assigned the structure β-D-glucopyranosyl-(1→2)-D-rhamnose.

Oligosaccharide **5** was composed of D-glucose and D-rhamnose (1:2). GLC–MS (program C) analysis of methylated **5** gave a single peak (T_{MS} 2.31), giving a MS spectrum (Table 6) consistent with the structure:

α-D-Rha*p*-(1→3)-β-D-Rha*p*-(1→2)-X[b] **2***b*	2.45	555 (0.4)	189 (18.3)	157 (4.9)	125 (8.7)	—	363 (100)	331 (3.4)	175 (6.6)	—	—	—	—	—	—
β-D-Glc*p*-(1→2)-D-Rha **4**	0.89 0.91	—	219 (4.4)	187 (29.6)	155 (6.7)	189 (69.5)	—	—	—	249 (81.8)	—	—	—	—	—
β-D-Glc*p*-(1→2)-α-D-Rha*p*-(1→3)-D-Rha **5**	2.31	—	219 (13.5)	187 (100)	155 (17.4)	—	393 (4.9)	361 (24.2)	189 (4.5)	—	363 (5.9)	331 (23.2)	299 (12.8)	249 (32.4)	423 (26.1)

[a]GLC retention times relative to methylated sucrose (program C).
[b]X = artifact produced by Smith type hydrolysis (see text).

Methylation analysis of **5** (Table 4) gave 2,3,4,6-tetra-*O*-methyl-D-glucose, 3,4-di-*O*-methyl-D-rhamnose, and 2,4-di-*O*-methyl-D-rhamnose (0.8:1:0.6). The ^1H and ^{13}C NMR data on **5** and reduced ($NaBH_4$) **5** (Table 5) are consistent with **5** being assigned the structure β-D-glucopyranosyl-(1→2)-α-D-rhamnopyranosyl-(1→3)-D-rhamnose, the α-D configuration being assigned to the non-reducing D-rhamnopyranosyl residue from the $J_{C,H}$ (169.5 Hz) value of the anomeric carbon signal at δ 100.6, assigned to that residue. The O-chain polysaccharide is thus chemically confirmed to have the structure:

$$\begin{array}{c}\rightarrow 4)\text{-}\beta\text{-D-Glc}p\text{-}(1\rightarrow 2)\text{-}\alpha\text{-D-Rha}p\text{-}(1\rightarrow 3)\text{-}\beta\text{-D-Rha}p\text{-}(1\rightarrow \\ 3 \\ \uparrow \\ 1 \\ \alpha\text{-D-Gal}p\end{array}$$

Figure 5 illustrates a molecular model representation of the polysaccharide repeating unit, showing the orientation of each glycosidic linkage and the proximity of the protons that lead to the network of nOe's used to sequence the polymer.

The LPS core oligosaccharide had $[\alpha]_D$ +98.9° (*c* 0.9, water) and was composed of D-glucose, D-galactose, 2-amino-2-deoxy-D-glucose, and D-*glycero*-D-*manno*-heptose in the molar ratio 3.8:1.0:0.9:1.0.

A parallel study of the LPS of *E. hermannii* ATCC 33652 showed that it had a polysaccharide O-chain having an identical structure with that of the *E. hermannii* ATCC 33650 strain.

Experimental

Cell growth and production of lipopolysaccharide

Escherichia hermannii (ATCC 33650 and 33652) were first grown in BHI (50 mL) in 250-mL baffled Erlenmeyer flasks incubated overnight at 37°C and 250 rpm, followed by transfer to BHI (1 L) in 4-L baffled Erlenmeyer flasks and further incubation at 37°C for 7 h at 200 rpm. The 1-L growths were used to inoculate a fermentor (28 L Microferm, New Brunswick Scientific) containing 28 L BHI and antifoam (5 mL). The bacteria were grown at 37°C at 200 rpm with aeration 25 L/min for 18 h. Growths were killed by phenol at a final concentration of 0.75% and, after keeping at 4°C for 4 h, the cells (ca. 350 g wet weight) were collected using a Sharples centrifuge. Collected cells were extracted with stirred 48% (w/v) aqueous phenol (12 min, 65°C) and, following low speed centrifugation at 4°C, the separated aqueous and phenol phases were collected, dialyzed against tap water until phenol-free, and the retentates were lyophilized. The lyophilized products dissolved in water (100 mL) were treated with ribonuclease and deoxyribonuclease (6 h, 37°C) followed by protease K (4 h, 37°C) and, following removal of insolubles, the LPS were obtained as precipitated gels by ultracentrifugation (105 000 × g, 16 h, 4°C). Yields: 3.1 g aqueous phase LPS; 0.3 g phenol phase LPS.

LPS (0.5 g) dissolved in 1.5% (v/v) acetic acid (100 mL) were heated for 2 h on a boiling water bath and, following removal of precipitated lipid A from the cooled solution by low speed centrifugation, the centrifugates were lyophilized. The lyophilizates dissolved in 0.05 M aqueous pyridinium acetate (5 mL, pH 4.7) were fractionated on a column (2.5 × 85 cm) of Sephadex G-50 (Pharmacia Fine Chemicals) using the same buffer as the eluant. The column eluate was monitored using a Waters 402 refractometer and fractions (10 mL) of the eluates were collected.

Analytical methods

Quantitative colorimetric methods used were (a) the phenol – sulfuric acid method for neutral glycoses (23), (b) the modified Elson–Morgan method for aminodeoxyhexoses (24), (c) the method of Chen *et al.* for phosphate (25), and (d) the periodate oxidation – thiobarbituric acid method for 3-deoxy-D-*manno*-octulosonate (26).

GLC was done with a Hewlett–Packard 5830A gas chromatograph fitted with a flame ionization detector and a model 18850A electronic

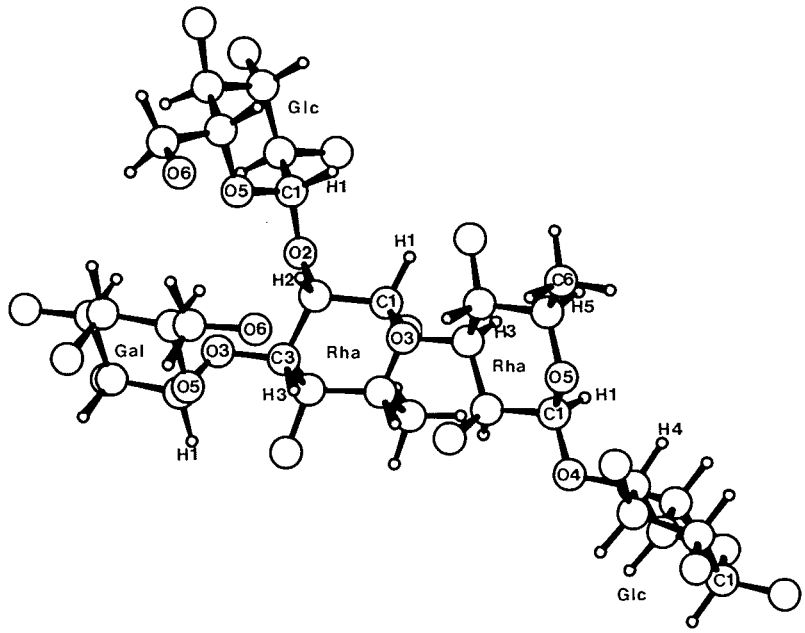

FIG. 5. The pentasaccharide sequence →4)-β-D-Glc*p*-(1→2)-[α-D-Gal*p*-(1→3)]-α-D-Rha*p*-(1→3)-β-D-Rha*p*-(1→4)-β-D-Glc*p*-(1→ is displayed in its minimum energy conformation. The network of nOe's arise from the proximity of anomeric protons (H-1) and the protons attached to the respective linkage carbon atoms are readily appreciated: H1**d**/H2**b**, H1**a**/H3**b**, H1**b**/H3**c**, and H1**c**/H4**d**.

integrator. For glycose derivative analysis, an OV 17 fused silica capillary column (0.32 mm diam. × 25 m) 007 series bonded phase (Quadrex Corp.) using temperature programs (A) 180°C (delay 2 min) – 240°C at 4°C/min, (B) 180°C (delay 2 min) – 240°C at 2°C/min, and (C) 220°C–280°C at 7°C/min. Retention times are quoted relative to D-glucitol hexaacetate (T_{GA}), 1,5-di-*O*-acetyl-2,3,4,6-tetra-*O*-methyl-D-glucitol (T_{GM}), or fully methylated sucrose (T_{MS}). GLC–MS analyses were made using a Hewlett–Packard 5985B system and GLC programs A–C with an ionization potential of 70 eV. Glycose configurations were determined by GLC of the acetylated or trimethylsilylated derived 2-(+)-butyl glycosides (9, 10).

TLC was carried out using preformed glass plates coated with silica gel 60 (Merck) using 1-propanol/concentrated ammonium hydroxide/water (6:3:1 v/v) as the mobile phase.

Gel filtrations were performed on columns of Sephadex G-50 (2 × 100 cm) or Bio-Gel P-2 (200–400 mesh) (1.6 × 100 cm).

Total hydrolysis of oligo- and polysaccharide samples (1 mg) was made in sealed tubes with 2 M trifluoroacetic acid at 100°C for 15 h followed by concentration to dryness.

Optical rotations were determined in 10-cm microtubes using a Perkin–Elmer 402 polarimeter, and concentrations were made by rotary evaporation below 45°C.

Hydrolysis methods

Selective hydrolysis (removal of D-galactopyranosyl non-reducing end groups) of O-polysaccharide (50 mg) was done with 0.5 M trifluoroacetic acid (100 mL) at 100°C for 1 h, followed by lyophilization.

Partial hydrolysis of O-polysaccharide (140 mg) to yield oligosaccharides was effected with 1 M trifluoroacetic acid (100 mL) at 95°C for 45 min, followed by evaporation to dryness.

Methylation analyses

Samples (1–2 mg) were methylated according to the Hakomori method (27) and the products were isolated by partition between dichloromethane and water. Methylated products were hydrolyzed with 2 M trifluoroacetic acid at 100°C for 16 h or 4 M trifluoroacetic acid at 125°C for 1 h, followed by evaporation to dryness. Released methylated glycoses were reduced ($NaBD_4$) and acetylated by heating with acetic anhydride and pyridine (1:1 v/v) at 95°C for 30 min, followed by direct GLC–MS (program B) analysis.

Periodate oxidation (ref. 22)

Polysaccharide (85 mg) in water (10 mL) containing sodium metaperiodate (0.2 g) was kept for 3 days in the dark at 20°C and, following the destruction of excess periodate with ethylene glycol (0.2 mL), the product was reduced by the addition of sodium borohydride (0.5 g). After 16 h at 20°C, excess borohydride was destroyed by acidification with 50% acetic acid and the product was recovered by lyophilization of the dialysed reaction mixture. Treatment of the polyol with 0.5 M trifluoroacetic acid (10 mL) for 24 h at 20°C, followed by lyophilization and Bio Gel P-2 gel filtration chromatography, afforded oligosaccharides.

Nuclear magnetic resonance spectroscopy

Polysaccharide and oligosaccharide samples were lyophilized from deuterium oxide and were dissolved at concentrations of 20 and 50 mg/500 μL. Spectra were recorded for samples in 5-mm tubes at 500 MHz for ^1H and 125 mHz for ^{13}C on a Bruker AM-500 spectrometer. Proton spectra were recorded at 303 and 310 K and ^{13}C spectra were recorded at 310 K employing ~1-W WALTZ decoupling as previously described (28).

Homonuclear two-dimensional spectroscopy was performed with Bruker DISNMRP software. COSY (12, 29) and NOESY (19) experiments were performed with suppression of the HOD resonance as previously described (6, 28). Mixing times of 100 and 150 ms were employed for NOESY experiments. Relayed COSY (13) experiments were carried out with fixed delays of 30 and 80 ms in two separate experiments to optimize coherence transfer for large and small scalar couplings (30). All homonuclear experiments were performed with quadrature detection in the F_1 dimension, and a total of $256t_1$ increments of 96 scans each (64 scans for COSY experiments) were recorded with a minimum delay between pulses of 1.2 s and a sweep width of 2500 Hz. The time domain data matrix was zero filled to either 1024 × 1024 or 2048 × 2048 points and, following resolution enhancement in both dimensions by a modified sine-bell function, the doubly transformed data were processed to give magnitude spectra. NOESY experiments were performed in the phase-sensitive mode (19). The symmetrical matrix was symmetrized about the diagonal for presentation and to reduce t_1 noise.

Heteronuclear shift correlation spectroscopy (14) was performed with quadrature detection in F_1 (31, 32), and a total of $64t_1$ increments

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12
For personal use only.

of 320 scans each were recorded for a spectral width in F_2 of 7800 Hz and 1500 Hz in F_1. Data were processed to give after zero filling a matrix ($t_1 \times t_2$) of 256 × 8192 points, and, following resolution enhancement, double transformation gave power spectra. Fixed delays of τ_1 = 3.4 ms and τ_2 = 1.7 ms were employed to select all multiplicities, and a recycle delay of ca. 1 s (one proton T_1) was used.

Potential energy calculations

Potential energy calculations using the GESA (20, 21) algorithm were performed for a hypothetical pentasaccharide unit β-D-Glc*p*-(1→2)-[α-D-Gal*p*-(1→3)]-α-D-Rha*p*-(1→3)-β-D-Rha*p*-(1→4)-β-D-Glc*p*, using coordinates generated from X-ray or neutron diffraction data as previously described (28). Atomic coordinates for α-D-galactopyranose residues were obtained from neutron diffraction data (33) while those for D-rhamnopyranose units were derived by bond modification of neutron diffraction data for α-D-mannopyranoside (34). The atomic coordinates for the heavy atoms of β-D-glucopyranose were taken from X-ray data (35).

COMMUNICATION

A study of thermodynamic acidities of enols with the semiempirical computational method AM1

NICK HENRY WERSTIUK AND DAVID ANDREW[1]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received January 2, 1990

NICK HENRY WERSTIUK and DAVID ANDREW. Can. J. Chem. **68**, 1467 (1990).

Using the semiempirical computational method AM1 we have computed the enthalpies of ionization of enols **1**–**21** and correlated these values with solution and estimated pK_a's. From this initial study it appears that, in general, it is possible to predict the pK's of acyclic enols within ±1 pK_a unit. On the basis of this correlation we predict the pK_a's of 1-hydroxy-1,3-butadiene (3-butenal enol) (9.7) and 1,1-difluoroacetone enol (9.6) and suggest that the previously estimated pK_a of 1,1-dichloroacetone enol (6.2) is low by approximately 3 pK units. We find computationally (this has been established experimentally) that the *Z*-enol of phenylacetaldehyde is less acidic than the *E*-enol.

Key words: enols, acidities, computational studies, AM1.

NICK HENRY WERSTIUK et DAVID ANDREW. Can. J. Chem. **68**, 1467 (1990).

Utilisant la méthode de calculs semi-empiriques AM1, on a calculé les enthalpies d'ionisation des énols **1**–**21** et on a établi une corrélation entre les résultats de ces calculs et les valeurs observées en solution ainsi qu'avec les valeurs estimées des pK_a. Sur la base de cette étude initiale, il semble que, en général, il est possible de prédire les valeurs des pK d'énols acycliques à ±1 unité de pK_a. Sur la base de cette corrélation, on peut prédire les valeurs des pK_a du 1-hydroxy-buta-1,3-diène (énol du but-3-ènal) (9,7) et de l'énol de la 1,1-difluoroacétone (9,6) et suggérer que la valeur de 6,2, estimée antérieurement pour le pK_a de l'énol de la 1,1-dichloroacétone, est environ 3 unités de pK_a trop basse. Sur la base des calculs — qui ont été confirmés d'une façon expérimentale — le énol-*Z* du phénylacétaldéhyde est moins acide que l'énol-*E*.

Enols are important intermediates in organic chemistry. The pK_a's of a number of these transient species have been obtained experimentally, mainly through the elegant work of Kresge and co-workers (1–7).[2] Guthrie, in elaborating a thermochemical approach for predicting the enol content of a simple ketone, estimated the pK_a's of 24 enols by a LFER method (8, 9).

To expand studies on the enthalpies of ionization[3,4] with the semiempirical computational method AM1 (10), we undertook a study of enols to establish whether the pK_a's of these transient species can be estimated computationally. We calculated heats of formation of 1-formylfluorene enol (**1**), mandelic acid enol (**2**), diphenylacetaldehyde enol (**3**), phenylacetaldehyde enol (**4**), methoxyacetophenone enol (**5**), acetophenone enol (**6**), isobutyraldehyde enol (**7**), acetone enol (**8**), and acetaldehyde enol (**9**) and the corresponding enolates. To extend this study to the ionization of an anionic species, heats of formation of the enol of pyruvate (CH_2=CH(OH)CCO-$^+$, neutralized by a unit positive charge, and its enolate (CH_2=CH(O-)COO-$^+$ were

calculated as well.[5] The optimized structures of these species including the location of the positive charge are shown as **1ON** and **1ONE**, respectively. Enol **1ON** is a planar species with the carboxylate oxygens symmetrically disposed with respect to the positive charge. Enolate **1ONE** is twisted; one carboxylate

[1]Recipient of a Natural Sciences and Engineering Research Council of Canada Summer-Student Research Scholarship, 1988.

[2]Also A. J. Kresge, personal communication. We thank Professor Kresge for providing us with the pK_a (11.57) of the enol of sodium pyruvate prior to publication.

[3]Computations (RHF) were carried out using AM1 or AMPAC, Version 2.1, which was ported to Sun 3/60 and IBM RT computers.

[4]The enthalpy of ionization of an enol EH is given by the equation

$$\Delta H_i = [\Delta H_f(E^-) - \Delta H_f(EH)] + \Delta H_f(H^+)$$

The geometries of EH and E^- were fully optimized in each case using the AM1 default parameters. $\Delta H_f(H^+)$ = 364.2 kcal/mol.

[5]It is possible within AM1 to use a point charge to represent an alkali metal cation. While ΔH_i for CH_2=CH(OH)COO^- is 450 kcal/mol, for CH_2=CH(OH)COO^+ it is 377.8 kcal/mol. It is clear from these values and Fig. 1(a) that this "ion pairing" is necessary in the case of anions in order to compute ΔH_i's that correlate with solution acidities. It is interesting to note also that the computed ΔH_i for the enol hydroxyl of CH_2=CH(OH)COOH is 345.0 kcal/mol. From eq. [1], the pK_a is estimated to be 9.4 in solution. Based on this value—it cannot be obtained experimentally—ionization of the carboxyl group of the enol of pyruvic acid followed by ion pairing in solution lowers the acidity of the enol by approximately 2.1 pK units.

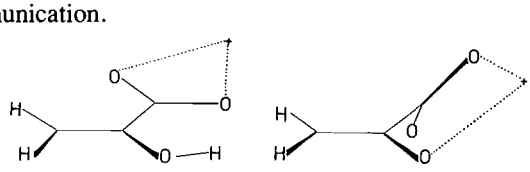
oxygen and the enolate oxygen interact with the positive charge. The ΔH_f data, ΔH_i's, and solution pK_a's of enols **1–10** are given in Table 1. The pK_a of **1** was obtained by Harcourt and More O'Farrell (11), and Kresge and co-workers have determined the pK_a's of **2–10** (1–7).[2] We also computed the ΔH_f's of methoxyacetone enol (**11**), the non-conjugated isomer of phenylacetone enol (**12**), 4-phenylbuten-2-one enol (**13**), *p*-methoxyacetophenone enol (**14**), chloroacetone enol (**15**), bromoacetone enol (**16**), ethyl pyruvate enol (**17**), 1,3-dichloroacetone enol (**18**), *p*-nitroacetophenone enol (**19**), and phenylacetone enol (**20**), 1,1-dichloroacetone enol (**21**), and their enolates (Table 1). The pK_a's of enols **11–21** have been estimated by Guthrie (8, 9). A correlation of the pK_a's and ΔH_i's of enols **1–21** is presented and discussed in this communication.



10N 10NE

Figure 1(a) shows a plot of the experimental pK_a's of enols **1–10** versus the computed ΔH_i's. Figure 1(b) shows a similar plot for enols **11–21**; this group of 11 enols was selected from the series of 24 studied by Guthrie to provide the widest range of structural types and acidities. Figure 1(c) shows a plot of both sets of data with the values for enols **20** and **21** excluded. Linear least-squares analysis yields slopes of 0.086, 0.121, and 0.090, for plots (a), (b), and (c), respectively. The equation of the regression line defined in Fig. 1(a) is shown as eq. [1] and the correlation coefficient is 0.88. Considering the wide range of structures studied, the narrow range of pK_a's, and the fact that ΔS_i (solution) is assumed to be invariant through the series, the correlation of the combined data is remarkable. Even though the uncertainties in the slope and intercept are high it appears that this method will be useful for estimating pK_a's of acyclic enols within ±1 pK unit.[6]

$$[1] \quad pK_a = 0.086(\pm 0.033)\Delta H_i - 20.0(\pm 11.6)$$

For the enols studied, we find, in general, that AM1 predicts *s-cis* isomers to be 1.6–3.8 kcal lower in energy than the *s-trans* isomers. There is some experimental support for this result. On the basis of the magnitude of the =CH-OH vicinal coupling constant (8.88 Hz), Capon and Guo (12) have suggested that (*E*)-1-hydroxy-1,3-butadiene exists in an *s-cis* conformation in 90:10 DMSO–CH_3OH. A smaller coupling constant (5.53 Hz) was taken as evidence that the *s-trans* conformer is the stablest species in the case of the *Z*-enol. However, AM1 predicts that *s-cis* conformers are the stablest structures in both cases. It is possible that the *Z*-enol exists as a twisted *s-cis* conformer in this medium to reduce steric inhibition to hydrogen bonding. Based on a computed ΔH_i of 345.1 kcal/mol, we predict the pK_a of (*E*)-1-hydroxy-1,2-butadiene to be 9.7.

The results obtained for the *E*- and *Z*-enols and enolates of phenylacetaldehyde and the enol and enolates of mandelic acid illustrate the potential utility of these computational studies. AM1 computes ΔH_i of the *E*-enol of phenylacetaldehyde to be 1.2 kcal/mol lower than ΔH_i of the *Z*-enol; this translates into a

[6]The equation of the line given in Fig. 1(c) is

$$pK_a = 0.90(\pm 0.027)\Delta H_i - 21.3(\pm 9.30)$$

The correlation coefficient is 0.86.

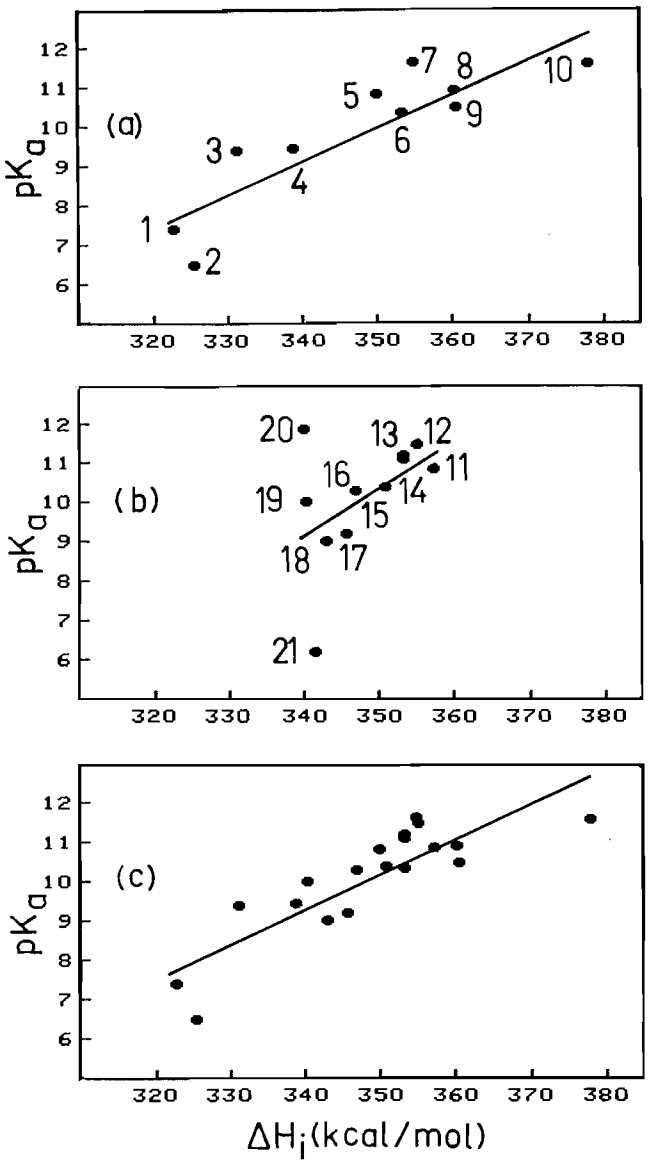


FIG. 1. (a) Plot of pK_a versus ΔH_i for enols **1–10**; (b) plot of pK_a versus ΔH_i for enols **11–21**; (c) plot of pK_a versus ΔH_i for enols **1–19**.

slightly higher pK_a ($\Delta pK = 0.10$) for the *Z* isomer than the *E* isomer. Kresge and co-workers have shown that the solution pK_a's of the *E*- and *Z*-enols are 9.46 and 9.76 ($\Delta pK = 0.30$), respectively (7). By studying a number of conformers of mandelic acid enol we find that, unlike the case of phenylacetaldehyde enol, ionization of the hydroxyl group *cis* to phenyl is preferred over ionization of the *trans* hydroxyl by 1.9 kcal/mol.

The difference between the pK_a (11.8) of phenylacetone enol (**20**) estimated by Guthrie (9) and the value (9.2) obtained using the computed ΔH_i deserves comment. According to AM1, the planar *Z*-enolate is 2.2 kcal/mol lower in energy than the *E*-enolate. One possible source of the difference between these predicted pK_a's is that solvation of the oxygen of *o*-phenyl phenolate used to estimate the pK_a of **20** is maximized only if the phenyl ring is twisted out of conjugation with the phenolate π-system. To probe the effect of deconjugating the phenyl group of the *Z*-enolate of **20**, the heat of formation was computed as a function of the phenyl twist angle. Based on the ΔH_f's of the planar *Z*-enolate and the 90° conformer, resonance stabilization by the phenyl group is 12.8 kcal/mol in the gas phase; a 30° twist results in only a small destabilization relative to the planar species. Based on eq. [1], the pK_a of the 90° conformer is predicted to be 10.5, which is closer to the value estimated by Guthrie. However, it seems unlikely that a highly twisted *Z*-enolate of phenylacetone could be the stablest species because the planar *E* isomer, in which solvation of the oxygen is not sterically inhibited, is only 2.2 kcal/mol higher in energy relative to the planar *Z* isomer. In this respect it is interesting to note that Kresge and co-workers used the experimentally determined pK_a of **4** to estimate the pK_a (9.75) of **20** (13).

Based on the plots shown in Fig. 1, it appears that the pK_a (6.2) estimated for 1,1-dichloroacetone enol (**21**) by Guthrie (9) is approximately 3 pK units too low. The reason for this is not clear, but it appears that the inductive effect of two chlorines has been overestimated. Here we predict that 1,1-difluoroacetone enol will be less acidic (ΔH_i = 343.7, pK_a = 9.6) than 1,2-dichloroacetone enol (predicted pK_a = 9.4). This is undoubtedly due to the +R effect of fluorine (14).

A characterization and catalytic study of Y zeolite supported Ni/Cu bimetallics

BRENDAN COUGHLAN AND MARK A. KEANE[1]
Physical Chemistry Laboratories, University College, Galway, Eire

Received October 4, 1989

BRENDAN COUGHLAN and MARK A. KEANE. Can. J. Chem. **68**, 1471 (1990).

A wide range of CuNiNaY and CuNiKY zeolites were prepared by ion exchange. The location of both Ni^{2+} and Cu^{2+} cations within the zeolite framework was monitored after various stages of thermal treatment and the reduction process of the transition metal ions in a flowing hydrogen atmosphere was investigated and correlated with reduction time and temperature. The metallic phase generated on reduction was characterized by X-ray diffraction line broadening. The catalytic activity of the reduced zeolites in the hydrogenation of benzene is discussed in the light of these physical characterizations.

Key words: zeolites, supported Ni/Cu bimetals, cation location, crystallite size, catalysis.

BRENDAN COUGHLAN et MARK A. KEANE. Can. J. Chem. **68**, 1471 (1990).

On a préparé une grande variété de zéolites des types CuNiNaY et CuNiKY par échange d'ions. On a déterminé la position des cations Ni^{2+} et Cu^{2+} dans le squelette des zéolites après divers stages du traitement thermique; de plus, on a examiné le processus de réduction des ions des métaux de transition dans un atmosphère formé d'un flux d'hydrogène et on a établi une corrélation avec le temps et la température de réduction. En se basant sur l'élargissement des rais de diffraction des rayons-X, on a caractérisé la phase métallique qui est générée lors de la réduction. À la lumière de ces caractérisations physiques, on discute de l'activité catalytique des zéolites réduits lors de l'hydrogénation du benzène.

Mots clés : zéolites, position des cations, grosseur cristalline, catalyse.

[Traduit par la revue]

1. Introduction

In the 1950's there was a strong interest in heterogeneous catalysis by alloys, due to the alleged validity of the Rigid Band Model (RBM). According to this model, upon alloying, the holes in the *d*-band of the transition metals could be filled (1). For the Ni/Cu system, Hall and Emmett (2) quote the critical composition of 40% Ni/60% Cu for a complete filling of the *d* holes. A number of reports that contradict the RBM (5–7) have since been presented. The majority of studies on the physical and catalytic properties of Ni/Cu bimetallics (2–10) deal with unsupported systems, i.e., films or powders. In some cases, reduction in hydrogen has been shown to generate a copper-rich phase that envelops a nickel-rich phase, i.e., the "cherry model" (6). In the case of highly dispersed alloy particles, some authors (9, 10) have considered the possibility of the formation of single phase microcrystals with unsegregated surfaces and a variety of metallic combinations that do not correspond to bulk alloys. For this reason, Sinfelt (11) has chosen the term "bimetallic clusters" rather than alloys in referring to highly dispersed supported bimetallic systems.

It has been shown by many workers that hydrogen reduction of Zeolite Y exchanged with Ni^{2+} and Cu^{2+} ions results in the formation of an alloy (12–15). The published results suggest that during reduction at temperatures above 690 K some of the Ni^{2+} and Cu^{2+} ions form large metal particles on the outer surface of the zeolite crystals. Total alloy reduction was found to occur on silica at 773 K (16). In addition, calcining prior to reduction resulted in the formation of much larger alloy particles (16) as opposed to the case of zeolites where precalcination yields smaller crystallites (13). The techniques normally employed to characterize monometallic catalysts are also applicable to the study of bimetallic systems. X-ray diffraction (11), H_2 chemisorption (3), and magnetic methods (12–14, 16) have all been used with varying success.

Data for 40 reactions over Ni/Cu alloys have been summarized by Ponec (17). In agreement with the Rigid Band Model, Hall and Emmet (2) observed a marked drop in hydrogenation activity over Ni/Cu films at 40% Ni/60% Cu. By comparison, the retarding effect of copper has also been observed at 70% Ni/30% Cu (18, 19). The catalytic activity of nickel with respect to benzene hydrogenation was found to decrease slowly with increasing copper concentration at temperatures below 373 K (20, 21) and to increase at higher temperatures (20). van Barneveld and Ponec (21) have attributed a positive alloy effect to an inhibition of side reactions. Indeed, copper addition has been found to suppress the rate of benzene hydrogenolysis to methane (22).

Bimetallic zeolites constitute an important chapter in the development of heterogeneous catalysts. There remains, however, much scope for further research. Additional data on the degree of reduction and crystallite sizes of the nickel and copper components supported on NaY and KY will be reported in this paper. The catalytic activity of these bimetallics, which also serves to characterize the system, will be discussed.

2. Experimental

The nickel/copper Y Zeolites were prepared by first exchanging with nickel cations as described previously (23). The dried zeolite was then refluxed with solutions of Cu $(NO_3)_2$, the concentrations of which were determined by assuming an exchange efficiency level of 80%. For copper exchange levels greater than ca. 7 Cu^{2+} per unit cell (U.C.), the exchange procedure was repeated. To prevent hydrolytic Na^+ or K^+ loss or exchange of hydroxylic nickel species, i.e., to ensure stoichiometric exchange, the pH of the nitrate solutions was kept at ca. 6. All the samples were air dried at 373 K for 24 h and stored over saturated NH_4Cl prior to analysis. Thermal analyses were conducted using a Perkin Elmer thermobalance operating in the TG mode to measure water loss and in the DTG mode to measure the rate of change of water loss as a function of temperature; the temperature was scanned at 40 K min^{-1} in the range 294–773 K under a nitrogen purge of 20 cm^3 min^{-1}. Atomic absorption (Ni^{2+} and Cu^{2+} concentrations) and flame emission (Na^+ and K^+ concentrations) techniques, using a Perkin Elmer 360 atomic absorption spectrophotometer, were employed to determine the cation contents.

The percent reduction of Ni^{2+} and (or) Cu^{2+} ions, supported on both

NaY and KY carriers, in flowing hydrogen was measured using a Na^+ back exchange technique. In each case, 3 g of hydrated sample, in pellet form (1.18–1.70 mm diameter), was reduced in a fixed bed catalytic reactor (23), in a 120 cm^3 min^{-1} stream of hydrogen at 723 K for 18 h. After reduction, the samples were stored over saturated NH_4Cl and the water content was determined. The hydrated reduced zeolite (100 mg), in powder form, was immersed in 50 cm^3 of 1 M $NaNO_3$ and the resultant suspension refluxed for 24 h. In this process, the Na^+ ions will be exchanged with the unreduced Ni^{2+} and (or) Cu^{2+} cations. On filtering the solution, the filtrate was made up to 100 cm^3 and analyzed for Ni^{2+} and Cu^{2+} ion concentration by atomic absorption in the 0–5 ppm range. The procedure was also repeated using the unreduced zeolite as a blank. The degree of reduction (α) is then given by:

$$\frac{\text{ppm } TM^{2+} \text{ in unred. sample} - \text{ppm } TM^{2+} \text{ in red. sample}}{\text{ppm } TM^{2+} \text{ in unred. sample}}$$

where TM^{2+} represents the Ni^{2+} or Cu^{2+} transition metal ions. Metal (Ni^{2+} and Cu^{2+}) reduction was also measured by an iodometric titration described elsewhere (23). The latter technique only gives the total level of metal cation reduction and does not differentiate between the individual levels of Ni^{2+} and Cu^{2+} reduction. Nevetheless, the total metal cation reduction levels measured by both Na^+ back exchange and iodometric titrations were in very close agreement (within ±4%). The possibility of a reoxidation of the small metal particles during the Na^+ back exchange process can be ruled out.

Examination of the samples for the presence of nickel and copper crystallites was performed by studying X-ray line broadening (Jeol JDX-85 diffractometer) around the nickel line at a 2θ angle of 52.2° and the copper line at a 2θ of 50.8° under the following conditions: time constant = 4; voltage = 30 kV; current = 20 mA; scan time = 0.5 min^{-1}; counts/s = 8 × 10^2; radiation = CoKα. A correction for instrument broadening under identical conditions was made using Ni and (or) Cu powder in a NaY/KY matrix.

All catalytic reactions were carried out under atmospheric pressure in a fixed bed tubular glass reactor (24, 25) operating in the differential mode at 473 K. The catalysts were pelletized without binder using a pressure of 4000 kg cm^{-1} and sieved in the mesh range 1.18–1.70 mm. Catalyst activation was the same as for the degree of reduction measurements (23, 26). Benzene was fed into the reactor from a precision motor driven syringe at a flow rate of 2.0 cm^3 h^{-1}. Product analysis was carried out using a Pye Unicam GCV chromatograph with a flame ionization detector. Mol% conversion to cyclohexane after 6 h on stream was used as a point of comparison between different catalysts. Full details of the experimental procedure are given elsewhere (24, 25).

Diffraction patterns of all the catalysts, before and after use in catalysis, were obtained to ensure maintenance of sample crystallinity. Infrared spectroscopy in the range 1200–350 cm^{-1} was also used as a check on crystallinity. The band at ca. 395 cm^{-1} has been assigned to a breathing of the pore opening in zeolites (27) and is thus the most sensitive to changes in crystallinity.

3. Results and discussion

The chemical compositions of the CuNiNaY and CuNiKY samples prepared by ion exchange are given in Tables 1 and 2. It may be noted that on back exchange of the Cu^{2+} ions into NiNaY and NiKY some of the Ni^{2+} ions are displaced. Sample crystallinity, monitored by X-ray diffraction and IR techniques, was maintained after the preparation of all the tabulated samples.

The reduction process in a wide range of monometallic (nickel and copper) Y Zeolites has been investigated in these laboratories (23, 26, 28). The degree of reduction of Ni^{2+} cations supported on Y Zeolites has been shown to be strongly dependent on the pretreatment conditions and nickel loading (23). The level of reduction is also dependent on the location of the metal cations within the zeolite lattice (26). The accessible nickel cations were found to be preferentially reduced while the migration of Ni^{2+} ions into the supercage was retarded with progressive reduction. The overall degree of reduction was also shown to be promoted by using lower heating and hydrogen flow rates and inhibited with sample precalcination (23). Most of the

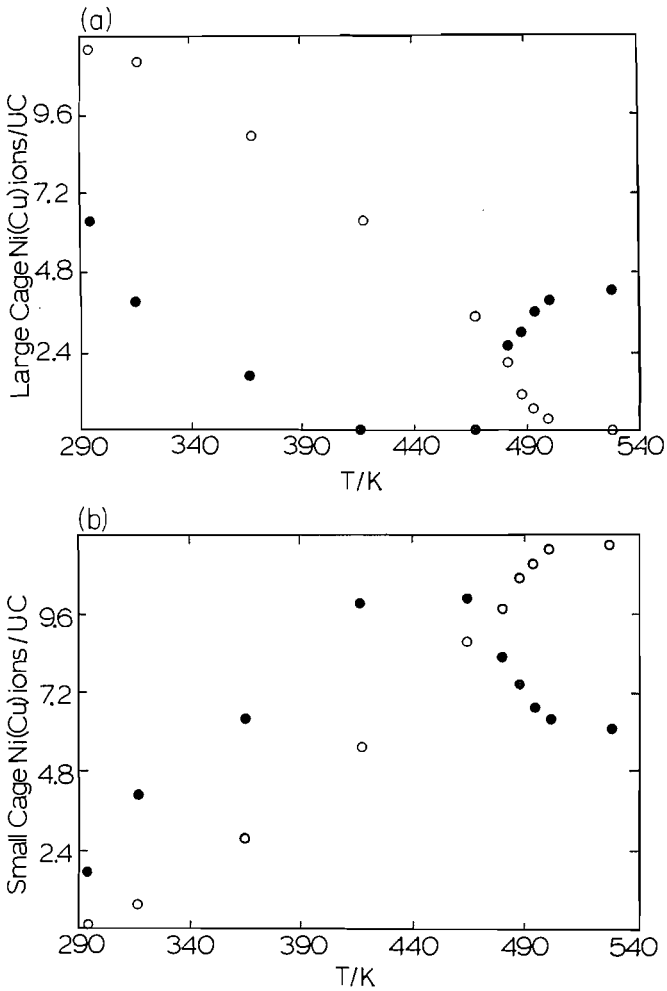

FIG. 1. Variation in the number of (a) large cage and (b) small cage Ni^{2+} (○) and Cu^{2+} (●) cations with increasing temperature on calcining $Cu_{8.0}Ni_{11.8}KY$ in a stream of nitrogen (120 cm^3 min^{-1}).

phenomena encountered with Ni^{2+} reduction are also associated with the Cu^{2+} system (28). However, the greater freedom of the copper ions to migrate into the supercages results in the equilibrium level of reduction being reached sooner than is the case for Ni^{2+} reduction, but the greater acidity associated with the monometallic copper samples ultimately results in an overall lower level of metal reduction.

There have been no published data on the nature of the competitive migration of metal ions in a bimetal exchanged zeolite. By employing a back exchange technique, the location of Ni^{2+} and Cu^{2+} ions in the zeolite lattice during different calcination steps and hence the effect of sample pretreatment on ion location and reduction was probed. In this case, the rehydrated calcined samples were treated with 2 M CsCl to remove any cation species present in the supercage. Because of its size, the Cs^+ ion is restricted from entering the sodalite units or hexagonal prisms. The number of Ni^{2+} and Cu^{2+} cations remaining in the small cages was then determined by atomic absorption. Figure 1 illustrates the migration of Ni^{2+} and Cu^{2+} in a $Cu_{8.0}$ $Ni_{11.8}$ KY sample at elevated temperatures. The Cs^+ back exchange measurements have yielded some very intriguing results. Although the Cu^{2+} ions are preferably admitted into the small cages at lower temperatures (<423 K), at higher temperatures the migrating Ni^{2+} ions exchange out the short-lived $S_I/S_{I'}$ Cu^{2+} (as well as the indigenous K^+ ions) and locate the entire

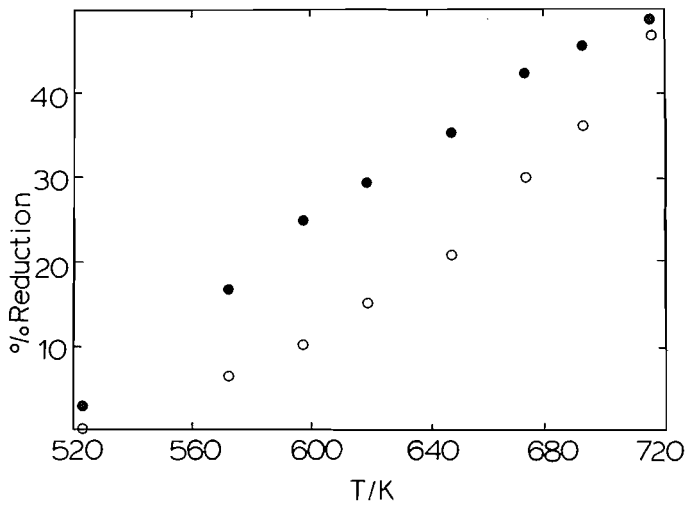

FIG. 2. Variation in the level of reduction (after 18 h) of Ni^{2+} (○) and Cu^{2+} (●) cations supported on $Cu_{7.3}Ni_{6.0}KY$ with increasing reduction temperature.

Ni^{2+} compliment within the small cavities. This reversal in migratory behavior may be explained by a greater relative ease of shedding the cationic water coating exhibited by the Cu^{2+} ions. From the DTG measurements, the Cu^{2+} ions are stripped of their water molecules at a lower temperature (446 K) than the Ni^{2+} ions (456 K) and locate preferentially in the small cages. A reversal in selectivity for the $S_I/S_{I'}$ sites occurs at 423 K. The location of the two metal ions within the zeolite lattice is such as to minimize the free energy of the system. The Ni^{2+} ions, in locating preferentially at the well-shielded S_I sites, lower the overall potential energy of the zeolite system. As a direct consequence, the number of Cu^{2+} ions located in the supercages is greater than that observed for the monometallic samples (28).

Figure 2 follows the variation in degree of metal cation reduction of a CuNiKY sample with reduction temperature. The supported copper ions are preferably reduced at lower temperatures, with Ni^{2+} reduction more evident at temperatures greater than 623 K. Although this is empirically identical to the situation encountered for the monometallic samples (23, 28), the level of reduction of both metal ions is lower. The reduction vs. time curves for the same sample are given in Fig. 3. Both curves are characterized by a gradual attainment of the equilibrium percent reduction value. The reduction behaviour is the same as that observed for the monometallic samples but the time necessary for the equilibrium reduction value to be attained is lower for the single metal component systems (23, 28), i.e., ca. 16 h for the Ni^{2+} exchanged zeolites and ca. 14 h for the Cu^{2+} exchanged zeolites compared with ca. 18 h for the Ni^{2+}/Cu^{2+} exchanged zeolites. The lengthy hydrogen treatment again indicates the involvement of a slow diffusion of hydrogen molecules to the inaccessible metal ions. The presence of Cu^{2+} ions in the open supercages must serve to restrict the passage of hydrogen molecules to the hidden Ni^{2+} ions.

Table 3 serves to show the effects of diluting NiNaY and NiKY samples with Cu^{2+} ions on the level of metal ion reduction. It is clear that the addition of Cu^{2+} suppresses Ni^{2+} reduction, the inhibitory effect increasing as the Ni^{2+}/Cu^{2+} ratio gets smaller. At the same time, the degree of Cu^{2+} reduction increases with copper content. However, the individual degree of reduction of the metal ions is lower than for the monometal samples (26, 28), as is the overall degree of reduction. The potassium based samples, with their lower associated

acidity (29), in accordance with the monometal samples (26, 28), exhibit a higher level of Ni^{2+} and Cu^{2+} reducibility. From the cation location data, the Cu^{2+} cations are displaced into the supercages where they are preferentially reduced (28), generating an acid function that ultimately inhibits reduction, particularly of the Ni^{2+} cations. Increasing the copper ion concentration promotes this effect with an overall lowering of Ni^{2+} reducibility.

To address further the role of acidity in inhibiting the reduction process, it was decided to investigate the effect of neutralizing the acidic centres by the adsorption of a base, NH_3, which, because of its small size may diffuse into the pore structure and "poison" the small cage Bronsted acid sites. The ammonia was adsorbed at 323 K by passing a stream of the gas at a flow rate of 120 cm^3 min^{-1} over the prereduced sample for a period of 15 min, which was sufficient to allow the temperature of the zeolite bed to fall back to 423 K after the initial temperature rise due to the heat of adsorption. Hydrogen was then reintroduced and the sample was flushed for 6 h at 423 K and treated for a further 24 h in a 120 cm^3 min^{-1} flow. Treating the samples with NH_3 has resulted in a marked increase in the overall degree of reduction; both metal cations exhibit higher levels of reduction over the untreated samples, Cu^{2+} ions in particular (Table 3). Nevertheless, the reduction of divalent nickel in the bimetallic sample is again less than that determined for the NiNaY and NiKY samples (26, 28). By analogy with electrochemistry, where the reducibility of metal ions is effectively measured by electrode potentials ($Ni^{2+}/Ni = -0.25$ V; $Cu^{2+}/Cu = +0.34$ V), it is to be expected that when the added complication of acidity is removed the Cu^{2+} ions are preferably reduced.

[a]Crystallites were undetected by X-ray diffraction.

The state of the two metals in bimetallic zeolites has been poorly characterized. The majority of studies have been concerned with obtaining evidence of interaction between the atoms of the two metallic components. The metal phases generated were characterized by X-ray line broadening using the Scherrer formula:

$$d = K\lambda/\beta \cos\theta$$

which relates the mean particle diameter (d) to the X-ray broadening (β) of the diffraction lines. In accordance with the work of Jenkins and deVries (30), a value of 0.9 was chosen for K. The lower limit of detection for this method is ca. 5 nm, with the result that it gives no information on the state of metal in the internal pore structure. X-ray line broadening is therefore diagnostic of the presence of nickel and (or) copper metal located on the external surface. It was observed that the peaks due to nickel ($2\theta = 52.2°$) and copper ($2\theta = 51.5°$) metal in the monometallic samples were shifted closer together (Ni^0: $2\theta = 52.0°$; Cu^0: $2\theta = 51.5°$) in the bimetallic samples. This observa-

tion suggests that there is an interaction between Ni^0 and Cu^0 generating two phases of an alloy: a nickel-rich phase corresponding to $2\theta = 52.0°$ and copper-rich phase at $2\theta = 51.5°$. From the data presented in Table 4, it can be deduced that reduction at 723 K results in nickel and copper phases on the external zeolite surface. It may be noted that as the level of copper exchange is increased, copper particle growth is promoted whereas the nickel phase is in the form of much smaller crystallites. This is in agreement with the conclusion of a number of workers (13, 14) that, in the bimetal zeolite, the higher reduction temperatures facilitate the diffusion of the more volatile copper component. In this study, the formation of larger copper crystallites is also the result of the increased level of Cu^{2+} reduction with copper exchange. As expected, the crystallite size of both metal components was increased with NH_3 treatment. In addition, the introduction of a precalcination step was observed to inhibit particle growth.

The catalytic hydrogenation of benzene over nickel Y Zeolites has been well characterized in a number of reports from these laboratories (24, 25, 31). The reaction conditions used in this study have already been successfully employed for comparing the catalytic activities of different nickel catalysts (25, 31). Under these conditions, cyclohexane is the primary product with trace amounts of methylcyclopentane isolated in the product mixture. The metal function promotes the hydrogenation reaction whereas skeletal isomerization occurs at the acid sites (31). Surface acidity has been shown to promote methylcyclopentane and ultimately coke formation (31). A knowledge of the nature of the metal surface is an essential prerequisite for a proper understanding of catalytic activity. In particular, the degree of cation reduction and the resultant dispersion of the active metal will have a direct influence on catalytic behaviour. Monometallic CuY Zeolites were catalytically inactive towards benzene hydrogenation at reaction temperatures up to 473 K. Nevertheless, the levels of benzene conversion over the supported nickel metal decreased markedly with increasing copper concentration, Table 5. This would seem to vindicate the theoretical approach that interprets catalytic action in terms of the chemical properties of nickel metal and regards the copper phase merely as a diluent. Such an approach predicts a simple type of additive behaviour. The inhibiting effect may be rationalized in terms of the lower degree of Ni^{2+} reduction in the Ni/Cu exchanged zeolites, which was increased with NH_3 treatment and is reflected by higher benzene conversions, Table 5. It should be noted that the less acidic potassium-based catalysts generated higher levels of cyclohexane.

TABLE 6. Effect of the Cu^{2+} exchange of NiNaY and NiKY on the level of coke formation; $W/F = 134.1$ g mol^{-1} h, $T = 473$ K

Zeolite sample	Ni^{2+}/Cu^{2+}	% Residual carbon

Hydrogenation activity has been shown to decrease with time on stream as a result of the generation of occluded polynuclear aromatic molecules, which restrict access to the intracrystalline metal sites (24, 31). To test if coke deposition was operative in this study, the residual carbon contents of a number of spent catalysts were measured and the results are presented in Table 6. The extent of coking was lowered upon copper addition to the nickel zeolites as evidenced by the lower residual carbon contents of the spent catalysts. The presence of copper metal must therefore serve to suppress the side reactions that initiate coke formation (24, 31). Moreover, only trace amounts of methylcyclopentane were generated during catalysis over the bimetallic zeolites. The incorporation of copper into nickel zeolites may also modify the adsorption and activity of any reaction intermediates. In fact the inhibition of coke formation with copper exchange has actually resulted in an increase in cyclohexane formation over the more acidic nickel-rich NaY samples, *i.e.*, CuNiNaY-71.52 and CuNiNaY-75.62, as shown in Table 5.

4. Conclusions

The interaction between Ni^{2+} and Cu^{2+} ions during calcination and reduction was investigated. Although Cu^{2+} ions are preferably admitted into the small cages at lower temperatures (<473 K), the migrating Ni^{2+} ions exchange out these small cage Cu^{2+} ions at higher temperatures. In the absence of zeolite acidity the Cu^{2+} ions are preferably reduced and the resultant copper metal phase is in the form of larger metal crystallites. In the scope of this study, Ni^0/Cu^0 alloy formation was not observed. Nevertheless, some bimetallic interplay does occur as a result of an intimate emplacement of the metals, which lowers the hydrogenation activity of the nickel component.

Electronic effects of heterocyclic substituents. Spectroscopical and theoretical (AM1) study in a series of heterocyclic carboxaldehydes

C. CATIVIELA[1] AND J. I. GARCIA

Instituto de Ciencia de Materiales de Aragón, Departamento de Química Orgánica y Química Física, Universidad de Zaragoza-C.S.I.C., 50009 Zaragoza, Spain

Received January 10, 1990

C. CATIVIELA and J. I. GARCIA. Can. J. Chem. **68**, 1477 (1990).

The electronic effects of a series of 18 heterocyclic carboxaldehydes (furans, thiophenes, pyrroles, and pyridines) have been studied by means of the correlation existing between ^{13}C chemical shifts of the carbonylic carbon and calculated total and π charges (AM1). The implications of this theoretical model to explain polar and resonance contributions to the total electronic effect are discussed.

Key words: heterocyclic substituents, electronic effects, ^{13}C NMR, DSP models.

C. CATIVIELA et J. I. GARCIA. Can. J. Chem. **68**, 1477 (1990).

Les effets électroniques d'une série de 18 aldéhydes hétérocycliques ont été etudiés à partir de la corrélation établie entre les déplacements chimiques du carbone carbonylique en RMN du ^{13}C et les charges, totales et π, calculées avec la méthode AM1. On discute de l'utilisation possible d'un modèle de ce type pour expliquer les contributions polaires et résonantes à l'effet électronique total.

Mots clés : substituants hétérocycliques, effets électroniques, RMN du ^{13}C, modèles biparamétriques.

[Traduit par la revue]

Introduction

The use of different parameters to describe the effects of substituents on a molecule has been of increasing interest in recent years, especially in Structure–Properties Relationship (SPR) methodology (1). Nevertheless, there are no systematic studies with regard to the use of such parameters when the substituent is a heterocyclic group. We previously reported (2, 3) the hypothesis that structural characteristics in an additive model could be used to describe heterocyclic substituents. Using a different approach, we now want to report our first results in determining the electronic effect of heterocyclic substituents by means of ^{13}C NMR spectroscopy.

The quantitative determination of the magnitude of the electronic effects of substituents has up to now been based on measuring their influence on reaction rates or the position of chemical equilibria. Over the last years, however, the effects of substituents on ^{13}C NMR chemical shifts have been increasingly used for this purpose. It has become evident that in suitable systems the influence of substituents on these shifts is predominantly a consequence of their polar and resonance effects. The most widely used systems for this study have been the shifts of the *para* ring carbons in benzenes (4) and of the side-chain carbons of ring-substituted styrenes (5, 6). Considerably less attention has been paid to the aromatic carbonyl compounds, although the understanding of the ways in which substituents modify the electronic environment of this site is of great interest because of the importance of this group in organic chemistry. Only very recently, an extensive work of Budesinsky and Exner (7) that deals with a series of substituted methyl benzoates has been published. Consequently, we have chosen to deal with a series of 18 heterocyclic carboxaldehydes as suitable models for determining the electronic influence of the corresponding heterocyclic fragments on the formyl moiety (Fig. 1).

Results and discussion

Formyl ^{13}C NMR chemical shifts of heterocyclic carboxaldehydes **1–18** relative to benzaldehyde (**19**) are collected in

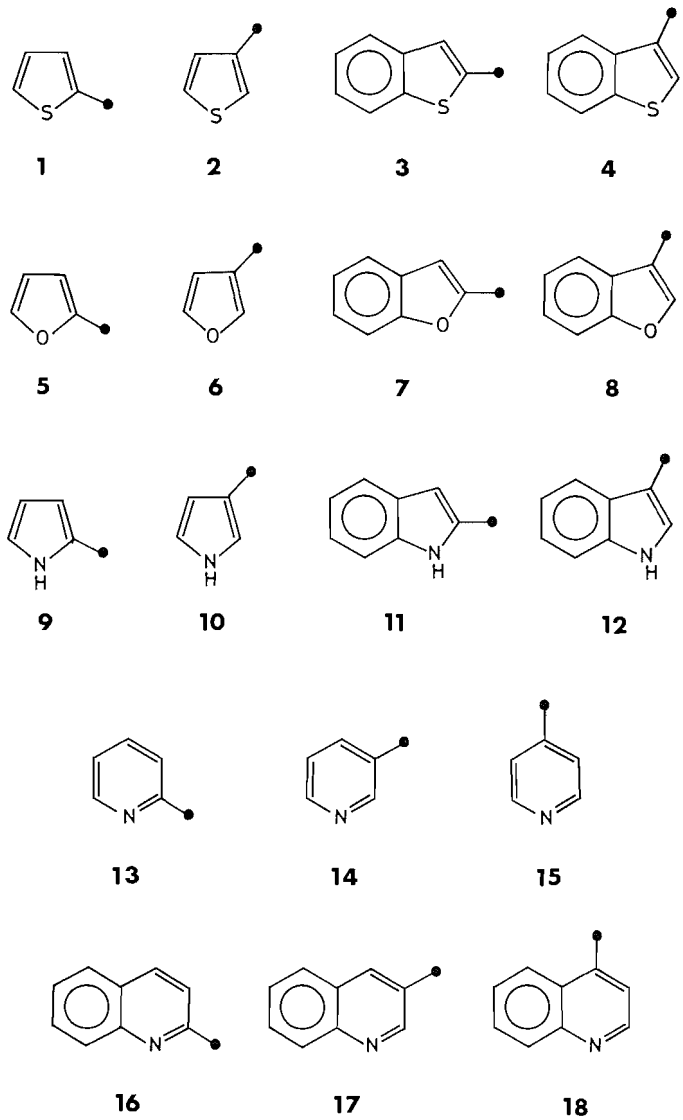

FIG. 1. Heterocyclic substituents included in the present study.

Table 1. As can be seen, chemical shifts cover a range of ca. 16 ppm, which seems to be broad enough to monitor substituent-induced changes. In substituted benzaldehydes and methyl benzoates, for instance, Substituent-induced Changes in chemical Shifts (SCS) cover a range of only ca. 3 ppm.

At first sight (Table 1), the great importance of the heteroatom in the heterocyclic ring appears evident. Thus, the whole range of 16 ppm is covered by compounds that are substituted at position 2, whereas 3- and 4-substituted compounds only cover about half of this range, ca. 8 ppm. Furans and pyrroles (**5–12**) show the most marked differences in shielding when comparing positions 2 and 3. Thiophenes and pyridines (**1–4, 13–18**) show comparatively fewer important differences in this respect.

As far as the heterocyclic families are concerned, five-membered heterocycles (**1–12**) show upfield shifts with respect to benzaldehyde (negative values of Δδ) that are in good accordance with the π-excessiveness of this type of heterocycle, and hence with the electron-donating character that is generally attributed to them.

On the other hand, six-membered heterocycles show downfield shifts (positive values of Δδ) in the case of 2- and 4-substitution (**13, 15, 16, 18**), whereas 3-substituted pyridine and quinoline carboxaldehydes (**14, 17**) show negative values of Δδ. These results are also in accordance with the π-deficient character of pyridines, which leads to an electron-withdrawing character at positions 2 and 4. Position 3 does not show the same effect because of the lack of resonance between the probe site and the heteroatom.

In any case, Δδ values of pyridines are, in absolute terms, much less important than those of the corresponding π-excessive heterocycles. This is undoubtedly due to the electron-withdrawing character of the probe site itself. This character of the formyl group leads to strong positive interactions with electron-donating substituents (such as π-excessive heterocycles) and to competitive interactions with electron-withdrawing substituents, such as pyridines, which diminish the overall SCS. These interactions, probe site – substituent, have already been described for analogous systems with similar effects on chemical reactivity (8).

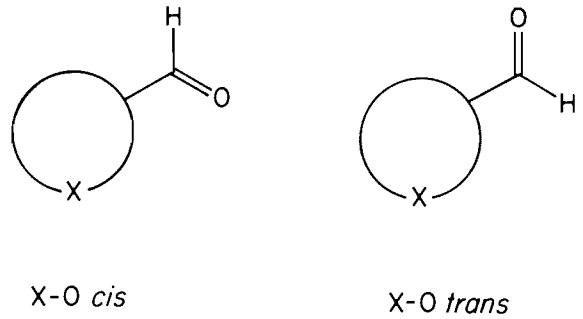

FIG. 2. X–O *cis* and X–O *trans* arrangements of the formyl group with respect to the heteroatom of the heterocyclic substituent.

As a consequence, the ^{13}C NMR chemical shift in these systems is a useful probe for electron-donating substituents, whereas it is less useful for electron-accepting substituents.

The ordering of electron-donating ability for the heterocyclic families studied is the following: furans > pyrroles > thiophenes > pyridines. However, the true dependence between the electronic character and the chemical shifts observed seems to be a complex relationship involving the type of heteroatom and the substitution position of the heterocyclic ring. To study this relationship in depth, theoretical calculations have been performed with the whole set of these structures.

Experimental chemical shifts have been frequently related to calculated changes in electron densities. The theoretical justification for investigating such a relationship arises from a consideration of terms related to the nuclear screening constant. It is generally accepted that for carbon chemical shifts, the paramagnetic constant governs the total shielding (5, 9). Using a number of assumptions, it is possible to represent this term by means of the well-known Karplus–Pople equation (10):

$$[1]\quad \sigma^{A}_{para} = \frac{-e^2\hbar^2}{2m^2c^2\,\Delta E}\langle r^{-3}\rangle_{2p}\left(\sum_{A} Q_A + \sum_{B\neq A} Q_B\right)$$

Although the Karplus–Pople equation provides a relatively solid theoretical framework for investigating the origin of chemical shifts, the correlations between these magnitudes and calculated charges are generally approached from an empirical perspective, because of the difficulty of dealing with the average excitation energy (AEE) term, ΔE. In our case, we have chosen the empirical approach, assuming the chemical similarity of the whole set of heterocyclic carboxaldehydes.

For this purpose, AM1 (11) formalism has been employed throughout the work. Bond lengths and valency angles have been fully optimized in all cases. Structures were kept planar to save computer time, and the two possible arrangements of the formyl group, X–O *cis* and X–O *trans* (Fig. 2), have been considered. Some calculations with full geometrical optimization were performed, however, to test the reliability of AM1 results. The formyl group remained planar in all cases, in agreement with experimental gas phase and *ab initio* studies (12, 13). This result proves the actual improvement of AM1 over the MNDO (14) method in representing rotation around single bonds in conjugated systems.

Conformational preferences calculated by AM1 also agree well with the available experimental gas phase and *ab initio* studies in all but one case, namely, that of thiphene-2-carboxaldehyde (**1**). AM1 gives the S–O *trans* conformation as 4.8 kJ mol^{-1} more stable than the corresponding S–O *cis* conformation, whereas *ab initio* 3-21G//3-21G calculations (13) give the converse preference with a difference in stability of 2.8 kJ

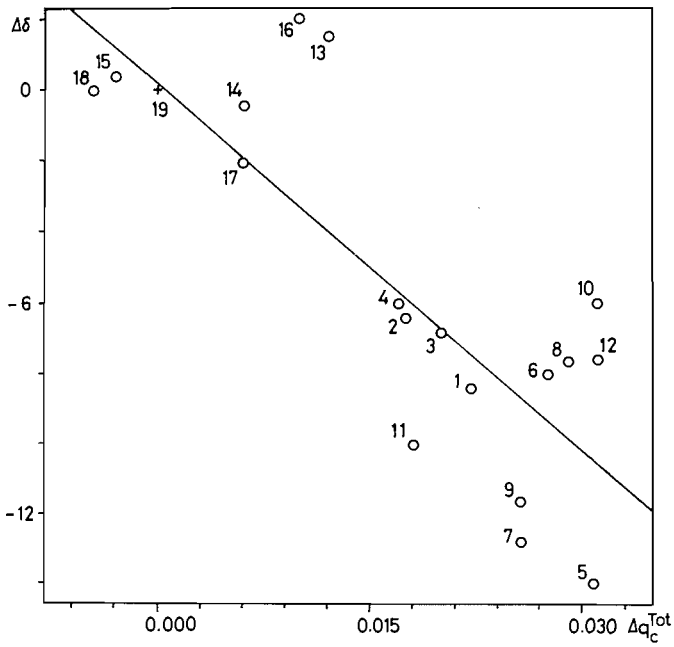

FIG. 3. Plot of Δq_C^{Tot} vs. $\Delta\delta$ (values relative to benzaldehyde, +).

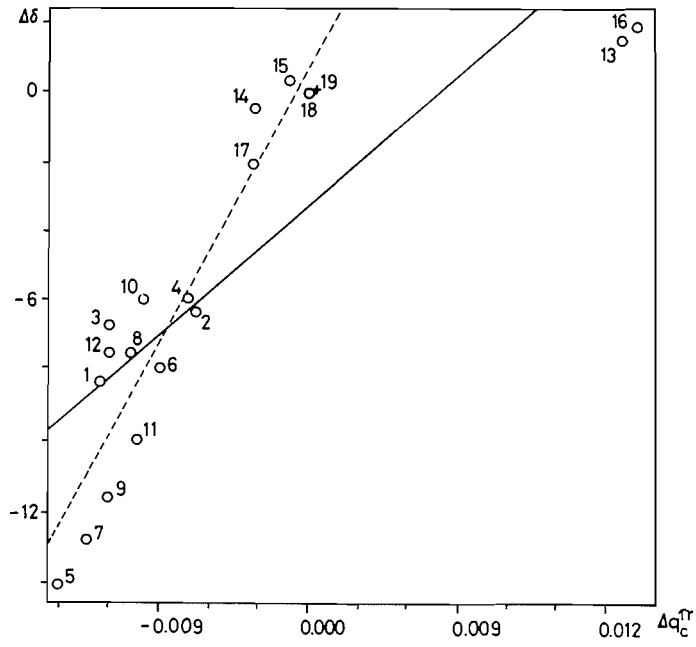

FIG. 4. Plot of Δq_C^{π} vs. $\Delta\delta$ (values relative to benzaldehyde, +). The dashed line corresponds to the regression line excluding compounds **13** and **16**.

mol^{-1}. This result, which can be logically extended to the corresponding benzo[*b*] derivative **3**, can be accounted for by the overestimation of lone pair – lone pair repulsions that have already been noticed with the AM1 method (15).

Because of this overestimation, charge distribution is comparatively less reliable for these compounds. C—O bond polarity in **1**, for instance, is calculated to be higher in the S–O *trans* conformation, whereas the converse tendency is found in *ab initio* STO-3G//STO-3G calculations (13). We have consequently decided to use the values corresponding to AM1 minima (even for compounds **1** and **3**) in order to be consistent with the method throughout the work.

Table 1 collects some of the results of AM1 calculations: total (q_C^{Tot}) and π (q_C^{π}) atomic charge density on the carbonylic carbon as established by Mulliken Population Analysis, and differences of atomic charge density relative to benzaldehyde (Δq_C^{Tot}, Δq_C^{π}).

Figure 3 plots the Δq_C^{Tot} values versus the corresponding $\Delta\delta$ ones. The slope is −343.8 ppm/electron, corresponding to the following regression line:

[2] $\Delta\delta = 0.3 - 343.8\ (\pm 128.1)\ \Delta q_C^{Tot}$

$r = 0.809,\ s = 3.0,\ n = 19,\ F_{1,17} = 32.09\ (p < 0.001)$

Although the model is highly significant from a statistical point of view, indicating that substituent-induced chemical shifts are systematic and electronic in origin, the standard error, *s*, is very large, which gives rise to a considerable scatter around the regression line. Moreover, total atomic charges do not predict the correct direction of chemical shifts. Electron-donating substituents, such as furans or pyrroles, are associated with an increased positive total atomic charge at the carbonyl carbon, i.e., a decreased electronic population at this site, whereas they induce upfield chemical shifts. This type of trend, which is contrary to chemical intuition, has already been noticed for other carbonyl compounds (5, 16), and it is generally explained by the strong relationship existing between changes in σ, π, and total atomic charges (5, 17).

This apparent contradiction vanishes, however, when considering only π charges. Figure 4 plots the corresponding Δq_C^{π} values versus $\Delta\delta$, giving a slope of 420.8 ppm/electron, in the right direction. This plot corresponds to the regression line:

[3] $\Delta\delta = -3.3 + 420.8\ (\pm 144.3)\ \Delta q_C^{\pi}$

$r = 0.831,\ s = 2.9,\ n = 19,\ F_{1,17} = 37.83\ (p < 0.001)$

If we examine the plot, it appears evident that 2-pyridine and 2-quinoline carboxaldehydes (**13, 16**) are placed at a considerable distance from the rest of the compounds. By discarding these two compounds, the remaining 17 carboxaldehydes fit the following regression line, the dashed line in Fig. 4:

[4] $\Delta\delta = 0.8 + 867.9\ (\pm 177.4)\ \Delta q_C^{\pi}$

$r = 0.937,\ s = 1.6,\ n = 17,\ F_{1,15} = 108.75\ (p < 0.001)$

As can be seen, not only does the statistical quality of the model improve, but the intercept approaches zero, as expected, and its value is within the standard error of the model (1.6 ppm). This fact confirms that compounds **13** and **16** are outliers in the regression sense. Two main explanations for this result are possible.

Firstly, the previously mentioned overestimation of lone-pair repulsions, which are known to be important in 2-substituted pyridines, could account for the observed deviation. So, whereas the $\Delta\delta$ values are shifted downfield by about 2 ppm with respect to 4-pyridine and 4-quinoline carboxaldehydes (**15, 18**), the difference in electron density is as large as 0.0200 electrons, which corresponds to a difference of 17.4 ppm, following the model. This difference in electron density is by far the most important noticed in all the families of compounds.

On the other hand, the breakdown in the regression line could be explained by the competitive interaction between two electron-withdrawing groups, such as 2-pyridine (or quinoline) and the formyl group. This phenomenon has been described, for instance, in the case of gas phase acidities of substituted benzaldehydes (8). Electron-donating substituents have a precise linear relationship when using the corresponding σ_R

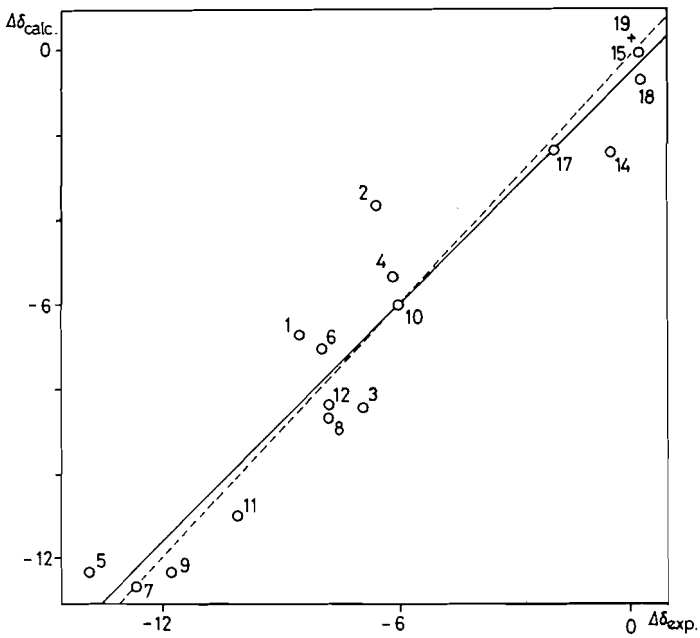

FIG. 5. Plot of experimental vs. calculated values of Δδ (values relative to benzaldehyde, +) corresponding to the DSP model, eq. [5]. The dashed line represents the bisectrix line.

values, whereas electron-withdrawing substituents lead to a breakdown of the regression line, with a slope of zero with respect to σ_R values.

As these two explanations are not mutually exclusive, it is very difficult to attribute the extent to which each contributes to the observed deviation. Further experimental and (or) theoretical work seems necessary in order to solve this question.

Returning to eq. [4], it is possible to verify that this model explains about 88% of the observed variation in chemical shifts. This means that the electron-donating or -accepting ability of heterocyclic substituents, quantified by means of their ^{13}C NMR chemical shifts, is fundamentally due to changes in π-electron density induced by the heterocycle on the probe site. The probe site used in the present work, the formyl group, appears to be quite sensitive to these electronic changes, as the high value of the slope, 867.9 ppm/electron, indicates.

The π-electron density changes can be ideally separated into polar and resonance contributions. Some authors have claimed (12) that resonance effects are more important at position 2 than they are at position 3 in the case of furans, pyrroles, and pyridines. This difference may explain why the observed SCS are more important at position 2 in these families of compounds. Equation [4] also shows the same trend except for compounds **11** and **12**. Indole-3-carboxaldehyde (**12**) is predicted to have an upfield chemical shift with respect to indole-2-carboxaldehyde (**11**). AM1 calculations did in fact show that the resonance is more important in compound **12** than in compound **11**. The π-bond order between the carbonylic carbon and the heterocyclic carbon linked to it is, for instance, 0.2493 for compound **12** and only 0.2289 for compound **11**. This result is in accordance with the known chemical reactivity of compound **12** (18).

We feel that two main conclusions can be extracted from this point of the discussion. On the one hand, the Δq_C^{π} values calculated by AM1 are fundamentally dominated by resonance contributions. On the other hand, polar contributions, which must always be more important on position 2, would explain the great difference between positions 2 and 3 as well as the anomalous result obtained for compounds **11** and **12** when eq. [4] is applied.

The separation of polar and resonance effects, either experimentally or theoretically, is a formidable task, which has only been partially achieved for the more simple substituents. It is clear, however, that any serious attempt to understand the electronic effects of heterocyclic substituents should deal with this matter.

In a preliminary attempt to evaluate these contributions from a theoretical point of view, we have calculated the 19 structures of the carboxaldehydes with the formyl group perpendicular to the aromatic ring. In this manner, changes in atomic charges can be fundamentally attributed to polar effects. Several Dual Substituent Parameter (DSP) models, based on quantum mechanics indices, have been tested, the best fit being obtained with the following equation:

$$[5]\quad \Delta\delta = 0.5 - 193.9\ (\pm 33.8)\ \Delta P_{CO}^{Tot} - 395.1\ (\pm 78.1)\ \Delta q_O^{90}$$

$$r = 0.965,\ s = 1.3,\ n = 17,\ F_{2,14} = 94.14\ (p < 0.001)$$

Where ΔP_{CO}^{Tot} represents the polarity of the C—O bond in planar structures (defined as the difference between the atomic charges of the carbon and the oxygen atoms), relative to benzaldehyde, mainly attributed to resonance contributions, and Δq_O^{90} is the atomic charge of the carbonylic oxygen, relative to benzaldehyde, when the formyl group is perpendicular to the aromatic ring, and therefore mainly attributed to polar contributions. Figure 5 plots experimental versus calculated Δδ values corresponding to eq. [5]. As can be seen, experimental trends for compounds **11** and **12** are now reproduced by the model.

Although we feel that this and similar results should be taken with extreme caution, the interest in modelling electronic effects in heterocyclic systems undoubtedly requires a more extensive experimental and theoretical effort in this direction, which will be the subject of future work.

Conclusions

Theoretical and experimental work leading to a better knowledge of the electronic effects of heterocyclic substituents and their transmission mechanisms is of prime importance for incorporating this class of molecular fragments into Structure–Properties Relationship studies. We have shown that ^{13}C NMR chemical shifts of the side chain of aromatic heterocyclic systems can be an excellent tool for monitoring the electronic effects of this type of substituent with respect to the classical benzene systems, taking the phenyl group as reference. Theoretical calculations have shown that the SCS are electronic in origin, and mainly due to changes in the π-electron distribution on the probe site. This change in π-electron density could be tentatively attributed to resonance effects, but some preliminary studies, as well as some discrepancies in experimental results, indicate that polar effects may play a part. We suggest that further experimental and theoretical work is necessary to determine precisely the part played by polar and resonance effects in this family of compounds.

Experimental

Heterocyclic carboxaldehydes **1, 2, 5, 9, 12–15, 17**, and **18** are commercial and were used as purchased. The remaining aldehydes **3, 4, 6–8, 10, 11**, and **16** were prepared following previously described procedures, and purified to obtain analytically pure samples.

^{13}C NMR spectra were recorded at room temperature on a Bruker

For personal use only.

WP 80 SY spectrophotometer using $CDCl_3$ as solvent in all but the case of compound **12**, which presents a weak solubility in this solvent. To obtain comparable chemical shifts, several spectra were recorded in mixtures of DMSO-d_6 and $CDCl_3$, and the corresponding δ value was extrapolated to pure $CDCl_3$.

Theoretical calculations were performed using the AMPAC (19) package of quantum mechanical programs, running on a DEC-VAX 8300 computer under the VMS operating system.

Received December 22, 1989

STEFAN STOYANOV, IVAN PETKOV, LIUDMIL ANTONOV, TATYANA STOYANOVA, PETROS KARAGIANNIDIS, and PARASKEVAS ASLANIDIS. Can. J. Chem. **68**, 1482 (1990).

The possible thione–thiol tautomerism of 2- and 4-mercaptopyridines, 2-mercaptopyrimidine, and 4,6-dimethyl-2-mercaptopyrimidine in solution is studied by means of absorption (UV–VIS) spectroscopy. In accordance with earlier observations, polar solvents and self-association shift the apparent tautomeric equilibrium significantly towards the thione form. In dilute solutions of nonpolar solvents the thiol form predominates. On standing, significant changes are observed in the absorption spectra of these tautomeric compounds in ethanol, dioxane, and water. The time course of the tautomerization, followed spectrophotometrically, reveals quantitative transformation of the thiol form to the corresponding symmetrical disulfides. The influence of concentration, temperature, and irradiation with indirect sunlight are discussed. This thione–disulfide process is reversible in water, starting either from the tautomeric thione or from its symmetrical disulfide, implying a possible importance in biological systems.

Key words: thione–thiol tautomerism, absorption spectra, thiol–disulfide oxidation, mercaptopyridines and pyrimidines.

STEFAN STOYANOV, IVAN PETKOV, LIUDMIL ANTONOV, TATYANA STOYANOVA, PETROS KARAGIANNIDIS et PARASKEVAS ASLANIDIS. Can. J. Chem. **68**, 1482 (1990).

Faisant appel à la spectroscopie d'absorption UV–VIS, on a étudié les possibilités de tautomérie dans les 2- et 4-mercaptopyridines, la 2-mercaptopyrimidine et la 4,6-diméthyl-2-mercaptopyrimidine en solution. Comme on l'avait observé antérieurement, l'utilisation de solvants polaires et l'auto-association déplacent fortement l'équilibre tautomère apparent vers la forme thione. Si on laisse reposer des solutions de ces composés dans l'éthanol, le dioxane et l'eau, on observe des changements importants dans les spectres d'absorption. Lorsqu'on détermine d'une façon spectrophotométrique la tautomérisation en fonction du temps, on note qu'il se produit une transformation quantitative de la forme thiol en disulfures symétriques correspondants. On discute de l'influence de la concentration, de la température et de l'irradiation par de la lumière solaire indirecte. Dans l'eau, ce processus thione–disulfure est réversible en partant soit de la thione tautomère ou de son disulfure symétrique; ce résultat indique qu'il pourrait avoir une certaine importance dans les systèmes biologiques.

Mots clés : tautomérie thione–thiol, spectre d'absorption, oxydation thiol–disulfure, mercaptopyridines et pyrimidines.

Introduction

It is well known that organic molecules bearing a mobile H atom undergo rapid and facile tautomeric transformations. Pyridines and pyrimidines substituted with an SH or an OH group at the 2 or 4 positions are fundamentally tautomeric heterocyclic systems and many theoretical and experimental studies have been reported (1–9). It is generally accepted that in solution both pyridine and pyrimidine substituted at the 2 or 4 position by potentially tautomeric groups XH (X = O or S) exist in lactam or thione forms rather than in lactim or thiol forms (Scheme 1).

X-ray crystallography (10, 11) revealed that 2-mercaptopyridine–pyridine-2-thione (**1**⇄**3**) exist as H-bonded dimers of **3** in the solid state. However, Beak *et al.* (8), on the basis of the UV spectra of 2- and 4-thiosubstituted pyridines in the gas phase, suggested that mercapto forms **1** and **5** are dominant in vapour. This was also confirmed from photoelectron spectroscopy (12). To approach the vapour phase environment, Beak *et al.* (8, 13–15) used dilute solutions in nonpolar solvents and concluded that the effect of self-association in **1**⇄**3** can significantly shift the apparent tautomeric equilibrium in solution. On the other hand, thiols are considered to be the most active groups found in cells and they are easily oxidized to the rather more stable disulfides, which can be reduced easily and completely back to thiols (16). It may be expected that resistance to oxidation of possible thiol forms to the corresponding disulfides **17**–**20** will influence this tautomeric thione–thiol equilibrium.

Thus the aim of this study is to investigate in detail some factors, including the nature of the solvent, stability, temperature, and concentration, that may influence this equilibrium.

Results and discussion

The absorption spectra of **1**⇄**3** in cyclohexane (Fig. 1) at different concentrations confirm the earlier observations (13, 15) that self-association can significantly shift the apparent tautomeric equilibrium in solution. Using the changing ratio in optical densities at λ_{max} of bands assigned to the thione and thiol chromophores as a function of concentration (13–15, 17), it is possible to evaluate the equilibrium constant of association (K_{assoc}), which is $(8.6 \pm 0.7) \times 10^4$ L mol^{-1}, i.e., an order of magnitude less than the value reported by Beak *et al.* (13).

Additional evidence for the existence of self-association is presented in Fig. 2, where the absorption spectra **1**⇄**3** in cyclohexane at different temperatures are presented. Evidently the monomer–dimer equilibrium is shifted towards the monomer thiol form **1** when the stable dimers of **3** are broken up by heating or dilution. The change in K_{assoc} for **1**⇄**3** in cyclohexane as a function of temperature allows calculation of the thermodynamic parameters ΔG^0_{assoc} (293 K) = −27.6 kJ mol^{-1}, $\Delta H^0_{assoc} = -49.6 \pm 2.5$ kJ mol^{-1}, and $\Delta S^0_{assoc} = -18.2 \pm 2.0$

eu, confirming earlier suggestions that **3** is somewhat less associated than its oxygen analog (15, 18, 19). The absorption spectra of **13**⇄**15** in water and ethanol exhibit spectral features of the thione form **15**, whereas in cyclohexane tautomeric equilibrium is shifted almost completely towards the thiol form **13**. Further evidence for the existence of thiol form **13** could be obtained by measuring the absorption spectra, in different volume ratios of dichloromethane and cyclohexane, of **13**⇄**15**. Because the thione form **15** is dominant in CH_2Cl_2, addition of cyclohexane shifts the tautomeric equilibrium towards the thiol form **13**. The opposite is observed when CH_2Cl_2 is added to the solution of **13**⇄**15** in cyclohexane. Obviously the nature of the solvent significantly shifts the apparent tautomeric equilibrium between isomers. Thus the solvent that is able to participate in

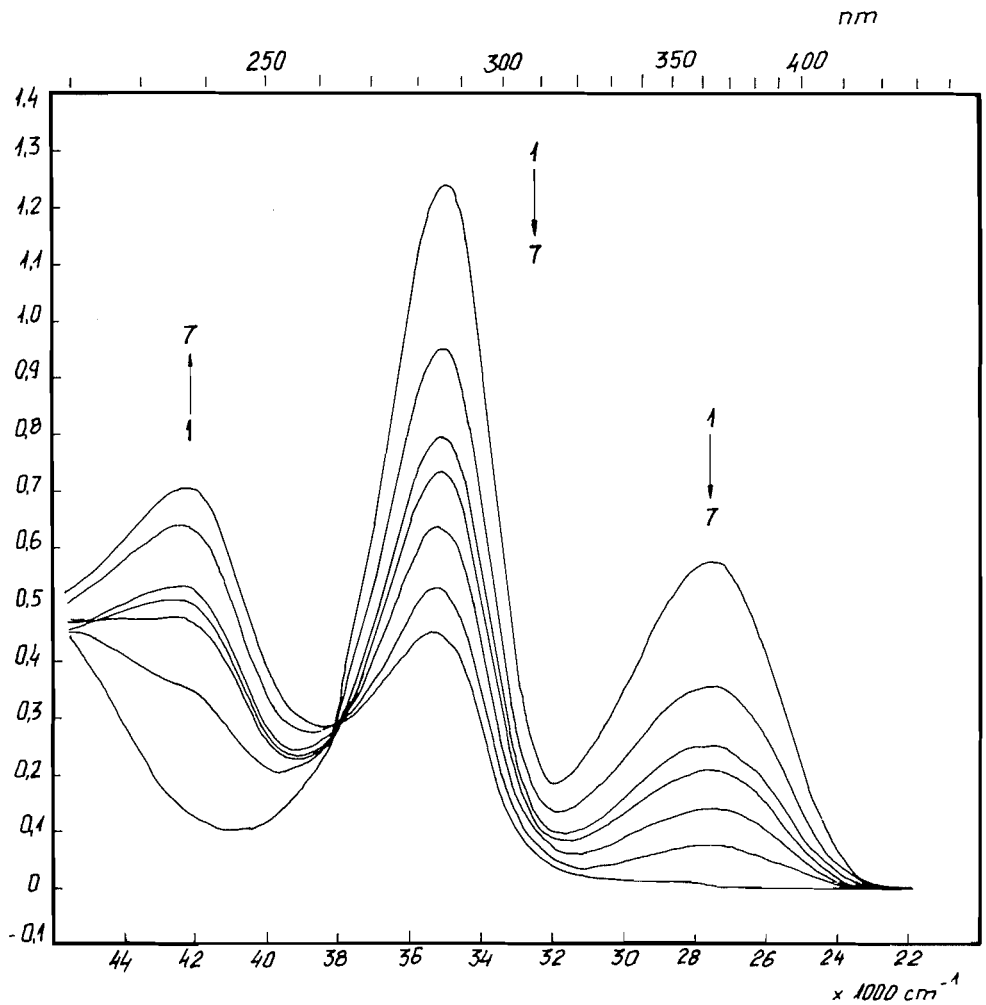

FIG. 3. Absorption spectra of **1**⇄**3** in ethanol, l = 2 cm, $c = 9.73 \times 10^{-5}$ M, in dark, recorded with time: 1, initial solution: 2, after–71 h; 3, 136 h; 4, 164 h; 5, 210 h; 6, 329 h; 7, 486 h.

hydrogen bonding, that can compete with the self-association and also participate in differential solvation of different dipoles of the associated and unassociated species, is responsible for such a shift (15, 17). Therefore, on dilution in dichloroethane, **1**⇄**3** and **9**⇄**11** reveal an apparent shift of tautomeric equilibrium towards the thiol forms **1** and **9**, while addition of ethanol, keeping the total concentration constant, leads back to formation of the thione forms **3** and **11**.

Qualitatively these observations are in accordance with the effect of self-association favoring the thione tautomer, the well-known rule that a more polar thione tautomer is preferentially stabilized in the more polar solvents, and with the proton donating ability of ethanol, which favors the thione form (1, 8, 14, 17, 20). Indeed in ethanol and water the tautomeric equilibrium is shifted almost exclusively towards the thione forms **3**, **7**, **11**, and **15**. Such large differences for tautomeric equilibria in nonpolar solvents and alcoholic or aqueous solution should not be regarded as surprising, since at dilution of $\leq 10^{-5}$ M in nonpolar solvents the position of the equilibrium might be expected to be close to that in the gas phase.

During the course of spectral studies in ethanol and water it was noticed that the absorption spectra of these tautomeric compounds reveal significant changes on standing at ambient laboratory conditions in the dark or in indirect sunlight. The absorption spectra of **1**⇄**3** in ethanol, recorded during 20 days in the dark, are presented in Fig. 3. The observed spectral features, i.e., appearance of a new maximum at 240 nm, disappearance of the maximum at 360 nm, and the ratio of absorbances $A_{\lambda_{240}}/A_{\lambda_{285}}$ at the end of the process, could be due to slow formation of the thermodynamically more stable thiol form **1** or to the corresponding oxidation product, 2,2′-pyridinedisulfide, **17**. Such a relatively slow process also takes place in ethanol with **5**⇄**7**, **9**⇄**11**, and **13**⇄**15**, leading irreversibly to almost quantitative transformation of the thione structures. The absorption characteristics of the corresponding thiols and disulfides may be expected to be very similar since the parent chromophore is the same and only the molar intensity should be doubled due to the noncoplanar structure of disulfides (21, 22). Therefore the IR, NMR, and TLC data for the final product of 2-pyridinethione transformation were compared with those for the corresponding disulfide **17**, showing full coincidence. The spectral characteristics of the individual thione forms and other disulfides together with the model N-CH_3 and S-CH_3 derivatives are presented in Table 1.

Additional evidence for the structure of the transformation products from the thione forms **3**, **7**, **11**, and **15** in ethanol comes from the quantitative comparison of their spectral data with those of disulfides **17**⇄**20**, taking into account the fact that two

moles of thione are oxidized through the corresponding thiol to one mole of symmetrical disulfide according to the following reaction (22):

[1] $2\,RSH + 1/2\,O_2 \rightarrow RSSR + H_2O$

where R is the corresponding pyridine or pyrimidine.

The estimated percentages of conversion to disulfides **17–20** in ethanol according to eq. [1] are 90, 89, 86, and 100%, respectively. Also, excellent agreement with the shape and positions of the absorption maxima is observed. When the concentrations used were less than 1×10^{-4} M, the process of thione–disulfide oxidation proceeded almost quantitatively. The changes in absorbances A_i at λ_{max} of the thione form with time were analyzed as being first-order kinetics, using the least-squares method. As Beak *et al.* (13–15) have shown, the evaluation of the effect of self-association is essential for reliable interpretation of solution data. Therefore, different concentrations were used to determine the rate constants (K_{obs}) of thione–disulfide oxidation and the data obtained are tabulated in Table 2.

These results clearly show that this oxidation is relatively slow and a marked dependence on the concentration is observed. Using Scheme 3, it is possible to explain the influence of concentration on K_{obs}. Upon dilution, the monomer–dimer equilibrium is shifted from the dimeric species where only the thione chromophore is observed (13) to the monomeric species where both tautomeric forms are possible. The thiol–disulfide oxidation takes place subsequently and the tautomeric equilibrium is restored again. Finally all the thione molecules are oxidized to the corresponding disulfide. At higher concentrations ($>1 \times 10^{-4}$ M), the calculated values of K_{obs} decrease (Table 2) and the relationship between $\ln(A_0/A_i)$ and τ(s) deviates from linearity due to the relative resistance of the self-associated thione form towards oxidation and the domination of dimer species in solution. When a deoxygenated solution of **9⇄11** in ethanol is used, the thione–sulfide transformation proceeds very slowly (Table 2), confirming our suggestion about the nature of the process involved.

A number of solvents, of different types, were used in order to evaluate their influence on the thione–thiol equilibrium and the thione–disulfide transformation. In CH_3CN, CH_2Cl_2, and $CHCl_3$ the thione form predominates and the rate of oxidation to the corresponding disulfides is rather slow.

In dioxane, the thione form also predominates but the thione–disulfide transformation proceeds relatively rapidly. However, the observed spectrum **1⇄3** differs slightly from that of the corresponding disulfide in the same solvent (Fig. 4) and only after 24 h does the final spectrum correspond to about 90% of the theoretically expected amount of **17**. This transformation is also enhanced by a decrease in the concentration of the initial thione (Table 2) and by an increase in the temperature (Table 3).

However, the addition of water partly restores the thione spectrum. Thus it is possible to observe the absorption characteristics of the thiol form along with those of the forming disulfide. The temperature and concentration dependence are readily accommodated by the well-known tendency of **3** to form

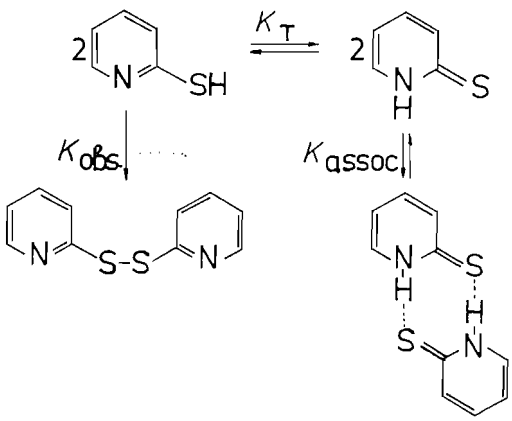

SCHEME 3

stable dimers that are broken up by heating or dilution. In water, the most polar solvent, the thione form dominates initially, but the thione–disulfide transformation is restored on standing at ambient conditions. The values of K_{obs} (Table 2) are relatively smaller than in ethanol. Surprisingly, when almost all the thione molecules of **9** are converted to the corresponding disulfide **19**, additional standing in the dark leads to the formation of ca. 85% of the initial thione form **9**. When dilute solutions (10^{-4}–10^{-5} M) of the model disulfides **17**–**20** in water are allowed to stand in the dark an almost complete transformation of the original spectrum, corresponding to that of the thiones, is observed. Moreover, additional standing in indirect sunlight induces reversion to the initial disulfide as shown by eq. [2]:

$$[2]\quad \text{Thione} \underset{\text{dark}}{\overset{\text{light}}{\rightleftharpoons}} \text{disulfide}$$

This practical thiol–disulfide redox system could have some importance in biological systems and resembles the reaction known as "disulfide interchange" (23), in which a thiol reacts with a disulfide to give a different thiol and disulfide pair as products. Thus the disulfides **17** and **18** investigated have been extensively used for the modification and estimation of protein thiol groups (24).

Apparently, in these potentially tautomeric heterocyclic systems, understanding the effects of molecular environment along with the relative stability of the thiol form may be pertinent to important aspects of their biological action.

Irradiation of solutions, even with indirect sunlight, leads to an increase of K_{obs}, or it enhances the thione–disulfide transformation (Table 2). Further studies are underway to clarify the influence of irradiation on the position of the tautomeric thione–thiol equilibrium in solution.

Experimental

Pyridine-2-thione, pyrimidine-2-thione, 4,6-dimethylpyrimidine-2-thione (Fluka), and pyridine-4-thione (Aldrich) were purified following the procedures described (25, 26) to obtain analytically pure materials. The IR, NMR, and absorption properties were consistent with those expected for the assigned structures. The disulfides **17**–**20** were prepared from the corresponding thiones through oxidation with equimolar amounts of H_2O_2 in water at room temperature and recrystallized from aqueous ethanol. The elemental analysis, mp (26, 27), and ^{1}H NMR for **17**–**19** are in accordance with those expected for the structures. For **20**: mp 166–168°C; ^{1}H NMR ($CDCl_3$) δ: 6.68 (s, H5.5′), δ 2.32 (s, CH_3). Anal. calcd. for $C_{12}H_{14}N_4S_2$: C 51.80, H 5.04, N 20.14, found: C 51.50, H 5.02, N 20.03.

The UV–VIS absorption spectra were obtained at appropriate temperatures on a Specord UV–VIS spectrophotometer with cells ranging from 0.01 to 10 cm. The temperature was kept constant within ±0.2°C by circulating thermostatted water in the cell holder. Spectrograde solvents were used as received in all measurements.

Liquides de toupies symétriques : leur tenseur de polarisabilité optique intrinsèque via deux expériences sous champ statique : CH_3CN

CLAUDE BROT

Laboratoire de physique de la matière condensée, Unité de recherche n° 190, associée au Centre national de la recherche scientifique, Université de Nice – Sophia Antipolis – Parc Valrose, 06034 Nice CEDEX, France

Reçu le 19 décembre 1989

CLAUDE BROT. Can. J. Chem. **68**, 1490 (1990).

On montre qu'en combinant pour un liquide un résultat expérimental de résonance magnétique nucléaire sous champ électrique avec sa constante de Kerr on peut obtenir des informations sur l'anisotropie optique de la molécule, car toutes les propriétés électriques statiques moléculaires s'éliminent. On emploie la formalisme des tenseurs d'incrément de polarisabilité en phase liquide développé par l'auteur pour les fluides de molécules quasi-ellipsoïdales. S'aidant de l'équation constitutive de la réfractivité dans le modèle utilisé, on peut obtenir les deux composantes distinctes du tenseur d'incrément de polarisabilité optique des molécules toupies symétriques constituant le liquide. On passe alors aux éléments de polarisabilité intrinsèque (*in vacuo*) par un calcul faisant intervenir le volume et la forme moléculaire (élongation de l'ellipsoïde) ainsi que l'indice de réfraction du liquide. Pour le cas de l'acétonitrile pur l'accord avec des mesures en phase vapeur publiées est excellent : On trouve, en unités 10^{-40} C^2 m^2 J^{-1}, la valeur 5,06 pour la polarisabilité moyenne et la valeur 2,52 pour son anisotropie, alors qu'une étude expérimentale publiée utilisant la diffusion dépolarisée de la lumière en phase gazeuse fournit respectivement les valeurs 4,96 et 2,49 à $\lambda = 633$ nm. Finalement et accessoirement, on suggère que les intercorrélations dipolaires dans l'acétonitrile sont peu importantes. En effet un formalisme analogue pour le calcul du moment permanent à partir de la permittivité statique fournit une valeur en accord à 1% près avec la valeur mesurée dans le gaz.

Mots clés : tenseurs de polarisabilité, liquides, constante de Kerr, RMN.

CLAUDE BROT. Can. J. Chem. **68**, 1490 (1990).

NMR line splitting under a strong static electric field (EF-NMR) allows one to measure the average alignment (second spherical harmonic) of the molecule studied under the influence of the field. This average alignment (per unit squared field) can be formulated theoretically by an expression involving the permanent dipole moment, the anisotropy of the static polarizability, etc. and possibly orientational intercorrelations within the liquid. On the other hand the Kerr constant per molecule can be represented by the *same* expression, multiplied by a factor that is independent of any *static* electrical property of the molecule (for a gas this factor would be simply proportional to the anisotropy of the *optical* polarizability). Consequently the ratio of the above experimental results contains information bearing only on the optical properties. The formalism of the "tensor of polarizability increment" developed by the author for liquids made up of ellipsoidal molecules is employed. It is shown that by combining the above ratio with the constitutive equation for the refractivity of the liquid, the two distinct principal elements of the tensor of polarizability increment of the symmetric top molecules constituting the liquid are immediately obtained. Using then the molecular volume, a van der Waals estimate for the elongation of the molecule, and the index of refraction of the liquid, one can calculate the elements of the optical polarizability tensor *in vacuo*. The method is illustrated by neat acetonitrile for which the necessary experimental data exist in the literature. One finds, in units 10^{-40} C^2 m^2 J^{-1}, 5.06 for the mean polarizability and 2.52 for its anisotropy. A published experimental study using depolarized light scattering in the gas phase indicates that the corresponding figures are 4.96 and 2.49 respectively at $\lambda = 633$ nm. Finally and accessorily, it is suggested that dipolar intercorrelations are weak in acetonitrile. Indeed, using an analogous formalism for the static permittivity of the liquid, a value for the permanent moment of the molecule is deduced. This value is within 1% of the experimental gas value.

Key words: polarizability tensors, liquids, Kerr constant, NMR.

I. Introduction

Nous utiliserons le tenseur des «polarisabilités incrémentielles» en phase liquide, dont la théorie a été développée dans des articles antérieurs (1–3). La molécule est supposée ellipsoïdale et immergée dans un continuum de permittivité relative ε. Un élément de ce tenseur, diagonalisé dans les axes moléculaires, s'écrit :

$$[1] \quad \alpha_{jj}^{*} = C_{jj} f_{jj} \alpha_{jj} - C_{jj} \frac{abc}{3} 4\pi\varepsilon_0(\varepsilon - 1)$$

Attention: Malgré une notation identique à celles d'auteurs antérieurs pour une polarisabilité effective en phase condensée, nos α^* en sont différents : ce sont des quantités *incrémentielles*, positives ou négatives. Ils sont exactement nuls si la molécule est remplacée par un ellipsoïde homogène ayant même permittivité que le milieu environnant, ce qui rend notre approche autoconsistante.

α_{jj} est l'élément correspondant de la polarisabilité *in vacuo*; a, b et c sont les demi axes principaux de la cavité ellipsoïdale, supposée homothétique de l'enveloppe van der Waals de la molécule; ε_0 égale $(4\pi)^{-1}$ dans le système esu, ou égale $8{,}854 \times 10^{-12}$ F m^{-1} dans le système SI. Pour les α ou les α^* la correspondance numérique entre ces systèmes est 10^{-24} esu = $1{,}11264\ 10^{-40}$ C^2 m^2 J^{-1}.

C_{jj} est l'élément du tenseur facteur de champ de cavité :

$$[2] \quad C_{jj} = \varepsilon/(\varepsilon - S_j(\varepsilon - 1))$$

$$[3] \quad S_z = \frac{abc}{2}\int_0^{\infty} \frac{\mathrm{d}s}{(s + c^2)^{3/2}(s + a^2)^{1/2}(s + b^2)^{1/2}} \text{ etc.}$$

$$\sum_{j=x,y,z} S_j = 1$$

$\boldsymbol{f}$ est le facteur tensoriel de champ interne pour la molécule dans sa cavité ellipsoïdale (éviter la confusion avec le facteur de champ de réaction) :

$$[5] \quad f_{jj} = \left\{1 - \frac{\varepsilon - 1}{\varepsilon} S_j \left[1 + (1 - S_j)\frac{3\alpha_{jj}}{abc\,4\pi\varepsilon_0}\right]\right\}^{-1}$$

Dans l'équation [1] le premier terme représente un effet d'induction sur la molécule, corrigé par le facteur de champ interne et par la présence de la cavité virtuelle. Le deuxième terme, négatif, représente un effet analogue pour la portion de continuum qui a été supposée soustraite. Nous ferons usage des formules obtenues précédemment pour la constante de Kerr K et pour la moyenne du second harmonique sphérique sous champ électrique statique, qu'on obtient à partir du dédoublement de certaines raies RMN provoqué par ce champ (EF-NMR). Les deux types d'expérience font intervenir le moment dipolaire permanent, si il existe, ainsi que les polarisabilités *statiques*. Les polarisabilités statiques *incrémentielles* sont celles définies plus haut, équations [1]–[5]. Nous les affectons d'un indice supérieur s. L'effet Kerr fait intervenir de plus les polarisabilités à fréquence optique. Nous les affectons d'un indice supérieur l (pour «lumière»). Elles sont analogues à celles définies par [1]–[5], sauf que partout la permittivité ε doit être remplacée par le caré de l'indice n^2.

II. Principe de la méthode

Commençons par l'effet Kerr. On a montré (2) qu'en négligeant les termes dus aux hyperpolarisabilités (cf. section finale) :

$$[6] \quad \frac{K}{N} = \frac{1}{30n^2kT\varepsilon_0}\left[\Gamma^{ls*} + \frac{\Lambda^{ls*}}{kT}\right]$$

N est le nombre de molécules par unité de volume.

Les quantités dans le crochet sont explicitées dans la référence 2 pour une toupie générale. Pour une toupie symétrique, en adoptant O_Z comme axe principal, notant $\alpha_\parallel = \alpha_{zz}$ et $\alpha_\perp = \alpha_{xx} = \alpha_{yy}$, avec la même convention pour les éléments incrémentiels correspondants, et puisque nécessairement le moment permanent μ est le long de O_Z, les formules données dans la référence 2 se réduisent à

$$[7] \quad \Gamma^{ls*} = (\alpha_\parallel^{l*} - \alpha_\perp^{l*})(\alpha_\parallel^{s*} - \alpha_\perp^{s*})$$

$$[8] \quad \Lambda^{ls*} = (\alpha_\parallel^{l*} - \alpha_\perp^{l*})(f_z^s\mu)^2$$

d'où

$$[9] \quad \frac{K}{N} = \frac{1}{30n^2kT\varepsilon_0}(\alpha_\parallel^{l*} - \alpha_\perp^{l*})\left[(\alpha_\parallel^{s*} - \alpha_\perp^{s*}) + \frac{(f_z^s\mu)^2}{kT}\right]$$

Passons au dédoublement des raies RMN (spin $> \frac{1}{2}$) sous l'effet d'un fort champ électrique statique E. Si on connait la constante de couplage quadrupolaire du noyau étudié, situé sur l'axe moléculaire, ce type d'expérience permet d'obtenir «l'alignement» moyen de l'axe moléculaire sous l'effet du champ, c.-à-d. la moyenne du second harmonique sphérique de l'angle θ entre l'axe moléculaire et le champ. Nous avons montré (3) que

$$[10] \quad \frac{\langle \frac{3}{2}\cos^2\theta - \frac{1}{2}\rangle}{E^2} = \frac{1}{15kT}\left[(\alpha_\parallel^{s*} - \alpha_\perp^{s*}) + \frac{(f_z^s\mu)^2}{kT}\right]$$

où E est le champ de Maxwell appliqué; les contributions en E^4 sont ici négligées, comme il est usuel.

Les formules [9] et [10] sont rigoureuses, dans le cadre du modèle, c'est-à-dire seulement si l'environnement de chaque molécule anisotrope est un quasi-continuum, en pratique un solvant de petites molécules isotropes. Dans un liquide pur de molécules anisotropes il faut mettre en facteur des équations [9] et [10] un facteur d'intercorrélation G dont la différence avec l'unité représente les possibles corrélations orientationnelles (4–6).

Il est remarquable, et tout à fait utile pour notre but, que ce facteur serait le même pour les équations [9] et [10], car le champ statique appliqué fait réagir les orientations possiblement corrélées de manière identique dans les deux case.

En divisant l'équation [9] par l'équation [10] on obtient donc, même pour un liquide pur, aussi bien polaire que non polaire :

$$[11] \quad \frac{K/N}{\langle \frac{3}{2}\cos^2 - \frac{1}{2}\rangle/E^2} = \frac{1}{2n^2\varepsilon_0}\left(\alpha_\parallel^{l*} - \alpha_\perp^{l*}\right)$$

où figure maintenant seulement des quantités optiques.

Les composantes de polarisabilité de cette équation sont du type «incrémentiel». Nous devons maintenant atteindre par elles leurs analogues intrinsèques, c'est-à-dire *in vacuo*. Mais d'abord il nous manque une équation. Celle-ci nous est donnée par l'équation constitutive de la réfractivité pour notre modèle des polarisabilités incrémentielles. Cette équation s'écrit pour un liquide pur (7) :

$$[12] \quad \mathrm{Tr}\alpha^{l*} = 0$$

Cette équation est évidente car elle signifie que si on ménage dans le liquide pur une cavité ayant le volume moléculaire moyen, qu'on y inserre une molécule identique à celles du liquide et qu'on laisse le système fluctuer, on n'a en moyenne rien changé. Elle donne pour n^2, si l'on connait les éléments *in vacuo* α_{jj}, des résultats voisins mais en meilleur accord avec l'expérience que la formule de Lorenz–Lorentz (7). Elle est aussi plus cohérente avec le modèle employé ici.

Pour une toupie symétrique, en dénotant l'anisotropie optique incrémentielle

$$[13] \quad \alpha_\parallel^{l*} - \alpha_\perp^{l*} = \Delta^{l*}$$

on tire de l'équation [12] :

$$[14] \quad \alpha_\parallel^{l*} = (2/3)\Delta^{l*}, \qquad \alpha_\perp^{l*} = -(1/3)\Delta^{l*}$$

Il suffira ensuite de résoudre les deux systèmes correspondants d'équations [1]–[5] pour obtenir les deux composantes distinctes du tenseur de polarisabilité optique *in vacuo*.

III. Illustrations par l'acétonitrile liquide

Nous considérons le liquide CH_3CN, très polaire, pour lequel il existe dans la littérature à la fois une mesure de constante de Kerr (4) et une mesure EF-NMR du noyau N (8). Nous adoptons la température 293 K pour notre illustration, et le système SI.

Premièrement la constante de Kerr. Il existe deux définitions usuelles pour cette constante, B et K, reliées par la formule

$$[15] \quad K = B\lambda/n$$

$$[16] \quad B = (n_\parallel - n_\perp)/E^2\lambda$$

avec les notations usuelles.

À la longueur d'onde $\lambda = 633 \times 10^{-9}$ m où l'indice $n = 1{,}34$, Beevers et Khanarian (4), à 293 K, ont mesuré $B = 49{,}9 \times 10^{-14}$ m V^{-2}. On en tire :

$$K = 23{,}57 \times 10^{-20}\ \mathrm{m^2\ V^{-2}}$$

$1/N$, qui figure dans le membre de gauche de notre équation [11], est égal au volume par molécule dans le liquide : $1/N = 10^{-6}M/dN_a$ où la masse molaire $M = 41{,}05$ et la densité à 293 K est $d = 0{,}7857$ (9). N_a et le nombre d'Avogadro. Ceci donne successivement :

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

[17] $1/N = 86{,}76 \times 10^{-30}\ \mathrm{m}^3$

[18] $K/N = 20{,}45 \times 10^{-48}\ \mathrm{m}^5\ \mathrm{V}^{-2}$

Nous passons à la mesure EF-NMR.

Sous un champ de $4 \times 10^6\ \mathrm{V\ m^{-1}}$ Hilbers et MacLean (8) ont déduit $\langle 3\cos^2\theta - 1\rangle = 0{,}82 \times 10^{-4}$ à 300 K. Ceci donne :

$$\langle \tfrac{3}{2}\cos^2\theta - \tfrac{1}{2}\rangle / E^2 = 2{,}56 \times 10^{-18}\ \mathrm{m^2\ V^{-2}}$$

Il nous faut ramener cette quantité à la valeur qu'elle aurait à 293 K, température adoptée ici. Pour ceci nous remarquons que pour une molécule très polaire comme CH_3CN le deuxième terme du crochet de notre équation [10] est largement dominant. Donc le membre de gauche de cette équation est très sensiblement inversement proportionnel au carré de la température. Ceci nous fournit à 293 K :

[19] $\langle \tfrac{3}{2}\cos^2\theta - \tfrac{1}{2}\rangle / E^2 = 2{,}684 \times 10^{-18}\ \mathrm{m^2\ V^{-2}}$

Utilisant les résultats expérimentaux [18] et [19] dans notre équation [11] nous obtenons :

$$\Delta^{l*} = \alpha_{\parallel}^{l*} - \alpha_{\perp}^{l*} = 2{,}42 \times 10^{-40}\ \mathrm{J^{-1}\ C^2\ m^2}$$

d'où, avec [14] : $\alpha_{\parallel}^{l*} = 1{,}615$ et $\alpha_{\perp}^{l*} = -0{,}8075$ en unités $10^{40}\ \mathrm{J^{-1}\ C^2\ m^2}$.

Pour obtenir les polarisabilités correspondantes *in vacuo*, nous devons résoudre le système d'équations [1]–[5] (avec $\varepsilon = n^2$), ce qui est faisable algébriquement. Dans ce système figure la quantité $4\pi a^2 c/3$ qui est le volume par molécule, $1/N$, donné par [17]. Il est nécessaire aussi d'estimer S_z (d'où $S_x = S_y = (1 - S_z)/2$). Pour ce faire nous utilisons les longueurs de liaison et les rayons de van der Waals tabulés (9) :

longueur C—C : 1,541 Å, longueur C—N : 1,158 Å
rayon de van der Waals de N : 1,5 Å
rayon de van der Waals moyen du méthyle : 2 Å

Un dessin à l'échelle montre que l'enveloppe de van der Waals de la molécule est légèrement piriforme (10), car le rayon du méthyle est supérieur à celui de l'azote. On peut cependant circonscrire cette enveloppe par un ellipsoïde de révolution de demi grand axe 3,125 Å et de demi petit axe 2,23 Å. Ceci donne un «volume de la molécule» égal à $65{,}1 \times 10^{-30}\ \mathrm{m^3}$. La différence entre le volume disponible par molécule (équation [17]) et cette valeur est évidemment attribuable à l'espace intermoléculaire nécessaire au mouvement thermique. Nous allons supposer que la cavité est homothétique à l'ellipsoïde de van der Waals de la molécule. Ceci est une simplification indispensable ici bien que des arguments partant sur les amplitudes de libration permettent de croire qu'elle est légèrement plus sphérique (7).

L'élongation c/a est donc alors $3{,}125/2{,}23 = 1{,}4$. Cette valeur est voisine de celle adoptée pour l'acétonitrile dans la référence 11. Les tables de la référence 12 indiquent qu'alors $S_z = 0{,}25$.

La résolution du système [1]–[5] donne alors successivement, en unités $10^{-40}\ \mathrm{C^2\ m^2\ J^{-1}}$:

[20] $\alpha_{\parallel}^{l} = 6{,}746, \qquad \alpha_{\perp}^{l} = 4{,}22$

d'où, pour la polarisabilité moyenne et son anisotropie :

[21] $\bar{\alpha}^{l} = (1/3)\mathrm{Tr}\,\alpha^{l} = 5{,}06$ et $\alpha_{\parallel}^{l} - \alpha_{\perp}^{l} = 2{,}52$

Nous pouvons comparer les valeurs [21] avec celles mesurées *directement* en phase vapeur par mesure de l'intensité de la diffusion dépolarisée de la lumière : À $\lambda = 633$ nm la référence 13 donne, dans les mêmes unités que ci-dessus :

[22] $\bar{\alpha}^{l} = 4{,}96$ et $\alpha_{\parallel}^{l} - \alpha_{\perp}^{l} = 2{,}49$

L'accord est excellent. La précision atteinte (1–2%) est même probablement fortuite, car il est vraisemblable que les ingrédients expérimentaux que nous avons utilisés (constante de Kerr et surtout EF-NMR) étaient affectées d'une erreur probable au moins égale.

L'adoption d'une cavité sphérique ($S_z = \frac{1}{3}$ dans nos équations) change peu la polarisabilité moyenne, mais fournit une anisotropie très sousestimée : $1{,}98 \times 10^{-40}\ \mathrm{C^2\ m^2\ J^{-1}}$.

IV. Discussion et conclusion

Nous avons dit Section II que dans notre expression de la constante de Kerr nous négligeons les termes d'hyperpolarisabilité. La validité de cette hypothèse mérite brève discussion. En principe ces termes peuvent s'obtenir directement par des mesures de production des harmoniques successifs d'une fréquence lumineuse sous champ électrique statique. La littérature ne fournit que peu de ces mesures, et encore avec de larges limites d'erreur. Il existe pourtant une étude (14) qui porte sur une série de méthanes substitués polaires à l'état vapeur en utilisant à la fois la mesure de l'effet Kerr, la dépolarisation de la lumière et les hyperpolarisabilités de la littérature; on conclut de cette étude que le terme d'orientation dipolaire (correspondant à notre équation [8]) est largement dominant. Le terme d'alignement d'anisotropie (notre eq. [7]) en représentent seulement quelques pour-cent et les termes d'hyperpolarisabilité encore moins. On retiendra de ceci que pour les corps polaires le fait de négliger les hyperpolarisabilités n'est pas grave, mais qu'il faudrait être beaucoup plus prudent pour des corps non polaires.

Nous passons à l'examen des possibles intercorrélations d'orientation représentées par $(G - 1)$ où G est un facteur de Kirkwood généralisé que nous avons omis dans nos équations [9] et [10] puisqu'il s'élimine de notre équation [11]. Il est rappelé que $(G - 1)$ théoriquement une combinaison du facteur de Kirkwood dipolaire $g_k = g_1$, de son analogue g_2 construit sur le deuxième harmonique sphérique moyen de l'angle θ_{ij} entre molécules, et enfin d'un facteur g_3 qui fait intervenir des intercorrélations à trois corps. La forme exacte de cette combinaison est controversée, deux formulations différentes ayant été proposées (5, 6).

Nous nous bornerons ici à examiner les possibles intercorrélations *polaires* dans l'acétonitrile liquide. La littérature (4, 11) donne g_k voisin de 0,75, mais ce chiffre est obtenu à partir de la formule de Kirkwood–Frohlich originelle qui suppose une cavité moléculaire sphérique. Voyons quel serait son analogue dans le cas d'une cavité ellipsoïdale. Pour ce faire nous utilisons l'équation constitutive de la permittivité statique dans ce modèle [1]. Elle s'écrit pour une toupie générale, en l'absence d'intercorrélations :

[23] $\Sigma[\alpha_{jj}^{s*} + f_j^{s2}\mu_j^2/kT] = 0 \qquad (j = x,y,z)$

Pour une toupie symétrique ($\mu \parallel O_Z$) l'équation [23] peut s'écrire :

[24] $$\mu^2 = -\frac{kT}{(f_z^s)^2}(2\alpha_{xx}^{s*} + \alpha_{zz}^{s*})$$

(Le signe négatif n'est pas surprenant car dans notre définition [1] le deuxième terme négatif domine à cause de la valeur élevée de ε).

Il est alors facile via nos équations [1], [5] et [24] de calculer μ selon le modèle. La valeur expérimentale de ε à 293 K est ε = 37,5 (15). Pour les polarisabilités statiques *in vacuo* α_{jj} nous utilisons nos valeurs des équations [20] augmentées empiriquement de 5% pour tenir compte des contributions atomiques. Nous obtenons $\mu_{\text{modèle}} = 13{,}0 \times 10^{-30}$ C m = 3,90 D. La littérature (16) donne la valeur 3,92 D obtenue par effet Stark sur le spectre microonde, et 3,96 D obtenue par mesure du viriel diélectrique. Si on adopte une valeur moyenne probable μ_{gaz} = 3,94 D, nous obtenons :

$$[25] \quad g_B = \mu^2_{\text{modèle}}/\mu^2_{\text{gaz}} = 0{,}98$$

où nous avons défini un nouveau paramètre de corrélation polaire g_B qui diffère de celui de Kirkwood en ce sens que dans un modèle à cavité ellipsoïdale prolate les plus proches voisines sont plus éloignées dans les directions axiales que dans les directions transverses (et l'inverse pour une cavité oblate).

Le fait que g_B soit indistinguable de l'unité vues les erreurs expérimentales probables indique que les corrélations polaires sont inexistantes ou peu importantes dans l'acétonitrile liquide.

Il est par contre difficile d'avoir des données sur les corrélations d'alignement représentées par $(g_2 - 1)$. Une étude expérimentale dynamique (17) (largeurs de Raie Raman et Rayleigh comparées) amène à conclure que $(g_2 - 1)$ est probablement positif, mais cette déduction dépend du modèle adopté, où intervient aussi un facteur de corrélation dynamique à priori inconnu. Une étude radiocristallographique semble permettre une conclusion analogue (18). Par contre, une étude (19) par simulation numérique de CH_3CN (potentiel représenté par 3 centres LJ + 3 charges sur atomes) montre pour le modèle utilisé de faibles corrélations d'alignement au-delà des premières molécules voisines en direction transverse. Quant au paramètre de corrélation à trois corps $(g_3 - 1)$, il semble impossible à évaluer avec certitude présentement, ni par voie théorique, ni par voie expérimentale.

Pour conclure nous revenons sur les articles originaux dont nous avons utilisé les données expérimentales : aussi bien les auteurs ayant travaillé à l'aide de la EF-NMR (8) que ceux ayant utilisé l'effet Kerr (4) interprétent leur résultat à l'aide d'un champ interne résultant d'une cavité supposée sphérique. À 293 K les premiers trouvent pour $\langle P_2(\cos\theta)\rangle/E^2$ la valeur $2{,}68 \times 10^{-18}$ m^2 V^{-2} (notre équation [19]) et les deuxièmes trouvent 2,13 dans les mêmes unités. À notre avis cette divergence est causée par l'utilisation d'une cavité sphérique. Notre traitement, par contre, nous semble réconcilier les deux types de mesure d'une part entre elles, d'autre part avec la valeur connue de l'anisotropie optique de la molécule CH_3CN.

Received January 16, 1990

MARTIN K. EHLERT, STEVEN J. RETTIG, ALAN STORR, ROBERT C. THOMPSON, and JAMES TROTTER. Can. J. Chem. **68**, 1494 (1990).

Zinc metal reacts with excess 3,5-dimethylpyrazole (Hdmpz) in the presence of O_2 to produce materials of composition $Zn(dmpz)_2(Hdmpz)_y$. Thermolysis of these materials results in the loss of Hdmpz and the formation of the $[Zn(dmpz)_2]_x$ polymer. Under appropriate conditions the pure dimer $[Zn_2(dmpz)_4(Hdmpz)_2]$ can be obtained in high yield. Crystals of bis[μ-(3,5-dimethylpyrazolyl-N^1,N^2)]bis[(3,5-dimethylpyrazolyl)(3,5-dimethylpyrazole)zinc(II)] are orthorhombic, a = 17.009(2), b = 29.239(2), c = 13.590(2) Å, Z = 8, space group *Fddd*. The structure was solved by heavy atom methods and was refined by full-matrix least-squares procedures to R = 0.037 and R_w = 0.042 for 913 reflections with $I \geq 3\ \sigma(I)$. The structure of $[Zn_2(dmpz)_4(Hdmpz)_2]$ contains nearly planar doubly dmpz bridged Zn_2 units capped at each end by strongly hydrogen-bonded dmpz···Hdmpz units. The zinc atoms display pseudotetrahedral coordination geometry with Zn—N = 1.991(3) (bridging) and 2.025(3) Å (terminal), and N—Zn—N = 99.6(2)–113.8(2)°.

Key words: zinc 3,5-dimethylpyrazolate complexes, crystal structure.

MARTIN K. EHLERT, STEVEN J. RETTIG, ALAN STORR, ROBERT C. THOMPSON et JAMES TROTTER. Can. J. Chem. **68**, 1494 (1990).

Le zinc métallique réagit avec un excés de 3,5-diméthylpyrazole (Hdmpz), en présence de O_2, pour donner des produits de composition $Zn(dmpz)_2(Hdmpz)_y$. La thermolyse de ces produits conduit à une perte de Hdmpz et à la formation de polymère $[Zn(dmpz)_2]_x$. Dans des conditions appropriées, on a obtenu le dimère $[Zn_2(dmpz)_4(Hdmpz)_2]$ avec un excellent rendement. Les cristaux du bis[μ-(3,5-diméthylpyrazolyl-N^1,N^2)]bis[(3,5-diméthylpyrazolyl)(3,5-diméthylpyrazole)zinc(II)] sont orthorhombiques, a = 17,009(2), b = 29,239(2) et c = 13,590(2) Å, Z = 8 et groupe d'espace *Fddd*. On a résolu la structure par la méthode aux atomes lourds et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs de R = 0,037 et R_w = 0,042 pour 913 réflexions avec $I \geq 3\sigma(I)$. La structure du $[Zn_2(dmpz)_4(Hdmpz)_2]$ contient des unités pratiquement planes de Zn_2 doublement pontés à des dmpz et capées à chaque extrémité par des unités dmps···Hdmpz fortement liées par des ponts hydrogènes. Les atomes de zinc présentent une géométrie de coordination pseudotétraédrique avec des longueurs de liaison Zn—N de pont de 1,991(3) et terminale de 2,025(3) Å et des angles N—Zn—N allant de 99,6(2) à 113,8(2)°.

Mots clés : composés du zinc 3,5-diméthylpyrazolate, structure cristalline.

[Traduit par la revue]

Introduction

Our interest in binary metal pyrazolates is part of a continuing investigation of complexes incorporating, as an exobidentate uninegative ligand, the pyrazolate moiety or its C-substituted derivatives (1, 2). The present account details our studies on zinc complexes incorporating the 3,5-dimethylpyrazolyl bridging ligand, ranging from a bimetallic, dimeric species of composition $[Zn_2(dmpz)_4(Hdmpz)_2]$, through a larger oligomer, to the polymeric $[Zn(dmpz)_2]_x$ material (Hdmpz = 3,5-dimethylpyrazole, dmpz = 3,5-dimethylpyrazolate). The dimeric species has been structurally characterized through a single crystal X-ray diffraction study. This represents the first binary zinc pyrazolate structure determination. Related poly(1-pyrazolate)borate zinc complexes were first reported by Trofimenko *et al.* some time ago (3). More recently, zinc and boron centres were featured in a number of polynuclear pyrazolyl bridged spiro species (4) and a variety of pyrazolyl gallate ligands have been used to complex divalent zinc ions (5–7). Bonati *et al.* have employed bis(1-pyrazolyl)methanes to complex zinc metal ions (8, 9) and Seel and Rodrian refer briefly to the complex $Na_2[Znpz_4]$ (pz = pyrazolate) (10). In addition, the vibrational assignments of a number of binary zinc pyrazolates have been discussed (11).

None of the above mentioned reports contains X-ray structure determinations, but recently a number of structural reports relevant to the present study have appeared. A report by Driessen *et al.* describes a compound in which the zinc centre is "tetrahedrally" coordinated by two 3,5-dimethylpyrazolyl moieties, one neutral 3,5-dimethylpyrazole, and a nitrate anion (12); Verweij *et al.* report a zinc complex in which the zinc is coordinated by the N2 atoms of two 3-methyl-5-phenylpyrazole molecules and two bromide anions in a distorted tetrahedral fashion (13); and Haanstra *et al.* describe a novel structure consisting of chains of zinc atoms linked by a bridging 1,8-bis(3,5-dimethylpyrazolyl)-3,6-dithiaoctane ligand (14). Of more than passing interest to the present study is a report on the binding of pyrazole in crystalline binary and tertiary complexes of liver alcohol dehydrogenase (15). In these complexes the pyrazole is directly bound to the active site zinc atom (with a Zn—N bond distance of 2.1 Å), and has a marked inhibitory effect on the enzyme function.

Experimental

Synthesis of $[Zn_2(dmpz)_4(Hdmpz)_2]$

Cleaned zinc metal shot (3.505 g, 53.61 mmol) and 3,5-dimethyl pyrazole (3.340 g, 34.75 mmol) were heated together with stirring, under dioxygen at 90°C. Sufficient acetone was added dropwise to the reaction mixture for the Hdmpz to dissolve completely, but without allowing the resultant solution to reflux (~3 mL acetone). After ~2 h a fine white precipitate was visible and this accumulated during the reaction. The reaction was allowed to proceed for 45 h. Acetone was added periodically throughout the reaction to maintain the Hdmpz in solution. The reaction mixture was then cooled to room temperature and extracted with 40 mL of acetone in small portions, suction filtered, the insolubles washed with a further 200 mL of acetone and then dried

in vacuo at room temperature for ~30 min. A fine white powder was collected in 99% yield based on the zinc metal reacted. *Anal.* calcd. for $[Zn_2(dmpz)_4(Hdmpz)_2]$: C 51.22, H 6.30, N 23.89; found: C 50.92, H 6.37, N 23.90.

Attempts to perform the above reaction in neat, molten Hdmpz, without the presence of acetone, necessitated the use of a higher temperature (Hdmpz mp = 108°C) and resulted in the production of a material of non-stoichiometric composition. Cleaned zinc metal shot (3.53 g, 54.0 mmol) and Hdmpz (5.88 g, 61.2 mmol) were reacted with stirring under a dioxygen atmosphere at 130°C for 48 h. a low yield (0.030 g) of a fine white powder was obtained as the zinc-containing product. Elemental analysis of the sample yielded the following results. Found: C 48.67, H 5.76, N 22.70. These results suggest the nominal composition, $Zn(dmpz)_2 \cdot 0.323Hdmpz$: *Anal.* calcd.: C 48.66, H 5.83, N 22.70. Evidence to be presented later suggests the material is a mixture of $[Zn_2(dmpz)_4(Hdmpz)_2]$ and higher oligomers of the formulation $Zn_x(dmpz)_{2x}$ which may or may not contain Hdmpz.

The dimer $[Zn_2(dmpz)_4(Hdmpz)_2]$ was obtained in crystalline form, suitable for single crystal X-ray diffraction studies, by reacting zinc metal with neat molten Hdmpz, without stirring, in the presence of limited dioxygen. A 2 g piece of zinc metal shot was covered with excess Hdmpz in a test tube. The tube was flushed with N_2 gas and then sealed with parafilm into which a pinhole was punched. The lower end of the tube was then maintained at 115°C for 5 days. After ~20 h, small colorless crystals could be seen forming on the zinc shot as well as near the Hdmpz/atmosphere interface. At the end of the reaction period the mixture was cooled and then extracted with acetone to remove excess Hdmpz and yield the insoluble, well formed, colorless crystals of $[Zn_2(dmpz)_4(Hdmpz)_2]$.

Synthesis of the $[Zn(dmpz)_2]_x$ polymer

Samples of material of composition $Zn(dmpz)_2$ were prepared on a 5–10 mg scale by thermolysis directly in differential scanning calorimetry (DSC) aluminum sample pans in the calorimeter. Two routes were employed: the first from $[Zn_2(dmpz)_4(Hdmpz)_2]$) heated at 240°C for 30 min and the second from the dimer/oligomer mixture heated at 170°C for 45 min. *Anal.* calcd. for $Zn(dmpz)_2$: C 46.99, H 5.53, N 21.92; found: (from $[Zn(dmpz)_4(Hdmpz)_2]$ C 46.75, H 5.35, N 21.76 and (from dimer/oligomer mixture) C 46.68, H 5.40, N 21.79. The material produced in these experiments is assumed to be polymeric, with an infinite chain structure, by analogy with the known structures of other binary metal(II) pyrazolates (1, 16). At higher temperatures the DSC thermogram shows that the onset of decomposition of the $[Zn(dmpz)_2]_x$ polymer, without melting, occurs at ~305°C.

Attempts to grow single crystals of the polymer were unsuccessful. Zinc shot was combined with excess Hdmpz without stirring in a nitrogen-filled tube at 175°C for 24 h. Air was allowed to diffuse slowly into the mixture. At the cessation of the reaction colorless crystals with the same morphology as those of $[Zn_2(dmpz)_4(Hdmpz)_2]$ and a fine white solid had grown as a coating on the zinc shot. Due to the presence of intractable decomposition products, the latter was not characterized further.

Physical characterization

Infrared spectra (4000–400 cm^{-1}) were recorded on a Perkin-Elmer Model 598 spectrometer. Samples were mulled in Nujol and sandwiched between KBr plates. Infrared frequencies are listed in Table 1.

Differential scanning calorimetry measurements were obtained with a Mettler DSC 20 Standard Cell and TC10 TA Processor.

X-ray powder diffraction patterns were recorded in the range 5–60° in 2θ using a Rigaku Rotaflex rotating anode X-ray powder diffractometer (Ni filtered Cu $K\alpha$ radiation). A simulated powder X-ray diffraction pattern for $[Zn_2(dmpz)_4(Hdmpz)_2]$ was generated using the computer program LAZY PULVERIX (17).

Single crystal X-ray analysis of $[Zn_2(dmpz)_4(Hdmpz)_2]$

A crystal *ca.* 0.20 × 0.25 × 0.34 mm in size was mounted in a general orientation. Unit-cell parameters were refined by least-squares on setting angles for 25 reflections (2θ = 20–39°) measured on a

diffractometer with Mo-$K\alpha$ radiation (λ = 0.71069 Å). Crystal data at 21°C are as follows

$C_{30}H_{44}N_{12}Zn_2$ f.w. = 703.52

Orthorhombic, a = 17.009(2), b = 29.239(2), c = 13.590(2) Å, V = 6759(1) $Å^3$, Z = 8, ρ_c = 1.383 Mg m^{-3}, $F(000)$ = 2944, μ(Mo-$K\alpha$) = 14.9 cm^{-1}. Absent reflections: hkl; $h + k$, $k + l$, odd; $0kl$, $k + l \neq 4n$; and $hk0$, $h + k \neq 4n$, uniquely indicate the space group $Fddd$.

Intensities were measured with graphite-monochromated Mo-$K\alpha$ radiation on a Rigaku AFC6S diffractometer. An ω–2θ scan at 32° min^{-1} over a range of (1.10 + 0.35 tan θ) degrees in ω (with up to 8 rescans, background/scan time ratio = 0.5) was employed. Data were measured to 2θ = 55°. The intensities of three check reflections, measured every 150 reflections throughout the data collection, showed only small random fluctuations. After data reduction,[1] an empirical absorption correction based on azimuthal scans for three reflections was applied, resulting in relative transmission factors ranging from 0.88 to 1.00. Of the 2128 independent reflections measured, 913 (42.9%) had intensities greater than or equal to $3\sigma(F^2)$ above background where $\sigma^2(F^2) = (S^2(C + 4B) + (0.035(F_o^2))^2)/Lp^2$ with S =

scan speed, C = scan count, B = total background count, and Lp = Lorentz-polarization factor.

The structure was solved by conventional heavy atom methods, the coordinates of the zinc atom being determined from the Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference Fourier synthesis. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms were fixed in calculated positions (N—H, C—H = 0.98 Å, B_H = 1.2 $B_{\text{bonded atom}}$). A difference map shows the N—H proton to be disordered about the twofold axis (rather than lying on the C_2 axis). Scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from ref. 18. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix refinement of 101 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at $R = 0.037$ and $R_w = 0.042$ for 913 reflections with $I \geq 3\sigma(I)$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the maximum parameter shift corresponded to 0.02σ. The mean error in an observation of unit weight was 1.43. The final difference map showed maximum fluctuations of -0.25 to 0.35 e Å^{-3}. The final positional and equivalent isotropic thermal parameters for the non-hydrogen atoms appear in Table 2. Bond lengths and angles are listed in Tables 3 and 4. Hydrogen parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, least-squares planes, and structure factors have been deposited.[2].

Results and discussion

The dimeric species $[Zn_2(dmpz)_4(Hdmpz)_2]$ can be formed in virtually quantitative yield by the reaction of zinc metal with excess Hdmpz in the presence of dioxygen at 90°C. The reaction involves the oxidation of zinc by molecular oxygen with the formation of the zinc complex and water. X-ray diffraction quality crystals of the dimer can be grown by a slight modification of the procedure used to prepare the material in bulk. The molecular structure (Fig. 1) consists of two zinc atoms bridged by two pyrazolate ions with each zinc atom being end-capped by a pyrazolate ion and a netural Hdmpz molecule. Strong hyrogen bonding occurs between the capping ligands [N(2)—H(1)···N(2) (x, 1/4 − y, 1/4 − z), H···N = 1.77, N···N = 2.612(7) Å, N—H···N = 141°] with the unique hydrogen atom being disordered between two possible sites. The molecule has exact (crystallographic) D_2 and approximate D_{2h} symmetry (with crystallographic twofold axes passing through the zinc and C(7) atoms). The zinc atoms are coordinated in a pseudotetrahedral fashion (N—Zn—N = 99.6(2) − 113.8(2)°) and are separated by a non-bonded distance of 3.748(1) Å in the qualitatively planar (to within 0.064(3) Å) six-membered Zn_2N_4 ring. The dihedral angles between normals to the central and terminal ZnN_2 planes is 87.9°. The bridging Zn—N distance of 1.991(3) Å is significantly shorter than the terminal Zn—N distance of 2.025(3) Å. This is consistent with the lengthening of the pyrazolyl N—N bond in the bridging ring to 1.395(5) Å and is also indicative of significant $p\pi$–$d\pi$ interaction between the pyrazolyl group and the metal (19). The effect is not as dramatic as that reported for the planar three-coordinate nickel complex $(\mu\text{-pz})_2[Ni(NO)]_2$ (20) in which the corresponding N—N distance is 1.457(4) Å. The Zn—N distances are similar to values of 1.981(5)–2.053(5) Å reported for other Zn(II) pyrazolate and pyrazole structures (12–14).

The infrared data for $[Zn_2(dmpz)_4(Hdmpz)_2]$ (Table 1) reflect the presence of strong hydrogen bonding in the molecule with the appearance of two broad ν_{NH} vibration bands centered at ~2380 and ~1860 cm^{-1}, significantly shifted from the broad band centered at ~3000 cm^{-1} in solid Hdmpz and the band at 3484 cm^{-1} in CCl_4 solutions of the ligand (21). Similar band shifts, involving ν_{OH} vibrations, have long been recognized as occurring in metal dimethylglyoxime complexes containing strong intramolecular hydrogen bonding (22). Bellamy *et al.* (23, 24) have examined in some detail correlations between infrared frequency shifts and hydrogen bond distances in crystals. The empirical correlation of Bellamy and Owen (24) predicts a frequency shift of about 2000 cm^{-1} for an intermolecular hydrogen bond with a N—H···N distance of 2.612 Å. The shifts we observe are less than this, which is no doubt at least partly due to the non-linear intramolecular N—H···N hydrogen bond. In addition, it should be noted that there is considerable uncertainty in the predicted shift due to its strong dependence on distance at short N···N distances. In $[Zn(dmpz)_2]_x$ these ν_{NH} bands are, as expected, missing as is the broad medium intensity band occuring at 870 cm^{-1} in the dimer. This latter band is likely associated with a N—H deformation vibration although it has been assigned previously to a C—H bending out-of-plane motion (21). Consistent with our assignment, this band is also missing in the spectrum of Nadmpz. The ring stretching (in plane) vibration which occurs at 1596 cm^{-1} in solid Hdmpz and CCl_4 solutions of the ligand (21) has been reported to shift to lower frequencies on coordination of Hdmpz to metals, for example: to 1556 cm^{-1} in $Co(Hdmpz)_2Cl_2$ (25), 1573 cm^{-1} in $Au(Hdmpz)(PPh_3)(BF_4)$, and 1575 cm^{-1} in Au(Hdmpz)Cl and $Au(Hdmpz)_2Cl$ (26). This band occurs at even lower frequencies in the coordinated deprotonated ligand: 1530 cm^{-1} in $[Cu(dmpz)]_x$ (25), 1512 cm^{-1} in $[Co(dmpz)_2]_x$ (25), and 1529

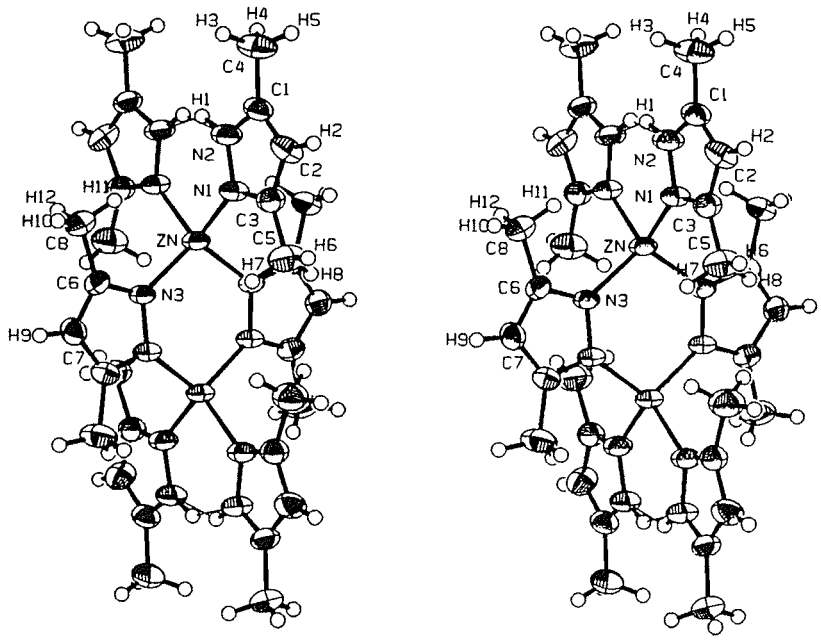

FIGURE 1. Stereoscopic view of the $[Zn_2(dmpz)_4(Hdmpz)_2]$ molecule; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

cm^{-1} in $[Zn(dmpz)_2]_x$ (present work). In spite of the fact that there are two crystallographically unique 3,5-dimethylpyrazole rings in $[Zn_2(dmpz)_4(Hdmpz)_2]$ and, moreover, that formally there are both neutral and deprotonated ligands present in this compound, only one band assignable to this ring stretching vibration is observed at 1525 cm^{-1}. On the basis of the low frequency observed for this vibration, one may conclude that all of the ligands are effectively anionic. This is somewhat surprising in the case of the capping ligands and is likely a consequence of the very strong hydrogen bonding associated with these ligands. The remainder of the infrared spectrum of the dimer is almost indistinguishable from that of the polymer $[Zn(dmpz)_2]_x$ with the exception of a weak unassigned band at 458 cm^{-1} in the polymer which appears as two bands at 439 and 461 cm^{-1} in the dimer, the former frequency presumably associated with the capping ligands and the latter with the bridging ligands. The band occurs at 412 cm^{-1} in solid Hdmpz.

When the experimental conditions used to obtain the dimer $[Zn_2(dmpz)_4(Hdmpz)_2]$ (reaction [1]) are altered somewhat a new product of nominal composition $Zn(dmpz)_2 \cdot 0.323Hdmpz$ is obtained (reaction [2]).

$$[1]\quad 2Zn + xs\ Hdmpz \xrightarrow[90°C,\ stirring,\ 45\ h]{O_2,\ acetone} [Zn_2(dmpz)_4(Hdmpz)_2] + 2H_2O$$

$$[2]\quad Zn + xs\ Hdmpz \xrightarrow[130°C,\ stirring,\ 48\ h]{O_2} Zn(dmpz)_2 \cdot 0.323Hdmpz + H_2O$$

Interestingly, DSC studies show that while the products of [1] and [2] can both be converted to the polymeric material $[Zn(dmpz)_2]_x$, the conditions for doing so differ. The DSC thermogram of the dimer (from [1]) shows an endothermic event at 230°C (ΔH = 150 kJ mol^{-1}). Weight difference measurements show a weight loss over the event of 28% representing the loss of two neutral Hdmpz ligands; moreover, elemental analysis of the product confirmed the composition $Zn(dmpz)_2$. On the other hand the DSC thermogram of the product of reaction [2]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

shows an endothermic event at 178°C (with no event at 230°C) and elemental analysis of the product of this thermolysis also confirmed the loss of neutral Hdmpz.

These observations seem to rule out the possibility that the product mixture formed in [2] is merely a mixture of the dimer and the polymer since, if this were the case, the thermogram would be expected to show an endothermic event at 230°C. Further evidence that at least one different compound is present in the product mixture from [2] comes from powder X-ray diffraction experiments. Thus, powder X-ray diffraction patterns were obtained for the dimer, $[Zn_2(dmpz)_4(Hdmpz)_2]$, the polymer $[Zn(dmpz)_2]_x$, and the product mixture from [2]. The pattern for the latter clearly shows the presence of the dimer, but lines corresponding to those of the polymeric species are all shifted from their positions in the pure polymer. We interpret this as indicating the presence of oligomeric species as described below. A computer simulation of the powder X-ray diffraction pattern of $[Zn_2(dmpz)_4(Hdmpz)_2]$ using parameters from the single crystal X-ray structure determination shows that the lattice *d*-spacings from the experimental powder diffraction pattern are consistent with those of the single crystal structure; however, peak intensities from the simulated and experimental patterns differ, suggesting preferred orientation in the powder sample.

It thus appears that the reaction between Hdmpz and Zn under the conditions specified in [2] produces a mixture of dimer and larger oligomers likely of the type $Zn_x(dmpz)_{2x}\cdot 2Hdmpz$ in which each oligomer is end-capped with the dmpz···Hdmpz units as for the dimer. This material, like the dimer, gives polymeric $Zn(dmpz)_2$ on heating. Some insight into the growth mechanism for the polymer comes from the observations in the DSC studies on the dimer/oligomer mixture. Namely that (*i*) separate events corresponding to the loss of neutral Hdmpz from different oligomers do not occur and (*ii*) the single endothermic event which does occur takes place at a lower temperature than that observed for the pure dimer. It appears that the larger $Zn_x(dmpz)_{2x}\cdot 2Hdmpz$ oligomers dissociate neutral Hdmpz molecules at a lower temperature than does the dimer and, moreover, that these oligomers and/or reactive intermediates formed on Hdmpz dissociation from them facilitate dissociation of Hdmpz from the dimer at this lower temperature.

In summary, Zn reacts with excess Hdmpz in the presence of O_2 to produce materials of composition $Zn(dmpz)_2(Hdmpz)_y$. Under appropriate conditions the pure dimer $[Zn_2(dmpz)_4(Hdmpz)_2]$ can be obtained in high yield and in crystalline form suitable for single crystal X-ray diffraction studies. The latter studies revealed a doubly dmpz bridged Zn_2 unit capped at each end by strongly, intramolecularly, H-bonded dmpz···Hdmpz units. A sample of composition $Zn(dmpz)_2\cdot 0.323Hdmpz$ is considered to be a mixture of the dimer and other oligomers of the type $Zn_x(dmpz)_{2x}\cdot 2Hdmpz$. Thermolysis of these materials results in the loss of Hdmpz and the formation of polymeric $[Zn(dmpz)_2]_x$. The temperature at which this occurs appears to depend on oligomer size with the polymerization proceeding at around 230°C in the case of pure dimer and at lower temperatures in the presence of larger oligomers.

Kinetics and mechanism of oxidation of iodide ion by the molybdenum (VI) – hydrogen peroxide system

CONCHITA ARIAS, FERNANDO MATA, AND JOAQUIN F. PEREZ-BENITO

Departmento de Quimica Fisica, Facultad de Quimica, Universidad de Barcelona, Marti i Franques, 1, 08028 Barcelona, Spain

Received January 5, 1990

CONCHITA ARIAS, FERNANDO MATA, and JOAQUIN F. PEREZ-BENITO. Can. J. Chem. **68**, 1499 (1990).

The kinetics of oxidation of potassium iodide by hydrogen peroxide in aqueous perchloric acid has been studied both in the absence and in the presence of sodium molybdate by means of the initial-rates method. The law found for the total initial reaction rate is

$$r_t = k_1 [I^-][H_2O_2] + k_2 [I^-][H_2O_2][[H^+] + k_3 [I^-][MoO_4^{2-}][H^+] / (a + [H^+])$$

The activation energies associated with rate constants k_1, k_2, and k_3 are 52 ± 1, 49 ± 1, and 42 ± 3 kJ mol^{-1}, respectively. A mechanism in agreement with the experimental kinetic data is proposed, according to which rate constants k_1, k_2, and k_3 correspond to the oxidations of iodide ion by H_2O_2, $H_3O_2^+$ and H_2MoO_5, respectively.

Key words: catalysis, hydrogen peroxide, iodide ion, kinetics, molybdate ion.

CONCHITA ARIAS, FERNANDO MATA et JOAQUIN F. PEREZ-BENITO. Can. J. Chem. **68**, 1499 (1990).

Faisant appel à la méthode des vitesses initiales et opérant tant en présence qu'en absence de molybdate de sodium, on a étudié la cinétique de l'oxydation de l'iodure de potassium par le peroxyde d'hydrogène dans l'acide perchlorique aqueux. La loi régissant la vitesse de réaction initiale globale est :

$$r_t = k_1 [I^-][H_2O_2] + k_2 [I^-][H_2O_2][[H^+] + k_3 [I^-][MoO_4^{2-}][H^+] / (a + [H^+])$$

Les énergies d'activation associées avec les constantes de vitesse k_1, k_2 et k_3 sont respectivement 52 ± 1, 49 ± 1 et 42 ± 3 kJ mol^{-1}. On propose un mécanisme en accord avec les données cinétiques expérimentales et selon lequel les constantes de vitesse k_1, k_2 et k_3 correspondent respectivement aux oxydations des ions iodures par le H_2O_2, le $H_3O_2^+$ et H_2MoO_5.

Mots clés : catalyse, peroxyde d'hydrogène, ion iodure, cinétique, ion molybdate.

[Traduit par la revue]

Introduction

The reaction between iodide ion and hydrogen peroxide in aqueous solution (overall stoichiometry: $3I^- + H_2O_2 + 2H^+ \rightarrow I_3^- + 2H_2O$) has been the subject of kinetic study for over a century (1–10). In particular, it has been established that several oxyanions, such as molybdate ion, have a catalytic effect on that reaction, what has been shown to be useful for the analytical determination of microquantities of those oxyanions (11–14). However, the kinetics of the iodide – hydrogen peroxide reaction in the presence of molybdenum(VI) as catalyst is not so well-known as that of the uncatalyzed reaction, and, as a result, there is considerable argument not only about the mechanism, but also as far as the rate law is concerned (15–17).

To clarify this matter, we have studied the reaction between iodide ion and hydrogen peroxide in aqueous solution both in the absence and in the presence of molybdenum(VI). The results are presented and discussed in detail in this paper.

Experimental section

All chemical reagents used in this work were supplied by Merck (analytical grade). The solvent was water previously purified by double distillation. The oxidant was hydrogen peroxide and the reductant potassium iodide. The kinetic runs were always done in perchloric acid aqueous media. After preparation, the stock solutions were deoxygenated by bubbling nitrogen (previously purified) through them.

The concentration of the hydrogen peroxide stock solution was determined by titration with potassium permanganate (previously standardized with sodium oxalate). The concentration of the perchloric acid stock solution was determined by titration with sodium hydroxide (previously standardized with potassium hydrogenphthalate). In the experiments with catalyst, the concentration of the sodium molybdate stock solution was determined by means of a Beckman DB-GT UV-vis spectrophotometer, by reduction of Mo(VI) to Mo(V) with tin(II) chloride and further complexation with potassium thiocyanate, measuring the absorbance of the molybdenum(V)–thiocyanate complex at 460 nm (18).

The kinetic runs were done in a volumetric flask provided with a double-wall system to allow peripheral circulation of water, so that the constancy of temperature during the runs was ensured. A constant flow of nitrogen was passed through the solutions during the runs to prevent possible interferences from oxygen. The concentration of iodine liberated in the iodide – hydrogen peroxide reaction was measured at regular intervals of time by titration with sodium thiosulfate (Tritisol reagent 0.1 N) using starch as indicator.

Results

The iodine liberated in the reaction was selected as the rate-monitoring species. Since iodide ion was also present in the experiments as a reactant, the following equilibrium has to be considered (19, 20):

[1] $I_2 + I^- \rightleftarrows I_3^-$

Consequently, the iodine liberated was present partially as I_2 and partially as I_3^-. While the use of a spectrophotometric method for monitoring the reaction would allow the determination of only one of those species, the use of a titration method (with thiosulfate ion as reductant and starch as indicator) allows the determination of the total $I_2 + I_3^-$ concentration. This is due to the fact that although the spectra of I_2 and I_3^- are very different, their respective redox properties are similar. Therefore titration was preferred over the spectrophotometric method.

The concentration of iodine liberated ($I_2 + I_3^-$) was determined at regular time intervals by titration with sodium thiosulfate. The results from four typical runs can be seen in Fig. 1. The kinetic data were deduced by using the initial-rates method to experiments done both in the absence and in the presence of molybdate ions. In the presence of molybdate ions, the total initial reaction rate (r_t) can be written as:

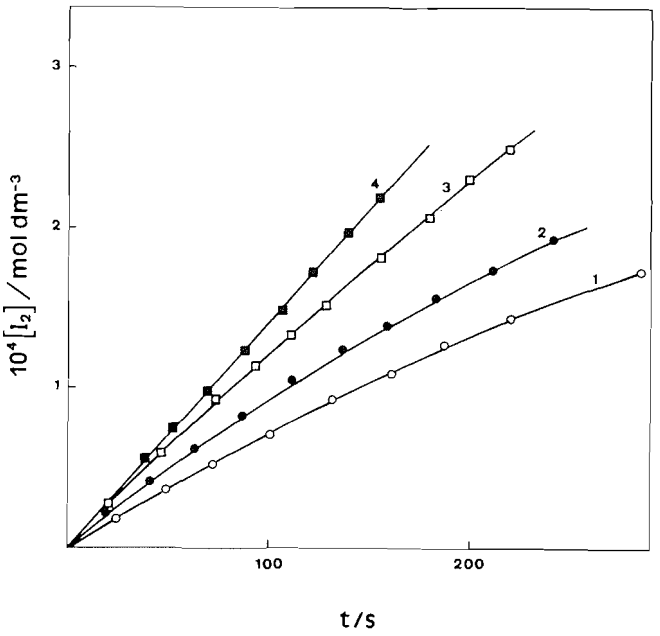

FIG. 1. Typical concentration of iodine vs. time plots. *1*: $[I^-] = 3 \times 10^{-2}$ mol dm^{-3}, $[H_2O_2] = 5 \times 10^{-4}$ mol dm^{-3}; *2*: $[I^-] = 5 \times 10^{-2}$ mol dm^{-3}, $[H_2O_2] = 5 \times 10^{-4}$ mol dm^{-3}; *3*: $[I^-] = 3 \times 10^{-2}$ mol dm^{-3}, $[H_2O_2] = 1 \times 10^{-3}$ mol dm^{-3}; *4*: $[I^-] = 1.5 \times 10^{-2}$ mol dm^{-3}, $[H_2O_2] = 5 \times 10^{-3}$ mol dm^{-3}. In all four cases: [Mo(VI)] = 5×10^{-7} mol dm^{-3}, $[H^+] = 5 \times 10^{-3}$ mol dm^{-3}, ionic strength = 0.20 mol dm^{-3} ($NaClO_4$), temperature 125.0°C.

[2] $r_t = r_u + r_c$

where r_u and r_c stand, respectively, for the contributions of the uncatalyzed and catalyzed reactions to the total initial rate. By doing the same experiment both in the presence and in the absence of molybdate ion, it was possible to determine r_t and r_u, respectively; the difference between them gave the value of r_c.

As can be seen in Fig. 2, r_t, r_u, and r_c are all directly proportional to the reductant concentration; i.e., both the uncatalyzed and the catalyzed reactions are first order in iodide ion. However, albeit both r_t and r_u increase linearly with the oxidant concentration, r_c is independent of that concentration (Fig. 3). Thus the kinetic orders of hydrogen peroxide are unity in the uncatalyzed reaction and zero in the catalyzed one.

As far as the hydrogen ion concentration is concerned, although the r_u vs. $[H^+]$ plot is linear (intercept different from zero), both the r_t vs. $[H^+]$ and r_c vs. $[H^+]$ plots are curves (Fig. 4). As can be seen in Fig. 5 for two typical sets of experimental conditions, $1/r_c$ increases linearly as increasing $1/[H^+]$. It can then be concluded that there are two distinct pathways involved in the uncatalyzed reaction, one zero order in hydrogen ion and the other first order, whilst the catalyzed reaction has non-definite kinetic order in hydrogen ion.

On the other hand, the values of r_t and r_c corresponding to various molybdate ion concentrations are given in Table 1. We can see that r_c is directly proportional to $[MoO_4^{2-}]$; i.e., the catalyzed reaction is first order as far as the catalyst is concerned.

Hence, the rate law found for the total reaction is:

[3] $$r_t = k_1[I^-][H_2O_2] + k_2[I^-][H_2O_2][H^+] + k_3[I^-][MoO_4^{2-}][H^+]/(a + [H^+])$$

where k_1 and k_2 are the rate constants corresponding to the two pathways involved in the uncatalyzed reaction (zero order and first order in H^+, respectively), and k_3 is the rate constant of the catalyzed reaction. Parameter a can be obtained from the $1/r_c$ vs. $1/[H^+]$ plots given in Fig. 5, its value at 25.0°C being $(1.00 \pm 0.03) \times 10^{-2}$ mol dm^{-3}. The activation parameters (energies, enthalpies, and entropies) associated with the rate constants have been determined from their variation with temperature (Fig. 6) by means of the Arrhenius and Eyring equations, and the results are given in Table 2. It is important to notice that since the total kinetic orders associated with rate constants k_1, k_2, and k_3 (second order, third order, and a non-definite order, respectively) are different, no kinetic nor mechanistic information can be inferred from a comparison of their corresponding activation entropies (21–23).

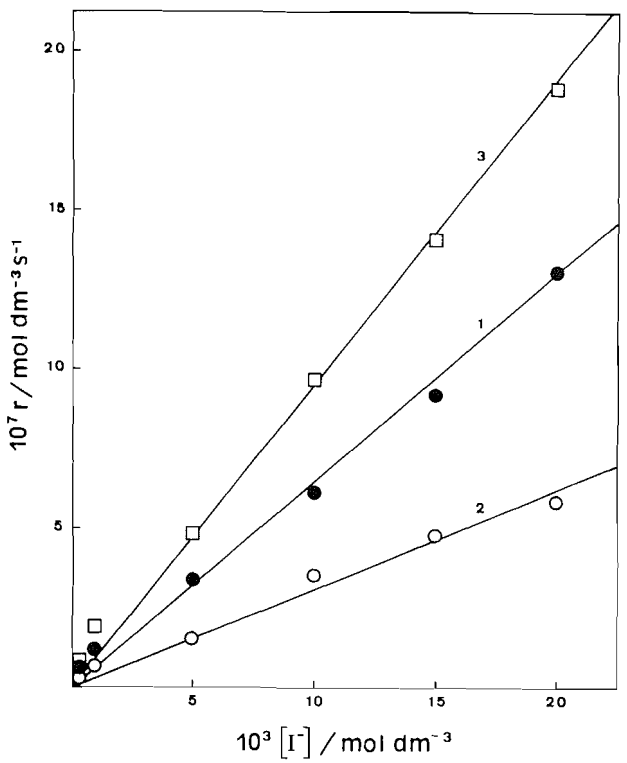

FIG. 2. Dependence of the reaction rates (*1*: r_u; *2*: r_c; *3*: r_t) on the iodide ion concentration. $[H_2O_2] = 5 \times 10^{-3}$ mol dm^{-3}, [Mo(VI)] = 5×10^{-7} mol dm^{-3}, $[H^+] = 5 \times 10^{-3}$ mol dm^{-3}, ionic strength = 0.20 mol dm^{-3} ($NaClO_4$), temperature = 25.0°C.

Discussion

According to the kinetic data obtained in this work, the overall mechanism that can be proposed for the oxidation of iodide ion by the molybdenum(VI) – hydrogen peroxide system is as follows:

[4] $$H_2O_2 + H^+ \overset{K_4}{\rightleftharpoons} H_3O_2^+$$

[5] $$H_2MoO_4 + H_2O_2 \overset{K_5}{\rightleftharpoons} H_2MoO_5 + H_2O$$

[6] $$H_2MoO_5 \overset{K_6}{\rightleftharpoons} HMoO_5^- + H^+$$

[7] $$I^- + H_2O_2 \xrightarrow{k_7} HIO + OH^-$$

[8] $$I^- + H_3O_2 \xrightarrow{k_8} HIO + H_2O$$

[9] $$I^- + H_2MoO_5 + H_2O \xrightarrow{k_9} HIO + H_2MoO_4 + OH^-$$

[10] $$I^- + HIO \xrightarrow{k_{10}} I_2 + OH^-$$

k_1	52±1	50±1	116±3
k_2	49±1	46±1	104±4
k_3	42±3	40±3	68±11

[a]The activation entropies are referred to the 1 mol dm^{-3} standard state.

First, we have considered in reaction [4] the equilibrium of protonation of hydrogen peroxide to enhance its oxidizing power, due to the fact that the electron density of $H_3O_2^+$ is lower than that of H_2O_2; i.e., $H_3O_2^+$ is a better oxidant than H_2O_2. Given the dissociation constants of molybdic acid (24), the predominant form of molybdenum(VI) in the perchloric acid media used in this work was H_2MoO_4. This species reacts reversibly with H_2O_2 in reaction [5] to form H_2Mo0_5; actually, the existence of peroxymolybdic acid, as well as that of other peroxyderivatives of molybdenum(VI), is already known (25, 26). The equilibrium between peroxymolybdic acid and hydrogenperoxymolybdate ion has been depicted in reaction [6].

On the other hand, since there are three rate constants involved in the experimental rate law (eq. [3]), it seems

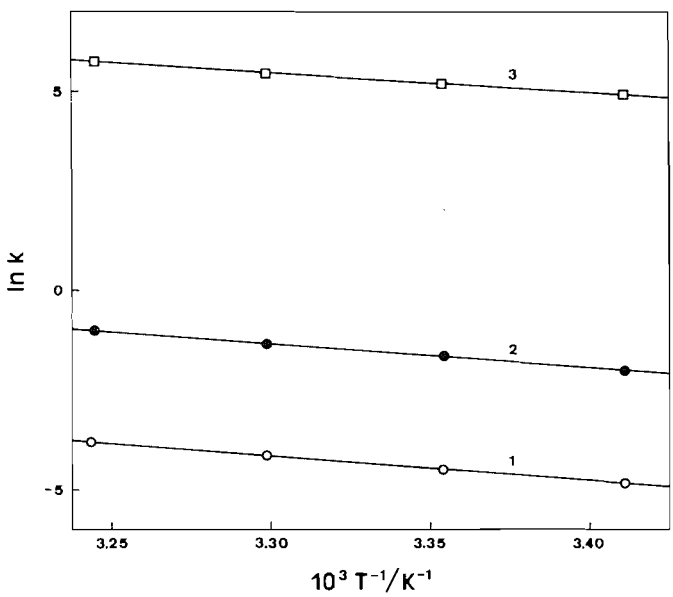

FIG. 6. Dependence of the experimental rate constants (*1*: k_1; *2*: k_2; *3*: k_3) on temperature. $[I^-] = 1 \times 10^{-3}$ mol dm^{-3}, $[H_2O_2] = 5 \times 10^{-3}$ mol dm^{-3}, [Mo(VI)] = 5×10^{-7} mol dm^{-3} (only for plot *3*), $[H^+] = 5 \times 10^{-3}$ mol dm^{-3}, ionic strength = 0.20 mol dm^{-3} ($NaClO_4$).

reasonable to conclude that there are also three active oxidants capable of reacting with iodide ion in rate-determining steps. In the mechanism proposed, these oxidants are H_2O_2, $H_3O_2^+$ and H_2MoO_5. These three species oxidize iodide ion to hypoiodous acid (reactions [7]–[9]). Finally, iodine is formed in reaction [10] by the well-known reaction between iodide ion and hypoiodous acid (8, 27).

It is important to notice that the oxidation of iodide ion by hydrogenperoxymolybdate ion has not been postulated. This is because the electron density of $HMoO_5^-$ is much higher than that of H_2MoO_5. Therefore, $HMoO_5^-$ is a much worse oxidant than H_2MoO_5. Moreover, the nucleophilic attack of I^- on $HMoO_5^-$ is considerably impeded by the fact that they are like-charged ions. It should also be noticed that reaction [9] can perfectly well be an elementary step, for, although it requires the trimolecular encounter of an ion and two molecules, one of the two molecules is the solvent. In this step, reaction [9], the catalyst H_2MoO_4 is recuperated.

The mechanism proposed for the uncatalyzed reaction (reactions [4], [7], [8], and [10]) is consistent with the ones proposed by other authors for the same reaction (5, 7, 27, 28). As far as the catalyzed reaction is concerned, albeit the mechanism given in reactions [5], [6], and [9] differs notably from previous proposals (16, 17), it is in better agreement with the experimental rate law (eq. [3]) found in this work.

Since iodine was selected as the rate-monitoring species, we can write for the total reaction rate:

$$[11] \quad r_t = d[I_2]/dt = k_{10}[I^-][HIO]$$

and, considering that reactions [7]–[9] are rate-determining, for the step given by reaction [10] is very fast (8, 27), the rate of formation of iodine must be given by the total rate of formation of hypoiodous acid through reactions [7]–[9]:

$$[12] \quad r_t = k_7[I^-][H_2O_2] + k_8[I^-][H_3O_2^+] + k_9[I^-][H_2MoO_5]$$

On the other hand, the concentrations of the intermediates $H_3O_2^+$ and H_2MoO_5 can be deduced from the equilibrium laws associated with reactions [4]–[6]:

$$[13] \quad [H_3O_2^+] = K_4[H_2O_2]_T[H^+] / (1 + K_4[H^+])$$

$$[14] \quad [H_2MoO_5] = K_5[H_2O_2][MoO_4^{2-}]_T[H^+] / z$$

z being defined as follows:

$$[15] \quad z = [H^+] + (K_6 + [H^+])K_5[H_2O_2]$$

It should be noticed that $[H_2O_2]_T$ in eq. [13] stands for the total concentration of hydrogen peroxide ($H_2O_2 + H_3O_2^+$) present in the experiments, whereas $[MoO_4^{2-}]_T$ in eq. [14] stands for the total concentration of catalyst ($H_2MoO_4 + H_2MoO_5 + HMoO_5^-$), that is, the initial concentration of sodium molybdate used to prepare the solutions.

Since the concentration of hydrogen ion in the experiments was relatively low, provided that the value of K_4 is low enough and that the value of K_5 is high enough, the following approximations can be applied:

$$[16] \quad K_4[H^+] \ll 1$$

$$[17] \quad [H^+] \ll (K_6 + [H^+])K_5[H_2O_2]$$

These approximations are indeed reasonable, for $H_3O_2^+$ is a very acidic species, since a very low value (2×10^{-5} at 25.0°C) has been reported for K_4 (28). This means that the free form of hydrogen peroxide (H_2O_2) was predominant in the experiments and, therefore, the total concentration of hydrogen peroxide $[H_2O_2]_T$ can also be approximately written in eq. [13] as $[H_2O_2]$. Moreover, it is well-known (25) that molybdenum(VI) is easily peroxidized (i.e., K_5 is very high). From eqs. [13]–[17], and by substituting $[H_2O_2]$ for $[H_2O_2]_T$, we obtain:

$$[18] \quad [H_3O_2^+] = K_4[H_2O_2][H^+]$$

$$[19] \quad [H_2MoO_5] = [MoO_4^{2-}]_T[H^+] / (K_6 + [H^+])$$

Finally, substitution of eqs. [18] and [19] in eq. [12] leads to:

$$[20] \quad r_t = k_7[I^-][H_2O_2] + K_4k_8[I^-][H_2O_2][H^+] + k_9[I^-][MoO_4^{2-}]_T[H^+] / (K_6 + [H^+])$$

We can see that the theoretical rate law (eq. [20]) based on the mechanism proposed is perfectly coherent with the experimental rate law found in this work (eq. [3]). A comparison of both rate laws (theoretical and experimental) leads to the following identities for the experimental rate constants k_1, k_2, and k_3, and the parameter a appearing in eq. [3]: $k_1 = k_7$, $k_2 = K_4k_8$, $k_3 = k_9$, and $a = K_6$. Hence the activation parameters given in Table 2 for the experimental rate constants k_1 and k_3 are actually the ones corresponding to the oxidations of iodide ion by hydrogen peroxide (eq. [7]) and peroxymolybdic acid (eq. [9]), respectively, whereas the activation parameters given in Table 2 for the experimental rate constant k_2 have only an apparent character, since they are actually combinations of the activation parameters corresponding to the oxidation of iodide ion by $H_3O_2^+$ (reaction [8]) and the thermodynamic parameters corresponding to the protonation of hydrogen peroxide (reaction [4]). We can also see in Table 2 that the true activation energy found for the I^-–H_2MoO_5 reaction (42 ± 3 kJ mol^{-1}) is considerably lower than both the true activation energy for the I^-–H_2O_2 reaction (52 ± 1 kJ mol^{-1}) and the apparent activation energy for the I^-–$H_3O_2^+$ reaction (49 ± 1 kJ mol^{-1}). It can then be concluded that the actual role of molybdenum(VI) as a catalyst of the reaction is to decrease the energetic barrier associated with the oxidation of iodide ion.

TAKU NAKANO, TEDDY G. TRAYLOR, and DAVID DOLPHIN. Can. J. Chem. **68**, 1504 (1990).

During the epoxidation of ethylene using iron *meso*-tetrakis(2,6-dichlorophenyl)porphyrin chloride and iodosopentafluorobenzene several *N*-alkylporphyrins were formed. The major product was 21-carboxymethyl-5,10,15,20-tetrakis(2,6-dichlorophenyl)porphyrin. This was derived, by oxidation, from the corresponding 21-formylmethyl complex which in turn was obtained from the initially formed *N*-hydroxyethylporphyrin, a compound not isolated due to its ready oxidation.

Key words: *N*-alkylporphyrins, suicide labelling, cytochrome P-450, hemin catalysis, epoxidation, oxidation.

TAKU NAKANO, TEDDY G. TRAYLOR et DAVID DOLPHIN. Can. J. Chem. **68**, 1504 (1990).

Lors de l'époxydation de l'éthylène à l'aide de la *méso*-tétrakis(2,6-dichlorophényl)porphyrine et de l'iodosopentafluorobenzène, il se forme plusieurs *N*-alkylporphyrines. Le produit principal est la 21-carboxyméthyl-5,10,15,20-tétrakis(2,6-dichlorophényl)porphyrine. Ce produit est formé par oxydation du complexe 21-formylméthyle correspondant qui est lui-même obtenu à partir de la *N*-hydroxyéthylporphyrine qui se forme initialement, mais qui n'a pas été isolée à cause de son oxydation très facile.

Mots clés : *N*-alkylporphyrines, marquage suicide, cytochrome P-450, catalyse héminique, époxydation, oxydation.

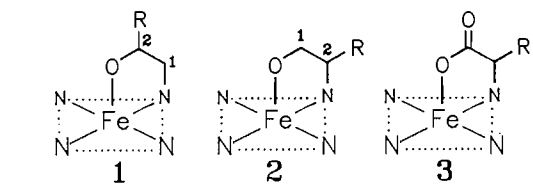
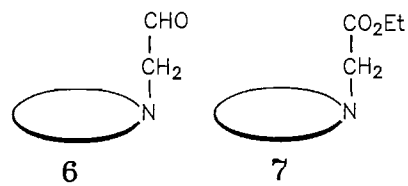
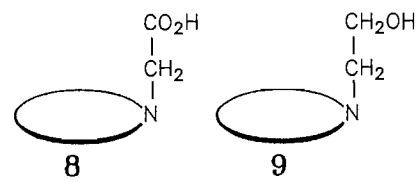
Introduction

Suicide inactivation during the metabolism of alkenes and alkynes results in *N*-alkylation of the heme prosthetic group of cytochromes P-450 (1). These reactions have been mimicked using simple iron tetraphenylporphyrins (2, 3) and the roles of σ-iron alkylporphyrins, their interconvertability to *N*-alkylporphyrins (4), their roles in nature (5), and as models for cytochrome P-450 (6) have been reviewed.

Normally, alkylation of a terminal alkene results in *N*-alkylation at the less substituted terminal C-atom (**1**). However, Mansuy and co-workers (7) have shown that the *N*-alkylation of iron *meso*-tetrakis(*p*-chlorophenyl)porphyrin by several terminal alkenes resulted in substitution, **2**, at the more substituted carbon atom (C-2). These reactions were complicated by apparent subsequent oxidation of the alcohol to the corresponding carboxylic acid (**2** → **3**). If oxidation occurs before or during alkylation then the observation of substitution at C-2 could be more complicated than had been suggested.







N = *meso*-Tetrakis(2,6-dichlorophenyl)porphyrin

5

Results and discussion

To understand and further explore the *N*-alkylation process we have studied the catalysis of epoxidation of the simplest alkene, ethylene. In a typical experiment iron *meso*-tetrakis(2,6-dichlorophenyl)porphyrin chloride (**4**) (8) in CH_2Cl_2 was cooled in a CCl_4 – dry ice bath and the solution saturated with ethylene. Excess iodosopentafluorobenzene was added and the reaction mixture allowed to warm to room temperature. After addition of further iodosopentafluorobenzene and standing for 1.5 h the original brown solution had turned greenish brown with a broad Soret band at 433 nm and additional broad peaks at 355, 565, and 643 nm. Demetallation ($FeCl_2$/HCl/CH_3CO_2H) followed by chromatography (silica gel) gave several fractions with identical optical spectra (Fig. 1). Elution with CH_2Cl_2 gave *meso*-tetrakis(2,6-dichlorophenyl)porphyrin (**5**) (8) followed by 21-formylmethyl-5,10,15,20-tetrakis(2,6-dichlorophenyl)-porphyrin (**6**) and then 21-ethoxycarbonylmethyl-5,10,15,20-tetrakis(2,6-dichlorophenyl)porphyrin (**7**).[1] Continued elution with CH_2Cl_2/acetone (9:1) gave 21-carboxymethyl-5,10,15,20-tetrakis(2,6-dichlorophenyl)porphyrin (**8**).

The optical spectra (Fig. 1) of all the *N*-alkylporphyrins are

[1] Ethanol for this esterification came from the $FeCl_2$ reduction of the ethylene oxide which was the principal product in the reaction.

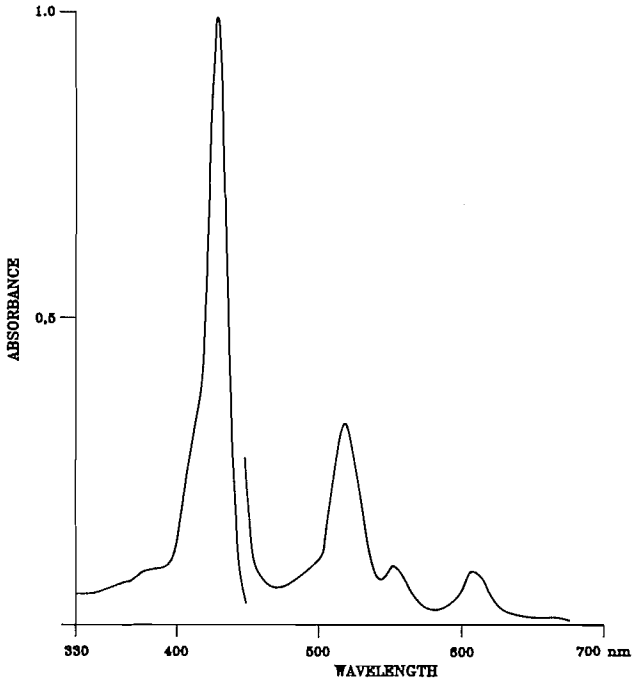


FIG. 1. Optical spectrum (CH_2Cl_2) of the *N*-alkylporphyrins **6–8**.

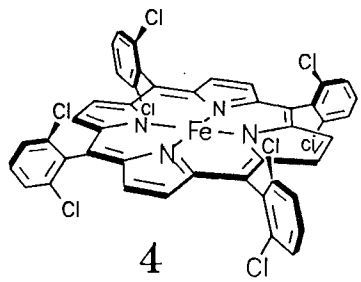


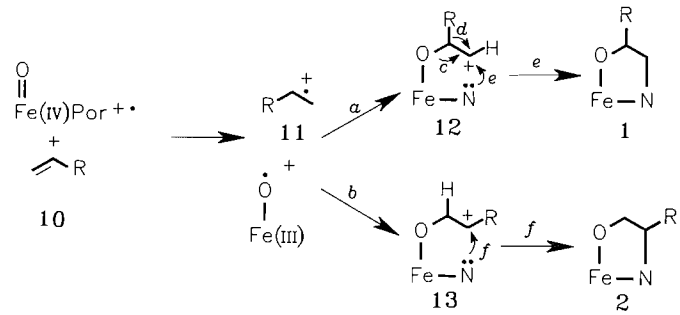
similar to those previously reported for the *N*-alkylation with 4,4-dimethyl-1-pentene (2). Traces of other *N*-alkylated species with similar optical spectra were not further characterized.

Remetallation of **6** followed by treatment with C_6F_5IO in CH_2Cl_2 gave **8** (after demetallation), showing that oxidation of the *N*-formylmethyl to the *N*-carboxymethyl group readily occurs under the reaction conditions for *N*-alkylation.

We presume that the absence of the *N*-hydroxyethylhemin (**9**) results from its rapid oxidation to carboxaldehyde and then to the carboxylic acid. Preliminary experiments on the epoxidation of 1-hexene using **4** and even more electron deficient porphyrins chlorinated on the β-positions of the porphyrin itself (9) show that these less basic porphyrins exhibit less of a tendency towards alkylation. We have proposed that the first step in alkene epoxidation (and *N*-alkylation) is a one-electron transfer from the olefin to the hemin (8). Since ethylene has a higher oxidation potential than other homologous alkenes the rate of formation of the *N*-hydroxyethyl complex with the less basic porphyrin could well be slower than its oxidation to the carboxaldehyde.

The observation that oxidation can occur after *N*-alkylation suggests that Mansuy's observation (3) of *N*-alkylation at C-2 of the alkene occurred independently of its oxidation to the *N*-carboxyalkyl complex (**3**). In fact, our initial proposal of a common intermediate for both epoxidation, *N*-alkylation, and substrate rearrangement can account for *N*-alkylation at both C-1 and C-2 of a terminal alkene.

The scheme shows formation of an olefin π-cation radical (**11**) via a one-electron oxidation of the olefin by the oxoferryl [Fe(IV)] porphyrin π-cation radical (**10**). Radical dimerization via route *a* could give a "primary carbonium ion" (**12**).[2] This common intermediate could then give epoxide (route *c*), product rearrangement (route *d*) and *N*-alkylation at C-1 (route *e*) while radical dimerization via route *b* would give the more stable "secondary carbonium ion" (**13**) which upon *N*-alkylation would give the alkylation at C-2 (route *f*) observed by Mansuy (3).



Experimental

Iron *meso*-tetrakis(2,6-dichlorophenyl)porphyrin chloride (**4**) (46 mg) in CH_2Cl_2 (40 mL) was placed in a 100 mL three-necked flask fitted with an ethylene-gas-bubbler and spinning bar. The solution was cooled in a CCl_4 – dry ice bath and ethylene was passed into the solution until saturation. Iodosylpentafluorobenzene (148 mg) was added and the solution stirred as a steady stream of ethylene was passed through the solution. The reaction mixture was then allowed to warm to room temperature and stirring continued until the optical spectrum showed no further formation of *N*-alkyl hemin (~1.5 h). At this time the original brown solution had changed to a green brown color with a broad Soret band at 433 nm and broad peaks at 355, 565, and 643 nm.

The mixture was taken to dryness on a rotatory evaporator and the *N*-alkylhemin was demetallated by treatment under N_2 with $FeCl_2$ (1 g) in concentrated HCl (2 mL) and acetic acid (38 mL). The solution immediately turned green. After 2 h, CH_2Cl_2 (50 mL) was added and air was passed through the mixture for a few minutes. Water (40 mL) was added and the separated organic layer was washed with aliquots of water (15 mL) until neutral. The organic layer was dried over anhydrous Na_2SO_4, filtered, and the filtrate chromatographed over silica gel to afford several fractions with identical optical spectra. Elution with CH_2Cl_2 gave *meso*-tetrakis(2,6-dichlorophenyl)porphyrin (**5**) (25 mg, 53%) and 21-formylmethyl-5,10,15,20-tetrakis(2,6-dichlorophenyl)porphyrin (**6**) (3.4 mg, 7.4%) and 21-ethoxycarbonylmethyl-5,10,15,20-tetrakis(2,6-dichlorophenyl)porphyrin (**7**) (0.9 mg, 2%). Continued elution with CH_2Cl_2:acetone (9:1, v:v) gave 21-carboxymethyl-5,10,15,20-tetrakis(2,6-dichlorophenyl)porphyrin (**8**) (6.8 mg, 14.8%).

The same products were obtained as above when (*i*) the ethylene was scrubbed by passing it through alkaline mercuric cyanide to remove any contaminating acetylene and (*ii*) the reaction was carried out under pressure in a stainless steel pressure tube.

21-Formylmethyl-5,10,15,20-tetrakis(2,6-dichlorophenyl)porphyrin (6)

An analytical sample was recrystallized from CH_2Cl_2. *Anal.* calcd. for $C_{46}Cl_8H_{24}N_4O$: C 59.26, H 2.59, N 6.01; found: C 59.18, H 2.54, N 5.99. ^1H NMR ($CDCl_3$, 270 MHz) δ −3.26 (s, 2H, N-CH_2CHO), −2.15 (s, 1H, N—*H*), 6.84 (s, 1H, N—CH_2CHO), 8.00 (s, 2H, pyrr. *a*, *b*), 8.38 (q, AB-system, J = 4.88 Hz, 4H, pyrr. *c*, *d*, *g*, *h*), 8.69 (d pyrr. *e*, *f*), 7.65–7.86 (c, 12H, ph). Excited state dipole moments and polarizabilities of some aromatic alkenes and alkynes

HEMANT K. SINHA, PAUL C. P. THOMSON, AND KEITH YATES
Department of Chemistry, Lash Miller Chemical Laboratories, University of Toronto, Ont., Canada M5S 1A1
Received February 14, 1990

HEMANT K. SINHA, PAUL C. P. THOMSON, and KEITH YATES. Can. J. Chem. **68**, 1507 (1990).

Electric field induced changes in the optical absorption spectra (electrochromism) have been used to obtain the excited state dipole moments and polarizabilities of styrene, 2-vinylnaphthalene, 2-naphthylacetylene, and 9-vinylanthracene. Excited state dipole moments of the order of 4–6 debye have been obtained for all these molecules except for 9-vinylanthracene, for which the excited state dipole moment is zero within experimental error. These results support earlier proposals of the involvement of charge transfer excited states in the fast and efficient acid-catalysed photohydration reactions of this type of substrate. 9-Vinylanthracene, on the other hand, under similar conditions reacts differently to give a dimer as the major photoproduct, and its reaction is not subject to acid catalysis. These results shed light on the importance of charge transfer excited states on the efficiency of photohydration reactions.

Key words: electrochromism, excited state, dipole moments, polarizabilities.

HEMANT K. SINHA, PAUL C. P. THOMSON et KEITH YATES. Can. J. Chem. **68**, 1507 (1990).

On a utilisé les changements induits par les champs électriques sur les spectres d'absorption optique (électrochromisme) pour obtenir les moments dipolaires ainsi que les polarisabilités des états excités du styrène, du 2-vinylnaphtalène, du 2-naphtylacétylène et du 9-vinylanthracène. Pour toutes les molécules étudiées, excepté le 9-vinylanthracène, on a obtenu des moments dipolaires des états excités qui étaient de l'ordre de 4 à 6 debye; dans le cas exceptionnel, le moment dipolaire de l'état excité est égal à zéro, dans les limites des erreurs expérimentales. Ces résultats supportent les propositions qui avaient été formulées antérieurement concernant l'implication des états excités du transfert de charge dans les réactions rapides et efficaces de photohydratation, catalysées par les acides, de ce type de substrat. Le 9-vinylanthracène, soumis aux mêmes conditions expérimentales, réagit toutefois différemment et conduit à la formation prépondérante d'un dimère comme photoproduit et cette réaction n'est pas catalysée par les acides. Ces résultats mettent en relief l'importance des états excités des transferts de charge sur l'efficacité des réactions de photohydratation.

Mots clés : électrochromisme, état excité, moments dipolaires, polarisabilités.

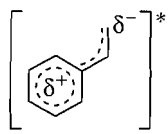
Introduction

Electrochromism (electric field induced change in the extinction coefficient) is probably the best known method for direct detection of the charge distribution in molecules in both their ground and excited states. Initially developed by Labhart, Czekalla, and Liptay, this method has been successfully used to obtain the ground and excited state electrical properties, such as dipole moments and polarizabilities, of both polar and nonpolar molecules (1–8).

For polar molecules, the ground state dipole moment of the molecule and the change in dipole moment on electronic excitation are the principal components that contribute to the electric field perturbation of the absorption spectrum. On the other hand, for nonpolar molecules it is the change in the induced dipole moment that contributes most to the electric field perturbation, and this is reflected in a change in the polarizability upon electronic excitation. Recent investigations by Liptay and co-workers (7) and Ponder and Mathies (8) have indicated that conjugated polyenes undergo large changes in polarizability upon electronic excitation, and the solution phase and gas phase polarizabilities of polyenes are very different. Excited state dipole moments of the order of 1–4 debye obtained for some symmetric polyenes have been explained as a result of symmetry breaking perturbations, either due to single bond rotation or inhomogeneous local solvent interactions. Several other experiments on aromatic systems have been carried out to evaluate the accuracy of various theoretical approximations involved in quantum mechanical calculations (9).

In this paper, we deal with the results of electrochromic measurements from a different viewpoint, namely to find support for the proposed mechanistic features of photohydration reactions. Recently, it has been observed that aromatic alkenes, alkynes, and allenes, on electronic excitation, can be directly protonated in neutral water or in dilute aqueous sulphuric acid solution, to produce appropriate carbocation intermediates (10–13), which lead efficiently to photohydration products. These reactions are catalysed by H_3O^+ as well as by general acids and are very fast in comparison to the corresponding ground state reactions (14). To explain the mechanistic features of these reactions, it has been proposed that a strongly polar excited state S_1 may be responsible for these fast excited state protonation reactions, as illustrated in structure **I**.



I

We believe that a high degree of charge transfer in the singlet excited states of these normally nonpolar molecules is the driving force for fast protonation reactions. Since electrochromism is the best method for direct detection of the difference in the charge distributions between the ground and excited states, it should be a valuable tool to probe the excited state charge transfer characteristics of those molecules which undergo efficient photohydration reactions. In turn this should shed light on the mechanism of photohydration reactions.

Theory

Liptay and Czekalla (1, 2) and Labhart (3) were the first to provide the necessary theoretical expression describing the changes in the optical absorption due to the application of a strong external electric field. According to them, the field induced change in the molar extinction coefficient ($\Delta\epsilon$) is given

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

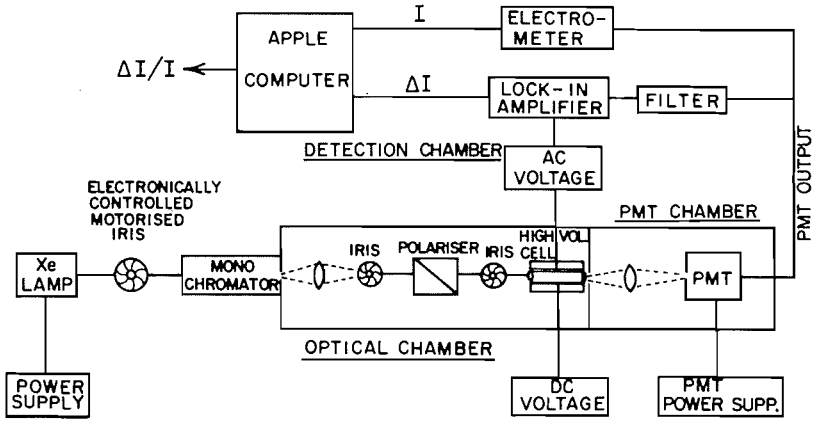


FIG. 1. Block diagram of electric field spectrometer.

by

$$[1]\quad \Delta\epsilon = F_{\text{int}}^2\epsilon\left[A_\chi + B_\chi/15h\frac{d/d\nu(\epsilon/\nu)}{(\epsilon/\nu)} + C_\chi/30h^2\frac{d^2/d\nu^2(\epsilon/\nu)}{(\epsilon/\nu)}\right]$$

where

$$[2]\quad A_\chi = 1/30(3\cos^2\chi - 1)\beta^2[3(\hat{m}\cdot\mu_g)^2 - \mu_g^2] + 3\beta(\alpha_{gm} - \bar{\alpha}_g)$$

$$[3]\quad B_\chi = 5\beta(\mu_g\cdot\Delta\mu) + 15/2\Delta\bar{\alpha} + (3\cos^2\chi - 1)\beta[3(\hat{m}\cdot\mu_g)(\hat{m}\cdot\Delta\mu) - (\mu_g\cdot\Delta\mu)] + 3/2(\Delta\alpha_m - \Delta\bar{\alpha})$$

$$[4]\quad C_\chi = 5\Delta\mu^2 + (3\cos^2\chi - 1)[3(\hat{m}\cdot\Delta\mu)^2 - \Delta\mu^2]$$

In the above equations F_{int} is the corrected electric field at the location of the molecule in solution, μ_g and α_g are the ground state dipole moment and polarizability, $\Delta\mu$ and $\Delta\alpha$ are the change in the dipole moment and polarizability upon electronic excitation, $\hat{m}$ is a unit vector in the direction of the transition moment, and χ is the angle between the electric field and polarization direction of the exciting light.

The formulation of eq. [1] is basically attributable to two effects, the orientation effect and the band shift effect. The orientation effect results from the anisotropic distribution of molecular orientation induced by the applied field. Therefore a polar molecule will tend to align its dipole moment with the field, and a nonpolar molecule whose ground state polarizability is anisotropic will tend to align the axis of greatest polarizability with the field. These effects are reflected in A_χ. The band shift effect will occur due to the interaction of the electric field with the electronic energy levels of a molecule. This interaction results in the change in the energy of the electronic transition if the ground state dipole moment and the polarizability are different from those in the excited state. Therefore the magnitude of the band shift effect is proportional to the change in the dipole moment and polarizability upon electronic excitation to the excited states. These effects are manifested in B_χ and C_χ.

Experimental

The complete setup of the electric field spectrometer designed in our laboratory can be divided into three chambers: optical chamber, pmt chamber, and detection chamber (see Fig. 1). Light from a 1000-W Xe lamp was collimated using a Kratos lamp housing and then passed through a water (or solvent) filter to prevent overheating of the monochromator (Kratos GM252) entrance lens/slit, and then through a motorized iris diaphragm (see Discussion later) before being dispersed by the grating. The monochromatic light is then further collimated onto a Glan–Thompson polarizing prism fitted with an iris diaphragm. The polarizer was mounted on a 360° rotable mount (Optikon) for accurately determining the angle of polarization. Polarized light is then allowed to fall on the quartz window of the high voltage cell (see Discussion later) of 10 cm path length before impinging on the photomultiplier tube (pmt) (Thorn Emi 9906B). The pmt was provided with a mu-metal shield to protect the tube from the background magnetic and electric fields from the field generating apparatus. As shown in Fig. 1, the optical chamber section just after the monochromator was enclosed in a light-tight housing made from aluminium sheet. The exit window of the cell was pressed against the opening of the aluminium sheet that separates the optical and pmt chambers, with the help of a Teflon ring. Since the quartz window and the opening of the aluminium sheet have the same dimensions, only light that travels through the sample cell will be collected by the pmt in the pmt chamber. This arrangement avoids stray light detection by the pmt.

The detection chamber mainly comprises electronic components. Figure 2 shows the block diagram of the electronics used in the construction. The ac field generating apparatus consists of an audio oscillator that supplies a 500-Hz sine wave to an audio amplifier. This amplifies the signal and then drives a step-up transformer to obtain the final ac potential applied to the cell (24 kV ptp). This potential was dropped across a voltage divider to provide a reference signal (1 V rms) for the lock-in amplifier and to give a 1-μV test signal. The dc power supply was also custom-built and can provide a variable dc potential ranging from 10 to 30 kV.

The output of the pmt was fed into a lock-in amplifier (PAR 128) tuned to ω (500 Hz) and an electrometer (Keithly 172). A custom-built additional filter tuned to ω was very helpful in reducing the noise level, and allowing work in the very sensitive region of the lock-in amplifier. The pmt output voltage was controlled by a negative feedback unit to maintain a particular voltage (light intensity) during the data collection at each wavelength. Since the light intensity varies considerably (20:1) across the full wavelength region (230–700 nm), some method of attenuation was required to maintain constant light intensity. The negative feedback unit controls the light level passing through the cell in two ways. A small degree of attenuation could be effected by varying the power to the lamp, but for higher attenuation a motorized iris was utilized. The output from the lock-in amplifier (ΔI) and the electrometer (I) are then digitized by an A/D converter, ratioed, and stored in an Apple IIe computer for further calculation.

Details of the cell used in this experiment are shown in Fig. 3. The cell body consisted of a Teflon tube fitted with two polished, hemicylindrical hollow stainless-steel electrodes, leaving a gap of 5.2 ± 0.1 mm between the parallel faces. Oil was circulated through the hollow cell to maintain constant temperature. Threaded plastic rings were used to hold the quartz window in place. Since high voltages of the order of 10–40 kV were to be used, 15-cm Teflon rings were

attached at each end as a safety precaution, and also to prevent the possibility of arc-over. The solution was circulated continuously from a reservoir to the cell by a micropump, to avoid any significant photochemical decomposition of the compound due to prolonged exposure to light.

Since the ac voltage was applied with a dc bias, the total field strength is given by $F_{ext} = \sqrt{2F_{ac}F_{dc}}$. The external electric field F_{ext} was converted to internal electric field F_{int} by taking into account the spherical cavity approximation, which is given by

$$F_{int} = F_{ext}\frac{3\xi}{2\xi + 1}$$

where ξ is the dielectric constant of the solvent used. The change in the molar extinction coefficient $\Delta\epsilon$ was obtained from the equation

$$\Delta\epsilon = -1/2.303cl\frac{I_F - I_{F=0}}{I_{F=0}}$$

where I_F and $I_{F=0}$ are the transmitted light intensities with and without the applied electric field, c is the concentration of the solute, and l is the pathlength of the cell. The data points were collected at two or three different angles χ. For each data point, depending on the signal strength, 5000–10 000 counts were taken over a period of 5–15 min and averaged. The derivative terms in eq. [1] were computed from a digitized absorption spectrum. The values of $\Delta\epsilon$ obtained from the electric field experiment were then least-squares fitted to zero, first, and second derivative terms to obtain A_χ, B_χ, and C_χ, and then the molecular parameters were calculated by using eqs. [2]–[4]. *p*-Nitroaniline (PNA) and *N,N*-dimethyl-*p*-nitroaniline (DMPNA) were subjected to electric field study as test samples to determine the accuracy of our instrument, since these molecules have already been studied by Liptay (4). The close agreement between the present and reported results (Table 1) indicates that the signals obtained from our instrument are not due to any experimental artifacts.

[b]Results obtained from this work.
[c]Results reported by Liptay (4).

Styrene (STY), 2-vinylnapththalene (VN), and 9-vinylanthracene (VA) were obtained from Aldrich chemicals and recrystallized from appropriate solvents. 2-Naphthylacetylene (NA) was synthesized by the earlier reported method (15) and purified by vacuum sublimation. Spectrograde dioxane from Aldrich chemicals was used as solvent, without further purification.

Results

The electric field spectra of STY, VN, NA, and VA are shown in Fig. 4. The discrete points are the values of $\Delta\epsilon$ obtained

from the electric field experiment. The solid lines are the theoretical curves obtained by a stepwise multiple linear regression fit of the experimental points to eq. [1]. The excellent fit between the experimental data points and theoretical curve indicates that the experimental results are accurately described by eq. [1].

If the molecule has the symmetry of the C_{2v} point group, as in the case of PNA and DMPNA, the calculation of the individual molecular parameters contained in eqs. [2]–[4] becomes simpler because of the definite directions of the dipole moment and transition moment vectors. Since the hydrocarbon molecules investigated here do not belong to the C_{2v} point group, some simplification of eqs. [2]–[4] is required to obtain the molecular parameters from A_χ, B_χ, and C_χ. In our derivation the ground state dipole moments of all these molecules have been assumed to be zero. This assumption is supported by the fact that the reported dipole moment μ_g of STY is close to zero (0–0.13 *D*) (16) and μ_g has been found to be zero or close to zero for various polyenes studied by Liptay *et al.* (17) and Ponder and Mathies (8). Molecular orbital calculations also show that the ground state dipole moments of these molecules are indeed very small.[1] Moreover, this assumption will not introduce any serious errors in the calculation of the change in the dipole moment upon electronic excitation ($\Delta\mu$), which is obtained from C_χ term.

Our experiments yield nonzero values of C_χ for all these molecules except for VA. These large values of C_χ, which give a measure of $\Delta\mu$ of the order of 4–6 debye, indicate that these molecules are quite polar in their Franck–Condon (FC) excited states. However, $\Delta\mu$ was found to be close to zero for VA, within experimental error. The values of $\hat{m}\cdot\Delta\mu$ were calculated by assuming that $\hat{m}$ and $\Delta\mu$ are parallel, which is reasonable for these molecules. The close agreement between the values of $\hat{m}\cdot\Delta\mu$ and $\Delta\mu$ indicate that the change in the dipole moment and transition moment directions are indeed nearly parallel. Setting $\mu_g = 0$, values of $\Delta\tilde{\alpha}$ and $\Delta\alpha_m$ can be calculated from B_χ and the values of $\alpha_{gm} - \tilde{\alpha}_g$ can be obtained from A_χ. All the molecular parameters are compiled in Table 2. The argument that the difference between the change in dipole moments for benzene or naphthalene and anthracene derivatives could be due to a change in the nature of their lowest electronic state can be ruled out on the basis of following points. For example, in benzene and naphthalene derivatives the lowest electronic states are of ^1L_b character, which is polarized along the long molecular axis, and in anthracene derivatives they are of ^1L_a character, polarized along the short molecular axis. In the case of STY, VN, and NA, since the substituents (vinyl group) are present along the

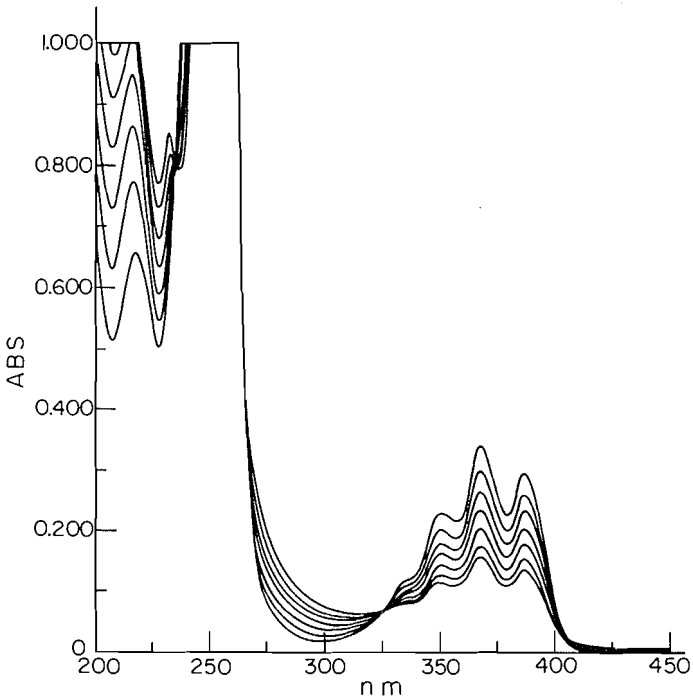

FIG. 5. Absorption changes of VA in acetonitrile on irradiation with 254-nm light. The irradiation was carried out on a Rayonet RPR-100 reactor. The time of irradiation was increased by 5 min from top trace to bottom trace.

long molecular axis, any change in the charge distribution on electronic excitation involving the substituents will be reflected in their ^1L_b type transition. On the other hand, since in VA the substituent is present along the short axis, any change will be more pronounced in its ^1L_a type transition. The fact that there is no change in the dipole moment of VA on electronic excitation could be due to the lack of coplanarity of the vinyl group and the anthracene ring in the ground state because of steric reasons. In fact, the angle between the vinyl group and anthracene ring in the ground state was calculated to be 60° ± 10° from molecular polarizability work (19). This is also manifested by the fact that the absorption spectrum of VA maintains a strong resemblance to that of the parent anthracene. Based on the results of this electric field study one would predict that VA may not undergo any appreciable photohydration reaction.

Figure 5 shows the change in the uv/vis absorption spectra of VA in pure acetonitrile (degassed with argon) upon irradiation with 254-nm uv light. Similar changes were observed when acetonitrile/water in 50% v/v was used as solvent. The major photoproduct obtained in both solvent systems is the same and was identified as a dimer resulting from intermolecular addition across the 9,10 positions of the anthracene moiety. This reaction of VA is completely different from that other aromatic alkenes/alkynes studied here. For example, STY, NA, and VN do not react in pure acetonitrile solvent to any appreciable extent, and in aqueous solution give exclusive and efficient photoaddition of water (10–15).

Discussion

In the case of polar aromatic molecules containing a donor and an acceptor group, a large change in the dipole moment upon electronic excitation is often detectable, which reflects the redistribution of electronic charges in the electronically excited state. However, this is the first time that large changes in the dipole moment have been detected in simple aromatic hydrocarbons containing an alkyne or alkene moiety as a side chain (Table 2). Though the concept of sudden polarization is well documented in the literature from both an experimental and theoretical point of view (20), this process is generally associated with a twisting of a central bond, thereby localizing the charge separation. Furthermore, changes in the dipole moment of the order of 1–3 debye for centrosymmetric polyenes, as observed by Ponder and Mathies (8), have again been attributed to the symmetry-breaking phenomena due to single bond rotations. In our experiments, since we are dealing with the FC excited states, it is very evident that in these molecules electronic excitation and charge separation are concurrent processes. These molecules behave more like electron donor–acceptor systems, where the aromatic ring acts as an electron donor and the alkene or alkyne moiety acts as an electron acceptor.

In the excited state, these molecules (VN, NA, and STY) are approximately 10^{11}–10^{13} times more reactive towards protonation than the corresponding ground states (10–15). This rate effect has been found to increase further on substituting electron donor groups on the aromatic ring, which is expected to further facilitate the charge transfer process. In the proposed mechanism of photohydration reactions, Wan and Yates (10) pointed out that the S_1 states (thermally relaxed first excited singlet states) probably possess a high degree of charge transfer, as shown by structure **I** for the styrene. This has also been postulated by a number of previous workers in their studies of the photoprotonation of aromatic alkenes and cycloalkenes (21, 22). Since alkenes and alkynes are generally known to undergo stabilizing twisting or bending motions upon electronic excitation (23–26), these molecules probably have a twisted or bent relaxed structure in the S_1 state. We believe that charge separation in the FC excited state is the driving force for the twisting or bending in these alkenes and alkynes, hence providing strong solvent stabilization due to the effective interaction between the solvent dipoles and the localized positive and negative charges on the solute. Twisting and the localization of charges would be further helpful in the efficient photoprotonation reaction, since the carbon being protonated is effectively rehybridized before proton transfer takes place. A change in the dipole moment of the order of 4–5 debye in VN and NA amounts to approximately 20% displacement of charges, if the centers of gravity of positive and negative charges are localized at the center of the naphthalene ring and β carbon atom respectively.

The changes in the polarizability upon electronic excitation in case of VN (31 Å^3) and NA (37 Å^3) are far larger than that observed for the parent naphthalene (1.4 Å^3) (9). These large excited state polarizabilities could create a large reaction field in the solution phase, which could explain the observed large excited state dipole moment of these simple hydrocarbon molecules. The value of $\Delta\alpha_m$ for VN and NA, which is nearly twice the value of $\Delta\bar{\alpha}$, suggests that the excited state polarizability is highly anisotropic and that the major change in the polarizability takes place along the direction of transition moment. Since the long wavelength transitions in 2-substituted naphthalenes, such as VN and NA, are known to be polarized along the long axis (29), from the values obtained for $\hat{m}\cdot\Delta\mu$ and $\Delta\alpha_m$ it can be concluded that the electronic transition directly affects the charge distribution around the alkene or alkyne moiety.

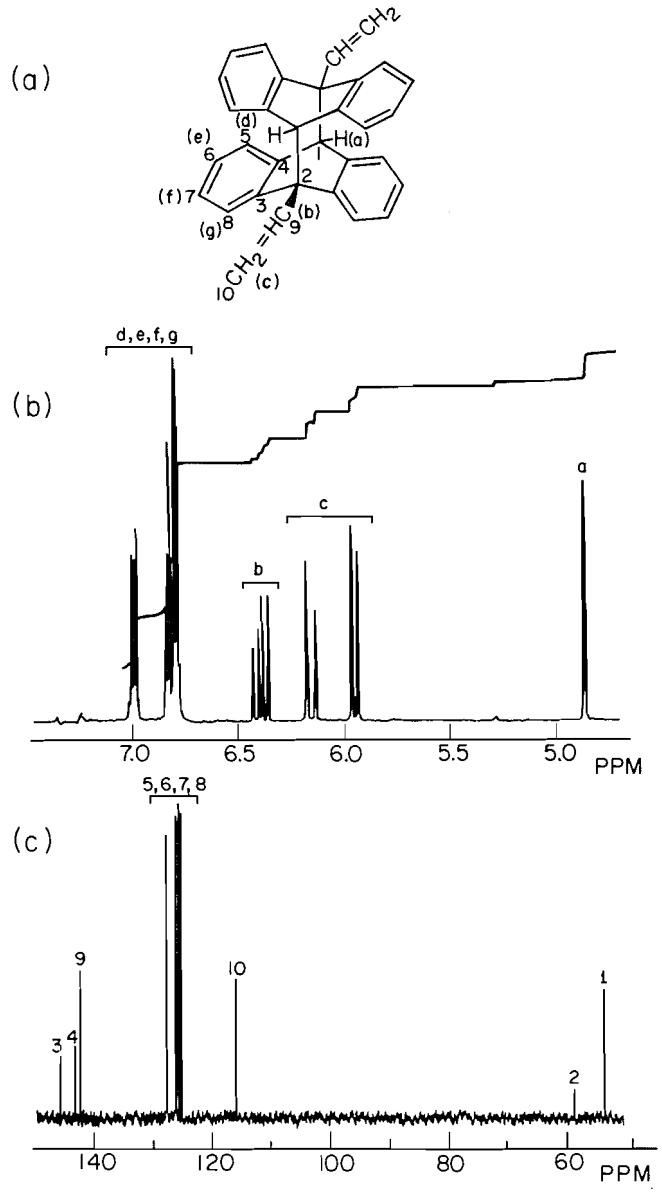

FIG. 6. Molecular structure of the dimer of (a) VA; (b) ^{1}H nmr chemical shifts; (c) ^{13}C nmr chemical shifts.

The study of the photophysics and photochemistry of VA suggests that, for aromatic alkenes and alkynes, other reaction pathways dominate, if significant charge separation in the excited state cannot take place. Since for VA the change in the dipole moment on electronic excitation is zero, which is indicative of no charge separation, the dominant photochemical reaction involves only the anthracene moiety and gives a photodimerization product leaving the alkene moiety intact. As mentioned earlier, the unreactive nature of the vinyl group in VA could be due to the lack of coplanarity between the anthracene ring and vinyl group in the ground state, and hence in the FC excited state, which leads to little or no conjugation or charge transfer. From this study it is quite clear that planarity of the initially excited system is required to bring about efficient charge separation in the excited states of these types of molecules. The type of photodimerization found for VA has been reported for a number of meso-substituted anthracenes in the litarature (27, 28). From this study it appears that photohydration is not necessarily a general reaction for all alkenes and alkynes. The change in the polarizability of VA on electronic excitation closely resembles that of anthracene itself (17 Å^3). This further supports the ineffective nature of the alkene moiety towards charge reorganization in VA.

The complete characterization of the dimer from VA was carried out by spectroscopic techniques. Irradiation of a solution (either 50:50 acetonitrile/water or pure acetonitrile) of VA with 254-nm uv light resulted in a white precipitate. A similar precipitate was also observed by Ebeid *et al.* in methanol, but the product was not characterized (30). The anthracene-like absorption (387, 368, 351 nm) completely disappeared in the absorption spectrum of the product, which is as expected because of the loss of conjugation across the whole anthracene system. The ^{13}C and ^{1}H nmr spectra are consistent with the proposed structure of the dimer (see Fig. 6). COSY, ATP, and HECTOR techniques were used to identify the ^{1}H and ^{13}C chemical shifts, which are shown in Fig. 6(b, c). The dimer (mp 178 ± 2°C) does not appear to be stable at high temperature, since it breaks down during the mass spectral analysis to give the monomeric mass (*m/e* 204) as the major peak. However, careful analysis revealed a small peak at *m/e* 408, corresponding to the dimeric mass. Such decompositions of anthracene dimers to give monomer at temperatures greater than 200°C have been reported in the literature (18). The complete details of the structural analysis, along with the X-ray studies, will be published later.

Retinylidene Schiff bases in surfactant-solubilized water pools in heptane

ANIL K. SINGH, CAMILLE SANDORFY, AND JANOS H. FENDLER[1]

Département de chimie, Université de Montréal, C.P. 6128, Succursale A, Montréal (Québec), Canada H3C 3J7

Received January 26, 1990

ANIL K. SINGH, CAMILLE SANDORFY, and JANOS H. FENDLER. Can. J. Chem. **68**, 1514 (1990).

All-*trans*-retinal (**1**) was reacted with *n*-butylamine in sodium bis(2-ethylhexyl)sulfosuccinate (AOT) reverse micelles in heptane to form all-*trans*-*N*-retinylidene–*n*-butylamine Schiff bases (**2**). The extent of protonation of **2** by 3-chloropropionic acid (CPA) to give **3** in AOT reverse micelles in heptane was found to depend on the ratio of [CPA] to [**2**], as well as on $[H_2O]/[AOT]$ (i.e., on the ω value). At any given [**2**] and ω values, increasing amounts of CPA increased the protonation and at any given constant [**2**] and [CPA], increasing ω values also increased the protonation. Over a period of 24 hours, there was only 4% decomposition of **2** in AOT reverse micelles in heptane at $\omega = 24$. Conversely, in three hours, 23% of **3** decomposed in the same system. The *trans* to *cis* photoisomerization of **2** in heptane occurred at a much faster rate in the presence of AOT reverse micelles than in their absence. The appearance of carboxylate peaks (FTIR, 1400–1500 cm^{-1}) indicated that the larger the AOT solubilized water pools, the greater the CPA dissociation. **1** also reacted with the α-NH_2 group of *l*-lysine (**4**) in AOT reverse micelles in heptane to give the corresponding Schiff base **6**. Protonation of **6** occurred either intramolecularly or by reaction with unreacted **4**. These results were discussed in terms of rhodopsin protonations.

Key words: retinylidene Schiff bases, reverse micelles, protonation of Schiff bases, *trans* to *cis* photoisomerization.

ANIL K. SINGH, CAMILLE SANDORFY et JANOS H. FENDLER. Can. J. Chem. **68**, 1514 (1990).

Opérant dans des micelles inversées de bis(2-éthylhexyl)sulfosuccinate de sodium (AOT) dans l'heptane, on a fait réagir le rétinal complètement *trans* (**1**) avec la *n*-butylamine pour obtenir la base de Schiff, *N*-rétinylidène–*n*-butylamine complètement *trans* (**2**). Dans des micelles inversées d'AOT dans l'heptane, on a trouvé que le taux de protonation du produit **2** (conduisant à la formation du produit protoné **3**), par l'acide 3-chloropropanoïque (ACP), dépend des rapports de [ACP]/[**2**] et de $[H_2O]/[AOT]$ (c'est à dire de la valeur ω). À des valeurs données de [**2**] et de ω, une augmentation de la quantité d'ACP provoque une augmentation de la protonation; par ailleurs, à des valeurs constantes de [**2**] et de [ACP], une augmentation des valeurs de ω augmente aussi la protonation. En 24 heures, dans des micelles inversées d'AOT dans l'heptane, à une valeur $\omega = 24$, il ne s'est produit que 4% de décomposition du composé **2**. Par ailleurs, dans le même système, 23% du composé **3** s'est décomposé en trois heures. La photoisomérisation *trans* à *cis* du composé **2** dans l'heptane se produit beaucoup plus rapidement en présence de micelles inversées d'AOT qu'en leur absence. L'apparition de bandes carboxylates (FTIR, 1400–1500 cm^{-1}) indique que plus les masses d'eau solubilisées par l'AOT sont grandes, plus l'ACP est dissocié. Dans des micelles inversées d'AOT dans l'heptane, le composé **1** réagit aussi avec le *l*-lysine (**4**) pour donner le base de Schiff correspondante (**6**). La protonation du composé **6** se fait soit d'une façon intramoléculaire ou par réaction avec du produit **4** qui n'a pas réagit. On discute de ces résultats en fonction des protonations de la rhodopsine.

Mots clés : bases de Schiff rétinylidène, micelles inversées, protonation des bases de Schiff, photoisomérisation *trans* à *cis*.

Rhodopsins (1, 2) belong to a major class of membrane-bound proteins and are involved in light-induced bioenergy transduction. The chromophore of rhodopsins is a retinal (**1**) analogue attached to a lysine residue of the apo-protein via a protonated Schiff base (PSB) linkage (Fig. 1). Both polar and apolar microenvironments surrounding the chromophore in the membrane-bound opsins have been suggested to be responsible for the several striking structural and functional features of rhodopsins (3–9). The role of water molecules near the active site of rhodopsin has also been considered (3, 4).

Retinylidene Schiff bases (SB) have been used extensively as rhodopsin models (9, 10). To clarify important chemical and photochemical properties of rhodopsins, in view of the possible polar, as well as nonpolar, nature of the rhodopsin active site, it is desirable to investigate retinylidene SB in a system that has both polar and nonpolar domains. Reverse micellar systems (11–16) mimic the polar pockets in enzymes well and provide unique microenvironments for substrate solubilization and interactions (11). Specifically, they may model the active site of rhodopsin insofar as micropolarity and acidity can be controlled by changing the amount of water solubilized (i.e., the [water]/[surfactant]: the ω value) (12). A bacteriorhodopsin model is presented here in which all-*trans*-retinal–*n*-butylamine SB has been introduced into reverse-micellar sodium bis(2-ethylhexyl)sulfosuccinate (AOT) in *n*-heptane.

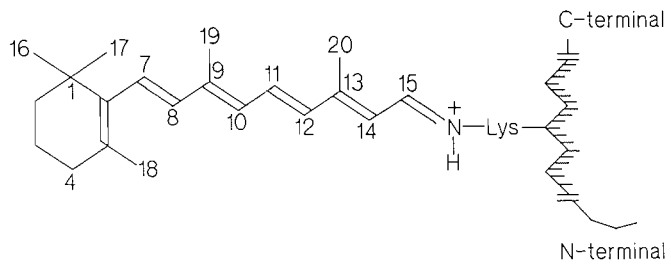

FIG. 1. Retinal attached to lysine via a protonated SB linkage in rhodopsins.

Materials and methods

All-*trans*-retinal, *l*-lysine, and N_α-*tert*-Boc-*l*-lysine were obtained from Sigma Chemical Company, U.S.A. Sodium bis(2-ethylhexyl)-sulfosuccinate (AOT), *n*-butylamine, *n*-heptane (spectrophotometric grade), 3-chloropropionic acid (CPA), trifluoroacetic acid (TFA), and methanesulfonic acid were obtained from Aldrich Chemical Company, U.S.A.

AOT was purified by dissolving in anhydrous, warm (40°C) methanol. The white, milky suspension was centrifuged and the clear supernatant liquid was collected. The methanolic solution was further stirred with activated carbon (Darco G-60 100 mesh) for 3 h. The carbon was separated by filtration and the AOT was recovered by removing the MeOH with a rotary evaporator. The white material was first dried under high vacuum (0.1 Torr; 1 Torr = 133.3 Pa) for 6 h and then over P_2O_5 overnight in an evacuated desiccator. Such purified AOT did not show absorption in the 250–450 nm region. UV–VIS

spectrophotometric measurements were made either on a Hewlett–Packard 8450 A diode array or on a Varian Carey 16 spectrophotometer.

All-trans-N-*retinylidene*–n-*butylamine Schiff base (2)*

All-*trans*-*N*-retinylidene–*n*-butylamine (**2**) was prepared by allowing all-*trans*-retinal (**1**) to react with a 3-mol excess of *n*-butylamine (freshly distilled under N_2) in the presence of a small amount of anhydrous sodium sulfate and a few beads of Linde 4A molecular sieves. The reaction mixture was kept under N_2 at 4°C overnight. The dark brown solution was filtered through a small Büchner filter directly into a Schlenk-type storage vessel in which it was carefully evaporated to dryness using high vacuum. The solid residue was redissolved in anhydrous ether and evaporated twice to assure complete removal of excess *n*-butylamine. The brownish-yellow solid melted at 63–64°C and exhibited a UV–VIS absorption band at 357 nm in *n*-heptane.

Micellization of all-trans-N-*retinylidene*–n-*butylamine Schiff base (2) in AOT in heptane*

Micellar solutions of SB **2** ($\sim 1.8 \times 10^{-5}$ M) in 10^{-2} M AOT in *n*-heptane with ω = 0, 8, 24, 48, and 72 ($\omega = [H_2O]/[AOT]$) were prepared by mixing the appropriate amount of the SB in respective AOT solutions. Transparent solutions were obtained up to $\omega = 24$. The solutions with ω exceeding 24 became cloudy. All of the solutions were prepared and stored in the dark to avoid light-induced changes in the SB. Protonation of the micellized SB was done by syringing in an appropriate amount of the acid.

All-trans-N-*retinylidene*–n-*butylamine Schiff base (2) formation in AOT reverse micelles in heptane*

A mixture of all-*trans*-retinal (λ_{max} 368 nm, 1.7×10^{-5} M) and *n*-butylamine (twofold excess) in AOT (1×10^{-2} M, *n*-heptane, H_2O, 0.08 M, ω = 8) solution was sonicated for 2 min. The transparent solution was kept in the dark at room temperature. The formation of SB **2** in the micellar medium was monitored by observing the growth of the absorption band at 357 nm. A control experiment was run by taking the reactants in *n*-heptane only.

Reaction of all-trans-*retinal (1) with* l-*lysine (4)*

l-Lysine (**4**, 0.0350 g) was added to the AOT solution (10 mL, 10^{-2} M in *n*-heptane, 0.08 M H_2O). The suspension was sonicated (90 W, 10 min) or vigorously stirred (Teflon, 30 min). Undissolved lysine was filtered out to obtain a transparent AOT–lysine solution. To this solution was added all-*trans*-retinal ($\sim 5.0 \times 10^{-5}$ M) and the mixture sonicated (90 W, 1 min) in the dark. The resulting solution was kept at room temperature (25°C) in the dark and the progress of the reaction was followed by UV–VIS spectrophotometric measurements. In a control experiment, a mixture of all-*trans*-retinal and *l*-lysine was stirred in *n*-heptane.

Treatment of N_α-tert-*Boc*-l-*lysine (5) with all*-trans-*retinal (1) in AOT micelles in heptane*

N_α-*tert*-Boc-*l*-lysine (**4**) and all-*trans*-retinal (**1**) were mixed in AOT solution (10^{-2} M, *n*-heptane, H_2O, 0.08 M) as described above. The mixture was kept at ambient temperature in the dark and its UV–VIS spectra recorded over a period of time.

Stability of SB (2) and PSB (3) in AOT micelles and heptane

SB (**2**) was constituted in AOT solutions in *n*-heptane/water by sonication. The resulting micellar-SB solutions were kept in the dark at ambient temperature. The UV–VIS spectra of the solutions were measured at different time intervals and changes in the absorbance at 357 nm due to SB **2** were noted. Micellar SB **2** was protonated by adding appropriate amounts of CPA. The solution was shaken and kept in the dark at ambient temperature. Any change in absorbance at 424 nm due to PSB **3** was noted.

Protonation of SB 2 by various acids

Appropriate amounts of different acid solutions in heptane, chloroform, or methanol were added from a microliter syringe to the solutions of **2** in different media of AOT micelles, heptane, chloroform, or methanol. Solutions of **2** turned yellow (depending upon the extent of protonation), giving PSB **3**, which showed a red-shifted absorption band between 420 and 445 nm.

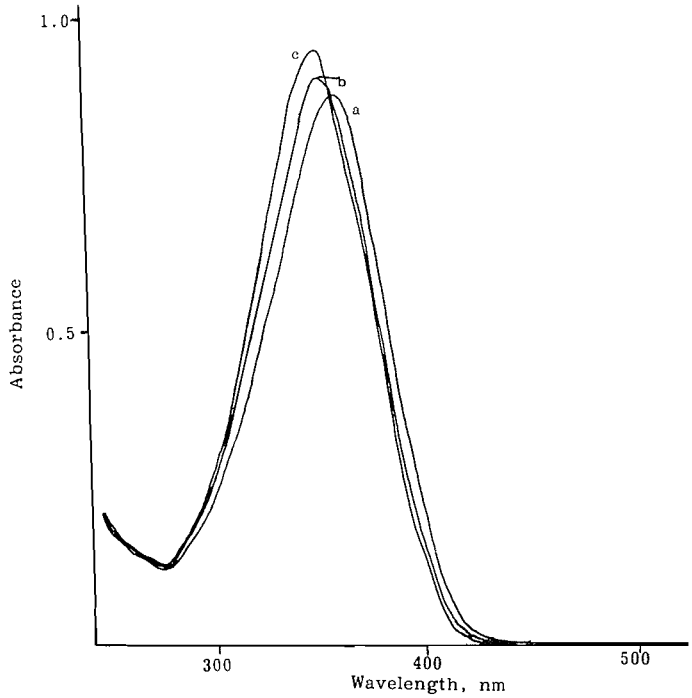

FIG. 2. Absorption spectra of 1.7×10^{-5} M all-*trans*-retinal and 3.4×10^{-5} M *n*-butylamine in 1.0×10^{-2} M AOT in heptane containing 0.08 M H_2O (ω = 8) (a) immediately, (b) 3 h, and (c) 6 h subsequent to mixing the components. The solution was kept in the dark at 22°C.

Irradiation of SB 2

Dilute solutions of SB **2** ($\sim 1.8 \times 10^{-5}$ M) in heptane or AOT micelles in heptane were taken in a quartz cell. The solutions were purged with dry N_2 and septum sealed. Direct irradiation (343 nm; ca. 1 μJ, 2-Hz laser pulses; Lambda-Physik excimer-dye laser) was performed on these samples. The action plots were made by observing the changes in the absorbance at 357 nm for initial-stage and long-time irradiation.

Determination of micellar size

SB **2** ($\sim 1.8 \times 10^{-5}$ M) was micellized in 10^{-1} M AOT in *n*-heptane at ω = 25 by briefly sonicating the sample. The clear solution was subjected to dynamic light scattering experiments using a digital correlator (Brookhaven Instruments Corporation model BI2030 AT) equipped with Microsoft Quick Basic (version 4.0).

FTIR studies on AOT reverse micelles in heptane and SB 2 constituted therein

SB **2** was micellized in AOT solutions as usual. The FTIR spectra were recorded either in 0.25 mM CaF_2 or 0.50 mM IRTRAA-2 liquid cells. Protonation of the micellized SB by CPA was done in an appropriate volumetric flask before taking the sample in the IR cell. All FTIR spectra were measured on a Nicolet 5DXB spectrophotometer with a resolution of 2 cm^{-1}.

Results and discussion

Formation of all-trans-N-*retinylidene*–n-*butylamine (2) in AOT reverse micelles in heptane*

All-*trans*-retinal (**1**) reacted with *n*-butylamine in AOT reverse micelles in heptane to give SB **2** (Fig. 2). The reaction was complete in about 6 h with the appearance of a new peak at 357 nm. The isosbestic point at 364 nm clearly indicated the conversion of retinal (λ_{max} 369 nm) to the corresponding SB. The micellar SB could be completely protonated by the addition of trichloro- or trifluoroacetic acid (λ_{max} PSB, 435–440 nm). The SB showed identical absorption bands in *n*-heptane and

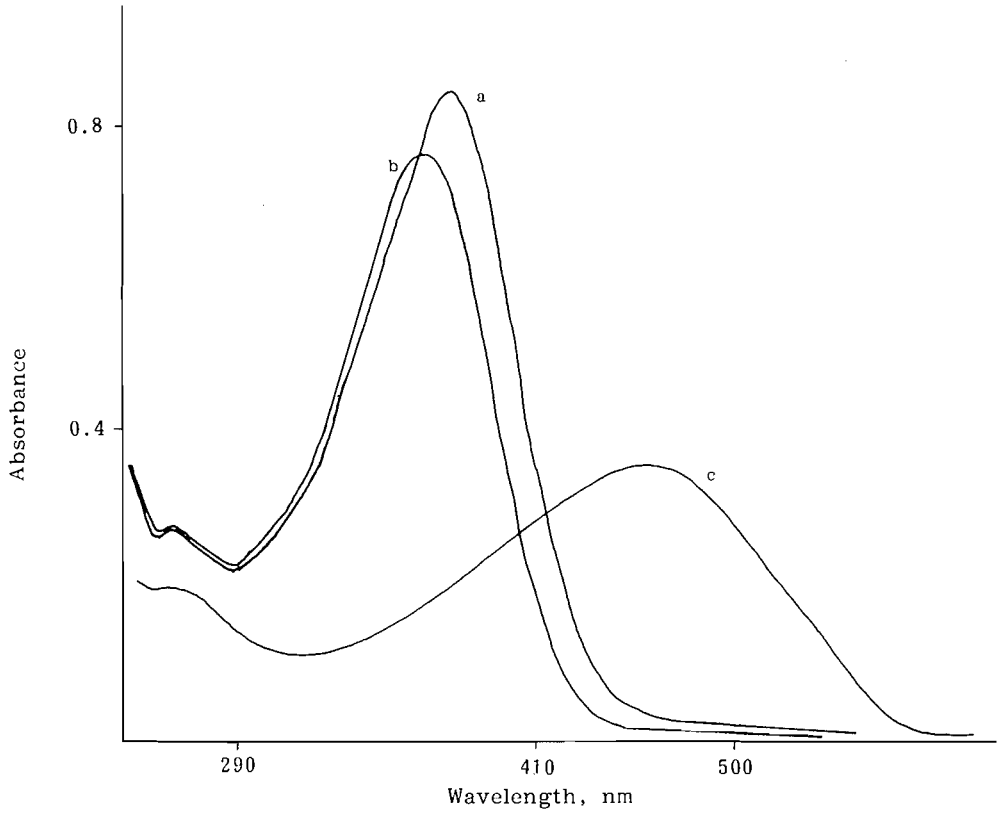

FIG. 3. Absorption spectra of 5.0×10^{-5} M all-*trans*-retinal and lysine (saturated solution) in 1.0×10^{-2} M AOT in heptane containing 0.08 M H_2O ($\omega = 8$) (a) immediately and (b) 5 h subsequent to mixing the components. The solution was kept in the dark at 22°C. Spectrum (c) was obtained subsequent to the addition of excess trifluoroacetic acid.

in AOT reverse micelles in heptane in the range of $\omega = 0$ to $\omega = 72$.

Reaction between l-lysine (4) and retinal (1) in AOT reverse micelles in heptane

l-Lysine (**4**) could be solubilized in AOT micelles in heptane. Cosolubilized all-*trans*-retinal (**1**) reacted with *l*-lysine (**4**), as evident from the appearance of a new UV–VIS peak at 356 nm. However, the retinylidene compounds were not stable, as evidenced by the isosbestic point at 350 nm (Fig. 3). No new peak appeared when *l*-lysine and retinal were stirred in heptane. There was approximately a 23% loss of retinylidene (either retinal or its lysine SB) compounds in AOT–lysine micellar media. Addition of trifluoroacetic acid to the product formed between retinal and *l*-lysine resulted in the formation of a new species with absorption maximum at 430 nm (Fig. 3). These observations indicate that a SB (λ_{max} 356 nm) is formed as a result of reaction between all-*trans* retinal and *l*-lysine in AOT micelles (Scheme 1), which upon protonation of its imine nitrogen exhibits the expected red shift in the absorption spectrum. Protonation of the amine group may also occur, but is not expected to influence the absorption maximum.

To determine which amino group (α or ε, or both) reacts, retinal was treated with N_α-*tert*-Boc-*l*-lysine (**5**) in AOT micellar solution. The only change observed in the absorption behavior of the mixture was a minor reduction (~7%) in the absorbance at the λ_{max} of retinal at 368 nm. Addition of trifluoroacetic acid to this mixture (after keeping it at ambient temperature for 24 h) caused the 368-nm band to shift to 398 nm. Apparently, the ε-amino group of lysine did not react with retinal. Therefore, retinal reacts with the α-NH_2 group of lysine in AOT micelles to give SB **6**.

Retinal–lysine Schiff bases could not be prepared at retinal concentrations higher than 10^{-2} M. The decomposition of the retinylidene compounds was rapid. In addition, correspondingly higher lysine concentrations were found to cause protonation of the retinal–lysine SB. Protonation of retinal–lysine Schiff bases can be caused either by an adjacent carboxyl proton (**6** → **8**) or by carboxylic groups of unreacted lysine (to give **9** or **10**; Scheme 2). The extent of various protonation possibilities will, however, depend upon the acid–base characteristic of the micellar site where the SB and lysine are localized. Self-protonated retinal–lysine Schiff bases showed an absorption band at 440 nm.

In the AOT micellar system, N_α-*tert*-Boc-*l*-lysine ionizes to release its carboxylic proton, which in turn protonates the ε-NH_2 group, rendering it electrophilic. A positively charged nitrogen does not react with the electrophilic retinyl aldehyde group (Scheme 3). Similarly, lysine may also ionize in AOT to release the acidic proton that protonates the more basic ε-NH_2 group (pK_a in H_2O, 10.53) rather than the less basic α-NH_2 group (pK_a in H_2O, 8.95).

It is interesting to note that in rhodopsin the ε-amino group reacts with retinal (α-amino of lysine is in the peptide bond), but in reverse micelles it does not. As indicated in Scheme 3, the ε-N of N_α-*tert*-Boc-*l*-lysine is rendered electrophilic due to its protonation by acidic surroundings. In the protein, however, the same ε-amino group reacts with retinal. Apparently, the acidic protein residues are either incapable of protonating the free ε-amino group of lysine or lie away from it. In other

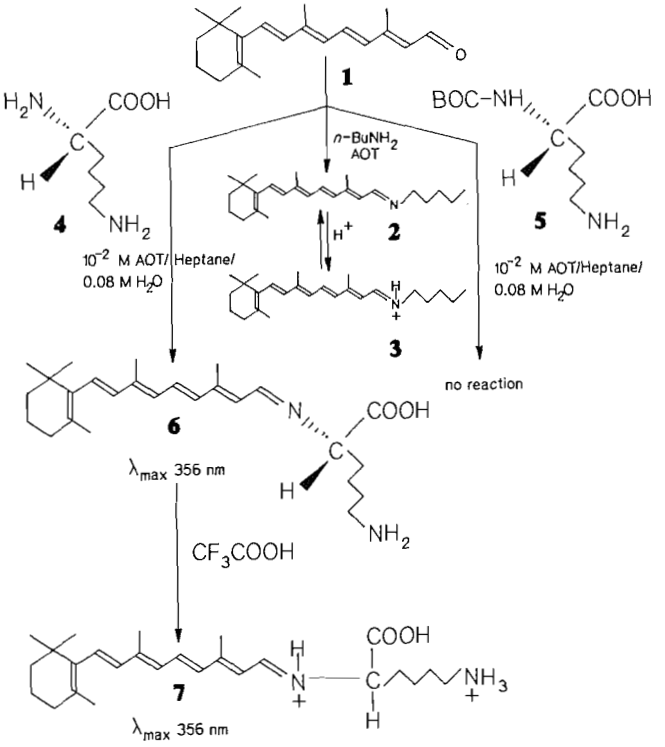
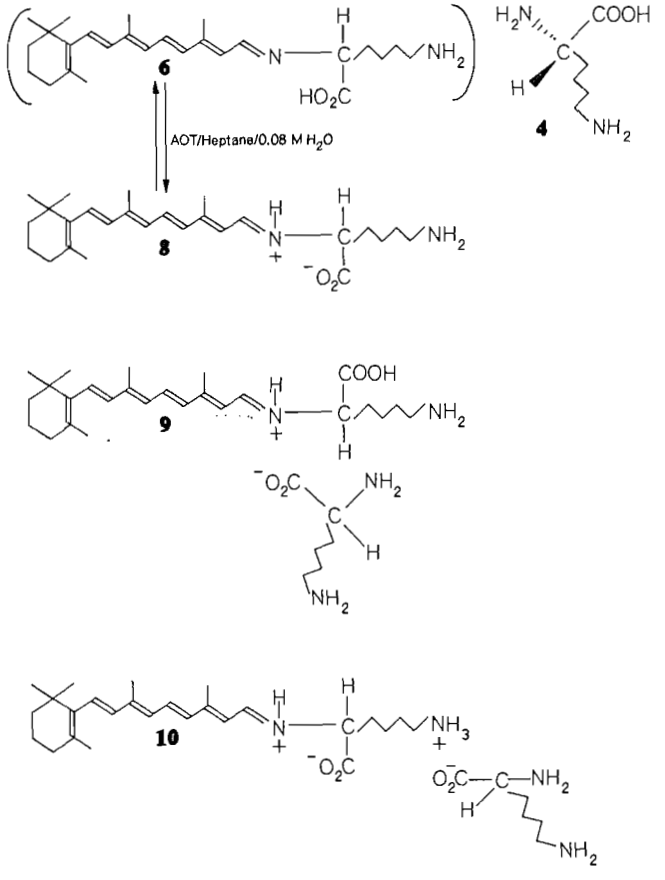
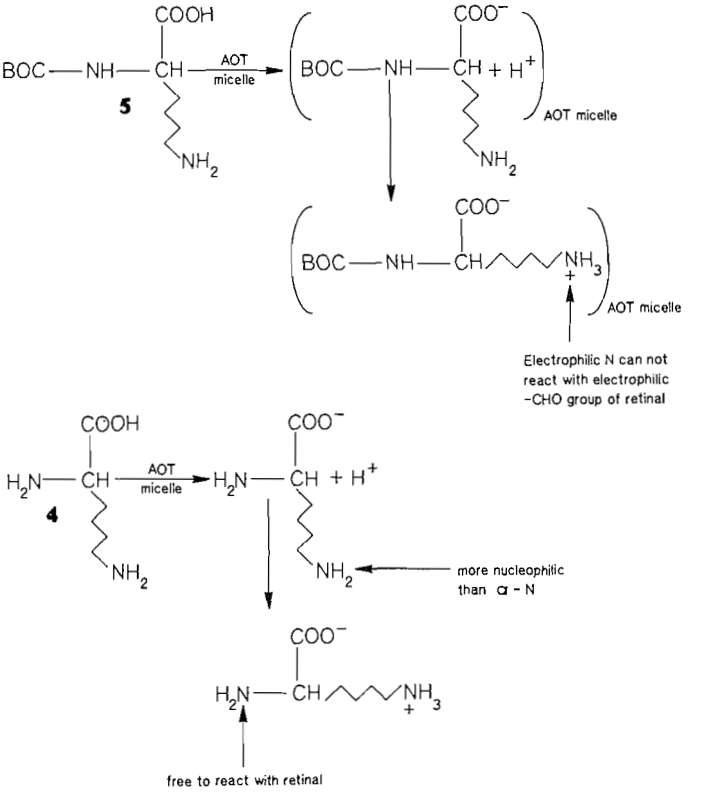


SCHEME 1



SCHEME 2



SCHEME 3

words, conformational changes in opsin during regeneration of bleached rhodopsin play important roles. These results also indicate that, prior to or during SB formation, water molecules and the acidic protein residues are at a distance from the lysine group. The SB formation may cause opsin to adapt a conformation that allows the acidic moiety and water to get closer to the imine group. Thus, SB formation between retinal and the ε-amino group of lysine occurs in a totally hydrophobic or nonplanar medium. If the rhodopsin active site has a polar pocket, it must be formed only after generation of the -C=N- chromophore.

Protonation of SB 2 by CPA in heptane

Protonation of 1.8×10^{-5} M SB **2** in *n*-heptane was studied by introducing an appropriate amount of 1.8×10^{-2} M 3-chloropropionic (CPA) acid. There was no appreciable extent of protonation (<0.50%) in an equimolar mixture of SB **2** and CPA. Large excess of CPA (CPA:SB ratio >100) caused ~15% of protonation.

Protonation of SB 2 by CPA in 10^{-2} M AOT reverse micelles in heptane ($\omega = 0$)

Protonation of SB **2** (~1.8×10^{-5} M AOT in *n*-heptane, $\omega = 0$) was done by adding calculated amounts of CPA solution in *n*-heptane. The extent of protonation was measured by monitoring the growth of a red-shifted UV–VIS absorption band at 443 nm. There was ca. 0.50% protonation of the SB in the presence of an equimolar amount of CPA. A maximum protonation of ca. 43% was obtained when the SB:CPA molar ratio reached ~1:180. At this molar ratio, only ca. 19% protonation was observed in the absence of AOT.

Protonation of SB 2 by CPA in AOT reverse micelles in heptane ($\omega = 8$)

A solution of SB **2** (ca. 1.8×10^{-5} M) was prepared in

TABLE 1. Extent of protonation in a 1:1 mixture of all-*trans*-retinylidene–*n*-butylamine Schiff base (**1**) and 3-chloropropionic acid in different media

Media	% Protonation
n-Heptane	~0.4
AOT/*n*-heptane/	
$\omega = 0$	0.6
$\omega = 5$	6
$\omega = 24$	17
$\omega = 45$	34
$\omega = 72$	67

AOT = 1×10^{-2} M; CPA = SB = 1.8×10^{-5} M.

10^{-2} M AOT–heptane with $\omega = 8$. For the preparation of AOT solutions, it was assumed that the AOT used contained no water. The extent of protonation was enhanced. An equimolar amount of CPA caused ca. 6% protonation, while a maximum of 51% protonation was observed in the presence of ca. 50 mol excess of CPA.

Protonation of SB 2 by CPA in AOT reverse micelles in heptane ($\omega = 24$)

The method of protonation was the same as described above. The extent of protonation was further enhanced. Thus, an equimolar amount of CPA caused 15% protonation. A maximum of 61% protonation could be achieved by only a 6 mol excess of CPA.

Protonation of SB 2 by CPA in AOT reverse micelles in heptane ($\omega = 48$)

Efficient protonation of SB **2** by CPA was observed in AOT in heptane, $\omega = 48$. Thus, at an equimolar amount of CPA, 34% protonation, and a maximum of 69% protonation at a CPA molar excess of 7 was observed.

Protonation of SB 2 by CPA in AOT reverse micelles in heptane ($\omega = 72$)

The appearance of turbidity caused difficulty in measuring the absorption spectra of AOT samples in heptane with $\omega = 72$. However, the solution remained clear for a few minutes, allowing quick measurements. The equimolar amount of CPA caused 67% protonation. As usual, further addition of CPA (ca. 2 mol excess) caused slight enhancement of only about 3%. Thus, most of the SB could be protonated by equimolar CPA only.

The presence of 0.48 or 0.72 M water in the micelles caused some material loss also. Thus, when the ratio of CPA/SB was 6 in AOT micelles having 0.48 M water, there was approximately 8% loss of retinylidene chromophore. The loss of retinylidene chromophores was greater in the presence of 0.72 M water in the micelle. Thus, when the ratio of [CPA] to [SB] was 3 there was approximately 23% loss of retinylidene chromophore.

The extent of protonation of a 1:1 mixture of SB **2** and CPA in AOT micelles with varying amounts of water is shown in Table 1. The extent of protonation depended on the molar ratio of CPA to SB **2** and on the amount of water present in the reverse micelles. At a given ω value, increasing amounts of CPA increased the extent of protonation to a point beyond which the addition of further CPA had no effect. In the absence of water ($\omega = 0.1$), 200-fold excess CPA was needed to reach the equilibrium protonation of **2**, whereas at $\omega = 48$ it took only a sixfold excess to protonate **2** to a much higher extent. It appears thus that availability of protons rather than acid strength is of overriding importance in SB protonation. Proton availability depends on the extent of CPA dissociation. This, in turn, is favored by the availability of water in higher concentrations in the reverse micelles. The extent of protonation is seen to increase linearly with the amounts of water present.

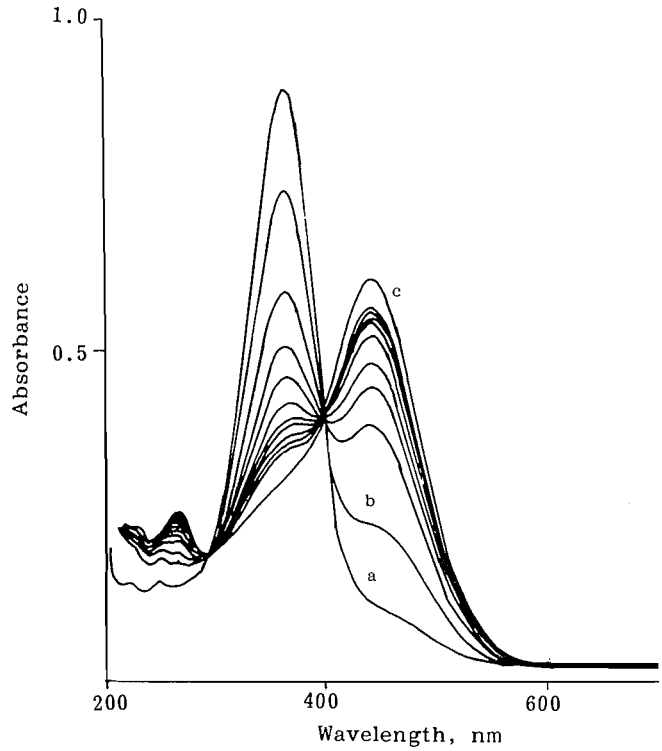

FIG. 4. Absorption spectra of 1.8×10^{-5} M all-*trans*-*N*-retinylidene–*n*-butylamine Schiff base (**2**) in methanol containing 0.24 M H_2O in (a) the absence and (b → c) in the presence of increasing amounts of 3-chloropropionic acid. [3-Chloropropionic acid] = 1.8×10^{-5} M (b) and 1.8×10^{-4} M (c).

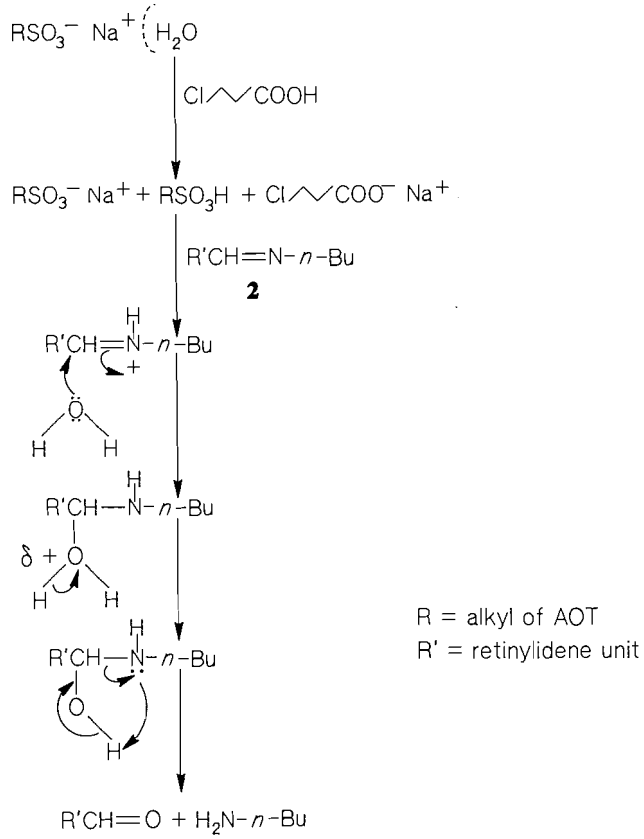
Protonation of SB 2 by methanesulfonic acid

AOT has sulfonate groups, which may be competing for CPA protons. The corresponding sulfonic acid may also cause the protonation of SB, though the sulfonic acid generated will be in small quantity as the molar ratio of AOT to CPA is very high (>500). Protonation of SB by methanesulfonic acid was studied in chloroform. Appropriate amounts of methanesulfonic acid in $CHCl_3$ (1.8×10^{-2} M) were added to a chloroform solution of the SB (1.8×10^{-5} M). Approximately 97% protonation was observed in a 1:1 mixture of SB and methanesulfonic acid.

Protonation of SB 2 by CPA in MeOH containing 0.24 M H_2O

The extent of protonation of the SB by CPA in methanol containing 0.24 M H_2O is shown in Fig. 4. A maximum of ~60% protonation occurred when the CPA:SB ratio was 10; when the ratio of CPA to SB was 1, only 17% protonation was observed. The acidity of CPA in methanol with 0.24 M water is found to be very similar to the acidity of the micellar system containing AOT (0.01 M) in *n*-heptane with 0.24 M H_2O and CPA. Clearly, the extent of ionization or, in other words, number of available protons, is important in causing the protonation of the SB. A maximum of 60% protonation occurred only when the CPA:SB ratio exceeded 10.



SCHEME 4

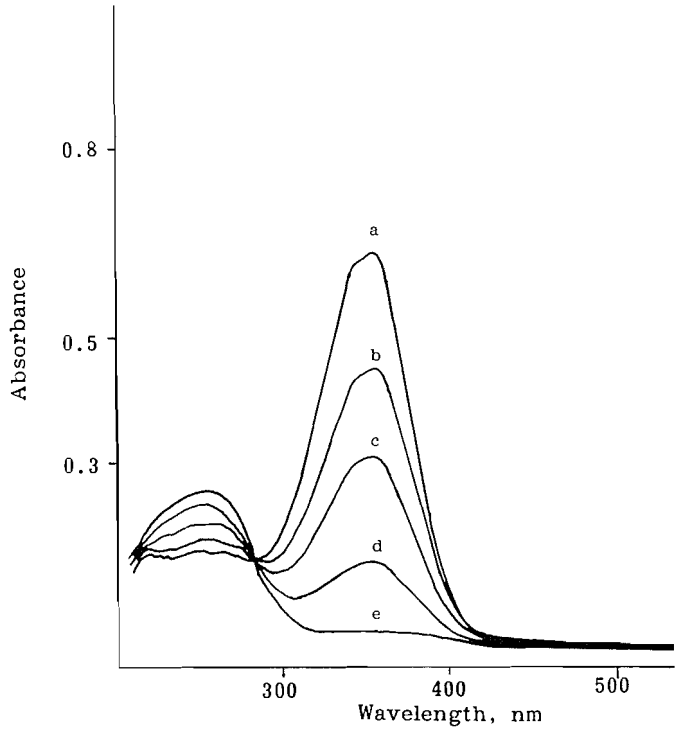


FIG. 5. Absorption spectra of 1.8×10^{-5} M deaerated all-*trans*-*N*-retinylidene–*n*-butylamine Schiff base (**2**) in 1.0×10^{-2} M AOT in heptane in the presence of 0.08 M H_2O ($\omega = 8$) prior (a) and subsequent to 10 (b), 20 (c), 40 (d), and 80 (e) min of irradiation by 343 mm, ca. 1 μJ, 2-Hz laser pulses.

Stability of SB 2 and its protonated form in AOT reverse micelles in heptane

SB **2** ($\sim 1.8 \times 10^{-5}$ M) in AOT–heptane micelles containing 0.24 M water was kept in the dark at ambient temperature and changes in absorbance at 357 nm were monitored at various time intervals. There was ca. 2% loss in the absorbance of SB over a period of 3 h. Over a period of 24 h, there was only ca. 4% loss of SB. Similarly, absorbance changes at 357 and 424 nm were monitored in a 1:1 mixture of SB:CPA in AOT micelles containing 0.24 M water. Addition of CPA caused ~17% protonation of the SB. In 3 h, about 23% of the SB and its protonated form hydrolyzed. After 24 h, 33% of the SB and 65% of PSB hydrolyzed. When CPA was present in sixfold excess over SB, the decomposition of the SB and PSB was faster. Thus during 3 h, about 52% of the SB and PSB hydrolyzed. After 24 h, 85% PSB hydrolyzed. When CPA was present in 20-fold excess over SB, the hydrolysis of PSB was faster and, in about 6 h, 82% of the PSB (λ_{max} 424 nm) hydrolyzed to retinal (λ_{max} 367 nm). The stability of SB and PSB was also studied in AOT micelles of the water pool (ω = 8). The SB was stable. Only ca. 5% loss of the chromophore occurred in 24 h. However, in the presence of CPA (CPA:SB, 1:1) the decomposition was rapid for the protonated SB. Thus, while only ~10% SB was hydrolyzed in about 8 h, ~50% PSB was hydrolyzed in the same period.

The stability of protonated SB **2** in MeOH containing 0.24 M water was also investigated. SB was protonated by adding an excess (20-fold) of CPA. Only ~12% PSB underwent hydrolysis to retinal over a period of 8 h. On the other hand, during the same period, about 52% PSB hydrolyzed in AOT micelles (0.24 M H_2O), even when the ratio of CPA to SB was only 1. Apparently the strong acidity of sulfonic acid formed in the micelle causes rapid decomposition of the SB (Scheme 4). However, the role of micellar catalysis in the hydrolysis reaction cannot be excluded.

Photolysis of SB 2 in AOT reverse micelles in heptane

Direct irradiation (343 nm) of the SB in AOT reverse micelles in heptane at ω = 8 for about 90 min resulted in complete loss of the chromophore at 357 nm (Fig. 5). Photolysis in heptane under similar conditions showed similar behavior but required more than 5 h for complete loss of the SB chromophore (see Fig. 6). Initial-stage irradiation action plots indicated the establishment of a photostationary state. At this point, the absorbance change at 357 nm was ca. 10% in both heptane and micellar media. Assuming that the SB undergoes only *trans* to *cis* photoisomerization during the initial stages of irradiation, it appears that the micellar medium has no significant effect on the photochemical quantum yield of the primary photoreaction. However, it influences the kinetics of this process.

Determination of the hydrodynamic radii of AOT reverse micelles in heptane containing SB 2

The hydrodynamic radii of AOT reverse micelles in heptane (ω = 25) containing $\sim 2 \times 10^{-5}$ M SB **2** were determined by dynamic light scattering to be 44 Å (13).

IR spectra of AOT reverse micelles and micellized SB in heptane

AOT solubilized in *n*-heptane showed the expected ester band at 1739 cm^{-1}. AOT-solubilized water showed -OH stretch and overtone frequencies. Figure 7 shows the IR spectral changes in the 1500–1800 cm^{-1} region as a function of water content in AOT reverse micelles in *n*-heptane. The intensity of the band at 1642 cm^{-1}, due to hydrogen-bonded species (13), increases with increase in water content. A plot of water content

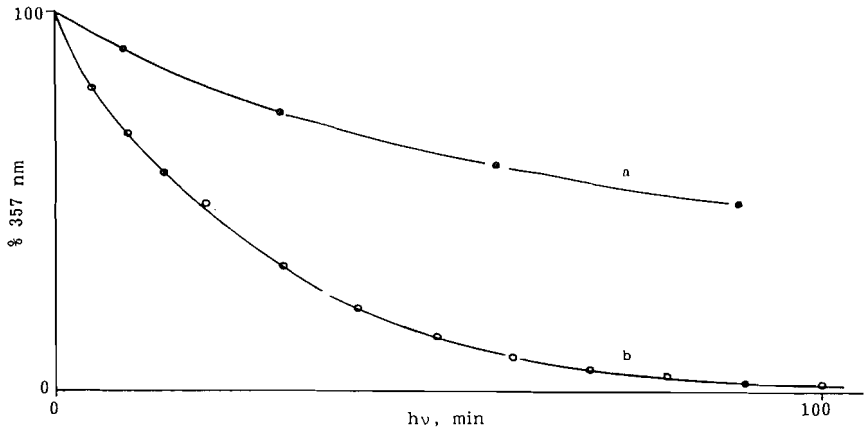

FIG. 6. Changes of concentrations of all-*trans*-*N*-retinylidene–*n*-butylamine (**2**) (a) in heptane and (b) in 1.0×10^{-2} M AOT in heptane in the presence of 0.08 M H_2O ($\omega = 8$) as a function of irradiation time, by repetitive 343 nm, ca. 1 μJ, 2-Hz laser pulses.

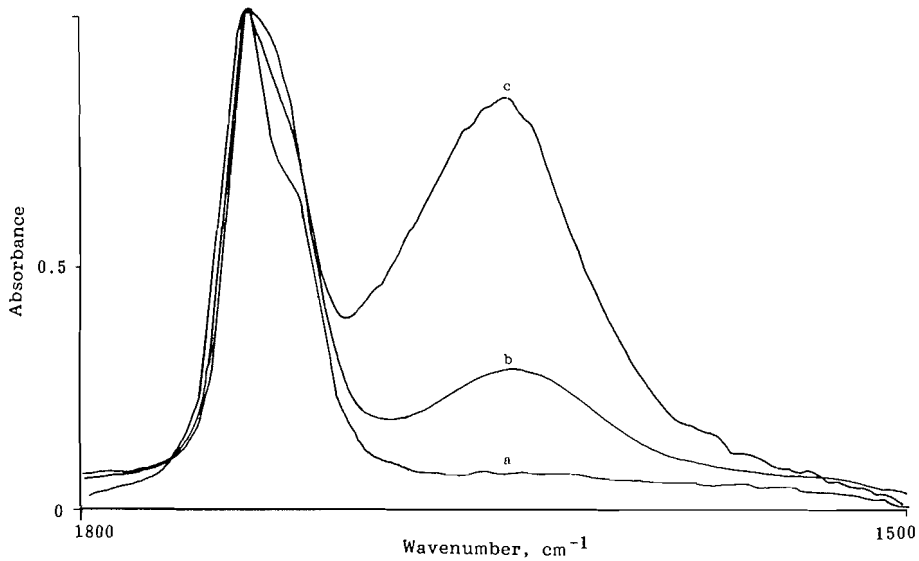

FIG. 7. FTIR difference spectra of 0.3 M AOT in heptane (a) in the absence and (b) in the presence of 1.5 M H_2O, $\omega = 5$, and (c) 7.5 M H_2O, $\omega = 25$ water.

in AOT reverse micelles vs. the intensity of the 1642 cm^{-1} band is shown in Fig. 8. This plot enables the estimation of the exact amount of water present in the AOT reverse micelles. As can be seen, a purified and vacuum-dried sample of AOT contained ~0.8% water ($\omega = 1.5$). AOT micelles containing 0.8% water do not show a band at 1642 cm^{-1}. The band at 1642 cm^{-1} is seen when the ω value is 5 or more. Apparently, water below $\omega = 5$ is used for solvating the AOT ion pair. Once five or more water molecules are present for each AOT molecule, their predominant state corresponds to a hydration shell around the now separated anion and cation. The 1500–1700 cm^{-1} region of the FTIR difference spectrum of SB **2** (1×10^{-1} M) solubilized in AOT reverse micelles in heptane ($\omega < 5$) is shown in Fig. 9. IR frequencies at 1624, 1598, and 1582 cm^{-1}, characteristic of C=N and C=C stretches of the retinylidene chromophore, are observed. Protonation by CPA, however, led to gelification and hydrolysis of the SB as seen from the aldehyde peak (1670.7 cm^{-1}) in Fig. 10. The IR spectrum of SB **2** solubilized in AOT reverse micelles in *n*-heptane with $\omega > 5$ was found to exhibit the C=N stretch, but the spectrum becomes complicated due to the presence of several interacting chromophores. Addition of CPA to a solution of SB **2** (~1×10^{-1} M) in AOT reverse micelles in *n*-heptane (3×10^{-1} M) with $\omega > 5$ led to the hydrolysis of the SB to retinal. The region of interest (1400–1700 cm^{-1}) was very complicated due to the changing nature of the water peaks. The water shows variable IR bands in AOT reverse micelles in *n*-heptane in the presence of SB, PSB, and CPA.

It was found that AOT reverse micelles (10^{-2} M) in *n*-heptane cannot take up more than 2×10^{-5} M SB **2**. The SB was reasonably stable and could be protonated by CPA even in the presence of 0.72 M water. However, it was not possible to record the difference in FTIR spectra of 2×10^{-5} M SB **2** in 1×10^{-2} M AOT reverse micelles in heptane in the range of $\omega =$ 5–50 micelles.

FTIR spectra of CPA solubilized in AOT reverse micelles in heptane

CPA solutions in CCl_4 (1×10^{-1} M) showed an intense IR band at 1718.7 cm^{-1} due to its -COOH group. Weak and broad bands were also present at 1529.6, 1550.5, 1438.4, 1272, 1250, and 1212 cm^{-1}. Different FTIR spectra of CPA (1×10^{-1} M) solubilized in AOT reverse micelles in heptane at $\omega < 2$ (3×10^{-1} M) showed positive bands due to CPA at 1706, 1724,

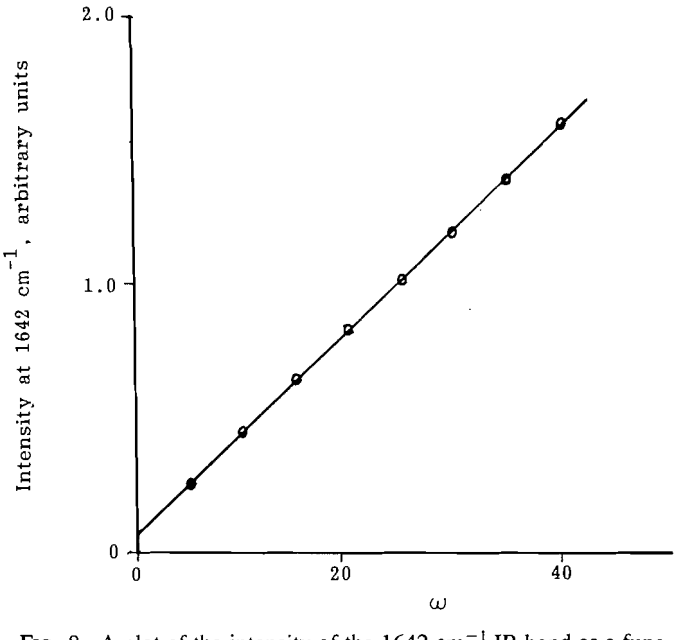

FIG. 8. A plot of the intensity of the 1642 cm^{-1} IR band as a function of water to surfactant ratio (ω) in 1.0×10^{-2} M AOT in heptane.

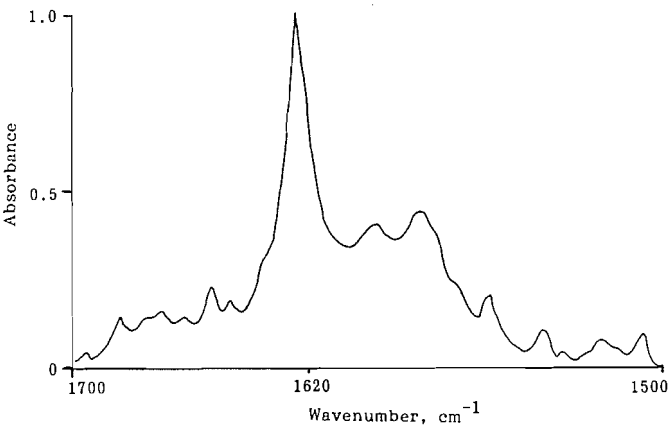

FIG. 9. FTIR difference spectrum (1700–1500 cm^{-1}) of 0.1 M all-*trans*-*N*-retinylidene–*n*-butylamine (**2**) in 0.3 M AOT in heptane ($\omega \approx 0$).

1421, 1396, 1290, 1284, 1278, 1253, 1188, and 1174 cm^{-1}. The intensity of bands at 1706 and 1421 cm^{-1} was almost equal. When CPA (1×10^{-1} M) was solubilized in AOT reverse micelles in heptane (3×10^{-1} M) containing 1.5 M water ($\omega > 5$), positive IR bands were observed at 1741 and 1716, and four strong bands were observed between 1400 and 1500 cm^{-1}. Different FTIR spectra of CPA solubilized in AOT reverse micelles in heptane with water content of more than 1.5 M were very complicated. The appearance of carboxylate peaks (1400–1500 cm^{-1}) indicated that the larger are the water pools, the greater is the dissociation of CPA in AOT reverse micelles. Also, the ionization of CPA occurs when water not directly attached to the hydration shell is available. Water molecules ($\omega < 5$) associated in the AOT hydration shell are not causing dissociation of CPA.

The meaning of pH in the aqueous pools of reversed micelles is somewhat elusive (11, 15, 16). It is only fruitful to report hydrogen ion concentrations as "effective" values defined by a given probe around its immediate environment. Probes used in

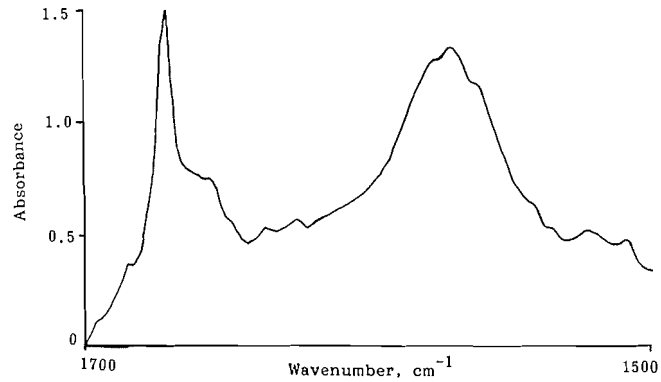

FIG. 10. FTIR difference spectrum (1700–1500 cm^{-1}) of 0.1 M all-*trans*-*N*-retinylidene–*n*-butylamine (**2**) in 0.3 M AOT in heptane ($\omega \approx 0$) in the presence of 0.1 M 3-chloropropionic acid.

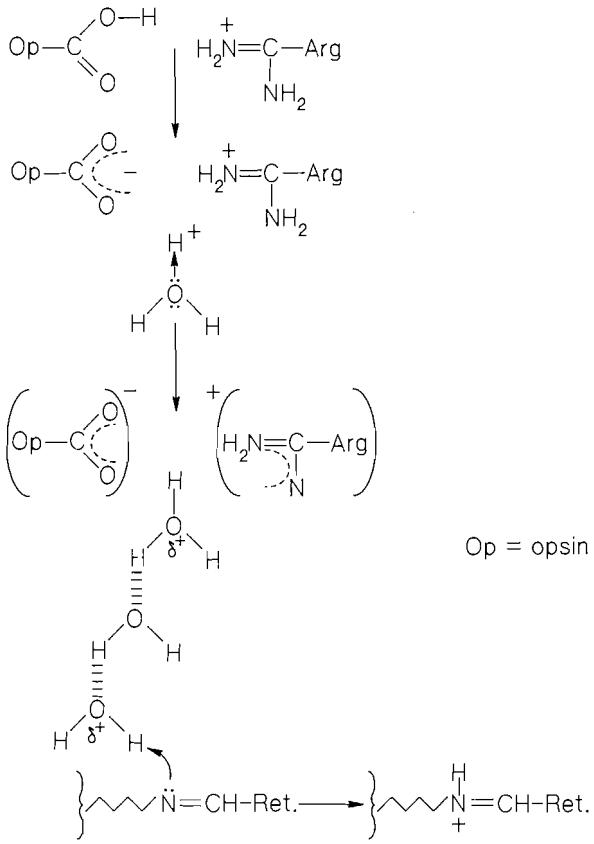
reversed micelles undergo absorption (17), infrared (18), and ^{31}P nmr chemical shift (19) changes in response to an alteration of the acidity of their environments. Depending on their position, they report effective pH values in the vicinity of the surfactant headgroups, in the middle of the water pool, or at some intermediate location between these two extremes. Furthermore, the micellar environment may well alter the behavior of the probes. This is a particularly serious problem for indicators whose pK_a values cannot a priori be assumed to be the same in reverse-micelle-entrapped water as in bulk water. Another point of concern is related to the question of exchange of protons between CPA and the sulfonate group of AOT, as shown in eq. [1].

[1] $$(\text{AOT–SO}_3^- \text{ Na}^+)_{\text{H}_2\text{O}} + \text{ClCH}_2\text{CH}_2\text{COOH} \rightarrow (\text{AOT–SO}_3^- \text{ Na}^+)_{\text{H}_2\text{O}} + (\text{AOT–SO}_3\text{H})^{11} + \text{ClCH}_2\text{CH}_2\text{CO}_2^- \text{ Na}^+$$

In such a situation, protonation of the SB can also be caused by the sulfonic acid derivative generated from AOT. The gross micellar structure is not expected to be affected by such exchange if the concentration of AOT is very high as compared to the added CPA. Probably the observed protonation of the SB is due to both the acids (CPA and sulfonic) present in the micelle. Apparently micelles provide an environment for the SB wherein finely tuned interactions and a delicate balance between the right amount and right kind of water influence the stability and protonation of the SB.

Conclusion

The present studies provide some insight into the mechanism of protonation in rhodopsins. It has recently been shown (20) that, in neutral solution, weak acids are incapable of fully protonating the retinylidene SB. In view of these observations, it is important to investigate the mechanism (9) by which weak glutamic (pK_a in H_2O, 3.86) and aspartic (pK_a in H_2O, 4.25) acid residues, present in the vicinity of SB chromophores, cause full protonation of the chromophore of rhodopsins. The driving force behind the shedding of protons by an acid residue in a protein may be provided by the need for the formation of an ion pair, which is required for attaining an appropriate protein conformation. Such ion pairs commonly occur in biologically active proteins. Thus, a positively charged residue in the vicinity of an acid residue can drive the acid and accelerate the proton release process. The released protons can then form hydronium ions with nearby water molecules. Large



SCHEME 5

numbers of hydronium ions thus generated can protonate the SB (Scheme 5).

Determination of dipole moment values of anisotropic molecules using Brot's formalism

P. BRITO AND M. MECHETTI

Instituto de Física, Facultad de Ciencias Exactas y Tecnología, Universidad Nacional de Tucumán, 4000 Tucumán, R. Argentina

Received June 23, 1989[1]

P. BRITO and M. MECHETTI. Can. J. Chem. **68**, 1523 (1990).

A method for the determination of dipole moment values based on Brot's theory is proposed. It takes into account the influence of the molecular anisotropies of shape and polarizability on the permittivity of a mixture. Starting from measurements performed on dilute solutions and from the knowledge of the molecular structure of some chlorinated derivatives of α-cyanostilbene and 1,3 derivatives of benzene, the best parameters of an ellipsoid used for the representation of a polar anisotropic molecule are determined. The dipole moments obtained, using benzene and tetrachloromethane as solvents, are finally compared to values from the literature.

Key words: dipole moment, Brot's formalism, molecular anisotropy.

P. BRITO et M. MECHETTI. Can. J. Chem. **68**, 1523 (1990).

On propose une méthode, basée sur la théorie de Brot, qui permet de déterminer les valeurs des moments dipolaires; elle tient compte de l'influence des anisotropies moléculaires de la forme ainsi que de la polarisabilité sur la permittivité d'un mélange. En se basant sur des mesures effectuées sur des solutions diluées et sur des connaissances de la structure moléculaire de certains dérivés chlorés de l'α-cyano-stilbène et de dérivés-1,3 du benzène, on a déterminé les meilleurs paramètres d'un ellipsoïde à être utilisés pour représenter une molécule polaire anisotrope. On a finalement comparé les valeurs obtenues pour les moments dipolaires dans le benzène et le tétrachlorométhane avec celles rapportées dans la littérature.

Mots clés : moment dipolaire, formalisme de Brot, anisotropie moléculaire.

Introduction

In this paper we propose a method of evaluating the dipole moment of polar molecules from measurements performed in polar–nonpolar dilute solutions, using results from Brot's theory (1) that take into account the molecular anisotropies of shape and polarizability. This paper follows earlier work (2, 3) in which different theoretical expressions for the permittivity of mixtures were discussed.

To apply this particular formalism using a model in the continuous approach, a previous knowledge of molecular structure is required. This allows the determination of the parameters of the best ellipsoid that must be used for the representation of a polar solute molecule. The proposed method differs from those based on the Debye (4) or Onsager (5) models, as well as from the others traditionally used, in the evaluation of the dipole moment, in spite of the fact that almost the same experimental data are necessary: the variations of the static permittivity and the refractive index of the solution with concentration, the densities of solute and solvent, or the variation of the specific volume of the mixture with concentration. The anisotropy of polarizability can be determined from the Kerr coefficients but if they are not known, as in our case, the ellipsoid can be considered as being composed of a medium characterized by a homogeneous permittivity $\varepsilon_{\infty 2}$ for relating both kinds of molecular anisotropies.

To apply the proposed method we have considered very dilute solutions of seven chlorinated derivatives of α-cyanostilbene and two 1,3 derivatives of benzene in benzene and tetrachloromethane. The dipole moment values obtained are finally compared with those determined by the use of the traditional formulas (6–9), the vectorial sum of bond dipole moments (10), or the CNDO/2 method (11).

Theoretical considerations

An expression for the static permittivity of pure liquids and dilute solutions taking into account the influence of the anisotropies of shape and polarizability was deduced by Brot in 1982. In the case of pure liquids these anisotropies have also been considered by other authors (12, 13).

The result obtained by Brot is

$$[1] \quad \frac{\varepsilon_{12} - \varepsilon_1}{N} = \frac{1}{3\varepsilon_0} \sum_{j=1}^{3} [\alpha_{jj}^* + f_j^2 \mu_j^2 / kT]$$

where ε_{12} and ε_1 are the static permittivities of the solution and the solvent and N is the number of solute molecules per unit volume. Otherwise

$$[2] \quad \alpha_{jj}^* = \{[1 + A_j(\varepsilon_1 - 1)]\alpha_{jj} - v\varepsilon_0(\varepsilon_1 - 1)\} f_j$$

is the effective polarizability increment and

$$[3] \quad f_j = \left\{1 - \frac{\varepsilon_1 - 1}{\varepsilon_1} A_j \left[1 + (1 - A_j)\frac{\alpha_{jj}}{v\varepsilon_0}\right]\right\}^{-1}$$

is the Scholte internal factor.

If a continuous model is used for the solution, the anisotropic solute molecule can be represented by an ellipsoid of half-axis a_j ($j = 1, 2, 3$), having a volume equal to the associated molecular volume in the pure liquid state and depolarizing factors A_j, in order to include shape anisotropy. The anisotropy of polarizability can be estimated by using a theoretical model in which both types of anisotropies are related by considering the ellipsoid made of a homogeneous medium characterized by a permittivity $\varepsilon_{\infty 2}$. In this case the elements of the polarizability tensor are

$$[4] \quad \alpha_{jj} = \frac{a_1 a_2 a_3}{3}(4\pi\varepsilon_0)\frac{(\varepsilon_{\infty 2} - 1)}{[1 + (\varepsilon_{\infty 2} - 1)A_j]}$$

When this result is used in eqs. [2] and [3], the expression for the static permittivity of the polar dilute solution reduces to

$$[5] \quad \frac{\varepsilon_{12} - \varepsilon_1}{\Phi_2} = \frac{\varepsilon_1(\varepsilon_{\infty 2} - \varepsilon_1)}{3} \sum_{j=1}^{3} \frac{1}{\varepsilon_1 + A_j(\varepsilon_{\infty 2} - \varepsilon_1)} + \frac{3}{9}\frac{\varepsilon_1^2}{\varepsilon_0} \sum_{j=1}^{3} \frac{\mu_j^2}{kTv} \left\{\frac{1 + A_j(\varepsilon_{\infty 2} - 1)}{\varepsilon_1 + A_j(\varepsilon_{\infty 2} - \varepsilon_1)}\right\}^2$$

Φ_2 being the solute volume fraction and v its specific volume.

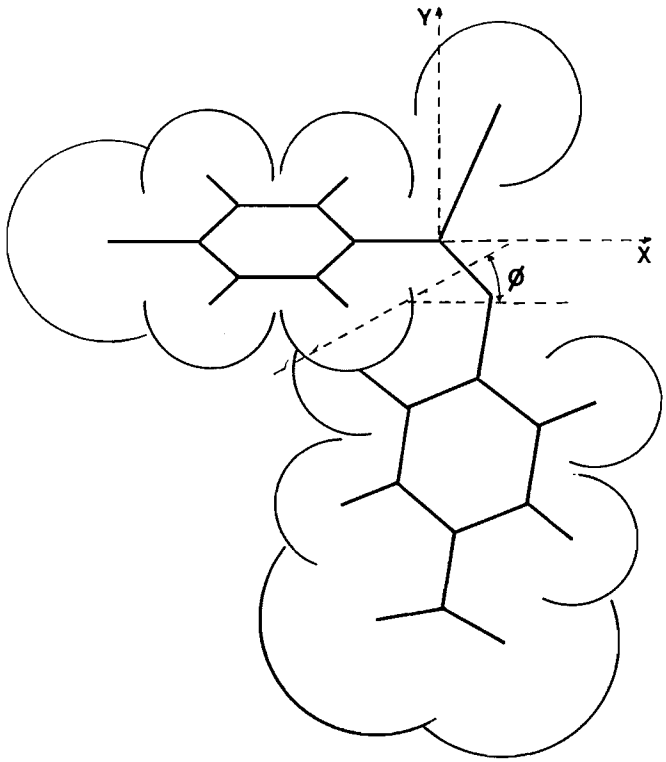

FIG. 1. Projection on the XY-plane of the molecular structure of 4-Cl-4′-*N*,*N*-dimethylamino-α-cyanostilbene. The external atoms are represented by its van der Waals spheres.

Method and results

The dipole moment values can be obtained from eq. [5] when the parameters of the ellipsoid that represents the solute molecule are determined. To do so it is necessary to know the molecular structure, from which it is possible to get the corresponding projections of this structure on three mutually perpendicular planes with the external atoms of the molecule represented by its van der Waals spheres. Then a set of points is chosen on each projection and the initial values of the different parameters of the ellipsoid, which is the geometrical figure leading to the best description of the chosen set of points, are determined. These parameters are the half-axis a_j, the Euler angles with respect to a given reference system, and the coordinates of the center. Due to the symmetry of the molecules considered, the a_3 direction is taken parallel to the Z-axis of the reference system. The projections on the XY-plane corresponding to two of the molecules studied are shown in Figs. 1 and 2. The angle ϕ between a_1 and the X-axis is also indicated.

The initial parameters are then changed by an iteration procedure until the difference between the volumes of ellipsoid and molecule is no greater than 1%. The associated molecular volume is estimated from density data or from the slope of the specific volume vs. concentration curve if the solute density is not known, as in the case of the α-cyanostilbenes. Another condition imposed in the iteration procedure is that the distance between each of the chosen points and the ellipsoid figure be less than 0.1 Å. The last two conditions make the difference between the present procedure and that followed in ref. 14 in which Brot's formalism was also applied for the case of chlorinated derivatives of the α-cyanostilbene. After the iteration procedure is concluded, the depolarizing factors of the molecules are calculated from

9	0.1785	0.2823	0.5392	27.02

$$[6]\quad A_j = \tfrac{1}{2}a_1a_2a_3\int_0^\infty \frac{du}{(u+a_j^2)(u+a_1^2)^{1/2}(u+a_2^2)^{1/2}(u+a_3^2)^{1/2}}$$

The values of the angles φ and of the calculated depolarizing factors appear in Table 1. The depolarizing factors found are the same for each substance regardless of which solvent (benzene or tetrachloromethane) is considered.

The value of the high frequency permittivity of the solute, $\varepsilon_{\infty 2}$, is also necessary for calculation of the dipole moment. If this permittivity is not known from relaxation measurements, it is usual to consider it equal to the square of the refractive index multiplied by a factor ranging between 1.0 and 1.1 (3). The permittivity $\varepsilon_{\infty 2}$ can also be estimated from eq. [1], extended to the high frequency limit. This last procedure was also followed in this work.

The available experimental data for the static permittivity, the specific volume, and the refractive index of a very dilute solution are usually written in the following forms (15, 16)

$$[7]\quad \varepsilon_{12} = \varepsilon_1 + \alpha w_2$$

$$[8]\quad v_{12} = v_1 + \beta w_2$$

$$[9]\quad n_{12}^2 = n_1^2 + \tau w_2$$

where ε_1, v_1 and n_1 stand for the solvent and w_2 is the solute

	2.6216	1.44	1.39–1.55

*The first row of values corresponds to C_6H_6 and the second to CCl_4. Substances **1**–**7**, refs. 15 and 16; **8** and **9**, refs. 17 and 18.
†μ_{gas}, ref. 22.

weight fraction. If the static permittivity of the solution and the solvent are replaced by the corresponding refractive index, eq. [1] yields

$$[10]\quad \tau = (1 + \beta d_1)\frac{n_1^2}{3}(\varepsilon_{\infty 2} - n_1^2)\sum_{j=1}^{3}\frac{1}{n_1^2 + A_j(\varepsilon_{\infty 2} - n_1^2)}$$

after expressions [7]–[9] are used. Finally, the dipole moment value can be obtained from eq. [1] as

$$[11]\quad \mu^2 = \frac{S}{\sum_j C_j^2 \cos^2\theta_j}$$

where

$$[12]\quad S = \frac{3\varepsilon_0 kTM_2}{\varepsilon_1^2 N_A}\left\{\frac{\alpha}{d_1} - \left(\frac{1 + \beta d_1}{d_1}\right)\frac{\varepsilon_1(\varepsilon_{\infty 2} - \varepsilon_1)}{3} \times \sum_{j=1}^{3}\frac{1}{\varepsilon_1 + A_j(\varepsilon_{\infty 2} - \varepsilon_1)}\right\}$$

and

$$[13]\quad C_j = \frac{1 + A_j(\varepsilon_{\infty 2} - 1)}{\varepsilon_1 + A_j(\varepsilon_{\infty 2} - \varepsilon_1)}$$

The angle θ_j in eq. [11] is the angle between the dipole vector and the a_j-axis of the ellipsoid and it is evaluated from the vectorial sum of the bond dipole moments. The values of the bond dipole moments used are (17, 18) as follows:

μ_{Cl} = 1.61 D in benzene; 1.60 D in tetrachloromethane.
μ_{CN} = 3.37 D in benzene.
μ_{NDMA} = 1.60 D in benzene; 1.52 D in tetrachloromethane.
μ_{Br} = 1.55 D in benzene; 1.52 D in tetrachloromethane.

The dipole moment values obtained from eq. [11] are shown in Table 2, where the high frequency permittivities and dipole moment values from the literature are also given. It must be pointed out that due to the fact that the benzene rings are in different planes for the α-cyanostilbenes when the *trans* configuration is used, the angle between these planes was taken to be equal to 58° in all cases except for the 2,6-dichloro-4′-*N*,*N*-dimethylamino-α-cyanostilbene, where the value 84° was used (19, 20). The nine polar substances considered in this work are

1 4-Cl-α-cyanostilbene
2 4-Cl-4′-*N*,*N*-dimethylamino-α-cyanostilbene
3 3-Cl-α-cyanostilbene
4 3-Cl-4′-*N*,*N*-dimethylamino-α-cyanostilbene
5 3,4-dichloro-α-cyanostilbene
6 3,4-dichloro-4′-*N*,*N*-dimethylamino-α-cyanostilbene
7 2,6-dichloro-4′-*N*,*N*-dimethylamino-α-cyanostilbene
8 1,3-dichlorobenzene
9 1,3-dibromobenzene

Discussion of results

The method generally employed to determine the dipole moment value of a polar molecule relates it to the static permittivity and the refractive index of a dilute solution through some traditional expressions such as those given by Hedestrand, Le Fevre and Vine, Guggenheim, and Halverstad and Kumler, in which the influence of the molecular anisotropies are not considered.

In this paper, the authors propose a method for evaluating the dipole moment based on the extension of the Onsager model made by Brot for solutions containing anisotropic molecules. The application of this method starts from the knowledge of the molecular structure of the polar molecule as well as of the van der Waals radii (21) of its external atoms. Using an iteration procedure, the parameters of the ellipsoid that represents the molecule are obtained. Calculations show that the depolarizing factors are the same for the two solvents considered. Nevertheless an appreciable difference is observed for the calculated high frequency permittivity values. This fact allows us to interpret any difference in the dipole moment values obtained in benzene and tetrachloromethane as due principally to the influence of polarizability anisotropy.

The results obtained for the dipole moments of the polar molecules considered, in the liquid state, are slightly different from those given in the literature (for the α-cyanostilbenes the range of values obtained from the usual formulas is indicated). The differences can be attributed to the influence of both types of anisotropy. Table 2 shows that in the case of 1,3-dichlorobenzene, the dipole moment of the ellipsoid (characterized by $a > b > c$ and $b/a = 0.88$) is greater than μ_{gas} but is in good agreement with the value 1.72 D given in ref. 23, which was calculated from heat of vaporization data.

Experimentally it is found that for the first six α-cyanostilbenes the dipole vector forms an angle with the *X*-axis greater than 80°, which is reduced to nearly 50° for substance **7**. In almost all cases the dipole has a big *Z*-component. These angles are given in refs. 15 and 16 and show good agreement with those obtained from the vectorial sum of bond dipole moments. For the *m*-dichloro and dibromo, the dipole vector is on the *XY*-plane and directed along the *ortho* position.

In the present work, the variation of the bond angle with the solvent has not been considered. Nevertheless, the results obtained from our method suggest that it is an accurate alternative procedure for evaluating the dipole moment of anisotropic polar molecules.

Density effects on ion mobilities in electron attaching fluids: CS_2, SF_6, and C_6F_6

NORMAN GEE, G. RAMANAN,[1] AND GORDON R. FREEMAN

Chemistry Department and Radiation Research Centre, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received March 22, 1990

NORMAN GEE, G. RAMANAN, and GORDON R. FREEMAN. Can. J. Chem. **68**, 1527 (1990).

Ion mobilities μ were measured at densities n ranging from those of the low density gas ($n < 0.01 n_c$, where n_c = critical fluid density) through the dense gas and low-density liquid transition region ($\sim 0.5 n_c$ to $2 n_c$) to the normal liquid ($\sim 3 n_c$). The mobility at a given density was constant over a 10-fold variation of electric field strength, typically in the range $0.1 < E(\mathrm{MV/m}) < 5$. In the gas phase changes in mobility were dominated by changes in gas density. Comparison with neutral molecule transport in SF_6 was used to illustrate the change in the effect of the ion on its local environment from that of molecular cluster formation to that of liquid electrostriction as density was increased. In the liquid, changes in ion mobility are dominated by changes in free volume. Mobilities in the present liquids could be described without reference to the activation energies suggested by the Arrhenius model.

Key words: ion, mobility, fluid, density, electron attaching.

NORMAN GEE, G. RAMANAN et GORDON R. FREEMAN. Can. J. Chem. **68**, 1527 (1990).

On a mesuré les mobilités ioniques μ à des densités allant de celles de gaz de basses densités ($n < 0{,}01 n_c$ où n_c = densité critique du fluide) à celles des gaz denses, puis à la région de transition des liquides de basses densités ($\approx 0{,}5 n_c$ à $2 n_c$) et finalement à celles des liquides normaux ($\approx 3 n_c$). A une densité donnée, la mobilité est constante, même lorsqu'on multiplie par 10 la force du champ électrique (généralement $0{,}1 < E(\mathrm{MV/m}) < 5$). En phase gazeuse, la mobilité est dominée par des changements dans la densité gazeuse. On a utilisé une comparaison avec le transport de molécules neutres dans le SF_6 pour illustrer le changement qui est observé dans l'effet de l'ion sur son environnement local lorsqu'on passe de la formation d'agrégat moléculaire à l'électrostriction du liquide causée par une augmentation de la densité. En phase liquide, les changements dans la mobilité ionique sont dominés par des dans changements dans le volume libre. On peut décrire les mobilités observées dans les liquides sans faire de référence aux énergies d'activation qui sont suggérées par le modèle d'Arrhénius.

Mots clés : ion, mobilité, fluide, densité, attachement d'électron.

[Traduit par la revue]

Introduction

Ion transport in low density gases (1) is largely governed by binary collisions between the ion and gas molecules, so the molecule number density n exerts a major effect. In the liquid phase the ion is in constant contact with fluid molecules; the mobility is often related to the fluid viscosity η (2). In recent years ion transport has been examined as a function of fluid density from that of a normal gas through that of the critical fluid to the density of a normal liquid (3–6): a transition from density control of the mobility to viscosity control occurred at $0.5 \leq n/n_c \leq 1.9$, corresponding to $0.6 \leq \eta/\eta_c \leq 3$ (subscript c denotes a critical fluid property). The bulk of the previous work was done in rare gas and hydrocarbon fluids in which extra electrons are not captured (non electron attaching fluids). As a result mobile electron states can also be observed.

In this work the study of ion transport is extended to the electron attaching fluids carbon disulfide, sulfur hexafluoride, and hexafluorobenzene. The electron capturing properties of these fluids are different from some other electron capturers such as carbon dioxide. In CO_2 extra electrons are not captured at $n < 9 \times 10^{25}$ molecules/m^3 (7). At higher densities electron attachment is stabilized by molecular clusters and capture becomes rapid. By contrast, molecules of CS_2, SF_6, and C_6F_6 at low densities already attach electrons (8–10). They also efficiently attach electrons when they are present as dilute solutes in liquid solvents (11–13). However, in the purified liquids of CS_2 (14) and C_6F_6 (13), electron states that are much more mobile than molecular ions are observed. There is indirect evidence from positronium studies that such might also be the case for purified liquid SF_6 (15). Ion mobilities μ in fluids of CS_2, SF_6, and C_6F_6 are here reported for densities from those of the low density gas, through those of the dense gas/low-density liquid transition region, to those of the normal liquid.

Experimental

A. Materials and sample preparation

These were the same as described in refs. 14 and 16.

B. Apparatus and techniques

The high pressure liquid (17) and gas (18) conductance cells were made of 1 cm thick glass and could withstand 6 MPa internal pressure. Diagrams of the cooling (19) and heating (20) setups have been published. Temperature monitoring and measurement at $T < 295$ K is described in ref. 21 and at $T > 295$ K in ref. 14. Four calibrated copper–constantan thermocouples were used, one of which was pushed down a hollow pin to a distance of 2 mm from the electrode outer surface and used to record the fluid temperature. Calibration of the thermocouples at $T < 295$ K is described in ref. 14. To calibrate the thermocouples at $T > 295$ K, they were wrapped snugly about the platinum element temperature probe of a Fluke 2189A Thermometry System. The probe was then immersed into a Dewar containing 710 Silicone fluid, the fluid heated using a Cenco 250W knife heater connected to a variable voltage adjuster, and the temperatures registered by the thermocouples/Fluke 2100A digital thermometer were calibrated to that registered by the 2189A Thermometry System.

The fluid between the plates of the cell was ionized using 0.3 or 1.0 μs pulses of X-rays from a Van de Graaf accelerater delivering (2 or 6) $\times 10^{-5}$ J/kg to the sample (22). The radiation-induced ion current was amplified using a Princeton Applied Research (PAR) 113 preamplifier. The ion mobility μ was obtained from the time t_d needed for the radiation-induced ion current to return to zero (14).

$$[1] \quad \mu = \ell^2 / t_d V$$

where the distance ℓ between the electrodes was measured directly using Do-All, model M-1 minus precision calipers, and the voltage V applied between the plates was obtained using the voltage sources cited in ref. 14. This method measures the mobility of the slowest ion.

[a]Cation mobility. In liquid CS_2 $\mu_- = (1.3 \pm 0.1)\,\mu_+$ (ref. 14); in SF_6 $\mu_- \approx \mu_+$; in gaseous C_6F_6 at $n > 40 \times 10^{25}$ molecules/m^3, $\mu_- \approx \mu_+$. For C_6F_6 at $n < 25 \times 10^{25}$ molecules/m^3 μ_- is given in the Results Sect. B.
[b]Ion mobilities at $T < 370$ K are reported in ref. 14. $T_c = 552$ K, $n_c = 354 \times 10^{25}$ molecules/m^3.
[c]$T_c = 318.7$K, $n_c = (303 \pm 4) \times 10^{25}$ molecules/m^3.
[d]$T_c = 516.8$K, $n_c = 180 \times 10^{25}$ molecules/m^3.

Whether this is the cation or anion is discussed further in the Result section.

C. Physical properties

The densities of the liquids and vapors were obtained as described in refs. 14, 16, and 23.

Results

A. Field independence

The ion mobilities in liquids were measured over a 10-fold variation of E, typically in the range $0.1 < E(\mathrm{MV/m}) < 5$. For the lower density gases, field strengths down to 3 kV/m were used. No field dependence was found. The value μ cited at each (n,T) in Table 1 was the average of > 10 measurements, half of which were made with positive and the other half with negative applied voltages. The average deviation of the measured values from the reported mean value in Table 1 was about 2%.

B. Nature of the ions

Absorption of energy from the radiation pulse produced electrons and cations:

[2] $M \rightsquigarrow M^+ + e^-$

The electron can react with all three of the present compounds to form anions.

In general, anions in both liquids and gases move faster than cations (see Figs. 1 and 2 of ref. 24 for extensive demonstration). Hence in CS_2 liquid the slowest ion was assumed to be the cation, and the cation mobility μ_+ was obtained from the time of flight method (eq. [1]). The current–time trace was slightly curved but there was not a separate portion indicating collection of the anions. Combination of the μ_+ values with a total conductance measurement gave the anion mobility $\mu_- = (1.3 \pm 0.1)\mu_+$. In the gas the current–time trace also showed a slight curvature except at $n < 3.8 \times 10^{26}$ molecules/m^3. At those lower densities a single linear decay was observed which indicated that $\mu_+ \approx \mu_-$.

A single linear decay was also observed in SF_6 at all conditions of the present work, in agreement with previous findings in SF_6 dense gas (25) and liquid (26) at 294 ± 2 K. Again the single linearly decaying signal means that $\mu_+ \approx \mu_-$. This is not unexpected since in the gas the ions are likely $SF_5^+(SF_6)_j$ and $SF_6^-(SF_6)_k$, which are the clustered forms of the main cation SF_5^+ (27) and main anion SF_6^- (28) produced in

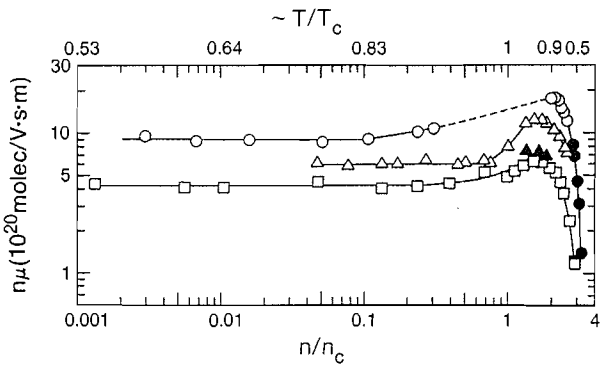

FIG. 1. Density-normalized mobility $n\mu$ as functions of reduced density n/n_c and temperature T/T_c in the liquid and coexisting vapor of CS_2 (○; ●, ref. 14), SF_6 (△; ▲, ref. 26), and C_6F_6 (□; ■, ref. 13). Temperatures and densities are listed in Table 1.

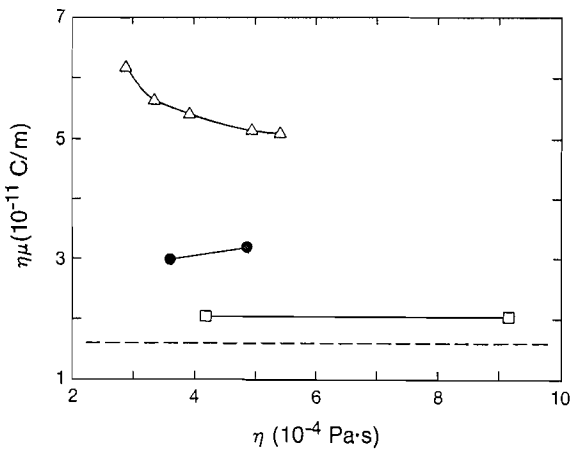

FIG. 2. Viscosity-normalized mobility plotted against liquid viscosity. Symbols as in Fig. 1. The dashed line indicates $\eta\mu_+$ in the hydrocarbon liquids *n*-pentane to *n*-tetradecane (38).

the low density gas. The values of $n\mu$ in low density SF_6 gas at room temperature are 15.6×10^{20} molecules/mV.s for SF_5^+ (29) and 14.6×10^{20} molecules/m.V.s for SF_6^- (27), which are only 7% different from each other. Clustering reduces the mobilities, and in the present system $\mu_+ \approx \mu_- = 6 \times 10^{20}$ molecules/m.V.s (Fig. 1); the extent of clustering of SF_6 molecules around the anion is evidently similar to that around the cation.

In liquid hexafluorobenzene the cations were found to be slower than the anions (13). We assume this to be also true at the conditions of Table 1, so the mobility obtained by eq. [1] is for cations. The signal trace in the liquid was slightly curved. In the gas at $n > 4 \times 10^{26}$ molecules/m^3 a single linear trace was obtained so $\mu_+ \approx \mu_-$. At $n < 2 \times 10^{26}$ molecules/m^3 a separate linear trace indicating collection of anions separate from the slower cations was found ($n/10^{26}$ molecules m^{-3}, $\mu_-/10^{-7}$ m^2 V^{-1} s^{-1}): 2.36, 20.4; 0.86, 71; 0.187, 329; 0.101, 650; 0.024, 2600.

Discussion

A. Effect of density and of viscosity

In liquids and gases the mobility of charged particles is field dependent at appropriately high fields (1). However, theoretical arguments based on the parity invariance of μ when the electric field is reversed indicated that a field-independent mobility must always be found at sufficiently low field strengths (30). The constant mobility found in this work at > 10-fold range of E indicated that the low field limit had been reached.

In low density gases and at a very low ion mole fraction, $n\mu$ at a given temperature is independent of density (1). The value of $n\mu$ can be related to the average ion–molecule momentum transfer cross section σ_{av} by (31):

$$[3] \quad n\mu = \frac{3e}{4M_r < v > \sigma_{av}}$$

In eq. [3] M_r is the ion-molecule reduced mass, e is the protonic charge, and $< v >$ is the average velocity of the ions relative to the molecules. Equation [3] is derivable from eq. [5-3-8] of ref. 1.

The present results are plotted as $n\mu$ against reduced density n/n_c in Fig. 1, along with other available results. The value in liquid C_6F_6 at 295 K agrees with previous work (13). The present values in liquid SF_6 are 1.7 times higher than earlier values (26); no reason for this is apparent.

In the saturated vapors, increasing the density requires increasing the temperature. Equation [3] for simple ions indicates that if σ_{av} were independent of ion temperature (kinetic energy), $n\mu$ would decrease as $T^{-1/2}$. In real systems the energy dependence of σ_{av} usually results in $n\mu$ increasing somewhat with increasing T at constant n, except where charge transfer dominates, in which case $n\mu$ decreases (1, 32, 33). In the present vapors the ions would be clustered with neutral molecules, which would increase their mass and tend to increase σ_{av} and decrease $n\mu$. The approximately constant value of $n\mu$ in the present gases at n/n_c up to 0.5 (Fig. 1) indicates a cancellation of opposing effects. For example, the charge-induced dipole attractions of an ion towards two molecules simultaneously, one on either side of the ion in the dense gas, would decrease the value of σ_{av}.[2] The tendency of multibody attractive interactions to decrease σ_{av} would counteract the tendency of clustering to increase σ_{av} in the dense gas.

In the dense vapor near n_c, $n\mu$ increases as n increases, due to destructive interference of the attractive, long range, charge-induced dipole interactions of the ion with more than one molecule at a time (5). At these high densities the distance between molecules is less than an ion diameter so the concept of a cluster is no longer useful. The continuum concept of electrostriction becomes applicable.

At normal liquid densities ($n/n_c > 2$) $n\mu$ decreases, because mobility is more related to the amount of remaining space between the molecules than to number density itself.

In normal liquids the ion mobility is often compared to the fluid viscosity η (2, 3, 24). Stokes' Law (34) and Walden's Rule suggest that

$$[4] \quad \mu \propto \eta^{-1}$$

so $\eta\mu$ = constant. Available values of η in the present liquids cover only a limited range of conditions (35–37). Values of $\eta\mu$ are shown in Fig. 2. At a given viscosity the ions are considerably more mobile than in the hydrocarbon liquids *n*-pentane to *n*-tetradecane (38). Using Stokes' Law, the effective radius R of the diffusing ion is

$$[5] \quad R = e/\,6\pi\eta\mu$$
$$= 8.5 \times 10^{-21}/\eta\mu, \text{ in SI}$$

[2]Note that destructive interference of attractive interactions does not imply a wave phenomenon.

[b]Arrhenius activation energy, eq. [9].
[c]T_m = temperature at the middle of the range used to obtain E.

so $R \approx 1.7 \times 10^{-10}$ m in SF_6, 2.7×10^{-10} m in CS_2, and 4.1×10^{-10} m in C_6F_6.

B. Comparison to neutral molecule diffusion

The effect of the charge of the ion on its immediate surroundings can be further examined by comparing its diffusion coefficient D_{ion} to that of the neutral molecule D_M. The value of D_{ion} can be obtained from that of μ using the Nernst–Einstein relation (1),

$$[6] \quad D_{ion} = \mu k_B T/e$$

Diffusion coefficients can be related to R, the effective radius of the diffusing particle by the Stokes–Einstein relation (39),

$$[7] \quad D = k_B T/S\pi R\eta$$

where the constant S has a value near 4 (slip boundary condition) for neutral molecule self diffusion in liquids. For ions in neutral molecular liquids or dense gases the charge particle interacts more strongly with the fluid molecules than does a neutral molecule, so $S \approx 6$ (sticking boundary condition) might apply. The difference in values of S suggests that in dense fluids $D_M/D_{ion} \approx 6/4 = 1.5$ if R is similar for the neutral molecule and ion.

Using available values of D_M (39, 40), D_M/D_{ion} is plotted against reduced density in Fig. 3. The ratio in SF_6 at $n/n_c < 0.5$ is 5.4. This is due to the longer range polarization interaction between ion and molecule compared to that between molecule and molecule, and probably a larger ionic radius because of clustering. At $n/n_c > 0.8$ the ratio decreases. The decrease in D_M/D_{ion} is attributed to (*a*) the ion interacts with several molecules at a time so there is destructive interference of the attractive, charge-induced dipole interactions; (*b*) the ion clustered by molecules becomes a less distinct entity in the denser fluid, as it attracts the many molecules in close proximity to it, which increases the local density and viscosity (electrostriction). This change in the effect of the charge is also responsible for the increase and subsequent decrease in $n\mu$ discussed in the previous section (Fig. 1). Under these circumstances ion transport and neutral molecule transport become similar and $D_M/D_{ion} \approx 1.5$, as expected from eq. [7] for the likely difference in S for ions compared to neutral molecules. The radius of the diffusing ions in liquid SF_6 is hence similar to that of a neutral SF_6 molecule.

This contrasts with the limited results in the liquids CS_2 and C_6F_6 where $D_M/D_{ion} = 2.0$ and 2.7, respectively. Hence the effective ionic radius in liquid CS_2 is likely ~ 1.3 times larger than that of a CS_2 molecule, and in liquid C_6F_6 is ~ 1.8 times larger than that of a C_6F_6 molecule.

C. Free volume model

Arrhenius plots are often used to interpret the temperature

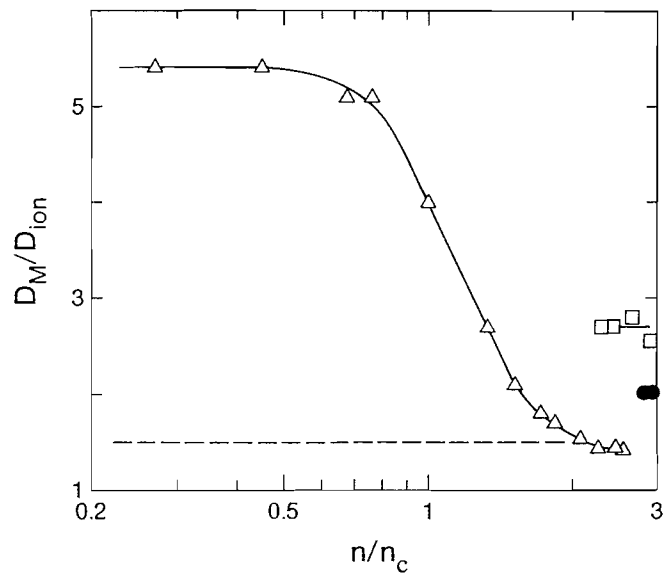

FIG. 3. Ratio of neutral molecule self-diffusion coefficient to ion diffusion coefficient in the same fluid plotted against reduced density n/n_c. Symbols as in Fig. 1. D_M values for SF_6 are from ref. 40 and for C_6F_6 from ref. 39. D_{ion} values were calculated from eq. [6]. The dashed line indicates the value 1.5 expected from eq. [7] between slip and stick boundary conditions.

dependence of diffusion coefficients in the liquid phase (37, 39, 41) and the associated activation energies are then discussed. Alternatively, transport could be described in terms of temperature and molar volume $v = 1/n$ without reference to an energy barrier (37, 39, 42–44). In liquids D_M could be fitted to $T^{1/2}$ $(v - v_0)/v_0$, where v_0 is the molar volume at which the liquid molecules are too crowded for diffusion to occur (5). Then, on the basis of eq. [6], a correlation between μ and $(v - v_0)/v_0T^{1/2}$ was expected and found (14, 38). The value of v_0 was that which gave the best approach of the μ curve to the origin. The lines for the *n*-alkane liquids *n*-hexane to *n*-tetradecane (38) and CS_2 (14) were slightly curved. To fit the results a small exponential coefficient was included:

$$[8] \quad \mu = \frac{A}{T^{1/2}}\left(\frac{v - v_0}{v_0}\right)\exp(-E/RT)$$

where A and E are the fitting parameters.

The liquid phase mobilities are shown as Arrhenius-type plots in Fig. 4. In terms of the Arrhenius model,

$$[9] \quad \mu \approx A_A \exp(-E_A/RT)$$

where A_A is the pre-exponential factor and E_A the activation energy, thermally activated processes over energy barriers

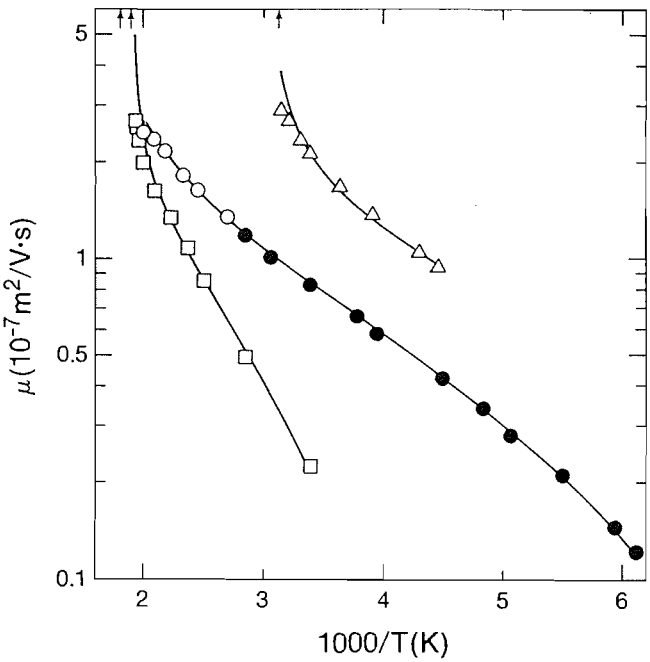

FIG. 4. Arrhenius plot of liquid phase ion mobilities. Symbols as in Fig. 1. The lines were calculated by eq. [8] using the parameter values in Table 2. Arrows indicate T_c.

would be inferred from the values of E_A (Table 2, Arrhenius lines not drawn in Fig. 4). However, the same results are better fitted by the free volume model, eq. [8], with only small values of E, to give the lines drawn in Fig. 4. The largest value of E, 0.8 kJ/mol for CS_2, is only 30% of the average thermal agitation energy RT_m (T_m = temperature at the middle of the range used to obtain E); hence E is considered to be a small exponential correction to the free volume model rather than an "activation energy". The most drastic difference between the models is for C_6F_6, for which E_A = 14 kJ/mol and E = 0.02 kJ/mol. The concept of activation largely disappears once the effect of free volume is accounted for.

Liquid–liquid equilibria for the water + ethanol + 2-ethyl-1-hexanol ternary system at several temperatures

HORACIO N. SOLIMO

Laboratorio de Físicoquímica, Instituto de Física, Facultad de Ciencias Exactas y Tecnología, Universidad Nacional de Tucumán Av. Independencia 1800, 4000 San Miguel de Tucumán, Argentina

Received January 5, 1990

HORACIO N. SOLIMO. Can. J. Chem. **68**, 1532 (1990).

Liquid–liquid equilibrium data for the system water + ethanol + 2-ethyl-1-hexanol were obtained at 298.15, 308.15, and 318.15 K. Data for the binodal curves have been determined by cloud-point method and conjugate points on tie-line were obtained by correlating the refractive index of the binodal curves as a function of composition. The tie-line data at each temperatures were satisfactorily correlated using the method of Othmer and Tobias and the plait points coordinates were estimated. The experimental data were also fitted with the UNIFAC group contribution method for the activity coefficients using the isoactivity conditions as restraint equations. From the experimental results, ethanol extraction by 2-ethyl-1-hexanol appears not to depend on temperature and 2-ethyl-1-hexanol could be selected as a promissory solvent for extraction of ethanol from aqueous solutions.

Key words: liquid–liquid equilibria, ethanol extraction, water + ethanol + 2-ethyl-1-hexanol ternary system.

HORACIO N. SOLIMO. Can. J. Chem. **68**, 1532 (1990).

Opérant à des températures de 298,15, 308,15 et 318,15 K, on a déterminé les données d'équilibre liquide-liquide pour le système eau + éthanol + 2-éthyl-hexan-1-ol. On a déterminé les données des courbes binodales à l'aide de la méthode du point de rosée et on a obtenu les points conjugués de la ligne de jonction qui permettent d'établir une corrélation entre les courbes binodales et la composition. Faisant appel à la méthode d'Othmer et de Tobias, on a pu établir une bonne corrélation entre les données relatives aux lignes de jonction pour chacune des températures et on a évalué les coordonnées des points de plissement. En se basant sur la méthode de contribution du groupe UNIFAC et utilisant les conditions d'isoactivité comme équations limites, on a ajusté les données expérimentales et les coefficients d'activité. A partir des données expérimentales, il semble que l'extraction de l'éthanol par le 2-éthyl-hexan-1-ol ne dépend pas de la température et l'on pourrait donc choisir le 2-éthyl-hexan-1-ol comme solvant pour l'extraction de l'éthanol à partir de solutions aqueuses.

Mots clés : équilibre liquide–liquide, extraction de l'éthanol, système tertiaire eau + éthanol + 2-éthyl-hexan-1-ol.

[Traduit par la revue]

Introduction

Liquid–liquid extraction provides an important alternative to distillation for the recovery of ethanol from dilute aqueous solutions. One possible extraction agent is 2-ethyl-1-hexanol (EH) which was selected as a good solvent for ethanol (1, 2). Mutual solubilities of water and EH at several temperatures have been previously measured, but our experimental results are not in agreement with those reported (3) (see Table 2). However, equilibrium data for the ternary system were not found in the literature.

If solvent extraction should be used for ethanol recovery from fermentation broth, a low volatility of the solvent is convenient because the evaporative purification of ethanol would be simpler and accompanied by considerable energy savings. Other requirements are a high distribution coefficient for ethanol, a high selectivity for ethanol compared with water, and a lack of toxicity to microorganism. EH has these characteristics though it is one of the most toxic solvent to ethanol-producing microorganism. This problem could be solved by making a barrier to solvent molecules as a protection against solvent toxicity (1).

To evaluate the potential of EH for the recovery of ethanol from aqueous solutions, the complete phase diagrams for water + ethanol + EH ternary system at 298.15, 308.15, and 318.15 K were obtained. Several tie-lines were determined for each temperature and the correlation of mutual solubility with tie line data (Othmer and Tobias' method) permitted the estimation of the plait point coordinates (4).

The binodal curves, tie-line data, and the plait point coordinates were also fitted by using the UNIFAC group contribution method (5) and the liquid–liquid equilibrium (LLE) interaction parameters reported by Magnussen *et al.* (6).

Experimental

Anhydrous ethanol (Merck, reagent grade) was dried with magnesium activated with iodine under reflux. The product was then fractionally distilled and the middle fraction collected. The last traces of water can be removed by passing the ethanol through a glass column (3 × 200 cm) packed with 0.3 nm molecular sieves.

2-Ethyl-1-hexanol (Sintorgan, commercial grade) was dried over freshly activated CaO and fractionally distilled under reduced pressure. The middle portion with bp 76–78°C at 9 Torr was collected (Purity: 99.9% by GC).

Water was bidistilled in an all-glass apparatus.

All organic purified chemicals were stored over activated molecular sieves to prevent water absorption.

Data for the saturation curves were determined by using the cloud-point method as described earlier (7). Binaries of known composition were shaken in an equilibrium cell equipped with magnetic stirrer and a jacket for circulating the isothermal water at the desired temperatures (±0.05°C). The third component was added from a microburet until the transition point was reached. The contents of the three components yielding a complete binodal curve were determined by weight.

The uncertainty in the observed values was determined by the accuracy of the observation of the transition point since the quantities of the titrating component and the titrated mixtures were accurately determined by weight. The uncertainty through the whole curve was less than 0.05 weight fraction % ethanol at each temperature.

After equilibrium was reached, the refractive index of the ternary mixtures was measured with a Jena Abbe refractometer at each temperature with an accuracy of ±0.0001, and with these values a

calibrating curve refractive index vs. weight fraction of ethanol was drawn.

Different weighted ternary mixtures with compositions within the heterogeneous region were shaken vigorously in the equilibrium cell for at least 2 h at constant temperature for the tie-line determinations. Preliminary experiments indicated that this time period was sufficient to reach equilibrium. The magnetic stirrer was then turned off and samples of each phase were taken. Samples were analyzed by

measuring their refractive index, and the compositions were obtained with the aid of a calibrating curve. The two end points of a tie-line were thus obtained. An independent material-balance of an equilibrium mixture must lie on a straight line joining the equilibrium layers.

Results and discussion

Densities and refractive indexes of the pure liquids were in good agreement with values published in the literature (8, 9) and are shown in Table 1.

Mutual solubilities of water with EH are listed in Table 2 along with literature values for comparison.

The experimental values for the binodal curves for the three temperatures studied are given in Tables 3, 4, and 5. The tie-line data are given in Table 6.

Figure 1 shows the liquid–liquid equilibrium diagram at 298.15 K containing the binodal curve, tie-lines, and the plait point for the water + ethanol + EH system. Similar plots are obtained at 308.15 and 318.15 K, but are not shown. Predicted LLE data by the UNIFAC method are also shown.

The tie-line data at all the temperatures are satisfactorily correlated by the method of Othmer and Tobias (10). The correlation is shown in Fig. 2 where the dependence of

solubility on temperature is clearly shown. Experimental plait points coordinates calculated by using the method of Othmer and Tobias, the UNIFAC plait points coordinates calculated by the same procedure, and the linear correlation coefficients for this method at the three temperatures are given in Table 7.

In selecting solvents, it is necessary to take into account the effect of aqueous ethanol concentration on the ethanol distribution coefficients and the selectivity for ethanol over water.

As shown in Table 8, the ethanol distribution coefficients defined as the ratio of the ethanol concentration (wt%) in organic phase to that in the aqueous phase are not constant, and they have a tendency to increase as ethanol concentration is increased. However, in the low ethanol concentration range the distribution coefficient may be considered to be constant. Similar conclusion can be derived from the distribution coefficient for water (defined as the equilibrium water content in solvent phase, which can be seen in Fig. 1, see also Table 8). The ratio of ethanol distribution coefficient to water distribution coefficient yield the selectivity ratio shown in Table 8.

Zane Egan *et al.* (11) conclude that solvents with experimental distribution coefficients for ethanol greater than 0.15 and a selectivity ratio greater than 10 are potential candidates for extraction process. As shown in Table 8, these extraction properties are largely exceeded by EH, making it a useful alternative for ethanol extraction.

Figure 3 shows a selectivity diagram on a free-solvent basis at all temperatures (12), where ethanol is the distributed substance. As can be seen, the selectivity at 298.15 K is slightly higher than that for the other temperatures studied. Therefore ethanol extraction could be carried out at room temperature, thus saving energy while preserving a fairly important heterogeneous zone. The experimental solubility of this system shows a normal temperature behaviour and similar conclusions are obtained with the UNIFAC method.

At the three temperatures studied the aqueous layer is richer in ethanol than the organic layer (see Figs. 1–3) in the lower ethanol concentration range, which is the most important region for extraction of fermentation broth. However, in the higher ethanol concentration region (above 39% at 298.15 K) an opposite situation is observed. At higher temperatures this situation occurs at lower ethanol concentrations (above 32% at 308.15 K and above 26% at 318.15 K). This is confirmed by the

fact that the ethanol distribution coefficients are higher than that above these ethanol concentrations as can be seen in Table 8.

The liquid–liquid equilibrium data of the ternary system were also predicted using the UNIFAC method (5), which allows the activity coefficients of the three components of both phases to be calculated. The group interaction parameters used were those obtained by Magnussen *et al.* (6) from experimental liquid–liquid equilibrium data and they are shown in Table 9. The equilibrium compositions were calculated using a computer program in which the compositions of the ends of tie-lines are found starting from hypothetical mixtures that give rise to conjugate experimental phases. Figure 1, in which the predicted binodal curve and tie-lines are displayed as continuous lines,

8 H_2O	342.4	−122.4	0.0

*From ref. 6.

shows that the UNIFAC method predicts an immiscibility region larger than that experimentally observed. The inaccuracy of the predictions as measured by the function

$$[1] \quad F_p = 100 \sqrt{\Sigma \Sigma \Sigma (W_{ijk} - \hat{W}_{ijk)2}/6M}$$

was 2.64% at 298.15 K, 2.66% at 308.15 K, and 2.46% at 318.15 K (wt%) where W_{ijk} is the experimental weight fraction of the component i in the phase j for tie-line k; $\hat{W}_{ijk}$ is the UNIFAC calculated weight fraction of the component i in the same phase and tie-line; and M is the number of tie-lines.

Conclusions

Liquid–liquid equilibrium data for the ternary mixture water + ethanol + EH were determined at 298.15, 308.15, and 318.15 K. Comparison of the experimental data for the three temperatures studied here shows that the immiscibility region becomes rather smaller as the temperature rises.

Figure 1, and the residuals of the UNIFAC predictions (F_p) of liquid–liquid equilibrium data for this system (2.64% at 298.15 K, 2.66% at 308.15 K, and 2.46% at 318.15 K), show a correct qualitative behaviour regarding mutual solubilities, but gave a poor quantitative agreement with the experimental data. This could probably be due to inappropriate values for the interaction parameters used for the calculation and the fact that the UNIFAC method had not taken into account the interaction between the OH group of both alcohols in the solution for LLE calculation.

From the analysis of the ethanol extraction properties of EH (see Table 8) it is possible to conclude that this solvent should be considered a potential extractant of ethanol from their aqueous solutions at room temperature.

Stabilization of iron-catalysed hydrogen peroxide decomposition by magnesium

JOHN ABBOT AND DOUGLAS G. BROWN
Chemistry Department, University of Tasmania, Hobart, Tasmania, Australia

Received January 5, 1990

JOHN ABBOT and DOUGLAS G. BROWN. Can. J. Chem. **68**, 1537 (1990).

Catalytic decomposition of alkaline hydrogen peroxide by iron can be retarded by introduction of magnesium ions. This effect has been studied to evaluate the possibility of stabilization via formation of an iron–magnesium complex species. Under alkaline conditions, magnesium reacts with initial hydrolysis products of Fe^{3+} to produce a colourless complex species, in which the metal centres are probably linked through oxy or hydroxy bridges. This species is produced when the Mg:Fe molar ratio exceeds 6:1, and this ratio is also significant when magnesium is introduced during peroxide decomposition experiments. The evidence suggests that complex formation is an important factor in producing stabilization, and cannot be disregarded in favour of an alternative explanation where superoxide radicals combine with Mg^{2+} to produce magnesium dioxide.

Key words: hydrogen peroxide, kinetics, iron, magnesium, stabilization.

JOHN ABBOT et DOUGLAS G. BROWN. Can. J. Chem. **68**, 1537 (1990).

L'introduction d'ions magnésium peut retarder la décomposition catalytique du peroxyde d'hydrogène alcalin par le fer. On a étudié cet effet dans le but d'évaluer la possibilité de le stabiliser par le biais de la formation d'un complexe fer–magnésium. Dans des conditions alcalines, le magnésium réagit avec les produits initiaux d'hydrolyse du Fe^{3+} pour donner un complexe incolore dans lequel les centres métalliques sont probablement liés par des ponts oxy ou hydroxy. Il y a production de cette espèce lorsque le rapport molaire Mg:Fe est supérieur à 6:1; ce rapport est aussi important lorsqu'on introduit du magnésium lors des expériences de décomposition du peroxyde. Les données suggèrent que la formation du complexe est un facteur important dans la stabilisation du produit et qu'on ne peut pas l'éliminer en faveur d'une explication alternative qui impliquerait une combinaison des radicaux superoxydes avec le Mg^{2+} pour donner du dioxyde de magnésium.

Mots clés: peroxyde d'hydrogène, cinétique, fer, magnésium, stabilisation.

[Traduit par la revue]

Introduction

The decomposition of hydrogen peroxide in the presence of iron has been studied for many years, particularly under acidic conditions (1–3), where iron is believed to act as a redox catalyst, participating in free radical processes. Although this catalytic process has been studied to a lesser extent at higher pH levels, there is also strong evidence for free radical processes under alkaline conditions (4, 5). At pH levels 10–13, this reaction is of particular interest as hydrogen peroxide is used as an industrial bleaching reagent under these conditions. Loss of hydrogen peroxide due to catalytic decomposition reactions in the presence of transition metals, particularly iron, copper, and manganese, has been a problem in the bleaching of mechanical pulps for manufacture of newsprint, as these metals are often found as trace elements in wood (6). It has been estimated that as much as 30% of the initial hydrogen peroxide charge introduced may be decomposed in these undesirable side reactions (7).

A wide range of chemicals have been tested as stabilizing agents for alkaline hydrogen peroxide systems (8). Complexing agents such as DTPA and EDTA are known to inhibit the catalytic decomposition by iron (4, 9, 10). Other reagents such as sodium silicate and magnesium salts also have proven stabilizing effects, and have widespread industrial application (5, 11). The mechanisms by which stabilization occurs is, however, not clear. The influence of magnesium on the iron-induced decomposition of hydrogen peroxide has been reported by a number of investigators (5, 12). There is some evidence that magnesium forms a "complex" with iron, bonding through hydroxy or oxy bridges. In the presence of carbohydrates, a complex with a Mg:Fe molar ratio of 6:1 has been reported (12, 13), and reduction of peroxide decomposition has been associated with the catalytic inactivity of this species.

Degradation of carbohydrates under alkaline conditions is also retarded by addition of magnesium salts (12, 14, 15). This process is found to be catalysed by the presence of iron, proceeding through a chain reaction involving free radical species (13). Stabilization under these conditions has been attributed to interruption of the chain reaction, through combination of magnesium ions and O_2^- to produce MgO_2 (13). A recent study concluded that this process also occurs during stabilization of peroxide decomposition, and complex formation between iron and magnesium was discounted (5). In the present study we have looked for further evidence for the formation of an iron–magnesium complex, and examined its influence on the peroxide decomposition reaction.

Experimental

Hydrogen peroxide was obtained from BDH Chemicals. Trace metal analyses of the peroxide and also Milli-Q deionized water were carried out by the CSIRO Marine Laboratories in Hobart, Tasmania, using atomic absorption, and the results are shown in Table 1. Levels of

metallic impurities in the peroxide are comparable to other reported analyses (16). Ferric nitrate (99.99 + %), potassium hydroxide (99.99%) of semiconductor purity and magnesium nitrate (99.99%) were supplied by Aldrich Chemicals and the manufacturers trace analyses are also given in Table 1.

All peroxide decomposition experiments were carried out at a constant temperature of 20°C in capped polyethylene bottles. The bottles were cleaned between experiments using warm dilute sulphuric acid, rinsed with water, dilute potassium hydroxide solution, and finally multiple washings with Milli-Q water.

Decomposition experiments were carried out in hydrogen peroxide solution with initial concentration 0.10 M prepared by addition of 5.0 mL concentrated hydrogen peroxide, ferric nitrate, and potassium hydroxide to an appropriate volume of Milli-Q water. The total volume of solution used was 500 mL. The initial amount of iron introduced was 9.71×10^{-5} mol in all experiments. Aged iron samples were prepared by allowing the solutions to stand at 20°C prior to addition of hydrogen peroxide. The extent of reaction was monitored by titrimetric determination of 10 mL samples withdrawn at intervals. Samples were acidified with sulphuric acid and excess potassium iodide added with a few drops of ammonium molybdate solution. The liberated iodine was titrated against standardized sodium thiosulfate solution (17).

Ultraviolet–visible spectra were recorded using a Varian DMS 100 spectrophotometer.

Results and discussion

Peroxide decomposition in the absence of iron

Hydrogen peroxide decomposition without introduction of ferric nitrate was found to depend on the pH of the alkaline solution. Figure 1 shows that, for a given pH level in the range pH 9–13, the decomposition reaction is first-order with respect to total peroxide concentration. The pH of these solutions was not observed to vary significantly during the initial course of reaction, up to 5% conversion. Table 2 shows the calculated first-order rate constants at each pH level studied.

Under alkaline conditions, the decomposition of hydrogen peroxide has been attributed to an uncatalysed, homogeneous bimolecular reaction involving the perhydroxy anion, HO_2^- (18, 19), and accounts for residual decomposition observed when complexing agents such as EDTA and DTPA are introduced (4). This "spontaneous" decomposition has been shown to be second-order with respect to peroxide concentration (4, 20).

Many previous investigations on alkaline peroxide decomposition have noted the importance of purification of the alkali, as this is usually the source of metallic impurities (4, 21). Semiconductor grades of sodium and potassium hydroxide containing very low levels of trace metals are now commercially available, and are well suited for this type of investigation. The very low residual levels of metallic impurities (Table 1) appear to catalyse the first-order peroxide decomposition reactions shown in Fig. 1.

Iron-catalysed decomposition of peroxide

Figure 2 shows the variation in hydrogen peroxide concentration at two pH levels for initial addition of ferric ions at 20°C. It is apparent that the initial rate of peroxide decomposition increases with alkalinity of the solution in the range pH 8–11. It has been reported (22, 23) that, under alkaline conditions, decomposition in the presence of iron can be represented by a first-order kinetic expression with respect to hydrogen peroxide concentration. Figure 3*a* shows that, for results at pH 11.0, there is a non-linear relationship between time and the logarithm of peroxide concentration, unless only the initial reaction period is considered. Other studies have also recognized that this system is indeed more complex than can be represented by a simple first-order process (21, 24). One analysis of kinetic data was interpreted on the basis of two parallel decomposition pathways (21). The first route was reported to depend on the concentration of undissociated hydrogen peroxide and the

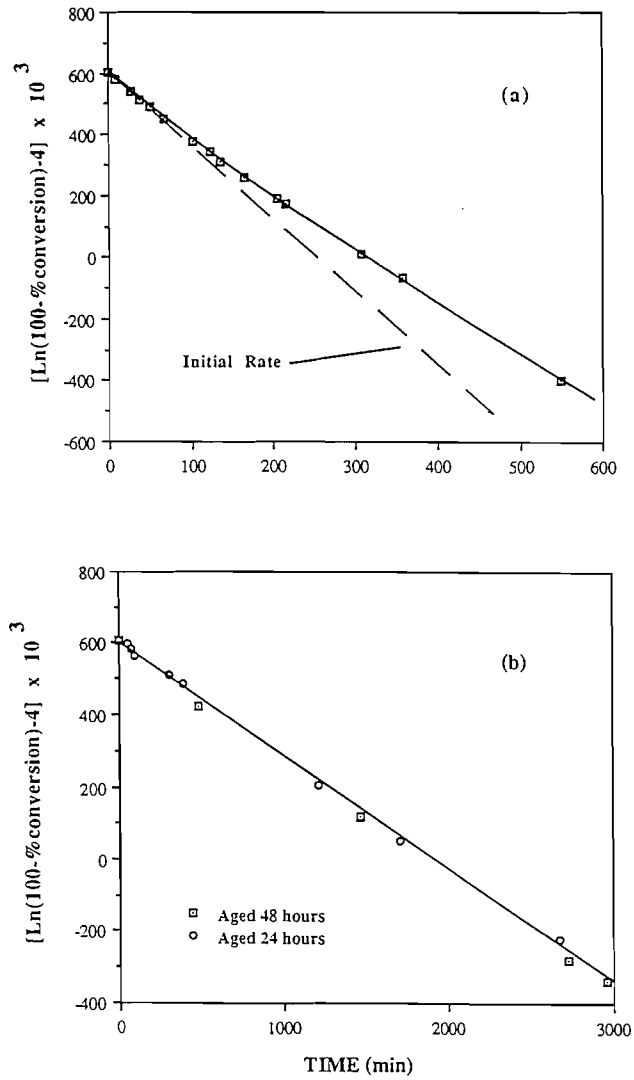

FIG. 3. Logarithmic plots for hydrogen peroxide decomposition at pH 11.0; (*a*) fresh solution, (*b*) after aging of iron for 24 h and 48 h.

alkalinity of the solution for a given metal ion concentration, while the second was independent of the concentration of molecular hydrogen peroxide (21).

An alternative, and probably more fruitful approach, is to recognize that the catalytic species itself evolves with time, and this will be reflected in any kinetic analysis which examines the relationship between decomposition rate and peroxide concentration, as time progresses.[1] Indeed, a declining concentration of the active catalytic species may explain why apparent orders of reaction in the range 1.8–2.0 with respect to peroxide have been reported (24).

It is well known that aqueous solutions of Fe^{3+} undergo hydrolysis to give complex mixtures of species (25), dependent on both pH and time. Hydrolysis products range from simple monomeric species such as $FeOH^{2+}$, through dimers and trimers including $Fe_2(OH)_2^{4+}$, to polymeric species represented by $[Fe(OH)_x(NO_3)_{3-x}]_n$ where $n \sim 900$ (26). The behaviour of such systems has been studied in detail at low pH (27–31), where attainment of equilibrium can occur very slowly, even requiring weeks or months. The evolution of iron species in strongly alkaline media appears to be less well defined, although

[1]J. Abbot and D. G. Brown. Int. J. Chem. Kinet. To be published.

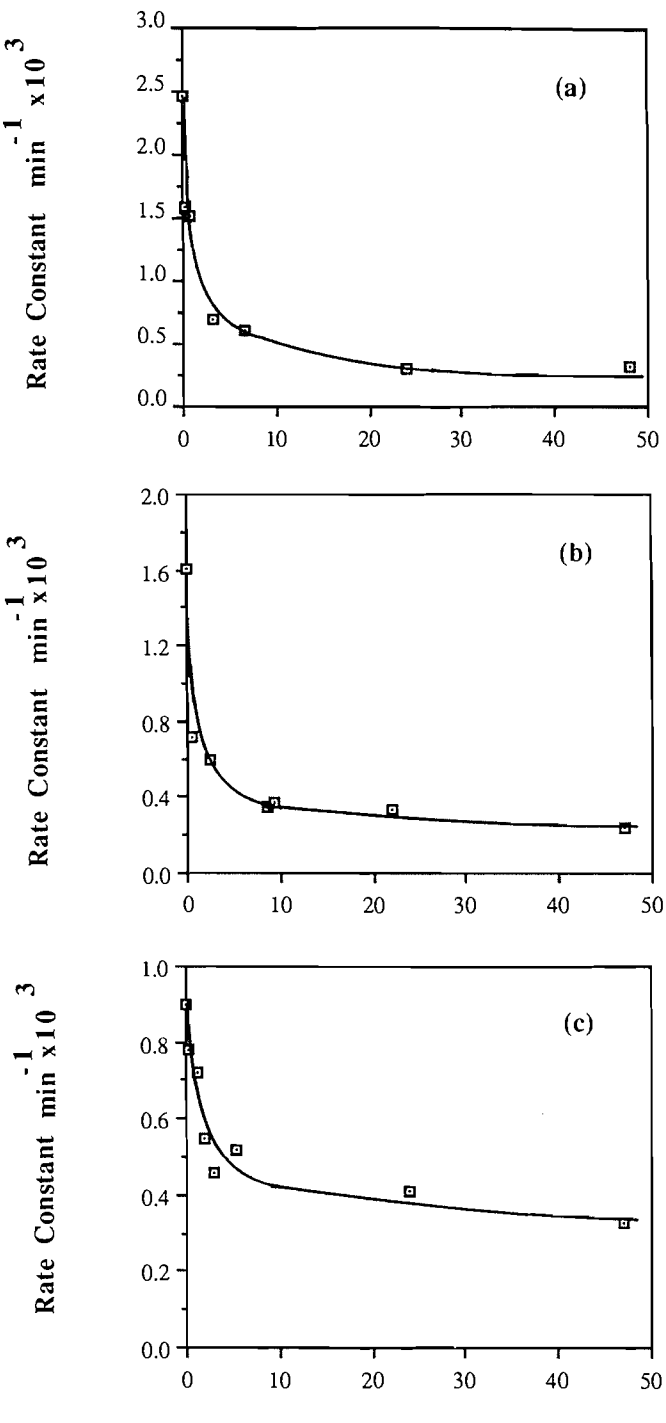

FIG. 4. Effect of aging of iron on initial reaction rates for an iron-catalysed peroxide decomposition at (*a*) pH 11.0, (*b*) pH 9.6, (*c*) pH 8.6.

it is established that the solutions "age" with time, and the aged iron species are less active towards decomposition of hydrogen peroxide (32). Aging of these iron solutions appears to be accompanied not only by an increased degree of polymerization, but replacement of hydroxyl bridges by oxy bridges in the polynuclear iron species (33, 34).

Figure 4*a* shows the variation in initial first-order rate constant for peroxide decomposition at pH 11.0 as the solution is allowed to age prior to addition of hydrogen peroxide. These

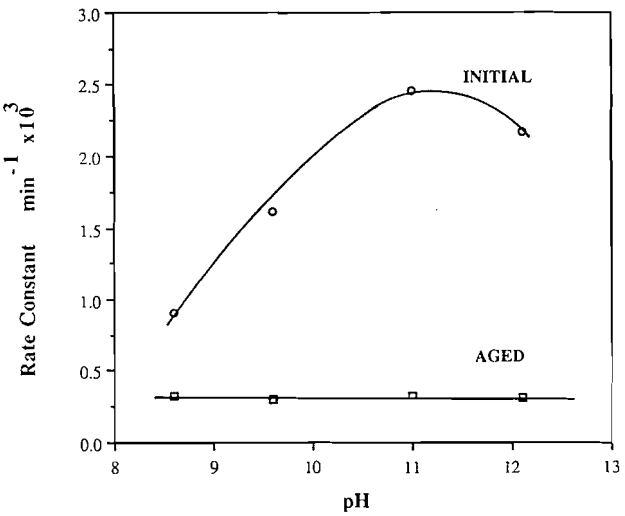

FIG. 5. Effect of pH on initial reaction rate and rate for aged systems (48 h) for iron-catalysed decomposition of hydrogen peroxide.

values have been calculated by subtracting the first-order rate constant for the reaction in the absence of iron (Table 2) from the observed total rate constant. It is apparent that, under the conditions used, the contribution to peroxide decomposition from the "blank" experiments is small compared to that due to the introduced iron. Aging of these solutions took place at pH 12.1, and addition of hydrogen peroxide was accompanied by a reduction in the pH of the solution. It is apparent that aging of the solution is accompanied by an initial rapid decline in catalytic activity of the species present. After about 20 h a constant level of activity is reached. This is also illustrated in Fig. 3*b*, which shows a first-order plot for results obtained after aging the catalysts for 24 and 48 h, respectively.

Figures 4*b* and *c* show that similar trends are observed for peroxide decomposition at pH 9.6 and 8.6, corresponding to aging of the solution at pH 11.0 and 10.2, respectively. The limiting value of the rate constant is observed to be almost independent of pH, as shown in Fig. 5. This figure also shows that the first-order rate constant for initial decomposition of hydrogen peroxide does, however, depend on the pH of the solution and exhibits a maximum at pH ~11. In calculating these values, the rate constants for the corresponding "blank" reactions have again been subtracted from the overall first-order rate constant for peroxide decomposition. A maximum in decomposition at pH ~11 in the presence of iron has been reported previously (24).

Formation of the iron–magnesium complex

Addition of magnesium nitrate to alkaline solutions at 20°C, with ferric nitrate initially introduced, caused precipitation within a few minutes. For systems with pH above 9 and a molar ratio for Mg:Fe in excess of 6:1, the precipitate dissolved on standing to produce a clear, colourless solution. Addition of magnesium to produce molar ratios less than 6:1 also caused precipitation, but complete dissolution did not occur even after standing for 24 h. For solutions with pH <9, the initially formed precipitate also did not dissolve to produce a clear, colourless solution, even when the molar ratio for Mg:Fe was in excess of 6:1. Dispersion of these precipitates by rapid stirring produced solutions containing a coloured colloidal suspension.

Figure 6 shows uv–visible spectra for alkaline iron solutions immediately after addition of ferric ions at pH 12.1, and after allowing the resulting solutions to stand for 24 h. Aging of the

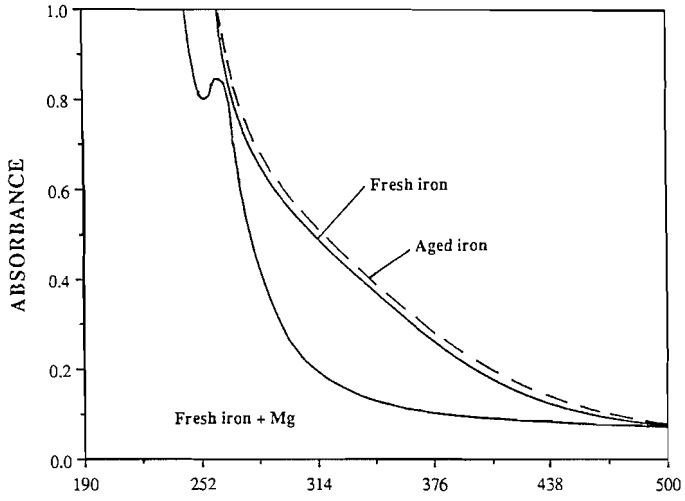

FIG. 6. Ultraviolet–visible spectrum for (*a*) alkaline solution of ferric nitrate at pH 12.1, (*b*) alkaline ferric nitrate with magnesium nitrate added.

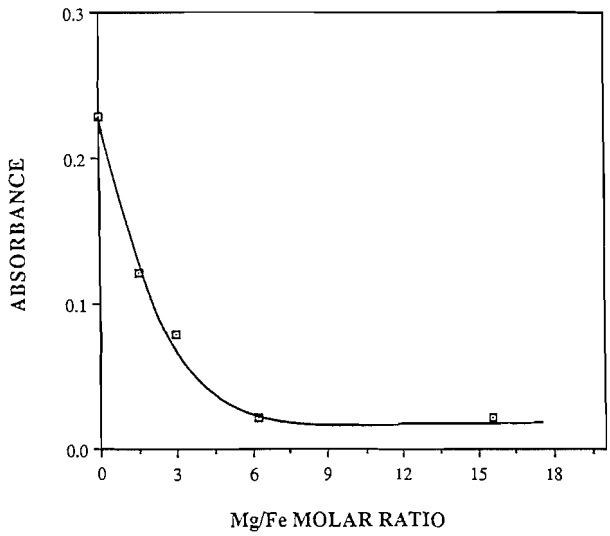

FIG. 7. Effect of Mg:Fe molar ratio on the absorbance at 376 nm.

system does not appear to have a significant influence in the visible region of the spectrum. Figure 6 also shows the corresponding spectrum for the alkaline magnesium-iron system (6:1 molar ratio) at the same total concentration of iron, after standing for about one hour at pH 12.1. The clear solution has an absorbance maximum at 255 nm. Little change in this spectrum was detected on further standing at 20°C.

The change in absorbance in the visible region can be used to follow the effect of Mg:Fe molar ratio on a freshly prepared alkaline solution at pH 12.1. Previously reported studies have shown a discontinuity in the visible absorbance spectrum corresponding to a molar ratio of ~6:1 for Mg:Fe for solutions containing gluconic acid (12). Selecting an arbitrary value of wavelength at 376 nm, Fig. 7 shows the influence of the Mg:Fe molar ratio on absorbance. For samples with Mg:Fe less than 6:1, the solution was stirred vigorously to obtain a homogeneous colloidal suspension prior to measurement of the absorbance. It is clear from Fig. 7 that, in the absence of gluconic

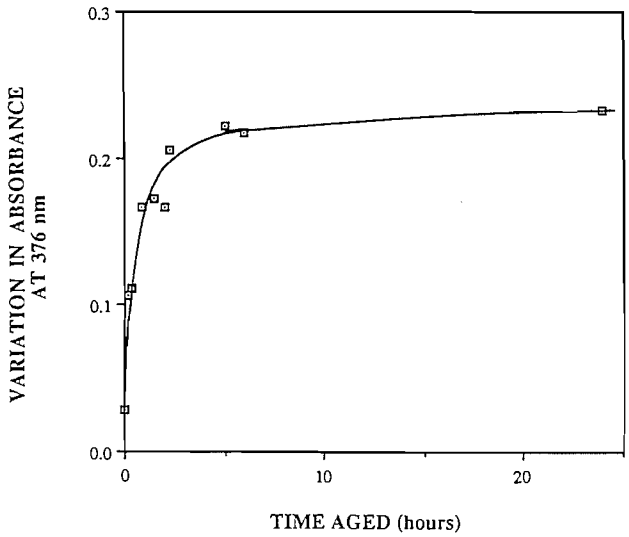

FIG. 8. Variation in absorbance at 376 nm with aging of alkaline ferric nitrate solution at pH 12.1 followed by addition of magnesium nitrate (Mg:Fe molar ratio 15:1).

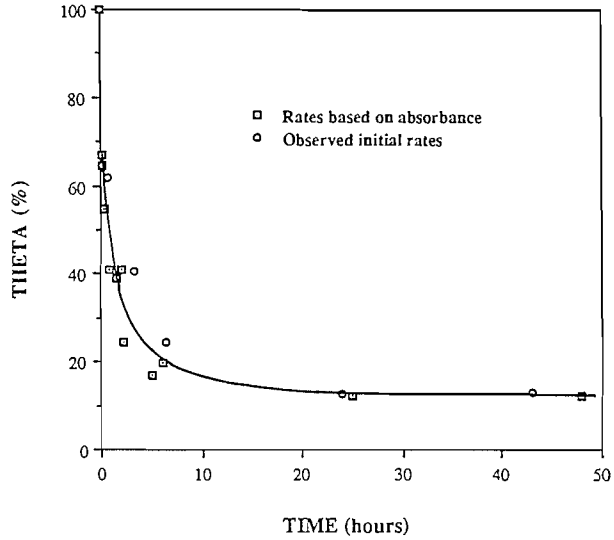

FIG. 9. Correlation between observed initial rate of peroxide decomposition, and rates calculated from absorbance measurements.

acid, there is also a marked discontinuity in absorbance at the 6:1 molar ratio.

Aging phenomena and the iron–magnesium complex

Addition of magnesium to freshly prepared alkaline iron solutions with pH > 10 and Mg:Fe > 6:1 were observed to give clear colourless solutions after dissolution of initially formed precipitates. In contrast, addition of magnesium to iron solutions aged for 24 h at similar pH levels produced no significant change in the absorbance spectra in the visible range. Addition of magnesium to the fully aged iron systems caused precipitation within a few minutes, and the solutions were vigorously stirred, as before, prior to absorbance measurements. It can be concluded that magnesium interacts only with initially produced hydrolysis products from Fe^{3+} to form the colourless complex. Although magnesium may also interact with the aged species, the products formed do not give rise to observable changes in the visible absorbance spectra. This property can be used to follow the progress of the aging process.

Iron solutions at pH 12.1 were allowed to age for various periods, after which magnesium nitrate was added to give a Mg:Fe ratio of 15:1, to provide a large excess of magnesium. The resulting mixtures were allowed to stand for at least an hour, vigorously stirred, and the absorbance spectrum measured in the visible region. The resulting series of spectra were intermediate between those obtained for the freshly prepared and the fully aged (24 h) samples. Figure 8 shows the difference in the measured absorbance at 376 nm between freshly prepared and aged iron after addition of magnesium as the duration of aging was increased. This shows that the absorbance at this wavelength decreases rapidly during the initial aging period, after addition of magnesium, reaching a constant value after an aging period of ~10 h, following the general behaviour of the activity profile in Fig. 4*a*.

The correlation between the activity of the iron species present at various times and the formation of the iron–magnesium complex as reflected by the absorbance measurements can be considered further. Figure 9 shows the change in initial activity of the iron species present, plotted as a percentage (θ) of initial activity, as aging progresses. These values can be compared with those for θ_{Abs}, calculated according to the expression

$$\theta_{Abs} = \left[\frac{k_F (A_A - A_S)}{(A_A - A_F)} + \frac{k_A (A_S - A_F)}{(A_A - A_F)} \right] \times 100\%$$

where k_F and k_A are the first-order rate constants for peroxide decomposition by the fresh and fully aged iron respectively; A_F, A_A, and A_S are the absorption values for fresh, fully aged, and partially aged samples respectively.

This expression assumes that the iron is either present as the more active, initially formed species, which complexes with magnesium, or a second less active species, and that the former is converted directly to the latter. This will almost certainly represent a simplification, as there are likely to be more than two hydrolysis products present at any particular time (25). However, Fig. 9 demonstrates that there is a reasonable correlation between θ and θ_{Abs}. This indicates that there is a direct relationship between peroxide decomposition rate and the presence of highly active initial hydrolysis products of Fe^{3+}, which can react with magnesium to produce the colourless complex.

Figure 10 shows the effect of increasing the molar ratio of Mg:Fe initially introduced on decomposition of hydrogen peroxide at pH 11.0. Increasing the amount of magnesium present inhibits peroxide decomposition up to the point where a 6:1 molar ratio is present. Further increases in this ratio appear to have little influence on the reaction. A significant increase in decomposition rate corresponding to an Fe/Mg molar ratio of 0.167 has been previously reported (5). These authors, however, discounted the significance of this ratio as evidence for complex formation in favour of stabilization through reaction between magnesium ions and superoxide radicals to produce magnesium dioxide and oxygen (5).

The existence of complex species formed between iron and magnesium with 6:1 stoichiometry in the presence of gluconic acid under alkaline conditions has been reported previously (12). Structures for this type of complex have been proposed, which involve oxy or hydroxy bridges between the metal centres. Structures of this type are well known for a wide variety of metals and have been extensively studied as hydrolysis products of individual metal ions (31, 35–37). Much less seems to be known about species containing mixed metal centres.

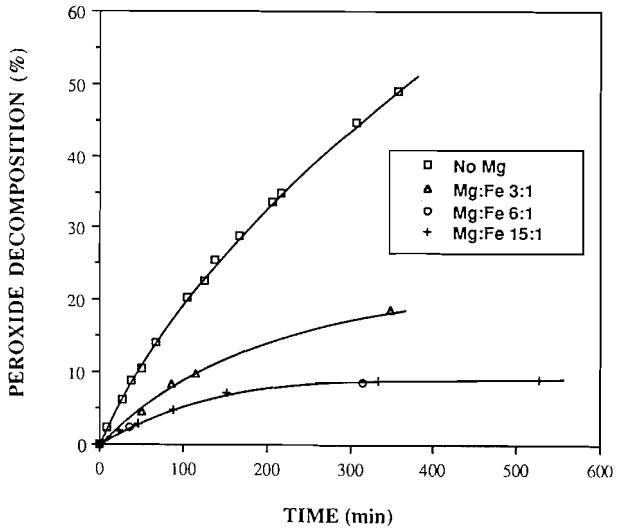

FIG. 10. The influence of magnesium addition on freshly prepared ferric nitrate solutions during peroxide decomposition at pH 11.0.

Iron–scandium and iron–zirconium complexes have been reported (38), and addition of tin salts to iron systems has been shown to stabilize peroxide decomposition under alkaline conditions (8).

The effect of a particular metal additive such as magnesium may not, however, be universal when used in conjunction with catalytically active ions such as iron, manganese, and copper. Addition of magnesium ions to alkaline systems containing manganese ions is reported to produce a rapid acceleration in the rate of peroxide decomposition (5, 39). Recent investigations[2] have confirmed this effect, again showing a correlation between complex formation followed by absorbance measurements, and catalytic activity of the species formed. Evidence for complex formation and structural details has also been provided for the alkaline Mn/Mg system through esr studies (39). These investigations showed that the manganese centres are well separated in the presence of magnesium, so that their environment does not permit significant interaction between Mn^{2+} centres (39). It would appear that the catalytic effects of combinations of hydrolysable metal ions are very specific, and simple explanations such as disruption of the free radical chain process by combination of free Mg^{2+} with intermediate species such as O_2^- are unlikely, particularly as this cannot explain an acceleration of decomposition.

The studies by Colodette *et al.* (5) have shown that the concentration profiles for superoxide anion radical species are perturbed by the addition of magnesium to the iron – alkaline peroxide system. We would infer that this reflects the activity of Fe—O—Mg bridged complex species, as opposed to Fe—O—Fe species, rather than a disruption of the free radical chain reaction by isolated Mg^{2+} ions. Further studies will be required to elucidate the role of the iron–magnesium complex species in producing a stabilization effect, and whether complex formation in other systems such as manganese–magnesium can give rise to species in which the catalytic activity is enhanced rather than suppressed.

The present study has provided additional evidence for complex formation leading to bridged species containing both iron and magnesium centres, thereby modifying the catalytic activity towards peroxide decomposition. These studies were carried out at 20°C, rather than at higher temperatures (50–70°C) usually encountered in commerical bleaching operations. Studies at the lower temperature facilitate measurement of the initial rapid aging process as well as the absorbance of the species present, and we believe that similar phenomena are likely to be observed at raised temperatures. It has also been noted that iron species present in water used for commercial bleaching processes are more likely to resemble "aged" rather than "fresh" iron (5, 32). The extent of interaction between magnesium ions and aged iron species is not clear from the present studies and further investigations will be needed to show whether alternative mechanisms for stabilization through introduction of magnesium are applicable in this situation.

Conclusion

Our studies confirm the existence of complex formation between magnesium and iron species in alkaline solutions above pH 9. Absorbance measurements indicate a stoichiometry of 6:1. The complex is formed through interaction of Mg^{2+} with initially formed hydrolysis products from ferric ions, and dissolves to give a colourless solution. Iron species produced by aging do not undergo reaction to give the colourless complex. These phenomena can be used to follow the progress of the aging process, and provide correlations between activity in peroxide decomposition and complex formation. The rapid peroxide decomposition rates observed for freshly prepared solutions of Fe^{3+} can be directly linked to the presence of initial hydrolysis species which can undergo complexation with magnesium. In the presence of hydrogen peroxide, under alkaline conditions, the Mg:Fe molar ratio of 6:1 is also significant, and suggests that formation of the complex under these conditions reduces the activity of iron towards peroxide decomposition.

Oxidative coupling of amines and carbon monoxide catalyzed by palladium complexes. Mono- and double carbonylation reactions promoted by iodine compounds

ILAN PRI-BAR AND HOWARD ALPER[1]

Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 6N5

Received November 28, 1989

ILAN PRI-BAR and HOWARD ALPER. Can. J. Chem. **68**, 1544 (1990).

Iodine is an effective promoter for the carbonylation of primary and secondary amines to ureas using palladium acetate as the catalyst and a base (e.g. K_2CO_3) in acetonitrile (3 h at 95°C and 2.7 atm). Oxamides are formed in excellent yields when secondary amines are carbonylated in the presence of iodide ion and oxygen, while primary amines give ureas as the principal product at 95°C, and oxamide at room temperature.

Key words: oxamides, ureas, double carbonylation, amines.

ILAN PRI-BAR et HOWARD ALPER. Can. J. Chem. **68**, 1544 (1990).

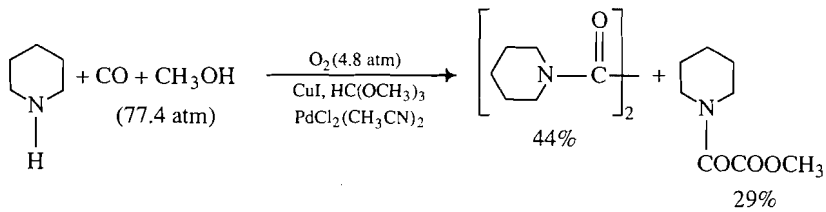
L'iode est un promoteur efficace de la réaction de carbonylation des amines primaires et secondaires qui les transforme en urées sous l'action de l'acétate de palladium qui agit comme catalyseur et d'une base (comme le K_2CO_3) dans l'acétonitrile (pendant 3 h à 95°C et à 2,7 atm). Il se forme des oxamides avec d'excellents rendements lorsqu'on effectue la carbonylation d'amines secondaires en présence d'ions iodures et d'oxygène; par ailleurs, les amines primaires conduisent principalement à des urées lorsqu'on effectue les réactions à 95°C et à des oxamides lorsqu'on effectue les réactions à la température ambiante.

Mots clés : oxamides, urées, double carbonylation, amines.

[Traduit par la revue]

One of the principal areas in homogeneous catalysis is metal-catalyzed carbonylation reactions. The carbonylation of nitrogen-containing compounds, in particular amines, has attracted considerable interest in recent years (1). For example, early studies on the conversion of amines to ureas, catalyzed by various transition metal complexes, often were carried out using stringent conditions and afforded products in low chemoselectivity and modest yields. A focus of the more recent investigations on the palladium-catalyzed carbonylation of amines to ureas has been on the application of Wacker type conditions (copper salt and oxygen) (2). In some instances, the reported yields are based on the amount of reactant consumed, which may be low, rather than on the actual quantity of amine used (2*b*). Also, the copper salt can participate in secondary oxidation reactions, resulting in low chemoselectivity (2*c*).

The double carbonylation of amines to oxamides can also be catalyzed by palladium compounds, using molecular oxygen as oxidant and cuprous iodide as the co-catalyst (3). For example, piperidine reacts in methanol, but at high pressure of carbon monoxide, to give 1,1′-oxalyldipiperidine in 44% yield and



an oxamate in 29% yield. Mixtures of products, including oxamides, result in the absence of a co-catalyst (4).

Iodine compounds (e.g. iodine, potassium iodide) have been employed in recent years as promoters for a number of reactions including the Monsanto acetic acid process, and rhodium-catalyzed carbonylation of benzyl chlorides with borate (5) or formate (6) esters. It is generally assumed that, in the Pd/Cu catalytic system, the main role of copper is to reoxidize *in situ* generated palladium(0) to palladium(II). However, it is conceivable that bimetallic palladium–copper complexes are involved in such processes (7). The use of iodine compounds instead of copper would, of course, rule out the possibility of heterobimetallic intermediates. We now wish to report that iodine and potassium iodide are effective promoters for the palladium catalyzed conversion of amines to ureas and oxamides under mild conditions. It should be noted that a heterogeneous iodide promoted oxidative carbonylation of amines to carbamate esters has been described by Fukuoka and co-workers (8). Elevated temperatures and pressures are required, and the role of the halide is unknown. Also, Chaudhari (9) has reported on the heterogeneous carbonylation of aniline using I^-/O_2. Not only is the process apparently limited to aromatic amines, but no double carbonylation occurs and much higher pressures are required.

Results and discussion

Treatment of primary or secondary amines (**1**, R′ = alkyl or aryl, R^2 = H, alkyl) with carbon monoxide in acetonitrile, in the presence of iodine, potassium carbonate, and a catalytic amount of palladium acetate, for 3 h at 95°C and 2.7 atm, affords di- and tetrasubstituted ureas (**2**). With the exception of diethylamine and di-*n*-butylamine, amines gave ureas in

$$2R'R^2NH + CO + I_2 \xrightarrow[CH_3CN,\ 95°C]{Pd(OAc)_2,\ K_2CO_3} (R'R^2N)_2CO + 2HI$$

(**1**) 2.7 atm (**2**)

reasonable to excellent yields (see Table 1 for results). The

ratio of substrate/iodine/$Pd(OAc)_2$ was 1.5/0.8/0.1 in these reactions.

The influence of several parameters on this reaction was examined using piperidine as the amine. No reaction occurs in the absence of either the palladium catalyst or iodine. A base is not required, but yields are low in its absence, presumably due to the partial conversion of the amine by HI to the ammonium salt. Other bases can be used including pyridine and calcium hydroxide. The yield of urea is dependent on the polarity of the solvent decreasing in the solvent order $CH_3CN > CH_2Cl_2 > THF > C_6H_6$. The addition of a small quantity of air or oxygen to the reaction mixture results in the formation of an oxamide, a product of double carbonylation, in addition to the monocarbonylation species (urea). In principle, a stoichiometric amount of water should also be formed in the reaction (not determined). The relative ratio of mono versus double carbonylation products depends on the proportion of oxygen to palladium. Higher yields of oxamides were realized by increasing the amount of oxygen, decreasing the palladium concentration, or increasing the reaction time. Superior results are attained for secondary amines by using potassium iodide as a promoter, and both carbon monoxide and oxygen.

$$R'R^2NH + CO + O_2 \quad (1)$$

$$\xrightarrow[\text{KI, } CH_3CN]{Pd(OAc)_2,\ K_2CO_3} [R'R^2NCO]_2 + [R'R^2N]_2CO + H_2O$$

95°C, 2.7 atm (3) (2)

As the results in Table 2 indicate, oxamides (**3**) are obtained in fine yields as the sole product from secondary amines, while ureas are the principal products formed in the case of primary amines. It is interesting to note that while di-n-butylamine gave only 2% urea on carbonylation in the presence of iodine (Table 1), carbonylation with potassium iodide and oxygen afforded the oxamide in 96% yield (Table 2). It is possible to increase the proportion of oxamide in the case of primary amines by effecting the reaction at lower temperature. Thus reacting n-butylamine for 16 h at room temperature (instead of 3 h at 95°C) gave the oxamide in 66% yield with the urea formed in 25% yield (compare entries 8 and 11 of Table 2).

As in the case of urea generation, piperidine was used as a probe to learn about factors which influence oxamide formation (Table 3). The conversion of piperidine to the oxamide is sluggish in the absence of iodide ion (Table 3, entry 1). As long as the iodide/$Pd(OAc_2)$ ratio is at least 2/1, increasing the proportion of potassium or tetra-n-butylammonium iodide has only a modest effect on product yields (entries 2–4, 8–9). The addition of potassium carbonate enhances the yield of oxamide (entries 5, 6).

Replacement of an inorganic iodide salt (KI) by a quaternary ammonium iodide has a significant effect on the reaction rate enabling one to perform the reaction at room temperature (entries 7, 8) and in a variety of solvents of which tetrahydrofuran is the most suitable (entries 8, 11–13). In these reactions, an unidentified black precipitate forms several minutes after addition of the reagents, suggesting that heterogeneous palladium species may play a role here. However, substitution of $Pd(OAc)_2$ by a heterogeneous palladium catalyst (Pd/C, Pd black, palladium oxide) results in low catalytic activity (entries 14–16). To ensure homogeneity of the catalytic system, the reaction was effected in the presence of triphenylphosphine with a 2:1 ratio of $PPh_3/Pd(OAc)_2$ affording oxamide in the highest yield (Table 3, entries 17, 18). Tetrabutylammonium iodide is still of value (entries 18, 19) and THF again is the preferred solvent (entries 18, 20, 21). Use of bidentate phosphine as the added ligand is not fruitful in terms of product formation (entries 22, 23).

Let us consider possible mechanisms for the iodine and iodide-oxygen promoted mono and double carbonylation reactions (Scheme 1). The results indicate that the mechanism of the oxidative dicarbonylation promoted by iodide differs from that of the iodine promoted monocarbonylation. For instance, the solvent effects are different in the two processes. In addition, while di-n-butylamine is readily converted to oxamide, the

generation of the urea is a sluggish reaction. Consequently, two separate catalytic cycles can be considered to rationalize these reactions (Scheme 1). Palladium acetate can react with carbon monoxide and iodine to form diiododicarbonylpalladium (**4**) (the formation of $(R'R^2NH)_2PdI_2$ by initial reaction of $Pd(OAc)_2$ with amine and iodine is also possible. Nevertheless, the end result in terms of formation of **2** and **3** is the same). Displacement of one of the iodo ligands by amine would give **5**. The latter can react in one of several ways. Reaction with carbon monoxide may afford the cationic palladium complex **6**. Amine addition to one of the carbonyl carbons of **6** may form **7** (Cycle I). The urea can then arise by reductive elimination and the by-product, palladium dicarbonyl (**8**) can undergo oxidative addition of iodine regenerating **4**. Alternatively, complex **5** can experience ligand migration, with addition of carbon monoxide to the vacant coordination site, to give **9** (Cycle II). Addition of another carbon monoxide unit would generate the ionic complex **10**. Amine addition to give **11**, followed by reductive elimination affords the oxamide and **8**. Reoxidation of the latter by oxygen and an ammonium iodide would regenerate **4**. Several of the proposed intermediates are analogous to those postulated in the palladium catalyzed carbonylation of halides to amides and α-ketoamides (10).

In conclusion, this research has demonstrated that amines can be converted to ureas in fine yields using iodine as a promoter for the palladium(II) catalyzed reaction. Also, oxamides are formed in good yields from secondary amines, and ureas from primary amines, when iodide and oxygen are used to induce the reaction. The experiment with *n*-butylamine at room temperature (last entry of Table 2) shows that primary amines can give oxamides as the principal product under appropriate conditions. Attractive features of these processes include the remarkably mild conditions, as well as the efficiency, ease of execution and work-up of the reactions.

Experimental

General data

A Perkin-Elmer 783 spectrometer was used for infrared spectral determinations, a VG7070E micromass spectrometer for mass spectra, and Varian EM-360 and XL-300 instruments were used to record nuclear magnetic resonance spectra. Gas chromatographic determinations were performed on a Varian 3400 instrument equipped with a OV-17 packed glass column, and a DB-1 capillary column.

Amines were purchased from commercial sources and were distilled prior to use. Solvents were dried by standard techniques. Reactions were carried out in a glass pressure vessel containing a magnetic stirring bar. The ureas and oxamides were characterized by comparison of infrared, nuclear magnetic resonance, and mass spectral data with those for authentic materials. Spiking of products with authentic samples, and analysis by gas chromatography, was also used to confirm the structures of the products. Standards of disubstituted ureas which were not commercially available were prepared by treatment of the corresponding isocyanate with a primary amine. Oxamides were prepared independently by reaction of oxalyl chloride with the appropriate amine.

General procedure for the iodine-promoted synthesis of ureas

Palladium acetate (0.022 g, 0.10 mmol), iodine (0.38 g, 1.5 mmol), and potassium carbonate (0.220 g, 1.6 mmol) were placed in a glass autoclave (85 mL). The reaction vessel was sealed and flushed three times with carbon monoxide. A 10 mL solution of acetonitrile containing the amine (1.5 mmol) and biphenyl (gc internal standard) was added by syringe using a rubber septum. The glass autoclave was pressurized to 2.7 atm (with CO) at ambient temperature, sealed, and heated in an oil bath at 95°C for 3 h. During this period, the color of the solution changed from red to pink. The autoclave was cooled to room temperature, the solution was filtered (precipitated inorganic salts), and the filtrate was analyzed by gas chromatography. Isolation of the urea was attained by concentration of the filtrate (rotary evaporation), followed by silica gel thin-layer chromatography, recrystallization or distillation. The ureas were characterized by comparison of infrared, nuclear magnetic resonance, and mass spectra with those for authentic materials and literature data. Disubstituted ureas which were not commercially available were independently prepared by treatment of a primary amine with the corresponding isocyanate.

General procedure for the carbonylation of amines in the presence of iodide ion and oxygen

To a mixture of $Pd(OAc)_2$ (0.022 g, 0.10 mmol), KI or $(C_4H_9)_4N^+I^-$ (0.2–0.8 mmol), K_2CO_3 (1.5 mmol) and triphenylphosphine (0.052 g, 0.20 mmol — if used) was added, under carbon monoxide, 10 mL of a THF solution containing 1.5 mmol of an amine and biphenyl (gc internal standard). Oxygen (20 mL, 1 atm) was added, and the autoclave (85 mL) was pressurized to 2.7 atm with carbon monoxide. The reaction mixture was stirred at 95°C for 3 h, cooled to room temperature, and then filtered. The filtrate (subjected to gc analysis) was concentrated by rotary evaporation, and the oxamide and/or urea were purified by crystallization or silica gel preparative thin-layer chromatography (9:1 petroleum ether – ethyl acetate). Oxamides were characterized by comparison of physical and spectral data with oxamides which were not commercially available were independently synthesized from oxalyl chloride and the appropriate amine.

Received January 19, 1990

TED SCHAEFER and RUDY SEBASTIAN. Can. J. Chem. **68**, 1548 (1990).

STO-3G and 4-31G MO computations are reported for a range of values of the folding angle in xanthene, the dihedral angle between the benzene planes. Unlike 9,10-dihydroanthracene but like dibenzo-p-dioxin, its "parent" molecules, the inversion or puckering potential for xanthene is calculated to be rather flat. The molecular energies between a folding angle of 180° (planar molecule) and 120° are reproduced by analytical functions of $\phi = \theta - 180°$, θ being the folding angle. The long-range spin–spin coupling constants between the methylene protons and the aromatic protons at 300 K are reported for xanthene dissolved in a CS_2/C_6D_{12} solvent mixture and in acetone-d_6 solution. These conformationally sensitive coupling constants are consistent with the theoretical puckering potentials and therefore with substantial "butterfly" motion at ambient temperatures. The computed geometries of xanthene are also given and briefly discussed.

Key words: xanthene, MO computations on inversion; xanthene, long-range spin–spin coupling constants; xanthene, internal motion; xanthene, inversion potentials.

TED SCHAEFER et RUDY SEBASTIAN. Can. J. Chem. **68**, 1548 (1990).

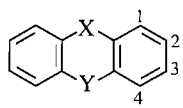
On a effectué des calculs d'OM aux niveaux STO-3G et 4-31G pour un ensemble de valeurs de l'angle de plissement du xanthène, l'angle dièdre entre les plans des deux noyaux benzéniques. Contrairement à ce qui a été observé avec le 9,10-dihydroanthracène, mais en accord avec ce qui a été observé avec la dibenzo-p-dioxine, ses molécules «parentes», on a calculé que le potentiel d'inversion ou de gauchissement du xanthène est relativement plat. On peut reproduire les énergies moléculaires calculées par des angles de plissement allant de 180° (molécule plane) à 120° à l'aide des fonctions analytiques $\phi = \theta - 180°$ dans lesquelles θ est l'angle de plissement. Opérant à 300 K, dans des solutions dans l'acétone-d_6 ou dans un mélange de CS_2/C_6D_{12}, on a mesuré les constantes de couplage spin–spin à longue distance entre les protons méthyléniques et les protons aromatiques. À la température ambiante, ces constantes de couplage qui sont sensibles à la conformation sont en accord avec les potentiels théoriques pour le gauchissement et donc avec un mouvement important du type «papillon». On rapporte aussi les géométries calculées pour le xanthène et on les discute brièvement.

Mots clés : xanthène, calculs d'OM pour l'inversion; xanthène, constantes de couplage spin–spin à longue distance; xanthène, mouvement interne; xanthène, potentiels pour l'inversion.

[Traduit par la revue]

Introduction

While 9,10-dihydroanthracene (X = CH_2 = Y in **1**) has a folded structure, the dihedral (folding) angle between the aromatic planes being 144.7° in the crystal (1), dibenzo-p-dioxin (X = Y = O in **1**) is apparently planar in such a state (2);



1

diffuse scattering suggests disorder which *may* arise (3) from inversion. Molecular orbital calculations with STO-3G and 4-31G basis sets (4) yield a folding angle of 141° and an inversion barrier of near 8 kJ/mol for 9,10-dihydroanthracene. The latter is consistent with the available experimental data for solutions. The computed geometries (4) also agree reasonably well with experiment. Again, the STO-3G MO computations for the dibenzo-p-dioxin (5) molecule predict a minimum energy at a folding angle of 180°, with a flat puckering potential near this angle. At ambient temperatures, nonplanar populations are appreciable for this potential. The expectation value of the folding angle is 168.3° at 300 K for this potential, in good agreement with values derived for static models from dipole moments (6) and from intramolecular nuclear dipole coupling constants in a nematic solvent (7), for example.

Xanthene (X = CH_2, Y = O), a structural hybrid of the two molecules above, does not appear to have been investigated in the crystalline form. In CCl_4 and benzene solutions at 298 K, the molar Kerr constants (8) indicate a folding angle of 160 ± 6°. Dipole moments, variously reported as 1.29, 1.09, 1.13, 1.14, and 1.43 D (8–10), apparently are consistent with a planar or a rapidly inverting nonplanar conformation (10). The dielectric relaxation times of xanthene in benzene solution at 293 K (11) have been interpreted tentatively in terms of an empirical (molecular mechanics) inversion potential of 0.8 kJ/mol. It seems that the puckering behaviour of xanthene may well approximate to that of the dioxin instead of to 9,10-dihydroanthracene.

Because the STO-3G and 4-31G bases provide reasonably accurate descriptions of the first two molecules above, it appears sensible to apply them to xanthene. Such computations are reported here. In addition, the long-range coupling constants between the methylene and ring protons are reported for CS_2 and acetone-d_6 solutions. These coupling constants are in principle sensitive to the folding angle in xanthene.

Experimental

Solutions, at a concentration of 3.9 mol% of xanthene in CS_2/C_6D_{12}/TMS and acetone-d_6/TMS solvent mixtures, were filtered into 5 mm o.d. nmr sample tubes. These were degassed by the freeze–pump–thaw procedure and were then flame-sealed to yield symmetrical tops. The ^1H nmr spectra were obtained from a Bruker AM 300 nmr spectrometer at a probe temperature of 300 K, just as described previously (12).

Molecular orbital calculations employed the computer program GAUSSIAN 86 (13) on an Amdahl 5870. The constraints on the optimization of bond angles and bond lengths included a mirror plane containing the oxygen atom and the carbon atom of the methylene

[a]The folding angle, θ, being 180° for the planar molecule.
[b]Relative energies, the total energy being −565.939 776 au for the STO-3G basis at θ = 169.96° and −572.163 613 au for the 4-31G basis at θ = 180°.
[c]These are the dihedral angles for the methylene protons, a value of 0° for ψ meaning that the C—H_a or C—H_b bond lies in the planes of the benzene moieties.

group, as well as planarity of the two benzene fragments. Computations were done for nine values of the folding angle, θ, with the STO-3G basis and for seven values of θ with the 4-31G basis.

Results and discussion

Molecular orbital calculations

Table 1 presents the energies for a range of folding angles. Immediately apparent is the very flat puckering potential near 180°, unlike that computed for 9,10-dihydroanthracene (4) but reminiscent of that for dibenzo-p-dioxin (5). The computations therefore suggest the likelihood of disorder in the crystal of xanthene, arising from a degree of butterfly motion. They are also consistent with the experimental data in solution, as described above.

The relative STO-3G MO energies between 120° and 180° are reproduced by eq. [1], where $\phi = \theta - 180°$. The stated errors are those at the 95% confidence interval.

$$[1]\quad V(\phi)/\text{kJ mol}^{-1} = (-1.65 \pm 0.20) \times 10^{-3}\phi^2 + (2.71 \pm 0.07) \times 10^{-6}\phi^4 + (0.142 \pm 0.060) \exp((1.14 \pm 0.10) \times 10^{-3}\phi^2)$$

The double-minimum potential, if present at all, is very shallow indeed, the planar form being computed as only 0.07 kJ/mol higher in energy than that corresponding to a folding angle of 169.96°. The expectation value of θ is computed as 163.0° at 300 K, in agreement with those of 160 ± 6° deduced from Kerr constant data for CCl_4 and benzene solutions (8).

The 4-31G MO energies can be fit by eq. [2], the indicated

$$[2]\quad V(\phi)/\text{kJ mol}^{-1} = (1.09 \pm 0.45) \times 10^{-3}\phi^2 + (2.59 \pm 0.17) \times 10^{-6}\phi^4 + (0.171 \pm 0.154) \exp((1.17 \pm 0.21) \times 10^{-3}\phi^2)$$

errors again being those at the 95% confidence level. Figure 1 compares the MO energies with the curve represented by eq. [2]. The theoretical potential has a single minimum, that at θ = 180°, and is rather steeper than that given by the STO-3G basis at the larger puckering amplitudes. Nevertheless, at 300 K, the expectation value of θ is computed as 165.4°, not much different than the 163.0° given by the minimal basis set.

Figures 2 and 3 display the computed geometries at the energy minimum for the STO-3G and 4-31G basis sets,

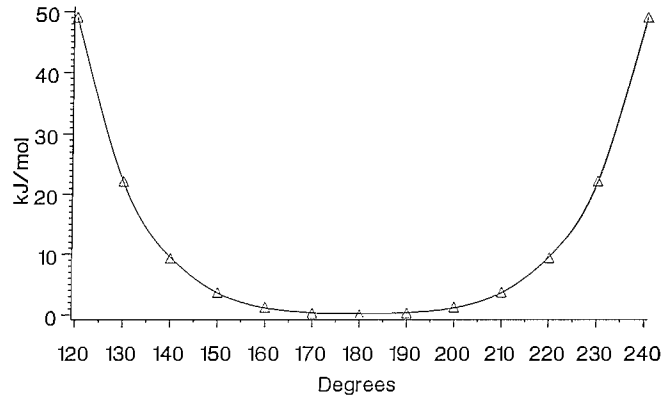

FIG. 1. The triangles represent the relative 4-31G MO energies of xanthene, the planar form with a folding angle of 180° being computed as most stable. The potential function, eq. [2] of the text, is given by the solid curve. The expectation value of the folding angle is 165.4° at 300 K.

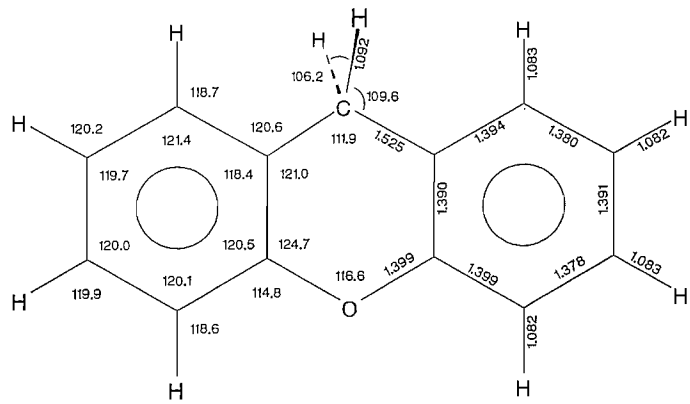

FIG. 2. The computed geometry of xanthene, based on the STO-3G basis set, is displayed for the folding angle of 170°, corresponding to the lowest energy. Bond angles are given in degrees and bond lengths in angstrom units.

respectively. In view of previous comparisons between computed and experimental geometries for the "parent" compounds (4, 5), it appears likely that an eventual structure determination will yield bond angles and lengths very similar to those in Figs. 2 and 3, with the following exception. The COC angle will likely be

$^5J_{14}$	0.408(2)	0.416(1)			

[a]3.9 mol% in CS_2 containing also 10.0 mol% of C_6D_{12} and 0.5 mol% TMS.
[b]3.9 mol% in acetone-d_6 containing also 0.5 mol% TMS.
[c]In hertz at 300.135$_2$ MHz to high frequency of internal TMS, numbers in parentheses being standard deviations in the last significant figure.
[d]The numbering of the aromatic protons is that in **1** of the text; note that H-1 is *ortho* to the methylene group and H-4 is *ortho* to the oxygen atom.
[e]No evidence was found for the existence of coupling constants between protons on different benzene moieties. The generally somewhat larger magnitudes of the coupling constants within the aromatic ring in acetone-d_6 solution relative to those in CS_2 solution are a common observation in this laboratory. The spectral data come from analyses with the computer program NUMARIT (22).

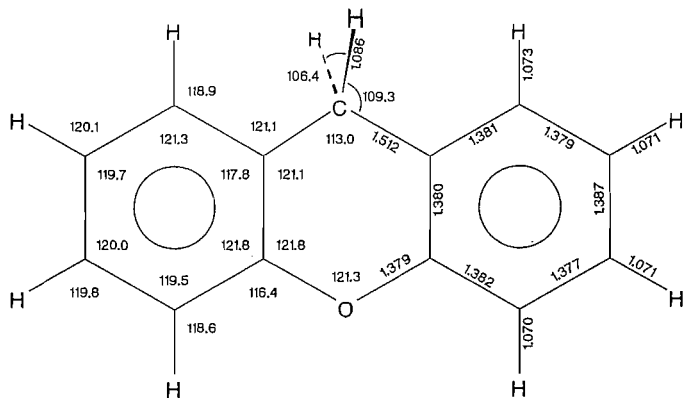

FIG. 3. The computed geometry of planar xanthene is shown as obtained with the 4-31G basis. The text discussed the reliability of the bond parameters.

close to the average of the two computed values. These values for dibenzo-p-dioxin have a mean of 115.9°, the experimental angle being 116.4(5)°.

The dipole moment of xanthene, as computed with the minimal basis set (Table 1) is very close to the lowest and most frequent experimental values (see above). The computed numbers also imply an insensitivity of the dipole moment to the folding angles of highest probability at ambient temperatures. The 4-31G basis yields dipole moments rather higher than those from experiment. A recent comparison (14) of minimal with split-valence basis sets, as to their reproduction of correct electron distributions in monosubstituted benzenes, should be consulted in this connection.

The long-range coupling constants

While the molecular orbital calculations refer to the free molecule, and while the theoretical puckering potentials are both in apparent agreement with experimental data in solution, it was thought desirable to provide a further experimental test of the internal motion of xanthene in solution. Such a test might well be provided by the long-range coupling constants for the methylene protons. Table 2 presents the spectral parameters for xanthene in solution and Fig. 4 displays some experimental and theoretical ^{1}H nmr spectra for this compound.

It is known (12, 15, 16) that ^6J(H,CH_2) in toluene derivatives is proportional to $\sin^2\psi$, where ψ is the angle by which the C—H bond of the side chain twists out of the benzene plane. If the value of ^6J at $\psi = 90°$ can be ascertained, then a measurement of ^6J yields $\langle\sin^2\psi\rangle$, the expectation value of $\sin^2\psi$. In toluene, for example, $^6J_{90}$ is −1.20 Hz (12). In benzyl X compounds, experience shows how $^6J_{90}$ depends on the electronegativity of X. Furthermore, ^5J(H,CH_2) depends (12) on $\langle\sin^2\psi\rangle$ and on $\langle\sin^2\psi/2\rangle$, so that ^5J for xanthene should be rather different for H-2 and H-4. Also, the ψ dependence of ^4J(H,CH_2) is known approximately (17).

In Table 1 the ψ values are given for various folding angles of xanthene. The theoretical potentials can be used to find $\langle\sin^2\psi\rangle$ and give 0.694 and 0.689 at 300 K for the 4-31G and STO-3G bases, respectively, and 0.245 and 0.248 for $\langle\sin^2(\psi/2)\rangle$. It is perhaps unfortunate that these numbers are very little different from those, 0.75 and 0.25, to be expected for rigid planar conformers with a regular tetrahedral geometry at the methylene site. Nevertheless, the following comparisons may be made.

The value of $^6J_{90}$ in benzyl X compounds is fairly reliably given in hertz (Hz) by 0.224 iota (ι) minus 1.653 (18), where the ι value, an inductive parameter, is taken from extensive tabulations (19). The ι value of the phenyl group is 2.295 (19), implying $^6J_{90}$ as −1.14 Hz in, say, diphenylmethane. On the somewhat questionable assumption that this number is applicable to xanthene (the second benzene moiety is, after all, not a phenyl group, among other criticisms), it follows that the ^6J of −0.748(1) in CS_2 solution yields 0.656 for $\langle\sin^2\psi\rangle$ while the −0.758(1) Hz in acetone-d_6 solution gives 0.665. The theoretical assessments of $\langle\sin^2\psi\rangle$ in the free molecule are 0.69. Were the molecule planar and rigid, a ^6J of about −0.85 Hz should have been observed, corresponding to a $\langle\sin^2\psi\rangle$ near 0.75. Again, were the molecule rigid with a folding angle of 145°, that in 9,10-dihydroanthracene, then $\langle\sin^2\psi\rangle$ would be near 0.60, corresponding to a ^6J of −0.68 Hz. These two extremes are therefore unlikely, in agreement with the theoreti-

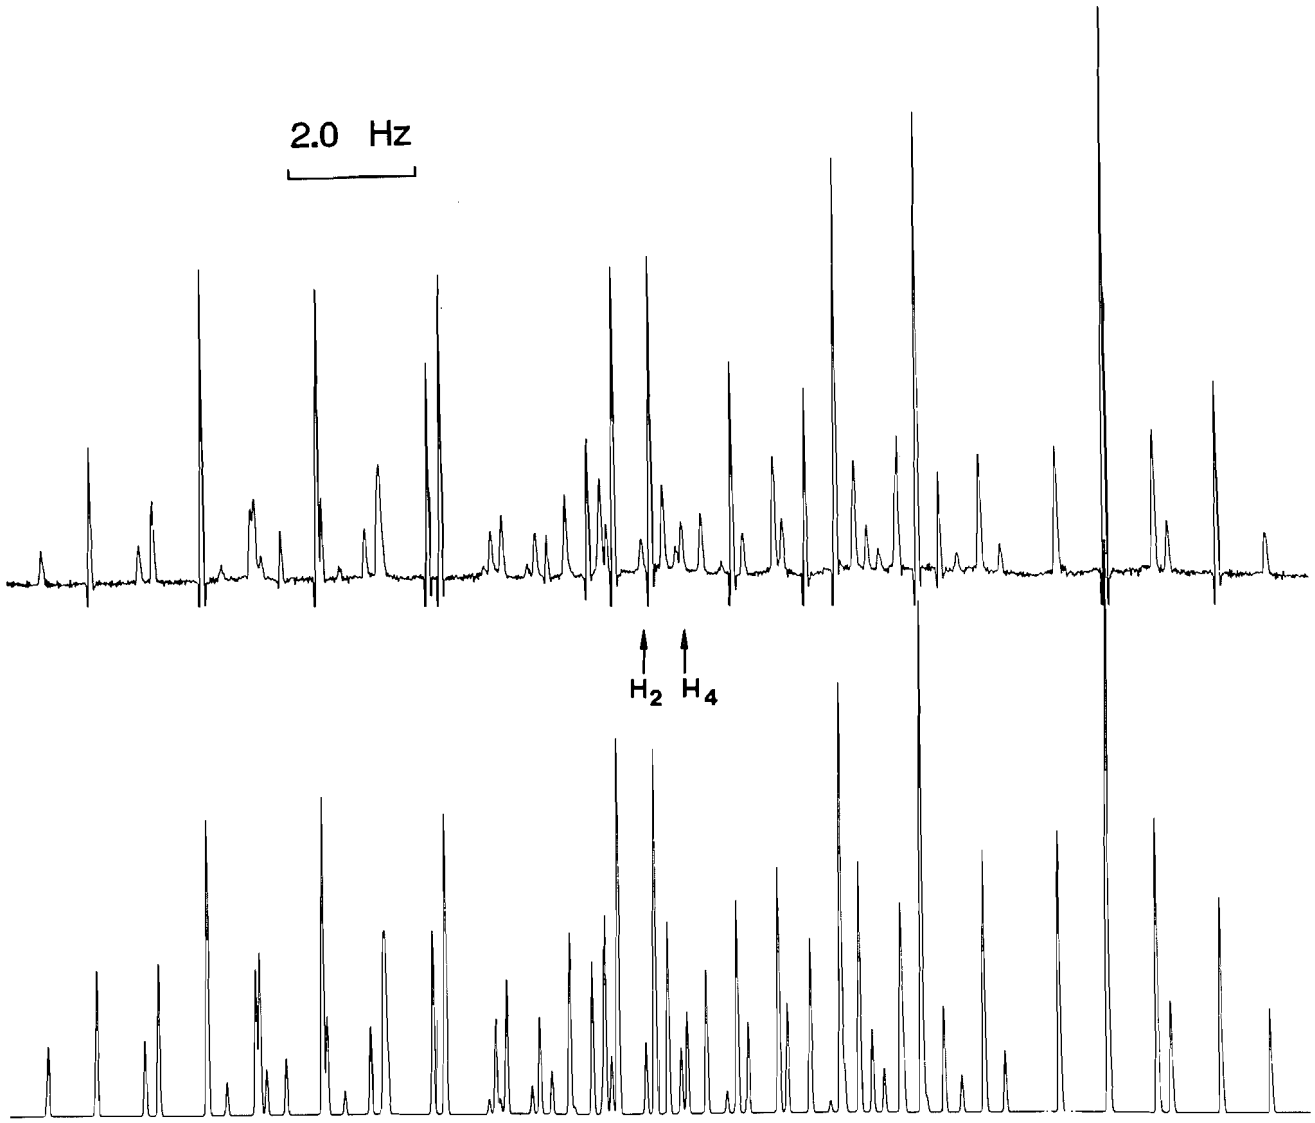

FIG. 4. The ^{1}H nmr spectrum is shown for the protons placed *ortho* and *para* to the methylene protons of xanthene in acetone-d_6 solution at 300 K. The chemical shifts of the two protons differ by 0.66 Hz at 300 MHz. The theoretical spectrum is based on the spectral parameters in Table 2 and assumes a linewidth at half-height of 0.04 Hz. There is no evidence for significant coupling interactions between protons situated on different benzene moieties.

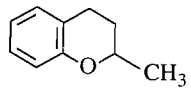
cal results for the free molecule. The measured value of ^6J suggests a somewhat larger amplitude of puckering than that given by the computations because $\langle\sin^2\psi\rangle$ decreases as the folding angle increases. In view of the uncertainty in $^6J_{90}$, it is probably best to conclude that ^6J is consistent with a flat puckering potential in polar and nonpolar media, not unlike those computed with STO-3G and 4-31G basis sets.

Turning to $^5J(\mathrm{H,CH_2})$, in toluene (12) it is given in hertz by $0.336\langle\sin^2\psi\rangle + 0.322\langle\sin^2(\psi/2)\rangle$. For xanthene, the multiplier of $\langle\sin^2\psi\rangle$, representing the $\sigma-\pi$ electron contribution to ^5J, should be reduced by the factor 1.14/1.20, just as the $\sigma-\pi$ contribution to ^6J has been reduced above. If the theoretical values of $\langle\sin^2\psi\rangle$ and $\langle\sin^2(\psi/2)\rangle$ are employed, then $^5J(\mathrm{H\text{-}2,CH_2})$ is calculated as 0.300(1) Hz for both potentials, to be compared with the experimental numbers, 0.283(1) and 0.287(1) Hz in CS_2 and acetone-d_6 solutions, respectively. $^5J(\mathrm{H\text{-}4,CH_2})$ is then calculated as 0.461 Hz (the $\langle\sin^2(\psi/2)\rangle$ values sum to unity for H-2 and H-4), as compared with the measured values of 0.410(1) and 0.422(1) Hz (Table 2). Alternatively, if the $\langle\sin^2\psi\rangle$ values derived from the measured ^6J are used, then $^5J(\mathrm{H\text{-}2,CH_2})$ becomes 0.287 Hz, very close to those measured, and $^5J(\mathrm{H\text{-}4,CH_2})$ becomes 0.451 Hz, still 0.03–0.04 Hz larger than the measured values. However, it is reasonable that a comparison of calculated and observed numbers is more appropriate for $^5J(\mathrm{H\text{-}2,CH_2})$ than for $^5J(\mathrm{H\text{-}4,CH_2})$ because the oxygen atom is attached to the carbon atom in the coupling path for $^5J(\mathrm{H\text{-}4,CH_2})$ and can perturb the coupling magnitude. It is known that ^5J is more sensitive to ring substitution in toluene derivatives than is ^6J (20). Accordingly, it is probable that the ^5J values for xanthene are again consistent with the theoretical puckering potentials.

$^4J(\mathrm{H\text{-}1,CH_2})$ for xanthene presents an interesting problem. A thorough investigation of orthobenzylic coupling constants in a wide variety of compounds (17) recommends the relationship $^4J/\mathrm{Hz} = -1.08\sin^2\psi - 0.32\cos^2\psi$. However (examine Fig. 3 of ref. 17), in the range of ψ between about 30 and 60°, this relationship appreciably underestimates the magnitude of ^4J. A good example is **2**, for which ^4J values of −0.84 and −1.11 Hz are measured, corresponding to ψ's of 45° and 75°, respectively (17), showing also that **2** does not invert on the time



2

scale defined by the difference between the two ^4J numbers. The mean value of the $\sin^2\psi$ values is 0.71_7 and the mean of the ^4J values is -0.97_5 Hz. The latter is very close to the $-0.986(1)$ and $-0.993(1)$ Hz measured for xanthene in CS_2 and acetone-d_6 solutions (Table 2), for which the theoretical potentials yield $\langle\sin^2\psi\rangle$ as 0.692(3) at 300 K. The relationship above, however, after adjustment of the multiplier of $\langle\sin^2\psi\rangle$ by a factor of 1.14/1.20 (reduced $\sigma-\pi$ contribution) would yield -0.81 Hz for ^4J in xanthene, as expected by examination of Fig. 3 in ref. 17; arc sin $(0.692)^{1/2} \sim 56°$, and for that ψ the relationship above underestimates the magnitude of ^4J by about 0.2 Hz. Accordingly, it may be concluded that ^4J(H-1,CH_2) in xanthene is consistent with a large amplitude motion in solution.

The results of the present investigation lend support to the interpretation of the rotational barriers measured for 9-arylxanthyl derivatives (21). One assumption in that interpretation was the facile puckering motion of the xanthene moiety.

Finally, it must be noted that, very likely, puckering potentials other than those discussed here will also be compatible with the magnitudes of the long-range coupling constants in Table 2. The discussion above does not, of course, claim a unique correspondence between experiment and theory.

The ^1H nuclear magnetic resonance spectral parameters of benzyl alkyl ethers (CH_3, CH_2CH_3, $CH(CH_3)_2$, and $C(CH_3)_3$) in CS_2 and acetone-d_6 solutions are obtained, as are those for the 3,5-dichloro derivatives (CH_3, CH_2CH_3, and $CH(CH_3)_3$) in acetone-d_6 solution. The long-range coupling constants between the methylene and *para* ring protons show that the apparent twofold barrier to rotation about the C_{sp^2}—C_{sp^3} bond is solvent and ring-substituent dependent. The apparent twofold barrier ranges from a vanishing value for benzyl methyl ether in CS_2 solution to as much as 4.6 kJ/mol for 3,5-dichlorobenzyl isopropyl ether in acetone-d_6 solution. The data imply that, for the free molecules, the conformation of highest energy has the CH_2—O bond in a plane perpendicular to that of the phenyl group. Molecular orbital computations with a minimal Gaussian basis set agree that, for benzyl methyl ether in the *exo* form (the methyl group pointing away from the phenyl moiety), this conformation is the least stable. However, geometry optimization procedures imply that the CH_2—O bond is twisted out of the ring plane by 30.3° in the most stable geometry of the *exo* form. Such procedures for the (distorted) *endo* form locate another stable conformer, in which the CH_2—O bond is twisted out of the phenyl plane by 45°, only 0.25 kJ/mol less stable than the most stable conformer of the *exo* form. These results, together with some computations for the *tert*-butyl derivative, are discussed in terms of the theoretical potentials for rotation about the C_{sp^2}—C_{sp^3} bond. The approximate potential surface is rather flat compared to kT at ambient temperatures for the free molecules, consistent with its sensitivity to the medium and to ring substituents.

Key words: ^1H NMR, benzyl alkyl ethers; long-range coupling constants in benzyl alkyl ethers; conformations, benzyl alkyl ethers; internal motion, benzyl alkyl ethers; MO computations on benzyl methyl ether.

TED SCHAEFER, KERRY J. COX, CHERRIE L. MORIER, CHRISTIAN BEAULIEU, RUDY SEBASTIAN et GLENN H. PENNER. Can. J. Chem. **68**, 1553 (1990).

On a déterminé les paramètres spectraux de la résonance magnétique nucléaire du ^1H des éthers $C_6H_5CH_2OR$ ($R = CH_3$, CH_2CH_3, $CH(CH_3)_2$ et $C(CH_3)_3$) dans des solutions dans le CS_2 et dans l'acétone-d_6 ainsi que ceux des dérivés 3,5-dichlorés ($R = CH_3$, CH_2CH_3, $CH(CH_3)_2$) dans des solutions dans l'acétone-d_6. Les constantes de couplage à longue distance entre les protons méthyléniques et les protons en position *para* du cycle montrent que la barrière binaire apparente à la rotation autour de la liaison C_{sp^2}—C_{sp^3} dépend à la fois du solvant et de la nature des substituants sur le cycle. La barrière binaire apparente varie d'une valeur pratiquement nulle pour le méthoxyméthylbenzène en solution dans le CS_2 à une valeur de près de 4,6 kJ/mol pour le 3,5-dichloro-1-isopropoxyméthylbenzène en solution dans l'acétone-d_6. Ces données impliquent que, pour les molécules libres, la conformation de plus haute énergie comporte une liaison CH_2—O qui est dans un plan perpendiculaire à celui du groupement phényle. Des calculs d'orbitales moléculaires, réalisés avec des ensembles de base Gaussienne minimale, suggèrent que le méthoxyméthylbenzène dans la forme *exo* (le groupement méthyle s'éloignant de la portion phényle) est la conformation la moins stable. Toutefois, si on fait appel à des méthodes impliquant une optimisation de la géométrie, on arrive à la conclusion que dans la géométrie la plus stable de la forme *exo* la liaison CH_2—O est déplacée de 30,3° par rapport au plan du cycle. Des telles méthodes appliquées à la forme *endo* (déformée) permettent de localiser un autre conformère stable dans lequel la liaison CH_2—O est déplacée de 45° par rapport au plan du noyau phényle; cette conformation n'est que 0,25 kJ/mol moins stable que le conformère le plus stable de la forme *exo*. Ces résultats utilisés de concert avec des calculs effectués sur le dérivé *tert*-butyle sont discutés en fonction des potentiels théoriques pour la rotation autour de la liaison C_{sp^2}—C_{sp^3}. La surface de potentiel approximative est assez plane si on la compare à kT aux températures ambiantes pour les molécules libres; cette observation est en accord avec sa sensibilité au milieu et aux substituants présents sur le cycle.

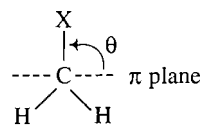
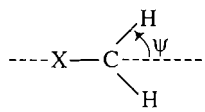
[Traduit par la revue]

Introduction

The barriers to rotation about the C_{sp^2}—C_{sp^3} bonds in benzyl fluoride and in benzyl chloride are solvent dependent and are also sensitive to the presence of *meta* substituents. In benzyl fluoride (1, 2) the internal rotational potential is very likely twofold and conformer **1** (X = F) is stabilized by about 2 kJ/mol in passing from a relatively nonpolar CS_2/C_6D_{12} medium to a polar acetone-d_6 environment. Qualitatively, this can be understood as a stabilization of the more polar form **1** by the polar medium or, perhaps, by a reduction of the attractive



1 $\psi = 30°$, $\theta = 90°$



2 $\psi = 60°$, $\theta = 0°$

interaction between the *ortho* C^-—H^+ bonds in the ring and the C^+—F^- bond (3) upon dissolution in the medium of higher dielectric constant. Again, two *meta* chlorine substituents stabilize conformation **2** by at least 2 kJ/mol relative to the parent molecule, possibly via an enhancement of the polarity of the *ortho* C—H bonds (1). Benzyl chloride behaves similarly, except that **1** (X = Cl) is the most stable conformer in each

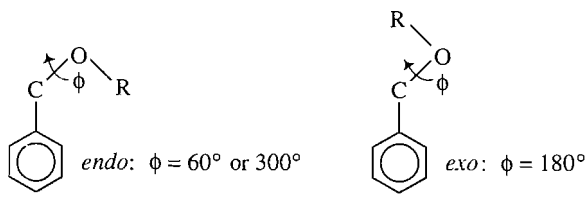
[e]For the ring protons only.
[f]There occur large correlations between chemical shifts and the coupling constants within the ring, but $^6J(H,CH_2)$ does not correlate significantly with other parameters.
[g]$\nu(CH)$ is 1070.3 Hz, $^3J(H,H)$ is 6.06(3) Hz.
[h]$\nu(CH)$ is 1097.5 Hz, $^3J(H,H)$ is 6.03(5) Hz, and $\nu(CH_3)$ is 347.6 Hz.

situation, so that the barrier to internal rotation increases in the polar solvent but decreases in the presence of *meta* chlorine substituents (4). Of course, in benzyl chloride the internal barrier is relatively large, about 11 kJ/mol in acetone-d_6 solution. The small barrier in benzyl fluoride (1, 2), probably less than 3 kJ/mol in the polar solvent, has the consequence that the most stable conformer can change from **2** to **1** under the appropriate conditions of solvent or *meta* substituent.

By way of contrast, the internal rotational potential in ethyl benzene is strikingly insensitive to solvent (5), perhaps as a consequence of its small polarity, and, tentatively, is a good approximation to its magnitude in the vapor phase (5, 6).

In benzyl alcohol the internal motion about the exocyclic C—C bond is also facile (7–9) but is complicated in principle by the possibility of attractive O—H...π interactions (10) or, alternatively, by repulsion between the lone-pair electrons on the oxygen atom and the π electrons of the ring (11, 12). The *exo* conformer, that with the O—H bond pointing away from the benzene moiety, is present to the extent of, at most, 25% in nonpolar solvents (9) and perhaps 30% in the gas phase at 422 K.

In the presence of groups larger than hydroxyl, that is, for the title compounds, simple steric considerations suggest that the endo form, **3**, would have a large barrier to rotation about the C_{sp^2}—C_{sp^3} bond, that with $\theta = 0°$ having a substantial repulsive energy between R and the *ortho* C—H bonds. The repulsion is absent in the *exo* form, **4**. Measurement of ^6J(H-4,CH_2) for the alkyl groups, R, indicates the freedom of motion about this bond. In this work, the ^{1}H nmr spectral parameters are determined for benzyl OR (R = CH_3, CH_2CH_3, $CH(CH_3)_2$ and R = $C(CH_3)_3$) in polar and nonpolar solvents, as well as for the 3,5-dichloro derivatives (R = CH_3, CH_2CH_3, $CH(CH_3)_2$). STO-3G computations for the motion about the exocyclic C—C bond are also reported for benzyl methyl ether. It appears that the barrier to rotation about this bond is small in the gas phase and in solution, although solvent and *meta* substituent perturbations are rather similar to those known for benzyl fluoride.



3 **4**

Experimental

The benzyl ethers were prepared from the corresponding benzyl bromides by the standard Williamson procedure, the reflux time for R = $C(CH_3)_3$, however, being raised to 1 week (13). Solutions of the ethers in CS_2/C_6D_{12} and acetone-d_6 (Tables 1 and 2) were filtered into 5 mm o.d. nmr sample tubes and were degassed by the freeze–pump–thaw procedure (minimum of four cycles). The 3,5-dichloro compounds (R = CH_3, CH_2CH_3, $CH(CH_3)_2$) were prepared as acetone-d_6 solutions.

The ^{1}H nmr spectra were obtained at a probe temperature of 300 K on an AM300 Bruker spectrometer in a way previously described in detail (1).

STO-3G MO computations (14), employing MONSTERGAUSS (15), were performed on an Amdahl 5870 system. The geometries of the various conformers of benzyl methyl ether were optimized with the constraint that the phenyl moiety remain planar.

Results and discussion

Spectral analyses

The ^{1}H nmr spectra were analyzed with the computer program NUMARIT (16), as reworked by R. Sebastian in this laboratory. The complete set of ^{1}H nmr spectral parameters for R = $CH(CH_3)_3$ are presented in Table 1. The occasionally larger magnitudes, in the polar relative to the nonpolar solvent, of the proton–proton coupling constants within the ring are a general result in this laboratory and most likely not an artifact. Because the intraring coupling constants vary very little among the compounds for different R, they are not presented for all R. Instead, Table 2 presents the chemical shifts and the long-range coupling constants between the methylene and ring protons. The latter are of immediate interest in the discussion below.

[g]Negative values of the apparent V_2 mean that **2** is the conformer of greater stability.

$^6J(H,CH_2)$ values for the 3,5-dichloro derivatives are found in Table 3.

Mobility about the C_{sp^2}—C_{sp^3} bond in the benzyl ethers

(i) Apparent V_2

Apparent twofold barriers to rotation about the C_{sp^2}—C_{sp^3} bond in the ethers can be found on the basis of the relationship $^6J(H,CH_2) = {}^6J_{90}\langle\sin^2\psi\rangle$. Here $^6J_{90}$ is the value of this σ–π coupling constant when ψ is 90° in **1** or **2**, and is known to be −1.02 Hz (17, 18). The expectation value, $\langle\sin^2\psi\rangle$, follows from the measured values of $^6J(H,CH_2)$ and can be related to an assumed twofold barrier by a hindered rotor model (19) or can also be computed classically for various potentials. Table 3 gives $\langle\sin^2\psi\rangle$ at 300 K for the ethers in the polar and nonpolar solvents, as well as the apparent twofold barriers to rotation about the exocyclic C—C bond.

It is clear that the barriers are small for all alkyl groups, implying that at least the larger groups are oriented to avoid the phenyl group during the rotation. In this way the size of the alkyl group will have a minor effect on the apparent V_2. The conformation with the oxygen atom in the plane of the phenyl group is stabilized in going from R = CH_3 to R = $CH(CH_3)_2$. For benzyl fluoride the analogous conformation appears (3) to be stabilized by attractive electrostatic forces between the C^+—F^- and *ortho* C^-—H^+ dipoles. Perhaps the C^+—O^- dipole increases in magnitude in the sequence CH_3, CH_2CH_3, $CH(CH_3)_2$, possibly because the group polarizabilities will increase in this order. The *tert*-butyl group, however, destabilizes the in-plane conformer, perhaps understandable if it is noted that torsional oscillations about both C—O bonds do occur and will be least hindered in the perpendicular conformer for this, the largest of the four alkyl groups.

While this rationalization of the observed sequence is speculative, the solvent effect on the conformer stabilities is unequivocal. The polar solvent stabilizes the perpendicular conformer, **1**, just as it does for benzyl fluoride (1) and benzyl chloride (4). The magnitude of this stabilization, at about 0.6 kJ/mol for the benzyl ethers, is only about 30% of that found for the benzyl halides (see further discussion below).

Again, the *meta* chlorine substituents enhance the stability of the in-plane conformer, **2**, by as much as 4 kJ/mol for R = $CH(CH_3)_2$ and as little as 3 kJ/mol for R = CH_3. The latter number is very similar to that (1) established for benzyl fluoride and its 3,5-dichloro derivative.

The apparent barriers in Table 3 strongly imply that the perpendicular form, **1**, will be the least stable in the free molecule for all the benzyl ethers. This implication follows from the data in Table 3 and from the reaction field model

(20) in which the energy difference between the conformers is roughly proportional (see eq. 13.18 and p. 562 of ref. 20) to $(\epsilon - 1)/(2\epsilon + 1)$; ϵ is the static dielectric constant of the medium. Because the change in the energy difference between the conformers in passing from the vapor to CS_2 solution is roughly the same as in going from the latter to an acetone solution (p. 562 of ref. 20), an estimate for benzyl methyl ether is that **2** is more stable than **1** by 0.8(2) kJ/mol in the vapor.

The discussion in this section assumes a twofold barrier, as is found for benzyl fluoride and benzyl chloride on the basis of MO computations (1, 4). However, the local symmetry of benzyl ethers is rather lower than that of the halides, so that the assumption of a twofold barrier is probably a first approximation. Accordingly, geometry-optimized STO-3G MO computations for benzyl methyl ether are also of interest.

(ii) Theoretical barriers in benzyl methyl ether

The STO-3G MO energies in Table 4 confirm the low barrier to rotation about the C_{sp^2}—C_{sp^3} bond in the *exo* form but also imply that the fourfold component is nearly as large as, and of opposite sign to, the twofold component (see caption to Fig. 1 for the potential). The minimum energy corresponds to a θ of 30.3°, the maximum to the perpendicular conformer, **1**, at θ = 90°. The latter is calculated to be 0.73 kJ/mol less stable than the in-plane conformer, **2**, in coincidental agreement with the value extrapolated from solution using the apparent V_2 values.

The theoretical potential has $\langle \sin^2 \psi \rangle$ as 0.515 at 300 K, whereas the extrapolated V_2 of 0.8(2) kJ/mol yields $\langle \sin^2 \psi \rangle$ as 0.520(6) at this temperature. The present experimental data cannot discriminate between a purely twofold and the theoretical, composite potential.

Furthermore, the theoretical data in Table 4 for the *endo* form indicate that, for θ values near those corresponding to minimum energies for the *exo* form, appreciable proportions of the *endo* form can exist at 300 K. Thus, at θ = 45°, the *endo* form is only 0.16 kJ/mol less stable than the *exo* form. Of course, the ^6J values do not distinguish between the *exo* and *endo* forms, being sensitive to θ and, presumably, not to ϕ. Thus, were benzyl methyl ether to exist exclusively in the *endo* form, the energies in Table 4 would imply a $\langle \sin^2 \psi \rangle$ of 0.486 at 300 K, a value less compatible with the extrapolated value of 0.520(6) above than is the value of 0.516 obtained from the theoretical potential for the *exo* form. But it would be unwise to attempt to estimate the population of the *endo* form on the basis of ^6J.

Figure 1 displays the theoretical potentials for rotation about the C_{sp^2}—C_{sp^3} bond for both forms of benzyl methyl ether. A semiquantitative description of the internal motion about this bond then implies that the molecule exists predominantly as the *exo* form near the extremes of the twist angle. However, for a large range of intermediate θ values, particularly near the minimum energies of the *exo* form, it is joined by comparable populations of the *endo* form. The somewhat higher energies of the latter for, say, $30° \leq \theta \leq 75°$, are substantially offset by its twofold degeneracy relative to the *exo* form, so that at 300 K the *endo* population is larger than the *exo* in parts of this range of θ.

The lower stability of the *endo* form at θ = 0° presumably arises from steric repulsion between the methyl and phenyl moieties. It is noted that both the *exo* and *endo* forms maintain a "dimethyl-ether-like" conformation about the C—O bonds for all θ values. More precisely, the methyl group is staggered about the opposite C—O bond to within a few degrees; deviation from exact staggering for a given θ is nearly the same for *exo* and *endo* forms. The repulsion between the methyl and phenyl moieties is reflected in the large ϕ values (Table 4) at low θ ranges. As θ increases, ϕ relaxes towards, but does not reach, the value of 60° defining a "pure" *endo* form. For $30° \leq \theta \leq 60°$, the methyl group is situated relatively far from the phenyl plane and the stability of the *endo* form approaches that of the *exo*. As θ increases further, towards 90°, the methyl group is again approaching a repulsive region of the phenyl group and *endo* stability decreases once more.

TABLE 4. Relative STO-3G MO energies[a] for rotation about the C_{sp^2}—C_{sp^3} bond in the *exo* and *endo* forms of benzyl methyl ether

θ/deg[b]	E_{exo}/kJ mol^{-1}	ϕ/deg[c]	E_{endo}/kJ mol^{-1}
0	0.00[d,e]	88.9	5.80
15	−0.12	80.8	2.50
30	−0.26	74.9	0.53
45	−0.18	71.4	−0.02
60	0.12	70.1	0.37
75	0.41	69.8	1.58
90	0.73	70.5	4.37

[a]All bond lengths and angles are optimized with the constraint that the phenyl group remain planar.

[b]This column refers to the energies of both *exo* and *endo* forms for rotation about the C_{sp^2}—C_{sp^3} bond, a zero value corresponding to the oxygen atom lying in the phenyl plane.

[c]This column refers to the *endo* form only (ϕ being 180° for the *exo* form), the deviation from 60° being a measure of the distortion of the "pure" *endo* form. See **1** and **2** of the text and note that a value greater than 60° for ϕ means that the methyl group "twists" away from the phenyl region.

[d]The total energy of this conformer is −378.885 498 au.

[e]The symmetry near the C—O bonds is C_{2v}-like for the *exo* form, as in dimethyl ether (22). If the methyl group is rotated about its O—C bond by 60°, computations give the energies as about 12.2 kJ/mol higher for all θ values of the *exo* form. In other words, the threefold barrier to rotation of the methyl group is near the value of 11.3 kJ/mol in dimethyl ether (24).

The stability of the *exo* form for low θ values is qualitatively understood by an argument similar to that for benzyl fluoride in which **1** is also of highest energy (1), the stability of the planar form, **2**, being attributed to electrostatic attraction between the C^+—F^- and the *ortho* C^-—H^+ dipoles.[3] The detailed electron distribution about the oxygen atom will be somewhat different than about fluorine, so the minimum in energy of the *exo* form need not occur exactly at θ = 0°. The greater stability of the in-plane conformer for the 3,5-dichloro derivative of benzyl methyl ether, relative to the parent compound (Table 3), would then follow from polarization of the σ electron framework by the electronegative substituents placed *ortho* to the ring C—H bonds in question. The latter acquire increased polarity, entailing a larger electrostatic stabilization of conformers having small θ values.

The computed dipole moments of benzyl methyl ether are rather insensitive to θ and ϕ. For example, they are 1.29 and 1.27 D for the *exo* form at θ = 0° and θ = 90°, respectively, and 1.27 D at both of these θ values for the *endo* form. The dipole moment of benzyl methyl ether is apparently unknown. That of dimethyl ether is 1.31 D (23). The present computations do not indicate a simple electrostatic interpretation of the observed solvent effects on the barrier.

An STO-3G computation for benzyl *tert*-butyl ether in the

[3]Discussion (21, 22) of the C—H dipole in various molecules are available.

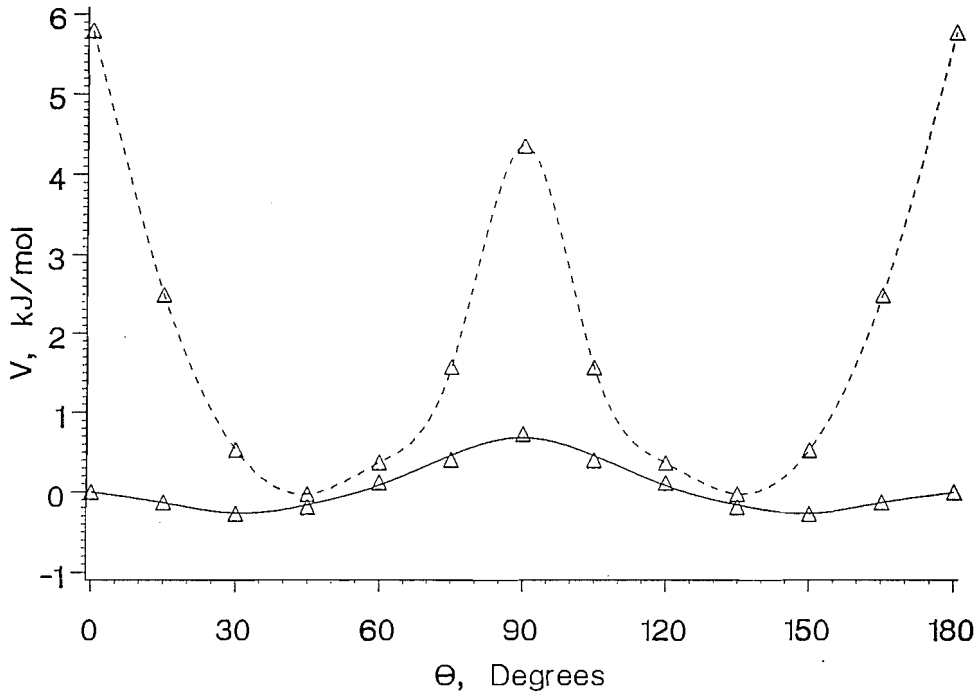

FIG. 1. The STO-3G MO relative energies (Table 4) of the *exo* and *endo* forms of benzyl methyl ether are plotted as a function of the angle, θ, by which the CH_2O—O bond twists away from the phenyl plane. The solid line (*exo*) is represented by the potential $V(\theta)/\text{kJ mol}^{-1} = 0.69 \sin^2\theta - 0.50 \sin^2 2\theta - 0.01 \sin^2 3\theta - 0.07 \sin^2 4\theta$, the standard error of the fit to the energies in Table 4 being 0.02 kJ/mol for each of the terms. The internal potential is dominated by the twofold, in $\sin^2\theta$, and the fourfold, in $\sin^2 2\theta$, terms. The dashed line (*endo*) has the potential $V(\theta)/\text{kJ mol}^{-1} = 5.80 - 1.06 \sin^2\theta - 4.46 \sin^2 2\theta - 0.37 \sin^2 3\theta - 1.72 \sin^2 4\theta - 0.64 \sin^2 6\theta$.

exo form, again wtih geometry optimization as for the benzyl methyl ether, gave a conformer of minimum energy at θ = 30.0°. In other words (see caption to Fig. 1), the conformation of lowest energy for the *exo* form does not depend on the size of the alkyl group, as expected. A fit of the computed energies gave the internal potential as $V(\theta)/\text{kJ mol}^{-1} = 0.58 \sin^2\theta - 0.48 \sin^2 2\theta - 0.22 \sin^2 3\theta - 0.00 \sin^2 4\theta - 0.10 \sin^2 6\theta$, with a standard error of 0.02 kJ/mol in each term. The leading terms in this expression are not very different from those for benzyl methyl ether, but the sixfold term, in $\sin^2 3\theta$, reduces the barrier at θ = 90° to 0.4 kJ/mol, smaller by 0.3 kJ/mol than that for the methyl compound. However, at 300 K, $\langle\sin^2\theta\rangle$ is 0.472 for the *tert*-butyl derivative, very close to that of 0.467 for the *exo* form of the methyl derivative. Qualitatively, the lower theoretical barrier for the larger alkyl group, surely existing predominantly in the *exo* orientation in the ether, is in agreement with the indications from $^6J(H,CH_2)$, discussed in a previous section as a relative destabilization of the in-plane conformer by the *tert*-butyl group.

Of course, the discussion in this section is based on the minimal basis set. It is conceivable that larger basis sets will alter the description; they are also much more demanding of computer time.

Summary and conclusions

The present discussion of the experimental data, in terms of an apparent twofold barrier to rotation about the C_{sp^2}—C_{sp^3} bond in various benzyl alkyl ethers in solution and in terms of theoretical potentials for this motion in the *exo* and *endo* forms of the free benzyl methyl ether molecule, is clearly a simplification of what is no doubt a rather convoluted potential surface defining the internal motion. A large number of conformers, as defined by different combinations of θ and ψ values, are most likely appreciably populated at ambient temperatures in the vapor and in solution. The solution data imply a solvent dependence of the potential surface, but also agree semiquantitatively with the theoretical potential for the *exo* form in that they indicate the perpendicular conformer as least stable in the vapor phase and, also, in that they are in reasonable, perhaps coincidental, agreement with the theoretical values of $\langle\sin^2\psi\rangle$. These, being near 0.5 at 300 K, suggest that the molecule samples a large variety of θ and ψ values, consistent with the somewhat flat (compared to kT) theoretical surface. Ideally, given computing time, this surface should be calculated with a larger basis set and its curvature used to calculate the thermodynamic functions at, say, 300 K.

The essentially equal computed stabilities of the *exo* and *endo* forms of benzyl methyl ether near a θ of 45° (Table 4) contrast sharply with the results for benzyl alcohol (9) using the same basis set. In the latter, the *endo* is 3.8 kJ/mol more stable than the *exo* form, this number changing very little as θ increases to 90°. In the ether, however, the *endo* form is 3.6 kJ/mol less stable than the *exo* for this θ value. If, as has been cogently argued (11, 12), the stability of the *endo* form of benzyl alcohol originates in repulsive interactions between the π system and the lone-pair electrons on the oxygen atom, then the relative stabilities of the *endo* and *exo* forms of the ether for this range of θ values may well imply repulsive $CH_3 \ldots \pi$ forces in the *endo* form. Alternatively, if the *endo* form of benzyl alcohol is being favored by attractive O—H...π forces, then the corresponding $CH_3 \ldots \pi$ attractions in the ether are considerably smaller near θ = 45° and become repulsions near θ = 90°. The ambiguities connected with the question of weak $CH_3 \ldots \pi$ hydrogen bonds are exemplified in a recent paper by Ōki and co-workers (25).

Optically pure (*S*)-cyclopent-2-en-1-ol and (*S*)-3-methoxycyclopentene

AMAL WAHHAB, DONALD F. TAVARES, AND ARVI RAUK[1]

Department of Chemistry, The University of Calgary, Calgary, Alta., Canada T2N 1N4

Received February 20, 1990

AMAL WAHHAB, DONALD F. TAVARES, and ARVI RAUK. Can. J. Chem. **68**, 1559 (1990).

Optically pure (*S*)-cyclopent-2-en-1-ol, $[\alpha]_D^{20}$ −137.9° (*c* 1.1, $CHCl_3$), and (*S*)-3-methoxycyclopentene, $[\alpha]_D^{20}$ −116.9° (*c* 3.86, *n*-hexane), were prepared from ethyl (1*R*,2*S*)-2-hydroxycyclopentanecarboxylate, which is readily available by yeast reduction of ethyl 2-oxocyclopentanecarboxylate. The optical purity of the alcohol was determined from its Mosher ester, and that of the ether by gas chromatography using a Ni-4-Pin column.

Key words: (*S*)-cyclopent-2-en-1-ol, (*S*)-3-methoxycyclopentene.

AMAL WAHHAB, DONALD F. TAVARES et ARVI RAUK. Can. J. Chem. **68**, 1559 (1990).

On a préparé du (*S*)-cyclopent-2-èn-1-ol, $[\alpha]_D^{20}$ −137,9° (*c* 1,1, $CHCl_3$), et du (*S*)-3-méthoxycyclopentène, $[\alpha]_D^{20}$ −116,9° (*c* 3,86, *n*-hexane), optiquement purs à partir du (1*R*,2*S*)-2-hydroxycyclopentanecarboxylate d'éthyle qui est facilement accessible par le biais d'une réduction du 2-oxocyclopentanecarboxylate d'éthyle à l'aide de levures. On a déterminé la pureté optique de l'alcool en se basant sur la chromatographie gazeuse (utilisant une colonne de Ni-4-Pin) de son ester de Mosher ainsi que de son éther.

Mots clés : (*S*)-cyclopent-2-èn-1-ol, (*S*)-3-méthoxycyclopentène.

Introduction

Our interest in the chiroptical and the spectroscopic characteristics of cyclic allylic alcohols and ethers created a need for chemically and enantiomerically pure 2-cyclopenten-1-ol **1** and 3-methoxycyclopentene **2**. Previously reported synthetic procedures for the preparation of the alcohol **1** fail in this respect. There are no reports of the preparation of the optically active ether **2** and it is not clear that the allylic alcohol could be converted to the ether without some racemization. Hill and Edwards (1) converted racemic **1** to the acid succinate, and partially resolved it with (+)-α-(1-naphthyl)-ethylamine. After eight recrystallizations and regeneration of the succinate, followed by $LiAlH_4$ reduction, the specific rotation of **1** was $[\alpha]_D^{21}$ +22.8° (*c* 5, CCl_4), corresponding to about 15% ee. Denney *et al.* (2) achieved partial asymmetric induction in the reaction of cyclopentadiene with *tert*-butylhydroperoxide and the cupric salt of (+)-α-ethyl camphorate, and obtained α-ethyl-β-Δ^2-cyclopentenyl camphorate, which upon $LiAlH_4$ reduction yielded **1**, $[\alpha]_D^{26}$ −13.6° (*c* 8.9, $CHCl_3$). Asami and Kirihara (3) reported that the asymmetric transformation of cyclopentene oxide with lithium (*S*)-2-[(pyrrolidin-1-yl)-methyl]pyrrolidide gave **1** in 49% yield and 31% ee, $[\alpha]_D^{30}$ −55° (*c* 1.35, CCl_4). In the work of Sharpless and co-workers (4) introducing kinetic resolution of allylic alcohols by enantioselective epoxidation, the reaction of racemic **1** was not reported. It failed to give satisfactory results in our hands.[2] Sato *et al.* (5) obtained **1** in 77% yield and 82% ee, $[\alpha]_D^{23}$ −105.8° (*c* 1.14, $CHCl_3$), by asymmetric reduction of 2-cyclopenten-1-one **3** with chiral aluminium hydride reagents. More recently, Kitamura *et al.* (6) reported that the BINAP–ruthenium(II)-catalyzed hydrogenation of **3** gave **1** in 50% yield and 79% ee.

Although the optically active ether **2** has not been reported, a few reports have appeared for racemic **2**. Alder and Flock (7*a*) prepared **2** by the reaction of 3-chlorocyclopentene with methanol, while Fleming and Thomas (7*b*) and Ishiyama *et al.* (7*c*) obtained **2** by methylation of **1**.

Inspired by the high enantioselectivity and the good yields of yeast reductions of ketones (8), we chose ethyl (1*R*,2*S*)-2-hydroxycyclopentanecarboxylate **5**, which is easily obtainable by yeast reduction of ethyl 2-oxocyclopentanecarboxylate **4**, as our starting point. Scheme 1 depicts our strategy to prepare the chemically and optically pure compounds **1** and **2**.

Results and discussion

The baker's yeast reduction of ethyl 2-oxocyclopentanecarboxylate **4** by a slight modification of the procedure of Tsuboi *et al.* (9) gave chemically and enantiomerically pure ethyl (1*R*,2*S*)-2-hydroxycyclopentanecarboxylate **5** in 80.3% yield. The more laborious procedure of Deol *et al.* (10) for the reduction of **4**, which involved the preparation of freshly cultivated batches of a sterile mutant of *Saccharomyces cerevisiae*, baker's yeast, under strictly controlled conditions, failed to give satisfactory reduction in our hands. The absolute configuration of **5** was assumed (and subsequently verified) to be the same as that of the product of Deol *et al.* Hence, the absolute configuration of the alcohol belongs to the *S* series.[3] This configuration is maintained all through the reaction sequence and will yield the (*S*)-2-cyclopenten-1-ol **1**. The specific rotation of **5**, $[\alpha]_D^{20}$ +15.1°, was slightly higher than that of the product obtained by Deol *et al.*, $[\alpha]_D^{20}$ +14.1°. ^1H and ^{13}C NMR analysis of the Mosher ester of **5** showed it to consist of one isomer only.

Hydrolysis of the hydroxy ester **5** with 25% NaOH, similar to the reported hydrolysis of ethyl (1*R*,2*S*)-hydroxycyclohexanecarboxylate (10), gave (1*R*,2*S*)-2-hydroxycyclopentanecarboxylic acid **6** in 74.2% yield, $[\alpha]_D^{20}$ +28.0°. ^1H and ^{13}C NMR and the specific rotation of **6** indicated that racemization under the hydrolysis conditions did not occur. Attempts to selectively protect the alcohol of **5** as the silyl ether in the presence of the acid functionality gave a mixture of protected alcohol and protected acid; therefore, excess *tert*-butyldimethylchlorosilane and increased reaction times were required to fully protect both functionalities. The *tert*-butyldimethylsilyl (1*R*,2*S*)-2-*tert*-

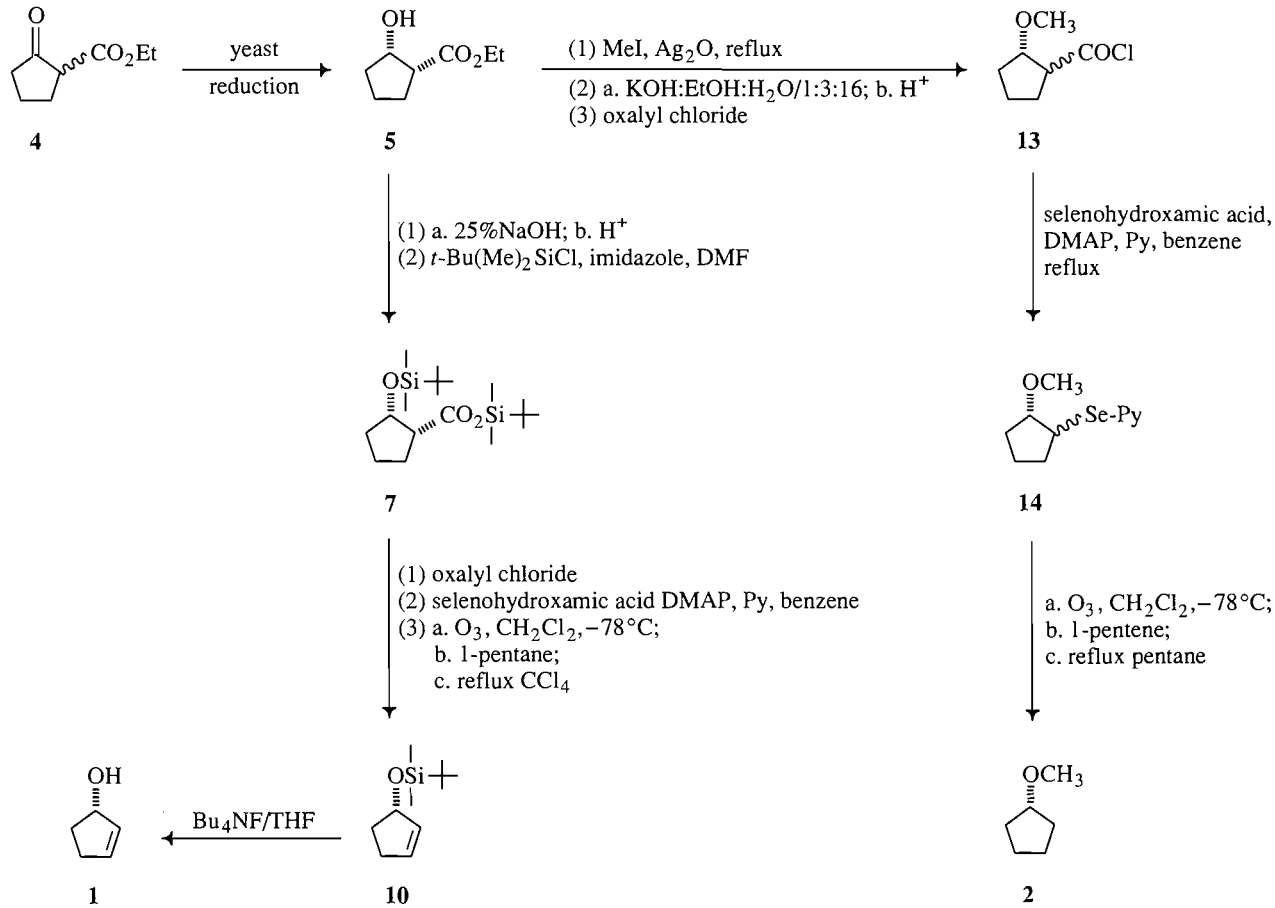
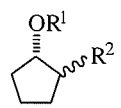
[3]Enzymes generally transform ketones into products possessing the *S*-configuration (where steric bulk determines the relative priorities) at the newly formed secondary alcohol unit. See K. Kieslich. Microbial transformations of chemical compounds excluding steroids and non-cyclic structures. G. Thieme, Stuttgart. 1976.



SCHEME 1

butyldimethylsiloxycyclopentanecarboxylate **7** obtained in 80% yield, $[\alpha]_D^{20}$ +24.6°, was reacted with oxalyl chloride following the procedure of Wissner and Grudzinskas (11) to give (1*R*,2*S*)-*tert*-butyldimethylsiloxycyclopentanecarbonyl chloride **8** quantitatively. The decarboxylative selenination of **8** according to the procedure of Barton *et al.* (12) gave 1-*tert*-butyldimethylsiloxy-2-(2′-pyridylseleno)cyclopentane **9** in 85.8% yield as a 7:1 mixture of two diastereomers. The epimerization at carbon 2 of **9** was expected, since the decarboxylative selenination proceeds via a radical mechanism (12). The major isomer is inferred to be the *trans* from the chemical shift of the alkoxy carbon, CH—O-, in the ^{13}C NMR spectrum, which appeared at 79.7 ppm compared to the minor at 75.8 ppm (13). The diastereomers of **9** were not separated, and were ozonized to give 1-*tert*-butyldimethylsiloxycyclopent-2-ene **10** in 77.2% yield. Deprotection of **10** gave (*S*)-2-cyclopenten-1-ol **1** in 46% isolated yield after chromatography and vacuum distillation. The specific rotation of **1**, $[\alpha]_D^{20}$ −137.9°, and the ^1H and ^{13}C NMR spectra of the MPTA ester of **1** and that of the racemic alcohol indicated that **1** was indeed enantiomerically pure.



6 (1*R*)R^1 = H, R^2 = -CO_2H
8 (1*R*)R^1 = *t*-Bu(Me)$_2$Si-, R^2 = -COCl
9 R^1 = *t*-Bu(Me)$_2$Si-, R^2 = -SePy
11 (1*R*)R^1 = -CH_3, R^2 = -CO_2Et
12 R^1 = -CH_3, R^2 = -CO_2H
Py = 2-pyridyl

It is worth noting that attempts to prepare optically active 2-phenylselenocyclopentanol by yeast reduction of 2-phenylselenocyclopentanone were not fruitful. The seleno moiety was unstable to the reduction conditions and was recovered as diphenyldiselenide. The α-seleno ketone without the yeast was stable in different buffered solutions, which leads us to think that the fermenting yeast is somehow interacting with the seleno moiety.[4] To our knowledge, this is the first report of such an observation, since α-dithianyl ketones and β-thianyl ketones have been reduced with yeast without reported troubles (8, 14).

The allylic ether **2** was synthesized by a parallel route starting from **5**. The reaction of **5** with a large excess of silver(I) oxide and methyl iodide gave ethyl (1*R*,2*S*)-2-methoxycyclopentanecarboxylate **11** in 86.4% yield, $[\alpha]_D^{20}$ +20.0°. Of several methods attempted for the hydrolysis of **11**, the most satisfactory were Ba(OH)$_2$:ethanol:H_2O (1:4:25), and KOH:ethanol:H_2O (1:3:16) with the former giving a 3.4:1 and the latter a 3:1 mixture of two diastereomers of (2*S*)-2-methoxycyclopentanecarboxylic acid **12**. The chemical shift, in the ^{13}C NMR spectrum, of the alkoxy carbon, C2, of the major isomer appeared at 83.8 ppm, and that of the minor at 85.4 ppm, indicating that the major isomer is most likely the *cis* diastereo-

[4] V. Kaija, H. Kai, E. Kari, and K. Matti. Chem. Abstr. **100**, 153628u (1984), reported that Se is incorporated into analogs of S-containing amino acids if yeast is grown in the presence of a source of inorganic Se.

mer[5] (13). The two diastereomers of **12** with oxalyl chloride in refluxing hexanes gave (2*S*)-2-methoxycyclopentanecarbonyl chloride **13** in 93% yield. Decarboxylative selenination of **13** gave (1*S*)-1-methoxy-2-(2-pyridylseleno)cyclopentane **14** in half the yield obtained from the same reaction with **8**. The ozonolysis of **14** and thermal decomposition of the selenoxide by pouring over refluxing pentane produced (*S*)-3-methoxycyclopentene **2** in 68% isolated yield, $[\alpha]_D^{20}$ −116.9°. To our knowledge, this is the first report of the synthesis of optically active **2**. The optical purity of **2** was determined by GC using a chiral column, Ni-4-Pin, and found to be 98.3%, i.e., approximately 97% ee.

A sample of **2** prepared by methylation of optically active **1** by silver(I) oxide/methyl iodide was found to be >99% optically pure by chiral GC analysis as described above. This result verifies that the methylation of **1** under these conditions proceeds without epimerization, and also confirms the optical purity of the allylic alcohol **1**.

Experimental

General information

Infrared spectra (IR) of liquids were recorded using KBr cells on a Nicolet 5-DX FT-IR prism grating spectrophotometer. Gas–liquid chromatography (GC) was accomplished with a Varian model 3700 gas chromatograph fitted with a DB-5, 30 m × 0.249 mm, fused silica column, 0.25 μm film thickness. Proton (^{1}H) and carbon (^{13}C) nuclear magnetic resonance (NMR) spectra were recorded on a 200 MHz Bruker AC-200 spectrometer and signal positions are given in ppm (δ). Flash column chromatography was done on 230–400 mesh silica gel. Rotations were measured on a Rudolph Autopol III automatic polarimeter. Ozone for ozonolysis was generated from a Welsbach ozonator model T-23. Solvents were purified and dried using standard methods. Baker's yeast, *Saccharomyces cerevisiae* type II, was purchased from Sigma. The chiral column was an OV-1 (25 m × 0.25 mm fused silica) coated with 0.25 μm Ni-4-Pin.

Yeast reduction of ethyl 2-oxocyclopentanecarboxylate

A suspension of baker's yeast (12.0 g), sugar (152 g), $MgSO_4$ (1.0 g), KH_2PO_4 (2.0 g), $NH_4H_2PO_4$ (2.0 g), and $CaCO_3$ (5.0 g) in deionized H_2O (1 L) was placed in a water bath at 35°C and allowed to ferment for 45 min (shaken occasionally). Ethyl 2-oxocyclopentanecarboxylate (10.2 g) was added dropwise and the last amount was transferred with the minimum volume of ethanol (1.5 mL). The mixture was magnetically stirred at room temperature for 18 h. A sample analysed by GC showed the disappearance of the starting material. The mixture was transferred to a separatory funnel and extracted with ether (5 × 250 mL). The combined ether extracts were washed with saturated NaCl solution and dried over anhydrous $MgSO_4$ and filtered. Evaporation of the solvent and fractional distillation of the residue under reduced pressure gave (1*R*,2*S*)-2-hydroxycyclopentanecarboxylate **5** in 80.3% yield, bp 59–61°C/0.4 Torr (1 Torr = 133.3 Pa), >98% pure;[6] $[\alpha]_D^{20}$ +15.1° (*c* 1.57, $CHCl_3$) (lit. (10) $[\alpha]_D^{20}$ +14.1° (*c* 1.7, $CHCl_3$)). ^{1}H NMR agreed well with reported data (10). ^{13}C NMR, δ: 174.6 (C=O), 73.6 (CH—O), 60.4 (CH_2—O), 49.5, 33.9, 26.1, 21.9, 14.0.

The Mosher ester of **5** (MTPA ester) was prepared using (*R*)-α-methoxy-α-trifluoromethylphenylacetic acid according to literature procedures (15). ^{1}H NMR ($CDCl_3$), δ: 7.55–7.35 (m, 5H, aromatic), 5.69–5.63 (m, 1H, CH—O), 4.2–3.89 (m, ABX_3, 2H, O—CH_2), 3.495 (d, *J* = 1.1 Hz, 3H, O—CH_3), 3.0–2.89 (8 lines, 1H, CH—CO_2), 1.2 (t, *J* = 7.6 Hz, 3H, CH_2—CH_3). ^{13}C NMR ($CDCl_3$), δ: 170.9 (C=O), 166.0 (C=O), 129.5, 128.3, 127.5, 126.1, 120.0, 79.8 (CH—O), 60.7 (O—CH_3), 55.2, 49.1, 32.3, 25.1, 21.6, 13.9.

Hydrolysis of hydroxy ester 5

The hydroxy ester **5** (17.14 g, 0.103 mol) was stirred with 25% NaOH aqueous solution (85.7 mL) at room temperature according to the procedure in ref. 10. The hydroxy acid **6** was obtained in 74.2% yield, $[\alpha]_D^{20}$ +28.0° (*c* 1.866, $CHCl_3$), as an oil that solidified on standing. IR (thin film): 3676–2291, 1711 cm^{-1}. ^{1}H NMR, δ: 6.8 (br, 2H, -OH and -CO_2H, exchange with D_2O), 4.50 (dd, 1H, *J* = 2.4, 4.6 Hz, CH—O), 2.77 (dt, 1H, *J* = 4.6, 9.2 Hz, CH—CO_2), 2.11–1.61 (m, 6H, ring CH_2's). ^{13}C NMR, δ: 178.7 (CO_2H), 73.9 (CH—OH), 49.6 (CH—CO_2H), 33.9, 25.9, 21.9.

Silylation of hydroxy acid 6

Following the procedure of Wissner and Grudzinskas (11), the hydroxy acid **6** (18.0 g, 0.135 mol), *tert*-butyldimethylchlorosilane (50.0 g, 0.332 mol), and imidazole (45.17 g, 0.663 mol) in DMF (80 mL) were stirred at room temperature. After 44 h, 50% of **6** had reacted. *tert*-Butyldimethylchlorosilane (25.0 g) and imidazole (22.5 g) were added and the reaction mixture was stirred a further 26 h. The reaction mixture was diluted with ether and washed three times with H_2O, then once with saturated NaCl solution. The solvent was removed by fractional distillation and the residue was distilled under reduced pressure to give the disilyl derivative of **7** in 80% yield, bp 120–124°C/0.7 Torr, as a colorless oil; $[\alpha]_D^{20}$ +24.6° (*c* 1.698, $CHCl_3$). ^{1}H NMR, δ: 4.35 (m, 1H, CH—O—Si), 2.7 (m, 1H, CH—CO_2), 2.2–1.5 (multiplets, 6H, ring CH_2's), 0.94 (s, 9H, *t*-Bu-Si), 0.92 (s, 9H, *t*-Bu-Si), 0.27, 0.25, 0.04, 0.03 (singlets, 3H each, CH_3—Si). ^{13}C NMR, δ: 172.9 (CO_2—Si), 75.6 (CH—O—Si), 53.0 (CH—CO_2Si), 34.9, 25.8, 25.6, 25.2, 21.6, 18.0, 17.6, −4.57, −4.61, −4.69, −4.84. Anal. calcd. for $C_{18}H_{38}O_3Si_2$: C 60.28, H 10.68; found: C 60.09, H 10.56.

Reaction of disilyl 7 with oxalyl chloride

Oxalyl chloride (2.3 mL, 26.2 mmol) was added dropwise to a mixture of disilyl **7** (7.56 g, 21.1 mmol) and 3 drops of DMF in CH_2Cl_2 (21 mL) cooled in an ice bath according to the procedure of Wissner and Grudzinskas (11). After work-up and evaporation of the solvent, the residue was connected to a vacuum pump and the by-product, *tert*-butyldimethylchlorosilane, was trapped. The acid chloride **8** (5.6 g, 100% yield) was used in the next step without distillation. IR (thin film): 1811 cm^{-1}. ^{1}H NMR ($CDCl_3$), δ: 4.70 (m, 1H, HC—O—Si), 3.24 (m, 1H, HC—COCl), 2.35–1.57 (m, 6H, ring CH_2's), 0.86 (s, 9H, *t*-Bu-Si), 0.11 (s, 3H, CH_3—Si), 0.08 (s, 3H, Si—CH_3). ^{13}C NMR ($CDCl_3$), δ: 172.2 (C=O), 75.8 (HC—O—Si), 63.7 (HC—COCl), 34.9, 25.6, 25.1, 22.2, 17.9, −4.4 (CH_3—Si), −5.2 (Si—CH_3).

Reaction of acid chloride 8 with selenohydroxamic acid

The acid chloride **8** (5.5 g, 20.9 mmol) in benzene (110 mL) was added dropwise over 30 min to a refluxing solution of selenohydroxamic acid (4.84 g, 27.6 mmol), pyridine (5.5 mL), and DMAP (0.264 g) in benzene (220 mL) under argon according to the procedure of Barton *et al.* (12). The crude product upon chromatography over silica (eluting with 3% EtOAc: pet. ether) gave the selenide **9** in 85.8% yield as a 7:1 mixture of two diastereomers. $[\alpha]_D^{20}$ −15.0° (*c* 1.093, $CHCl_3$). ^{1}H NMR ($CDCl_3$), δ: major 8.41 (m, 1H), 7.38 (m, 2H), 6.99 (m, 1H), 4.30 (m, 1H, HC—O), 3.9 (m, < 1H, HC—Se), 2.5–1.5 (multiplets, 6H, ring CH_2's), 0.85 (s, 9H, *t*-Bu-Si), 0.029 (s, 3H, CH_3—Si), 0.019 (s, 3H, Si—CH_3). ^{13}C NMR ($CDCl_3$), δ: major 156.5, 149.9, 135.7, 125.7, 120.1 (pyridyl carbons), 79.7 (HC—O—Si), 48.6, 33.8, 30.6, 25.7 (*t*-Bu-Si), 22.4, 17.9, −4.7 (CH_3—Si), −4.8 (Si—CH_3); minor 75.8 (CH—O). Anal. calcd. for $C_{16}H_{27}NOSeSi$: C 53.92, H 7.64, N 3.93; found: C 54.26, H 7.78, N 3.74.

Ozonolysis of selenide 9

The selenide **9** (6.4 g) in CH_2Cl_2 was cooled in a Dry Ice – acetone bath and ozone (2.5% O_3) was bubbled through the solution until the

[5] J. Pascual and J. Vinas. Chem. Abstr. **55**, 4383e (1961), reported that the saponification of methyl *cis*-2-methoxycyclopentanecarboxylate with $Ba(OH)_2$ gave 87% *cis*-2-methoxycyclopentanecarboxylic acid.

[6] NOTE ADDED IN PROOF: Noyori *et al.* (J. Am. Chem. Soc. **111**, 9134 (1989)) reported that the hydrogenation of the methyl esters of **4** by (*R*)-BINAP–Ru complex gave a 99:1 mixture of the *trans* hydroxy ester (92% ee) and its C2 epimer (93% ee).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

blue color persisted. Oxygen was passed through the solution to drive off excess ozone and, very cautiously, 1-pentene (37 mL) was added to the cold mixture, and the reaction mixture was added over refluxing CCl_4 (177 mL) at a rate to maintain reflux. After completion of addition, the mixture was refluxed for a further 30 min, then the solvents were removed under reduced pressure. The allylic silyl ether **10** was obtained by vacuum distillation of the residue in 77.2% yield, 35°C/0.5 Torr); $[\alpha]_D^{20}$ −84.9° (*c* 0.855, $CHCl_3$). ^1H NMR ($CDCl_3$), δ: 5.92 (m, 1H, HC=), 5.7 (m, 1H, =CH), 4.94 (m, 1H, HC—O), 2.6–2.21 (m, 3H), 1.67 (m, 1H), 0.84 (s, 9H, *t*-Bu-Si), 0.02 (s, 6H, CH_3—Si—CH_3). ^{13}C NMR ($CDCl_3$), δ: 133.9 (HC=), 133.4 (=CH), 78.1 (HC—O), 33.5, 31.0, 26.0 (*t*-Bu-Si), 18.3, −4.6 (CH_3—Si—CH_3). Exact Mass calcd. for $C_{11}H_{22}OSi$: 198.3822; found: 198.3828.

(S)-2-Cyclopenten-1-ol ***1***

Tetrabutylammonium fluoride (47.9 mL, 1.0 M solution in THF) was added via a syringe to the silyl ether **10** (9.5 g, 47.9 mmol) under argon. After stirring the reaction mixture at room temperature for 90 min, the mixture was transferred to a separatory funnel, and the organic layer was washed with a saturated solution of NaCl and dried over anhydrous $MgSO_4$. The solvent was removed by fractional distillation and the residue was subjected to flash column chromatography to remove the by-product, *t*-Bu-Si(CH_3)$_2$—O—Si(CH_3)$_2$-*t*-Bu, eluting with 10% ether:pentane, then with 25% ether:pentane. Alcohol **1** was obtained in 46% isolated yield, bp 51.5–53°C/aspirator (lit. (16) bp 78°C/59 Torr); $[\alpha]_D^{20}$ −137.9° (*c* 1.10, $CHCl_3$); $[\alpha]_D^{20}$ −113.1° (*c* 1.045, *n*-hexane). IR (thin film): 3325 (O—H), 3058 (H—C=), 1615 (C=C), 1047 (C—O). ^1H NMR ($CDCl_3$), δ: 5.88 (m, 1H, HC=), 5.75 (m, 1H, =HC), 4.77 (m, 1H, CH—O), 3.1 (bs, 1H, -O—H), 2.42 (m, 1H), 2.16 (m, 2H), 1.6 (m, 1H). ^{13}C NMR ($CDCl_3$), δ: 134.4 (CH=), 133.2 (=CH), 77.0 (HC—OH), 32.9, 30.7. The MTPA ester exhibited the following spectroscopic properties: ^1H NMR ($CDCl_3$), δ: 7.57–7.52 (m, 2H), 6.2–6.17 (m, 1H, CH—O), 5.96–5.91 (m, 2H, HC=CH), 3.56 (d, J = 1.2 Hz, 3H, O—CH_3), 2.62–2.22 (m, 3H), 1.97–1.8 (m, 1H). ^{13}C NMR ($CDCl_3$), δ: 166.3 (C=O), 139.08 (CH=), 129.4, 128.3, 128.0 (=CH), 127.35, 126.2, 120.4, 83.03 (CH—O), 55.3 (O—CH_3), 31.0, 29.48. The MTPA ester of the racemic alcohol had the following: ^{13}C NMR ($CDCl_3$), δ: 166.3 (C=O), 139.21, 139.08, 132.46, 132.32, 129.4, 128.3, 128.0, 127.35, 127.26, 126.2, 120.4, 83.12, 83.03, 55.3, 31.0, 29.48, 29.35.

Methylation of hydroxy ester ***5***

A mixture of hydroxy ester **5** (0.5 g, 3.16 mmol), methyl iodide (0.8 mL, 12.6 mmol), and Ag_2O (0.73 g, 3.15 mmol) was refluxed according to the procedure of Mislow (17). After 18 h, 14.2% of **5** remained unreacted. Methyl iodide (1 mL) and Ag_2O (0.8 g) were added and the mixture was refluxed for a further 6 h (progress of the reaction was followed by GC). Ether was added and the mixture was filtered through Celite, and the solvent was removed by fractional distillation. Chromatography of the residue over flash silica (eluting with 15% ether:pet. ether) yielded methoxy ester **11** in 86.4% yield, $[\alpha]_D^{20}$ +20° (*c* 1.311, $CHCl_3$). ^1H NMR ($CDCl_3$), δ: 4.24–4.0 (16 lines ABX_3, 2H, O—CH_2), 3.97–3.88 (m, 1H, CH—O), 3.25 (s, 3H, O—CH_3), 2.9–2.74 (8 lines, 1H, CH—CO_2), 2.2–1.47 (m, 6H, ring CH_2's), 1.22 (t, J = 17.5 Hz, 3H, -CH_3). ^{13}C NMR ($CDCl_3$), δ: 172.6 (C=O), 84.0 (CH—O), 60.0 (O—CH_2), 57.0 (O—CH_3), 49.4, 30.4, 25.2, 22.5, 21.9, 14.2. Anal. calcd. for $C_9H_{16}O_3$: C 62.77, H 9.36; found: C 62.40, H 9.38.

Hydrolysis of methoxy ester ***11***

A mixture of methoxy ester **11** (4.186 g, 24.3 mmol), KOH (11.63 g, 207 mmol), ethanol (34.9 mL), and H_2O (186 mL) was refluxed for 45 min, then it was cooled and extracted with ether. The aqueous layer was carefully acidified with ice-cold 8% H_2SO_4 and extracted with ether. Evaporation of ether gave the methoxy acid **12** in 95% yield as a 3:1 mixture of diastereomers accompanied by 1.5% of 1-cyclopentenecarboxalic acid as a by-product. Hydrolysis of **11** (0.5 g) with $Ba(OH)_2$ (2.0 g) and ethanol (8 mL) in H_2O (50 mL), stirring at room temperature overnight, gave a 3.4:1 mixture of diastereomers, with the major being the same as above. ^1H NMR ($CDCl_3$), δ: 11.48 (br s, 1H, CO_2H), 4.03 (m, 1H, CH—O), 3.339 and 3.334 (two singlets), 2.87 (m, 1H, CH—CO_2), 2.2–1.55 (m, 6H, ring CH_2's). ^{13}C NMR ($CDCl_3$), δ: major 177.9 (C=O), 83.8 (CH—O), 60.0 (O—CH_3), 49.3, 30.3, 25.6, 21.8; minor 181.0 (C=O), 85.4 (CH—O), 56.9 (O—CH_3), 50.3, 32.1, 28.5, 23.4.

Methoxy acid chloride ***13***

A mixture of methoxy acid **12** (3.34 g, 23.2 mmol) and oxalyl chloride (2.7 mL) in hexane (20 mL) was refluxed overnight. Evaporation of the solvent and excess oxalyl chloride gave acid chloride **13** in 93% yield, pure enough to use in the next step. IR (thin film): 1797, 1791 cm^{-1}. ^1H NMR ($CDCl_3$), δ: 4.12 (m, 1H, CH—O), 3.34 (s, 3H, O—CH_3), 3.28–3.17 (8 lines, 1H, CH—COCl), 2.25–1.62 (m, 6H, ring CH_2's). ^{13}C NMR ($CDCl_3$), δ: 175.6 (C=O), 84.8 (CH—O), 62.2 (O—CH_3), 57.1, 32.0, 29.1, 23.2.

Decarboxylative selenination of acid chloride ***13***

The acid chloride **13** (2.29 g, 14.1 mmol) in benzene (70 mL) was added dropwise to a refluxing solution of selenohydroxamic acid (3.0 g, 17.4 mmol), DMAP (0.168 g), and pyridine (3.5 mL) in benzene (140 mL) as described for acid chloride **8**. After work-up, the methoxy selenide **14** was obtained in 42% yield as a 4.8:1 mixture of two diastereomers. ^1H NMR ($CDCl_3$), δ: major diastereomer 8.42 (m, 1H), 7.41 (m, 2H), 7.0 (m, 1H), 4.14 (m, 1H, CH—O), 3.88 (m, 1H, CH—Se), 3.35 (s, 3H, O—CH_3), 2.37 (m, 1H), 2.1–1.6 (multiplets, 5H). ^{13}C NMR ($CDCl_3$), δ: major diastereomer 150.0 (Se—C=N), 135.9, 125.8, 120.3 (pyridyl carbons), 88.4 (CH—O), 44.9 (CH—Se), 31.4, 30.9, 23.1. Anal. calcd. for $C_{11}H_{15}NOSe$: C 51.57, H 5.90, N 5.47; found: C 51.66, H 5.99, N 5.42.

Ozonolysis of methoxy selenide ***14***

Methoxy selenide **14** (3.06 g, 11.9 mmol) in CH_2Cl_2 (75 mL) was ozonized at −78°C (2.5% ozone) as described for **9**. 1-Pentene (24.6 mL) in CH_2Cl_2 (20 mL) was added cautiously to the cold solution and the mixture was added to refluxing pentane. The solvents were removed by fractional distillation and the residue was distilled under reduced pressure to yield 3-methoxycyclopentene **2** (68%); $[\alpha]_D^{20}$ −116.9° (*c* 3.86, *n*-hexane). ^1H NMR ($CDCl_3$), δ: 6.06–6.01 (m, 1H, CH=), 5.92–5.86 (m, 1H, =CH), 4.51–4.43 (m, 1H, CH—O), 3.33 (s, 3H, O—CH_3), 2.56–1.68 (multiplets, 4H, ring CH_2's). ^{13}C NMR ($CDCl_3$), δ: 135.7, 130.5 (CH=CH), 86.1 (CH—O), 55.7 (O—CH_3), 31.0, 29.3. Chromatography of **2** using a Ni-4-Pin chiral column, isothermal at 60°C and 20 psi (1 psi = 6.9 kPa), showed it to be 98.3% optically pure (97% ee). A sample of **2** prepared by an overnight reflux of a mixture of (*S*)-**1** (200 mg), Ag_2O (400 mg), and methyl iodide (8 mL) was >99% optically pure.

A deuterium labelling study into the insertion of diphenylacetylenes into iron–aryl bonds

IAN R. BUTLER,[1] JOANNE L. ELLIOT, AND JEAN HOUDE, JR.
Chemistry Department, The University of Ottawa, Ottawa, Ont., Canada K1N 6N5

Received January 23, 1990

IAN R. BUTLER, JOANNE L. ELLIOT, and JEAN HOUDE, JR. Can. J. Chem. **68**, 1564 (1990).

The mechanism of the reaction of dicarbonyl(η^5-cyclopentadienyl)phenyliron, **1**, with diphenylacetylene to give 2,3-diphenyl-[1*H*]-inden-1-one has been investigated using a partially deuterated **1**. The mechanistic pathway of the reaction is discussed in terms of the labelling of the indenones obtained. The reaction of phenylacetylene with **1** gives a mixture of products including 2,4,6-triphenyl-4′-methylbenzophenone and C-4,C-6a-dihydro-4-(4′-methylphenyl)-2-phenylpentalene(1-*r*-3a*H*)one.

Key words: indenones, acetylenes, iron, carbonyl.

IAN R. BUTLER, JOANNE L. ELLIOT et JEAN HOUDE, JR. Can. J. Chem. **68**, 1564 (1990).

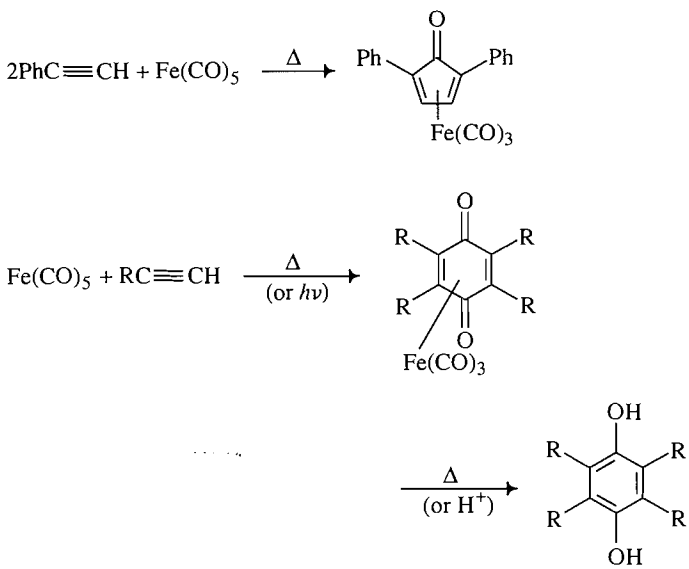
Utilisant un composé **1** partiellement deutéré, on a examiné le mécanisme de la réaction du dicarbonyl(η^5-cyclopentadiényl)phénylfer, **1**, avec le diphénylacétylène qui conduit à la 2,3-diphényl-[1*H*]-indèn-1-one. On discute des diverses voies mécanistiques de la réaction en fonction de la position des marqueurs dans les indénones obtenues. La réaction du phénylacétylène avec le composé **1** conduit à un mélange de produits incluant la 2,4,6-triphényl-4′-méthylbenzophénone et la C-4,C-6a-dihydro-4-(4′-méthylphényl)-2-phénylpentalène(1-*r*-3a*H*)one.

Mots clés : indénones, acétylènes, fer, carbonyl.

[Traduit par la revue]

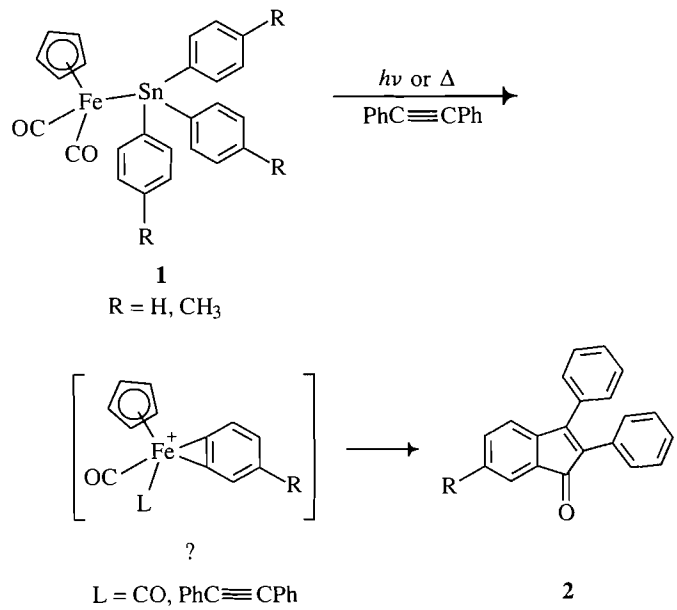
Introduction

The reactions of iron carbonyls and their derivatives with acetylenes have been studied extensively (1–10), since the initial discoveries and pioneering work of Reppe (1, 2). Some typical organic products obtained from such reactions are substituted quinones and cyclopentadienones or their metal complexes arising from multiple insertion of acetylenes and carbon monoxide into iron–carbon bonds, Scheme 1 (3, 4).



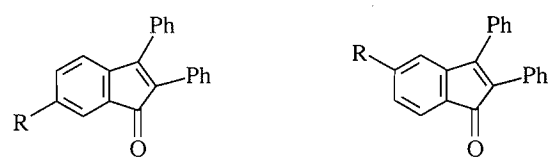
SCHEME 1

In 1971, Nesmeyanov *et al.* (11) reported interesting thermal and photolytic reactions of Fp-($SnAr_3$), **1** (Fp = dicarbonyl(η^5-cyclopentadienyl)iron, Ar = phenyl, *p*-tolyl), with diphenylacetylene to give 2,3-diaryl-[1*H*]-inden-1-ones, **2**, in yields of 10–67%. Their proposed mechanism for this reaction included the suggestion of an iron–benzyne intermediate, Scheme 2.



SCHEME 2

This mechanism is unlikely, however, since a mixture of **2***a* and **2***b* would be expected on this basis, whereas only **2***a* was observed.



2*a* **2***b*

Later, in 1979, Kolobova and Goncharenko reported a series of photochemical reactions including the reaction of Fp-(2-thienoyl) and Fp-(2-furanoyl) with diphenylacetylene to give thienyl and furanyl indenone isosteres (Scheme 3) (12). The structural identification of **4***a* was made on the basis of a comparison with related isomers prepared from the reaction of diphenylacetylene with the 2-thienoylchloride·aluminum

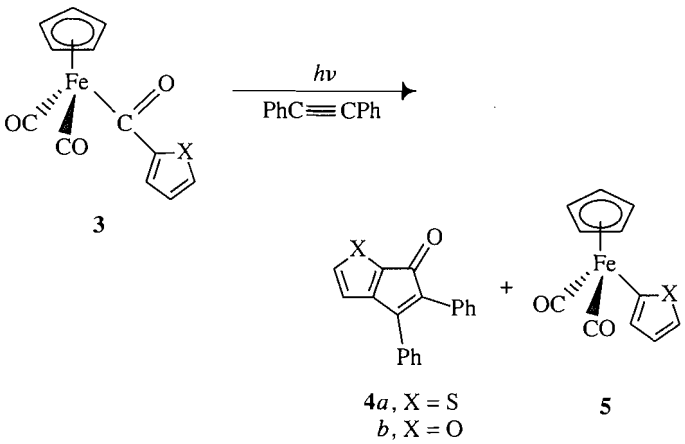
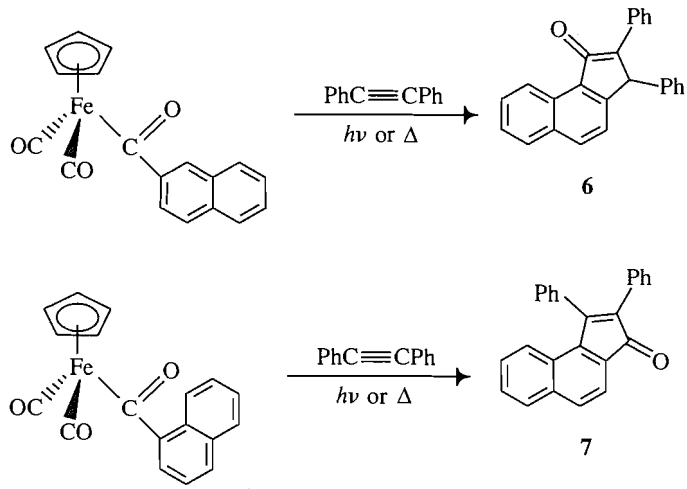
trichloride complex. We have recently completed a study in this area and our results indicate the product assignments to be in error (13).



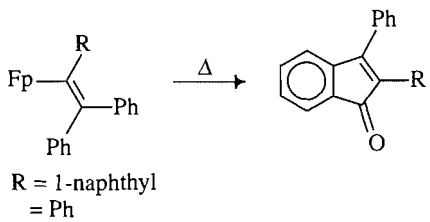
SCHEME 3

In our own work, we have carried out several investigations to clarify the mechanistic details of these reactions as well as to exploit their synthetic utility (14–16). The thermal and photochemical reactions of Fp-(1- and 2-naphthoyls) with diphenylacetylene and 1-phenylprop-2-yne were found to give the products **6** and **7** respectively, in addition to a substantial number of by-products including mono and 1,1′-bis-naphthyl ferrocenes (16) (Scheme 4). These results indicate that the



SCHEME 4

insertion of diphenylacetylene precedes that of carbon monoxide. Further work was done to show that indenones could be obtained directly from Fp-(1,2,2-triarylvinyl) derivatives, Scheme 5 (15), which we proposed as reaction intermediates.



SCHEME 5

To integrate all the available information into a complete plausible mechanism for these processes, we decided to investigate the prototype reaction of all those documented, namely the reaction of Fp-phenyl with diphenylacetylene.

Experimental

All solvents used were predried and were freshly distilled prior to use, with the exception of decalins, which were used as received (Aldrich). Column chromatography was carried out using neutral Alumina (Brockman Grade I) using columns of 5 cm (diam.) × 15 cm (length). Mass spectra were recorded using a VG-Analytical-1000 instrument (operating at 70 eV with a probe temperature of 150°C). The ^{1}H nmr and ^{13}C nmr spectra were obtained using a Varian XL-300 instrument using $CDCl_3$ in each case as solvent, unless otherwise stated (terminology used: d = doublet, t = triplet, ABd = ABdoublet, m = multiplet, bs = broad singlet, s = singlet, ddd = doublet of doublets, dt = doublet of triplets).

*Preparation of (η^5-cyclopentadienyl)dicarbonyl(benzoyl-d$_5$)iron (**15**)*

Benzoyl chloride-d_5 was prepared from commercially available bromobenzene-d_5 via benzoic acid-d_5 using standard synthetic procedures. A solution of sodium dicarbonyl-(η^5-cyclopentadienyl)ferrate in THF (100 mL) prepared from tetracarbonyl-bis(η^5-cyclopentadienyl)di-iron (7.08 g, 20.0 mmol) (17) and a 3% sodium amalgam (1.0 g, 43.5 mmol Na) was added to a solution of benzoylchloride-d_5 (6.55 g, 45.0 mmol) in THF (100 mL) cooled to −70°C. Following solvent removal under vacuum, the product was extracted with dichloromethane and chromatographed, eluting with diethyl ether to give initially Fp_2 (1.2 g) followed by the product Fp-benzoyl-d_5, which, following solvent reduction, was precipitated from solution by addition of hexanes to yield 6.10 g, 53%. IR, ν_{CO}: 2020, 1967, 1618 cm^{-1}; ^{1}H nmr, δ: 4.90 (s); mass spectrum, *m/e* (rel. intensity): 259 (18.6); $M^{+\cdot}$ − CO, 232 (7.1); 231 (47.3); 204 (13.3); 203 (100.0); 201 (12.7); 200 (133); 147 (24.1); 146 (12.5); 138 (5.7); 121 (29.6).

*Reaction of Fp-benzoyl-d$_5$ with diphenylacetylene (**9**)*

A mixture of Fp-benzoyl-d_5 (2.87 g, 10 mmol) and diphenylacetylene (3.56 g, 20 mmol) was refluxed in decalins (25 mL) under a nitrogen atmosphere for 10 min. After cooling, the reaction mixture was chromatographed on a neutral alumina column and the following fractions collected, eluting with progressively more polar mixtures of hexanes and diethyl ether commencing with neat hexane: (i) 1,1′-bis-(phenyl-d_5)ferrocene (0.35 g, 28%); ^{1}H nmr: 4.24 (t, 4), 4.48 (t, 4); mass spectrum, *m/e* (rel. int.): 350 (4.8); 349 (28.8); 348 (100.0), $M^{+\cdot}$; 347 (6.3); 346 (7.8); 267 (4.1); 202 (10.3); 174 (3.9); 146 (22.8); 120 (5.4); 119 (6.2); (ii) phenyl-d_5-ferrocene; ^{1}H nmr: 4.00 (s, 5), 4.24 (t, 2), 4.60 (t, 2); mass spectrum, *m/e* (rel. int.): 268 (10.3); 267 (45.4), ($M^{+\cdot}$); 180 (37.4); (iii) deuterated 2,3-diphenyl-[1*H*]-inden-1-one; mass spectrum, (accurate masses, rel. int.): 289.1397 (5.19); 288.1392 (20.66); 287.1351 (96.46); 286.1294 (100.0); 285.1283 (50.65); 284.1143 (10.15); 284.1324 (2.95); 283.1143 (10.15); 283.0758 (2.83). The ratio of d_4- to d_5-indenone was calculated to be approximately 63:37 by mass spectroscopy (calculated by averaging a number of spectra by comparison with pure undeuterated sample to obtain normal peak distributions), and by ^{1}H nmr was estimated at 61:39 by integration and with respect to an undeuterated sample and mixtures of the two; ^{13}C nmr: 196.34 (CO), 155.20, 145.17, 133.35, 132.69, 132.34, 130.68, 129.91, 128.88, 128.71, 128.52, 128.43, 128.35, 128.21, 128.00, 127.77, 127.67, 122.91, 121.19.

Reaction of Fp-benzoyl-d$_5$ with p-tolyl(phenyl)acetylene

A mixture of *p*-tolyl(phenyl)acetylene (0.55 g, 2.86 mmol) and Fp-benzoyl-d_5 (0.8 g, 2.80 mmol) was heated in decalin (10 mL) to reflux, and maintained at reflux for 5 min. The cooled sample was poured directly onto a neutral alumina column as described in the general experimental section. Following elution with hexanes to remove decalins, the following fractions were isolated: (i) yellow band (120 mg) eluted with hexane/diethyl ether (90:10), identified as a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

mixture of ferrocene (trace), phenyl-d_5-ferrocene; (ii) orange band (170 mg), eluted with hexane/diethyl ether (90:10), identified as 1,1′-bis-(phenyl-d_5)ferrocene by mass and ^{1}H nmr spectroscopy; (iii) bright orange (0.25 g), eluted with hexane/diethyl ether (50:50), identified initially by mass spectroscopy, parent ions at *m/e* 300/301 as the indenone-containing fraction; and (iv) red/brown, Fp_2, eluted with diethyl ether. Comparison of ^{1}H nmr spectra of the indenone-containing fraction with those of authentic sample of non-deuterated indenones prepared from the similar reaction of Fp-*p*-tolyl with diphenylacetylene (4) indicated the mixture to be composed of **22***d* and **23***d* (unable to distinguish by ^{1}H nmr) and **25***d* in the approximate ratio of 64:36 (total 31%). A tlc indicated the presence of a fourth orange product, with parent ion at *m/e* 300 present in only trace quantity.

22*d*, **23***d*, and **25***d* (mixed isomers); mass spectrum, *m/e* (rel. int.): 302 (35.5); 301 (100.0); 300 (88.4); 299 (7.7); 287 (97.9); 286 (38.9); 285 (24.2); 284 (13.0); 283 (9.4); 272 (5.7); 270 (7.2); 269 (8.0); 261 (5.9); 267 (5.6); 258 (12.3); 257 (26.1). A sample free of **25***d* was obtained by fractional crystallization and the ^{1}H nmr spectrum is shown in Fig. 5. The ^{1}H nmr spectrum of **25***d* is similar to that of **25** (undeuterated) obtained from the reaction of Fp-toloyl with diphenylacetylene (11) with the exception of the absence of peaks due to the 3-phenyl group at ~δ 7.4. Chromatography using the chromatoron of mixtures of **22***d*, **23***d*, and **25***d* gave initial separation, by hexane, of **22***d*, **23***d* from **25***d* but, on increasing the polarity slightly to augment band removal, resulted in the mergence of the bands into one diffuse band.

*Reaction of Fp-benzoyl with bis-*p*-tolyacetylene*

The thermal reaction of Fp-benzoyl (1.42 g, 5.0 mmol) with bis-*p*-tolylacetylene (2.06 g, 10 mmol) in refluxing decalins according to the procedure outlined above gives, on isolation of the red/orange fraction following column chromatography, the indenones **26** (7%) and **27** (28%), which were identified by ^{1}H nmr and mass spectroscopy. **26**: ^{1}H nmr: 2.31 (s, 3), 2.34 (s, 3), 7.03 (s, 1), 7.10–7.39 (m's, 10), 7.52 (ddd, 1); mass spectrum, *m/e* (rel. int.): 311 (24.3); 310 (100.0); $M^{+\cdot}$, 309 (18.2); 296 (10.6); 295 (43.4); 294 (5.8); 293 (7.8); 282 (3.0); 281 (4.7); 280 (5.1); 279 (5.8); 267 (9.4); 266 (12.1); 265 (19.1); 252 (17.5). **27**: ^{1}H nmr: 2.30 (s, 3), 2.36 (s, 3), 6.99 (ABd, 1), 7.13 (ABd, 1), 7.14 (ABd, 2), 7.38 (bs, 5); mass spectrum *m/e* (rel. int.): 311 (25.3); 310 (100.0); $M^{+\cdot}$, 309 (18.3); 296 (10.0); 295 (41.0); 294 (5.5); 293 (7.6); 282 (3.2); 281 (4.9); 279 (3.8); 267 (9.5); 266 (12.6); 263 (20.3); 253 (4.8); 252 (18.3). Other products obtained were 1,1′-bis(*p*-tolyl)ferrocene and hexa(4-methylphenyl)benzene (identified by spectral comparison with previously prepared samples).

*Reaction of Fp-*p*-toloyl with phenyl acetylene*

A mixture of Fp-*p*-toloyl (2.0 g, 6.8 mmol) and phenylacetylene (2.5 g, 24.5 mmol) in decalins was gently refluxed for 15 min. Thereafter the reaction mixture was examined by tlc (eluant hexanes/diethyl ether, 70:30) and was shown to contain a large number (>10) of compounds. Subsequent chromatography on a neutral alumina support gave the following fractions, which were initially examined by mass spectroscopy to establish which compounds had not been previously characterized. In addition to the usual bands containing ferrocene and Fp-*p*-tolyl and Fp-*p*-toloyl, several new compounds were observed, which had the following parent ions: (i) 276, identified as *p*-tolylferrocene; (ii) 286 (18%), obtained as a white crystalline substance identified as C-3,C-4,C-6a-trihydro,4-(4′-methylphenyl)-2-phenyl(1-*r*-3a*H*)one, **28**; ^{1}H nmr: 2.35 (s, 3), 3.75 (dd, 1), 3.85 (ddd, 1), 4.37 (dd, 1), 5.78 (dd, 1), 6.03 (dd, 1), 6.85 (d, 1), 7.00 (d, 2), 7.13 (d, 2), 7.30 (m, 3), 7.48 (d, 2); mass spectrum, *m/e* (rel. int.): 287 (22.4); 286.1366 (accurate mass), $M^{+\cdot}$ (100.0); 285 (15.0); 271 (17.3); 258 (13.9); 257 (15.1); 243 (31.2); 242 (16.3); 241 (18.0); 240 (7.3); 229 (13.9); 228 (21.7). The proton nmr of this compound is shown in Fig. 1, together with that of C-3,C-4,C-6a-trihydro,4-(1-naphthyl)-2,3-phenyl(1-*r*-3a*H*)one; (iii) 424 (26%), **29**, isolated as an off-white solid and identified as 2,4,6-triphenyl,4′-methylbenzophenone; ^{1}H nmr: 2.30 (s, 3), 6.98–7.83 (m's, 21); mass spectrum, *m/e* (rel. int.): 425 (31.7); 424.1820 (accurate mass), $M^{+\cdot}$ (100.0); 423 (38.8); 347 (31.5); 334 (10.2); 333 (37.7); 305 (10.6); 304 (17.0); 203 (17.7); 302 (21.7). The red-brown bands containing Fp_2 were shown by mass spectroscopy to contain *p*-tolyl substituted cyclopentadienyls, parent ions *m/e* 444, in addition to the parent Fp_2, parent ion at *m/e* 354.

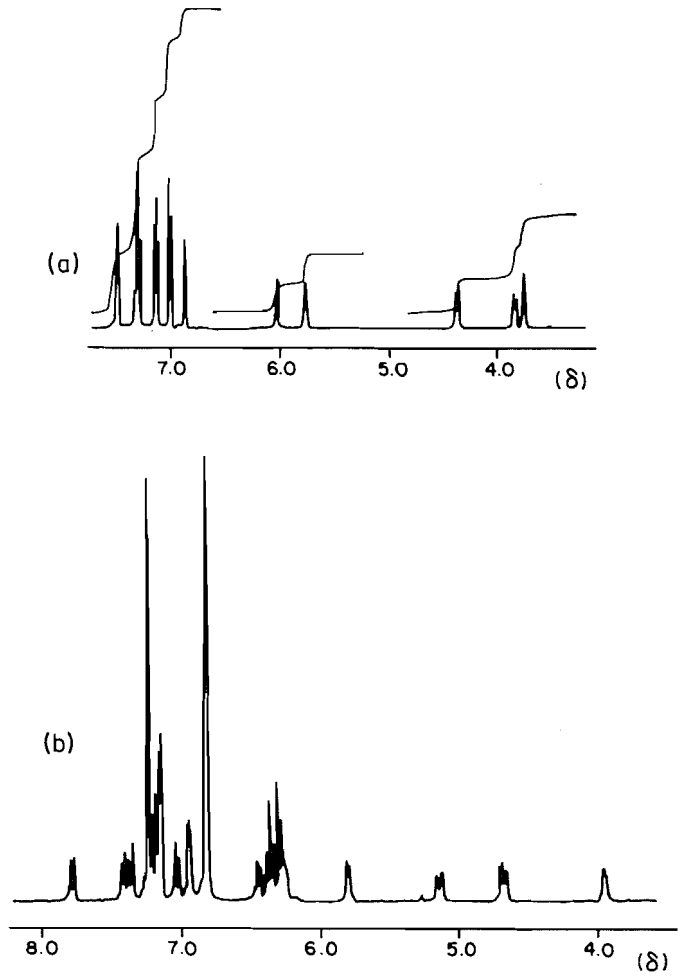


FIG. 1. The ^{1}H nmr spectra (aromatic region) of (a) **28**; (b) C-3,C-4,C-6a-trihydro,4-(1-naphthyl)-2,3-phenyl(1-*r*-3a*H*)one. (δ 4–9).

*Reaction of Fp-*m*-toloyl with bis(*m*-tolyl)acetylene*

A mixture of Fp-*m*-toloyl (296 mg, 1.0 mmol) with bis(*m*-tolyl)-acetylene (206 mg, 1.0 mmol), prepared by the palladium-catalyzed reaction of acetylene with *m*-iodotoluene, was refluxed for 5 min. The cooled reaction mixture was chromatographed on a neutral alumina column to give the following fractions: (i) a pale yellow band shown by mass spectroscopy to be composed mainly of the starting acetylene; (ii) a diffuse orange band shown by mass spectroscopy and ^{1}H nmr to contain a mixture of Fp-*m*-tolyl and *m*-tolylferrocene with parent masses at *m/e* 268 (14%) and 276 (100%), respectively; (iii) a bright orange band, identified as 2,3-(3-methylphenyl),5-methyl-[1*H*]-inden-1-one, **32** (37 mg, 11%); ^{1}H nmr: 2.27 (s, 3), 2.33 (s, 3), 2.60 (s, 3), 6.73 (d, 1), 6.89 (t, 1), 6.93–7.28 (series of m's, 9); mass spectrum, *m/e* (rel. int.): 326 (4.2); 325 (26.8); 324 (100.0), $M^{+\cdot}$; 323 (11.8); 310 (10.7); 309 (45.5); 307 (6.5); 295 (5.1); 266 (11.0); 265 (14.9); 263 (5.9); (iv) a bright orange band identified as 2,3-(3-methylphenyl),7-methyl-[1*H*]-inden-1-one, **33** (91 mg, 28%); ^{1}H nmr: 2.25 (s, 3), 2.33 (s, 3), 2.33 (s, 3), 6.70 (bs, 1), 7.00 (dt, 1), 7.03 (bs, 1), 7.05–7.30 (series of m's, 7), 7.44 (d, 1); mass spectrum, *m/e* (rel. int.): 326 (4.4); 325 (26.1); 324 (100.0), $M^{+\cdot}$; 323 (11.7); 310 (11.9); 309 (44.7); 266 (10.2); 265 (11.6); (v) Fp_2; (vi) a faint brown band subsequently shown by mass spectroscopy, parent ion at *m/e* 618, to contain the trimerized acetylene.

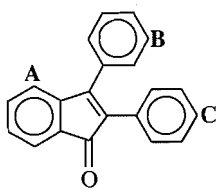
Results and discussion

It was decided to investigate the reaction of Fp–Ph with diphenylacetylene, using deuterium labelled Fp–Ph, since this reaction may be considered as the prototype of the more general reaction of Fp–aryls with diaryl acetylenes. One of the standard methods of preparation of Fp–Ph is via the photochemical deinsertion (reverse aryl migration) of carbon monoxide from the Fp–benzoyl derivative (18). Since such reactions also occur thermally (19), the Fp–aroyl derivatives can be used as alternate reactants generating the desired Fp–aryl compound *in situ*. Fp–(benzoyl-d_5) was thus reacted with diphenylacetylene in decalins at reflux for 10 min, under an inert atmosphere. Following column chromatography, 2,3-diphenylinden-1-one(-d_4 and -d_5), **8**, was obtained in 36% yield with smaller quantities of (d_5-phenyl)ferrocene, **9**; bis-1,1′-(d_5-phenyl)ferrocene, **10**; hexaphenylbenzene, **11**; and Fp_2 (Scheme 6).

The mass spectrum obtained of the indenone indicated a mixture (approx. 61:39) of the d_4- and d_5-indenones (Fig. 2). This result was verified using ^{1}H nmr, by comparison of the spectrum with that of an undeuterated sample, although the exact positions of the labels were found to be difficult to establish. ^{13}C spectroscopy at 75 MHz indicated no distinguishable differences in the chemical shift of deuterated and undeuterated samples of **8**; however, there were distinct differences in the relative peak heights of the resonances (Fig. 3). By carrying out ^{13}C/^{1}H heteronuclear correlation experiments,



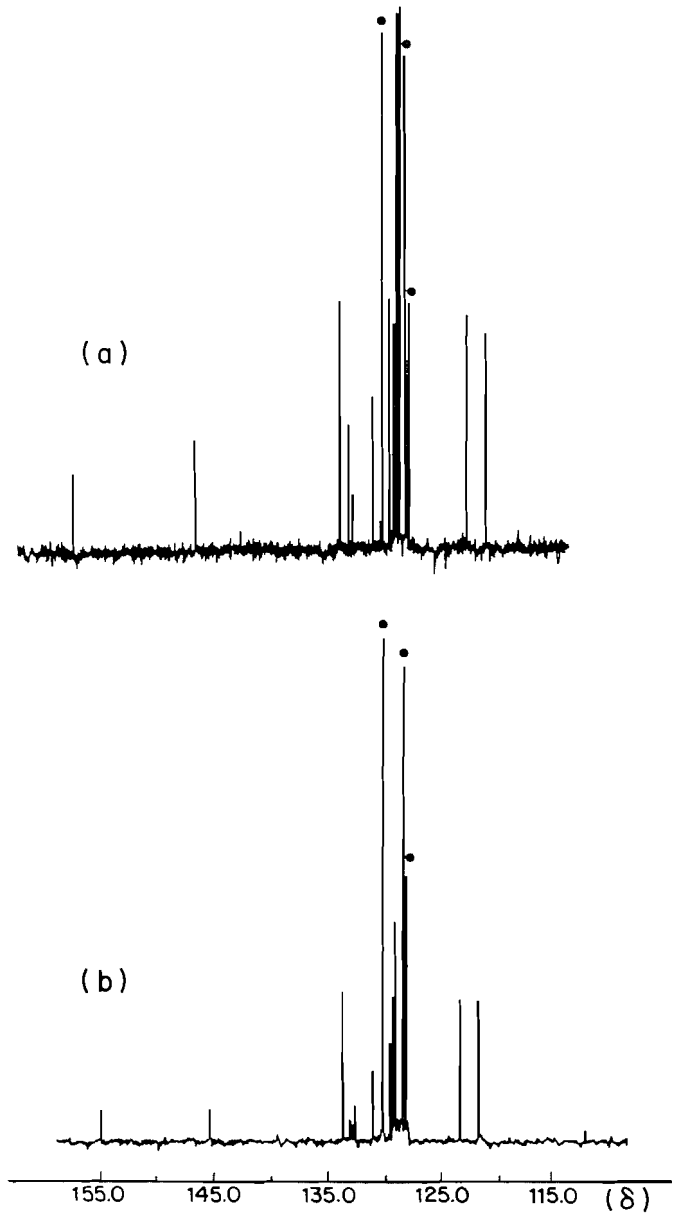


FIG. 3a. The ^{13}C spectrum of (a) non-deuterated and (b) deuterated 2,3-diphenylindene-1-one. The 3-phenyl position carbon resonances are unaffected by deuteration.

we were able to assign the individual resonances in the ^{13}C spectrum. The most important feature of the spectra was that ^{13}C resonances in ring C, when compared to the spectrum of the undeuterated sample, were observed to be much more intense than those in rings A and B. This is indicative of partial deuteration of rings A and B, since deuteration would give rise

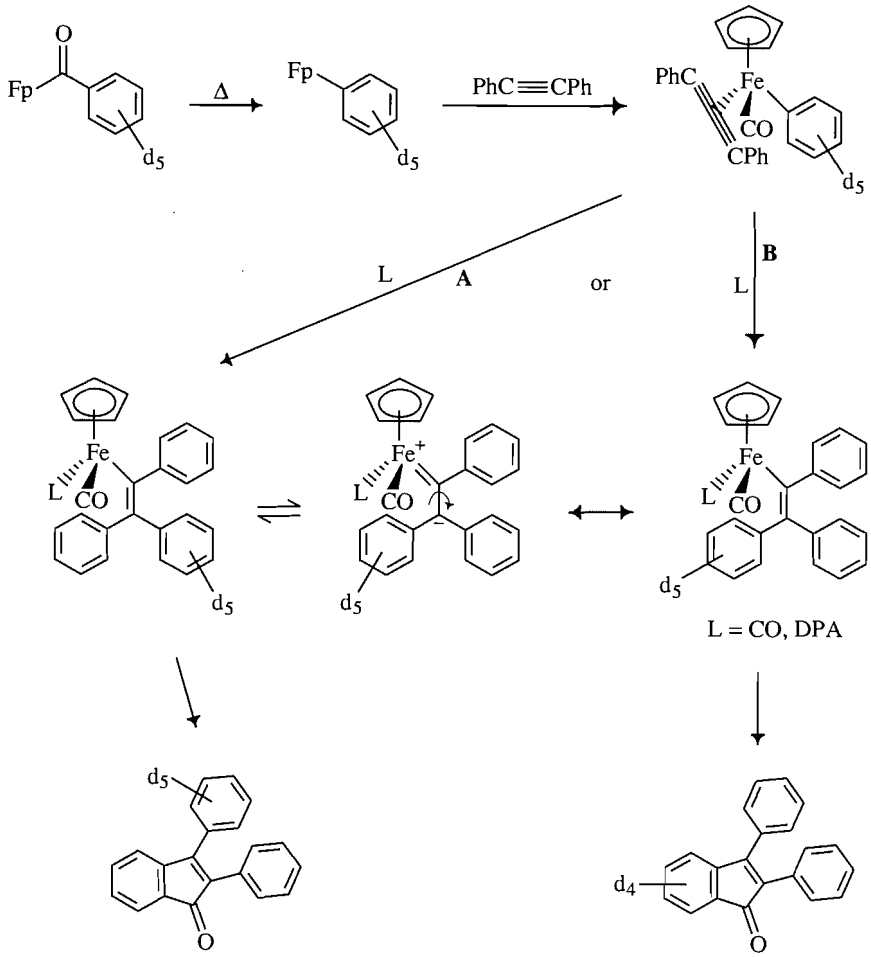
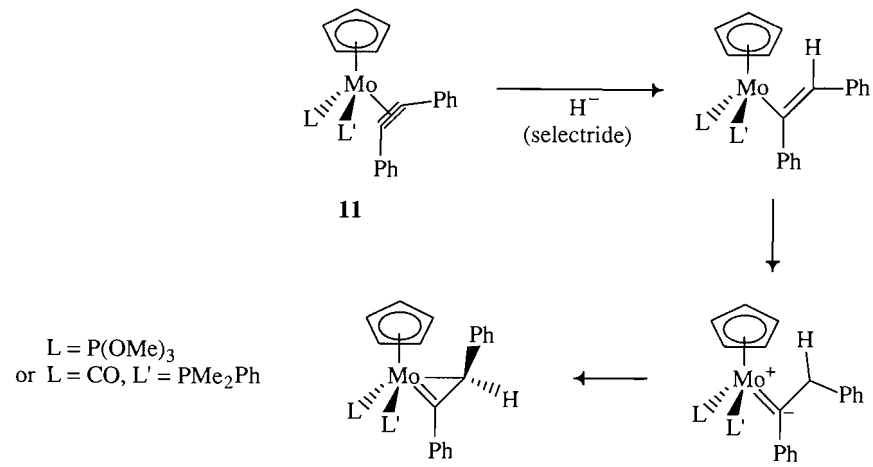


SCHEME 7

to lower peak intensities due to coupling into three lines as well as a loss in nOe. Confirmation of these results was obtained using deuterium nmr, which showed that deuteration had occurred in rings A and B mutually exclusively. These observations are consistent with a reaction mechanism involving insertion of the acetylene into the iron–carbon sigma (σ) bond followed by a *cis–trans* isomerization of the σ-alkene obtained. A simplified mechanism is shown in Scheme 7. It should be noted that there are two alternate modes of insertion of the acetylene. Based on existing experimental reports (20), path B is more likely. The postulated rearrangement step is similar to that observed by Green and co-workers (21) as an intermediate in the synthesis of the molybdenum cyclic alkylidene complex, Scheme 8.



SCHEME 8

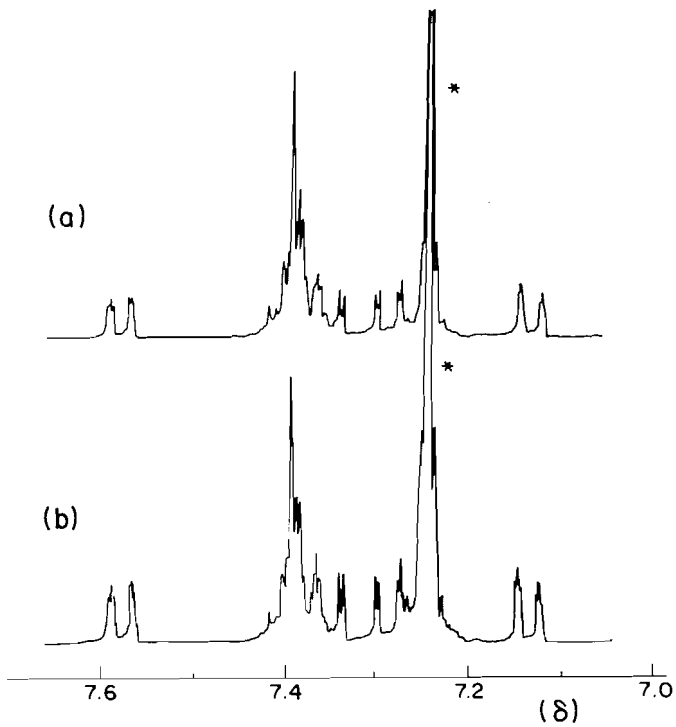


FIG. 3b. The ^1H spectrum of (a) non-deuterated and (b) deuterated 2,3-diphenylindene-1-one.

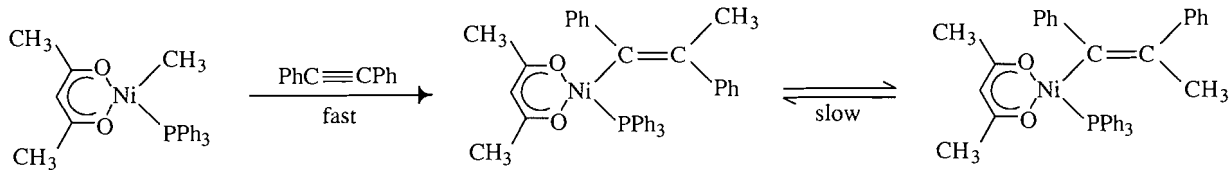
Similarly, related rearrangements have been reported by a number of workers, the most notable of these being that of Bergman and Huggins (22), Scheme 9, and Reger *et al.* (23–33), Scheme 10.

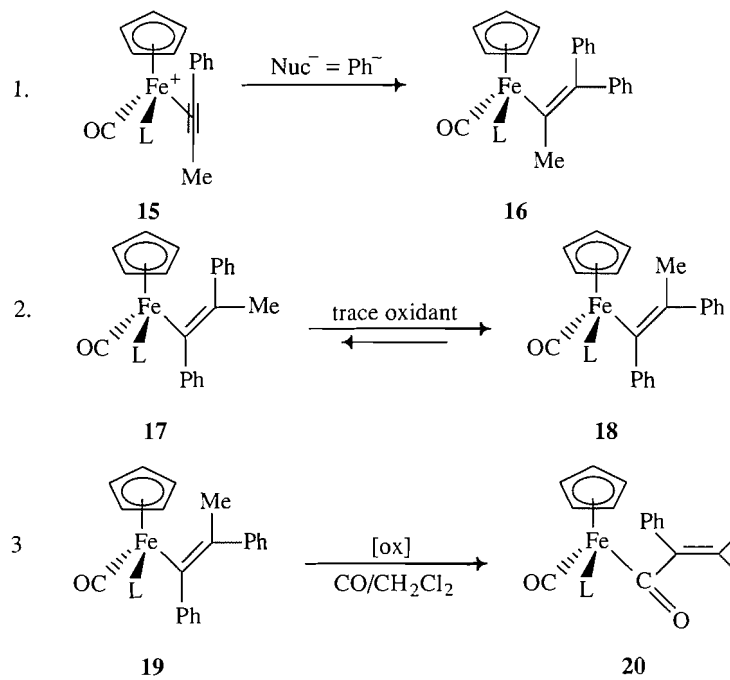
In the reaction shown in Scheme 9, Bergman observed the initial methyl migration to give the *E* isomer, which underwent a slower equilibration to give a mixture of *E* and *Z* isomers. In a series of papers, Reger and co-workers examined the reactions of cationic iron complexes with a range of nucleophiles. The products of such reactions are identical to the proposed reaction intermediates reported here. For example, the reaction of the cationic acetylene complex (Scheme 10.1) undergoes nucleophilic attack to give the σ alkenyl complex; complexes of this type can equilibrate in the presence of trace oxidants such as ferricinium salts, alumina, or ceric salts, Scheme 10.2. They have also shown that such complexes undergo facile carbonyl insertion to give mixtures of isomers under similar conditions (Scheme 10.3). In addition, they have been able to develop a simple set of rules for assignment of the correct stereochemistry of the iron–alkenyl complexes in which the ligand L is a phosphine or phosphite. In our work, we have shown that alkenyl iron complexes (Scheme 5) decompose cleanly to give indenone products on thermolysis (15).

To further test the mechanism proposed, we decided to carry out further related reactions. A similar reaction of d_5-benzoyl Fp with phenyl(*p*-tolyl)acetylene again gave a complex product mixture from which the indenone mixture containing **22***d*–**25***d*



13 **14***a* **14***b*

SCHEME 9



15 **16** **17** **18** **19** **20**

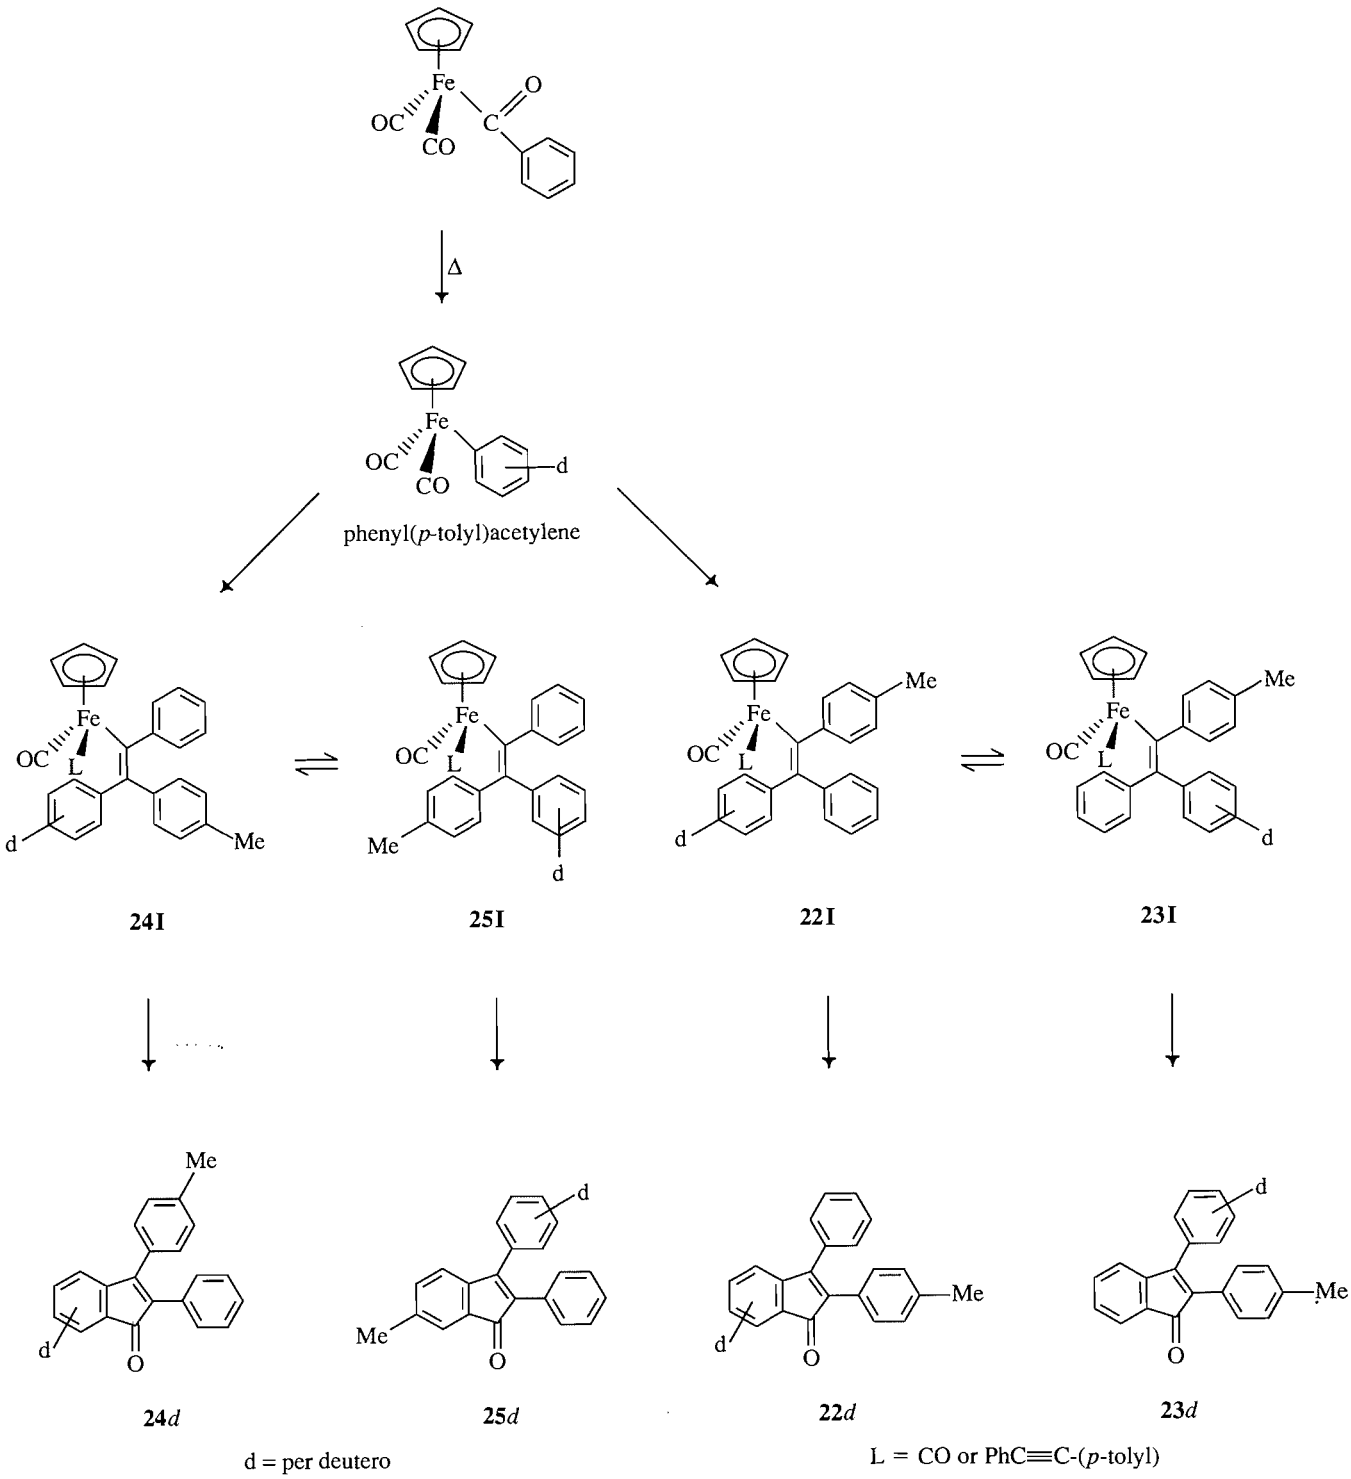
was separated, in 31% combined yield (Scheme 11). These were identified by ^{1}H nmr and mass spectroscopy. On attempted separation, two major indenone fractions were noted. These were identified as **25***d* and a mixture of **22***d* and **23***d* (major products) (not separable by column chromatography). Only a trace of the last indenone, assumed to be **24***d*, was obtained. The individual characterizations were carried out by ^{1}H nmr using comparison of spectra of authentic undeuterated samples (11, 14). The ratio of **22***d* + **23***d* to **25***d* is approximately 64:36, obtained by integration of the methyl singlets in the ^{1}H nmr specturm. Based on the results obtained in the reaction of Fp–benzoyl by Nesmeyanov *et al.* (11) and us, a higher proportion of **25***d* may have been expected. The result demonstrates that insertion of the acetylene into the Fe–C bond gives predominantly the intermediates **22I** and **23I** as opposed to **24I** and **25I** (Scheme 11).



SCHEME 11

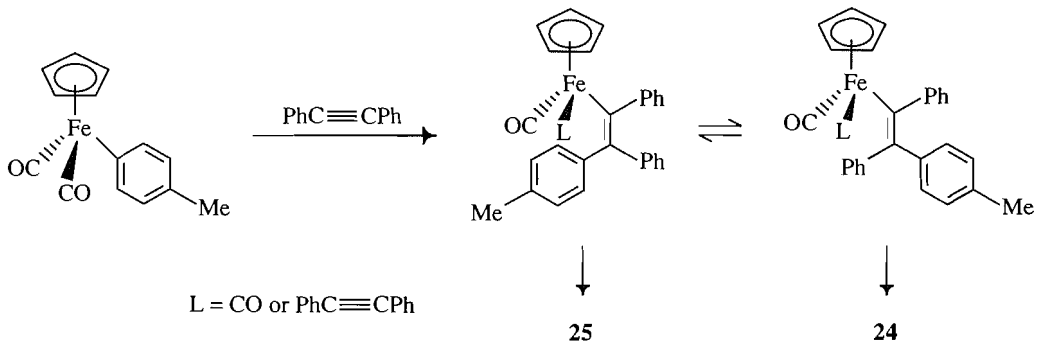

SCHEME 12

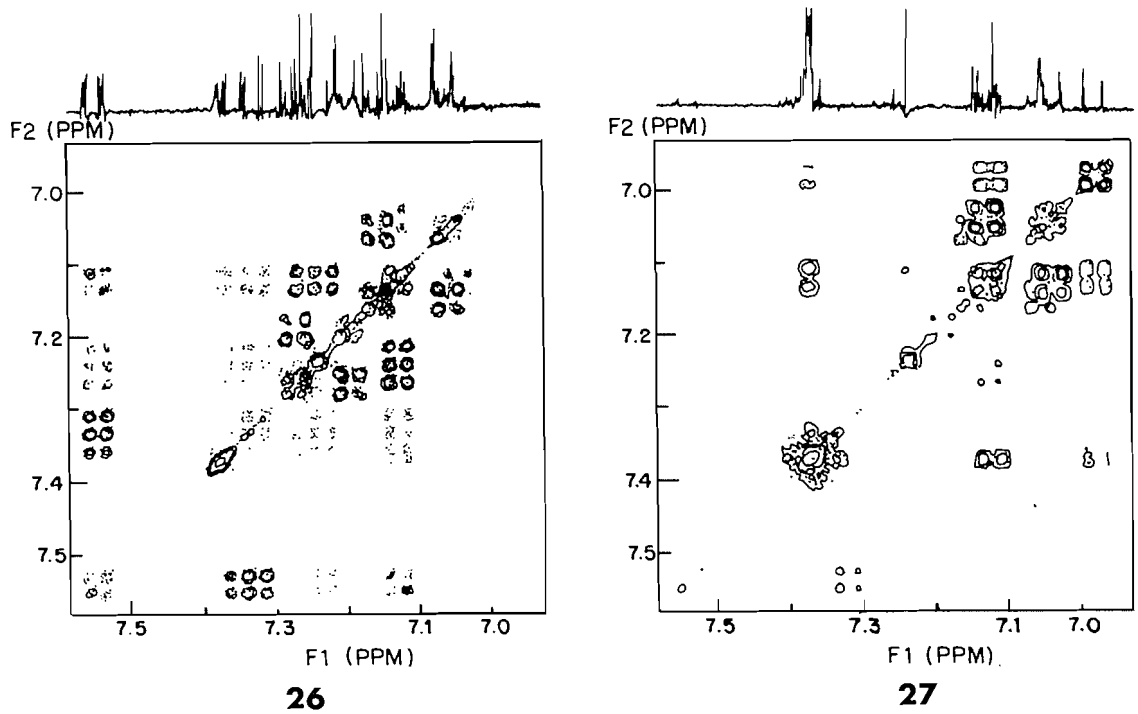

FIG. 4. The ^{1}H COSY spectra of **26** and **27** (aromatic region).

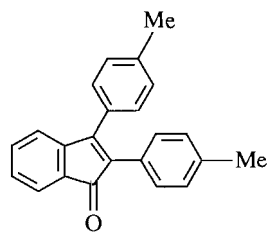
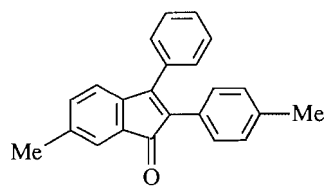
Based on our proposed mechanism, the reaction of Fp-*p*-tolyl with diphenylacetylene would give the intermediates **24I** and **25I** (undeuterated). Nesmeyanov (11) isolated only **25** and no **24**. The finding here that **24***d* is only a minor product indicates that the **25I** is either favoured in the equilibrium and (or) it is kinetically more reactive towards the metallation reaction (Scheme 12).

The reaction of benzoyl–Fp with bis-*p*-tolylacetylene again gave a mixture of two indenones (combined yield 29%), which were separated by preparative plate tlc. These were identified as **26** and **27** using 2D ^{1}H nmr spectroscopy (Fig. 4).

In all the foregoing reactions, mono- and bis-substituted ferrocenes, Fp_2, and trimerized arylacetylenes were isolated as by-products. To test the scope of the reaction with other acetylene derivatives the reaction of Fp-*p*-tolyl with phenylacetylene was carried out. In this reaction a range of products was also observed; however, the indenone products are not the dominant ones. The major products isolated were two colourless compounds **28** and **29**. The former is similar to one in



26



27

the reaction of Fp–Me with trifluoromethylacetylene, reported by Green and co-workers (34) obtained via the photolytic decomposition of the metal complex **30**, and also to the decarbonylated product obtained by us in the reaction of Fp–*o*-F-phenyl with 2-ethynylpyridine (14), **31**, while the latter is an analogue of the compounds we have previously observed to be found in the case of the Fp–naphthoyl reactions with diphenylacetylene (16). We have conducted preliminary experiments on a substantial variety of Fp–aryl groups such as

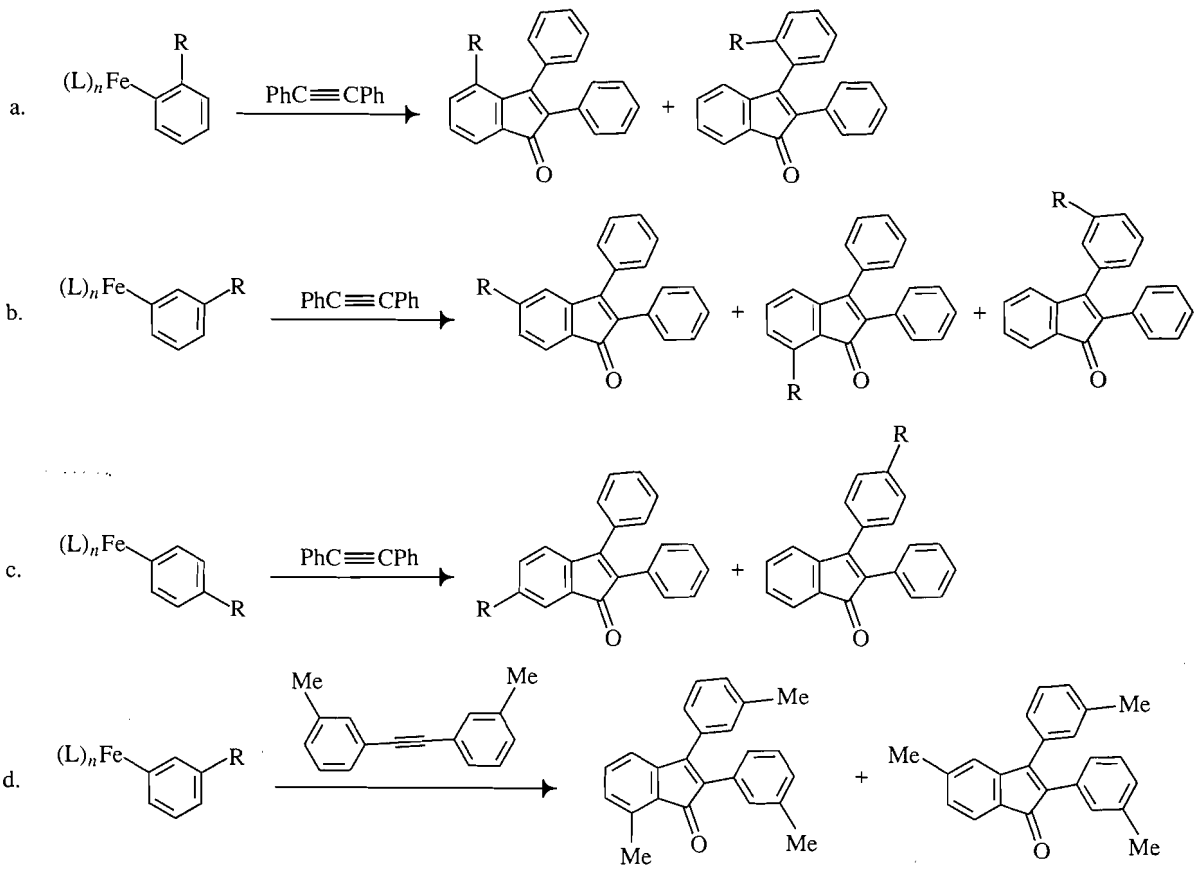
anisoyl, *o*-toloyl, 2-nicotinoyl, 2-quinoloyl, *o*-biphenyl, and in addition have carried out reactions of Fp–benzoyl with phenyl-(aryl)acetylenes (aryl = anisyl, *o*-tolyl, nicotinyl, 2-quinolyl, *o*-biphenyl, triphenylsilyl), and observe that in each case the predicted cyclopentenones are formed, although the yields in some cases are very low.

In general it is now possible to predict the expected cyclopentenones that will be formed in the reaction of Fp–aryls with acetylenes, Scheme 13; however, the ratio of isomers obtained will be determined by the nature of the aryl group. We have tested this hypothesis by carrying out the reaction of Fp–*m*-tolyl with bis-*m*-tolylacetylene, in which we predicted



32 **33**

that two isomeric indenones (Scheme 13d) would be formed (the *meta*-substituted acetylene was used to limit the number of possible isomers). Indeed two such indenones are formed: **32** and **33**, in the approximate ratio of 1:2.5. This experiment also gives an indication of the preference for metallation at a position *para* to the methyl group versus metallation at the position *ortho* to the methyl.

Acknowledgements

The authors would like to acknowledge useful discussions with Dr. R. Bergman, and funding in the form of an operating grant from the Natural Sciences and Engineering Research Council of Canada. We express our sincere gratitude to Dr. Clem Kazakoff of the University of Ottawa, who recorded the several hundred mass spectra used during this and related investigations.

Determination of the structure and absolute configuration of the glycerolphosphate-containing capsular polysaccharide of *Pasteurella haemolytica* serotype T3 by high-resolution nuclear magnetic resonance spectroscopy[1]

JAMES C. RICHARDS[2] AND ROBERT A. LEITCH

Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received February 7, 1990

JAMES C. RICHARDS and ROBERT A. LEITCH. Can. J. Chem. **68**, 1574 (1990).

The specific capsular polysaccharide antigen produced by *Pasteurella haemolytica* serotype T3 was found to be a high molecular weight teichoic acid composed of equal molar amounts of D-galactose, glycerol, and phosphate and a nonstoichiometric amount of *O*-acetate. Structural analysis of the polymer employed a combination of one- and two-dimensional ^{1}H and ^{13}C nuclear magnetic resonance methods at high field. Homo- and heteronuclear chemical shift correlation techniques, together with *J*-resolved and nuclear Overhauser effect (nOe) difference experiments led to the unambiguous assignments of the ^{1}H and ^{13}C resonances corresponding to the D-galactose and glycerol structural units and established that the repeating unit of the polysaccharide antigen was composed of →4)-α-D-Gal*p*-(1→1)-L-glycerol-(3→ units joined by phosphate diester groups. The chirality of the glycerol moiety was established by conformational analysis of a 1-*O*-α-D-galactopyranosyl-*S*-glycerol fragment (**2**) obtained from the teichoic acid by depolymerization with HF, from which the stereochemistry of the glycerol methine carbon centre was related to that of the D-glycose from $^{1}H-^{1}H$ nOe and ^{3}J values. The chirality was confirmed by gas–liquid chromatographic and mass spectral analysis of the (−)-camphanate ester of 2,3-di-*O*-methylglycerol derived from permethylated **2**. The D-galactosyl residues are partially mono-*O*-acetylated at C-2 and C-3.

Key words: *Pasteurella haemolytica*, capsular polysaccharide, NMR analysis.

JAMES C. RICHARDS et ROBERT A. LEITCH. Can. J. Chem. **68**, 1574 (1990).

On a trouvé que le polysaccharide capsulaire de l'antigène spécifique produit par la *Pasteurella haemolytica* du sérotype T3 est un acide teichoïque de poids moléculaire élevé et composé de quantités équimolaires de D-galactose, de glycérol et de phosphate et d'une quantité non stoechiométrique de *O*-acétate. L'analyse structurale du polymère est basée sur une combinaison de méthodes mono- et bi-dimensionnelles de la résonance magnétique nucléaire du ^{1}H et du ^{13}C à haut champ. Les techniques de corrélation de déplacements chimiques homo- et hétéro-nucléaires combinées à des expériences de différences d'effet Overhauser nucléaire (eOn) ou résolues pour le *J* ont permis d'attribuer sans ambiguités les bandes des spectres du ^{1}H et du ^{13}C des unités structurales de D-galactose et de glycérol et ont permis d'établir que pour le polysaccharide de l'antigène l'unité de base est →4)-α-D-Gal*p*-(1→1)-L-glycerol-(3→ qui est jointe par des groupements diesters phosphates. On a établi la chiralité de l'unité glycérol en se basant sur une analyse conformationnelle d'un fragment 1-*O*-α-D-galactopyranosyl-*S*-glycérol (**2**), obtenu à partir de l'acide teichoïque par dépolymérisation à l'aide de HF, dont la stéréochimie du carbone méthinique du glycérol a été reliée à celle du D-glycose sur la base des valeurs de l'eOn et des ^{3}J. La chiralité a été confirmée par une analyse par chromatographie en phase gaseuse et spectres de masse de l'ester (−)-camphanate du 2,3-di-*O*-méthylglycérol obtenu à partir du produit **2** perméthylé. Les résidus D-galactosyles sont partiellement mono-*O*-acétylés aux positions C-2 et C-3.

Mots clés : *Pasteurella haemolytica*, polysaccharide capsulaire, analyse RMN.

[Traduit par la revue]

Introduction

Pasteurella haemolytica is a Gram-negative, encapsulated bacterium that is associated with several diseases of domestic animals. The organism has been differentiated into two distinct biotypes, designated A and T, and 16 serotypes are presently recognized (1). Serotypes belonging to biotype A are associated with pneumonia in cattle in sheep of all ages, while serotypes belonging to biotype T cause acute systemic disease in young adult sheep (2). Serotype specificity is thought to be related to the polysaccharide capsular antigens (3) and considerable chemical and immunological information has been recently acquired on these antigens (4). In addition, *P. haemolytica* cell wall lipopolysaccharide (LPS) is antigenic (5) and the LPS of several serotypes has been reported to be chemically (6, 7) and immunologically related (8).

The structures of the specific capsular polysaccharide antigens from several *P. haemolytica* serotypes have been recently reported by Adlam *et al.* (3, 9–12). These antigens were found to be high molecular weight polymers composed of repeating oligosaccharide units containing glycosyl residues only (serotypes A1 and A2) (3, 12), or either phosphate or glycerolphosphate diester linkages (serotypes A7, T4, and T15) (9–11) to form teichoic acid-like structures (13). *Pasteurella haemolytica* serotypes T4 and T15 produce chemically similar but antigenically unique capsular polysaccharides composed of repeating, partially *O*-acetylated, →6)-α-D-Gal*p*-(1→2)-glycerol-(1→ (ref. 9) or →4)-α-D-Gal*p*-(1→2)-glycerol-(1→ (ref. 10) units joined by phosphate diester groups, respectively. This paper records the application of nmr techniques to the structural analysis of the *P. haemolytica* serotype T3 specific capsular polysaccharide antigen, which also has a teichoic acid-like structure.

Results and discussion

Isolation and characterization

Pasteurella haemolytica serotype T3 specific capsular polysaccharide was obtained from the bacterial cell growth by extraction into aqueous sodium chloride solution followed by purification as its insoluble cetyltrimethylammonium salt (14). Extraction of saline washed cells by the modified aqueous phenol method (15) afforded an additional amount of capsular polysaccharide following removal of LPS (16) by ultracentrifugation. Ion-exchange chromatography of the latter material on

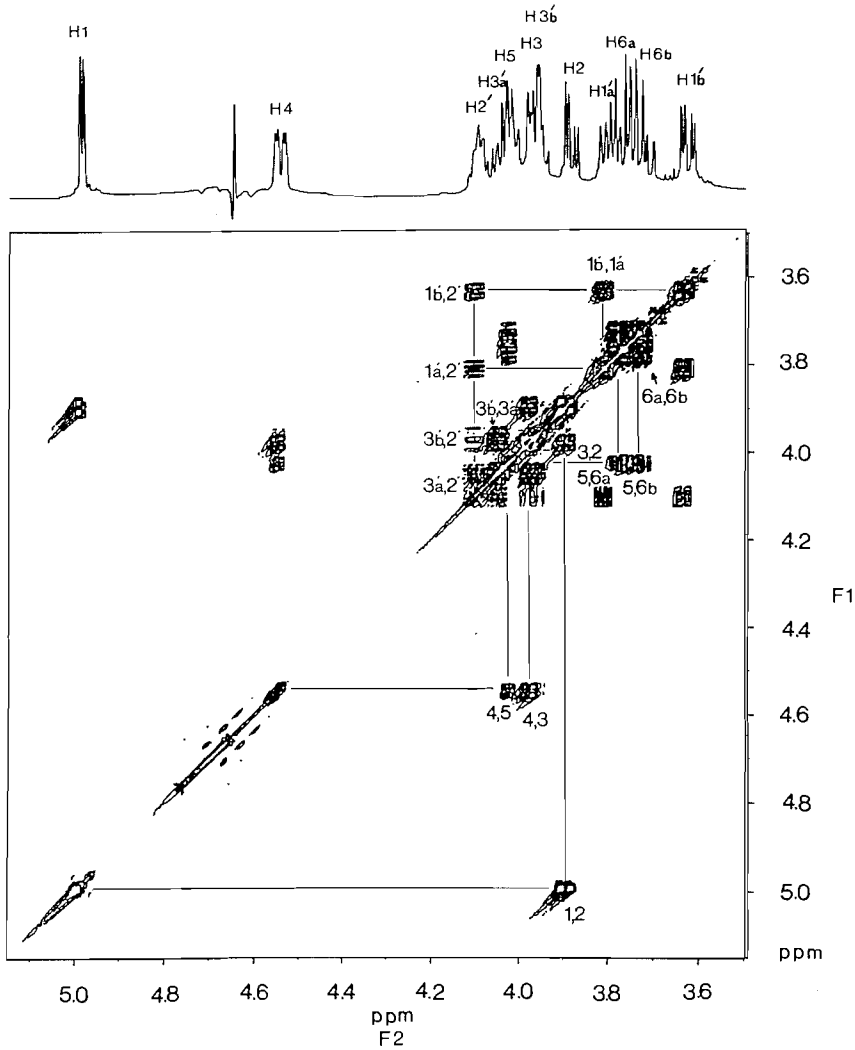

FIG. 1. Contour plot of the 2D COSY spectrum of the *O*-deacetylated *P. haemolytica* serotype T3 capsular polysaccharide at 310 K. Assignments of the cross-peaks are shown and the connectivity pathways corresponding to the D-galactopyranosyl (H-1–H-6b) and the glycerol (H-1a′–H-3b′) subspectra are indicated by the solid lines below and above the diagonal, respectively.

DEAE–Sephacel gave a single peak, which eluted at the beginning of the sodium chloride gradient and which was homogeneous with respect to neutral glycose and phosphate.

The purified polysaccharide had a high molecular weight as evidenced by its elution point (K_{av} 0.1) on a Sephacryl S300 gel filtration system and gave a positive precipitin reaction in immunodiffusion against mouse antiserum to *P. haemolytica* serotype T3 cells. The polymer was freely soluble in water and gave $[\alpha]_D$ 53.0° (*c* 0.46, water). Complete acid hydrolysis of the capsular polysaccharide afforded D-galactose as the only detectable glycose, glycerol, and phosphate. The absolute configuration of the galactosyl residues was established by glc analysis of the corresponding trimethylsilylated *R*-2-butyl glycoside derivatives (17). Quantitative analysis of the acid hydrolysis products by glc–ms of the peracetylated alditol derivatives indicated D-galactose and glycerol to be present in equal molar amounts. The phosphate content of the polymer was determined colorimetrically (18) to be 22% (as PO_4).

The ^{1}H nmr spectrum of the capsular polysaccharide was complex owing to partial substitution (0.68 mole equivalents) by ester-linked acetyl groups. Removal of the *O*-acetyl substituents with dilute aqueous ammonia led to considerable simplification of the ^{1}H nmr spectrum, revealing that the polysaccharide was composed of regular repeating monomeric units: whereas the original polysaccharide showed complex spectral patterns in the low-field region (4.8–5.2 ppm) of the spectrum, the *O*-deacetylated polysaccharide showed only a single anomeric ^{1}H resonance (4.99 ppm).

Examination of the ^{31}P nmr spectrum of the *O*-deacetylated polysaccharide (Na^+ salt, pD ≈ 7.8) revealed a single ^{31}P resonance at 0.86 ppm, which could be attributed to phosphodiester groups (19).

The combined analytical results indicated that the polysaccharide has a regular structure composed of D-galactose, glycerol, phosphate, and ester-linked acetate in the molar ratio of 1.0:1.0:1.0:0.7.

Nuclear magnetic resonance analysis of the O*-deacetylated polysaccharide*

The structure of the chemical repeating unit of the capsular polysaccharide was determined by high resolution one- and two-dimensional ^{1}H and ^{13}C nmr techniques (6). Structural analysis by nmr methods requires unequivocal assignment of the ^{1}H and ^{13}C resonances. The overall strategy was to assign

fully the ^{1}H nmr spectrum of the *O*-deacetylated polysaccharide using two-dimensional homonuclear chemical shift correlation (COSY) and *J*-resolved experiments, followed by subsequent assignment of the carbon-13 resonances from a 2D heteronuclear ^{1}H–^{13}C chemical shift correlation map. It was to be expected that the nmr parameters would lead to the identification of the monomeric components, including the relative stereochemisty, ring form, and anomeric configuration of the glycose residues and the position of phosphate groups. The arrangement of monomeric components within the repeating unit would then be determined from ^{1}H–^{1}H nOe measurements. Finally, the positions of the ester-linked acetyl groups could be deduced from a comparison of the ^{1}H nmr spectra of the original and *O*-deacetylated polysaccharides.

Examination of the connectivities defined by the cross-peaks observed in the COSY contour plot (Fig. 1) led to the identification of the two independent networks of scalar coupled protons representing subspectra corresponding to the galactosyl ring system and the glycerol moiety. The characteristic chemical shift value (4.989 ppm) and the single vicinal ^{1}H–^{1}H coupling ($J_{1,2}$ = 3.8 Hz) of the anomeric proton resonance of the galactosyl residue provided a convenient starting point for delineation of the connectivity pathway of the corresponding subspectrum (H-1 to H-6b). The seven ^{1}H resonances associated with the residue were well resolved and were readily assigned from the appropriate cross-peaks (Table 1). The methylene proton double doublet (^3J = 3.9 Hz, ^2J = 10.7 Hz) observed in the high-field region of the spectrum (3.629 ppm) provided easy access into the spin system associated with the glycerol moiety (Fig. 1). The connectivity relationships between the two methylene proton resonances at 3.629 ppm (H-1b′) and 3.806 ppm (H-1a′) and between each of these resonances and the methine resonance at 4.100 ppm (H-2′) were readily established from the appropriate cross-peaks in the COSY contour plot. Cross-peaks relating all five ^{1}H resonances belonging to this subspectrum were apparent along the line parallel to the F1 axis at the chemical shift value of the central methine proton (4.100 ppm), leading to the assignment of the resonances corresponding to H-3a′ (4.046 ppm) and H-3b′ (3.967 ppm).

Many of the ^{1}H–^{1}H coupling constants could be measured directly from the 1D ^{1}H nmr spectrum using resolution enhancement techniques (20) or from the appropriate cross-peaks in the COSY spectrum. On the basis of the magnitude of the ring proton coupling constants (Table 1), it was evident that the D-galactosyl residues are present as α-pyranosyl units having the $^4C_1$ ring conformation (21). The H-4 resonance (4.542 ppm) of the galactosyl residues showed, in addition to homonuclear coupling to H-3 ($J_{3,4}$ = 3.1 Hz) and H-5 ($J_{4,5} \approx$ 1 Hz), heteronuclear coupling to phosphorus-31 ($^3J_{H,P}$ = 9 Hz), which indicated C-4 to be the site of phosphate substitution. This was evident from the *J*-resolved spectrum of the *O*-deacetylated polysaccharide (Fig. 2), which permitted a distinction to be made between homo- and heteronuclear coupling (22, 23).

Considerable resonance overlap combined with heteronuclear ^{1}H–^{31}P coupling precluded the direct measurement of the coupling constants associated with the glycerol H-3a′ and H-3b′ resonances. These coupling constants were determined from the 2D *J*-resolved spectrum, which clearly revealed the occurrence of heteronculear coupling to phosphorus-31 of the glycerol H-3 resonances ($J_{H,P} \approx$ 7 Hz), establishing the presence of 3-phosphoglycerol units in the capsular polysaccharide.

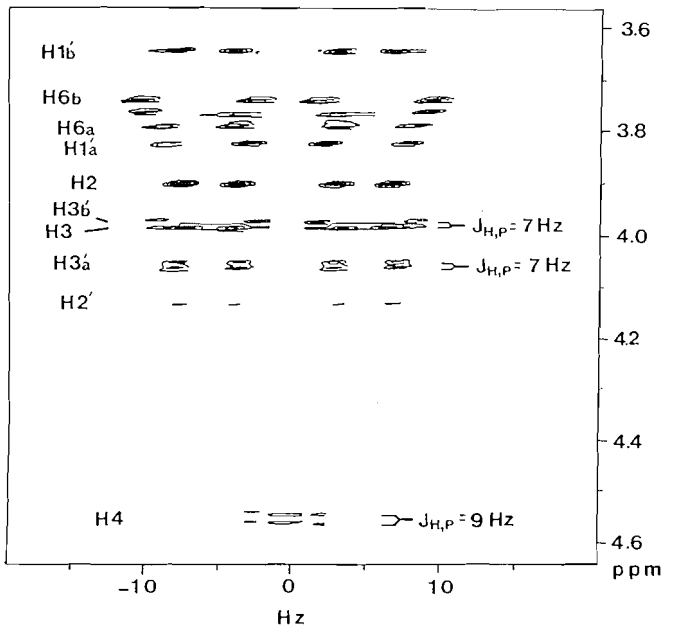

FIG. 2. Contour plot of part of the 2D *J*-resolved spectrum of the *O*-deacetylated *P. haemolytica* serotype T3 capsular polysaccharide at 310 K. Proton resonance assignments and the phosphorus-31 coupled doublets are indicated. Signals due to H-5 were weak and are not visible at the indicated contour level.

The subspectra corresponding to the 4-phospho-α-D-galactopyranosyl and the 3-phosphoglycerol residues could be exactly calculated by computer simulation employing the proton and phosphorus-31 coupling constant values determined from the *J*-resolved spectrum (Fig. 2). The composite simulated ^{1}H nmr spectrum of the *O*-deacetylated polysaccharide is in complete agreement with the experimental spectrum (Fig. 3).

Since only a single phosphate group was indicated by ^{31}P nmr, it follows from the foregoing ^{1}H nmr analysis that the repeating unit of the capsular polysaccharide is composed of monophosphate diester units. The phosphoglycerol moiety could be present either as a side chain phosphate diester substituent on a repeating galactan chain or as an integral part of a linear repeating unit to form a teichoic acid-type (13) structure. A distinction between these two arrangements was made from ^{1}H–^{1}H nOe measurements, which established connectivities between the anomeric and aglyconic protons of adjacent residues (24, 25). The nOe difference spectrum (26) obtained on the *O*-deacetylated polymer is shown in Fig. 4.

Saturation of the anomeric proton resonance (4.989 ppm) of the D-galactopyranosyl residues showed a nOe at H-2 (3.890 ppm) within the pyranosyl ring system together with a nOe of similar magnitude at one of the terminal methylene protons, H-1b′ (3.629 ppm), of the 3-phosphoglycerol moiety, establishing that the D-galactosyl residues are α-linked to the terminal position of the polyolphosphate. It follows that the repeating unit of the capsular polysaccharide of *P. haemolytica* serotype T3 is composed of →4)-α-D-Gal*p*-(1→1)-glycerol-(3→ units joined by phosphate diester groups.

These structural conclusions were reinforced from a detailed analysis of the ^{13}C nmr data. The ^{13}C nmr spectrum of the *O*-deacetylated capsular polysaccharide showed nine well-resolved resonances that were unambiguously assigned (Table 2) by correlation with resonances of the directly attached protons from a 2D heteronuclear ^{1}H–^{13}C chemical shift correlation map (Fig. 5). As expected, the resonances corresponding to C-4, C-3, and C-5 of the α-D-galactopyranosyl residue and to C-2′ and C-3′ of the glycerol moiety were split or broadened (C-3) due to phosphorus coupling. Unequivocal identification of the ^{13}C resonances arising from the three methylene carbon atoms was made from a DEPT experiment (27). The signal at 61.72 ppm, observed in the region of the spectrum characteristic of primary hydroxyl carbons (60–64 ppm) (28), was assigned from the corresponding ^{1}H–^{13}C correlation to C-6 of the α-D-galactopyranosyl residue, while the downfield shifted methylene resonances at 69.25 (s) and 67.60 ppm (d, $J_{C,P}$ = 6.1 Hz) could be attributed to C-1′ and C-3′ of the 3-phosphoglycerol moiety, respectively. The relatively deshielded value of the methylene singlet at 69.25 ppm is consistent with substitution at that position (28).

Depolymerization of the polysaccharide

Depolymerization of the *O*-deacetylated capsular polysaccharide (**1**) with aqueous HF afforded the phosphate-free disaccharide **2**, which was obtained chromatographically pure by gel filtration on Sephadex G15. The disaccharide was identified as 1-*O*-α-D-galactopyranosyl-glycerol from its ^{1}H and ^{13}C nmr spectra. Assignment of the ^{1}H nmr spectrum of the disaccharide was made from selective decoupling experiments (Table 1). The ^{13}C nmr spectrum showed nine signals that could be readily assigned (Table 2) by comparison with data reported for methyl α-D-galactopyranoside (29) and glycerol (28), and was consistent with substitution at one of the terminal methylene carbons (C-1′) of glycerol. The ^{13}C chemical shifts of the oligosaccharide were similar to those observed for the *O*-deactylated polysaccharide except that the phosphate-substituted carbon atoms, C-4 and C-3′, were downfield shifted (5.6 and 4.5 ppm, respectively) in the spectrum of the latter (Table 2).

Saturation of H-1 of the D-galactopyranosyl residue of **2** produced positive nOe at H-2 (~10%) and at the high-field methylene proton (3.571 ppm), H-1b′ (~6%), of the glycerol unit, confirming the position of the glycosidic linkage at C-1′.

In agreement with its proposed structure, the permethylated derivative of disaccharide **2** gave a protonated molecular ion in its ci ms at *m/z* 339, together with characteristic fragment ions (30) at *m/z* 219 (A_1), 187 (A_2), and 161 (J_1).

Absolute configuration of the glycerol-3-phosphate residues

The remaining structural feature of the *O*-deacetylated polysaccharide to be determined is the absolute configuration of the 3-phosphoglycerol moiety. L-Glycerol-3-phosphate (as its cytidine diphosphate derivative) has been implicated in the biosynthesis of the cell wall teichoic acids of Gram-positive bacteria and its stereochemical integrity is maintained in the derived poly(glycosyl-glycerolphosphates) (13, 31, 32). It would be tempting to assume that L-glycerol-3-phosphate is also the precursor of the glycerol-containing extracellular teichoic acid-like capsular antigens (33). Indeed, in one instance the 3-phosphoglycerol component of a teichoic acid-like capsular polysaccharide antigen, that from *Escherichia coli* K2, has been shown (34) to have the L-configuration. However, the membrane bound teichoic acid (lipoteichoic acid) from *Streptococcus lactis* has been found to be composed of D-glycerol-3-phosphate residues (35). It was therefore mandatory to establish the absolute configuration of the 3-phosphoglycerol moiety present in the *P. haemolytica* T3 antigen and this was accomplished by examination of the conformational dependence of the vicinal ^{1}H–^{1}H coupling constants $J_{1a',2'}$ and $J_{1b',2'}$ in the disaccharide **2**.

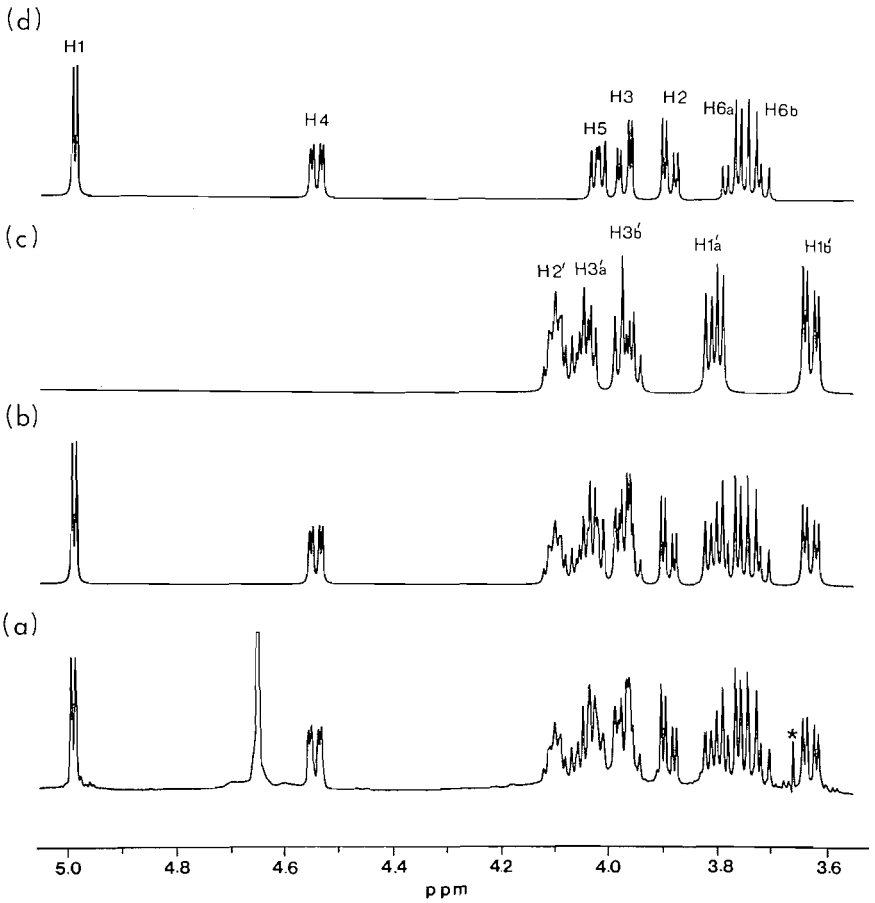

FIG. 3. The ^{1}H nmr spectrum of the *O*-deacetylated *P. haemolytica* serotype T3 capsular polysaccharide at 310 K. (a) Observed spectrum. (b) Simulated spectrum using experimental σ and J values. (c) Subspectrum of the contribution to the simulated spectrum from the glycerol residues. (d) Subspectrum of the contribution to the simulated spectrum from the D-galactopyranosyl residues. The low intensity peaks observed in (a) are due to incomplete *O*-deacetylation and the signal denoted by an asterisk is from a minor impurity of tris(hydroxymethyl)methylamine.

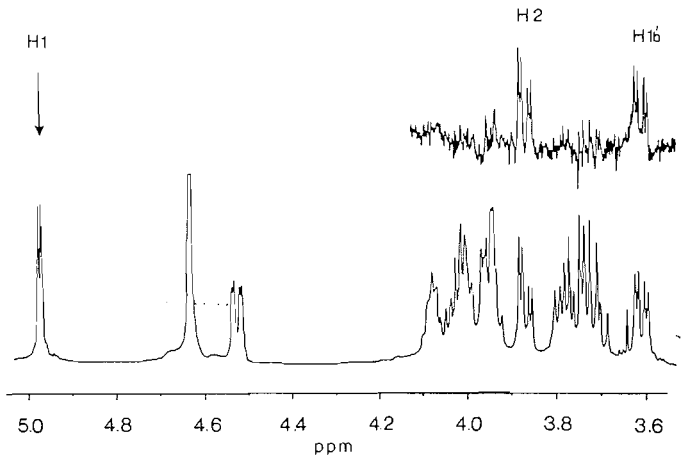

FIG. 4. The ^{1}H nmr spectrum of the *O*-deacetylated *P. haemolytica* serotype T3 capsular polysaccharide at 310 K. Inset shows nOe difference spectrum obtained by saturation of the H-1 resonance of the α-D-galactopyranosyl residues.

Stereochemical assignment of the ^{1}H resonances from the C-1′ methylene protons was essential for configurational analysis. The observation that saturation of the anomeric proton of the α-D-galactopyranosyl residue imparts an nOe at only one of the diastereomeric methylene protons, H-1b′ of the *O*-1 linked glycerol moiety, led to the required stereochemical assignments. In addition, the conformation of the 1-*O*-α-D-galactopyranosyl-glycerol fragment (**2**) was probed by potential energy calculations.

Since the conformation about the glycosidic linkage is to a large extent governed by the *exo*-anomeric effect (36), the minimum energy conformation of the disaccharide **2** was calculated using the HSEA method (36, 37).[3] Interproton distances calculated for the molecule were consistent with the nOe data (Table 3). The ^{1}H–^{1}H nOe are generally observed when interproton distances are less than ca. 2.8 Å (38). Thus, a nOe would be anticipated between the anomeric and the 1′-*pro-S* protons, which are separated by 2.5 Å in the minimum energy conformation, but not between H-1 and the 1′-*pro-R* hydrogen, which have an internuclear separation of 3.0 Å. Since saturation of H-1 of the α-D-galactopyranosyl residue in **2** produced a nOe at only the high-field methylene proton (3.571 ppm), H-1b′ of the glycerol moiety, and no detectable nOe was observed for the low-field methylene proton (3.762 ppm), H-1a′, the two diastereotopic methylene protons were assigned to the 1′-*pro-S* and the 1′-*pro-R* hydrogen atoms, respectively (Table 3). Furthermore, since specific deshielding effects are known (39) to be correlated to short oxygen-to-proton distances, the observed deshielding of H-1a′ relative to H-1b′

[3]The HSEA minimum energy molecule gives a shallow energy well for the range of torsional angles, Φ, −60–−45° and ψ, 15–95° with a minimum energy at Φ = −55° and ψ = 65°. The torsion angles are defined as follows: Φ, H-1—C-1—O-1—C-1′; ψ, C-1—O-1—C-1′—H-1*R*′.

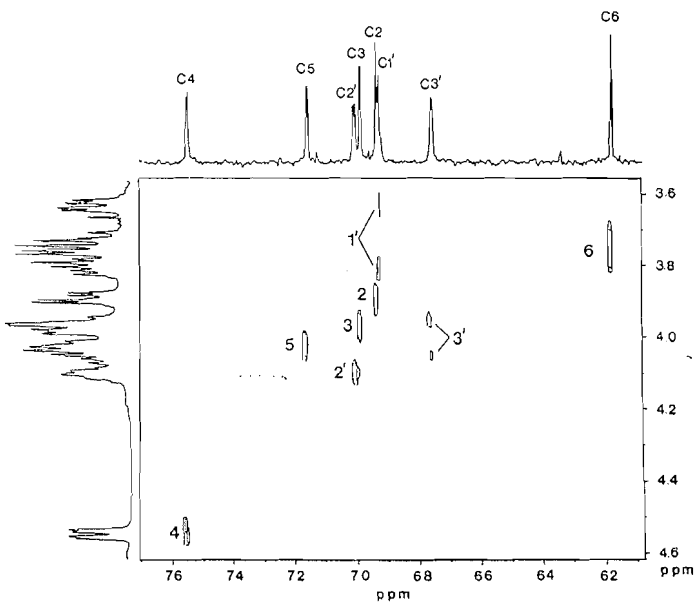

FIG. 5. Part of the heteronuclear $^1H-^{13}C$ nmr chemical shift correlation map of the *O*-deactylated *P. haemolytica* serotype T3 capsular polysaccharide at 310 K. The respective ^{13}C and ^1H 1D projections are displayed above and at the side and the correlated resonances are labelled.

(~0.2 ppm) can be related to the close proximity of the former hydrogen atom to the D-galactopyranosyl ring oxygen, O-5. This is evident in the minimum energy conformation where the H-1R′ to O-5 internuclear distance is 2.5 Å, while the H-1S′ to O-5 separation is greater than 3 A (Table 3). Analogously, in α-(1-6)-linked D-glycopyranosyl disaccharides the glycosylated C-6 *pro-R* hydrogen has been observed (40, 41) to be shifted to lower field than the corresponding *pro-S* hydrogen.

A comparison of chemical shift and nOe values from the *O*-deacetylated polysaccharide with those from oligosaccharide **2** (Table 3) would suggest that the average conformation about the glycosidic linkages of the α-D-galactopyranosyl-(1→1)-L-glycerol units within the intact polymer (**1**) is similar to that of the free disaccharide.

The three staggered conformations about the C-1′—C-2′ bond for the two stereoisomers at C-2′ of the glycerol moiety of 1-*O*-α-D-galactopyranosyl-glycerol are shown in Fig. 6. Substantial experimental evidence from the conformational analysis of polyols in solution (42–44) would suggest that conformers in which the vicinal oxygen atoms adopt a *gauche* rotational orientation (*O*e and *O*g) are most heavily populated, while those in which the vicinal oxygen atoms have a *trans* disposition (*O*t) are considerably less populated. The tendency of the vicinal oxygen atoms to preferentially adopt a *gauche* rotational arrangement has been observed in a number of instances (attractive "*gauche* effect") (45–47).

If it is assumed that the *O*t rotamer does not make a significant contribution to the conformation about the C-1′—C-2′ bond in the disaccharide **2**, then the chirality at C-2′ can be assigned from the magnitude of the observed vicinal coupling constants ($^3J_{1',2'}$).[4] In this case, the $^3J_{1',2'}$ values can be considered as the

[4]A similar assumption has been invoked for the analysis of the rotameric populations about the C-5—C-6 bond in 1,6-linked disaccharides (48, 49).

Chirality at C-2′	O_e	Conformation O_g	O_t
S				$J_{1R',2'} > J_{1S',2'}$	$J_{1R',2'} = J_{1S',2'}$	$J_{1R',2'} < J_{1S',2'}$
R				$J_{1S',2'} > J_{1R',2'}$	$J_{1S',2'} = J_{1R',2'}$	$J_{1S',2'} < J_{1R',2'}$

FIG. 6. Staggered conformations about the C-1′—C-2′ bond of 1-*O*-α-D-galactopyranosyl-glycerol related to the chirality at C-2′. Designation of the rotamers is according to ref. 42 and relative $^3J_{1',2'}$ values are indicated for each conformation.

weighted average of the individual coupling constants from the *O*e and *O*g conformers, which can be described in terms of a Karplus relationship (50): if C-2′ has *S* chirality, $J_{1R',2'} \geq J_{1S',2'}$; whereas, if C-2′ has *R* chirality, $J_{1S',2'} \geq J_{1R',2'}$ (Fig. 6). Since $J_{1R',2'}$ (i.e., $J_{1a',2'} = 5.9$ Hz) was found to be greater than $J_{1S',2'}$ (i.e., $J_{1b',2'} = 3.9$ Hz), it follows that 1-*O*-α-D-galactopyranosly-glycerol (**2**) has *S* chirality at C-2′ and that the glycerol-3-phosphate component in the capsular polysaccharide has the L-configuration.

The foregoing result was also rigorously confirmed by degradation of the disaccharide **2** to a glycerol derivative of known chirality (Scheme 1).[5] Thus, methanolysis of permethylated 1-*O*-α-D-galactopyranosyl-glycerol afforded, without loss of the chiral integrity at C-2′, 2,3-di-*O*-methyl glycerol, which was converted to the corresponding (−)-camphanate ester having 2′*S*-chirality (**3**) as determined by comparison of its glc retention time and ms with those of an authentic standard.

Positions of O*-acetyl substituents*

A detailed analysis of the COSY spectrum of the native polysaccharide led to the location of the *O*-acetyl substituents. Subspectra corresponding to three distinct 4-phospho-α-D-galactopyranosyl ring systems were delineated, which could be assigned to galactosyl residues exclusively mono-substituted at either O-3 (~50%) or O-2 (~20%), and to unsubstituted galactosyl residues (~30%). The substitution pattern was evident from the low-field position of resonances of the protons attached to the carbons bearing the acetate esters (Table 4) (51): 5.10 ppm from H-3 of the 3-substituted residues and 5.04 ppm from H-2 of the 2-substituted residues.

Similar complex *O*-acetyl substitution patterns have been identified for the *P. haemolytica* serotypes T4 (9) and T15 (10) antigens as well as for the *E. coli* K62 (52) and *Neisseria*

meningitidis group H (53, 54) polysaccharides, with the latter three antigens having essentially the same structure.

The *P. haemolytica* biotype T capsular antigens (serotypes T3, T4, and T15) form a group of structurally related poly(galactosyl-glycerolphosphates) (Table 5) where the T3 and T15 antigens appear to differ only in the mode of substitution at the 3-phosphoglycerol units. The stereochemistry of the 2-substituted 3-phosphoglycerol units of the T15 antigen has not been established, although it too probably has the L-configuration since the T15 polysaccharide is reported (10) to react similarly with both *P. haemolytica* T15 and *E. coli* K62 specific antisera. The 3-phosphoglycerol released from the *O*-deactylated K62 polymer (the K2 antigen) has been shown (34) to have the L-configuration by enzymic oxidation mediated by L-glycerol-3-phosphate dehydrogenase.

Conclusion

In the present study, a combination of 1D and 2D high-resolution nmr techniques was employed for the structural analysis of a glycerolphosphate-containing teichoic acid. Nuclear magnetic resonance techniques were used to probe the

stereochemisty of the glycerol moiety within the structure by relating the chirality of the glycerol methine carbon centre to that of D-galactopyranose by ^{1}H–^{1}H nOe and ^3J-values. The absolute configuration of the galactose was readily established by a chemical method. This technique would also be applicable for stereochemical assignment of other 1-*O*-glycosylglycerol derivatives provided stereoselective nOe are observed between the glycosyl anomeric and glycerol C-1 methylene protons.

Experimental

Pasteurella haemolytica *serotype T3 capsular polysaccharide*

Bacterial culture

Pasteurella haemolytica serotype T3 (NRCC 4015) was obtained from the Veterinary Infectious Disease Organization (VIDO), Saskatoon, Sask., and the cells were grown in 4-L baffled conical flasks as previously described (16) (yield, ca. 8 g wet weight/L).

Isolation and purification

The bacterial growth was suspended in aqueous sodium chloride (2.5%, w/v) solution and, after stirring at 22°C overnight, the cellular material was removed by low speed centrifugation. The supernatant was dialysed against running tap water (2 days), digested with ribonuclease, deoxyribonuclease, and proteinase K, and, following further dialysis against distilled water, crude capsular polysaccharide was obtained by precipitation with three volumes of 95% ethanol. The crude capsular polysaccharide material was redissolved in water and purified by precipitation with cetyltrimethylammonium bromide (1%, w/v, final concentration). After keeping the solution at 4°C overnight, the precipitated complex was collected by centrifugation and then dissolved in 2 M sodium chloride solution. After extensive dialysis against distilled water, pure capsular polysaccharide was recovered by lyophilization.

An additional yield of capsular polysaccharide was obtained by extraction of the cellular material using the modified hot phenol – water extraction method (15, 16). The aqueous phase was extensively dialysed against running tap water until phenol free and then lyophilized. The lyophilyzate was taken up in aqueous saline (2.5%, w/v) and subjected to ultracentrifugation (4°C, 105 000 × *g*, 10 h) to remove lipopolysaccharide. The supernatant was dialysed until salt free and lyophilized to afford capsular polysaccharide. which was purified by ion-exchange chromatography on a column of DEAE–Sephacel.

O-*Deacetylation*

Capsular polysaccharide (25 mg) in aqueous ammonia (5%, v/v, 1 mL) was stirred at 35°C for 3 h. Excess ammonia was removed by flushing with nitrogen and the solution was lyophilized (yield, 22 mg). The *O*-deacetylated polymer was converted to its sodium salt by passing an aqueous solution through a column (0.5 × 2 cm) containing Rexyn 101 (Na^+ form) cation exchange resin.

Chromatography

Capsular polysaccharide (15 mg) in water (0.5 mL) was applied to a column (1.2 × 40 cm) of DEAE–Sephacel (Pharmacia) equilibrated with 0.05 M Tris-HCl buffer (pH 7.2). The column was eluted with the same buffer (25 mL), followed by a 0–1.0 M sodium chloride gradient in the same buffer, and fractions (1 mL) were collected and assayed for neutral glycose (55) and phosphate (18).

Gel filtration of polysaccharide samples (25 mg) was carried out on a column (2.5 × 50 cm) of Sephacryl S300 (Pharmacia) using 0.05 M pyridinium acetate (pH 4.5) as the eluant. The column eluant was continuously monitored for changes in refractive index using a Waters

R403 differential refractometer, and fractions were analyzed for aldose and phosphate.

Immunodiffusion

Double diffusion studies (56) were made at 4°C in 1% sodium chloride agarose gels using capsular polysaccharide concentrations of 1 mg/mL. Precipitin lines were allowed to develop over 2 days. Antiserum to *P. haemolytica* serotype T3 was prepared by immunization of mice with formalin-killed cells of the bacterium.

Analytical methods

Quantitative colorimetric methods used were phenol – sulfuric acid for neutral glycoses (55) and the method of Chen *et al.* (18) for phosphate.

Glycoses were determined by glc of their alditol acetate derivatives (57) using inositol as internal standard. Samples (2 mg) were hydrolyzed in sealed glass tubes with 3 M hydrochloric acid (1 mL) for 3 h at 100°C or with 1 M sulfuric acid (1 mL) for 12 h at 100°C followed by neutralization (Ag_2CO_3 or $BaCO_3$, respectively) and concentration to dryness *in vacuo*. The liberated free glycoses were reduced ($NaBH_4$) and acetylated as previously described (58).

Gas–liquid chromatography employed a Hewlett Packard model 5710A gas chromatograph fitted with a hydrogen flame-ionization detector, a model 3380A electronic integrator, and a fused silica capillary column (0.3 mm × 25 m) containing 3% (w/w) OV17, using the temperature program, 180°C (for 2 min) to 240°C at 2°C/min. Development was made with nitrogen at 25 mL/min and retention times are quoted relative to D-glucitol hexaacetate (T_{GA}).

The glc–ms measurements were performed with a Hewlett Packard 5985B system employing the aforementioned glc conditions by electron impact (ei) with an ionization potential of 70 eV or by chemical ionization (ci) with methane as the reagent gas.

Absolute configurations of glycoses were established by conversion to the corresponding trimethylsilyated *R*-2-butylglycoside derivatives (17) followed by comparison of the glc retention times and mass spectra with those of authentic reference compounds.

Nuclear magnetic resonance measurements

All spectra were obtained on a Bruker AM-500 spectrometer equipped with an Aspect 3000 computer, using standard Bruker software. Samples were twice lyophilized from deuterium oxide and dissolved at concentrations of 15–45 mg/mL.

Proton and carbon-13 measurements were made on polysaccharide (sodium salt, pD ≈ 7.8) or oligosaccharide samples in 5-mm tubes at 310 K or 300 K, respectively. Proton spectra, recorded at 500 MHz, were obtained using a spectral width of 1.8 kHz, a 8 or 16 K data block, and a 90° pulse. Resolution enhancement was implemented using a Gaussian line shape transformation (20) with values of −3.0 Hz and +0.1 for the line and Gaussian broadening factors, respectively. Chemical shifts are expressed relative to internal acetone (δ 2.225 ppm). The nOe difference spectra were obtained by sequential irradiation of each line in a multiplet (26) for a total irradiation time of either 200 ms for polysaccharide samples or 400 ms for oligosaccharide samples.

Broadband proton-decoupled ^{13}C nmr spectra were obtained at 125 MHz using a spectral width of 25 kHz, a 32 K data block, and a 90° pulse employing WALTZ decoupling (59). Heteronuclear $^1J_{C,H}$ coupling constants were measured using gated decoupling (60). DEPT spectra (27) were obtained with broadband proton decoupling, a 135° proton pulse, and 3.3 ms delay between pulses. Chemical shifts are referenced to that of external 1,4-dioxane (δ 67.40 ppm).

Two-dimensional homonuclear proton chemical shift correlation (COSY) (61) and *J*-resolved (62) experiments were measured by employing the conventional pulse sequences. The COSY spectra were obtained using a data set ($t_1 \times t_2$) of 512 × 2048 points for a spectral width of 830 Hz. The data matrix was zero-filled to 1024 × 2048 points and, following resolution enhancement in both dimensions by a non-shifted sine bell function, the data were processed to give magnitude spectra with symmetrization. The *J*-resolved spectrum was obtained using a data matrix of 64 × 2048 points and spectral widths of 1859 and ±29.1 Hz in the chemical shift (F_2) and coupling constant (F_1) dimensions, respectively. Following zero-filling in t_1 to give 128 × 2048 points, a non-shifted sine bell function was applied in both time domains, and the transformed data were tilted 45° and symmetrized. For both experiments, a recycle delay (T) of 1.6 s was used, and 32 transients were collected for each t_1 value.

Two-dimensional heteronuclear carbon–proton chemical shift correlations were carried out with quadrature detection in F_1 (63) using a data matrix of 128 × 2048 points and spectral widths of 6945 and 451 Hz for the respective carbon-13 (F_2) and proton (F_1) chemical shift domains. A recycle delay of 1.5 s was employed and the fixed delays, τ_1 and τ_2, were set at 3.2 and 1.6 ms, respectively, to select for all multiplicities. Composite broadband proton decoupling was carried out during the acquisition of 1000 transients for each of the 128 t_1 increments. The data matrix was zero-filled in t_1 to 256 × 2048 points and, following resolution enhancement in both dimensions by means of a Lorentz-to-Gauss transformation, the data were processed to give a power spectrum.

Phosphorus-31 spectra were measured at 202 MHz on solutions (ca. 2 mL) in 10-mm sample tubes by employing a spectral width of 10 kHz, a 16 K data set, and 90° pulse. Chemical shifts are referenced to that of an external sample of 85% phosphoric acid.

Spectral simulations were performed using the Bruker Panic program. The spin systems corresponding to the galactosyl and the glycerol moieties were simulated separately, and were then co-added, employing line widths of 3.0 Hz, to give a composite simulated spectrum.

Potential energy calculations

Semi-empirical potential energy calculations were performed by the HSEA method (36, 37) to estimate the minimum energy conformation about the glycosidic bond of disaccharide **2**. Calculations were performed in five-degree steps across the Φ and ψ ranges and the glycosidic bond angle was set at 117°. Atomic coordinates for the α-D-galactopyranose unit were taken from neutron diffraction data of Takagi and Jeffery (64). The heavy atom coordinates for the glycerol moiety were generated by bond modification (65) of D-glucitol X-ray diffraction data (66); the central C—C bond of D-glucitol was replaced by a C—H bond, in which the H atom was positioned along the C—C bond vector, to generate the C-1′—C-2′—C-3′ skeleton of glycerol. Coordinates for hydrogen atoms were generated as previously described (67) using a C—H bond length of 1.10 Å. The torsion angles, Φ and ψ, are defined according to Bock (65).

Depolymerization of the capsular polysaccharide

O-Deacetylated capsular polysaccharide (5 mg) was dissolved in 48% (w/v) aqueous hydrofluoric acid (0.2 mL) and, after the reaction mixture was kept at 4°C for 60 h, excess hydrogen fluoride was removed by evaporation by passing a stream of nitrogen over the solution. The residue was dried over sodium hydroxide *in vacuo* and the phosphate-free product (4 mg) was obtained by gel filtration on a column (1.7 × 95 cm) of Sephadex G-15 eluted with 0.05 M pyridinium acetate (pH 4.5). The product, 1-*O*-α-D-galactopyranosyl-L-glycerol (**2**), showed a single spot on tlc (silica gel) developed with ethyl acetate – acetic acid – methanol–water (12:3:3:5) having R_f 0.36, and gave $[\alpha]_D$ 78.8° (*c* 0.26, water) and the ^1H and ^{13}C nmr data recorded in Tables 1 and 2. A sample (1 mg) of the disaccharide **2** was permethylated as previously described (58). The permethylated derivative eluted as a single peak on glc: ms (ci) *m/z*: 339 (M+1, 1.7%), 219 (67.2), 187 (100.0), 163 (8.3), 103 (23.9).

Degradation of 1-O-α-D-galactopyranosyl-L-glycerol (2)

The permethlyated sample of **2** was treated with methanolic hydrogen chloride (3%, w/v, 1 mL) in a sealed glass tube at 90°C for 14 h and the excess methanolic HCl was removed under a stream of nitrogen. To the residue in dry pyridine (0.5 mL) was added an excess of (1*S*)-(−)-camphanoyl chloride (Aldrich) (ca. 10 mg) and the solution was stirred at room temperature for 3 h. The reaction was quenched by

addition of dilute aqueous sodium carbonate (5%, w/v, 1 mL) and the product, 2,3-di-*O*-methyl-L-glycerol camphanate (**3**), was extracted into methylene chloride (1 mL). The methylene chloride extract was washed with water (3 × 1 mL) and dried over anhydrous sodium sulfate prior to glc–ms analysis using the aforementioned conditions. The glc retention time (T_{GA} 0.74) and ms were identical to those of an authentic sample obtained from L-glyceric acid.[5]

General methods

Commerical reagents and solvents were analytical grade. Concentrations were made under reduced pressure at bath temperatures below 40°C. Optical rotations were determined at 22°C in 10-cm microtubes using a Perkin–Elmer model 243 polarimeter.

Calculation of the second electron affinities of atoms

YUFEI GUO[1] AND M. A. WHITEHEAD

Theoretical Chemistry Group, Department of Chemistry, McGill University, 801 Sherbrooke Street West, Montreal, P.Q., Canada H3A 2K6

Received February 6, 1990

YUFEI GUO and M. A. WHITEHEAD. Can. J. Chem. **68**, 1585 (1990).

The second electron affinities of the atoms helium to krypton are calculated using the self-interaction corrected generalized exchange local-spin-density functional theory with the correlation energy functional. The dependence of the second electron affinities of the elements O, S, and Se on the Watson sphere radius is discussed. The present results are compared with other theoretical values and experimental data for the elements helium through krypton.

Key words: second electron affinity, density functional theory.

YUFEI GUO et M. A. WHITEHEAD. Can. J. Chem. **68**, 1585 (1990).

Faisant appel à une combinaison de la théorie fonctionnelle de la densité locale de spin avec échanges généralisés, corrigée pour les auto-interactions et de la corrélation d'énergie fonctionnelle, on a calculé les deuxièmes affinités électroniques des atomes des éléments allant de l'hélium au krypton. On discute de la relation qui existe entre les deuxièmes affinités électroniques du O, du S et du Se et le rayon de la sphère de Watson. On compare ces résultats avec les valeurs calculées à l'aide d'autres théories ainsi qu'avec les données expérimentales des éléments allant de l'hélium au krypton.

Mots clés : deuxième affinité électronique, théorie fonctionnelle de la densité.

I. Introduction

Theoretical and experimental investigation of the electron affinities (EA) of atoms has attracted much attention (1–12), because the electron affinity not only leads to understanding microscopic electron structure and the stability of macroscopic matter (13), but tests the reliability of the theory itself. The first electron affinities of atoms can be reproduced very well in the self-consistent-field (SCF) calculation by either the correlation-corrected accurate Hartree–Fock (HF) theory (2, 4–6, 12), or the correlation and self-interaction corrected approximate local-spin-density functional (SIC–LSD) theory (7–11), in agreement with experiment (1,3).

Since Fischer *et al.* (2) reported the electron affinity for the alkaline-earth element Ca from a multi-configuration Hartree–Fock (MCHF) calculation in almost perfect agreement with the measured electron affinity from an elegant experiment by Pegg *et al.* (3), many publications evaluating electron affinities for the alkaline-earth elements, noble gases, and actinides have been published (4, 5, 10–12). The theoretical calculations show that the singly charged negative ions for most atoms in the periodic table are stable, even for alkaline-earth elements, noble gases, and actinides.

Some doubly charged negative ions have been found in nature. For example, the doubly charged negative ion of oxygen, O^{2-}, has been found in oxide crystals during the study of their magnetic properties (14). Other doubly charged negative ions of atoms, like N^{2-}, S^{2-}, Se^{2-}, etc., also exist in solids (15–18). The investigation of doubly charged negative ions is interesting. Furthermore, chemists need the second electron affinities of atoms in their calculation of molecular properties. For example, in Orsky and Whitehead's definition of hardness for an acid and a base (19),

$$\eta_A = 1/4\ (I_{A^+} - A_{A0})$$

and

$$\eta_B = 1/4\ (I_{B0} - A_{B^-})$$

where η_A and η_B are the hardness for the acid A and base B, I_{B0} and I_{A^+} are the first and second ionization potentials, and A_{A0} and A_{B^-} the first and second electron affinities for atom A, respectively. This theory was developed and used in molecular calculations (20),[2,3] and it becomes essential to know the second electron affinities of atoms to evaluate the hardnesses for a base of the atom or group.

Baughan (21) calculated the first, second, and third electron affinities of atoms using the lattice-energy data of some ionic crystals and the spectroscopic data of the corresponding molecules; he also estimated the values of the second electron affinities for elements O, S, and Se and the third electron affinity for N by extrapolation, starting from the first, second, and third ionization potentials of the corresponding atom.

HF calculations of doubly charged negative ions in a crystal have been performed by Gásper and Csavinszky (22), who presented the solution for O^{2-}, and Watson (14), who published the analytic form of wave functions, the one-electron eigenvalues, the two-electron integrals, and the total energy for the doubly charged negative ion, O^{2-}. The SCF calculation for a doubly charged negative ion is much more difficult than that for a neutral atom, a positive ion, or even a singly charged negative ion, since the asymptotic form of the potential function becomes positive when the atomic radial variable r approaches infinity.

The generalized exchange local-spin-density functional (LSD–GX) theory derived by Manoli and Whitehead (23) with the self-interaction correction (SIC) (24) and the Vosko, Wilk, and Nusair (VWN) (25) correlation energy functional has been very successful in predicting the ionization potentials and first electron affinities of atoms (8–10) and as reliable as HF theory, because the LSD–GX–SIC statistical total energy of an atom is very close to the HF value. Therefore, this theory is expected to be as reliable as HF in calculating the second electron affinities of atoms, and very much more convenient.

The second electron affinities in LSD–GX–SIC theory are obtained using the Watson sphere to simulate the environment of the doubly charged negative ion in the crystal and adjusting

TABLE 1. The statistical total energies (Ry) for the singly and doubly charged negative ions of oxygen in the Watson sphere aided LSD–GX–SIC theory with correlation correction

	Without Watson sphere energy charge on sphere			With Watson sphere energy charge on sphere		
Ionicity	+2	+1	0	+2	+1	0
−1	−150.0894	−150.1131	−150.1310	−163.5258	−156.8166	−150.1310
−2	−149.4502	−149.5549	—	−164.2259	−156.8741	—
EA(2)	−0.6392	−0.5582		+0.7001	+0.0575	

the Watson sphere radius to make the calculated values fit experiment for O, S, and Se. The best second electron affinities occur with a Watson sphere radius of about 3.0 au for these three elements. This Watson sphere radius is assumed suitable for other elements, and is applied to estimate the second electron affinities of the elements helium to krypton.

II. Method

In SIC–LSD theory, the asymptotic form of the potential is

$$[1] \quad V(r) = -\frac{Z - N + 1}{r}$$

as r approaches infinity; Z and N are the atomic number and the number of electrons in an atom. For the doubly charged negative ion, $N = Z + 2$, and eq. [1] becomes

$$[2] \quad V(r) = \frac{1}{r}$$

This is a repulsive interaction. Physically, the second extra electron is not bound by a singly charged negative ion in its free state because of the repulsive potential surrounding the isolated negative ion. Numerically, there is a continuous solution of the Schrödinger equation with the asymptotic potential of eq. [2], instead of a bound wave function.
