SCHEME 1. Structures of dihydro and tetrahydropterins.

Several authors have postulated the involvement of trihydropterin radicals ($^{\bullet}PnH_3$) as intermediates, for example in the autooxidation of PnH_4 (8, 9). Such radicals have been produced in strongly acid media by chemical oxidizing agents (10, 11) and more recently in acetonitrile by photochemical methods (12). They have been characterized in those systems by esr. However, although frequent reference has been made to the coloration of these solutions (8, 9, 11), definitive investigations of the absorption spectra of $^{\bullet}PnH_3$ radicals appear to be lacking. The main reason for this is that to date only relatively mild oxidizing agents, such as oxygen and $Fe(CN)_6^{3-}$, have been used. These react relatively slowly with PnH_4 and its derivatives, which

means that the ambient concentrations of radicals are low and their optical absorbances cannot be properly differentiated from those of parent compounds and the PnH_2 and pterin (Pn) products. The object of this work was to find an alternative one-electron oxidant, which would still sequentially convert PnH_4 to PnH_2 and Pn via a radical mechanism, but at the same time could be used under conditions that would permit the absorption spectrum of $^{\cdot}PnH_3$ to be recorded.

The azide radical, $^{\cdot}N_3$, which normally reacts with aromatic systems specifically by electron transfer (13, 14), was chosen as a suitable oxidant. The radical can be generated conveniently through the oxidation of N_3^- by $^{\cdot}OH$ radicals, produced in the pulse radiolysis of N_2O-saturated solutions. The following relevant reactions (15, 16) take place immediately after the pulse and are complete within 10 ns:

$$[1]\quad 4.36H_2O \rightarrow 2.90\, e_{aq}^- + 2.90\, H^+ + 0.52\, {}^{\cdot}H + 0.47\, H_2 + 0.73\, H_2O_2 + 2.90\, {}^{\cdot}OH$$

$$[2]\quad N_2O + H_2O + e_{aq}^- \rightarrow N_2 + OH^- + {}^{\cdot}OH$$

$$[3]\quad {}^{\cdot}OH + N_3^- \rightarrow OH^- + {}^{\cdot}N_3$$

The coefficients in reaction [1] are moles per 10 MJ of radiation energy absorbed.

Azide has the advantage over several other radicals in that it does not itself absorb significantly above 300 nm, provided complexation with N_3^- is eliminated by keeping the N_3^- concentration below 0.2 M. Also the $^{\cdot}H$ atoms are removed by reaction with N_3^- to form $^{\cdot}HN_3^-$ (14) which is a potential reducing agent and would be inert to PnH_4.

This paper demonstrates that $^{\cdot}N_3$ sequentially oxidizes tetrahydropterins to their dihydro and pterin forms. It also reports the spectra of trihydropterin radicals derived from unsubstituted tetrahydropterin (PnH_4), 6,7-dimethyltetrahydropterin ($Pn(Me)_2H_4$), and 6-carboxylated tetrahydropterin ($Pn(CO_2^-)H_4$). The latter was produced by reaction of $^{\cdot}CO_2^-$ with pterin.[4] Experiments were carried out mainly at neutral pH and pH 10.

Experimental

Pulse radiolysis experiments were conducted at 23 ± 2°C in 1 cm optical path length "supercil" cells on solutions, which were flushed after each radiation pulse. For some experiments, the electron beam source was the 1.5 MeV Van de Graaff accelerator at the University of Calgary, but most of the pulse radiolysis was done with the 8 MeV linear accelerator in the U.S. Department of Energy Radiation Laboratory at the University of Notre Dame. Methods of dosimetry and other experimental details for these two facilities have been given in refs. 17 and 13, respectively. γ-Radiolysis was carried out at room temperature in an Atomic Energy of Canada Gamma Cell, either at Calgary or Notre Dame. Dose rates were checked routinely with the Fricke dosimeter solution (16) with the ferric ion yield taken from the literature as 1.61 mole per MJ of radiation energy absorbed (15).

Absorption spectra of solutions were measured on a Cary 219 Spectrophotometer and absorbance coefficients were used routinely to determine concentrations of tetrahydropterins. For PnH_4 and $Ph(Me)_2H_4$, the first λ_{max} was at 297 nm for both pH 7 and 10. The value of ϵ_{max} was also the same at both pH's and equal to 8200 ± 200 M^{-1} cm^{-1} for the former and 8500 ± 200 M^{-1} cm^{-1} for the latter. It may be noted that these pH coincidences were fortuitous, as some PnH_3^- was present with PnH_4 at pH 10 (pK PnH_4 amide ~ 10.4 (18)) and a trace of PnH_5^+ (pK ~ 5.6 (18)) occurs at pH 7. $Pn(CO_2^-)H_4$ had λ_{max} = 302 nm and ϵ_{max} = 8020 ± 200 M^{-1} cm^{-1} at pH 10.

[4]Details of $^{\cdot}CO_2^-$ reductions will be presented elsewhere (M. Farahani, P. S. Surdhar, R. Allen, C. Schoneich, K.-D. Asmus and D. A. Armstrong. To be published).

All chemicals were the purest available and solutions were made up in triply-distilled or chromatographically-purified deionized water with 10–20 mM phosphate buffer present. They were deaerated by purging with nitrous oxide, nitrogen, or argon before use. Solutions of tetrahydropterins were kept free of air to avoid oxidation by oxygen. Sources of pterin derivatives were tetrahydropterin sulphate, K and K Laboratories; 6,7-dimethyl-5,6,7,8-tetrahydropterin, pterin-6-carboxylic acid, and pterin, Fluka. Pterin obtained from the Sigma Chemical Company gave identical results.

Results and discussion

Two and four electron-equivalent oxidation by $^{\cdot}N_3$

Tetrahydropterin derivatives in N_2O-saturated solutions, containing 0.02 to 0.05 M sodium azide, were subjected to oxidation by $^{\cdot}N_3$ produced by γ radiolysis over measured periods of time (5–15 min). Absorption spectra were taken several minutes after each successive addition of this oxidant, when the radical reactions had ceased. An illustration of one of these spectrophotometric titrations has been given in Fig. 1*a* for 6,7-dimethyltetrahydropterin at pH 10. The observations at pH 7 were similar. The numbers on the curves correspond to the number of minutes of exposure to radiation, and each ten minutes corresponds to the addition of 32 μmol of $^{\cdot}N_3$ per litre. The initial spectrum, very similar to the "ten minute spectrum", was omitted.

At the start of the oxidation, there were isobestic points at 318 and 286 nm, and, as illustrated for 318 nm in the inset, the absorbances at these wavelengths did not change until two equivalents of $^{\cdot}N_3$ had reacted per mole of $Pn(Me)_2H_4$. Beyond this point, two new isobestic points appeared at 267 and 332 nm. Finally there was no change in absorbance at any wavelength for oxidizing equivalents in excess of 4.1 per mole of $Pn(Me)H_4$ initially present, and at that point the spectrum corresponded to that of 6,7-dimethylpterin. The solubility of this compound in 0.02 M phosphate buffer at pH 7 and 10 and 23°C was found to be about 20 μM. A fine precipitate appeared in the latter stages of the oxidative titration, if the initial $Pn(Me)_2H_4$ concentration exceeded this. In separate experiments with unsubstituted pterin, no oxidation by $^{\cdot}N_3$ was seen, and this appeared true for all pterin derivatives examined here.

When $Pn(Me)_2H_4$ was allowed to react with oxygen in an aerated solution and the conversion to 6,7-dimethyl-7,8-dihydro-pterin ($Pn(Me)_2H_2$) was followed spectrophotometrically, as in earlier work (2), isobestic points were observed at the same wavelengths as those seen initially in Fig. 1*a*. Also, the spectrum at the two electron equivalence point in Fig. 1*a* ($e_{oxd}/Pn(Me)_2H_4$ = 2.0) was found to be within experimental error the same as that of $Pn(Me)_2H_2$, produced by oxidation of $Pn(Me)_2H_4$ with two equivalents of $Fe(CN)_6^{3-}$ (6, 7) or by oxidation with air. The results in Fig. 1*a* can therefore be explained on the basis of three major species being present during the titration: (*a*) $Pn(Me)_2H_4$ and $Pn(Me)_2H_2$ from $e_{oxd}/(Pn(Me)_2H_4)_0$ = 0 to 2.1; and (*b*) $Pn(Me)_2H_2$ and $Pn(Me)_2$ from $e_{oxd}/(Pn(Me)_2H_4)_0$ = 2.1 to 4.1. The fact that the titration requires a slight excess of $^{\cdot}N_3$ can be explained by the presence of the reducing entity $^{\cdot}HN_3^-$, which is formed with one tenth the yield of $^{\cdot}N_3$ (see Introduction) and could reconvert some Pn and PnH_2 to their reduced forms.

The effects observed with PnH_4 and $Pn(CO_2^-)H_4$ were different to the extent that there was no clearcut two-electron equivalent end point, although oxidation again ceased at the four-electron equivalent point. This has been illustrated for the case of the carboxylated tetrahydropterin at pH 10 in Fig. 1*b*. The presence of the isobestic point between the absorbances of the

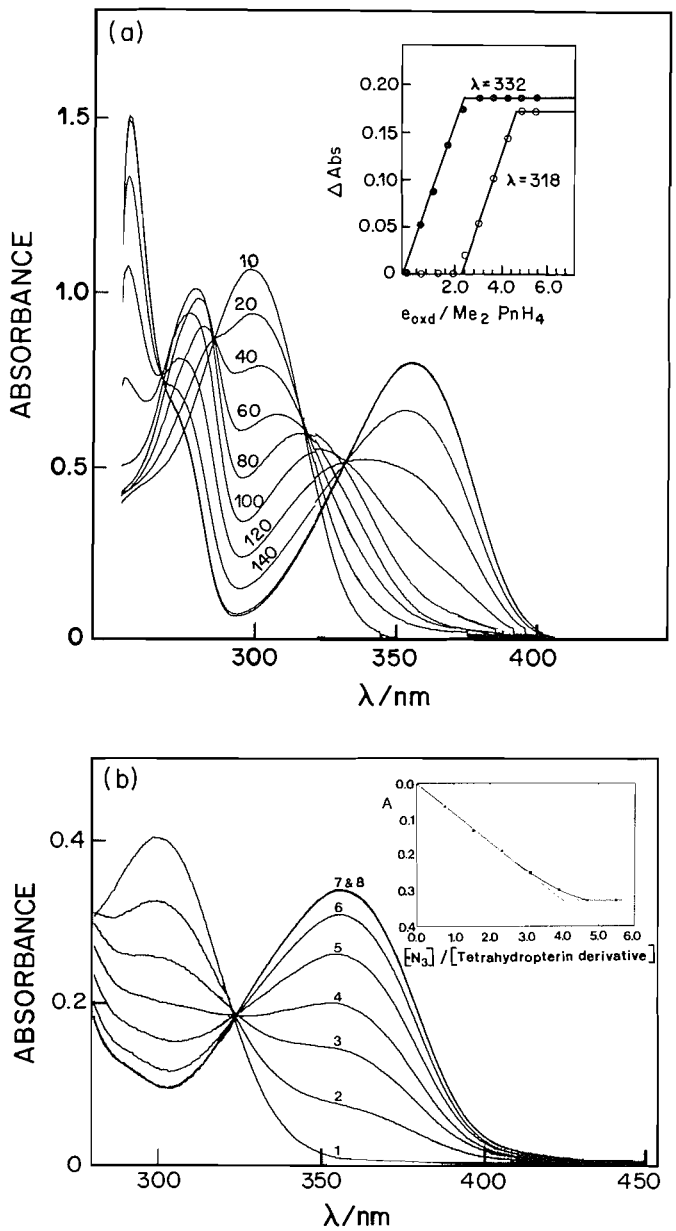

FIG. 1. Spectrophotometric titrations of tetrahydropterins in N_2O-saturated 40 mM NaN_3 solutions at pH 10. (*a*) 62 μM 6,7-dimethyltetrahydropterin. Numbers on curves correspond to minutes of exposure to γ radiation; (*b*) 50 μM 6-carboxylated tetrahydropterin. Numbered curves correspond to 0 (*1*), 8 (*2*), 16 (*3*), 24 (*4*), 32 (*5*), 40 (*6*), 48 (*7*) and 56 min (*8*) of γ radiation. Insets: Changes in absorbance versus moles of oxidant $^{\bullet}N_3$ per mole of initial tetrahydropterin.

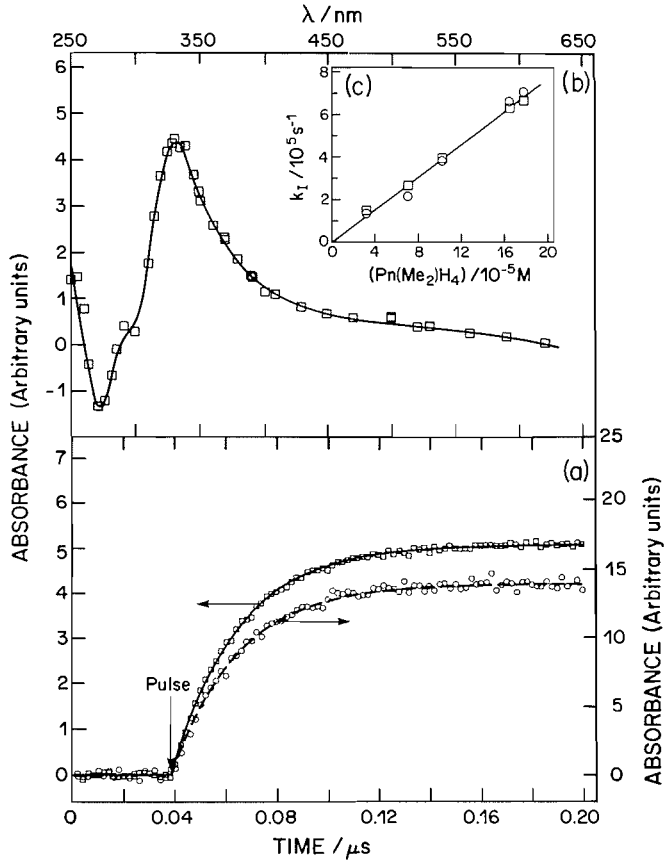

FIG. 2. Growth of absorbance of radicals produced by $^{\bullet}N_3$ oxidation illustrated for 6,7-dimethyltetrahydropterin at pH 7 in 0.05 M NaN_3 solutions. (*a*) Kinetics of growth at 330 nm (□) and 400 nm (○) for 103 μM solutions. Lines are fitted first-order growth curves. (*b*) Differential spectrum—changes in absorbance when radical formation was complete plotted against wavelength—for a 32 μM solution. (*c*) Pseudo first order rate constants for growth at 330 nm (□) and 400 nm (○) plotted against concentration of the tetrahydropterin.

tetrahydropterin and pterin implies that pterin is present right from the start of the titration and that the 7,8-dihydropterin never builds up to a significant concentration.

The earlier research with $Fe(CN)_6^{3-}$ (6, 7) as oxidant showed that the first non-radical product of one electron oxidation was a quinonoid dihydropterin (6, 7). This rearranged to 7,8-dihydropterin in a process, which was on a sub-second time scale for "unhindered" tetrahydropterins, like PnH_4, but could be observed by spectrophotometry for the 6,7-dimethyl derivative. Also, with the exception of this derivative, the quinonoid dihydropterins disproportionated quite rapidly with their 7,8-isomers to yield the PnH_4 and Pn forms. The present observations for unsubstituted PnH_4 are in agreement with this. The finding that $Pn(CO_2^-)H_4$ behaved similarly is consistent with the fact that blocking groups were required at both C-6 and C-7 to fully inhibit the disproportionation. In summary, therefore, the products and stoichiometry observed on the oxidation of tetrahydropterins with $^{\bullet}N_3$ are similar to those seen with $Fe(CN)_6^{3-}$. However, as will be appreciated from the next section, the primary one-electron oxidation step is much faster.

Pulse radiolysis observation of one electron oxidation

Kinetics of $^{\bullet}PnH_3$ Growth:

The reaction of $^{\bullet}N_3$ radicals with tetrahydropterin derivatives was followed by observing the changes in absorption (ΔA) at wavelengths in the region λ = 250 to 650 nm. Examples of the growth of ΔA *with time at* λ = 330 and 400 nm are shown in Fig. 2*a* for 103 μM 6,7-dimethyltetrahydropterin at pH 7. For solutions of a particular tetrahydropterin at a given pH, the growth obeyed pseudo first-order kinetics at all wavelengths with similar rates. Plots of the pseudo first-order rate constants versus concentrations of the tetrahydropterin were linear, as illustrated by the example in Fig. 2*c*. This is consistent with reaction [4].

$$[4] \quad {}^{\bullet}N_3 + PnH_4 \rightarrow N_3^- + \cdot PnH_4^+$$

as the rate-controlling process, the values of k_4 calculated from the slopes of such plots have been summarized in Table 1.

Reference to Table 1 shows that, while the differences are comparable to the ±15% experimental uncertainty, there is a consistent pH dependence of k_4 for each derivative. For the case

TABLE 1. Rate constants for oxidation by $^{\bullet}N_3$

Tetrahydropterin	Rate constants* pH 10	pH 7
PnH_4	5.7	4.1
$Pn(Me)_2H_4$	4.3	3.8
$Pn(CO_2^-)H_4$	4.2	2.9

*Units: 10^9 M^{-1} s^{-1}; uncertainties ±15%.

of $Pn(Me)_2H_4$, Kallen and Jencks (18) have determined the pK of the 3,4-amide group to be 10.4. This means that at pH 10 about 26% of the compound will be in the deprotonated enolate form (see structures in Introduction, Scheme 1). Based on $^{\bullet}N_3$ oxidation rates for model aromatic compounds (13), one would expect a slightly higher rate constant for this species. Allowing for the fractions of enolate (0.26) and amide (0.74) forms and assuming $k_4 = 3.8 \times 10^9$ M^{-1} s^{-1} for the latter, one finds from the pH 10 rate constant $k_{4e} = 5.7 \times 10^9$ M^{-1} s^{-1}

[4e] $^{\bullet}N_3 + PnH_3^- \rightarrow N_3^- + \cdot PnH_3$

for the PnH_3^- form of $Pn(Me)_2H_4$. In accord with this, when the rate constant was determined at pH 11.5 where 95% of the $Pn(Me)_2H_4$ would have been in the PnH_3^- form, the rate constant was found to be 5.8×10^9 M^{-1} s^{-1}. Since the amide ionization constants for the other tetrahydropterins are probably similar to that of $Pn(Me)_2H_4$, the trends with pH for the other compounds in Table 1 can be rationalized on a similar basis. The lower rate constants for the carboxylated derivative suggest that the presence of the CO_2^- group exerts a small inhibitory effect, perhaps by partially blocking access to the N-5 position. The rates at both pH's are also largest for the unsubstituted PnH_4.

The rate constants for the oxidation of the PnH_4 derivatives at pH 7 and for $Pn(Me)_2H_3^-$ are comparable to those for the $^{\bullet}N_3$ oxidation of phenolates (13) and of the dihydroflavin molecule (19), which has a number of structural similarities to tetrahydropterin. They are several orders of magnitude larger than the rate constants for oxidation of tetrahydropterins by $Fe(CN)_6^{3-}$ (~ 10^6 M^{-1} s^{-1} (7)) and oxygen (~ 1 M^{-1} s^{-1} (8)) at the same pH's. This can be attributed primarily to the much higher reduction potential of $^{\bullet}N_3$ (20) ($E^0(^{\bullet}N_3/N_3^-)$ = 1.33 V (21); $E^0(Fe(CN)_6^{3-}/Fe(CN)_6^{4-})$ = 0.36 V (22); E^0 (O_2/O_2^-) = −0.16 (21)).

As shown in Fig. 2*a*, for typical conditions, growth of the radical absorbance was complete at a microsecond or less. The change in absorbance at that point and before significant radical decay has been plotted against λ in Fig. 2*b* for the case of a 32 μM solution of $PnMe_2H_4$ at pH 7. Similar data were obtained for each PnH_4 derivative at neutral pH and pH 10. These "differential spectra" were independent of PnH_4 concentration, apart from expected minor variations in intensity due to the greater losses of $^{\bullet}N_3$ by combination at lower PnH_4 concentration (15).

The lifetimes of the present pterin radicals were surprisingly long and their decays could not be followed quantitatively with present apparatus. However, first half lives were in the region of 0.1 s. This means that rate constants for self reaction are in the region of 10^6 M^{-1} s^{-1} or less, and that $^{\bullet}PnH_3$ radicals are much more stable kinetically than many other biological radicals, such as flavin and nicotinamide radicals.

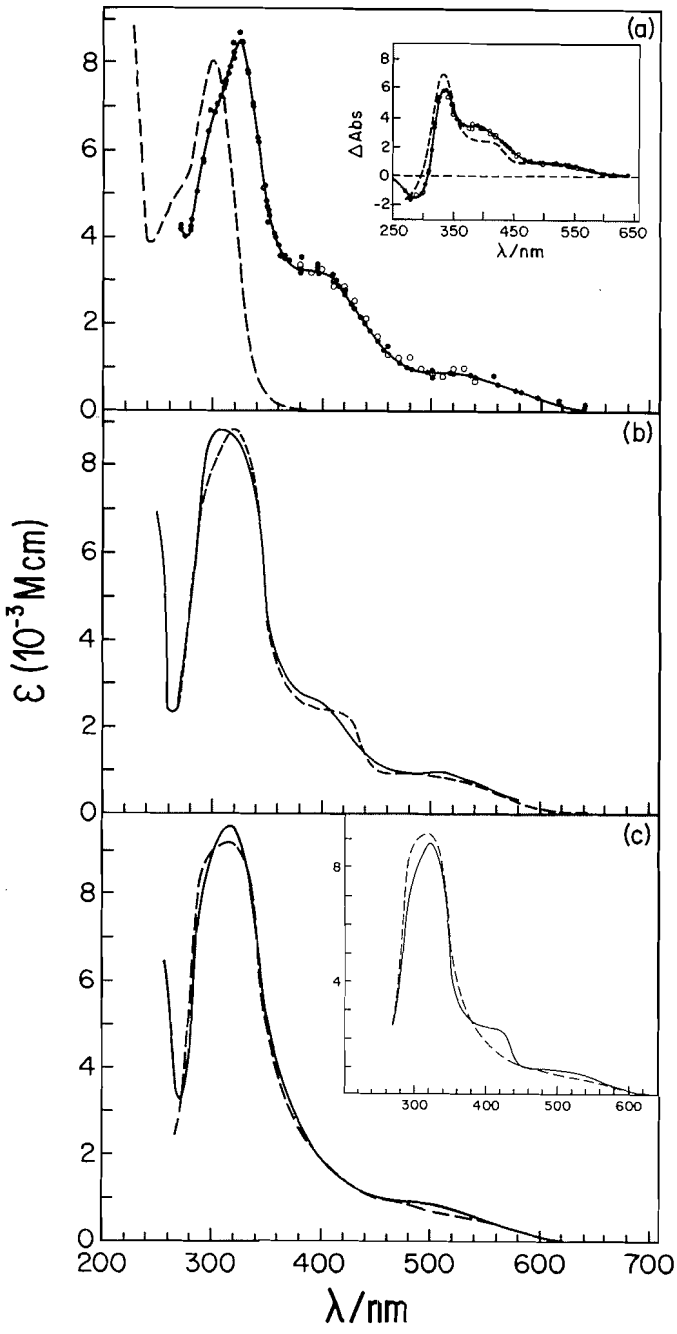

FIG. 3. Absorption spectra of radicals formed by $^{\bullet}N_3$ oxidation of tetrahydropterins. (*a*) 6-Carboxylated tetrahydropterin radical at pH 10 – solid line (filled and open circles were obtained at Notre Dame and Calgary, respectively). The dashed line is the spectrum of the parent compound. Inset: Differential spectra of radicals from: 6-carboxylated tetrahydropterin (solid line and circles) and tetrahydropterin (dashed line). (*b*) Radicals from 6,7-dimethyltetrahydropterin (solid line) and tetrahydropterin (dashed line) at pH 10. (*c*) As for (*b*) at pH 7. Inset: Comparison of the spectra of the radicals formed from PnH_4 at pH 10 (solid line) and pH 7 (dashed line).

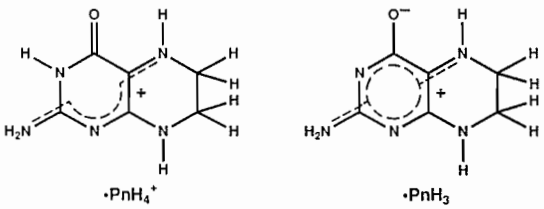
Spectra of the radicals

Spectra of the radicals, derived by adding the values of ΔA (divided by the concentration of radicals produced per pulse) to the absorbance coefficient of the PnH_4 derivative determined at each given wavelenth on a Cary 219 spectrophotometer at the same pH, are shown in Fig. 3*a*, *b*, and *c*. The data for the carboxylated derivative, prepared by $^{\bullet}CO_2^-$ reduction of Pn, has been presented in more detail in Fig. 3*a*. The spectrum of this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

tetrahydropterin was typical of those of the tetrahydropterins studied here, which all exhibited peaks near 300 nm and stronger absorption below 240 nm. Further discussion of $Pn(CO_2^-)H_4$ will be given elsewhere,[4] but it may be noted here that no evidence for the previously reported (23) absorbance near 380 nm was seen. It appears that this may have been due to experimental artifacts.

The isobestic point at 318 nm in Fig. 3*a* corresponds with the cross over from gain in absorbance to loss in the differential spectrum in the inset of the same Figure. It is important to note that these ΔA vs. λ plots are characteristic "signatures" of the parent compound and its daughter radical. When a comparison of the data points for the carboxylated tetrahydropterin (the solid line and points) with the corresponding ΔA vs. λ plot for tetrahydropterin, shown by the dashed line, was made on an enhanced scale, the differences of up to 1000 M^{-1} cm^{-1} units at several λ indicated that the radicals were different.[4] This is also shown to some extent by a comparison of the absolute spectra at pH 10 in Fig. 3*a* and *b*.



SCHEME 2. Two forms of "PnH" radical.

The structures of the two $^{\bullet}PnH_3$ species formed by removal of electrons from PnH_4 and PnH_3^- in Scheme 1 are shown in Scheme 2. Molecular orbital calculations (9, 11) on these predicted high spin densities on N-5 in both $^{\bullet}PnH_4^+$ and $^{\bullet}PnH_3$, but it was clear that other canonical forms would also contribute significantly, especially in $^{\bullet}PnH_3$ where a relatively large spin density was found (9) on C-4a. For the following reasons the data of the present study also demonstrate that there is significant delocalization of the unpaired electron from N-5 in the $^{\bullet}PnH_3$ radicals. First, recent research (24) has shown that aminyl cation radicals with α-hydrogen are susceptible to deprotonation, viz:

[5] $\quad -\dot{N}\overset{+}{H}-CH(R)- \rightarrow H^+ + -NH-\dot{C}(R)-$

with pK in the region of 8. Had this occurred here the spectrum seen would have been that of an α-carbon radical localized on C-6, and such a species does not absorb strongly above 300 nm (24, 25). Second, the 6-carboxylated tetrahydropterin would be susceptible to reaction [6], which has been shown to proceed on a microsecond or shorter time scale with α-carboxylated aminyl radicals (26). Again this would give a C-6 localized α-carbon radical and an absorption very different from that observed here. It is therefore evident that the radicals are stabilized by electron delocalization to the extent that these processes do not occur or take place on a 0.1 s or longer time scale. This delocalization is clearly reflected in the wavelength at which the absorption occurs and its intensity.

[6[$\quad -\dot{N}\overset{+}{H}-CH(CO_2^-)- \rightarrow CO_2 + -NH-\dot{C}H-$

The exact structures to be associated with the spectra in Fig. 3 remain to be determined. However, the pK of the amide group in the parent molecules is ~ 10.4 (18). In the radical the pK of this group should be the same or less. Since further experiments at pH 11.5 showed no significant change in absorbance from that of the radical form at pH 10, it appears that loss of the amide proton has occurred at that pH. At pH 7 there are some small differences in the absorption spectra, which suggest protonation may take place in that region. These are illustrated for the radicals of unsubstituted PnH_4 in the inset of Fig. 3*c*.

Finally, although this appears to be the first report of a UV/visible spectrum of $^{\bullet}PnH_3$ type radicals, the "tailing" absorbances in Fig. 3*a*, *b* and *c* at wavelengths above 400 nm are consistent with earlier reports of coloration of oxidized solutions of PnH_4 and its derivatives (9–11). The results reported here should stimulate further research on $^{\bullet}PnH_3$ radicals and assist in quantifying data relating to the kinetics of their reactions.

The reaction of (η^5-cyclopentadienyl)dicarbonyliron(2-thienoyl) with acetylenes; a mechanistic study using proton nuclear magnetic resonance, and application in synthesis

IAN R. BUTLER[1]

Chemistry Department, University of Ottawa, Ottawa, Ont., Canada K1N 6N5

Received January 23, 1990

IAN R. BUTLER. Can. J. Chem. **68**, 1979 (1990).

The thermal reactions of dicarbonyl-η^5-cyclopentadienyl(2-thienoyl)iron with a series of substituted acetylenes to give indenones and cyclopentathiophenones have been reinvestigated. The results obtained support a reaction mechanism involving initial acetylene insertion followed by that of carbon monoxide, in contradiction to the previously reported results. The reaction products were identified and characterized primarily using 2D ^{1}H nmr spectroscopy.

Key words: acetylene, carbon monoxide, iron, indenone, mechanism, thienyl.

IAN R. BUTLER. Can. J. Chem. **68**, 1979 (1990).

On a réetudié les réactions thermiques du dicarbonyl-η^5-cyclopentadiényl(2-thienoyl)fer avec une série d'acétylènes substituées qui conduisent à des indénones et à des cyclopentathiophénones. Les résultats obtenus sont en accord avec un mécanisme réactionnel impliquant une insertion initiale de l'acétylène, suivie de celle du monoxyde de carbone; ce mécanisme est en contradiction avec les résultats rapportés antérieurement. Pour identifier et pour caractériser les produits réactionnels, on a principalement fait appel à la spectroscopie rmn du ^{1}H en 2D.

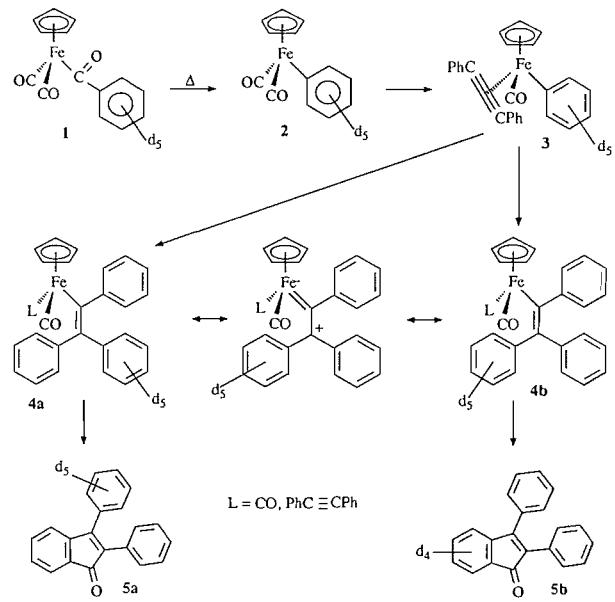
Mots clés : acétylène, monoxyde de carbone, fer, indénone, mécanisme, thiényle.

[Traduit par la revue]

Introduction

The insertion of acetylenes into metal–carbon bonds is a synthetically useful procedure, although the mechanistic details of such processes are not fully understood. Recently we have elucidated some of the mechanistic features of one specific type of reaction in this class, namely that of the thermal reaction of dicarbonyl-η^5-cyclopentadienyliron(I)aryls, FPAr, with diarylacetylenes to give [1*H*]-2,3-diarylinden-1-ones, using deuterium labelled samples (1). A summary of the proposed mechanistic results is shown in Scheme 1, for the reaction of Fp(phenyl-d_5) with diphenylacetylene. In addition to the indenone products, ferrocene and mono and 1,1′-bis(phenyl-d_5) ferrocene are observed as by-products, indicating the transfer of the σ bound phenyl group to the η^5-cyclopentadienyl ring. By studying the reactions (photochemical and thermal) of the related Fp(1- and 2-naphthoyl) compounds with diphenylacetylene, we were able to show that the insertion of the diarylacetylene precedes that of carbon monoxide, Scheme 2 (2). Moreover, by independent synthesis of the proposed intermediate, **4** (undeuterated) in Scheme 1, we were able to show that such compounds decompose cleanly to [1*H*]-2,3-diphenylinden-1-one (3).

On surveying the literature, we encountered a report by Kolobova and co-workers documenting a similar reaction of Fp-2-thienoyl, **11**, with diphenylacetylene under photolytic conditions to give indenone isostere **12** as the major reaction product, in addition to Fp-2-thienyl (4, 5), Scheme 3. Product **12** is not what would be predicted if our tentative reaction mechanism is correct, assuming that thermal and photochemical reactions have common reaction intermediates. Moreover, the reaction of Fp-2-thienoyl with (triphenylgermyl)phenylacetylene gives a single indenone product, **13** (6), which has been structurally characterized by the same research group. This result is in apparent contradiction to their earlier findings. For these reasons we decided to investigate a series of reactions of Fp-2-thienoyl with a range of disubstituted acetylenes to establish a mechanistic pathway for the thermal process, and compare the results obtained with those of reported photochemical reactions.



SCHEME 1

Experimental

All reactions were carried out under an atmosphere of dry nitrogen; however subsequent column chromatographic separations were carried out under aerobic conditions. ^{1}H nmr spectra were recorded using a Varian XL-300 spectrometer, using $CDCl_3$ as solvent unless otherwise stated. Mass spectra were obtained, using electron impact ionization on a VG Analytical 7070E instrument (at 70 MeV) at the University of Ottawa Mass Spectroscopy Centre. Neutral alumina (Aldrich Chemical Co.) was used throughout for column chromatographic separations. In addition, a mode 7924 chromatatron supplied by Harrison Research was used with a silica gel support (Merck 7749-60 PF_{254} plates). Substituted acetylenes were prepared by palladium-catalysed coupling reactions of phenylacetylene and the appropriate aryl halide (7). Derivatives of dicarbonyl(η^5-cyclopentadienyl)iron, (Fp), were prepared either by reaction of sodium dicarbonyl(η^5-cyclopentadienyl)

ferrate with the appropriate aroyl halide (8), or by reaction of dicarbonyl(η^5-cyclopentadienyl)iron iodide with the appropriate aryllithium (9). The solvent was decalins (mixture of *cis* and *trans* isomers), which was degassed prior to use. The standard procedure was to heat the reaction mixture using an isomantle as heat source, with good agitation. In general the reaction mixtures darken, becoming almost black, with, at reflux, rapid effervescence accompanied by a dense smoke-like vapour above the reaction mixture. The melting points reported are uncorrected. Two dimensional nmr experiments were conducted using conventional experimental parameters; dd = doublet of doublets, m = multiplet, bs = broad singlet, ad = asymmetric doublet. Yields quoted are based on isolated, crystallized samples, unless otherwise stated.

Reaction of Fp-2-thienoyl with diphenylacetylene

A mixture of Fp-2-thienoyl (5.32 g, 18.4 mmol) (4, 5) and diphenylacetylene (7.50 g, 42.1 mmol) was refluxed in decalins (25 mL) for 10 min. The cooled reaction mixture was chromatographed on a neutral alumina (Grade 1) column, (50 cm × 20 cm (diameter)). Initial elution with hexane gave decalins and a pale yellow fraction (subsequently shown to be predominantly diphenylacetylene). Subsequent incremental addition of diethyl ether eluted a series of coloured fractions, followed by a red/brown band of Fp_2. A red fraction (violet on drying), which was bound strongly to the column, was eluted with ethyl acetate. This was combined with the previous mixed coloured solutions. The coloured fractions were reapplied to a second column on which the following fractions, in order of elution, were obtained: (*i*) yellow, identified as ferrocene by mass spectroscopy and nmr; (*ii*) violet (55 mg), ^{1}H nmr: 6.81 (s, 1); 6.88 (d, 1); 6.91 (d, 1); 6.98–7.26 (m's 9). Mass spectrum: parent ion at *m/e* 572 (see below); (*iii*) red (250 mg), obtained as a slightly impure powder. ^{1}H nmr: 4.24 (s, 5); 6.44 (dd, 1); 6.72 (dd, 1); 6.86–7.40 (m's, approx. 14); 7.61 (dd, 1). Attempted recrystallization and purification by further chromatographic steps were unsuccessful in obtaining a pure crystalline sample; (*iv*) violet, identified as 4*H*-cyclopenta-[*b*]-thiophen-4-one-5,6-diphenyl, **14**; (*v*) violet and orange mixture of **14** and **15**; (*vi*) orange, identified as 2-phenyl 3-(2-thienyl)-[1*H*]-inden-1-one, **15**. The mixed fraction (*v*) was further separated twice using the chromatatron to give pure samples of **14** and **15**.

14 (14%), ^{1}H nmr ($CDCl_3$): 7.12 (d, 1, J_{H-H} = 4.8 Hz); 7.17 (d, 1); 7.28 (bs, 3); 7.30–7.35 (m's, 5); 7.48–7.50 (2d, 2). Mass spectrum: *m/e* (rel. int.) 290 (8.1); 289 (20.9); 288 (100.0), $M^{+\bullet}$; 287 (43.3); 273 (2.2); 272 (6.5); 260 (7.9); 259 (20.7); 258 (23.1); 255 (3.8); 226 (5.3); 215 (17.3); 189 (4.5); 179 (11.6). *Anal.* calcd. for $C_{19}H_{12}OS$: C 78.15, H 4.20; found: C 78.65, H 4.64. Melting point 161–162°C, lit. 164–165°C (9).

15 (26%), ^{1}H nmr ($CDCl_3$): 7.12 (dd, 1); J_{H-H} = 3.8, 8.0 Hz; 7.28–7.37 (series of multiplets, 9); 7.46 (dd, 1, J_{H-H} = 1.0, 5.1); 7.56 (ddd, 1). Mass spectrum: *m/e* (rel. int.) 290 (6.9); 289 (24.4); 288 (100.0), $M^{+\bullet}$; 287 (63.8); 272 (4.5); 271 (21.4); 260 (14.3); 259 (38.4); 258 (41.6); 255 (12.5); 226 (12.7); 215 (13.0); 189 (5.3); 129 (19.0); 113 (6.9); 108 (5.9). *Anal.* calcd. for $C_{19}H_{12}OS$: C 78.15, H 4.20; found: C 78.43, H 4.60. Crystalline samples of **15** exist in two forms, (*a*) as orange crystals and (*b*) as deep red crystals. Melting point 118–119°C (colour change at 115°C for orange crystalline samples), lit. 124°C (10).

Reaction of 2-thienoylchloride with diphenylacetylene and aluminum trichloride

To a solution of 2-thienoyl chloride (1.46 g, 10 mmol) and aluminum trichloride (1.33 g, 10 mmol) in dichloromethane (20 mL) maintained at 0°C in an ice bath, was added a solution of diphenylacetylene (1.78 g, 10 mmol) in dichloromethane (10 mL). The mixture was stirred at this temperature for 30 min before being carefully hydrolyzed by the addition of 20 mL of a 6 M solution of HCl. The organic layer was separated, dried over magnesium sulphate, filtered, and reduced in volume to a few mL. The mixture was then chromatographed using the chromatatron. Initial elution with hexane gave unreacted diphenylacetylene and blue 1,2,3-triphenylazulene (210 mg, 5.9 mmol) which was subsequently crystallized from the hexanes. Continued elution gave a colourless ultraviolet-active band and two indenone-containing coloured bands; however, in each of the latter cases, a colourless compound was present as a contaminant. Crystallization of the fractions gave mixtures of colourless crystals of **17***a* and *b* and the violet [6*H*]-cyclopenta-[*b*]-thiopen-6-one-4,5-diphenyl **12** and orange 2-phenyl-3-(2′-thienyl)-[1*H*]-inden-1-one, **15**, respectively. ^{1}H nmr study of the hand-selected violet and red crystals, respectively, indicated that **17** was still present as an impurity, thus the spectra were compared with a series of authentic samples previously prepared. Using this procedure, the violet fraction was shown conclusively not to be **14**, since a 2,3-disubstituted thienyl ring (doublets at 6.98 and 7.68, respectively) was evident. The orange sample was identical (ir, ^{1}H nmr) to that of an authentic sample of **15**.

16 (1,2,3-triphenylazulene, 14%), ^{1}H nmr ($CDCl_3$): 7.00–7.08 (m's, 2), 7.10–7.18 (m's, 4), 7.24–7.41 (m's, 6); 7.55 (t, 1); 8.32 (s, 1); 8.36 (s, 1). Mass spectrum: 357 (24.8); 356 (79.2); 278 (4.7); 277 (3.0); 276 (4.5); 183 (20.5); 111 (100.0); 83 (5.0); 73 (4.4); 58 (20.7); 39 (14.9); 30 (15.3). Melting point 216– 216.5°C, lit. 209–210°C (11), 216–217°C (12).

17 (mixed isomers, 37%), Mass spectrum: *m/e* (rel. int.) 326 (13.0); 325 (11.0); 324 (34.2); 223 (8.1); 289 (15.7); 288 (4.4); 261 (7.7); 179 (14.4); 178 (100.0).

17*a*, ^{1}H nmr: 7.12 (dd, 1, J_{H-H} = 4.9, 3.9); 7.16–7.58 (m's, 10);

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

7.69 (dd, 1, J_{H-H} = 1.1, 4.9); 7.77 (dd, 1, J_{H-H} = 1.1, 3.9). **17***b*: 6.93 (dd, 1, J_{H-H} = 4.9, 3.9); 7.16–7.58 (m's, 12, including dd at 7.51, J_{H-H} = 4.9, 1.2, and dd at 7.56, J_{H-H} = 3.9, 1.2).

Reaction of Fpbenzoyl with phenyl(2-thienyl)acetylene

A mixture of Fpbenzoyl (1.41 g, 5.0 mmol) and phenyl(2-thienyl) acetylene (1.38 g, 7.5 mmol) in decalins (60 mL) was refluxed for 15 min. After cooling, the reaction mixture was passed through an alumina precolumn (4 cm depth) to remove insoluble impurities. The alumina was washed with dichloromethane and the washings were combined with the mixture. The mixture was then chromatographed, using conventional chromatography and the standard procedure outlined above to give the following fractions: (*i*) pale yellow identified as residual phenyl(2-thienyl)acetylene; (*ii*) 1,1′-diphenyl ferrocene, parent ion at *m/e* 338, spectroscopically (ir, nmr) identical to an authentic sample; (*iii*) phenyl ferrocene, parent ion at *m/e* 262, identical to an authentic sample; (*iv*) red, identified as 2-(2′-thienyl)3-phenyl-[1*H*]-inden-1-one, **20**, (24%); (*va*) violet + orange (collected as a mixture and rechromatographed using the chromatatron to give (*vb*) violet, **14** (8%), and orange, **15** (10%).

20, ^{1}H nmr ($CDCl_3$): 6.87 (dm, 1); 6.93 (dd, 1, J_{H-H} = 3,7, 5.1); 7.27 (dd, 1, J_{H-H} = 1.1, 5.1); 7.40 (dd, 1, J_{H-H} = 1.1, 3.7); 7.42–7.46 (m's 2); 7.47–7.54 (overlapping m's, 4) Mass spectrum: *m/e* (rel. int.) 290 (6.8); 289 (22.5); 288 (100.0), $M^{+\bullet}$; 287 (44.7); 271 (10.1); 259 (31.9); 258 (37.4); 255 (7.3); 226 (12.2); 215 (11.3); 213 (9.1); 189 (5.3); 129 (17.6). *Anal.* calcd. for $C_{21}H_{14}OS$: C 78.18, H 4.20; found: C 78.43, H 4.60. Melting point 155–156°C.

*Reaction of Fp-2-thienoyl with phenyl(*p*-tolyl)acetylene*

A sample of Fp-2-thienoyl (2.0 g, 6.9 mmol) and phenyl (4-methylphenyl)acetylene (1.0 g, 5.2 mmol) were refluxed in decalins for 10 min. After cooling, the mixture was chromatographed on an alumina support to give, initially, decalins and excess acetylene (eluted with hexane) and, subsequently, a deep orange/red band (eluted with 50/50 hexanes/diethyl ether), followed by Fp_2 (trace, eluted with 90/10 diethyl ether/dichloromethane). Examination of the red/orange fraction by tlc indicated that it contained three coloured compounds: (*i*) pale orange (present in low concentration), (*ii*) violet, (*iii*) orange. The initial pale orange fraction was shown to be a mixture of compounds present in low quantities with parent ions of *m/e* 466, 600, 576, and 665, respectively. Further chromatography using the chromatatron separated the violet, (subsequently shown to be [4*H*]-cyclopenta-[*b*]-thiophen-4-one-5-phenyl-6-(4′-methylphenyl), **21***a*), and a second orange cyclopentenone fraction; however, further examination of the orange fraction by ^{1}H nmr indicated it to be an isomeric mixture of **22***a* and **23***a*, thus a further chromatographic separation, using the chromatatron, eluting with hexane, was attempted. This proved to be unsuccessful also. Final product identification of the mixture was made by ^{1}H nmr spectroscopy. Yields of **21***a*, **22***a*, and **23***a* were 6%, 12%, and 11% respectively, based on the acetylene.

21*a* (violet), ^{1}H nmr: 2.33 (s, 3); 7.08 (ad, 2, part of AB system), 7.12 (ad, 1, J_{H-H} = 4.8 Hz); 7.14 (ad, 1, J_{H-H} = 4.8 Hz); 7.17 (ad, 2, *J*~6.6 Hz); 7.34–7.38 (m's, 3); 7.48–7.52 (m's, 2). Mass spectrum: *m/e* (rel. int.) 303 (24.1); 302 (100.0), $M^{+\bullet}$; 301 (27.2); 287 (39.0); 285 (10.0); 273 (10.1); 272 (5.0); 271 (9.0); 269 (10.8); 259 (28.2); 213 (6.1); 143.5 (7.7); 129 (19.3).

22*a*, **23***a* (ratio of isomers 52:48), ^{1}H nmr: 2.36 (s, 3); 2.38 (s, 3); 7.06–7.59 (m's, 22). Mass spectrum: *m/e* (rel. int.): 303 (23.6); 302 (100.0), $M^{+\bullet}$; 301 (29.0); 288 (11.1); 287 (48.9); 286 (13.9); 285 (14.6); 273 (11.9); 269 (14.2); 259 (27.9); 258 (36.9); 239 (9.8); 226 (10.6).

*Reaction of Fp-2-thienoyl, **11**, with bis-*p*-tolylacetylene*

A solution containing Fp-2-thienoyl, **11** (0.5 g, 1.75 mmol), and bis-*p*-tolylacetylene (0.3 g, 1.46 mmol) in decalins (10 mL) was refluxed for 10 min. The solution mixture was examined by tlc, and two major indenone products were apparent (coloured bands with similar R_f values). Following a short precolumn to remove non-soluble and highly polar fractions, the mixture was chromatographed on a neutral alumina column to give the following fractions: (following ferrocene, hexa(*p*-tolyl)benzene, identical with an authentic sample, and Fp-thienyl) (*i*) violet, identified as a mixture of **21***b* and **22***b* (15%); (*ii*) red/orange, identified as **22***b* (16%). Band (*i*) was rechromatographed using the chromatatron to give additional pure 4*H*-cyclopenta[*b*]-thiophen-4-one-5,6-bis(4′-methylphenyl), **21***b* (8%), and additional 6-methyl-2-(4-methylphenyl)-3-(2-thienyl)-[1*H*]-inden-1-one, **22***b* (7%). Compounds **21***b* and **22***b* were subsequently crystallized from hexanes.

21*b* (violet), ^{1}H nmr: 2.33 (s, 3); 2.36 (s, 3); 7.11 (d, 1, J_{H-H} = 4.7 Hz); 7.09 (d, 2); 7.15 (d, 1, *J* = 4.7 Hz); 7.14 (d, 2); 7.15 (d, 2). Mass spectrum: *m/e* (rel. int.) 318 (10.2); 317 (22.3); 316 (100.0), $M^{+\bullet}$; 315 (9.8); 302 (6.4); 301 (25.9); 273 (5.8); 272 (7.2); 271 (7.7) 258 (7.4); 243 (6.1); 226 (5.6).

22*b* (red), ^{1}H nmr: 2.35 (s, 3); 2.37 (s, 3); 7.08 (dd, 1, J_{H-H} = 3.7, 5.1); (7.14) (ad, 2); 7.17 (d, 1) (overlapped); 7.19 (ad, 2); 7.21 (broad s, 1); 7.35 (dd, 1, *J* = 1.1, 3.7); 7.38–7.41 (2m's, 2); 7.44 (dd, 1, *J* = 1.1, 5.1). Mass spectrum: *m/e* (rel. int.) 318 (8.0); 317 (23.6); 316 (100.0), $M^{+\bullet}$; 315 (13.4); 302 (6.2); 301 (29.0); 300 (5.2); 299 (6.2); 287 (6.2); 283 (5.6); 273 (9.9); 272 (9.6); 271 (9.6); 258 (9.6); 239 (5.3); 151 (5.9); 149 (5.5); 136 (11.7); 129 (12.3); 57 (13.9); 41 (12.7); 34 (12.9).

Reaction of Fp-2-thienoyl with 1-naphthyl(phenyl)acetylene

A mixture containing Fp-2-thienoyl, **11** (1.0 g, 3.5 mmol), and 1-naphthyl(phenyl)acetylene (0.5 g, 2.2 mmol) in decalins (15 mL) was refluxed for 10 min. After cooling, the mixture was analyzed using tlc. In addition to several pale yellow bands, three intensely coloured spots, (red/violet, violet and orange) with similar R_f values characteristic of substituted cyclopentadienones, were observed. The mixture was initially chromatographed on a neutral alumina column, eluting initially with hexanes, then increasing the polarity by gradual incremental addition of diethyl ether. The highly coloured fractions (combined crude yield 37%), were collected as a mixture and, following concentration of the solution by vacuum distillation of the solvent at room temperature, were rechromatographed using the chromatatron. The products were eluted with a 5% solution of diethyl ether in hexanes in the following order: (*i*) red/violet, identified as **25** (5%) following concentration and crystallization from hexanes; (*ii*) violet, identified as **26** (13%), on crystallization from hexanes; (*iii*) orange, identified as **27** (19%) on concentration and crystallization from hexanes.

25 (red violet), ^{1}H nmr: δ 7.19 (m's, 7); 7.38 (td, 1); 7.48 (td, 2); 7.53 (td, 1), 7.90 (broad t's, 3). Mass spectrum: *m/e* (rel. int.) 339 (27.2); 338 (100.00), $M^{+\bullet}$; 337, (27.2); 310 (13.3); 309 (25.9); 308 (34.5); 305 (17.8); 276 (15.5); 263 (12.1); 261 (14.0); 260 (12.4); 154 (13.5); 153 (10.4); 28 (13.8). Melting point 143°C.

26 (violet), ^{1}H nmr: 7.14–7.48 (m's, 11); 7.76 (dd, 1), 7.84 (dd, 2). Mass spectrum: 339 (26.2); 338 (100.00), $M^{+\bullet}$; 337 (23.7); 309 (21.5); 308 (24.7); 305 (10.2); 276 (10.8); 168 (10.2); 167 (10.1); 154 (10.5); 149 (29.8); 57 (18.0); 43 (11.7). Melting point 118°C.

27 (orange), ^{1}H nmr: 6.95 (t, 1), 7.29–7.45 (m's, 6); 7.51 (2Xdd's, 2), 7.66 (t, 2); 7.74 (d, 1); 7.89 (2t's, 2). Mass spectrum: *m/e* (rel. int.) 339 (23.5); 338 (100.00), $M^{+\bullet}$; 337 (19.6); 309 (17.0); 308 (21.1); 305 (27.1); 272 (10.8); 276 (18.0); 154 (12.0); 138 (10.3); 57 (50.5); 56 (34.4); 43 (35.9); 42 (17.2); 41 (36.9); 29 (27.3); 27 (14.8). Melting point 166°C.

Reaction of Fp-2-thienoyl with phenyl(2-thienyl)acetylene

A mixture of Fp-2-thienoyl, **11** (1.44 g, 5 mmol), and phenyl(2-thienyl)acetylene (1.84 g, 10 mmol) in decalin (10 mL) was refluxed for 10 min. After cooling, the reaction was filtered through a short (10 cm) alumina precolumn, thereafter the reconstituted mixture was chromatographed using the chromatatron to give the following fractions, in order of elution: (*i*) orange, identified as ferrocene (8%); (*ii*) violet (14%), identified as **29**; (*iii*) violet (trace) (**30**); (*iv*) deep violet (11%), identified following crystallization from hexanes as **31**; (*v*) orange, unidentified, shown to be a mixture of two compounds by tlc, with parent ions at *m/e* 450 and 584 respectively; (*v*) red/brown, Fp_2 (6%); (*vi*) yellow, Fp-2-thienoyl (11%).

29, ^{1}H nmr ($CDCl_3$): 7.01 (dd, 1, J_{H-H} = 3.7, 5.1); 7.21 (dd,

Reaction of Fp-2-thienoyl with bis(trimethylsilyl)acetylene

A mixture of Fp-2- thienoyl (300 mg, 1.04 mmol) and bis(trimethylsilyl)acetylene (1.0 g, 5.88 mmol) was refluxed with decalins (6 mL) for 10 min. The mixture was then chromatographed on a neutral alumina column, eluting initially with hexanes to remove the decalins and unreacted bis(trimethylsilyl)acetylene, followed by the following bands: (*i*) ferrocene; (*ii*) 2-thienylferrocene (16); (*iii*) a mixture containing **32, 33**, and **34** (eluted with diethyl ether); (*iv*) Fp_2. Each of the fractions was initially characterized by mass spectroscopy. The mixed reactions were rechromatographed to give pure samples of **33** and **34**; however, only a trace of impure **32** could be isolated.

32, mass spectrum: parent ion at *m/e* 280.

33 (violet, 26 mg, 17%), ^{1}H nmr: 0.28 (s, 9); 7.02 (d, 1); 7.05 (dd, 1); 7.07 (d, 1); 7.11 (dd, 1); 7.38 (dd, 1). Mass spectrum: *m/e* (rel. int.) 292 (14.4); 291 (22.3); 290 (100.0), $M^{+\bullet}$; 289 (9.0); 277 (12.5); 276 (17.5); 275 (83.0); 268 (14.4); 247 (17.0); 217 (14.0); 216 (18.7); 205 (12.0); 204 (22.6); 203 (16.3); 192 (17.6); 171 (19.3).

34 (orange/red, 11 mg, 7%), ^{1}H nmr: 0.11 (s, 9); 7.02 (d, 1); 7.14 (dd, 1); 7.15 (dd, 1); 7.17 (d, 1); 7.41 (dd, 1). Mass spectrum: *m/e* (rel. int.) 292 (14.8); 291 (23.0); 290 (100.0), $M^{+\bullet}$; 289 (10.2); 278 (19.0); 277 (11.0); 276 (22.0); 275 (74.2); 247 (20.2); 217 (16.6); 216 (18.8); 205 (41.8); 192 (58.6); 191 (31.2).

One other product with parent ion *m/e* 395 was observed but not characterized.

Reaction of Fp-1-naphthoyl with bis-1-naphthylacetylene

Bis-1-naphthylacetylene was prepared from the reaction of naphthyl iodide and acetylene, catalysed by bis(triphenylphosphine)palladium dichloride/copper(I) iodide in diethylamine. The reaction of Fp-1-naphthoyl (1.66 g, 50 mmol) with bis-1-naphthylacetylene (2.78 g, 10.0 mmol) in decalene was carried out according to the general procedure, and the red product chromatographed on neutral alumina to give [1*H*]-[*e*]-benzoinden-1-one 2,3-bis(1-naphthyl) 31%, ^{1}H nmr ($CDCl_3$): δ 6.70–8.10 (series of overlapping multiplets). Mass spectrum: *m/e* (rel. int.) 433 (35.7); 432 (100.0), $M^{+\bullet}$; 431 (12.3); 403 (14.2); 402 (11.1); 400 (16.8); 308 (13.8); 304 (10.4); 276 (17.6); 200 (13.1); 186 (37.6); 177 (11.4); 149 (11.7).

Results and discussion

This investigation is centred on the thermal reactions of dicarbonyl(η^5-cyclopentadienyl)-2-thienoyliron, Fp-2-thienoyl, **11**, with a series of disubstituted acetylenes to compare with the literature results for the similar photochemical reactions. Compound **11** is conveniently prepared in high yield from the metathesis of NaFp with 2-thienoyl chloride in diethyl ether or THF (4, 13). The reactions of **11** with a series of acetylenes were all carried out under an inert atmosphere. However, all subsequent chromatographic steps were carried out aerobically. Although many by-products were obtained in each reaction, we focused on the isolation and characterization of cyclopentenone products.

When Fp-2-thienoyl is reacted with a stoichiometric excess of diphenylacetylene at reflux for 10 min, we observe a number of readily identifiable products such as ferrocene, Fp_2 and 2-thienylferrocene in addition to four unidentified coloured bands. On tlc comparison of these coloured fractions with an authentic sample of [1*H*]-2,3-diphenylinden-1-one, it was established that three of the bands had similar R_f values. Following complete separation by column chromatography, it was established that two of the coloured bands were iron complexes and the other two were isomeric indenone-like products. The latter compounds were positively identified as **14** (violet) and **15** (yellow/orange) by ^{1}H nmr spectroscopy. The identity of **15** was initially established using ^{1}H nmr COSY spectroscopy (Fig. 1*a*). The spectrum of **15** clearly indicates a monosubstituted thienyl ring. The resonances of the thienyl ring protons of **15** are observed as doublets of doublets at 7.09, 7.36, and 7.46 δ, respectively, the low field resonance assigned to the proton which is α to the sulphur atom, and the high field resonance to the proton which is α to the cyclopentalene substituent.

The thienyl ring proton resonances in **14** are observed at 7.13 and 7.18, respectively (Fig. 1*b*). The assignment of structure **14** as opposed to **12** was made on the basis of a spectral comparison with that of 2-thienoyl chloride and phenyl-2-thienyl ketone in which the resonances of the α- and β-thienyl protons are separated considerably, unlike those of **14**. Kolobova *et al.* (4) had reported that **14** is red, in apparent contradiction to our findings here and in contradiction to another documented characterization of the same compound by Ivanov and Mondeshka, who had prepared the compound by the base-catalyzed dehydrative cyclization of 2,3-diphenyl-3-(2′-thienyl)hydroxypropanoic acid (10, 14). It should be noted also that the spectral properties of **12** reported by Kolobova *et al.* are very similar to those reported for **14** by Ivanov and Mondeshka (both compounds dark violet, mp 161–162°C, Ivanov (164–165°C, Kolobova) uv λ_{max}, (e, X10^3): 267 (4.67); 510 (3.10), Ivanov. 261 (25.4); 508 (2.9), Kolobova). It seems fair to conclude that Kolobova and co-workers have misassigned the structures of **12** and **14**. A tlc study of the products derived from photochemical reactions showed that they are identical to those observed in thermal reaction. Our structural results are in agreement with those of Ivanov. The identity of **15** was unequivocally established by us, using X-ray crystallography to corroborate these findings.[2] We decided to probe the reasons for the structural misassignments.

The erroneous literature structural assignments for **12** and **14** had been made partially on the basis of a structural comparison with products obtained from the aluminum trichloride catalyzed reaction of 2-thienoyl chloride with diphenylacetylene. The report documents the formation of several products on a 17 mmol scale from this reaction, including **16** (28%) formed by acetylene dimerization, and indenones **12** (15%) and **14** (19%). In our hands, although we observe two intense coloured spots on tlc corresponding to indenones or their isosteres, we find that the actual indenone yields are very low, due to the formation of

[2]The X-ray structures of **15** and **21b** have been determined **15**: $C_{19}H_{12}OS$, space group $P2_1/n$, cell parameters are as follows: a = 9.532(3), b = 17.096(4), c = 9.577(4), β = 109.54°, V = 1470.8(8) Å^3. **24***b*: $C_{21}H_{16}OS$, space group $P2_1/n$, cell parameters, a = 5.7974(6), b = 19.1044(10), c = 15.0025(15), β = 100.910(9), V = 1631.58(25)-Å^3. Complete crystallographic data will be reported in a forthcoming paper together with that of related derivatives.

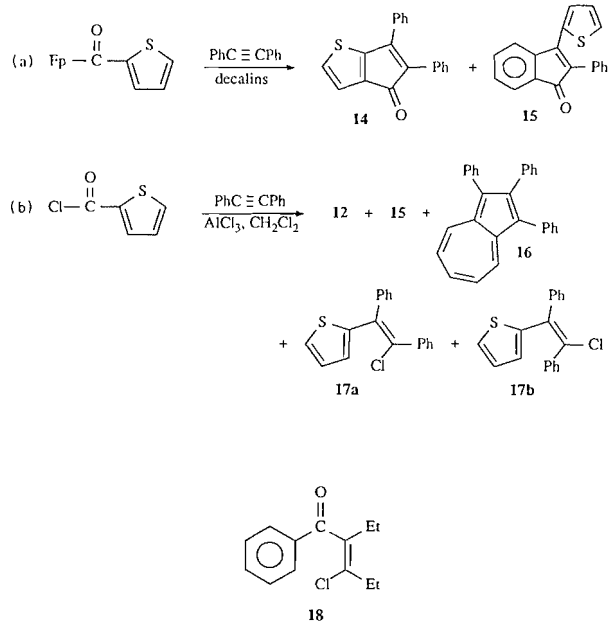
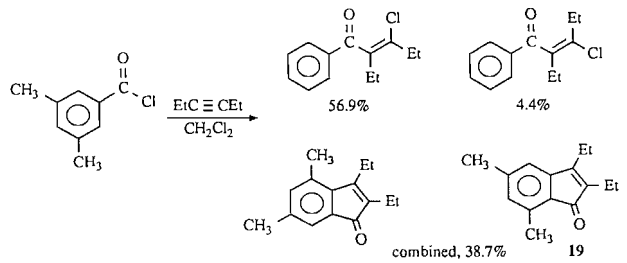
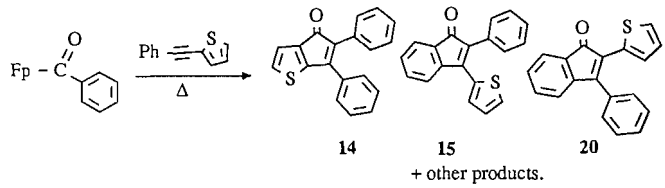


SCHEME 4

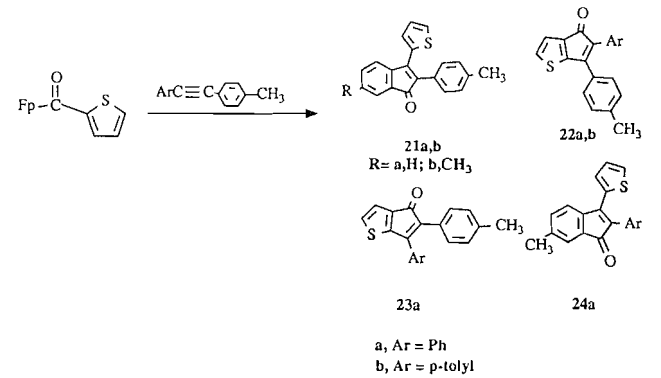


SCHEME 5

large amounts of the colourless **17** (mixture of *cis* and *trans* isomers), which elutes concurrently with the indenone fractions, resulting in mixtures. Attempted isolation of the pure coloured compounds following several chromatographic steps, including preparative plate tlc, was unsuccessful; all samples were contaminated with **17**. However, we were able to identify each of the coloured compounds present by ^{1}H nmr spectral comparison with that of pure samples of **17***a,b* and authentic samples of the indenones (Fig. 1*d*). The orange compound present was identified as **15**, while the violet fraction was identified as **12** (thienyl proton resonances at δ 6.98 (d) and 7.68 (d), respectively, $J_{H-H} = 4.4$ Hz). It should be noted that **14** and **12** are virtually indistinguishable in colour and have identical R_f values on tlc in a range of hexane/diethyl ether mixtures. Our results are in accord with those obtained by Martens and Hoornaert (15), who studied a series of similar reactions, observing, for example, **18** as the major product formed (80%) in the reaction of benzoyl chloride·aluminum trichloride adduct with 3-hexyne. Interestingly, the same authors report the formation of two indenones from the reaction of 3,5-dimethylbenzoyl chloride·aluminum trichloride adduct with 3-hexyne, Scheme 5. To account for the formation of **19**, in which the carbonyl function is no longer *meta* to both methyl groups, they propose a relatively complex mechanism to account for the apparent migration. In the present case, a further complexity is required to account for the formation of **15**, albeit in low yield. This may suggest a similarity between the reaction mechanism, in that the aryl groups are capable of migration with



SCHEME 6



SCHEME 7

respect to the carbonyl group. This result probably warrants an independent mechanistic study of the aluminum trichloride catalyzed reaction. Our conclusion is that, unlike the reactions of benzoyl and naphthoylchlorides with diphenylacetylene in the presence of $AlCl_3$, which give high yields of indenones and benz(*e*)indenones respectively, the reaction of 2-thienoylchloride to give the thienyl isosteres is only of limited applicability.

To further test the proposed mechanism, the reaction of Fpbenzoyl with 2-thienyl(phenyl)acetylene was carried out (Scheme 6). We obtained a mixture of isomeric products including **14**, **15**, and **20**, the latter being the major product (24%), in addition to phenylferrocene and Fp_2. Compound **20** is red, possessing a similar ^{1}H nmr spectrum to that of **15** (Fig. 1*b*), with the exception that the resonances of the *ortho*-disubstituted phenyl group are shifted considerably in comparison (Fig. 1*c*).

The reactions of Fp-2-thienoyl with phenyl(4-methylphenyl) acetylene and bis(4-methylphenyl)acetylene, respectively, were carried out to verify the previous regiochemical results, and, in addition, to examine the electronic effect of substituents. The products obtained were structurally characterized using ^{1}H nmr. Compounds **21***a* and **24***a* were obtained as a mixture, following column chromatography and recrystallization, from the former reaction. Only a trace of the compound assumed to be **22***a* was observed. The results are summarized in Scheme 7. In the latter reaction, only **21***b* and **22***b* are observed with **21***b* predominant. These results are consistent with earlier findings, indicating that preferential metalation takes place in the following order: *p*-tolyl > phenyl > 2-thienyl. The reaction of Fp-2-thienoyl with phenyl(1-naphthyl)acetylene gave three isomeric products as indicated in Scheme 8*a*. In this case the major product is **27**, again consistent with our proposed reaction mechanism. This result contrasts with our previous findings in the case of the reaction of Fp-naphthoyls with diphenylacetylene, in which 1,2-naphthyl disubstituted products predominate (2). In the present case, the formation of products **25** and **28** may be disfavoured because of steric interaction in the reaction intermediate, Fig. 4. The preferred σ alkenyl complex will be the one with a bulky group adjacent to the iron, which at first sight is contrary to normal expectations. However, obviously a secondary influence on the ratio of reaction products will also be the

steric crowding in the resultant σ-alkenyl complex, with maximum significance anticipated near the iron centre. In the present case, since three isomeric products are obtained with traces of a fourth, a balance between these factors and the kinetics of isomerism of individual σ-alkenyl complexes and ring closure steps must exist. In an attempt to test whether a general reaction would be limited to the reactions of acetylenes with at least one non-bulky substituent, we carried out the

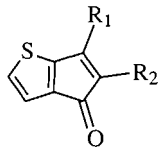
reaction of Fp-1-napthoyl with bis(1-naphthyl)acetylene. The product [1*H*]-[*e*]-benzoinden-1-one-2,3-bis(1-naphthyl) was observed, although heating for 20 min was required. This indicates that the reaction is still possible with relatively bulky groups on the acetylene and on the iron centre (Scheme 8*b*).

Finally, we carried out the reaction of Fp(2-thienoyl) with phenyl(2-thienyl)acetylene in an attempt to prepare analogues containing more than one thienyl group. Two major products were observed, as indicated in Scheme 9. Only a trace of the product assumed to be **31** was observed. The identification of **30** was made on the basis of a spectral comparison with **14**, **22***a*, **22***b*, and **24***a*.

The reaction of Fp-2-thienoyl with bis(trimethylsilyl)acetylene was attempted; however, following work up, only a low yield of the expected cyclopentenone **32** was obtained, in addition to ferrocene, 2-thienylferrocene, **33** and **34**. The latter are presumably formed by a metal-catalyzed exchange of the 2-thienyl group with one trimethylsilyl group. No evidence for the formation of **35** was observed.



32: $R_1 = R_2 = Si(CH_3)_3$
33: R_1 = 2-thienyl; $R_2 = Si(CH_3)_3$
34: $R_1 = Si(CH_3)_3$; R_2 = 2-thienyl
35: $R_1 = R_2$ = 2-thienyl

Figures 1–3 show representative COSY ^1H nmr spectra used in the assignment of structures. The two dimensional technique allows a simple assignment of thienyl resonances in most cases, readily differentiating mono and 1,2-disubstituted thienyl compounds, even when there is considerable resonance overlap. In Fig. 1, the general differences between isomers **14**, **15** and **20**, which may be taken as representative compounds, can be observed. The position of the thienyl proton resonances is indicative of whether it is present in the 2, 3, or disubstituted position of the indenone or thienyl isostere. In light of the use of photoreactive polythienyl compounds as insecticides, there are similar potential applications for these thienyl derivatives, and a programme of screening is underway.

Cyclobutene photochemistry. Substituent and wavelength effects on the photochemical ring opening of monocyclic alkylcyclobutenes[1]

WILLIAM J. LEIGH,[2] KANGCHENG ZHENG,[3] AND K. BRADY CLARK[4]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received March 26, 1990

WILLIAM J. LEIGH, KANGCHENG ZHENG, and K. BRADY CLARK. Can. J. Chem. **68**, 1988 (1990).

The photochemical ring opening of *cis*- and *trans*-3,4-dimethyl-, 1,3,4-trimethyl-, and 1,2,3,4-tetramethylcyclobutene (**1**, **3**, and **4**, respectively) has been investigated in hydrocarbon solution with 193 nm and 214 nm light sources. Ring opening is non-stereospecific in all cases at both wavelengths. The ratio of dienes formed by the formally allowed to formally forbidden pathways in the photolysis of these compounds is highest (ca. 2) for the trimethylcyclobutenes, and approximately 1 for both *cis* and *trans* isomers of the di- and tetramethylcyclobutenes with 193 nm excitation. The diene distributions from photolysis of all compounds but *cis*-**3** show slight wavelength dependence. Gas- and solution-phase UV absorption spectra are reported for **3** and **4**, and indicate that there are at least three singlet excited states accessible in the 185–230 nm region in these molecules. The $\pi,R(3s)$ state is the lowest energy state in the gas phase in **3** and **4**. The results verify that orbital symmetry factors do not play a role (or a consistent one, at least) in controlling the stereochemistry of the reaction, but they do not allow a firm assignment of the excited state(s) responsible for ring opening. Direct photolysis of these compounds also results in fragmentation to yield *Z*-2-butene (from *cis*-**3** and **4**) or *E*-2-butene (from *trans*-**3** and **4**) in addition to propyne or 2-butyne. The 2-butenes are formed with greater than 90% stereospecificity in all cases. The structures of the four 3-methyl-2,4-hexadiene isomers obtained from photolysis of **3** have been assigned on the basis of ^{1}H NMR spectroscopy and the results of thermolysis of the two cyclobutene isomers.

Key words: cyclobutene, photolysis, Rydberg, orbital symmetry, far-UV, solution phase, UV spectra.

WILLIAM J. LEIGH, KANGCHENG ZHENG et K. BRADY CLARK. Can. J. Chem. **68**, 1988 (1990).

Opérant en solution dans les hydrocarbures et utilisant des sources lumineuses de 193 et de 214 nm, on a étudié l'ouverture photochimique du cycle des *cis*- et *trans*-3,4-diméthyl-, 1,3,4- et 1,2,3,4-tétraméthylcyclobutènes (respectivement **1**, **3** et **4**). Dans tous les cas et à toutes les longueurs d'onde, l'ouverture du cycle n'est pas stéréospécifique. Avec une excitation de 193 nm, le rapport des dienes qui se forment par des voies permises/voies interdites est maximal (environ 2) avec les triméthylcyclobutènes alors qu'il est égal à approximativement 1 pour les isomères tant *cis* que *trans* des di- et tétraméthylcyclobutènes. À part le cas du produit *cis*-**3**, la distribution des dienes est insensible à la longueur d'onde. On a déterminé les spectres UV des produits **3** et **4** tant en solution qu'en phase gazeuse; ils indiquent qu'il existe au moins trois états singulets excités accessibles dans la région de 185 à 230 nm de ces molécules. Pour les composés **3** et **4**, en phase gazeuse, l'état $\pi,R(3s)$ possède l'énergie la plus basse. Les résultats confirment que les facteurs de symétrie orbitalaire ne jouent pas un rôle (au moins important) dans le contrôle de la stéréochimie de la réaction; ils ne permettent toutefois pas déterminer avec certitude quel(s) est (sont) le(s) état(s) excité(s) de l'ouverture du cycle. La photolyse directe de ces composés conduit aussi à une fragmentation conduisant au *Z*-2-butène (à partir des composés *cis*-**3** et **4**) ou au *E*-2-butène (à partir des *trans*-**3** et **4**) en plus du propyne ou du 2-butyne. Dans tous les cas, les 2-butènes se forment avec une stéréospécificité supérieure à 90%. Les structures des quatre 3-méthyl-2,4-hexadiènes isomères qui se forment par photolyse du produit **3** ont été attribuées sur la base de leurs spectres RMN du ^{1}H et des résultats de la thermolyse des deux cyclobutènes isomères.

Mots clés : cyclobutène, photolyse, Rydberg, symétrie orbitalaire, UV lointain, solution, spectre UV.

[Traduit par la revue]

Introduction

We have recently reported the initial results of a study of the stereochemistry of the photochemical ring opening of simple alkylcyclobutenes (1). Prior to this study, there existed only one reported example that illustrated the stereochemical course of this reaction in alkylated systems (2), in spite of the fundamental role that the thermal and photochemical interconversions of cyclobutene and butadiene play in pericyclic reaction theory (3). The earlier study indicated that photochemical ring opening proceeds stereospecifically and in disrotatory fashion (2), as the theory predicts (3). The absence of conjugating substituents appears to be a general requisite for ring opening to occur except in rather special systems. Thus, while arylcyclobutenes do not undergo ring opening upon photolysis (4), benzocyclobutenes have been reported to do so non-stereospecifically (5) and Dewar aromatics open adiabatically (6). The photochemical ring opening of cyclobutene itself in solution has been reported by Adam *et al.* (7).

Photolysis of *cis*- and *trans*-3,4-dimethylcyclobutene (*cis*- and *trans*-**1**, respectively) in hydrocarbon solution with 185 nm light (at low conversions and under monochromatic conditions, where only the cyclobutene absorbs the light) leads in both cases to mixtures of all three geometric isomers of 2,4-hexadiene (eq. [1]) (1). The two isomers afford different mixtures of the 2,4-hexadienes, in both cases weighted in favour of the formally forbidden isomers that would be formed by the conrotatory ring-opening pathway. Similarly, 185 nm photolysis of bicyclo-[4.2.0]oct-6-ene yields *cis,cis*- and *cis,trans*-1,3-cyclooctadiene in a ratio of 3:1 (1). An earlier study reported similar results for this compound, but the formation of the *cis,trans* isomer was attributed to secondary diene photolysis by the long-wavelength component of the low pressure Hg lamp that was used as the light source (8). Since our initial study

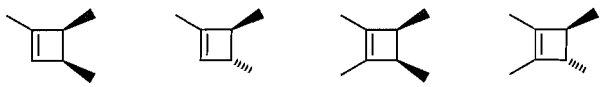
[1] 
was published, an additional report that illustrates the non-stereospecificity of the process in simple systems has appeared (9).

We now wish to report the results of 193 and 214 nm photolysis of *cis*- and *trans*-1,3,4-trimethylcyclobutene (*cis*-**3** and *trans*-**3**, respectively) and *cis*- and *trans*-1,2,3,4-tetramethylcyclobutene (*cis*-**4** and *trans*-**4**, respectively) in hydrocarbon solution, and the results of 193 nm photolysis of *cis*- and *trans*-**1** under similar conditions. The present study was



undertaken to obtain additional examples that might illustrate the generality of the process, and investigate the possibility that the non-stereospecificity of the reaction may result from participation of *two* excited states (the π,π^* and $\pi,R(3s)$ Rydberg states) in solution. Rydberg state involvement in alkene photochemistry has been postulated in order to account for the high yields of carbene-derived products that are commonly observed upon photolysis of alkenes in solution (10).[5] The yields of such products are known to increase (at the expense of π,π^*-derived products) with the extent of alkyl substitution at the double bond. There is a similar substituent effect on the relative energies of the π,π^* and $\pi,R(3s)$ states in alkenes, as determined by gas-phase UV absorption (12) and fluorescence emission spectroscopy (13), and the $\pi,R(3s)$ state is the lowest energy state in tri- and tetrasubstituted alkenes (12, 14). We have recently reported evidence for carbene involvement in cyclobutene photochemistry (15). Although we were unable to quantify the extent of carbene involvement in those cases, the results suggest that the $\pi,R(3s)$ state does contribute to the photochemistry of alkylcyclobutenes, as it does in the case of simpler alkenes. Compounds **3** and **4** were chosen for the present study to provide a series of compounds in which the relative π,π^* and $\pi,R(3s)$ state energies might vary systematically, assuming that substituent effects on the excited state manifold in alkylcyclobutenes parallel those known for simple alkenes.

Results

Cyclobutenes **3** and **4** were synthesized as mixtures of *cis* and *trans* isomers by the route shown in eq. [2] (1, 16, 17). The isomeric cyclobutenes were separated and each was purified to >99.9% purity by semi-preparative vapour-phase chromatography (vpc). The preparation of *cis*- and *trans*-**4** by a different

[2] 
route has been reported previously (18*a*–*c*), while *cis*- and *trans*-**3** are evidently new compounds. The *cis* isomers of **3** and **4** were also prepared stereospecifically by routes analogous to that reported for *cis*-**1** by Brauman and Archie (18*g*).

The *cis* and *trans* isomers of all three cyclobutenes in the series **1**, **3**, and **4** can be differentiated on the basis of their UV absorption (*vide infra*) and ^{1}H NMR spectra. In the ^{1}H NMR spectra of the *trans* isomers, the doublet due to the C_3/C_4 methyl groups is situated at lower field than that in the spectrum of the corresponding *cis* isomer by 0.1–0.2 ppm. Furthermore, the quartet due to the C_3/C_4 protons is situated at ca. 0.6 ppm higher field in the *trans* compared to the *cis* isomers.

Ultraviolet absorption spectra of the *cis* and *trans* isomers of **1**, **3**, and **4** were recorded in deoxygenated pentane solution and are shown as plots of molar extinction coefficient (ϵ) versus wavelength in Fig. 1. Qualitative gas-phase (ca. 2 Torr; 1 Torr = 133.3 Pa) UV absorption spectra were also recorded for **3** and **4**, and are shown along with the solution phase spectra in Fig. 1.

Photolysis of deoxygenated, 0.02 M pentane solutions of **3** and **4** with the unfocussed pulses from an Ar/F_2 excimer laser (193 nm; ca. 20 mJ/pulse) produced mixtures of the isomeric 3-methyl-2,4-hexadienes (**5**; from *cis*- and *trans*-**3**) or 3,4-dimethyl-2,4-hexadienes (**6**; from *cis*- and *trans*-**4**), along with fragmentation products, as shown in eqs. [3] and [4]. The dienes were identified in each case by coinjection of photolysates taken

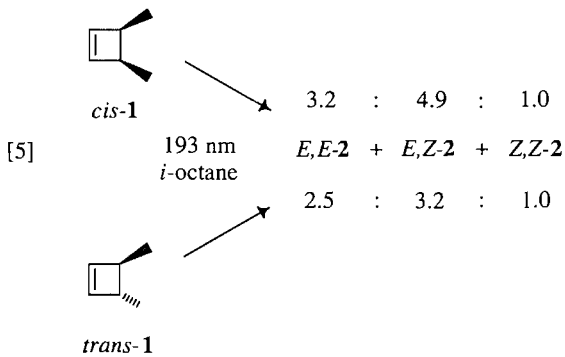
to ca. 10% conversion with authentic samples of each of the pure materials. In the photolyses of *cis*-**3**, *trans*-**3**, and *cis*-**4**, the isomeric dienes accounted for 93–97% of the detectable products of similar volatility to the starting materials. Photolysis of *trans*-**4** gave four additional products that could not be identified. One of these was formed in ca. 6% yield, while the rest were formed in yields of 4% or less. In this case, the dienes **6** accounted for ca. 84% of the product mixture.

The C_3- and C_4-hydrocarbon products were identified after photolysis (214 nm) of 0.06 M isooctane solutions of **3** and **4**, by VPC spiking experiments with authentic samples. It was determined that the 2-butenes are formed with at least 90% stereospecificity in all cases (i.e., *Z*-2-butene from *cis*-**3** and **4**; *E*-2-butene from *trans*-**3** and **4**). The yields of these products were not determined.

The various isomers of **5** were identified on the basis of ^{1}H NMR spectroscopy (19) and the results of gas-phase thermolysis of *cis*- and *trans*-**3** at 180°C. The latter results are shown in Table 1. The high degree of stereospecificity associated with the thermal ring opening of monocyclic cyclobutenes is well established (3, 18). Thermolysis of *trans*-**3** affords only one of the isomers of **5** as the major product, that with vicinal vinylic (H4–H5) coupling of 15.5 Hz in its ^{1}H NMR spectrum and which can thus be identified as *E,E*-**5** (19). Thermolysis of *cis*-**3** affords two different isomers in highest yield (Table 1), one with H4–H5 coupling of 15.4 Hz and one with H4–H5 coupling of 11.7 Hz. These can be identified as *Z,E*- and *E,Z*-**5**, respectively. The remaining isomer, formed as a minor product in the thermolyses of both *cis*- and *trans*-**3**, exhibits vicinal vinylic coupling of 11.4 Hz and can thus be identified as *Z,Z*-**5**.

The relative yields of isomeric dienes from photolysis of **3** and **4** were determined from the slopes of plots of concentration versus excitation dose (number of pulses), constructed from runs monitored between 0.5 and ca. 5% conversion. Figure 2 shows examples of such plots for photolysis of *cis*- and *trans*-**3** with 193 nm light. The yields of the fragmentation products were not determined. They were shown to be *E*- or *Z*-2-butene and propyne (from **3**) or 2-butyne (from **4**) by GC/MS analysis (see experimental section).

Photolyses of 0.02 M isooctane solution of *cis*- and *trans*-**1** were carried out under similar conditions with the 193 nm laser, and afforded *E,E*-, *E,Z*-, and *Z,Z*-**2** in the relative yields shown in eq. [5].



[5]

Compounds **3** and **4** were also photolysed as deoxygenated 0.1 M (**3**) or 0.06 M (**4**) pentane solutions with a Zn resonance lamp (214 nm), and relative isomeric diene yields were determined in similar fashion to the 193 nm runs. Examples of such plots for the 214 nm photolyses of *cis*- and *trans*-**3** are shown in Fig. 3. In these experiments, the accuracy of the VPC integrations for *E,Z*- and *Z,Z*-**5** at low conversions are considerably lower than those for the other two diene isomers, because they elute on the tail of the solvent and (or) cyclobutene. Thus, the yields of these two isomers of **5** in the 214 nm photolyses have been calculated from the slopes of the concentration vs. time plots in the 2.5–4% conversion range. The yields of minor, unidentified products were similar in each case to those obtained from 193 nm photolysis (*vide supra*). Tables 2 and 3 list the relative diene yields from photolysis of **3** and **4**,

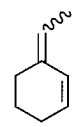
respectively, with the 193 nm and 214 nm light sources. The yields listed in Tables 2 and 3 were calculated from the slopes of the concentration vs. time plots, and normalized to a total of 100%.

The 214 nm photolyses of *cis*- and *trans*-**3** were carried out under nearly identical conditions, so the differences in the slopes of the concentration vs. time plots (Fig. 3) are representative of differences in the quantum yields for diene formation in these cases.

Control experiments were carried out to ensure that the relative product yields reported in Tables 2 and 3 correspond to primary photolysis yields, and suffer no distortion due to secondary photolysis of the dienes (1, 20). To this end, we have photolysed solutions of **3** and **4** containing small amounts of an additional photolabile diene as a control compound, and examined the photolysate after ca. 4% conversion for isomerization of the diene. In this work, 3-ethylidenecyclohexene (**7**) was chosen as the control diene because its VPC retention time under our conditions is much different than those of the various isomers of **3**–**6**. In a typical experiment, a deoxygenated



7

pentane solution containing *cis*-**3** (0.10 M) and a mixture of *E*- and *Z*-**7** (enriched in one of the isomers; 0.002 M) was irradiated with the 214 nm light source. Analysis of the photolysate up to ca. 4% conversion of *cis*-**3** showed there to be a change of less than 5% in the relative amounts of *E*- and *Z*-**7** present. The photostationary state for photolysis of **7** alone under similar conditions is $E\text{-}7/Z\text{-}7 \approx 1.0$. Analogous results were obtained from similar experiments carried out for the 214 nm irradiations of *trans*-**3** and *cis*-**4**, and for the 193 nm irradiation of *cis*-**3**.

Toluene-sensitized photolysis of *cis*-**4** was carried out to determine whether the triplet state of the cyclobutene contributes to ring opening. After ca. 15% conversion of *cis*-**4**, VPC analysis of the photolysate showed the presence of one new (unidentified) product that is not formed in the direct photolysis of *cis*-**4**; none of the isomers of **6** could be detected in the photolysate within the sensitivity limits of our VPC method.

Discussion

UV absorption spectroscopy

The solution-phase UV absorption spectra of **1**, **3**, and **4**

exhibit minor differences throughout the series, the main general feature being that in all three sets of compounds, the prominent bands in the spectra of the *trans* isomers are broader and more diffuse than those of the *cis* isomers. The source of this relative broadening in the spectra of the *trans* isomers can be better understood, at least qualitatively, from consideration of the gas-phase spectra of **3** and **4**. The gas-phase spectra show regular variations with the stereochemistry at the 3,4 positions, which are washed out in the solution-phase spectra due to broadening of the individual vibronic transitions.

The gas-phase spectra of *cis*- and *trans*-**3** (Fig. 1c,d) consist of at least two absorption bands in the 185–220 nm region. The spectrum of *cis*-**3** is similar to that of 1-methylcyclobutene (**8**) (21). The relatively weak, long-wavelength band (λ_{max} = 209 nm) observed in both spectra can be assigned to $\pi,R(3s)$ absorption (12, 14), by analogy with Robin's assignment of a similarly placed band in the spectrum of **8** (14). This band is reduced in intensity in the solution-phase spectra of *cis*- and *trans*-**3**, consistent with the Rydberg assignment. On the basis of the spectra of *cis*- and *trans*-**4** (*vide infra*), we assign the absorption in the 185–205 nm region as due to overlapping transitions to two electronic states, one centred below 185 nm and the other at 193–200 nm. In the solution-phase spectra, all vibrational fine structure is lost, and the intensity of the longer wavelength (193–200 nm) component seems to be reduced compared to the gas-phase spectra. The reduction in absorption intensity in the condensed phase is consistent with a Rydberg assignment for this band, perhaps $\pi,R(3p)$ (12, 14). The shorter wavelength band should be assigned to π,π^* absorption, by analogy with the spectra of simple alkenes (12, 14). The relative extinction coefficients of the $\pi,R(3s)$ and $\pi,R(3p)$ absorptions are approximately equal in the spectra of *cis*- and *trans*-**3**, while the extinction coefficient of the highest energy transition (relative to those of the lower energy bands) is much higher in *cis*-**3** than it is in the *trans* isomer.

The gas-phase spectra of *cis*- and *trans*-**4** show similar trends to those of the corresponding isomers of **3**, except the various absorptions are better separated and much richer in vibrational fine structure. The three weak bands centred at 214, 221, and 228 nm can be assigned to the $\pi,R(3s)$ progression. The appearance of these three bands, with a separation of ca. 1400 cm^{-1}, is a general feature in the gas-phase spectra of tetraalkyl ethylenes (14). The spectrum of *trans*-**4** clearly demonstrates two additional absorptions at shorter wavelengths. The two bands centred at 203 nm (separation $\approx$ 1000 cm^{-1}), occurring on the rising edge of the higher energy absorption band(s) at wavelengths less than 195 nm, can be assigned to $\pi,R(3p)$ absorption based on their considerably reduced intensity in the solution-phase spectra. In the spectrum of *cis*-**4**, we identify the $\pi,R(3p)$ absorptions as the two vibronic bands at 201 nm and 206 nm; i.e., at the same positions as the two more prominent bands in the spectrum of the *trans* isomer. The shift of both Rydberg bands to longer wavelengths with increasing alkyl substitution at the C=C bond follows the trends observed in simpler alkenes (14). As is the case for **3**, the relative intensities of these two absorptions are similar in the two isomers of **4**, and the high energy absorption (<195 nm) is relatively much stronger in *cis*-**4** than in the *trans* isomer. The high energy (<195 nm) band can be assigned to π,π^* absorption, and is again comparatively more intense in *cis*-**4** than in the *trans* isomer.

It is interesting to note that the two long-wavelength Rydberg progressions in the spectra of *cis*- and (in particular) *trans*-**4** appear to be retained in the solution-phase spectra, although they are shifted somewhat to shorter wavelengths, reduced in intensity relative to the short-wavelength absorptions, and devoid of fine structure. These characteristics are precisely those of Rydberg absorptions, though evidently much less dramatic than should be expected for "pure" Rydberg transitions (12, 14). The fact that these bands are observable in the solution-phase spectra may indicate that the Rydberg transitions are substantially mixed with valence transitions (22). Thus, the valence components are responsible for the sizeable oscillator strengths of these bands in the solution spectra. These components may involve the σ-manifold; Robin has noted that the σ,π^* transition is of fairly low energy in small-ring cycloalkenes (12).

While we are thus unable to completely assign the solution-phase spectra of **3** and **4** with certainty, it is clear that at least *three* singlet excited states are accessible in these compounds upon direct absorption of light in the 185–220 nm region. Based on previous work (12, 14), two of these are presumably assignable to the π,π^* and σ,π^* states, with the latter being the lowest energy (vertical) state in *cis*- and *trans*-**4**.

*Solution-phase photochemistry of **1**, **3**, and **4***

Photolysis of **3** and **4** results in non-stereospecific ring opening, in competition with stereospecific, formal $\sigma_{2s} + \sigma_{2s}$ cycloreversion. The relative contribution of the latter process to overall product yield has not been quantified in the present study. As a general observation, *cis* and *trans* isomers afford different mixtures of isomeric dienes in each case, so the product distributions are not governed by the relative thermodynamic stabilities of the various diene isomers. In the case of **6**, the distribution of the three isomers at 90°C (in HMPA) has recently been reported to be $(E,E):(E,Z):(Z,Z) \approx (1.0):(0.23):(0.21)$ (23), clearly a much different distribution than those obtained from photolysis of **4**, even allowing for the differences in temperature and solvent.

A potential problem of particular significance in studies of this type is the lability of **5** and **6** towards direct photoisomerization (20). Thus, it is particularly important to rule out secondary diene photolysis as a contributor to the apparent non-stereospecificity with which **3** and **4** undergo photochemical ring opening (1). Such problems can be minimized by working with solutions of high optical density at the excitation wavelength, and monitoring the progress of the photolyses at very low conversions, as has been done in the present study. A particularly valuable control experiment to examine secondary diene photolysis involves including a small amount of an additional photolabile diene (such as **7**) in the photolysis mixtures, and monitoring its direct photoisomerization along with the formation of products from cyclobutene photolysis. Control experiments of this type have been carried out for the 193 and 214 nm photolyses of *cis*- and *trans*-**3** and the 214 nm photolysis of *trans*-**4**, and demonstrate that secondary diene photolysis does not contribute significantly to the observed diene distributions from **3** and **4** in any case.

We have previously considered three possible reasons for the non-stereospecificity of the photochemical ring opening of cyclobutenes (1): (i) adiabatic (disrotatory) π,π^*-state ring opening to yield diene(s) in the first excited singlet state; (ii) competitive ring opening from two or more excited states (e.g., π,π^* and $\pi,R(3s)$); and (iii) competitive ring opening from both excited and vibrationally excited ground state surfaces, the latter formed via internal conversion from the excited state. Of

TABLE 4. Substituent and wavelength dependence on the "allowed/forbidden" ratios from far-UV photolysis of alkylcyclobutenes in hydrocarbon solution at 23°C[a]

λ (nm)	*cis*-**1**	*trans*-**1**	*cis*-**3**	*trans*-**3**	*cis*-**4**	*trans*-**4**
193	0.9	0.9	2.0	2.1	1.2	1.1
214	—	—	2.1	2.1	0.6	1.0

[a]Ratio of the yields of formally allowed to formally forbidden diene isomers; e.g., (*E,E*-**5** + *Z,Z*-**5**)/(*E,Z*-**5** + *Z,E*-**5**) or the inverse. Errors are ca. ±10%.

course, a fourth possibility is that excited-state ring opening (from any state) is simply not controlled by orbital symmetry factors. Previously, we ruled out the first possibility (in general) on the basis of the diene distributions from photolysis of *cis*- and *trans*-**1** with 185 nm light; the fact that *both* cyclobutene isomers give diene mixtures weighted in favour of the formally forbidden isomers is incompatible with such a mechanism as the exclusive one for their formation (1). Table 4 summarizes the relative yields of isomeric dienes from **1**, **3**, and **4** as the ratios of formally allowed to formally forbidden diene isomers formed from each compound at the different excitation wavelengths, from which it can be seen that the 193 nm photolyses of *cis*- and *trans*-**3** and **4** all afford diene mixtures weighted in favour of the formally allowed isomers. Thus, the behaviour of these derivatives *is* consistent with partial ring opening by the adiabatic pathway. Of the compounds that we have studied to date, only **1** yields diene mixtures that are incompatible with this mechanism.

The second possibility, and the one that we set about to study in the present work, is that ring opening ensues from *two* (or more) excited states in solution. In favourable circumstances, one would expect that competitive ring opening from two or more excited states should be revealed in the form of a regular trend in the isomeric diene distributions as the separation between the excited states involved is varied through substitution (24). It is well known that the (π,π^*)–$(\pi,R(3s))$ state separation in alkenes can be altered through alkyl substitution at the double bond (10, 14) and, from the spectroscopic results presented earlier for **3** and **4**, it is clear that the same is true in alkylcyclobutenes. Thus, if both these states are involved in ring opening, one should expect an increase in the Rydberg component in *cis*- and *trans*-**4** compared to **3**. With 193 nm excitation, *cis*- and *trans*-**3** both give diene mixtures weighted in favour of the isomers corresponding to formal ring opening by the allowed disrotatory pathway, while from *cis*- and *trans*-**4**, only a slight preference for the allowed products is observed. The product ratios from *cis*- and *trans*-**1** are weighted in favour of the forbidden isomers. Thus, the present results show no evidence for a regular variation in diene distribution (formally allowed vs. formally forbidden) that might be linked to the variation in the (π,π^*)–$(\pi,R(3s))$ state separation that accompanies increasing alkyl substitution at the C=C bond, at least when the results are analysed in this way. It should be recognized, though, that the trend in diene distribution with substituent that is expected according to this mechanism will only be (easily) discernible if reaction from the Rydberg state is either completely stereospecific or completely random. This, of course, may not be the case.

The diene distributions obtained from photolysis of all these compounds except *cis*-**3** are altered slightly by variation of the excitation wavelength. Again, however, no consistent trend is evident in the data. When the diene distributions are analysed according to orbital symmetry selection rules, it can be seen that only *cis*-**4** shows a change in the ratio of formally allowed to formally forbidden dienes. The fact that wavelength dependence is observed in the diene distributions from photolysis of these compounds is consistent with ring opening ensuing from either two (or more) competing excited states or from both the excited state and vibrationally activated ground state surfaces. The absence of diene products in the toluene-sensitized photolysis of *cis*-**4** verifies (16*f*) that the triplet state is not involved in ring opening. If more than one singlet excited state is involved in the reaction, then the absence of a trend in the formally allowed/forbidden diene distributions with substituent (at a single wavelength) indicates at least that orbital symmetry factors do not play a *consistent* role in the photochemical ring opening of simple cyclobutenes. In this regard, it is interesting to note that the nonsymmetric cyclobutene derivatives *cis*- and *trans*-**3** both afford higher yields of the formally allowed diene isomers than do **1** and **4**, which possess a high degree of *molecular* symmetry.

The present study underlines the fact that the non-stereospecificity observed previously for the photochemical ring opening of simple cyclobutenes is quite general. However, it does not allow firm conclusions to be made regarding the reasons for this behaviour. The observation of slight wavelength dependence in the distribution of isomeric dienes from the reaction suggests that two or more excited states may contribute to ring opening in simple systems, but other possibilities could also be consistent with this result. Further mechanistic studies of this reaction, a central issue in photochemical pericyclic reaction theory, are in progress.

Experimental

^{1}H NMR spectra were recorded on Varian EM390 (90 MHz) or Bruker AM500 (500 MHz) spectrometers in carbon tetrachloride (or deuteriochloroform where noted) and ^{13}C NMR spectra were recorded at 125.6 MHz on the Bruker AM500; all are reported in parts per million downfield from tetramethylsilane. Infrared spectra were recorded on a Perkin–Elmer 283 spectrometer in carbon tetrachloride solution or as the neat liquids (where noted); spectra are reported in wavenumbers, calibrated using the 1601.9 cm^{-1} polystyrene absorption. Mass spectra were recorded on a VG7070 mass spectrometer interfaced with a Varian 3700 gas chromatograph, equipped with a 30 m × 0.25 mm DB-1 fused silica capillary column (Chromatographic Specialties, Inc.). Exact masses were determined on a VGH ZABE mass spectrometer, and employed a mass of 12.000000 for carbon.

Ultraviolet absorption spectra were recorded using a Perkin–Elmer Lambda 9 spectrometer equipped with a model 3600 data station. The spectrometer sample compartment was continuously flushed with nitrogen. Spectra were recorded in 1-cm Suprasil UV cells (Hellma) that were fitted with a stopcock for gas phase spectra. For solution-phase spectra, the sample and reference solutions were deoxygenated with argon prior to recording the spectrum. Gas-phase spectra were recorded in single beam mode, after recording the spectrum of the empty, evacuated (to 30 mTorr) cell for background correction. Samples of the cyclobutene were introduced into the cell from a cold finger attached to a high vacuum line, and the system pressure was measured with a Varian 801 vacuum gauge.

Analytical VPC separations were carried out using a Hewlett–Packard 5890 gas chromatograph (injector temperature = 120°C) equipped with a flame ionization detector, a Hewlett–Packard HP-3396 recording integrator, and a 1.0-μm SPB-1 wide-bore capillary column (30 m × 0.75 mm i.d. borosilicate; Supelco, Inc.). The detector response was not calibrated.

Semi-preparative VPC separations employed a Hewlett–Packard 5750B gas chromatograph equipped with a thermal conductivity detector (detector temperature = 120°C) and one of the following

stainless steel columns: (a) 3.8% UC W982 on 80/100 Supelcoport (24 ft × 1/4 in.); or (b) 20% oxybis(dipropionitrile) (ODPN) on Chromosorb 80/100 PNAW (20 ft × 1/4 in.).

n-Pentane and 2,2,4-trimethylpentane (isooctane) were Baker Photrex grade and used as received from the supplier, as were toluene (Fisher Reagent) and citraconic anhydride, maleic anhydride, 2-aminopyridine, propionic anhydride, acetophenone, lead tetraacetate, triphenylphosphine, 4-vinylcyclohexene, and potassium *tert*-butoxide, all from Aldrich Chemical Co. 2-Butene (mixture of isomers) was used as received from Canada Liquid Air, Inc. for synthetic purposes. *Cis*- and *trans*-2-butene and propyne were used for VPC analyses as received from Canada Liquid Air, Inc. 2-Butyne for VPC spiking experiments was part of a calibrated mixture of C_2–C_4 alkynes (Scott, Inc.). Cyclobutenes *cis*- and *trans*-**1** were synthesized as part of our earlier study (1). *E* and *Z*-ethylidenecyclohexene (**7**) were synthesized as a mixture according to the published procedure (25). The mixture was enriched in one of the isomers by semi-preparative VPC (column (a)), and exhibited a ^{1}H NMR spectrum that agreed satisfactorily with that previously reported (25).

Synthetic photolyses employed a Hanovia 450-W medium pressure mercury lamp with quartz or Pyrex immersion wells (Ace Glass, Inc.), or a Rayonet photochemical reactor fitted with 12 253.7-nm lamps and a merry-go-round apparatus.

Preparation of compounds

Cis- and *trans*-1,3,4-trimethylcyclobutene (*cis*- and *trans*-**3**) and *cis* and *trans*-1,2,3,4-tetramethylcyclobutene (*cis*- and *trans*-**4**) were prepared by routes similar to those published previously for related methylated cyclobutenes (1, 15), starting with the acetophenone-sensitized photocycloadditions of citraconic anhydride or dimethylmaleic anhydride (prepared by the method of Baumann and Bossard (26)) with 2-butene (17), followed by hydrolysis of the bicyclic anhydrides and bisdecarboxylation of the resulting dicarboxylic acids with lead tetraacetate (27). In both syntheses, the two cyclobutene isomers were obtained in similar yields. They were separated and repeatedly purified by semi-preparative VPC using a combination of columns (a) and (b). Analytical VPC analysis showed them to be of >99.90% purity in every case. They had the following spectral characteristics:

trans-*1,3,4-Trimethylcyclobutene* (trans-*7*): IR (neat): 3030 (m), 2949 (s), 2920 (m), 2880 (m), 2860 (m), 1638 (w), 1449 (m), 1368 (m), 1347 (w), 1299 (m), 1268 (w), 1025 (w), 1000 (w), 970 (w), 811 (m), 778 (w), 572 (w); ^{1}H NMR, δ: 1.05 (d, 6H), 1.62 (br s, 3H), 2.05 (br q, 2H), 5.66 (br s, 1H); MS (*m/e* (I)): 96 (40), 81 (100), 79 (45), 77 (18), 67 (30), 65 (20), 63 (17), 53 (54), 41 (72). Exact Mass calcd. for C_7H_{12}: 96.0960; found: 96.0922.

cis-*1,3,4-Trimethylcyclobutene* (cis-*3*): IR (neat): 3038 (s), 2956 (s), 2933 (s), 2886 (s), 2716 (w), 1641 (s), 1616 (w), 1466 (m), 1442 (s), 1376 (s), 1329 (m), 1316 (m), 1273 (m), 1193 (w), 1091 (m), 1039 (m), 806 (s), 631 (w), 601 (m); ^{1}H NMR, δ: 0.90 (d, 6H), 1.55 (br s, 3H), 2.66 (m, 2H), 5.64 (br s, 1H); MS (*m/e* (I)): 96 (27), 95 (4), 81 (100), 79 (18), 77 (7), 67 (16), 56 (10), 57 (18), 53 (26), 41 (38), 39 (23).

trans-*1,2,3,4-Tetramethylcyclobutene* (trans-*4*): IR (neat): 2952 (s), 2924 (s), 2912 (s), 2874 (s), 1692 (w), 1447 (s), 1367 (m), 1337 (w), 1299 (m), 1279 (w), 1202 (w), 1124 (m), 1068 (w), 1021 (w), 995 (w), 962 (w); ^{1}H NMR, δ: 0.99 (d, 6H), 1.53 (s, 6H), 1.93 (q, 2H); MS (*m/e* (I)): 110 (52), 95 (100), 81 (15), 77 (10), 67 (50), 55 (45), 53 (21), 51 (8), 41 (34). Exact Mass calcd. for C_8H_{14}: 110.1120; found: 110.1102.

cis-*1,2,3,4-Tetramethylcyclobutene* (cis-*4*): IR (neat): 2953 (s), 2929 (s), 2906 (s), 2866 (s), 1688 (w), 1461 (m), 1435 (s), 1374 (s), 1326 (w), 1316 (m), 1289 (m), 1211 (w), 1133 (m), 1096 (m), 1024 (m), 996 (m), 976 (w), 658 (m), 628 (m); ^{1}H NMR, δ: 0.90 (d, 6H), 1.48 (s, 6H), 2.58 (br q, 2H); MS (*m/e* (I)): 110 (37), 109 (3), 95 (100), 91 (5), 81 (14), 79 (9), 77 (7), 67 (48), 56 (14), 55 (37), 53 (18), 51 (7), 41 (29), 39 (20).

3-Methyl-2,4-hexadienes (Z,Z-, Z,E-, E,Z-, *and* E,E-*5*) (19)

Authentic samples of *Z,E*-**5** and *E,E*-**5** as a mixture of isomers were prepared by iodine-catalysed dehydration of *E*-4-hexen-3-ol, which was synthesized by 1,2-addition of ethyllithium to *E*-3-penten-2-one (28). A mixture of lithium (1.5 g, 0.21 g-atom) and bromoethane (13 g, 0.12 mol) was refluxed in anhydrous ether (30 mL) for 0.5 h. A solution of *E*-3-penten-2-one (2.5 g, 0.03 mol; prepared by the method of House *et al.* (28)) in anhydrous ether (10 mL) was then added dropwise over 0.5 h, with vigorous stirring and cooling to 1–5°C. Stirring was continued for a further 4 h at 5°C. Ice water (20 mL) was added, and the resulting mixture was acidified with 5% hydrochloric acid (10 mL) and then stirred for 0.5 h at room temperature. The ether layer was separated, and the aqueous fraction remaining was extracted with ether (2 × 10 mL). The combined ether fractions were washed with saturated bicarbonate, dried over anhydrous sodium sulfate, and filtered. The solvent was removed on the rotary evaporator to yield a slightly yellow oil (2.3 g, 75%); the major component of this product was identified as *E*-4-hexen-3-ol on the basis of its ^{1}H NMR spectrum (δ(CCl_4): 0.84 (t, 3H), 1.17 (s, 3H), 1.43 (q, 2H), 1.67 (d, 3H), 2.63 (br, 1H), 5.46 (s, 1H), 5.49 (q, 1H).

The crude alkenol from above was combined with propionic anhydride (10 mL) and a crystal of iodine in a 25-mL round-bottom flask fitted with a reflux condenser and magnetic stirrer (29). After the initial frothing had subsided, the mixture was stirred at 130°C for 1 h. After cooling to room temperature, the mixture was poured into ether (30 mL) and the solution was washed with saturated aqueous bicarbonate (3 × 40 mL) and water (2 × 20 mL), and then dried over anhydrous sodium sulfate. The bulk of the solvent was removed by careful distillation, and the resulting liquid was then bulb-to-bulb distilled with gentle heating under vacuum. VPC analysis of the distillate (1.2 g) showed it to consist predominantly of ether, *Z,E*-**5** (*vide infra*), and *E,E*-**5** in a ratio of ca. 3:2:4. Pure samples of the two isomeric dienes were isolated by semi-preparative VPC (column (b)) and had the following spectral characteristics:

Z,E-*3-Methyl-2,4-hexadiene* (Z,E-*5*): IR: 3040 (m), 3000 (m), 2968 (s), 2920 (s), 2882 (m), 2860 (m), 1652 (w), 1540 (w), 1449 (s), 1380 (m), 1110 (w), 1070 (w), 1035 (w), 960 (s), 922 (m), 828 (w), 770 (w); ^{1}H NMR, δ: 1.69 (d, *J* = 7.0 Hz, 3H), 1.74 (br s, 3H), 1.80 (d, *J* = 6.6 Hz, 3H), 5.22 (q, *J* = 7.0 Hz, 1H), 5.59 (dq, *J* = 15.4, 6.6 Hz, 1H), 6.36 (d, *J* = 15.4 Hz, 1H); MS (*m/e* (I)): 96 (25), 81 (62), 79 (15), 77 (6), 67 (12), 55 (12), 53 (17), 44 (73), 41 (20), 39 (17).

E,E-*3-Methyl-2,4-hexadiene* (E,E-*5*): IR: 3036 (s), 2998 (m), 2958 (s), 2918 (s), 2878 (m), 2858 (s), 1629 (m), 1518 (w), 1446 (s), 1379 (m), 1108 (w), 1078 (w), 1059 (w), 1022 (m), 960 (s), 920 (m), 834 (w), 788 (w), 720 (w); ^{1}H NMR, δ: 1.67 (s, 3H), 1.69 (d, *J* = 7.0 Hz, 3H), 1.74 (d, *J* = 6.6 Hz, 3H), 5.32 (q, *J* = 7.0 Hz, 1H), 5.45 (dq, *J* = 15.5, 6.7 Hz, 1H), 5.95 (d, *J* = 15.5 Hz, 1H); MS (*m/e* (I)): 96 (15), 81 (28), 79 (6), 67 (5), 55 (6), 53 (8), 44 (75), 41 (8), 40 (10), 39 (6).

The former isomer is one of two major products in the thermolysis of *cis*-**3**, while the latter is formed as the major product in the thermolysis of *trans*-**3** (*vide infra*). The ^{1}H NMR spectrum of *E,E*-**5** matches that reported previously and assigned to this isomer (19*b*).

A portion of the mixture of *Z,E*- and *E,E*-**5** (0.3 g) and acetophenone (0.05 g) was dissolved in pentane, placed in a quartz tube, and deoxygenated by bubbling dry nitrogen through the solution for 15 min. The solution was then irradiated in a Rayonet reactor (300 nm) for 6 h, producing a mixture of all four isomers of **5** in relative amounts (*Z,Z*):(*E,Z*):(*Z,E*):(*E,E*) ≈ 2:1:3.5:4 (by VPC analysis). The solvent was removed by careful distillation, and the isomeric dienes were separated from acetophenone and a small amount of polymeric material by bulb-to-bulb distillation under vacuum. The four dienes were isolated by semi-preparative VPC (column (b)), eluting in the order (*Z,Z*) < (*E,Z*) < (*Z,E*) < (*E,E*) (they elute in the same order from the SPB-1 column). The second isomer is one of two major products from thermolysis of *cis*-**3** (*vide infra*). The first two dienes that eluted exhibit the following spectral characteristics:

Z,Z-*3-Methyl-2,4-hexadiene* (Z,Z-*5*): IR: 3020 (s), 2968 (s), 2936 (s), 2920 (s), 2876 (m), 2860 (s), 1645 (w), 1540 (w), 1450 (s), 1375 (m), 1035 (m), 910 (m), 800 (w), 715 (w); ^{1}H NMR, δ: 1.51

(d, J = 6.8 Hz, 3H), 1.59 (dd, J = 6.9, 1.6 Hz, 3H), 1.75 (s, 3H), 5.27 (q, J = 6.7 Hz, 1H), 5.46 (dq, J = 11.5, 6.9 Hz, 1H), 5.76 (d, J = 11.5 Hz, 1H); MS (*m/e* (I)): 96 (12), 81 (25), 79 (7), 67 (5), 55 (5), 53 (6), 44 (83), 41 (8), 40 (9), 39 (8).

E,Z-*3-Methyl-2,4-hexadiene* (E,Z-**5**): IR: 3010 (s), 2962 (s), 2926 (s), 2858 (m), 1643 (w), 1536 (w), 1444 (s), 1412 (w), 1378 (m), 1366 (w), 1000 (w), 958 (m), 908 (w), 893 (w), 798 (w), 708 (w); ^{1}H NMR, δ: 1.67 (d, J = 6.6 Hz, 3H), 1.74 (s, 3H), 1.76 (dd, J = 7.3, 1.4 Hz, 3H), 5.28 (dq, J = 11.7, 7.2 Hz, 1H), 5.33 (q, J = 6.6 Hz, 1H), 5.72 (d, J = 11.7 Hz, 1H); MS (*m/e* (I)): 96 (5), 81 (10), 79 (3), 67 (3), 55 (3), 53 (3), 44 (90), 41 (3), 40 (10), 39 (3).

3,4-Dimethyl-2,4-hexadienes (E,E-, E,Z-, *and* Z,Z-*6*)

Authentic samples of *E,E*- and *E,Z*-**6** were prepared by dehydration of 3,4-dimethyl-3,4-hexanediol with iodine and propionic anhydride (29), and isolated from the reaction mixture by semi-preparative VPC (column (a)). The *Z,Z* isomer was prepared from *E,E*-**6** by direct photoisomerization (20). A deoxygenated solution of *E,E*-**6** (0.030 g) in pentane (30 mL) in a quartz tube was irradiated in the Rayonet reactor (254 nm) for 12 h, affording a mixture of *Z,Z*-, *E,Z*-, and *E,E*-**6** in a ratio of 2.5:6:1 (by VPC). The solvent was removed on the rotary evaporator, the residue was bulb-to-bulb distilled under vacuum, and the dienes were isolated by semi-preparative VPC (column (b)). They were identified on the basis of comparisons of their ^{1}H NMR spectra to those previously published (29). The three isomers elute from the SPB-1 column in the order (*Z,Z*) < (*E,Z*) < (*E,E*).

Thermolysis of cis- *and* trans-*3*

Samples of *cis*- and *trans*-**3** (ca. 5 mg) were placed in 7-mm Pyrex tubes, attached to a vacuum line, cooled with liquid nitrogen, evacuated, and finally sealed. They were then pyrolysed in an oil bath at 180°C for 3 h. The tubes were opened and analysed by VPC, which indicated thermal ring opening to be complete and afforded the relative yields of the isomeric 3-methyl-2,4-hexadienes (**5**) listed in Table 1. The values listed are the average of three runs for each compound, each analysed in triplicate.

Photolysis of 1, 3, and 4

Quantitative cyclobutene photolyses employed the pulses (193 nm, ca. 10 ns, 20–30 mJ, 1 Hz repetition rate) from a Lumonics TE-861M excimer laser filled with an argon/fluorine/helium mixture, or a 16-W Philips 93106E zinc resonance lamp (214 nm). The Zn resonance lamp was surrounded by a metal case, which incorporates a 1-in. port to contain the sample cell. The lamp was given a 20 min warm-up period before each experiment and cooled with a stream of dry nitrogen.

The photolyses were carried out at ambient temperature (ca. 23°C) in 10 × 25 mm cylindrical Suprasil UV cells (Hellma). Solutions of **3** or **4** in pentane (0.02 M for the 193 nm photolysis; 0.06 M (**4**) or 0.10 M (**3**) for the 214 nm photolyses), with 0.001 M isooctane as internal standard, were deoxygenated with a stream of dry nitrogen in an ice bath for ca. 10 min prior to photolysis. The photolyses were monitored between 0.5 and 5–10% conversion by withdrawing aliquots at suitable time intervals for VPC analysis. Relative product yields were determined from the slopes of concentration versus time plots constructed for all components of the mixture relative to internal standard. The concentration vs. time plots were linear up to at least 3% conversion in each case. Figures 2 and 3 show examples of such plots for the photolyses of *cis*- and *trans*-**3** with 193 nm and 214 nm light. The integrals for *Z,Z*- and *E,Z*-**5** are less accurate than those for the other two isomers of **5**, particularly at low conversions of **3**, because these dienes elute on the tails of the solvent and (or) cyclobutene peaks under our VPC conditions. The isomeric dienes **5** and **6** were identified by VPC coinjection of 193 nm photolysates (carried to ca. 10% conversion) with each of the authentic diene samples on the SPB-1 capillary column.

The photolyses of **3** and **4** were also carried out as 0.06 M solutions in deoxygenated isooctane with the 214 nm lamp to ca. 15% conversion, in order to identify the C_3 and C_4 hydrocarbons. These products were identified by VPC spiking experiments using authentic samples with the SPB-1 megabore column. This column is capable of resolving propyne, 2-butyne, *E*-2-butene, and *Z*-2-butene to baseline at 30°C with low (ca. 8 mL/min) flow rates. Propyne and 2-butyne were identified as products from photolysis of **3** and **4**, respectively. *Z*-2-Butene was identified in the photolysates from the *cis* isomers of **3** and **4**; the yield of *E*-2-butene from these two compounds was estimated to be <10% that of the *Z* isomer. Similarly, the *trans* isomers of **3** and **4** were shown to afford *E*-2-butene with >90% stereospecificity. The yields of the C_3 and C_4 products were not determined.

In the photolyses of *cis*-**3**, *trans*-**3**, and *cis*-**4**, the corresponding isomeric dienes accounted for 93–97% of the detectable products of similar volatility to the starting materials, for both excitation wavelengths. In these three cases, the photolysates each contained one or two additional products formed in yields (<3%) too small to enable isolation. Photolysis of *trans*-**4** at both wavelengths gave four products in addition to those shown in eq. [3]; one of these was formed in ca. 6% yield, while the rest were formed in yields of 4% or less. In this case, the isomeric **6** accounted for 84% of the product mixture.

Control experiments

A few control experiments were carried out in order to rule out secondary isomerization of the initially formed dienes due to their direct photoisomerization in the 193 nm and 214 nm cyclobutene photolyses. In these experiments, deoxygenated pentane solutions of the cyclobutene, containing internal standard (isooctane; 0.001 M) and a mixture of *E*- and *Z*-**7** (0.002 M; $E/Z = 2.59 \pm 0.05$) were irradiated with the 193 or 214 nm light sources to ca. 4% conversion of the cyclobutene, with the photolysate being monitored periodically by VPC for the formation of isomeric diene products and for *cis,trans* photoisomerization of **7**. For example, after photolysis of a pentane solution of cis-**4** (0.06 M), *E*-/*Z*-**7** (0.002 M), and isooctane (0.001 M) with 214 nm light to 4% conversion, the relative amounts of *E*- and *Z*-**7** present after 4% conversion was $E/Z = 2.49 \pm 0.05$. The relative yields of *E,E*-, *E,Z*-, and *Z,Z*-**6** (from concentration vs. time plots) were identical to those from the photolysis without added **7**. The photostationary state for **7**, determined by separate irradiation of a 0.002 M solution of the dienes at 214 nm, was determined to be E/Z = 1.0. Similar experiments were carried out with the 193 nm photolysis of *cis*-**3** (0.02 M + 0.002 M **7** in pentane), and the 214 nm photolyses of both *cis*- and *trans*-**3** (0.1 M **3** + 0.002 M **7**). The change in the relative amounts of *E*- and *Z*-**7** present at 4–6% conversion was negligible in all cases, and the relative yields of the isomers of **5** were identical to those from the photolyses in the absence of **7**.

Irradiation of a deoxygenated pentane solution of *cis*-**4** (0.01 M) and toluene (0.02 M) in a Rayonet reactor fitted with 12 253.7-nm lamps resulted in the formation of only one volatile product, which eluted before *cis*-**4** on the SPB-1 capillary column but was not identified. Dienes *E,E*-, *E,Z*-, and *Z,Z*-**6** could not be detected in the photolysate after ca. 15% conversion of *cis*-**4**, within the detection limits of our analytical method.

Acknowledgments

We thank Dr. D. Hughes (McMaster University) for acquiring the high field ^{1}H NMR spectra, and the McMaster University Regional Mass Spectrometry Facility for the mass spectra and exact mass determinations. Lithium aluminium hydride reduction of some triarylvinyl bromides and acetates catalyzed by some transition metal chlorides

CRAIG A. OBAFEMI AND CHOI CHUCK LEE[1]

Department of Chemistry, Obafemi Awolowo University, ILE–IFE, Nigeria

Received January 3, 1990

CRAIG A. OBAFEMI and CHOI CHUCK LEE. Can. J. Chem. **68**, 1998 (1990).

A number of triarylvinyl halides and acetates were reduced with lithium aluminium hydride using various transition metal chlorides as catalysts. The vinylic halides were reduced to the corresponding alkenes while the vinylic acetates were reduced to mixtures of triarylketones and alcohols. The reduction of labeled vinylic halides did not result in any scrambling of the label from C-2 to C-1. The reactions took place under mild conditions and relatively fast reaction times.

Key words: triarylvinyl chlorides, triarylvinyl acetates, lithium aluminium hydride reduction, 1,2,2-triarylethanol, 1,1,2-tri-*p*-tolyl[1-^{13}C]ethane.

CRAIG A. OBAFEMI et CHOI CHUCK LEE. Can. J. Chem. **68**, 1998 (1990).

On a réduit un certain nombre d'acétates et d'halogénures de triarylvinyle à l'aide de l'hydrure double de lithium et d'aluminium, utilisant divers chlorures de métaux de transition comme catalyseurs. Les halogénures de vinyle sont réduits en alcanes correspondants alors que les acétates vinyliques sont réduits en des mélanges de triarylcétones et de triarylalcools. La réduction d'halogénures vinyliques marqués ne conduit à aucun brouillage du marqueur de la position C-2 à C-1. Les réactions sont conduites dans des conditions douces et elles se réalisent relativement rapidement.

Mots clés : chlorures de triarylvinyle, acétates de triarylvinyle, réduction à l'aide de l'hydrure double de lithium et d'aluminium, 1,2,2-triaryléthanol, 1,1,2-tri-*p*-tolyl[1-^{13}C]éthane.

The conversion of organic halides to the corresponding hydrocarbons, which is an important synthetic procedure, has been accomplished with organolithium–copper complexes, titanium chloride – magnesium complexes (1–4), and by the combination of lithium aluminium hydride (LAH) and transition metal chlorides (5). The results with the latter system indicate that $LiAlH_4/NiCl_2$, in particular, is capable of reducing primary, cyclic, and aromatic halides in quantitative yields.

However, by comparison, little has been reported regarding the $LiAlH_4$ reduction of triarylvinyl halides and acetates, without transition metal halides as catalysts (6).

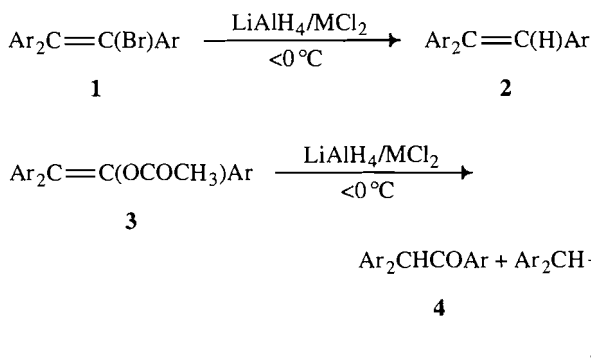
In a report of Lee and Weber (6), triarylvinyl bromides were reduced to the corresponding olefins by $LiAlH_4$, by refluxing for 12 h. On the other hand, reduction of triarylvinyl acetates required refluxing with $LiAlH_4$ for 5 h, twice (7).

This paper reports the reduction of some ^{13}C-labeled and unlabeled triarylvinyl halides and acetates using lithium aluminium hydride catalyzed by some transition metal chlorides.

Results and discussion

The general reaction procedure involved mixing the appropriate vinyl halide or acetate with the transition metal chloride (1 mole equivalent) in tetrahydrofuran (THF) followed by the addition of lithium aluminium hydride in THF (10 mole equivalents) slowly at temperatures well below 0°C. The reduction results are summarized in Table 1. Generally, the various vinyl halides **1** were completely reduced to the corresponding alkenes, **2**, within 15 min (reactions monitored by ^{1}H nmr and ir), while the various vinyl acetates gave mixtures of ketones, **4**, and alcohols, **5**. A second further reduction of the mixture **4** and **5** gave only **5**.

The two types of reductions, of halides and acetates, are of different natures. The acetates are, presumably, being reduced as normal ester reductions, with lithium aluminium hydride,



to enolates, some of which are converted to the enol, in equilibrium with the ketone form, and reduced to the alcohol via the keto form. The part remaining as the enolate affords the ketone upon work-up:

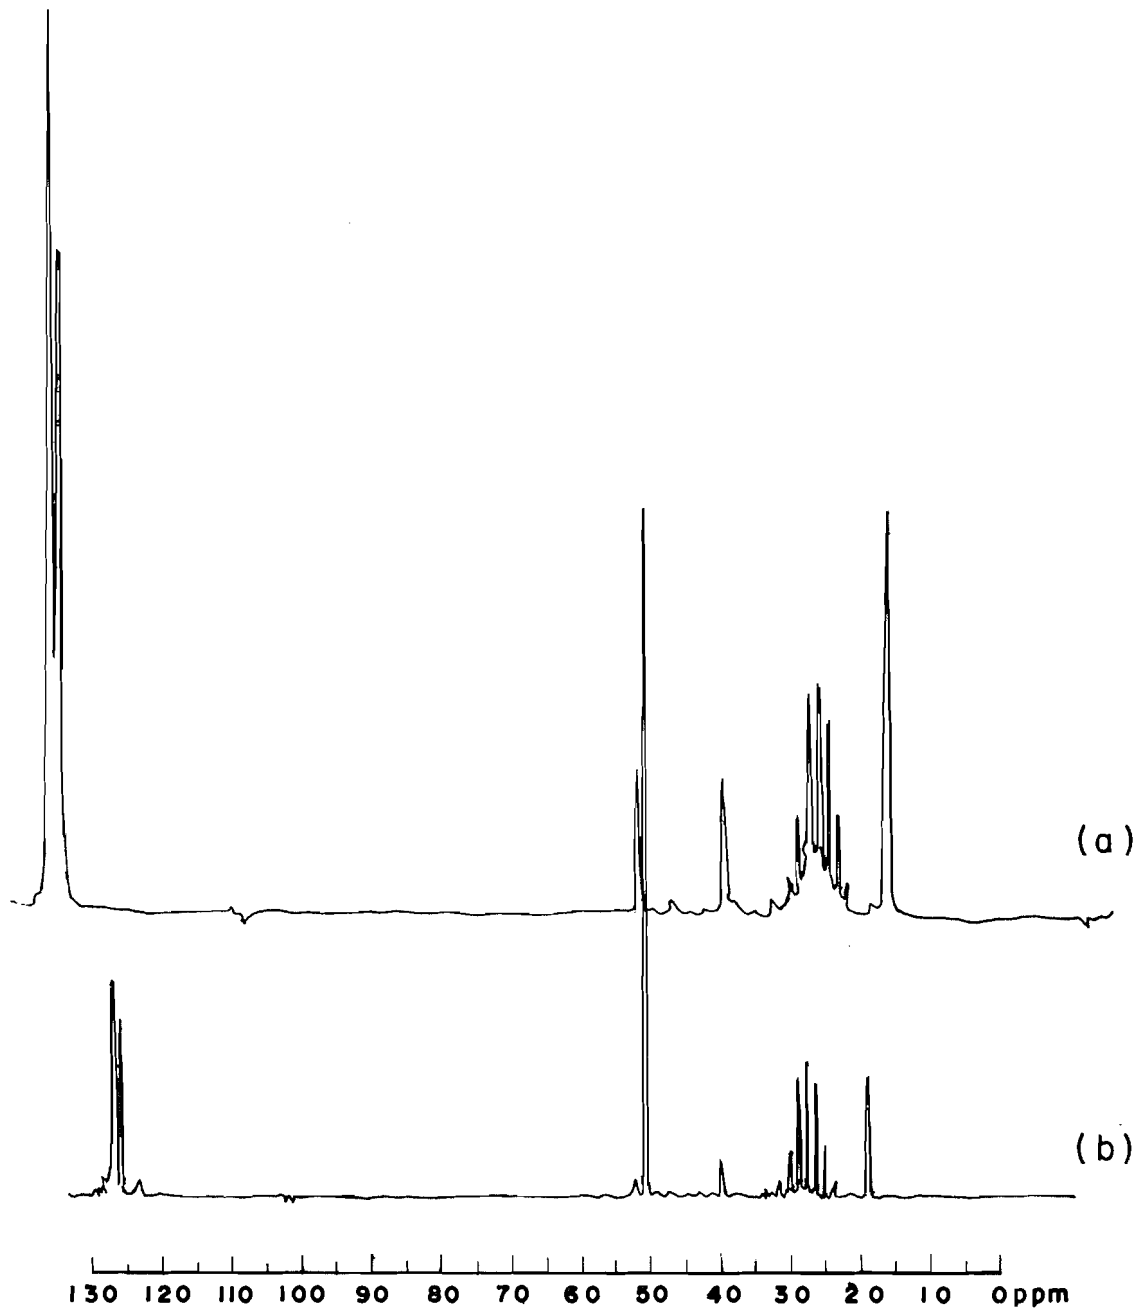

FIG. 1. The ^{13}C nmr spectrum of (a) ordinary 1,1,2-tritolylethane; (b) 1,1,2-tritolyl[1-^{13}C]ethane.

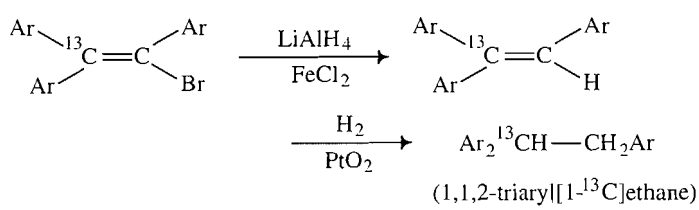
The halides, on the other hand, are possibly reduced via an initial electron-transfer process or metallation reaction. A direct S_N2 displacement process is eliminated, since starting with either the *E* or *Z* isomer (experiment 10) affords the *E* and *Z* alkenes in equimolar amounts.

Experiments were also carried out with carbon-13 labeled trianisylvinyl bromide and tri-*p*-tolylvinyl bromide (trianisyl-[2-^{13}C]vinyl bromide and tri-*p*-tolyl[2-^{13}C]vinyl bromide), prepared as already described in the literature (7, 8). They were reduced under conditions similar to those used for unlabeled vinyl substrates. The alkene products were hydrogenated catalytically to the corresponding triarylalkanes and then subjected to ^{13}C nmr analysis (7, 9). The ^{13}C enrichment was found to be located on C-1 of each alkane, indicating that no rearrangement occurred during the reduction processes:



Ar = 4-$CH_3OC_6H_4$〰
= 4-$CH_3C_6H_4$〰

Figure 1 shows the ^1H-decoupled ^{13}C nmr in acetone-d_6 for unenriched 1,1,2-tri-*p*-tolylethane and 1,1,2-tri-*p*-tolyl[1-^{13}C]-ethane, respectively.

[c] Products when reduced twice with LAH.

Experimental

The various vinylic substrates were prepared according to literature procedures (7–13). The reactions were performed as illustrated by the following typical procedures.

Reduction of trianisylvinyl bromide

Trianisylvinyl bromide (0.50 g, 1.18 mmol) in tetrahydrofuran (20 mL) was added to ferrous chloride (anhydrous, 0.15 g, 1.18 mmol in a 100-mL round-bottomed flask. The flask was cooled in liquid nitrogen and lithium aluminium hydride (0.45 g, 1.18 mmol) in THF (20 mL) was added slowly. There was an immediate black coloration and gas evolution. The reaction mixture was then kept for 5–15 min with occasional swirling. The excess $LiAlH_4$ was destroyed with cold water (2 mL) and the THF solution separated. The black residue was further extracted with THF or ether and the combined organic layer dried over anhydrous magnesium sulfate. The solvent was evaporated to afford the trianisylethene, identical with an authentic sample via mp, mixture mp, nmr, and mass spectrum (0.37 g, after recrystallization from acetone/methanol, 91% yield).

Reduction of trianisylvinyl acetate

Trianisylvinyl acetate (0.50 g, 1.24 mmol) was reduced as above (acetate/$FeCl_2$/$LiAlH_4$ = 1:1:10). After extraction and evaporation of THF, the ^1H nmr of the product showed it to be a mixture of 1,2,2-trianisylethanol and the corresponding ketone derivative (**4**). A second treatment under similar conditions afforded the pure alcohol, 1,2,2-trianisyl ethanol (mp 112–114°C, nmr, and ms) (0.4 g, 89% yield).

Platinum oxide catalyzed reduction of trianisyl[x-^{13}C]ethene

Trianisyl[x-^{13}C]ethene (300 mg, 0.87 mmol), obtained from $NiCl_2$-catalyzed $LiAlH_4$ reduction of trianisyl[2-^{13}C]vinyl bromide as described above, was dissolved in ethyl acetate (20 mL) and hydrogenated catalytically (PtO_2) under 40 psi (1 psi = 6.9 kPa) pressure for 15 h, after which the solvent was removed under reduced pressure. The crude 1,1,2-trianisyl[x-^{13}C]ethane was purified by column chromatography, using an alumina column and eluting with petroleum ether (bp 40–60°C)/diethyl ether (20:1) to give the pure hydrocarbon (260 mg, 86%), mp 88–89°C (lit. (13) mp 86–87°C).

The carbon-13 labeled trianisylethane was subjected to ^{13}C nmr analysis. The analysis showed that the ^{13}C-label was at the C-2 position of the original trianisylvinyl bromide; that is, there was no scrambling of the label during either the $LiAlH_4$ reduction or the catalytic hydrogenation, and the product was, in fact, 1,1,2-trianisyl[1-^{13}C]ethane.

Substitution reactions of $M_3(CO)_{12}$ (M = Fe, Ru) and $Ru_4(\mu\text{-}H)_4(CO)_{12}$ involving a range of ferrocenyl phosphines are described. Compounds isolated and characterized include $Fe_3(CO)_{11}PFcPh_2$, $Fe_3(CO)_{10}(PBuFcPh)_2$, $Fe(CO)_4L$ (L = PFc_2Ph, PFc_3), $Ru_3(CO)_{11}L$ (L = PFc_3, PFc_2Ph, $PFcPh_2$), $Ru_3(CO)_{10}L_2$ (L = PFc_2Ph, $PFcPh_2$), and $Ru(CO)_4PFc_3$. $Ru_4(\mu\text{-}H)_4(CO)_{10}$(L—L) and $Ru_3(CO)_{10}$(L—L) result from reactions with L—L = $(Ph_2PC_5H_4)_2Fe$. The structure of two derivatives are described. Crystals of $Ru_3(CO)_{11}(PFcPh_2)$ are triclinic, space group $P\text{-}1$, a = 8.576(1), b = 11.150(2), c = 9.160(3) Å, α = 76.65(1), β = 80.75(1), γ = 72.02(1)°, Z = 2, final R_W = 0.027 from 3144 observed reflections. $Ru_3(CO)_{10}(Ph_2PC_5H_4)_2Fe$, monoclinic crystals, space group $C\ 2/c$, a = 17.005(2), b = 18.411(1), c = 14.961(1) Å, β = 117.112(8)°, Z = 4, final R_W = 0.023 from 2395 observed reflections.

Key words: ferrocenylphosphines, ruthenium carbonyl derivatives, structures, synthesis, iron carbonyl derivatives.

STEPHANIE T. CHACON, WILLIAM R. CULLEN, MICHAEL I. BRUCE, OMAR BIN SHAWKATALY, FREDERICK W. B. EINSTEIN, RICHARD H. JONES et ANTHONY C. WILLIS. Can. J. Chem. **68**, 2001 (1990).

On décrit les réactions de substitutions des $M_3(CO)_{12}$ (M = Fe et Ru) et $Ru_4(\mu\text{-}H)_4(CO)_{12}$ avec une série de ferrocénylphosphines. Les composés isolés et caractérisés sont: $Fe_3(CO)_{11}PFcPh_2$, $Fe_3(CO)_{10}(PBuFcPh)_2$, $Fe(CO)_4L$ (L = PFc_2Ph, PFc_3), $Ru_3(CO)_{11}L$ (L = PFc_3, PFc_2Ph, $PFcPh_2$), $Ru_3(CO)_{10}L_2$ (L = PFc_2Ph, $PFcPh_2$), et $Ru(CO)_4PFc_3$. Les produits $Ru_4(\mu\text{-}H)_4(CO)_{10}$(L—L) et $Ru_3(CO)_{10}$(L—L) se forment par réaction avec L—L = $(Ph_2PC_5H_4)_2Fe$. On décrit les structures de deux dérivés. Les cristaux de $Ru_3(CO)_{11}(PFcPh_2)$ sont tricliniques et ils appartiennent au groupe d'espace $P\text{-}1$, avec a = 8,576(1), b = 11,150(2) et c = 9,160(3) Å, α = 76,65(1), β = 80,75(1), et γ = 72,02(1)°, Z = 2, R_W = 0,027 pour 3144 réflexions. Les cristaux de $Ru_3(CO)_{10}(Ph_2PC_5H_4)_2Fc$ sont monocliniques et ils appartiennent au groupe d'espace $C\ 2/c$, avec a = 17,005(2), b = 18,411(1) et c = 14,961(1) Å, β = 117,112(8)°, Z = 4 et R_W = 0,023 pour 2395 réflexions.

Mots clés : ferrocénylphosphines, dérivés du ruthénium carbonyl, structures, synthèses, dérivés du Fe carbonyl.
[Traduit par la revue]

Tertiary phosphine substituted metal carbonyl complexes are generally very well known (1) although there have been only a few studies in this area involving ferrocenylphosphines such as PFc_nPh_{3-n}, n = 1–3 (2–8) (FcH = $Fe(\eta\text{–}C_5H_5)_2$), and 1,1′-disubstituted ferrocene derivatives such as dppf, 1,1′-bis(diphenylphosphino)ferrocene (2, 9, 10). Phosphine derivatives are generally prepared by direct reaction of the phosphine with the metal carbonyl. Sometimes, and especially in the case of $Fe_3(CO)_{12}$, cluster breakdown is found so that the isolated products are phosphine derivatives of mononuclear carbonyls, e.g. $Fe(CO)_4(PR_3)$ and $Fe(CO)_3(PR_3)_2$ (3, 5, 8, 11–16). Reactions of this type involving $Ru_3(CO)_{12}$ usually afford trinuclear products (17–20). Photosubstitution of $Ru_3(CO)_{12}$ seems to occur largely from higher energy states whereas photofragmentation involves the lowest excited state (20). The use of the radical anion, sodium diphenylketyl, as a catalyst has recently greatly facilitated the preparation of a wide range of derivatives $Ru_3(CO)_{12-n}L_n$, n = 1–4, because the reactions are essentially stoichiometric (21). The method is also useful for the synthesis of derivatives of $Fe_3(CO)_{12}$. Salts of the bis(triphenylphosphine)iminium ion, ppn^+, are also effective catalysts (22).

In view of the success in trapping a benzyne fragment on a metal cluster from reactions of arylphosphines with $M_3(CO)_{12}$ (M = Ru, Os) (23–25) directly or stepwise, we have initiated a study of the corresponding reactions of ferrocenylphosphines in the hope that this will lead to the trapping of a ferrocyne fragment. The present paper describes the synthesis of some derivatives of $Fe_3(CO)_{12}$ and $Ru_3(CO)_{12}$, because of our interest in their pyrolysis products, and the crystal structures of $Ru_3(CO)_{11}(PFcPh_2)$ and $Ru_3(CO)_{10}(\mu\text{-dppf})$. The thermal decomposition of $Ru_3(CO)_{10}(PFcPh_2)_2$ to a benzyne complex has been reported (25).

Experimental section

Reactions were carried out in a nitrogen atmosphere by using standard Schlenk procedures. Solvents were dried and distilled before use. Separation of products was usually achieved by column chromatography on Florisil or neutral alumina (activity I) by using petroleum ether (35–60°C bp fraction)/diethyl ether mixtures as eluent. ^1H NMR spectra were recorded from $CDCl_3$ solutions by using Bruker WH400 or WP80 and Varian XL300 instruments. Infrared spectra, usually of C_6H_{12} solutions, were run on a Bowman Fourier Transform or a Perkin Elmer 589 spectrometer. Mass spectra were obtained from a Kratos MS 50 instrument; only peaks with high m/e values are listed and electron impact ionization was used unless otherwise stated. Elemental analyses were determined by Mr. P. Borda of the Chemistry Department, University of British Columbia. Melting points were measured by using a Kofler microheating stage and are uncorrected. A Hanovia 100W lamp (903A-1) was used for UV irradiations. To minimize

thermal reactions the irradiated solution was kept cold by means of a Dry Ice/cold-finger inserted into the closed reaction vessel which was held 10 cm from the lamp.

Preparation of n-*butylferrocenylphenylphosphine, PBuFcPh.*

A hexane solution of *n*-BuLi (0.20 mol) was added to ferrocene (25 g, 0.13 mol) in diethyl ether (150 mL). The solution was stirred (20 h) at 20°C after which it was cooled to −78°C and $PhPCl_2$ (15 g, 0.08 mol) was added dropwise. The stirred solution was allowed to warm to 20°C. After 2 h, water (100 mL) was added. The ether layer was separated, reduced in volume, and chromatographed on alumina. Ferrocene eluted with a petroleum ether/diethyl ether mixture (20:1); PBuFcPh eluted with a 9:1 mixture of solvents and was isolated as as yellow orange solid, mp 38–39°C, ~40% yield. ^{1}H NMR δ 0.94–0.88 (m, 3), 1.50–1.38 (m, 4), 1.99–1.91 (m, 2), 4.14 (s, 5), 4.30–4.27 (m, 2), 4.35–4.32 (m, 2), 7.31–7.28 (m, 3), 7.50–7.45 (m, 2). Mass spec. *m/z* 350 (P^+), 293 ($P - Bu^+$), 216 ($P - Ph - Bu^+$), 186 (Fc^+), 121 ($CpFe^+$), 77 (Ph^+).

Anal. calcd. for $C_{20}H_{23}FeP$: C 68.58, H 6.63; found: C 68.41, H 6.60.

1. Reaction of triferrocenylphosphine with $Fe_3(CO)_{12}$ The phosphine (26–28) (90 mg, 0.20 mmol) and $Fe_3(CO)_{12}$ (100 mg, 0.20 mmol) in THF (10 mL) were gently refluxed for 10 min. Cyclohexane (10 mL) was added to the reaction mixture and the THF removed under vacuum. The residual solution was chromatographed on alumina. The only significant product, the known compound $Fe(CO)_4(PFc_3)$, eluted with petroleum ether. It was isolated as an orange solid in 80% yield mp 225–230°C dec. (lit (4) 225–230°C dec.). The mass spectrum showed a parent peak at *m/z* 754 and others associated with stepwise loss of CO.

2. Reaction of PFc_2Ph *with* $Fe_3(CO)_{12}$

(*a*) Bisferrocenylphenylphosphine (29) (190 mg, 0.40 mmol) and $Fe_3(CO)_{12}$ (200 mg, 0.40 mmol) were reacted as in experiment 1. The only product $Fe(CO)_4(PFc_2Ph)$, an orange red solid, mp 165°C, was isolated following chromatographic work-up on Florisil (~80% yield. ^{1}H NMR δ 3.98 (s, 10), 4.48–4.40 (m, 6), 4.60–4.52 (m, 2), 7.52–7.38 (m, 3), 8.23–7.95 (m, 2). Mass spec. (probe temperature 100°C) *m/z* 646 (M^+), 618, 590, 562, 534, 478. Infrared ν(CO) 2040s, 1970s, 1937vs, 1932vs cm^{-1}.

Anal. calcd. for $C_{30}H_{23}Fe_3O_4P$: C 55.77, H 3.60, O 9.91; found: C 55.79, H 3.70, O 9.92.

(*b*) A stirred solution of the phosphine (80 mg, 0.20 mmol) and $Fe_3(CO)_{12}$ (100 mg, 0.20 mmol) in THF (10 mL) at 20°C was treated with 1 mL of a solution of sodium diphenylketyl in THF (~0.025 M). After 10 min the reaction mixture was worked up to give a low yield of $Fe(CO)_4(PFc_2Ph)$.

3. Reaction of $PFcPh_2$ *with* $Fe_3(CO)_{12}$. Ferrocenyldiphenylphosphine (29–30) (73.4 mg, 0.20 mmol) and $Fe_3(CO)_{12}$ (100 mg, 0.20 mmol) were reacted as follows.

(*a*) The same condition as in experiment 2(*b*) afforded $Fe_3(CO)_{11}(PFcPh_2)$ as an unstable dark green solid, mp 95–100°C dec., in high yield (~80%) following chromatographic work-up on Florisil (diethyl ether/dichloromethane 4:1). ^{1}H NMR δ 3.93 (s, 5), 4.18–4.08 (m, 2), 4.55–4.40 (m, 2), 7.75–7.53 (m, 10). The mass spectrum was essentially that of $Fe(CO)_4(PFcPh_2)$ (q.v). Infrared ν(CO) 2085m, 2033s, 2012s, 2002sh cm^{-1}.

Anal. calcd. for $C_{33}H_{10}Fe_4O_{11}P$: C 58.02, H 3.57, O 11.89; found: C 57.79, H 3.63, O 12.20.

(*b*) The same conditions as in experiment 1 afforded $Fe_3(CO)_{11}(PFcPh_2)$, (~40% yield) and $Fe(CO)_4(PFcPh_2)$, an orange solid mp 169–173°C dec. (~20% yield) following separation on Florisil. The $Fe(CO)_4$ derivative eluted with petroleum ether. ^{1}H NMR δ 3.78 (s, 5), 4.56–4.45 (m, 4), 7.70–7.33 (m, 10). Mass spec. (probe temperature 140°C) *m/z* 538 (m^+), 510, 482, 454, 426, 370. Infrared ν(CO) 2050s, 1977m, 1947s, 1936s cm^{-1}.

Anal. calcd. for $C_{26}H_{10}Fe_2O_4P$: C 58.02, H 3.57, O 11.89; found: C 57.79, H 3.62, O 12.20.

(*c*) The reagents were dissolved in hexanes (10 mL) and irradiated for 60 min. Chromatographic work-up afforded $Fe_3(CO)_{11}(PPh_2Fc)$ in ~40% yield.

4. Reaction of $Fe_3(CO)_{12}$ *with PBuFcPh.* The carbonyl (100 mg, 0.20 mmol) and the phosphine (70 mg, 0.20 mmol) in hexanes (10 mL) were irradiated for 45 min. The solvent was reduced in volume and the residue chromatographed on alumina. A 1:1 mixture of petroleum ether/diethyl ether eluted a dark green solid which is probably $Fe_3(CO)_{11}$(PBuFcPh). Infrared ν(CO) 2083w, 2030m, 2010m, 2007m cm^{-1}. Another olive green band was eluted with diethyl ether. This was identified as $Fe_3(CO)_{10}(PBuFcPh)_2$, mp 59–62°C dec., moderate yield. Infrared ν(CO) FT 2053s, 2029w, 2007vs, 1980s, 1959sh, 1945sh, 1930w, 1816m, 1794 m cm^{-1}. ^{1}H NMR δ 2.40–0.70 (m(br), 9), 4.60–2.95(m(br), 9), 7.88–7.15 (m)br), 5).

Anal. calcd. for $C_{50}H_{46}Fe_5O_{10}P_2$: C 52.30, H 4.05, O 13.94; found: C 51.88, H 4.00, O 14.09.

Attempts to purify $Fe_3(CO)_{11}$(PBuFcPh) by recrystallization resulted in decomposition and the production of $Fe(CO)_4$(PBuFcPh), a yellow solid, mp 73–75°C. ^{1}H NMR δ 0.70–1.70 (m, 9), 4.00 (s, 5), 4.33–4.22 (m, 1), 4.50–4.33 (m, 3), 7.55–7.40 (m, 3), 7.93–7.65 (m, 2). Mass spec. (probe temperature 110°C *m/z* 518 (M^+), 490, 482, 434, 406, 350, 293. Infrared ν(CO) 2050s, 1975s, 1943vs, 1936vs cm^{-1}.

5. Reaction of PFc_3 *with* $Ru_3(CO)_{12}$. A stirred solution of $Ru_3(CO)_{12}$ (117 mg, 0.18 mmol) and PFc_3 (107 mg, 0.18 mmol) in THF (5 mL) was treated dropwise with sodium diphenylketyl in THF as described for experiment 2(*b*). After 10 min the reaction mixture was chromatographed on Florisil. Elution with diethyl ether gave $Ru_3(CO)_{11}(PFc_3)$ as an orange solid, 80% yield, mp 115–116°C dec., R_F 0.56 in 7:1 petroleum ether/diethyl ether. Infrared ν(CO) 2097(m), 2044(s), 1981(sh), 1960(sh) cm^{-1}. Mass spec. (probe temperature 210°C) *m/z* 640, 612, 586, 529, 500, 472, 444, 415, 389.

Anal. calcd. for $C_{41}H_{27}Fe_3O_{11}P_3Ru_3$: C 41.13, H 2.27; found: C 41.45, H 2.47.

6. Preparation of $Ru(CO)_4(PFc_3)$

(*a*) $Ru_3(CO)_{11}(PFc_3)$ (25 mg) in hexane (15 mL) was irradiated for 40 min with the 100 W lamp as described above. The yield of $Ru(CO)_4(PFc_3)$ was 45% as judged from the ^{1}H NMR spectrum of the mixture that contained $Ru(CO)_4(PFc_3)$, $Ru_3(CO)_{11}(PFc_3)$, and $Ru_3(CO)_{12}$. The phosphine derivatives were not separable by column chromatography, although $Ru_3(CO)_{12}$ was isolated as a pure fraction.

(*b*) A solution of pure $Ru_3(CO)_{11}(PFc_3)$ in hexane/diethyl ether slowly deposited a few orange crystals of $Ru(CO)_4(PFc_3)$ on standing. ^{1}H NMR δ 4.74–4.69 (m, 1), 4.65–4.56 (m, 3), 4.52 (s, 5), Infrared (FT) ν(CO) 2061(s), 1981(w), 1943(s) cm^{-1}.

7. Reaction of PFc_2Ph *with* $Ru_3(CO)_{12}$.

(*a*) The carbonyl (100 mg, 0.16 mmol) and phosphine (74.8 mg, 0.16 mmol) were treated with ketyl as in experiment 2(*b*). An orange solid $Ru_3(CO)_{11}(PFc_2Ph)$, mp 147–150°C dec., was the main product (~80% yield) isolated following chromatography on alumina (petroleum ether/diethyl ether 1:2) R_f 0.53, 7:1 petroleum ether/diethyl ether. ^{1}H NMR δ 4.15–4.05 (m, 2), 4.20 (s, 5), 4.40–4.31 (m, 2), 4.55–4.42 (m, 4), 7.43–7.27 (m, 3), 7.90–7.60 (m, 2). Mass spec. (FAB) *m/z* 1089 (M^+), 1061, 1033, 1005, 977, 949, 921, 893, 876, 865, 848, 837, 820, 809, 781. Infrared (FT) ν(CO), 2096w, 2045s, 2028m, 2015s, 1955w, 1984s, 1966vw, 1958vw cm^{-1}.

Anal. calcd. for $C_{37}H_{23}Fe_2O_{11}PRu_3$: C 40.79, H 2.13, O 16.15; found: C 41.11, H 2.20, O 16.0.

A second fraction $Ru_3(CO)_{10}(PFc_2Ph)_2$, a dark red solid, mp 117–119°C dec., was eluted, in low yield, with diethyl ether/dichloromethane 18:1. ^{1}H NMR δ 4.13 (m, 2), 41.9 (s, 10), 4.40 (m, 2), 4.45 (m, 2), 4.49 (m, 2), 7.36–7.29 (m, 3), 7.81–7.67 (m, 2). Mass spec. (FAB) *m/z* 889, 815, 714. Infrared (FT) ν(CO) (CH_2Cl_2), 2075w, 2044w, 2029s, 2005sh, 1988s, 1974vw, 1957vw, 1948vw cm^{-1}.

Anal. calcd. for $C_{62}H_{46}Fe_4O_{10}P_2Ru_3.1.5CH_2Cl_2$: C 45.75, H 2.97, O 9.60; found: C 45.75, H 3.21, O 10.34.

[c]$I > 2.3\delta(I)$.

(*b*) The carbonyl (251 mg, 0.39 mmol) and phosphine (3.76 mg, 0.79 mmol) were treated with the ketyl as in experiment 2(*b*). $Ru_3(CO)_{10}(PFc_2Ph)_2$ was eluted from an alumina column with 18:1 diethyl ether/dichloromethane and was isolated as a dark red solid, 251 mg (86% yield), R_f 0.22, petroleum ether/diethyl ether 7:1.

(*c*) Both substitution products were isolated in low yield after the reactants, 1:1 mole ratio, were refluxed in THF for 10 min.

8. Reaction of $PFcPh_2$ with $Ru_3(CO)_{12}$

(*a*) The phosphine (57.9 mg, 0.16 mmol) and $Ru_3(CO)_{12}$ (100 mg, 0.16 mmol) were treated with the ketyl as in experiment 2(*b*). Chromatography on alumina with diethyl ether/$CHCl_3$, 1:1, eluted $Ru_3(CO)_{11}(PFcPh_2)$ as the only product, orange solid, mp 112–115°C dec. R_f 0.52, petroleum ether/diethyl ether, 7:1. ^{1}H NMR δ 3.97 (s, 5), 4.21–4.18 (m, 2), 4.52–4.49 (m, 2), 7.43–7.40 (m, 6), 8.03–7.48 (m, 4). Mass spec. (FAB) *m/z* 981 (M^+), 953, 925, 897, 869, 841, 813, 785, 757, 740, 729, 712, 701, 684, 673, 656, 628, 600, 572. Infrared (FT) ν(CO) 2099sh, 2095m, 2060sh, 2046s, 2028sh, 2015s, 2003sh, 1997sh, 1986m, 1970w, 1964w cm^{-1}.

Anal. calcd. for $C_{33}H_{19}FeO_{11}PRu_3$: C 40.38, H 1.96, O 17.93; found: C 40.78, H 2.15, O 17.97.

(*b*) The same quantities of reagents were refluxed gently in THF for 10 min. Chromatography on alumina afforded $Ru_3(CO)_{11}(PFcPh_2)$ as in (*a*), in low yield, together with a second fraction which also eluted with 1:1 diethyl ether/$CHCl_3$. This was identified as $Ru_3(CO)_{10}(PFcPh_2)_2$, a dark purple solid. mp 103–107°C dec. R_F 0.20, petroleum ether/ diethyl ether (7:1). ^{1}H NMR δ 3.93 (s, 5), 4.20 (m, 2), 4.45 (m, 2), 7.75–7.35 (m, 10). Infrared (FT) ν(CO) 2075s, 2063s, 2045vs, 2019m, 1998s, 1990sh, 1976m, 1960m, 1921w cm^{-1}.

Anal. calcd. for $C_{54}H_{38}Fe_2O_{10}P_2Ru_3$: C 48.99, H 2.90, O 12.07; found: C 49.24, H 3.00, O 12.25.

(*c*) The carbonyl (360 mg, 0.56 mmol) and phosphine (412 mg, 1.11 mmol) were treated with the ketyl as in experiment 2(*b*). $Ru_3(CO)_{10}(PFcPh_2)_2$ was eluted from an alumina column with 1:1 diethyl ether/chloroform. The yield of dark purple solid was 593 mg (80%).

9. Reaction of $Ru_3(CO)_{12}$ with dppf.

(*a*) A mixture of $Ru_3(CO)_{12}$ (100 mg, 0.156 mmol) and Fe(η-$C_5H_4PPh_2)_2$, dppf (9) was dissolved in dry THF (20 mL). The catalyst [ppn][OAc] (15 mg) was added to the reaction mixture and the colour changed immediately to dark red. The reaction mixture was left stirring for 5 min, after which time solvent was removed *in vacuo*. The residue was redissolved in the minimum amount of dichloromethane and purified by preparative TLC. (Kieselgel GF_{254}, developing with 3/1/1 light petroleum/diethyl ether/acetone). The following bands were obtained: band 1 (orange, R_f 0.92) identified (IR) as $Ru_3(CO)_{12}$; band 2 (orange, R_f 0.83) trace, identified as dppf by comparison with an authentic sample; band 3 (dark red, R_f 0.71) was recrystallized from CH_2Cl_2/cyclohexane at −30°C to give dark red crystals of $Ru_3(CO)_{10}$(μ-dppf). $2C_6H_{12}$ (146 mg. 76.5% yield), mp 205°C dec. Infrared ν(CO) 2086s, 2020(sh), 2010vs, 1972(sh), 1967w cm^{-1}. ^{1}H NMR ($CDCl_3$) δ 1.43 (s, 24), 4.36 (m, 4), 4.47 (m, 4), 7.43 (m, 20). ^{13}C NMR ($CDCl_3$) δ 28.7 (s, C_6H_{12}), 73.7 (d, *J*(CP) = 7 Hz, C(1))

Anal. calcd. for $C_{56}H_{52}FeO_{10}P_2Ru_3$: C 51.98, H 4.05; found: C 51.39, H 4.00.

(*b*) *Preparation of* $Ru_3(CO)_8(\mu\text{-}dppf)_2$. A mixture of $Ru_3(CO)_{12}$ (50 mg, 0.078 mmol) and dppf (88 mg, 0.158 mmol) was dissolved in dry THF (40 mL). The reaction mixture was heated at reflux point for 1 h, after which time the reaction, which was monitored by TLC, was judged to be complete. After cooling, the solvent was removed *in vacuo* and the mixture was separated by using column chromatography on silica. Light petroleum eluted a trace amount of dppf; acetone eluted $Ru_3(CO)_8(dppf)_2$ which was recrystallized from CH_2Cl_2/heptane; mp 160°C dec. (67% yield). Infrared (CH_2Cl_2) ν(CO) 2052m, 1980vs (br), 1910w cm^{-1}. ^1H NMR ($CDCl_3$) δ 7.73 (m, 40), 4.21–3.90 (m, 16). Mass spec. (FAB) m/z 1636 $(P\text{-}1)^{+\ -1}$.

Anal. calcd. for $C_{76}H_{56}O_8Fe_2P_4Ru_3$: C 55.78, H 3.45; found: C 54.78, H 3.76.

10. Hydrogenation of $Ru_3(CO)_{10}(\mu\text{-}dppf)$. The complex (100 mg, 0.09 mol) was dissolved in cyclohexane and the solution was placed in the glass liner of a small autoclave which was then charged with hydrogen (225 psi). The reactants were heated (80°C, 18 h), cooled, and the solvent was removed. The solid residue given gave seven bands on a preparative TLC plate. Only band 6 (R_f = 0.50, 3/1/1 light petroleum/acetone/diethyl ether) contained a significant amount of material which was identified as $Ru_4(\mu\text{-}H)_4(CO)_{10}(\mu\text{-}dppf)$ (50 mg, 46% yield) by comparison with an authentic ample.

11. Preparation of $Ru_4(\mu\text{-}H)_4(CO)_{10}(\mu\text{-}dppf)$. A mixture of $Ru_4(\mu\text{-}H)_4(CO)_{12}$ (100 mg, 0.134 mmol) and dppf (78 mg, 0.14 mmol) was dissolved in THF (25 mL). A THF solution of the ketyl was added (0.2 mL) and the reaction solution darkened immediately. The solvent was removed *in vacuo*, the residue redissolved in the minimum volume of dichloromethane and purified by preparative TLC (3/1/1 petroleum ether/diethyl ether/acetone). Only band 5 (R_f = 0.50), of six, contained sufficient material for characterization. This solid was recrystallized from dichloromethane/methanol at −30°C to give dark red crystals of $Ru_4(\mu\text{-}H)_4(CO)_{10}(dppf)$ (80 mg, 48% yield) mp 160°C (dec.). ^1H NMR ($CDCl_3$) δ 4.4 (m, 8), 7.4(m, 20), −16.9 (s, 4). Mass spec. (FAB) m/e 1244 (P^+). Infrared ν(CO) 2088w(sh), 2076s, 2054s, 2036vs, 2016s, 1990m, 1985m, 1977s cm^{-1}.

Crystal structure analysis of $Ru_3(CO)_{10}(\mu\text{-}dppf)$[2]

A single crystal of $Ru_3(CO)_{10}Fe[C_5H_4P(C_6H_5)_2]_2$ was selected and affixed to the end of a glass fibre and mounted on the diffractometer. Unit cell dimensions and the orientation matrix were determined by least-squares analysis of the setting angles of 25 reflections, widely distributed in reciprocal space ($23° < 2\theta < 31°$), which were accurately centred. Crystal data are given in Table 1.

The intensities of a unique data set ($\pm h$, k, l) were measured as outlined in Table 1. Two standards, measured at regular intervals, showed small fluctuations in intensity (all < ±2%) and data were scaled accordingly. All data were corrected for absorption (T range 0.779–0.840) (31). The structure was solved by heavy-atom techniques. Refinement of the non-hydrogen atoms with isotropic temperature factors converged at R_F 0.056. Subsequently these atoms were refined with anisotropic temperature factors. Hydrogen atom coordinates were calculated (d(C—H) =0.95 Å) and their isotropic temperature factors were set equal to U_{iso} of the C atoms to which they were attached. Refinement (hydrogen atom parameters invariant) led to R_F = 0.018. Hydrogen atoms parameters were recalculated and their positional parameters were allowed to refine and an extinction parameter (32) was added. The structure was refined to completeness (all shift-to-error ratios < 0.01). Final R_F = 0.017. All features in a final difference map were < 0.24(5) e $Å^{-3}$.

Refinement throughout was by least-squares analysis minimizing the function $\Sigma w(|F_o| - |F_c|)^2$. The weighting scheme, w, was unity in the early stages of refinement and $1/[\sigma(F))^2 + 0.0003F^2)]$ in the final cycles. Neutral scattering factors with anomalous dispersion corrections were used (33). Computer programs were run on a VAX 11/750 computer (34). Atomic coordinates are listed in Table 4, selected bond lengths and angles in Table 5, and a PLUTO plot (34) of the molecule is shown in Fig. 2.

Crystal structure analysis of $Ru_3(CO)_{11}(PFcPh_2)$[2]

Dark red–purple crystals of the complex were obtained from

hexanes. The data collection and analysis proceeded in essentially the same way as for $Ru_3(CO)_{10}$(dppf). Pertinent data are given in Table 1, selected interatomic distances and angles in Table 3, atomic coordinates in Table 2. A SNOOPI plot (34) of the molecule is shown in Fig. 1.

Results and discussion

The reactions of the ferrocenylphosphines PFc_nPh_{3-n}, $n = 1–3$, with $Fe_3(CO)_{12}$ and $Ru_3(CO)_{12}$, and $Fe(\eta\text{-}C_5H_4PPh_2)_2$, dppf, with $Ru_3(CO)_{12}$ were investigated under a variety of conditions. Because of some difficulties in obtaining the quoted literature yields of compounds PFc_nPh_{3-n}, $n = 1–2$, procedures for their synthesis via LiFc and chlorophosphines have been investigated and these offer some improvement in the ease of isolation of the products (35). If an excess of *n*-BuLi is present in the mixture (it is used to lithiate FcH), reaction with $PhPCl_2$ can result in the isolation of the new phosphine PBuFcPh as described in the Experimental section.

Ferrocenylphosphines are expected to be reasonably bulky and to gain some measure of this, the cone angle (1, 36) for PFc_3 was determined from the crystallogaphic data available for $Ru(CO)_4)(PFc_3)$ (37) by using scale drawings (36). The model assumed a van der Wasls radius of 1.2 Å (38) for the appropriate hydrogen atom and a P—Ru distance of 2.28 Å.

The calculated angle is 178° which is only slightly less than the 182° determined for $(P(CMe_3)_3$. The cone angle for other ferrocenyl phosphines can be calculated by using the equation $\theta = 2/3\Sigma\theta_i/2$, $i = 1–3$, and the known cone angles of PBu_3 and PPh_3 which are 132° and 145°, respectively. Results are as follows: PFc_3, 178°; PFc_2Ph, 167°; $PFcPh_2$, 156°; PBuFcPh, 152°. For comparison the value for $P(CHMe_2)_3$ is 160°.

In the preparative work described next, most attention was

given to the isolation and characterization of complexes which would be useful for further studies relating to the trapping of ferrocyne.

Iron carbonyl complexes. Providing mild conditions are used, it is possible to prepare carbonyl substituted derivatives of $Fe_3(CO)_{12}$ (11, 14, 15, 29, 34–41) but only limited information is available about thermal decomposition of these clusters to products other than derivatives of $Fe(CO)_5$ (41). $Fe_3(CO)_{12}$ can be activated for substitution reactions by the diphenylketyl radical anion (21) to produce, for example, $Fe_3(CO)_{11}(PPh_3)$ in high yield; these are very mild conditions. We now find that this approach is successful for the synthesis of $Fe_3(CO)_{11}(PFcPh_2)$, a complex that is also produced under mild thermal and photochemical conditions. Purification of $Fe_3(CO)_{11}(PFcPh_2)$ for microanalysis is difficult and the electron impact mass spectrum is that of its decomposition product $Fe(CO)_4(PFcPh_2)$. However, the colour and infrared spectrum of the cluster derivative is characteristic (11).

Another unstable cluster derivative, $Fe_3(CO)_{11}(PBuFcPh)$, is produced from a photochemical reaction. This same reaction also affords some $Fe_3(CO)_{10}(PBuFcPh)_2$ which is more stable and better characterized. The ν(CO) band envelope has the typical pattern and a bridging carbonyl band is clearly seen in the solution spectrum (11). Reaction of $Fe_3(CO)_{12}$ with the more bulky phosphines PFc_2Ph and PFc_3 even under mild conditions results in cluster breakdown and the formation of $Fe(CO)_4L$. The compound with L = PFc_3 is a previously known product of the reaction of $Fe(CO)_5$ with PFc_3 (4). Two other $Fe(CO)_4L$ derivatives that are reasonably stable and adequately characterized were also isolated where L = $PFcPh_2$ and PBuFcPh.

Ruthenium carbonyl derivatives

As anticipated (11) the radical anion-initiated reaction of $Ru_3(CO)_{12}$ with the ferrocenylphosphines in 1:1 molar ratio afforded good yields of the monosubstituted derivatives $Ru_3(CO)_{11}L$, L = PFc_3, PFc_2Ph, $PFcPh_2$. The crystal structure of $Ru_3(CO)_{11}(PFcPh_2)$ is described below (see Fig. 1). The infrared spectra of these complexes are similar to those of other derivatives of this type such as $Ru_3(CO)_{11}(PPh_3)$.

Two disubstituted complexes $Ru_3(CO)_{10}L_2$, L = PFc_2Ph, $PFcPh_2$ were prepared from ketyl-initiated reaction by utilizing a 1:2 molar ratio of reactants. (In one radical anion initiated reaction a small amount of $Ru_3(CO)_{10}(PFc_2Ph)_2$ was produced from a 1:1 mixture of starting materials. It is possible that this results from a concurrent thermal reaction.) Only one mono-

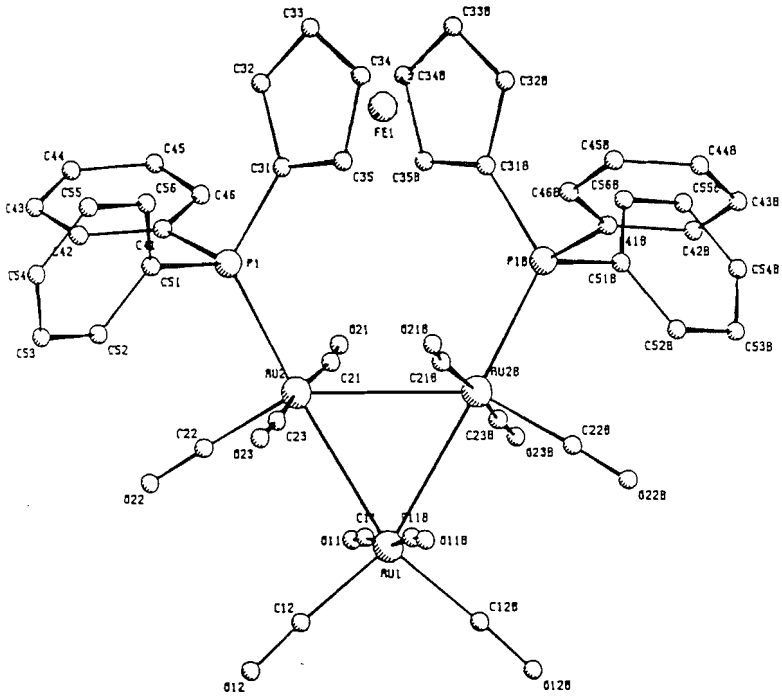

FIG. 2. PLUTO plot of $Ru_3(CO)_{10}(dppf)$.

nuclear ruthenium compound, $Ru(CO)_4(PFc_3)$, was isolated during these studies. This crystallized out during attempts to purify $Ru_3(CO)_{11}(PFc_3)$; it can be prepared in a more controlled manner by ultraviolet irradiation of solutions of $Ru_3(CO)_{11}(PFc_3)$. Its structure (37) is that of a slightly distorted trigonal bipyramid with the ligand in an axial position. This is the expected structure for derivatives of $M(CO)_5$ (M = Fe, Ru, Os) (42); notable exceptions are $M(CO)_4(SbPh_3)$, M = Ru, Os, where the ligand occupies an equatorial position.

Some of the thermal reactions afford complexes which have the formula $Ru_3(CO)_9L_3$ based on their spectroscopic properties. These were not fully characterized because of problems with obtaining analytically pure samples (35) (complexes with the lowest degree of substitution and the lowest number of ferrocenyl substituents on the phosphorous atom are the easiest to crystallize) and because such compounds are less interesting from the point of view of thermal decomposition to ferrocyne fragments.

When radical anion catalysis is used in the reaction between $Ru_3(CO)_{12}$ and dppf a number of products are obtained. These are difficult to isolate by chromatography and are generally unstable in solution. One product, however, was air-stable and proved to be the complex $Ru_3(CO)_{10}(\mu\text{-dppf})$ whose determined structure is shown in Fig. 2. This compound is much better prepared (76% yield) from the carbonyl and ligand by a [ppn][OAc] catalysed reaction (22) in THF solution. The complex can be isolated as an unsual bis-cyclohexane solvate as indicated by the microanalytical results and by the spectroscopic properties.

The thermal reaction between $Ru_3CO)_{12}$ and dppf in a 1:2 mole ratio in refluxing cyclohexane affords a purple solid which is probably $Ru_3(CO)_8(\mu\text{-dppf})_2$. The FAB mass spectrum shows a strong peak at m/e 1636 (calc M^+ 1637). The infrared spectrum is very similar to that of the dppm, $Ph_2PCH_2PPh_2$, analogue (43). The hydrogenation of $Ru_3(CO)_{10}(\mu\text{-dppf})$ affords one major product and a number of minor uncharacterized ones. The major product has a $\nu(CO)$ spectrum and presumably structure similar to that of $Ru_4(\mu\text{-H})_4(CO)_{10}(\mu\text{-dppm})$ (44) and the FAB mass spectrum shows a parent ion at m/z 1244. Presumably hydrogen displaces one PR_2 group from $Ru_3(CO)_{10}(\mu\text{-dppf})$ to give a monodentate dppf complex which aggregates to the Ru_4 complex. This product can be prepared directly from the ketyl-catalyzed reaction of $Ru_4(\mu\text{-H})_4(CO)_{12}$ with dppf.

The mass spectra of the complexes deserve some comments. Electron impact spectra are adequate for the characterization of $M(CO)_4L$ complexes and they show strong parent peaks and stepwise loss of carbonyl groups. Although useful electron impact spectra of iron cluster derivatives have been reported (40), in the present instance the spectra of both $Fe_3(CO)_{10}(PBuFcPh)_2$ and $Fe_3(CO)_{11}(PFcPh_2)$ show peaks associated with $[Fe(CO)_4L]^+$ only. The ruthenium complexes do not afford parent ions and seem to fragment at both the ligand and the cluster; the spectra also depend on the probe temperature. For example, the spectrum of $Ru_3(CO)_{10}(PFcPh_2)_2$ has peaks at the following m/z values: 770 ($[Ru_3(CO)_{10}PPh_2]^+$), 713 ($[Ru_2(CO)_5L]^+$), 655 ($[Ru_3(CO)_3L]^+$), 630 ($[Ru_2(CO)_2L]^+$), etc.

Fast atom bombardment (FAB) mass spectra are known to give better results for clusters (45). Attempts were made to obtain FAB mass spectra for $Fe_3(CO)_{11}(PFcPh_2)$ and the $Ru_3(CO)_{11}L$, and $Ru_3(CO)_{10}L_2$ complexes; a number of common solvents were used without any success. Ultimately we found that diallyl phthalate can be used as a solvent for $Ru_3(CO)_{10}L_2$ and the FAB mass spectra show parent peaks and peaks associated with stepwise loss of ten carbonyl groups. A further series corresponding to $[Ru_2(CO)_7L]^+ \rightarrow [Ru_2L]^+$ is also present.

Structural studies

The structure of $Ru_3(CO)_{11}(PFcPh_2)$ is shown in Fig. 1. Structural studies have been made on a wide range of derivatives of $Ru_3(CO)_{12}$ of formula $Ru_3(CO)_{12-n}L_n$ (n = 1–4) where L is a monodentate ligand and some general trends have emerged

[a]Atoms indicated by primes have been transformed by $(\bar{x}, y, 1/2 - z)$.
[b]Rigid body: Ru(1), Ru(2), Ru(2′), Fe, P, P′.
[c]Corrected for motion of C riding on corresponding Ru.
[d]Calculated from distance Ru—C (corrected for motion of C riding on Ru), distance Ru···O (corrected for motion of O riding on Ru) and angle Ru—C—O.
[e]Cp is the centroid of C(31)—C(35).

(21, 46, 47); those of relevance to the structure of $Ru_3(CO)_{11}(PFcPh_2)$ are as follows: (*i*) *P*-ligands coordinate equatorial sites, (*ii*) the Ru—Ru bond *cis* to *P*-ligands is the longest of the three separations, and (*iii*) bonds from axial CO groups to Ru are generally longer than those from equatorial CO groups except when the latter are *cis* to a *P*-ligand. Taking these in turn (*i*) is certainly true, as is (*ii*). The longest Ru—Ru bond is *cis* to the ligand and has a length of 2.9000(6) Å. Pöe and co-workers (48) have shown that a reasonable curve can be obtained if the *cis* Ru—Ru bond length is plotted against the cone angle of L. As discussed above the cone angle of $PFcPh_2$ is 156° and the measured bond length of 2.90 Å is not far from that which would be predicted on the bases of the curve. With regard to (*iii*), at the unsubstituted ruthenium atoms, the axial bonds Ru(2)—C(6) (1.940(6) Å) and Ru(2)—C(7) (1.950(6) Å) seem longer than the equatorial Ru—C bonds (1.915(6) and 1.919(6) Å). The situation is less clear at Ru(3) where the axial Ru—C distances are 1.917(6) and 1.941(6) Å and equatorial Ru—C distances are 1.931(6) and 1.904(6) Å. At the substituted ruthenium atom Ru(1) the axial Ru—C bonds are 1.889(5) and 1.940(6) Å whereas the equatorial Ru—C bond, which should be longer in this case, is intermediate at 1.910(5) Å.

The Ru—P distance of 2.369(1) Å lies in the range 2.24 to 2.43 Å noted by Bruce and co-workers (47). A plot of Ru—P distance against ligand cone angle results in a smooth curve (48) but based on a cone angle of 156°, the observed Ru—P distance is shorter than would be predicted. Otherwise the structure shown in Fig. 1 resembles other known $Ru_3(CO)_{11}L$ derivatives in that the metal cluster skeleton is distorted from the D_{3h} symmetry found in $Ru_2(CO)_{12}$, principally by rotation of the $Ru(CO)_4$ unit (46, 47).

The structure of $Ru_3(CO)_{10}(\mu\text{-dppf})$ is shown in Fig. 2. The *R*-value of 1.7% is one of the lowest obtained for a ruthenium carbonyl derivative. Because of this, some corrected distances have been calculated and these are listed in Table 5; in general they are systematically longer than the uncorrected lengths (as

might be expected) with corrections far longer than would be expected from the least-squares esd.

The ligand occupies equatorial positions (see (*i*) above). The longer Ru(2)—Ru(2′) bond, 2.9284(5) Å, is situated *cis* to *two* Ru—P bonds (see (*ii*) above) and this length is greater than the longest bond in $Ru_3(CO)_{11}(PFcPh_2)$, (2.9000(6) Å) and in fact, is longer than that found in any $Ru_3(CO)_{12-n}L_n$ (n = 1–4) derivative[3] (46, 47). This lengthening is probably not entirely due to a repulsive *cis* effect as the Ru—Ru bond length of other $Ru_3(CO)_{10}$(L–L) complexes do not follow the trend. Some results are as follows (L—L, supported bond length, unsupported bond length(s)): dppe; 2.856(1), 2.855(1), 2.847(1) (49); dppm, 2.834(1), 2.841(1), 2.860(1) Å (50); $Ph_2PC(=CH_2)PPh_2$, 2.836(1), 2.862(1), 2.840(1) Å (51); $\overleftarrow{PPhCH_2PPhC}_6H_4$, 2.884(1), 2.851(1), 2.848(1) Å (52), and to reiterate dppf, 2.9284(5), 2.8600(4), 2.8600(4) Å. It seems that these Ru—Ru lengths are largely controlled by steric demands and the bite of the ligand, a point that has been made before (53).

The bonds from the axial carbonyl group to the unique Ru(1) in $Ru_3(CO)_{10}$(μ-dppf) are longer (1.942(4) Å) than those from the axial carbonyl (1.907(4) Å), and this is true for the other known $Ru_3(CO)_{10}$(L—L) structures. The axial Ru(2)—C(22) bond is also shorter (1.877(3) Å) than the axial Ru(2)—C bonds (1.923(4), 1.949(3) Å) contrary to (*iii*) above and again this trend is found in all the other $Ru_3(CO)_{10}$(L—L) structures (49–52). For example, in the dppe derivative Ru(2)—C(31) axial (1.933(2) Å) is longer than Ru(2)—C(32) equatorial (1.891(2) Å) (49).

The Ru(2)—P distance in the dppf derivative (2.3503(8) Å) is marginally shorter than those observed in $Ru_3(CO)_{11}(PFcPh_2)$ (2.369(1) Å). However it should be pointed out that it is longer than other Ru—P bonds measured in $Ru_3(CO)_{10}$(L—L) complexes, the longest being 2.334(2) Å when L—L = dppm (49). This again is an indication of strong steric interactions because on electronic grounds long Ru—Ru bonds should be associated with short Ru—P bonds.

Finally, it should be pointed out that dppf is a reasonably flexible ligand that can form chelated complexes; for comparison the Rh—P bond length in $[Rh(dppf)(nbd)]^+$ is 2.356(1) Å and the measured P.....P distances range from 3.447(1) Å in $(dppf)PdCl_2$ to 3.783(1) Å in $(dppf)Mo(CO)_4$ (54).

Synthesis and properties of DNA oligomers containing an O4-ethylated thymine. d(e^{4}TpA), d(Ape^{4}T), d(Ape^{4}TpA), and d(Tpe^{4}TpT)[1]

GARRY W. BUCHKO, FRANK E. HRUSKA,[2] AND KRISHAN L. SADANA
Department of Chemistry, The University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received February 21, 1990

GARRY W. BUCHKO, FRANK E. HRUSKA, and KRISHAN L. SADANA. Can. J. Chem. **68**, 2011 (1990).

Syntheses via the phosphotriester method are described for DNA oligonucleotides containing O4-ethylated thymine (e^{4}Thy) and adenine (Ade) bases, d(e^{4}TpA), d(Ape^{4}T), and d(Ape^{4}TpA), for their unmodified analogs, d(TpA), d(ApT), and d(ApTpA), and for d(Tpe^{4}TpT). ^{1}H NMR chemical shift data obtained from 10 to 70°C at 300 and 500 MHz show that these molecules form right-handed minihelices at low temperature in aqueous solution; the presence of the O4-ethyl group does not seem to have a drastic effect on the stacking geometry of the thymine base. The presence of right-handed stacking is confirmed by circular dichroic data obtained over a similar temperature range. Coupling constants for the sugar ring indicate that the e^{4}Tp unit of d(e^{4}TpA) does not show the shift towards the 3′-*endo* (*N*) pucker noted for the corresponding unit of d(e^{4}TpT). A prominent quasimolecular ion peak $[M - H]^-$ is observed for the modified and unmodified molecules in the spectra obtained by Fast Atom Bombardment mass spectrometry (FAB-MS) operating in the negative ion mode, indicating that the labile O4-ethyl group is sufficiently stable to withstand the ionization process used in this method. In addition, a number of fragment ion peaks such as $[O4\text{-ethylthymine} - H]^-$ are observed that reveal the potential of FAB-MS for characterizing DNA oligomers modified by alkylating agents.

Key words: oligonucleotides, O-alkylation, stereochemistry, NMR, mass spectrometry.

GARRY W. BUCHKO, FRANK E. HRUSKA et KRISHAN L. SADANA. Can. J. Chem. **68**, 2011 (1990).

On décrit la synthèse, par la méthode du phosphotriester, des oligonucléotides de l'ADN contenant les bases O4-éthylées de la thymine (e^{4}Thy) et de l'adénine (Ade), d(e^{4}TpA), d(Ape^{4}T) et d(Ape^{4}TpA), et leurs analogues qui ne sont pas modifiés, d(TpA), d(ApT), d(ApTpA) et d(Tpe^{4}TpT). Les données relatives aux déplacements chimiques en RMN du ^{1}H, obtenues de 10 à 70°C à 300 et à 500 MHz, montrent que, en solution, à basse température, ces molécules forment des minihélices tournant vers la droite; la présence de groupements O-éthyles ne semble pas affecter beaucoup la géométrie de l'empilement de la base thymine. La présence d'un empilement tournant à droite est confirmé par les données de dichroïsme circulaire obtenues sur la même plage de températures. Les constantes de couplage dans les cycles des sucres indiquent que l'unité e^{4}Tp de d(e^{4}TpA) ne présente pas le déplacement vers la forme 3′-*endo* (*N*) replissée qui a été observée pour l'unité correspondante de d(e^{4}TpT). On a déterminé les spectres de masse par bombardement avec des atomes rapides (SM-BAR) en mode d'ion négatif des molécules tant modifiées que non-modifiées et on observe toujours un pic prédominant qui est pratiquement moléculaire $[M - H]^-$; ce résultat indique que le groupement labile O-éthyle est suffisamment stable pour supporter le processus d'ionisation utilisé dans cette méthode. De plus, on a observé un certain nombre de pics correspondants à des ions de fragmentation, comme $[O4\text{-éthylthymine} - H]^-$, qui révèlent le potentiel de la SM-BAR pour caractériser des oligomères d'ADN qui ont été modifiés par des agents alkylants.

Mots clés : oligonucléotides, O-alkylation, stéréochimie, RMN, spectrométrie de masse.

[Traduit par la revue]

Introduction

Alkylating agents such as alkyl nitrosoureas react with the oxygen atoms of DNA bases to form the O2- and O4-alkylthymines (r^{2}Thy, r^{4}Thy) and O6-alkylguanine (r^{6}Gua), or with the polynucleotide backbone to form alkyltriesters (1). Experimental evidence indicates that the altered thymine (Thy) and guanine (Gua) bases can mispair during replication and lead to mutations (1). On the other hand, the formation of the alkyltriesters does not lead to misincorporation of bases, though their presence has been shown to inhibit in vitro replication by *E. coli* DNA polymerase I (2). Some insight into the action of these agents is provided by the structural information obtained at the monomer level by X-ray crystallographic (3–8) and NMR (9, 10) investigations of O-alkylated nucleosides. More useful are the structural data for oligomer duplexes containing an O-alkylated base, but studies on such duplexes are limited (11, 12).

As part of our study of the structural consequences of base modification, we have been synthesizing DNA oligomers[3] containing r^{4}Thy. Since this base is labile in acid and basic solution (9, 13), these syntheses require considerable care, and for this reason our investigation was begun with molecules containing only r^{4}Thy and the parent Thy base. Initially we described (14) the synthesis of e^{4}TpT and Tpe^{4}T, the O4-ethylated analogues of TpT. This was followed (15) by the synthesis of the corresponding O4-isopropylated dimers, i^{4}TpT and Tpi^{4}T, and the trimer Tpi^{4}TpT. Also provided was their characterization by NMR, Fast Atom Bombardment mass spectrometry (FAB-MS), and circular dichroism (CD). Here we extend our work to oligomers containing an adenine (Ade) as well as an e^{4}Thy base: e^{4}TpA (**1**), Ape^{4}T (**2**), and Ape^{4}TpA (**3**) (Fig. 1). In addition, we report our methods for the synthesis of Tpe^{4}TpT (**7**). ^{1}H NMR as well as FAB-MS and CD data are provided for comparison with the unmodified analogues, TpA (**4**), ApT (**5**), and ApTpA (**6**), and with the oligomers discussed in our earlier manuscripts (14, 15). The data are discussed in terms of the conformational properties of the molecules in aqueous solution.

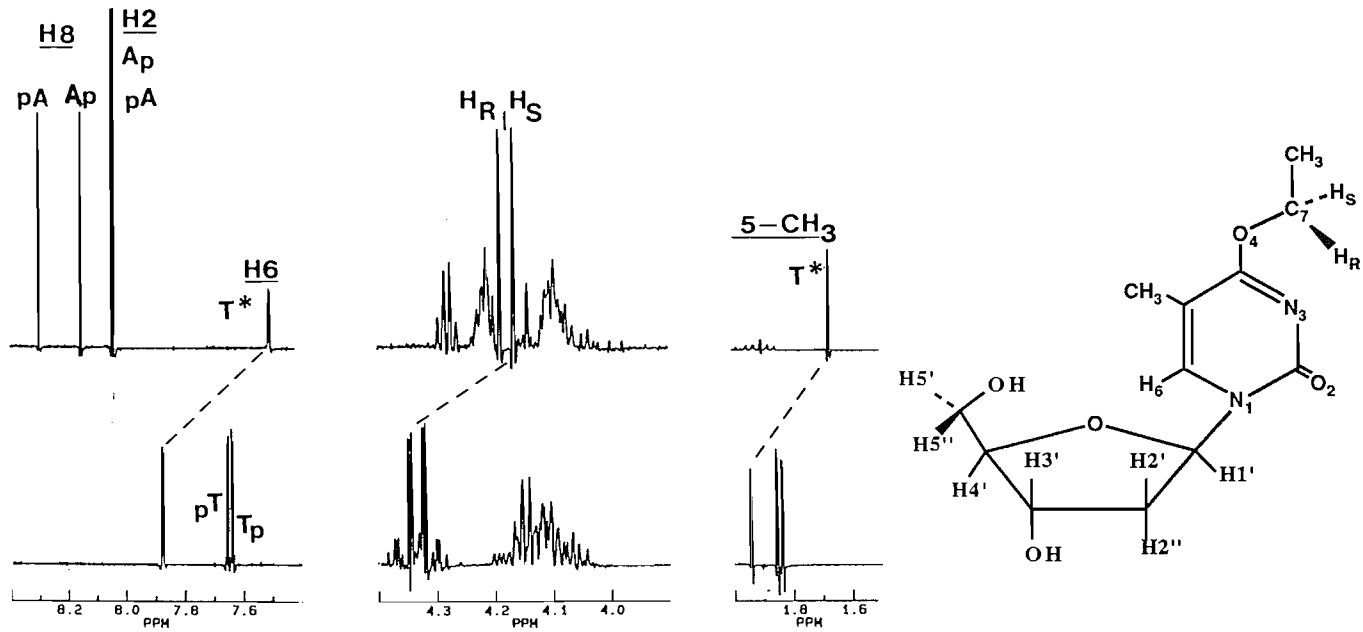

FIG. 1. Right, structure and numbering of e^4dT (O4-ethylthymidine). The methylene and methyl carbons of the O4-ethyl group are denoted C7 and C8, respectively; H_R and H_S refer to the *pro-R* and *pro-S* methylene protons of C7. Left, partial 300 MHz ^{1}H NMR spectra (27°C) of Ape^{4}TpA (**3**) (upper) and of Tpe^{4}TpT (**7**) (lower). The chemical shifts (δ) are in ppm relative to DSS. Note the intense H_R, H_S bands (joined by dashed lines) at 4.18 ppm and 4.33 ppm in the spectra of **3** and **7**, respectively. T* denotes the e^4Thy base.

Experimental

Materials and methods

2′-Deoxythymidine (dT), 2′-deoxyadenosine (dA), and the reagents used for protection, coupling, and deblocking were purchased (Aldrich or Sigma Chemical Co.). 5′-*O*-4,4′-Dimethoxytrityl-6-*N*-benzoyl-adenosine was obtained from Cruachem Inc. whereas the protected thymidines were synthesized and purified as described by Buchko *et al.* (14). Chromatographic solvents were purchased from Fisher Scientific. Thin-layer chromatography (TLC) was carried out on Kieselgel 60 F_{254} plates (Merck). Kieselgel 60 (Merck) was used for dry-column flash chromatographic (DCFC) purification of the precursors. Deprotected oligomers were purified initially by descending paper chromatography (Whatman paper No. 1) using solvent B′ (*n*-butanol:ethanol:water = 4:1:5 v/v, organic phase), followed by purification by HPLC (Perkin Elmer Series 4 liquid chromatograph) using a semipreparative ODS-Hypersil column and a gradient of methanol and 0.1 M aqueous ammonium acetate (pH 6.0). The strategy used for the synthesis of **1**, **2**, and **3** is shown in Scheme 1.

Synthetic methods

3′-Acetyl-4-(1,2,4-triazol-1-yl)-thymidine (**8**) and *5′*-O-*4,4′-dimethoxytrityl*-O-*4-ethylthymidine* (**9**) were synthesized according to Buchko *et al.* (14), except that the 4,4′-dimethoxytrityl group (DMT) was used in place of the *tert*-butyldimethylsilyl (TBDMS) group for 5′-protection in **9**. This change in the 5′-protecting group was necessary for our synthesis of **3**, which involves 5′-extension of the appropriately blocked **1** (see **15** below). The extension initially requires the removal of the 5′-protecting group from **15**. If TBDMS had been used for 5′-protection, then 5′-deprotection of **15** would have required tetra-*n*-butylammonium fluoride (TBAF), a reagent that also effects an undesirable removal of the 2-chlorophenyl group used for phosphate protection (14, 16). On the other hand, the 5′-DMT group is conveniently removed by a reagent, $ZnBr_2$, that leaves the protected phosphate intact.

3′-O-*Acetyl-6*-N-*acetyl-2′-deoxyadenosine* (**10**)

5′-*O-tert*-Butyldimethylsilyl-2′-deoxyadenosine (**11**) was prepared following Ogilvie (17), and converted to 5′-*O-tert*-butyldimethylsilyl-3′-*O*-acetyl-6-*N*-acetyl-2′-deoxyadenosine (**12**) using acetic anhydride. Molecule **10** was obtained by desilylation of **12** using TBAF (17).

6-N-*Benzoyl-2′-deoxyadenosine* (**13**) was prepared via Schaller *et al.* (18) and converted to 5′-*O-tert*-butyldimethylsilyl-6-*N*-benzoyl-2′-deoxyadenosine (**14**) following Ogilvie (17).

e^4TpA (**1**)

Molecule **9** was phosphorylated with 2-chlorophenyl phosphodichloridate and condensed with **10** using 2,4,6-triisopropylbenzenesulfonyl chloride (TPSCl) and tetrazole (14) to give **15**, the fully protected dimer. Molecule **15** was purified and then deprotected by sequential treatment with (i) $ZnBr_2$ for detritylation (19), (ii) oximate for phosphate deprotection, and (iii) ethanolic sodium ethoxide for removal of the 6-*N*- and 3′-*O*-acetyl groups.

Ape^{4}TpA (**3**)

Molecule **15** was detritylated with $ZnBr_2$ and purified by DCFC. The product was phosphorylated with 2-chlorophenyl phosphodichloridate and coupled with 5′-*O*-4,4′-dimethoxytrityl-6-*N*-benzoyl-2′-deoxyadenosine. The fully protected trimer **16** was then deblocked sequentially as described above.

Ape^{4}T (**2**)

Molecule **14** was phosphorylated and condensed with **8** to give **17**. Molecule **17** was deprotected, as described in the synthesis of Tpe^{4}T (14), by (a) TBAF for 1 min and (b) sodium ethoxide. Note that, because of the presence of the 6-*N*-benzoyl group, the sodium ethoxide treatment had to be extended to 12 h from the 1 h required for deprotection of Tpe^{4}T (14).

Molecules **4**, **5**, and **6**, the unmodified analogues of **1**, **2**, and **3**, were prepared by replacing sodium ethoxide with sodium hydroxide (pH > 13) during deblocking of the fully blocked forms of **1**, **2**, and **3**.

Tpe^{4}TpT (**7**)

This molecule was prepared from the fully blocked form of the O4-isopropylated trimer Tpi^{4}TpT (**18**), the synthesis of which was described by Buchko *et al.* (14). Treatment of **18** with $ZnBr_2$, oximate reagent, and sodium ethoxide yielded **7**. Note that the sodium ethoxide both removes the 3′-*O*-acetyl protecting group and effects an alkoxy exchange, replacing the O4-isopropyl with the O4-ethyl function on the central base. Exchange of O4-isopropyl groups by O4-methyl

[a]Temperature in 0°C. Spectra acquired at 300.1 MHz (**1**, **2**, **4**) and 500.1 MHz (**3**, **5**, **6**, **7**). Proton labelling (Fig. 1): 5M, 5-methyl; 7A and 7B: diastereotopic C7 methylene protons at low and high field, respectively (no absolute assignment to H_R and H_S can be made here); 8M: 8-methyl protons of the O4-ethyl group.

[b]δ is given to only three significant figures when the analysis was complicated by strong coupling or peak overlap. If the overlap is particularly severe, only the general location of the proton is indicated to two significant figures.

[c]A crossover in the H_R and H_S protons of **3** is suggested by the temperature dependence of their spectral band.

more prominent peaks are reported here as follows: m/z (relative intensity, [ionic species]), with the relative intensity normalized to the molecular ion $[M - H]^-$. *e^4TpA*: 582 (100, $[M - H]^-$); 674 (5.6, [M + glycerol − H]$^-$); 554 (9.7, $[M - CH_2CH_3]^-$); 153 (58, [O4-ethylthymine − H]$^-$); 349 (39, [3′-e^{4}dTMP − H]$^-$); 330 (20, [5′-dAMP − H]$^-$); 134 (39, [adenine − H]$^-$). *Ape^{4}T*: 582 (100, $[M - H]^-$); 674 (5.5, [M + glycerol − H]$^-$); 554 (12, $[M - CH_2CH_3]^-$); 153 (24, [O4-ethylthymine − H]$^-$); 349 (60, [5′-e^{4}dTMP − H]$^-$); 330 (14, [3′-dAMP − H]$^-$); 134 (94, [adenine − H]$^-$). *Ape^{4}TpA*: 895 (100, $[M - H]^-$); 867 (13, $[M - CH_2CH_3]^-$); 662 (78, [Ape^{4}Tp − H]$^-$ + [pe^{4}TpA − H]$^-$); 330 (217, [3′-dAMP − H]$^-$ + [5′-dAMP − H]$^-$); 153 (126, [O4-ethylthymine − H]$^-$); 134 (435, [adenine − H]$^-$). *TpA*: 554 (100, $[M - H]^-$); 646 (6.8, [M + glycerol − H]$^-$); 125 (49, [thymine − H]$^-$); 321 (22, [3′-dTMP − H]$^-$); 330 (22, [5′-dAMP − H]$^-$); 134 (19, [adenine − H]$^-$). *ApT*: 554 (100, $[M - H]^-$); 646 (12, [M + glycerol − H]$^-$); 330 (19, [3′-dAMP − H]$^-$); 321 (69, [5′-dTMP − H]$^-$); 134 (57, [adenine − H]$^-$); 125 (52, [thymine − H]$^-$). *ApTpA*: 867 (100, $[M - H]^-$); 634 (80, [ApTp − H]$^-$ + [pTpA − H]$^-$); 330 (146, [3′-dAMP − H]$^-$ + [5′-dAMP − H]$^-$); 134 (185, [adenine − H]$^-$); 125 (131, [thymine − H]$^-$). *Tpe^{4}TpT*: 877 (100, $[M - H]^-$); 653 (36, [Tpe^{4}Tp − H]$^-$ + [pe^{4}TpT − H]$^-$); 321 (80, [3′-dTMP − H]$^-$ + [5′-dTMP − H]$^-$); 573 (5, [Tpe^{4}T − H]$^-$ + [e^{4}TpT − H]$^-$); 153 (27, [O4-ethylthymine − H]$^-$); 125 (182, [thymine − H]$^-$).

^{1}H NMR experiments

^{1}H NMR spectra were obtained at 300.1 MHz (Bruker AM300) and 500.1 MHz (Bruker AM 500, McMaster University). The samples were contained in 5 mm (o.d.) tubes at concentrations in D_2O (3.0–12.0 mM) that preclude significant intermolecular interaction. The concentrations were obtained from UV absorbance measurements at 260 nm. The molar extinction coefficients per residue (ε_{260}) were taken from ref. 22 (**4**: 11 700; **5**: 11 400) or calculated by the method described therein (**6**: 12 500). The ε_{260} of **1** (9030), **2** (8800), **3** (10 800), and **7** (6570) were obtained by correcting the ε_{260} of the corresponding *unmodified* molecule for the Thy to e^{4}Thy substitution. For this correction, we used $\varepsilon_{260} = 3200$ for an e^{4}dT unit, which we estimated from the UV absorption profile of this monomer and the ε_{max} provided by Singer *et al.* (20). The solutions contained 0.01 M sodium phosphate buffer (pH = 6.9), EDTA (0.001 M) to chelate paramagnetic ions, 0.1 M NaCl to maintain a constant ionic strength, and, for an NMR reference, a trace of *tert*-butanol (assigned a chemical shift of 1.231 ppm on the DSS scale). The samples were lyophilized twice from 99.8% D_2O and taken up in 99.9% D_2O. One-dimensional (1D) FIDs were collected at 10°C intervals from 10 to 70°C in 16K of computer memory and processed with a Lorentz-to-Gaussian lineshape transform prior to zero-filling to 32K. The HDO resonance was suppressed by presaturation (Bruker PRESAT. AU microprogram). Conventional homonuclear decoupling, nOe, and two-dimensional (COSY-45°) (23) and relayed coherence transfer (24) experiments were carried out for spectral assignments. Spectra for the trimers at 10 and 70°C were also obtained at 500 MHz (Bruker AM500). Spectra were analyzed (NUMARIT) (25) at two temperatures (10 or 20°C, and 70°C), and computer-generated spectra confirmed the data.

Circular dichroism experiments

Circular dichroic spectra were obtained on a Jasco J-500A spectropolarimeter using a cell equipped for temperature control with a water bath. The molecules were studied at concentrations $(0.46–3.64) \times 10^{-4}$ M (calculated from UV absorbance measurements) in the phosphate buffer solution used for the NMR experiments.

Results and discussion

Nuclear magnetic resonance spectra, data, and assignments

Tables 1 and 2 provide ^{1}H chemical shift (δ) and coupling constant (J) data; partial 1D NMR spectra of the trimers **3** and **7** are shown in Fig. 1. The methods used to assign the spectral bands have been listed by Buchko *et al.* (14, 15); our assignments for **4** and **5** are in agreement with those of Kan *et al.* (26), and Cheng and Sarma (27). Data provided by Mellema *et al.* (28) were useful for assigning our trimer spectra. As noted earlier (14), the C7 methylene protons of the O4-ethyl group of an e^{4}dT fragment are diastereotopic because of the chiral centres in the sugar; the *pro-R* and *pro-S* atoms are designated H_R and H_S (Fig. 1). At the nucleoside level (e^{4}dT), H_R and H_S are isochronous (A_2X_3 pattern for the O4-ethyl group); this isochronicity indicates that the chiral sugar is too distant from the ethyl group to induce detectable differential shielding (Δ) in these protons (5, 14). A temperature-dependent Δ was evident (14) in the ABX_3 patterns observed for e^{4}TpT (**19**) and Tpe^{4}T (**20**) and attributed to intramolecular base stacking. A temperature-dependent Δ is also apparent in the H_R, H_S band of the all-pyrimidine trimer (**7**) (4.32 ppm, Fig. 1; Fig. 7 below) and in the corresponding bands of the adenine-containing dimers **1** and **2**. Note that no Δ is apparent in the spectrum of **3** at 27°C (intense quartet at 4.18 ppm; Fig. 1) though differential shielding is observed in **3** at other temperatures. We are not able to provide an absolute assignment of H_R and H_S, and so they are denoted in Tables 1 and 2 as 7A (less shielded) and 7B (more shielded).

Chemical shift temperature profiles: pyrimidine units

Temperature profiles of the chemical shifts are useful for assessing which conformations prevail in solution (29, 30). At our concentrations, intermolecular association should not be serious for the dimers and trimers, although Altona (29) has suggested that some association can occur at concentrations of ~10 mM, particularly when the oligomer contains bases such as methylated adenines, which have a strong tendency to stack. Even in the absence of complications from association effects, deriving conformations for single-stranded oligomers from δ data is complicated because the molecules exhibit considerable flexibility by interconverting between several stacked and unstacked forms that differ in their sugar pucker, in the orientation of the bases about the glycosyl link (χ), and so on. Thus, we shall restrain ourselves to more or less qualitative statements regarding the influence of the O4-alkylation on the positioning of the Thy base in any ordered structure that may form. The chemical shifts of the pyrimidine base should be determined mainly by intramolecular factors, particularly for our trimers in which the pyrimidine is sandwiched between the terminal bases. The profiles discussed below suggest that the e^{4}Thy and Thy derivatives form right-handed (RH) base-stacked structures at low temperature and that the O4-ethyl group has no large effect on the orientation of the pyrimidine base within the stack.

(a) *5-Methyl (5M) protons*

These profiles (Fig. 2) reveal association of the Pyr bases with an Ade on their 5′ side. At the monomer level, e^{4}dT and dT, O4-ethylation leads to a deshielding of 0.09 ppm for the 5M protons; neither monomer shows any temperature dependence. If Thy or e^{4}Thy is located at the 5′ end of an adenine-containing dimer (**1** and **4**), or in the central position of an all-pyrimidine trimer, **7** and **21** (TpTpT), the 5M protons experience only small upfield shifts ($\Delta\delta < 0.07$ ppm, where $\Delta\delta$ is the chemical shift of a proton in an oligomer relative to the corresponding monomer). In contrast, when the pyrimidine is located at the 3′ end of an adenine-containing dimer (**2** and **5**), or is flanked by two Ade bases as in the trimers **3** and **6**, the 5M protons are shifted upfield at 10°C relative to the monomers: ~0.35 ppm for e^{4}Thy of **2** and

[a]Temperature in 0°C. Spectra acquired at 300.1 MHz (**1**, **2**, **4**) and 500.1 MHz (**3**, **5**, **6**, **7**). Proton labelling (Fig. 1). Other couplings showing little variation: $^2J(2'2'')$: −14.1 ± 0.2 Hz; $^2J(5'5'')$: −12.6 ± 0.2 Hz (Np) or −11.6 ± 0.2 Hz (pNp, pN); for the O4-ethyl, $^2J(RS)$ = −10.6 Hz and $^3J(78)$ = 7.1 Hz; $^4J(56)$: 1.1–1.2 Hz (e^4Thy) and 1.2–1.3 Hz (Thy). Only the sums of connected coupling constants are significant if δ2′ ~ δ2″ or if δ5′ ~ δ5″. Bold-faced Js are from first-order analyses.

[b]J cannot be obtained due to spectral overlap.

3, and ~0.28 ppm for Thy of **5** and **6**. Note that the Δδ for e^4Thy on the one hand, and for Thy on the other, are identical to within 0.04 ppm at the dimer and trimer levels; this indicates that the Ade base on the 5′ side of the pyrimidine is the main source of the 5M shielding in the trimers, with little, if any, shielding derived from the Ade on the 3′ side. Increasing the temperature to 70°C leads to a downfield shift of 0.12–0.15 ppm for the 5M protons of **2**, **3**, **5**, and **6**, and their shifts approach those of the monomers. The trends in Fig. 2 suggest that e^4Thy and Thy of **2**, **3**, **5**, and **6** participate in a RH base-stacked structure. In such a conformation, the 5M group lies over the Ade in the 5′ direction and would experience the substantial ring current shielding of this purine. On the other hand, an Ade located on the 3′ side of the pyrimidine is not expected to cause significant shielding of the 5M group. Earlier NMR data were interpreted in terms of RH folding for TpA (26, 27) and for the pTpA segment of TpTpA (31). Also, the small Δδ for the NpA and large Δδ for the ApN are strong indications that the Thy and e^4Thy bases are *anti* about the *N*-glycosyl bond (26–31); both e^4dT and dT assume this conformation in the crystal state (5, 32). In the trimers **7** or **21**, the central base is flanked by pyrimidines that sustain a smaller ring current and are less inclined than purines to base stack; in these cases, Δδ for the central base is slight (<0.03 ppm) and shows little temperature dependence (Fig. 2). The somewhat larger Δδ(e^4Thy) for **2** and **3** relative to Δδ(Thy) for **5** and **6** could be due to an effect of O4-ethylation on the extent of base stacking, or on the orientation of the pyrimidine relative to the stacked Ade base in the 5′ direction; our data do not warrant further comment on this matter.

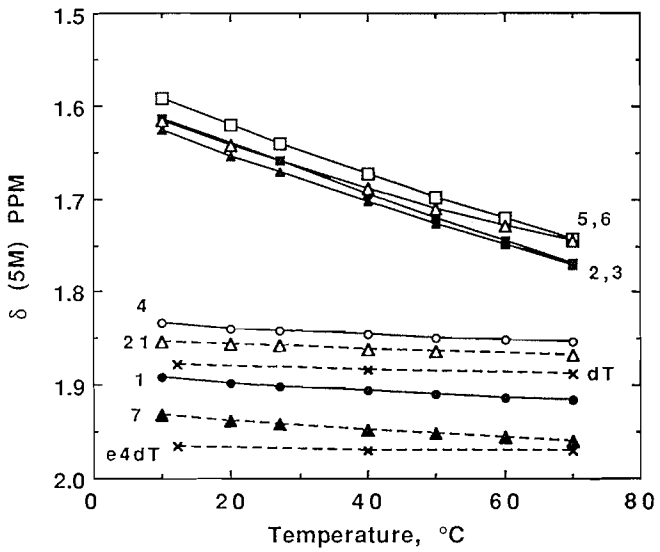

FIG. 2. Temperature profile of the chemical shifts (δ in ppm from DSS) of the 5-methyl (5M) protons of e⁴Thy (solid symbols) and Thy (open symbols). Connected by solid lines: e⁴TpA (**1**, ●), TpA (**4**, ○), Ape⁴T (**2**, ■), ApT (**5**, □), Ape⁴TpA (**3**, ▲), and ApTpA (**6**, △). Connected by dashed lines: pe⁴Tp unit of Tpe⁴TpT (**7**, ▲) and pTp unit of TpTpT (**21**, △); ×: monomers e⁴dT and dT.

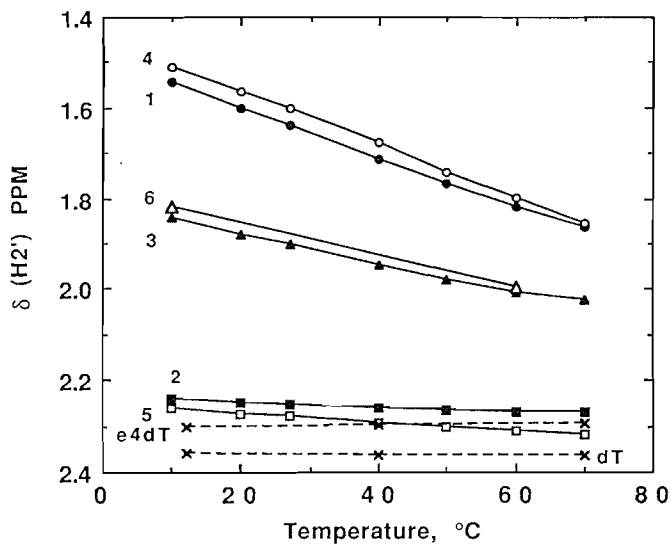

FIG. 3. Temperature profiles for the H2′ chemical shifts (δ in ppm from DSS) for the e⁴Thy (solid symbols) and Thy (open symbols) nucleotidyl units. Connected by solid lines: e⁴TpA (**1**, ●), TpA (**4**, ○), Ape⁴T (**2**, ■), ApT (**5**, □), Ape⁴TpA (**3**, ▲), and ApTpA (**6**, △). Connected by dashed lines: monomers e⁴dT and dT.

(b) *Sugar H2′ protons*

These profiles (Fig. 3) reveal association of Thy and e⁴Thy with an Ade base on the 3′ side. The δ(H2′) of dT and e⁴dT are identical to within 0.07 ppm and independent of temperature. In dimers **1** and **4**, an Ade base is on the 3′ side of the e⁴Tp and Tp units, and molecular models of RH structures show that H2′(Np) can enter the shielding regions above the plane of this purine. Consistent with RH helix formation are the large Δδ(H2′) at 10°C for **1** (0.76 ppm) and **4** (0.85 ppm), as are the large downfield shifts (~0.34 ppm) observed when the temperature is increased to 70°C. On the other hand, in the RH stack of dimers **2** and **5**, H2′ of the pe⁴T and pT moieties is distant from the Ade of the Ap unit; these protons are not expected to sense its ring current and indeed their δ behave like those of the monomers. The behaviour of H2′(Np) of **1** and **4** also contrasts with that of H2′(Np) of their all-pyrimidine analogs, e⁴TpT and TpT, which show a greatly reduced temperature dependence in the 10–70°C range (14), in line with smaller ring currents of the pT base.

Consistent with a RH structure for the pNpA segments of the trimers **3** and **6** is the upfield shift, Δδ, of H2′ for their pNp moieties at 10°C (pe⁴Tp: 0.46 ppm; pTp: 0.54 ppm) and the downfield shift (~0.20 ppm) when the temperature is elevated to 70°C. No such effects are observed for the pNp fragment of the all-pyrimidine trimers **7** (Table 1) and **21** (33). However, it is surprising that Δδ(H2′) for the trimers at 10°C is only 60% of that for the dimers **1** and **4**. Initially we thought that this reduction might be indicative of a competition between the terminal Ade bases for stacking with the central base. This view, however, is not consistent with the data in Fig. 2, which show that Δδ(5M) are similar at the dimer and trimer levels. Oltshoorn *et al.* (34) also observed an anomalous H2′ shift of similar magnitude for H2′ of the central pAp unit of ApApA relative to the Ap unit of ApA. They presented a rationale for this anomaly based on (a) the populations of the g^+ conformers of the C4′—C5′ (γ) bond and (b) the deshielding of H2′ by O5′ when γ is g^+. Unfortunately, the complexity of the NMR spectrum of **3** did not permit determination of accurate values of $J(4'5')$ and $J(4'5'')$ of the pe⁴Tp unit (Table 2) and so a comparison of the g^+ populations of the e⁴Thy units of **1** and **3** cannot be made. On the other hand, accurate values for these couplings could be determined for **4** and **6** (Table 2); these indicate that the g^+ population is larger for pTp (**6**) relative to Tp (**4**), and so the Oltshoorn interpretation may account for our δ(H2′) anomalies. But, whatever the cause of the reduced H2′(pNp) shielding at the trimer level, the important message is that it operates whether the pNp base is Thy or e⁴Thy, and so we have further support for the contention that O4-ethylation has no drastic effects on the conformation of our molecules.

(c) *Sugar H2″ protons*

In Fig. 4 we compare H2″ profiles for the Np fragments of e⁴TpA (**1**) and TpA (**4**) with those for H2″(Np) of the all-pyrimidine dimers e⁴TpT (**19**) and TpT (**22**) (data from refs. 14 and 35). Also compared are profiles of H2″(pNp) of Ape⁴TpA (**3**) and ApTpA (**6**) with the H2″(pNp) protons of the all-pyrimidine trimers Tpe⁴TpT (**7**) and TpTpT (**21**). For the all-pyrimidine molecules, we note that δH2″ is independent of temperature in the 10–70°C range. (Note also that H2″ for an e⁴Thy unit is shifted downfield (~0.1 ppm) relative to the corresponding Thy data; a comparable effect was observed at the monomer level (9), and so must be an intranucleoside effect.) In the Ade-containing molecules at 10°C, H2″ is shifted upfield, the shift being slightly larger (10–15%) for the Thy units (**4**: 0.43 ppm; **6**: 0.35 ppm) than for e⁴Thy units (**1**: 0.38 ppm; **3**: 0.31 ppm). At 70°C, the shielding effect is reduced by about 40%, and the δ(H2″) approach those of the all-pyrimidine molecules. Profiles are not given for the H2″(pN) of the isomers Ape⁴T (**2**) and TpT (**22**), but our data for these dimers indicate that an Ade base on the 5′ side has much smaller shielding effect (<0.08 ppm) on H2″(pN). Thus, the data in Fig. 4 confirm stacking of a e⁴Tp and Tp base with an Ade on its 3′ side.

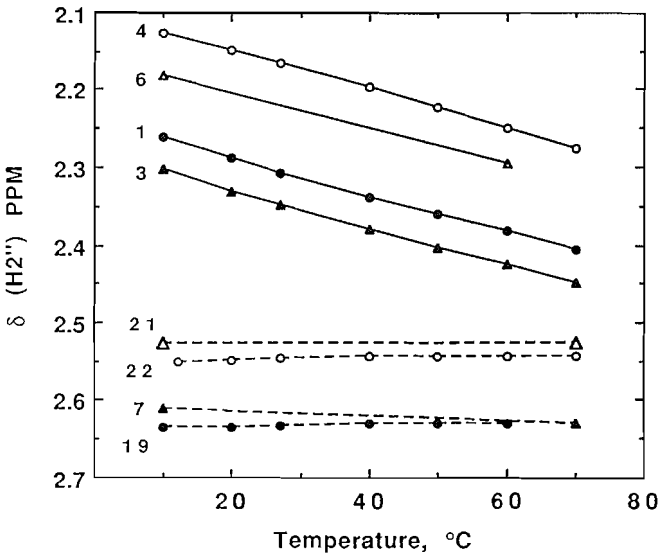

FIG. 4. Temperature profiles for the H2″ chemical shifts (δ in ppm from DSS) for the e⁴Thy (solid symbols) and Thy (open symbols) nucleotidyl units. Connected by solid lines: e⁴TpA (**1**, ●), TpA (**4**, ○), Ape⁴TpA (**3**, ▲), and ApTpA (**6**, △). Connected by dashed lines: e⁴Tp of e⁴TpT (**19**, ●), Tp of TpT (**22**, ○), pe⁴Tp of Tpe⁴TpT (**7**, ▲), and pTp of TpTpT (**21**, △). Data for **19** and **22** are from ref. 14.

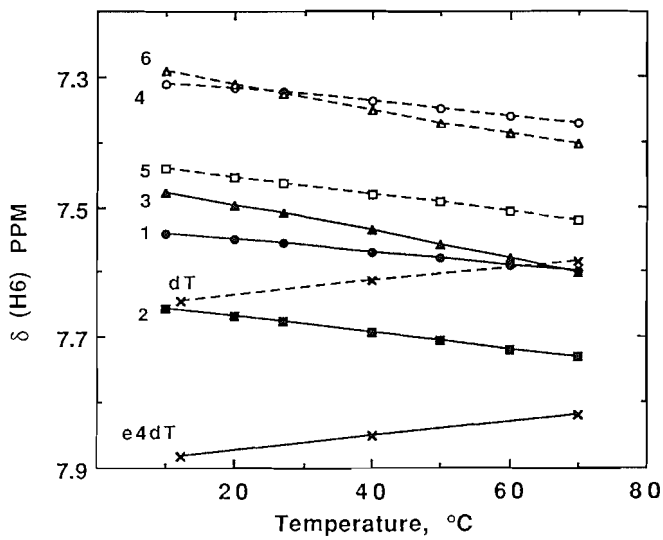

FIG. 5. Temperature profile for the H6 chemical shifts (δ in ppm from DSS) for e⁴Thy (solid lines and symbols) and Thy (dashed lines, open symbols). e⁴TpA (**1**, ●), TpA (**4**, ○), Ape⁴T (**2**, ■), ApT (**5**, □), Ape⁴TpA (**3**, ▲), and ApTpA (**6**, △). ×: monomers e⁴dT and dT.

(d) *Base H6 protons and sugar H1′*

The e⁴dT and dT data in Fig. 5 show that O4-ethylation effects a deshielding of 0.23 ppm in the H6 chemical shift, and in each monomer, H6 shifts upfield by ~0.06 ppm as the temperature is increased to 70°C. Relative to the corresponding monomer, the δ(H6) at 10°C are shifted upfield in the NpA (**1**: 0.34 ppm; **4**: 0.33 ppm), the ApN (**2**: 0.23 ppm; **5**: 0.20 ppm), and the ApNpA (**3**: 0.41 ppm; **6**: 0.36 ppm), and in each instance H6 shifts downfield as the temperature increases. It is remarkable that, if a correction of 0.23 ppm is made for the effect of O4-alkylation, the corresponding profiles for the e⁴Thy and Thy bases (NpA, etc.) are identical to within ~0.05 ppm over the entire temperature range. The H6 chemical shifts relative to the monomer reflect a variety of factors including sugar phosphorylation, ring current effects from the adjacent Ade bases, and solvent effects (14), and so are not easily interpreted in conformational terms. However, the correspondence of the two sets of profiles provides support for the contention that the stacking geometries are not drastically affected by O4-ethylation. This contention is further supported by the correspondence in the H1′ profiles (Fig. 6), which show similar upfield shifts for the e⁴Thy and Thy nucleotidyl fragments of the NpA, ApN, and ApNpA relative to the monomers. In each case, this shift is slightly larger for the Thy, but never by more than 0.05 ppm in the 10–70°C range.

(e) *O-Alkyl chemical shifts*

It would be useful to discuss the chemical shifts of the diastereotopic C7 methylene (H_R, H_S) and C8 methyl protons of the *O*-ethyl group in light of the conclusions based on the temperature profiles discussed above. In general, this group in the oligomers shows an ABX_3 pattern (Fig. 1 and Table 1), that is, the C7 protons are not identically shielded, but have a differential shielding (Δ) that depends on the molecule and the solution temperature. Figure 7 shows that at 10°C both C7 protons are shielded relative to e⁴dT and shift downfield as the temperature increases, presumably due to the stacking–destacking process (14). In the case of the all-pyrimidine trimer **7**, the upfield shifts at 10°C are small (0.07 ppm, 0.04 ppm), no doubt a reflection of the reduced ring currents and propensity for stacking of the flanking Thy bases; small upfield shifts (<0.07 ppm) were observed for the dimers **19** and **20** as well (14). The upfield shifts are also small in dimer **1** (0.07 ppm, 0.09 ppm), and so, bearing in mind the striking upfield shift experienced at 10°C by the H2′ of e⁴Tp (**1**) (0.76 ppm; Fig. 3), we conclude that the C7 protons do not enter the strongly shielding regions above an Ade base stacked on the 3′ side of the e⁴Thy base. However, larger shielding is experienced by the C7 protons in dimer **2** (0.16 ppm, 0.18 ppm) and in trimer **3** (0.22 ppm, 0.23 ppm). These trends, along with the 5M profiles (Fig. 2), point to a better overlap of the 5M-C5-C4-O4-C7 segment of the e⁴Thy base with an Ade on the 5′ side than with an Ade on the 3′ side, a result easily reconciled with a RH helical stack.

On the other hand, the C8 methyl protons show much less variation (Table 2; refs. 14, 35). In e⁴dT, δ(H8) = 1.36 ppm and is constant to within 0.001 ppm from 10 to 70°C; for all dimers and trimers in this temperature range, δ(H8) differs by ≤0.05 ppm from the monomer value. This constancy is consistent with a predominantly extended conformation for the *O*-ethyl group (anti-periplanar C4-O4-C7-C8), which projects the methyl group away from the stacked bases. Such an extended conformer was observed in the crystal structure of e⁴dT (5).

A result which surprised us is that, for all of the molecules whose profiles are given in Fig. 7, the two C7 protons are shifted upfield to quite similar extents over the temperature range examined. In the anti-periplanar orientation of the C4-O4-C7-C8 bond, the H_S proton flanks the e⁴Thy base on its 5′ face whereas H_R does so on the 3′ face (5),[4] and so we expected in molecule

[4]We denote as 5′ or 3′ the face that points to the 5′ or 3′ end of a strand in a normal B-DNA.

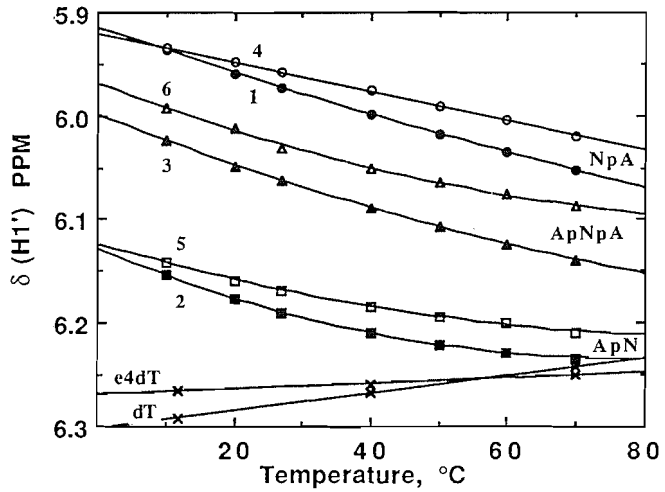

FIG. 6. Temperature profiles for the H1′ chemical shifts (δ in ppm from DSS) for e⁴Thy (solid symbols) and Thy (open symbols) nucleotidyl units. e⁴TpA (**1**, ●), TpA (**4**, ○), Ape⁴T (**2**, ■), ApT (**5**, □), Ape⁴TpA (**3**, ▲), and ApTpA (**6**, △). ×: monomers e⁴dT and dT.

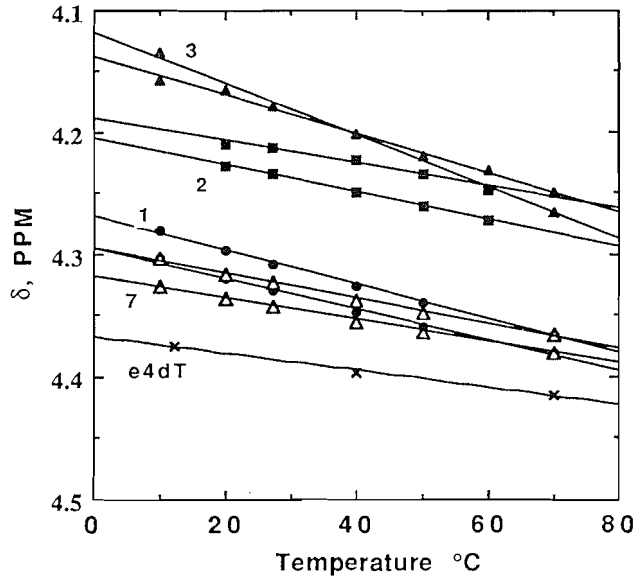

FIG. 7. Temperature profiles for the ^{1}H chemical shifts (δ ppm from DSS) of the H_R and H_S methylene protons of the O4-ethyl group. Solid symbols: e⁴TpA (**1**, ●), Ape⁴T (**2**, ■), and Ape⁴TpA (**3**, ▲). Open triangles: Tpe⁴TpT (**7**, △). An absolute assignment of the H_R and H_S protons could not be made; they are referred to as 7A (less shielded) and 7B (more shielded) in th bles. The protons are equivalent in the monomer e⁴dT (×).

2, for example, that one C7 proton, namely H_S, would be more influenced by the stacking of the Ap base, which occurs on the 5′ face. However, the similarity in upfield shifts indicates that the association of an Ade base on one particular face exerts comparable shielding on the two C7 protons. Theory (36) indicates that a number of factors (ring current, etc.) contribute to the magnetic fields near a purine base. This leads to a complex dependence of the magnetic shielding on position, and so we will not attempt to derive more precise information about stacking geometry of our flexible systems. Thus, at this point, we are uncertain whether Δ, in addition to the individual H_R and H_S chemical shifts, will prove, as we originally hoped (14), to be a generally useful quantity for monitoring local melting in e⁴Thy-containing oligomers.

(f) *Purine nucleotidyl shifts*

No temperature profiles are given for the Ap and pA units. However, the data in Table 1 show that the effect of replacing a Thy base by e⁴Thy on proton shifts of these fragments is never larger than 0.06 ppm. Overall, the purine δ data provide no evidence for any large conformational changes attributable to this replacement. Nor are they consistent with any significant purine–purine stacking, which could result from looping out of the central pyrimidine base.

Sugar conformation

Using plots of $\Sigma 1' (= J(1'2') + J(1'2''))$ to monitor changes in the sugar pucker, we noted that the modified Np fragment of e⁴TpT and of i⁴TpT (14, 15, 37) shows an unusual temperature dependence in the range 10–70°C, shifting from 2′-*endo* (*S*) towards 3′-*endo* (*N*) at low temperature. Figure 8 provides $\Sigma 1'$(Np) and $\Sigma 1'$(pNp) profiles that allow us to assess the influence of O4-ethylation in our Ade-containing dimers and trimers. The vertical axis of Fig. 8 also provides the %*S* (2′-*endo*) conformation calculated according to Rinkel and Altona (38); these populations are only approximate (±(10–15)%), and are included to provide the reader with an alternate view of the major trends defined by the primary data, $\Sigma 1'$. Considering first e⁴TpA and TpA at 70°C, we note that O4-ethylation reduces $\Sigma 1'$(Np) by about 0.6 Hz, a reduction comparable to that observed at the nucleoside level (14). Lowering the temperature to 10°C has little effect (<0.3 Hz) on these $\Sigma 1'$. Similarly, for the e⁴TpT and TpT at 70°C, we note a small decrease (~0.7 Hz) in $\Sigma 1'$(Np) due to the ethylation. However, $\Sigma 1'$(e⁴Tp) of e⁴TpT shows a large decrease (1.5 Hz) as the temperature is reduced to 10°C; this decrease is not seen for the Np unit of TpT. Since the $\Sigma 1'$ for the monomers (e⁴dT, dT) is constant in the 10–70°C range (14), the differences in behaviour of the $\Sigma 1'$ are reasonably related to intramolecular base stacking. In other words, the O4-ethylation of a Tp unit of a stacked TpN dimer causes a shift towards 3′-*endo* (*N*) if pN = pT, but not if pN = pA.

Another striking feature of the 10°C dimer data is the large difference (~3.0 Hz) between $\Sigma 1'$(Np) for e⁴TpT and TpA. This shows that the sugar of the 3′-thymidylyl unit can show a wide range of *N*,*S* populations depending on whether the base is alkylated or not, and on whether a Thy or Ade base occupies the pN unit.

The effects of O4-ethylation on the central pNp of the trimers parallel those for the dimer Np units discussed above. Thus, at 10°C, O4-ethylation effects a decrease of 1.5 Hz in $\Sigma 1'$(pNp) for the TpNpT pair whereas at 70°C these $\Sigma 1'$(pNp) differ by only 0.2 Hz. In contrast, the $\Sigma 1'$(pNp) for the ApNpA pair remain constant over the entire temperature range. We have not included in Fig. 8 any $\Sigma 1'$ data for dimer pN units. However, available data for these fragments of TpT, Tpe⁴T, ApT, and Ape⁴T (Table 2; refs. 14, 35) reveal that O4-ethylation in the 10–70°C interval leads to only a small (≤0.6 Hz) decrease in $\Sigma 1'$(pN), an effect comparable to that observed at the monomer level. In addition, our data (Table 2; refs. 14, 15, 35) show that O4-alkylation has little effect on the sugar pucker of either a thymidylyl or adenosyl residue adjacent to the modified segment.

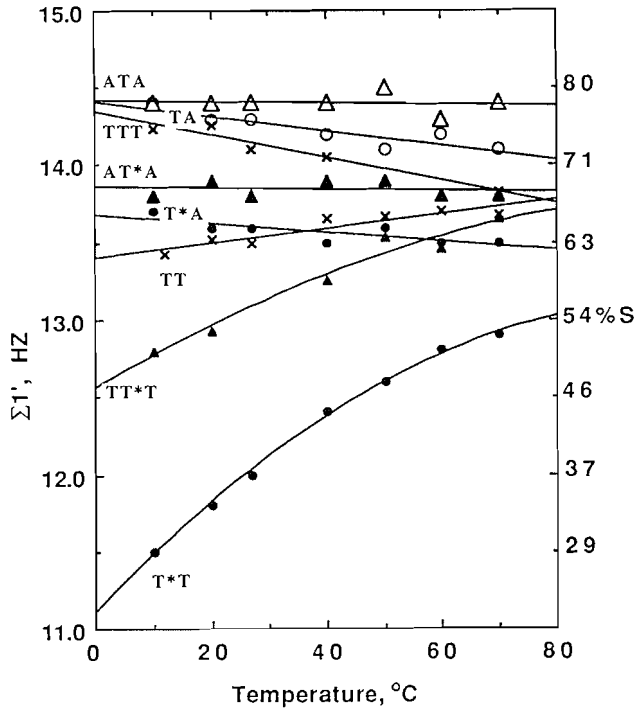

FIG. 8. Temperature profiles of $\Sigma 1' = J(1'2') + J(1'2'')$ in Hz for (a) the Np sugars of e^4TpA (**1**, ●), TpA (**4**, ○), e^4TpT (**19**, ●), and TpT (**22**, x), and (b) the pNp sugars of Ape^{4}TpA (**3**, ▲), ApTpA (**6**, △), Tpe^{4}TpT (**7**, ▲), and TpTpT (**21**, ×). The data are from Table 2, or from the width of the H1′ band; data for **19**, **21**, and **22** are from refs. 14, 15, and 35. The right vertical axis provides the *%S* (2′-*endo*) calculated from Σ1′ according to ref. 38. T* represents an e^4Thy unit.

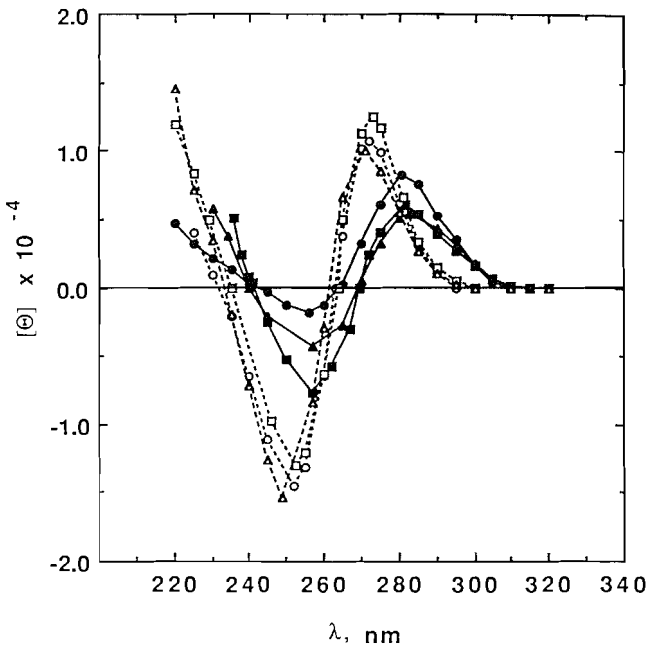

FIG. 9. Circular dichroism (CD) spectra (10–11°C). Solid symbols and lines: e^4TpA (**1**, ●), Ape^{4}T (**2**, ■), and Ape^{4}TpA (**3**, ▲). Open symbols and dashed lines: TpA (**4**, ○), ApT (**5**, □), and ApTpA (**6**, △). The vertical axis gives [θ] in deg M^{-1} cm^{-1}, the molar ellipticity per residue.

In summary, our Σ1′ data reveal an interesting sequence-dependent effect of O4-alkylation on sugar pucker that is manifest at low temperature, presumably as a consequence of the formation of minihelical conformations. Whether this phenomenon will appear in molecules larger than our dimers and trimers remains to be seen. Patel and co-workers (12, 39) have, in their NMR work, shown that e^4Thy can be accommodated into RH double helical DNA, but their data were not interpreted in terms of a precise sugar conformation for the modified nucleotide.

Populations for the *gauche*$^+$ (g^+), *trans* (t), and *gauche*$^-$ (g^-) conformers of the C4′—C5′ (γ) bond can be calculated from the $J(4'5')$ and $J(4'5'')$ data (Table 2) following Haasnoot *et al.* (40). At the low temperature, the Np fragments of the dimers and trimers show preferences for g^+ in the narrow ranges 59 ± 1% (Tp, e^4Tp) and 72 ± 1% (Ap), whereas the pN and pNp lie in the range 80 ± 5%; increasing the temperature to 60–70°C lowers the g^+ population by ~10%. The g^- conformer is always least populated. Calculations (according to Buchko *et al.* (15)) with the available $\Sigma' = J(5'P) + J(5''P)$ data in Table 2 show that the commonly observed *trans* conformer of the C5′—O5′ bond predominates (80–90%) at the lower temperature, and shows a small destabilization (~10%) at the high temperature. Similar trends in β and γ are generally observed for dimers and trimers containing only the normal bases, and so it seems that, for our modified oligomers, O4-alkylation of thymine is not reflected in the conformation of these bonds.

Circular dichroism

The CD spectra of **1**–**6** at 10–11°C are shown in Fig. 9. For the unmodified molecules, positive and negative maxima are observed at 271–273 nm and 250–253 nm, respectively. The general features of the dimer spectra **4** and **5** are in good agreement with literature data (41, 42); we are not aware of published data for **6**. Upon O4-ethylation, the long-wavelength maxima are red-shifted by about 10 nm, in contrast with the small (~1 nm) red shift in λ_{max} observed in the UV absorption spectra (see above); a smaller (~5 nm) red shift occurs in the negative maxima. On the other hand, CD spectra reported by Weinfeld *et al.* (42) reveal little effect of *phosphate* ethylation on the positions of the positive and negative bands of a number of dimers. As the temperature is increased to 70°C, the magnitudes of the CD maxima of **1**–**6** decrease by 30–50%. Overall, these results are consistent with the formation of right-handed minihelices at low temperature, as indicated by the δ data discussed above.

Mass spectrometric experiments

FAB-MS data for molecules **1**–**7** provided in the experimental section, as well as those for the homopyrimidine dimers reported by Buchko *et al.* (14, 15, 35), demonstrate the utility of this technique for characterizing DNA oligomers containing an r^4T base as well as their unmodified analogs. In the negative ion mode, the molecular mass was easily confirmed for molecules **1**–**7** by the presence of a prominent quasimolecular ion peak $[M - H]^-$; in some instances a glycerol adduct peak, $[M + \text{glycerol} - H]^-$, was also observed and served as further confirmation. Also of diagnostic value was the presence of a variety of intense ion peaks assignable to fragments bearing an O4-ethylthyminyl unit.

Recently, Buchko (35) reported FAB-MS data (negative ion

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

mode) for the largest of our molecules, e^4TpApe^4TpA, a tetramer with two e^4Thy units. Its mass was confirmed by the intense $[M - H]^-$ ion at m/z 1228. The presence of three prominent fragment ion peaks provided some sequence information: the first (m/z 994) is assignable to the fragment $[M - A - H]^-$, resulting from the loss of the terminal 3′-adenosyl unit by cleavage of its O—C5′ bond; the second (m/z 662) corresponds to $[M - e^4TpA - H]^-$, which would result from the cleavage of either the O—C5′ bond of the pe^4Tp unit or the C3′—O bond of the pAp unit; the third (m/z 349) corresponds to [3′-e^4dTMP − H]$^-$ and confirms the presence of a terminal e^4Thy. Thus, our data are demonstrating that, though O4-alkyl groups are labile (1, 9), they are sufficiently stable to withstand the mild ionizing conditions employed in FAB-MS. Thus we are optimistic about the potential of this method for characterizing longer DNA oligomers containing r^4Thy bases.

Asymmetric synthesis of podophyllotoxin analogs

JAMES L. CHARLTON,[1] GUY L. PLOURDE, K. KOH, AND ANTHONY S. SECCO
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received January 8, 1990

JAMES L. CHARLTON, GUY L. PLOURDE, K. KOH, and ANTHONY S. SECCO. Can. J. Chem. **68**, 2022 (1990).

Two analogs of podophyllotoxin, with the same absolute stereochemistry as the natural product, have been synthesized from the cycloadduct between α-hydroxy-α′-phenyl-*o*-quinodimethane and the fumarate of *S*-methyl lactate. After initial attempts to produce the cycloadduct from photochemically generated α-hydroxy-α′-phenyl-*o*-quinodimethane failed, a study of the thermal generation and reaction of α-hydroxy-*o*-quinodimethane with the fumarate and acrylate of *S*-methyl lactate was made. A comparison was made of the diastereoselectivity of these cycloaddition reactions to those previously reported, in which the *o*-quinodimethane was generated photochemically. The α-hydroxy-*o*-quinodimethane was produced both by the known thermolysis of benzocyclobutenol and by thermolysis of 1-hydroxy-1,3-dihydrobenzo[*c*]thiophene-2,2-dioxide. The diastereomeric excess for the cycloaddition reactions was found to be greater than 95% with modest (ca. 55%) isolated yields of the major cycloadducts. Following these model studies, it was found that α-hydroxy-α′-phenyl-*o*-quinodimethane produced thermally from 1-hydroxy-3-phenyl-1,3-dihydrobenzo[*c*]thiophene-2,2-dioxide could be added to the fumarate of *S*-methyl lactate with high diastereoselectivity and good yield. The product of this reaction was converted to the podophyllotoxin analogs **7** and **17**.

Key words: *o*-quinodimethanes, asymmetric, Diels–Alder, lactate, podophyllotoxin, lignan.

JAMES L. CHARLTON, GUY L. PLOURDE, K. KOH et ANTHONY S. SECCO. Can. J. Chem. **68**, 2022 (1990).

Utilisant le cycloadduit obtenu par condensation de 1′α-hydroxy-α′-phényl-*o*-quinodiméthane et du fumarate du lactate de *S*-méthyle, on a synthétisé deux analogues de la podophyllotoxine possédant la même stéréochimie que le produit naturel. Il n'a pas été possible de produire le cycloadduit à partir de l'α-hydroxy-α′-phényl-*o*-quinodiméthane obtenu photochimiquement; on a donc utilisé une méthode thermique pour générer 1′α-hydroxy-*o*-quinodiméthane et pour réaliser sa réaction avec le fumarate du lactate de *S*-méthyle. On a effectué une comparaison de la diastéréosélectivité de ces réactions de cycloaddition avec celles rapportées antérieurement, alors que 1′*o*-quinodiméthane avait été généré d'une façon photochimique. L'-α-hydroxy-*o*-quinodiméthane a été obtenu par la thermolyse connue du benzocyclobuténol ainsi que par la thermolyse du 1-hydroxy-1,3-dihydrobenzo[*c*]thiophène-2,2-dioxyde. On a trouvé que l'excès de diastéréomères est plus grand que 95% alors que le rendement en cycloadduits principaux isolés n'est que de 55%. À la suite de ces études modèles, on a trouvé que 1′α-hydroxy-α′-phényl-*o*-quinodiméthane obtenu thermiquement à partir du 1-hydroxy-3-phényl-1,3-dihydrobenzo[*c*]thiophène-2,2-dioxyde peut être additionné au fumarate du lactate de *S*-méthyle avec une excellente diastéréosélectivité et un excellent rendement. Le produit de cette réaction peut être transformé dans les analogues **7** et **17** de la podophyllotoxine.

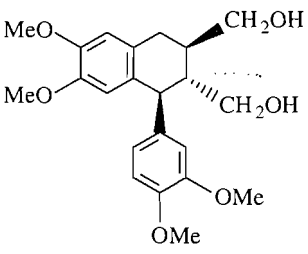
Mots clés : *o*-quinodiméthanes, asymétrique, Diels–Alder, lactate, podophyllotoxine, lignane.

[Traduit par la revue]

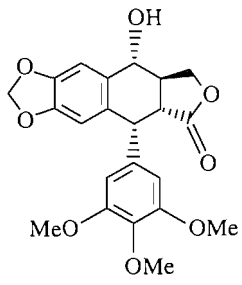
Introduction

The synthesis of aryl tetralin ligans such as dimethyl isolariciresinol or podophyllotoxin requires the stereoselective and asymmetric synthesis of several contiguous chiral centers.

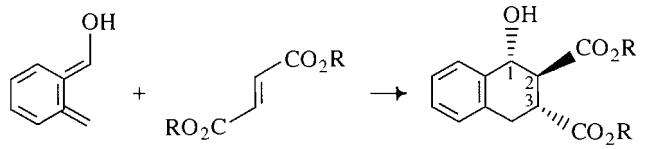
As an approach to these systems, we have been investigating the Diels–Alder reactions of *ortho*-quinodimethanes (*o*-QDMs) (1–4). In our earlier work, we studied the reactions of chiral α-alkoxy-*o*-QDMs with achiral dienophiles, a method that we eventually used for the synthesis of dimethyl isolariciresinol (3). While these Diels–Alder additions gave good relative stereoselectivity, the absolute stereoselectivity was poor (diastereomeric excess (de) 70%). In addition, the method was not useful for the synthesis of systems having the relative stereochemistry found in podophyllotoxin and compounds of similar relative stereochemistry. In more recent work, we discovered that the fumarate of *S*-methyl lactate would add to α-hydroxy-*o*-QDM with very high asymmetric induction (de >90%), giving cycloadducts with the same relative stereochemistry as podophyllotoxin at centers 1, 2, and 3 (1, 5).



Isolariciresinol dimethyl ether



Podophyllotoxin



A synthesis of podophyllotoxin itself would require the asymmetric addition of the fumarate of *S*-methyl lactate to an *E*,*E*-α-hydroxy-α′-aryl-*o*-QDM as illustrated (the first asymmetric synthesis of podophyllotoxin has recently been published, ref. 6). There was some doubt about the viability of this approach since earlier work on the cycloaddition of aryl substituted *o*-QDMs with fumarates had shown that the product usually had the 4-aryl and neighboring 3-carboxyl groups *trans* to one another, unlike the desired cycloadduct above (7, 8).

As a model for the proposed podophyllotoxin study we carried out the sequence of reactions shown in Scheme 1 and prepared the optically pure analog **7**, a compound that was previously prepared in racemic form by Macdonald and Durst (9).

Results and discussion

On the basis of the original work of Sammes and co-workers, it was anticipated that the simplest method for the preparation of

Ar = 3,4,5-trimethoxyphenyl; R = *S*-methyl lactylcarboxy

Podophyllotoxin

the *o*-quinodimethane **1** would be the photolysis of *o*-benzylbenzaldehyde (10). Unfortunately, when *o*-benzylbenzaldehyde was irradiated in the presence of the fumarate of *S*-methyl lactate **2** (benzene, 25°C, 450-watt medium pressure Hg lamp, Pyrex filter), no cycloadducts formed after 6 h. The only product detectable in the nmr spectrum was the maleate of *S*-methyl lactate, and the ratio of dilactyl maleate to dilactyl fumarate appeared to be approximately 90:10. Increasing the irradiation time to 30 h did not result in any further change to the reaction mixture. In the hope of increasing the rate of adduct formation, the irradiation was carried out at 110°C in toluene. After 24 h of irradiation at this temperature, only 10% of a possible cycloadduct (appearance of nmr signal near 5 ppm) had formed, in addition to the isomerization of the fumarate.

In view of the problems with the photochemical preparation of the *o*-quinodimethane **1**, we turned to methods of thermally generating α-hydroxy-*o*-quinodimethanes. While several methods of thermally preparing *o*-quinodimethanes are known, we were unsure whether the reaction conditions required (solvent, temperature, etc.) would be appropriate for high asymmetric induction in the subsequent addition of the *o*-quinodimethane to the chiral fumarate. To establish suitable experimental conditions, we generated α-hydroxy-*o*-quinodimethane from benzocyclobutenol (**8**, ref. 11) and 1-hydroxy-1,3-dihydrobenzo[*c*]thiophene-2,2-dioxide (**9**, ref. 12), and determined the diastereoselectivity of its reaction with both the fumarate and acrylate of *S*-methyl lactate, **2** and **10** (5).

While the thermolysis of benzocyclobutenols to *E*-α-hydroxy-*o*-quinodimethanes was established as a viable procedure by the pioneering work of Sammes and co-workers (13), the corresponding pyrolysis of the benzosulfone **9** to the α-hydroxy-*o*-quinodimethane had not been previously reported. Refluxing benzocyclobutenol **8** in toluene (110°C), in the presence of acrylate **10** (3 equiv.) and a trace of hydroquinone, gave a 73% yield of the cycloadduct **11** (after chromatography, 50:50 ethyl acetate/hexane) (1). A trace of a second isomer **13** could also be detected in the nmr of the crude product (**13**:**11** = 5:95) and, although we never isolated and characterized this adduct, it was suspected that it had the structure **13** because of its large *trans*-H,1,H-2 coupling constant of 9 Hz.

Refluxing benzocyclobutenol (**8**) in toluene in the presence of fumarate **2** (2 equiv.) gave exclusively **12** in 58% yield after chromatography (15% ethyl acetate in hexane) (1). **12** was also the exclusive product (55% isolated yield) when the sulfone **9** was added dropwise (in CH_2Cl_2) to a refluxing solution of fumarate **2** in toluene, showing that hydroxy sulfones such as **9** do thermalize readily to the corresponding α-hydroxy-*o*-quinodimethane. Attempts to prepare cycloadducts with the acrylate **10** using sulfone **9** as a precursor failed completely, with only *o*-methylbenzaldehyde and the starting acrylate being isolated from the reaction. This failure is presumably due to the lower reactivity of the acrylate in the Diels–Alder reaction, and the presence of SO_2 from the thermolysis of the sulfone, which may form sulfurous acid with traces of water and catalyze the tautomerization of the *o*-quinodimethane to *o*-methylbenzaldehyde. The asymmetric induction observed (ca. 95% de) in the reactions of thermally generated α-hydroxy-*o*-quinodimethane with the acrylate and fumarate of *S*-methyl lactate is comparable to that observed at ambient temperature when the *o*-quinodimethane was generated photochemically (1).

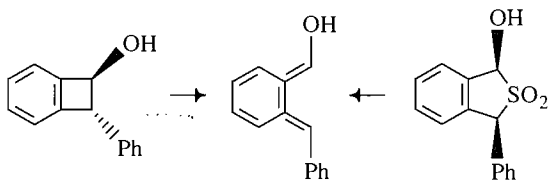
13

Turning our attention once again to Scheme 1, we considered the choice of generating the *o*-quinodimethane **1** from *trans*-1-hydroxy-2-phenylbenzocyclobutenol **14** or from *cis*-1-hydroxy-3-phenylsulfone **15**.

In view of the thermal instability of **14**, and the difficulties that others have had in its preparation (14–16), we decided against the benzocyclobutenol approach. We were pleased to find that slowly adding a methylene chloride solution of the sulfone **15** (17) to a refluxing toluene solution of the fumarate **2** led to a crystalline adduct in 55% yield after chromatography (20% ethyl acetate in hexane). Alternatively, the cycloadduct could be crystallized directly from the reaction mixture in 40% yield.



14 1 15

The nmr of the crude reaction mixture indicated that an isomeric cycloadduct was also present. This adduct (5% yield) was subsequently purified by careful chromatography but, although it was fully characterized, its relative and absolute stereochemistry were not determined.[2]

Although we tentatively assigned structure **3** to the major cycloadduct on the basis of the 9-Hz coupling constant between H-1 and H-2, more absolute proof of its structure was required. Treating the adduct with butyl lithium in THF converted it to the lactone **4**, proving the *cis*-1,3 arrangement of the 1-hydroxyl and 3-carboxyl groups in the cycloadduct. In addition, X-ray crystallographic analysis of a crystal of **4** yielded the structure shown in Fig. 1, confirming the relative stereochemistry in **4** and, by inference, the relative stereochemistry in **3**.

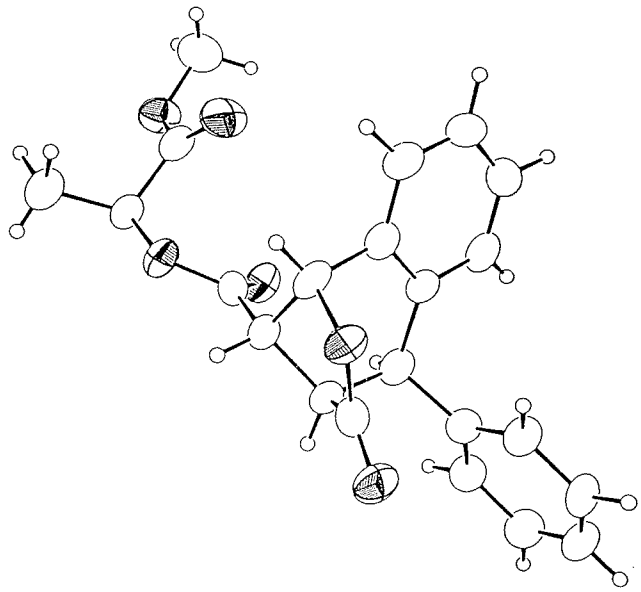


FIG. 1. Diagram of the lactone, **4**; thermal ellipsoids at 50% probability level.

Since the absolute stereochemistry of the lactyl group is known (*S*), then the absolute stereochemistries of **3** and **4** can be assigned as shown in Scheme 1.

Several routes from the cycloadduct **3** to the podophyllotoxin analog **7** were considered. Reduction of the 2-ester group in **3** with Super Hydride[3] has precedence in the literature (8), but we were unable to obtain selective reduction in high yield using this procedure. Since conversion of the ester at the 3 position to the acid would protect it during reduction by Super Hydride (18), we attempted to selectively hydrolyze the lactone **4**. This was

[2]The small coupling constant between H-1 and H-2 (3.2 Hz) suggests that this minor isomer has a *cis*-1,2 stereochemistry.

[3]Super Hydride is a registered trademark of Aldrich Chemical Company for lithium triethylborohydride.

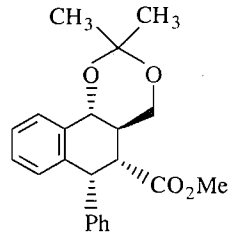
accomplished in aqueous, acidic *tert*-butyl alcohol (which also hydrolyzes the carboxymethyl group in the lactyl side chain), to give **5**. Selective reduction of the lactyl ester in **5** with Super Hydride gave the acid-diol **6**. Both **5** and **6** were extremely polar and could not be purified by chromatography on silica gel and we were also unable to crystallize these compounds. The acid-diol **6** was converted to its methyl ester/acetonide **16**, which we were able to purify by chromatography and fully characterize.

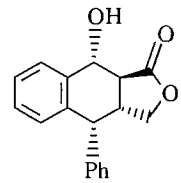
When **6** was treated with dicyclohexylcarbodiimide (DCC) in THF, it was converted to the lactone **7** (isolated by chromatography on silica gel, 30% EtOAc/hexane, and recrystallization from CH_2Cl_2/hexane), whose nmr was identical to that of the racemic compound published earlier by Macdonald and Durst (9).

The complete reaction sequence shown in Scheme 1 can be carried out with purification of only the cycloadduct **3** (chromatography on silica gel) and the final product **7** (chromatography on silica gel), to give an overall yield of 16% based on the hydroxy sulfone **15**.

In the course of our investigation we also attempted to reduce the lactone **4** with Super Hydride.[3] On work-up in dilute acid we obtained the optically pure lactone **17** in 70% yield as a crystalline solid. The high yield of this procedure suggests that it may be applicable to preparation of other pericarbonyl lignans.



16



17

The work described here is being extended to the asymmetric synthesis of natural lignans and other lignan analogs.

Experimental

The ^{1}H nmr spectra were recorded on a Bruker AM-300 instrument using tetramethylsilane as internal standard. The ir spectra were recorded on a Perkin Elmer 881 spectrometer. Merck Kieselgel 60 was used for all chromatography. Exact Mass/mass spectra were obtained on an Analytical VG 7070E-HF instrument. Melting points were measured on a hot stage instrument and are uncorrected. Optical rotations were recorded on a Rudolf Research Corporation Autopol III instrument.

1-Hydroxy-3-phenyl-1,3-dihydrobenzo[c]*thiophene-2,2-dioxide,* ***15***

15 was prepared, using the procedure described for **9** (17), but without base extraction of the final product. To a solution of *o*-benzylbenzaldehyde (4.35 g, 22.2 mmol) in benzene (100 mL) was added a solution of sulfur dioxide (18 g) in benzene (15 mL). The volume of the solution was adjusted to fill the reaction vessel (~300 mL); the solution was flushed with nitrogen and irradiated for 20 h using a 450-watt Hanovia medium pressure mercury lamp located in a water-cooled, Pyrex probe immersed in the solution. The probe was cleaned every five hours. The solution was evaporated and the residue triturated with carbon tetrachloride to afford a yellowish solid (4.0 g, 69%) corresponding to the *cis*-hydroxy sulfone; ^{1}H nmr ($CDCl_3$) δ: 3.1 (br s, 1H, OH), 5.3 (s, 1H, H-2), 5.67 (s, 1H, H-1), 7.1–7.7 (m, 9H, aromatics), identical to that previously reported (17).

(−)-1-Hydroxy-1,2,3,4-tetrahydronaphthalene-2-carboxylate of (S)*-methyl lactate,* ***11***

To a solution of benzocyclobutenol **8** (32.2 mg, 0.268 mmol) in toluene (7 mL) was added (*S*)-methyl lactyl acrylate (127 mg, 0.804 mmol, 3 equiv.) and hydroquinone (2 mg). The solution was refluxed for 6 h, cooled, and the solvent evaporated. Chromatography on silica gel using 50% ethyl acetate/hexane as eluant afforded a colourless solid (54.4 mg, 73%, see ref. 1 for properties).

(−)-1-Hydroxy-1,2,3,4-tetrahydronaphthalene-2,3-dicarboxylate of (S)*-methyl lactate,* ***12***

Method A: From benzocyclobutenol 8

To a solution of benzocyclobutenol **8** (28 mg, 0.23 mmol) in toluene (5 mL) was added (*S*)-methyl lactyl fumarate (221 mg, 0.77 mmol, 3.3 equiv.) and 4Å molecular sieves (20 mg). The solution was refluxed for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

4 h, cooled, and the solvent evaporated. Chromatography on silica gel using 15% ethyl acetate/hexane as eluant afforded a colourless solid (55 mg, 58%; see ref. 1 for properties).

Method B: From benzosulfone ***9***

To a refluxing solution of (*S*)-methyl lactyl fumarate (292 mg, 1.01 mmol, 1.5 equiv.) in toluene (5 mL) containing zinc oxide powder (50 mg) was slowly added a methylene chloride solution (5 mL) of hydroxy sulfone **9** (124 mg, 0.67 mmol). After addition of the methylene chloride solution, the mixture was refluxed for another 20 min, cooled, eluted through a short silica gel column with ethyl acetate, and evaporated. The residual oil was purified by chromatography on silica gel using 20% ethyl acetate/hexane as eluant to afford a colourless solid (152 mg, 55%). Recrystallization from hexane gave colourless plates (see ref. 1 for properties).

(−)-1-Hydroxy-4-phenyl-1,2,3,4-tetrahydronaphthalene-2,3-dicarboxylate of (S)*-methyl lactate,* ***3***

To a refluxing solution of (*S*)-methyl lactyl fumarate **2** (973 mg, 3.38 mmol, 1.5 equiv.) in toluene (20 mL) containing zine oxide powder (200 mg) was slowly added, over a period of 1 h, a solution of hydroxy sulfone **15** (580 mg, 2.23 mmol) in methylene chloride (25 mL). The solution was then refluxed for 20 min, filtered through a short silica gel column using ethyl acetate as eluant, and evaporated to give a yellow oil (2 isomers, 90:10 ratio from ^{1}H nmr of crude). The crude product was purified by chromatography using 15% ethyl acetate/hexane as eluant to afford a colourless oily material for each isomer: 582.9 mg, 54%, major; 60.6 mg, 5.6%, minor; 643.5 mg, 60%, total yield. Recrystallization of the major isomer from isopropyl alcohol afforded colourless needles. The major isomer could also be obtained in 40% yield by recrystallization of the crude product from isopropyl alcohol. The minor isomer could not be crystallized.

Major isomer, ***3***: mp 142–143°C; $[\alpha]_D$ −215° (*c* 0.2, $CHCl_3$); ir (CH_2Cl_2): 3476 (OH), 1742 (CO) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.09 (d, 3H, *J* = 7.0, CH_3), 1.53 (d, 3H, *J* = 7.2, CH_3), 3.33 (dd, 1H, *J* = 9.5, 12.5, H-2), 3.55 (dd, 1H, *J* = 5.7, 12.5, H-3), 3.73 (s, 3H, OCH_3), 3.82 (s, 3H, OCH_3), 4.69 (d, 1H, *J* = 5.7, H-4), 4.91 (q, 1H, *J* = 7.0, CH), 4.98 (d, 1H, *J* = 9.5, H-1), 5.32 (q, 1H, *J* = 7.2, CH), 7.13 (m, 8H, aromatics), 7.82 (d, 1H, *J* = 7.4, H-8); ms, *m/e* (rel. %): 484 (<0.1), 362 (1.6), 335 (17), 334 (75), 249 (13), 248 (16), 247 (9), 232 (20), 231 (100). Minor isomer: $[\alpha]_D$ +50° (*c* 0.18, $CHCl_3$); ir (CH_2Cl_2): 3477 (OH), 1737 (CO) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.32 (d, 3H, *J* = 6.9, CH_3), 1.59 (d, 3H, *J* = 7.2, CH_3), 3.41 (dd, 1H, *J* = 3.1, 11.9, H-2), 3.60 (s, 3H, OCH_3), 3.71 (overlapping dd, 1H, *J* = 11.5, H-3), 3.81 (s, 3H, OCH_3), 4.02 (d, 1H, *J* = 4.0, OH), 4.17 (d, 1H, *J* = 11.1, H-4), 4.97 (q, 1H, *J* = 6.9, CH), 5.27 (q, 1H, *J* = 7.2, CH), 5.44 (overlapping dd, 1H, *J* = 3.5, H-1), 6.76 (d, 1H, *J* = 7.8, H-5), 7.12–7.35 (m, 7H, aromatics), 7.43 (d, 1H, *J* = 7.8, H-8); ms, *m/e* (rel. %): 484 (0.1), 334 (18), 250 (19), 249 (16), 248 (17), 247 (12), 232 (22), 231 (100).

Lactone, ***4***

To a solution of hydroxycycloadduct **3** (448.8 mg, 0.93 mmol) in dry tetrahydrofuran (20 mL) was added, at −78°C under nitrogen, *n*-butyllithium in hexanes (2.5 M, 0.37 mL, 0.93 mmol). The solution was stirred at −78°C for 15 min, then at room temperature for 0.5 h. Aqueous ammonium chloride (5%, 30 mL) was added, and the solution stirred for 15 min, extracted with methylene chloride, dried ($MgSO_4$), and evaporated to give an oil (316.2 mg, 90%, >90% pure by ^{1}H nmr). Chromatography on silica gel using 15% ethyl acetate/hexane as eluant afforded a colourless solid (185.4 mg, 51%). Recrystallization from hexane/methylene chloride gave colourless flakes. Crystals were suitable for X-ray analysis; mp 135–136°C; $[\alpha]_D$ −39.3° (*c* 0.18, $CHCl_3$); ir (CH_2Cl_2): 1788 (CO, lactone), 1748 (CO, ester) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.42 (d, 3H, *J* = 7.0, CH_3), 3.35 (td, 1H, *J* = 0.8, 4.9, H-3), 3.51 (s, 3H, OCH_3), 3.94 (t, 1H, *J* = 5.1, H-2), 4.95 (d, 1H, *J* = 4.9, H-4), 5.00 (q, 1H, *J* = 7.0, CH), 5.52 (d, 1H, *J* = 5.1, H-1), 7.0–7.4 (m, 9H, aromatics); ms, *m/e* (rel. %): 380 (0.4), 362 (4.3), 334 (32), 276 (16), 248 (32), 231 (79), 220 (22), 205 (68), 204 (100), 192 (39). Exact Mass calcd. for $C_{22}H_{20}O_6$: 380.1259; found: 380.1254.

Hydroxy diacid, ***5***

To a solution of (*S*)-lactyl lactone **4** (57.6 mg, 0.15 mmol) in *tert*-butyl alcohol (7 mL) was added aqueous HCl (10%, 15 mL). The solution was heated for 3 days using a sand bath maintained at 80°C. Aqueous sodium bicarbonate (5%) was then slowly added until the solution was basic. The solution was extracted with methylene chloride, the aqueous portion reacidified (10% HCl), extracted with ethyl acetate, and dried ($MgSO_4$), and the solvent evaporated to give a colourless solid (42.2 mg, 72%). The product (~90% pure, ^{1}H nmr) could not be recrystallized or chromatographed on silica and was therefore used without further purification; mp 122–130°C; ^{1}H nmr ($CDCl_3$) δ: 1.54 (d, *J* = 7.1, CH_3), 3.24 (dd, *J* = 9.8, 12.4, H-2), 3.54 (dd, *J* = 5.6, 12.4, H-3), 4.67 (d, *J* = 5.4, H-4), 4.98 (d, *J* = 9.8, H-1), 5.31 (q, *J* = 7.1, CH), 6.95–7.33 (m, aromatics), 7.74 (d, *J* = 7.8, H-8), obtained from crude product.

The dimethyl ester of **5** was obtained by treating the crude diacid **5** with diazomethane followed by chromatography (15% ethyl acetate/hexane); ^{1}H nmr ($CDCl_3$) δ: 1.54 (d, 3H, *J* = 7.2, CH_3), 3.28 (dd, 1H, *J* = 9.7, 12.4, H-2), 3.52 (dd, 1H, *J* = 5.8, 12.4, H-3), 3.58 (s, 3H, OCH_3), 3.82 (s, 3H, OCH_3), 4.68 (d, 1H, *J* = 5.8, H-4), 4.73 (d, 1H, *J* = 3.4, OH), 4.97 (dd, 1H, *J* = 3.1, 9.7, H-1), 5.28 (q, 1H, *J* = 7.2, CH), 6.90–7.35 (m, 8H, aromatics), 7.81 (d, 1H, *J* = 7.9, H-8); ms, *m/e* (rel %): M^+ not observed, 394 (1.1), 334 (29.9), 263 (36), 262 (78.2), 249 (10.1), 248 (10.5), 247 (9.9), 232 (20.2), 231 (100).

Dihydroxy acid, ***6***

To a solution of crude hydroxy diacid **5** (77.5 mg, 0.2 mmol) in dry tetrahydrofuran (40 mL) was added, at 0°C under nitrogen, lithium triethylborohydride in tetrahydrofuran (1 M, 1.3 mL, 1.3 mmol, 6.5 equiv.). The solution was stirred at 0°C for 5 min, then at room temperature for 20 h. Dilute aqueous HCl (10%) was added, and the solution stirred for 1.5 h, saturated with NaCl, extracted with ethyl acetate, dried ($MgSO_4$), and evaporated to give a brownish oily material (59.3 mg, 98%). The product (~80% pure, ^{1}H nmr) could not be crystallized or chromatographed on silica and was therefore used without further purification; ir (CH_2Cl_2): 3695 (OH), 1744 (CO) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 2.53 (m, H-2), 3.06 (dd, *J* = 6.3, 12.1, H-3), 4.35 (dd, *J* = 4.6, 10.7, H-11), 4.62 (d, *J* = 6.3, H-4), 4.86 (d, *J* = 10.1, H-1), 6.85–7.31 (m, aromatics), 7.75 (d, *J* = 7.7, H-8), H-11′ was not observed. Data obtained from crude product.

Methyl ester of dihydroxy acid ***6***

The methyl ester of **6** was obtained by treating the dihydroxy acid with excess diazomethane in diethyl ether and evaporation of the solvent. Purification by chromatography on silica gel was not possible; ^{1}H nmr ($CDCl_3$) δ: 2.59 (m, H-2), 3.05 (dd, *J* = 6.5, 12.1, H-3), 3.49 (s, OCH_3), 4.31 (dd, *J* = 4.5, 10.6, H-11), 4.59 (d, *J* = 6.5, H-4), 4.85 (d, *J* = 10.2, H-1), 6.88–7.32 (m, aromatics), 7.73 (d, *J* = 7.7, H-8), obtained from crude product.

Acetonide, ***16***

This compound was prepared according to a procedure previously reported (19). To a solution of crude dihydroxy ester (see above, 64.8 mg, 0.21 mmol) in 2,2-dimethoxypropane (5 mL) was added *p*-toluenesulfonic acid (trace). The solution was stirred at room temperature overnight. Ethyl acetate was added, the organic solution washed with aqueous sodium bicarbonate (5%), dried ($MgSO_4$), and the solvent evaporated to give a semicrystalline product (44.9 mg, 61%). Chromatography on silica gel using 15% ethyl acetate/hexane as eluant gave a colorless oil that could not be crystallized; $[\alpha]_D$ −179.4° (*c* 0.36, $CHCl_3$); ir (CH_2Cl_2): 1742 (CO) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.56 (s, 3H, CH_3), 1.60 (s, 3H, OCH_3), 2.50 (m, 1H, H-2), 3.02 (dd, 1H, *J* = 6.7, 12.3, H-3), 3.40 (s, 3H, CH_3), 3.68 (t, 1H, *J* = 10.9, H-11), 4.14 (dd, 1H, *J* = 4.3, 11.1, H-11′), 4.57 (d, 1H, *J* = 6.7, H-4), 4.79 (d, 1H, *J* = 10.4, H-1), 6.87–7.26 (m, 8H, aromatics), 7.56 (d, 1H, *J* = 7.8, H-8); ms, *m/e* (rel. %): 352 (2.1), 337 (12), 277 (73), 217 (100), 205

(42), 195 (32). Exact Mass calcd. for $C_{22}H_{24}O_4$: 352.1674; found: 352.1671.

Podophyllotoxin analog, 7

The hydroxycycloadduct **3** (532.5 mg, 1.1 mmol) was treated with *n*-BuLi to give the crude lactone **4**. The lactone **4** (445 mg) was then hydrolysed and the residual hydroxy diacid **5** (287.2 mg) was reduced with Super Hydride ($LiBHEt_3$, ref. 14). No purification was performed for any of these first three steps. To a solution of this crude dihydroxy acid **6** (187 mg) in dry tetrahydrofuran (15 mL) was added dicyclohexylcarbodiimide (DCC, 145 mg, 0.7 mmol) in tetrahydrofuran (1 mL). The solution was stirred at room temperature for 24 h and worked up according to literature procedure (4),[2] with addition of water and acetic acid followed by evaporation of the solvent to give a semicrystalline material (241 mg). Purification by trituration with methylene chloride followed by chromatography on silica gel using 25% ethyl acetate/hexane as eluant gave a colourless solid (92.1 mg, 30% from **3**, 16.5% overall from **15**). Recrystallization from hexane/methylene chloride afforded colourless plates; mp 225–227°C (226–227°C for racemic material (9)); $[\alpha]_D$ −151° (*c* 0.12, $CHCl_3$); ir (CH_2Cl_2): 3320 (OH), 1777 (CO) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.18 (d, 1H, J = 7.7, OH), 2.87 (m, 2H, H-2, H-3), 4.11 (br t, 1H, J = 9.5, H-11), 4.61 (dd, 1H, J = 6.6, 8.8, H-11′), 4.78 (d, 1H, J = 4.3, H-4), 4.89 (br t, 1H, J = 8.5, H-1), 7.05–7.39 (m, 8H, aromatics), 7.70 (d, 1H, J = 7.8, H-8); ms, *m/e* (rel. %): 280 (51), 262 (35), 218 (45), 217 (54), 119 (53), 117 (100). Exact Mass calcd. for $C_{18}H_{16}O_3$: 280.1099; found: 280.1104.

Pericarbonyl lactone, 17

To a solution of (*S*)-lactyl lactone **4** (228.3 mg, 0.60 mmol) in dry tetrahydrofuran (25 mL) was added, at 0°C under nitrogen, lithium triethylborohydride in tetrahydrofuran (1 M, 1.8 mL, 1.8 mmol, 3 equiv.). The solution was stirred at 0°C for 10 min, then at room temperature for 5 h. Dilute aqueous HCl (10%, 20 mL) was added and the solution was stirred overnight. The solution was diluted with water, extracted with methylene chloride, dried ($MgSO_4$), and evaporated to give a white solid (119.8 mg, 71%). Recrystallization from carbon tetrachloride afforded colourless needles; mp 162–164°C; $[\alpha]_D$ −75.6° (*c* 0.18, $CHCl_3$); ir (CH_2Cl_2): 3577 (OH), 1776 (CO) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.74 (dd, 1H, J = 9.9, 14.5, H-2), 2.91–3.03 (m, 1H, H-3), 3.35 (br s, 1H, OH), 3.56 (dd, 1H, J = 8.6, 11.1, H-11), 4.43 (dd, 1H, J = 7.0, 8.6, H-11′), 4.51 (d, 1H, J = 5.7, H-4), 5.07 (d, 1H, J = 9.9, H-1), 6.91–7.80 (m, 9H, aromatics); ms, *m/e* (rel. %): 280 (30), 217 (8), 202 (5), 195 (6), 178 (7), 165 (11), 118 (10), 117 (100). Exact Mass calcd. for $C_{18}H_{16}O_3$: 280.1099, found: 280.1076.

X-ray analysis

Crystal data:

$C_{22}H_{19}O_6$ fw = 379.39

Monoclinic, $P2_1$, a = 9.745 (3), b = 8.974 (4), c = 11.633 (3) Å, β = 110.72 (2)°, V = 951.4 (6) $Å^3$, Z = 2, ρ_c = 1.324 g cm^{-3}, μ = 7.61 cm^{-1}, $F(000)$ = 398 (−150°C; CuKα, λ = 1.54178 Å). Data were collected using a crystal of the lactone **4** measuring 0.25 × 0.25 × 0.10 mm on a Rigaku AFC5R diffractometer with an ω–2θ scan type. 1298 unique reflections were measured within the region bounded by h, k, $\pm l$. Data were corrected for Lorentz and polarization effects yielding 1260 observed reflections with $I > 3\sigma(I)$. The structure was solved by direct methods and refined by full-matrix least-squares techniques minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, where $w = 4F_o^2\sigma^{-2}(F_o^2)$. All non-H atoms were corrected for anomalous scattering and an extinction correction ($g = 0.26 \times 10^{-4}$) was applied. Final agreement factors, $R = \Sigma||F_o| - |F_c||\Sigma|F_o|$ and $R_w = [\Sigma w(|F_o| - |F_c|)^2/|\Sigma wF_o^2]^{1/2}$ were 0.030 and 0.042, respectively, for the 1260 observed data. The goodness of fit was 1.50 on the last cycle of refinement, which showed a maximum Δ/σ of 0.02. The final difference map indicated electron density fluctuations of −0.13 to 0.42 e $Å^{-3}$. Positional and isotropic thermal parameters are given in Table 1 for all non-H atoms; bond distances involving non-H atoms are listed in Table 2. H atom coordinates, complete lists of bond lengths and angles, temperature factors, and structure factors have been deposited as supplementary material.[4]

An asymmetric synthesis of 2-amino-6,7-dihydroxy-1,2,3,4-tetrahydronaphthalene (ADTN)

JAMES L. CHARLTON,[1] KEVIN KOH, AND GUY L. PLOURDE
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received April 9, 1990

JAMES L. CHARLTON, KEVIN KOH, and GUY L. PLOURDE. Can. J. Chem. **68**, 2028 (1990).

An asymmetric synthesis of 2-amino-6,7-dimethoxy-1,2,3,4-tetrahydronaphthalene, which can be converted to the title compound by a literature procedure, is described. The synthesis, starting from 2-amino-4,5-dimethoxybenzoic acid and the acrylate of *S*-methyl lactate, was accomplished in eight steps in 11% overall yield and >97% optical purity.

Key words: *o*-quinodimethanes, Diels–Alder, asymmetric, cycloaddition, induction, diastereoselective, ADTN.

JAMES L. CHARLTON, KEVIN KOH et GUY L. PLOURDE. Can. J. Chem. **68**, 2028 (1990).

On décrit une synthèse asymétrique du 2-amino-6,7-diméthoxy-1,2,3,4-tétrahydronaphtalène qui peut être transformé dans le composé mentionné dans le titre par une procédure décrite dans la littérature. La synthèse, à partir de l'acide 2-amino-4,5-diméthoxybenzoïque et de l'acrylate du lactate de *S*-méthyle, a été réalisée en huit étapes, avec un rendement global de 11% et une pureté optique >97%.

Mots clés : *o*-quinodiméthanes, Diels–Alder, asymétrique, cycloaddition, induction, diastéréosélective, ADTN.

Introduction

Since the initial discovery that 5,6-dihydroxy-2-(dimethylamino)tetralin possesses dopaminergic activity, many other 2-aminotetralin derivatives have been synthesized and tested for analogous behavior (1; for reviews see 2). These drugs interact with D_2 dopamine receptors and there is interest in them as potential antipsychotic and anti-Parkinsonian drugs. Like many other drugs, the potency of the 2-aminotetralin derivatives as central nervous system active agents is directly related to their absolute stereochemistry (and conformation) (2, 3), which necessitates the preparation of pure enantiomers of the drugs in question. In most instances pure enantiomers have been obtained by resolution of racemic mixtures but the parent compound, (*R*)-(+)-2-amino-6,7-dihydroxy-1,2,3,4-tetrahydronaphthalene (ADTN), has been recently prepared by a chiral pool synthesis starting from (*R*)-*N*-(trifluoroacetyl)aspartic anhydride (4).

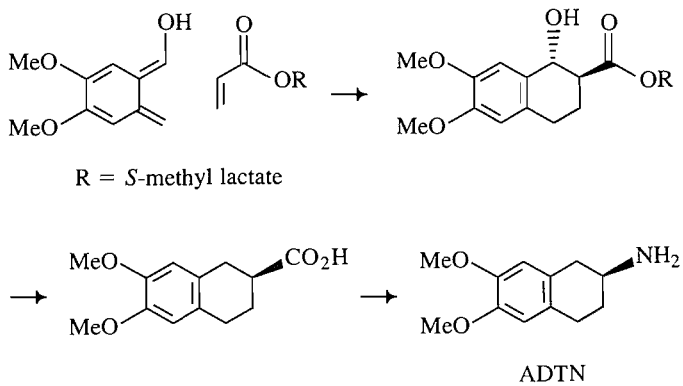
We recently discovered that the acrylate of *S*-methyl lactate adds with high asymmetric induction to α-hydroxy-*o*-quinodimethane (5) and this discovery inspired the proposal of an asymmetric synthesis for ADTN, which is outlined in Scheme 1.

The Diels–Alder cycloaddition would be followed by hydrogenolysis of the hydroxyl group, hydrolysis of the lactyl ester, and, finally, conversion of the carboxylic acid group to the amine by a procedure that has already been published for the racemic acid (6).

If the synthetic route outlined in Scheme 1 could be accomplished it would make possible the asymmetric synthesis of analogs of ADTN via derivatives of the starting *o*-quinodimethane and lactyl acrylate. An asymmetric route of this type would be more versatile than the chiral pool synthesis since the latter is tied to a specific chiral synthon that becomes part of the product molecule.

Results and discussion

Our first task in tackling the proposed synthesis outlined in Scheme 1 was to choose a method of preparing the very reactive and transient *o*-quinodimethane (*o*-QDM). Among the many methods for preparing *o*-QDMs (7), the photolysis of an *o*-methyl benzaldehyde is experimentally the easiest and therefore we prepared 2-methyl-4,5-dimethoxybenzaldehyde **1**, using (in part) published procedures (8–11), as a precursor to the *o*-QDM.



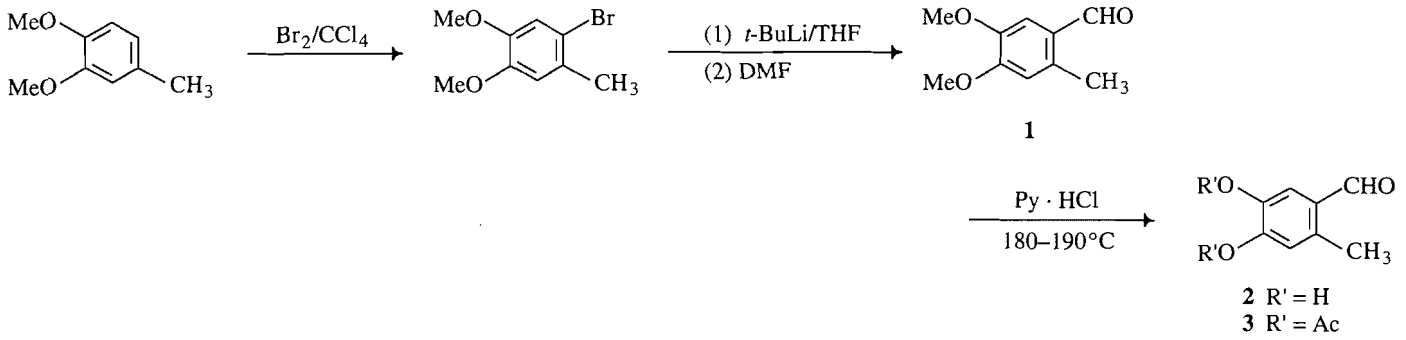
SCHEME 1

Unfortunately, as we previously reported, aldehyde **1** did not form a trappable *o*-QDM on irradiation (11). However, conversion of **1** to the diacetate **3** provided an aldehyde that could be trapped with the acrylate of *S*-methyl lactate to give essentially a single cycloadduct **4** in 85% yield. Although we did not determine the absolute stereochemistry of **4**, we assumed it to be that shown, by analogy to previous work (5).

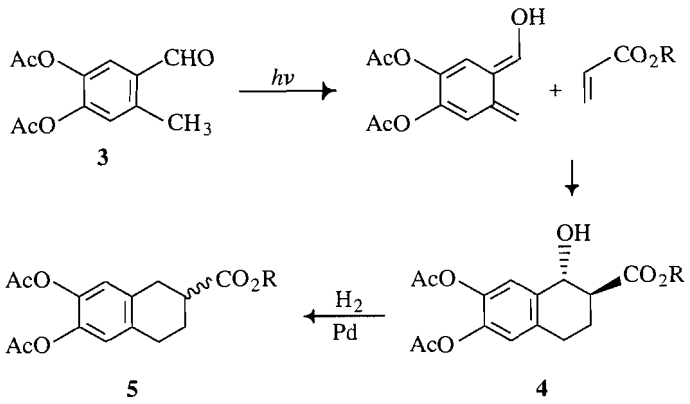
Disappointingly, the conversion of the cycloadduct **4** to the deoxy derivative *S*-**5**, under a variety of reduction conditions, could not be achieved in high yield without epimerization of the chiral centre at the 2 position, presumably due to dehydration/reduction competing with hydrogenolysis.

In view of the difficulty encountered with the hydrogenolysis of **4**, we turned our attention to alternate methods for the preparation of the dimethoxy *o*-QDM. Following the earlier work of Sammes and co-workers (12), we have previously shown that α-hydroxy-*o*-QDM generated thermally from benzocyclobutenol adds to lactyl acrylate with the same asymmetric selectivity as that generated photochemically from *o*-methylbenzaldehyde (13). Thus we prepared 4,5-dimethoxybenzocyclobutenol **7** from 2-bromo-4,5-dimethoxybenzaldehyde **6** using the method of Durst and co-workers (14) in hopes of using

[1]Author to whom correspondence may be addressed.



it as an *o*-QDM precursor. The yields of the benzocyclobutenol **7** using Durst's method were rather variable (30–50%) and alternate routes for its synthesis were sought. Although Jung *et al.* had very little success using a benzyne route to prepare 4,5-methylenedioxybenzocyclobutenyl acetate from 4,5-methylenedioxyanthranilic acid (8%) (15), we were able to prepare 4,5-dimethoxybenzocyclobutenyl acetate **8** from 4,5-dimethoxyanthranilic acid in very reasonable yield (45%). The acetate was readily converted to the alcohol **7** with ammonia in methanol (85%).



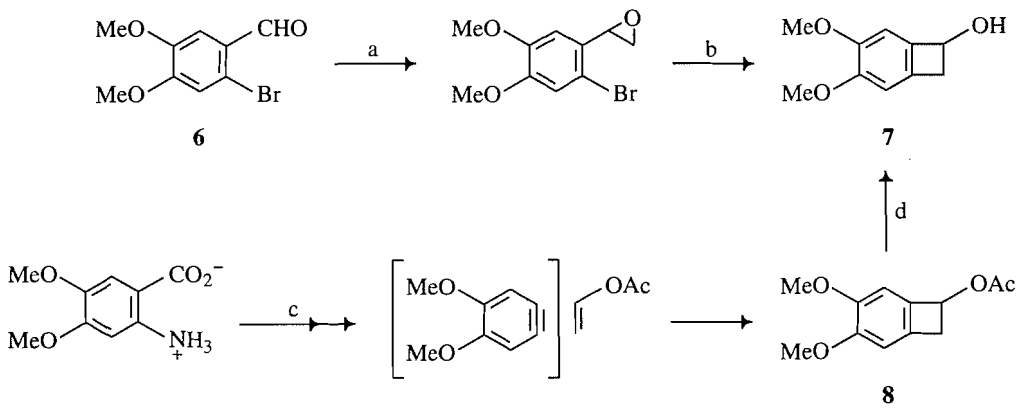
R = *S*-methyl lactate

Heating the benzocyclobutenol **7** in a toluene solution of the acrylate of *S*-methyl lactate gave one major and three minor cycloadducts in the ratio of 9:1 (major:total of minor; from nmr integration). The major cycloadduct **9** could be isolated by chromatography on silica gel in 80% yield. Hydrogenolysis of **9** under rather mild conditions (1 atm H_2 (101.3 kPa), 5% Pd on C, methanol/acetic acid (50:50), room temperature) cleanly gave the deoxy ester **10** in 80% yield. This ester could be hydrolysed to the corresponding acid **11** with potassium carbonate in methanol/water without epimerization of the chiral center. The acid was converted to the hydrochloride salt of the 2-aminotetralin **13** using a method previously developed by Narula and Schuster (16). The amine was recovered from the salt by neutralization with aqueous NaOH and extraction to give material with an $[\alpha]_D^{20}$ −85.7° (lit. (4) $[\alpha]_D$ +86.5 for the *R* isomer).

The amine **13** was previously reported to be a yellow oil (4), while we found that it was a crystalline solid with a melting point of 85–86°C. This, as well as small differences between reported nmr data and our nmr data, may be due to small amounts of impurities in the formerly prepared material (4). The configurational purity of **13** was determined by preparation of the amide with (−)-α-methoxy-α-(trifluoromethyl)phenylacetic acid (Mosher's acid) and analysis by nmr as has been described previously (4). For comparison purposes the mixture of diastereomeric amides was also prepared from racemic 4,5-dimethoxy-2-aminotetralin. The nmr spectrum of the diastereomeric amides showed well-separated singlets in the aromatic region at 6.24, 6.29, 6.32, and 6.35 ppm when the spectrum was recorded in C_6D_6. The amide from **13** showed major peaks at 6.29 and 6.32 corresponding to the *S*-(−) enantiomer (4). Assuming that the purity of the Mosher's acid was >99%, integration indicated that the optical purity of **13** was >97%. The demethylation of **13** to (*S*)-(−)-ADTN has been described elsewhere (17).

Experimental

The ^{1}H nmr spectra were recorded on a Bruker AM-300 instrument using tetramethylsilane as internal standard. The ir spectra were recorded on a Perkin Elmer 881 spectrometer. Merck Kieselgel 60 or Aldrich 28,859-4 was used for all chromatography. Elemental analyses were performed by Guelph Chemical Laboratories Ltd., Guelph, Ontario, Canada. Exact Mass/mass spectra were obtained on an Analytical VG 7070E-HF instrument. Melting points were measured



(a) $(CH_3)_3S^+I^-$, OH^-; (b) *n*BuLi, $MgBr_2$; (c) *i*-AmONO, heat; (d) NH_3/CH_3OH

2-Bromo-4,5-dimethoxytoluene

A solution of bromine (0.72 g) in CCl_4 (10 mL) was added dropwise to a solution of 3,4-dimethoxytoluene (0.68 g, 4.47 mmol), in CCl_4 (15 mL), with stirring at room temperature until the colour of bromine persisted. The mixture was washed with water, dried ($MgSO_4$), and evaporated to give a red oil (0.919 g, 90%), which was purified by chromatography on silica gel (EtOAc/hexane, 5:95); ^1H nmr ($CDCl_3$) δ: 2.32 (s, 3H), 2.82 (s, 3H), 2.83 (s, 3H), 6.72 (s, 1H), 6.99 (s, 1H).

*2-Methyl-4,5-dimethoxybenzaldehyde, **1***

2-Bromo-4,5-dimethoxytoluene (0.221 g, 0.96 mmol) in THF (2 mL) was added to a solution of *tert*-butyllithium (1.53 mL of 1.25 M in pentane, 2 equiv.) in THF (3 mL) at −78°C under nitrogen. After 45 s, *N*,*N*-dimethyl formamide (0.14 g, 2 equiv., anhydrous) in THF (1 mL) was added. The solution was stirred for 5 min at −78°C and then at room temperature for 2 h. The reaction was quenched with aqueous HCl (10%, 10 mL), saturated with sodium chloride, extracted with CH_2Cl_2, dried ($MgSO_4$), and evaporated to give an oil (0.144 g). Chromatography of the oil (EtOAc/hexane) gave a colourless solid (100 mg, 58%); mp 71–72°C; ir (CH_2Cl_2): 1733 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.63 (s, 3H), 3.92 (s, 3H), 3.95 (s, 3H), 6.69 (s, 1H), 7.35 (s, 1H), 10.22 (s, 1H); ms, *m/e* (rel. %): 181 (11), 180 (100), 179 (45), 165 (19), 151 (15), 109 (17). Exact Mass calcd. for $C_{10}H_{12}O_3$: 180.0783; found: 180.0786.

*2-Methyl-4,5-dihydroxybenzaldehyde, **2***

2-Methyl-4,5-dimethoxybenzaldehyde (0.47 g, 2.61 mmol) was mixed with pyridinium hydrochloride (1.21 g, 4 equiv.) and heated to 180–190°C under nitrogen for 4 h. The mixture was cooled and digested in aqueous 10% HCl (50 mL). Some residual tar was removed by filtration and the filtrate extracted with ethyl acetate. Drying ($MgSO_4$) and evaporation gave a pale green solid (0.336 g, 84%), which could be purified by chromatography on silica (EtOAc/hexane, 60:40); mp 171–173°C; ir (CH_2Cl_2): 3538, 1684 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.54 (s, 3H), 6.70 (s, 1H), 7.27 (s, 1H), 10.07 (s, 1H); ms, *m/e* (rel. %): 153 (8), 152 (90), 151 (100), 124 (5), 123 (45). Exact Mass calcd. for $C_8H_8O_3$: 152.0474; found: 152.0472.

*2-Methyl-4,5-diacetoxybenzaldehyde, **3***

2-Methyl-4,5-dihydroxybenzaldehyde (0.206 g, 1.35 mmol), acetic anhydride (0.291 g, 0.27 mL, 2.1 equiv.), and pyridine (0.32 g, 3 equiv.) were dissolved in CH_2Cl_2 (15 mL) and stirred for 1.5 h. The mixture was poured into water (100 mL), stirred for 1 h, then extracted with CH_2Cl_2, washed with 10% aqueous HCl, dried ($MgSO_4$), and evaporated to give a pale yellow solid (0.31 g, 97%), which could be recrystallized from CH_2Cl_2; mp 93–96°C; ir (CH_2Cl_2): 1775, 1705, 1694 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.30_4 (s, 3H), 2.30_6 (s, 3H), 2.66 (s, 3H), 7.12 (s, 1H), 7.64 (s, 1H), 10.12 (s, 1H); ms, *m/e* (rel. %): 236 (3), 194 (25), 152 (100), 151 (29), 124 (23). Exact Mass calcd. for $C_{12}H_{12}O_5$: 236.0685; found: 236.0670.

*(1R,2S)-(−)-1-Hydroxy-6,7-diacetoxy-1,2,3,4-tetrahydronaphthalene-2-carboxylate of S-methyl lactate, **4***

2-Methyl-4,5-diacetoxybenzaldehyde **3** (0.093 g, 0.394 mmol), the acrylate of *S*-methyl lactate (0.094 g, 1.5 equiv.), and hydroquinone (2 mg) were dissolved in benzene and deoxygenated by flushing with nitrogen. The solution was irradiated (Hanovia 450-W, medium pressure mercury lamp, through 1 mm Pyrex) for 24 h, the solvent evaporated, and the residue chromatographed on silica gel (35–75% EtOAc/hexane) to give a colourless oil (0.132 g, 85%); $[\alpha]_D^{20}$ −24° (*c* 1.43, $CHCl_3$); ir (CH_2Cl_2): 3575, 3492, 1771 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.54 (d, 3H, *J* = 7.09), 2.00 (m, 1H), 2.15 (m, 1H), 2.26_5 (s, 3H), 2.26_8 (s, 3H), 2.80 (m, 3H), 3.78 (s, 3H), 4.90 (d, 1H, *J* = 9.54), 5.25 (q, 1H, *J* = 7.09), 6.91 (s, 1H), 7.47 (s, 1H); ms, *m/e* (rel. %): 394 (7), 352 (20), 310 (48), 292 (36), 249 (35), 223 (42). Exact Mass calcd. for $C_{19}H_{22}O_9$: 394.1264; found: 394.1266.

*1-Acetoxy-4,5-dimethoxybenzocyclobutene, **8***

A solution of 4,5-dimethoxyanthranilic acid (1.40 g, 7.08 mmol) in tetrahydrofuran (20 mL) was added to a refluxing solution of vinyl acetate (70 mL) and isoamyl nitrite (1.67 g, 1.9 mL, 2 equiv.) over a period of 30 min. After refluxing for 15 h, the vinyl acetate was evaporated on a rotary evaporator and the resulting brown-red oil distilled in a short path distillation apparatus (0.05 Torr (1 Torr = 133.3 Pa), 130°C) to give 1.24 g of red oil. This oil was chromatographed on silica gel (EtOAc/hexane) to give a pale yellow oil (0.71 g, 45%, solidifies on cooling), which nmr indicated was essentially free of impurities; mp 33–35°C; ir (CH_2Cl_2): 1737 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.10 (s, 3H), 3.14 (dd, 1H, *J* = 1.52, 13.9), 3.53 (dd, 1H, *J* = 4.30, 13.9), 3.85 (s, 3H), 3.86 (s, 3H), 5.80 (dd, 1H, *J* = 1.63, 4.30), 6.71 (s, 1H), 6.82 (s, 1H); ms, *m/e* (rel. %): 222 (20), 181 (11), 180 (100), 179 (47), 165 (16), 163 (15), 162 (21). Exact Mass calcd. for $C_{12}H_{14}O_4$: 222.0892; found: 222.0891.

*4,5-Dimethoxybenzocyclobutenol, **7***

Dimethoxybenzocyclobutenyl acetate **8** (0.458 g, 2.06 mmol) was stirred in methanol/NH_4OH (7:3, 10 mL) at room temperature for 6 h. The mixture was acidified with aqueous 10% HCl and extracted with CH_2Cl_2. The resulting crude product (yellow solid) was chromatographed on silica (EtOAc/hexane) to give colourless crystals (0.317 g, 85%); mp 107–109°C; ir (CH_2Cl_2): 3593 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.30 (s, 1H), 2.95 (dd, 1H, *J* = 1.4, 13.72), 3.50 (dd, 1H, *J* = 4.20,

13.72), 3.84 (s, 3H), 3.85 (s, 3H), 5.20 (dd, 1H, J = 1.4, 4.2), 6.70 (s, 1H), 6.80 (s, 1H); ms, *m/e* (rel. %): 181 (12), 180 (100), 179 (58), 165 (24), 151 (53). Exact Mass calcd. for $C_{10}H_{12}O_3$: 180.0787; found: 180.0781.

(1R,2S)-(−)-1-Hydroxy-6,7-dimethoxy-1,2,3,4-tetrahydronaphthalene-2-carboxylate of S-methyl lactate, ***9***

Dimethoxybenzocyclobutenol **7** (88.0 mg, 0.489 mmol), the acrylate of *S*-methyl lactate (232 mg, 3 equiv., ref. 5), and hydroquinone (2 mg) were dissolved in toluene (7 mL) and refluxed for 6 h. The solvent was evaporated on a rotary evaporator and the resulting oil chromatographed on silica gel (eluant EtOAc/hexane) to give a pale yellow oil (153 mg, 93%), which appeared by nmr to be a mixture of one major and three minor (<9%) isomers. Careful rechromatography on silica gel (25% EtOAc/hexane) gave the major cycloadduct as a colourless oil that would solidify on cooling (132 mg, 80%); mp 76–78°C; $[\alpha]_D^{20}$ −31.6° (*c* 1.33, $CHCl_3$); ir (CH_2Cl_2): 3492, 1739 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.55 (d, 3H, J = 7.12), 2.00 (m, 1H), 2.15 (m, 1H), 2.80 (m, 3H), 3.80 (s, 1H), 3.84 (s, 3H), 3.87 (s, 3H), 4.92 (d, 1H, J = 9.12), 5.25 (q, 1H, J = 7.12), 6.55 (s, 1H), 7.17 (s, 1H); ^{13}C nmr (75.5 MHz, $CDCl_3$) δ: 16.75, 23.73, 27.79, 48.84, 52.85, 55.81, 55.86, 68.68, 70.59, 109.43, 110.55, 127.51, 129.30, 147.56, 148.12, 172.19, 174.54; ms, *m/e* (rel. %): 339 (10), 338 (52), 321 (10), 320 (34), 233 (42), 206 (63), 205 (51). Exact Mass calcd. for $C_{17}H_{22}O_7$: 338.1367; found: 338.1372.

2S-(−)-6,7-Dimethoxy-1,2,3,4-tetrahydronaphthalene-2-carboxylate of S-methyl lactate, ***10***

Cycloadduct **9** (123 mg, 0.362 mmol) and 5% Pd/C (120 mg) were stirred in acetic acid/methanol (50:50, 15 mL) under 1 atm. of H_2 at room temperature for 15 h. The mixture was then filtered, evaporated to near dryness, dissolved in CH_2Cl_2 (50 mL), washed with 5% aqueous $NaHCO_3$, dried ($MgSO_4$), and evaporated to a colourless oil that crystallized on standing (95.5 mg, 82%); mp 67–68°C; $[\alpha]_D^{20}$ −37.3° (*c* 0.88, $CHCl_3$); ir (CH_2Cl_2): 1740 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.51 (d, 3H, J = 7.05), 1.85 (m, 1H), 2.20 (m, 1H), 2.70 (m, 3H), 3.00 (m, 2H), 3.75 (s, 3H), 3.85 (s, 6H), 5.14 (q, 1H, J = 7.05), 6.57 (s, 1H), 6.60 (s, 1H); ^{13}C nmr (75.5 MHz, $CDCl_3$) δ: 16.85, 25.61, 27.94, 31.09, 39.72, 52.25, 55.76, 66.28, 68.32, 111.33, 111.52, 126.35, 127.19, 147.02, 147.09, 171.19, 174.72; ms, *m/e* (rel. %): 322 (96), 192 (7), 191 (58), 190 (100), 189 (21), 175 (24), 176 (11). Exact Mass calcd. for $C_{17}H_{22}O_6$: 322.1416; found: 322.1425.

2S-(−)-6,7-Dimethoxy-1,2,3,4-tetrahydronaphthalene-2-carboxylic acid, ***11***

The ester **10** (113 mg, 0.349 mmol) and potassium carbonate (200 mg) were stirred in methanol/water (20:1, 20 mL) at room temperature for 15 h. Most of the solvent was then evaporated and the residue dissolved in 5% aqueous $NaHCO_3$, washed with CH_2Cl_2, acidified with 10% aqueous HCl, and finally extracted with ethyl acetate. Drying ($MgSO_4$) and evaporation gave a colourless solid that could be recrystallized from CH_2Cl_2/hexane (79.5 mg, 95%); mp 145.5–147°C; $[\alpha]_D^{20}$ −41.8° (*c* 0.67, $CHCl_3$); ir (CH_2Cl_2): 1708 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.85 (m, 1H), 2.25 (m, 1H), 2.75 (m, 3H), 2.95 (m, 2H), 3.84_1 (s, 3H), 3.84_3 (s, 3H), 6.58 (s, 1H), 6.59 (s, 1H); ms, *m/e* (rel. %): 237 (13), 236 (100), 191 (9), 190 (22), 175 (21), 164 (26), 159 (15). Exact Mass calcd. for $C_{13}H_{16}O_4$: 236.1049; found: 236.1046.

Benzyloxycarbamate of 2S-(−)-1-amino-6,7-dimethoxy-1,2,3,4-tetrahydronaphthalene, ***12***

Dimethoxytetralincarboxylic acid **11** (76.5 mg, 0.324 mmol), diphenylphosphoryl azide (107 mg, 1.2 equiv.), and triethylamine (39.4 mg, 1.2 equiv.) were refluxed in dry benzene for 2 h. Benzyl alcohol (105 mg, 3 equiv.) was added and the mixture refluxed a further 24 h. The solvent was then evaporated and the residual yellow oil chromatographed on silica gel (20% EtOAc/hexane) to give a colourless solid (88.5 mg, 80%); mp 130–131.5°C; $[\alpha]_D^{20}$ −23.3° (*c* 0.56, $CHCl_3$); ir (CH_2Cl_2): 1720 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.80 (m, 1H), 2.05 (m, 1H), 2.60 (dd, 1H, J = 16.0, 7.0), 3.05 (dd, 1H, J = 16.0, 4.80), 2.80 (m, 1H), 3.82 (s, 3H), 3.83 (s, 3H), 4.05 (m, 1H), 4.80 (d, 1H, J = 6.0), 5.10 (s, 2H), 6.52 (s, 1H), 6.57 (s, 1H), 7.35 (m, 5H); ms, *m/e* (rel. %): 341 (7), 233 (11), 191 (14), 190 (100), 91 (24), 77 (6). Exact Mass calcd. for $C_{20}H_{23}O_4N$: 341.1627; found: 341.1589.

Hydrochloride of 2S-(−)-1-amino-6,7-dimethoxy-1,2,3,4-tetrahydronaphthalene

A mixture of carbamate **12** (69.5 mg, 0.204 mmol) and 5% Pd/C (40 mg) in 10% anhydrous HCl in methanol (30 mL) was stirred under H_2 (1 atm) at room temperature for 8 h. The solution was filtered, and evaporated to leave a beige solid (48 mg, 97%) that could be recrystallized from methanol/ether; mp 213–214°C (lit. (4) mp 212–214°C); $[\alpha]_D^{20}$ −65.1° (*c* 0.215, CH_3OH) (lit. (4) $[\alpha]_D$ +73.2); ^1H nmr ($CDCl_3$) δ: 2.05 (m, 1H), 2.40 (m, 1H), 2.85 (m, 2H), 2.06 (dd, 1H, J = 15.4, 10.7), 3.25 (dd, 1H, J = 15.4, 4.38), 3.62 (m, 1H), 3.78 (s, 3H), 3.82 (s, 3H), 6.54 (s, 1H), 6.56 (s, 1H), 8.6 (bs, 3H).

2S-(−)-1-Amino-6,7-dimethoxy-1,2,3,4-tetrahydronaphthalene, ***13***

The hydrochloride salt of **13** (see above) (32 mg, 0.131 mmol) was dissolved in dilute aqueous base (0.1 M NaOH, 20 mL) and saturated aqueous NaCl (5 mL) was added. Extraction with CH_2Cl_2, drying ($MgSO_4$), and evaporation gave a colourless oil (16.1 mg, 60%) that solidified on cooling; mp 85–86°C; $[\alpha]_D^{20}$ −85.7° (*c* 0.105, CH_3OH), (lit. (4) $[\alpha]_D$ +86.5); ir (CH_2Cl_2): 3378, 3299 (weak) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.5–1.74 (m, 3H), 1.98 (m, 1H), 2.50 (dd, 1H, J = 9.23, 15.75), 2.80 (m, 2H), 2.92 (dd, 1H, J = 4.68, 15.75), 3.16 (m, 1H), 3.84 (s, 6H), 6.55 (s, 1H), 6.58 (s, 1H); ms, *m/e* (rel. %): 208 (6.4), 207 (51), 192 (7.6), 191 (10), 190 (85), 175 (34), 165 (18), 164 (100). Exact Mass calcd. for $C_{12}H_{17}O_2N$: 207.1259; found: 207.1259.

Mosher's acid amide of 2S-(−)-1-amino-6,7-dimethoxy-1,2,3,4-tetrahydronaphthalene

The *S*-(−)-amide was prepared from the crude amine **13** using the literature method (4); ^1H nmr (C_6H_6) δ: 1.36 (m, 1H), 1.66 (m, 1H), 2.32 (dd, 1H, J = 15.8, 8.49), 2.43 (m, 2H), 2.81 (dd, 1H, J = 15.8, 5.05), 3.13 (m, 3H), 3.41 (s, 3H), 3.44 (s, 3H), 4.28 (m, 1H), 6.29 (s, 1H), 6.32 (s, 1H), 6.42 (d, 1H, J = 7.72), 7.02–7.2 (m, 3H), 7.74 (d, 2H, J = 7.75). The amide from the racemic amine exhibited the signals above as well as the signals for the other diastereomer. The two sets of signals were well resolved only in the aromatic region where the other diastereomer showed signals at δ 6.24 and 6.35.

Received March 13, 1990

GIOVANNA BARBARELLA, MASSIMO LUIGI CAPOBIANCO, LUISA TONDELLI, and VITALIANO TUGNOLI. Can. J. Chem. **68**, 2033 (1990).

The preferential protonation sites of the homo dimers deoxycytidylyl-(3′,5′)-deoxycytidine, thymidylyl-(3′,5′)-thymidine, and deoxyadenylyl-(3′,5′)-deoxyadenosine were established by nitrogen-15 and carbon-13 NMR in dimethyl sulfoxide, in the presence of varying amounts of CF_3COOH. The nitrogen-15 NMR data show that in d(CpC) the capability of the two N3 nitrogens to accept the proton is slightly different. In d(TpT) and d(ApA) the protonation of the phosphate group leads to significant variations of the chemical shift of the carbons adjacent to phosphorus.

Key words: deoxydinucleotides, protonation, ^{15}N and ^{13}C NMR.

GIOVANNA BARBARELLA, MASSIMO LUIGI CAPOBIANCO, LUISA TONDELLI et VITALIANO TUGNOLI. Can. J. Chem. **68**, 2033 (1990).

Faisant appel à la RMN du ^{15}N et du ^{13}C, dans le diméthylsulfoxyde, en présence de quantités variables de CF_3COOH, on a déterminé les sites de protonation préférentielle des homo dimères, désoxycytidyllyl-(3′,5′)-désoxycytidine, thymidylyl-(3′,5′)-thymidine et désoxyadénylyl-(3′,5′)-désoxyadénosine. Les données de la RMN du ^{15}N montrent que, dans le d(CpC), les deux azotes N3 possèdent des capacités différentes d'accepter le proton. Dans le d(TpT) et le d(ApA), la protonation du groupement phosphate conduit à des variations importantes des déplacements chimiques des carbones adjacents du phosphore.

Mots clés : désoxydinucléotides, protonation, RMN du ^{15}N et du ^{13}C.

[Traduit par la revue]

Nucleic acids in living systems may contain sequences characterized by a high content of a given base, the biological and chemical behaviour of which depend upon the pH (cf., for example, the d($C_4A_4C_4A_4C_4$) sequence present in the DNA of *Oxytricha nova* (1)). Changes in conformation of oligonucleotides caused by protonation, in particular those of oligomers containing cytosine, are a matter of current interest (2, 3).

The preferential protonation sites of nucleosides, nucleotides, and deoxydinucleotides are easily established by nitrogen-15 NMR in dimethyl sulfoxide (4–9). Extensive carbon-13 NMR work has demonstrated that this is also a useful technique for determining the preferred position of proton attack on purines and purine derivatives (10–12). The pK_{BH^+} values of nitrogen bases in DMSO are generally smaller than in H_2O (10); thus the data obtained by nitrogen-15 and carbon-13 NMR in DMSO can be used as guidelines to understand the acid–base equilibria of nucleic acid components in water.

We present here a nitrogen-15 and carbon-13 NMR study of the protonation of the homo dimers deoxycytidylyl-(3′,5′)-deoxycytidine, thymidylyl-(3′,5′)-thymidine, and deoxyadenylyl-(3′,5′)-deoxyadenosine in dimethyl sulfoxide. The main lines of our nitrogen-15 and carbon-13 NMR work on deoxydinucleotide monophosphates have been described in a previous paper (9). In the present study an additional question to answer is whether nitrogen-15 or carbon-13 NMR, or both, are capable of revealing the slight differences that are likely to exist in the capability of the two N3 nitrogens of d(CpC) and the two N1 nitrogens of d(ApA) to accept the proton.

Results and discussion

The structure and the numbering scheme of d(CpC), d(TpT), and d(ApA) are reported in Fig. 1. Tables 1 and 2 give the nitrogen-15 chemical shifts of d(CpC) and d(ApA) in the presence of different amounts of CF_3COOH. The nitrogen-15 chemical shifts of d(TpT), 0.12 M in dimethyl sulfoxide, are 155.0, 154.9 (N1); 143.0, 142.4 (N3). Due to the fact that d(TpT) has only "pyrrole-like" nitrogens (13), no significant variations of $\delta(^{15}N)$ are found when CF_3COOH is added, as protonation only occurs at the phosphate group (*vide infra*). Consequently, the $\delta(^{15}N)$ values of d(TpT) as a function of added acid are not reported. Tables 3–5 give the carbon-13 chemical shifts and the relevant carbon–proton coupling constants of d(CpC), d(TpT), and d(ApA), respectively, at different concentrations of CF_3COOH.

The conformational properties of d(CpC), d(ApA), and d(TpT) in water have been described in an early work by Cheng and Sarma (14). No data are available for the same substrates in DMSO, a solvent where stacking interactions are negligible (15). For d(CpC) some information can be gained by comparison with the $\delta(^{15}N)$ values of the corresponding nucleoside (5, 9). The $\delta(^{15}N)$ differences between d(CpC) and cytidine indicate the existence of a certain degree of self-association of the dimer, with hydrogen bondings between the amino groups of one molecule (which are *deshielded* in the dimer compared

to the monomer) and the N3 nitrogens of another molecule (which are *shielded* compared to the monomer (9)). This is confirmed by proton data, which show that progressive dilution of d(CpC) in DMSO leads to a progressive displacement of the resonance of the amino protons towards lower frequencies (15). However, proton NMR shows also (see the experimental section) that even the hydroxyl groups are involved in the self-association process, indicating that the self-association scheme for d(CpC) in DMSO is more complicated than for cytidine (16).

The carbon-13 chemical shifts of d(CpC), d(TpT), and (ApA) are close to those for the corresponding monomers (9, 17). It is worth noting that in d(TpT) the chemical shifts for the C3′ and C5′ carbons adjacent to the phosphate group are very similar to those of d(CpC) and d(ApA), suggesting that the geometry of the sugar–phosphate backbone of the three homo dimers is nearly the same.

Protonation of deoxycytidylyl-(3′,5′)-cytidine

The two possible binding sites for proton are N3 and the phosphate group, but the former should have a pK_{BH^+} at least 2 pK units larger than the latter (9, 18, 19) and should be protonated first. In agreement with this, both N3 signals are displaced *upfield* by several ppm on acid addition (10–12). Table 1 shows that the trend of variation of $\delta(^{15}N)$ with increasing amounts of added acid is similar to that observed for cytidine itself and for the cytidylyl group of deoxycytidylyl-(3′,5′)-deoxyguanosine (9). The upfield shifts of the N3 nitrogens are paralleled by smaller but sizeable downfield shifts of the amino nitrogens, owing to the fact that in the protonated form there is a larger delocalization of the lone pair of the amino group into the pyrimidine ring (6, 9). Figure 2a–d gives the spectrum of d(CpC) after addition of 0, 1, 2, and 3 molar equivalents of acid, respectively. The two N3 resonances appear first as two sharp lines separated by only 0.7 ppm (Fig. 2a). Addition of 1 molar equivalent of acid displaces both lines towards lower frequencies by more than 30 ppm while the line separation increases up to 3.6 ppm (Fig. 2b). Moreover, owing to the relatively slow intermolecular hydrogen exchange in dimethyl sulfoxide, the resonance lines of the two nitrogens are considerably broadened. As the amount of acid reaches 2 molar equivalents, the lines become sharp again and separated by only 0.8 ppm (Fig. 2c). Finally, by further addition of acid the two resonances collapse into a single broad line (Fig. 2d). Since the N3 chemical shifts are weighted averages of the δ values for the protonated and unprotonated species, i.e., δ depends on the position of the equilibrium $B + H^+ \rightleftarrows BH^+$, this behaviour indicates that there is a different capability of the N3 nitrogens of the 3′-dCp and 5′-pdC moieties to accept the proton. Assuming that the chemical shift difference between a

protonated and an unprotonated nitrogen is 60 ppm (Table 1), it is easily calculated that one of the N3 nitrogens of Fig. 2b is 6% more protonated than the other. The existence of this difference is in agreement with the fact that the pK values reported for 2′-, 3′-, and 5′-cytidine monophosphates (18, 19) are slightly

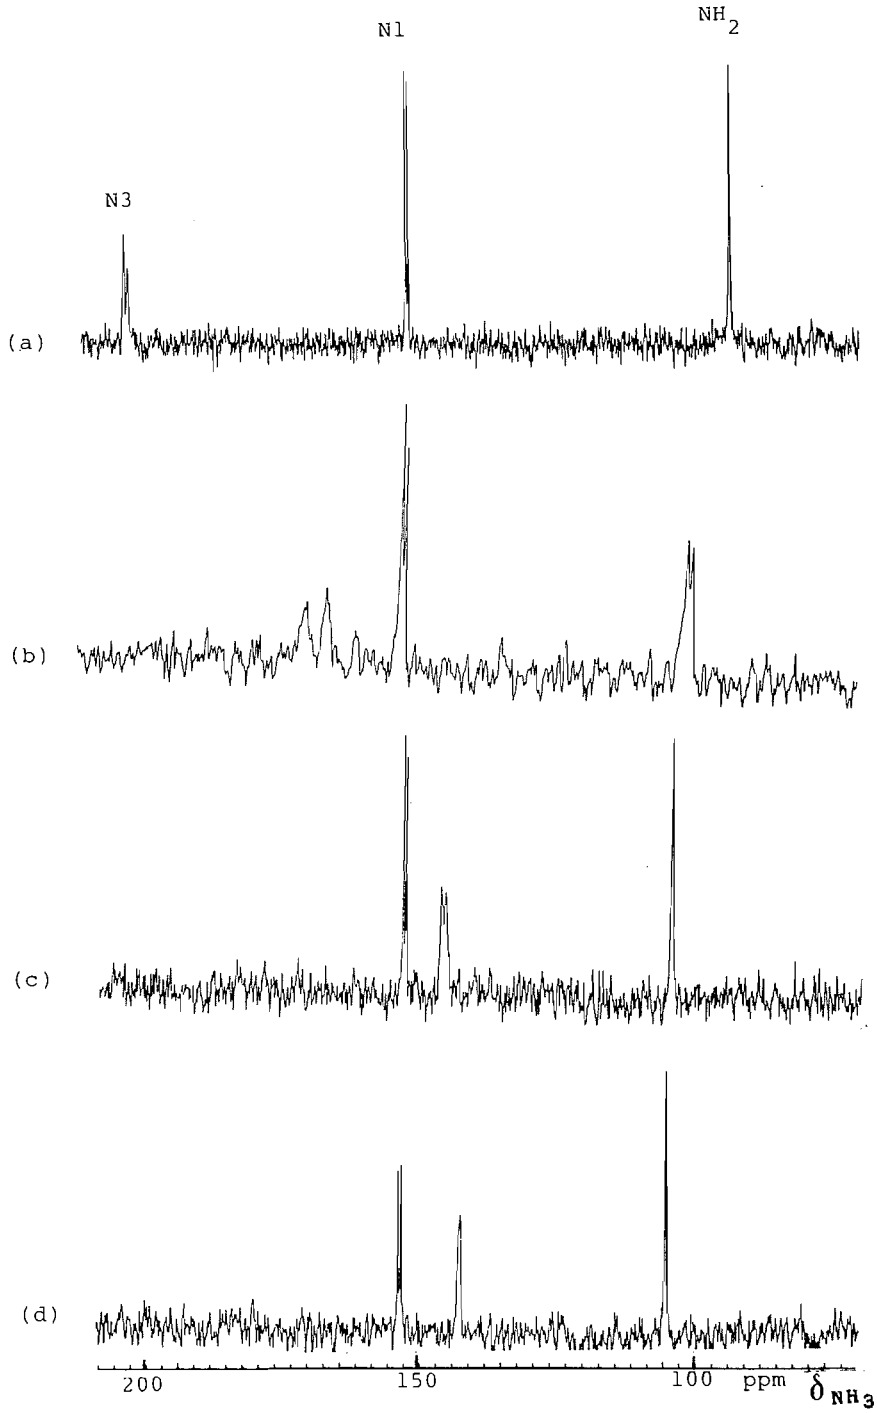

FIG. 2. Natural abundance 30.408 MHz nitrogen-15 NMR spectrum of deoxycytidylyl-(3′,5′)-deoxycytidine in dimethyl sulfoxide, in the presence of varying amounts of CF_3COOH. (a) 0 mol. equiv.; (b) 1 mol. equiv.; (c) 2 mol. equiv.; (d) 3 mol. equiv.

different. Unfortunately, the conflicting values reported by the different authors for 3′- and 5′-cytidine monophosphates make it difficult to establish which of the two N3 nitrogens of d(CpC) is the more basic simply by comparison with the pK_{BH^+} values for these nucleotides. A clue to identify which one of the two nitrogens of Fig. 2b is the more protonated can be found in the proton spectrum of the amino hydrogens of d(CpC) in DMSO *before acid addition*. Both amino protons of d(CpC) appear as broad doublets, indicating restricted rotation around the C4—NH_2 bond (20, 21). However, for one of the two amino groups the separation between the proton resonance lines is larger than for the other (see the experimental section). This may be taken as evidence of a larger degree of restricted rotation and, consequently, of a larger amount of negative charge on the corresponding N3 nitrogen (see Fig. 3 of ref. 9), which, in turn, becomes a better proton acceptor in the presence of CF_3COOH. Comparison with Raszka's proton data on 5′-cytidine monophosphate (21) in water suggests that this amino group may be that belonging to the 5′-dpC moiety of d(CpC), which is hydrogen bonded to the phosphate group of another molecule. In agreement with this, addition of sodium phosphate to the DMSO solution (see the experimental section) changes dramati-

For personal use only.

cally the spectrum of the amino protons, which both become hydrogen bonded to the phosphate anion and show the same proton line separation.

Table 2 shows that the trend in variation of $\delta(^{13}C)$ and $^{n}J_{CH}$ following acid addition is similar to that observed for cytidine and the cytidylyl moiety of deoxycytidylyl-(3′,5′)-guanosine monophosphate (9). The preferential protonation at N3 is clearly indicated by the change of the chemical shifts and coupling constants of the adjacent C2 and C4 carbons. However, contrary to nitrogen-15, carbon-13 data do not reveal that one of the two N3 nitrogens is a better proton acceptor than the other. This is shown, for example, by the fact that the chemical shift difference between the two C2 and between the two C4 carbons flanking the protonated nitrogen, after addition of 1 molar equivalent of acid, is too small to be significant.

Protonation of thymidylyl-(3′,5′)-thymidine

The carbon-13 chemical shifts of d(TpT) in water have already been reported (17, 22) and are larger than those in DMSO, given in Table 4. Since the major differences are found for the carbons of the bases, this is probably due to the effect of the stacking interactions existing in H_2O.

Table 4 shows that addition of CF_3COOH does not lead to $\delta(^{13}C)$ changes for the carbons of the pyrimidine bases. Indeed, as already mentioned, d(TpT) has only a single site available for protonation, i.e., the phosphate group. Consequently, only the carbons bound to the phosphate group and those of the ribose rings show chemical shift changes following acid addition. Progressive addition of CF_3COOH leads to a significant *downfield* shift of C3′ belonging to the 5′-pT moiety and of C5′ belonging to the 3′-Tp moiety, while the chemical shift of all ribose carbons moves *upfield*, although by smaller amounts.

Protonation of deoxyadenynyl-(3′,5′)-deoxyadenosine

It is known that addition of acid to a solution of d(ApA) may lead to hydrolysis of the glycosylic bond. We found that this is also the case for a DMSO solution containing trifluoracetic acid, but in DMSO the hydrolysis requires several hours to be completed. Since under our experimental conditions a nitrogen-15 spectrum requires at least overnight accumulation, we could only obtain $\delta(^{15}N)$ values for addition of 0.5 and 1.0 molar equivalents of CF_3COOH (Table 2). For larger amounts of acid, only the spectrum of protonated adenine[2] was observed. Since a much shorter time is required for a carbon-13 spectrum, the $\delta(^{13}C)$ values in the presence of up to 2 molar equivalents of acid are reported in Table 5.

The more basic nitrogen of adenosine is N1, with a pK_{BH^+} very close to that of the N3 of cytidine and about two units larger than that predicted for the phosphate group (9, 18, 19). On these grounds one would expect that addition of 0.5–1.0 molar equivalents of CF_3COOH would lead to the exclusive protonation of N1. This is not, however, the case.

Addition of 0.5 molar equivalents of acid displaces the resonances of the two N1 nitrogens towards lower frequencies by several ppm, as expected for protonation at these sites (4). This is also shown by the variations of the chemical shifts of C2 and C6, the carbons flanking N1, and by the variations of $^{1}J_{C2-H2}$ and $^{3}J_{C6-H2}$ (ref. 23 and footnote 2). However, the chemical shift increments of the two N1 nitrogens, −7.1 and −9.1 ppm respectively, are smaller than would be expected on the basis of the comparison with adenosine, for which, following addition of 0.31 molar equivalents of CF_3COOH, an increment of −16 ppm is found in δ(N1) (4). Moreover, Table 5 shows that, for only 1 molar equivalent of acid added, the chemical shift of the C3′ and C5′ carbons next to phosphorus *increases* by 1.7 and 1.1 ppm, respectively. Comparison with the changes in $\delta(^{13}C)$ for the same carbons in d(CpC) and d(TpT) indicates clearly that protonation also occurs at the phosphate group. Thus, in d(ApA), protonation of the phosphate group is competitive with that of N1.

Table 2 shows also that protonation leads to the increase of the $\delta(^{15}N)$ difference of the two N1 nitrogens (2.1 ppm for 0.5 mol. equiv. of acid added). As in the case of d(CpC), this indicates that there is a different capability of the two N1 nitrogens to accept the proton. It is worth noting that upon acid addition the N1 resonance lines become broader than those of the N3's in d(CpC), indicating that the intermolecular hydrogen exchange is slower on the NMR time scale (note also that on addition of 1 mol. equiv. of acid the N1 lines become so broad as to be undetectable). As in the case of d(CpC), the $\delta(^{13}C)$ changes of d(ApA) are unable to reveal the small differences in the capability of the two N1 nitrogens to accept the proton.

Conclusions

The preferential protonation sites of the homo dimers deoxycytidylyl-(3′,5′)-deoxycytidine, thymidylyl-(3′,5′)-thymidine, and deoxyadenynyl-(3′,5′)-deoxyadenine are easily established either by nitrogen-15 or carbon-13 NMR in dimethyl sulfoxide. It is possible, however, to detect the small differences in the capabilities of the two N3 nitrogens of d(CpC) and the two N1 nitrogens of d(ApA) to accept the proton only by nitrogen-15 NMR. Small differences in basicity may become important at pH values near the physiological one (cf., for example, ref. 24); thus it would be useful to establish whether protonation of d(CpC) and d(ApA) follows the same trend in water as in dimethyl sulfoxide.

The data reported here show that nitrogen-15 NMR is very informative, but that carbon-13 NMR also gives a great deal of useful information, not only on the protonation of the pyrimidine or purine moieties, but also on that of the phosphate group. Indeed, protonation of phosphate leads to significant variations in the $\delta(^{13}C)$ values of the carbons next to phosphorus. Thus, ^{13}C NMR looks very promising for conformational analysis of oligonucleotides, particularly where conformational changes induced by pH variations are concerned.

Experimental

All dinucleoside monophosphates were prepared according to published procedures (25). The sodium salts were obtained from the corresponding ammonium derivatives by treatment with Dowex 50W8 (Na^+ form).

NMR spectra

All spectra were run with a Bruker CXP-300 spectrometer at the probe temperature (25°C). The resonance frequencies were 75.485 MHz for ^{13}C, 30.408 for ^{15}N, and 300 MHz for ^{1}H. The concentrations were 0.3 M and 0.15 M for the nitrogen spectra of d(CpC) and d(ApA), respectively, and 0.1 M for all carbon and proton spectra.

Carbon-13 chemical shifts are relative to TMS as internal reference. The assignments were carried out by carbon–proton correlated spectroscopy and by comparison with literature data (11, 22, 23).

Nitrogen-15 spectra were run with a 10-mm dedicated probe. In most cases broadband decoupled and inverse gated-decoupled spectra were recorded. Although this is a rather time-consuming technique for

[2] $\delta(^{13}C)$ values of a solution of adenine 0.1 M in DMSO: 152.3 (C2); 151.1 (C4); 117.4 (C5); 155.3 (C6); 139.2 (C8). Addition of 2 mol. equiv. of CF_3COOH gives: 145.3 (C2); 149.8 (C4); 115.6 (C5); 151.6 (C6); 143.8 (C8).

obtaining nitrogen-15 natural abundance NMR information, we found that it gave more reliable results than the various INEPT techniques. However, we are unable to say whether this is attributable to the difficulties inherent in using an old spectrometer or to some physical features of the dimers under investigation in DMSO, or both. Typical conditions for gated-decoupled spectra (required to suppress the unfavourable $^{15}N-^{1}H$ nuclear Overhauser enhancement) were as follows: sweep width 10 kHz; pulse width 40°; repetition time 7 s; data points 16 k. The free induction decays were transferred to a New Methods Research Specstation equipped with a DEC microVax II, zero-filled to 32 k, and Fourier transformed. The chemical shifts were measured with respect to an external 1 M solution of HNO_3 and converted to the NH_3 scale using the conversion factor $\delta(NH_3)$ = 376 ppm (p. 74, ref. 13). The assignments were made on the basis of the corresponding monomers (4–6).

The proton spectrum of d(CpC) in DMSO showed two broad doublets (belonging to the two different amino groups), resonating at 7.17 ppm (proton separation: 0.04 ppm) and 7.35 ppm (proton separation: 0.11 ppm). Addition of Na_3PO_4 to the solution resulted in two broad doublets centered at 7.27 and 7.09 ppm, both with a doublet separation of 0.1 ppm. The proton spectrum of d(CpC) in DMSO also shows a single broad signal centered at 5.50 ppm for the two hydroxyl groups. Progressive dilution leads to the progressive separation of the resonances, which also become sharper. The spectrum of a 2×10^{-3} M solution shows a sharp doublet centered at 5.38 (C3′-O*H*) ppm and a sharp triplet centered at 5.51 ppm (C5′-O*H*). The same signal separation of the two hydroxyl groups, with appearance of long-range proton–proton couplings, is also obtained when Na_3PO_4 is added to the solution.

Hypoglucaemic triterpenoid saponins from *Boussingaultia baselloides*

ALFONSO ESPADA, JAIME RODRIGUEZ, M. CARMEN VILLAVERDE, AND RICARDO RIGUERA[1]
Departamento de Química Orgánica, Facultad de Química, Universidad de Santiago de Compostela, Spain

Received March 22, 1990

ALFONSO ESPADA, JAIME RODRIGUEZ, M. CARMEN VILLAVERDE, and RICARDO RIGUERA. Can. J. Chem. **68**, 2039 (1990).

New saponins with hypoglucaemic activity (**1–4**) and momordin Ic (**5**) have been isolated from the methanolic extract of the leaves of *Boussingaultia baselloides*. They were shown by spectroscopy and chemical transformation to be derivatives of 12,20(29)-dien-30-noroleanic acid. Boussingoside A_1 (**1**) exhibits very strong hypoglucaemic activity in rats. Acid hydrolysis of the saponin **1** yielded five transformation products (**6–10**), though one of them (larreagenin A (**6**), which has been reported in the literature as a genuine plant metabolite) is considered to be an artifact formed by the acid treatment.

Key words: *Boussingaultia baselloides*, Basellaceae, boussingosides, triterpenoid saponins, hypoglucaemic activity.

ALFONSO ESPADA, JAIME RODRIGUEZ, M. CARMEN VILLAVERDE et RICARDO RIGUERA. Can. J. Chem. **68**, 2039 (1990).

On a isolé de nouvelles saponines ayant une activité hypoglycémique (**1–4**) et la momordine Ic (**5**) à partir d'extraits méthanoliques des feuilles de *Boussingaultia baselloides*. Faisant appel à la spectroscopie et à des transformations chimiques, on démontre que ces composés sont des dérivés de l'acide (29)-12,20-diène-30-noroléanique. La boussingoside A_1 (**1**) exhibe une forte activité hypoglycémique chez les rats. L'hydrolyse acide de la saponine **1** conduit à cinq produits de transformation (**6–10**) dont l'un d'eux (la larréagénine A (**6**), qui est répertoriée dans la littérature comme un vrai métabolite végétal) est considéré comme un artefact résultant du traitement acide.

Mots clés : *Boussingaultia baselloides*, Basellaceae, boussingosides, saponines triterpénoïdes, activité hypoglycémique.

Introduction

Two members of the herbaceous climbing plant family Basellaceae have been reported in Colombia (1, 2). One of these species, *Boussingaultia baselloides* H.B.K., known as insuline, is used in folk medicine (as a drink made by adding 4–6 fresh chopped *B. baselloides* leaves to approximately 150 mL of boiling water and reduction of the volume to a third), mainly for treatment of *diabetes* but also as an analgesic. In this paper we report the isolation of new triterpenoid glycosides responsible for the hypoglucaemic activity of the crude plant extract. This work constitutes the first research on an intact polar extract of a member of the Basellaceae family.

In the course of this study we have isolated and identified, by spectroscopic analysis (2D-NMR experiments and FAB-MS) and chemical transformation, four new nor-triterpenoid saponins with hypoglucaemic activity.

Results and discussion

The aerial parts of the plant, collected in Tuluá (Colombia), were extracted successively with petroleum ether and MeOH. The MeOH extract was then partitioned between *n*-BuOH and H_2O. Chromatographic separation of the BuOH soluble fraction, which showed hypoglucaemic activity, afforded a complex mixture of triterpenoid glycosides. This mixture was successively subjected to several separation techniques (Sephadex LH-20, DCCC, and HPLC) to give the pure compounds **1–5** (Fig. 1). We have named compounds **1–4** boussingosides A_1 (**1**), A_2 (**2**), B (**3**), and C (**4**); compound **5**, momordin Ic, has previously been reported in *Momordica cochinchinensis* (Cucurbitaceae) (3).

Boussingoside A_1 (**1**) was crystallized from methanol as a white microcrystalline powder (mp 213–215°C) that was subjected to fast atom bombardment MS (FAB-MS) (negative ion mode). A quasi-molecular ion was observed at *m/z* 615 $[M - H]^-$ indicating a molecular weight of *m/z* 616 and a molecular formula of $C_{35}H_{52}O_9$. The ^1H NMR spectrum of **1** showed a doublet at δ 4.93 (J = 7.9 Hz) attributable to the anomeric proton of a β-pyranoside. The ^{13}C NMR spectrum showed the anomeric carbon at δ 106.9, a carboxylic signal at δ 179.4 ppm, and four signals in the sugar region corresponding to glucuronic acid. The fragment at *m/z* 440 found in the FAB-MS, $[M - H - 175]^-$, clearly indicates the separation of this sugar; in fact, glucuronic acid was identified (GC–MS as alditol acetate) after hydrolysis of **1** (see Table 1).

Compound **1** also exhibited two olefinic bonds, one with signals at δ_H 5.43 and δ_C 122.9 and 144.1, indicating a $\Delta^{12(13)}$ double bond, and the other at δ_H 4.71 and 4.76 and δ_C 106.9 (CH_2 inferred from DEPT and XHCOR experiments) and δ 149.0, due to the C20—C29 double bond. The presence of five methyl singlets upfield in the ^1H NMR spectrum and comparison with the literature (4, 5) confirmed a nor-olean skeleton.

Further information about the structure of **1** was obtained from COSY and nOe experiments. Thus the double doublet at δ_H 3.34 (J = 11.9 and 4.0 Hz), H3α, was shown to be correlated in the ^1H–^1H COSY spectrum (Fig. 2) with two multiplets at 2.16 ppm (H2α) and 1.80 ppm (H2β). Furthermore, the double doublet at δ_H 3.17 (J = 13.7 and 4.9 Hz), H18, correlates with two signals at 2.20 (m) and 2.58 (t, J = 13.7 Hz) corresponding to protons H19β and H19α respectively. The stereochemistry at C18 was determined by irradiation of the signal at 3.17 (H18), which caused nOe on the broad singlet at 5.43 corresponding to H12. All these assignations were corroborated by a 2D-XHCOR experiment (see Fig. 3) and the assignation of the methyl groups was corroborated by a XHCORR-LR spectrum (Fig. 4) of compound **2**. We observe the following correlations: Me24/C4 (two bonds) (no correlation was observed with C3), Me23/C3 (three bonds), Me23/C4 (two bonds), Me27/C13, Me27/C8 (both three bonds), and Me27/C14 (two bonds), Me26/C8 (two bonds), Me26/C14 (three bonds), and finally Me25/C10 (two bonds).

On the basis of the above data, we concluded that boussingoside A_1 (**1**) is 3-*O*-[β-D-glucuronopyranosyl]-30-norolean-12,20(29)-dien-28-oic acid.

Boussingoside A_2 (**2**) was obtained as a microcrystalline white powder (mp 218–220°C), and presents a FAB-MS

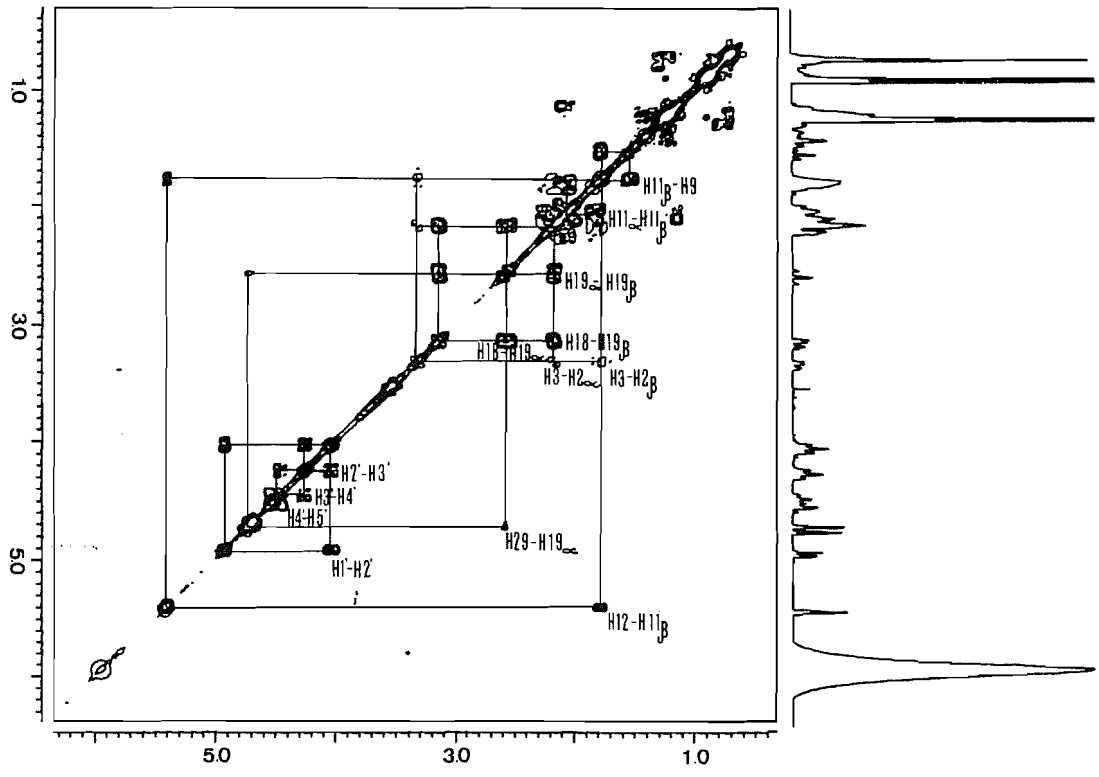

FIG. 2. ^1H–^1H COSY of boussingoside A_1.

(negative ion mode) spectrum showing a quasi-molecular ion at m/z 777 $[M - H]^-$, and thus a molecular weight m/z 778 and a molecular formula $C_{41}H_{62}O_{14}$. It also showed fragments corresponding to the cleavage of two sugars at m/z 614 $[M - H - \text{glucose}]^-$ and 439 $[M - H - \text{glucose} - \text{glucuronic acid}]^-$. The ^{13}C and ^1H NMR spectra are also similar to those of boussingoside A_1 (**1**) (see Table 2), but in addition present one upfield β-anomeric signal at δ_C 95.7 (δ_H 6.24, J = 7.9 Hz) and other peaks that correspond to a glucose unit attached to C28 of the aglycone through an ester bond. Thus boussingoside A_2 (**2**) is 3-*O*-[β-D-glucuronopyranosyl]-30-norolean-12,20(29)-dien-28-*O*-[β-D-glucopyranosyl] ester.

To confirm these structures and also to get information on the sugar unit bound through the ester bond at C28 or the acetal

bond at C3, we proceeded to study the acid and basic hydrolyses of **1** and **2**. Treatment of **2** with 0.5 N KOH gave a single sugar, glucose, and another product that was shown by HPLC and its spectroscopic data to be identical to boussingoside A_1 (**1**), implying that glucose must be bound to the C28 carboxylic group of the aglycone. Acid treatment of **2** gave, in turn, glucose and glucuronic acid (which were identified by GC–MS as alditol acetates) and a complex mixture of five lipophilic products which was identical in composition to that obtained

[a]In C_5D_5N.
[b]In CD_3OD.

from **1** (see below), thus proving that **1** and **2** have the same aglycone.

Acid hydrolysis of **1** with HCl in methanol gave, as expected, glucuronic acid and the aforementioned mixture of five nortriterpenes (**6**–**10**; Fig. 4), which were separated by HPLC and identified by ^{1}H NMR and MS (6).

Boussingosides B (**3**) and C (**4**) were crystallized in MeOH. Their ^{1}H NMR spectra showed only four upfield methyl singlets instead of the five of **1** and **2**. In both **3** and **4** the methyl group at C23 of the aglycone is replaced by a -CH_2OH group, as indicated by the 6–8 ppm shift of C3, C4, and C5 (Table 2). The spectra of compound **3** showed two anomeric groups with signals at δ_C 95.9 and 105.1, and two doublets at δ_H 4.53 and 5.46. The remaining signals were assigned to two glucose units by comparison with published data (4). In keeping with this, the FAB-MS (negative mode) of **3** presents a quasi-molecular ion at *m/z* 797 $[M - H]^-$ (molecular weight 798, molecular formula

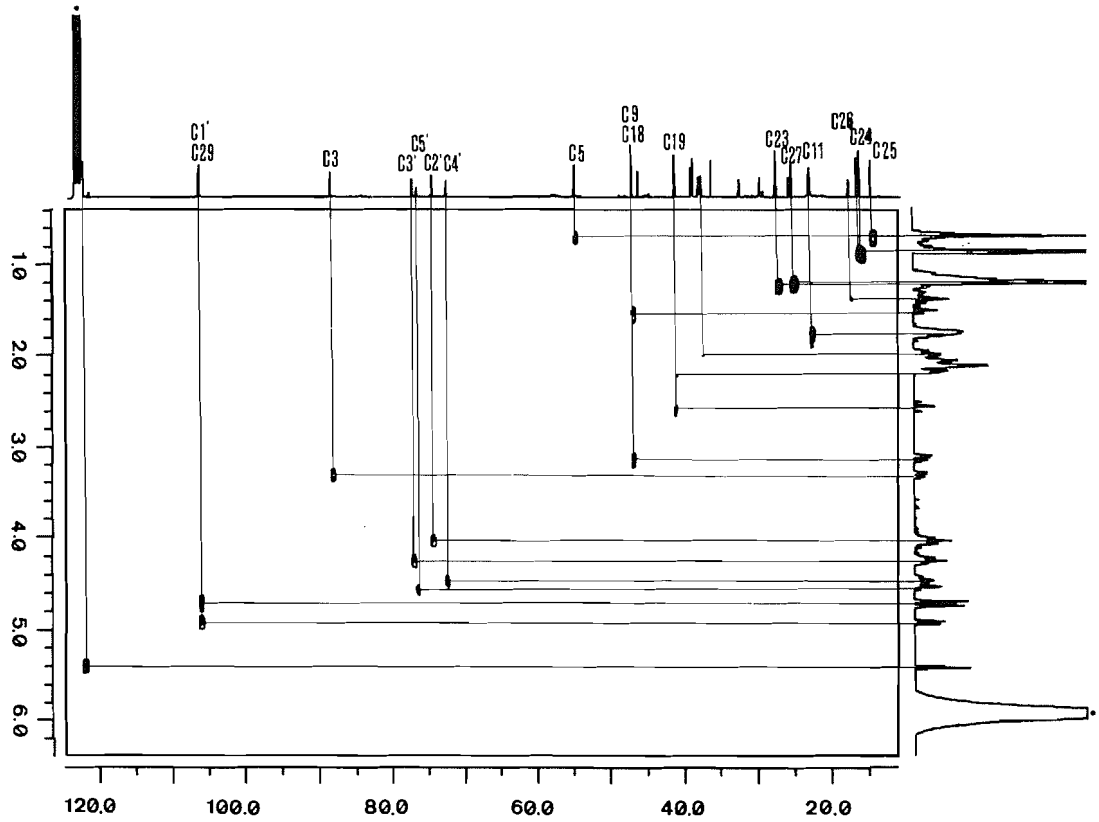

FIG. 3. XHCORR of boussingoside A_1 (J = 130 Hz).

$C_{41}H_{66}O_{15}$) and also shows fragments at m/z 634 $[M - H - 163]^-$ and 471 $[M - H - 326]^-$ corresponding to the successive elimination of two glucose units bound to a tetraoxygenated aglycone.

Thus boussingoside B (**3**) is a 3-*O*-[β-D-glucopyranosyl]-30-norolean-12,20(29)-dien-23-hydroxy-28-*O*-[β-D-glucopyranosyl] ester.

The ^{13}C NMR spectrum of boussingoside C (**4**) presents only one anomeric signal at 107.0 (δ_H 5.23 d, J = 7.5 Hz). Its FAB-MS (negative mode) shows an m/z 631 $[M - H]^-$ and a fragment at m/z 454 $[M - H - 177]^-$, indicating the loss of a glucuronic acid unit and proving that compound **4** is 3-*O*-[β-D-glucuronopyranosyl]-30-norolean-12,20(29)-dien-23-hydroxy-28-oic acid.

Compound **6**, larreagenin A, has been reported as a metabolite isolated from *Larrea divaricata* (7), but it has always been obtained after acid hydrolysis of the mixture of saponins (6). We suspected that compound **6** was an artifact generated during the acid treatment. This was confirmed by its appearing even when **1** was hydrolyzed under milder conditions (1 N HCl) than those described in the literature.

Preliminary pharmacological studies[2] have shown that the aqueous extract of the plant and boussingoside A_1 have hypoglucaemic activity.

[2]In rats with induced diabetes, intraperitoneal injection of a dose of aqueous extract equivalent to (10 g dried aerial parts)/kg significantly reduced glucose levels from over 399 mg/% to 60 mg/% after 8 h. A 20 mg/kg dose of boussingoside A_1 had a similar effect. R. Cadena and J. A. Otero, unpublished results.

Experimental

General

All melting points were taken on a Kofler Thermogeräte apparatus and are uncorrected. ^1H NMR spectra were taken on a Bruker WM-250 spectrometer. The ^1H NMR, ^{13}C NMR, and DEPT spectra of the glycosides were obtained in C_5D_5N and CD_3OD at 298 K. HPLC was performed with a Waters model 6000A chromatograph equipped with a pump and a model R401 differential refractometer. DCCC was carried out with an Eyela model 300-S apparatus equipped with 300 tubes. Conventional and FAB mass spectra were obtained on a Kratos MS50 mass spectrometer equipped with a Kratos FAB source. The FAB mass spectra were obtained by dissolving the samples in a glycerol matrix and bombarding with Xe atoms of 2–8 kV energy. GC–MS analyses were carried out on a Carlo Erba MFC 500 HRGC/MS chromatograph using a 0.25 mm × 10 m SP-2330 capillary column, column temperature 240°C, injection temperature 50°C for 1 min and 12°/min up to 240°C maintained for 2 min.

Two-dimensional experiments

The two-dimensional ^1H–^1H COSY spectra (64 × 1K) of the boussingosides were obtained by accumulating 32 scans per t_1; the relaxation delay was 3 s. The data were zero-filled to 512 in F_1 and subjected to Fourier transformation using Gaussian data manipulation in both dimensions and symmetrized.

The two-dimensional ^1H–^{13}C heteronuclear shift correlation (XHCORR) spectra (256 × 1K) of **1** and **2** for directly bonded protons and carbons were obtained by accumulating 80 scans per t_1; the relaxation delay was 3 s and the value of J_{CH} selected was 130 Hz. The long-range correlation XHCORR (256 × 2K) spectrum of boussingoside A_2 was obtained by accumulating 88 scans per t_1; the relaxation delay was 2 s and the value of J_{CH} selected was 9 Hz. Both XHCORR data (long range and direct correlation) were zero-filled to 512 in F_1 and subjected to Fourier transformation using Gaussian data manipulation in F_2.

Plant material

Plants were collected in Tuluá, Colombia. Voucher specimens were deposited at the herbaria of the Universities of Santiago de Cali, Colombia, and Santiago de Compostela, Spain (SANT 18191).

Extraction and isolation

The ground leaves of the plant (200 g) were extracted successively with petroleum ether and MeOH giving respectively 30 g and 36.2 g of dry extract. The MeOH extract was defatted with *n*-hexane (2 × 200 mL), CCl_4 (200 mL), and CH_2Cl_2 (2 × 200 mL), and partitioned between *n*-BuOH and H_2O. The BuOH extract (12.6 g) was dissolved in a minimal amount of MeOH, and the solution dropped into Me_2CO and centrifuged. The precipitate was filtered off and the filtrate concentrated under reduced pressure to give 9.7 g of dry extract, which was separated in five fractions (A–E) on a Sephadex LH-20 column using MeOH as eluent and TLC monitoring. Fraction B (1.5 g) was purified by DCCC with $CHCl_3$–MeOH–H_2O (7:13:8) in ascending mode (flow rate 12 mL/h). Fractions 35–40 contained boussingoside A_2 (**2**) (110 mg) and fractions 80–95 boussingoside A_1 (**1**) (80 mg) in pure form. Fractions 40–60 (150 mg) were pooled and rechromatographed by DCCC with $CHCl_3$–MeOH–H_2O (7:13:8) in ascending mode (flow rate 8 mL/h), giving compound **5** (28 mg) and boussingoside C (**4**) (11 mg) in pure form and boussingoside B (**3**) (7 mg), which was repurified by HPLC with MeOH–H_2O 55% (reversed phase, Partisil ODS-M9 column).

Boussingoside A_1 (**1**): mp 213–215°C. ^1H and ^{13}C NMR as in Tables 1 and 2 respectively. FAB-MS (negative ion mode) m/z (relative int.): 615 ($[M - H]^-$, 100), 440 ($[M - H - 175]^-$, 70). FAB–MS (positive ion mode): 683 ($[M - 2H + 3Na]^+$, 80), 661, ($[M - H + 2Na - 162]^+$, 100), 507 ($[M - 2H + 3Na - 176]^+$, 40).

Boussingoside A_2 (**2**): mp 218–220°C. ^1H and ^{13}C NMR as in Tables 1 and 2. FAB-MS (negative ion mode) m/z (relative int.): 777 ($[M - H]^-$, 100), 614 ($[M - H - 163]^-$, 24), 569 ($[M - H - 163 - 44]^-$, 10), 439 ($[M - H - 163 - 175]^-$, 6). FAB-MS m/z (relative int.) (positive ion mode): 823 ($[M - H + 2Na]^+$, 76), 661 ($[M - 2H + 3Na - 162]^+$, 32).

Boussingoside B (**3**): mp 218–220°C. ^1H NMR (CD_3OD) δ_H: 0.80 (s, 3H, 25-Me), 0.90 (s, 3H, 26-Me), 1.08 (s, 3H, 24-Me), 1.30 (s, 3H, 27-Me), 4.53 (d, 1H, J = 7.7 Hz, H-1′), 4.71 (bs, 2H, H-29), 5.41 (bs, 1H, H-12), 5.46 (d, 1H, J = 7.8 Hz, H-1″). ^{13}C NMR, see Table 2. FAB-MS (negative ion mode) m/z (relative int.): 797 ($[M - H]^-$, 100), 634 ($[M - H - 163]^-$, 24), 471 ($[M - H - 163 - 163]^-$, 10). FAB-MS m/z (relative int.) (positive ion mode): 843 ($[M - H + 2Na]^+$, 76), 821 ($[M + Na]^+$, 32), 659 ($[M - H + Na - 162]^+$, 10).

Boussingoside C (**4**): mp 218–220°C. ^1H NMR (C_5D_5N) δ_H: 0.85 (s, 3H, 25-Me), 0.92 (s, 3H, 26-Me), 0.95 (s, 3H, 24-Me), 1.12 (s, 3H, 27-Me), 4.71–4.75 (bs each, 2H, H-29), 5.23 (d, 1H, J = 7.5 Hz, H-1′), 5.43 (bs, 1H, H-12). ^{13}C NMR, see Table 2. FAB-MS

(negative ion mode) m/z (relative int.): 631 ($[M - H]^-$, 100), 454 ($[M - H - 177]^-$, 29), 410 ($[M - H - 177 - 44]^-$, 17). FAB-MS m/z (relative int.) (positive ion mode): 699 ($[M - 2H + 3Na]^+$, 85), 675 ($[M - H + 2Na]^+$, 45), 523 ($[M - 2H + Na - 176]^+$, 18), 479 ($[M + Na - 176]^+$, 19).

Basic hydrolysis

Boussingoside A_2 (**2**) (25 mg) was refluxed in 0.5 N KOH (20 mL) for 2 h. The mixture was brought to pH 6 with 1 N HCl and extracted with *n*-BuOH (2 × 20 mL). The organic phase was washed with H_2O (3 × 20 mL), affording boussingoside A_1 (**1**).

Acid hydrolysis of 2

When **2** was treated with acid (see below) it gave two sugars and a mixture of triterpenes (**6**–**10**) identical to that obtained by similar treatment of **1**. The sugar fraction was dissolved in H_2O (10 mL), $NaBH_4$ (20 mg) was added, and the mixture was stirred at room temperature for 2 h. After addition of AcOH to eliminate excess $NaBH_4$, the mixture was concentrated to dryness and codistilled with MeOH (2 × 5 mL), and the resulting alditols were acetylated with Ac_2O–pyridine (1:1, 10 mL) by refluxing overnight. The solution was washed with H_2O and extracted with CH_2Cl_2, and the alditol acetates were then identified as those of glucose and glucuronic acid by GC–MS.

Acid hydrolysis of 1

To a solution of boussingoside A_1 (**1**) (20 mg in 10 mL of MeOH) was added 10 mL of 1 N HCl and the mixture was refluxed for 4.5 h. The mixture of aglycones was extracted with CH_2Cl_2 (3 × 20 mL) and subjected to HPLC on a μ-Porasil column (30 cm × 7.8 mm i.d.) with *n*-hexane–EtOAc (75:25) as eluent, affording compounds **6**–**10**.

Compound 6: ^{1}H NMR $CDCl_3$: 0.76 (s, 3H, H-25), 0.80 (s, 3H, H-26), 0.85 (s, 3H, H-24), 0.99 (s, 3H, H-27), 1.13 (s, 3H, H-23), 1.45 (s, 3H, H-29), 3.23 (m, 1H, H-3). Synthesis of protein conjugates and analogues of *N*-acetylneuraminic acid

RENÉ ROY[1] AND CRAIG A. LAFERRIÈRE
Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 6N5

Received May 3, 1990

RENÉ ROY and CRAIG A. LAFERRIÈRE. Can. J. Chem. **68**, 2045 (1990).

N-Acetylneuraminic acid (**1**) was prepared from the salivary gland mucins of the Chinese swiftlet by an improved procedure using acidic resin hydrolysis. Compound **1** was transformed into the known acetochloroneuraminic acid (**3**) by a new two-step procedure. Koenigs–Knorr glycosylation of **3** followed by subsequent reductive ozonolysis of the 2-propenyl α-glycoside afforded the key aldehyde precursors **7** and **8**, which were coupled to bovine serum albumin or tetanus toxoid by reductive amination. The factors influencing the extent of incorporation were investigated. A series of *N*-acetylneuraminic acid analogues modified at strategic functionalities were also synthesized.

Key words: sialic acid, *N*-acetylneuraminic acid, neoglycoproteins, bovine serum albumin, tetanus toxoid.

RENÉ ROY et CRAIG A. LAFERRIÈRE. Can. J. Chem. **68**, 2045 (1990).

L'acide *N*-acétylneuraminique (**1**) a été préparé selon une procédure améliorée à partir de la mucine des glandes salivaires d'hirondelles asiatiques. La méthode fait intervenir une hydrolyse par de la résin cationique acide. Le composé **1** a été transformé en dérivé acide acétochloroneuraminique connu (**3**) par une nouvelle méthode en deux étapes. Une glycosylation de **3** par la méthode de Koenigs–Knorr, suivie d'une ozonolyse réductive du α-glycoside de propèn-2-yle conduit aux précurseurs aldéhydes clés **7** et **8** qui sont ensuite couplés à l'albumine bovin et à l'anatoxine tétanique par amination réductrice. Les facteurs influençant le niveau d'incorporation ont été étudiés. Une série d'analogues de l'acide *N*-acétylneuraminique modifiés aux fonctionnalités stratégiques a aussi été synthétisée.

Mots clés : acide sialique, acide *N*-acétylneuraminique, néoglycoproteines, albumine bovin, anatoxine tétanique.

Introduction

The sialic acids represent a family of more than 30 naturally occurring derivatives of neuraminic acid (1). The most ubiquitous member of the sialic acids is *N*-acetylneuraminic acid (Neu5Ac, **1**). It is present in the capsular polysaccharide fractions of a number of pathogenic bacteria (2, 3). It was also identified in the glycoprotein mucins of higher animals, the most abundant source being the *Collocalia* mucoid, the nest-cementing glycoprotein substance of the Chinese swiftlet (4) from whose nests it can be isolated in large quantity (5% w/w) (5). *N*-Acetylneuraminic acid (**1**) is also an important constituent of the cell wall glycolipids (gangliosides) (1). More recently, the N-linked oligosaccharide sequences of the envelope glycoproteins gp120 of the human immunodeficiency viruses (HIV) were characterized and were shown to contain high levels of Neu5Ac (**1**) (6).

In the glycoproteins and glycolipids, the sialic acids, which are exclusively α-linked, occupy the penultimate nonreducing end of the oligosaccharide chains. Therefore, it is not surprising to find that they play forefront roles in a number of biochemical and immunochemical events. For instance, Neu5Ac alone or Neu5Ac terminated oligosaccharides were shown to be responsible for influenza virus adhesion onto erythrocytes (7) and human nasal mucins. Bacterial adherence and colonization of intestinal tracts by *Escherichia coli* is another event caused by the binding interactions between the bacterial pili and the sialic acids of the epithelial cell walls (8). Bacterial toxins (tetanus, diphtheria) (9), animal and plant lectins (10), interferon (11), and mycoplasma pneumoniae (12) are other representative examples of such interactions, which use Neu5Ac as cell surface receptors. Moreover, the sialic acids in the glycoprotein hormone of human chorionic gonadotropin (hCG) can modulate its hormonal activity (13). On the other hand, the absence of sialic acids on glycoproteins may have beneficial effects. Thus, the uptake or sequestration of senescent cells by macrophages (14) and liver hepatocyte receptors (15) can trigger the catabolism of useless cells. Perhaps the most interesting features of the sialic acids are their roles as differentiation (16) and oncodevelopmental (17) antigens. As such, they constitute key functional entities in the design of specific oncogenic markers.

It was therefore anticipated that the synthesis of well-defined artificial neoglycoproteins, containing sialic acids as the sole carbohydrate antigen, would constitute excellent probes for studying some of the interactions mentioned above. Such tools may have useful applications in the study of lectins and antibody–carbohydrate interactions at the molecular level (10). These neoglycoproteins may also be useful for the detection and screening of endogenous lectins by immunocytochemical staining (18), which might permit cell targeted drug delivery. We have also previously mentioned that neoglycoproteins and copolymers containing Neu5Ac represented good inhibitors of the adherence of influenza A virus to chicken erythrocytes (19). This phenomenon could constitute the basis of a therapy against the common cold.

As mentioned previously (20, 21), our initial goals were to produce specific anti-sialic acid antibodies (potentially monoclonals) that might be useful for the quantitation of sialyloligosaccharides present in large quantities in the serum of cancer patients (17). Our first attempts were directed to terminal anti-Neu5Ac antibodies, irrespective of the type of linkages between the Neu5Ac and the next carbohydrate residues, usually α-(2,6) or α-(2,3)-galactose. Therefore, the present work describes the synthesis of antigenic Neu5Ac residues α-linked to two different carrier proteins, namely bovine serum albumin (BSA) and tetanus toxoid (TT). These two proteins are known for their large difference in immunogenicities in model animals. The synthesis of some analogues modified at strategic functionalities is also depicted. These sialic acid derivatives are intended to be used as inhibitors in the study of sialic acid interactions with lectins and antibodies.

Results and discussion

Preparation of the aldehyde precursors 7 and 8

For the present study, sialic acid as an α-linked glycoside of *N*-acetylneuraminic acid (Neu5Ac, **1**) was required in a form

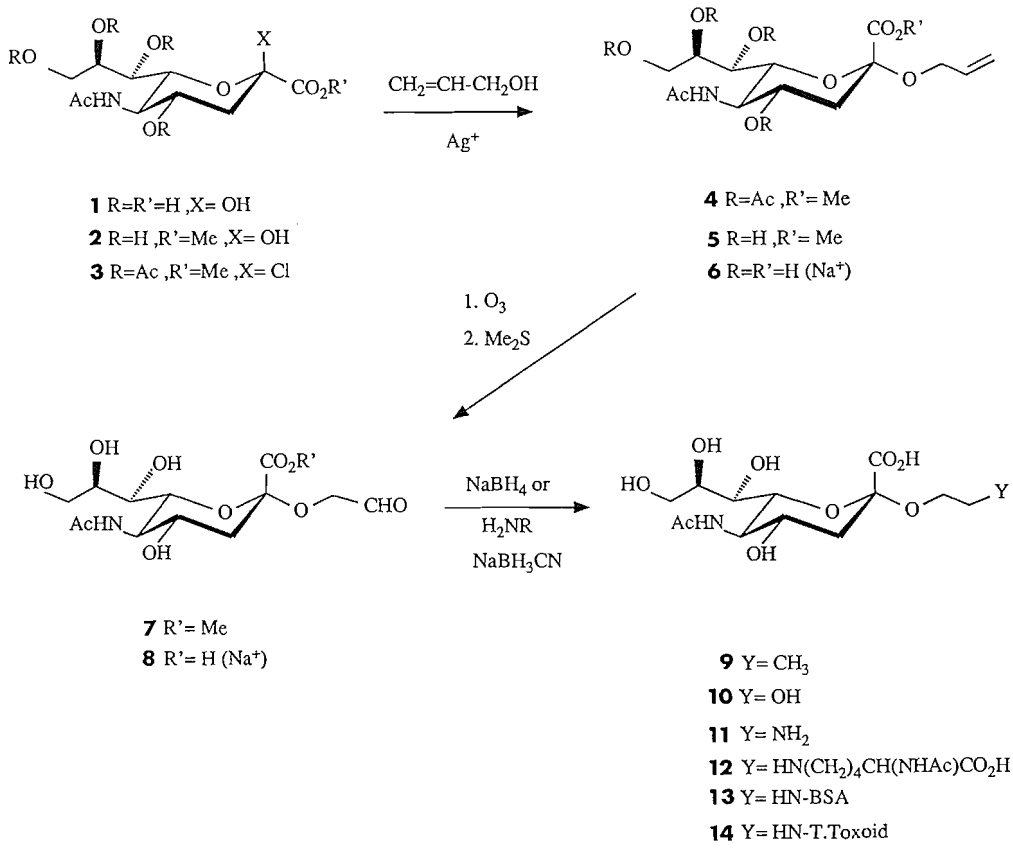

SCHEME 1

suitable for covalent attachment to the ϵ-amino groups of the lysine residues of the carrier proteins. Previous studies by us (22) and by others (23) demonstrated the usefulness of reductive amination (24) for the direct reduction of a Schiff base formed between aldehyde groups and the amine functionalities present on the proteins. Hence, 2-oxoethyl α-glycoside of Neu5Ac (**8**) was sought as an appropriate precursor for the conjugation. Large scale preparation of the starting Neu5Ac (**1**) could have been achieved as described previously using 0.025 M H_2SO_4 hydrolysis of the *Collocalia* mucins present in the bird's nest substances (5). The method suffers, however, from being tedious in the neutralization step because of the large volume of solution required. We anticipated that hydrolysis by a cationic resin (H^+) should be amenable to a straightforward isolation sequence since, after filtration, the reaction mixture could be directly loaded onto the formate anion column as originally suggested (5). After optimization of the reaction conditions, a temperature of 75°C and a hydrolysis time of 6 h with a 2:1 weight ratio of commercial bird's nest and resin Rexyn 101 (H^+) were used. The yield of pure Neu5Ac (**1**) varied from 2.5 to 5% by weight depending on the source of the bird's nest.

Having secured the supply of Neu5Ac (**1**), it was then transformed into the known (25) acetochloroneuraminic acid (**3**) via a new two-step sequence (21) (Scheme 1). The methyl ester (**2**) was prepared in methanol containing H^+ resin according to Kuhn *et al.* (25) in an almost quantitative yield. The chloride (**3**) was directly prepared by treatment of the methyl ester (**2**) with acetyl chloride in acetic acid whereby the intermediate peracetylated ester was further tranformed into the chloride (**3**) because the required HCl was generated *in situ* during the reaction conditions. This is in contrast to a recent publication (26) in which acetic acid was omitted and which failed, in our hands, to give good yield of the desired chloride (**3**). The unstable **3** thus obtained was of >95% purity (^{1}H NMR) and was usually suitable for the following transformations. The α-allyl glycoside (**4**) (21, 27, 28) was prepared using silver salicylate (29) as catalyst rather than the polymeric one originally employed (27). The Koenigs–Knorr glycosylation occurred with complete stereocontrol giving rise to the α-allyl glycoside **4** in 90% yield. The anomeric configuration of the sialic acid, for which there is no anomeric proton, was determined indirectly by empirical rules (30), which predict the proton chemical shifts of H-4 and H-7 of Neu5Ac α-glycosides to occur at 4.83 and 5.30 ppm respectively. It was also directly determined (*vide infra*) by the three-bond heteronuclear gated decoupling spectrum (31) between C-1 and H_{3ax} ($^3J_{C\text{-}1,H\text{-}3ax}$, ∠180°) which showed a coupling of 5.7 Hz in the free acid **6**. Deacetylation of **4** with sodium methoxide in methanol provided crystalline ester **5** in 93% yield. Treatment of the methyl ester **5** with 0.1 N aqueous NaOH gave the free acid **6** also in 93% yield. Reductive ozonolysis of the allyl group in **6** afforded the key aldehyde **8** in quantitative yield after lyophilization. The ozonolysis was also performed on the allyl ester **5** to provide the aldehyde ester **7** in 95% isolated yield. Evidence that the aldehyde group exists in the hydrated form in aqueous solution was seen by the ^{1}H NMR spectra of **7** and **8**, which showed the aldehydic proton at 5.12 ppm (Table 1), and by the ^{13}C NMR spectrum, which showed the carbonyl at 89.6 ppm (acetal) (Table 2).

*Synthesis of the protein conjugates **13**, **14** by reductive amination*

[d]Based on 59 lysine residues.

achieved using sodium cyanoborohydride because this reducing agent is known to be selective for the imine functionality while being inert toward the carbonyl functions. This procedure, which was pioneered by Gray (24) on reducing sugars, was further improved by Roy *et al.* (22) using optimized conditions of buffers, pH, and temperature. To obtain protein conjugates covering the entire range of Neu5Ac incorporation, optimization of the reaction conditions was again set forth (Table 3). Using borate buffer (0.2 M, pH 9.0) as suggested by Roy *et al.* (22) on reducing sugars and BSA as model protein, the level of incorporation of **8** onto the lysine group was only marginal even after 6 days at 37°C (entry 9), as opposed to neutral sugars (21–24). Thus, it became apparent that the free aldehyde in the acid **8** did not behave like neutral free reducing sugars (22–24). Therefore, the original procedures (23, 24) using 0.2 M phosphate buffer were reinvestigated. As observed from Table 3, there was no improvement in coupling efficiency when only the molar ratio of the aldehyde to the amine was increased (entries 3 and 4) at 50°C in phosphate buffer pH 7.0. There was a slight improvement when both the aldehyde and the hydride

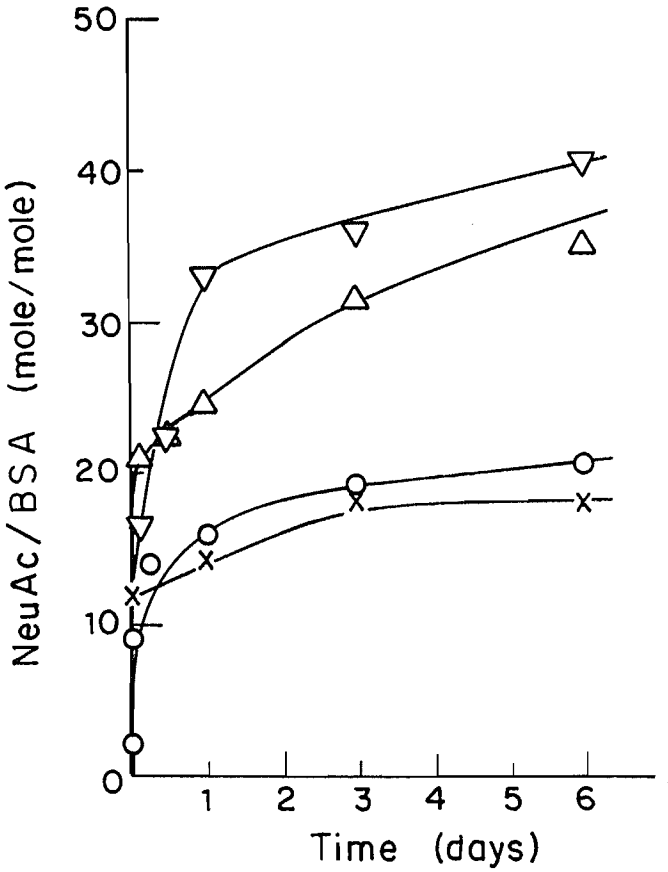

FIG. 1. Time course of reductive amination of **7** (▽,△) or **8** (○,×) into BSA. (×) entry **6** (Table 3); (○) entry **8**; (△) entry **10**; (▽) entry **12**.

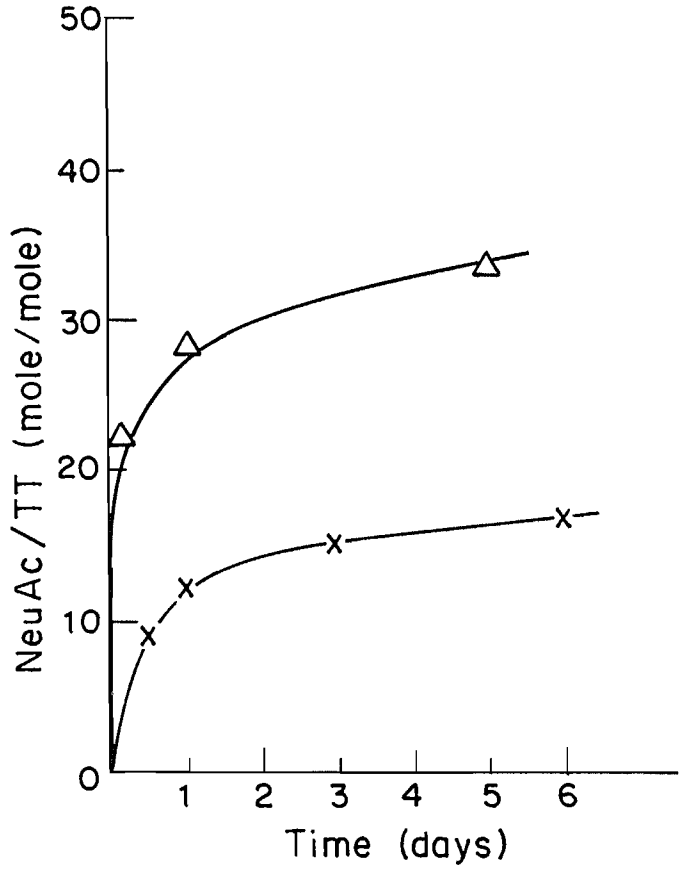

FIG. 2. Time course of reductive amination of **7** (△) or **8** (×) into TT. (×) 0.2 M phosphate buffer pH 7.0, 37°C, **8**: NH_2: $NaBH_3CN$ (10:1:30); (△) like (×) with **7** and 25% DMSO.

ratios were increased relative to that of the amine (entries 1 and 2). There was also no temperature effect observed between 37°C and 50°C in the same buffer (entries 2,3 and 6,7). A detrimental effect could be seen when the amount of hydride reagent used was too high (entries 4 and 7) at 50°C. No solvent effect could be noticed (entries 2,5 and 6,8). Thus, a maximum of approximately 23 Neu5Ac residues out of 59 lysines (32) were effectively coupled onto BSA, while 16 Neu5Ac residues out of ~66 lysines could be coupled to TT (33). The level of incorporation of Neu5Ac in all the above procedures was conveniently measured by a specific colorimetric method using resorcinol (34), while the amount of protein within the sample was determined using the Lowry method (35). Previous workers (22–24) using amino acid analysis showed the level of incorporation of the sugar content to agree within ±1–2 residues compared to the colorimetric tests.

We postulated that the restricted incorporation of the acid **8** in comparison to neutral sugars (22–24), where complete substitution was possible, could be due to the anionic nature of both the BSA protein (pI 4.9) and the aldehyde **8**, which would cause repulsive electrostatic interactions. Therefore, conjugations with the aldehyde ester **7** were initiated in the hope of minimizing these repulsive interactions (Fig. 1). As shown from Table 3 (entry 10 vs. entry 2), there was a noticeable improvement in the level of reductive amination. This was further increased (entries 11, 12 vs. entry 10) when methanol or dimethyl sulfoxide was used as cosolvent. There was almost no pH effect (between 6 and 9) in the 0.2 M phosphate buffer at 37°C, a pH of 6 being only slightly less efficient than the other three higher pH's. Under the optimum conditions (see Experimental), a conjugate having 53 Neu5Ac residues per BSA molecule was achieved with the methyl ester **7**. A similar set of experiments was effected on the tetanus toxoid; the results are illustrated in Fig. 2.

Interestingly, at the end of the reaction time (usually 3–6 days) the Neu5Ac–protein conjugates **13** or **14** obtained from the reductive amination of the ester **7** did not have any of the remaining ester functionality. This was ascertained by ^1H NMR spectroscopy, by the colorimetric hydroxamic acid test (36) for esters, by immunoelectrophoresis, and by *Vibrio cholerae* neuraminidase treatment (1) of the protein conjugates (not shown). The above enzyme was known to be inactive toward the esters of sialic acids (1) but in the present study it hydrolysed 96% of the Neu5Ac **1** in the conjugates, thus confirming the absence of the ester function within the conjugates.

As control experiments, it was shown that the reagent $NaBH_3CN$ or BSA alone was not capable of inducing the ester hydrolysis of **5** in the phosphate buffer. It is suggested that the hydrolysis could have been catalyzed by the neighboring amine group, which was reductively alkylated in the aglycon portion, or by the intramolecular assistance of a suitably positioned hydroxyl group. The basis for this assumption was supported by the set of transformations leading to the sialic acid analogues described below. These specifically modified sialic acid derivatives were prepared in order to be utilized as potential inhibitors for the interaction studies between sialic acid and specific lectins such as wheat germ agglutinin (10) or antibodies (19) prepared against the protein conjugates **13** and **14**.

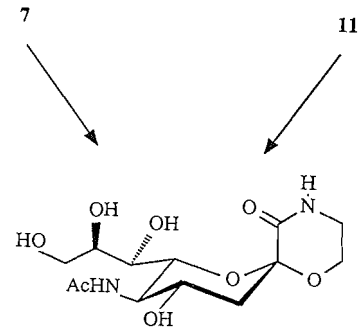
Synthesis of sialic acid analogues

The 2-propenyl glycoside ester **5** was reduced to the corresponding 2-propyl glycoside ester using hydrogen on 5% palladium–charcoal in 95% yield. The ester was then hydrolyzed to the free acid **9** by 0.1 N aqueous NaOH in 92% yield. The aldehyde **8** was converted to the 2-hydroxyethyl glycoside **10** in 67% yield using sodium borohydride. The corresponding 2-aminoethyl glycoside **11** was obtained directly from the aldehyde **8** by reductive amination in the presence of ammonium actate (51%). The $[\alpha]_D$ of **11** (−18.5°) agreed well with the one previously obtained ($[\alpha]_D$ −17°) by Holmquist and Brossmer (37), who synthesized it by glycosylation of **3** with 2-(benzyloxycarbonylamino)ethanol in the presence of silver carbonate in 14% overall yield after deprotection. When the above reductive amination was effected on the methyl ester **7** rather than the free acid **8**, a side product tentatively assigned the lactam structure **15** was produced together with **11** (Scheme 2). This is of particular interest since the reductive amination of **7** with the two proteins might have given a similar cyclic lactam during the conjugation. To establish whether or not this was the case, the amino acid **11** was treated with a carbodiimide (EDC), and the same product (**15**) resulting from the reductive amination of the ester **7** with ammonium acetate was obtained. When the same sequence of reductive amination of **7** was performed with N^{α}-acetyl-(L)-lysine, the free acid **12** was obtained as a single product; no methyl ester was present. The acid **12** proved to be the same as the one obtained from the acid **8**. Thus, the above results indicated that the formation of the lactam (**15**) is selective for the primary amine **11** and that ester hydrolysis also occurred upon reductive amination of **7** with either N^{α}-acetyl-(L)-lysine alone or with the proteins. These results confirmed the observations made above, although the mechanism by which the ester self-hydrolyzed during the reductive amination was not fully understood. As mentioned above, it is possible that the hydrolysis occurred by an intramolecular catalyzed reaction due to the proximity of the ε-amino groups. We have also mentioned previously that most of the Neu5Ac residues (>96%) could be hydrolyzed from the protein conjugates **13** and **14** by *Vibrio cholerae* neuraminidase. This could not have been the case with a cyclic amide such as **15**.

The acid group was the next functionality to be modified. This was done by reduction of the C-1 carbomethoxy group of **5** by lithium borohydride in a MeOH–THF mixture. The resulting hydroxymethyl derivative **16** (~quant.) showed the disappearance of the carbonyl band of **5** at 1725 cm^{-1} together with the C-1 ^{13}C NMR signal at 171.2 ppm. The new methylene signal was shifted to 61.3 ppm. The amide analogue **17** was obtained by ammonolysis of the ester **5** in 84% yield. These two derivatives constitute important modifications because they deprive the Neu5Ac residue of its anionic character, which is essential to most of its biochemical and immunochemical functions (1).

The other functional group manipulations were then centered on the acetamido function (Scheme 3). The amide **5** was hydrolyzed in refluxing tetramethylammonium hydroxide to afford the free amine **18** in 80% yield after purification by size exclusion chromatography. The product was ninhydrin positive on tlc. Furthermore its ^1H NMR showed the disappearance of the *N*-acetamido signal at 2.03 ppm with concomitant upfield shift of its H-5 signal at 3.24 ppm. Similarly, the ^{13}C NMR spectrum of **18** showed the displacement of the C-5 signal from 53.1 ppm in **5** or **6** to 53.9 ppm (0.8 ppm downfield). The signals for C-4 and C-6 were also affected since they shifted



15

SCHEME 2

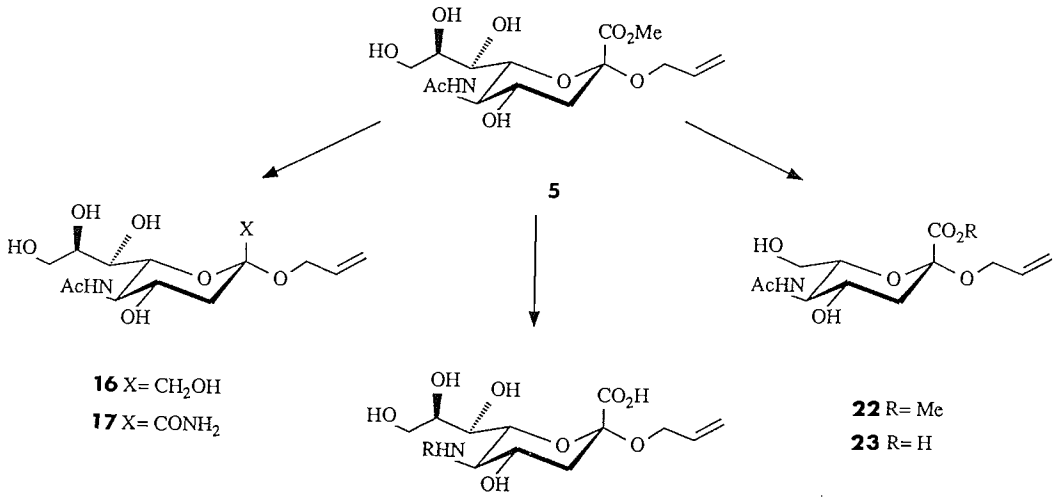
upfield by 2.0 ppm (67.4 and 71.9 ppm respectively) relative to that in **6**. These observations were previously made on a polymer of Neu5Ac (38). The new amide derivatives **19** and **21** were obtained in yields of 80 and 86% respectively upon treatment of **18** with the corresponding bromoacetyl and acetoxyacetyl chloride. The intermediate acetoxy derivative **20** needed to be hydrolyzed at the ester functionality during the isolation of **21**. It is of interest to mention that **21** corresponds to an α-allyl glycoside of the important *N*-glycolylneuraminic acid (Neu5Gc). It is also worth mentioning that the above entry to the Neu5Gc series was more convenient (38) than the previous one (1) using the unstable 1,3-dioxolan-2,4-dione as glycolylating reagent.

Finally, the last derivative of Neu5Ac synthesized was the corresponding C-7 analogue of the α-allyl glycoside. Hence, the vicinal diol array in the side chain was simultaneously cleaved and reduced using periodate and borohydride anions supported on anionic resins (39). The isolation of **22** thus appeared straightforward since only a filtration of the resin was required. The low yield obtained (59%) was attributed to the partial hydrolysis of the methyl ester under the reaction conditions that generated the acid **23** *in situ*, which then remained on the resin. In fact, further treatment of the recuperated resin with acetic acid showed the release of some **23** (tlc).

In conclusion, antigenic and immunogenic (19–21) forms of *N*-acetylneuraminic acid were synthesized having BSA or TT as protein carriers. The series of conjugates having different levels of incorporation will be used to evaluate the role of the avidity phenomena encountered in lectin– and antibody–Neu5Ac interactions. The key functional group manipulations should allow the systematic evaluation of the exact binding epitopes with rabbit anti-sialic antibodies already obtained (19).

Experimental

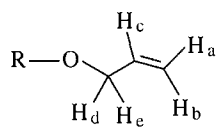
Melting points were determined on a Gallenkamp apparatus and are uncorrected. The ^1H and ^{13}C NMR spectra were recorded on a Varian XL-300 or a Varian Gemini 200 at 300 and 200 MHz respectively for protons and at 75.4 and 50.3 MHz respectively for carbons. The proton chemical shifts (δ) are given relative to internal Me_4Si (δ = 0) for $CDCl_3$ solutions and relative to acetone (δ = 2.225) for D_2O solutions. The carbon chemical shifts are given relative to dioxane (δ = 67.4) for D_2O solutions. The analyses were done as a first-order approximation. Optical rotations were measured on a Perkin Elmer 241 polarimeter and were run at room temperature (~25°C). IR spectra were taken as KBr pellets using a Perkin Elmer 783 spectrophotometer. Mass spectra were recorded on a VG 7070-E spectrometer for CI, EI, and FAB-MS. Combustion analyses were performed by Guelph Chemical Laboratories Ltd. (Ont.). Thin-layer chromatography (tlc) was performed



SCHEME 3

using silica gel 60 F-254 plates and column chromatography on silica gel 60 (230–400 mesh). The developed plates were sprayed or dipped with a solution of ceric sulfate (1%) and ammonium molybdate (2.5%) in 10% aqueous sulfuric acid and heated at ~150°C. The following solvent combinations (v/v) were used for tlc on silica gel: *n*-propanol–water, 7:3 (A) and 8:2 (B); ethyl acetate (C); chloroform–methanol 7:3 (D); acetonitrile – 10% acetic acid 8:2 (E); ethyl acetate – acetic acid – water 3:2:1 (F). Water soluble products were purified or desalted by size exclusion chromatography on Sephadex G-10. The products were monitored with a Waters R403 refractive index monitor. The *Collocalia* mucoids (edible bird's nest) were obtained from local Chinese groceries. Ozone was generated from a Welsbach instrument.

Protons of the allyl group present in some of the compounds are designated as H_a, H_b, H_c, H_d, and H_e as defined below and as previously described by Tahir and Hindsgaul (40).



They were, however, described using a lower resolution instrument and thus some coupling constants (ex. H_a–$H_{d,e}$) were not observed. These protons generally showed the same multiplicity pattern throughout and only their chemical shifts varied: H_a, dd, $J_{a,b}$ = 1.5 Hz, $J_{a,c}$ = 10.5 Hz; H_b, dd, $J_{a,b}$ = 1.5 Hz, $J_{b,c}$ = 17.0 Hz; H_c, m; H_d and H_e ddd, $J_{d,e}$ = 12.5 Hz, $J_{c,d}$ = $J_{c,e}$ = 5.5 Hz.

*5-Acetamido-3,5-dideoxy-D-*glycero-*D-*galacto-*2-nonulopyranosonic acid* **1** *(Neu5Ac)*

Water (1.6 L) was added to edible bird's nest (200 g) and the resulting suspension was blended for ~5 min in a Waring blender. Rexyn 101 cation exchange resin (100 g) in the acid form was then added to the mixture. The reaction vessel was immersed in a thermostated water bath at 75°C and the content was mechanically stirred. After 6 h, the mixture was cooled to room temperature and filtered over gauze bandage in a large Büchner funnel. The resulting solution was directly loaded onto a Dowex 1X8 (20–50 mesh) column (3.5 × 40 cm) in the formate form. The column was washed with 2 L water followed by a linear gradient of formic acid (0–2 M). Fractions of 10 mL were collected and aliquots (100 μL) testing positive for sialic acid by the resorcinol method (34) were pooled and freeze-dried. The yields of pure **1** varied from 5 to 10 g (2.5–5% w/w) depending on the brand of bird's nest used. The solid obtained had mp 177–183°C (dec.); $[\alpha]_D$ −30.8° (*c* 1, H_2O) (lit. (5) mp 184–186°C; $[\alpha]_D$ −32.1°); R_f 0.47 (A). Negative FAB-MS for $C_{11}H_{18}NO_9$: 308 (M − 1). Both ^1H and ^{13}C NMR spectral data are in complete agreement with literature values (1, 5).

*Methyl 5-acetamido-3,5-dideoxy-D-*glycero-*D-*galacto-*2-nonulopyranosonate* **2** *(Neu5Ac methyl ester)*

The methyl ester **2** was prepared following the procedure of Kuhn *et al.* (25). Briefly, a solution of **1** (2.99 g, 9.7 mmol) in 50 mL methanol containing Amberlite IR-120 (H^+) (2.0 g) was stirred overnight at room temperature. The clear solution was filtered on a filter paper and evaporated to a volume of ~5 mL. Ether was added to turbidity and **2** crystallized on standing. It was recuperated by filtration (3.18 g, 9.7 mmol, ~quant.); mp 193.5–194.7°C; $[\alpha]_D$ −28° (*c* 3.5, H_2O) (lit. (25) mp 179–180°C; $[\alpha]_D$ −28°); R_f 0.55 (A). ^1H and ^{13}C NMR spectra were identical to those published (1).

*Methyl (5-acetamido-4,7,8,9-tetra-*O*-acetyl-3,5-dideoxy-D-*glycero-*β-D-*galacto-*2-nonulopyranosylchloride)onate* **3** *(acetochloro-neuraminic acid)*

Compound **2** (0.47 g, 1.5 mmol) was added to freshly distilled acetyl chloride (10 mL, some preparation required preactivation with 1.5 mL MeOH) containing acetic acid (5 mL) and cooled to 0°C. The flask was sealed and kept 24–48 h at room temperature. The extent of the reaction was followed by tlc in ethyl acetate. When the transformation was deemed complete, the reaction mixture was evaporated to dryness and coevaporated a few times with dry toluene. The chloride **2** was obtained as a foam (0.75 g, 1.5 mmol, ~quant.); $[\alpha]_D$ −61° (*c* 1, $CHCl_3$) (lit. (25) $[\alpha]_D$ −63°); R_f 0.32 (C). Its ^1H NMR showed it to be >95% pure in both $CDCl_3$ (41) and C_6D_6 (42), and it was used directly for the next step.

*Methyl (allyl 5-acetamido-4,7,8,9-tetra-*O*-acetyl-3,5-dideoxy-D-*glycero-*α-D-*galacto-*2-nonulopyranosid)onate* **4**

The chloride **3** (0.75 g, 1.4 mmol) was dissolved in dry (4A molecular sieves) allyl alcohol (5 mL) containing freshly prepared silver salicylate (0.35 g) and 4A molecular sieves (0.5 g). The reaction was stirred for 2 h at room temperature in the dark. The slurry was filtered over Celite and washed with CH_2Cl_2. The resulting clear solution was evaporated to dryness and the residue was dissolved in CH_2Cl_2 (25 mL). The organic solution was successively washed with cold 5% aqueous sodium bicarbonate, 5% aqueous sodium thiosulfate, and finally with water. The organic layer was dried over sodium sulfate

and evaporated to a clear oil that was homogeneous by tlc (90% yield). An analytical sample was obtained by crystallization from methanol–ether (0.59 g, 1.1 mmol, 73%). The glycoside **4** has mp 153.6–157.7°C; $[\alpha]_D$ −14.2° (*c* 1, $CHCl_3$) (lit. (27) mp 154–156°C, $[\alpha]_D$ −13° (MeOH)); R_f 0.30 (C); ^1H NMR ($CDCl_3$) δ: 5.83 (4 × d, 1H, $J_{b,c}$ = 17.0, $J_{a,c}$ = 10.5, $J_{c,d} \approx J_{c,e} \approx$ 5 Hz, H_c), 5.35 (m, 1H, H8), 5.30 (dd, 1H, $J_{7,8}$ = 8.5, $J_{6,7}$ = 1.8 Hz, H7), 5.26 (dd, 1H, $J_{b,c}$ = 17.0, $J_{a,b} \approx J_{b,d} \approx J_{b,e} \approx$ 1.5 Hz, H_b), 5.14 (d, 1H, $J_{5,NH} \approx$ 10 Hz, NH), 5.13 (dd, 1H, $J_{a,c}$ = 10.5, $J_{a,b} \approx J_{a,d} \approx J_{a,e} \approx$ 1.5 Hz, H_a), 4.83 (m, 1H, H4), 4.27 (dd, 1H, $J_{9,9'}$ = 12.5, $J_{8,9}$ = 2.7 Hz, H9), 4.27 (m, 1H, H5 or H6), 4.03–4.11 (m, 3H, H_d, H_e, H5 or H6), 3.84 (dd, 1H, $J_{9,9'}$ = 12.5, $J_{8,9'}$ = 5.8 Hz, H9′), 3.76 (s, 3H, Me-ester), 2.59 (dd, 1H, $J_{3ax,3eq}$ = 12.0, $J_{3eq,4}$ = 4.8 Hz, H_{3eq}), 1.86, 2.00, 2.02, 2.11, 2.13 (5 × s, 15H, N, O-Ac), 1.96 (dd, 1H, $J_{3ax,3eq} \approx J_{3ax,4} \approx$ 12 Hz, H_{3ax}); ^{13}C NMR ($CDCl_3$) δ: 171.2, 170.9, 170.4, 170.3 (N, O-Ac), 168.5 (CO_2Me), 133.6, 117.4 (allyl), 98.5 (C-2), 72.5 (C-6), 69.0 (C-8), 68.5 (C-7), 67.3 (CH_2-allyl), 66.0 (C-4), 62.3 (C-9), 49.3 (C-5), 38.0 (C-3), 23.1 (N-Ac), 21.0, 20.7 (2×), 20.61 (O-Ac). Anal. calcd. for $C_{23}H_{33}NO_{13}$: C 51.97, H 6.26, N 2.64; found: C 52.22, H 6.46, N 2.82.

*Methyl (allyl 5-acetamido-3,5-dideoxy-D-*glycero-*α-D-*galacto-*2-nonulopyranosid)onate **5***

Compound **4** (1.00 g, 1.9 mmol) was de-*O*-acetylated in dry methanol (20 mL) containing a few drops of 1 M NaOMe. The reaction was complete after 2 h at room temperature. The solution was neutralized with Amberlite 120 (H^+) resin, filtered, and evaporated to ~5 mL. Compound **5** crystallized upon addition of ether to afford 0.64 g of pure material (93%) having mp 143–144°C; $[\alpha]_D$ −10.1° (*c* 1, MeOH); R_f 0.49 (D); ν_{max}: 3380, 2944, 1750, 1650, 1570, 1440 cm^{-1}; ^1H and ^{13}C NMR, see Tables; pos. FAB-MS for $C_{15}H_{25}NO_9$: 364 (M + 1). Anal. calcd. for $C_{15}H_{25}NO_9$: C 49.58, H 6.94, N 3.86; found: C 49.47, H 7.10, N 3.98.

*Allyl 5-acetamido-3,5-dideoxy-D-*glycero-*α-D-*galacto-*2-nonulopyranosidonic acid **6** (Neu5Ac allyl glycoside)*

The ester **5** (0.28 g, 0.77 mmol) was treated for <1 h at room temperature with 0.1 M aqueous NaOH (5 mL). The reaction mixture was cooled to 0°C and neutralized with Rexyn 101 (H^+) resin (pH reached 2). After the solution was filtered, the pH was quickly readjusted to 7 with 0.1 M NaOH and then the solution was lyophilized to yield **6** as a white powder (0.25 g, 0.72 mmol, 93%); mp 245–250°C (dec.); $[\alpha]_D$ −9.1° (*c* 0.66, H_2O); R_f 0.57 (B); neg. FAB-MS for $C_{14}H_{23}NO_9$: 348 (M − 1).

*Methyl (2-oxoethyl 5-acetamido-3,5-dideoxy-D-*glycero-*α-D-*galacto-*2-nonulopyranosid)onate **7***

The allyl ester **5** (68 mg, 0.19 mmol) was dissolved in methanol (15 mL). The solution was cooled to −78°C, purged with oxygen for 5 min, and treated with ozone by bubbling till the solution remained blue. After 10 min, the ozone was evacuated with nitrogen for 15 min and, while at −78°C, dimethyl sulfide (0.5 mL) was added. The resulting solution was allowed to warm to room temperature over a 1 h period. The clear solution was then evaporated to give **7** as a homogeneous oil (66 mg, 0.18 mmol, 95%). The product was freed of its DMSO by-product by desalting on a G-10 column using water as eluent; $[\alpha]_D$ −10.3° (*c* 1, H_2O); R_f 0.35 (E), 0.61 (B); pos. FAB-MS for $C_{14}H_{23}NO_{10}$: 366 (M + 1). Anal. calcd.: C 46.07, H 6.35, N 3.83; found: C 45.65, H 6.39, N 3.79.

*2-Oxoethyl 5-acetamido-3,5-dideoxy-D-*glycero-*α-D-*galacto-*2-nonulopyranosidonic acid **8***

The above procedure was repeated on the sodium salt of **6** (1.0 g, 2.70 mmol) in methanol (50 mL). The yield of **8** was 1.0 g (2.70 mmol, quant.); $[\alpha]_D$ −1.8° (*c* 1, H_2O); R_f 0.27 (E); ν_{max}: 3390, 2940, 1620, 1560, 1060 cm^{-1}; neg. FAB-MS for $C_{13}H_{20}NO_{10}$: 350 (M − 1).

*Propyl 5-acetamido-3,5-dideoxy-D-*glycero-*α-D-*galacto-*2-nonulopyranosidonic acid **9***

The allyl ester **5** (26 mg, 0.072 mmol) was dissolved in methanol (10 mL) containing 5% Pd on charcoal (25 mg). Hydrogen gas was bubbled through the solution for 1 h. The reaction mixture was centrifuged to remove the catalyst and evaporated to dryness. Crystals of the methyl ester of **9** formed upon standing in the cold (25 mg, 0.068 mmol, 95%); mp 145.5°C; $[\alpha]_D$ −8.9° (*c* 0.7, H_2O); R_f 0.52 (E); ν_{max}: 3390, 1725, 1650, 1560, 1440, 1040 cm^{-1}. Anal. calcd. for $C_{15}H_{27}NO_9 \cdot H_2O$: C 46.99, H 7.10; found: C 46.56, H 6.93.

The above ester (10 mg) was dissolved in 0.1 N NaOH (3 mL) and the hydrolysis was allowed to proceed for 30 min at room temperature. The reaction mixture was cooled to 0°C, neutralized with H^+ resin, and filtered. The pH of the filtrate was readjusted to 7.0 with 0.1 N NaOH and the solution was lyophilized to give **9** as a homogeneous white powder (9 mg, 92%); $[\alpha]_D$ −4.1° (*c* 0.37, H_2O); pos. FAB-MS for $C_{14}H_{25}NO_9$: 352 (M + 1), 374 (M + Na).

*2-Hydroxyethyl 5-acetamido-3,5-dideoxy-D-*glycero-*α-D-*galacto-*2-nonulopyranosidonic acid **10***

The aldehyde **8** (27 mg, 0.077 mmol) was dissolved in methanol (2 mL). Sodium borohydride (10 mg) was then added. After 2 h, when tlc indicated the complete disappearance of **8**, a few drops of acetic acid were added to neutralize the excess borohydride. The reaction mixture was evaporated to dryness. The residue was dissolved in water and desalted on a column of Sephadex G-10 using water as eluant. The combined fractions in the void volume were pooled and lyophilized to give **10** as a white powder (18 mg, 0.051 mmol, 67%); $[\alpha]_D$ −7.6° (*c* 0.3, H_2O); R_f 0.39 (B); neg. FAB-MS for $C_{13}H_{23}NO_{10}$: 352 (M − 1).

*2-Aminoethyl 5-acetamido-3,5-dideoxy-D-*glycero-*α-D-*galacto-*2-nonulopyranosidonic acid **11***

Compound **8** (18 mg, 0.051 mmol) was reductively aminated in methanol (2 mL) saturated with ammonium acetate. Sodium cyanoborohydride (10 mg) was added and the solution was refluxed. After 24 h, the cooled reaction mixture was evaporated several times with methanol and finally dissolved in water (1 mL). The aqueous solution was desalted on a Sephadex G-10 column using water as eluant. The combined required fractions were freeze-dried to yield **11** (9.2 mg, 0.026 mmol, 51%); $[\alpha]_D$ −18.5° (*c* 1, H_2O) (lit. (37) $[\alpha]_D$ −17°); R_f 0.17 (B); neg. FAB-MS for $C_{13}H_{25}N_2O_9$: 352 (M − 1).

*2-[N$^\epsilon$-(N$^\alpha$-Acetyl-(L)-lysyl)]ethyl 5-acetamido-3,5-dideoxy-D-*glycero-*α-D-*galacto-*2-nonulopyranosidonic acid **12***

The aldehyde **8** (34 mg, 0.097 mmol) was dissolved in 0.2 M phosphate buffer pH 7.0 (1 mL) containing N^α-acetyl-(L)-lysine (30 mg, 0.15 mmol, Sigma). Sodium cyanoborohydride (13 mg, 0.21 mmol) was added to the reaction mixture, which was stirred at room temperature for 48 h. Acetic acid (0.25 mL) was added, and after 3 h the solution was directly loaded on a Sephadex G-10 desalting column. The desired product **12** was eluted with 30 mM aqueous ammonium bicarbonate to yield 40 mg (0.076 mmol, 78%) of a white powder after lyophilization; $[\alpha]_D$ −6.5° (*c* 0.9, H_2O); R_f 0.31 (F); ^1H NMR (D_2O) δ (aglycon): 4.16 (dd, 1H, $J_{\alpha,\beta}$ = 8.2 and 4.9 Hz, H_α), 3.87 (m, 1H, OCH_2CH_2N), 3.25 (t, 2H, *J* = 4.7 Hz, OCH_2-CH_2N), 3.08 (t, 2H, *J* = 7.8 Hz, H_ϵ), 2.04 (s, 3H, N^α-Ac), 1.69–1.82 (m, 5H, H_{3ax} + $4H_{\beta,\gamma}$), 1.42 (q, 2H, H_γ); ^{13}C NMR (D_2O) δ (aglycon): 22.8, 23.2, 26.0, 31.8, 47.9, 48.1, 55.5, 60.0, 174.4, 179.2; FAB-MS for $C_{21}H_{37}N_3O_{13}$: 522 (M − 1). Anal. calcd. for $C_{21}H_{37}N_3O_{13} \cdot NH_4HCO_3$: C 43.91, H 7.03, N 9.30; found: C 43.30, H 7.53, N 9.07.

*Conjugation of **7** or **8** onto BSA and tetanus toxoid **13**, **14***

The aldehydo acid **8** or ester **7** added in various proportions (see Table 3) was dissolved in 0.2 M phosphate buffer of the pH indicated in the table but generally being at pH 7.0 (2 mL). The protein bovine serum albumin or tetanus toxoid (10 mg) was added to the buffer solution and stirred for 1 h at 37°C. Cyanoborohydride was then added. Aliquots were taken at appropriate time intervals and dialyzed exhaustively against running water for 24 h, then with distilled water for 48 h. The sample was then diluted to a fixed volume and the sialic acid content was measured by the resorcinol method (34). The protein content was measured by the Lowry procedure (35). The samples were lyophilized and weighed. The conjugates were characterized

For personal use only.

by SDS-PAGE and by serological assays (double immunodiffusion, ELISA, quantitative precipitation, and immunoelectrophoresis) (to be published).

Typical procedure for a conjugate Neu5Ac$_{53}$/BSA

Bovine serum albumin (BSA, Pentex, Miles Laboratories) (11 mg, 0.16 μmol) was dissolved in 0.2 M phosphate buffer pH 7.0 (2 mL). The ester **7** (22 mg, 60 μmol) dissolved in the same buffer (0.3 mL) was added to the protein solution, followed by methanol (1 mL). The solution was stirred for 20 min at 37°C. Then $NaBH_3CN$ (20 mg, 317 μmol) was added to the reaction mixture, which was stirred for 4 days at 37°C. The solution of the conjugate was transferred to a dialysis bag (10 kDa MW cutoff) and dialyzed for 3 days against distilled water. The solution was diluted to 10 mL and three aliquots of 250 μL each were tested for sialic acid by the resorcinol method as above. The solution was lyophilized, giving a white powder (14 mg) containing an average of 53 Neu5Ac residues per mole of BSA.

*Bicyclic lactam **15***

Method A

The 2-aminoethyl glycoside **11** (7 mg, 0.020 mmol) was dissolved in MeOH (3 mL) containing EDC (3 mg). After 24 h at room temperature, an additional portion of EDC was added (3 mg) and the solvent evaporated to dryness after 24 h. The lactam **15** was purified by silica gel chromatography using a gradient of ethanol and methanol as eluant (2 mg).

Method B

The aldehydo ester **7** (4 mg) was dissolved in MeOH (1 mL) containing ammonium acetate (20 mg). After 1 h at room temperature, sodium cyanoborohydride was added (2 mg). The reaction mixture was evaporated to dryness after 4 h. The residue was dissolved in 0.03 M ammonium bicarbonate (~1 mL) and desalted on a Sephadex G-10 column using the same solvent as eluant. The pooled fractions containing **15** were freeze-dried to yield 3 mg of a mixture of **11** and **15** as white powder. Compound **15** isolated from method A had ν_{max}: 3420, 1650, 1560, 1350, 1040 cm^{-1}; ^{1}H NMR (D_2O) δ: 1.63 (dd, 1H, $J_{3ax,3eq} \approx J_{3ax,4} \approx 12$ Hz, H-3ax), 2.03 (s, 3H, NAc), 2.44 (dd, 1H, $J_{3ax,3eq} = 12$, $J_{3eq,4} = 5$ Hz, H-3eq), 3.32–4.50 (m, 11H, remaining); ^{13}C NMR (D_2O) δ: 97.5, 74.2, 71.5, 69.6, 69.0, 64.7, 56.1, 53.4, and 23.3 (signals lacking because signal-to-noise ratio was too high for 3 mg sample); pos. FAB-MS for $C_{13}H_{22}N_2O_8$: 335 (M + 1).

*Allyl 5-acetamido-3,5-dideoxy-D-*glycero*-α-D-*galacto*-2-nonulopyranoside **16***

The ester **5** (21 mg, 0.058 mmol) was dissolved in methanol (0.5 mL) to which was added THF (5 mL). $LiBH_4$ (1 mg) was added to the solution and the reduction was allowed to proceed for 1 h at room temperature. The reaction mixture was neutralized with resin (H^+) and evaporated after filtration. The remaining boric acid was eliminated as trimethyl borate after repeated coevaporation of the residue from methanol. The reduced product **16**, which resisted crystallization, was obtained in quantitative yield (19 mg, 0.058 mmol); $[\alpha]_D$ −15.4° (*c* 1.8, H_2O); R_f 0.50 (E); ν_{max}: 3400, 1640, 1560, 1050 cm^{-1}; pos. FAB-MS for $C_{14}H_{25}NO_8$: 336 (M + 1).

*Allyl 5-acetamido-3,5-dideoxy-D-*glycero*-α-D-*galacto*-2-nonulopyranosidonamide **17***

The ester **5** (40 mg, 0.11 mmol) was dissolved in methanol (5 mL). Methanol (5 mL) presaturated with NH_3 gas was then added to the ester solution. The reaction was allowed to proceed for 1 h at room temperature. The solution was concentrated on the Büchi evaporator and **17** crystallized upon standing. The crystals were recuperated by filtration to give **17** in 84% yield (32 mg, 0.092 mmol); mp 82–87°C; $[\alpha]_D$ −3.6° (*c* 2.0, H_2O); R_f 0.63 (E); ν_{max}: 3400, 1690, 1600, 1385, 1040 cm^{-1}; pos. FAB-MS for $C_{14}H_{24}N_2O_8$: 349 (M + 1).

*Allyl 5-amino-3,5-dideoxy-D-*glycero*-α-D-*galacto*-2-nonulopyranosidonic acid **18***

The acetamido ester **5** (95 mg, 0.26 mmol) was dissolved in water (1 mL). To the solution was added 20% tetramethylammonium hydroxide (1 mL) (20% w/w in MeOH, Aldrich). The reaction was refluxed and monitored by tlc, which indicated the transformation to be complete after 5 h. The reaction mixture was neutralized with acetic acid and evaporated to dryness. The remaining residue was dissolved in water (1 mL) and desalted on a Sephadex G-10 column (3.0 × 60 cm) by elution with water. The positive fractions (resorcinol and ninhydrin) were pooled and lyophilized to afford **18** (64 mg, 0.21 mmol) as a white powder in 80% yield; $[\alpha]_D$ −18.0° (*c* 0.9, H_2O); R_f 0.26 (E); ν_{max}: 3400, 1610, 1400, 1130 cm^{-1}; FAB-MS for $C_{12}H_{21}NO_8$: 308 (M + 1) and 306 (M − 1).

*Allyl 5-bromoacetamido-3,5-dideoxy-D-*glycero*-α-D-*galacto*-2-nonulopyranosidonic acid **19***

The amine derivative **18** (67 mg, 0.22 mmol) was dissolved in methanol (2 mL) containing triethylamine (0.5 mL). The solution was cooled to −70°C and a few drops of bromoacetyl chloride were added. After disappearance of starting material by tlc (molybdate and ninhydrin), the solvents were evaporated to dryness. The residue was dissolved in water and desalted on a Sephadex G-10 column as before. The pooled fractions of **19** were freeze-dried to give a white powder (75 mg, 0.18 mmol, 80%); $[\alpha]_D$ −8.0° (*c* 0.1, H_2O); R_f 0.53 (E); neg. FAB-MS for $C_{14}H_{22}BrNO_9$: 426 and 428 (M − 1).

*Allyl 3,5-dideoxy-5-hydroxyacetamido-D-*glycero*-α-D-*galacto*-2-nonulopyranosidonic acid **21***

Compound **18** (34 mg, 0.11 mmol) was dissolved in methanol (2 mL) containing triethylamine (0.5 mL) and the solution was cooled to −70°C. Acetoxyacetyl chloride (50 μL, Aldrich) was added dropwise. The reaction was judged instantaneous by tlc, whereby **20** could be isolated or could be allowed to proceed for an additional hour to ensure complete de-*O*-acetylation of the intermediate **20** (0.1 N NaOH may be added to accelerate the hydrolysis). The reaction mixture was evaporated to dryness and treated as above for **19**. The yield of **21** obtained as a white powder after lyophilization was 86% (39 mg, 0.095 mmol); mp 245°C (dec.); $[\alpha]_D$ −3.8° (*c* 0.4, H_2O); R_f 0.48 (d); ν_{max}: 3430, 1600, 1410, 1080 cm^{-1}; FAB-MS for $C_{14}H_{23}NO_{10}$: 366 (M + 1) and 364 (M − 1) respectively.

*Allyl 5-acetamido-3,5-dideoxy-α-D-*galacto*-2-heptulopyranosidonic acid **23***

Sodium borohydride (5 g) was dissolved in water (20 mL) and mixed with Amberlite IRA 400 anion exchange resin (10 g) (Cl^- form). After 1 h, the resin was decanted and fresh sodium borohydride in water was again added. After 10 min, the resin was filtered and rinsed with water and allowed to dry at room temperature. Similarly, a fresh portion of the same resin (5 g, Cl^- form) was treated with three 30-mL portions of 0.5 M aqueous sodium metaperiodate over several hours. The resin was finally rinsed with water and allowed to dry at room temperature.

The methyl ester **5** (20 mg, 0.055 mmol) was dissolved in dry methanol (2 mL) to which was added the above resin (0.5 g each, of the IO_4^- and BH_4^- forms). After stirring for 3 h at room temperature, the solution was filtered and evaporated to give **22** (9.8 mg, 0.032 mmol, 59%). A sample of pure **22** was obtained after freeze-drying; mp 67.5–72.4°C; $[\alpha]_D$ +2.0° (*c* 0.5, H_2O); R_f 0.72 (D); ν_{max}: 3390, 1725, 1650, 1560, 1440, 1040 cm^{-1}; pos. FAB-MS for $C_{13}H_{21}NO_7$: 304 (M + 1).

A sample of the ester **22** was treated with 0.1 N NaOH as previously for **5** to afford a quantitative yield of **23** stored in the sodium form; $[\alpha]_D$ −21.3° (*c* 0.5, H_2O); R_f 0.31 (E).

Acknowledgments

We are grateful to the Natural Sciences and Engineering Research Council of Canada (NSERC) for generous support of this project. We also wish to thank Dr. P. Rousseau from the Armand-Frappier Institute (Quebec) for a gift of tetanus toxoid, and Mr. R. A. Pon (M.Sc. from this department) for the T. toxoid conjugation. Finally, we acknowledge the assistance of the following: Mr. R. Capoor and Dr. H. Dettman for running some of the NMR experiments, Dr. C. Kazakoff for the mass spectra, and Mr. L. Cousineau and Mr. L. Sabourin (summer

students) for the bird's nest hydrolysis. We also thank Mrs. Monique Lévesque for typing the manuscript.

Synthesis and biological activity of (*R*)-2′-fluorocarminomycin

HANS H. BAER[1] AND FERNANDO HERNÁNDEZ MATEO[2]

Ottawa–Carleton Chemistry Institute, Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received April 9, 1990

HANS H. BAER and FERNANDO HERNÁNDEZ MATEO. Can. J. Chem. **68**, 2055 (1990).

Methyl 3-amino-2,3,6-trideoxy-2-fluoro-β-L-talopyranoside was hydrolyzed to the free sugar, (*R*)-2-fluorodaunosamine hydrochloride, which was converted into the α-1,4-di-*O*-acetyl-*N*-trifluoroacetyl derivative. The latter was condensed with carminomycinone by use of trimethylsilyl triflate as the activating agent, and the product was deprotected to give the title compound. Cytotoxicity of the new fluoroanthracycline against a number of tumor cell lines in vitro equalled that of parent carminomycin, and activities of the two compounds against P-388 murine leukemia in vivo were the same, although the fluoro derivative was fourfold less potent and appeared to be somewhat less toxic.

Key words: (*R*)-2-fluorodaunosamine hydrochloride, synthesis; (*R*)-2′-fluorocarminomycin, synthesis and biological activity.

HANS H. BAER et FERNANDO HERNÁNDEZ MATEO. Can. J. Chem. **68**, 2055 (1990).

On a hydrolysé le méthyl-3-amino-2,3,6-tridésoxy-2-fluoro-β-L-talopyranoside en sucre libre, le chlorhydrate de la (*R*)-2-fluorodaunosamine, que l'on a transformé en dérivé α-1,4-di-*O*-acétyl-*N*-trifluoroacétyle. On a condensé ce dernier avec la carminomycinone à l'aide de triflate de triméthylsilyle comme agent activateur et on a déprotégé le produit pour obtenir le composé mentionné dans le titre. Les effets cytotoxiques in vitro de cette nouvelle fluoroanthracycline contre de nombreuses lignes de cellules tumorales sont équivalents à ceux de la carminomycine naturelle. Par ailleurs, l'activité antitumorale in vivo des deux composés contre la leucémie murine P-388 demeure la même quoique le dérivé fluoro s'est avéré quatre fois moins puissant et est apparu comme étant quelque moins toxique.

Mots clés : synthèse du chlorhydrate de la (*R*)-2-fluorodaunosamine, synthèse et activité biologique de la (*R*)-2′-fluorocarminomycine.

Introduction

In our first article (1) from a program concerned with the synthesis of anthracycline antitumor agents fluorinated in the sugar moiety, a rationale was provided for attempts to procure derivatives bearing a fluorine atom at the position C-2′, and the question of a possible effect of stereochemistry at that position was discussed. Prior and concurrent work by Horton *et al.* (2) has shown that certain structural modifications of daunorubicin (**1***a*), substituted at C-2′ by iodine, bromine, or chlorine, exhibited significantly enhanced antitumor activity and decreased toxicity, but only when the halo atom was axially oriented (**1***b* and 4′-epimers; *R*-2′ configuration); the nature of the halogen atom appeared to have little influence on activity, but *S*-2′ epimers **1***c* (equatorial halogen) were inactive (2). Although Horton *et al.* had previously demonstrated (3) that the 3′-amino group in anthracyclines is not essential for antitumor activity, as was confirmed by the properties of the 3′-deamino-3′-hydroxy (or acetoxy) derivatives **1***b*, we targeted 3′-amino-2′-fluoro glycosides in the hope of gaining further insights into the factors that govern drug efficacy and toxicity.

Our first efforts in that direction (1, 4) had produced (*S*)-2′-fluorodaunorubicin (**2**), also synthesized by Lukacs and co-workers (5), which proved active against a variety of tumor cell lines in vitro and against L1210 murine leukemia in vivo but showed a somewhat lower potency as compared with parent **1***a*. Compound **2** was nontoxic at the highest dose level tested (4), contrary to **1***a*, and it was intriguing to observe retention of activity (albeit diminished) in a derivative bearing an *equatorial* 2′-halo substituent. This raised expectations that an analog having an axial 2′-fluoro substituent might be a superior drug, and we set out first to prepare (*R*)-2-fluoro-L-daunosamine, in the form of its methyl β-pyranoside (6), as the sugar component

	R^1	R^2	R^3	R^4
1*a*	H	H	NH_2	Me
1*b*	H	I, Br, or Cl	OH or OAc	Me
1*c*	I, Br, or Cl	H	OH or OAc	Me
1*d*	H	F	OH	Me
2	F	H	NH_2	Me
3	H	H	NH_2	H
4	H	F	NH_2	H

required for synthesis of such an analog. While that work was in progress, the Umezawas and co-workers (7) published a study highly relevant to this topic, namely, the synthesis of 3′-deamino-(*R*)-2′-fluoro-3′-hydroxydaunorubicin (**1***d*) and its 14-hydroxy derivative (i.e., the corresponding adriamycin analog); strong antitumor activity and low toxicity were displayed by both of these compounds, especially so by the latter. We now record the synthesis of (*R*)-2′-fluorocarminomycin (**4**) and the results of biological testing in comparison with parent carminomycin (**3**). The latter drug has been stated (8) to be more potent than **1***a*, from which it differs structurally solely by its lack of the 4-methyl ether group (9).

Results and discussion

The synthesis of **4** proceeded essentially in analogy to that of **2** (4), except for the step of aglycon glycosylation. Thus, methyl 3-amino-2,3,6-trideoxy-2-fluoro-β-L-talopyranoside (**5**) (6) was hydrolyzed with 4 M hydrochloric acid to give the free amino

sugar hydrochloride **6**, obtained as a crystalline, anomeric mixture. The sugar was sequentially *N*-trifluoroacetylated and *O*-acetylated under the general conditions of daunosamine acylation (10), affording the acyl derivatives **7** and **8** isolated crystalline as pure α-anomers. (By contrast, their (*S*)-2 epimers had been obtained (4) as anomeric mixtures.) The yields of **6–8** were 88–91%.

Compound **8** was condensed with carminomycinone (**10**) by use of trimethylsilyl triflate as the activating agent, according to the method employed by Terashima and co-workers (11) for a synthesis of 4-demethoxydaunorubicin. The 4′-*O*-acetyl-*N*-trifluoroacetyl anthracycline **11** was isolated crystalline in 51% yield; since 33% of unchanged **8** was recovered, the yield based on sugar actually consumed in the reaction was 75%.[3] Sodium methoxide-catalyzed *O*-deacetylation of **11** gave (*R*)-2′-fluoro-*N*-trifluoroacetylcarminomycin (**12**), characterized by tlc only, which was directly *N*-deprotected by treatment with aqueous barium hydroxide, to furnish a 82% overall yield of the target compound **4**, analytically characterized both as the free base and as its hydrochloride **4***a*.

The ^{1}H nmr data for the new compounds (see the Experimental) were in full accord with the depicted structures, and it may be noted in particular that the magnitudes of all observed ^{1}H–^{19}F coupling constants conformed well with expectations based on previous, detailed discussions (1, 6). Mention of a few salient points may suffice. Thus, the vicinal coupling between the fluorine atom and the anomeric proton ($^3J_{H\text{-}1,F\text{-}2}$) in **7–9**, **11**, and **4** was 8.3 ± 0.3 Hz (9.7 Hz in **4***a*), which provided unambiguous proof for an H-1*eq*,F-2*ax gauche* relationship and, hence, the α-anomeric configuration. The $^3J_{H\text{-}1,F\text{-}2}$ value empirically calculated (1, 6, 12) for a 2-deoxy-2-fluorohexopyranose having a 1*ax*,2*ax*,3*eq* substituent arrangement is 6 Hz. By contrast, $^3J_{H,F}$ values for vicinal, *trans*-diaxial nuclei are usually in the range of 19–34 Hz, depending on electronegativity of substituents present (13); examples are $^3J_{H\text{-}1,F\text{-}2}$ = 20.5 Hz for **5** (6) and 22 Hz for **6**-β, and $^3J_{F\text{-}2,H\text{-}3}$ = 33–34 Hz for **5** (6), **7–9**, and **11**. (The $^3J_{F\text{-}2,H\text{-}3}$ values for **4**, **4***a*, and **6**-α should fall in the same range, but they could not be determined.) The geminal coupling constants $^2J_{H\text{-}2,F\text{-}2}$ of **4**, **4***a*, **6**-α, **7–9**, and **11** were all in the range of 48–49.3 Hz, whereas that of **6**-β was 51 Hz, in agreement with empirically calculated (1, 6, 12) values of 48 and 51 Hz, respectively.

Further confirmation of the α-anomeric configuration of the glycoside **11** and its precursors **7** and **8** was derived from their ^{13}C nmr spectra, which displayed C-1 signals (for **11**, read C-1′ etc.) as doublets with $^2J_{C\text{-}1,F\text{-}2}$ = 30.4 ± 1 Hz, C-3 signals as doublets with $^2J_{F\text{-}2,C\text{-}3}$ = 16.0 ± 0.4 Hz, and C-4 signals as singlets ($^3J_{F\text{-}2,C\text{-}4}$ = 0 Hz). The magnitude of $^2J_{C\text{-}1,F\text{-}2}$ indicated an *anti* orientation of the anomeric oxygen atom with respect to the fluorine atom; the $^2J_{F\text{-}2,C\text{-}3}$ values were as expected for structures wherein the coupled C-atom does not bear an electronegative substituent *anti* to the F-atom, and zero vicinal coupling $^3J_{F\text{-}2,C\text{-}4}$ was in line with the *gauche* F-2—C-4 arrangement (6, 13, 14). Finally, the nmr parameters for **4**, **11**, and **8** were in excellent harmony with those reported (7) for **1***d*, its 3′,4′-diacetate, and their progenitor 1,3,4-tri-*O*-acetyl-2,6-dideoxy-2-fluoro-α-L-talopyranose.

Biological activity

Tests to compare antitumor activity of the fluorocarminomycin **4***a* with that of parent carminomycin (**3**) hydrochloride were performed by Bristol–Myers Company, Wallingford, Connecticut. Both compounds showed equally high potencies in vitro, in cytotoxicity tests against five human ovarian and colon cancer cell lines (A2780DDP, A2780S, HCT-116, HCT/VM46, and HCT/VP35), with IC-50 values ranging from <0.001 to 0.03 μg/mL. Tests in vivo against murine P-388 lymphocytic leukemia showed **4** and **3** to be equally active, achieving median survival time increases (T/C values) of ~200%, although **3** was about fourfold more potent in terms of effective dose levels (Table 1). Acute toxicity appeared to be lower in **4**, as judged from a slower onset of weight loss at higher doses, but no toxic deaths occurred within 5 days after treatment with either drug at the dose levels tested.

[3]For condensation of 1,4-di-*O*-acetyl-*N*-trifluoroacetyldaunosamine with 4-demethoxydaunorubicin, followed by 4′-*O*-deacetylation of the product, Terashima and co-workers (11) reported a 70% yield. By use of the corresponding 1,4-bis-*p*-nitrobenzoate, the condensation was almost quantitative and the 4′-*O*-deprotected product was elaborated in 83% yield (11). We encountered initial difficulties in attempting to prepare the 1,4-bis-*p*-nitrobenzoate (**9**) of **7**, and although this ester was eventually obtained (for ^{1}H nmr data, see the section for **8** in the Experimental), its full characterization and (possibly advantageous) use for glycosylation of **10** were dispensed with, the goal of the project having meanwhile been attained.

TABLE 1. Antitumor activity in vivo of carminomycin and (*R*)-2'-fluorocarminomycin against murine P-388 lymphocytic leukemia[a]

Compound (hydrochloride)	Dose (mg/kg)[b]	MST[c] (days)	T/C[d] (%)	AWC[e] (g)
3	1.2	12	133	−0.9
	0.6	19	211	−0.8
	0.3	15.5	172	0.6
	0.15	13	144	0.0
4	2.4	18	200	−0.5
	1.2	16.5	183	−0.1
	0.6	12.5	139	0.4
	0.3	12	133	0.3
	0.15	11	122	0.2
Control		9	100	0.8

[a]In CDF_1 mice (six per test) inoculated i.p. with 10^6 P-388 cells on day 0.
[b]Single dose administered i.p. on day 1.
[c]Median survival time.
[d]Ratio of MST of treated mice to that of untreated controls.
[e]Average weight change recorded on day 4.

Experimental

General preparative and instrumental methods were the same as those previously employed (1, 4, 6). The following solvent combinations (v/v) were used for thin-layer chromatography (tlc) and column chromatography on silica gel: methanol–chloroform, 1:3 (A) and 1:6 (B); methanol–acetone, 1:1 (C); and ethyl acetate – hexanes, 1:1 (D) and 1:2 (E). Optical rotations were measured at ~25°C. Infrared data (ν_{max}) obtained for all new compounds were consistent with the structures, and only a few especially significant bands are listed. Mass-spectral data (*m/z*) were obtained in the chemical ionization mode, using ether as the ionizing gas. The ^1H nmr spectra were recorded at 300 MHz from solutions in deuteriochloroform, unless otherwise indicated.

3-Amino-2,3,6-trideoxy-2-fluoro-α,β-L-talose hydrochloride (6)

A solution of amino glycoside **5** (6) (385 mg) in 4 M hydrochloric acid (40 mL) was boiled under reflux for 6 h, after which time the hydrolysis was complete (tlc, solvent A). The acid was evaporated under diminished pressure with repeated additions of water, and the remaining aqueous solution of the product was treated with activated charcoal and concentrated, to give a greenish solid that was thoroughly dried over KOH *in vacuo*. Trituration with hot acetone then removed the colored impurity and gave **6** as a crystalline monohydrate (415 mg, 88%), mp 201°C; $[\alpha]_D$ −35° (*c* 1, H_2O); ^1H nmr (DMSO-d_6 + D_2O) δ: 5.14 (dd, ~0.6H, $J_{1,2} \approx 1.5$, $J_{1,F} = 8$ Hz, H-1α), 4.69 (d, ~0.4H, $J_{1,F} = 22$ Hz, H-1β), 4.57 (dnm, ~0.4H, $J_{2,F} \approx 51$ Hz, H-2β), 4.51 (dnm, ~0.6H, $J_{2,F} = 49.3$ Hz, H-2α), 4.07 (q, ~0.6H, $J_{5,6} = 6.4$ Hz ($J_{4,5} < 1$ Hz), H-5α), 3.5-region (m, H-3,4,5β), 1.18 and 1.14 (2 d, total intensity 3H, $J = 6.4$ Hz, *C*-Me); *m/z*: 166 (100%, $M^+ + 1 -$ HCl), 148 (47%, $M^+ + 1 -$ HCl − H_2O). Anal. calcd. for $C_6H_{13}ClFNO_3 \cdot H_2O$ (219.6): C 32.81, H 6.88, N 6.38; found: C 32.65, H 6.88, N 6.33.

2,3,6-Trideoxy-2-fluoro-3-trifluoroacetamido-α-L-talopyranose (7)

Trifluoroacetic anhydride (2.45 mL) in dry ether (10 mL) was added dropwise at 0°C to a magnetically stirred suspension of **6** (350 mg) in dry ether (20 mL). Cooling was discontinued after 45 min and the solution kept at room temperature for 2.5 h, after which time tlc (solvent A) revealed the complete conversion of **6** (R_f 0.15) into a single, new product (R_f 0.5). The excess of reagent was removed by coevaporation with several added portions of ether. To reverse *O*-acylation, a solution of the residue in dry methanol (30 mL) was first rendered slightly alkaline (pH ~ 8) with methanolic 0.5 M $NaOCH_3$ and, after 1 h, the pH was adjusted to 7 with a few drops of acetic acid in methanol. Concentration of the mixture followed by column chromatography (solvent D) afforded **7** (410 mg, 91%), mp 134–135°C; $[\alpha]_D$ −51° (*c* 1, Me_2CO); ν_{max}^{KBr}: 3400, 1715, 1530 cm^{-1}; ^1H nmr (acetone-d_6) δ: 8.06 (br, exchangeable, NH), 6.01 (dd, exchangeable, $J_{OH,F} = 2.5$, $J_{1,OH} = 4.5$ Hz, OH-1), 5.29 (ddd (dd after D_2O exchange), $J_{1,2} = 1.7$, $J_{1,F} = 8.6$ Hz, H-1), 4.57 (d of septets, $J_{2,F} = 49.3$, $J_{2,4} = 1.2$, $J_{1,2} = 1.8$, $J_{2,3} = 3$ Hz, H-2), 4.43 (dt (t after D_2O exchange), 0.5H, $J_{2,3} = J_{3,4} = 3$, $J_{3,NH} = 8.3$ Hz, downfield part of ddt for H-3, with upfield part coinciding with the H-5 signal; $J_{3,F} \approx 33$ Hz), 4.32 (qd, $J_{4,5} = 1.6$, $J_{5,6} = 6.6$ Hz, H-5), 3.63 (d, ($J_{4,OH} \approx 10$ Hz) of nm with $W \approx 6$ Hz; nm after D_2O exchange, H-4), 3.26 (dd, exchangeable, $J_{F,OH} = 3.9$, $J_{4,OH} = 9.9$ Hz, OH-4), 1.21 (d, 3H, $J = 6.6$ Hz, *C*-Me). Upon the addition of D_2O to the sample solution (to produce the exchange phenomena just listed), the spectrum showed a set of additional (weak) signals, attributable to the β-anomer arising by anomerization; ^{13}C nmr (50.29 MHz, acetone-d_6) δ: 157.7 (q, $^2J_{F,C} = 38$ Hz, CF_3CO), 116.7 (q, $^1J_{F,C} \approx 290$ Hz, CF_3), 92.4 (d, $^2J_{1,F} = 30.4$ Hz, C-1), 88.7 (d, $^1J_{2,F} = 175.7$ Hz, C-2), 69.7 (s, C-4), 66.7 (s, C-5), 49.1 (d, $^2J_{F,C} = 15.6$ Hz, C-3), 16.8 (s, C-6); *m/z*: 262 (53%, $M^+ + 1$), 244 (100%, $M^+ + 1 - H_2O$). Anal. calcd. for $C_8H_{11}F_4NO_4$ (261.2): C 36.79, H 4.25, F 29.10, N 5.36; found: C 36.90, H 4.47, F 29.26, N 5.38.

1,4-Di-O-acetyl-2,3,6-trideoxy-2-fluoro-3-trifluoroacetamido-α-L-talopyranose (8)

Compound **7** (457 mg) was treated for 15 min at −17°C with acetic anhydride (12 mL) containing 1 drop of concentrated H_2SO_4. Complete conversion of the slow-moving **7** into a single product (R_f 0.55) was indicated by tlc (solvent D). The mixture was stirred with ice water and aqueous $NaHCO_3$ to decompose the excess of anhydride, and the product was extracted into $CHCl_3$. The extract was washed with water, dried (Na_2SO_4), and evaporated, and the solid residue was chromatographed on a column of SiO_2 (solvent E), to give colorless **8** (548 mg, 91%), mp 148–149°C (recrystallized from ether–hexane); $[\alpha]_D$ −110.3° (*c* 1, $CHCl_3$); ν_{max}^{KBr}: 3330 and 3260 (NH), 1750, 1550 cm^{-1}; ^1H nmr δ: 6.72 (d, $J_{3,NH} \approx 8.5$ Hz, NH), 6.32 (dd, $J_{1,2} = 1.7$, $J_{1,F} = 8.4$ Hz, H-1), 5.175 (nm, $W_H = 7$ Hz, H-4), 4.57 (ddt, $J_{2,3} = J_{3,4} = 3.5$, $J_{3,NH} = 8.7$, $J_{3,F} = 33.5$ Hz, H-3), 4.51 (d of nm, $J_{2,F} = 48$ Hz, H-2), 4.20 (qd, $J_{4,5} \approx 1$, $J_{5,6} = 6.5$ Hz, H-5), 2.18 and 2.14 (2 s, 3H each, 2 OAc), 1.19 (d, 3H, $J = 6.5$ Hz, *C*-Me); ^{13}C nmr (50.29 MHz, $CDCl_3$) δ: 171.0 and 168.4 (2 s, 2 *Me*CO), 157.0 (q, $^2J_{C,F} = 38.4$ Hz, CF_3CO), 115.4 (d, $^1J_{C,F} = 288.3$ Hz, CF_3), 90.1 (d, $^2J_{1,F} = 32.4$ Hz, C-1), 84.2 (d, $^1J_{2,F} = 182.6$ Hz, C-2), 68.1 and 67.2 (2 s, C-4,5), 46.25 (d, $^2J_{3,F} = 16.4$ Hz, C-3), 20.5 and 20.1 (2 s, 2 *CO*Me), 16.1 (s, C-6). *m/z*: 346 (1%, $M^+ + 1$), 286 (100%, $M^+ + 1 -$ AcOH). Anal. calcd. for $C_{12}H_{15}F_4NO_6$ (345.2): C 41.74, H 4.38, F 22.01; found: C 41.93, H 4.48, F 21.79.

The analogous *1,4-di-O-p-nitrobenzoate* **9**, obtained as a pale yellow solid from **7** by treatment with *p*-nitrobenzoyl chloride and pyridine, showed the following ^1H nmr data: δ: 8.35–8.20 (m, 8H, arom.), 6.81 (d, $J_{3,NH} = 7.8$ Hz, NH), 6.69 (dd, $J_{1,2} = 1.5$, $J_{1,F} = 8.5$ Hz, H-1), 5.56 (m, $W_H = 6.5$ Hz, H-4), 4.80 (ddt, $J_{2,3} \approx J_{3,4} \approx 3.5$, $J_{3,NH} = 8$, $J_{3,F} = 33$ Hz, H-3), 4.78 (d of nm, $J_{2,F} \approx 48$ Hz, H-2), 4.44 (qd, $J_{4,5} = 0.8$, $J_{5,6} = 6.5$ Hz, H-5), 1.27 (d, 3H, $J = 6.5$ Hz, *C*-Me).

Carminomycinone (30)

Aglycon **10** was prepared (9*c*,*d*) by hydrolysis of carminomycin hydrochloride with aqueous 0.1 M HCl (30 min at 100°C). The red crystalline precipitate was washed well with water and dried in a desiccator; mp 235–236°C (lit. (9*c*) mp 233–235°C); ^1H nmr (200 MHz) δ: 13.43, 12.91, and 12.13 (3 s, 3 phenolic OH), 7.85, 7.68, and 7.28 (dd, t, and dd, 1H each, $J = 1.25$ and 8 Hz, H-1,2,3), 5.26 (m (dd after D_2O exchange), $J_{7,8e} = 2$, $J_{7a,8a} = 5$ Hz, H-7), 4.61 (s, exchangeable, OH-9), 3.93 (d, exchangeable, $J_{7,OH} = 6.6$ Hz, OH-7), 3.17 (dd, $J_{8e,10e} = 2$, $J_{10a,10e} = 18.6$ Hz, H-10e), 2.94 (d, $J = 18.6$ Hz, H-10a), 2.39 (s, 3H, CH_3-14), 2.32 (dt, $J_{7,8e} = J_{8e,10e} = 2$, $J_{8a,8e} = 14.5$ Hz, H-8e), 2.14 (dd, $J_{7a,8e} = 5$, $J_{8a,8e} = 14.5$ Hz, H-8a).

*7-O-(4-O-Acetyl-2,3,6-trideoxy-2-fluoro-3-trifluoroacetamido-α-L-talopyranosyl)-carminomycinone (**11**)*

Aglycon **10** was dried overnight at 110°C in an oil-pump vacuum, and the solvents CH_2Cl_2 and ether were bidistilled from P_2O_5 and NaH, respectively. The reaction flask and granular molecular sieve 4A (3 g) contained therein were flame-dried and allowed to cool in a desiccator. The reaction was performed under N_2 with strict exclusion of atmospheric moisture. A solution of **8** (380 mg, 1.1 mmol) in CH_2Cl_2 (10 mL) and ether (8 mL) was placed over the molecular sieve, the mixture was cooled to −40°C, and trimethylsilyl triflate (0.84 mL) was introduced rapidly by syringe. The mixture was then stirred at 0°C for 1 h before **10** (525 mg, 1.4 mmol) in CH_2Cl_2 (15 mL) was added. Stirring was then continued at room temperature, and the reaction was monitored by tlc (solvent D), which revealed a gradual consumption of **8** (R_f 0.45) and **10** (R_f 0.1), and formation of **11** (R_f 0.33) as the main product accompanied by traces of a minor product (R_f 0.25). A moderate proportion of **8** appeared unreacted after 24 h; therefore, the mixture was cooled again to −40°C and stirred for 15 min with added trimethylsilyl triflate (0.1 mL), and **10** (100 mg) was then added at 0°C. Stirring was continued for a further 24 h at 25°C, but some **8** still persisted. The mixture was processed by shaking with ethyl acetate (150 mL) and saturated, aqueous $NaHCO_3$ (50 mL). The phases were separated, and the aqueous phase was extracted exhaustively with ethyl acetate. The combined organic phases were dried ($MgSO_4$) and evaporated, and the residue was chromatographed on a column (30 g of SiO_2) with solvent E, to give unreacted **8** (125 mg, 33% recovery) followed by **11** (374 mg, 51%; 75.6% taking into account the recovered **8**). Compound **11** was a red powder, mp 156–166°C; $[\alpha]_D$ +168° (*c* 0.5, $CHCl_3$); ν_{max}^{KBr}: 3520, 3440, 3320 (br), 1730, 1600 cm^{-1}; ^1H nmr δ: 13.35, 12.90, and 12.05 (3 s, 3 phenolic OH), 7.87, 7.70, and 7.31 (dd, t, and dd, $J \approx 1$ and 8 Hz, H-1,2,3), 6.71 (d, $J_{3',NH}$ = 8.3 Hz, NH), 5.58 (dd, $J_{1',2'}$ = 1.2, $J_{1',F} \approx 8$ Hz, H-1′), 5.27 (dd, $J_{7,8e} = 2$, $J_{7,8a} = 4.5$ Hz, H-7), 5.18 (nm, $W \approx 4$ Hz, H-4′), 4.65 and 4.49 (2 nm, 0.5H each, $J_{2',F}$ = 48.6 Hz, H-2′), 4.38 (qd, $J_{4',5'} \approx 1$, $J_{5',6'}$ = 6.5 Hz, H-5; the outer parts of the H-5 signal were overlapped by two dt, 0.5H each, for H-3′, with $J_{2',3'} \approx J_{3',4'} \approx 3$, $J_{3',NH} = 8$, $J_{3',F} \approx 34$ Hz), 3.85 (s, exchangeable, OH-9), 3.24 (dd, $J_{8e,10e}$ = 1.9, $J_{10a,10e}$ = 19 Hz, H-10e), 2.97 (d, J = 19 Hz, H-10a), 2.41 (s, 3H, CH_3-14), 2.36 (dnm, with downfield nm partly obscured by CH_3-14 signal, $J_{8a,8e} \approx 16$ Hz, $J_{7,8e}$ and $J_{8e,10e} \approx 1$–2 Hz, H-8e), 2.19 (s, 3H, AcO-4′, superposed on H-8a signal), 1.23 (d, 3H, J = 6.5 Hz, CH_3-6′); ^{13}C nmr (75.43 MHz, $CDCl_3$, assignments by aid of ADEPT experiment): (a) aglycon, δ: 210.3 (C-13), 190.1 and 185.7 (C-5,12), 162.3, 156.3, and 156.1 (C-4,6,11), 137.0, 124.8, and 119.6 (C-1,2,3), 136.4, 132.9, and 132.5 (C-6a,10a,12a), 115.6, 111.3, and 110.4 (C-4a,5a,11a), 76.0 (C-9), 71.3 (C-7), 35.4 and 33.2 (C-8,10), 24.6 (C-14); (b) carbohydrate moiety, δ: 170.8 (*Me*CO), 100.2 (d, $^2J_{1',F}$ = 31.4 Hz, C-1′), 85.1 (d, $^1J_{2',F}$ = 179.7 Hz, C-2′), 68.7 (s, C-4′), 65.9 (s, C-5′), 46.7 (d, $^2J_{3',F}$ = 16.2 Hz, C-3′), 20.6 (*CO*Me), 16.4 (s, C-6′). Quartets near δ 157 and 115 for the CF_3CO group were too weak to be accurately determinable. Anal. calcd. for $C_{30}H_{27}F_4NO_{12}$ (669.5): C 53.82, H 4.07, N 2.09; found: C 53.89, H 4.11, N 1.98.

*7-O-(3-Amino-2,3,6-trideoxy-2-fluoro-α-L-talopyranosyl)-carminomycinone (**4**, (R)-2′-fluorocarminomycin) and its hydrochloride **4**a*

To a solution of **11** (360 mg) in methanol (50 mL) was added methanolic 1 M $NaOCH_3$ (5 mL), at room temperature, whereby the orange-red solution turned deep purple. After 1 h, saponification of **11** (R_f 0.4) to (*R*)-2′-fluoro-*N*-trifluoroacetylcarminomycin **12** (R_f 0.25) was complete (tlc with solvent D). The solution was neutralized with methanolic acetic acid, and evaporated, to give crude **12** as a brown solid. The solid was dissolved under N_2 in a saturated, aqueous $Ba(OH)_2$ solution (20 mL) at 25°C. After 30 min the purple mixture was neutralized by addition of solid carbon dioxide until an orange color persisted, diluted with water (10 mL), and extracted exhaustively with $CHCl_3$. The red extracts were dried ($MgSO_4$) and evaporated to give a brownish-purple solid that was triturated with a little fresh $CHCl_3$, isolated by suction filtration, and dried. The product (**4**-monohydrate, 244 mg, 82.6%) showed an elongated spot (R_f 0.5–0.25) and a minor impurity (R_f 0.7) in tlc (solvent C); mp 217–219°C, ν_{max}^{KBr}: 3500, 3400, 1715, 1600 cm^{-1}; ^1H nmr δ: 7.87, 7.70, and 7.31 (dd, t, and dd, $J \approx 1$ and 8 Hz, H-1,2,3), 5.53 (dd, $J_{1',2'} \approx 1$, $J_{1',F} \approx 8.5$ Hz, H-1′), 5.28 (nm, H-7), 4.62 and 4.38 (2 nm, 0.5H each, $J_{2',F}$ = 48.5 Hz, H-2′), 4.16 (q, $J_{5',6'}$ = 6.5 Hz, H-5′), 3.48 (nm, H-4′), 3.23 (dd, $J_{8e,10e} \approx 1.5$, $J_{10a,10e}$ = 19 Hz, H-10e), 2.97 (d, J = 19 Hz, H-10a, superposed on cm for H-3′), 2.40 (s, 3H, CH_3-14, superposed on m for H-8e), 2.17 (dd, $J_{7,8a}$ = 4, $J_{8a,8e}$ = 15 Hz, H-8a), 1.35 (d, 3H, J = 6.4 Hz, CH_3-6′). Anal. calcd. for $C_{26}H_{26}FNO_{10}\cdot H_2O$ (549.5): C 57.77, H 5.03, N 2.59; found: 57.88, H 5.02, N 2.40.

For preparation of the *hydrochloride* **4***a*, a solution of **4** in 0.1 M HCl (40 mL) was first extracted with ethyl acetate for removal of the aforementioned impurity (R_f 0.7), and then evaporated to dryness with additions of ethanol and benzene. The red solid obtained gave a single spot (R_f 0.2) in tlc (solvent B). It was recrystallized from ethanol–ether and dried *in vacuo* over KOH, and weighed 173 mg (82.6%); mp 217–218°C (with sintering from 206°C); $[\alpha]_D$ +214 ± 15° (*c* 0.05, CH_3OH); ν_{max}^{KBr}: 3400 (br), 1710, 1610 cm^{-1}; ^1H nmr (DMSO-d_6) δ: 7.83 (m, 2H) and 7.43 (d, J = 7.4 Hz) for H-1,2,3; 5.60 (s, exchangeable, OH-9), 5.41 (dd, $J_{1',2'}$ = 1.1, $J_{1',F}$ = 9.7 Hz, H-1′), 5.31 (d, $J_{4',OH}$ = 6.5 Hz, exchangeable, OH-4′), 5.06 (nm, H-7), 4.64 and 4.47 (2 nm, 0.5 H each, $J_{2',F}$ = 49.2 Hz, H-2′), 4.32 (~q, $J_{5',6'}$ = 6.6 Hz, H-5′), 3.62 (m, $W_H \approx 14$ Hz, narrowed further after D_2O exchange, H-4′), 3.4 (H-3′, signal partly obscured by DOH peak), 2.96 (AB-q, 2H, H-10a,e), 2.30 (s, 3H, CH_3-14), 2.18 (m, 2H, H-8a,e), 1.22 (d, 3H, J = 6.6 Hz, CH_3-6′); ^{13}C nmr (50.23 MHz, DMSO-d_6): (a) aglycon, δ: >200 (C-13, not observed), 190.3 and 186.3 (C-5,12), 161.7, 156.3, and 155.7 (C-4,6,11), 137.7, 124.9, and 119.3 (C-1,2,3), 137.1, 134.5, and 133.2 (C-6a,10a,12a), 116.0, 111.0, and 110.1 (C-4a,5a,11a), 74.7 (C-9), 70.8 (C-7), ~37.5 and 31.5 (C-8,10), 24.2 (C-14); (b) carbohydrate moiety, δ: 99.0 (d, $^2J_{1',F}$ = 31 Hz, C-1′), 80.4 (d, $^1J_{2',F}$ = 185 Hz, C-2′), 66.2 (C-4′), 65.6 (C-5′), 54.5 (d, $^2J_{3',F}$ = 16 Hz, C-3′), 16.2 (C-2′).

Acknowledgments

Financial support by the Natural Sciences and Engineering Research Council of Canada and through a NATO Grant for International Collaboration (CRG 890759) is gratefully acknowledged. Dr. T. W. Doyle, Director, Pharmaceutical Research and Development Division, Bristol-Myers Company, is thanked for a generous donation of carminomycin and for arranging the biological tests, and Drs. A. Crosswell and J. E. Schurig of the same company are thanked for performing the tests.

The chlorination of propiophenone; determination of pK_a value and of the course of the reaction

J. Peter Guthrie[1] and John Cossar

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received December 11, 1989[2]

J. Peter Guthrie and John Cossar. Can. J. Chem. **68**, 2060 (1990).

Chlorination of propiophenone in alkaline aqueous solution leads to formation of α-hydroxypropiophenone as the first detectable intermediate; this undergoes slower oxidation to aromatic acids without any accumulation of further intermediates. From the rates of the initial chlorination we have been able to determine the pK_a value as 17.56 ± 0.51.

Key words: propiophenone, chlorination, hydrolysis, rearrangement, pK_a.

J. Peter Guthrie et John Cossar. Can. J. Chem. **68**, 2060 (1990).

La chloration de la propiophénone en solution aqueuse alcaline conduit à la formation de l'α-hydroxypropiophénone en tant que premier intermédiaire décelable; ce composé s'oxyde lentement en acides aromatiques sans accumulation subséquente d'intermédiaires. La mesure des vitesses de chloration initiale nous a permis de déterminer un pK_a de 17,56 ± 0,51.

Mots clés : propiophénone, chloration, hydrolyse, transposition, pK_a.

Introduction

We have developed a method for determining pK_a values of simple ketones by analysis of the kinetics of chlorination in alkaline solution (1, 2). This method has been applied to a series of ring-substituted acetophenones (3). We now wish to report its application to propiophenone. Propiophenone is known to undergo halogenation followed by cleavage to benzoic acid (4). This was believed to involve formation of α,α-dihalopropiophenone, followed by hydrolysis and oxidative cleavage (5). We now find that, at least under the conditions we use for kinetics, the actual reaction course is different, and that propiophenone undergoes one rapid chlorination, followed by rapid hydrolysis that competes with the second chlorination, and then slow further oxidation of the α-hydroxypropiophenone. Furthermore, the oxidation products include not just benzoic acid but mandelic acid, atrolactic acid, and phenylglyceric acid (6).

Results

In Table 1 are the results of our kinetics studies of propiophenone. This reaction at first appeared deceptively simple because the absorbance–time curves could be fitted to an integrated rate law, eq. [1], with a single exponential followed by a linear decrease in absorbance; see Fig. 1. We have not identified the process responsible for the slow decrease in absorbance at long times. If this were followed to completion we assume that it would become nonlinear, and probably exponential, but the time required would be inordinately long. For the length of time that we did follow the reaction, the slow final phase was satisfactorily linear, as shown by the behavior of the residuals plot. However closer examination of the data

$$[1] \quad \text{Absorbance} = a_1 + a_2 \exp(-a_3 t) + a_4 t$$

showed that there were consistent deviations of calculated from experimental absorbance values in the sense to be expected if there were a faster process with a small amplitude. The data gave a better fit to an integrated rate law with two exponential terms, eq. [2]; see Fig. 2. In Fig. 2 the quantity labeled log $(A - A_\infty)$ is corrected by subtracting subsequent terms in the rate law.

$$[2] \quad \text{Absorbance} = a_1 + a_2 \exp(-a_3 t) + a_4 \exp(-a_5 t) + a_6 t$$

Thus in terms of eq. [1] we plot log (Absorbance $- a_1 - a_4 t$), and in terms of eq. [2] we plot log (Absorbance $- a_1 - a_6 t$) or log (Absorbance $- a_1 - a_4 \exp(-a_5 t) - a_6 t$). The key indication that eq. [1] is inadequate and eq. [2] is satisfactory comes from examination of the residuals plots, of $A_{obs} - A_{calc}$, in Fig. 2. In Fig. 2a there is a clear pattern of deviations, first negative, then positive, then negative again, which are large relative to the noise level in the residuals plot; by contrast, in Fig. 2b the residuals curve shows no deviations from the zero line that are consistently greater than the noise level. Now that microcomputers provide convenient access to computational power and graphics display, use of residuals plots should be seen as an essential part of data analysis, to confirm that the fitting process truly accounts for all systematic variations in the data, leaving only random noise.

The observation of an integrated rate law with two exponentials implies the accumulation of an intermediate. Product isolation experiments at a time when most of the propiophenone had reacted but much of the intermediate had not been consumed gave a mixture, which was shown by nmr analysis and chromatographic isolation to have 2-hydroxy-1-phenyl-1-propanone, HPP,[3] as the major component and the only neutral material present besides residual propiophenone. HPP was identified by comparison with an authentic sample, and with spectroscopic data from the literature. The nmr spectrum of the isolated material showed no sign of 1-hydroxy-1-phenyl-2-propanone, HPA. When the reaction was followed by hplc analysis of samples quenched at suitable times it was found that propiophenone disappeared rapidly, with HPP as the only detectable neutral product. However, these experiments were done with ketone in excess, so that hypochlorite was totally consumed. There was a subsequent reaction of the HPP, which represents base-catalyzed isomerization to HPA.

The presence of HPP implies rapid hydrolysis of 2-chloro-1-phenyl-1-propanone, CPP. To confirm this we prepared a sample of CPP and demonstrated that it undergoes rapid hydroxide-catalyzed hydrolysis: see Table 2. The second-order rate

[a]In aqueous solution at 25°C, ionic strength 1.0 (KCl). Followed by absorbance measurements at 292 nm unless otherwise stated. Absorbance–time data were fitted to $y = a_1 + a_2 \exp(-a_3 t) + a_4 \exp(-a_5 t) + a_6 t$. n is the stoichiometry, calculated from eq. [3]. f is the fraction of CPP that undergoes hydrolysis to HPP, calculated from eq. [4].
[b]Not included in the least-squares fit to eq. [4] (Table 3).
[c]Followed by hplc. Peak integration – time data were fitted to $y = a_1 + a_2 \exp(-a_3 t) + a_4 \exp(-a_5 t)$.
[d]k_{II}[OCl], calculated from κ_ψ*[OCl]/[ketone], for comparison with uv kinetics.

constant for this hydrolysis is 1.45 ± 0.06 M^{-1} s^{-1}. This is similar to the rate constant observed for monochloroacetone, i.e., 1.19 M^{-1} s^{-1} (2). Clearly, hydrolysis of CPP is fast relative to subsequent reactions of hydroxypropiophenone. The actual chlorination is normally slower than enolate formation (7, 8), so that the overall kinetics are first order in [OCl^-] except at very high [OCl^-]. The rate constant for enolate formation is 0.026 M^{-1} s^{-1} (see below), which is almost 100 times slower than that for hydrolysis, and the overall chlorination reaction will be slower still at the hypochlorite concentrations used for kinetics.

Following the kinetics of propiophenone chlorination by uv spectroscopy at the absorbance maximum for hypochlorite was not completely satisfactory because the initial rapid reaction was accompanied by only a small change in absorbance, which changed from an increase to a decrease with changing reagent concentrations. Under conditions where the absorbance change was very small, the rate of the initial reaction could not be determined reliably at the λ_{max} of the hypochlorite. The initial reaction could be followed by hplc, where we could cleanly follow disappearance of propiophenone or appearance of HPP, the only observable intermediate under the conditions employed. However, it was only feasible to use this technique with low concentrations of hypochlorite and ketone in excess, in order to have amounts of products that could be accurately measured. If the hypochlorite concentrations were high, then the rates became too fast for sampling. These data are also found in Table 1.

The minimum mechanism for these kinetics is shown in Scheme 1. For the overall reaction described by Scheme 1 we can derive an equation for the absorbance as a function of time. We start with the differential equations, [3], where k_{13} is the steady-state rate constant for conversion of propiophenone into CPP, n is the number of moles of hypochlorite consumed per mole of propiophenone, and f is the fraction of CPP that is hydrolyzed to HPP rather than undergoing a second chlorination.

$$\text{[3]}\quad \begin{aligned} d[\text{Prop}]/dt &= -k_{13}[\text{Prop}] \\ d[\text{HPP}]/dt &= k_{13} f[\text{Prop}] - k_{45}[\text{HPP}] \\ d[OCl^-]/dt &= -k_{13}[\text{Prop}](1 + (1-f)(n-1)) \\ &\quad - k_{45}[\text{HPP}](n-1) \end{aligned}$$

Integration, and substitution into the equation for the total absorbance, Absorbance = $\epsilon_{\text{Prop}}[\text{Prop}]l + \epsilon_{\text{HPP}}[\text{HPP}]l + \epsilon_{\text{OCl}}[\text{OCl}]l$, leads to eq. [4]:

$$\begin{aligned} \text{[4]}\quad \text{Absorbance} &= \epsilon_{\text{OCl}}\{[\text{OCl}]_0 - n[\text{Prop}]_0\}l \\ &+ [\text{Prop}]_0 l\{\epsilon_{\text{Prop}} - \epsilon_{\text{HPP}} k_{13} f/(k_{13} - k_{45}) \\ &\quad + \epsilon_{\text{OCl}}(n - k_{13} f(n-1)/(k_{13} - k_{45}))\} \exp(-k_{13} t) \\ &+ [\text{Prop}]_0 l\{\epsilon_{\text{HPP}} k_{13} f/(k_{13} - k_{45}) \\ &\quad + \epsilon_{\text{OCl}} k_{13} f(n-1)/(k_{13} - k_{45})\} \exp(-k_{45} t) \\ &= \text{Absorbance}_0 + \alpha \exp(-k_{13} t) + \beta \exp(-k_{45} t) \end{aligned}$$

from which we can derive expressions for n and f:

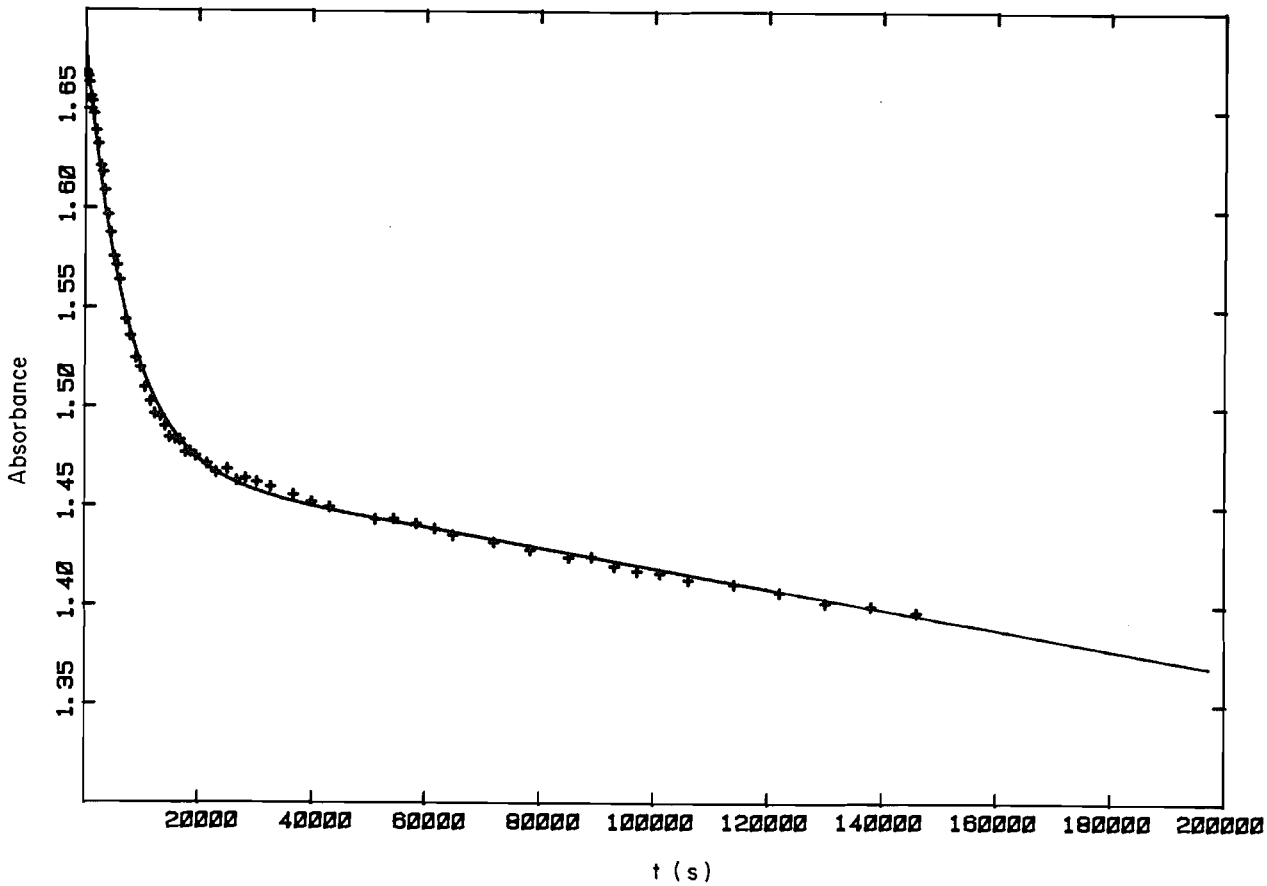

FIG. 1. Chlorination of propiophenone; absorbance–time curve for the reaction of 7.44×10^{-6} M propiophenone with 4.58×10^{-4} M hypochlorite in 0.0999 M hydroxide at ionic strength 1.0. The data were fitted by least squares to $A = a_1 + a_2 \exp(-a_3 t) + a_4 t$.

[5] $$n = \{(a + b)/([\text{Prop}]_0 l) - \epsilon_{\text{Prop}}\}/\epsilon_{\text{OCl}}$$

[6] $$f = b(k_{13} - k_{45})/(k_{13}[\text{Prop}]_0 l(\epsilon_{\text{HPP}} + (n - 1)\epsilon_{\text{OCl}}))$$

Values for n and f are included in Table 1.

For substituted acetophenones we found that the first chlorination step was rate determining under the usual conditions for chlorination kinetics (3), and the observed rates followed the rate law given in eq. [7]:

[7] $$v = k_{\text{obs}}[\text{Ketone}]$$
$$k_{\text{obs}} = \{k_{\text{II}}^0 + k_{\text{II}}^-[\text{OH}^-]\}[\text{OCl}^-]$$

If the same rate law applied for k_{13} of propiophenone, then in terms of Scheme 1, $k_{\text{II}}^0 = k_{12}k_{23}^0 K_w/k_{21}K_a^{\text{HOCl}}$, and $k_{\text{II}}^- = k_{12}k_{23}^-/k_{21}$. For the initial phase of the kinetics, where the rate of chlorination of propiophenone is being followed, it was found that the pseudo-first-order rate constants for a set of experiments at fixed hydroxide concentration were not linearly dependent upon hypochlorite concentration, but showed a tendency to level off at high $[\text{OCl}^-]$. Thus for propiophenone enolate, halogenation and reprotonation are competitive. For this situation we may derive the following expression for the rate law:

[8] $$k_{\text{obs}} = k_{13} = \frac{k_{12}(k_{23}^0 K_w/K_a^{\text{HOCl}} + k_{23}^-[\text{OH}^-])[\text{OCl}^-]}{k_{21} + (k_{23}^0 K_w/([\text{OH}^-]K_a^{\text{HOCl}}) + k_{23}^-)[\text{OCl}^-]}$$

This may be transformed into a form convenient for fitting to the data:

[9] $$k_{\text{obs}} = k_{13} = (a_1 + a_2[\text{OH}^-])/(1/[\text{OCl}^-] + a_1/a_3[\text{OH}^-] + a_2/a_3)$$

where $a_1 = k_{\text{II}}^0$, $a_2 = k_{\text{II}}^-$, and $a_3 = k_{12}$. The data from Table 1 were fitted to eq. [7]. A few runs, where the uncertainties in the rate constants for the initial phase were very large, were not included in these calculations. To include the hplc data, we calculated initial "pseudo-first-order rate constants" $= k_{\text{obs}}[\text{OCl}^-]_0/[\text{Prop}]_0$; these experiments were actually done with ketone in excess. We can use the observed pseudo-first-order rate constants, defined by $v = k_{\text{obs}}[\text{OCl}]$, because the major reaction path is conversion of propiophenone to hydroxypropiophenone, which consumes only one OCl^-. In general one must remember that the observed rate constant includes the stoichiometry number for ketone in excess conditions, but not for hypochlorite in excess conditions (1). The above discussion assumes that $[\text{OCl}^-]$ is essentially constant throughout a particular kinetics experiment. Examination of the concentrations and stoichiometries in Table 1 shows that in each case, for reactions with OCl^- in excess, less than 10% of the OCl^- was consumed. We also fitted the second-order rate constants for the hplc experiments to eq. [7]. For the determination of the pK_a it was more satisfactory to use the directly measured rate constants at low $[\text{OCl}^-]$ for low $[\text{OH}^-]$ (these are data from hplc experiments) and extrapolated values at high $[\text{OH}^-]$ (these are data from uv kinetics) to give the final fit to eq. [7]. The required extrapolation was carried out by fitting data at constant $[\text{OH}^-]$ to eq. [10], and calculating the apparent second-order rate constant from the parameters so obtained.

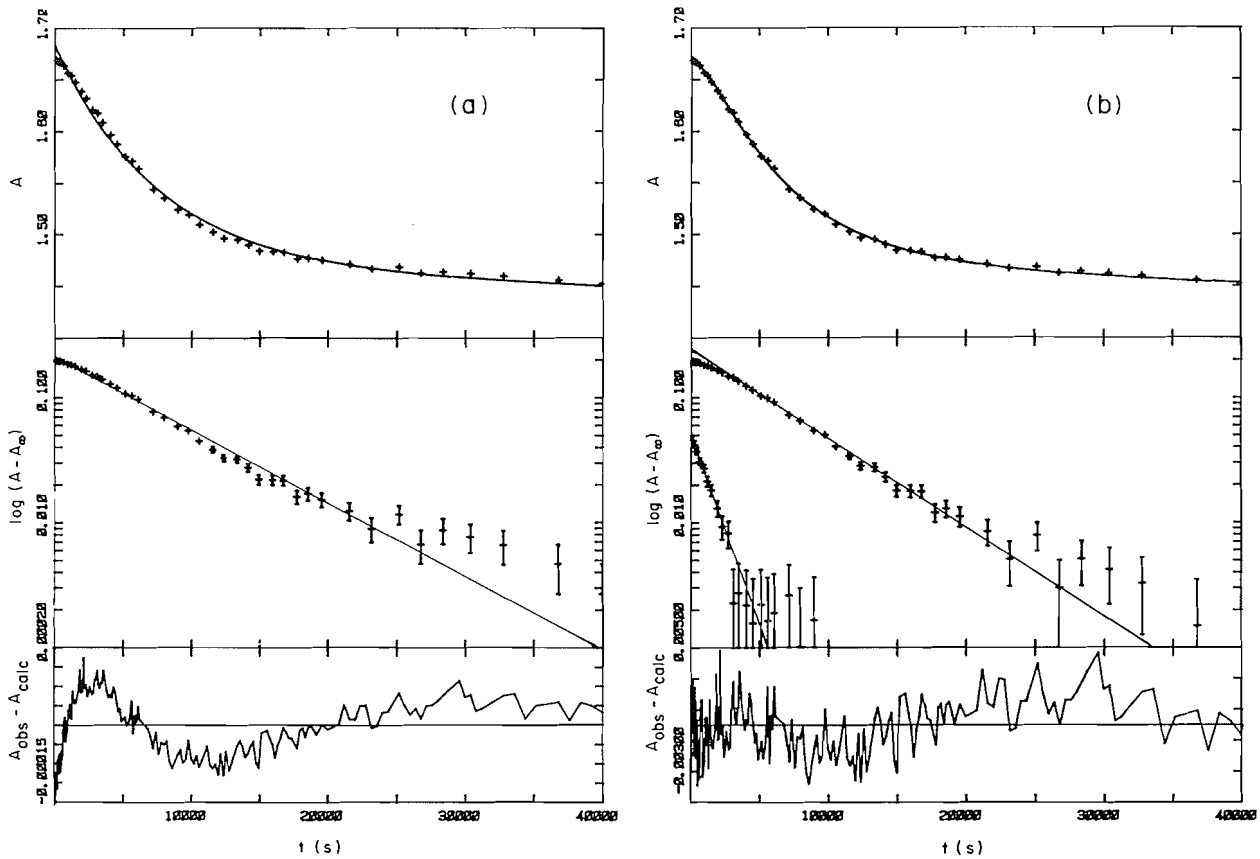

FIG. 2. Chlorination of propiophenone; absorbance–time curve for the reaction of 7.44×10^{-6} M propiophenone with 4.58×10^{-4} M hypochlorite in 0.0999 M hydroxide at ionic strength 1.0. Only data for the first 40 000 s of reaction are shown. These figures show the corresponding semilog and residuals plots as well. (a) The data were fitted to $A = a_1 + a_2 \exp(-a_3 t) + a_4 t$. (b) The data were fitted by least squares to $A = a_1 + a_2 \exp(-a_3 t) + a_4 \exp(-a_5 t) + a_6 t$. The semilog plots show $\log(A - A_0)$ corrected for subsequent terms in the rate law as described in the text.

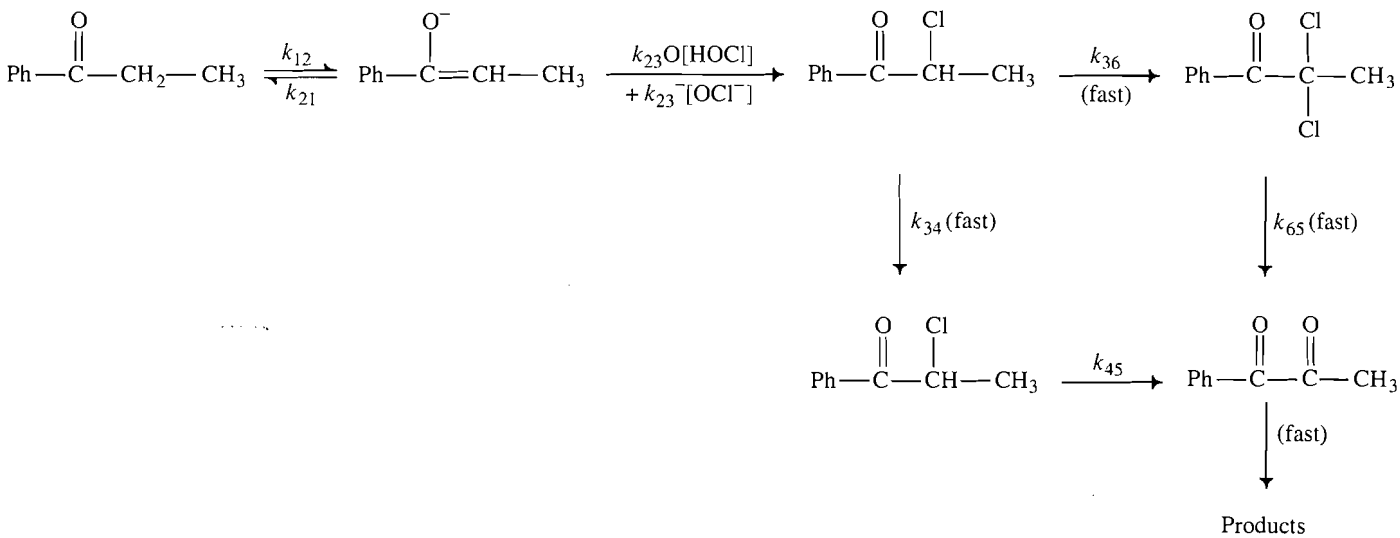

SCHEME 1

[10] $k_{obs} = b_1/(1 + b_2/[OCl^-])$

In terms of the parameters of eq. [4], $b_1 = a_3[OH^-]$, and $b_2 = a_3/(a_1 + a_3[OH^-])$. Then $b_1/b_2 = a_1 + a_2[OH^-]$. The fit to eq. [7] was largely determined by the data from hplc kinetics, but the precision of the derived parameters was improved when the extrapolated values were included. The parameters from the two sets of calculations are in good agreement. The parameters determined by least squares, and the pK_a value based on a_1, are found in Table 3. Figure 3b shows the experimental points and the surface fitted to them using eq. [7].

The kinetics of the second phase of propiophenone chlorination (Table 1) showed a clear dependence on hydroxide concentration, and seemed to depend on hypochlorite concentration as

well. However, kinetics starting with HPP (Table 2) clearly show no dependence on hypochlorite concentration. These kinetics, based on simple single exponential behavior, give inherently more reliable rate constants. The best description of the kinetics appears to be eq. [11], with $k_{OH} = 3.87 \times 10^{-3}$ M^{-1} s^{-1}. Figure 3b shows the experimental points and the surface so calculated.

$$[11] \quad k_{obs} = k_{OH}[OH^-]$$

For propiophenone the stoichiometry of the halogenation was calculated using eq. [3]; these values are given in Table 1. The total consumption of halogenating agent over the course of a reaction was greater than 3 hypochlorites per propiophenone, and appeared to approach a limit of 6. A value as high as 6 is intelligible in terms of the reactions shown in Scheme 2. The numbers in square brackets under the final products in Scheme 2 represent the number of equivalents of hypochlorite consumed to form that product.

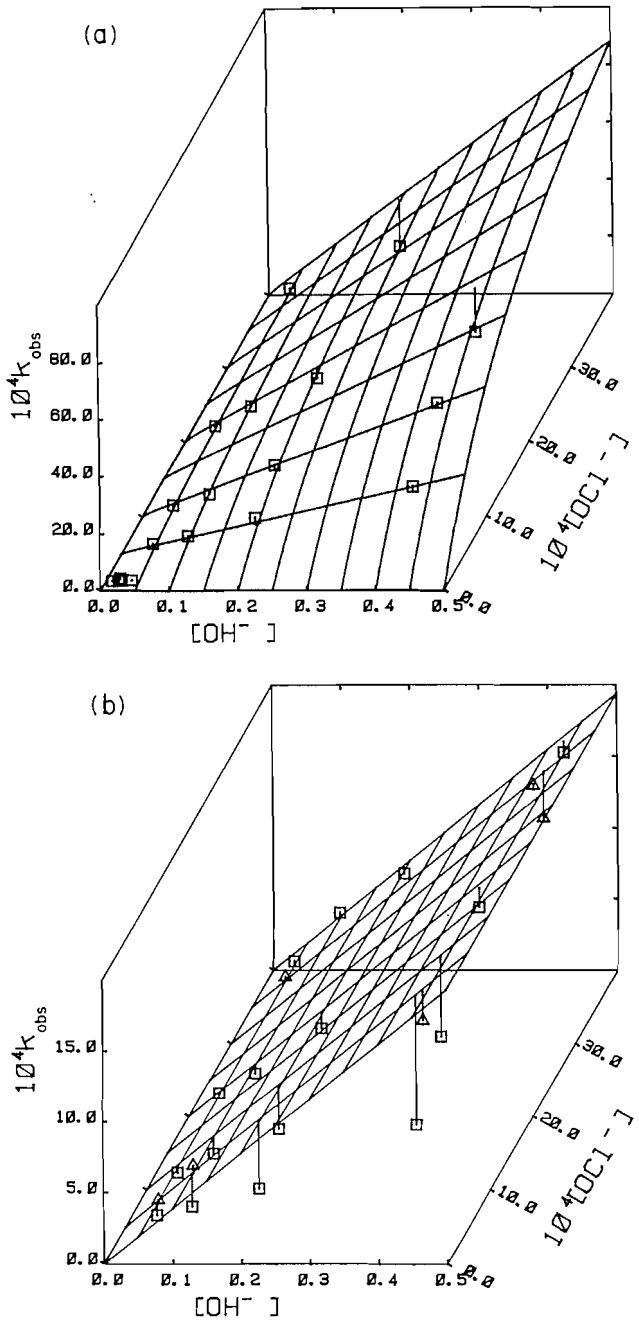

FIG. 3. Chlorination of propiophenone. (a) Initial phase; k_{obs} as a function of $[OCl^-]$ and $[OH^-]$. The surface is calculated using eq. [7], with parameters determined by least-squares fitting. (b) Second phase; k_{obs} as a function of $[OCl^-]$ and $[OH^-]$. The surface is calculated using eq. [9], with an average second-order rate constant from Table 2.

The stoichiometry number shows little dependence on $[OCl^-]$ at fixed $[OH^-]$, but shows a definite decline as $[OH^-]$ increases. The data do not really define a curve, but the high $[OH^-]$ limit might be 3. Figure 5 shows the average stoichiometry numbers for each $[OH^-]$ as a function of $[OH^-]$, with a line fitted to the data on the assumption that the limiting values are $n = 6$ and $n = 3$, eq. [12]. These limiting values are plausible in terms

$$[12] \quad n = 3 + 3/(1 + 4.08[OH^-])$$

of predominant formation of phenylglycerate at high $[OH^-]$ (6) and of benzoate at low $[OH^-]$. Production of benzoate suggests a crucial partitioning either at 3-chloro-1-phenyl-1,2-propanedione or 3-hydroxy-1-phenyl-1,2-propanedione, with high $[OH^-]$ favoring hydrolysis of the chloro compound and (or) rearrangement of the hydroxy compound, and low $[OH^-]$ favoring chlorination. Scheme 2 is complex, and much remains to be determined. At that, this scheme may be too simple, because a reasonable mechanism can be written involving rearrangement of chloroketones rather than hydroxyketones; this would give the same products. Evidence in hand suggests that benzoate, mandelate, atrolactate, and 2-phenylglycerate are all products of the reaction; further investigations of the later stages of the chlorination of propiophenone are underway, and will be reported in due course.[4]

The fraction of CPP that undergoes hydrolysis to HPP can be calculated using eq. [4], and the values are given in Table 1. The precision of these values is not high, but there is a trend for f to increase at low $[OCl^-]$ and decrease at high $[OCl^-]$, and there is no apparent relationship to $[OH^-]$. This suggests that the rate law for the second chlorination leading to 2,2-dichloro-1-phenyl-2-propanone is $v = k_{36}[OH^-][OCl^-][CPP]$. If so, then

$$[13] \quad 1/f = 1 + k_{36}[OCl^-]/k_{34}$$

A very approximate value of $k_{36} = 120\ M^{-2}\ s^{-1}$ can be extracted from the data, but this is only an order of magnitude estimate at this time.

If we use the measured extinction coefficients, k_{13} values calculated from eq. [9], k_{45} values calculated from eq. [11], n values calculated from eq. [12], and f values calculated from eq. [13], we can approximately reproduce the observed values of the preexponential factors α and β. In particular, we reproduce the alternation in sign of α with changing concentrations of hypochlorite. Since α and β are frequently small differences in large numbers, considerable uncertainty is to be expected in the calculated values.

The hplc kinetics also showed double exponential behavior, with initial formation of HPP being followed by conversion of most of it into another, very similar, compound. This second product was shown to be 1-hydroxy-1-phenyl-2-propanone, HPA. The hplc kinetics were carried out with ketone in excess, so the second phase of the reaction represents a process not involving hypochlorite, and occurring after the hypochlorite had been consumed. The wavelength used for hplc analysis was chosen for efficient detection of HPP, and was not efficient for HPA, so the precision of the analytical data for HPA formation in these experiments was low. The rate constants for disappearance of HPP in the hplc kinetics, expressed as second-order rate constants $k_{obs}/[OH^-]$, are similar to the analogous second-order rate constants calculated for the second phase of the uv kinetics starting with propiophenone, and to the second-order rate constants calculated from uv kinetics starting with HPP. This demonstrates that the rate-determining step for both chlorination and isomerization is the same, namely proton abstraction by OH^-.

That the equilibrium constant for isomerization favored HPA, rather than HPP with the carbonyl conjugated with the benzene ring, surprised us but has been confirmed in other work to be reported later.[4]

We have prepared 2-hydroxy-1-phenyl-1-propanone and studied its kinetics of chlorination. The observed rates match the rates of the second phase of propiophenone chlorination, although less precisely than one would wish: see the Discussion.

The initial product of chlorination of 1-phenyl-2-hydroxy-1-propanone is expected to be 2-chloro-1-phenyl-2-hydroxy-1-propanone. This would be expected to have an extremely

[4] J. P. Guthrie and J. Cossar, work in progress.

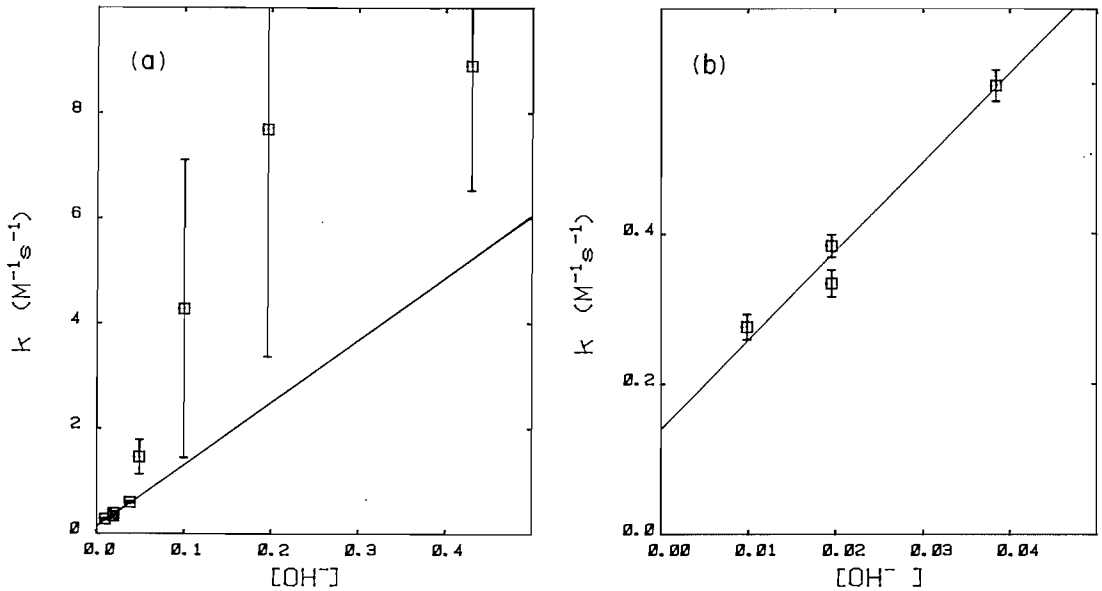

FIG. 4. Chlorination of propiophenone; k_2 at low concentrations of [OCl^-] as a function of [OH^-]. The line is calculated using parameters determined by least-squares fitting. short lifetime before losing chloride ion to give 1-phenyl-1,2-propanedione.

Discussion

For propiophenone, the kinetics of chlorination were not simple first order. The absorbance–time curves could only be described by using two exponential terms. This contrasts with the behavior seen for acetone or acetophenone where the first chlorination step is clearly rate limiting under similar conditions. This complexity arises because of slower reaction of the hydroxyketone formed by hydrolysis of the monochlorinated starting material. The shift in behavior from acetophenone to propiophenone was unexpected.

The second chlorination of propiophenone does not appear to compete with hydrolysis at very low hypochlorite concentrations, as in the kinetics followed by hplc, but can compete at the highest hypochlorite concentrations used for uv kinetics, as shown by the f values deduced from the integrated rate law. It is surprising that the halogenation rate constant is as slow as it seems to be, because the corresponding rate constant for propiophenone is ca. $4 \times 10^4\ M^{-1}\ s^{-1}$. Introducing a chlorine has caused a dramatic decrease in the rate of chlorination. This is likely to be partially a steric effect because the rate constant for the reaction of isobutyrophenone enolate with hypochlorite is ca. $1 \times 10^4\ M^{-1}\ s^{-1}$. Since methyl and chloro are roughly the same size, there could be a steric explanation for a 4-fold decrease in rate constant, but this leaves a 90-fold additional decrease to be explained for CPP. The equilibrium constant for the second halogenation step is likely to be less favorable than for the first (1), and thus, with a smaller thermodynamic driving force, the rate constant is less.

The rate constants for the reaction of hypochlorite with α-hydroxypropiophenone should match, whether they are measured starting with α-hydroxypropiophenone or with propiophenone. Although the observed rate constants are close, there are differences amounting to a factor of two at low [OCl^-]. We have established that hydrolysis of chloropropiophenone is rapid with respect to the observed reaction. It is likely that there is a partitioning of α-chloropropiophenone between

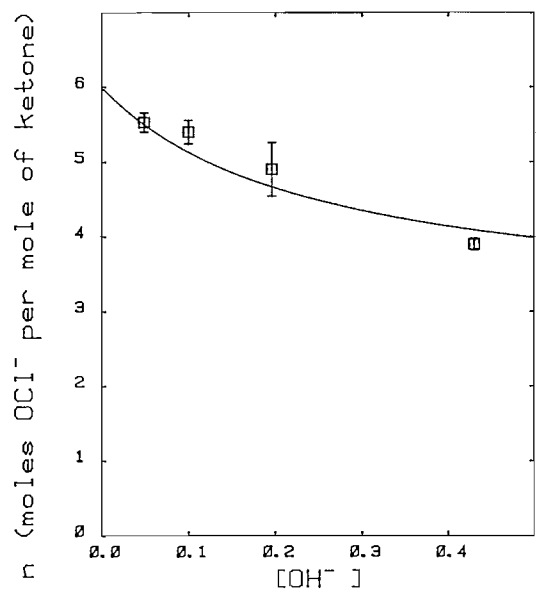

FIG. 5. Chlorination of propiophenone: overall stoichiometry, n, (moles of OCl^- per mole of propiophenone) as a function of [OH^-]. Values for different [OCl^-] and the same [OH^-] were very similar and have been averaged. The line is calculated assuming limiting values of $n = 3$ and $n = 6$ for $n = 3 + 3/(1 + 4.08[OH^-])$.

chlorination and hydrolysis, but it is very probable, by analogy with simpler ketones (2), that hydrolysis of the α,α-dichloropropiophenone is also rapid, and we know[5] that 1-phenyl-1,2-propanedione reacts rapidly. Thus the only intermediate that might reasonably be expected to accumulate is α-hydroxypropiophenone, and hplc experiments have confirmed that this is the only detectable intermediate for the conditions used. Nonetheless, the direct kinetics of α-hydroxypropiophenone chlorination give rate constants that are independent of [OCl^-], while the second phase of the kinetics of propiophenone chlori-

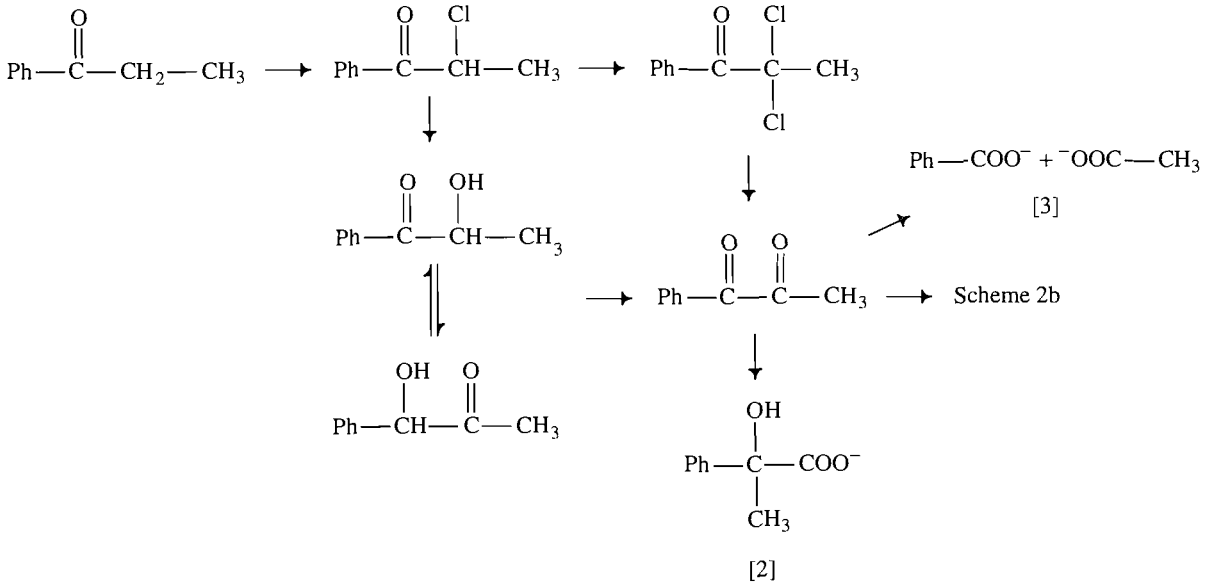
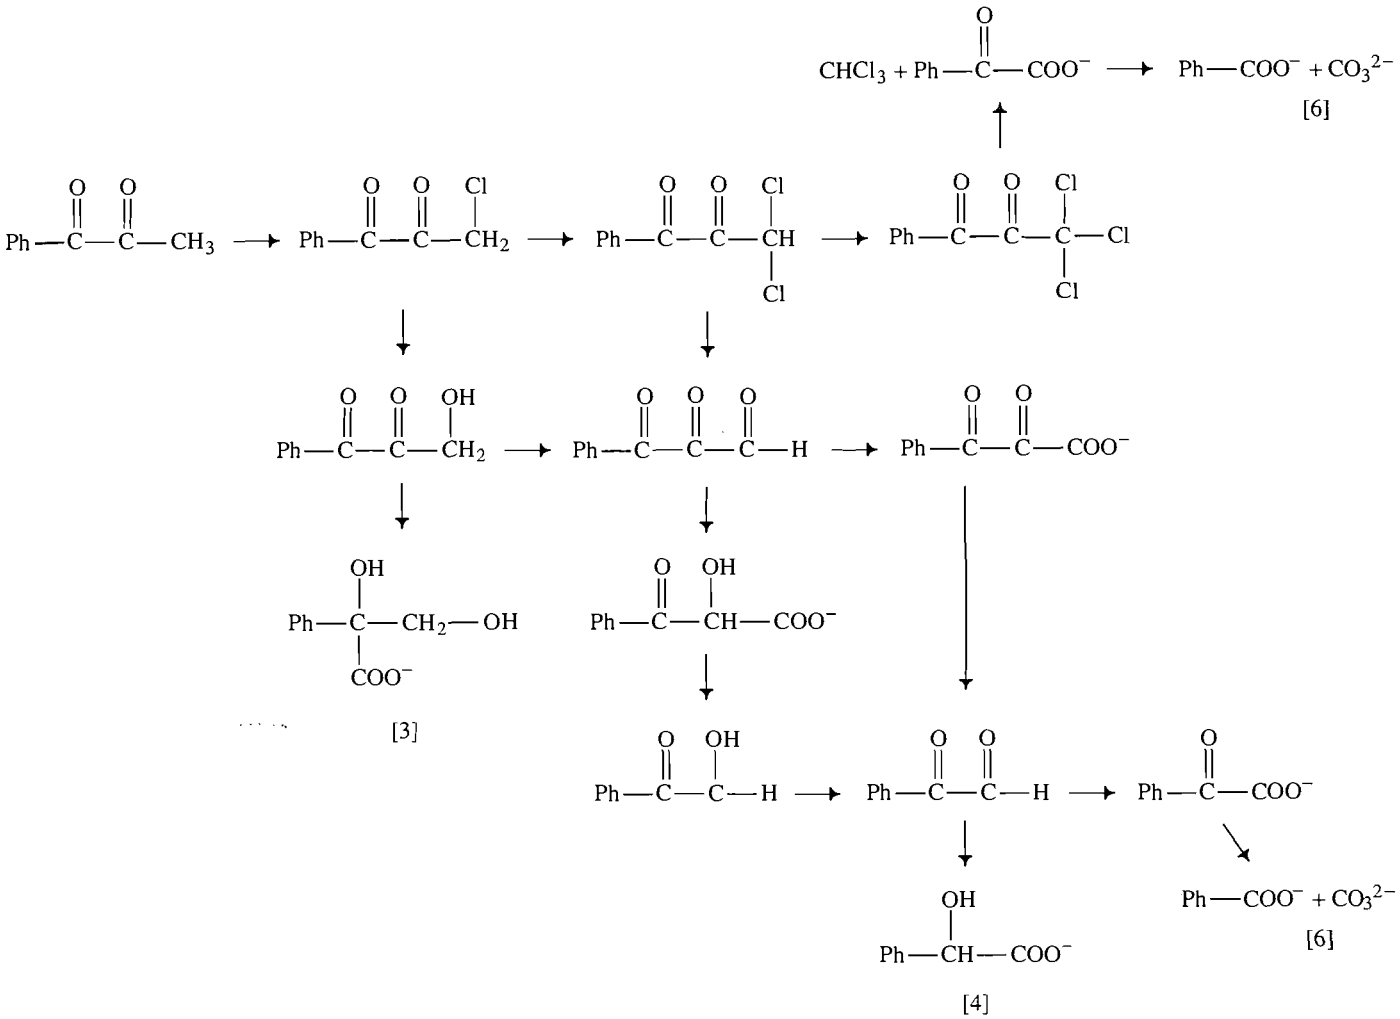


SCHEME 2a



SCHEME 2b

nation gave rate constants that seemed to show a dependence of $[OCl^-]$ at low $[OCl^-]$ although the rates become independent of $[OCl^-]$ at high $[OCl^-]$, and these limiting values matched those found in experiments starting with HPP.

This discrepancy is disturbing, but we suspect that it arises from the complexity of the reaction being followed when one starts with propiophenone. The rate constants for the two phases of the reaction that can be detected differ by factors of 2.6–4.7, which means that only the last small part of the absorbance change is solely determined by the hydroxypropiophenone

reaction, and the parameters determined by the least-squares procedure are highly correlated. Thus we conclude that the uv kinetics starting with propiophenone are of little use in quantitative determination of the kinetics of either the initial or the later reactions, although they are useful in qualitatively defining the process.

For propiophenone, the hydroxyketone accumulated as an intermediate and was the only detectable intermediate in the reaction. The initial reaction is expected to be chlorination to give α-chloropropiophenone; we have shown that hydroxide-catalyzed hydrolysis of the chloroketone is rapid. This hydrolysis would be expected to be slow by the classical S_N2 mechanism, because it takes place at a secondary center (9). It would be expected to be slow by the classical S_N1 solvolysis mechanism because reaction occurs next to a carbonyl group. Although S_N1 reactions at tertiary centers next to a carbonyl are known, they occur at rates similar to those at the analogous secondary centers with the acyl function replaced by hydrogen (10). In any case the reaction rate is first order in hydroxide, so that it cannot be solvolysis. A plausible mechanism is addition of hydroxide, followed by intramolecular nucleophilic displacement.

The alkaline hydrolysis of α-chloropropiophenone has been observed before (11), but under the conditions used (50% aqueous ethanol) the solvolysis was slower, and isomerization of α-hydroxypropiophenone to 1-phenyl-1-hydroxy-2-propanone occurred at very similar rates. Our findings are different in that we observed no isomerization, but the reaction is faster in pure water, and consequently can be carried out at a lower temperature (25°C rather than 60°C).

The rates of deprotonation for Me-CO-CH_3, 0.173 M^{-1} s^{-1} (12), Me-CO-CH_2-Me, 0.038 M^{-1} s^{-1} (13, 14), and Me-CO-$CHMe_2$, 0.0026 M^{-1} s^{-1} (13, 14), or Ph-CO-CH_3, 0.244 M^{-1} s^{-1} (15), Ph-CO-CH_2-Me, 0.0259 M^{-1} s^{-1} (this work), and Ph-CO-$CHMe_2$, 0.00243 M^{-1} s^{-1} (16), 0.0031 M^{-1} s^{-1} (17) show a similar progressive decrease with increasing level of substitution. The relative rates are 1:0.22:0.015 and 1:0.11:0.010 respectively. Propiophenone, pK_a 17.56, is more acidic than acetophenone, pK_a 18.24 (18), 18.4 (3), and isobutyrophenone, pK_a 18.18 (17), 18.26 (16), is very similar to acetophenone. The difference between propiophenone and acetophenone is barely outside experimental error. If it is real, it suggests that there are opposing effects of methyl substitution upon ketone acidity. This seems plausible enough, because methyl groups would stabilize the C=C of the enol or enolate, but would also introduce a destabilizing *cis* interaction with either the O^- or phenyl. There could be interference with solvation of the O^-, and there might be an electronic effect whereby electron release by methyl is acid weakening. With this many effects it is easier to rationalize than to predict. Bordwell *et al.* found pK_a values, in dimethyl sulfoxide as solvent, of 24.7, 24.4, and 26.3 for acetophenone, propiophenone, and isobutyrophenone, respectively (19).

We have been able to determine a pK_a value for propiophenone by analysis of the kinetics of chlorination. The chlorination reactions followed paths that were unexpected because of the remarkably rapid alkaline hydrolysis of the initial chloroketone product. The behavior of propiophenone was further complicated because of unexpectedly slow chlorination of HPP, the first observable intermediate in the reaction. Chlorination of even such a simple substrate as propiophenone is clearly a very complicated reaction, and further investigation will be needed to unravel all of the complexities.

Experimental

Materials

Sodium hydroxide and potassium chloride were reagent grade, used without further purification. Sodium hypochlorite solutions were prepared by bubbling chlorine into aqueous sodium hydroxide; the hypochlorite concentration of the resulting solution was determined either by the absorbance at 292 nm, using $\epsilon_{292} = 352$, or by titration (2). The sodium hydroxide concentration of kinetics solutions was determined by titration (2). All extinction coefficients, ϵ, are in units of M^{-1} cm^{-1}.

Propiophenone, Aldrich "99%", was purified by distillation; bp 107–109°C (20 Torr; 1 Torr = 133.3 Pa); mp 17–18.5°C (lit. (20) mp 18.6°C); uv spectrum in water: λ_{max} 244 (ϵ_{max} 12 000); $\epsilon_{292} = 800$.

2-Chloro-1-phenyl-1-propanone

Propiophenone (13.4 g, 0.1 mol), in diethyl ether (300 mL), was placed in a round-bottomed flask fitted with a reflux condenser and cooled in a Dry Ice – acetone bath while chlorine gas (5.7 g, 0.08 mol) was bubbled in. Cooling was continued with an ice–water bath while HCl gas was fed in slowly for 15 min until the reaction started and the mixture began to reflux. The reaction was nearly complete after 10 min, as judged by the disappearance of color. After 20 min further standing with cooling by the ice–water bath, the solution was washed into a separatory funnel using petroleum ether (bp 60–80°C) (200 mL) and washed once with water (250 mL), once with 1 M $KHCO_3$ (250 mL), and once with 1 M KCl (250 mL). The organic layer was dried with Na_2SO_4 and evaporated to yield a yellow liquid (15.5 g). ^1H nuclear magnetic resonance indicated that the product was 40% propiophenone and 60% monochloropropiophenone. Fractional distillation gave pure material in the final fraction: bp 130–131°C (20 Torr) (lit. (21) bp 126.5–127°C (18 Torr)); uv (in 1 M KCl): λ_{max} 252 nm (ϵ_{max} 11 000 ± 300), $\epsilon_{246} = 10\,000$, $\epsilon_{292} = 1600$; ^1H nmr (200 MHz, $CDCl_3$) δ: 1.74 (3H, d, J = 7 Hz, CH_3-), 5.26 (1H, q, J = 7 Hz, CH_3-CHCl-), 7.42–7.46 (3H, m) and 7.96–8.06 (2H, m, C_6H_5-CO).

2-Hydroxy-1-phenyl-1-propanone

2-Chloro-1-phenyl-1-propanone (1.5 g, 8.9 mmol) was dissolved in methanol (60 mL) and added to 1000 mL of 0.011 M NaOH and stirred vigorously for 10 min at room temperature (23°C). The base was then neutralized with 4 M H_3PO_4 (3 mL) to approximately pH 7. The neutral solution was extracted with $CHCl_3$ (200 mL, 100 mL, 100 mL) and evaporated to yield 1.3 g of a viscous liquid. Thin-layer chromatography (tlc) showed about 80% conversion to the ketol. The mixture was chromatographed on a column of silica (40 g) and eluted with 10% EtOAc in petroleum ether. The second uv-active component eluted was almost pure ketol (1.056 g). This was crystallized from Et_2O at −80°C, filtered in the cold, washed with cold pentane, and dried in vacuum at 0°C, to give 0.784 g (5.22 mmol, 59%) of the ketol, mp 18–19°C; uv (in 1 M aqueous KCl, average of 3 experiments): λ_{max} 246.5 (ϵ_{max} 11 400 ± 100), ϵ_{292} 850; ^1H nmr (200 MHz, $CDCl_3$, TMS) δ: 1.46 (3H, d, J = 7 Hz, CH_3-CH(OH)-), 3.82 (1H, d, J = 6 Hz, HO-), 5.17 (1H, quintet, J = 7 Hz, CH_3-CH(OH)-), 7.45–7.68 (3H, m, aromatic H, *m* and *p*), 7.91–7.97 (2H, m, aromatic H, *o*), 2.09 (0.04 H, s, CH_3- of 1-hydroxy-1-phenyl-2-propanone).

1-Hydroxy-1-phenyl-2-propanone

1-Phenyl-1,2-propanedione-2-oxime (Aldrich, 99%) (2.0 g, 12 mmol) was dissolved in ethanol (15 mL) and added to a solution of KBH_4 (1.0 g, 20 mmol) in 75% ethanol/25% water (20 mL). The solution was heated to 50°C for 3 min; an initially formed yellow color disappeared by this time. The solution was stirred at room temperature for 2 h, and then concentrated to 10 mL, added to 1 M aqueous Na_2CO_3 (30 mL) and extracted with ether (3 × 50 mL). The extracts were dried (Na_2SO_4) and evaporated, yielding 2.1 g of a white solid. Crystallization from 50% ethanol – water (40 mL) gave 1.0 g pure 1-hydroxy-1-phenyl-2-propanone oxime, mp 112–113°C (lit. (22) mp 112°C). A second crop from 35% ethanol gave 0.4 g, mp 111–112°C; ^1H nmr (60 MHz, in 1:1 CD_3OD:$CDCl_3$) δ: 1.9 (3H, s), 4.3 (2H, br), 5.3 (1H, s), 7.3–7.4 (5H, m). 1-Hydroxy-1-phenyl-2-propanone oxime (0.8 g, 4.8 mmol) was dissolved in 90% levulinic acid/10% water (15 mL) and let stand at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

room temperature for 16 h. The solution was added to pH 7 phosphate buffer, 0.5 M in phosphate (250 mL), and extracted with $CHCl_3$ (3 × 120 mL). The extracts were dried (Na_2SO_4) and evaporated, yielding 0.9 g of oily liquid containing about 10–20% levulinic acid. Chromatography on silica (50 g), eluting with a gradient of 0–20% EtOAc in petroleum ether, gave 445 mg of material that was 80–90% pure by ^1H nmr analysis. This material was given a bulb-to-bulb distillation (50–70°C at 0.1 Torr) and then crystallized at low temperature with 2:1 ether/pentane as solvent. In this way 260 g of material, mp 9.5–11°C, was obtained (lit. (23) bp 66°C at 0.2 Torr); uv (1 M KCl) λ_{max} 258 nm (ϵ_{max} 410), ϵ_{292} 235; ^1H nmr analysis showed less than 3% of HPP; ^1H nmr (200 MHz, $CDCl_3$) δ: 2.01 (3H, s, CH_3-CO), 4.58 (1H, d, J = 4 Hz, OH), 5.06 (1H, d, J = 3 Hz, CH), 7.27–7.33 (5H, m, C_6H_5).

Methods

Thin-layer chromatography was carried out using Analtech 250-μm Silica Gel GF plates or Macherey–Nagel Polygram SIL G/UV precoated plastic sheets (0.25 mm). Column chromatography was carried out using Terochem silica gel, no. 1918.

The hplc analyses were carried out using C18 reverse phase columns (Waters Radial Pak), with mixtures of aqueous buffers and methanol as eluting solvent, and uv detection.

Least-squares calculations were carried out using FORTRAN programs written for the purpose; nonlinear least squares and the Marquardt algorithm (24) were used for other than straight line correlations.

Kinetics procedures

All reactions were studied in aqueous solution at 25°C and ionic strength 1.0 M (KCl) using apparatus and procedures previously described (2). Reactions were initiated by injecting (Hamilton syringe) a known amount of a stock solution of the ketone into thermally equilibrated hydroxide/hypochlorite solution in a quartz uv cell.

Hydrolysis of chloropropiophenone

A stock solution of α-chloropropiophenone in methanol was kept in a refrigerator between uses; the uv spectrum did not change, indicating that there was no deterioration. Freshly prepared hydroxide solutions, ionic strength 1 M with KCl, were titrated immediately before use and immediately after the runs, with 0.05 M HCl standardized against tris base. Kinetics were initiated by injecting a suitable amount of stock solution of α-chloropropiophenone into hydroxide solution previously thermostatted in 5- or 10-cm quartz cells; reaction was followed at 246 nm. The kinetics showed a rapid increase in absorbance followed by a slower (300 times slower) decrease in absorbance. The second phase is attributed to equilibration with 1-hydroxy-1-phenyl-2-propanone; further discussion of this behavior will be deferred to a subsequent paper.[4] Data for 20 half-lives of the initial reaction were fitted to a single exponential plus linear tail form of the integrated rate law, leading to the rate constants shown in Table 2.

Chlorination of propiophenone and hydroxypropiophenone

Reactions monitored by uv absorbance were carried out as described above. Reactions monitored by hplc were carried out in a thermostatted flask and samples were taken and injected at suitable intervals using an autosampler. In some cases 1.0-mL samples were taken manually and quenched ($NaHSO_3$ and H_3PO_4) for later analysis. The peaks for HPP and HPA were assigned by comparison with those for authentic samples prepared as described above.

Product studies

Propiophenone (103 mg, 0.766 mmol) was added to 2 L of a solution 0.040 M in NaOH and 0.0050 M in NaOCl. After 40 min (4 half-lives for the first phase of reaction and less than 1 half-life for the second phase) 1 M $NaHSO_3$ solution (10 mL) was added to stop the reaction. Extraction of the alkaline solution with diethyl ether (3 × 300 mL), drying, and evaporation gave 45.8 mg; tlc and nmr analysis showed that the major component was 2-hydroxy-1-phenyl-1-propanone with some propiophenone present. Acidification of the aqueous solution using concentrated HCl (9 mL), followed by extraction with diethyl ether (3 × 300 mL), drying, and evaporation gave 64 mg; tlc identified benzoic acid as a major component, although two other spots were seen. The crude material extracted from the alkaline product solution was purified by column chromatography on silica gel using 1:1 $CCl_4/CHCl_3$ as eluant with a linear gradient from 0 to 5% ethanol. Kugelrohr distillation at 70°C, 0.2 Torr; uv (in 1 M aqueous KCl): λ_{max} 246 nm (ϵ_{max} 10 000); ^1H nmr (200 MHz, $CDCl_3$, TMS) δ: 1.46 (3H, d, J = 7 Hz, CH_3-), 3.80 (1H, br, OH), 5.13 (1H, quartet, J = 7 Hz, CH(OH)), 7.38–7.62 (3H, m, aromatic), 7.82–7.92 (2H, m, aromatic). Exact Mass calcd. for $C_9H_{10}O$: 150.06792; found: 150.06807.

Stabilities in the gas phase of the hydrogen bonded complexes, $YC_6H_4OH\text{-}X^-$, of substituted phenols, YC_6H_4OH, with the halide anions X^- (Cl^-, Br^-, I^-)

GARY J. C. PAUL AND PAUL KEBARLE
Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received May 8, 1990

GARY J. C. PAUL and PAUL KEBARLE. Can. J. Chem. **68**, 2070 (1990).

The equilibria, YPhOH + Br^- = YPhOH-Br^-, involving 26 differently substituted phenols, were determined with a pulsed high pressure mass spectrometer. The $-\Delta G^0$ evaluated from the equilibrium constants represent the hydrogen bond free energies in YPhOH-Br^-. These data and data for X^- = Cl^- and I^-, determined previously in this laboratory, are used to examine the substituent effects on the hydrogen bonding. It was found that the hydrogen bond energies in YPhOH-X^- increase approximately linearly with the gas phase acidities of the phenols, YPhOH. This is in agreement with earlier observations that showed the bond energies in AH-B^-, where AH were oxygen and nitrogen acids and B^- closed shell anions, increase with increasing acidity of AH.

A detailed analysis of the substituent effects, which is possible for YPhOH-X^-, shows that the relationship with the acidity of AH can be divided into two parts. One is the increasing extent of actual proton transfer from AH on formation of the hydrogen bonded complex. Such proton transfer occurs in YPhOH-X^- only for the series X^- = Cl^-. The second effect, which occurs for Cl^- and is dominant for Br^- and I^-, is not directly related to the acidity of the phenols (or AH in general) but depends on a similarity of the substituent effects on the acidity and the stabilization of YPhOH-X^- (or AH-B^- in general). The dominant contribution to YPhOH-X^- stabilization in this case is due to the field effects of the substituents, i.e., π delocalization plays only a small part. Therefore, the correlation with the acidity of YPhOH, where π delocalization is important, is not very close.

Key words: hydrogen bonding, substituent effects, ion–molecule equilibria, stability constants, thermochemistry.

GARY J. C. PAUL et PAUL KEBARLE. Can. J. Chem. **68**, 2070 (1990).

Utilisant un spectromètre de masse pulsé à haute pression, on a déterminé les équilibres YPhOH + Br^- = YPhOH-Br^- impliquant 26 phénols portant des substituants différents. Le $-\Delta G^0$ évalué à partir des constantes d'équilibre représente les énergies libres des liaisons hydrogènes du YPhOH-Br^-. On a utilisé ces données ainsi que celles de l'équilibre X^- = Cl^- et I^-, déterminées antérieurement dans ce laboratoire, pour examiner l'effet des substituants sur les liaisons hydrogènes. On a trouvé que les énergies des liaisons hydrogènes dans les composés YPhOH-X^- augmentent approximativement de façon linéaire avec les acidités des phénols YPhOH en phase gazeuse. Ces résultats corroborent les observations antérieures qui démontrent que les énergies de liaison dans les composés du type AH-B^-, ou AH représente des acides oxygénés ou azotés et B^- un anion ayant sa couche électronique complète, augmentent avec l'acidité de AH.

Une analyse détaillée des effets des substituants, qui est possible pour les composés du type PhOH-X^-, montre que les relations avec l'acidité peuvent être divisées en deux effets. Le premier effet se rapporte à l'augmentation du taux de transfert actuel du proton à partir de l'acide libre lors de la formation du complexe lié par des liaisons hydrogènes. Un tel transfert de protons se produit uniquement dans les composés où X^- = Cl^-. Le deuxième effet qui se manifeste avec l'ion Cl^- et qui est prépondérant dans le cas des ions Br^- et I^- n'est pas directement relié à l'activité des phénols (ou AH en général) mais dépend de la similarité des effets des substituants sur l'acidité et sur la stabilisation du composé YPhOH-X^- (ou du AH-B^- en général). Dans ce cas, la contribution prépondérante à la stabilisation des composés du type YPhOH-X^- est due aux effets de champ des substituants, c.-à-d. la délocalisation des électrons π intervient faiblement. On peut conclure que la corrélation avec l'acidité des phénols YPhOH où la délocalisation π est importante n'est pas parfaite.

Introduction

In the present work Gibbs free energies, $-\Delta G^0_1$, corresponding to the gas phase reaction [1] involving phenols with substituents Y, were determined from measurements of equilibria [1] with a pulsed high pressure mass spectrometer (PHPMS).

[1] YPhOH + X^- = YPhOHX^-

X^- = Br^- and 26 differently substituted phenols were involved in the present determinations. Data for a smaller set of 5 phenols and Cl^- were published earlier (1) and data for 5 phenols and I^- are available from previous unpublished work from this laboratory.[1] These combined results provide quite a complete set of data for the effect of substituents Y on the hydrogen bonding of the phenols to the halide ions. Such data are of interest in a number of areas. For example, hydrogen bonded adduct ions AHX^-, where AH are analytes with protic hydrogens, are observed in analytical mass spectrometric techniques such as Chemical Ionization, Fast Atom Bombardment, Laser Desorption, Thermospray, and Electrospray and therefore knowledge regarding the stability of such ions is useful in these areas. However, our principal interest in these data derives from previous work (1, 2–5), which attempted to establish some general principles concerning the stability of hydrogen bonded ion–molecule complexes involving ions B^- with complete electron shells.

A very simple and useful systemization was the observation that for compounds AH with protic hydrogens such as the oxygen acids (alcohols, carboxylic acids, phenols) the strength of the hydrogen bond to a given negative ion B^-, in the complex AHB^-, increases regularly with increase of the gas phase acidity of AH (1, 2–5). Thus, a plot of the hydrogen bond energies in complexes to Cl^-, involving a series of AH as diverse as HOH, alcohols ROH, carboxylic acids RCO_2H, and substituted phenols, shows a regular, monotonic increase of

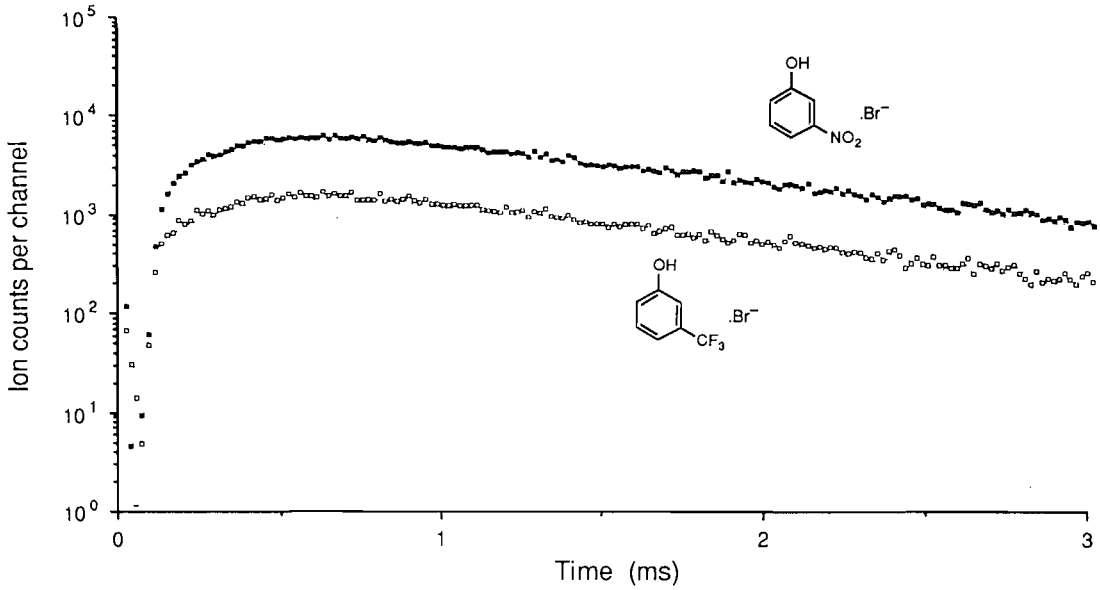

FIG. 1. Raw data plot: ion intensity versus time after the 20 μs ionizing electron pulse. Obtained with a gas mixture of 2.6 Torr CH_4, 0.9 mTorr 3-NO_2PhOH, 2 mTorr 3-CF_3PhOH, and 3.4 mTorr CH_2Br_2 at 423 K. Br^- ions result from dissociative electron capture by CH_2Br_2. The Br^- transfer equilibrium [2] becomes established some 0.3 ms after the electron pulse. The decrease of ion intensity after ~0.5 ms is due to diffusion of the ions to the wall.

bonding with increasing gas phase acidity of AH (4). Similar relationships involving an even larger variety of compounds AH and F^- and Cl^- have been obtained by Larson and McMahon (6).

On trying to understand the nature of this relationship, it is useful to restrict the AH to a series of closely related compounds such as the substituted phenols. The first investigation of this series (1) involved Cl^-. The YPhOHCl$^-$ series differs from the Br^- and I^- series in one important respect. The gas phase acidity of HCl is higher than that of unsubstituted phenol (7). However, strongly acidifying substituents such as -CN and -NO_2 lead to phenols whose acidity is higher than that of HCl (7). Therefore, in the YPhOHCl$^-$ series there will be a significant increase of proton transfer from the phenols to Cl^- with increasing acidity of the phenols.

In a series of AH with X^- for which a large increase of the extent of proton transfer occurs, the increased exothermicity of the complex forming reaction may derive largely from the exothermicity of the proton transfer. In such a case the increase of the "hydrogen bond energy" AH-X^- as measured by $-\Delta G_1^0$ will directly follow the acidity of AH but the cause will be trivial. Of more interest is the question whether the bond energy is related to the acidity in the absence of substantially increased proton transfer. Due to the much higher gas phase acidity of HBr and HI, relative to HCl (7), the formation of the complexes in reaction [1] involving Br^- and I^- is expected to involve at all times complexes corresponding largely to AH-X^-, i.e., involving a much lower proton transfer increase. A comparison of the substituent effects on $-\Delta G_1^0$ for these series with that for Cl^- should allow one to unravel the importance and nature of the effects in the absence of proton transfer.

Interesting theoretical studies of complexes hydrogen bonded to Cl^- have been reported by Hirao and co-workers (8). Hydrogen bonded complexes of the type ROHX$^-$ form also in dipolar aprotic solvents. For a relevant study of YPhOHCl$^-$, see Kolthoff and Chantooni (9); for data on phenol phenoxide complexes, see Bordwell *et al.* (10).

Experimental

The measurements of equilibria [1] for $X^- = Br^-$ were performed with PHPMS apparatus that has been described in detail previously (11). The measurement methodology was similar to that used in the earlier work (1).

In addition to [1], equilibria [2] also were determined.

[2] YPhOH-Br^- + Y′PhOH = YPhOH + Y′PhOH-Br^-

These equilibria provide ΔG_1^0 differences, i.e., $\Delta G_2^0 = \Delta G_1^0$(Y′PhOH) $- \Delta G_1^0$(YPhOH).

The time dependence of the ion intensities observed for one reaction [2], involving 3-CF_3 and 3-NO_2 phenol, is shown in Fig. 1. The vertical distance between the two ion intensities becomes constant for $t > 0.3$ ms. In the logarithmic ion intensity plot used, constant distance means a constant ion ratio and this indicates the establishment of equilibrium [2].

The Br^- ions required for the measurements of [1] and [2] were obtained by adding ~1 mTorr of CH_2Br_2 (1 Torr = 133.3 Pa) to the methane carrier gas reaction mixture. Dissociative electron capture of near thermal electrons by CH_2Br_2 leads to formation of Br^-.

Checks for the invariance of the equilibrium constant K_1 with the partial pressure of the given phenol are shown in Fig. 2. Similar checks involving different partial pressure ratios of the two reacting phenols were also performed for equilibria [2].

The $-\Delta G_1^0$ involving $X^- = I^-$ were determined in earlier work[1] using similar techniques. For a description of equilibria measurements involving I^- and ROH and RCO_2H molecules, see Caldwell and Kebarle (12).

Results and discussion

(a) Results

The $-\Delta G_1^0$ values obtained from measurements of equilibrium constants K_1, see Experimental, and the equation: $\Delta G^0 = -RT \ln K$, involving Br^-, are shown on a scale of increasing $-\Delta G_1^0$ values in Fig. 3. All measurements were performed at 150°C (423 K). The $-\Delta G_1^0$ values will be called bromide affinities, BrA. Values for BrA only up to ~14 kcal/mol could be obtained by the direct measurements of equilibria [1]. As the

[a]Data for Br^-, present work, Cl^-, refs. 1, 5, I^-, ref. 2. Standard state 1 atm, 423 K. ΔH_1^0 can be approximately evaluated from: $\Delta H_1^0 = \Delta G_1^0 + T\Delta S_1^0$, where $-\Delta S_1^0 \approx 25$ (Cl^-), 23 (Br^-), and 21 (I^-) (cal K^{-1} mol^{-1}). Entropy changes from ref. 5 (Cl^-), estimated (Br^-), ref. 2 (I^-). Furthermore, ΔS_1^0 is approximately constant for whole substituent series and for given X^-, see ref. 1.

BrA increases, K_1 increases, and beyond a given point the Br^- intensity becomes too small for reliable measurements. The BrA shown in Fig. 3 that are larger than 14 kcal/mol were obtained from equilibria [2], which provide relative BrA. By combining the relative BrA with the absolute BrA due to equilibria [1] a complete scale of BrA extending up to 19 kcal/mol for the most acidic phenol, 4-$NO_2C_6H_4OH$, was obtained, see Fig. 3. These BrA's are summarized in Table 1. The more limited data for the iodide affinities[1] and the chloride affinities (1) are given in Table 2, which also includes the corresponding bromide affinities to facilitate an easy comparison of the three sets of data.

(b) Hydrogen bond energy in YPhOH-X^-, gas phase acidities, and substituted effect analysis

A plot of the hydrogen bond energies in YPhOH-Br^- relative to the unsubstituted phenol versus the relative gas phase acidities of the phenols (7) is shown in Fig. 4. A fairly good correlation (correlation coefficient $r = 0.956$) is observed. However, a much better correlation ($r = 0.998$) is obtained in Fig. 5 where the plot is against the acidities of the substituted benzoic acids.

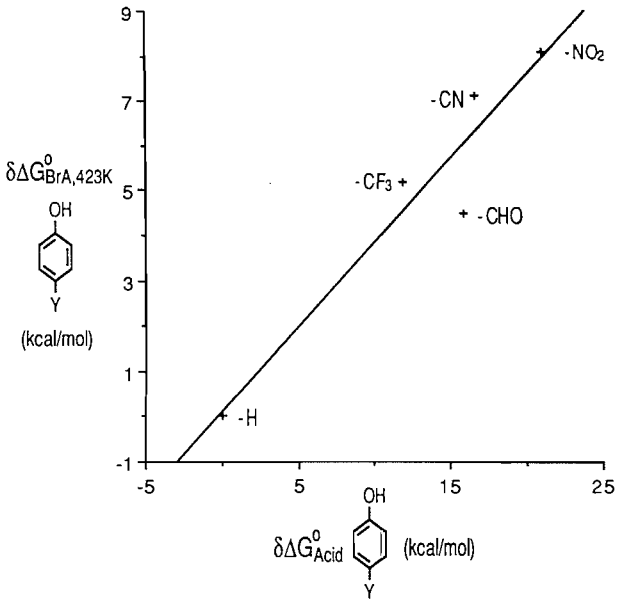

FIG. 4. Plot of $\delta\Delta G^0$ for Br^- hydrogen bonding to phenols versus relative gas phase acidities of phenols.

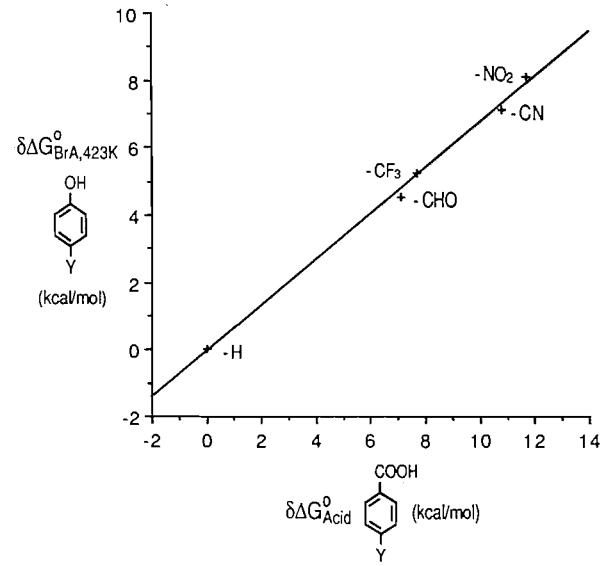

FIG. 5. Plot of $\delta\Delta G^0$ for Br^- hydrogen bonding to phenols versus relative gas phase acidities of benzoic acids.

This comparison reveals at a glance that when extensive proton transfer from AH to X^- is not involved, as is the case for $X^- = Br^-$, see Introduction, the relationship of H bond Gibbs energies with the acidity of the AH (YPhOH in the present case) is only indirect, i.e., a consequence of a similarity of the substituent effect on the acidity and the hydrogen bonding ability. The much better correlation with the benzoic acids means a greater similarity with the substituent effects on the acidity of the benzoic acids. The causes for the better agreement with the benzoic acids can be deduced from a comparison of the deviations for specific substituents observed in Figs. 4 and 5.

[a]ρ values obtained form linear regression analysis of eq. [3], where $\delta\Delta G^0$ corresponds to experimentally determined ΔG^0 for reaction: $PhOHX^- + YPhOH = PhOH + YPhOHX^-$. Since $\delta\Delta S^0 \approx 0$ (1), $\delta\Delta G^0$, even though determined at 423 K, is also valid at 298 K, i.e., $\delta\Delta G^0_{298} \approx \delta\Delta G^0_{423}$.
[b]Correlation coefficient.
[c]Gas phase acidities.

However, a more general examination of the substituent effects in the hydrogen bonded complexes, $YPhOH\text{-}X^-$ is even more illuminating and provides a more comprehensive view.

Taft *et al.* (13) have developed and refined greatly the analysis of substituent effects and it has been shown (14) that the approach is theoretically justified. The present analysis is based on Taft and Topsom (13*a*). The separation of the substituent effect $\delta\Delta G^0$ into contributions due to π electron delocalization (resonance), R, and field/inductive effects, F, for a substituent in a given position to the functional group, either *para*- or *meta*-, is obtained from eq. [3], which includes also polarizability, α, effects.

$$[3] \quad -\delta\Delta G^0 = \rho_R\sigma_R + \rho_F\sigma_F + \rho_\alpha\sigma_\alpha$$

σ_R, σ_F, and σ_α are reaction system independent parameters that rank the resonance, field, and polarizability capacity of the given substituent; these values have been tabulated (13*a*). The parameters ρ_R, ρ_F, and ρ_α depend on the given reaction, and their magnitude is determined by regression analysis for the best fit when the experimentally determined $\delta\Delta G^0$ for the given reaction system is substituted into eq. [3].

The experimentally determined $\delta\Delta G^0$ of the bromide affinities plotted versus the $\delta\Delta G^0$ calculated with the best fit ρ parameters for *para* substituents are shown in Fig. 6. A very good correlation (correlation coefficient $r = 0.991$) is observed. The polarizability contributions were neglected in the fit shown. A somewhat better fit, $r = 0.995$, is obtained with inclusion of the polarizability. The ρ parameters for both fits are given in Table 3. Since the emphasis of the present discussion will deal with the changes of ρ_R and ρ_F for the different systems and the ρ_α values in all cases are very small, see Table 3, the polarizability will not be considered in the further discussion.

A plot of $\delta\Delta G^0$ of the BrA for *meta* substituents and the best fit π parameters is shown in Fig. 7. A very good fit is obtained also for this system.

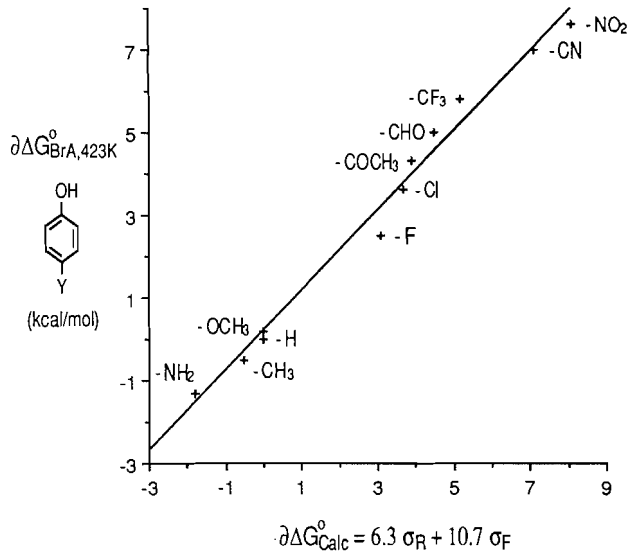

FIG. 6. $\delta\Delta G^0$ for Br^- and substituted phenols versus $\delta\Delta G^0$ calculated with Taft σ parameters, see eq. [3]. Substituents in *para* position.

Since a much more restricted number of substituents was used in the determinations (ref. 1 and footnote 1) involving Cl^- and I^- and since the ρ values depend somewhat on the number of substituents included in the fit, regression analyses for these three ions and the same restricted set of substituents, in *para* position, were obtained. The resulting plots for Cl^- and I^- are shown in Figs. 8 and 9. The ρ values and the correlation coefficients from the restricted fits for Cl^-, Br^-, and I^- are given in Table 3. A comparison of the ρ_R and ρ_F values for Br^-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

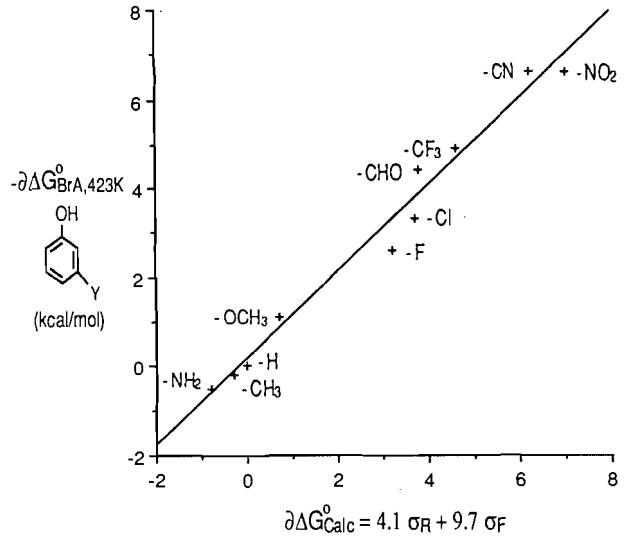

FIG. 7. $\delta\Delta G^0$ for Br^- and substituted phenols as in Fig. 6 but for *meta* substituents.

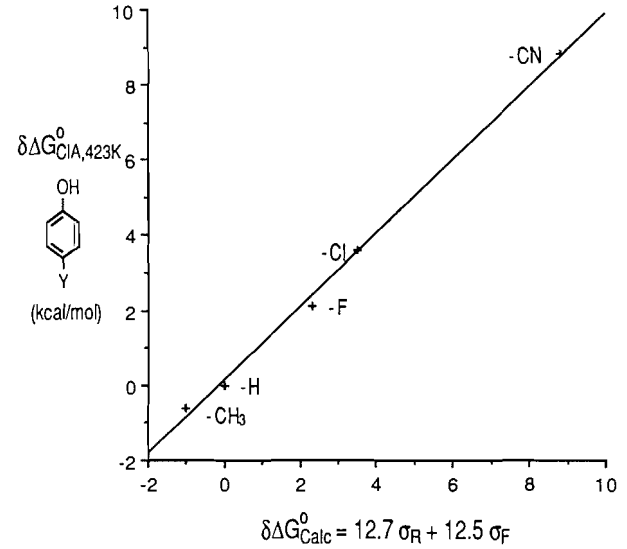

FIG. 8. Same as Fig. 6 but for Cl^- and *para* substituents.

between the extended plot, Fig. 6, and the restricted plot, see Table 3, shows that the ρ_F is essentially the same while ρ_R changes only a little, i.e., from 6.3 to 7.6. This indicates that the restricted plots for results for Cl^-, Br^-, and I^- provide ρ_F and ρ_R values that are still quite meaningful.

Also included in Table 3 are the ρ values for the substituent effect on the gas phase acidities of phenols and benzoic acids obtained by Taft and Topsom (13*a*). Examining first the data for the *para* position, one finds that the ρ_F values decrease in the following order: phenol acidity 18.6, benzoic acidity 15, X^- affinity to phenols: Cl^- 12.5, Br^- 10.4, I^- 9.7. This order agrees with expectation, when one considers the gradually increasing delocalization of the negative charge (phenols to benzoic acids) and the increasing remoteness of the negative charge from the substituent, present for the whole series.

Considering the ρ_R values, it is significant to note that the X^- affinity plots for *para* substituents, which in all cases include both π donor and π acceptor substituents, see Figs. 6, 8, 9, give good linear relationships. The same is true for the gas phase

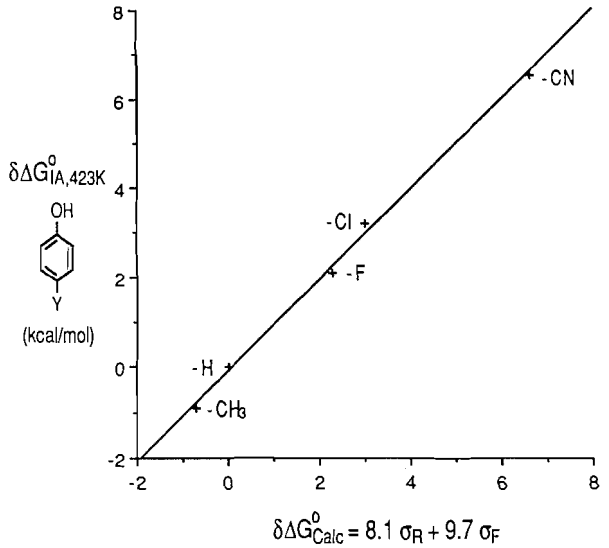

FIG. 9. Same as Fig. 6 but for I^- and *para* substituents.

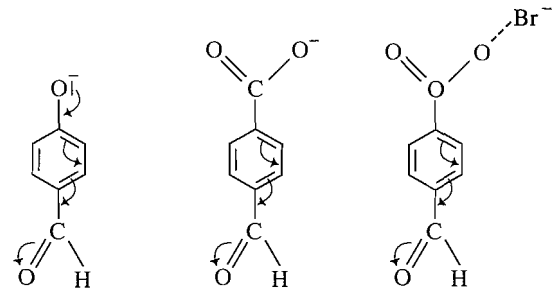
acidities of *para* substituted benzoic acids, see (13*a*) values reported in Table 3. On the other hand, it is known (13*a*) that for the *para* substituted phenol acidities a single straight-line relationship cannot be obtained for both strong π donors, i.e., -OH, $-OCH_3$, $-NH_2$, and strong π acceptors, i.e., CN, NO_2, CHO, because the reaction centre, O^-, is very strongly π donating to the benzene ring and thus suppresses π donation by π donor substituents (13*a*). The separate ρ_R values for the phenols (13*a*) given in Table 3 are $\rho_R = 22$ for π donor and $\rho_R = 49$ for π acceptor. Comparing the π acceptor value with the ρ_R values for benzoic acids, $\rho_R = 14.6$, and the X^- affinities, $\rho_R = 12.7$ (Cl^-), 7.6 (Br^-), 8.1 (I^-), one finds that the latter are very much smaller and fairly close together. This result could have been anticipated from the plots of the Br^- affinities versus the acidities of phenols and benzoic acids, see Figs. 4 and 5.

The similarity between the ρ_R values for benzoic acids and the X^- affinities reflects the expected dominant stabilization for π accepting substituents in these systems, see resonance structures **II** and **III**.



The benzoate anion and the $YPhOHX^-$ complexes lack the direct, into the ring π donation, by the negative functional group exhibited by the phenoxides, structure **I**. The stabilizing effect of π accepting substituents for the $YPhOHX^-$ systems thus derives only from a π shift from the ring into the substituent, which is induced by the negative charge on X^- and is similar to that occurring in the benzoate anions. On this basis one expects NO_2 and CHO, the most strongly π accepting substituents (σ_R: CN, 0.10; NO_2, 0.18; HCO, 0.19, from ref. 13*a*), to show the largest deviations in the X^- affinity –

phenol acidity plot, Fig. 4, and exactly this is found to be the case.

The ρ_R values for the π-YPhOHX$^-$ systems are Cl$^-$, 12.7; Br$^-$, 7.6; I$^-$, 8.1. On the basis of the increasing remoteness of X$^-$ in the above series one would have expected the values to decrease monotonically, i.e., ρ_B (Br$^-$) $\geq \rho_R$ (I$^-$). The small reversal of the experimental result for this pair is probably due to experimental error. The observed much larger ρ_R (Cl$^-$) probably also includes the effect of an actual partial proton transfer from YPhOH to Cl$^-$, which occurs for this series.

To provide an illustration for the actual magnitudes of the resonance $R = \rho_R\sigma_R$ and $F = \rho_F\sigma_F$ contributions to $\delta\Delta G^0$, see eq. [3], the R and F values evaluated from the ρ values in Table 3 and σ values of Taft (13*a*) for the substituent effect on the phenols hydrogen bonded to Br$^-$ are shown in Table 4. The corresponding R and F terms for the gas phase acidities of *para* substituted phenols and benzoic acids are also provided for comparison. Examination of the values in Table 4 shows that the F effects are almost completely dominant for both the *para* and *meta* substituted YPhOHBr$^-$. This explains the similarity between the $\delta\Delta G_3^0$ values for the *meta* and *para* YPhOHX$^-$ systems, see Table 4 and Figs. 6 and 7, and also the similarity of those with the substituent effects on benzoic acid acidities, which are also dominated, but somewhat less so, by the F effects, see Table 4.

The stabilizing effect of electron-withdrawing substituents in YPhOHBr$^-$ for *ortho* substituents is somewhat smaller than that for *meta* $\approx$ *para*, see Table 1. This holds for both small size substituents like F and large substituents like NO$_2$. Since the field effect is the dominant factor in all these systems, the somewhat smaller stabilization for the *ortho* compounds should be due to the unfavorable orientation of the dipole, produced by the substituent, relative to the negative charge, i.e., Br$^-$.

Conclusions

The findings for the YPhOHX$^-$ systems can be generalized to AH.B$^-$ hydrogen bonded complexes. For a given related series of AH with increasing gas phase acidity, the increased strength of the hydrogen bond, as measured by the energy required for the dissociation to AH + B$^-$, consists of two contributions. One is the gradually increasing extent of actual proton transfer from AH to B$^-$ on formation of the complex. This effect is very important when the acidity of BH is close and becomes smaller than that of AH. The second contribution can be best observed when it is dominant, i.e., when the acidity of BH is much larger than that of AH for the whole AH series. This contribution is due to effects in AH that increase the dipole in A$^-$-H$^+$ and thus the hydrogen bond energy. The major effects in this case are field type effects in AH. The negative charge of the approaching B$^-$ also induces some π delocalization in AH. This R effect is less important. Since changes of the structure of AH that increase the acidity of AH also increase the favorable F and the less important R stabilization in AH B$^-$, the hydrogen bonding in AH B$^-$ tracks, but only partially so, the acidity of AH. The substituted phenols-X$^-$ complexes are especially useful since for these systese a convincing dissection of the above effects is possible. This is so because the contrast between the effects on acidity and hydrogen bonding is especially strong, due to the large R effect in the phenoxides, see structures **I**–**III**, which develops only after complete deprotonation of AH. Somewhat similar and even larger differences between hydrogen bonding ability and acidity are observed for the carbon acids, where the acidity may be almost entirely due to resonance stabilization after deprotonation, as is the case for cyclopentadiene (4).

Introduction

A systematic study of the effect of methyl and ethyl substituents on the conformations of conjugated dienes by ultraviolet photoelectron spectroscopy (UPS) and the computational methods AM1 and MMX was initiated recently (1). This work was undertaken for several reasons. The initial goal was to establish whether or not AM1 (2) is useful for carrying out conformational analysis and detailing conjugative and homoconjugative interaction in dienes. This was to be achieved by correlating the results of computational studies with the UPS of dienes whose conformational dynamics are well defined. The overall objective was to establish whether or not a combination of AM1 and UPS can be used to elucidate the structure of highly alkylated dienes, especially when there are no vicinal protons on the double bonds; the classical approach of using the magnitude of the coupling constant to determine that stereochemistry cannot be used in these cases. In our view these studies are also timely because there is renewed interest (3–5) in the conformational analysis of dienes, a subject that occupied the attention of experimentalists and theoreticians for decades.[4] Our plan was to study a series of alkyl-substituted 1,3-dienes computationally by AM1, to calculate heats of formation as a function of the dihedral (twist) angle between the double bonds, to identify the stablest conformations, and to calculate the π_-, π_+ splittings for planar (*s-cis* and *s-trans*) and nonplanar conformations. By comparing these values to the splittings obtained experimentally by UPS (see ref. 6 for a comprehensive review on conformational analysis by UPS), we hoped to establish whether combined AM1/UPS studies will be useful generally for obtaining information on conformational dynamics and conjugative and homoconjugative interactions of alkyl-substituted polyenes in the gas phase, and, of course, for determining structure. In fact, a study of this type recently led to a redetermination and correction of the photoelectron (pe) spectrum of (*Z*)-2-methylpentadiene (1).

Encouraged by this initial success, we undertook a study of four isomeric dimethyl-2,4-hexadienes, the products of photochemical ring opening of 1,3,4,4- and 1,3,3,4-tetramethylcyclobutenes (**1** and **2**, respectively) (7), to extend this research to more highly alkylated butadienes. Our strategy was to study (*E*)-2,3-dimethyl-2,4-hexadiene (*E*-**3**) and (*Z*)-2,3-dimethyl-2,4-hexadiene (*Z*-**3**) obtained from **1** to establish whether the results of an AM1/UPS study correlate with the structures of these dienes assigned previously with a high degree of certainty (8). This was to be followed by an identical study of the isomeric 2,4-dimethyl-2,4-hexadienes obtained from **2** in order to identify the (*E*) and (*Z*) isomers, which, as far as we were aware, had not yet been accomplished with certainty (9). The results of our study are documented and discussed in this publication.

separated by preparative gc (7). In Fig. 1 are shown pe spectra (a) and (b) of *E*-**3** and *Z*-**3** obtained from **1**. Figure 2 shows the pe spectra of the hexadienes obtained from **2**. Table 1 lists the ionization energies (IE's) corresponding to the first three low-energy bands and the π_-, π_+ splittings (ΔIE's); it is seen that these dienes exhibit a range of splittings.

Computational studies

Planar s-trans-*dienes*

To determine how accurately AM1 computes splittings and rotational barriers of dienes, several studies were carried out. Firstly, the splittings of a series of planar *s-trans* dienes (2-methylbutadiene, 2,3-dimethylbutadiene, (*E*,*E*)-2,4-hexadiene, and 2,5-dimethyl-2,4-hexadiene) were obtained computationally, assuming Koopmans' theorem, as the difference between the eigenvalues (ϵ_i's) of the HOMO (π_-) and the NHOMO (π_+). The structures were fully optimized in all cases. For these dienes, a π_-, π_+, σ ordering of the highest three levels is predicted by AM1. In Table 2 are listed the eigenvalues

TABLE 1. Vertical ionization energies of dimethyl-2,4-hexadienes

[a]Estimated error ±0.025 eV.
[b]π_+, π_- splitting.

of π_-, π_+, and the first σ level, the difference between π_- and π_+, and the experimentally determined ΔIE_v's (10). On this basis it is clear that AM1 predicts splittings of planar *s-trans* dienes with good accuracy, although the computed eigenvalues are approximately 0.6 eV higher than the IE_v's. It should be noted here that AM1 assigns the three highest MO's of butadiene

TABLE 2. Vertical ionization energies and eigenvalues of dienes

as π_-, σ, π_+. This is not in accord with Heilbronner's analysis (11) or the results of *ab initio* calculations (12), which yield a π_-, π_+, σ ordering, as does MNDO.[5]

Planar and twisted s-cis *dienes*

Table 2 also lists the π_- and π_+ eigenvalues of 1,2-dimethylenecyclobutane, 2,3-dimethylenebicyclo[2.2.1]heptane, and 1,2-dimethylenecyclohexane computed by AM1, along with the experimentally determined IE_v's and the ΔIE_v's (13, 14). While AM1 computes the splittings for dimethylenecyclobutane and dimethylenenorbornane with good accuracy, MNDO computes the twist angle and the splitting for dimethylenecyclohexane with greater accuracy than AM1.

Butadiene

Figure 3 shows how ΔH_f for butadiene depends on the C1—C2—C3—C4 dihedral (twist) angle. Beginning with the planar *s-cis* conformer, the dihedral angle was incremented 15° and the geometry was optimized at each stage.

The heats of formation are reproducible to ±0.1 kcal regardless of the increment (15° or 30°) or the starting dihedral angle (0° or 180°). It should be pointed out that identical ΔH_f's were computed when the optimization criteria were increased by 10 times and the SCF criteria by 100 times (PRECISE). The values for the barrier to rotation (1.97 kcal) and the difference in energy between the planar *s-trans* and *s-cis* conformers (0.81 kcal) are lower than the experimental values for the barrier (3.90–4.70 kcal) (15, 16) and the energy difference (2.50–3.08 kcal) (15, 16). By subtracting scaled corrections of 1.8, 1.4, 1.0, 0.7, 0.4, and 0.2 kcal from the ΔH_f values computed for dihedral angles of 180°, 165°, 150°, 135°, 120°, and 105°, respectively, the rotational barrier and the *s-trans* − *s-cis* energy difference for butadiene can be brought into the experimental ranges. This also brings the computed ΔH_f for butadiene (29.9 kcal/mol before correction) closer to the experimental value of 26.6 kcal/mol (17).

*(*E*)-2,3-Dimethyl-2,4-hexadiene (*E*-**3**)*

Figure 4(a) shows how ΔH_f of (*E*)-2,3-dimethyl-2,4-hexadiene (*E*-**3**) obtained computationally depends on the C2—C3—C4—C5 dihedral (twist) angle; conformation *E*-**3**-c1 is the starting point (dihedral angle 180°) with the conformations

[5]This work.

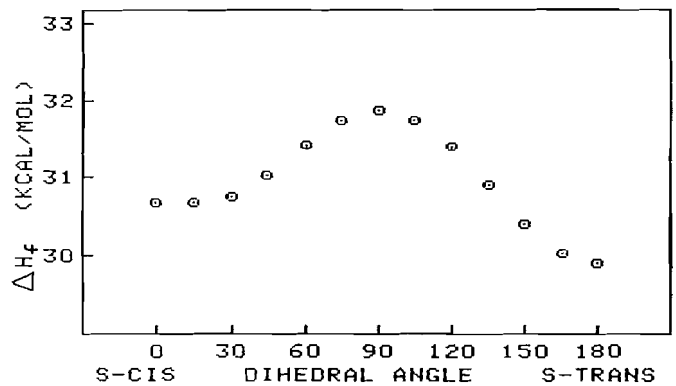

FIG. 3. Plot of ΔH_f of butadiene versus dihedral angle.

of the methyl groups locked as indicated in this structure. On the basis of these calculations, *E*-**3**-c1 is predicted to be the stablest conformation of *E*-**3** and it should be preferentially populated in the gas phase. In principle, the ΔH_f values for the various conformers with dihedral angles between 180° and 90° could be adjusted by the corrections estimated for butadiene. However, it is important to point out here that it has been shown experimentally and computationally that alkyl substituents at C2 and C3 lower the barrier to rotation and the difference in energy between twisted *s-cis* and planar *s-trans* conformations of 1,3-dienes (4, 18). Thus the correction factors estimated for butadiene should be considered as maximum values when applied to methylated derivatives, and their use in adjusting the computed ΔH_f values for *E*-**3** will not alter the conclusion reached on the basis of Fig. 4(a). Figure 4(b) shows plots of the eigenvalues of the HOMO, NHOMO, and the first σ level as a function of dihedral angle. It is important to note here that AM1 computes a π_-, π_+, σ order for these highest occupied MO's. The HOMO (π_-) and NHOMO (π_+) eigenvalues exhibit different dependencies on the twist angle (Fig. 4(b)) and the splittings range from 2.15 to 0.5 eV as shown in Fig. 4(c); as shown in Fig. 4(b) the π_- eigenvalue is less sensitive to the twist angle than the π_+ eigenvalue; the eigenvalue of the first σ level is essentially insensitive to twist angle and is slightly stabilized as the dihedral angle approaches 90°. That the computed splitting (2.15 eV) (Table 3) for planar *s-trans-E*-**3** is in good

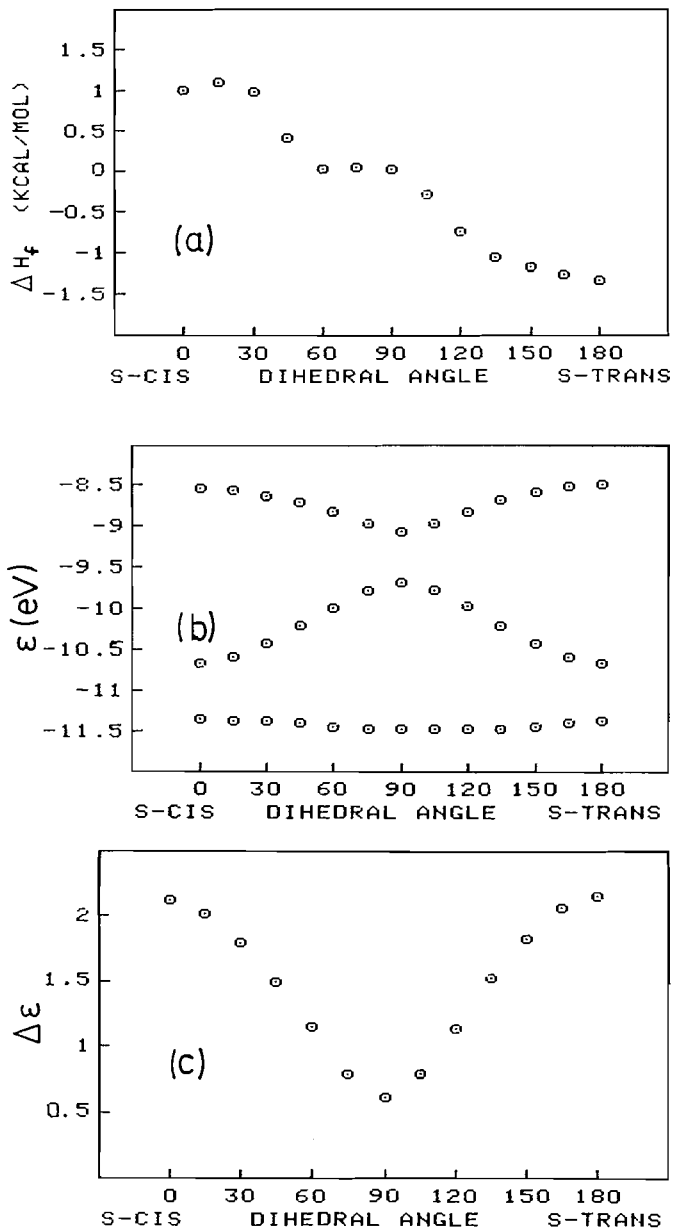

FIG. 4. (a) Plot of ΔH_f of *E*-**3** versus dihedral angle; (b) plot of π_-, π_+, and σ eigenvalues of *E*-**3** versus dihedral angle; (c) plot of π_-, π_+ splitting of *E*-**3** versus dihedral angle.

agreement with the ΔIE_v (2.04 ± 0.05 eV) obtained experimentally establishes the validity of the AM1 calculations. As shown in Fig. 4(b), the HOMO will show a lower sensitivity to twist angle than the NHOMO and the "splitting" will not be zero at a dihedral angle of 90°. As is seen from the HOMO of *E*-**3** (Fig. 5(a)), the C-H's of the C8 methyl interact homohyperconjugatively with the π-system. This is not the case for the NHOMO (Fig. 5(b)). Drawings of the HOMO and NHOMO of *E*-**3** were obtained using DRAW3D (19), a modified version of DRAW (20), which generates MOs by stacking MO contours generated by DEN3D (19); DEN3D is a modified version of DENSITY (21). In these plots, the 0.01 au contours are stacked. According to Heilbronner's analysis (11),

this interaction is the source of the reduced splitting observed for planar *s-trans*-1,3-dienes bearing methyl groups at C2 and C3, relative to dienes substituted with methyl groups at the terminal carbons. For example, the splittings of butadiene, 2,4-hexadiene, 2-methylbutadiene, and 2,3-dimethylbutadiene are 2.47, 2.47, 1.96, and 1.58 eV, respectively (10). This homohyperconjugative interaction would account for the fact that the π_-, π_+ splitting of *E*-**3** (2.04 ± 0.05 eV) is 0.4 eV less than the splitting of 2,5-dimethyl-2,4-hexadiene (2.45 eV) (10). It is important to note that this differential stabilization of the HOMO in the planar *s-trans* conformation also accounts for the different sensitivities, relative to *E*-**3**, of the HOMO and NHOMO IE's of substituted dienes where twisted conformations are preferentially populated in the gas phase. That the splitting is not zero at a dihedral angle of 90° is primarily due to the fact that the double bonds are unequally substituted; one bears four alkyl substituents and the other only two. Consequently, for the 90° conformation, the HOMO should be localized on C1, C2, C3, C7, and C8 and the NHOMO on C4, C5, and C6. MO's generated by DEN3D/DRAW3D (not shown) for this conformation show that this is the case.

The effect of the C8 methyl conformation on the HOMO and NHOMO eigenvalues was probed by driving the H12—C8—C3—C2 dihedral angle through 15° increments with the other dihedrals locked as shown in *E*-**3**-c1. We find that the eigenvalues of both MO's are essentially insensitive to the twist angle. This study shows that the homohyperconjugative interaction, which results in a stabilization of the HOMO by 0.4 eV, is essentially independent of conformation of the C8 methyl group.

(Z)-2,3-Dimethyl-2,4-hexadiene (Z-3)

Figure 6(a) includes two plots; one (⊙) shows the dependency of ΔH_f of (*Z*)-2,3-dimethyl-2,4-hexadiene (*Z*-**3**) on dihedral angle. In this case the starting point is *Z*-**3**-c1 with the conformations of the methyl groups locked as shown in this structural formula. Since there is buttressing of the methyl groups in this case, a study was carried out with full optimization of all parameters as the C2—C3—C4—C5 dihedral angle was incremented by 15°. These results (●) are also included in Fig. 6(a). It is seen that conformers with dihedral angles in the region of 105°–135° should be preferentially populated for *Z*-**3**. This conclusion is reached even if the heats of formation of the conformers with dihedral angles ranging from 90 to 180° are adjusted downward by the corrections deduced for butadiene. Here, as in the case of *E*-**3**, AM1 computes a π_-, π_+, σ order for the three highest occupied MO's, and Fig. 6(b) shows plots of the eigenvalues of π_-, π_+, and σ as a function of dihedral angle. For dihedral angles between 105 and 135°C, the computed splittings range from 0.8 to 1.5 eV. For *Z*-**3**, we also carried out computational studies with optimization criteria increased 10 times and SCF criteria by 100 times (PRECISE) and the results are shown in Fig. 6(c) (⊙, methyl groups locked as in *Z*-**3**-c1; ●, full optimization). It is seen that when the methyl dihedrals are locked, the ΔH_f's computed with the different optimization and SCF criteria are virtually identical. In the case where the structures are fully optimized at each stage, the differences in the ΔH_f's are small. These results establish that the default optimization and SCF criteria can be used to compute the ΔH_f as a function of twist angle for methyl-substituted 1,3-butadienes, especially if the methyl conformations are locked. For a dihedral angle of 120°, the computed splitting is 1.12 eV (Table 3); the experimental value is 1.17 ± 0.05 eV. AM1 calculations on (*Z*)-2-methyl-1,3-pentadiene established that the planar *s-trans* conformer is 3.0–3.9 kcal/mol higher in energy than the planar *s-trans* (*E*) isomer depending on the conformations of the methyl group (1). That (*Z*)-1,3-pentadiene was calculated to be 0.4 kcal/mol higher in energy than the (*E*) isomer establishes that the 1,3 CH_3,CH_3 steric interaction of planar *s-trans* *Z*-**3** increases the energy by 2.7–3.6 kcal relative to *E*-**3**; this steric interaction twists *Z*-**3**. In the case of *Z*-**3**, twisted *s-cis* conformers are not populated because of the prohibitive steric interaction between the C2 and terminal methyls.

The differential sensitivities of HOMO and NHOMO of the 2,3-dimethylhexadienes to twist angle predicted by AM1 are corroborated experimentally by the IE_v's of *Z*-**3**. Relative to *E*-**3**, the NHOMO is destabilized by 0.57 eV and the HOMO is stabilized by 0.3 eV, precisely as predicted by AM1 (Fig. 6(b)).

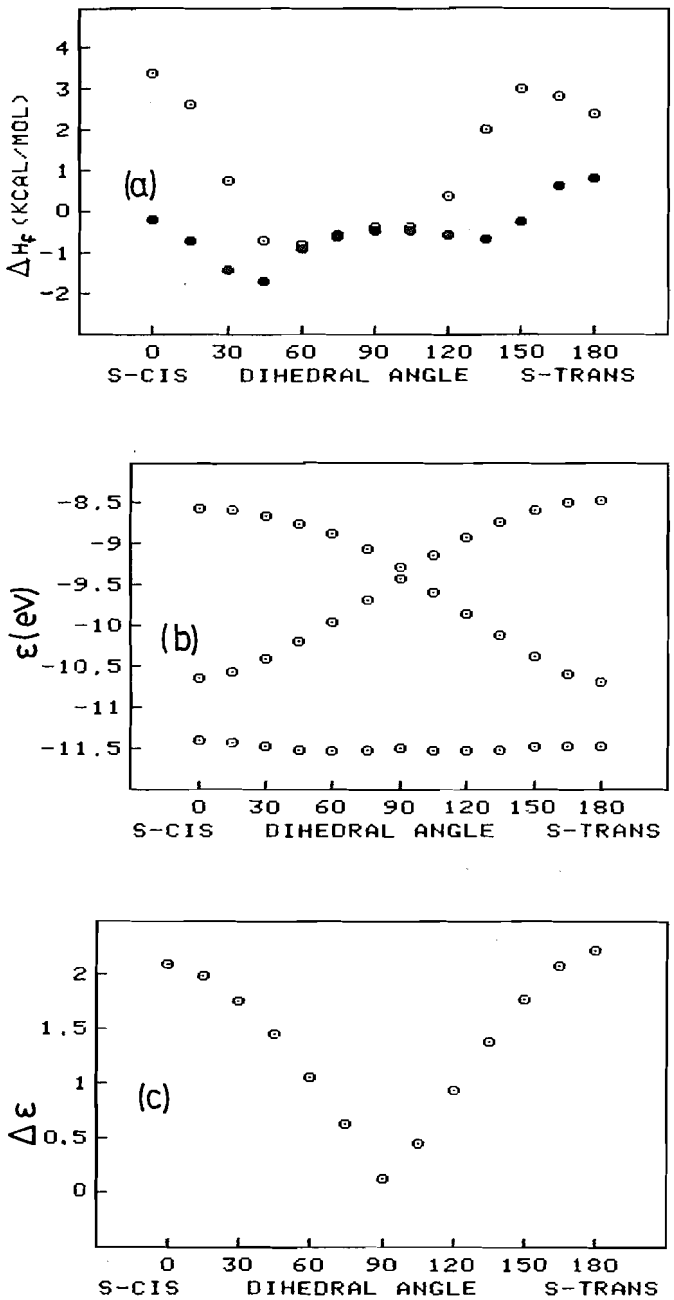

FIG. 7. (a) Plot of ΔH_f of *E*-**4** versus dihedral angle; (b) plot of π_-, π_+, and σ eigenvalues of *E*-**4** versus dihedral angle; (c) plot of π_-, π_+ splitting of *E*-**4** versus dihedral angle.

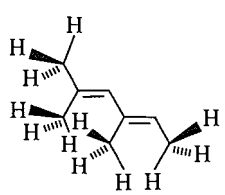
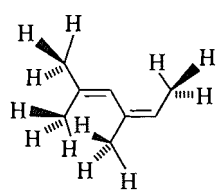
(F) (E)*-2,4-Dimethyl-2,4-hexadiene* (E-*4*)

Figure 7(a) shows a plot (⊙) of ΔH_f versus dihedral angle for (*E*)-2,4-dimethyl-2,4-hexadiene (*E*-**4**). In this case, the starting conformation is *E*-**4**-c1 with the methyl groups locked as shown in this structural formula. The results of an analogous



E-**4**-cl



Z-**4**-cl

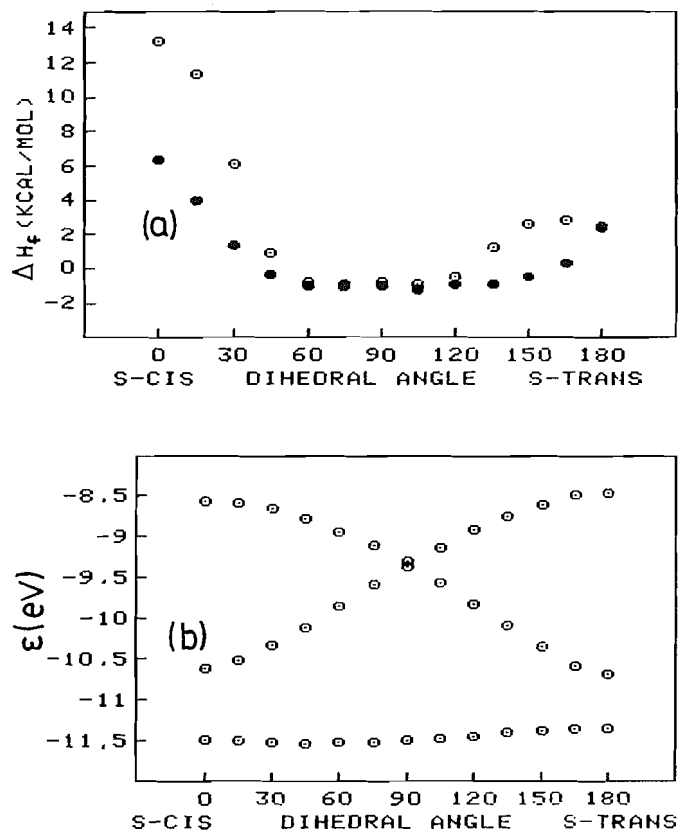


FIG. 8. (a) Plot of ΔH_f of *Z*-**4** versus dihedral angle; (b) plot of π_-, π_+, and σ eigenvalues of *Z*-**4** versus dihedral angle.

study involving full optimization of *E*-**4** are also given (●) in Fig. 7(a). On the basis of these results, twisted *s-cis* conformers with dihedral angles in the range of 45°–60° will be preferentially populated in the gas phase. Figure 7(b) shows how the eigenvalues of π_-, π_+, and σ depend on the dihedral angle. Figure 7(c) shows how the computed splitting depends on the dihedral angle.

A splitting of 1.45 eV computed by AM1 (Table 3) for a dihedral angle of 45° is in good agreement with the experimentally observed value of 1.48 ± 0.05 eV. For this twisted *s-cis* diene the π_- and π_+ bands are broader — the FWHM is approximately 0.8 eV — than the bands of *E*-**3** (planar *s-trans*) (0.5 eV) and *Z*-**3** (twisted *s-trans*) (0.5 eV). Here too, as in the case of *Z*-**3**, the differential sensitivities of π_- and π_+ to twist angle predicted by AM1 are corroborated by the shifts of π_- and π_+ relative to the bands of *E*-**3**: 0.17 eV for π_- and 0.39 eV for π_+. These shifts correlate well with the shifts predicted by AM1 as seen in Fig. 7(b). Thus we assign structure *E*-**4** to the 2,4-dimethyl-2,4-hexadiene, which exhibits a ΔIE_v of 1.48 ± 0.05 eV.

As is the case for *Z*-**3**, *E*-**4** is twisted by a 1,3 interaction of the methyls at C2 and C4; buttressing of these methyls by the terminal methyls in the planar *s-trans* conformations could lead to greater steric strain than in the case of *Z*-**3**. In the case of *E*-**4**, twisted *s-cis* conformers can be populated because there is no steric interaction between the C2 and terminal methyls.

(Z)-2,4-Dimethyl-2,4-hexadiene (Z-*4*)

Figure 8(a) shows plots of ΔH_f versus dihedral angle for (*Z*)-2,4-dimethyl-2,4-hexadiene (*Z*-**4**), starting with *Z*-**4**-c1. In one study, the methyls were locked (⊙) and in the other, geometries were fully optimized (●). According to these

results, conformations with dihedral angles ranging from 60° to 120° will be preferentially populated in this case. Figure 8(b) shows how the eigenvalues of π_-, π_+, and σ depend on dihedral angle. On the basis of the data summarized in Figs. 8(a) and 8(b), the splitting will range between 0.95 and 0.15 eV. The computed splittings for dihedral angles of 120° and 60° are 0.89 and 0.91 eV, respectively (Table 3), and the experimental ΔIE_v for the second isomer of **4** is 0.84 ± 0.05 eV. Here too, as in the case of *Z*-**3** and *E*-**4**, the differential sensitivities of π_- and π_+ to twist angle predicted by AM1 are corroborated by the shifts relative to *E*-**3**; π_- is stabilized by 0.47 eV and π_+ is destabilized by 0.73 eV, in good agreement with the eigenvalues given in Fig. 8(b) for dihedral angles of 120° and 60°. Thus we assign structure *Z*-**4** to the 2,4-dimethyl-2,9-hexadiene, which exhibits a ΔIE_v of 0.84 ± 0.05 eV.

The narrower range of conformations populated in the case of *Z*-**4** is likely due to several factors. In case of the planar *s-cis* conformation there is a steric interaction between the C2 and terminal methyls; for the planar *s-trans* conformation, opening of the C2—C3—C4 bond angle is restricted by a steric interaction of the terminal methyl at C4 with the hydrogen at C3.

Conclusions

Through a study of a group of alkyl-substituted 1,3-dienes we found that a combination of AM1 computations and He(I) photoelectron spectroscopy (UPS) can be used for conformational analysis and for studying conjugative and homoconjugative interactions of this class of compounds. Using AM1/UPS we have determined the structures of the isomeric (*E*)- and (*Z*)-2,4-dimethyl 2,4-hexadienes obtained from the photolysis of 1,3,3,4-tetramethylcyclobutene.

Experimental

Preparation of dienes

Dienes *E*-**3**, *Z*-**3**, *E*-**4**, and *Z*-**4** obtained from photolysis of **1** and **2** (7) were >99% pure by vpc analysis (7).

Ultraviolet photoelectron spectroscopy

The He(I) pe spectra of *E*-**3**, *Z*-**3**, *E*-**4**, and *Z*-**4** were obtained on a pe spectrometer (22) operated in the conventional mode, and are averages of 50–100 scans.

Computational studies

Computational (RHF) studies were carried out using AM1, Version 2.1, of the general purpose molecular orbital computational package AMPAC (2) modified to run on Sun 3/60 and IBM RT computers. Optimizations were carried out using the AM1 default parameters. For butadiene and *Z*-**3**, optimizations were also carried out using PRECISE. This increases the optimization criteria by 10 times and the SCF criteria by 100 times. The MO density plots were obtained using DEN3D and DRAW3D (19) and printed as SUN 3/60 masterfiles on a Laser Jet II printer.

The metabolites of *Talaromyces flavus*: Part 1. Metabolites of the organic extracts

WILLIAM A. AYER[1] AND JULIE S. RACOK
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received February 5, 1990

WILLIAM A. AYER and JULIE S. RACOK. Can. J. Chem. **68**, 2085 (1990).

The soil fungus *Talaromyces flavus* (Klöcker) Stolk and Samson is an effective biological control for Verticillium wilt of eggplant (*Solanum melongena* L.), a disease caused by the fungus *Verticillium dahliae* Kleb. The organic soluble metabolites produced when the fungus is grown in liquid still culture include D-glucono-1,4-lactone (**1**), 5-hydroxymethylfurfural (**5**), the previously unreported tetraketides, 4,6-dihydroxy-5-methylphthalide (**3**) and methyl 4-carboxy-5-hydroxyphthalaldehydate (**8**), a hexaketide, 7-hydroxy-2,5-dimethylchromone (**6**), and a metabolite believed to be 3-hydroxymethyl-6,8-dimethoxycoumarin (**10**). A number of higher order polyketides have been isolated including altenusin (**11**), dehydroaltenusin (**12**), and the previously unreported desmethyldehydroaltenusin (**14**). A structurally and biosynthetically interesting spirocyclic metabolite, which we have named talaroflavone (**16**), as well as a related compound, deoxytalaroflavone (**18**), have also been obtained.

Key words: *Talaromyces flavus*, fungal metabolites, talaroflavone, 4,6-dihydroxy-5-methylphthalide.

WILLIAM A. AYER et JULIE S. RACOK. Can. J. Chem. **68**, 2085 (1990).

Le champignon du sol *Talaromyces flavus* (Klöcker) Stolk et Samson contrôle biologiquement et d'une façon efficace la flétrissure par le Verticillium de l'aubergine (*Solanum melongena* L.), une maladie causée par le champignon *Verticillium dahliae* Kleb. Les métabolites organiques solubles qui sont produits lorsqu'on fait croître le champignon dans un milieu de culture comprennent : la D-glucono-1,4-lactone (**1**), le 5-hydroxyméthylfurfural (**5**), les tétrakétides 4,6-dihydroxy-5-méthylphtalide (**3**) et 4-carboxy-5-hydroxyphtalaldéhydate de méthyle (**8**) qui n'avaient pas été rapportés antérieurement, un hexakétide, la 7-hydroxy-2,5-diméthylchromone (**6**), ainsi qu'un métabolite que l'on croit être la 3-hydroxyméthyl-6,8-diméthoxycoumarine (**10**). On a aussi isolé un certain nombre de polykétides d'ordre plus élevé, dont l'alténusine (**11**), la déhydroalténusine (**12**) ainsi que la desméthyldéhydroalténusine (**14**) qui n'avait pas été rapportée antérieurement. On a aussi obtenu un métabolite spirocyclique, intéressant d'un point de vue structural et biosynthétique, que l'on a appelé talaroflavone (**16**) ainsi qu'un composé apparenté, la désoxytalaroflavone (**18**).

Mots clés : *Talaromyces flavus*, métabolites de champignon, talaroflavone, 4,6-dihydroxy-5-méthylphtalide.

[Traduit par la revue]

Introduction

The soil fungus *Talaromyces flavus* (Klöcker) Stolk and Samson is the most common species of its genus. This ascomycete is frequently isolated from soil, although it may also occur on organic materials undergoing decomposition. The species is widespread in its distribution but it is most commonly reported from the warmer regions of the world (1, 2). Our interest in the metabolites produced by *T. flavus* was stimulated by the report of its effectiveness as a biological control for Verticillium wilt of eggplant (*Solanum melongena* L.), a disease caused by the fungus *Verticillium dahliae* Kleb. (3). The Verticillium wilt organism is a widespread soil inhabitant that infects a variety of herbaceous and woody plants. Further details regarding this biological control and the nature of the wilting disease are discussed in Part 2 of this series.

A number of metabolites of polyketide origin have been isolated from species of *Talaromyces* (4–10) other than *T. flavus*. The imperfect (conidial) state of *T. flavus*, *Penicillium dangeardii* Pitt, produces three metabolites that are reported to show antibiotic activity (11–15). The isolation of a water soluble compound possessing antibiotic activity from *T. flavus* has recently been reported (16). In addition to the aforementioned antifungal action against *V. dahliae*, *T. flavus* is reported to display biological activity towards the plant pathogens *Sclerotinia sclerotiorum* (Lib.) de Bary (17), *Rhizoctonia solani* Kühn (18), and *V. albo-atrum* Reinke and Berth. (19). The adoption of a biological control agent for a soilborne disease requires that the organism be able to establish itself in different soils.[2] Studies of the edaphic parameters associated with the establishment of *T. flavus* as a biological control suggest that it may be suitable for widespread use (21, 22). In view of these observations we have undertaken an investigation of the metabolites produced by the strain ATCC 52201 (UAMH 4890) of *T. flavus*, when it is grown in liquid still culture. In this paper we report the isolation of the organic soluble metabolites produced by *T. flavus*. The following paper describes the isolation of the water soluble metabolites and reports on the biological activity of the fungus and on labelling studies undertaken to examine the incorporation of [1-^{13}C] labelled acetate into the biosynthetically interesting metabolites we obtained.

Preliminary studies indicated that *T. flavus* grows best on a malt extract medium (as compared to potato dextrose broth and Czapek medium). Liquid still cultures of *T. flavus* were grown on this medium for 4 weeks. The culture broth was decanted from the mycelium by filtration. The mycelium was subjected to Soxhlet extraction with ethyl acetate or methanol. Addition of methanol to the two extracts afforded an insoluble white solid identified as D-mannitol. The methanol soluble portions of the ethyl acetate and methanol Soxhlet extracts were each subjected to chromatography over silica gel. The ubiquitous metabolites methyl linoleate, linoleic acid, a triglyceride, a diglyceride, and ergosterol were isolated. Identification of the fatty acid residues comprising the di- and triglyceride was achieved by analysis of their mass spectral fragmentation patterns. The triglyceride contains linolenic, linoleic, and palmitic acids, while the diglyceride carries the latter two acyl groups (24). The fungal broth exhibits mild antibacterial activity against *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and *Streptococcus pyogenes* and antifungal activity towards *V. dahliae*. Extraction of the broth with ethyl acetate removes the antibacterial activity; however, the antifungal activity remains in the aqueous broth.

The ethyl acetate extract of the broth was dissolved in aqueous methanol and extracted with Skellysolve B, dichloromethane, and ethyl acetate. Each of the three extracts was subjected to chromatography over silica gel. The major component of the Skellysolve B extract was identified as the triglyceride. The ethyl acetate extract yields D-glucono-1,4-lactone (**1**). The dichloromethane extract is a source of metabolites of polyketide origin, which are the subject of this report.

Discussion

The ethyl acetate portion of the organic broth extract yields D-glucono-1,4-lactone (**1**), accounting for 50% of the weight of this fraction. Recrystallization of **1** from acetic acid gives a white powder, mp 127–129°C. The chemical ionization mass spectrum (cims) shows an ion at 196 (M + 18, 100), which indicates a molecular weight of 178 and a molecular formula of $C_6H_{10}O_6$ for lactone **1**. The highest mass peak in the high resolution mass spectrum (hrms) at m/z 160 ($M^+ - 18$) may be attributed to the facile β-elimination of water from the γ-lactone. The infrared spectrum (ir) spectrum displays a broad hydroxyl absorption at 3300 cm^{-1} and a γ-lactone carbonyl at 1776 cm^{-1}. The coupling pattern among the six carbinolic hydrogens was determined by spin decoupling and $^1H-^1H$ COSY experiments. The ^1H and ^{13}C nmr data obtained for the metabolite agree with those reported (25, 26) for D-glucono-1,4-lactone (**1**). This is the first example of the isolation of this metabolite from a fungal source. A sample of **1** was prepared by heating a solution of D-glucono-1,5-lactone in acetic acid (27, 28). The mixture melting point of synthetic and natural lactones is undepressed. Acetylation of **1** affords the tetraacetate **2**, identical (mp, nmr, ir, hrms, optical rotation) with an authentic sample. D-Glucono-1,4-lactone (**1**) is also abundant in the aqueous broth. Its role in the biological control of *V. dahliae* by *T. flavus* is discussed in the following paper.

4,6-Dihydroxy-5-methylphthalide (**3**), mp 240–241°C, precipitates from the chromatography eluent as colorless needles. Compound **3** has the molecular formula $C_9H_8O_4$ as determined by hrms. The ir spectrum shows a broad hydroxyl absorption at

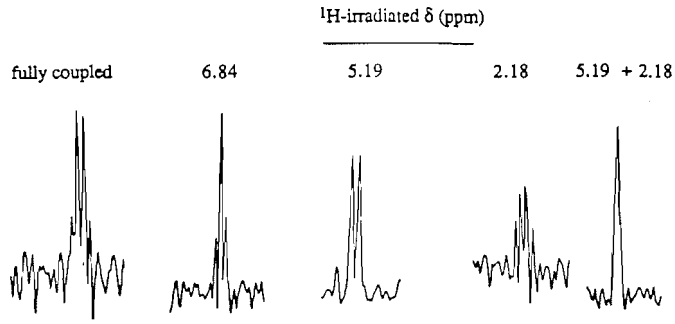

FIG. 1. $^1H-^{13}C$ decoupling of carbonyl carbon of **3**.

3360 cm^{-1} and a carbonyl band at 1730 cm^{-1}. The ultraviolet (uv) absorptions at 213, 259, and 306 nm each shift bathochromically ca. 20 nm on addition of base. Neutralization with acid restores the spectrum, indicative of a phenolic chromophore. The ^1H nmr spectrum of the phthalide consists of five singlets including an aromatic hydrogen (δ 6.84), a methylene signal (δ 5.19), and a methyl resonance (δ 2.18). Broad downfield singlets at δ 8.92 and 8.64 (D_2O exchangeable) are ascribed to the phenolic hydrogens. Nuclear Overhauser enhancement (nOe) experiments were performed to determine the relative orientation of the substituents on the phthalide ring; however, presaturation of the methyl, methylene, or methine singlets showed no nuclear Overhauser enhancements. In spin decoupling experiments, the half width ($w_{1/2}$) of each of the singlets was unaffected. To distinguish between the two structures consistent with these data, 4,6-dihydroxy-5-methylphthalide and 4,6-dihydroxy-7-methylphthalide, we examined the long range $^1H-^{13}C$ coupling constants. In the fully coupled spectrum the carbonyl carbon (δ 171.6) consists of four lines (Fig. 1). Irradiation of the aromatic hydrogen (δ 6.84) simplifies the signal to a triplet (J = 2 Hz), representative of the three-bond coupling ($^3J_{CH}$) of the carbonyl carbon with the methylene hydrogens (δ 5.19). When these hydrogens are irradiated the carbonyl carbon becomes a doublet ($^3J_{CH}$ = 3 Hz), consistent with 4,6-dihydroxy-5-methylphthalide (**3**), as this multiplicity results from coupling with the aromatic hydrogen. Irradiation of the methyl signal (δ 2.18) has no effect on the carbonyl signal multiplicity. The multiplicity changes observed for the other carbons enable us to assign the complete spectrum. Irradiation of the aromatic hydrogen (δ 6.84) simplifies the phenolic carbon at δ 158.5 to a quartet ($^3J_{CH}$ = 4 Hz) so that this signal is assigned as C-6. The carbon at δ 119.3 is also simplified to a quartet ($^2J_{CH}$ = 6 Hz) and is assigned as C-5. Saturation of the methylene hydrogens (δ 5.19) eliminates their coupling with the C-4 phenolic carbon (δ 151.2). The signal at δ 126.1 becomes a doublet, indicative of its coupling ($^3J_{CH}$ = 6 Hz) with the aromatic hydrogen (H-7), and is assigned as C-3a. The signal at δ 125.2 shows no coupling and is assigned as C-7a. The ^{13}C nmr assignment for 4,6-dihydroxy-5-methylphthalide (**3**) is summarized in Table 1. In the hrms, compound **3** loses a hydrogen atom to give a radical ion at m/z 179 and then carbon monoxide to afford the base peak at m/z 151. One of the noteworthy features in the ir spectrum of metabolite **3** is the carbonyl absorption at 1730 cm^{-1}. This absorption is at low frequency for a γ-lactone. This is the same frequency reported (29) for its regioisomer, 5,7-dihydroxy-6-methylphthalide, where intramolecular hydrogen bonding is responsible for the lower frequency absorption. The shift to lower frequency in this case is attributed to intermolecular hydrogen bonding in the thin film used to obtain the spectrum.

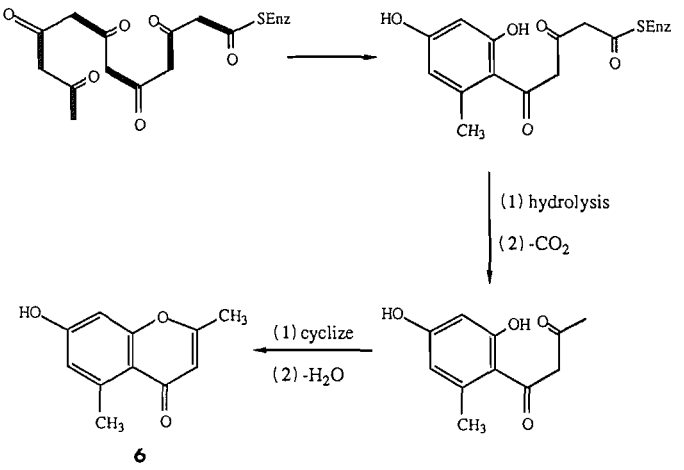
[a]In acetone-d_6.

4,6-Dihydroxy-5-methylphthalide (**3**) is not reported as a natural product. It has been prepared synthetically (29) and our physical and spectral data agree with those of a synthetic sample of this phthalide.[3] Treatment of **3** with potassium carbonate and methyl iodide in refluxing acetone affords white flakes of 4,6-dimethoxy-5-methylphthalide (**4**), whose physical and spectral data (mp, nmr, ir, uv, hrms) correspond with those obtained from an authentic sample[3] as well as with those reported (30) for the natural product **4**, *O*-methylsilvaticol, isolated from *Aspergillus silvaticus*. Although most of the carbons of **4** are readily assigned (Table 1), the long range $^1H-^{13}C$ couplings of three carbons, δ 124.8, 126.1, and 128.9, were examined to confirm their identification. The carbon at δ 124.8 is a singlet and is assigned as C-7a by analogy with the dihydroxy metabolite **3**. The carbons at δ 126.1 and 128.9 are multiplets in the fully coupled spectrum; however, irradiation of the methylene hydrogens (δ 5.51) simplifies the former to a quartet ($^2J_{CH}$ = 6 Hz) and the latter to a doublet ($^3J_{CH}$ = 6 Hz). This doublet is characteristic of the multiplicity of C-3a in the dihydroxy metabolite **3** so that the signal at δ 128.9 is assigned as such. The quartet at δ 126.1 (C-5) arises from the coupling of this carbon with the methyl hydrogens. This ^{13}C nmr assignment differs from that proposed by Achenbach *et al.* (29) and from that reported (30) for the natural product; however, it is consistent with the change in chemical shifts expected in phenolic systems on *O*-methylation (30).

5-Hydroxymethylfurfural (**5**), isolated as a yellow oil, has the molecular formula $C_6H_6O_3$ as determined from its hrms. The loss of a hydrogen atom and carbon monoxide in the mass spectrum to give the base peak (m/z 97), absorption bands at 2840 and 2700 (w) cm^{-1} in the ir spectrum, and a singlet in the ^1H nmr spectrum at δ 9.58 that does not exchange on addition of D_2O indicate that compound **5** is an aldehyde. The uv absorptions at 221 and 281 nm indicate a furfural chromophore. The ^1H and ^{13}C nmr spectra of **5** are consistent with those reported (31). We believe that 5-hydroxymethylfurfural (**5**) is an artifact in the broth extract as it is known to arise through dehydration of D-glucose (32). When the D-glucose was added to the fungal medium after the autoclaving process, the amount of 5-hydroxymethylfurfural (**5**) in the broth extract was reduced by ca. 90%.

[3]We thank Professor H. Achenbach for providing us with the samples and spectra of 4,6-dihydroxy-5-methylphthalide and 4,6-dimethoxy-5-methylphthalide.



6

SCHEME 1

White flakes of 7-hydroxy-2,5-dimethylchromone (**6**), $C_{11}H_{10}O_3$, sublime at 200°C. The phenolic nature of **6** is evident as its uv spectrum displays a bathochromic shift on addition of base, which reverts to the original spectrum on neutralization with acid. The ir spectrum displays a broad hydroxyl absorption (3400–3000 cm^{-1}) and γ-pyrone absorptions at 1649, 1618, and 1557 cm^{-1}. The ^1H nmr spectrum shows *meta*-related hydrogens at δ 6.64 (d, J = 2.5 Hz) and 6.62 (dq, J = 2.5, 1.0 Hz). This latter hydrogen has been shown by spin decoupling experiments to be coupled to the methyl group at δ 2.70 (bs), which, when irradiated, results in a 32% nOe enhancement of the hydrogen at δ 6.62 (H-6). The vinylic hydrogen (H-3) at δ 6.00 (q, J = 1.0 Hz) is coupled to the C-2 methyl group at δ 2.31 (d, J = 1.0 Hz) and shows an nOe enhancement of 12% when the C-2 methyl is presaturated. Metabolite **6** has been isolated from the roots of *Polygonum cuspidatum*, a plant used in Chinese and Japanese traditional medicine (33), and from a rhubarb, *Rhei rhizoma* (34). Treatment of 7-hydroxy-2,5-dimethylchromone (**6**) with diazomethane affords the monomethyl ether (**7**), whose physical and spectral data (mp, nmr, ir, uv, hrms) agree with those reported (35, 36). The biosynthesis of **6** does not seem to follow the pattern of most chromones that arise from a pentaketide precursor but probably originates from a hexaketide precursor as illustrated in Scheme 1.

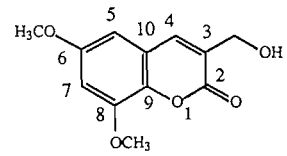
The most colorful metabolite isolated is a granular yellow solid that decomposes on melting at 190°C, for which we propose the structure methyl 4-carboxy-5-hydroxyphthalaldehydate (**8**). Its molecular formula, as determined by hrms, is $C_{10}H_8O_6$. The uv spectrum of **8** consists of maxima at 225, 293, and a long wavelength absorption at 428 nm. Addition of base causes a bathochromic shift of only the 293 nm absorption. A ^{13}C nmr signal at δ 196.6 (d), a ^1H nmr resonance at δ 10.46 that does not exchange on addition of D_2O, and the loss of a hydrogen atom and carbon monoxide from the ion at m/z 193 in the mass spectrum support the presence of the aldehyde functionality. A broad hydroxyl absorption in the ir spectrum (3560 to 2400 cm^{-1}) and a ^{13}C nmr signal at δ 169.4 (s) are evidence for the carboxylic acid moiety. A singlet in the ^1H nmr spectrum at δ 3.53 (3H) and ^{13}C nmr signals at δ 160.1 (s) and 56.4 (q), together with the loss of a methoxy group (m/z 193) in the hrms, are consistent with the presence of a methyl ester. Singlets in the ^1H nmr spectrum at δ 6.79 and 6.45 are attributed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

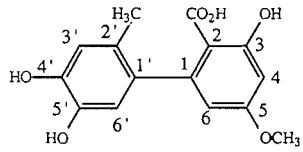
to hydrogens in a *para* relationship on the aromatic ring. Presaturation of the methoxy singlet (δ 3.53) results in an nOe enhancement of 7% of the signal at δ 6.45. There remains only a hydroxyl group not accounted for, and the ^{13}C nmr signal at δ 166.3 (s) is consistent with this. Evidence as to the relative orientation of the four substituents on the aromatic ring is provided by the reduction of **8** with sodium borohydride. After the reaction proceeds for 15 s, the bright yellow color of the solution fades and, after 10 min, the starting material is converted to a more polar compound as seen by tlc. The ir spectrum of the reduction product **9** possesses a broad hydroxyl absorption at 3240 cm^{-1}. The aldehyde and ester methoxyl signals disappear from the ^1H nmr spectrum and are replaced by a singlet (δ 5.01, 2H). A similar reaction has been observed in the sodium borohydride reduction of 3,5-dihydroxy-4-methylphthalaldehydic acid methyl ester, affording metabolite **3** (37). This suggests that metabolite **8** may be a derivative of a precursor to **3**. The presence of a γ-lactone ring in compound **9** is supported by a carbonyl band at 1755 cm^{-1} in the ir spectrum and the two-hydrogen singlet at δ 5.01 in the ^1H nmr spectrum. Compound **8** is relatively unstable, presumably due to aerial oxidation. The ^1H nmr spectrum of **8** a few days after isolation shows that the three singlets are doubled and the intensity of the aldehyde signal is reduced. Thin-layer chromatography (tlc) shows more polar material shortly after purification. Attempts to acetylate or methylate compound **8** failed to yield tractable products. These difficulties, together with the paucity in which metabolite **8** is produced, have precluded further studies to confirm its structure.

A metabolite whose structure is consistent with that of 3-hydroxymethyl-6,8-dimethoxycoumarin (**10**) has the molecular formula $C_{12}H_{12}O_5$. A carbonyl band at 1711 cm^{-1} and double bond absorptions at 1657 and 1592 cm^{-1} in the ir spectrum are consistent with the coumarin skeleton. The uv maxima at 256 and 286 nm do not shift on addition of base, indicating that the hydroxyl group is not phenolic. The ^1H nmr spectrum shows *meta*-related hydrogens at δ 6.65 and 6.48 (each a doublet, J = 2.6 Hz). A triplet (1H, J = 1.4 Hz) at δ 7.70, whose chemical shift is consistent with that of a coumarin hydrogen on the β-carbon of the double bond, is coupled to a doublet at δ 4.55 (2H, J = 1.4 Hz), supporting the hydroxymethyl substitution at the α-carbon. Methoxy groups resonate at δ 3.90 and 3.81. Although ^{13}C nmr would allow the two metabolites to be distinguished, compound **10** was not isolated in quantities sufficient to allow detection of the 12 carbon signals. The most significant nOe result is that the signal for the aromatic hydrogen (δ 6.48) is enhanced when the vinylic hydrogen at δ 7.70 is presaturated and vice versa, suggesting that these two hydrogens are *peri* to one another. On the basis of the data available, we suggest that metabolite **10** is 3-hydroxymethyl-6,8-dimethoxycoumarin.

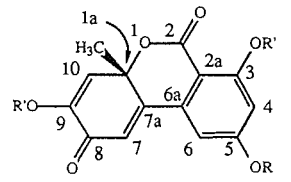
A number of higher order polyketides arising from a heptaketide precursor have been isolated. The first of these, altenusin (**11**), crystallizes as white flakes, mp 194–196°C. Its hrms provides the molecular formula $C_{15}H_{14}O_6$. The ^1H nmr spectrum shows aromatic singlets at δ 6.47 and 6.40 and *meta*-related hydrogens at δ 6.27 and 6.04 (each a doublet, J = 2.6 Hz). A methoxy signal is seen at δ 3.65 and an aromatic methyl at δ 1.77. The mp, ^1H nmr, and ir data agree with those reported (38) for altenusin (**11**). In Table 2, the ^{13}C nmr data (not previously reported) are compared with calculated values (39). Altenusin (**11**) was first reported from *Alternaria tenuis* in 1957 (40); however, the structure for the metabolite was not



10



11



12, R = CH_3, R' = H

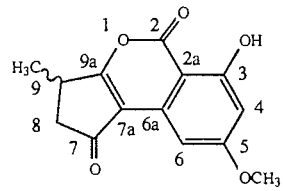
17, R = $COCH_3$



18

established until 1970 (38). It has since been isolated from *A. kikuchiana* (41). Two metabolites closely related to altenusin (**11**) have been isolated in the form of their acetates since the corresponding alcohols were difficult to purify. The ^1H nmr spectrum of a somewhat impure sample of the first of these alcohols, dehydroaltenusin (**12**), displays a hydrogen bonded hydroxyl hydrogen at δ 11.30. *meta*-Related hydrogens at δ 6.73 and 6.63 (each a doublet, J = 2.3 Hz) and a methoxy signal at δ 3.91 reflect the similarity of one aromatic ring of altenusin (**11**) with that in dehydroaltenusin (**12**). Downfield singlets appear at δ 6.69 and 6.28 and a methyl group resonates at δ 1.73 (s). The crystal structure of (±)-dehydroaltenusin has been described (42); however, its structure was initially misassigned and it was reported that a triacetate had formed (38). In our hands, acetylation of dehydroaltenusin (**12**) affords a diacetate, $C_{19}H_{16}O_8$, the properties of which are consistent with structure **13**. The ir spectrum shows no hydroxyl absorption but carbonyl bands for aromatic (1776 cm^{-1}) and aliphatic (1732 cm^{-1}) acetates are observed. Absorptions at 1688 and 1664 cm^{-1} are consistent with the unsaturated ketone moiety. The ^1H nmr spectrum shows *meta*-related hydrogens at δ 6.77 and 6.60 (each a doublet, J = 1.9 Hz) and a methoxy group at δ 3.86, consistent with those found for the aromatic ring of dehydroaltenusin (**12**) and altenusin (**11**). Presaturation of the methoxy group results in a 24% enhancement of the signal at δ 6.77 and a 17% enhancement of the resonance at δ 6.60. Presaturation of this latter hydrogen enhances not only the methoxy signal but also the vinylic hydrogen at δ 6.36 (s); nOe experiments show a 22% enhancement of the vinylic hydrogen at δ 6.30 (q, J = 1.4 Hz) when the methyl group at δ 1.73 (d, J = 1.4 Hz) is presaturated. A signal for an aromatic acetoxyl methyl is observed at δ 2.42 and one for a deshielded aliphatic methyl at δ 2.29. Dehydroaltenusin (**12**),[4] like altenusin (**11**), has been isolated from *Alternaria tenuis* and *A. kiku-*

[4]Due to the small amount of metabolites **12**, **14**, and **18** isolated, no attempt was made to determine if they were optically active. Our requests for an authentic sample of **12** were not answered.

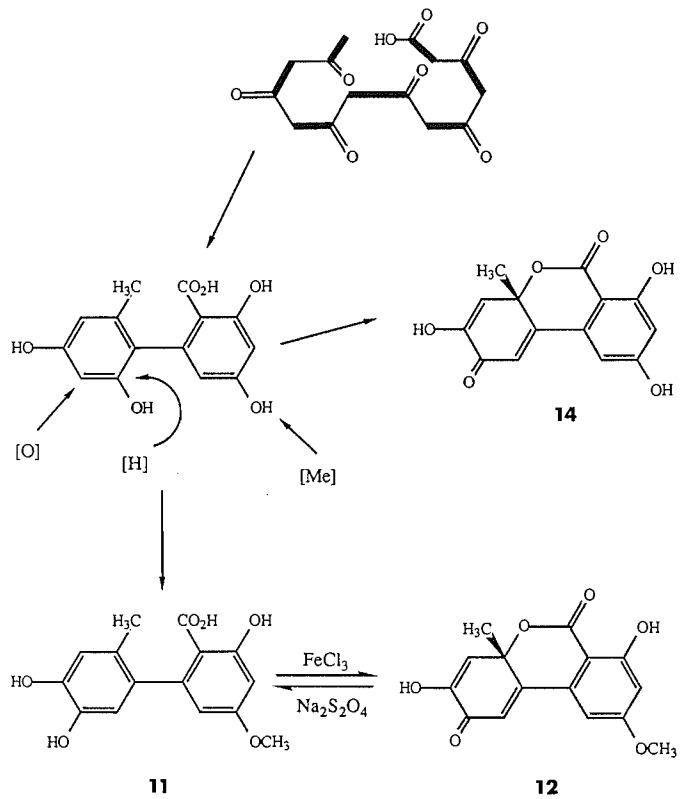
chiana (40). Desmethyldehydroaltenusin (**14**)[4] is the second metabolite isolated in the form of its acetate (**15**). The sequential loss of three molecules of ketene from the parent ion ($C_{20}H_{16}O_9$) in the mass spectrum affords an ion corresponding to a molecular formula $C_{14}H_{10}O_6$, which differs from that of dehydroaltenusin (**12**) by a methylene unit. Desmethyldehydroaltenusin triacetate (**15**) fragments in the same manner as dehydroaltenusin diacetate (**13**), with the fragment ions consistently found 14 mass units lower. The ^1H nmr spectrum of the triacetate **15** is similar to that of dehydroaltenusin diacetate (**13**) as *meta*-related hydrogens are observed at δ 7.10 and 6.97 (each a doublet, J = 1.7 Hz) and a four-bond coupling of 1.5 Hz is observed between the vinylic hydrogen at δ 6.31 and the methyl signal at δ 1.74. A one-hydrogen singlet resonates at δ 6.37. Acetyl methyl signals are apparent at δ 2.43, 2.31, and 2.29. The methoxy signal present in the ^1H nmr spectrum of the diacetate **13** is absent in the triacetate **15**. Formation of altenusin (**11**) and dehydroaltenusin (**12**), and the previously unreported desmethyldehydroaltenusin (**14**), may be envisaged as proceeding by cyclization of a heptaketide precursor to give the biphenyl derivative shown in Scheme 2. An oxidation and reduction sequence, and methylation of the phenol indicated, afford the biphenyl metabolite altenusin (**11**). Its δ-lactone derivative, dehydroaltenusin (**12**), forms by oxidative cyclization of **11**. The chemical interconversion of **11** and **12** has been achieved (38, 41): oxidation of **11** to **12** with ferric chloride and reduction of **12** to **11** with sodium dithionate.

We believe that this biphenyl intermediate is also the precursor to the structurally and biosynthetically interesting spirocyclic metabolite, talaroflavone (**16**). This white solid, with molecular formula $C_{14}H_{12}O_6$, decomposes on melting at 230°C. The ir spectrum displays a broad hydroxyl absorption at 3240 cm^{-1}, a γ-lactone carbonyl at 1748 cm^{-1}, and α,β-unsaturated cyclopentenone bands at 1723 and 1617 cm^{-1}. The uv absorptions at 217, 257, and 296 nm shift bathochromically on addition of base. Neutralization with acid gives back the original spectrum, indicative of the phenolic chromophore. The ^1H nmr spectrum shows *meta*-related hydrogens at δ 6.44 and 6.05 (each a doublet, J = 2.0 Hz), both of which show a nuclear Overhauser enhancement (6% and 8%, respectively), when the methoxy signal at δ 3.80 is irradiated. These ^1H nmr data



SCHEME 2

resemble those for the aromatic portion of metabolites **11**, **12**, and **14**. A carbinolic hydrogen at δ 4.74 and a ^{13}C nmr signal at δ 79.7 are consistent with a secondary alcohol. An allylic coupling (J = 1.5 Hz), as well as a 6% nOe, is observed between the methyl signal at δ 1.86 and the vinylic hydrogen at δ 6.34. A comparison of the ^{13}C nmr data (Table 3) for the aromatic ring of 4,6-dihydroxy-5-methylphthalide (**3**), 5,7-dihydroxy-6-methylphthalide (29), and metabolite **16** shows chemical shift differences of the carbons at the ring junctions (C-3a and C-7a), depending on whether the carbonyl group is *peri* to the aromatic hydrogen or *peri* to the hydroxyl group. The ^{13}C nmr data for the aromatic portion of metabolite **16** agree best with the latter phthalide. Signals in the ^{13}C nmr spectrum at δ 202.0, 171.4, and 131.4 (43) and ^1H nmr resonances at δ 1.86 and 6.34 are consistent with a 3-methylcyclopentenone. A third ring joining the aromatic and enone portions of **16**, incorporating the quaternary spiro carbon (δ 94.2) and the ester carbonyl (δ 170.2), fulfills the final site of unsaturation. The parent ion in the mass spectrum of talaroflavone (**16**) is also the base peak, suggesting that the molecule does not contain sites for facile fragmentation. Talaroflavone (**16**) is optically active, $[\alpha]_D$ = +181° (*c* 0.74, methanol). Attempts to discern the stereochemistry at the spiro center (C-3) and of the C-5′ hydroxyl of **16** have proved troublesome; however, data obtained from the diacetate (**17**) have provided some evidence for C-5′. The diacetate **17** has the molecular formula $C_{18}H_{16}O_8$, as determined by hrms. The ir spectrum shows no hydroxyl absorption; however, there is a carbonyl absorption at 1777 cm^{-1} (aromatic acetoxyl) and 1732 cm^{-1} (acetoxyl and cyclopentenone), together with a double bond absorption at 1621 cm^{-1}. The ^1H nmr spectrum shows aromatic hydrogens at δ 6.93 and 6.61, downfield ca. δ 0.5 from their resonances in the dihydroxy form. This is consistent with the acetylation of an *ortho* or *para*

TABLE 3. ^{13}C chemical shifts of the aromatic portion of 4,6-dihydroxy-5-methylphthalide (**3**),[a] 5,7-dihydroxy-6-methylphthalide,[a] and talaroflavone (**16**)[b]

[b,c,d,e]Assignments may be interchanged.

phenolic hydroxyl (44). An aromatic acetate methyl resonates at δ 2.35 and an aliphatic one at δ 1.82, upfield from its expected position by ca. δ 0.3. The hydrogen at δ 4.74 in the alcohol **16** shifts downfield δ 1.07 on acetylation (δ 5.81), consistent with that expected for a secondary alcohol. The ^{13}C nmr spectrum of **17** shows two additional signals for acetate carbonyls in the region δ 165–170 and methyl carbon resonances at δ 20.4 and 19.8. The ketone carbonyl is shifted upfield in **17** to δ 197.1 from 202.0, suggesting the loss of hydrogen bonding. The ^{13}C nmr assignments for the alcohol **16** and the acetate **17** are summarized in Table 4. The changes in chemical shift of the aromatic carbons of **16** on acetylation are consistent with those expected (45). The upfield shift of the aliphatic acetate methyl in the ^1H nmr spectrum of **17** provides the clue to the stereochemistry at C-5′. There are two diastereoisomers in which the aliphatic methyl group lies inside the shielding cone of the aromatic ring and two where this methyl lies away from the aromatic ring and should exhibit a more characteristic chemical shift (ca. δ 2.1). This upfield shift of the C-5′ acetate methyl, ascribed to the diamagnetic anisotropy of the benzene ring, leads us to believe that the configuration at C-5′ of talaroflavone (**16**) is one in which this acetate methyl lies within the shielding cone of the aromatic ring. The optical rotary dispersion (ord) spectrum of the acetate **17** is a positive plain curve and the circular dichroic (cd) spectrum shows a positive Cotton effect. Attempts to crystallize talaroflavone diacetate (**17**) failed to give crystals suitable for X-ray analysis. The mono- and di-*p*-nitrobenzoates of talaroflavone (**16**) were prepared; however, poor yields were obtained and suitable crystals could not be prepared.

A metabolite we have named deoxytalaroflavone (**18**), mp 178–180°C, has the molecular formula $C_{14}H_{12}O_5$. The ir spectrum shows a hydroxyl absorption (3400–2800 cm^{-1}), together with bands representative of the α-pyrone and α,β-unsaturated ketone moieties (1713, 1679, 1610, and 1565 cm^{-1}). The ^1H nmr spectrum consists of a downfield hydroxyl hydrogen at δ 11.35, *meta*-related hydrogens at δ 6.70 and 6.69 (each a doublet, J = 2.3 Hz), and a methoxy group at δ 3.94, again resembling that observed for the aromatic portion of talaroflavone (**16**) and the other heptaketide derived metabolites (**11**, **12**, and **14**). The aromatic hydrogen at δ 6.69 (H-6) is further downfield in **18** compared to its chemical shift in **16** (δ 6.05), probably because of the proximity to the ketone carbonyl. The ^1H nmr spectrum of deoxytalaroflavone (**18**) contains a saturated spin system; namely, a hydrogen resonating at δ 3.43 is coupled to a methyl group at δ 1.46 (d, J = 6.9 Hz) and to two methylene hydrogens (δ 2.95 (dd, J = 6.6, 19.0 Hz) and δ 2.31 (dd, J = 1.3, 19.0 Hz)). Only eight of the 14 carbons of metabolite **18** are visible in the ^{13}C nmr spectrum, due to the small amount of material available. The molecular formula of **18**, $C_{14}H_{12}O_5$, differs from that of talaroflavone (**16**), $C_{14}H_{12}O_6$, by one oxygen atom. Its formation from talaroflavone (**16**) may be envisaged in three steps as illustrated in Scheme 3.

Labelling studies undertaken to examine the incorporation of [1-^{13}C] labelled acetate into the biosynthetically interesting metabolites reported above and the results of our efforts to identify the source of the biological activity of the fungus are the subject of the following paper.

Experimental

High resolution electron impact mass spectra (hreims) were recorded on an A.E.I. MS-50 mass spectrometer coupled to a Data General Nova

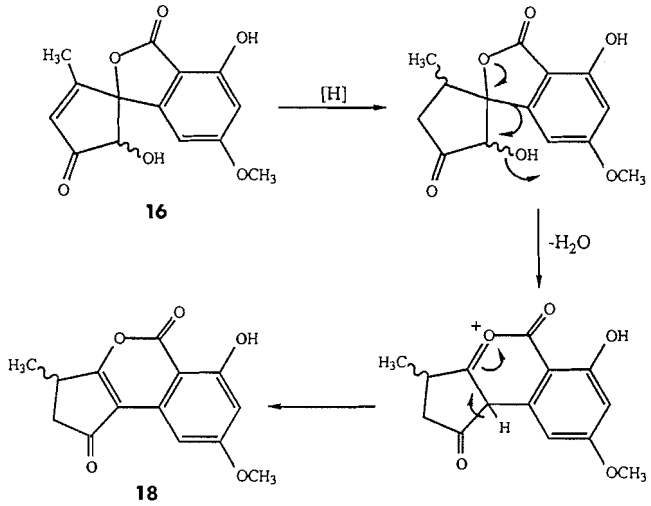

SCHEME 3

4 computer. Unless diagnostically significant, peaks with intensities less than 30% of the base peak are omitted. Low resolution mass spectra (lrms) were recorded on an A.E.I. MS-12 mass spectrometer. Chemical ionization mass spectra (cims) were recorded on an A.E.I. MS-12 mass spectrometer with ammonia as the reagent gas. Fourier transform infrared (ftir) spectra were recorded as thin films cast from $CHCl_3$, CH_2Cl_2, CH_3COCH_3, or CH_3OH on a Nicolet 7199 FT interferometer. ^1H nuclear magnetic resonance (^1H nmr) spectra were measured on a Bruker WH-200, WH-360, WH-400, AM-300, or AM-400 spectrometer with an Aspect 2000 or 3000 computer system. Residual $CHCl_3$ in $CDCl_3$, CHD_2OD in CD_3OD, or CHD_2COCD_3 in CD_3COCD_3 was employed as the internal standard (assigned as δ 7.26, 3.30, and 2.04, respectively, downfield from tetramethylsilane (TMS)). ^{13}C nuclear magnetic resonance (^{13}C nmr) spectra were measured on a Bruker AM-300, WH-400, or AM-400 spectrometer. $CDCl_3$, CD_3OD, or CD_3COCD_3 was employed as the internal standard (assigned as δ 77.0, 49.0, or 29.8, respectively, downfield from TMS). Ultraviolet (uv) spectra were obtained on a Hewlett Packard 8450A diode array spectrophotometer. Optical rotations were measured on a Perkin Elmer 241 polarimeter. Circular dichroic (cd) – optical rotary dispersion (ord) spectra were measured on a Jasco model SS20 cd–ord spectrometer. Melting points were recorded on a Fisher–Johns or Leitz–Wetzlar melting point apparatus and are uncorrected. Analytical thin-layer chromatography (tlc) was carried out on aluminum sheets precoated (0.2 mm) with silica gel 60 F-254 (E. Merck, Darmstadt). Materials were detected under an ultraviolet (uv) lamp (254 or 350 nm), or by spraying with a solution of phosphomolybdic acid (5%) containing a trace of ceric sulfate in aqueous sulfuric acid (5%, v/v), or a solution of anisaldehyde (2%) in aqueous sulfuric acid (10%, v/v), followed by charring on a hot plate. Flash column chromatography (46) was performed with Merck Silica Gel 60 (40–63 μm). All solvents except diethyl ether and *n*-hexane were distilled prior to use. Skellysolve B refers to Skelly Oil Company light petroleum, bp 62–70°C.

Growth of Talaromyces flavus *and extraction of the metabolites*

The strain (ATCC 52201; UAMH 4890) of *T. flavus* used in this study was obtained from the American Type Culture Collection, Rockville, Maryland. It was isolated from sclerotia of *Sclerotina minor* buried in soil at Beltsville, Maryland. The strains (UAMH 5360, 5366) of *V. dahliae* used were obtained from D. R. Fravel, Soilborne Diseases Laboratory, Beltsville, Maryland. Stock cultures of *T. flavus* were maintained at 4°C in slant tubes containing Difco potato dextrose agar. To initiate liquid still cultures of the fungus, an aqueous spore suspension of *T. flavus* was used to inoculate two agar plates (10% filtered V-8 juice (Campbell Soup Company Ltd.), 1% glucose, 2% agar). After incubation for 2 weeks, the plate cultures were blended in a Waring blender with ca. 200 mL of sterile water and 20-mL aliquots were inoculated into each of 10 2.8-L Fernbach flasks charged with 1 L of sterile malt extract medium (2% (w/v) glucose, 2% (w/v) malt extract, and 0.1% (w/v) peptone). The culture was kept at room temperature for 4 weeks. The culture broth was decanted from the mycelium by filtration through cheesecloth, concentrated *in vacuo* to ca. 1 L, and continuously extracted with ethyl acetate for 48 h. The organic extract was dried and concentrated to give an oil (ca. 1 g), which was dissolved in aqueous methanol (85:15, 100 mL) and extracted with Skellysolve B (3 × 100 mL), dichloromethane (3 × 100 mL), and ethyl acetate (3 × 100 mL). The organic extracts were dried and concentrated to give oils, which were chromatographed as described below. The mycelium was washed with methanol, air-dried, and subjected to continuous extraction in a Soxhlet extractor with ethyl acetate for 6 h or with methanol for 24 h. The organic extract was dried, concentrated, and separated as described below.

Isolation of the metabolites

Methanol was added to the crude mycelium extract. The insoluble material was filtered off (D-mannitol, 9.2 g). The methanol soluble portion was subjected to flash chromatography, eluting with benzene followed by benzene–ether (9:1). This afforded methyl linoleate, a triglyceride, ergosterol, and linoleic acid. Methanol was added to the crude ethyl acetate mycelium extract. D-Mannitol (1.5 g) was filtered off and the methanol soluble portion evaporated to dryness (200 mg). It was dissolved in aqueous methanol (90:10, 100 mL) and extracted with *n*-hexane (3 × 100 mL), dichloromethane (3 × 100 mL), and ethyl acetate (3 × 100 mL). Each of the extracts was dried over anhydrous sodium sulfate, filtered, and the solvents were removed under reduced pressure to give the hexane extract (170 mg), dichloromethane extract (12 mg), and the ethyl acetate extract (18 mg). The hexane extract was subjected to flash chromatography, eluting with Skellysolve B – acetone (93:7). This afforded the triglyceride, ergosterol, and a diglyceride. The hexane portion of the ethyl acetate broth extract was subjected to flash chromatography, eluting with Skellysolve B – ether (7:1). The major metabolite isolated was the triglyceride. Purification of the metabolites isolated from the dichloromethane and ethyl acetate fractions of the broth extract are described under their appropriate headings.

D-Glucono-1,4-lactone (1)

D-Glucono-1,4-lactone (**1**) was isolated from the ethyl acetate portion of the broth extract by flash chromatography, eluting with toluene–acetone – acetic acid (35:65:1). It crystallized after evaporation of the eluent. Recrystallization from acetic acid gave D-glucono-1,4-lactone (**1**) as a white powder (124 mg), mp 127–129°C (lit. (27) mp 132–135°C); tlc: R_f 0.29 (toluene–acetone – acetic acid 35:65:1); ftir (acetone cast): 3300 (br), 1776, 1182, 1100, 985 cm^{-1}; ^1H nmr (methanol-d_4) δ: 4.54 (1H, dd, J = 4.8, 6.5 Hz, H-4), 4.35 (1H, dd, J = 4.7, 6.5 Hz, H-3), 4.24 (1H, d, J = 4.7 Hz, H-2), 3.97 (1H, ddd, J = 3.9, 4.8, 5.7 Hz, H-5), 3.77 (1H, dd, J = 3.9, 11.7 Hz, H-6), 3.69 (1H, dd, J = 5.7, 11.7 Hz, H-6′); ^{13}C nmr (CD_3OD–D_2O 1:1) δ: 177.5 (s, C-1), 81.0 (d, C-4), 74.4, 74.2, 71.4 (3 × d, C-2, C-3, C-5), 63.8 (t, C-6); hreims, m/z calcd. for $C_6H_{10}O_6$ (M^+): 178.0477; found: M^+ not detected, 160 (21), 142 (4), 103 (24), 73 (100); cims, m/z: 196 (M + 18).

Acetylation of D-glucono-1,4-lactone (1)

Pyridine (1.0 mL) was added to a solution of D-glucono-1,4-lactone (**1**, 9.0 mg) in acetic anhydride (1.0 mL). The reaction was allowed to stand at room temperature for 6 h. Toluene (5.0 mL) was added to the mixture and the solution was evaporated under reduced pressure. Flash chromatography of the crude reaction product, eluting with Skellysolve B – acetone (2.5:1), afforded D-glucono-1,4-lactone tetraacetate (**2**) as white needles (15.6 mg), mp 101–102°C (lit. (27) mp 103°C); tlc: R_f 0.29 (Skellysolve B – acetone 2.5:1); $[\alpha]_D$ +59° (*c* 1.0, acetone) (lit. (27) $[\alpha]_D$ +60.3° (acetone)); ftir (acetone cast): 1806, 1751, 1373, 1224, 1194, 1067, 1046 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 5.62 (1H, dd, J = 3.0, 5.5 Hz, H-3), 5.35 (1H, ddd, J = 3.0, 5.0, 8.0 Hz, H-5), 5.23 (1H, d, J = 3.0 Hz, H-2), 4.96 (1H, dd, J = 5.5, 8.0 Hz, H-4), 4.58 (1H, dd, J = 3.0, 12.0 Hz, H-6), 4.15 (1H, dd, J = 5.0, 12.0 Hz, H-6′), 2.19 (3H, s, $OCOCH_3$), 2.12 (3H, s, $OCOCH_3$), 2.10 (3H, s,

*4,6-Dihydroxy-5-methylphthalide (**3**) (4,6-dihydroxy-5-methyl-1(3*H*)-isobenzofuranone)*

4,6-Dihydroxy-5-methylphthalide (**3**) was isolated by flash chromatography of the dichloromethane portion of the ethyl acetate broth extract, eluting with dichloromethane–methanol (97:3). It crystallized from the eluent as colorless needles (4.8 mg), mp 240–241°C (lit. (29) mp 241–242°C); tlc: R_f 0.19 (dichloromethane–methanol 97:3); uv (methanol): 213 (4.50), 259 (3.92), 306 (3.58) nm; 1 drop 0.1 N NaOH: 232 (4.35), 278 (3.75), 328 (3.58) nm; 1 drop 0.1 N NaOH – 1 drop 0.1 N HCl: 212 (4.48), 259 (3.91), 307 (3.58) nm; ftir (acetone cast): 3360 (br), 1730, 1610, 1470, 1450, 1342, 1092, 1024, 770 cm^{-1}; ^1H nmr (acetone-d_6) δ: 8.92 (1H, br s, O*H*), 8.64 (1H, br s, O*H*), 6.84 (1H, s, H-7), 5.19 (2H, s, H-3), 2.18 (3H, s, C-5 CH_3); (methanol-d_4) δ: 6.77 (1H, s, H-7), 5.19 (2H, s, H-3), 2.14 (3H, s, C-5 CH_3); ^{13}C nmr (acetone-d_6) δ: 171.6 (s, C-1), 158.5 (s, C-6), 151.2 (s, C-4), 126.1 (s, C-3a), 125.2 (s, C-7a), 119.3 (s, C-5), 102.6 (d, C-7), 68.5 (t, C-3), 9.2 (q, C-5 CH_3); (methanol-d_4) δ: 174.2 (s, C-1), 159.1 (s, C-6), 151.5 (s, C-4), 126.3 (s, C-3a), 124.7 (s, C-7a), 120.5 (s, C-5), 102.1 (d, C-7), 69.7 (t, C-3), 9.2 (q, C-5 CH_3); hreims, *m/z* calcd. for $C_9H_8O_4$ (M^+): 180.0422; found: 180.0421 (55), 179 (13), 151 (100); cims, *m/z*: 198 (M^+ + 18).

*Methylation of 4,6-dihydroxy-5-methylphthalide (**3**)*

A solution of 4,6-dihydroxy-5-methylphthalide (**3**, 4.2 mg), potassium carbonate (30.0 mg), and methyl iodide (0.1 mL) in dry acetone (5.0 mL) was heated under reflux for 2.5 h. The reaction mixture was filtered and the solvent was removed under reduced pressure, yielding a white solid that was taken up in dichloromethane (10.0 mL). The solution was stirred at room temperature for 0.5 h. It was then filtered and the solvent was removed under reduced pressure, yielding a pale yellow solid (6.3 mg) that was purified by flash chromatography, eluting with Skellysolve B – ethyl acetate (4:1). This afforded white flakes of 4,6-dimethoxy-5-methylphthalide (**4**, 3.5 mg), mp 162–162.5°C (lit. (29) mp 162°C); tlc: R_f 0.27 (Skellysolve B – ethyl acetate 4:1); uv (methanol): 214 (3.75), 255 (3.08), 304 (2.78) nm; ftir ($CHCl_3$ cast): 3000, 2970, 2950, 1765, 1740, 1616, 1466, 1417, 1152, 1127, 1045, 767 cm^{-1}; ^1H nmr (acetone-d_6) δ: 7.02 (1H, s, H-7), 5.51 (2H, s, H-3), 3.96 (3H, s, OCH_3), 3.93 (3H, s, OCH_3), 2.14 (3H, s, C-5 CH_3); ^{13}C nmr (acetone-d_6) δ: 171.1 (s, C-1), 160.8 (s, C-6), 154.0 (s, C-4), 128.9 (s, C-3a), 126.1 (s, C-5), 124.8 (s, C-7a), 100.9 (d, C-7), 68.9 (t, C-3), 59.4 (q, OCH_3), 56.6 (q, OCH_3), 9.6 (q, C-5 CH_3); hreims, *m/z* calcd. for $C_{11}H_{12}O_4$ (M^+): 208.0736; found: 208.0738 (61), 207 (7), 179 (100); cims, *m/z*: 209 (M + 1), 226 (M + 18).

*5-Hydroxymethylfurfural (**5**)*

5-Hydroxymethylfurfural (**5**) was isolated by flash chromatography of the dichloromethane portion of the ethyl acetate broth extract, eluting with dichloromethane–methanol (97:3). Further purification was achieved by flash chromatography, eluting with Skellysolve B – ethyl acetate – acetic acid (60:40:1). This afforded 5-hydroxymethylfurfural (**5**) as a clear, pale yellow oil (7.5 mg), tlc: R_f 0.33 (dichloromethane–methanol 97:3), 0.28 (Skellysolve B – ethyl acetate – acetic acid 60:40:1); uv (methanol): 221 (3.43), 281 (3.49) nm; ftir (CH_2Cl_2–CH_3OH cast): 3370 (br), 2920, 2840, 2700, 1674, 1522, 1396, 1191, 1022 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 9.58 (1H, s, C*H*O), 7.19 (1H, d, *J* = 3.5 Hz, H-3), 6.50 (1H, d, *J* = 3.5 Hz, H-4), 4.70 (2H, s, CH_2OH), 1.62 (1H, br s, O*H*); (acetone-d_6) δ: 9.57 (1H, s, C*H*O), 7.36 (1H, d, *J* = 3.5 Hz, H-3), 6.56 (1H, d, *J* = 3.5 Hz, H-4), 4.62 (2H, s, CH_2OH); ^{13}C nmr (acetone-d_6) δ: 178.1 (d, *C*HO), 163.0 (s, C-5), 153.7 (s, C-2), 123.3 (d, C-3), 110.2 (d, C-4), 57.6 (t, C-6); hreims, *m/z* calcd. for $C_6H_6O_3$ (M^+): 126.0317; found: 126.0321 (70), 125 (16), 97 (100); cims, *m/z*: 144 (M + 18).

*7-Hydroxy-2,5-dimethylchromone (**6**) (7-hydroxy-2,5-dimethyl-4*H*-1-benzopyran-4-one)*

7-Hydroxy-2,5-dimethylchromone (**6**) was isolated by flash chromatography of the dichloromethane portion of the ethyl acetate broth extract, eluting with dichloromethane–methanol (97:3). It crystallized from the eluent as white flasks (3.4 mg), mp 200°C (subl.) (lit. (36) mp 257–260°C, sublimes at 200°C); tlc: R_f 0.25 (dichloromethane–methanol 97:3); uv (methanol): 241 (4.12), 249 (4.13), 288 (3.92) nm; 1 drop 0.1 N NaOH: 254 (4.19), 325 (3.95) nm; 1 drop 0.1 N NaOH – 1 drop 0.1 N HCl: 241 (4.12), 2.49 (4.13), 288 (3.92) nm; ftir (methanol cast): 3400–3000 (br), 1649, 1618, 1557, 1162 cm^{-1}; ^1H nmr (methanol-d_4) δ: 6.64 (1H, d, *J* = 2.5 Hz, H-8), 6.62 (1H, dq, *J* = 2.5, 1.0 Hz, H-6), 6.00 (1H, q, *J* = 1.0 Hz, H-3), 2.70 (3H, bs, C5 CH_3), 2.31 (3H, d, *J* = 1.0 Hz, C-2 CH_3); ^{13}C nmr (methanol-d_4) δ: 182.0 (s, C-4), 166.6 (s, C-2), 163.1 (s, C-7 or C-9), 161.5 (s, C-7 or C-9), 143.7 (s, C-5), 118.0 (d, C-3), 115.7 (s, C-10), 111.4 (d, C-6), 101.7 (d, C-8), 23.0 (q, C-5 CH_3), 19.8 (q, C-2 CH_3); hreims, *m/z* calcd. for $C_{11}H_{10}O_3$ (M^+): 190.0630; found: 190.0632 (100), 162 (14), 150 (11); cims, *m/z*: 191 (M + 1).

*Methylation of 7-hydroxy-2,5-dimethylchromone (**6**)*

An excess of diazomethane in ether was added to a solution of **6** (1.3 mg) in methanol (3 drops) and the reaction mixture was allowed to stand at 0°C for 5 h. The solution was then warmed to room temperature and filtered to afford a cream colored solid, which was taken up in chloroform (5.0 mL). Evaporation to dryness and recrystallization of the solid from ether gave white flakes of 7-methoxy-2,5-dimethylchromone (**7**, 1.2 mg), mp 115–117°C (lit. (35) mp 115–117°C); tlc: R_f 0.54 (dichloromethane–methanol 97:3); uv (methanol): 248 (3.71), 280 (3.57) nm; ftir (CH_2Cl_2 cast): 1663, 1612, 1574, 1179, 1157 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.66 (2H, bs, H-6, H-8), 6.01 (1H, q, *J* = 0.6 Hz, H-3), 3.86 (3H, s, OCH_3), 2.80 (3H, bs, C-5 CH_3), 2.29 (3H, d, *J* = 0.6 Hz, C-2 CH_3); ^{13}C nmr ($CDCl_3$) δ: 163.6, 162.3, 159.2, 142.6, 116.2, 116.0, 111.8, 98.5, 55.6, 23.0, 20.0; hreims, *m/z* calcd. for $C_{12}H_{12}O_3$ (M^+): 204.0787; found: 204.0783 (100), 176 (6), 164 (5); cims, *m/z*: 205 (M + 1).

*Methyl 4-carboxy-5-hydroxyphthalaldehydate (**8**)*

Methyl 4-carboxy-5-hydroxyphthalaldehydate (**8**) was obtained by flash chromatography of the dichloromethane portion of the ethyl acetate broth extract, eluting with dichloromethane–methanol (97:3). It crystallized from the eluent as yellow granules (2.8 mg), mp 190°C (dec.); tlc: R_f 0.35 (dichloromethane–methanol 97:3); uv (methanol): 225 (4.15), 293 (3.90), 428 (2.65) nm; 1 drop 0.1 N NaOH: 229 (4.19), 305 (3.95), 426 (2.90) nm; 1 drop 0.1 N NaOH – 1 drop 0.1 N HCl: 226 (4.14), 293 (3.90), 427 (2.64); ftir (methanol cast): 3560–2400 (br), 1757 (m), 1655, 1635, 1440, 1351, 1281, 1243, 1102, 1080 cm^{-1}; ^1H nmr (methanol-d_4) δ: 10.42 (1H, s, C*H*O), 6.70 (1H, s, Ar*H*), 6.38 (1H, s, Ar*H*), 3.52 (3H, s, $COOCH_3$); (acetone-d_6) δ: 10.46 (1H, s, C*H*O), 6.79 (1H, s, Ar*H*), 6.45 (1H, s, Ar*H*), 3.53 (3H, s, $COOCH_3$); ^{13}C nmr (methanol-d_4) δ: 196.6 (d, *C*HO), 169.4 (s), 166.3 (s), 160.1 (s), 136.8 (s), 122.7 (s), 114.6 (s), 103.9 (d), 102.4 (d), 56.4 (q, $COOCH_3$); hreims, *m/z* calcd. for $C_{10}H_8O_6$ (M^+): 224.0320; found: 224.0317 (30), 193 (95), 192 (86), 164 (100); cims, *m/z*: 225 (M + 1), 242 (M + 18).

*Reduction of methyl 4-carboxy-5-hydroxyphthalaldehydate (**8**)*

To a solution of methyl 4-carboxy-5-hydroxyphthalaldehydate (**8**, 2.0 mg) in methanol (1.0 mL) was added sodium borohydride (0.5 g). After 15 s the yellow color of the solution faded. After 10 min acetic acid (1 N, 2 drops) was added and the solvent was removed *in vacuo* to afford a clear, pale yellow oil. Purification of the reduction product by elution with dichloromethane–methanol (96:4) through a small silica gel pipette column afforded the reduction product as a clear, pale yellow oil (**9**, 1.3 mg); tlc: R_f 0.26 (dichloromethane–methanol 96:4); ftir (methanol cast): 3240 (br), 2920, 2840, 1755, 1618, 1466, 1368, 1347, 1242, 1098, 1032 cm^{-1}; ^1H nmr (acetone-d_6) δ: 6.74 (1H, s, Ar*H*), 6.35 (1H, s, Ar*H*), 5.01 (2H, s, OCH_2).

*3-Hydroxymethyl-6,8-dimethoxycoumarin (**10**) (3-hydroxymethyl-6,8-dimethoxy-2*H*-1-benzopyran-2-one)*

The coumarin (**10**) was obtained by flash chromatography of the dichloromethane portion of the ethyl acetate broth extract, eluting with dichloromethane–methanol (97:3). The crude metabolite was furher purified by passage through a small silica gel pipette column, eluting with dichloromethane–methanol (98:2), and then through another

For personal use only.

column that was eluted with Skellysolve B – ethyl acetate – acetic acid (45:55:1). It was obtained as an amorphous solid (1.2 mg); tlc: R_f 0.36 (dichloromethane–methanol 97:3), 0.23 (dichloromethane–methanol 98:2), 0.26 (Skellysolve B – ethyl acetate – acetic acid 45:55:1); uv (methanol): 256 (4.11), 286 (4.17) nm; 1 drop 0.1 N NaOH: 255 (4.09), 284 (4.19) nm; ftir (CH_2Cl_2 cast): 3360 (br), 1760 (sh), 1711, 1657, 1592, 1205, 1162 cm^{-1}; ^1H nmr ($CDCl_3$–CD_3OD 4:1) δ: 7.70 (1H, t, J = 1.4 Hz, H-4), 6.65 (1H, d, J = 2.6 Hz, H-7), 6.48 (1H, d, J = 2.6 Hz, H-5), 4.55 (2H, d, J = 1.4 Hz, CH_2OH), 3.90 (3H, s, OCH_3), 3.81 (3H, s, OCH_3); ^{13}C nmr ($CDCl_3$) δ: 148.1 (s, C-4a), 138.7 (d, C-4), 128.6 (s, C-1a), 103.0 (d, C-5 or C-7), 101.2 (d, C-5 or C-7), 61.3 (t, CH_2OH), 56.3 (q, OCH_3), 55.8 (q, OCH_3); hreims, m/z calcd. for $C_{12}H_{12}O_5$ (M^+): 236.0685; found: 236.0691 (100), 235 (11), 207 (20); cims, m/z: 237 (M + 1), 254 (M + 18).

*Altenusin (**11**) (3,4′,5′-trihydroxy-5-methoxy-2′-methyl(1,1′-biphenyl)-2-carboxylic acid)*

Altenusin (**11**) was obtained by flash chromatography of the dichloromethane portion of the ethyl acetate broth extract, eluting with dichloromethane–methanol (97:3). The crude metabolite was further purified by dry flash chromatography, eluting with toluene–acetone – acetic acid (50:50:1), and then passed through a small silica gel pipette column, eluting with Skellysolve B – ethyl acetate – acetic acid (45:55:1). Altenusin (**11**) crystallized from the eluent as white flakes (5.0 mg), mp 194–196°C (lit. (38) mp 195–198°C); tlc: R_f 0.30 (toluene–acetone – acetic acid 50:50:1), 0.29 (Skellysolve B – ethyl acetate – acetic acid 45:55:1); ftir (CH_2Cl_2–CH_3OH cast): 3600–2800 (br), 1645 (w), 1610, 1582, 1518, 1270, 1204, 1158 cm^{-1}; ^1H nmr ($CDCl_3$–CD_3OD 1:1) δ: 6.47 (1H, s, H-3′ or H-6′), 6.40 (1H, s, H-3′ or H-6′), 6.27 (1H, d, J = 2.6 Hz, H-4 or H-6), 6.04 (1H, d, J = 2.6 Hz, H-4 or H-6), 3.65 (3H, s, OCH_3), 1.77 (3H, s, C-2′ CH_3); ^{13}C nmr ($CDCl_3$–CD_3OD 1:1) δ: 172.8 (s, CO_2H), 164.1 (s, C-3 or C-5), 163.1 (s, C-3 or C-5), 146.2 (s, C-1), 143.0 (s, C-4′ or C-5′), 141.3 (s, C-4′ or C-5′), 133.9 (s, C-1′), 126.6 (s, C-2′), 115.9 (d, C-3′ or C-6′), 115.2 (d, C-3′ or C-6′), 110.1 (d, C-6), 105.9 (s, C-2), 99.5 (d, C-4), 55.0 (q, OCH_3), 18.5 (q, C-2′ CH_3); hreims, m/z calcd. for $C_{15}H_{14}O_6$ (M^+): 290.0790; found: 290.0788 (56), 272 (26), 246 (100), 245 (32), 244 (52); cims, m/z: 247 (M + 1 – CO_2).

*Dehydroaltenusin (**12**)*

Dehydroaltenusin (**12**) was obtained by flash chromatography of the dichloromethane portion of the ethyl acetate broth extract, eluting with dichloromethane–methanol (97:3). The crude metabolite was further purified by flash chromatography, eluting with dichloromethane–methanol (99:1), and then passed through a small silica gel pipette column, eluting with Skellysolve B – ethyl acetate – acetic acid (50:50:1). It was further chromatographed in the same manner with dichloromethane–methanol (98:2). This afforded dehydroaltenusin (**12**), which still contained some impurities; ^1H nmr ($CDCl_3$) δ: 11.30 (1H, s, C-3 OH), 6.73 (1H, d, J = 2.3 Hz, H-4 or H-6), 6.69 (1H, s, H-10), 6.63 (1H, d, J = 2.3 Hz, H-4 or H-6), 6.28 (1H, s, H-7), 3.91 (3H, s, OCH_3), 1.73 (3H, s, C-1a CH_3). It was allowed to stand at room temperature for 24 h with acetic anhydride (0.3 mL) and pyridine (0.3 mL). Ethyl acetate (5.0 mL) and toluene (1.0 mL) were added to the reaction mixture and the solvents were removed under reduced pressure. This afforded the crude diacetate (**13**), which was purified by passage through a small silica gel pipette column, eluting with Skellysolve B – acetone (2:1). Dehydroaltenusin diacetate (**13**) crystallized from the eluent as white flakes (0.6 mg), mp 190–193°C (lit. (38) mp 185°C); tlc: R_f 0.39 (Skellysolve B – acetone 2:1), ftir (CH_2Cl_2 cast): 1776, 1732, 1688, 1664, 1617, 1370, 1192, 1144, 800 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.77 (1H, d, J = 1.9 Hz, H-4), 6.60 (1H, d, J = 1.9 Hz, H-6), 6.36 (1H, s, H-7), 6.30 (1H, q, J = 1.4 Hz, H-10), 3.86 (3H, s, OCH_3), 2.42 (3H, s, ArOCOCH_3), 2.29 (3H, s, C-9 OCOCH_3), 1.73 (3H, d, J = 1.4 Hz, C-1a CH_3); hreims, m/z calcd. for $C_{19}H_{16}O_8$ (M^+): 372.0845; found: 372.0848 (10), 330 (59), 288 (63), 270 (10), 260 (24), 244 (38), 232 (17), 165 (100); cims, m/z: 390 (M + 18).

*Desmethyldehydroaltenusin (**14**)*

Desmethyldehydroaltenusin (**14**) was obtained by flash chromatography of the dichloromethane portion of the ethyl acetate broth extract, eluting with dichloromethane–methanol (97:3). The crude metabolite was further purified by dry flash chromatography, eluting with Skellysolve B – ethyl acetate – acetic acid (50:50:1). It was then passed through a small silica gel pipette column, eluting with dichloromethane–methanol (98:2). This afforded desmethyldehydroaltenusin (**14**), which was still somewhat impure. It was allowed to stand at room temperature for 24 h with acetic anhydride (0.3 mL) and pyridine (0.3 mL). Ethyl acetate (5.0 mL) and toluene (1.0 mL) were added to the reaction mixture and the solvents were removed *in vacuo*. This afforded the crude triacetate (**15**), which was purified by passage through a small silica gel pipette column, eluting with Skellysolve B – acetone (2:1). Desmethyldehydroaltenusin triacetate (**15**) was obtained as an amorphous solid (1.0 mg); tlc: R_f 0.33 (Skellysolve B – acetone 2:1); ftir (CH_2Cl_2 cast): 1777, 1680, 1660, 1610, 1365, 1190, 1150, 1122, 1015 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.10 (1H, d, J = 1.7 Hz, H-4 or H-6), 6.97 (1H, d, J = 1.7 Hz, H-4 or H-6), 6.37 (1H, s, H-7), 6.31 (1H, q, J = 1.5 Hz, H-10), 2.43 (3H, s, ArOCOCH_3), 2.31 (3H, s, OCOCH_3), 2.29 (3H, s, OCOCH_3), 1.74 (3H, d, J = 1.5 Hz, C-1a CH_3); hreims, m/z calcd. for $C_{20}H_{16}O_9$ (M^+): 400.0794; found: 400.0784 (3), 358 (100), 316 (63), 274 (89), 256 (29), 246 (31), 230 (62), 218 (16); cims, m/z: 418 (M + 18).

*Talaroflavone (**16**) (spiro[5′-hydroxy-2′-methyl-cyclopent-2′-ene-4′-one-1′,3,7-hydroxy-5-methoxy-1(3*H*)-isobenzofuranone])*

Talaroflavone (**16**) was obtained by flash chromatography of the dichloromethane portion of the ethyl acetate broth extract, eluting with dichloromethane–methanol (97:3). The crude metabolite was further purified by passing it through a small silica gel pipette column, eluting with Skellysolve B – ethyl acetate – acetic acid (45:55:1). It crystallized from the eluent as white flakes (3.0 mg), mp 230°C (dec.); tlc: R_f 0.25 (dichloromethane–methanol 97:3), 0.28 (Skellysolve B – ethyl acetate – acetic acid 45:55:1); $[\alpha]_D$ +181° (c 0.74, methanol); uv (methanol): 217 (4.19), 257 (3.66), 296 (3.28) nm; 1 drop 0.1 N NaOH: 228 (4.19), 256 (3.58), 325 (3.41) nm; 1 drop 0.1 N NaOH – 1 drop 0.1 N HCl: 216 (4.20), 257 (3.71), 295 (3.34) nm; ftir (methanol cast): 3240 (br), 1748, 1723, 1617, 1204, 1162, 1152, 1004 cm^{-1}; ^1H nmr (methanol-d_4) δ: 6.44 (1H, d, J = 2.0 Hz, H-4 or H-6), 6.34 (1H, q, J = 1.5 Hz, H-3′), 6.05 (1H, d, J = 2.0 Hz, H-4 or H-6), 4.74 (1H, s, H-5′), 3.80 (3H, s, OCH_3), 1.86 (3H, d, J = 1.5 Hz, C-2′ CH_3); ^{13}C nmr (methanol-d_4) δ: 202.0 (s, C-4′), 171.4, 170.2, 168.5 (3 × s, C-1, C-2′, C-5), 159.9 (s, C-7), 150.8 (s, C-3a), 131.4 (d, C-3′), 106.5 (s, C-7a), 103.5 (d, C-4 or C-6), 101.0 (d, C-4 or C-6), 94.2 (s, C-1′), 79.7 (d, C-5′), 56.5 (q, OCH_3), 13.4 (q, C-2′ CH_3); hreims, m/z calcd. for $C_{14}H_{12}O_6$ (M^+): 276.0634; found: 276.0633 (100), 258 (64), 248 (30), 247 (21), 230 (17), 220 (39), 219 (64); cims, m/z: 277 (M + 1), 294 (M + 18).

*Acetylation of talaroflavone (**16**)*

Pyridine (0.5 mL) was added to a solution of talaroflavone (**16**, 4.0 mg) in acetic anhydride (0.5 mL). The reaction mixture was allowed to stand at room temperature for 22 h. Ethyl acetate (5.0 mL) and toluene (1.0 mL) were added to the mixture and the solution was evaporated under reduced pressure. The crude acetylation product was passed through a small silica gel pipette column, eluting with Skellysolve B – acetone (2.5:1) to afford talaroflavone diacetate (**17**) as a clear, colorless oil (3.0 mg), tlc: R_f 0.21 (Skellysolve B – acetone 2.5:1); ord (methanol): $[\alpha]_{265}$ +33°: cd (methanol): $\Delta\Sigma_{235}$ 6.3 L mol^{-1} cm^{-1}; $\Delta\Sigma_{325}$ 0.27 L mol^{-1} cm^{-1}; ftir (CH_2Cl_2 cast): 3080, 2920, 2840, 1777, 1732, 1621, 1491, 1371, 1256, 1221, 1189, 1143 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.76 (1H, d, J = 2.0 Hz, H-4 or H-6), 6.42 (1H, d, J = 2.0 Hz, H-4 or H-6), 6.35 (1H, q, J = 1.5 Hz, H-3′), 5.84 (1H, s, H-5′), 3.85 (3H, s, OCH_3), 2.39 (3H, s, ArOCOCH_3), 1.87 (6H, br s, C-5′ OCOCH_3, C-2′ CH_3); (methanol-d_4) δ: 6.93 (1H, d, J = 2.0 Hz, H-4 or H-6), 6.61 (1H, d, J = 2.0 Hz, H-4 or H-6), 6.49 (1H, q, J = 1.5 Hz, H-3′), 5.81 (1H, s, H-5′), 3.89 (3H, s, OCH_3), 2.35 (3H, s, ArOCOCH_3), 1.86 (3H, d, J = 1.5 Hz, C-2′ CH_3), 1.82 (3H, s, C-5′ OCOCH_3); ^{13}C nmr ($CDCl_3$) δ: 195.3 (s), 170.8 (s), 169.0 (s), 168.4 (s), 166.1 (s), 165.3 (s), 150.1 (s), 147.9 (s), 131.5 (d), 111.3 (s), 110.9 (d), 104.9 (d), 90.7 (s), 76.9 (d), 56.4 (q), 20.7 (q), 20.1 (q), 13.7 (q); (methanol-d_4) δ: 197.1 (s), 172.0 (s), 170.8 (s), 170.0 (s), 168.1 (s), 167.2 (s), 151.5 (s), 149.5 (s), 133.2 (d), 112.4 (s), 112.1 (d), 106.7 (d), 92.7 (s), 78.1 (d),

57.2 (q), 20.4 (q), 19.8 (q), 13.3 (q); hreims, m/z calcd. for $C_{18}H_{16}O_8$ (M^+): 360.0845; found: 360.0850 (12), 318 (100), 276 (97), 258 (99), 248 (6), 247 (25), 230 (6), 220 (10), 219 (24).

Deoxytalaroflavone (18)

Deoxytalaroflavone (**18**) was obtained by flash chromatography of the dichloromethane portion of the ethyl acetate broth extract, eluting with dichloromethane–methanol (97:3). It was further purified by flash chromatography, eluting with dichloromethane–methanol (99:1). This afforded white flakes of deoxytalaroflavone (**18**, 3.0 mg), mp 178–180°C; tlc: R_f 0.35 (Skellysolve B – acetone 2:1); ftir (CH_2Cl_2 cast): 3400–2800 (br), 1713, 1679, 1610, 1565, 1390, 1239, 1226, 1200, 1109, 797, 733, 691 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 11.35 (1H, s, C-3 O*H*), 6.70 (1H, d, J = 2.3 Hz, H-4 or H-6), 6.69 (1H, d, J = 2.3 Hz, H-4 or H-6), 3.94 (3H, s, OCH_3), 3.43 (1H, ddd, J = 1.3, 6.6, 6.9 Hz, H-9), 2.95 (1H, dd, J = 6.6, 19.0 Hz, H-8), 2.31 (1H, dd, J = 1.3, 19.0 Hz, H-8′), 1.46 (3H, d, J = 6.9 Hz, C-9 CH_3); ^{13}C nmr ($CDCl_3$) δ: 134.6 (s), 115.3 (s), 103.3 (d), 103.1 (d), 56.1 (q), 42.9 (t), 28.4 (d), 21.1 (q); hreims, m/z calcd. for $C_{14}H_{12}O_5$ (M^+): 260.0685; found: 260.0688 (100), 245 (8), 232 (16), 217 (45), 204 (8), 189 (13), 161 (19); cims, m/z: 261 (M + 1), 278 (M + 18).

The metabolites of *Talaromyces flavus*: Part 2. Biological activity and biosynthetic studies

WILLIAM A. AYER[1] AND JULIE S. RACOK
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received February 5, 1990

WILLIAM A. AYER and JULIE S. RACOK. Can. J. Chem. **68**, 2095 (1990).

The soil fungus *Talaromyces flavus* (Klöcker) Stolk and Samson is an effective biological control for Verticillium wilt of eggplant (*Solanum melongena* L.), a disease caused by the fungus *Verticillium dahliae* Kleb. The water soluble metabolites isolated from the broth when the fungus is grown in liquid still culture, hydroxymethylmaltol (**1**), 5,6-dihydro-3,5-dihydroxy-6-hydroxymethyl-2*H*-pyran-2-one (**3**), and D-glucono-1,4-lactone (**5**), do not show antifungal activity against *V. dahliae*; however, hydrogen peroxide displays this inhibition. This peroxide has been detected in the *T. flavus* broth and it, together with **5**, is the product of the glucose oxidase catalyzed oxidation of D-glucose. The results of the search for this antifungal activity are presented. [1-^{13}C] Labelled sodium acetate was utilized as a precursor for studying the biosynthesis of the *T. flavus* metabolites 4,6-dihydroxy-5-methylphthalide (**7**), methyl 4-carboxy-5-hydroxyphthalaldehydate (**8**), and talaroflavone (**9**). The incorporation of label into these compounds is discussed.

Key words: *Talaromyces flavus*, fungal metabolites, hydrogen peroxide, biosynthesis, talaroflavone.

WILLIAM A. AYER et JULIE S. RACOK. Can. J. Chem. **68**, 2095 (1990).

Le champignon du sol *Talaromyces flavus* (Klöcker) Stolk et Samson contrôle biologiquement et d'une façon efficace la flétrissure par le Verticillium de l'aubergine (*Solanum melongena* L.), une maladie causée par le champignon *Verticillium dahliae* Kleb. Les métabolites organiques solubles dans l'eau qui sont isolés du bouillon de culture du champignon, l'hydroxyméthylmaltol (**1**), la 5,6-dihydro-3,5-dihydroxy-6-hydroxyméthyl-2*H*-pyran-2-one (**3**) et la D-glucono-1,4-lactone (**5**), ne présentent pas d'activité contre la moisissure *V. dahliae*; toutefois le peroxyde d'hydrogène présente une telle inhibition. Ce peroxyde a été détecté dans le bouillon du *T. flavus* et, avec le produit **5**, ils sont les produits de l'oxydation du D-glucose catalysée par la glucose oxydase. On présente les résultats de la recherche de cette activité contre la moisissure. On a utilisé du [1-^{13}C]-acétate de sodium comme précurseur pour l'étude de la biosynthèse des métabolites suivants du *T. flavus* : 4,6-dihydroxy-5-méthylphtalide (**7**), 4-carboxy-5-hydroxyphtalaldéhydate de méthyle (**8**) et talaroflavone (**9**). On discute de l'incorporation de ce marqueur dans ces composés.

Mots clés : *Talaromyces flavus*, métabolites de champignons, peroxyde d'hydrogène, biosynthèse, talaroflavone.
[Traduit par la revue]

Introduction

In Part 1 of this series (1) we reported the isolation and structure determination of the organic soluble metabolites produced by the soil fungus *Talaromyces flavus* (Klöcker) Stolk and Samson. Our interest in the metabolites produced by this fungus was stimulated by the report of its effectiveness as a biological control for Verticillium wilt of eggplant (*Solanum melongena* L.), a disease caused by the fungus *Verticillium dahliae* Kleb. (2). This disease develops slowly, beginning with a yellowing of the lower leaves, and causes a stunting of growth, a reduction in fruit size, and vascular discoloration. The penetration of Verticillium wilt in the host occurs through the root system and progress is primarily in the xylem. Neither crop rotation nor soil fumigants have been useful in reducing losses from the disease in eggplant. Crop rotation is not effective because the pathogen may persist as microsclerotia in the soil in the absence of a known host for many years. Soil fumigants delay the onset of symptoms and are used to reduce disease severity; however, the adverse effects on the environment and high cost disfavor their use. The main effect of a vascular pathogen like *V. dahliae* is to disrupt the passage of water through the stem. This may be attributed to the physical presence of the pathogen mycelium, the development of tyloses that block the xylem, or to gummosis within the vessels. Parasites like *Verticillium* in vessels cause a 4- to 60-fold increase in the resistance of the stem to water flow (3, 4). Further xylem occlusion comes from high molecular weight polysaccharides produced by the pathogen or cleaved from the xylem walls by hydrolytic enzymes.[2] *Verticillium dahliae* is the cause of a wilting disease in a wide variety of host organisms, most severely in eggplant, tomato, potato, and cotton. Among isolates of this species, there is considerable variation in morphology and pathogenicity. Generally, the pathogenicity of isolates of *V. dahliae* is nonspecific, although some isolates have restricted or unique host ranges (5–7). We found that *T. flavus* displays antifungal activity against the strain of *V. dahliae* isolated from eggplant; however, a strain of *V. dahliae* isolated from tomato did not show this biological activity. A plug to plug bioassay performed to determine the mode of action of *T. flavus* against *V. dahliae* revealed that, after 2 weeks, there is a distinct area between the fungi that shows no growth. There are no obvious signs of intermingling or broken hyphae so that there seems to be no antagonism of *V. dahliae* by *T. flavus*. Although the physical mechanism of biological control of *V. dahliae* by *T. flavus* is not clear, we engaged in an investigation of the metabolites of the *T. flavus* broth in search of the antifungal activity.

Discussion

Biological activity and the Talaromyces flavus *broth*

The bioassay developed to follow the antifungal activity of *T. flavus* against *V. dahliae* involves seeding an agar plate with *V. dahliae* and then injecting 100 μL of the *T. flavus* broth into a stainless steel vessel placed in the center of the plate. The sample diffuses into the medium and after 7–10 days the

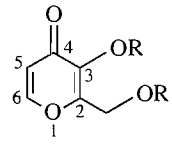
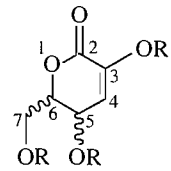
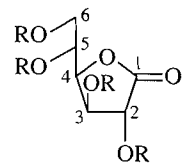
bioassay results are noted. *Verticillium dahliae* produces two types of spores: white conidial spores and black chlamydospores. The latter are a part of the microsclerotia, which store many nutrients, and are the means by which *V. dahliae* survives in the soil. The white conidial spores do not survive as long since they store fewer nutrients. The bioassay shows a large zone of inhibition by the *T. flavus* aqueous broth toward the production of microsclerotia by *V. dahliae*. It appears that by restricting *V. dahliae* microsclerotia production *T. flavus* controls Verticillium wilt of eggplant. The pH of the *T. flavus* broth drops from 5.8 to ca. 2.5–3.0 after 5 days' growth. This acidic pH is then maintained during the remainder of the growth period. Cation and anion exchange columns were tested to determine whether the active compound was charged; however, the eluent possessed antifungal activity in both cases. Neither reverse phase chromatography nor steam distillation removed the antifungal component. Passage of the broth through Sep-Pak cartridges (C_{18} and amino) failed to provide purification of the antifungal component. Iron(II) sulfate and iron(III) nitrate were added individually to see if an active metabolite capable of chelation was present. No chelate extracted into organic solvent and the fungal broth retained its activity. The ^{1}H nmr spectrum of the fungal broth shows resonances between δ 3 and 5, which we presumed were those of sugars. Attempts to remove the sugars by chromatography over charcoal and Celite resulted in the loss of biological activity. Some loss in activity was observed when a portion of the broth was autoclaved to determine if a heat sensitive compound was responsible for this biological activity. Dialysis with tubing of exclusion limit 1000 daltons revealed that, after 24 h, the contents of the dialysis bag had lost its activity, implying that the molecular weight of the active compound was less than 1000. Chromatography over Sephadex G-50, eluting with water, or Bio-Gel P-2, eluting with water–ethanol (90:10), gave positive bioassay results. The active fractions were pooled and subjected to acetylation. The major fraction (ca. 66%) appears, from its ^{1}H nmr spectrum, to be composed of acetylated sugars, while the minor portion (ca. 33%) was shown by gas chromatographic (gc) analysis to be a mixture of three compounds. Gas chromatographic mass spectral (gc–ms) separation provides the molecular weights of these acetates, 226, 286, and 346. Methanolysis of the acetates did not regenerate the biological activity; however, their identification was pursued. The diacetate **2** of hydroxymethylmaltol (**1**) has the molecular formula $C_{10}H_{10}O_6$, as determined by high resolution mass spectrometry (hrms). The loss of two molecules of ketene in the mass spectrum affords the base peak at m/z 142, corresponding to the molecular formula of the alcohol **1**, $C_6H_6O_4$. The infrared spectrum (ir) spectrum of **2** shows acetate absorptions at 1780 and 1741 cm^{-1} and γ-pyrone bands at 1656 and 1585 cm^{-1}. The ultraviolet (uv) maximum at 292 nm is consistent with a γ-pyrone chromophore and shows no bathochromic shift on addition of base. The ^{1}H nuclear magnetic resonance (nmr) spectrum indicates vinylic hydrogens at δ 7.06 and 6.24 (each a doublet, J = 7.0 Hz), a methylene (δ 4.83), and acetyl methyls (δ 2.30 and 2.12). The carbons of these acetates are seen at δ 170.0 (s), 167.9 (s), 20.6 (q), and 20.4 (q), together with singlet carbons (δ 157.1 (C-4), 155.6 (C-2), and 137.0 (C-3)), doublet carbons (δ 130.5 (C-6) and 103.8 (C-5)), and a methylene carbon (δ 61.3). The carbonyl carbon (C-4, δ 157.1) is coupled ($^3J_{CH}$ = 8 Hz) to the C-6 hydrogen (δ 7.06), in agreement with that reported (8). The isolation of hydroxymethylmaltol (**1**) is not surprising since the fungus was grown on a malt extract medium.



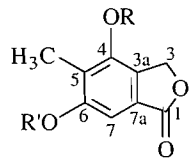
1, R = H
2, R = $COCH_3$



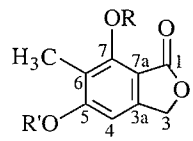
3, R = H
4, R = $COCH_3$



5, R = H
6, R = $COCH_3$



7, R, R' = H
7*a*, R = H, R' = CH_3
7*b*, R = CH_3, R' = H
7*c*, R, R' = CH_3



7*d*, R, R' = CH
7*e*, R = CH_3, R' = H

The second of the three acetates isolated is the triacetate (**4**) of 5,6-dihydro-3,5-dihydroxy-6-hydroxymethyl-2*H*-pyran-2-one (**3**). The parent ion in the hrms (m/z 286) corresponds to the molecular formula $C_{12}H_{14}O_8$. One acetate is lost as acetic acid and the other two as ketene to afford the base peak at m/z 142. The ir spectrum shows acetate carbonyl bands at 1778 and 1750 cm^{-1}. The ^{13}C nmr spectrum consists of the carbonyl carbon (δ 157.1, C-2, s), vinylic carbons (δ 139.8, C-3, s, and 125.9, C-4, d), oxygenated methines (δ 77.9, C-6, d, and 64.3, C-5, d), and a methylene carbon (δ 62.0, C-7, t). The ^{1}H nmr spectrum indicates that the vinylic hydrogen (δ 6.43, H-4) is coupled (J = 4.0 Hz) to H-5 (δ 5.61), which, in turn, is coupled (J = 5.5 Hz) to H-6 (δ 4.75). Although the stereochemistry of compound **3** was not determined, it is probable that it is derived from dehydration of D-glucono-1,5-lactone (via oxidation of D-glucose).

The third acetate isolated is the tetraacetate (**6**) of D-glucono-1,4-lactone (**5**) whose identification was discussed previously (1). Although lactone **5** shows no antifungal activity against *V. dahliae*, it is one of two products produced in the oxidation of D-glucose by glucose oxidase, whose isolation from *T. flavus* was recently reported (9, 10). This enzyme, whose kinetics and mechanism of action have been studied, is an oxidoreductase and oxidizes D-glucose to D-gluconic acid (11–13) (Fig. 1). The primary product of the oxidation of an aldose could be the aldonic acid, the γ- or the δ-lactone (14). These interconvert in aqueous solution and the proportions of each depend on the pH. The δ-lactone (**5***a*) has been shown, by means of optical rotation studies, to be the predominant kinetically controlled product of the oxidation of both anomers of glucose. D-Glucono-1,5-lactone (**5***a*) was not isolated from the fungal broth; however, it may undergo hydrolysis to the thermodynamically more stable (15, 16) γ-lactone (**5**) or dehydration to compound **3**. The other product of the enzyme oxidation, hydrogen peroxide, inhibits

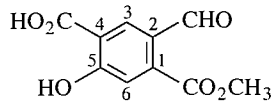
FIG. 2. Detection of H_2O_2 using horseradish peroxidase.

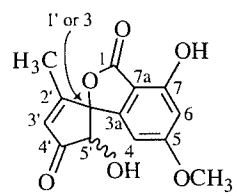
microsclerotia production by *V. dahliae*. We have observed that, as the concentration of hydrogen peroxide is increased from 2.7 to 3.6 to 7.5 μL/mL, microsclerotia production by *V. dahliae* is reduced. Microsclerotia production is restored after catalase has been added to the broth. Attempts to detect hydrogen peroxide in the broth utilizing paper chromatography by spraying with a ferrous cyanate reagent (17, 18) failed to produce coloration. It has been reported (9, 10) that the concentration of peroxide in the *T. flavus* broth is low (12 μg/mL) so that a more sensitive test for detecting hydrogen peroxide was employed (19) (Fig. 2). The first reaction, catalyzed by horseradish peroxidase (HRP), produces iodine that, in the presence of excess iodide, exists in equilibrium with the triiodide ion. This ion has an extinction coefficient (ε) at 353 nm of $2.55 \times 10^4\ M^{-1}\ cm^{-1}$. The change in absorbance at 353 nm is measured after completion of the reaction and, knowing that this procedure gives $\Delta A_{353} = 0.255$ for 0.1 M hydrogen peroxide, the concentration of hydrogen peroxide in the broth is estimated to be 50 μg/mL. This is a lower estimate than those concentrations (100–120 μg/mL) utilized in the bioassay (performed a month earlier) to see a similar zone of inhibition; however, it is possible that the hydrogen peroxide concentration decreases as the broth ages. Although the ultraviolet experiments for determining the concentration of a peroxide is not specific for hydrogen peroxide, the fact that addition of catalase to the broth destroys the inhibitory effect *T. flavus* has on the production of microsclerotia by *V. dahliae* strongly supports the proposal that hydrogen peroxide is the causative agent of the antifungal activity. *tert*-Butylhydroperoxide did not inhibit microsclerotia production by *V. dahliae*. The antifungal activity between *T. flavus* and *V. dahliae* occurs in the soil. Our studies, which involve growing *T. flavus* in still culture and utilizing the bioassay developed for use on an agar plate, appear to mimic nature well.

Biosynthetic studies of Talaromyces flavus *metabolites*

The metabolites from the *T. flavus* broth extract whose biosyntheses we were interested in studying include 4,6-dihydroxy-5-methylphthalide (**7**), methyl 4-carboxy-5-hydroxyphthalaldehydate (**8**), and the spirocyclic metabolite, talaroflavone (**9**). These metabolites are presumed to have a polyketide



8



9

biogenesis and thus [1-^{13}C] labelled sodium acetate was chosen as the precursor for the biosynthetic studies. The precursor was administered to the fungus in 3–10 mmol batches (1 mmol/L culture medium) after 9, 16, and 23 days growth, and the fungus was harvested after 30 days. The advantage of multiple over single-dose feeding lies in the opportunity it affords to maintain a steady precursor concentration while avoiding the toxic effects due to excessively high concentrations (20). To follow the labelling pattern of ^{13}C enriched metabolites, it was first necessary to assign the ^{13}C chemical shifts for the metabolites. The ^{13}C nmr spectra of metabolites **7**, **8**, and **9** were assigned in Part 1 of this series (1). Two regioisomeric types of phthalides are known in nature: one in which the hydroxyl group is *peri* to the carbonyl (**7***d*, **7***e*, for example) and the other in which the aromatic hydrogen is *peri* to the carbonyl (**7**–**7***c*). Their biogeneses may be envisaged by cyclization of a tetraketide precursor and methylation with *S*-adenosylmethionine (SAM) to afford 3-methylorsellinic acid (**7***f*) (21, 22) (Scheme 1). Oxidation of the C-6 methyl group leads to the phthalide backbone of 5,7-dihydroxy-6-methylphthalide (**7***d*) (23, 24), and nidulol (**7***e*) (23, 25). Formation of the phthalide **7** isolated from *T. flavus* and its *O*-methylated derivatives (**7***a*–**7***c*) appears to involve a reduction of the acid moiety and an oxidation of the methyl group. This reduction is not commonly encountered in the biosynthesis of polyketides. Possible intermediates include 3,5-dihydroxy-4-methylphthalaldehydic acid (**8***a*) (26), which may also be a precursor to metabolite **8**.

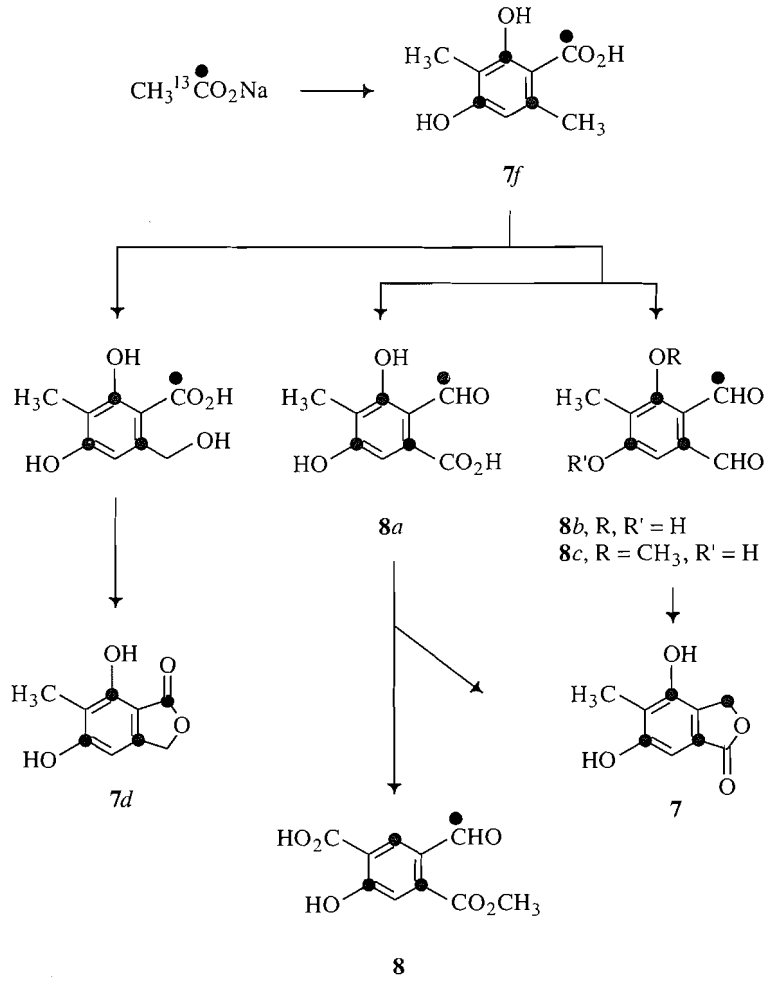
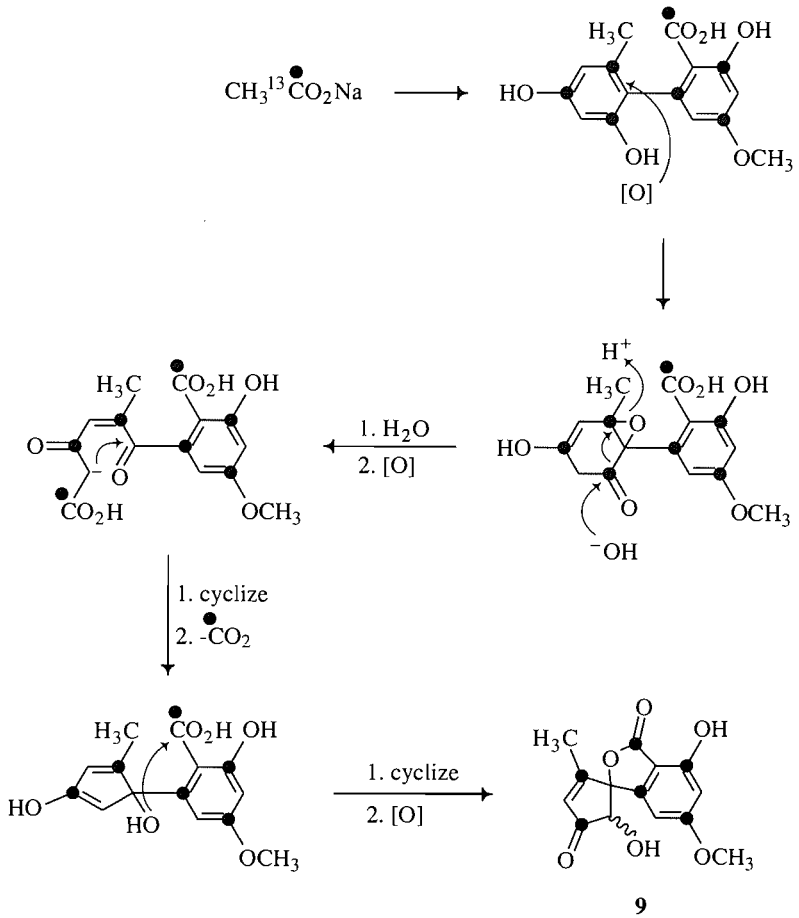


SCHEME 1

Reduction of the aldehyde and lactonization affords the regioisomer 4,6-dihydroxy-5-methylphthalide (**7**). A Cannizzaro reaction of dialdehyde **8***b* would provide the natural product **7** regioselectively. The mono-*O*-methyl derivative, quadrilineatin (**8***c*), from *Aspergillus quadrilineatus*, is reported (27) to give 6-hydroxy-4-methoxy-5-methylphthalide (silvaticol, **7***b*) (25) on treatment with dilute sodium hydroxide. If this oxidation–reduction sequence of the methyl and acid groups is occurring, the methylene carbon of **7** (from C-1 of acetate) should be labelled and the carbonyl carbon, originating from C-2, should not be enriched. The ^{13}C nmr spectrum of the labelled phthalide compared to that at natural abundance indicates that label has been incorporated (about 6% enrichment) at four carbons. The enhanced signals include the phenolic carbons (δ 159.1 and 151.5), the quaternary carbon (δ 124.7), and the methylene carbon (δ 69.7). In addition to the intense methylene resonance, the carbonyl carbon (δ 174.2) shows no enrichment, confirming its origin from C-2 of acetate as well as the unusual oxidation–reduction sequence along the pathway to 4,6-dihydroxy-5-methylphthalide (**7**). The isolation of **7** completes the family of phthalide natural products since both mono-*O*-methyl (**7***a*, **7***b*) and the dimethyl (**7***c*) derivatives of **7** have been reported (23, 25). Nidulol (5-hydroxy-7-methoxy-6-methylphthalide, **7***e*), silvaticol (6-hydroxy-4-methoxy-5-methylphthalide, **7***b*), and *O*-methylsilvaticol (4,6-dimethoxy-5-methylphthalide, **7***c*) are reported from *A. silvaticus* (25), indicating that some organisms have the capability to produce metabolites of either phthalide type.

The pathway from 3-methylorsellinic acid (**7***f*) to methyl 4-carboxy-5-hydroxyphthalaldehydate (**8**) involves an oxidation of the methyl group, methylation of the acid, and a reduction of the C-3 hydroxyl bearing carbon, perhaps via intermediate **8***a*. We have not ruled out the possibility that this reduction occurs before aromatization. The ^{13}C nmr spectrum of the labelled metabolite compared to that at natural abundance shows that label has been incorporated (about 6% enrichment) at four carbons. The enhanced signals include the aldehyde carbon (δ 196.6), the phenolic carbon (δ 166.3), a quaternary carbon (δ 136.8), and an aromatic methine (δ 103.9). The enrichment is consistent with that expected if metabolite **8** arises from the pathway outlined in Scheme 1. The C-3 methine carbon (δ 103.9) is enriched so that it must arise from a carbon that bore an oxygen functionality, supporting the proposal that there has been a reduction along the route. The methyl ester of acid **8***a* and metabolite **7** are reported to promote the root growth of Chinese cabbage seedlings at concentrations of 50 ppm (26).

As discussed in Part 1 of this series (1), the structurally and biosynthetically interesting spirocyclic metabolite, talaroflavone (**9**), is thought to originate from the heptaketide biphenyl derivative that leads to altenusin, dehydroaltenusin, and desmethyldehydroaltenusin. Feeding [1-^{13}C] labelled sodium acetate to *T. flavus* results in the incorporation of label at six carbons of **9**. Comparison of the intensity of the signals in the labelled spectrum with those at natural abundance indicates that the six labelled carbons (about 2.5% enrichment) are those furthest downfield, at δ 202.0, 171.4, 170.2, 168.5, 159.9, and



9

SCHEME 2

150.8. A biosynthetic pathway that accounts for this and for the bond joining the two unlabelled centers, C-3 and C-5′, is illustrated in Scheme 2. Oxidation of the heptaketide derived biphenyl intermediate affords the dihydroarene oxide shown. The intermediacy of arene oxides in the enzyme catalyzed hydroxylation of arenes is well precedented (28). Epoxide opening, hydrolysis of the ketone, tautomerization of the enol, and oxidation of the benzylic alcohol provides the keto acid. Cyclization of an anion generated α to the acid, followed by decarboxylation, provides the cyclopentadiene derivative. Lactonization and oxidation at the carbon α to the ketone affords talaroflavone (**9**). We have not been able to determine the stereochemistry at C-1′ and C-5′ of talaroflavone (**9**) so that the orientation of the intermediates in the cyclization reactions and in the final oxidation step is not known.

Experimental

For general experimental details see Part 1 of this series (1).

Gas chromatograms (gc) were obtained from a Hewlett Packard 5750 gas chromatograph equipped with an OV-17 Chromosorb W/80–100 mesh column (6 ft × 3/16 in.). The injector and detector temperatures were 250°C and the column was heated to 150°C. Helium was used as the carrier gas. Gas chromatography – mass spectrometry (gc–ms) data were obtained from a Varian 1400 gas chromatogram linked with an A.E.I. MS-12 mass spectrometer. Detection was done by chemical ionization using ammonia as the carrier gas. The gas chromatogram was equipped with a 30-m Supelco SPB 5 column. The column temperature was initially 50°C and then raised 10°C/min to 250°C. Sephadex G-50 and LH-20 gels were obtained from Pharmacia Fine Chemicals, Uppsala, Sweden. Bio-Gel P-2 (100–200 mesh (wet), exclusion limit 1800 daltons) was obtained from Bio-Rad Laboratories, Richmond, California. Sep-Paks (C_{18} and amino) were obtained from Waters Associates, Milford, Massachusetts. Reverse phase thin-layer chromatography (tlc) plates were obtained from Whatman Ltd. ($MKC_{18}F$ reversed phase TLC plates, 200 μm thickness). C-18 reverse phase flash silica gel was obtained from Toronto Research Chemicals Inc., Downsview, Ontario. The cation exchange resin used was AGC-244 (Ionic Form H, Baker, strong acid, sulfonated polystyrene, 10% crosslinking, 30–80 mesh) and the anion exchange resin was Dowex-3 (weak base, primary and secondary amine, 20–50 mesh). Dialyses were performed with Spectrapor 6 dialysis tubing (MWCO 1000, flat width 18 mm, diameter 11.5 mm). Sodium acetate [1-^{13}C] (91.8 at.% ^{13}C) was obtained from MSD Isotopes.

Growth of Talaromyces flavus *and isolation of the aqueous metabolites*

Talaromyces flavus (ATCC 52201; UAMH 4890) was grown in liquid still culture in 10 L batches at room temperature as reported in the experimental section of Part 1 of this series (1). After 4 weeks the mycelium was separated from the culture broth by filtration through cheesecloth. The broth was concentrated *in vacuo* to ca. 1 L and continuously extracted with ethyl acetate for 48 h. The fungal broth was concentrated to a syrup and passed over a column of Sephadex G-50, eluting with water, or a column of Bio-Gel P-2, eluting with water – 95% ethanol (90:10). The active fractions were pooled and freeze-dried. A portion of the freeze-dried syrup was subjected to acetylation (acetic anhydride (1.0 mL) – pyridine (1.0 mL), room temperature, 24 h). The reaction mixture was taken up in ethyl acetate (10.0 mL) and toluene (5.0 mL) and the solvents were removed under reduced pressure to afford a dark brown oil, which was then purified by flash chromatography, eluting with dichloromethane–methanol (99:1). The clear, colorless oil (150 mg) contained the acetates of hydroxymethylmaltol (**1**), 5,6-dihydro-3,5-dihydroxy-6-hydroxymethyl-2*H*-

pyran-2-one (**3**), and D-glucono-1,4-lactone (**5**), which were separable with repeated chromatography.

*Hydroxymethylmaltol (**1**)*

The diacetate of hydroxymethylmaltol (**1**) was obtained as a clear, colorless oil (**2**, 0.6 mg), tlc: R_f 0.21 (dichloromethane–methanol 99:1); uv (methanol): 292 (3.92) nm; ftir (CH_2Cl_2 cast): 1780 (m), 1741, 1656, 1585, 1370, 1222, 1195, 1175, 1101, 1065, 882, 759 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.06 (1H, d, J = 7.0 Hz, H-6), 6.24 (1H, d, J = 7.0 Hz, H-5), 4.83 (2H, s, CH_2OCOCH_3), 2.30 (3H, s, C-3 $OCOCH_3$), 2.12 (3H, s, C-2 $OCOCH_3$); ^{13}C nmr ($CDCl_3$) δ: 170.0 (s, $OCOCH_3$), 167.9 (s, $OCOCH_3$), 157.1 (s, C-4), 155.6 (s, C-2), 137.0 (s, C-3), 130.5 (d, C-6), 103.8 (d, C-5), 61.3 (t, CH_2), 20.6 (q, $OCOCH_3$), 20.4 (q, $OCOCH_3$); hreims, m/z calcd. for $C_{10}H_{10}O_6$ (M^+): 226.0477; found: 226.0475 (14), 184 (66), 142 (100).

*5,6-Dihydro-3,5-dihydroxy-6-hydroxymethyl-2*H*-pyran-2-one (**3**)*

The triacetate of 5,6-dihydro-3,5-dihydroxy-6-hydroxymethyl-2*H*-pyran-2-one (**3**) was obtained as a clear, colorless oil (**4**, 0.6 mg), tlc: R_f 0.21 (dichloromethane–methanol 99:1); ftir (CH_2Cl_2 cast): 1778, 1750, 1665, 1655, 1580, 1425, 1372, 1227, 1198, 1136, 1047 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.43 (1H, d, J = 4.0 Hz, H-4), 5.61 (1H, dd, J = 4.0, 5.5 Hz, H-5), 4.75 (1H, dt, J = 5.5, 4.5 Hz, H-6), 4.38 (1H, dd, J = 4.5, 12.5 Hz, H-7), 4.29 (1H, dd, J = 4.5, 12.5 Hz, H-7′), 2.25 (3H, s, $OCOCH_3$), 2.11 (3H, s, $OCOCH_3$), 2.08 (3H, s, $OCOCH_3$); ^{13}C nmr ($CDCl_3$) δ: 170.3 (s, $OCOCH_3$), 169.6 (s, $OCOCH_3$), 168.0 (s, $OCOCH_3$), 157.1 (s, C-2), 139.8 (s, C-3), 125.9 (d, C-4), 77.9 (d, C-6), 64.3 (d, C-5), 62.0 (t, C-7), 20.6 (q, $OCOCH_3$), 20.5 (q, $OCOCH_3$), 20.2 (q, $OCOCH_3$); hreims, m/z calcd. for $C_{12}H_{14}O_8$ (M^+): 286.0688; found: 286.0694 (0.1), 244 (9), 226 (13), 202 (13), 184 (68), 156 (15), 142 (100); cims, m/z: 304 (M + 18).

Biosynthetic studies of Talaromyces flavus *metabolites*

Incorporation of [1-^{13}C] labelled acetate

Talaromyces flavus was grown in liquid still culture on a sterile malt extract medium in 10 2-L Fernbach flasks (1 L of medium per flask) as described in the experimental section of Part 1 of this series (1). After nine days' growth, a sterile solution of sodium [1-^{13}C] acetate (0.082 g, 1.0 mmol) in distilled water (5.0 mL) was injected into each flask. After a further 7 and then 14 days, an additional 1.0 mmol of labelled acetate was injected into each flask. After 4 weeks' growth, the mycelium was removed by filtration through cheesecloth, washed with methanol, and air-dried. The fungal broth was concentrated *in vacuo* to ca. 1 L and subjected to continuous extraction with ethyl acetate for 48 h. The crude extract was evaporated to dryness *in vacuo* and then dissolved in aqueous methanol (85:15, 100 mL). This solution was extracted with *n*-hexane (3 × 100 mL) and then dichloromethane (3 × 100 mL). The organic extracts were dried over anhydrous sodium sulfate, filtered, and the solvents were removed under reduced pressure. The crude dichloromethane extract (ca. 1 g) was separated by flash chromatography over silica gel, eluting with dichloromethane–methanol (97:3). The fractions were further purified as indicated previously (1) for 4,6-dihydroxy-5-methylphthalide (**7**), methyl 4-carboxy-5-hydroxyphthalaldehydate (**8**), and talaroflavone (**9**).

[1-^{13}C] Acetate labelled metabolites

*4,6-Dihydroxy-5-methylphthalide (**7**) (4,6-dihydroxy-5-methyl-1-(3*H*)-isobenzofuranone)*

4,6-Dihydroxy-5-methylphthalide (**7**, 4.2 mg, ca. 6% incorporation), ^{13}C nmr (methanol-d_4) enriched signals δ: 159.1 (C-6), 151.5 (C-4), 124.7 (C-7a), 69.7 (C-3); natural abundance signals δ: 174.2 (C-1), 126.3 (C-3a), 120.5 (C-5), 102.1 (C-7), 9.2 (C-5 CH_3).

*Methyl 4-carboxy-5-hydroxyphthalaldehydate (**8**)*

Methyl 4-carboxy-5-hydroxyphthalaldehydate (**8**, 4.0 mg, ca. 6% incorporation), ^{13}C nmr (methanol-d_4) enriched signals δ: 196.6 (C-2 *C*HO), 166.3 (C-5), 136.8 (C-1), 103.9 (C-3); natural abundance signals δ: 169.4 (C-4 CO_2H, 160.1 (C-1 CO_2CH_3), 122.7 (C-4), 114.6 (C-2), 102.4 (C-6), 56.4 (C-1 CO_2CH_3).

*Talaroflavone (**9**) (spiro[5′-hydroxy-2′-methyl-cyclopent-2′-ene-4′-one-1′,3-7-hydroxy-5-methoxy-1(3*H*)-isobenzofuranone])*

Talaroflavone (**9**, 5.0 mg, ca. 2.5% incorporation), ^{13}C nmr (methanol-d_4) enriched signals δ: 202.0 (C-4′), 171.4, 170.2, 168.5 (C-2′, C-1, C-5), 159.9 (C-7), 150.8 (C-3a); natural abundance signals δ: 131.4 (C-3′), 106.5 (C-7a), 103.5, 101.0 (C-4, C-6), 94.2 (C-3), 79.7 (C-5′), 56.5 (OCH_3), 13.4 (C-2′ CH_3).

Biological studies of the aqueous broth and metabolites of Talaromyces flavus

Inhibition of Verticillium dahliae *by* Talaromyces flavus

The inhibition of growth of *Verticillium dahliae* by *Talaromyces flavus* was determined by agar diffusion using an aqueous test solution. Presterilized vessels (5/16 in. o.d. × 5/16 in. long cylinder cut from 304 stainless steel tubes) were placed onto Mueller Hinton agar plates that had been swabbed with *V. dahliae*. The *T. flavus* aqueous test solution (100 μL) was placed into the stainless steel vessel. The plates were incubated at 24°C. The solution diffused into the medium and after 10–14 days the growth of the microsclerotia of *V. dahliae* was noted. The bioassay was carried out in the same manner as described above when testing hydrogen peroxide (Fisher, 30% by weight) and *tert*-butylhydroperoxide (Aldrich, 70% by weight). Test results were noted after 7–10 days.

Hydrogen peroxide detection

The catalase enzyme was obtained from bovine liver (Sigma, twice recrystallized) containing ca. 0.01 mg thymol/mL. The solution consists of 22 mg protein/mL (1 199 000 units/mL). The molecular weight of the enzyme is 250 000 g/mol so that the solution concentration is 88 μM. A 2 μM solution was utilized in which 2.0 μL (contains 50–55 units of enzyme) was added to the fungal broth (100 μL, ca. 0.3 μmol of H_2O_2). The bioassay was performed as described above.

In the ultraviolet study for the detection of peroxide, sodium iodide (0.75 g), citric acid (2.42 mL of a 0.5 M solution), and sodium hydroxide (1.0 mL of a 1.0 M solution) were combined to make up a 100 mL test solution of pH 3.8, in which the concentration of iodide ion is 0.05 M. To 10.0 mL of this solution was added 5.0 μL of horseradish peroxidase (ca. 1.0 μM). The absorbance of this solution at 353 nm was measured. The fungal broth (1.0 μL; a 100 mL aliquot of the broth ([1 L] concentrated from the 10-L batch grown) was concentrated to 10 mL) was then added and the reaction was allowed to proceed for 20 min. The absorbance of the solution at 353 nm was measured and the change in absorbance was calculated knowing that 0.1 M hydrogen peroxide gives ΔA_{353} = 0.255. The enzyme assay resulted in a ΔA_{353} = 0.0357.

Antibacterial studies

The biological activity of crude extracts of *T. flavus* (ethyl acetate and methanol mycelium extracts and ethyl acetate broth extract) was tested against several bacteria using the Kirby–Bauer agar diffusion assay. In this bioassay, filter paper discs soaked with the crude extract solution (5.0 mg/mL in methanol) or the pure metabolites (2.0 mg/mL in methanol) were placed on the surface of an agar medium (Mueller–Hinton) containing a standardized suspension of bacteria. After 24 h of incubation at 37°C the surface of the agar acquired a turbid appearance (a positive result was recorded when transparent haloes (inhibition zone) remained around the filter paper discs). A solvent blank and standard concentrations of an antibiotic (Penicillin G 10 units and Cephalothin 30 μg, Sensitivity Discs, Difco Laboratories) were used to compare the relative antibacterial activity of the crude extracts. The inhibition zone diameters obtained with the crude extracts were somewhat smaller than those produced by Penicillin G (>22 mm) and Cephalothin (>18 mm). D-Glucono-1,4-lactone (**5**) and 4,6-dihydroxy-5-methylphthalide (**7**) show inhibition zones half the size of those produced by the standard antibiotics.

T. Bruce Grindley, Ronald D. Curtis, Rasiah Thangarasa, and Roderick E. Wasylishen. Can. J. Chem. **68**, 2102 (1990).

Carbon-13 and ^{119}Sn nuclear magnetic resonance spin-lattice relaxation times at 8.48 T and at 4.70 T have been measured at several temperatures for a number of 2,2-di-*n*-butyl-1,3,2-dioxastannolane derivatives, most of which were prepared from monosaccharide derived diols. The tin nuclei in these compounds, which are at either pentacoordinate or hexacoordinate sites, have ^{119}Sn T_1 values that are relatively short, between 13 ms and 300 ms. At 8.48 T, chemical shift anisotropy is the only important mechanism for relaxation of the ^{119}Sn nuclei in these compounds. However, at 4.70 T, the ^{1}H,^{119}Sn dipole–dipole mechanism also contributes slightly. The principal components of the ^{119}Sn chemical shift tensor for the pentacoordinate site in the dimeric structure of methyl 4,6-*O*-benzylidene-2,3-dibutylstannylene-α-D-glucopyranoside (**1**) were determined directly from the static ^{119}Sn spectrum of a powdered sample and indirectly from slow spinning CP/MAS spectra using both the Herzfeld–Berger procedure and computer simulation. The tin shift tensor for **1** in the solid state is non-axially symmetric with $\eta = 0.49 \pm 0.03$. The chemical shift anisotropy determined from the solid state experiments, 748 ± 20 ppm, was in good agreement with the value obtained from the solution T_1 data, 720 ± 50 ppm. For compounds containing both pentacoordinate and hexacoordinate tin atoms, the ^{119}Sn relaxation data indicate that the tin chemical shift anisotropies for the hexacoordinate sites are approximately 1.6 times those of the pentacoordinate sites.

Key words: ^{119}Sn NMR, NMR relaxation, stannylene acetals, 1,3,2-dioxastannolanes.

T. Bruce Grindley, Ronald D. Curtis, Rasiah Thangarasa et Roderick E. Wasylishen. Can. J. Chem. **68**, 2102 (1990).

On a mesuré, à différentes températures, à 8.47 T et à 4.70 T, les temps de relaxation spin-réseau de la résonance magnétique nucléaire du ^{13}C et du ^{119}Sn d'un certain nombre de dérivés 2,2-di-*n*-butyl-1,3,2-dioxostannolanes dont la plupart sont préparés à partir de diols dérivés de monosaccharides. Les noyaux d'étain de ces composés qui sont des sites pentacoordonnés ou hexacoordonnés ont des valeurs de T_1 de ^{119}Sn relativement courtes, entre 13 ms et 300 ms. À 8.48 T l'anisotopie du déplacement chimique est le seul mécanisme important pour la relaxation des noyaux de ^{119}Sn de ces composés. Cependant à 4.70 T le mécanisme dipôle–dipôle ^{1}H,^{119}Sn contribue également mais faiblement. Faisant appel à la fois au procédé de Herzfeld–Berger et à une simulation par ordinateur on a déterminé, directement à partir du spectre statique d'un échantillon en poudre et indirectement à partir du spectre CP/MAS à faible rotation, la composante principale du tenseur du déplacement chimique du ^{119}Sn, pour le site pentacoordonné de la structure dimère du 4,6-*O*-benzylidène-2,3-dibutylstannylène-α-D-glucopyrannoside de méthyle (**1**). Le tenseur du déplacement de l'étain pour le composé **1** à l'état solide a une symmétrie non-axiale avec $\eta = 0{,}49 \pm 0{,}03$. L'anisotropie du déplacement chimique, déterminée à partir d'expériences dans l'état solide, de 748 ± 20 ppm s'accorde parfaitement avec la valeur de 720 ± 50 ppm obtenue à partir des données T_1 en solution. Dans le cas des composés contenant des atomes d'étain pentacoordonnés et hexacoordonnés, les données de relaxation du ^{119}Sn indiquent que les anisotropies du déplacement chimique pour les sites hexacoordonnés sont environ 1,6 fois plus élevés que celles des sites pentacoordonnés.

Mots clés : RMN du ^{119}Sn, relaxation RMN, acétals de stannylène, 1,3,2-dioxastannolanes.

[Traduit par la revue]

Introduction

The value of ^{119}Sn nmr spectroscopy in the study of the chemistry of tin-containing species is evident from the number of papers appearing in which this topic is of central importance (1). Most of this literature has been concerned with the measurement and application of tin chemical shifts and spin–spin coupling constants. Spin-lattice relaxation has been much less studied and most authors have chosen to examine molecules containing tetracoordinate tin (2–6). For tetracoordinate tin, T_1 values of 0.5–7 s have been reported (2–6). For tetraalkyltin compounds (2, 4), trialkyltin halides (2, 4, 5), and tin tetrahalides (3), the dominant relaxation mechanism in solution is spin rotation (2–5) with ^{1}H,^{119}Sn dipole–dipole relaxation contributing as the temperature is lowered. Even for molecules as large as dimethyldiphenyltin or hexamethylditin, spin rotation is the dominant mechanism at room temperature and $B_0 = 5.87$ T (5). In still larger molecules such as the tri-*n*-butylstannyl ethers derived from monosaccharides (6), spin rotation makes a significant contribution to the rate of spin-lattice relaxation but the rate is dominated by the ^{1}H,^{119}Sn dipole–dipole mechanism. Chemical shift anisotropy has been found to contribute slightly to the relaxation of ^{119}Sn nuclei in one molecule containing tetracoordinate tin, Ph_3SnCl (5).

In recent years, it has become evident that an important part of tin chemistry will involve species that have the tin in coordination sites of coordination number greater than four. Five and six coordinate species are common and seven (7, 8) and even eight (8) coordinate species have been observed. One solution nmr study has appeared of the relaxation of ^{119}Sn in higher coordinate tin species but it was conducted at room temperature on dialkyltin sulfates in concentrated sulfuric acid (9). These compounds were shown to exist as mixtures of species at lower temperatures and may have contained mixtures of rapidly equilibrating species at room temperature. The ^{119}Sn T_1 values for these compounds were short, 3–54 ms, and relaxation was dominated by chemical shift anisotropy. Also, the tin atom in di-*n*-butyltin diacetate has a coordination number greater than four (7, 10) and its spin-lattice relaxation was shown to be field dependent (6). Although it was suggested that the field dependence may result from the chemical exchange known to take place in this and other diorganotin dicarboxylates (6, 7, 11), the results of the present work indicate that the chemical shift

anisotropy relaxation mechanism is probably responsible for the field-dependent tin spin-lattice relaxation times.

In this study we report the results of ^{13}C and ^{119}Sn spin-lattice relaxation measurements of carefully characterized compounds (12–14) that contain tin in pentacoordinate or hexacoordinate environments. The compounds examined are typical examples of the 2,2-di-*n*-butyl-1,3,2-dioxastannolane derivatives that serve as intermediates in the widely used stannylene reaction (15).

Experimental

Variable temperature ^{119}Sn nmr spectra were recorded on Nicolet NT-360 NB and Bruker MSL-200 spectrometers at 8.48 T (134.62 MHz) and 4.70 T (74.62 MHz), respectively. Probe temperatures were calibrated using observed ^1H nmr chemical shift differences for pure ethylene glycol or methanol samples in capillary tubes in the solvent of interest (16). Spin-lattice relaxation times were measured by the inversion–recovery method using relaxation delays greater than $5 \times T_1$ and at least 12 variable delays; T_1 values were calculated using a three-parameter fitting procedure available in Nicolet and Bruker software. Nuclear Overhauser enhancements (nOe) were evaluated by the difference method using minimum delays between acquisitions of $10 \times T_1$. Solution data were referenced with respect to external tetramethyltin, which was set to 0.0 ppm.

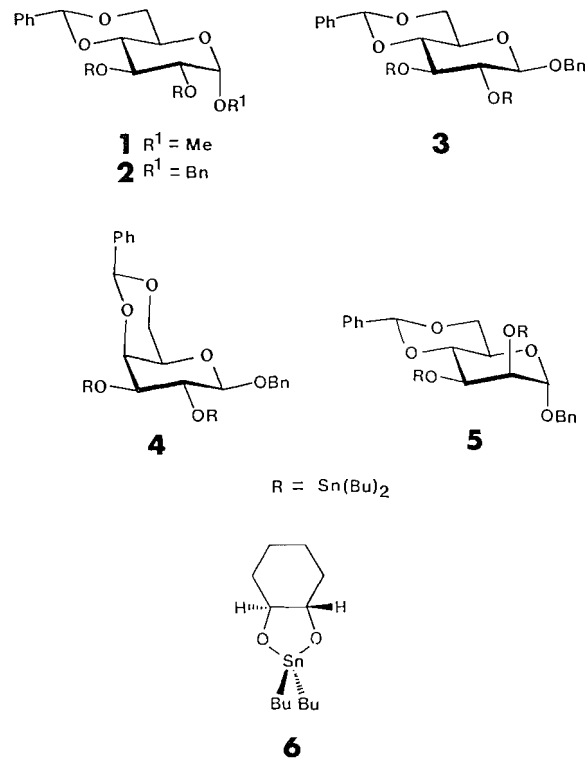
Solutions of tin derivatives for the nmr studies were prepared as follows. An equimolar mixture of the diol and di-*n*-butyltin oxide in benzene was refluxed for 12 h in an apparatus for the azeotropic removal of water. By the end of the reflux period, the solution was homogeneous. The reaction flask was attached to a vacuum line, the benzene removed under vacuum, and the previously dried nmr solvent distilled onto the solid 1,3,2-dioxastannolane derivative through the vacuum system. The resulting solution was poured, under vacuum, through a sintered glass frit into the nmr tube, which was then sealed. The sources of the diols used for preparation of the 2,2-di-*n*-butyl-1,3,2-dioxastannolane derivatives have been described elsewhere (12–14).

Solid state MAS ^{119}Sn nmr spectra were recorded on the Bruker MSL-200 with spinning rates of 3.5–4.5 kHz. Conditions for the Hartmann–Hahn match were optimized on a sample of tetracyclohexyltin (17). All spectra were acquired with high power proton decoupling and 90° pulse lengths of 3–4 μs. The static ^{119}Sn nmr spectrum was acquired with the addition of a tin 180° pulse after the cross-polarization period in order to generate a Hahn echo before acquisition (18). This was found to be essential in order to observe the total CSA pattern without significant distortion. Solid state nmr spectra were referenced with respect to hexamethylditin, which has a ^{119}Sn chemical shift of −97.35 ppm with respect to tetramethyltin (17).

Computer simulations of the CP/MAS spectra were carried out on a VAX-8800 computer using the simulation routine of Clayden *et al.* (19).

Results and discussion

The molecules chosen for study were methyl 4,6-*O*-benzylidene-2,3-*O*-dibutylstannylene-α-D-glucopyranoside (**1**), benzyl 4,6-*O*-benzylidene-2,3-*O*-dibutylstannylene-α-D-glucopyranoside (**2**), benzyl 4,6-*O*-benzylidene-2,3-*O*-dibutylstannylene-β-D-glucopyranoside (**3**), benzyl 4,6-*O*-benzylidene-2,3-*O*-dibutylstannylene-β-D-galactopyranoside (**4**), benzyl 4,6-*O*-benzylidene-2,3-*O*-dibutylstannylene-α-D-mannopyranoside (**5**), and the dibutylstannylene derivative of (*S*,*S*)-1,2-cyclohexanediol (**6**), more properly named 8,8-di-*n*-butyl-7,9,8-dioxastannabicyclo[4,3,0]nonane (**6**). Compounds **1**–**4** exist as dimers in solution (13, 20). The formation of a dimer from two monomer molecules requires that one oxygen atom from each monomer becomes tricoordinate and that the two tin atoms become pentacoordinate. In the carbohydrate derivatives **1**–**5**, the oxygen atoms are diastereotopic; hence, three dimers



are possible for each. The different dimers will be designated using conventional carbohydrate nomenclature by means of the numbers of the two oxygen atoms that are tricoordinate (see Fig. 1). Compound **1** has been studied by X-ray crystallography (21). It is present as a 3,3 dimer in the solid state and in solution (13, 20, 21). Compound **2** also exists as the 3,3 dimer in solution (13). Compound **3** is present as a mixture of the 3,3 dimer and the 2,3 dimer (13); however, the proportion of the 2,3 dimer is small, particularly in toluene-d_8. Hence, only the ^{13}C and ^{119}Sn nmr signals of the 3,3 dimer of compound **3** were studied. Compound **4** is present as the 2,2 dimer in the solvent used here, chloroform-*d*. Compound **5** is present in chloroform-*d* as a mixture of a 3,3 dimer and a trimer (14). The two species equilibrate rapidly at room temperature and T_1 measurements on the individual species can only be made at 255 K and below. Compound **6** is also present as a rapidly equilibrating mixture at room temperature that must be studied at low temperature if the individual components, the dimer, trimer, and tetramer in this case, are to be examined (12). The oligomers higher than the dimer for compounds **5** and **6** provide species in which some of the tin atoms are hexacoordinate.

Carbon-13 relaxation

Carbon-13 spin-lattice relaxation times are given in Tables 1–3. Relaxation for protonated carbons in large molecules such as **1**–**6** normally takes place by the intramolecular $^1H,^{13}C$ dipole–dipole mechanism (22, 23). In agreement with this assessment, nOe measurements for compound **1** at room temperature yielded nOe enhancements within experimental error of the maximum, 1.99, for all carbons.

Molecules **1**–**4** may be regarded as having a large rigid core that is approximately planar with an appendant axial methoxy (**1**) or benzyloxy (**2**) group or benzylidene ring (**4**) (Fig. 1). The C—H bond vectors for the seven skeletal carbons in the central core of **1**–**4** lie perpendicular to the central plane with the following exceptions: the C—H vectors for one of the C-6 hydrogens in **1**–**4**, for C-1 in **1** and **2**, and for C-4 in **4** lie at

angles of about ±20° with respect to the central plane. The near identity of T_1 values (±10%) obtained for all of these carbons, even the ones for which the C—H bond vectors are not perpendicular to the central plane, indicates that motion of compounds **1**–**4** is essentially isotropic. Carbon-13 relaxation data for compound **5** were more difficult to obtain since only at low temperatures (<255 K) were the individual signals sharp enough for T_1 measurements to be made. The trimer of **5** has no symmetry and the dimer has C_2 symmetry; hence, four signals are expected for each type of carbon and the similar chemical shifts of the skeletal carbons result in a number of signal overlaps. Nevertheless, those values that could be measured were similar in magnitude, indicating that rotations of compound **5** may also be considered isotropic. Compound **6** is expected to behave similarly.

In general, ^{13}C nmr spin-lattice relaxation times of the skeletal carbons of compounds **1** and **2** decrease as the temperature decreases, as is expected for relaxation via the $^1H,^{13}C$ dipole–dipole mechanism in the extreme narrowing regime (22, 23). The increase is linear from 313 to 273 K for carbons of compound **1** and from 348 to 273 K for carbons of compound **2**, but shows curvature at lower temperatures. The rotational correla-

tion time (τ_c) at the temperature at which the T_1 reaches a minimum can be determined from eqs. [1] and [2] (22, 23),

$$[1]\quad R_1^{DD} = (T_1^{DD})^{-1}$$
$$= N/10\,\{(\mu_0/4\pi)\,\gamma_H\gamma_C\,(h/2\pi)\,r_{CH}^{-3}\}^2 f(\tau_c, \omega)$$

$$[2]\quad f(\tau_c, \omega) = \tau_c\{1/(1+(\omega_H-\omega_C)^2\tau_c^2) + 3/(1+\omega_C^2\tau_c^2) + 6/(1+(\omega_H+\omega_C)^2\tau_c^2)\}$$

where N is the number of bonded protons, γ_H and γ_C are the magnetogyric ratios of ^1H and ^{13}C respectively, r_{CH} is the C—H bond length, and ω_H and ω_C are the Larmor frequencies in rad s^{-1} for ^1H and ^{13}C, respectively. The T_1 minimum at 90.8 MHz is calculated to occur at a τ_c value of 1.39 ns. From the plot of ln R_1 versus $1/T$ for C-1 of compound **1**, it is clear that the ^{13}C T_1 values obtained at the two lowest temperatures are almost identical, indicating that these are approximately the values of T_1 at the T_1 minimum. Taking the T_1 minimum to be 0.18 ± 0.01 s, a value of r_{CH} = 1.134 ± 0.01 Å can be determined from eqs. [1] and [2]. This value is a vibrationally averaged C—H bond length and is typical of the values obtained from relaxation measurements (23*b*, 25).

The T_1 values for the two butyl groups for compounds **1–4** are larger than those of the skeletal carbons, indicating that they are involved in independent motion in addition to overall reorientation. The observed T_1 values also increase down the hydrocarbon chains, as is commonly observed for anchored alkyl groups (23, 24). There are slight but consistent differences between the T_1 values for each of the carbons in the pairs of butyl groups for each compound, which indicates that the butyl groups move independently at slightly different rates.

Motion of phenyl groups has been studied by means of their ^{13}C T_1 values (26). In monosubstituted benzenes, anisotropic motion is observed in which rotation about the C-1—C-4 axis is preferred. Because the C—H bond vector for C-4 lies along the axis of rotation, its relaxation is not affected by this motion and its T_1 values are normally much shorter than those of the *ortho* and *meta* carbons (26), which are identical. For compound **1**, the T_1 values for the *ortho* and *meta* carbons were much larger than that of the *para* carbon. These observations indicate that rotation of the phenyl group about its symmetry axis occurs much faster than overall rotations of the molecule.

Tin-119 relaxation

Tin-119 spin-lattice relaxation times are given in Tables 4–6. Nuclear Overhauser enhancement measurements at 8.48 T were

made for compounds **1**–**4** at room temperature, for compound **5** at 223 K, and for compound **6** at 218 K. In every case the size of the nOe effect was below the level of detection, estimated as 2%, where % nOe is defined as $(\eta_{obs}/\eta_{max}) \times 100\%$. At 4.74 T, nOe values were measured for compounds **4** and **5** at the temperatures given in Tables 4 and 5. The values measured were small, 10% or less. Thus, $^1H,^{119}Sn$ dipole–dipole interactions do not contribute to relaxation of tin nuclei at 8.48 T and only contribute slightly to the relaxation of tin nuclei at 4.70 T in the molecules studied here. The only two mechanisms remaining that could cause relaxation of ^{119}Sn nuclei here are chemical shift anisotropy (CSA) and spin rotation (SR).

Figure 2 shows plots of $\ln R_1$ as a function of inverse temperature for tin nuclei of compound **4** at 8.48 and 4.70 T. The origin of the curves is described later in the text. At 8.48 T, the rates increase linearly as the temperature decreases until approximately 273 K, when the rate of increase lessens. Similar results were observed at 4.70 T where a linear dependence of the logarithm of the tin relaxation rate versus inverse temperature was observed from 245 to 336 K. Since nOe measurements for compound **4** indicated that the relative contribution of the $^1H^{119}Sn$ dipole–dipole is negligible, the linear increase in the natural logarithm of the rate of relaxation with increase in inverse temperature is expected only if the dominant mechanism of relaxation is CSA (23). If the spin-rotation mechanism was contributing to ^{119}Sn relaxation in compound **4**, curvature would be observed at the high temperature ends of the plots in Fig. 2 since contributions from this relaxation mechanism increase with an increase in temperature. The curvature in the plots at temperatures less than 273 K at 8.48 T and below 245 K at 4.70 T is consistent with the curvatures observed in similar plots of ^{13}C relaxation rate versus inverse temperature that were ascribed to leaving the region of extreme narrowing. For the ^{119}Sn nuclei of compound **4** at 134.62 MHz, a T_1 minimum of 27 ms is observed at 227 ± 5 K; below this temperature the relaxation rate decreases as temperature decreases. At 74.62 MHz, the ^{119}Sn T_1 minimum for the tin nuclei of compound **4** should occur at a lower temperature than at 134.62 MHz. As can be seen in Fig. 2, the T_1 minimum may not quite have been reached at the lowest temperature employed in this study, 213 K.

The efficiency of the CSA mechanism depends on the applied magnetic field squared. Therefore, the importance of this mechanism can be evaluated from relaxation measurements at two different applied fields, B_0 and B_0', using the following expression (27):

$$[3] \quad R_1(B_0)^{CSA} = [R_1(B_0)_{obs} - R_1(B_0')_{obs}]/[1 - (B_0'/B_0)^2]$$

Using the observed T_1 values of 98.9 and 276 ms measured at 329 K at 8.48 and 4.7 T, respectively, a T_1^{CSA} value of 347 ± 73 ms at 4.7 T is calculated, which is equivalent to 83 ± 17% of the total relaxation. The $^1H,^{119}Sn$ dipole–dipole relaxation time at 329 K can be calculated to be 10.6 s from the % nOe value at 325 K or 1.6 s from eq. [3] if it is assumed that the $^1H,^{119}Sn$ dipole–dipole relaxation causes the remainder of the relaxation not accounted for by the CSA mechanism.

For comparison purposes, the $^1H,^{119}Sn$ dipole–dipole relaxation time for the ^{119}Sn nuclei of **4** can be calculated using eq. [1] and constants appropriate for tin. The distance between the tin atom and protons on the butyl α-carbons was estimated to be 2.77 Å based on average Sn—C bond lengths in pentacoordinate tin atoms in crystal structures of 1,3,2-dioxastannolanes as summarized in ref. 28. Distances to the β-protons were calculated to be 3.30, 3.05, and 3.17 Å to the four butyl β-protons, to the two intramonomer Sn-O-C protons, and to the one extramonomer Sn-O-C proton, respectively, using average geometries from ref. 28 or from ref. 29 when values were unavailable in ref. 28. A value of 1.60×10^{-10} s was calculated for τ_c at 323 K by means of eqs. [1] and [2] using a carbon T_1 value of 0.37 s for compound **4** and the C—H bond length of 1.134 Å calculated earlier. If it is assumed that the above 11 protons cause the dipolar relaxation of the tin nuclei, a value of T_1 of 8.3 s is calculated using eq. [1], in good agreement with the observed value of 10.6 s, considering the large uncertainties in both values.

Plots of $\ln R_1$ versus $1/T$ for the ^{119}Sn nuclei of compound **1** displayed behaviour similar to compound **4**, with a T_1 minimum of 28 ms observed at 232 ± 5 K. Relaxation rates for compounds **2** and **3** in toluene-d_8 increased linearly with inverse temperature with slight curvature at the lowest temperatures used in this study. Again, this is consistent with CSA being the major source of tin relaxation in these compounds.

The ^{119}Sn CP/MAS nmr spectrum of crystalline **1** recorded at a spinning rate of 3.99 kHz at 296 K is shown in Fig. 3. Immediately apparent in this figure is a series of closely spaced

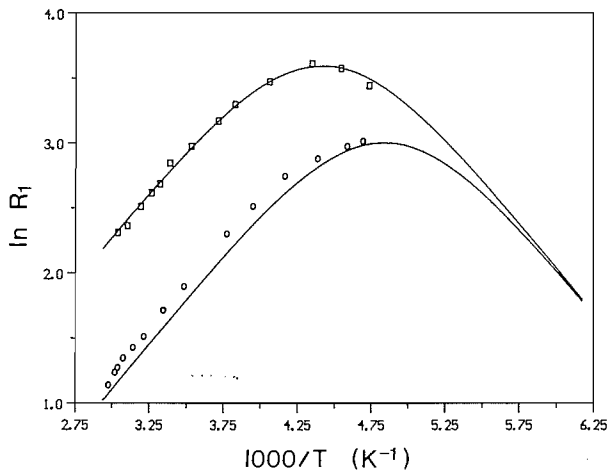

FIG. 2. Tin-119 relaxation rates for compound **4** at 8.48 T (upper) and 4.70 T (lower) as functions of inverse temperature.

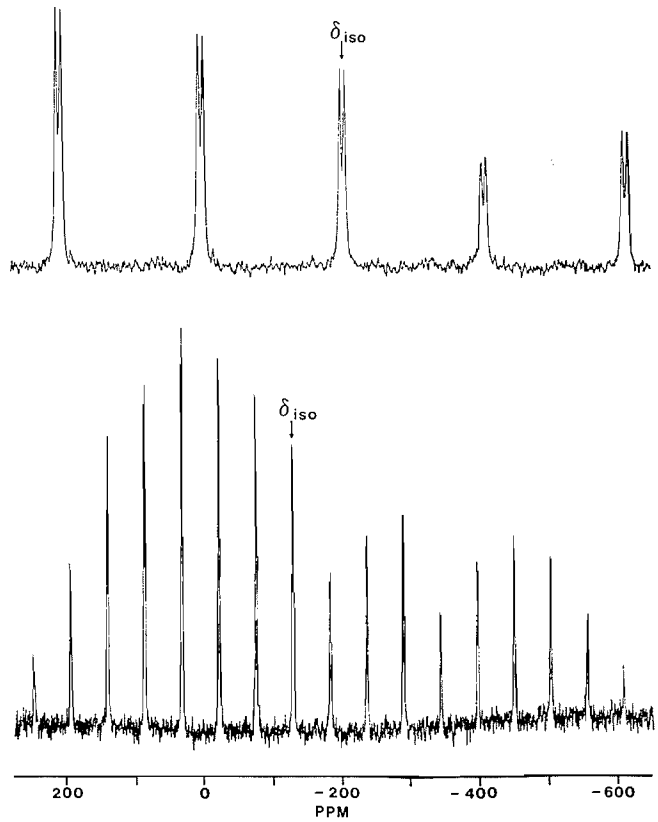

FIG. 3. Tin-119 solid state nmr spectrum for compound **1** obtained with magic angle sample spinning at 3.99 kHz. The expanded region shows the $N = 0$ and ± 1, ± 2 spinning sidebands. The isotropic chemical shifts for site 1 ($\delta_{iso} = -126.8$ ppm) and site 2 ($\delta_{iso} = -128.6$ ppm) are labelled with arrows and are referenced with respect to $(C_6H_{11})_4Sn$ at −97.35 ppm (17).

pairs of resonances. Comparison with spectra run at other spinning speeds indicates that the two isotropic ^{119}Sn chemical shifts (shown in the expansion of Fig. 3) are −126.8 ppm (site 1) and −128.6 ppm (site 2). The X-ray diffraction results for compound **1** indicated that the two halves of the 3,3 dimer of compound **1** have slightly different geometries in the solid state so that the two pentacoordinate tin atoms are in different environments (21). This loss of symmetry accounts for the observation of two different ^{119}Sn chemical shifts in the CP/MAS spectrum and is consistent with results from solid state ^{13}C CP/MAS experiments on this sample (13). Harris and co-workers had noted earlier that two isotropic signals were observed in ^{119}Sn CP/MAS nmr spectra of compound **1** but had not reported the ^{119}Sn chemical shifts.[2] Analysis of the spinning

sideband pattern for site 1 using the graphical method of Herzfeld and Berger (31) provided estimates for the principal components of the ^{119}Sn chemical shift tensor δ_{11}, δ_{22}, and δ_{33}. It should be noted that in order to directly apply the equations and method outlined in ref. 31 to the ^{119}Sn CP/MAS results for compound **1**, spinning speeds in excess of 4.1 kHz are essential so that the value of the parameter μ used in the calculation is less than 15 (31). That is, the magnitude of the tin chemical shift anisotropy for compound **1** is so large that conditions of a "slow spinning" CP/MAS spectrum, for which Herzfeld and Berger numerically evaluated their derived expressions, are only applicable above spinning speeds of 4.1 kHz. For a ^{119}Sn spectrum of compound **1** acquired at a spinning speed of 4.2 kHz, the principal components of the chemical shift tensor for site 1 ($\delta = -126.8$ ppm) were determined to be 237, −16, and −601 ppm. These values were employed as starting estimates for a more accurate analysis of the spinning sidebands by the computer simulation method of Clayden *et al.* (19). The values obtained for site 1 were 248 ± 15 ppm, 4 ± 15 ppm, and −632 ± 15 ppm for δ_{11}, δ_{22}, and δ_{33}, respectively. The estimated uncertainties are large because the experimental peak intensities are difficult to obtain accurately due to spectral overlap with peaks from site 2. In addition, when the chemical shift anisotropy is large, as in this case, the higher order sidebands are often reduced in intensity in the experimental spectrum because of line broadening effects associated with slight inaccuracies in setting the magic angle. As can be seen from Fig. 3, the relative intensities of all the observed spinning sidebands are quite similar, indicating that the chemical shift anisotropy for both sites is approximately the same within experimental error. Additional support for the conclusion that the chemical shift tensors for the two sites are quite similar came from the results of a ^{119}Sn nmr spectrum recorded on a static sample of compound **1**. In this latter spectrum, the discontinuities corresponding to the δ_{11} and δ_{33} principal components were sharp and there was no discernible splitting of the resonance associated with δ_{22}. Thus, the three principal components of the ^{119}Sn chemical shift tensor of compound **1** were determined directly from this spectrum and are 246 ± 10 ppm, −2 ± 10 ppm, and −627 ± 10 ppm for δ_{11}, δ_{22}, and δ_{33}, respectively. The magnitude of the chemical shift anisotropy, $\Delta\delta$, as defined according to the convention of Haeberlen (32):

$$[4] \quad \Delta\delta = (\delta_{11} + \delta_{22})/2 - \delta_{33}$$

was found to be 758 ± 30 ppm according to the MAS simulation results and 748 ± 20 ppm from ^{119}Sn nmr experiments on the static sample. The asymmetry parameter, η, defined by eq. [5],

$$[5] \quad \eta = (\delta_{11} - \delta_{22})/(\delta_{iso} - \delta_{33})$$

was determined to be 0.48 ± 0.04 from the MAS simulations and 0.49 ± 0.03 from the static spectrum. For the purpose of further comparison, the ^{119}Sn chemical shift anisotropy parameters derived from the static spectrum will be considered.

The results from the solid state ^{119}Sn nmr spectra can be related to the observations made in solution if it is assumed that the geometries about the tin atoms are similar on both states. The similarity of ^{119}Sn and ^{13}C nmr chemical shifts from solution and from solid samples suggests that this assumption is correct. As mentioned above, the chemical shift anisotropy for compound **1** is not axially symmetric and the expression defining the magnitude of the spin-lattice relaxation time due to chemical shift anisotropy must include the effect of the non-axial symmetry as follows (32, 33):

TABLE 7. Tin-119 nmr relaxation parameters for pentacoordinate sites in compounds **1**–**5**[a]

trimer "c"	Chloroform-*d*	685	12.4

[a]From Simplex optimization.

$$[6] \quad 1/T_1^{CSA} = R_1^{CSA} = (\gamma B_0)^2[2\{(\delta_{xy})^2 + (\delta_{xz})^2 + (\delta_{yz})^2\} + (2/15)(\Delta\delta)^2(1 + \eta^2/3)]g(\tau_c, \omega)$$

where $g(\tau_c, \omega) = \tau_c/(1 + \omega_0^2\tau_c^2)$, and δ_{xy}, δ_{xz}, and δ_{yz} are the off-diagonal chemical shift tensor elements. The off-diagonal elements are normally considered to be insignificant, in which case eq. [6] simplifies to

$$[7] \quad 1/T_1^{CSA} = R_1^{CSA} = (2/15)(\gamma B_0)^2(\Delta\delta)^2(1 + \eta^2/3)g(\tau_c, \omega)$$

The maximum of $g(\tau_c)$, which corresponds to the T_1 minimum, occurs when $\omega_0\tau_c = 1.0$. Thus, given the Larmor frequency, τ_c at the T_1 minimum can be calculated directly and was determined to be 1.183×10^{-9} and 2.132×10^{-9} s at 134.62 and 74.62 MHz, respectively. The T_1 minimum observed for compound **1** at 134.62 MHz was 28 ± 2.8 ms and occurred at a temperature of 232 ± 5 K (Table 4). From this value and with $\eta = 0.49 \pm 0.03$, the magnitude of the chemical shift anisotropy determined from eq. [7] is 762 ± 50 ppm, similar to the results observed in the solid state, 748 ± 20 ppm. These results suggest that the off-diagonal tensor elements are indeed small and may be negligible if the chemical shift anisotropies in the solid state and solution are similar.

Chemical shift anisotropies can be calculated for compound **4** from the solution T_1 minima of 27 ms at 232 K and 134.62 MHz and 49 ms at 213 K and 74.62 MHz, respectively, if it is assumed that the η value is identical to that determined for compound **1**. Values of $\Delta\delta$ were calculated to be 781 ± 39 ppm and 779 ± 39 ppm from relaxation data obtained at 134.62 and 74.62 MHz, respectively.

A more rigorous procedure for extracting $\Delta\delta$ from the ^{119}Sn nmr relaxation data in Tables 4 and 5 is to fit all of the variable temperature data to eq. [7]. We have assumed that the temperature dependence of τ_c can be described by eq. [8]:

$$[8] \quad \tau_c = \tau_\infty e^{(E_A/RT)}$$

and used a Downhill Simplex Method (34) to obtain $\Delta\delta$, E_A, and τ_∞ for each of the compounds **1**–**5**. The results are summarized in Table 7. Only the high-field ^{119}Sn nmr relaxation data were used for compounds **1**–**4**.

In Fig. 2, the upper curve is a fit of the high-field relaxation data for compound **4** to eq. [7]. The lower curve in this figure is the calculated rate of CSA relaxation at 4.70 T as a function of inverse temperature, generated using the parameters from the high-field data. Note that at all temperatures the observed rate of relaxation at 4.70 T is slightly greater, approximately 10%, than that calculated. We attribute this additional relaxation to the ^{119}Sn,^{1}H dipole–dipole mechanism at 4.70 T. The contribution of this mechanism to the 8.48 T relaxation data will be negligible, as confirmed by our nOe measurements.

Compound **5** was present as a mixture of dimer and trimer that were equilibrating at room temperature. The trimer has no symmetry and hence three signals are observed, two in the pentacoordinate region labelled b and c, and one in the hexacoordinate region. The signals of the individual species could only be measured at temperatures less than 255 K at 8.48 T and less than 243 K at 4.70 T. The T_1 values determined are reported in Table 5. From 248 to 233 K, the ^{119}Sn relaxation rates are temperature invariant or perhaps increase slightly with decrease in temperature. However, at the two lowest temperatures, the relaxation rates decrease with decrease in temperature. This behaviour is consistent with the results for compounds **1**–**4**; at the higher temperatures, the plots are in the T_1 minimum region; at the lowest temperatures, dimers, trimers, and tetramers all appear to be in the slow tumbling regime.

Chemical shift anisotropies for compound **5** can be calculated from the T_1 minima if, again, it is assumed that η is 0.49 ± 0.03. Using T_1 minima values of 38 and 65 ms at 8.48 and 4.70 T for site b of the trimer, values of $\Delta\delta$ of 658 ± 33 and 676 ± 34 ppm, respectively, are obtained. Simplex optimization using both the 4.70 and 8.48 T data gives $\Delta\delta = 666$ ppm. For site c of the trimer, T_1 minima of 35 ms (8.48 T) and 58 ms (4.7 T) yield calculated values of $\Delta\delta$ of 686 ± 34 and 716 ± 36 ppm, respectively. For the dimer tin nuclei, T_1 minima values of 25 and 56 ms give larger values for $\Delta\delta$, 812 ± 41 and 729 ± 37 ppm at 8.48 and 4.7 T, respectively. The corresponding values obtained for compound **5** from Simplex optimization of the combined 4.70 and 8.48 T data (Table 7) support the conclusions reached from the T_1 minima. The shorter T_1 values observed for the hexacoordinate tin site in the trimer indicate that it has a larger chemical shift anisotropy than the pentacoordinate tin sites. If it is assumed that the η value for the hexacoordinate site in the trimer of compound **5** is the same as that determined for compound **1**, T_1 minima values of 14 and 26 ms yield calculated values of $\Delta\delta$ of 1080 ± 55 and 1070 ± 55 ppm at 8.48 and 4.7 T, respectively. Chemical shift anisotropies in the trimer are, on average, approximately 1.6 times greater for the hexacoordinate site than for the pentacoordinate sites.

Compound **6** exists in solution as a complex equilibrating mixture of dimers, trimers, tetramers, and pentamers (12). The equilibria between these oligomeric species only becomes slow enough that T_1 values can be measured for the individual types of tin nuclei at temperatures less than 228 K. For the dimer and trimer tin nuclei, the three T_1 values measured are approximately the same, suggesting that the relaxation times for the ^{119}Sn nuclei in these oligomers are close to the T_1 minimum. The relaxation times of the two types of tin nuclei in the tetramer increase with decreasing temperature, as expected if τ_c for the tetramer of compound **6** were in the slow tumbling regime. The nOe values for compound **6** at 218 K were too small to be measured reliably. There is no reason to believe that ^{119}Sn spin-lattice relaxation for compound **6** occurs other than by the CSA mechanism. The ratios of the chemical shift anisotropies of the hexacoordinate to pentacoordinate tin nuclei in the trimer and the tetramer can be obtained from eq. [9], which was derived from eq. [7].

$$[9] \quad T_{1P}^{CSA}/T_{1H}^{CSA} = (\Delta\delta_H/\Delta\delta_P)^2(1 + \eta_H^2/3)/(1 + \eta_P^2/3)$$

In eq. [9], the subscripts P and H indicate parameters associated with the pentacoordinate and hexacoordinate sites, respectively. The value of $\eta^2/3$ is considerably less than 0.1 provided that η is not too much larger than the value obtained for compound **1** from the solid-state nmr experiments. If it is assumed that η is of this magnitude or is the same for the hexacoordinate site in the trimer as in compound **1**, ratios of $\Delta\delta$ values can be obtained. For compound **6**, the ratios of chemical shift anisotropies of hexacoordinate to pentacoordinate tin nuclei for the trimers and tetramers are calculated to be 1.45 and 1.46, respectively, slightly smaller than the average 1.6 value obtained for the trimer of compound **5**.

Summary

The results of this study indicate that the rates of nmr spin-lattice relaxation for pentacoordinate and hexacoordinate ^{119}Sn nuclei in a series of substituted 1,3,2-dioxastannolane derivatives at moderate field strengths (5–9 T) are one to two orders of magnitude greater than those previously measured for ^{119}Sn in tetracoordinate environments (2–6). For the series of compounds studied here (**1**–**6**), ^{119}Sn relaxation was shown to be caused almost entirely by the chemical shift anisotropy mechanism; for tetracoordinate tin atoms, spin rotation and (or) ^{1}H,^{119}Sn dipole–dipole relaxation are dominant (2–6). Tin-119 nmr spectra of a solid sample of compound **1** indicate that the chemical shift tensor is non-axially symmetric ($\eta = 0.49 \pm 0.03$) with $\Delta\delta = 748 \pm 20$ ppm. For this same sample in solution, essentially the same value of $\Delta\delta$ is obtained from the minimum value of the ^{119}Sn T_1 as a function of temperature. The magnitudes of the chemical shift anisotropies determined from solution relaxation data for compounds **2**–**6** and for compound **1** in solution and in the solid state indicate that $\Delta\delta$ is on the order of 740 ± 75 ppm for tin nuclei in pentacoordinate environments in 1,3,2-dioxastannolanes. Interestingly, the solution ^{119}Sn relaxation results indicate that the chemical shift anisotropy values for tin nuclei in hexacoordinate sites, $\Delta\delta = 1100 \pm 100$ ppm, are somewhat larger than those determined for tin in pentacoordinate sites. Further solid-state experiments are necessary to verify this last conclusion.

Finally, the similar values of $\Delta\delta$ obtained for **1** in chloroform solution and in the solid state suggest that eq. [7] adequately describes the rate of CSA relaxation in solution. The implication is that, in the case of compound **1**, it is unnecessary to consider the unsymmetrical elements of the CSA tensor in the expression for R_1^{CSA} (eq. [6]).

The shelf- or use-life of a material which decomposes by an autocatalytic reaction is shown to be inversely proportional to the rate of heat generation during the induction period of the degradation reaction. Calorimetric measurement of the rate of heat generation during the induction period takes only a few hours. It can often be done at or very near the actual storage or use temperature of the material. Measurements on Lovastatin (2-methylbutanoic acid 1,2,3,7,8,8*a*-hexahydro-3,7-dimethyl-8-[2-(tetrahydro-4-hydroxy-6-oxo-2*H*-pyran-2-yl)ethyl]-1-naphthalenylester) are used as an example of this application.

Key words: autocatalytic, calorimetry, oxidation, decomposition, Lovastatin, Mevacor.

On démontre que la période de période de péremption d'un produit qui se decompose par un mécanisme autocatylique est inversement proportionnelle au taux de réchauffement du produit au cours de la période d'induction de la réaction de dégradation. Les mesures calorimétriques de ce taux de réchauffement au cours de la période d'induction ne demandent que quelques heures et ils peuvent souvent être déterminés dans ou près du lieu d'entreposage; ou on peut utiliser la température du produit. Comme exemple d'application de la méthode, on présente des données relatives au Lovastatin (2-méthylbutanoate du 1, 2, 3, 7, 8, 8*a*-hydro-3,7-diméthyl-8-[2-(tétrahydro-4-hydroxy-6-oxo-2*H*-pyran-2-yl)éthyl]-1-naphtalényle).

Mots clés : autocatalytique, calorimétrie, oxydation, décomposition, Lovastatin, Mevacor.

[Traduit par la revue]

Introduction

Many organic materials undergo autocatalytic degradation. Four disparate examples are oxidation of polymers (1), oxidation of fats and oils leading to rancidity (2), and oxidation of the drug Lovastatin (2-methylbutanoic acid 1,2,3,-7,8,8*a*-hexahydro-3,7-dimethyl-8-[2-(tetrahydro-4-hydroxy-6-oxo-2*H*-pyran-2-yl)ethyl]-1-naphthalenyl ester) (3). Autocatalytic degradation reactions of commercially important organic materials usually are oxidation reactions involving atmospheric oxygen or ozone, or premature polymerization of monomers. The degradation process involves first an induction or initiation period which may range from minutes to years depending on the material, the concentrations of reactants, environmental factors such as ionizing radiation, and the temperature. The addition of antioxidants and other stabilizers serve to extend the induction period (4, 5). The induction period is followed by a relatively short period of time characterized by a rapidly increasing rate of reaction which usually goes through a maximum and then begins to decrease. The reaction occurring during the induction period normally has only a very slight effect on the physical and chemical properties of the material. Large changes in the properties of the material occur during the degradation reaction (1). Thus, a prediction of the useful life of the material is equivalent to a prediction of the length of the induction period.

Prediction of the useful life of a material which degrades by a rate law other than autocatalytic is straightforward, since in these cases it is only necessary to calculate the time to reach an unacceptable amount of degradation from the rate law for the reaction. Usually the quantitative rate law will not vary significantly from lot to lot since it is dependent on reactions of the bulk material. In contrast, the induction period for an autocatalytic reaction often varies markedly from lot to lot since it is dependent on trace impurities, degree of crystallinity, surface area, and other similar factors which all involve trace constituents of the bulk material which are not constant from lot to lot. Thus, a method for measuring some parameter which can be reliably used to predict shelf-life for these materials on a lot to lot basis is needed.

Prediction of shelf-life for materials undergoing autocatalytic decomposition is currently done by measuring induction times at elevated temperatures (6). Measurements are usually made at as low a temperature as patience, time, and detection limits will allow, then an extrapolation is done to obtain the induction time at the actual use or storage temperature of the material. Using an elevated temperature inserts the uncertainty of assuming a constant activation energy over the temperature interval of the extrapolation. After the extrapolation, questions remain even as to the validity of a relative stability order, since the stability order at high temperature may not be the same as that at the lower use temperature (6). Extrapolation over 100 to 200°C is not uncommon in current practice, and changes in the activation energy caused by changes in reaction mechanism over such a temperature range would not be surprising.

Several recent papers (2, 3, 7–9), have shown how isothermal calorimetry can be used as a relatively rapid and unambiguous method to determine the kinetic rate law for degradations of organic materials. Isothermal calorimetry is also a common method used for the detection of a large thermal

event occurring at the end of the induction time, and hence can be used as a method for determining the induction times (6, 10). These previous calorimetric studies have focused on identifying the major decomposition reaction or have used the calorimetric signal from the decomposition reaction simply as a time marker. The focus of this paper is to use calorimetry to study the reactions occurring during the induction period.

Isothermal calorimetry, and in particular large sample (typically 1 to 100 g), heat conduction calorimetry, can often provide both kinetic and chemical data at low temperature on the reaction(s) occurring during the induction period. The attainable detection limit of 0.2 μW allows degradation rates as low as 0.01% per year to be measured in favorable cases (3). Furthermore, the output from a heat conduction calorimeter is directly proportional to the rate of reaction, and therefore is a measure of the instantaneous rate of reaction. Thus, it is not necessary to wait for reaction products to accumulate as in the case of integral methods, and in the absence of interfering reactions, measurements can be made very early in the induction period. The purpose of this paper is to demonstrate that accurate shelf-life predictions can be made from calorimetric measurements of the rate of heat production taken during the induction period of an autocatalytic degradation reaction.

Theory

The rate of an initiation reaction can be expressed as

$$[1] \quad (d\alpha_i/dt) = kf(\text{concentrations})$$

where α_i is the fraction of reaction that has occurred, k is the rate constant, t is the time, and f(concentrations) is a function of the concentrations of sites and reactants that are active in the initiation reaction. The rate constant k is given as a function of temperature by

$$[2] \quad k = A \exp -E^*/RT$$

where A is a constant, E^* is the Arrhenius activation energy, R is the gas constant, and T is the Kelvin temperature.

For the reactions of interest in the context of this paper, f(concentrations) will usually not change during the induction period, and therefore the rate equation for the reaction will be pseudo-zero order. Setting f(concentrations) $= c$, a constant, eq. [1] thus becomes

$$[3] \quad (d\alpha_i/dt) = kc = cA \exp -E^*/RT$$

which, on integration from $\alpha_i = 0$ at $t = 0$ gives

$$[4] \quad \alpha_i = kct$$

When $\alpha_i = 1$, i.e. at the end of the induction time, $kc = 1/t_i$ where t_i is the length of the induction period. Note that for zero order kinetics, α_i is equal to the fraction of the induction time that has elapsed. Substituting this result into eq. [3] gives

$$[5] \quad (d\alpha_i/dt) = cA \exp -E^*/RT = 1/t_i$$

which relates the induction time to the temperature as shown in eq. [6].

$$[6] \quad -\ln t_i = \ln cA - E^*/RT$$

If t_i is known as a function of temperature, the activation energy for the initiation reaction may be obtained by plotting $\ln t_i$ against $1/T$ and calculating the slope, which is equal to E^*/R. Note that a linear plot will not be obtained if E^* is not constant or if the reaction is not zero or pseudo-zero order, i.e. if c is not constant. The objective of this study, however, is to avoid having to do a direct determination of t_i for every lot of material.

The total amount of heat produced by the initiation reaction to any time t during the induction period is given by

$$[7] \quad Q_i = -\Delta H_i \beta_i D_o \alpha_i$$

where ΔH_i is the enthalpy change for the initiation reaction, β_i is the fraction of the sample which reacts in the initiation reaction, and D_o is the mass of the sample. The rate of heat production during the induction period is then

$$[8] \quad dQ_i/dt = q_i = -\Delta H_i \beta_i D_o (d\alpha_i/dt)$$

Substituting $1/t_i$ for $(d\alpha_i/dt)$ as shown in eq. [5] and rearranging gives

$$[9] \quad t_i = -\Delta H_i \beta_i (D_o/q_i)$$

which shows that t_i is linearly proportional to the reciprocal of the heat production rate if $\Delta H_i \beta_i$ is constant during the induction period. Relative values of D_o/q_i are therefore a measure of the relative induction times of different lots of a given material. Such a relative measurement is sufficient for many purposes. An absolute value of t_i can be calculated from measurements of D_o/q_i if $\Delta H_i \beta_i$ is known. The slope of a plot of t_i versus D_o/q_i gives the value of $\Delta H_i \beta_i$ for the initiation reaction. In order to make such a plot, both t_i and D_o/q_i must be measured on a set of calibration samples. Alternatively, $\Delta H_i \beta_i$ may be estimated from known reactions and thermochemical data.

The activation energy for the initiation reaction may be obtained by measuring q_i as a function of temperature. Substituting $q_i/-\Delta H_i \beta_i D_o$ from eq. [8] for $(d\alpha_i/dt)$ in eq. [5], rearranging and taking the natural logarithm gives

$$[10] \quad \ln q_i/D_o = \ln (-\Delta H_i \beta_i cA) - E^*/RT$$

The activation energy may thus be obtained by plotting $\ln q_i/D_o$ against $1/T$ which should give a straight line with slope equal to $-E^*/R$.

The only assumption made in the derivation is that the initiation reaction is zero order. This assumption may be tested by measuring q_i at several points during the initiation period. If q_i is a constant throughout the induction period, then the zero order assumption must be correct. (See eq. [6] in ref. 3.) Also, if the plot of $\ln q_i/D_o$ vs. $1/T$ is linear, then the activation energy must be invariant over the range of temperatures plotted, $\Delta H_i \beta_i c$ must be a constant, and the assumption of zero order must also be true.

The time to the maximum rate of reaction, t_m, is often used implicitly as a surrogate for the induction time in discussions of autocatalytic kinetic data (2, 6) although there has been no basis in fact or theory given for a relationship between t_i and t_m. Although some systems show a sudden, sharp rise in the thermal signal at the end of the induction period (10), the junction between the induction time and the rapidly rising period of reaction is often a continuous curve with no definitive t_i point (2, 3). Thus, t_m is often much more precisely defined and hence much easier to measure than t_i. This empirical data treatment using t_m in place of t_i is usually successful in predicting relative stability order, and therefore

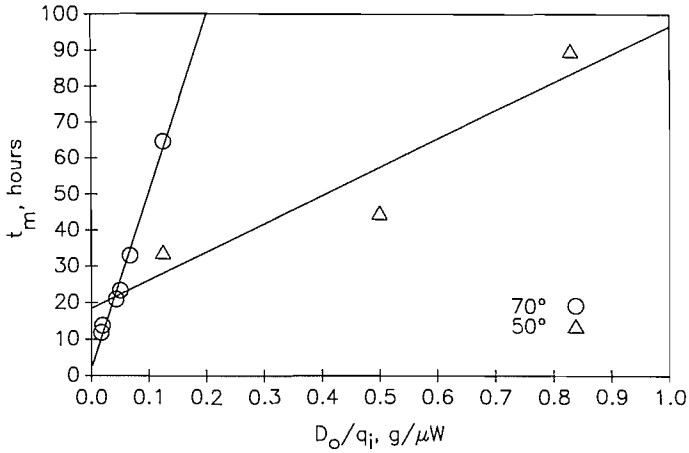

FIG. 1. Time required to achieve the maximum rate of heat production versus the reciprocal of the heat rate measured during the induction period for oxidative decomposition of Lovastatin, 2-methylbutanoic acid 1,2,3,7,8,8*a*-hexahydro-3,7-dimethyl-8-[2-(tetrahydro-4-hydroxy-6-oxo-2*H*-pyran-2-yl)ethyl]-1-naphthalenyl ester.

must have some basis in fact, albeit unknown. From the success of predictions based on t_m, it follows that t_m must be linearly proportional to t_i for different samples of the same material. Thus, for plots of t_m versus D_o/q_i, eq. [9] becomes

$$[11] \quad t_m = (t_m - t_i) - \Delta H_i\beta_i(D_o/q_i)$$

simply by adding $(t_m - at_i)$ =constant to both sides. A linear plot of t_m versus D_o/q_i will be obtained for samples with differing D_o/q_i if $(t_m - at_i)$ is in fact a constant. The intercept of such a plot is equal to $(t_m - t_i)$ and thus t_i can be obtained from the t_m data.

Experimental

Measurements were made as described in ref. 3. Briefly, samples (1 to 3 g) were enclosed with air in sealed containers and placed in the calorimeter at 70°C. Data on the heat production rate were collected continuously until a value for t_m was obtained. Sample aging was assumed to begin when the sample was placed in the calorimeter, i.e. we assumed $t = 0$ and $\alpha_i = 0$ at this point in time. Experimental lots of Lovastatin used in this study were obtained and the heat rates measured within a few days of manufacture. Induction heat rate data were obtained on some early, experimental lots of Lovastatin at 50°C. These data were reported in ref. 3 and are included in Fig. 1. Current production lots of Lovastatin have an induction heat rate at 50°C which is below the detection limit (0.2 μW) of the measurement, consistent with the shelf-life of several years at room temperature.

Results

D_o/q_i and t_i data taken on Lovastatin at 70°C in this study together with similar data at 50°C from ref. 3 are plotted according to eq. [11] in Fig. 1. The linear relationship between t_m and D_o/q_i validates both eqs. [10] and [11]. The slopes of the two plots in Fig. 1 give values of $\Delta H_i\beta_i$ of −0.28 and −1.75 J/g of sample at 50 and 70°C, respectively. The fact that $\Delta H_i\beta_i$ varies much more than expected with temperature is evidence that the induction reaction is different at the two temperatures.

Discussion

The theory given above may also be tested with data from the literature. Plots of ln t_i or ln t_m against $1/T$ have been found to be linear for oxidative degradation of polyolefins with and without antioxidants over a significant range of temperature (4, 6). Also, published data on rates of heat production from oxidative degradation of Lovastatin during the induction period generally show the rate to be constant (3). Data on oxidation of unsaturated fatty acids and seed lipids show constant or only very slowly rising rates of heat production, particularly during the early part of the induction period (2). These data show the zero order assumption to be generally valid. A very slow increase in the heat rate during the induction period is simply an indication of the beginnings of the major degradation reaction and is expected to occur in those cases which do not show an abrupt change in the rate at the end of the induction period. This overlap of reactions in time causes the difficulty mentioned above in actually determining a value for t_i from the experimental data.

Changes in activation energy of the initiation reaction are indicated by a change of slope in a plot of ln t_i or ln t_m against $1/T$. These changes are usually fairly abrupt. For example, the activation energy for polyolefin oxidation has been shown to change around 150°C by this method (6). Induction period heat rates can provide further information concerning changes in mechanism occurring with changing temperature. Induction period data on Lovastatin, for example, show the rate of induction period heat generation to decrease markedly between 60 and 70°C even though the induction time decreased with the temperature increase (3). Such changes in E^* and/or c are indicative of a change in the reaction mechanism and thus are a warning that data collected above the change temperature cannot be used to predict stability below the temperature of the change in mechanism. These data reinforce the need for rapid means of testing stability at low temperature.

Once it has been verified that the induction reaction is described by a zero order rate law, a determination of relative stability can be made simply by measurement of the relative values of D_o/q_i. Since a measurement of q_i requires only about 1 to 8 h with current, commercially available calorimeters, this method opens the possibility of doing reasonably fast quality control measurements.

To predict absolute stability, a calibration constant (i.e. $\Delta H_i\beta_i$ or the slope of a plot similar to that shown in Fig. 1) must be determined. For materials with very large t_i values this may not be practical. Also, estimation of $\Delta H_i\beta_i$ may not be possible because the reactions contributing to the measured heat rate are not known. However, the method described in this paper may be used to fairly rapidly (~10 days) determine the activation energy (i.e. measurement of D_o/q_i as a function of temperature), and then, if E^* is found to be constant to a high enough temperature, t_i or t_m may be measured at the high temperature. Thus, after sufficient calibration, a complete prediction of the useful shelf-life of a given material would require only that q_i be measured at some convenient temperature in the range of constant activation energy.

The measurement temperature may be chosen to be the same as the use temperature, but an elevated temperature is often helpful because it increases the heat rate and thus decreases the error in the measurement. However, too high a temperature of measurement can cause problems by shortening the induction period until it becomes too short for meaningful measurements.

Another difficulty encountered with Lovastatin in this study was the presence at $t = 0$ of reactions with decaying exponen-

For personal use only.

tial kinetics. (See ref. 3 for examples.) Such reactions must be allowed to decay before an accurate measurement of q_i can be made. The presence of such reactions delays the time at which a relative stability prediction may be made, but does not increase the time required to make a measurement if the sample is allowed to age outside the calorimeter for a proper period of time.

The results presented in this paper and collected from the literature show that the rapidly rising autocatalytic part of the degradation process begins when the products of the induction reaction reach a critical concentration in the material. This is entirely consistent with previous works on mechanisms of autocatalytic oxidations and polymerizations. What is new in this work is that the concentration of induction reaction products are shown to increase linearly with time as required by pseudo-zero order kinetics.

RATAN LAL GUPTA and KOCHI ISMAIL. Can. J. Chem. **68**, 2115 (1990).

Electrical conductance and density measurements of $[x\mathrm{NaNO_3} + (1 - x)\mathrm{KNO_3}] + R\mathrm{H_2O}$ system were taken as functions of x, R, and temperature. The mixed alkali effect on molar conductance (Λ) was found to be negligible upto $R = 25$ and becomes significant in the region where $R < 25$. It has been shown that for mixed electrolytic system in aqueous medium the concentration range at which the mixed alkali effect on Λ starts becoming significant can be predetermined by plotting the difference in Λ of the two pure electrolytic solutions versus R. The concentration dependence of Λ has been described satisfactorily by the expression $\Lambda = \Lambda_{FLK} \exp(Bc + Cc^2)$ where Λ_{FLK} is the Falkenhagen–Leist–Kelbg equation for Λ, B and C are empirical constants, and c is the molar concentration. The observed values of the ion-size parameter have indicated more ionic association in $\mathrm{KNO_3}$ solution than in $\mathrm{NaNO_3}$ solution.

Key words: electrical conductance, sodium nitrate, potassium nitrate, mixed alkali effect.

RATAN LAL GUPTA et KOCHI ISMAIL. Can. J. Chem. **68**, 2115 (1990).

On a mesuré la conductivité électrique et la densité du système $[x\mathrm{NaNO_3} + (1 - x)\mathrm{KNO_3}]R\mathrm{H_2O}$ en fonction de x, de R et de la température. On a trouvé que l'effet des alcalins mixtes sur le conductivité (Λ) est faible jusqu'à une valeur de $R = 25$ et qu'il devient important lorsque $R < 25$. Pour le système électrolytique mixte en milieu aqueux, on a démontré que l'intervalle de concentration dans lequel l'effet des alcalins mixtes commence à se faire sentir peut être prédéterminé en faisant un graphique de la différence entre les Λ des deux solutions électrolytiques pures en fonction de R. L'équation $\Lambda = \Lambda_{FLK} \exp(Bc + Cc^2)$, dans laquelle Λ_{FLK} est l'équation de Falkenhagen–Leist–Kelbg pour Λ, B et C sont des constantes empiriques et c est la concentration molaire, permet de décrire correctement la relation qui existe entre la concentration et la conductivité Λ. Les valeurs observées pour le paramètre de la grosseur de l'ion indiquent qu'il y a plus d'association en solution dans le $\mathrm{KNO_3}$ qu'en solution dans le $\mathrm{NaNO_3}$.

Mots clés : conductivité électrique, nitrate de soude, nitrate de potasse, effet des alcalins mixtes.

Introduction

Properties of ternary systems containing two alkali metal ions in a fixed glassy medium are interesting due to a phenomenon known as mixed alkali effect (MAE) which is of both practical and theoretical importances (1, 2). This phenomenon refers to non-additivity of various physical properties caused when the relative amounts of the alkali metal ions are varied while the concentration of the glassy medium is a constant. Normally MAE is most pronounced for properties related to ionic transport.

Attempt are being made to look for the MAE in media other than glass. In hydrate melt medium MAE also is found to be present but to a lesser extent (3–6). Another suitable medium for investigating MAE is the aqueous medium. Investigation of MAE on transport properties in aqueous medium has a two-fold interest. (*i*) Data on the properties of mixed aqueous electrolytes are necessary because many systems of practical, biological, geological or chemical interest involve mixed aqueous electrolytes. Studies on the transport properties of mixed aqueous electrolytes have, however, been relatively few compared to those on their thermodynamic properties. (*ii*) One of the characteristics of MAE is that it shows a complicated dependence on the total alkali metal ion concentration. To examine this aspect, aqueous medium is more convenient. Any mixed alkali metal ion system in aqueous medium can be represented as $[x\mathrm{M_1A} + (1 - x)\mathrm{M_2A}] + R\mathrm{H_2O}$, where M_1 and M_2 are the two alkali metal ions and R is the number of moles of $\mathrm{H_2O}$. Our previous attempt (7) to look for MAE in aqueous medium by measuring electrical conductances of a mixture of sodium and potassium thiocynates in water at 25°C has shown that significant MAE on molar conductance exists only in the region where $R < R_0 \simeq 10$. In view of the fact that NaSCN solution exhibits specific conductance maximum at $R \simeq 10$ and for KSCN solution it occurs at $R \simeq 6$, the value of R_0 is considered to have a correlation with the concentration (lower one) at which the specific conductance maximum of one of the constituent electrolytes of the mixed system occurs (7). Furthermore, it has been suggested that in the region where MAE exists the mixed electrolytic system has a quasi-crystalline-type structure. To further examine this type of dependence of MAE on R or on the total alkali metal ion concentration, electrical conductances of another mixed electrolyte, viz., $[x\mathrm{NaNO_3} + (1 - x)\mathrm{KNO_3}] + R\mathrm{H_2O}$, are reported here as functions of x, R, and temperature.

Experimental section

$\mathrm{NaNO_3}$ (BDH, Laboratory Reagent) and $\mathrm{KNO_3}$ (BDH, Laboratory Reagent) were recrystallized from their solutions in doubly distilled water and were then dried for several days over anhydrous $\mathrm{CaCl_2}$ in a vacuum desiccator. Using these salts molal solutions were prepared. To convert molal concentrations into molar concentrations densities of the solutions were measured using a calibrated glass pycnometer of about 7 mL capacity. Conductivity measurements were made at 1 kHz using the CDM 83 conductivity meter (Radiometer, Copenhagen) and a dip type CDC 304 conductivity cell. This cell has three electrodes in the form of pure platinum bands on a glass tube. All measurements were made in a thermostated (±0.02°C) water bath.

Results and discussion

The experimental values of molar conductance of $[x\mathrm{NaNO_3} + (1 - x)\mathrm{KNO_3}] + R\mathrm{H_2O}$ system measured as functions of x, R, and temperature are presented in Table 1.[3] The density data are

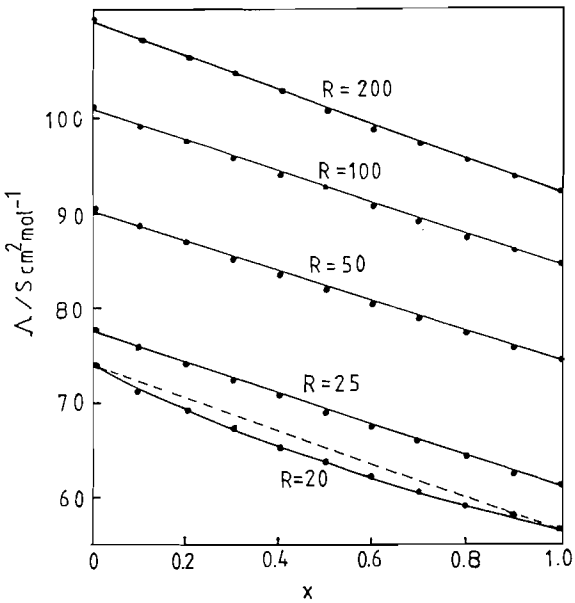

FIG. 1. Variation of Λ of $[x NaNO_3 + (1 - x)KNO_3] + RH_2O$ system with x at 298 K for different R values.

presented as a function of temperature in Table 2.[3] The measured values of conductance were found to be reproducible to within ±0.75% accuracy.

Variation of Λ *with* x

The variation of Λ with x at different R values is shown in Fig. 1. At all experimental tempertures less than 1% deviation of Λ from additivity has been observed upto $R = 25$. Rysselberghe and Nutting (8) also reported less than 1% deviation from additivity in Λ of $[xNaNO_3 + (1 - x)KNO_3] + 55.56H_2O$ system at 298 K. The MAE is, however, considered to be not very significant when the non-additivity in Λ is <1%. At $R = 20$, on the other hand, 2% deviation of Λ from additivity (Fig. 1) has been observed for $x = 0.5$ at 298 K thereby envisaging the occurrence of the MAE on Λ. Earlier it was suggested (7), as mentioned in the Introduction, that the MAE on electrical conductance starts becoming significant when the value of R falls in the concentration range where conductivity maximum of at least one of the components of the mixed electrolytic solution appears. The existence of MAE at $R = 20$ in the $[xNaNO_3 + (1 - x)KNO_3] + RH_2O$ system is, however, contrary to our above suggestion since conductivity maximum has not been observed or reported for KNO_3 solution upto saturation point and for $NaNO_3$ solution it is found at $R \simeq 6.9$. What is then the concentration range at which the MAE on Λ becomes significant in an aqueous medium? To seek a probable answer to this question we have plotted in Fig. 2 the difference (ΔΛ) in the Λ values of (*i*) NaSCN and KSCN solutions (7) and (*ii*) $NaNO_3$ and KNO_3 solutions as a function of R at 298 K. It is evident from Fig. 2 that at high R values ΔΛ depends linearly on R and at some concentration range deviation from the linear dependence starts to take place. It is very interesting to observe that the concentration range at which the MAE on Λ starts becoming significant coincides with the concentration range where dependence of ΔΛ on R deviates from linearity. Incidentally, in the case of NaSCN and KSCN solutions the concentration range around which ΔΛ deviates from linearity coincides with the range at which NaSCN solution exhibits specific conductance maximum. In Fig. 2 we also checked the dependence of ΔΛ on R for a few other pair of electrolytes, viz., RbCl and CsCl (at 296 K), NaCl and KCl (at 298 K), and LiCl and RbCl (at 296 K),

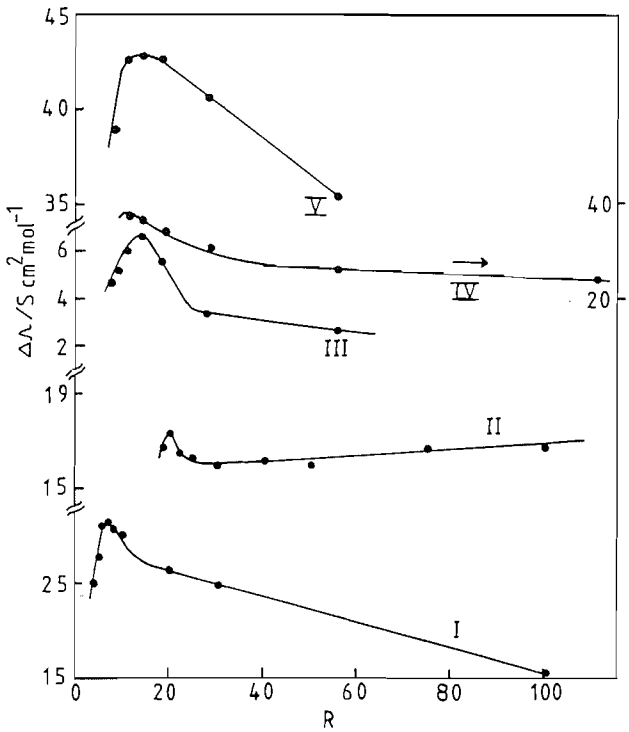

FIG. 2. Plot of difference in Λ values of aqueous electrolytic solutions at 25°C vs. R (*I*, NaSCN and KSCN; *II*, $NaNO_3$ and KNO_3; *III*, RbCl and CsCl (at 23°C); *IV*, NaCl and KCl; and *V*, LiCl and RbCl (at 23°C).

with the help of their reported data (9–11). In all cases, the dependence of ΔΛ on R follows a general trend, viz., (*i*) linear dependence at large R values, (*ii*) at some concentration range, which depends on the pair of electrolytes considered, deviation from linearity is observed and (*iii*) the plot of ΔΛ vs. R passes through a maximum at some lower R value. Therefore, for mixed electrolyte systems in aqueous medium the concentration range at which the MAE on Λ begins to become significant can be predetermined by plotting the difference in Λ of the two pure electrolytic solutions versus R.

Variation of Λ *with* R

We recently reported (7) a new isothermal equation of the form

$$[1] \quad \Lambda = \Lambda_{FLK} \exp(Bc + Cc^2)$$

to describe the concentration dependence of Λ of electrolytic solutions, both single and mixed electrolytes, from dilute region upto high concentration. In eq. [1], B and C are empirical constants and c is the molar concentration. Concentration in the exponential part of eq. [1] can also be expressed in other units. Λ_{FLK} refers to the Falkenhagen–Leist–Kelbg (FLK) equation (12) for Λ and is of the form

$$[2] \quad \Lambda_{FLK} = \left[\Lambda_0 - \frac{B_1 c^{1/2}}{1 + B_0 a_0}\right]\left[1 - \frac{B_2 c^{1/2} F}{1 + B_0 a_0}\right]$$

For 1:1 electrolytes, $B_1 = 82.501/\eta_0(DT)^{1/2}$, $B_2 = 82.04 \times 10^4/(DT)^{3/2}$, $B_0 = 50.29 \times 10^8 c^{1/2}/(DT)^{1/2}$, and $F = [\exp(0.2929 B_0 a_0) - 1]/0.2929 B_0 a_0$. Λ_0 is the molar conductance of the solution at infinite dilution, η_0 is the viscosity of water, D is the dielectric constant of water at temperature T, and a_0 is known as the ion-size parameter. In eq. [1] the parameters whose values need to be determined are Λ_0, a_0, B, and C. While fitting data to eq. [1] it was reduced to a three-parameter equa-

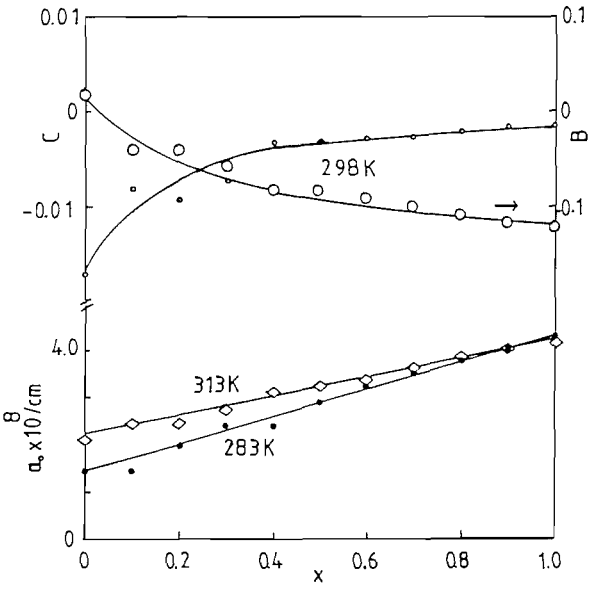

FIG. 3. Variation of a_0, B, and C of $[x NaNO_3 + (1 - x)KNO_3] + RH_2O$ system with x.

tion, by substituting the reported (13) values of Λ_0 for $x = 0$ and $x = 1$ and for other values of x the corresponding Λ_0 values were estimated using the additivity principle (14). The best-fit values of a_0, B, and C obtained by using an iterative least-squares fitting program are listed in Table 3.

It is evident from Table 3 and Fig. 3 that a_0 increases linearly with x. At 298 K $a_0 = 1.99$ Å for KNO_3 solution ($x = 0$) and for $NaNO_3$ solution ($x = 1$) $a_0 = 4.36$ Å. Association into ionic pairs is reported (15–17) in aqueous solutions of both $NaNO_3$ and KNO_3. The considerably low value of a_0 for KNO_3 solu-

tion, also observed by others (15), envisages more ionic association in KNO_3 solution than in $NaNO_3$ solution. Increase in the degree of association of alkali salts in aqueous medium with increasing size of the alkali metal ion was also reported by Kay (15). From Fig. 3 it can further be seen that the a_0 parameter for $NaNO_3$ solution is almost temperature independent whereas the a_0 of KNO_3 solution increases with increase in temperature. This is analogous to the observation made by Goldsack *et al.* (10) in the cases of NaCl and KCl solutions. The degree of ionic association in KNO_3 solution therefore seems to decrease with increasing temperature.

The dependence of B and C parameters on x is also shown in Fig. 3 at one particular temperature. C, which is always a negative quantity, has the lowest value for pure KNO_3 solution and its value increases rapidly as K^+ ions are replaced by Na^+ ions. In the range from $x = 0.5$ to $x = 1.0$, C appears to remain almost independent of the x value. In the case of B, it has a highest positive value for KNO_3 solution and its value decreases with increasing x value, becoming negative above a particular value of x. The value of x at which B becomes zero is dependent on the temperature. For example, at 298 K $B = 0$ at $x = 0.04$ whereas at 288 K $B = 0$ at $x = 0.16$. Similar behaviour was observed in the case of $[x\text{NaSCN} + (1 - x)\text{KSCN}] + R\text{H}_2\text{O}$ system also (7). This type of dependence of B on x may be explained by correlating, in the light of Wishaw-Stokes equation (18), the exponential part of eq. [1] to the reciprocal of viscosity of the system. Consequently, solutions whose B is positive and C is negative may be expected to show negative viscosity (relative viscosity < 1). In fact, aqueous KNO_3 solution is known (9) to exhibit negative viscosity nearly upto 318 K. At 298 K the viscosity of KNO_3 solution is therefore expected to decrease with concentration upto $c = B/C = 1.2$ mol dm^{-3}, which is in good agreement with the experimentally observed value (9). Furthermore, the B parameter appears to have a relation with the ΔE parameter of the Samoilov model (19) for hydration of ions.

Catalysis by α-cyclodextrin of the reaction of formic acid with bromine

OSWALD S. TEE,[1] BUSHRA JAVED, AND SUSAN R. MIKKELSEN
Department of Chemistry and Biochemistry, Concordia University, Montréal, P.Q., Canada H3G 1M8

Received June 12, 1990

OSWALD S. TEE, BUSHRA JAVED, and SUSAN R. MIKKELSEN. Can. J. Chem. **68**, 2119 (1990).

α-Cyclodextrin (CD) modestly increases the rate of oxidation of formic acid by bromine. The variation of rate constants with $[Br^-]$ is consistent with dominance of the formation of a $CD{\cdot}Br_3^-$ complex in determining the fraction of free Br_2 and the $CD{\cdot}Br_2$ complex, under the reaction conditions. Potentiometric measurements support a dissociation constant of about 0.2 mM for the $CD{\cdot}Br_3^-$ complex, in agreement with an earlier spectrophotometric value. Analysis of the rate increases with [CD] implies that $CD{\cdot}Br_2$ is more reactive (~10 times) than free Br_2 towards formate ion, as was found for phenols. These conclusions differ from those of another recent study.

Key words: catalysis, α-cyclodextrin, oxidation, formic acid, bromine.

OSWALD S. TEE, BUSHRA JAVED et SUSAN R. MIKKELSEN. Can. J. Chem. **68**, 2119 (1990).

L'α-cyclodextrine (CD) provoque une légère augmentation de la vitesse d'oxydation de l'acide formique par le brome. La variation des constantes de vitesse avec la $[Br^-]$ est en accord avec le fait que, dans les conditions de la réaction, les fractions de Br_2 libre et sous la forme de complexe $CD{\cdot}Br_2$, sont dominées par la formation d'un complexe $CD{\cdot}Br_3^-$. Des mesures potentiométriques suggèrent que la constante de dissociation du complexe $CD{\cdot}Br_3^-$ est égale à environ 0,2 mM; cette valeur est en accord avec une valeur spectrophotométrique obtenue antérieurement. L'analyse de l'augmentation de la vitesse avec une augmentation de la [CD] implique que, comme on l'a observé avec les phénols, le $CD{\cdot}Br_2$ est plus réactif (environ 10 fois) que le Br_2 libre vis-à-vis de l'ion formate. Ces conclusions diffèrent de celles rapportées dans une étude récente.

Mots clés : catalyse, α-cyclodextrine, oxydation, acide formique, brome.

[Traduit par la revue]

Formic acid is oxidized by bromine in aqueous solution, and the acidity dependence of the rate suggests that reaction occurs on its anion, eq. [1](1). It has recently been reported that α-cyclodextrin (CD) (2) brings about small increases in the rate of this reaction (3). We have made similar observations, in the course of studies[2] into the effects of cyclodextrins on reactivity (4), but our interpretation of the rate increase differs in regard to the size and origin of the catalysis.

[1] $HCO_2^- + Br_2 \longrightarrow H^+ + 2Br^- + CO_2$

Earlier work showed that the attack of bromine on phenols (5) is modestly catalyzed by CD (6), whereas related debrominations are strongly catalyzed (7). A prior study (8) of the effect of CD on the bromination of anisole helped to identify the equilibria that are needed for data analysis. In particular, we found that addition of CD to Br_2 in 0.01 M KBr solution causes large increases in the uv absorbances due to Br_3^-, consistent with the formation of a strong $CD{\cdot}Br_3^-$ complex (K_d = 0.17 mM) (8).

In their study, Han *et al.* (3) used potentiometry to measure a CD complexation having K_f = 4690 M^{-1} (K_d = 0.213 mM) under conditions where Br_3^- formation is significant ($[Br^-]$ = 0.1 M); it was ascribed to formation of a $CD{\cdot}Br_2$ complex, but no account was taken of the binding of Br_3^- to CD. Based on the value of K_f and the kinetics of oxidation, it was concluded that $CD{\cdot}Br_2$ is half as reactive as Br_2 towards formate ion and that rate increases arise because CD converts unreactive Br_3^- to $CD{\cdot}Br_2$ (3).

In contrast, we have concluded that $CD{\cdot}Br_2$ is 3–31 times as reactive as Br_2 towards phenols (6). Our studies of the effects of CD on brominations (6–8) have used K_d = 2.1 mM for $CD{\cdot}Br_2$, as reported by Breslow and Campbell (9). The present paper reports recent findings that resolve these discrepancies.

We find that the kinetics of oxidation[3] of HCOOH in the presence of added CD are also consistent with eq. [1], but the rate is increased modestly (~1.4× in 0.1 M KBr), indicating some form of catalysis by CD. Without any catalysis, the reaction would be strongly inhibited due to the complexations of Br_2 and Br_3^- by CD (8).

With Br^- and HCOOH present in excess and the pH fixed, the disappearance of Br_2 is first order, eq. [2] (1, 3). In the presence of CD there is an additional process, which is attributed to the reaction of formate ion with the $CD{\cdot}Br_2$ complex, eq. [3] (3).

[2] $Br_2 \xrightarrow{k_1}$ products

[3] $CD + Br_2 \underset{K_B}{\rightleftharpoons} CD{\cdot}Br_2 \xrightarrow{k_2}$ products

Then, neglecting the binding of HCOOH to CD,[4] the observed first-order rate constant should have the form:

[4] $k^{obsd} = (k_1 + k_2[CD]/K_B)f_B$

where f_B is the fraction of free bromine.[5] The difference between our approach and that of Han *et al.* is in respect of the form chosen for f_B. We use:

[5] $f_B = KK_BK_T/(K_BK_T(K + [Br^-]) + [CD](KK_T + K_B[Br^-]))$

[1]Author to whom correspondence may be addressed.

[2]We are studying the effect of CD on the bromination of a variety of substrates, to expand on our earlier findings (4–8).

[3]Oxidation was followed by monitoring bromine disappearance, using the stopped-flow method and uv spectrophotometry (5–8).

[4]To allow a direct comparison with the work of Han *et al.*, we neglect the weak binding of HCOOH to CD (3) and also the weak complex between CD and Br^-, although earlier papers took explict account of the latter (6–8).

[5]Similar treatments have been used previously (3, 6, 8).

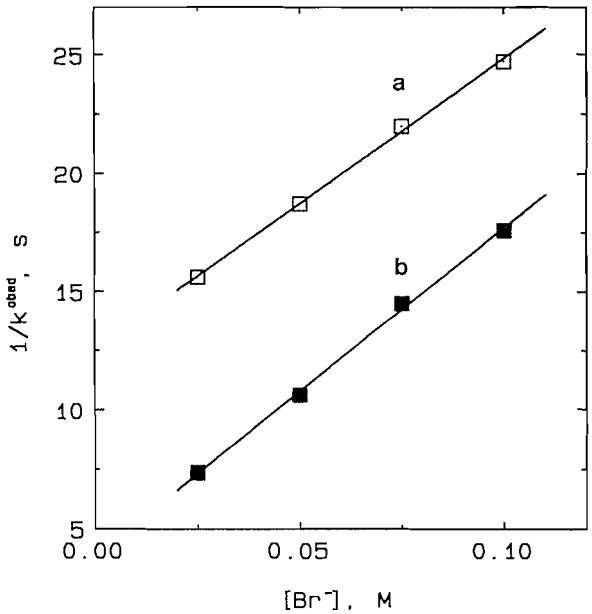

FIG. 1. Effect of bromide ion on the rate constants for the oxidation of formic acid by bromine in the absence (a) and presence (b) of 5 mM α-cyclodextrin. At 25°C using [HCl] = 0.01 M, [HCOOH] = 0.1 M, $[Br_2]_0$ = 0.05 mM, I = [KBr] + [HCl] + [NaCl] = 0.110 M.

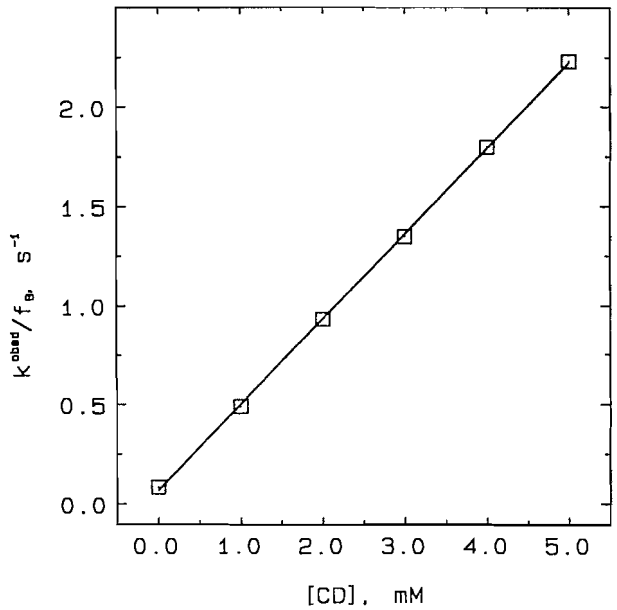

FIG. 2. Effect of α-cyclodextrin on the rate constants for the oxidation of formic acid by bromine, plotted according to eq. [7]. Conditions as for Fig. 1, but with I = [KBr] + [HCl] = 0.11 M (cf. Fig. 2 of ref. 3).

where K, K_B, and K_T are the dissociation constants of Br_3^-, $CD{\cdot}Br_2$, and the $CD{\cdot}Br_3^-$ complex, respectively, and take K = 0.0562 M, K_B = 2.1 mM, and K_T = 0.17 mM (6, 8).

If the binding of Br_3^- to CD is very weak or nonexistent, K_T is large and eq. [5] reduces to

$$[6] \quad f_B = KK_B/(K_B(K + [Br^-]) + [CD]K)$$

This is effectively the form used by Han *et al.*, with K = 0.0588 M and K_B = 0.213 mM (3). Both eqs. [5] and [6] have $[Br^-]$ in their denominators but they are not equally sensitive to its value because of the importance of $CD{\cdot}Br_3^-$ in the former.

In eq. [5] the dominant terms in the denominator involve $[Br^-]$, so that f_B decreases from 0.059 to 0.017 for $[Br^-]$ = 0.025–0.100 M ([CD] = 5 mM). Adding bromide ion produces more Br_3^- and particularly $CD{\cdot}Br_3^-$, at the expense of Br_2 and $CD{\cdot}Br_2$. In contrast, in eq. [6] the dominant term is $[CD]K$ so that f_B hardly varies (0.040–0.038) under the same conditions. Increasing $[Br^-]$ produces more Br_3^-, but the fraction of $CD{\cdot}Br_2$ is large and almost constant (0.94–0.90).

With these considerations in mind, we have measured the effect of varying $[Br^-]$ on the rate of oxidation in the presence and absence of added CD. In both cases the reaction is slower at higher $[Br^-]$ and, as shown in Fig. 1, $1/k^{obsd}$ varies linearly with $[Br^-]$. For reaction in the absence of CD this dependence is due to the increasing formation of unreactive Br_3^- (10); when CD is present it is consistent with dominance of the formation of the $CD{\cdot}Br_3^-$ complex, also unreactive (6, 8).

We have also used potentiometry[6] to measure the *apparent* binding of Br_2 to CD at $[Br^-]$ = 0.10, 0.05, and 0.01 M,[7] with 0.1 M HCl to suppress HOBr (11), and obtained values of "K_B" = 0.126, 0.202, and 0.587 mM, respectively. If the method measured *only* the formation of $CD{\cdot}Br_2$ these values should be virtually constant. The trend to higher values at low $[Br^-]$ is consistent with stronger binding of Br_3^- to CD, which decreases in importance at low $[Br^-]$,[8] and with a weaker binding of Br_2. Thus, while the potentiometric method measures *free* Br_2, the variation of $[Br_2]$ with [CD] is governed largely by the formation of $CD{\cdot}Br_3^-$. Interpreted in this light, the potentiometric measurements give K_T = 0.21, 0.17, and 0.10 mM, in good agreement with the spectrophotometric value of 0.17 ± 0.02 mM (8). Accordingly, we continue to believe that Br_3^- binds more strongly than Br_2 to CD, similar to the situation found with I_3^- and I_2 (12).

Finally, we consider the question of the catalysis by the $CD{\cdot}Br_2$ complex. As reported for pH 1 (3), increasing [CD] brings about small rate increases at other pH values. For analysis of the data, eq. [4] can be rearranged to[5]

$$[7] \quad k^{obsd}/f_B = k_1 + k_2[CD]/K_B$$

Figure 2 shows rate data plotted according to eq. [7], and from the slope we obtain k_2 = 0.902 s^{-1}, whereas k_1 = 0.0850 s^{-1}. Thus, in our view, $CD{\cdot}Br_2$ is ~10 times *more reactive* than Br_2 towards HCOOH. We can also estimate an apparent dissociation constant, $K_{TS} = k_1{\cdot}K_B/k_2$ = 0.20 mM, which reflects the binding of the oxidation transition state to CD (4). Similar catalytic ratios (6) and K_{TS} values (4) have been found for the reaction of bromine with phenols, and other substrates.[2]

[6]Measurements were made at 25°C with Ag/AgCl reference and Pt working electrodes. All solutions were prepared immediately prior to use. Calibration lines of E vs. $-\log[Br_2]$, constructed for each $[Br^-]$, had slopes very close to the theoretical value of 0.02958. For experiments with varying $[CD]_t$ (0.1–10 mM) these lines were used to find $[Br_2]$, from which $[Br_3^-] = [Br_2][Br^-]/K$ was calculated; the values of [CD] and $[CD{\cdot}Br_2]$ (or $[CD{\cdot}Br_3^-]$) were then obtained through the equations for material balance. From these concentrations we calculated values of K_B (or K_T). The approach is close to that in ref. 3.

[7]Experiments at lower $[Br^-]$ were not successful.

[8]Ultraviolet–visible spectrophotometry clearly shows that the binding of Br_3^- to CD dominates the equilibria controlling free Br_2, even at $[Br^-]$ = 0.01 M (8).

On the structure and reactivity of a stabilized phosphorane: methyl (triphenylphosphoranylidene)acetate

MARGARET H. KAYSER[1]
Department of Chemistry, University of New Brunswick, P.O. Box 5050, Saint John, N.B., Canada E2L 4L5

AND

DONALD L. HOOPER
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received February 23, 1990

MARGARET H. KAYSER and DONALD L. HOOPER. Can. J. Chem. **68**, 2123 (1990).

In the absence of a source of acidic protons, methyl (triphenylphosphoranylidene)acetate **1** exists as a mixture of the *cis* and *trans* isomers even at room temperature. Acidic protons catalyze the interconversion of the two forms and facilitate the reaction of the ylide with active carbonyl compounds such as benzaldehyde or phthalic anhydride.

Key words: stabilized phosphoylide, structure, reactivity.

MARGARET H. KAYSER et DONALD L. HOOPER. Can. J. Chem. **68**, 2123 (1990).

En l'absence d'une source de protons acides, l'acétate de méthyl(triphénylphosphoranylidène) (**1**) existe sous la forme d'un mélange des isomères *cis* et *trans*, même à la température ambiante. Les protons acides catalysent l'interconversion des deux formes et facilitent la réaction de l'ylure avec les composés carbonylés actifs, comme le benzaldéhyde ou l'anhydride phtalique.

Mots clés : phosphoylure stabilisé, structure, réactivité.

[Traduit par la revue]

Introduction

Stabilized phosphorane **1** has been widely used in the synthesis of α,β-unsaturated esters (1), and the mechanism and stereoselectivity of condensations of **1** with aldehydes have been investigated by a number of groups (2). Nevertheless, this apparently simple reaction still presents interesting and unexpected behaviour.

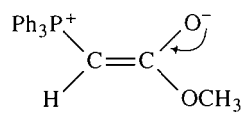
$Ph_3P{=}CH{-}COOR$ (**1**, R = CH_3) $\qquad$ $Ph_3P{-}CH_2COOR\ Br^-$ (**2**)

For example, the reaction of benzaldehyde with the stabilized ylide **1** in THF was followed by ^{31}P NMR at −20°C (3). No intermediates were found and the only two observable signals were identified as the unreacted ylide **1** (at δ 16.5) and triphenylphosphine oxide (δ 23.3) (3).

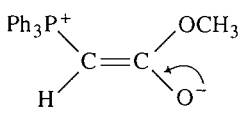
While repeating the experiment, we noted a behaviour that had not been reported previously. In our experiment, the spectrum of ylide **1** recorded at −20°C consisted of two singlets in the ratio of 3:1 at δ 17.85 and δ 16.35, respectively. Upon addition of freshly distilled benzaldehyde (cooled to −20°C) the two signals collapsed to a single peak at δ 17.30. As the temperature was allowed to rise, the product, triphenylphosphine oxide, appeared at δ 29.81 and the progress of the reaction could be monitored by the disappearance of the peak at δ 17.30 and the increase of the signal at δ 29.81.

During the course of the reaction both peaks drifted slightly but no other signals were observed. It was not clear to us why, upon addition of benzaldehyde, the ylide's two signals were replaced with a new peak at δ 17.30, or whether the new peak represented a somehow transformed ylide or an intermediate.

It has been nearly 20 years since stabilized ylides were investigated (4–8) by ^1H NMR. The results of these studies may be summarized as follows: at −40°C or lower, ylide **1** gives the signals of two distinct forms, with signal coalescence above room temperature. This observation was attributed to the temperature dependent equilibrium between the geometrical isomers: the major **1**-*cis* and the minor **1**-*trans* (5, 6). The stereochemistry was assigned on the basis of electrostatic considerations and of coupling constants for the two isomers (6). The $\Delta G^{\ddagger}$ for the *cis*–*trans* interconversion was calculated to be of the order of 10 kcal/mol (7).



1-*cis*



1-*trans*

Another interesting characteristic, noted at the time, was that the methine proton of the ylide *appeared to exchange rapidly at higher temperatures*. The authors suggested that the proton exchanged with the conjugate acid **2** present in trace amounts in the ylide (6, 7).

Results and discussion

We decided to extend these experiments with particular attention to the effect of moisture and conjugate acid. Figure 1(a) shows a typical room temperature proton spectrum of **1** in $CDCl_3$. The expected coupling of the methine proton to phosphorus is not observed. Exchange of this labile proton could be catalyzed by traces of atmospheric water, conjugate acid, or even DCl present in the solvent (see Scheme 1). In fact the effect of moisture was readily observable; the width of signals and the presence or absence of P–H coupling varied according to the amount of atmospheric water absorbed into the solution. After extensive drying of solute and solvent, the spectrum in Fig. 1(b) was obtained, showing the existence even at room temperature of both isomeric forms. Figure 1(c) shows the low temperature spectrum of an undried sample, with full P–H coupling and good separation of the signals of the two isomeric forms. As drying the sample has almost the same effect as a decrease in temperature by 50°C, we conclude that the presence of water in the solution is a major determinant of the rate of isomer interconversion.

Addition of a trace quantity of butyllithium to a solution of

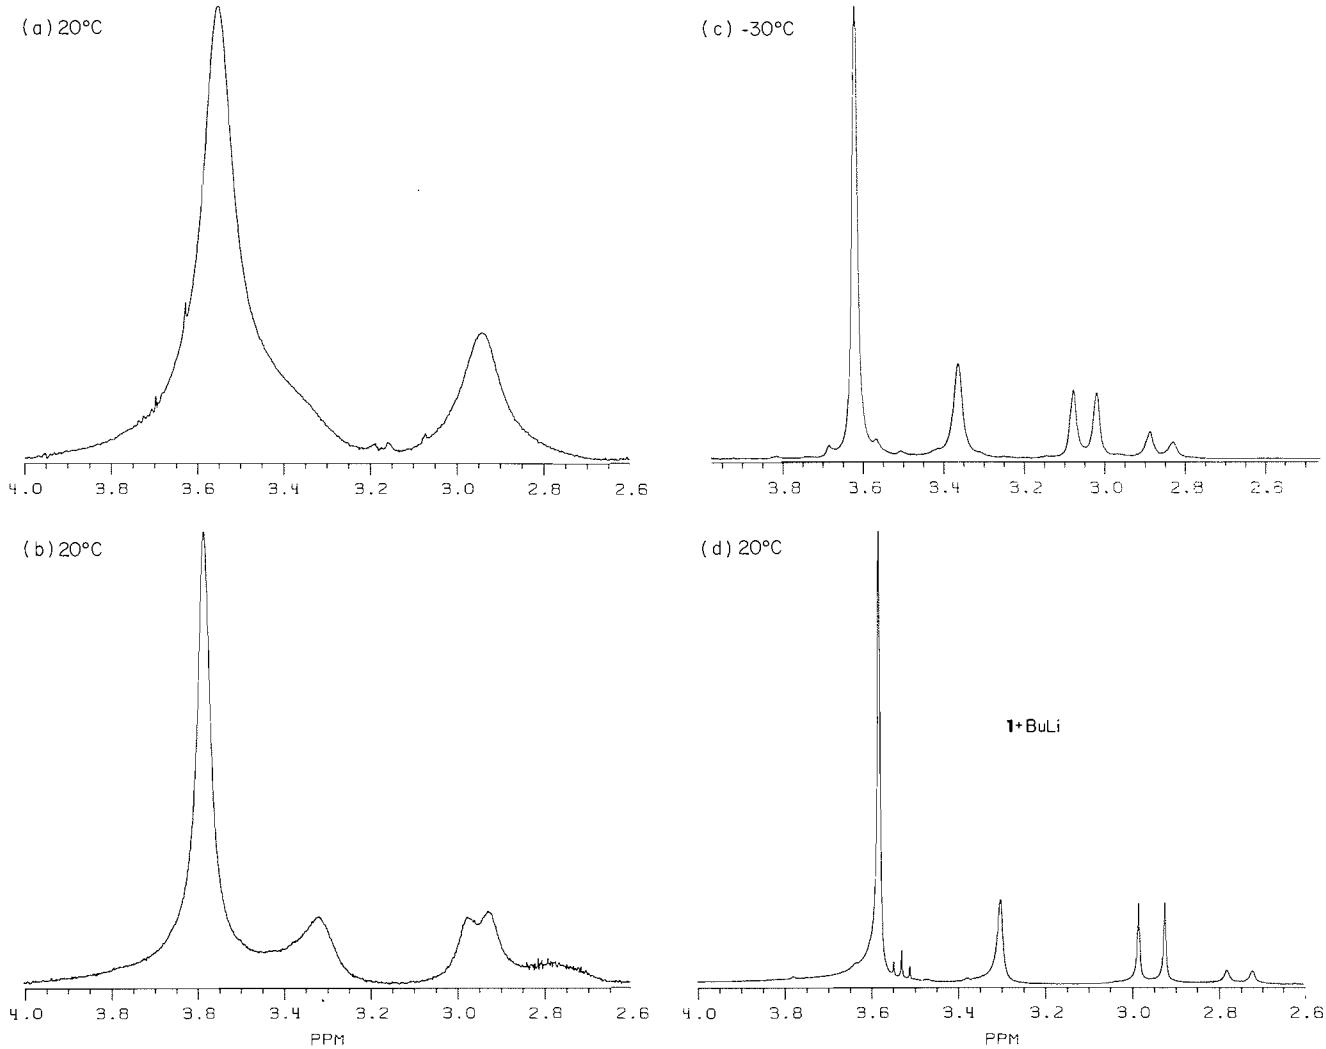

FIG. 1. Proton NMR spectra of phosphorane **1**.

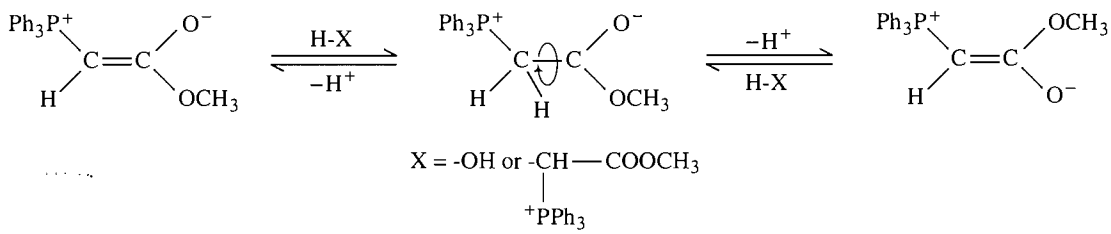

SCHEME 1

1 gives a room temperature spectrum, Fig. 1(d), where isomer interconversion is slower than in an undried sample at −60°C. The effect of butyllithium might have been anticipated, as BuLi removes *both* water and conjugate acid, and traces of DCl, and would be expected to stabilize the enolate ions **1**-*cis* and **1**-*trans* by complexation of Li^+ cation with the negatively charged oxygen. Stabilization of the enolate structure of the phosphorane would increase the double bond character of the C—C bond and decrease the rate of *cis–trans* interconversion.

The above effects are also evident in the ^{31}P and ^{13}C spectra recorded as a function of temperature.

Thus, in the ^{13}C spectrum of **1** recorded at room temperature, the carbon of the methoxy group appears as a singlet at 49.73 ppm, while the methine carbon signal is a doublet centered at 29.78 ppm with a J_{P-C} of 126 Hz. In the coupled spectrum the methine carbon is observed as a very broad peak, indicating that proton exchange is rapid on the ^{13}C time scale.

Upon lowering the temperature below −40°C, or adding a trace of BuLi at room temperature, the methine proton exchange ceases and signals for the two isomeric forms emerge. The methine carbon signal appears as the overlapping sets of doublets in the coupled spectrum illustrated in Fig. 2.

The coalescence temperature for the methine carbon signals is 0°C for a non-dried sample. It increases to 20°C upon addition

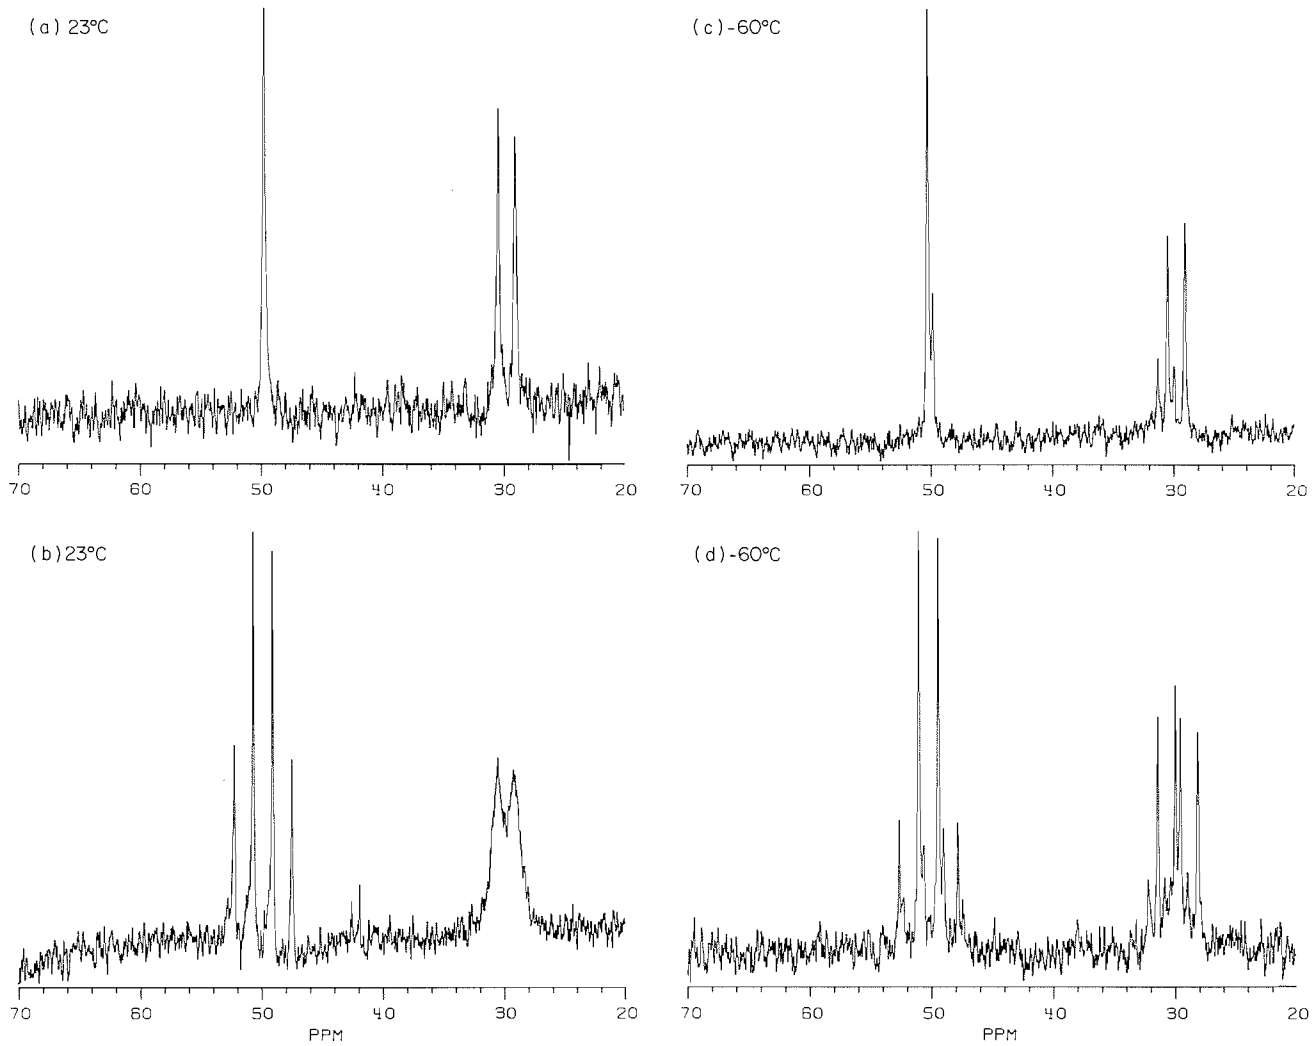

FIG. 2. ^{13}C NMR spectra of ylide **1** recorded at +23 and −60°C; (a) and (c) fully decoupled; (b) and (d) off-resonance.

of molecular sieves to the $CDCl_3$ solution of the ylide, and to 60°C when the solution is treated with a drop of butyllithium.

At room temperature a proton decoupled ^{31}P signal for the phosphorane **1** is seen as a broad peak with a shoulder. Under scrupulously anhydrous conditions it resolves into two relatively broad but distinct peaks: the major *cis* isomer at 17.83 ppm ($\nu_{1/2}$ 16.36 Hz), and the minor *trans* isomer at 16.30 ppm ($\nu_{1/2}$ 43.60). At −40°C both peaks, major at 17.58 ppm and minor at 16.20 ppm, are very sharp, with half-height line widths of 1.47 Hz and 3.00 Hz respectively.

The variable temperature ^{31}P NMR study of **1** that has not been dried prior to the experiment shows that, as the temperature increases, the broadening of the two signals is accompanied by a slight drift in their chemical shifts. Coalescence occurs at approximately 50°C (Table 1).

When the same sample is treated with BuLi, the chemical shifts are unaffected by the increase in temperature and the two singlets remain distinct even at 50°C.

Addition of solid conjugate acid **2** to a solution of dry ylide in $CDCl_3$ (dried over molecular sieves) affects the spectra of **1** in the same way as the conjugate acid formed *in situ* when traces of atmospheric water are absorbed and interact with the ylide. Only in the presence of an available acidic proton is there a rapid *cis–trans* interconversion. Thus, we postulate that a low energy mechanism for the interconversion involves the protonated ylide as a short-lived intermediate. Clearly, rotation about the C—C single bond of this intermediate requires less energy than rotation about the C—C double bond of either enolate form (Scheme 1).

20	210	18.194	50	29.49	50

[a]Ylide **1** and benzaldehyde were obtained from Aldrich. Fresh samples were used without further purification.

As expected, these findings have a bearing on the reactivity of the phosphorane. When ylide **1** is trapped in its enolic forms, with the negative charge primarily on the oxygen atom, the reaction at the carbon atom should be reduced.

Thus, during the variable temperature ^{31}P NMR study of the condensation of purified phosphorane **1** with freshly distilled benzaldehyde, the addition of cooled benzaldehyde to a $CDCl_3$ solution of **1** at −30°C resulted in an instantaneous collapse of the two ylide peaks to a new signal. It took, however, over 60 min and a gradual increase in temperature to +20°C before any significant quantity (>5%) of the product triphenylphosphine oxide could be observed (Table 2). By contrast, when a similar study was carried out using non-purified reagents, the product was formed even at −25°C (Table 3).

Additional evidence for the involvement of catalytic activity of all acidic protons was provided by the reaction of benzaldehyde with phosphorane **1** to which 2 drops of BuLi were added. Since BuLi removes *all* sources of acidic protons while Li^+ ion stabilizes the enolate forms, the two isomers remained distinct even upon addition of benzaldehyde. The ensuing condensation was very slow. In the course of the variable temperature ^1H NMR study of this reaction, after 90 min at −15°C only traces of product could be detected, while the control reaction (where neither ylide nor benzaldehyde was purified and no BuLi was added) showed 40% product formation.

To verify if one of the enolic forms might react more readily with benzaldehyde we carried out the following experiment. The solution of ylide **1** in $CDCl_3$, dried over molecular sieves, was treated with a few drops of BuLi at −40°C. The ^1H NMR spectrum showed sharp signals for *cis* and *trans* isomers in the ratio 75:25. After the addition of 0.25 equivalents of freshly distilled benzaldehyde in cold, dry $CDCl_3$, spectra were recorded at regular intervals as the temperature was allowed to rise from −35 to +22°C over a period of several hours. First traces of product, *trans* methylcinnamate, were detected after 90 min at −15°C. After 6 h at 22°C a large part of the benzaldehyde was converted into the product, but the ratio of *cis* and *trans* isomers remained unchanged throughout the experiment (Fig. 3).

Thus, the "reactive ylide" is the ylide undergoing interconversion. As this process is slow in the presence of BuLi even at room temperature, the reaction with benzaldehyde is correspondingly slow.

Confirmation of the participation of an acidic proton comes from the study of the condensations of the ylide with cyclic anhydrides.

When cooled phthalic anhydride is added to a $CDCl_3$ solution of **1** at −35°C, the ylide signals instantly disappear in favour of two new signals (δ 18.78 and 17.01). The signal at δ 18.78 corresponds to an acyclic intermediate (Scheme 2). The second peak at δ 17.01, which moves monotonically to higher frequencies as the reaction progresses with rising temperature, represents an equilibrium between the ylide and an intermediate, with the proportion of the intermediate increasing with time.[2]

The ylide treated with BuLi reacts with phthalic anhydride almost as fast as the untreated ylide. This can be explained by the fact that the first step in the condensation of the ylide with a cyclic anhydride is the formation of an acyclic intermediate bearing an acidic proton (see Scheme 2). Thus the reaction with cyclic anhydride is autocatalyzed, and does not depend on the external source of acidic protons.

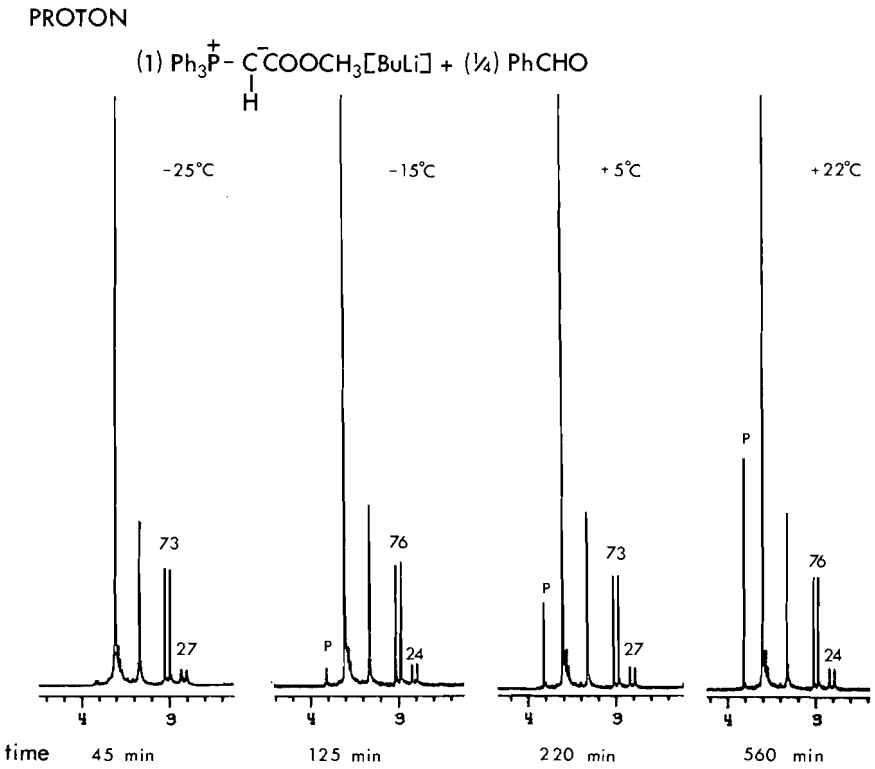

FIG. 3. Variable temperature ^1H NMR spectra of the reaction of ylide **1** (1 equiv.) with benzaldehyde (0.25 equiv.) in the presence of a trace quantity of BuLi. Relative proportions of the major and minor isomeric forms of the ylide are indicated above the methine proton signals.

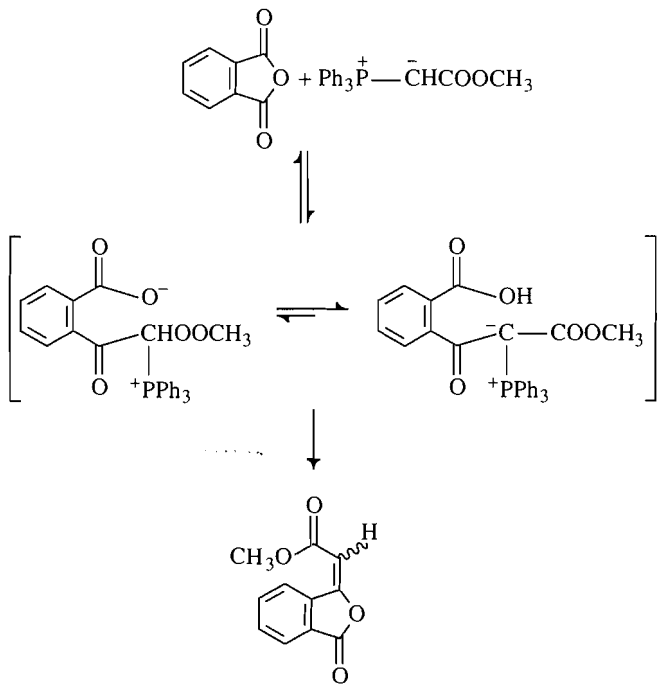

SCHEME 2

The results of this study can be summarized as follows:

(a) Ylide **1** undergoes *cis–trans* interconversion, which is catalyzed by traces of acidic proton.

(b) During rapid *trans–cis* interconversion the negative charge is more available on the carbon atom, resulting in enhanced nucleophilicity.

(c) The addition of a small quantity of BuLi removes traces of all acid catalysts and stabilizes the enolic forms, thus diminishing the reactivity of the ylide.

(d) The reaction of the ylide with an anhydride generates an acyclic intermediate bearing a highly acidic proton and is therefore autocatalyzed.

In conclusion, the ylide is most reactive during a rapid *trans–cis* interconversion catalyzed by traces of acidic protons. Larger quantities of acidic contaminant convert an equivalent part of the ylide to its conjugate acid. Thus, when acids were reportedly used to activate ketonic carbonyl groups (9) toward the reactions with stabilized ylides, the successful condensation could occur as long as the ylide was in excess.

Experimental

Nuclear magnetic resonance spectra were recorded at 361 MHz (^1H), 91 MHz (^{13}C), and 146 MHz (^{31}P) on the Nicolet 360 NB spectrometer of the Atlantic Region Magnetic Resonance Centre, and some ^{31}P spectra were recorded at 81 MHz on the Varian XL-200 spectrometer of the University of New Brunswick. All spectra were in $CDCl_3$ solutions. Calibration of the spectra was done with respect to TMS as internal reference (^1H and ^{13}C) or 85% H_3PO_4 as external standard (^{31}P). Temperature control was by the usual Nicolet method. Calibration of the thermocouple showed an estimated error of less than 1° in the temperature range used. Line widths were measured by the Nicolet LF routine.

For all experiments carried out under anhydrous conditions, methyl (triphenylphosphoranylidene)acetate **1** (obtained from Aldrich) was dried (see below), benzaldehyde was freshly distilled and stored in a vial under nitrogen until used, and phthalic anhydride was crystallized from dry chloroform.

To remove traces of water, **1** was subjected to azeotropic drying with benzene. To remove traces of conjugate acid, a very strong base

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

such as BuLi or MeLi was necessary. Treatment with weaker bases, crystallization, and sublimation were not successful.

1. General procedure for reaction of ylide **1** with benzaldehyde under anhydrous conditions: freshly dried ylide **1** (3.7 mmol) was dissolved in 2 mL of $CDCl_3$ (Silanor* C, dried over molecular sieves) and placed in an oven-dried (at 150°C for 2 h), nitrogen-swept NMR tube. After a room temperature spectrum was recorded, the temperature was lowered to −30°C and another spectrum was recorded. Freshly distilled benzaldehyde (3.7 mmol), dissolved in dry $CDCl_3$ and kept under nitrogen, was frozen in liquid nitrogen, thawed, and added rapidly to the ylide solution, which was maintained at −30°C. The tube was swept with nitrogen or argon and equilibrated at −30°C for 3–5 min prior to the recording of the first spectrum. Subsequent spectra were recorded at regular intervals, as the temperature was raised.

2. The general procedure for reaction of **1** with benzaldehyde when anhydrous conditions were not specified was substantially similar to the one described above. However, ylide **1** obtained from Aldrich was used without further purification and benzaldehyde was not redistilled immediately prior to the experiment. The NMR tubes were oven-dried but experiments were not carried out under inert (nitrogen or argon) atmosphere.

3. For the reaction carried out in the presence of BuLi, modified procedure 2 was employed. Two drops of BuLi (2.5 M in hexanes) were syringed into the solution of ylide **1** in $CDCl_3$ (dried over molecular sieves). Room temperature and low temperature spectra were recorded and the subsequent steps were repeated as described above.

Vinyl ether hydrolysis. XXIII. Solvent isotope effect on the reaction of divinyl ether catalyzed by the hydronium ion[1]

A. J. KRESGE[2] AND M. LEIBOVITCH

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received June 18, 1990

A. J. KRESGE and M. LEIBOVITCH. Can. J. Chem. **68**, 2129 (1990).

Rates of hydrolysis of divinyl ether (CH_2=CHOCH=CH_2), measured in dilute H_2O and D_2O solutions of perchloric acid at 25°C, provide the catalytic coefficients $k_{H^+} = 0.0084\ M^{-1}\ s^{-1}$ and $k_{D^+} = 0.0028\ M^{-1}\ s^{-1}$, and these lead to the isotope effect $k_H/k_D = 3.0$. The magnitude of this isotope effect indicates that this reaction occurs by rate-determining hydron transfer from catalyst to substrate and thus follows the conventional mechanism for vinyl ether hydrolysis.

Key words: divinyl ether, vinyl ether hydrolysis, solvent isotope effect.

A. J. KRESGE et M. LEIBOVITCH. Can. J. Chem. **68**, 2129 (1990).

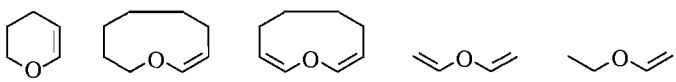
Opérant à 25°C, dans des solutions d'acide perchlorique diluées dans le H_2O et le D_2O, on a mesuré les vitesses d'hydrolyse de l'éther divinylique (CH_2=CHOCH=CH_2); on en déduit que les coefficients catalytiques sont égaux à $k_{H^+} = 0{,}0084\ M^{-1}\ s^{-1}$ et $k_{D^+} = 0{,}0028\ M^{-1}\ s^{-1}$, et ces valeurs conduisent à un effet isotopique $k_H/k_D = 3{,}0$. L'amplitude de cet effet isotopique indique que l'étape déterminant la vitesse de cette réaction implique le transfert d'un hydron du catalyseur au substrat, ce qui correspond au mécanisme conventionnel pour l'hydrolyse des éthers vinyliques.

Mots clés : éther divinylique, hydrolyse des éthers vinyliques, effet isotopique du solvant.

[Traduit par la revue]

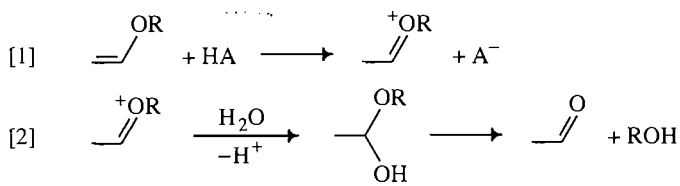
Introduction

In connection with our studies of the influence of structure upon reactivity in the acid-catalyzed hydrolysis of vinyl ethers, we recently determined that there is no significant ring-size effect in going from the 6-membered cyclic substrate, 2,3-dihydropyran, **1**, to its 9-membered cyclic homolog, oxacyclonon-2-ene, **2** (1). This conclusion was based upon a rate constant for **2** estimated from the measured rate of reaction of oxacyclonon-2,8-diene, **3**, and a factor allowing for the additional vinyl group in **3**, derived from published rate constants for divinyl ether, **4** (2), and ethyl vinyl ether, **5** (3).



1 **2** **3** **4** **5**

This procedure assumes that **4** reacts by the same mechanism as **5**, i.e., by the conventional mechanism for vinyl ether hydrolysis, which consists of rate-determining proton transfer from catalyst to substrate, eq. [1], followed by rapid hydration of the ensuing alkoxycarbocation and rapid decomposition of the hemiacetal intermediate, eq. [2] (4). The original report on



the hydrolysis of **4** (2), however, contains no mechanistic information. We have therefore supplied that by determining the solvent isotope effect on this reaction catalyzed by the hydronium ion.

Experimental

Materials

Divinyl ether (Marshallton Research Laboratories, Inc.) was purified by distillation. All other materials were best available commercial grades. Solutions were prepared with deionized H_2O purified further by distillation or with D_2O (Merck, Sharpe, and Dohme) as received.

Kinetics

Rates of reaction were determined spectroscopically by monitoring the decrease in vinyl ether absorbance at $\lambda = 210$ nm. Measurements were made using a Cary model 2200 spectrometer whose cell compartment was thermostatted at 25.0 ± 0.1°C. Aqueous acid solutions, 3.0 mL in volume, contained in quartz cuvettes were allowed to come to temperature equilibrium with the spectrometer cell compartment, and reactions were then initiated by adding 5.0 μL quantities of acetonitrile stock solutions of divinyl ether; final concentrations of divinyl ether in the reaction mixtures were ca. 1×10^{-3} M. All reactions followed the first-order rate law accurately, and observed first-order rate constants were calculated by least-squares fitting to appropriate linear or exponential functions.

Results

Rates of hydrolysis of divinyl ether were measured in H_2O and D_2O solutions of perchloric acid over the concentration ranges $[HClO_4] = 0.005$–0.1 M and $[DClO_4] = 0.04$–0.1 M. The ionic strength of these solutions was held constant at 0.10 M through the addition of sodium perchlorate as required. The data are summarized in Table 1 and are displayed in Fig. 1.

It may be seen that observed first-order rate constants are proportional to acid concentration in both solvents. Linear least-squares analysis gave the catalytic coefficients $k_{H^+} = (8.42 \pm 0.13) \times 10^{-3}\ M^{-1}\ s^{-1}$ and $k_{D^+} = (2.84 \pm 0.10) \times 10^{-3}\ M^{-1}\ s^{-1}$; these lead to the isotope effect $k_H/k_D = 2.97 \pm 0.11$.

The catalytic coefficient determined here for the reaction in H_2O solution agrees will with the reported value $k_{H^+} = 8.29 \times 10^{-3}\ M^{-1}\ s^{-1}$ (2).

Discussion

The isotope effect determined here for hydrolysis of divinyl ether catalyzed by the hydronium ion, $k_H/k_D = 3.0$, is large. Proton transfer from the hydronium ion involves bonding changes in the two non-reacting bonds of this ion, in addition to bond-breaking of the reacting bond, and these nonreactive bonding changes provide an inverse ($k_H/k_D < 1$) secondary contribution to the isotope effect that offsets a primary effect in

the normal ($k_H/k_D > 1$) direction (5); an observed effect of $k_H/k_D = 3.0$ is in fact near the maximum overall value expected for this kind of system (6). The presently determined isotope effect thus contains a sizable primary component and is therefore clear evidence of rate-determining proton transfer from the catalyst to the substrate. This indicates that hydrolysis of divinyl ether does occur by the conventional mechanism shown in eqs. [1] and [2].

This mechanism in the present case leads to the formation of vinyl alohol as one of the hemiacetal decomposition products, eq. [3]. This alcohol is the enol tautomer of acetaldehyde, and

[3] 
it will ketonize to the aldehyde, eq. [4], under the reaction conditions. The specific rate of this ketonization reaction, however, $k_{H^+} = 33$ M^{-1} s^{-1} (7), is very much greater than the rate constant determined here for hydrolysis of divinyl ether, $k_{H^+} = 0.0084$ M^{-1} s^{-1}, and ketonization of vinyl alcohol will consequently be an invisible fast process following the slower hydrolysis reaction.

Ultrasonic absorption studies in aqueous solutions of modified β-cyclodextrins

DAVID J. JOBE AND RONALD E. VERRALL
Department of Chemistry, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

AND

VINCENT C. REINSBOROUGH[1]
Department of Chemistry, Mount Allison University, Sackville, N.B., Canada E0A 3C0

Received January 10, 1990

DAVID J. JOBE, RONALD E. VERRALL, and VINCENT C. REINSBOROUGH. Can. J. Chem. **68**, 2131 (1990).

Ultrasonic absorption studies over the frequency range 0.6–210 MHz were conducted in aqueous solutions of the following modified β-cyclodextrins (β-CD): 2,6-*O*-dimethyl-β-CD (DMβCD), 2,3,6-*O*-trimethyl-β-CD (TMβCD), and hydroxypropyl-β-CD (HPβCD). Anomalous ultrasonic absorption found in the three systems was attributed to three relaxations in the DMβCD and HPβCD systems and two in the TMβCD system. These relaxations were assigned to hydrogen bond "wig-wagging", to CD cavity water exchange, and to bond rotation within the CD units. The 1:1 DMβCD/decyltrimethylammonium bromide system was also investigated ultrasonically in solution.

Key words: ultrasonic absorption, modified β-cyclodextrins, surfactant inclusion, relaxation frequency.

DAVID J. JOBE, RONALD E. VERRALL et VINCENT C. REINSBOROUGH. Can. J. Chem. **68**, 2131 (1990).

Opérant sur un intervalle de fréquence allant de 0,6 à 210 MHz, on a étudié les spectres d'absorption ultrasonique de solutions aqueuses des β-cyclodextrines (β-CD) modifiées suivantes : 2,6-*O*-diméthyl-β-CD (DMβCD), 2,3,6-*O*-triméthyl-β-CD (TMβCD) et hydroxypropyl-β-CD (HPβCD). L'absorption ultrasonique anormale qui a été observée dans ces trois systèmes est attribuée à trois relaxations dans les systèmes DMβCD et HPβCD et à deux relaxations dans le système TMβCD. On a attribué ces relaxations à un «wig-wag» de la liaison hydrogène, à un échange d'eau dans la cavité des CD et à une rotation de liaison à l'intérieur des unités des CD. On a aussi examiné à l'aide d'ultrasons des solutions du système 1:1 DMβCD/bromure de décyltriméthylammonium.

Mots clés : absorption ultrasonique, β-cyclodextrines modifiées, inclusion de surfactant, fréquence de relaxation.

[Traduit par la revue]

Introduction

The ultrasonic technique is an important investigative tool in the elucidation of basic solution processes and reaction mechanisms occurring in the microsecond to nanosecond range. One such area still not well understood is the inclusion of guest molecules by cyclodextrins in their cavities. Yet, the type of mechanisms that are often postulated to be taking place in the inclusion process, such as hydrogen-bond formation and ejection of water molecules from the cavity, should be able to be detected by ultrasonic resonance spectroscopy. In two previous independent ultrasonic studies in aqueous solutions of cyclodextrins (1, 2), α-cyclodextrin and γ-cyclodextrin were found to show modest anomalous absorptions in the ultrasonic range from which characterizations of the appropriate relaxation processes were attempted. β-Cyclodextrin proved too insoluble to yield sufficient absorption data.

Yet, β-cyclodextrin (β-CD) is the cyclodextrin of most interest because its cavity size allows for the best spatial fit for many common guest moieties such as the phenyl group and surfactant hydrocarbon tails (3, 4). Its use in the food, drug, and agricultural industries as an encapsulating agent to protect sensitive molecules in hostile environments is growing rapidly and it would be of special interest to determine the fundamental processes at work when this particular cyclodextrin plays host to other molecules in solution.

One avenue by which this might be accomplished is by using modified β-cyclodextrins (Fig. 1), which often have much greater water solubilities while still possessing approximately the same size of cavity as does simple β-CD. Consequently, in this investigation, three modified β-cyclodextrins were examined ultrasonically in solution at 25.0°C to determine whether excess absorption was present and, if so, to assign credible causes. The three were 2,6-*O*-dimethyl-β-cyclodextrin (DMβCD), 2,3,6-*O*-trimethyl-β-cyclodextrin (TMβCD), and hydroxypropyl-β-cyclodextrin (HPβCD). Also, to examine the effect inclusion has upon the ultrasonic absorption, the surfactant decyltrimethylammonium bromide (DTAB) was mixed in equimolar ratios with DMβCD and these solutions were subjected to ultrasonic probing. DTAB forms 1:1 inclusion complexes with DMβCD (5), and it has a sufficiently high critical micelle concentration (0.066 mol dm^{-3} DTAB at 25.0°C) to rule out monomer–micelle exchange as giving rise to any unusual ultrasonic absorption (6, 7).

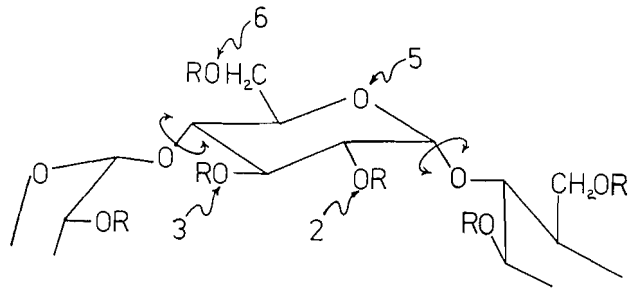

FIG. 1. Numbering of oxygen atoms in the basic glucose unit in modified β-cyclodextrins that consist of seven such units. Arrows indicate effect of "wig-wagging" motion. R can be H or an organic substituent.

Experimental

Cyclodextrins DMβCD and TMβCD were obtained from Chinoin while HPβCD was a mixture of β-cyclodextrins with various degrees of substitution of hydroxyl by hydroxypropyl groups specially formulated by Janssen Biotech as a drug delivery system. The percent of

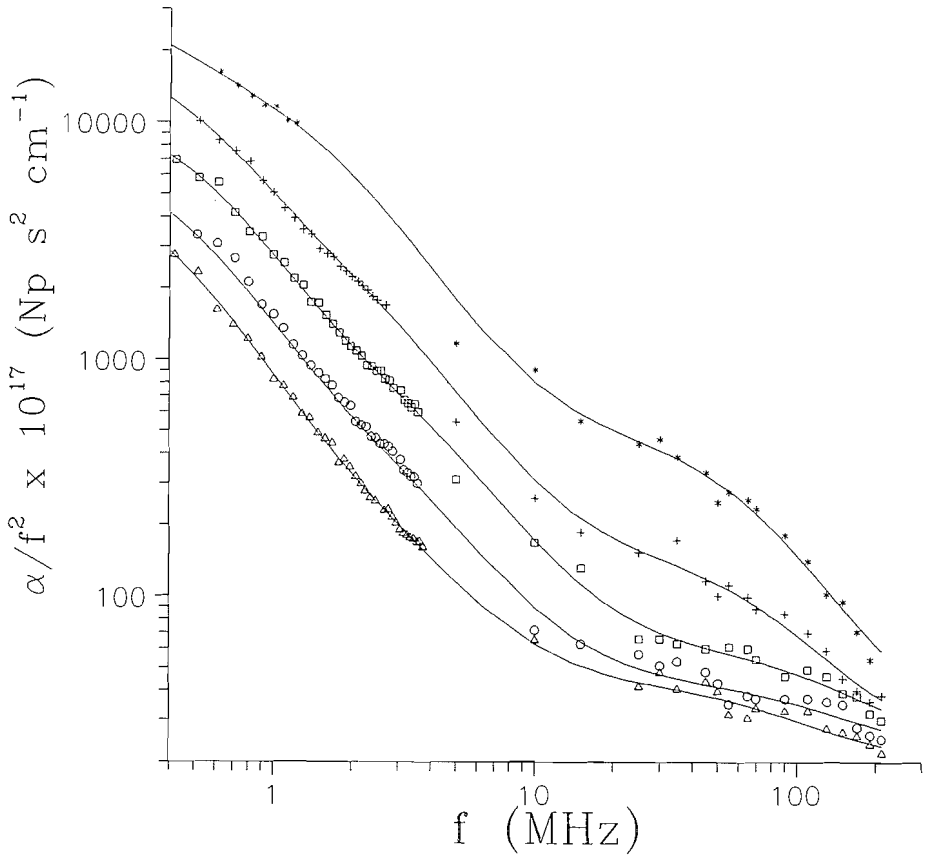

FIG. 2. Plot of α/f^2 (Np s^2 cm^{-1}) versus frequency (MHz) for DMβCD solutions: (△) 0.029 mol dm^{-3}; (○) 0.051 mol dm^{-3}; (□) 0.074 mol dm^{-3}; (+) 0.115 mol dm^{-3}; and (*) 0.223 mol dm^{-3}.

hydroxypropyl substitution was given at 16.48% and the molecular weight as 1300 (Batch FG 22716). The surfactant decyltrimethylammonium bromide (DTAB) was obtained from Kodak-Eastman and was recrystallized twice from ethanol and dried under vacuum.

Ultrasonic absorption was measured in solution at 25.0°C over the frequency range 0.6–210 MHz by using two methods: the cylindrical resonator technique (0.62–7.2 MHz) (1, 8) and the pulsed technique (10–210 MHz) (9). In preliminary work, where the range of the resonator technique was extended to provide overlap with the range of the ultrasonic technique, no discrepancies between the experimental results of the two methods were noted. Since the resonator technique is less accurate than the pulsed technique around 10 MHz, overlap of the two ranges was sacrificed to provide better stability of the standing wave in the former method. Heat buildup was made negligible in the resonator technique by operating only in the off-resonance mode. Sound velocity measurements were obtained by using a Mapco Nusonic (model 6080) sound velocimeter which employed the "sing around" method.

The resonator cell was similar in design to one previously described (10). The standing wave was generated using a pair of 5-MHz, overtone polished, quartz crystals (Valpey–Fisher) and a 10-V p-p signal from a Hewlett–Packard 3325A frequency synthesizer that produced a signal with ±0.001 Hz stability. The resulting voltage from the cavity was measured using a Fluke 8922A True RMS voltmeter. An AT&T 6300 PC equipped with an AST Research IEEE-488 GPIB interface was used to control the synthesizer and (or) acquire data from the synthesizer and voltmeter via a Fluke 1120 A IEEE Bus Translator. The computer programme was able to locate the resonance peak, digitize and calculate the half-power bandwidth (f_n), and scan up to the next peak to repeat the process. At the resonance frequency (f_r), the sound absorption α/f^2 (α is the sound absorption coefficient of the solution) was calculated using the half-power bandwidth and the sound velocity (c) from the expression:

$$[1] \quad (\alpha/f^2)_{soln} = (\pi/cf_r)[(f_n)_{soln} - (f_n)_{ref}] + (\alpha/f^2)_{ref}$$

where the subscripts "soln" and "ref" refer to the values for the solution under study and for a nonrelaxing reference solution with a matching sound velocity, respectively. Aqueous NaCl solutions were used originally as the reference but, when these gave rise to corrosion problems, methanol solutions were substituted with no apparent differences in ultrasonic absorption measurements. The error in these measurements was estimated to be ±6%.

The pulsed apparatus used to obtain sound absorption data in the 10–210 MHz range has been described previously (9). Two cells having fundamental frequencies of 5 and 10 MHz were used to cover this range. Absorption measurements were obtained at the odd harmonic frequencies of the fundamental frequency. The value for the absorption coefficient was calculated from the changes in the sound attenuation with the distance the sound wave travelled through the solution. The error in the pulsed technique was estimated as 5–10%.

Results and discussion

All four aqueous systems investigated, DMβCD, TMβCD, HPβCD, and 1:1 DMβCD/DTAB, showed anomalous ultrasonic absorption over the frequency range 0.6 MHz–210 MHz. Graphs of α/f^2 plotted against frequency are shown in Figs. 2–5. The strongest absorptions occurred with DMβCD where, for example, α/f^2 exceeded 4000 × 10^{-17} Np s^2 cm^{-1} at 1.0 MHz in 0.115 mol dm^{-3} DMβCD. By comparison, α/f^2 was 50 × 10^{-17} Np s^2 cm^{-1} for 0.1 mol dm^{-3} α-CD at 25°C (2); the background value for pure H_2O is 20 × 10^{-17} Np s^2 cm^{-1}.

A simple inspection of the frequency dependence of the ultra-

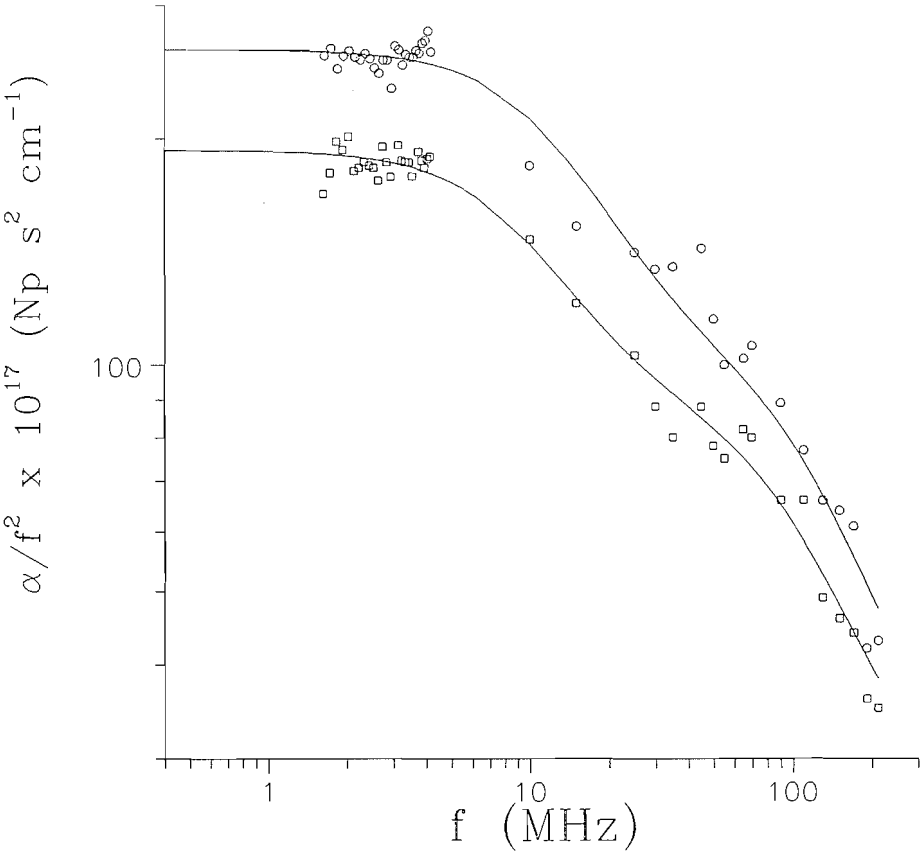

FIG. 3. Plot of α/f^2 (Np s^2 cm^{-1}) versus frequency (MHz) for TMβCD solutions: (□) 0.150 mol dm^{-3} and (○) 0.175 mol dm^{-3}.

sound absorption in Figs. 2–5 shows that a single relaxation is insufficient to account for the observed absorptions in any of the four systems. The ultrasonic absorption data were thus analyzed in each system according to the following relationship (1):

$$[2] \quad \alpha/f^2 = \sum_{i=1}^{n} (A_i/[1 + \{f/f_i\}^2]) + B$$

where n is the number of relaxations, A_i is the relaxation amplitude, f_i the relaxation frequency, and B the "classical" or background contribution to the sound absorption. The fitting of the absorption data to eq. [2] was made using a nonlinear least-squares fitting routine based on the Marquardt algorithm. The analysis of the data yielded values of the relaxational parameters as well as a measure of chi-square (χ^2), a plot of the standard residuals, and the standard deviation for the coefficients. By far the best fit was obtained when three relaxations were assumed in all systems except for TMβCD solutions where two relaxations worked best. Employing more or less than three relaxations markedly worsened the fits and caused the residuals to be distributed randomly. The best fit results for A_1, A_2, and A_3 and f_1, f_2, and f_3 are shown in Table 1. The value of B was set at 22×10^{-17} Np s^2 cm^{-1}, which is a reasonable value for non-relaxing aqueous solutions of these concentrations.

The DMβCD system is the most easily characterized in terms of ultrasonic relaxation processes because of its extended concentration range of strongly absorbing solutions. The first relaxation frequency (f_1) is concentration independent at 0.44 ± 0.06 MHz. Since f_1 is at the edge of the accessible frequency range of the apparatus, the error in this number may be greater than indicated. The problem does not arise with f_2 and f_3, which are 3 ± 1 MHz and approximately 100 MHz, respectively, and, within the larger error associated with ultrasonic measurements at low amplitudes, were also concentration independent. Also, as the concentration of DMβCD was increased, the amplitude contribution in terms of the parameter A_2 for the second relaxation process increased substantially from 5% of the total amplitude at the lowest DMβCD concentrations to 55% at 0.223 mol dm^{-3} DMβCD.

TMβCD in solution absorbed ultrasound so weakly that it was only possible to obtain absorption data close to its solubility limit. No low frequency relaxation corresponding to A_1 and f_1 of DMβCD was discernible but this may have been due to poor resolution. However, the TMβCD counterparts of the second and third processes for DMβCD appeared at 13 MHz and 100 MHz respectively.

HPβCD is as water soluble as DMβCD (approximately 0.4 mol dm^{-3}) and sound absorption was sufficiently pronounced in the HPβCD system to discern three relaxations: $f_1 = 0.87 \pm 0.06$ MHz, $5 < f_2 < 30$ MHz, and $f_3 = 150$ MHz. Changing the HPβCD concentration did not seem to affect the relative proportions of the amplitudes. Thus, DMβCD and HPβCD demonstrated unexpectedly large ultrasonic absorption while TMβCD showed far less absorption than did simple β-CD at comparable concentrations (1, 2).

When DTAB was introduced into DMβCD solutions of identical concentration, the three processes remained but the ultrasonic absorption decreased about sevenfold for A_1, was

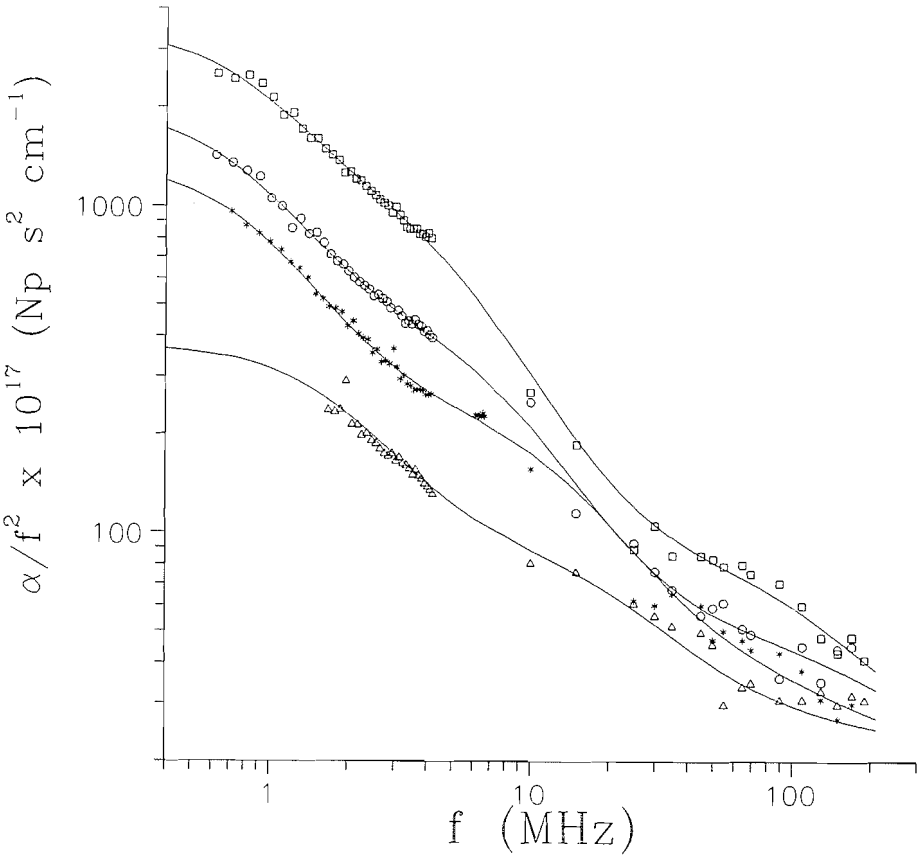

FIG. 4. Plot of α/f^2 (Np s^2 cm^{-1}) versus frequency (MHz) for HPβCD solutions: (△) 0.051 mol dm^{-3}; (*) 0.105 mol dm^{-3}; (○) 0.140 mol dm^{-3}; and (□) 0.215 mol dm^{-3}.

halved for A_2, but was unchanged for A_3 without affecting the values of the respective relaxation frequencies.

The first relaxation characterized by A_1 and f_1 was not found with the simple cyclodextrins and must then be due to some relatively slow process not available to the latter. The mechanism that suggests itself is flexing of the β-CD rings, which is possible only with the modified β-CD's because substitution at the hydroxy positions (O(2), O(3), and (or) O(6)) destroys the intramolecular hydrogen bonding between O(2) and O(3) of adjacent glucosyl units. This hydrogen bonding causes β-CD to be a rigid molecule in the crystal (11) and presumably the solution situation is the same.

This "wig-wagging" motion of the glucosyl units will be pronounced with DMβCD where only the O(3) position is available for hydrogen bonding. With HPβCD, where a fraction of the O(2), O(3), and O(6) positions has hydroxypropyl groups, this motion is also available to some degree. However, as modelling reveals, persubstitution in the case of TMβCD is accompanied by sufficient steric hindrance to quench this flexibility of the β-CD ring entirely and to cause the torus of TMβCD to be as rigid as that of unmodified β-CD. This could account for the first relaxation being observed strongly in DMβCD solutions, to a lesser extent in HPβCD solutions, but not observed in the TMβCD and unmodified β-CD systems.

Similar conformational changes in solution have been assigned to relaxations in the ultrasonic range around 1 MHz (12). However, more compelling is an argument through the A_1 values, which can be used to estimate the volume change for the process responsible for the first relaxation through the relationship (13):

$$[3] \quad A_1 = \frac{7\pi\Delta V^2 K}{\beta_0 RT f_1 (K+1)^2} \cdot \frac{[\mathrm{CD}]}{c}$$

where K is the equilibrium constant for the process, β_0 is the adiabatic compressibility of the pure solvent, and c is the sound velocity in the solution. The factor 7 is required because there are seven glucose units in the β-CD torus. The value of K can be approximated through the Boltzmann relationship, $K = \exp(-\Delta E/RT)$, where the rate-determining step is assumed to be the breaking of hydrogen bonds. From the X-ray data for β-CD (11), the hydrogen-bond distances can be used to calculate ΔE from the empirical relationship $E_{HB} = -55/r_{HB}^3$ (kcal mol^{-1}) (14).

From eq. [3], plotting A_1 values against $[CD]/c$ should yield straight lines through the origin; ΔV can be obtained from the slope. Figure 6 shows this plot for the DMβCD and HPβCD systems. In the latter, the linear portion has a non-zero intercept, which may indicate that a critical amount of HPβCD must be present before the first relaxation has a measurable amplitude. For the DMβCD system, ΔV is 18 cm^3 mol^{-1}, which is, remarkably, the correct estimated volume change one would expect for a broken intramolecular hydrogen bond to reform with a water molecule. For each glucose unit in β-CD to flex, one hydrogen bond must in fact be broken. In the HPβCD system, ΔV is 41 cm^3 mol^{-1}, reflecting the slightly more than two hydrogen bonds that, per unit, must be severed before a similar movement takes place in this molecule. Given the assumptions involved in these calculations, the exact coinci-

dence of calculated and predicted ΔV values must be a happenstance. However, that the values should emerge correctly does add credence to the model.

When the surfactant DTAB is included in the cavity of DMβCD, the amplitude of the first relaxation process is greatly diminished (Table 1). In terms of the proposed model, the presence of the included guest would presumably eliminate wig-wagging in the bound DMβCD. From the reduced amplitudes, the concentration of free DMβCD can be obtained from Fig. 6. In the 50 and 70 mmol dm^{-3} DMβCD/DTAB systems, the free DMβCD concentrations are thus found to be 6 and 12 mmol dm^{-3} DMβCD, while 4 and 8 mmol dm^{-3} DMβCD respectively are the values calculated through the association constant of 850 dm^3 mol^{-1} for the 1:1 complex (5). Again, the close agreement is reassuring and means that wig-wagging as a possible explanation for the first relaxation is at least self-consistent.

The second relaxation occurs in the range 3–30 MHz where

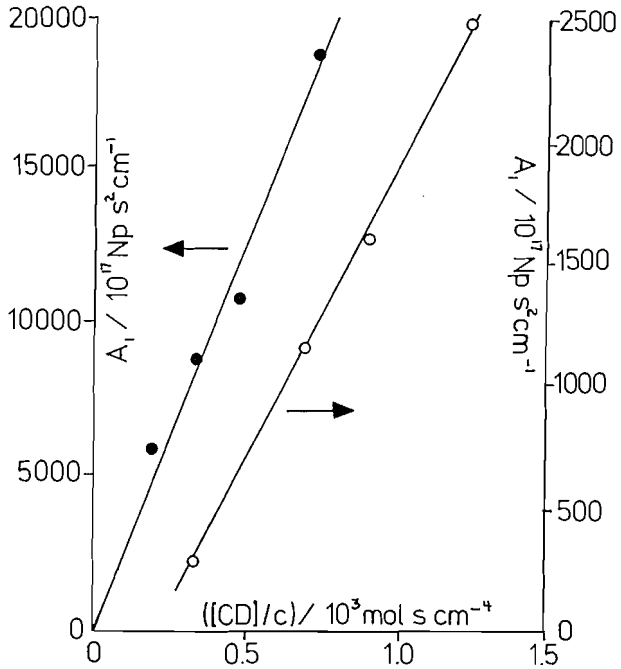

FIG. 6. Plot of A_1 versus [CD]/c for aqueous solutions of DMβCD (closed circles) and HPβCD (open circles). The arrows indicate the appropriate A_1 axis.

Kato *et al.* (1) and Rauh and Knoche (2) obtained similar results with unmodified α-CD and γ-CD in aqueous solution and which they attributed to changes in the water structure within the CD cavity. This interpretation is consistent with our results since it was observed with each modified β-CD and was dramatically reduced when surfactant entered the β-CD cavity to form a 1:1 inclusion complex. With DTAB in the cavity, fewer water molecules would be able to enter and exit the cavity. The first and second relaxations appear, from the ultrasonic data, to be coupled. In fact, one would expect that the wig-wagging of the glucose units and the movement of water molecules moving in and out of the cavity would be interrelated.

The third relaxation at approximately 100 MHz was not noted in previous ultrasonic studies in α-CD nor in γ-CD solutions (1, 2). At least for α-CD, this may have been due to experimental uncertainty since this relaxation, although present in all of the modified β-CD systems investigated here, was relatively weak. In fact, the ultrasonic absorption contribution associated with this high relaxation was so weak that it may elude better characterization for some time in the future. One point of interest that may help to identify the responsible process was that this relaxation in the present work was unaffected by surfactant inclusion in the CD cavity. A possibility is that this high relaxation frequency is associated with rotation about the C(5)—C(6) bond, which in unmodified CD favors the (−)-*gauche* orientation but in modified CD often has the substituted group pointing inwards in a (+)-*gauche* configuration as the principal orientation. This is especially the case when a guest inclusate molecule is present (11). This may explain why this third frequency is observed with only modified CD's.

In summary, ultrasonic spectroscopy identifies three fast processes occurring with modified β-cyclodextrins in solution. The lowest frequency relaxation is attributed to a wig-wagging of the individual glucosyl groups in the CD ring. Movement of water molecules in and out of the cyclodextrin cavity gives rise to the second relaxation, as argued by other workers (1, 2). For the third, very weak, highest frequency relaxation, its assignment is tentatively made to a non-ring bond rotation.

Stereocontrolled construction of A.B.C.[6.6.6] tricycle via transannular Diels–Alder reaction of 14-membered macrocycle with acetylene as dienophile

YAO-CHANG XU, MICHEL CANTIN,[1] AND PIERRE DESLONGCHAMPS[2]

Laboratoire de synthèse organique, Département de chimie, Faculté des sciences, Université de Sherbrooke, Sherbrooke (Québec), Canada J1K 2R1

Received May 8, 1990

YAO-CHANG XU, MICHEL CANTIN, and PIERRE DESLONGCHAMPS. Can. J. Chem. **68**, 2137 (1990).

The syntheses of the acyclic dienynes **14***a* (*cis-trans*-acetylene) and **14***b* (*trans-trans*-acetylene) are described. The tandem macrocyclization and transannular Diels–Alder reaction of the allylic chloride **14***b* was conducted in the presence of Cs_2CO_3 at 85°C in one-pot to provide tricyclic product **16**, with the two hydrogens in ring B being *cis*. On the other hand, treatment of the allylic chloride **14***a* under the same conditions afforded 14-membered macrocycle **17**, which could be transformed at 250°C into a similar tricyclic product **18** with the two hydrogens in ring B being *trans*, along with an interesting by-product **19**. The mechanism for the formation of **19** is also discussed.

Key words: stereocontrolled synthesis, macrocycle, tricyclic compound, transannular Diels–Alder reaction.

YAO-CHANG XU, MICHEL CANTIN et PIERRE DESLONGCHAMPS. Can. J. Chem. **68**, 2137 (1990).

On décrit la synthèse des diénynes *cis-trans*-acétylène **14***a* et *trans-trans*-acétylène **14***b*. La macrocyclisation et cyclisation transannulaire de Diels–Alder effectuées sur le chlorure allylique **14***b*, en présence de carbonate de cesium à 85°C, conduisent directement au produit tricyclique **16** possédant deux hydrogènes *cis* en jonction de cycle. Par ailleurs, le chlorure allylique **14***a* a fournit dans les mêmes conditions, le macrocycle **17** qui, à 250°C, a conduit au produit tricyclique **18** possédant deux hydrogènes *trans* en jonction de cycle et au produit secondaire **19**. Un mécanisme est proposé pour la formation de ce produit secondaire.

Mots clés : synthèse stéréocontrôlée, macrocycle, produit tricyclique, réaction de Diels–Alder transannulaire.

The key problem to the synthesis of such natural products as steroids and terpenes is how to build up the polycyclic skeleton with a controlled stereoselectivity (1). Numerous methods such as aldol condensation (2), biomimetic cyclization (3), intramolecular Diels–Alder reaction (4), and intramolecular Michael addition (5) have been developed to synthesize these classes of compounds, and success has been achieved in terms of both efficiency and stereoselectivity in the construction of the polycyclic systems.

In the present paper, we would like to report a new methodology named the transannular Diels–Alder reaction, which can be applied to the synthesis of an A.B.C.[6.6.6] tricyclic compound like **2** from macrocyclic dienyne **1** with controlled stereoselectivities in a single step (Scheme 1). The tricyclic compound **2**, which possesses easily manipulable double bond and ester functionalities, could serve as a potential precursor to such polycyclic natural products as tanshinones (6), estrones (7), and luvigenin (8).

The results presented below follow our continuing effort in a general study, which demonstrates the power of the transannular Diels–Alder reaction of macrocycles in the construction of polycyclic molecules. Preliminary communications about this new transannular cycloaddition on different systems appeared in the literature a year ago (9, 10). The same transannular Diels–Alder reaction of 13-membered macrocycles has also been reported by us very recently (11).

Synthesis of acyclic dienyne

The synthesis of the dienophile moiety **9**, which is an essential step in the assembling of acyclic dienyne **11**, was carried out according to the procedures indicated in Scheme 2 starting from commercially available 3-butyn-1-ol. Treatment of the starting material **3** with dihydropyran in the presence of *p*-toluenesulfonic acid gave protected alcohol **4** (12). Upon addition of *n*-butyllithium, the resulting acetylene anion opened ethylene oxide by nucleophilic attack to form alcohol **5** (13), which was subsequently converted to methanesulfonate ester (mesylate) **6** by methanesulfonyl chloride in the presence of triethylamine (14). Introduction of the malonate connector was accomplished by alkylation of the sodium salt of dimethyl malonate with **6** in a mixture of DMF and THF with potassium iodide. It should be noted that the use of a large excess of sodium hydride resulted in the elimination of the mesylate to form a

conjugated enyne by-product. Deprotection of the THP ether with pyridinium *p*-toluenesulfonate as catalyst in methanol (15) followed by mesylation (14) of the resulting alcohol afforded the desired acetylenic dienophile **9** in an excellent overall yield of 60% from starting material **3**.

The assembly between the acetylenic dienophile **9** and dienes **10** was easily achieved by, first, deprotonation of **9** with sodium hydride, followed by alkylation of the resulting anion with the allylic chlorides **10**, which were prepared previously in our laboratory (16). As indicated in Scheme 3, the coupling reaction of **9** with *cis-trans* diene **10***a* took place smoothly to give 93% yield of dienyne **11***a*, while the reaction of **9** with the *trans-trans* diene **10***b* afforded 75% yield of **11***b*, along with 20% of recovered starting material **9**. The introduction of the second connector by the procedure used previously for the preparation of **7** provided tetraester **12** in variable yields (48–85%). Again, we encountered the same elimination problem as before. In those cases where the tetraester **12** was obtained in lower yields, the mesylate elimination was observed in larger quantities. However, reasonable yields of the tetraester **12** (80–85%) could be obtained when sodium hydride was used without excess. The THP ether in **12** was then hydrolyzed as usual to give dienyne alcohol **13** (15).

Macrocyclization and Diels–Alder reaction

Having assembled the requisite carbon chain and placed appropriate functional groups at each end, the dienyne **13** was readied for construction of the 14-membered macrocycle, in a manner developed earlier by us (9), by conversion of the alcohol functionality to an electrophile such as halide. Therefore, the allylic alcohol **13***b* was transformed into allylic chloride **14***b* by Meyers' procedure using LiCl, CH_3SO_2Cl, and *s*-collidine in DMF as indicated in Scheme 4 (17). The macrocyclization was conducted by adding a solution of the crude allylic chloride **14***b* in THF to a stirred suspension of cesium carbonate in a mixture of DMF and THF (1:1) at 85°C over a period of 12 h, using high dilution technique (3.0×10^{-3} M) to avoid dimerization. After the addition was finished, the stirring was continued at 85°C for 24 h. At this stage, a tricyclic product **16** was obtained in an overall yield of 41% from the allylic alcohol **13***b*, presumably via formation, first, of the intermediate of 14-membered macrocycle **15**, followed by transannular Diels–Alder cycloaddition. The tandem macrocyclization and transannular Diels–Alder reaction of **14***b* could also be carried out in a low boiling solvent like acetonitrile, leading to the same tricyclic product **16** in comparable overall yield (37%).

The failure to isolate the macrocyclic intermediate **15** simply suggests that the Diels–Alder reaction is very much facilitated in the transannular process, so that it can take place even under the mild conditions and with a poorly activated dienophile such as acetylene. The enhanced reactivities of the transannular cycloaddition, especially with those macrocycles having *trans-trans* dienes, have been observed in our laboratory (9*b*). The structure of the tricyclic product **16** has been fully characterized by spectroscopic data. From the molecular model of the macrocycle **15**, the concerted [4 + 2] cycloaddition of *trans-trans* diene and acetylene dienophile should lead to a tricyclic compound with the two hydrogens at C(7) and C(10) being *cis* each other, as shown in **16**. The relative stereochemistry of these two hydrogens was indeed found to be *cis* by X-ray crystallography (18), which confirmed the prediction of the molecular model analysis.

Having completed the transannular Diels–Alder reaction of the macrocycle **15** (*trans-trans*-acetylene), we then turned our attention to a similar macrocyclic system **17**, which has *cis-trans*-acetylene geometry. As indicated in Scheme 5, the allylic alcohol **13***a* was first converted to allylic chloride **14***a*, by Meyers' procedure, in 79% yield (17). The macrocyclization of **14***a* was carried out by a similar procedure, used before for the allylic chloride **14***b*. Macrocyclic product **17** was isolated as a white solid in 87% yield. In contrast with macrocycle **15**, the success in isolating macrocycle **17** is apparently due to its low reactivity in the transannular Diels–Alder reaction, which required temperatures as high as 250°C to effect, as indicated, the subsequent step. A possible explanation for the difference in the reactivities is that, due to steric interactions, the *cis-trans* diene moiety in molecule **17** hinders formation of the *cisoid*

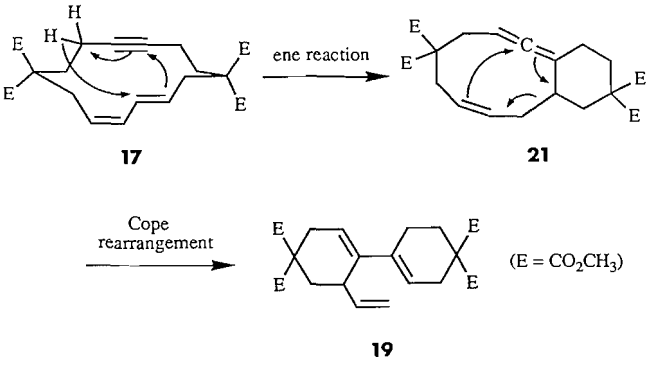

SCHEME 7

conformation, which is required for the concerted Diels–Alder reaction to take place (19). Efforts to carry out the X-ray analysis of the 14-membered macrocycle **17** having an interesting triple bond in the structure have so far failed, due to the difficulty in obtaining single crystals. However, the structure of macrocycle **17** was established by spectroscopic information (^{13}C and ^{1}H nmr, ir, ms). Especially, the conservation of the olefin geometries has been clearly indicated by comparing the ^{1}H nmr data with the data for its precursor **14***a*.

The transannular Diels–Alder reaction was carried out by heating the macrocycle **17** in a sealed tube at 250°C for 90 min, providing the expected tricyclic product **18** as a white solid in 23% yield along with an unusual compound **19** in 67% yield as a major product. The structure of **18** was determined by conventional spectroscopic data (^{1}H and ^{13}C nmr, ir, ms). The relative *trans* stereochemistry of the two protons at C(7) and C(10) can be reasonably predicted by inspection of molecular models. According to a similar analysis to that for macrocycle **15**, the concerted [4+2] cycloaddition of **17** having a *cis-trans* diene and a triple bond as a dienophile should lead to structure **18**, which has two *trans* hydrogens at the ring junctions. Further confirmation of the structure of compound **18** has been easily obtained from the comparison of the spectroscopic data with data for compound **16**, which is the only stereoisomer of compound **18**.

Isolation of the compound **19** raised very interesting questions regarding both its structure characterization and the mechanism to account for its formation. X-ray crystallography of **19** is impossible because the compound did not form single crystals. The ^{1}H nmr coupling pattern of **19** clearly indicates that there is a terminal olefin in the structure. Decoupled ^{13}C nmr shows that compound **19** has six olefinic carbons, while coupled ^{13}C nmr indicates that one olefinic carbon has two protons (triplet), three olefinic carbons have one proton (doublet), and two have no proton (singlet). The uv spectrum of the compound **19** was found to have absorptions at λ_{max} (hexane) 230 mμ (ε = 12 000), λ_{sh} 236 and 245 mμ, which are characteristic for the conjugated diene of a 1,1′-bicyclohexenyl system (λ = 233, 239, 246 mμ) (20). The above spectroscopic data correlate very well with our proposed structure **19**. Furthermore, chemical evidence has been obtained by selective hydrogenation of the terminal vinyl group of compound **19** using carbonyltris(triphenylphosphine)rhodium(I) hydride as a catalyst (21) to produce reduced product **20** (Scheme 6). Compound **20** could be easily identified by nmr spectroscopy, which clearly indicates the presence of an ethyl group in the molecule. However, the planned [4+2] cycloaddition of **19** with tetracyanoethylene led to a complex mixture.[3]

A possible mechanism for the formation of **19** from **17** is presented in Scheme 7. First, the macrocycle **17** may undergo an intramolecular ene reaction to form the bicyclic intermediate **21**. This type of ene reaction is not unprecedented because similar results with macrocyclic compounds have been observed in our laboratory.[4] The intermediate **21** with an allene and an olefin functional group in the 10-membered ring could then undergo a Cope rearrangement to form product **19**. Again, this type or rearrangement was found in the literature with a similar 10-membered ring system (22).

In summary, we have demonstrated a simple and general method for the construction of A.B.C.[6.6.6] tricyclic compounds with controlled stereoselectivities, in a synthetically useful yield, by varying the geometry of the olefins in the macrocycle precursor. The key steps involved in the synthesis of these tricycles are the macrocyclization and the subsequent transannular Diels–Alder reaction, which are very facile and moderate yielding processes. The Diels–Alder reaction is dependent on the geomety of the olefins. The present study should provide a useful model for the synthesis of natural products containing polycyclic structure. Studies in this direction are under investigation in our laboratory.

Experimental

Infrared spectra (ir) were recorded on a Perkin–Elmer 681 spectrophotometer, using chloroform ($CHCl_3$), or run as neat films on sodium chloride cells. The ^{1}H nmr and ^{13}C nmr spectra were taken on a Bruker WM-250 spectrometer in deuteriated chloroform ($CDCl_3$) or

[3]The reaction of **19** with tetracyanoethylene gave an inseparable mixture that contains a number of products possibly resulting from [2+2] and [4+2] reactions.

benzene (C_6D_6). The following abbreviations are used in the text: s, singlet; d, doublet; t, triplet; q, quadruplet; and m, multiplet. Mass spectra (ms) were recorded on a VG-Micromass ZAB-1F mass spectrometer. Melting points (mp) were measured on a Büchi or a Reichert melting point apparatus and were not corrected. Ultraviolet (uv) spectra were recorded on a Varian Cary 210 spectrophotometer. Thin-layer chromatography (tlc) was performed using Silica Gel 60 F-250. For flash column chromatography Merck Kieselgel (no. 9385) was used.

Unless otherwise noted, all reagents were obtained from commercial suppliers and used without further purification. Acetonitrile, amines, dimethylformamide (DMF), hexamethylphosphoramide (HMPA), and dichloromethane (CH_2Cl_2) were distilled from calcium hydride; methanol from magnesium and iodine; acetone and ethyl acetate from potassium carbonate; benzene, toluene, diethyl ether, and tetrahydrofuran (THF) from sodium and benzophenone ketyl. Purified and dried reagents were kept under argon. Unless otherwise specified, all reactions were carried out under argon atmosphere.

*1-[(Tetrahydro-2*H*-pyran-2-yl)oxy]-3-butyne (**4**)*

3-Butyn-1-ol (**3**) (7.75 g, 0.111 mol) was added dropwise to 3,4-dihydro-2*H*-pyran (13.0 g, 0.155 mol) and *p*-toluenesulfonic acid monohydrate (50 mg, 0.26 mmol) at 0°C. The resulting mixture was stirred for 90 min at room temperature, and then treated with saturated Na_2SO_4 solution (50 mL) and extracted with CH_2Cl_2 (3 × 50 mL). The combined organic layers were dried over $MgSO_4$, filtered, and evaporated. The residue was distilled (90°C, 40 Torr (1 Torr = 133.3 Pa)) to give protected butyne **4** (14.1 g, 82%) as a colorless oil; ir ($CHCl_3$): 3310, 3010, 2940, 2880, 1130, 1075, 1030 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 4.65 (1H, t, J = 3.5 Hz, -OC*H*O-), 3.88–3.79 and 3.61–3.52 (4H, 2m, $-CH_2CH_2OCHOCH_2-$), 2.49 (2H, td, J = 7.0 Hz, 1.0 Hz, $-CH_2C{\equiv}CH$), 1.97 (1H, t, J = 1.0 Hz, $-CH_2C{\equiv}CH$), 1.90–1.48 (6H, m, $-OCHOCH_2(CH_2)_3$); ms *m/e*: 153 (M^+-H).

*6-[(Tetrahydro-2*H*-pyran-2-yl)oxy]-3-hexyn-1-ol (**5**)*

To a stirred solution of butyne **4** (5.7 g, 37 mmol) in a mixture of HMPA/THF (1:3, 200 mL) was slowly added *n*-butyllithium (1.66 M in hexanes, 24.3 mL, 39 mmol) by a syringe pump over a period of 30 min at −78°C, until orange coloration persisted. Ethylene oxide (25 mL, 37 mmol) was added and the reaction mixture was maintained at −20°C for 24 h. After the mixture was warmed to room temperature, it was quenched with saturated NH_4Cl solution (100 mL), diluted with H_2O (100 mL), and extracted with hexanes/diethyl ether (2:1, 6 × 750 mL). The combined organic layers were dried over $MgSO_4$, filtered, and evaporated. The crude residue was purified by flash chromatography (hexanes/ethyl acetate; 4:1) to give alcohol **5** (6.7 g, 91%) as a colorless oil; ir ($CHCl_3$): 3630, 3470, 3020, 2950, 2880, 1120, 1030 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 4.64 (1H, t, J = 3.5 Hz, -OC*H*O-), 3.93–3.76 and 3.60–3.47 (4H, 2m, $-CH_2CH_2OCHOCH_2-$), 3.68 (2H, t, J = 6.0 Hz, $-CH_2CH_2OH$), 2.51–2.39 (4H, m, $-CH_2CH_2C{\equiv}CH_2CH_2-$), 1.90–1.48 (7H, m, $-OCHOCH_2(CH_2)_3$ and $-CH_2OH$); ms/*e*: 197 (M^+-H), 167 (M^+-CH_2OH).

*6-Methanesulfonyloxy-1-[(tetrahydro-2*H*-pyran-2-yl)oxy]-3-hexane (**6**)*

General procedure A

To a stirred solution of alcohol **5** (2.50 g, 12.6 mmol) and triethylamine (3.5 mL, 25 mmol) in dichloromethane (50 mL) was added methanesulfonyl chloride (1.22 mL, 15.8 mmol) at 0°C in dropwise fashion. The resulting mixture was stirred for 30 min at 0°C, and then diluted with CH_2Cl_2 (100 mL). The organic layer was washed with H_2O (3 × 50 mL), dried over $MgSO_4$, filtered, and evaporated. The crude residue was purified by flash chromatography (hexanes/ethyl acetate; 3:1) to give mesylate **6** (3.4 g, 98%) as an oil; ir ($CHCl_3$): 3030, 3010, 2950, 2880, 1360, 1175, 1030 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 4.62 (1H, t, J = 3.5 Hz, -OC*H*O-), 4.26 (2H, t, J = 6.8 Hz, $-CH_2CH_2OSO_2CH_3$), 3.90–3.74 and 3.56–3.46 (4H, 2m, $-CH_2CH_2OCHOCH_2-$), 3.04 (3H, s, $-OSO_2CH_3$), 2.62 (2H, tt, J = 6.8Hz, 2.4 Hz, $-C{\equiv}CCH_2CH_2OSO_2CH_3$), 2.45 (2H, tt, J = 7.0 Hz, $-C{\equiv}CCH_2CH_2OCHO-$), 1.90–1.48 (6H, m, $-OCHOCH_2(CH_2)_3$); ms *m/e*: 275 (M^+-H).

*Methyl 2-carbomethoxy-8-[(tetrahydro-2*H*-pyran-2-yl)oxy]-5-octynoate (**7**)*

General procedure B

To a stirred sodium hydride suspension (2.46 g, 61.5 mmol) in a mixture of DMF/THF (1:1, 200 mL) was added dimethyl malonate (7.1 mL, 61.5 mmol) at 0°C in dropwise fashion. The mixture was stirred at room temperature for 15 min, then transferred by syringe to mesylate **6** (3.41 g, 12.3 mmol). Potassium iodide (2.39 g, 14.4 mmol) was added and the resulting mixture was heated at 80°C for 3.5 h. After cooling to room temperature, the reaction mixture was quenched with saturated NH_4Cl solution (100 mL), diluted with H_2O (100 mL), and extracted with diethyl ether (4 × 400 mL). The combined organic layers were dried over $MgSO_4$, filtered, and evaporated. The crude residue was purified by flash chromatography (hexanes/ethyl acetate; 17:3) to give malonate **7** (3.3 g, 85%) as an oil; ir ($CHCl_3$): 3010, 2950, 1750, 1730, 1440, 1030 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 4.64 (1H, t, J = 3.5 Hz, -OC*H*O-), 3.95–3.72 and 3.56–3.46 (4H, 2m, $-CH_2CH_2-OCHOCH_2-$), 3.76 (6H, s, $CH_2(CO_2CH_3)_2$), 3.75 (6H, s, $-CH(CO_2CH_3)_2$), 3.62 (1H, t, J = 7.3 Hz, $-CH(CO_2CH_3)_2$), 3.41 (2H, s, $CH_2(CO_2CH_3)_2$), 2.45 (2H, tt, J = 7.2 Hz, 2.3 Hz, $-C{\equiv}CCH_2CH_2OH-$), 2.25 (2H, m, $-C{\equiv}CCH_2CH_2CH-$), 2.08 (2H, q, J = 75 Hz, $-C{\equiv}CCH_2CH_2CH-$), 1.90–1.49 (6H, m, $-OCHOCH_2(CH_2)_3$); ms *m/e*: 312 (M^+), 228 M^+-THP), 211 (M^+-OTHP).

*7,7-Biscarbomethoxy-3-heptyn-1-ol (**8**)*

General procedure C

To a stirred solution of malonate **7** (3.00 g, 9.6 mmol) in anhydrous methanol (175 mL) was added pyridinium *p*-toluenesulfonate (480 mg, 1.9 mmol) and the resulting mixture was heated at 60°C for 1 h. After the mixture was cooled to room temperature, it was treated with brine (100 mL), diluted with H_2O (100 mL), and extracted with ethyl acetate (6 × 125 mL). The combined organic layers were dried over $MgSO_4$, filtered, and evaporated. The crude residue was purified by flash chromatography (hexanes/ethyl acetate; 4:1) to give alcohol **8** (2.15 g, 98%) as a viscous oil; ir ($CHCl_3$): 3540, 3010, 2950, 1750, 1740, 1730, 1440, 1220, 1050 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 3.75 (6H, 2, $-CH(CO_2CH_3)_2$), 3.68 (2H, t, J = 6.1 Hz, $-CH_2OH$), 3.60 (1H, t, J = 7.3 Hz, $-CH(CO_2CH_3)_2$), 2.61 (2H, tt, J = 6.1 Hz, 2.3 Hz, $-C{\equiv}CCH_2$ CH_2OH), 2.27 (2H, m, $-C{\equiv}CCH_2CH_2CH-$), 2.09 (2H, q, J = 7 Hz, $-C{\equiv}CCH_2CH_2CH-$), 1.93 (1H, br s, $-CH_2OH$); ms *m/e*: 229 (MH^+), 211 (MH^+-H_2O), 198 (MH^+-OCH_3).

*Methyl 8-methanesulfonyloxy-2-carbomethoxy-5-octynoate (**9**)*

The general procedure A was followed, using triethylamine (2.54 mL, 18 mmol), methanesulfonyl chloride (877 μL, 11.4 mmol), alcohol **8** (2.1 g, 9.1 mmol), and dichloromethane (30 mL). Mesylate **9** (2.7 g, 98%) was obtained as a solid; mp 44–45°C; ir ($CHCl_3$): 3030, 2950, 2840, 1740, 1440, 1350, 1240 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 4.25 (2H, t, J = 6.8 Hz, $-CH_2OSO_2CH_3$), 3.74 (6H, s, $-CH(CO_2CH_3)_2$), 3.58 (1H, t, J = 7.3 Hz, $-CH_2CH(CO_2CH_3)_2$), 3.05 (3H, s, $-OSO_2$ CH_3), 2.61 (2H, tt, J = 6.8 Hz, 2.3 Hz, $-C{\equiv}CCH_2CH_2O-$), 2.24 (2H, m, $-C{=}CCH_2CH_2CH-$), 2.07 (2H, q, J = 7 Hz, $-C{=}CCH_2$ CH_2CH-); ms *m/e*: 306 (M^+), 275 (M^+ —OCH_3).

*(2Z,4*E*)-7,7-Biscarbomethoxy-13-methanesulfonyloxy-1-[(tetrahydro-2*H*-pyran-2-yl)oxy]-2,4-10-yne (**11**a)*

General procedure D

To a stirred sodium hydride suspension (72 mg, 1.8 mmol) in DMF/THF (1:1, 12 mL) was added a solution of mesylate **9** (493 mg, 1.6 mmol) in DMF/THF (1:1, 4 mL) at room temperature. The mixture was stirred for 10 min and then transferred to a solution of allylic chloride **10***a* (466 mg, 2.2 mmol) in DMF/THF (1:1, 4 mL). The resulting mixture was stirred for 5 h at room temperature, then quenched with saturated NH_4Cl solution (20 mL), diluted with H_2O (20 mL), and extracted with hexanes/diethyl ether (1:2, 5 × 75 mL). The combined organic layers were washed with H_2O (50 mL) and brine (50 mL), dried over $MgSO_4$, filtered, and evaporated. The crude residue was purified by flash chromatography (hexanes/ethyl acetate; 7:3) to give mesylate **11***a* (734 mg, 93%), as an oil; ir ($CHCl_3$): 3020,

2950, 2860, 1730, 1440, 1350, 1200, 1179 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.38 (1H, dd, J = 15.0 Hz, 11.1 Hz, -CH_2CH=CH-CH=$CHCH_2O$-), 6.07 (1H, t, J = 11.0 Hz, -CH_2CH=CH-CH=$CHCH_2O$-), 5.57–5.49 (2H, m, -CH_2CH=CH-CH=$CHCH_2O$-), 4.63 (1H, t, J = 3.5 Hz, -OCHO-), 4.34 (1H, ddd, J = 12.7 Hz, 6.4 Hz, 1.3 Hz, -CH=CHCHHO-), 4.24 (2H, t, J = 6.8 Hz, -$CH_2OSO_2CH_3$), 4.16 (1H, ddd, J = 12.7 Hz, 7.4 Hz, 1.2 Hz, -CH=CHCHHO-), 3.92–3.82 and 3.56–3.47 (2H, 2m, -OCHOCH_2-), 3.72 (6H, s, -$CH_2C(CO_2CH_3)_2CH_2$-), 3.04 (3H, s, -OSO_2CH_3), 2.70 (2H, d, J = 7.6 Hz, -CH_2CH=CH-CH=CH-), 2.60 (2H, tt, J = 6.8 Hz, 2.0 Hz, -C≡CCH_2CH_2O-), 2.10 (4H, m, -C≡CCH_2CH_2-CH-), 1.89–1.48 (6H, m, -OCHOCH$_2$(CH_2)$_3$-); ms m/e: 486 (M^+), 455 (M^+-OCH_3), 403 ($M^+-C_5H_7O$).

*(2E,4E)-7,7-Biscarbomethoxy-13-methanesulfonyloxy-1-[(tetrahydro-2H-pyran-2-yl)oxy]-2,4-tridecadien-10-yne (**11**b)*

The general procedure D was followed, using sodium hydride (106 mg, 2.7 mmol), mesylate **9** (769 mg, 2.5 mmol), allylic chloride **10***b* (875 mg, crude product), DMF (14 mL), and THF (14 mL). Mesylate **11***b* (921 mg, 75%) was obtained along with recovered starting material **9** (153 mg, 20%). **11***b*: ir ($CHCl_3$): 3040, 2950, 2850, 1730, 1440, 1360, 1200, 1180 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.15 (2H, m, -CH_2CH=CH-CH=$CHCH_2O$-), 5.73 (1H, td, J = 14.7 Hz, 6.0 Hz, -CH_2CH=CH-CH=CHCH_2O-), 5.46 (1H, td, J = 14.5 Hz, 7.2 Hz, -CH_2CH=CH-CH=$CHCH_2O$-), 4.63 (1H, t, J = 3.5 Hz, -OCHO-), 4.25 (3H, m and t, J = 6.9 Hz (for t), -CH=CHCHHO- and -$CH_2OSO_2CH_3$), 3.98 (1H, ddd, J = 13.2 Hz, 6.7 Hz, 0.8 Hz, -CH=CHCHHO-), 3.98–3.81 and 3.59–3.48 (2H, 2m, -OCHOCH_2-), 3.72 (6H, s, -$CH_2C(CO_2CH_3)_2CH_2$-), 3.05 (3H, s, -OSO_2CH_3), 2.68 (2H, d, J = 7.7 Hz, -CH_2CH=CH-CH=CH-), 2.60 (2H, tt, J = 6.9 Hz, 2.0 Hz, -C≡CCH_2CH2O-), 2.10 (4H, m, -C=CCH_2CH_2-CH-), 1.89–1.51 (6H, m, -OCHOCH$_2$(CH$_2$(CH_2)$_3$-); ms m/e: 384 ($M^+-C_5H_{10}O_2$), 353 (M^+−OTHP−CH_3OH).

*Methyl (11E,13Z)-2,9,9-tricarbomethoxy-15-[(tetrahydro-2H-pyran-2-yl)oxy]-11,13-pentadecadien-5-ynoate (**12**a)*

The general procedure B was followed, using dimethyl malonate (725 μL, 6.4 mmol), sodium hydride (260 mg, 6.5 mmol), DMF (10 mL), THF (10 mL), mesylate **11***a* (626 mg, 1.3 mmol), and potassium iodide (280 mg, 1.7 mmol). Tetraester **12***a* (ranging from 323 mg to 572 mg, 48–85%) was obtained; ir (neat): 3000, 2950, 2860, 1740, 1435, 1200 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.38 (1H, dd, J = 15.0 Hz, 11.2 Hz, -CH_2CH=CH-CH=-CH=$CHCH_2O$-), 6.08 (1H, t, J = 10.9 Hz, -CH_2CH=CH-CHCHCH_2O-), 5.60–5.47 (2H, m, -CH_2CH= CH-CH=CHCH_2O-), 4.63 (1H, t, J = 3.5 Hz, -OCHO-), 4.34 (1H, ddd, J = 12.7 Hz, 6.4 Hz, 1.4 Hz, -CH=CHCHHO-), 4.17 (1H, ddd, J = 12.7 Hz, 7.4 Hz, 1.2 Hz, -CH=CHCHHO-), 3.92–3.81 and 3.56–3.49 (2H, 2m, -OCHOCH_2-), 3.74 and 3.71 (12H, 2s, -$CH_2CH(CO_2CH_3)_2$ and -$CH_2C(CO_2CH_3)_2CH_2$-), 3.57 (1H, t, J = 7.3 Hz, -$CH_2CH(CO_2CO_3)_2$), 2.70 (2H, d, J = 7.1 Hz, -C(CO_2-CH_3)CH_2 CH=), 2.25–2.19 and 2.14–2.01 (8H, m, -CH_2CH_2C≡-CCH_2CH_2-), 1.84–1.48 (6H, m, -OCHOCH$_2$(CH_2)$_3$); ms m/e: 522 (M^+), 507 (M^+-CH_3), 491 (M^+-OCH_3).

*Methyl (11E,13E)-2,9,9-tricarbomethoxy-15-[(tetrahydro-2H-pyran-2-yl)oxy]-11,13-pentadecadien-5-ynoate (**12**b)*

The general procedure B was followed, using dimethyl malonate (1.05 mL, 9.2 mmol), sodium hydride (367 mg, 9.2 mmol), mesylate **11***b* (921 mg, 1.9 mmol), potassium iodide (353 mg, 2.1 mmol), DMF (23 mL), and THF (23 mL). Tetraester **12***b* (780 mg, 80%) was isolated and used immediately for the preparation of **13***b*, without spectroscopic characterization.

*Methyl (11E,13Z)-2,9,9-tricarbomethoxy-15-hydroxy-11,13-pentadecadien-5-ynoate (**13**a)*

The general procedure C was followed, using pyridinium *p*-toluenesulfonate (32 mg, 0.127 mmol), tetraester **12***a* (323 mg, 0.62 mmol), and anhydrous methanol (10 mL). Alcohol **13***a* (265 mg, 97%) was obtained as a viscous oil; ir (neat): 3530, 3470, 3010, 2950, 2840, 1740, 1435, 1200 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.37 (1H, dd, J = 15.5 Hz, 11.2 Hz, -CH_2CH=CH-CH=$CHCH_2OH$), 6.03 (1H, t, J = 11.2 Hz, -CH_2CH=CH-CH=$CHCH_2OH$), 5.61–5.30 (2H, m, -CH_2CH= CH-CH=CHCH_2OH), 4.31–4.28 (2H, br s, =CHCH_2OH), 3.74 and 3.72 (12H, 2s, -$CH_2CH(CO_2CH_3)_2$ and -$CH_2C(CO_2CH_3)_2CH_2$-), 3.57 (1H, t, J = 7.3 Hz, -$CH_2CH(CO_2CH_3)_2$), 2.71 (2H, d, J = 7.6 Hz, =CHCH_2C(CO_2CH_3)$_2CH_2$-), 2.26–2.19 and 2.13–2.02 (8H, 2m, -CH_2CH_2C≡CCH_2CH_2-), 1.59 (1H, s, -CH_2OH); ms m/e: 438 (M^+), 420 (M^+-H_2O), 407 (M^+-OCH_3).

*Methyl (11E,13E)-2,9,9-tricarbomethoxy-15-hydroxy-11,13-pentadecadien-5-ynoate (**13**b)*

The general procedure C was followed, using pyridinium *p*-toluenesulfonate (63 mg, 0.25 mmol), tetraester **12***b* (780 mg, 1.5 mmol), and anhydrous methanol (20 mL). Alcohol **13***b* (511 mg, 78%) was obtained as a viscous oil; ir (neat): 3540, 3460, 3000, 2950, 2840, 1740, 1430, 1220 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.14 (2H, m, -CH_2CH=CH-CH=$CHCH_2OH$), 5.77 (1H, dt, J = 17.2 Hz, 5.6 Hz, -CH_2CH=CH-CH=CHCH_2OH), 5.50 (1H, dt, J = 14.4 Hz, 7.3 Hz, -CH_2CH=CH-CH=$CHCH_2OH$), 4.16 (2H, t, J = 5.7 Hz, =CHCH_2OH), 3.74 and 3.71 (12H, 2s, -$CH_2CH(CO_2CH_3)_2$ and -$CH_2C(CO_2CH_3)_2CH_2$-), 3.57 (1H, t, J = 7.3 Hz, -$CH_2CH(CO_2CH_3)_2$), 2.68 (2H, d, J = 7.6 Hz, =CHCH_2C(CO_2CH_3)$_2CH_2$-), 2.26–2.19 and 2.13–2.02 (8H, 2m, -CH_2CH_2C≡CCH_2CH_2-), 1.41 (1H, t, J = 5.8Hz, -CH_2OH); ms m/e: 423 (M^+-CH_3), 420 (M^+-H_2O), 407 (M^+-OCH_3).

*Methyl (11E,13Z)-2,2,9-tricarbomethoxy-15-chloro-11,13-pentadecadien-5-ynoate (**14**a)*

To a stirred solution of alcohol **13***a* (291 mg, 0.66 mmol) in DMF (7 mL) were added lithium chloride (113 mg, 2.7 mmol) and *s*-collidine (263 μL, 2.0 mmol) at room temperature. After the mixture was cooled to 0°C, methanesulfonyl chloride (128 μL, 1.7 mmol) was added. The resulting mixture was stirred for 30 min, then diluted with H_2O (20 mL) and extracted with hexanes/diethyl ether (2:1, 3 × 30 mL). The combined organic layers were dried over $MgSO_4$, filtered, and then evaporated. The crude residue was purified by flash chromatography (hexanes/ethyl acetate; 17:3) to give allylic chloride **14***a* (238 mg, 79%), which was used immediately for the next cyclization without spectroscopic characterization.

*Methyl (11E,13E)-2,9,9-tricarbomethoxy-15-chloro-11,13-pentadecadien-5-ynoate (**14**b)*

To a stirred solution of allylic alcohol **13***b* (330 mg, 0.75 mmol) and lithium chloride (232 mg, 5.5 mmol) in DMF (7.5 mL) was added *s*-collidine (400 μL, 3.0 mmol) at room temperature. The mixture was stirred for 10 min and then cooled to 0°C. Methanesulfonyl chloride (170 μL, 2.2 mmol) was added. The reaction mixture was stirred at 0°C for 45 min, and then diluted with H_2O and extracted with hexanes/ethyl ether (2:1, 4 × 75 mL). The combined organic layers were washed successively with saturated $Cu(NO_3)_2$ solution (20 mL), saturated $NaHCO_3$ solution (10 mL), and brine (2 × 20 mL), and then dried over $MgSO_4$, filtered, and evaporated to give crude allylic chloride **14***b*; ^1H nmr (C_6D_6) δ: 5.78 (2H, m, -CH_2CH=CH-CH=$CHCH_2Cl$), 5.51–5.35 (2H, m, -CH_2CH=CH-CH=CHCH_2Cl), 3.64–3.58 (3H, m, =CHCH_2Cl and -$CH_2CH(CO_2CH_3)_2$), 3.27 (12H, s, -$CH_2CH(CO_2CH_3)_2$ and -$CH_2C(CO_2CH_3)_2CH_2$-), 2.75 (2H, d, J = 7.8 Hz, =CHCH_2C(CO_2CH_3)$_2CH_2$-), 2.37–2.12 (8H, 2m, -CH_2CH_2C≡CCH_2CH_2-).

*(7,10-cisoid)-5,5,12,12-Tetracarbomethoxytricyclo[8.4.0.0^{2,7}]tetradeca-1,7-diene (**16**)*

To a stirred suspension of cesium carbonate (848 mg, 2.6 mmol) in a mixture of DMF/THF (1:1, 195 mL) was added a solution of allylic chloride **14***b* (238 mg, 0.52 mmol) in THF (5 mL) at 85°C by syringe pump over a period of 12 h. After addition, the stirring was continued for 24 h. The reaction mixture was allowed to cool to room temperature, and then filtered and evaporated. The crude residue was purified by flash chromatography (hexanes/CH_2Cl_2/ethyl acetate; 17:2:1) to give tricyclic compound **16** (130 mg, 41% for last 3 steps) as a solid; mp 164–166°C; ir ($CHCl_3$): 3020, 2950, 1730, 1450, 1430, 1230 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 5.50 (2H, s, -C(8)H=C(9)H-), 3.77 and 3.69

(12H, 2s, $(CO_2CH_3)_4$), 2.67 (4H, m, -C(3)H_e-, -C(7)H-, -C(10)H- and -C(14)H_e-), 2.48 (4H, d, J = 11.6 Hz, -C(4)H_e-, -C(6)H_e-, -C(11)H_e-, and -C(13)H_e-), 1.69 (4H, m, -C(3)H_a-, -C(4)H_a-, -C(13)H_a-, and -C(14)H_a-), 1.47 (2H, t, J = 12.8 Hz, -C(6)H_a- and -C(11)H_a-); ^{1}H nmr (C_6D_6) δ: 5.43 (2H, s, -C(8)H=C(9)H-), 3.35 and 3.25 (12H, 2s, $(CO_2CH_3)_4$), 2.85 (2H, d, J = 10.5 Hz, -C(7)H- and -C(10)H-), 2.76 (2H, dt, J = 13.0 Hz, 2.9 Hz, -C(4)H_e- and -C(13)H_e-), 2.67 (2H, dd, J = 12.0 Hz, 2.6 Hz, -C(6)H_e- and -C(11)H_e-), 2.52 (2H, m, -C(3)H_e- and -C(14)H_e-), 1.69 (6H, m, -C(3)H_a-, -C(4)H_a-, -C(6)H_a-, -C(11)H_a-, -C(13)H_a-, and -C(14)H_a-); ^{13}C nmr ($CDCl_3$) δ: 172.2 (s, (CO_2CH_3)$_4$), 127.9 and 127.4 (d, -C(8)H=C(9)H-), 55.3 (s, -C(5)- and -C(9)-), 52.7 and 52.5 (q, $(CO_2CH_3)_4$), 40.0 (t, -C(6)- and -C(11)-), 35.2 (d, -C(7)- and -C(10)-), 32.6 (t, -C(4)- and -C(13)-), 25.1 (t, -C(3)- and -C(14)-); ms m/e: 420 (M^+). Exact mass (M^+) calcd.: 420.1785; found: 420.1781. The structure for **16** has also been determined by X-ray crystallography and the details will be reported soon (18).

The same reaction using acetonitrile as a solvent was conducted in exactly the same way as above. Thus, the reaction of **14***b* (crude product) with cesium carbonate (700 mg, 2.1 mmol) in CH_3CN (210 mL) provided a tricyclic product (67 mg, 37% for last 3 steps) that has spectral data identical to the data for compound **16**.

*(1Z,3E)-6,6,13,13-Tetracarbomethoxy-1,3-cyclotetradecadien-9-yne (**17**)*

To a stirred suspension of cesium carbonate (848 mg, 2.6 mmol) in a mixture of DMF/THF (1:1, 190 mL) at 80°C was added a solution of allylic chloride **14***a* (238 mg, 0.52 mmol) in THF (5 mL) at 80°C by syringe pump over a period of 10 h. After the addition, the stirring was continued for 5 h. The reaction mixture was allowed to cool to room temperature, then filtered and evaporated. The crude residue was purified by flash chromatography (hexanes/CH_2Cl_2/ethyl acetate; 17:2:1), to yield a solid that was crystallized in hexanes/CH_2Cl_2 to give macrocyclic compound **17** (191 mg, 87%) as a solid; mp 146–159°C; ir ($CHCl_3$): 3020, 2960, 1730, 1460, 1440, 1220 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.40 (1H, dd, J = 14.8 Hz, 11.4 Hz, -C(1)H=C(2)H-C(3)H=C(4)H-), 6.19 (1H, t, J = 11.0 Hz, -C(1)H=C(2)H-C(3)H=C(4)H-), 5.35 (1H, dt, 14.7 Hz, 7.3 Hz, -C(1)H=C(2)H-C(3)H=C(4)H-), 5.04 (1H, dt, J = 10.4 Hz, 8.4 Hz, -C(1)H=C(2)H-C(3)H=C(4)H-), 3.73 and 3.72 (12H, 2s, $(CO_2CH_3)_4$), 2.97 (2H, d, J = 7.2 Hz, -C(3)H=C(4)H-C(5)H_2-), 2.82 (2H, d, J = 8.5 Hz, -C(14)H_2-C(1)H=C(2)H-), 2.15–0.98 (8H, m, -CH_2C=CCH_2CH_2); ^{13}C nmr ($CDCl_3$) δ: 171.3 and 170.9 ((CO_2CH_3)$_4$), 133.4 (=C(2)H-), 130.6 (-C(3)H=), 128.6 (=C(4)H-), 123.3 (-C(1)H=), 80.9 and 70.9 (-C(9)≡C(10)-), 58.4 and 56.4 (-C(6)- and C(13)-), 35.0 (-C(5)H_2-), 29.2 (-C(14)H_2-), 29.9 and 29.4 (-C(8)H_2C≡CC(11)H_2-), 13.4 (-C(7)H_2CH_2C≡ CCH_2C(12)H_2-); ms m/e: 420 (M^+). Stereocontrolled construction of A.B.C.[6.6.6] tricycle via transannular Diels–Alder reaction of 14-membered triene macrocycle

MICHEL CANTIN,[1] YAO-CHANG XU, AND PIERRE DESLONGCHAMPS[2]

Laboratoire de synthèse organique, Département de chimie, Faculté des sciences, Université de Sherbrooke, Sherbrooke (Québec), Canada J1K 2R1

Received May 7, 1990

MICHEL CANTIN, YAO-CHANG XU, and PIERRE DESLONGCHAMPS. Can. J. Chem. **68**, 2144 (1990).

The synthesis of the four acyclic trienes **11***a*, *b* and **20***a*, *b* is reported. The tandem macrocyclization and stereoselective transannular Diels–Alder reaction of acyclic trienes **11***b* (*trans-trans-cis*) and **20***b* (*trans-trans-trans*) were observed in the presence of Cs_2CO_3 at 85°C to give tricycles **30** (TST) and **32** (CAT) respectively. However, treatment of acyclic trienes **11***a* (*cis-trans-cis*) and **20***a* (*cis-trans-trans*) under the same conditions yielded the 14-membered macrocycles **21** and **23**, which were stereoselectively transformed at 250°C into tricycles **22** (CST) and **24** (CAT) respectively in excellent yield.

Key words: stereocontrolled synthesis, macrocycle, tricyclic compound, transannular Diels–Alder reaction.

MICHEL CANTIN, YAO-CHANG XU et PIERRE DESLONGCHAMPS. Can. J. Chem. **68**, 2144 (1990).

La préparation des quatre triènes acycliques **11***a*, *b* et **20***a*, *b* est rapportée. En présence de Cs_2CO_3 à 85°C, les triènes **11***b* (*trans-trans-cis*) et **20***b* (*trans-trans-trans*) se transforment stéréosélectivement dans les tricycles **30** (TST) et **32** (CAT) respectivement par réaction de macrocyclisation suivie d'une réaction de Diels–Alder transannulaire stéréocontrôlée. Par contre, le traitement des triènes acycliques **11***a* (*cis-trans-cis*) et **20***a* (*cis-trans-trans*) dans les mêmes conditions conduit aux macrocycles à 14 membres **21** et **23** respectivement. Par chauffage à 250°C, ces derniers sont respectivement transformés dans les tricycles **22** (CST) et **24** (**CAT**) avec un excellent rendement.

Mots clés : synthèse sterécontrôlée, macrocycle, produit tricyclique, réaction de Diels–Alder transannulaire.

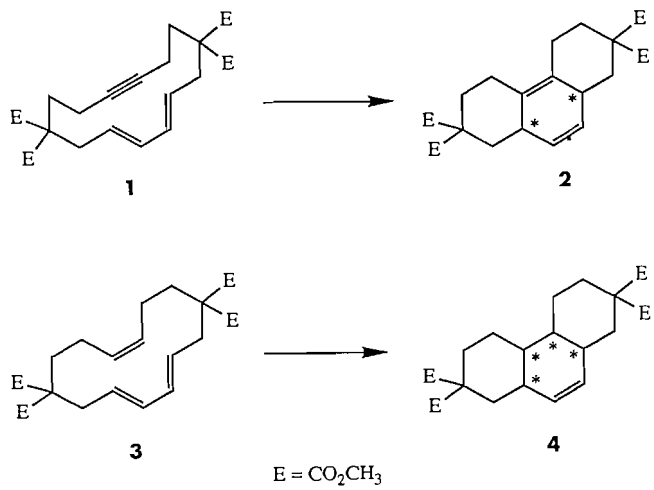
In the preceding article (1), we described the synthesis of A.B.C.[6.6.6] tricyclic compound **2** via the transannular Diels–Alder reaction of 14-membered dienyne macrocycle **1** (Scheme 1). The tricyclic Diels–Alder adduct **2**, which has two chiral centers on the unsaturated ring B, could be constructed stereoselectively by changing the geometry of the diene double bonds. This new methodology, which is complementary with other known methods such as aldol condensation (2), biomimetic cyclization (3), intramolecular Diels–Alder reaction (4), and intramolecular Michael addition (5), provides a powerful tool for the synthesis of polycyclic carbon skeletons of natural products such as steroids and terpenes (6).

In this article, we would like to report our continued study (7, 13) of this new method with a different macrocyclic system **3**, which contains three unsubstituted olefins. As indicated in Scheme 1, transannular Diels–Alder reaction of 14-membered triene macrocycle **3** results in the formation of a new tricyclic product **4**, which possesses four chiral centers and one double bond on the B ring. It is believed that this will provide even greater applications in the synthesis of polycyclic natural products.



SCHEME 1

Synthesis of acyclic triene

Our basic strategy for the preparation of the acylic trienes is to use the coupling reaction of dienes and dienophiles, which was developed earlier (7) and utilized extensively in our laboratory. As indicated in Scheme 2, the synthesis of *cis* dienophile **6** was achieved by stereoselective *syn* hydrogenation, with a Lindlar catalyst (8), of the triple bond of **5**, whose synthesis was reported previously (1). Syntheses of dienes **7***a* (*cis-trans*) and **7***b* (*trans-trans*) were also performed in our laboratory and their synthetic details will be reported in the near future (9). The coupling reaction of the dienophile with each diene was conducted by deprotonation of malonate **6** with sodium hydride, followed by alkylation of the resulting anion with allylic chlorides **7***a* and **7***b*, which provided *cis-trans-cis* and *trans-trans-cis* acylic triene products **8***a* and **8***b* respectively in good yields. Introduction of the second malonate connector was accomplished by substitution of the methanesulfonate ester group of **8***a* and **8***b* with the sodium salt of dimethyl malonate in the presence of potassium iodide to provide **9***a* and **9***b*. The THP ethers of **9***a* and **9***b* were cleaved by hydrolysis in methanol with pyridinium *p*-toluenesulfonate as catalyst to give the corresponding alcohols **10***a* and **10***b* respectively (10), which were then converted to allylic chlorides **11***a* and **11***b* by Meyers' procedures using LiCl, CH_3SO_2Cl, and *s*-collidine in DMF (11). Purification by chromatography on silica gel caused a small amount of decomposition of allylic chlorides **11***a* and **11***b*; however, this problem could be avoided if they were used immediately for the subsequent macrocyclization step without flash chromatography.

The synthesis of the other two acyclic trienes **20***a* (*cis-trans-*

SCHEME 3

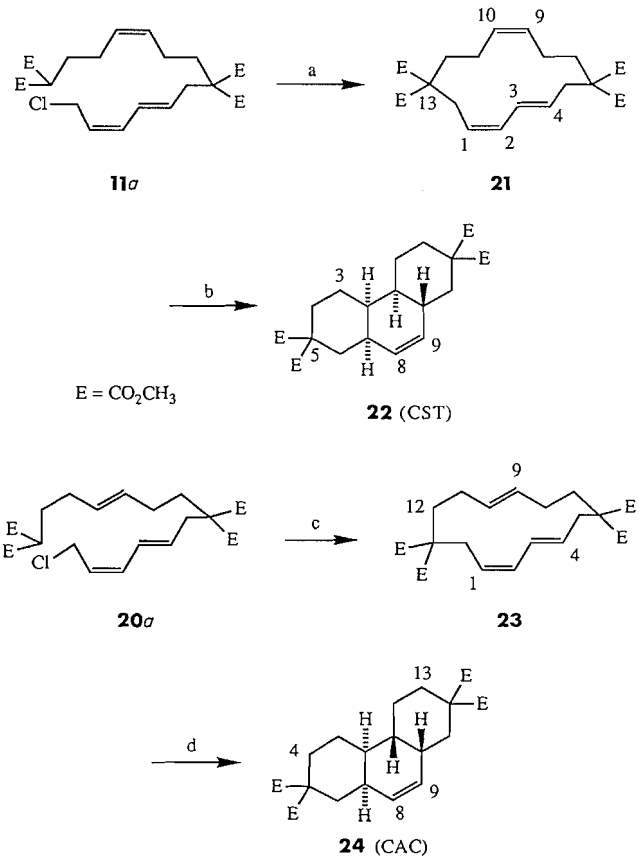
trans) and **20***b* (*trans-trans-trans*) is outlined in Scheme 3 starting with the preparation of *trans* dienophile **16**. The commercially available *trans*-β-hydromuconic acid **12** was converted to its corresponding diester **13** in almost quantitative yield with sulfuric acid in ethanol. Reduction of the ester groups with lithium aluminum hydride in ether yielded diol **14**, which was subsequently transformed into methanesulfonate ester **15** in excellent yield by methanesulfonyl chloride and triethylamine (12). Introduction of two malonate groups at either end of the molecule was achieved by alkylation of **15** with the sodium salt of dimethyl malonate to give *trans* dienophile **16**. The coupling reaction of dienophile **16** and dienes **7***a* and **7***b* was carried out according to the procedure previously used for the preparation of **8**, to provide acyclic trienes **18***a* (*cis-trans-trans*) and **18***b* (*trans-trans-trans*) respectively. As expected, a dialkylation by-product **17***a* was obtained, and hydrolysis of the two THP ether groups gave the corresponding diol **37***a* in 14% yield. Interestingly, no dialkylation product **17***b* was observed. Following the same reaction sequences and conditions as indicated in Scheme 2 for the preparation of **11** from **9**, crude compounds **18***a* and **18***b* were hydrolyzed (10), and resulting alcohols **19***a* and **19***b* were converted to allylic chlorides **20***a* and **20***b* respectively (11).

Macrocyclization and Diels–Alder reaction

Having synthesized the requisite carbon chain and appropriate functional groups at each end, the four acyclic trienes **11***a, b* and **20***a, b* were ready for construction of the 14-membered macrocycles. The macrocyclizations and transannular Diels–Alder reactions for acyclic trienes **11***a* (*cis-trans-cis*) and **20***a* (*cis-trans-trans*) are presented in Scheme 4. According to the procedures developed earlier in our laboratory (7, 9, 13, 14), the macrocyclization of **11***a* was conducted by adding a solution of allylic chloride **11***a* in CH_3CN, by syringe pump, to a stirred suspension of cesium carbonate in CH_3CN at 85°C over a period of 12 h, using high dilution technique (2×10^{-3} M) to avoid dimerization. Macrocyclic product **21** (*cis-trans-cis*) was isolated as a white solid in 87% yield. Similarly, acyclic triene **20***a* was cyclized under the same conditions to give 14-membered macrocycle **23** (*cis-trans-trans*) in 60% yield. The macrocyclization of **20***a* was also carried out in a mixture of THF/DMF (1:1), leading to the same macrocycle **23** in comparable yield (55%).

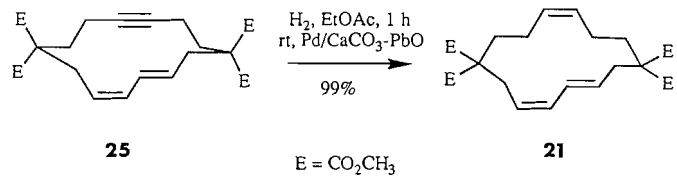
The *cis-trans-cis* macrocycle **21** could also be obtained by chemo- and stereoselective *syn* hydrogenation of the triple bond from dienyne macrocycle **25** with a Lindlar catalyst in quantitative yield (Scheme 5) (8). The synthesis of dienyne macrocycle **25** was described in the preceding paper (1). The structures of macrocycles **21** and **23** were determined on the basis of spectroscopic data (^{13}C and ^{1}H nmr, ir, and ms). The olefin geometry of **21** (*cis-trans-cis*) and **23** (*cis-trans-trans*) was retained in the cyclization reaction as demonstrated by comparing their ^{1}H nmr data with those of the acyclic triene precursors **11***a* and **20***a* respectively.

As indicated in Scheme 4, the transannular Diels–Alder reaction of **21** was carried out by thermolysis in a sealed quartz tube at 250°C for 90 min, providing only one tricyclic product **22** in 92% yield with *cis-syn-trans* (abbreviated as CST) stereochemistry for protons at ring conjunctions. Similarly, thermolysis of macrocycle **23** at the same temperature for 2 h gave a new tricyclic compound **24** (*cis-anti-cis*; CAC) in the same yield. The structures of tricyclic products **22** and **24** were

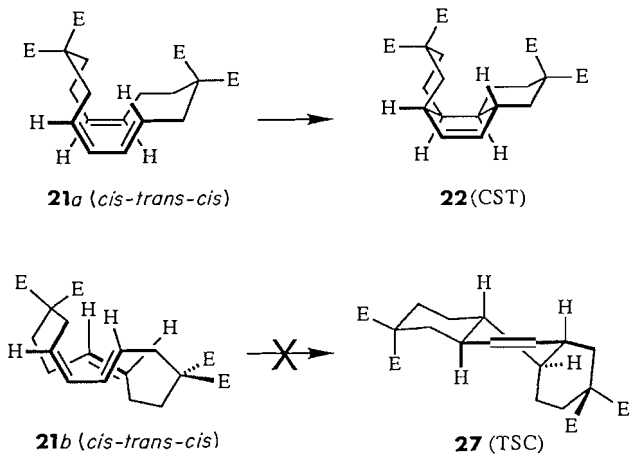


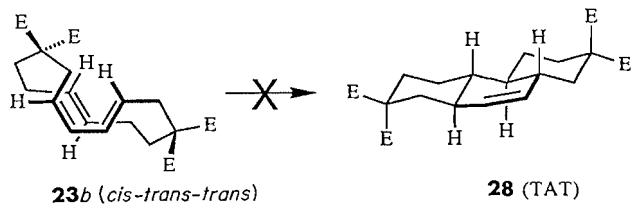
(a) Cs_2CO_3, CH_3CN, 85°C, 2.0 x 10^{-3}M, 17 h, 87%;
(b) 250°C in sealed tube, 90 min, 92%;
(c) Cs_2CO_3, CH_3CN, 85°C, 2.2 x 10^{-3}M, 17 h, 60%;
Cs_2CO_3, DMF/THF(1:1), 85°C, 2.0 x 10^{-3}M, 17 h, 55%;
(d) 250°C in sealed tube, 2 h, 92%.

SCHEME 4



SCHEME 5





SCHEME 6

determined on the basis of conventional spectroscopic data including ^{13}C and ^{1}H nmr, ir, ms, and HCCORR. Unfortunately, tricyclic compounds **22** and **24** did not yield single crystals, suitable for X-ray crystallography, to confirm the proposed structures. The relative stereochemistry of the four hydrogens at the ring conjunctions of tricycles **22** and **24**, however, can be reasonably assigned by molecular model analysis, which has been successfully and extensively used in our laboratory to predict the stereochemisty of tricyclic products from transannular Diels–Alder reactions (1, 7*a*,*b*). Based on theoretical analysis, each triene macrocycle can lead at most to two different tricyclic diastereoisomers. As shown in Scheme 6, the molecular model shows that the triene macrocycle **21** with *cis-trans-cis* olefin geometry can adopt two different conformations **21***a* and **21***b*, which may lead to tricycles **22** (CST) and **27** (TSC). However, it is not difficult to recognize from these molecular models that conformation **21***b* cannot undergo Diels–Alder reaction because it is sterically impossible to reach a boat transition state for the newly forming B ring, which must be attained for Diels–Alder reaction to take place. Therefore, macrocyle **21** can give only one tricyclic product **22** with CST stereochemistry. Similarly, triene macrocycle **23** with *cis-trans-trans* olefin geometry can adopt two different conformations **23***a* and **23***b* (Scheme 6). Transannular Diels–Alder reaction of **23***a* produces **24** with *cis-anti-cis* (CAC) stereochemistry. Conformation **23***b*, which is similar to **21***b*, cannot undergo Diels–Alder reaction to produce tricycle **28** because it is impossible to reach a boat transition state due to the steric encumbrance. As a result, only one diastereoisomer **24** (CAC) is expected from macrocycle **23**.

Macrocyclization of *trans-trans-cis* acyclic triene **11***b* was performed by adding a solution of crude **11***b* in THF to a stirred suspension of cesium carbonate in a mixture of DMF and THF (1:1) at 85°C over a period of 13 h in high dilution (2×10^{-3} M) (Scheme 7). The stirring was continued for 24 h after the addition was finished. At this stage, tricyclic product **30** (TST) was isolated as the sole product in an overall yield of 69% from allylic alcohol **10***b*, presumably via a transannular Diels–Alder reaction of 14-membered macrocycle intermediate **29**. The same reaction in CH_3CN gave the same tricycle **30** in comparable overall yield (60%). The tandem macrocyclization and transannular Diels–Alder reaction was also observed for *trans-trans-trans* acyclic triene **20***b* under the same conditions,

E = CO_2CH_3

SCHEME 8

leading to a new tricyclic product **32** (CAT) in 26% overall yield from **19***b* in DMF/THF mixture, and 25% yield in CH_3CN. The failure to isolate macrocycles **29** and **31** simply suggests that the Diels–Alder cycloadditions are very much facilitated in this transannular process, so they can take place even under the mild conditions and with a non-activated dienophile such as an alkyl substituted olefin. In contrast with the isolable macrocycles **21** and **23**, the increased reactivities of **29** and **31** can be explained by the fact that formation of the *cisoid* dienes, which is required for the concerted Diels–Alder reaction, poses much less steric encumbrance, when the diene moiety has a *trans-trans* geometry (15).

The structures of the two tricyclic products **30** (TST) and **32** (CAT) were also determined on the basis of both spectroscopic data and molecular model. According to the analysis proposed above, macrocyclic intermediate **29** with *trans-trans-cis* olefin geometry could take two different conformations, **29***a* and **29***b*, which would lead to tricycles **30** and **33** respectively by the transannular cycloaddition. From the molecular model, it is easy to see that transformation from conformation **29***b* to tricycle **33** experiences a higher transition energy due to the 1,3 steric interactions between the two axial carbomethoxy groups and newly forming double bond (Scheme 8). From this analysis, Diels–Alder reaction of **29** would be predicted to produce a mixture of two, **30** and **33**, but with tricycle **30** much favored. In fact, we only obtained one product, and this must be tricycle **30** with *trans-syn-trans* (TST) stereochemistry. Indeed, X-ray crystallography showed that compound **30** did possess the TST stereochemistry (16), which correlated well with the molecular model analysis.

Similarly, *trans-trans-trans* macrocycle intermediate **31** can possess two different conformations **31***a* and **31***b*. Diels–Alder reactions of both conformations are sterically possible, and this will produce tricycles **32** (CAT) and **34** (TAC) respectively. It is interesting to note that tricycle **34** is in fact the mirror image of tricycle **32**. Therefore, no matter which conformation **31** adopts, it will lead to only one diastereoisomer since **32** (CAT) is identical to **34** (TAC). The structure has been determined by spectroscopic data (^1H and ^{13}C nmr, ir, and ms), although it could not be confirmed by X-ray analysis due to the difficulty in obtaining single crystals.

In summary, we have demonstrated a simple and general methodology for the syntheses of A.B.C.[6.6.6] carbotricyclic compounds in moderate to excellent yields, in a stereocontrolled manner, by varying the geometry of triene macrocycles. The acyclic trienes with different *cis* and *trans* double bonds were assembled by coupling dienes and dienophiles, and the macrocycles were synthesized by intramolecular S_N2 displacement of allylic chlorides with malonate anions in good yields. The transannular Diels–Alder reaction of macrocycles with a non-activated dienophile is a facile and a good yielding process, even under mild conditions. By comparison with the series previously studied where the transannular Diels–Alder reactions with dienophiles substituted by a methyl group gave unpredictable side-products in some cases (7), the present series

with no methyl substituent on the dienophile lead to the predictable tricycles with no side reaction. The present method, along with the others developed earlier by us (1, 7, 13), should find broad applications in synthesizing polycyclic natural products. Studies towards this goal are currently under investigation in our laboratory.

Experimental

Infrared spectra (ir) were recorded on a Perkin–Elmer 681 spectrophotometer, using chloroform ($CHCl_3$), or run as neat films on sodium chloride cells. The ^1H nmr and ^{13}C nmr spectra were taken on a Bruker WM-250 spectrometer in deuteriated chloroform ($CDCl_3$) or benzene (C_6D_6). The following abbreviations are used in the text: s, singlet; d, doublet; t, triplet; q, quadruplet; and m, multiplet. Mass spectra (ms) were recorded on a VG-Micromass ZAB-1F mass spectrometer. Melting points (mp) were measured on a Büchi or a Reichert melting point apparatus and were not corrected. Thin-layer chromatography (tlc) was performed using silica gel 60 F-250. For flash column chromatography Merck Kieselgel (no. 9385) was used.

Unless otherwise noted, all reagents were obtained from commercial suppliers and used without further purification. Acetonitrile, amines, dimethylformamide (DMF), hexamethylphosphoramide (HMPA), and dichloromethane (CH_2Cl_2) were distilled from calcium hydride; methanol from magnesium and iodine; acetone and ethyl acetate from potassium carbonate; benzene, toluene, diethyl ether, and tetrahydrofuran (THF) from sodium and benzophenone ketyl. Purified and dried reagents were kept under argon. Unless otherwise specified, all reactions were carried out under argon atmosphere.

*Methyl (5Z)-2-carbomethoxy-8-methanesulfonyloxy-5-octenoate (**6**)*

Hydrogen was bubbled through a stirred solution of alkyne methanesulfonate ester **5** (1.1 g, 3.5 mmol) in ethyl acetate (100 mL), and a Lindlar catalyst (palladium on calcium carbonate, poisoned with lead, 200 mg) was added. The reaction mixture was maintained under these conditions for 6 h, and then filtered and concentrated to give *cis*-alkene methanesulfonate ester **6** (1.1 g, 98%) as a pure oil; ir (neat): 3020, 2960, 1740, 1435, 1350, 1175 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 547 (2H, m, $-CH_2CH{=}CHCH_2-$), 4.20 (2H, t, J = 6.8 Hz, $CH_3SO_2OCH_2CH_2-$), 3.74 (6H, s, $-CH_2CH(CO_2CH_3)_2$), 3.37 (1H, t, J = 7.3 Hz, $-CH_2CH(CO_2CH_3)_2$), 3.01 (3H, s, $CH_3SO_2OCH_2-$), 2.47 (2H, q, J = 6.7 Hz, $=CHCH_2CH_2O-$), 2.10 (2H, q, J = 7.3 Hz, $=CHCH_2CH_2CH(CO_2CH_3)_2$), 1.97 (2H, m, $=CHCH_2CH_2CH(CO_2CH_2)_2$); ms m/e: 309 (MH^+).

*(2Z,4E,10Z)-7,7-Biscarbomethoxy-13-methanesulfonyloxy-1-[(tetrahydro-2H-pyran-2-yl)oxy]-2,4,10-tridecatriene (**8**a)*

General procedure A

To a stirred sodium hydride suspension (45 mg, 1.1 mmol) in a mixture of DMF/THF (1:1, 8 mL) was added a solution of methanesulfonate ester **6** (313 mg, 1.0 mmol) in a mixture of DMF/THF (1:1, 2 mL) at room temperature. After the mixture was stirred for 10 min, it was transferred to a solution of allylic chloride **7***a* (287 mg, 1.3 mmol) in a mixture of DMF/THF (1:1, 2 mL). The resulting mixture was stirred for 5 h at room temperature, then quenched with saturated NH_4Cl solution (20 mL), diluted with H_2O (20 mL), and extracted with hexanes/diethyl ether (1:2, 5 × 50 mL). The combined organic layers were washed with H_2O (40 mL) and brine (40 mL), dried over $MgSO_4$, then filtered and evaporated. The crude residue was purified by flash chromatography (hexanes/ethyl acetate; 7:3) to give coupling product **8***a* (463 mg, 93%) as an oil; ir (neat); 3020, 2950, 2860, 1730, 1440, 1360, 1170 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.39 (1H, dd, J = 15.4 Hz, 11.1 Hz, $-CH_2CH{=}CH{-}CH{=}CHCH_2O-$), 6.08 (1H, t, J = 11.2 Hz, $-CH_2CH{=}CH{-}CH{=}CHCH_2O-$), 5.59–5.47 and 5.42–5.34 (4H, 2m, $-CH_2CH{=}CH{-}CH{=}CHCH_2O-$ and $-CH_2CH{=}CHCH_2-$), 4.62 (1H, t, J = 3 Hz, $-OCHO-$), 4.32 (1H, ddd, J = 12.7 Hz, 6.4 Hz, 1.4 Hz, $-CH{=}CHCHHO-$), 4.22–4.12 (3H, superposed t and m, J = 6.7 Hz, $-CH_3SO_2OCH_2-$ and $-CH{=}CHCHHO-$), 3.90–3.82 and 3.55–3.48 (2H, 2m, $-OCHOCH_2-$), 3.72 (6H, s, $-CH_2C(CO_2CH_3)_2CH_2-$), 3.01 (3H, s, CH_3SO_2O-), 2.71 (2H, d, J = 7.2 Hz, $=CHCH_2C(CO_2CH_3)CH_2-$), 2.46 (2H, q, J = 6.8 Hz, $-CH_2CH_2C(CO_2CH_3)_2CH_2-$), 2.01–1.48 (10H, m, $-CH_2CH{=}CHCH_2-$ and $-OCHOCH_2(CH_2)_3$); ms m/e: 470 (M^+-H_2O), 386 (M^+-(OTHP + H)).

*(2E,4E,10Z)-7,7-Biscarbomethoxy-13-methanesulfonyloxy-1-[(tetrahydro-2H-pyran-2-yl)oxy]-2,4,10-tridecatriene (**8**b)*

The general procedure A was followed, using sodium hydride (89 mg, 2.2 mmol), methanesulfonate ester **6** (561 mg, 1.8 mmol), allylic chloride **7***b* (603 mg, 2.8 mmol), DMF (8 mL), and THF (8 mL). Coupling product **8***b* (718 mg, 80%) was obtained; ir (neat): 3020, 2950, 2860, 1730, 1440, 1350, 1170 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.16 (2H, m, $-CH_2CH{=}CH{-}CH{=}CHCH_2O-$), 5.72 (1H, dt, J = 14.5 Hz, 6.1 Hz, $-CH_2CH{=}CH{-}CH{=}CHCH_2O-$), 5.57–5.32 (3H, m, $-CH_2CH{=}CH{-}CH{=}CHCH_2O-$ and $-CH_2CH{=}CHCH_2-$), 4.62 (1H, t, J = 4 Hz, $-OCHO-$), 4.30–4.17 (3H, t and hidden m, J = 6.6 Hz, $CH_3SO_2OCH_2-$ and $-CH{=}CHCHHO-$), 3.98 (1H, dd, J = 13.1 Hz, 6.5 Hz, $-CH{=}CHCHHO-$), 3.89–3.82 and 3.55–3.46 (2H, m, $-OCHOCH_2-$), 3.72 (6H, s, $-CH_2C(CO_2CH_3)_2CH_2-$), 3.01 (3H, s, CH_3SO_2O-), 2.70 (2H, d, J = 7.6 Hz, $-CH{=}CHCH_2C(CO_2CH_3)CH_2-$), 2.47 (2H, q, J = 6.8 Hz, $-CH_2CH_2C(CO_2CH_3)_2CH_2-$), 2.00–1.51 (10H, m, $-CH_2CH{=}CHCH_2-$ and $-OCHOCH_2(CH_2)_3$); ms m/e: 387 (M^+-OTHP).

*Methyl (5Z,11E,13Z)-2,9,9-tricarbomethoxy-15-[(tetrahydro-2H-pyran-2-yl)oxy]-5,11,13-pentadecatrienoate (**9**a)*

General procedure B

Dimethyl malonate (512 μL, 4.6 mmol) was added dropwise to a stirred sodium hydride suspension (179 mg, 4.5 mmol) in a mixture of DMF/THF (1:1, 16 mL) at 0°C. The reaction mixture was stirred for 15 min at room temperature, then transferred by syringe to methanesulfonate ester **8***a* (445 mg, 0.91 mmol). Potassium iodide (151 g, 0.91 mmol) was added and the resulting mixture was refluxed at 80°C for 3.5 h. The reaction mixture was cooled to room temperature, quenched with saturated NH_4Cl solution (10 mL), diluted with H_2O (10 mL), and extracted with diethyl ether (4 × 40 mL). The combined organic layers were dried over $MgSO_4$, filtered, and evaporated. The crude residue was purified by flash chromatography (hexanes/ethyl acetate; 17:3) to give tetraester **9***a* (408 mg, 85%) as an oil; ir ($CHCl_3$): 3000, 2950, 2860, 1740, 1440, 1200 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.38 (1H, dd, J = 14.8 Hz, 11.3 Hz, $-CH_2CH{=}CH{-}CH{=}CHCH_2-$), 6.08 (1H, t, J = 11.1 Hz, $-CH_2CH{=}CH{-}CH{=}CHCH_2-$), 5.57–5.47 (2H, m, $-CH_2CH{=}CH{-}CH{=}CHCH_2-$), 5.44–5.27 (2H, m, $-CH_2CH{=}CHCH_2-$), 4.62 (1H, t, J = 3.4 Hz, $-OCHO-$), 4.34 (1H, dd, J = 12.7 Hz, 6.3 Hz, $-CH{=}CHCHHO-$), 4.23 (1H, dd, J = 13.2 Hz, 7.5 Hz, $-CH{=}CHCHHO-$), 3.92–3.81 and 3.55–3.46 (2H, 2m, $=CHCH_2OCHOCH_2-$), 3.73 and 3.71 (12H, 2s, $-CH_2CH(CO_2CH_3)_2$ and $-CH_2C(CO_2CH_2CH_3)_2CH_2-$), 3.36 (1H, t, J = 7.2 Hz, $-CH_2CH(CO_2CH_3)_2$), 2.70 (2H, d, J = 7.5 Hz, $=CHCH_2C(CO_2CH_3)_2CH_2-$), 2.06–1.50 (14H, 2m, $-CH_2CH_2CH{=}CHCH_2CH_2-$ and $-OCHOCH_2(CH_2)_3$); ms m/e: 524 (M^+), 506 (M^+-H2O), 386 (M^+-OCH_3).

*Methyl (5Z,11E,13E)-2,9,9-tricarbomethoxy-15-[(tetrahydro-2H-pyran-2-yl)oxy]-5,11,13-pentadecatrienoate (**9**b)*

The general procedure B was followed, using dimethyl malonate (1.0 mL, 8.7 mmol), sodium hydride (288 mg, 7.2 mmol), mesylate **8***b* (705 mg, 1.4 mmol), potassium iodide (280 mg, 1.7 mmol), DMF (19 mL), and THF (19 mL). Tetraester **9***b* (681 mg, 90%) was obtained; ir ($CHCl_3$): 3000, 2950, 2860, 1740, 1440, 1220 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.15 (2H, m, $-CH_2CH{=}CH{-}CH{=}CHCH_2O-$), 5.71 (1H, dt, J = 14.7 Hz, 6.1 Hz, $-CH_2CH{=}CH{-}CH{=}CHCH_2O-$), 5.48 (1H, dt, J = 14.4 Hz, 7.4 Hz, $-CH_2CH{=}CH{-}CH{=}CHCH_2O-$), 5.34 (2H, m, $-CH_2CH_2CH{=}CHCH_2CH_2-$), 4.63 (1H, t, J = 3.4 Hz, $-OCHO-$), 4.25 (1H, dd, J = 13.1 Hz, 6.0 Hz, $-CH{=}CHCHHO-$), 2.98 (1H, dd, J = 13.2 Hz, 6.6 Hz, $-CH{=}CHCHHO-$), 3.90–3.82 and 3.55–3.46 (2H, 2m, $=CHCH_2OCHOCH_2-$), 3.73 and 3.71 (12H, 2s, $-CH_2CH(CO_2CH_3)_2$ and $-CH_2C(CO_2CH_3)_2CH_2-$), 3.36 (1H, t, J = 7.2 Hz, $-CH_2CH(CO_2CH_3)_2$), 2.68 (2H, d, J = 7.6 Hz, $=CHCH_2C(CO_2CH_3)_2CH_2-$), 2.09–1.49 (14H, 2m, $-CH_2CH_2CH=$

$CHCH_2CH_2$- and -$OCHOCH_2(CH2)_3$); ms *m/e*: 524 (M^+), 493 (M^+-OCH_3), 422 ($M^+-C_5H_{10}O_2$).

*Methyl (5Z,11E,13Z)-2,9,9-tricarbomethoxy-15-hydroxy-5,11,13-pentadecatrienoate (**10**a)*

General procedure C

To a stirred solution of tetraester **9***a* (401CO g, 0.76 mmol) in anhydrous methanol (15 mL) was added pyridinium *p*-toluenesulfonate (19 mg, 0.08 mmol) and the resulting mixture was heated at 60°C for 1 h. The mixture was allowed to cool to room temperature, and then treated with brine (10 mL), diluted with H_2O (10 mL), and extracted with ethyl acetate (6 × 10 mL). The combined organic layers were dried over $MgSO_4$, filtered, and evaporated. The crude residue was purified by flash chromatography (hexanes/ethyl acetate; 4:1) to give alcohol **10***a* (148 mg, 44%) as a viscous oil; ir (neat): 3530, 3470, 3000, 2950, 2860, 1735, 1435, 1210 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.36 (1H, dd, *J* = 14.7 Hz, 11.1 Hz, -CH_2CH=C*H*-CH=$CHCH_2OH$), 6.02 (1H, t, *J* = 11.1 Hz, CH_2CH=CH-C*H*=$CHCH_2OH$), 5.59–5.50 (2H, m, -CH_2CH=CH-CH=$CHCH_2OH$), 5.40–4.30 (2H, m, -CH_2CH_2CH=$CHCH_2CH_2$-), 4.28 (2H, br s, =$CHCH_2OH$), 3,73 and 3.71 (12H, 2s, -$CH_2CH(CO_2CH_3)_2$ and -$CH_2C(CO_2CH_3)_2CH_2$-), 3.36 (1H, t, *J* = 7.2 Hz, -$CH_2CH(CO_2CH_3)_2$, 2.71 (2H, d, *J* = 7.1 Hz, =$CHCH_2$-$(CO_2CH_3)_2$-CH_2-), 2.08–1.87 (8H, m, -CH_2CH_2CH=$CHCH_2CH_2$-), 1.66 (1H, s, =$CHCH_2OH$); ms *m/e*: 422 (M^+-H_2O).

*Methyl (5Z,11E,13E)-2,9,9-tricarbomethoxy-15-hydroxy-5,11,13-pentadecatrienoate (**10**b)*

The general procedure C was followed, using pyridinium *p*-toluenesulfonate (32 mg, 0.13 mmol), tetraester **9***b* (668 mg, 1.3 mmol), and anhydrous methanol (13 mL). Alcohol **10***b* (526 mg, 94%) was obtained as a viscous oil; ir (neat): 3520, 3470, 3000, 2950, 2860, 1730, 1430, 1220 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.16 (2H, m, -CH_2CH=C*H*-C*H*=$CHCH_2O$-), 5.77 (1H, dt, *J* = 14.6 Hz, 5.9 Hz, -CH_2CH=CH-CH=C*H*CH_2O-), 5.49 (1H, dt, *J* = 14.2 Hz, 7.1 Hz, -CH_2CH=CH-CH=$CHCH_2O$-), 5.35 (2H, m, -CH_2CH_2CH=C*H*CH_2CH_2-), 4.16 (2H, t, *J* = 5.9 Hz, =$CHCH_2OH$), 3.74 and 3.72 (12H, 2s, -$CH_2CH(CO_2CH_3)_2$ and -$CH_2C(CO_2CH_3)_2CH_2$-), 3.36 (1H, t, *J* = 7.1 Hz, -$CH_2CH(CO_2CH_3)_2$), 2.69 (2H, d, *J* = 7.6 Hz, =$CHCH_2$-$(CO_2CH_3)_2$-CH_2-), 2.04–1.85 (8H, m, -CH_2CH_2CH=$CHCH_2CH_2$-), 1.55 (1H, t, *J* = 3 Hz, -CH_2OH); ms *m/e*: 422 (M^+-H_2O).

*Methyl (5Z,11E,13Z)-2,9,9-tricarbomethoxy-15-chloro-5,11,13-pentadecatrienoate (**11**a)*

General procedure D

To a stirred solution of alcohol **10***a* (135 mg, 0.31 mmol) in DMF (2.5 mL) were added lithium chloride (110 mg, 2.6 mmol) and *s*-collidine (108 ml, 1.4 mmol) at room temperature. The resulting mixture was cooled to 0°C and methanesulfonyl chloride (80 μL, 1.0 mmol) was added. After the thick mixture was stirred for 30 min, it was diluted with H_2O (15 mL) and extracted with hexanes/diethyl ether (2:1, 3 × 20 mL). The combined organic layers were dried over $MgSO_4$, filtered, and evaporated. The crude residue was purified by flash chromatography (hexanes/ethyl acetate; 17:3) to give allylic chloride **11***a* (126 mg, 89%) as an oil; ^1H nmr ($CDCl_3$) δ: 6.38 (1H, dd, *J* = 14.8 Hz, 11.7 Hz, -CH_2CH=C*H*-CH=$CHCH_2Cl$), (1H, t, *J* = 10.8 Hz, -CH_2CH=CH-C*H*=$CHCH_2Cl$), 5.72–5.50 (2H, m, -CH_2CH=CH-CH=C*H*CH_2Cl), 5.38–5.32 (2H, m, -CH_2CH_2CH=C*H*CH_2CH_2-), 4.18 (2H, d, *J* = 8.2 Hz, =$CHCH_2Cl$), 3.73 and 3.72 (12H, 2s, -$CH_2C(CO_2CH_3)_2CH_2$- and -$CH_2CH(CO_2CH_3)_2$), 3.36 (1H, t, *J* = 7.1 Hz, -$CH_2CH(CO_2CH_3)_2$), 2.74 (2H, d, *J* = 7.5 Hz, -$C(CO_2CH_3)_2CH_2CH$=), 2.10–1.88 (8H, m, -CH_2CH_2CH=$CHCH_2CH_2$-).

*Methyl (5Z,11E,13E)-2,9,9-tricarbomethoxy-15-chloro-5,11,13-pentadecatrienoate (**11**b)*

General procedure E

To a stirred solution of allylic alcohol **10***b* (371 mg, 0.84 mmol) and lithium chloride (297 mg, 7.0 mmol) in DMF (9 mL) was added *s*-collidine (432 μL, 3.0 mmol) at room temperature. The mixture was stirred for 10 min and then cooled to 0°C. Methanesulfonyl chloride (170 μL, 2.2 mmol) was added and the reaction mixture was stirred at 0°C for 45 min, then diluted with H_2O and extracted with hexanes/ethyl ether (2:1, 4 × 50 mL). The combined organic layers were washed successively with saturated $Cu(NO_3)_2$ solution (20 mL), saturated $NaHCO_3$ solution (10 mL), and brine (2 × 20 mL), and then dried over $MgSO_4$, filtered, and evaporated to give crude allylic chloride **11***b*; ^1H nmr (C_6D_6) δ: 5.88 (2H, m, -CH_2CH=C*H*-C*H*=$CHCH_2O$-), 5.64–5.20 (4H, m, -CH_2CH=CH-CH=C*H*CH_2O- and -CH_2CH_2CH=C*H*CH_2CH_2-), 3.61 (2H, d, *J* = 7.2 Hz, =$CHCH_2Cl$), 3.34 and 3.32 (13H, m, -$CH_2C(CO_2CH_3)_2CH_2$-, -$CH_2CH(CO_2CH_3)_2$, and -$CH_2CH(CO_2CH_3)_2$, 2.85 (2H, d, *J* = 7.7 Hz, -$C(CO_2CH_3)_2CH_2$-CH=), 2.15–1.99 (8H, m, -CH_2CH_2CH=$CHCH_2CH_2$-).

*(2E)-1,4-Biscarboethoxy-2-butene (**13**)*

To a stirred solution of *trans*-β-hydromuconic acid **12** (1.56 g, 8 mmol) in benzene/ethanol (absolute; 5:2, 70 mL) was added concentrated sulfuric acid (3 drops) and the resulting mixture was heated at 90°C for 48 h. After it was cooled to room temperature, K_2CO_3 was added to neutralize the acidic solution. The mixture was diluted with diethyl ether (200 mL), dried over $MgSO_4$, filtered, and concentrated to give diester **13** (2.1 g, 99%) as a colorless oil; ir (neat): 2980, 2920, 1740, 1370, 1170 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 5.69 (2H, tt, *J* = 3.8 Hz, 1.8 Hz, -CH_2CH=C*H*CH_2-), 4.13 (4H, q, *J* = 7.2 Hz, (=$CHCH_2$-$CO_2CH_2CH_3)_2$), 3.08 (4H, m, -CH_2CH=$CHCH_2$-), 1.25 (6H, t, *J* = 7.2 Hz, (=$CHCH_2CO_2CH_2CH_3)_2$); ms *m/e*: 200 (M^+), 154 ($M^+-CH_3CH_2OH$).

*(3E)-3-Hexen-1,6-diol (**14**)*

To a stirred suspension of lithium aluminum hydride (970 mg, 23 mmol) in anhydrous diethyl ether (90 mL) was added a solution of diester **13** (3.1 g, 16 mmol) in anhydrous diethyl ether (10 mL) over a period of 30 min at room temperature. The mixture was stirred for 30 min followed by addition of Glauber's salt ($Na_2SO_4 \cdot 10H_2O$, 1 g). The stirring was continued for another 30 min before filtering. The filtrate was washed with acetone (5 × 100 mL) and the combined organic layers were dried over $MgSO_4$, filtered, and evaporated. The crude residue was purified by flash chromatography (hexanes/acetone; 1:1) to give diol **14** (1.7 g, 94%) as a viscous oil; ir (neat): 3350, 2940, 2890, 1430, 1050 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 5.52 (2H, tt, *J* = 3.8 Hz, 1.7 Hz, -CH_2CH=C*H*CH_2-), 3.64 (4H, t, *J* = 6.1 Hz, ($HOCH_2CH_2CH$=)$_2$), 2.28 (4H, q, *J* = 5.7 Hz, -CH_2CH=$CHCH_2$-), 2.04 (2H, br s, (*H*OCH_2CH_2CH=)$_2$); ms *m/e*: 116 (M^+), 98 (M^+-H_2O).

*(3E)-1,6-Bismethanesulfonyloxy-3-hexene (**15**)*

To a stirred solution of alcohol **14** (1.7 g, 15 mmol) in dichloromethane (58 mL) were added triethylamine (5.1 mL, 36 mmol) and methanesulfonyl chloride (2.7 mL, 34 mmol) at 0°C in dropwise fashion. The reaction mixture was stirred for 30 min at 0°C and then diluted with CH_2Cl_2 (100 mL). The organic layer was washed with H_2O (3 × 40 mL), dried over $MgSO_4$, filtered, and evaporated. The crude residue was purified by flash chromatography (hexanes/ethyl acetate; 3:1) to give methanesulfonate ester **15** (3.9 g, 97%) as a solid; mp 60–63°C; ir: 3020, 2960, 2900, 1350, 1170 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 5.56 (2H, tt, *J* = 3.7 Hz, 1.6 Hz, -CH_2CH=C*H*CH_2-), 4.23 (4H, t, *J* = 6.5 Hz, (-OCH_2CH_2CH=)$_2$), 3.00 (6H, s, (CH_3SO_2-$OCH_2CH_2CH)_2$), 2.47 (4H, q, *J* = 5.5 Hz, -CH_2CH=$CHCH_2$-).

*(3E)-1,1,6,6-Tetracarbomethoxy-3-butene (**16**)*

The general procedure B was followed, using dimethyl malonate (7.55 mL, 66 mmol), sodium hydride (2.6 g, 65 mmol), DMF/THF (1:1, 220 mL), dimesylate **15** (3.0 g, 11 mmol), and potassium iodide (1.8 g, 11 mmol). The crude product was pumped under vacuum for 1 h and then purified by flash chromatography (hexanes/ethyl acetate; 17:3) to give tetraester **16** (2.8 g, 73%); ir (neat): 2950, 1740, 1430, 1240, 1150 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 5.38 (2H, m, -CH_2CH=C*H*CH_2-), 3.73 (12H, s, (=$CHCH_2CH_2CH(CO_2CH_3)_2$)2), 3.38 (2H, t, *J* = 7.2 Hz, (=$CHCH_2CH_2CH(CO_2CH_3)_2)_2$), 1.99 (8H, m, (=$CHCH_2CH_2CH$-)$_2$); ms *m/e*: 345 ($MH^+$), 312 ($M^+-CH_3OH$).

*Methyl (5E,11E,13Z)-2,9,9-tricarbomethoxy-15-hydroxy-5,11,13-pentadecatrienoate (**19**a)*

General procedure F

To a stirred sodium hydride suspension (84 mg, 2.1 mmol) in DMF/THF (1:1, 6 mL) was added dropwise a solution of tetraester **16** (1.5 g, 4.25 mmol) in DMF/THF (1:1, 6 mL) at 0°C. The reaction mixture was stirred for 10 min at room temperature and then transferred to a solution of allylic chloride **7***a* (466 mg, 2.2 mmol) in DMF/THF (1:1, 6 mL). The resulting mixture was stirred for 4.5 h and then quenched with saturated NH_4Cl solution (20 mL), diluted with H_2O (20 mL), and extracted with hexanes/ether (2:1, 4 × 100 mL). The combined organic layers were dried over $MgSO_4$, filtered, and evaporated to give a crude residue that contained product **18***a*.

Pyridinium *p*-toluenesulfonate (45 mg, 0.18 mmol) was added to a stirred solution of the above crude residue in anhydrous methanol (18 mL). The resulting mixture was heated at 60°C for 90 min before it was cooled to room temperature. After the volatiles were removed, the viscous residue was purified by flash chromatography (hexanes/ethyl acetate; 6:4) to give alcohol **19***a* (767 mg 83%) and diol **37***a* (79 mg, 14%). **19***a*: ir (neat): 3540, 3460, 3010, 2950, 2840, 1740, 1440, 1220 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.35 (1H, dd, J = 14.8 Hz, 11.3 Hz, -CH_2CH=C*H*-CH=$CHCH_2$-), 6.03 (1H, t, J = 11.0 Hz, -CH_2CH=CH-C*H*=$CHCH_2$-), 5.60–5.48 (2H, m, -CH_2CH=CH-CH=C*H*CH_2-), 5.38 (2H, m, -CH_2CH=C*H*CH_2-), 4.29 (2H, br d, J = 5.4 Hz, =$CHCH_2OH$), 3.73 and 3.71 (12H, s, -$CH_2CH(CO_2CH_3)_2$ and -$CH_2C(CO_2CH_3)_2CH_2$-), 3.36 (1H, t, J = 7.2 Hz, -$CH_2CH(CO_2CH_3)_2$), 2.70 (2H, d, J = 7.6 Hz, =$CHCH_2C(CO_2CH_3)_2CH_2$-), 2.04–1.90 (8H, m, -$CHCH_2CH_2CH$=$CHCH_2CH_2$-), 1.61 (1H, br s, =$CHCH_2OH$); ms m/e: 422 ($M^+ - H_2O$).

37*a*: ir (neat): 3420, 3030, 2960, 2850, 1730, 1440, 1230 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.35 (2H, dd, J = 14.7 Hz, 11.6 Hz, (-CH_2CH=C*H*-CH=$CHCH_2$-)$_2$), 6.03 (2H, t, J = 11.0 Hz, (-CH_2CH=CH-C*H*=$CHCH_2$-)$_2$), 5.60–5.47 (4H, m, (-CH_2CH=CH-CH=C*H*-CH_2-)$_2$), 5.37 (2H, br s, (-CH_2CH_2CH-)$_2$), 4.29 (4H, d, J = 6.8 Hz, (=$CHCH_2OH$)$_2$), 3.71 (12H, s, (=$CHCH_2CH_2CH_2C(CO_2CH_3)_2$-$CH_2$-)$_2$), 2.70 (4H, d, J = 7.4 Hz, (=$CHCH_2CH_2C(CO_2CH_3)_2CH_2$-)$_2$), 1.98 (8H, s, (=$CHCH_2CH_2C$-)$_2$), 1.58 (2H, s, (=$CHCH_2OH$)$_2$).

*Methyl (5E,11E,13E)-2,9,9-tricarbomethoxy-15-hydroxy-5,11,13-pentadecatrienoate (**19**b)*

The general procedure F was followed, using sodium hydride (76 mg, 1.9 mmol), tetraester **16** (1.25 g, 3.6 mmol), allylic chloride **7***b* (390 mg, 1.8 mmol), DMF (9 mL), THF (9 mL), pyridinium *p*-toluenesulfonate (48 mg, 0.19 mmol), and anhydrous methanol (18 mL). Alcohol **19***b* (361 mg, 47% for last two steps) was obtained; ir (neat): 3540, 3460, 3000, 2960, 2850, 1730, 1440, 1230 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.14 (2H, m, -CH_2CH=C*H*-C*H*=$CHCH_2OH$), 5.77 (1H, dt, J = 14.3 Hz, 5.8 Hz, -CH_2CH=CH-CH=C*H*CH_2OH), 5.49 (1H, dt, J = 14.6 Hz, 7.3 Hz, -CH_2CH=CH-CH=$CHCH_2OH$), 5.37 (2H, m, -CH_2CH_2CH=C*H*CH_2CH_2-), 4.17 (2H, d, J = 5.8 Hz, =$CHCH_2OH$), 3.73 and 3.71 (12H, s, -$CH_2CH(CO_2CH_3)_2$ and -$CH_2C(CO_2CH_3)_2CH_2$-), 3.36 (1H, t, J = 7.3 Hz, -$CH_2CH(CO_2CH_3)_2$), 2.67 (2H, d, J = 7.6 Hz, =$CHCH_2C(CO_2CH_3)_2CH_2$-), 2.04–1.89 (8H, m, -$CHCH_2CH_2CH$=$CHCH_2CH_2$-), 1.61 (1H, br s, =$CHCH_2OH$); ms m/e: 422 ($M^+ - H_2O$).

*Methyl (5E,11E,13Z)-2,9,9-tricarbomethoxy-15-chloro-5,11,13-pentadecatrienoate (**20**a)*

The general procedure D was followed, using *s*-collidine (650 μL, 5.0 mmol), allylic alcohol **19***a* (535 mg, 1.2 mmol), lithium chloride (473 mg, 10 mmol), DMF (14 mL), and methanesulfonyl chloride (300 μL, 3.9 mmol). Allylic chloride **20***a* (505 mg, 90%) was obtained; ^1H nmr ($CDCl_3$) δ: 6.36 (1H, dd, J = 14.7 Hz, 11.4 Hz, -CH_2CH=C*H*-CH=$CHCH_2$-), 6.10 (1H, t, J = 10.9 Hz, -CH_2CH=CH-C*H*=$CHCH_2$-), 5.71–5.53 (2H, m, -CH_2CH=CH-CH=C*H*CH_2-), 5.38 (2H, br s, -CH_2CH_2CH=C*H*CH_2CH_2-), 4.17 (2H, d, J = 8.0 Hz, =$CHCH_2Cl$), 3.73 and 3.71 (12H, 2s, -$CH_2C(CO_2CH_3)_2CH_2$- and -$CH_2CH(CO_2CO_2CH_3)_2$, 3.36 (1H, t, J = 7.2 Hz, -$CH_2CH(CO_2CH_3)_2$), 2.72 (2H, d, J = 7.6 Hz, -$C(CO_2CH_3)_2CH_2CH$=), 2.01–1.90 (8H, m, -CH_2CH_2CH=$CHCH_2CH_2$-).

*Methyl (5E,11E,13E)-2,9,9-tricarbomethoxy-15-chloro-5,11,13-pentadecatrienoate (**20**b)*

The general procedure E was followed, using *s*-collidine (175 μL, 1.3 mmol), allylic alcohol **19***b* (145 mg, 0.33 mmol), lithium chloride (195 mg, 4.6 mmol), DMF (5.5 mL), and methanesulfonyl chloride (76 μL, 1.0 mmol). Allylic chloride **20***b* (505 mg, 90%) was obtained. ^1H nmr (C_6D_6) δ: 5.82 (2H, m, -CH_2CH=C*H*-C*H*=$CHCH_2Cl$), 5.56 (1H, dt, J = 14.8 Hz, 7.4 Hz, -CH_2CH=CH-CH=$CHCH_2Cl$), 5.43–5.27 (3H, m, -CH_2CH=CH-CH=C*H*CH_2Cl and -CH_2CH_2CH=C*H*CH_2CH_2-), 3.57 (2H, d, J = 7.2 Hz, =$CHCH_2Cl$), 3.31 and 3.29 (13H, m, -$CH_2C(CO_2CH_3)_2CH_2$-, -$CH_2CH(CO_2CH_3)_2$ and -CH_2CH-$(CO_2CH_3)_2$), 2.82 (2H, d, J = 7.6 Hz, -$C(CO_2CH_3)_2CH_2CH$=), 2.18–1.93 (8H, m, -CH_2CH_2CH=$CHCH_2CH_2$-).

*(1Z,3E,9Z)-6,6,13,13-Tetracarbomethoxy-1,3,9-cyclotetradecatriene (**21**)*

General procedure G

To a stirred suspension of cesium carbonate (475 mg, 1.5 mmol) in CH_3CN (135 mL) was added a solution of allylic chloride **11***a* (126 mg, 0.27 mmol) in CH_3CN (5 mL) by syringe pump over a period of 12 h at 85°C. After the addition was finished, the reaction mixture was stirred for 5 h. The mixture was allowed to cool to room temperature, then filtered and evaporated. The crude residue was purified by flash chromatography (hexanes/CH_2Cl_2/ethyl acetate; 17:2:1), and the solid obtained was crystallized from hexanes/CH_2Cl_2 to give macrocyclic compound **21** (100.5 mg, 87%; 81% after crystallization); mp 156–164°C; ir ($CHCl_3$): 3020, 2960, 1730, 1450, 1430, 1210 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.57 (1H, dd, J = 14.9 Hz, 11.1 Hz, -C(1)H=C(2)H-C(3)*H*=C_4H-), 6.15 (1H, t, J = 10.9 Hz, -C(1)H=C(2)*H*-C(3)H=C(4)H-), 5.44–5.31 (3H, m, -C(1)H=C(2)H-C(3)H=C(4)*H*- and -CH_2C(9)*H*=C(10)*H*CH_2-), 4.98 (1H, dt, J = 10.3 Hz, 9.7 Hz, -C(1)*H*=C(2)H-C(3)H=C(4)H-), 3.73 (12H, s, $(CO_2CH_3)_4$), 2.80 (4H, m, -C(5)H_2- and -C(14)H_2-), 2.10–1.50 (8H, m, -C(7)H_2C(8)H_2CH=CHC(11)H_2C(12)H_2-); ^{13}C nmr ($CDCl_3$) δ: 171.5 ((CO_2CH_3)$_4$), 132.3 (=*C*(2)H-), 129.5 (-*C*(3)H=), 128.6 (=*C*(4)H- and -*C*(9)H=*C*(10)H-), 124.3 (-*C*(1) H=), 57.4 and 56.5 (-*C*(6)- and -*C*(13)-), 52.6 and 52.6 ((CO_2CH_3)$_4$), 35.3 and 29.6 (-C_5H_2-and -*C*(14)H_2-), 31.9 and 30.7 (-*C*(8)H=CH*C*(11)H_2-), 22.4 and 21.2 (-*C*(7)H_2- and -*C*(12)H_2-); ms m/e: 422 (M^+). *(1Z,3*E*,9*Z*)-6,6,13,13-Tetracarbomethoxy-1,3,9-cyclotetradecatriene (**21**)*

Hydrogen was bubbled through a stirred solution of macrocyclic compound **25** (29 mg, 69.0 μmol) in ethyl acetate (3 mL), and a Lindlar catalyst (palladium on calcium carbonate, poisoned with lead, 3 mg) was added. The reaction mixture was maintained under these conditions for 1 h, and then filtered and concentrated to give a macrocyclic compound (29 mg, 100%), whose spectroscopic data are identical with macrocycle **21** obtained previously by macrocyclization of allylic chloride **11***a*.

*(*trans-*1,10*,cisoid-*1,2*,trans-*2,7*)-*5,5,12,12-Tetracarbomethoxytricyclo[8.4.0.0^{2,7}]tetradec-8-ene (**30**)*

General procedure I

To a stirred suspension of cesium carbonate (420 mg, 1.3 mmol) in a mixture of DMF/THF (1:1, 121 mL) was added a solution of allylic chloride **11***b* (crude product) in THF (5 mL) by syringe pump over a period of 12 h at 85°C. After the addition was finished, the stirring was continued for 24 h. The reaction mixture was cooled to room temperature, and then filtered and evaporated. The crude residue was purified by flash chromatography (hexanes/CH_2CL_2/ethyl acetate; 17:2:1) to give tricyclic compound **30** (72 mg, 69% for last 3 steps; 56% after crystallization) as a white solid; mp 164–166°C; ir ($CHCl_3$): 3020, 2950, 1730, 1450, 1230 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 5.65 (2H, s, -C(8)H=C(9)H-), 3.74 and 3.69 (12H, 2s, $(CO_2CH_3)_4$), 2.59 (2H, dd, J = 10.4 Hz, 2.0 Hz, -C(4)H_e- and -C(13)H_e-), 2.45 (2H, dd, J = 13.1 Hz, 1.9 Hz, -C(6)H_e-C(11)H_e-), 1.77 (8H, m, -C(3)H_e-, -C(4)-H_a-, -C(6)H_a-, -C(7)H-, -C(10)H-, -C(11)H_a-, -C(13)H_a-, -C(14)H_e-), 1.31–1.24 (4H, m, -C(3)H_a-, -C(1)H-, -C(2)H-, -C(14)H_a-); ^{13}C nmr ($CDCl_3$) δ: 172.7 and 171.5 (($CO_2CH_3)_4$), 133.9 (-C(8)H=C(9)H-), 55.1 (-C(5)- and -C(12)-), 52.6 (($CO_2CH_3)_4$), 40.9 (-C(1)- and -C(2)-), 36.9 (-C(6)- and -C(11)-), 36.2 (-C(7)- and -C(10)-), 32.2 (-C(4)- and -C(13)-), 24.8 (-C(3)- and -C(14)-); ms m/e: 422 (M^+). Exact mass (M^+) calcd.: 422.1741; found: 422.1937. The structure of compound **30** has also been determined by X-ray crystallography and its details will be reported (16).

The same reaction in CH_3CN was carried out according to the above general procedure I. Thus, the reaction of allylic chloride **11***b* (crude product) with cesium carbonate (1.2 g, 3.7 mmol) in 405 mL of CH_3CN provided a tricyclic compound (216 mg, 60% for last three steps) that has spectroscopic data identical with tricycle **30**.

*(*cis-*1,10*,transoid-*1,2*,trans-*2,7*)-*5,5,12,12-Tetracarbomethoxytricyclo[8.4.0.0^{2,7}]tetradec-8-ene (**32**)*

The general procedure I was followed, using chloride **20***b* (crude product), acetonitrile (200 mL), and cesium carbonate (570 mg, 1.75 mmol). Tricyclic compound **32** (35 mg, 25%) was obtained as a solid; mp 107–110°C; ir ($CHCl_3$): 3020, 2950, 1730, 1350, 1330, 1220 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 5.57 and 5.38 (2H, m, and d, J = 9.9 Hz, -C(8)H=C(9)H-), 3.75, 3.74, 3.70, 3.69 (12H, 4s, $(CO_2CH_3)_4$), 2.52–0.97 (16H, m); ^{13}C nmr ($CDCl_3$) δ: 172.7, 171.6, and 171.4 (($CO_2CH_3)_4$), 131.3 and 130.7 (-C(8)H=C(9)H-), 55.2 (-C(5)- and -C(12)-), 52.6 and 52.5 (($CO_2CH_3)_4$), 39.4, 36.4, 35.4, and 37.6 (4d, -C(1)-, -C(2)-, -C(7)-, -C(10)-,), 34.1, 33.8, 31.5, 25.6, 25.2, and 22.5 (6t, -C(3)-, -C(4)-, -C(6)-, -C(11)-, -C(13)-, -C(14)-); ms m/e: 422 (M^+). Exact mass (M^+) calcd.: 422.1941; found: 422.1937.

The same reaction in a mixture of DMF/THF was conducted using the above procedure. Thus, the reaction of allylic chloride **20***b* crude product) with cesium carbonate (1.8 g, 5.5 mmol) in a mixture of DMF/THF (1:1; 220 mL) gave a tricycle (48 mg, 26% for last three steps) that was found to be identical spectroscopically with **32**.

Nouveaux modèles siliciés dérivés de la quinoléine

MICHELINE GRIGNON-DUBOIS,[1] MICHELLE FIALEIX ET BERNADETTE REZZONICO

Laboratoire de chimie organique et organométallique, Université de Bordeaux I, 351, Cours de la libération, 33405 Talence CÉDEX, France

Reçu le 19 décembre 1989[2]

MICHELINE GRIGNON-DUBOIS, MICHELLE FIALEIX et BERNADETTE REZZONICO. Can. J. Chem. **68**, 2153 (1990).

La silylation de la quinoléine par le système $Me_3SiCl/Li/THF$ a été réexaminée. Elle nous a permis d'isoler de nouveaux produits tri-, tétra- et hexasiliciés dont nous avons étudié la stéréochimie. La comparaison de nos résultats à ceux obtenus avec le naphtalène montre l'influence de l'atome d'azote sur l'orientation de la silylation.

Mots clés : silylation, quinoléine, polysilyl-hydro-quinoléines.

MICHELINE GRIGNON-DUBOIS, MICHELLE FIALEIX, and BERNADETTE REZZONICO. Can. J. Chem. **68**, 2153 (1990).

Silylation of quinoline with $Me_3SiCl/Li/THF$ reagent has been studied. We obtained new tri-, tetra-, and hexasilylated derivatives whose stereochemistry has been established using NMR data. Comparison of these results to those previously obtained from naphthalene shows the effect of nitrogen on the silylation process.

Key words: silylation, quinoline, polysilyl-hydro-quinolines.

La voie organosilicique est aujourd'hui reconnue comme une méthode de choix pour la fonctionnalisation des substrats organiques (1). D'autre part, la quinoléine constitue un squelette important en chimie thérapeutique (2). La silylation de la quinoléine constituait donc une stratégie attractive pour accéder à des synthons polysiliciés précurseurs de quinoléines fonctionnelles. Elle avait déjà donné lieu à quelques travaux. Ainsi, l'utilisation de $Me_3SiHgSiMe_3$ conduit à la bis-4,4′(*N*-triméthylsilyl dihydro-1,4-quinoléine) avec 75% de rendement (3). Par ailleurs, le réactif $Me_3SiCl/Li/Et_2O$/toluène avait permis à Nogaideli et Akhobadze (4) d'isoler, à côté de ce même dérivé (rdt. 20%), la bis-triméthylsilyl-1,4 dihydro-1,4 quinoléine, **1**, avec 15% de rendement. Enfin, Sulzbach et Iqbal (5) en remplaçant le mélange Et_2O/toluène par le THF avaient pu favoriser le produit de disilylation **1**; cependant, le rendement restait faible (31%) et aucune précision n'était apportée sur la présence éventuelle d'autres produits ou de substrat n'ayant pas réagi.

L'intérêt de cette réaction et le caractère incomplet des résultats de la littérature nous ont conduits à la réexaminer en utilisant, comme réactif, le système $Me_3SiCl/Li/THF$.

Résultats et discussion

Nos premiers essais ont été conduits dans les conditions décrites par Sulzbach et Iqbal (5) à savoir : 3 équiv. de Li, 3 équiv. de Me_3SiCl à 0°C. Au bout d'une heure (durée utilisée par ces auteurs), on constate que le milieu contient encore du lithium et de la quinoléine qui n'a pas réagi (CCM, SiO_2; éluant : hexane/EtOH : 80 : 20 (vol.)). Nous avons donc laissé les réactifs en contact jusqu'à disparition totale du produit de départ soit 6 h. Par distillation, nous avons ainsi pu isoler, à côté de de la bis-triméthylsilyl-1,4 dihydro-1,4 quinoléine, **1** (rdt. 35%), deux produits originaux **2** (rdt. 15%) et **3** (rdt. 25%) qui sont respectivement tétra- et hexasiliciés (fig. 1).

Ces résultats nous ont conduits à examiner l'influence de la quantité de réactifs sur l'orientation de la réaction (tableau 1). Nous avons ainsi constaté que :

(i) avec 2 équivalents, conditions théoriquement optimales pour favoriser le dérivé disilicié, celui-ci ne se forme qu'avec 30% de rendement; les produits **2** et **3** sont déjà présents dans le mélange réactionnel, ce qui indique que la réaction s'effectue sous contrôle cinétique;

(ii) avec 4 ou 6 équivalents, les rendements en produits de di- et tétrasilylation **1** et **2** varient peu; par contre, la proportion d'hexasilylation (**3**) augmente. Avec 12 équivalents, cette dernière devient largement prépondérante et le dérivé **3** devient le produit majeur de la réaction.

Notons que la fragilité de la liaison Si—N rend les composés **1**–**3** très sensibles à l'air ou à l'humidité. En particulier, l'isolement du produit **3**, qui, en outre, est stériquement encombré, nécessite de travailler en atmosphère parfaitement inerte.

La figure 1 rend compte de l'obtention de ces composés. Elle ferait intervenir la formation initiale d'un anion radical $\mathbf{Q}^{\cdot-}$ par transfert d'électron du métal au substrat, mécanisme généralement admis avec les systèmes conjugués (6). Une première silylation sur l'atome d'azote conduit au radical résonnant $\mathbf{Q}^{\cdot}$ qui, par capture d'un électron permet une deuxième silylation. Elle peut intervenir sur le sommet 4, donnant naissance au dérivé **1** qui est stable dans le milieu ou sur le sommet 2. Dans ce dernier cas, le dérivé disilicié qui en résulte, très réactif, se silyle à nouveau, donnant lieu à une compétition entre l'attaque de la double liaison de type styrénique et celle du noyau aromatique adjacent qui s'effectue en 6–7. Le produit tétrasilicié résultant de cette dernière n'a jamais été isolé; il conduit à une nouvelle réaction permettant la formation du dérivé **3**.

Ces résultats présentent une certaine analogie avec ceux observés par Laguerre *et al.* (7) à partir du naphtalène qui leur avait permis d'isoler aussi un produit hexasilicié (fig. 2). Cependant la fixation des 3ème et 4ème groupes silyle était univoque puisque l'analogue carboné de **2** ne se formait pas et les 5ème et 6ème silylations s'effectuaient sur des sommets différents. Ceci montre l'influence de l'atome d'azote dans ces réactions.

Abandonné au contact de l'air ou de silice, le dérivé disilicié, **1**, s'aromatise avec perte d'un groupe silyle, conduisant à la triméthylsilyl-4 quinoléine (**4**, rdt. 80%) (fig. 3) qui est identique au produit obtenu avec 36% de rendement par silylation de la bromo-4 quinoléine (8). Par action de chlorure d'acétyle, on isole la *N*-acétyl triméthylsilyl-4 dihydro-1,4 quinoléine (**5**, rdt. 82%).

De même, l'aromatisation de la tétrasilyl-1,2,3,4 tétrahydro-1,2,3,4 quinoléine, **2**, par l'oxygène de l'air conduit à la

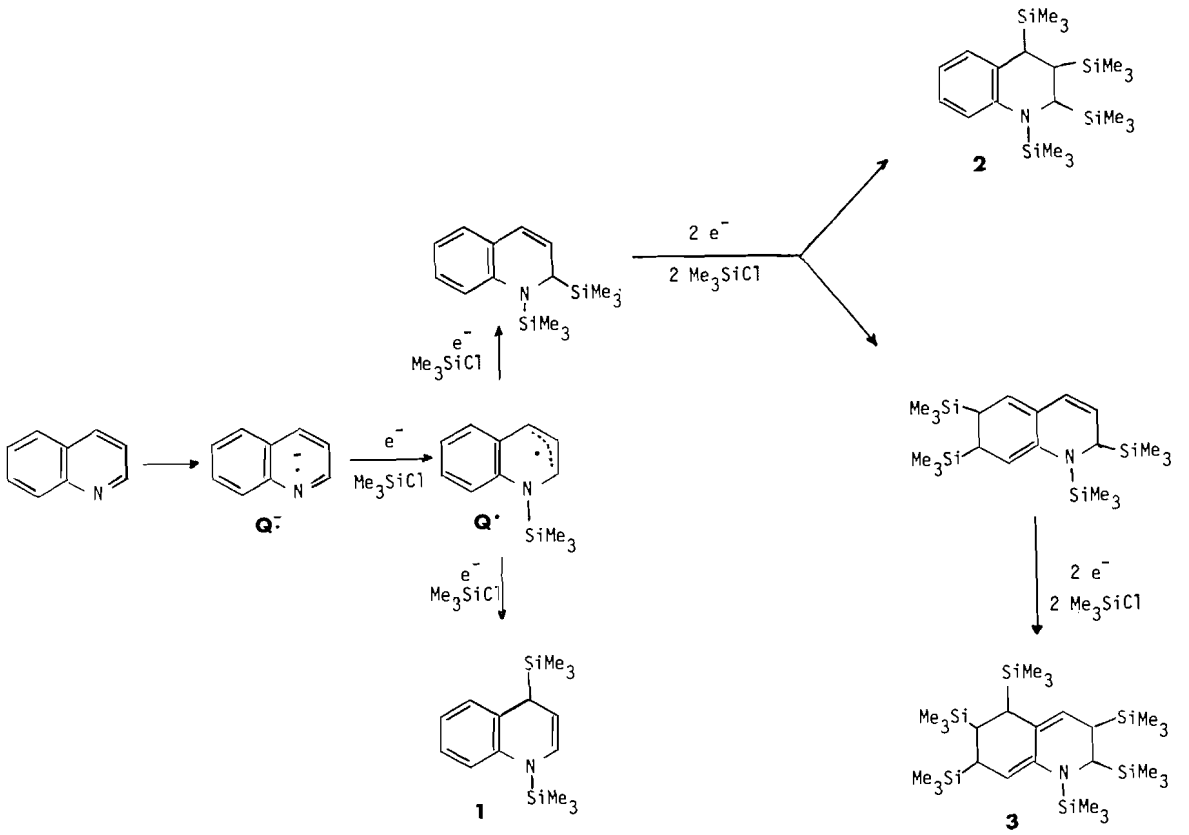

FIG. 1

TABLEAU 1. Influence de la quantité de réactif sur la silylation

(Li/Me_3SiCl) n° d'équivalents	Rdt en produits 1	2	3
2	30	10	15
3	40	15	20
4	44	16	30
6	40	15	40
12	10	13	70

triméthylsilyl-4 quinoléine, **4**, et non pas à son isomère **6**, comme on aurait pu s'y attendre (fig. 3). Pour le confirmer, nous avons synthétisé ce dernier (rdt. 20%) à partir de la bromo-3 quinoléine. À partir de la tétrakis-triméthylsilyl-1,2,3,4 tétrahydro-1,2,3,4 quinoléine, **2**, nous avons également isolé le dérivé **7** par méthanolyse de la liaison N—Si (rdt. quant.); son obtention nécessite d'opérer sous atmosphère parfaitement inerte faute de quoi il évolue, vers la triméthylsilyl-4 quinoléine, **4**. L'action du chlorure d'acétyle conduit au dérivé *N*-acétylé, **8** (rdt. 70%) (fig. 3). Notons que les composés **2**, **7** et **8** sont originaux.

La quinoléine hexasiliciée, **3**, est particulièrement fragile et évolue soit à l'air, soit par chauffage prolongé, soit enfin en présence de réactif à caractère acide (silice, chlorure d'acétyle) avec perte de silicium et aromatisation du cycle azoté. On isole ainsi les composés **9** et **10** avec un rendement global de 80–90% : **9**/**10** ~ 70 : 30 (fig. 4). Placé en solution dans l'éthanol absolu, le dérivé **3** se désilyle et conduit au composé **10** en quelques heures (rdt. 89%). Par ailleurs, l'addition

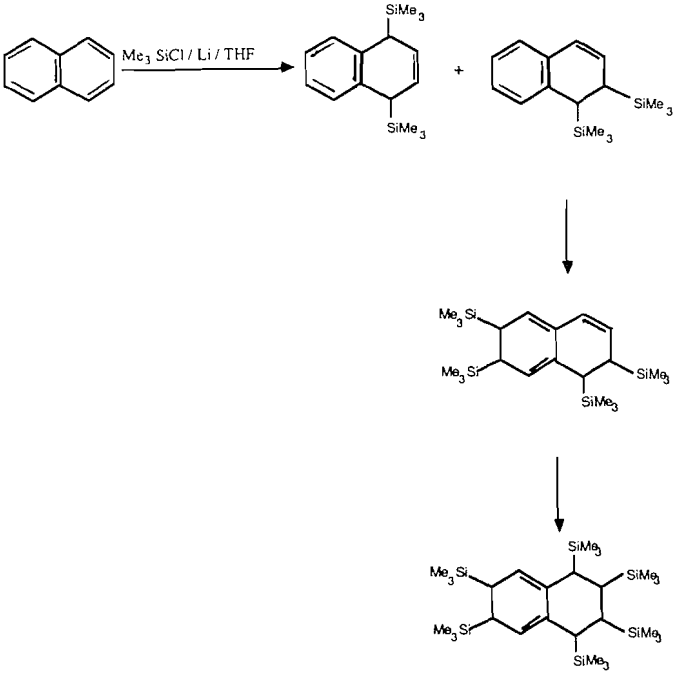

FIG. 2

d'éther provoque la formation d'un précipité que nous avons identifié au tétrakis-triméthylsilyl-2,5,6,7 tétrahydro-5,6,7,8 quinoléine (**11**, rdt. 80%) (fig. 4). Les produits **9**, **10** et **11** sont originaux et confirment la structure proposée pour le dérivé hexasilicié **3**. Il est vraisemblable que le composé **10** se forme à partir de l'intermédiaire **11** dont le groupe silyle en α de l'azote doit être labile en milieu acide. Le passage du composé

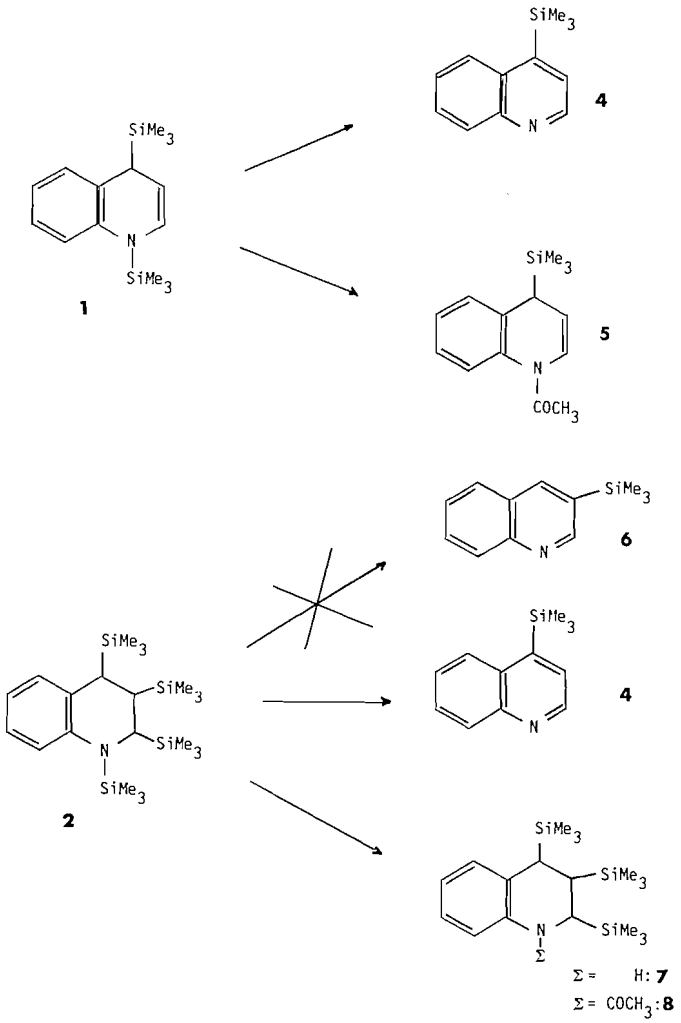

FIG. 3

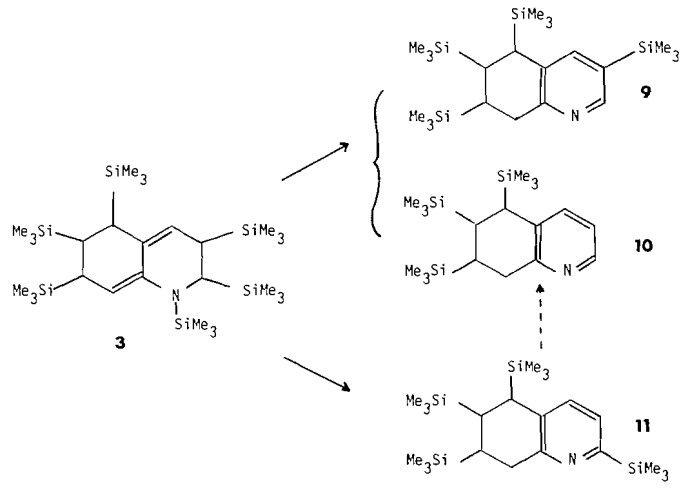

FIG. 4

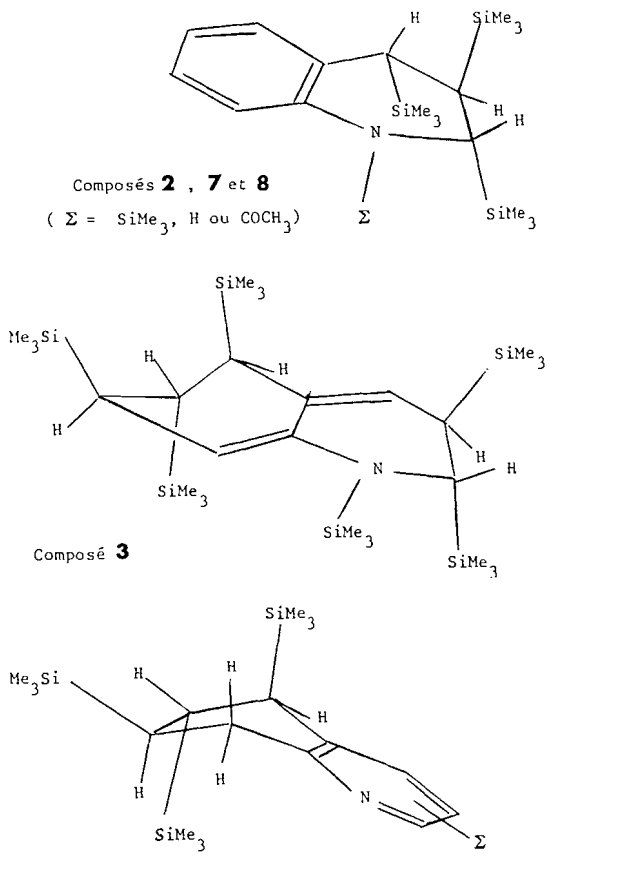

FIG. 5

3 au produit aromatique **11** en présence d'éther peut s'expliquer par la présence de traces d'eau, d'oxygène ou de péroxyde qui permettent une aromatisation douce du squelette.

Les structures spatiales de tous les dérivés obtenus ont été essentiellement déterminées par RMN ^1H et ^{13}C (tableaux 2–4). Ainsi dans le cas de la tétrakis-triméthylsilyl-1,2,3,4 tétrahydro-1,2,3,4 quinoléine, **2**, la présence de trois signaux couplés entre eux entre 1,9 et 3,1 ppm avec des intégrations correspondant à un proton, auxquels on associe les 3 CH observés en ^{13}C entre 30 et 47 ppm confirment l'enchaînement proposé. De plus, à partir des valeurs des constantes de couplage $^3J(^1H,^1H)$ et en utilisant la relation établie par Laguerre et coll.[3] dans le cas de cyclanes polysiliciés, $^3J = 11{,}5\cos^2\theta - 1{,}6\cos\theta + 0{,}6$, nous sommes en mesure de proposer les stéréochimies relatives de tous nos composés (fig. 5). Ces résultats montrent que les disilylations de type 1–2, conduisant à la fixation des siliciums sur les sommets 3 et 4 (composé **2**) et 6 et 7 (composé **3**), s'effectuent en *trans* alors que l'addition de type 1–4, conduisant au composé **3** (sommets 3 et 5), s'effectue en *cis*. Les contraintes stériques jouent vraisemblablement là un rôle important.

Partie expérimentale

Réaction de silylation

Nous avons utilisé du THF distillé sur sodium et benzophénone afin d'enlever les traces d'eau. Le lithium est préalablement granulé par fusion dans l'huile de vaseline puis lavé au THF. La réaction est conduite à la rampe à vide sous atmosphère d'argon. À une suspension de 0,2 at.g de lithium finement granulé, dans 150 mL de THF et 0,26 mol de Me_3SiCl fraîchement distillé, on ajoute goutte à goutte 0,1 mol de quinoléine de telle sorte que la température du milieu réactionnel soit maintenue entre 0 et 5°C. L'avancement de la réaction est suivi par CCM (SiO_2; hexane/EtOH : 80 : 20). Au bout de 5 h environ, on note la disparition du produit de départ. Le THF est alors évaporé à la rampe à vide. On ajoute ensuite 120 mL de cyclohexane, solvant dans lequel LiCl précipite ce qui permet de l'éliminer par filtration. Le filtrat est ensuite évaporé et redissout dans 120 mL de

cyclohexane afin d'éliminer les sels qui pourraient subsister. On obtient ainsi une huile jaune dont les constituants sont isolés par rectification à la rampe à vide.

Acétylation

Le chlorure d'acétyle (0,04 mol) préalablement distillé sur magnésium est additionné à 0,02 mol de substrat *N*-silylé. Le mélange est agité à température ambiante pendant 6 h. Puis le solvant et l'excès de chlorure d'acétyle sont éliminés à l'évaporateur rotatif. Le produit d'acétylation est ensuite purifié sur colonne de silice.

Les produits d'aromatisation **4**, **6** et **9–11** sont purifiés sur colonne de silice.

Caractéristiques physico-chimiques des produits obtenus

Les points de fusion ont été mesurés sur un appareil Mettler FP 61. Les analyses centésimales ont été effectuées au service central

Oxidation of substituted anilines by horseradish peroxidase compound II

JIN HUANG AND H. BRIAN DUNFORD
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2
Received March 5, 1990

JIN HUANG and H. BRIAN DUNFORD. Can. J. Chem. **68**, 2159 (1990).

The kinetics of oxidation of eight monosubstituted anilines catalyzed by horseradish peroxidase compound **II** has been studied at pH 7.00 and 7.60. With *p*-toluidine the rates of oxidation by compound **II** have been measured at 21 pH values between 3.60 and 10.25. The rate–pH profile indicates that an acidic form of compound **II** and the electrically neutral, unprotonated form of *p*-toluidine are reactive. The correlation of rate constants for the substituted anilines with the substituent constant σ in the Hammett equation suggests that the aromatic amine donates an electron to compound **II** in the rate-controlling step and loses a proton simultaneously. The value of ρ, the susceptibility factor in the Hammett equation, is -6.0 ± 0.7. The reactivity of anilines with HRP-II observed in this study is lower than that of anilines with HRP-I observed previously, although the value of ρ is the same within experimental error (D. Job and H. B. Dunford. Eur. J. Biochem. **66**, 607 (1976)). The difference in reactivity is explained by the relative complexities of the reactions of compounds **I** and **II**.

Key words: horseradish peroxidase, peroxidase compound **II**, aniline oxidation, Hammett correlation, enzymatic oxidation.

JIN HUANG et H. BRIAN DUNFORD. Can. J. Chem. **68**, 2159 (1990).

Opérant à des pH de 7,00 et de 7,60, on a étudié la cinétique de l'oxydation de huit anilines monosubstituées, catalysée par le composé **II** de la peroxydase du raifort (HRP-II). Pour la *p*-toluidine, on a déterminé les vitesses d'oxydation à 21 pH différents entre 3,60 et 10,25. La relation entre la vitesse et le pH indique que les formes réactives sont d'une part une forme acide du composé **II** et d'autre part la forme non-protonée et électriquement neutre de la *p*-toluidine. La corrélation des constantes de vitesse des anilines substituées avec la constante de substituant σ de l'équation de Hammett suggère que l'amine aromatique donne un électron au composé **II** dans l'étape qui détermine la vitesse et qu'elle perd simultanément un proton. La valeur de ρ, le facteur de susceptibilité de l'équation de Hammett, est égal à $-6,0 \pm 0,7$. La réactivité des anilines pour le HRP-II qui a été observée dans ce travail est plus faible que la réactivité des anilines pour le HRP-I qui a été observée antérieurement; la valeur de ρ est toutefois la même, aux erreurs expérimentales près (D. Job et H. B. Dunford. Eur. J. Biochem. **66**, 607 (1976)). La différence de réactivité est expliquée par les complexités relatives des réactions des composés **I** et **II**.

Mot clés : peroxydase du raifort, composé **II** de la peroxydase, oxydation de l'aniline, corrélation de Hammett, oxydation enzymatique.

[Traduit par la revue]

Introduction

The reaction of aromatic amines (and other organic substrates) with horseradish peroxidase (EC 1.11.1.7, donor–H_2O_2 oxidoreductase) may be summarized as follows (1–3):

[1] $\mathrm{HRP} + \mathrm{H_2O_2} \rightarrow \mathrm{HRP\text{-}I} + \mathrm{H_2O}$

[2] $\mathrm{HRP\text{-}I} + \mathrm{AH_2} \rightarrow \mathrm{HRP\text{-}II} + \cdot\mathrm{AH}$

[3] $\mathrm{HRP\text{-}II} + \mathrm{AH_2} \rightarrow \mathrm{HRP} + \cdot\mathrm{AH}$

Horseradish peroxidase and its two oxidized intermediates, compounds **I** and **II**, are represented by HRP, HRP-I, and HRP-II, respectively, the aromatic amines by AH_2, and their free radical product by $\cdot$AH. However, the general scheme above does not provide the details of events taking place on either the enzyme or the substrate during an oxidation process. Therefore a number of separate investigations have been conducted on HRP-catalyzed oxidation of various substrates to provide a better understanding and to explore the potential applications of peroxidatic action on specific substrates. Examples can be found in refs. 4 to 6.

The enzymatic oxidation of aromatic amines plays a significant role in many biotransformation processes such as chemical carcinogenesis and drug metabolism (7–9). Horseradish peroxidase in the presence of hydrogen peroxide is a useful tool for modeling the extra-hepatic biooxidation of xenobiotics (10, 11).

Substituent electronic effects are often used as a probe into the reaction mechanism of aromatic compounds. The Hammett equation provides a general description of substituent effects upon rates and equilibria of aromatic molecules (12):

$$[4] \quad \log\left(\frac{k_X}{k_H}\right) = \rho\sigma$$

where k_X and k_H denote rate or equilibrium constants for reactions of the substituted and unsubstituted compounds, respectively; σ is the substituent constant, determined by the nature and position of the substituent, and ρ is the reaction constant, also known as the susceptibility factor, which depends on the features and conditions of the reaction. A modified form of the Hammett equation with σ replaced by a different substituent constant σ^+ is known as the Brown–Okamoto equation. It can correlate reactions deviating from the Hammett equation because of the generation of positive charge capable of resonance interaction with a substituent (13). A linear correlation by the Hammett relationship is an indication that a single mechanism is operating through the reaction series.

The Hammett $\rho\sigma$ correlation was previously established in the oxidation of substituted anilines by compound **I** of HRP. Compounds **I** and **II** are two major intermediates in peroxidase reactions. It is therefore interesting to see whether the reactions between compound **II** of HRP and substituted anilines are also correlated by the Hammett equation, and if they are, how the correlation reflects the different structure and reactivity of compound **II** from those of compound **I**.

In this study, eight *para* or *meta* monosubstituted anilines were chosen to react with compound **II** of horseradish peroxidase. The rate–pH profile for one aromatic amine, *p*-toluidine, is also obtained. The Hammett relationship is employed to correlate the kinetic behaviors of the substituted anilines. The

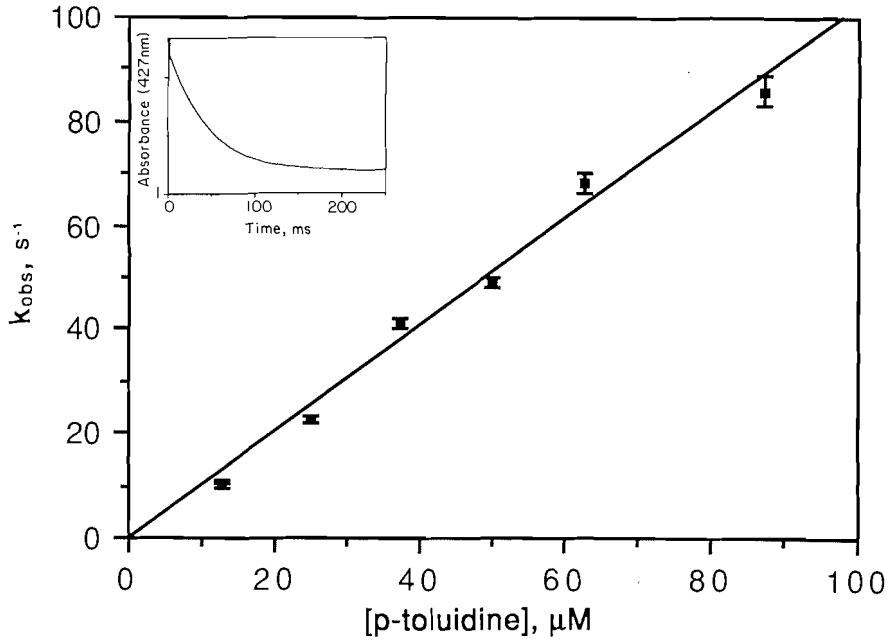

FIG. 1. Plot of k_{obs} versus *p*-toluidine concentration for the oxidation of *p*-toluidine by horseradish peroxidase compound **II**. The reactions were carried out in phosphate buffer, ionic strength 0.11 M; pH 7.60; [HRP-II], 1.0 μM; temperature 25.0°C. The inset shows an example of first order exponential trace (25 μM *p*-toluidine) from which k_{obs} was obtained.

different reactivity of anilines with compound **II** observed in this study compared to that of anilines reacting with compound **I** of HRP is discussed.

Experimental

HRP, grade I, purchased from Boehringer–Mannheim as an ammonium sulfate precipitate, was dialyzed against water deionized in a Milli-Q water purification system. After dialysis the RZ, the ratio of absorbance at 403 to 280 nm, was 3.28. The concentration of HRP was determined spectrophotometrically at 403 nm using a molar absorptivity of $1.02 \times 10^5\ M^{-1}\ cm^{-1}$ (14). Hydrogen peroxide was obtained as a 30% solution from Fisher. The concentration of diluted H_2O_2 stock solution was determined by peroxidase assay as described elsewhere (15). All the aromatic amines, obtained from various sources (*p*-aminophenol and *p*-toluidine from BDH, *p*-phenetidine and *m*-phenetidine from Eastman, aniline from Mallinckrodt, and 3-aminoacetophenone, 4-aminobenzoic acid, and sulfanilic acid from Aldrich), were of reagent grade and were used without further purification.

For each substrate, a stock solution of around 10 mM concentration was prepared by dissolving a weighed amount of the compound in volumetric flasks with purified water. All substrate solutions were stored in dark brown bottles to prevent photochemical reactions. The substrate solution for each experiment was then made by diluting the stock solution to the desired concentration with an appropriate buffer immediately before the measurement.

All buffer solutions had an ionic strength of 0.11 M, adjusted by adding 0.1 M KNO_3 as an inert salt. Acetate buffer was used between pH 3.60 and 5.39, phosphate buffer between pH 5.58 and 7.60, Tris buffer between pH 8.05 and 9.04, and carbonate buffer between pH 9.30 and 10.25. All pH measurements were made with a Fisher Accumet Model 420 digital pH meter which was calibrated with standard buffers from Fisher.

Kinetic measurements for three substrates (3-aminoacetophenone, 4-aminobenzoic acid, and sulfanilic acid) were performed on a Cary 219 spectrophotometer while the kinetic measurements for other substrates were made on a Photal (formerly Union Giken) stopped-flow spectrophotometer Model RA-601. The 1-cm observation cells of both spectrophotometers were thermostated at 25.0°C for all measurements.

The enzyme concentration for all kinetic measurements was 1 μM, prepared with appropriate buffers. At least a 10-fold excess of substrates was used to maintain pseudo-first-order conditions.

HRP-II solution was freshly prepared prior to the experiments by addition of one equivalent of H_2O_2 and one equivalent of $K_4Fe(CN)_6$ to the native HRP solution. To ensure that no HRP-I was present, the preparation of HRP-II was monitored at 411 nm, the isobestic point between native HRP and HRP-II. No change in absorbance was observed. After the absence of HRP-I had been established, the HRP-II reactions were monitored at 427 nm, where the maximum difference in absorbance between native HRP and HRP-II is expected.

For stopped-flow experiments one drive syringe was filled with HRP-II solution and the other was filled with the substrate solution. Between five and eight traces were collected for each substrate concentration. The relative standard deviation was below 5% in most cases and never beyond 10%. For measurements with the Cary spectrophotometer, 3 mL of freshly prepared compound **II** solution was pipetted into the observation cell. The reference cuvette was filled with purified water. The reaction was initiated by adding a calculated volume of the substrate solution into the cell containing HRP-II. The instrument was started immediately after the addition of the substrate. Measurements of relative absorbance at regular time intervals from the recorded trace followed by a nonlinear least-square analysis on computer gave the observed pseudo-first-order rate constants.

Results

With substrate in excess of HRP-II, pseudo-first-order kinetics was observed. One example is shown in the inset of Fig. 1. The corresponding differential rate expression is

$$[5] \quad -\frac{d[\text{HRP-II}]}{dt} = k_{obs}[\text{HRP-II}]$$

where k_{obs} is the observed pseudo-first-order rate constant. The apparent second order rate constant, k_{app}, is related to k_{obs} by the equation

$$[6] \quad k_{obs} = k_{app}[AH_2]$$

where $[AH_2]$ is the substrate concentration. Values of k_{app} were then obtained from the slopes of plots of k_{obs} versus $[AH_2]$, as shown by an example in Fig. 1.

A plot of log k_{app} versus pH is shown in Fig. 2 for the oxidation of *p*-toluidine by HRP-II. It appears from Fig. 2 that

[a]Value (pH 7.60) reported in ref. 22.

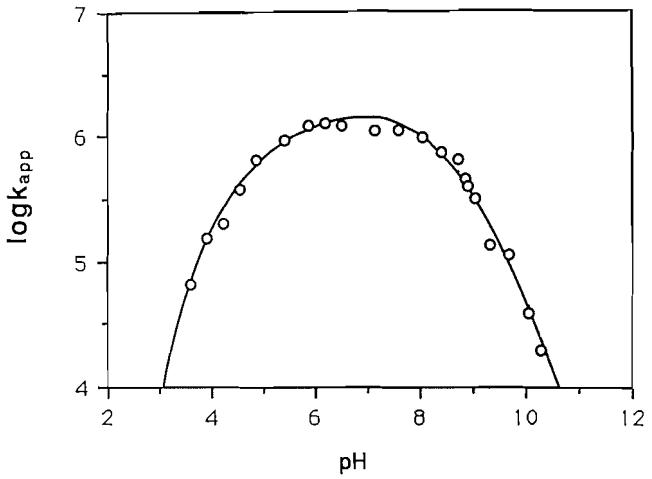

FIG. 2. The rate–pH profile for the reaction of horseradish peroxidase compound **II** with *p*-toluidine at 25.0°C and ionic strength 0.11 M. The curve was computed on the basis of best-fit parameters obtained by a nonlinear least-square analysis of the data with eq. [8].

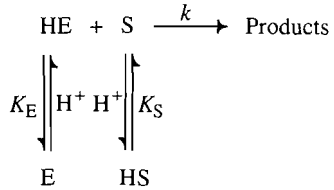
two ionizations which affect the kinetics of the reaction are occurring.

The Hammett plot of log (k_X/k_H) versus σ (see eq. [4]) is shown in Fig. 3. The second order rate constants at pH 7.60 and pH 7.00 along with the Hammett σ values of different substrates, are listed in Table 1. Values of k_{app} used to construct the plot are averages of values obtained at the two pH's. The purpose of conducting measurements at two different pH's is to confirm that k_{app} values for the Hammett plot were measured in such a region where the substituent effect, instead of the pH effect, is predominant. As can be seen from Table 1, the k_{app} values at two pH's are the same within experimental error.

The slope of the Hammett plot in Fig. 3 is equal to ρ in the Hammett equation. The value of ρ is -6.0 ± 0.7.

Discussion

The simplest mechanism which will account for the experimental data is one in which the neutral unprotonated amine reacting with an acidic form of the enzyme:



[7]

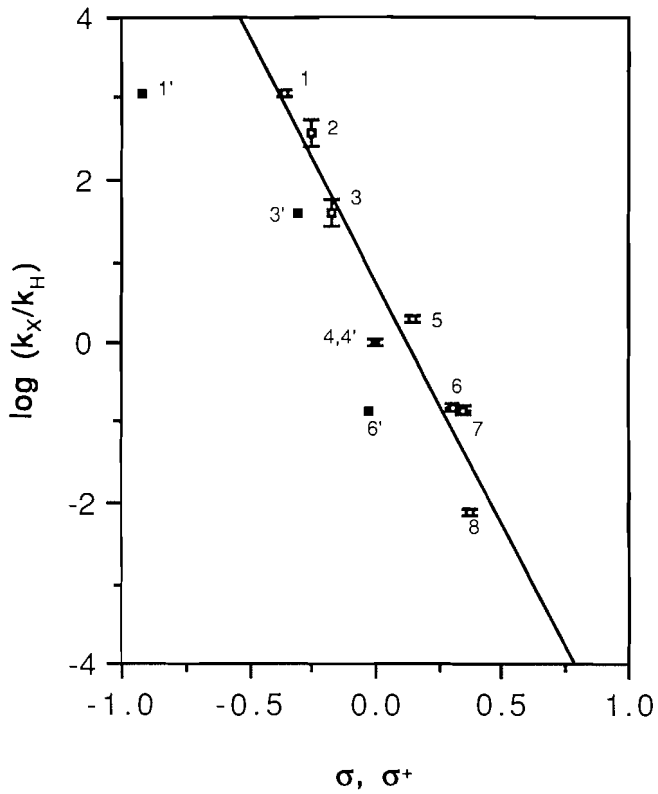


FIG. 3. Hammett plot (□) and Brown–Okamoto plot (■) for the oxidation of various *p*- and *m*-substituted anilines by horseradish peroxidase compound **II**. k_X is the rate constant for the substituted aniline and k_H for aniline. The σ values are those listed in Table 1 and the σ^+ values are those obtained by Brown and Okamoto (13). Substituent groups: (1,1′) *p*-OH; (2) *p*-OC_2H_5; (3,3′) *p*-CH_3; (4,4′) H; (5) *m*-OC_2H_5; (6,6′) *m*-$COCH_3$; (7) *p*-COO^-; (8) *p*-SO_3^-.

The k_{app}–pH relationship corresponding to eq. [7] can be described as follows:

$$[8]\quad k_{app} = \frac{k}{\left[1+\frac{K_E}{[H^+]}\right]\left[1+\frac{[H^+]}{K_S}\right]}$$

Using nonlinear least-square analysis, the experimental log k_{app} – pH data points shown in Fig. 2 were fitted to eq. [8]. The best-fit parameters are $k = (1.2 \pm 0.1) \times 10^6$ M^{-1} s^{-1}; $K_E = (2.8 \pm 0.3) \times 10^{-9}$ M, $pK_E = 8.6 \pm 0.1$; $K_S = (1.5 \pm 0.2) \times 10^{-5}$ M, $pK_S = 4.8 \pm 0.1$. The curve computed on the basis of the best-fit parameters is also shown in Fig. 2. Previous studies on

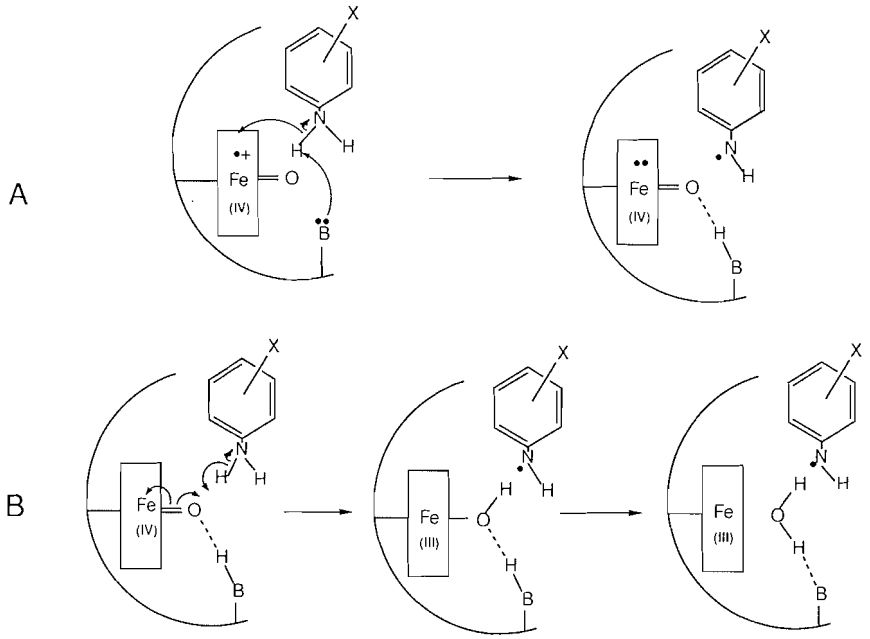

FIG. 4. Schematic representation of relative complexities of compound **I** and compound **II** reactions. (*A*) Relatively simple reaction of compound **I** with anilines. An electron is transferred to the porphyrin ring (represented by the rectangle) neutralizing the π-cation radical of compound **I**. (*B*) Relatively complicated reaction of compound **II** with anilines. An electron is transferred to iron(IV) and two protons are transferred to the ferryl oxygen atom forming a water molecule as the leaving group.

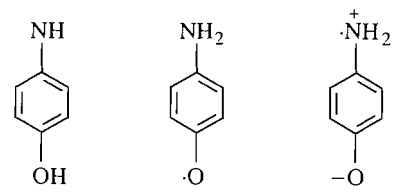
HRP-II reactions with different substrates have proved the existence of an acid–base group on the enzyme with a pK_a value of 8.6 so that our present results are in excellent agreement (5). The pK_{BH+} of *p*-methyl anilinium ion (protonated *p*-toluidine) was reported to be 5.08 in water at 25°C (18), which can be corrected for this study by considering ionic strength in terms of the extended Debye–Hückel equation (19). The pK_{BH+} so corrected is 4.97. Similarly there is a good agreement between our pK_S value computed from the kinetic results and the literature value for the ionization of protonated *p*-toluidine.

The adherence to the Hammett equation for *para* or *meta* monosubstituted anilines, as can be seen from Fig. 3, shows that all of the anilines react with compound **II** by the same mechanism. One conclusion can be drawn immediately, that is, the neutral forms of the anilines are reacting in all aniline oxidations by compound **II**. A negative slope of the Hammett plot indicates that electron-donating groups, as we expected, facilitate the oxidation of anilines. This suggests that the removal of one electron from a substrate is the rate-controlling step in the oxidation of anilines. The loss of one electron from a substrate is accompanied by the simultaneous loss of a proton, so that a positive charge at the reaction site is not formed. The experimental data are better correlated by the Hammett $\rho\sigma$ relationship, instead of the Brown–Okamoto $\rho\sigma^+$ relationship (the correlation coefficients in the two cases are 0.931 and 0.887, respectively). The plot of rate constants against σ^+ values can be seen in Fig. 3. Unfortunately, some of the relevant σ^+ values are not available in the literature. A mechanism similar to ours has been suggested by different authors (20–23).

There have been discussions about the *p*-aminophenol oxidation by HRP as to whether it reacts as a substituted aniline or as a substituted phenol (21), in other words, whether the one electron oxidation and proton abstraction occur from the amino group, yielding free radical **1** or from the hydroxyl group, yielding free radical **2**.



1 **2** **3**

Though **2** was cited as an oxidation product (24), there is evidence suggesting the oxidation occurs at the amino group. In oxidation by compound **I**, the rate constant for *p*-aminophenol seems to fit the Hammett plot for the aniline series. However, this could result from the oxidation on the hydroxyl group being retarded by partial diffusion control (21). Later studies on reactions between phenols and compound **II** showed the obvious deviation of *p*-aminophenol from the Hammett plot of the phenol series, favoring the possibility of *p*-aminophenol reacting as a substituted aniline (22). An ESR study of HRP-catalyzed oxidation of *p*-aminophenol performed under alkaline conditions demonstrated that the one electron oxidation product is a zwitterion radical **3** with the electron removed from the amino group (25). The fit of the data for *p*-aminophenol to the Hammett plot for anilines in this study also suggests that the removal of an electron and a proton takes place at the amino group instead of at the hydroxyl group. This is interesting considering the fact that the reactivity of anilines is generally lower than that of phenols.

Compared with the ρ value[1] of -7.0 ± 0.7 for the reaction of anilines with compound **I**, the ρ value obtained in this study for the reaction of anilines with compound **II** is -6.0 ± 0.7. Thus the substituent susceptibility of compound **II** reactions is the same within experimental error as that observed for the

[1]Standard deviations are calculated based on the original data in ref. 21.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

corresponding compound **I** reactions. This is in contrast with the results for phenols[1] where ρ is -6.9 ± 0.5 for compound **I** (21) and -4.6 ± 0.5 for compound **II** (22). In an independent work, published since this manuscript was first submitted, a ρ value of -5.75 was obtained for substituted anilines reacting with HRP-II, in close agreement with our results presented here (23). In their work mainly different substituted anilines were used. As another comparison, the rate constants of anilines reacting with HRP-II obtained in this study are about one order of magnitude lower than those of anilines reacting with HRP-I (21). A proposed mechanism for anilines reacting with both compound **I** and compound **II** is depicted in Fig. 4. It is widely accepted that compound **I** is a porphyrin π-cation radical (26). During the oxidation of anilines by compound **I**, the aromatic electron-deficient compound **I** acts as the direct target for an electron donated from amines (27, 28). While in the case of compound **II** reactions, in addition to the transfer of an electron to Iron(IV), two protons are also transferred to the ferryl oxygen forming a water molecule which leaves from the inner coordination sphere of the iron (29). This comparison indicates that the reduction of compound **II**, which involves more bond-breaking and bond-formation steps, is a more complicated chemical process than the reduction of compound **I** (29). This explains a lower order-of-magnitude in the reactivity of anilines with HRP-II than with HRP-I.

The absorption spectra, fluorescence spectra, fluorescence lifetimes, fluorescence quenching, phosphorescence spectra, phosphorescence lifetimes, and picosecond transient absorption spectra of several purinyl-pyridinium salts have been measured in several solvents at room temperature and in ethanol glasses at 77 K. It is concluded that the previously observed photochemical transformation of *N*-[9-(2′,3′,5′-tri-*O*-acetyl-β-D-ribofuranosyl)purin-6-yl]pyridinium chloride **1** into the highly fluorescent tri-*O*-acetylluminarosine **6** occurs via an excited triplet state. It is also shown that intersystem crossing in purinyl-pyridinium salts is induced by an intermolecular charge-transfer interaction with the counter ions.

Key words: purinyl-pyridinium salts, fluorescence, phosphorescence.

BOHDAN SKALSKI, STEFAN PASZYC, RYSZARD W. ADAMIAK, RONALD P. STEER et RONALD E. VERRALL. Can. J. Chem. **68**, 2164 (1990).

Opérant dans divers solvants à la température ambiante et dans des verres dans l'éthanol à 77 K, on a mesuré les spectres d'absorption, les spectres de fluorescence, les temps de vie de fluorescence, la désactivation de la fluorescence, les spectres de phosphorescence, les temps de vie de phosphorescence et les spectes d'absorption des transitions de picosecondes de plusieurs sels purinyl-pyridinium. On en conclut que la transformation photochimique qui n'avait pas été rapportée antérieurement du chlorure de *N*-[9-(2′,3′,5′-tri-*O*-acétyl-β-D-ribofuranosyl)purin-6-yl]pyridinium (**1**) en tri-*O*-acétylluminarosine (**6**) qui est très fluorescent se produit par le biais d'un état triplet excité. On démontre aussi que la transition intersystème dans les sels de purinyl-pyridinium est induite par une interaction de transfert de charge intermoléculaire avec les contre-ions.

Mots clés : sels de purinyl-pyridinium, fluorescence, phosphorescence.

[Traduit par la revue]

Introduction

Pyridinium salts derived from nucleic acid bases (1, 2) are of interest because they are involved in side processes in oligonucleotide synthesis (1, 3, 4) and are valuable intermediates in the nucleoside chemistry (5, 6). As part of an ongoing investigation of the photochemistry of a series of purinyl-pyridinium cations **1**–**5** (Fig. 1), we reported recently (7, 8) the photochemical transformation of *N*-[9-(2′,3′,5′-tri-*O*-acetyl-β-D-ribofuranosyl)purin-6-yl]pyridinium chloride, **1**, into tri-*O*-acetylluminarosine **6**. The latter compound is highly fluorescent and is therefore of particular interest for the possible use as a fluorescent, molecular probe in nucleic acids (24).

In the course of these experiments we also attempted to convert other purine-derived pyridinium salts into related analogs of luminarosine using similar methods and conditions. However, these initial attempts were unsuccessful, as salts **3**, **4**, and **5** appeared to be photochemically stable, and only traces of the desired analog of luminarosine could be detected after prolonged irradiation of **2**. The results of these experiments suggest that the photochemical reactivity of purinyl-pyridinium salts apparently depends strongly upon the nature of the substituents in the purine moiety and prompted us to investigate further the photophysical properties of these compounds (9).

We have shown previously that excitation of the ground state cation of *N*-(purin-6-yl)pyridinium chloride, **1**, results in proton transfer to give a photochemically stable, excited zwitterion (10). In this paper, we report the results of a detailed photophysical study of several purinyl-pyridinium salts in aqueous and non-aqueous solutions at room temperature and in ethanol glasses at 77 K. The results provide both a better understanding of the differences between the photochemical reactivity of pyridinium cations **1**–**5** and the basis for more detailed mechanistic studies (25).

Experimental

Materials

Spectrograde ethanol (95%) (Merck) and HPLC grade methanol and acetonitrile (BDH Omnisolv) were used as received. Water was purified using a Millipore Super-Q system. The pyridinium salts, *N*-[9-(2′,3′,5′-tri-*O*-acetyl-β-D-ribofuranosyl)purin-6-yl]pyridinium chloride, **1**; *N*-(9-methylpurin-6-yl)pyridinium chloride, **2**; *N*-(purin-6-yl)pyridinium chloride, **3**; *N*-[2-isobutyramido-9-(2′3′5′-tri-*O*-acetyl-β-D-ribofuranosyl)purin-6-yl]pyridinium chloride, **4**; and *N*-(2-amino-purin-6-yl)pyridinium chloride, **5**, were synthesized and purified according to procedures described previously (1, 2). The purity of these compounds was checked by HPLC techniques using a reversed phase column (Delta Pak C-4, Waters-Millipore), and eluting isocratically with a water–acetonitrile mixture (5:1, v/v) containing 0.25 M ammonium acetate.

Methods

Steady state absorption and fluorescence spectra were recorded in 1 cm quartz cuvettes, using Cary (Varian) 118 and Spex Fluorolog 222 spectrophotometers, respectively. The concentrations of the solutions for the fluorescence measurements were adjusted so that the absorption at the excitation wavelength did not exceed 0.05. Low temperature

(77 K) fluorescence and phosphorescence emission, excitation and excitation polarization spectra were measured in rigid ethanol glasses in a quartz tube of 5 mm path length using a quartz Dewar – cold finger assembly. Background emissions from the Dewar and solvent alone were found to be insignificant. The emission and emission excitation spectra were corrected with the aid of a Spex Datamate computer. Fluorescence quantum yields were determined as described previously (11), using quinine sulphate (ϕ_f = 0.51 in 0.1 N H_2SO_4) (12) as a standard.

Fluorescence lifetimes were measured using a mode-locked, synchronously-pumped, cavity-dumped, frequency-doubled, picosecond dye laser excitation system. Details of this and the time-correlated, single-photon counting detection system have been reported elsewhere (13). Phosphorescence lifetimes were measured by exciting samples with a single 308 nm pulse from a Lumonics HyperEX-400 XeCl excimer laser and observing the decays with a Tektronix 7704 A oscilloscope equipped with a programmable digitizer. Measurements of the transient absorption spectra were performed at the Canadian Center for Picosecond Laser Flash Photolysis, Concordia University, Montreal. Samples were excited with either the third (355 nm) or the fourth (266 nm) harmonic of a double-beam, passively mode-locked Nd-YAG laser system (14). The energy of the excitation pulse varied between 1.1 and 1.5 mJ, and the pulse width was ca. 30 ps.

Results and discussion

The uv–visible absorption and fluorescence emission spectra of pyridinium salts **1**, **2**, **4**, and **5** in water are shown in Fig. 2. Data consisting of their long-wavelength absorption maxima, fluorescence maxima, fluorescence quantum yields, and excited state lifetimes in water, acetonitrile, and methanol are compiled in Table 1.

The absorption spectra show two relatively strong transitions in the 250–400 nm range (cf. Fig. 2A). The lower energy

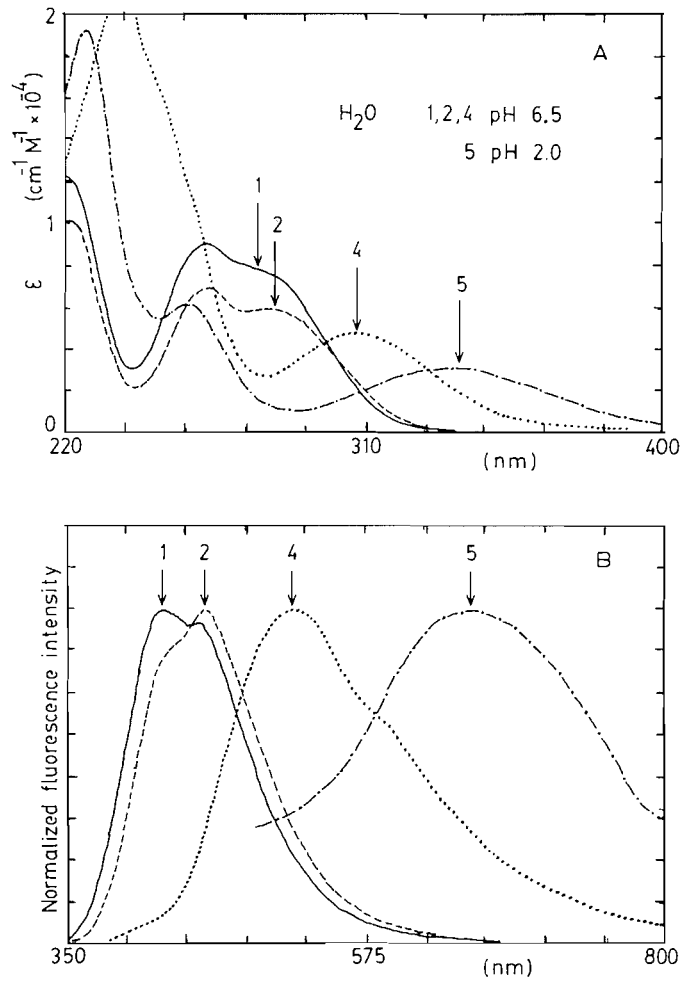

FIG. 2. Ultraviolet–visible absorption (*A*) and fluorescence emission (*B*) spectra of salts **1**, **2**, **4**, and **5** in water. The samples were excited at 310 nm (**1**, **2**, and **4**) and 340 nm (**5**).

transition, the position of which strongly depends on the nature of the substituent in the purine moiety, has a considerable degree of charge-transfer (CT) character. It results from the intramolecular interaction between the purine part (donor) and the positively charged pyridinium ring (acceptor) of the two coplanar (15) π-electronic systems. In the case of salts **1** and **2**, these CT transitions overlap strongly with the higher energy absorption bands (λ_{max} at 255–260 nm) and are only visible as shoulders. In the case of salts **4** and **5**, the CT bands are significantly red-shifted and are well-separated from the adjacent higher energy absorptions. The difference in energies of the CT transitions of **4** and **5** compared with **1** and **2** is consistent with the greater electron-donating power of these purines containing 2-isobutyramido and 2-amino substituents.

In the case of salt **5**, a pH-dependent absorption similar to that reported previously (10) for *N*-(purin-6-yl)pyridinium chloride, **3**, is observed (Fig. 3). We assign this effect of pH to the existence of a ground state prototropic equilibrium (cation ⇄ zwitterion) characterized by an isosbestic point at 380 nm, similar to that previously found in **3**. However, the estimated ground state p*K* of **5**, p*K* = 7.8, is an order of magnitude higher than that of **3** (p*K* = 6.7) (10), reflecting the incremental electron donating effect of the 2-amino substituent in the former.

The fluorescence spectra of **1**–**5** are characterized by broad,

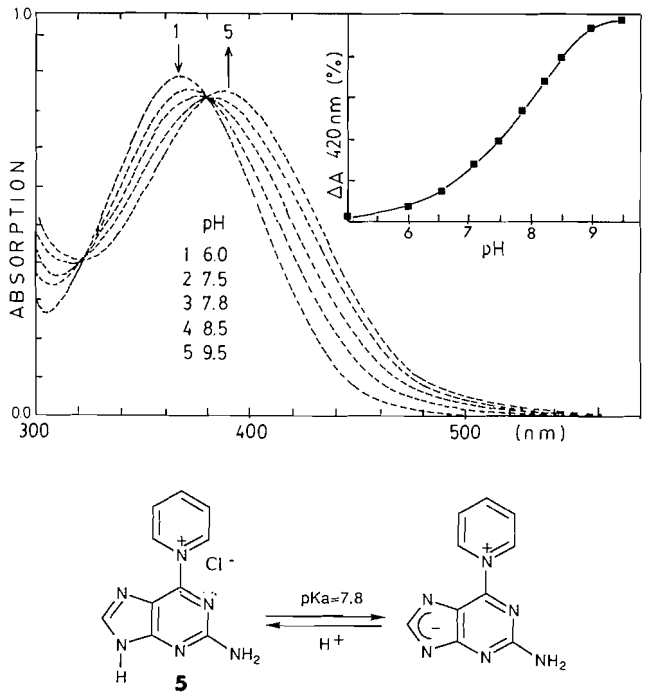

FIG. 3. The ground state prototropic equilibrium and pH dependence of the absorption spectra of salt **5** (2.9×10^{-4} M). The inset shows the corresponding "titration" curve from which the value of $pK_a = 7.8$ is determined.

structureless bands (Fig. 2*B*) which exhibit large Stokes shifts. The fluorescence spectrum of **5**, which exhibits the largest Stokes shift, does not change over the pH range 2.0–9.0. Because its ground state pK is 7.8, excitation of both the ground state cation of **5** at pH < 5 and its ground state zwitterion at pH $\simeq 9$ must therefore produce the same fluorescent species. We conclude that the excited cation is very short-lived under these conditions, and yields the zwitterion quantitatively. The excited state pK of the cation must therefore be less than 2.

The results in Table 1 show that both the absorption and fluorescence spectra of salts **1–5** exhibit a negative solvatochromism, i.e. the transition energies decrease with decreasing solvent polarity. The dipole moments of both the cations and zwitterions of these molecules must therefore be smaller in their excited, S_1, states than in their ground, S_0, states. Similar solvent effects are commonly encountered in pyridinium betaines (16) and other, similar molecules (17) which exhibit intramolecular charge transfer.

The fluorescence quantum yields and lifetimes of these salts vary considerably with the nature of the substituent on the purine ring. The rate constants for radiative (k_f) and total non-radiative (Σk_{nr}) decay of the S_1 states of these compounds may be calculated from $k_f = \phi/\tau$ and $\Sigma k_{nr} = (1 - \phi)/\tau$. The values of k_f and k_{nr} reveal that the largest part of the variations in lifetime and quantum yield with both solvent and molecular structure is due to the differences in their non-radiative decay rates. For the photochemically unreactive compounds, **2–5**, Σk_{nr} increases in the order **2** < **3** < **4** < **5** which correlates with the increasing electron-donating ability of the purine moieties of these molecules. The quantum yields of compounds **4** and **5** are very low and the estimated non-radiative rate constant of **5** is of the order of $10^{10}\,s^{-1}$ in water.

There are at least three different possible mechanisms of intramolecular non-radiative relaxation of the $S_{1,ct}$ states of these molecules; (*i*) intersystem crossing to the triplet state, (*ii*) reversible intramolecular electron-transfer proceeding to the ground state via the intermediate cation diradical, similar to that observed in *N*-prenylquinolinium and -pyridinium salts (18), and (*iii*) rapid torsional relaxation, a mechanism which is known to operate in a number of intramolecular CT complexes of the molecular rotor type (19). Taking into account the results of transient absorption and low temperature emission measurements (*vide infra*), the major mode of non-radiative deactivation of the $S_{1,ct}$ state of salt **1** appears to be intersystem crossing, while deactivation via reversible, intramolecular electron transfer and/or the torsion of pendant substituents are probably the major non-radiative decay paths of **4** and,

especially, **5**. The total non-radiative decay constants of salts **1** and **2** are considerably larger in methanol than in either water or acetonitrile (cf. Table 1). This, together with the observation of rapid photodegradation of these samples in methanol, suggests that the quenching in methanol is due to an electron-transfer-mediated photochemical process, similar to that observed for various iminium salts and related *N*-heteroaromatic cations (electron acceptors) and alcohols (electron donors) (20).

Fluorescence quenching

We previously observed (9) that the photochemical transformation of **1** into luminarosine, **6**, is strongly affected by the presence of small amounts of some inorganic salts. In the case of sodium iodide the formation of **6** was almost completely suppressed at concentrations of NaI as low as 10^{-5} M. Bearing in mind this observation, we examined the quenching of the fluorescence of **1–3** by various counter ions (I^-, Br^-, Cl^-, and SO_4^{2-}) in water using $NaClO_4$ to maintain the solutions at constant ionic strength. Stern–Volmer plots for the quenching of **1** are shown in Fig. 4. The Stern–Volmer plot for the fluorescence quenching by I^- obtained from lifetime measurements (τ_0/τ vs. $[I^-]$) is perfectly linear over the whole range of I^- concentrations used, whereas those from steady-state experiments (ϕ_0/ϕ vs. $[I^-]$) show a distinct, upward curvature (cf. Fig. 4). This points to a substantial contribution of static quenching to the overall quenching process (21). Some degree of ion pairing in the ground state is thus indicated.

The results of the quenching studies show that at a concentration of 10^{-5} M, NaI has practically no effect on the fluorescence emission of **1**. From this observation one may conclude that the formation of **6** involves an intermediate state with a lifetime which is much longer than that of the singlet. The most likely candidate is the excited triplet state, and this is confirmed by transient absorption studies (*vide infra*).

It is also interesting to note that the efficiency of quenching decreases with increasing oxidation potential of the ions ($I^- > Br^- > Cl^- > SO_4^{2-}$; Fig. 4), and with decreasing electron accepting power of the pyridinium salts. Values of the Stern–Volmer constants, K_{SV}, and the calculated quenching constants, k_q ($k_q = K_{SV}/\tau_0$), for quenching of the fluorescence of **1–3** by NaI are collected in Table 2. These results are consistent with quenching via electron transfer (22), a conclusion which is further supported by the results of low temperature studies (*vide infra*). However, collisional deactivation, especially in the case of **3**, can not be ruled out at this time.

Low temperature studies

The low temperature emission, excitation and fluorescence polarization spectra of salts **1–5** were recorded at 77 K in solid ethanol glasses. Salts **1–4** exhibit both fluorescence and phosphorescence. For these compounds the fluorescence emission spectra (F) were obtained by recording the total luminescence (L) and the phosphorescence (P) spectra separately and then subtracting the latter from the former, after normalization in the

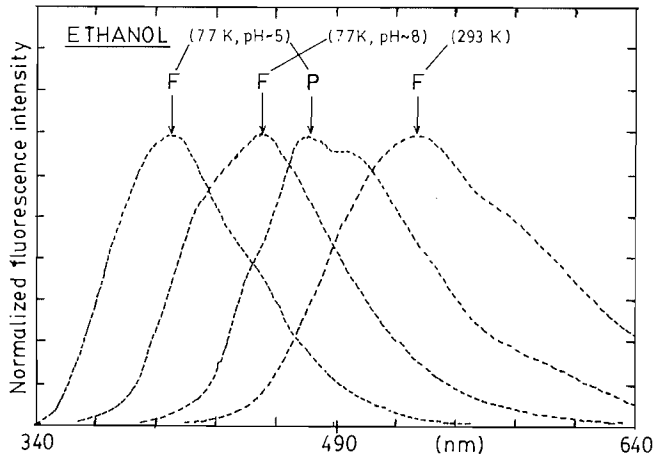

FIG. 6. Normalized, low-temperature fluorescence and phosphorescence spectra of salt **3** compared with its room-temperature fluorescence emission spectrum.

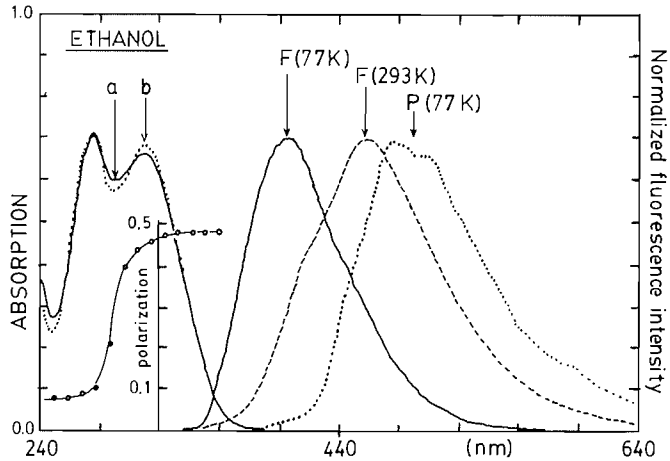

FIG. 7. Comparison of the room-temperature (293 K) absorption, a, and fluorescence emission, F, spectra of **2** with its low temperature (77 K) phosphorescence excitation, b, fluorescence emission, F, and phosphorescence emission, P, spectra. Inset: fluorescence – polarization excitation spectrum.

long wavelength spectral region. The results for **1** are shown in Fig. 5. The ratios of the quantum yields of phosphorescence to that of fluorescence, ϕ_p/ϕ_f, were then estimated from the areas under the appropriate emission curves. These data are summarized in Table 3, together with other useful spectroscopic and photophysical quantities.

The phosphorescence of salt **3** only appeared when its solution was acidified (before freezing) with $HClO_4$ to pH $\simeq$ 5. At this pH, **3** exists entirely in the protonated (cationic) form, and since the excited state proton transfer reaction is completely quenched upon freezing, the observed phosphorescence must be due entirely to the cation triplet. Increasing the pH of the solution to pH $\simeq$ 8 results in the complete disappearance of the phosphorescence, and the appearance of a new, red-shifted fluorescence (cf. Fig. 6). At this pH, **3** exists entirely in the zwitterionic form, and we therefore assign this new fluorescence to the excited zwitterion. No phosphorescence could be detected from **5** with our instrument.

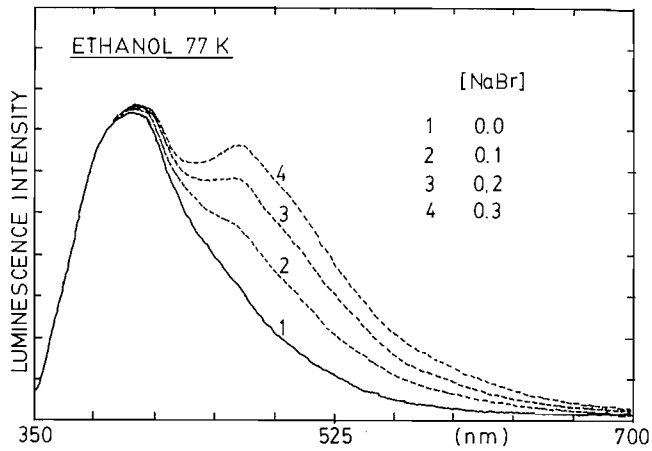

FIG. 8. The effect of sodium bromide on the low-temperature luminescence of salt **1**. Spectra are normalized at short wavelength spectral region.

The phosphorescence spectra exhibit some vibrational structure, whereas the fluorescence is structureless. In each case the fluorescence bands at 77 K are markedly blue-shifted compared to those obtained at room temperature (cf. Figs. 6 and 7). Both the low-temperature fluorescence excitation (not shown) and phosphorescence excitation spectra match the corresponding room-temperature absorption spectra very well (cf. Fig. 7). The fluorescence – polarization excitation spectra yield large values of the polarization (close to the upper limit of 0.5), which are constant across the long-wavelength absorption bands (cf. Fig. 7, inset). The absorption and fluorescence emission transition moments are therefore colinear and one may conclude that the lowest energy absorption bands are associated with only one electronic transition.

The most photochemically reactive salt, **1**, has the highest value of ϕ_p/ϕ_f, and this ratio appears to depend upon the extent of intramolecular CT interaction, i.e., it decreases with increasing intramolecular CT character of the molecule. Note in this regard that both **5** and the zwitterion of compound **3** are essentially non-phosphorescent. The enhancement of the intersystem-crossing rate in salts which exhibit a weaker intramolecular CT interaction (especially **1**) can be qualitatively rationalized by considering the intermolecular interaction with the counter ions. Figure 8 shows that, in the case of **1**, the ϕ_p/ϕ_f ratio increases significantly upon addition of sodium bromide to the solution before freezing. The same effect, albeit to a smaller extent, occurs in **2** and the cationic form of **3**. For the zwitterionic form of **3**, **4**, and **5**, the addition of up to 0.3 M NaBr had practically no effect on their low temperature luminescence spectra. We conclude that intersystem crossing in the excited purinyl-pyridinium salts is induced by interaction with the counterions, and that this process proceeds via *inter*molecular CT rather than by a heavy atom effect. High triplet yields following the charge-transfer quenching of fluorescence have been also reported for some aromatic molecules (23). It is reasonable to expect that intermolecular CT interaction will dominate in those salts which exhibit weaker intramolecular charge transfer interactions, thus leading to higher triplet yields in these compounds.

Transient absorption spectra

The transient absorption spectra of salts **1**–**3** are shown in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

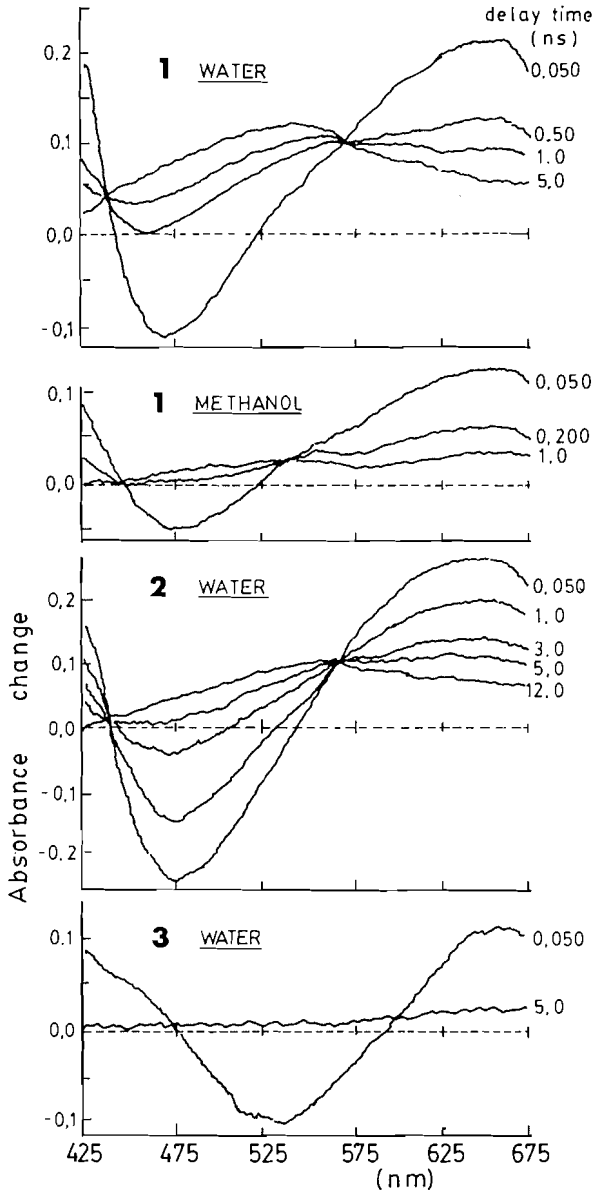

FIG. 9. Picosecond transient-absorption spectra of salts **1**, **2**, and **3**. The solvent and the delay times for each compound are given in the figure.

Fig. 9. The spectra, measured immediately after excitation, show broad absorption signals in the region 625–675 nm and negative signals at ca. 470 nm for **1** and **2**, and 525 nm for **3**. For each compound the negative and positive bands disappear at the same rate, rates which are identical (within an experimental uncertainty of ca. 25%) to the previously measured rates of fluorescence decay of the same molecules (cf. Table 1). Thus, the spectra taken at a delay of 50 ps can be safely assigned to the fluorescent state in each case. The negative signals are due to spontaneous emission while the positive ones are due to singlet–singlet absorption by the S_1 state. For salts **1** and **2** in water the decrease in the singlet–singlet absorption is accompanied by the growth of new, long-lived, broad bands at 545 and 559 nm, respectively, which we assign to the $T_n \leftarrow T_1$ transition. Salt **1** in methanol exhibits only a small residual triplet–triplet absorption after 1 ns, confirming that most of the fluorescent singlet state undergoes deactivation by photochemical reaction with the solvent. As seen in Fig. 9, the singlet excited state of **3** decays without formation of any detectable triplet–triplet absorption.

The results of the transient absorption measurements in water are very consistent with those obtained in ethanol glasses at 77 K and support our earlier conclusion (based on the quenching experiments) that the excited triplet state of **1** is involved in the photochemical transformation into luminarosine **6**.

Conclusions

The results of the photophysical studies of purinyl-pyridinium salts show that the photochemical formation of luminarosine from **1** is associated with a much higher triplet yield in this salt as compared with salts **2**–**5**, which are photochemically unreactive. Intersystem crossing is significant only in those salts which exhibit weaker intramolecular CT interactions and is induced by intermolecular CT interaction with the counterions.

Received October 11, 1989[2]

This paper is dedicated to Professor Arthur S. Perlin on the occasion of his 67th birthday

PAUL C. KLINE, ANTHONY S. SERIANNI, SHAW-GUANG HUANG, MICHAEL HAYES, and ROBERT BARKER. Can. J. Chem. **68**, 2171 (1990).

Proton transient nuclear Overhauser enhancement (TnOe) and spin-lattice relaxation times (T_1) have been used to evaluate the conformations of several monosaccharides and disaccharides containing (^{13}C) and (^2H) substitution. Absolute $^1H-^1H$ internuclear distances were determined by TnOe and DESERT (deuterium substitution effects on relaxation times) experiments on conformationally rigid methyl β-D-galactopyranoside and α- and β-D-xyloses, respectively. The DESERT method was extended to examine *O*-glycoside conformation in two blood-group disaccharides that were prepared enzymically with (^{13}C) and (or) (^2H) substitution. Preferred disaccharide conformations deduced from these distance measurements are compared to those determined from $^{13}C-^{13}C$ and $^{13}C-^1H$ spin coupling constants, theoretical calculations, and crystallographic studies.

Key words: TnOe, DESERT, carbohydrate conformation.

PAUL C. KLINE, ANTHONY S. SERIANNI, SHAW-GUANG HUANG, MICHAEL HAYES et ROBERT BARKER. Can. J. Chem. **68**, 2171 (1990).

On a utilisé l'effet Overhauser nucléaire transitoire du proton (TnOe) et les temps de relaxation spin-réseau (T_1) pour évaluer les conformations de plusieurs mono- et di-saccharides contenant des substituants ^{13}C et ^2H. On a déterminé les distances internucléaires $^1H-^1H$ absolues grâce à des expériences de TnOe et d'effets de substitution par le deutérium sur les temps de relaxation (DESERT) effectuées sur le β-D-galactopyranoside de méthyle et sur les α- et β-D-xyloses qui sont rigides d'un point de vue conformationnel. On a étendu la méthode DESERT pour examiner la conformation *O*-glycoside de deux disaccharides de groupes sanguins dans lesquels on a incorporé d'une façon enzymatique des substituants ^{13}C et (ou) ^2H. On a comparé les conformations préférées des disaccharides qui ont été déduites à partir de ces mesures de distance avec celles déterminées à partir de constantes de couplage $^{13}C-^{13}C$ et $^{13}C-^1H$, de calculs théoriques et d'études cristallographiques.

Mot clés: TnOe, DESERT, conformation de hydrate de carbone.

Introduction

Carbohydrates play diverse roles in biological systems. In addition to their role in energy production, they are involved in the recognition of self, the regulation of protein turnover, and the control of gene expression. Both furanosyl and pyranosyl rings are components of many biologically important molecules, most notably the polysaccharides and nucleic acids. These rings possess significantly different conformational properties that confer different overall behavior to the biopolymers that contain them. How these properties are exploited by the cell may be important to understanding the mechanisms of biological recognition and catalysis.

Many chemical and biochemical studies have focused on the conformational properties of carbohydrates and carbohydrate-containing structures. The underlying motivation behind these studies is the expectation that, if all molecular forces affecting conformation can be identified and quantified, predictions of preferred conformations can be made from a knowledge of primary structure. Experimental determinations of molecular conformation in solution rely heavily on nuclear magnetic resonance (NMR) spectroscopy. Relationships between vicinal spin coupling constants (^3J) and molecular torsion angles have been established for homo- ($^1H-^1H$, $^{13}C-^{13}C$) (1–4) and heteronuclear ($^{13}C-^1H$) (5–7) spin systems in carbohydrates. Structural information can also be obtained from proton spin-lattice relaxation times (T_1) (8)[3] and nuclear Overhauser effects (nOe) (10, 11). Specific $^1H-^1H$ internuclear distances estimated from these latter time-dependent parameters may be used to establish conformation, provided that correlations between distance and conformation are known. These correlations can be made by computer-assisted studies of crystal structures. Ideally, pairs of protons are studied whose internuclear distances can be used to discriminate between potential conformations. In other words, targeted interproton distances should be sensitive to molecular conformation, ideally with a given distance–conformation pair being unique.

The interpretation of NMR parameters in conformationally flexible molecules (e.g., oligosaccharides) depends on the conformational model invoked, since the number and distribution of conformational states, and their lifetimes, affect the observed values. The choice of a model often relies on chemical intuition, since the relative energies and lifetimes of the individual conformational states are often unknown, although

computational methods can be helpful in addressing these questions. Experimental validation of a chosen model can sometimes be achieved through the measurement of several complementary NMR parameters (i.e., J, T_1, nOe) in the molecule.

Conformational studies of disaccharides involve the assessment of ring, exocyclic, and O-glycoside bond conformations. With respect to the latter, vicinal $^{13}C-^{1}H$ ($^{3}J_{C,H}$) and $^{13}C-^{13}C$ ($^{3}J_{C,C}$) spin coupling constants across the O-glycoside bond are the only available couplings to assess linkage conformation since no $^{3}J_{H,H}$ coupling pathways exist. $^{3}J_{C,H}$ and $^{3}J_{C,C}$ values are not readily obtained without the use of labeled compounds, although in some cases $^{3}J_{C,H}$ values can be measured in unlabeled compounds with the use of heteronuclear multiple bond correlation spectroscopy or other methods (12). (^{13}C)- and (^{2}H)-substituted compounds have been used to measure several trans-glycoside $^{13}C-^{1}H$ and $^{13}C-^{13}C$ spin couplings in methyl β-D-lactoside and deduce a preferred O-glycoside bond conformation (13*a*); similar approaches have been used to study the conformations of other oligosaccharides (13*b*).

In addition to vicinal spin coupling constants, internuclear distances between pairs of inter-residue protons should depend on linkage conformation, making nOe measurements useful in determining conformation. This study examines this dependency and describes two NMR methods to estimate absolute $^{1}H-^{1}H$ internuclear distances in carbohydrates in solution. Two conformationally rigid monosaccharides (**1**,**2**) have been examined as a means to compare distances obtained in solution with those determined by crystallography. These methods have also been applied to evaluate O-glycoside conformation in two blood-group disaccharides (**3**,**4**).

Experimental

Materials

Methyl β-D-galactopyranoside **1** and D-xylose **2** were purchased from Sigma Chemical Company. Potassium (^{13}C)cyanide ($K^{13}CN$, 99 at.%), deuterium oxide ($^{2}H_2O$, 98 at.%), and methanol-$^{2}H_4$ ($C^{2}H_3O^{2}H$, 98 at.%) were purchased from Cambridge Isotope Laboratories. Deuterium gas ($^{2}H_2$, 98 at.%) was purchased from Merck and Co., Inc.

Preparations

Methyl β-D-lactoside **3** (O-β-D-galactopyranosyl-(1 → 4)-methyl-β-D-glucopyranoside) was prepared chemically from peracetylated β-lactose using the Koenigs–Knorr method (14).

O-β-D-Galactopyranosyl-(1 → 4)-methyl-$^{2}H_3$-β-D-(1-^{13}C,^{2}H)glucopyranoside was prepared enzymically from UDP-D-galactose and methyl-$^{2}H_3$-β-D-(1-^{13}C,^{2}H)glucopyranoside with lactose synthase (EC 2.4.1.22) isolated from milk according to procedures described previously (15, 16). The multiply enriched hexopyranoside was prepared as follows. D-Arabinose was treated with $K^{13}CN$, and the resulting (1-^{13}C)cyanohydrins were reduced catalytically with $^{2}H_2$/Pd–$BaSO_4$ (17). The products (D-(1-^{13}C,^{2}H)glucose and mannose) were separated by chromatography (17, 18). D-(1-^{13}C,^{2}H)Glucose was treated with $H^+/C^{2}H_3O^{2}H$ (19, 20) under reflux, and the resulting glycoside mixture was chromatographed on a column of Dowex 1 × 8 (200–400 mesh) ion-exchange resin in the OH^- form (21). Fractions were assayed with phenol – sulfuric acid (22). Four well-resolved peaks eluted, and the β-pyranoside was identified by its characteristic ^{13}C chemical shifts (23).

O-β-D-Galactopyranosyl-(1 → 4)-methyl-β-D-(4-^{2}H)glucopyranoside was prepared as described above, using methyl β-D-(4-^{2}H)glucopyranoside as the acceptor. D-(4-^{2}H)Glucose was prepared enzymically from dihydroxyacetone phosphate and DL-(1-^{2}H)glyceraldehyde (24) using rabbit muscle aldolase (25). O-β-D-Galactopyranosyl-(1 → 4)-methyl-β-D-(1-^{13}C)glucopyranoside was prepared from D-(1-^{13}C)-glucose (17).

O-α-L-Fucopyranosyl-(1 → 2)-methyl-β-D-galactopyranoside **4** was prepared enzymically from GDP-L-fucose (26) and methyl β-D-galactopyranoside using galactoside 2-L-fucosyl-transferase (EC 2.4.1.69) from bovine submaxillary glands (27). Methyl β-D-(1-^{13}C)-galactopyranoside and methyl β-D-(2-^{2}H)galactopyranoside were used as acceptors to generate the corresponding labeled disaccharides. These labeled galactopyranosides were generated by Fischer glycosidation (see above) of the labeled hexose. D-(1-^{13}C)Galactose was prepared as described previously (17, 28). D-(2-^{2}H)Galactose was prepared by molybdate-catalyzed epimerization (29) of D-(1-^{2}H)talose (24).

D-(2-^{2}H)Xylose was prepared from KCN and D-(1-^{2}H)threose as described previously (17, 24, 28). D-(1-^{2}H)Threose was prepared from KCN and D-glyceraldehyde via reduction with $^{2}H_2$ and Pd–$BaSO_4$ in $^{2}H_2O$ (24, 30).

Instrumentation

^{1}H (300 MHz) and ^{13}C (75 MHz) NMR spectroscopy was performed on a Nicolet NT-300 FT-NMR (Notre Dame) equipped with quadrature phase detection and a 293B pulse programmer. ^{1}H and ^{13}C spin-lattice relaxation times (T_1) were measured by the inversion–recovery method (31).

Transient proton nOe measurements (TnOe) (32) were performed on a WM-300 FT-NMR spectrometer (Cornell) and were conducted as follows. Normal (off-resonance) and selectively inverted (on-reso-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12

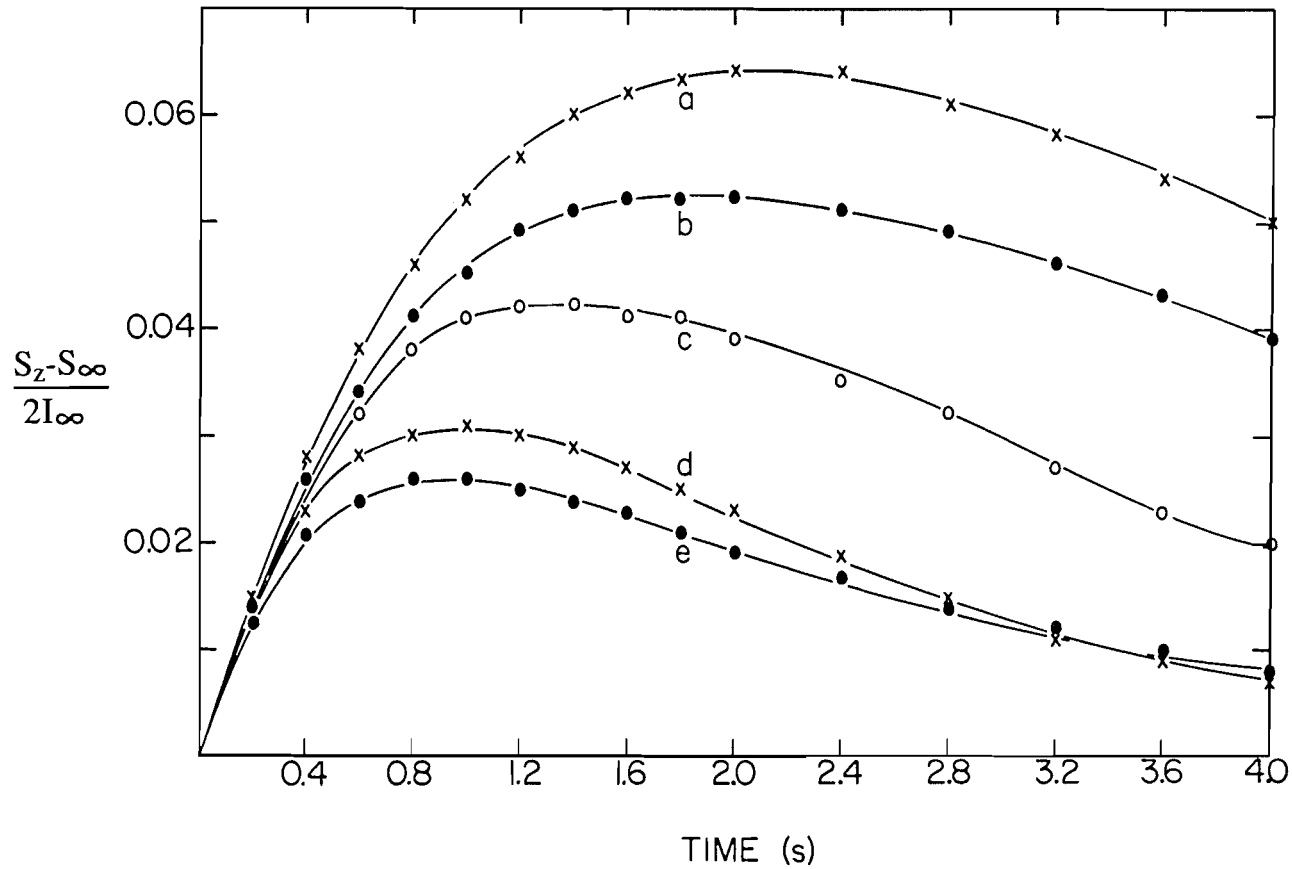

FIG. 1. Theoretical curves showing the transient nOe effect on spin S when spin I is inverted for various values of T_{1I} and T_{1S} (see text). Values of T_{IS} and T_{II}, respectively, for each curve are as follows: a, 2.1 s, 2.1 s; b, 1.0 s, 4.0 s; c, 1.0 s, 2.1 s; d, 1.0 s, 1.0 s; e, 0.5 s, 2.1 s.

nance) spectra were obtained for each τ value in the experiment (see below). A pulse program was written such that off- and on-resonance spectra were obtained in the same experiment by adding scans alternately to each spectrum (each occupying one half of the computer memory). This approach minimized errors due to resolution loss and (or) field drift during the course of the experiment. Enhancement rates were determined by spectral subtraction, followed by signal integration.

High-resolution rapid-scan cross-correlation ^{1}H NMR spectra in ^2H_2O were obtained at 620 MHz at the NMR Facility for Biomedical Studies, Department of Chemistry, Carnegie-Mellon University, Pittsburgh, PA, which is partly supported by NIH Grant P41 RR 00292.

Transient proton nuclear Overhauser enhancement (TnOe) (32*a–c*)

Consider two nuclei, I and S. The integrated Bloch equations describing the change in *z*-magnetization as a function of time, *t*, for I (I_z) and S (S_z) are

$$[1] \quad I_z = Ae^{\lambda_+ t} + Be^{\lambda_- t} + I_\infty$$

and

$$[2] \quad S_z = \frac{-(\rho_I + \lambda_+)}{\sigma_{IS}} Ae^{\lambda_+ t} + \frac{-(\rho_I + \lambda_-)}{\sigma_{IS}} Be^{\lambda_- t} + S_\infty$$

where I_z and S_z are the *z*-magnetizations of I and S, ρ_I is the spin-lattice relaxation rate of I, ρ_S is the spin-lattice relaxation rate of S, σ_{IS} is the cross-relaxation rate between I and S, I_∞ and S_∞ are the *z*-magnetizations of I and S, respectively, at infinite time after the perturbation, and $\lambda_\pm = 1/2\,[-(\rho_I + \rho_S) \pm \sqrt{(\rho_I - \rho_S)^2 + 4\sigma_{IS}^2}]$ The internuclear distance between protons I and S can be obtained by evaluating the cross-relaxation rate, σ_{IS}. For small molecules, σ_{IS} is obtained by applying a selective 180° pulse to one nucleus (I) and observing the time-dependent effect of this inversion on nucleus S. At $t = 0$, then, $I_z = -I_\infty$ (for a perfect 180° pulse) and $S_Z = S_\infty$. Under these conditions, $A + B = -2I_\infty$ considering a short t such that $\lambda_\pm t \ll 1$. Using Taylor's series, eq. [2] can be simplified to obtain the form

$$[3] \quad S_z = \frac{-(\rho_I + \lambda_+)}{\sigma_{IS}} A\lambda_+ t + \frac{-(\rho_I + \lambda_-)}{\sigma_{IS}} B\lambda_- t + S_\infty$$

where t = time between the application of the selective 180° pulse and the application of the 90° observe pulse. A plot of $(S_z - S_\infty)$ against t will yield a curve with an initial slope equal to

$$[4] \quad -1/\sigma_{IS}[\rho_I(A\lambda_+ + B\lambda_-) + A\lambda_+^2 + B\lambda_-^2]$$

Substituting $(A\lambda_+ + B\lambda_-) = 2\rho_I I_\infty$,

$$B = \frac{-2I_\infty(\rho_I + \lambda_+)}{\lambda_+ - \lambda_-}$$

and, for λ_+ and λ_-, we obtain

$$S_Z = S_\infty + 2I_\infty\sigma_{IS}t$$

A plot of $(S_Z - S_\infty)/2I_\infty$ against t yields a curve with an initial slope equal to the cross-relaxation rate, σ_{IS}. In the extreme-narrowing limit that is valid for small molecules, the value of σ_{IS} is related to r_{IS} through the equation (32*b*)

$$[5] \quad \sigma_{IS} = \frac{3\gamma_H{}^4\hbar^2}{4r_{IS}^6}\tau_r$$

where γ_H = magnetogyric ratio for ^{1}H, $\hbar$ = Planck's constant divided by 2π, and τ_r = the rotational correlation time for reorientation of the IS vector. The rotational correlation time can be obtained by measuring ^{13}C relaxation times for protonated carbons in the molecule, since (33)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

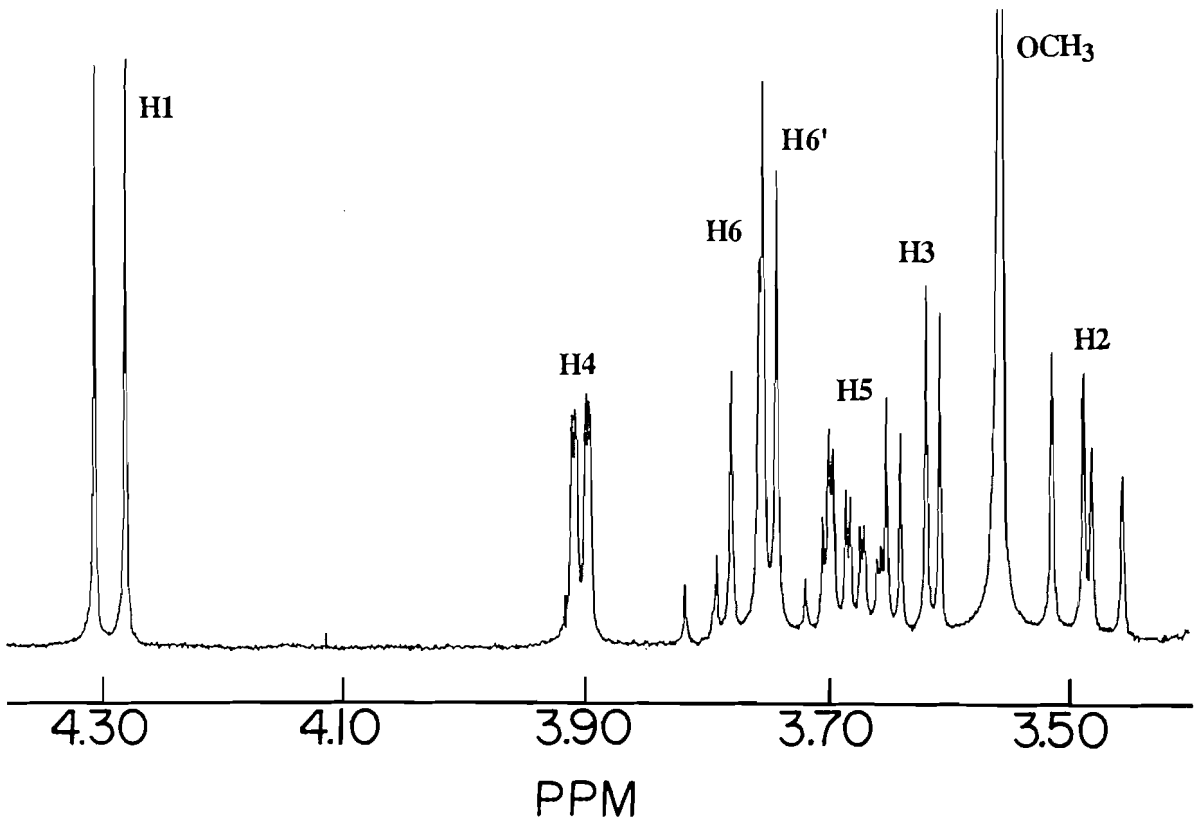

FIG. 2. The 300 MHz ^{1}H NMR spectrum of methyl β-D-galactopyranoside **1** in ^2H_2O showing signal assignments.

$$[6] \quad \frac{1}{T_{1,C}} = \frac{N\gamma_H^2\gamma_C^2\hbar^2}{r_{CH}^6}\tau_r$$

where λ_C = magnetogyric ratio for ^{13}C, N = number of directly bonded protons, and r_{CH} = the C—H bond length; eq. [6] assumes that the protonated carbons relax exclusively through a dipole–dipole mechanism as shown previously in other carbohydrate systems (9, 13).

The transient nOe experiment, then, involves selective inversion of nucleus I, a waiting period τ, followed by the application of a non-selective 90° observe pulse to monitor the change in intensity of nucleus S. Plotting $(S_z - S_\infty)/2I_\infty$ against τ yields σ_{IS}. Under similar solution conditions, τ_r is obtained by measuring ^{13}C spin-lattice relaxation times of protonated carbons in the molecule. From σ_{IS} and τ_r, r_{IS} is determined.

Equations [1] and [2] can be used to generate theoretical enhancement curves using different values for ρ_I, ρ_S, and σ_{IS}. If I is inverted, the time dependence of S is described by

$$[7] \quad \frac{S_Z - S_\infty}{2I_\infty} = \left[\frac{\sigma}{\sqrt{(\rho_S - \rho_I)^2 + 4\sigma^2}}\right][e^{\lambda+t} - e^{\lambda-t}]$$

which can be solved to produce theoretical curves (Fig. 1). These curves illustrate the effect of ρ_I and ρ_S on the shape of enhancement curves. Short T_1 values cause the enhancement to reach a maximum more quickly. For molecules with short relaxation times (i.e., larger molecules), therefore, estimates of the initial slope, and consequently of r_{IS}, will be less precise.

The accuracy of estimating r_{IS} will depend on the accuracy of the measured σ_{IS} and τ_r, the latter being derived from the ^{13}C spin-lattice relaxation time. However, one can estimate from eq. [5] that a 100% error in σ_{IS} or τ_r will produce less than a 15% error in r_{IS}.

Since r_{CH} has been reported with great accuracy, τ_r will not have a larger error than $T_{1,C}$, which is measured experimentally with an accuracy of ±5%. The accuracy of σ_{IS} obtained from the initial slope of a plot of $(S_Z - S_\infty)/2I_\infty$ vs. t is ±20%. Therefore we believe that the r_{IS} values reported in this study are accurate to ±10%.

Deuterium substitution effects on ^1H relaxation times (DESERT) (34)

Nuclear spin-lattice relaxation of proton I in a small molecule tumbling isotropically and relaxing intramolecularly through a single nearby proton S, is described by the equation

$$[8] \quad \frac{1}{T_{1,I}} = \frac{2\gamma_H^4\hbar^2(I_S(I_S + 1))}{r_{IS}^6}\tau_{IS}$$

where γ_H, $\hbar$, r_{IS}, and τ_{IS} have their usual meanings, and I_S = spin of S. Substituting $I_S = 1/2$,

$$[9] \quad \frac{1}{T_{1,I}} = \frac{3\gamma_H^4\hbar^2}{2r_{IS}^6}\tau_{IS}$$

When I relaxes through more than one proton, r_{IS}^{-6} is replaced by the summation of all pertinent inverse r^6 distances.

Equation [8] is modified when I relaxes through a dissimilar nucleus (i.e., ^{13}C or ^2H) to the form

$$[10] \quad \frac{1}{T_{1,I}} = \frac{4\gamma_H^2\gamma_S^2\hbar^2(I_S(I_S + 1))}{3r_{IS}^6}\tau_{IS}$$

where γ_S = magnetogyric ratio of S and I_S = spin of S. When S = ^2H, then

$$[11] \quad \frac{1}{T_{1,I}} = \frac{8\gamma_H^2\gamma_D^2\hbar^2}{3r_{IS}^6}\tau_{IS}$$

Considering a model three-site system, H_a, H_b, and H_c, the relaxation rate of H_a, $1/T_{1,Ha}$, equals

$$[12] \quad 3/2\gamma_H^4\hbar^2[r_{ab}^{-6} + r_{ac}^{-6}]\tau_r$$

When H_c is deuterated, the relaxation rate of H_a changes to

TABLE 1. Proton T_1 values[a] for methyl β-D-galactopyranoside **1** at 26°C in ^2H_2O

Proton	T_1(s)	$T_1/T_{1,H\text{-}1}$	
		Experimental	Calculated[b]
H-1	1.5	1.0	1.0
H-2	6.5	4.2	4.2
H-3	1.9	1.2	1.3
H-4	1.8	1.2	1.3
H-5	1.1	0.73	0.94
H-6	1.0	0.67	0.36
H-6′	0.97	0.63	0.40

[a]Nonselective; 50 mM glycoside.
[b]Using eq. [9].

$$[13]\quad \frac{3\gamma_H^4\hbar^2\tau_r}{2r_{ab}^6}+\frac{8\gamma_H^2\gamma_D^2\hbar^2\tau_r}{3r_{ac}^6}$$

Subtracting [13] from [12] yields

$$[14]\quad \Delta\frac{1}{T_{1,H_a}}=\frac{3\gamma_H^4\hbar^2\tau_r}{2r_{ac}^6}-\frac{8\gamma_H^2\gamma_D^2\hbar^2\tau_r}{3r_{ac}^6}$$

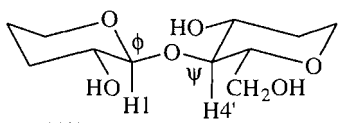
or

$$[15]\quad r_{ac}^{-6}=\frac{\Delta T_{1,H_a}^{-1}}{\gamma_H^2\hbar^2\tau_r(3/2\gamma_H^2-8/3\gamma_D^2)}$$

The internuclear distance between H_a and H_c is estimated by measuring the spin-lattice relaxation rate of H_a in the presence and absence of deuterium at H_c. As in the transient nOe experiment, τ_r is obtained from ^{13}C relaxation rates (eq. [6]).

Internuclear ^1H–^1H distance calculations and calculations of relative T_1 values

Internuclear ^1H–^1H distances in **1**, **2**, and **3** were determined from crystal structure data using the DANFIG program implemented on a VAX 11/730 computer. ^1H–^1H distances in **3** were determined as a function of the *O*-glycoside torsion angles, ϕ and Ψ, by systematically increasing ϕ from 0° (defined as that angle found in the crystal structure) to 360° in 30° increments, holding Ψ constant. Angle Ψ was then incremented by 30°, and the process was repeated until Ψ had been rotated 360°.



Internuclear ^1H–^1H distances, r, were converted to r^{-6} values and used to predict relative spin-lattice relaxation times (T_1) using eq. [9], assuming that $1/T_1$ is proportional to the sum of all r^{-6} distances for values of r within 5 Å of the proton site under consideration, and that the molecule under consideration tumbles isotropically in the region of extreme motional narrowing.

Conformationally rigid structures: monosaccharides

Nonselective proton spin-lattice relaxation in methyl β-D-galactopyranoside

The 300 MHz ^1H NMR spectrum of methyl β-D-galactopyranoside **1** is shown in Fig. 2. Proton T_1 values obtained on **1** in ^2H_2O at 26°C are 1–2 s for all protons except H-2 (Table 1). The enhanced T_1 of H-2 (6.5 s) suggests that this proton is relatively isolated from the other protons in **1**; indeed, H-2 is antiperiplanar to both H-1 and H-3 and does not experience 1,3-interactions with ring protons.

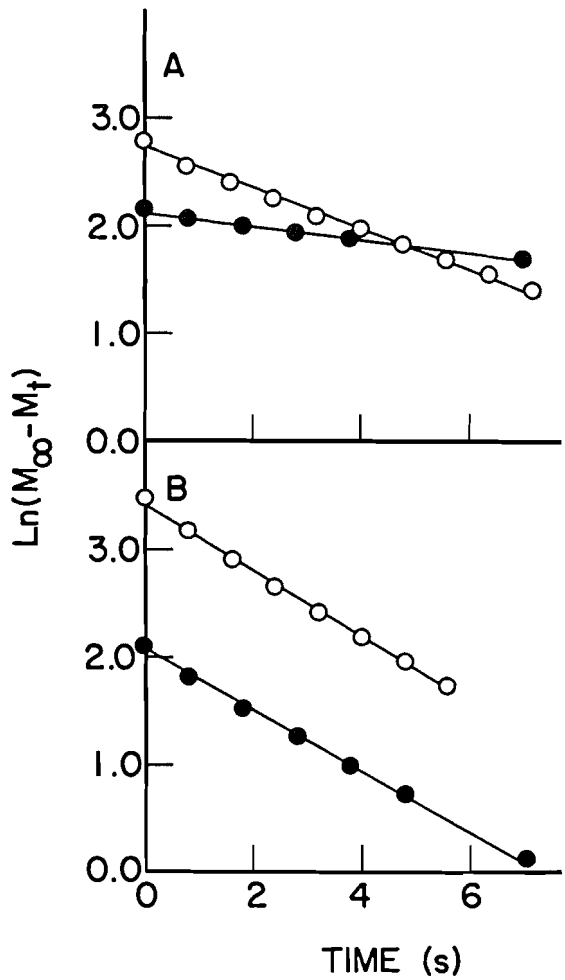

FIG. 3. Spin-lattice relaxation curves for H-1 of α-xylopyranose (5.3 s) and α-D-(2-^{2}H)xylopyranose (16.4 s)(A), and β-D-xylopyranose (3.2 s) and β-D-(2-^{2}H)xylopyranose (3.6 s)(B) at 27°C. Data for natural compounds are shown in open symbols, and data for deuterated compounds are shown in filled symbols.

This result can be predicted from ^1H–^1H internuclear distances estimated from X-ray diffraction data (35) if two assumptions are made, namely, that eq. [9] accurately describes proton relaxation in **1** and that the crystal and solution conformations of **1** are similar. Under similar solution conditions, the ratio of selective to non-selective T_1's for H-1 was found to be 1.4, in close agreement with the theoretical value of 1.5 expected for protons that relax solely via the proton–proton dipole mechanism (8), thus validating the use of eq. [9]. For each proton in **1**, inverse r^6 distances between it and all other carbon-bonded protons within 5 Å[4] were used to calculate relative relaxation times using eq. [9] (Table 1). Good agreement is observed between calculated and experimental values for H-2, H-3, and H-4. The disparities observed for H-5, H-6, and H-6′ suggest that hydroxymethyl group conformation and dynamics differ in the solid and solution states; indeed, in the crystal, one conformation is preferred (*gt*), whereas in aqueous solution, a

[4]At distances >5.0 Å, dipolar contributions to relaxation become small due to the r^6 dependence and can, therefore, be ignored.

distribution of conformers appears to exist, with *gt* and (or) *tg* predominating (13).

DESERT studies on D-*xylopyranoses* **2**a *and* **2**b

D-Xylopyranose **2** is a good model compound to evaluate the DESERT experiment (34) in a conformationally rigid pentopyranose. The distance between H-1 and H-2 was determined in each anomer by measuring the T_1 of H-1 in natural D-xylopyranoses and in D-(2-^2H)xylopyranoses (Fig. 3). Using a C-1—H-1 bond length of 1.07 Å, a rotational correlation time of 1.67×10^{-11} s was calculated from eq. [6] using the observed C-1 T_1 of 2.5 s (determined using D-(1-^{13}C)xylose). From T_1 values obtained from data in Fig. 3 and eq. [15], H-1—H-2 distances of 2.19 Å and 2.70 Å were calculated for α-(**2***a*) and β-(**2***b*) D-xylopyranose, respectively. Since both anomers highly prefer the $^4C_1$ conformation (36), H-1 and H-2 will be closer in space in **2***a* (eq–ax) than in **2***b* (ax–ax). Distances obtained from the DESERT experiment are consistent with this fact, with magnitudes that agree well with those obtained on methyl xylopyranosides by crystallography (37, 38). Furthermore, in the same experiment, the H-2—H-3 distance (ax–ax) in **2***b* was calculated to be 2.77 Å, which is also consistent with average ax–ax distances in pyranosyl rings. This result shows that ax–ax and ax–eq distances, which differ on average by ~0.5 Å, are distinguishable by the DESERT method.

Transient nOe studies on methyl β-D-*galactopyranoside* **1**

The TnOe method was applied to methyl β-D-galactopyranoside **1** as an example of a conformationally rigid aldohexopyranose ring. The ^1H NMR spectrum of **1** at 300 MHz (Fig. 2) shows that the H-1 doublet is well isolated from the remaining signals of the carbon-bonded protons, and that the H-2 and H-5 multiplets are nearly fully resolved. Therefore, the H-1 signal could be selectively inverted with a 180° pulse, and time-dependent enhancements in the signals of H-3 and H-5 recorded by difference spectroscopy (Fig. 4). Initial slopes were estimated by inspection, and cross-relaxation rates (σ) of

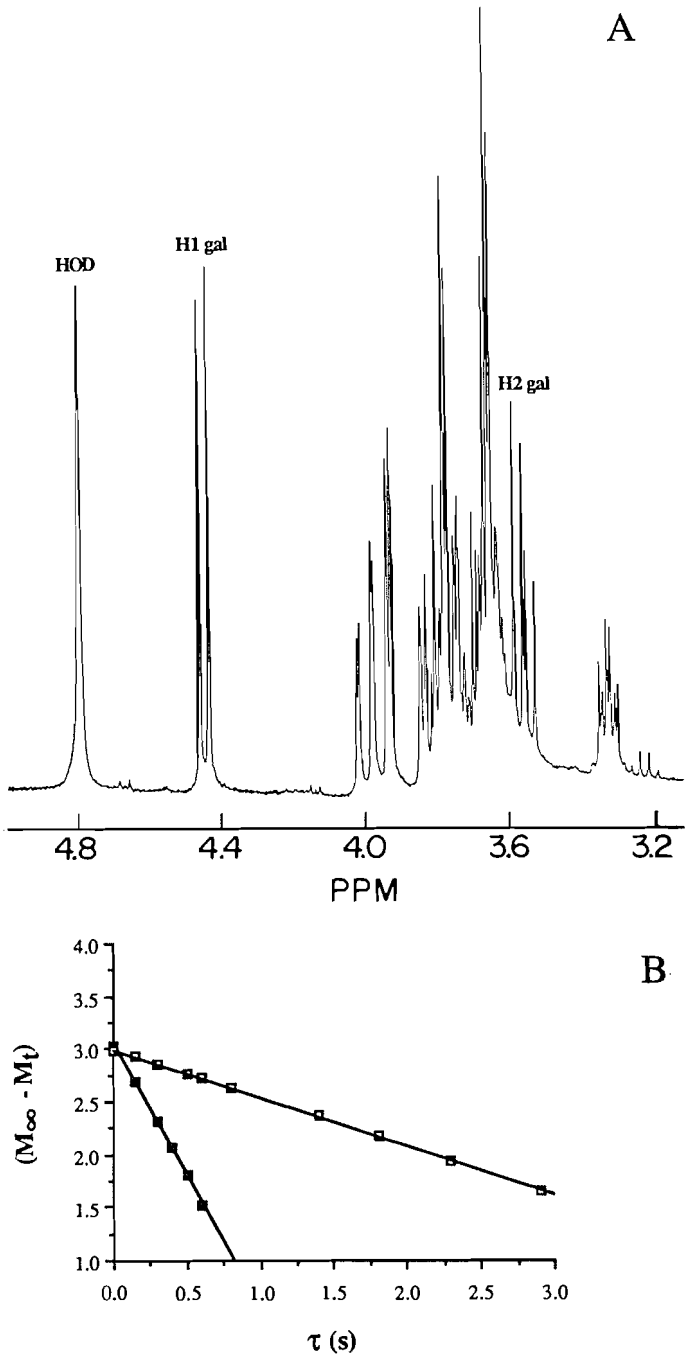

FIG. 6. (A) The 300 MHz ^1H NMR spectrum of *O*-β-D-galactopyranosyl-(1 → 4)-methyl-$^2H_3$-β-D-(1-^{13}C,^2H)glucopyranoside in ^2H_2O. Removal of the intense methyl aglycone signal permits the observation of H-2 Gal. (B) Spin-lattice relaxation time curves for H-1 Gal (0.40 s, filled symbols) and H-2 Gal (2.18 s, open symbols) for labeled disaccharide in (A).

TABLE 4. ^{13}C NMR parameters[a] for disaccharide **4** in ^2H_2O

Moiety	Chemical shifts (ppm)							Coupling constants (Hz)			
	C-1	C-2	C-3	C-4	C-5	C-6	CH_3	$^1J_{C-1,C-2}$	$^2J_{C-1,C-3}$	$^2J_{C-1,C-5}$	$^3J_{C-1,C-6}$
Gal	104.2	79.7	74.7	70.2	76.3	62.4	58.6	48.1	5.0	0	4.2
Fuc	101.5	69.9	71.1	73.4	68.3	16.6					

[a]Chemical shifts are referenced (external) to the anomeric carbon of β-D-(1-^{13}C)glucopyranose (97.4 ppm), and are accurate to ±0.1 ppm. Coupling constants are accurate to ±0.1 Hz.

0.050 s^{-1} and 0.083 s^{-1} were determined for the H-1—H-3 and H-1—H-5 pairs, respectively (Fig. 4). Using a rotational correlation time of 2.97×10^{-11} s determined from C-1 T_1 (1.4 s), internuclear distances of 2.52 Å and 2.31 Å were calculated for the H-1—H-3 and H-1—H-5 pairs, respectively. X-ray crystallography yields corresponding distances of 2.53 Å and 2.29 Å (35). Thus, in conformationally rigid systems, the TnOe method provides reliable interproton distances in solution.

Conformationally mobile structures: disaccharides

^1H and ^{13}C NMR spectra of disaccharides **3** *and* **4**

The ^1H and ^{13}C NMR spectra of **3** have been assigned previously (13). The 620 MHz ^1H NMR spectrum of **4** is shown in Fig. 5 (non-anomeric region). Signals have been assigned to specific protons in the galactose (Gal) and fucose (Fuc) constituents, and their chemical shifts are given in Table 2. Lemieux *et al.* (39) previously assigned ^1H chemical shifts for **4** based on a ^1H spectrum obtained at 270 MHz. Our analysis revealed a disparity in the assignments for H-3 Fuc, H-3 Gal, H-2 Fuc, and H-4 Fuc (Fig. 5). The multiplets for H-3 Fuc and H-3 Gal are very similar in pattern (i.e., vicinal couplings to H-2 and H-4 are similar in the Gal and Fuc moieties), making these assignments prone to misassignment. Our reassignment of H-3 Gal was confirmed by the ^1H NMR spectrum of **4** substituted with ^{13}C at C-1 Gal; in this spectrum one of the H-3 quartets contained an additional splitting due to coupling to C-1 ($^3J_{C-1,H-3}$ = 0.9 Hz) and can be assigned unequivocally to H-3 Gal. The expected multiplet patterns for H-2 Fuc and H-4 Fuc are significantly different, allowing assignments to be made with confidence at 620 MHz.

The $^1H-^1H$ spin couplings in **4** are given in Table 3. These values are comparable to those found in the corresponding methyl glycopyranosides (Table 3), indicating that the α(1 → 4) glycosidic linkage does not significantly affect ring conformation. $^3J_{H-1,H-2}$ in the fucopyranosyl ring is larger in the disaccharide, which may reflect a small conformational change in the ring and (or) a small substituent effect on $^3J_{H-1,H-2}$. If the former is responsible, then a larger $^3J_{H-1,H-2}$ would imply a decrease in the dihedral angle between H-1 (eq) and H-2 (eq) induced by a slight flattening of the fucose ring. A similar increase was not observed in the galactosyl moiety of **3**.

^{13}C NMR spectra of **4** were obtained on the natural compound and on the (1-^{13}C)Gal derivative. Comparison of these spectra permitted the unequivocal assignments of all galactosyl resonances (Table 4); C-3 and C-5 were assigned by comparison of observed $^2J_{C,C}$ values to those reported previously for β-D-(1-^{13}C)galactopyranose (2, 3) and methyl β-D-(1-^{13}C)galactopyranoside (13). Fucose assignments were taken from the work of Rosevear *et al.* (27) without further verification.

Correlation between proton internuclear distances, O-glycoside bond conformation, and dynamic NMR parameters

Conformational studies of flexible molecules based on proton internuclear distances require a careful choice of proton pairs; to assess *O*-glycoside conformation, only inter-residue proton pairs are relevant. However, not all inter-residue pairs have equal utility, as illustrated in the following discussion.

The crystal conformation of β-lactose **3** (40) yields approximate proton internuclear distances, from which estimates of the

[a] In Å.

relative efficiencies of dipolar relaxation "sinks" can be made for each proton in the molecule. H-1 and H-2 of the galactose (Gal) moiety were examined because of their proximity to the glycoside linkage (Tables 5 and 6). Because the hydroxymethyl group of the glucose (Glc) constituent is close to these protons, calculations were performed on the *gg* and *gt* conformations, which appear to be preferred in aqueous solution (13). The *trans-gauche* (*tg*) conformation seems to be least preferred (13) and was not considered.

In the crystal conformation (40), φ (O5—C1—O1—C4′) = 70.7° and Ψ (C1—O1—C4′—C3′) = 108.0°, which places H-1 (unprimed atoms denote atoms in the Gal ring) and H-4′ (primed atoms denote atoms in the Glc ring) in close proximity (2.42 Å) (Table 5). In addition to H-4′, other major contributors to H-1 relaxation are the intra-residue protons, H-3 and H-5. In the crystal conformation, it can be shown from calculations using eqs. [9] and [11] that the T_1 of H-1 should increase by ~26% when H-4′ is substituted with deuterium.

In contrast to H-1, H-2 does not relax appreciably through inter-residue protons in the crystal conformation (Table 6).

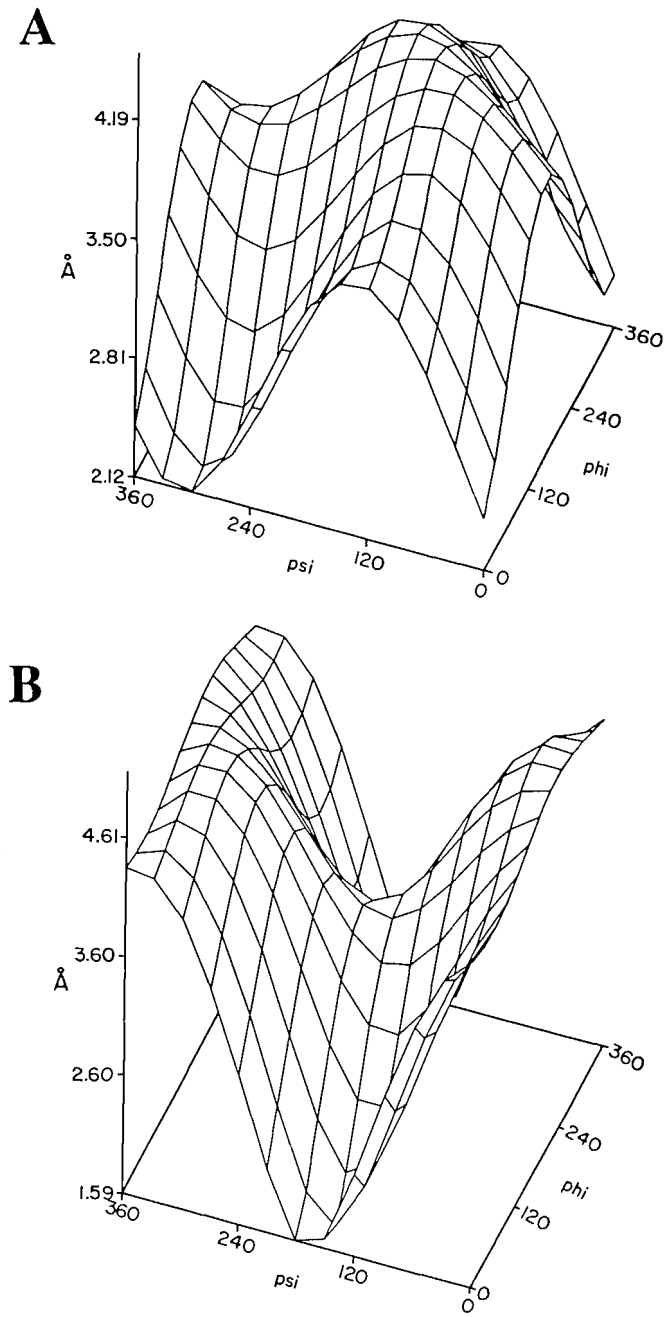

FIG. 7. Surface-contour plots of ^{1}H-^{1}H internuclear distance versus *O*-glycoside dihedral angles, ϕ and Ψ, in **3**. (A) For H-1–H-4′. (B) For H-2–H-4′.

However, comparison of its T_1 with that of H-1 can provide a means to evaluate conformation because of the sensitivity of the T_1(H-2)/T_1(H-1) ratio to three-dimensional structure (Table 7, Fig. 6).

The crystal structure represents only one conformation that **3** may assume. Distances between various pairs of protons in **3** were determined as a function of linkage conformation by systematically varying ϕ and Ψ in 30° increments. Data for the H-1–H-4′ and H-2–H-4′ pairs are given in Tables 8 and 9, and surface-contour plots of these data are shown in Fig. 7. From an analysis of all inter-residue proton pairs, it appears that H-1–H-4′ and H-2–H-4′ distances will be most useful for the following reasons. The H-1 and H-2 signals of **3** are resolved in ^{1}H spectra obtained at ≥300 MHz; the H-2 signal is most easily observed in the trideuteromethyl glycoside (Fig. 6A). In addition, data in Fig. 7 reveal two unique distance–conformation maps for these pairs, which improves the discrimination between potential conformers, and distances vary over a sufficient range to permit their use in conformational analysis.

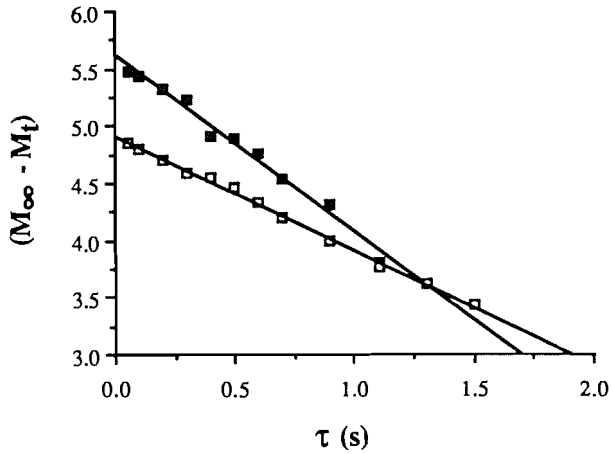

FIG. 8. Spin-lattice relaxation curves at 30° for H-1 Fuc of **4** (0.65 s, filled symbols), and H-1 Fuc of **4** deuterated at H-2 Gal (1.1 s, open symbols).

DESERT experiments on disaccharides **3** *and* **4**

DESERT experiments were performed on **3** and **4** to assess *O*-glycoside conformation. In **3**, the T_1 of H-1 Gal was measured in the natural compound and the derivative deuterated at H-4′ Glc (Table 10); in **4**, the T_1 of H-1 Fuc was measured in the natural compound and the derivative deuterated at H-2 Gal (Fig. 8, Table 10). Relaxation times increased by a factor of 1.7 upon deuteration, suggesting qualitatively that H-1 Gal in **3**, and H-1 Fuc in **4**, are in close spatial proximity to the respective deuterated sites. To assess these internuclear distances quantitatively, *isotropic* rotational correlation times, τ_r, were determined for **3** and **4** by ^{13}C NMR using compounds substituted with ^{13}C at C-1 Glc (**3**) and C-1 Gal (**4**) and eq. [6] (Table 10). From the T_1 and τ_r data in Table 10, and eq. [15], average internuclear distances between H-1 Gal and H-4′ Glc in **3**, and H-2 Gal and H-1 Fuc in **4**, were calculated (Table 10). For **3**, $r_{\text{H-1 Gal,H-4′ Glc}} \cong$ 2.0 Å, which constrains Ψ to 270°–360° and ϕ to 330°–360° (Table 8). This preferred conformational region is consistent with that deduced previously for **3** based on studies of $^3J_{C,C}$ and $^3J_{C,H}$ across the *O*-glycoside bond (13). The T_1 of H-2 Gal is essentially unaffected upon ^{2}H substitution at H-4′ Glc, indicating that these protons are distant in space (>4.0 Å). This latter observation is consistent with the preferred conformational region determined from $r_{\text{H-1 Gal,H-4′ Glc}}$. Further confirmation of this preferred conformational space derives from the ratio, T_1(H-2 Gal/T_1(H-1 Gal) = 5.8 (Fig. 6, Table 7).

The internuclear distance of ~2.0 Å between H-1 Fuc and H-2 Gal of disaccharide **4** also significantly constrains the conformational options of the *O*-glycoside linkage in this structure. This distance requires that H-1 Fuc and H-2 Gal be oriented *cis* (i.e., on the same face of the molecule).

TABLE 10. NMR parameters used in DESERT experiments on disaccharides **3** and **4**

Compound[a]	τ_r (s)	T_1 (protio) (s)	T_1 (deutero) (s)	$r_{H,H}$[b] (Å)
3	5.7×10^{-11}	0.37	0.64	1.9
4	5.6×10^{-11}	0.65	1.1	2.1

[a]Disaccharide 50 mM in 10 mM acetate (Na^+) buffer, pD 5.2, in ^2H_2O, 30°C. Compound **3** was deuterated at H-4′ Glc; T_1 of H-1 Gal was measured. Compound **4** was deuterated at H-2 Gal; T_1 of H-1 Fuc was measured.

[b]For **3**, $r_{\text{H-1 Gal,H-4' Glc}}$; for **4**, $r_{\text{H-1 Fuc,H-2 Gal}}$.

This *O*-glycoside conformation is consistent with results obtained from hard-sphere calculations by Lemieux *et al.* (39).

Conclusions

$^1H-^1H$ internuclear distance determinations by NMR are valuable in determining the structure and conformation of molecules in solution. The one-dimensional NMR experiments employed in this study yield accurate distances in carbohydrates that are conformationally rigid and tumble isotropically (e.g., **1** and **2**). The TnOe method can be applied to natural (i.e., unlabeled) compounds, but the experimental protocol is more demanding and requires a stable spectrometer for accurate results. In contrast, the DESERT method is easier to perform, but requires specifically deuterium-substituted compounds. Although this requirement may be considered a drawback, in some cases appropriately labeled disaccharides can be prepared enzymically from deuterated monosaccharides in a straightforward manner, as illustrated in this study.

The results of the DESERT experiments on **3** and **4** suggest that the *O*-glycoside bond in these disaccharides is relatively rigid in aqueous solution, that is, the conformational excursions about the linkage must be limited in amplitude. A source of error in the present treatment of DESERT data lies in the assumption that **3** and **4** tumble isotropically in solution. ^{13}C relaxation measurements on **3**, for example, have suggested that tumbling may be slightly anisotropic (13, 41). Increasing oligosaccharide size is likely to enhance anisotropic motion, especially in linear or extended oligosaccharides, and this motion will need to be treated explicitly in $^1H-^1H$ internuclear distance studies of these compounds. In highly branched oligosaccharides, however, anisotropic motion may not be as significant.

The availability of two-dimensional nOe spectroscopy (42) does not preclude the use of 1-D NMR methods to evaluate the spatial proximity of protons in some instances. A simple 1-D DESERT experiment that yields one or more absolute $^1H-^1H$ distances may be sufficient to resolve a conformational uncertainty. In addition to their utility in DESERT studies, deuterated oligosaccharides may be desirable in some cases to edit complex 2-D nOe spectra, and (or) to enhance nOe's between selected sites. It is likely that isotopic labeling will be used more routinely in the future to facilitate the interpretation of complex 2-D NMR spectra of oligosaccharides, in ways similar to those used currently in protein structure determinations (43, 44).

Acknowledgments

PIERRE AUDET, RODRIGUE SAVOIE, and MICHEL SIMARD. Can. J. Chem. **68**, 2183 (1990).

A stoichiometric complex of formula maleic acid·2H_2O·18-crown-6 has been obtained from maleic acid and the macrocyclic polyether 18-crown-6. Crystals of this complex have been shown by X-ray diffraction crystallography to belong to the *Cc* space group of the monoclinic system. The acid molecules in the adduct are linked to each other through a water molecule, giving infinite [-acid-H_2O-]$_n$ chains. They are also linked to the crown ether via water molecules. The infrared and Raman spectra of the complex are presented and compared to those of crystalline maleic acid.

Key words: maleic acid/18-crown-6, structure, X-ray, spectra.

PIERRE AUDET, RODRIGUE SAVOIE et MICHEL SIMARD. Can. J. Chem. **68**, 2183 (1990).

Un complexe de formule acide maléique·2H_2O·18-couronne-6 a été obtenu à partir de l'acide maléique et de l'éther macrocyclique 18-couronne-6. La diffraction des rayons X a démontré que ce complexe cristallise dans le groupe d'espace *Cc* du système monoclinique. Dans le solide, les molécules d'acides sont reliées entre elles par l'intermédiaire de molécules d'eau, pour former des chaînes infinies [-acide-H_2O-]$_n$. Le lien entre les molécules d'acides et de l'éther en couronne se fait également par l'intermédiaire de molécules d'eau. Les spectres infrarouge et Raman du complexe sont présentés et comparés à ceux de l'acide maléique à l'état cristallin.

Mot clés : acid maléique/éther 18-couronne-6, structure, rayons-X, spectres.

Introduction

The macrocyclic polyether 18-crown-6 ((-CH_2-CH_2-O-)$_6$, henceforth called 18C6) readily forms complexes with neutral molecules with hydrogen bonding capacity. In these adducts, the linking of the proton donor with the ether is commonly achieved through a bridging water molecule, which is weakly bound to two adjacent oxygen atoms of the crown (1). This typical acid···OH_2···18C6 arrangement has been found in the CH_2(CN)COOH·H_2O·18C6 adduct, which has been characterized by X-ray diffraction (2). Various complexes of 1:1:1 or 2:2:1 (acid:water:18C6) stoichiometry, in which the acid·OH_2 units are presumably attached to one or both sides of the crown, have also been obtained with halogenated derivatives of acetic acid (3). In a complex with oxalic acid, both ends of the acid were found to be attached to different crown molecules in a polymer-like fashion: -18C6-H_2O-HOOCCOOH-OH_2-18C6- (4). We have found a similar 1:2:1 stoichiometry (acid: water:18C6) in a complex formed with maleic acid (HOOC-CH=CH-COOH). As the vibrational spectra of this complex clearly indicated that the conformation of the acid in this adduct was different from that in the pure crystalline acid (5), we have determined its molecular and crystal structure by X-ray diffraction crystallography. The results of these different types of investigation are reported in this paper.

Experimental

The complex was prepared by dissolving equimolar quantities of 18C6 (0.264 g) and maleic acid (0.116 g) in 5 mL of THF to which a small quantity of distilled water (0.05 mL) had been added. Precipitation of crystalline platelets (mp 62–63°C) occurred at low temperature (ca. −5°C) after addition of 1 mL of diethyl ether. The complex was filtered under reduced pressure, washed with a small amount of cold diethyl ether, and dried in air. Its stoichiometry was first established by titration of the acid by NaOH (calcd.: 27.88%; found: 27.6%), from the integrated intensity of the ^{1}H nmr peaks (in $CDCl_3$, using a Varian EM360A instrument; δ 3.68 (24 H, 18C6), 6.43 (2H, acid), and 6.91 (6H, H_2O and acid)), and from the elemental analysis (calcd.: C 46.15% and H 7.75% found: C 46.6% and H 7%).

The Raman spectra of the samples, contained in sealed capillary cells, were recorded on a Spex model 1400 microcomputer-controlled spectrometer, using ca. 200 mW (at the sample) of excitation power from the 514.5 nm green line of a Spectra Physics model 2020 argon ion laser. The low-temperature measurements were made in a conventional liquid nitrogen cryostat. The spectra were typically recorded at 2 cm^{-1} slit width, with an integration time of 2 s at each frequency interval of 2 cm^{-1}. The infrared spectra of Nujol and hexachlorobutadiene mulls of the polycrystalline complex pressed between Irtran-4 windows were recorded on a Beckman 4250 spectrophotometer.

For X-ray study, a plate-shaped hexagonal crystal of dimensions 0.095 (001, 00$\bar{1}$) × 0.24 (01$\bar{1}$, 0$\bar{1}$1) × 0.34 (11$\bar{1}$, $\bar{1}\bar{1}$1) × 0.34 (1$\bar{1}\bar{1}$, $\bar{1}$11) mm was mounted on a Nonius-CAD4 diffractometer. The unit cell dimensions were derived from the angular setting of 25 well-centered reflections in the range 43 ≤ 2θ ≤ 48°. The final parameters and other crystal data of interest are presented in Table 1. The data collection for the complex was done over all the Laue sphere, by the ω/2θ scan technique, with graphite monochromatized copper radiation. The intensities of seven standard reflections monitored every hour during the experiment showed that the crystal slowly decomposed in the X-ray beam, the intensities having decreased by 13.6% during data collection. This decay was considered at the reduction stage. After averaging of the 8785 measured reflections to the Laue *m* symmetry (anomalous dispersion of oxygen atoms taken into account), 3715 reflections were considered observed ($I/\sigma(I) \geq 1.96$; $R_I = 0.035$). The Lorentz and polarization corrections were applied to the data.

The structure was solved using direct methods (MULTAN-80)[2] combined with difference Fourier syntheses (SHELX-76). The refine-

ments, based on F's, minimized the quantity $\Sigma w\Delta F^2$ using the block-diagonal approximation in the last cycles. All non-hydrogen atoms were refined anisotropically and hydrogen atoms isotropically. The refinement was concluded when the indicators given in Table 2 reached their minimum values. The scattering curves for the non-hydrogen atoms were taken from ref. 6 and those for H atoms from ref. 7.

Results and discussion

Crystal structure

The X-ray structure determination confirmed the 1:2:1 (acid:H_2O:18C6) stoichiometry indicated from the elemental analysis. The atomic numbering adopted is shown in Fig. 1 and a stereoview of the structural units is presented in Fig. 2, showing the thermal ellipsoids at the end of the refinement. Crystal data of interest are given in Table 1 and the refined coordinates with isotropic temperature factors of the non-hydrogen atoms are found in Table 3. The overall structure of the crystalline complex can be represented by a polymeric chain of acid units linked through water molecules, with crown molecules alternately attached to opposite sides of the chains.

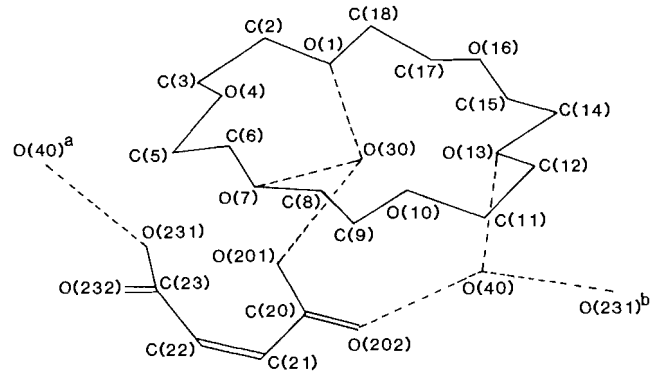

FIG. 1. Atomic numbering adopted for the complex maleic acid·$2H_2O$·18-crown-6; a: x, $1 - y$, $\frac{1}{2} + z$; b: x, $1 - y$, $-\frac{1}{2} + z$.

The 18-crown-6 distances and angles are part of the supplementary material.[3] The average C—O distance is 1.421 Å (range 1.403–1.438 Å) while the average value for C—C distances is 1.483 Å (range 1.473–1.496 Å). The value of the C—O—C bond angles, 112.8° (range 111.5°–114.2°), is slightly higher than that of the C—C—O bond angles, 109.3° (range 108.2°–110.2°). These features are consistent with the corresponding parameters found in structures containing the 18C6 molecule (11–13). The detailed conformation of the 18-crown-6 is best described in terms of the torsion angles about the ring bonds. Those about C—C bonds are all close to *gauche* (average value 68.4°, range 65.7°–71.4°) and those about C—O bonds are close to *trans* (average value 171.6°, range 169.9°–179.4°). These values are consistent with the very small departure of the crown conformation from the D_{3d} symmetry.

The bond distances, bond angles, and torsion angles for the maleic acid moiety in the complex are given in Table 4. There are marked differences between the C=O and C—OH bond lengths in the molecule (C=O: 1.205(3) and 1.207(3) Å, compared to C—OH: 1.311(3) and 1.323(3) Å). In the complex, the acid molecules are involved in an intermolecular hydrogen bonding network, with the localized C=O and C—OH groups acting as hydrogen donor and acceptor respectively.

The intramolecular hydrogen bond normally formed in the maleic acid molecule (14) is not found in the present case and the molecule is not planar (Fig. 3). While the main torsion angle of the carbon skeleton is close to that for the *cis* conformation, C(20)—C(21)—C(22)—C(23) = −4.3(4)°, a large departure from planarity occurs for one of the COOH groups at one end of the molecule, as indicated by the torsion angle C(21)—C(22)—C(23)—O(232) = −82.4(3)°. This is unusual since in most compounds containing maleic acid this molecule is locked into a planar conformation by an internal hydrogen bond. A situation in all respects comparable to the present one was, however,

[3]Tables of the bond distances, angles and torsion angles of the 18-crown-6 molecule, of the anisotropic thermal parameters, the refined H-atom coordinates, and the structure factor amplitudes have been deposited and may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Tables of distances and bond angles for the crown part of the complex and for the hydrogen atoms, and the refined H-atom coordinates, have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

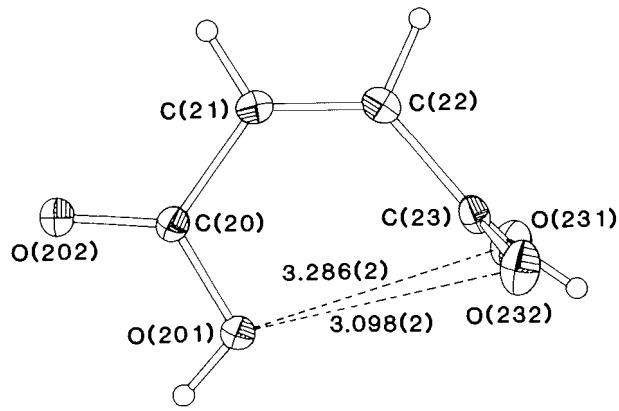

FIG. 3. Maleic acid molecule (top view) with intramolecular O···O distances.

observed by Town and Small (15) in the doubly ionized maleate anion, where repulsions between the two carboxylate ends caused a large rotation of one of the COO^- planes (τ = 81.4°).

The crown ether, the water, and the maleic acid molecules are linked together through a series of hydrogen bonds in the crystalline complex. A stereoview of the unit cell showing how the various units are associated is reproduced in Fig. 4. It is seen that the two -COH groups of the acid act as hydrogen donors to form two strong hydrogen bonds with water molecules where O···O distances are 2.536(2) and 2.644(3) Å. These hydrogen bonds are nearly linear, the angles O(201)—H(201)···O(30) and O(231)—H(231)···O(40) having a value of 172(3)°. One of the C=O groups of the acid plays the role of a hydrogen acceptor, forming a weaker hydrogen bond with a water molecule O(40), with d(O···O) = 2.837(3) Å. It is this water molecule which links, through two other hydrogen bonds, the next acid molecule and the crown ether. This arrangement of the structural units can best be described by a pseudo-polymer (maleic acid···$H_2O)_n$, with the crown ether molecules interacting on each side of the chain. Three weak hydrogen bonds exist between the crown and the water molecules; the O(1)···O(30), O(7)···O(30), and O(13)···O(40) distances are in the range 2.863(3)–2.970(2) Å. The other geometrical parameters characterizing these hydrogen bonds are given in Table 5. The structure of the complex with maleic acid differs somewhat from those obtained with other carboxylic acids, such as with cyanoacetic (2) and oxalic (4) acids, in which the acid molecules were separated from each other by a crown.

Vibrational spectra

The crown ether in the complex has a structure that departs very little from the highly regular one of D_{3d} symmetry, in contrast with the rectangular shape adopted by this molecule in the pure solid (16). The vibrational bands of the ether moiety in the infrared and Raman spectra of the complex (see Figs. 5–7) are consequently very similar to those of other compounds, such as K^+·18C6·Br^-, in which this symmetry is adopted (17, 18); they also differ markedly from those of the solid uncomplexed compound (19). Generally speaking, the higher symmetry of the crown results in a simplification of its vibrational spectra by comparison to those of the crystalline solid or those in which its structure is distorted.

The conformation of the maleic acid molecule in the complex is also quite different from that adopted in the pure crystalline acid (5, 20). To understand the resulting differences in the vibrational spectra of this species in the two states, the spectra of crystalline maleic acid first have to be interpreted. This

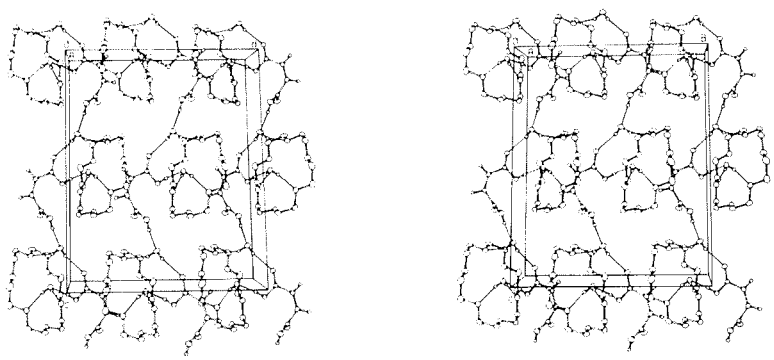

FIG. 4. Stereoview of the unit cell. Hydrogen atoms have been omitted for clarity and hydrogen bonding is indicated by thin lines.

molecule is planar in the crystal, with one of the O—H groups involved in a very short and asymmetric internal hydrogen bond (O···O = 2.5 Å). This has a very pronounced effect on the frequencies of the OH vibrational modes.

The infrared spectrum of crystalline maleic acid Fig. 5B) shows three broad regions of absorption in the 1000–1800 cm^{-1} region. The first, at ca. 1150 cm^{-1}, can be confidently assigned to the out-of-plane OH bending mode (γ(OH), by comparison with the corresponding vibration at 1121 cm^{-1} in KHC_2O_4 (O···O = 2.52 Å) and at 1180 cm^{-1} in $LiHC_2O_4$ (O···O = 2.45 Å) (21). The other two, in the 1440 and 1570 cm^{-1} regions, also arise from OH vibrations, as they are not present in the spectrum of the crystalline [$(OD)_2$] compound (22). These two bands were previously assigned to the in-plane bending vibration (δ(OH)) (22), but we believe that they arise from both the OH stretching ν(OH) and the in-plane bending vibrations. However, it is difficult to provide an unambiguous individual assignment for these two bands. In $NaHC_2O_4$, KHC_2O_4, $KHC_2O_4 \cdot H_2O$, and $LiHC_2O_4$, with O···O distances varying from 2.57 to 2.45 Å, the δ(OH) occurs in the 1450–1520 cm^{-1} region (21). On the other hand, an empirical relation between O···O distances and the frequency of the ν(OH) mode (23) indicates that the latter should also occur in this same frequency range. One indication in favor of the assignment of the band at high frequency to the δ(OH) mode is the occurrence of the strong doublet at 1565/1585 cm^{-1} in both the infrared (Fig. 5B) and Raman (Fig. 6B) spectra. This doublet and the strong peak at 1633 cm^{-1} are better explained by coupled C═O, C═C, and δ(OH) motions, as they are quite strong in the Raman spectrum, where the ν(OH) generally causes little scattering. One also notes that each band in the 1440, 1570, and 1710 cm^{-1} regions is split in both the Raman and infrared spectra, possibly through an intermolecular vibrational coupling effect (factor-group splitting) in the crystal.

Upon complex formation with 18C6, the maleic acid molecule adopts a twisted conformation that breaks the very short internal hydrogen bond formed in the crystal. This causes the ν(OH) mode to move out of the mid-frequency region and the frequency of the δ(OH) vibration to decrease considerably. The strong infrared bands near 1440 and 1570 cm^{-1} therefore vanish (Fig. 5A) and the Raman spectrum is considerably simplified in the 1500–1800 cm^{-1} region, where only two major peaks

remain, besides the band at 1632 cm^{-1} due to the bending mode of H_2O (Fig. 6A). These occur at 1728 cm^{-1} (ν(C═O)) and 1680 cm^{-1} (ν(C═C)), the latter appreciably shifted from its position at 1634 cm^{-1} in the spectrum of the crystal, as a result of a slight increase in C═C bond length and decreased coupling with the δ(OH) mode. Coupled ν(C—O) and δ(OH) vibrations in the complex are probably responsible for the sharp peaks at 1433 and 1349 cm^{-1} and for the broad band at 1302 cm^{-1} in the infrared spectrum. Corresponding bands are found at 1387 and 1320 cm^{-1} in the Raman spectrum of an aqueous solution of maleic acid (24). Other characteristic shifts in the Raman spectra are those of the δ_{as}(CH) and γ_s(CH) modes, which occur at 1216 and 1018 cm^{-1} in the spectra of the pure crystal and at 1206 and 988 cm^{-1} in those of the complex. It is noteworthy that the Raman spectrum of the maleic acid moiety in the complex (Fig. 6) is very similar to that of the acid in aqueous solution (24), which means that the change of conformation noted above, or a similar one, also occurs upon dissolution of the acid in water.

Although the structure of the complex with maleic acid is somewhat different from that of the corresponding one with oxalic acid (4), there is a marked similarity in the high-frequency region of the vibrational spectra of these adducts. In particular, one finds in the Raman spectrum of the maleic acid complex (Fig. 7B) a broad band with a maximum near 3450 cm^{-1}, which corresponds to a very intense band at slightly higher frequency in the infrared spectrum (Fig. 7A). The Raman band is split into three components at 3401, 3427, and 3448 cm^{-1} at −185°C, the latter peak being approximately twice as intense as the first two. This triplet arises from the stretching vibrations of the weakly bound water molecules (O···O = 2.84–2.97 Å) linking the oxalic molecules between themselves and with the crown ether.

The two OH groups of the maleic acid molecules in the complex are involved in hydrogen bonds of very different energy with neighboring water molecules, as indicated by the two O···O distances of 2.54 and 2.64 Å. It seems logical to assign the two bands at 2024 and 2570 cm^{-1} in the infrared spectrum of the complex (Fig. 7) to the stretching vibrations of these two OH groups. The average of these two frequencies (2300 cm^{-1}) agrees reasonably well with the 2400 cm^{-1} value estimated from the pK_a of maleic acid (1.83), which has been shown to be related to the ν(OH) stretching frequency of various acids complexed by 18C6 (25). The 2570 cm^{-1} infrared band, with weaker Raman counterpart, has a frequency which is lower than that expected (ca. 2850 cm^{-1}) (23) for the 2.64 Å O···O distance noted above. It is therefore possible that the observed peak is but one of several components of complex sets of bands resulting from a Fermi resonance interaction between the ν(OH) mode and the first overtone of the δ(OH) vibrations, the other components being overshadowed by the strong series of peaks arising from C—H stretching modes of the crown in the 2900 cm^{-1} region. The 2024 cm^{-1} band, asigned to the ν(OH) vibration of the acid OH group involved in the short hydrogen

bond, has a frequency which is somewhat higher than that expected for the corresponding very short 2.54 Å O···O distance (ca. 1800 cm^{-1}) (23). However, this frequency varies very rapidly with changes in the intermolecular distance in this region and, in fact, the observed frequency of 2024 cm^{-1} corresponds statistically to an O···O distance of ca. 2.55 Å, which is quite close to the value obtained from the X-ray structure determination.

Synthesis of chromanes using pyruvic acid dimethylhydrazone dianion

I. TAPIA, V. ALCÁZAR, AND J. R. MORÁN

Department of Organic Chemistry, University of Salamanca, Plaza de los Caídos 1-5, 37008 Salamanca, Spain

Received January 18, 1990

I. TAPIA, V. ALCÁZAR, and J. R. MORÁN. Can. J. Chem. **68**, 2190 (1990).

Chromanes were prepared in medium yield from methyl salicylate and the dianions of pyruvic or α-oxobutyric acid dimethylhydrazones.

Key words: chromane, pyruvic acid, dimethylhydrazone, dianion.

I. TAPIA, V. ALCÁZAR et J. R. MORÁN. Can. J. Chem. **68**, 2190 (1990).

On a préparé des chromanes avec des rendements modestes en utilisant le salicylate de méthyle et les dianions des diméthylhydrazones des acides pyruvique ou α-oxobutyrique comme produits de départ.

Mots clés : chromane, acide pyruvique, diméthylhydrazone, dianion.

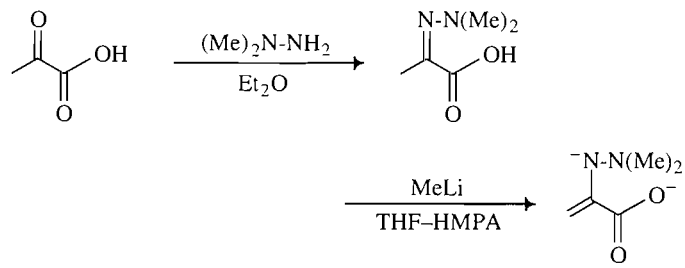
Introduction

We have recently found that the dianion of pyruvic acid dimethylhydrazone **1** is a strong nucleophile, which reacts readily with alkyl halides and with carbonyl and carboxyl compounds (1). The dimethylhydrazone of pyruvic acid can easily be obtained in ether, as a crystalline solid, from stoichiometric amounts of dimethylhydrazine and the acid. When this substance is treated with MeLi (2 equiv.) in THF/HMPA, a solution of the yellow dianion **1** is generated (Fig. 1).

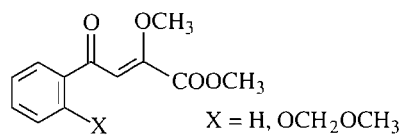


1

FIG. 1

Results and discussion

After acid work-up and treatment with diazomethane, reaction of **1** with methyl benzoate yielded compound **I** (Fig. 2).



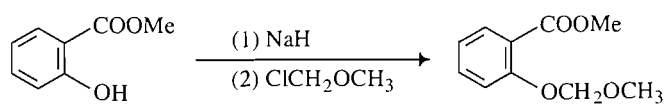
I

FIG. 2

The spontaneous loss of the dimethylhydrazine group under acid conditions made this reaction synthetically attractive for accomplishing chromane synthesis, if an *ortho* hydroxyl group is present in the aromatic ring.

The reaction of methyl salicylate with the dianion **1** is complicated due to the presence of the phenolic hydroxyl group. Protection of this group was readily achieved in basic medium with chloromethyl methyl ether (2) in toluene, affording **2** (3).

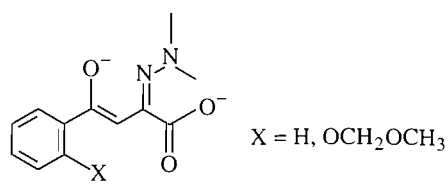
This protective group can be cleaved under the acid conditions necessary to cyclize the chromane (Fig. 3).



2

FIG. 3

The reaction of **1** (2 equiv.) with protected methyl salicylate, followed by cold acid work-up and diazomethane treatment, yielded the enolic compound **II** (Fig. 4). However, if deprotection of the phenolic group is carried out under harsher acid conditions, the expected chromane **3** (4) is obtained.



II

FIG. 4

The presence of two carboxymethyl groups on the aromatic ring, as in the case of 4,6-dihydroxyisophthalate (5), allowed the synthesis of both benzopyrane or benzodipyrane rings depending on the amount of the dianion added.

This result can be explained if it is taken into account that the attack on the first ester group yields an acid ketone, which is readily deprotonated by the excess of **1**. The second carboxymethyl group on this electron-rich aromatic ring is less reactive.

Additionally the hindered carboxymethyl group of methyl 2,6-dihydroxybenzoate reacted well with the dianion of the recently crystallized hydrazone, to afford, after diazomethane treatment, the chromane **6**.

We also prepared protected 5-dimethylamine and 5-nitromethyl salicylates; however, in both cases the reaction with the dianion **1** failed to produce the expected chromanes.

To study the synthesis of 3-substituted chromanes, we also used the dimethylhydrazone of α-oxobutyric acid. The reaction of its dianion with the methoxy methyl ether of methyl salicylate led to the expected chromane **7** (7). However we tried to obtain the dimethylhydrazone of phenyl pyruvic acid, an impure and

unstable compound was formed. Attempts to condense the dianion of this material with protected methyl benzoate yielded only complex mixtures (cf. Table 1).

Experimental

Melting points were obtained in a Kofler hot-stage apparatus and are uncorrected. IR spectra were recorded on a Beckman Acculab II. NMR spectra were recorded on a Bruker WP 200 SY instrument (200 MHz ^{1}H, 50.3 MHz ^{13}C). Chromatographies were run on SiO_2 columns eluting with hexane/EtOAc mixtures of increasing polarity as eluent.

N,N-*Dimethylhydrazone of pyruvic acid*

Dimethylhydrazine (10 g, 0.166 mol) in 100 mL of ether was added dropwise to a solution of 14.6 g (0.166 mol) of pyruvic acid in 50 mL of ether at 0°C. Once addition was finished, the solution was kept at 0°C for 1 h. The solid was removed from the solution by filtration and was crystallized in chloroform/hexane, affording 16.3 g (75%) of pyruvic acid dimethylhydrazone; mp 106°C; IR (Nujol) ν: 1670, 1280, 1210, 860, 820 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 2.73 (6H, s), 2.19 (3H, s) ppm; ^{13}C NMR δ: 168 (s), 162 (s), 44 (q, 2C), 20 (q) ppm.

N,N-*Dimethylhydrazone of α-oxobutyric acid*

Dimethylhydrazine (2.94 g, 0.05 mol) in 50 mL of ether was added dropwise to a solution of 5 g (0.05 mol) of α-oxobutyric acid in 50 mL of ether at 0°C. When addition was finished, 5 mL of hexane was added and the solution was kept at 5°C for 1 h, after which a solid precipitated. Filtration of the solid afforded 6.1 g (87%) of α-oxobutyric acid dimethylhydrazone; mp 71°C ($CHCl_3$/hexane); IR (Nujol) ν: 1670, 1220, 870, 820 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 2.66 (6H, s), 2.48 (2H, q, J = 8 Hz), 0.96 (3H, t, J = 8 Hz) ppm; ^{13}C NMR δ: 171 (s), 162 (s), 44 (q, 2C), 27 (t), 10 (q) ppm.

Condensation of dianion with methyl salicylate derivatives. General procedure

A solution of the dimethylhydrazone of the pyruvic acid (200 mg, 1.53 mmol) in THF (4 mL) and HMPA (6 mL) under nitrogen was treated with MeLi (1.5 M) in hexane at 0°C. As soon as a yellow colour developed in the solution the amount of MeLi was recorded and the same amount was added again. The yellow solution was then treated with the salicyl derivative (0.76 mmol) dissolved in THF (2 mL).

After 1 h, the mixture was added over water and extracted with ether. The aqueous phase was then acidified with 2 N HCl, heated in a water bath for 10 min, and extracted with EtOAc. Esterification with CH_2N_2/Et_2O and chromatography on SiO_2 yielded the pure compounds.

*2-Methoxycarbonyl-4*H*-1-benzopyran-4-one*, **3**: mp 120°C (lit. (4) mp 120°C, MeOH); IR (Nujol) ν: 1730, 1650, 1500, 1260, 970, 760 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 8.19–7.39 (4H, m), 7.07 (1H, s), 4.01 (3H, s) ppm; ^{13}C NMR δ: 178 (s), 161 (s), 156 (s), 151 (s), 134 (d), 126 (d), 125 (d), 124 (s), 118 (d), 115 (d), 53 (q) ppm. Anal. calcd. for $C_{11}H_8O_4$: C 64.70, H 3.95; found: C 64.52, H 3.83.

*7-Hydroxy-2,6-bis(methoxycarbonyl)-4*H*-1-benzopyran-4-one, chromone*, **4**: mp 197°C (EtOAc/hexane); IR ($CHCl_3$) ν: 3000, 1730, 1650, 1600, 1250 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 11.4 (1H, s), 8.74 (1H, s), 7.06 (1H, s), 7.02 (1H, s), 4.01 (6H, s) ppm. Anal. calcd. for $C_{13}H_{10}O_7$: C 56.12, H 3.62; found: C 56.23, H 3.60.

*2,8-Bis(methoxycarbonyl)-4*H*,6*H*-benzo(1,2-b;5,4-b′)dipyran-4,6-dione*, **5**: mp 228°C (lit. (6) mp 225–226°C); IR (Nujol) ν: 3020, 1760, 1680, 1620, 1270, 990, 810, 780 cm^{-1}; ^{1}H NMR (DMSO-d_6) δ: 8.63 (1H, s), 8.10 (1H, s), 6.99 (2H, s), 3.96 (6H, s) ppm. Anal. calcd. for $C_{16}H_{10}O_8$: C 58.19, H 3.05; found: C 58.02, H 3.10.

*5-Hydroxy-2-methoxycarbonyl-4*H*-1-benzopyran-4-one*, **6**: mp 109–110°C (EtOAc/hexane); IR (Nujol) ν: 3000, 1750, 1660, 1280, 980, 810, 770 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 12.1 (1H, s), 7.60 (1H, t, J = 9 Hz), 7.04 (1H, s), 7.03 (1H, d, J = 9 Hz), 6.85 (1H, d, J = 9 Hz), 4.02 (3H, s) ppm; ^{13}C NMR δ: 183 (s), 161 (s), 160 (s), 156 (s), 153 (s), 136 (d), 114 (d), 112 (d), 111 (s), 108 (d), 53 (q). Anal. calcd. for $C_{11}H_8O_5$: C 60.00, H 3.66; found: C 59.85, H 3.50.

*2-Methoxycarbonyl-3-methyl-4*H*-1-benzopyran-4-one*, **7**: mp 99°C (EtOAc/hexane); IR (Nujol) ν: 1740, 1650, 1610, 1240, 950, 750 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 8.11–7.27 (4H, m), 3.93 (3H, s), 2.29 (3H, s) ppm; ^{13}C NMR δ: 178 (s), 162 (s), 155 (s), 148 (s), 134 (d), 126 (d), 125 (d), 124 (s), 122 (s), 118 (d), 53 (q), 10 (q) ppm. Anal. calcd. for $C_{12}H_{10}O_4$: C 66.05, H 4.62; found: C 66.35, H 4.55.

Reçu le 15 février 1990

JEAN-PIERRE REBOUL, PIERRE BROUANT, JACQUES BARBE, CLAUDE CARANONI, CATHERINE SOULA, ALAIN MARSURA, FRANÇOIS THOMASSON, CUONG LUU-DUC et GÉRARD PEPE. Can. J. Chem. **68**, 2192 (1990).

La structure à l'état solide de l'isopropyl-1-phényl-2-diaza-1,3-one-6-bicyclo[3,3,0]octène-2 a été déterminée par diffraction des rayons X (a = 10,039(3) Å; b = 8,683(3) Å; c = 15,505(6) Å; β = 90,72(9)°; $P2_1/c$; R = 0,047). Cette structure a été comparée, d'une part, à celle d'autres (Δ-2)-imidazolines différemment substituées et, d'autre part, à la géométrie moléculaire de la substance étudiée en solution par spectroscopie de résonance magnétique nucléaire du proton. Si la structure de l'imidazolylcétone cyclique considérée est la même tant à l'état solide qu'en solution, en revanche, elle diffère notablement de celles des imidazolines apparentées.

Mots clés : (Δ-2)-imidazolines, structure cristalline, RMN, conformations.

JEAN-PIERRE REBOUL, PIERRE BROUANT, JACQUES BARBE, CLAUDE CARANONI, CATHERINE SOULA, ALAIN MARSURA, FRANÇOIS THOMASSON, CUONG LUU-DUC, and GÉRARD PEPE. Can. J. Chem. **68**, 2192 (1990).

The solid state configuration of 1-isopropyl-2-phenyl-1,3-diaza-6-one-bicyclo[3.3.0]oct-2-ene was determined from X-ray diffraction data (a = 10.039(3) Å; b = 8.683(3) Å; c = 15.505(6) Å; β = 90.72(9)°; $P2_1/c$; R = 0.047). This structure is compared to those of three other related (Δ-2)-imidazolines. Molecular structure in solution was investigated by ^{1}H nuclear magnetic resonance spectroscopy. Results clearly indicate that the title compound has the same structure in the solid state as in solution. On the contrary, this configuration differs appreciably from those of other (Δ-2)-imidazolines considered in this report.

Key words: (Δ-2)-imidazolines, crystal structure, NMR, conformations.

Introduction

Il existe plusieurs voies de synthèse pour accéder aux (Δ-2)-imidazolines. Certaines font appel à une hétérocylisation à partir de l'éthylènediamine (1, 2); d'autres utilisent des substrats divers : amidines (3) ou benzyloxy-guanidines (4). Cependant, parmi les méthodes proposées, seule celle développée par Marsura *et al.* (5) permit l'accès aux (Δ-2)-imidazolines différemment substituées. On a pu ainsi disposer de différentes molécules dont l'étude structurale présente un intérêt en raison de l'isomérie possible.

Ainsi, ont été successivement étudiées l'isopropyl-1-diphényl-2,4-pivaloyl-5-(Δ-2)-imidazoline **1** (6), la benzyl-1-diphényl-2,4-acétyl-5-(Δ-2)-imidazoline **2** et l'isopropyl-1-diphényl-2,4-benzoyl-5-(Δ-2)-imidazoline **3** (7).

Le travail présenté concerne une molécule apparentée : l'isopropyl-1-phényl-2-diaza-1,3-one-7-bicyclo[3,3,0]octène-2, **4**, schématisée sur la figure 1. On a voulu en comparer la structure cristalline tant, d'une part, à la structure en phase dissoute que, d'autre part, à la structure cristalline des autres (Δ-2)-imidazolines antérieurement étudiées.

zène anhydre (20 mL). On agite le tout 24 h à température ambiante, puis 1 h à la température de reflux de la triéthylamine. On filtre, on évapore sous vide et le résidu est repris par du chloroforme. On lave plusieurs fois la phase chloroformique à l'eau, on la sèche sur sulfate de sodium anhydre et on l'évapore. Le résidu, repris par le minimum d'éther, cristallise à 4°C et présente une phase cristalline stable à la température ordinaire.

T_f(**4**) : 132°C; Rdt : 44%. Analyse (valeurs théoriques) : C %, 74,21 (74,35); N %, 11,34 (11,56); H %, 7,44 (7,49).

2. Radiocristallographie

Les données cristallographiques de **4** sont rapportées dans le tableau 1.

Les monocristaux ont été obtenus par évaporation lente à 273 K d'une solution saturée dans le chloroforme. La maille et le groupe de symétrie ont été déduits de l'analyse de clichés de diffraction effectués en chambre de précession. L'absence systématique des réflexions du type $k = 2n + 1$ sur $0k0$ et $l = 2n + 1$ sur $h0l$ conduit au groupe d'espace $P2_1/c$. Les paramètres cristallins ont été affinés sur un diffractomètre automatique 4 cercles CAD4 Enraf Nonius à monochromateur de graphite (λ (MoKα̃) = 0,7107 Å) à l'aide de 25 réflexions indépendantes à 293 K en balayage θ/2θ avec une vitesse de 10°/min et une amplitude θ = (2,75 + 1,25 tg θ). La densité mesurée par flottaison d'un monocristal dans un mélange benzène/tétrachlorure de carbone conduit à admettre la présence de quatre molécules dans la maille. Trois réflexions de référence, de variation inférieure à 3%, ont été contrôlés toutes les 75 réflexions. Les intensités mesurées ont été corrigées des facteurs de Lorentz et de polarisation. Aucune correction d'absorption n'a été effectuée. La structure a été résolue par les méthodes directes à l'aide du programme SHELX (8). Les facteurs de structure normalisés $E > 1,2$ ont été retenus pour la détermination de phase. La carte de densité électronique correspondant aux meilleurs figures de mérite fait apparaître l'ensemble des atomes de la molécule.

L'affinement de la structure a été conduit par minimisation par moindre carré de la fonction $\Sigma w(|F_o|-|F_c|)^2$ à l'aide du programme SHELX. Les facteurs de diffusion de Cromer et Mann (9) ont été utilisés pour les atomes d'azote, de carbone et d'oxygène. Les atomes autres que ceux d'hydrogène ont été affectés de facteurs de température isotropes, ce qui a conduit à un facteur résiduel de 0,15. L'usage de facteurs anisotropes de température a permis d'atteindre un facteur résiduel de 0,08. L'introduction des atomes d'hydrogène dans une position préalablement calculée (distance de 1,08 Å et angle dépendant de l'hybridation des atomes porteurs), suivie d'un cycle d'affinement, a conduit à un facteur résiduel final de 0,047. Les valeurs des facteurs de diffusion données par Stewart, Davidson et Simpson (10) ont été appliquées aux atomes d'hydrogène. Le nombre de paramètres affinés pour la structure est de 235. Le schéma de pondération est $w = 1/(\sigma^2(F_o) + 0,02\ F_o^2)$.

3. Résonance magnétique nucléaire du proton

Les spectres ont été enregistrés à température ambiante sur un spectromètre Bruker AC 200 FT fonctionnant à 200,132 MHz (UFR de Pharmacie de Grenoble). L'acquisition est en mode FT et la détection en mode quadrature. Les spectres ont été enregistrés dans 16 K points,

2. Les tableaux suivants sont disponibles : facteurs thermiques anisotropes, facteurs de structure observés et calculés, coordonnées atomiques des atomes d'hydrogène, distances et angles concernant les atomes d'hydrogène, plans moyens des différents cycles contenus dans la molécule. On peut les acheter en s'adressant au Dépôt des données non publiées, ICIST, Conseil national de la recherche du Canada, Ottawa (Ontario), Canada K1A 0S2.

On peut également se procurer les tableaux de coordonnées atomiques des atomes d'hydrogène, et de distances et angles concernant les atomes d'hydrogène, en s'adressant au directeur, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, Royaume-Uni.

C(5)—C(6)	1,532(3)	C(24)—C(25)	1,385(3)
C(6)—C(7)	1,503(3)	C(25)—C(26)	1,383(3)

Résultats et discussion

La représentation de la molécule est donnée sur la figure 2.

Les coordonnées des atomes autres que ceux d'hydrogène sont données dans le tableau 2, les longueurs de liaison dans le tableau 3, les angles de liaison dans le tableau 4 et quelques angles de torsion significatifs dans le tableau 5.

Le cycle central imidazoline montre une planéité satisfaisante si on considère la valeur de la déviation maximum (D_{max}) des atomes de ce cycle à leur plan moyen qui est de 0,052(2) Å (tableau 6).

Cependant, une meilleure planéité est trouvée si on tient uniquement compte des atomes C(4)—N(3)—C(2)—N(1) définissant un plan moyen (A'). On note ici, en effet, une déviation maximum de 0,013(2) Å. La distance de 0,139(2) Å de l'atome C(5) à ce plan correspond à une légère forme enveloppe du cycle imidazoline.

Afin de situer les substituants par rapport au cycle central imidazoline, on a envisagé, outre le plan moyen (A) dont il vient

TABLEAU 6. Comparaison structurale des composés **1, 2, 3, 4** (déviation maximum en Å par rapport au plan moyen A* et τ entre les plans moyens* en degré)

	1(6)	**2**(7)	**3**(7)	**4**
Déviation maximum (Å)	0,089(8)	0,069(3)	0,020(5)	0,052(2)
τ(A,B)	34,1(6)	42,0(3)	49,8(6)	34,1(2)
τ(A,C)	110,2(9)	36,5(3)	69,8(6)	40,3(2)
τ(A,D)	176(3)	101,9(3)	147,0(2)	139,7(4)
τ(A,E)	73,1(8)	85,8(4)	124,5(8)	

*Les plans moyens sont ainsi définis : (A), C(4)—N(3)—C(2)—N(1)—C(5); (B), C(21)—C(22)—C(23)—C(24)—C(25)—C(26); (C), C(5)—C(6)—C(7)—O(60); (D), N(1)—C(9)—H(90); (E); cycle benzénique fixé en position 1 chez **1, 2** et **3**.

d'être question, les différents plans moyens (B), (C) et (D) définis dans le tableau 6.

D'une manière générale, pour préciser les positions relatives de deux plans moyens (X) et (Y), on définit un angle de torsion τ(X, Y) à partir de deux paires de pseudo-atomes, chaque paire étant spécifique d'un plan moyen donné. Ainsi pour le plan moyen (X) on considère comme pseudo-atomes, d'une part, le centroïde CX2 des atomes définissant (X) et, d'autre part, l'éxtrémité CX1 d'un vecteur dont le module vaut 1 Å, qui est perpendiculaire à (X) et qui passe par le centroïde CX2. En ce qui le concerne, le plan moyen (Y) est caractérisé par une autre paire de pseudo-atomes CY1 et CY2. L'angle τ(X, Y) est alors l'angle de torsion entre les pseudo-atomes CX1—CX2—CY2—CY1.

On a calculé les angles de torsion entre le plan moyen (A) du cycle central imidazoline et les différents plans moyens (B), (C) et (D). Les résultats sont donnés dans le tableau 6.

D'autre part, le calcul de la position du centroïde de chacun des quatre plans moyens (A), (B), (C) et (D) montre que si (A) est pris pour référence, le centroïde de (B) se trouve en dessous

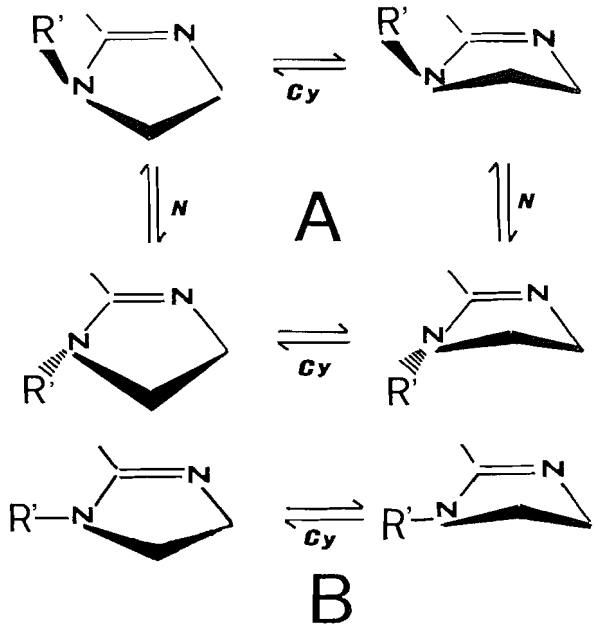

FIG. 3. Processus d'interconversion dans les cas d'azote sp^3 (A) et d'azote sp^2 (B). L'inversion de l'azote est indiquée par N, celle du cycle par Cy.

de (A) à une distance de 0,613(7) Å et le centroïde de (C) se trouve aussi en dessous de (A) mais à une distance de 1,408(3) Å. Pour des raisons stériques, tous les substituants sont ainsi en position *trans* par rapport au cycle central imidazoline.

Quant au plan moyen (B), il révèle avec une déviation maximum de 0,016 Å une planéité satisfaisante du cycle benzénique. L'atome C(2), qui est à 0,144 Å de (B), est considéré comme hors de ce plan.

Comparaison structurale de ***4*** *avec ses analogues* ***1, 2*** *et* ***3*** *en phase solide*

Cette comparaison est faite à l'aide de la déviation maximum des différents atomes à leur plan moyen ainsi que des angles de torsion τ(A,B), τ(A,C), τ(A,D) entre le plan moyen (A) du cycle central imidazoline et les plans (B), (C) et (D) dont les valeurs sont données dans le tableau 6.

De l'analyse des valeurs des déviations maximum, on peut déduire que les quatre composés montrent une conformation plus ou moins plane du cycle imidazoline avec une légère tendance à une forme enveloppe.

La conjugaison du système π du cycle benzénique fixé sur l'atome C(2) avec les électrons de la liaison imine intracyclique C(2)—N(3), se trouve affaiblie comme en témoignent les valeurs relativement élevées de l'angle de torsion τ(A,B).

Afin de comparer par rapport au cycle imidazoline la position relative des substituants isopropyle ou benzyle fixés sur l'atome N(1), on a calculé l'angle de torsion τ(A,D) entre le plan moyen (A) du cycle imidazoline et le plan moyen (D) défini comme le plan passant par les atomes N(1), C(9) et H(90) pour le substituant isopropyle et comme le plan passant par les atomes N(1), C(90) et C(benzylique) dans le cas du substituant benzyle.

En ce qui concerne le groupement carbonyle lié à l'atome C(8), les valeurs de l'angle de torsion τ(A,C) traduisent de grandes variations dans son orientation par rapport au cycle imidazoline.

Enfin, la position relative par rapport au cycle imidazoline du substituant phényle fixé sur l'atome C(4), peut permettre une comparaison des composés **1, 2** et **3**. On a, dans ce but, calculé

TABLEAU 8. Effet Overhauser nucléaire

Composés	Atomes irradiés	Effet sur H(910)–H(912)	Effet sur H(920)–H(922)
1	H(50)	14	33
3	H(50)	0	50
4	H(80)	6	8
4	H(40)	1,5	3

dans chaque cas l'angle de torsion τ(A,E) entre le plan moyen (A) du cycle imidazoline et le plan moyen (E) calculé à partir des atomes du cycle benzénique du substituant phényle. On n'observe, d'une manière générale, que de faibles variations chez ces angles de torsion.

Comparaison de le structure de **4** *en phase solide et en solution*

Pour ce faire, on a étudié les déplacements chimiques des protons significatifs de **4** en solution dans différents solvants. Les résultats sont rassemblés dans le tableau 7. On a ainsi cherché à préciser l'orientation des protons portés par C(4) et C(5) et à résoudre le problème de la conformation autour de N(1).

En ce qui concerne, tout d'abord, les protons H(910)–H(912) et H(920)–H(922) des groupements méthyles du substituant isopropyle, on remarque qu'ils sont logiquement anisochrones car : (a) d'une part, le doublet électronique libre de N(1) crée une zone d'anisotropie magnétique (11) et (b) d'autre part, le groupement carbonyle apporte une contribution qui est limitée à une portion d'espace (12).

Les valeurs des constantes de couplages J^3 (H(40)–H(50)) données dans le tableau 7 sont en accord avec des observations antérieures (13) concernant la situation *cis* ou *trans* des protons (H(40) et H(50)).

Une géométrie *cis* autour de la jonction C(4)—C(5) est imposée ici par la structure bicyclique de **4**. La valeur de la constante de couplage J^3 (H(40)–H(50)) atteint 9,00 Hz et confirme la valeur moyenne plus faible (5–7 Hz) relevée dans le cas d'une situation *trans* de ces mêmes protons (13). Reste l'orientation du substituant isopropyle, car l'atome d'azote porteur peut être considéré soit dans un état d'hybridation sp^3, soit dans un état d'hybridation sp^2. Les processus d'interconversion attendus sont alors schématisés sur la figure 3.

Il faut noter que la cyclisation entre C(4) et C(5) limite considérablement les processus d'inversion de cycle qui sont notés Cy sur la figure 3. En revanche, deux conformations sont possibles dans le cas où l'azote N(1) est de type sp^3, alors qu'il n'en est qu'une seule si l'azote est de type sp^2. La mesure des effets A.S.I.S. (Aromatic Solvent Induced Shift) qui sont empiriques et d'interprétation aléatoire dans le cas des composés **1, 2** ou **3** car tributaires de la mobilité du groupement carbonyle et donc du plan tournant de référence associé, peut avoir une signification structurale dans le cas de **4** à cause de la géométrie imposée au groupement carbonyle par la cyclisation entre C(4) et C(5). Les valeurs positives enregistrées pour H(40) et H(50) et données dans le tableau 8 confirment bien la position des deux protons en arrière d'un plan orthogonal à la liaison C(6)=O(60) et, de ce fait permet de situer raisonnablement, toujours dans cette positive relative, à la fois le proton H(90) et les protons H(910)–H(912) du groupe isopropyle. Les protons H(920)–H(922) montrent, quant à eux une valeur voisine de zéro et seraient donc proches du plan, voire même dans le plan indiqué. Ces résultats sont plutôt en faveur d'une géométrie tétragonale de l'azote N(1) car c'est la seule susceptible d'expliquer les effets mesurés sur les groupes de protons. En effet, une géométrie trigonale de N(1) aurait pour conséquence de rejeter certains des protons observés en avant du plan de référence et des valeurs négatives seraient donc au contraire obtenues.

On a enfin effectué la mesure des effets Overhauser nucléaires. Les résultats de eOn-1D sont résumés pour l'essentiel dans le tableau 8.

On peut y constater tout d'abord que les pourcentages d'effet dans le cas de **4** sont très inférieurs à ceux observés dans le cas de **1** et de **3**, avec une intensité toujours supérieure pour les protons H(920)–H(922). Ces résultats qui sont en faveur de l'hypothèse pour **4** d'un azote N(1) tétragonal et d'un substituant isopropyle dans une situation conformationnelle quasiment identique à celle observée pour **1** et **3**, sont complémentaires des précédents. De plus, la conformation privilégiée du groupement isopropyle implique un alignement approximatif de l'un des méthyles avec H(40) et H(50). Dans ces conditions, par suite d'un effet «trois spins» (14), la saturation des protons H(920)–H(922) du méthyle doit conduire à un effet positif sur H(50) et négatif sur H(40) alors que la saturation sélective de l'autre groupe méthyle formant un triangle avec H(40) et H(50), doit montrer une augmentation du signal de H(50) mais pratiquement pas d'effet sur H(40). Les expériences d'irradiations sélectives ont confirmé ces prévisions.

Conclusion

Il apparaît, à la lumière des résultats de la cristallographie et de la RMN du proton que l'isopropyl-1-phenyl-2-diaza-1,3-one-6 bicyclo[3,3,0]octène-2 montre la même structure moléculaire en phase solide ou en solution dans les solvants apolaires. Il est également acquis que l'azote N(1) est hybridé sp^3 dans les trois structures imidazolines avec une conformation privilégiée du groupement isopropyle situé au dessus du plan moyen du cycle imidazoline. Cependant, la géométrie de la molécule diffère sensiblement de celles antérieurement décrites pour des (Δ-2)-imidazolines apparentées.

Modelling complex solution equilibria. I. Fast, worry-free least-squares refinement of equilibrium constants

PIERRE G. POTVIN

Department of Chemistry, York University, 4700 Keele Street, North York, Ont., Canada M3J 1P3

Received May 11, 1990

PIERRE G. POTVIN. Can. J. Chem. **68**, 2198 (1990).

The methods of Steepest Descent, Gauss–Newton (first-order Taylor series) and Newton–Raphson (second-order Taylor series) least-squares iteration were examined in the context of the refinement of estimated equilibrium constants β in solution. Under certain conditions, all three can produce corrections to the parameters that overshoot the global minimum and diverge therefrom, owing to the shape of the parameter surface. The latter two methods are problematic when the β parameters are overestimated, or when their logarithms are underestimated, whence a useful approximation to the analytical second and higher derivatives was found for any data type. This reduces an exact, infinite-order Taylor series expression of any observable to a simple first-order expression. As illustrated with experimental pH data, faster, more reliable refinement results without overshoot or divergence problems, and without resort to computationally onerous algorithms, such as the Marquardt–Levenberg, Fletcher–Powell, or Hartley–Wentworth methods.

Key words: equilibrium constants, least-squares, Gauss–Newton, complex solution equilibria.

PIERRE G. POTVIN. Can. J. Chem. **68**, 2198 (1990).

Dans le contexte du calcul des constantes d'équilibre β ou autres paramètres déterminant un équilibre complexe en solution, les méthodes d'itération sur les moindres carrés dites Steepest-Descent, Gauss–Newton (basée sur une série de Taylor de premier ordre) et Newton–Raphson (basée sur une série de Taylor de second ordre) sont hazardeuses. Selon la nature de la surface paramétrique, chacune peut donner des corrections aux paramètres β qui survoltent le minimum global et/ou mènent à la divergence. Avec les deux dernières méthodes, ces problèmes n'existent que lorsque les constantes β sont sur-estimées ou que leurs logarithmes sont sous-estimés. Dans ces cas, une description éxacte de toute donnée expérimentale par une série de Taylor d'ordre infini peut alors être réduite à une expression de premier ordre, grâce à l'application d'une bonne approximation aux dérivés d'ordres supérieurs. Telles que calculées pour des données expérimentales de pH, les corrections qui en résultent ont un comportement presqu'idéal, sans divergence, qui rend le calcul plus fiable et plus rapide, sans recours à des algorithmes onéreux tels que ceux de Marquardt–Levenberg, de Fletcher–Powell ou de Hartley–Wentworth.

Mots clés : constantes d'équilibre, moindres carrés, Gauss–Newton, équilibres en solution complexes.

Introduction

The advent of computers has ushered in a large number of programmes to solve complex equilibrium problems where earlier, linear and graphical treatments had failed or could not be applied (for a review, see ref. 1). Since the publication of GAUSS (2), most have been based on the Gauss–Newton (G–N) iterative method of least-squares. Problems inherent in this and the seldom-used Newton–Raphson (N–R) second-order variant (3) are overshoot of the minimum and divergent behaviour when corrections to the initial estimates of the experimental parameters are calculated. These problems can be traced to two sources. One is purely operational: numerically approximated derivatives, still used in some recent programmes (4–6), sometimes lead to matrices with near-zero determinants and, thus, ill-behaved inverses. This can easily be avoided with analytical (exact) derivatives even with single-precision computer arithmetic. The programme LEAST (7) made the first use of exact derivatives of any kind, in this case of the mass-balance sums (an explicit function), but statistical rigour demands the use of derivatives of a non-explicit function (*e.g.* the measured quantity itself). Such were implemented only recently in SUPERQUAD (8) to treat emf data, although the approach had been outlined earlier (9).

The other source of overshoot and divergence is the complex shape of the parameter surface itself, whereas the G–N and N–R methods are based on Taylor series expressions of the surface that are truncated at first- or second-order terms. To counter these problems of either or both types, several algorithms have been incorporated in the basic G–N method. Harley's and Wentworth's algorithms seek to "optimize" the corrections to produce the closest approach to the minimum under the assumption that the parameter surface is approximately parabolic near the minimum (10). The programme BEST makes the same assumption in a crude, heuristic search of the parameter surface (11). The Marquardt–Levenberg technique (12), imported from optic design, empirically and iteratively modifies the "normal" G–N equations in cases of divergence until there is sufficient second-order character to avoid it. This has become a standard-issue tool of several of the newer published (4, 5, 8, 13) and commercial curve-fitting programmes. It is powerful yet largely unnecessary for equilibrium problems when exact derivatives are available. The Fletcher–Powell algorithm (14) is an approximative N–R approach that avoids the matrix inversions. All of these are computationally expensive procedures that can be readily avoided with the approach described herein.

Part 1

Experimental section

pH data were obtained during triplicate titrations at 25 ± 0.1°C by 0.0997 ± 0.001 M NaOH of 3.50 ± 0.05 mL aliquots of 3.872 ± 0.04 × 10^{-3} M solutions of ligand **1** (17) in 0.10 M NaCl containing 1.908 ± 0.001 × 10^{-2} M HCl and 3.813 ± 0.04 × 10^{-3} M $Zn(NO_3)_2$. The titration was performed in a jacketed vessel with a Metrohm 535 buret under the control of a Metrohm 636 titro-processor, using variable volume (≥5 μL) increments suited to the instantaneous pH–volume slope and a 20 s delay before recording the volume and pH. The pH was measured using a Metrohm combination glass microelectrode, with an accuracy of ±0.002 pH units. At pH > 8.3, precipitation of $Zn(OH)_2$ occurred. Previous experiments over a 2.0–10.0 pH range (62 points) in the absence of metal had established that only 3 equiv. of base were consumed to deprotonate the ligand. Using the convention $\log \beta_{ijk} = [H_iZn_jL_k^{(i+2j)+}]/[H^+]^i[Zn^{2+}]^j[L]^k$, the

For personal use only.

following log protonation constants were used with the Zn^{2+} data: $\log \beta_{101} = 7.604 \pm 0.012$, $\log \beta_{201} = 14.396 \pm 0.011$, $\log \beta_{301} = 20.510 \pm 0.011$. The value for pK_w ($-\log \beta_{-100}$) was 13.78 ± 0.03, in accord with tabled values (19).

The Zn^{2+} data within the pH range of 2.0 to 8.3 (23–24 data points per titration) were treated by the FORTRAN-77 programme JACOBI[1] on a VAX 8600 computer, making use of the method described herein. This programme was able to reproduce the literature value for the oxygenation of a μ-hydroxobiscobalt(II) complex of bis-tren from the original data using weighting by the inverse pH–volume slope (11). For the Zn^{2+} data, the calculations used weighting by inverse variances (18) calculated from all sources of experimental error, according to

$$\frac{1}{w_{n,n}} = \sigma_n^2 = \sigma_0^2 + \sum_{k=1}^{n_i} \sigma_k^2 \left(\frac{dF_n}{dP_k}\right)^2$$

where σ_0^2 is the variance in the measurement of the observable, σ_k^2 is the variance of the kth of n_i invariable parameters, and where dF_n/dP_k is the derivative of the nth observable with respect to that parameter as described in the Appendix. A ±5 μL error in titrant volume was included. Numerically, the most important contributors to the variances were the initial volume and titrate concentrations, not because these bore large experimental errors, but because of large derivatives of pH with respect to these. The pH was continuously corrected for changes in ionic strength occasioned during refinement, according to the Avdeef–Bucher procedure (15). The upper pH cut-off was confirmed by checking that $[Zn^{2+}][OH^-]^2$ did not exceed the known K_{sp} for $Zn(OH)_2$. The 12 species considered included $ZnOH^+$ and $Zn(OH)_{2(aq)}$ using literature values (19) for $\log \beta_{-110}$ and $\log \beta_{-210}$ and taking ±0.03 uncertainties in these values. The calculation of the correlation coefficients between the unknown parameters and of their uncertainties of fit followed the procedure of Hamilton (4, 20). The final values of the unknown parameters were $\log \beta_{011} = 3.709 \pm 0.010$, $\log \beta_{-111} = -3.945 \pm 0.010$ and $\log \beta_{111} = 10.622 \pm 0.011$. Alternative models were also tested, i.e. in the absence of one of the complexes or in the presence of other species, such as $(\mathbf{1})Zn(OH)_2$ or octahedral complexes $(\mathbf{1})_2Zn^{2+}$, $(\mathbf{1})_2ZnH^{3+}$, or $(\mathbf{1})_2ZnH^{4+}$, or dimetallic species $(\mathbf{1})Zn_2$. One or more of the following then occurred: (*a*) the standard deviations of the fit became unacceptably high and/or (*b*) the refined log β values for the 1:1 species became unreasonably small and/or (*c*) s became much larger and/or (*d*) the correlation coefficients became significant (>0.9) and/or (*e*) the R-ratio test (4, 20, 21) failed.

Results and discussion

In the process of discovering which species S are present in a mixture of reactants R at equilibrium, one postulates a set of chemically feasible species and one estimates the equilibrium constants that specify their formation from the reactants, according to

$$[S_i]_n = \beta_i \prod_{j=1}^{n_r} [R_j]_n^{a_{i,j}}$$

$$\text{or} \qquad \log [S_i]_n = \log \beta_i + \sum_{j=1}^{n_r} a_{i,j} \log [R_j]_n$$

where $a_{i,j}$ is the number of moles of the jth reactant entering into the formation of the ith species with formation constant β_i. By one convention, the first n_r species are the free reactants themselves. Hence, $\beta_i = 1$, $a_{i,i} = 1$, and $a_{i,j \neq i} = 0$ for $i = 1$ to n_r. This method of defining equilibria through formation constants can be implemented whenever the number of mass-balance sums equals the number of reactants and excludes systems involving ligand substitution equilibria (however, see the accompanying paper for the treatment of such systems).

The total reactant concentrations $[T_j]_n$, one for each of n_r reactants, are known at any nth of n_d data points. With titration data, for example, this involves the initial titrate volume v_0, the titrant increments v_n, and the reactant concentrations $[R_j]^*$ and $[R_j]^+$, in the titrate and titrant, respectively:

$$[T_j]_n = \frac{v_0[R_j]^* + v_n[R_j]^+}{v_0 + v_n}$$

As these totals must at all times agree with the mass-balance sums,

$$[T_j]_n^{\text{calc}} = \sum_{i=1}^{n_s} a_{i,j}[S_i]_n$$

one can know the concentrations of all species at all points, given any set of β values, that will reconcile these two totals. This is performed as described in the Appendix. With known reactant concentrations and some physical measurement that will relate to the concentration of one or more species, iterative adjustments can be made to initial estimates of the unknown β until the resulting species concentrations best reproduce the experimental data. With at least as many measurements as there are unknowns, this refinement is performed by a variety of methods that seek to minimize the sum (s) of the squares of the

$$s = \sum_{n=1}^{n_d} w_{n,n}(O_n - F_n)^2 = (\boldsymbol{O} - \boldsymbol{F})^t \mathbf{w} (\boldsymbol{O} - \boldsymbol{F})$$

differences between observed (O_n) and calculated (F_n) measurements, weighted by estimates of the variances ($1/w_{n,n}$) due to the experimental errors affecting the measurements. Any other parameter, such as $[R]^+$ or $[R]^*$ values, can be similarly determined if the β values are all known.

A typical two-dimensional parameter surface is pictured in Fig. 1, generated by variation of two log formation constants[2] used to reproduce the pH titration data described in the Experimental Section. Every cross-section in Fig. 1 has the same shape (Fig. 2, trace *a*): a minimum well flanked by a plateau region for small parameter values and an exponential region for large values.

The method of Steepest Descent (S-D) is based on the simple assumption that the greatest decrease in s will lie along the steepest slope, i.e. the calculated corrections should vary as the slope of the surface according to

$$\log \beta_j^0 - \log \beta_j \propto \frac{\delta s}{\delta \log \beta_j}$$

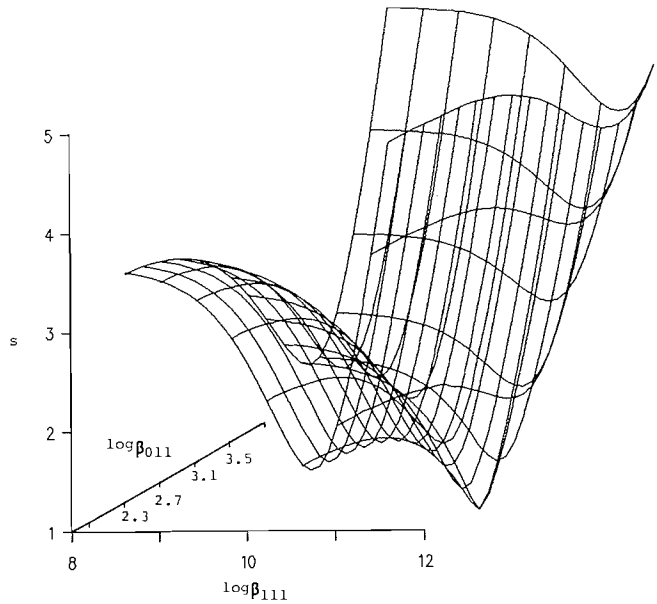

FIG. 1. Plot of s for log β_{111} values between 8.62 and 10.62, log β_{011} values between 1.70 and 4.70, and log β_{-111} held at -3.94. Grid lines are at 0.4 intervals in the log β_{111} dimension and 0.2 intervals in the log β_{011} dimension.

where log β_j^0 are new estimates (ideally, values at the minimum) for any jth parameter. The derivative with respect to any jth log β is given by

$$\frac{\delta s}{\delta \log \beta_j} = -2 \sum_{n=1}^{n_d} w_{n,n}(O_n - F_n)\frac{\delta F_n}{\delta \log \beta_j}$$

$$= -2\mathbf{J}^t\mathbf{w}(\boldsymbol{O} - \boldsymbol{F})$$

where the $\delta F/\delta$ log β elements, whose calculation is detailed later, form the $n_p \times n_d$ Jacobian matrix $\mathbf{J}$. For the cross-section of Fig. 2, this is plotted as trace b. The S-D method is practically useless for very small values of log β_j where the slope is very small and produces strong overshoot in other regions, unless it is scaled down by a proportionality constant suitably determined at each cycle.

The G–N method approximates all regions of each cross-section as linear, with

$$s = s^0 + \sum_{j=1}^{n_\beta} \frac{\delta s}{\delta \log \beta_j}(\log \beta_j - \log \beta_j^0)$$

where s^0 and the n_β parameters log β_j^0 are unknown values at the minimum. The matrix $\mathbf{J}^t\mathbf{w}(\boldsymbol{O} - \boldsymbol{F})$ is not invertible, however. It must instead be assumed that s^0 is zero at the minimum, and the problem must be re-expressed as a first-order Taylor series in the observable:

$$O_n = F_n + \sum_{q=1}^{n_p} \frac{\delta F_n}{\delta \log \beta_q}\Delta \log \beta_q$$

$$\text{or} \qquad \boldsymbol{O} - \boldsymbol{F} = (\Delta^{G\text{-}N})^t\mathbf{J}$$

where Δ log β elements are the corrections at any iteration forming vector $\Delta^{G\text{-}N}$. Then

$$\mathbf{J}^t\mathbf{w}(\boldsymbol{O} - \boldsymbol{F}) = \mathbf{J}^t\mathbf{w}\mathbf{J}\Delta^{G\text{-}N}$$

$$\Delta^{G\text{-}N} = (\mathbf{J}^t\mathbf{w}\mathbf{J})^{-1}\mathbf{J}^t\mathbf{w}(\boldsymbol{O} - \boldsymbol{F})$$

where $\mathbf{J}^t\mathbf{w}\mathbf{J}$ is called the $n_p \times n_p$ Hessian matrix. The actual values of the G–N corrections at various points along the cross-section are plotted in Fig. 3, trace b, alongside the ideal corrections plotted as trace c. Trace b always lies above trace c. In the steep region where log β_j values are overestimated, therefore, better estimates to log β_j^0 are always obtained by assuming that s^0 is zero at the minimum (Fig. 2, trace c). These consistently undershoot the minimum and result in a lower value of s. On the other hand, when log β_j values are underestimated,

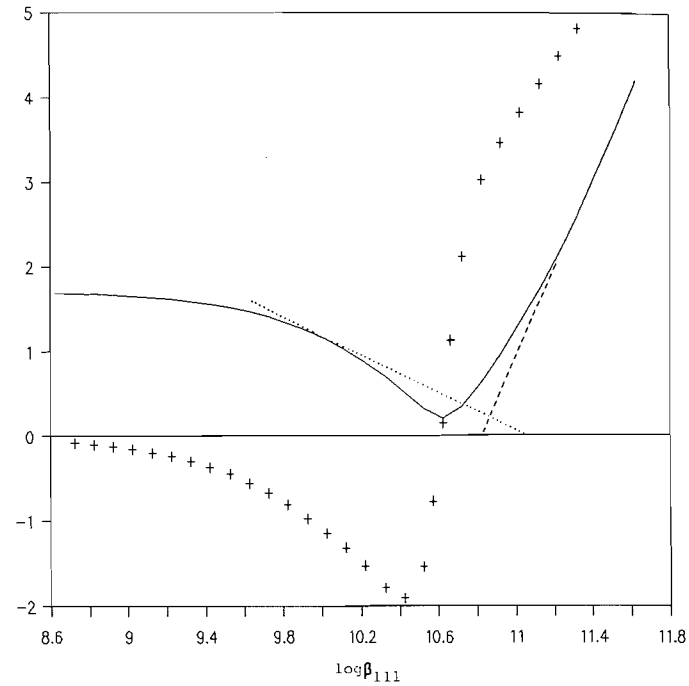

FIG. 2. Plots of (a) s for varying values of log β_{111} with log β_{011} = 3.71 and log $\beta_{-111} = -3.94$ (solid line); (b) $\delta s/\delta$ log β_{111} (++++); (c) interpolation from log $\beta_{111} = 11.40$ (----); (d) interpolation from log $\beta_{111} = 10.00$ (····).

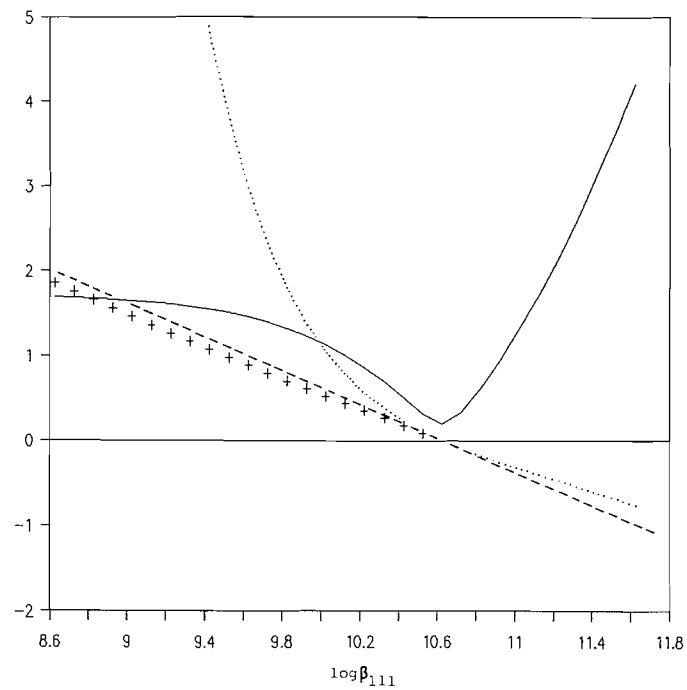

FIG. 3. Plots of (a) s for varying values of log β_{111} with log β_{011} = 3.71 and log $\beta_{-111} = -3.94$ (solid line); (b) $\Delta^{G\text{-}N}$ (····); (c) distance from the minimum or Δ^{ideal} (----); (d) Δ^{mod} (++++).

overshoot is always obtained (Fig. 2, trace *d*). Below certain critical values of $\log \beta_j$, viz. near the minimum in the slope of *s*, the overshoot leads to higher values of *s*. At the extreme, in the plateau region, infinitely high estimates of $\log \beta_j^0$ result.

The Newton–Raphson method, used in STEW (3) but quickly abandoned thereafter by its authors, makes the true assumption that the gradient of the second-order surface approaches zero at the minimum. The surface is given by

$$s = s^0 + \sum_{j=1}^{n_\beta} \left\{ \frac{\delta s}{\delta \log \beta_j} + \frac{1}{2} \sum_{k=1}^{n_\beta} \frac{\delta^2 s}{\delta \log \beta_j \delta \log \beta_k} (\log \beta_k - \log \beta_k^0) \right\} (\log \beta_j - \log \beta_j^0)$$

where

$$\frac{\delta^2 s}{\delta \log \beta_j \delta \log \beta_k} = 2 \sum_{n=1}^{n_d} w_{n,n} \left(\frac{\delta F_n}{\delta \log \beta_j} \frac{\delta F_n}{\delta \log \beta_k} - \frac{\delta^2 F_n}{\delta \log \beta_j \delta \log \beta_k} (O_n - F_n) \right)$$

In matrix notation, the surface is then written as

$$s = s^0 + (\Delta^{N-R})^t \{ \mathbf{J}^t \mathbf{w} (\boldsymbol{O} - \boldsymbol{F}) + [\mathbf{J}^t \mathbf{w} \mathbf{J} - \mathbf{G}^t \mathbf{w} (\boldsymbol{O} - \boldsymbol{F})] \Delta^{N-R} \}$$

where $\mathbf{G}$ is the $n_p \times n_p \times n_d$ matrix of second derivatives. For overestimated $\log \beta_j$ values, the second derivative rapidly slopes off and the third derivative rapidly approaches zero as $\log \beta_j$ increases. Thus, first-order terms soon dominate, and the behaviour resembles that of the G–N method in giving undershoot. For the other portion of the surface, the behaviour is quite different. If the gradient vector (in braces) is set to zero, then the corrections are

$$\Delta^{N-R} = (\mathbf{J}^t \mathbf{w} \mathbf{J} - \mathbf{G}^t \mathbf{w} (\boldsymbol{O} - \boldsymbol{F}))^{-1} \mathbf{J}^t \mathbf{w} (\boldsymbol{O} - \boldsymbol{F})$$

where Δ^{N-R} is the $n_p \times 1$ vector of corrections. However, this produces a discontinuity in the calculated corrections whenever the $\delta^2 s/(\delta \log \beta)^2$ terms (the diagonal elements of the Hessian $\mathbf{J}^t \mathbf{w} \mathbf{J} - \mathbf{G}^t \mathbf{w} (\boldsymbol{O} - \boldsymbol{F})$) are zero, i.e. where the first derivative is at its minimum: the Hessian matrix is no longer invertible as its determinant is then zero. Just beyond this discontinuity, the corrections strongly overshoot because the inverse of the second derivative is large and positive; just below, they produce divergence toward $-\infty$ because the inverse is large and negative. Every higher-order zero-gradient approach will behave in this same way because every μth-order derivative of *s* has $\mu - 1$ roots. As the N–R method applied to equilibrium constant problems is thus flawed, the use of the Fletcher–Powell algorithm (14), which approximates it, seems ill-founded.

The situation is not improved if the cross-section is converted to an anti-log scale, i.e. about minimum values β_j^0 (Fig. 4, trace *a*). For large values of β_j, the G–N method would approximate this as linear, with

$$s = s^0 + \sum_{j=1}^{n_\beta} \frac{\delta s}{\delta \beta_j} (\beta_j - \beta_j^0)$$

By assuming that s^0 is zero at the minimum, new estimates to β_j^0 are thereby obtained which consistently overshoot the minimum (Fig. 4, trace *b*). This gets worse further and further from the minimum where the linear approximation holds less and less well. For underestimated values of β_j, undershoot is obtained (Fig. 4, trace *c*). Since no advantage is gained by expressing the problem in terms of β values, computer calculations using $\log \beta$ values are to be preferred, for three reasons: (*a*) the Hessian elements are more uniform in size, affording more reliable inverses without resort to higher arithmetic precision, (*b*) β values need to be protected from becoming negative during refinement, and (*c*) they can exceed the machine's limits on number sizes (*e.g.* $10^{\pm 38}$ for a VAX). However, overshoot could in theory be avoided by refining $\log \beta$ terms when these are overestimated and refining β terms when they are underestimated. In fact, the approach described herein simulates this while actually calculating with $\log \beta$ values throughout.

For the three unknown system described in the Experimental Section, Table 1 reports the G–N correction vectors, calculated from representative starting points, alongside the corresponding ideal corrections. The labelling convention $\log \beta_{ijk}$ is used for convenience and here denotes $[H_i Zn_j L_k^{(i+2j)+}]/[H^+]^i [Zn^{2+}]^j [L]^k$. As predicted from Figs. 2 and 3, severe overshoot occurs with positive corrections of underestimated $\log \beta$ values. (The G–N vector for case 3 appears to lead to divergence for $\log \beta_{111}$ but actually does not. Although the corresponding S-D correction is positive, a large negative G–N element is calculated for the underestimated $\log \beta_{111}$ because the diagonal of the Hessian is dominated by the large value corresponding to the overestimated $\log \beta_{-111}$. On the next cycle, the G–N vector reverses direction and a positive correction to $\log \beta_{111}$ is calculated.) Application of these raw G–N vectors would lead to increases in *s*. Although this can nevertheless be productive, as *s* will always be reduced on the next cycle, a machine algorithm will normally abort whenever *s* increases. As well, such large shifts make the calculation of the new species concentrations (and the new *s*) very difficult (see Appendix). Attenuation of these large shifts is desirable, and several strategies have been explored.

One strategy, the Hartley–Wentworth (H–W) parabolic interpolation (10), is illustrative of inefficient refinement. It seeks to "optimize" the attenuation by applying two different lengths of the raw G–N vector, fitting the initial and resultant *s* values to a parabolic function of the scaling required, and estimating that function's minimum. For the large G–N vectors of Table 1, severe attenuation is needed. In this implementation, therefore, the refinement was accelerated by first scaling the raw G–N vectors, such that the largest element did not exceed a generous maximum of 3 log units, before applying the H–W algorithm. Even so, this strategy is inefficient because, as is evident from Fig. 2, the assumption of a parabolic surface is rarely a good one and much computation is wasted calculating chimeric parabolic minima. Several improvements to the basic algorithm can be devised (such as applying it only if *s* increases) but the root problem is that *at least* three re-calculations of the species concentrations (and of *s*) are needed on each cycle. At each re-calculation, new derivatives become available

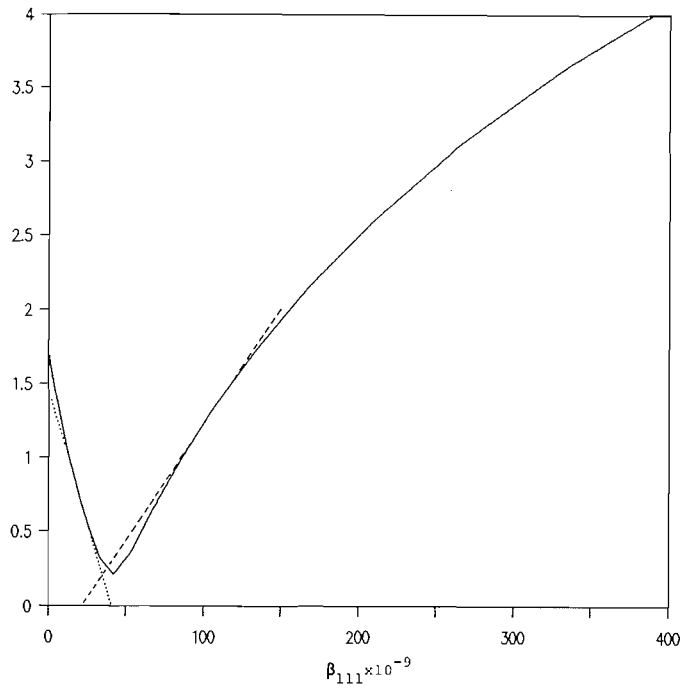

FIG. 4. Plots of (*a*) *s* for varying values of β_{111} with $\beta_{011} = 10^{3.71}$ and $\beta_{-111} = 10^{-3.94}$ (solid line); (*b*) interpolation from $\beta_{111} = 10^{11}$ (----); (*c*) interpolation from $\beta_{111} = 10^{10.3}$ (····).

(see Appendix) and it is more efficient to calculate new, more relevant corrections therefrom than to re-scale the old ones. The parabolic interpolation used in BEST (11) is similarly flawed: in the best circumstances,[3] 11.55 s were required for case 1 in Table 1.

Another inefficient strategy enjoying some popularity (4, 5, 8, 13) is the Marquardt–Levenberg algorithm (12). Here, the basic equations are modified:

$$(\Delta^{M-L})^* = ((\mathbf{J}^t\mathbf{w}\mathbf{J})^* + \lambda\mathbf{I})^{-1}(\mathbf{J}^t\mathbf{w}(\boldsymbol{O} - \boldsymbol{F}))^*$$

The superscript * denotes normalized elements, **I** is the identity matrix, and λ is a scalar. As prescribed by the algorithm, λ is kept as small as possible, but is increased whenever an increase in *s* is detected until sufficiently small Δ^{M-L} elements are obtained that generate a lower *s*. The Hessian is thus given second-order character to swing the correction vector from a purely G–N direction towards the S-D direction given by $\mathbf{J}^t\mathbf{w}(\boldsymbol{O} - \boldsymbol{F})$. Quite apart from the extra computations for normalization, one cycle requires more than one inversion of the modified Hessian and, like the H–W algorithm, more than one re-calculation of *s* whenever the raw G–N vector (λ = 0) produces an increase in *s*. For the large G–N vectors of Table 1, many re-calculations would be required on the first cycle and the speed with which λ can be increased becomes crucial. An immediate improvement can be obtained by first scaling down the length of the raw G–N vector, much as was done with the H–W algorithm. However, if the largest G–N element is kept to a reasonable maximum (*e.g.* 3 log units), the M–L algorithm, like the H–W algorithm, is hardly ever needed.[4]

Indeed, a simpler and much more economical strategy is to choose a general-purpose attenuation of G–N vectors. The results of using three different maxima are reported in Table 2. As expected, too generous an allowance can result in an increase in *s* (and aborted refinement), while one too stingy requires more computation. There is no rule governing the choice of a maximum other than by trial and error. Those used here were suitable for this particular situation, but there is no guarantee that they would not be excessive in some other situation. Nevertheless, this remains a good and reliable strategy.

In all of these strategies, the directions of the raw G–N vectors were preserved. When the largest elements overwhelm the smaller ones as in several of the cases in Table 1, adjustment of the length amounts to a neglect of the smaller elements. Since only positive corrections give overshoot, one should be able to use the full negative corrections to improve the efficiency. The results of using positive-only scaling are also given in Table 2. Indeed, fewer cycles and less time are required when the refinement is successful, but it is more prone to failure. Further, temporary divergence can cause failure of a different sort: In case 3, the second cycle calculates a positive correction to $\log \beta_{111}$, but subsequent scaling affords an undetectably small decrease in s ($<10^{-6}$) and the refinement aborts.

Although this problem might be managed with a higher arithmetic precision or a lowering of the detection limit, a simpler solution is to refuse large negative corrections if the corresponding S-D elements are not also negative. The remaining problem of choosing an appropriate maximum can be entirely and neatly circumvented as follows: The G–N corrections of underestimated $\log \beta$ (Fig. 3, trace *b*) are exponentially dependent on the distance from the minimum (given in trace *c*). Indeed, cases 7*a* to 7*c* in Table 1 illustrate this well: a unit decrease in $\log \beta_{011}$ (i.e. a ten-fold decrease in β_{011}) leads to a *ca.* ten-fold increase in the G–N correction to it, while the other corrections are invariant. A logarithmic modification suggests itself. Indeed, a useful function is

$$\Delta_q{}^{mod} = \log (\ln 10\Delta_q{}^{G-N} + 1)$$

Along the cross-section of Fig. 3, where $\log \beta_{011}$ and $\log \beta_{-111}$ were held at their minimum values, *nearly ideal* corrections of underestimated $\log \beta_{111}$ result (trace *d*). As expected for the cases of Table 1, the modified correction vectors are of much more reasonable size. There is still overshoot of the minimum values (after all, the G–N elements are initially directing us toward the minima of the local cross-sections), but, as illustrated by cases 7*a* to 7*c*, such overshoot (by *ca.* 1.73) is essentially constant along any one cross-section. Such is not true of the scaled G–N vectors: *e.g.* a maximum correction of 3 log units leads to overshoot by 2 (for case 7*a*), 1 (for 7*b*) or 0 (for 7*c*) log units. This invariance of the overshoot allows

[3]Comparisons with BEST are inappropriate. Increments are added by trial and error, one parameter at a time. Variances are not calculated as weighting is by inverse pH–volume slopes that are numerically approximated. This produces very flat-bottomed minima and leads to different final values (here, $\log \beta_{011} = 3.59$, $\log \beta_{-111} = -4.12$, $\log \beta_{111} = 10.53$) with no estimates of the errors or correlations. Starting with values 2 log units below this minimum (i.e. analogous to case 1 of Table 1), refinement needed to proceed in two stages: one cycle with an increment of 2 (the ideal!) and nine cycles with increments of 0.01.

[4]The M–L formulation is nevertheless useful whenever the Hessian's determinant is near zero, as can arise with numerically-approximated derivative elements of **J**. A small but finite value of λ ensures a meaningful inverse.

us the luxury of tolerating it *whether or not an increase in* s *results*, as the first iteration will always lead to the same point on the parameter surface, s will always decrease on the next iteration, and overshoot will not recur.

By combining these observations, a new strategy can be formulated. It involves element-by-element examination of the raw G–N vector, as follows. For any qth element, (*a*) if $\Delta_q^{\text{G-N}} \leq 0$ and $\Delta_q^{\text{S-D}} \leq 0$, $\Delta_q = \Delta_q^{\text{G-N}}$; (*b*) if $\Delta_q^{\text{G-N}} < -0.1$ (an arbitrary value) but $\Delta_q^{\text{S-D}} > 0$, $\Delta_q = -0.1$; (*c*) if $\Delta_q^{\text{G-N}} > 0$, $\Delta_q = \Delta_q^{\text{mod}}$; if two successive increases in s are detected (this has yet to be witnessed), $\Delta_q = 0$.

The results of applying this strategy are reported in Table 2. The trivial additional cost of computing Δ^{mod} elements, which is often only required on the first iteration, is more than compensated by the avoidance of scaling. Fast, worry-free refinement results. For most cases, the speed compared very favourably with the best results obtained with scaling. For all intents and purposes, overshoot and divergence problems can thus be eliminated.

There is a sound theoretical basis for this function (*vide infra*) which guarantees its success for all complex equilibrium problems where the analytical measurements are functions of the concentrations of one of more species, or of their logarithms.

Part 2. Theoretical basis

Experimental data such as absorbance under Beer's Law or nmr chemical shift for rapidly equilibrating species are functions of the concentrations of the n_s species S present in solution. Such data can be generalized as

$$F_n = \sum_{i=1}^{n_s} \alpha_i [S_i]_n$$

With absorbance data, F_n is the nth absorbance observed at some wavelength λ and α_i is $\epsilon_{\lambda,i} l$, where $\epsilon_{\lambda,i}$ is the extinction coefficient of the ith species at λ and l is the light pathlength. With nmr data, F_n is the nth chemical shift measurement of some νth nucleus and α_i is $a_{i,\nu}\sigma_{\nu,i}/[T_\nu]_n$, where $a_{i,\nu}$ is the number of nuclei of the νth type in the ith species, $[T_\nu]_n$ is the total concentration of the νth nucleus, and $\sigma_{\nu,i}$ is the chemical shift of the νth nucleus in the ith species. The unknown ϵ or σ parameters (one for each unknown β) are most easily determined in separate but straightforward G–N refinements, parallel to those of the unknown β or log β parameters, and will not be considered further.

The first and second derivatives of F_n have the form

$$\frac{\delta F_n}{\delta P_j} = \sum_{i=1}^{n_s} \alpha_i \frac{\delta [S_i]_n}{\delta P_j} = \ln 10 \sum_{i=1}^{n_s} \alpha_i [S_i]_n \frac{\delta \log [S_i]_n}{\delta P_j}$$

$$\frac{\delta^2 F_n}{\delta P_q \delta P_r} = \sum_{i=1}^{n_s} \alpha_i \frac{\delta^2 [S_i]_n}{\delta P_q \delta P_r} = \ln 10 \sum_{i=1}^{n_s} \alpha_i [S_i]_n \times \left\{ \frac{\delta^2 \log [S_i]_n}{\delta P_q \delta P_r} + \ln 10 \frac{\delta \log [S_i]_n}{\delta P_r} \frac{\delta \log [S_i]_n}{\delta P_q} \right\}$$

The first and second derivatives of the log species concentrations are given in the Appendix by

$$\frac{\delta \log [S_i]_n}{\delta P_q} = \frac{\delta \log \beta_i}{\delta P_q} + \sum_{k=1}^{n_r} a_{i,k} \frac{\delta \log [R_k]_n}{\delta P_q}$$

where

$$\frac{\delta \log [R_k]_n}{\delta P_q} = -\sum_{j=1}^{n_r} u_{n,k,j} a_{q,j} [S_q]_n \frac{\delta \log \beta_q}{\delta P_q}$$

and

$$\frac{\delta^2 \log [S_i]_n}{\delta P_q \delta P_r} = \sum_{k=1}^{n_r} a_{i,j} \frac{\delta^2 \log [R_k]_n}{\delta P_q \delta P_r}$$

where

$$\frac{\delta^2 \log [R_k]_n}{\delta P_q \delta P_r} = -\ln 10 \sum_{j=1}^{n_r} u_{n,k,j} \sum_{i=1}^{n_s} a_{i,j} [S_i]_n \frac{\delta \log [S_i]_n}{\delta P_q} \frac{\delta \log [S_i]_n}{\delta P_r}$$

When P values are underestimated, $\delta^2 \log [R]/\delta P_q \delta P_r$ elements have very small numerical values when $q \neq r$. This arises because the individual $\delta \log [S_i]/\delta P_q$ elements are small unless $i = q$, whence they are dominated by the $\delta \log \beta_q/\delta P_q$ term. If P are log β elements this term is simply 1 when $i = q$. If P are β elements, then $\delta \log \beta_q/\delta P_q = 1/\ln 10 \beta_q$. Therefore, when log β or β values are underestimated, an approximation can be written

$$\frac{\delta^2 \log [R_k]_n}{\delta P_q \delta P_r} \approx -\ln 10 \sum_{j=1}^{n_r} u_{n,k,j} a_{q,j} [S_q]_n \frac{\delta \log \beta_q}{\delta P_q} \frac{\delta \log \beta_q}{\delta P_r}$$

$$\approx 0 \quad \text{if} \quad q \neq r$$

$$\approx \ln 10 \frac{\delta \log [R_k]_n}{\delta P_q} \frac{\delta \log \beta_q}{\delta P_q} \quad \text{if} \quad q = r$$

This is easily verified with pH data and holds especially well if one or more of the other unknown log β values is overestimated. It also holds well in those regions of the data where the corresponding species is a minor component of the mixture. This suggests an exponential dependence of $\delta \log [R_k]_n/\delta \log \beta_q$ on log β_q (i.e. a linear dependence on β_q, or constant $\delta \log [R]/\delta \beta_q$). In fact, the dependence is sigmoidal, with an exponential increase for small log β_q and sloping off that starts near the minimum values of log β_q. The more underestimated log β_q, the better the approximation.

For any μth order, it can be shown that

$$\frac{\delta^\mu \log [R_k]_n}{\delta P_q \delta P_r \delta P_s \ldots} \approx 0 \quad \text{if} \quad q \neq r \quad \text{or} \quad q \neq s \quad \text{etc.}$$

$$\approx \ln 10 \frac{\delta^{\mu-1} \log [R_k]_n}{\delta P_q^{\mu-1}} \quad \text{if} \quad q = r = s, \quad \text{etc.}$$

$$\approx (\ln 10)^{\mu-1} \frac{\delta \log [R_k]_n}{\delta P_q} \{\delta \log \beta_q/\delta P_q\}^{\mu-1} \quad \text{if} \quad q = r = s, \quad \text{etc.}$$

The same result is obtained if the analytically derived μth derivatives are examined under the initial assumption. Thus, all μth derivatives are linear in β_q.

Under the initial assumption, the second derivative of F_n can be reduced to a multiple of the first:

[a]An increase in s was encountered.
[b]An undetectable change in s was obtained.

$$\frac{\delta^2 F_n}{\delta P_q \delta P_r} = \ln 10 \sum_{i=1}^{n_s} \alpha_i [S_i]_n \left\{ \sum_{k=1}^{n_r} a_{i,k} \frac{\delta^2 \log [R_k]_n}{\delta P_q \delta P_r} + \ln 10 \frac{\delta \log [S_i]_n}{\delta P_r} \frac{\delta \log [S_i]_n}{\delta P_q} \right\}$$

$$\approx 0 \quad \text{if} \quad q \neq r$$

$$\approx (\ln 10)^2 \sum_{i=1}^{n_s} \alpha_i [S_i]_n \left\{ \frac{\delta \log \beta_q}{\delta P_q} \sum_{k=1}^{n_r} a_{i,k} \frac{\delta \log [R_k]_n}{\delta P_q} + \frac{\delta \log \beta_q}{\delta P_q} \frac{\delta \log \beta_i}{\delta P_q} \right\}$$

$$\approx (\ln 10)^2 \sum_{i=1}^{n_s} \alpha_i [S_i]_n \left\{ \frac{\delta \log \beta_q}{\delta P_q} \frac{\delta \log [S_i]_n}{\delta P_q} \right\}$$

$$\approx \ln 10 \frac{\delta F_n}{\delta P_q} \frac{\delta \log \beta_q}{\delta P_q} \quad \text{if} \quad q = r$$

In general, then,

$$\frac{\delta^\mu F_n}{\delta P_q \delta P_r \delta P_s \ldots} \approx 0 \quad \text{if } q \neq r \quad \text{or} \quad q \neq s \quad \text{or} \quad q \neq t, \quad \text{etc.}$$

$$\approx (\ln 10)^{\mu-1} \frac{\delta F_n}{\delta P_q} \left(\frac{\delta \log \beta_q}{\delta P_q} \right)^{\mu-1} \quad \text{if} \quad q = r = s = t, \quad \text{etc.}$$

An infinite-order Taylor series can be written to describe the observations:

$$O_n = F_n + \sum_{q=1}^{n_p} \left\{ \frac{\delta F_n}{\delta P_q} + \frac{1}{2!} \sum_{r=1}^{n_p} \left(\frac{\delta^2 F_n}{\delta P_q \delta P_r} + \frac{1}{3!} \sum_{s=1}^{n_p} \left[\frac{\delta^3 F_n}{\delta P_q \delta P_r \delta P_s} + \cdots \right] \Delta P_s \right) \Delta P_r \right\} \Delta P_q$$

where ΔP are the corrections to the n_p parameters, $P^\infty - P$, that will generate the values at the minimum. When the parameters are underestimated, this simplifies to

$$O_n - F_n \approx \sum_{q=1}^{n_p} \left\{ \frac{\delta F_n}{\delta P_q}\Delta P_q + \frac{1}{2!}\frac{\delta^2 F_n}{\delta P_q^2}(\Delta P_q)^2 + \frac{1}{3!}\frac{\delta^3 F_n}{\delta P_q^3}(\Delta P_q)^3 + \cdots \right\}$$

$$\approx \sum_{q=1}^{n_p} \frac{\delta F_n}{\delta P_q}\left\{ \Delta P_q + \frac{1}{2!}\ln 10\frac{\delta \log \beta_q}{\delta P_q}(\Delta P_q)^2 + \frac{1}{3!}\left(\ln 10\frac{\delta \log \beta_q}{\delta P_q}\right)^2(\Delta P_q)^3 + \cdots \right\}$$

$$\approx \frac{1}{\ln 10}\sum_{q=1}^{n_p} \frac{\delta P_q}{\delta \log \beta_q}\frac{\delta F_n}{\delta P_q}\{e^{\ln 10 \Delta P_q \delta \log \beta_q/\delta P_q} - 1\}$$

$$\approx \frac{1}{\ln 10}\sum_{q=1}^{n_p} \frac{\delta P_q}{\delta \log \beta_q}\frac{\delta F_n}{\delta P_q}\{10^{\Delta P_q \delta \log \beta_q/\delta P_q} - 1\}$$

If one sets

$$\Delta_q^{G\text{-}N} = \frac{1}{\ln 10}\frac{\delta P_q}{\delta \log \beta_q}\{10^{\Delta P_q \delta \log \beta_q/\delta P_q} - 1\}$$

and performs a normal G–N determination of the $\Delta_q^{G\text{-}N}$ vector using the normal Jacobian and Hessian matrices, i.e. using $\Delta_q^{G\text{-}N} = (\mathbf{J}^t\mathbf{w}\mathbf{J})^{-1}\mathbf{J}^t\mathbf{w}(\boldsymbol{O} - \boldsymbol{F})$ as described above, then "infinite-order" corrections are given by

$$\Delta P_q = \frac{\delta P_q}{\delta \log \beta_q}\log (1 + \ln 10 \Delta_q^{G\text{-}N} \delta \log \beta_q/\delta P_q)$$

Note that if the parameters P are log β elements, then this infinite-order treatment amounts to a first-order treatment in terms of β elements, because

$$O_n - F_n \approx \frac{1}{\ln 10}\sum_{q=1}^{n_p} \frac{\delta F_n}{\delta \log \beta_q}\{10^{\Delta \log \beta_q} - 1\} \approx \frac{1}{\ln 10}\sum_{q=1}^{n_p} \frac{\delta F_n}{\delta \log \beta_q}\frac{\Delta \beta_q}{\beta_q}$$

$$\approx \sum_{q=1}^{n_p} \frac{\delta F_n}{\delta \beta_q}\Delta \beta_q$$

Thus, when the parameters are underestimated, the observable can be linearized. Further,

$$w_n(O_n - F_n)^2 \approx \sum_{q=1}^{n_p} \frac{\delta F_n}{\delta \beta_q} w_n(O_n - F_n)\Delta \beta_q$$

and

$$s = \sum_{n=1}^{n_d} w_n(O_n - F_n)^2 \approx \sum_{n=1}^{n_d}\sum_{q=1}^{n_p} \frac{\delta F_n}{\delta \beta_q} w_n(O_n - F_n)\Delta \beta_q = \sum_{q=1}^{n_p} \frac{\delta s}{\delta \beta_q}\Delta \beta_q$$

In other words, an "infinite-order" refinement of underestimated log β amounts to minimizing s in terms of β, and should therefore afford the undershoot depicted in Fig. 4, trace *c*.

Experimental data such as emf or pH are functions of the logarithms of the species concentrations and lead to slightly different results. Such data can be represented by

$$G_n = A + B\sum_{i=1}^{n_s} \gamma_i \log [S_i]_n$$

For pH, $G_n = pH_n$, $A = 0$, $B = 1$, $\gamma_1 = 1$ (using the convention that H^+ is the first species), and $\gamma_{i \neq 1} = 0$. Calibration of the electrode, by the Avdeef–Bucher (15) or Jameson–Wilson (16) procedures, is necessary to directly read $-\log [H^+]$. For emf data, $G_n = E_n$ and, assuming Nernstian behaviour, $A = E^0$, $B = \ln 10RT/nF$ and γ_i is the coefficient of the ith species (positive for products, negative for reactants) in the half-cell reaction at the monitoring electrode. (In many, if not most, situations, a single species enters into the half-cell reaction at the monitoring electrode and all other γ values will be zero.) Because of non-Nernstian behaviour, both A and B are usually determined by calibration in individual experimental situations (B is a response slope and A is a sum of the standard reduction potentials at the monitoring and reference electrodes, as well as any boundary and/or liquid junction potentials).

The first and second derivatives with respect to any qth parameter are simply

$$\frac{\delta G_n}{\delta P_q} = B\sum_{i=1}^{n_s} \gamma_i \frac{\delta \log [S_i]_n}{\delta P_q}$$

$$\frac{\delta^2 G_n}{\delta P_q \delta P_r} = B\sum_{i=1}^{n_s} \gamma_i \frac{\delta^2 \log [S_i]_n}{\delta P_q \delta P_r}$$

When β or log β parameters are underestimated, then

$$\frac{\delta^2 G_n}{\delta P_q \delta P_r} \approx 0 \quad \text{if} \quad q \neq r$$

$$\approx \ln 10 B\sum_{i=1}^{n_s} \gamma_i \sum_{k=1}^{n_r} a_{i,k}\frac{\delta \log [R_k]_n}{\delta P_q}\frac{\delta \log \beta_q}{\delta P_q} \quad \text{if} \quad q = r$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

$$\approx \ln 10B\frac{\delta \log \beta_q}{\delta P_q}\left(-\gamma_q\frac{\delta \log \beta_q}{\delta P_q} + \sum_{i=1}^{n_s}\gamma_i\frac{\delta \log [S_i]_n}{\delta P_q}\right) \quad \text{if} \quad q = r$$

$$\approx \ln 10\frac{\delta G_n}{\delta P_q} - \ln 10B\gamma_q\left(\frac{\delta \log \beta_q}{\delta P_q}\right)^2 \quad \text{if} \quad q = r$$

where, in many emf and all pH situations, $\gamma_q = 0$. In general,

$$\frac{\delta^\mu G_n}{\delta P_q \delta P_r \delta P_s \ldots} \approx 0 \text{ if } q \neq r \text{ or } q \neq s, \text{ etc.}$$

$$\approx (\ln 10)^{\mu-1}\frac{\delta G_n}{\delta P_q} - (\ln 10)^{\mu-1}B\gamma_q\left(\frac{\delta \log \beta_q}{\delta P_q}\right)^\mu \quad \text{if } q = r = s, \text{ etc.}$$

An infinite-order treatment leads to

$$O_n - G_n \approx \sum_{q=1}^{n_p}\left(\frac{\delta P_q}{\delta \log \beta_q}\frac{1}{\ln 10}\frac{\delta G_n}{\delta P_q}\{10^{\Delta P_q \delta \log \beta_q/\delta P_q} - 1\} - B\gamma_q\frac{\delta \log \beta_q}{\delta P_q}\{10^{\delta \log \beta_q/\delta P_q} - 1\}\right)$$

or

$$O_n - G_n + B\sum_{q=1}^{n_p}\gamma_q\frac{\delta \log \beta_q}{\delta P_q}\{10^{\delta \log \beta_q/\delta P_q} - 1\} \approx \sum_{q=1}^{n_p}\frac{\delta G_n}{\delta P_q}\Delta_q^{G\text{-}N}$$

In the rare cases where the γ_q are non-zero, the observables are modified by the constant terms in γ_q. Let this constant be represented by c. For instance, with $P_q = \log \beta_q$,

$$c = 9B\sum_{q=1}^{n_p}\gamma_q$$

A normal G–N treatment can be performed to obtain

$$\Delta^{G\text{-}N} = (\mathbf{J}^t\mathbf{w}\mathbf{J})^{-1}\mathbf{J}^t\mathbf{w}(\mathbf{O} - \mathbf{F} + \mathbf{c})$$

where $\mathbf{c}$ is a $n_d \times 1$ vector of constants c, and the same expression can be used to calculate ΔP_q elements from $\Delta_q^{G\text{-}N}$ elements, as before.

Appendix

Differentiation of the jth total reactant concentration $[T_j]_n$ at any nth point with respect to any parameter P_q gives

$$\frac{\delta [T_j]_n}{\delta P_q} = \ln 10\sum_{i=1}^{n_s}a_{i,j}[S_i]_n\left(\frac{\delta \log \beta_i}{\delta P_q} + \sum_{k=1}^{n_r}a_{i,j}\frac{\delta \log [R_k]_n}{\delta P_q}\right)$$

If one sets

$$(\mathbf{u}^{-1})_{n,j,k} = \sum_{i=1}^{n_s}a_{i,j}[S_i]_n a_{i,k}$$

where, at any nth point, the elements $\mathbf{u}^{-1}{}_{n,j,k}$ form an invertible $n_r \times n_r$ matrix, then rearrangement leads to

$$\frac{\delta \log [R_k]_n}{\delta P_q} = \sum_{j=1}^{n_r}u_{n,k,j}\left(\frac{1}{\ln 10}\frac{\delta [T_j]_n}{\delta P_q} - \sum_{i=1}^{n_s}a_{i,j}[S_i]_n\frac{\delta \log \beta_i}{\delta P_q}\right)$$

Further, we have

$$\frac{\delta \log [S_m]_n}{\delta P_q} = \frac{\delta \log \beta_m}{\delta P_q} + \sum_{k=1}^{n_r}a_{m,k}\frac{\delta \log [R_k]_n}{\delta P_q}$$

Generally one does not refine the invariable parameters (8, 11), and $\delta[T]/\delta \log \beta$ terms are normally zero. However, the derivatives with respect to these are used in the calculation of variances (*vide supra*) and co-variances (8), whence $\delta \log \beta/\delta P$ terms are zero and $\delta[T]/\delta P$ terms are obtained by differentiation of the definitions of [T]. For instance, with titration data,

$$\frac{\delta [T_j]_n}{\delta P_q} = \frac{1}{v_0 + v_n}\left(v_0\frac{\delta [R_j]^*}{\delta P_q} + v_n\frac{\delta [R_j]^+}{\delta P_q}\right) + \frac{[R_j]^* - [R_j]^+}{(v_0 + v_n)^2}\left(v_n\frac{\delta v_0}{\delta P_q} + v_0\frac{\delta v_n}{\delta P_q}\right)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

The $\delta^2 \log [R_k]_n/\delta P_q \delta P_r$ terms are obtained by further differentiation, as in

$$\frac{\delta^2[T_j]_n}{\delta P_q \delta P_r} = \ln 10 \sum_{i=1}^{n_s} a_{i,j}[S_i]_n \left(\ln 10 \frac{\delta \log [S_i]_n}{\delta P_q} \frac{\delta \log [S_i]_n}{\delta P_r} + \sum_{k=1}^{n_r} a_{i,k} \frac{\delta^2 \log [R_k]_n}{\delta P_q \delta P_r} \right)$$

Rearrangement, as before, leads to

$$\frac{\delta^2 \log [R_k]_n}{\delta P_q \delta P_r} = \frac{1}{\ln 10} \sum_{j=1}^{n_r} u_{n,k,j} \left(\frac{\delta^2[T_j]_n}{\delta P_q \delta P_r} - (\ln 10)^2 \sum_{i=1}^{n_s} a_{i,j}[S_i]_n \frac{\delta \log [S_i]_n}{\delta P_q} \frac{\delta \log [S_i]_n}{\delta P_r} \right)$$

and we have

$$\frac{\delta^2 \log [S_i]_n}{\delta P_q \delta P_r} = \sum_{k=1}^{n_r} a_{i,j} \frac{\delta^2 \log [R_k]_n}{\delta P_q \delta P_r}$$

Note that $\delta^2[T_j]_n/\delta P_q \delta P_r$ elements are not normally required and usually zero, but are available from the definitions of $[T]_n$.

The concentrations of the species are required at all data points. In LEAST (7), these were determined and refined together with the unknown parameters, with minimization of the residuals in the analytical (total) concentrations of the reactants. Not only does this approach generate very large matrices for inversion, it does not constitute a valid least-squares analysis. Instead, the species concentrations are calculated by reconciling the species definitions with the mass-balance sums in separate Gauss–Newton iterations at each point. This is most easily accomplished by setting up first-order Taylor series of the experimental mass-balance sums as functions of μth estimates of the reactant concentrations, viz.

$$[T_j]_n = \sum_{i=1}^{n_s} a_{i,j}[S_i]_n^{\mu} + \sum_{m=1}^{n_r} \frac{\delta[T_j]_n}{\delta[R_m]_n} ([R_m]_n^{\infty} - [R_m]_n^{\mu})$$

which in matrix notation is written

$$[\mathbf{T}] = \mathbf{a}^t[\mathbf{S}]^{\mu} + \mathbf{H}\Delta^{\mu}$$

with the j,mth element of the $n_r \times n_r$ invertible matrix $\mathbf{H}$ obtained by letting $P_q = [R_m]_n$ in the earlier expression for $\delta[T_j]_n/\delta P_q$. Then

$$H_{j,m} = \sum_{i=1}^{n_s} a_{i,j}[S_i]_n a_{i,k}/[R_m]_n = (\mathbf{u}^{-1})_{n,j,m}/[R_m]_n$$

Better estimates of $[\mathbf{R}]$ values are obtained by setting

$$[\mathbf{R}]_n^{\mu+1} = [\mathbf{R}]_n^{\mu} + \Delta^{\mu} = [\mathbf{R}]_n^{\mu} + \mathbf{H}^{-1}([\mathbf{T}] - \mathbf{a}^t[\mathbf{S}]_n^{\mu}) = [\mathbf{R}]_n^{\mu}[\mathbf{I} + \mathbf{u}([\mathbf{T}] - \mathbf{a}^t[\mathbf{S}]_n^{\mu})]$$

This is continued until some convergence criterion is met (generally when the concentrations change by $\leq 0.01\%$), and the values of the elements of $\mathbf{u}_n$ at the last ($\mu = \infty$) iteration are carried over into the calculation of the derivatives of the observable. If the data are arranged in smooth increasing or decreasing order, as in titration experiments, then the final $[R]_n$ values can serve as initial estimates for the $(n+1)$th point, i.e. $[\mathbf{R}]_{n+1}^{\mu=1} = [\mathbf{R}]_n^{\mu=\infty}$. Then $\mathbf{a}^t[\mathbf{S}]_{n+1}^{\mu=1} = \mathbf{a}^t[\mathbf{S}]_n^{\mu=\infty}$, $\mathbf{u}_{n+1} = \mathbf{u}_n$, and a first correction to $[\mathbf{R}]_{n+1}$ can proceed, without matrix inversion, with the new $[\mathbf{T}]$ elements. Initial estimates need then only be provided for the first data point. In practice, the elements of Δ are large and require damping, especially near equivalence points. The corrections to the concentrations are generally limited to $\pm 90\%$ of the concentrations, but this limit is progressively decreased if convergence is difficult (>20 cycles). This procedure, essentially that used in MICMAC (5), ensures eventual convergence. Inclusion of higher terms in the Taylor series expansion did not provide sufficient benefit to justify the additional computations required. Additional cycles are needed with pH data to account for changes in ionic strength (15).

Modelling complex solution equilibria. II. Systems involving ligand substitutions and uncertainties in equilibrium constants derived from formation constants

PIERRE G. POTVIN

Department of Chemistry, York University, 4700 Keele Street, North York, Ont., Canada M3J 1P3

Received May 11, 1990

PIERRE G. POTVIN. Can. J. Chem. **68**, 2208 (1990).

A general formalism is presented that expresses equilibrium constants K as combinations of *pseudo*-formation constants ψ. For equilibria involving complexes as reactants that undergo ligand substitutions, this formalism allows a reduction in the number of equations needed to model the system for faster calculation of species concentrations and refinement of unknown parameters. Gauss–Newton refinement of log ψ parameters is shown to be equivalent to that of log K parameters. Equations are developed for the calculation of uncertainties in log K and correlation coefficients between them from the corresponding values obtained for log ψ parameters. These equations can also be used to calculate the same quantities for constants (such as K_a's) derived from true formation constants.

Key words: Gauss–Newton, ligand substitution, equilibrium constants, formation constants.

PIERRE G. POTVIN. Can. J. Chem. **68**, 2208 (1990).

On décrit un formalisme pour exprimer une série de constantes d'équilibre K en combinaisons de *pseudo*-constantes de formation ψ. Ceci permet de réduire le nombre d'équations nécessaires à décrire un système d'équilibres impliquant des réactifs complexes qui subissent des échanges de ligands. Ainsi, le calcul des concentrations des espèces présentes en solution et le raffinement des constantes d'équilibre inconnues sont accélérés. Le raffinement des constantes log ψ par la méthode Gauss–Newton est équivalent à celui des constantes log K. On dérive les équations nécessaires au calcul des incertitudes dans les paramètres log K et les coefficients de corrélation entre eux à partir des mêmes quantités obtenues pour les paramètres log ψ. Ces équations servent aussi au calcul de ces quantités pour toute constante (telle qu'un K_a) dérivée de vraies constantes de formation.

Mots clés : Gauss–Newton, échange de ligands, constantes d'équilibre, constantes de formation.

Introduction

In the accompanying paper, as in most computational approaches, the calculation of derivatives needed for the least squares determination of equilibrium constants assumed that all n_s species S present in any solution were *formed* from the n_r reactants R that were mixed together, according to

$$[1] \quad [S_i]_n = \beta_i \prod_{j=1}^{n_r} [R_j]_n^{a_{i,j}}$$

$$\text{or} \qquad \log [S_i]_n = \log \beta_i + \sum_{j=1}^{n_r} a_{i,j} \log [R_j]_n$$

for $i = 1$ to n_s at any nth of n_d data points. The coefficient $a_{i,j}$ represents the number of molecules of the jth reactant entering in the formation of the ith species, and β_i is the *formation constant* governing this process. The reactants, being species themselves, can by convention be ordered first; thus, for $i = 1$ to n_r, $a_{i,i} = 1$ but $a_{i,j\neq i} = 0$ and $\beta_i = 1$. The species concentrations obey the mass-balance relations

$$[2] \quad [T_j]_n^{\text{calc}} = [R_j]_n^{\text{tot}} = \sum_{i=1}^{n_s} a_{i,j}[S_i]_n$$

where $[T_j]_n$ represents the analytical total concentration of the jth reactant at the nth point for $j = 1$ to n_r, known from the quantities of each reactant that were mixed. This method of defining species (from "free" reactants) is the most often used and the most convenient since eqs. [1] and [2] can be combined into n_r equations in n_r unknowns that completely describe the system.

$$[T_j]_n^{\text{calc}} = \sum_{i=1}^{n_s} a_{i,j}\beta_i \prod_{k=1}^{n_r} [R_k]_n^{a_{i,k}}$$

There are numerous experimental situations where this convenience is not available. For instance, in the $Cu(en)_2^{2+}/C_2O_4^{2-}/H^+$ system studied by DeWitt and Watters (1), one reactant, $Cu(en)_2^{2+}$, supplies two mass-balance sums, $[Cu]^{tot}$ and $[en]^{tot}$ ($= 2[Cu]^{tot}$). Defining the ligand exchange products $Cu(en)C_2O_4$ and $Cu(C_2O_4)_2^{2-}$ as being formed from Cu^{2+}, en and $C_2O_4^{2-}$ would assume a non-negligible $[Cu^{2+}]$ and that $Cu(en)_2^{2+}$ is a product of known formation constant. The formation constants for such complexes as reactants are not always known. If they are very large, as in this case, the calculated concentrations of the dissociation products, in this case $[Cu^{2+}]$, will be very small. This can lead to serious computational difficulties (numerical over- and underflow) when calculating the concentrations of the other species containing them since inversion is involved (see Appendix of the previous paper).

To treat such systems, the programme DALSFEK (2) uses general equilibrium constant definitions. For n_e equilibria giving rise to n_e new species,

$$[3] \quad K_k = \prod_{i=1}^{n_s} [S_i]_n^{q_{k,i}} \qquad \text{or} \qquad \log K_k = \sum_{i=1}^{n_s} q_{k,i} \log [S_i]_n$$

for $k = 1$ to n_e, where the coefficient $q_{k,i}$ is the number of molecules of the ith species entering into the kth equilibrium, positive for products and negative for reactants. This is much less convenient to use, since n_r mass-balance sums and n_e equilibrium definitions must be solved for n_s ($= n_r + n_e$) unknowns at all points to completely describe the system. This results in much slower calculations of the species concentrations and the process can ascribe intermediate values of [S] that do not reconcile with the mass-balance sums.

There is a simple solution to this problem. The formalism described herein converts constants K to products thereof, termed *pseudo*-formation constants ψ, and back again, by redefining the reactants. By this expedient, the number of equations needed to model the system can be reduced to n_r

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

as before to greatly accelerate the calculations of species concentrations, the most time-consuming step in the iterative refinement of equilibrium constants. Further, it is shown that Gauss–Newton (G–N) refinement of either K or ψ leads to the same result. Finally, the formalism allows the development of equations to calculate the uncertainties in the final values of K and the correlation coefficients between them solely from the uncertainties in the final values of ψ and the correlation coefficients between these. This facility extends to normal systems not involving ligand substitutions for the calculation of derived constants (*e.g.* pK_a's) and their errors.

The Formalism

A subset of n_r species S of the n_s total species are selected and, by convention, ordered first in the list and labelled *pseudo*-reactants R^{ψ}. Then n_r identity equations are added to the equilibrium definitions [3], linearized by taking logarithms, to generate a set of n_s equations in n_s unknowns. In matrix notation, the vector of log $[R^{\psi}]$ and log K values is the product of the vector of log [S] values and of the square matrix **u** containing the coefficients:

$$\begin{bmatrix} \log [R^{\psi}_1]_n \\ \log [R^{\psi}_2]_n \\ \dots \\ \log [R^{\psi}_{nr}]_n \\ \log K_1 \\ \log K_2 \\ \dots \\ \log K_{ne} \end{bmatrix} = \begin{bmatrix} 1 & 0 & \dots & 0 \\ 0 & 1 & \dots & 0 \\ \dots & \dots & \dots & \dots \\ 0 & 0 & \dots & 1 \\ q_{1,1} & q_{1,2} & \dots & q_{2,ns} \\ q_{2,1} & q_{2,2} & \dots & q_{2,ns} \\ \dots & \dots & \dots & \dots \\ q_{ne,1} & q_{ne,2} & \dots & q_{ne,ns} \end{bmatrix} \begin{bmatrix} \log [S_1]_n \\ \log [S_2]_n \\ \\ \log [S_{nr}]_n \\ \log [S_{nr+1}]_n \\ \log [S_{nr+2}]_n \\ \\ \log [S_{ns}]_n \end{bmatrix} = \mathbf{u} \log [S]$$

If the n_r R^{ψ} are judiciously chosen (*vide infra*), then **u** is invertible. Let $\upsilon = \mathbf{u}^{-1}$. Then the log species concentrations can be written as

$$\log [S_i]_n = \sum_{j=1}^{n_r} \upsilon_{i,j} \log [R^{\psi}_j]_n + \sum_{k=1}^{n_e} \upsilon_{i,n_r+k} \log K_k$$

for $i = 1$ to n_s. If we set

$$[4] \quad \log \psi_i = \sum_{k=1}^{n_e} \upsilon_{i,n_r+k} \log K_k$$

where $\log \psi_i = 0$ for $i = 1$ to n_r, then

$$[5] \quad \log [S_i]_n = \log \psi_i + \sum_{j=1}^{n_r} \upsilon_{i,j} \log [R^{\psi}_j]_n$$

$$\text{or} \qquad [S_i]_n = \psi_i \prod_{j=1}^{n_r} [R^{\psi}_j]_n^{\upsilon_{i,j}}$$

These have the same form as eq. [1] and constants ψ can be termed *pseudo*-formation constants. The coefficients υ in eq. [5] play the same role as coefficients a in eqs. [1] and [2]. New mass-balance sums of the same form as eq. [2] can then be defined

$$[6] \quad [T^{\psi}_j]_n^{\text{calc}} = [R^{\psi}_j]_n^{\text{tot}} = \sum_{i=1}^{n_s} \upsilon_{i,j} [S_i]_n$$

for $j = 1$ to n_r, where the analytical total concentrations of these *pseudo*-reactants $[T^{\psi}]$ are related to the analytical total reactant concentrations [T] through

$$[T^{\psi}_j]_n = \sum_{k=1}^{n_r} a_{k,j} [T_k]_n$$

Therefore, eq. [5] can be combined into eq. [6] to give n_r equations in n_r unknowns to completely model the system. Further, if **u** is invertible, then the sub-matrix of $\mathbf{a}^t$ formed by the first n_r columns is also invertible. Let matrix $\boldsymbol{\alpha}$ be that inverse. Then

$$[T_k]_n = \sum_{k=1}^{n_r} \alpha_{k,j} [T^{\psi}_j]_n$$

To illustrate, consider the DeWitt–Watters system, in which both pH and absorbance measurements were made. Over the pH range examined, only en undergoes protonations. We first write out the equilibrium definitions,

$$\begin{bmatrix} \log K_w \\ \log K_{a1} \\ \log K_{a2} \\ \log K_{s1} \\ \log K_{s2} \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ -1 & 0 & -1 & 0 & 0 & 1 & 0 & 0 & 0 \\ -1 & 0 & 0 & 0 & 0 & -1 & 1 & 0 & 0 \\ 0 & -1 & 1 & -1 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & -1 & 0 & 0 & 0 & -1 & 1 \end{bmatrix} \begin{bmatrix} \log [H^+] \\ \log [Cu(en)_2^{2+}] \\ \log [en] \\ \log [C_2O_4^{2-}] \\ \log [OH^-] \\ \log [enH^+] \\ \log [enH_2^{2+}] \\ \log [Cu(en)C_2O_4] \\ \log [Cu(C_2O_4)_2^{2-}] \end{bmatrix} = \mathbf{q} \log [S]$$

and the mass-balance sums

$$\begin{bmatrix} [H]^{\text{tot}} \\ [Cu]^{\text{tot}} \\ [en]^{\text{tot}} \\ [C_2O_4]^{\text{tot}} \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 & -1 & 1 & 2 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 1 & 1 \\ 0 & 2 & 1 & 0 & 0 & 1 & 1 & 1 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 1 & 2 \end{bmatrix} \begin{bmatrix} [H^+] \\ [Cu(en)_2^{2+}] \\ [en] \\ [C_2O_4^{2-}] \\ [OH^-] \\ [enH^+] \\ [enH_2^{2+}] \\ [Cu(en)C_2O_4] \\ [Cu(C_2O_4)_2^{2-}] \end{bmatrix} = \mathbf{a}^t [S]$$

The first four species are chosen as *pseudo*-reactants. Matrix **u** is generated as described above, then inverted to produce

$$\begin{bmatrix} \log [H^+] \\ \log [Cu(en)_2^{2+}] \\ \log [en] \\ \log [C_2O_4^{2-}] \\ \log [OH^-] \\ \log [enH^+] \\ \log [enH_2^{2+}] \\ \log [Cu(en)C_2O_4] \\ \log [Cu(C_2O_4)_2^{2-}] \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ -1 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 1 & 0 & 1 & 0 & 0 & 1 & 0 & 0 & 0 \\ 2 & 0 & 1 & 0 & 0 & 1 & 1 & 0 & 0 \\ 0 & 1 & -1 & 1 & 0 & 0 & 0 & 1 & 0 \\ 0 & 1 & -2 & 2 & 0 & 0 & 0 & 1 & 1 \end{bmatrix} \begin{bmatrix} \log [H^+] \\ \log [Cu(en)_2^{2+}] \\ \log [en] \\ \log [C_2O_4^{2-}] \\ \log K_w \\ \log K_{a1} \\ \log K_{a2} \\ \log K_{s1} \\ \log K_{s2} \end{bmatrix}$$

Further, we find

$$\psi_1 = \psi_2 = \psi_3 = \psi_4 = 1$$
$$\psi_5 = K_w$$
$$\psi_6 = K_{a1}$$
$$\psi_7 = K_{a1}K_{a2}$$
$$\psi_8 = K_{s1}$$
$$\psi_9 = K_{s1}K_{s2}$$

Thus all species concentrations are expressed as products of the K's and $[H^+]$, $[Cu(en)_2^{2+}]$, [en], and $[C_2O_4^{2-}]$.

The matrix $\boldsymbol{\alpha}$ is obtained by inversion of the first four columns of **a**.

$$\begin{bmatrix} [H^+_\psi]^{tot} \\ [Cu(en)_2^{2+}{}_\psi]^{tot} \\ [en_\psi]^{tot} \\ [C_2O_4^{2-}{}_\psi]^{tot} \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & -2 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} [H]^{tot} \\ [Cu]^{tot} \\ [en]^{tot} \\ [C_2O_4]^{tot} \end{bmatrix}$$

This gives total *pseudo*-reactant concentrations (denoted by ψ subscripts) in terms of those of real reactants. Thus, $[en_\psi]^{tot} = 0$ since $[en]^{tot} = 2[Cu]^{tot}$, i.e. $Cu(en)_2^{2+}$ constitutes the only source of en.

For the simple DeWitt–Watters system, this matrix $\boldsymbol{\upsilon}$ could have been written out directly but other choices of *pseudo*-reactants can also apply, involving perhaps $Cu(C_2O_4)_2^{2-}$ and enH^+. The formalism is, however, general to any equilibrium system, the only requirement being that the choice of *pseudo*-reactants be such that the **u** matrix resulting be invertible. This amounts to a requirement that the first n_r columns of $\mathbf{a}^t$ be invertible. Indeed, many combinations of species can be used as reactants to generate the same equilibria.

Least-squares refinement of log ψ

During least-squares refinement by the G–N method, corrections are made to estimates of the parameters, and are obtained from the derivatives of the measured quantity with respect to those parameters (see previous paper). The derivatives at any nth data point of any observable function F with respect to log K parameters are obtained by implicit differentiation from those taken with respect to log ψ parameters, as in

$$\frac{\delta F_n}{\delta \log K_k} = \sum_{i=1}^{n_s} \frac{\delta F_n}{\delta \log \psi_i} \frac{\delta \log \psi_i}{\delta \log K_k} = \sum_{i=1}^{n_e} \upsilon_{n_r+i,k} \frac{\delta F_n}{\delta \log \psi_i} = \sum_{i=1}^{n_e} z_{i,k} \frac{\delta F_n}{\delta \log \psi_i}$$

for $k = 1$ to n_e. Since log ψ_i for $i = 1$ to n_r will equal zero and not be refined, one can define a new square invertible matrix **z** formed as the lower right $n_e \times n_e$ submatrix of $\boldsymbol{\upsilon}$. Then, using the same matrix notation as in the accompanying paper, this can be rewritten as $\mathbf{J}_K = \mathbf{J}_\psi \mathbf{z}$, where the subscript K or ψ refers to $\delta F/\delta \log K$ and $\delta F/\delta \log \psi$ terms, respectively.

The G–N correction vector is given by

$$\begin{aligned} \Delta_K{}^{G-N} &= (\mathbf{J}_K{}^t \mathbf{w} \mathbf{J}_K)^{-1} \mathbf{J}_K{}^t \mathbf{w}(\mathbf{O} - \mathbf{F}) \\ &= ((\mathbf{J}_\psi \mathbf{z})^t \mathbf{w} (\mathbf{J}_\psi \mathbf{z}))^{-1} (\mathbf{J}_\psi \mathbf{z})^t \mathbf{w}(\mathbf{O} - \mathbf{F}) \\ &= \mathbf{z}^{-1} (\mathbf{J}_\psi{}^t \mathbf{w} \mathbf{J}_\psi)^{-1} (\mathbf{z}^t)^{-1} (\mathbf{z}^t) \mathbf{J}_\psi{}^t \mathbf{w}(\mathbf{O} - \mathbf{F}) \\ &= \mathbf{z}^{-1} \Delta_\psi{}^{G-N} \end{aligned}$$

where **w** is a matrix of weighting factors, **O** is the vector of observed data, and **F** is the vector of observables calculated from the current set of parameters, all of which are independent of the method of defining species. This also follows from eq. [4], since at any μth iteration, the elements of vector Δ_K are added to the μth estimates of log K values to generate the $(\mu + 1)$th estimates, and

$$\begin{aligned} (\Delta_\psi)_i &= (\log \psi_{n_r+i})^{\mu+1} - (\log \psi_{n_r+i})^{\mu} \\ &= \sum_{k=1}^{n_e} \upsilon_{n_r+i} [(\log K_k)^{\mu+1} - (\log K_k)^{\mu}] \\ &= \sum_{k=1}^{n_e} z_{i,k} (\Delta_K)_k \end{aligned}$$

Thus correction of log ψ parameters amounts to simultaneous and appropriate correction of all subject log K parameters. The final log K values are then obtainable from the final log ψ values by

$$\log K_k = \sum_{i=1}^{n_e} u_{n_r+k,n_r+i} \log \psi_{n_r+i} = \sum_{i=1}^{n_e} q_{k,n_r+i} \log \psi_{n_r+i}$$

It can be verified that this also holds true for the Newton–Raphson corrections, but, curiously, not for the method of Steepest Descent, where, instead, $\Delta_K{}^{S-D} = \mathbf{z}^t \Delta_\psi{}^{S-D}$.

Uncertainties and correlations in log K

After refinement, it is of interest to obtain uncertainties in the final log K values and the correlation coefficients between them. The uncertainty in any ith log ψ will be given by

$$\sigma_{\psi_i} = \sigma_0 (H_\psi)_{i,i}^{1/2}$$

where $\mathbf{H}_\psi$ is the inverted Hessian $(\mathbf{J}_\psi{}^t \mathbf{w} \mathbf{J}_\psi)^{-1}$ and $\sigma_0{}^2$ is an estimate of the variance of an observation of unit weight (see accompanying paper). The correlation coefficient between the ith and jth parameters will be given by

$$c_{\psi_i\psi_j} = (H_\psi)_{i,j} / \{(H_\psi)_{i,i} (H_\psi)_{j,j}\}^{1/2} = (H_\psi)_{i,j} \sigma_0{}^2 / \sigma_{\psi_i} \sigma_{\psi_j}$$

TABLE 1. Formation constants and corresponding derived constants[a]

i	$\log \beta_i$	σ_{β_i}	$c_{\beta_i\beta_1}$	$c_{\beta_i\beta_2}$	$c_{\beta_i\beta_3}$	$\log K_i$	σ_{K_i}	$c_{K_iK_1}$	$c_{K_iK_2}$	$c_{K_iK_3}$
1	3.7091	0.0101	1	0.03	−0.03	3.7091	0.0101	1	−0.72	0.69
2	−3.9446	0.0096	0.03	1	0.50	−7.6537	0.0137	−0.72	1	−0.75
3	10.6224	0.0111	−0.03	0.50	1	−6.9133	0.0152	0.69	−0.75	1

[a]Four decimal places were carried in the calculation, though only two are significant.

Since, from above, $\mathbf{H}_K = \mathbf{z}^{-1}\mathbf{H}_\psi(\mathbf{z}^t)^{-1}$, then the uncertainty in the ith log K will be

$$\sigma_{K_i} = \sigma_0\left\{\sum_{j=1}^{n_e}(z^{-1})_{i,j}\sum_{k=1}^{n_e}(z^{-1})_{i,k}(H_\psi)_{j,k}\right\}^{1/2}$$

Remembering that $\mathbf{z}^{-1}$ is the lower-right $n_e \times n_e$ submatrix of $\mathbf{u}$ (i.e. the last n_e columns of $\mathbf{q}$),

$$\sigma_{K_i} = \sigma_0\left\{\sum_{j=1}^{n_e} q_{i,n_r+j}\sum_{k=1}^{n_e} q_{i,n_r+k}c_{\psi_j\psi_k}(H_\psi)_{j,j}{}^{1/2}(H_\psi)_{k,k}{}^{1/2}\right\}^{1/2}$$

$$= \left\{\sum_{j=1}^{n_e} q_{i,n_r+j}\sum_{k=1}^{n_e} q_{i,n_r+k}c_{\psi_j\psi_k}\sigma_{\psi_j}\sigma_{\psi_k}\right\}^{1/2}$$

Similarly, the correlation coefficient between the ith and jth log K values can be written

$$c_{K_iK_j} = (H_K)_{i,j}/\{(H_K)_{i,i}(H_K)_{j,j}\}^{1/2}$$

$$= (H_K)_{i,j}\sigma_0{}^2/(\sigma_{K_i}\sigma_{K_j})$$

$$= (\sigma_0{}^2/\sigma_{K_i}\sigma_{K_j})\sum_{k=1}^{n_e} q_{i,n_r+k}\sum_{l=1}^{n_e} q_{i,n_r+l}(H_\psi)_{k,l}$$

$$= (\sigma_0{}^2/\sigma_{K_i}\sigma_{K_j})\sum_{k=1}^{n_e} q_{i,n_r+k}\sum_{l=1}^{n_e} q_{i,n_r+l} \times c_{\psi_k\psi_l}(H_\psi)_{k,k}{}^{1/2}(H_\psi)_{l,l}{}^{1/2}$$

$$= (1/\sigma_{K_i}\sigma_{K_j})\sum_{k=1}^{n_e} q_{i,n_r+k}\sum_{l=1}^{n_e} q_{i,n_r+l}c_{\psi_k\psi_l}\sigma_{\psi_k}\sigma_{\psi_l}$$

Thus, the uncertainties and correlation coefficients of a model expressed in terms of log K parameters can be obtained from the corresponding quantities when the system is modelled in terms of log *pseudo*-formation constants, without requiring knowledge of the Hessian elements involved.

These last results also have application in systems of equilibria without ligand exchanges, where derived constants, such as K_a's, are often of greater interest than the formation constants β. These are products of the β constants, and the uncertainties in their logarithms would, by normal error propagation rules, be the sum of the uncertainties in the log β components. But these uncertainties are *not* additive and the uncertainties in the derived constants, as well as the correlation coefficients between them, should instead be calculated using these equations.

For instance, in the experimental system described in the accompanying paper, the acidity and the basicity of the Zn^{2+} complex are of interest. The log β results are reported in Table 1. To obtain information on complex acidity, one writes three constants K derived from the three β that define Zn^{2+} complexes:

$$\begin{bmatrix}\log K_M\\ \log K_{a2}\\ \log K_{a1}\end{bmatrix} = \begin{bmatrix}1 & 0 & 0\\ -1 & 1 & 0\\ 1 & 0 & -1\end{bmatrix}\begin{bmatrix}\log \beta_{011}\\ \log \beta_{-111}\\ \log \beta_{111}\end{bmatrix}$$

where

$$\begin{bmatrix}\log \beta_{011}\\ \log \beta_{-111}\\ \log \beta_{111}\end{bmatrix} = \begin{bmatrix}\log [LZn^{2+}]\\ \log [LZnOH^{+}]\\ \log [LZnH^{3+}]\end{bmatrix} - \begin{bmatrix}0 & 1 & 1\\ -1 & 1 & 0\\ 1 & 1 & 1\end{bmatrix}\begin{bmatrix}\log [H^+]\\ \log [L]\\ \log [Zn^{2+}]\end{bmatrix}$$

(The full $\mathbf{q}$ and $\mathbf{a}$ matrices are not needed for this purpose.) If we set $\beta_1 = \beta_{011}$, $\beta_2 = \beta_{-111}$, and $\beta_3 = \beta_{111}$, the non-trivial equations for the σ_K and c_{KK} are

$$\sigma_{K_{a2}} = \{(\sigma_{\beta_1})^2 - 2c_{\beta_1\beta_2}\sigma_{\beta_1}\sigma_{\beta_2} + (\sigma_{\beta_2})^2\}^{1/2}$$

$$\sigma_{K_{a1}} = \{(\sigma_{\beta_1})^2 - 2c_{\beta_1\beta_3}\sigma_{\beta_1}\sigma_{\beta_3} + (\sigma_{\beta_3})^2\}^{1/2}$$

$$c_{K_MK_{a2}} = \{-(\sigma_{\beta_1})^2 + c_{\beta_1\beta_2}\sigma_{\beta_1}\sigma_{\beta_2}\}/\{\sigma_{K_M}\sigma_{K_{a2}}\}$$

$$c_{K_MK_{a1}} = \{(\sigma_{\beta_1})^2 - c_{\beta_1\beta_3}\sigma_{\beta_1}\sigma_{\beta_3}\}/\{\sigma_{K_M}\sigma_{K_{a1}}\}$$

$$c_{K_{a1}K_{a2}} = \{-(\sigma_{\beta_1})^2 + c_{\beta_1\beta_3}\sigma_{\beta_1}\sigma_{\beta_3} + c_{\beta_1\beta_2}\sigma_{\beta_1}\sigma_{\beta_2} + c_{\beta_2\beta_3}\sigma_{\beta_2}\sigma_{\beta_3}\}/\{\sigma_{K_{a1}}\sigma_{K_{a2}}\}$$

The calculation results are also reported in Table 1, where $K_1 = K_M$, $K_2 = K_{a2}$, and $K_3 = K_{a1}$. Thus $pK_{a2} = 7.65 \pm 0.01$ and $pK_{a1} = 6.91 \pm 0.02$.

IAN R. BUTLER and JEAN-LOUIS ROUSTAN. Can. J. Chem. **68**, 2212 (1990).

Ferrocenyldipyridyls and ferrocenyl-*o*-phenanthrolines have been synthesized by the direct reaction of lithioferrocenes with the appropriate dipyridine or 1,10-phenanthroline. The spectroscopic properties of these potential new ligands are described and the synthesis of bis-2,2′-dipyridyl(6-ferrocenyl-2,2′-dipyridyl)ruthenium dichloride, **8**, in its hydrated form is reported.

Key words: ferrocene, dipyridine, phenanthroline, ruthenium.

Introduction

Over the past decade or so, there has been an intensive research effort directed at the photochemical reactions of transition metal complexes containing dipyridyl or phenanthrolyl ligands. In particular, one family of such complexes, the tris chelating complexes of ruthenium, have found widespread application in, for example, the photocatalytic water splitting reaction (1–5), photooxidation reactions (6), and the catalytic epoxidation of alkenes (7). Numerous papers have described the chemical modifications of dipyridyl and/or 1,10-phenanthrolyl ligands to change the bulk properties of their complexes. For example, in the synthesis of surfactant tris-(2,2′-dipyridyl) ruthenium complexes, the dipyridyl ligand(s) have been suitably modified by incorporation of aliphatic side chains and polar groups (8, 9). In related studies, bulky substituted dipyridyls have been employed in, for example, epoxidation reactions (7).

We have been recently interested in the preparation of transition metal complexes containing ferrocenylpyridyls (10), in relation to their potential chemotherapeutic properties.[2] We were stimulated to diversify our studies to include the synthesis of the hitherto unknown ferrocenyldipyridyl by a recent report documenting the use of triferrocenylbenzenes as photosensitizers in the catalytic production of hydrogen from methanol (11). We felt that the synthesis of ferrocenyldipyridyls might lead to the preparation of novel complexes with unusual photocatalytic activity.

The Ziegler and Zeiser nucleophilic alkylation of pyridines provides the most direct method of alkylation at a position *ortho* to the N atom (12). This method has been applied to the synthesis of mono- and bispyridylferrocenes (30–35% yield) and quinolylferrocenes (2% yield) (13). In this paper we have used this method to prepare ferrocenyldipyridines and ferrocenyl-*ortho*-phenanthrolines. In addition, the preparation of the first metal complex to be prepared from these ligands is described.

[2]The reaction of ferrocenyllithium for 24 h with *o*-quinoline in diethyl ethers in our hands gives yields in excess of 20% of 2-ferrocenylquinoline. I. R. Butler and J. L. Elliott, unpublished results.

Experimental section

All solvents used in the reactions described were freshly distilled, following drying by standard procedures; however, solvents used for chromatographic separations were of reagent grade. Standard Schlenk type glassware was used throughout for the manipulation of air-sensitive compounds. All reactions were carried out under an inert atmosphere unless otherwise stated. ^{1}H nmr spectra were recorded using a Varian XL-300 instrument using $CDCl_3$ or D_2O as solvent (abbreviations used: d = doublet, s = singlet, dt = doublet of triplets, ad = asymmetric doublet, b = broad, etc.). Mass spectra were obtained using VG Analytical 7070E instrument (at 70 eV) equipped with a Digital PDP 8A data processing unit at the University of Ottawa Mass Spectroscopy Centre, 2,2′-Dipyridine was obtained from the Lancaster Chemical Company and was used as supplied, and *n*-butyllithium solutions in hexanes (Aldrich Chemical Co.) were used throughout. Bis-2,2′-dipyridyldichlororuthenium was prepared from ruthenium trichloride·trihydrate using the literature procedure (14). Column chromatographic separations were carried out using neutral alumina (Brockman Grade 1). Thin layer chromatographic analyses were carried out using metal or plastic backed silica gel plates.

*General procedure for the preparation of mono-substituted ferrocenyl derivatives, **1–5***

A sample of solid monolithioferrocene/dilithioferrocene·THF (15–18)[3] (approximate ratio mono:di = 80:20) was prepared in THF. This solid was suspended in diethyl ether (approximate 1.0 g per 20 mL). To the cooled stirred solution (−70°C) was added a 10% molar excess (with respect to lithium) of the appropriate reagent (2,2′-dipyridyl, 2,3′-dipyridyl, 2,4′-dipyridyl, 4,4′-dipyridyl, or 1,10-phenanthroline). After allowing the reaction mixture to warm up slowly to 18°C, it was stirred for 2–3 days before being hydrolyzed under aerobic conditions with water (approximate equal volume with respect to the solvent).

The organic layer was separated and the remaining solid was further extracted with dichloromethane (until almost colourless). The combined organic fraction was taken to dryness (rotary evaporator) to leave a solid or oily solid. At this point, the composition of the reaction mixture was analyzed by tlc (eluent mixture of hexanes/diethyl ether

[3]When lithioferrocenes are prepared in THF, a solid crystalline adduct of mono- and dilithioferrocene can be obtained; however, prolonged periods of stirring result in the formation of ferrocene substituted cyclic ethers, in which the THF has ring expanded to a seven-membered ring by partial incorporation of the *n*-butyl group (I. R. Butler, unpublished results). A solution of monolithioferrocene, prepared from *n*-butyllithium and ferrocene in diethyl ether (24 h), may be substituted, resulting in only a small diminution in yield.

ca. 50/50), and the major product bands were identified by visual inspection as the most intense coloured bands present. Column chromatographic separation was then effected and the major products isolated. The elements used were mixtures of hexane, diethyl ether, dichloromethane, and ethyl acetate in increasing polarity throughout the separation. The desired mono-substituted compounds were eluted using Et_2O/CH_2Cl_2 (50/50) mixtures. Crystallization of the major product from hexane/diethyl ether gave the monosubstituted derivatives. The yields are variable; we have repeated the experiment on scales ranging from 1.0 to 10.0 g and have obtained yields between 20 and 44%.[4] Yields for specific compounds: **1**: 6-ferrocenyl-2,2′-dipyridine, 35–40%, **2**: 2-ferrocenyl-1,10-phenanthroline, 20–35%, **3**: 2-ferrocenyl-4,2′-dipyridine, 20–25%, **4**: 2-ferrocenyl-4,4-dipyridine, 16–22%, **5**: 6-ferrocenyl-3,2′-dipyridine, 23–30%.[5]

The labelling of the atoms in each of the rings of a dipyridyl begins with the nitrogen atom and proceeds so that the carbon atom bonded to the other ring has the lowest possible number.

[4]The yields obtained for the symmetrical dipyridines, e.g. 2,2′- and 4,4′-, are higher, since there are fewer isomeric by-products formed. The analytical data is given for anhydrous samples — ^{1}H nmr indicates a tendency to crystallize as hydrates in wet solvents.

[5]We have noted that using different samples of alumina, of the same nominal grade, obtained from different sources, can give different results. Using neutral alumina, Brockman I, we have found that diethyl ether is sufficiently polar to elute the monosubstituted ferrocenes, and a mixture of dichloromethane/ether, 50/50, is sufficient to elute the disubstituted ferrocenes in most circumstances. However, it is recommended that a trial column be run on a microscale before bulk separation.

General procedure for the preparation of ***6, 7***

An identical procedure was used to that in the preparation of **1–4** replacing monolithioferrocene with dilithioferrocene·TMED which was prepared by the published procedure (15). The ratio of the heterocylic reagent (2,2′-dipyridine or 1,10-phenanthroline) added was based on a 1:1.1 stoichiometry w.r.t. lithium added. In this case, the major product compounds, identified by tlc as deep orange/red bands, were eluted with dichloromethane.[2] **6**: 1,1′-bis-(6-(2,2′-dipyridyl)) ferrocene (20%), **7**: 1,1′-bis-(2(1,10-phenanthroyl))ferrocene (14%).

6, ^{1}H nmr ($CDCl_3$) δ: 4.37 (t, 4H, β-C_5H_4), 4.89 (t, 4H, α-C_5H_4), 7.02 (dd, 2H, $J_{5-4} = 7.8$ Hz, $J_{5-3} = 1.0$ Hz, H-5), 7.22 (ddd, 2H, $J_{5'-4'} = 7.7$ Hz, $J_{5'-6'} = 4.3$ Hz, $J_{5'-3'} = 1.7$ Hz, H-5′), 7.32 (t, 2H, $J_{4-3} = 7.8$ Hz, H-4), 7.66 (ddd, 2H, $J_{4'-3'} = 8.1$ Hz, $J_{4'-6'} = 1.1$ Hz), 7.70 (dd, 2H, H-3), 8.00 (ddd, 2H, $J_{3'-6'} = 0.9$ Hz, H-3′), 8.33 (ddd, 2H, H-6′). Mass spectrometry 495(38.1), 494(100.0), $M^{+\bullet}$, 492(17.9), 339(24.3), 276(13.7), 275(61.7), 249(22.1), 247(18.1). *Anal.* calcd. for $C_{30}H_{22}FeN_4$: C 72.89, H 4.49, N 11.33; found: C 72.90, H 4.86, N 11.61.

7, ^{1}H nmr ($CDCl_3$) δ: 4.46 (t, 4H, β-C_5H_4), 5.28 (t, 4H, α-C_5H_4), 7.14 (d, 2H, $J_{5-6} = 8.4$ Hz, H-5), 7.18 (d, 2H, $J_{3-4} = 8.8$ Hz, H-3), 7.28 (d, 2H, H-6), 7.51 (d, 2H, H-4), 7.53 (dd, 2H, $J_{8-7} = 8.0$ Hz, $J_{8-9} = 4.3$ Hz, H-8), 8.13 (dd, 2H, $J_{7-9} = 1.7$ Hz, H-7), 9.08 (dd, 2H, H-9). *Anal.* calcd. for $C_{34}H_{22}FeN_4$: C 75.29, H 4.09, N 10.33; found: C 75.36, H 4.21, N 10.23.

Preparation of bisdipyridyl(6-ferrocenyl-2,2′-dipyridyl)ruthenium dichloride·hexahydrate, ***8***

The title compound was prepared essentially by an adaptation of the procedure of Dose and Wilson (19) and Wrighton *et al.* (20) initially used for the preparation of related derivatives. To a degassed solution of ethanol/water, 75% (20 mL) was added dichlorobisdipyridylruthenium (14) (200 mg, 380 μmol), and **1** (156 mg, 460 μmol). The mixture was refluxed under an argon atmosphere for 6 h. (The reaction progress can be conveniently monitored by tlc using a 50/50, ethanol/acetone solvent mixture as eluent. The product, a yellow-orange band, elutes behind the purple diffuse band of the starting ruthenium complex.) The solvent was then removed and the solid obtained was washed with diethyl ether to remove excess ligand. Concentration of the dichloromethane washings and fractional crystallization, again by slow ether diffusion, gives a further crop of crystals. Combined yields are 74%. The resultant crystalline product, isolated as a solvate containing water and dichloromethane, is insoluble in diethyl ether and acetone, but soluble in water. *Anal.* calcd. for $C_{40}H_{32}Cl_2FeN_6Ru \cdot 6H_2O$: C 51.51, H 4.76, N 9.01; found: C 51.68, H 4.71, N 8.85. ^{1}H nmr δ, (D_2O): 9.04 (bd, 1); 8.89–8.96 (m, 17); 8.86 (bd, 1); 8.56 (bd, 1); 8.19 (bd, 1); 8.10–8.18 (m, 1); 7.82 (dd, 10); 7.66 (td, 1), 7.59 (dd, 2); 7.54 (tm, 1); 7.50 (dm, 1); 7.36 (dm, 1); 7.30 (dm, 1); 7.24 (m, 1); 7.16 (dm, 1); 6.97 (td, 1); 4.37 (m, 1); 3.75 (m, 1); 3.61 (m, 1); 3.25 (m, 1); 4.01 (s, 5).

An alternate separation procedure is to extract the product into a few mL of water, remove the solvent under vacuum at 40°C, and recrystallize as described above. The solid was then washed with the minimum quantity of CH_2Cl_2 to remove any unreacted dichlorobisdipyridylruthenium, which dissolves preferentially in this solvent. The remaining solid was repeatedly extracted with CH_2Cl_2. After concentration of the combined extracts, a top layer of diethyl ether was added. Slow diffusion into the lower CH_2Cl_2 phase resulted in the crystallization of the deep orange product.

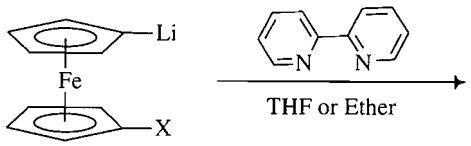
Results and discussion

The objective of this work was to synthesize ferrocenyl derivatives of dipyridine and 1,10-phenanthroline. There are several alternate strategies available for such a synthesis, such as the copper, nickel, or palladium catalyzed reaction of a ferrocenyl Grignard reagent with, for example, halo-dipyridyls, or the reaction of ferrocenylmagnesium bromide (21) or ferrocenylzinc chloride (22, 23) with a halodipyridine or halophenanthroline. Although each of these approaches would be

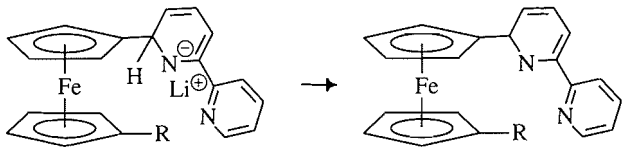
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

expected to give reasonable yields of ferrocenyl substituted dipyridines and phenanthrolines, they require the preparation of either halogenoferrocenes and/or halogenodipyridines and phenanthrolines, which add unnecessary synthetic steps. The alternate approach would be to employ the direct reaction of lithioferrocenes with the appropriate heteroaromatic compound. In such an approach the yields are expected to be much lower than in the final steps of the formerly described alternatives, however, the synthesis would involve essentially a one pot, one step reaction. Thus this method of synthesis was the one of choice toward the targeted compounds.

All reactions were run under the same set of experimental conditions. In every case, a mixture of products was obtained, but the one shown to predominate by tlc analysis of the crude organic phase was obtained in a pure form by column chromatography. Typically, a suspension of the lithioferrocene in diethyl ether under nitrogen was reacted over a period of 3 days with the heterocycle, followed by a standard work-up in air to achieve oxidation of the expected dihydro intermediate (24) into the desired aromatic product.



X = H, Li



R = H(**1**), 6-(2,2'-dipyridyl) (**6**)

Under these conditions, on scales from 1 to 10 g, dipyridylferrocene **1** was obtained in 37% average yield (range 30–44%) which compares favourably with the 32% yield reported for the synthesis of 2-pyridylferrocene from a 48 h reaction at reflux in cyclohexane between pyridine and lithioferrocene (formed *in situ* from ferrocene and *n*-butyllithium in excess) (13).

The disubstituted derivative **6**, bearing a 2,2'-dipyridinyl substituent on each of the Cp rings, was similarly prepared in 20% yield from the reaction of dilithioferrocene with an excess of 2,2'-dipyridine.

In both compounds **1** and **6**, functionalization of the heterocyclic base at the C-6 position was clearly indicated by ^{1}H nmr spectroscopy at 300 MHz, which resolved all the proton resonances. The nmr data are presented in the Experimental section, and the chemical shift differences between the protons of **1** and **6**, and the equivalent ones found in the 2,2'-dipyridine, are indicated in Table 1. In the latter, the magnetically equivalent H-6 and H-6' protons *ortho* to the N atoms are the most deshielded at 8.67 ppm with the smallest vicinal couplings constant of 4.5 Hz. All the other J_{2H-H} couplings not involving H-6,6' are close to 8.0 Hz. In the monosubstituted **1** selected as an example, all but one of the seven heterocyclic protons present have three vicinal couplings close to 8 Hz. The remaining one with J_{2H-H} = 4.8 Hz is also the most deshielded at 8.66 ppm and is therefore readily identified as H-6' which leaves the C-6 position as the only possible site of attachment of the Cp ring. The remainder of the spectrum is assigned on the basis of the spin multiplicity and the J values pertaining to each proton resonance. Relative to the monosubstituted compound **1**, all the heterocyclic protons of the disubstituted derivative **6** are shifted upfield by 0.1–0.6 ppm.

^{1}H nmr spectroscopy was similarly used to establish that the alkylation at a position *ortho* to the N atom had occurred in the predominant monosubstituted products **3, 4**, and **5**, isolated from the reaction of the 2,3'-, 2,4'-, and 4,4'-dipyridines respectively. The disubstituted phenanthrolylferrocene derivative **7** was isolated as a side product from the synthesis of the monosubstituted complex **6** in addition to the direct synthesis from dilithioferrocene.

In general, in phenanthrolyl compounds **2** and **7**, with the exception of the H-3 resonances in **2**, all heterocyclic proton resonances are shifted upfield in comparison to unsubstituted

1,10-phenanthroline (Table 2). Proton H-3 will be affected by tha annular current of the ferrocene ring according to the established effects (25). In all new compounds **1–7**, all substituted cyclopentadienyl ring protons are shifted downfield considerably relative to the unsubstituted cyclopentadienyl ring protons.

All new compounds gave clear parent ions in their electron impact mass spectra (m/e 340 for **1, 3, 4, 5**; 364 for **2**; 494 for **6**, and 542 for **7**). Typically, a major peak is observed at m/e, $M^{+\bullet}-65$ corresponding to the loss of a cyclopentadienyl ring for the monosubstituted ferrocenes.

Preparation of the ruthenium complex, 8

The ruthenium complex was synthesized using a modification of the literature procedure (19) used for the synthesis of the parent trisdipyridyl complex, in that it was obtained by the direct reaction dichloro-bis-2,2′-dipyridylruthenium(II) with the ligand **1** in refluxing ethanol. It was isolated as a red/orange solid which can be recrystallized from dichloromethane/ether by the slow diffusion method. **8** is soluble in water, but only sparing soluble in most organic solvents. The assignment of the structure was confirmed by ^{1}H nmr, but the full characterization of individual proton resonances was difficult, due to overlap of the different dipyridyl resonances. Elemental analysis of the crystalline solid and ^{1}H nmr are consistent with the formulation of **8** as a hexahydrate. The single crystal X-ray structural determination of **8** has been carried out; unfortunately the chloride anions and the water of crystallization show considerable disorder which is under current analysis.[6] The integrity of the cation is, however, not in question.

The Ru—N bond lengths range from 2.03–2.15 Å, which are short but compare with those of $[Ru(2,2'\text{-dipy})_3]^{2+}\bullet 2PF_6^-$, which have an average value of 2.056(6) Å, (26). In the latter case, the relatively short bond lengths were explained in terms of considerable π-bonding between the delocalized π^*-orbitals on the bipyridine ligands and the ruthenium core. In the case of **8**, the longest Ru—N bond (2.15 Å) is the one to the ferrocene-substituted pyridyl ring. A bond lengthening would be predicted using this argument since ferrocene can be considered to be a good electron donor, as is witnessed in the upfield chemical shifts of the dipyridyl and phenanthrolyl proton resonances of the substituted compounds **1–7** in comparison to those in the free ligands. It is conceivable that the lengthening might be in part due to steric influence of the bulky ferrocenyl substituent.

With the continued interest in the chemistry of dipyridyl and phenathrolyl ligands extending into the region of cancer chemotherapy (27, 28), in addition to the known chemotherapeutic nature of the ferricinium ion (29) and the stereoselective splitting of DNA (30, 31) these compounds should prove to be an interesting ligand source for future investigations. We are currently testing complex **8** in the photo-water splitting reaction.

[6]Crystal data: monoclinic, space group $P2_1/n$, with lattice parameters a, 12.8609(21), b, 19.1581(24), c, 17.8598(15) Å; β = 102.0741(10)°; V = 4303.2(10) Å^3, Z = 2. The full details will be published independently (I. R. Butler, E. J. Gabe, and G. J. Gainsford).

Photolysis of *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2LX$ (L = PPh_3, PBu_3; X = Br, I), at 12 K in 1,2-epoxyethylbenzene, results in CO loss. The product is formed as a specific isomer of $(\eta^5\text{-}C_5H_5)Mo(CO)LX$, isomer **1**. This isomer, upon warming, yields only *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2LX$ in its reaction with CO. Photolysis of *cis*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2LX$ (L = PPh_3, PBu_3; X = Cl, Br, I) under similar conditions also results in CO loss to generate the unsaturated intermediate, $(\eta^5\text{-}C_5H_5)Mo(CO)LX$ as a different geometric isomer, isomer **2**. The unsaturated intermediate, isomer **2**, reacts thermally with CO to generate only *cis*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2LX$. The geometry of these unsaturated intermediates and their interaction with solvent is discussed.

Key words: mechanism, isomerism, photochemistry, molybdenum.

JEFF D. DEBAD et ROSS H. HILL. Can. J. Chem. **68**, 2216 (1990).

La photolyse du *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2LX$ (L = PPh_3, PBu_3; X = Br, I), à 12 K dans le 1,2-époxyéthylbenzène, provoque une perte de CO. Le produit est formé sous la forme d'un isomère spécifique du $(\eta^5\text{-}C_5H_5)Mo(CO)LX$, l'isomère **1**. La réaction de cet isomère, par chauffage avec du CO, ne fournit que le *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2LX$. La photolyse du *cis*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2LX$ (L = PPh_3, PBu_3; x = Cl, Br, I), dans des conditions semblables, conduit aussi à une perte de CO et fournit un intermédiaire insaturé, un $(\eta^5\text{-}C_5H_5)Mo(CO)LX$ sous la forme d'un isomère géométrique différent, l'isomère **2**. Cet intermédiaire insaturé, l'isomère **2**, réagit thermiquement avec le CO pour ne régénérer que le *cis*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2LX$. On discute de la géométrie de ces intermédiaires insaturés et de leur interaction avec les solvants.

Mots clés : mécanisme, isomérie, photochimie, molybdène.

[Traduit par la revue]

Introduction

We wish to report the results of our study concerning the photochemistry of the complexes $(\eta^5\text{-}C_5H_5)Mo(CO)_2LX$ (X = Cl, Br, I, L = PPh_3, PBu_3). Previously, we investigated the low temperature photochemistry of the isoelectronic series of compounds $(\eta^5\text{-}C_5Me_5)Re(CO)_2X_2$ (X = Me, Cl, Br, I) (1). For this series of rhenium complexes we found that *cis–trans* isomerism was a result of dissociative loss of CO to generate a single intermediate, regardless of the starting isomer used, which reacted with free CO to produce a *trans* geometry in the product, reaction [1]. This was in agreement with reports of the room temperature solution studies which indicated the observation of only *cis–trans* isomerism for these Re complexes (2).

[1] *cis/trans*-$(\eta^5\text{-}C_5H_5)Re(CO)_2X_2$

$$\xrightarrow{h\nu} (\eta^5\text{-}C_5H_5)Re(CO)X_2 + CO$$

$$(\eta^5\text{-}C_5H_5)Re(CO)X_2 + CO \xrightarrow{\Delta} \textit{trans}\text{-}(\eta^5\text{-}C_5H_5)Re(CO)_2X_2$$

Previous reports indicated that molybdenum phosphine complexes of the type $(\eta^5\text{-}C_5H_5)Mo(CO)_2PR_3X$ undergo a photoinduced isomerism (3). The reaction, given by reaction [2], is a geometrical isomerism of the basal ligands. Unlike the rhenium complexes, the molybdenum complexes were reported to undergo isomerism in either direction via photochemical initiation. The study of Alway and Barnett (3) measured quantum yields, at room temperature, for the reaction starting from either *cis-* or *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2PPh_3X$ (X = Br, I) under a variety of conditions. Based on the small observed variation in reaction quantum yield in the presence of either CO, PPh_3, or X^- the authors suggested that the majority of the isomerism occurred through a non-dissociative pathway. There was however evidence for photosubstitution *via* both a CO and PR_3 loss which was independent of the isomerism process.

[2] *cis*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2LX$

$$\underset{}{\overset{h\nu}{\rightleftharpoons}} \textit{trans}\text{-}(\eta^5\text{-}C_5H_5)Mo(CO)_2LX$$

The above results suggest that the CO loss products in these molybdenum complexes are geometrically rigid. If this is true *cis-* and *trans*-isomers of a given complex should generate distinct CO loss products.

We therefore undertook a low temperature study of the photoreactions of both *cis-* and *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2PR_3X$. The points we wished to investigate were (*1*) the geometry of the unsaturated fragments produced by CO loss from the *cis* and *trans* isomers, (*2*) the relative importance of loss of CO and loss of L (L = PPh_3, PBu_3), and (*3*) evidence for non-dissociative *cis-trans* isomerism.

Results

The FTIR monitored photolysis ($320 < \lambda < 400$ or broad band) of *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2PBu_3Br$ in 1,2-epoxyethylbenzene at 12 K leads to the loss of absorption intensity due to the starting complex, 1958 and 1869 cm^{-1}, and the appearance of new absorptions in the spectral region studied, Fig. 1*a*.[3] The absorption bands due to *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2PBu_3Br$ decrease in intensity proportionately to the relative extinction coefficients of the starting material.

The production of free CO in the glass is evidenced by an absorption at 2128 cm^{-1}. An intermediate monocarbonyl adduct is indicated by the absorption at 1803 cm^{-1}. The mono-

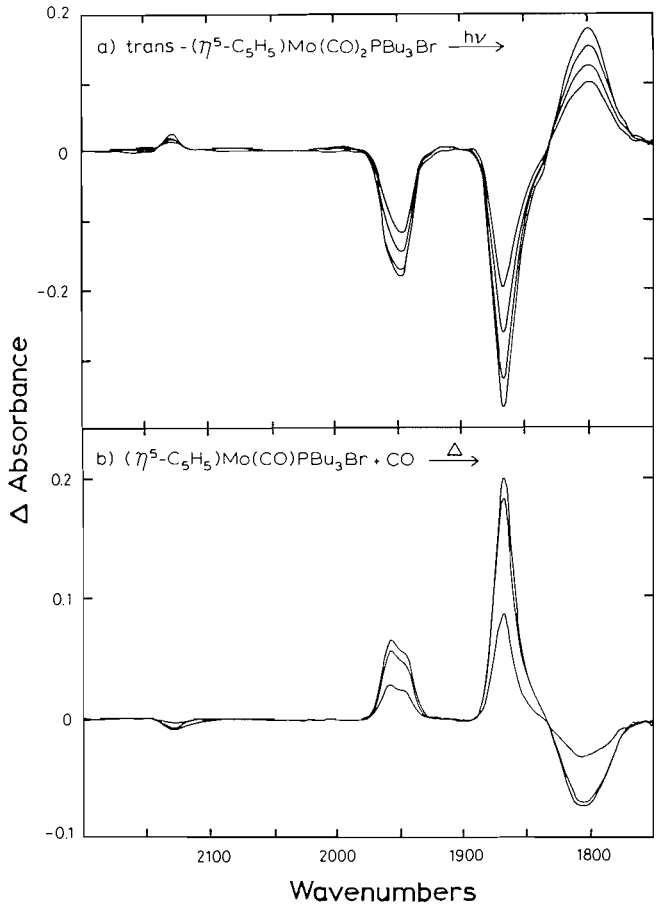

FIG. 1. FTIR spectral changes associated with (*a*) irradiation of *trans*-(η^5-C_5H_5)Mo(CO)$_2$PBu$_3$Br for 120, 240, 480, and 1020 s followed by (*b*) warming-photogenerated (η^5-C_5H_5)Mo(CO)PBu$_3$Br to 20 K, 30 K, and 80 K.

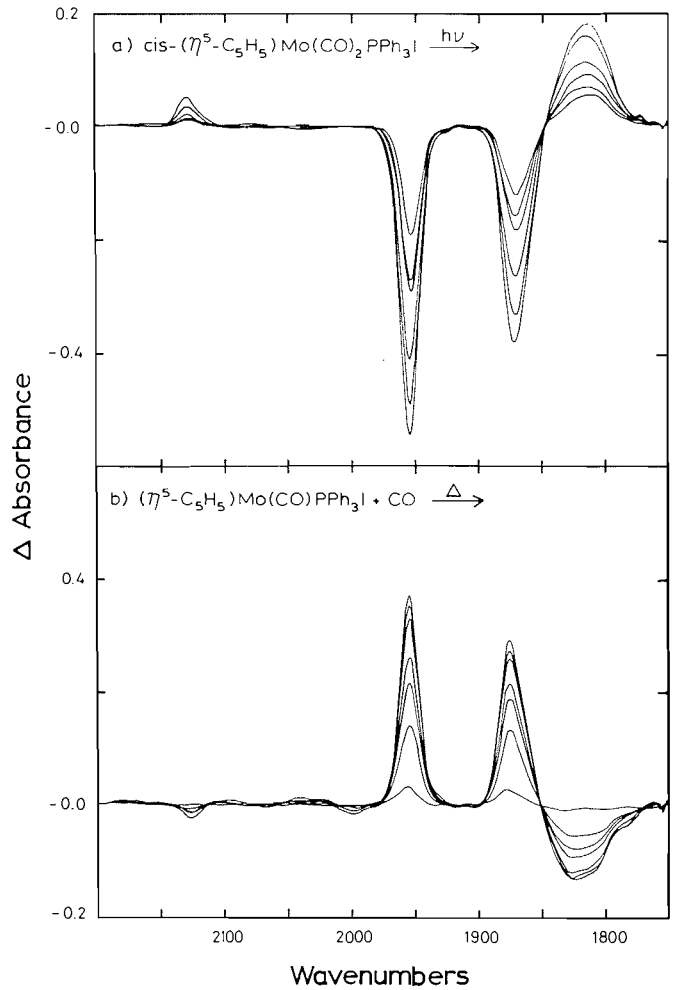

FIG. 2. FTIR spectral changes associated with (*a*) irradiation of *cis*-(η^5-C_5H_5)Mo(CO)$_2$PPh$_3$I for 10, 20, 30, 90, 450, and 1110 s followed by (*b*) warming-photogenerated (η^5-C_5H_5)Mo(CO)PPh$_3$I to 20 K, 40 K, 60 K, 80 K, 100 K, 110 K, and 120 K in the glass.

carbonyl is assigned as (η^5-C_5H_5)Mo(CO)PBu$_3$Br, isomer **1**. In addition to these absorptions an absorption band is observed to grow at 1726 cm^{-1}. This latter absorption is a result of solvent photolysis. This has been confirmed by photolysis of the solvent in the absence of any added complex and the 1726 cm^{-1} absorption band is observed to be produced.

Upon warming, the signal due to the monocarbonyl, (η^5-C_5H_5)Mo(CO)PBu$_3$Br, decreased in intensity, as did the absorption due to free CO at temperatures of ~65 K, Fig. 1*b*. The only new absorptions observed are those due to *trans*-(η^5-C_5H_5)Mo(CO)$_2$PBu$_3$Br. It should be noted that no new species are detected during warming. That none of the *cis* complex is formed is indicated by a comparison of the spectra obtained prior to and after thermal back reaction. If some *cis*-(η^5-C_5H_5)Mo(CO)$_2$PBu$_3$Br has been formed it would have been detectable. Although the absorption bands of the *cis*- and *trans*-isomers overlap, the relative extinction coefficients are quite different as expected because of the different angles between the CO ligands (4). This difference in relative extinction coefficients allows for the detection of any isomerism. The FTIR absorptions of the relevant complexes are summarized in Table 1.

The above experiment was repeated using *trans*-(η^5-C_5H_5)-Mo(CO)$_2$PR$_3$X, R = Ph, X = Br, I; R = Bu, X = I. In each case the results obtained were analogous to those described above. The FTIR data for these complexes, and their CO loss products is summarized in Table 1.

Similarly, photolysis of the *cis*-(η^5-C_5H_5)Mo(CO)$_2$PPh$_3$I complex under identical conditions results in loss of FTIR absorption at 1955 and 1875 cm^{-1}. In addition, the appearance of two new absorptions, at 2128 cm^{-1} due to free CO and a new monocarbonyl band at 1814 cm^{-1}, are observed, Fig. 2*a*. The monocarbonyl band is assigned as due to (η^5-C_5H_5)Mo(CO)-PPh$_3$I as it is the logical photoproduct from CO loss.

The CO loss product resultant from photolysis of the *trans* isomer showed a carbonyl band at 1820 cm^{-1}. The shift of 6 cm^{-1} is indicative of a different stereochemistry in the unsaturated species. We will henceforth refer to this photoproduct, produced from *cis*-(η^5-C_5H_5)Mo(CO)$_2$PPh$_3$I, as isomer **2** of (η^5-C_5H_5)Mo(CO)PPh$_3$I.

Warming of the glass containing CO and isomer **2** of (η^5-C_5H_5)Mo(CO)PPh$_3$I results in a reaction in which both the metal fragment and the CO are consumed, Fig. 2*b*. The back reaction becomes noticeable at temperatures as low as 20 K. During warming no new unsaturated species is formed and the band due to (η^5-C_5H_5)Mo(CO)PPh$_3$I decreases in intensity without significant shift in position. The only detectable product of this reaction is *cis*-(η^5-C_5H_5)Mo(CO)$_2$PPh$_3$I as evidenced by the ratio of intensity of the peaks which grow in at 1955 and 1875 cm^{-1}, which is ~1:1.

In this system we observe only that isomer **2** be produced via

[a]The extinction coefficients have an associated error of 20%.

photolysis. The last pertinent fact is if we has produced any of isomer **1** directly in the photolysis this in turn would have, upon warming, produced *trans*-(η^5-C_5H_5)Mo(CO)$_2$PPh$_3$I. This was not observed: the only product observed upon reaction with CO is *cis*-(η^5-C_5H_5)Mo(CO)$_2$PPh$_3$I.

A similar series of experiments were conducted with *cis*-(η^5-C_5H_5)Mo(CO)$_2$PR$_3$X, R = Ph, X = Cl, Br; R = Bu, X = Cl, Br, I. The result was photoinduced CO loss leading to isomer **2** of the monocarbonyl adducts. Each of these monocarbonyl adducts reacted with CO upon warming to produce *cis*-(η^5-C_5H_5)Mo(CO)$_2$PR$_3$X. The FTIR spectra are summarized in Table 1.

Discussion

The low energy absorptions in the electronic spectra of the molybdenum complexes have been assigned as due to ligand field ($\lambda \sim 400$–500 nm) and charge transfer ($\lambda < 400$ nm) absorptions (3). Reports of the solution chemistry of molybdenum complexes indicated that the efficiency of both isomerism and substitution were higher in the region $\lambda = 366$ nm than could be induced with visible irradiation. We therefore conducted our study using the wavelength region 320 nm $< \lambda <$ 400 nm. In some cases the result was compared with broad band photolysis and no difference in behavior was observed.

Previously, photosubstitution of CO in (η^5-C_5H_5)Mo(CO)$_2$PR$_3$X was suggested to occur via CO loss in room temperature solution (3). Our results indicate that CO loss, according to reaction [3], is the only observable process upon photolysis of (η^5-C_5H_5)Mo(CO)$_2$PR$_3$X at 12 K. This finding is consistent with a recently published report of the photochemistry of (η^5-C_5H_5)Mo(CO)$_3$Cl which was found to undergo CO loss in inert gas matrices at 12 K (5).

$$[3]\quad (\eta^5\text{-}C_5H_5)Mo(CO)_2LX \xrightarrow{h\nu} (\eta^5\text{-}C_5H_5)Mo(CO)LX + CO$$

L = PPh$_3$, PBu$_3$; X = Cl, Br, I

The thermal back reaction with CO is very fast, occurring at temperatures as low as 20 K. This is probably an indication of the ability of the solvent, a glass, to separate the photogenerated CO from the metal photoproduct rather than the true energetics of the back reaction with free CO. In fact, although the reaction with CO occurs at these low temperatures, the system may be warmed to 100 K where the reaction with CO is still not complete. In no case do the different intermediates produced by photolysis of *cis*- and *trans*-(η^5-C_5H_5)Mo(CO)$_2$PR$_3$X interconvert. Irrespective of temperature, back reaction with CO results in efficient production of the starting complex, in its original geometry, reaction [4]. This result indicates that the isomers are rigid at temperatures of 100 K. Of interest now is the geometry of these unsaturated fragments.

$$[4]\quad \textit{trans}\text{-}(\eta^5\text{-}C_5H_5)Mo(CO)_2LX \underset{\Delta}{\overset{h\nu}{\rightleftharpoons}} (\eta^5\text{-}C_5H_5)Mo(CO)LX + CO$$

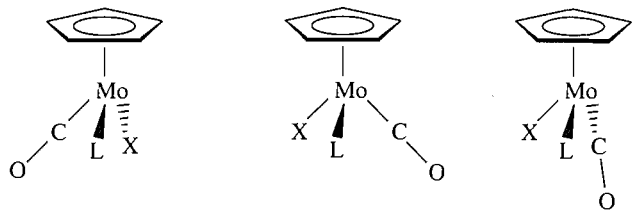
isomer 1

$$\textit{cis}\text{-}(\eta^5\text{-}C_5H_5)Mo(CO)_2LX \underset{\Delta}{\overset{h\nu}{\rightleftharpoons}} (\eta^5\text{-}C_5H_5)Mo(CO)LX + CO$$

isomer 2

The most reasonable geometry consistent with our results is one in which the remaining ligands retain their position following CO loss. The proposed structures for these isomers are shown below. In each case the stereochemistry is the result of removing a CO ligand from the precursor complexes. For isomer **2** there are two possible geometries shown, these are a result of loss of either of the two inequivalent CO ligands from the precursor molecules, *cis*-(η^5-C_5H_5)Mo(CO)$_2$LX. We have no probe to distinguish between these and cannot rule out the

possibility that both are formed. Although we have represented both **1** and **2** as unsaturated it is possible that interaction with solvent occurs such that solvent fills this vacant site.



isomer **1** isomer **2**

The observation of two isomers reported here is not without precedent. The isoelectronic molecule $(\eta^5\text{-}C_5H_5)V(CO)_3$, observed recently in a variety of matrices (6), was found to show local C_s symmetry. In addition the isotopomer, $(\eta^5\text{-}C_5H_5)\text{-}V(CO)_2(^{13}CO)$, was found to exist as two isomers.[4]

Two reasons may explain these results. Either there is an electronic preference for this geometry or solvation imposes this geometry. We have been unable to obtain direct evidence about the solvation of these species. Some data are suggestive of only a weak interaction with solvent. Both of these species are highly reactive and react with CO at temperatures of 20 K, indicating that any interaction with the solvent must be weak. In addition the geometry of these fragments is retained prior to solvation indicating that the observed rigidity may not be solely attributable to solvation. The isoelectronic fragment, $(\eta^5\text{-}C_5H_5)V(CO)_3$[6] discussed above, was claimed to be a naked tricarbonyl species. It should be noted however that it is well established that $Mo(CO)_5$, produced photochemically in an inert gas matrix, is solvated (7). In the case of $Fe(CO)_4$ both the naked molecule and a species of the type $Fe(CO)_4(G)$ (G = Xe, CH_4, and N_2) may be observed (8). Given that the glass used here contains both oxygen and aromatic groups it is likely that some solvation, albeit weak,[5] occurs.

The results are consistent with CO loss to generate a rigid unsaturated fragment with a stable geometry. It appears likely that the CO is lost from one position in each case and the thermal back reaction returns the CO to that position. Since the CO loss is a result of a photochemical reaction this conclusion is not a necessary result of microscopic reversibility.

Our findings are consistent with the earlier (3) observation that photoisomerism in solution occurs independent of CO photosubstitution. Here we have shown that at low temperatures CO loss does not result in isomerism. In view of the results in solution it is likely that the unsaturated complex which we have shown to be rigid at 100 K is interconverting only slowly at room temperature.

The other processes observed in the earlier paper (3), intermolecular isomerism and phosphine loss, have not been observed under our conditons. Since phosphine loss would require the ejection of PR_3 from the solvation shell, it is not surprising that we do not observe this process (9). That direct isomerism is not observed may be a result of either the rigidity of the glass in which we monitor the reaction or simply that the isomerism, even in the excited state, must overcome a substantial energy barrier.

Experimental

The complexes *cis-* and *trans-*$(\eta^5\text{-}C_5H_5)Mo(CO)_2LX$, L = PPh_3, PBu_3; X = Cl, Br, I, were prepared and purified by published methods (10–12). FTIR spectra were obtained with a Bruker IFS 85 spectrophotometer with 1 cm^{-1} resolution. Samples were cooled with a CTI-Cryogenics Model 22 cryocooler attached to a 350R compressor system. Temperatures were controlled and monitored using a Lake Shore Cryotronics silicon diode sensor (DT500 DRC) in conjunction with a model DRC 80C temperature controller.

The solvent used in the spectroscopic studies, 1,2-epoxyethylbenzene, was obtained from Aldrich and used without further purification.

Measurements of the extinction coefficients

A 1,2-epoxyethylbenzene (1.0 mL) solution of *trans-*$(\eta^5\text{-}C_5H_5)Mo(CO)_2PBu_3I$ (0.0083 g) was prepared and its FTIR spectrum measured at 298 K in a 0.127 mm path length FTIR cell. A similar measurement was made on the same cell containing only the 1,2-epoxyethylbenzene solvent. From the observed absorbances at 1954 and 1873 cm^{-1}, of 0.125 and 0.281, the respective extinction coefficients of the bands were determined as 647 and 1456 M^{-1} cm^{-1}.

The extinction coefficients were also measured at 12 K from the samples used for photolysis experiments. The concentration was calculated on the basis of FTIR absorbance at room temperature. The spectra obtained at lower temperatures were then subtracted from the spectrum of pure solvent at these temperatures and the extinction coefficients calculated from the difference, i.e. the absorbance solely due to *trans-trans-*$(\eta^5\text{-}C_5H_5)Mo(CO)_2PBu_3I$. The extinction coefficients calculated in this manner are given in Table 1.

The extinction coefficients of the stable complexes were all measured in the same way, the results for the different complexes are given in Table 1.

For unsaturated intermediates the extinction coefficients were calcaulated on the basis of assuming a 100% yield for the photolysis. The thermal back reaction with CO which should yield the same result was also determined and gave agreeable results within the estimated 20% error.

Photolysis of $(\eta^5\text{-}C_5H_5)Mo(CO)_2PR_3X$

Several experiments were conducted in the same manner; here we describe a typical experiment. The complex, *trans-*$(\eta^5\text{-}C_5H_5)Mo(CO)_2PPh_3I$, was dissolved in 1,2-epoxyethylbenzene to produce a solution of optical density 0.55 for its most intense IR absorption band in the carbonyl region at 1883 cm^{-1}. The sample was then transferred to a CaF_2 faced FTIR cell and loaded into the cold head of the cryostat. The sample chamber was evacuated and then cooled to 12 K. During the cool down FTIR spectra were obtained at different temperatures. At 12 K the sample was photolysed with the water filtered output of a 75 W high pressure Hg lamp for 10 s. The FTIR was then recorded again and the procedure of photolysis-record spectra was repeated until no further reaction occurred upon photolysis. At this time the compressor was turned off and the sample allowed to warm. FTIR spectra were recorded at 10 K intervals during warming until a temperature of 100 K was reached. At this point the sample was cooled to 12 K and its FTIR spectra obtained.

The FTIR spectra obtained are discussed in the Results section. The sample was then warmed to room temperature and its FTIR spectrum recorded. In other experiments the use of both H_2O and a Corning 7-51 filter isolated the wavelength range 320–400 nm for photolysis.

Acknowledgment

We wish to thank the Natural Sciences and Engineering Research Council of Canada for support of this work through an operating grant.

[4]A referee has suggested that the C_s structure observed in ref. 5 is a result of rotomers of the $\eta^5\text{-}C_5H_5$ ring. We agree that this is possible in the case of ref. 5. However, we rule this out in our case since such rotomers would not be expected at temperatures as high as 100 K nor would they be expected to result in stereospecific chemistry in their reactions with CO.

[5]The supposition that solvation is weak is based on the assumption that the reaction with CO which occurs at temperatures as low as 20 K is an indication of the weak interaction between metal and solvent. This conclusion is valid if the mechanism of replacement of solvent is dissociative.

The synthesis and X-ray structures of η^1-, η^3-, and η^5-dienolate complexes of manganese carbonyl

ANDREW P. MASTERS, JOHN F. RICHARDSON,[1] AND TED S. SORENSEN
The Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received June 18, 1990

ANDREW P. MASTERS, JOHN F. RICHARDSON, and TED S. SORENSEN. Can. J. Chem. **68**, 2221 (1990).

The η^1-, η^3-, and η^5-ester dienolate complexes of $Mn(CO)_n$ have been prepared and the crystal structures of the phenyl ester member have been obtained for all three bonding modes. The allyl (*anti*-η^3) member shows some bonding distortions compared to a simple allyl ligand. The structure of the η^5-1-oxapentadienyl ligand complex is substantially different from a rhenium analog in that the organic ligand is non-planar with significantly different bond distances. The η^5-complex reacts rapidly with triphenylphosphine to generate the *syn*-η^3-complex.

Key words:

On a préparé les complexes η^1-, η^3- et η^5-esters diénoliques du $Mn(CO)_n$ et on a déterminé les structures cristallines des esters phényliques des trois modes de liaison. Par comparaison avec le produit allylique portant un ligand simple, le dérivé allylique (*anti*-η^3) présente quelques distorsions de liaison. Comparée à la structure de son analogue du rhénium, celle du complexe portant un ligand η^5-1-oxapentadiényle est très différente; son ligand organique n'est pas plan et les distances des diverses liaisons sont assez différentes. Le complexe η^5 réagit rapidement avec la triphénylphosphine pour donner le complexe *syn*-η^3.

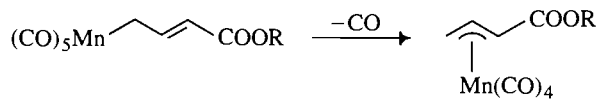
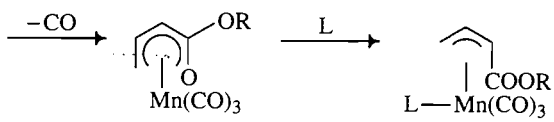
Introduction

The interconversion of transition metal complexes containing η^1-, η^3-, or η^5-bonded acyclic ligands is an important area of organometallic chemistry. To date interest in acyclic groups capable of such interconversions has largely centered on the pentadienyl ligand (1), however a dienolate ligand also has the same possible bonding modes (2). In this paper we describe the preparation and X-ray structural characterization of an organometallic series having the same organic ligand but, separately, involving all three bonding types. The work encompasses the manganese carbonyl complexes of the dienolate esters shown below. Crystals suitable for X-ray crystallographic study were obtained only for the series with R = Ph.



R = Et **1***a* **2***a*
R = Ph **1***b* **2***b*



3*a*
3*b*

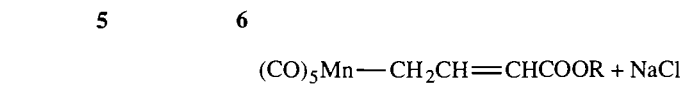
4 (L = PPh_3)

Simple η^1-alkyl or allyl, η^3-allyl, and η^5-pentadienyl complexes of $Mn(CO)_n$ are well-known.[2] However, functionalized derivatives such as **1**, **2**, or **3** have been less studied and there are no examples of these having been prepared by the stepwise procedure described here, although this procedure has recently been reported for the pentadienyl ligand itself (4). Several η^5-dienolate complexes of transition metals have been prepared by unusual routes (5) and a rhenium complex has been characterized by X-ray (6). η^3-Dienolate complexes are known for other transition metals but these are relatively rare for manganese and have not been structurally characterized.

The preparation of the η^5-dienolate complex was also of interest synthetically. The goal, based on dienyl chemistry (7), was to show that reforming the η^3-complex would yield the isomeric *syn*-η^3-geometric isomer, **4**.

Results and discussion

Details for the preparation of the η^1-complex **1***a* have been described elsewhere (2). It is readily made from $Na^+[Mn(CO)_5^-]$ and ethyl (*E*)-4-chloro-2-butenoate (**6**, R = Et) in THF and can be isolated as a stable, air-sensitive, pale yellow oil.



5 **6** **1**

The corresponding phenyl ester, **1***b*, could be made in a similar way, in this case giving a somewhat less air-sensitive crystalline solid. Both η^1-complexes could be decarbonylated by heating the compounds at 80°C without solvent to give the corresponding yellow η^3-dienolate complexes **2***a*, *b* in high yields. Further decarbonylation of **2***a*, *b* was achieved by refluxing them in cyclohexane for 12 h to yield the η^5-dienolate complexes **3***a*, *b*. These were isolated by flash chromatography as an air-sensitive dark yellow oil and a dark orange crystalline solid, respectively, which were very soluble in pentane. The phenyl ester **3***b* could be stored for several months under nitrogen at 0°C. Attempts to decarbonylate the η^3-complex **2***a* by heating the neat compound to 120°C or by irradiation of a solution (hexane or THF) with an ultraviolet lamp resulted in further evolution of carbon monoxide, but this was accompanied by considerable decomposition. Although there was some evidence for the formation of the η^5-complex the yields were

very low. In some recently published (8) η^1- and η^3-Cp(CO)Fe – ester dienolate work, an attempt to prepare the corresponding η^5-complex was unsuccessful. It is not clear why the iron and manganese systems should be different in this regard.

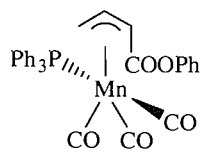
Spectroscopic characterization of the η^1-, η^3-, and η^5-complexes

The IR spectra for the η^1- and η^3-bonded complexes **1** and **2** contain a weak band in the carbonyl region (1738 cm^{-1} for **1***b* and 1736 cm^{-1} for **2***b*) assigned to the carbonyl stretch of the ester functionality. The position of this band is similar to what one would expect for an α,β-unsaturated ester. This band is not present in the spectra for the η^5-complexes. Similarly, a weak band at 1618 cm^{-1} for the η^1-complex **1***b*, assigned to the stretching mode of the free double bond, is not observed in either the η^3- or η^5-complexes.

The ^1H NMR spectral data and assignments for complexes **1**, **2**, and **3** are presented in Table 1. For the η^3-complex, there are two possible geometries, *anti* (H_c—H_d *trans*) or *syn* (H_c—H_d *cis*). The assignment assumes the *anti* configuration observed in the solid state (*vide infra*) with the coupling constants $J_{ac} > J_{bc}$ and $J_{cd} > J_{bc}$. The size of the J_{cd} coupling constant (10 Hz) is somewhat ambiguous, but one expects that the *anti* isomer will have formed because this geometry is present in the η^1-complex and it is expected to be the thermodynamically more stable product. The methylene protons of the ethyl group in the η^3-complex **2***a* are diastereotopic and appear as a complex multiplet. This is not observed for the η^5-complex **3***a*.

The reaction of the η^5-complex **3**b *with triphenylphosphine*

This complex was found to react rapidly with triphenylphosphine at room temperature to give high yields of the *syn*-η^3-complex **4**. The ^1H NMR spectrum of this adduct shows a J_{cd} coupling constant of 6.7 Hz, confirming that this isomer now has a *syn* geometry and coincidentally providing confirmatory evidence that the original η^3-isomer had the *anti* geometry.



4

The structures of the η^1-, η^3-, and η^5-complexes

Bond length and bond angle data for the three complexes are given in Tables 2 and 3. Ortep representations of the three structures are given in Figs 1, 2, and 3. A schematic showing the relationship between the three structures is presented in Fig. 4.

The structure of the η^1-complex is close to an ideal octahedral arrangement of the carbonyl and organic ligands. There is only a small distortion of the angles between the carbonyl ligands (88.5–93.7° compared to the ideal 90°) but a slightly greater distortion relative to the organic ligand; three C(1)—Mn—carbonyl angles are less than 90° (82.5–88.5°) indicating a deviation toward the ligand while C(1)—Mn—C(11) is 91.4°, probably for steric reasons as it is juxtaposed with C(2) of the ligand. The axial Mn—CO bond distance (Mn—C(13), 1.824(4) Å) is significantly shorter than any of the equatorial Mn—CO distances (average distance 1.858 Å), presumably because of increased π-character of the axial bond which is trans to the σ-bonded ligand. Shorter axial Mn—CO bond lengths relative to mean equatorial Mn—CO distances have been observed in other manganese carbonyl complexes (9). The Mn—C(1) bond length (2.214(3) Å) is comparable to that for other manganese carbonyl alkyl complexes such as $MeMn(CO)_5$ (2.185(11) Å) (10) and $CH_3COCH_2Mn(CO)_4(PPh_3)$ (2.210(5) Å) (11).

The structure of the η^3-complex **2***b* is similar to those reported for related manganese complexes (7, 12, 13), with the η^3-dienolate ligand adopting the W-conformation. The allyl

C(4)—O(2)—C(5)	115.9(3)	116.8(3)	118.7(3)

ligand plane (C(1)—C(2)—C(3)—C(4)) intersects the equatorial plane of the carbonyl ligands (C(12)—Mn—C(13)) at an angle of 77.1°, which compares with 70.7° in *syn*-η^3-$(C_5H_7)Mn(CO)_3PMe_3$ (7) and 71.0° in the allyl complex η^3-$(C_3H_5)Mn(CO)_2(P(OMe_3)_2$ (12). The bond angle of the allyl portion of the dienolate ligand (C(1)—C(2)—C(3)) is comparable to that in η^3-$(C_3H_5)Mn(CO)_2(P(OMe_3)_2$ (122.5(4)° vs. 124.5(15)°), and is somewhat smaller than the corresponding angle for the η^1-complex (126.7(3)°) where C(2) and C(3) are not coordinated. There is some asymmetry in the allyl part of the ligand, the C(1)—C(2) bond length (1.381(6) Å) is significantly shorter than that for C(2)—C(3) (1.412(5) Å), a feature which is also observed (7) in the related complex *syn*-η^3-$(C_5H_7)Mn(CO)_3PMe_3$. The allyl ligand carbon atoms C(1) and C(3) are also bonded to manganese in an asymmetric fashion, indicated by the distances of these atoms to the equatorial plane (−0.345 and 0.023 Å), and the Mn—allyl bond lengths (Mn—C(1) 2.254(4) Å and Mn—C(3) 2.186(3) Å). The Mn—C(3) distance is comparable to that for the σ-bond in the η^1-complex **1***b* (2.214(3) Å). A possible explanation for this arrangement is that the allyl ligand has a small degree of σ—π bonding character, as shown below **7**, rather than a completely delocalized π-allyl bonding.

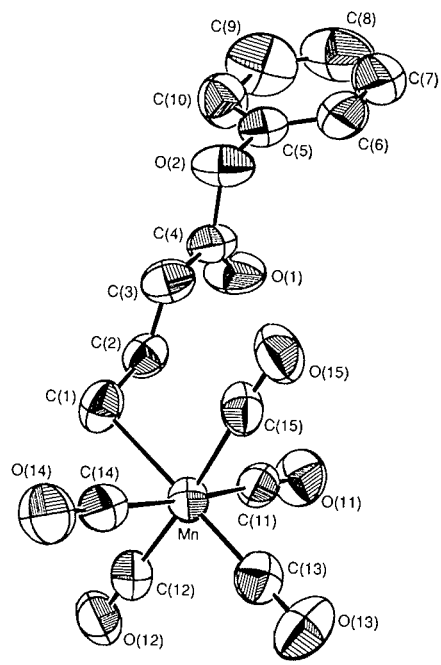

FIG. 1. ORTEP drawing (50% probability level) of the η^1-complex **1***b*.

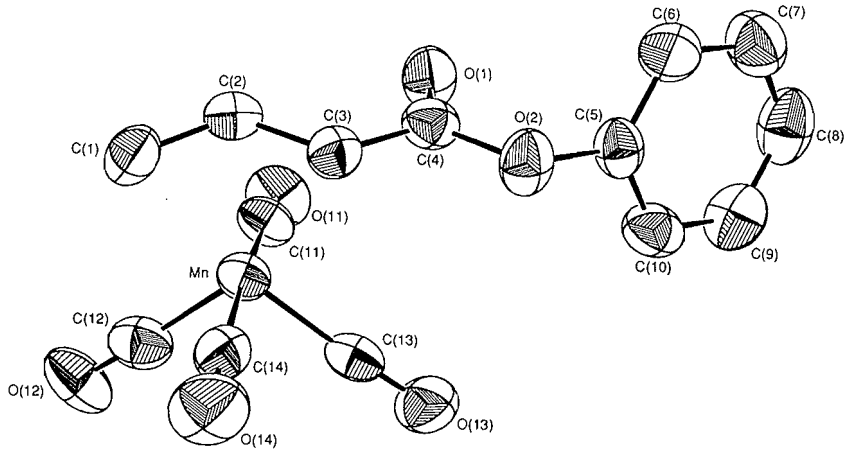

FIG. 2. ORTEP drawing (50% probability level) of the η^3-complex **2***b*.

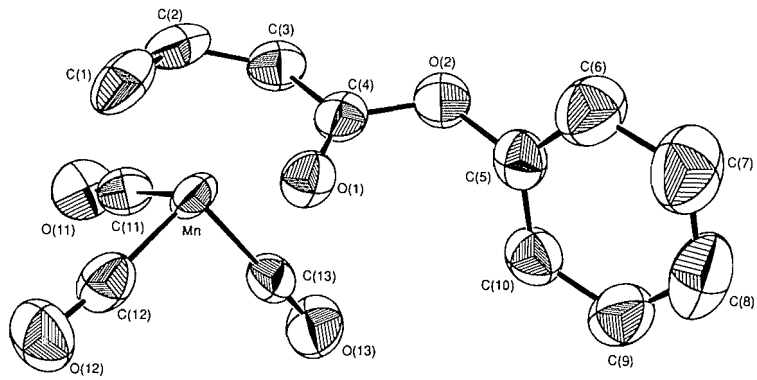

FIG. 3. ORTEP drawing (50% probability level of the η^5-complex **3***b*.

After our studies were completed, an X-ray structure of an η^3-iron ester dienolate complex was reported (8). In contrast to the manganese structure reported here, the two allyl bond lengths in the iron complex are nearly identical, 1.430(6) and 1.421(6) Å. It is difficult to compare other parameters because the iron complex lacks defined symmetry planes (Cp and CO are the only other ligands).

The general structural features of the η^5-complex are similar to those for η^5-cyclohexadienylmanganese tricarbonyl (14) and the related complex (6) η^5-$(C_4H_5O)Re(PPh_3)_2CO$, C(1) is *trans* to C(13), C)3) is *trans* to C(12) and O(1) is *trans* to C(11) with these atoms forming a very distorted octahedron. However, unlike the rhenium complex the dienolate ligand is not quite planar, O(1) and C(4) are out of the plane C(1)—C(2)—C(3) by −0.218 and 0.142 Å, respectively. Another important difference is that the C(3)—C(4) bond is longer than the corresponding bond in the rhenium complex (1.441(7) vs. 1.40(2) Å) with a concomitant shortening of the C(4)—O(1) bond (1.237(6) vs. 1.30(1) Å for the rhenium complex). The Mn—C(4) distance for this complex is also significantly longer than the other Mn—C distances (see Table 2). This distortion is consistent with a degree of n-donor character in the complex as shown in **8**, whereas the rhenium complex more resembles a pentadienyl ligand → M case. Unlike the η^3-complex the allyl part of the organic ligand is quite symmetrical as indicated by the bond distances C(1)—C(2) (1.400(7) Å), C(2)—C(3) (1.401(7) Å), Mn—C(1) (2.152(4) Å), and Mn—C(3) (2.159(5) Å).

In comparing the three structures (see Fig. 4 and Table 2) it is clear that there is a large spread in the Mn—CO distances (1.751(5)–1.893(4) Å). The longest Mn—CO distances occur where CO is *trans* to CO *i.e.* Mn—C(11), Mn—C(12), Mn—C(14), and Mn—C(15) in the η^1-complex, and Mn—C(11) and Mn—C(14) in the η^3-complex. The shortest Mn—CO distance appears in the η^5- complex for the carbonyl which is *trans* to O(1), Mn—C(11). This substantial *trans* influene of O(1) can be explained by donation to manganese by this oxygen with accompanying donation into the antibonding π-orbital of the *trans* CO. Such an effect has been observed in other manganese carbonyl complexes containing oxygen donor ligands (15). The average Mn—CO distance in the η^5-complex is also the shortest of the three (1.795 Å compared to 1.851 Å for **1***b* and 1.837 Å for **2***b*). This overall trend would be consistent with an increasing overall π-contribution from the dienolate ligand as the coordination of this ligand is increased.

The axial CO's in the η^3- and η^5-complexes are bent towards the dienolate ligand compared to a true octahedron as indicated by angle C(12)—Mn—C(13) (102.9(2)° in **2***b*, 98.2(2)° in **3***b*). In the case of the η^3-complex such a distortion would accommodate the restricted "bite angle" of the allyl ligand. Coversely in the η^3-complex, the equatorial CO's are bent away from the dienolate ligand as shown by the angles C(11)—Mn—C(14) and C(11)—Mn—C(12) (173.8(2) and 86.3(2)°, respectively). In contrast to the η^3-complex the *trans* influence of the cordinated oxygen in the η^5-complex allows

C(11) to take up a more octahedral site as indicated by the near perfect octahedral angles C(11)—Mn—C(12) and C(11)—Mn—C(13) (89.8(2) and 89.7(2)°, respectively).

Experimental

All procedures were performed under an atmosphere of argon or dried nitrogen using a combination of syringe, transfer needle, and Schlenk techniques. Infrared analysis was performed using a Nicolet 5DX FT instrument. Mass spectrometric analyses were obtained on a Kratos MS80, and ^{1}H, ^{13}C NMR spectra on a Varian XL-200.

Tetrahydrofuran was distilled from benzophenone ketyl under nitrogen, hexane, and deuterated solvents were dried over sieve dust prior to use. Flash chromatography was performed using silica (Merck 9385) and methylene chloride.

Phenyl 4-chloro-2-butenoate was prepared by treating phenyl 2-butenoate (from 2-butenoyl chloride and phenol) with *N*-bromosuccinimide followed by treatment of the purified bromide with lithium chloride in dimethylformamide. The preparation of η^1-4-oxo-4-ethoxy-2-butenyl manganese pentacarbonyl **1***a* has been described elsewhere (2).

η^1-4-Oxo-4-phenoxy-2-butenyl manganese pentacarbonyl **1**b

The anion $Na^+[Mn(CO)_5^-]$ was prepared according to the literature procedure (16) from 0.5 g (1.28 mmol) of dimanganese decacarbonyl in 40 mL THF. This solution was decanted using a transfer needle into a flask containing 0.5 g (2.54 mmol) of phenyl 4-chloro-2-butenoate in 5 mL of THF and the mixture stirred for 10 min. The solvent was then evaporated to give a yellow solid residue which was extracted with 4 × 50 mL of warm (40°C) hexane. The extract was filtered and concentrated to a volume of 100 mL and cooled to −10°C. On standing 0.75 g of cream cubic crystals were obtained (83% yield), melting point 95–96°C (decomposed).

Infrared (hexane, cm^{-1}): 2113(m), 2052(w), 2021(vs), 1999(s), 1738(m), 1618(w). ^{1}H NMR ($CDCl_3$): 7.65(dt, 1H, *J* = 15 Hz and 9.6 Hz), 7.1–7.5(m, 5H), 5.81(d, 1H, *J* = 15 Hz), 1.94(d, 2H, *J* = 9.7 Hz). ^{13}C NMR ($CDCl_3$): 8.2(CH_2), 110.2(CH), 121.8(CH), 125.3(CH), 129.3(CH), 161.1(C). Mass spectrum (*m/e*, % base peak): 328 (1, M − CO) 300(1), 272(1), 244(1), 216(40), 148(66), 94(72). *Anal.* calcd. for $C_{15}H_9MnO_7$:C 50.58, H 2.31, found: C 50.01, H 2.31.

η^3-4-Oxo-4-phenoxy-2-butenyl manganese tetracarbonyl **2**b

Complex **1***b* (0.34 g, 0.94 mmol) was heated to 85–90°C for 30 min, by which time the evolution of carbon monoxide had ceased. The resulting semisolid yellow residue was then dissolved in 20 mL hexane, the solution filtered, and cooled to −20°C. After standing overnight, 0.19 g of fine yellow needles were obtained. These were recrystallized to give an analytically pure sample (0.17 g, 55% yield) mp 66–67°C.

Infrared (hexane, cm^{-1}): 2084(s), 2021(w), 2001(vs), 1975(s), 1736(m). ^{1}H NMR ($CDCl_3$): 7.12–7.53 (m, 5H), 5.79 (ddd, 1H), 3.09 (d, 1H, *J* = 7.3 Hz), 2.70 (d, 1H, *J* = 10.3 Hz), 2.37 (d, 1H, *J* = 14 Hz). ^{13}C NMR ($CDCl_3$): 45.2(CH), 46.5(CH_2), 96.5(CH), 121.7(CH), 125.8(CH), 129.4(CH), 150.7(C). FIG. 4. Models of the crystal structures of **1***b*, **2***b*, and **3***b* showing the relationships between the three structures (C(12)—Mn—C(13) are in the same plane in each model).

η^3-4-Oxo-4-ethoxy-2-butenyl manganese tetracarbonyl **2**a

In a round-bottomed flask attached to a bubbler, 0.1 g of **1***a* was heated to 80°C for 1 h, by which time the evolution of carbon monoxide had ceased. The resulting yellow oil was dissolved in 1 mL of methylene chloride and purified by flash chromatography to yield **2***a* as a yellow oil (0.08 g, 88% yield).

Infrared (CH_2Cl_2, cm^{-1}): 2090(m), 2000(s), 1970(s), 1710(m). ^1H NMR, ($CDCl_3$): 1.30(t, J = 7.2 Hz, 3H); 2.26(d, J = 12.9 Hz, 1H); 2.53(d, J = 10.4 Hz, 1H); 2.99(d, J = 8.5 Hz, 1H); 4.22(tq, 2H); 5.67(ddd, 1H). ^{13}C NMR, ($CDCl_3$): 14.4(CH_3), 45.3(CH_2), 46.8(CH), 60.5(CH_2), 96.1(CH). Mass spectrum (*m/e*, %base peak): 224(1), 196(5), 168(10), 124(4), 100(20), 68(12), 55(23), 43(100). *Anal.* calcd. for $C_{10}H_9MnO_6$: C 42.88 H 3.24; found: C 40.11, H 3.04. The elemental analysis for this compound could not be improved, even by repeated purification.

η^5-4-Oxo-4-phenoxy-2-butenyl manganese tricarbonyl **3**b

Complex **2***b* (0.49 g, 1.49 mmol) was dissolved in 5 mL cyclohexane and the solution was refluxed for 10 h under a stream of nitrogen. The deep yellow solution was then concentrated to 2 mL under vacuum and applied directly to a flash chromatography column. The product eluted first followed by a small amount of unreacted **2***b*. After evaporation of the solvent the crude product solidified on standing to give large orange plates (0.38 g, 84% yield) which were analytically pure, mp, 48°C. Crystals suitable for X-ray crystallography were obtained from a concentrated solution in pentane maintained at −20°C for several days.

Infrared (CH_2Cl_2, cm^{-1}): 2036(s), 1959(s), 1932(s). ^1H NMR ($CDCl_3$): 6.9–7.45 (m, 5H), 5.58 (ddd, 1H), 5.12 (d, 1H, J = 6.7 Hz), 3.61 (d, 1H, J = 9.6 Hz), 2.03 (d, 1H, J = 13.6 Hz). ^{13}C NMR ($CDCl_3$): 57.0(CH), 62.0(CH_2), 107.5(CH), 121.2(CH), 126.6(CH), 129.7(CH). Mass spectrum (*m/e*, %): 300(0.1, M), 272(1), 244(12), 216(61), 148(79), 94(47), 69(10), 68(36), 66(12), 65(13), 55(81). *Anal.* calcd. for $C_{13}H_9MnO_5$: C 52.02 H 3.02; found: C 52.10, H 3.04.

η^5-4-Oxo-4-ethoxy-2-butenyl manganese tricarbonyl **3**a

This was prepared in the same way as **3***b* and yielded 0.036 g dark yellow oil (76%). This product was air-sensitive and decomposed slowly in solution even at reduced temperature.

Infrared (CH_2Cl_2, cm^{-1}): 2050(s), 1960(s), 1935(s). ^1H NMR ($CDCl_3$): 1.22(t, J = 7.1 Hz, 3H); 1.93(d, J = 14 Hz, 1H); 3.54(d, J = 9.5 Hz, 1H); 3.92(q, J = 7.2 Hz, 2H); 4.86(d, J = 7.0 Hz, 1H); 5.46(ddd, 1H). ^{13}C NMR ($CDCl_3$): 14.1(CH3), 57.0(CH), 60.3(CH_2), 61.9(CH_2), 105.7(CH).

η^3-4-Oxo-4-phenoxy-2-butenyl manganese tricarbonyl triphenylphosphine

Complex **3***b* (0.1 g, 0.33 mmol) was dissolved in 20 mL of hexane and 0.08 g (0.32 mmol) of finely ground triphenylphosphine was added in small portions with stirring. The yellow precipitate which forms was filtered off, and purified by flash chromatography to give 0.17 g (94% yield) of **4** as pure yellow microcrystals, mp 120°C.

Infrared (CH_2Cl_2, cm^{-1}): 2014(s), 1945(s), 1918(s), 1715(m). ^1H NMR ($CDCl_3$): 2.98(dd, J = 6.7 Hz, J_{HP} = 3.2 Hz, 1H); 3.17(d, J = 8.2 Hz, 1H); 3.52(d, J = 13.4 Hz, 1H); 4.33(m, J_{HP} = 13.1 Hz, 1H); 7.04–7.44(m, 5H); 7.44–7.60(m, 15H). *Anal.* calcd. for $C_{31}H_{24}MnO_5P$: C 66.20, H 4.30; found: C 66.04, H 4.54.

X-ray crystallography

Crystals of the three complexes were obtained from hexane or pentane solution as light yellow plates. The crystal data and experimental details are given in Table 4. Cell constants and orientation matrices were determined by least-squares refinement of the diffraction geometry of 25 accurately centered reflections. The choice of space groups was confirmed using the program TRACER (17) and by the successful solution and refinement of the structures. For compound **2***b* the alternate choice of space group *Pnma* required mirror symmetry or an inversion centre on the molecule, and was therefore ruled out. Data were collected at room temperature on an Enraf-Nonius CAD4 automated diffractometer using the ω–2θ scan technique. As a check on crystal and electronic stability three representative reflections were measured every 60 min. The intensities of these reflections showed only a statistical variation so a correction was not applied. The data were corrected for Lorentz and polarization effects as well as absorption (Gaussian method).

The structures were solved by Patterson techniques which revealed the position of the Mn atom in each case. The remaining atoms were located in succeeding difference Fourier syntheses. Hydrogen atom positions were calculated using ideal geometries (d(C—H) = 1.0 Å) and added to the structure factor calculation iwth isotropic thermal parameters set to $1.3B_{iso}$ of the bonded C atom. H atom parameters were recalculated after each cycle but not refined. Refinement was carried out by full-matrix least-squares on F, minimizing the function $\Sigma w(|F_o| - |F_c|)^2$ where the weight w is defined as $[\sigma^2(F) + 0.00002F^2]^{-1}$ for the three structures. All computations were performed using the XRAY 76 system of programs (18) implemented on a Honeywell computer with a MULTICS operating system. Scattering factors for non-H atoms were those of Cromer and Mann (19) and those for H were taken from ref. 20. Anomalous dispersion effects were included in F_c; the values for $\Delta f'$ and $\Delta f''$ were those of Cromer (21). Refinement of the enantiomeric model of the η^3-complex showed no significant improvement in the agreement factors.

The models converged with the largest Δ/σ being less than 0.02 in all structures. The highet peaks of residual electron density were 0.44(8), 0.45(7), and 0.40(8) e Å^3 for the η^1-, η^3-, and η^5-complexes respectively, and were associated with the Mn atom in each case. Plots of $\Sigma(|F_o| - |F_c|)^2$ vs. $|F_o|$, reflection order in data collection, sin θ/l, and various classes of indices showed no unusual trends. The final atomic coordinate and B_{eq} for the non-H atoms are given in Tables 5, 6, and 7.[3]

Kinetics of self-exchange of bis(1,4,7-trithiacyclononane)iron(III)/(II) in acetonitrile and in acidic aqueous solution

HIDEO DOINE AND THOMAS W. SWADDLE

Department of Chemistry, The University of Calgary, Calgary, Alta., Canada T2N 1N4

Received June 18, 1990

HIDEO DOINE and THOMAS W. SWADDLE. Can. J. Chem. **68**, 2228 (1990).

The rate constant k_{ex} of the $Fe([9]aneS_3)_2^{3+/2+}$ self-exchange reaction cannot be measured in most common solvents because of spontaneous reduction of the $Fe([9]aneS_3)_2^{3+}$ ion, which is also sensitive to photolysis by visible light. However, in CD_3CN at -41 to -19°C, reproducible proton-decoupled ^{13}C NMR line broadening measurements are possible, and give $k_{ex} = (5.3 \pm 0.3) \times 10^4$ kg mol^{-1} s^{-1} at 0°C, $\Delta H^* = 10.3 \pm 1.8$ kJ mol^{-1}, and $\Delta S^* = -116 \pm 7$ J K^{-1} mol^{-1}, at ionic strength $I = 0.1$ mol kg^{-1}. Proton NMR line broadening experiments are marginally practicable in very acidic water (2.0 mol kg^{-1} D_2SO_4/D_2O) near 0°C, and give $k_{ex} = 3.2 \times 10^6$ kg mol^{-1} s^{-1} at 1°C. The relative k_{ex} values of these and other low-spin/low-spin $Fe^{III/II}$ self-exchange reactions follow the predictions of the Marcus–Hush theory at least qualitatively. The effect of ionic strength, however, is less than predicted, probably because of the formation of less reactive anion–cation pairs.

Key words: electron transfer kinetics, crown thioether complexes.

HIDEO DOINE et THOMAS W. SWADDLE. Can. J. Chem. **68**, 2228 (1990).

Dans la plupart des solvants usuels, il n'est pas possible de mesurer la constante de vitesse k_{ex} de la réaction d'auto-échange du $Fe([9]aneS_3)_2^{3+/2+}$; cette situation est causée par la réduction spontanée de l'ion $Fe([9]aneS_3)_2^{3+}$, qui est aussi sensible à la photolyse par la lumière visible. Toutefois, dans le CD_3CN, entre -41 et -19°C, il est possible d'obtenir des élargissements reproductibles des raies des spectres de rmn du ^{13}C découplés du proton et on peut en déduire que, à 0°C et à une force ionique $T = 0{,}1$ mol kg^{-1}, $k_{ex} = (5{,}3 \pm 0{,}3) \times 10^4$ kg mol^{-1} s^{-1}, $\Delta H^* = 10{,}3 \pm 1{,}8$ kJ mol^{-1}, et $\Delta S^* = -117 \pm 7$ J K^{-1} mol^{-1}. Les expériences d'élargissment des raies de la rmn du proton ne sont pas très faciles à réaliser en milieu très acide (2,0 mol kg^{-1} de D_2SO_4/D_2O), près de 0°C; on a pu toutefois pu établir que, à 1°C, $k_{ex} = 3{,}2 \times 10^6$ kg mol^{-1} s^{-1}. Les valeurs relatives de k_{ex} pour ces réactions d'auto-échange et celles d'autres réactions semblables des $Fe^{III/II}$ faible spin/faible spin suivent au moins qualitativement les prédictions de la théorie de Marcus-Hush. Toutefois, l'effet de la force ionique n'est même pas prédit; probablement à cause de la formation de paires d'anion-cation moins réactives.

Introduction

The number of outer sphere electron transfer (OSET) reactions of the self-exchange type

[1] $ML_n^{z+} + ML_n^{(z+1)+} \rightleftharpoons ML_n^{(z+1)+} + ML_n^{z+}$

of which the rate constant k_{ex} can be measured directly by techniques currently available is surprisingly small, particularly if one seeks to compare redox reactivity in aqueous and non-aqueous to solvents or, as in the case of our continuing research program, to assess the effects of hydrostatic pressure on k_{ex} in terms of current theory. For reactions that are too rapid for isotopic sampling techniques, NMR line-broadening methodology is often applicable in principle, but requires that either ML_n^{z+} or $ML_n^{(z+1)+}$ be diamagnetic. In addition, the exchange rate must fall within the NMR timeframe, the NMR spectrum of the diamagnetic species should contain at least one well-separated singlet that is substantially shifted following electron transfer, the solubilities of the oxidized and reduced species must be sufficiently high in the solvent of choice, and losses of either species during the experiment through redox reactions with the solvent or with impurities must be insignificant.

Iron(III)/(II) couples in which both members are present exclusively in the low-spin state in solution would seem to be attractive candidates for self-exchange rate studies, since the iron(II) complex is diamagnetic and, furthermore, the iron–ligand bond lengths are typically almost identical in the two oxidation states, so that the Franck–Condon restrictions are minimal and OSET is correspondingly fast (1). In practice, however, the iron(III) complex is usually too strongly oxidizing to survive for long in solution, and the choice of sufficiently senstitive NMR-active nuclei is often limited to ligand protons which may give an overly complex spectrum. The $Fe(phen)_3^{3+/2+}$ couple (phen = 1,10-phenanthroline) is a case in point, but reliable k_{ex} data have been obtained for it in both acetonitrile and aqueous acid at low temperatures (2–4).

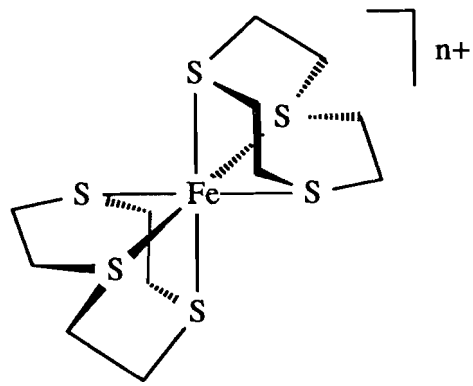

FIG. 1. Bis(1,4,7-trithiacyclononane)iron(II) or -(III) ion (schematic).

Crown thioether ligands such as 1,4,7-trithiacyclononane ([9]aneS$_3$) have recently opened up new opportunities in coordination chemistry, as they are surprisingly effective π-acidic ligands for metal ions in some unusual higher oxidation states, and also tend to enforce spin-pairing in lower oxidation states (5). Thus, Wieghardt and co-workers (6, 7) have characterized salts of the complexes $Fe([9]aneS_3)_2^{2+}$ and $Fe([9]aneS_3)_2^{3+}$ (Fig. 1) and report that they are low-spin. These complexes are of special interest in that the Fe—S bond lengths are actually some 3 pm *longer* in $Fe([9]aneS_3)_2^{3+}$ than in $Fe([9]aneS_3)_2^{2+}$, as a result of the π-acid action of the ligands

(8). The iron(III) complex, however, is a strong oxidant ($E_{1/2}$ in acetonitrile is +0.98 V vs. ferricenium/ferrocene, or +1.44 V vs. NHE) and tends to decompose in solution and in the solid state (6–8). Measurement of k_{ex} is therefore difficult — too difficult, in fact, for our intended high pressure studies. We believe, however, that it is worthwhile to report here the results of our successful exploratory measurements at atmospheric pressure, made possible through the use of low temperatures, highly acidic conditions (in the case of water as solvent) (8), and the exclusion of light.

Experimental

Preparation of materials

Acetonitrile-d_3 (Aldrich, 99 atom%) was treated with P_2O_5 and distilled under reduced pressure. Deuterium oxide (Aldrich, 99.8 atom%) and D_2SO_4 (Sigma, 98 atom%) were used as received.

Purple $[Fe([9]aneS_3)_2](PF_6)_2$ was prepared from [9]aneS$_3$ (Aldrich) by the method of Wieghardt *et al.* (6) except that a nitrogen atmosphere was maintained when the reaction mixture was heated. *Anal.* Calcd. for $FeC_6H_{12}S_3P_2F_{12}$: C 20.4, H 3.4; found: C 20.4, H 3.3. The proton NMR spectrum in CD_3CN (Fig. 2) and the visible absorption spectrum in water (maxima at 523 and 395 nm, molar absorbance ϵ = 54.5 and 52.0 L mol^{-1} cm^{-1}, respectively) were in good agreement with those given in the literature (6).

Dark green $[Fe([9]aneS_3)_2](PF_6)_3$ was made from $[Fe([9]aneS_3)_2](ClO_4)_2$ by the published method (7). [*Warning:* perchlorate salts of crown thioether complexes are potentially explosive (5).] The dry solid decomposed in less than two weeks at 20°C but could be kept for at least one month *in the dark* (see below) at about 0°C without detectable

decomposition. *Anal.* calcd. for $FeC_6H_{12}S_3P_3F_{18}$: C 16.9, H 2.84; found: C 16.6, H 2.90.

The uv–visible absorption spectra of $Fe([9]aneS_3)_2^{3+}$ in acetonitrile and in aqueous sulfuric acid were obtained with a Cary 219 spectophotometer and are given in Table 1. Attempts to obtain the spectrum in acetonitrile on a Cary 17H spectrophotometer, which has reversed optics and so exposes the sample to unmonochromated light of high intensity, revealed that $Fe([9]aneS_3)_2^{3+}$ is very sensitive to photolysis by visible light (some 5% Fe^{III} was lost per 10 min in the Cary 17H). Following this observation, all solutions and solids containing $Fe([9]aneS_3)_2^{3+}$ were handled with minimal exposure to light. Reproducible spectra may be obtained with standard optics if they are run promptly at low temperatures (and, for aqueous solutions, at high acidities with a small excess of bromate ion to suppress reduction of the Fe^{III}). The spectrum in acetonitrile is in good agreement with that given by Wieghardt and co-workers (7); the spectrum in aqueous acid, which is significantly more intense, has not been reported previously.

NMR measurements

All spectra were run on a Bruker AM-400 spectrometer fitted with a variable temperature unit. The ^{13}C spectra were obtained at 100.614 MHz (pulse width 3.5 μs, 64k, offset −6700 Hz, spectral width 120 ppm) with proton decoupling (offset 8532.381 Hz, 1 W). For the line broadening experiments, solutions were made up by weight from the requisite amounts of $Fe([9]aneS_3)_2^{2+}$ and $Fe([9]aneS_3)_2^{3+}$ hexafluorophosphates and the appropriate solvent. Linewidths $\nu_{1/2}$ of the proton-decoupled ^{13}C signal could be measured with a precision of ±0.02 Hz or better in CD_3CN, but multiple determinations of $\nu_{1/2}$ for the $Fe([9]aneS_3)_2^{2+}$ reference resonance in absence of iron(III) gave 3.5 ± 0.3 Hz, and in general the reproducibility of $\nu_{1/2}$ for $Fe([9]aneS_3)_2^{2+}/Fe([9]aneS_3)_2^{3+}$ mixtures was ±5%. The poor signal-to-noise (s/n) ratio in water limited the reproducibility of $\nu_{1/2}$ to ±10%.

Results

It was estalished spectrophotometrically that $Fe([9]aneS_3)_2^{3+}$ underwent no significant decomposition in the dark over 5 h at −20°C in acetonitrile, and therefore there was no loss of $Fe([9]aneS_3)_2^{3+}$ in the course of the NMR experiments with this solvent, as described below. In aqueous sulfuric acid (2.0 mol kg^{-1}) at 21°C, some decomposition occurred after one h even in the dark, according to the visible spectrum, but loss of $Fe([9]aneS_3)_2^{3+}$ over the duration of a typical NMR experiment at 1°C with such solutions was shown spectrophotometrically to be always less than 5%, i.e., within the uncertainty in k_{ex}.

The proton NMR spectrum of $Fe([9]aneS_3)_2^{2+}$ is very complex because of proton–proton spin coupling (Fig. 2), and therefore not well suited to line broadening studies. Fortunately, the proton-decoupled ^{13}C spectrum gives a single peak with quite good s/n ratio, in part because of the nuclear Overhauser effect. In the presence of an added paramagnetic solute, the width $\nu_{1/2}$ ($= 1/\pi T_2$, where T_2 is the transverse relaxation time)

[a]Average line width without $Fe^{III} = 3.5 \pm 0.3$ Hz; uncertainty in $\Delta\nu_{1/2} = 5\%$.

of the proton-decoupled ^{13}C line will be affected according to eq. [2].

$$[2]\quad T_2(^{13}C)^{-1} = T_2(\text{lattice})^{-1} + T_2(C{-}H)^{-1} + \delta k[E] + \alpha[E]$$

in which [E] is the concentration of electron spins, k[E] is the inverse spin–lattice relaxation time T_1^{-1} for ^{13}C-paramagnetic interactions, α[E] is proportional to T_1^{-1} for the ^1H-paramagnetic interaction, and δ is the ratio T_1/T_2 for ^{13}C-paramagnetic coupling (δ is generally slightly greater than unity) (9, 10). Thus, even in the absence of chemical exchange, a linear dependence of $\nu_{1/2}$ on the concentration of a paramagnetic solute might be found.

$$[3]\quad \nu_{1/2} = \nu_{1/2\ (\text{natural})} + k'[E]$$

It was therefore necessary to show that the term k'[E] was negligible before attempting to extract k_{ex} values from $Fe([9]aneS_3)_2^{3+}$-induced broadening of the $Fe([9]aneS_3)_2^{2+}$ ^{13}C resonance. This was done by measuring the effect on $\nu_{1/2}(^{13}C)$ for $Fe([9]aneS_3)_2^{2+}$ in CD_3CN of relatively high concentrations (up to 0.0082 mol kg^{-1}; $[Fe^{II}] = 0.05$ mol kg^{-1}) of the paramagnetic, but chemically non-exchanging, solute $Cr(acac)_3^0$ (tris(2,4-pentanedionato)chromium(III)). In no case was the line broadening as large as 0.8 Hz. Since the magnitude of this effect is known to decrease in the order $Mn^{II} > Cr^{III} > Fe^{III} > Co^{II}$ (10), and since the concentrations of $Fe([9]aneS_3)_2^{3+}$ used were 6–8 fold smaller than $[Cr(acac)_3^0]$, it can safely be concluded that the term k'[E] amounted to no more than 0.1 Hz in the kinetic experiments.

The ^{13}C line broadening measurements on the $Fe([9]aneS_3)_2^{3+/2+}$ system in CD_3CN were carried out at low temperatures, to obviate any loss of $Fe([9]aneS_3)_2^{3+}$, and are summarized in Table 2. Since k'[E] has been shown to be less than 0.1 Hz, its contribution to the measured line broadening $\Delta\nu_{1/2}$ is entirely negligible. The chemical exchange rate constants k_{ex}

$$[4]\quad k_{ex} = \pi\Delta\nu_{1/2}/[Fe([9]aneS_3)_2^{3+}]$$

increase with increasing ionic strength I at a given temperature, as qualitatively expected for reactions between ions of like charge, and Fig. 3 shows that no single fit of all the k_{ex} data to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

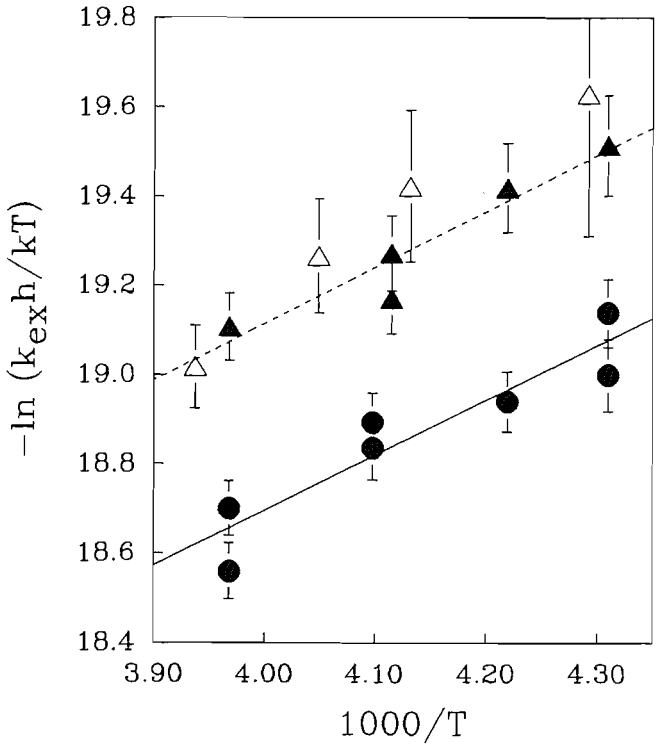

FIG. 3. Eyring plots showing temperature and ionic strength dependence of k_{ex} for the $Fe([9]aneS_3)_2^{3+/2+}$ self-exchange in CD_3CN. Circles and solid line: $I = 0.146$ to 0.148 mol kg^{-1}. Filled triangles and broken line: $I = 0.080$ mol kg^{-1}. Open triangles: $I = 0.092$ mol kg^{-1} (not fitted to Eyring equation).

the Eyring equation

$$[5] \quad k_{ex} = (k_B T/h) \exp(\Delta S^*/R) \exp(-\Delta H^*/RT)$$

where ΔH^* and ΔS^* are the enthalpy and entropy of activation, respectively, and the other symbols have their usual SI meanings, is possible. The data set for which $I = 0.092$ mol kg^{-1} ($[Fe^{III}] = 0.981$ mmol kg^{-1}) is seen in Fig. 3 to have excessively large uncertainties at the lower temperatures; this is because the line broadening induced by the added Fe^{III} is insufficiently large relative to the uncertainties in $\nu_{1/2}$ (Table 2), and this data set is therefore not considered further except to note that the error bars span the data set with the slightly smaller ionic strength. For the two remaining data sets of Fig. 3, eq. [5] gives $\Delta H^* = 10.2 \pm 1.8$ kJ mol^{-1} with $\Delta S^* = -115 \pm 7$ J K^{-1} mol^{-1} at $I = 0.147$ mol kg^{-1}, and $\Delta H^* = 10.4 \pm 1.9$ kJ mol^{-1} with $\Delta S^* = -117 \pm 8$ J K^{-1} mol^{-1} at $I = 0.0796$ mol kg^{-1}. We may interpolate these to give $\Delta H^* = 10.3 \pm 1.8$ kJ mol^{-1} and $\Delta S^* = -116 \pm 7$ J K^{-1} mol^{-1} at $I = 0.1$ mol kg^{-1}, which generate $k_{ex} = 5.3 \times 10^4$ kg mol^{-1} s^{-1} at 0°C and 8.5×10^4 kg mol^{-1} s^{-1} at 25°C. Unfortunately, solubility limitations, together with inadequate line broadening at low $[Fe^{III}]$, made it impossible to investigate the ionic strength dependence of k_{ex} by addition of an inert electrolyte or by extension of the reactant concentrations beyond the limits mentioned above.

These data are valid representations of the rate of electron transfer only if the rate of ligand exchange is much lower. The proton NMR spectrum of a solution containing $Fe([9]aneS_3)_2^{2+}$ and free [9]aneS$_3$ (1 mmol kg^{-1} in each) in CD_3CN showed no shifting or broadening of the sharp ($\nu_{1/2} \simeq 0.3$ Hz) [9]aneS$_3$ peaks, from −35 to 0°C. Thus, no ligand exchange was occurring on the NMR time scale. The analogous experiment involving $Fe([9]aneS_3)_2^{3+}$ and the free ligand is not possible, since $Fe([9]aneS_3)_2^{3+}$ in acetonitrile oxidizes [9]aneS$_3$ immediately on mixing (cf. the reaction of $Fe(H_2O)_6^{3+}$ and [9]aneS$_3$ in methanol to give $Fe([9]aneS_3)_2^{2+}$ (5)). However, this fact in itself means that $Fe([9]aneS_3)_2^{3+}$ must be substitutionally inert to survive in solution for as long as it does. Thus, the $Fe([9]aneS_3)_2^{3+/2+}$ electron transfer reaction is truly outer-sphere.

Attempts to obtain line broadening data on the $Fe([9]ane_3)_2^{3+/2+}$ system in acetone, *N,N*-dimethylformamide and nitromethane were abandoned because decomposition of the iron(III) complex was found to be rapid in these reagent-grade solvents. The solubilities of the PF_6^- salts in acetone were too low for NMR studies in any case.

In water, decomposition of $Fe([9]ane_3)_2^{3+}$ near 0°C was minimized by making the acidity high, as noted above, but the solubilities of the PF_6^- or ClO_4^- salts were low and led to poor s/n ratios in ^{13}C NMR spectra. A rough estimate of the $Fe([9]ane_3)_2^{3+/2+}$ exchange broadening of the already very broad ^{13}C line in 1.14 mol kg^{-1} D_2SO_4/D_2O, with $[Fe([9]ane_3)_2^{2+}] = 1.41$ and $[Fe([9]ane_3)_2^{3+}] = 0.142$ mmol kg^{-1}, gave a rough k_{ex} value of $(5 \pm 2) \times 10^6$ kg mol^{-1} s^{-1} at −1°C. The 400 MHz ^1H NMR spectrum of $[Fe([9]ane_3)_2](ClO_4)_2$ (3.14 mmol kg^{-1}) in 2.0 mol kg^{-1} D_2SO_4/D_2O gave a low though usable *s/n* ratio, but it was necessary to treat the methylene proton resonances as a singlet of width 55.7 Hz for a $Fe([9]ane_3)_2^{3+/2+}$ line broadening study. This study gave $\nu_{1/2} = 228$ and 586 Hz for $[Fe([9]ane_3)_2^{3+}] = 0.231$ and 0.527 mmol kg^{-1} respectively at 1°C, whence $k_{ex} = 3.2 \times 10^6$ kg mol^{-1} s^{-1} at $I \simeq 2.0$ mol kg^{-1} (sulfuric acid is effectively monobasic at these concentrations).

Discussion

Table 3 shows the measured values of k_{ex} for low-spin/low-spin iron(III)/(II) self exchange reactions in acetonitrile and water, together with values that we have calculated from Marcus–Hush theory as described elsewhere (1, 4, 14) but with no attempt to allow for possible ion pairing. The calculations involve the assumptions that the contributions to the free energies of activation from internal reorganization are negligible, that electron transfer is adiabatic, that the reactants can be treated as spheres of known radii, and that the nuclear frequency factor can be taken to be 1×10^{11} s^{-1}.

The first assumption is acceptable if the change in the Fe—ligand bond lengths caused by oxidation or reduction is negligible; this is indeed the case, within ±3 pm (1, 3, 8, 11, 13). This assumption is vindicated by the remarkably low ΔH^* found in acetonitrile for the $Fe([9]aneS_3)_2^{3+/2+}$ exchange, just as for $Fe(phen)_3^{3+/2+}$ in acetonitrile and in water (the instability of $Fe([9]aneS_3)_2^{3+}$ precluded measurement of ΔH^* for $Fe([9]aneS_3)_2^{3+/2+}$ in aqueous solution). The Marcus–Hush calculations take the reactants to be spherical, but this is clearly unrealistic for the diabolo-shaped $Fe([9]aneS_3)_2^{n+}$ complexes, in which the closest-approach distance to the central Fe may be estimated from the data of ref. 6 to range from 300 to 550 pm. As a compromise, the effective radii r_1 and r_2 of the respective reactants $Fe([9]aneS_3)_2^{2+}$ and $Fe([9]aneS_3)_2^{3+}$ are taken to be 500 pm, and, for the corresponding $Fe([9]aneN_3)_2^{3+/2+}$ complexes, 465 pm (13). Electron transfer is assumed to occur with maximum probability at a separation $\sigma = (r_1 + r_2)$. The choice of nuclear frequency factor is also somewhat arbitrary, albeit traditional (1), and hence the predicted values of k_{ex} are not absolute. It is common experience that simple applications of

TABLE 3. Measured and predicted rate constants for low-spin iron(III)/(II) self exchange reactions

Couple	k_{ex}[a] /kg mol^{-1} s^{-1}	I /mol kg^{-1}	k_{MH}[b] /kg mol^{-1} s^{-1}
$Fe([9]aneS_3)_2^{3+/2+}/CD_3CN$	5.3×10^4	0.1	3.8×10^6[c]
$Fe([9]aneS_3)_2^{3+/2+}/D_2O$	3.2×10^6	2.0	5.2×10^7[c]
$Fe(phen)_3^{3+/2+}/CD_3CN$[d]	7.3×10^6	0.2	8.1×10^8
$Fe(phen)_3^{3+/2+}/D_2O$[d]	1.3×10^7	0.4	5.3×10^9
$Fe([9]aneN_3)_2^{3+/2+}/D_2O$[e]	4.6×10^3	0.05	3.8×10^6
$Fe(\eta^5\text{-}C_5H_5)_2^{+/0}/CD_3CN$[f]	3.5×10^6	0.01	6.1×10^6

[a]0°C except as stated.
[b]Calculated from Marcus–Hush theory for the stated ionic strength, with the assumptions that the nuclear frequency = 1×10^{11} s^{-1}, $r(HSO_4^-) = 280$ pm, $r(PF_6^-) = 300$ pm.
[c]Present work; $r_1 = r_2 = 500$ pm.
[d]Reference 4; $r_1 = r_2 = 700$ pm.
[e]Reference 11; k_{ex} at 25°C, estimated from the Marcus cross relationship; $r_1 = r_2 = 465$ pm.
[f]Reference 12; $r_1 = r_2 = 400$ pm.

Marcus–Hush theory typically predict k_{ex} values that are some 30- to 1000-fold too high even for reactions thought to be adiabatic (1). Thus, in view of the various assumptions and approximations made, the present systems conform as well as most to the predictions of Marcus–Hush theory.

It will be seen from Table 3 that the *relative* values of the observed k_{ex} follow the sequences predicted from Marcus–Hush theory (as applied here) qualitatively at least. In particular, the reactivity sequence $Fe(phen)_3^{3+/2+} > Fe(\eta^5\text{–}C_5H_5)_2^{+/0} > Fe([9]aneS_3)_2^{3+/2+} > Fe([9]aneN_3)_2^{3+/2+}$ is accounted for. Exact comparisons are impossible because of differences in ionic strength, but adjustment for these differences by the Brønsted–Bjerrum–Christiansen equation

$$[6] \quad \ln (k_I/k_0) = 2z_1z_2CI^{1/2}/(1 + BaI^{1/2})$$

as described elsewhere (14) consolidates this sequence; for example, k_{ex} is estimated to be 23 times greater for $Fe(phen)_3^{3+/2+}$ than for $Fe([9]aneS_3)_2^{3+/2+}$ in acidic water at the common $I = 0.4$ mol kg^{-1}, and 53 times greater in acetonitrile at $I = 0.2$ mol kg^{-1} (0°C). In the same way, it emerges that a given self-exchange reaction may be somewhat faster in water than in acetonitrile, but the difference will not be large. It should be noted that k_{ex} for $Fe([9]aneN_3)_2^{3+/2+}$ in water was estimated *indirectly* from the Marcus cross-relation, and at 25°C rather than 0°C (11), but its position in the above sequence seems assured.

The foregoing notwithstanding, great caution must be exercised in the application of conventional treatments of interionic effects (exemplified by eq. [6]) to electron transfer reactions between ions (eq. [1]). According to eq. [6], the k_{ex} values represented by the circles in Fig. 3 should be some 140% larger than corresponding values from the set shown as triangles, whereas the actual difference is only about 40%. Indeed, several authors have reported that ionic strength effects on electron exchange reactions between two ions of like charge are anomalous or even undetectable at the relatively high electrolyte concentrations dictated by practical considerations in experiments such as those described here (4, 14–17). This phenomenon appears to be due, at least in part, to the formation of relatively unreactive ion pairs with the counterion, as this would act in opposition to the accelerating effect of ionic strength (14, 18–22). Indeed, k_{ex} for the ferricenium/ferrocene self-exchange, in which ion pairing is likely to be unimportant, is close to that predicted from Marcus–Hush theory, whereas k_{ex} values for the 3+/2+ reactions, for which significant ion pairing is inevitable, are some two orders of magnitude too slow (Table 3). However, a detailed application of the Fuoss treatment of ion pairing to the data of Table 3, as described elsewhere (14, 22), led to no significant changes in the overall picture of relative reactivity in these low-spin iron(III)/(II) systems.

In any event, it appears that k_{ex} values for all the reactions listed in Table 3 approach the predictions of Marcus–Hush theory reasonably closely, in view of the limitations noted above. This may be taken to imply that these reactions are essentially adiabatic, or else non-adiabatic to similar degrees. It should be noted, however, that even the reaction for which k_{ex} comes closest to the predictions, the ferricenium/ferrocene exchange, may not be adiabatic (23).

Thin-layer ultraviolet–visible reflectance spectroelectrochemistry with a spinning-grating monochromator

DAVID H. JONES AND A. SCOTT HINMAN[1]

Department of Chemistry, The University of Calgary, Calgary, Alta., Canada T2N 1N4

Received April 9, 1990

DAVID H. JONES and A. SCOTT HINMAN. Can. J. Chem. **68**, 2234 (1990).

A thin-layer UV–visible spectroelectrochemistry system has been constructed using a commercially available spinning-grating monochromator. The spectroelectrochemical experiment is capable of scanning a wavelength range of 369 to 617 nm in 2.1 ms. The time delay between successive scans is 83 ms. The maximum peak-to-peak noise level in a 300-point spectrum collected during 2.1 ms with a spectral bandwidth of 2 nm is 0.03 absorbance units. The anodic spectroelectrochemistry of tetraphenylporphinatocopper(II), studied using the system, is presented.

Key words: thin-layer spectroelectrochemistry, rapid-scanning spectroscopy, spinning-grating monochromator, tetraphenylporphinatocopper(II).

DAVID H. JONES et A. SCOTT HINMAN. Can. J. Chem. **68**, 2234 (1990).

Utilisant un monochromateur à réseau tournant disponible commercialement, on a construit un système de spectroélectrochimie UV-visible sur couches minces. Lors de ces expériences spectroélectrochimiques, il est possible de balayer les longueurs d'onde allant de 369 à 617 nm en 2,1 ms. Le délai entre deux balayages successifs est de 83 ms. Le niveau maximal de bruit pic à pic dans un spectre de 300 points collectés en 2,1 ms avec une largeur de bande de 2 nm est de 0,03 unités d'absorbance. On présente la spectroélectrochimie anodique du tétraphénylporphinatocuivre(II) qui a été étudié à l'aide de ce système.

Mots clés : spectroélectrochimie sur couches minces, spèctroscopie à balayage rapide, monochromateur à réseau tournant, tétraphénylporphinatocuivre(II).

[Tradiut par la revue]

Introduction

Thin-layer UV–visible spectroelectrochemistry is an established electroanalytical technique for the *in situ* spectroscopic study of redox processes (see ref. 1 for a discussion). To take full advantage of the short electrolysis times possible in thin layer spectroelectrochemical cells, it is desirable to utilize optical analyzers which have the capability of acquiring and processing several complete spectra in a few seconds. Recent improvements in the design of thin layer cells allow very short electrolysis times, even in highly resistive solvent/supporting electrolyte systems (2–7). These advances further increase the possibilities for the combination of thin-layer electrochemistry with techniques for rapid spectral acquisition.

To date, rapid spectral acquisition in spectroelectrochemical experiments has been accomplished using two different types of optical instrument. Rapid scanning spectrophotometers, based on oscillating galvanometer mirrors, have been utilized in thin layer spectroelectrochemical experiments (8–10) as well as in diffusion-controlled experiments with optically transparent electrodes (11–15). More recently, linear diode array multichannel optical analyzers, which allow for simultaneous wavelength detection, have been utilized in thin-layer spectroelectrochemistry (4, 7).

This laboratory has investigated an alternative approach to doing short timescale thin layer spectroelectrochemistry using a commercially available spinning-grating monochromator. This monochromator utilizes a diffraction grating mounted directly onto the shaft of a dc servo motor. The motor rotates continuously at approximately 700 rpm, allowing the acquisition of complete spectra at intervals of 80 to 100 ms. Furthermore, a variety of triggering options are provided which allow convenient interfacing with computers and electrochemical equipment. These features, coupled with the low cost of the device, make it an attractive alternative to other commercially available rapid spectral acquisition systems for use in spectroelectrochemical experiments.

Experimental

Thin-layer UV-visible spectroelectrochemical system: design and operation

A schematic of the thin-layer UV-visible spectroelectrochemical system is shown in Fig. 1. The optical design is analogous to that of a single-beam spectrophotometer, with the exception that the "sample" (spectroelectrochemical cell) and monochromator positions are reversed.

A 75 W xenon arc lamp is used as a light source. The radiation passes through a second order blocking filter (2.00 cm acetone) and is focussed onto a 7 mm diameter Pt mirror'disc working electrode in the thin layer spectroelectrochemical cell by means of a spherical mirror. The angle of incidence is about 45°. The use of a reflectance-type cell, as opposed to the more common transmission-type cell employing optically transparent electrodes, provides greater sensitivity to small absorbance changes by virtue of the longer optical pathlengths achieved. The cell employs a radial concentric configuration of working and counter electrodes, which has previously been shown to be optimum in terms of minimizing the effects of the high solution resistance within the thin layer cavity (2). The advantages of this type of cell and the details of its construction have been fully discussed in a previous publication (6). The only modification in the present work is the inclusion of a thin black card positioned normal to the electrode surface and the plane of incidence of the optical beam, which serves to deflect stray light reflected from the surface of the quartz window.

Light which is specularly reflected from the electrode surface is focussed onto the entrance slit of a Rofin-Sinar RSO 6101 spinning-grating monochromator by means of a second spherical mirror. The blaze wavelength of the monochromator grating is 500 nm. The monochromator has an *f*/number of 9, and a reciprocal linear dispersion of 2 nm/mm. A Hamamatsu R268 photomultiplier tube (PMT) detector is placed at the monochromator exit slit. The anode current of the PMT is amplified with a Keithley model 427 current amplifier.

The output of the current amplifier is monitored with a Macintosh II computer fitted with a G. W. Instruments Macadios II analog–digital interface card. The interface card allows analog data to be digitized and

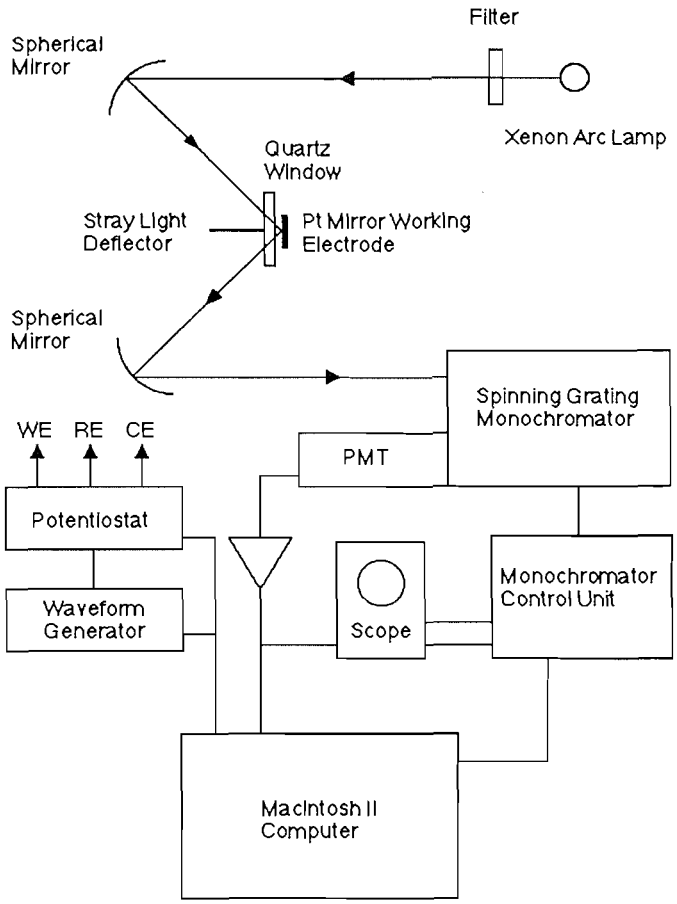

FIG. 1. Schematic of the thin layer UV–visible spectroelectrochemical system.

placed into memory at rates of up to 200 kHz. As configured, the full-scale voltage recognized by the 12-bit ADC is 10 V. In order to gain maximum benefit from the 12-bit resolution, the output of the current amplifier is monitored with an oscilloscope and the maximum signal is adjusted to slightly less than 10 V by varying the PMT supply voltage.

The spinning-grating monochromator is used in conjunction with a Rofin Sinar 6200 monochromator control unit, which provides a flash trigger voltage during each grating rotation. This pulse is used to synchronize the various aspects of the spectroelectrochemical experiment. On the first trigger pulse following initiation of the experiment by the operator, the computer either applies a preselected voltage step directly to the adder input of a Hi-Tek model DT 2101 potentiostat, or triggers the start of a voltage ramp as derived from a Hi-Tek model PPR1 waveform generator. Subsequent pulses from the monochromator initiate the acquisition of a 300 point integer array by the computer at a rate of 7 μs per point. The time between trigger pulses is sufficient to allow the data to be converted to floating point format and added into a second array, providing real-time signal averaging. The time at which the flash trigger occurs in relation to the grating position is variable in one nm increments by means of a thumbwheel switch on the monochromator control unit. This allows convenient control of the wavelength range scanned in the experiment. By appropriate ratioing of sample and background energy spectra collected in this manner, both transmittance and absorbance spectra may be obtained. The system is controlled using a Think Technologies Lightspeed Pascal computer program which accesses the Macadios II input–output and data manipulation libraries. Wavelength calibration of the monochromator is performed by measuring the absorption spectra of several narrow bandwidth filters.

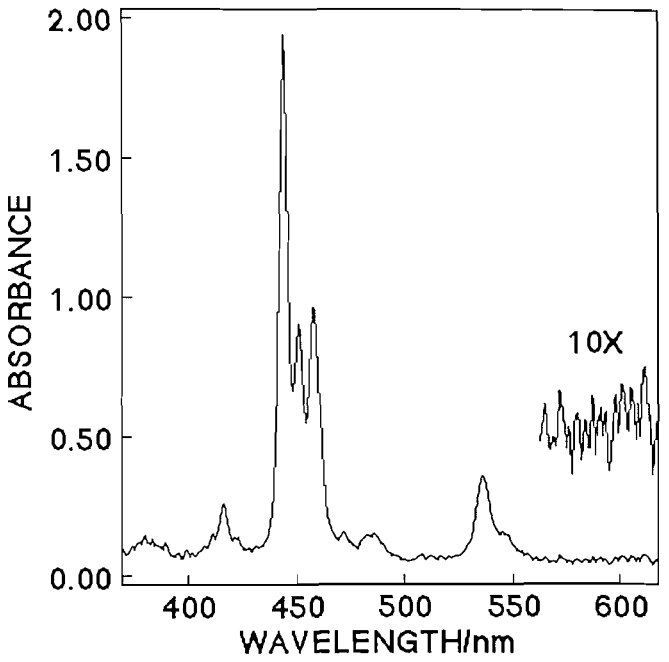

FIG. 2. Single scan of the visible spectrum of a holmium oxide glass filter.

Reagents and solutions

All solutions employed in spectroelectrochemical experiments contained 4.6×10^{-4} M tetraphenylporphinatocopper(II) (TPPCu) dissolved in 1,2-dichloroethane. Tetra-*n*-butylammonium hexafluorophosphate ($TBAPF_6$) in 0.16 M concentration was employed as supporting electrolyte. TPPCu was prepared from tetraphenylporphine (Aldrich) and CuBr according to Adler's DMF method (16). The crude product was subjected to chromatography (dry silica with CH_2Cl_2 eluant) and recrystallized from CH_3OH–CH_2Cl_2. The UV-visible spectrum (CH_2Cl_2) of the final product was identical to that previously reported (17). The UV–visible spectrum of the complex in 1,2-dichloroethane was also recorded: λ/nm (log ($\epsilon/M^{-1}\,cm^{-1}$)): 415 (5.66); 536.9 (4.31).

1,2-Dichloroethane (Fisher) was shaken with neutral alumina (Woelm activity I) and distilled from P_2O_5 onto CaH_2 prior to use. $TBAPF_6$ (Aldrich) was recrystallized from isopropanol–water and dried *in vacuo* at 110°C overnight.

Results and discussion

The shortest period of rotation obtainable with the monochromator was determined by measuring the time interval between successive trigger pulses, and was found to be 83 ms. It is important to note, however, that the entire UV–visible wavelength region appears at the exit slit of the monochromator for only a small fraction (*ca.* 3 %) of this time. The wavelength range covered in the present experiments (369 to 617 nm) is thus scanned in only 2.1 ms, so that the light beam is only sampled for 2.5% of the total time. When compared to a linear diode array, which samples light continuously, this amounts to a considerable loss of throughput and therefore, inherently poorer signal-to-noise ratios. It was envisaged, however, that the use of a high intensity light source would at least partially compensate for this effect. Also, a photomultiplier tube was chosen as the detector. While a PMT does not necessarily provide superior signal-to-noise ratios as compared to photodiodes, its fast response and greater sensitivity were viewed to be advantageous for this application.

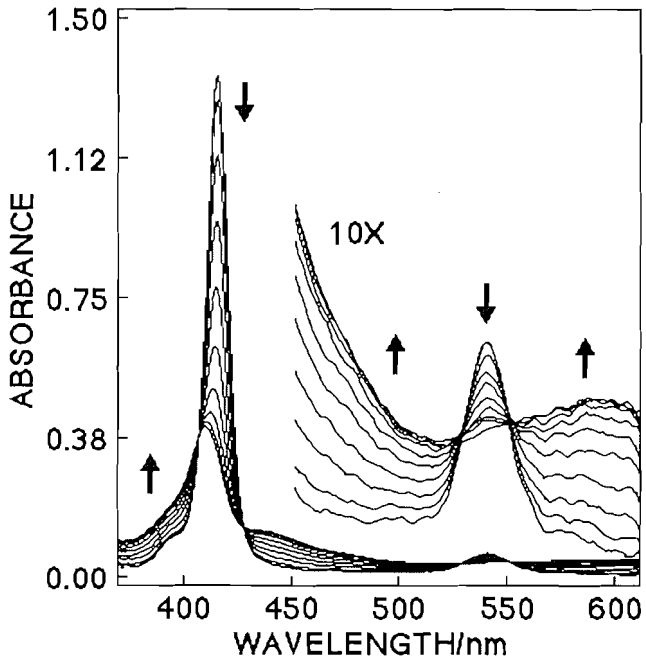

FIG. 3. Thin layer single potential step chronoabsorptometry of the one electron oxidation of 0.46 mM TPPCu in $C_2H_4Cl_2$/0.16 M $TBAPF_6$. Applied potential step vs. aqueous SCE was 0.80 to 1.10 V. Each spectrum is the average of 16 scans collected 83 ms apart during successive 1.3 s periods. Total electrolysis time was 12.0 s. Spectra were smoothed using a 15 point second order Savitzky–Golay routine.

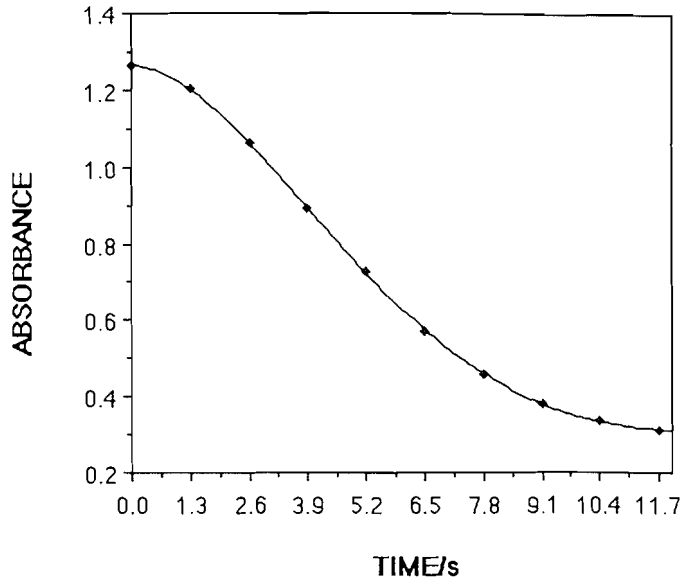

FIG. 4. Average absorbance at 415 nm plotted as a function of electrolysis time. Data were collected during the single potential step chronoabsorptometric experiment shown in Fig. 3.

The short time in which the wavelength region of interest is scanned requires that a fast response current amplifier be used in order to avoid loss of spectral resolution and wavelength accuracy. The Keithley model 427 amplifier used in this work has a rise time of 0.01 ms. Also, the ADC must be capable of operating at high sampling rates. The sampling time of 7 μs utilized in the present experiments provides for a digital resolution of 0.81 nm per point.

Figure 2 illustrates the visible spectrum of a holmium oxide glass filter obtained from a single scan. The spectrum was determined with the filter placed in the optical path between the light source and the thin layer spectroelectrochemical cell so that the throughput would closely match that expected in a typical spectroelectrochemical experiment. A 0.2 mm monochromator slit width was employed, giving a spectral bandwidth of 2 nm. The unusually sharp absorption peaks in the spectrum are clearly resolved. The overall resolution provided by the system is thus more than adequate for most condensed phase UV–visible experiments. No detectable change in the position of peak maxima was observed over a period of 2–3 h, indicating excellent stability in the rotation rate of the grating. The maximum peak-to-peak noise level evident in the spectrum is 0.03 absorbance units. Given the relatively high resolution employed, and that the entire spectrum was acquired in only 2.1 ms with an acquisition rate of 7 μs per data point, this figure was deemed acceptable. The noise level may, of course, be reduced using signal averaging and digital filtering techniques. Moreover, where lower resolution is acceptable, a wider slit width may be employed to further improve the signal-to-noise ratio.

In order to demonstrate the performance of the system during an actual spectroelectrochemical experiment, the anodic spectroelectrochemistry of 0.46 mM TPPCu in $C_2H_4Cl_2$/ 0.16 M $TBAPF_6$ was studied. In this solvent/supporting electrolyte system, TPPCu undergoes two successive one-electron oxidations with half wave potentials of 0.94 and 1.32 V vs. SCE. The two electrode reactions correspond to the stepwise formation of a porphyrin ring π-radical cation and π-dication (18). Both processes were studied using thin layer single potential step chronoabsorptometry as well as thin layer linear potential sweep chronoabsorptometry. In these techniques, either a potential step or a potential ramp is applied to the Pt mirror working electrode and the absorbance changes in the adjacent thin electrolyte layer are monitored with time.

The thin layer single potential step chronoabsorptometry of the first oxidation is shown in Fig. 3. The optical pathlength was calculated to be 63 μm for this and subsequent experiments, which corresponds to a thin layer thickness of *ca.* 22 μm (6). During the electrolysis time of 12.0 s, it was possible to collect nine spectra, each obtained by averaging 16 successive scans. Four isosbestic points are observed at 407, 428, 529, and 551 nm. The spectral changes are typical of π-radical cation formation as seen for a number of TPP complexes (18). The short timescale is clearly adequate to define the spectral changes occurring, provided the signals are of sufficiently high absorbance.

Figure 4 presents the average absorbance at 415 nm observed during successive 1.3 s intervals plotted as a function of total elapsed electrolysis time. The data are from the same potential step chronoabsorptometric experiment from which the spectra of Fig. 3 were recorded. It is evident that the absorbance change during the first 1.3 s interval is considerably less than that observed in the next few intervals. Such delays in the onset of the electrolysis have been observed in even the fastest thin layer cells (3), and result from the high solution resistivity within the thin layer cavity. This high resistivity results in long RC time constants associated with charging the double layer capacitance at various points on the electrode. By virtue of the associated solution *iR* drop, it delays the charging of the double layer capacitance and onset of electrolysis at points on the working electrode surface placed further from the counter electrode until current flow to points closer to the counter electrode subsides.

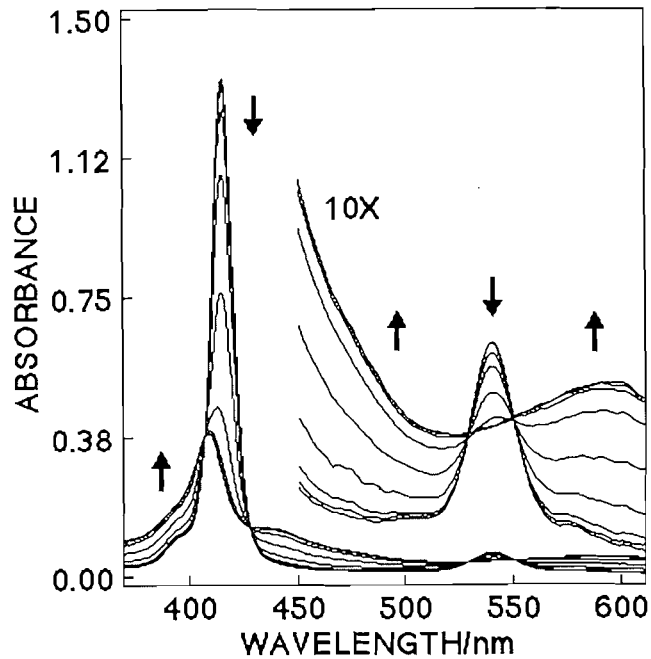

FIG. 5. Thin layer linear potential sweep chronoabsorptometry of the one electron oxidation of 0.46 mM TPPCu in $C_2H_4Cl_2$/0.16 M $TBAPF_6$. The applied potential was swept between 0.80 and 1.20 V vs. aqueous SCE at a scan rate of 4.2 mV/s. Each spectra is the average of 128 scans collected 83 ms apart during a 10.6 s period. Total experiment time was 96 s. Spectra were smoothed using a 15 point second order Savitzky–Golay routine.

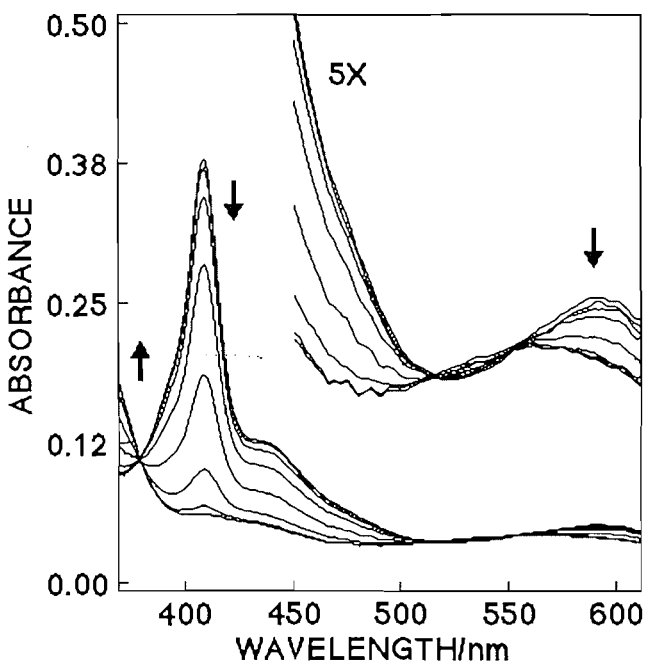

FIG. 6. Thin layer linear potential sweep chronoabsorptometry of the one electron oxidation of 0.46 mM TPPCu in $C_2H_4Cl_2$/0.16 M $TBAPF_6$. The applied potential was swept between 1.24 and 1.60 V vs. aqueous SCE at a scan rate of 4.2 mV/s. Each spectrum is the average of 128 scans collected 83 ms apart during a 10.6 s period. Total experiment time was 85 s. Spectra were smoothed using a 15 point second order Savitzky–Golay routine.

(More complete discussions of this effect can be found in refs. 3, 6, 19, and 20.) Thus, under the conditions of this experiment, the shortest time frame accessible is limited by the electrochemical response rather than the rate at which spectra may be acquired. Even so, the very short time required for complete electrolysis compares very favourably with what is evident in the recent literature for other thin layer spectroelectrochemical systems (see refs. 4 and 7, for examples), especially in view of the highly resistive nature of the solvent employed.

Provided the electrogenerated intermediates under study are sufficiently stable, it is possible to improve the S/N levels in the spectra by employing a linear sweep potential program. Through an appropriate choice of scan rate, the experiment time may be extended, thus affording opportunity for further signal averaging. Figures 5 and 6 show the spectral changes observable during the first and second one electron oxidations of TPPCu respectively. The spectral changes associated with the second oxidation (Fig. 6) show three isosbestic points at 379, 524, and 543 nm. The spectral changes are typical of π-dication formation (18).

Conclusions

The thin layer spectroelectrochemical system constructed using a spinning-grating monochromator appears to provide an economical and versatile means of performing short timescale thin layer spectroelectrochemistry. The quality of the spectral data obtained using the system is sufficient to characterize the spectral properties of electrogenerated intermediates which are stable on the timescale of a few seconds. The system is simple to assemble and experimentally flexible. Modification of the experiment to scan different wavelength regions in the UV–NIR range could easily be accomplished by altering the source, detector, and blaze wavelength of the grating in the monochromator unit. Furthermore, the variety of triggering and data acquisition options offered by the computer and monochromator control unit provide scope for a variety of spectroelectrochemical experiment designs.

Reactions of organic anions. 174.[1] Vicarious Nucleophilic Substitution of hydrogen (VNS) in nitrobenzofuroxans and the Boulton–Katritzky rearrangement of the VNS products

STANISŁAW OSTROWSKI AND KRZYSZTOF WOJCIECHOWSKI[2]

Institute of Organic Chemistry, Polish Academy of Sciences, Kasprzaka 44/52, PL-01-224 Warszawa, Poland

Received March 1, 1990

STANISŁAW OSTROWSKI and KRZYSZTOF WOJCIECHOWSKI. *Can. J. Chem.* **68**, 2239 (1990).

The Vicarious Nucleophilic Substitution of hydrogen in 4-nitrobenzofuroxan derivatives by carbanions of chloromethyl phenyl sulfone, chloromethyl *p*-tolyl sulfone, chloromethyl *tert*-butyl sulfone, and *N*,*N*-dimethyl chloromethane sulfonamide proceeds at positions 5 and 7. In some cases the Boulton–Katritzky rearrangement of the products obtained, leading to more stable 7-substituted isomers, was observed.

Key words: carbanions, nitrobenzofuroxans, sulfones, Vicarious Nucleophilic Substitution, Boulton–Katritzky rearrangement.

STANISŁAW OSTROWSKI et KRZYSZTOF WOJCIECHOWSKI. Can. J. Chem. **68**, 2239 (1990).

La substitution nucléophile déléguée de l'hydrogène de dérivés du 4-nitrobenzofuroxan par des carbanions des chlorométhyl phényl sulfone, chlorométhyl *p*-tolyl sulfone, chlorométhyl *tert*-butyl sulfone et *N*,*N*-diméthyl chlorométhane sulfonamide se produit dans les positions 5 et 7. Dans quelques cas, on a observé une transposition de Boulton–Katritzky des produits obtenus qui a conduit à la formation des isomères substitués en position 7, qui sont plus stables.

Mots clés : carbanions, nitrobenzofuroxans, sulfones, substitution nucléophile déléguée, transposition de Boulton–Katritzky.

[Traduit par la revue]

Introduction

The Vicarious Nucleophilic Substitution of hydrogen (VNS) is a general reaction between carbanions bearing leaving groups at the carbanionic center and nitroarenes (2). This reaction proceeds via addition of the carbanions to the aromatic ring to give anionic σ-adducts, which undergo base-induced β-elimination of HX to *ortho* and (or) *para* nitrobenzylic carbanions. The final products are formed upon protonation.

It has been shown that the VNS reaction also proceeds with highly electrophilic arenes, which do not contain nitro groups (3–7).

Various heterocycles containing in their moieties the quinoid system (e.g., quinones (8), 2,2-disubstituted benzimidazoles (9), etc.) can also add nucleophiles. Similarly, benzofuroxans in reactions with nucleophiles (e.g., secondary amines) give adducts (in position 5) and then, via the furoxan ring opening – ring closure process, form 5-substituted benzofurazan derivatives (10). Reactions of carbanions with benzofuroxans have been extensively studied (11). Depending on the structure of the starting materials, they lead to quinoxaline di-*N*-oxide or benzimidazole *N*-oxide derivatives.

Results and discussion

We expected that benzofuroxan, containing the highly electrophilic quinoid system, should undergo the VNS process. However, when benzofuroxan was reacted with chloromethyl phenyl sulfone (**2***a*) in the presence of powdered sodium hydroxide in dimethyl sulfoxide, both starting materials were consumed but no defined products were isolated.

Electrophilic properties of the benzofuroxan ring are increased by the introduction of the nitro group. Thus, 4- and 5-nitrobenzofuroxan ought to be more active in reactions with carbanions bearing leaving groups, leading to the VNS products. In a preliminary experiment 4-nitrobenzofuroxan was reacted with chloromethyl phenyl sulfone (**2***a*), in the presence of powdered sodium hydroxide in dimethyl sulfoxide. TLC analysis of the reaction mixture indicated formation of two products, probably *ortho* (5-) and *para* (7-) isomers of phenylsulfonylmethyl-4-nitrobenzofuroxan. However, after work-up only one product was isolated. In the residue no traces of the second isomer were detected. On the basis of chemical shifts and coupling constants in the ^{1}H NMR spectrum,[3] we found it to be 7-phenylsulfonylmethyl-4-nitrobenzofuroxan (**3***aa*). The reactions of carbanions of chloromethyl *tert*-butyl sulfone (**2***d*) and chloromethyl sulfonamide (**2***c*) with **1***a* proceeded similarly, also resulting in the formation of 7-substituted products (Table 1). These results were contrary to our expectations. Taking into account the previous observations, that bicyclic nitro compounds such as 1-nitronaphthalene (13) and 5- and 8-nitroquinolines (14) undergo the VNS preferentially in the position *ortho* to the nitro group, we expected a similar reaction course in the reaction of 4-nitrobenzofuroxan, namely substitution at position 5.

To clarify the results obtained, particularly to establish the position of the carbanion attack and what kind of products were initially formed and detected by TLC, we have performed several experiments using substituted 4-nitrobenzofuroxan derivatives in which the VNS could take place only in one position. We prepared for this purpose 5-methoxy-4-nitrobenzofuroxan (**1***b*). This relatively unstable compound, due to an interaction of the NO_2 group with the neighbouring OMe substituent, slowly undergoes the Boulton–Katritzky rearrangement (15) giving 7-methoxy-4-nitrobenzofuroxan (**1***c*). Compound **1***c* reacted with chloromethyl *p*-tolyl sulfone (**2***b*) to give two products. After separation of these products by preparative TLC we found that one of them was still converting to another one. This is a result of *retro* transformation. Since the *p*-tolylsulfonylmethyl group is sterically more demanding than the OCH_3 group, its interactions with the nitro group led to the formation of the thermodynamically more stable product **3***bb*. So the mixture of products **3***cb* (35%) and **3***bb* (20%), when kept for a few days,

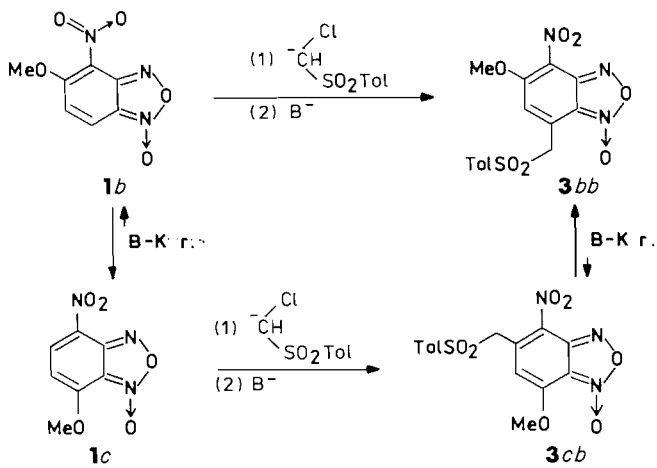
gave finally only the 7-substituted product **3***bb*. The reaction of the mixture of furoxans **1***b* and **1***c*, in which the 4-nitro-5-methoxy isomer **1***b* was the major component (80%), gave products **3***cb* and **3***bb*, but in quite different ratio (detected immediately after the reaction) (Table 1). Nevertheless, the product **3***bb* was obtained at the end as the more stable one. The following scheme summarizes the observed reaction course:

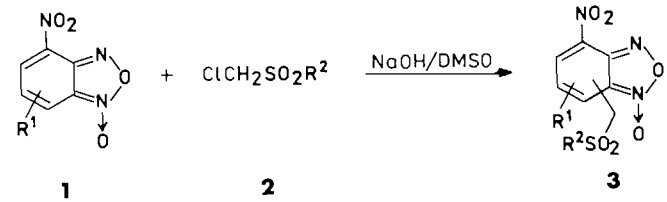


B-K r. - Boulton - Katritzky rearangment

SCHEME 2

Thus we found that the attack in both the *ortho* and *para* positions to the NO_2 group in benzofuroxan derivatives was possible, but in each case the less thermodynamically stable isomer of the product easily converts into the more stable one, sometimes during work-up of the reaction mixture.

The reaction between 5-nitrobenzofuroxan (**4**) and the chloromethyl *p*-tolyl sulfone (**2***b*) failed. Only traces of the corresponding 4-(*p*-tolylsulfonyl)methyl-5-nitrobenzofuroxan (**5**) were isolated.



R¹=H (*a*), 5-OMe (*b*), 7-OMe (*c*)
R²=Ph (*a*), Tol (*b*), NMe_2 (*c*), Bu^t (*d*)

SCHEME 3

Attempted reactions of nitrobenzofuroxans with other carbanions typical for the VNS, such as phenoxyacetonitrile ($PhOCH_2CN$) and *tert*-butyl *N,N*-diethyldithiocarbamoylacetate ($Et_2NCS_2CH_2CO_2Bu^t$), were unsuccessful. Although in the reactions of these compounds with **1***a* both starting materials were consumed, no defined products were isolated.

Experimental

^1H NMR spectra were recorded with a Varian EM-360 (60 MHz) spectrometer in acetone-d_6 (compounds **3***ba* and **3***ca* in $CDCl_3$); coupling constants are expressed in hertz (Hz). Mass spectra were recorded with a Finnigan 8200 spectrometer. Melting points (Table 1) are uncorrected. Preparative TLC was performed on 2-mm plates using silica gel Merck 60 and chloroform as eluent. All new compounds gave satisfactory microanalyses. Starting materials were prepared according to known procedures. Furoxan **1***c* was prepared by nitration of 7-methoxy-benzofuroxan (15*a*) and the spontaneous Boulton–Katritzky rearrangement (mp 165–166°C ($CHCl_3$)). All reactions were carried out according to the given procedure.

General procedure

A solution of furoxan (1 mmol) and sulfone (**2***a–d*, 1.2 mmol) in DMSO (1 mL) was added to a stirred suspension of sodium hydroxide (0.5 g, 12.5 mmol) in DMSO (4 mL). The reaction was carried out at 20–25°C for 20 min. The reaction mixture was poured into dilute HCl with ice (100 mL); the product was extracted with ethyl acetate (2 × 20 mL), washed with water (2 × 15 mL), and dried over $MgSO_4$. After evaporation of the solvent the product was isolated by column chromatography (silica gel 230–300 mesh, Merck, $CHCl_3$ as eluent). An analytical sample was recrystallized from $CHCl_3$.

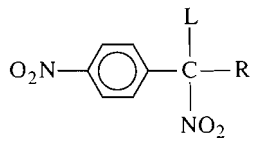
Kinetics, isotope effects of the reaction of 1-(4-nitrophenyl)-1-nitroalkanes with DBU in tetrahydrofuran and chlorobenzene solvents

WLODZIMIERZ GALEZOWSKI AND ARNOLD JARCZEWSKI[1]
Department of Chemistry, A. Mickiewicz University, Grunwaldzka 6, 60-780 Poznań, Poland

Received May 15, 1990

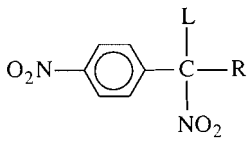
WLODZIMIERZ GALEZOWSKI and ARNOLD JARCZEWSKI. Can. J. Chem. **68**, 2242 (1990).
The kinetics of the reaction of



(R = Me, Et, *i*-Pr; NPNE, NPNP, MNPNP respectively; L is H or D) with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) base in tetrahydrofuran (THF) and chlorobenzene (CB) solvents are reported. The products of these proton transfer reactions are ion pairs absorbing at λ_{max} = 460–480 nm. The equilibrium constants in THF were $K_r^{25°C}$ = 2060, 560, 3.7 and in CB $K_r^{25°C}$ = 500, 220, 4.7 mol^{-1} dm^3 for NPNE, NPNP, MNPNP respectively. The thermodynamic parameters of the reactions are also quoted. The substrate reacts with DBU in both THF and CB solvents in a normal second-order proton transfer reaction. In the case of deuteron transfer, isotopic D/H exchange is much faster than internal return. The reactions show low values of enthalpy of activation $\Delta H^{\neq}$ = 14.3, 18.1, 24.2 and 13.0, 15.1, 18.6 kJ mol^{-1} for NPNE, NPNP, and MNPNP in THF and CB respectively, and large negative entropies of activation $-\Delta S^{\neq}$ = 141, 139, 146; 140, 146, 160 J mol^{-1} deg^{-1} for the same sequence of substrates and solvents. The kinetic isotope effects are large, $(k_H/k_D)_{20°C}$ = 12.2, 13.0, 10.1; 12.9, 12.0, 10.2 for the above sequence of substrates and solvents, and show no difference with changes in either steric hindrance of the C-acids or polarity of the solvents.

Key words: proton transfer, kinetic isotope effect.

WLODZIMIERZ GALEZOWSKI et ARNOLD JARCZEWSKI. Can. J. Chem. **68**, 2242 (1990).
On a examiné la cinétique des réactions du



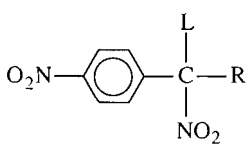
(R = Me, Et, *i*-Pr; respectivement NPNE, NPNP, MNPNP; L = H ou D) avec la base 1,8-diazabicyclo[5.4.0]undéc-7-ène (DBU) dans le tétrahydrofurane (THF) et le chlorobenzène (CB). Les produits de ces réactions de transfert de charge sont des paires d'ions qui absorbent à des λ_{max} allant de 460 à 480 nm. Dans le THF, les constantes d'équilibre de ces complexes, $K_r^{25°C}$ = 2060, 560 et 3,7, alors dans le CB, $K_r^{25°C}$ = 500, 220, 4,7 mol^{-1} dm^3 respectivement pour NPNE, NPNP et MNPNP. On rapporte aussi les paramètres thermodynamiques des réactions. Le substrat réagit avec le DBU, tant dans le THF que dans le CB, par le biais d'une réaction normale de transfert de proton du deuxième ordre. Dans le cas du transfert d'un deutéron, l'échange isotopique D/H est beaucoup plus rapide que le retour interne. Les valeurs des enthalpies d'activation sont relativement basses, $\Delta H^{\neq}$ = 14,3, 18,1, 24,2 et 13,0, 15,1 et 18,6 kJ mol^{-1} pour NPNE, NPNP et MNPNP respectivement dans le THF et le CB alors que les valeurs des entropies d'activation négatives sont élevées, $-\Delta S^{\neq}$ = 141, 139 et 146; 140, 146 et 160 J mol^{-1} deg^{-1} pour la même séquence de substrats et de solvants. Les effets isotopiques cinétiques sont importants, $(k_H/k_D)_{20°C}$ = 12,2, 13,0 et 10,1; 12,9, 12,0 et 10,2 pour la séquence de substrats et de solvants mentionnés plus haut; ils ne montrent pas de différences suivant l'empêchement stérique des C-acides ou la polarité du solvant.

Mots clés : transfert de proton, effet isotopique cinétique.

[Traduit par la revue]

Introduction

The reaction of



molecules of different steric hindrance, where R is Me, Et, *i*-Pr (NPNE, NPNP, MNPNP respectively), with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) has already been examined in acetonitrile (MeCN) solvent (1). We found that this bimolecular proton transfer reaction gave a dissociated product in MeCN to a large extent, contrary to earlier reports (2–5). Therefore the applicability of the Benesi–Hildebrand method (6) has been carefully discussed, to explain why it gave incorrect results in previous papers, published by different authors (1). We also found large values of the primary deuterium kinetic isotope effect (KIE) despite the high polarity of the solvent, acetonitrile (MeCN), in which the reaction was carried out. High values of the primary deuterium kinetic isotope effect ($k_H/k_D > 10$) in MeCN solvent have been found for a series of reactions of C-acids with different strong bases such as DBU (3), tetramethylguanidine (TMG) (7, 8), phenyltetramethylguanidine (PhTMG) (5, 9), or 2,7-dimethoxy-1,8-bis(dimethylamino)naphthalene (10). These values, ranging

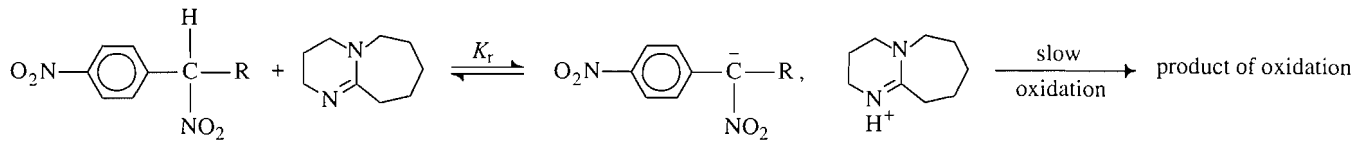
between 12 and 16, were generally in agreement with the maximum values observed by Rogne and co-workers (11–13) and Kresge and Powell (14).

When the extremely large values of KIE observed in toluene and chlorobenzene (15) were suggested to be artefacts of isotopic exchange (11–13), a number of attempts were made to determine the factors influencing the kinetic isotope effect. These studies included the use of deuterated =NH bases (11, 16), in an effort to eliminate the resulting "scrambling" effect previously observed (11, 14). However, the most common view has been that high polarity solvents reduced the large isotope effects mainly because of coupling of the motion of the proton with that of the solvent molecules (15, 17, 18) increasing the effective masses of the transferred hydron. However, our former studies (1, 5, 7–9) provided reason to believe that this reduction is not very large, suggesting that the KIEs are not very sensitive to the polarity of the solvent in which the proton transfer reaction was carried out. This suggested that the reactions in polar solvents follow an uncoupled mechanism (19) in which solvent reorganization precedes the proton transfer step, and is supported by the fact that the energy of activation is a complex function in which the part corresponding to the solvation effects in ionogenic reactions usually prevails (20). Taking into account that this idea is inconsistent with previously published results (7, 15–18), the intention of the present paper is to approach the problem using two different solvents, tetrahydrofuran (THF) and chlorobenzene (CB), for the series of reactions of 1-(4-nitrophenyl)-1-nitroalkanes that have already been studied in MeCN solvent (1). We purposely chose THF and CB solvents because of the dramatic difference in KIE (12.7 and 50) previously found by Caldin *et al.* (18) for similar reactions.

Results and discussion

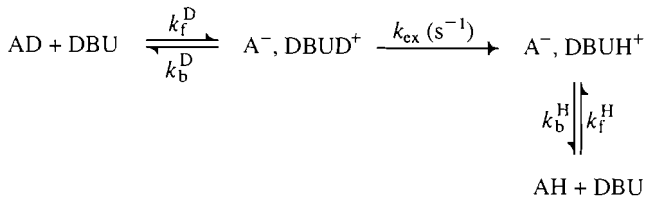
The reaction of 1-(4-nitrophenyl)-1-nitroalkanes with DBU base in THF and CB solvents proceeds by the following scheme:



(AH) (DBU) (A^-, $DBUH^+$)

SCHEME 1

where R = Me, Et, *i*-Pr. The exchange reaction of the deutero analogues takes place by Scheme 2:



SCHEME 2

The product of the reactions (λ_{max} = 465 and 476 nm in CB and THF respectively) appears to be an ion pair, showing negligible conductivity of its solution ($\kappa < 4 \times 10^{-7}$ ohm^{-1} cm^{-1}) for concentrations of the substrates equal to $c_{AH} = 2 \times 10^{-3}$ M and $c_{DBU} = 1 \times 10^{-2}$ M. This product is different from that in MeCN solvent (1) where it is mostly free ions. This is consistent with the earlier findings of Rogne and co-workers (21) who reported a large bathochromic shift of the absorption band for the product of the reaction of NPNM with guanidines after acetonitrile was replaced by toluene as solvent. He suggested that different species absorbed in the two solvents.

The anion of the ion-pair product is stabilized by the countercation, as manifested by the blue shift of the absorption band compared to that of the free anion (λ_{max} = 508–515 nm). Considering these observations, we claim that in both THF and CB solvents the product of the reaction is an ion pair as shown in Schemes 1 and 2.

The corresponding equilibrium constants estimated by the Benesi–Hildebrand (6) method are collected in Table 1. The degrees of conversion found for these reactions carried out in THF and CB are considerably less than those in MeCN solvent (1), which is certainly due to dissociation of the ion pairs in MeCN. Comparison of the thermodynamic parameters of these reactions (Table 2) in THF shows that the equilibrium constants decrease due to the increase in enthalpy of reaction ΔH^0 caused by reduction of the stabilization energy of the anion by the resonance, along with the increase in bulk of the R substituent of these C-acids. This conclusion is supported by the parallel decrease of molar extinction coefficients ϵ (Table 1).

The reaction of normal C-acids with DBU follows pseudo-first-order kinetics (Scheme 1).

Exchange reactions may cause large errors in the deuteron transfer kinetics as already mentioned (11–14, 22). The concentration of exchangeable protons in the reaction medium, despite careful drying of both the DBU base (ca. 0.3% H_2O) (1) and solvents, is still much larger than the deuterated C-acid concentration of 2×10^{-5} M. Therefore conditions assuring irreversibility of D/H exchange assumed by Melander and Saunders hold here (23*a*).

When the equilibrium constant is not very large, then the reactions of the deutero analogues (Scheme 2) may follow either of the two following cases:

1. $k_b^D >> k_{ex}$: the isotopic exchange will have no influence on the kinetics (24), and the observed rate constants will be a function of base concentration c_B according to the following equation:

[1] $k_{obs}^D = k_f^D c_B + k_b^D$

2. $k_f^D c_B << k_{ex} + k_b^D$, excluding case 1; Melander and Saunders (23*a*) considered case 2 when, in addition, $k_{ex} >> k_b^D$, and came to the conclusion that, for ordinary isotope effects, if the initial curved part of the end-point method plots is neglected, eq. [2] is valid:

[2] $k_{obs}^D = k_f^D c_B$

TABLE 1. Equilibrium constants for the reactions of 1-(4-nitrophenyl)-1-nitroalkanes with DBU in THF and CB solvents at 25°C

NPNP	467	220 ± 30	24000 ± 1000
MNPNP	464	4.7 ± 0.2	15000 ± 500

TABLE 2. Thermodynamic parameters of the reactions of 1-(4-nitrophenyl)-1-nitroalkanes with DBU in THF solvent

C-acid	ΔH^0 ($kJ\,mol^{-1}$)	ΔS^0 ($J\,mol^{-1}\,deg^{-1}$)	ΔG^0 ($kJ\,mol^{-1}$)
NPNE	−57.5 ± 0	−129 ± 1	−18.9 ± 1
NPNP	−50 ± 1	−114 ± 5	−16 ± 2
MNPNP	−38 ± 2	−117 ± 5	−3 ± 2

This approach can be extended by not assuming that $k_{ex} \gg k_b^D$; then the steady-state approximation yields, for case 2, when initial parts of the end-point or Guggenheim method plots are omitted:

$$[3] \quad k_{obs}^D = k_f^D c_B \frac{k_{ex}}{k_b^D + k_{ex}}$$

Since the plots of k_{obs}^D vs. c_{DBU} (data from Tables 3 and 4) pass through the origin, in contrast to the same plots for proton transfer, then case 1 cannot be valid. Moreover the shapes of the end-point or Guggenheim method plots (not shown), with curvature at the very beginning, are exactly as predicted by Melander and Saunders (23*b*) for fast isotopic exchange.

It was recently stressed by Thibblin and Ahlberg (22) that reaction branching may lead to miscellaneous large kinetic isotope effects. A reconsideration of large KIEs in hydron transfer reactions from substrates activated by nitro groups was suggested, despite the fact that there was no specific reason to invoke branching.

Actually, internal return and isotopic exchange can be considered as such competitive processes. Hence, according to eq. [3], the slope of k_{obs}^D vs. c_{DBU} could be smaller than k_f^D, providing the overestimated KIE values in Tables 3 and 4. However, careful examination of the data in Tables 3 and 4 leads to the conclusion that $k_{ex} \gg k_b^D$; thus eq. [2] is valid and the KIEs are not distorted.

We can assume that the equilibrium constants for proton and deuteron transfer are similar (20). For the reaction of NPNE and NPNP with DBU, $k_f^H c_{DBU} > k_b^H$ (k_b^H at 25°C is 0.4, 0.5, and 1.9 s^{-1} in THF and 0.3, 0.3, and 2.9 s^{-1} in CB for NPNE, NPNP, and MNPNP, respectively). Then $k_f^D c_{DBU} > k_b^D$, which is contrary to the case 2 inequality above if $k_{ex} \gg k_b^D$ is not true. Therefore for these reactions k_{ex} must be much greater than k_b^D to preserve steady-state conditions. For the reactions of MNPNP with DBU in both THF and CB solvents the inequality $k_b^H c_{DBU} > k_b^H$ is not valid, thus the condition that $k_f^D c_{DBU} > k_b^D$ is not fulfilled. However, for these reactions the values of the KIE are even smaller than for the other two C-acids, showing that internal return does not cause reduction of k_f^D (eq. [3]).

Another possibility of reaction branching that may cause a false KIE is oxidation of a reaction intermediate (22, 25). In our experiments oxidation processes were slow enough to be neglected.

In conclusion, in the case of a concentration of C-acid comparable to or smaller than the concentration of exchangeable H^+ in the system, the use of tertiary amines does not prevent D/H exchange in the product of these reactions. However, in the case of large kinetic isotope effects and excess of exchangeable protons this exchange, which is much faster than internal return, does not disturb the determined rate constants and KIE.

The D/H exchange of α-CH hydrogens in cyclic amidines has recently been reported (26). However, the rate of this exchange seems to be too slow to influence our experiments. Even if this exchange were fast enough, it would be just an additional source of exchangeable protons, which are already present in the bulk of the reaction medium. The possible deuteration of DBU base could change its basicity a little; however, this effect would be insignificant due to a large excess of the base concentration over that of the deuterated C-acid.

The rate constants for the reactions of 1-(4-nitrophenyl)-1-nitroalkanes (NPNE, NPNP, MNPNP) with DBU base are collected in Tables 3 and 4. These rate constants are not very dependent on the polarity of the solvent used. The fastest reaction took place in acetonitrile, k_f^H = 1630, 431, 37 at 20°C for NPNE, NPNP, and MNPNP respectively (1), and the slowest in THF, k_f^H = 730, 190, 6.47, while for CB the corresponding values were k_f^H = 1470, 305, 13 $dm^3\,mol^{-1}\,s^{-1}$. This is not in agreement with the polarity of the solvents.

The rate constants are considerably reduced, by about two orders of magnitude, as the bulk of the alkyl group on the C(1) atom is increased from NPNE to MNPNP. The steric and polar effects of the alkyl groups cooperate in reducing the rate constants k_f. However, the polar effects of different β-alkyl groups on the transition state energy would be expected to be nearly the same (27).

The most convincing argument for the influence of steric factors on the rate constants k_f comes from the fact that a small decrease (by a factor of 2) took place in the k_f values, for the deprotonation of nitroalkanes previously examined, when methyl was replaced by the *i*-Pr group (28) in the appropriate C-acid molecule. The increase in bulk of the alkyl substituent of the C-acid caused progressive desolvation of the transition state, reducing the freedom of the motion within the activated complex, increasing the distance of the proton transfer, and decreasing the rate of reaction. The higher steric demands of the C-acid and the base are reflected in the large negative values of entropy of activation $\Delta S^{\neq}$ (Table 5). The activation parameters collected in Table 5 are characteristic for ionogenic bimolecular reactions in aprotic solvents.

We presume that the changes of $\Delta S^{\neq}$ values with increasing steric hindrance result from two processes operating in opposite directions. The reduction of free motion decreases the entropy of activation while desolvation of the activated complex enhances this value. These entropy changes are consistent with our former suggestions for proton abstraction from 4-nitrophenylcyanomethane and phenyl-(4-nitrophenyl)cyanomethane by TMG and PhTMG in MeCN solvent (5, 8).

The activation parameters are not very sensitive to the polarity of the solvents (Table 5 and ref. 1). The enthalpies of activation $\Delta H^{\neq}$ are compensated by the entropies of activation $\Delta S^{\neq}$. Then the increase of $\Delta S^{\neq}$ and $\Delta H^{\neq}$ values together with the polarity of the solvent should be regarded as typical characteristics of these reactions.

The first is commonly interpreted as a better organization of the polar solvent in the vicinity of the initial state. The second seems to be a result of the increase of the effective mass of the transferred proton and in consequence the reduction of the quantum mechanical tunnelling, so the observed potential energy barrier should be larger (18). However, a comparison of the values of the equilibrium constants (Table 1) shows that the stability of the ion pairs — more polar species than the

transition state — in MeCN (1) is not larger than in THF or CB solvents. This suggests that not only the dielectric constant of the solvent but also the polarizability and its ability for specific interactions play no trifling role in the transition state stabilization. Caldin and co-workers (15, 29) had earlier indicated the importance of specific solvation for the kinetics of similar reactions.

The KIEs (Tables 3 and 4) are large and, except those for NPNP and MNPNP in THF, exceed the semiclassical value determined by Bell (30). Caldin and Rogne (31) state that the small enthalpy values for the reaction of NPNM with DBU in toluene, equal to 8.4 kJ mol^{-1}, suggest quite a large tunnelling effect, despite a rather low potential energy barrier, which is not a favourable condition for the tunnelling.

In our case we cannot find any correlation between the height of the energy barrier and the KIE values. The energy barrier for the reaction of MNPNP with DBU is very like that for NPNM with TMG, showing rather moderate KIEs that, in the case of THF and CB, are even smaller than those for reactions having smaller $\Delta H^{\neq}$ values (R = Me, Et).

THF and CB were the solvents chosen to carry out these kinetic measurements, despite their close values of dielectric constant, since in these solvents Caldin and Mateo (15) found large differences in KIE for similar reactions of NPNM with TMG, as a result of proton tunnelling. In our case the KIE values are practically independent of the polarity of the solvent. The $(k_H/k_D)_{20°C}$ values in MeCN were 12.8, 13.4, 13.7 for NPNE, NPNP, and MNPNP respectively (1), and 12.2, 13.0, 10.1; 12.9, 12.0, 10.22 for the above sequence of substrates in THF and CB solvents (Tables 3, 4). This supports the uncoupled mechanism, in which proton transfer follows the reorganization of solvent molecules for highly polar MeCN as well as for CB or THF. The same conclusion can be drawn on the basis of almost equal values of KIE for the reactions of C-acids of very different steric hindrance, which should have different solvation of the transition state.

KIE values for the reaction of NPNE with DBU in toluene (2) are very similar to the values collected in Tables 3 and 4, supporting our present suggestion of low dependence of KIE on the polarity of the solvent. However, our former measurements of the reaction of NPNE with PhTMG gave the KIE values 8.5, 6.1, and 16 for acetonitrile, benzonitrile, and chlorobenzene solvents respectively (5, 8). Therefore further experiments are needed to resolve this problem.

Tunnelling effects for the reactions of 1-(4-nitrophenyl)-1-nitroalkanes with DBU are presented in Table 5. The isotope effects on the activation parameters indicate small, but significant, contributions of the tunnelling effect to the proton transfer in all systems including MeCN solvent (1), except for NPNP and MNPNP with DBU in THF. The isotope effects on the energies of activation exceed the value of 4.6 kJ mol^{-1} or 5.7 kJ mol^{-1} resulting from the loss of the zero point energy between the initial and transition states for both the stretching and bending vibrations of the C—L bond.

The ratios of preexponential factors fall in the range of $0.5 < A_H/A_D < 1$. These isotope effects on the activation parameters are not large, and independent of the polarity of the solvent (1) (Table 5). The ratios of the quantum mechanical tunnelling factor, $Q_t^H/Q_t^D = 1.4–1.6$, show at least a 50% contribution of tunnelling effects to the overall KIE values.

The ratios of the preexponential factors A_H/A_D for the reactions of NPNP and MNPNP with DBU in THF are larger than unity, with normal values of $\Delta H^{\neq}_{D} - \Delta H^{\neq}_{H}$. This phenomenon has already been observed (30, 32), and explained as stronger solvation of the transition state for the deuteron in comparison with the proton transfer reaction (2). However, this is not consistent with our present observation, assuming that the proton transfer is not coupled with the motion of solvent molecules. Therefore we have no conclusive explanation of this fact, and the Melander and Saunders interpretation (23*c*) of the phenomenon seems also to be very unlikely.

These results confirm our earlier general conclusion (5, 7, 9) that the values of kinetic isotope effects and also of the tunnelling effect are influenced by the polarity of the solvent to an extent much less than was formerly assumed (15).

Experimental

The substrates

1-(4-Nitrophenyl)-1-nitroethane (NPNE), 1-(4-nitrophenyl)-1-nitropropane (NPNP), and 2-methyl-1-(4-nitrophenyl)-1-nitropropane (MNPNP) were prepared according to procedures previously published (1). The deuterated analogues were prepared by the modified exchange method in which the neutralization of the anion of the appropriate

For personal use only.

C-acid was effected using acetate buffer (2 g CH_3COONa, 10 cm^3 D_2O, 3 cm^3 20% DCl, instead of concentrated DCl in D_2O) (7), which eliminates the noxious Nef's reaction of the nitronic acid as described by Bordwell and Boyle (33).

Tetrahydrofuran (THF)

The commercial product (Reachim) was dried over CaH_2 and fractionally distilled from $LiAlH_4$. The middle fraction was collected at 66 ± 0.5°C.

Chlorobenzene (CB)

The reagent grade product was fractionally distilled from P_2O_5. The middle fraction at 132 ± 0.5°C was collected. Both solvents were purified and stored under a positive pressure of argon.

1,8-Diazabicyclo[5.4.0]undec-7-ene (DBU)

This was purified and stored as previously described (1).

Equilibrium and kinetic measurements

The equilibrium constants were measured as previously described (1) using a Specord M-40 spectrophotometer. The kinetic measurements for both the normal and deuterated substrates were carried out using a stopped-flow spectrophotometer. The kinetic and equilibrium measurements were performed at controlled temperatures using a circulating bath connected to the cell block of the spectrophotometer to keep the temperature constant within ±0.1°C.

The pseudo-first-order kinetics were performed using 2×10^{-5} M concentration of C-acids and a varying concentration of the base (Tables 3, 4). The concentrations of the base were always in large excess to ensure pseudo-first-order kinetics. From the kinetic curves the pseudo-first-order rate constants k_{obs} were calculated using the Guggenheim method. The observed rate constants for proton transfer reactions were a function of base concentration according to the following equation:

$$[4] \quad k_{obs} = k_f^H c_B + k_b^H$$

where k_f^H and k_b^H are the rate constants of the forward and reverse reactions respectively and c_B is the concentration of the base. The second-order rate constants are the calculated slopes of k_{obs} versus base concentration. The intercepts for proton transfer are the rate constants of the backward reaction k_b^H (not quoted in Tables 3 and 4). For reactions of the deutero analogues the initial part of the kinetic curves (less than one tenth of the reaction half-lifetime) was ignored to minimize the possible error caused by D/H exchange, in accordance with Bergson (34) and Melander and Saunders (23*a*), who suggested that this procedure reduces the probability of the results being distorted by the effects of isotopic exchange. The remaining part of the Guggenheim plot was a good straight line. Then eq. [2] was applied in order to determine second-order rate constants k_f^D.

The activation parameters were evaluated from the temperature dependence of the second-order rate constants k_f by means of a least-squares fit to the transition state theory equation.

HARBHAJAN S. RANDHAWA, RAJNI SACHDEVA, and SUSHIL K. SURI. Can. J. Chem. **68**, 2249 (1990).

Charge transfer (CT) interactions between aromatic hydrocarbons, namely, benzene, biphenyl, phenanthrene, naphthalene, and anthracene, and herbicides of the triazine series, viz. Atraton, Trietazine, and Simetone, have been investigated by conductometric methods. The stoichiometries of the complexes have been established and the molar conductivities of the CT complexes determined. The effect of the nature of the electron donors, electron acceptors, and the solvent media on the conductivity of the CT complexes has been studied.

Key words: conductivity, charge transfer interactions, hydrocarbons, herbicides.

HARBHAJAN S. RANDHAWA, RAJNI SACHDEVA et SUSHIL K. SURI. Can. J. Chem. **68**, 2249 (1990).

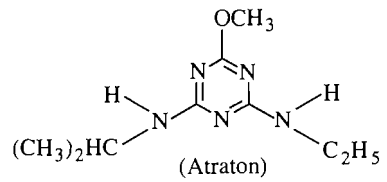
Utilisant la méthode conductimétrique, on a étudié les interactions de transfert de charge (TC) entre les hydrocarbures aromatiques, en particulier le benzène, le biphényle, le phénantrène, le naphtalène et l'anthracène, et les herbicides de la série triazine comme l'Atraton, la triétazine et la Simétone. On a établi la stoechiométrie des complexes et on a déterminé les conductivités molaires des complexes de transfert de charge. On a étudié l'effet de la nature des groupes électrodonneurs, des groupes électroattracteurs et du solvant sur la conductivité des complexes de transfert de charge.

Mots clés : conductivité, interactions de transfert de charge, hydrocarbures, herbicides.

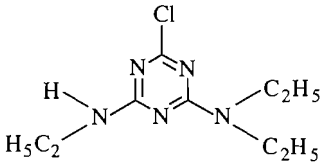
[Traduit par la revue]

Introduction

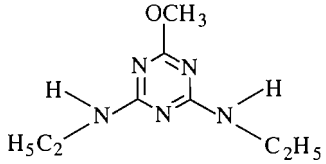
Our earlier research was devoted to fusibility diagram studies on charge transfer (CT) interactions of aromatic hydrocarbons with a variety of polar organic molecules, in relation to the stoichiometries and energetics of the CT complexes (1–3). Congruent compounds of unusual stoichiometries were formed in the donor–acceptor systems. The area under the curve of the congruent compound cannot be fixed as the sole criterion to predict the relative strength of CT complexes in the absence of thermodynamic parameters. As an extension to this study, the CT interactions between five aromatic hydrocarbons, namely benzene, biphenyl, phenanthrene, naphthalene, and anthracene, as π-donors, (4), and three herbicides of the triazine series, viz. 1,3,5-triazine-2,4-diamine, *N*-ethyl-6-methoxy-*N'*-(1-methylethyl) (Atraton), 1,3,5-triazine-2,4-diamine, 6-chloro-*N,N,N'*-triethyl (Trietazine), and *N,N'*-diethyl-6-methoxy-1,3,5-triazine-2,4-diamine (Simetone) as π-acceptors (5), have been investigated. The biologically active π-electron acceptors, which were selected in view of their practical importance, have the following molecular structure:



(Atraton)



(Trietazine)



(Simetone)

The conductometric technique was employed to study the CT interactions. The CT complex (DA) formed by partial or complete transfer of an electron from the donor D to the acceptor A (6, 7) tends to dissociate into ions D^+ and A^- in a solvent media of sufficiently high dielectric constant according to the scheme (8–10).

$$D + A \rightleftharpoons DA$$

$$DA \rightleftharpoons D^+ + A^-$$

The extent of dissociation depends on the nature of D, A, and the dielectric constants of the solvent media. The formation of the CT complex can, therefore, be followed by observing the variation of electrical conductivity (σ) of D on the addition of A, or vice versa, in suitable solvent media. The plot of σ as a function of composition of D or A generally results in a maximum, which determines the stoichiometry of the CT complex (11–13). We have preferred this method as it is free from uncertainties arising from the masking of CT bands by absorption bands of the components and the products.

The studies reported in this manuscript are aimed at (i) establishing the stoichiometry of the CT complexes formed between aromatic hydrocarbons and herbicides and (ii) correlating the parameters characterizing the CT complexes with those of D, A, and the media.

Experimental

Analytical reagent grade aromatic hydrocarbons, namely, benzene, biphenyl, phenanthrene, naphthalene, and anthracene, and three solvents, namely cyclohexane, dichloromethane, and trichloromethane (BDH), were purified by following standard procedures (14, 15). The Atraton, Simetone, and Trietazine were obtained from Ciba Geigy Ltd. and were reported to have a purity of 99.9%, 99.4%, and 99.9%, respectively. These chemicals were further purified by crystallization from *n*-propanol before use.

Equimolar stock solutions (5×10^{-4} M) of aromatic hydrocarbons and the electron acceptors in the three solvent media (viz. cyclohexane,

*Values from ref. 16.

dichloromethane, and trichloromethane) were mixed in the conductivity cell, keeping the total volume constant but varying the volumes of donor and acceptor solutions. The conductance measurements were made on a Philips PR 9500 conductivity bridge using a conductivity cell (cell constant = 0.890 dm^{-1}) fitted with platinized platinum electrodes. The conductivity cell was standardized employing a 0.02 M solution of potassium chloride. All measurements were made at 50 cps in a thermostat maintained at 298.15 ± 0.01 K.

The measured values of electrical conductance were plotted as a function of composition of D or A. The molar conductivity coefficients, σ_M's, were computed using the expression (11):

$$\alpha\sigma_M = \frac{1}{M}\,\frac{\sigma_p - \sigma_0}{\sigma_0}$$

where M is the molar concentration of the donor or acceptor at the conductivity peak of the complex. σ_p is the conductivity at the conductivity peak, σ_0 is the linearly interpolated conductivity value read off from a base line joining the conductivities of the pure donor and acceptor solutions, and α is the dissociation constant of the complex.

Results and discussion

The electrical conductances of solutions containing varying amounts of A and D in different solvent media were plotted against the mole fraction A. A representative plot of conductance versus concentration for the phenanthrene–Simetone complex in chloroform is shown in Fig. 1. The appearance of a maximum in the plot is indicative of complexation in the D–A system (11–13). The composition of the CT complex formed between D and A was deduced from the stoichiometric maximum. The presence of a well-developed maximum in the conductivity–concentration plots observed in all systems studied is indicative of the fact that in the various aromatic hydrocarbon (donor) – herbicides of the triazine series (acceptor) systems, π–π type charge transfer complexes are formed. The observed stoichiometries of the CT complexes investigated in chloroform as solvent and their σ_p values are listed in Table 1. From the 1:4 stoichiometries of π–π complexes, observed in these systems, we infer that an expected arrangement of four donor molecules around an acceptor molecule is either of tetrahedral or square planar geometry, and the most probable arrangement of two donors about the acceptor in 1:2 stoichiometry is linear.

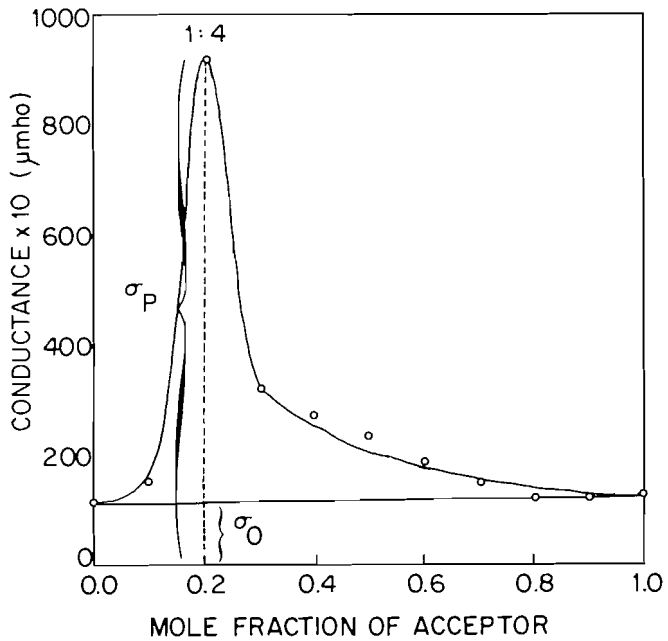

FIG. 1. Plot of conductance vs. mole fraction of simetone (acceptor) in phenanthrene–simetone system in chloroform solution at 298.15 ± 0.01 K.

The molar conductivity coefficients, calculated by the procedure of Gutmann and Keyzer (11), exhibited no definite order in the systems when α was assumed to be unity in all cases. This may be attributed to differences in the α values of CT complexes and their deviation from unity.

The numerical value of σ_p is a measure of the total number of ions carrying the current when D and A are mixed in stoichiometric proportions corresponding to the CT complex. When the solvent medium, concentrations of D and A, and the experimental parameters are kept the same for a fixed donor, the values of σ_p reflect the electron affinity of the acceptors and, for a fixed acceptor, they reflect the donicity of the donor provided all complexes dissociate to the same extent and the

*Values from ref. 16.

differences in configuration are not too great. The σ_p values are expected to be high when the CT complex between D and A is strong.

Apparently, the values of σ_p for CT complexes of aromatic hydrocarbon donors with different acceptors increase with a decrease in the ionization potential of the donor and follow the order: anthracene > naphthalene > phenanthrene > biphenyl > benzene. We are unable to correlate the σ_p values of CT complexes with the electron affinity of the acceptors due to the non-availability of electron affinity values for the acceptors.

The results of conductance measurements of the CT complexes in different solvents are recorded in Table 2. It is observed that the value of σ_p increases as the dielectric constant of the medium increases. This appears to be due to an increase in the total number of ions carrying the current at the stoichiometric point as the CT complexes are expected to ionize to a greater extent in the solvent of higher dielectric constant. This is in accordance with earlier investigations, which revealed that the extent of electron transfer in CT complexes is enhanced by increase in the solvent polarity (17).

DANIEL CABARET and MICHEL WAKSELMAN. Can. J. Chem. **68**, 2253 (1990).

A lipodisaccharide possessing a reactive aldopentose unit, 6-*O*-octyl-β-D-galactopyranosyl-(1→5)-L-arabinose **6**, was obtained by glycoside synthesis. To avoid a possible intramolecular acyl transfer, benzoyl protecting groups and mild conditions of detritylation were used in the preparation of the furanosyl acceptor. The reductive alkylation of N^{α}-*Z*-L-lysine was then studied and compared to that of previously prepared liposaccharides. In this reaction, amphiphilic five-membered hemiacetals are generally more reactive than their six-membered analogues. The newly prepared disaccharide is the most reactive of the series and also the easiest to prepare. Therefore this reagent has been selected for a future study on the chemical modification of enzymes and the use in organic solvents of the biocatalysts obtained.

Key words: liposaccharides, reductive alkylation.

DANIEL CABARET et MICHEL WAKSELMAN. Can. J. Chem. **68**, 2253 (1990).

Le 6-*O*-octyl β-D-galactopyranosyl-(1→5)-L-arabinose **6**, un lipodisaccharide ayant une fonction aldopentose réactive, a été obtenu par synthèse osidique. Pour éviter un transfert d'acyle intramoléculaire dans la préparation de l'accepteur furanosyle, des groupes protecteurs benzoates et des conditions douces de détritylation ont été utilisés. Le réactif **6** a ensuite été comparé à d'autres liposaccharides dans la réaction d'alkylation réductrice de la N^{α}-*Z*-L-lysine. Dans cette condensation, les hémiacétals amphiphiles à cinq chaînons sont généralement plus réactifs que leurs analogues à six chaînons. Le lipodisaccharide **6** étant le plus réactif de la série, et aussi le plus facile à préparer, a été retenu pour une étude ultérieure de modification chimique d'enzymes.

Mots clés : liposaccharides, alkylation réductrice.

Introduction

The mild and selective reductive alkylation of the lysine residues of proteins with reducing sugars leads to interesting neoglycoproteins (1, 2). In this 1-deoxyglycitolation reaction, unsubstituted aldopentoses exhibit faster rates of condensation with amines than their more stable aldohexose analogs (3, 4). In a search for liposaccharidic reagents for the preparation of lipoglycosylated enzymes suitable for use in polar organic solvents (5), we came upon the problem of long condensation time, which could be detrimental to the catalytic activity of the new biocatalyst. For our purpose, a lipofuranose might be a valuable compound. However, in a polar solvent, a disaccharide is better able to maintain the essential layer of water around the enzyme than is a monosaccharide derivative. Therefore the synthesis of the 6-*O*-octyl-β-D-galactopyranosyl-(1→5)-L-arabinose **6**, having a reactive aldopentofuranose end, has now been achieved and its reductive condensation with N^{α}-*Z*-L-lysine compared with that of some of the previously prepared lipodisaccharides (6, 7).[2]

Results and discussion

Synthesis

The use of a stoichiometric amount of chlorotriphenylmethane in pyridine below 25°C avoids the ditritylation of the pentofuranoses and selectively gives the monotrityl derivatives (9). In these conditions, L-arabinose **1** afforded the 5-*O*-trityl-L-arabinose **2** in good yield. As benzoyl groups do not migrate as readily as acetyl ones during the cleavage of a trityl protecting group (10), benzoylation was preferred to acetylation in the next step of the synthesis. Thus, treatment of the benzoylated arabinose **3** with trimethylchlorosilane and sodium iodide (11) gave the glycosyl acceptor **4**. Königs–Knorr condensation with the previously described 2,3,4-tri-*O*-acetyl-6-*O*-octyl-α-D-galactopyranosyl bromide donor (7), in the presence of mercuric cyanide, led to the protected disaccharide **5**. Removal of the ester protecting groups yielded the liposaccharide **6**, having six free hydroxyl functions (Fig. 1).

To confirm that no intramolecular acyl transfer had occurred, the parallel synthesis of compound **6** using the very stable benzyl protection was realized. Phase transfer catalyzed alkylation of the tritylated arabinose **2** furnished the benzyl α- and β-arabinosides **3′**α and **3′**β. Cleavage of the trityl group by means of $BF_3 \cdot Et_2O$ (10) afforded the glycosyl acceptors **4′**α and **4′**β. Condensation with the same glycosyl donor as above gave the protected disaccharides **5′**α and **5′**β. Zemplén deacetylation resulted in the isolation of the benzyl *O*-(6-*O*-octyl-β-D-galactopyranosyl)-(1→5)-2,3-di-*O*-benzyl-α- and β-L-arabinosides **7**α and **7**β. Hydrogenolysis (H_2, Pd/C, MeOH) of the β-arabinoside **7**β gave a product having the same ^1H and ^{13}C NMR characteristics as those of compound **6**, unambiguously establishing the structure of that disaccharide. In an unexpected way (12), catalytic hydrogenation of the **7**α isomer under the same experimental conditions led to the alditol **8**.

Reductive alkylation of N^{α}-Z-L-*lysine*

The mechanism of the 1-deoxyglycitolation of an amine is represented in Scheme 1. The rate-determining ring opening of the hemiacetal structure *a*, to give the reactive hydroxyaldehyde *b*, depends on the stability of *a*. The effect of ring size on the stabilities of cyclic hemiacetals relative to acyclic hydroxyaldehydes has been studied in simple cases; the six-membered ring is more stable than the five-membered one, and both of them are more stable than the larger rings (13, 14). Reductive condensation of unsubstituted aldopentoses with amines is faster than that of aldohexoses, and the reductive alkylation of unsubstituted reducing disaccharides is a slow process (3, 4).

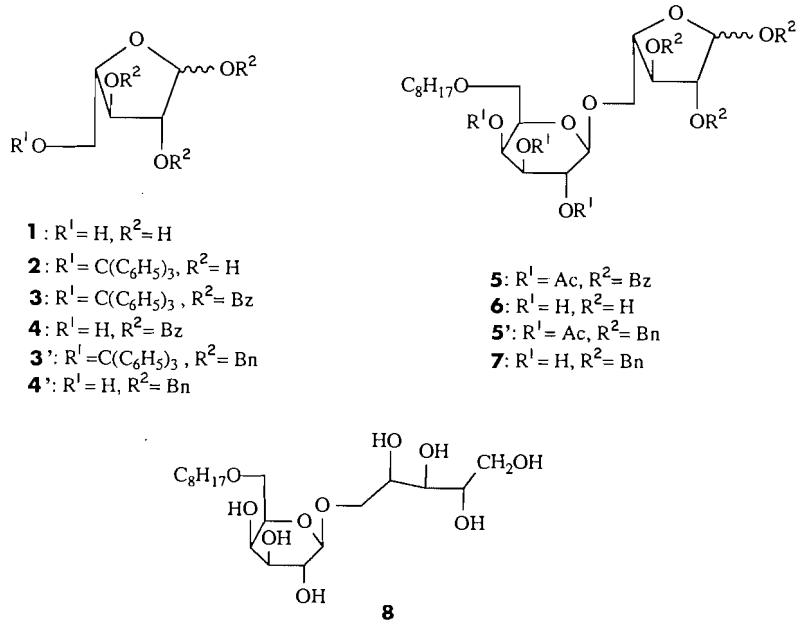

FIG. 1. Synthesis of the 6-*O*-octyl-β-D-galactopyranosyl-(1→5)-L-arabinose **6**.

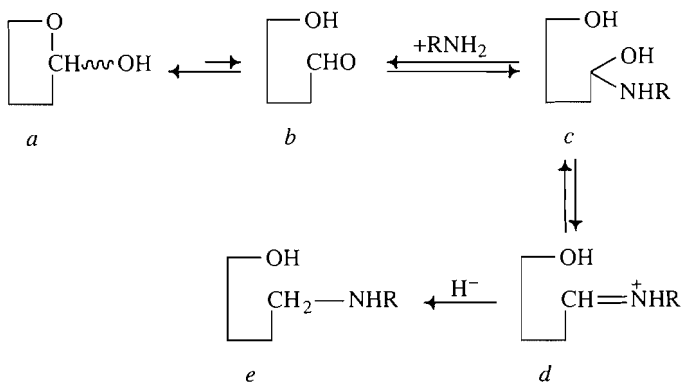

SCHEME 1. Mechanism of the 1-deoxyglycitolation reaction (*a*: hemiacetal; *b*: hydroxy-aldehyde; *c*: hemiaminal; *d*: immonium ion; *e*: alkylated amine).

However, in the reactions described in the literature, an equilibrium between the furanose and the pyranose forms of the saccharide, through the acyclic hydroxyaldehyde, might occur. In the case of the 5-substituted aldopentose **6** the formation of the pyranose isomers is not possible. Furthermore, the variation of the amphiphilicity of the liposaccharide could play a role in the reaction.

A series of liposaccharides has previously been prepared (Fig. 2). We have now estimated the relative reactivities of these lipodisaccharides and compare them to that of the melibiose **9***a* and to the newly prepared reagent **6** in the model reaction with N^{α}-*Z*-L-lysine (8). Preparative condensations, under different experimental conditions, have sometimes shown the formation of small amounts of bis-deoxyglycitolated derivatives resulting from the further reductive alkylation of the monoalkylated product (see the Experimental). If we reasonably assume that the relative reactivity of the monosubstituted amine formed does not change very much by varying the nature of the disaccharide, a reactivity scale can be established by following the consumption of N^{α}-*Z*-L-lysine under mild reductive conditions close to those of the chemical modification of an enzyme (Table 1).

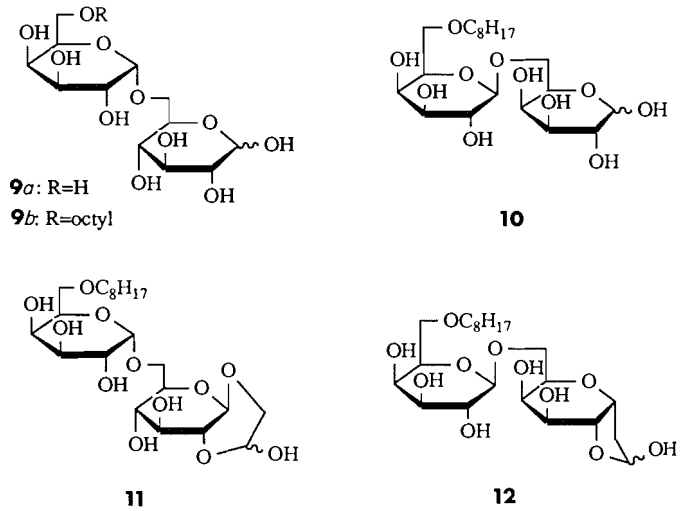

FIG. 2. Structures of the other liposaccharides: **9***b*, **10**, **11**, **12**, and melibiose **9***a*. **9***b*: 6-*O*-octyl-α-D-Gal*p*-(1→6)-D-Glc; **10**: 6-*O*-octyl-β-D-Gal*p*-(1→6)-D-Gal; **11**: 6-*O*-octyl-α-D-Gal*p*-(1→6)-β-D-gluco-pyrano[1,2-*b*]-1,4-dioxan-5-ol; **12**: 6-*O*-octyl-β-D-Gal*p*-(1→6)-α-D-galactopyrano[2,1-*b*]-oxolan-5-ol.

TABLE 1. Variation with time of the percentage of the N^{α}-*Z*-L-lysine that has reacted with the lipodisaccharides in the presence of an excess of $NaBH_3CN$ (at 4°C in a 0.1 M borate buffer)

Time (h)	Reagent					
	9*a*	**9***b*	**10**	**11**	**12**	**6**
	Percentage of consumed lysine					
4	8	9	7	20	34	30
24	13	15	12	30	52	57
48	27	31	24	39	59	66

The experimental order found is the following: **6**, **12** (ref. 8) ≥ **11** (ref. 6), **10** (ref. 7), **9***b* (ref. 6), **9***a*. The lipodisaccharides having a five-membered hemiacetal structure (furanose **6** and oxolanol **12**) react more rapidly than the six-membered hemiacetals (dioxanol **11** and pyranoses **10**, **9***b*, or **9***a*). The reactivity of the 6′-*O*-octyl melibiose is not very different from that of melibiose itself. The arabinose **6** is the most reactive of the series. Moreover, its synthesis is shorter than that of the oxolanol **12**; therefore this lipodisaccharide has been selected for a future study on condensation with enzymes.

Experimental

General methods

The ^{1}H NMR spectra were recorded at 300 MHz and the ^{13}C NMR spectra at 20 or 75 MHz in $CDCl_3$ or CD_3OD. The chemical shifts (δ, in ppm) are relative to internal TMS. The optical rotations were measured with a Perkin–Elmer 241 polarimeter. The melting points were determined with a Mettler FP61 apparatus, and are uncorrected. Thin-layer chromatography was performed on precoated silica gel 60 F_{254} plates (Merck) and visualized by charring with sulfuric acid. Column chromatography was run on silica gel G60.

A Gilson HPLC chromatograph equipped with a SPD-6A Shimadzu UV spectrophotometer, a C-R 5A Shimadzu integrator, and a Brownlee C_{18} Spheri 5 (22.5 cm) column was used.

5-O-Trityl-L-arabinose **2**

The method described for the synthesis of the D(−) isomer ($[\alpha]_{589}$ +16.3° (*c* 0.85, ethanol, 20 h)) was followed (9). To a solution of L(+)-arabinose (1.5 g, 10 mmol) in 20 mL of dried pyridine was added triphenylmethane chloride (3.1 g, 11 mmol). After stirring for 24 h at room temperature, the pyridine was evaporated. The residue was dissolved in dichloromethane and washed with aqueous sodium bicarbonate. After drying over Na_2SO_4, evaporation of the solvent gave a syrup that was purified on a silica gel column (eluent: 9.1 dichloromethane–methanol) to give **2** (3.06 g, 78% yield); R_f 0.56; mp 68°C; $[\alpha]_{589}$ −15.3°, $[\alpha]_{546}$ −17.1° (*c* 0.85, ethanol, 20 h); ^{1}H NMR (CD_3OD) δ: 5.41 (H-1β, J_{1-2} = 4.5 Hz), 5.38 (H-1α, J_{1-2} = 2.5 Hz), 4.10 (H-2α and H-3α), 4.35 (H-4α), 3.45 (H-5Aα, J_{4-5A} = 3.44 Hz, J_{5A-5B} = 10 Hz), 3.38 (H-5Bα, J_{4-5B} = 5.7 Hz); ^{13}C NMR δ: 103.9 (C-1α), 97.3 (C-1β), 83.5–65.5 (C-2–C-5). Anal. calcd. for $C_{24}H_{24}O_5$: C 73.45, H 6.16; found: C 73.26, H 6.30.

1,2,3-Tri-O-benzoyl-5-O-trityl-L-arabinose **3**

To a solution of trityl arabinose **2** (1.96 g, 5 mmol) in pyridine (10 mL), benzoyl chloride (2.32 g, 16.5 mmol) was added dropwise with stirring over a period of 3 h, at room temperature. After evaporation of the pyridine, the residue was dissolved in dichloromethane and washed with a saturated sodium bicarbonate solution. Drying (Na_2SO_4) and evaporation gave a syrup that was chromatographed (85:15 pentane – ethyl acetate) to give the title compound **3** (2.9 g, 82%); R_f 0.48, the two α and β isomers were not separated; ^{1}H NMR ($CDCl_3$) δ: 6.82 (H-1β, J_{1-2} = 4.7 Hz), 6.66 (H-1α, $J_{1-2} \leq$ 1 Hz), 6.10 (H-3β, J_{3-4} = 5.6 Hz), 5.80 (H-2β, J_{2-3} = 6.6 Hz), 5.71 (H-2α, J_{2-3} = 0.9 Hz), 5.68 (H-3α, J_{3-4} = 3.3 Hz), 4.71 (H-4α), 4.5 (H-4β), 3.6 (H-5Aα), 3.55 (H-5Aβ), 3.46 (H-5Bβ), 3.40 (H-5Bα); ^{13}C NMR δ: 99.96 (C-1α), 94.77 (C-1β), 80.75–63.54 (C-2–C-5). Anal. calcd. for $C_{45}H_{36}O_8$: C 76.69, H 5.15; found: C 76.91, H 5.09.

1,2,3-Tri-O-benzoyl-L-arabinose **4**

To a solution of the trityl derivative **3** (1.6 g, 2.27 mmol) in dry acetonitrile (20 mL) under Ar at 0°C were added NaI (1.02 g, 6.8 mmol) and then chlorotrimethylsilane (0.74 g, 6.8 mmol). The mixture was stirred for 2 h at 0°C and diluted with diethyl ether. The solution was washed with water and with $Na_2S_2O_3$, dried (Na_2SO_4), and evaporated. The residue was purified by column chromatography (1:1 pentane – diethyl ether) to give **4** (0.69 g, 66%); R_f 0.32; ^{1}H NMR ($CDCl_3$) δ: 6.86 (H-1β, J_{1-2} = 4.53 Hz), 6.69 (H-1α), 5.96 (H-3β, J_{3-4} = 5.6 Hz), 5.95 (H-2β, J_{2-3} = 6.68 Hz), 5.82 (H-2α, J_{2-3} = 0.9 Hz), 5.58 (H-3α, J_{3-4} = 3.7 Hz), 4.57 (H-4α), 4.38 (H-4β), 4.06 (H-5Aβ, J_{4-5A} = 4.51 Hz, J_{5A-5B} = 12.1 Hz), 4.02 (H-5Aα and H-5Bα), 3.99 (H-5Bβ, J_{4-5B} = 5.9 Hz); ^{13}C NMR δ: 99.76 (C-1α), 94.29 (C-1β), 80.76–62.23 (C-2–C-5). Anal. calcd. for $C_{26}H_{22}O_8$: C 67.53, H 4.80; found: C 67.29, H 4.80.

O-(2,3,4-Tri-O-acetyl-6-O-octyl-β-D-galactopyranosyl)-(1→5)-1,2,3-tri-O-benzoyl-L-arabinose **5**

To a solution of **4** (325 mg, 0.7 mmol) and 6-*O*-octyl-2,3,4-tri-*O*-acetyl-α-D-galactopyranosyl bromide (**7**) (440 mg, 0.91 mmol) in dichloromethane (15 mL), was added $Hg(CN)_2$ (250 mg, 1 mmol). After stirring for 48 h at room temperature, the solution was filtered on Celite, and washed with water and a KI solution. Evaporation of the solvent gave a crude product, which was applied to a silica gel column and eluted with 7:3 pentane – ethyl acetate to give **5** (435 mg, 72%); R_f 0.54; ^{1}H NMR ($CDCl_3$) δ: 6.81 (H-1β, J_{1-2} = 4.34 Hz), 6.43 (H-1α, $J_{1-2} \leq$ 1 Hz), 5.91 (H-3β, J_{3-4} = 4.97 Hz), 5.84 (H-2β, J_{2-3} = 6.32 Hz), 5.75 (H-2α, J_{2-3} = 1.0 Hz), 5.55 (H-3α, J_{3-4} = 3.6 Hz), 5.41 (H-4′α, $J_{4'-5'}$ = 2.8 Hz), 5.31 (H-4′β, $J_{4'-5'}$ = 1.5 Hz), 5.24 (H-2′α, $J_{2'-3'}$ = 9.5 Hz), 5.16 (H-2′β, $J_{2'-3'}$ = 9.5 Hz), 5.02 (H-3′α, $J_{3'-4'}$ = 3.4 Hz), 4.94 (H-3′β, $J_{3'-4'}$ = 3 Hz), 4.60 (H-1′α, $J_{1'-2'}$ = 7.9 Hz), 4.59 (H-1′β, $J_{1'-2'}$ = 7.9 Hz), 3.83 (H-5′), 3.5–3.3 (H-6′); ^{13}C NMR δ: 101.9 (C-1′α isomer), 100.71 (C-1′β isomer), 99.94 (C-1α), 94.72 (C-1β). Anal. calcd. for $C_{46}H_{54}O_{16}$: C 64.02, H 6.31; found: C 64.21, H 6.51.

6-O-Octyl-β-D-galactopyranosyl-(1→5)-L-arabinose **6**

Compound **5** (300 mg, 0.35 mmol) was dissolved in methanol (10 mL) and treated with sodium methoxide (20 mg). After stirring for 2 h at room temperature, Amberlite CG-50 (200 mg) was added. Filtration of the solution and evaporation of the methanol gave a solid that was purified by chromatography with 8:2 dichloromethane–methanol as eluent. The title compound **6** was obtained (97 mg, 65%); R_f 0.58; mp 125°C; $[\alpha]_{589}$ −15.1°; $[\alpha]_{546}$ −18.6° (*c* 1, methanol); ^{1}H NMR (CD_3OD) δ: 5.02 (H-1β, J_{1-2} = 4.53 Hz), 4.99 (H-1α, J_{1-2} = 1.5 Hz), 4.15 (H-1′β, $J_{1'-2'}$ = 7.3 Hz), 4.13 (H-1′α, $J_{1'-2'}$ = 7.3 Hz); ^{13}C NMR δ: 105.31 (C-1′α), 105.20 (C-1′β), 103.62 (C-1α), 97.48 (C-1β). Anal. calcd. for $C_{19}H_{36}O_{10}\cdot 0.5H_2O$: C 52.64, H 8.60; found: C 52.91, H 8.55.

Benzyl 2,3-di-O-benzyl-5-O-trityl-α- and β-L-arabinosides (3′α and 3′β)

To a solution of the trityl arabinose **2** (1 g, 2.55 mmol) in benzyl bromide (3 mL) was added crushed KOH (0.5 g). After addition of tetrabutylammonium bromide (50 mg) as catalyst, the mixture was stirred overnight at room temperature. Diethyl ether was added, the ether solution was decanted, washed with water, dried (Na_2SO_4), and evaporated. The residue was chromatographed with 1:1 pentane–dichloromethane as eluent to give **3′**α and **3′**β.

3′α (670 mg, 40%); R_f 0.62; $[\alpha]_{578}$ −27.9°, $[\alpha]_{546}$ −31.7° (*c* 4, dichloromethane); ^{1}H NMR ($CDCl_3$) δ: 5.15 (H-1, J_{1-2} = 1.0 Hz), 4.27 (H-4), 4.09 (H-2, J_{2-3} = 2.8 Hz), 4.00 (H-3, J_{3-4} = 6.24 Hz), 3.29 (H-5); ^{13}C NMR δ: 105.05 (C-1), 88.25–62 (C-2–C-5).

3′β (230 mg, 14%): R_f 0.42; $[\alpha]_{578}$ +42.3°, $[\alpha]_{546}$ +47.9° (*c* 6, dichloromethane); ^{1}H NMR δ: 4.92 (H-1, J_{1-2} = 4.12 Hz), 4.22 (H-3, J_{3-4} = 5.9 Hz), 4.17 (H-4), 4.05 (H-2, J_{2-3} = 6.9 Hz), 3.29 (H-5); ^{13}C NMR δ: 98.87 (C-1), 84.27–62 (C-2–C-5).

Benzyl 2,3-di-O-benzyl-α- and β-L-arabinosides (4′α and 4′β)

To a solution of **3′**α (430 mg, 0.65 mmol) in dichloromethane (15 mL), borontrifluoride etherate (0.3 mL) and methanol (0.6 mL) were added.[2] The mixture was stirred at room temperature for 2 h. Then the reaction was poured on water, washed with saturated sodium bicarbonate, and dried (Na_2SO_4). Evaporation gave a residue, which after column chromatography (1:1 pentane – diethyl ether) yielded compound **4′**α (218 mg, 80%). **4′**α: R_f 0.36; $[\alpha]_{578}$ −82.4°, $[\alpha]_{546}$ −92.6° (*c* 2, dichloromethane); ^{1}H NMR ($CDCl_3$) δ: 5.18 (H-1, J_{1-2} = 0.97 Hz), 4.20 (H-4), 4.09 (H-2, J_{2-3} = 2.8 Hz), 4.0 (H-3, J_{3-4} = 6.2 Hz), 3.85 (H-5A, J_{4-5A} = 2.9 Hz, J_{5A-5B} = 11.9 Hz), 3.66 (H-5B, J_{4-5B} = 4.0 Hz); ^{13}C NMR δ: 105.27 (C-1), 82.89–62.26 (C-2–C-5).

The **4′**β isomer was obtained by the same method: R_f 0.28;

$[\alpha]_{578}$ +51.3°, $[\alpha]_{546}$ +58.5° (*c* 2, dichloromethane); ^{1}H NMR δ: 4.97 (H-1, J_{1-2} = 4.43 Hz), 4.21 (H-3, J_{3-4} = 6.1 Hz), 4.07 (H-2, J_{2-3} = 7.1 Hz), 4.05 (H-4), 3.69 (H-5A, J_{4-5A} = 3.17 Hz, J_{5A-5B} = 11.9 Hz), 3.57 (H-5B, J_{4-5B} = 5.02 Hz); ^{13}C NMR δ: 99.59 (C-1), 82.33–64.03 (C-2–C-5). Anal. calcd. for $C_{26}H_{28}O_5$: C 74.26, H 6.71; found: C 74.51, H 6.70.

Benzyl O-*(2,3,4-tri-*O*-acetyl-6-*O*-octyl-β-*D*-galactopyranosyl)-(1→5)-2,3-di-*O*-benzyl-α- and β-*L*-arabinosides (5′α and 5′β)*

α Isomer

The experimental conditions were the same as those described for the synthesis of the benzoylated derivative **5** using, however, 82 mg (0.19 mmol) of the glycosyl acceptor **4′α** and 94 mg (0.19 mmol) of the 2,3,4-tri-*O*-acetyl-6-*O*-octyl-α-D-galactopyranosyl bromide glycosyl donor. Purification by chromatography (1:1 pentane-diethyl ether) yielded compound **5′α** (72 mg, 45%); R_f 0.61; $[\alpha]_{578}$ −43.4°, $[\alpha]_{546}$ −48.8° (*c* 1.3, dichloromethane); ^{1}H NMR ($CDCl_3$) δ: 5.34 (H-4′), 5.14 (H-2′, $J_{2'-3'}$ = 10.4 Hz), 4.98 (H-1, J_{1-2} = 1.4 Hz), 4.94 (H-3′, $J_{3'-4'}$ = 3.4 Hz), 4.53 (H-1′, $J_{1'-2'}$ = 8.0 Hz), 4.10 (H-4), 4.01 (H-2, J_{2-3} = 3.08 Hz), 3.90 (H-5A, J_{4-5A} = 4.3 Hz, J_{5A-5B} = 12.2 Hz), 3.88 (H-3, J_{3-4} = 6.3 Hz), 3.75 (H-5B, J_{4-5B} = 3.3 Hz), 3.73 (H-5′), 3.45 (H-6′A, $J_{5-6'A}$ = 6.0 Hz, $J_{6'A-6'B}$ = 9.8 Hz), 3.36 (H-6′B, $J_{5-6'B}$ = 6.7 Hz); ^{13}C NMR δ: 104.20 (C-1), 100.28 (C-1′), 88.50–67.85 (C-2–C-5 and C-2′–C-6′).

β isomer

Under the same experimental conditions, starting from **4′β**, **5′β** was obtained with 61% yield; R_f 0.53; $[\alpha]_{578}$ +18.4°, $[\alpha]_{546}$ +20.8° (*c* 1.1, dichloromethane); ^{1}H NMR ($CDCl_3$) δ: 5.41 (H-4′), 5.23 (H-2′, $J_{2'-3'}$ = 10.3 Hz), 4.98 (H-3′, $J_{3'-4'}$ = 3.4 Hz), 4.94 (H-1, J_{1-2} = 4.3 Hz), 4.50 (H-3), 4.47 (H-1′, $J_{1'-2'}$ = 7.8 Hz), 4.10 (H-4), 4.06 (H-2, J_{2-3} = 7 Hz), 3.96 (H-5A, J_{4-5A} = 6.4 Hz, J_{5A-5B} = 10 Hz), 3.79 (H-5′), 3.67 (H-5B, J_{4-5B} = 6.1 Hz), 3.50 (H-6′A, $J_{5-6'A}$ = 5.9 Hz, $J_{6'A-6'B}$ = 9.7 Hz), 3.42 (H-6′B, $J_{5-6'B}$ = 6.8 Hz); ^{13}C NMR δ: 101.02 (C-1′), 99.07 (C-1), 84.47–67.74 (C-2–C-5 and C-2′–C-6′). Anal. calcd. for $C_{46}H_{60}O_{13}$: C 67.29, H 7.37; found: C 67.20, H 7.37.

Benzyl O-*(6-*O*-octyl-β-*D*-galactopyranosyl)-(1→5)-2,3-di-*O*-benzyl-α- and β-*L*-arabinoside (7α and 7β)*

Compounds **5′α** and **5′β** were deacetylated by the same procedure used for compound **5**. The title compounds were purified by column chromatography (9:1 dichloromethane–methanol) (80% yields).

α Isomer: R_f 0.68; $[\alpha]_{578}$ −58.5°, $[\alpha]_{546}$ −65.2° (*c* 1.1, dichloromethane); ^{1}H NMR ($CDCl_3$) δ: 5.28 (H-1, J_{1-2} = 0.9 Hz), 4.27 (H-1′, $J_{1'-2'}$ = 6.8 Hz), 4.21 (H-4), 4.06 (H-2), 4.05 (H-5A, J_{4-5A} = 2.7 Hz, J_{5A-5B} = 12.7 Hz), 3.94 (H-3), 3.82 (H-5B, J_{4-5B} = 2.3 Hz), 3.73 (H-6′A, $J_{5'-6'A}$ = 5.4 Hz, $J_{6'A-6'B}$ = 10.1 Hz), 3.66 (H-6′B, $J_{5'-6'B}$ = 5.2 Hz); ^{13}C NMR δ: 104.95 and 105.45 (C-1 and C-1′).

β Isomer: R_f 0.62; $[\alpha]_{578}$ +12.2°, $[\alpha]_{546}$ +13° (*c* 0.7, dichloromethane); ^{1}H NMR δ: 4.98 (H-1, J_{1-2} = 4.3 Hz), 4.24 (H-1′, $J_{1'-2'}$ = 7.6 Hz), 4.23 (H-3, J_{3-4} = 6 Hz), 4.12 (H-4), 4.05 (H-2, J_{2-3} = 6.7 Hz), 4.04 (H-2′, $J_{2'-3'}$ = 9.3 Hz), 3.97 (H-3′, $J_{3'-4'}$ = 3.1 Hz), 3.72 (H-5A, J_{4-5A} = 5.6 Hz, J_{5A-5B} = 10.2 Hz), 3.64 (H-5B, J_{4-5B} = 7 Hz), 3.44 (H-5′); ^{13}C NMR δ: 103.35 (C-1′), 99.29 (C-1).

Hydrogenolysis of 7α

To a solution of compound **7α** (36 mg, 0.05 mmol) in methanol (15 mL), 30 mg of 5% Pd/C was added, and the hydrogenolysis was performed in a Parr apparatus for 2 h under a 50 psi hydrogen atmosphere (1 psi = 6.9 kPa). The catalyst was removed and the filtrate concentrated. Chromatography (7:3 ethyl acetate – methanol) yielded **8** (18 mg, 80%); R_f 0.28; ^{1}H NMR (CD_3OD) δ: 4.46 (H-1′, $J_{1'-2'}$ = 7.3 Hz), 3.75 (H-2′, $J_{2'-3'}$ = 9.7 Hz), 3.68 (H-3′, $J_{3'-4'}$ = 3.1 Hz); ^{13}C NMR δ: 105.32 (C-1′), 75.05–64.90 (C-2–C-5 and C-2′–C-6′). The ^{1}H and ^{13}C NMR spectra are identical to those of the reference product obtained by reduction of **6** with $NaBH_3CN$.

Hydrogenolysis of 7β

Under the same experimental conditions, compound **7β** (15 mg) was hydrogenolysed in the presence of Pd/C (35 mg) to give **6**. A second hydrogenolysis did not give the reduced product **8**. Thin-layer chromatography showed, however, the presence of a small amount of **8** in addition to **6**.

Determination of the N^{α}*-Z-L-lysine 1-deoxyglycitolation reactivity scale*

The reactions with the various disaccharides were performed simultaneously. In a typical experiment, N^{α}-Z-L-lysine (5.62 mg, 0.02 mmol) was dissolved in 1 mL of a 0.1 M borate buffer, pH 8.0. The mixture was cooled to 4°C, then 0.05 mmol of the carbohydrate was added. Stirring was maintained for 30 min before addition of $NaBH_3CN$ (32 mg, 0.5 mmol). Aliquots (50 μL) were withdrawn at intervals, directly diluted with 4 mL of the HPLC eluent (acetonitrile–water: 35–65 v/v), and 5 μL of the resulting solution was injected. The reaction was followed by comparing the initial and the sample absorbance of the N^{α}-Z-L-lysine HPLC peak at 190 nm. The values obtained were reproducible in a 3% range.

Preparative coupling of liposaccharides with N^{α}*-Z-L-lysine*

Under different experimental conditions, preparative non-optimized experiments were performed to characterize the end products.

Reductive alkylation with 6

Carbohydrate **6** (42 mg, 0.1 mmol), N^{α}-Z-lysine (112 mg, 0.4 mmol), and sodium cyanoborohydride (63 mg, 1 mmol) were dissolved in a 0.1 M borate buffer, pH 8.0 (2 mL). Stirring at room temperature was maintained for 16 h. The mixture was evaporated to dryness and the residue chromatographed on silica gel, and eluted with methanol to give reduced carbohydrate **8** (11 mg, 25%) and 1-deoxyglycitolated N^{α}-Z-L-lysine (36 mg, 52%); R_f 0.38; ^{1}H NMR (CD_3OD) δ: 0.9 (3H, octyl), 5.1 (2H, *Z*), 7.2 (5H, *Z*). High resolution MS (FAB^+), calcd. for MH^+, $C_{33}H_{57}N_2O_{13}$: 689.386; found: 689.431.

*Reductive alkylation with 9*b

A solution of N^{α}-Z-L-lysine (45 mg, 0.16 mmol), ***9b*** (75 mg, 0.16 mmol), and sodium cyanoborohydride (100 mg) in water (5 mL) was adjusted to pH 7 with 0.1 M hydrochloric acid. The solution was kept for 3 days at 60°C. Water was evaporated and the product was purified by chromatography on silica gel, with water as eluent. ***9b*** (18 mg, 25%), reduced carbohydrate (15 mg, 20%), and alkylated amine (34 mg, 30%) were isolated; R_f 0.43 (water–methanol – ethyl acetate, 1:2:3); ^{1}H NMR (CD_3OD) δ: 0.85–1.80 (15H octyl + 6H lysine), 3.0–4.5 (massif), 5.06 (2H benzyl), 7.2–7.4 (5H benzyl). High resolution MS (FAB^+), calcd. for MH^+, $C_{34}H_{59}N_2O_{14}$: 719.396; found: 719.352.

Reductive alkylation with 10

Using the same experimental conditions as for ***9b***, the 1-deoxyglycitolated N^{α}-Z-L-lysine was obtained in 22% yield; R_f 0.48 (water–methanol – ethyl acetate: 1:2:3); ^{1}H NMR (CD_3OD) δ: 0.8–0.95 (3H, octyl), 1.20–1.40 (12H, octyl), 1.40–1.80 (6H, lysine), 2.90–3.20 (2H, lysine and 2H on C1), 3.40–4.20 (H lysine and carbohydrate), 4.28 (d, *J* = 8, H1′), 5.05 (2H, benzyl) and 7.15–7.25 (5H, benzyl). High resolution MS (FAB^+), calcd. for MH^+, $C_{34}H_{59}N_2O_{14}$: 719.396; found: 719.367.

Reductive alkylation with 12

Compound **12** (50 mg, 0.104 mmol), N^{α}-Z-L-lysine (29 mg, 0.104 mmol), and sodium cyanoborohydride (65 mg, 1.04 mmol) in 0.1 M borate buffer, pH 8 (5 mL), were stirred for 16 h at room temperature. After chromatography, 39 mg of a mixture of mono- and di-alkylated amine (in a 72:28 ratio) was isolated; R_f 0.39 (methanol). High resolution MS (FAB^+): monoalkyl, calcd. for MH^+, $C_{36}H_{61}N_2O_{14}$: 745.412; found: 745.400; and dialkyl, calcd. for MH^+, $C_{58}H_{101}N_2O_{24}$: 1209.6; found: 1209.4.

The antioxidant activities of phenolic antioxidants in free radical peroxidation of phospholipid membranes

LAWRENCE ROSS COATES BARCLAY,[1] KIMBERLY ANN BASKIN, KELLY ANDREA DAKIN, STEVEN JEFFFREY LOCKE, AND MELINDA RUTH VINQVIST

Department of Chemistry, Mount Allison University, Sackville, N.B., Canada E0A 3C0

Received July 3, 1990

LAWRENCE ROSS COATES BARCLAY, KIMBERLY ANN BASKIN, KELLY ANDREA DAKIN, STEVEN JEFFREY LOCKE, and MELINDA RUTH VINQVIST. Can. J. Chem. **68**, 2258 (1990).

Autoxidation of dilinoleoylphosphatidylcholine (DLPC) bilayers photoinitiated by benzophenone takes place by a free radical chain mechanism according to product studies of the *cis,trans* and *trans,trans*-9- and -13-linoleate hydroperoxides formed and kinetic studies of the reaction order as a function of light intensity. The absolute rate constant for hydrogen abstraction from DLPC bilayers by peroxyl radicals is found to be 36.1 M^{-1} s^{-1} at 37°C. Preliminary measurements of activities of phenolic antioxidants, α-tocopherol (α-T), 2,2,5,7,8-pentamethyl-6-hydroxychroman (PMHC), 2,5,7,8-tetramethyl-6-hydroxychroman-2-carboxylate (Trolox), and 2,6-di-*tert*-butyl-4-methylphenol (BHT) by oxygen uptake studies during inhibition periods using photoinitiation gave uncorrected inhibition rate constants, κ_{inh}, for α-T, PMHC, and Trolox several orders of magnitude lower than observed earlier in chlorobenzene. Three series of phenolic antioxidants, (*a*) polyalkyl-6-hydroxychromans, (*b*) polyalkyl-4-methoxyphenols, and (*c*) trialkylphenols, were examined for their antioxidant activities in DLPC membranes during thermally initiated autoxidation by azobis-2,4-dimethylvaleronitrile (DMVN). The corrected inhibition rate constants, k_{inh}, observed in (*a*), α-T (5.8×10^3), PMHC (17.8×10^3), Trolox (5.8×10^3), 2,2-dimethyl-5,7-diisopropyl-6-hydroxychroman, **4***a* (55×10^3), and 2,2,5-trimethyl-7-*tert*-butyl-6-hydroxychroman, **5***a* (61×10^3) M^{-1} s^{-1}, are dramatically lower, by several orders of magnitude, than those measured earlier in chlorobenzene and significantly lower (about 1/40–1/10) than those measured in solution in *tert*-butyl alcohol and less than k_{inh} measurements (1/2–1/5) in aqueous SDS micelles. The k_{inh} values for series (*b*) were 2,3,5,6-tetramethyl-4-methoxyphenol (TTMMP) (2.1×10^3), 2,3,6-trimethyl-4-methoxyphenol (TMMP) (10.4×10^3), and 2,6-di-*tert*-butyl-4-methoxyphenol (DBHA) (27.5×10^3) M^{-1} s^{-1} and for (*c*) were 2,6-di-*tert*-butyl-4-methylphenol (BHT) (3.7×10^3) and 2,4,6-trimethylphenol (TMP) (0.56×10^3) M^{-1} s^{-1}. The results show an overall leveling and depression of antioxidant activities in DLPC membranes in the series (*a*), (*b*), (*c*) compared to those reported in solution in chlorobenzene, where large differences were attributed to steroelectronic effects of the *para* ether oxygen stabilizing the derived phenoxyl radicals in (*a*) and (*b*) types. The results in aqueous micellar and membrane systems are interpreted in terms of polar solvation effects. Hydrogen bonding by water at both the ether and phenolic groups decreases the activity of the (*a*) series. Hydrogen bonding at the phenolic hydroxyl appears to be the more significant factor since steric hindrance to H-bonding at hydroxyl allows **4***a* and **5***a* to be the most active antioxidants of the α-tocopherol series (*a*) and DBHA to be the most active antioxidant of the (*b*) series.

Key words: antioxidant activities, phenols, membranes, peroxidation, kinetics.

LAWRENCE ROSS COATES BARCLAY, KIMBERLY ANN BASKIN, KELLY ANDREA DAKIN, STEVEN JEFFREY LOCKE et MELINDA RUTH VINQVIST. Can. J. Chem. **68**, 2258 (1990).

En se basant sur la nature des produits obtenus, soit les hydroperoxydes des acides *cis,trans*- et *trans,trans*-9- et -13-linoléiques ainsi que sur des études cinétiques établissant l'ordre de la réaction en fonction de l'intensité lumineuse, on a pu établir que l'autooxydation de bicouches de dilinoléylphosphatidylcholine (DLPC), photoinitiée par la benzophénone, se produit par un mécanisme radicalaire en chaîne. On a établi que, à 37°C, la constante absolue de la vitesse d'enlèvement de l'hydrogène des bicouches de DLPC, par les radicaux peroxyles, est de 36,1 M^{-1} s^{-1}. Des mesures préliminaires des activités des antioxydants phénoliques suivants : α-tocophérol (α-T), 2,2,5,7,8-pentaméthyl-6-hydroxychromane (PMHC), 2,5,7,8-tétraméthyl-6-hydroxychromane-2-carboxylate (Trolox) et 2,6-di-*tert*-butyl-4-méthylphénol (BHT), basées sur l'absorption d'oxygène durant les périodes d'inhibition de la photoinitiation, ont permis d'obtenir des constantes d'inhibition de vitesses non-corrigées, k_{inh}, pour l'α-T, le PMHC et le Trolox; les valeurs obtenues sont plusieurs ordres de grandeur plus faibles que celles observées antérieurement dans le chlorobenzène. On a examiné les propriétés antioxydantes de trois séries de composés phénoliques, (*a*) les polyalkyl-6-chromanes, (*b*) les polyalkyl-4-méthoxyphénols et (*c*) les trialkylphénols, dans des membranes de DLPC, durant des autooxydations initiées thermiquement par l'azobis-2,4-diméthylvaléronitrile (DMVN). Les constantes d'inhibition de vitesses corrigées, k_{inh}, observées avec les produits de la série (*a*), α-T ($5,8 \times 10^3$), PMHC ($17,8 \times 10^3$), Trolox ($5,8 \times 10^3$), 2,2-diméthyl-5,7-diisopropyl-6-hydroxychromane (**4***a*) (55×10^3) et 2,2,5-triméthyl-7-*tert*-butyl-6-hydroxychromane (**5***a*) (61×10^3 M^{-1} s^{-1}) sont dramatiquement inférieures (plusieurs ordres de grandeur) à celles mesurées antérieurement dans le chlorobenzène, de beaucoup inférieures (1/40–1/10) à celles mesurées en solution dans le *tert*-butanol et moins que les valeurs de k_{inh} mesurées (1/2–1/5) dans des micelles aqueuses de SDS. Les valeurs de k_{inh} mesurées pour les produits de la série (*b*) sont 2,3,5,6-tétraméthyl-4-méthoxyphénol (TTMMP) ($2,1 \times 10^3$ M^{-1} s^{-1}), 2,3,6-triméthyl-4-méthoxyphénol (TMMP) ($10,4 \times 10^3$ M^{-1} s^{-1}) et 2,6-di-*tert*-butyl-4-méthoxyphénol (DBMA) ($27,5 \times 10^3$ M^{-1} s^{-1}) et pour la série (*c*) elles sont 2,6-di-*tert*-butyl-4-méthylphénol (BHT) ($3,7 \times 10^3$ M^{-1} s^{-1}) et 2,4,6-triméthylphénol (TMP) ($0,56 \times 10^3$ M^{-1} s^{-1}). Ces résultats démontrent que, pour les produits des séries (*a*), (*b*) et (*c*) dans les membranes de DLPC, les activities antioxydantes sont nivelées et plus faibles que celle observées en solution dans le chlorobenzène où les grandes variations ont été attribuées aux effets stéréoélectroniques stabilisants de l'oxygène en *para* des radicaux phénoxyles dérivés des produits des types (*a*) et (*b*). On interprète les résultats obtenus en solutions aqueuses en fonction d'effets polaires de solvatation. Les liaisons hydrogènes de l'eau avec les fonctions éthers et hydroxyles de dérivés de la série (*a*) diminuent leur activité. Les liaisons hydrogènes des

groupments hydroxyles semblent avoir une influence prépondérante puisque l'empêchement stérique aux liaisons hydrogènes qui existe dans les composés **4***a* et **5***a* leur permet d'être les antioxydants les plus actifs de la série des α-tocophérols (*a*); les mêmes facteurs pourraient expliquer l'activité du composé DBHA de la série (*b*).

Mots clés : activités des antioxydants, phénols, membranes, peroxydation, cinétique.

Introduction

Peroxidation of unsaturated lipids in biomembranes disrupts important protective properties of natural membranes, and various in vivo pathological events are implicated as a result of this oxidation (1–8). Consequently the mechanism of action and activity of protective free radical chain-breaking antioxidants continues to be of outstanding interest (9–21). The role of phenolic antioxidants in this regard is of particular interest since the discovery that α-tocopherol (vitamin E) is the major lipid-soluble chain-breaking antioxidant in human blood (21). The protective action of various water-soluble and lipid-soluble antioxidants is the subject of several recent reviews (22–25).

In the past decade, it has been shown that classical kinetic methods of autoxidation, well known in homogeneous solution (26–29), are applicable to heterogeneous environments such as aqueous micelles (30–32) and, more importantly, in phospholipid bilayers (33–37), which mimic biomembranes in many respects (38). This free radical chain mechanism for autoxidation of organic substrates is generally represented by the reaction sequence shown in eqs. [1]–[3]:

[1] Initiation: formation of R·(or ROO·), rate = R_i

[2] (*a*) Propagation: $R\cdot + O_2 \xrightarrow{\text{fast}} ROO\cdot$

(*b*) $ROO\cdot + RH(\text{substrate}) \xrightarrow{k_p} ROOH + R\cdot$

[3] Termination: $ROO\cdot + ROO\cdot \xrightarrow{2k_t}$ nonradical products + O_2

For systems following this reaction scheme, the rate of oxygen uptake is first order in the concentration of substrate, RH, and one-half order in the rate of chain initiation, R_i, so that eq. [4] applies:

$$[4] \quad -d[O_2]/dt = k_p/2k_t^{1/2}[RH] \times R_i^{1/2}$$

For *quantitative* kinetics studies, the R_i must be controlled, for example by using a thermal azo initiator, R—N=N—R, which decomposes at a known and controlled rate to form carbon radicals, known to react very rapidly (39) with molecular oxygen to form propagating peroxyl radicals, ROO·. Alternatively, the R_i can be controlled by photochemical initiation (32). The "cage effect" on radicals generated in bilayers is known to be very much greater than in homogeneous solution (33), and the R_i must be measured, for example, by the addition of a phenolic antioxidant, ArOH, known to trap two peroxyls (9), and by measuring the time, τ, during which oxygen uptake is suppressed. During this period, eqs. [5]–[7] apply:

[5] $ROO\cdot + ArOH \xrightarrow{k_{inh}} ROOH + ArO\cdot$

[6] $ROO\cdot + ArO\cdot \xrightarrow{\text{fast}} ROOHArO$

$$[7] \quad R_i = 2 \times [ArOH]/\tau$$

The suppressed oxygen uptake is now given by eq. [8]:

$$[8] \quad -d[O_2]/dt = k_p/k_{inh}[RH] \times R_i/2[ArOH]$$

The susceptibility of a substrate to undergo autoxidation, referred to as its *oxidizability*, is expressed as a ratio of rate constants according to eq. [9]:

$$[9] \quad k_p/2k_t^{1/2} = -d[O_2]/dt/[RH] \times R_i^{1/2}$$

The absolute rate constants of propagation, k_p, and termination, $2k_t$, for autoxidation are expected to provide much more significant data on the reactivity and dynamics of peroxyl radicals in membranes than the simple ratios. It is especially important to establish the antioxidant activities of common phenolic antioxidants in phospholipid membranes by determinations of inhibition rate constants, k_{inh}, in order to better judge their protective action against biomembrane peroxidation. Absolute rate constants for autoxidation are well known in homogeneous solution (28, 29). More recently Burton, Ingold, and co-workers (10) have determined the antioxidant activity of α-tocopherol and synthetic phenolic antioxidants by measurements of the inhibition rate constants, k_{inh}, during the induction periods of autoxidation in homogeneous solution. Some measurements of phenolic antioxidant activities (k_{inh}) have also been made during suppressed autoxidation of linoleate in sodium dodecyl sulfate (SDS) micelles (11, 16, 32).

The determination of antioxidant activities of chain-breaking antioxidants *in membrane systems* is acknowledged to be a more difficult task (11). Furthermore, such measurements depend on determinations of the propagation rate constant, k_p, which must be measured independently in the same system in order to determine k_{inh} from the kinetics (e.g., eq. [8]).

We have recently undertaken such a study of absolute rate constants for lipid peroxidation and inhibition in phosphatidylcholine bilayers (35, 40) compared to such results in solution and in SDS micelles. This study has now been extended to include other phenolic antioxidants. We report herein on the details of this research, which includes results for three classes of phenolic antioxidants: (*a*) α-tocopherol (α-T), and the structurally related hydroxychromans: 2,2,5,7,8-pentamethyl-6-hydroxychroman (PMHC), and 2,5,7,8-tetramethyl-6-hydroxychroman-2-carboxylate (Trolox); (*b*) the alkylated 4-methoxyphenols: 2,3,5,6-tetramethyl-4-methoxyphenol (TTMMP), 2,3,6-trimethyl-4-methoxyphenol (TMMP), and 2,6-di-*tert*-butyl-4-methoxyphenol (DBHA); (*c*) the polyalkylphenols: 2,6-di-*tert*-butyl-4-methylphenol (BHT), 2,4,6-trimethylphenol (TMP).

These kinetic studies were carried out using dilinoleoylphosphatidylcholine (DLPC) bilayers, which have definite advantages as model membranes. The oxidation products from controlled free radical peroxidation of the linoleoyl moiety are known. Furthermore, these bilayers can be readily purified and they undergo rates of photochemically and thermally initiated peroxidation that can be controlled, and measured by a sensitive pressure transducer.

Results

1. Photoinitiated peroxidation of DLPC bilayers with benzophenone

[a]At least two HPLC analyses were averaged. The error limits were 5%. The ratio of total C-9 to C-13 substitution products was essentially 1:1 in each case.

[b]Calculated from the total oxygen consumption at the time the sample was taken from the reaction.

solution and in bilayers are known to be the conjugated diene 9- and 13-hydroperoxide positional isomers having the *cis,trans* and *trans,trans* configuration. Porter and co-workers studied the ratio of *cis,trans* to *trans,trans* hydroperoxide products in detail, and advanced a mechanism involving a competition beween H-atom abstraction from activated methylene groups and β-scission of peroxyl radicals to account for the relative amounts of *cis,trans* (kinetic) and *trans,trans* (thermodynamic) products (41–44). We observed the same products for benzophenone-photoinitiated free radical peroxidation of linoleate in SDS micelles (32). On the other hand, reaction of linoleate with singlet oxygen yields a different product distribution, namely, approximately equal amounts of two conjugated (9- and 13-) and two nonconjugated ((10- and 12-) hydroperoxides (45). Because of the possible formation, by energy transfer, of singlet oxygen in our ketone-sensitized oxidations, we conducted some product analyses. The results are summarized in Table 1. The products formed were the 9- and 13-substituted hydroperoxides, as expected of a free radical chain peroxidation, and the *cis,trans* to *trans,trans* ratios found for up to 10% DLPC oxidation are similar to those reported for thermally initiated autoxidation of DLPC bilayers; e.g., 1.26 at 37°C (44), or 1.17 at 45°C (34).

(*b*) *Kinetics studies*

So that the classical rate law, expressed in eq. [4], can be followed exactly, the kinetic order of oxygen uptake must be one-half in the rate of chain initiation, R_i. To check this kinetic order, the dependence of the rate of O_2 consumption with variation of the R_i was measured at seven different light intensities. A typical result for multilamellar vesicles (MLV) of DLPC is illustrated in Fig. 1. In this case, the measured kinetic order (e.g., 0.507) is indicative of half-order dependence on the R_i. In all kinetic runs *using MLV*, the kinetic order in the R_i approximated one half and normally was between 0.50 and 0.53. However, unilamellar vesicles (ULV) of DLPC exhibited different behavior. Plots of kinetic order vs. light intensity were often decidedly non-linear (not shown) and the approximated kinetic order usually higher (e.g., >0.70). The type of liposome particle appears to exert an effect on the kinetics (*vide infra*).

Absolute rate constants of propagation, k_p, and termination, $2k_t$, for autoxidation of linoleate have been measured in solution, in micelles, and recently in DLPC bilayers, and most of the available data are summarized in Table 2. Details of the procedures used and calculations for the rotating sector method are described elsewhere (29, 32, 46). As pointed out earlier, benzophenone has certain advantages as a photoinitiator for rotating sector measurements (32), e.g., no dark rate and no correction for nitrogen evolution as required for azo initiators.

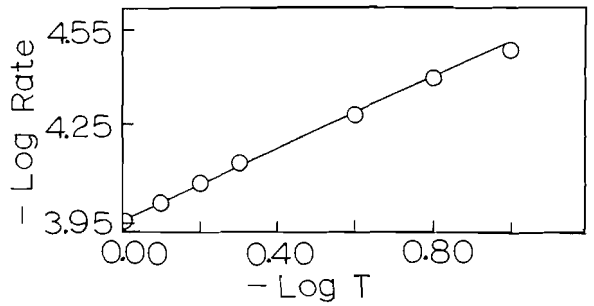

FIG. 1. Kinetic order plot of oxygen consumption as a function of light intensity (200 W super pressure Hg arc, through neutral density filters) for autoxidation of multilamellar (MLV) DLPC liposomes (5.45×10^{-5} mol) containing benzophenone (8.23×10^{-7} mol).

The k_p found for DLPC in MLV, 36.1 $M^{-1} s^{-1}$ at 37°C (Table 2, entry 7), was used in subsequent calculations of inhibition rate constants. This value is about the same, within experimental error, as that found using a water-soluble derivative of benzophenone (BP^-) as photoinitiator (Table 2, entry 8).

Typical experimental traces for the effects of the antioxidants α-T, PMHC, Trolox, and BHT on the inhibited autoxidation of DLPC liposomes, when reaction is photoinitiated with benzophenone, are illustrated in Fig. 2. The inhibition rate constants (k_{inh}) were determined from measurements of oxygen uptake during the inhibition periods by using the integrated expression for the kinetics during inhibition (9, 40), e.g., eq. [10]:

$$[10] \quad \Delta[O_2]_t = -k_p/k_{inh} \times [RH] \ln (1 - t/\tau)$$

where τ is the total inhibition period, and the oxygen uptake, $[O_2]_t$, is measured at various times, t, during the suppressed reaction. Typical data, to illustrate this method, for an α-T-inhibited reaction are given in Table 3. Linear plots were obtained for $\Delta[O_2]$ versus $-\ln(1 - t/\tau)$ for α-T, PMHC, Trolox, and BHT through 70% of the inhibition period, as illustrated in Fig. 3. Values of k_{inh} determined from the slopes of these plots, using the k_p as determined under these conditions (36.1 $M^{-1} s^{-1}$), are summarized in Table 4. These values were comparable (generally within 10%) to those calculated by averaging amounts of oxygen consumed at points during the induction period. The procedure using photoinitiation by benzophenone is very convenient for control and measurements of these kinetics. Nevertheless, inaccuracies in the calculated values of k_{inh} may result because the low rates of oxygen uptake by the DLPC substrate during inhibition periods could not be corrected for the possible competing reaction with ketyl radicals:

$$(C_6H_5)_2\dot{C}OH + O_2 \rightarrow (C_6H_5)_2C(OH)OO\cdot$$

This correction could be significant because chain lengths during inhibition periods for these benzophenone-photoinitiated runs are quite low (range of $\nu \sim 3$–9). Consequently, thermal azo initiators were used to repeat these experiments for determinations of k_{inh}.

2. Inhibition rate constants for phenolic antioxidants during thermally initiated autoxidation of DLPC liposomes with azo initiators

The antioxidant action of three classes of phenolic inhibitors was determined during autoxidation of DLPC in MLV liposomes, where reaction was initiated by the lipid-soluble azo initiator azobis-2,4-dimethylvaleronitrile (DMVN). Typical experimental traces for the antioxidant effects of (a) the

vitamin E class, (b) the polyalkyl 4-methoxyphenols, and (c) two polyalkyl phenols are illustrated in Fig. 4 (a), (b), and (c) respectively. Detailed experimental results, typical of all of the data obtained, are given in Tables 5 (*a*), (*b*), and (*c*) for an antioxidant from each class. Plots of oxygen uptake, $\Delta[O_2]_t$, versus $-\ln(1 - t/\tau)$ (eq. [10]) during the inhibition periods for typical antioxidants studied by this method are shown in Fig. 5 (a), (b), and (c). Values of k_{inh} for these three classes of inhibitors, determined from the slopes of these plots and using $k_p = 36.1$ $M^{-1} s^{-1}$ as before, are given in Table 6. Measurements in bilayers give rise to errors due to the necessity of using a coevaporation method to insert lipid-soluble initiators and inhibitors into the hydrophobic phase *before* bilayer preparation. There results a "lag time" in each induction period while the sample and oxygen equilibrate to the bath temperature (37°C). Ideally for these determinations the oxygen uptake measurements should start simultaneously with the start of loss of inhibitor ($\tau_{t=0}$). Under our conditions with thermal initiators, a correction was applied by timing the induction period and oxygen uptake after an equilibration period, usually several minutes. The error in k_{inh} due to this lag time was minimized by this correction and long overall induction periods, usually several hours. In addition, the accuracy of our k_{inh} values in bilayers depends on the accuracy of the measured k_p. The value of 36.1 $M^{-1} s^{-1}$ is reliable considering the various measurements made (Table 2). Overall, our k_{inh} values determined by thermal initiation are considered accurate to approximately ±20%, sufficiently accurate for comparisons with results from other media.

The water-soluble phenolic antioxidant, Trolox, has received considerable attention (ref. 10, and references therein). It is of particular interest because it exhibits antioxidant action when aqueous solutions are injected into autoxidations initiated in either the aqueous or lipid phases of lipsomes or micelles (36). Immediately after the measurement of the inhibition period with each lipid-soluble antioxidant, one or two inhibition periods were determined using Trolox. In this way Trolox provided a useful internal reference for determining the rate of chain

initiation (R_i), and a means for comparing antioxidant activities of the other phenols.

Discussion

1. The mechanism for benzophenone-photoinitiated autoxidation of DLPC in multilamellar vesicles

A photosensitized reaction of oxygen with an organic substrate may be initiated by hydrogen abstraction by the sensitizer triplet followed by free radical autoxidation (Type I mechanism), or reaction could occur via a Type II mechanism involving energy transfer to form singlet oxygen followed by reactions such as the *ene* reaction. These processes are both well known (47, 48). Product studies can distinguish between these pathways. The products from the singlet oxygen reaction are not controlled by abstraction of the reactive allylic hydrogens, and a more complex mixture results from linoleate compared to that from the Type I pathway. Our results from product studies of the *cis,trans* and *trans,trans* hydroperoxides formed from benzophenone-initiated autoxidation (Table 1) indicate that hydrogen abstraction followed by free radical autoxidation predominates, there being no evidence for products arriving from reaction with singlet oxygen. The inhibition effects observed for chain-breaking antioxidants as illustrated in Fig. 2 also support a free radical peroxidation pathway. In the DLPC bilayer system, the doubly allylic hydrogens compete successfully with oxygen for benzophenone triplet. In this respect the mechanism is comparable to that reported for linoleate in SDS micelles (32).

For bimolecular chain termination of peroxyl radicals, i.e., the mechanism of eq. [3], the rate of oxidation is proportional to $R_i^{1/2}$; in our system this should mean the square root of the light intensity. This indeed is approximately the case for DLPC in multilamellar liposomes (MLV) where kinetic orders range from 0.507 to 0.532 and good linear plots are obtained (e.g., Fig. 1). The higher kinetic orders and nonlinear behavior with light intensity observed with unilamellar vesicles (ULV) were unexpected. The measured rate of oxygen uptake is greater for ULV than for MLV systems, as observed earlier for methyl linoleate in saturated ULV (35). We suggest that this phenomenon is due to the effect of particle size on the kinetics. ^{31}P NMR spectra of our ULV, prepared using the French pressure cell, indicate particle sizes less than 100 nm in cross section as observed before (49, 50). In such small liposomes, the probability of one peroxyl radical meeting another to terminate the chain reaction in the same liposome diminishes, so the termination rate decreases (e.g., $2k_t$ drops) and the oxygen uptake increases. In addition, the mechanism becomes complicated by some *first-order* termination of peroxyls. The nature of this reaction is not clear but it could proceed by cleavage reactions of peroxyl or derived alkoxyl radicals, which,in these particles, are more likely to diffuse to the aqueous surface where the polar medium promotes β-scission (51). The system is further complicated by the possibility of aggregation during peroxidation, especially at higher conversions (34). This problem does not arise in larger MLV; presumably these particles provide the opportunity for polar peroxyls (52) to diffuse towards the surface and terminate. One can also speculate that, in closely packed layers of lipsomes, termination might even occur by collisions of peroxyls between successive layers.

Lipsomes do present challenging systems for these quantitative kinetic studies but MLV systems of known chemical composition appear to behave nearly ideally in autoxidation with regard to both kinetic order in substrate (34) and R_i, provided low oxidative conversions are used, e.g., 10% overall or, here, 5% per linoleate chain. The kinetic rate constant of chain propagation, k_p, for linoleate only decreases by a factor of 2–3 in aqueous micelles and bilayers compared to homogeneous solution (Table 2). However, the chain termination rate

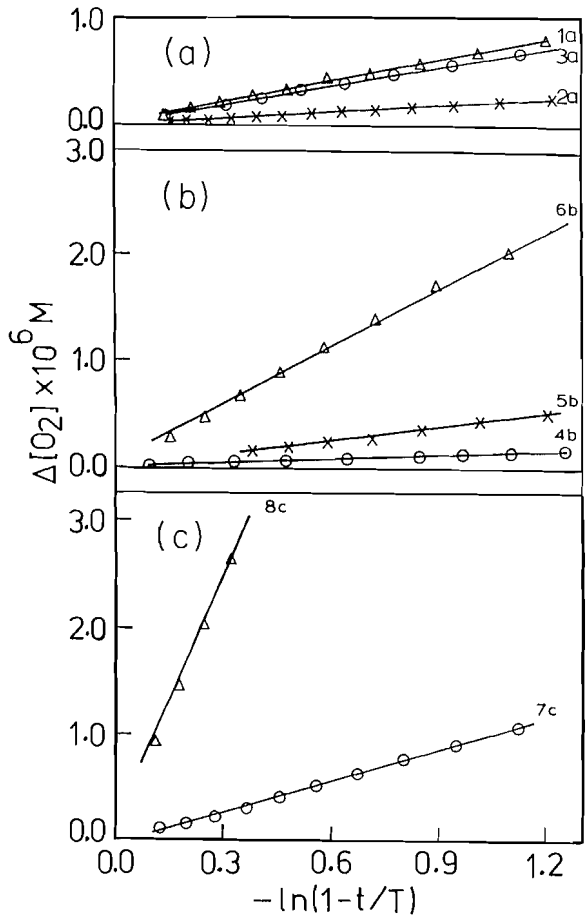

FIG. 5. Plots of oxygen uptake during inhibition periods versus $-\ln(1 - t/\tau)$ during autoxidation of DLPC MLV bilayers thermally initiated by DMVN in phosphate buffer, pH 7.0. Data for the plots are from typical experiments as outlined in Table 5. Amounts of DLPC, DMVN, and antioxidants are given in Table 6. The k_{inh} values (Table 6 also) are obtained from the slopes, which equal $k_p[RH]/k_{inh}$. (a) **1***a*, α-Toc; **2***a*, PMHC; **3***a*, Trolox. (b) **4***b*, DBHA; **5***b*, TMMP; **6***b*, TTMMP. (c) **7***c*, BHT; **8***c*, TMP.

constant, $2k_t$, decreases remarkably in these aqueous systems. As discussed earlier (32), this is most probably due to diffusion of polar peroxyl radicals from the hydrophobic phase towards the aqueous phase where they are stabilized by hydrogen bonding. This is also in line with similar observations made earlier for homogeneous solution (53). The water-soluble ketone, BP^-, is very convenient as a photoinitiator because it can be injected into the reaction after the liposomes are prepared. Its effect may be due to partial distribution into the bilayer phase, as was found in micelles (32).

2. The activities of phenolic antioxidants in DLPC bilayers

Various factors, including electronic effects, steric effects, and solvent effects, need be considered in assessing the antioxidant action of phenolic inhibitors. In aqueous microenvironments of bilayers and micelles the system is further complicated by the possible effects of aggregation and the possibility of limiting diffusion phenomena. Furthermore, the experimental method employed can affect the results even when similar systems are examined (*vide infra*).

With these complications in mind, we compare in Table 7 the k_{inh} values of our three classes of antioxidants determined by the thermal initiation procedure in bilayers with those found in other media including homogeneous solution in chlorobenzene, and, for class (a) antioxidants, *tert*-butyl alcohol, and in micelles. The following striking differences characterize the activities of these phenolic antioxidants in different media:

1. *The activities of the three types, with the exception of DBHA (4b) and BHT (7c), are dramatically reduced in bilayers*, by several orders of magnitude compared with those in homogeneous solution in chlorobenzene. For the hydroxychromans (class *a*), which were studied in all four media, the activities are very significantly decreased, by factors of about 7–18, in

	0.491	0.675	62.5	38.6	4.0
	0.552	0.803	75.7	44.6	3.9
	0.613	0.951	89.6	51.7	3.9
	0.675	1.123	107.0	62.1	3.9

[a]Class *a*: k_{inh} (calculated from slope) = $5.3 \times 10^3 M^{-1} s^{-1}$; k_{inh} (averaged from points) = $(5.3 \pm 0.1) \times 10^3 M^{-1} s^{-1}$; $R_i = 1.67 \times 10^{-7} M s^{-1}$. Class *b*: k_{inh} (calculated from slope) = $30.6 \times 10^3 M^{-1} s^{-1}$; k_{inh} (averaged from points) = $(33.6 \pm 1.6) \times 10^3 M^{-1} s^{-1}$; $R_i = 1.69 \times 10^{-8} M s^{-1}$. Class *c*: k_{inh} (calculated from slope) = $3.7 \times 10^3 M^{-1} s^{-1}$; k_{inh} (averaged from points) = $(4.3 \pm 0.2) \times 10^3 M^{-1} s^{-1}$; $R_i = 4.24 \times 10^{-8} M s^{-1}$.

[b]Class *a*: α-T, 5.04×10^{-9} mol; DMVN, 9.53×10^{-7} mol. Class *b*: DBHA, 1.27×10^{-8} mol; DMVN, 3.10×10^{-6} mol. Class *c*: BHT, 1.32×10^{-8} mol; DMVN, 3.18×10^{-6} mol. These were the amounts of inhibitor and initiator at the start of each run, corrected for loss during the lag time.

[c]Reaction volumes were, respectively, 5.36×10^{-5} L (5.76×10^{-5} mol) DLPC for class *a* (α-T); 1.10×10^{-4} L (1.13×10^{-4} mol) DLPC for class *b* (DBHA); and 5.61×10^{-5} L (5.74×10^{-5} mol) DLPC for class *c* (BHT).

[d]See footnote *e*, Table 3.

tert-butyl alcohol[2] as compared to chlorobenzene. There is a further *drop* in activity in aqueous SDS, which by our measurements[3] amounts to decreases in the ratio $k_{inh}ROH/k_{inh}SDS \sim 5–14$ and a further decrease in k_{inh} for bilayers, where $k_{inh}SDS/k_{inh}DLPC = 3–5$ for the three hydroxychromans.

2. *The antioxidant activities of all three classes of inhibitors are quite similar in bilayers (e.g., a leveling effect) in contrast to remarkable differences observed in homogeneous solution.* In the case of chlorobenzene solution, certain substituted hydroxy anisoles (DBHA) and phenols (BHT) exhibited k_{inh} orders of magnitude less than the hydroxychromans (ref. 10, Table 7). These different antioxidant activities of phenols, such as polyalkylhydroxychromans (e.g., vitamin E) and hydroxyanisoles, during inhibition of autoxidation of styrene in chlorobenzene were interpreted by Ingold and co-workers (10) in terms of carefully considered electronic and steric effects. In particular, they concluded that the stabilization of the phenoxyl radical formed in the rate-determining inhibition step (eq. [15]) depends mainly on the extent of orbital overlap between the 2*P*-type lone pairs on the *para* ether oxygen and the aromatic π system, referred to as the stereoelectronic effect (9, 10).

[2]The k_{inh} for the inhibition reaction for methyl linoleoylperoxy radical with α-tocopherol was earlier reported as $51 \times 10^4 M^{-1} s^{-1}$ in *tert*-butyl alcohol, in reasonable agreement with our value since an estimation was used for k_p (57).

[3]Our values in SDS differ from those reported (11), probably due to initiation in different phases.

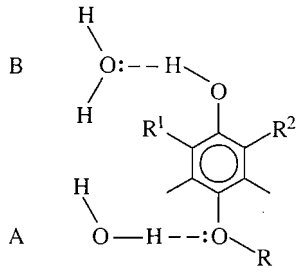

FIG. 6

The reduction in antioxidant activities of class *a* phenols in aqueous micelles was attributed by us earlier (32) to the effect water may have of tying up the electron lone pairs on the *para* ether oxygen, thereby reducing the reactivity of the phenolic hydrogen by dampening the stereoelectronic effect exerted by the ether oxygen lone pairs in homogeneous solution. This explanation was presented in more detail by Pryor *et al.* (11), who also presented evidence that hydrogen bonding of the phenolic hydroxyl to water in class *a* antioxidants is responsible for the dramatic drop in activity in aqueous micelles. This conclusion was supported by the fact that BHT with no *para* oxygen, and in which two *ortho tert*-butyl groups inhibit hydrogen bonding, has about the same antioxidant activity in micelles as in chlorobenzene (see Table 7). These hydrogen bonding interactions are shown schematically in Fig. 6. Water can associate with the ether oxygen through its protic hydrogen, thereby localizing the 2*P* lone pair on the oxygen as in A, and also associate the protic phenolic hydroxyl at a lone pair on water as in B, thereby inhibiting facile transfer of the phenolic hydrogen to peroxyl radicals.

The antioxidant activities of these classes of phenols in phospholipid membranes are controlled by two kinds of environmental influences:

1. *The main influence appears to be the operation of solvation effects of water.* We assume that these antioxidants reside near the polar head group region of the bilayers as demonstrated for vitamin E (54) and, furthermore, that the trapping of polar peroxyl radicals occurs in this region. In these circumstances, the activity of most of these phenols is reduced by hydrogen bonding with water at both sites (viz. Fig. 6). The combined effects of interaction at A and B level the antioxidant activity of the hydroxychromans (**1***a*–**3***a*) towards that of BHT (**7***c*), whereas in chlorobenzene the latter is several orders of magnitude less active than the hydroxychromans (Table 7). Some idea of the relative importance of hydrogen bonding at sites B and A (Fig. 6) can be seen in a qualitative manner by comparing the k_{inh} of antioxidants in class *b* containing one methyl *ortho* to methoxy (**5***b*) with the activity of **6***b*, which has two such *ortho* methyls. We find the activity of **5***b* to be in the range of the hydroxychromans (**1***a*–**3***a*, Table 7) indicating that the overall deactivation due to hydrogen bonding is approximately the same for **5***b* as for **1***a*–**3***a*. The activity of **6***b* in bilayers is significantly less, by a factor of approximately one fifth. It is known that the two *ortho* methyls in **6***b* force the methoxy group into a position perpendicular to the aromatic ring (10), which accounts for the drop in activity of **6***b* by as much as tenfold compared to the hydroxychromans in solution. Hydrogen bonding at this *para* methoxy alone is not expected to further reduce the activity of **6***b* in aqueous bilayers. Thus the additional drop in activity of **6***b* by a factor of about one fifth that of **5***b* must be due to hydrogen bonding at the phenolic hydroxyl group.

The comparatively higher activity of DBHA (**4***b*) compared to other phenols in bilayers is rather surprising in view of its diminished activity in solution, the latter being attributed to steric hindrance, provided by two *ortho tert*-butyl groups, to the approach of the peroxyl radical (10). If hydrogen bonding at the hydroxyl is blocked in **4***b* (55), its relatively higher activity must be due to a balance between such steric hindrance effects, hydrogen bonding at the *para* ether oxygen, and the stabilization that bulky *ortho* alkyls impart to the phenoxyl radical formed on hydrogen atom transfer (56). We suggest that the main effect operating to give DBHA higher "residual" activity is steric hindrance to hydrogen bonding at the phenolic hydroxyl. To test this we measured the antioxidant activities of the trialkylphenols **7***c* and **8***c*. In solution the latter has about six times the activity of **7***c*. In contrast, the relative activities switch dramatically in bilayers so that **7***c* (BHT) is seven times more active than **8***c*. The latter is a very poor inhibitor of peroxidation in aqueous bilayers. The low activity of **8***c* compared to **7***c* is thus attributed to hydrogen bonding at the phenolic hydroxy, which is most probably the more important solvation effect. This effect is probably prominent in suppressing the antioxidant activities of the hydroxychromans (**1***a*–**3***a*) in model membranes.

2. *There appears to be an effect of the bilayer structure of the membrane on phenolic antioxidant activity.* As noted above, k_{inh} values for hydroxychromans drop by one fourth in aqueous bilayers compared to those in aqueous micelles. Micelles are more fluid and dynamic aggregates than bilayers. Nevertheless, even in micelles, the reduced antioxidant activity of lipophilic phenols such as α-tocopherol was attributed to their limiting diffusion between micelles (16). "Diffusion control" is expected to be more pronounced in bilayers, at least in the case of α-tocopherol where the phytyl side chain is known to suppress its transfer between liposomal membranes (12). All of our experiments were done above the phase transfer temperatures of DLPC, where presumably diffusion within the membrane is more facile than in the less fluid gel state. However, long hydrocarbon chains and derived peroxyl radicals aggregated into a bilayer are not expected to have the same freedom of motion as in homogeneous solution. The higher antioxidant activity of PMHC in bilayers compared to α-tocopherol may in part be due to greater freedom of diffusion of the former in the membrane. If the peroxyl radical diffuses to the surface region to terminate with the phenolic antioxidant, as is postulated, additional constraints would be placed on the system. In addition, the reactivity of peroxyl radicals is suppressed by hydroxyl bonding (58) and such interaction could operate in this polar region.

Our quantitative studies of antioxidant activities in membranes permit rationalization of some other literature results. For example, Niki and co-workers (59) reported the very interesting observation that the ratio k_{inh}/k_p for α-tocopherol in soybean PC liposomes is much smaller than in homogeneous solution in *tert*-butyl alcohol. Using their ratio of rate constants for α-tocopherol in liposomes and our $k_p = 36.1\ M^{-1}\ s^{-1}$ gives an estimated $k_{inh} = 2.1 \times 10^3\ M^{-1}\ s^{-1}$ for α-tocopherol in their bilayers, in reasonable agreement with our result (Table 6) considering the assumptions made. Spin labeling studies show that α-tocopherol scavenges lipophilic radicals closer to the membrane surface (59). This is in general agreement with our results indicating that antioxidant action takes place mainly in this region of the membranes with resulting depression of their activity by solvation effects. Trolox is a remarkable water-soluble antioxidant that can be used for quantitative measurements of peroxyl radical formation in either bilayer or micellar

5*a*		0.15–0.16	4–12	6.1±0.6

[a]See Table 8, footnote *b*.

[b]The procedure of ref. 10 was followed, using concentrations of styrene 5.22 M and AIBN 1.74×10^{-2} M at 30°C.

[c]For runs in chlorobenzene, the R_i was calculated from the induction period with the inhibitor studied: in DLPC bilayers the R_i was determined using Trolox (see Table 6).

[d]At least three determinations were made in chlorobenzene and two in DLPC bilayers. k_{inh} values are calculated from the plot of $\Delta[O_2]$ versus $-\ln(1 - t/\tau)$ and using $k_p = 41$ $M^{-1} s^{-1}$ (10) for runs in chlorobenzene.

[e]For experimental conditions see Table 8.

[f]Taken from Table 7.

systems for autoxidations initiated by either water-soluble or lipid-soluble initiators (36). Such results can be rationalized if Trolox can trap peroxyl radicals at the surface of membranes and micelles as we propose. The lower k_{inh} of Trolox, one third that of PMHC, may be due to its proposed site of action at the polar membrane surface and (or) its distribution between aqueous and membrane phases. This is currently under investigation.

Our results have important implications for the role of chain-breaking phenolic antioxidants (e.g., vitamin E) in real biological systems. It is now evident that the activity of phenolic antioxidants measured in homogeneous solution cannot be extrapolated to estimate their absolute or even relative activities in biological membranes. Autoxidation studies on biological fluids including human blood plasma (18, 20) and blood (60) indicate the importance of natural water-soluble antioxidants, such as ascorbate, protein thiols, and urate, which trap damaging peroxyl radicals in the aqueous phase before they can attack the membrane lipids, thereby sparing the α-tocopherol in the lipid phase, which can be regarded as the "last defence" against damaging peroxyl radical attack.

Recently two new synthetic α-T model compounds, 2,2-dimethyl-5,7-diisopropyl- (**4***a*) and 2,2,5-trimethyl-7-*tert*-butyl-6-hydroxychroman (**5***a*), were made available for us to determine antioxidant activities. Such model compounds are of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

particular interest to our present investigation. Although they have lower antioxidant activities than the α-T model compound PMHC, as measured by reaction with a stable phenoxyl radical in solution (62), the additional bulk of two *ortho* isopropyl gorups in **4***a* and a *tert*-butyl in **5***a* compared to methyls in our series *a* compounds is expected to further hinder hydrogen bonding at the phenolic hydroxyl by water (Fig. 6, B) and allow for an *increase* in antioxidant activity in aqueous bilayers.

We measured the antioxidant activities of **4***a* and **5***a* in solution in chlorobenzene for reaction with poly(styrylperoxyl) radicals using known procedures (10) and the results are given in Table 9. The k_{inh} values for **4***a* and **5***a relative* to that found in our study for PMHC (Table 9), 0.66 and 0.55 respectively, are the same as the relative rate constants for reaction with a phenoxyl radical solution (62). The k_{inh} values for **4***a* and **5***a* are similar to that of 5,7-dimethyltocol, 180×10^4 M^{-1} s^{-1} (10), which also lacks a substituent at position 8. This indicates that the main effect causing the reduction of the activity of **4***a*, **5***a* compared to PMHC (**2***a*) is the lack of stabilizing electron-donating alkyl group at position 8 in the former; steric hindrance to attack by peroxy radicals in solution evidently is not significant in these compounds. The k_{inh} values of **4***a* and **5***a* in DLPC bilayers were determined as before (Table 8) and the results, summarized in Table 9, indicate that they exhibit a similar marked drop in activity by at least an order of magnitude compared to values in homogeneous solution. This reduction in k_{inh} is interpreted in terms of hydrogen bonding by water especially at the *para* ether oxygen (*vide supra*). However, it is remarkable that these synthetic model tocopherols are very significantly *more reactive as antioxidants in bilayers* than any other antioxidants of the vitamin E class, *a* (Table 6). They are more active, by approximately one order of magnitude, than α-tocopherol itself and three to four times more active than PMHC. This is further demonstration of the importance of hydrogen bonding at the phenolic hydroxyl in controlling the antioxidant activity. The higher residual activity in **4***a* and **5***a* is attributed to additional steric hindrance to such hydrogen bonding provided by the two *ortho* isopropyl groups in **4***a* and a *tert*-butyl group in **5***a* so that hydrogen atom transfer in the rate-controlling inhibition step is more facile.

All our results demonstrate the need to measure antioxidant activities of compounds in model membrane systems as well as in solution in order to judge their protective capacity against peroxyl radical attack in natural biological systems. There is the interesting possibility that some new synthetic hindered phenolic antioxidants of the class *a* type are much more potent antioxidants in membranes than judged from measurements in homogeneous solution (63).

Experimental

1. Chemicals and preparations

(a) Buffers

Phosphate buffer for membrane preparations was prepared from NaH_2PO_4 and Na_2HPO_4 (each 0.05 M) (pH 7.0) in glass-distilled water containing Na_2EDTA (1×10^{-4} M). Possible traces of heavy metal ions were removed by passing the buffer through Chelex (50–100 mesh, Biorad). Phospholipid dispersions for ^{31}P NMR studies were prepared in 0.054 M Tham (Fisher) buffer containing 1×10^{-4} M Na_2EDTA and adjusted to pH 7.0 with HCl.

(b) Reagents

The initiator (DMVN) was purchased from Polysciences and recrystallized from methanol, mp 70–72°C (dec.), (lit. (61) mp 75–76°C). The solid was stored at −30°C and solutions of known concentration were prepared in chloroform or methanol before use. Trolox, a gift from Hoffman-LaRoche, Nutley, New Jersey, was used as freshly prepared solutions in phosphate buffer. α-Tocopherol (Eastman-Kodak) was stored in known concentrations in hexane under argon at −30°C. 2,6-Di-*tert*-butyl-4-methylphenol (BHT) was obtained from Serdary Research Lab. 3,5-Di-*tert*-butyl-4-hydroxy-anisole (DBHA) and 2,4,6-trimethylphenol (TMP) were obtained from Aldrich. 2,2,5,7,8-Pentamethyl-6-hydroxychroman (PMHC), 2,3,5,6-tetramethyl-4-methoxyphenol (TTMMP), and 2,3,6-trimethyl-4-methoxyphenol (TMMP) were gifts from Dr. Graham Burton, National Research Council, Ottawa. Solutions of known concentrations of these antioxidants were prepared in methanol for coevaporation methods, and stored at −30°C.

L-α-Dilinoleoylphosphatidylcholine (DLPC) was purchased from Avanti Polar Lipids. The DLPC was checked for the presence of peroxides by chromatography on reverse phase TLC plates (Whatman KC18F) developed with 90:10 methanol/water. Traces of hydroperoxides were detected as pink spots on spraying with *N,N*-dimethyl-*p*-phenylenediamine dihydrochloride solution and phospholipid was detected by spraying with molybdenum blue spray reagent (Sigma) followed by heating at 110°C. Where necessary, peroxides were removed by preparative HPLC on a 10 × 250 mm Vydac (C18) column by elution with methanol/water/cyclohexane (90:10:5) by the procedure reported earlier (34). The multilamellar vesicles (MLV) of DLPC containing known amounts of initiator and inhibitor were prepared by coevaporation of known amounts of each from methanol, followed by vortex stirring in buffer and 10 freeze–thaw cycles as reported earlier (34). Unilamellar vesicles (ULV) were prepared by three passes through a mini French pressure cell under argon at 20 000 psi (1 psi = 6.9 kPa) (50, 62).

2. Analysis

(a) Autoxidation product analysis

The *cis,trans* and *trans,trans* 9- and 13-hydroperoxides derived from linoleate were reduced by triphenylphosphine to the hydroxy compounds, converted into methyl esters by transesterification, and analyzed by HPLC by the procedure reported (34).

(b) ^{31}P Nuclear magnetic resonance

^{31}P NMR spectra were measured on MLV and ULV DLPC dispersions in Tham buffer (pH 7.0) on a Nicolet 360 NB FT NMR spectrometer operating at 146.15 MHz using the conditions reported (34). The MLV exhibited the typical broad asymmetric signals with chemical shift anisotropy of approximately 40 ppm whereas the ULV showed narrower symmetrical ^{31}P peaks. Examples of these two types of spectra were illustrated in earlier reports (34, 50).

3. Autoxidation procedures

Autoxidations were carried out at 37°C under approximately 760 Torr (1 Torr = 133.3 Pa) of oxygen using a dual channel stainless steel apparatus (34). Measurements of oxygen uptake during inhibition periods required a very sensitive pressure transducer. For this purpose, the sensitivity was at least five times that used previously. Ideally one needs to measure such oxygen uptake from the very beginning of the inhibition period. However some lag time is encountered during which the sample and calibrated glass cell must warm from room temperature to 37°C. This can cause error in measurements of oxygen uptake especially for the more active antioxidants. A correction was made for this by estimating the amounts of inhibitor and initiator used up during this lag time and correcting the calculations for the amount of inhibitor used during the warm-up period.

Acknowledgements

This research was supported by grants from the Natural Sciences and Engineering Research Council of Canada, and the Terry Fox Fund for Cancer Research (N.B.), which are gratefully acknowledged. We are indebted to Roger Smith and Allister MacDonald for their assistance in the design and construction of sensitive apparatus for oxygen pressure measurements. We thank Dr. Graham Burton (NRC, Ottawa) for samples of phenolic antioxidants PMHC, **5b** and **6***b*. We also

wish to thank Dr. Kazuo Mukai (Ehime University, Japan) for new hydroxychromans **4***a* and **5***a*. NMR measurements were made at the Atlantic Regional Magnetic Resonance Centre at Dalhousie University.

^{113}Cd NMR studies of Hofmann-type clathrates and related compounds: Evidence for two room temperature orientational glasses[1]

S. NISHIKIORI,[2] C. I. RATCLIFFE,[3] AND J. A. RIPMEESTER

Chemistry Division, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received February 26, 1990

S. NISHIKIORI, C. I. RATCLIFFE, and J. A. RIPMEESTER. Can. J. Chem. **68**, 2270 (1990).

^{113}Cd magic angle spinning NMR, with and without ^{1}H cross-polarisation and decoupling, has been used to study a number of Hofmann-type clathrates and related compounds. The ^{113}Cd chemical shift shows a great sensitivity to the environment of Cd, even for complexes with closely related structures. The presence of five resonances due to Cd surrounded by $C_xN_{(4-x)}$ (where $x = 0$ to 4) in $Cd(CN)_2$ and $Cd(CN)_2 \cdot C_6H_{12}$ indicates a static disorder of the CN groups, which makes these materials orientational glasses.

Key words: ^{113}Cd NMR, Hofmann-type clathrates, $Cd(CN)_2$, disorder, orientational glass.

S. NISHIKIORI, C. I. RATCLIFFE et J. A. RIPMEESTER. Can. J. Chem. **68**, 2270 (1990).

On a utilisé l'angle magique de rotation en rmn du ^{113}Cd, avec ou sans découplage et polarisation croisée du ^{1}H, pour étudier un certain nombre de clathrates du type de Hofmann et de composés apparentés. Le déplacement chimique du ^{113}Cd est très sensible à l'environnement du Cd, même pour des complexes de structures très apparentées. La présence de 5 raies de résonance pour des Cd entourés par $C_xN_{(4-x)}$ (où $x = 0$ à 4) dans $Cd(CN)_2$ et $Cd(CN)_2 \cdot C_6H_{12}$ indique qu'il existe un désordre statique des groupements CN qui transforme ces matériaux en verres orientationnels.

Mots clés : RMN du ^{113}Cd, les clathrates du type de Hofmann, $Cd(CN)_2$, désordre, verre orientationnel.

[Traduit par la revue]

Introduction

The Hofmann-type clathrates are an interesting type of host–guest system in which the host consists of a layered framework of cyano-bridged metal atoms, usually square planar Ni and octahedral Cd (1–3). The layers are held apart by ammonia molecules coordinated to the Cd atoms at right angles to the layers. Between the layers and coordinating groups are cavities which, in most cases, are large enough to hold a guest molecule such as benzene. A great number of related compounds have been produced by varying the coordinating amino-bearing molecules (3–5) and replacing the square planar Ni atom with a tetrahedral Cd atom (6, 7). Recently, in the course of the latter studies it was found that $Cd(CN)_2$ itself can also form clathrates. In some cases the distinct layered structure of the true Hofmann-type is lost, but the common feature of all is the system of cyano-bridged Ni and/or Cd atoms. Many of these host systems also form stable compounds when the guest molecules are lost, though a structural change usually occurs (6).

Although a great deal of work has been done on the preparation and structure of these compounds, there is still much scope for solid-state NMR studies. Here we present some ^{113}Cd NMR results. ^{113}Cd has a large chemical shift range and should be sensitive to small changes in its environment (8) and is recently finding use in solid state NMR (e.g., refs. 9–11). In many of the X-ray structural studies of Hofmann and related materials it has been possible to distinguish the C and N atoms of the CN groups; frequently one metal is coordinated entirely by C or entirely by N. However, there are some cases where the two have not been distinguished. It was of interest, first of all, to see whether solid state ^{113}Cd NMR was sensitive enough to distinguish the different coordination situations and, if so, to determine whether disorder was responsible for the X-ray indistinguishability of C and N.

Experimental

$Cd(NH_3)_2Ni(CN)_4 \cdot 2C_6H_6$ was prepared by the following method. Into 100 mL of water 0.01 mol of cadmium chloride and potassium tetracyanonickelate were added, and 10 mL of 2-aminoethanol ($NH_2—CH_2CH_2—OH$) was poured into the mixture with stirring until the mixture turned into a yellow solution. After 5 mL of 28% ammonia aqueous solution was dissolved in the yellow solution, neat benzene was placed on the solution surface. The clathrate was obtained as yellow polycrystals after standing for a week at room temperature.

$Cd(en)Ni(CN)_4 \cdot 2C_6H_6$ was obtained by the same method in which 1.3 mL of distilled ethylenediamine was used instead of 5 mL of aqueous ammonia.

$Cd(en)Cd(CN)_4 \cdot 2C_6H_6$, $Cd(en)Cd(CN)_4$, and $Cd(CN)_2 \cdot C_6H_{12}$ were prepared by methods reported in refs. 12, 13, and 14, respectively. The crystals were grown at 279 K.

$Cd(CN)_2$ was obtained by thermal decomposition of $Cd(CN)_2 \cdot C_6H_{12}$ (14). Powdered $Cd(CN)_2 \cdot C_6H_{12}$ was kept at ca. 350 K for 24 h in the atmosphere. The conclusion of the decomposition was confirmed by the X-ray diffraction powder pattern.

^{113}Cd NMR spectra were obtained at 39.92 MHz using a Bruker CXP 180 pulse spectrometer and 4.24T cryomagnet with a Doty Scientific magic angle spinning probe. Samples were contained in 7 mm o.d. sapphire tubes with Kel-F end caps. Spinning rates of 3.4–4.6 kHz were used. ^{1}H cross-polarisation and decoupling was used in most cases with CP times of 4–10 ms and matched r.f. fields of ~50 kHz. Spectra of $Cd(CN)_2$ and its cyclohexane clathrate were obtained using a simple phase cycled pulse sequence (CYCLOPS) (15) with recycle times of 100 and 60 s, respectively. No cross-polarisation signal could be found for the latter material, for which ^{2}H NMR results (to be reported later) indicate that the cyclohexane is undergoing rapid pseudo-isotropic reorientation at room temperature. Chemical shifts are given relative to $Cd(NO_3)_2 \cdot 4H_2O$. Note that all materials studied are diamagnetic.

Results and discussion

Spectra are shown in Figs. 1–3 and the chemical shifts and relevant linewidths are collected in Table 1. Figure 1 shows the spectra for three different Cd/Ni Hofmann-type compounds. In all three structures (16–19) the Cd is surrounded by four cyano N atoms and two N atoms of the other ligands in a distorted octahedral coordination. The chemical shift data illustrate the great sensitivity to small changes in the environ-

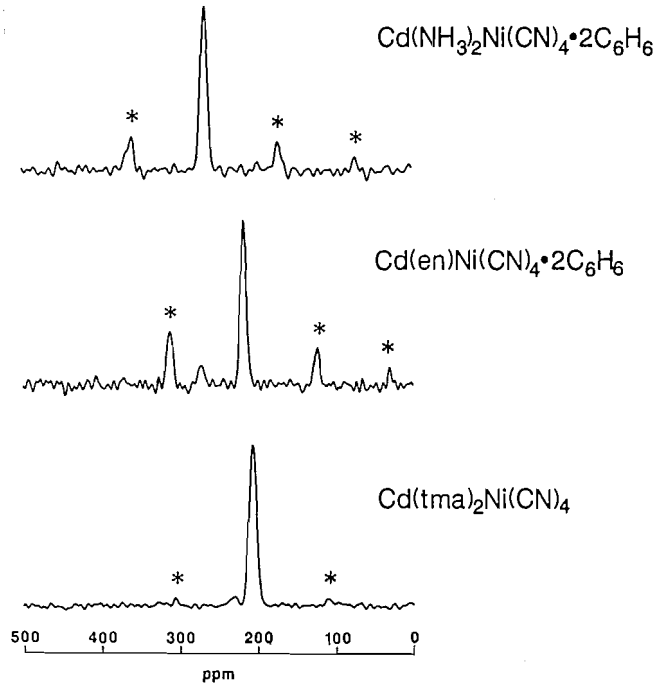

FIG. 1. ^{113}Cd CP/MAS spectra of several Cd/Ni Hofmann-type and related compounds (* indicates spinning sidebands).

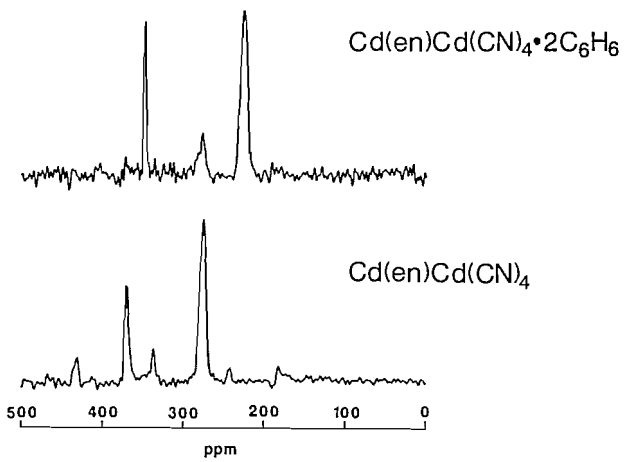

FIG. 2. ^{113}Cd CP/MAS spectra of $Cd(en)Cd(CN)_4 \cdot 2C_6H_6$ clathrate and $Cd(en)Cd(CN)_4$. Note the presence of $Cd(en)Cd(CN)_4$ in the top spectrum as a product when the clathrate loses the guest material.

ment of the Cd atom. Figure 2 (top) shows the spectrum of $Cd(en)Cd(CN)_4 \cdot 2C_6H_6$ clathrate. Partial loss of guest is evident from the appearance of weaker lines due to the empty host material (Fig. 2, bottom). The spectrum of this clathrate may be compared with that of the equivalent Cd/Ni clathrate (middle spectrum of Fig. 1). The broader line at 225 ppm matches the line observed at 217.6 ppm in the Cd/Ni clathrate and is thus assigned to the distorted octahedral $Cd(N)_6$. The much sharper line at 348.2 ppm must then be assigned to the distorted tetrahedral $Cd(C)_4$. This is in accord with the known structure which is ordered (6). Similar assignments may be made for the two major lines in the spectrum of $Cd(en)Cd(CN)_4$ whose structure also has distinct $Cd(N)_6$ and $Cd(C)_4$ (6). The weaker line at 337 ppm in this spectrum is presumed to be due to impurity.

The spectra of $Cd(CN)_2$ and the clathrate $Cd(CN)_2 \cdot C_6H_{12}$ proved to be of greater interest, Fig. 3. The isostructural

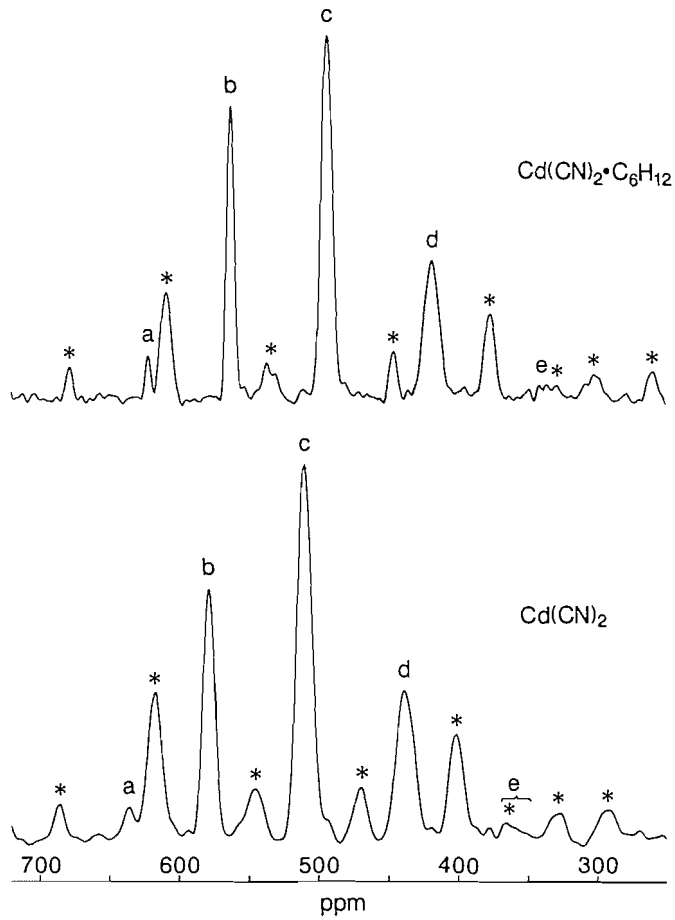

FIG. 3. ^{113}Cd MAS spectra of $Cd(CN)_2 \cdot C_6H_{12}$ and $Cd(CN)_2$. The five lines indicated correspond to *a*, CdC_4; *b*, CdC_3N; *c*, CdC_2N_2; *d*, $CdCN_3$; and *e*, CdN_4 (* indicates spinning side bands).

clathrate $Cd(CN)_2 \cdot CCl_4$ is one clathrate for which the X-ray structural studies failed to distinguish the C and N atoms of the cyanide groups (14) and the C_6H_{12} clathrate is presumed to behave in the same way. Its ^{113}Cd NMR spectrum shows five distinguishable resonances, each with its manifold of spinning sidebands. Four lines are resolved and the presence of the fifth becomes evident on close inspection when all the sidebands have been accounted for. After consideration of the different structural possibilities compatible with the X-ray data, it becomes quite clear that the five lines are unequivocal evidence for *static disorder* of the CN groups. (*1*) Ordered structure: $Cd(C)_4$ and $Cd(N)_4$ would give rise to two resonances of equal intensity. (*2*) Static disorder: distribution of C, N about each Cd would give CdC_4, CdC_3N, CdC_2N_2, $CdCN_3$, CdN_4 and therefore five resonances of various intensities. Spatial averaging would mean that X-ray structure determination could not distinguish C and N. (*3*) Dynamic disorder: rapid reorientation of cyano groups would produce a situation where, on time average, each site has $\frac{1}{2}N + \frac{1}{2}C$ and all Cd are equivalent on the NMR timescale. This would give one resonance.

Four of the five resonances can also be found directly in the spectrum of $Cd(CN)_2$ and like the clathrate, the fifth is broad and overlapped by a spinning sideband. There can be no doubt that this material also has a static disorder of the CN groups. Shugam and Zhdanov (20) reported the crystal structure of $Cd(CN)_2$ which was analyzed by the powder X-ray diffraction method. They applied space group $P\bar{4}3m$ ($Z = 2$) to the crystal assuming an isomorphism with $Zn(CN)_2$ (21). In the symmetry of $P\bar{4}3m$

*Shifts relative to $Cd(NO_3)_2 \cdot 4H_2O$; en = ethylenediamine, $NH_2CH_2CH_2NH_2$; tma = trimethylamine, $(CH_3)_3N$; shifts in parentheses ( ) are weak lines of decomposition products or impurities.
†Estimated values.

there are inevitably two kinds of Cd atoms and four C and N atoms in one unit cell. Namely, their result suggests the ordered structure. A recent single crystal study (22) indicated the same structure, *but* the authors remark that they were unable to conclusively distinguish the C and N atoms. However, in an even more recent X-ray diffraction study of single crystal $Cd(CN)_2$ (23) the space group was found to be $Pn\bar{3}m$ ($Z = 2$). This means there is one kind of Cd atom and no distinction between C and N atoms. This result suggests the static disorder of the CN groups and supports our NMR result.

Since both structures are statically disordered they are in fact also orientational glasses. The alkali metal cyanides, NaCN and KCN, show dynamic disorder of the CN^- ions in their room temperature cubic phases, but, on cooling, their first non-cubic phases (orthorhombic) are orientational glasses in which the CN are aligned but are disordered with respect to a head and tail sequence (24). Since the NMR results indicate that in $Cd(CN)_2$ and its clathrate the CN are static on the NMR timescale (*i.e.*, reorientation must be slower than 10^{-4} Hz) at room temperature, the next questions that come to mind are whether the CN begin to reorientate at higher temperatures and whether there might be a transition to a phase with dynamic disorder. A calorimetric scan on the $Cd(CN)_2$ sample indicated no transitions between room temperature and 400 K. Unfortunately, the clathrate loses the cyclohexane guest a little above room temperature. Room temperature MAS spectra were obtained of samples of $Cd(CN)_2$ and the clathrate which had been cooled to 77 K for about 20 min and of $Cd(CN)_2$ which had been heated to 450 K for about 10 min. There were no significant changes following thermal treatment. This suggests either (*a*) rapid equilibration at room temperature or (*b*) reorientation is so slow even at 456 K that is has no effect on the frozen-in disorder.

When the spectra in Fig. 3 are inspected more closely it is found that the linewidths decrease downfield. (The separation between the peaks also decreases downfield.) Assuming that CdC_4 has the largest downfield shift and CdN_4 the smallest, by analogy with the results in Fig. 2, the most likely explanation of the changing linewidths is a cumulative broadening effect due to the N atoms. There are two probable contributors to this broadening: (*a*) The major factor is likely to be unresolved ^{113}Cd—^{14}N spin–spin coupling. J couplings between ^{113}Cd and ^{15}N, of the order of 137–190 Hz, have been observed in a number of materials (8). (*b*) The ^{113}Cd—^{14}N dipole–dipole interaction is not completely removed by MAS due to interactions with the ^{14}N nuclear quadrupole (*cf.* the same effect in ^{13}C NMR (25)). The five resonances can then logically be assigned assuming progressively fewer C atoms towards the high field end.

Table 2 lists the intensities of the five lines observed in the $Cd(CN)_2$ clathrate spectrum, including the contributions of the spinning sidebands. If the distribution of C and N atoms were entirely random the statistical distribution of species indicated in the table would be expected. Clearly there is an enhancement of the CdC_2N_2 species relative to the others. This can only happen if there are energy differences between the five species. The observed distribution is then the product of the statistical distribution and a Boltzmann factor. The sample was prepared at 279 K, but the spectrum was obtained at 297 K. Presently we do not know whether the material could have annealed over a period of time to an equilibrium distribution at 297 K or whether the 279 K distribution remained frozen in. Consequently the energy differences have been calculated for both temperatures. The differences between the two sets are not large. The results show that when all Cd are four coordinated by CN the CdC_4 and CdN_4 species are energetically the least favoured.

Finally, we also note that underlying the range of observed shifts there seems to be a rough correlation of the shifts with the

TABLE 2. Intensity distribution of the five lines in the $Cd(CN)_2 \cdot C_6H_{12}$ clathrate spectrum

Cd coordination	Statistical distribution %	Observed distribution %	ΔE relative to C_2N_2 (kJ/mol) Equilib. 279 K	Equilib. 297 K
C_4	6.25	2.0	3.32	3.54
C_3N	25	22.8	0.90	0.95
C_2N_2	37.5	50.3	0	0
CN_3	25	23.2	0.86	0.91
N_4	6.25	1.7	3.70	3.94

average distance from Cd to N or C atoms; the closer the atoms the further downfield the shift. This is certainly true for a comparison between Cd with C atoms and with N atoms, where the Cd—C distances are generally more than 0.1 Å shorter than Cd—N. The known and some estimated average distances are indicated in Table 1. Cd—C and Cd—N distances of 2.095 and 2.211 Å, respectively, were estimated for the $Cd(CN)_2 \cdot C_6H_{12}$ clathrate assuming Cd—N to be 0.116 Å longer than Cd—C (the average of the difference found in the other Cd—C≡N—Cd compounds). Correlations have been sought previously between the chemical shift tensor or the isotropic shift and various coordinate bond parameters (reviewed in ref. 8). In one such study no obvious correlation was found between average Cd—O distances and the isotropic shifts, whereas one was found between bonding distance anisotropies and the chemical shift anisotropy (26). Another study concluded that bond length dispersion, local site symmetry, and ligand type *all* contribute to the chemical shift anisotropy (8, 27, 28). Thus it is clear that, in general, correlations are not straightforward.

To conclude, it can be seen that ^{113}Cd NMR is a very sensitive means of distinguishing different Cd sites in Hofmann-type clathrates and related solids. It has provided unequivocal evidence that $Cd(CN)_2$ and its cyclohexane clathrate are orientational glasses with respect to CN group disorder. Furthermore, it would be of interest to use ^{113}Cd NMR to study the disorder implied in several other Cd–ligand–Cd–cyano complexes which have recently been found to have indistinguishable C and N atoms in X-ray diffraction studies (7, 23).

Alkyne and alkene complexes of (tetramesitylporphyrinato)ruthenium(II)

NIMAL RAJAPAKSE, BRIAN R. JAMES,[1] AND DAVID DOLPHIN
Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received June 2, 1990

NIMAL RAJAPAKSE, BRIAN R. JAMES, and DAVID DOLPHIN. Can. J. Chem. **68**, 2274 (1990).

The reactions of benzene or toluene solutions of Ru^{II}(TMP), where TMP is the dianion of 5,10,15,20 – tetramesitylporphyrin, with some acetylenes and alkenes are reported. Acetylene yields the isolable $[Ru(TMP)]_2(\mu\text{-}C_2H_2)$ species; while with phenylacetylene or diphenylacetylene, 1:1 π-complexes are formed. The π-complexes $Ru(TMP)(C_2H_4)$ and $Ru(TMP)(C_2H_4)(^iPrOH)\cdot{}^iPrOH$ are isolated from reactions with ethylene, and a similar cyclohexene species is characterized *in situ*. The findings are relevant to O_2-epoxidation of alkenes catalyzed by the *trans*-$Ru(TMP)(O)_2$ complex.

Key words: ruthenium, porphyrin (tetramesityl), alkene complexes, alkyne complexes.

NIMAL RAJAPAKSE, BRIAN R. JAMES et DAVID DOLPHIN. Can. J. Chem. **68**, 2274 (1990).

On a examiné les réactions des quelques acétylènes et alcènes avec des solutions de Ru^{II}(TMP) (dans lequel TMP est le dianion de la 5,10,15,20-tétramésitylporphyrine) dans le benzène ou le toluène. L'acétylène fournit des espèces $[Ru(TMP)]_2(\mu\text{-}C_2H_2)$ qui peuvent être isolées; avec le phénylacétylène ou le diphénylacétylène, il se forme des complexes-π 1:1. On a isolé les complexes-π $Ru(TMP)(C_2H_4)$ et $Ru(TMP)(C_2H_4)(^iPrOH)\cdot{}^iPrOH$ à partir des réactions avec l'éthylène; on a aussi caractérisé *in situ* un espèce semblable qui se forme lors de la réaction avec le cyclohexène. Ces résultats sont utiles dans la compréhension de l'époxydation des alcènes par le O_2 catalysé par le complexe *trans*-$Ru(TMP)(O)_2$.

Mot clés : ruthénium, porphyrine (tétramésityl), complexes d'alcènes, complexes d'alcynes.

[Traduit par la revue]

Introduction

The organometallic chemistry of ruthenium porphyrins has developed in recent years (1–6), and is particularly of current interest because of reports on the catalytic O_2-oxygenation of unsaturated and saturated hydrocarbons using *trans*-dioxo complexes of sterically hindered derivatives of ruthenium porphyrins (7–10). The interaction of ruthenium porphyrins with ethylene has been studied, and the Ru(porp)(THF)(η^2-C_2H_4) species (porp = OEP, TPP)[2] characterized (3, 11), but there are no other reports on reactions with alkynes or other alkenes. In the more general area of metalloporphyrin chemistry, the only alkyne π-complex reported to date is Mo(TTP)(PhC≡CPh) (12), while the reaction of $[Rh(OEP)]_2$ with RC≡CH (R = H, Ph) yields $[Rh(OPE)]_2(\mu\text{-CRCH})$ species (13).

In the present work, the reactions of the Ru(TMP) complex (14, 15) with acetylene, phenylacetylene, diphenylacetylene, ethylene, and cyclohexene are studied, and organometallic products are prepared and characterized.

Experimental procedure

Bis-dinitrogen(tetramesitylporphyrinato)ruthenium(II), Ru(TMP)$(N_2)_2$ was synthesized according to the literature procedure (14, 15). Carbon monoxide and ethylene impurities in acetylene (Matheson) were removed by three freeze–pump–thaw cycles at −130°C using an *n*-pentane/liquid N_2 slush-bath. The phenylacetylenes were used as received from Aldrich Chemicals. Ethylene (Matheson) was dried by passing through an Aquasorb tube (Mallinckdrodt). The ^1H and $^{13}C\{^1H\}$ NMR data for the complexes were measured on a Varian XL-300 MHz instrument (FT mode), and the former are given in Table 1. The molecular weight of the bridged acetylene complex was determined by the Signer method (16), using CH_2Cl_2 as solvent.

Bis(tetramesitylporphyrinato)ruthenium(II)–(μ-acetylene), 1

Some Ru(TMP)$(N_2)_2$ (8 mg, 8.8×10^{-3} mmol) was dissolved in benzene (1 mL) under an N_2 atmosphere and degassed by three freeze–pump–thaw cycles. The resulting dark brown solution was exposed to acetylene (1 atm) and shaken. Upon being left under room light for 16 h, the solution turned greenish-black. The solvent was then removed by evacuation and the resulting black solid vacuum-dried (10^{-3} mm Hg) for 24 h at 25°C; yield 8 mg, 100%. *Anal.* Calcd. for $C_{114}H_{106}N_6Ru_2$: C 76.48, H 5.97, N 6.25; Found: C 76.1, H 6.0, N 6.4. Mol. wt.: 1565, calcd. for $[Ru(TMP)]_2(\mu\text{-}C_2H_2)$ 1790 g mol^{-1}. NMR (C_6D_6): $^{13}\{^1H\}$ (see Fig. 1): 263.8 (Ru═C); 144.5 (α-C); 139.1, 138.7, 138.2, 137.3 (the mesityl carbons 2,3,5,7 with no attached H); 130.6 (β-C); 128.0 (the mesityl carbons 4,6 with 1 attached H — obscured by benzene peaks in Fig. 1*A*); 119.8 (*meso*-C 1); 24.0 (*p*-Me, C 9); 21.4, 21.3 (*o*-Me, C 8, C 10). ^{13}C[gated ^{1}H-decoupled]: the 263.8 resonance gives a doublet at 262.7 and 265.0.

Diphenylacetylene(tetramesitylporphyrinato)ruthenium(II)

In an N_2-filled glove-box, Ru(TMP)$(N_2)_2$ (3 mg, 3.3×10^{-3} mmol) and PhC≡CPh (1.2 mg, 6.7×10^{-3} mmol) were placed in an NMR tube fitted with an attachment to a vacuum-line. The tube was removed from the glove-box, and C_6D_6 (0.5 mL) added by vacuum transfer to the NMR tube cooled in liquid N_2; the tube was subsequently flame-sealed. The *in situ* species formed within 10 min.

Phenylacetylene(tetramesitylporphyrinato)ruthenium(II)

An *in situ* sample of this species was prepared using the procedure described above for the diphenylacetylene species, but using instead PhC≡CH.

Ethylene(tetramesitylporphyrinato)ruthenium(II)

Some Ru(TMP)$(N_2)_2$ (5 mg, 5.5×10^{-3} mmol) was dissolved in benzene (1 mL) and the solution degassed as described above. The solution was then exposed to 1 atm C_2H_4 with shaking for 5 min. The mixture was then evacuated to dryness and the product isolated in near quantitative yield. *Anal.* calcd. for $C_{58}H_{56}N_4Ru$: C 76.54, H 6.20, N 6.16; found: C 75.8, H 6.4, N 6.1.

Ethylene(2-propanol)(tetramesitylporphyrinato)ruthenium(II)·2-propanol

Some Ru(TMP)$(N_2)_2$ (8 mg, 8.8×10^{-3} mmol) was dissolved in THF (1 mL) and the solution degassed as described above. The resulting dark brown solution was then exposed to 1 atm C_2H_4 for 5 min. 2-Propanol (1 mL) was then vacuum transferred to the THF solution. The brown powder which precipitated overnight was filtered and dried under Ar; yield 5 mg, 60%. *Anal.* calcd. for $C_{64}H_{74}N_4O_2Ru$: C 74.60, H 7.04, N 5.44; found: C 73.7, H 6.9, N 5.4.

TABLE 1. ^{1}H NMR data for Ru(TMP)-acetylene and -alkene derivatives[a]

Complex	Porphyrin ligand[b]				Axial ligand
	Pyrrole-H	*m*-H	*p*-Me	*o*-Me	
$[Ru]_2(\mu\text{-}C_2H_2)$	7.92	7.15, 6.92	2.39	1.91, 1.32	10.44 s (Ru=C—H)
Ru(PhC≡CH)	8.75	7.22, 7.08	2.45	2.23, 1.78	4.00 m (*o*-, *m*-, *p*-H), −7.40 s (≡C—H)
Ru(PhC≡CPh)	8.35	7.20,[c] 7.15	2.40	1.95, 1.70	6.58 t (*p*-H), 6.37 m (*m*-H), 5.00 d (*o*-H)
$Ru(C_2H_4)$[d]	8.44	7.20, 7.10	2.45	2.16, 1.89	−3.27 s (CH_2CH_2)
$Ru(C_2H_4)(^i\text{PrOH})\cdot{}^i\text{PrOH}$[e]	8.57	7.18,[c] 7.13	2.46	2.12, 2.13	−3.11 s (CH_2CH_2); 3.40 m (C—H), 0.73 d (CH_3) 0.00 br s (OH)
$Ru(C_6H_{10})$	8.50	7.18[e,f]	2.45	2.10[f]	4.72 m (*CH*=*CH*), 1.55 m (CH_2CH=CHCH_2), 1.24 m ($CH_2CH_2CH_2CH_2$)

[a]Shifts in ppm relative to TMS. In C_6D_6 *in vacuo* at room temperature, unless stated otherwise; s = singlet, d = doublet, t = triplet, m = multiplet, br = broad. The integrations in each case are consistent with the proposed formulations. *Ru* = Ru(TMP).

[b]All porphyrin ligand resonances are singlets.

[c]Resonance hidden under residual solvent peak.

[d]In toluene-d_8

[e]The resonances listed for the axial PrOH are averaged signals because of exchange with free PrOH present; for free PrOH, δ = 4.0 m (CH), 1.6 br (OH), 1.2 d (CH_3).

[f]Single resonances observed for *m*-H and *o*-Me instead of expected two, because of cyclohexene ligand exchange (see text); the cyclohexene signals are also averaged between those of the coordinated and free alkene, the latter appearing at δ 5.70 m (*CH*=*CH*), 1.95 m (CH_2CH=CHCH_2), and 1.52 m ($CH_2CH_2CH_2CH_2$). Resonances for the coordinated cyclohexene were obtained by measuring (in the absence of excess alkene) the spectrum of a solution of an isolated, impure, solid product containing some Ru(TMP)(C_6H_{10}): −1.08 m ($CH_2CH_2CH_2CH_2$), −1.75 m (CH_2CH=CHCH_2), −3.15 m (*CH*=*CH*).

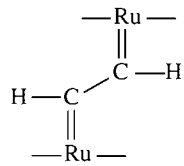
Cyclohexene(tetramesitylporphyrinato)ruthenium(II)

The species was prepared *in situ* by vacuum transferring excess cyclohexene (1 μL, ~10^{-2} mmol) into a solution of Ru(TMP) prepared by degassing a benzene solution (1 mL) of Ru(TMP)(N_2)$_2$ (3 mg, 3.3 × 10^{-3} mmol).

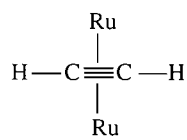
Results and discussions

The greenish-black complex isolated from the reaction of Ru(TMP) with acetylene is formulated as [Ru(TMP)]$_2$(μ-C_2H_2), **1**. The low-field ^{1}H NMR signal at δ 10.44, which integrates for one proton per Ru(TMP) moiety, is typical of a (porp)Ru=C—H proton (5). Based on data for the phenylacetylene complex (see below), a π-bonded acetylene complex is expected to be reddish-brown and give an acetylene proton signal at about −7 ppm. Further, the ^{13}C[^{1}H] signal (Fig. 1*A*) at 263.8 ppm is characteristic of a metal carbene complex (17). The results of an NMR attached-proton-test (APT) experiment (Fig. 1*B*) show that the carbene-type carbon atom contains either one or three protons, while in a ^{13}C NMR gated-proton-decoupled spectrum the singlet at 263.8 ppm splits to a doublet, confirming that only one proton is attached. The molecular weight calculated from data obtained by the Signer method (16) is consistent with the dinuclear formulation. Another possible structure, **2**, is considered much less likely because of steric problems created by the *ortho*-methyl groups of the TMP ligand: models suggest this, and the situation is analogous to the TMP ligand preventing the unwanted formation of the μ-oxo dinuclear species in the catalytic O_2-oxygenation work (7–10). In the related rhodium complex [Rh(OEP)]$_2$ (μ-C_2H_2), the acetylene proton resonance is observed at δ −9.92, very different to the data for **1**; the species was formulated as a Rh—CH=CH—Rh unit (13).

It is worth noting that formation of **1** appears to require at least laboratory light to proceed, the C_2H_2 reaction being arrested in the dark (for example, in the NMR probe). Treatment of solutions of **1** with 1 atm CO or phosphites readily liberates the C_2H_2 (seen at δ 1.48 in C_6D_6) and the corresponding Ru(TMP)$(CO)_2$ (14) or Ru(TMP)[$P(OR)_3$]$_2$ (18, 19) species.



1



2

In contrast to C_2H_2 itself, PhC≡CPh and PhC≡CH form 1:1 π-complexes with Ru(TMP). The coordinated PhC≡CPh ligand gives rise to three ^{1}H NMR signals (Table 1); the *o*-phenyl protons appear at 5.00 ppm and are shifted upfield by about 1.5 ppm compared to the *m*- and *p*-protons, perhaps because of a bending of the phenyl groups away from the porphyrin plane. Such bending is evident in the Mo(TTP)(PhC≡CPh) structure, where the Ph—C≡C angles are found to be 145° and 136° by X-ray crystallography (12). In the Ru(TMP)(PhC≡CH) species, all the acetylene phenyl protons appear further upfield as a multiplet at 4.00 ppm, implying less bending and "more equivalence" among the phenyl protons that are now closer to the porphyrin ring-current; the ≡C—H proton is seen at −7.40 ppm, an upfield shift of 8.55 ppm from the corresponding peak of the free ligand.

In the two isolated ethylene complexes, the upfield shift of the single C_2H_4 resonance due to the porphyrin ring-current is ~8.4 ppm, which compares well with the values reported for Ru(porp)(C_2H_4)(THF) complexes (porp = OEP, TPP) (5). The C-analyses for the ethylene complexes are somewhat unsatisfactory, but problems with elemental analyses of metallopor-

phyrins are not uncommon; the ^{1}H NMR data leave no doubt as to the identity of the complexes. The resonances listed for the axial 2-propanol ligand (Table 1) are averaged signals resulting from exchange with the solvate alcohol.

The Ru(TMP)(cyclohexene) species is observed *in situ* but attempts to isolate this complex resulted in partial loss of the alkene ligand during the work-up procedures. The ^{1}H NMR data for the porphyrin ligand are essentially the same for all the alkene systems; however, only one peak each for the *m*-H and the *o*-Me protons is observed for the cyclohexene species and, coupled with the observation of only one set of broad ^{1}H NMR signals for the alkene ligand in the *in situ* system, there is clearly rapid exchange between free and coordinated cyclohexene. Also, the ^{1}H NMR data for solutions of the C_2H_4 complexes under an atmosphere of C_2H_4 now show a single, averaged, broad resonance at 5.3 ppm, close to that of free C_2H_4; with decreasing concentration of C_2H_4 in the solution, the signal gradually moves upfield towards that of the coordinated C_2H_4 at δ −3.27. Some NMR data for the coordinated cyclohexene were obtained from an impure sample of Ru(TMP)(C_6H_{10}) (Table 1), and the olefinic resonance is seen at δ −3.15, close to that of the coordinated ethylene signal.

The Ru(TMP)(C_2H_4) complex was stable to loss of C_2H_4 on subjection to a 10^{-3} mm Hg vacuum at 20°C for several hours; in solution, the complex on exposure to air or air/C_2H_4 mixtures led to rapid formation of *trans*-Ru(TMP)$(O)_2$ (7, 9, 14), which is thus clearly more stable thermodynamically than the C_2H_4 complex or the Ru(TMP)$(N_2)_n$ complexes (n = 1, 2), the latter readily being formed under N_2 atmospheres (14, 15). Under the conditions of catalytic O_2- or aerobic-epoxidation of alkenes using Ru(TMP)L_2 precursors (L = MeCN, THF), the catalysis operating via the Ru(TMP)$(O)_2$ species (7–10), there will be a competition between O_2 and alkene for the metal site. The situation is somewhat akin to that in catalytic homogeneous hydrogenation of alkenes, which can occur via so-called "hydride" or "unsaturate" routes depending on whether the H_2 or alkene interacts initially with the metal (20); in most cases, however, hydridoalkene intermediates are eventually formed, although steps involving H-atom transfer from a metal to non-coordinated alkene (as in the net alkene epoxidation) have been established in a few systems (20).

PIERRE D. HARVEY, LIANGBING GAN, and CHRISTIANE AUBRY. Can. J. Chem. **68**, 2278 (1990).

Four diarylideneacetone compounds ($(RCHCH)_2CO$, where the aryl groups are phenyl (dba), 1-naphthyl (1-dNapha), 2-naphthyl (2-dNapha), and 3-(*N*-ethylcarbazoyl) (dNECa)), and $4\text{-}(C_5H_5)Fe(C_5H_4C_6H_4CHCH(CO)CHCH(C_6H_5)$ (dba-Fc) have been prepared and characterized. The compounds are found to be fluorescent and photochemically and reversibly electrochemically active. The lowest-energy absorption bands for the diarylideneacetones are assigned to a charge transfer (CT) electronic transition, except for dba-Fc, in which a ferrocenyl ligand field transition assignment is made. The 77 K CT absorption and fluorescence bands are vibrationally structured (vibrational spacings = 1260–1360 cm^{-1}). While the fluorescence decay at 293 K is monoexponential, the excited state fluorescence lifetimes (τ_F) for the 77 K samples exhibit double exponential decays, the short component being 0.38–0.64 ns and the long one 3.5–10.9 ns. The photophysical results are interpreted in terms of excited state deactivation processes dominated by radiationless pathways that are associated with the presence of fluorescent species with different geometries. Only the dNECa compound is found to be fluorescent in solution at 298 K (τ_F = 1.65 ns; ϕ_F = 0.39 ± 0.02). Cyclic voltammetry and coulometry measurements suggest that a reversible one-electron reduction process and an irreversible higher potential one-electron reduction process take place in the −1 to −2 V vs. SSCE range. In addition, dba-Fc also exhibits an electrochemically reversible one-electron oxidation wave at 0.52 V vs. SSCE centered at the ferrocenyl group. These results together with the spectroscopic electronic data have permitted evaluation of the reduction potentials of the lowest singlet (CT excited states ($E^{1-/*}$); they range from 1.4 to 2.2 V vs. SSCE, with dba being the strongest photooxidizing agent and dNECa the weakest. Photoinduced intermolecular electron transfer reactions have been investigated by steady state fluorescence techniques and picosecond flash photolysis spectroscopy for dNECa and dba, respectively. The bimolecular deactivation rate constants, k_q, for the reductive photoinduced electron transfer reactions of dNECa with diphenylamine (DPA) (k_q = (2.65 ± 0.25) × 10^7 M^{-1} s^{-1}) and *N,N,N',N'*-tetramethylphenylenediamine (TMPM) (k_q = (1.38 ± 0.03) × 10^8 M^{-1} s^{-1}) have been obtained in THF solutions at 293 K. No fluorescence quenching is observed when oxidative and energy transfer quenchers are used with dNECa. For the non-emissive dba compound at room temperature, picosecond flash photolysis experiments show that quenching of the broad dba transient band (~500 nm) does indeed occur between 5 and 10 ns.

Key words: dibenzylideneacetone, charge transfer, photoelectron transfer.

PIERRE D. HARVEY, LIANGBING GAN et CHRISTIANE AUBRY. Can. J. Chem. **68**, 2278 (1990).

Quatre ligands diarylidineacétones ($(RCHCH)_2CO$ où les groupes aryles sont phényl- (dba), 1-naphtyl- (1-dNapha), 2-naphtyl- (2-dNapha) et 3-(*N*-éthylcarbazoyl)- (dNECa)), et $4\text{-}(C_5H_5)Fe(C_5H_4C_6H_4CHCH(CO)CHCH(C_6H_5)$ (dba-Fc) ont été préparés et caractérisés. Les composés sont fluorescents, photo- et réversiblement électrochimiquement actifs. Les bandes d'absorption de plus basse énergie pour les composés diarylidèneacétones sont attribuées à un transfert de charge (CT), excepté pour dba-Fc pour lequel une attribution de champ de ligand localisé au groupe ferrocényle a été faite. Les bandes d'absorption et de fluorescence CT sont vibrationnellement structurées (espacements vibrationnels = 1260–1360 cm^{-1}). Contrairement aux données obtenues à 293 K, les durées de vie de fluorescence (τ_F) pour tous les échantillons à 77 K montrent une double décroissance exponentielle; la composante de courte durée est 0.38–0.64 ns et la composante de plus longue durée est 3.5–10.9 ns. Les résultats photophysiques sont interprétés par des processus de désactivation des états excités qui sont dominés par des chemins non-radiatifs associés à la présence d'espèces fluorescentes de géométries différentes. Seul le dNECa est fluorescent en solution à 298 K (τ_F = 1.65 ns; ϕ_F = 0.39 ± 0.02). Les mesures de voltamétrie cyclique et de coulométrie suggèrent qu'un processus réversible de réduction d'un électron survient à bas potentiel et qu'un processus irréversible (1 électron) survient à plus haut potentiel négatif dans la région de −1 à −2 V vs. SSCE. De plus, le dba-Fc montre une vague d'oxydation de 1 électron à 0.52 V vs. SSCE électrochimiquement réversible et centrée au groupe ferrocényle. Ces résultats et les données spectroscopiques ont permis l'évaluation des potentiels redox ($E^{1-/*}$) des états singulets CT de plus basse énergie; ils se situent dans la région de 1.4 à 2.2 V vs. SSCE, le dba étant le plus puissant photooxydant et dNECa le plus faible. Les réactions de photo-transfert d'électron intermoléculaires ont été étudiées par les techniques d'état stationnaire de fluorescence et par spectroscopie photolyse éclair picoseconde pour le dNECA et le dba respectivement. Les constantes de désactivation bimoléculaire, k_q, pour les photo-transferts d'électron du dNECa avec la diphénylamine (DPA) (k_q = (2.65 ± 0.25) × 10^7 M^{-1} s^{-1}) et *N,N,N',N'*-tétraméthylphénylenediamine (TMPM) (k_q = (1.38 ± 0.03) × 10^8 M^{-1} s^{-1}) sont obtenues dans les solutions de TMF à 293 K. Aucune désactivation de la fluorescence du dNECa n'est observée lorsque des désactivateurs de type oxydant et de transfert d'énergie sont employés. Aucun quenching de la fluorescence n'est observé pour le dNECa lorsque les désactivateurs sont du type de transfert d'énergie ou oxydant. Pour le composé non-luminescent dba à la température ambiante, les expériences de photolyse éclair picoseconde montrent un effet quenching de la bande large transitoire du dba (~500 nm) par le désactivateur réducteur DPA dans la région entre 5 et 10 ns.

Mots clés : dibenzylidèneacétone, transfert de charge, photo-transfert d'électron.

Introduction

The cross-conjugated dibenzylideneacetone (dba; see structure in Scheme 1) is a commonly used ligand capable of stablizing various organometallic compounds (1). More particularly, binuclear complexes of Pd(0) and Pt(0) of the type $M_2(dba)_3$ have been prepared in which weak metal–metal interactions are present in the ground state (2). Recently, electronic absorption, emission, and excitation spectra and excited state lifetimes (τ_e) of the $M_2(dba)_3$ complexes have been reported (3, 4). These complexes appear to be photochemically inert toward oxidative addition reactions in the presence of chlorinated hydrocarbons (CH_2Cl_2, $CHCl_3$, and $ClCH_2CH_2Cl$) and oxygen.[2] These results suggest that the lowest triplet excited state (^{3}MLCT*) is a relatively poor reducing agent. The redox properties of this excited state are consistent with these findings; $E^{0+/*}(^3\text{MLCT}^*) = -0.33$ V vs. SSCE.[2] In an attempt to tune photoreactivity in these organotransition binuclear complexes, electroactive (5) and chromophoric groups have been attached to the organic bridging moiety (CH=CH (CO) CH=CH). There are many examples of changes in spectroscopic properties and reactivity changes induced in a metal center by reduction of a redox-active substituent (6). Hypothetically, appropriate chromophoric pendent groups should also be capable of mediating either electron or energy transfer reactions with the bimetallic centers.

In the first part of this paper, we wish to report a detailed characterization of the electronic excited state properties of some diarylideneacetone compounds (see structures in Scheme 1) in which the chromophoric aryl groups possess various known ground and excited state redox and photophysical behaviors. The selected substituents are the phenyl (dba), 1-naphthyl (1-dNapha), 2-naphthyl (2-dNapha), and 3-(*N*-ethylcarbazoyl) (dNECa) groups. In these cases, the aryl-localized excited states are expected to be $\pi\pi^*$ in nature (7–11) but, in the dba case, the CO between the styrenyl groups gives rise to the possibility of a relatively low-energy $n\pi^*$ state (7). However, it will be shown unambiguously that the lowest singlet excited states are CT states in which the aryl groups are the donors and the $(CH{=}CH)_2CO$ group is the acceptor.

In the second part of this paper, it will be shown from electrochemistry, coulometry, and spectroscopic data that the CT states should be efficient *photooxidizing agents*. Indeed, steady state fluorescence techniques (for dNECa) and picosecond flash photolysis spectroscopy (for dba) are used to show that fluorescence quenching occurs *only* when reductive quenchers are used with dNECa and that transient absorptions for dba vanish with the same quenchers.

To our knowledge, there are no spectroscopic, electrochemical, or photophysical data on the compounds, except for the model molecule, dba, for which only a few superficial investigations have been reported (3, 12). To pursue research on the photochemistry of triply bridged binuclear compounds with dba type ligands, a better understanding of the excited state properties of the ligands themselves is necessary.

Experimental

Chemicals

Benzaldehyde, 1- and 2-naphthaldehyde, 3-(*N*-ethylcarbazyl)aldehyde (NEC-3-CHO), and polymethyl methacrylate (PMMA; Aldrich Chemical Co.) were used as received. 9,10-Diphenylanthracene was used as a standard for emission quantum yield measurements (ϕ_F = 1.0) (13); it was purified by repeated sublimation. Acetone, ethanol, methylene chloride, carbon tetrachloride, methylene iodide, iodoform (Anachemia), tetrahydrofuran (THF), and 2-methyltetrahydrofuran (2MeTHF; Aldrich Chemical Co.) were purified according to standard procedures (14). The spectrograde solvents benzene, ethyl acetate, acetone, ethyl ether, and chloroform (Fisher) were used as received; purity was checked by UV–VIS spectroscopy. Chloroform-*d* and benzene-d_6 (Aldrich Chemical Co.) were used as received. The solid quenchers (Aldrich Chemical Co.) anthracene, naphthalene, biphenyl, *N,N,N',N'*-tetramethylphenylenediamine (TMPM), and diphenylamine (DPA) were purified by repeated fractional sublimation and were kept in the dark when not in use. Methyl viologen dichloride (Aldrich Chemical Co.) was purified by recrystallization from ethanol, and $S_2O_8Na_2$ (Anachemia) was used as received. Tetra-*n*-butylammonium hexafluorophosphate ($TBAPF_6$; Aldrich Chemical Co.) was recrystallized three times from ethanol. All samples were degassed either by bubbling Ar(g) through the solution or by freeze–pump–thaw methods.

Instrumentation

The ^{1}H and ^{13}C NMR spectra were obtained on a Bruker WM 250-MHz spectrometer at 293 K. The mass spectra were collected on a VGZAB-1F spectrometer in EI mode at 70 eV. The FT-IR spectra were measured on a BOMEM DA 3.002 spectrometer. The UV–VIS spectra at 298 K were acquired on a Perkin–Elmer Lambda or a Cary model 14 (Varian) spectrometer using standard 1 cm^2 quartz cuvettes. The 77 K UV–VIS spectra were obtained using a low-temperature cell (pathlength = 1.0 cm) and a Cary model 14 (Varian) spectrophotometer. The spectra were all corrected for baseline deviation and glass contraction. The emission spectra measurements were made on a Spex double monochromator Fluorolog model 1902 instrument; the source was a 500-W HgXe high-pressure lamp. The 298 K measurements were made using air-tight 1 cm^2 quartz cells, while the 77 K experiments were performed using a low-temperature EPR quartz Dewar (Wilmad Glass Co.) and cylindrical quartz tubes. The excitation spectra were automatically corrected by the instrument while emission spectra were manually corrected at every 1 nm for the spectrophotomer response using standard lamp corrections. In all 77 K experiments, the bandpasses were 2 nm for both excitation and emission slits. Fluorescence lifetime measurements were performed on a homemade photon counting system; a complete description of the instrument and testing for multiple exponential deconvolution fits and procedures is given elsewhere (15). The 298 and 77 K measurements were performed with the same spectrofluorimetric cell setups as used for the measurements of fluorescence spectra mentioned above.

The Raman spectra were measured on an Instruments S.A. Raman spectrometer equipped with a U-1000 Jobin–Yvon 1.0 double monochromator using the 647.1 nm red line and the 514.5 nm green line of Spectra-Physics krypton and argon ion lasers, respectively, for excitation. All electrochemical measurements were performed with a PAR 173 potentiostat and a PAR 175 universal programmer. Pt disk electrodes (0.5 mm diameter) were polished with alumina (5 μm size) for 5 min in 1:1 CH_3OH/H_2O before use. Different electrochemical cells were used for the cyclic voltammetric and coulometric measurements. The cyclic voltammetric cell was a one-compartment cell (2 cm diameter) in which the working, the Pt (1 cm × 1 cm) gauze auxiliary, and the SSCE reference electrodes were inserted. Coulometry measurements were performed in a H-cell with Pt (1 cm × 1 cm) gauze working and auxiliary electrodes. The SSCE reference electrode in the bulk electrolysis experiments was connected to the working compartment by a fritted disk and separated by a 3% agar-agar solution. The coulometry measurement setup was checked using ferrocene as a standard. The flash photolysis experiments were performed at the Picosecond Flash Photolysis Center at Concordia University. The difference absorption spectra were obtained using a pulsed Nd:YAG laser made by Quantel (fwhm ~ 30 ps). The pulsed 1062 nm laser beam was passed through a frequency doubler and tripler. The 355 nm excitation light was selected by dichroic mirrors, passed through a delay line (20–10 ns), and then used to excite the samples. Typically each excitation pulse was ~2–3 mJ. The rest of the light was passed

through dichroic mirrors to select the 1062 nm light, which was then transformed into a continuum (400–700 nm). This continuum was then used to probe the samples.

The detection system and computer hardware were a commercially available EG&G multichannel analyser model OMA 2. The data processing was performed with a Digital RT-11 computer. A more complete description of the apparatus can be found elsewhere (16). Except for the Raman, IR, and UV–VIS spectroscopic and all the 77 K measurements, all the solutions were degassed by freeze–pump–thaw methods or by Ar(g) bubbling the solutions for 30 min. It has been verified that the Ar(g) method has no effect on τ_F compared to the freeze–pump–thaw method.

ϕ_F was measured using 9,10-diphenylanthracene as a standard (ϕ_F = 1.00 ± 0.05). The complete methodology can be found in ref. 13 and references therein. The procedures involved the use of solutions with optical densities identical or nearly identical for both samples and standards in the 0.00–0.05 absorbance range. Three measurements were performed and the experimental error was set as being the difference between the average and the largest and smallest measured values.

Synthesis

Dibenzylideneacetone (dba) and di(1-naphthylidene)acetone (1-dNapha) were synthesized in quantitative yields and purified according to standard procedures outlined for dba (17*a*). Both compounds have been characterized by standard spectroscopic techniques, elemental analysis, and melting points. The data are consistent with the *trans* geometry of the α and β olefinic hydrogens (see details below). 4-Ferrocenylbenzaldehyde was prepared according to published procedures (17*b*).

Dibenzylideneacetone (dba)

Melting point 106°C (uncorrected) (lit. (17) mp 106–107°C); IR (solid state) ν_{max}: 3136 (w), 3086 (w), 3055 (m), 3030 (m), 3005 (w), 1673 (m; ν(C=O)), 1652 (s), 1625 (m), 1600 (s), 1575 (s), 1493 (m), 1450 (m), 1343 (m), 1309 (m), 1284 (w), 1259 (w), 1200 (s), 1159 (w), 1105 (m), 1083 (m), 1027 (w), 980 (s), 923 (m), 884 (m), 852 (m) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 7.09 (d, 1H, $^3J_{HH}$ = 16.0 Hz, CH_α), 7.43 (m, 3H), 7.64 (m, 2H), 7.75 (d, 2H, $^3J_{HH}$ = 16.0 Hz, CH_β); ^{13}C NMR ($CDCl_3$) δ: 125.3 ($^{13}C_\alpha H$), 128.2, 128.8, 130.3, 134.7, 143.1 ($^{13}C_\beta H$), 188.7 (^{13}CO); MS $m/e^{+\cdot}$: 234 (100), 205 (18), 131 (48), 103 (59). Anal. calcd. for $C_{17}H_{14}O$: C 87.15, H 6.02; found: C 86.79, H 6.25%.

Di(1-naphthylidene)acetone (1-dNapha)

Melting point 242°C (uncorrected); IR (solid state) ν_{max}: 3042 (vw), 1667 (s; ν(C=O)), 1617 (s), 1590 (s), 1570 (m), 1510 (w), 1403 (w), 1353 (m), 1320 (w), 1240 (w), 1117 (m), 1073 (w), 1033 (w), 980 (s), 890 (w), 800 (s), 777 (vs), 700 (w), 590 (w), 537 (w), 500 (w) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 7.25 (d, 1H, $^3J_{HH}$ = 15.7 Hz, CH_α), 7.58 (m, 3H), 7.93 (m, 3H), 8.29 (d, 1H), 8.66 (d, 1H, $^3J_{HH}$ = 15.7 Hz, CH_β); ^{13}C NMR ($CDCl_3$) δ: 123.3 ($^{13}C_\alpha H$), 125.0, 125.3, 126.1, 126.8, 128.0, 130.6, 131.5, 132.0, 133.6, 140.2 ($^{13}C_\beta H$), 188.5 (^{13}CO); MS $m/e^{+\cdot}$: 334 (51), 214 (35), 196 (80), 181 (71), 155 (100), 128 (82). Anal. calcd. for $C_{25}H_{18}O$: C 89.79, H 5.43%; found: C 88.84, H 5.60%.

Di(2-naphthylidene)acetone (2-dNapha) and di[3-(*N*-ethylcarbazoylidene)] acetone (dNECa) were synthesized according to a procedure modified from that outlined for dba (17*a*); to a cooled solution of 50 mL 1:1 ethanol/10% NaOH aqueous solution was added dropwise an ethanol-saturated solution containing 23.4 mmol of the corresponding aldehyde and 0.87 mL of acetone (11.7 mmol). The solution was stirred for 16 h. The yellow oil that formed was then separated by decantation. To the oily residue, a minimal amount of acetone (~10 mL) was added; then water was added dropwise until precipitation occurred (at a 1:1 V/V ratio of acetone and water). The yellow solid was filtered and dried *in vacuo* (10^{-6} Torr at 293 K; 1 Torr = 133.3 Pa) for 48 h. Purity was checked by TLC and no trace of the starting materials and monocondensed product (aryl-CH=CH—(CO)—CH_3) was observed. Repetitive preparation of the materials provided 3–4 g each time (60–80% yield). The spectroscopic data are consistent with the *trans* geometry of the α and β olefinic hydrogens (see details below).

Di(2-naphthylidene) acetone (2-dNapha)

Melting point 114°C (uncorrected); IR (solid state) ν_{max}: 3050 (w), 3020 (vw), 1671 (m; ν(C=O)), 1651 (s), 1627 (s), 1586 (vs), 1507 (w), 1440 (w), 1395 (w), 1370 (m), 1317 (w), 1273 (w), 1203 (w), 1192 (w), 1177 (w), 1133 (w), 1107 (m), 987 (vs), 980 (m), 915 (w), 905 (w), 890 (w), 867 (s), 827 (vs) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 7.25 (d, 1H, $^3J_{HH}$ = 15.9 Hz, CH_α), 7.54 (m, 2H), 7.84 (m, 4H), 7.95 (d, 1H, $^3J_{HH}$ = 15.9 Hz, CH_β), 8.05 (s, 1H); ^{13}C NMR δ: 123.7 ($^{13}C_\alpha H$),

Anal. calcd. for $C_{33}H_{28}N_2O$: C 84.56, H 6.02, N 5.99%; found: C 83.88, H 6.28, N 5.87%.

For the 4-ferrocenyldibenzyldeneacetone (dba-Fc) compound, the procedure was as follows: to a solution of 20 mL 1:1 ethanol/10% NaOH aqueous solution, an ethanol-saturated solution containing 1.07 g (3.69 mmol) 4-ferrocenylbenzaldehyde and 0.54 g (3.86 mmol) $CH_3(CO)CHCHC_6H_5$ was added dropwise. After stirring for 1 h, the solution was filtered to give a red solid as crude product. The product was purified by column chromatography on Al_2O_3, eluting with hexane and CH_2Cl_2, and recrystallized from benzene/hexane (1.0 g, mmol, 65%).

4-Ferrocenyldibenzylideneacetone (dba-Fc)

Results and discussion

Part I: CT states

1. Nature of the excited states

The lowest singlet–singlet absorption band for dba has been tentatively assigned by several research groups (2*e*, 12*a*, *b*). The proposed assignments were $n-\pi^*$ (2*e*), $\pi-\pi^*$ (12*a*), and charge transfer (CT) (12*b*). Since the absorptivity is 30 000 M^{-1} cm^{-1}, the $n-\pi^*$ assignment is ruled out. Moreover, the vibrational progression in the 77 K fluorescence spectra (1260 cm^{-1}; see text below) does not support this assignment. The $\pi-\pi^*$ assignment was based upon the observation of a linear relationship between λ_{max} and the nature of substituents attached to the cross-conjugated moiety (CH=CH=(CO)—CH=CH) (12*a*). However, such agreement between an empirical equation and experimental data may be fortuitous. Moreover, the vibrational spacings observed in the lowest energy band ($\pi-\pi^*$) of styrene (1050 ± 50 cm^{-1} (18)), which are attributable to ν(C=C) in this excited state, greatly differ from our results on the diarylideneacetones. Finally, based upon a study of solvent polarity and substituent effects, a CT assignment has been proposed (12*b*). The results of the present work establish the latter proposed assignment.

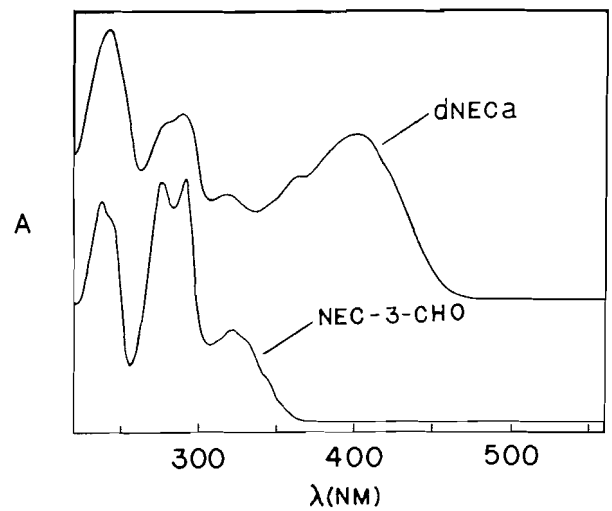

FIG. 1. Comparison between the electronic absorption spectra of dNECa and NEC-3-CHO in THF solution at 293 K.

The 293 K UV data for the five compounds are listed in Table 1. The low-energy bands exhibit no vibrational structure at this temperature. Their absorptivities are fairly large (26 000–

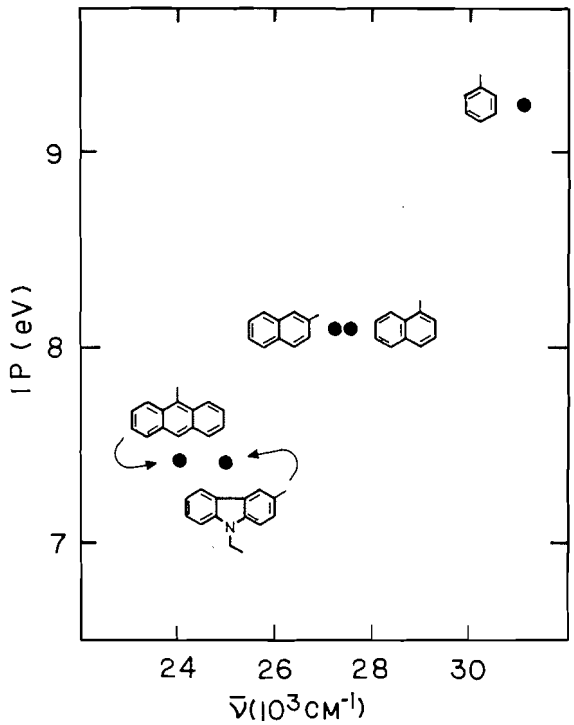

FIG. 2. Graph of the variation of the IP of the unsubstituted aromatic compounds versus $\bar{\nu}_{max}$ (CT) in the diarylideneacetone compounds. The data point associated with anthracene is taken from ref. 21 for IP and 11 for $\bar{\nu}_{max}$ (CT).

33 000 $M^{-1} cm^{-1}$), indicating that the electronic transition(s) is (are) strongly allowed in character. Red shifts of this electronic band are observed with an increase in solvent polarity (319, ether; 325, chloroform; 331 nm, ethanol) for dba, in agreement with the previously reported data (12*b*). Comparison of the absorption spectra of the diarylideneacetones with those of the corresponding aromatic aldehydes is more informative. Figure 1 shows the UV–VIS spectra of dNECa and 3-(*N*-ethylcarbazoyl)aldehyde (NEC-3-CHO) in THF at 293 K. The high energy region for both compounds is practically identical (in terms of the band energies and shapes) and basically represents the "fingerprint" region of the aryl group. These singlet electronic bands have been previously assigned by polarization techniques and are all $\pi-\pi^*$ (19): $^1A_1 \rightarrow {}^1L_b$ (350), $^1A_1 \rightarrow {}^1L_a$ (280), and $^1A_1 \rightarrow {}^1B_a$ (270 nm). On the other hand, the strong 400-nm band that appears only in the dNECa spectrum must then arise from interactions between the aryl groups and the CH=CH—(CO)—CH=CH moiety (CT).

Recent literature data have shown that the CT band energies arising from interactions between different aromatic compounds (donors) and the tropylium cation (acceptor) follow a linear relationship with the IP of the aromatics (20). Figure 2 shows the same dependence of the transition energies of the CT bands in the diarylideneacetones on the IP of the aromatic compounds (21). This experiment indicates that the aryl groups are indeed the donors, and the $(CHCH)_2CO$ group is the acceptor moiety of the CT interactions. Interestingly, recent results (5) for a di(ferrocenylidene)acetone (IP = 6.85 eV (22), ν_{max} (CT) = 19 600 cm^{-1} (THF; 293 K) (5)) follow this linear relationship.

The 77 K absorption and fluorescence spectra for the four diarylideneacetone compounds are shown in Figs. 3–6. The 77 K electronic bands are vibrationally structured in contrast to the 293 K spectra in fluid solutions and rigid PMMA film.

Figure 7 shows the UV–VIS spectrum of 1-dNapha in PMMA as an example, and the comparison between the 77 and 293 K spectra in 2MeTHF is shown in Figs. 4 and 5 for 1-dNapha and 2-dNapha, respectively. Except for dNECa (see text below), all attempts to observe 293 K fluorescence (or phosphorescence) in fluid and rigid media failed. The proposed vibrational analyses for the 77 K absorption and fluorescence spectra are given in Tables 2–5. For the dba, 1-dNapha, and dNECa absorption spectra, two vibrational progressions are observed, the first one in the high energy region and the second one in the low energy one. This observation is indicative of two electronic bands.

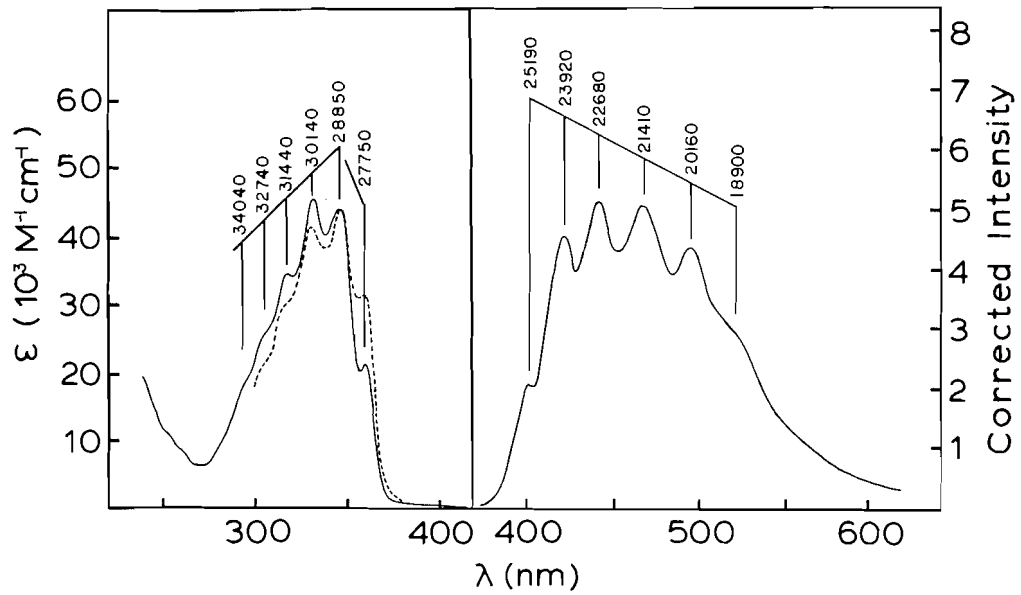

FIG. 3. Left: electronic absorption (—) and fluorescence excitation (---); λ_{emi} = 475 nm) spectra of dba in 2MeTHF at 77 K. Rigth: fluorescence spectrum of dba under the same conditions. The scale for the fluorescence excitation spectrum is the same as for the fluorescence spectrum.

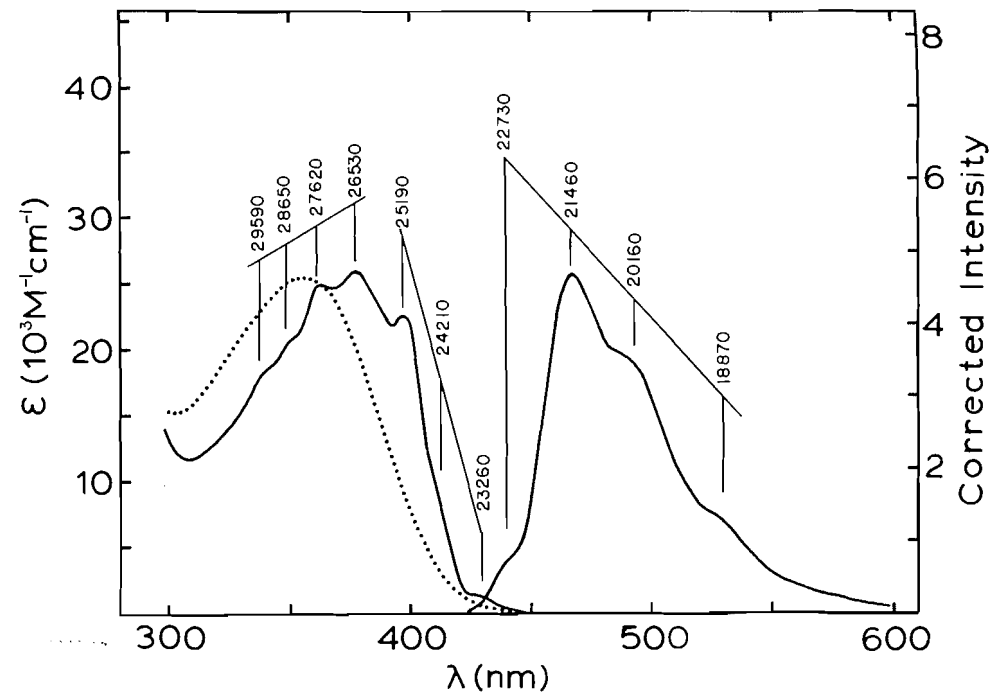

FIG. 4. Electronic absorption (left) and fluorescence spectra (right) of 1-dNapha in 2MeTHF at 77 (–) and 293 K (...).

Indeed, for 2-dNapha, the vibrational spacing remains constant, but two well-resolved electronic bands are observed (see Fig. 5). In support of this observation, the fluorescence spectra for 1- and 2-dNapha do not exhibit a mirror-image relationship with the lowest energy electronic band (see Figs. 4 and 5), while in the cases of dba and dNECa, this relationship appears to be somewhat better (23). The second absorption band is also believed to be CT.

The 293 K vibrational spectra for the four compounds have been obtained, with the exception of the Raman spectrum of 1-dNapha (all attempts to obtain any Raman data for this compound failed). Table 6 compares the averaged vibrational frequencies (or spacings) of both absorption and fluorescence spectra, and the *closest* observed Raman frequencies. The ground state vibrational frequencies observed in the fluorescence spectra were not, or only very weakly, apparent in the FT-IR spectra, but they were observed in the Raman spectra. Figure 8 shows the FT-IR and Raman spectra of dba at 293 K as an example. In this case, a peak is observed at 1261 cm^{-1} in the Raman spectrum (1260 in the fluorescence spectrum) while a rather weak feature of 1265 cm^{-1} in CCl_4 solution and 1261 cm^{-1} in the solid state is found in the FT-IR spectra. The Raman spectra of the 2-dNapha and dNECa compounds are shown in Fig. 9. This vibrational mode is assigned to ν(C—C). No electronic absorption features

attributable to an $n \rightarrow \pi^*$ transition have been observed in the 298 and 77 K spectra, and no emission from such an $n\pi^*$ state has been detected in this work. It is believed that such a state would lie nearby in energy, especially in the dba case where the 0–0 transition in absorption is observed at 360 nm. From results of this work there is no evidence for an $n\pi^*$ effect on the CT fluorescence.

2. Photophysical properties

The fluorescence lifetimes, τ_F, are reported in Table 7. Curiously, all 77 K data show that the fluorescence decays are composed of two components: a short-lived one (ranging from 0.38 to 0.64 ns) of higher intensity, and a longer-lived one (3.51–10.9 ns) of weaker intensity. This behavior is not concentration dependent so the possibility of an aggregation phenomenon is ruled out. At 293 K, the fluorescence decay for dNECa is monoexponential, suggesting that the 77 K results are due to temperature (and perhaps viscosity) related intramolecular phenomena. This dual kinetic pattern is not new; an earlier paper reported the triplet–triplet absorption spectra for dba and mentioned that two closely spaced electronic bands exhibiting different deactivation kinetics were observed (12*c*). The data were not interpreted. The fact that there is a temperature-dependent equilibrium between the *s,cis–s,trans* and *s,cis–s,cis* forms of dba compounds (24) could be at the origin of this phenomenon. Since it has been established that the *s,cis–s,trans* form is predominant between 293 and 200 K (24), the short-lived fluorescent species can perhaps be related to this particular form, and the long-lived species to the *s,cis–s,cis* form. Interestingly, the intensity ratio of the two components depends on the nature of the aromatic group. Again steric interactions may play a role in this behavior. No investigation of the temperature dependence of the fluorescence kinetic parameters was attempted. A careful investigation of the excitation wavelength and

viscosity effects on τ_F and ϕ_F should shed light on this 77 K phenomenon.

The fluorescence quantum yield, ϕ_F, is 0.39 ± 0.02 for dNECa at 298 K and the radiative, k_F (ϕ_F/τ_F), and nonradiative, k_{nr} ($(1-\phi_F)/\tau_F$), rate constants are 2.4×10^8 and 3.7×10^8 s^{-1}, respectively. The theoretical radiative rate constant, $k_F^{(t)}$ (s^{-1}), can be evaluated from the Birks and Dyson relationship (25):

$$[1] \quad k_F^{(t)} = 2.88 \times 10^{-9} \frac{\int \frac{n^3(\bar{\nu})F(\bar{\nu})\,d\bar{\nu}}{F(\bar{\nu})\,d\bar{\nu}}}{\int \frac{}{\bar{\nu}^3}} \int \frac{\epsilon(\bar{\nu})\,d\bar{\nu}}{n(\bar{\nu})\bar{\nu}}$$

where $n(\bar{\nu})$ is the refractive index of the medium at frequency $\bar{\nu}$, $F(\bar{\nu})$ is the corrected fluorescence intensity (function of $\bar{\nu}$), and ϵ is the absorptivity (also function of $\bar{\nu}$). Generally, the $k_F^{(t)}$ value compares well with k_F if there is no intramolecular hydrogen bonding, solvent–solute specific interaction, or charge transfer state from intramolecular distortion. For dNECa, a value of 3.9×10^8 s^{-1} is calculated, which does not agree perfectly with k_F (2.4×10^8 s^{-1}). This situation was previously observed for some *N*- and 3-substituted derivatives of carbazoles (26) and was interpreted, in part, in terms of the presence of a rough mirror-image relationship between the fluorescence and lowest-energy absorption bands. For dNECa, a rather rough mirror-image relationship is also observed (at 77 and 298 K; see Fig. 6). The CT absorption band envelope is difficult to define accurately; this situation causes large uncertainties in the estimation of the $\int \epsilon(\bar{\nu})d\bar{\nu}/n(\bar{\nu})\bar{\nu}$ integral. Taking into account these facts, we feel that the comparison between k_F and $k_F^{(t)}$ is still reasonable.

No emission is observed for the dba-Fc (see explanations below).

Part II: Electron transfer reactions

1. Excited state redox properties

A one-electron reduction was previously identified as the first process in ground state dba and some of its substituted derivatives, on the basis of the magnitude of the anodic–cathodic potential gap measured by cyclic voltammetry (12*d*, *e*). The one-electron nature of this process has been verified by coulometry measurements (0.99 e for dba). Cyclic voltammograms (CV) were acquired for the five compounds, and the reduction potentials for the first and second one-electron reductions are listed in Table 8. A typical CV is shown in Fig. 10. The first reduction process occurs in the −1.15 to −1.51 V vs. SSCE region and appears to be electrochemically reversible (except for dNECa), while the second process is found in the −1.65 to −1.95 V vs. SSCE range and is electrochemically irreversible in all cases. The reversibility conditions are met when the anodic

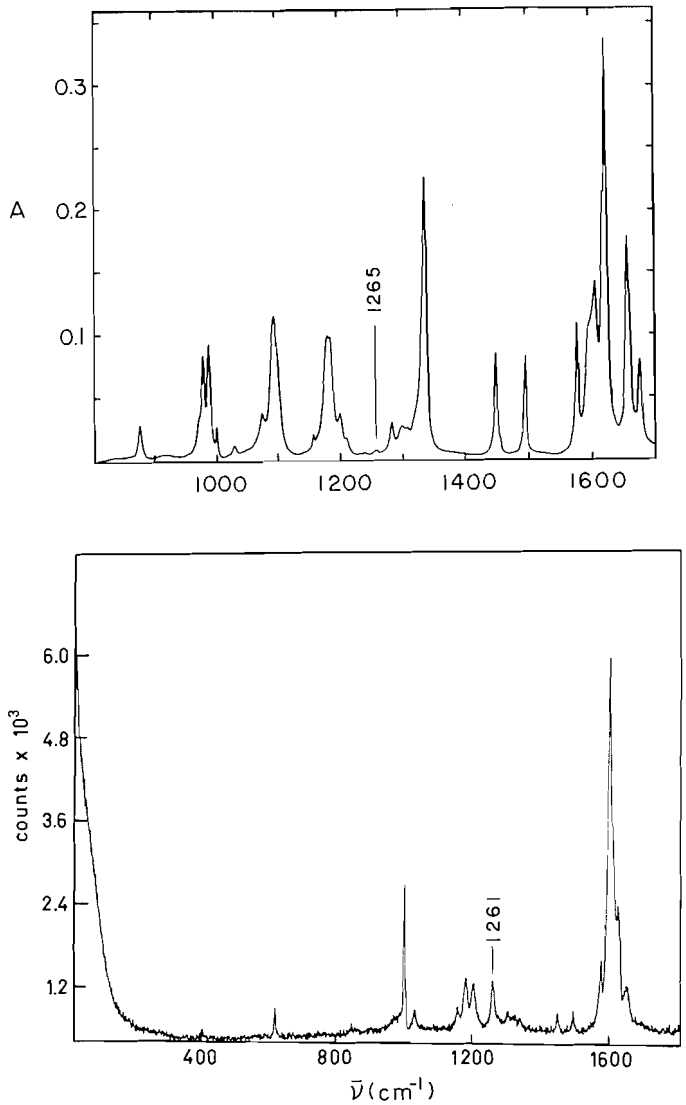

FIG. 8. Upper: FT-IR spectrum of dba in CCl_4 ($\sim 5 \times 10^{-3}$ M) at 293 K; experimental conditions: 100 scans, 2 cm^{-1} resolution. Lower: microRaman spectrum of solid dba at 293 K; experimental conditions: 1 scan, 1 data point/cm^{-1}, 1 s/point, 514.5 nm laser excitation, 10 mV laser power at the sample, 32× objective, 300-μm slit widths, no smoothing.

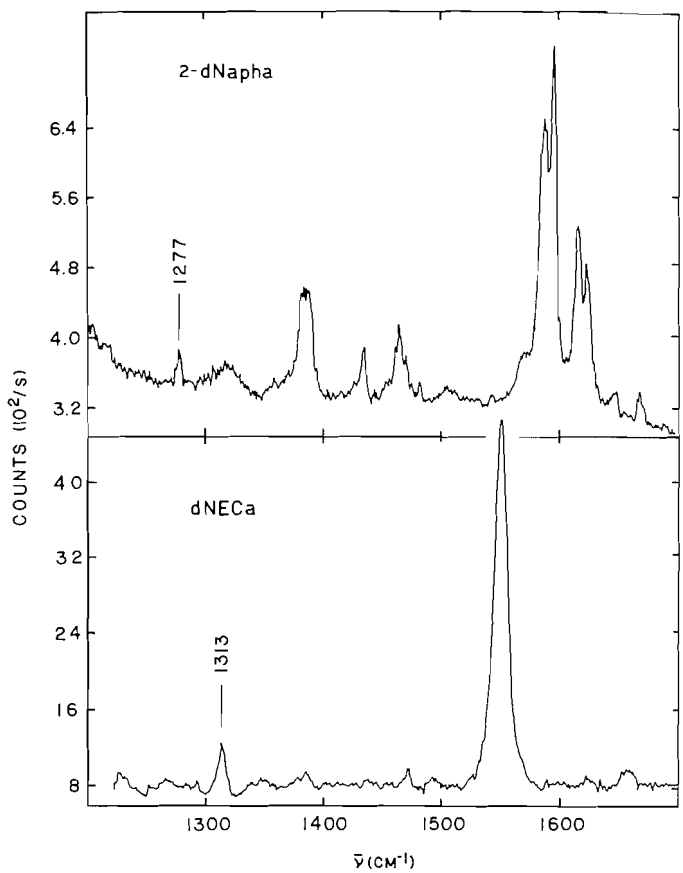

FIG. 9. Upper: microRaman spectrum of solid 2-dNapha at 293 K; experimental conditions: 1 scan, 1 data point/cm^{-1}, 1 s/point, 647.1 nm laser excitation, 5 mW laser power at the sample, 32 × objective, 300-μm slit widths, no smoothing. Lower: microRaman spectrum of solid dNECa at 293 K; experimental conditions: same as above except 10 mW laser power at the sample.

peak current is equal to the cathodic one, and when the potential gaps between the anodic and cathodic peaks are 57 mV for a one-electron process. The potential gaps between the anodic and cathodic peaks were typically ~100 mV at a 200 mV/s scan rate for the first process. At lower scan rates (10–20 mV/s), these gaps decrease to 75 mV. A 60 mV gap is not achieved, presumably due to uncompensated current IR drop from the resistivity induced by the CH_2Cl_2 solutions. In view of the linear relationship between the peak currents and the square of the scan rates, the first reduction processes are diffusion controlled. There is no oxidation process in the 0–2 V vs. SSCE range except for dba-Fc ($E^{0/1+}$ = 0.52 V vs. SSCE), for which an electrochemically reversible one-electron oxidation centered at the ferrocenyl group takes place. Under the same experimental conditions, we find the same oxidation wave at 0.33 V vs. SSCE for the ferricenium/ferrocene couple. This process is also diffusion controlled.

With the knowledge that the first reduction process is a one-electron process, the 77 K lowest singlet excited state properties have been evaluated (see details in Table 8). The first singlet excited state reduction potentials range from 1.7 to 2.2 V vs. SSCE for dba, dba-Fc, and 1- and 2-dNapha, while the value is smaller for dNECa (1.4 V vs. SSCE). The carbazoyl group is generally found to be a better electron donor in the excited state (9), which can explain the lower value of the photoreduction potential in the latter case, while dba was found to be a poor photo donor (12*f*). Nevertheless, these diarylideneacetones should be strong *photooxidizing agents* in their lowest singlet excited state (4). The absence of spectroscopic data for the triplet excited states precludes evaluation of the redox properties in these states.

TABLE 7. Fluorescence lifetimes of the diarylideneacetones[a]

[d]Not observed.
[e]Since there is no fluorescence or vibrational progression in the absorption spectrum, the $E(S_1)$ value is estimated from the difference ν_{max}(dba) − ν_{max}(dba-Fc) using the 293 K data of Table 1.

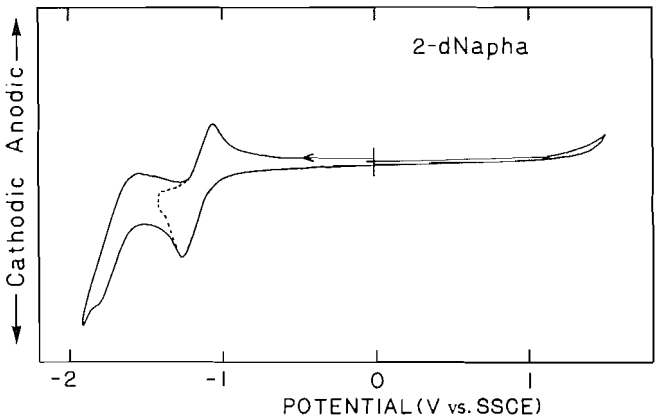

FIG. 10. Cyclic voltammogram of 2-dNapha in CH_2Cl_2 solution containing 0.1 M TBA (PF_6) at 293 K, scan rate 200 mV/s.

2. Fluorescence quenching of dNECa

Based on the known properties of various quencher molecules, Q, for accepting or donating electrons or accepting energy from excited sensitizer molecules, M, bimolecular quenching reactions can be classified as due to (1) energy transfer:

[2] $M^* + Q \rightarrow M + {}^3Q^*$

(2) oxidative quenching:

[3] $M^* + Q \rightarrow M^+ + Q^-$

or (3) reductive quenching:

[4] $M^* + Q + M^- + Q^+$

In this work, Q was oxygen, anthracene ($E(Q^*) = 1.85$), naphthalene ($E(Q^*) = 2.63$), and biphenyl ($E(Q^*) = 2.85$ eV; ref. 27) for energy transfer reactions; MV^{2+}, $S_2O_8{}^{2-}$, CH_2Cl_2, $CHCl_3$, and CH_2I_2, CHI_3 for oxidative quenching reactions; and TMPM ($E(Q^+/Q) = 0.11$ V; ref. 28) and DPA ($E(Q^+/Q) = 0.93$ V; ref. 29) for reductive quenching reactions. In freshly prepared homogeneous solutions at 293 K (THF or acetonitrile), no fluorescence quenching is observed for the energy transfer and oxidative quenchers, while normal linear Stern–Volmer behavior is observed for TMPM and DPA with bimolecular quenching rate constants, k_q, of $(1.38 \pm 0.03) \times 10^8$ M^{-1} s^{-1} and $(2.65 \pm 0.25) \times 10^7$ M^{-1} s^{-1}, respectively. The decrease in k_q with an increase in $E(Q^+/Q)$ supports the hypothesis of a reductive quenching mechanism, which is in agreement with the electrochemical, coulometric, and spectroscopic findings of Sect. I.

On the other hand, the absence of dNECa fluorescence quenching with anthracene suggests that the non-emissive triplet state must lie below 1.85 eV. Moreover, the absence of fluorescence for dba-Fc strongly indicates that efficient intramolecular fluorescence quenching occurs. Knowing that ferrocene is a well-established energy transfer quencher (E_T(ferrocene) < 15 000 cm^{-1}; ref. 30), it is reasonable to believe that the CT triplet state for dba lies above one centered in the ferrocenyl moiety.

The fluorescence quenching experiments show that, in the presence of an appropriate donor, dNECa undergoes photoinduced reduction. To further verify that the same electron phototransfer behavior occurs with dba, flash photolysis experiments are necessary.

3. Flash photolysis of dba with DPA

The transient absorption spectrum of (the non-emissive) dba in benzene solution at room temperature obtained from pulse radiolysis measurements has already been reported (λ_{max} = 500 nm; ref. 12*c*). For picosecond flash photolysis experiments with delay times between 50 ps and 5 ns (λ_{exc} = 355 nm), the same spectrum is generated for dba in THF, although it is somewhat less resolved than the reported spectrum. As expected in the presence of DPA, a bimolecular quenching reaction between the photoproduced dba transient and DPA takes place. It manifests itself by the great decrease ($\Delta A = 0.080 \pm 0.025$) of the dba transient absorption between 5 and 10 ns. The equipment used did not allow us to investigate the 250–425 and 675–900 nm ranges and delay time greater than 10 ns. No k_q measurement was attempted.

Conclusion

It has been demonstrated spectroscopically that the lowest singlet excited state for dba (and its aryl derivatives) is a CT state (aryl group → $(CH{=}CH)_2CO$). Electrochemical and electronic spectroscopic data indicate that dba should be a strong photooxidizing agent. Indeed, the fluorescent dNECa model compound (for dba) in 293 K fluid solutions exhibits photoinduced bimolecular reactions that are consistent with a reductive quenching mechanism. Further support for the photoacceptor properties of dba is provided by the picosecond flash photolysis spectra, which show that the dba transient band is quenched by the reductive quencher DPA.

The observations made on the dba ligand in this work are of great importance for photochemical studies of the $M_2(dba)_3$ complexes (M = Pd, Pt). Although these complexes appear

photochemically inert in solution, the photoinduced formation of transient $M_2^+(dba)_2(dba^-)$ species is thermodynamically favorable, and one may attempt to increase the lifetime of the charge separation state via chemical modifications in order to promote chemistry at the M(I) centers. Picosecond flash photolysis investigations on the $M_2(dba)_3$ (M = Pd, Pt) and $Pd_2(dba\text{-}Fc)_3$ complexes are in progress.

Acknowledgments

This research was supported by grants from NSERC (Canada), FCAR (Quebec), and the University of Sherbrooke. P.D.H. thanks Mr. S. Bérubé and Mr. G. Boulay for acquiring the NMR and mass spectra, respectively. We are grateful to Prof. I. S. Butler (McGill University) and Prof. G. Durocher (University of Montreal) for providing access to the Raman and fluorescence spectrometers, respectively. P.D.H. is indebted to Mr. Marc-André Séguin (Montreal) for the fluorescence lifetime measurements, and to Mr. Ghislain Goffoy (Sherbrooke) and Mr. Marc Lafontaine for technical assistance in the fluorescence quenching experiments. The assistance of Dr. D. K. Sharma (Picoseconde Flash Photolysis Center, Concordia University) in the transient ps spectra measurements is also acknowledged.
