L'irradiation d'une solution d'acétonitrile contenant du *para*-dicyanobenzène (**1**), du 3,3-diphényltétrahydrofurane (**2**) et du perchlorate de magnésium conduit à la formation de 4,4-diphényl-1,3-dioxane (**7**). De la même manière, l'irradiation d'une solution d'acétonitrile contenant du produit (**1**), du 1-méthoxy-2,2-diphénylcylopentane (**5**) et du perchlorate de magnésium conduit à la formation du 6,6-diphényl-2-méthoxytétrahydropyrane (**8**). Le mécanisme proposé pour ces réactions implique la formation des cations radicaux $\mathbf{2}^{+\cdot}$ et $\mathbf{5}^{+\cdot}$ par le biais de réactions au cours desquelles le premier état singulet excité du composé **1** agit comme photosensibilisateur (transfert d'électron). Les cations radicaux $\mathbf{2}^{+\cdot}$ et $\mathbf{5}^{+\cdot}$ se clivent alors pour donner les cations radicaux 1,5. La réaction du site cationique avec de l'eau, suivie par une oxydation additionnelle du site radicalaire par l'anion perchlorate, fournit le carbocation diphénylalkyle qui peut se cycliser par le biais d'un intermédiaire à six chaînons pour fournir les produits observés **7** et **8**. Alors que l'addition d'autres perchlorates (lithium et tétra-*n*-butylammonium) conduit aussi à la formation des produits **7** et **8**, le trifluoroacétate de lithium est inefficace. La proposition selon laquelle l'eau est impliquée comme nucléophile est corroborée par l'incorporation de ^{17}O dans les produits **7** et **8** lorsqu'on additionne de l'eau enrichie en ^{17}O au mélange réactionnel.

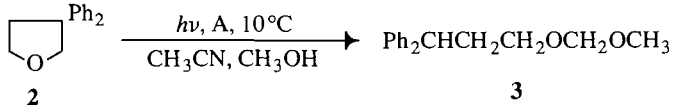
Introduction

The photosensitized (electron transfer) carbon–carbon bond cleavage of 2,2-diphenylethyl ethers is a well-known reaction (1,3). For example, irradiation of an acetonitrile–methanol (3:1) solution of *para*-dicyanobenzene (**1**) (an electron-accepting photosensitizer) and 3,3-diphenyltetrahydrofuran (**2**) results in the formation of methyl 3,3-diphenylpropyl formaldehyde acetal (**3**) (60% yield after 20% conversion) (reaction 1) (1*b*). The mechanism for this reaction (Scheme 1) involves carbon–carbon bond cleavage of the radical cation of **2** to give an intermediate 1,5 radical cation. The cationic site is trapped by nucleophilic solvent (methanol), the radical site is reduced to the carbanion by electron transfer from the radical anion of the photosensitizer ($\mathbf{1}^{-\cdot}$), and the carbanion is protonated to give the observed product. When the solvent is acetonitrile–water (3:1), 3,3-diphenylpropanol (**4**) is formed (1*b*). This product results from an analogous reaction, trapping of the carbocation with water, followed by hydrolysis of the initially formed hemiacetal. When this irradiation is carried out in the absence of a nucleophile, no reaction occurs.

Reaction 1



2 **3**

A = 1,4-Dicyanobenzene (**1**)

Similar irradiation of an acetonitrile–methanol (3:1) solution of *para*-dicyanobenzene (**1**) and methyl 2,2-diphenylcyclopentyl ether (**5**) also results in carbon–carbon bond cleavage to yield 5,5-diphenylpentanal dimethyl acetal (**5**) (reaction 2) (1*b*). Again, when the irradiation is carried out in the absence of added nucleophile, no reaction takes place.

Metal salts are known to have a profound effect on photoinduced electron transfer reactions (4). However, the mode of action of the salt has not always been firmly established. It has been suggested that separation of the initially formed radical ion pair ($A^{-\cdot}$ ... $D^{+\cdot}$), to the solvent dissociated radical ions ($A^{-\cdot}$) and ($D^{+\cdot}$) may be facilitated by the addition of salts serving as alternative counterions. Metal salts, particularly magnesium perchlorate, are also known to enhance the lifetime of the radical ion pair, by slowing down the back electron transfer from the sensitizer radical anion to the donor radical cation, presumably through stabilizing ionic interactions of the cation with the radical anion.

One of the main objectives of this work was to determine the effect of added metal salts on the photosensitized (electron transfer) reactions involving the radical cations of 3,3-diphenyltetrahydrofuran (**2**), and methyl 2,2-diphenylcyclopentyl ether

[1]This is part 25 of the series Radical Ions in Photochemistry. Preceding publications in these series are refs 1. and 2.

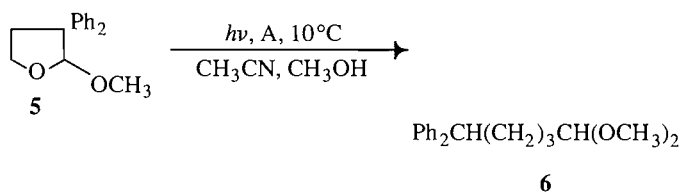
A = 1,4-Dicyanobenzene (**1**) :B = Methanol or acetonitrile

SCHEME 1

(**5**). Our initial thought was that an increase in the lifetime of the 1,5 radical cation might lead to intramolecular cyclization into the terminal phenyl ring, providing a new synthesis of seven-membered ring compounds. There are several examples of this cyclization involving 1,4 radical cations, but this reaction has yet to be observed with 1,5 radical cations (5).

Reaction 2



A = 1,4-Dicyanobenzene (**1**)

Results

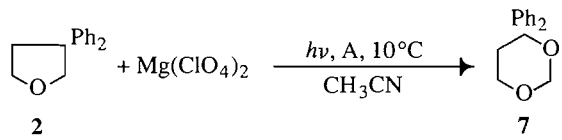
The irradiation procedure was similar to that used for reactions 1 and 2 except that the solvent was pure acetonitrile, dried in the usual way, and the salt (0.3 M) was added. Progress of the reaction was followed by capillary column gas chromatography using a mass selective detector (gc/ms).

The irradiation of an acetonitrile solution of *para*-dicyanobenzene (**1**) (0.02 M), 3,3-diphenyltetrahydrofuran (**2**) (0.02 M), and magnesium perchlorate (0.3 M) leads to the formation of 4,4-diphenyl-1,3-dioxane (**7**) (45% yield at 86% conversion). A trace of 3,3-diphenylpropanol (**4**) was also detected (gc/ms) (reaction 3). When water (1 M) was added to the solution, the two products **7** and **4** were formed in almost equal amounts, and when the water concentration was increased further (4 M), **4** was the only product. The structural assignment of **7** was based on spectral (^{1}H and ^{13}C nmr, and mass spectra) evidence, in comparison with reported data (6).

Reaction 3 was repeated after having added an equivalent (0.02 M) of water isotopically labelled with ^{17}O (16% enriched). Mass spectral analysis of the isolated product **7** established the fact that ^{17}O (ca. 10%) had been incorporated at the 3-position.

Other perchlorate salts, lithium and tetra-*n*-butyl ammonium, had a similar effect on the photosensitized (electron transfer) reaction of **2**. The major products were **7** and **4** in both reactions. A metal salt with a different anion, lithium trifluoroacetate, was also tried and no **7** was detected after the usual irradiation period.

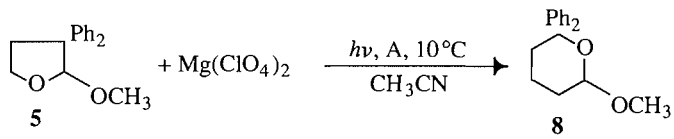
Reaction 3



A = 1,4-Dicyanobenzene (**1**)

The irradiation of an acetonitrile solution of **1**, methyl 2,2-diphenylcyclopentyl ether (**5**), and magnesium perchlorate led to formation of 6,6-diphenyl-2-methoxytetrahydropyran (**8**) in 30% yield (reaction 4). The structure of **8**, a new compound, was established by spectral and elemental analyses. The proton at the 2-position appears in the ^{1}H nmr spectrum as a doublet of doublets at 4.44 ppm with coupling constants of 2.17 and 9.69 Hz. This is indicative of a proton shifted downfield by two adjacent oxygen atoms and in the axial position, coupled by an axial–equatorial and an axial–axial proton interaction. From

Reaction 4



A = 1,4-Dicyanobenzene (**1**)

this we infer that the favoured conformation of this compound places the methoxy group in the equatorial position. This conformation minimizes the repulsive 1,3-diaxial interaction at the expense of the stabilizing anti-periplanar interaction of the polar carbon–oxygen bond of the methoxy group with a nonbonding pair of electrons on the oxygen of the tetrahydropyran ring—the anomeric effect (7).

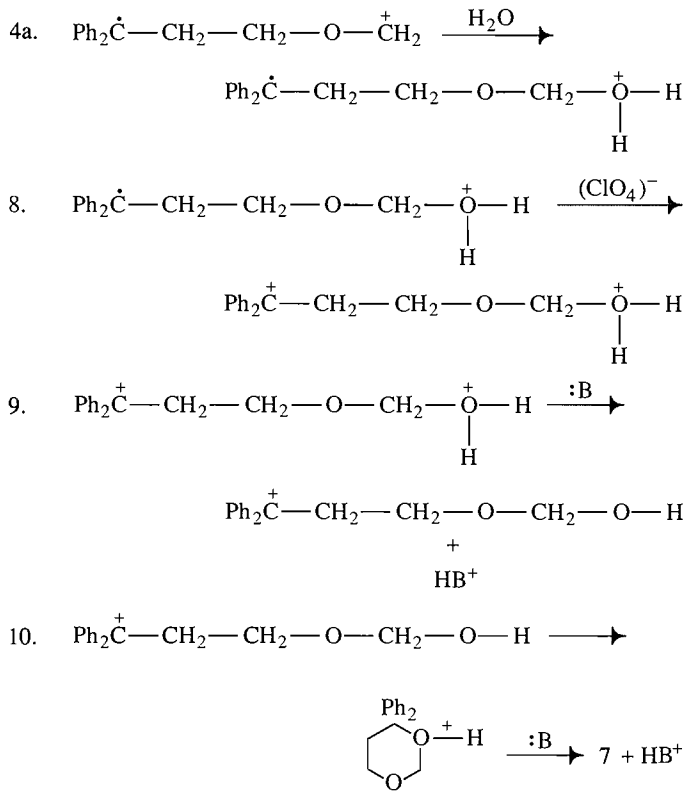
This irradiation was also carried out in the acetonitrile–water-^{17}O (0.02 M) solution. Mass spectral analysis of the product **8** indicated that ^{17}O (ca. 10%) was incorporated at the 1-position.

In marked contrast to these results observed with the cyclic systems **2** and **5**, the irradiation of the acyclic analogue, methyl 2,2-diphenylethyl ether, under conditions identical to those used for reactions 3 and 4 gave a complex mixture with diphenylmethane as the major product; benzhydrol and methyl diphenylmethyl formaldehyde acetal were only minor products.

Discussion

The mechanism summarized in Scheme 1 is adequate to describe the formation of **3** and **4** from **2** (reaction 1) and **6** from **5** (reaction 2) (1*b*). The additional aspects of the mechanism, required to account for the formation of **7** and **8** (reactions 3 and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.



SCHEME 2

4), are outlined in Scheme 2. The initial steps, up to the formation of the 1,5 radical cation, are essentially the same with or without added salts.

Step 4a represents the nucleophilic attack on the cationic site of the 1,5 radical cation by adventitious water. The perchlorate salts that were added to the reaction mixture are hydrated. The procedure used to dry, store, and transfer the acetonitrile may also be inadequate to prevent the introduction of the small amount of water sufficient to trap the carbocation. The involvement of water is indicated by the isotopic oxygen incorporation when an equivalent amount of ^{17}O-enriched water was added to the reaction mixture. An alternative possibility, incorporation of oxygen from the perchlorate anion, seems unlikely; the perchlorate anion is a poor nucleophile.

The key step in the proposed mechanism for formation of **7** and **8** is the further one-electron oxidation of the radical to generate the diphenylalkyl cation (step 8). The most likely oxidant in the reaction mixture is the perchlorate anion, which is known to be a powerful oxidant in acidic media. The acidity of the reaction mixture is difficult to estimate; however, reaction of the cationic site of the 1,5 radical cation with water leads to the distonic 1,6 radical cation that is protonated on the oxygen. The lifetime of this intermediate may be long enough to influence the oxidation potential of the perchlorate anion. The diphenylalkyl radical has a relatively low oxidation potential (ca. 0.23 V) (8). The proximity of the acidic proton in the distonic 1,6 radical cation may account for the fact that these cyclic systems undergo this reaction much more efficiently than the acyclic analogue.

The final step, cyclization of the carbocation to the oxygen through a six-membered cyclic intermediate, is a favourable process (step 10). Cleavage of the acyclic analogue leads rapidly to solvent-separated species and reencounter is less likely.

These reactions are unusual. The photosensitized (electron transfer) process generally involves only a single electron. Products resulting from the transfer of two electrons in the same direction are rarely observed (9). This reaction will add a useful extension to the synthetic utility of the photoinduced electron transfer process. We continue to search for conditions that will favour cyclization of a 1,5 radical cation.

Experimental

General information

The mass spectral analyses were performed on a VG Analytical Instruments double focusing mass spectrometer (reverse geometry), model ZAB-E (ion source: electron impact; accelerating voltage: 8000 V; instrument resolution: 1000; high mass: 300; and low mass: 100). The ^1H nmr spectra were recorded on a Nicolet Magnetics Corp. narrow bore 360 MHz spectrometer and are reported in parts per million downfield from TMS. The ^{13}C nmr spectra were recorded on the Nicolet spectrometer operating at 90 MHz. Infrared spectra were recorded on an air-purged Perkin Elmer 180 grating spectrometer and are reported in wave numbers. The gc/ms analyses were done on an Hewlett Packard 5890A GC/5970 mass selective detector interfaced with an H. P. 9816 microcomputer. The column was 25 m × 0.2 mm, 5% phenyl methyl silicone on fused silica with a film thickness of 0.25 μm. Combustion analysis was performed by Canadian Microanalytical Services Ltd., Vancouver, B.C. Acetonitrile (Fisher ACS grade) was distilled successively from sodium hydride and phosphorus pentoxide, and was then passed through a column of basic alumina, refluxed over calcium hydride for 24 h (under a nitrogen atmosphere), and fractionally distilled. The preparation of **2** and **5** and the conditions for the irradiation have been described (1).

Irradiations

Irradiation of 3,3-diphenyltetrahydrofuran (2)

A solution of 3,3-diphenyltetrahydrofuran (**2**) (168 mg, 7.49×10^{-4} mol), *para*-dicyanobenzene (**1**) (84 mg, 6.5×10^{-4} mol), and magnesium perchlorate (1.272 g) in 30 mL acetonitrile was irradiated at 10°C for 50 h. Flash column chromatography using 90% methylene chloride and 10% hexanes was employed to separate the product, 4,4-diphenyl-1,3-dioxane (**7**), from the starting material **2** and the photosensitizer **1**. At 86% conversion, the acetal **7** was obtained in 45% yield; ^1H nmr (360 MZ) in $CDCl_3$: 7.22–7.39(m, 10H), 4.94(s, 2H), 3.96(t, 2H, J = 5.4 Hz), 2.52(t, 2H, J = 5.4 Hz) (in agreement with the reported spectrum (6)); ^{13}C nmr (90 Mz) in $CDCl_3$: 144.6, 132.3, 128.4, 127.8, 127.0, 126.2, 89.3, 79.4, 63.9, 35.5. Trace amounts of 3,3-diphenylpropanol (**4**) and benzonitrile were detected (gc/ms) and were identified by comparison (mass spectra and retention times) with authentic samples.

Incorporation of ^{17}O in the reaction product 7

Conditions similar to those described above were used except one mole equivalent of water-^{17}O (16% enriched) was added to the reaction mixture. The product, **7**, was isolated as described above and mass spectral analyses were done using the ZAB-E mass spectrometer. The ^{17}O-enriched product showed an increase in the $M+1$ peak relative to the molecular ion peak of 8.2 ± 0.6% relative to the unenriched product, **7**. An increase in the mass peak (m/z) 211 relative to 210, corresponding to a loss of formaldehyde, of 9.6 ± 2.1% was observed relative to the unenriched product **7**. The mass peak 183 relative to 182 (loss of C_3H_6O) showed an increase of 11.5 ± 3.2% relative to the unenriched product **7**.

Irradiation of methyl 2,2-diphenylcyclopentyl ether (5)

A solution of methyl 2,2-diphenylcyclopentyl ether (**5**) (502 mg, 1.99×10^{-3} mol), *para*-dicyanobenzene (**1**) (255 mg, 1.99×10^{-3} mol), and magnesium perchlorate (1.34 g) in 30 mL acetonitrile was irradiated at 10°C for 24 h. Gradient medium pressure liquid chromatography (mplc) using methylene chloride and hexanes as eluent separated the product, 2,2-diphenyl-6-methoxytetrahydropyran (**8**), from the photosensitizer **1**. Trace amounts of benzonitrile were detected by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

gc/ms. The acetal (**8**) was recrystallized from ethanol–water to yield colourless needles (mp 74–76°C) in 30% yield; ir (PE 180) neat: 3090(m), 3065(m), 3025(m), 2990(m), 2955(s), 2845(m), 1595(m), 1495(s), 1460(s), 1445(s), 1395(s), 1355(s), 755(s), 695(s); ^{1}H nmr (360 MHz) in $CDCl_3$: 7.49–7.09(m, 10H), 4.44 (dd, 1H, J = 2.17 Hz, 9.69 Hz), 3.57 (s, 3H), 2.67–2.62 (m, 1H) 1.87–1.74 (m, 5H); ^{13}C nmr (90 MHz) in $CDCl_3$: 148.6 (t, J = 7.4 Hz),143.0 (dt, J = 6.9 Hz, 13.2 Hz), 128.6 (dd, J = 7.6 Hz, 160.2 Hz), 127.9 (dd, J = 7.7 Hz, 159.7 Hz), 127.1 (dt, J = 7.1 Hz, 157.7 Hz), 126.9 (dt, J = 7.6 Hz, 160 5 Hz), 126.3 (dt, J = 7.5 Hz, 160.3 Hz), 124.8 (dt, J = 6.8 Hz, 159.3 Hz), 98.7 (dm, J = 154.0 Hz), 80.7 (s), 55.8 (dq, J = 4.3 Hz, 142.2 Hz), 34.4 (mt, J = 5.6 Hz, 110 Hz, 129.5 Hz), 30.9(mt, J = 3.5 Hz, 7.1 Hz, 128.8 Hz), 19.8 (mt, J = 128.1 Hz); ms: 268, 252, 236, 208, 203, 180, 165, 152, 128, 115, 105, 91, 77. Anal. calcd. for $C_{18}H_{20}O_2$: C 80.56, H 7.51; found: C 80.62, H 7.69.

Incorporation of ^{17}O in the reaction product 8

Irradiation of similar mixtures of **1**, **5**, and $Mg(ClO_4)_2$ in acetonitrile containing one mole equivalent of water-^{17}O (16% enrichment) led to the incorporation of ^{17}O in the product **8**, which was isolated by the procedure described above. Mass spectral analyses were carried out using the ZAB-E mass spectrometer on the product, and the ratio of relevant peaks was compared with the ratio observed from the unenriched product. The molecular ion was not normally observed in this case. The relative abundance of the peak (m/z) 237 to 236 (loss of methanol) showed an increase of 2.3 ± 5.1% relative to the unenriched **8**. Mass peaks 209/208 (loss of C_3H_8O) showed an increase of 9.1 ± 0.3% and the mass peaks of 181/180 showed an increase of 5.0 ± 0.3% relative to the unenriched product **8**.

Acknowledgments

Acknowledgment is made to the Natural Sciences and Engineering Research Council of Canada for support of this work. We thank Dr. D. L. Hooper and the Atlantic Regional Magnetic Resonance Centre at Dalhousie University for the 360 MHz nmr spectra and for help in the preparation of the manuscript. We also thank Dr. R. K. Boyd and Mr. D. J. Embree at the Atlantic Regional Laboratories of the National Research Council of Canada for the mass spectra run on the ZAB-E spectrometer.

Abietinarins A (**1**) and B (**2**), two new 1-[4*H*]-anthracenone derivatives, have been isolated from the Northeastern Pacific marine hydroid *Abietinaria* sp. The proposed structures for abietinarins A (**1**) and B (**2**) are based on spectroscopic analysis. Abieitinarin A (**1**) exhibited significant cytotoxicity in an in vitro L1210 bioassay.

Key words: cytotoxic, hydroid, abietinarins, metabolites, marine.

The smallest common members of the invertebrate phylum Cnidaria are the marine hydroids (class Hydrozoa). Very little is known about the taxonomy and natural history of most hydroids and there is a corresponding lack of knowledge about hydroid secondary metabolism. The handful of hydroids examined to date have yielded a variety of polyhydroxylated steroids (1), a series of halogenated monoterpenoids (2), a family of brominated β-carbolines (3), a group of polyketide derived aromatic antibiotics (4), and a cytotoxic diphenyl-*p*-menthane derivative (5). A broad screening program carried out by the Atlantic Research Laboratory of the National Research Council of Canada, designed to discover bioactive metabolites in marine invertebrates collected from Canadian coastal waters, uncovered weak antiviral activity and host-cell cytotoxicity in extracts of the hydroid *Abietinaria* sp. Bioassay-guided fractionation of the *Abietinaria* sp. extracts led to the isolation of two new cytotoxic metabolites, abietinarins A (**1**) and B (**2**), whose structures we now wish to report.

Samples of *Abietinaria* sp. were collected by hand using SCUBA off the southern coast of Vancouver Island, B.C. Freshly collected hydroid specimens were immediately frozen and stored below −5°C until needed. Thawed samples of *Abietinaria* sp. (1 kg dry wt.) were extracted whole with methanol at room temperature for 24 h prior to the removal of the solids by vacuum filtration. Concentration of the methanol filtrate *in vacuo* gave an aqueous suspension that was exhaustively extracted with dichloromethane. Fractionation of the dichloromethane soluble material by Sephadex LH 20 chromatography (MeOH) gave a crude mixture of the abietinarins. Further separation of this crude mixture by silica gel high performance liquid chromatography (CH_3CN/CH_2Cl_2 3:97) gave pure samples of abietinarins A (**1**) (4 mg) and B (**2**) (2.5 mg).

Abietinarin A (**1**), obtained as a yellow solid, gave a parent ion in the electron impact high resolution mass spectrum (EIHRMS) at *m/z* 314.1520 Da appropriate for a molecular formula of $C_{19}H_{22}O_4$ (ΔM +0.2 mmu). Prominent peaks at *m/z* 296.1405 ($C_{19}H_{20}O_3$; ΔM −0.7 mmu) and *m/z* 281.1170 ($C_{18}H_{17}O_3$; ΔM −0.7 mmu) Da in the mass spectrum of **1** were assigned to ($M^+ - H_2O$) and ($M^+ - H_2O - CH_3$) fragment ions, respectively. The limited amount of abietinarin A available prevented us from obtaining a satisfactory ^{13}C NMR spectrum. Fortunately, however, the information obtained from a series of ^1H NMR experiments, when combined with the IR and mass spectral data, proved sufficient to define the structure of abietinarin A (**1**).

The observation of a series of scalar and dipolar $^1H/^1H$ couplings identified the naphthalenic fragment "**i**" in abietinarin A. Double resonance experiments showed that a pair of aromatic proton resonances at δ 6.84 (H7) and 6.99 (H5) were *meta* coupled (J = 2.5 Hz). The upfield resonance (δ 6.84; H7) was also scalar coupled to an aromatic methyl resonance that appeared at δ 2.86 (Me14), indicating that the methyl group was *ortho* to the aromatic proton. Irradiation of this aromatic methyl resonance induced a nOe in the upfield aromatic resonance (δ 6.84: H7) in agreement with this assignment. Irradiation of the downfield aromatic resonance (δ 6.99: H5) induced nOe's in a deshielded methyl resonance (δ 3.89: OMe), assigned to an aromatic methyl ether, as well as in a third aromatic proton resonance at δ 7.06 (H10). The lack of scalar coupling between this latter aromatic resonance and the two other aromatic resonances indicated that the methyl ether had to occupy the position between the *meta* coupled protons, and that the third aromatic proton (δ 7.06: H10) had to be on an adjacent ring as shown in "**i**". A nOe observed between the aromatic methyl resonance at δ 2.86 (Me14) and a highly deshielded resonance at δ (15.45 (OH9), assigned to a chelated phenolic proton, revealed the spatial proximity of the methyl and phenolic functionalities as shown.

The remaining fragment of abietinarin A had to account for an elemental composition of $C_7H_{12}O_2$ and two sites of unsaturation. An intense band at 1619 cm^{-1} in the IR spectrum of **1** was assigned to a carbonyl stretching vibration. The frequency of the band was nearly identical to that observed for the C1 ketone functionality (1620 cm^{-1}) in the previously reported metabolite

"i"

garveatin C (**3**) (4*a*). This similarity in carbonyl stretching frequencies suggested that there was a ketone functionality (C1) attached *ortho* to the phenolic hydroxyl in fragment "**i**" of abietinarin A. The downfield shift of the phenolic OH resonance (δ 15.45: OH9) was consistent with intramolecular hydrogen bonding between the phenol and C1 ketone, as expected in this arrangement of functional groups. Double resonance experiments identified a seven spin system in the ^{1}H NMR spectrum of abietinarin A that consisted of a methine resonance at δ 3.70 (H3), coupled to an exchangeable resonance at δ 2.99 (OH3) and to another methine resonance at δ 3.37 (H4), which was in turn coupled to a methyl resonance at δ 1.48 (Me13) and to the previously assigned aromatic resonance at δ 7.06 (H10) (Table 1). The scalar coupling between the methine resonance at δ 3.37 (H4) and the aromatic resonance at δ 7.06 (H10) was assigned to allylic coupling, which required that a methine carbon (C4), bearing a methyl group (Me13) and another methine carbon (C3), be attached *ortho* to H10 on fragment "**i**". The most deshielded resonance in this spin system (δ 3.70: H3) was assigned to a carbinol methine residue on the basis of its chemical shift and its observed scalar coupling to an exchangeable resonance at δ 2.99, assigned to an alcohol proton. The remaining carbon and hydrogen atoms (C_3H_6) in abietinarin A could be accounted for by a pair of geminal methyls (δ 1.24, s, Me12: 1.32, s, Me11) and an attached quaternary carbon. Linking the quaternary carbon to the C1 ketone and the C3 methine carbons created a six-membered ring, which accounted for the final site of unsaturation in abietinarin A (**1**).

The relative stereochemistry of the hydroxyl and methyl groups at C3 and C4 in abietinarin A (**1**) was assigned as *cis* on the basis of the 2.5 Hz vicinal coupling observed between H3 and H4. In either possible half-chair conformation of the aliphatic ring, the H3 and H4 protons have pseudoequatorial/pseudoaxial relationships with each other resulting in a dihedral angle of approximately 60°, which is consistent with the small vicinal H3/H4 coupling constant. Irradiation of the Me12 resonance at δ 1.24 induced nOe's in H3 (δ 3.70) and H4 (δ 3.37) in agreement with the assigned stereochemistry. The nOe results also indicated that the preferred conformation of the aliphatic ring has the C3 hydroxyl in a pseudoaxial orientation and the C4 methyl in a pseudoequatorial orientation.

TABLE 1. ^{1}H NMR data for abietinarins A (**1**) and B (**2**). Recorded in CD_3CN at 400 MHz. Chemical shifts are in ppm from internal TMS

Proton	Abietienarin A (**1**)	Abietinarin B (**2**)

Abietinarin B (**2**), isolated as a pale yellow oil, gave a parent ion in the EILRMS at m/z 314 Da, suggesting that it had the same molecular formula as abietinarin A (**1**). The ^{1}H NMR (Table 1) and IR spectra of abietinarin B (**2**) closely resembled the corresponding spectra of abietinarin A (**1**), revealing that the two metabolites were very similar in structure. In particular, the aromatic resonances were virtually identical in the ^{1}H NMR spectra of both metabolites, indicating that they contained identical naphthalenic fragments "**i**". A series of upfield resonances in the ^{1}H NMR spectrum of abietinarin B (**2**) could be assigned to the *gem*-dimethyl (**2**: δ 1.14, s, 6H: Me11 and

Me12), carbinol methine (**2**: δ 3.48, d, J = 11 Hz: H3) benzylic methine (**2**: δ 2.93, br dq, J = 11, 7 Hz: H4) and secondary methyl (**2**: δ 1.52, d, J = 7 Hz: Me13) functionalities found in the aliphatic ring of abietinarin A (**1**). The coupling constant observed between H3 and H4 in abietinarin B (**2**) (J = 11 Hz) implied that both of these protons occupied pseudoaxial orientations and, therefore, that the C3 hydroxyl and Me13 were *trans* to each other. Double resonance and nOe experiments confirmed the proposed connectivities in abietinarin B (**2**) just as they had in abietinarin A (**1**). Hence, abietinarin B (**2**) is simply a diastereomer of abietinarin A (**1**), having the opposite configuration at either C3 or C4.

Abietinarins A (**1**) and B (**2**) are closely related to the garveatins (e.g., garveatin C (**3**)) and the garvins (e.g., 2-hydroxygarvin A (**4**)) previously isolated from the Northeastern Pacific hydroid *Garveia annulata* (4*b*). *Abietinaria* sp. thus becomes the second hydroid known to elaborate 1-[4*H*]-anthracenone-based polyketide-derived metabolites. Abietinarin A (**1**) exhibited significant cytotoxicity in an in vitro L1210 bioassay (ED_{50} <10 μg/mL).[3] The small amount of abietinarin B (**2**) available prevented us from testing its cytotoxicity.

Experimental

Abietinarins A(**1**) and B(**2**) were extracted and purified as described in the text.

The chlorination of isobutyrophenone: determination of its pK_a value and of the course of the reaction

J. PETER GUTHRIE[1] AND JOHN COSSAR
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received July 4 1989

J. PETER GUTHRIE and JOHN COSSAR. Can. J. Chem. **68**, 397 (1990).

Chlorination of isobutyrophenone in alkaline aqueous solution leads to formation of α-hydroxyisobutyrophenone as the first detectable intermediate; a slow subsequent oxidation gives benzoate. From the rates of the initial chlorinations we have been able to determine the pK_a value for the ketone as 18.18 ± 0.50. α-Chloroisobutyrophenone undergoes surprisingly rapid alkaline hydrolysis, $k_{OH} = 71.9 \pm 1.5\ M^{-1}\ s^{-1}$.

Key words: isobutyrophenone, chlorination, enolization, pK_a, hydrolysis.

J. PETER GUTHRIE et JOHN COSSAR. Can. J. Chem. **68**, 397 (1990).

La chloration de l'isobutyrophénone, réalisée en solution alcaline, conduit à la formation de l'α-hydroxyisobutyrophénone comme premier intermédiaire détectable; une oxydation ultérieure lente conduit au benzoate. Sur la base des vitesses initiales de chloration, on a déterminé que la valeur du pK_a pour la cétone est égale à 18,18 ± 0,50. La vitesse d'hydrolyse alcaline de l'α-chloroisobutyrophénone est étonnamment rapide, $k_{OH} = 71{,}9 \pm 1{,}5\ M^{-1}\ s^{-1}$.

Mots clés : isobutyrophénone, chloration, énolisation, pK_a, hydrolyse.

Introduction

We have developed a method for determining pK_a values of simple ketones by analysis of the kinetics of chlorination in alkaline solution (1, 2). This method has been applied to a series of ring substituted acetophenones (3). We now wish to report its application to isobutyrophenone. Isobutyrophenone would have been expected to undergo ready monochlorination to produce α-hydroxyisobutyrophenone. We found that in fact α-hydroxyisobutyrophenone is the only detectable intermediate, and that this undergoes further reaction with hypochlorite to give benzoate.

Results

Biphasic kinetics were observed, with an initial rapid reaction followed by a tenfold slower reaction. The overall kinetics of chlorination of isobutyrophenone could be followed by UV, and showed two well-separated phases. A product isolation experiment after the first reaction had run to completion (about 14 half-lives for the first reaction and one for the second) showed 43% α-hydroxyisobutyrophenone and 57% benzoic acid, with no other detectable components. In the initial kinematics experiments the progress of reaction was followed at 292 nm, λ_{max} for OCl^-. At this wavelength there is an initial rapid decrease in absorbance followed by a larger, slower decrease. Interpretation of the absorbance change was simpler when reaction was followed at 230 nm, where the extinction coefficient of OCl^- is small. At 230 nm there was an initial decrease in absorbance followed by a slower increase. In both cases the integrated rate law was of the form:

$$[1]\quad \text{Absorbance} = a_1 + a_2 \exp(-a_3 t) + a_4 \exp(-a_5 t)$$

For a reaction of the type:[2]

$$\text{iBP} \xrightarrow{k_1} \text{HBP} \xrightarrow{k_2} \text{BA}$$

where k_1 and k_2 are pseudo-first-order rate constants including $[OCl^-]$, which is effectively constant within an experiment, we find that:

$$[\text{iBP}] = [\text{iBP}]_0 \exp(-k_1 t)$$

$$[\text{HBP}] = [\text{iBP}]_0\{k_1/(k_2 - k_1)\} \times \{\exp(-k_1 t) - \exp(-k_2 t)\}$$

$$[OCl^-] = [OCl^-]_0 - n[\text{iBP}]_0 + [\text{iBP}]_0(1 + k_2 n/(k_2 - k_1)) \exp(-k_1 t) + [\text{iBP}]_0 n k_1/(k_2 - k_1) \exp(-k_2 t)$$

$$[\text{BA}] = [\text{iBP}]_0\{1 + 1/(k_1 - k_2)\} \times \{k_2 \exp(-k_1 t) - k_1 \exp(-k_2 t)\}$$

$$[2]\quad \text{Absorbance}/l = \epsilon_{\text{iBP}}[\text{iBP}] + \epsilon_{\text{HBP}}[\text{HBP}] + \epsilon_{OCl}[OCl^-] + \epsilon_{\text{BA}}[\text{BA}]$$

$$= \epsilon_{OCl}\{[OCl]_0 - n[\text{iBP}]_0\} + \epsilon_{\text{BA}}[\text{iBP}]_0 + \exp(-k_1 t)\{\epsilon_{\text{iBP}}[\text{iBP}]_0 + \epsilon_{\text{HBP}} k_1[\text{iBP}]_0/(k_2 - k_1) + \epsilon_{OCl}[\text{iBP}]_0(1 + nk_2/(k_2 - k_1)) + \epsilon_{\text{BA}} k_2/(k_1 - k_2)\} + \exp(-k_2 t)\{-[\text{iBP}]_0 k_1/(k_2 - k_1)\}\{\epsilon_{\text{HBP}} + n\epsilon_{OCl} - \epsilon_{\text{BA}}\}$$

$$n = (a_1/(l\epsilon_{OCl}) - [OCl^-]_0)/[\text{iBP}]_0$$

where n = the number of moles of hypochlorite consumed per mole of isobutyrophenone in the complete reaction; we assume that the first phase consumes one mole of hypochlorite per mole of ketone. The validity of this assumption is shown by the good agreement of observed and calculated values of a_2: see below.

For kinetics followed at 230 nm the expression for absorbance is simplified by setting ϵ_{OCl} to zero; for kinetics followed at 292 nm the expression is simplified by setting ϵ_{BA} to zero.

For experiments at 292 nm, n can be calculated for the runs

where both exponential terms were evaluated. The values so obtained are found in Table 1. These values require that more than one mole of hypochlorite be consumed as a result of the second phase of reaction. Upon reflection it is clear that in addition to the cleavage of α-hydroxyisobutyrophenone, which is expected to consume one mole of hypochlorite, there should also be a rapid consumption of the acetone produced as a by-product with a stoichiometry of 2 moles of hypochlorite per acetone at a high $[OCl^-]/[OH^-]$ ratio, and 3 moles of hypochlorite at a low $[OCl^-]/[OH^-]$ ratio (2). This expectation is approximately fulfilled, although some runs showed higher than expected stoichiometries. It is possible to calculate values of the parameters a_2 and a_4 from n, the rate constants, and the extinction coefficients. When this is done the values obtained are in reasonable agreement with the observed values. The average ratios of calculated to observed parameters were a_2, 0.96 ± 0.17; a_4, 1.03 ± 0.06. One reason for imperfect agreement is that the very slow second phase was not followed as long as would be desirable, and often to only one or two half-lives, so that the least-squares parameters are uncertain, and subject to correlation. For runs in part (a) of Table 1, the initial excess of OCl^- is often too small to preserve good pseudo-first-order conditions throughout the second phase, although it is always large enough for the first phase to be pseudo first order. That this was the case became clear only as the stoichiometry was determined. In consequence, the rate constants determined in these experiments are bound to be less accurate. For runs in part (b) of Table 1, the excess of OCl^- is larger and these problems do not arise. There is no obvious trend when data from both sets are compared in plots, so we have used all of the data in the least-squares analysis presented below.

For reactions followed at 230 nm, the interpretation of a_1, a_2, and a_4 is simpler:

$$a_1/l[\text{iBP}]_0 = \epsilon_{BA}$$

$$a_2/l[\text{iBP}]_0 = \epsilon_{iBP} + \epsilon_{HBP}k_1/(k_2 - k_1)$$

$$a_4/l[\text{iBP}]_0 = -k_1/(k_2 - k_1)\{\epsilon_{HBP} - \epsilon_{BA}\}$$

The calculated values are in reasonable accord with the parameters from least-squares fitting. The average ratios of calculated to observed values were a_1, 0.98 ± 0.07; a_2, 1.16 ± 0.04; a_4, 1.19 ± 0.04.

We prepared α-chloroisobutyrophenone and measured its rate of hydrolysis to confirm that this was rapid relative to its formation by chlorination of isobutyrophenone. We also prepared α-hydroxyisobutyrophenone and showed that its rate of reaction with hypochlorite matched the second phase of reaction of isobutyrophenone.

For low concentrations of hydroxide it was necessary to use quite low concentrations of hypochlorite to make chlorination the rate determining step for the initial phase of the reaction; this made both phases slow, and the second phase very slow indeed. Kinetics under conditions where chlorination was clearly rate limiting were needed to determine the pK_a of isobutyrophenone; these kinetics were not possible by the UV method because the low concentrations of hypochlorite involved (with hypochlorite in excess) led to very small absorbance changes. By HPLC we could follow either the disappearance of isobutyrophenone (with OCl^- in excess) or the appearance of α-hydroxyisobutyrophenone (with ketone in excess). In the latter situation, $d[\text{HBP}]/dt = k_{obs}[\text{iBP}][OCl^-]$ and, since [iBP] is essentially fixed, pseudo-first-order conditions prevail. For isobutyrophenone there can be no question but that the stoichiometry number is 1 for the initial reaction. In general one must remember that the observed rate includes the stoichiometry number, for ketine in excess conditions, but not for hypochlorite in excess conditions (1). All of these rate constants are found in Table 1.

For substituted acetophenones we have found that the first chlorination step was rate determining under the usual conditions for chlorination kinetics (3), and the observed rates followed the rate law given in eq. [3]:

$$[3] \quad \begin{aligned} v &= k_{obs}[\text{Ketone}] \\ k_{obs} &= \{k_{II}^0 + k_{II}^-[OH^-]\}[OCl^-] \end{aligned}$$

If the same rate law applied for isobutyrophenone, then in terms of Scheme 1,

$$k_{II}^0 = k_{12}k_{23}^0K_w/k_{21}K_a^{HOCl}, \quad \text{and} \quad k_{II}^- = k_{12}k_{23}^-/k_{21}.$$

For the initial phase of the kinetics, where the rate of chlorination of isobutyrophenone is being followed, it was found that the pseudo-first-order rate constants for a set of experiments at fixed hydroxide concentration were not linearly dependent upon hypochlorite concentration, but showed a tendency to level off at high $[OCl^-]$. Thus, for isobutyrophenone enolate, halogenation and reprotonation are competitive. For this situation we may derive the expression for the rate law given in eq. [4]:

$$[4] \quad k_{obs} = \frac{k_{12}(k_{23}^0K_w/K_a^{HOCl} + k_{23}^-[OH^-])[OCl^-]}{k_{21} + (k_{23}^0K_w/K_a^{HOCl} + k_{23}^0[OH^-])[OCl^-]}$$

This may be transformed into a form convenient for fitting to the data, shown in eq. [5]:

$$[5] \quad k_{obs} = (a_1 + a_2[OH^-])/(1/[OCl^-] + a_1/a_3[OH^-] + a_2/a_3)$$

where $a_1 = k_{II}^0$, $a_2 = k_{II}^-$, and $a_3 = k_{12}$. The data from Table 1 were fitted to eq. [5]. Figure 1 shows the dependence of the corresponding second-order rate constants upon the concentrations of hydroxide and hypochlorite. For the determination of the pK_a it was more satisfactory to use the directly measured second-order rate constants at low $[OCl^-]$ for low $[OH^-]$ and extrapolated values at high $[OH^-]$ to give a fit to eq. [3]; the extrapolation was carried out by fitting data at constant $[OH^-]$ to eq. [6], and calculating the apparent second-order rate con-

$$[6] \quad k_{obs} = b_1/(1 + b_2/[OCl^-])$$

stant from the parameters so obtained. Simple algebra shows that b_1/b_2 from eq. [6] is equal to $a_1 + a_2[OH^-]$ from eq. [5]. Within the uncertainties of the parameters, as calculated by the least-squares procedure, the same parameter values were obtained in fitting to eq. [3] with or without the extrapolated values, but the uncertainties were smaller if the extrapolated values were included. This treatment of the data is shown in Fig. 2 and Table 2.

Table 3 contains the rate constants for the hydrolysis of α-chloroisobutyrophenone. The rate of this reaction is first order in hydroxide ion, with a second-order rate constant of 71.9 ± 1.5. In the same table are rate constants for the further reaction of α-hydroxyisobutyrophenone with alkaline hypochlorite. This reaction occurs at the same rate as the second phase of the overall reaction of isobutyrophenone. The rate law for this reaction has two terms, one zero order in $[OH^-]$ and one first order in $[OH^-]$; both are first order in $[OCl^-]$. This is equivalent to

eq. [3]. All of the data for this reaction, both from experiments starting with isobutyrophenone and from experiments starting with α-hydroxyisobutyrophenone, were fitted by least squares to eq. [3]. Figure 3 illustrates these concentration dependences. A plausible pair of transition state structures corresponding to the compositions indicated by the kinetics is shown in Scheme 2.

Discussion

For isobutyrophenone the absorbance–time curves could only be described by using two exponential terms. This contrasts with the behavior seen for acetone or acetophenone where the first chlorination step is clearly rate limiting under similar conditions. This complexity arises because of slower reaction of

the hydroxyketones formed by hydrolysis of the monochlorinated starting material. It is perhaps surprising that the subsequent oxidative cleavage is as fast as it is, and also that the hydrolysis of the chloroketone is so rapid.

α-Hydroxyisobutyrophenone accumulated as the only detectable intermediate in the reaction. The initial reaction is expected to be chlorination to give α-chloroisobutyrophenone; we have shown that hydroxide-catalyzed hydrolysis of this chloroketone is rapid. The hydrolysis of α-chloroisobutyrophenone is remarkably fast, with a rate constant of 71.9 M^{-1} s^{-1}, compared to 1.19 M^{-1} s^{-1} for monochloroacetone (2).

This hydrolysis would be expected to be slow by the classical S_N2 mechanism, because it takes place at a tertiary center (4). It would also be expected to be slow by the classical S_N1 solvolysis mechanism because reaction occurs next to a carbonyl group. Although S_N1 reactions at tertiary centers next to a carbonyl are known, they occur at rates similar to the analogous secondary centers with the acyl function replaced by hydrogen

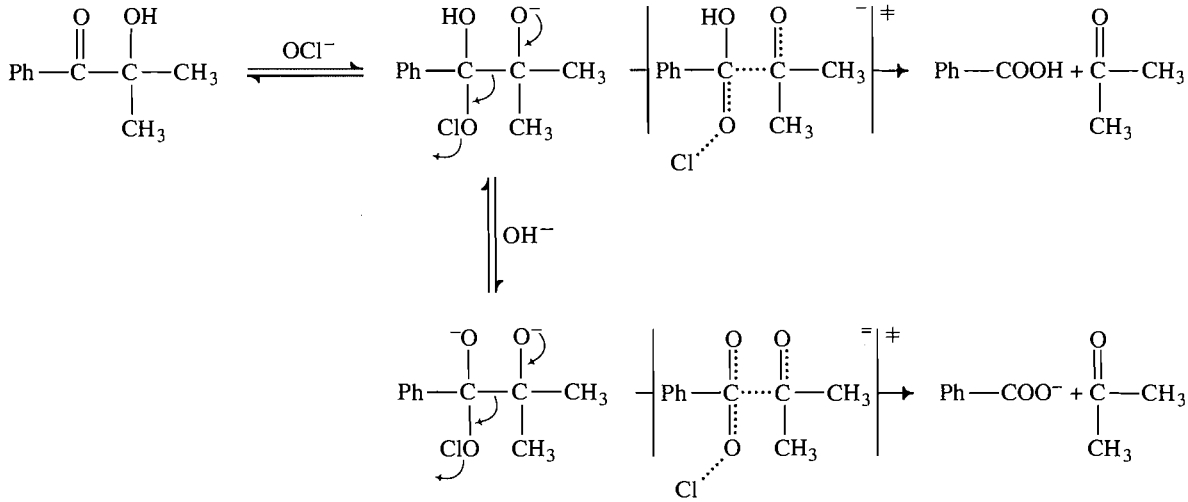

SCHEME 2

(5). In any case the reaction rate is first order in hydroxide so that it cannot be solvolysis. A plausible mechanism is addition of hydroxide, followed by intramolecular substitution.

This oxidation of α-hydroxyisobutyrophenone is unexpected and somewhat puzzling. When it first became clear that there was a second oxidation occurring, we wondered if the first step might be an alkaline ketol rearrangement to 3-hydroxy-3-phenyl-2-butanone, which could then undergo halogenation and haloform cleavage to atrolactic acid, or more likely (by analogy with acetophenone) halogenation, hydrolysis, and rearrangement to 2,3-dihydroxy-3-phenylbutanoic acid; or by addition of hypochlorite to the carbonyl, followed by fragmentation to give acetone and benzoic acid; or by hypochlorite ester formation, followed by hydroxide addition to the carbonyl and fragmentation to acetone and benzoic acid. When HPLC analysis, monitoring the absorptions due to aromatic compounds, was used to follow the course of the chlorination of isobutyrophenone, the only species observed were the starting material, the hydroxyketone, and benzoic acid. The rate of benzoic acid formation is first order in hypochlorite and approximately zero order in hydroxide (there is a term first order in hydroxide and first order in hypochlorite but this is less important); thus the rate determining step cannot be a hydroxide-catalyzed rearrangement, and since neither 3-hydroxy-3-phenyl-2-butanone (the product of an alkaline ketol rearrangement) nor atrolactic acid (derived from 3-hydroxy-3-phenyl-2-butanone by a standard haloform reaction) were observed to accumulate, rearrangement cannot be a pre-equilibrium step followed by rate determining cleavage by hypochlorite. Thus regardless of whether atrolactic acid or 2,3-dihydroxy-3-phenylbutanoic acid is stable to the reaction conditions, we can state that an alkaline ketol rearrangement is not part of the mechanism. We can rule out these paths on the basis of the observed product as well, because any plausible route to benzoate would have to pass through acetophenone as an intermediate, and acetophenone would give extensive formation of mandelate under at least some of the experimental conditions used (3). The remaining ambiguity is whether addition of hypochlorite to the carbonyl or esterification at the α-hydroxyl initiates the cleavage reaction. Esterification seems inherently unlikely in alkaline solution; although *tert*-butyl hypochlorite is synthesized in alkaline solution (6), the equilibrium is doubtless displaced towards the ester by phase separation. *tert*-Butyl hypobromite is prepared from *tert*-butyl alcohol and hypobromous acid and is destroyed by carbonate (7). The most probable mechanism appears to be addition of hypochlorite to the carbonyl to give an anionic adduct, which then undergoes fragmentation. An analogous mechanism has been proposed for the oxidative cleavage of α-ketols by alkaline hydrogen peroxide (8).

For the reasons outlined above, we suggest that the reactions occurring are as shown in Scheme 2.

The rate of enolization of isobutyrophenone which we determined was $0.0031\ M^{-1}\ s^{-1}$ at 1.0 M ionic strength, which is in satisfactory agreement with a direct measurement by Kresge and co-workers, $0.00243\ M^{-1}\ s^{-1}$ at 0.1 M ionic strength (9). The pK_a value which we found, 18.18, is very similar to the more precise value determined by Kresge, 18.26 (9). Thus our method has again been shown to lead to valid pK_a results, with relatively simple kinetics measurements.

The very old-fashioned reaction of ketones with chlorine in alkaline solution has abundant surprises still to be found. The hydrolysis of α-chloroketones is well known to be fast, but that the process can be faster for a tertiary than for a primary center seems startling. The cleavage of an α-hydroxyketone by hypochlorite is a reminder of how powerful the thermodynamic driving force for chlorine oxidations really is.

Experimental

Materials

Sodium hydroxide and potassium chloride were reagent grade, used without further purification. Sodium hypochlorite solutions were prepared by bubbling chlorine into aqueous sodium hydroxide; the hypochlorite concentration of the resulting solution was determined either by the absorbance at 292 nm or by titration (2). The sodium hydroxide concentration of kinetics solutions was determined by titration (2).

Isobutyrophenone, Aldrich "97%", was purified by distillation, bp 117–118°C (25 Torr; 1 Torr = 133.3 Pa). UV spectrum in water: $\lambda_{max} = 245.5$, $\epsilon_{max} = 12\,000$; $\epsilon_{292} = 760$.

α-Chloroisobutyrophenone

Isobutyrophenone, 3.00 g (20.2 mmol) in ether, 50 mL, containing aqueous HCl, 1 mL, was treated with excess chlorine gas for 2 h with cooling in an ice bath and then 2 h at room temperature. The ether solution was washed once with conc. aq. Na_2SO_4 and once with conc. aq. $NaHCO_3$, dried (Na_2SO_4), and evaporated. The residue was purified by Kugelrohr distillation (70–75°C, 0.5 Torr) to give 3.49 g of

viscous liquid. ^{1}H NMR analysis showed it to be ca. 90% product and 10% starting material. A pure sample was obtained by column chromatography on silica gel, eluting with 1:1 $CHCl_3$:CCl_4. UV: λ_{max} 252, ϵ_{max} 7700 in H_2O; λ_{max} 247.5, ϵ_{max} 8100 in 0.1 M aq. NaOH. ^{1}H NMR ($CDCl_3$) δ: 1.92, (s, 6H), C*H*$_3$-C, 7.5, 8.2, (m, total of 5H), aromatic C-*H*. Literature (10) bp 69–70°C, 0.4 Torr; (11) bp 119–120°C, 18 Torr; ^{1}H NMR (CCl_4) δ: 1.80 (6H, s), 7.7 (5H, m).

α-Hydroxyisobutyrophenone

α-Chloroisobutyrophenone, 413 mg (2.26 mmol) was stirred for 3 days at room temperature in 0.1 M aq. $NaHCO_3$, 300 mL. The pH of the solution was ca. 8.6; solution of the starting material was complete after 12 h. Extraction with ether, 3 × 150 mL, drying of the extracts (Na_2SO_4), and evaporation gave 366 mg of viscous liquid; 98%. UV: λ_{max} 247.5, ϵ_{max} 9600 in H_2O; λ_{max} 247.5, ϵ_{max} 9600 in 0.1 M aq. NaOH; λ_{max} 244.5, ϵ_{max} 11700, log ϵ_{max} 4.07 in 95% ethanol; lit. (12) λ_{max} 245, log ϵ_{max} 4.05 in 90% ethanol. ^{1}H NMR ($CDCl_3$) δ: 1.60, (s, 6H), C*H*$_3$-C, 7.7 and 8.0 (m, total of 5H), aromatic C-*H*. Literature (8) ^{1}H NMR (CCl_4) δ: 1.52 (6H, s), 7.2–7.5 and 7.8–8.0 (total of 5H, m).

Methods

TLC was carried out using Analtech 250 μm silica gel GF plates or Macherey–Nagel, Polygram SIL G/UV precoated plastic sheets (0.25 mm). Column chromatography was carried out using Terochem silica gel, no. 1918.

HPLC analyses were carried out using C18 reverse phase columns (Waters Radial Pak), with mixtures of aqueous buffers and methanol as eluting solvent, and UV detection.

Least-squares calculations were carried out using FORTRAN programs written for the purpose; non-linear least squares and the Marquardt algorithm (13) were used for other than straight line correlations.

Kinetics procedures

All reactions were studied in aqueous solution at 25°C and ionic strength 1.0 M (KCl) using apparatus and procedures previously described (2). Reactions were initiated by injecting (Hamilton syringe) a known amount of a stock solution of the ketone into thermally equilibrated hydroxide/hypochlorite solution in a quartz UV cell.

Hydrolysis of chloroisobutyrophenone

A stock solution was prepared in 80% methanol:20% water. Freshly prepared hydroxide solutions, ionic strength 1 M with KCl, were titrated immediately before use and immediately after the runs, with 0.05 M HCl standardized against tris base. Kinetics were initiated by injecting a suitable amount of stock solution of chloroketone into hydroxide solution previously thermostatted in 5 or 10 cm quartz cells, and were followed by monitoring absorbance at 247 nm, the λ_{max} of the product. pH values were taken at the end of the reaction and had changed by no more than 0.01 pH unit.

Chlorination of isobutyrophenone and hydroxyisobutyrophenone

Reactions monitored by UV absorbance were carried out as described above. Reactions monitored by HPLC were carried out in a thermostatted flask and samples were taken and injected at suitable intervals using an autosampler. In some cases 1.0-mL samples were taken manually and quenched ($NaHSO_3$ and H_3PO_4) for later analysis. The peaks for HPP and HPA were assigned by comparison with those for authentic samples prepared as described above.

Product studies

Isobutyrophenone (0.00107 M), NaOH (0.1 M), KCl (0.9 M), and NaOCl (0.003 M), in a volume of 1 L, were allowed to stand for 20 h, which is 17 half-lives for the initial reaction based on the starting concentration of hypochlorite, and about one half-life for the second reaction. Extraction with ether, 3 × 200 mL, drying of the extracts (Na_2SO_4), and evaporation gave 112 mg, shown by ^{1}H NMR analysis to be 70% α-hyroxyisobutyrophenone and 30% benzoic acid. Only two UV positive spots were detected by TLC analysis. No isobutyrophenone was detectable. Treatment of the aqueous reaction solution with 0.5 g $NaHSO_3$ and acidification with HCl, followed by extraction with ether, 3 × 200 mL, drying of the extracts, and evaporation gave 39 mg, shown by NMR and TLC analysis to be benzoic acid. The mass balance was 99.9%.

Synthesis and transannular Diels–Alder reaction of a 13-membered macrocyclic triene having a tetrasubstituted enol ether as dienophile

GERVAIS BÉRUBÉ[1] AND PIERRE DESLONGCHAMPS

Laboratoire de synthèse organique, Départment de chimie, Faculté des sciences, Université de Sherbrooke, Sherbrooke (Québec), Canada J1K 2R1

Received July 17, 1989

GERVAIS BÉRUBÉ and PIERRE DESLONGCHAMPS. Can. J. Chem. **68**, 404 (1990).

The syntheses of the acyclic triene *trans–trans–cis* **27** and *trans–trans–trans* **31** are described. Macrocyclization and concomitant transannular Diels–Alder reaction were performed with the chloride derivative obtained from the *trans–trans–cis* triene alcohol **27** yielding a mixture of the tricyclic compounds *trans–syn–trans* **33** and *cis–syn–cis* **34**. On the other hand, macrocyclization of the chloride derived from *trans–trans–trans* triene **31** was not successful.

Key words: transannular process, Diels–Alder reaction, macrocyclic triene, macrocyclization, tricyclic compounds, organic synthesis.

GERVAIS BÉRUBÉ et PIERRE DESLONGCHAMPS. Can. J. Chem. **68**, 404 (1990).

La synthèse des triènes acycliques *trans–trans–cis* **27** et *trans–trans–trans* **31** est décrite. Une réaction de macrocyclisation suivie d'une réaction de Diels–Alder transannulaire a été observée en partant du dérivé chlorure du triène *trans–trans–cis* alcool **27** donnant un mélange des composés tricycliques *trans–syn–trans* **33** et *cis–syn–cis* **34**. Par contre, la macrocyclisation du dérivé chlorure du triène *trans–trans–trans* alcool **31** n'a pas été réussie.

Mots clés : procédés transannulaires, réaction Diels–Alder, triènes macrocycliques, macrocyclisation, composés tricycliques, synthèse organique.

The synthesis of polycyclic natural products like steriods and terpenes is a well-documented subject (1). These compounds can be obtained via numerous methods such as aldol condensation (2), biomimetic cyclization of polyenes (3), or by intramolecular Diels–Alder reaction (4*a–c* (reviews), 4*d–h* (specific examples)). We (5) and others (6) have recently been investigating a new strategy for the construction of such polycyclic compounds, which makes use of the transannular Diels–Alder process on a macrocyclic triene, i.e., **1** → **2** (Scheme 1).

To demonstrate the feasibility of this new strategy, one[2] of the examples that we have examined is the reaction **3** → **4**, which should give rise to a tricyclic structure containing quaternary centers at positions 9 and 10 (steroid membering). This substitution pattern is found in nature in compounds such as germine (**5**) (Scheme 2), a steroid alkaloid of the Veratrum family (7), or batrachotoxin (**6**), one of the most poisonous compounds known (8). It can also be found in other compounds like rosenonolactone (**7**) (9) or forskolin (**8**) (10).

Synthesis of the acyclic triene precursors

The synthesis of the monosilylated derivative of *trans–trans*-hexa-2,4-diene-1,6-diol **14** (Scheme 3) was carried out starting from the *trans*-unsaturated aldehyde **10** (11). Emmons–Horner reaction of **10** with ethyl diisopropyl phosphonoacetate (12) gave the *trans–trans* diene ester **11**. The tetrahydropyranyl group in **11** was then replaced by a *tert*-butyl dimethyl silyl protecting group (PPTS, CF_3COOH, MeOH (13); *t*-Bu$(CH_3)_2SiCl$, imidazole, THF (14)) to produce the silylated diene ester **13** via intermediate formation of **12**. Reduction of **13** with diisobutyl aluminium hydride gave the required diene alcohol **14** which was then converted into the *trans–trans*-allylic chloride **15** (LiCl, CH_3SO_2Cl, *s*-collidine, DMF) (15), which is described in Scheme 4.

The dioxolane malonate **9** (Scheme 4) was prepared (16) from the Michael reaction of dimethyl malonate with methyl vinyl ketone followed by ketalization with ethylene glycol. Condensation of allylic chloride **15** with the sodium salt of dimethyl malonate **9** gave the corresponding diene **16** in 89% yield.

Decarbalkoxylation of **16** (17) gave the monoester **17**, which was reduced to the alcohol **18** with diisobutyl aluminium hydride and protected as the benzyl ether **19**. Acid hydrolysis of **19** with pyridinium *p*-toluenesulfonate (13) afforded the ketone alcohol **20**, which was reprotected as its silyl ether **21** (14). The Emmons–Horner reaction of the lithium salt of phosphonate **22** (18) with ketone **21** in toluene proceeded slowly (90–100 h) to give a mixture of α,β-unsaturated esters **23** (79%, *cis*:*trans* = 1:1 ratio) as shown by ^{1}H nmr. Reduction of **23** with diisobutyl aluminium hydride afforded a mixture of allylic alcohols, which were separated by chromatography, the *trans–trans–cis* alcohol **24** being less polar than the *trans–trans–trans* isomer **28**.

The *trans–trans–cis* triene acyclic precursor **27** was prepared from the *cis*-alcohol **24** in the following way: compound **24** was converted into the allylic chloride **25** (LiCl, CH_3SO_2Cl, *s*-collidine, DMF) (15), which was then treated with an excess of dimethyl sodium malonate to give the substituted malonate **26**. Cleavage of the silyl ether protecting group with fluoride ion (14) afforded the *trans–trans–cis* alcohol **27**. The *trans–trans–trans* triene acyclic precursor **31** was prepared from **28** using a similar procedure via the intermediate formation of **29** and **30**.

Macrocyclization and Diels–Alder reaction

The best results for macrocyclization and Diels–Alder reaction were obtained with the allylic chloride **32** (Scheme 5) derived from the *trans–trans–cis* triene alcohol **27** using a pseudo high-dilution technique. The crude allylic chloride **32** prepared (LiCl, CH_3SO_2Cl, *s*-collidine, DMF) (15) from alcohol **27** was dissolved in *N,N*-dimethylformamide (DMF) and added over a period of 22 h (syringe pump) directly into a suspension of sodium hydride in a mixture of tetrahydrofuran and DMF at 70°C. This produced compounds **33** and **34** along with a mixture of monodecarboxylated products **35** in a ratio of 13:6:3 and with an overall yield of 68%. These compounds were separated by chromatography and the structure of compound **33** was fully confirmed by X-ray crystallography (19). The general structure

of compounds **34** and **35** was established by their spectral data[3] relative to compound **33**.

The ^{1}H nmr spectrum of **33** shows the following characteristic signals: an angular methyl at 0.74 ppm (similar to an angular methyl at the ring junction of a *trans* decalin where the methyl is axial to both rings), and the methylene group of the methoxymethyl ether as an AB system (two doublets) at 4.53 ppm. The methylene protons are diastereotopic, have different chemical shifts, and appear as two doublets.

The ^{1}H nmr spectrum of **34** shows the following characteristics: an angular methyl at 1.05 ppm, and the methylene group of the methoxymethyl ether as a singlet at 4.67 ppm. The methylene protons are diastereotopic and should in principle appear as doublets; however, they have the same chemical shift. Being angular at a *cis* decalin ring junction, the angular methyl is shifted downfield at 1.05 ppm as it is normally observed. The relative stereochemistry of the *cis–syn–cis* tricycle **34** has not been rigorously established by X-ray crystallography since this compound is not crystalline, but its assignment is based on the preceding criteria and on the following analysis. Using molecular models, and assuming that the Diels–Alder reaction must take place via a boat-like transition state, it can be readily seen that the *trans–trans–cis* macrocyclic triene **36**, which must have been formed from **32**, can undergo two different transannular cycloadditions leading either to a *trans–syn–trans* (TSC) or a *cis–syn–cis* (CSC) tricycle with ring B in a boat form (cf. **33A** and **34A**), both of which have ring A in a chair

[3]The minor formation of monodecarboxylated products is presumably due to the presence of a small quantity of sodium hydroxide in the medium, which induced partial hydrolysis and decarboxylation.

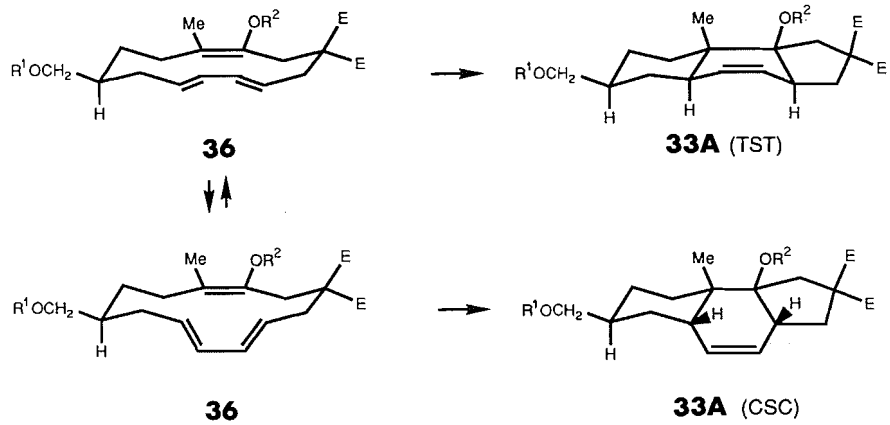

SCHEME 6

form with the benzyloxymethylene group in an equatorial position as shown in Scheme 6.[4]

To confirm that the above Diels–Alder reaction is the result of a transannular process, the mixture of α,β-unsaturated esters **23** dissolved in toluene was heated in a sealed tube at 210°C for 18 h. No Diels–Alder product was observed and starting material was recovered quantitatively. Since the isomeric compounds **23** have an activated dienophile (due to the conjugation with the ester function) and did not undergo an intramolecular Diels–Alder reaction at 210°C, this clearly confirms that transannular Diels–Alder can take place with much greater ease (70°C) and even with a poorly activated dienophile.

The *trans–trans–trans* acyclic precursor **31** was also converted into the corresponding allylic chloride and submitted to the above experimental conditions for macrocyclization. In this series, we failed to isolate any specific compounds having a macrocyclic or a tricyclic structure; rather we observed essentially complete decomposition of the starting material. This is likely due to the fact that the macrocyclization reaction must have failed. We have also observed in other series that the yield of macrocyclization of acyclic trienes having the *trans–trans–trans* geometry can indeed be low (5*e*).

In conclusion, we have shown in this work that the macrocyclization of an acyclic triene can yield a macrocycle that undergoes a very facile transannular Diels–Alder reaction by comparison with the simple intramolecular process. However, the success of the process depends on the ease of macrocyclization, which varies as a function of the geometry of the unsaturations (20). This work also shows that transannular Diels–Alder reaction on macrocycles is potentially a powerful strategy for the construction of polycyclic compounds (21). Further work in this direction is in progress.

Experimental

The ir spectra were taken on a Perkin–Elmer 681 spectrophotometer. Proton nmr spectra were recorded on a Bruker WP-80 or Bruker WM-250 instrument. The following abbreviations have been used: s, singlet; d, doublet; dd, doublet of doublets; dt, doublet of triplets; ddd, doublet of doublets of doublets; ddt, doublet of doublets of triplets; t, triplets; q, quartet; and m, multiplet. Chemical shifts are reported in δ values relative to tetramethylsilane or chloroform as internal standard. Carbon nuclear magnetic resonance spectra were recorded on a Bruker WP-80 or Bruker WM-250 instrument (chloroform as internal standard). Mass spectra were obtained on a Micromass ZAB-2F instrument. Melting points were determined on a Büchi M-50 or on a Reichert apparatus and are uncorrected.

Thin-layer chromatography was performed using silica gel 60 F-250. For flash chromatography, Merck Kieselgel 60 (230–400 mesh A.S.T.M.) was used. All solvents used in chromatography were distilled. Unless otherwise noted, starting materials and reactants were obtained commercially and were used as such or purified by standard means. All solvents and reactants purified and dried were stored under argon.

Anhydrous reactions were performed under an inert atmosphere of argon. Organic solutions were dried over magnesium sulfate, and were evaporated on a rotatory evaporator and under reduced pressure.

Dioxolane 9

Dimethyl malonate (18 mL, 20.8 g, 157 mmol) in dry benzene (200 mL) was stirred at room temperature with potassium carbonate (21.7 g, 151 mmol) and methyl vinyl ketone for 21 h. Water was added and the mixture was extracted with ether. The organic layer was dried, filtered, and the solvents evaporated. The crude product was then refluxed in benzene (250 mL, Dean–Stark) with ethylene glycol (9.6 mL, 10.68 g, 170 mmol) and *p*-toluenesulfonic acid (10 mg, 5.8×10^{-2} mmol) for 18 h. It was then washed with sodium bicarbonate solution (2×30 mL, 5% aqueous) and with distilled water (4×30 mL). The organic layer was dried, filtered, and the benzene evaporated. The residue was purified by flash chromatography (hexane:acetone, 4:1) to give the dioxolane **9** (26.3 g, 75% overall); ir ($CHCl_3$): 1740 (C=O), 1300–1120 (C—O), 1060 (C—O); nmr ($CDCl_3$) δ: 3.93 (4H, s, -OCH_2CH_2O-), 3.73 (6H, s, $2 \times$ -CO_2CH_3), 3.42 (1H, t, $J = 7.24$ Hz, -CH(CO_2CH_3)$_2$), 2.25–1.50 (4H, m, -CH_2CH_2-), 1.31 (3H, s, -CH_3); ms *m/e* (70 eV): 231 ($M^+ - CH_3$), 215 ($M^+ - OCH_3$). Exact mass calcd.: 231,0868 ($M^+ - CH_3$); found: 231,0868 ($M^+ - CH_3$).

trans-*Aldehyde 10*

A mixture of commercially available *cis*-2-butene-1,4-diol (22.04 g, 0.25 mol), 3,4-dihydro-2*H*-pyran (23.14 g, 0.27 mol), and *p*-toluenesulfonic acid (242 mg, 1.27 mmol) in dry ethyl acetate (500 mL) was stirred at 0°C for 40 min and at room temperature for 30 min. Then sodium bicarbonate (525 mg, 6.25 mmol) was added and the mixture was stirred for 30 min, filtered, and the solvent was evaporated. The crude oil was purified by flash chromatography. Elution with a mixture of ethyl acetate:hexane (15:85) gave the bis-tetrahydropyranyl derivative (9.55 g, 15%) and elution with a mixture of ethyl acetate:hexane (50:50) gave the mono-tetrahydropyranyl derivative (22.7 g, 53%).

Mono-derivative: ir ($CHCl_3$): 3620 (OH, free), 3650–3250 (OH, associated), 1025 (C—O); nmr ($CDCl_3$) δ: 6.20–5.50 (2H, m, -CH=CH-), 4.68 (1H, br s, -OCHO-), 4.60–3.30 (6H, m, -CH_2CH_2O-, $2 \times$ =CHCH_2O-), 2.18 (1H, br s, OH), 1.65 (6H, m, -$CH_2CH_2CH_2$O-).

Bis-derivative: ir ($CHCl_3$): 1025 (C—O); nmr ($CDCl_3$) δ: 5.75 (2H, t, $J = 4.0$ Hz, -CH=CH-), 4.63 (2H, br s, $2 \times$ -OCHO-), 4.55–3.20 (8H, m, $2 \times$ -CH_2CH_2O-, $2 \times$ =CHCH_2O-), 1.64 (12H, m, $2 \times$ -$CH_2CH_2CH_2CH_2$O-).

[4]With its *trans–syn–trans* geometry, ring B of compound **33** is locked in the boat conformation, and this is clearly revealed in the X-ray analysis (19).

A solution of the preceding alcohol (mono-tetrahydropyranyl derivative) (10 g, 58 mmol), sodium acetate (14.3 g, 174 mmol), crushed molecular sieves (3Å, 20 g), and pyridinium chlorochromate (PCC, 18.8 g, 87 mmol) in dry methylene chloride (250 mL) was stirred at 0°C for 30 min and at room temperature for 1 h. Then ether (250 mL) was added and the resulting mixture was filtered through Celite and sodium sulfate. The filtrate was then evaporated to give *trans*-aldehyde **10** (9.4 g, 95% crude), which was used without any purification; ir ($CHCl_3$): 2860 and 2740 (C—H, aldehyde), 1690 (C=O), 1645 (C=C), 1040 (C—O); nmr ($CDCl_3$) δ: 9.59 (1H, d, J = 7.6 Hz, -C*H*O-, 6.92 (1H, dt, J = 15.6 Hz, 3.6 Hz, -CH_2CH=), 6.36 (1H, ddt, J = 15.6 Hz, 7.4 Hz, 1.5 Hz, =C*H*CHO-), 4.69(1H, m, -OC*H*O-), 4.40 (2H, m, =CHCH_2O-), 4.15–3.15 (2H, m, -CH_2CH_2O-), 1.69 (6H, m, -$CH_2CH_2CH_2CH_2$O-).

Ester ***11***

To a stirred suspension of sodium hydride (2.6 g (60% in oil), 64.9 mmol) in anhydrous THF (100 mL) at 0°C was added via cannula a solution of ethyl diisopropylphosphonoacetate (17.8 g, 70 mmol) in anhydrous THF (50 mL). When gas evolution had ceased, the resulting solution was cooled to −50°C and a solution of *trans*-aldehyde **10** (9.2 g, 54 mmol) in anhydrous THF (50 mL) was added via cannula. The reaction was allowed to warm to 0°C and stirred for 2 h. After that period, ether (500 mL) and saturated ammonium chloride (100 mL) were added. The aqueous layer was separated and extracted with ether (3 × 50 mL). The combined organic layers were washed with brine (2 × 50 mL), dried, filtered, and evaporated. The residue was purified by flash chromatography (ethyl acetate:hexane, 1:9) to give the ester **11** (6.6 g, 50%); ir ($CHCl_3$): 1710 (C=O), 1650 and 1620 (C=C), 1140 and 1025 (C—O); nmr ($CDCl_3$) δ: 7.27 (1H, dd, J = 15.3 Hz, 11.0 Hz, -C*H*=CHCO_2Et), 6.40 (1H, ddt, J = 15.3 Hz, 11.0 Hz, 1.4 Hz, -CH_2CH=C*H*-), 6.17 (1H, dt, J = 15.3 Hz, 5.3 Hz, -CH_2CH=CH-), 5.86 (1H, d, J = 15.3 Hz, -CH=C*H*CO_2Et), 4.64 (1H, t, J = 3.3 Hz, -OC*H*O-), 4.34–4.08 (2 × 1H, ddd, J = 14.7 Hz, 5.3 Hz, 1.4 Hz, -CH_2OTHP), 4.21 (2H, q, J = 7.1 Hz, -CH_2CH_3), 3.84–3.50 (2 × 1H, m, -CH_2CH_2O-), 1.69 (6H, m, -$CH_2CH_2CH_2CH_2$O-), 1.28 (3H, t, J = 7.1 Hz, -CH_2CH_3); ms m/e (70 eV): 240 (M^+). Exact mass calcd.: 240.1362 (M^+); found: 240.1372 (M^+).

Hydroxy-ester ***12***

A solution of ester **11** (6.4 g, 26.6 mmol), pyridinium *p*-toluenesulfonate (PPTS, 670 mg, 2.6 mmol), and trifluoroacetic acid (TFA, one drop) in methanol (100 mL) was stirred at 50°C for 2.5 h. Then methanol was evaporated and the residue, dissolved in ether (10 mL), was filtered through silica. The filtrate was then evaporated to give hydroxy-ester **12** (4.1 g, 98% crude), which was used without any purification.

Silyl ether ***13***

To a solution of crude hydroxy-ester **12** (4.1 g, 26 mmol) in dry THF (300 mL) at 0°C was added *tert*-butyldimethysilyl chloride (7.9 g, 52 mmol) and imidazole (7.15 g, 105 mmol). The reaction mixture was allowed to warm to room temperature and stirred for 1 h. Ether (600 mL) was added and the organic phase was washed with distilled water (4 × 100 mL), dried, filtered, and evaporated to give silyl ether **13** (9.5 g crude, 130%), which was used without any purification.

Alcohol ***14***

Crude silyl ether **13** (9.5 g crude, theoretically 26 mmol), dissolved in dichloromethane (175 mL) at −78°C, was treated with a solution of diisobutylaluminium hydride (55 mL of 1 M solution in hexane, 55 mmol) and stirred for 45 min. Then the reaction mixture was quenched with saturated ammonium chloride (80 mL) and allowed to warm to room temperature. The viscous solution was filtered on a pad of Celite using ether as eluent. Solvents were evaporated and the residue was dissolved in ether (300 mL). The ethereal phase was washed with 5% aqueous sodium bicarbonate (3 × 50 mL) and with water (3 × 50 mL). The ethereal phase was dried, filtered, and evaporated to yield, after flash chromatography (hexane:acetone, 4:1), the alcohol **14** (5.8 g, 95% from ester **11**); ir ($CHCl_3$): 3620 (OH, free), 3660–3250 (OH, associated), 1665 and 1628 (C=C), 1255 (Si-CH_3), 1150–980 (C—O) and Si—O); nmr ($CDCl_3$) δ: 6.50–5.50 (4H, m, -C*H*=C*H*—C*H*=C*H*-), 4.19 (4H, m, -CH_2OH and -CH_2OSi$(CH_3)_2$C$(CH_3)_3$), 1.45 (1H, m, -CH_2O*H*), 0.92 (9H, s, -Si$(CH_3)_2$C$(CH_3)_3$), 0.08 (6H, s, -Si$(CH_3)_2$C$(CH_3)_3$).

Allylic chloride ***15***

To a solution of allyl alcohol **14** (987 mg, 4.33 mmol), *s*-collidine (640 μL, 586 mg, 4.83 mmol), and lithium chloride (224 mg, 5.28 mmol) in dry *N*,*N*-dimethylformamide (DMF, 10 mL), at 0°C, was added methanesulfonyl chloride (370 μL, 547 mg, 4.78 mmol). The reaction mixture was stirred at 0°C for 1 h and at room temperature for 1 h. Then the solution was poured in a funnel containing water and ice and extracted with a mixture of ether and hexane (1:4, 100 mL, 3 × 20 mL). The organic layers were combined and washed with water (3 × 20 mL), then dried, filtered, and the solvent evaporated. The crude product **15** (906 mg, 85%) was used without any purification since it decomposes on silica. Nevertheless the allylic chloride **15** can be stored in frozen benzene; ir ($CHCl_3$): 1660 and 1630 (C=C), 1255 (Si-CH_3), 1180–1050 (C—O and Si—O); nmr ($CDCl_3$) δ: 6.50–5.50 (4H, m, -C*H*=C*H*—C*H*=C*H*-), 4.18 (4H, two d, J = 5.5 Hz and 8.6 Hz, -CH_2-Cl and -CH_2O-), 0.92 and 0.08 (9H and 6H, two s, -Si$(CH_3)_2$C$(CH_3)_3$).

Diene ***16***

Sodium hydride (63.4 mg (60% in oil), 1.6 mmol) was added to a solution of dioxolane **9** (350 mg, 1.42 mmol) in a mixture of tetrahydrofuran (THF) and DMF (5:1, 8 mL) at 0°C. The reaction was allowed to warm to room temperature and stirred for 1 h. Then, at 0°C, a solution of crude allylic chloride **15** (395 mg, 1.6 mmol) in THF:DMF (5:1, 4 mL) was added. After addition, the mixture was stirred at room temperature for 12 h. The reaction mixture was then evaporated and the residue, dissolved in ether (50 mL), was washed with saturated ammonium chloride (40 mL). The aqueous layer was extracted with ether (3 × 10 mL). The combined organic layers were washed with brine (2 × 30 mL), dried, filtered, and evaporated. The crude oil was purified by flash chromatography (hexane:acetone, 4:1) to give the diene **16** (579 mg, 89%); ir ($CHCl_3$): 1730 (C=O), 1255 (Si-CH_3), 1055 (C—O); nmr ($CDCl_3$) δ: 6.16 (1H, ddt, J = 14.75 Hz, 10.0 Hz, 1.5 Hz, -C*H*=CHCH$_2$O-), 6.07 (1H, dd, J = 14.75 Hz, 10.0 Hz, -CH_2CH=C*H*-), 5.67 (1H, dt, J = 14.75 Hz, 5.0 Hz, -CH= C*H*CH_2O-), 5.47 (1H, dt, J = 14.75 Hz, 7.7 Hz, -CH_2CH=CH-), 4.19 (2H, d, J = 5.0 Hz, =CHCH_2O-), 3.92 (4H, m, -OCH_2CH_2O-), 3.71 (6H, s, 2 × -CO_2CH_3), 2.64 (2H, d, J = 7.7 Hz, -CH_2CH=CH-), 1.97 (2H, m, -CH_2CH_2C$(CO_2CH_3)_2$), 1.54 (2H, m, -CH_2CH_2C$(CO_2CH_3)_2$), 1.30 (3H, s, -CH_3), 0.90 and 0.06 (9H and 6H, two s, -Si$(CH_3)_2$C$(CH_3)_3$); ms m/e (70 eV): 456 (M^+), 441 (M^+-CH_3), 399 ($M^+-C(CH_3)_3$). Exact mass calcd.: 441.2308 (M^+-CH_3); found: 441.2296 (M^+-CH_3).

Ester ***17***

A solution containing diene **16** (5.05 g, 11 mmol), lithium chloride (1.03 g, 24.2 mmol), and water (250 μL, 250 mg, 13.8 mmol) in DMF (30 mL) was stirred at 165°C for 2.5 h. Then the solution was dried with magnesium sulfate and filtered on silica with ether as eluant. Evaporation of the solvent gave a crude oil, which was purified by flash chromatography (hexane:acetone, 85:15) to afford ester **17** (2.7 g, 61%); ir ($CHCl_3$): 1730 (C=O), 1255 (Si-CH_3), 1050 (C—O); nmr ($CDCl_3$ δ: 6.16 (1H, ddt, J = 14.5 Hz, 10.0 Hz, 1.5 Hz, -C*H*=CHCH$_2$O-), 6.05 (1H, dd, J = 14.5 Hz, 10.0 Hz, -CH_2CH=C*H*-), 5.66 (1H, dt, J = 14.5 Hz, 5.1 Hz, -CH=C*H*CH_2O-), 5.56 (1H, dt, J = 14.5 Hz, 7.3 Hz, -CH_2CH=CH-), 4.18 (2H, d, J = 5.1 Hz, =CHCH_2O-), 3.91 (4H, m, -OCH_2CH_2O-), 3.66 (3H, s, -CO_2CH_3), 2.50–2.20 (3H, m, -C*H*—CO_2CH_3 and -CH_2CH=CH-), 1.80–1.55 (4H, m, -CH_2CH_2CH—CO_2CH_3), 1.30 (3H, s, -CH_3), 0.90 and 0.06 (9H et 6H, two s, -Si$(CH_3)_2$C$(CH_3)_3$); ms m/e (70 eV): 398 (M^+), 383 (M^+-CH_3), 367 (M^+-OCH_3). Exact mass calcd.: 383.2253 (M^+-CH_3); found: 383.2251 (M^+-CH_3).

Alcohol ***18***

To a stirred solution of ester **17** (2.7 g, 6.78 mmol) in dichloromethane (100 mL), at −78°C, was added dropwise diisobutylaluminium hydride (DIBAH, 17 mL, 1.7 mmol, 1 M in hexane). The mixture was stirred for 30 min at −78°C after which it was quenched with aqueous

saturated NH_4Cl solution (60 mL), and allowed to warm to room temperature. The resulting slurry was filtered through Celite with ether as eluent. The filtrate was then evaporated and the residue, dissolved in ether (20 mL), was washed with 5% aqueous sodium bicarbonate (3 × 50 mL) and with water (3 × 50 mL). The ethereal phase was dried, filtered, and evaporated to yield, after flash chromatography (hexane:acetone, 4:1), the alcohol **18** (2.05 g, 82%); ir ($CHCl_3$): 3630 (OH, free), 3600–3350 (OH, associated), 1255 (Si-CH_3), 1050 (C—O); nmr ($CDCl_3$) δ: 6.20 (1H, ddt, J = 14.5 Hz, 10.0 Hz, 1.5 Hz, -C*H*=$CHCH_2O$-), 6.07 (1H, dd, J = 14.5 Hz, 10.0 Hz, -CH_2CH=C*H*-), 5.72–5.57 (2H, m, -C*H*=CH—CH=C*H*CH_2O-), 4.19 (2H, d, J = 5.1 Hz, =$CHCH_2O$-), 3.93 (4H, m, -OCH_2CH_2O-), 3.54 (2H, multiplet, -CH_2OH), 2.13 (2H, dd, J = 7.0 Hz, 6.8 Hz, -$CHCH_2CH$=), 1.77–1.35 (6H, m, -$CH_2CH_2CHCH_2OH$), 1.31 (3H, s, -CH_3), 0.91 and 0.06 (9H and 6H, two s, -$Si(CH_3)_2C(CH_3)_3$); ms m/e (70 eV): 371 (M^+-H), 355 (M^+-CH_3), 352 (M^+-H_2O). Exact mass calcd.: 355.2304 (M^+-CH_3); found: 355.2308 (M^+-CH_3).

Benzyl ether ***19***

To a stirred suspension of sodium hydride (378 mg (60% in oil), 9.45 mmol) in a mixture of THF:DMF (5:1, 30 mL), at 0°C, was added the alcohol **18** (2.23 g, 6 mmol) dissolved in the same solvent (18 mL). The reaction was allowed to warm to room temperature and was stirred for 1 h. Then freshly distilled benzyl bromide (860 μL, 1.24 g, 7.23 mmol) was added and the mixture stirred at room temperature for 17 h. The reaction mixture was quenched with aqueous saturated NH_4Cl solution (50 mL), and was extracted with ether:hexane (1:4, 200 mL). The aqueous phase was extracted again with the same solvent (2 × 50 mL). The combined organic layers were washed with brine (2 × 50 mL), dried, filtered, and evaporated. The residue was purified by flash chromatography (hexane:acetone,25:5) to give the benzyl ether **19** (2.53 g, 92%); ir ($CHCl_3$): 1255 (Si-CH_3), 1060 (C—O); nmr ($CDCl_3$ δ: 7.32 (5H, m, aromatic protons), 6.18 (1H, ddt, J = 15.0 Hz, 10.0 Hz, 1.5 Hz, -C*H*=$CHCH_2O$-), 6.03 (1H, dd, J = 15.0 Hz, 10.0 Hz, -CH_2CH=C*H*-), 5.70–5.53 (2H, m, -C*H*=CH—CH=C*H*CH_2O-), 4.48 (2H, s, -$CH_2\phi$), 4.20 (2H, dd, J = 5.1 Hz, 1.2 Hz, =$CHCH_2O$-), 3.91 (4H, m, -OCH_2CH_2O-), 3.33 (2H, d, J = 5.8 Hz, -$CHCH_2O$-), 2.16 (2H, m, -$CHCH_2CH$=), 1.80–1.35 (5H, m, -$CH_2CH_2CH_2CH_2O$-), 1.30 (3H, s, -CH_3), 0.91 and 0.07 (9H and 6H, two s, -$Si(CH_3)_3C(CH_3)_3$); ms m/e (70 eV): 460 (M^+), 445 (M^+-CH_3), 403 ($M^+-CH_3)_3$), Exact mass calcd.: 445.2773 (M^+-CH_3); found: 445.2773 (M^+-CH_3).

Ketol ***20***

A solution of benzyl ether **19** (1.8 g, 3.9 mmol) and pyridinium tosylate (28 mg, 0.39 mmol) in wet acetone (20 mL, 5% water) was stirred at 65°C for 5 h and then concentrated. The residue, dissolved in ether (200 mL), was washed with a solution of sodium bicarbonate (2 × 30 mL, 5% aqueous) and with brine (2 × 30 mL). The organic layer was dried and filtered, giving, after concentration, the crude ketol **20** (1.45 g), which was used without purification for the next step. An analytical sample was obtained by flash chromatography (hexane:acetone, 3:2); ir ($CHCl_3$): 3610 (OH, free), 3600–3300 (OH, associated), 1710 (C=O), 1080 (C—O); nmr ($CDCl_3$) δ: 7.32 (5H, m, aromatic protons), 6.21 (1H, ddt, J = 15.0 Hz, 10.0 Hz, 1.4 Hz, -C*H*=$CHCH_2OH$), 6.05 (1H, dd large, J = 15.0 Hz, 10.0 Hz, -CH_2CH=C*H*-), 5.73 (1H, dt, J = 15.0 Hz, 6.0 Hz, -CH=C*H*CH_2OH), 5.64 (1H, dt, J = 15.0 Hz, 7.4 Hz, -CH_2CH=CH-), 4.46 (2H, s, -$CH_2\phi$), 4.16 (2H, d, J = 6.0 Hz, =$CHCH_2OH$), 3.33 (2H, dd, J = 5.4 Hz, 1.6 Hz, -$CHCH_2O$-), 2.44 (2H, t apparent, J = 7.4 Hz, -$CHCH_2CH$=), 2.12 (2H, m, -$CH_2C(O)CH_3$), 2.10 (3H, s, -$C(O)CH_3$), 1.80–1.55 (4H, m, -$CHCH_2CH_2C(O)$-, -CH_2OH); ms m/e (CI, CH_4): 303 (M^++H), 285 (M^+-OH). Exact mass calcd.: 285.1855 (M^+-OH); found: 285.1858 (M^+-OH).

Silyl ether ***21***

To a solution of crude ketol **20** (1.45 g) in dry THF (30 mL) was added *tert*-butyldimethylsilyl chloride (1.3 g, 8.6 mmol) and imidazole (1.06 g, 15.6 mmol) at 0°C. The reaction mixture was allowed to warm to room temperature, stirred for 1 h, and then concentrated. The residue, dissolved in ether (200 mL), was washed with distilled water (4 × 40 mL), and the ethereal phase was dried, filtered, and evaporated to an oil. The residue was purified by flash chromatography (hexane:acetone, 9:1) to give silyl ether **21** (1.58 g, 97% yield from **19**); ir ($CHCl_3$): 1710 (C=O), 1255 (Si-CH_3), 1110 (C—O); nmr ($CDCl_3$) δ: 7.32 (5H, m, aromatic protons), 6.17 (1H, ddt, J = 15.0 Hz, 10.0 Hz, 1.4 Hz, -C*H*=$CHCH_2O$-), 6.04 (1H, dd, J = 15.0 Hz, 10.0 Hz, -CH_2CH=C*H*-), 5.65 (1H, dt, J = 15 Hz, 5.5 Hz, -CH=C*H*CH_2O-), 5.59 (1H, dt, J = 15.0 Hz, 7.4 Hz, -CH_2CH=CH-), 4.46 (2H, s, -$CH_2\phi$), 4.19 (2H, dd, J = 5.5 Hz, 1.3 Hz, =$CHCH_2O$-), 3.34 and 3.30 (2H, part AB of an ABX system, J_{AB} = 10.0 Hz, J_{AX} = 5.3 Hz, J_{BX} = 5.4 Hz, -$CHCH_2OBn$), 2.44 (2H, t apparent, J = 7.4 Hz, -$CHCH_2CH$=), 2.13 (2H, m, -$CH_2C(O)CH_3$), 2.10 (3H, s, -$C(O)CH_3$), 1.80–1.55 (3H, m, -$CHCH_2CH_2C(O)$-), 0.91 and 0.07 (9H and 6H, two s, -$Si(CH_3)_2C(CH_3)_3$); ms m/e (CI, CH_4): 417 (M^++H); 399 (M^+-OH); 359 ($M^+-C(CH_3)_3$). Exact mass calcd.: 417.2825 (M^++H); found 417.2819 (M^++H).

α,β-Unsaturated esters ***23***

To a stirred solution of phosphonate **22** (4.14 g, 17 mmol) in dry toluene (40 mL) was added *n*-butyllithium (7.34 mL of 2.2 M solution in hexane, 16 mmol) at 0°C. The reaction mixture was allowed to warm to room temperature and stirred for 15 min. The solution was then treated with ketone **21** (1.34 g, 3.23 mmol) dissolved in dry toluene (40 mL), and stirred at 0°C for 30 min and at room temperature for 90 h to 150 h, i.e., until the starting material has disappeared by thin-layer chromatography (toluene:acetone, 96:4). Then, distilled water (5 mL) was added and the toluene evaporated. The residue, dissolved in ether (300 mL), was washed with distilled water (4 × 50 mL). The ethereal layer was dried, filtered, and concentrated to an oil. The crude oil was purified by flash chromatography (toluene:acetone, 50:1) to give the esters **23** (1.37 g, 79%); ir ($CHCl_3$): 1715 (C=O), 1630 (C=C), 1255 (Si-CH_3), 1105 and 1060 (C—O); nmr ($CDCl_3$) δ: 733 (5H, m, aromatic protons), 6.26–5.97 (2H, m, -CH=C*H*—C*H*=$CHCH_2O$-), 5.72–5.54 (2H, m, -C*H*=CH—CH=C*H*CH_2O-), 4.79 and 4.76 (2H, two s, -OCH_2OCH_3), 4.19 and 4.48 (2H, two s, -$CH_2\phi$), 4.19 (2H, dd, J = 5.2 Hz, 1.2 Hz, =$CHCH_2O$-), 3.77 and 3.73 (3H, two s, -CO_2CH_3), 3.49 and 3.45 (3H, two s, -OCH_2OCH_3), 3.37 (2H, d, J = 5.7 Hz, -$CHCH_2OBn$), 2.51–2.12 (4H, m, -CH_2CH_2C= and -$CHCH_2CH$=), 2.00 and 1.87 (3H, two s, CH_3C=CCO_2CH_3), 1.72 (1H, m, -$CHCH_2CH_2C$=), 1.5 (2H, m, -$CHCH_2CH_2C$=), 0.91 and 0.07 (9H and 6H, two s, -$Si(CH_3)_2C(CH_3)_3$); ms m/e (CI, CH_4): 532 (M^+), 531 (M^+-H), 517 (M^+-CH_3). Exact mass calcd.: 517.2985 (M^+-CH_3); found: 517.2978 (M^+-CH_3).

Alcohols trans–trans–cis ***24*** *and* trans–trans–trans ***28***

The esters **23** (1.45 g, 2.7 mmol) dissolved in dichloromethane (50 mL) were treated, at −78°C, with a solution of diisobutylaluminium hydride (6.8 mL of 1 M solution in hexane, 6.8 mmol) and stirred for 15 min. Then the reaction mixture was quenched with Glauber's salt ($Na_2SO_4\cdot10H_2O$, 3.0 g) and was allowed to warm until the solution became cloudy. The mixture was dried with magnesium sulfate and was filtered on a pad of Celite using ether as eluent. The solvents were evaporated and the residue was purified by flash chromatography (hexane:acetone, 85:15) to give alcohols *trans–trans–cis* **24** (less polar) and *trans–trans–trans* **28** (more polar) (1.0 g, 73%, ≃1:1).

methanesulfonyl chloride (78 μL, 115 mg, 1.0 mmol). The mixture was stirred at 0°C for 15 min at room temperature for 1 h. Then the reaction mixture was poured over a solution of sodium bicarbonate (25 mL, 5% aqueous) and was extracted with ether (150 mL). The organic layer was washed with a saturated solution of copper nitrate (3 × 2 mL) and with water (4 × 25 mL). The ethereal phase was dried, filtered, and evaporated to an oil. The crude allylic chloride **32** was used without any purification since it decomposes on silica.

B. Alkylation

A suspension of sodium hydride (18 mg (60% in oil), 0.45 mmol) in a mixture of dry THF:DMF (1:1, 40 mL) was stirred at 70°C. The crude allylic chloride **32** dissolved in DMF (4 mL) was added, over 22 h (with a syringe pump), directly into the suspension of sodium hydride. Once the addition was complete, the mixture was stirred 1 h. The reaction mixture was concentrated under vacuum, then diluted with ether (200 mL). The organic phase was washed with a saturated solution of ammonium chloride (3 × 20 mL) and with water (5 × 25 mL), dried, filtered, and evaporated to an oil. The residue was purified by flash chromatography (hexane:acetone, 4:1) to give a mixture of Diels–Alder adducts (66 mg, 68%).

*Separation of Diels–Alder adducts **33, 34, 35***

The two main Diels–Alder adducts and the decarboxylated products were separated by flash chromatography. The mixtures of solvents used were acetone:hexane (1:4) and acetone:toluene (4:96) (**33:34:35** ≃ 13:6:3).

R_f of Diels–Alder adducts

Solvents	**33**	**34**	**35**
Acetone:hexane (1:4)	0.30	0.34	0.34 and 0.40
Acetone:toluene (4:96)	0.30	0.26	0.43

Compound **33**: ir ($CHCl_3$): 1730 (C=O), 1605 (C=C), 1170–1000 (C—O); nmr ($CDCl_3$) δ: 7.33 (5H, m, aromatic protons), 5.88 (1H, dt apparent, J = 8.3 Hz, 3.1 Hz, 7-H), 5.72 (1H, dt apparent, J = 8.3 Hz, 3.3 Hz, 6-H), 4.63 and 4.43 (2H, two d, parts A and B of an AB system, J_{AB} = 7.4 Hz, -OCH_2OCH_3), 4.51 (2H, s, -$CH_2\phi$), 3.74 and 3.70 (6H, two s, 2 × -CO_2CH_3), 3.34 (2H, d, J = 5.6 Hz, -$CHCH_2OBn$), 3.21 (3H, s, -OCH_2OCH_3), 2.78 (1H, dd, J = 13.3 Hz, 12.1 Hz, 13-H_β), 2.71 and 2.60 (2H, two d, parts A and B of an AB system, J_{AB} = 15.0 Hz, 11-H_2), 2.40 (1H, m, 8-H), 2.23 (1H, dd, J = 12.1 Hz, 6.4 Hz, 13-H_α), 1.85 (1H, m, 5-H), 1.80–1.35 (7H, m, -$CH_2CH_2CHCH_2$-), 0.74 (3H, s, -CH_3). ms m/e (70 eV): 486 (M^+), 471 (M^+-CH_3), 454 (M^+-CH_3OH), 424 ($M^+-CH_3OCH_2OH$). Exact mass calcd.: 486.2617; found: 486.2608.

Compound **34**: ir ($CHCl_3$): 1730 (C=O), 1130–1000 (C—O); nmr ($CDCl_3$) δ: 7.33 (5H, m, aromatic protons), 5.65 (1H, dt apparent, J = 10.1 Hz, 3.2 Hz, 7-H), 5.51 (1H, dt apparent, J = 10.1 Hz, 1.8 Hz, 6-H), 4.67 (2H, s, -OCH_2OCH_3), 4.49 (2H, s, -$CH_2\phi$), 3.76 and 3.71 (6H, two s, 2 × -CO_2CH_3), 3.29 (3H, s, -OCH_2OCH_3), 3.27 (2H, d, J = 6.2 Hz, -$CHCH_2OBn$), 3.01 (1H, m, 8-H), 2.86 and 2.58 (2H, two d, parts A and B of an AB system, J_{AB} = 16.5 Hz, 11-H_2), 2.53 (2H, m, 5-H and 13-H_β), 1.86 (1H, t apparent, J = 13.5 Hz, 13-H_α), 1.76–1.10 (7H, m, -$CH_2CH_2CHCH_2$-), 1.05 (3H, s, -CH_3); ms m/e (70 eV): 424 ($M^+-CH_3OCH_2OH$). Exact mass calcd.: 424.2250 ($M^+-CH_3OCH_2OH$); found: 424.2251 ($M^+-CH_3OCH_2OH$).

Compound **35**: ir ($CHCl_3$): 1730 (C=O), 1605 (C=C), 1170–1000 (C—O); nmr ($CDCl_3$) δ: mixture of isomers → decarboxylated tricyclic compounds; ms m/e (70 eV): 428 (M^+), 396 (M^+-CH_3OH), 366 ($M^+-CH_3OCH_2OH$). Exact mass calcd.: 366.2194 ($M^+-CH_3OCH_2$-OH); found: 366.2194 ($M^+-CH_3OCH_2OH$).

Following a similar experimental procedure *trans–trans– trans* triene alcohol **31** was converted into the corresponding allylic chloride and the macrocyclization was attempted as described above, but no specific products could be isolated from the resulting reaction mixture.

Methylammonium lead(II) halides, $CH_3NH_3PbX_3$ (X = Cl, Br, I), have been investigated by single-crystal X-ray diffraction, ^2H and ^{14}N nmr, adiabatic calorimetry, and other methods. The chloride (CL) has transitions at 171.5 and 177.4 K, the bromide (BR) at 148.4, 154.2, and 235.1 K, and the iodide (IO) at 162.7 and 326.6 K. The respective entropies of transition (J K^{-1} mol^{-1}) are 11.0 and 5.1 for CL; 8.7, 3.4, and 5.3 for BR; and 16.1 and 1.9 for IO. The highest-temperature phase, phase *I*, of each halide is of the cubic (*Pm3m*) perovskite type. The cation in CL(*I*) and BR(*I*) could not be localized in the electron density maps; the thermal motion of the halogen atom is highly anisotropic. The ln $T_1(^2H)$ vs. T^{-1} plots (*N*-deuterated samples as well as $CD_3NH_3PbCl_3$) show significant departures from linearity: the temperature variation of $T_1(^2H)$ in BR(*II*) and IO(*II*) can be represented by functions of the type $\ln T_1(H) = k_0 - k_2T^{-2}$, which give adequate analytical representations of $T_1(^2H)$ and $T_1(^{14}N)$ in phase *I* as well. On cooling, BR(*II*) and IO(*II*) exhibit small quadrupole splittings QS(^2H), which can be represented to a high degree of correlation by $QS(^2H) = k(T_{tr} - T)^n$, i.e. they appear to exhibit critical behaviour with respect to *T*. The ^{14}N nmr results indicate that the C—N bond in phase *I* reorientates in an isotropic potential at a rate approaching that of the freely rotating methylammonium ion. Below phase *I* this motion takes place in an increasingly anisotropic potential in BR(*II*) and IO(*II*) and is essentially arrested in CL(*II*), BR(*III*), and IO(*III*). The temperature dependence of the activation energy E_a for the cation reorientation and other aspects of the non-Arrhenius behaviour are discussed, and the $CH_3NH_3PbX_3$ perovskites are compared with the corresponding $(CH_3NH_3)_2TeX_6$ halides, utilizing preliminary ^2H nmr results on $(CH_3ND_3)_2TeBr_6$. The electrical conductivity, between 0 and 95°C, of $CH_3NH_3PbI_3$ increases with temperature and exhibits no discontinuity at T_{tr} = 326.6 K; the activation energy for the conduction process is estimated as ~0.4 eV.

Key words: crystal structure, $MeNH_3PbCl_3$ and $MeNH_3PbBr_3$; heat capacity, $MeNH_3PbX_3$ (X = Cl, Br, I); methylammonium lead halides; solid-state NMR, ^2H and ^{14}N; spin-lattice relaxation, non-Arrhenius behaviour.

OSVALD KNOP, RODERICK E. WASYLISHEN, MARY ANNE WHITE, T. STANLEY CAMERON et MICHIEL J. M. VAN OORT. Can. J. Chem. **68**, 412 (1990).

On a étudié les halogénures de méthylammonium plomb(II), $CH_3NH_3PbX_3$ (X = Cl, Br ou I) par diffraction des rayons-X sur un monocristal, par rmn du ^2H et du ^{14}N, par calorimétrie adiabatique ainsi que par d'autres méthodes. Le chlorure (CL) a des transitions à 171,5 et 177,4 K, le bromure (BR) en présente à 148,4, 154,2 et 235,1 K alors que pour l'iodure (IO) elles se situent à 162,7 et 326,6 K. Les entropies respectives de ces transitions (J K^{-1} mol^{-1}) sont 11,0 et 5,1 pour le Cl, 8,7, 3,4 et 5,3 pour le Br et 16,1 et 1,9 pour le IO. Pour chacun des halogénures, la phase observée à la température la plus élevée, la phase *I*, est du type perovskite cubique (*Pm3m*). Les cations des formes CL(*I*) et BR(*I*) ne peuvent pas être localisés dans les sections de densités électroniques; le mouvement thermique de l'atome d'halogène est très anisotrope. Les courbes du ln $T_1(^2H)$ vs. T^{-1} (des échantillons *N*-deutérés ainsi que du $CD_3NH_3PbCl_3$) présentent des déviations importantes par rapport à la linéarité: pour les formes BR(*II*) et IO(*II*), la variation de $T_1(^2H)$ en fonction de la température peut être représentée par des fonctions du type ln $T_1(H) = k_0 - k_2T^{-2}$ qui fournissent aussi des représentations analytiques adéquates de $T_1(^2H)$ et $T_1(^{14}N)$ de la phase *I*. Lors de leur refroidissement, les formes BR(*II*) et IO(*II*) présentent de faibles couplages quadrupolaires, QS(^2H), qui peuvent être représentées avec un grand degré de corrélation par l'équation $QS(^2H) = k(T_{tr} - T)^n$, c'est-à-dire qu'elles semblent présenter un comportement critique par rapport à *T*. Les résultats de la rmn du ^{14}N indiquent que la liaison C—N de la phase *I* se réoriente dans un potentiel isotrope à une vitesse qui approche celle de l'ion méthylammonium qui tournerait librement. En dessous de la phase *I*, ce mouvement se produit dans un potentiel de plus en plus anisotrope pour les formes BR(*II*) et IO(*II*) et il est essentiellement arrêté pour les formes CL(*II*), BR(*III*) et IO(*III*). On discute de la relation qui existe entre la température et l'énergie d'activation E_a de la réorientation du cation ainsi que d'autres aspects du comportement qui ne se conforment pas à la loi d'Arrhénius; de plus, utilisant des données préliminaires de rmn du ^2H obtenues à l'aide du $(CH_3ND_3)_2TeBr_6$, on compare les perovskites $CH_3NH_3PbX_3$ avec les halogénures $(CH_3NH_3)_2TeX_6$ correspondants. Entre 0 et 95°C, la conductivité électrique du $CH_3NH_3PbI_3$ augmente avec une augmentation de la température sans présenter une discontinuité à la valeur de T_{tr} = 326,6 K; on évalue l'énergie d'activation du processus de conduction à environ 0,4 eV.

Mots clés : structure cristalline, $MeNH_3PbCl_3$ et $MeNH_3PbBr_3$; capacité thermique $MeNH_3PbX_3$ (X = Cl, Br, I); halogénures de methylammonium plomb; RMN de l'était solide, ^1H et ^{14}N; relaxation spin-réseau, comportement «non-Arrhenius».

[Traduit par la revue]

The cubic $CH_3NH_3PbX_3$ (X = Cl, Br, I) perovskites described by Weber (2) are compounds unusual in several respects. Their colour intensifies rapidly from the cream white chloride to the reddish-orange bromide and black iodide, pointing to a charge-transfer character of the Pb—X bonds and possibly to photoconduction (2). The $CH_3NH_3^+$ ion is nominally at the centre of a simple cubic cell (*Pm3m*, *Z* = 1, Pb in 1(*a*) − 000), i.e. at 1(*b*) − $\frac{111}{222}$ (site symmetry *m3m*) and inside a cuboctahedral cage formed by 12 nearest X neighbours at 3(*d*) − $\frac{1}{2}00$ etc. It is clear that if this is the crystallographically correct

unit cell, then (*i*) the cation must be orientationally disordered in a manner consistent with the observed average symmetry;[2] (*ii*) the major component of the disorder would be expected to be dynamic; and (*iii*) reduction of the thermal motion of the cation on cooling is likely to result in the occurrence of transitions to phases of lower symmetry but closely related to the respective cubic phases. In this paper we report on our investigation of the validity of these expectations by single-crystal X-ray diffraction, solid-state ^2H and ^{14}N nmr, and adiabatic calorimetry, with minor assistance from other methods.[3]

The following abbreviations will be used: CL, $CH_3NH_3PbCl_3$; CLD, $CD_3NH_3PbCl_3$; BR, $CH_3NH_3PbBr_3$; IO, $CH_3NH_3PbI_3$.

Experimental

Preparation

BR and IO were prepared as described in ref. 2 (for IO cf. also ref. 1). They were authenticated by X-ray powder diffractometry and IO also by chemical analysis: a duplicate determination of Pb as $PbCrO_4$ gave 33.51 wt% Pb (theory, 33.42 wt%). The room-temperature lattice parameters of both (and of CL) agreed reasonably well with those of ref. 2. However, in the diffraction pattern of IO some of the lines corresponding to Weber's cubic IO (a = 6.27 Å) were split up or broadened, indicating that IO at room temperature is not strictly cubic.

CL was prepared by the method described in ref. 2 for BR, using CH_3NH_3Cl instead of CH_3NH_3Br, and also by direct conversion of solid $PbCl_2$ in an excess of hot concentrated aqueous solution of CH_3NH_3Cl. The method of ref. 2 modified for CL gave a pure product only when the molar CH_3NH_3/Pb ratio was at least 12. When a smaller excess was used, the product was pure white instead of cream-coloured as in the $PbCl_2$ method, but on standing it eventually discoloured. The powder diffraction pattern of the aged product contained a number of unidentified impurity lines, possibly of Pb(OH)Cl or a related compound.

Single crystals of CL and BR suitable for structure analysis were obtained by dissolving CL or BR in hot concentrated aqueous solution of the respective CH_3NH_3X halide and allowing the resulting solution to cool slowly. IO is the least soluble of the three halides and attempts to obtain in this way crystals of a size and quality suitable for single-crystal diffraction failed.

Partially *N*-deuterated samples of CL, BR, and IO required for the nmr studies were prepared using D-containing solutions. CLD was prepared by direct conversion of $PbCl_2$ using CD_3NH_3Cl.

X-ray diffraction

CAD-4 four-circle diffractometer; Mo $K\alpha_1$, λ = 0.70926 Å (graphite monochromator); T = ~18°C. Lorentz, polarization, and absorption corrections applied. Anisotropic temperature factor defined as $\exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{23}klb^*c^* + 2U_{13}hla^*c^* + 2U_{12}hka^*b^*)]$.

CH_6Cl_3NPb fw = 345.62

Cubic, *Pm3m* (no. 221) (systematic absences, none); a = 5.657(2) Å, V = 181.0(2) Å^3, Z = 1; θ-range, 2–40°, μ_{Mo} = 233 cm^{-1}, ρ_c = 3.171(4) g/cm^3, $F(000)$ = 152. Crystal, 0.22 × 0.32 × 0.38 mm^3. Reflections: total measured, 781; unique total, 150; unique used, 150 ($I > 2\sigma(I)$). R_{merg} = 11.5% before and 7.0% after absorption corrections.

CH_6Br_3NPb fw = 478.98

Cubic, *Pm3m* (no. 221) (systematic absences, none); a = 5.902(2) Å, V = 205.6(2) Å^3, Z = 1; θ-range, 2–40°, μ_{Mo} = 339 cm^{-1}, ρ_c = 3.818(7) g/cm^3, $F(000)$ = 206. Crystal, 0.22 × 0.26 × 0.26 mm^3. Reflections: total measured, 869; unique total, 166; unique used, 166 ($I > 2\sigma(I)$). Intensities collected twice, second collection used in refinement. R_{merg} = 12.2% before and 8.9% after absorption corrections.

Nmr measurements[4]

^2H spectra of all three compounds were obtained with partially *N*-deuterated material, $CH_3N(H, D)PbX_3$. The exact D content was not determined, nor was the effect of the deuteration on the transition temperatures. In addition, ^2H spectra were obtained with CLD. Samples (sealed in cylindrical thin-walled tubes of 0.9 cm o.d. and approximately 1 cm high) were placed in standard thin-walled 10 mm o.d. nmr tubes for all measurements.

Measurements were carried out at 8.48 T with a Nicolet 360NB spectrometer using a broad band (16–58 MHz) variable-temperature 10 mm probe supplied by Nicolet. The ^2H and ^{14}N frequencies were 55.427 and 26.083 MHz, respectively. Spin–lattice relaxation time experiments were performed using the inversion recovery pulse sequence, which employs compensating pulses (10); the ^2H and ^{14}N $\pi/2$ pulse widths were 30–40 and 45–60 μs, respectively. T_1 values were calculated from peak heights (obtained at ten or more delays) by a nonlinear, three-parameter least-squares fitting procedure available in the Nicolet software (11). As a check on possible frequency dependence $T_1(^2H)$ values in CL(I) and BR(I) at room temperature were also measured at 30.7 MHz on a Bruker MSL-200 spectrometer and found to be within experimental error (≤3%) of the corresponding values obtained at the higher frequency.

Calorimetry[4]

The heat capacities were measured in an adiabatic calorimeter from 30 to 345 K for CL, from 30 to 300 K for BR, and from 30 to 350 K for IO, using sample masses of 14.6883 g (CL), 12.8235 g (BR), and 17.9217 g (IO). The calorimeter was operated in the heat-pulse mode and gave direct values of $C_p = q/\Delta T$ from the measurement of the temperature increase ΔT for a measured heat pulse q; in most of the experiments it was used in the automated (12) mode. Temperatures were measured with a calibrated Pt resistance thermometer to an accuracy of 0.005 K. The accuracy of the overall determinations, as estimated from previous heat capacity measurements on NBS-49 benzoic acid (13), was ±1%.

Transition temperatures T_{tr} were defined by small ΔT measurements in the regions of the transitions. Transition enthalpies were measured by the long-heat method, and entropies of transition were evaluated as $\Delta T_{tr} = \int[C_p(\text{measured}) - C_p(\text{baseline})](dT/T)$ in the region of the transition (12). The results are summarized in Table 1.

Infrared spectra

In alkylammonium halides containing N—(H, D)···X bonds the spectral features of most interest are the NH and ND stretching absorptions, for their numbers and frequencies yield information concerning the type and strength of the hydrogen bonding. In this respect the spectra of partially *N*-deuterated $CH_3NH_3PbX_3$ samples were disappointing. The heavy continuous absorption in the 2000–4000 cm^{-1} region[5] increased from CL to IO and precluded the kind of examination of the individual ν(NH) and ν(ND) features that has proved so informative in other methylammonium (8, 14, 15) and especially ammonium (16) salts. Nevertheless, the spectra did permit qualitative estimates to

[2]In this respect the $CH_3NH_3PbX_3$ halides differ from $(CH_3NH_3)_2SnCl_6$ at room temperature, in which the cation is also surrounded by 12 Cl atoms (three at 3.46 Å and six at 3.59 Å from N) but *oriented*: the C—N bond coincides with a threefold rotation axis, consistent with the 3*m* site symmetry of the cation (3–8).

[3]Partial results of the nmr experiments were reported in a previous communication (9). The lattice parameters of the three halides and their variation with temperature will be reported and discussed in Part 3.

[4]The results of these measurements are in Tables A to E. Copies of this material can be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[5]This absorption is largely due to the mismatch between the refractive indices of the mulling oil (Nujol, fluorolube) and the highly refracting sample powder.

TABLE 1. Calorimetric characteristics of the transitions in $CH_3NH_3PbX_3$ (ΔH_{tr} in J mol^{-1}, ΔS_{tr} in J K^{-1} mol^{-1})

be made of the strength of the N—H···X bond, and the discontinuous changes with temperature which were observed in the profiles of certain absorption bands (not assigned in detail) in the 1300–1700 cm^{-1} region[6] for all three compounds testified to the existence of transitions. The temperatures of the latter were estimated as 175, 150, and 165 for CL, BR, and IO, respectively. The nature of these changes could not be ascertained from the ir evidence.

Electrical conductivity

To determine the conductivity of the black IO and its temperature variation the powder was pressed at ~7 kbar to wafers 5 × 25 mm^2 in area and about 1 mm thick. The wafers were visually of good quality but brittle, and the ease with which they fragmented on handling severely limited the scope of the experiment. A fragment approximately 4.7 × 17 × 1 mm^3 in size was fixed onto a sheet of mica with silicone grease and the mica sheet in turn was fixed onto a copper heater block. Copper wires 0.005″ diameter and 20 mm long were then attached to the sample at two silver-paint contacts 11 mm apart and connected to a Keithley 619 electrometer with 24 gauge copper leads. Temperature was measured with a chromel–alumel thermocouple with the measuring junction on the mica near the sample. The sample assembly was contained in a bell jar which was evacuted to ~10^{-5} Torr to prevent deterioration of the sample surface in the heating experiments. Without this precaution the surface was soon covered with a yellow coating (cf. ref. 1). Thermal history effects, possibly due to cracking, were seen in the absolute resistivity of the sample on thermal cycling.

Results

X-ray diffraction

The available X-ray evidence confirms *Pm*3*m* as the space group of CL(*I*) and BR(*I*). Since for $Z = 1$ this symmetry is incompatible with a unique orientation of the cation within the cuboctahedral X_{12} cage (see above), the cation must be disordered over at least six and at most 48 equivalent C—N orientations, not taking into account the H atoms. The effective contribution of the C and N atoms to the total diffracted intensity is thus very small relative to the contributions from Pb at (0, 0, 0) and X at (½, 0, 0) etc. Consistent with this expection, *F* maps phased[7] with Pb and X revealed no features that could be

[6]This region was relatively transparent from 10 to 300 K.

[7]With Pb and X placed as above, all the F_0 signs will be determined: in CL all will be positive and in BR the signs will be negative only when all three Br atoms contribute in antiphase to Pb.

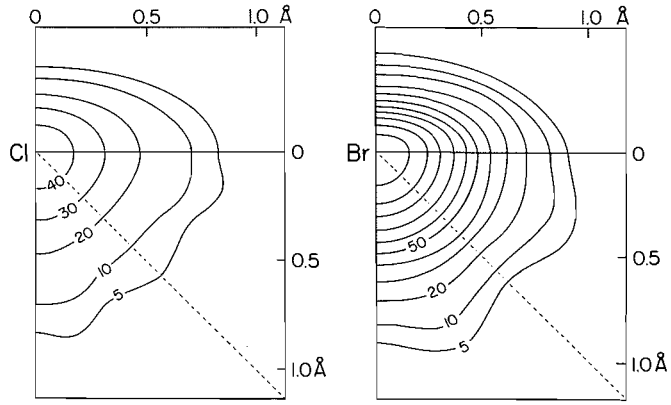

FIG. 1. Electron density (F_o) maps of $CH_3NH_3PbX_3$ (X = Cl, *left*; X = Br, *right*). Sections through X at (0, 0, ½), contours in e/Å^3, distances from X in axial directions in Å; a_1 direction down from X; a_2 direction horizontal to the right; a_3 axis up from X. Electron-density distribution in the Pb—X bond (*upper*, Pb at (0, 0, 1) up from X in the page) and perpendicular to the Pb—X bond (*lower*, Pb projecting onto X).

attributed with any confidence to the presence of the C and N atoms. The mean peak maxima (e/Å^3) in the *F* maps corresponded to Pb (906, 988) and X (44, 110) (first value CL, second value BR). In addition, small series-termination peaks associated with the Pb maxima were present, 21, 9, and 7 e/Å^3 in the CL map and 11–14 e/Å^3 in the BR map. Away from the Pb and X regions the maps were flat, with electron density values between 5 and −5 e/Å^3.

In these circumstances structure determinations were limited to refinements of the U_{iso}(Pb), U_{11}(X) (∥ to the Pb—X bond), and U_{33}(X) (⊥ to the Pb—X bond) parameters (Å^3). For CL this resulted in $R = 4.6\%$, $R_w = 3.6\%$, U_{iso}(Pb) = 0.0200(2), U_{11}(Cl) = 0.0212(19), U_{33}(Cl) = 0.1269(71), and U_{33}/U_{11} = 6.0(9). For BR, $R = 5.5\%$, $R_w = 4.6\%$, U_{iso}(Pb) = 0.0210(4), U_{11}(Br) = 0.0209(12), U_{33}(Br) = 0.1341(33), and U_{33}/U_{11} = 6.4(5). With the Pb atom so heavily dominating the scattering intensities, no attempt was made to determine whether the very large U_{ii}(X) anisotropy could be accounted for better on a model incorporating multiple positional disorder of the X atom, e.g. with X in 12(*h*) or 24(*l*) of *Pm*3*m*, although the flattening, along the broken lines in Fig. 1, of the electron density contours of X in planes perpendicular to the Pb—X bonds would suggest that such a disorder is a distinct possibility.

Existence of transitions

Discontinuous changes with temperature in the ^{2}H nmr spectra (see below) and in the ir spectra pointed to the existence of transitions in all three halides. The estimates of T_{tr} obtained from the nmr spectra (178(5) K for CL, 150(3) and 227(5) K for BR, and 168 and 321 K for IO) agreed quite well with those from the ir spectra (see Experimental). In particular, the existence of the transition above room temperature in IO confirmed the conclusion from X-ray powder diffraction that IO at room temperature is not cubic.

The transition temperatures were determined more accurately from heat capacity measurements (Figs. 2–4). These measurements revealed that the transition in CL and the lower transition in BR are in fact closely-spaced double transitions; the upper transitions in BR and IO are single (Table 1). All the transitions were reversible, highly reproducible, and independent of the thermal history of the sample. The number of phases that exist

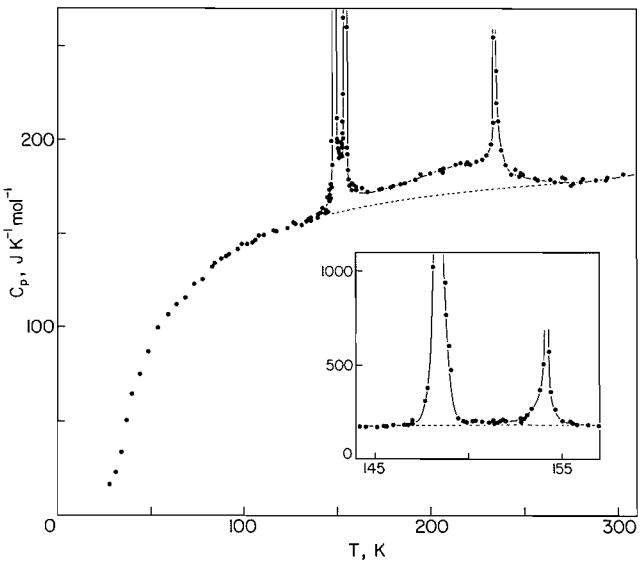

FIG. 3. Variation of C_p of $CH_3NH_3PbBr_3$ with temperature.

between 30 and 373 K is thus three for CL, four for BR, and three for IO. Phase *I* is cubic in all three compounds.

For brevity, the temperature of the upper ($I \leftrightarrow II$) transition will be referred to as $T_{tr,u}$ and that of the $II \leftrightarrow III$ transition as $T_{tr,l}$.

^2H nmr spectra

A single, sharp line was observed in the spectra of CL above 178(5) K, or BR above ~235 K, and of IO above ~318 K. On cooling below these temperatures the three compounds behaved differently. The single line in the CL spectrum split suddenly by ~40 kHz into a symmetric Pake doublet (17). A similar splitting was observed also in BR (~42 kHz) and IO (~39 kHz), but only on cooling below ~150 and ~165 K, respectively. In the intermediate range a small quadrupole splitting (QS) was seen in the spectra of BR and IO. This splitting, which developed with decreasing temperature but did not exceed 8 kHz, is described in detail below. These reproducible changes in the spectra were taken to be associated with transitions in the three solids and used to estimate T_{tr}.

The variation of the spin–lattice relaxation time $T_1(^2H)$ with T

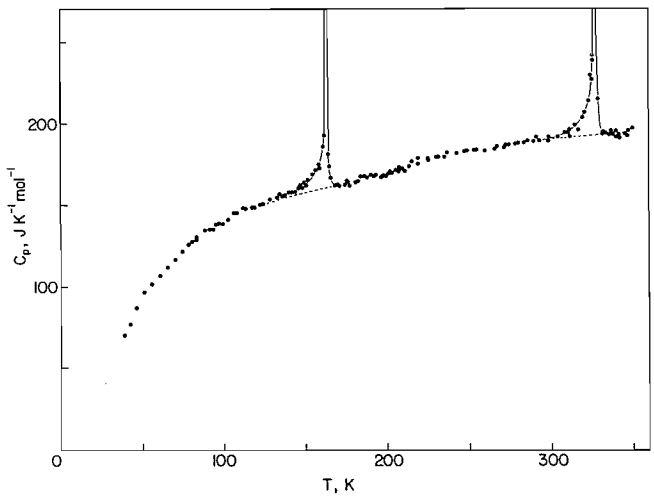

FIG. 4. Variation of C_p of $CH_3NH_3PbI_3$ with temperature.

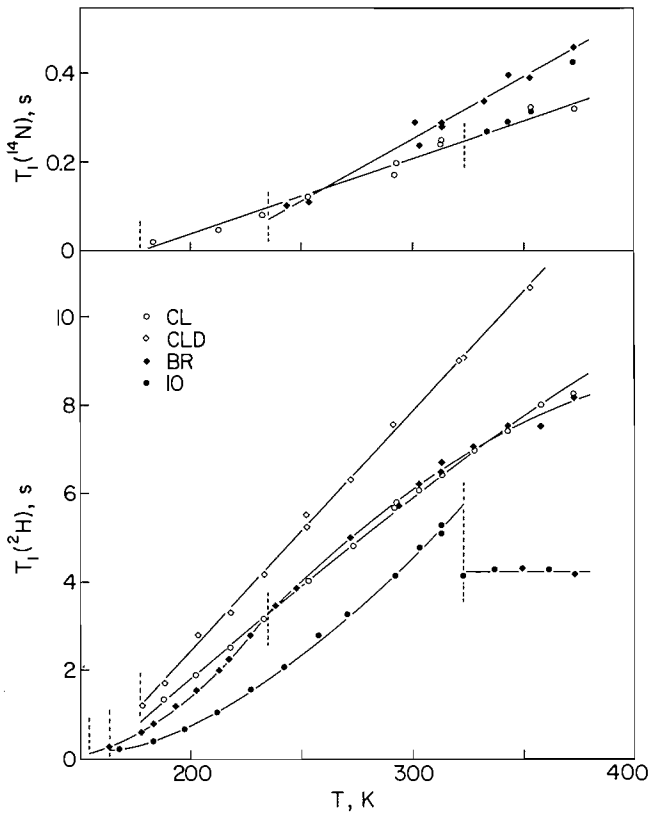

FIG. 5. Variation of $T_1(^2H)$ (*bottom*) and $T_1(^{14}N)$ (*top*) in $CH_3N(D, H)_3PbX_3$ with temperature. The transition temperatures of the undeuterated compounds are indicated by broken lines; $T_{tr,u}$(CLD) is taken to be the same as $T_{tr,u}$(CL).

in phase *I* could be represented by a straight line for CLD and by parabolas of only slight curvatures for CL and BR (Fig. 5). In contrast, the $T_1(^2H)$ variation with T in BR(*II*) and IO(*II*) was clearly nonlinear (parabolic fits gave $r^2 = 0.999$, $\sigma = 0.037$ s for BR(*II*) and $r^2 = 0.999$, $\sigma = 0.071$ s for IO(*II*)), and the $T_1(^2H)$ vs. T plot for IO(*I*) was different again in that its mean slope was zero.

The quasilinearity of the $T_1(^2H)$ vs. T plots implies nonlinearity of the corresponding Arrhenius plots ln $T_1(^2H)$ vs. T^{-1}. Indeed, the experimental points in the Arrhenius plots fall on

upward convex curves in all five cases. Since at this stage it was considered futile to postulate a mechanism for the non-Arrhenius behaviour, we looked instead for an adequate empirical representation of the temperature variation of $T_1(^2H)$ that would be useful for manipulative purposes (smoothing) and retain the theoretical advantages offered by Arrhenius-type plots. After a number of trials it was found that *all* the $T_1(^2H),T$ pairs for CL(*I*), CLD(*I*), and BR(*I*) could be satisfactorily ($r^2 > 0.99$) fitted to quadratic polynomials $\ln T_1 = k_0 + k_1T^{-1} + k_2T^{-2}$, regression on cubic polynomials resulting in only marginal improvements. Further, it seemed reasonable to assume that as $T^{-1} \rightarrow 0$, the activation energy E_a for the reorientation of the D-containing groups in phase falls asymptotically to zero, i.e. $k_1 = -2k_2T^{-1}$ and $\ln T_1(^2H) = k_0 - k_2T^{-2}$. Refitting the data to this two-term quadratic gave r^2 and σ which differed only insignificantly from those obtained from the unconstrained quadratic regressions. This justified adoption of the two-term fits for phase *I*. In fact, the same applied to the data for IO(*II*), but for BR(*II*) the unconstrained quadratic regression gave $\sigma = 0.029$ compared to 0.041 for the two-term fit. Nevertheless, it was felt that it would be more consistent with the other sets of data to adopt the two-term fit for BR(*II*) also. Exponential and simple power regressions gave significantly poorer results for all the sets of Fig. 5. The coefficients and figures of merit of the expressions considered to be adequately faithful approximations to the (at present unknown) functional dependence of $\ln T_1$ on temperature are listed in Table 2. The rectified plots are shown in Fig. 6.

In contrast to the other four phases, in IO(*I*) the $T_1(^2H)$ values were considerably smaller than expected and practically independent of temperature (Fig. 5). This fall-off and the pseudo-constancy over the observation interval suggest intervention of an additional relaxation mechanism or, more likely, some modification of the cation reorientation mechanism operating in CL(*I*) and BR(*I*) (see below).

The small QS(^{2}H) in phase *II* increased gradually, on cooling, from zero at $T_{tr,u}$ to about 4 kHz at $T_{tr,1}$ in BR and about 7.5 kHz in IO. The temperature variation of this QS is suggestive of an

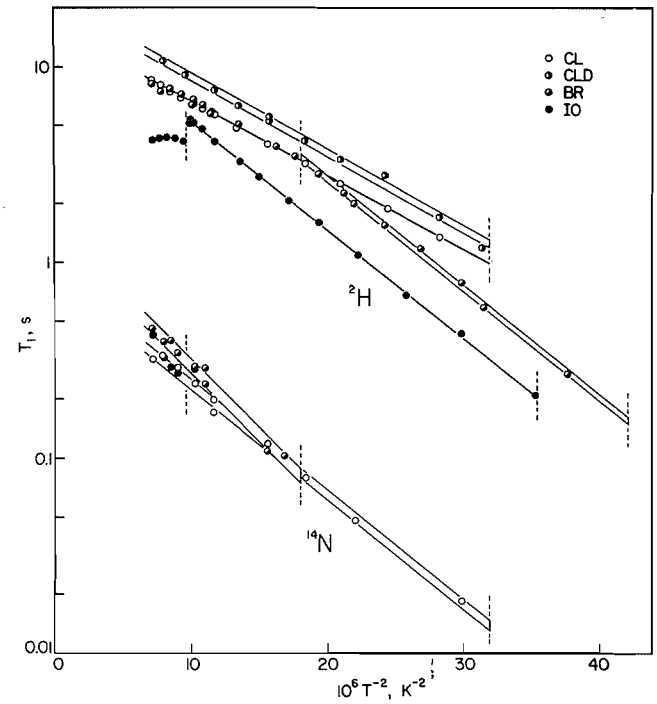

FIG. 6. Rectification of the data of Fig. 5

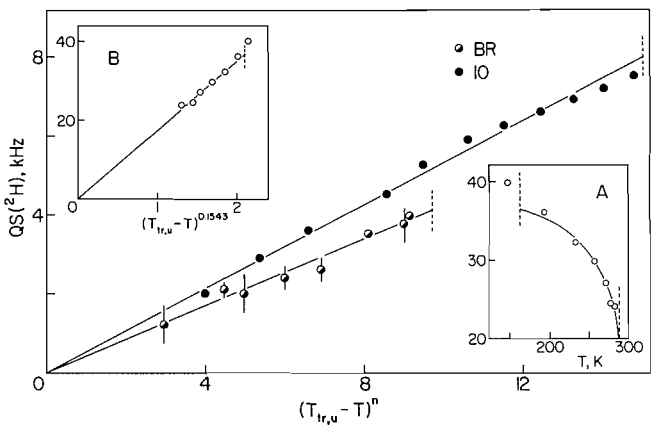

FIG. 7. Variation of the quadrople splitting QS(^{2}H) in BR(*II*) and IO(*II*) with $(T_{tr,u} - T)^n$ (see text). (*Inset A*) Variation of QS(^{2}H) in $(CH_3ND_3)_2TeBr_6$(*II*) with temperature. (*Inset B*) Variation of QS(^{2}H) in $(CH_3ND_3)_2TeBr_6$(*II*) with $(T_{tr,u} - T)^{0.1543}$ (rectification of plot *A*, see text). Transition temperatures of the undeuterated compounds are indicated by vertical broken lines.

ordering process, with QS(^{2}H) as an order parameter. Fitting the observed QS(^{2}H) to $k(T_{tr,u} - T)^n$ indeed resulted in a high degree of correlation (Fig. 7):[8]

BR: $k = 0.416$, $n = 0.517(36)$, $r^2 = 0.972$, $\sigma = 0.18$ kHz

IO: $k = 0.531$, $n = 0.532(11)$, $r^2 = 0.993$, $\sigma = 0.16$ kHz.

As noted above, on cooling through $T_{tr,1}$ the single line in the CL spectrum split suddenly to a symmetric doublet of ~40 kHz, and in the BR and IO spectra the splitting already present

[8]While these regressions are statistically highly significant, to demonstrate criticality with certainty requires having values of the order parameter as close to T_{tr} as possible. Unfortunately, extracting QS(^{2}H) from the close, poorly resolved doublets at sample temperatures closer to $T_{tr,u}$ than in Fig. 7 is so unreliable as to be of little value.

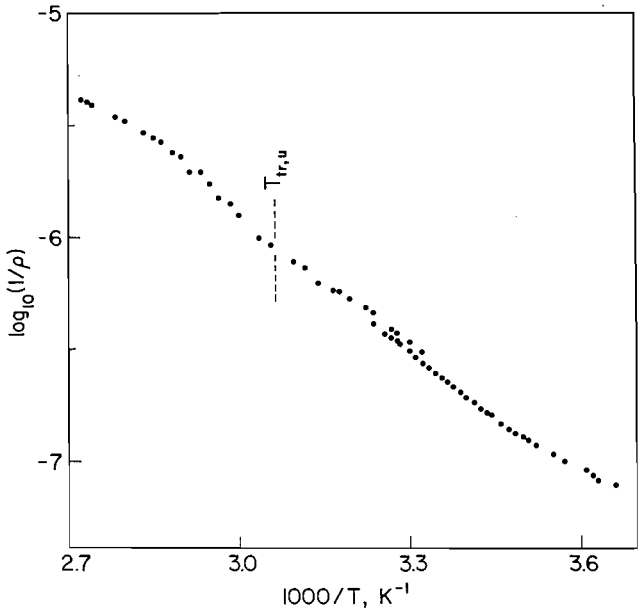

FIG. 8. Temperature dependence of the electrical resistivity ρ (Ω cm) of IO between 0 and 95°C (fourth cooling and fifth heating run, thermal hysteresis evident).

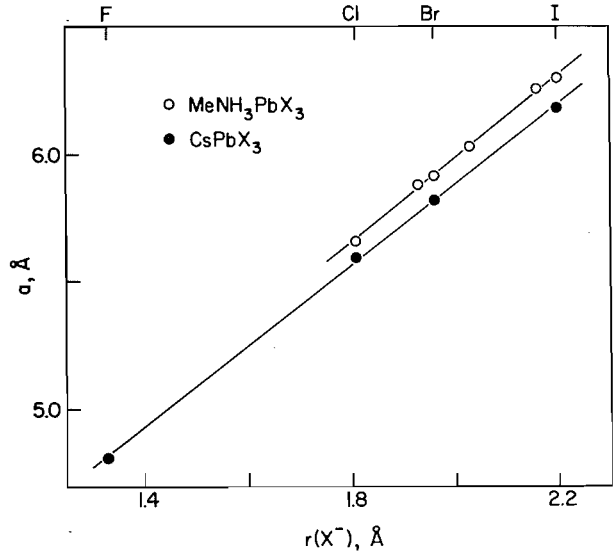

FIG. 9. Variation of the lattice parameter a of cubic $CH_3NH_3PbX_3$ and $CsPbX_3$ at room temperature with the ionic radius $r(X^-)$. $MeNH_3PbX_3$: single anion, this work; mixed anions, ref. 2. $CsPbX_3$: X = F, ref. 18; X = Cl, Br, I, ref. 19. Where a was measured above room temperature, the value has been adjusted by assuming a to change by 0.01%/K. For $MeNH_3PbI_3$ and $CsPbI_3$, where T_{tr} (cubic ↔ noncubic) > 293 K, $\bar{a} = (V/Z)^{1/3}$ is used in place of a.

suddenly increased to ~42 and ~39 kHz, respectively. These splittings remained practically constant on further cooling to 130 K, the lowest temperature attained in the present nmr measurements. The corresponding value for CLD was 37 kHz at 163 K.

^{14}N nmr spectra

These could only be obtained in phase *I*. The single-line signal disappeared at 173–183 K for CL, 233–238 K for BR, and 323–333 K for IO. The $\ln T_1(^{14}N)$ values showed a similar nonlinear variation with T^{-1} as the $\ln T_1(^2H)$ values and like the latter could be fitted, to a high degree of correlation, to $\ln T_1(^{14}N) = k_0 - k_2T^{-2}$ (Table 2, Fig. 6). Indeed, in this respect the same remarks apply to them as to $\ln T_1(^2H)$.

Electrical conductivity of IO

The resistivity of the pressed IO compact decreased on heating from ~1.3×10^7 Ω cm at 0°C to ~2.6×10^5 Ω cm at 94°C, i.e. 50-fold over the 100 K interval, and was unaffected by the presence or absence of daylight. The Arrhenius plot (Fig. 8) is essentially linear if the problems with the sample are taken into account. The activation energy for the conduction process obtained from the plot is 0.39 eV. There was no evidence of a discontinuity in the temperature variation of ρ at $T_{tr,u}$.

Discussion

In some respects the $CH_3NH_3PbX_3$ perovskites resemble the corresponding $CsPbX_3$ halides, while in others they differ considerably. In the following and in Part 3 we shall compare the two series wherever possible, in order to see to what extent the differences are due specifically to the composite nature of the $CH_3NH_3^+$ cation.

Volume properties

The room-temperature lattice parameter a of $CH_3NH_3PbX_3(I)$ varies linearly with the effective radius of X^- (Fig. 9). The straight line also accommodates Weber's (2) mixed cubic phases $CH_3NH_3Pb(Cl, Br)_3(I)$ and $CH_3NH_3Pb(Br, I)_3(I)$. This variation is similar to that observed for $CsPbX_3$. The regression lines for the two series are very nearly parallel, and that even when $CsPbF_3$ is included.

With the mean position of X taken as $3(d) - \frac{1}{2}00$ etc. of $Pm3m$, the Pb^{vi}—X distances in $CH_3NH_3PbX_3(I)$ are about 0.1 Å longer than those in the corresponding $CsPbX_3$, i.e. ~2.83 Å in CL, ~2.96 Å in BR, and ~3.15 Å in IO. This slight lengthening of the Pb—X bond over $CsPbX_3$ does not affect the character of the bond appreciably, judging by the similarity of colour: $CsPbCl_3$ is pale yellow (20) compared to the off-white CL, while the bromides are both orange and the iodides both black.

Electron-density distribution

The lack of cation features in the F maps of CL(I) and BR(I) confirms the indefiniteness of the cation position in the X_{12} cage, consistent with the expectation from the mismatch of the site symmetry at the centre of the cage and the symmetry of the cation.

The anisotropy of $U_{ii}(X)$ is commonly observed in cubic AMX_3 perovskites and their congeners (cf. ref. 21). It is associated with the volume of the X_{12} cage available to the cation (usually expressed in terms of the geometric tolerance factor $t = (r_A + r_X)/(r_M + r_X)\sqrt{2}$) and also with $T_{tr,u}$ (Fig. 27 of ref. 21). In the present case it is the magnitude of the $U_{ii}\perp/U_{ii}\parallel$ ratio which is noteworthy as well as the magnitude of the $U_{ii}\perp$ value itself. With $U_{ii}\perp = U_{33} \sim 0.13$ Å^2 significant interaction of the thermal motion of X with the cation motion is to be expected. Evidence of this is seen in the irregularity of the electron-density contours of X in planes containing X and perpendicular to the Pb—X bond (Fig. 1).

Transitions

The temperatures of the transition from the cubic phase I to phase II are related to the dimensions of the unit cell: $T_{tr,u}(K) = 1.202 \exp 0.891a$ ($r^2 = 0.994$, $\sigma = 7.5$ K). This relation, which can be interpreted in terms of the mean cation–anion distance $a\sqrt{3}/2$ or the X···X distance $a/\sqrt{2}$, does not appear to be accidental, for the $T_{tr,u}$ in the corresponding cubic $CsPbX_3$ (X =

Cl, Br, I) pervoskites (19, 20) can be represented similarly by $T_{tr,u} = 1.163 \exp 1.006a$ ($r^2 = 1.000$, $\sigma = 3$ K; the a value corrected to room temperature, cf. caption of Fig. 9).[9] The ratio $T_{tr,u}(CsPbX_3)/T_{tr,u}(CH_3NH_3PbX_3)$ for a given X is roughly 1.8. This parallel between the two series indicates that the nature of the cation (i.e. whether simple or composite, hydrogen-bonding or nonbonding) is at most a secondary factor responsible for the occurrence of the transition. The *cause* of the transition is to be sought in the lattice dynamics of the three-dimensional $[PbX_{6/2}]_\infty$ framework, although the *position* of the transition on the T scale is cation-sensitive and the effect on $T_{tr,u}$ of replacing a structureless cation with a composite one can be dramatic.[10]

Since a complete discussion of the dependence of $T_{tr,u}$ on the sizes and masses of the participating atoms would require detailed knowledge of the mechanism of the transition in each particular case — available only for a few compounds at present — empirical relationships like the above are not without value even though the reasons for their existence are not clear. Apart from the two Pb series the $T_{tr,u}$ of cubic $AMBr_3$ and AMI_3 are largely lacking, but for the few AMF_3, $AMCl_3$ pairs where both a and $T_{tr,u}$ are known the two regression parameters appear to be of the same order as for $CsPbX_3$ and $CH_3NH_3PbX_3$. In NH_4MF_3 (M = Mg, Mn, Co, Zn) the transition from the cubic $Pm3m$ phase on cooling involves a restriction on the reorientational freedom of the cation (22, 23) and the size of M would be expected to play a rôle, albeit a less direct one than the size of X. Indeed, $T_{tr,u}$ of NH_4MF_3 can be represented as $0.00057 \exp 2.983a$ ($r^2 = 0.952$, $\sigma = 7.7$ K ~ 10% of the $T_{tr,u}$ range).

Thermal properties

The shapes of the C_p peaks at ~175 K for CL and ~150 K for BR suggest that in each case both components of these double transitions are first-order. This is supported by the observation that the single crystal of BR used in the X-ray diffraction experiment shattered almost explosively on cooling through $T_{tr,1}$.

The $I \leftrightarrow II$ transition in BR is first-order with a long tail of pre-transition excess C_p. The evaluation of C_p(baseline) is necessarily somewhat uncertain and the overlap of the $II \leftrightarrow III$ transition peak with the excess C_p component is severe. Nevertheless, assuming that the C_p values between 80 and 130 K and between 270 and 303 do not contain significant excess contributions, the baseline between 80 and 303 K can be represented by a cubic polynomial ($f = 25$, $r^2 = 0.997$, $\sigma = 1.0$ J K^{-1} mol^{-1}). With this baseline approximation $\Delta C_p = C_p$(measured) − C_p(baseline) was estimated in the interval 200–235.2 K. Regressing ln ΔC_p on ln $[1 - (T/T_{tr})]$ ($r^2 = 0.95$, Fig. 10) gave 0.34(2) for the critical exponent. The excess C_p thus conforms to the same type of temperature dependence as QS(^{2}H) and represents another parameter of the ordering process in phase *II*. For IO this procedure for evaluating ΔC_p for the $I \leftrightarrow II$ transition is rendered uncertain owing to the difficulties in choosing a proper baseline (cf. Fig. 4). The pre-transition excess C_p associated with the $II \leftrightarrow III$ transition in IO does not appear to be proportional to a power of $T_{tr,1} - T$.

[9]Cubic $CsPbF_3$ is obtained by cooling the stoichiometric melt to room temperture (18). The existence of a phase transition at 615°C has been inferred from the shape of the liquidus line in the CsF–PbF_2 system, but no thermal effect was observed on cooling pure $CsPbF_3$ at normal cooling rates. Prolonged annealing of the cubic phase at 300°C produced a perovskite-like noncubic phase stable at room temperature.

[10]The effect of the cation on $T_{tr,u}$ in cubic AMX_3 alkali and ammonium perovskites and related halides is discussed in terms of the geometric tolerance factor t in ref. 21.

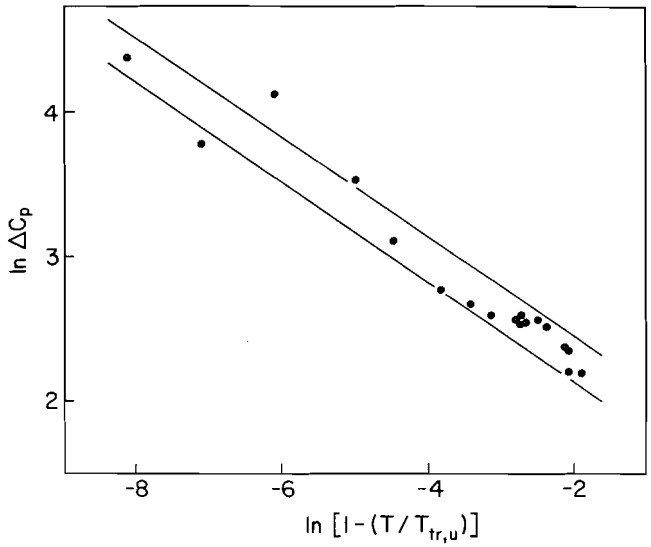

FIG. 10. Variation of ln ΔC_p of BR(*II*) with ln $[1 - (T/T_{tr,u})]$.

The total entropy of transition, $\Sigma\Delta S_{tr}$, increases only slightly from CL to IO: 16.1(2), 17.4(2), and 18.0(2) J K^{-1} mol^{-1}, pointing to similarity in the gross behaviour of the three systems, but the individual ΔS_{tr} sequences differ.

^{2}H nmr spectra

For a methylammonium ion with its C—N axis fixed in the structure the expected quadrupole splitting would be QS(^{2}H) = $\frac{3}{4}(e^2qQ/h) \sim 130$ kHz (24) if the ion does not undergo rotational reorientations about that axis (rigid-lattice spectrum), and QS(^{2}H) = $\frac{3}{8}(3\cos^2\beta - 1)(e^2qQ/h) \sim 43$ kHz (25) if such reorientations take place (C_3 jumps, β = CNH ~ 109.5°). An observed splitting smaller than the latter value would imply that the C—N axis is undergoing some motion. The single sharp line in the ^{2}H spectra of phase *I* of all three halides, the 40–42 kHz splitting below $T_{tr,u}$ in CL and at $T_{tr,1}$ in BR and IO, and the temperature dependent splitting of 0–8 kHz in BR(*II*) and IO(*II*) can then be interpreted as follows. In phase *I* the cation undergoes overall reorientations in an isotropic potential. In CL below $T_{tr,u}$ the C—N reorientation is suddenly frozen but the reorientation about the C—N axis persists. In BR and IO below $T_{tr,u}$, however, the C—N bond continues to reorientate. This motion is progressively slowed down on further cooling and, more importantly, takes place in an increasingly anisotropic potential until at $T_{tr,1}$ it suddenly stops.[11]

^{14}N nmr spectra

The absence of splitting on the single ^{14}N resonance line in phase *I* and the large values of $T_1(^{14}N)$ again indicate that the C—N bond in all three crystals undergoes very fast reorientations in an isotropic potential. Assuming $T_1^{-1} = \frac{3}{2}\pi^2\chi^2\tau_\perp$, χ = 1106.7(15) kHz (27), $\tau_\perp$ (s) = $5.512 \times 10^{-14} T_1^{-1}$, we have, at

[11]A very similar situation appears to exist in $CH_3NH_3SnBr_3$ (26): ^{81}Br nqr and ^{1}H nmr measurements indicate that the cubic ↔ noncubic transition occurs at ~232 K (235.1 K in BR) and another transition at ~180 K (154.2 K in BR). The second moment in the ^{1}H nmr spectrum was 0.5(1) G^2 in the cubic phase and 8.0(5) G^2 below 180 K, and in each phase was almost constant. However, in the intermediate phase it increased continuously with decreasing temperature from ~0.5 to ~8 G^2. The quadrupole splitting in the ^{119}Sn Mössbauer spectrum was ~0 at 293 K but 0.54(3) mm/s at 93 K, indicating a nonzero EFG at the Sn nucleus in the lowest phase. These observations are all consistent with the above interpretation for BR.

TABLE 3. Activation energies E_a(kJ/mol) = $0.01662k_2T^{-1} = CT^{-1}$ for the reorientation of ^2H and ^{14}N containing groupings*

*Since the T_{tr} of the partially *N*-deuterated samples are not known, the calorimetric T_{tr} of $CH_3NH_3PbX_3$ have been used instead. The isotopic effect on T_{tr} is probably quite small (cf. ref. 34).

the end of the observation intervals,

$T = 178$ K, $T_1 = 0.015(2)$ s, $\tau_\perp = 3.8(5)$ ps

$T = 373$ K, $T_1 = 0.34(5)$ s, $\tau_\perp = 0.16(3)$ ps

for CL and

$T = 235$ K, $T_1 = 0.080(14)$ s, $\tau_\perp = 0.67(12)$ ps

$T = 373$ K, $T_1 = 0.47(5)$ s, $\tau_\perp = 0.12(2)$ ps

for BR. For comparison, in $CH_3ND_3^+NO_3^-(I)$ at 355 K the corresponding T_1 and $\tau_\perp$ values are 0.0119 s and 4.7 ps, and in the melt at 393 K, 0.0168 s and 3.3 ps, respectively (28), i.e. reorientation rates about thirty times slower than in CL and BR. However, very fast overall cation reorientations comparable to those in $CH_3NH_3PbX_3(I)$ may be expected to occur in the cubic *anti*-fluorite quasi-perovskites $(CH_3NH_3)_2MX_6$ (29, 30); the two classes of compounds are compared below.

If the methylammonium ion is treated as a prolate spheroid (C—H = 1.08 Å, N—H = 1.02 Å, C—N = 1.48 Å, ∠HCN = ∠CNH = 109.5°), the correlation time $\tau_{\perp,free}$ for the inertial rotation of the free ion about an axis perpendicular to the C—N bond can be expressed (e.g. ref. 31)[12] as $\tau_{\perp,free} = (2I_\perp/3\pi k)^{\frac{1}{2}}T^{-\frac{1}{2}} = 2.34 \times 10^{-12}T^{-\frac{1}{2}}$ for $CH_3NH_3^+$ and $2.49 \times 10^{-12}T^{-\frac{1}{2}}$ for $CH_3ND_3^+$. From this, $\tau_{\perp,free} = 0.18$, 0.15, and 0.13 ps at $T = 178$, 235, and 373 K, respectively, for $CH_3NH_3^+$ and 0.19, 0.16, and 0.13 ps, respectively, for $CH_3ND_3^+$. These values indicate that the reorientations of the C—N axis in phase *I*, while not inertial, take place with a rapidity which at the upper limit of our experimental range approaches that calculated for the free ion.

The disappearance of the ^{14}N signal below $T_{tr,u}$ in all three halides is not inconsistent with the conclusion from the ^2H spectra. Any reduction in the isotropy of the potential in which the cation moves would introduce a quadrupole splitting which would be a fraction of the ~700 kHz value expected for a rigid-lattice spectrum (28). However, the QS(^{14}N) arising from even a modest reduction of the isotropy in phase *I* might still fall outside the available instrumental range, and this appears to be the case here.

[12]Calculations using the expression for $\tau_{inertial}$ of ref. 32 or other such expressions (cf. ref. 33) lead to very similar results.

Activation energy E_a *for rotational reorientation*

The inverse proportionality of E_a to T within the existence interval of a phase (Table 3) is a feature peculiar to the $CH_3NH_3PbX_3$ halides. Because of this temperature dependence E_a can be compared only when the structural situations are similar, i.e. at the same reduced temperatures $T/T_{tr,u}$ or $T/T_{tr,l}$ (Fig. 11).

At $T_{tr,u}$ the $E_a(^2H)$ values are about the same for CL(*I*) and CLD(*I*), while for BR(*I*) the $E_a(^2H)$ is only about 70% of that for CL(*I*). A similar reduction is observed between $E_a(^2H)$ of BR(*II*) and IO(*II*), while at $T_{tr,l}$ the two $E_a(^2H)$ values are very similar, E_a(BR, *II*)/E_a(IO, *II*) = 1.05(3). The reduction at $T_{tr,u}$ is to be expected, for the cuboctahedral Br_{12} cage is larger than the Cl_{12} and N—H···Br interactions are weaker than N—H···Cl interactions, thereby facilitating the reorientational process.

The $E_a(^2H)$ values for CL(*I*) are similar to those estimated from ^1H nmr studies of the trigonal $(CH_3NH_3)_2PtCl_6(I)$ (3, 4), 3.6(5) kJ/mol,[13] but much smaller than the corresponding values obtained for the NH_3 reorientation in the β and γ phases of CD_3NH_3Cl, 26.4 and 32.0 kJ/mol, respectively (35), pointing to stronger hydrogen bonding in methylammonium chloride (cf. ref. 15). The similarity of the $E_a(^2H)$ values in CL(*I*) and CLD(*I*) suggests that the CD_3 and ND_3 reorientations about the C—N bond are correlated, i.e. the activation energy for the rigid-body C_3 reorientation of the cation is significantly lower than that for internal rotation (cf. refs. 3 and 4 for a similar conclusion involving $(CH_3ND_3)_2PtCl_6(I)$ and $(CD_3NH_3)_2PtCl_6(I)$; also refs. 36 and 37).

The $E_a(II)/E_a(I)$ for ^2H at $T_{tr,u}$ is available only for BR, where it is 1.55(7), which corresponds to a difference of 3.2(3) kJ/mol. The reorientation of the cation is thus significantly more hindered in BR(*II*) even at temperatures ≤8 K of $T_{tr,u}$, i.e. within less than 10% of the existence range of BR(*II*).

At $T_{tr,u}$ (and at $T/T_{tr,u}$ up to 1.14) the activation energies $E_a(^{14}N)$ for C—N tumbling in phase *I* of all three halides are the same within the statistics (Fig. 11). This points to the mechanism of the C—N reorientation having essentially the same character in all three compounds.

[13]The C—N axis in these trigonal crystals coincides with the unique crystallographic C_3 axis (see below).

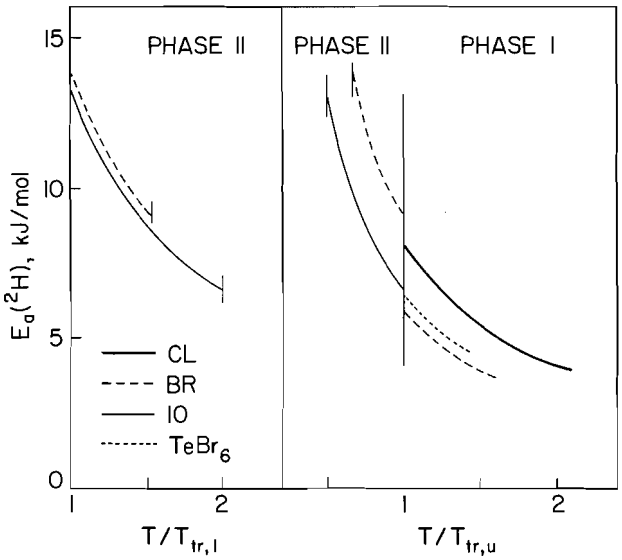

FIG. 11. Variation of the activation energy E_a for the reorientation of the ^2H and ^{14}N containing groupings of the methylammonium ion in CL, BR, IO, and the hexabromotellurate (smoothed data).

Relationship of the ^2H and ^{14}N nmr parameters in phase I

Using the analytical representations of Table 2 we obtain

$$[1]\quad T_1(^2H)/T_1(^{14}N) = A \exp C'T^{-2}$$

$$A = \exp [k_0(^2H) - k_0(^{14}N)],\ C' = -k_2(^2H) + k_2(^{14}N)$$

$$[2]\quad E_a(^{14}N)/E_a(^2H) = C(^{14}N)/C(^2H).$$

These expressions indicate that, to the extent to which the analytical representations are faithful, the reorientational behaviour of the ^2H and ^{14}N atoms as described by the spin–lattice relaxation time T_1 is mutually determined. In particular, the $E_a(^{14}N)/E_a(^2H)$ ratio for each crystal is constant over the experimental T interval: 1.49(4) for CL(*I*), 1.94(15) for BR(*I*).

The $T_1(^2H)/T_1(^{14}N)$ ratio in CL varies from 70(10) at $T_{tr,u}$ to 25(2) at 373 K; in BR, from 42(11) at $T_{tr,u}$ at 18(3) at 373 K. At $T_{tr,u}$(BR) the ratio is the same, within 1σ, for CL and BR. With increasing temperature a small difference appears to develop, but even at 373 K the two values are only $\sim 2\sigma$ from each other. In terms of $T/T_{tr,u}$, however, the $T_1(^2H)/T_1(^{14}N)$ vs. $T/T_{tr,u}$ curve for BR is only about 60% the height of the curve for CL.

The relaxation time $T_1(^2H)$(CL) increases, over the 177–373 K interval, from 0.98 to 8.37 s, i.e. about eightfold. In contrast, $T_1(^{14}N)$(CL) over the same interval increases from 0.015 to 0.34 s, i.e. about 23-fold. In attempting to rationalize this difference in the temperature dependence we recall that $T_1(^{14}N)$ and $T_1(^2H)$ probe different motions. The largest component of the ^{14}N EFG tensor lies along the C—N axis, hence $T_1(^{14}N)$ probes the reorientational motion of the C—N bond vector directly, and the $T_1(^{14}N)$ values are independent of reorientational motions of the ND_3 groups about the C—N axis. The largest component of the ^2H EFG tensor lies along the N—D axis; $T_1(^2H)$ thus probes the motion of the N—D bond vector, but here the $T_1(^2H)$ values will depend on the motions of the CD_3 and ND_3 groups about the C—N axis *as well as* on reorientations *of* the C—N axis.

Qualitatively, the greater temperature dependence of $T_1(^{14}N)$ relative to $T_1(^2H)$ indicates that at temperatures at which thermal activation of the C—N reorientation begins to become significant the reorientational motion of the N—D bond vector is already very rapid.

Similar conclusions apply to BR, for which $T_1(^2H)$ increases, from 235 to 373 K, by a factor of ~ 2.5 and $T_1(^{14}N)$ by a factor of ~ 6.

$T_1(^2H)$ anomaly in IO(I)

The $T_1(^2H)$ at $T > T_{tr,u}$ is lower than immediately below $T_{tr,u}$ and remains approximately constant over a 50 K interval, while simultaneously $T_1(^{14}N)$ increases with temperature at least as rapidly as in CL(*I*) and BR(*I*) (Figs. 5 and 6). This puzzling behaviour implies that the thermal activation energy for the ^2H reorientation above $T_{tr,u}$ is close to zero, while that for the C—N reorientation is comparable to those for CL(*I*) and BR(*I*) (Table 3). Since the main difference between IO(*I*) and the other two cubic halides is in the volume of the X_{12} cavity, we have the paradox that by making available to the cation a larger volume the reorientational motion of the *N*-hydrogens slows down.

The lowering of $T_1(^2H)$ is unlikely to be attributable to extraneous factors precisely because its onset coincides with $T_{tr,u}$. If it were due, for example, to the presence of a paramagnetic species, such species would have to be generated by the transition mechanism, a process difficult to envisage in the circumstances; the electrical conductivity of IO(*I*) varies smoothly through $T_{tr,u}$ (Fig. 8). Because the anomaly almost certainly involves the N—H···I bonding, we hope that we shall be able to elucidate its origin from a detailed comparison of $CD_3NH_3PbI_3$ and $CH_3ND_3PbI_3$ which is now being initiated.

Comparison with $(CH_3NH_3)_2MX_6$

Methylammonium hexahalometallates(IV) at room temperature are known to crystallize in one of the three structure types:[14] (*i*) *anti*-$CdCl_2$ (*anti*-*C*19, $R\bar{3}m$) (5, 39): X = Cl, M = Pd, Pt, Se, Sn, Pb; X = Br, M = Pd, Pt, Se, Sn; X = I, M = Pt; (*ii*) *anti*-CdI_2 (*anti*-*C*6, $P\bar{3}m1$) (40): X = Cl, M = Te; and (*iii*) *anti*-CaF_2 (*anti*-*C*1, $Fm3m$ or superstructure) (29): X = Br or I, M = Te. The C_{3v} cation site symmetry in the *anti*-$CdCl_2$ and *anti*-CdI_2 structures requires the C—N bond to be located in an oriented C_3 axis, hence 120° reorientations (CH_3 and NH_3 motions correlated or independent) about this fixed bond are naturally compatible with the respective space-group symmetries and indeed are observed in these phases (up to 400 K for X = Cl and M = Sn, Pt) (4, 29, 30).[15]

In contrast, in the *anti*-CaF_2 structure the crystallographic site symmetry of the cation in the $Fm3m$ cell is T_d and the cation is surrounded by four MX_6^{2-} anions with the M atoms at the alternate corners of cubes of $\frac{1}{2}a$ edge length. The 12 H atoms nearest to the cation form a cuboctahedron of T_d symmetry but with dimensions almost consistent with O_h symmetry. This situation thus resembles the cation coordination in $CH_3NH_3PbX_3$ but is more restrictive as regards reorientation: it is best understood by comparing $CH_3NH_3PbX_3$(*I*) and the *anti*-CaF_2 $(CH_3NH_3)_2TeX_6$ with the corresponding ammonium salts, NH_4MF_3 and $(NH_4)_2MX_6$, which are essentially isostructural with the respective $CH_3NH_3^+$ salts and have been extensively studied. From ir studies of the isotopically isolated NH_3D^+ ion (21, 41, 42) it is known that in the *anti*-CaF_2 $(NH_4)_2MX_6$ the N—H bonds avoid pointing at the corners of the

[14]The *C*19 structure type is topologically related to the *C*1 type, whereas the *C*6 type is not (38).

[15]The estimated $E_a(^1H)$ (kJ/mol) for the correlated C_3 rotations are 4.2(5) in the hexachlorostannate (4), 3.6(5) in the hexachloroplatinate (4), and 5–7 in the hexachlorotellurate (30); and for the uncorrelated rotations, 7.2(10) in the hexachlorostannate and 8.5(10) in the hexachloroplatinate (4).

$\frac{1}{2}a$ cube that are occupied by the M atoms. Instead, each points, along a C_3 diagonal, at an unoccupied corner to form a symmetrically trifurcated N—H···3X bond to X atoms belonging to different MX_6^{2-} ions each. In the *Pm3m* NH_4MF_3 perovskites, however, all eight corners of the cube are occupied by M atoms. The geometry of the $[MF_{6/2}]_\infty$ framework in these crystals being unfavourable to simultaneous formation of four equivalent, linear N—H···F bonds, the NH_4^+ ion strives to achieve such a bond *dynamically*, one at a time, by large-amplitude libration. Thus while the cation in both cases is inside an X_{12} cage of cubic symmetry, in $(NH_4)_2MX_6$ its *effective* symmetry coincides with the crystallographic site symmetry at the centre of the cage, whereas in NH_4MF_3 it is only D_{2d}. We may reasonably assume that in respect of hydrogen bonding $CH_3NH_3^+$ in these salts resembles the ammonium ion. This raises the question of how the structural difference between $CH_3NH_3PbX_3(I)$ and the *anti*-CaF_2 $(CH_3NH_3)_2TeX_6$ is reflected in the reorientational behaviour of the cation.

Cubic $(CH_3NH_3)_2TeBr_6$ is known (43) to undergo at $T_{tr,u}$ = 289 K a first-order transition to phase *II* (all Br atoms equivalent, cf. ref. 29) and another first-order transition, at $T_{tr,1}$ = 164 K, to phase *III*. Exploratory ^2H nmr measurements on the *N*-deuterated compound up to 413 K (M. Gruwel and R. E. Wasylishen, unpublished results) show that the variation of $T_1(^2H)$ with temperature in phase *I* can be represented as $\ln T_1 = 2.725(23) - 111210(2430)T^{-2}$ (T_1 in s, $f = 10$, $r^2 = 0.995$, $\sigma = 0.017 \sim 2.4\%$ of the $\ln T_1$ range), similar to CL(*I*), CLD(*I*), and BR(*I*).[16] Because of the relatively high $T_{tr,u}$ of this bromide the $T/T_{tr,u}$ at the end of the experimental temperature range was only 1.43, but within this range the E_a vs. $T/T_{tr,u}$ curve (Fig. 11) is seen to parallel the corresponding curve for BR(*I*); at $T_{tr,u}$, E_a = 6.40(14) kJ/mol, i.e. 0.56(22) kJ/mol higher than $E_a(T_{tr,u})$ of BR(*I*). This difference indicates that E_a is probably marginally higher in $(CH_3NH_3)_2TeBr_6(I)$, which would be consistent with the slightly smaller Br_{12} cage in this crystal (the difference in $\frac{1}{2}a$ at room temperature is 0.2 Å ~ 3.5%, cf. ref. 29), but it provides no information bearing on the above question.

The extent of dissimilarity in the reorientational behaviour of the two crystals can be assessed somewhat better in phase *II*. The QS(^2H) of the *N*-deuterated $(CH_3NH_3)_2TeBr_6$ at 283 K, the temperature closest to $T_{tr,u}$ = 289 K in the exploratory experiments, was 23.9(5) kHz. Further cooling increased QS(^2H) at a faster rate than in BR(*II*), or IO(*II*), the value at 193 K being 36.0(5) kHz (Fig. 7A). At 148 K in phase *III*, i.e. 16 K below $T_{tr,1}$, QS(^2H) was 39.9(5) kHz and thus indicative of a fixed C—N axis. From the currently available results it is not possible to determine the variation of QS(^2H) at temperatures closer to $T_{tr,u}$ than 6 K. Fitting the QS(^2H) (kHz) values to $k(T_{tr,u} - T)^n$ (Fig. 7B) gave k = 17.47, n = 0.1543, r^2 = 0.974, σ = 0.8 kHz, which would suggest that critical behaviour might be a possibility. This would not be inconsistent with the variation of C_p with T in phase *II* of this bromide (Figs. 2, 4, and 6 of ref. 43), although the steepness of the rise of QS(^2H) on cooling just below $T_{tr,u}$ and the coexistence of an unsplit single line of phase *I* with the sharp doublet with QS(^2H) ~ 24 kHz in the 283 K spectrum indicate that further work is required. However, regardless of whether the QS(^2H) develops from zero at $T_{tr,u}$ (as in BR(*II*) and IO(*II*)) and reflects a critical process, or jumps from zero directly to a substantial value on cooling through $T_{tr,u}$, the behaviour of the hexabromotellurate in this respect differs significantly from that of BR and IO. The combined observations imply that the structural change associated with the $I \rightarrow II$ transition results in an almost immmediate hindrance of the reorientation of the C—N bond, and that this hindrance is much stronger than in BR(*II*) at any reduced temperature. The C—N reorientation is completely arrested in phase *III*. This interpretation is consistent with the behaviour of the second moment in the ^1H nmr spectrum of the hexabromotellurate (29). Above $T_{tr,u}$ the moment was found to be small, 0.4(1) G^2 (0.5(1) G^2 for the iodo compound), but below $T_{tr,u}$ its temperature variation appeared to mimic that of the QS(^2H) (Fig. 7): only a few degrees below $T_{tr,u}$ its value was already ~3.5 G^2 and it continued to increase on further cooling to ~6 G^2 at $T_{tr,1}$.

Conclusions

The combined results of our X-ray diffraction, calorimetric, ^2H and ^{14}N nmr and other studies of the $CH_3NH_3PbX_3$ (X = Cl, Br, I) perovskites can be summarized as follows:

In addition to phase *I* (of *Pm3m* symmetry) which exists above the upper transition temperature $T_{tr,u}$, each of the three halides has low-temperature phases. The transition temperatures were determined and the transitions characterized by heat capacity measurements in the ~30 to ~350 K range (Table 1, Figs. 2–4). In phase *I* the cation is inside a cuboctahedral (O_h) cage formed by twelve X atoms undergoing strongly anisotropic thermal motions. X-ray diffraction (Fig. 1) has revealed that the cation is positionally highly disordered, and evidence from ^2H and ^{14}N nmr spectra shows that it reorientates in an isotropic potential at a rate which at 373 K approaches that expected for inertial rotation. In the chloride (CL), the tumbling of the C—N axis ceases on cooling through $T_{tr,u}$, whereas in the bromide (BR) and iodide (IO) it continues, at a decreasing rate and in an increasingly anisotropic potential, into phase *II* but ceases at the $II \rightarrow III$ transition. Reorientation *about* the C—N axis in all three halides persists down to the lower end of our nmr temperature range, ~150 K.

The spin–lattice relaxation time $T_1(^{14}N)$ probes directly the reorientational motion of the C—N axis, independently of the motions of the ND_3 or CD_3 groups about that axis. In contrast, $T_1(^2H)$ probes the motion of the N—D bond about *and with* the C—N axis. The temperature variation of $T_1(^2H)$ in CL(*I*), BR(*I*), BR(*II*), and IO(*II*), and that of $T_1(^{14}N)$ in CL(*I*), BR(*I*), and probably IO(*I*), display non-Arrhenius behaviour but can be represented analytically with good accuracy by expressions of the type $\ln T_1 = k_0 - k_2T^{-2}$ (Table 2, Fig. 6). The activation energies E_a for the reorientation of the H- and N-containing groups thus depend on temperature, $E_a = C/T$ (Table 3, Fig. 11). This implies that the reorientation is not a simple thermally activated process but is controlled by additional factors.[17] The similarity of $E_a(^2H)$ for *C*- and *N*-deuterated CL(*I*) suggests that the CH_3 and NH_3 reorientations about the C—N axis are correlated. The passage from BR(*I*) to BR(*II*) is accompanied by a significant increase in E_a, $E_a(II)/E_a(I) \sim 1.6$, which corresponds to a difference of ~3.2 kJ/mol. The temperature variation of the $T_1(^{14}N)/T_1(^2H)$ ratio in CL(*I*) and BR(*I*) indicates that at temperatures at which thermal activation of the C—N

[16]Regression of $\ln T_1$ on T^{-1} gave $r^2 = 0.989$, $\sigma = 0.026 \sim 3.6\%$ of the $\ln T_1$ range, with a temperature-independent E_a of 5.4(2) kJ/mol. However, the distribution of signs of the deviations from the regression line appeared to be biased. The transition temperatures of the *N*-deuterated hexabromotellurate were taken to be the same as those for the undeuterated compound.

[17]This matter will be dealt with more fully in Part 3, together with the results of our X-ray and neutron diffraction investigations.

reorientation begins to become significant the N—D reorientational motion is already very rapid. The $T_1(^2H)$ values in IO(*I*) show anomalous behaviour the reasons for which are not yet understood.

The quadrupole splitting QS(^{2}H) observed in the spectra of BR(*II*) and IO(*II*) develops from zero at $T_{tr,u}$ and increases with decreasing temperature to ~4 kHz at the $II \rightarrow III$ transition in BR and ~8 kHz in IO. Its variation with temperature can be represented by $QS(^2H) = k(T_{tr,u} - T)^n$: for BR, $n = 0.52(4)$, $r^2 = 0.972$, $\sigma = 0.18$ kHz; for IO, $n = 0.53(2)$, $r^2 = 0.993$, $\sigma = 0.16$ kHz. This is consistent with the temperature variation of the excess heat capacity in BR(*II*) (Fig. 10) and strongly suggests that QS(^{2}H) in BR(*II*) and IO(*II*) may be regarded as an order parameter of a critical ordering process.[17]

While N—H···X hydrogen bonding in phase *I*, as measured by the lowering of the ν(NH) frequency in the ir spectra, is weaker than in the simple CH_3NH_3X halides, it is stronger than in the previously (15) investigated trigonal $(CH_3NH_3)_2PtCl_6$: the estimated mean of the ν_s(NH) and ν_a(NH) frequencies in $CH_3NH_3PbCl_3$ falls about halfway between those in CH_3NH_3Cl and $(CH_3NH_3)_2PtCl_6$.

The present results for the $CH_3NH_3PbX_3$ perovskites are compared in some detail with the available corresponding results for the cubic $(CH_3NH_3)_2TeX_6$, both from the literature and from our preliminary investigation of $(CH_3NH_3)_2TeBr_6$.

Acknowledgments

We wish to thank Professor M. H. Jericho and Mr. A. M. Putnam for the electrical conductivity measurements; Dr. M. Falk for obtaining the ir spectra; and Dr. D. Adhikesavalu, Dr. A. Linden, Miss K. N. Robertson, Mr. M. L. H. Gruwel, and Mr. J. B. Macdonald for their contributions to particular aspects of this investigation. Research grants to the first four authors and a Graduate Scholarship to the fifth author from the Natural Sciences and Engineering Research Council of Canada are acknowledged.

The direct electrochemical synthesis of d^{10} metal ion derivatives of some anionic bidentate oxygen donors

THEODORE A. ANNAN, CLOVIS PEPPE,[1] AND DENNIS G. TUCK[2]

Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received August 4, 1989

THEODORE A. ANNAN, CLOVIS PEPPE, and DENNIS G. TUCK. Can. J. Chem. **68**, 423 (1990).

The electrochemical oxidation of a sacrificial anode (M = Zn, Cd, Hg, In, Sn) in non-aqueous solutions of 3-hydroxyflavone, 1′-hydroxy-2′-acetonaphthone, or 2-ethoxyphenol (= HL) gives ZnL_2, CdL_2, HgL, InL_3, or SnL_2 (not all combinations). Adducts with 2,2′-bipyridine (bpy) or *N,N,N′,N′*-tetramethylethanediamine (tmen) have also been prepared in some cases. Certain zinc and cadmium compounds produce paramagnetic species on exposure to the atmosphere. The structure of $Zn(C_{15}H_9O_3)_2$tmen has been determined; the crystals are orthorhombic, space group *Pbcn*, cell dimensions a = 18.817(2) Å, b = 13.886(3) Å, c = 12.567(3) Å, Z = 4, R = 0.0758 for 773 unique observed reflections. The corresponding data for $Cd(C_{12}H_9O_2)_2$bpy are orthorhombic, space group *Pbca*, cell dimensions a = 20.338(4) Å, b = 30.473(5) Å, c = 9.316(2) Å, Z = 8, R = 0.0457 for 2623 unique observed reflections. Both molecules have MO_4N_2 kernels, but each shows significant differences in the two M—O bond lengths to the dioxo ligand, and there are concomitant effects in the C—O and C—C bond distances in the ligands.

Key words: electrochemical synthesis, d^{10} metal ions, X-ray crystallography, zinc complex, cadmium complex.

THEODORE A. ANNAN, CLOVIS PEPPE et DENNIS G. TUCK. Can. J. Chem. **68**, 423 (1990).

L'oxydation électrochimique d'une anode qui est sacrifiée (M = Zn, Cd, Hg, In et Sn) dans des solutions non-aqueuses de 3-hydroxyflavone, de l'hydroxy-2′-acétonaphtone ou de 2-éthoxyphénol (= HL) fournit les composés ZnL_2, CdL_2, HgL, InL_3 ou SnL_2 (pas nécessairement toutes les combinaisons). Dans quelques cas, on a aussi préparé les adduits avec la 2,2′-bipyridine (bpy) ou la *N,N,N′,N′*-tétraméthylèneéthanediamine (tmen). Lorsqu'on soumet un certain nombre de composés du zinc et du cadmium à l'atmosphère, on obtient des espèces paramagnétiques. On a déterminé la structure du produit $Zn(C_{15}H_9O_3)_2$tmen; les cristaux sont orthorhombiques, groupe d'espace *Pbcn*, avec a = 18,817(2), b = 13,886(3) et c = 12,567(3) Å, Z = 4 et R = 0,0758 pour 773 réflexions uniques qui ont été observées. Les données correspondantes pour le produit $Cd(C_{12}H_9O_2)_2$bpy sont cristaux orthorhombiques, groupe d'espace *Pbcn*, avec a = 20,338(4), b = 30,473(5) et c = 9,316(2) Å, Z = 8 et R = 0,0457 pour 2623 réflexions uniques qui ont été observées. Les deux molécules comportent un noyau de MO_4N_2; toutefois, chacune présente des différences importantes dans les deux longueurs des liaisons M—O conduisant au ligand dioxo et ces différences donnent lieu à des effets concomitants dans les longueurs des liaisons C—O et C—C de ces ligands.

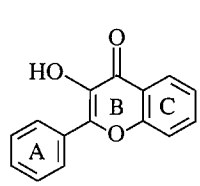
Mots clés : synthèses électrochimiques, ions métalliques d^{10}, diffraction des rayons-X, complexe du zinc, complexe du cadmium.

[Traduit par la revue]

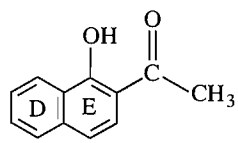
Introduction

The method of direct electrochemical synthesis developed in this laboratory consists in oxidizing a sacrificial metallic anode in a non-aqueous solution containing the appropriate ligand or ligand precursor to produce the appropriate metallic derivative, and a number of publications have established the wide applicability of this technique for the preparation of inorganic and organometallic derivatives of Main Group and transition metals. Recent studies have demonstrated the direct electrochemical synthesis of derivatives of many weak organic acids, including metal thiolates (1–4), metal acetylides (5), metal diethyldithiophosphates (6), metal dialkyldithiocarbamates (6), metal diphenylphosphides (7), and metal catecholates (8–10).

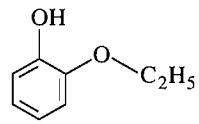
The present work was prompted by these last studies, which showed that under the conditions of the electrochemical experiment, the product tends to be in a low oxidation state, so that for example with catechol or other aromatic 1,2-diols, tin gave $Sn^{II}(O_2R)$ derivatives (9), and with indium, the products were the unusual $In^{I}[OR(OH)]$ derivatives (10). It therefore seemed appropriate to study compounds containing adjacent —OH and —OR groups, in the hope that these would also form chelate complexes of metals in unusual oxidation states. We have therefore investigated the electrochemical reactions of three weak organic acids, namely 3-hydroxyflavone ($C_{15}H_9O_3H$), 1′-hydroxy-2′-acetonaphthone ($C_{12}H_9O_2H$), and 2-ethoxyphenol ($C_8H_9O_2H$) with indium, tin, zinc, cadmium, and mercury.



$C_{15}H_9O_3H$



$C_{12}H_9O_2H$



$C_8H_9O_2H$

The tin derivative was the hoped-for tin(II) species, but the final indium product proved to be the result of disproportionation. The zinc and cadmium derivatives show unusual redox properties. In the course of this work, we have also established the molecular structure of $Zn(C_{15}H_9O_3)_2$tmen and $Cd(C_{12}H_9O_2)_2$bpy, each of which shows a number of interesting features.

[e]Mole ratio HL:bpy ≈ 2:1.
[f]Mole ratio HL:bpy ≈ 1:1.
[g]Not recorded.

naphthone, 2,2′-bipyridine (bpy), and *N,N,N′,N′*-tetramethylethanediamine (tmen) were used as supplied (Aldrich). Tetraethylammonium perchlorate was prepared by mixing aqueous solutions of $NaClO_4$ and Et_4NBr; the product was recrystallized from hot aqueous ethanol (9:1, v:v). Solvent were dried and distilled before use, and stored over drying agents.

Metal analyses were by atomic absorption spectrophotometry, and microanalysis was performed by Guelph Chemical Laboratories. Infrared spectroscopy involved the use of samples as KBr discs with a Nicolet 5DX instrument. Nuclear magnetic resonance spectra were recorded on a Bruker AC 300 L spectrometer. Electron spin resonance spectra were measured with a Varian E12 instrument, using the calibration and solution handling techniques described elsewhere (11).

Electrochemical synthesis

The method of preparing these new compounds was essentially the same as those used in our previous papers (1–10). The solution phase was contained in a 100 mL round-bottomed flask with a Schlenk arm; a metal rod suspended through rubber septum formed the anode of the cell, and a platinum wire was the cathode. In the case of mercury, the element was contained in small cup into which a platinum wire was inserted. Details of solution composition are given in Table 1, and Table 2 gives the analytical results for each compound synthesized. The use of an atmosphere of dry nitrogen is critically important in the derivatives of 1′-hydroxy-2′-acetonaphthone, as is the use of freshly distilled oxygen-free solvents. These rigorous precautions are not necessary in the other systems studied, since the derivatives can be safely handled in air.

The isolation of the product varied according to the system in question. In only three did precipitation occur completely during the electrolysis; $Hg(C_{15}H_9O_3)$ and $Cd(C_8H_9O_2)_2$ were collected by filtration, washed with diethyl ether, and dried *in vacuo*, while $Zn(C_{12}H_9O_2)_2$ was collected, recrystallized from hot toluene, and dried. With Sn, Zn, and $Cd(C_{15}H_9O_3)_2$, $Zn(C_8H_9O_2)_2$ and $Zn(C_{12}H_9O_2)_2bpy$, precipitation did not begin until the electrolysis had proceeded for some time, but solid continued to form over a period of ca. 12 h after the end of the experiment. This material was collected, washed with diethyl ether, and dried. In the case of $Zn(C_{15}H_9O_3)_2bpy$, the clear solution obtained at the end of the electrolysis was evaporated to dryness, and the product washed successively with acetonitrile (to remove Et_4NClO_4), toluene, and diethyl ether, and dried. Similarly, for $Cd(C_{15}H_9O_3)_2bpy$ the clear solution obtained at the end of the electrolysis was reduced in volume by ca. 50%; addition of diethyl ether produced a solid which was collected and washed in the usual way. Finally, in the case of $In(C_{15}H_9O_3)_3$, the clear solution phase deposited finely divided indium as the electrolysis proceeded; at the end of the experiment, the filtrate from this reaction was cooled to 0°C, which caused the indium(III) species to precipitate. This material was collected, washed, and dried.

TABLE 2. Analytical results for metal–dioxo compounds

Compound	Colour	M% Found	M% Calcd.
$Zn(C_{15}H_9O_3)_2$	Yellow	12.7	12.1

ρ_0 (g cm^{-3})	1.33	1.49
Crystal dimensions (mm)	0.26 × 0.15 × 0.10	0.46 × 0.38 × 0.23
Absorption coefficient, μ (cm^{-1})	8.21	7.08
2θ angle (deg)	4–40	4–45
Background time/scan time	0.5	0.5
Total reflections measured	1546 ($+h$, $+k$, $+l$)	3798 ($+h$, $+k$, $+l$)
Unique data used ($I \geq 3\sigma(I)$)	773	2623
No. of parameters (NP)	104	200
$R = \Sigma\Delta/\Sigma\|F_o\|$	0.0758	0.0457
$R_w = [\Sigma w\Delta^2/\Sigma w\phi_0^2]^{1/2}$	0.0766	0.0483
Largest peak in final difference Fourier, e/Å^3	0.36	0.38
Largest shift/error value on final cycle	0.01	0.01

Crystallographic analysis

In both X-ray crystallographic studies, involving $Zn(C_{15}H_9O_2)_2$tmen (**1**) and $Cd(C_{12}H_9O_2)_2$bpy (**2**), the crystal was mounted along its longest dimension on a Syntex $P2_1$ automated diffractometer with Mo-Kα radiation (λ = 0.71069 Å) and a graphite monochromator. Data were collected (θ–2θ scan, width Kα_1 − 1° to Kα_2 + 1°, scan speeds 2.02–4.88° min^{-1}) at 21°C by the procedures described previously (12). The crystal of **1** was mounted on a glass fibre with epoxy resin adhesive, while **2** was sealed in a capillary tube, but the procedures were otherwise essentially the same in each case. The intensities of three check reflection were monitored at regular intervals, and no significant decay was observed during the time required for data collection. The cell parameters were measured, checked for dimensions and symmetry from axial photographs, and refined from data from 30 strong reflections in the range $15 < 2\theta < 25°$ reflections. Data used in the structure determinations were corrected for Lorentz and polarization effects, and analytically for absorption. Pertinent crystal and experimental data are given in Table 3. The densities were measured by the flotation method, using carbon tetrachloride – benzene mixtures.

The systematic absences for **1** ($0kl$ for $k = 2n$, $h0l$ for $l = 2n$, $hk0$ for $h + k = 2n$, $h00$ for $h = 2n$, $0k0$ for $k = 2n$, and $00l$ for $l = 2n$) identified the space group as *Pbcn*. For **2**, the space group *Pbca* was identified by the systematic absences $0kl$ for $k = 2n$, $h0l$ for $l = 2n$, $hk0$ for $h = 2n$, $h00$ for $h = 2n$, $0k0$ for $k = 2n$, and $00l$ for $l = 2n$. Direct methods and Fourier techniques were used to solve the structure in these centrosymmetric space groups, with refinement by full-matrix least-squares methods. In the final stages of the refinement of **1**, Zn, O, and N and the carbon atoms of the tmen ligand (C16—C18) were refined with anisotropic thermal parameters and the remaining carbon atoms isotropically; hydrogen atoms were fixed in idealized positions (r(C—H) = 0.95 Å), and assigned isotropic thermal parameters 10% higher than those of the bonding carbon atoms. Due to the small size of the crystal, and the consequent small unique data set used in the analysis, C10—C15 and C4—C9 were refined as rigid groups, using C—C bond lengths of 1.395 Å, and angles of 120°. Unit weights were used in the initial stages, while in the final cycles the weighting scheme used was of the form $W = \sigma^2(F) + 0.00001F^2$. The refinement, minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, converged at R = 0.0758 and R_w = 0.0766; these values clearly reflect the restricted data set available.

For the final stages of the refinement of the structure of **2**, Cd, O, and N atoms were refined with anisotropic thermal parameters and the carbon atoms were treated isotropically. Hydrogen atoms were again fixed in idealized positions, and the weighting scheme was that used in the case of **1**. The refinement minimizing the function $\Sigma w(|F_o| - |F_c|)^2$ converged at R = 0.0457 and R_w = 0.0483.

The computer programs and the source of scattering factors were those used in earlier work (12). Fractional atomic coordinates are given in Tables 4 and 6, and bond lengths and angles in Tables 5 and 7. Tables of thermal parameters, hydrogen atom coordinates, and observed and calculated structure factor amplitudes, are available as supplementary data. The structures are shown in Figs. 1 and 2. The cell diagrams have been deposited.[3]

Results and discussion

Electrochemical

The electrochemical oxidation of the various metals investigated obviously provides a convenient route to the compounds listed in Table 2. As in the earlier systems studied in this laboratory, the products are obtained in a one-step high yield synthesis, and the method readily lends itself to working on a larger scale than that which we chose to use in the present studies. The electrochemical route is obviously simpler than that involving a sequence of reactions starting from metal salt + parent acid.

The stoichiometry of the electrochemical reactions is indicated by the electrochemical efficiency, defined as moles of

[a] $U_{eq} = \frac{1}{3}[\Sigma_i\Sigma_j U_{ij} a_i^* a_j^* \boldsymbol{a}_i \cdot \boldsymbol{a}_j]$; all carbon atoms were refined isotropically.

metal dissolved per Faraday of charge (E_F). The values in Table 1 show that for all R(OH) solutes with zinc, cadmium, and tin anodes, $E_F = 0.51 \pm 0.02$ mol F^{-1} which implies the reactions

Cathode

[1] $2R(OH) + 2e \rightarrow 2RO^- + H_2$

Anode

[2] $2RO^- + M \rightarrow M(OR)_2 + 2e$

corresponding to the formation of products with the metal in the +II state for these elements. For indium, $E_F = 1.02$ mol F^{-1}, implying the formation of an indium(I) species at the anode, but the subsequent disproportionation in solution is evidenced by the deposition of indium metal, and by the isolation of $In(C_{15}H_9O_3)_3$. For mercury and $C_{15}H_9O_2(OH)$, the product is formally a mercury(I) species, but we were not able to measure E_F with any degree of accuracy.

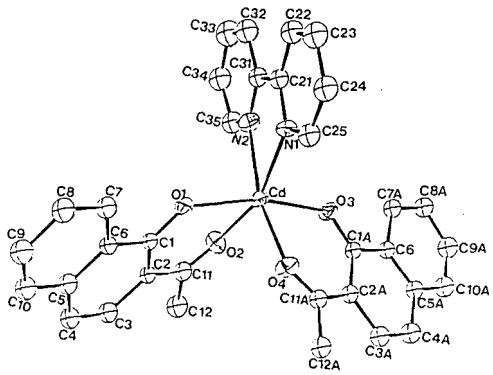

FIG. 1. The molecular structure of $Zn(C_{15}H_9O_3)_2$tmen (**1**); ORTEP diagram, with atoms drawn as 30% probability ellipsoids. The numbering system is shown; unlabelled and labelled atoms are related by a two-fold axis. Hydrogen atoms have been omitted for the sake of clarity.

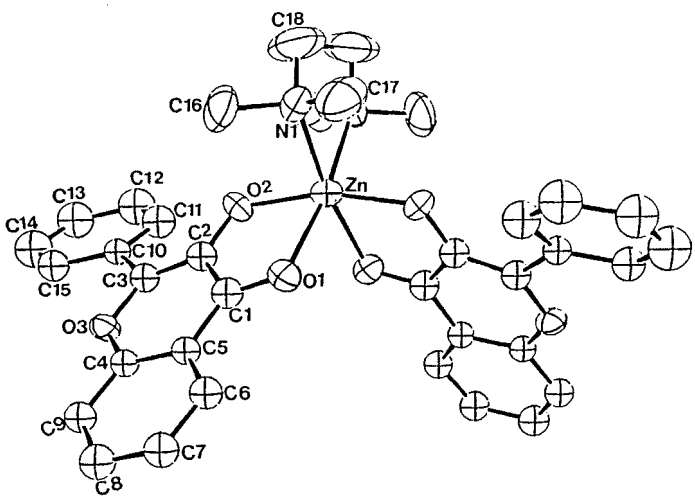

FIG. 2. The molecular structure of $Cd(C_{12}H_9O_2)_2$bpy (**2**); comments as in Fig. 1.

Preparative

(1) 3-Hydroxyflavone derivatives

Amongst the three organic compounds investigated, derivatives of 3-hydroxyflavone are the easiest to prepare. No deposition of metal on the electrode was detected during the electrolysis, except in the case of the indium compound (see below). All the compounds are air stable materials, and were obtained in high yields.

The compounds $M(C_{15}H_9O_3)_2$ (M = Zn, Cd) are the natural derivatives expected with the metal in its +II oxidation state. When the electrolysis was conducted in the presence of bpy, the 1:1 addition compounds $M(C_{15}H_9O_3)_2$bpy were obtained, and both $M(C_{15}H_9O_3)_2$ compounds reacted with tmen in acetonitrile or acetonitrile:toluene (1:1) to form the crystalline 1:1 addition compounds $M(C_{15}H_9O_3)_2$tmen in yields better than 80%. With tin and mercury, the products are those of the element in the low oxidation state, and in the case of tin, the stable $Sn(C_{15}H_9O_3)_2$ compound is isolated as a crystalline yellow solid. The electrochemical oxidation of mercury leads to the formation of the mercurous flavonate, in contrast to the behaviour of the other elements of the same group; $Hg(C_{15}H_9O_3)$ is readily oxidized to $HgI(C_{15}H_9O_3)$ by reaction with half an equivalent of I_2 in toluene.

[3] $2Hg(C_{15}H_9O_3) + I_2 \rightarrow 2HgI(C_{15}H_9O_3)$

supporting the assumption that the initial electrochemical reaction yields a mercury(I) derivative. The presence of toluene in the final product was demonstrated by the characteristic ν(C—H) infrared bands at 2839 + 2959 cm^{-1}.

The isolation of the indium(III) flavonate can be explained in terms of the initial formation of an indium(I) species electrochemically, followed by disproportionation according to the stoichiometry

[4] $3In(C_{15}H_9O_3) \rightarrow 2In + In(C_{15}H_9O_3)_3$

In keeping with this argument, during the initial stages of the electrolysis we observed the formation of a yellow solid, which quickly decomposes shortly after its formation with the deposition of metallic indium, which can be isolated in the quantity required by the stoichiometry of reaction [4].

(2) 2-Ethoxyphenol derivatives

During the electrochemical experiments with this compound, we observed considerable heating in the cell and a significant increase in the current flowing in the circuit, although this could be controlled by decreasing the applied voltage. A considerable deposition of metal on the cathode of the cell was also observed, especially in the preparation of $Cd(C_8H_9O_2)_2$. To overcome this difficulty, a small beaker (1 cm diameter, 1 cm height) was placed below the platinum cathode to collect the metal which is deposited during the electrolysis, and thereby avoid the contamination of the insoluble product which falls away from the area immediately below the electrode.

The results are similar to those for the flavonates discussed above. With zinc and cadmium, $M(C_8H_9O_2)_2$ and $Zn(C_8H_9O_2)_2$bpy are M^{II} complexes and call for no special comment. We were not able to achieve the electrochemical synthesis of $Cd(C_8H_9O_2)_2$bpy. In each of several attempts, large quantities of metallic cadmium deposited on the platinum cathode, and changing the solvent did not eliminate this deposition. It seems probable that the $Cd(C_8H_9O_2)_2$bpy compound formed electrochemically undergoes subsequent cathodic reduction to cadmium metal

[5] $Cd(C_8H_9O_2)_2bpy + 2e^- \rightarrow Cd + 2C_8H_9O_2^- + bpy$

It is also worth noting that this bipyridine adduct could not be prepared by a direct reaction between $Cd(C_8H_9O_2)_2$ and bpy in refluxing toluene, since the initial cadmium compound was recovered unchanged. This result suggests that the solid $Cd(C_8H_9O_2)_2$ has a homo-polymeric structure which is not easily broken down even by a strong bidentate donor.

Attempts to prepare indium ethoxyphenolato derivatives were unsuccessful; a considerable amount of metallic indium was deposited at the cathode, suggesting the *in situ* reduction of the indium compound formed electrochemically.

(3) 1′-Hydroxy-2′-acetonaphthone derivatives

The electrochemical reduction of 1′-hydroxy-2′-acetonaphthone, followed by the oxidation of anodic zinc, leads to $Zn(C_{12}H_9O_2)_2$, and to $Zn(C_{12}H_9O_2)_2$bpy when the bidentate ligand is present in the solution phase. The oxidation of cadmium produced a yellow compound, identified as $Cd(C_{12}H_9O_2)_2$. During the formation of this substance, the deposition of metallic cadmium at the cathode was observed, but the use of a small beaker under the electrode (see above) prevented any contamination of the final product. $Cd(C_{12}H_9O_2)_2$bpy was prepared from previously formed $Cd(C_{12}H_9O_2)_2$ by reaction with 2,2′-bipyridine in toluene; crystals suitable for X-ray diffraction were grown from this solution.

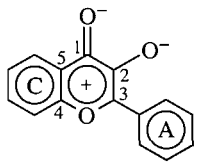
		C(34)—C(35)—N(2)	122.3(8)
		C(24)—C(25)—N(1)	123.7(7)

Experiments using a tin anode lead to considerable deposition of metal at the cathode of the cell, and similarly with indium anodes. We observed deposition of indium metal in the cell. No compound of sensible formulation could be isolated in either case.

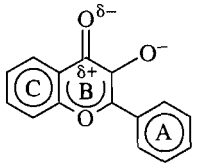
The structure of $Zn(C_{15}H_9O_3)_2tmen$ (1)

The molecular structure of this compound (Fig. 1) shows that it has the expected six-coordination at zinc, but an examination of the actual bond distances and angles (Table 6) reveals some interesting details. The most striking is the difference in the two Zn—O bond distances within the C_2O_2Zn ring of the flavonate ligand. The bond to O2, the phenolic oxygen of the parent compound (Zn—O2 = 1.980(1) Å), is significantly shorter than that to the ketonic oxygen (2.240(1) Å), and associated with this effect are different C—O bond distances (C2—O2 = 1.318(1) Å, C1—O1 = 1.266(1) Å), and a C—C bond (C1—C2 = 1.468(2) Å) which is longer than normal in conjugated systems. We return to the bond distances in the rings below. The Zn—O average bond length of 2.110 Å can be compared with values found in the determination of structures of similar molecules. In Zn_3(crotonate)$_6$(quinoline)$_2$ (13), both tetrahedral ZnO_3N and octahedral ZnO_6 kernels are found, with Zn_{tet}—O = 1.956 Å (av) over the range 1.938(2)–1.976(2) Å, and Zn_{oct}—O = 2.109 Å (av) over the range 2.038–2.177(2) Å. Very similar Zn_{tet}—O distances are reported for other related M_2Zn crotonate complexes. Similarly, in $Zn(C_7H_8O_5)(H_2O)_2$, the Zn—O bond distances to the oxygen atoms of the 4-oxoheptanedioato ligand are 2.179(2) and 2.213(3) Å (14), and in solvated Zn-propanedienate (15), the mean Zn—O distance in bonds involving the diketonate is 2.020(7) Å, so that the values reported in Table 6 agree well with the previous results. The Zn—N distance (2.229(1) Å) is similar to those reported for related species (e.g., refs. 13, 16). Equally, the N—Zn—N angle, and the C—C and C—N distances within the tmen ligand are reasonably close to those in other Main Group complexes (e.g., ref. 17).

The relevance of bond lengths within the ZnO_2C_2 ring to those in the C_5O ring (B) of the flavonate can now be addressed. We should first emphasise a point made in the Experimental section, that the small crystal size restricted the treatment of the experimental data. We found it necessary to fix the C—C bond lengths within rings A and C, so that the results in Table 6 are conditioned by this treatment. In a subsequent refinement in which this restriction was removed, the bond lengths and angles in ring B (and elsewhere) did not change significantly, but the ratio of data points to output results fell below an acceptable level. We believe that the values in Table 6 are sufficiently sound to support the conclusion that the Zn—O and C—O distances in the ZnO_2C_2 do indeed differ significantly. Equally, within ring B we identify two relatively long C—C bonds (C1—C2 = 1.468(2) and C1—C5 = 1.455(2) Å) and two shorter ones (C2—C3 = 1.350(2) and C4—C5 (constrained)). The C—O distances (av. 1.357(1) Å) are typical of those found in conjugated heterocyclic rings (18), and a particularly close analogy exists with the cadmium(II)-2,6-dimethyl-4*H*-pyran-4-one complex (19). The conclusion is that rings B and C involve not only the expected form **3** in which the positive charge is completely delocalized, but also a significant contribution from **4**



3



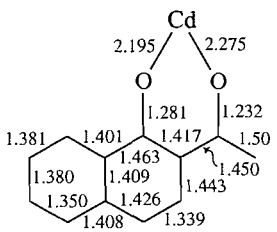
4

The effect of this charge distribution upon the chemistry of this and related molecules will be discussed elsewhere.

The structure of $Cd(C_{12}H_8O_2)_2bpy$ (2)

As in the case of the zinc compound just discussed, the structure of **2** (Fig. 2) is based on a six-coordinate cadmium atom with a CdO_4N_2 kernel. The Cd–bpy system is essentially identical to that in $Cd(S_2CSC_4H_9\text{-}n)_2bpy$ (20), and need not be discussed further.

The bond lengths in the CdO_2C_2 ring again establish the asymmetry of this system. The Cd—O bonds are 2.195(4) and 2.275(5) Å in length, and the relevant C—O bond distances are 1.281(7) and 1.232(8) Å. These and other averaged values are as shown



Ring D (see Fig. 2) shows insignificant deviations from the hexagonal symmetry of the aromatic C_6 ring, but in ring E there are two relatively long C—C bonds (C1—C6, av. 1.463(8) Å, and C2—C3, av. 1.443(9) Å), and one short bond (C3—C4, av. 1.339(9) Å). The interpretation of these results in terms of the contributing structures is that the delocalization which would give **6** is much less significant than one might have expected, and that **7** makes an important contribution to the overall structure and reactivity of this molecule.

For personal use only.

The average Cd—O bond distance of 2.235 Å (range 2.183(4)–2.289(5) Å) compares favourably with those in other six-coordinate cadmium species. The average value in $CdZn_2$-(crotonate)$_6$(quinoline)$_2$, which involves a CdO_6 kernel, is 2.266 Å (range 2.212(3)–2.314 Å) (13), and the bond to the neutral ligand in $Cd(NO_3)_2(C_7H_8O_2)_3$ ($C_7H_8O_2$ = 2,6-dimethyl-4*H*-pyran-4-one) is 2.283(4) Å (19). A range of 2.25–2.35 Å in CdO_6 species was suggested from an earlier review of the literature (21).

Although the effects are different from those identified in $Zn(C_{15}H_9O_3)_2$tmen, there are equally structural features in **2** which suggest interesting chemical properties. One of these is noted briefly below.

Spectroscopic information

The characterization of the products depended on elemental analysis and spectroscopic results. The most prominent feature in the ir spectra of these compounds, compared to the spectra of the parent compounds, is the absence of the O—H stretching absorption. In the derivatives of 3-hydroxyflavone and 1′-hydroxy-2′-acetonaphthone, we also observed a significant shift of the C=O stretching absorption to lower frequencies, from 1609 cm^{-1} to *ca.* 1550 cm^{-1} for 3-hydroxyflavone, and from 1625 cm^{-1} to *ca.* 1590 cm^{-1} for 1′-hydroxy-2′-acetonaphthone.

It was not possible to obtain the nmr spectrum of every compound prepared. The derivatives of 1′-hydroxy-2′-acetonaphthone form solutions which when in contact with air become paramagnetic, and the ethoxyphenolato complexes have poor solubility in most common organic solvents. The derivatives of 3-hydroxyflavone show in their ^1H nmr spectra (in d_6-DMSO) the characteristic absorptions of the ligands and the absence of the OH resonance found at 9.65 ppm in the parent compound. We have obtained ^{13}C nmr spectra for the bisflavonates of zinc and cadmium(II), and for the parent 3-hydroxyflavone, also in d_6-DMSO. The most important feature of these spectra is the downfield shift of the carbonyl resonances from 172.9 ppm in the parent compound to 178.0 (Cd derivative) and 178.2 ppm (Zn), which undoubtedly can be associated with the coordination of the oxygen to the metal centre as confirmed by the X-ray analysis.

The reaction of the Zn and Cd 1′-hydroxy-2′-acetonaphthone derivatives with air (*i.e.*, presumably O_2) to produce paramagnetic species has been briefly investigated by electron spin resonance (esr) spectroscopy. The spectrum of a sample of solid $Cd(C_{12}H_9O_2)$.bpy exposed to the air for ca. 10 min was a broad featureless singlet, very similar to that obtained when an alkaline solution of the parent $C_{12}H_9O(OH)$ was allowed to react with atmospheric oxygen. In contrast, the esr spectrum of a solution of $Cd(C_{12}H_9O_2)$.bpy after exposure to air has a number of sharp features. Further work on these systems is proceeding.

Received July 18, 1989

TURGUT GÜNDÜZ, ESMA KILIÇ, MUSTAFA TASTEKIN, and GÜLEREN OZKAN. Can. J. Chem. **68**, 431 (1990).

Nine symmetrical aliphatic dicarboxylic acids, namely oxalic, malonic, succinic, glutaric, adipic, pimelic, suberic, azelaic, and sebacic acids, were titrated conductimetrically with tetrabutylammonium hydroxide in pyridine and pyridine–benzene mixtures ((2 + 1), (1 + 1), (1 + 2), (1 + 3), and (1 + 4)). Titration curves of the acids exhibited two distinct and stoichiometric end-points in media of dielectric constants 13.5, 10.0, 8.2, 6.3, 5.3, and 4.7, respectively. The closer investigations of the titration curves revealed that three factors mainly influence the shapes of the titration curves: dielectric constant of the medium, number of the methylene groups in the acid, and formation of hydrogen bonds between several species. As dielectric constant of the medium decreases, conductivity of the medium also decreases at any point in the titration curve. Increase in the number of methylene groups from one to five decreases conductivity of the medium linearly at the first end-points of the acids, from then the conductivity becomes practically constant in acids having five to eight methylene groups in pyridine and pyridine–benzene mixtures of 2 + 1 and 1 + 1 ratios.

Key words: conductimetric titration in pyridine, conductimetric titration in pyridine–benzene mixtures, symmetrical aliphatic dicarboxilic acids.

TURGUT GÜNDÜZ, ESMA KILIÇ, MUSTAFA TASTEKIN et GÜLEREN OZKAN. Can. J. Chem. **68**, 431 (1990).

Utilisant de l'hydroxyde de tétrabutylammonium, faisant appel à la conductimétrie et opérant dans la pyridine ainsi que dans des mélanges ((2 + 1), (1 + 1), (1 + 2), (1 + 3) et (1 + 4)) de pyridine–benzène, on a titre neuf acides dicarboxyliques aliphatiques symétriques, soit les acides oxalique, malonique, succinique, glutarique, adipique, pimélique, subérique, azélaïque et sébacique. Dans ces milieux dont les constantes diélectriques sont respectivement de 13,5, 10,0, 8,2, 6,3, 5,3 et 4,7, les courbes de titration des acides présentent chacune deux points distincts et stoechiométriques. Un examen plus approfondi des courbes de titration monter que trois facteurs principaux influencement la forme des courbes de titration, soit la constante diélectrique du milieu, le nombre de groupements méthylènes dans les molécules d'acides ainsi que la formation de liaisons hydrogènes entre diverses espèces. Une diminution de la constante diélectrique du milieu provoque une diminution de la conductivité du milieu à tous les points de la courbe de titration. Lorsque le nombre de groupements méthylène passe de un à cinq, on observe une diminution linéaire de la conductivité du milieu; pour les acides comportant de cinq à huit groupements méthylènes qui ont été examinés dans la pyridine ainsi que dans des mélanges 2 + 1 ainsi que 1 + 1 de pyridine–benzène, la conductivité devient toutefois pratiquement constante.

Mots clés : titrations conductimétriques dans la pyridine, titrations conductimétriques dans des mélanges pyridine–benzène, acides dicarboxyliques aliphatiques symétriques.

[Traduit par la revue]

Introduction

There are a number of publications on the titrations of dicarboxylic acids in nonaqueous media (1–9). However, with only one exception there is no systematic report on the titrations of these compounds in nonaqueous media; the exception being potentiometric titrations of the compounds in pyridine, 2-propanol, and their mixture with benzene (9). Here we report the results on conductimetric titrations of nine symmetrical aliphatic dicarboxylic acids: oxalic, malonic, succinic, glutaric, adipic, pimelic, suberic, azelaic, and sebacic. Solutions (0.001 M) of these compounds in solvent pyridine ($\epsilon = 13.6$) and in mixtures of pyridine and benzene ($\epsilon = 2.2$) ((2 + 1), (1 + 1), (1 + 2), (1 + 3), and (1 + 4)) were titrated conductimetrically with tetrabutylammonium hydroxide (0.036 M) dissolved in propan-2-ol. The conductimetric titration curves of the acids have exhibited two distinct end-points each corresponding to one carboxylic group in the medium of dielectric constants from 13.6 to 4.7. These are important observations in media of lower dielectric constants. Potentiometric (9) titrations did not yield the same information.

Experimental

Apparatus

An Orion Model 101 conductivity meter equipped with an Orion Cat No. 99.01.01 conductivity cell (cell constant of 1.04 cm^{-1}) was used. The conductimetric titrations were carried out in the same cell as in ref. 10.

Chemicals

Tetrabutylammonium hydroxide (TBAOH) was purchased from Merck AG as a 0.100 M solution in propan-2-ol-methanol and was diluted with pure, dry propan-2-ol to give an approximately 0.040 M solution. This solution was standardized against primary standard benzoic acid and its true concentration was found to be 0.036 M (mean value of five runs). The solution was kept in a dark-coloured ground glass stoppered flask in a refrigerator. Solutions prepared and kept under these conditions was found to be stable for at least six months.

Benzoic acid (sublimed) was purchased from Merck AG.

Pyridine and benzene were purchased from Merck AG and used after further purification (12).

Oxalic, malonic, and succinic acids were purchased from Merck AG (99% pure) and used as received.

Glutaric, pimelic, and suberic acids were purchased from Sigma and used as received. Adipic and azelaic acids were purchased from Fluka (purum, 99%) and used without further purification. Sebacic acid was purchased from Riedel de Haen (pure 99%) and used without further purification.

Results and discussion

The conductimetric titration curves of the nine symmetrical aliphatic dicarboxylic acids in solvent pyridine are shown in Fig. 1. The titration curves have been normalized (ordinate axis

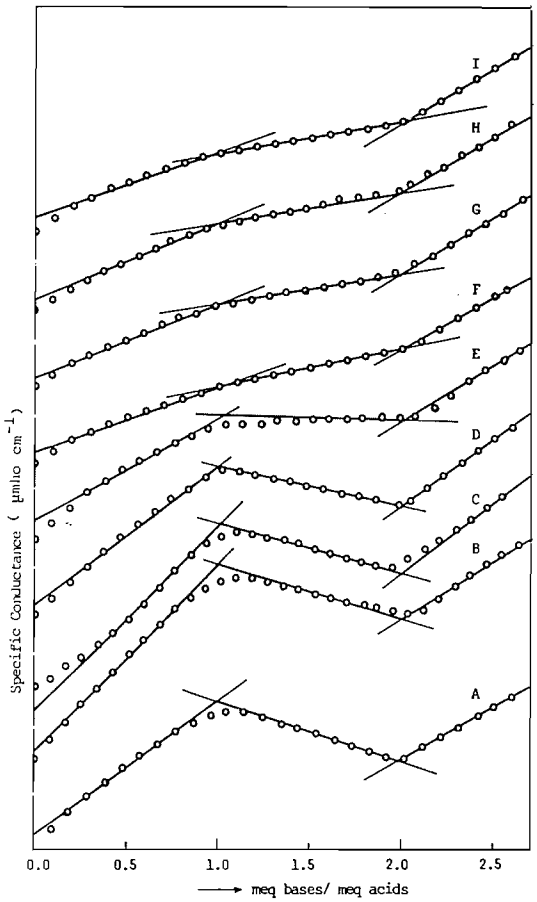

FIG. 1. Conductimetric titration of the solutions (0.001 M) of symmetrical aliphatic dicarboxylic acids with tetrabutylammonium hydroxide (0.036 M) in pyridine solvent at 25°C and under nitrogen atmosphere. Ordinate axis is not in scale. Curves are drawn for qualitative comparison only: (*A*) oxalic, (*B*) malonic, (*C*) succinic, (*D*) glutaric, (*E*) adipic, (*F*) pimelic, (*G*) suberic, (*H*) azelaic, (*I*) sebacic acids.

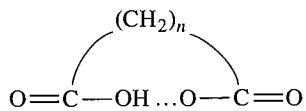
is not in scale). Titrations have been carried out under nitrogen at 25°C. As can be seen from the figure all acids show two stoichiometric and distinct end-points. This means that these compounds can be determined stepwise when they are dissolved in solvent pyridine in concentrations as low as 0.001 M.

Closer investigation of the titration curves revealed that several factors play important roles on the shape of the titration curves. These factors are (*i*) intra- and intermolecular hydrogen bonding, (*ii*) formation of ion-pairs, and (*iii*) number of methylene groups on the dicarboxylic acids. Only singly charged ions can be present in regions before the first end-point. Singly charged ions in nonaqueous aprotic solvents such as pyridine may form intra- (**I**) and intermolecular (**II**) hydrogen bonds as well as ion-pairs. Since titration curves up to first end-point show that the conductivity increases smoothly, there



(**I**)

$$HOOC(CH_2)_nCOOH \cdots OOC(CH_2)_nCOOH$$

(**II**)

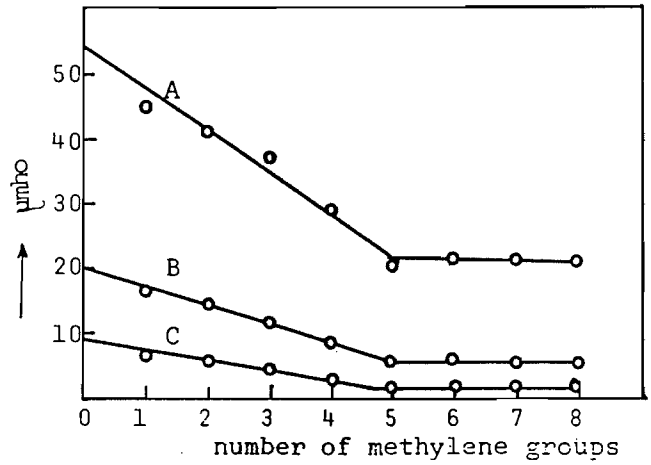


FIG. 2. The decrease in conductivities at the first end-points of symmetrical aliphatic dicarboxylic acids with increasing number of methylene group. (*A*) In pyridine solvent, (*B*) in 2 + 1 pyridine–benzene mixture, (*C*) in 1 + 1 pyridine–benzene mixture. Titrations were carried out under nitrogen at 25°C. Readings were taken in a standard solution of specific conductance (0.110 mol KCl per liter at 25°C) at 0.0129 mho cm^{-1}.

should be no intermolecular hydrogen bonds (**II**). Otherwise maxima at the half-neutralization points would appear before the first end-points (13–16).

Figure 1 further shows that the first end-points of acids having up to four methylene groups are very sharp; while those of acids having five to eight methylene groups are less sharp. A possible explanation is that for acids with up to four methylene groups, the mobility of the doubly charged ion is smaller than the mobility of the singly charged anion. Doubly charged anion can form two hydrogen bonds with propan-2-ol (propan-2-ol enters the media as the solvent of the titrant), $PrOH \cdots OOC(CH_2)_nCOO \cdots HOPr$, whereas the singly charged anion can form only one hydrogen bond, $PrOH \cdots OOC(CH_2)_nCOOH$. Since the former is bulkier than the latter, doubly charged entity is less mobile than the singly charged entity. Furthermore, doubly charged anions can form ion-pairs more readily than singly charged anions, as their electrical charge is higher. Anion of higher electrical charge attracts cations more readily to form ion-pairs. These factors are not as effective for dicarboxylic acids with five to eight methylene groups. However, the mobilities of doubly charged anions of these acids are very slightly more mobile than their singly charged anions. This can be explained by the increased number of methylene groups in these acids. As the number of methylene groups increases, the inductive effects between two carboxylic groups decreases. Consequently each carboxylic group of the dicarboxylic acid may react independently, as if they were monocarboxylic acids.

The second end-points of all acids are either sharp or very sharp. The slopes of the titration curves for the longer chainlength acids before the first end-point are practically identical, measuring 0.35, 0.38, 0.37, 0.37 for pimelic, suberic, azelaic, and sebacic acids respectively. This indicates that the inductive effects between the two carboxylic groups are negligible in acids having five or more methylene groups. After second end-points, the slopes of the titration curves are 0.57, 0.59, 0.58, and 0.58, respectively. Similar regularities are not observed for oxalic, malonic, succinic, glutaric, and adipic acids before the first end-point. However, past the second end-point the slopes of the titration curve of all acids are

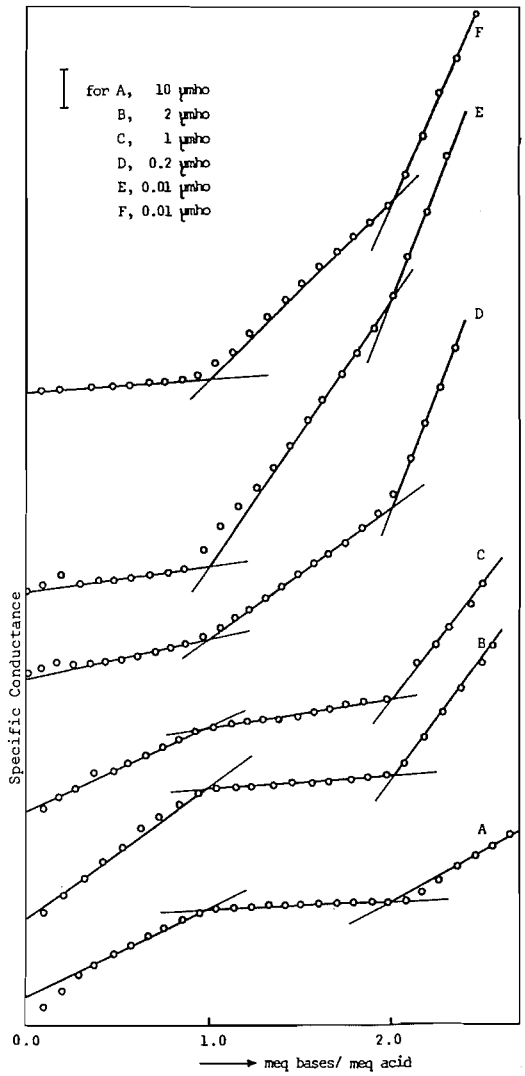

FIG. 3. The conductimetric titrations of adipic acid in pyridine (*A*) and pyridine–benzene mixtures of 2 + 1 (*B*) 1 + 1 (*C*) 1 + 2 (*D*) 1 + 3 (*E*), 1 + 4 (*F*). Dielectric constants of the media are 13.6, 10.0, 8.2, 6.3, 5.3, and 4.7 respectively. Titrations are carried out at 25°C under nitrogen.

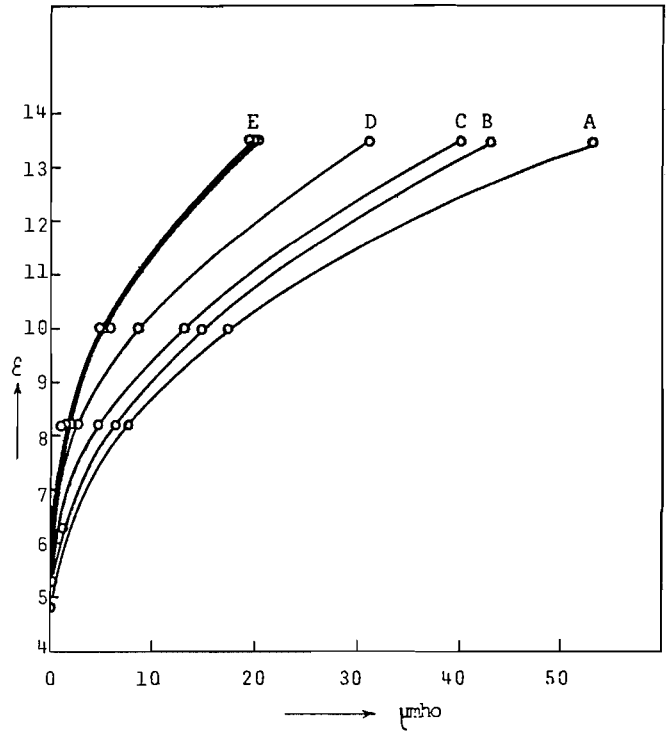

FIG. 4. Relationships between dielectric constants of solvents and conductivities of the solutions at first end-points (0.001 M) of (*A*) malonic, (*B*) succinic, (*C*) glutaric, (*D*) adipic, (*E*) pimelic, (*E*) suberic, (*E*) suberic, (*E*) azelaic, and (*E*) sebacic acids. Titrations were carried out in pyridine and pyridine–benzene mixtures of 2 + 1, 1 + 1, 1 + 2, 1 + 3, and 1 + 4 ratios at 25°C. Standard solution of tetrabutylammonium hydroxide (0.036 M) was used as titrant; titrations were carried out under nitrogen.

approximately the same. Here the composition of solutions are nearly the same; there are doubly charged anions of short or long chainlength irrespective of the presence of hydrogen bonding.

Except for oxalic acid the first end-point conductivities decrease monotonically with increasing number of methylene groups until the number of methylene group is five (pimelic acid) and then the conductivities become practically constant, Fig. 2*A*. This means that in pimelic, suberic, azelaic, and sebacic acids the carboxylic groups do not influence each other inductively; an observation in accordance with literature data (9, 11) obtained by potentiometric means.

Titrations of the acids in pyridine–benzene mixtures of ratios 2 + 1, 1 + 1, 1 + 2, 1 + 3, and 1 + 4 have also been carried out and two distinct, stoichiometric end-points for each acid have been obtained. Dielectric constants of these mixed solvents have been calculated by the equation (17)

$$\epsilon_{mixt} = x_1 \epsilon_1 + x_2 \epsilon_2$$

and found to be 10.0, 8.2, 6.3, 5.3, and 4.7, respectively. Titration curves for adipic acid in different media are given in Fig. 3. The curves are normalized to facilitate comparison. The figure clearly shows that carboxylic acids can be titrated in media of dielectric constants as low as 4.7 in mixed pyridine and benzene. In 2 + 1 and 1 + 1 pyridine–benzene mixtures, conductivities at first end-points decrease linearly with increasing number of methylene groups, up to five (pimelic acid) and then become a constant when for methylene number ranging from five to eight, Fig. 2*B* and *C*.

Another feature is the smooth relationship between the conductivities at first end-points and dielectric constants of the medium for each acid, Fig. 4. Figure 4 shows that the curves for pimelic, suberic, azelaic, and sebacic acids are nearly superimposed. The same relationship is observed between the first end-point conductivities of the acids and their number of methylene groups. This means that the methylene groups and dielectric constants both exert the same sort of effects on the symmetrical aliphatic dicarboxylic acids. The conductimetric titration curves of the dicarboxylic acids in solvent pyridine exhibit much more detailed and instructive curves than potentiometric titration curves. In the potentiometric titration of adipic acid, only one end-point corresponding to two equivalent protons is observed (9) in the same solvent. The higher homologues of adipic acid exhibit the same properties as adipic acid.

Conclusions

The following conclusions can be drawn from the conductimetric titration curves obtained for solution of nine symmetrical aliphatic dicarboxylic acids with tetrabutylammonium hy-

droxide in pyridine ($\epsilon = 13.6$) and pyridine–benzene mixtures, dielectric constant of benzene being 2.2

1. The titration curves obtained for the solutions of the symmetrical aliphatic dicarboxylic acids in pyridine and in pyridine–benzene mixtures show two distinct and stoichiometric end-points in media of dielectric constants between 13.6 and 4.7.

2. The conductivities at the first end-points of the symmetrical aliphatic dicarboxylic acids decrease almost linearly with increasing number of methylene group up to five and then becomes practically constant for pimelic, suberic, azelaic, and sebacic acids. A very similar trend is observed for media of decreasing dielectric constants. Pimelic, suberic, azelaic, and sebacic acids exhibit practically the same conductivity at the first end-points in the same media.

3. Doubly-charged anions of pimelic, suberic, azelaic, and sebacic acids are more mobile than their singly charged anions, because of decreasing inductive effects.

4. As for the shapes of the titration curves, hydrogen bonding between anions and propan-2-ol and the formation of ion-pairs play an important role.

5. The conductimetric titration curves of the dicarboxylic acids provide more details than their potentiometric titration curves. Thus in titrations conductimetric method should be preferred.

Solubility of nonpolar gases in 2,6-dimethylcyclohexanone

MARIA ASUNCION GALLARDO, MARIA DEL CARMEN LOPEZ, JOSE SANTIAGO URIETA, AND CELSO GUTIERREZ LOSA
Química Física, Facultad de Ciencias, Universidad de Zaragoza, 50009-Zaragoza, Spain

Received April 19, 1989

MARIA ASUNCION GALLARDO, MARIA DEL CARMEN LOPEZ, JOSE SANTIAGO URIETA, and CELSO GUTIERREZ LOSA. Can. J. Chem. **68**, 435 (1990).

Solubility measurements of He, Ne, Ar, Kr, Xe, H_2, D_2, N_2, CH_4, C_2H_4, C_2H_6, CF_4, SF_6, and CO_2 in 2,6-dimethylcyclohexanone at temperatures 273.15 to 303.15 K and at a gas partial pressure of 101.33 kPa are reported. Standard changes in Gibbs energy, enthalpy, and entropy for the dissolution process at 298.15 K are also presented. Results for both solubility and thermodynamic functions are compared with those for cyclohexanone and 2-methylcyclohexanone. The scaled particle theory is used to obtain the effective Lennard–Jones (6,12) pair potential parameters for 2,6-dimethylcyclohexanone and, from these, the values it predicts for the solubility of the studied gases in the solvent are obtained.

Key words: gas solubility, Henry coefficient, 2,6-dimethylcyclohexanone, thermodynamic functions of solution, non-polar gases.

MARIA ASUNCION GALLARDO, MARIA DEL CARMEN LOPEZ, JOSE SANTIAGO URIETA et CELSO GUTIERREZ LOSA. Can. J. Chem. **68**, 435 (1990).

Opérant à des températures allant de 273,15 à 303,15 K et à une pression partielle de gaz de 101,33 kPa, on a mesuré les solubilités du He, du Ne, du Ar, du Kr, du Xe, du H_2, du D_2, du N_2, du CH_4, du C_2H_4, du C_2H_6, du CF_4, du SF_6 et du CO_2 dans la 2,6-diméthylcyclohexanone. On en a tiré les changements standard de l'énergie de Gibbs, de l'enthalpie et de l'entropie du processus de dissolution à 298,15 K. On a comparé les résultats obtenus tant pour les solubilités que pour les fonctions thermodynamiques avec celles rapportées antérieurement pour la cyclohexanone et la 2-méthylcyclohexanone. On a fait appel à la théorie de la particule scalaire pour déterminer les paramètres effectifs de Lennard–Jones (6,12) pour le potentiel de paire de la 2,6-diméthylcyclohexanone et, à partir de ceux-ci, les valeurs qu'elles permettent de prédire pour la solubilité des gaz étudiés dans ces solvants.

Mots clés : solubilité des gaz, coefficient de Henry, 2,6-diméthylcyclohexanone, fonctions thermodynamiques de solution, gaz non-polaires.

[Traduit par la revue]

Introduction

This paper is a continuation of our work on the solubility of non-polar gases (1–8) to study the influence exerted by the presence of different features in the solvent molecule. In this particular case we were interested in seeing how the solubility changes with the introduction of methyl groups as substituents in the solvent cyclohexanone. Previously, the solubility of fourteen non-polar gases in cyclohexanone and 2-methylcyclohexanone was measured and published in this journal (4, 7). Here we present the solubility of the same fourteen gases in 2,6-dimethylcyclohexanone. This solvent was chosen because it not only has one more methyl substituent but its relative position in the cycle is the same as that of the methyl group in 2-methylcyclohexanone. Therefore the molecule is "symmetrical" and both methyl groups are equivalent (the product used was a mixture of *cis–trans* stereoisomers). The values of the thermodynamic functions for the solution process are also reported and compared with those for the other cyclohexanones. Finally, using the scaled particle theory for solubility of gases (9, 10) the effective Lennard–Jones (6,12) pair potential parameters for the solvent will be calculated and our experimental results will be compared with the values predicted by that theory.

Experimental

In refs. 2, 11 details of the apparatus and the procedure have been given. The experimental technique is based on the determination of the volume of gas which dissolves in a known mass of solvent at a constant temperature and pressure. The total pressure is chosen to be such that the partial pressure of gas is about 101.33 kPa. The solute mole fraction in the liquid phase, x_2, was derived by assuming the gas phase to be ideal. The temperature of the air thermostatic bath holding the apparatus was controlled to within ±0.2 K. Temperature control in the solution vessel was to within ±0.05 K. Precision in the mole fraction x_2 is estimated to be ±0.7% with the exception of gases with low solubility (He and Ne) for which it is approximately ±2.0%. The non-ideality of the gas phase was not considered due to the lack of the necessary data to get the gas virial coefficients for the solvent and the mixture. However, empirical approaches (12, 13) were used to estimate the critical data for the solvent and the necessary parameters, and from these the mentioned virial coefficients in the case of the most soluble gases, to give an idea of the error introduced by considering ideal gas phase behaviour. In the least favourable instances, Xe, C_2H_4, C_2H_6, and SF_6, such estimations led to mole fractions about 1%, 1%, 1.5%, and 2.3%, respectively, higher than when ideality is assumed.

For CO_2 dry gas was used (the procedure was slightly different, see ref. 2) and the number of moles in the solution vessel at constant pressure and temperature was determined by taking into account the non-ideality of CO_2 by means of its second virial coefficient. The solute mole fraction in the liquid phase is obtained by subtracting the number of moles of CO_2 in the gas phase above the liquid from the number of moles of gas in the solution vessel. The volume of this gas phase is so small that any corrections to account for its non-ideality are certainly smaller than the experimental error.

All the gases were from Sociedad Española del Oxígeno, except Ne and CF_4, which were from Baker. Their mole-percentage purities were: He 99.995, Ne 99.9, Ar 99.9990, Kr 99.95, Xe 99.995, H_2 99.99, D_2 99.4, N_2 99.998, CH_4 99.95, C_2H_4 99.90, C_2H_6 99.0, CF_4 99, SF_6 99.5, and CO_2 99.998.

The solvent was 2,6-dimethylcyclohexanone (mixture of *cis–trans* stereoisomers) and was a Fluka product. Its purity was checked by GLC to be 98.2%. The main impurities were identified as cyclohexanone, 2-methylcyclohexanone, and some other methylated and dimethylated cyclohexanones, all of which are products that have similar gas solubilities to that of 2,6-dimethylcyclohexanone (4, 7). The refractive index was also measured (n_D(293.15 K) = 1.44686) but no literature values were found for it. The vapour pressures and the densities of 2,6-dimethylcyclohexanone were determined in the working temperature range and fitted by least squares to equations

Results and discussion

Experimental equilibrium mole fraction of gas, x_2, in 2,6-dimethylcyclohexanone at temperatures between 273.15 and 303.15 K and at a gas partial pressure of 101.33 kPa are displayed in Table 1. These x_2 (101.33 kPa, T) data were fitted by a least-squares method to an equation of the form

[3] $-\ln x_2 = A_0 + A_1 \times T^{-1}$

Table 1 contains the coefficients A_i for the different gases. The standard deviation, σ, defined as

[4] $\sigma^2 = \Sigma [\ln x_{2,i} - (A_0 + A_1 \times T_i^{-1})]^2/(n-2)$

is also included in Table 1.

The standard changes in partial molar Gibbs energy, $\Delta G^0_{m,2}$, partial molar enthalpy, $\Delta H^0_{m,2}$, partial molar entropy, $\Delta S^0_{m,2}$, and Hildebrand entropy, ΔS_H, for the dissolution process were calculated using equations (14–16):

[5] $\Delta G^0_{m,2} = -RT \ln x_2(\text{sat})$

[6] $\Delta H^0_{m,2} = RT\left[\frac{\partial \ln x_2(\text{sat})}{\partial \ln T}\right]$

[7] $\Delta S^0_{m,2} = R\left[\frac{\partial \ln x_2(\text{sat})}{\partial \ln T} + \ln x_2\right]$

[8] $\Delta S_H = R\left[\frac{\partial \ln x_2(\text{sat})}{\partial \ln T}\right]_{\text{sat},P}$

where R is the gas constant, T is the absolute temperature, and x_2(sat) is the mole fraction of the gas in the liquid phase in equilibrium with the gas at a partial pressure of 101.33 kPa. In the derivations of eqs. [5]–[8] both ideal behaviour of the gas and validity of the laws for dilute solutions are assumed (14–16).

The values obtained for the thermodynamic functions of the solution of the studied gases in 2,6-dimethylcyclohexanone at 298.15 K are given in Table 2.

When comparing the solubility of the studied gases in 2,6-dimethylcyclohexanone, 2-methylcyclohexanone (7), and cyclohexanone (4), it is seen that the solubility of any of the studied gases is always higher in 2,6-dimethylcyclohexanone than in 2-methylcyclohexanone and higher in this solvent than in cyclohexanone in the temperature range studied (as an example, the solubility of He, Ar, Kr, and Xe in the three cycloketones as a function of $1/T$ is plotted in Fig. 1). The only exception is CO_2. For this gas the solubility in 2,6-dimethylcyclohexanone only becomes higher than in 2-methylcyclohexanone above a certain temperature in between 273.15 and 298.15 K.

Consequently with the solubility sequence, the more methyl groups the cyclohexanone has, the lower the partial molar Gibbs energy for the dissolution process becomes.

As far as the sequence of increasing solubility of gases in 2,6-dimethylcyclohexanone is concerned, it is found to be basically the same as for cyclohexanone and 2-methylcyclohexanone though there are some interchanges in the positions of some of the most soluble gases depending on the temperature, examples of which are SF_6 and Kr, Xe and C_2H_4, and C_2H_6 and CO_2.

Table 2 shows the variation of the standard partial molar enthalpy of solution, $\Delta H^0_{m,2}$, (this thermodynamic function is directly related via eq. [6] to the variation of solubility with temperature) with the solubility of gases. As in the case of other solvents (15), there is a tendency of the temperature coefficient of solubility to decrease with increasing solubility of the gas, e.g. the more soluble the gas, the smaller its standard partial molar enthalpy of solution. He, Ne, H_2, and D_2 show increasing solubilities with temperature and positive values for $\Delta H^0_{m,2}$, while the most soluble gases (Xe, C_2H_4, C_2H_6, and CO_2) have very negative values for $\Delta H^0_{m,2}$, and solubility decreases with temperature.

That the standard partial molar enthalpy $\Delta H^0_{m,2}$ decreases with the increase of solubility of gas holds for the three different solvents considered here (see Fig. 1). Moreover, according to

*Theoretical values of $\Delta H^0_{m,2}$ and $\Delta S^0_{m,2}$ were calculated using both $l_1 = 1.48 \times 10^{-4}$ K^{-1} and $l_1 = 0$). Column 2 shows the fitted values of x_2 at 298.15 K from our experimental fitting coefficients in Table 1. Column 3 contains the values of x_2 at 298.15 K calculated via SPT

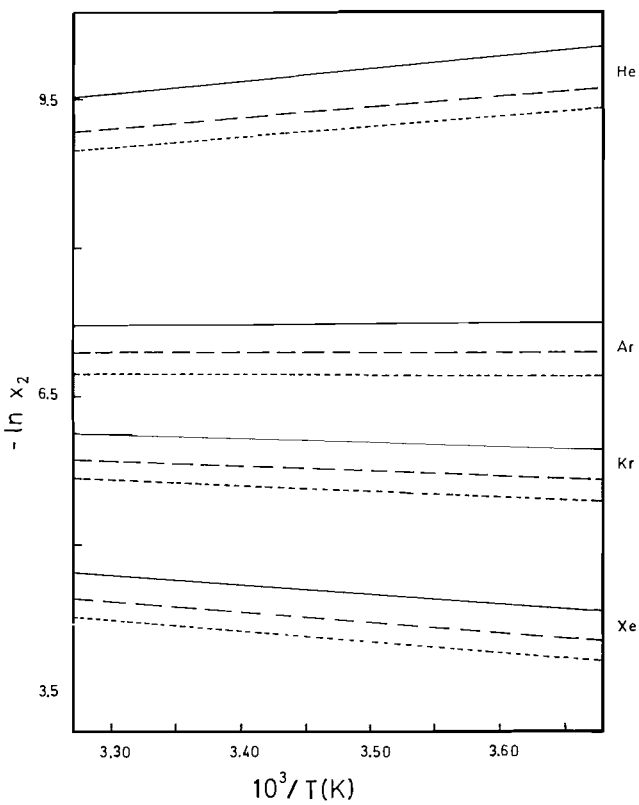

FIG. 1. The lines in the plot represent the fitting of experimental gas solubility data to eq. [3] for different solvents: — cyclohexanone (4), – – – 2-methyl-cyclohexanone (7), - - - 2,6-dimethylcyclohexanone.

the solubility sequence, for any given gas, $\Delta H^0_{m,2}$ at 298.15 K is always lower in 2,6-dimethylcyclohexanone than in 2-methylcyclohexanone and is lower in this solvent than in cyclohexanone; the only exception is CO_2.

The standard partial molar entropy $\Delta S^0_{m,2}$ for dissolution in 2,6-dimethylcyclohexanone of the gases studied follows the same pattern and has values similar to other organic solvents[1] but no tendencies are detected when comparing the values for a given gas in the three cyclohexanones (4, 7).

The scaled particle theory (SPT) allows an evaluation of effective Lennard–Jones pair potential parameters for the solvent from a knowledge of both gas solubility data and the corresponding parameters for gases (9, 10), and it has also been used to predict Henry coefficients of gases in different solvents (1–4, 6, 7, 9, 10, 17, 19, 20, and references therein) and the thermodynamic magnitudes associated with the solution process. The theory stipulates that dissolution takes place in two steps: (*a*) creation in the solvent of a cavity of the right size to accommodate the solute molecule, and (*b*) insertion of the solute molecule into the cavity, then the solute interacts with the solvent. The partial molar Gibbs energy for the cavity formation is calculated using the SPT expressions derived by Reiss *et al.* for hard spheres (10, 21). The calculation of the partial molar Gibbs energy coming from the interaction involves more approximations (10) and it is usually made on the basis of an effective Lennard–Jones (6,12) potential corrected with a term for dipole – induced dipole interactions. Objections can be made to the use of the induction contribution term obtained by this model, since pair additivity is assumed in deriving it. An option to avoid this would be the use of just a Lennard–Jones (6,12) pair potential, thus the effective parameters would include all the induction effects in them. In this work the Lennard–Jones pair potential parameters presented are those obtained when the first option is adopted to allow comparisons with other solvents, the parameters of which were obtained in the same way.

The properties of gases required for the calculations were

[1]See, for example, the review on thermodynamic functions for dissolution of gases in organic solvents by Wilhelm and Battino, ref. 14. Due to the hydrophobic effect for water the experimental values of $\Delta S^0_{m,2}$ are much more negative than for any other solvent (16–18).

2,6-Dimethylcyclohexanone	6.292	665

*From ref. 3, 4.
†From ref. 7.

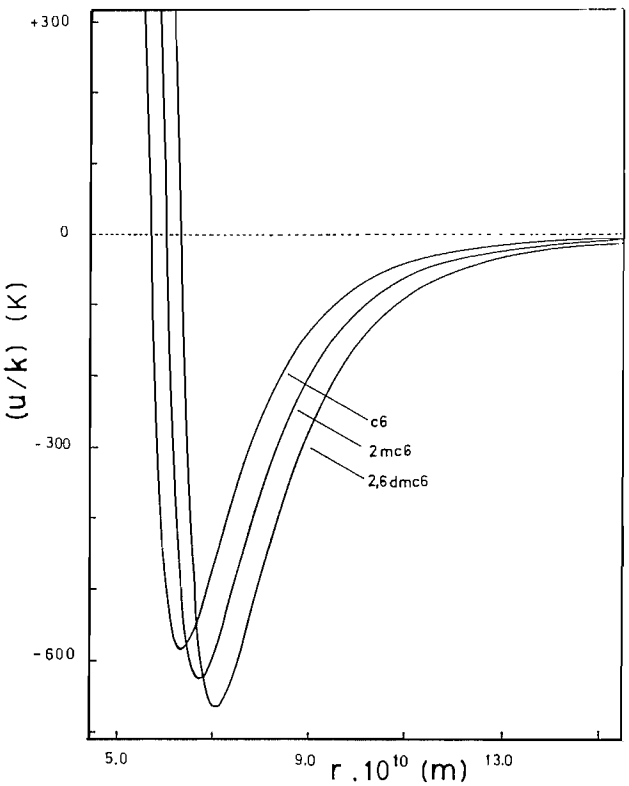

FIG. 2. Lennard–Jones (6,12) pair potential as a function of the interparticle distance for cyclohexanone (c6), 2-methylcyclohexanone (2mc6), and 2,6-dimethylcyclohexanone (2,6dmc6) with the parameters σ_1 and ϵ_1/k obtained from gas solubility data (refs. 4 and 7, and present work).

taken from the literature (22); the dipole moment of 2,6-dimethylcyclohexanone was estimated to be 3.13 D from dielectric permittivity measurements. The values found for the effective Lennard–Jones (6,12) pair potential parameters for 2,6-dimethylcyclohexanone are shown in Table 3. These values can be considered an average of the *cis* and *trans* stereoisomers since the product used in the experimental measurements was a mixture of the two. There is a clear increase in the distance parameter in the order cyclohexanone, 2-methylcyclohexanone, 2,6-dimethylcyclohexanone, as would be expected (given the increasing size of the molecule) since the distance parameter is, in a way, a measure of the diameter of the molecule.

The energy parameter also increases in the same sequence, meaning a deeper potential well as the cyclohexanone becomes more methylated. In Fig. 2, the Lennard–Jones (6,12) potential is represented for the three cyclohexanones using the parameters estimated from our gas solubility data.

The value obtained for the linear coefficient of the effective hard sphere diameter at 298.15 K of 2,6-dimethylcyclohexanone, $l_1 = (1/a_1)(\partial a_1/\partial T)_P$, was $l_1 = -1.58 \times 10^{-4}\ K^{-1}$ from the solubility data of rare gases at different temperatures (23), and $l_1 = -1.48 \times 10^{-4}\ K^{-1}$ from enthalpy solution data (24). The agreement between both methods is ordinary (4, 7, 24).

Once the parameters for the solvent were known, calculations were made to obtain the theoretical values of the thermodynamic functions in the solution process. The results obtained are shown in Table 2. The agreement between the calculated and experimental values for $\Delta G^0_{m,2}$ and x_2 follows the same pattern as for other solvents (1–4, 6, 7, 17, 20, 25) and can be considered satisfactory if one takes into account the simplifications in the theory. The same result as in literature is found for enthalpies and entropies of solution (4, 7, 24): the introduction of temperature dependence in the effective hard-sphere diameter of the solute ($l_1 \neq 0$) leads to $\Delta H^0_{m,2}$ and $\Delta S^0_{m,2}$ values that agree with the experimental values for gases closest to being hard-spheres (polarizability approaching zero): He and Ne. The use of $l_1 = 0$ leads to values for $\Delta H^0_{m,2}$ and $\Delta S^0_{m,2}$ more in agreement with the experimental ones for gases such as Ar, Kr, CH_4, or CF_4.

TATSUYA MENO, KATSUYA SAKO, MASAHIKO SUENAGA, MIYUKI MOURI, TERUO SHINMYOZU, TAKAHIKO INAZU, and HIROYUKI TAKEMURA. Can. J. Chem. **68**, 440 (1990).

2,2,11,11,20,20-Hexadeuterio[3.3.3](1,3,5)cyclophane **1**-d_6 and its precursor, [3.3.3](1,3,5)cyclophane-2,11,20-trione **2**, were synthesized and their conformational behavior was examined by a variable temperature ^{1}H NMR method; **1**-d_6 (ca. 1% CD_2Cl_2 solution) exists in a mixture of the conformer A (C_{3h}) and the conformer B (C_s) in a 27:73 ratio at −70°C with the energy barriers for the trimethylene bridge inversion processes (A ⇌ B, B ⇌ B) being 12.4 kcal/mol (T_c = −7°C, 270 MHz). Conformer B is more stable than A by 0.4 kcal/mol based on the populations of both conformers. In contrast to the conformational behavior of **1**, inversion of the tricarbon bridges of **2** is not frozen even at −90°C because of the increased flexibility of these tricarbon bridges.

Key words: conformational analysis, cyclophane, tri-*n*-butyltin deuteride.

TATSUYA MENO, KATSUYA SAKO, MASAHIKO SUENAGA, MIYUKI MOURI, TERUO SHINMYOZU, TAKAHIKO INAZU et HIROYUKI TAKEMURA. Can. J. Chem. **68**, 440 (1990).

On a synthétisé le 2,2,11,11,20,20-hexadeutéro[3.3.3](1,3,5)cyclophane (**1**-d_6) ainsi que son précurseur la [3.3.3](1,3,5)-cyclophane-2,11,20-trione (**2**) et on a examiné leur comportement conformationnel en faisant appel à une méthode de RMN VT ^{1}H; à −70°C, le **1**-d_6 en solution à environ 1% dans le CD_2Cl_2 existe sous la forme d'un mélange du conformère A (C_{3h}) et du conformère B (C_s) dans les proportions 27 : 73; les varrières d'énergie pour le processus d'inversion du pont triméthylène (A ⇌ B, B ⇌ B) sont de 12,4 kcal/mol (T_c = −7°C, 270 MHz). Sur la base des populations de chacun des conformères, on peut déduire que le conformère B est plus stable que le conformère A par environ 0,4 kcal/mol. Dû à une flexibilité accrue des ponts à trois atomes de carbones, le comportement conformationnel du composé **2** diffère de celui du composé **1**; à −90°C, l'inversion des ponts à trois carbones du composé **2** n'est pas figée.

Mots clés : analyse conformationnelle, cyclophane, deutérure tri-*n*-butyle d'étain.

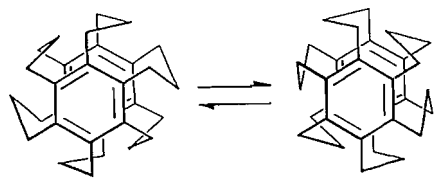
[3.3.3](1,3,5)Cyclophane **1**, one of the lowest homologs of the multibridged [3_n]cyclophanes, was first synthesized by Hübert in 1967 by internal cyclotrimerization of aromatic triyne on a Ziegler catalyst (1). Later, Misumi and co-workers reported an alternative three-step synthesis of **1** by sulfur elimination from 2,13,22-trithia[4.4.4](1,3,5)cyclophane in 8.6% overall yield (2). The stereochemical aspects of conformationally mobile multibridged [3_n]cyclophanes are of particular interest in connection with correlated trimethylene bridge inversion as exemplified by the inversion process of six trimethylene bridges (**3A** ⇌ **3B**) of our final target molecule, [3_6](1,2,3,4,5,6)cyclophane **3**. As a first step for the conformational study of multibridged [3_n]cyclophanes, we undertook the conformational analysis of [3_3](1,3,5)cyclophane systems, in which steric interactions among the trimethylene bridges would be a minimum in multibridged [3_n]cyclophanes.



3A **3B**

FIG. 1. Correlated inversion process of the six trimethylene bridges in **3**.

So far, only one conformational study of an aza analog of **1**, *N*,*N*′,*N*″-tritosyl-2,11,20-triaza[3_3](1,3,5)cyclophane **4**, has been reported by Vögtle *et al.* (3); a single isomer was observed at low temperatures and the energy barrier for the trimethylene bridge inversion was estimated to be 12.6 kcal/mol. Crystal structures of 2,11,20-trithia[3_3]cyclophane **5** (4, 5) and trione **2**[3] show that they exist in the conformer with a C_s symmetry exclusively, although disorder of one of the sulfur bridges is observed in **5** (4). Reportedly the singlet of the benzylic protons of **5** remains unchanged as low as −110°C, suggesting a

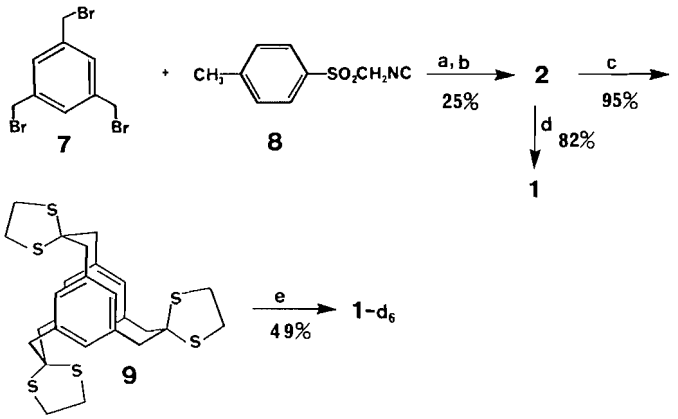
low energy barrier for the trimethylene bridge inversion (3*b*). Our work is the first complete conformational analysis of tribridged [3.3.3]cyclophane systems.

We report here the synthesis of 2,2,11,11,20,20-hexadeuterio[3_3](1,3,5)cyclophane **1**-d_6 and its precursor trione **2**, as well as their VT ^{1}H NMR study. This study certainly provides us with basic data for the understanding of the conformational behavior of more highly bridged [3_n]cyclophanes. In the preceding papers, we reported the conformational analyses of [3.3]*meta*- and *para*-cyclophanes (6*a*,*b*).



SCHEME 1. Synthetic route of **1**-d_6: (a) *n*-Bu_4NI, NaOH, CH_2Cl_2–H_2O; (b) conc. HCl; (c) $HSCH_2CH_2SH$, $BF_3 \cdot OEt_2$, AcOH; (d) 100% $NH_2NH_2 \cdot H_2O$, KOH, $HO(CH_2)_3OH$; (e) *n*-Bu_3SnD, AIBN, xylene.

The coupling reaction of *p*-tolylsulfonylmethyl isocyanide (TosMIC) **8** with 1,3,5-tris(bromomethyl)benzene **7**, followed by acid treatment, afforded the trione **2** in 25% yield. The Wolff–Kishner reduction of the carbonyl groups provided **1** in 82% yield (7*a*,*b*). Our method constitutes a simpler alternative method for the synthesis of **1**. The trione **2** was converted, by a conventional method in 95% yield, into thioacetal **9**, which was reduced with tri-*n*-butyltin deuteride in the presence of AIBN in refluxing xylene to afford **1**-d_6 in 49% yield (6, 8).

At 20°C, **1**-d_6 (270 MHz, ca. 1% solution in CD_2Cl_2) shows benzylic and aromatic protons at 2.71 (br s) and 6.51 (s) ppm, respectively. Both protons are strongly temperature dependent, as shown in Fig. 2. The aromatic signal broadens as the temperature is lowered. It becomes three broad peaks at −30°C, and finally it appears as three singlets at 6.36, 6.52, and 6.71 ppm with relative intensities being 1:2:1 at −70°C (Fig. 3).

Scheme 2 shows possible trimethylene bridge inversion processes for **1** (9). There are two discernible conformational isomers: the conformers A (C_{3h}) and B (C_s). Two types of isomerization processes are considered: isomerizations between two different conformers (A ⇌ B) and the same conformers (B ⇌ B). In principle, therefore, there should be two different free-energy barriers for the corresponding rate processes.

The aromatic proton signals are assigned as follows, based on the fact that inner aromatic protons (H_i) of 1,4-dioxa[4.3.3]-metacyclophane-d_4, **6**-d_4, experience a through-space deshielding, in the following order, from the bridge deuteriums of C-2 or C-11 constrained to proximity: boat–boat > chair–boat > chair–chair (6*a*). (Conformer A, H_a 6.52 ppm; B, H_c 6.36, $H_{a'}$ 6.52, and H_b 6.71 ppm.) Populations of the A and B isomers are estimated to be 27:73 on the basis of the integral of the aromatic signals: 6.36 (B, H_c) and 6.52 (A, H_a + B, $H_{a'}$) ppm.

As shown in Fig. 2, the benzylic signal broadens as the temperature is lowered. The broad signal begins to split into two broad peaks at −7°C, and finally it becomes four sets of an AB quartet. The four doublets due to the axial protons of a benzylic position appearing at a higher field at 2.43 (J = 13.7 Hz) ppm are overlapped with each other, whereas the equatorial

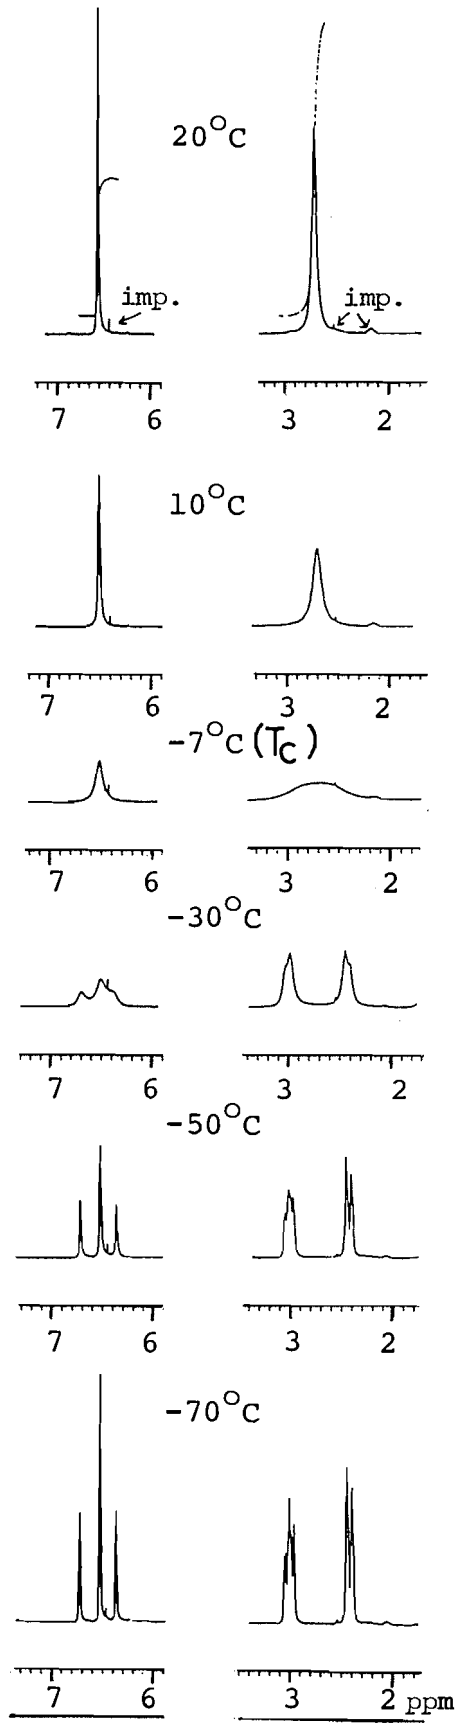

FIG. 2. The ^{1}H nmr spectra of **1** at various temperatures (270 MHz, CD_2Cl_2).

protons appear as four sets of a doublet. On the basis of the chemical shifts of the corresponding protons observed in **6**-d_4, the following assignments are made for the equatorial protons (Fig. 4): A, H_{eq} 2.99 (J = 13.7 Hz) ppm; B, H'''_{eq} 3.01 (J = 13.7 Hz), H'_{eq} 2.99 (J = 13.7 Hz), H''_{eq} 3.03 (J = 13.7 Hz) ppm.

The energy barriers for the trimethylene bridge inversion processes (A $\rightleftharpoons$ B, B $\rightleftharpoons$ B) are estimated to be ca. 12.4 kcal/mol due to the T_c = −7°C, chemical shift differences, and geminal coupling constants of the benzylic protons (10);[4] identical energy barriers are obtained for the two types of inversion processes. The value is comparable to those of **6**-d_4 (12.1–12.3 kcal/mol) (6*a*) and triaza analog **4** (12.6 kcal/mol) (3*a*) but is slightly higher than those of [3.3]*meta*- (11.6 (6*a*), 10–11 kcal/mol (11)) and *para*-cyclophane (12.0 (6*b*), 11.7 kcal/mol (12)). Populations of the isomers show that the B isomer is more stable than A by 0.4 kcal/mol. The structure of the preferred isomer B in solution is in agreement with those found in the crystalline state of the [3_3](1,3,5)cyclophane derivatives (ref. 4 and footnote 3). These results reveal that the trimethylene bridges in **1** do not undergo a correlated inversion process but move independently.

The trione **2** shows benzylic and aromatic protons at 3.76 and 6.85 ppm, respectively, as sharp singlets at room temperature (ca. 1% CD_2Cl_2 solution, 270 MHz). Both signals remain unchanged, except for slight broadening of the bands, even at −90°C, suggesting a much lower energy barrier for the tricarbon bridge inversion in **2** than in **1**. We qualitatively interpret this result as indicating that the torsional energy difference between the preferred conformer (**2e** for **2**, **1s** for **1**) and the transition conformer (**2s** for **2**, **1e** for **1**) is much less in **2** than in **1**. In the transition state four H/H eclipsed interactions in **1** (**1e**) whereas two CH_2/CO staggered interactions in **2** (**2s**) are regarded as significant for the major torsional energy, since the phenyl/benzyl eclipsed interactions of both conformers are estimated to be identical (Fig. 7). Therefore the energy barrier for the tricarbon bridge inversion is estimated to be much higher in **1** than in **2** according to the following data; the energy difference between eclipsed and staggered conformations of ethane is 3 kcal/mol, while that of acetaldehyde is only 1.1 kcal/mol (13).

On the other hand, the aromatic protons of the thioacetal **9** exhibit a very broad signal even at room temperature, as shown in Fig. 6, indicating an increased energy barrier for the bridge inversion due to the introduction of heavy 5-membered rings into the bridges.

A study on the correlated trimethylene bridge inversion of [3_3](1,2,3)cyclophane and the synthesis of the higher homologs is in progress.

Experimental

All melting points were uncorrected. Proton nuclear magnetic resonance (^{1}H nmr) spectra were recorded on either a Hitachi R-20B (60 MHz), a JEOL JNM-GSX 270 (270 MHz), or a JEOL JNM-GX 400 (400 MHz) spectrometer. Chemical shifts are reported as δ values (ppm) relative to internal Me_4Si. Mass spectra were obtained on a Hitachi RMU-6MG mass spectrometer at an ionization energy of 70 eV; m/z values reported include the parent ion peak. Infrared (ir) spectra were obtained on a JASCO IR-700 spectrophotometer as KBr disks. Elemental analyses were performed by the Service Centre of

[4] $\Delta G_c^{\ddagger}$ (kcal/mol) = $2.303 \times 1.987 T_c\ (10.319 - \log_{10} k_c + \log_{10} T_c)$ where $k_c = (\pi/\sqrt{2})[(\nu_A - \nu_B)^2 + 6J^2]^{1/2}$.

the Elementary Analysis of Organic Compounds affiliated with the Faculty of Science in Kyushu University.

Silica gel chromatography utilizes Daiso gel IR-60 and Merck silica gel 60 for column chromatography, Merck silica gel PF_{254} for preparative tlc, and Merck silica gel F_{254} (0.2 mm on aluminum) for analytical purposes.

1,3,5-Tris(bromomethyl)benzene **7** (*5a*) was prepared by the $LiAlH_4$ reduction of 1,3,5-tris(ethoxycarbonyl)benzene (quantitative), followed by bromination of the triol with PBr_3 in $CHCl_3$ (71%). *n*-Bu_3SnD was prepared by the $LiAlD_4$ reduction of *n*-Bu_3SnCl (14). Xylene was distilled from CaH_2. AIBN was recrystallized from MeOH.

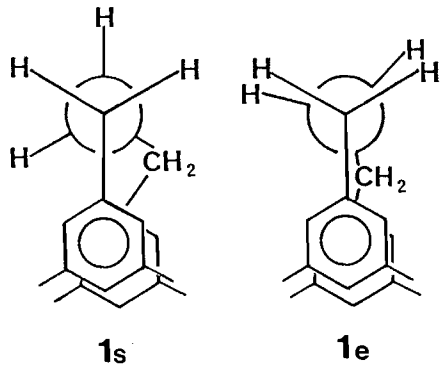

FIG. 8. Conformations of the trimethylene bridge in **1**: the most stable conformation (staggered) **1s** and the transition state (eclipsed) **1e**.

[3.3.3](1,3,5)Cyclophane-2,11,20-trione (2)

To a refluxing mixture of *n*-Bu_4NI (5 g), NaOH (70 g) dissolved in water (120 mL), and CH_2Cl_2 (1.5 L) was added dropwise a mixture of the bromide **7** (15.0 g, 42.0 mmol) and TosMIC **8** (12.3 g, 63.0 mmol) in CH_2Cl_2 (1.0 L) over a period of 8 h with vigorous stirring. After the addition, the mixture was stirred for an additional 2 h. After cooling, the mixture was washed with water (1.5 L × 4) and concentrated to a volume of ca. 600 mL. To the concentrate was added concentrated HCl (100 mL), and the mixture was stirred at room temperature for 2 h. The mixture was washed successively with water (200 mL × 3) and brine (200 mL), and concentrated to dryness to give brown semisolid material. Similar reactions were repeated three times on the same scale and the combined products were chromatographed on silica gel (250 g) with CH_2Cl_2. Concentration of the eluate afforded pale brown crystals, which were triturated with MeOH and collected by filtration to give **2** as colorless crystals (4.99 g, 25%). A sample was recrystallized from $MeOH/CH_2Cl_2$ (3:7) to provide colorless needles, mp 284.5°C; ir (KBr): 1698 (C=O) cm^{-1}; R_f (Si gel, CH_2Cl_2) 0.25; ms *m/z*: M^+ 318. Anal. calcd. for $C_{21}H_{18}O_3$: C 79.23, H 5.70; found: C 78.94, H 5.83.

2,2,11,11,20,20-Hexadeuterio[3.3.3](1,3,5)cyclophane (1-d_6)

A mixture of the trione **2** (970 mg, 3.05 mmol), 1,2-ethanedithiol (5.0 mL, 59.6 mmol), AcOH (50 mL), and $BF_3 \cdot Et_2O$ (0.3 mL, 2.38 mmol) was stirred at room temperature for a day. Then an additional amount of $BF_3 \cdot Et_2O$ (0.2 mL, 1.59 mmol) was added and the mixture was stirred for 3 h. The reaction was quenched by the addition of water (100 mL), and the mixture was extracted with $CHCl_3$ (300 mL × 1, 100 mL × 2). The combined organic portion was washed successively with saturated $NaHCO_3$ solution (200 mL) and water (400 mL × 4), dried over $MgSO_4$, and filtered. The filtrate was concentrated to dryness *in vacuo* and the resulting powder was collected by filtration, washed successively with MeOH and acetone, and recrystallized from xylene to give colorless crystals (1.58 g, 95%); mp 298.3–298.8°C; ^{1}H nmr (400 MHz, $CDCl_3$): 3.53 (s, 12H, —SCH_2CH_2S—), 3.58 (br s, 12H, benzylic H), 6.40–8.40 (br s, 6H, ArH); ms *m/z*: M^+ 546. Anal. calcd. for $C_{27}H_{30}S_6$: C 59.29, H 5.53; found: C 59.40, H 5.41.

A mixture of the thioacetal **9** (286 mg, 0.523 mmol), freshly prepared *n*-Bu_3SnD (3.0 mL, 11.2 mmol), AIBN (100 mg), and xylene (27 mL) was refluxed for a day with stirring under N_2. After cooling, the mixture was concentrated to a volume of ca. 10 mL and chromatographed on silica gel (50 g) with hexane. Concentration of the eluate gave **1**-d_6 as colorless crystals, which were further purified by preparative tlc (silica gel) with hexane (72 mg, 49%). A sample for microanalysis was sublimed (90°C, 1 Torr; 1 Torr = 133.3 Pa); mp 153–154.5°C; ir (KBr): 2182, 2142, 2098 (—CD_2—) cm^{-1}; R_f (Si gel, hexane) 0.28; ms *m/z*: M^+ 282. Anal. calcd. for $C_{21}H_{18}D_6$: C 89.30, H + 1/2D 8.56; found: C 89.31, H + 1/2D, 8.65.

ALAN R. KATRITZKY, STANISLAW RACHWAL, and JING WU. Can. J. Chem. **68**, 446 (1990).

1-(Hydroxymethyl)benzotriazole and aromatic amines react to give an equilibrium mixture of *N*-mono- and *N*,*N*-bis(benzotriazolylmethyl)arylamines. Electron-releasing substituents on the arylamine ring shift the equilibrium towards the *N*,*N*-bis(benzotriazolylmethylated) products, and removal of water formed in the reaction leads to these bis derivatives in quantitative yields. These products were isolated as mixtures of three isomers, the benzotriazolyl-1,1′, -1,2′, and -2,2′ derivatives; these mixtures were characterized by full assignment of their ^{13}C NMR spectra and by partial separation and enrichment. Electron-withdrawing substituents on the arylamine ring increase the isomer interconversion energy barriers and make *N*,*N*-bis(benzotriazolylmethyl)arylamines more resistant to hydrolysis. A strong influence of *ortho* alkyl groups on the stability and NMR spectral properties of *N*,*N*-bis(benzotriazolylmethyl)arylamines is interpreted on the basis of steric hindrance.

Key words: Mannich reaction, benzotriazole isomerization, substituent effects, anilines, bis(benzotriazolylmethyl)arylamines.

ALAN R. KATRITZKY, STANISLAW RACHWAL et JING WU. Can. J. Chem. **68**, 446 (1990).

Le 1-(hydroxyméthyl)benzotriazole et les amines aromatiques réagissent pour donner des mélanges à l'équilibre des *N*-mono- et *N*,*N*-bis(benzotriazolylméthyl)arylamines. La présence de substituants électrorépulsifs sur le noyau des amines aromatiques déplace l'équilibre vers les produits *N*,*N*-bis(benzotriazolylméthylés), et l'élimination de l'eau qui se forme au cours de cette réaction conduit à la formation de ces bis-dérivés avec un rendement quantitatif. On a isolé ces produits sous la forme de mélanges de trois isomères comprenant les dérivés benzotriazolyl-1,1′, -1,2′ et -2,2′; on a caractérisé ces mélanges en attribuant toutes les bandes des spectres RMN du ^{13}C ainsi que par des séparations et des enrichissements partiels. La présence de substituants électrodonneurs sur les amines aromatiques augmente l'énergie d'interconversion entre les isomères et rend les *N*,*N*-bis(benzotriazolylméthyl)arylamines plus résistantes à l'hydrolyse. Les groupements alkyles présents en *ortho* influencent fortement la stabilité et les propriétés spectrales des *N*,*N*-bis(benzotriazolylméthyl)arylamines; on interprète ces résultats en se basant sur des facteurs d'empêchement stérique.

Mots clés : réaction Mannich, isomérisation benzotriazole, effets de substituants, anilines, bis(benzotriazolylméthyl)arylamines.

Introduction

Primary aromatic amines react rapidly with 1-(hydroxymethyl)benzotriazole in ethanolic solution (1) or in aqueous suspension (2) to give the corresponding mono-*N*-(benzotriazolylmethyl)arylamines regardless of the ratio of the reagents. The same result is obtained by mixing benzotriazole, formaldehyde, and arylamine (3); instead of formaldehyde, other alkyl- and aryl-aldehydes can be used (1, 2). All of these reactions proceed essentially quantitatively. In the case of primary aliphatic amines, the picture is more complex: *N*-mono(benzotriazolylmethyl)alkylamines, *N*,*N*-bis(benzotriazolylmethyl)alkylamines, and compounds of type $(BtCH_2NR)_2CH_2$ have all been isolated (4).[2]

Mannich reactions of arylamines with formaldehyde and N–H heterocyclic systems frequently lead to stable monoadducts with N—CH_2—N bonds. Several such reactions, e.g., with succinimides (5, 6) benzimidazoles (7–10), benzimidazolin-2-thiones (11–13), benzoxalin-2-ones (14), 4-oxothiazolidines (15, 16), 1,2,4-triazoline-3-thiones (17), 4-quinazolinones (18–20), 2-mercaptobenzothiazole (21), 5-chlorobenzotriazole (22), and 5-nitrobenzotriazole (23), have recently been reported, mainly due to pharmacological interest in the adducts. Under similar conditions, however, arylamines condense with two molar equivalents of 1-(hydroxymethyl)-3,5-dimethylpyrazole giving their *N*,*N*-bis(pyrazol-1-ylmethyl) derivatives (24, 25) with an N—CH_2—N(Ar)—CH_2—N group. At elevated temperatures, arylamines react with formaldehyde to give *N*,*N*′,*N*″-triphenylhexahydrotriazines (26).

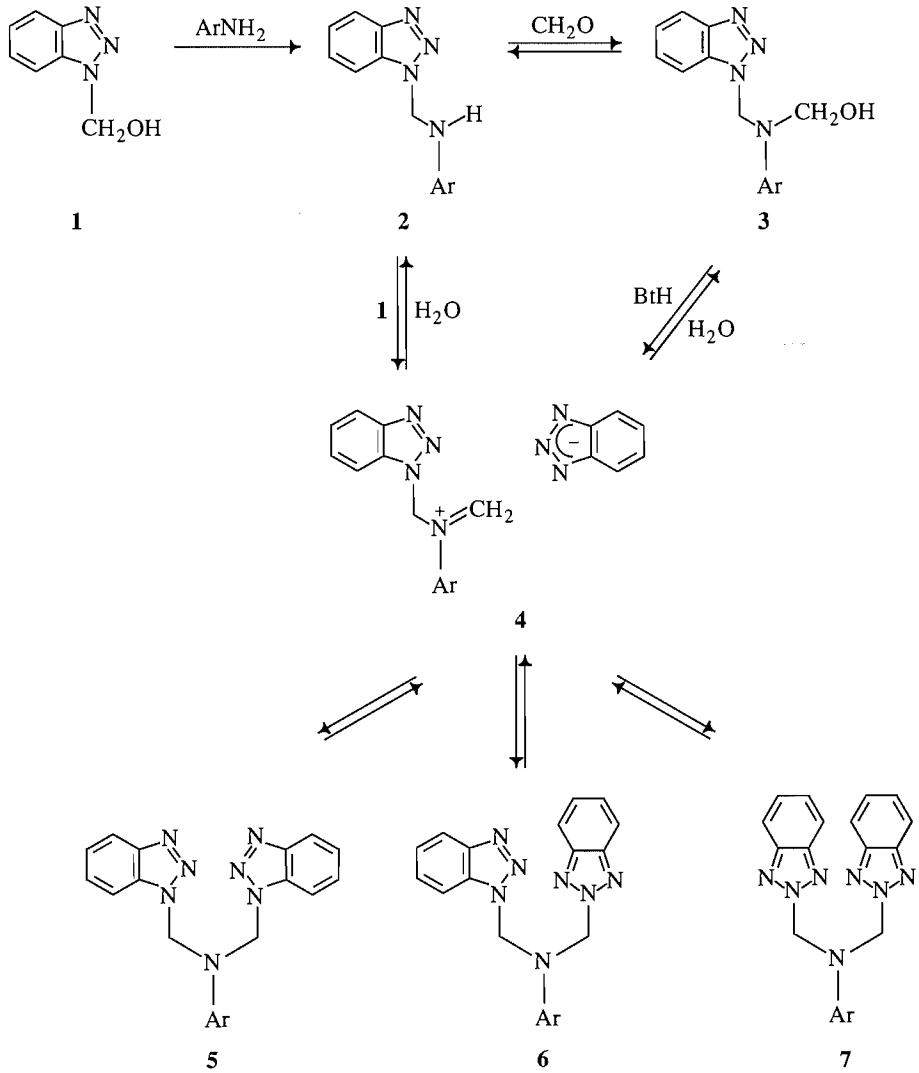
Bis(benzotriazolylmethylation) of aromatic amines

The goal at the beginning of these investigations was the elucidation of a route to *N*,*N*-bis(benzotriazolylmethyl)arylamines, compounds that were expected to be convenient precursors for *N*,*N*-dialkylarylamines. We initially investigated 4-butylaniline and modified the reported procedure (1) for *N*-benzotriazolylmethylation of arylamines. Butyl substitution of the ring increased the solubility of the products and facilitated the investigations.

Monitoring an equimolar mixture of 1-hydroxymethylbenzotriazole (**1**) and *N*-(benzotriazol-1-ylmethyl)-4-butylaniline (**2***c*) by NMR revealed a fast reaction at 20°C. The strongest new peak in the spectrum at δ 6.25 (presumably from **5**) was observed after a few minutes; its intensity grew, while the methylene signals of **1** and **2** (both at δ 6.04–6.06) diminished in intensity. Thus, after 20, 60, 105 min, and 13 h, the intensity of the 6.25 peak was respectively 3, 7, 13, and 75% of that of the methylene signal of the starting reagent. Further reaction was slow, indicating an equilibrium between the products and the starting materials. Because other methylene singlets (of lower intensity) were also observed, more precise estimates of the ratio of the products to the starting materials were obtained using the butyl group signals (which did not change during the reaction) as a reference. The integral ratio of the signals at δ 6.05 to those of two butyl methylene groups at δ 1.20–1.60, representing percentage of the starting materials remaining in the mixture, was as follows: 98 (20 min), 89 (60 min), 82 (105 min), 55 (13 h), 46 (24 h), and 45% (4 days).

Mixtures of aromatic amines with 1-(hydroxymethyl)benzotriazole, monitored by the NMR technique, revealed the



For the significance of *a–l* in the designation of Ar see Table 1

SCHEME 1

formation of compounds possessing isolated methylene groups. The strongest signal was usually recognized as that of the corresponding *N*-(benzotriazol-1-ylmethyl)arylamine **2**, by comparison of the spectrum of the reaction mixture with that of the authentic compound. Further signals at lower field, in order of decreasing intensity, were assigned to the three isomeric *N*,*N*-bisbenzotriazolylmethylated arylamines **5**, **6**, and **7**, respectively (Scheme 1). Other small methylene signals, of total intensity usually <5%, are attributed to unstable intermediates such as **3**. (Later in this paper, to avoid repetition, reference to **5** can mean a mixture of **5**, **6**, and **7**.)

For direct comparison of substituent effects, reaction mixtures of the same initial molar concentration were investigated at elevated temperatures to increase the rate of equilibration. Thus, a mixture of 1-(hydroxymethyl)benzotriazole (5 mmol) and aniline (2.5 mmol) in DMSO-d_6 (10 mmol) was kept at 100°C for 1 h. In addition to the 1-(hydroxymethyl)benzotriazole methylene singlet at δ 6.06, a doublet at δ 6.09 turning into a singlet upon addition of D_2O (methylene group of **2***a*), a singlet at δ 6.24 (**5***a*), a pair of equal singlets at δ 6.34 and 6.55 (**6***a*), and a small singlet at δ 6.58 (**7***a*) were assigned as indicated. Very small singlets were also observed at δ 6.25, 6.30, and 6.33 (possibly **3***a* and (or) similar structures). The molar ratios of the products at equilibrium for this, and for similar reaction mixtures, are given in Table 1.

As shown in Table 1, *para* electron-releasing substituents in the aniline ring favor formation of the *N*,*N*-bis(benzotriazolylmethylated) products (**5**, **6**, and **7**), whereas electron-withdrawing *para* or *meta* substituents shift the equilibrium towards *N*-mono(benzotriazolylmethylated) amines **2**. *ortho*-Alkyl anilines form an exception to this rule, as properties of the adducts cannot be directly correlated with the σ_o constants given in Table 1. Evidently, more complex parameters reflecting steric interactions (29, 30) should be used here. Thus, reaction of 1-(hydroxymethyl)benzotriazole with 2-methyl- or 2-ethylaniline leads to a product ratio similar to that obtained from 3-chloroaniline, because of steric hindrance. Whereas **2***i* and **2***j* are unstrained in the *anti* conformation, a second benzotriazolylmethyl substituent on the nitrogen atom (in **5***i* and **5***j*) causes steric repulsions with the *ortho* group in the planar conformation: hence **5***i* and **5***j* have higher energy and are less readily formed. Similar examples are commonplace, e.g.,

methylation of *p*-toluidine by a bulky methylating agent gave exclusively *N,N*-dimethyl-*p*-toluidine but, under the same conditions, *o*-toluidine formed only a mono-*N*-methylated derivative (31).

However, excessive steric hindrance can reverse the preference. In 2,6-diisopropylamine derivatives, even *N*-monosubstitution by the benzotriazolylmethyl group (**2***k*) causes rotation of the nitrogen-ring bond. The *N*-monosubstituted amine, having lost the conjugation of the lone pair with the ring, easily undergoes further benzotriazolylmethylation to give **5**–**7***k* (Fig. 1), just as occurs for aliphatic primary amines, e.g., benzylamine **2***l* (Table 1).

Under more stringent conditions (refluxing in toluene and trapping the water), aromatic amines react with 2 moles of **1** to form *N,N*-bis(benzotriazolylmethyl)arylamines in quantitative yields. Use of benzotriazole, an aromatic amine, and aqueous formaldehyde gives similar results. Alkylation of the amine nitrogen atom by **1**, leading in the first step to **2**, and then in a second step to **5** (or its isomer **6**), is a feasible reaction route. However, intermediate amine-formaldehyde adducts of type **3** are probably also involved, especially when the amine and benzotriazole react with aqueous formaldehyde. The *N,N*-bis(benzotriazolylmethyl)arylamines thus obtained were characterized by CHN analysis (Table 2).

The formation of **5** from **2** is reversible: decomposition of **5** to **1** and the mono-*N*-substituted aniline **2** was observed in moist DMSO solutions of **5** at elevated temperatures. 2-Ethylaniline derivative **5***j* could not be satisfactorily analyzed because of its rapid hydrolysis in air. However, in the crystalline state, adducts **5** are stable, and insensitive towards moist air, for months at room temperature.

Bis(benzotriazolylmethylation) fails for a few aromatic amines: 4-nitroaniline, and 2- and 4-aminopyridines, gave only the *N*-monosubstituted aromatic amines **2** under the standard conditions. Prolonged heating of *N*-(benzotriazolylmethyl)-4-nitroaniline with **1** at 150°C led only to benzotriazole as a product of decomposition of **1**. 4-Chloroaniline was easily bis(benzotriazolylmethylated), whereas 3-chloroaniline required an extended reaction time for bis(benzotriazolylmethylation) to be accomplished. Although 3-nitroaniline gave only its mono

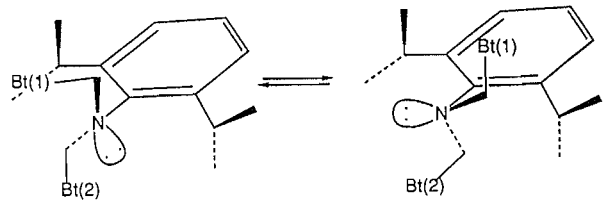

FIG. 1. Conformations of the molecules of **6***k*.

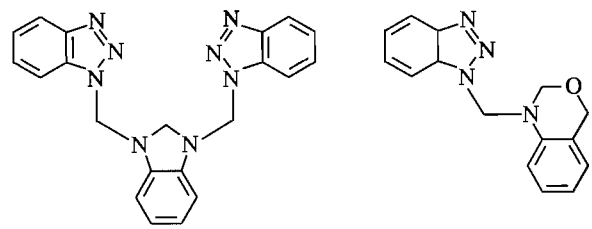
derivative **2***h* under standard reaction conditions, the *N,N*-bis isomer mixture (**5***h*, **6***h*, **7***h*) was formed upon prolonged reflux in toluene.

The behavior of the amine towards 1-(hydroxymethyl)benzotriazole (**1**) can be correlated with the amine basicity (32), cf. pK_a of 4-anisidine, 5.40; 4-toluidine, 5.15; aniline, 4.67; 4-chloroaniline, 4.05; 3-chloroaniline, 3.52; 3-nitroaniline, 2.52; and 4-nitroaniline, 1.13. The basicity of the amino groups in 2- and 4-aminopyridines cannot be measured directly, as the ring nitrogen atom is the more basic and undergoes preferential protonation (33); values estimated from the Hammett equation (34) are 2.3 for 2-amino- and 2.0 for 4-amino-pyridine. These examples suggest that amines with pK_a above 2.4 undergo *N,N*-bis(benzotriazolylmethylation) whereas less basic amines give only *N*-mono(benzotriazolylmethylated) derivatives **2** under the conditions applied.

Attempted use of aliphatic aldehydes other than formaldehyde to give *N,N*-bis(benzotriazolylalkylated) aromatic amines failed. Complex and undefined mixtures were always obtained (TLC, NMR), probably because of self-condensation, possibly catalyzed by benzotriazole and (or) amines. Heating benzotriazole with propionaldehyde in acetic acid formed 2,6-diethyl-4-(benzotriazol-1-yl)-5-methyl-1,3-dioxane (35). Attempted bis(benzotriazolylalkylation) of aliphatic amines was also previously reported to fail (1).[2]

Certain *o*-substituted anilines afford cyclic products: *o*-phenylenediamine with four molar equivalents of benzotriazole and excess of formaldehyde gave cycloadduct **8** instead of the expected tetra(benzotriazolylmethylated) derivative. Such tetraadducts resulted from Mannich reactions of *o*-phenylenediamine with pyrazoles (24). Similarly, bis(benzotriazolylmethylation) of 2-aminobenzyl alcohol gave adduct **9**.



8 **9**

Structures **8** and **9**

Isomerization and stability of *N,N*-bis(benzotriazolylmethyl)anilines

The rapid equilibration of *N*-(1-benzotriazol-1-yl-alkyl)-amines with their benzotriazol-2-yl analogs in solution is well known (36, 37). As expected, we found that all three isomers **5**, **6**, and **7** are present in solutions of the newly synthesized *N,N*-bis(benzotriazolylmethyl)anilines. In the ^1H NMR spectra, the methylene groups of different isomers resonate as easily recognizable singlets at slightly different field; two singlets

[c]The product was not analyzed because of its instability in air.

of equal intensity are observed for isomers **6** due to the two different methylene groups present. The ratio of these methylene group integrals reflects the percentage of the isomers in the investigated sample. Data obtained from the ^1H NMR spectra of the crude products, isolated by simple evaporation of the solvent, are collected in Table 3. The *N,N*-bis(benzotriazol-1-yl) isomers **5** dominate strongly in the product mixtures deriving from anilines bearing electron-releasing groups. However, for the less basic anilines bearing electron-withdrawing groups, the dominance of **5** is less marked and, in some instances, isomers **6** can dominate (4-chloroaniline derivatives).

Surprisingly, in view of literature data (36), and of our previous experience (37, 38), the individual isomers of the *N,N*-bis(benzotriazolylmethyl)arylamines are relatively stable in solution, at room temperature. The crude oily or glassy mixtures of isomers **5**, **6**, and **7** could often be converted into crystalline materials by trituration at room temperature with ether; sometimes cooling to Dry Ice temperatures was required. Solutions of the crystalline samples so obtained, although

For personal use only.

mixtures of the same isomers, were found to contain them in proportions different than those observed in the solutions of the crude amorphous materials. For example, a solution of the crude 4-toluidine derivative showed an isomer ratio 54:43:3, whereas a solution of the crystalline material showed 86:14:0, for isomers **5***b*, **6***b*, and **7***b* respectively. Recrystallization from THF gave a crystalline sample enriched in isomer **5***b*, which then showed in solution the ratio 94:6:0 (Table 3). Sometimes the pure isomers **5** could be obtained. Crystalline samples enriched in isomers **6** could then be isolated from the filtrates. These various crystalline samples of the *N*,*N*-bis(benzotriazolylmethyl)arylamines were characterized by C, H, N analysis and by melting points (Table 2).

Substituents on the aniline ring of the *N*,*N*-bis(benzotriazolylmethyl)anilines strongly influence the interconversion rates of the individual isomers. Thus, no isomerization was observed when solutions of the aniline (**5–7***a*) and 4-chloroaniline (**5–7***f*) derivatives in chloroform were stored at 25°C for several weeks, whereas fast equilibration (within hours) occurred in chloroform solutions of the 4-anisidine (**5–7***d*) and 4-dimethylaminoaniline (**5–7***e*) derivatives. The isomers in these last two series undergo relatively fast equilibration (days at 20°C) even in the solid state.

Isomerization of **5** to a benzotriazol-2-yl derivative **6** requires the benzotriazolyl N—CH_2 bond to undergo ionization giving the ion pair **4** (Scheme 1), and the ease or difficulty of this ionization determines the reaction barrier. Electron-withdrawing substituents on the aniline ring increase the barrier to isomerization by destabilizing cation **4**: hence the individual isomers are the most stable when derived from amines of low basicity.

The same ionization pattern as for **4** is required in the hydrolysis of *N*,*N*-bis(benzotriazolylmethyl)arylamines (**5–7**) to hydroxymethylbenzotriazole (**1**) and the *N*-mono(benzotriazolylmethyl)arylamines **2**. Indeed, a similar lowering of the hydrolysis rate by electron-withdrawing substituents on the arylamine ring is found. Thus, the *p*-anisidine derivative, **5***d*, undergoes fast hydrolysis in DMSO solution at room temperature, and the aniline derivative, **5***a*, is hydrolysed at 60°C over hours, whereas *N*,*N*-bis(benzotriazolylmethyl)-3-nitroaniline (**5***h*) is inert to hydrolysis even at 60°C. A similar substituent influence was reported previously for the hydrolysis of Mannich bases derived from arylamines and succinimide (6).

Hence the influence of substituents in the aniline ring is diametrically different on (i) the equilibria between the mono- (**2**) and bis-(benzotriazolylmethylated) (**5–7**) arylamines and (ii) the reaction barriers between these products. Electron-releasing substituents on the aniline ring make the amine more basic, and favor formation of the bis(benzotriazolylmethylated) products under the equilibrium conditions, but also cause these products to be less stable (reactive) when the conditions are changed.

Proton and carbon NMR spectra of *N*,*N*-bis(benzotriazolylmethyl)arylamine isomers. Structural considerations

The *N*,*N*-bis(benzotriazolylmethyl)arylamines (isomers **5–7**) show characteristic N—CH_2—N methylene group resonances in their ^{1}H NMR spectra (Table 3). A downfield shift of a methylene group attached to a benzotriazolyl N(2) atom, of about 0.2 ppm in comparison with the isomer with the group at N(1), is a well-established characteristic for the benzotriazolyl series. Thus 1-ethylbenzotriazole (39) exhibits its methylene quartet at δ 4.67 and 2-ethylbenzotriazole (39) at δ 4.82. This behavior is caused by a stronger diamagnetic anisotropy of the 2-benzotriazolyl system. This diamagnetic influence of the 2-benzotriazolyl moiety acts over a long range, causing significant shifts even of the signals of quite distant groups. In isomers **6**, not only is the resonance of the methylene group adjacent to the 2-benzotriazolyl moiety shifted in comparison with isomers **5**, but also that of the 1-benzotriazolylmethyl group is moved downfield by about 0.1 ppm.

Full analysis of the ^{1}H NMR spectra was possible for the *N*,*N*-bis(benzotriazol-1-ylmethyl)arylamines **5**, the major components of the isomer product mixtures (Table 4). Small differences in chemical shifts of the methylene groups of **5** given in Tables 3 and 4 may result from different isomer concentrations in the product samples used. Spectra of the isomerically purest **5** were used for the assignments of Table 4, whereas other isomers of *N*,*N*-bis(benzotriazolylmethyl)arylamines present in the crude product mixtures (Table 3) could have some influence on the chemical shifts of **5**.

The benzotriazolyl H(4) signals are easily distinguished in medium resolution spectra near δ 8.00 ppm, as a doublet with $J_{4,5}$ (average value 8.2 Hz) the same as in 1-methylbenzotriazole (40). The benzotriazolyl H(5)–H(7) form a 6H multiplet regardless of substituent on the arylamine ring.

The two benzotriazol-1-ylmethyl substituents on the arylamine nitrogen atom strongly influence the arylamine ring proton signals. Significant downfield shifts of the *ortho* and *para* proton resonances (Table 7) reflect the electron-withdrawing effect of the benzotriazol-1-ylmethyl moieties, rather than the diamagnetic anisotropy of the benzotriazole system, as they depend strongly on the arylamine ring substituent. The opposite shift of the 6-position proton signals in the two *ortho*-substituted products, **5***i* and **5***j*, compared to all other compounds **5**, is explained by the different geometry caused by steric hindrance.

Although, in the ^{13}C NMR, the 1-benzotriazolylmethylene carbons of isomer **6** resonate at almost the same field as the analogous methylene carbons of isomer **5**, the carbon NMR spectra could nevertheless be fully analyzed even for unseparated isomer mixtures of **5**, **6**, and **7**. (In the proton spectra, overlapping aromatic signals precluded analysis.)

^{13}C NMR spectra of the isolated bis(1,1′-benzotriazolyl) derivatives from aniline (**5***a*), *p*-toluidine (**5***b*), *p*-anisidine (**5***d*), and *p*-*N*,*N*-dimethylaniline (**5***e*), identified the six resonances of the 1-benzotriazolyl moiety. These chemical shifts are close to the values reported for 1-methylbenzotriazole (14), allowing the assignment to the individual 1-benzotriazole carbons (Table 5).

Because of low solubility in chloroform, spectra of the 3-nitroaniline derivatives, **5***h* and **6***h*, were taken in DMSO-d_6. The influence of the nitro group allowed full assignments of the ^{13}C NMR resonances for isomer **6***h*. The strong signals at δ 118.0 and 126.6, and a weak signal at 143.7 in the spectra of **6***h*, by comparison with 2-methylbenzotriazole (41) (117.5, 125.9, and 144.3), were assigned to the carbon pairs C-4,7, C-5,6, and C-3a,7a, respectively. Solvent and the *N*-substituent thus have little influence on the 2-benzotriazolyl carbon shifts. This assumption for the 1-benzotriazolyl system allowed assignment, by comparison with 1-methylbenzotriazole (41), of six of the resonances of **6***h* (Table 6). The remaining six resonances, at δ 110.7, 115.0, 121.1, 130.2, 146.0, and 148.6, were assigned (42) to the 3-nitroaniline ring carbons 2, 4, 6, 5, 1, and 3, respectively.

Comparison of the spectra of adducts **5** and **6** (usually as mixtures of both) with those of the starting arylamines allowed complete assignment of the benzotriazolyl and amine ring

[b]A solution in DMSO-d_6.

carbon resonances. Peak intensities helped in these assignments. Thus, for the symmetrical molecules of **5**, resonances of the benzotriazole carbons carrying protons and those of *ortho* or *meta* amino ring carbons gave peaks of similar intensity. Derivatives of *ortho*- or *meta*-monosubstituted amines gave arylamine ring signals of intensity half those of the benzotriazolyl C(4)–C(7) carbons. Similar reasoning was applied for isomers **6**. In the mixtures, the exact ratio of **5**:**6** was known from the proton NMR.

As seen in Table 7, in the *N,N*-bis-benzotriazol-1-ylmethyl isomers **5**, the amine *ortho* and *para* carbon resonances are shifted 4–8 and 5–9 ppm downfield, respectively, whereas the *meta* peaks were shifted less than 1 ppm, all compared to the parent arylamines. Dependence of these shifts on other *para* or *meta* substituents in the arylamine ring indicates nonadditive substituent effects on the carbon-13 NMR spectra (42, 43). The benzotriazol-2-ylmethyl substituent possesses an opposite, although smaller, effect as the observed shifts of the *ortho* and

para carbon resonances of **6** were only 2–5 and 3–6 ppm, respectively. The *ipso* carbons were usually shifted about 1–3 ppm downfield, in relation to the starting amines, in both **5** and **6**. For comparison, substitution of the aniline amino protons by two methyl groups shifts the *ipso*, *ortho*, *meta*, and *para* carbon-13 NMR signals (44) 4.3, −2.0, 0.1, and −1.5 ppm, respectively. Therefore the benzotriazol-1-ylmethyl substituent is electron withdrawing, whereas the benzotriazol-2-ylmethyl group demonstrates weak electron-releasing ability. Benzotriazol-2-yl as a substituent on the benzene ring was reported (45) to possess a strong electron-withdrawing influence (σ_p = 0.5).

Much stronger shifts of the *ortho* and *para* carbon signals in the spectra of the mono- and di-*ortho*-substituted products, **5***i–k* and **6***i–k*, result from steric hindrance at the amino group, which causes distortion of the $(BtCH_2)_2N$ group around the N—C(aryl) bond to such degree that overlapping of the nitrogen electron pair with the aryl π orbital is at least significantly decreased (Fig. 1). Similarly, the *ortho* and *para* carbon resonances of *N*,*N*-2,6-tetramethylaniline (48) are shifted downfield by 14.2 and 7.3 ppm, respectively, in comparison with 2,6-dimethylaniline. The isopropyl groups of **6***j* show as two methyl doublets in the ^{1}H NMR (δ 0.69 and 0.77, J = 6.8 Hz) and as two peaks in the ^{13}C NMR spectra (δ 23.6 and 24.5), which lends strong support to the structure proposed (Fig. 1).

Experimental

Melting points were determined with a hot-stage microscope and are uncorrected. The ^{1}H and ^{13}C NMR spectra were recorded on a Varian VXR-300 instrument in $CDCl_3$ solution (except when stated otherwise) with $(CH_3)_4Si$ as internal standard. Dry ether or THF means the solvent refluxed with sodium–benzophenone and distilled prior to use. 1-(Hydroxymethyl)benzotriazole was prepared according to the literature method (49). Benzotriazole and all amines used were commercial specimens.

Preparation of N-*(benzotriazol-1-ylmethyl)-4-butylaniline (2*c*)*

To a stirred solution of benzotriazole (7.36 g, 60 mmol) and 4-butylaniline (8.96 g, 60 mmol) in water (60 mL) and ethanol (20 mL) was added 37% formaldehyde (4.50 mL, 60 mmol). A white precipitate started to form immediately. The mixture was stirred at 25°C for 2 h and then stored at 5°C overnight. The precipitate was filtered off, washed with aqueous ethanol (1:1, 20 mL) followed by ethanol (10 mL), and dried in air at room temperature to give pure **2***c* (15.89 g, 94%) as white needles, mp 136°C; ^{1}H NMR (DMSO-d_6) δ: 0.86 (t, J = 7.3 Hz, 3H), 1.27 (hextet, J = 7.5 Hz, 2H), 1.46 (quintet, J = 8.1 Hz, 2H), 2.41 (t, J = 7.3 Hz, 2H), 6.05 (d, J = 8.0 Hz, 2H), 6.40 (t, J = 8.0 Hz, 1H, NH), 6.79 (d, J = 8.6 Hz, 2H), 6.92 (d, J = 8.4 Hz, 2H), 7.31 (t, J = 6.9 Hz, 1H), 7.41 (t, J = 6.9 Hz, 1H), 7.88 (d, J = 8.3 Hz, 1H), 7.95 (d, J = 8.4 Hz, 1H); ^{13}C NMR (DMSO-d_6) δ: 13.9, 22.1, 33.7, 34.5, 58.2, 110.4, 113.2, 119.3, 124.0, 127.4, 129.0, 132.4, 132.9, 143.2, 146.0. Anal. calcd. for $C_{17}H_{20}N_4$: C 72.83, H 7.19, N 19.98; found: C 72.68, H 7.22, N 20.15.

Other N-*(benzotriazol-1-ylmethyl)anilines 2 prepared according to the procedure given for 4-butylaniline*

N-(Benzotriazol-1-ylmethyl)aniline (**2***a*) was obtained in 82% yield as white needles, mp 139°C (lit. (4) mp 138–139°C); ^{1}H NMR (DMSO-d_6) δ: 6.07 (d, J = 7.1 Hz, 2H), 6.61 (t, J = 7.3 Hz, 1H), 6.85 (d, J = 7.7 Hz, 2H), 7.09 (m, 3H), 7.31 (t, J = 8.2 Hz, 1H), 7.45 (dd, J = 7.3 and 8.3 Hz, 1H), 7.94 (d, J = 8.3 Hz, 1H), 8.01 (d, J = 8.3 Hz, 1H); ^{13}C NMR (DMSO-d_6) δ: 57.2, 110.9, 112.8, 117.9, 119.0, 123.7, 126.9, 128.9, 132.2, 145.5, 145.7.

N-*(Benzotriazol-1-ylmethyl)*-p-*anisidine (2*d*)* was obtained in 87% yield as colorless needles, mp 140°C; ^{1}H NMR (DMSO-d_6) δ: 3.59 (s, 3H), 6.12 (d, J = 7.5 Hz, 2H), 6.73 (d, J = 9.0 Hz, 2H), 6.80 (d, J = 9.0 Hz, 2H), 7.00 (t, J = 7.5 Hz, 1H, NH), 7.38 (t, J = 8.0 Hz, 1H), 7.54 (t, J = 8.0 Hz, 1H), 8.03 (d, J = 8.3 Hz, 1H), 8.09 (d, J = 8.2 Hz, 1H); ^{13}C NMR (DMSO-d_6) δ: 55.4, 58.5, 110.8, 114.3, 114.6, 119.2, 123.8, 127.0, 132.3, 139.3, 145.9 and 152.5. Anal. calcd. for $C_{14}H_{14}N_4O$: C 66.13, H 5.55, N 22.03; found: C 66.11, H 5.54, N 22.18.

N-*(1-Benzotriazol-1-ylmethyl)-3-chloroaniline (2*g*)* was obtained in 92% yield as colorless prisms, mp 176°C; ^{1}H NMR (DMSO-d_6) δ: 6.09 (d, J = 7.1 Hz, 2H, CH_2), 6.60 (d, J = 7.9 Hz, 1H), 6.78 (d, J = 7.9 Hz, 1H), 6.89 (s, 1H), 7.04 (t, J = 8.0 Hz, 1H), 7.35 (dd, J = 8.4 and 7.3 Hz, 1H), 7.50 (m, 2H), 7.97 (d, J = 8.4 Hz, 1H), 8.02 (d, J = 8.4 Hz, 1H); ^{13}C NMR (DMSO-d_6) δ: 56.6 (CH_2), 110.9, 111.3, 112.4, 117.4, 119.1, 123.8, 127.1, 130.2, 132.1, 134.0, 145.6, and 147.2. Anal. calcd. for $C_{13}H_{10}ClN_4$: C 60.59, H 3.91, N 21.74; found: C 60.98, H 4.23, N 21.64.

N-*(Benzotriazol-1-ylmethyl)-2-methylaniline (2*i*)* was obtained in 93% yield as colorless prisms, mp 146°C; ^{1}H NMR (DMSO-d_6) δ: 2.16 (s, 3H), 6.14 (d, J = 6.8 Hz, 2H), 6.8 (m, 2H), 6.94 (m, 3H), 7.32 (t, J = 8.2 Hz, 1H), 7.45 (dd, J = 8.3 and 7.0 Hz, 1H), 7.95 (d, 8.4 Hz, 1H), 8.05 (d, 8.4 Hz, 1H); ^{13}C NMR (DMSO-d_6) δ: 17.7, 57.4, 110.2, 111.2, 117.7, 119.0, 122.2, 123.7, 126.6, 126.9, 130.1, 132.2, 143.4, 145.6. Anal. calcd. for $C_{14}H_{14}N_4$: C 70.57, H 5.92, N 23.51; found: C 70.19, H 5.85, N 23.57.

N-*(Benzotriazol-1-ylmethyl)-2-ethylaniline (2*j*)* was obtained in 92% yield as colorless needles, mp 110°C; ^{1}H NMR δ: 1.14 (t, J = 7.5 Hz, 3H), 2.50 (q, J = 7.5 Hz, 2H), 5.36 (t, J = 7.0 Hz, 1H), 6.12 (d, J = 7.0 Hz, 2H), 6.70 (m, 1H), 7.01 (m, 3H), 7.28 (t, J = 8.3 Hz, 1H), 7.37 (t, J = 8.0 Hz, 1H), 7.71 (d, J = 8.2 Hz, 1H), 7.98 (d, J = 8.0 Hz, 1H); ^{13}C NMR δ: 13.1 (Et), 23.7 (Et), 58.1 (N—CH_2—N), 109.9, 111.5, 119.4, 119.4, 119.6, 123.9, 126.9, 127.3, 128.3, 128.6, 132.4, 142.2, 146.1. Anal. calcd. for $C_{15}H_{16}N_4$: C 71.40, H 6.39, N 22.21; found: C 71.81, H 6.34, N 22.23.

Reaction of N-*(benzotriazol-1-ylmethyl)-4-butylaniline (2*c*) with 1-(hydroxymethyl)benzotriazole at 22°C*

A mixture of 1-(hydroxymethyl)benzotriazole (0.75 g, 5 mmol) and **2***c* (1.40 g, 5 mmol) was dissolved in DMSO-d_6/$CDCl_3$ (3 + 3 mL). A sample of such solution (0.2 mL) diluted with deuteriochloroform (0.4 mL) was transferred into an NMR tube and the reaction monitored by ^{1}H NMR. The sample was stored at 22°C in intervals between the NMR measurements. With time, the intensity of the methylene signals of the starting materials (both at δ ca. 6.05) decreased, whereas new signals at a lower field (the major one at δ 6.25) appeared and grew in intensity. Integrals representing the percentage of the starting materials in the reaction mixture as a function of time are given in the discussion part of the paper.

Investigation of the reaction equilibria between 1-(hydroxymethyl)-benzotriazole and arylamines in DMSO

A solution of arylamine (2.5 mmol), 1-(hydroxymethyl)benzotriazole (0.75 g, 5 mmol), and DMSO-d_6 (0.71 mL, 10 mmol) was heated at 100°C under argon for 1 h. A sample of the solution obtained (0.1 mL) was diluted with deuteriochloroform (0.5 mL) and the NMR spectrum was taken with precise integrals to get the molar ratio between the compounds in the mixture. In general, the NMR region that usually focused most attention was that at δ 6.00–6.60, where resonances of the methylene groups of the products and starting materials were observed. Very often, analysis of other signals in the spectra (aryl protons, substituents on the amine ring) gave help and further support in the estimation of percentage of the starting materials and products present in the reaction mixtures. In some instances, integrals of the carbon resonances in the ^{13}C NMR spectra of the mixtures were used for the same purpose. The data obtained are collected in Table 1.

Reaction of N-*(benzotriazol-1-ylmethyl)-4-butylaniline (2*c*) with 1-(hydroxymethyl)benzotriazole (1) in refluxing toluene*

A solution of **1** (1.49 g, 10 mmol) and **2***c* (2.80 g, 10 mmol) in

toluene (30 mL) was heated at reflux for 3 h under a Dean–Stark water trap. The solvent was evaporated at 90°C (rotary vacuum evaporator) to give analytically pure *N*,*N*-bis(benzotriazolylmethyl)-4-butylaniline in 100% yield as a viscous oil (Table 2).

N,N-*Bis(benzotriazolylmethylation) of aromatic amines with benzotriazole and aqueous formaldehyde. General procedure*

A mixture of benzotriazole (11.91 g, 100 mmol), an aromatic amine (50 mmol), 37% formaldehyde (11.2 mL, 150 mmol), and toluene (50 mL) was stirred at 60°C for 1 h and then refluxed with a Dean–Stark trap for 3 h. Water (about 11 mL) separated in the trap. The solvent was evaporated under reduced pressure and the residue was heated in vacuum at 90°C for 2 h (by means of a rotary vacuum evaporator) to remove traces of toluene. The viscous oil obtained usually became glassy after cooling to room temperature. The glass could be reversibly liquefied by heating to 100–120°C. In many instances, the glassy product was turned into a crystalline material upon trituration with dry ether. Isomer mixtures **5**, **6**, **7***a–g* and *k* (Tables 2 and 3) were obtained by this procedure.

N,N-*Bis(benzotriazolylmethylation) of 3-nitroaniline*

A mixture of benzotriazole (23.82 g, 200 mmol), 3-nitroaniline (13.81 g, 100 mmol), 37% formaldehyde (17.98 mL, 240 mmol), and toluene (200 mL) was stirred and heated to reflux under a Dean–Stark trap for 2 weeks. The precipitate obtained was filtered off from the hot mixture, washed with ether, and dried in a vacuum oven to give analytically pure *N*-(benzotriazol-1-ylmethyl)-3-nitroaniline **2***h* (5.02g, 19%) as yellow needles, mp 209°C; ^{1}H NMR (DMSO-d_6) δ: 6.19 (d, J = 7.1 Hz, 2H, CH_2), 7.25 (ddd, J = 8.2, 2.1, and 1.1 Hz, 1H, aniline-H(6)), 7.32 (t, J = 7.8 Hz, 1H, aniline-H(5)), 7.37 (td, J = 8.2 and 1.0 Hz, 1H, Bt-H(5)), 7.44 (ddd, J = 7.8, 2.2, and 1.2 Hz, 1H, aniline-H(4)), 7.53 (td, J = 8.1 and 1.0 Hz, 1H, Bt-H(6)), 7.72 (t, J = 2.1 Hz, 1H, aniline-H(2)), 7.88 (t, J = 7.1 Hz, 1H, N-H), 7.98 (dt, J = 8.4 and 0.9 Hz, 1H, Bt-H(7)), 8.03 (dt, J = 8.4 Hz and 0.9 Hz, 1H, Bt-H(4)); ^{13}C NMR (DMSO-d_6) δ: 56.1 (CH_2), aniline: 106.6, 112.0, 118.9, 121.9, 146.8 and 148.5, Bt: 110.6, 118.8, 123.7, 127.0, 131.9 and 145.4 ppm. Anal. calcd. for $C_{13}H_{11}N_5O_2$: C 58.0, H 4.1, N 26.0; found: C 58.3, H 4.1, N 26.4%.

The filtrate was kept at room temperature for 1 h. The precipitate was filtered off, washed with ether, and dried in a vacuum oven (50°C, 30 Torr; 1 Torr = 133.3 Pa) to give an analytically pure mixture of the isomers containing 75% of *N*,*N*-bis(benzotriazol-1-yl-methyl)-3-nitroaniline **5***h* (14.25 g, 36%).

The filtrate obtained from the above sample was stored in a freezer for 3 days. The precipitate obtained was filtered off, washed with ether, and dried in a vacuum oven to give an analytically pure sample of the isomers containing 80% of *N*-(benzotriazol-2-ylmethyl)-*N*-(benzotriazol-1-ylmethyl)-3-nitroaniline **6***h* (7.81 g, 20%).

N,N-*Bis(benzotriazolylmethylation) of 2-methylaniline*

A stirred mixture of benzotriazole (2.38 g, 20 mmol), *o*-toluidine (1.07 mL, 10 mmol), 37% formaldehyde (4.0 mL, 53 mmol), and cyclohexane (30 mL) was heated at reflux under a Dean–Stark water trap for 4 h. The solvent was evaporated (rotary vacuum evaporator) and the residual oil was triturated under argon with dry ether (20 mL). The crystalline material obtained was filtered off and dried in a vacuum oven to give an analytically pure mixture of isomeric *N*,*N*-bis(benzotriazolylmethyl)-2-methylanilines **5–7***i* (1.17 g, 31%) (Table 2).

N,N-*Bis(benzotriazolylmethylation) of 2-ethylaniline*

A solution of *N*-(benzotriazol-1-ylmethyl)-2-ethylaniline (1.26 g, 5 mmol) and 1-(hydroxymethyl)benzotriazole (0.74 g, 5 mmol) in toluene (20 mL) was heated at reflux under a Dean–Stark trap for 2 h. The solvent was evaporated by heating the solution at 90°C under pressure of 35 Torr. According to ^{1}H NMR, the product obtained was a mixture of *N*,*N*-bis(benzotriazolylmethyl)-2-ethylaniline, *N*-(benzotriazol-1-ylmethyl)-2-ethylaniline, and benzotriazole in a molar ratio of 1:1:1.

A solution of *N*-(benzotriazol-1-ylmethyl)-2-ethylaniline (2.52 g, 10 mmol) and 1-(hydroxymethyl)benzotriazole (1.49 g, 10 mmol) in chloroform (100 mL) was refluxed for 8 h in a Soxhlet apparatus filled with anhydrous magnesium sulfate (6.00 g, 50 mmol) to trap the water formed. The solvent was evaporated to give analytically pure *N*,*N*-bis(benzotriazolylmethyl)-2-ethylaniline, as a mixture of its three isomers (Table 3).

Condensation of benzotriazole with formaldehyde and o-phenylenediamine. Preparation of 1,3-bis(benzotriazol-1-yl-methyl)-2,3-dihydrobenzimidazole (8)

To a stirred solution of *o*-phenylenediamine (5.41 g, 50 mmol) and benzotriazole (11.19 g, 100 mmol) in toluene (50 mL) was added a 37% solution of formaldehyde (14.98 mL, 200 mmol) and the mixture obtained stirred at 60°C for 1 h followed by reflux under a Dean–Stark trap for 16 h. The solvent was evaporated (vacuum rotary evaporator) to give an oil, which turned into a glassy material upon cooling to room temperature. The crude product was dissolved in boiling ethanol–dioxane (200 + 200 mL) and the solution was stored at −5°C for 24 h to give **8** (4.26 g, 22%) as colorless prisms, mp 178–179°C; ^{1}H NMR δ: 4.94 (s, 2H), 5.87 (s, 4H), 6.82 (m, 4H), 7.34 (m, 2H), 7.42 (m, 4H), 8.01 (d, J = 8.2 Hz, 2H); ^{13}C NMR δ: 58.9, 71.4, 106.8, 108.9, 118.9, 118.8, 119.7, 123.3, 127.0, 131.8, 137.9, 145.0. Anal. calcd. for $C_{21}H_{18}N_8$: C 65.95, H 4.74, N 29.30; found: C 65.76, H 4.73, N 29.08.

*Condensation of benzotriazole with formaldehyde and 2-aminobenzyl alcohol: formation of 1-(benzotriazol-1-ylmethyl)-1,4-dihydro-2*H*-3,1-benzoxazine (9)*

A mixture of 2-aminobenzyl alcohol (4.92 g, 40 mmol), benzotriazole (4.48 g, 40 mmol), 37% formaldehyde (7.49 mL, 100 mmol), and toluene (40 mL) was stirred at 60°C for 1 h followed by reflux under a Dean–Stark trap for 2 h. The solvent was evaporated under reduced pressure (rotary vacuum evaporator) and the residue was dried at 90°C under vacuum (50 Torr) for 30 min.

The crude product was obtained as a very sticky oil (10.99 g), and crystallized from ethanol to give pure **9** (7.20 g, 67%), colorless prisms, mp 122°C; ^{1}H NMR δ: 4.68 (s, 2H, $ArCH_2O$), 4.87 (s, 2H, NCH_2O), 6.09 (s, 2H, NCH_2N), 6.89 (d, J = 7.8 Hz, 1H, Ar), 6.98 (m, 1H, Ar), 7.26 (m, 2H, Ar), 7.34 (m, 3H, Bt), 8.04 (d, J = 7.7 Hz, 1H, Bt) ppm; ^{13}C NMR δ: 66.0 (CH_2), 67.2 (CH_2), 79.9 (CH_2), Bt: 109.9, 120.0, 123.9, 127.5, 132.6, and 146.2, Ar: 118.6, 122.2, 125.3, 127.7, and 141.7 ppm. Anal. calcd. for $C_{15}H_{14}N_4O$: C 67.65, H 5.30, N 21.04; found: C 67.57, H 5.26, N 21.16.

Hydrolysis of N,N-*bis(benzotriazolylmethyl)arylamines by deuterium oxide*

To a solution of an *N*,*N*-bis(benzotriazolylmethyl)arylamine (0.05 mmol) in DMSO-d_6 (0.5 mL) was added deuterium oxide (0.09 mL, 5 mmol) and the solution kept at elevated temperature for the period of time specified below. NMR spectra (^{1}H and ^{13}C) taken for the solution allowed estimation of the percentage of *N*,*N*-bis(benzotriazolylmethyl)arylamine (isomers **5**, **6**, and **7**) as well as those of the hydrolysis products (O or N deuterated) analogues of **1** and **2**) in the reaction mixture. The results obtained are as follows:

4*d* (Ar = 4-$MeOC_6H_4$):	complete hydrolysis at 20°C within 2 h
5*b* (Ar = 4-MeC_6H_4):	no reaction at 20°C after 24 h, 32% (15 min) and 88% (60 min) of hydrolysis at 60°C
5*a* (Ar = Ph):	8.5% (1 h) and 37% (12 h) of hydrolysis at 60°C
5*f* (Ar = 4-ClC_6H_4):	46% (4 h) and 76% (12 h) of hydrolysis at 60°C
5*h* (Ar = 3-$NO_2C_6H_4$)	no evidence of hydrolysis after 24 h at 60°C

Received April 17, 1989

ALAN R. KATRITZKY, STANISLAW RACHWAL, and JING WU. Can. J. Chem. **68**, 456 (1990).

Grignard reactions of *N,N*-bis(benzotriazolylmethyl)arylamines afford the corresponding *N,N*-dialkylarylamines in high yields. Electron-releasing substituents on the aryl ring facilitate the reaction. Arylamines are *N,N*-dialkylated with two different alkyl groups by a stepwise procedure: *N*-benzotriazolylmethylation of an amine followed by a Grignard reaction to introduce the first alkyl group, and repetition of the same procedure to introduce the second alkyl group. Grignard reagents derived from 1,4-dihalobutane, upon reaction with *N,N*-bis(benzotriazolylmethyl)arylamines, give the corresponding *N*-aryl-hexahydroazepines together with acyclic products.

Key words: azepine, tertiary arylamines.

ALAN R. KATRITZKY, STANISLAW RACHWAL et JING WU. Can. J. Chem. **68**, 456 (1990).

Les *N,N*-bis(benzotriazolylméthyl)arylamines soumises à des réactions de Grignard fournissent les *N,N*-dialkylarylamines correspondantes avec des rendements élevés. La présence de substituants électrodonneurs sur les noyaux aryles facilite la réaction. Pour arriver à la *N,N*-dialkylation des arylamines par deux groupements alkyles différents, on procède par étapes : la benzotriazolylméthylation de l'amine suivie par une réaction de Grignard permet d'introduire le premier groupement alkyle et la répétition de la même séquence d'introduire le second groupement. Les réactifs de Grignard obtenus à partir de 1,4-dihalobutane réagissent avec les *N,N*-bis(benzotriazolylméthyl)arylamines pour conduire aux *N*-aryl-hexahydroazépines correspondantes aux côtés de produits acycliques.

Mots clés : azépine, arylamines tertiaires.

[Traduit par la revue]

Introduction

Arylamines condense with 1-(hydroxymethyl)benzotriazole under mild conditions to give the corresponding *N*-(benzotriazolylmethyl)arylamines in high yields (1). Treatment of these adducts with Grignard reagents leads to substitution of the benzotriazolyl moiety by an alkyl or aryl group, and this is in many cases the preferred method for the *N*-monoalkylation of arylamines (2). Under similar conditions, alkylamines, hydroxylamines, and hydrazines give their *N,N*-bis(benzotriazolylmethylated) derivatives, which upon treatment with Grignard reagents are transformed into the corresponding *N,N*-dialkylated alkylamines (3), hydroxylamines (3), and hydrazines (4).

Tertiary dialkylarylamines are products of interest in many areas of applied chemistry. Several reports have appeared recently on their preparation: (i) by nucleophilic substitution of aromatic halides with dialkylamines (5) or (dialkylamino)-tributyltin (6); (ii) by dealkylation of quaternary ammonium salts (7), (iii) by dialkylation of arylamines with alcohols (8–13) or ethers (14, 15), (iv) by reductive dialkylation of arylamines with aldehydes on a Pd/C catalyst (16), and (v) by reductive transformation of nitroarenes into dialkylaminoarenes using aldehydes and carbon monoxide (17) or aldehydes and hydrogen in the presence of a noble metal catalyst (18).

All these methods, however, suffer limitations, especially when complex alkyl groups have to be introduced. 4-Chloronitrobenzene reacted with dibutylamine to give *N,N*-dibutyl-4-nitroaniline in only 15% yield and not at all with diisopropylamine (5). Dealkylations of quaternary ammonium salts are limited to *N*-methyl and *N*-ethyl substituents (7). Aniline dialkylation in the presence of a ruthenium catalyst was successful with *n*-alkyl alcohols, but failed for secondary alcohols (8). Reductive dialkylation of nitrobenzene with isobutyraldehyde and carbon monoxide gave only 10% of *N,N*-diisobutylaniline (17). Nitrobenzene with butyraldehyde, hydrogen, and a platinum catalyst gives *N,N*-dibutylaniline, but isobutyraldehyde forms only the *N*-monoalkylated product (18).

Our recently disclosed method for the *N,N*-bis(benzotriazolylmethylation) or arylamines (19) prompted us to subject these adducts to Grignard reagents. We now report that this provides a superior method for the *N,N*-dialkylation of aromatic amines.

Results and discussion

Preparation of symmetrical N,N-*dialkylarylamines (**7**, $R^1 = R^2$)*

Similarly to *N*-mono(benzotriazolylmethylated) arylamines (2), *N,N*-bis(benzotriazolylmethyl)arylamines **1** are easily reduced by sodium borohydride and react readily with Grignard reagents to produce *N,N*-dimethyl- or *N,N*-dialkyl-arylamines **7**, respectively (Scheme 1). The alkyl groups in the product contain an extra methylene as compared to the Grignard reagent and this method is therefore especially valuable when effective alkylating agents for direct alkylation of the amine are not easily available (e.g., neopentyl), or for alkylating agents that easily undergo elimination in basic solution. Thus, we now report the synthesis of *N,N*-di(β-phenethyl)anilines, a previously unknown class. Again, 3-butenyl bromide, although less susceptible to elimination than phenethyl bromide, gave only 37% of *N,N*-bis(3-butenyl)aniline (**7***h*) in the direct dialkylation of aniline (20). Under our conditions, product **7***h* was obtained quantitatively, and analytically pure, from the reaction of *N,N*-bis(benzotriazolylmethyl)aniline with allylmagnesium bromide.

N,N-Dialkylarylamines prepared by this new method can be generally obtained in good yields (Table 1). The products were fully characterized by their ^{1}H and ^{13}C NMR spectra (Tables 2, 3). The method and the results obtained are comparable to those reported previously for the reaction of *N,N*-bis(phenylthiomethyl)aniline with Grignard reagents (21), but with the great advantages of the easier preparation of starting *N,N*-bis(benzo-

triazolylmethyl)anilines in comparison with their phenylthiomethyl analogs, and of the avoidance of harmful and unpleasant thio reagents, intermediates, and side products.

The only limitations of our new method, Tables 1, 3, are the following:

(a) The alkyl groups of the prepared *N*,*N*-dialkylarylamines are all linked to the nitrogen by a methylene group. No secondary or tertiary alkyl groups can be introduced.

(b) Protection is required for arylamines bearing substituents sensitive towards Grignard reagents.

(c) The crude amines **7** obtained are sometimes contaminated by *N*-alkyl-*N*-methylamines **8**, especially when secondary alkyl Grignard reagents (22, 23) are used.

Several recent reports on the successful use of 1,4-bis(halomagnesio)butane in organic synthesis, e.g., preparation of 1-(*o*-aminophenyl)cycloalkanols (26), oximes of 3-(hydroxycyclopentyl)-2-alkanones (27), 1-*tert*-butylcyclopentanol (28), spirolactones derived from pyridine and pyrazine 2,3-dicarboxylic acids (29), and 1-(3-hydroxypropyl)cyclopentanols (30, 31), prompted us to try 1,4-bis(halomagnesio)butane reagents in reactions with *N*,*N*-bis(benzotriazolylmethyl)arylamines **1**. Direct application of reaction conditions similar to those used previously in the reactions of **1** with ordinary Grignard reagents gave complex mixtures. Vacuum fractional distillation and (or) column chromatography gave the expected hexahydroazepines (32, 33) **9** together with acyclic products **10–12**. In the successful reactions of 1,4-di(bromomagnesio)butane, intramolecular coordination of the magnesium atom in the active intermediate by an oxygen atom seems to be required for high yields of the cyclic products. This could not happen in our case, leading to low yields of **9**.

We believe that molecules of the intermediate *N*-(benzotriazol-1-ylmethyl)-*N*-(4-halomagnesiobutyl)aniline, because of weak magnesium coordination at the reaction center, were attacked further by Grignard reagent giving *N*,*N*-dialkylated products **11** and **12** (and more complex molecules), as the main reaction course. The intermediate is also reduced by a second molecule of the Grignard reagent giving the *N*-methyl derivative **10**.

Substituent influences

We failed to get two different groups in the final product **7** by stepwise Grignard reaction of **1** via **4**. Thus, *N*,*N*-bis(benzotriazolylmethyl)-4-anisidine, when reacted with 1 molar equivalent of isopropylmagnesium bromide, gave exclusively *N*,*N*-diisobutyl-4-anisidine together with the unchanged starting material **1**. None of intermediate **4** was detected, indicating that the cation **6** forms from the molecule of **4** much more easily than **2** from **1** (destabilizing effect of the electron-withdrawing benzotriazolyl group), causing the reaction **4** → **7** to be much faster than the reaction **1** → **4** (Scheme 1). This illustrates the decisive influence of substituents on the stability of the ion pair intermediate **2**.

For a direct comparison of the reactivity towards Grignard

reagents of *N*,*N*-bis(benzotriazolylmethyl)anilines **1** bearing different substituents on the aniline ring, a mixture of one mole each of *N*,*N*-bis(benzotriazolylmethylated) 4-anisidine and 4-chloroaniline was reacted with two molar equivalents of isopropylmagnesium bromide. The derivative of 4-anisidine proved to be much more reactive than that of 4-chloroaniline as, after work-up of the reaction, *N*,*N*-diisopropyl-4-anisidine was found by the NMR technique to be present to the extent of 28 mol% compared to only 8 mol% of *N*,*N*-diisobutyl-4-chloroaniline in a mixture with unreacted starting materials. This phenomenon can be explained in terms of the relative reactivity of cation **2**: the chlorine substituent on the aryl group ($\sigma = 0.23$, ref. 34) effectively destabilizes cation **2**, whereas the methoxy group ($\sigma = -0.27$, ref. 34) has just the opposite effect.

Asymmetrically N,N-*dialkylated arylamines. Stepwise procedure*

Although the above experiment excluded the possibility of the preparation of *N*,*N*-dialkylated arylamines with two different alkyl groups by stepwise Grignard reactions on **1**, such dialkylation of arylamines succeeds well on applying a stepwise procedure. Mono-benzotriazolylmethylation of an arylamine and subsequent Grignard reaction to **3** were described in our previous papers (1–2). Further benzotriazolylmethylation of secondary alkylarylamine to **4** followed by its Grignard reaction to **7** is now demonstrated to be a good route to *N*,*N*-dialkylarylamines having two different alkyl groups (**7***k*–**7***m*).

Additionally, such a stepwise route also allows for dialkylation of the electron-poor amines, which do not form adducts **1**. Thus, 4-aminopyridine was transformed into 4-(benzotriazolylmethyl)aminopyridine, then by reaction with benzylmagnesium chloride to 4-phenethylaminopyridine **3***j*, which by repeated benzotriazolylmethylation followed by a second Grignard reaction gave the final product 4-(*N*,*N*-diphenethylamino)pyridine (**7***j*) in the overall total yield of 21% (four steps).

A unique phenomenon was observed in this case, which is responsible for the corresponding low yield of **7***j*. Thus, reaction of 4-(benzotriazolylmethyl)aminopyridine with benzylmagnesium chloride afforded, apart from the expected 4-phenethylaminopyridine (70%), another product, 4-(2-methylbenzylamino)pyridine (17%). Although the fact that benzyl Grignard reagents can also undergo reactions with electrophiles as their mesomeric forms, with the negative charge localized on the *ortho* carbon, is well known (35, 36), such a reaction course was never observed in any of our other cases where benzyl Grignard reagent was used. The reason seems to be the difference in a steric hindrance of cation **2** and an analogous cation derived from a mono(benzotriazolylmethylated) aniline. A nucleophilic attack of the benzyl anion by its more sheltered

ortho carbon atom can be effective only when there is enough space around the electrophile.

In general, however, a 2-phenylethyl group (or two such groups) can be efficiently introduced on the arylamine nitrogen atom by a reaction of the benzotriazolylmethylated intermediate with a benzyl Grignard reagent, giving a 2-phenylethylamino function. This application of our method is of special interest, as 2-phenylethylamine and its derivatives are important for their biological activity and wide natural occurrence (37–45).

Experimental

Melting points were determined on a Thomas–Hoover capillary melting point apparatus and were not corrected. NMR spectra (^1H and ^{13}C) were taken on a Varian VXR-300 instrument in $CDCl_3$ solvent with tetramethylsilane as the internal standard for ^1H and ^{13}C. Low and high resolution mass spectra were determined at 70 eV with an A.E.I. MS-30 mass spectrometer operating with a Kratos DS-55 data system. Elemental analyses were performed in house under the supervision of Mr. M. Courtney. Ether and THF for the Grignard reaction were dried by reflux under argon with sodium/benzophenone and distilled immediately prior to use. Silica gel used for column chromatography was 230–400 mesh.

Reaction of N,N-*bis(benzotriazolylmethyl)aniline with isopropylmagnesium bromide. Preparation of* N,N-*diisobutylaniline (7a)*

To a solution of isopropylmagnesium bromide prepared from isopropyl bromide (2.92 g, 120 mL) and magnesium turnings (2.92 g, 120 mmol) in ether (40 mL) was added a suspension of *N,N*-bis(benzotriazolylmethyl)aniline (10.00 g, 28 mmol) in ether–toluene (20 + 10 mL). The mixture obtained was stirred under argon for 16 h and then poured into ice water (400 g), neutralized with acetic acid, and the organic layer separated. The water phase was washed twice with ether (2 × 100 mL). The combined organic phase was washed with water (100 mL), followed by 10% sodium hydroxide (100 mL) and again by water (100 mL). The solution was dried over anhydrous potassium carbonate and the solvent was evaporated by means of a rotary vacuum evaporator to give crude *N,N*-bis(2-methylpropyl)aniline (**7***a*) as an oily substance of purity about 80% (according to NMR, from the ratio of integrals of **7***a* protons, calculated on the basis of the resonance at δ 3.13, to the sum of the integrals observed in the spectrum) (6.24 g, 87%). The product was characterized in Tables 1–3. Similar processes were used for the preparation of amines **7***b*–**7***e*.

Preparation of the picrate of N,N-*bis(2-methylpropyl)aniline (7a)*

A mixture of crude *N,N*-bis(2-methylpropyl)aniline (5.0 g, 19.5 mmol) and 65% picric acid (8.81 g, 25 mmol) was heated under

vacuum to evaporate the water. The semisolid material obtained was stirred with methanol (15 mL) at −5°C for 5 h. The precipitate obtained was filtered off, washed with cold (−5°C) methanol (10 mL), and recrystallized from absolute ethanol (5 mL) to give an analytically pure sample of the picrate of **7***a* (2.20 g, 26%).

The picrates of **7***b*–**7***e* were obtained from the analytical samples purified by column chromatography (silica gel; toluene/hexane, 1:1).

*Preparation of 4-chloro-*N,N*-diisobutylaniline (7*f*)*

37% Aqueous formaldehyde (22.8 mL, 0.3 mol) was added to a solution of benzotriazole (23.83 g, 200 mmol) and *p*-chloroaniline (12.76 g, 100 mmol) in toluene (150 mL) heated to 60°C. Much heat was evolved and the solution started to boil. After stirring for 1 h, the content was refluxed under a Dean–Stark water trap for 3 h and allowed to cool to room temperature. To this solution was added isopropylmagnesium bromide prepared from isopropyl bromide (36.90 g, 300 mmol) and magnesium turnings (9.72 g, 400 mmol) in ether (150 mL). Much solid precipitated and the solution began to boil. The mixture was stirred and heated at reflux under argon for 2 h and then poured into ice water (200 g). The mixture obtained was neutralized with acetic acid and extracted twice with ether (2 × 200 mL). The ethereal solution was washed with water (2 × 400 mL), 10% sodium

For personal use only.

hydroxide (2 × 200 mL), and again with water (2 × 400 mL), and dried over sodium carbonate monohydrate (50 g) for 3 h. The solvent was removed (rotary vacuum evaporator) to give crude **7***f* (20.35 g) as a reddish-brown viscous liquid.

According to its ^{1}H and ^{13}C NMR spectra, the crude product consisted of 4-chloro-*N*,*N*-diisobutylaniline (**7***f*) (40%, characteristic doublet of the methylene group at δ 3.10), starting 4-chloro-*N*,*N*-bis(benzotriazol-1-ylmethyl)aniline (**1***f*) (30%, methylene singlet at δ 6.18), 4-chloro-*N*-isobutylaniline (**3***f*) (19%, CH_2 doublet at δ 2.88), and 4-chloro-*N*-isobutyl-*N*-methylaniline (**5***f*) (10%, CH_2 doublet at δ 3.15 and CH_3 singlet at δ 2.90).

An analytical sample of 4-chloro-*N*,*N*-diisobutylaniline (**7***f*) (0.06 g) was prepared from the crude mixture by column chromatography (30 g of silica gel and a 1:1 hexane/benzene as the eluent).

Preparation of N,N-*bis(cyclohexylmethyl)aniline (7g)*

To a stirred solution of *N*,*N*-bis(benzotriazol-1-ylmethyl)aniline (**1***a*) (7.15 g, 20 mmol) in dry THF (20 mL) was added dropwise a Grignard reagent prepared by a reaction of cyclohexyl chloride (7.11 mL, 60 mmol) with magnesium turnings (1.94 g, 5 mmol) in ether (40 mL). The mixture obtained was stirred under argon for 50 h, and then poured into a 20% solution of ammonium chloride (100 mL). The resulting mixture was shaken with toluene (100 mL) and the toluene extract was washed with water (100 mL) followed by 10% sodium hydroxide (100 mL), again with water, and finally dried over anhydrous sodium carbonate. Evaporation of the solvent under reduced pressure afforded a crude product (9.66 g) consisting, according to its NMR spectra, of *N*,*N*-bis(cyclohexylmethyl)aniline (**7***g*) and *N*-(cyclohexylmethyl)-*N*-methylaniline (**8***g*) in a molar ratio of 3:1. Column chromatography (80 g, of silica gel; 2:1 hexane/benzene) of a crude sample (1.47 g) afforded pure **7***g* (0.38 g). The second fraction gave **8***g* (0.04 g); ^{1}H NMR δ: 0.86–1.02 (m, 2H), 1.12–1.30 (m, 3H), 1.62–1.81 (m, 6H), 2.94 (s, 3H), 3.11 (d, J = 6.7 Hz, 2H), 6.62–6.73 (m, 3H), 7.18–7.28 (m, 2H); ^{13}C NMR δ: 26.0, 26.6, 31.1, 36.9, 39.6, 59.7, 111.6, 115.4, 129.0, 149.5. Exact mass calcd. for $C_{14}H_{21}N$: 203.1674; found: 203.1674.

Preparation of N,N-*bis(1-buten-4-yl)aniline (7h)*

N,*N*-Bis(benzotriazol-1-ylmethyl)aniline (**1***a*) (10.66 g, 30 mL) dissolved in dry THF (250 mL) was added to a solution of the Grignard reagent prepared from allyl bromide (17.31 mL, 200 mmol) and magnesium turnings (6.05 g, 250 mmol) in dry ether (120 mL). The mixture was stirred and heated at reflux under argon for 50 h. The ether slowly evaporated and, after 24 h of heating, the temperature of the reaction mixture reached 60°C and then continued to grow slowly to finally reach 72°C. The reaction mixture was poured onto crushed ice (200 g) and toluene (100 mL) was added, followed by sodium bicarbonate (16.8 g, 200 mmol). The mixture obtained was stirred at 20°C for 12 h. The precipitate was filtered off and washed with ethanol (50 mL), followed by ethyl acetate (2 × 100 mL). The filtrate and the washings were collected and the organic phase was separated. The aqueous phase was washed additionally with ethyl acetate (100 mL) and the solution obtained, in ethyl acetate, was added to the main organic fractions. The toluene/ethyl acetate solution of the product mixture was then washed with 10% sodium hydroxide (200 mL), followed by water (200 mL), and dried over anhydrous potassium carbonate. The solvent was evaporated (rotary vacuum evaporator) to give almost analytically pure **7***h* (6.01 g) as a yellowish oil. The compound was characterized as its picrate (Table 1).

Sodium borohydride reduction of N,N-*bis(benzotriazol-1-ylmethyl)-2-ethylaniline. Preparation of* N,N-*dimethyl-2-ethylaniline (7i)*

A mixture of 2-ethylaniline (6.06 g, 50 mmol), benzotriazole (11.91 g, 100 mmol), 37% aqueous formaldehyde (9.12 mL, 120 mmol), and toluene (100 mL) was stirred for 2 h at 20°C and then stirred and heated under reflux for 3 h with a Dean–Stark water trap. The solvent was removed to give a clear orange oil (19.44 g). A solution of this oil (19.28 g) and sodium borohydride (1.77 g, 46.8 mmol) in 1,4-dioxane (50 mL) was heated under reflux for 4.5 h. The reaction mixture was diluted with ether (200 mL) and washed with 5% sodium hydroxide (100 mL). The organic layer was separated, washed with water (2 × 100 mL), and dried over anhydrous sodium carbonate (10 g). The solvent was evaporated to give crude **7***i* (6.16 g) as an orange liquid. The compound was characterized as its picrate (Table 1).

Preparation of 4-(phenethylamino)pyridine (3, R^1 = $PhCH_2$, Ar = 4-pyridyl) and 4-(2-methylbenzylamino)pyridine (3, R^1 = o-$CH_3C_6H_4$, Ar = 4-pyridyl)

A mixture of 4-aminopyridine (9.41 g, 100 mmol), benzotriazole (11.91 g, 100 mmol), and 37% formaldehyde (8.24 mL, 110 mmol) in toluene (100 mL) was stirred at 60°C for 1 h, followed by reflux under a Dean–Stark trap for 3 h. To the obtained suspension of 4-(benzotriazol-1-ylmethylamino)pyridine in toluene was added a solution of benzylmagnesium chloride obtained from magnesium turnings (8.50 g, 350 mmol) and benzyl chloride (34.5 mL, 300 mmol) in ether (100 mL). Evolution of heat was observed and the mixture started to boil. The mixture was stirred at reflux for 16 h and then poured into ice water (500 mL) and ammonium chloride (100 g). Acetic acid was added dropwise to the mixture until the precipitate of magnesium hydroxide dissolved. The organic layer was separated and the water phase was washed twice with ether (2 × 100 mL). The combined organic solutions were washed with water (100 mL), 10% sodium hydroxide (100 mL), and finally with water (100 mL). The solution was dried over anhydrous sodium carbonate (5 g) and the solvent was evaporated under reduced pressure. The oil obtained was dissolved in ether–hexane (50 + 50 mL) and stored at 0°C for 3 days. The deposited prisms were filtered off, washed with ether, and dried in a vacuum oven to give analytically pure 4-(2-methylbenzylamino)pyridine (3.37 g, 17%), mp 118°C; ^{1}H NMR δ: 2.35 (s, 3H), 4.30 (d, J = 5.1 Hz, 2H), 4.46 (bt, 1H), 6.46 (d, J = 6.5 Hz, 2H), 7.22 (m, 4H), 8.19 (d, J = 6.4 Hz, 2H); ^{13}C NMR δ: 18.9, 45.1, 107.6, 126.3, 127.9, 128.1, 130.6, 135.5, 136.2, 150.1, and 153.3. Anal. calcd. for $C_{13}H_{14}N_2$: C 78.75, H 7.12, N 14.13; found: C 78.50, H 7.07, N 14.09.

The filtrate and the washings were combined and stored in a freezer for 2 weeks. The crystals obtained were filtered off, washed with hexane, and dried in a vacuum desiccator at 20°C to give 4-(phenethylamino)pyridine (13.88 g, 70%), of purity about 90%; ^{1}H NMR δ: 2.91 (t, J = 7.0 Hz, 2H), 3.43 (dt, J = 6.0 and 7.0 Hz, 2H), 4.38 (bt, 1H), 6.42 (d, J = 6.4 Hz, 2H), 7.25 (m, 5H), and 8.15 (d, J = 6.4 Hz, 2H); ^{13}C NMR δ: 35.1, 43.7, 107.6, 126.7, 128.7 (4 C, *ortho* and *meta*), 138.5, 149.8, 153.2.

4-(Phenethylamino)pyridine picrate recrystallized from ethanol as orange prisms, mp 136°C. Anal. calcd. for $C_{19}H_{17}N_5O_7$: C 53.40, H 4.01, N 16.39; found: C 53.00, H 3.93, N 16.21.

Preparation of N,N-*diphenethyl-4-pyridinamine (7j)*

4-(Phenethylamino)pyridine (9.33 g, 47 mmol), benzotriazole (5.96 g, 50 mmol), and 37% formaldehyde (5.00 mL, 67 mmol) in toluene (200 mL) were stirred and heated at reflux under a Dean–Stark water trap for 18 h. Excess formaldehyde and part of the toluene were distilled off to concentrate the solution to 100 mL. To the solution was added a Grignard reagent prepared from benzyl chloride (34.5 mL, 300 mmol) and magnesium turnings (8.5 g, 350 mmol) in dry ether (80 mL). The mixture obtained was stirred at reflux (about 65°C) for 16 h and poured into ice water (500 g). Chloroform (300 mL) and sodium carbonate monohydrate (50 g) were added and the whole was stirred at 20°C for 1 h. The solution was filtered and the precipitate was washed thoroughly with chloroform (2 × 50 mL). The filtrate and the washings were washed with 10% sodium hydroxide (100 mL) and dried over anhydrous potassium carbonate. Evaporation of the solvent afforded crude *N*,*N*-diphenethyl-4-pyridineamine (21.47 g) as a brownish oil. A sample of the crude product (2.25 g) was subjected to column chromatography (silica gel, methylene chloride) to give biphenyl (0.43 g) as the first fraction. The second fraction gave *N*,*N*-diphenethyl-4-pyridinamine (**7***j*) as a colorless oil (0.49 g) (total yield 4.68 g, 33%). Amine **7***j* is characterized in Tables 1–3. The third fraction afforded the recovered starting *N*-phenethyl-4-pyridinamine (0.21 g, 22%).

Preparation of N-*methyl*-N-*phenethylaniline (7k)*

A mixture of *N*-methylaniline (10.72 g, 100 mmol), benzotriazole (11.91 g, 100 mmol), aqueous formaldehyde (37%, 9.12 mL,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

120 mmol), and toluene (100 mL) was stirred for 2 h and then heated under reflux for 3 h with a Dean–Stark water trap. The solvent was removed (rotary vacuum evaporator) to give a mixture (23.86 g) of *N*-(benzotriazol-1-ylmethyl)-*N*-methylaniline and *N*-(benzotriazol-2-ylmethyl)-*N*-methylaniline (84% and 16%, respectively, according to the NMR spectra). To a solution of benzylmagnesium chloride prepared from benzyl chloride (2.30 mL, 20 mmol) and magnesium turnings (1.23 g, 30 mmol) in ether (30 mL) was added a solution of the isomeric mixture of *N*-methyl-*N*-(benzotriazolylmethyl)anilines (2.38 g, 10 mmol) in THF (20 mL) at a rate to keep a gentle reflux. After stirring at room temperature for 24 h, the reaction mixture was poured into 10% ammonium chloride (100 mL) and extracted with toluene (100 mL, 2 × 50 mL). The combined organic solutions were washed with water (50 mL), 10% sodium hydroxide (50 mL), and again with water (2 × 50 mL), and dried over anhydrous sodium carbonate (10 g). Evaporation of the solvent gave *N*-methyl-*N*-phenethylaniline (**7***k*) as a yellow liquid. The compound was characterized as the picrate (Table 1).

Preparation of N-*butyl*-N-*phenethylaniline (7*m*)*

To a stirred solution of benzotriazole (37.65 g, 316 mmol) and aniline (29.58 g, 316 mmol) in 95% ethanol (200 mL) was added butyraldehyde (27.61 g, 379 mmol). Precipitation of a white solid occurred. The mixture was stirred at 20°C for 3 h. The precipitate formed was filtered off, washed with 1:1 ether/hexane (3 × 20 mL), and dried in a vacuum desiccator to give *N*-(1-benzotriazolylbutyl)aniline (37.66 g). To a stirred warm solution of this compound (35.00 g) in dry THF (150 mL) was added sodium borohydride (2.49 g, 65.7 mmol). The mixture was heated under reflux for 27 h. The semi-clear solution obtained was washed with 10% NaOH (100 mL) and diluted with THF (100 mL). The organic substances were extracted into chloroform (2 × 100 mL), and dried over anhydrous sodium carbonate followed by molecular sieves (3 Å). Removal of the solvent afforded *N*-butylaniline (21.80 g) as a clear yellow liquid. The ^{1}H NMR spectrum of the product was in accordance with the reported data (46).

The *N*-butylaniline obtained was *N*-(benzotriazolylmethylated) and then the adduct obtained was subjected to a Grignard reaction with benzylmagnesium chloride, applying procedures similar to those given above for preparation of **7***k*, to give *N*-butyl-*N*-phenethylaniline (**7***m*) (Table 1).

Reaction of N,N-*bis(benzotriazol-1-ylmethyl)aniline with less than an equimolar amount of isopropylmagnesium bromide*

To a stirred solution of *N,N*-bis(benzotriazol-1-ylmethyl)aniline (10.66 g, 30 mmol) in dry ether (40 mL) was added a solution of the Grignard reagent prepared from 2-bromopropane (3.75 mL, 40 mmol) and magnesium turnings (1.21 g, 50 mmol) in ether (20 mL). The mixture was stirred at 25°C for 40 h, poured into ice water (100 mL), neutralized with acetic acid, and extracted with methylene chloride (2 × 100 mL). The solution was washed with water (100 mL) followed by 10% sodium carbonate and dried over anhydrous potassium carbonate. Evaporation of the solvent gave a mixture consisting of the starting material (63% mol; a characteristic methylene singlet in the ^{1}H NMR spectrum at δ 6.22) and *N,N*-diisobutylaniline (37% mol; a characteristic methylene doublet at δ 3.15). Neither the mixed (half-reacted) product, *N*-(benzotriazol-1-ylmethyl)-*N*-isobutylaniline, nor its hydrolysis product, *N*-isobutylaniline, was detected in the reaction mixture.

Reaction of a mixture of N,N-*bis(benzotriazolylmethyl)*-p-*anisidine and* N,N-*bis(benzotriazolylmethyl)-4-chloroaniline with isopropylmagnesium bromide*

To a stirred suspension of *N,N*-bis(benzotriazolylmethyl)-*p*-anisidine (1.02 g, 2.6 mmol) and *N,N*-bis(benzotriazolylmethyl)-4-chloroaniline (1.15 g, 2.9 mmol) in dry ether (40 mL) was added an ethereal solution of isopropylmagnesium bromide (4.16 mL, 5.0 mmol). Concentration of the Grignard reagent was estimated on the basis of the volume of propane evolved after treatment of a sample of the Grignard solution with water. The reaction mixture was stirred at 25°C for 20 h. The mixture was then poured into ice water and extracted with chloroform (2 × 50 mL). The chloroform solution was washed with water and dried over anhydrous magnesium sulfate. Evaporation of the solvent afforded a semisolid material (1.20 g), which according to ^{1}H NMR consisted of *N,N*-bis(benzotriazol-1-ylmethyl)-4-chloroaniline and its Bt,Bt-1,2 isomer (total 49 mol%; the characteristic methylene singlets at δ 6.20, 6.29, and 6.48; Bt,Bt-1,1 and -1,2 isomers, respectively), *N,N*-bis(benzotriazol-1-ylmethyl)-*p*-anisidine (15 mol%; the characteristic methylene singlet at δ 6.09), *N,N*-diisobutyl-4-chloroaniline (8 mol%; characteristic methylene doublet at δ 3.11), and *N,N*-diisobutyl-*p*-anisidine (28 mol%; characteristic doublet at δ 3.02).

Reaction of N,N-*bis(benzotriazolylmethyl)aniline with 1,4-di(bromomagnesio)butane*

A mixture of aniline (9.31 g), benzotriazole (23.83 g), and toluene (150 mL) heated to about 60°C turned into a clear solution. After 1 h, 37% aqueous formaldehyde was added and the stirring at 60°C was continued for an additional hour, followed by reflux under a Dean–Stark water trap for 2 h. To this solution was added the Grignard reagent prepared from 1,4-dibromobutane (43.19 g, 200 mmol) and magnesium turnings (12.15 g, 500 mmol) in dry ether (150 mL). Evolution of heat and formation of precipitate was observed. The mixture obtained was refluxed for 3.5 h under argon. The reaction mixture was poured into ice water (500 mL), neutralized with acetic acid, and extracted with ether (2 × 250 mL). The ethereal solution was washed with water (500 mL) followed by 10% sodium hydroxide (300 mL) and water (500 mL), and dried over anhydrous magnesium sulfate (40 g). Evaporation of the solvent (rotary vacuum evaporator) afforded a dark oil (10.50 g), which was partially separated by distillation. A fraction of yellow liquid (0.68 g, bp 68–75°C/0.03 Torr; 1 Torr = 133.3 Pa) was subjected to column chromatography (90 g silica gel, 2:1 hexane/benzene) to give pure *1-phenylhexahydroazepine* **9***a* (0.02 g) as a yellow liquid; ^{1}H NMR δ: 1.51–1.59 (m, 4H), 1.74–1.83 (m, 4H), 3.45 (t, *J* = 5.9 Hz, 4H), 6.62 (t, *J* = 9 Hz, 1H), 6.69 (d, *J* = 7.9 Hz, 2H); ^{13}C NMR δ: 27.1, 27.8, 49.0, 111.1, 115.1, 129.2, 148.9. Exact mass calcd. for $C_{12}H_{17}N$: 175.1361; found: 175.1354. The second fraction gave pure N-*methyl*-N-*pentylaniline (26)* **10***a* (0.02 g) as a colorless liquid; ^{1}H NMR δ: 0.90 (t, *J* = 6.8 Hz, 3H), 1.25–1.41 (m, 4H), 1.57 (quintet, *J* = 7.3 Hz, 2H), 2.92 (s, 3H), 3.29 (t, *J* = 7.4 Hz, 2H), 6.63–6.75 (m, 3H), 7.19–7.28 (m, 2H); ^{13}C NMR δ: 14.1, 22.6, 26.3, 29.4, 38.2, 52.8, 112.0, 115.7, 129.1, 149.4. Exact mass calcd. for $C_{12}H_{19}N$: 177.1518; found: 177.1522. The third fraction gave pure N-*pentylaniline (47)* (0.03 g) as a colorless liquid; ^{1}H NMR δ: 0.92 (t, *J* = 6.9 Hz, 3H), 1.32–1.41 (m, 4H), 1.61 (quintet, *J* = 2.6 Hz, 1H), 3.09 (t, *J* = 7.1 Hz, 2H), 3.58 (br, 1H), 6.59 (d, *J* = 7.6 Hz, 2H), 6.68 (t, *J* = 7.3 Hz, 1H), 7.17 (t, *J* = 7.4 Hz, 2H); ^{13}C NMR δ: 14.0, 22.5, 29.2, 29.3, 43.9, 112.6, 117.0, 129.2, 148.5. Exact mass calcd. for $C_{11}H_{17}N$: 163.1361; found: 163.1347.

Reaction of N,N-*bis(benzotriazol-1-ylmethyl)-4-toluidine with 1,4-di(iodomagnesio)butane*

A mixture of *p*-toluidine (1.07 g, 10 mmol), 37% aqueous formaldehyde (2.3 mL, 30 mmol), benzotriazole (2.38 g, 10 mmol), and toluene (50 mL) was stirred at 60°C for 1 h, followed by reflux under a Dean–Stark water trap for 11 h. The obtained solution of *N,N*-bis(benzotriazolylmethyl)-4-toluidine was added dropwise to a solution of the Grignard reagent obtained from 1,4-diiodobutane (6.20 g, 20 mmol) and magnesium turnings (1.22 g, 50 mmol) in ether (140 mL). The mixture obtained was refluxed under argon for 21 h, then poured into ice water (100 mL), and neutralized with acetic acid. The organic layer was separated, washed with water (100 mL) followed by 10% NaOH (2 × 100 mL), and dried over anhydrous sodium carbonate (25 g) for 10 h. After the solvent was removed, a yellow liquid (2.72 g) was obtained.

A sample of the reaction mixture (1.79 g) was separated by column chromatography (80 g silica gel, 1:1 hexane/benzene) to give as the first fraction N,N-*diamyl-4-toluidine* **11** (0.13 g); ^{1}H NMR δ: 0.88 (t, *J* = 6.5 Hz, 6H), 1.20–1.35 (m, 8H), 1.5–1.6 (m, 4H), 2.23 (s, 3H), 3.21 (t, *J* = 7.1 Hz, 4H), 6.56 (d, *J* = 8.5 Hz, 2H), 7.00

(d, J = 8.3 Hz, 2H). ^{13}C NMR δ: 14.1, 20.1, 22.7, 29.4, 31.9, 51.3, 112.1, 124.3, 129.7, 146.2. Exact mass calcd. for $C_{17}H_{29}N$: 247.2300; found: 297.2293. The second fraction gave *1-(p-methylphenyl)hexahydroazepine* **9***b* (0.11 g); ^{1}H NMR δ: 1.50–1.60 (m, 4H), 1.72–1.82 (m, 4H), 2.23 (s, 3H), 3.41 (t, J = 5.9 Hz, 4H), 6.60 (d, J = 8.6 Hz, 2H), 7.00 (d, J = 8.7 Hz, 2H); ^{13}C NMR δ: 20.2, 27.2, 27.8, 49.2, 111.2, 124.0, 129.8, 146.8. Exact mass calcd. for $C_{13}H_{19}N$: 189.1518; found: 189.1514. The third fraction gave *N-amyl-N-methyl-p-toluidine* **10***b* (0.01 g); ^{1}H NMR δ: 0.90 (t, J = 6.9 Hz, 3H), 1.24–1.40 (m, 4H), 1.50–1.65 (m, 2H), 2.23 (s, 3H), 2.88 (s, 3H), 3.17–3.29 (m, 2H), 6.54–6.66 (m, 2H), 6.99–7.07 (m, 2H); ^{13}C NMR δ: 14.1, 20.2, 22.6, 26.2, 29.7, 38.4, 53.1, 112.6, 125.1, 129.6, 147.5. Exact mass calcd. for $C_{13}H_{21}N$: 191.1674; found: 191.1668. The fourth fraction gave a mixture of oligomers (0.04 g) in which **12***b* dominated; ^{1}H NMR δ: 0.85–0.93 (m, 6H), 1.23–1.36 (m, 16H), 1.46–1.60 (m, 12H), 2.23 (s, 9H), 3.14–3.25 (m, 12H), 6.55–6.64 (dd, 6H), 7.00 (d, J = 8.6 Hz, 6H).

Une étude théorique (SCF PS-HONDO + CI) de la stabilité de l'anion tribromure Br_3^- a été réalisée. À partir de considérations orbitalaires qualitatives et de calculs MNDO, nous proposons une première approche du mécanisme de substitution électrophile par Br_3^-. Il implique une attaque axiale de l'ion linéaire Br_3^-, dont les sites les plus électrophiles sont les atomes de brome terminaux, bien qu'ils portent une charge négative. Ce modèle suggère des arguments rendant compte de la sélectivité en position *para* observée expérimentalement. Des calculs effectués sur une série de systèmes MBr_3 mettent en évidence l'importance de la nature du contre-ion pour la vitesse et la sélectivité de la réaction.

Mots clés : bromation, tribromure, mécanisme, parabromophénol.

A theoretical study (SCF PS-HONDO + CI) of the stability of the tribromide anion Br_3^- has been carried out. On the basis of qualitative MO arguments and MNDO calculations, we propose a first approach to the mechanism of electrophilic aromatic substitution by Br_3^-. It involves an axial attack of linear Br_3^-, the most electrophilic sites of which are terminal bromine atoms, although they bear a negative charge. This model suggests some arguments to explain the *para* versus *ortho* selectivity experimentally observed. Calculations performed on a series of MBr_3 systems emphasize the importance of the countercation for the rate of the reaction as well as for its selectivity.

Key words : bromination, tribromide, mechanism, parabromophenol.

Introduction

Dans un précédent mémoire (1), nous avons montré tout l'intérêt d'utiliser le tribromure de tétrabutylammonium ($TBABr_3$) comme agent très sélectif de bromation en *para* de composés aromatiques activés. Cette réaction s'effectue dans des conditions douces avec d'excellents rendements et inhibition totale des polybromations quand le solvant employé, dont le rôle est essentiel, ne présente aucun caractère acide ou basique. La plupart des auteurs (2) supposaient une dissociation préalable de l'ion Br_3^- avec formation de dibrome selon :

$$Br_3^- \rightleftharpoons Br_2 + Br^-$$

le dibrome libéré étant alors l'agent réel de la bromation. Dans les solvants protiques ou basiques, ou si le milieu réactionnel est acidifié, l'équilibre est fortement déplacé vers la formation du dibrome (1) qui est alors responsable de la bromation. Par contre, dans les solvants sans caractère acido-basique, tels que le chloroforme, l'acétonitrile ou le tétrachlorure de carbone, les mesures de la constante de dissociation de l'anion Br_3^- ont montré que cet ion est très peu dissocié. En outre, il a été prouvé (3) que si le pouvoir électrophile du dibrome est plus élevé que celui de Br_3^-, ce dernier permet des bromations plus sélectives. En nous basant sur cette importante sélectivité de l'attaque électrophile, quand $TBABr_3$ est employé, nous pensons que l'ion tribromure est bien l'agent bromant.

En utilisant le tribromure de pyridinium, Sharma *et al.* (4) ont postulé que Br_3^- et Br_2 réagissaient tous les deux en concurrence sur un même composé phénolique et se fixaient sur des pôles différents : Br_3^- bromerait en *para*, tandis que Br_2 le ferait en *ortho*. L'explication, considérant principalement la taille des entités réactives et l'encombrement respectif des positions *ortho* et *para*, ne nous semble pas entièrement satisfaisante en l'absence de données sur la géométrie d'approche des réactifs.

Nous pensons que des calculs de répartition de charges et la théorie des orbitales moléculaires peuvent permettre une approche plus satisfaisante du mécanisme de la réaction de bromation des composés aromatiques par l'ion tribromure.

Avant d'aborder cette étude, il est nécessaire de préciser la nature du réactif, Br_3^-, et de rappeler certains résultats déjà établis.

La structure et les propriétés physico-chimiques des polyhalogénures d'ammonium ont déjà fait l'objet de nombreuses études. Il s'agit de composés ioniques (5) formés d'un cation R_4N^+ et d'un anion trihalogénure X_3^-. Certains tribromures ont déjà été étudiés par diffraction X (6*a*–*c*) et par spectroscopie de résonance nucléaire quadrupolaire (6*d*, 7). Ces examens ont confirmé que ces composés sont ioniques, que le groupe Br_3^- est linéaire, et que ses liaisons sont plus longues (2,78 Å) que dans la molécule Br_2 (2,28 Å), mais la distribution de la densité électronique dans ces anions n'est pas encore bien précisée. De plus, dans les études cristallographiques, les valeurs trouvées pour l'ion Br_3^- associé au cation R_4N^+ à l'état solide, pourraient ne pas refléter exactement celles de l'ion libre Br_3^- en solution. Ces résultats ont d'ailleurs été l'objet d'avis divergents (8). Il nous semble normal d'avoir affaire à des anions Br_3^- plus ou moins symétriques selon leur degré d'association

avec le cation correspondant. En outre, il existe différentes formes cristallines qui possèdent une structure symétrique ou non symétrique, avec une certaine possibilité d'ambiguïté pour les deux symétries.

En ce qui nous concerne, nous avons déjà mis en évidence la stabilité de $TBABr_3$, supérieure à celle des tribromures de pyridinium et de triméthylphénylammonium, en phase gazeuse, dans un spectromètre de masse. Nous avons identifié la présence de l'ion Br_3^- (9). Dans les conditions de l'ionisation chimique par des ions négatifs, $TBABr_3$ présente un plasma d'anions Br_3^- majoritaires qui se sont révélés être d'excellents agents bromants, d'une façon sélective, de phénols et d'amines aromatiques (10). Cette analogie des résultats en phase gazeuse et condensée permet de minimiser le rôle du solvant, dans le cas où il assure la stabilité de Br_3^-, et justifie une première approche théorique du mécanisme de cette réaction.

Résultats

1. Description de l'ion Br_3^- (méthode PS-HONDO)

(a) Choix de la méthode de calcul

L'obtention de données quantitatives avec une marge d'erreur acceptable pour des espèces telles que l'anion Br_3^-, se heurte à deux difficultés :

Le nombre des électrons présents dans le système rend difficile l'utilisation d'une méthode du type *ab initio* auto-cohérente (SCF) classique. Aussi avons-nous choisi une méthode dans laquelle seuls les électrons de la couche externe sont traités *ab initio*, les électrons internes étant remplacés par un potentiel (11). C'est la méthode des pseudo-potentiels PS-HONDO 1 (12).

Une autre difficulté provient de la présence d'espèces chargées négativement qui impliquent la présence d'orbitales diffuses occupées. Nous avons donc enrichi la base interne du programme HONDO d'un ensemble d'orbitales *s*, *p*, *d*, soit finalement 11 Gaussiennes contractées en deux orbitales *s*, deux orbitales *p*, et une orbitale *d*. L'étape SCF a été suivie d'une interaction de configuration (IC) suivant la méthode des perturbations de Möller–Plesset (13) que a été réalisée à l'aide du programme CIPSI (14).

(b) Résultats

Les résultats sont présentés dans le tableau 1 : les longueurs de liaison ont été optimisées au niveau SCF pour Br_2, et Br_3^- avec une géométrie linéaire, qui est la plus stable, comme le montre la figure 1. La distance internucléaire d'équilibre calculée pour Br_2 est de 2,33 Å contre une valeur expérimentale de 2,28 Å (14).

Les caractéristiques géométriques sont en accord avec les données cristallographiques (6). Il est important de noter que les

TABLEAU 1. Energie de référence des systèmes

	Longueur de la liaison Br—Br (Å)	Energie (ua) SCF	Energie (ua) SCF + IC
Br^-		−13,09958	−13,18905
Br—Br	2,33	−26,04177	−26,21403
$(Br—Br—Br)^-$	2,67	−39,17532	−39,43703

FIG. 3. Approches modèles de la position *para* du phénol. Les valeurs des paramètres optimisés correspondent à une distance C—Br de 2 Å. Les autres paramètres ont été maintenus constants avec les valeurs suivantes : C—C = 1,43 Å, C—O = 1,36 Å, O—H = 0,96 Å, C—H = 1,08 Å, C—O—H = 110°.

sommets 1 et 3 portent une charge (charge atomique nette résultant du calcul SCF) légèrement supérieure à un demi-électron et que, corrélativement, le brome central est très légèrement positif. Si la molécule se plie, on prévoit une diminution des charges négatives aux extrémités de la molécule : à la limite, pour un angle de 60°, on aurait une symétrie d'ordre 3 et chaque brome porterait 1/3 de charge électronique négative. Neanmoins cet effet est peu marqué au voisinage de 180°, puisque jusqu'à 90° la répartition des charges n'est pas profondément perturbée. L'énergie de stabilisation calculée de Br_3^- par rapport à (Br_2 + Br^-) est de 89 kJ mol^{-1}.

(c) Aspect orbitalaire de la réactivité de Br_3^- ; comparaison avec Br_2

On sait que les interactions acido-basiques peuvent être classées en deux catégories : les interactions « dures », de type électrostatique, et les interactions « molles » de type orbitalaire.

La charge positive de l'atome central (+0,06) est trop faible pour que ce site présente un caractère électrophile dur notable.

Si on examine maintenant les orbitales frontalières de Br_3^- (figure 2), on constate que la plus basse orbitale vacante (BV) est antisymètrique : elle ne peut donc présenter de recouvrement important avec un nucléophile, symbolisé par une orbitale atomique (OA) *p*, que le long de l'axe moléculaire. L'éventualité d'une intervention de la seconde OM vacante doit être écartée, compte tenu de son niveau d'énergie trop élevé. Ainsi, Br_3^- présente deux sites acides mous en 1 et 3. Comparée à celle de Br_2 (voir figure 2), l'orbitale BV de Br_3^- est sensiblement plus basse en énergie. Or Br_2 est considéré comme un acide mou dans les réactions envisagées, et de ce point de vue, Br_3^- se présenterait donc comme un acide plus mou que Br_2.

L'examen des orbitales moléculaires conduit donc à un résultat apparemment paradoxal : Br_3^- ne manifeste des propriétés électrophiles qu'au niveau des atomes terminaux qui sont chargés négativement.

II. Étude de la réactivité de l'ion Br_3^- sur le phénol (méthode MNDO)

Afin d'étayer les conclusions suggérées par l'examen des OM de l'ion tribromure et d'interpréter les principaux résultats

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12

expérimentaux, un certain nombre de calculs modèles ont été effectués.

En raison de la taille du système étudié, la méthode semi-empirique MNDO dans sa version 4.00 (16) a été choisie. Nous avons utilisé les paramètres atomiques publiés par les auteurs suivants : Dewar et Thiel (17) pour C, H, N, O; Dewar et Healy (18) pour Br; Thiel (19) pour Li. Il ne faut pas attendre d'une telle technique une bonne précision sur l'énergie absolue, en l'absence, notamment, de fonctions diffuses et de corrélation électronique : c'est pourquoi nous avons évité d'argumenter à partir de données thermodynamiques que nous n'avons signalées qu'exceptionnellement et à titre purement indicatif. A fortiori, nous n'avons pas tenté de déterminer la structure et l'énergie des états de transition. Ceci, outre les causes d'erreur précédentes, eût nécessité l'optimisation complète des nombreux paramètres géométriques; d'autre part, certaines étapes de la réaction impliquent des séparations de paires d'ions dont l'énergie, en l'absence de solvant, serait très largement surévaluée. Tout cela rendrait très aléatoire la validité des résultats.

Nous pensons, en revanche, que les variations d'énergie pour diverses configurations relatives des réactifs sont un guide semi-quantitatif utile pour l'élucidation de ce mécanisme.

(a) Réactivité comparée des pôles 1 et 2 de l'ion tribromure et géométrie optimale d'approche des réactifs

Nous avons effectué une simulation du début de la coordonnée réactionnelle correspondant à l'approche en *para* du phénol des pôles 1 et 2 de Br_3^-, respectivement. Pour cela, nous avons fait varier la distance C(4)—Br(1) ou C(4)—Br(2) de 2,5 à 2,0 Å, en optimisant les paramètres géométriques des atomes les plus directement impliqués (figure 3, structures **1** et **2**). À titre indicatif, la distance C(4)—Br a été trouvée égale à 1,91 Å dans le «complexe σ» $(Br\phi OH)^+$. On constate (figure 4) que l'approche du pôle 1 de Br_3^- est beaucoup plus aisée que celle du pôle 2; le gain d'énergie atteint plus de 80 kJ mol^{-1} à 2 Å. De plus, Br_3^- adopte une géométrie grossièrement perpendiculaire au plan du cycle ce qui assure un bon recouvrement de sa BV avec la HO du phénol, en éloignant autant que possible de ce dernier les atomes Br(2) et Br(3), ce qui minimise les répulsions entre orbitales occupées des deux entités. Ainsi se trouve confirmée l'hypothèse selon laquelle ce sont les atomes terminaux du tribromure qui, bien que chargés négativement, présentent un caractère électrophile. La conséquence immédiate est que l'on peut attendre de cet ion une réactivité sensiblement plus faible que celle du dibrome. L'approche de Br_2, réalisée dans les mêmes conditions, le montre clairement (figure 4).

Une troisième géométrie d'approche est envisageable, qui pourrait justifier la sélectivité en *para* par l'intervention d'une liaison hydrogène Br—H—O, selon le mécanisme de la figure 5. Nous avons donc calculé l'énergie du système **5** (figure 3), dans lequel la distance C(4)—Br(1) (2,5 Å) et la distance H—Br(3) (3,0 Å, valeur justifiée plus loin) ont été maintenues constantes, alors que les distances Br—Br et tous les angles et dièdres de la chaîne C(4)—Br(1)—Br(2)—Br(3)—H ont été optimisés. L'énergie de ce système se situe à 76,7 kJ mol^{-1} au dessus de celle des réactifs à distance infinie, soit 23,6 kJ mol^{-1} au dessus de la géométrie d'approche la plus favorable **1**, pour une même distance C(4)—Br de 2,5 Å. Ce mécanisme apparait donc comme improbable.

La géométrie optimale du complexe phénol–tribromure est plane (structure **6** de la figure 3), avec une distance H—Br de 3 Å. La liaison hydrogène apporte dans cette structure une stabilisation calculée de 16,7 kJ mol^{-1}. Cette valeur est très insuffisante pour compenser la perte de coplanéité du groupement phénol (6,27 kJ mol^{-1}, calcul MNDO), la répulsion entre les systèmes du phénol et de l'ion tribromure, et la diminution du recouvrement entre la BV du tribromure et la HO du phénol imposés par la structure **5**.

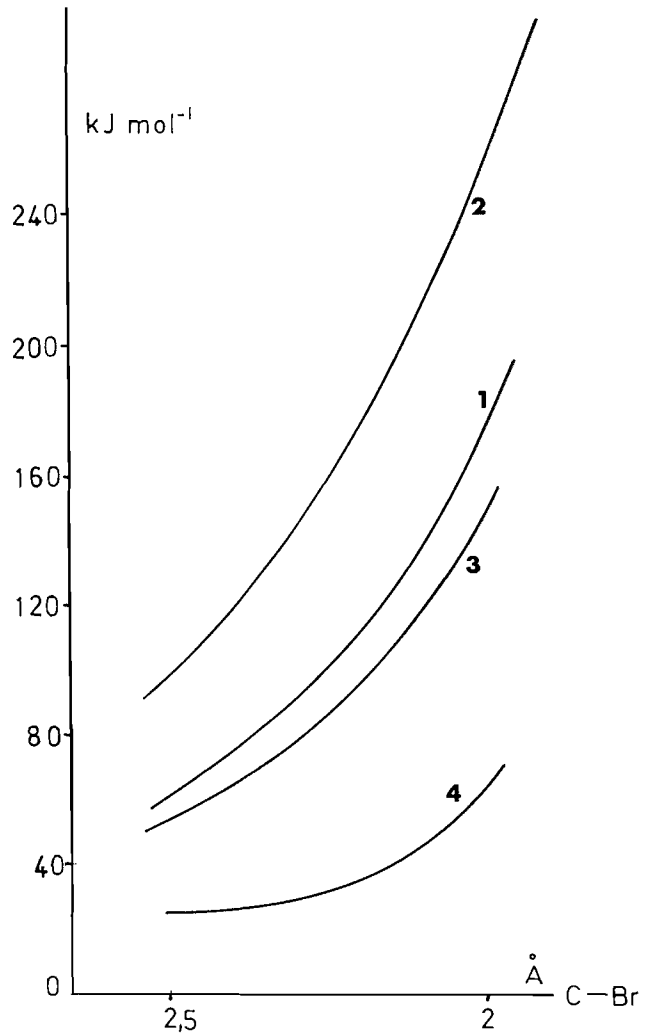

FIG. 4. Variation de l'énergie MNDO des structures 1–4 (figure 3) en fonction de la distance C—Br. L'origine des énergies correspond aux deux réactifs à distance infinie.

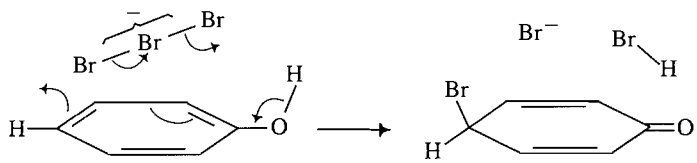

FIG. 5. Mécanisme concerté faisant intervenir une liaison hydrogène.

(b) Rôle du contre-ion ou de molécules polaires

La figure 6 rassemble les résultats des calculs MNDO de Br_3^- et de systèmes MBr_3 où M = H^+, Li^+, H_2O, NH_4^+, et $(CH_3)_4N^+$. L'effet de ces ions ou entités polaires est d'affaiblir la liaison Br(2)—Br(3) qui s'allonge de 2,25 Å (valeur optimisée pour Br_3^-) à 2,47 Å quand M = H^+. De façon concomitante, la liaison Br(1)—Br(2) se raccourcit jusqu'à 2,18 Å, tendant vers 2,17 Å (valeur optimisée pour Br_2). Il faut noter que, selon ce calcul, Br_3H ne se dissocie pas spontanément en HBr + Br_2; cette réaction ne demande cependant qu'une faible énergie (19,6 kJ mol^{-1}). (Expérimentalement, on

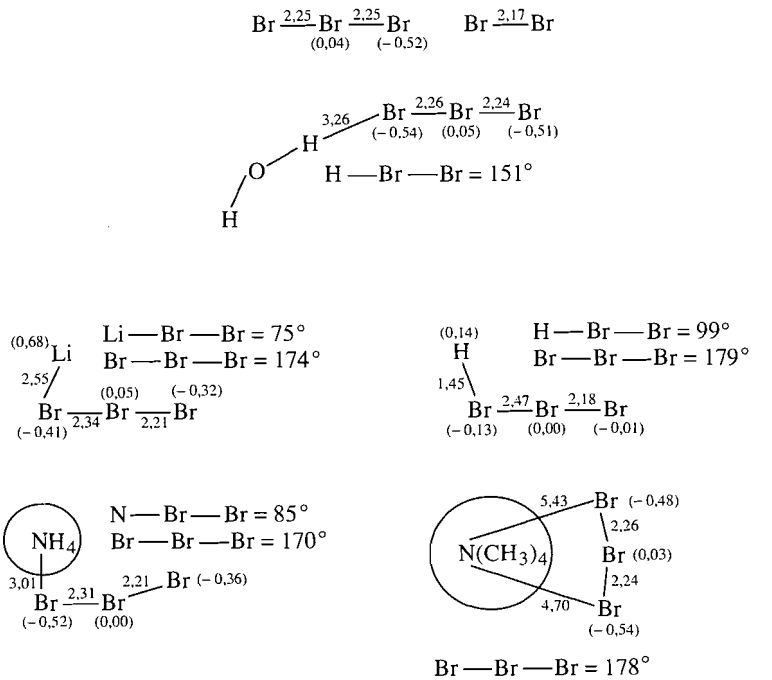

FIG. 6. Structures optimisées (MNDO) de systèmes du type MBr_3. Les charges atomiques nettes résultant du calcul SCF-MNDO sont indiquées entre parenthèses.

observe une libération de Br_2 par Br_3^- en solution acide.) À l'inverse, un gros cation, comme le tétraméthylammonium, ne perturbe que faiblement l'entité Br_3^- et s'associe de façon pratiquement symétrique avec les deux bromes terminaux.

Afin de déterminer le rôle du contre-ion dans la réactivité de Br_3^-, nous avons analysé le système $LiBr_3$ + ϕOH dans l'approche optimale (structure **3** de la figure 3 et de la figure 4). Le cation lithium (17) a été choisi en raison de son pouvoir polarisant élevé, afin d'exalter les différences éventuelles avec Br_3^- seul, modèle de MBr_3 où M serait le cas limite du très gros cation (situé à l'infini).

Nous constatons que l'approche est plus facile que dans le cas de Br_3^- seul : ceci était prévisible si on remarque (figure 6) que la présence de Li^+ diminue la charge négative de Br(1). Ensuite, la structure **3** (figure 3) montre que la liaison Br(2)—Br(3) s'allonge sensiblement, avec 2,45 Å contre 2,34 Å dans $LiBr_3$. La rupture de cette liaison ne demande plus qu'une énergie très faible (7,5 kJ mol^{-1}). En revanche, la structure **1** (figure 3) présente une distance Br(2)—Br(3) de 2,24 Å pratiquement inchangée par rapport à Br_3^-. Au contraire, c'est la liaison Br(1)—Br(2) qui tend, dans ce dernier cas, à s'affaiblir.

Ainsi, si on assimile la coordonnée réactionnelle à la distance C(4)—Br(1), il ressort que le système contenant un petit cation tend à se comporter, dès le début de la réaction, comme Br_2 + ϕOH.

À l'inverse, les systèmes à gros cations ne tendent pas à la formation de Br_2. Dans ce cas, le départ de $Br(3)^-$, d'une part est donc plus tardif, et d'autre part entraîne une inversion de polarisation spectaculaire du groupement Br(1)—Br(2) (cf. structure **4**, figure 3), de sorte que le départ des ions $Br(3)^-$ et $Br(2)^-$ est probablement quasi-synchrone. On peut raisonnablement supposer que, bien que le complexe σ $(Br\phi OH)^+$ soit commun aux bromations par Br_2 et par Br_3^-, dans le cas de Br_3^- isolé ou avec un contre-ion peu polarisant, l'étape cruciale est la rupture de Br(2)—Br(3); en revanche, lors de la bromation par Br_2 ou par Br_3^- en présence d'un cation fortement polarisant, cette étape serait la rupture de Br(1)—Br(2). Bien entendu,

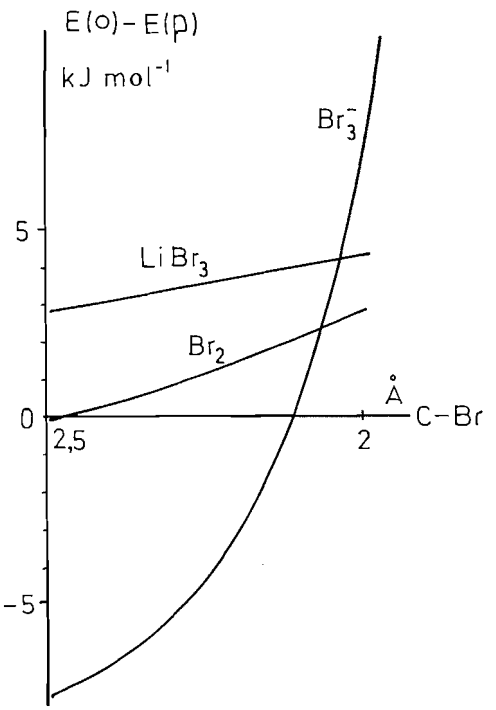

FIG. 7. Différence d'énergie calculée (MNDO) entre les approches optimales des pôle *ortho* et *para* de Br_3^-, Br_3Li et Br_2, en fonction de la distance C—Br.

avec des cations intermédiaires, un spectre d'états de transition compris entre ces deux cas limites peut être attendu.

Ainsi, plus le pouvoir polarisant du cation augmente, plus la réaction ressemblera à celle du dibrome lui-même, avec pour conséquences principales la perte de sélectivité et l'augmentation de la vitesse.

(c) Sélectivité ortho/para

L'étude théorique de ce point est beaucoup plus délicate : il

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

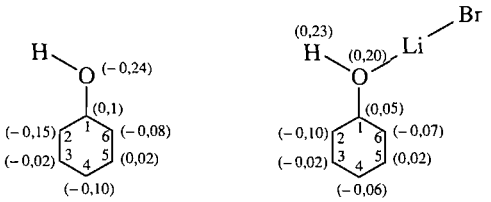

FIG. 8. Charges nettes calculées (MNDO) pour la molécule de phénol et l'agrégat phénol + LiBr.

suffit en effet de moins de 10 kJ mol^{-1} de différence d'énergie d'activation entre deux réactions concurrents pour assurer une très large sélectivité.

Les calculs MNDO montrent, à une distance C(4)—Br(1) de 2,0 Å, que l'approche de Br_3^- est plus facile en position *para* qu'en position *ortho*, la différence étant de 6,9 kJ mol^{-1}. Ce résultat est conforme aux données expérimentales et d'un ordre de grandeur satisfaisant, alors que l'état de transition n'est pas encore atteint. Néanmoins, il doit être considéré avec prudence, compte tenu du fait que tous les paramètres n'ont pas été optimisés. Plus que les valeurs absolues de l'énergie, nous considérons que le gradient énergétique en début de réaction est un élément de discussion utile. Nous avons donc porté, figure 7, la différence d'énergie entre les approches en *ortho* et *para* des trois entités Br_3^-, $LiBr_3$ et Br_2, pour une distance C—Br(3) variant de 2,5 à 2,0 Å. Les paramètres optimisés sont ceux présentés sur la structure **1** (figure 3), pour l'approche *para*, et les paramètres correspondants, pour l'approche *ortho*. Nous avons cependent, en outre, optimisé l'angle dièdre C(2)—C(1)—O—H pour permettre une éventuelle stabilisation électrostatique entre Br(1) et l'atome d'hydrogène de la fonction phénol, lors de l'approche en *ortho*.

Deux remarques peuvent être faites.

(i) La géométrie optimale de l'approche qui fait intervenir le brome terminal et une conformation de Br_3^- quasi perpendiculaire au plan du cycle amène à considérer comme secondaire le rôle des effets stériques lorsqu'un petit contre-ion est utilisé. En effet, dans ce cas, il se forme une liaison localisée avec un seul des atomes de brome terminaux, laissant l'autre disponible (cf. figure 7). En revanche, un gros cation comme $(CH_3)_4N^+$ s'associe presque symétriquement avec les deux bromes terminaux, augmentant l'encombrement stérique, et favorisant ainsi la substitution en *para*.

(ii) Si on considère (figure 7) la différence d'énergie des approches *para* et *ortho* de Br_3^- en fonction de la distance C—Br, on constate qu'il semble exister une corrélation entre la sélectivité et la charge du brome terminal. Le gradient des courbes obtenues croît en effet de Br_2 à $LiBr_3$ et à Br_3^-, ce qui montre que les interactions électrostatiques jouent également un rôle dans la sélectivité. L'examen des charges nettes calculées du phénol (MNDO, figure 8) montre une situation complexe. Le pôle le moins chargé est le carbone 6 *ortho*. En fait, pour Br_3^- isolé, C(2) est préféré à C(6) par suite de la possibilité d'une interaction stabilisante avec l'hydrogène phénolique. Celui-ci tend en effet à sortir du plan du cycle pour se rapprocher de Br(1). C'est d'ailleurs ce qui explique qu'au début de l'approche, vers 2,5 Å (figure 7), le pôle 2 est favorisé par rapport au pôle *para* lui-même, cette préférence disparaissant si on bloque l'hydrogène phénolique en position *anti* par rapport à C(2). Quand la distance C—Br atteint environ 2 Å, le pôle *ortho* se trouve défavorisé par les interactions du brome terminal avec C(2) et l'oxygène fortement négatif.

Ces deux points sont en accord avec les résultats expérimentaux obtenus par l'action de $TBABr_3$ en présence de LiBr, en milieu biphasique : la sélectivité au profit du pôle *para* diminue (*para* : *ortho* = 78 : 22). Le cation lithium peut avoir trois effets allant dans ce sens. Par association avec Br_3^-, il diminue la charge du brome terminal et le dégage de la proximité du gros cation TBA^+; par association avec le phénol selon $(\phi\text{-OHLi})^+$ Br^-, il diminue les charges négatives sur l'ensemble de la molécule de phénol (figure 8), en particulier en position 2 et sur l'atome d'oxygène.

Conclusion

La structure orbitalaire de l'anion tribromure montre que les pôles terminaux, quoique chargés négativement, sont les plus électrophiles. Cette considération qualitative est corroborée par les calculs modèles (MNDO) des systèmes correspondant aux deux approches des pôles 1 et 2 du tribromure de la position *para* du phénol. Cette situation paradoxale explique en premier lieu la lenteur de la bromation du phénol par les tribromures, comparée à la bromation par le dibrome. La nature du contre-ion apparaît comme très importante du point de vue de la vitesse et de la sélectivité. Un cation fortement polarisant diminue la charge négative du pôle électrophile et favorise une scission précoce de Br_3^- en Br^- et Br_2, la réaction se rapprochant alors de celle du dibrome lui-même. Inversement, un cation volumineux, peu polarisant, diminue la vitesse de réaction, retarde la libération du premier ion Br^-, et favorise la sélectivité en *para* en exaltant les interactions électrostatiques.

La géométrie préférentielle d'attaque de Br_3^-, pratiquement perpendiculaire au plan du phénol, semble minimiser l'importance de facteurs stériques, qui demeurent ainsi comparables à ceux du dibrome. Ces facteurs peuvent cependant être indirectement invoqués en présence d'un gros cation qui encombre simultanément les deux pôles électrophiles de l'ion tribromure, ce qui favorise aussi la bromation en position *para*.

Remerciements

Nous remercions le Pr. W. Thiel (Bergische Universität Gesamthochschule, Wuppertal) pour nous avoir communiqué, avant publication, les paramètres du lithium.

Dimethyltitanocene is an excellent catalyst for the redistribution of alkoxy- and siloxyhydrosilanes. The redistribution reactions of triethoxysilane, diethoxymethylsilane, 1,3,5,7-tetramethylcyclotetrasiloxane, pentamethyldisiloxane, and H—$(SiMe_2O)_n$—$SiMe_2H$ (n = 1 to 3) are described. The mechanism of these reactions is discussed in terms of TiH mediated displacements. The possibility of both Ti(III) and Ti(IV) mediated displacements are considered and a mechanism involving the former, which fits all of the experimental data, is proposed.

Key words: siloxanes, alkoxysilanes, redistribution, catalysis, dimethyltitanocene.

SHIXUAN XIN, CLARE AITKEN, JOHN F. HARROD, YING MU et E. SAMUEL. Can. J. Chem. **68**, 471 (1990).

Le diméthyltitanocène est un excellent catalyseur pour la redistribution des alcoxy- et siloxyhydrosilanes. On décrit les réactions de redistribution du triéthoxysilane, du diéthoxyméthylsilane, du 1,3,5,7-tétraméthylcyclotétrasiloxane, du pentaméthyldisiloxane et des H—$(SiMe_2O)_n$—$SiMe_2H$ (n = 1 à 3). On discute du mécanisme de ces réactions en fonction de déplacements effectués sous l'influence du TiH. On a considéré la possibilité que les déplacements s'effectuent sous l'influence du Ti(III) ainsi que du Ti(IV) et on propose une mécanisme impliquant le premier qui permet d'expliquer l'ensemble des données expérimentales.

Mots clés : siloxanes, alcoxysiloxanes, redistribution, catalyse, diméthyltitanocène.

[Traduit par la revue]

Introduction

We have recently described the use of dimethyltitanocene, **1**, as a catalyst for the oligomerization of organosilanes (1). In the course of a wider study of the reactions of silicon hydrides with group 4 metallocenes and their derivatives, we have now found that **1** is also a very effective catalyst for the redistribution of alkoxy- and siloxysilanes. The catalysis of siloxane redistribution by platinum group metal complexes has been previously studied in detail by Curtis *et al.* (2).

In this paper we describe the reactions of a number of alkoxy and siloxysilanes with **1** and show how these reactions may be exploited for the synthesis of polysiloxanes.

Results

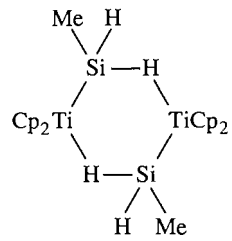
Reactions of alkoxysilanes with dimethyltitanocene

Commercial trimethoxysilane is usually deliberately contaminated with small amounts of chlorosilanes to inhibit the slow but dangerous disproportionation to methylsilicate and silane. These contaminants are difficult to remove and impaired our attempts to identify the products resulting from reaction of **1** with trimethoxysilane. We therefore attempted to use **1** to scavenge the active chlorine from a sample of trimethoxysilane. As long as the amount of **1** was less than sufficient to remove all active chlorine the strategy worked and it was rapidly converted to insoluble dichlorotitanocene (identified by comparison of its IR spectrum with that of an authentic sample). If the amount of **1** exceeded the amount necessary to remove all of the active chlorine, reduction of the excess **1** to the previously reported blue–black titanocene(III) complexes occurred (1, 3). These reduced titanocene species proved to be a potent catalyst for the disproportionation reaction and the trimethoxysilane was rapidly and completely converted to methylsilicate and silane.

Reaction of diethoxymethylsilane with a catalytic amount of **1** led to the rapid conversion of the reactant to triethoxymethylsilane and methylsilane, according to reaction [1]. When the

[1] $3\,(EtO)_2MeSiH \longrightarrow MeSiH_3 + 2\,(EtO)_3MeSi$

Cp_2TiMe_2 reaction was carried out on a synthetic scale with a 1:2 ratio of **1** to diethoxymethylsilane, dark blue needles of what appeared to be a pure compound crystallized out from the reacting solution. The crystals were slightly soluble in toluene-d_8 and the dark blue solution gave an ^{1}H-NMR spectrum corresponding to a mixture of the *cis*- and *trans*-isomers of the dimer **2**. The assignment was made by comparison of the spectrum with that of a sample of **2**, made by reaction of methylsilane with **1**, and by comparison with the spectrum of the previously characterized phenylsilyl analogue (1).



2

The ^{1}H-NMR resonances were assigned as follows: *cis*-isomer: Cp, 4.69 and 4.58; Si—H (terminal), 4.91 (q), $J_{H—H}$ = 3.65 Hz; CH_3, 0.88 (d); Si—H (bridge), −10.11 (broad s); *trans*-isomer: Cp, 4.68 and 4.61; Si—H (terminal), 5.00, $J_{H—H}$ = 3.65 Hz; CH_3, 0.855 (d); Si—H (bridge), −10.11 (broad s). The spectral parameters for the Si—H (terminal) and CH_3 resonances are cited for the spectrum observed while decoupling at −10.11 ppm. Without this decoupling the resonances are poorly resolved multiplets. The Si—H (bridge) resonances of the two isomers are not resolved at 200 MHz even with the methyl resonance decoupled. By integration of the Cp resonances, the *cis*/*trans* isomer ratio is ca. 1.2.

An X-ray crystallographic study of the dark blue needles

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

gave the same crystal parameters and diffraction pattern as a sample of bis[bis(cyclopentadienyl)-μ-ethoxytitanium(III)].[1] The latter compound, which is dark green in the pure state, is virtually insoluble in toluene. It may be reasonably concluded that the crystalline product of the reaction of **1** with diethoxymethylsilane is a mixture of titanocene(III) ethoxide with **2**, and that **2** is selectively extracted from the mixture by trituration with toluene. The presence of **2** is also evident from the NMR spectrum of the mother liquor from which the crystalline product precipitates.

Reaction of 1,3,5,7-tetramethylcyclotetrasiloxane (D_4') with ***1***

A reaction of **1** with a several molar excess of D_4' in hydrocarbon solvent resulted in the rapid transformation of the orange **1** into dark blue reduced titanium species and subsequently to the formation of dark blue needles. Attempts to separate the crystals revealed that they were coated with a gelatinous material which rendered their purification impossible.

The origin of the gelatinous material became obvious when a reaction of pure D_4' was carried out in the presence of a catalytic amount of **1**. In this case, the change in color from yellow to blue was again observed, together with the evolution of a steady stream of gas bubbles. The evolved gas was collected and shown by IR spectroscopy to be mainly methylsilane. After some time, the reaction mixture became an immobile gel and after about 24 h a rigid, blue colored glass was obtained.

Examination of the reaction mixture by NMR in the period prior to gelation revealed the presence of methylsilane in solution and also the presence of **2**. These observations lead to the conclusion that the catalytic reaction being observed is that shown in reaction [2]:

$$[2] \quad 3\text{—}(MeHSiO)_4\text{—} \xrightarrow{Cp_2TiMe_2} 8\text{—}(MeSiO_{3/2})\text{—} + 4\,MeSiH_3$$

The catalytic disproportionation of 1,1,3,3-tetramethyldisiloxane (E′E′) and some related compounds[2]

Reaction of pure E′E′ with a catalytic amount of **1** leads to the usual color change from yellow to blue and a vigorous evolution of gas. The gas was shown to be dimethylsilane by IR spectroscopy. The composition of the liquid phase was monitored by GC and the disappearance of E′E′ was initially accompanied by a very rapid production of E′DE′ and E′D_2E′. The cyclics D_n were produced much more slowly and in smaller amounts. The profile of such a reaction is shown in Fig. 1. After several hours the viscosity of the reaction mixture had increased considerably. Removal of volatile material at this point by pumping under high vacuum left a rigid, rubbery, but still soluble residue, corresponding to about a 70% yield based on E′E′. By GPC, this polymer was shown to have a polystyrene-equivalent number average molecular weight of ca. 9500 Dalton, with a polydispersity of 1.6. The ^{1}H- and ^{29}Si-NMR and the IR spectra of this material were indistinguishable from those of an authentic sample of linear poly(dimethylsiloxane). The volatile fraction consisted of a mixture of lower molecular weight ring and chain siloxanes whose mole fraction decreased

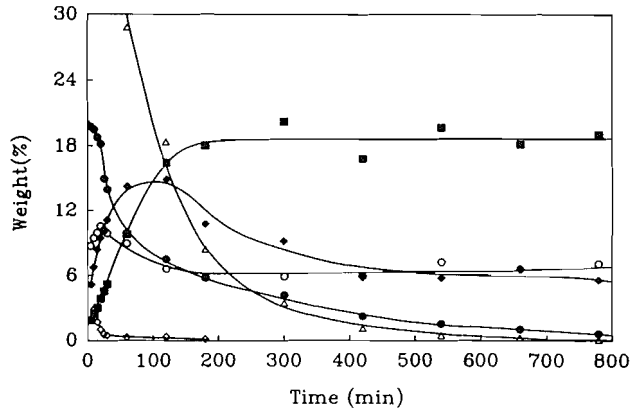


FIG. 1. Reaction profile for the catalytic redistribution of E′E′. [Cp_2TiMe_2] = 0.05 *M* in neat [E′E′] at 20°C. ◇, E′E′; △, E′DE′; ●, E′D_2E′; ◆, D_3; ■, D_4; ○, D_5.

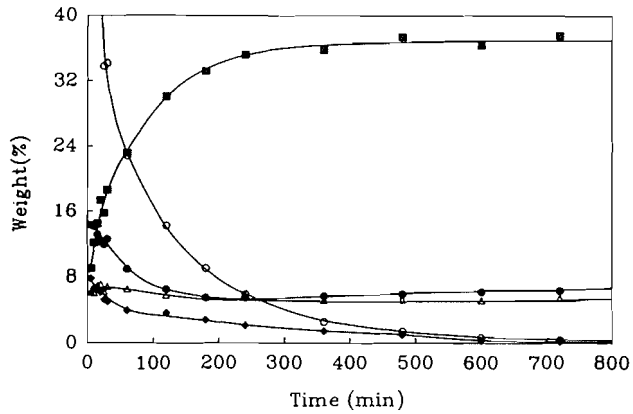

FIG. 2. Reaction profile for the catalytic redistribution of E′DE′. [Cp_2TiMe_2] = 0.056 *M* in neat [E′DE′] at 20°C. ○, E′DE′; ◆, E′D_2E′; △, D_3; ■, D_4; ●, D_5.

rapidly with increasing molecular weight and became vanishingly small above Si_{10}.

The redistribution of E′DE′ was also studied and a typical profile of reaction products is shown in Fig. 2. The rate of reaction of E′DE′ is between one and two orders of magnitude slower than that of E′E′. The most striking difference in the initial product composition is the enhancement in production of D_4 and D_5 and the diminution of the amount of E′D_2E′ in the E′DE′ reaction compared to the E′E′ reaction. This suggests a greater propensity for direct formation of small cyclics, relative to linear products, in the E′DE′ reaction. The trend appears to continue throughout the reaction, but it is likely that depolymerization equilibria contribute to the small cyclics at later stages in the reaction.

This interpretation is supported by the results of a run in which the initial reactant consisted of an equimolar mixture of E′E′ and E′DE′, shown in Fig. 3. In this reaction, the E′E′ had almost completely reacted by the time of the first measurement. At this point the amount of E′DE′ was slightly greater than the initial amount, but much less than would be expected if the conversion of E′E′ to E′DE′ was proceeding at the same rate as in the reaction shown in Fig. 1. The amounts of small cyclics are more like those in Fig. 2 than in Fig. 1 and both D_3 and D_5 pass through a minimum, reinforcing the hypothesis that the small cyclics are produced by depolymerization in the later stages of the reaction.

The influence of ligand chain length on intramolecular ring

[1]The crystal parameters for this compound are as follows: tetragonal, *P*-4*n*2, a = 8.238(1) Å, c = 15.717(2) Å, V = 1066.7 Å^3.

[2]We adopt the same abbreviations for methylsiloxanes as used by Curtis and Epstein (2). In this formalism the following labels are used: $Me_3SiO_{1/2}$ (E), $Me_2HSiO_{2/2}$ (E′) (E′), $Me_2SiO_{2/2}$ (D), $MeHSiO_{2/2}$ (D′).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12

closure is dramatically illustrated by the results of a reaction of E′D_2E′, shown in Fig. 4. In this case, the reactant is converted almost exclusively into D_3 in the early stages of the reaction. There are, however, small amounts of D_4 and D_6 and a trace of D_5 produced.

The reaction of EE′ leads almost exclusively to the formation of Me_2SiH_2 and EDE, with only trace amounts of heavier products. A profile for this reaction is shown in Fig. 5.

It was of interest to establish whether or not ring-opening polymerization of small cyclics could be a source of the high molecular weight product. To this end a reaction of D_3 with a catalyst generated by reaction of dimethyltitanocene with E′E′ was followed. The reaction was very slow compared to the reactions of the Si—H containing reactants and even after 50 h almost all of the reacted D_3 could be accounted for by the small cyclic products D_4, D_5, and D_6. It may therefore be concluded that ring-opening polymerization plays no significant part in the redistribution reactions.

Discussion

The catalytic redistribution of siloxanes under the influence of noble metal complexes, such as Vaska's and Wilkinson's complexes, has been studied very thoroughly by Curtis and his collaborators (2). It is essential therefore that the results obtained in the present study be compared to those reported by Curtis. The titanocene catalysts described herein are considerably more reactive than the noble metal complexes and they give larger amounts of small ring products. Nevertheless the gross features of the reactions are sufficiently similar to presume that there may be mechanistic similarities between the two types of system.

The entry of the dimethyltitanocene into the catalytic cycle to give an initial complex analogous to that proposed by Curtis *et al.* could occur by the reactions shown in [3]–[5].

[3] $Cp_2TiMe_2 + HMe_2SiOSiMe_2H \longrightarrow Cp_2TiMe(SiMe_2OSiMe_2H) + CH_4$

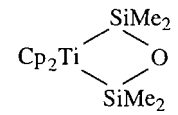
[4] $Cp_2TiMe(SiMe_2OSiMe_2H) \longrightarrow Cp_2Ti + Me_3SiOSiMe_2H$

[5] $Cp_2Ti + HMe_2SiOSiMe_2H \longrightarrow Cp_2Ti(H)SiMe_2OSiMe_2H$

3

This proposition is supported by the detection of both methane and EE′ in the initial reaction products.

Although the intermediate **3** could in principle lose H_2 to give a four-membered metallocycle, **4**, again analogous to that



4

proposed by Curtis *et al.*, we have not been able to devise a plausible mechanism involving such an intermediate, which at the same time would be expected to give the experimentally observed extremely high conversion rate of E′E′ to E′DE′. Furthermore, it is impossible to accommodate an additional hydride ligand in the coordination sphere of **4** without exceeding the normal oxidation limit of Ti. Such an additional hydride ligand is an explicit requirement of the Curtis mechanism, as proposed for Ir (Rh).

Rather than conversion of **4** to the next Curtis-type intermediate, **5**, it is simpler to assume a direct rearrangement of **3** through hydride (TiH) displacement of the $OSiMe_2H$. An even

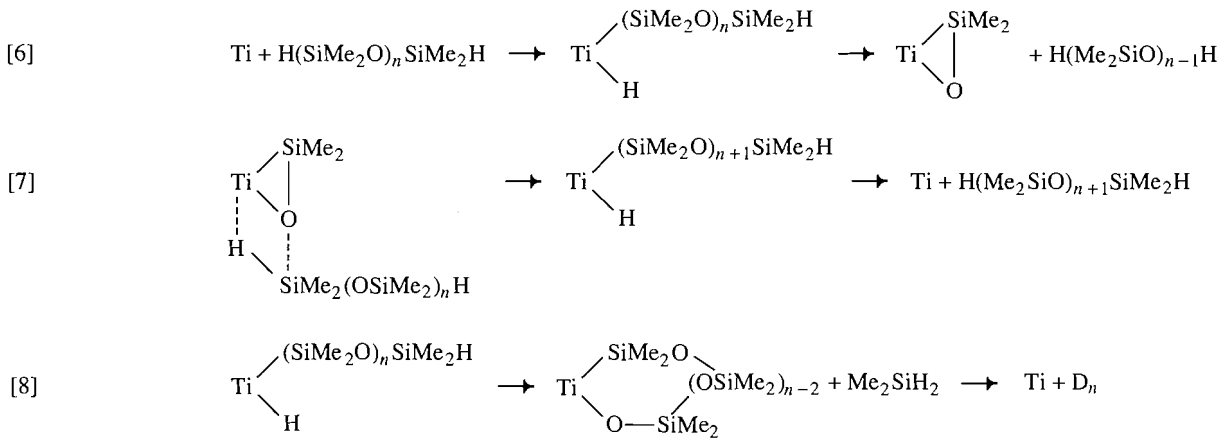
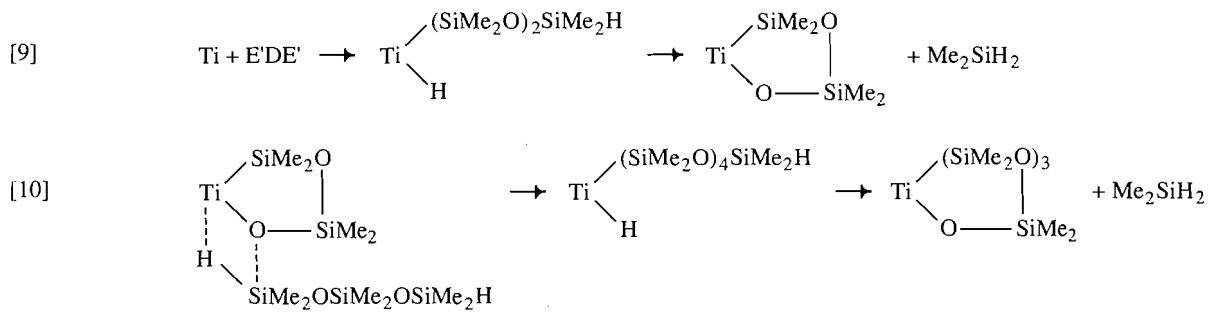


SCHEME 1. Mechanism involving σ-bond metathesis at Ti(IV).

more direct route to **5** would be via the oxidative addition of E′E′ to Cp_2Ti by cleavage of the Si—O linkage. To be favored, such an oxidative addition would require that the sum of the bond energies for the new Ti—Si and Ti—O bonds, plus the positive $T\Delta S$ for the associative process, exceed the energy of the sacrificed Si—O bond. Given the general oxophilicity of Ti(IV) and the fact that titanium is observed in the present study to acquire alkoxy and siloxy groups from silicon, this seems a reasonable assumption. For much the same reasons as adduced by Curtis, it is difficult to avoid the involvement of a silanone intermediate if one is restricted to a mechanism involving monomeric Ti(IV). Such a silanone may be generated either directly from **3**, by hydride (TiH) displacement of Me_2SiH_2, or by elimination of Me_2SiH_2 from **5**. A simple mechanism which fits most of the experimental observations is illustrated in the following scheme (Cp ligands omitted for clarity). See Scheme 1.[3]

Reaction [7] accounts for the linear chain propagation. Reaction [8] accounts for the formation of ring compounds. The highly selective conversion of E′D_2E′ to D_3 strongly supports this type of mechanism. The intermediate metallocycle is expected to be most stable for small values of n. The high yield of D_4 from the reaction of E′DE′ suggests the intermediacy of a metallocycle with $n = 4$ (reaction [8]). This metallocycle would most likely arise from the sequence of steps:



It is interesting to compare the evolution of the reactions shown in Figs. 1 and 2 in view of the fact that there is about the same amount of E′DE′ after 5 min of reaction of E′E′ as there is after 10 min reaction of E′DE′, yet the amounts of other species present and subsequently appearing in the mixture are rather different. The results show that the simultaneous presence of both E′E′ and E′DE′ promotes the formation of larger amounts of E′D_2E′ than are produced when E′E′ is absent. This is fully in line with the above mechanism, since E′D_2E′ is the product of reaction of E′DE′ with the dimethylsilanone complex. Since the latter is only generated directly from E′E′, absence of the E′E′ would suppress formation of E′D_2E′. The formation of rings is also suppressed by the presence of the highly reactive E′E′ since the rate of the ring-opening reactions, e.g. [7] and [10], when the attacking reagent is E′E′ is apparently faster than the putative ring-forming reductive elimination reactions [8].

The rate of reaction [8] will decrease rapidly with increasing siloxane chain length and eventually analogous intermolecular reactions will compete. The extension of longer polymer chains is therefore most likely to occur by attack of the terminal Si—H of a longer chain species with a small ring metallocycle, at least until the reaction is very well advanced.

A mechanism based on Ti(IV) intermediates presents a number of serious problems, not least of which is our failure to observe any Ti(IV) species during either catalytic or stoichiometric reactions. The absence of NMR observable species strongly suggests that most, if not all of the titanium is in the Ti(III) state. In the case of the alkoxysilane redistribution reactions, most of the titanium is demonstrably present as Ti(III).

A fatal objection to the mechanism shown in reactions [6] to

[3]The suggestion that σ-bond metathesis is important in the catalytic reactions of group 14 hydrides with group 4 metallocenes is due to T. D. Tilley, personal communication. The σ-bond metathesis mechanism has been proposed to explain a number of early transition metal and lanthanide reactions (4).

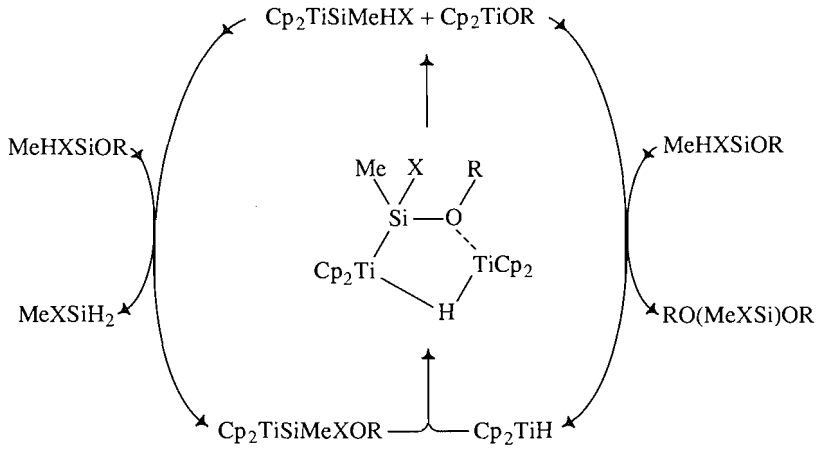

SCHEME 2. Mechanism involving bimetallic Ti(III) intermediates.

[10] is its inability to account for the products of the EE′ reaction. The steps shown in [6] would lead to the formation of Me_3SiH and EDE′ as initial products, whereas the observed products are Me_2SiH_2 and EDE. It is worth noting that Curtis *et al.* obtained ED′E as the principal product from this reaction catalyzed by Vaska's complex (2). They attributed the formation of the D′ units to metal-catalyzed Me_3SiO/Me exchange, a process notably absent in the titanocene-catalyzed reaction.

A final difficulty with the Ti(IV)-based σ-bond metathesis mechanism is that we have been unable to accommodate the results of alkoxysilane redistribution reactions in such a scheme. In Scheme 2, which invokes the intermediacy of bimetallic Ti(III) intermediates, we illustrate a mechanism which seems to satisfy all of the experimental observations. In this scheme, when R = Et and X = OEt, we have the diethoxymethylsilane case. When X = Me and R = $SiMe_2H$ we have the tetramethyldisiloxane case and when X and R are both part of a D_4' ring system we have the D_4' polymerization case (in this case the TiOR and TiSiMeHX remain joined together throughout the cycle). The products of the EE′ reaction find a natural explanation in this scheme as does the failure to detect Ti(IV) species in the system.

The formation of cyclics in the E′E′ redistribution reaction would require an intramolecular metathesis of the Ti—O bond by the terminal Si—H group of the R ligand rather than intermolecular attack in the right hand loop of Scheme 2. All of the arguments applied above to the pattern of cyclics formation in the σ-bond metathesis mechanism apply equally to the mechanism of Scheme 2.

We are continuing attempts to isolate titanium-containing intermediates from the E′E′ redistribution reaction to obtain more substantive evidence in favor of this or some related type of mechanism.

Experimental

All solvents were dried and degassed by standard techniques prior to use. Dimethyltitanocene was synthesized by a literature procedure (5). The following compounds were obtained from Petrarch Systems Inc.: E′E′, E′E, E′DE′, E′D_2E′, E′D_3E′, D_4, D_4', D_5, $(MeO)_3SiH$, and $Me(EtO)_2SiH$. The E′E′ was further purified by distillation prior to use, the other siloxanes were used as received.

Gas chromatography

Analyses of the products of the E′E′ redistribution reactions were carried out on a Shimadzu GC-8A chromatograph equipped with a H_2 flame detector and a DB-5 30 m capillary column. Stationary phase: 95% dimethyl-, 5% diphenylpolysiloxane. Inlet port temperature 300°C. Column temperature 100–300°, programmed at 8°C per min. Carrier gas flow rate 0.5 mL min^{-1}. Calibration was carried out with the commercial siloxane compounds listed above. Products heavier than pentasiloxanes were identified by GC-MS.

Products of the methyldiethoxysilane–dimethyltitanocene reaction

(i) Catalytic reaction

A sample of diethoxymethylsilane (10 g, 75 mmol) was placed in a reactor which had previously been purged with argon and charged with dimethyltitanocene (100 mg). The reactor was warmed to 50°C and the evolved gas was collected in a liquid nitrogen cooled receiver. After 30 min the reaction was stopped and the condensate was distilled twice by allowing the receiver to warm slowly to −10°C and collecting the product in a new receiver at liquid nitrogen temperature. The resulting distillate (1.00 g; 22 mmol; 87%) had NMR and IR spectra indistinguishable from an authentic sample of $MeSiH_3$.

The undistilled residue was then distilled at ambient pressure to remove catalyst residues. The product (bp = 123–125°C/15 mm Hg; 8.50 g; 48 mmol; 96%) was shown by comparison with an authentic sample to be triethoxymethylsilane. The yields are based on reactant, assuming reaction [1].

(ii) Stoichiometric reaction

A sample of dimethyltitanocene (50 mg) was dissolved in previously degassed toluene (5 mL) in a Schlenk tube and methyldiethoxysilane (0.1 mL) was added. After about 5 min gas evolution was observed and the solution rapidly turned from orange to dark blue. The reaction mixture was left undisturbed for 12 h and then the supernatant liquid was decanted to leave a residue of well formed blue–black crystals. The product was partially dissolved in toluene-d_8 (0.5 mL), filtered, and its ^{1}H-NMR spectrum was measured. The spectrum was identical to that of a sample of **2** prepared *in situ* by bubbling methylsilane through a solution of dimethyltitanocene (10 mg) in toluene-d_8 (1 mL).

Redistribution reactions

In a typical redistribution reaction, a sample of dimethyltitanocene (50 mg) was placed in a 20 mL capacity Schlenk tube, equipped with a rubber septum and a magnetic stirrer. After the reactor was purged with argon, previously degassed reactant (5 mL) was injected and the catalyst was rapidly dissolved. Within a few minutes the catalyst color changed from yellow to dark blue, or (in the case of tetramethyldisiloxane) olive green. The color change was accompanied by gas evolution and the gas was periodically sampled by syringe and analysed by GC and IR spectroscopy. The presence of CH_4, SiH_4 (the $(MeO)_3SiH$ reaction), $MeSiH_3$ (D_4' and $(EtO)_2MeSiH$ reactions), and Me_2SiH_2 (E′E′ and E′DE′ reactions) in the gaseous products was established by comparison of IR spectra and GC retention times with authentic samples.

In the case of tetramethyldisiloxane redistribution, the liquid fraction of the reaction mixture was also periodically sampled and analysed by GC. The products up to Si_5 were identified by calibration with authentic standards. Products of higher mass were identified by GC/MS.

Fluorination of sulfur-containing amino acids: Reaction of xenon difluoride with cysteine derivatives

XIAOLING HUANG,[1] BARRY J. BLACKBURN,[2] STEVE C. F. AU-YEUNG, AND ALEXANDER F. JANZEN
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received May 26, 1989

XIAOLING HUANG, BARRY J. BLACKBURN, STEVE C. F. AU-YEUNG, and ALEXANDER F. JANZEN. Can. J. Chem. **68**, 477 (1990).

The reaction of XeF_2 with cysteine derivatives $RSCH_2CH(NHR)COOR$, i.e., *S*-benzyl-*N*-trifluoroacetyl-L-cysteine methyl ester, *S*-benzyl-*N*-carbobenzoxy-L-cysteine *p*-nitrophenyl ester, and *S*-methyl-*N*-trifluoroacetyl-L-cysteine methyl ester is described. The fluorinated products $PhCHFSCH_2CH(NHR)COOR$, $PhCH_2SCHFCH(NHR)COOR$, and $FCH_2SCH_2CH(NHR)COOR$ were identified by ^1H and ^{19}F nuclear magnetic resonance spectroscopy. $PhCH_2SCHFCH(NHR)COOR$ loses HF within 24 hours to give *Z*- and *E*-$PhCH_2SCH{=}C(NHR)COOR$. If the reaction with XeF_2 is carried out in the presence of moisture the sulfoxide $RS(O)CH_2CH(NHR)COOR$ and sulfone $RSO_2CH_2CH(NHR)COOR$ are produced.

Key words: fluorination, XeF_2, amino acids, cysteine.

XIAOLING HUANG, BARRY J. BLACKBURN, STEVE C. F. AU-YEUNG et ALEXANDER F. JANZEN. Can. J. Chem. **68**, 477 (1990).

On décrit la réaction du XeF_2 avec des dérivés de la cystéine, $RSCH_2CH(NHR)COOR$, comme l'ester méthylique de la *S*-benzyl-*N*-trifluoroacétyl-L-cystéine, l'ester *p*-nitrophénylique de la *S*-benzyl-*N*-carbobenzoxy-L-cystéine et l'ester méthylique de *S*-méthyl-*N*-trifluoroacétyl-L-cystéine. Utilisant la résonance magnétique nucléaire du ^1H et du ^{19}F, on a identifié les produits fluorés $PhCHFSCH_2CH(NHR)COOR$, $PhCH_2SCHFCH(NHR)COOR$ et $FCH_2SCH_2CH(NHR)COOR$. Le composé $PhCH_2SCHFCH(NHR)COOR$ perd du HF en moins de 24 heures pour donner les *Z*- et *E*-$PhCH_2SCH{=}C(NHR)COOR$. Si l'on effectue la réaction avec le XeF_2, en présence d'humidité, il se forme du sulfoxyde $RS(O)CH_2CH(NHR)COOR$ et de la sulfone $RSO_2CH_2CH(NHR)COOR$.

Mots clés : fluoration, XeF_2, acides aminés, cystéine.

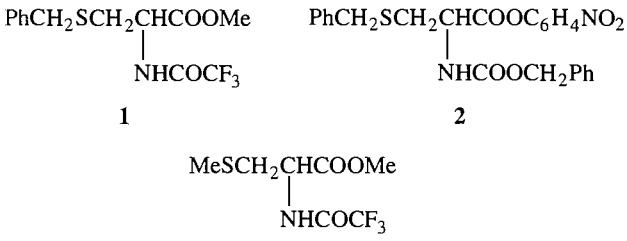
Results and discussion

The reaction of XeF_2 with organosulfides (1–5) has been applied previously to biotin (6), methionine, and methionylglycine derivatives (7), and as a continuation of our work on sulfur-containing amino acids we have carried out reactions with several cysteine derivatives **1–3**.

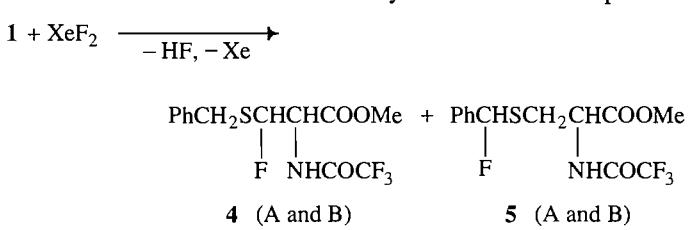


1

2

3

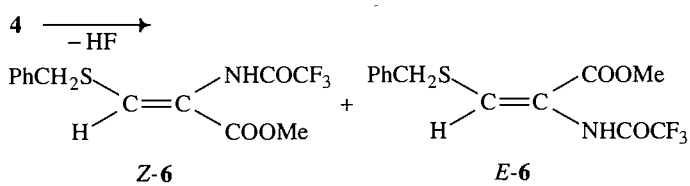
Reaction of **1** with XeF_2 was carried out at 0–5°C in acetonitrile solution over a period of 1 h. Monofluorination of both $-CH_2-$ groups in **1** occurred to give products **4** and **5** in approximately a 1:1 ratio in a combined yield of 70–80%. Products **4** and **5** were identified by ^1H and ^{19}F nmr spectroscopy (Table 1) and the nmr data are in agreement with earlier assignments of fluoromethionine (7) and fluoroalkylsulfides (2–5). Both **4** and **5** contain two chiral centers and the presence of diastereomers (A and B) is confirmed by ^1H and ^{19}F nmr (Table 1). The vicinal couplings $^3J(HH)$ and $^3J(HF)$, which reflect the rotamer populations, and the ^1H and ^{19}F nmr chemical shifts differ significantly for the diastereomers of **4** and **8**, but for **5**, where the chiral centers are separated by three bonds, only the ^{19}F nmr chemical shifts differ significantly.



4 (A and B) **5** (A and B)

Products **4** and **5** were not separated and purified because of moderately rapid decomposition, complete within 24 h at 20°C. Decomposition could not be prevented by lowering the temperature to 0°C or by removing HF from the reaction mixture under reduced pressure or by bubbling a stream of nitrogen through the reaction mixture, or by chemical treatment with NaF, $NaHCO_3$, Et_3N, or $(Me_3Si)_2NH$ (8), all of which failed to stop decomposition of **4** and **5**.

Decomposition of **4** gave mainly alkenes *E*-**6** and *Z*-**6**, which are stable indefinitely and were separated by tlc and characterized by elemental analysis, mass spectrometry, and ^1H and ^{19}F nmr. The chemical shifts of the olefinic hydrogens of *Z*-**6** (8.47 ppm) and *E*-**6** (7.64 ppm) differ significantly and the higher field resonance may tentatively be assigned to the *E* isomer (9).



Z-**6** *E*-**6**

Product **5**, which contains a fluorobenzyl substituent, gave more complex decomposition products, including [MeOC(O)-

TABLE 1. The ^1H and ^{19}F nmr data for some cysteine derivatives in CD_3CN[a]

Compound	Chemical shift (ppm)		Coupling constant (Hz)		
	δH(CHF)	δF(CHF)	^2J(HF)	^3J(HH)	^3J(HF)
4 $PhCH_2SCHFCH(NHCOCF_3)COOMe$					
Isomer A	6.13	−157.7	53.6	3.5	12.0
Isomer B	5.95	−160.3	53.3	4.9	24.4
5 $PhCHFSCH_2CH(NHCOCF_3)COOMe$					
Isomer A	6.81	−144.6	55.2		
Isomer B	6.81	−147.2	55.2		
7 $PhCH_2SCHFCH(NHCOOCH_2Ph)COOC_6H_4NO_2$					
Isomer A	6.26	−158.4	54.5	3.4	11.3
Isomer B	6.09	−160.6	54.1	5.0	24.1
10 $FCH_2SCH_2CH(NHCOCF_3)COOMe$	5.57	−180.6	52.8		

[a]Chemical shifts were measured relative to internal CHD_2CN (1.93 ppm) and C_6F_6 (−162.9 ppm) and converted to the TMS and $CFCl_3$ scales. CF_3 groups in **4**, **5**, and **10** are found in the range −74.5 to −75.2 ppm.

$CH(NHCOCF_3)CH_2S-]_2$, $PhCH_2SSCH(NHCOCF_3)COOMe$, $PhCH_2SSCH_2Ph$, and PhC(O)H.

Fluorination of **2** proceeded in the same manner as **1**, except that product **8** appeared to decompose even faster than **5** and therefore reliable nmr spectra of **8** could not be obtained.

$$\mathbf{2} + XeF_2 \xrightarrow[-HF,\,-Xe]{} PhCH_2SCH(F)CH(NHCOOCH_2Ph)COOC_6H_4NO_2 + PhCH(F)SCH_2CH(NHCOOCH_2Ph)COOC_6H_4NO_2$$

7 (A and B) **8**

However, **7** was stable enough for ^1H and ^{19}F nmr identification and both diastereomers (A and B) were detected by nmr (Table 1). HF elimination within 24 h converted **7** to alkene *E*-**9** and the latter was identified by mass spectrometry and ^1H nmr.

$$\mathbf{7} \xrightarrow[-HF]{} PhCH_2SCH{=}C(COOC_6H_4NO_2)NHCOOCH_2Ph$$

E-**9**

Loss of the nitrophenyl protecting group during the reaction with XeF_2 and during subsequent work-up made **2** a more difficult compound to study than **1**.

The reaction of **3** with XeF_2 was briefly studied and the product **10** was identified by ^1H and ^{19}F nmr (Table 1). This reaction confirms the result obtained with methionine and methionylglycine (7), namely, that fluorination with XeF_2 occurs preferentially at a primary rather than a secondary hydrogen.

$$\mathbf{3} + XeF_2 \xrightarrow[-HF,\,-Xe]{} CH_2SCH(F)CH_2CHCOOMe\ (NHCOCF_3)$$

10

The postulated intermediate in the α-fluorination of organosulfides is a sulfur(IV) difluoride R_2SF_2 (2–5). Since it is known that R_2SF_2 undergoes rapid hydrolysis, e.g., Ph_2SF_2 to Ph_2SO (3, 4) or Me_2SF_2 to Me_2SO (5), a test for intermediate **11** was carried out by reacting **1** with XeF_2 at 0–5°C, followed by immediate addition of water. The sulfoxide **12** was indeed formed, as expected if **11** is an intermediate in the fluorination reaction. On occasion, this reaction also produced the sulfone $PhCH_2SO_2CH_2CH(NHCOCF_3)COOMe$ **13**, and sulfones have

$$\mathbf{1} + XeF_2 \xrightarrow[-Xe]{} [PhCH_2SCH(F)CH_2CHCOOMe\ (F)\ (NHCOCF_3)]$$

11

$$\xrightarrow[-2HF]{H_2O} PhCH_2S(=O)CH_2CHCOOMe\ (NHCOCF_3)$$

12

been identified previously in related reactions of XeF_2 (3). In a similar reaction of **3** with XeF_2 in the presence of small amounts of water, the sulfoxide $MeS(O)CH_2CH(NHCOCF_3)COOMe$ **14** was formed.

Experimental

The ^1H and ^{19}F nmr spectra were recorded on a Bruker WH90 spectrometer at 90 and 84.66 MHz, respectively. The reaction progress, involving disappearance of XeF_2 and appearance of fluorinated products and HF (as well as BF_4^- from reaction with glass nmr tubes), was routinely monitored by ^{19}F nmr. Mass spectra were obtained on a Finnigan 1015 quadrupole instrument at 70 eV and samples were introduced on the solids probe. Elemental analyses were performed by Galbraith Laboratories, Knoxville, Tenn.

The tlc separations were carried out on silica gel plates using a petroleum ether:benzene:chloroform:methanol = 2:1:0.8:0.05 mixture.

The following compounds were commercial samples: XeF_2 (PCR/SCM), *S*-benzyl-*N*-carbobenzoxy-L-cysteine *p*-nitrophenyl ester **2** (Sigma), *S*-benzyl-L-cysteine (Aldrich), and *S*-methyl-L-cysteine (Aldrich).

S-Benzyl-*N*-trifluoroacetyl-L-cysteine was prepared from *S*-benzyl-L-cysteine by the method of Weygand and Geiger (10). Esterification was carried out by dissolving *S*-benzyl-*N*-trifluoroacetyl-L-cysteine (0.53 g, 1.7 mmol) in 1,2-dichloroethane (3 mL), adding p-$MeC_6H_4SO_3H \cdot H_2O$ (30 mg) in anhydrous methanol (0.9 mL), and heating the mixture for 7 h. The solvent was pumped off, methanol added twice, and the mixture pumped off to dryness. The residue was washed with cold and warm (40°C) water, dried in air, and purified by two sublimations at 100–104°C/0.5 Torr (1 Torr = 133.3 Pa) to give *S*-benzyl-*N*-trifluoroacetyl-L-cysteine methyl ester **1** (477 mg, 85%, mp 64°C, lit. (11) mp 62–64°C), identified by ^1H and ^{19}F nmr and

ms m/z: 321 (M^+). *S*-Methyl-L-cysteine (1 g) was esterified (12) with 15 mL of 2 M methanolic HCl for 2 h at 60°C and, after removal of excess methanol, treated with trifluoroacetic anhydride in CH_2Cl_2 at 0–25°C for 30 min followed by removal of volatile material to give *S*-methyl-*N*-trifluoroacetyl-L-cysteine methyl ester **3**, identified by nmr and ms m/z: 245 (M^+).

Reaction of XeF_2 with S-*benzyl*-N-*trifluoroacetyl*-L-*cysteine methyl ester* ***1***

In a typical reaction, XeF_2 (34.5 mg, 0.20 mmol) was weighed into a PTFE bottle which was then cooled to 5–10°C and CD_3CN (0.2 mL) added. Cysteine **1** (60 mg, 0.18 mmol) in CD_3CN (0.7 mL) was added with stirring within 5 min. The reaction mixture was stirred for 50 min and the solution allowed to reach room temperature. During this time, the solution turned slightly yellow. The mixture was transferred into an nmr tube and the fluorocysteine products **4** and **5** were identified at this stage by ^1H and ^{19}F nmr (Table 1).

After standing for 24 h at 25 or 0°C, the ^{19}F nmr signals of **4** and **5** disappeared and the HF peak appeared. The solution now contained *Z*-**6** and *E*-**6**, as described below.

(Z)- and (E)-Methyl N-*trifluoroacetyl*-3-*benzylthio*-2-*amino*-2-*propenoate* ***6***

Typically, the reaction of **1** with XeF_2 was carried out as described above, and the mixture allowed to stand for 24 h or longer. HF was then pumped off and the mixture separated by tlc. The major components were *E*-**6** and *Z*-**6** in about a 3:1 ratio. Anal. calcd. for $C_{13}H_{12}F_3NO_3S$: C 48.91, H 3.79, N 4.38; found: C 49.4, H 3.9, N 4.2. *E*-**6**, ^1H nmr ($CDCl_3$) δ: 3.80 (CH_3), 4.10 (CH_2), 7.35 (Ph), 7.56b (NH), 7.64 (CH); ^{19}F nmr ($CDCl_3$) δ: −76.36 (CF_3). *Z*-**6**, ^1H nmr ($CDCl_3$) δ: 3.90 (CH_3), 4.00 (CH_2), 7.35 (Ph), 8.3 (b, NH), 8.47 (CH); ^{19}F nmr ($CDCl_3$) δ: −77.05 (CF_3). Mass spectrum m/z: 319 (M^+).

To simplify the preparation of *Z*-**6** and *E*-**6**, the reaction of XeF_2 with **1** was carried out for 30 min (as described above), after which dry nitrogen gas was bubbled through the reaction mixture for 15 min (to remove HF) and the products *Z*-**6** and *E*-**6** separated by tlc.

A small amount of solid was separated by tlc and tentatively identified as the cystine derivative $[MeOC(O)CH(NHCOCF_3)CH_2S\text{-}]_2$ on the basis of nmr and ms m/z: 460 (M^+), 401 ($M^+ - CO_2Me$).

S-*Benzyl*-N-*trifluoroacetyl*-L-*cysteine sulfoxide methyl ester* ***12*** *and sulfone* ***13***

XeF_2 (44 mg, 0.26 mmol) was dissolved in CH_3CN (0.6 mL) in a PTFE bottle that had been set on a cold plate at 5–10°C. A solution of **1** (75 mg, 0.23 mmol) in CH_3CN was added with stirring within 5 min. The reaction solution was stirred for 30 min at 5–10°C and then 1 mL cold water was added. The solution was neutralized with a clear solution of $Ca(OH)_2$ until pH 8. The solution was extracted twice with CH_2Cl_2. The combined extracts were dried with 4A molecular sieve and the solvent removed under vacuum. Recrystallization of the solid residue from 1:1 benzene:petroleum ether gave sulfoxide **12** (9 mg, 12%), identified by nmr and ms m/z: 337 (M^+). Anal. calcd. for $C_{13}H_{14}F_3NO_4S$: C 46.29, H 4.18, N 4.15; found: C 46.3, H 4.4, N 4.6.

In some reactions, separation of the above mixture by tlc gave an additional minor component tentatively identified as sulfone **13** ms m/z: 353 (M^+). Anal. calcd. for $C_{13}H_{14}F_3NO_5S$: C 44.19, H 3.99, N 3.96; found: C 45.7, H 4.1, N 4.0.

Reaction of XeF_2 with S-*benzyl*-N-*carbobenzoxy*-L-*cysteine* p-*nitrophenyl ester* ***2***

Reactions of XeF_2 with **2** were typically carried out as described above for **1**, but the loss of the nitrophenyl protecting group during reaction with XeF_2 and during subsequent work-up made **2** a more difficult compound to study than **1**. Product **7** (diastereomers A and B) was identified by nmr (Table 1). On standing, an olefinic ^1H peak appears at 7.71 ppm assigned to *E*-**9**, ms m/z: 464 (M^+).

The ms and ^1H nmr of additional products that were separated by tlc suggested the presence of $PhCH_2SSCH_2Ph$ m/z 246 (M^+), $PhCH_2SSSCH_2Ph$ m/z 278 (M^+), and benzaldehyde.

Reaction of XeF_2 with S-*methyl*-N-*trifluoroacetyl*-L-*cysteine methyl ester* ***3***

The reaction was carried out as described above for **1** and **2** and the product $FCH_2SCH_2CH(NHCOCF_3)COOMe$ **10** was identified by ^1H and ^{19}F nmr (Table 1) and ms m/z: 263 (M^+), but purification was not successful. Various reaction mixtures also showed the presence of (*E*)- and (*Z*)-$MeSCH{=}C(NHCOCF_3)COOMe$ with olefinic ^1H nmr peaks at 7.66 and 8.33 ppm, respectively, and ms m/z: 243 (M^+), 196 ($M^+ - CH_2S$). Additional ms peaks at m/z 261 and 277 are assigned to $CH_3S(O)CH_2CH(NHCOCF_3)COOMe$ **14** and $CH_3SO_2CH_2CH(NHCOCF_3)COOMe$ **15**. The yield of sulfoxide **14** could be increased by carrying out the reaction of XeF_2 and **3** in the presence of small amounts of water. Evidently, the reaction with XeF_2 did not stop at the monofluorination stage and the reaction was not pursued further.

Dielectric polarization and molecular interaction. Part III. Styrene, benzene, and ethyl vinyl ether – acrylonitrile – cyclohexane systems

GAMAL R. SAAD, MAGDI M. NAOUM, AND HANNA A. RIZK[1]
Department of Chemistry, Faculty of Science, University of Cairo, Cairo, Egypt

Received April 21, 1989

GAMAL R. SAAD, MAGDI M. NAOUM, and HANNA K. RIZK. 1990. Can. J. Chem. **68**, 480 (1990).

The apparent molecular polarization at infinite dilution of acrylonitrile in constant-ratio mixtures of styrene, benzene, and ethyl vinyl ether in cyclohexane leads to the inference of the equilibrium constants of the association process between the acid and the base, and the dipole moments of the complexes formed. The results are mainly consistent with the concept of dipole–dipole interaction.

Key words: dielectric polarization, molecular interaction, styrene, acrylonitrile, cyclohexane.

GAMAL R. SAAD, MAGDI M. NAOUM et HANNA K. RIZK. Can. J. Chem. **68**, 480 (1990).

La polarisation moléculaire apparente à dilution infinie de l'acrylontrile dans des mélanges à rapport constant de tyrène, de benzène et d'éthoxybutène dans le cyclohexane permet d'évaluer les constantes d'équilibre du processus d'association entre l'acide et la base ainsi que les moments dipolaires des complexes qui se forment. Les résultats sont généralement en accord avec le concept d'une interaction dipole.

Mots clés: polarisation diélectrique, interactions moléculaires, styrène, acrylonbitrile, cyclohexane.

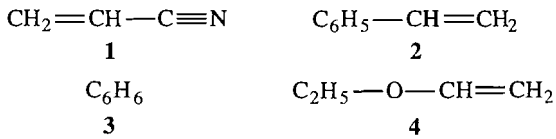
In Part I (1) and Part II (2) of this series the systems used for molecular interaction investigation using dielectric polarization measurements (3) were those in which hydrogen bonding (4, 5) was dominant in complex formation, the acids being ketoanilides and diketones, and the base triethylamine. This work extends the investigation to three bases, namely, styrene, **2**, benzene, **3**, and ethyl vinyl ether, **4**, using the same acid acrylonitrile, **1**, and the inert, non-polar solvent cyclohexane, so that other types of interacions (6, 7) leading to association complexes could be studied.



1 **2** **3** **4**

Experimental

Acrylonitrile (B.D.H.), styrene (Merck), benzene (Analar), ethyl vinyl ether (Merck), and cyclohexane (PROLABO, France) were purified according to recommended procedures (8). The purity of these compounds was checked by comparing their physical constants with those in literature (8).

Preparation of solutions, and measurements at 30°C of dielectric constant, ϵ, density, d, refractive index for the sodium-D line, n_D, were carried out as described before (1, 9).

Results

To calculate the equilibrium constant, K, of the association process, and the dipole moment, μ_{AB}, of the complex, the following original equation of Few and Smith (3) was applied:

$$[1] \quad \frac{\Delta P}{P^*_A - P_A} = 1 + \frac{M_B}{KW_B d}$$

Here P^*_A = molecular polarization at infinite dilution of the acid, A, in a constant-ratio mixture of the active polar base, B, and the inert, non-polar solvent, cyclohexane, S; P_A = molecular polarization at infinite dilution of the acid, A, in the inert solvent cyclohexane, S; ΔP = increase in molecular polarization at infinite dilution associated with the formation of 1 mol of the association complex, AB, i.e., equals $P_{AB} - P_A - P_B$; W_B = weight fraction of the base, B, in a given solvent mixture, BS, which, at the same time, was considered to be approximately equal to that of th base in very dilute solutions of the acid in the same solvent mixture; M_B = molecular weight of the base, B; d = density of the solvent mixture, BS, which was also taken to be approximately equal to the density of very dilute solutions of the acid in the same solvent mixture, and K = equilibrium constant of the association process A + B = AB, where the active masses were expressed in terms of their concentrations in mol per cm^3.

However, it was found that in the two systems styrene–acrylonitrile–cyclohexane and ethyl vinyl ether – acrylonitrile – cyclohexane, the values of the molecular polarization, P^*_A, at infinite dilution of acrylonitrile in the various constant-ratio solvent mixtures were sufficiently close to one another, and to the value of its molecular polarization, P_A, at infinite dilution in the inert solvent cyclohexane. The fact that this behaviour was not observed in the system benzene–acrylonitrile–cyclohexane, for which the dielectric constant of the base benzene (2.272) differs only slightly from that of the inert solvent cyclohexane (2.007), whereas it appeared in the former two systems, for which the dielectric constants of the bases styrene and ethyl vinyl ether (2.46 and 4.06, respectively) differ markedly from that of cyclohexane, might lead one to suggest that it is due to solvent effect. An approximate correction for this effect has thus been made only for these two systems. That is, the molecular polarizations of acrylonitrile at various concentrations in a constant-ratio mixture of the base, B, in the inert solvent, S, were graphically interpolated at a dielectric constant value equal to that of cyclohexane. The polarization so obtained for acrylonitrile was denoted as P^*_A(corr.); this term was substituted for P^*_A in eq. [1] when the base was either styrene or ethyl vinyl ether.

A summary of the results is given in Tables 1–3 for styrene, benzene, and ethyl vinyl ether – acrylonitrile – cyclohexane systems, respectively.[2]

Discussion

Tables 1–3 show that the apparent solution moment, μ_2, of acrylonitrile in the various constant-ratio solvent mixtures for each system increases with increasing concentration of the base, signifying an increase in complex formaion. This suggests an estimate can be made of the fraction of acrylonitrile introduced in the constant-ratio mixture of the base in cyclohexane, which is complexed with the base at infinite dilution. For this purpose, the following equation also suggested by Few and Smith (3) has been used, except that P^*_A(corr.) was substituted for P^*_A when the base is either styrene or ethyl vinyl ether.

[2] $P^*_A - P_A = \Delta P(\Delta W_A/W_A)$

The values of this fraction expressed as $\Delta W_A/W_A$ are listed in Table 13. Here W_A is the weight fraction of acrylonitrile in a constant-ratio mixture of the base and cyclohexane, and ΔW_A the amount of A which passes into the form of the complex AB. It is obvious from Table 13 that an increase in the proportion of

8.308	0.270	14.840	0.394	13.410	0.228
9.348	0.289	17.656	0.453	15.933	0.272

the base in the solvent mixture favours complex formation, as is to be expected. Moreover, for a given solvent mixture, the tendency toward complex formation with acrylonitrile is highest for styrene, **2**, and least with ethyl vinyl ether, **4**. This is consistent with the fact that the equilibrium constant, K, of the association complex, as determined in the present work, decreases in the sequence

$$2 > 3 > 4$$

To account for these results, it may first be assumed that acrylonitrile interacts with styrene in cyclohexane by means of local dipole – induced dipole force. That is, the electron-deficient sites of local dipoles in any of these two types of molecules are approached by the electron-rich centers in the molecule of the other type. Thus, while the methylene hydrogen atoms of acrylonitrile are approached by the styrene phenyl groups, those of styrene itself are directed toward the electron-rich centers at the nitrogen atom of acrylonitrile. At the same time, it might be expected that the stereospecific approach of the styrene molecule with its phenyl groups directed toward the methylene group of acrylonitrile is favoured, because of the location of the latter group with respect to the negative end of the molecular dipole moment. The assumption that the interaction between acrylonitrile and styrene is mainly governed by long-range forces might be extended to the case of benzene as a base. That is, the benzene molecules solvate the electron-deficient sites in acrylonitrile. This means again that the benzene rings are mainly directed toward the methylene hydrogen atoms of acrylonitrile, whereby interactions occur between these hydrogens as positive sites of local dipoles, and the π-electron cloud of benzene.

It is thus evident from above that whilst the orientations of styrene molecules with references to an acrylonitrile molecule are determined by dipole – induced dipole interactions at the negative end of the dipole moment of acrylontrile, and also by local dipole – induced dipole interactions at the positive end of this moment, the orientations of benzene molecules with respect to an acrylonitrile molecule are only determined by local dipole – induced dipole interactions. Accordingly, the observed greater equilibrium constant of the association process between acrylonitrile and styrene than that between acrylonitrile and benzene in cyclohexane could be ascribed to the stronger dipole – induced dipole forces in the former case.

Furthermore, the assumption of local dipole – induced dipole interaction may also be extended to the ethyl vinyl ether molecule as a base. Here, the ethoxy and methylene groups would be, respectively, directed toward the methylene and cyano groups of the acrylonitrile molecule. However, owing to the non-planarity of the ether molecule in contrast to the styrene and benzene molecules, the association complexes formed would not involve parallel alignment of molecules, so that the equilibrium constant of these complexes would be lower than that of complexes involving either styrene or benzene molecules, as is observed.

Finally, it may be added that although the orientations of the base molecules with reference to the acrylonitrile molecule in cyclohexane seem to be dominated by dipole–dipole forces, other forces are also quite possible.

The simultaneous influence of organic solvent and salt on the iodide-peroxodisulphate reaction

MANUEL BALÓN AND CARMEN CARMONA[1]

Departamento de Química Física, Facultad de Farmacia, Universidad de Sevilla, 41012 Sevilla, Spain

Received August 14, 1989

MANUEL BALÓN and CARMEN CARMONA. Can. J. Chem. **68**, 483 (1990).

To study the additivity of medium effects, the rates of reaction between peroxodisulphate and iodide ions have been measured in several salt – water – organic solvent mixtures. The results are consistent with Symons's hypothesis of the influence of salts and organic solvents on the equilibrium between bound water, free OH, and lone pair groups.

Key words: medium effects, kinetics, iodide, peroxodisulphate.

MANUEL BALÓN et CARMEN CARMONA. Can. J. Chem. **68**, 483 (1990).

Dans le but de vérifier l'hypothèse d'une additivité dans effets de solvants, on a mesuré les vitesses de réaction des ions peroxodisulfate et iodure, dans plusieurs mélanges de sel – eau – solvants organiques. Les résultats sont en accord avec l'hypothèse de Symon sur l'influence des sels et des solvants organiques sur l'équilibre entre l'eau et les groupements OH libres et les paires d'électrons libres.

Mots clés : effets de solvants, cinétique, iodure, peroxodisulfate.

Introduction

The influence of the medium on peroxodisulphate–iodide reaction has been reported previously (1–8). The effects of different added salts on this reaction were shown to be very specific and dependent upon the nature and concentration of the cations (5). Although this fact has sometimes been explained on the basis of ion pair formation, it is, in general, difficult to accurately interpret the data for this reaction in terms of ionic association. Some recent studies support the above statement. However, in spite of the importance of ion pair formation in media of low dielectric constant, this assumption can not explain the experimental results (7).

On the other hand, the kinetic salt effects (5) and the reactivity in water – organic solvent mixtures (8) has been successfully explained by modification on the water structure because of the presence of salt and organic solvent, respectively. Solvent mixtures with positive excess Gibbs free energy of mixing and structure-making salts diminish or just slightly increase the rate constant (2, 8), while evident rate constant increases are observed for structure-breaking salts and solvent mixtures with negative Gibbs free energy of mixing (5, 8). However, the simultaneous influence of both factors, i.e., organic solvent and salt, has never been studied. Thus in the present work, we have followed the reactivity in water–organic solvent–salt mixtures to analyze the additivity of medium effects. Mixtures of organic solvent and salt belonging to the two different groups mentioned above have been selected (9, 10).

Experimental

All reagents were of AnalaR grade and were used without further purification. Kinetic runs were carried out as described in literature (7). The concentrations of reactants were $|KI| = 0.25\ mol\ dm^{-3}$ and $|K_2S_2O_8| = 2 \times 10^{-4}\ mol\ dm^{-3}$. The solutions also contained $K_2(H_2edta)$ (edta = ethylendiaminetetraacetate) to prevent catalysis by some metal ions that could be present as impurities ($|K_2(H_2edta)| = 5 \times 10^{-4}\ mol\ dm^{-3}$). The organic solvents and compounds used were *tert*-butyl alcohol (TBA), acetonitrile (acn), dimethysulfoxide (dmso), *N*,*N*′-dimethylformamide (dmf), and sucrose. The water–organic compound mixtures were prepared by weight and the dielectric constant data are taken from the literature (11, 14). In each case the organic solvent was found to be inert in relation to the reactants and products. The salts were LiCl, KCl, KF, KBr, Me_4NBr, and Et_4NBr. In every case, the salt concentrations were 0.025, 0.050, 0.075, and $0.100\ mol\ dm^{-3}$.

Rate constants in duplicate or triplicate runs were reproducible to within better than 2%.

Results and discussion

The rate constants in the water – organic compound – salt mixtures are recorded in Table 1 and those in water – dmso and water – dmf in Table 2. As can be seen, the general pattern of the rate constants for all systems is remarkably similar. Thus, inorganic salts behave as sucrose, i.e., they produce an increase in rate constant, while TBA, acn, and tetralkylammonium salts decrease the rate constant. However, before trying any explanation on the experimental results, the following fact should be realized. On interpreting the medium effect on reaction rates between ions of the same charge sign, one point should be taken into account (15, 16). The addition of salts increases the ionic strength and thereby increases the rate constant. This effect could mask the real behavior of the system and lead to mistaken interpretation of experimental results. Thus, to make clear the existence of specific effects on this reaction, it is of interest to examine the results by applying a standard allowance for the long-range Debye–Hückel interactions and to obtain a corrected rate constant $k^{0\prime}$, defined by the following equation

$$[1] \quad \log k^{0\prime} = \log k - 2AZ_AZ_B\frac{\sqrt{I}}{1+\sqrt{I}}$$

where $A = 1.814 \times 10^6/(DT)^{3/2}$, D is the macroscopic dielectric constant, Z_A and Z_B the charges of the reactants, and the other symbols have their usual meaning.

The values of the corrected rate constants $k^{0\prime}$ and the slopes, m, of some representative plots (not shown) of $k^{0\prime}$ against salt concentration are recorded in Table 2. As can be seen in this table, a rather different pattern is now observed. While tetralkylammonium salts produce a decrease in rate constant on increasing salt concentration, the effect of LiCl is just the

opposite of that observed before and the other inorganic salts do not seem to bring about any important change in the rate constant. Moreover, the increase in rate constant due to the increase of sucrose concentration is lost and the $k^{0\prime}$ values in sucrose–water mixtures are only slightly higher than those in pure water.

Thus, substances which diminished the rate constant still maintain the same effect (TBA, acn, or tetralkylammonium salts), but those which increased k (except $k^{0\prime}$ for LiCl) have no effect or just a minor positive effect on $k^{0\prime}$. Therefore, the significant rate increase of k with increasing inorganic salt concentration was apparently due to an ionic strength effect. This effect was strong enough to overcompensate the real behaviour of LiCl which is similar, although less pronounced (16), to that observed for Me_4NBr and Et_4NBr.

As can be seen in Table 2, the effect of salts has near zero or negative influence on the rate constant in sucrose–water mixtures independent of the sucrose concentration. However, in TBA and acn–water mixtures the negative effect decreases with

increasing organic solvent content. In fact, the differences observed between Me_4NBr and Et_4NBr at low mole fraction TBA are mitigated at high alcohol proportions. Although no clear conclusions can be drawn from the sucrose – water – salts mixtures, owing to the small influence on reactivity of sucrose concentration, it can be said that in TBA–water–LiCl or tetralkylammonium salts these is a cancellation of added cosolvent and salt effects. The existence of such cancellation could be due to the dominance of hydration effects on reactivity patterns)17).

Therefore, the interpretation of experimental results has to be based on the different interactions between organic solvents and salts with water. Although there are several ways of interpretation that such interaction leads to a classification of salts and cosolvents into different groups (18–23), the present results are better explained using Symons's theory (24) on the influence of salts and organic solvents on the equilibrium between bound water and $(OH)_{free}$ or $(LP)_{free}$ groups. Assuming that a fundamental step in the reaction studied must be an electron transfer from the iodide to the peroxodisulphate ion (1) and that this transfer will be favoured through solvation from $(OH)_{free}$ groups of water, the reactivity pattern could be explained. The substances that diminish $(OH)_{free}$ concentration should produce a decrease in rate constant and those that increase $(OH)_{free}$ concentration an increase in rate constant. According to Symons (24), alcohol and bases cause a loss of $(OH)_{free}$ groups and hence a decrease in rate constant. Tetralkylammonium salts can also induce a great decrease in $(OH)_{free}$ concentration, an effect so pronounced that their influence on rate constant is not compensated by the ionic strength effect. This gives rise to an overall decrease in rate constant even after the ionic strength correction. As would be expected (24), the alkali halide salts induce minor changes in $k_{0\prime}$, the differences between KCland LiCl or NaCl (see Tables 2 and 3) probably being due to the slight differences in solvation of the respective cations. These changes in solvation could also explain the smaller influence of the weakly solvated ClO_4^-anion (24) (see Table 3) (Et_4NCLO_4) as compared with the Br^- anion (Et_4NBr).

Since sucrose is a weak polybasic acid (25) for which two dissociation constants have been determined, it can be suggested that sucrose interacts with water to cause a slight increase of $(OH)_{free}$ groups and hence a small increase in rate constant. In this sense, it can be said that the spectroscopic changes induced by addition of sucrose to water are, in general, small and similar to those produced by potassium nitrate (26).

Finally, if the decrease of the OH groups concentration gives rise to a decrease in the reactivity, solvents such as dmso or dmf should also decrease the rate constant. As can be seen in Table 2, the observed order is

$$k^{0\prime}_{H_2O} > k^{0\prime}_{acn} > k^{0\prime}_{dmf} > k^{0\prime}_{dmso}$$

which qualitatively agrees with the effective base-strength of the cosolvents in water (24).

Phenylfluorophosphoranes: axial–equatorial fluorine exchange in $RC_6H_4PF_3H$ and intermolecular exchange in the $PhPF_2(H)OMe$–MeOH–base system

LEONARD J. KRUCZYNSKI, ALBERTA E. LEMIRE,[1] KIRK MARAT, AND ALEXANDER F. JANZEN
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received June 14, 1989

LEONARD J. KRUCZYNSKI, ALBERTA E. LEMIRE, KIRK MARAT, and ALEXANDER F. JANZEN. Can. J. Chem. **68**, 488 (1990).

Activation parameters for axial–equatorial fluorine exchange in arylfluorophosphoranes $RC_6H_4PF_3H$, where R = *o*-CF_3, *m*-CF_3, *p*-CF_3, *m*-CH_3, were studied by the dynamic nmr technique: $\Delta G^{\ddagger}_{298}$ varied between 53 and 56 kJ mol^{-1}.

The synthesis of difluoromethoxyphenylphosphorane, $PhPF_2(H)OMe$, from $PhPF_2$ and MeOH is catalyzed by small amounts of Et_3N, pyridine, $PhPF_3H$, or HF. Rapid intermolecular ligand exchange occurs in $PhPF_2(H)OMe$ after addition of methanol and a base such as triethylamine or pyridine. Under these conditions, exchange of fluorine, hydrogen, and methoxy ligands occurs, as shown by ^1H, ^{19}F, and ^{31}P nmr. From a line shape analysis of the $^{31}P\{^1H\}$ nmr spectrum, the rate of P—F cleavage was found to be first order (1.17 ± 0.2) in Et_3N concentration, with $\Delta G^{\ddagger}_{298}$ = 50 kJ mol^{-1} and $\Delta S^{\ddagger}$ = −67 J mol^{-1} deg^{-1}.

An equilibrium constant of 1.8 at 25°C was found for the reaction of $PhPF_2(H)OMe$ with $PhPF_2$.

Key words: axial–equatorial fluorine exchange in $RC_6H_4PF_3H$ intermolecular exchange in the $PhPF_2(H)OMe$–MeOH–base system; ^{31}P and ^{19}F nmr study of ligand exchange in phosphoranes.

LEONARD J. KRUCZYNSKI, ALBERTA E. LEMIRE, KIRK MARAT et ALEXANDER F. JANZEN. Can. J. Chem. **68**, 488 (1990).

Faisant appel à la technique de la rmn dynamique, on a déterminé les paramètres d'activation de l'échange axial–équatorial du fluor dans des arylfluorophosphanes, $RC_6H_4PF_3H$, dans lesquels R = *o*-CF_3, *m*-CF_3, *p*-CF_3 et *m*-CH_3; la valeur du $\Delta G^{\ddagger}_{298}$ varie de 53 à 56 kJ mol^{-1}.

La synthèse des difluorométhoxyphénylphosphoranes, $PhPF_2(H)OMe$, à partir du $PhPF_2$ et du MeOH est catalysée par de faibles quantités de Et_3N, de pyridine, de $PhPF_3H$ ou de HF. L'addition de méthanol et d'une base, comme la triéthylamine ou la pyridine, provoque un échange intermoléculaire rapide de ligands dans le $PhPF_2(H)OMe$. Dans ces conditions, on a pu montrer par rmn du ^1H, du ^{19}F et du ^{31}P qu'il se produit un échange des ligands fluor, hydrogène et méthoxy. En se basant sur une analyse de la forme des bandes du spectre rmn du $^{31}P\{^1H\}$, on a trouvé que la vitesse de clivage de la liaison P—F est du premier ordre (1,17 ± 0,2) en Et_3N alors que le $\Delta G^{\ddagger}_{298}$ = 50 kJ mol^{-1} et le $\Delta S^{\ddagger}$ = −67 J mol^{-1} deg^{-1}.

Par la réaction du $PhPF_2(H)OMe$ avec le $PhPF_2$, à 25°C, on a trouvé que la constante d'équilibre est égale à 1,8.

Mots clés : échange axial–équatorial du fluor dans des $RC_6H_4PF_3H$ échange intermoléculaire dans le système $PhPF_2(H)OMe$–MeOH–base; étude en rmn du ^{31}P et du ^{19}F de l'échange de ligands dans les phosphoranes.

[Traduit par la revue]

Stereoselective bond-cleavage is difficult to observe in five- and six-coordinate compounds if accompanied by axial–equatorial scrambling of ligands, as illustrated by the $PhPF_3H$–$PhPF_4H^-$ or $PhPF_4$–$PhPF_5^-$ systems (1, 2), although the introduction of three phenyl substituents can avert this problem, as demonstrated by the Ph_3TeF_3–$Ph_3TeF_2^+$ or Ph_3TeF_2Cl–Ph_3TeFCl^+ systems (3). In this paper we describe another, albeit unsuccessful, attempt at slowing down axial–equatorial ligand exchange, namely, by the introduction of trifluoromethyl or methyl substituents into the phenyl ring of $PhPF_3H$. The role of catalysts in phosphorane synthesis, as well as intermolecular ligand exchange in phosphoranes, was studied in the $PhPF_2(H)OMe$–MeOH–base system and the results compared to a previous study of intra- and intermolecular ligand exchange in the $PhPF_3H$–$PhPF_4H^-$ system (1).

Axial–equatorial exchange in phosphoranes $RC_6H_4PF_3H$

The phosphoranes $RC_6H_4PF_3H$ were prepared by the addition of HF to the corresponding aryldifluorophosphines (4)

[1] $RC_6H_4PF_2 + HF \longrightarrow RC_6H_4P(F^a)(H)(F^e)(F^a)$

R = *o*-CF_3, *m*-CF_3, *o*-CF_3, *m*-CH_3

and the compounds identified by ^{31}P nmr (Table 1), as well as ^{19}F and ^1H nmr. During some preparations, impurities $RC_6H_4P(O)F_2$ and $RC_6H_4P(O)FH$ were observed and their ^{31}P nmr data are also recorded in Table 1, but these impurities do not interfere with the axial–equatorial exchange process.

Addition of small amounts of Et_3N to $RC_6H_4PF_3H$ leads to the formation of $RC_6H_4PF_2$ and the onset of intermolecular fluorine exchange, and reactions [2] and [3] are consistent with the behavior reported for $PhPF_3H$ (1).

[2] $2RC_6H_4PF_3H + Et_3N \rightarrow RC_6H_4PF_2 + Et_3NH^+\ RC_6H_4PF_4H^-$

[3] $RC_6H_4PF_3H + RC_6H_4PF_4H^- \rightleftharpoons RC_6H_4PF_3H\text{-}F\text{-}PF_3HC_6H_4R^-$

In the absence of a base, axial–equatorial fluorine exchange in $RC_6H_4PF_3H$ may be studied by comparing the variable-temperature $^{31}P\{^1H\}$ nmr spectra with line shapes calculated by the method described previously for $PhPF_3H$ (1). A least-squares analysis of the data gave the activation parameters for axial–equatorial exchange listed in Table 2, with $\Delta G^{\ddagger}_{298}$ values in the range 52.9 to 56.0 kJ mol^{-1}, which may be compared to 55.6 kJ mol^{-1} for $PhPF_3H$ (1). These results show that trifluoromethyl or methyl substituents have only a slight effect on the activation barriers, and our attempt to slow down axial–equatorial scrambling in five-coordinate species by this approach was not successful, therefore $RC_6H_4PF_3H$ is not a suitable "rigid" probe of site-specific bond cleavage at ambient temperature.

Intermolecular exchange in the $PhPF_2(H)OMe$–MeOH–base system

The synthesis of $PhPF_2(H)OMe$ was found to be catalyzed

by the addition of small amounts of Et_3N, pyridine, $PhPF_3H$, or HF.

[4] $PhPF_2 + MeOH \xrightarrow[PhPF_3H \text{ or } HF]{Et_3N,\ pyr}$ 
Without an added catalyst, the formation of $PhPF_2(H)OMe$ at 27°C from $PhPF_2$ (0.65 *M*) and MeOH (0.65 *M*) is complete within about 1 h, as seen in Fig. 1, with a half-life of formation of 28 min, but addition of Et_3N (3.6×10^{-3} *M*) or $PhPF_3H$ (6.8×10^{-2} *M*) reduces the half-life to 6.6 and 2.5 min, respectively. The reaction of HF with $PhPF_2$ is rapid and occurs on mixing in an nmr tube while MeOH (1.2 *M*) reacts more rapidly with $PhPF_3H$ (1.2 *M*) than with $PhPF_2$, the reaction being complete within 2 min. Catalysis by HF and $PhPF_3H$ can thus be accounted

[5] $PhPF_2 + HF \rightarrow PhPF_3H$

[6] $PhPF_3H + MeOH \rightarrow PhPF_2(H)OMe + HF$

for by the more rapid reactions [5] and [6] as compared to the uncatalyzed formation of $PhPF_2(H)OMe$. Pyridine also catalyzes reaction [4] and the synthesis of $PhPF_2(H)OMe$ with 1% added pyridine was complete within 5 min at −10°C, but the mechanism of pyridine or Et_3N catalysis remains unclear.

$PhPF_2(H)OMe$ is chemically stable below 10°C and undergoes no intermolecular ligand exchange in solvents such as C_6H_6, CH_2Cl_2, or CH_3CN, but above 10°C decomposition slowly sets in after about 5 h. A sample of $PhPF_2(H)OMe$ plus 10% MeOH, without solvent or base, shows no exchange below 2°C, however, with excess MeOH there is rapid exchange above 2°C but the equilibrium remains essentially towards the $PhPF_2(H)OMe$ side.

The $PhPF_2(H)OMe$–MeOH–base system (5) is of some interest because hydrogen, fluorine, and methoxy exchange can be observed by ^1H, ^{19}F, and ^{31}P nmr. A typical sample made

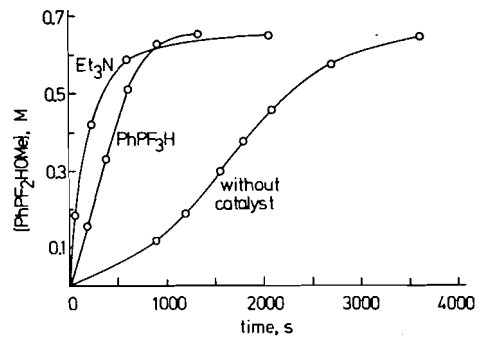

FIG. 1. Formation of $PhPF_2(H)OMe$ from $PhPF_2$ (0.65 *M*) and MeOH (0.65 *M*) without catalysts and with catalysts Et_3N (3.6×10^{-3} *M*) and $PhPF_3H$ (6.8×10^{-2} *M*) at 300 K in C_6H_6 solution.

up from $PhPF_2(H)OMe$ (1 *M*), MeOH (1 *M*), and Et_3N (0.09 *M*) contains $PhPF_2(H)OMe$ (80%), PhPFOMe (1%), and $PhP(OMe)_2$ (7%) at equilibrium, plus some PhP(O)(H)OMe and PhP(O)F(OMe). Kinetic information may be obtained by studying the line broadening of nmr peaks due to $PhPF_2(H)OMe$ in $PhPF_2(H)OMe$–MeOH–base samples and comparing experimental and calculated nmr spectra.

The rate of P—F cleavage in a $PhPF_2(H)OMe$–MeOH–Et_3N sample was studied by $^{31}P\{^1H\}$ nmr and from the variable-temperature spectrum it was found that $E_a = 33$ kJ mol^{-1} and $\Delta S^{\ddagger} = -67$ J mol^{-1} deg^{-1} (Fig. 2). By varying the Et_3N concentration, it was found that the exchange process is first order (1.17 ± 0.2) in Et_3N concentration. Variable-temperature ^{19}F nmr spectra of a $PhPF_2(H)OMe$ (0.67 *M*) – MeOH (0.30 *M*) – pyridine (0.04 *M*) sample in C_6D_6 over the temperature range −49 to 8°C, gave $E_a = 39$ kJ mol^{-1}. By keeping the concentration of $PhPF_2(H)OMe$ (1 *M*) and Et_3N (0.14 *M*) constant, but varying that of MeOH (1.47 to 3.94 *M*), it was possible to show by $^{31}P\{^1H\}$ nmr that the rate of P—F bond cleavage is independent of MeOH concentration. These results suggest a

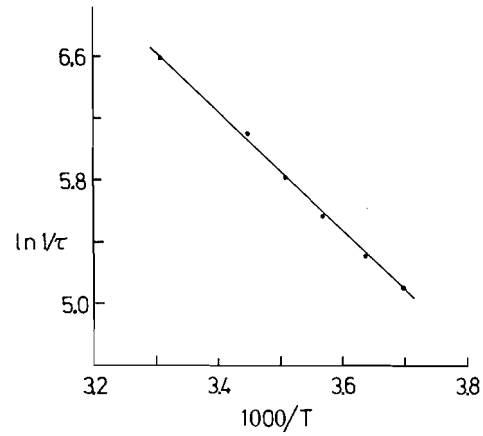

FIG. 2. Plot of ln $1/\tau$ vs. $1/T$ for $PhPF_2(H)OMe$–MeOH–base system. $^{31}P\{^1H\}$ nmr sample contained $PHPF_2(H)OMe$ (1 *M*), MeOH (1 *M*), and Et_3N (0.14 *M*) in CD_2Cl_2 (2 mL).

mechanism very similar to that proposed for base-initiated P—F bond cleavage in the $PhPF_3H$–$PhPF_4H^-$ system (1), namely, the slow production of PhPFOMe and anion $PhPF_3(H)OMe^-$, reaction [7], followed by rapid fluorine exchange between five- and six-coordinate phosphorus species, reaction [8]. Since the nmr spectral lines of PhPFOMe show no line broadening

[7] $2PhPF_2(H)OMe + base \rightarrow PhPF(OMe) + baseH^+\ PhPF_3(H)OMe^-$

[8] $PhPF_2(H)OMe + PhPF_3(H)OMe^- \rightleftharpoons PhPF_2(H)OMe—F—PhPF_2(H)OMe^-$

throughout the exchange process, a simple base-promoted loss of HF (to give PhPFOMe) from $PhPF_2(H)OMe$ is ruled out as a mechanism of rapid exchange in the $PhPF_2(H)OMe$–MeOH–base system.

The appearance of PhPFOMe and $PhP(OMe)_2$ indicates that P—OMe and P—H bond cleavage also occurs in $PhPF_2(H)OMe$–MeOH–base samples. That bond cleavage is rapid and reversible was demonstrated by ^1H and ^{19}F nmr. For example, the methoxy signal in $PhPF_2(H)OMe$ at 16°C changes from a doublet $^3J(HP) = 14.8$ Hz of triplets $^4J(HF) = 1.1$ Hz to a single peak, averaged with the MeOH peak, in a $PhPF_2(H)OMe$–MeOH–base sample, but at −42°C exchange is stopped and separate methoxy peaks are observed for $PhPF_2(H)OMe$ and MeOH.

In an attempt to gain information about the relative rates of P—F versus P—OMe and P—H bond cleavage, variable-temperature ^{19}F nmr spectra of $PhPF_2(H)OMe$–MeOH–pyridine samples were recorded from −49 to 10°C and compared with calculated spectra based on different exchange mechanisms (Fig. 3). Unfortunately, the fast exchange limit, where clear differences are predicted by the calculated line shapes, required temperatures well above 10°C, but these led to decomposition of the $PhPF_2(H)OMe$–MeOH–base samples. Therefore, the mechanism of P—OMe and P—H bond cleavage remains unclear. The fact that the rate of P—F cleavage is independent of MeOH concentration (*vide supra*), plus the demonstration that P—F cleavage in the $PhPF_3H$–$PhPF_4H^-$ system (1) is not accompanied by P—H bond cleavage leads us to assume that cleavage of P—F bonds occurs more rapidly than P—OMe or P—H bonds in the $PhPF_2(H)OMe$–MeOH–base system.

$PhPF_2(H)OMe$ may be converted to $PhP(OMe)_2$ by adding a base and an excess of MeOH, reaction [9]. Thus a sample containing $PhPF_2(H)OMe$ (1 *M*), MeOH (2.5 *M*), and Et_3N (0.7 *M*) at 37°C gave $PhP(OMe)_2$ in 90% yield. On the other hand, adding $PhPF_2$ to $PhPF_2(H)OMe$, reaction [10],

[9] $PhPF_2(H)OMe + MeOH + Et_3N \rightarrow PhP(OMe)_2 + Et_3N\cdot(HF)_n$

[10] $PhPF_2(H)OMe + PhPF_2 \rightleftharpoons PhPFOMe + PhPF_3H$

or mixing $PhPF_2$ and MeOH in a 2:1 ratio, results in the formation of PhPFOMe (5). Since $PhPF_2(H)OMe$ can be prepared *in situ* from $PhPF_2$ and MeOH, therefore, controlling the amounts of $PhPF_2$, MeOH, and base leads to convenient synthesis of either PhPFOMe or $PhP(OMe)_2$.

Equilibrium [10] involves fluorine exchange which is very slow on the nmr time scale and all species gave well-resolved

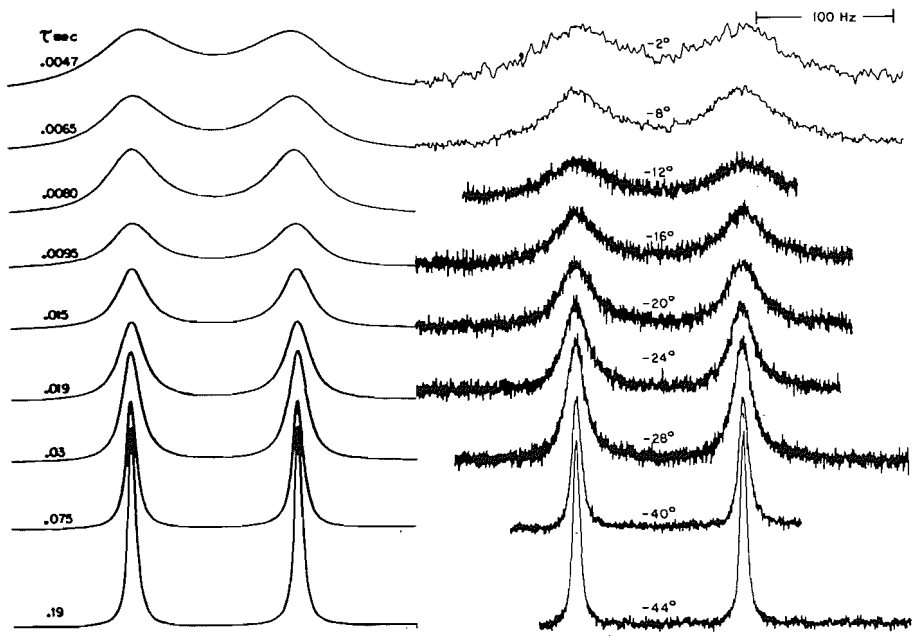

FIG. 3. Typical temperature-dependent experimental (right) and calculated (left) ^{19}F nmr spectra of $PhPF_2(H)OMe$–MeOH–base system. Sample contained $PhPF_2(H)OMe$ (0.67 *M*), MeOH (0.29 *M*), and pyridine (0.04 *M*) in C_6D_6 (2 mL) (F—P coupling omitted).

nmr signals, hence from ^{19}F and ^{1}H nmr peak integrations an equilibrium constant of 1.8 at 25°C was calculated.

Experimental

The nmr spectra were recorded on a Bruker WH90 spectrometer at 90(^{1}H), 84.66(^{19}F) and 36.44(^{31}P) MHz. Line-shapes were calculated using a modified version of the program EXCHSYS (6), as described for the $PhPF_3H$–$PhPF_4H^-$ system (1), and temperatures were calibrated by the method of Van Geet (7).

o-, *m*-, and *p*-Bromobenzotrifluoride were obtained from Aldrich Chemical Co. and $PhPF_2(H)OMe$ (5) and *o*-$CF_3C_6H_4PF_2$ (8) were prepared as described previously. $(Et_2N)_2PCl$ was made in 61% yield from PCl_3 (28 g, 0.20 mol) and Et_2NH (58 g, 0.79 mol) in petroleum ether (275 mL) at −78 to 25°C, according to the method of Burg and Slota (9). $PhP(OMe)_2$ was made from $PhPCl_2$, HOMe, and pyridine in petroleum ether (10); it was also prepared in 90% yield from $PhPF_2(H)OMe$ (2 mmol), MeOH (5 mmol), and Et_3N (1.4 mmol) at 37°C in an nmr tube. HF solutions were prepared by condensing 1–2 g of anhydrous HF into 10 mL acetonitrile. The following compounds were identified by their nmr spectra: $PhPF_2$ (11), $PhP(O)F_2$ (12), PhPF(OMe) (5), $PhP(OMe)_2$ (12), PhP(O)H(OMe) (12), PhP(O)F(OMe) (11), and $PhPF_3H$ (1, 13).

m-*$CF_3C_6H_4PCl_2$*

m-$CF_3C_6H_4Br$ (25 g, 0.11 mol) in ether (25 mL) was added to Mg turnings (2.8 g) in ether (5 mL) and the reaction initiated with an iodine crystal and periodically cooled to 0°C to slow down the rate of reaction. After the addition was complete, the mixture was stirred for 1 h and then $(Et_2N)_2PCl$ (23 g, 0.11 mmol) added dropwise with stirring at 0°C. After standing at 25°C for 12 h, the mixture was cooled to −78°C and gaseous HCl bubbled in. The ether layer was decanted off and the precipitate washed twice with 30 mL of ether. Extracts were combined and more HCl bubbled in. The ether layer was again decanted off and evaporated on rotary evaporator to give *m*-$CF_3C_6H_4PCl_2$ (14) (15 g, 72% yield).

A similar procedure was used for *o*-, *p*-$CF_3C_6H_4PCl_2$ and *m*-$CH_3C_6H_4PCl_2$.

m-*$CF_3C_6H_4PF_2$*

NaF (14 g, 0.33 mol) was dried under vacuum with a flame for 15 min and added to dry sulfolane (25 mL). *m*-$CF_3C_6H_4PCl_2$ (15 g, 61 mmol) in sulfolane (10 mL) was added and the reaction mixture heated at 120–140°C for 4 h under N_2 atmosphere. After a further 12 h at 25°C, ^{31}P nmr confirmed the presence of *m*-$CF_3C_6H_4PF_2$ and some *m*-$CF_3C_6H_4P(O)F_2$, but no unreacted *m*-$CF_3C_6H_4PCl_2$. Distillation under vacuum gave *m*-$CF_3C_6H_4PF_2$ (5 g, 30%) and some *m*-$CF_3C_6H_4P(O)F_2$.

A similar procedure was used for *o*-, *p*-$CF_3C_6H_4PF_2$ and *m*-$CH_3C_6H_4PF_2$.

m-*$CF_3C_6H_4PF_3H$*

HF (1.2 equiv.) in acetonitrile was added to *m*-$CF_3C_6H_4PF_2$ (2.6 g, 12 mmol), prepared as described above. Excess HF and acetonitrile was removed under vacuum and distillation under reduced pressure gave a central fraction containing *m*-$CF_3C_6H_4PF_3H$ and some *m*-$CF_3C_6H_4P(O)F_2$. Since the latter oxide did not interfere with the axial–equatorial exchange process, this fraction was used for the nmr study. A typical nmr sample contained *m*-$CF_3C_6H_4PF_3H$ (2.1 mmol) in 2 mL of 2:1 v/v toluene–C_6D_6.

A similar procedure was used for *o*-, *p*-$CF_3C_6H_4PF_3H$ and *m*-$CH_3C_6H_4PF_3H$.

Samples of $RC_6H_4PF_3H$ and $RC_6H_4PF_2$ were stored in sealed tubes in a freezer until required for nmr studies.

Pentacarbonylmanganese enolate and dienolate complexes. Preparative and mechanistic considerations

ANDREW P. MASTERS AND TED S. SORENSEN
The Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received June 5, 1989

ANDREW P. MASTERS and TED S. SORENSEN. Can. J. Chem. **68**, 492 (1990).

Reactions of pentacarbonyl manganate anion with 4-halocrotonate esters or 2-halocarboxylate esters result in a complex set of inorganic and organic products, usually including the expected dienolate (or enolate) complexes. The reaction variables include the counterion, solvent, and halo group. The mechanism of the reaction has been investigated by conducting a thorough characterization of the reaction products under various conditions and also by carrying out model reactions. One can rationalize most of the non-organometallic products using either a radical or carbanion mechanism, but the latter seems to fit the available data better. Experimental procedures for optimizing the yield of the organometallic dienolate or enolate complexes have been worked out.

Key words: pentacarbonyl manganate, metalate nucleophilicity, enolate complex, nucleophilic substitution, ^{55}Mn NMR spectroscopy.

ANDREW P. MASTERS et TED S. SORENSEN. Can. J. Chem. **68**, 492 (1990).

Les réactions de l'anion pentacarbonyl manganate avec les esters 4-halocrotonates ou 2-halocarboxylates conduisent à la formation d'un ensemble de complexes de produits organiques et inorganiques qui contiennent généralement les complexes diénolates (ou énolates) attendus. Les facteurs qui influencent la réaction comprennent le contre-ion, le solvant et la nature de l'halogène. Dans le but de déterminer le mécanisme de la réaction, on a procédé à un examen minutieux des produits obtenus au cours de réactions réalisées sous diverses conditions et on a réalisé diverses réactions modèles. On peut rationaliser la formation de la plupart des produits qui ne sont pas des organométalliques par des mécanismes soit radicalaires ou carbanioniques; toutefois, ces derniers semblent mieux accommoder les données disponibles. On a déterminé les conditions expérimentales appropriées pour obtenir les meilleurs rendements possibles de complexes diénolates ou énolates.

Mots clés : pentacarbonyl manganate, nucléophilicité métallate, complexe énolate, substitution nucléophile, spectroscopie RMN du ^{55}Mn.

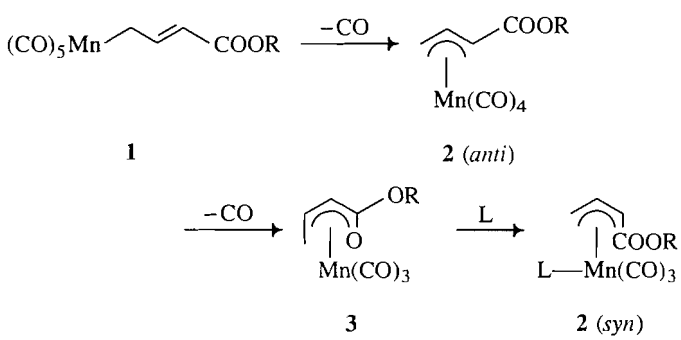
The metal-centered anion $Mn(CO)_5^-$ has been extensively used to prepare $R\text{-}Mn(CO)_5$ type compounds (R = alkyl, perfluoroalkyl, etc.). However, there are numerous instances where eq. [1] fails, where the yields are inexplicably poor, or

[1] $M^+Mn(CO)_5^- + RX \rightarrow RMn(CO)_5 + X^- + M^+$

where other products such as $Mn_2(CO)_{10}$ are formed. In fact the present study evolved when we had difficulties in applying eq. [1] to the synthesis of a simple ester dienolate complex (R = dienolate).

For a background to transition-metal enolate complexes, the recent papers of Heathcock and co-workers (1) provide an extensive bibliography. Dienolate complexes of transition metals have even more potential bonding modes, including the straightforward η^1-, η^3-, or η^5-complexes **1**, **2**, or **3**. The initial intent of our work was to study the synthetic utility of the η^3-complex, with the expectation that the geometry in these could be controlled via the η^5-complex, as indicated below:



1 **2** (*anti*)

3 **2** (*syn*)

However, the most common and practicable route to the η^3-complexes of $Mn(CO)_4$ involves the initial preparation of the η^1-complex.

Mechanistically, the eq. [1] reaction has been shown to occur with at least some inversion of configuration in the case of 2-bromopropionate (2), and other metallate anions have shown similar S_N2 (or S_N2-like) reactivity. There is, however, some literature discussion at present concerning the role of single electron transfer (S.E.T.) in nucleophilic substitution reactions. The radical chain ($S_{RN}1$) mechanism can be tested for in well-defined ways, but substitutions where the overall process is envisioned as two closely timed events (S.E.T. followed by leaving group loss and geminate recombination) can be virtually indistinguishable from S_N2 mechanisms (the recent papers of Bordwell and Wilson (3) provide an extensive bibliography of work in this area).

The overall aims of this study were (1) to carry out a reasonably complete analysis of all of the products and by-products of eq. [1], where R = ester enolate or dienolate. This includes varying a number of experimental parameters to optimize the yields of the desired products. (2) In conjunction with (1), to formulate mechanisms to account for all of the products and by-products observed. This study also involves carrying out extra experiments designed simply to answer certain mechanistic questions.

Results and discussion

The reaction between $Mn(CO)_5^-$ and commercially available ethyl 4-bromocrotonate **4** seemed a likely method for preparing the parent η^1-dienolate ester complex **5** (eq. [2]). For example,

allyl chloride gives the corresponding η^1-adduct in good yield (4).

[2] $Mn(CO)_5^- + Br\text{-}CH_2$ (H, H, COOEt) → $(CO)_5Mn\text{-}CH_2$ (H, H, COOEt) + Br^-

4 5

$Mn(CO)_5Br$ $OC\text{—}Mn\text{—}Mn\text{—}CO$ (CO, CO, CO, CO, CO, CO, CO, CO)

6 7

However, initial attempts at this reaction gave $Mn_2(CO)_{10}$ as the main isolable manganese product (column chromatography). At this point it was assumed that $Mn_2(CO)_{10}$ was a decomposition product of a labile η^1-adduct **5**. Because of such potential work-up problems, we moved to an *in situ* examination of reaction mixtures using ^{55}Mn NMR spectroscopy and IR spectroscopy. This allows one to rapidly examine the manganese products formed and to therefore rapidly monitor the effect of various experimental variables connected with the eq. [2] reaction.

^{55}Mn NMR spectroscopy shows broad but separate resonances for a number of different manganese carbonyl environments. The most extensive study in this area is by Calderazzo *et al.* (5), showing chemical shifts varying over nearly 3000 ppm. Line widths vary from a few Hz (MnO_4^-) to many kHz. The manganese compounds of relevance in this work are listed in Tables 1 and 2, together with our measured chemical shifts and $W_{1/2}$ values. A few other compounds that were available to us are also included in these tables. These agree reasonably well with the older data (5) in those cases where we have repeated some of the measurements. The use of ^{55}Mn NMR as an analytical tool is hampered because very broad lines are difficult to observe on a high resolution spectrometer. However, we have invariably backed up the ^{55}Mn assignments using IR spectroscopy, even though this may not be explicitly discussed in the text.

A tetrahydrofuran (THF) solution of $Na^+Mn(CO)_5^-$ at 25°C shows a single ^{55}Mn peak at −2675 ppm, $W_{1/2}$ ca. 7000 Hz (the anion). Rapid mixing with ethyl 4-bromocrotonate results in the immediate formation of a precipitate of sodium bromide, and the ^{55}Mn NMR spectrum (Fig. 1) showed the loss of the −2675 peak and the formation of three new resonances at −1156, −1929, and −2281 ppm, corresponding to $Mn(CO)_5Br$ **6**, the η^1-complex **5** (subsequently verified), and $Mn_2(CO)_{10}$ **7**, respectively. The relative yields by integration (using a variable correction factor, as discussed in the Experimental) gave 25% **6**, 34% **5**, and 42% **7**. The products of this reaction could be separated by flash chromatography, confirming the NMR identifications. The η^1-complex **5** was isolated as a pale yellow air-sensitive oil in ca. 20% yield and was fully characterized.

Using the above analytical procedures, most of the eq. [1] experimental conditions were then varied. This included changing

[b]Literature value (5).

the solvent, the counterion, the halogen leaving group, and the relative stoichiometry of $Mn(CO)_5^-$ and halo ester. These results are summarized in Table 3 and there are several obvious conclusions:

1. The chloride leaving group gives the best yield of **5**.
2. The lithium counterion (which had been used in the initial work) is particularly bad. The Na^+, K^+, and PPN^+ (bistriphenylphosphineiminium) counterions give quite similar results, although PPN^+ is best.
3. The use of a cation complexing crown ether is useful, as is the addition of 5% dimethylformamide or 4% HMPA. There has been much related work in this area (6).
4. It is not very convenient to vary the solvent in the case of the Li^+, Na^+, or $K^+Mn(CO)_5^-$ salts, since these are usually prepared *in situ* in THF. However, the PPN^+ salt is soluble in a variety of solvents. Comparing THF and $CHCl_3$ (Table 3), there is very significantly less η^1-adduct **5** and much more $Mn_2(CO)_{10}$ in the latter case.

Overall, the best results are obtained using $PPN^+Mn(CO)_5^-$ together with the chloride leaving group and THF solvent, giving a near quantitative yield of the η^1-complex. Obviously, in this case, one uses a 1:1 stoichiometric ratio of both reactants. However, in those reactions where one obtains significant amounts of $Mn(CO)_5Br$ and $Mn_2(CO)_{10}$, it is not clear that a 1:1 stoichiometry is the best choice. We therefore conducted a study where the reactant stoichiometry was varied, and this is summarized in Table 4. As expected, the chloride leaving group results are not much affected, but for the bromide there are substantial changes in products, particularly in the amount of $Mn(CO)_5Br$ being formed. The results shown in Tables 3 and 4 also indicate a clearcut difference between bromo and chloro esters, since the latter *never* give any $Mn(CO)_5Cl$ product.

The purely organic products

From flash chromatography of a crude reaction mixture involving a significant yield of $Mn(CO)_5Br$ (see Table 3), a diethyl ether eluant was found to yield a colorless oil containing the purely organic compounds. This material was a complex mixture but could be separated by preparative GLC into the individual components, identified by MS and NMR spectroscopy as compounds **8**, **9**, **10**, and **11**. Diesters **8** and **9** are known (7) and the reported ^1H NMR spectra agree with those found here. Compound **11** was isolated as a single geometric isomer (assigned *trans*), but consisted of a mixture of two

diastereomers, only partly resolved by GLC. Nevertheless, by careful fraction cutting, enough pure material could be obtained for an ^{1}H NMR spectrum of the pure diastereomers, although we were not able to make a definitive assignment from this.

The reaction of $Mn(CO)_5^-$ with 2-halocarboxylate esters

Given the variable product distributions found for the 4-halocrotonate esters, it was decided to conduct a study of the reactions of simple 2-halocarboxylate esters. This involved the organic compounds $R^1R^2XCCOOEt$, where X was Cl, Br, and I, and R^1 and R^2 were H,H; H,CH_3; and CH_3,CH_3. There are two previous reports dealing with the title reactions, a communication in which 2-bromopropionate was used (2) and a later study using methyl 2-chloroacetate (8).

In our study, the $Mn(CO)_5^-$ was used as the sodium salt in THF, or as the PPN^+ salt in THF or chloroform. The reactions were carried out by rapid mixing of one equivalent of $Mn(CO)_5^-$ with one equivalent of the 2-haloester (unless otherwise

Using the sodium salt in THF, the results of this reaction are given in Table 5. The general trends in the primary system parallel those found for crotonates, i.e., high yields of the η^1-adduct with Cl, poor yields with Br, together with considerable $Mn(CO)_5Br$ and $Mn_2(CO)_{10}$. The primary iodo compound gave no η^1-adduct, a result also verified for a 1:2 or a 1:0.5

stoichiometric ratio of $Mn(CO)_5^-$ to iodoacetate. In the first case, the $Mn(CO)_5I$:$Mn_2(CO)_{10}$ product ratio was 86:14, while in the latter, the figures were 0:100. The tertiary system was unreactive when X was Cl, gave only $Mn_2(CO)_{10}$ for X = Br, and a mixture of $Mn(CO)_5I$ and $Mn_2(CO)_{10}$ for X = I. For the secondary system with X = Cl, only a very slow reaction occurred to give a trace of η^1-adduct after several days but with X = Br or I, all three products were formed (η^1-adduct, $Mn(CO)_5X$, and $Mn_2(CO)_{10}$).

The reaction of the nine halo esters with the PPN^+ salt in THF gave the results shown in Table 6. A noteworthy observation is the virtual absence of $Mn_2(CO)_{10}$ in any of these reactions, a result which was also seen in the crotonate system using the same salt and solvent. Yields of the η^1-adduct are excellent for either primary chloride or bromide, and even the secondary systems give reasonable yields. In those cases where there is some initial $Mn(CO)_5Br$ or $Mn(CO)_5I$ formed, one sees a rapid subsequent reaction with the also present Br^- or I^- (from the displacement reaction) giving $Mn(CO)_4Br_2^-$ or $Mn(CO)_4I_2^-$ salts, which are both polar and nonvolatile (9). A simple flash chromatography gave good isolated yields of pure primary and secondary η^1-enolates, which were fully characterized (see Experimental).

Using the PPN^+ salt in $CHCl_3$ (Table 7) gave markedly different results from the THF solvent, in that $Mn_2(CO)_{10}$ was again a major product. This solvent, as $CDCl_3$, was useful, however, for *in situ* ^1H NMR studies. This same counterion–solvent system was also used to vary the stoichiometry of the reactants (Table 8).

The purely organic products

This section refers to the characterization of the purely organic products derived from reactions where $Mn(CO)_5X$ (or $Mn_2(CO)_{10}$) is the manganese species formed. The products observed are actually very dependent on the solvent system (THF vs. $CDCl_3$) and both series will be discussed.

Because the primary system gives relatively large amounts of substitution in most cases, the secondary and tertiary halo esters are the most convenient for this study. Using the PPN^+ salt in $CDCl_3$, the deuterochloroform appears to serve as an efficient "trapping agent". *In situ* ^1H NMR spectroscopic examination of the secondary system reaction products in $CDCl_3$ (Br or I) shows a mixture of ethyl 2-deuteropropionate and the η^1-adduct. For the tertiary esters, the bromo system gives ethyl 2-deutero-2-methylpropionate (54%) and unreacted starting material, whereas the iodo system gives 74% of the deutero ester. Although the primary system was dominated by the η^1-adduct, it was possible to also observe the characteristic ^1H triplet for CDH_2COOEt, in addition to some starting material. These ^1H assignments were further verified by preparative GLC isolation

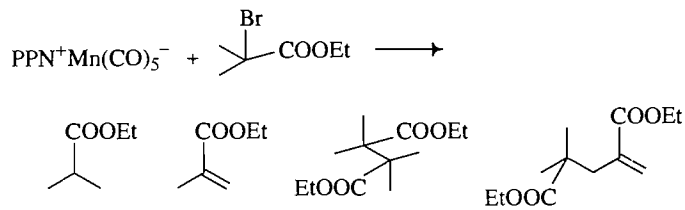
of the deutero esters in the secondary and tertiary cases, followed by both MS and a further ^1H NMR spectrum, this time of the pure compound. In the primary case, the deutero ethyl acetate and solvent were codistilled from the manganese compounds, and a ^1H NMR spectrum of the pure ester obtained. All of this data is summarized in Table 9.

Using the PPN^+ salt in THF gives a very different set of organic products, apparently because THF does not "trap" the reactive organic intermediate formed. In the tertiary bromo case, where no η^1-adduct was present, approximately 80% of the theoretical organic molecular weight was distillable from the crude reaction mixture. GLC analysis (including preparative GLC where needed) indicated the following compounds and abundances:



12 (35%) **13** (6%) **14** (36%) **15** (3%)

Using the sodium salt in THF, very similar results were obtained, except that 25% of starting material was present in addition to **12**–**15** (36%, 16%, 14%, 1%, respectively).

With the primary and secondary systems, some thermally labile η^1-adduct was always present and the distillation procedure was difficult to implement. However, we believe that products related to **12**–**15** are also formed here.

Possible mechanisms for the $Mn(CO)_5^-$ reactions

Initially, it was believed that the 4-bromocrotonate **4** results could be explained on the basis of a "single" primary mechanism, starting with electron transfer (mechanism 1). The various products formed would then represent a case of later competitive cage vs. non-cage reactions. However, this mechanism does not account very well for some aspects of the $Mn_2(CO)_{10}$ formation, nor are the purely organic products entirely consistent with a radical mechanism, at least in the case of the $CDCl_3$ solvent (see later). We therefore considered a second mechanism (Mechanism 2) in which somewhat different competing reactions are postulated. Although Mechanism 2 is shown with an initial S.E.T. step (1′) and a geminate recombination (3′), these

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

two steps could be replaced by a single and separate S_N2 displacement (shown as 3a'). The competition is between steps 2' and 3' (or 2' and 3a'). Other key differences in Mechanisms 1 and 2 involve how $Mn_2(CO)_{10}$ is formed, and the mechanism by which the organic dimers are produced.

The formation of transition metal carbonyl bromides from anions is obviously a halogen–metal exchange (H.M.E.) reaction but this terminology does not imply any particular mechanism and, as shown in Mechanisms 1 and 2, several possible routes seem reasonable in our particular case, providing yet another differentiation between these two overall schemes.

Mechanism 1

(1) $Mn(CO)_5^- + Br\text{-}CH_2\text{-}CH{=}CHCOOEt \xrightarrow{S.E.T.} Mn(CO)_5^{\bullet} + [Br\text{-}CH_2\text{-}CH{=}CH\text{-}COOEt]^{\bullet -}$

(2) $Mn(CO)_5^{\bullet} + [Br\text{-}CH_2\text{-}CH{=}CHCOOEt]^{\bullet -} \xrightarrow{cage} Mn(CO)_5^{\bullet} + Br^- + \dot{C}H_2\text{-}CH{=}CHCOOEt$

(3) Geminate recombination $\xrightarrow{cage} Mn(CO)_5\text{-}CH_2\text{-}CH{=}CHCOOEt + Br^-$ **5**

(4) $Mn(CO)_5^{\bullet} + BrCH_2CH{=}CHCOOEt \xrightarrow{non\text{-}cage} Mn(CO)_5Br + \dot{C}H_2\text{-}CH{=}CHCOOEt$

(5) $2\,Mn(CO)_5^{\bullet} \xrightarrow{non\text{-}cage} Mn_2(CO)_{10}$

(6) $2\,\dot{C}H_2\text{-}CH{=}CH\text{-}COOEt \xrightarrow{non\text{-}cage}$ dimers

Mechanism 2

(1') $Mn(CO)_5^- + Br\text{-}CH_2\text{-}CH{=}CHCOOEt \xrightarrow{S.E.T.} Mn(CO)_5^{\bullet} + [Br\text{-}CH_2\text{-}CH{=}CH\text{-}COOEt]^{\bullet -}$

(2') $Mn(CO)_5^{\bullet} + [Br\text{-}CH_2\text{-}CH{=}CHCOOEt]^{\bullet -} \xrightarrow{cage} Mn(CO)_5Br + \bar{C}H_2\text{-}CH{=}CH\text{-}COOEt$

(3) $Mn(CO)_5^{\bullet}\,[Br\text{-}CH_2\text{-}CH{=}CH\text{-}COOEt]^{\bullet -} \xrightarrow[recombination]{geminate} Mn(CO)_5\text{-}CH_2CH{=}CH\text{-}COOEt + Br^-$ **5**

or

(3a') $Mn(CO)_5^- + Br\text{-}CH_2\text{-}CH{=}CH\text{-}COOEt \xrightarrow[S_N2\ reaction]{after\ Br^-\ loss}$ **5**

(4) $Mn(CO)_5^- + Mn(CO)_5Br \longrightarrow Mn(CO)_{10} + Br^-$

(5) $\bar{C}H_2CH{=}CH\text{-}COOEt + Br\text{-}CH_2\text{-}CH{=}CH\text{-}COOEt \xrightarrow[S.E.T.\ "mechanism"]{probable}$ dimers + Br^-

In attempting to distinguish between Mechanisms 1 and 2, we should make it clear that we are not primarily concerned with the mechanism of the "S_N2" substitution reaction, i.e., whether S.E.T. is, or is not, involved. Studies of $(CH_3)_3Sn^-$ nucleophilic reactions (10) and Bordwell's recent studies (3) illustrate the complexities involved in such a case. Our major concern is to understand how the other "aberrant" reactions are occurring, i.e., the formation of $Mn(CO)_5X$, $Mn_2(CO)_{10}$, organic dimers, etc., since the curtailment of these reactions would obviously result in better yields of the desired product.

Reactions designed to differentiate between Mechanisms 1 and 2

The nature of the organic dimerization reactions

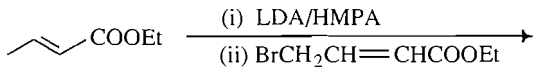
Experiments designed to probe the nature of the reactive organic intermediates have been performed in both the crotonate and simple carboxylate series. In the former, we have attempted to separately generate both the radical and the carbanion of debrominated **4**, and to observe what dimeric products are formed.

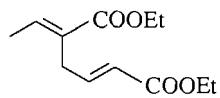
$Mn_2(CO)_{10} \xrightarrow{h\nu} 2\,Mn(CO)_5^{\bullet}$

$Mn(CO)_5^{\bullet} + \mathbf{4} \longrightarrow Mn(CO)_5Br + \dot{C}H_2CH{=}CH\text{-}COOEt$

$2\,\dot{C}H_2\text{-}CH{=}CH\text{-}COOEt \longrightarrow$ **8** and **9**

The photolysis of $Mn_2(CO)_{10}$ is known (11) to give $Mn(CO)_5^{\bullet}$ radicals, which in turn have been shown to abstract halide from organohalides (11). Using this procedure on 4-bromocrotonate **4**, followed by work-up of the reaction and analysis by GLC, shows only two dimeric products, the previously observed diesters **8** and **9** in a ratio of ca. 36:64. These two esters are easily rationalized as direct coupling products of the corresponding radical. Since four dimers are observed in the $Mn(CO)_5^-$ reaction, of which **8** and **9** are in the minority, one could conclude that a radical intermediate was not involved here. However, attempts using the corresponding carbanion were also ambiguous. The carbanion could not be prepared in pure THF and a THF–HMPA mixture had to be used. Reaction of the carbanion with the bromocrotonate gave only one major product, the dimer **16**, a reaction previously reported (12).

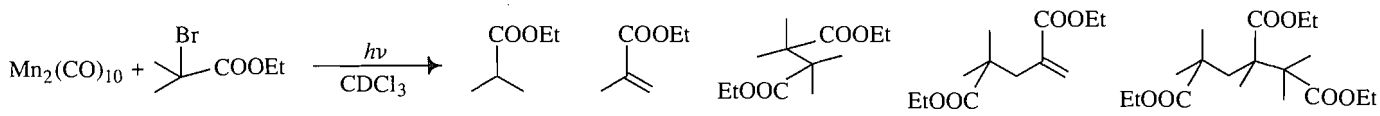




16

This dimer may in fact arise from a base-catalyzed rearrangement of **9**. In any case, neither of these reactions resembles the product mixture found for the $Mn(CO)_5^-$ reaction. In both cases the cyclopropyl products are not formed. The most probable mechanism for forming cyclopropyl products involves a Michael addition of the dienolate (or radical) to the bromocrotonate, followed by displacement of Br^- or $Br^{\bullet}$. The actual conditions in the $Mn(CO)_5^-$ reaction more closely resemble those of the photolysis experiment, so the lack of cyclopropyl products **10** and **11** in this case is probably more noteworthy than in the model carbanion case. In the latter we are not only using a different solvent mixture but the relative concentrations of carbanion and bromoester are probably very different, i.e., we are adding the completely formed dienolate to an equimolar amount of bromocrotonate in the model reaction. Overall, however, these two model experiments are disappointingly ambiguous.

Experiments were also carried out with the simple halocarboxylate esters. We particularly wanted to see if radical



12 (13%) **13** (5%) **14** (36%) **15** (4%) **17** (9%)

intermediates were "quenched" by $CDCl_3$. Photolysis experiments were therefore carried out on the primary, secondary, and tertiary bromocarboxylate esters, together with $Mn_2(CO)_{10}$, in $CDCl_3$ at ca. 25°C. The tertiary system was also photolyzed for comparison in THF solvent.

In the primary case, the main products were ca. 50% diethyl succinate and 11% ethyl acetate. No detectable (less than 3% of the total) $CH_2DCOOEt$ was observed in the latter compound. In the secondary case, the products were 47% diethyl 2,3-dimethylsuccinate (1:1 *meso-d,l*) and 21% ethyl propionate, in addition to 27% recovered starting material. In the tertiary case, diethyl 2,2,3,3-tetramethylsuccinate **14** was the major product (36%), together with 13% ethyl 2-methylpropionate **12**, 5% ethyl methacrylate **13**, 4% dimer **15**, and 9% of the trimeric structure **17**. A similar pattern of products was found for the THF solvent system. These products are in good agreement with those previously reported for radical reactions of $(CH_3)_2\dot{C}$-COOEt (13), where the radical is produced by a completely different process.

There is obviously a striking difference in $CDCl_3$ solvent between the behavior of the photolysis-generated organic intermediate (expected to be a radical) and the intermediate produced in the $Mn(CO)_5^-$ reactions. In the latter case, the $CDCl_3$ efficiently trapped the intermediate and no dimeric products were formed. In the photolysis experiments, some hydrogen atom abstraction appears to be occurring, since debrominated esters are found, but this abstraction is occurring from the starting material or products thereof, and to the apparent exclusion of the much more abundant $CDCl_3$ solvent. In agreement, no trace of hexachloroethane was detected by GLC in any of the systems studied. No attempt was made to generate the simple enolates in $CHCl_3$, but the base abstraction of the chloroform proton is a well-known reaction. Attempts to trap a dichlorocarbene–cyclohexane adduct were unsuccessful, but it is quite possible that CCl_3^- would be relatively stable in nonpolar solvents (i.e., loss of Cl^- requires solvation).

Tentative conclusions on radical vs. enolate intermediates

Even though the deuterium abstraction reactions favor an enolate mechanism, most of the products formed in the $Mn(CO)_5^-$/THF reaction (tertiary bromide) are identical to those seen in the corresponding photolysis reaction. However, the tetramethyl succinate **14** has previously been prepared from the enolate and bromide (14) or via radical coupling (12), and one can explain the formation of dehalogenated ester **12** and methacrylate **13** by invoking either a radical or enolate mechanism. However, diester **15** (3% yield) formation seems unlikely via an enolate mechanism, but the Michael addition of the radical to **13**, followed by disproportion (e.g., with the simple radical), would yield **15**, and indeed this ester is also a product of the photolysis reaction (in fact to a much larger extent). The formation of the trimeric ester **17** is exclusive to the photolysis reaction and corresponds to the coupling of the simple radical with the Michael addition radical discussed above. Overall, the available evidence is somewhat contradictory, but the balance of evidence favors a carbanion (enolate) model (Mechanism 2) for the majority of the reaction products.

The $Mn_2(CO)_{10}$ forming reactions

There are several observations from Tables 3–8 that relate directly to the question of how $Mn_2(CO)_{10}$ is formed. We have also carried out additional control experiments.

From studies where the $Mn(CO)_5^-$:RX stoichiometry was varied, e.g., Table 4 (X = Br), one notes that a 2:1 excess of $Mn(CO)_5^-$ gave no $Mn(CO)_5Br$ and 79% $Mn_2(CO)_{10}$, whereas a reverse 1:2 molar ratio gave 51% $Mn(CO)_5Br$ and only 14% $Mn_2(CO)_{10}$. This suggests that under the reaction conditions (THF, Na^+ salt, 25°C) $Mn(CO)_5^-$ reacts with RBr in a competitive manner (as outlined in Mechanism 2) to produce both $RMn(CO)_5$ and $Mn(CO)_5Br$. However, the latter is also reactive with $Mn(CO)_5^-$ to give $Mn_2(CO)_{10}$ and this third competing reaction builds up as one forms more of the $Mn(CO)_5Br$. Where there is enough $Mn(CO)_5^-$, this latter reaction then goes to completion, but in the normal course, one is depleted in $Mn(CO)_5^-$ before all of the $Mn(CO)_5Br$ is consumed.

The other observation is that $Mn_2(CO)_{10}$ formation is strongly solvent and counterion dependent. Using the PPN^+ $Mn(CO)_5^-$ salt in THF produces essentially no $Mn_2(CO)_{10}$, whereas the Na^+ salt produces large amounts. As well, the PPN^+ salt in $CDCl_3$ (Table 7) also produces large amounts of $Mn_2(CO)_{10}$ in some cases.

To verify that these conclusions were sound, we have separately studied the reaction of $Mn(CO)_5^-$ and $Mn(CO)_5X$ (X = Br or I) in both chloroform and THF solvents. Both the PPN^+ and Na^+ salts of $Mn(CO)_5^-$ were used.

When $Na^+Mn(CO)_5^-$ was reacted with $Mn(CO)_5Br$ in THF, a rapid reaction took place and ^{55}Mn NMR and IR spectroscopies confirmed the essentially quantitative formation of $Mn_2(CO)_{10}$. The PPN^+ salt also reacted rapidly with both $Mn(CO)_5Br$ and $Mn(CO)_5I$ in $CDCl_3$, *but in THF the reaction required about 4 h*. In addition, the reaction was accompanied by CO evolution and the major stoichiometry appeared to be

$$Mn(CO)_5^- + 2Mn(CO)_5Br \rightarrow Mn_2(CO)_{10} + Mn(CO)_4Br_2^- + 2CO$$

A competitive experiment was also carried out involving the PPN^+ salt in $CDCl_3$ and a mixture of both $Mn(CO)_5Br$ and $Mn(CO)_5I$. The latter reacted about 10% faster.

The reaction of $NaMn(CO)_5$ with $Mn(CO)_5I$ in THF has been studied by Wilkinson, Hursthouse, and co-workers (15*a*). They used a 2:1 ratio of the compounds and reported the formation of the trimeric anion $Mn_3(CO)_{14}^-$ in 31% yield after an extended reaction time. These results are not inconsistent with those reported here if one assumes that the reaction proceeds:

$$Mn(CO)_5^- + Mn(CO)_5I \rightarrow Mn_2(CO)_{10} + I^- \rightarrow Mn_2(CO)_9I^- + CO \xrightarrow{Mn(CO)_5^-} Mn_3(CO)_{14}^- + I^-$$

i.e., that an "excess" of $Mn(CO)_5^-$ is required in this case. The mixed $MnRe(CO)_{10}$ and ligand-substituted derivatives of $Mn_2(CO)_{10}$ have also been prepared by similar reactions to those we reported here (15*b*).

Clearly, the solvent–counterion effects in these model reactions resemble those encountered in the main reactions and

it seems to us that most of the $Mn_2(CO)_{10}$ must be formed from a reaction of $Mn(CO)_5^-$ and $Mn(CO)_5X$, i.e., as outlined in Mechanism 2, rather than by the radical coupling mechanism shown in Mechanism 1. Therefore, both the $Mn_2(CO)_{10}$ and the organic products formed seem better accommodated by Mechanism 2. If we assume Mechanism 2 for the moment, there are a few other comments which are relevant with regard to the results presented in the various tables.

1. The formation of $Mn(CO)_5Br$ seems to be slower than that of $Mn(CO)_5I$. Since both react at a similar rate with $Mn(CO)_5^-$, one gets more $Mn_2(CO)_{10}$ in the bromo cases (the $Mn(CO)_5^-$ is present for a longer time) (see Tables 5 and 7).

2. With the 1:1 RX:$Mn(CO)_5^-$ stoichiometry, one conversely gets more recovered starting material in the bromide case (Table 9) compared to iodide ($Mn(CO)_5^-$ is lost in forming $Mn_2(CO)_{10}$).

Overall conclusions for preparing $Mn(CO)_5$-enolates or -dienolates

1. In RX + $Mn(CO)_5^-$ reactions, the X = Cl leaving group is preferred if it is reactive enough. If not, X = Br is better than X = I.

2. If the bromide is used, one may have to carefully adjust the stoichiometry of the starting materials to maximize the yield of $RMn(CO)_5$.

3. The PPN^+ salt in THF solvent is particularly favorable for cases where bromides or iodides are used. Lithium salts are particularly unfavorable and may give no $RMn(CO)_5$ product.

Concluding discussion

Preliminary experiments were also carried out between $Mn(CO)_5^-$ and several allylic bromides. Although allyl bromide and other primary bromides worked quite well, secondary allylic bromides usually gave extensive coupling of the organic product. These results mirror the 2-halocarboxylate and 4-halocrotonate results to some extent and indicate the rather fine dividing line between the substitution and H.M.E. reactions.

Experimental

All procedures involving organometallic species were performed under an atmosphere of argon or nitrogen. A combination of syringe, transfer needle, and Schlenk techniques were used.

Infrared analysis was performed using a Perkin–Elmer 467 or a Nicolet 5DX FT instrument. Mass spectrometric analyses were obtained on a Kratos MS80, and ^1H, ^{55}Mn, and ^{13}C NMR spectra on a Varian XL-200. The ^{55}Mn NMR chemical shifts are reported with respect to potassium permanganate in D_2O, and were calculated using the signal for dimanganese decacarbonyl as a secondary reference. For very broad signals in a conventional high-resolution spectrometer one loses signal intensity in the FID during the pulse time itself and in the subsequent dead time before the receiver is turned on. This signal loss was not a major problem in our work but we have attempted to correct for these intensity errors. Integration of signals was performed using manually set parameters and the values thus obtained were then adjusted using calibration parameters determined for mixtures of organometallic species of known concentration, i.e., very similar to a GC calibration. Gas chromatographic (GC) analyses were carried out using a Hewlett–Packard 5890.

THF was distilled from benzophenone ketyl under nitrogen and deuterated solvents were dried over molecular sieve dust prior to use. The majority of compounds were available from commercial sources and were used without further purification, except ethyl 4-bromo-2-butenoate, which was obtained as technical grade (Aldrich) and distilled prior to use (spinning band). Ethyl 2-iodoethanoate, ethyl 2-iodopropanoate, and ethyl 2-iodo-2-methylpropanoate were prepared by treating the corresponding bromo-ester with sodium iodide in acetone. Ethyl 2-chloropropanoate and ethyl 4-chloro-2-butenoate were obtained from the corresponding bromides using lithium chloride in dimethylformamide. The anions $PPN^+[Mn(CO)_5^-]$ (16), $Li^+[Mn(CO)_5^-]$ (16, 17), $Na^+[Mn(CO)_5^-]$ (18), and $K^+[Mn(CO)_5^-]$ (19) were prepared according to literature procedures from $Mn_2(CO)_{10}$ (Strem Chemicals).

In situ *reactions of $M^+[Mn(CO)_5^-]$ with halo-esters*

Solutions of the anions (0.128 molar) were filtered, and transferred to a nitrogen-purged graduate cylinder fitted with a rubber septum; known volumes (ca. 2 mL) of the solution were transferred by syringe into a 10 mm NMR tube containing a known amount of halo-ester, and shaken. Where the reaction was carried out in the presence of 18-crown-6 (Aldrich), this was added to the anion solution prior to mixing.

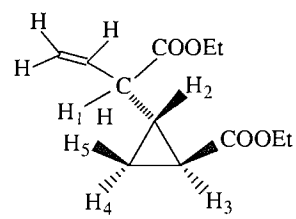
The reaction of $Na^+[Mn(CO)_5^-]$ with ethyl 4-bromocrotonate ***4***

In a 10-mL round-bottom flask fitted with a rubber septum, 4 mL of $Na^+[Mn(CO)_5^-]$ solution (prepared from 0.96 g of $Mn_2(CO)_{10}$ (0.245 mmol) in 4 mL of THF) was added with stirring to 0.96 g (0.50 mmol) of ethyl 4-bromocrotonate in 2 mL of THF. The reaction mixture was then stirred for 30 min after which the solvent was removed at reduced pressure and the residue then extracted with 2 × 5 mL of pentane. The extracts were combined and the solvent evaporated. The residue was applied to a 1 × 15 cm flash chromatography column of silica gel and eluted with methylene chloride. After initial bands of $Mn_2(CO)_{10}$, followed by $Mn(CO)_5Br$ and a small quantity (0.001 g) of the η^3-complex **2** (R = Et), the η^1-complex **5** eluted as a broad pale-yellow band (0.0492 g). The infrared and ^1H NMR of the last fraction indicated that the sample was pure (33% yield). Further elution of the column with diethyl ether yielded 0.0135 g of a colourless liquid, the GC of which (3% OV17, 2 mm × 2 m glass column) indicated the presence of four organic products. Samples of these were isolated by GC (3% OV17, 4 mm × 2 m glass column) and identified as follows:

Ethyl trans*-2-(2-carbethoxycyclopropyl)-3-butenoate* ***11*** (43% of total "organic" product)

Diastereomer A: ^1H NMR ($CDCl_3$): 1.22 (t, J = 7.1 Hz, 3H), 1.24 (t, J = 7.0 Hz, 3H), 2.58 ("t", J = 8 Hz, 1H), 4.13 (q, J = 7.0 Hz, 2H), 4.18 (q, J = 7.0 Hz, 2H), 5.1 and 5.2 (d × 2, J = 16.4 and 11.2 Hz, 2H), 5.85 (m, 1H), 0.82 (m, 1H), 1.62 (m, 1H), 1.75 (m, 1H). One proton is hidden by the methyl peaks.

Diastereomer B: The *trans* stereochemistry in this compound was inferred from the coupling constants, which in turn were arrived at by extensive decoupling experiments and computer simulations. The following numbering system is arbitrarily used here:



Chemical shifts	Coupling constants (Hz)
1. 2.54	J_{12} = 8
2. 1.79	J_{23} = 4
3. 1.48	J_{24} = 8
4. 1.2–1.3 (peak is obscured)	J_{25} = 6
5. 0.92	J_{34} = 4
	J_{35} = 8
	J_{45} = −4

$COOEt(CH_3)$	1.24, t, J = 7
	1.26, t, J = 7
(CH_2)	4.16, q, J = 7
	4.19, q, J = 7
Vinyl	5.17, d, J = 16.8
	5.19, d, J = 10.0
	5.88, m

For personal use only.

The coupling between H_2 and H_3 is 8 Hz, which is in the range expected for a *trans* orientation of protons on a cyclopropane ring (20).

Ethyl E-*5-carbethoxy-2,6-heptadienoate* **9** (21%): ^{1}H NMR ($CDCl_3$): 1.24 (t, J = 7.3 Hz, 3H), 1.26 (t, J = 7.2, 3H), 2.34–2.8 (m, 2H), 3.17 (dt, J = 8.1 and 6.2 Hz, 1H), 4.18 (q, J = 7.2 Hz, 2H), 4.2 (q, J = 7.1 Hz, 2H), 5.21 (m, 2H), 5.72–5.96 (m, 2H), 6.88 (dt, J = 10 and 15 Hz, 1H); GC–MS (*m/e*, % base peak): 226 (3, M^+), 181 (55), 180 (68), 153 (81), 152 (78), 134 (66), 125 (69), 113 (70), 108 (35), 107 (88), 106 (73), 97 (67), 85 (97), 81 (92), 80 (79), 79 (100), 78 (76), 77 (77), 69 (35), 68 (82), 67 (79), 57 (64), 55 (61), 54 (47), 53 (67), 43 (49), 41 (78). See ref. 7.

Ethyl E-*4-(2'-carbethoxycyclopropyl)-2-butenoate* **10** (21%): ^{1}H NMR ($CDCl_3$): 1.25 (t, J = 6.9 Hz, 3H), 1.28 (t, J = 7.1 Hz, 3H), 2.2 (m, 2H), 4.14 (q, J = 7.0 Hz, 2H), 4.21 (q, J = 7.0 Hz, 2H), 5.85 (d, J = 15.6 Hz, 1H), 6.94 (dt, J = 6.4 and 15.6 Hz, 1H), 0.70–0.95 (m, 2H), 1.45 (m, ca. 1H); GC–MS (*m/e*, % base peak): 226 (1, M^+), 181 (80), 153 (45), 152 (80), 135 (29), 134 (73), 125 (37), 123 (28), 107 (79), 106 (63), 98 (66), 97 (80), 85 (55), 81 (100), 80 (47), 79 (92), 78 (79), 77 (48), 68 (65), 67 (46), 66 (27), 57 (30), 55 (90), 54 (38), 53 (65), 43 (30), 41 (50).

Ethyl E,E-*2,6-octadien-1,8-dioate* **8** (14%): ^{1}H NMR ($CDCl_3$): 1.28 (t, J = 7.1 Hz, 6H), 2.37 ("d", J = 6.8 Hz, 4H), 4.17 (q, J = 7.2 Hz, 4H), 5.85 (d, J = 15.5 Hz, 2H), 6.96 (dt, J = 6.7 and 15.7 Hz, 2H); GC–MS (*m/e*, % base peak): 226 (1, M^+), 181 (87), 153 (56), 152 (94), 135 (30), 134 (28), 125 (42), 114 (25), 113 (25), 111 (38), 107 (80), 106 (30), 97 (28), 86 (44), 85 (100), 76 (77), 75 (30), 74 (92), 73 (54), 72 (35), 69 (25), 68 (95), 67 (48), 57 (77), 55 (68), 53 (40), 43 (28), 41 (55). See ref. 7.

η^1-4-Oxo-4-ethoxy-2-butenyl manganese pentacarbonyl **5**: Infrared (methylene chloride, cm^{-1}): 2110 (w), 2018 (m), 2005 (s), 1690 (w), 1610 (w); ^{1}H NMR ($CDCl_3$): 1.27 (t, J = 7.1 Hz, 3H), 1.88 (d, J = 9.6 Hz, 2H), 4.17 (q, J = 7.0 Hz, 2H), 5.65 (d, J = 15.1 Hz, 1H), 7.45 (dt, 1H); $\{^1H\}^{13}$C NMR ($CDCl_3$): 8.1 (CH_2), 14.4 (CH_3), 59.7 (CH_2), 111.5 (CH), 158.5 (CH); MS (*m/e*, % base peak): 224 (5), 196 (30), 168 (80), 124 (45), 100 (95), 68 (80), 55 (100). Anal. calcd. for $C_{11}H_9MnO_7$: C 42.88, H 2.94%; found: C 39.78, H 3.25%. The elemental analysis for this compound could not be improved, even by repeated purification.

The reaction of ethyl 2-bromo-2-methylpropanoate with $PPN^+[Mn(CO)_5^-]$ in THF

In a 10-mm NMR tube 0.11 g, (0.15 mmol) of $PPN^+[Mn(CO)_5^-]$ was added to 0.05 g (0.26 mmol) of ethyl 2-bromo-2-methylpropanoate in 3 mL of THF, and the mixture shaken. The solution was then allowed to stand for 5 h. GC analysis of the crude reaction mixture indicated that **12**, **13**, **14**, and **15** were formed in the reaction. These volatile components were obtained by distillation (trap to trap, ca. 0.1 Torr; 1 Torr = 133.3 Pa) from the reaction mixture. The first three were easily identified by comparison to the known compounds (retention time, MS fragmentation, and ^{1}H NMR). Compound **15** was isolated by preparative GC and identified on the basis of the MS and the reported (13) ^{1}H NMR spectrum. The residue from this distillation was dissolved in 4 mL of THF, filtered, and pentane slowly added to the filtrate. Oily material formed, which was separated by decantation and washed with pentane. This oil solidified to a resinous material (0.04 g) that could not be crystallized. The infrared spectrum of this oil contained bands (in THF) at 2081 (w), 2007 (s), 1973 (s), 1925 (s), and 1907 (sh), which probably correspond to $PPN^+[Mn(CO)_4Br_2^-]$.

Ethyl 2-methylpropanoate **12**: GC–MS (*m/e*, % base peak): 116 (50), 89 (51), 88 (55), 73 (55), 71 (70), 43 (100).

Ethyl 2-methyl-2-propenoate **13**: GC–MS (*m/e*, % base peak): 114 (52), 99 (55), 86 (68), 70 (60), 69 (100), 41 (90).

Diethyl 2,2,3,3-tetramethylsuccinate **14**: ^{1}H NMR ($CDCl_3$): 1.23 (s, 12H), 1.26 (t, J = 7.1 Hz, 6H), 4.10 (q, J = 7.1 Hz, 4H); GC–MS (*m/e*, % base peak): 185 (50), 157 (51), 116 (97), 88 (90), 87 (100), 84 (55), 83 (90), 70 (50), 69 (85), 59 (77), 57 (45), 55 (60), 43 (90), 42 (47), 41 (95).

Diethyl 2,2-dimethyl-4-methylenepenta-1,5-dioate **15** (13): ^{1}H NMR ($CDCl_3$): 1.18 (s, 6H), 1.264 and 1.31 (t × 2, J = 7.1, 7.1 Hz, 6H), 2.64 (s, 2H), 4.11 (q, J = 7.1 Hz, 2H), 4.2 (q, J = 7.1, 2H), 5.53 ("s", 1H), 6.22 (d, J = 1.6 Hz, 1H); GC–MS (*m/e*, % base peak): 228 (4), 155 (59), 154 (50), 127 (25), 109 (87), 81 (100), 68 (30), 67 (32), 59 (37), 43 (45), 41 (94).

Photolysis of dimanganese decacarbonyl with halo-esters

The photolyses were carried out, using a G.E. 250-W sun lamp, in Pyrex tubes fitted with septa placed in a water cooled jacket.

Ethyl 4-bromo-2-butenoate

Dimanganese decacarbonyl (0.2 g, 0.51 mmol) and ethyl 4-bromo-2-butenoate (0.2 g, 1.04 mmol) in 8 mL of THF were irradiated for 4.5 h. The infrared spectrum of the crude reaction mixture indicated that some $Mn(CO)_5Br$ and $Mn_2(CO)_8Br_2$ were formed, in addition to a considerable amount of an insoluble white solid. After removing the THF solvent, the residue was extracted with 3 × 20 mL of pentane, and the extracts combined, filtered, and evaporated to give 0.08 g of a yellow oil from which flash chromatography (silica/methylene chloride) yielded 0.07 g colourless oil. The GC (10-m methyl silicone column) and ^{1}H NMR spectrum of this fraction indicated that it contained ethyl 5-carboethoxy-2,6-heptadienoate **9** (64%) and ethyl 2,6-octadien-1,8-dioate **8** (36%).

Ethyl 2-bromoethanoate

Dimanganese decacarbonyl (0.10 g, 0.26 mmol), and ethyl 2-bromoethanoate (0.081 g, 0.49 mmol) in 3 mL of deuterochloroform were irradiated for 3 h. The colourless solution was filtered to remove the white powder that formed. A singlet in the ^{1}H NMR spectrum of the filtered solution at 2.63 ppm was assigned to diethyl succinate (50% yield) and this was confirmed by GC analysis (3% OV1, 2 mm × 2 m glass column) and comparison with authentic material. Unreacted ethyl 2-bromoethanoate was also present (29%). One resonance in the ^{1}H NMR spectrum (singlet, 3.28 ppm, 8% of the total integration as CH_2 protons) remained unidentified.

The reaction of $Mn(CO)_5^-$ with $Mn(CO)_5Br$

(i) $Na[Mn(CO)_5]$ and $Mn(CO)_5Br$ in THF solvent

A THF solution of $Na[Mn(CO)_5]$ (0.128 M) was prepared from $Mn_2(CO)_{10}$, as previously referred to, and this was added rapidly to an equimolar amount of $Mn(CO)_5Br$. Clean conversion of the $Mn(CO)_5Br$ to $Mn_2(CO)_{10}$ was observed by ^{55}Mn NMR and IR spectroscopy within 10 min. The solution was filtered, evaporated, and the residue applied to a 1 cm × 15 cm flash chromatography column (silica gel, methylene chloride). The first yellow band yielded $Mn_2(CO)_{10}$ in 84% yield.

(ii) $PPN[Mn(CO)_5]$ and $Mn(CO)_5Br$ in chloroform

The salt $PPN[Mn(CO)_5]$, 0.1476 g (0.202 mmol), was dissolved in 2.0 mL of $CHCl_3$ and added to solid $Mn(CO)_5Br$, 0.0535 g (0.195 mmol), and the mixture shaken. The reaction was complete within a few minutes and IR and ^{55}Mn NMR spectroscopy showed that $Mn_2(CO)_{10}$ was the major product formed.

(iii) $PPN[Mn(CO)_5]$ and $Mn(CO)_5Br$ in THF

This reaction was performed as in (ii) but in this case there was no observable reaction after 10 min (IR spectroscopy). However, after ca. 4 h, the IR and ^{55}Mn NMR spectra indicated the presence of both $[Mn(CO)_4Br_2^-]PPN^+$ and $Mn_2(CO)_{10}$.

(iv) $PPN[Mn(CO)_5]$ and $Mn(CO)_5Br$–$Mn(CO)_5I$ in chloroform

This reaction was performed as in (ii) using approximately equimolar ratios of the three compounds. ^{55}Mn NMR spectroscopy of the residual $Mn(CO)_5Br$ and $Mn(CO)_5I$ was used for the analytical determination (see previous section on ^{55}Mn peak integration methods).

Ethyl 2-bromopropanoate

This photolysis was carried out in the same way as that described above for ethyl 2-bromoethanoate using 0.1 g (0.26 mmol) of dimanganese decacarbonyl and 0.09 g (0.50 mmol) of ethyl 2-bromopropanoate.

The ^{1}H NMR spectrum of the crude reaction mixture contained resonances that were assigned to 1:1 *meso-d,l* diethyl 2,3-dimethylsuccinate (47%), unreacted ethyl 2-bromopropanoate (21%), and ethyl propanoate (21%). The assignments were confirmed by comparison with authentic materials (GC and ^{1}H NMR analysis).

Ethyl 2-bromo-2-methylpropanoate

Dimanganese decacarbonyl and 0.05 g (0.13 mmol) of ethyl

2-bromo-2-methylpropanoate in 3 mL of freshly distilled THF (or $CDCl_3$) were irradiated for 30 min. The solvent was then removed under reduced pressure and the oily residue extracted with hexane, filtered, and evaporated. GC analysis indicated that the extract contained six components, of which starting material (8%), ethyl 2-methylpropanoate **12** (17%), ethyl 2-methyl-2-propenoate **13** (12%), diethyl 2,2,3,3-tetramethyl succinate **14** (45%), and diethyl 2,2-dimethyl-4-methylenepenta-1,5-dioate **15** (5%) were readily identified by GC–MS (see section where these same products were produced from $Mn(CO)_5^-$ reaction). The remaining component was isolated by preparative GC and shown to be diethyl 3-carbethoxy-2,2,3,5,5-pentamethylhexa-1,6-dioate **17** (13%), by comparison of the ^1H NMR spectrum to that previously reported (13).

The preparation and reactions of ω-bromoacylmanganese pentacarbonyls

ANDREW P. MASTERS AND TED S. SORENSEN
The Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received July 10, 1989

ANDREW P. MASTERS and TED S. SORENSEN. Can. J. Chem. **68**, 502 (1990).

The reaction of ω-bromoacyl chlorides Br—CH_2—$(CH_2)_n$—COCl and $Mn(CO)_5^-$ is reported. In the case of $n = 0$, one obtains ketene, $Mn(CO)_5Br$, and chloride ion. In contrast, the corresponding chloro compound gives the known chloroacyl manganese complex. With $n = 1$, 2, or 3, one can isolate the corresponding ω-bromoacylmanganese complexes. On mild heating, the $n = 1$ complex produces only ethylene and $Mn(CO)_5Br$. The $n = 2$ and 3 complexes are also relatively labile on heating in THF solution and produce the 1-alkene as the major organic product. In chloroform solution, the corresponding ω-bromoalkyl complex is produced initially on heating, but further heating again produces mainly the 1-alkene. However, the $n = 2$ complex also produces appreciable amounts of cyclopropane.

Key words: bromoacylmanganese pentacarbonyl, pentacarbonyl manganate, ethylene, cyclopropane.

ANDREW P. MASTERS et TED S. SORENSEN. Can. J. Chem. **68**, 502 (1990).

On a étudié les réactions des chlorures de ω-bromoacyles (Br—CH_2—$(CH_2)_n$—COCl) avec le $Mn(CO)_5^-$. Dans le cas où $n = 0$, on obtient du cétène, du $Mn(CO)_5Br$ et de l'ion chlorure. Par opposition, le composé chloré correspondant fournit le complexe chloroacyl manganèse connu. Lorsque $n = 1$, 2 ou 3, on peut isoler les complexes ω-bromoacylmanganèse correspondants. Lorsqu'on le chauffe légèrement, le complexe dans lequel $n = 1$ ne conduit qu'à d'éthylène et de $Mn(CO)_5Br$. Les complexes dans lesquels $n = 2$ ou 3 sont aussi relativement labiles; lorsqu'on les soumet à un chauffage, en solution dans le THF, le produit organique majeur est le 1-alcène. En solution dans le chloroforme, il y a formation des complexes ω-bromoalkyles correspondants; mais, si l'on continue le chauffage, il y a principalement formation du 1-alcène. Toutefois, le complexe dans lequel $n = 2$ conduit à la formation d'une quantité appréciable de cyclopropane.

Mots clés: bromoacylmanganèse pentacarbonyl, pentacarbonyl manganate, éthylène, cyclopropane.

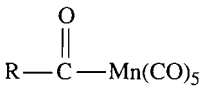
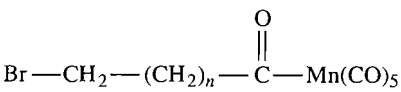
Acylmanganese pentacarbonyls **1** are a very well-known class of organometallic compounds (1). The readily lose carbon monoxide to form the alkyl complex **2** and the mechanism of this reversible reaction has been elegantly determined by labelling studies (2) and supported by later theoretical calculations (3).



1

2

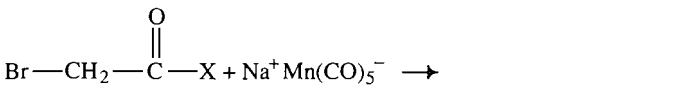
A great many derivatives of **1** are known, but there has been no systematic study of cases where R = —$(CH_2)_n$—CH_2Br, **3**, although most of the corresponding chloro compounds have been prepared. The fact that the first member of this series ($n = 0$) reacted in a totally different way compared to the chloro analog makes the extension to the bromo analogs non-trivial. Our interest was mainly in the fate of the organic part of these complexes when they were subjected to thermolysis, i.e., unsaturated ($16e^-$) organometallics often add oxidatively to a C—Br bond. It was planned to study acyl system **3** where n was varied from 0 to 3. The usual route for preparing such complexes is to react the corresponding acyl halide with $Mn(CO)_5^-$ salts.



3

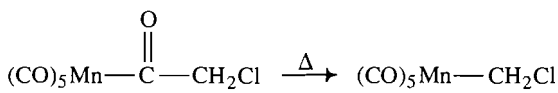
Results

2-Bromoacetyl chloride (or bromide) **4** reacts with sodium pentacarbonylmanganate to give a near quantitative yield of ketene, $Mn(CO)_5Br$, and sodium chloride (bromide).



4 X = Cl or Br

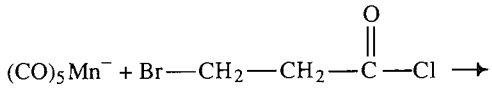
This reaction is in fact a very general ketene synthesis, which has been described in other publications (4). The reaction of $Mn(CO)_5^-$ with acyl chlorides to give acylmanganese organometallics is normally a rapid reaction and it is surprising in this case to find this process completely superseded by the ketene-forming reaction. One might postulate that the acyl manganese complex corresponding to **3** ($n = 0$) is initially formed and that this then rapidly eliminates $Mn(CO)_5Br$, but the evidence is against this (4). The 2-chloroacyl manganese compound **5** can in fact be prepared in the normal way, as previously reported (5), and repeated in this study. This compound on heating gives the alkyl species **6** together with other unidentified material.



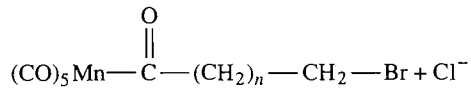
5 **6**

This experience with **5** suggests that **3** ($n = 0$) might be a reasonably stable species, once formed, but we have not explored possible alternative approaches to this synthesis.

3-Bromopropanoyl chloride **7** reacts with $Mn(CO)_5^-$ to give the crystalline acyl complex **3** ($n = 1$). The complex was characterized by ^1H and ^{55}Mn NMR spectroscopy, and by IR spectroscopy. When **3** ($n = 1$) was heated above the melting point, gas evolution occurred at ca. 62°C and the color changed from

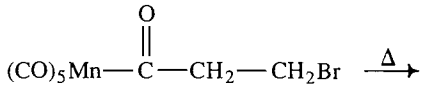


7



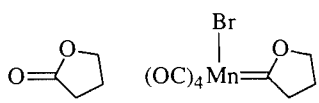
3 ($n = 1$)

pale yellow to orange. The formation of the orange $Mn(CO)_5Br$ was confirmed by TLC separation and comparison of the IR spectrum to that of the authentic compound. Heating a solution of **3** ($n = 1$) in deuterochloroform at 75°C for 4 h (sealed NMR tube) produced only one ^1H NMR product peak, at 5.38 ppm, assigned to ethylene and confirmed along with carbon monoxide by gas chromatography. The only manganese-containing species was $Mn(CO)_5Br$. In tetrahydrofuran solution (THF), the reaction of **3** ($n = 1$) was more rapid ($t_{1/2}$ ca. 10 min at 60°C) but the products produced were the same. All of these results are consistent with the following reaction stoichiometry.



$$Mn(CO)_5Br + CH_2{=}CH_2 + CO$$

The preparation of 4-bromobutanoylmanganese pentacarbonyl **3** ($n = 2$) proceeded as for the $n = 1$ case, but the compound was relatively air and (or) moisture sensitive. The major products from the air interaction were $Mn(CO)_5Br$ and δ-butyrolactone **8**. Heating **3** ($n = 2$) above the melting point led to gas evolution and the formation of an orange residue. Flash chromatography led to an 81% recovered yield of $Mn(CO)_5Br$ and 4% of a second orange solid. This product had ν_{CO} peaks at 2097(m), 2027(sh), 2013(s), and 1967(s) and ^1H NMR peaks at δ 2.09 (t, t), 2H; 4.18 (t, $J = 7.9$ Hz), 2H; and 5.21 (t, $J = 9.0$ Hz), 2H. These results are consistent with the carbene complex **9**, in that the spectral data are very similar to the previously reported (6) iodo complex of **9**. Complex **9** was also produced in very low yields by heating a THF solution of **3** ($n = 2$) and lithium bromide or by irradiating **3** ($n = 2$) in deuterochloroform with a sun lamp.



8 9

$$(OC)_5Mn{-}CH_2{-}CH_2{-}CH_2{-}Br$$

10

Heating a chloroform-*d* solution of **3** ($n = 2$) at 75°C for 3 h in a sealed NMR tube cleanly produced the corresponding alkyl complex **10**, showing a characteristic ^1H NMR spectrum (particularly the high field peak at 0.90 ppm for CH_2 bound to manganese). On standing overnight at room temperature, partial conversion back to the acyl complex was seen. If the solution is heated to 125°C for 1 h, considerable decomposition occurs and the manganese shows up as an insoluble brown powder of unknown composition. The ^1H NMR spectrum showed a singlet at 0.24 ppm, assigned to cyclopropane (12%), and peaks attributable to propene (38%). Both of these identifications were confirmed by gas chromatography. When **3** ($n = 2$) was heated in THF-d_8 solution at 60°C for 2 h, no intermediate alkyl complex **10** was seen. The major organic product was propene, with a trace (<1%) of cyclopropane. The manganese was mainly in the form of $Mn(CO)_5Br$, as judged by IR spectroscopy.

The formation of 5-bromopentanoylmanganese pentacarbonyl **3** ($n = 3$) proceeded in good yield and this solid was characterized in a similar way to the lower members. Heating the solid above the melting point at 70°C gave a fairly clean conversion to $Mn(CO)_5Br$. Heating a deuterochloroform solution at 70°C for 3.5 h gave the haloalkyl complex **11**, characterized as for

$$(CO)_5Mn{-}CH_2{-}CH_2{-}CH_2{-}CH_2Br$$

11

10 by the distinctive ^1H NMR spectrum. As with **10**, complex **11** was partly converted back to the acyl complex on cooling overnight. Heating the solution at 120°C for 1 h gave 85% 1-butene and an unidentified manganese-containing product (insoluble brown powder). Heating **3** ($n = 3$) in THF-d_8 at 60°C for 4 h gave directly 90% 1-butene, and $Mn(CO)_5Br$ was the major manganese-containing product. No alkyl complex **11** was observed nor was any cyclobutane observed.

Discussion

The n = *1 case*

Under all three reaction conditions (melt, chloroform, or THF solvent) ethylene is readily produced and we believe that a fragmentation process is the most likely here. One possibility is the direct fragmentation of **3** ($n = 1$), eq. [1], but no sign of $Mn(CO)_6^+$ (7) was observed in the *in situ* ^{55}Mn spectrum when this reaction was monitored by NMR spectroscopy. A more likely reaction is the initial loss of CO, and then fragmentation, eq. [2], perhaps even involving a cyclic transition state. The fragmentation of an alkyl complex intermediate is a third alternative (eq. [3]).

[1] 
$$H_3C{=}CH_2 + [Mn(CO)_6^+\ Br^-]$$

[2]  $CH_2{=}CH_2 + Mn(CO)_5Br$

[3] 
$$CH_2{=}CH_2 + Mn(CO)_5Br$$

Although a cationic ethylene complex, $Mn(CO)_5(\eta^2\text{-}C_2H_4)BF_4$, is known (8), there is no evidence for a similar complex (bromide anion) in our case.

The n = *2 case*

The formation of δ-butyrolactone **8** on air/water exposure of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

3 (n = 2) is consistent with the formation of the cationic carbene intermediate **12** (eq. [4]). When **12** loses CO, one obtains the relatively air-stable neutral complex **9**.

Stone and co-workers (6) have previously prepared the chloro analog of **3** (n = 2) and also the chloroalkyl analog of **10**. Although their chloroacyl compound is unreactive, the monophosphine analog reacts with silver tetrafluoroborate to give a cationic carbene complex that is an isolatable monophosphine-substituted derivative of **12**.

In our case, it is not really clear why one sees no evidence for **12** in the absence of air. It is possible that one has an equilibrium of **3** (n = 2) and **12** which is favorable to the former, but that by removing **12** by oxidation one can eventually produce large amounts of butyrolactone and $Mn(CO)_5Br$. In fact, the abnormal O_2 sensitivity of **3** (n = 2) can be nicely accounted for with this assumption.

[4] 
12

$\xrightarrow{O_2/H_2O}$ $Mn(CO)_5Br$ + **8**

However, the major reaction occurring in solution in the absence of oxygen is not likely to involve **12**. The formation of the alkyl complex **10** in chloroform solution and the fact that **10** is not seen in THF solution implies that a stabilizing THF coordination of unsaturated intermediates is involved at some point in the reaction mechanism. One route for such stabilization could involve $16e^-$ intermediates such as **13**, **14**, **15**, or **16**. In eq. [5], we show a plausible route to the organic products involving a metallocycle intermediate **14**, although other mechanisms are certainly not ruled out. The route shown as eq. [5] has much analogy in platinum metallocycle chemistry, where metallocycles are well characterized and details of the thermolysis reactions have been investigated (9).

The fact that the chloroform solution reactions require a much higher temperature than those in THF, and the fact that considerable cyclopropane is formed in the former case, can be accounted for by the eq. [5] mechanism, i.e., **13** and **14** can be stabilized by weak THF coordination. Also, since the propene-forming route might involve further intermediates **15** and **16**, there is probably more chance for the direct reductive elimination of cyclopropane from **14** (or an $18e^-$ equivalent), compared to THF solution. The formation of an insoluble manganese "powder" in chloroform solution is also consistent with the presence of very reactive unsaturated manganese species, whereas in THF such species "hold together" long enough for $Mn(CO)_5Br$ to be the eventual manganese product.

The postulate of a metallocycle intermediate, while reasonable, is certainly not a requirement since the cyclopropane could be formed by a concerted 1,3-elimination much like that shown in eq. [1] or eq. [2].

The n = *3 case*

The formation of 1-butene here parallels the observations made for the n = 2 situation (propene). The 1-butene can be explained using the eq. [5] mechanism but the evidence for a metallocyclic intermediate would have been stronger if some cyclobutane had been observed.

Other possible routes to 1-butene (or propene) could involve β-hydride abstraction (10) in the alkyl complexes to give $Mn(CO)_5H$ ($Mn(CO)_4H$) and alkenyl bromide, followed by re-

[5]

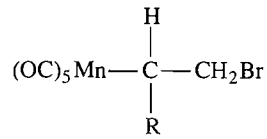
For personal use only.

duction of the latter by the $Mn(CO)_4H$ ($Mn(CO)_5H$). However, in chloroform solution $Mn(CO)_5H$ might have also reduced the solvent (11), which was not observed. Furthermore, no evidence for $Mn(CO)_5H$ was seen in *in situ* ^{55}Mn NMR studies.

Another possibility might involve reversible rearrangement of **10** or **11** to the bromoalkylmanganese complex **17** (10), followed by the same fragmentation process described for the $n = 1$ case.



17 R = Me or Et

Conclusion

A ω-bromoacylmanganese pentacarbonyl complex **3** ($n = 0$) is not formed from $Mn(CO)_5^-$ and the bromoacyl halide. One can, however, form the 3-bromopropionyl complex **3** ($n = 1$). This complex is readily fragmented to ethylene in a relatively low temperature process involving the loss of both the bromine atom and the carbonyl group. ω-Bromoacylmanganese pentacarbonyl complexes **3** with $n = 2$ or 3 show no tendency to reductively eliminate a cycloalkanone (even though one sees decarbonylation on heating, the a priori possibility of this reaction was not ruled out in a sealed tube experiment). The $n = 2$ case produces some cyclopropane, perhaps from a metallocycle intermediate. However, the major thermolysis product in both cases is the 1-alkene.

Experimental

All procedures involving the preparation and reactions of $Mn(CO)_5^-$ were performed under an atmosphere of argon or nitrogen (purified by passing the gases through columns of silica gel and molecular sieves). A combination of syringe, transfer needle, and Schlenk techniques was used (12). The acyl complexes are much more air stable and were handled without using dry box or vacuum line techniques, although some non-rigorous inert gas protection was used as a precaution, particularly with **3** ($n = 2$). Infrared analysis was performed using a Perkin–Elmer 467 or a Nicolet 5DX FT instrument, using 0.1-mm liquid cells. NMR spectroscopy was performed on a Varian XL-200 instrument. For ^{55}Mn NMR (49.33 MHz), chemical shifts are reported with respect to potassium permanganate in D_2O. However, this reference is well outside the window (50 kHz) for the ^{55}Mn signal in the acyl complexes, and the "sharp" signal for a very small amount of $Mn_2(CO)_{10}$ was used as a secondary reference. The high receptivity of ^{55}Mn allows one to use ca. 0.1 M solutions of the acyl complexes. The ^{55}Mn chemical shift tabulations of Calderazzo *et al.* (13) were used as a guide in setting up the spectrometer offsets. Gas analysis was performed on a Carle gas chromatograph designed for gas sampling. All melting points are uncorrected. Flash chromatography was performed according to literature procedures (14) using 0.040–0.063 mm silica gel (E. Merck 9385) and methylene chloride (distilled from P_2O_5) as eluant (unless otherwise noted). THF was distilled from benzophenone ketyl under nitrogen or argon. $CDCl_3$ was dried over molecular sieve 3A powder (3–5 μM) prior to use.

The ω-bromoacyl chlorides were either commercially available or were prepared from the commercially available acid using thionyl chloride.

3-Bromopropanoylmanganese pentacarbonyl **3** (n = *1*)

Dimanganese decacarbonyl (0.20 g, 0.51 mmol) was reduced with 1% sodium amalgam in 10 mL THF. The solution was transferred by syringe to 0.18 g 3-bromopropanoyl chloride (1.05 mmol) in 2 mL THF and stirred for 30 minutes at room temperature, by which time a white precipitate had formed in the yellow solution. The solvent was then removed at reduced pressure and the oily residue extracted with two 10-mL aliquots of hexane, filtered, and the volume of the combined extracts reduced to ca. 10 mL. The product crystallized upon cooling to 0°C and after filtering and washing with cold hexane yielded 0.19 g white needles (57% yield), mp 57.5°C; Infrared (hexane, cm^{-1}): 2117(m), 2055(m), 2016(s), 1648(m); ^1H NMR ($CDCl_3$): 3.45 (m, $-CH_2CH_2-$) ppm; $\{^1H\}^{13}C$ NMR ($CDCl_3$): 25.8 ($-CH_2CO$), 67.5 ($-CH_2Br$), and 144 (CO) ppm; ^{55}Mn NMR (THF): −1830 ppm, $W_{1/2} = 6100$ Hz. Anal. calcd. for $C_8H_4BrMnO_6$: C 29.03, H 1.22%; found: C 27.58, H 1.41%.

4-Bromobutanoylmanganese pentacarbonyl **3** (n = *2*)

This complex was prepared in a similar way to 3-bromopropanoylmanganese pentacarbonyl. Thin-layer chromatography indicated that the yellow solid isolated was contaminated with manganese pentacarbonyl bromide. Flash chromatography (methylene chloride/silica) of the crude material, followed by recrystallization from hexane, gave pale yellow needles in 19% isolated yield, mp 55°C. The crude yield of product was considerably higher but purification of the somewhat fragile and atmosphere-sensitive product resulted in some loss of material. Infrared (methylene chloride, cm^{-1}): 2117(m), 2052(m), 2013(s), 1638(m); ^1H NMR ($CDCl_3$): 2.01 (dt, 2H), 3.12 (t, J = 6.7 Hz, 2H), 3.39 (t, J = 6.3 Hz, 2H); ^{55}Mn NMR (THF): −1874 ppm, $W_{1/2} = 7250$ Hz. Anal. calcd. for $C_9H_6BrMnO_6$: C 31.33, H 1.75%; found: C 31.45, H 1.81%.

5-Bromopentanoylmanganese pentacarbonyl **3** (n = *3*)

The procedure followed for the preparation of this compound was the same as that described for 3-bromopropanoylmanganese pentacarbonyl. White needles were isolated in 71% yield, mp 52.5°C; Infrared (hexane, cm^{-1}): 2115(m), 2052(m), 2009(s), 1659(m); ^1H NMR ($CDCl_3$): 1.5–1.9 (m, 4H), 2.96 (t, J = 6.7 Hz, 2H), 3.35 (t, J = 6.6 Hz, 2H); $\{^1H\}^{13}C$ NMR ($CDCl_3$): 23.2 ($-CH_2CO$), 31.9 ($-CH_2-$), 33.2 ($-CH_2-$), 65.9 ($-CH_2Br$), 143.9 (CO); ^{55}Mn NMR (THF): −1880 ppm, $W_{1/2} = 7300$ Hz. Anal. calcd. for $C_{10}H_8BrMnO_6$: C 33.45, H 2.25%; found: C 32.47, H 2.29%.

The thermal decomposition of 3-bromopropanoylmanganese pentacarbonyl **3** (n = *1*)

In 5-mm NMR tubes, 20 mg (0.06 mmol) 3-bromopropanoylmanganese pentacarbonyl **3** ($n = 1$) was dissolved in 0.5 mL deuterochloroform or 0.5 mL THF-d_8. The solutions were degassed by several freeze–thaw cycles and sealed under vacuum (0.1 Torr; 1 Torr = 133.2 Pa) and then placed in an oil bath at 75°C. The decomposition was followed by ^1H NMR (200 MHz), the tubes being inverted and centrifuged prior to running the spectrum. The only peak observed was a signal at δ 5.38 ppm (ethylene). When the decomposition was complete, the samples were opened while connected to a manifold, and the released gases analysed by GC.

The thermal decomposition of 4-bromobutanoylmanganese pentacarbonyl **3** (n = *2*)

This was carried out in a similar fashion to the experiment described for **3** ($n = 1$) using 5.0 mg (0.015 mmol) of acyl compound. In $CDCl_3$ after heating for 3 h at 75°C, the ^1H NMR spectrum showed only the alkyl complex **10**, δ 0.90, t (J = 8.0 Hz), 2H ($Mn-CH_2-$); 2.16, dt, 2H; 3.34, t (J = 7.5 Hz), 2H ($-CH_2Br$). Continued heating for 1 h at 125°C led to considerable decomposition, but ^1H peaks at 0.24 ppm (cyclopropane) and 1.72, d (J = 6.2 Hz), 3H; 4.95, d (J = 12) 1H; 5.05, d (J = 19) 1H; and 5.88, m, 1H (propene) accounted for 12 and 38% of the total proton integration. The reaction was cleaner in THF-d_8, giving propene and only a trace of cyclopropane.

The thermal decomposition of 5-bromobutanoylmanganese pentacarbonyl **3** (n = *3*)

This was carried out in a similar fashion to the experiment for **3** ($n = 1$), using 25 mg (0.070 mmol) of acyl compound. After heating for 3 h at 75°C in $CDCl_3$, ^1H NMR peaks were observed at δ: 0.97, t (J = 7.5), 2H ($Mn-CH_2$); 1.90 (m), 4H; 3.43, t (J = 6.5), 2H ($-CH_2Br$). On heating the solution to 120°C for 1 h, a reasonably clean (85%) spectrum of 1-butene was observed (also confirmed by GC gas analysis). An even cleaner spectrum of 1-butene was observed in THF-d_8 after heating the acyl complex for 4 h at 60°C.

2-Chloroacetylmanganese pentacarbonyl ***5***

This was prepared by a literature procedure (5) and purified by flash chromatography and recrystallization from hexane, mp 35°C; Infrared ($CDCl_3$): 2123(w), 2054(m), 2024(s), 1658(w); reported in heptane (5): 2117, 2055, 2014, 2007, 1654; ^1H NMR ($CDCl_3$) δ: 4.35(s); reported (5) 4.37.

The thermal decomposition of ***5***

In a 5-mm NMR tube, 10 mg of **5** was dissolved in 0.5 mL of $CDCl_3$ and the tube was sealed. After heating for 5 min at 70°C, about half of **5** had been converted to the alkyl complex **6** (^1H NMR, δ: 3.60, s; reported (15) 3.52. After heating for 30 min, little of **5** remained. However, new resonances at 3.0, 2.2, and 1.85 ppm had appeared in addition to the peak for **6** at 3.60 ppm.

Bromo carbene complex ***9***

This complex was formed in only very small yields, the 4% from heating the pure liquid acyl complex at 70°C being the highest. The complex **9** was isolated as an orange solid by flash chromatography of the melt material. The infrared and ^1H NMR data are reported in the Results section. The data reported for the corresponding iodo complex are quite similar (7), but the data for a dimeric carbene complex origi-
are quite similar (7), but the data for a dimeric carbene complex (16) are considerably different. The small quantities involved here did not allow for a confirmatory elemental analysis.

WOF_4.bipy was prepared from the reaction of WOF_4 with 2,2′-bipyridyl (bipy) in the melt or in solution in CH_2Cl_2 or CH_3CN.

The adduct, which is not moisture-sensitive at room temperature, was characterized by elemental analysis, X-ray powder data, and vibrational spectroscopy. WOF_4.bipy is almost insoluble in the usual organic solvents, and the species which were observed in CH_2Cl_2 or CH_3CN by ^1H NMR and Raman spectroscopy resulted from the dismutation of WOF_4.bipy into WO_2F_2.bipy and WF_6.bipy.

This transformation in solution was revealed by the slow growing of crystals identified as WO_2F_2.bipy and by the ^1H NMR spectrum which displayed lines assigned to the independently synthesized and characterized species WF_6.bipy. Unlike the WOF_4 adduct, the tungstyl adduct is moisture-sensitive, its crystal structure showed that the tungsten atom is surrounded by a very distorted octahedron of ligands with each nitrogen of the bipy ligand *trans* to one oxygen atom and the two fluorine atoms *trans* to each other. The space group, unit cell parameters, and R factor for $C_{10}H_8F_2N_2O_2W$ are as follows: monoclinic, $P2_{1/n}$ (No. 14) (alternate setting of the standard space group $P2_{1/c}$), $a = 8.637(1)$ Å, $b = 13.823(2)$ Å, $c = 9.526(2)$ Å, $\beta = 109.98(2)°$, $V = 1068.8(6)$ Å^3, $Z = 4$, and $R = 0.044$ for 806 ($I > 3\sigma(I)$) of 1471 total reflections and 94 parameters.

Key words: 2,2′-bipyridyl adducts, tungsten oxide tetrafluoride, tungsten dioxide difluoride.

LUCILE ARNAUDET, ROLAND BOUGON, BUU BAN, PIERRETTE CHARPIN, JACQUES ISABEY, MONIQUE LANCE, MARTINE NIERLICH et JULIEN VIGNER. Can. J. Chem. **68**, 507 (1990).

WOF_4.bipy a été préparé par réaction de WOF_4 avec le 2,2′-bipyridyl (bipy) à l'état fondu ou en solution dans CH_2Cl_2 ou CH_3CN.

L'adduit, qui n'est pas sensible à l'humidité à la température ambiante, a été caractérisé par analyse élémentaire, le diagramme de diffraction X de poudre et la spectroscopie vibrationnelle. WOF_4.bipy est presque insoluble dans les solvants organiques courants, et les espèces observées dans CH_2Cl_2 ou CH_3CN par RMN ^1H et spectroscopie Raman proviennent d'une dismutation de WOF_4.bipy en WO_2F_2.bipy et WF_6.bipy.

Cette transformation en solution est révélée par la croissance lente de cristaux identifiés comme étant WO_2F_2.bipy et par le spectre RMN ^1H qui indique la présence de raies attribuables à l'espèce WF_6.bipy synthétisée et caractérisée par ailleurs. Contrairement à l'adduit du WOF_4, le dérivé du tungstyle est sensible à l'humidité atmosphérique, la détermination de sa structure par diffraction des rayons X a montré que le tungstène s'y trouve entouré d'un octaèdre très déformé de ligands, chaque atome d'azote du ligand bipy est en position *trans* d'un atome d'oxygène, et les deux atomes de fluor sont en position *trans* l'un par rapport à l'autre. Le groupe d'espace, les paramètres de la maille élémentaire et le facteur R sont comme suit : $C_{10}H_8F_2N_2O_2W$, monoclinique, $P2_{1/n}$ (N° 14) (variante d'orientation du groupe d'espace standard $P2_{1/c}$), $a = 8{,}637(1)$ Å, $b = 13{,}823(2)$ Å, $c = 9{,}526(2)$ Å, $\beta = 109{,}98(2)°$, $V = 1068{,}8(6)$ Å^3, $Z = 4$, et $R = 0{,}044$ pour 806 ($I > 3\sigma(I)$) reflections sur un total de 1471 et 94 paramètres.

Mots clés : adduits du 2,2′-bipyridyl, oxytétrafluorure de tungstène, dioxydifluorure de tungstène.

Introduction

The ability of tungsten oxide tetrafluoride to form adducts with a nitrogen-base such as pyridine (py) has been recently (1) demonstrated. The stability of the adducts was found to be dependent on the coordination number of the tungsten atom. For instance, the adduct WOF_4.2py with a seven-fold coordination of the tungsten atom was found to decompose easily into the WOF_4.py adduct for which the coordination number of the tungsten atom is six. The effect of the coordination number and of the nature of the nitrogen-base on the stability and reactivity of the tungsten oxide tetrafluoride adducts has been further investigated using the bidentate molecular ligand 2,2′-bipyridyl (bipy).

Experimental

Apparatus

Volatile fluorides were manipulated in an all-metal vacuum line equipped with Teflon or metal valves. Other volatile materials were purified and transferred in a glass vacuum line designed to handle highly moisture-sensitive materials. Solid products were handled in glove boxes flushed with dry nitrogen. Infrared spectra were recorded in the range 4000–200 cm^{-1} on a Perkin-Elmer Model 283 spectrophotometer. Spectra of solids were obtained by using small crystals pressed between AgCl windows in an Econo press (Barnes Engineering Co), or ground and pressed in KBr pellets.

Raman spectra of the solutions contained in 5 mm o.d. NMR tubes, or of powders in 0.5 mm o.d. glass capillaries were recorded on a Coderg Model T 800 spectrophotometer using the 514.5 nm exciting line of an Ar ion Spectra Physics laser filtered with a Coderg premonochromator. Below 2000 cm^{-1}, the frequency accuracy was estimated to be approximately ±3 cm^{-1} for the infrared spectra, and ±1 cm^{-1} for the Raman spectra; above 2000 cm^{-1}, the accuracy was estimated to be twice these values. The ^{19}F and the ^1H NMR spectra of the solutions in standard tubes were obtained on a Varian NV 14 spectrometer and a Bruker WP spectrometer operating at 56.4 and 60 MHz, respectively. Samples were referenced externally with respect to $Si(CH_3)_4$ (^1H) and $CFCl_3$ (^{19}F). A positive chemical shift

denotes a resonance occurring at high frequency of the reference compound. The chemical shift accuracy was estimated to be approximately ±0.05 ppm.

X-ray diffraction

X-ray powder diffraction patterns of the samples sealed in 0.3 mm o.d. glass capillaries were obtained by using a Phillips camera (diameter 11.46 cm) using Ni-filtered CuKα radiation. Crystals suitable for structural determination were selected in the dry box under a microscope and sealed inside 0.3 mm o.d. glass capillaries to protect them from the atmosphere. X-ray diffraction was carried out using an Enraf-Nonius CAD4 automated diffractometer. Cell dimensions were obtained by a least-squares refinement of the setting angles of 25 reflections with θ between 8 and 12°. Intensities were corrected for Lorentz polarization and absorption by using successively the empirical methods based on ψ-scans of top reflections (0.963 to 1) and DIFABS (2) (0.777 to 1.311). The structure was solved by the heavy-atom method and refined by full-matrix least squares (F) with W, F, and O atoms refined anisotropically. H atoms were included in the refinement at calculated positions: they were not refined but constrained to ride on their C atoms. All calculations were performed on a Micro VAX II computer with the Enraf-Nonius structure determination package (3). Analytical scattering factors for neutral atoms (4) were corrected for both $\Delta f'$ and $\Delta f''$ components of anomalous dispersion. Other experimental details appear with the crystal data in Table 3 and in the supplementary material.[2]

Materials

Tungsten oxide tetrafluoride was obtained by the literature (5) procedure and purified by sublimation *in vacuo* at ca. 50°C. Tungsten hexafluoride used for this preparation was obtained from Comurhex. 2,2′-Bipyridyl from Aldrich-Chemie was sublimed under vacuum at ca. 50°C; methylene chloride (Prolabo) was dried over Na–Pb alloy under reflux. Acetonitrile (Prolabo) was dried over P_2O_5 followed by treatment and storage on 5A molecular sieves. To avoid consumption of material, acetonitrile-d_3 was only treated with, and stored on, 5A molecular sieves. Microanalyses were carried out by Analytische Laboratorien, Elbach, West Germany.

Preparation of WOF_4.bipy and formation of WO_2F_2.bipy

To obtain single crystals for X-ray structure determination, several preparative methods were used. In a typical preparation, 0.1902 g (0.689 mmol) of WOF_4 in 10 cm^3 of dichloromethane was poured under vacuum onto a solution of 0.2152 g (1.378 mmol) of 2,2′-bipyridyl in 10 cm^3 of dichloromethane. The white crystalline powder that instantly precipitated was filtered off and washed under vacuum with dichloromethane to remove the excess of 2,2′-bipyridyl. The powder was finally pumped to dryness at room temperature. Other preparations were achieved using either 2,2′-bipyridyl in the melt, or in a solution in acetonitrile. For the latter either an excess of 2,2′-bipyridyl or the stoichiometric amount was used. All the solid products so prepared were found to have the same X-ray powder pattern. *Anal.* calcd. for $WOF_4.C_{10}H_8N_2$: W 42.55, F 17.59, C 27.80, H 1.87, N 6.48; found: W 42.30, F 17.47, C 27.63, H 1.83, N 6.40.

The attempts that were made to grow single crystals of WOF_4.bipy by very slow evaporation of the solvent from saturated solutions or drop to drop mixing of the reagents were not successful as far as the initial purpose was concerned. The few small colorless crystals which grew in CH_2Cl_2 or CH_3CN on standing over WOF_4.bipy for several days were identified as WO_2F_2.bipy from the X-ray single crystal study.

Results and discussion

Tungsten oxide tetrafluoride reacts with 2,2′-bipyridyl either in the melt or in solvents such as CH_3CN or CH_2Cl_2 to yield the adduct WOF_4.bipy. This adduct was found to be stable in the open air, and its X-ray powder pattern (Table 1) did not show signs of alteration after exposure of the solid to the atmospheric moisture for several days. When heated under vacuum in a sealed tube, WOF_4.bipy was found to decompose at 180°C and crystals of 2,2′-bipyridine sublimed onto the cold part of the tube.

The adduct WO_2F_2.bipy has been reported (6) as being obtained from the reaction of $WOF_2(OC_2H_5)_2$, 2,2′-bipyridyl, and HF in ethanol solution. Some properties including some of the vibrational data and an X-ray diffraction pattern were also given (6) but no structural determination was presented. This tungstyl adduct was obtained from dismutation of WOF_4.bipy during the work reported here and its crystal structure was determined. The circumstances of its formation are discussed in the last part of this section.

Vibrational spectra

The frequencies observed for the infrared and Raman spectra of the solid adducts WOF_4.bipy and WO_2F_2.bipy and for free bipy are summarized in Table 2. These data show that the formation of the adducts leads to a significant change from the spectra of the free ligand. Comparable changes, observed in the infrared absorption spectra of adducts having 2,2′-bipyridyl as ligand, have already been described and discussed. Due to the abundant literature regarding the complexes of bipy, only illustrative references are quoted here (7–30). The interpretation of the spectra given by the authors was based on those published for bipy and other heteroaromatic compounds (7, 28–30). The bands in the range 3150–3050 cm^{-1} have been assigned to the C—H stretches, in the range 1650–1300 cm^{-1} to C—C and C—N stretches of the ring and the deformations of the C—C—H angles, in the range 1250–1000 cm^{-1} to the in-plane deformations of the C—H bonds, in the range 1030–990 cm^{-1} to the breathing vibrations of the ring, in the range 980–700 cm^{-1} to the out-of-plane deformations of the C—H bonds, in the range 650–600 cm^{-1} to the in-plane ring bending, and in the range 750–400 cm^{-1} to the out-of-plane deformations of the ring.

A striking feature brought about by the donor–acceptor interaction is the shift of the breathing vibration (11) of the ring, observed at 995 cm^{-1} in the Raman spectrum of the free ligand versus 1027 and 1028 cm^{-1} for WOF_4.bipy and WO_2F_2.bipy, respectively. Also characteristic of the coordination of the

ligand is the appearance (7, 11, 22) in the infrared spectrum of molecular adducts of bipy of a strong band in the range 1310–1319 cm^{-1}. This band was reported to be missing in the infrared spectrum of free bipy. In line with these observations, the present study showed that strong new infrared bands appeared at 1323 cm^{-1} and 1313–1320 cm^{-1} for $WOF_4.bipy$ and $WO_2F_2.bipy$, respectively, and that these bands corresponded to the strong Raman bands found at 1300 cm^{-1} for free bipy, at 1332 cm^{-1} for $WOF_4.bipy$, and at 1312–1318 cm^{-1} for $WO_2F_2.bipy$. The very weak infrared band found at 1306 cm^{-1} for free bipy probably corresponds to the same vibration. As a whole, the bands due to the ring stretches and the deformations of the C—C—H angles as well as those of the C—H stretches are shifted to higher frequencies in the spectra of the adducts. Judged from the massif of infrared bands in the range 3150–3050 cm^{-1}, the positive shift of the C—H stretching frequencies was found to be more pronounced for $WOF_4.bipy$ than for $WO_2F_2.bipy$. The transfer of electronic density from the nitrogen lone-pair to the tungsten atom may account for the positive shifts of the frequencies of the ligand bipy.

Due to the numerous bands of bipy, the vibrations associated with the W, F, or O atoms are somewhat difficult to assign. However, a comparison with the infrared spectra of similar adducts of bipy (6, 19, 20, 21, 23, 25) made it possible to propose the following assignments for $WOF_4.bipy$: W—F

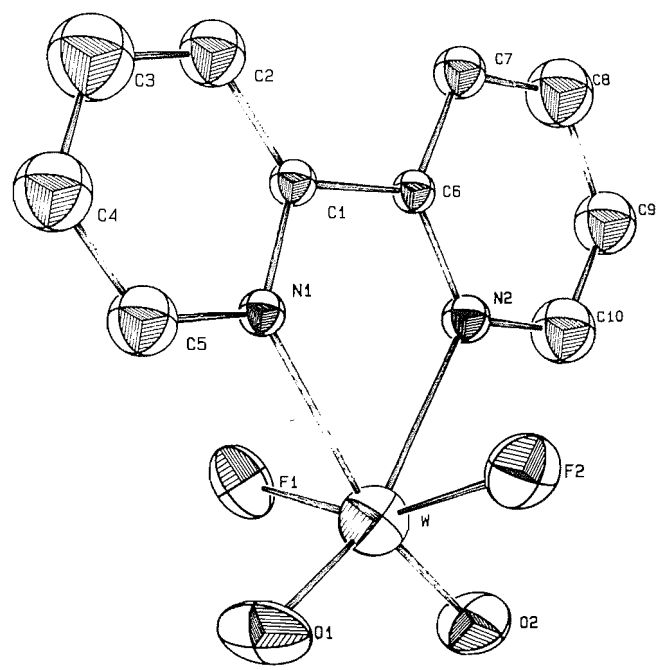

FIG. 1. ORTEP drawing of the molecular unit $WO_2F_2.bipy$ with the hydrogen atoms omitted.

[e]Data (ABXY-type spectrum) for the solution of WOF_4.bipy in acetonitrile after removal of the lines assigned to WF_6.bipy (see text).

vibrations at 494 cm^{-1}, 527 cm^{-1}, 580 cm^{-1}, and 638 cm^{-1} (IR); W—O vibration at 968 cm^{-1} (IR) (965 cm^{-1} (R)), and for WO_2F_2.bipy: W—F vibration at 495 cm^{-1}, 508 cm^{-1}, 575 cm^{-1}, and 635 cm^{-1}; tungsten–oxygen vibrations at 918 cm^{-1}, 958 cm^{-1} (R), (915 cm^{-1}, 960 cm^{-1} (IR)). The infrared bands previously reported by Buslaev *et al.* (6) for WO_2F_2.bipy were at 925 cm^{-1} and 976 cm^{-1} for the W—O vibrations and at 596 cm^{-1} for the strongest W—F vibration.

Crystal structure of WO_2F_2.bipy

The molecular stereochemistry of the adduct WO_2F_2.bipy was established by a single-crystal study. Crystal data are given in Table 3. Final positional and thermal parameters with their estimated standard deviations are given in Table 4. The relevant distances and angles are given in Table 5. Figure 1 shows the molecular unit and atomic labeling scheme, and Fig. 2 gives a stereoscopic view of the molecular packing.

The coordination polyhedron of the tungsten atom is a very distorted octahedron with each nitrogen of the bipy ligand *trans* to one oxygen atom. The F(1)—W—F(2) axis is strongly bent (154.8°) due to the steric effect of the tungsten oxygen double bond, while the angle O(1)—W—O(2) in the equatorial plane is very much larger (107.7°) than the angle N(1)—W—N(2) (70.5°). Because of the significant difference in the two sets of bond lengths and based on the usual (1, 31) relative lengths of the bonds W—O(terminal) and W—F(terminal), the sets with mean bond distances of 1.667 Å and 1.847 Å are unambiguously attributed to the W—O and W—F bonds, respectively.

Solution studies

From the ^1H and ^{19}F NMR signal intensities, it would appear that the solubility of the adduct WOF_4.bipy in the usual organic solvents is very low. In fact, no ^{19}F NMR signals could be observed with the CW type instrument which was used. However, use of an FT instrument allowed ^1H NMR spectra to be observed for proton signals of saturated solutions of WOF_4.bipy in CH_3CN or CH_2Cl_2. The signals of the bipyridyl ligand were found to be shifted downfield from those of the free ligand in the same solvent by an average of 0.55 ppm, and to be temperature independent in the range 303–243 K. The peaks observed for a solution in CH_3CN are listed in Table 6. The Raman spectra of these solutions also displayed lines shifted from those of the free ligand. One of them, observed at 1315 cm^{-1}, was more in correspondence with that observed at 1312–1318 cm^{-1} for WO_2F_2.bipy in the solid than that of WOF_4.bipy observed at 1332 cm^{-1} in the solid. Since the lines of the free ligand were found to be not significantly shifted from the solid to the solutions, it is inferred that the ^1H NMR and Raman signals observed for the solutions are those of the ligand bound to WO_2F_2 rather than to WOF_4. The growing of crystals of WO_2F_2.bipy from these solutions gives further support to this conclusion. The assumption by which a slow hydrolysis of WOF_4.bipy is taking place would be an obvious explanation for the formation of the WO_2F_2 adduct. However, as mentioned above, WOF_4.bipy is not moisture-sensitive in the solid, and according to the study performed by Il'in *et al.* (32), the hydrolysis of WOF_4 in acetonitrile requires more than traces of

For personal use only.

water to yield species containing the tungstyl group. The use of dry materials as well as sealed tubes does not favor the assumption of an accidental hydrolysis. As an alternate mechanism, a solvent-assisted dismutation of WOF_4.bipy yielding WO_2F_2.bipy and WF_6.bipy was considered. The direct synthesis (34) of WF_6.bipy which was achieved gave support to this assumption as the lines of this species were found together with those of WO_2F_2.bipy in the ^1H NMR spectrum of the solution of WOF_4.bipy.

Conclusion

Tungsten oxide tetrafluoride forms a one-to-one molecular adduct with the bidentate ligand 2,2′-bipyridyl. Owing to the negligible solubility of this adduct in the usual organic solvents, and to its low vapor pressure below its decomposition temperature, the crystal structure of WOF_4.bipy could not be obtained. However, the structure of the corresponding tungstyl adduct which was formed from slow solvent assisted dismutation of the WOF_4 adduct was determined. One driving force for this dismutation to occur might be the lowering in the coordination number of the tungsten atom from seven in WOF_4.bipy to six in WO_2F_2.bipy. Such a stabilization through reduction of the coordination number has already been observed (1) for the adduct of WOF_4 with the monodentate ligand pyridine. However, this effect is probably limited to the oxide fluoride derivatives since the coordination number of the tungsten atom in WF_6.bipy must be at least eight. The absence of short ligand–tungsten bonds probably accounts for the higher coordination number in this adduct.

Repulsive *gauche* conformational effect. Analysis of seven-membered rings containing *endo* and *exo* sulfur atoms

P. DIONNE AND M. ST-JACQUES[1]

Département de chimie, Université de Montréal, C.P. 6128, Succ. A, Montréal (Québec), Canada H3C 3J7

Received September 21, 1989

P. DIONNE and M. ST-JACQUES. Can. J. Chem. **68**, 513 (1990).

The so-called repulsive *gauche* conformational effect associated with sulfur is investigated through a study of 3-methylthio-1,5-benzodioxepin (**1**) and 3-methylthio-1-benzoxepin (**2**), together with 3-fluoro- and 3-chloro-1,5-benzodithiepins (**3** and **4**), by ^{13}C and ^{1}H dynamic nuclear magnetic resonance methods. The results show that, while compounds **2**, **3**, and **4** exhibit a large amount of the C_e conformation, the *TB* form predominates for compound **1**. Intramolecular stereoelectronic $\sigma-\sigma^*$ orbital interactions are analyzed, together with several other factors (steric, electrostatic, and solvation), to explain the observed conformational behaviour.

Key words: *gauche* effect, seven-membered rings, 1,5-benzodithiepins, variable temperature NMR, orbital interactions.

P. DIONNE et M. ST-JACQUES. Can. J. Chem. **68**, 513 (1990).

On a étudié l'effet conformationnel *gauche* répulsif associé à l'atome de soufre en examinant la 3-méthylthio-1,5-benzodioxépine (**1**), la 3-méthylthio-1-benzoxépine (**2**) ainsi que les 3-fluoro- et 3-chloro-1,5-benzodithiépines (**3** et **4**), par des méthodes de résonance magnétique nucléaire dynamique du ^{13}C et du ^{1}H. Les résultats démontrent que, alors que l'on détecte la présence de quantités importantes de la conformation C_e dans les composés **2**, **3** et **4**, la forme *TB* prédomine pour le composé **1**. On a analysé les interactions stéréoélectroniques intramoléculaires des orbitales $\sigma-\sigma^*$ ainsi que plusieurs autres facteurs (stérique, électrostatique et de solvatation) afin de pouvoir expliquer le comportement conformationnel observé.

Mots clés : effet *gauche*, cycles à sept chaînons, 1,5-benzodithiépines, RMN à température variable, interactions orbitales.

[Traduit par la revue]

Introduction

Over the last few years, we have been interested in the mechanism of the *gauche* effect (1) and the underlying molecular interactions as revealed by the conformational analysis of some 3-substituted 1,5-benzodioxepins (2, 3) and 1-benzoxepins (4, 5). These results have shown that the seven-membered heterocycles can provide information complementary to analogous six-membered molecules because of the greater ring flexibility, giving rise to the twist boat (*TB*) form in addition to the axial chair (C_a) and the equatorial chair (C_e) conformations. Such studies unravelled the nature of the molecular orbital interaction involved. According to the rationalizations formulated earlier by Zefirov *et al.* (6) from studies of six-membered ring molecules, the conformational feature of the oxygen-containing seven-membered rings studied (2–5) was characteristic of attractive or negligible *gauche* effects. Our present aim is to analyze the repulsive *gauche* effect (6, 7) through the conformational study of seven-membered rings containing *endo* and *exo* sulfur atoms interacting with other heteroatoms such as in the series **1**–**6**.

6 Y = O ; Z = CH_2 ; X = OCH_3

[1]Author to whom correspondence may be addressed.

We therefore report the high-field variable temperature ^{13}C nmr spectral analyses of 3-methylthio-1,5-benzodioxepin (**1**), 3-methylthio-1-benzoxepin (**2**), 3-fluoro-1,5-benzodithiepin (**3**), and 3-chloro-1,5-benzodithiepin (**4**). The data are completed with 3-methoxy-1,5-benzodithiepin (**5**), reported earlier by Ménard and St-Jacques (8), 3-methoxy-1-benzoxepin (**6**) from the work of Lachapelle and St-Jacques (4), and the trends observed are discussed in the framework of a theoretical model for the *gauche* effect (9, 10).

Results and spectral analyses

The high-field ^{13}C nmr spectra of compounds **1**–**4** were obtained at temperatures varying between 0 and −135°C. The solvents used were CHF_2Cl (more polar solvent) and CH_3OCH_3 (less polar solvent), both containing some CD_2Cl_2 for nmr locking purposes.

Figure 1 shows the 100.62 MHz ^{13}C spectral modifications observed in CHF_2Cl at low temperature for compound **1**. Each carbon signal has been assigned using as reference published chemical shifts obtained for the 1,5-benzodioxepin family (3). The aromatic C-6,7 carbons, being quite remote from the site of substitution, give signals characteristic of the nature of the ring conformation (*C* or *TB*) adopted. Thus, the most deshielded C-6,7 signal corresponds to the *C* form while the upfield signal is characteristic of the *TB* form (3). In contrast, the C-3 carbon provides information on the axial–equatorial nature of the *C* forms (C_a or C_e). For example, it is found that the C-3 signal of the C_a form is more deshielded than that of the *TB* and C_e forms, while the signal of the C_e form is the most shielded of the three conformations (3). The above information, and the unequal intensity of the signals corresponding to each of the three forms at −135°C, allows complete assignment of the other chemical shifts as given in Table 1.

In the less polar CH_3OCH_3 solvent, the ^{13}C nmr spectrum of compound **1** at −135°C shows only two lines, indicating a

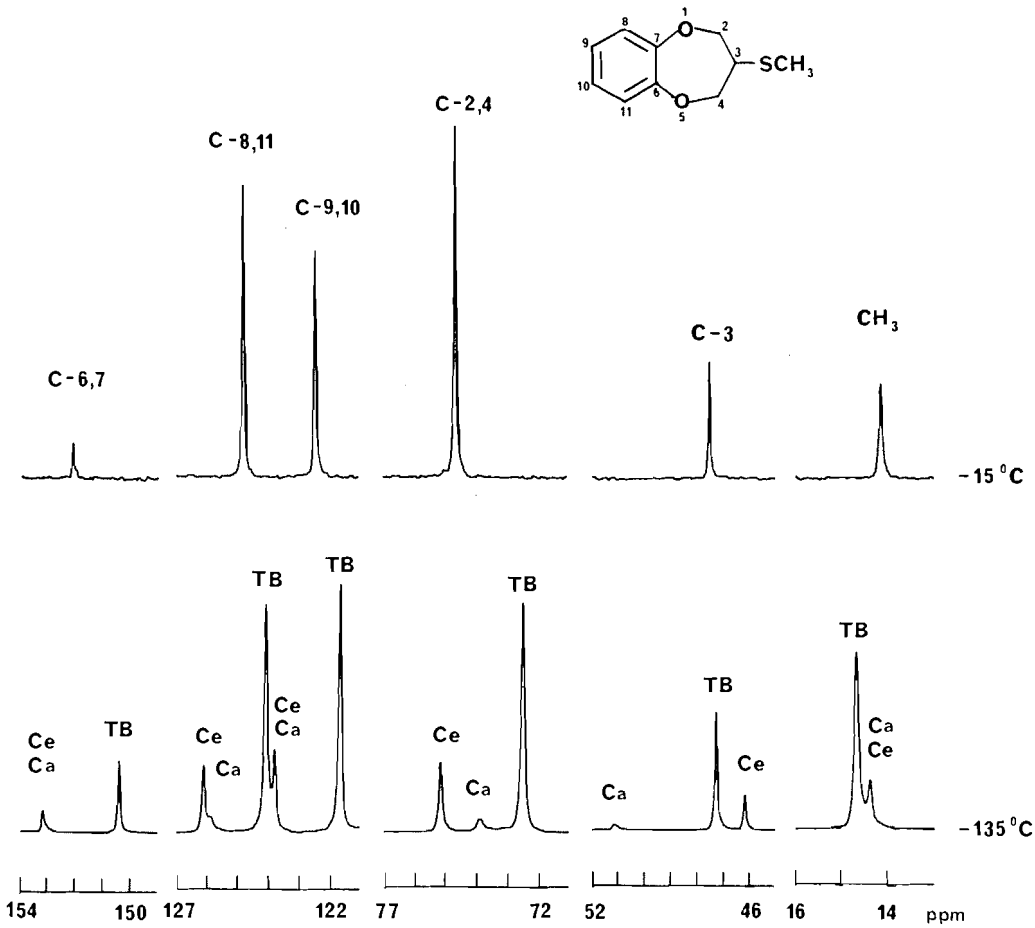

FIG. 1. 100.62 MHz ^{13}C spectra of **1** in CHF_2Cl at −15°C and −135°C (C_e = equatorial chair, C_a = axial chair, and *TB* = twist boat).

C_e:*TB* population ratio of 36:64. Indeed, in the C-3 region, the signal corresponding to the chair form at 46.17 ppm identifies the C_e conformation (46.14 ppm in CHF_2Cl). However, the signal of the *TB* form located at 47.22 ppm in CHF_2Cl has shifted to 45.44 ppm in CH_3OCH_3, corresponding to a shielding of 1.78 ppm. The solvent change also affects the chemical shifts of the CH_3 signals for the two forms, C_e (shielding of 1.15 ppm) and *TB* (shielding of 1.65 ppm) as shown in Table 1.

Figure 2 illustrates the 100.62 MHz ^{13}C nmr spectral modifications observed at low temperature for compound **2** in CHF_2Cl. At −20°C, all signals have been assigned, using the results from the $^1H/^{13}C$ Heteronuclear shift Correlation experiment (HC COSY) (11), carried out at room temperature in $CDCl_3$, in order to distinguish between the C-4 and C-5 carbons whose signals are too close to be assigned with confidence by the above method. All pertinent data are reported in Table 1.

At −120°C, several carbon signals have split into two lines of intensity ratio 9:91. Based on earlier results for the 1-benzoxepin family (4, 5), the two close signals, found in the C-6 region at 137.33 and 136.88 ppm, indicate the presence of two chair forms. Indeed, the nmr spectrum of 3-methoxy-1-benzoxepin (**6**) (4) at −125°C revealed that the C-6 signal of the *TB* form is found at 130.54 ppm while the C_e and C_a forms are located at 137.04 and 137.95 ppm respectively. Thus, a difference of more than 6 ppm exists between the *C* and the *TB* signals.

The association of each family of signals is best carried out using the C-4 and C-5 signals as probe because previous results showed that the C_a signal is the more shielded (5). Therefore, the signals in the C-4 and C-5 region of **2** are assigned as follows: in the C-4 region, the intense signal (91%) at 33.56 ppm represents the C_e form while the upfield signal (30.44 ppm) integrating for 9% corresponds to the C_a form, and similarly for the C-5 signals. The chemical shifts for the complete analysis are summarized in Table 1.

In the less polar solvent, CH_3OCH_3, the C_a:C_e population ratio of **2** at −120°C is 4:96. All pertinent data are reported in Table 1.

As for the published 1,5-benzodioxepin (3) and 1-benzoxepin families (4, 5), the aromatic C-8,11 and C-9,10 signals of the 1,5-benzodithiepin derivatives (**3**–**5**) can also provide information on the seven-membered ring conformation, whereby the *TB* signal is always found upfield from that of the *C* form (8). Finally, the C-3 signals reveal the nature of the three forms C_a, C_e, or *TB*, whereby the C_a signal is the most shielded, the C_e signal is the most deshielded, and the *TB* signal is found in between.

Figure 3 shows the 100.62 MHz ^{13}C nmr spectral changes observed for compound **3** in CH_3OCH_3. Firstly, it is important to note that this compound contains C–F coupling constants $^1J_{C-F} \approx 170$–180 Hz (12) and $^2J_{C-F} \approx 20$–25 Hz (13). At 0°C, the signals are broadened due to the slowing down of the conformational interconversion process. Lowering the temperature to −120°C yields a well-resolved spectrum in which the various carbons show signals with two or three peaks in a ratio of 7:90:3. Using the C-8,11 signals as conformational probe, the following analysis can be carried out: the downfield signals

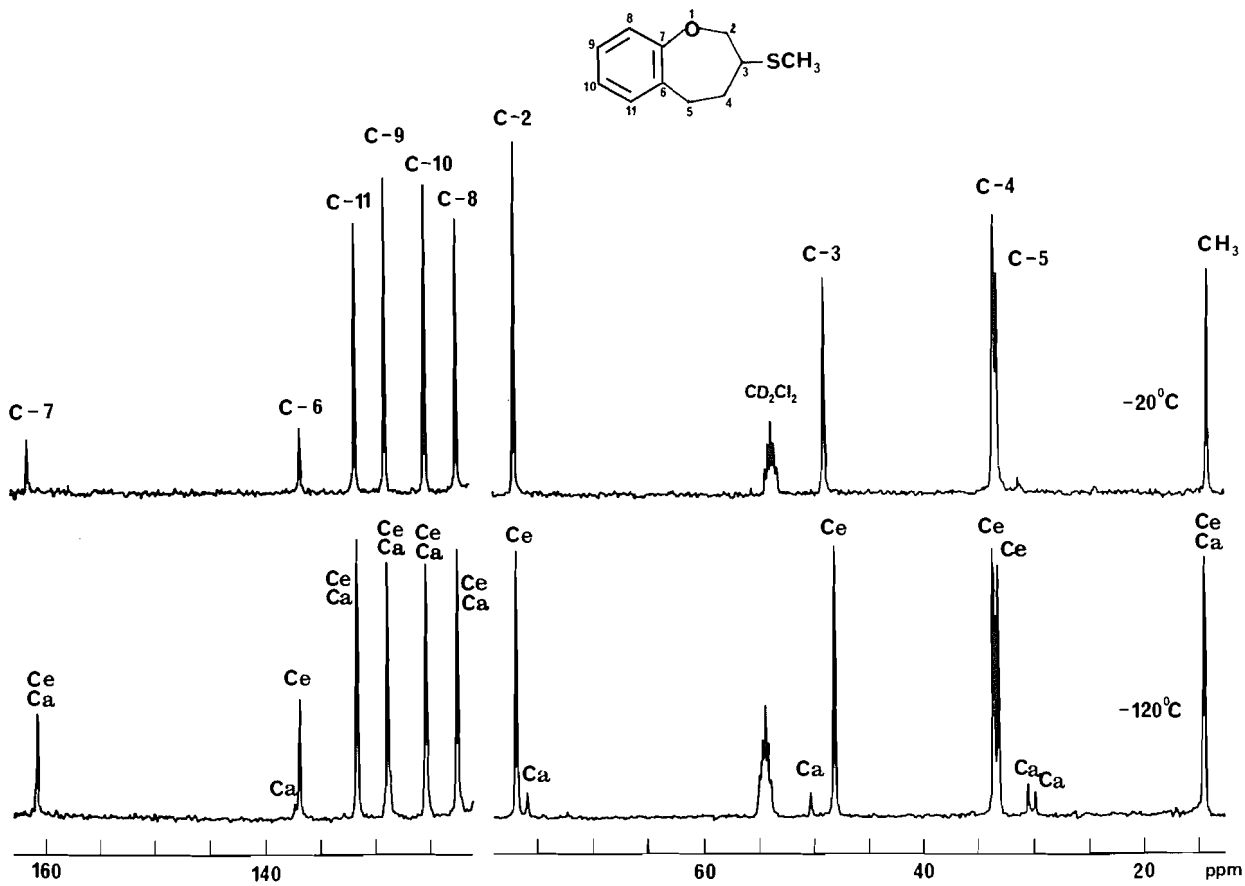

FIG. 2. 100.62 MHz ^{13}C spectra of **2** in CHF_2Cl at −20°C and −120°C.

at 135.23 and 135.54 ppm are deemed characteristic (8) of the *C* forms while the signal at 131.70 ppm corresponds to the *TB* form. Furthermore, the C-3 carbon signals identify each form. The most intense signal (90%) at 95.72 ppm is characteristic of the C_e form while the upfield signal at 86.13 ppm corresponds to the C_a form (7%). Between the C_a and the C_e forms appears the *TB* signal at 90.62 ppm. The chemical shifts of all other carbons have been assigned by integration and the results are reported in Table 1.

In the more polar CHF_2Cl solvent at −120°C, compound **3** reveals a C_a:C_e:*TB* population ratio of 20:79:1, as indicated in Table 1.

Spectral modifications have also been observed for compound **4** and the assignment of all signals has been made using the same procedure as described for compound **3**. Three conformations have been found in the polar CHF_2Cl solvent in a ratio of 6:92:2 for the C_a:C_e:*TB* forms, while in the less polar CH_3OCH_3 solvent, only the C_e form is detected. The results are also summarized in Table 1.

Discussion

The SCH_3 substituent is well known to exhibit an important steric effect (14). For example, the data in Table 2 (6, 14–16) show that the equatorial preference of cyclohexylmethyl sulfide is higher than that of the heavy halogen and methoxy substituents. But when the SCH_3 substituent interacts with a vicinal polar OCH_3 substituent, as in *trans*-1-methylthio-2-methoxycyclohexane, a conformational population change occurs that is larger than predicted on steric grounds (32% of axial conformation in CCl_4, $-\Delta G^\circ = 0.4$ kcal/mol) (6). It was suggested by Zefirov *et al.* (6) that this additional perturbation originates from an O/S repulsive *gauche* effect.

In comparison, Eliel and Juaristi (17) have studied this same interaction in 5-methylthio-1,3-dioxane and 5-methoxy-1,3-dithiane. Their results suggested that the O/S interaction is attractive for the 5-methylthio-1,3-dioxane while the S/O interaction is repulsive for 5-methoxy-1,3-dithiane (the following convention is used in the present paper: O/S indicates that the oxygen atom is located inside the ring and the sulfur atom is outside the ring and conversely for S/O). The repulsive S/O interaction was explained in terms of a probable repulsive overlap of the filled $3p$ orbital on sulfur with the $2sp^3$ filled orbital on oxygen. However the apparently conflicting results between the S/O and O/S interactions have left the issue unresolved.

Earlier works (3, 5) aimed at characterizing the O/O *gauche* effect in the seven-membered rings have shown that σ–σ^* orbital interactions play a significant role and it appears important to assess the O/S and S/O *gauche* interaction in light of this underlying framework.

It is therefore advantageous to divide the analysis of our results in two parts. The first part will consider compounds **1** and **2** for which the sulfur atom is located outside the ring, in the SCH_3 substituent (models for the O/S interaction), while the second part focuses on derivatives from the 1,5-benzodithiepin family (**3**, **4**, and **5**), containing *endo* sulfur atoms (model for the S/O interaction).

The O/S interaction

Unlike the analogous six-membered compounds, the particu-

[a]These signals were not observed because of coalescence.
[b]These signals were not observed, either because of peak overlapping or too small signal-to-noise ratio.
[c]Compound **5** exists as a mixture of three conformations C_e, C_a, and *TB* in ratio 88:8:4 respectively, in the CH_3OCH_3 solvent (8).

lar seven-membered system represented by compounds **1** and **2** is characterized by the presence of the *TB* conformation, in addition to the C_a and C_e forms.

For compound **1**, three conformations (C_a:C_e:*TB* = 7:22:71) are observed in CHF_2Cl but only two forms, *TB* and C_e (64:36), have been detected in the less polar CH_3OCH_3 solvent. Because increasing solvent polarity should attenuate the repulsive electrostatic interactions (18), the more polar C_a form is observed (MMX calculations (19) reveal that dipole moments are C_a, μ = 3.34D; C_e, μ = 1.09D; and *TB*, μ = 1.77D). Furthermore, in each of the two solvents, compound **1** exists predominantly in the *TB* form, as also found for the analogous methoxy derivative (2). But the presence of the C_e form for compound **1** contrasts with the methoxy derivative for which the C_e form is never observed.

Recent studies of 1-benzoxepin derivatives (4, 5) have shown that the *TB* form is not stabilized relative to the chair form in this family. Our results for compound **2** reveal that it exists predominantly in the C_e form while the *TB* form is not detected. By comparison, the relative populations of the conformers for the analogous methoxy derivative are C_a:C_e:*TB* = 70:20:10 in CHF_2Cl (4). Is this greater C_e preference shown by **2** indicative of some change in the underlying orbital interactions (9) as the OCH_3 substituent is replaced by SCH_3?

Before assessing the bond–antibond molecular orbital interactions present in the conformations of **1** and **2**, it is useful to review briefly the theory of the σ–σ^* interactions (9, 20, 21).

The stabilization energy resulting from an interaction between a doubly occupied bonding molecular orbital (σ) and an empty antibonding orbital (σ^*) is proportional to $S^2/\Delta E$, where S is the overlap integral and ΔE is the energy difference between the σ and σ^* orbitals. These two terms can either decrease or increase the stabilization energy as follows:

(a) First, for a series of compounds, the ΔE term increases stabilization as the energy level of the bonding orbital σ increases and (or) the energy level of the antibonding orbital σ^* decreases (22).

(b) Second, the effect of the overlap S term is best illustrated using a polar C—X bond. The electronic density in the molecular orbital σ_{C-X} is concentrated on the most electronegative atom X whereas, in the σ^*_{C-X} orbital, the electronic density is concentrated on the less electronegative atom C and it increases with increasing electronegativity of X (9, 22). Thus, overlap is increasingly effective with increasing electronegativity of X for interactions of the type σ–σ^*_{C-X}.

The overlap contribution is therefore predicted to be more stabilizing for the σ_{C-H}–σ^*_{C-X} interaction and less stabilizing for σ_{C-X}–σ^*_{C-H} relative to the σ_{C-H}–σ^*_{C-H} interaction (9).

For a given compound existing in several different conformations, the dominant orbital interaction for each conformer can be determined as follows:

1. All orbital interactions about the C(α)—C(β) bond are listed for each conformation (the α carbon is the site of substitution).

2. The σ–σ* interactions having a weak overlap are neglected and the other σ–σ* interactions are considered potentially more stabilizing. For each of the remaining interactions, the σ orbital is associated with the C—Y bond having the least electronegative Y atom, while the σ* orbital originates from the C—X bond having the most electronegative X atom (i.e., σ_{C-Y}–σ^*_{C-X}, where X is more electronegative than Y).

3. When more than one interaction remains for a given conformation: (a) If the S term is similar for these interactions, then the ΔE parameter determines which is the dominant interaction. (b) On the other hand, if the differences in the ΔE values are comparable, then the S term is determinant. (c) Finally, if both terms, ΔE and S, are significantly different, then the situation becomes complex when the effects of ΔE and S oppose each other.

Figure 4 shows the relative order of the energy levels of the σ_{C-X} and σ^*_{C-X} orbitals for the bonds involved in the analysis of compounds **1–6**. These data were derived from the results of CNDO/2 and *ab initio* calculations (10), from the analysis of ionization potentials of CH_3X molecules (23, 24), and from photoelectron spectra (25). Together, they allow qualitative predictions regarding the importance of the various σ–σ* orbital interactions potentially significant in each of the observed conformations.

The σ–σ* interactions involving at least one polar bond for conformations C_e and C_a are listed under structures **7** and **8**. Because of poor overlap, the σ_{C-O}–σ^*_{C-S} interaction in **7** and the σ_{C-O}–σ^*_{C-H}, σ_{C-H}–σ^*_{C-S}, and σ_{C-S}–σ^*_{C-H} interactions in **8** are neglected (for each structure, the interactions in parentheses are excluded because of poor overlap). Then the most stabilizing (or dominant) interactions are σ_{C-S}–σ^*_{C-O} for the C_e form (**7**) and σ_{C-H}–σ^*_{C-O} for the C_a form (**8**). Now, the difference between these two interactions is located in the σ orbital (σ_{C-H} and σ_{C-S}). Theoretical studies (9) indicate that the relative strength of the overlap contribution in σ–σ* interactions depends most sensitively on the nature of the antibonding rather than the bonding orbital. Furthermore, the small differences between the electronegativity of the hydrogen and sulfur atoms (2.1 and 2.5 respectively (26)) suggest that the overlap contribution is similar for both interactions. Since the ΔE term is smaller for the σ_{C-S}–σ^*_{C-O} interaction, the greater strength of the σ_{C-S}–σ^*_{C-O} interaction should favor the C_e

form over the C_a form. In contrast, the *TB* conformation (**9**) involves all the stabilizing σ–σ* interactions found in both the C_a and C_e forms. The fact that *TB* is the major form observed is in agreement with orbital interactions being operative. In addition, the *TB* form avoids any steric interactions present in the C_a form.

Similarly, compound **2** possesses the same σ–σ* orbital interactions as compound **1** for which the σ_{C-S}–σ^*_{C-O} interaction in C_e is strongest. Because the *TB* ring conformation is not accessible to compound **2**, the C_e form should then be more stabilized than C_a by this interaction, as observed. However, this feature for **2** is different from that of the analogous methoxy derivative **6** for which the C_a form is favored (4). Indeed, the data in Table 2 suggest that the SCH_3

5-Chlorobenzocycloheptene	0.03	16

substituent in compound **2** should prefer the C_e position on steric grounds. But the similarity of the C_a:C_e ratio for **2** and cyclohexylmethyl sulfide, in view of steric interaction with one electron lone pair in **2**, suggests that a contribution of the σ_{C-S}–σ^*_{C-O} interaction is present but not overly dominant.

The S/O, S/F, and S/Cl interactions

Recent studies of 1,5-benzodithiepin derivatives (8) have shown that the *TB* form is not stabilized specifically in this system and the parent compound exists exclusively in the chair conformation. For compounds **3**, **4**, and **5**, Table 1 reveals a large amount of the C_e form and small quantities of the *TB* form together with an intermediate quantity of the C_a form.

The experimental conformational data describing the axial–equatorial equilibrium in cyclohexane derivatives, summarized in Table 2, suggest that the amount of the C_e form should be similar for compounds **4** (X = Cl) and **5** (X = OCH_3) and less abundant for **3** (X = F). In contrast, dipolar interactions should contribute to invert this order for F and Cl in the seven-membered heterocycles. Indeed, because the C—F bond is more polar than the C—Cl bond, there exists a greater dipole–dipole destabilization of the C_a form, which leads to an increase in the amount of the C_e form. Furthermore, the orientation of the dipole moment of the halogen substituents is different from that of the methoxy group (the dipole moment of the halogen is located along the C—X bond, while that of the methoxy group bisects the C—O—C angle of the most stable rotamer). For these reasons it is more useful, in the absence of precise geometrical information, to compare the conformational behavior of compounds **3**, **4**, and **5** in the more polar solvent, assuming that under these conditions dipolar interactions are sufficiently attenuated to be of minimal importance (18).

Based on steric interactions alone, the relative populations of the C_e form should follow the order $OCH_3 \approx Cl > F$, which contrasts with the experimental populations as shown in Table 1. The fact that the C_e form is found to be predominant for these three compounds (in the two solvents used), as well as published considerations (6, 8), suggests that part of the stabilization of the C_e form should arise from a repulsive *gauche* effect. Accordingly, the bond–antibond orbital interactions will be examined to identify the origin of the repulsive feature.

Structures **10** and **11** show the σ–σ^* orbital interactions present in the C_a and C_e forms for compounds **3–5**. For the C_a form (**10**), the σ_{C-H}–σ^*_{C-X} interaction is dominant and is a function of each X substituent. On the other hand, the dominant interaction in the C_e form (**11**) is σ_{C-S}–σ^*_{C-X}. Then, this interaction stabilizing the C_e form (**11**) should be stronger and should contribute to the trend observed for compounds **3–5**.

Taking into account the nature of X in compounds **3–5**, the specific dominant interaction for each C_e form is σ_{C-S}–σ^*_{C-F}, σ_{C-S}–σ^*_{C-Cl}, and σ_{C-S}–σ^*_{C-O} respectively. Variations in overlap (*S* term) caused by changes in the σ^*_{C-X} orbitals

suggest that the stabilizing order should be Cl < O < F, whereas the ΔE term predicts a different one: O < F < Cl. Then, both the *S* and the ΔE terms indicate that the σ_{C-S}–σ^*_{C-F} interaction should be more stabilizing than the σ_{C-S}–σ^*_{C-O} interaction, as supported by the experimental results showing that the C_e populations for compounds **3** (X = F) and **5** (X = OCH_3) are 79% and 61% respectively in CHF_2Cl.

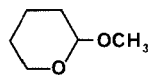
In contrast, the magnitude of the σ_{C-S}–σ^*_{C-Cl} interaction is determined by a competition between opposing ΔE and *S* terms. Accurate evaluation of each term is not possible for these compounds, but a comparison of the C_e populations for Cl, F, and OCH_3 (92%, 79%, and 61% respectively) suggests that the ΔE term, favoring the C_e form, is more important and is responsible in a large part for the trend observed.

Comparison of the S/O and O/S interactions

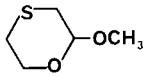
The molecular orbital σ_{C-S}–σ^*_{C-O} interaction is found to be common to compounds **1** and **2** (O/S interaction) as well as to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

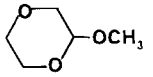
5 (S/O interaction) and it stabilizes the C_e form for all three molecules. The strength of this interaction can also usefully be pointed out using the six-membered compounds **12** and **13** as described below.



12



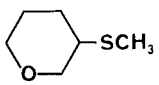
13



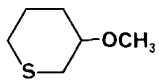
14

While the axial preference (80% in MeCN) for the 2-methoxytetrahydropyran (**12**) (27) is due to the anomeric effect (28), it is observed that introducing a sulfur atom at position 4 of the ring, as in **13**, stabilizes the C_e form and reduces the axial population to 56% in MeCN (29). This observation cannot be explained by dipole–dipole repulsion between the substituent and the sulfur atom because when the sulfur atom is replaced by an oxygen atom, as in **14**, the C_a form (73% in MeCN) is favored (29, 30). The results of the present work on σ–σ^* molecular orbital interactions suggests that the significant σ_{C-S}–σ^*_{C-O} interaction present in the C_e form (**13**), which opposes the η_O–σ^*_{C-O} interaction, is largely responsible for its behavior.

We can now address the question of whether the σ_{C-S}–σ^*_{C-O} interaction is of different intensity when the sulfur atom changes from an *endo* to an *exo*cyclic position (S/O or O/S) because of different angle constraints?



15



16

Firstly, the σ_{C-S}–σ^*_{C-O} interaction is involved in both six-membered cyclic compounds **15** and **16**. In a polar solvent (acetone), the $-\Delta G°$ values of **15** and **16** are 1.30 ± 0.19 and 1.19 ± 0.03 kcal/mol at 183 K and 178 K respectively (31, 32). Several contributing factors are involved in these compounds. For example, in a polar solvent the dipole–dipole interactions are attenuated, favoring the C_a form, and the steric interactions are generally stronger for the SCH_3 substituent than for OCH_3. The recently published method (33) of estimating the strength of the *gauche* interactions in 3-aminothiacyclohexane provides a useful framework for the analysis of **15** and **16**. It was suggested that the *gauche* interaction between a substituent X and the heterocyclic atom Y can be estimated from the following equation: $(X/Y) = -\Delta G° - (X/CH_2)_{gauche}$ where the $(X/CH_2)_{gauche}$ interaction is considered empirically as half of the *A* value of the X group. Applying this method to compounds **15** and **16**, the following values are obtained: (S/O) = 0.77 kcal/mol and (O/S) = 0.89 kcal/mol.

Furthermore, for each $(X/Y)_{gauche}$ interaction, the contributions from steric interactions are estimated as follows (33). For compound **15**, the $(O/CH_2)_{gauche}$ interaction (0.30 kcal/mol) is 0.34 times the $(Me/CH_2)_{gauche}$ interaction and the term $\Delta = (X/Y) - [(X/CH_2) \times (Y/CH_2)/(Me/CH_2)]$ then corresponds to the difference between the (X/Y) interaction and the value from an "exclusively steric" point of view. The Δ terms obtained for compound **15** and **16** are 0.59 and 0.70 kcal/mol respectively and correspond to the (S/O) and (O/S) interactions other than steric. Furthermore, the positive sign of Δ indicates that these interactions are repulsive.

Considering the approximate nature of this method, it appears that the calculated (S/O) and (O/S) *gauche* interactions are similar for compounds **15** and **16**. Even though this method is limited quantitatively, it provides a useful reference point and offers an indication as to the presence of interactions other than steric ones.

In the light of the above analysis, the σ_{C-S}–σ^*_{C-O} interaction should in principle be independent of the location of the S atom in compounds **1** and **5**, assuming that the angles between the two interacting orbitals are similar in the C_e form of both compounds. Indeed, MMX calculations (19) reveal that the dihedral angles between the C—O and C—S bonds in the C_e form are 172° and 166° for compounds **1** and **5** respectively. But the presence of the *TB* form for compound **1** prevents a definitive conclusion from being reached. Indeed, the stabilization of this form is most likely due to the fact that its flexibility allows the interacting σ orbitals to adopt a near-perfect antiperiplanar arrangement.

Conclusion

In studies of the *gauche* effect, repulsive or attractive interactions have been invoked to explain specific conformational preferences. Results presented herein indicate that the origin of this effect involves molecular orbital interactions associated with at least one polar bond. In addition to the steric and electrostatic interactions, it appears that the underlying σ–σ^* interactions are important in conformational analysis and, together with the anomeric effect (n–σ^*), constitute important features of the general theory of stereoelectronic molecular orbital interactions.

Experimental

Routine ^1H nmr spectra were recorded on a Bruker WH-90 spectrometer as solutions in $CDCl_3$ (10% w/v) containing Me_4Si as reference.

The 2D proton–carbon heteronuclear chemical shift correlation (HC COSY) spectrum was obtained using the standard pulse sequence (9). The experiment was performed on a Varian VXR-300 spectrometer operating at 75.431 MHz for ^{13}C with F_2 = 299.949 MHz in the second dimension. The spectrum was acquired with 256 × 1K data points.

The low temperature ^1H nmr spectra at 400.13 MHz and ^{13}C nmr spectra at 100.62 MHz were obtained using a Bruker WH-400 spectrometer equipped with a B-VT-1000 variable temperature unit. Calibration using a thermocouple inside a solvent-containing nmr tube indicates that the low temperatures reported are accurate within ±3°C.

Proton samples in standard 5-mm tubes (degassed and sealed) were recorded as solutions in CHF_2Cl and CF_2Cl_2 (10–20 mg in 0.55 mL of solution) containing Me_4Si and about 15–20% of CD_2Cl_2 or CD_3COCD_3 for field locking purposes. For proton spectra, the typical instrumental parameters used are as follows: flip angle = 10°–70°; scan width (SW) = 5000 Hz; data size = 8 and 16K; aquisition time (AQ) = 0.8–1.0 s; relaxation delay (RD) = 0.01 s.

For all ^{13}C nmr spectra, the following parameters are typical: flip angle = 20°–60°; SW = 20 000 Hz; data size = 8–16K; AQ = 0.43 s; RD = 0.6 s. The ^{13}C samples were studied at low temperature, as solutions in CHF_2Cl or CH_3OCH_3 (100–150 mg in 2.2 mL of solution) containing Me_4Si and about 15–20% of CD_2Cl_2 as locking agent, in standard 10-mm tubes that had been degassed and sealed. Integrations were carried out by using Bruker software and are precise within ±2% (34).

The high resolution mass spectra were taken using a modified MS-9 spectrometer at 70 eV.

The dipole moments and dihedral angles were obtained by MMX molecular mechanics calculations on an IBM/AT computer, using the PCMODEL program (19) purchased from Serena Software, Box 3076, Bloomington, IN 47402-3076.

2H-2,3-Dihydro-3-methylthio-1,5-benzodioxepin (**1**)

A round-bottomed flask containing 10 mL of dry ether, fitted with a magnetic stirrer, rubber septum, and maintained under argon was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

cooled to 0°C in an ice bath. Afterwards, 4.8 mL (0.082 mol) of methanethiol was added. Commercial methyllithium (1.4 M) (Aldrich) (60 mL, 0.082 mol) was introduced via syringe at a rate such that gas (CH_4) evolution did not become excessively violent. During the course of the addition of CH_3Li, a white solid separated. When the addition of CH_3Li was completed, the ether and unreacted CH_3SH were removed by an argon current at room temperature.

Afterwards, a solution of 50 mL of dry THF and 2.0 g (0.016 mol) of 2*H*-2,3-dihydro-3-mesyl-1,5-benzodioxepin (3) was added and the mixture was heated at ~50°C for 2 days. The solution was cooled to room temperature, filtered, and the solvent was evaporated. The product was purified by flash chromatography on silica gel by using 25% dichloromethane and 75% hexane as eluent, giving 2.8 g (88%) of a colorless liquid; ^{1}H nmr δ($CDCl_3$): 6.98 (4H, s, Ar), 4.56 (2H, dd, CH_2), 4.07 (2H, dd, CH_2), 3.3 (1H, m, CH), 2,2 (3H, s, CH_3). Exact mass calculated for $C_{10}H_{12}O_2S$: 196.0558; found (70 eV): 196.0557.

2,3,4,5-Tetrahydro-3-methylthio-1-benzoxepin (**2**)

This product was prepared by a method similar to that for compound **1** from 1.04 g (0.0043 mol) of 2,3,4,5-tetrahydro-3-mesyl-1-benzoxepin (4). Purification by flash chromatography on silica gel using a 15:85 mixture of dichloromethane and hexane gave 375 mg (45%) of a colorless liquid; ^{1}H nmr δ($CDCl_3$): 7.0–7.2 (4H, m, Ar), 4.3–4.5 (1H, m, H-2), 3.60 (1H, dd, H-2) 2.7–3.0 (4H, m, H-4, H-5, H-3), 2.15 (3H, s, CH_3), 1.5–1.6 (1H, m, H-4). Exact mass calculated for $C_{11}H_{14}OS$: 194.0765; found (70 eV): 194.0764.

1,3-Dibromo-2-fluoropropane (ref. 35)

This product was made using the method described in ref. 36.

3-Fluoro-1,5-benzodithiepin (**3**)

A mixture of 4.03 g of K_2CO_3 and 10 mL of pentanol was brought to reflux. Afterwards, 0.912 g (0.007 mol) of 1,3-dibromo-2-fluoropropane was added. The reflux was maintained for 10 h. The mixture was cooled to room temperature, filtered, and extracted with ether and brine. The organic layer was dried with $MgSO_4$, filtered, and the solvent was evaporated. The yellow oil was purified by flash chromatography with 10:90 dichloromethane:hexane as eluent to give 0.381 g (26%) of a colorless liquid; ^{1}H nmr δ($CDCl_3$): 7.72–7.17 (4H, m, Ar), 5.03 (1H, m, CH), 3.23–2.75 (4H, m, CH_2). Exact mass calculated for $C_9H_9S_2F$: 200,0130; found (70 eV): 200.0101.

2-Chloro-1,3-propanediol

This product was made and characterized using the method described in ref. 37.

2-Chloro-1,3-ditosylate propane

This compound was synthesized by a standard method (38), using the 2-chloro-1,3-propanediol as starting product.

3-Chloro-1,5-benzodithiepin (**4**)

At 0°C, to 0.50 g (0.004 mol) of benzenedithiol was added 1.4 M commercial methyllithium (5.4 mL, 0.008 mol) via syringe at a rate such that gas (CH_4) evolution did not become excessively violent. A white solid was formed. Afterwards, a solution of 1.4 g (0.004 mol) of 2-chloro-1,3-ditosylate propane in 10 mL of THF was added. The mixture was stirred for 4 h, filtered, and the solvent was evaporated. The product was purified by flash chromatography on silica gel by using 95:5 hexane:dichloromethane as eluent. A colorless liquid was obtained, 0.12 g (14%); ^{1}H nmr δ($CDCl_3$): 7.74–7.20 (4H, m, Ar), 4.50 (1H, m, CH), 3.36 (2H, dd, CH_2). Exact mass calculated for $C_9H_9S_2Cl$: 215.9834; found (70 eV): 215.9841.

The substrate- and stereoselectivity of microbial reductions of 1,4-dithiaspiro[4.5]decanones and 1,5-dithiaspiro[5.5]undecanones

TETSUO TAKEMURA,[1] YOSHIKO HOSOYA, AND NOBUO MORI

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162, Japan

Received August 8, 1989

TETSUO TAKEMURA, YOSHIKO HOSOYA, and NOBUO MORI. Can. J. Chem. **68**, 523 (1990).

The title spirocyclic ketones, possessing possible substitution patterns 1,4-dithiaspiro[4.5]decan-6-one (**1***a*), -7-one (**3***a*), and -8-one (**5***a*), and 1,5-dithiaspiro[5.5]undecan-7-one (**2***a*), -8-one (**4***a*), and -9-one (**6***a*), have been reduced with new strains of yeast (*Saccharomyces cerevisiae*, JCM 1819 and JCM 2214). Reductions of the prochiral ketones **1***a*–**4***a* occur with high enantiofacial selectivity on the preparative scale (up to 99% ee). The product alcohols (1,4-dithiaspiro[4.5]decan-6-ol (**1***b*) and -7-ol (**3***b*) and 1,5-dithiaspiro[5.5]undecan-7-ol (**2***b*) and -8-ol (**4***b*)) have the *S* configuration, as confirmed by 2D COSY experiments of the (*S*)-MTPA esters of **1***b*–**4***b* using the configuration correlation model of Mosher.

Key words: microbial reduction, *Saccharomyces cerevisiae*, dithiaspiro ketones, substrate- and stereoselectivity, H,H-COSY spectra.

TETSUO TAKEMURA, YOSHIKO HOSOYA et NOBUO MORI. Can. J. Chem. **68**, 523 (1990).

Utilisant de nouvelles variétés de levures (*Saccharomyces cerevisiae*, JCM 1819 et JCM 2214), on a réduit les cétones spirocycliques mentionnées dans le titre et possédant divers types de substituants (les 1,4-dithiaspiro[4.5]décan-6-one (**1***a*), -7-one (**3***a*) et -8-one (**5***a*) ainsi que les 1,5-dithiaspiro[5.5]undécan-7-one (**2***a*), -8-one (**4***a*) et -9-one (**6***a*)). À l'échelle préparative, les réductions des cétones prochirales **1***a*–**4***a* se produisent avec une haute énantiosélectivité. Les alcools obtenus (les 1,4-dithiaspiro[4.5]décan-6-ol (**1***b*) et -7-ol (**3***b*) ainsi que les 1,5-dithiaspiro[5.5]undécan-7-ol (**2***b*) et -8-ol (**4***b*)) possèdent la configuration *S*; cette conclusion découle d'expériences COSY en 2D effectuées sur les esters (*S*)-MTPA des composés **1***b*–**4***b* en utilisant le modèle de configuration de Mosher.

Mots clés : réduction microbiologique, *Saccharomyces cerevisiae*, dithiaspiro cétones, substrats et stéréosélectivité, spectres COSY du H,H.

[Traduit par la revue]

Biocatalysts have already demonstrated high utility and potential in certain areas of current importance in preparative organic chemistry (1). The asymmetric microbial reduction of the carbonyl group is one of the viable biological methods because of the broad substrate specificity involving dehydrogenase (or reductase) enzymes available in microorganisms. The most promising and popular microorganism for this purpose is *Saccharomyces cerevisiae* (e.g., common bakers' yeast) (1, 2). Bakers' yeast mediated reductions of acyclic ketones for the preparation of chiral building blocks have been extensively documented (2). Cyclic ketones as substrates of biocatalysts are also important for their stereochemical aspects (1, 3). Although several microbial reductions of cyclic ketones have recently been reported (4), no systematic study on spiro cyclic ketones has so far been undertaken (3*b*, 3*d*, 4*e*). There is a current interest in defining rules for the structural limits of acceptability of nonconventional substrates by synthetically useful biocatalysts.

In this paper we report on the structural- and stereospecificity of microbial reductions, by two new strains of *Saccharomyces cerevisiae*, of 1,4-dithiaspiro[4.5]decanones (**1***a*, **3***a*, and **5***a*) and 1,5-dithiaspiro[5.5]undecanones (**2***a*, **4***a*, and **6***a*), which include all possible patterns of these spiroketone skeletons. In addition, the present approach provides the features of the biocatalytic reductions of cyclic ketones possessing synthetically important protective groups, i.e., five- and six-membered thioketals.

Results

The substrate ketones **1***a*–**6***a* were obtained in 20–67% yields from 1,2-, 1,3-, and 1,4-cyclohexanediones (**7**, **8**, and **9** respectively) and 1,2-ethane- and 1,3-propanedithiols (**10** and **11** respectively) by the usual acetalization procedure (5). The racemic alcohols (±)-**1***b*–**4***b* and achiral alcohols **5***b* and **6***b* required for reference purposes were prepared by reduction of **1***a*–**6***a* with lithium aluminum hydride.

Screening various strains of *Saccharomyces cerevisiae* proved that type cultures JCM 1819 and JCM 2214 (microorganisms A and B respectively) were sufficiently active toward spiroketones **1***a*–**6***a*.[2] In each case, the sole product of the microbial reduction was the corresponding alcohol as shown in Scheme 1. The substrate specificities of the microbial reductions of ketones **1***a*–**6***a* (reaction time vs. % conversion) are summarized in Table 1.

The prochiral spiroketones **1***a*–**4***a* were each subjected to preparative scale (151–642 mg) microbial reduction under the usual aerobic conditions (substrate concentration, 30 mg/100 mL). Ketones **5***a* and **6***a* were omitted because both the substrates and products are achiral. Each reaction was terminated when GLC analysis[3] showed it to be an appropriate conversion level (82–100%). The product alcohols and, in some cases, unchanged ketones were easily purified by PTLC. Optically active **1***b*–**4***b* are unknown substances. Their structures were confirmed by comparisons with the racemic compounds characterized earlier. The results obtained are also summarized in Scheme 1 and Table 1.

The ee's of the optically active alcohols were determined by chiral HPLC analysis of their 3,5-dinitrophenyl urethanes (6) and (or) by preparing their MTPA esters (7*a*) and monitoring the 400 MHz ^{1}H NMR absorptions of the externally diastereo-

[1]Author to whom correspondence may be addressed.

[2]Bakers' yeast (purchased from Oriental Yeast Co. Ltd., Japan) showed much less reactivity toward these ketones under the same reaction conditions.

[3]The total loss of material for the GLC analysis was less than 1% in each preparative run.

[c]All specific rotations were measured in $CHCl_3$.
[d]The preparative experiment was not carried out.
[e]Repeated experiments under similar conditions (at least once) gave similar results; e.g., 93% conv./10.0 days – 65% conv./3.0 days, 83–93% ee for run 7.

meric protons specified in the experimental section. The ee values determined by these procedures are also given in Table 1.

The absolute configurations of the product alcohols depicted in Scheme 1 were deduced from the Mosher rule (7*b*) analyses of their MTPA esters (**1***c*–**4***c*) obtained by treatment of the corresponding optically active and racemic alcohols with freshly prepared (*S*)-α-methoxy-α-trifluoromethylphenylacetyl chloride (7). The ^1H NMR chemical shifts of the esters were assigned on the basis of two-dimensional (2D) homonuclear proton correlation spectroscopy (COSY) experiments. The partial 2D ^1H COSY contour plots (400 MHz; $CDCl_3$) for the (*S*)-MTPA esters of (−)- and (±)-**4***b* are shown (aromatic proton resonances omitted) in Fig. 1 as examples of the model for (*S*)-MTPA esters of (*S*)- and (*R*)-**4***b* as an example of the analysis. The ^1H NMR chemical shift differences (Δδ values) for the diastereomeric MTPA esters (**1***c*–**4***c*) used for the configuration determinations are summarized in Table 2.

Discussion

A standard procedure as given in the experimental section was used for the incubation of the spirocyclic ketones **1***a*–**6***a* in growing cultures of *S. cerevisiae* to compare differences in enzymatic reduction resulting from the structural variations of the substrates. It is very important that although the reaction rate varied, the spiroketones examined were all good substrates, irrespective of the ring members of thioketal moieties, the position of the carbonyl group, and the microorganisms used. The substrate specificity of the enzyme systems is fairly broad.

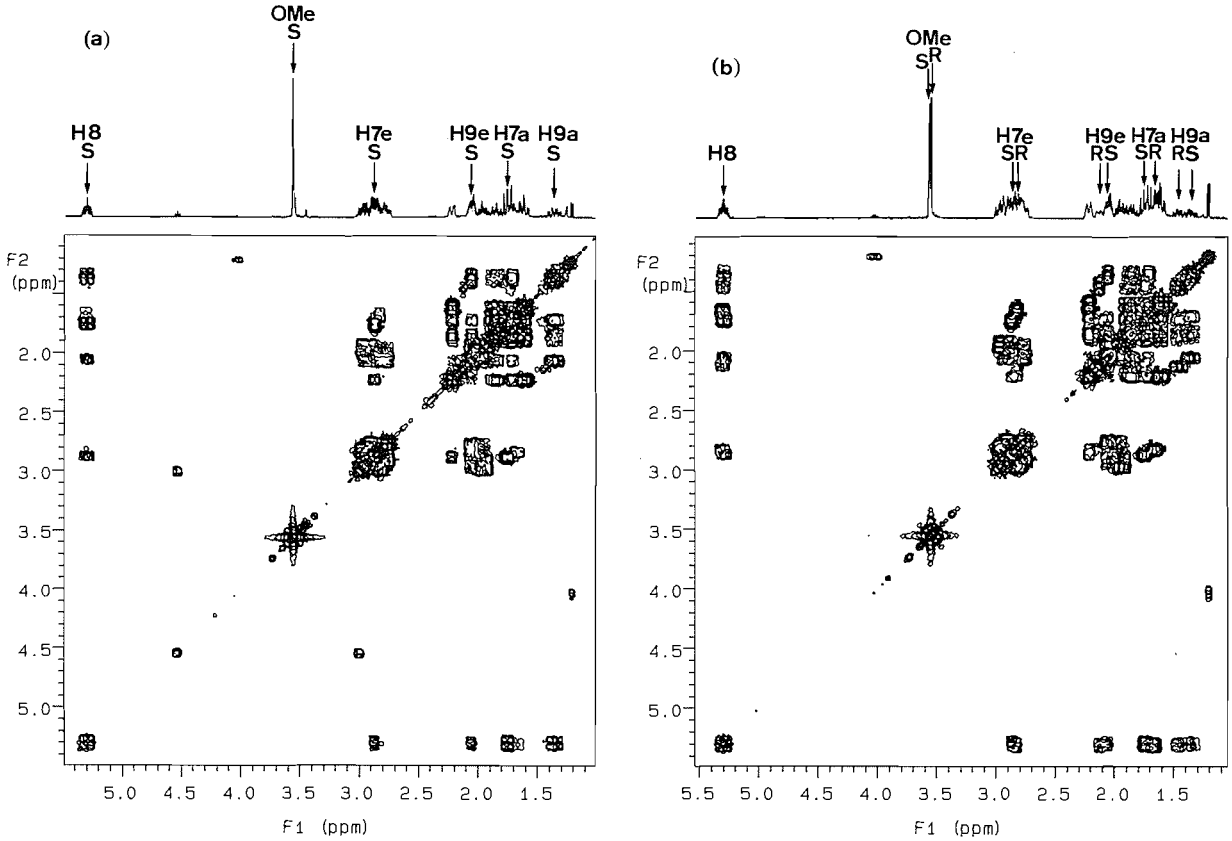

FIG. 1. Partial 2D ^{1}H COSY contour plots for the (*S*)-MTPA esters of (a) (−)- and (b) (±)-**4***b* (400 MHz; $CDCl_3$).

TABLE 2. ^{1}H NMR chemical shift differences for the diastereomeric MTPA esters[a]

Compound	Proton[b] chemical shift difference, Δδ (I − II) in ppm		
	R_L moiety	R_S moiety	Methoxyl
1*c*	2,3 (+0.16)	7a (−0.043), 7e (−0.035)	(+0.029)
2*c*	2a (+0.354), 2e (+0.234)	8a (−0.056), 8e (−0.08)	(+0.010)
	4a (−0.08),[c] 4e (+0.068)		
3*c*	2,3 (+0.009)	8a (−0.115), 8e (−0.09)	(+0.006)
	6a (+0.089), 6e (+0.061)	9a (−0.036), 9e (−0.038)	
4*c*	7a (+0.088), 7e (+0.063)	9a (−0.090), 9e (−0.07)	(+0.015)

[a]Values in parentheses are differences in δ(Δδ), ppm, obtained by subtracting the chemical shift of the indicated protons of diastereomer II from that of the corresponding protons in I.
[b]The symbols "a" and "e" are used to denote axial and equatorial protons respectively.
[c]An exceptional upfield shift of R_L moiety.

While **4***a* against strain B (93% conv./10 days) was the poorest substrate of all substrate–microorganism combinations, its rate of reduction was still fast enough to permit a preparative scale reaction. No substantial amounts of by-products were detected by TLC and GLC in the reaction mixture, indicating that the reaction is chemoselective. Hence the recovery of material was virtually quantitative by this method, with the total yields of isolated, purified products being 75–98%.

As observed in entries 1–8, both strains A and B showed the same tendency to give the optically active alcohol products of high optical purities (83–99% ee). The ketone **2***a* (99–100% conv./1.1–1.7 days, 96–99% ee) possessing a flexible 6-membered ring gave better results compared to **1***a* (82–95% conv./3.5–3.6 days, 86–87% ee) possessing a less flexible (i.e., a smaller change in shape would be expected) 5-membered ring (8). The opposite is true where the prochiral center is further separated from the spiro-carbon atom (i.e., **3***a* (97–100% conv./1.0–3.8 days, 96–97% ee) vs. **4***a* (93–95% conv./6.9–10 days, 83–92% ee)). In this case, the higher %ee was obtained for **3***a* with the less flexible 5-membered ketal moiety β to the carbonyl. This substrate dependence on both rate and enantioselectivity (i.e., **2***a* > **1***a* and **3***a* > **4***a*) of the reaction are probably due to the preferable binding modes[4] (3*a*) of

[4]The fact that bakers' yeast mediated reduction of flexible open chain analogs of **2***a* (2*l*) and **4***a* (2*f*) constantly gave excellent %ee's (>96% ee and >99% ee respectively) may support the contribution of better fitting of substrates at the active sites of enzyme systems.

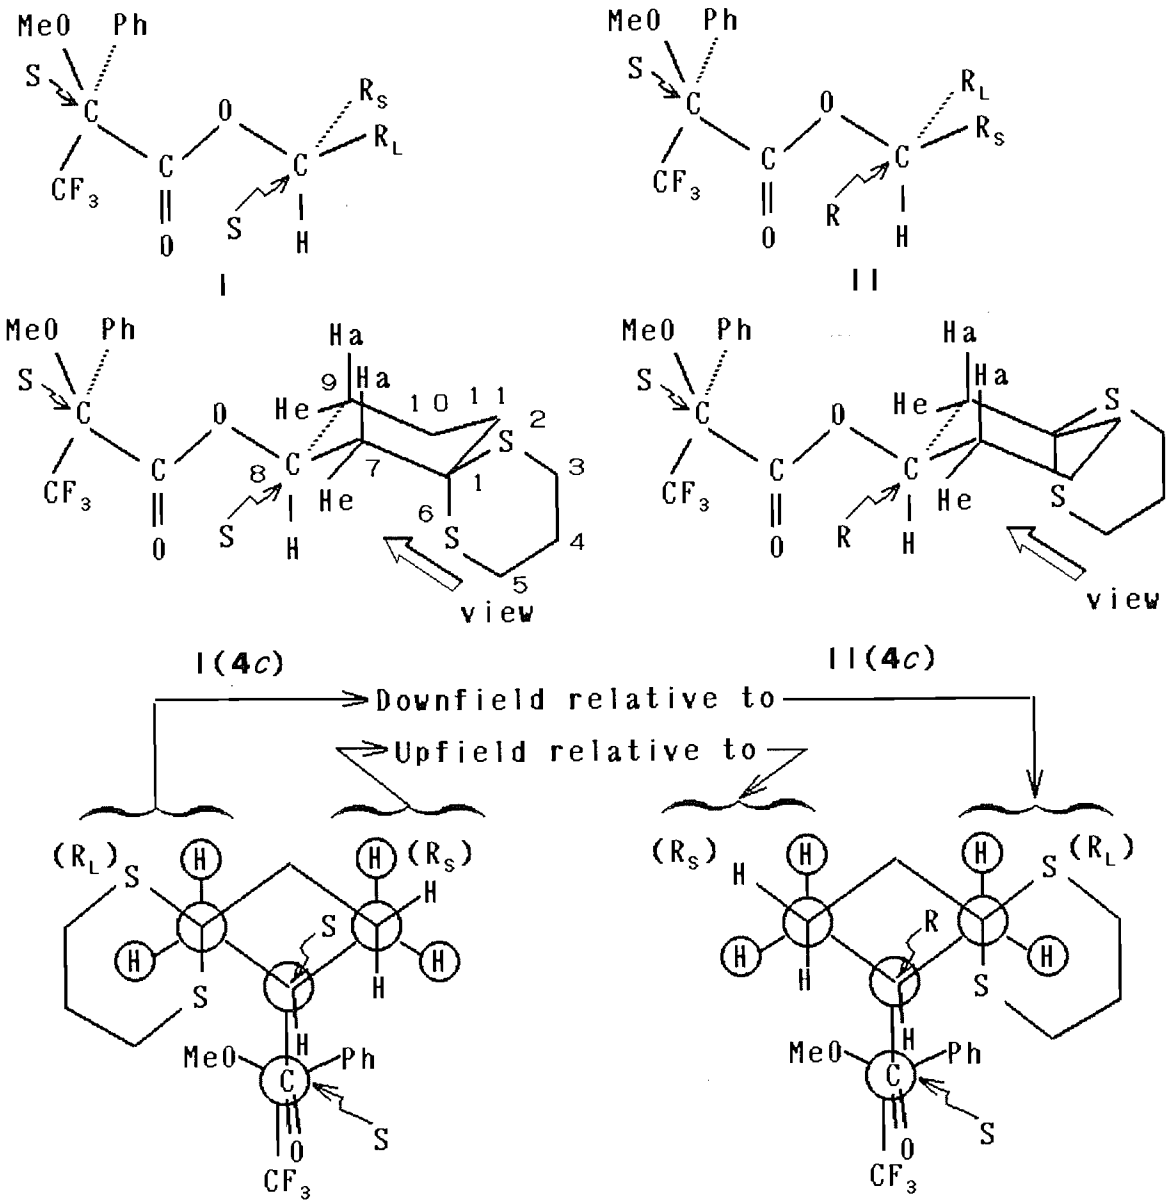

FIG. 2. Configurational correlation model for (*S*)-MTPA esters of (*S*)- and (*R*)-**4***b*.

the substrates **2***a* and **3***a* to the enzyme systems of the microorganisms.

2D COSY analysis was employed as a reliable technique for the assignment of otherwise difficult NMR absorptions of the MTPA esters **1***c*–**4***c*. ^{1}H 2D COSY spectra clearly depicted the H6—H7 correlation of **1***c* and the H7—H8 correlation of **2***c*. Similarly, the 2D technique was also found effective in the assignment of the H6—H7—H8 and H7—H8—H9 networks of **3***c* and **4***c* (see Fig. 1) respectively. The H2—H3 (**1***c* and **3***c*) or H2—H3—H4 (**2***c* and **4***c*) networks on thioketal rings have been successfully assigned, since these networks are independent of other proton networks in the ^{1}H COSY spectra. The absolute configurations of product alcohols **1***b*–**4***b* were then deduced based on the ^{1}H NMR chemical shift differences for the diastereomeric MTPA esters (Table 2). According to Dale and Mosher (7*b*), the most populated conformation, the *S,S* diastereomer I, would have the R_S moiety eclipsed with the phenyl group and the R_L moiety (thioketal side) with the methoxyl group as shown in Fig. 2 (7*b*). Owing to shielding effects of the phenyl group, the $R_S(R_L)$ moiety of I should appear upfield (downfield)[5] in the ^{1}H NMR spectrum relative to that of the *S,R* diastereomer II, as was observed for each of the MTPA esters **1***c*–**4***c* derived from the present microbial reductions. The observed downfield shifts of the methoxyl protons of *S,S* diastereomer I compared to those of II in all cases examined ($\Delta\delta$ +0.006 to +0.029 ppm as shown in Table 2) would be attributable to the deshielding effect of the thioketal rings due to the anisotropy of the carbon–sulfur bonds in the rings (9).[6] Accordingly, the absolute configurations of all

[5]Although an exceptional upfield shift (−0.08 ppm) was observed for H4a of the R_L moiety in **2***c*, the downfield shift of this moiety as a whole is still apparent from the summation (+0.576 ppm) of all chemical shift differences of the moiety in **2***c*.

[6]Since the anisotropy of the carbon–sulfur single bond is opposite in sense to that of the carbon–carbon single bond, the axial hydrogens of thioketal rings in **2***c* and **4***c* also resonate at lower field than the equatorial hydrogens of the same rings (see experimental section for the assignments based on their coupling constants) as suggested for α-trithioacetaldehyde (9).

For personal use only.

microbial products **1***b*–**4***b* can be determined to be *S*. Thus, the present reductions of prochiral ketones **1***a*–**4***a* occur with predictable stereochemistry, i.e., hydride delivery to the Re face of the carbonyl group, in accord with Prelog's rule (10). The same configuration was also reported for (+)-(1*S*)-1-spiro[4.4]nonanol prepared by microbial reductions of the corresponding carbocyclic spiroketones with *Curvularia lunata* and *Rhodotorula rubra* (3*d*). Since the stereochemical course of reduction is dependent on the relative steric bulk of the substituents attached to the carbonyl group, it is reasonable to extend Prelog's rule to the prediction of the stereochemical outcome for the microbial reductions toward spirocyclic compounds.

Experimental

Melting points were determined on a Yamato Scientific apparatus and are uncorrected. IR and MS spectra were recorded on Hitachi 215 and Hitachi M-80 (70 eV) instruments, respectively. NMR spectra were obtained on the following instruments using $(CH_3)_4Si$ as internal standard: ^1H (100 MHz) and ^{13}C (25 MHz) spectra, JEOL JNM-FX100; ^1H (400 MHz) spectra, Varian XL-400; ^1H (400 MHz) 2D correlation spectra, Varian UNITY-400. Optical rotations were measured on a Jasco DIP-181 digital polarimeter. HPLC was carried out on Shimadzu LC-3A liquid chromatograph equipped with Shimadzu SPD-6A UV spectrophotometric detector. GLC analyses were performed on Shimadzu GC-4CM or GC-14A instruments using Chemipack A, 3% Silicone OV-17 on Chromosorb W AW DMCS, or 10% Silicone GE SE-30 on Celite 545 columns, and TLC analyses with Merck silica gel 60 F_{254}. The optical densities (OD, with 1-cm pathlength glass cuvette at λ = 660 nm) of the culture mediums were monitored using a Shimadzu UV-250 spectrophotometer. Preparative TLC was carried out with silica gel 60 PF_{254} (Merck Art 7747 or 7749). 1,2-Cyclohexanedione (**7**) and 1,2-ethanedithiol (**10**) were purchased from Tokyokasei Kogyo, and 1,3- and 1,4-cyclohexanedione (**8** and **9** respectively) and 1,3-propanedithiol (**11**) from Aldrich. All substrates used were GLC-pure. Unless otherwise indicated, IR spectra were determined on KBr pellets and ^1H and ^{13}C NMR spectra and optical rotations in C^2HCl_3 and $CHCl_3$ solutions, respectively.

*Preparations of dithiaspiro ketones (**1**a–**6**a)*

*1,4-Dithiaspiro[4.5]decan-7-one (**3**a)*

A mixture of 27.9 g (0.25 mol) of dione **8**, 12.5 g (0.132 mol) of dithiol **10**, and 12.1 g (0.064 mol) of *p*-toluenesulfonic acid monohydrate (*p*-TsOH·H_2O) in 600 mL of benzene was heated under reflux in a Dean–Stark apparatus for 3.5 h, water (ca. 2 mL) formed during the reaction being continuously removed. The reaction mixture was then washed with two 400-mL portions of 5% aqueous Na_2CO_3. The aqueous layer was extracted with two 400-mL portions of benzene. All the benzene solutions were combined, washed twice with 1000 mL of water, dried ($MgSO_4$), and then evaporated. The oily residue was chromatographed on silica gel with benzene elution to give **3***a* as a crystalline solid (9.25 g, 37.2% yield). Kugelrohr distillation of the solid afforded pure **3***a*: 7.25 g (29.2% yield); bp 160°C/0.6 Torr (1 Torr = 133.3 Pa); mp 40–41°C; IR: 1715 cm^{-1}; ^1H NMR δ: 1.80–2.16 (2H, m), 2.16–2.44 (4H, m), 2.90 (2H, br s), and 3.34 (4H, s) ppm; ^{13}C NMR δ: 24.92 (C-9), 39.37 (C-2,3), 39.96 (C-10), 40.66 (C-8), 57.63 (C-6), 68.16 (C-5), and 206.63 (C-7) ppm; MS *m/e* (rel. int.): 188 (100), 160 (27), 145 (42), 131 (99), and 118 (34). Anal. calcd. for $C_8H_{12}OS_2$: C 51.03, H 6.42, S 34.05; found: C 51.05, H 6.43, S 33.67.

The remaining substrates were prepared by the same basic procedure.

*1,4-Dithiaspiro[4.5]decan-6-one (**1**a)* (lit. (11)) (from dione **7** and dithiol **10**): 66.7% yield; bp 125°C/0.8 Torr (lit. (11*b*) bp 94°C/0.2 Torr); mp 57.2–57.8°C (lit. (11*b*) mp 57.5°C); IR: 1695 cm^{-1}; ^1H NMR δ: 1.45–2.05 (4H, m), 2.38 (2H, m, $W_{1/2}$ = 11 Hz), 2.70 (2H, m, $W_{1/2}$ = 10 Hz), and 3.29 (4H, s) ppm.

*1,5-Dithiaspiro[5.5]undecan-7-one (**2**a)* (lit. (12)) (from dione **7** and dithiol **11**): 37.8% yield; bp 130–145°C/0.24 Torr (lit. (12*b*) bp 140°C/0.001 Torr); mp 53.2–53.6°C (lit. (12*b*) mp 53–54°C); IR: 1700 cm^{-1}; ^1H NMR δ: 1.55–3.50 (m) ppm.

*1,5-Dithiaspiro[5.5]undecan-8-one (**4**a)* (from dione **8** and dithiol **11**): 25.6% yield; bp 150°C/0.3 Torr; mp 73.0°C; IR: 1720 cm^{-1}; ^1H NMR δ: 1.68–2.46 (8H, m) and 2.60–3.0 (6H, m) ppm; ^{13}C NMR δ: 21.30 (C-10), 25.10 (C-3), 26.09 (C-2,4), 36.56 (C-11), 40.31 (C-9), 50.78 (C-6), 52.71 (C-7), and 206.63 (C-8) ppm; MS *m/e* (rel. int.): 202 (100), 159 (15), 145 (33), and 128 (44). Anal. calcd. for $C_9H_{14}OS_2$: C 53.43, H 6.98, S 31.69; found: C 53.43, H 6.99, S 31.38.

*1,4-Dithiaspiro[4.5]decan-8-one (**5**a)* (lit. (13)) (from dione **9** and dithiol **10**): 25.5% yield; bp 118°C/1.2 Torr (lit. (13*a*) 100–102°C/0.1 Torr); IR (CCl_4): 1714 cm^{-1}; ^1H NMR δ: 2.15–2.68 (8H, m) and 3.40 (4H, m) ppm; ^{13}C NMR δ: 38.9 (C-2,3), 40.8 (C-7,9), 42.1 (C-6,10), 66.3 (C-5), and 209.3 (C-8) ppm.

*1,5-Dithiaspiro[5.5]undecan-9-one (**6**a)* (from dione **9** and dithiol **11**): 19.5% yield; bp 146–160°C/0.77 Torr; mp 102.7–103.2°C; IR: 1712 cm^{-1}; ^1H NMR δ: 1.80–2.19 (2H, m), 2.19–2.65 (8H, m), and 2.65–2.96 (4H, m) ppm; ^{13}C NMR δ: 25.8 (C-3), 26.4 (C-2,4), 37.4 (C-7,11), 37.6 (C-8,10), 48.3 (C-6), and 209.5 (C-9) ppm; MS *m/e* (rel. int.): 202 (98), 145 (96), 127 (62), 99 (21), and 74 (100). Anal. calcd. for $C_9H_{14}OS_2$: C 53.43, H 6.98, S 31.69; found: C 53.22, H 6.90, S 31.54.

*Preparation of alcohols **1**b–**6**b*

The same procedure was used for each. The appropriate dithiaspiro ketone (**1***a*–**6***a*, 0.005 mol) in dry ether (20 mL) was added dropwise with stirring to a cooled (0°C) suspension of lithium aluminum hydride (0.005 mol) in dry ether (5 mL). The resulting mixture was stirred for 1 h and water (0.2 mL) was then added carefully, followed by 10% aqueous sodium hydroxide (0.32 mL) and further water (0.4 mL). The mixture was filtered and the filtrate dried ($MgSO_4$), evaporated, and Kugelrohr distilled. The products obtained were as follows.

*1,4-Dithiaspiro[4.5]decan-6-ol ((±)-**1**b)* (lit. (14)): 95.5% yield; bp 90°C/0.8 Torr; IR (CCl_4): 3445 cm^{-1}; ^1H NMR δ: 1.00–2.66 (9H, m), 3.27 (4H, s), and 3.48–3.46 (1H, m) ppm; ^{13}C NMR δ: 25.7 (C-9), 32.6 (C-8), 39.0 (C-2,3), 39.1 (C-7), 40.3 (C-10), 75.3 (C-5), and 75.8 (C-6) ppm; MS *m/e* (rel. int.): 190 (88.6), 131 (100), and 105 (50.0).

*1,5-Dithiaspiro[5.5]undecan-7-ol ((±)-**2**b)* (lit. (15)): 96.4% yield; bp 102°C/0.8 Torr; IR (CCl_4): 3450 cm^{-1}; ^1H NMR δ: 1.00–2.28 (10H, m), 2.28–3.20 (5H, m), and 4.03 (1H, m, $W_{1/2}$ = 10.5 Hz) ppm; ^{13}C NMR δ: 20.3 (C-10), 21.2 (C-9), 25.2 (C-2,4), 26.0 (C-3), 27.6 (C-11), 34.5 (C-8), 55.8 (C-6), and 69.4 (C-7) ppm; MS *m/e* (rel. int.): 204 (100), 145 (76.0), 119 (36.9), and 106 (34.7).

*1,4-Dithiaspiro[4.5]decan-7-ol ((±)-**3**b)*: 97.5% yield; bp 151°C/3.8 Torr; mp 82–84°C; IR: 3245 cm^{-1}; ^1H NMR δ: 1.00–2.52 (9H, m), 3.29 (4H, s), and 3.54–3.96 (1H, m) ppm; ^{13}C NMR δ: 23.2 (C-9), 33.9 (C-10), 38.0 (C-2), 39.0 (C-3), 41.8 (C-8), 50.5 (C-6), 66.9 (C-5), and 69.5 (C-7) ppm; MS *m/e* (rel. int.): 190 (93), 147 (100), 105 (39), and 97 (52). Anal. calcd. for $C_8H_{14}OS_2$: C 50.49, H 7.41, S 33.69; found: C 50.39, H 7.39, S 33.64.

*1,5-Dithiaspiro[5.5]undecan-8-ol ((±)-**4**b)* (lit. (16)): 98.3% yield; bp 135°C/1.0 Torr; mp 64–66°C (lit. (16) mp 67.0–68.6°C; IR: 3270 cm^{-1}; ^1H NMR δ: 1.0–2.24 (9H, m), 2.32–3.14 (6H, m), and 3.96 (1H, m, $W_{1/2}$ = 16 Hz) ppm; ^{13}C NMR δ: 19.5 (C-10), 25.8 (C-3), 26.3 (C-2,4), 34.8 (C-9), 37.4 (C-11), 45.0 (C-7), 49.4 (C-6), and 66.7 (C-8) ppm; MS *m/e* (rel. int.): 204 (100), 130 (23), 129 (24), 112 (30), 97 (51), and 74 (50).

*1,4-Dithiaspiro[4.5]decan-8-ol (**5**b)* (lit. (12*b*, 13*c*)): 91.9% yield; bp 98°C/0.75 Torr; mp 84.2–84.5°C (lit. (13*c*) mp 83–85°C); IR: 3260 cm^{-1}; ^1H NMR δ: 1.20–2.40 (9H, m), 3.38 (4H, m), and 3.56–3.88 (1H, m) ppm; ^{13}C NMR δ: 34.4 (C-7,9), 38.3 (C-2), 38.7 (C-3), 39.5 (C-6,10), 67.6 (C-5), and 68.0 (C-8) ppm.

*1,5-Dithiaspiro[5.5]undecan-9-ol (**6**b)*: 97.0% yield; bp 140°C/0.7 Torr; mp 79.8–80.5°C; IR: 3370 cm^{-1}; ^1H NMR δ: 1.73–2.07 (9H, m), 2.07–2.24 (2H, m), 2.32–2.47 (4H, m), and 3.75 (1H, m, $W_{1/2}$ = 15.2 Hz) ppm; ^{13}C NMR δ: 25.9 (C-3), 26.0 (C-2), 26.4 (C-4), 30.3 (C-7,11), 34.7 (C-8,10), 49.3 (C-6), and 68.7 (C-9) ppm; MS *m/e* (rel. int.): 204 (100), 145 (62), 112 (72), 79 (62), and 41 (74). Anal. calcd. for $C_9H_{16}OS_2$: C 52.90, H 7.89, S 31.38; found: C 52.92, H 7.86, S 31.17.

General incubation procedure for microbial reductions

The cultures of *Saccharomyces cerevisiae* (JCM 1819 and JCM 2214) were obtained from the Japan Collection of Microorganisms, JCM, Wako, Saitama, Japan. The culture medium (pH 6.2) for these microorganisms was prepared by dissolving 42 g of Difco dehydrated YM broth in 2 L of distilled water and was sterilized at 120°C for 20 min before incubation. The yeast was precultivated in a Sakaguchi flask containing 100 mL of the above medium at 24–25°C with shaking. This culture (OD = 1.2–2.8) was transferred into a 10-L jar fermenter containing 1.9 L of the same medium for preparative runs, and incubation was maintained for another 3–5 h at 24°C. Then the substrate ketone (151–642 mg) in EtOH (10–40 mL) was added to the culture (OD = 0.2–1.2, logarithmic phase) and the incubation was continued for a suitable period (0.8–10 days) at 23–25°C with good agitation and aeration. A part of the incubation mixture (3 mL) was pipetted out and extracted with ether at a regular time interval. Each ether extract was subjected to GLC. The products were identified by comparison with authentic samples. Yields of the products were determined on the basis of the peak areas on GLC and are expressed as the relative percent for the total amount of a whole reaction product extracted. Small scale reactions (substrate: EtOH: medium = 30 mg: 2 mL: 100 mL) in Sakaguchi flasks were performed with basically the same procedure.

Isolation of metabolites in preparative scale reactions

The following general procedure was employed. When sufficient (82–100%) reduction had occurred, the mixture was brought to pH 7 with 10% aqueous NaOH (pH usually moved downward to show ca. 5 at harvest), then filtered through Celite, saturated with NaCl, and extracted with dichloromethane (2–3 L). The dried ($MgSO_4$) dichloromethane extract was evaporated and the residual oil (ca. quantitative recovery) was separated into its components by PTLC on silica gel with hexane/ethyl acetate (2:1–3:1) development followed by Kugelrohr distillation. The overall data are summarized in Table 2. The individual reactions gave the following results; IR and NMR spectra for each product were identical with those detailed above.

Reduction of 1,4-dithiaspiro[4.5]decan-6-one

Run 1: The spiroketone (**1***a*, 597 mg, 3.17 mmol) with JCM 1819 for 3.6 days (95% conversion) gave spiroalcohol (+)-(6*S*)-**1***b* (561.6 mg, 93.1% yield, 86.6% ee), bp 110°C/0.8 Torr; $[\alpha]_D^{23}$ +6.37° (*c* 1.020, *l* = 0.1).

Run 2: The ketone (**1***a*, 600.8 mg, 3.19 mmol) with JCM 2214 for 3.5 days (82% conversion) gave unchanged **1***a* (61.7 mg, 10.3% yield) and alcohol (+)-(6*S*)-**1***b* (466.9 mg, 76.9% yield, 85.8% ee), bp 160°C/2.1 Torr; $[\alpha]_D^{23}$ +6.96° (*c* 1.150, *l* = 0.1).

Reduction of 1,5-dithiaspiro[5.5]undecan-7-one

Run 3: The ketone (**2***a*, 597.4 mg, 2.95 mmol) with JCM 1819 for 1.7 days (100% conversion) gave alcohol (+)-(7*S*)-**2***b* (546 mg, 90.5% yield, 99.4% ee), bp 119°C/0.8 Torr; $[\alpha]_D^{22.5}$ +38.3° (*c* 1.175, *l* = 0.1).

Run 4: The ketone (**2***a*, 642.1 mg, 3.17 mmol) with JCM 2214 for 1.1 days (99% conversion) gave alcohol (+)-(7*S*)-**2***b* (637.5 mg, 98.4% yield, 96.4% ee), bp 130–139°C/0.24 Torr; $[\alpha]_D^{24.2}$ +35.5° (*c* 2.36, *l* = 1.0).

Reduction of 1,4-dithiaspiro[4.5]decan-7-one

Run 5: The ketone (**3***a*, 602.1 mg, 3.20 mmol) with JCM 1819 for 1.0 days (100% conversion) gave alcohol (−)-(7*S*)-**3***b* (559.4 mg, 91.9% yield, 97.2% ee), bp 150°C/0.6 Torr; mp 56–58°C; $[\alpha]_D^{27}$ −2.94° (*c* 1.020, *l* = 0.1).

Run 6: The ketone (**3***a*, 601.1 mg, 3.19 mmol) with JCM 2214 for 3.8 days (97% conversion) gave unchanged **3***a* (13.5 mg, 2.25% yield) and alcohol (−)-(7*S*)-**3***b* (503.5 mg, 82.9% yield, 95.6% ee), bp 150°C/0.6 Torr; mp 59°C; $[\alpha]_D^{27}$ −3.48° (*c* 1.005, *l* = 0.1).

Reduction of 1,5-dithiaspiro[5.5]undecan-8-one

Run 7: The ketone (**4***a*, 150.6 mg, 0.744 mmol) with JCM 1819 for 6.9 days (95% conversion) gave alcohol (−)-(8*S*)-**4***b* (122.8 mg, 80.7% yield, 92.4% ee), bp 100°C/0.7 Torr; $[\alpha]_D^{25}$ −8.3° (*c* 5.540, *l* = 0.1).

Run 8: The ketone (**4***a*, 150.6 mg, 0.744 mmol) with JCM 2214 for 10.3 days (93% conversion) gave alcohol (+)-(8*S*)-**4***b* (113.7 mg, 74.8% yield, 83.1% ee), bp 100°C/0.7 Torr; $[\alpha]_D^{25}$ −5.65° (*c* 4.690, *l* = 0.1).

Enantiomeric excess determinations of microbial products **1**b–**4**b

The optical purities of alcohols **1***b*–**4***b* were determined by the HPLC analyses of the corresponding 3,5-dinitrophenylurethane (DNPU) derivatives, employing a chiral stationary phase. A Sumipax OA 1000 5-μm 4 mm × 50 cm column (Sumitomo Chemical Co., Ltd., Osaka) was used with hexane-1,2-dichloroethane-ethanol (100:20:5 for **1***b*–**3***b* derivatives or 100:20:1 for **4***b* derivatives) as solvent; flow rate 1.0 mL/min (60–80 kg/cm^2).

Absolute configuration determinations of microbial products **1**b–**4**b

The optically active and racemic alcohols **1***b*–**4***b* were converted to their MTPA esters **1***c*–**4***c* in quantitative yields by the standard literature procedure (7) using freshly prepared (−)-(2*S*)-α-methoxy-α-trifluoromethylphenyl acetyl chloride: $[\alpha]_D^{22.2}$ −130.9° (*c* 1.725, *l* = 1.0, CCl_4) (lit. (7) $[\alpha]_D$ 129.0 ± 0.2° (*c* 5.17, CCl_4)). The absolute configurations of the alcohols **1***b*–**4***b* derived from the microbial reductions were then determined by 1D and 2D ^{1}H NMR (400 MHz) examination of the signals from the specified protons of the MTPA esters (see Fig. 1 and Table 1). The esters of the racemic alcohols were used to provide the necessary reference peaks (i.e., *S*,*R*-diastereomers) for determining the Δδ values including shift direction for each pair of diastereotopic protons (7*b*). The chemical shifts of reference peaks are shown in brackets, if assignable, after each chemical shift of the following MTPA esters (i.e., *S*,*S*-diastereomers) of the microbial products. The peaks used also in ee determination are marked with a dagger.

*MTPA ester of 1,4-dithiaspiro[4.5]decan-6-ol (**1**c)*: IR (CCl_4): 1741 cm^{-1}; ^{1}H NMR (400 MHz) δ: 1.358 [1.358] (1H, m, H-8a), 1.57 (1H, m, H-9a), 2 (1H, m, H-9e), 1.817 [1.860] (1H, ddt, *J*(7a,7e) = 14.2, *J*(6,7a) = 6.3, *J*(7a,8e) = 5.2, H-7a), 1.98 [1.98] (1H, m, H-9a), 2.005 [2.04] (1H, m, H-7e), 2.185 [2.185] (2H, ddd, *J*(10a,10e) = 14.3, *J*(9a,10a) = 9.0, *J*(9e,10a) = 4.6, H-10a; dt, *J*(10a,10e) = 14.3, *J*(9e,10e) = *J*(9a,10e) = 4.6, H-10e), 3.220 [3.060]† (4H, m, H-2,3), 3.622 [3.593]† (3H, m, -OMe), and 5.178 [5.190] (1H, dd, *J*(6,7a) = 6.3, *J*(6,7e) = 3.0, H-6) ppm.

Conformational isomerism in squaraines: saturation transfer NMR studies on hydroxy squaraines

PETER M. KAZMAIER, GORDON K. HAMER, AND RICHARD A. BURT
Xerox Research Centre of Canada, 2660 Speakman Drive, Mississauga, Ont., Canada L5K 2L1

Received July 31, 1989

This paper is dedicated to the memory of Professor Don Tavares

PETER M. KAZMAIER, GORDON K. HAMER, and RICHARD A. BURT. Can. J. Chem. **68**, 530 (1990).

The proton and ^{13}C NMR of azulene and dialkylaminohydroxyphenyl squaraines have been investigated. The four-membered ring carbon resonances occur in the 180–190 ppm range and are attributed to the cyclobutenediylium character of this structure. Some charge delocalization from the central ring to the pendent aromatic substituents was also observed, indicative of a substituent effect of the squaraine moiety on aminoaromatic systems equivalent to that of a formyl or acetyl group. Hydroxy squaraines **10** and **11** show the presence of two isomeric squaraine species in the proton NMR in deuterochloroform. Saturation transfer experiments confirm that these species are readily interconverted, and *cis/trans* isomerism (**9***a* ⇆ **9***b*) is consistent with these observations. The free energy difference between the two isomers at 318 K is calculated to be 3.0 and 3.2 kJ/mol for hydroxysquaraines **10** and **11** respectively.

Key words: squaraines, saturation transfer, NMR.

PETER M. KAZMAIER, GORDON K. HAMER et RICHARD A. BURT. Can. J. Chem. **68**, 530 (1990).

On a examiné les spectres RMN du proton et du ^{13}C de l'azulène et des dialkylaminohydroxyphényl squaraïnes. Les résonances des carbones du cycle à quatre chaînons sont observées dans la plage allant de 180 à 190 ppm et elles sont attribuées au caractère cyclobutènediylium de cette structure. On a aussi observé une certaine délocalisation de la charge du noyau central vers les substituants attachés au noyau aromatique; ces observations suggèrent qu'il existe un effet de substituant de la portion squaraïne sur les systèmes aminoaromatiques équivalent à celui d'un groupement formyle ou acyle. Dans les spectres RMN du proton des hydroxy squaraïnes **10** et **11** en solution dans le deutérochloroforme, on observe la présence de deux espèces isomères. Des expériences de transfert de saturation confirment que ces espèces se transforment facilement l'une dans l'autre; une isomérie *cis/trans* (**9***a* ⇆ **9***b*) est en accord avec ces observations. On a calculé que, à 318 K, les différences d'énergie libre entre les deux isomères sont de 3,0 et de 3,2 kJ/mol respectivement pour les hydroxysquaraïnes **10** et **11**.

Mots clés : squaraïnes, transfert de saturation, RMN.

[Traduit par la revue]

Introduction

Squaraines are 1,3-derivatives of squaric acid **1** in which the substituents are amines or highly electron-donating aromatic or heterocyclic groups (1). Since the discovery of these compounds by Treibs and Jacob in 1965 (2), their electronic structure has been the subject of considerable discussion. Treibs and Jacob depicted the structure of bis-2-pyrrylsquaraines by **2** because the properties of **2** were similar to the properties of the trimethine cyanine dyes (3) (for example compare the structures of **3** and **4**). At a later time Sprenger and Ziegenbein (4) described the electronic structures as either **5** or a hybrid of **5** and **6**. Canonical form **5** is particularly attractive because it corresponds to a Hückel aromatic system ($N = 0$).

More recently the consensus has shifted back to the original Treibs and Jacob proposal (5, 6), i.e., that a dipolar cyanine structure (e.g., **3**) and not a cyclobutenediylium structure best represents the electronic configuration of these compounds. The evidence for this conclusion rests on several observations.

1. The visible spectra of squaraines show close similarity to cyanine dyes (7).
2. The solubility of squaraines, like cyanines, is very low in most organic solvents consistent with a dipolar structure.
3. Squaraines, like cyanines, readily undergo addition with nucleophilic reagents.[1]
4. More recently, semiempirical molecular orbital (MNDO) studies (7) on **3** have shown a distinct polyene character to the squaraine chromophore. This quinoid character is enhanced when explicit solute/solvent interactions are taken into account.

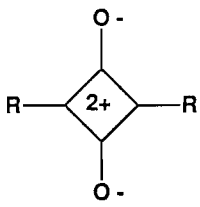
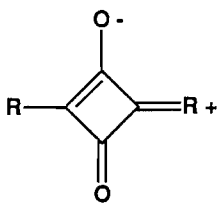
4



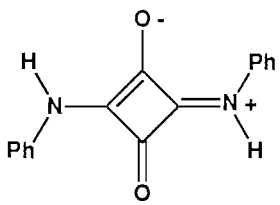
5



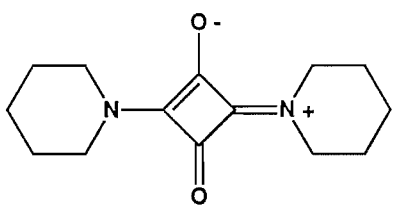
6

Support for this description can also be gleaned from work on amino squaraines. Both experimental and theoretical studies (9, 10) on a related series of aminosquaraine compounds (**7** and **8**) indicated that these compounds experience considerable C—N π-bonding between the central four-membered ring and the amino substituents, supporting the MNDO evidence presented for aryl squaraines.

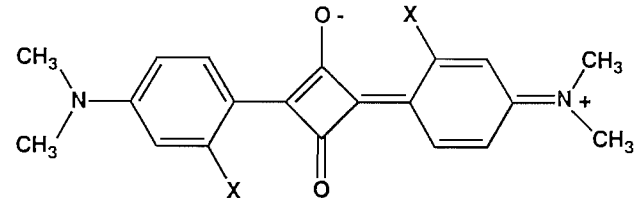
The conclusion that canonical form **6** best approximates the electronic structure of squaraines leads to a number of implications for the NMR of these compounds. If the central ring has the charge distribution of **6** rather than **5**, then one would expect this ring to behave more like an α,β-unsaturated ketone than an aromatic system.



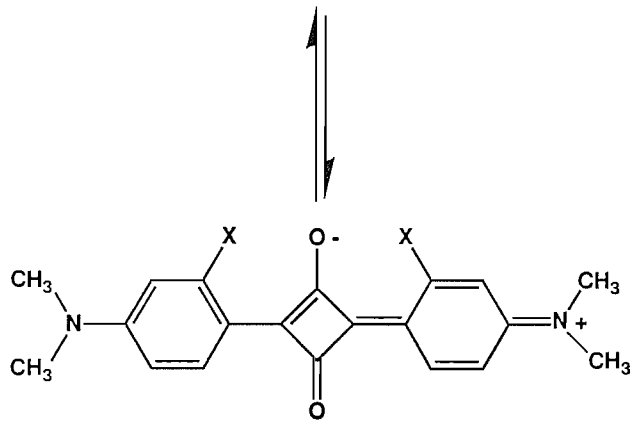
7



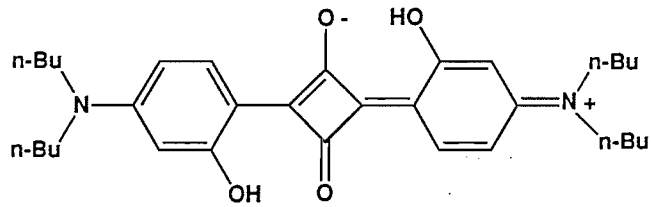
8



9a



9b



10

Secondly, canonical representation **6** indicates that the positive charge is delocalized to the pendent aromatic groups and that these groups would have a pseudo-quinoid structure.

Thirdly, if one considers squaraines such as **9**, then the dipolar canonical structure **6** predicts that the partial double bond character in the bond connecting the 4-membered ring to the 6-membered ring would make this rotational barrier high and, if the thermodynamics permit it, both isomers should be observable by NMR. Although many of these predictions are amenable to validation by ^{1}H or ^{13}C NMR, no ^{13}C NMR study of these materials has been reported. In this paper we report our findings on the ^{1}H and ^{13}C NMR of squaraines and report the observation of squaraine rotational isomers for the first time.

Experimental

Compounds were prepared by methods described in the literature (1, 4, 12, and 13) or as described below. Carbon NMR spectra were run on dilute (saturated) solutions (10^{-1} to 10^{-3} M) in $CDCl_3$ on a Bruker WM-250 spectrometer operating at 62.9 MHz. No attempt was made to standardize the concentrations since the solubilities of the squaraines varied widely. Proton spectra were also recorded in $CDCl_3$ solution on the same spectrometer at 250.13 MHz. Tetramethylsilane (TMS) was used as an internal chemical shift reference for both ^{1}H and ^{13}C spectra. Infrared spectra were recorded on a Beckman IR-4250. Combustion analyses were performed by Galbraith Laboratories, Knoxville, Tennessee.

Preparation of 3-(dibutylamino)phenol

A single-neck 250-mL round-bottomed flask with an air condenser, water condenser, nitrogen inlet, and magnetic stirbar was charged with 3-aminophenol (21.8 g, 0.2 mol) and tributyl phosphate (53.2 g, 0.2 mol). While stirring, the reaction mixture was heated to 120°C and then cautiously to 210°C to avoid an excessive exotherm. After heating at 210°C for 2.5 h, the reaction mixture was cooled. When the increase in viscosity made stirring difficult, aqueous sodium hydroxide (200 mL of 3.6 M solution) was added quickly and the mixture heated (80°C) until homogeneous, and then stirring was continued overnight. The mixture was transferred to a 1-L separatory funnel, extracted with ether (3 × 500 mL), and then the ether solution was dried over sodium sulfate. The product was isolated by rotary evaporation (35.2 g, 80%). Since this amino phenol oxidizes readily, it was passed through a column of silica gel just prior to use in the squaraine formation reaction. IR (CCl_4): 3410 br, 2980, 2960, 2900, 1633, 1592, 1517, 1380, 1206 cm^{-1}. ^1H NMR ($CDCl_3$, TMS) δ: 0.94 (t, 6H, CH_3), 1.3 (m, 4H, CH_2), 3.2 (m, 4H, NCH_2), 5.6 (br s, 1H, OH), 6.2 (m, 3H, Bz), 7.02 (t, 1H, BzH5, J_{12} = 8.09).

*Preparation of bis(4-dibutylamino-2-hydroxyphenyl)squaraine (**10**)*

A 3-necked 500-mL round-bottomed flask equipped with a thermometer, magnetic stirbar, and a 10-mL Dean–Stark trap topped with a condenser and nitrogen inlet was charged with squaric acid (4.38 g, 36.0 mmol), toluene (60 mL), and 1-butanol (150 mL). The mixture was stirred rapidly and heated to 100°C over 15 min at which time the squaric acid started to dissolve. When solution was complete, the 3-dibutylaminophenol (17 g, 76.9 mmol) was added dropwise in toluene (80 mL) over 20 min. A color change to red, then black, indicated that squaraine formation was underway. The reaction mixture was heated rapidly to reflux (internal temperature 105°C) and reflux was maintained for 2 h. Upon cooling to room temperature, the crystals were isolated by filtration and were thoroughly washed with ethyl acetate before drying under vacuum to constant weight (7.4 g, 40%); mp 196–197°C. UV–visible ($CHCl_3$, λ_{max} (log ε)): 668 (5.45). IR (KBr): 1610 cm^{-1} (squaraine carbonyl). Anal. calcd. for $C_{32}H_{44}N_2O_4$: C 73.81, H 8.52, N 5.38; found: C 73.88, H 8.30, N 5.30.

*Preparation of bis(8-hydroxy-9-julolidinyl)squaraine (**11**)*

A 3-necked 300-mL round-bottomed flask equipped with a thermometer, magnetic stirbar, and a 10-mL Dean–Stark trap topped with a condenser and nitrogen inlet was charged with squaric acid (1.72 g, 15.1 mmol), toluene (75 mL), and 1-butanol (75 mL). The mixture was stirred rapidly and heated to 100°C over 15 min at which time the squaric acid started to dissolve. When solution was complete, the amine (5.72 g, 30.2 mmol) was added in one portion. A color change to blue-green indicated that squaraine formation was underway. The reaction mixture was heated rapidly to reflux (internal temperature 105°C) and refluxed for 2 h. Upon cooling to room temperature, the crystals were isolated by filtration and thoroughly washed with ethyl acetate before drying under vacuum to constant weight (95%); mp 255°C (dec.). UV–visible (CH_3CN, λ_{max} (log ε)): 645 (5.51). IR (KBr): 1625 cm^{-1} (squaraine carbonyl). Anal. calcd. for $C_{28}H_{28}N_2O_4$: C 73.66, H 6.18, N 6.14; found: C 73.02, H 6.34, N 6.02.

Preparation of bis(9-julolidinyl)squaraine

Bis(9-julolidinyl)squaraine was prepared by a procedure identical to that described for **11**. The isolated yield was 49%; mp 226°C (dec.). UV–visible ($CHCl_3$, λ_{max} (log ε)): 660 (5.45). IR (KBr): 1603 cm^{-1} (squaraine carbonyl). Anal. calcd. for $C_{28}H_{28}N_2O_2$: C 79.22, H 6.65, N 6.60; found: C 79.32, H 6.71, N 6.62.

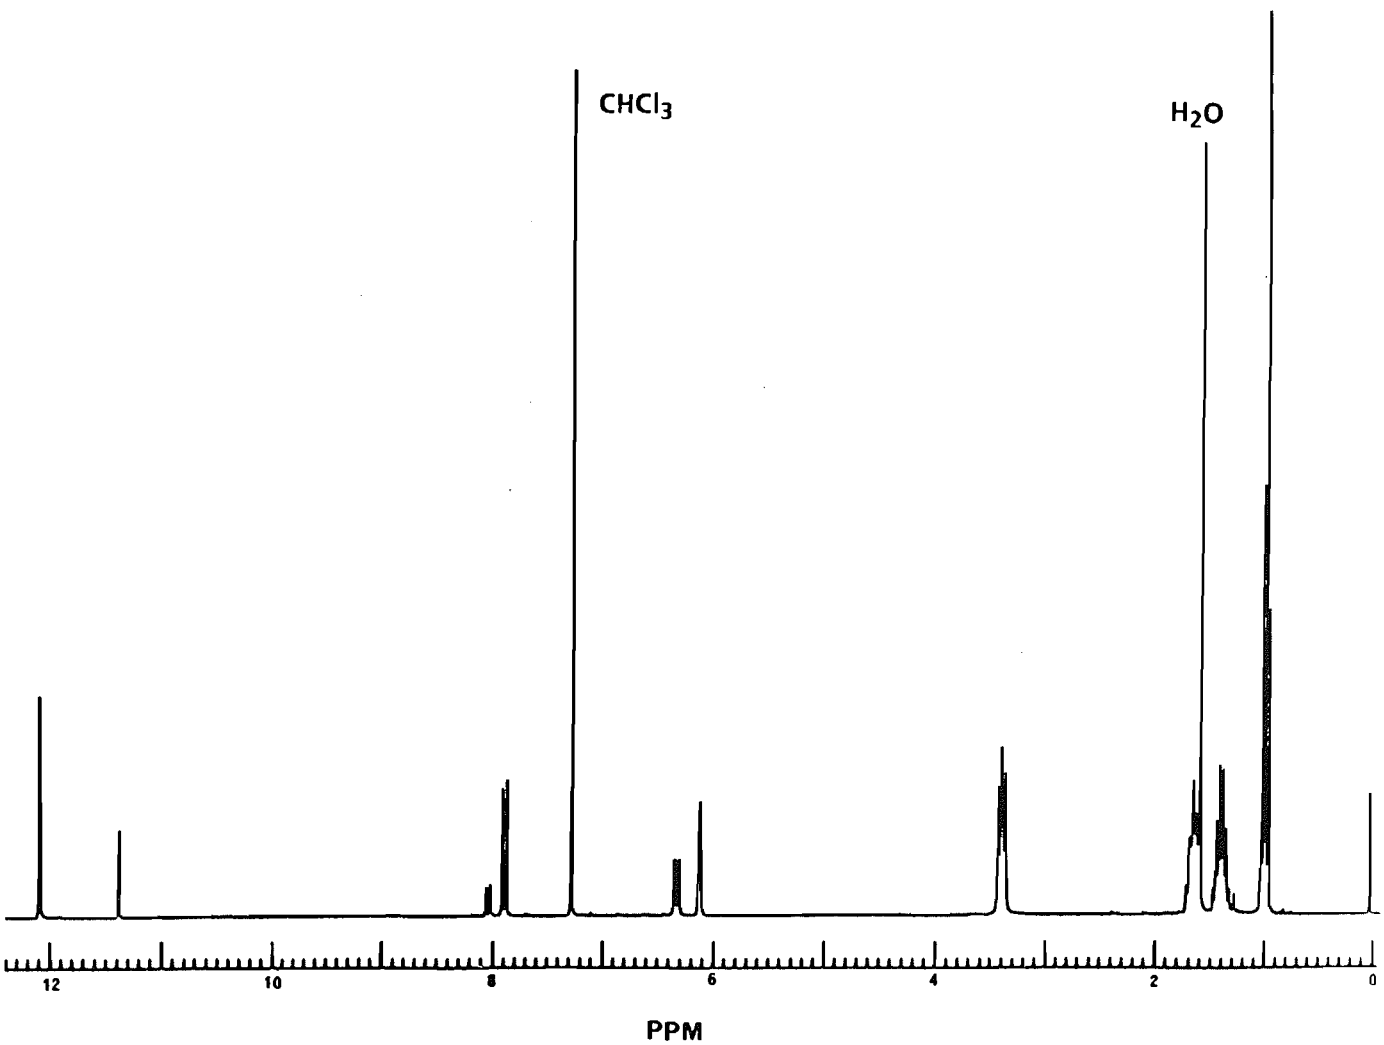

FIG. 2. The 250 MHz ^{1}H NMR spectrum of bis(4-dibutylamino-2-hydroxyphenyl)squaraine.

Results and discussion

Although many squaraines have been prepared (11–13) in our laboratory, most of these compounds are too insoluble to permit the accumulation of solution ^{13}C NMR spectra. Some compounds initially appear soluble enough but crystallize out of solution after several hours before spectrum accumulation is complete. For these reasons fewer ^{13}C NMR spectra are available than proton spectra.

Table 1 compares the ^{13}C chemical shifts of bisguaiazulenylsquaraine to the parent guaiazulene. Since the complete proton spectrum can be assigned for this molecule, it was straightforward to assign the carbon resonances by a series of selective heteronuclear low-power decoupling experiments. The quaternary carbons 9 and 10 were assigned by long-range coupling to the guaiazulene ring protons. The squaraine carbons appear at 183.09 ppm and 184.43 ppm in this compound. The two signals can be assigned by long-range coupling as shown in Fig. 1. The oxygen-bearing carbons are not coupled to any protons in the guaiazulene groups while the other 4-membered ring carbon is coupled to proton H2 ($^3J_{CH}$ = 1.7 Hz).

The strong deshielding observed for these carbons is not only restricted to bisguaiazulenylsquaraine. Table 2 summarizes the chemical shifts of the 4-membered ring resonances for three other compounds. In all cases the chemical shifts for these resonances fall in the range 180–190 ppm. This strong deshield-

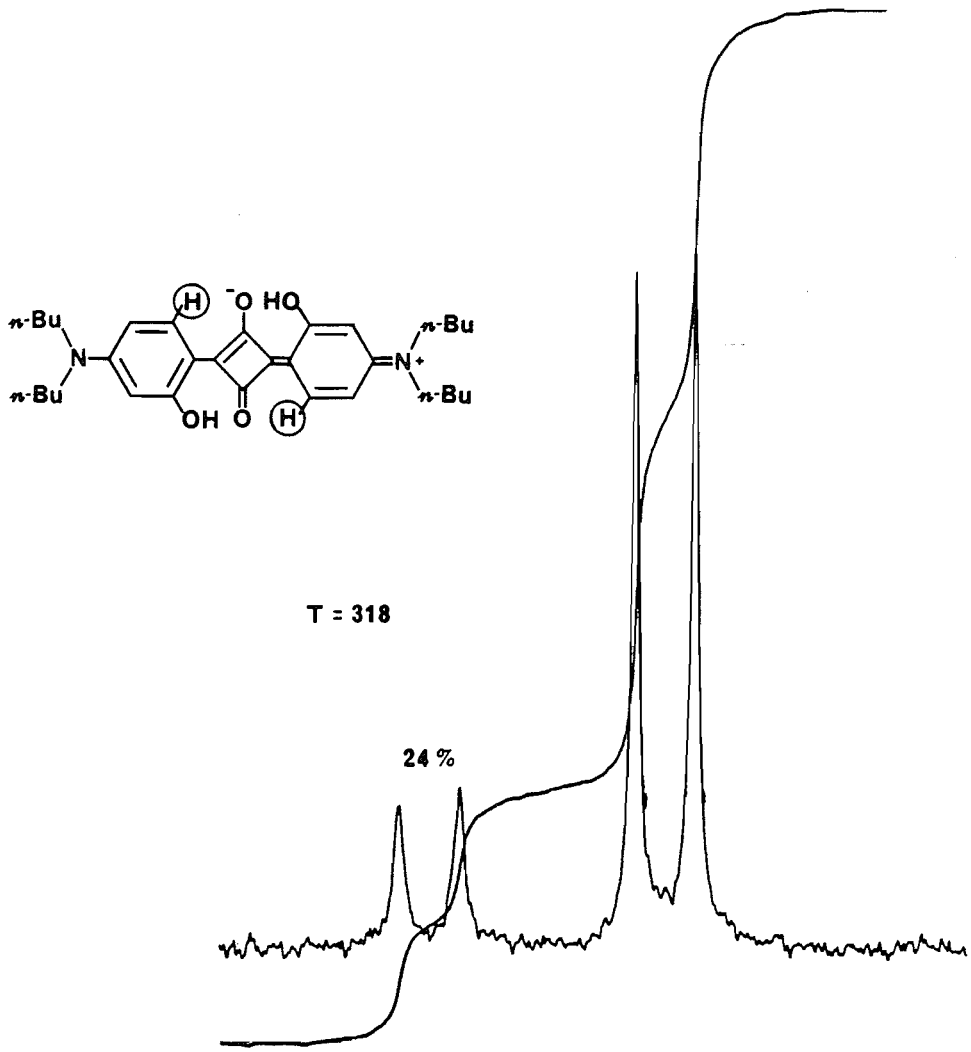

FIG. 3. The relative intensities of the *ortho* hydrogen resonances in bis(4-dibutylamino-2-hydroxyphenyl)squaraine.

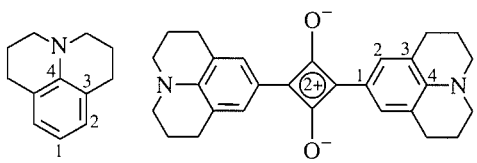
TABLE 3. A comparison of the carbon chemical shifts for bisjulolidinylsquaraine to julolidine



Carbon	Julolidine	Squaraine	Δδ
C-1	115.8	119.5	3.7
C-2	126.9	130.0	3.1
C-3	121.6	121.8	0.2
C-4	143.0	149.2	6.2

ing for the ring is consistent with substantial cyclobutendiylium character for this moiety (14–17).

If one turns one's attention to the pendent guaiazulene groups in bisguaiazulenylsquaraine (Table 1), then several carbons show sizeable downfield (10 ppm) shifts from the parent guaiazulene. If one compares these shifts observed for bisguaiazulenylsquaraine to the shifts reported for 1-substituted azulene (18–20), then 10-ppm substituent shifts in the 7-membered ring are only observed on mono nitration. These results suggest that some positive charge is delocalized into the 7-membered ring. The methyl group on C-8 is strongly deshielded (4.15 ppm) because of the strong steric interaction between this methyl group and the squaraine oxygen.

Table 3 summarizes the chemical shifts for the julolidine group in bis-9-julolidinylsquaraine. In this compound the chemical shifts of the julolidine group in the squaraine are similar to the parent julolidine. The shift differences are approximately what one would expect if a carbonyl substituent were placed on julolidine (e.g., formyl or acetyl) *para* to the nitrogen.

In conclusion then, the ^{13}C NMR of squaraines investigated suggests that the squaraine ring system has substantial cyclobutendiylium character. Chemical shift changes in the pendent aromatic substituents are consistent with some electron density donation to the squaraine moiety. The magnitude of the electron density donation is approximately that experienced by aromatic aminoaldehydes.

A study of Dreiding and CPK models of the compounds described in Table 2 suggests that, whereas the azulene and julolidine squaraines are planar, the guaiazulene and bis(4-dimethylamino-2-methylphenyl)squaraines are decidedly nonplanar. The relative insensitivity of the squaraine carbon

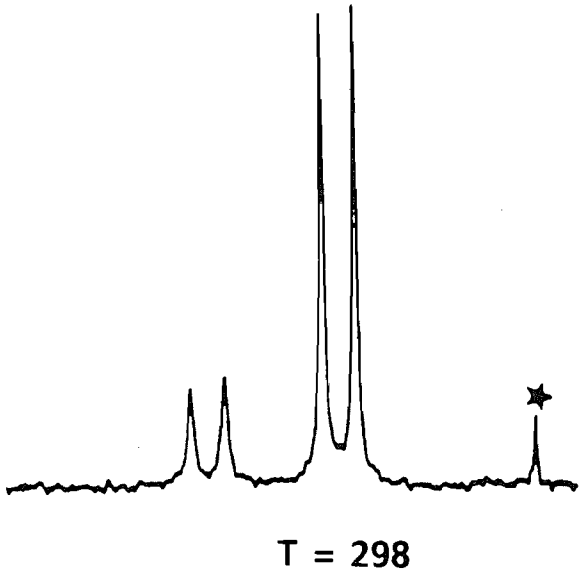


FIG. 4. The unperturbed *ortho* hydrogen resonances before irradiation at 298 K.

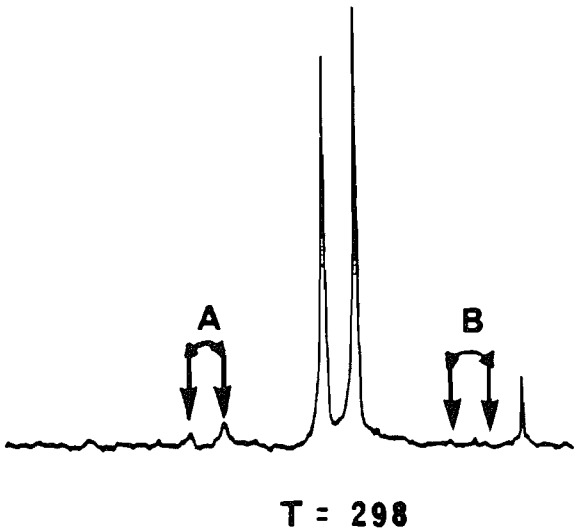

FIG. 5. The effect of decoupling at frequency A at 298 K.

resonances to chromophore planarity and the small squaraine-induced shifts in the julolidine (Table 3) and guaiazulene squaraines (Table 1) suggests that π-donation is relatively unimportant as a means of stabilization.

In the introduction it was pointed out that for squaraines such as **10**, a dipolar canonical structure such as **6** would predict that two isomers (*cis* and *trans*) would be observable if thermodynamics were to permit it. The 250-MHz ^{1}H NMR spectrum of bis(4-dibutylamino-2-hydroxyphenyl)-squaraine **10** is shown in Fig. 2. For both the OH (δ = 12.09, 11.38) and *ortho* protons (δ = 8.02, 7.87) two resonances are observed. Figure 3 shows the *ortho* protons clearly as two doublets ($^1J_{HH}$ = 9.2 Hz). The minor isomer makes up 24% of the total; a similar result is obtained from integration of the OH resonances.

To establish that the major and minor components do, in fact, arise from equilibrating conformational isomers, a series of ^{1}H saturation transfer experiments were carried out. The results are shown in Figs. 4–7 for the *ortho* proton doublets. Figure 4 shows the unperturbed spectrum; the starred peak is a ^{13}C

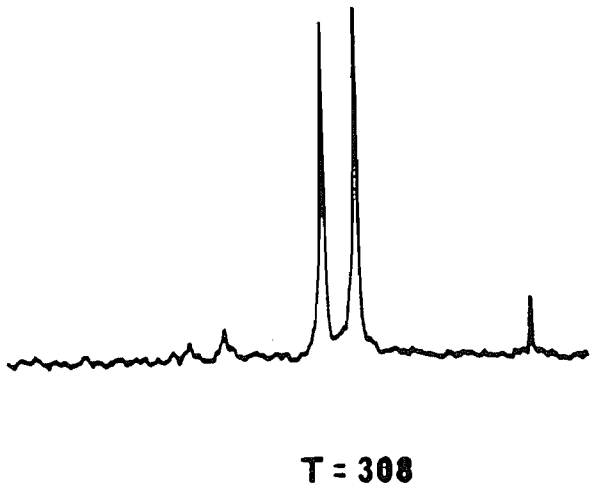

FIG. 6. The effect of decoupling at frequency A at 308 K.

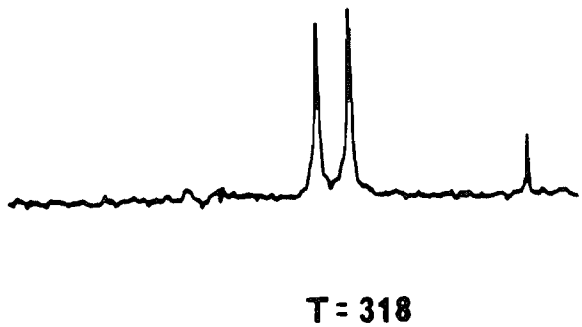

FIG. 7. The effect of decoupling at frequency A at 318 K.

satellite of the residual $CHCl_3$ of the $CDCl_3$ solvent and serves as a convenient internal intensity standard. In the saturation transfer experiment the minor isomer resonance (Fig. 5, A) was saturated by rapidly shifting the frequency of the low power decoupler between the two peaks of the doublet (21). After ca. 100 frequency-shift cycles the decoupler was gated off and the spectrum acquired in the normal way. As shown in Fig. 5, the minor resonance is almost completely suppressed by this technique and the intensity of major doublet is decreased. To confirm that this effect is the result of saturation transfer and not "spill-over" from the decoupler, the decoupler frequency was shifted an equal distance to the low frequency side of the major doublet (B) and the experiment repeated; the result was identical to the control spectrum, Fig. 4. Further evidence of conformational isomerism is provided by Figs. 6 and 7. As one expects, at higher temperatures the rate of interconversion is increased and consequently saturation transfer becomes more efficient.

Molecular models suggest that *cis,trans* isomerism is not an unreasonable explanation for this phenomenon. This compound is not unique in demonstrating this kind of isomerism. Compound **11** shows a similar behaviour. The magnitude of the rotational barrier could not be determined because of the low solubility of these compounds at low temperatures. However, the success of the saturation transfer, and the observation that addition of a hydrogen-bonding solvent such as CD_3OD to a $CDCl_3$ solution of **10** collapses the pair of doublets to a single doublet, suggests that the barrier is smaller than the 49–74 kJ/mol barrier normally associated with cyanines (8, 22).

For personal use only.

The free energy difference between the two isomers at 318 K is calculated to be 3.0 and 3.2 kJ/mol for hydroxysquaraines **10** and **11** respectively.

Kinetics of the reduction of the tropylium and xanthylium cations by 1,4-dihydropyridine derivatives

JOHN W. BUNTING AND M. MORGAN CONN
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received June 14, 1989

JOHN W. BUNTING and M. MORGAN CONN. Can. J. Chem. **68**, 537 (1990).

The pH-dependences of the apparent second-order rate constants (k_2^{app}) for the reduction of 2,4,6-cycloheptatrien-1-ol and 9-xanthydrol by each of 1-benzyl-1,4-dihydronicotinamide (BNH) and 10-methyl-9,10-dihydroacridine (MAH) have been measured in 20% acetonitrile – 80% water, at 25°C and ionic strength 1.0. For each of these reactions, the pH-dependence of k_2^{app} is only consistent with reduction occurring via the aromatic cation (either tropylium or xanthylium) that is present in equilibrium with these alcoholic species. The relative second-order rate constants (k_2^{BNH}/k_2^{MAH}) for reductions by these two reducing agents (1700 for tropylium and 770 for xanthylium) are similar for these two cations. These ratios are also similar to those observed for a variety of nitrogen heteroaromatic hydride acceptors, even though the absolute magnitudes of these rate constants vary by 10^{10}-fold. The second-order rate constants for the reductions of the tropylium and xanthylium cations are predicted reasonably well by their pK_{R^+} values, with the latter cation being (7×10^5)-fold more reactive than its π-isoelectronic *N*-methyl acridinium cation. The xanthylium cation has the greatest k_2^{BNH}/k_{OH} ratio yet observed for any heteroaromatic cation, and this value further extends the known range of this ratio as a function of reactivity.

Key words: hydride transfer, kinetics of reduction, 1,4-dihydropyridine derivatives, tropylium cation, xanthylium cation.

JOHN W. BUNTING et M. MORGAN CONN. Can. J. Chem. **68**, 537 (1990).

Opérant à 25°C et à une force ionique de 1,0, dans des solutions contenant 20% d'acétonitrile et 80% d'eau, on a mesuré la relation qui existe entre le pH et les constantes apparentes de vitesse du deuxième ordre (k_2^{app}) pour la réduction du cyclohepta-2,4,6-trièn-1-ol et du xanthydr-9-ol soit par le 1-benzyl-1,4-dihydronicotinamide (BNH) ou par la 10-méthyl-9,10-dihydroacridine (MAH). Pour chacune de ces réactions, la relation entre le pH et le k_2^{app} ne correspond qu'à celle attendue pour une réduction se produisant par le biais d'un cation aromatique (soit tropylium ou xanthylium) qui est présent à l'équilibre dans ces espèces alcooliques. Les constantes relatives des vitesses de réaction du second ordre (k_2^{BNH}/k_2^{MAH}) pour les réductions par ces deux agents réducteurs (1700 pour le tropylium et 770 pour le xanthylium) sont semblables pour ces deux cations. Même si les valeurs absolues de ces constantes de vitesse varient par des facteurs allant jusqu'à 10^{10}, ces rapports sont aussi similaires à ceux observés pour un grand nombre de dérivés hétéroaromatiques azotés accepteurs d'hydrure. Utilisant les valeurs des pK_{R^+} des cations, on peut aussi prédire assez correctement les constantes de vitesse du deuxième ordre pour les réductions des cations tropylium et xanthylium; ce dernier cation est environ 7×10^5 fois plus réactif que le cation *N*-méthyl acridinium qui lui est π-isoélectronique. La valeur du rapport k_2^{BNH}/k_{OH} du cation xanthylium est la plus élevée à avoir été observée jusqu'à maintenant et cette valeur élargit la plage connue de ce rapport en fonction de la réactivité.

Mots clés : transfert d'hydrure, cinétique de la réduction, dérivés 1,4-dihydropyridines, cation tropylium, cation xanthylium.

Kinetic studies of the hydride transfer reaction described by eq. [1] are currently under active investigation in many laboratories (1–10). This reaction formally involves hydride transfer from a donor (DH) to an acceptor (A^+), and can be considered a hydride transfer between two heteroaromatic cations, when a dihydropyridine derivative (DH) is used to reduce a nitrogen heteroaromatic cation (A^+).

[1] $A^+ + DH \rightarrow AH + D^+$

Reactions of this type originally attracted interest as mechanistic probes of the chemistry of enzymic reactions employing the nicotinamide coenzyme redox couple (NAD(P)H–NAD(P)$^+$) (11, 12). More recently, rate–equilibrium correlations of such reactions have been vigorously explored in connection with the application of Marcus theory to the hydride transfer process (1, 13–15). There is now a significant body of literature relating to the reduction of a variety of pyridinium, quinolinium, isoquinolinium, acridinium, and phenanthridinium cations (2). Various 1,2- and 1,4-dihydropyridine derivatives have been used as the hydride donor species, with 1,4-dihydronicotinamides and 9,10-dihydroacridines being the most commonly investigated hydride donors. We felt that a significant addition to this area would be provided by a quantitative investigation of the rates of reduction of a wider variety of cationic acceptor species (A^+) than has been the case up until now. As an initial effort towards such an extension, we have chosen to measure the rates of reduction of the tropylium (**1**) and xanthylium (**2**) cations by both 1-benzyl-1,4-dihydronicotinamide (**3** = BNH) and 10-methyl-9,10-dihydroacridine (**4** = MAH).

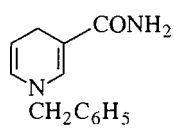
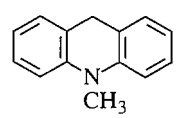
2



3



4

Several considerations were involved in the choice of these two cations. Firstly, we wished to include aromatic cations other than the nitrogen heteroaromatic species that have been predominantly investigated to date. Secondly, we required cations for which the second-order rate constants for hydroxide ion attack were available (16, 17), since we wished to continue our comparisons (18) of the rates of reduction with the rates of reaction with hydroxide ion as a standard nucleophile. Thirdly, we wished to choose cations that might be expected to be more reactive than the cations investigated to date. Because the tropylium (16) and xanthylium (19) cations have pK_{R^+} values

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

considerably lower than any of the nitrogen heterocyclic cations previously studied, they should fulfill this third criterion since linear free energy relationships between the second-order rate constant for reduction and pK_{R^+} have been established for other series of cations (18, 20, 21). Fourthly, the xanthylium cation is an attractive acceptor, since it is π-isoelectronic with the acridinium cations that have been the subjects of numerous investigations in this area.

The choice of 1-benzyl-1,4-dihydronicotinamide and 10-methyl-9,10-dihydroacridine as hydride donors was based upon our earlier observations (2) of an approximately constant relative reactivity for these two donors towards several acceptor cations. We wished to explore whether this relative reactivity would also be applicable to two quite different cationic acceptors chosen according to the criteria indicated above.

Experimental

Materials

Tropylium tetrafluoroborate and 9-hydroxyxanthene (9-xanthydrol) were both obtained from Aldrich Chemical Co. They were recrystallized from ethanol and aqueous ethanol, respectively, and characterized by ^{1}H NMR spectroscopy. The tropylium salt displayed a clean singlet δ 9.34 (in CF_3CO_2H relative to $(CH_3)_4Si$), and 9-hydroxyxanthene showed δ 2.25 (br s, OH), 5.68 (s, 1H), 6.90–7.60 (m, 8H) (in $CDCl_3$). 1-Benzyl-1,4-dihydronicotinamide and 10-methyl-9,10-dihydroacridine were synthesized as previously reported (2, 22). All compounds were stored in dark bottles in a vacuum desiccator over Drierite. Potassium chloride, potassium hydroxide, and all buffer species (CH_2ClCO_2H/KOH (pH = 2.5–3.7), CH_3CO_2H/KOH (pH = 4.0–5.5), NaH_2PO_4/Na_2HPO_4 (pH = 6.2–7.2), and $(HOCH_2)_3CNH_2$/HCl (pH = 7.7–8.7)) were the best commercially available grades. Acetonitrile was spectroscopic grade.

Kinetic studies

All rate data were obtained in buffered aqueous solutions containing 20% or 30% acetonitrile (v/v) (see below), at 25°C and ionic strength 1.0 (KCl). Stock solutions of reagents for kinetic studies were kept in the dark when not in use and discarded after a maximum of 48 h. Care was taken to ensure that complete solubility of the reactants and products was maintained before and during all kinetic runs. Solubility limitations were the major consideration in defining the highest accessible concentration of the excess component in each reaction system. The reaction between **2** and **3** proved to be incompatible with 20% acetonitrile containing phosphate buffer, although solubility was maintained under these conditions in 30% acetonitrile. The choice of specific experimental conditions was sometimes influenced by the occurrence of slow reactions of one or more of the individual components. In all cases, conditions were chosen so that such background reactions occurred at less than 1% of the rate of the reduction under investigation.

All reactions were followed spectrophotometrically under pseudo-first-order conditions with 17- to 200-fold excesses of the acceptor species over the hydride donors ([BNH] = 0.04 mM and [MAH] = 0.02 mM). Most reactions were followed on a Varian Cary 210 spectrophotometer, with digitized absorbance data being recorded on a Commodore 4048 computer. Occasional runs were also followed on a Unicam SP-1800 spectrophotometer equipped with a Unicam AR-25 linear recorder. Data were collected for at least 95% of each reaction, with the exception of some very slow reactions between **2** and **3** in which data were only obtained over the first 75% of the reaction. The pH was measured at the end of each kinetic run on a Radiometer PHM82 pH meter equipped with a GK2401B combination electrode.

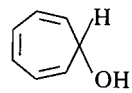
Pseudo-first-order rate constants were calculated by fitting the absorbance (A) at time (t) to the relationship:

$$A = A_f + (A_i - A_f)\exp(-k_{obs}t)$$

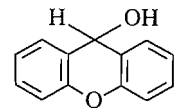
via the Marquardt algorithm, treating the initial absorbance (A_i), the final absorbance (A_f), and the pseudo-first-order rate constant as parameters to be evaluated.

Results

In aqueous solutions, the tropylium ($pK_{R^+} = 4.76$ (16)) and xanthylium ($pK_{R^+} = -0.83$ (19)) cations exist in equilibrium with their hydroxide adducts (**5** and **6**, respectively). The alcohols **5** and **6** are the predominant species present in most of the reactions in the current study, although the tropylium cation is the major species in the most acidic solutions investigated for the reaction with MAH. The predominance of these alcoholic species in these reactions had both advantages and disadvantages. The advantage lay in the fact that what proved to be very fast reactions of these cationic acceptors could be studied under routine pseudo-first-order conditions in which only low equilibrium concentrations of the acceptor species were present. The disadvantage lay in the limited solubilities of **5** and **6** in the predominantly aqueous media in use. Clean kinetic data were only obtainable below 3.5 mM for **5** and below 2.2 mM for **6**.



5



6

1-Benzyl-1,4-dihydronicotinamide (**3**, λ_{max} = 357 nm) and the 10-methylacridinium cation (the oxidation product from **4**) are the only species with significant absorbances above 300 nm in the current studies. Reactions of BNH were followed by the disappearance of the absorbance due to this species at 357 nm. Reactions of MAH produced the very characteristic absorption spectrum (23) of the 10-methylacridinium cation over the range 330–450 nm. Kinetic data were obtained by following the increase in absorbance at the intense maximum at 356 nm.

Pseudo-first-order rate constants (k_{obs}) were evaluated at six acceptor concentrations at each pH. In all cases k_{obs} was found to be cleanly proportional to the total concentration ($[A^+] + [AOH]$) of the acceptor species in solution (e.g., Figs. 1 and 2). Apparent second-order rate constants (k_2^{app}) were evaluated from the slopes of plots of k_{obs} vs. ($[A^+] + [AOH]$) at each pH. Standard errors in each k_2^{app} were in the range ±2%–±6%. The pH dependences of k_2^{app} are displayed in Figs. 3 and 4.

The pH-dependent pseudo-second-order rate constants are defined by:

$$-\frac{d[DH]}{dt} = k_2^{app}([A^+] + [AOH])[DH]$$

$$= k_2^{app}(1 + K_{R^+}/[H^+])[A^+][DH]$$

$$= k_2[A^+][DH]$$

$$[2] \qquad k_2^{app} = k_2/(1 + K_{R^+}/[H^+])$$

The pH-dependence shown in Fig. 3 for the reaction of **1** with **4** was fitted to eq. [2], with $k_2 = 15.1(\pm 0.6)\ M^{-1}\ s^{-1}$ and $pK_{R^+} = 4.82(\pm 0.05)$. For the other three reactions, log k_2^{app} appears to be linear in pH with negative unit slope. These latter three reactions were investigated over pH ranges for which $K_{R^+} \gg [H^+]$, and under this condition eq. [2] simplifies to $k_2^{app} = k_2[H^+]/K_{R^+}$; i.e.,

$$\log k_2^{app} = \log k_2 + pK_{R^+} - pH$$

Thus for each of these reactions, k_2 may be readily evaluated from the experimental data in Figs. 3 and 4.

The second-order rate constants (k_2) for each of these four reactions are summarized in Table 1. Data for the reaction of **2** with **3** in 30% acetonitrile have been corrected to 20%

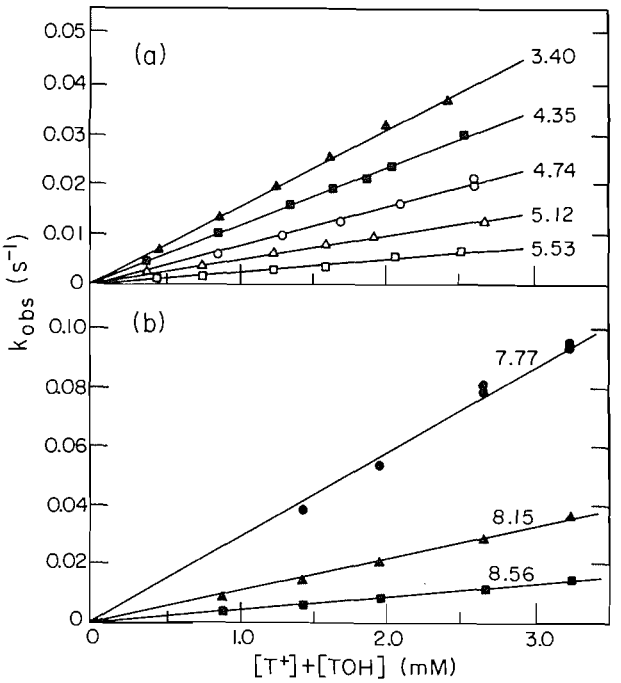

FIG. 1. Concentration dependence of the pseudo-first-order rate constants for reduction of the tropylium cation (T^+) in equilibrium with its hydroxide adduct (TOH): (a) by 10-methyl-9,10-dihydroacridine (0.02 mM); (b) by 1-benzyl-1,4-dihydronicotinamide (0.04 mM) in solutions with pH as indicated. All data are in 20% acetonitrile – water.

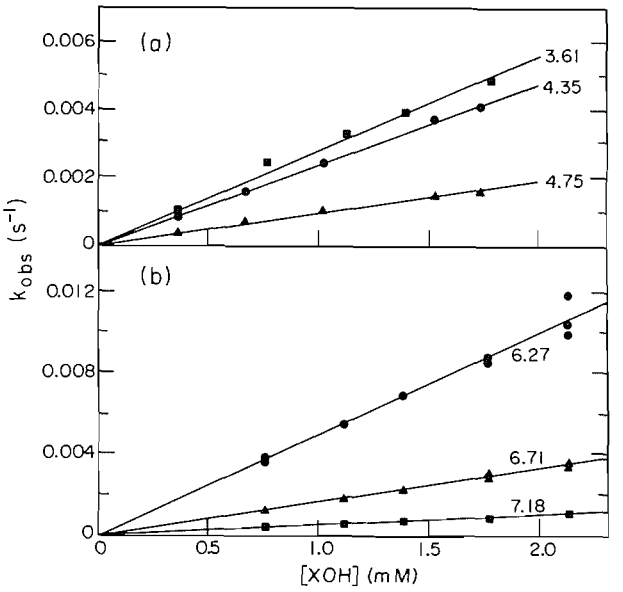

FIG. 2. Concentration dependence of the pseudo-first-order rate constants for the reduction of 9-xanthydrol (XOH): (a) by 10-methyl-9,10-dihydroacridine (0.02 mM); (b) by 1-benzyl-1,4-dihydronicotinamide (0.04 mM) in solutions with pH as indicated. Data for pH 3.61 in (a) and all data in (b) are in 30% acetonitrile – water; other data are in 20% acetonitrile – water.

acetonitrile using a factor of 4.6. This factor was obtained from the observation that k_2^{app} for the reaction of **2** with **4** is 4.6-fold smaller in 30% acetonitrile than in 20% acetonitrile at pH 3.6. We have assumed that the solvent effects on the reduction of the xanthylium cation will be similar for the two different reductants.

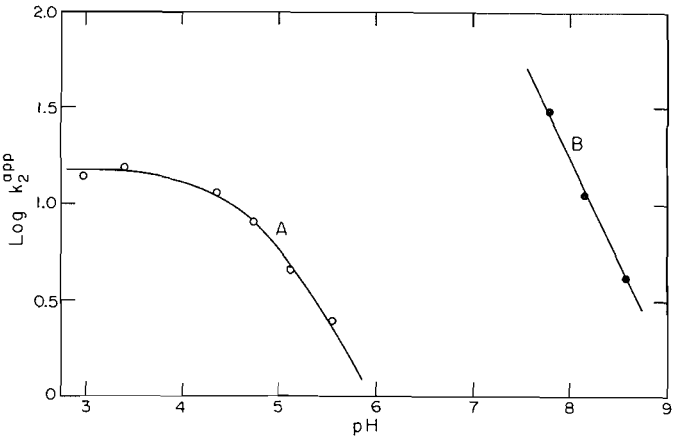

FIG. 3. The pH-dependence of k_2^{app} for the reduction of the tropylium cation: (A) by 10-methyl-9,10-dihydroacridine (the curve is eq. [2] with k_2 = 15.1 and pK_{R^+} = 4.82); (B) by 1-benzyl-1,4-dihydronicotinamide (the line has slope −1). All data in 20% acetonitrile – water.

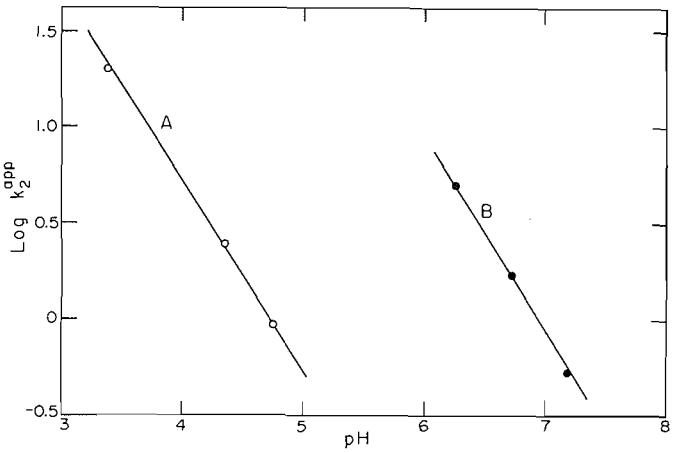

FIG. 4. The pH-dependence of k_2^{app} for the reduction of 9-xanthydrol: (A) by 10-methyl-9,10-dihydroacridine (20% acetonitrile – water); (B) by 1-benzyl-1,4-dihydronicotinamide (30% acetonitrile – water). Both lines have slope −1.

TABLE 1. Second-order rate constants for reduction of tropylium and xanthylium cations[a]

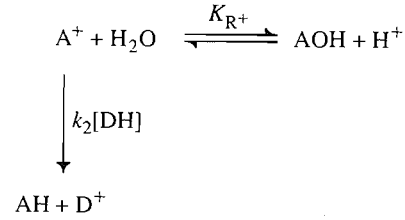
Oxidant	Reductant	$k_2(M^{-1}\ s^{-1})$
Tropylium cation	MAH	15.1(±0.6)
	BNH	$2.5(\pm0.3)\times10^4$
Xanthylium cation	MAH	$3.5(\pm0.3)\times10^5$
	BNH	$2.7(\pm0.2)\times10^8$
	BNH	$5.9(\pm0.5)\times10^7$ [b]

[a]At 25°C, in 20% CH_3CN – 80% H_2O, ionic strength 1.0 (unless stated otherwise).
[b]At 25°C, in 30% CH_3CN – 70% H_2O, ionic strength 1.0.

Discussion

The pH–rate profiles shown in Figs. 3 and 4 are consistent with a reaction that occurs as outlined in Scheme 1. This scheme generates the rate constant relationship given in eq. [2].

Of the four reactions included in the current study, only one reaction appears to have been investigated previously. Grishin and Yasnikov (24) reported a kinetic investigation of the



SCHEME 1

reaction of the tropylium cation with three N-substituted 1,4-dihydronicotinamides in 50% ethanol – water at 25°C. For the *N*-benzyl derivative (**3**), they reported a third-order rate constant, $k_3 = 5.4 \times 10^8\ M^{-2}\ min^{-1}$, which was defined in a way that is equivalent to eq. [3] at neutral pH. This equation is equivalent to eq. [4], and so a second-order rate constant $k_2 = k_3K_{R^+}$ can be evaluated provided that pK_{R^+} for the tropylium cation can be evaluated in 50% ethanol – water. If one uses $pK_{R^+} = 3.1$ for this cation in this solvent (25), then $k_2 = 7000\ M^{-1}\ s^{-1}$, which is only 28% of the value obtained for this same reaction in 20% acetonitrile – water in the current study. In this light, the 4.6-fold decrease in rate reported above, for the reaction of the xanthylium cation with MAH upon going from 20% to 30% acetonitrile, is not unreasonable. Other dramatic rate changes with small changes in solvent polarity have also been reported in related reductions (26, 27), although, in general, solvent effects seem to be quite variable for this type of reaction (5, 28).

$$[3]\quad \text{Rate} = k_3[DH][AOH][H^+]$$

$$[4]\quad = k_3K_{R^+}[DH][A^+]$$

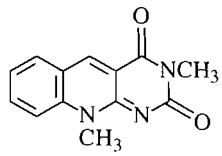
As anticipated above, the tropylium and xanthylium cations proved to be much more reactive than any of the nitrogen heteroaromatic cations that have previously been examined with these two reductants. For instance, the 10-methylacridinium cation reacts with 1-benzyl-1,4-dihydronicotinamide with $k_2 = 400\ M^{-1}\ s^{-1}$ under the current experimental conditions (29). Thus, the xanthylium cation reacts with this reductant (7×10^5)-fold faster than does the π-isoelectronic acridinium cation. Interestingly, $\Delta(\log k_2)/\Delta pK_{R^+} = -0.54$ when one compares these two cations reacting with this reductant. This value is similar to the slopes of the relationships in eqs. [5] and [6], respectively, for the reduction of quinolinium (21) and isoquinolinium (20) cations by BNH.

$$[5]\quad \log k_2 = -0.56\ pK_{R^+} + 7.3$$

$$[6]\quad \log k_2 = -0.50\ pK_{R^+} + 4.9$$

The reactivity of the tropylium cation with BNH is predicted reasonably well by the linear free energy relationship for C-4 reduction of quinolinium cations. Thus extrapolation of eq. [5] to $pK_{R^+} = 4.82$ gives $k_2 = 4.0 \times 10^4\ M^{-1}\ s^{-1}$ compared with the value of $2.5 \times 10^4\ M^{-1}\ s^{-1}$ that is experimentally observed. The tropylium cation is much more reactive than predicted by eq. [6] for isoquinolinium cations ($k_2 = 310\ M^{-1}\ s^{-1}$ for $pK_{R^+} = 4.82$). The 10-methylacridinium cation and the xanthylium cation are both somewhat more reactive (8-fold and 5-fold, respectively) than predicted by eq. [5] for quinolinium cations.

The k_2^{rel} values for the reduction of the tropylium (1700) and xanthylium cations (770) by BNH and MAH are given in Table 2. This table also includes all literature data that we have been able to locate for the reduction of a common oxidant by these two reductants. With two exceptions, the k_2^{rel} values in this table lie within the range 770–1700. One of these exceptions (the 2-methyl-5-nitroisoquinolinium cation with $k_2^{rel} = 120$) is not unexpected since the reduction of this cation by BNH is known to be complicated by the presence of nonproductive complexation between these two reactants (2, 22). The other exception involves the 10-methylacridinium cation for which k_2^{rel} appears to be "normal" in acetonitrile solution (4) but is reported to be threefold larger in 80% 2-propanol – 20% water (13). Thus, aside from these two exceptions, k_2^{rel} varies by only twofold despite the fact that the individual reactivities of these oxidants vary by 10^{10}-fold with either of these reducing agents individually. Note that the neutral oxidant, **7**, shows the same k_2^{rel} as the cationic oxidants in Table 2. There is almost constant selectivity towards these two reducing agents over a 10^{10}-fold change in reactivity. This phenomenon represents a further expression of a Ritchie N^+ correlation (31) for organic cation reactivity.



7

Although these organic cations show essentially constant selectivity towards two reducing agents, such a constant selectivity is not observed if one compares the relative reactivities of these same cations towards one of these reducing agents and nucleophilic attack by hydroxide ion. Such a comparison is presented in Table 3 for reduction by 1-benzyl-1,4-dihydronicotinamide. This table includes data for the xanthylium and tropylium cations, and also data for several nitrogen heteroaromatic cations for which both k_{OH} and k_2 (for reduction by BNH in 20% acetonitrile – 80% water) are available. The k_2/k_{OH} ratios vary (9×10^6)-fold. Enhanced k_2/k_{OH} reactivities have previously been demonstrated (18) for cations that give 1,4-dihydropyridine reduction products when compared with the *N*-methyl isoquinolinium cation, which gives a 1,2-dihydropyridine. In that work it was also noted that the k_2/k_{OH} ratio shows a significant increase with increasing reactivity (k_2). Consistent with this conclusion, we now find that the xanthylium cation, which is the most reactive cation in reductions by BNH, also displays by far the largest k_2/k_{OH} ratio (= 7.7). The tropylium cation has k_2/k_{OH} smaller than might have been expected in terms of this reactivity–selectivity relationship. Nevertheless, this cation does display k_2 consistent with its pK_{R^+}, and k_2/k_{OH} is greater for this cation than for any *N*-heteroaromatic cation other than the *N*-methyl acridinium ion.

We have recently suggested (32) that the order of k_2/k_{OH} ratios that is observed for cations generating 1,4-dihydropyridine reduction products can be traced to the importance of charge-transfer interactions between the cation and reductant. Other workers have also concluded that such charge-transfer species may lie on the reaction coordinate for these formal hydride transfer processes (3, 30). It should be noted that it has been established (32–34) that the order of charge-transfer absorption maxima (λ_{max}) with a common donor species follows the order: xanthylium > tropylium > 10-methylacridinium > 1-methylquinolinium > 1-methylpyridinium. Fur-

thermore, this order also reflects the order of stabilities of charge-transfer complexes between these cations and a common donor species (32). It therefore transpires that the choice of the xanthylium and tropylium cations for the current study has provided a valuable extension of the general structure–reactivity relationships that are emerging with respect to hydride transfer reactions of the type described by eq. [1].

NMR study of π–σ* stereoelectronic interactions in 3-substituted benzocycloheptene derivatives

Y. AUBIN AND M. ST-JACQUES[1]

Département de chimie, Université de Montréal, C.P. 6128, Succ. A, Montréal (Québec), Canada H3C 3J7

Received July 4, 1989

Y. AUBIN and M. ST-JACQUES. Can. J. Chem. **68**, 543 (1990).

Dynamic NMR methods are used to study 3-substituted benzocycloheptene derivatives, useful models for investigating the conformational effect of the stereoelectronic π–σ* orbital interaction. The 11 compounds studied are divided in two subgroups, the first one containing mainly halogenated derivatives (F, Cl, Br, and OCH_3) and the second consisting of oxy derivatives (OCH_3, OCH_2CH_3, $OCH{=}CH_2$, OAc, *p*-OPh-R, where R = H, OCH_3, and NO_2). The results for the first series show the presence of two chair conformations (C_a and C_e) characterized by a decreasing C_a population with increasing electronegativity of the substituent. This trend suggests the presence of a dominant π–σ* interaction for Cl and Br stabilizing the C_a form. The larger C_e population observed for F suggests that a strong attractive interaction with the aromatic *peri* hydrogen is present in this compound. Finally, in the oxy-substituent series, the populations trend does not correspond to that predicted from the π–σ* orbital interaction, but the individual population perturbations appear to be caused primarily by electrostatic interactions involving the nonsymmetrical polar substituents.

Key words: low temperature NMR, conformational analysis, seven-membered rings, orbital interactions, benzocycloheptene derivatives.

Y. AUBIN et M. ST-JACQUES. Can. J. Chem. **68**, 543 (1990).

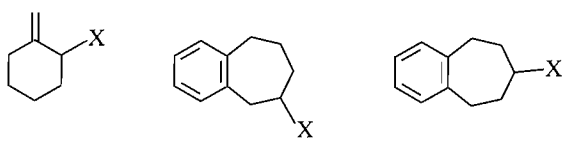
On a utilisé des méthodes de RMN dynamique pour étudier des benzocycloheptènes substitués en position 3 qui sont de bons modèles pour évaluer l'effet conformationnel de l'interaction stéréoélectronique de l'orbitale π–σ*. Les 11 composés étudiés ont été divisés en deux sous-groupes : le premier comprend principalement des dérivés halogénés (F, Cl, Br et OCH_3) alors que le second est formé de dérivés oxygénés (OCH_3, OCH_2CH_3, $OCH{=}CH_2$, OAc et *p*-OPh-R dans lequel R = H, OCH_3 et NO_2). Les résultats obtenus avec la première série de composés démontrent que deux conformations chaises (C_a et C_e) sont présentes et que la population de la conformation C_a diminue avec une augmentation de l'électronégativité du substituant. Cette tendance suggère que, pour les substituants Cl et Br, il existe une interaction π–σ* dominante qui stabilise la forme C_a. La présence d'une population plus élevée de C_e avec le F suggère que, dans ce composé, l'hydrogène aromatique en *péri* exerce une forte interaction attractive. Enfin, dans les composés oxygénés, les variations des populations ne correspondent pas à celles que l'on pourrait prévoir en se basant sur l'interaction de l'orbitale π–σ*; toutefois, les perturbations dans les populations individuelles semblent refléter principalement des interactions électrostatiques impliquant les substituants polaires qui ne sont pas symétriques.

Mots clés : RMN à basse température, analyse conformationnelle, cycles à sept chaînons, interactions orbitales, dérivés de benzocycloheptène.

[Traduit par la revue]

Introduction

Earlier results on derivatives of methylenecyclohexane (1) predict, for α-halogens (**1**), an increase in the population of the axial chair conformation (C_a) with the size of the halogen substituent. This prediction was based on the contribution from two interactions: the first one (allylic strain or $A^{(1,3)}$ strain) destabilizes the C_e conformer while the second stabilizes the C_a form through a π–σ* orbital interaction as proposed by Lessard and co-workers (2).



1 **2** **3**

Results for analogous oxy derivatives of methylenecyclohexane show that substituents containing an unsaturated moiety show greater preference for the C_e form than predicted by the π–σ* interaction (2). This apparent deviation was rationalized in terms of an unsaturation effect (2).

Our aim was to investigate the conformational consequence of the π–σ* interaction and the unsaturation effect through a study of 3-substituted derivatives of benzocycloheptene. This system, having a chair geometry, is complementary to methylenecyclohexane and can more easily be studied by low temperature NMR techniques such as were used to characterize the conformational properties of 4- and 5-substituted derivatives (3) represented by structures **2** and **3**. Two groups of substituents were selected: the first comprises mainly the halogen substituents (compounds **5**–**8**) whereas the second contains saturated and unsaturated 3-oxy derivatives (**8**–**14**). It was believed that the first group should reveal the effect of electronegativity on the π–σ* interaction while the second might shed some light on the unsaturation effect and, if confirmed, permit its characterization.

and the spectral parameters are listed in Table 1. Because carbon–fluorine couplings in the spectrum of compound **5** facilitate the assignation of its ^{13}C NMR spectrum at high and low temperatures, it is considered first.

Figure 1 illustrates the proton-decoupled 100.62 MHz carbon-13 NMR spectrum of **5** in CH_3OCH_3 at 0 and −120°C. At low temperature each signal has separated into two components of unequal intensity (15:85) indicative of two conformers. The signal identification at 0°C is done directly, using the carbon–fluorine coupling constants. The largest C—F coupling is observed for the C3 carbon at 95.15 ppm ($^1J_{C3-F}$ = 174.2 Hz). The C4 signal (35.85 ppm) can be distinguished from that of C7 (36.15 ppm) by a splitting arising from the coupling constant $^2J_{C4-F}$ = 22.0 Hz. Similarly the C5 signal is assigned to the doublet at 28.31 ppm ($^3J_{C5-F}$ = 9.3 Hz) and the C6 carbon to the singlet at 28.74 ppm.

The known stereodependence (4) of $^3J_{CF}$ can be used to determine the nature of the conformers of **5** in addition to assigning the signals of the ^{13}C NMR spectrum at −120°C. The magnitude of this coupling constant depends on the dihedral angle F—C3—C4—C5, and for this purpose angles were calculated, using the Still–Steliou MODEL 2.93 program to model the geometry of the C_e and C_a conformers: the values obtained are 158° and 45° respectively. According to ref. 4, the large coupling constant $^3J_{C5e-F}$ = 13.7 Hz observed for the doublet at 28.62 ppm is indicative of an angle near 160–180° and therefore identifies C5 of the C_e form (represented by C5e) while the C5a carbon is found at 26.05 ppm (doublet with $^3J_{C5a-F}$ = 4.3 Hz).

The carbon-13 chemical shift substituent effects[2] were calculated and listed in Table 2; these parameters are useful in assigning the signals of each of the two conformers for some of the other compounds. Thus, for **5** (X = F), the γ-*gauche* effect involving C5 is −6.97 ppm and γ-*anti* is −4.40 ppm.

Another way to characterize the conformers is provided by the magnitude of the proton–proton coupling constant $^3J_{H3-H4}$ measured from the ^1H NMR spectra at low temperature. In a previous ^1H NMR study of benzocycloheptene, St-Jacques and Vaziri (6) measured proton coupling constants from partially deuterated derivatives of benzocycloheptene, and the two coupling constants of interest are $^3J_{3e-4e}$ = 6.6 Hz and $^3J_{3a-4a}$ = 12.6 Hz. The corresponding coupling constants determined for compound **5** (X = F) from the ^1H NMR spectrum in CHF_2Cl at −120°C are $^3J_{3e-4e}$ = 5.0 Hz for the minor form (C_a) and $^3J_{3a-4a}$ = 11.5 Hz for the major conformer (C_e). Integration revealed an intensity ratio of 15:85 for C_a:C_e.

Knowing the nature of the major and minor conformers, the other signals of the ^{13}C NMR spectrum of **5** (X = F) at −120°C can now be assigned. The C3 signals are readily located at 94.02 ppm (C_e) and 97.16 ppm (C_a), whereas C4e is observed at 36.04 ppm ($^2J_{C4e-F}$ = 21.6 Hz) and C4a at 32.99 ppm

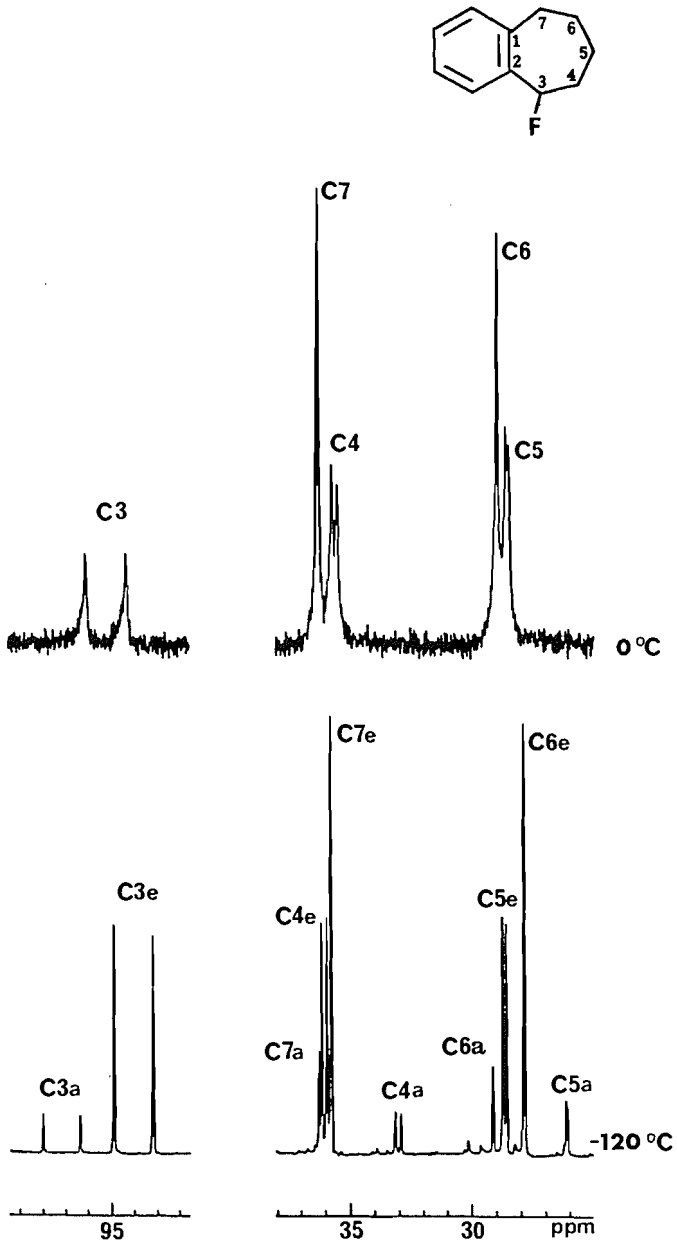

FIG. 1. The 100.62 MHz ^{13}C spectra of **5** at 0°C and −120°C (e = equatorial chair and a = axial chair).

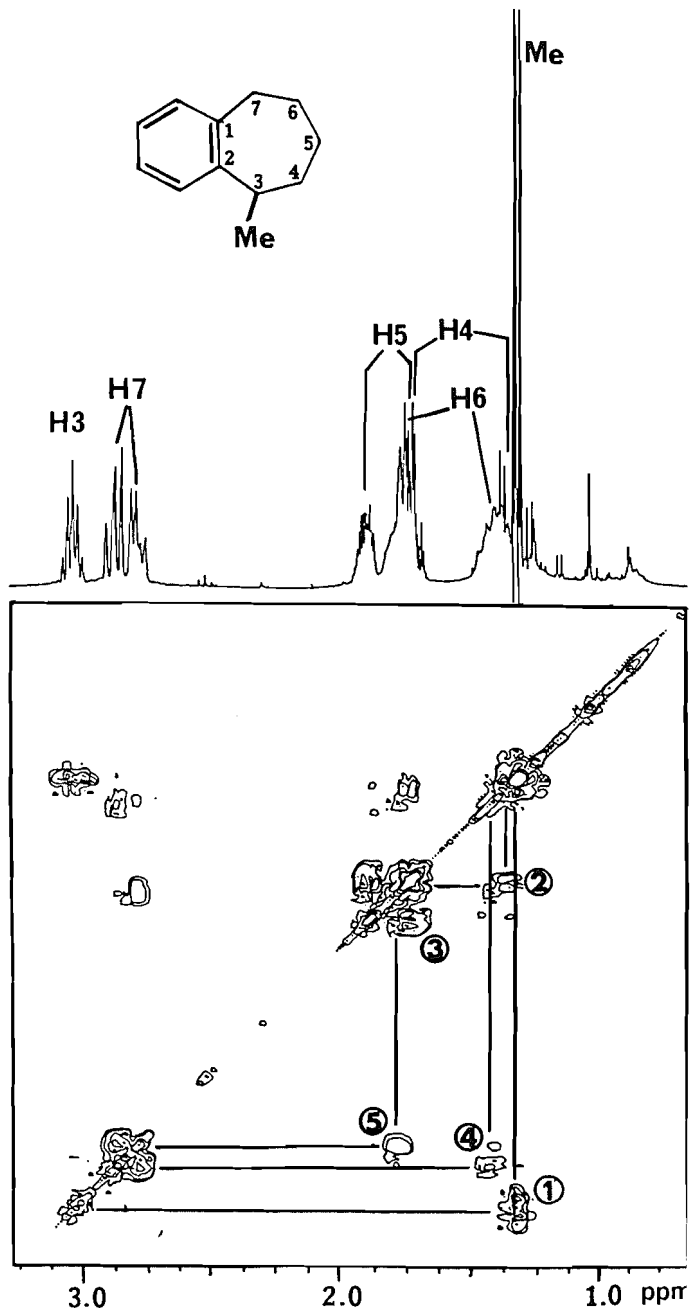

FIG. 2. The 400 MHz two-dimensional ^1H NMR (COSY) spectrum of **4** in $CDCl_3$ at room temperature.

($^2J_{C4a-F}$ = 23.6 Hz). These two last signals show a separation of 3 ppm, arising from differences in β effects. This parameter was used to identify the conformers of other compounds. Finally, the C6 signals are found at 29.09 ppm (C_a) and 27.81 (C_e) while the C7 carbons are at 36.27 ppm (C_a) and 35.77 ppm (C_e).

The spectral analysis of **4**, **6**, **12**, **13**, and **14** required two-dimensional NMR techniques such as a COSY-45 experiment (7) and a heteronuclear correlation (HETCOR) (8, 9) experiment performed at 25°C in $CDCl_3$. The experimental details of these experiments are described in the experimental section. The results, used to assign the signals of the carbon-13 NMR spectra at high temperature, are exemplified by the spectral analysis of derivative **4** (X = CH_3).

Figure 2 shows both 2D-NMR plots as recorded for **4** (X = CH_3) on a WH-400 (COSY-45) and a VXR-300 (HETCOR) spectrometer. In the 2D COSY contour spectrum, the off-diagonal signals represent correlations between coupled protons whose chemical shifts are obtained from peaks along the diagonal line. The H3 proton, being a benzylic methyne, is the most downfield aliphatic proton (3.00 ppm) and the H7 protons are easily assigned at 2.84 ppm (H7) and 2.74 ppm (H7′) because they are deshielded by the aromatic ring. These three proton signals serve as reference for the analysis. The correlation peak 1 arises from coupling between H3 with H4 at 1.36 ppm and the methyl group at 1.29 ppm. Correlation 2 arises from coupling between H4 with H4′ and H5 at 1.68 ppm, while the coupling of H5 with H5′ (1.87 ppm) gives rise to a part of the correlation peak 3. While H7 and H7′ are readily assigned, the correlation peaks 4 and 5 arise from the coupling

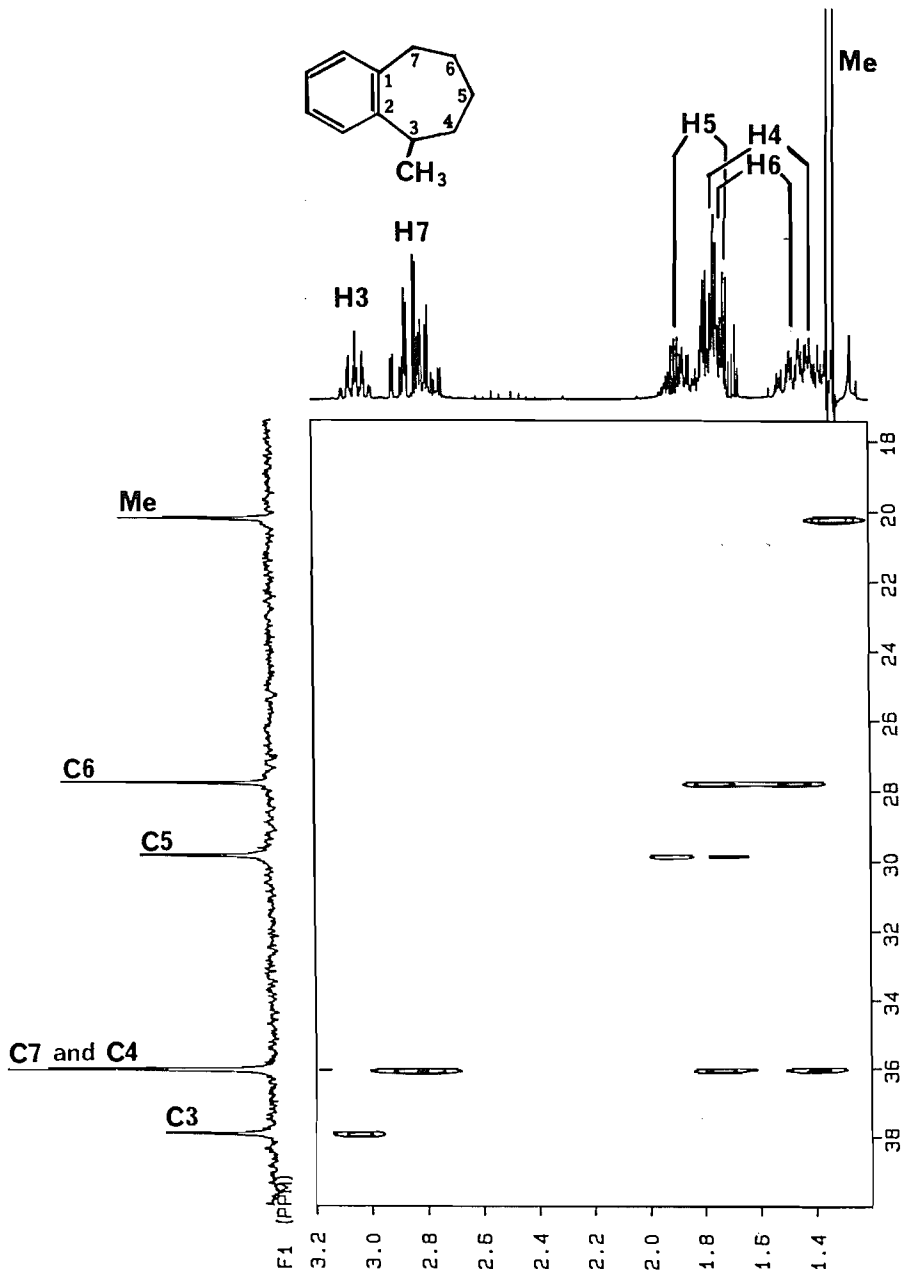

FIG. 3. 2D proton–carbon heteronuclear chemical shift correlation (HETCOR) of **4** in $CDCl_3$ at room temperature at 75.431 MHz for ^{13}C with F_2 = 299.949 MHz in the second dimension.

of H7 with H6 (1.43 ppm) and H7′ with H6′ (1.76 ppm) respectively. The correlation peak 3 also indicates the coupling between H5 and H6′.

Using the known proton chemical shifts, the ^{13}C NMR signals can then be identified by the HETCOR experiment at 25°C. The experiment performed in $CDCl_3$ cannot differentiate between C4 and C7 because the signals overlap. However, the ^{13}C NMR spectrum at 0°C in the CH_3OCH_3 (Fig. 3) reveals two distinct signals, a sharp one (37.31 ppm) and a broadened signal slightly upfield (37.34 ppm), representing C7 and C4 respectively. The signals of the ^{13}C spectra at low temperature were identified using substituent effects. The γ and δ substituent effects derived from the C5 and C6 signals provide useful information on the major conformer, in this case C_e. All substituents studied produce similar γ and δ effects on the chemical shifts of the carbons on the benzocycloheptene ring listed in Table 2. Integration of the spectra in CHF_2Cl and CH_3OCH_3 at −120°C gave 10% of the C_a form of **4** in each solvent.

The very small intensity of the ^{13}C lines of the minor form in the NMR spectrum of derivative **6** (X = Cl) at −120°C required an analysis using substituent effects to assign its lines. The nature of the major form (C_a) is confirmed by the proton–proton coupling constant $^3J_{H3-H4}$ of 5.2 Hz measured in the ^1H NMR spectrum at −120°C in CH_3OCH_3. Integration revealed ≈99% of the C_a form and 1% of C_e form for which several signals are identified. Changing the solvent to CHF_2Cl causes the minor signals of **6** to disappear. Similarly, in both solvents the spectra of compound **7** (X = Br) show signals of the C_a conformer only.

The analysis of the ^{13}C spectra of compounds **8**–**14** at high

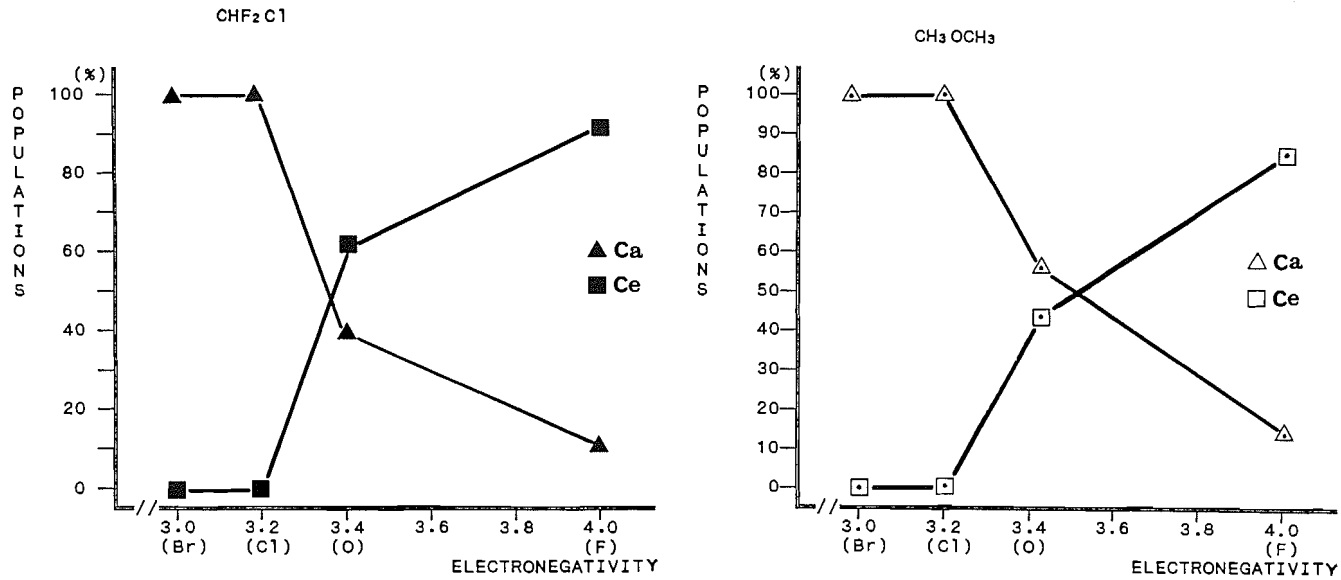

FIG. 4. Plots of the population of the C_e and C_a forms versus the electronegativity of Br, Cl, and F in CH_3OCH_3 and CHF_2Cl solutions. Data for OCH_3 are included as references for oxygen.

and low temperatures is based on chemical shift substituent effects and a close resemblance of all the spectral behavior observed for the derivatives studied. Their chemical shifts and populations are summarized in Table 1.

Discussion

The ^{13}C NMR spectra of derivatives **4–14** (except **7**) revealed the presence of two conformations (C_a and C_e) whose relative populations, given in Table 1, are quite different from those of the families of benzocycloheptene (3) represented by compounds **2** and **3**. The ratio of the two forms should be influenced by electrostatic interactions, steric interactions, solvation effects, and stereoelectronic $\pi-\sigma^*$ orbital interactions. Such orbital interactions were not possible for families **2** and **3**.

Information on steric repulsion is provided by the data obtained for **4** (X = CH_3). The two steric interactions found in the methylenecyclohexane system, allylic strain ($A^{(1,3)}$) and *syn*-diaxial repulsion, are also found in the 3-substituted benzocycloheptene derivatives, as illustrated by structures **15** and **16**, in which allylic strain becomes benzylic strain.

C_e C_a

15 **16**

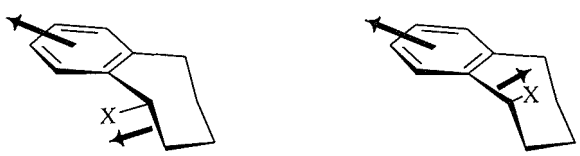
The presence (3) of 10% of the C_a form for **4** suggests that the benzylic strain of the methyl group in **15** is less destabilizing for the C_e form than the *syn*-diaxial interactions (1,3 and 1,4, as illustrated in **16**) are destabilizing for the C_a form.

To explain the results obtained for the polar substituted derivatives (**5–14**), it is useful to divide them into two subgroups: the first one includes mainly the halogen compounds (**5–8**) while the second contains the oxy derivatives (**8–14**). The OCH_3 substituent (**8**) is included in both subgroups for reference purposes, as will be explained below.

The first subgroup: compounds 5–8

Figure 4 illustrates the population change of the C_a and C_e forms with substituent electronegativity in two solvents, the more polar CHF_2Cl and the less polar CH_3OCH_3. It is seen that in each solvent the population of the C_a form decreases as the substituent electronegativity increases. The large C_a populations for the Cl and Br derivatives cannot be explained by steric arguments. The ΔG^0 values given by Jensen and Bushweller (10) for the substituents of the first group in cyclohexane (0.5 kcal/mol for Br and Cl, 0.3 kcal/mol for F, and 0.6 kcal/mol for OCH_3) cannot account for the observed trend for these four substituents because the predicted C_a populations, based solely on steric arguments, should be F > Cl $\approx$ Br > OCH_3. Furthermore, the $A^{(1,3)}$ effect, also of steric origin, should counterbalance this trend, producing a levelling effect. It therefore appears clear that these effects are not dominant.

In addition, electrostatic effects would be determined by the orientations of two dipole moments (3, 11) present in these benzocycloheptene derivatives, as illustrated by structures **17** and **18**. The C_e form (with parallel dipoles) is expected to be

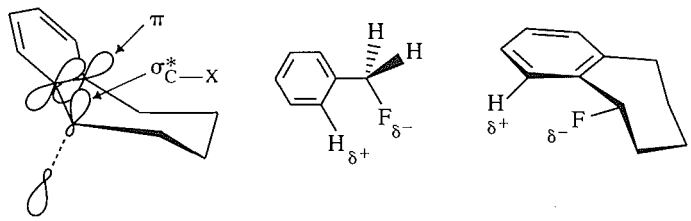


C_e C_a

17 **18**

more polar than the C_a form with oppositely oriented dipoles, and the latter should be favored in a nonpolar solvent (3, 11). Calculations using the Still–Steliou MODEL 2.93 program have confirmed that the C_e form is the more polar one. Thus, as substituent electronegativity increases, the C_a form should also increase, contrary to observations for the first subgroup. Furthermore, a change of solvent from CH_3OCH_3 to CHF_2Cl should stabilize C_e more than C_a and shift the equilibrium toward C_e (4). This solvent effect is indeed observed for **5**

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.



19 20 21

(X = F) and **8** (X = OCH_3) but not for **6** (X = Cl) and **7** (X = Br). Therefore the high proportion of the C_a form for **6** and **7** does not appear to be determined by dominant electrostatic interactions, although these no doubt contribute.

In light of the preceding arguments, the π–σ* stereoelectronic effect is required to explain the conformational behavior of the Cl and Br substituents. The relevance of this interaction was suggested from studies of oxy derivatives of methylenecyclohexane by Lessard and co-workers (2).

Generally, an occupied molecular orbital near an unoccupied molecular orbital can lead, under proper conditions, to a stabilizing interaction between them (12, 13). For the π–σ* interaction in the benzocycloheptene derivatives considered in this work, the orbitals involved are the π orbital of the benzo ring (at the C2 position) and the σ* anti-bonding orbital of the carbon-substituent bond at C3, as illustrated by structure **19**. For maximum interaction, two conditions are needed: (1) the π and σ* orbitals must be parallel for effective overlap to occur and (2) the energy difference (or energy gap) between the π and σ* orbitals should be as small as possible. These conditions are represented by the following expression:

$$E \propto -S^2/|e_1^0 - e_2^0|$$

where E is the stabilization energy, S is the overlap integral, and e_i^0 is the energy of orbital i.

According to the requirement for effective overlap, the geometry of the C_a form is better than that of C_e. For derivatives **5**–**7** (X = F, Cl, and Br), the calculated (using the Still–Steliou MODEL 2.93 program) π—C2—C3—σ* dihedral angles of the C_a form vary from 23° to 17° as we pass from F to Br. Moreover, the S term is influenced by the substituent electronegativity whereby increasing substituent electronegativity produces greater electronic density localized at the carbon atom of σ*, and thus stabilization will be greater (13).

The fact that the C_a population decreases with increasing substituent electronegativity (Fig. 4) suggests that the energy gap ($e_1^0 - e_2^0$) might be more important than the S term in the π–σ* interaction.

The relevant energy orbitals, determined by *ab initio* and CNDO/2 calculations (14) and supported by ionization potentials of molecules of type CH_3X (15, 16), are schematically represented in Fig. 5. The relative order of the $\sigma^*_{C—X}$ orbital energies suggests (assuming the $|e_1^0 - e_2^0|$ term is predominant) that the population of the C_a form should decrease with an energy gap increase. Thus, the relative order of the C_a populations should be Br > Cl > F > OCH_3, instead of the relative order observed: Br ≥ Cl ≫ OCH_3 > F. This inversion of F and OCH_3 suggests the existence of either a particular stabilizing effect in the C_e form of the F derivative (**5**) or the presence of a destabilizing effect in the C_e form of the OCH_3 derivative (**8**). In fact, it was shown previously (in the analysis of CH_3 derivative **4**) that the benzylic strain $A^{(1,3)}$ is destabilizing for the C_e form.

Penner *et al.* (17) have published results on the benzylic

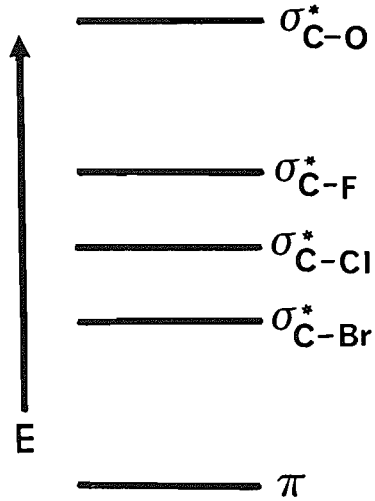


FIG. 5. Relative order of antibond orbital energies of C—X bond in various X—CH_2—CH_2—Y and CH_3—X molecules.

"anomeric" effect in benzyl fluoride and benzyl chloride. Their calculations show a significant stabilization of the expected unfavored planar geometry **20**, resulting from a coulombic attraction between the fluorine atom and the *ortho* hydrogen on the aromatic ring. The fluorine atom bears a negative charge of −0.401 electron while the hydrogen has a positive charge of +0.227 electron, which results in a stabilization of 62.9 kJ mol^{-1} for the planar conformation. The C_e form of **5** (X = F) has a geometry (**21**) quite similar to that found stabilizing for benzyl fluoride, and thus it is possible that the OCH_3–F inversion, noted in Fig. 4, is due to an interaction of this type.

Penner *et al.* (17) also reported an attractive coulombic interaction for the benzyl chloride, but less stabilizing than for benzyl fluoride. For the halogen derivatives (**6**, X = Cl, and **7**, X = Br), this effect should stabilize the C_e form. Thus the large C_a population found for both derivatives is compatible with a strong π–σ* interaction that overrides any attractive coulombic interaction.

In conclusion, the data obtained for the first subgroup show evidence for the π–σ* interaction as the major stabilizing factor for the C_a form of **6** and **7** (X = Cl and Br). The analysis of **5** (X = F) points out an attractive coulombic interaction, which is strongly stabilizing for the C_e form. The data suggest that **8** (X = OCH_3) is borderline and its $C_a \rightleftharpoons C_e$ equilibrium is determined by the balance of several interactions.

The second subgroup: compounds 8–14

First of all, the analysis of the oxy derivatives, within the framework of the π–σ* interaction, should be based on the effective electronic density at the oxygen atom of each substituent, that is to say, on the electron-withdrawing ability of the R part of the -OR substituents. Thus the electronic density should be greater on the oxygen atom if R is a methyl group and, as a consequence, the energy of the anti-bonding orbital $\sigma^*_{C—OCH_3}$ should be higher. Because of electron delocalization in the acetyl group, the electronic density on oxygen should be lower and, equally so, the energy of the $\sigma^*_{C—OAc}$ orbital. Thus, the energy of the $\sigma^*_{C—OR}$ orbitals should increase in the following order: $\sigma^*_{C—OAc} < \sigma^*_{C—OPh} < \sigma^*_{C—OCH_3}$. Therefore, the populations of the C_a form, if determined by the π–σ* interaction, should be in the increasing order OCH_3 < OPh < OAc, because the smaller the energy gap between the π

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12

For personal use only.

and the $\sigma^*_{C—OR}$ orbitals, the stronger is the stability obtained from the π–σ^* interaction.

The oxy derivatives of methylenecyclohexane (2) show a C_a trend (OAc < OPh < OCH_3) that is opposite to that predicted from the π–σ^* interaction. The inversion of OCH_3 and OAc could not be explained by the authors, who have proposed an unsaturation effect as a specific interaction characterizing an oxy derivative with a substituent containing an unsaturated moiety. However, no details of its mechanism of action were proposed.

Our system shows a specific trend for the five oxy derivatives studied (OCH_3 **8**, OCH_2CH_3 **9**, $OCH{=}CH_2$ **10**, OAc **11**, and OPh **12**) and, for the three substituents mentioned above, the increasing order of axial populations is OPh < OAc < OCH_3. This trend is different from both that observed in the methylenecyclohexane family and that predicted from the effective electronegativity of the oxygen atom in the π–σ^* framework.

Comparison of OCH_3 and OCH_2CH_3 (8 and 9)

Now let us analyze the conformational trends of the OCH_3 (**8**) and the OCH_2CH_3 (**9**) derivatives. The C_e population of the OCH_2CH_3 derivative changes from 50% in CH_3OCH_3 to 80% in $CHFCl_2$ whereas for the OCH_3 substituent the trend is similar, but the total conformational change is reduced to 16%, that is, from 44% (CH_3OCH_3) to 60% (CHF_2Cl). The two derivatives differ only by a -CH_2- unit, which should not induce electronic perturbation on the oxygen atom. These substituents should also have a similar steric effect, but it is observed that the C_a population for OCH_2CH_3 is less than that for OCH_3 in the two solvents: 56% for OCH_3 and 50% for OCH_2CH_3 in the CH_3OCH_3 compared to 40% for OCH_3 and only 20% for OCH_2CH_3 in CHF_2Cl. The population difference is most probably due to electrostatic interactions associated with the characteristic rotamer difference between the two groups, which could affect the overall dipole moment.

Comparison of OCH_2CH_3 and $OCH{=}CH_2$ (9 and 10)

In the polar solvent (CHF_2Cl), the OCH_2CH_3 (**9**) and the $OCH{=}CH_2$ (**10**) derivatives show, respectively, 80% and 83% of the C_e form. Stabilization is therefore similar for these two derivatives and thus no unsaturation effect appears to be manifest. On the other hand, in the less polar solvent (CH_3OCH_3), the populations of the C_e form become 50% (OCH_2CH_3) and 82% ($OCH{=}CH_2$). Thus for the OCH_2CH_3 derivative an increase of the solvent polarity induces a great change in the C_e population: from 50% to 80%, but for the $OCH{=}CH_2$ substituent the solvent polarity increase has essentially no effect on the C_e amount. In the latter case, the observed behavior is similar to that noted for the *p*-$OPhOCH_3$ (**13**) derivative, as will be discussed further.

The phenoxy derivatives 12–14

The *para* hydrogen on the phenoxy ring (OPh) was replaced by an electron-withdrawing group (NO_2) and an electron-donating group (OCH_3). The results in THF-d_8 (Table 1) show 86% of the C_e form for the *p*-$OPhOCH_3$ derivative, 89% for OPh, and 88% for *p*-$OPhNO_2$. The constancy of these values suggests that delocalization involving the unsaturated part of the substituents is not a significant factor.

Behavior of the OAc derivative (11)

The observed C_e populations for OAc (**11**) and OCH_3 (**8**) are respectively 71% and 44% in the less polar solvent (CH_3OCH_3), while in the more polar solvent (CHF_2Cl) they become 65% (OAc) and 60% (OCH_3). These data show a small increase in the C_a population of OAc with an increase in the solvent polarity, but an increase in the C_e population of OCH_3. Therefore the more polar solvent stabilizes the C_a form for the OAc derivative and stabilizes the C_e form for OCH_3. Moreover, when the polarity of the solvent is increased, the C_a population of OAc (35% in CHF_2Cl) tends toward the C_a population of OCH_3 (40% in CHF_2Cl). These observations suggest, firstly, that the C_a form of OAc is more polar than the C_e form (as was confirmed by calculations using the Still–Steliou MODEL 2.93 program), contrary to what is calculated for compounds of the first subgroup, and, secondly, that the C_a form is destabilized by electrostatic interactions (11), which are responsible for the equatorial tendency of this substituent. It would therefore appear that in a polar solvent the electrostatic interactions are attenuated and only the intrinsic interactions of the molecule are operating, that is to say, the steric and orbital interactions. Therefore the particular behavior of the OAc derivative appears not to be due to an unsaturation effect but is caused by specific electrostatic interactions. Moreover, OAc is a complex group, and a change of 6% is too small to be used as evidence for a special effect.

Conclusion

The results obtained for both classes of substituents show a strong π–σ^* interaction for Cl and Br substituents but do not provide evidence for a novel effect arising from unsaturation in the oxygenated substituents of the 3-substituted benzocycloheptene family. The conformational behavior of the oxy derivatives can be rationalized from contributions of steric and electrostatic origin whereas the F substituent shows a strong attractive coulombic interaction.

Experimental

Melting points are uncorrected and were determined with a Thomas–Hoover (Uni-melt) melting point apparatus. High resolution MS spectra at 70 eV were recorded by using a Kratos MS-50 spectrometer.

Routine ^1H NMR spectra were taken on a Bruker WH-90 or a Varian VXR-300 spectrometer: solutions were typically 10% in $CDCl_3$ containing TMS as reference.

The variable temperature ^1H NMR spectra at 400.13 MHz and ^{13}C NMR spectra at 100.62 MHz were obtained by using a Bruker WH-400 spectrometer equipped with a variable temperature B-VT-1000 unit. Calibration, using a thermocouple inside a solvent-containing NMR tube, indicates that the low temperatures reported are exact within 3°C.

All ^{13}C NMR spectra were recorded with broadband proton decoupling, and the following instrumental parameters are typical: flip angle, 79°; SW = 20 000 Hz, data size = 16 K, AQ = 0.41 s. The spectra were recorded as solutions in CHF_2Cl, CH_3OCH_3, or THF-d_8 (100–150 mg in 2.2 mL of solution) containing TMS and about 15–20% of CD_2Cl_2 as locking agent, in standard 10-mm tubes that have been degassed and sealed.

^1H NMR spectra were recorded as solutions in CHF_2Cl, CF_2Cl_2, or THF-d_8 (5–10 mg in 0.55 mL of solution) containing TMS and about 15–20% of CD_2Cl_2 or CD_3COCD_3 (for locking purposes), in standard 5-mm tubes, which were degassed and sealed. The typical instrumental parameters used are as follows: flip angle = 30–87°; SW = 5000 Hz; data size = 8 and 16 K; AQ = 0.90–1.82 s.

Integrations were carried out by using Bruker software. The uncertainty is estimated as ±2% from standard deviation (18).

For the 2D COSY experiment, the following pulse sequence (7) was used: RD–90°–t_1–45°–acq. A spectral width of 2100 Hz was used with quadrature detection to collect a 256 × 1K data matrix. The

For personal use only.

matrix was zero-filled in the t_1 dimension and transformed in the magnitude mode by using the sine-bell square function.

The heteronuclear correlations were performed by using the HETCOR sequence (8, 9). Spectral widths of 300 Hz in the proton dimension and 1680 Hz in the carbon dimension were used to collect 128 FID in quadrature detection. The matrix was zero-filled in the t_1 dimension and transformed in the magnitude mode by using a Gaussian function to obtain a pseudo-echo shape of the peak.

*3-Methylbenzocycloheptene (**4**)*

This compound was prepared by catalytic hydrogenation of 3-methylenebenzocycloheptene (obtained by Wittig reaction (19) on benzosuberone) over palladium–charcoal (10%) at 35 psi (1 psi = 6.9 kPa) in AcOEt. The product obtained was identical to that described in ref. 20.

3-Hydroxybenzocycloheptene

Benzosuberone was reduced by $LiAlH_4$ in Et_2O using the standard procedure (21). ^1H NMR, δ($CDCl_3$): 1.80 (7H), 2.80 (2H), 4.25 (1H), 7.26 (4H).

*3-Fluorobenzocycloheptene (**5**)*

To a solution of 3-hydroxybenzocycloheptene (2 g, 12.3 mmol) in 100 mL of anhydrous CH_2Cl_2 at −25°C, 2.6 mL (36.9 mmol) of DAST ($(C_2H_5)_2NSF_3$) was added. The mixture was stirred overnight at room temperature, was afterwards cooled at −25°C, and 80 mL of methanol was added; the resulting solution was poured onto 800 mL of saturated aqueous $NaHCO_3$. This aqueous mixture was extracted with CH_2Cl_2 and the organic layer was washed with 5% HCl and brine. The organic layer was dried over $MgSO_4$ and the solvent was evaporated. The residue was distilled with a Kugelrohr distillation apparatus at 78°C/1 Torr (1 Torr = 133.3 Pa), and 1.2 g (63%) of a colorless liquid was obtained. ^1H NMR, δ($CDCl_3$): 1.70 (6H), 2.61 (2H), 5.60 (1H), 7.30 (4H); mass spectrum, calcd. for $C_{11}H_{13}F$, *M*: 164.1001; found (70 eV): 164.1002 (M^+), 144 ($M - HF)^+$.

*3-Chlorobenzocycloheptene (**6**)*

This compound was prepared as described by Huigsen *et al.* (21) from 3-hydroxybenzocycloheptene.

*3-Bromobenzocycloheptene (**7**)*

At 0°C, 1.33 mL (14.2 mmol) of PBr_3 was added to 2 g (12.3 mmol) of neat 3-hydroxybenzocycloheptene. After 2 h of stirring, 100 mL of hexane was added and the resulting organic layer was washed with the same amount of water. The organic layer was dried over $MgSO_4$ and the solvent was evaporated to give 2.5 g (89%) of yellow liquid. ^1H NMR, δ($CDCl_3$): 2.06 (7H), 3.30 (1H), 5.47 (1H), 7.14 (4H); mass spectrum, calcd. for $C_{11}H_{13}Br$, *M*: 224.0200; found (70 eV): 224.0220 (M^+), 144 ($M - HBr)^+$.

*3-Methoxybenzocycloheptene (**8**)*

This compound was prepared by alkylation of the alkoxide ion of 3-hydroxybenzocycloheptene with methyl iodide to obtain the product described in ref. 22.

*3-Ethoxybenzocycloheptene (**9**)*

This compound was prepared by the procedure for **8**. ^1H NMR, δ($CDCl_3$): 1.24 (3H, t), 1.70 (5H), 2.04 (1H), 2.67 (1H), 2.98 (1H), 3.44 (2H, q), 4.41 (1H), 7.15 (4H); mass spectrum, calcd. for $C_{13}H_{18}O$, *M*: 190.1358; found (70 eV): 190.1336 (M^+).

*3-Vinyloxybenzocycloheptene (**10**)*

This compound was prepared using the method described by Kodama *et al.* (5). ^1H NMR, δ($CDCl_3$): 1.85 (5H), 2.79 (1H), 2.89 (1H), 4.48 (1H), ABX: 4.38 (1H, A, dd), 4.11 (1H, B, dd), 6.45 (1H, X, dd), 7.20 (4H); mass spectrum, calcd. for $C_{13}H_{16}O$, *M*: 188.1201; found (70 eV): 188.1199 (M^+).

*3-Acetoxybenzocycloheptene (**11**)*

Esterification of 3-hydroxybenzocycloheptene by acetic anhydride in pyridine give the desired compound, described in ref. 5.

*3-Phenoxy, 3-paramethoxy, and 3-paranitrobenzocycloheptene (**12**, **13**, and **14**)*

These three compounds were prepared by the same method as next described for **12**. To a suspension of 0.53 g (22 mmol) of NaH in 25 mL of THF, a solution of 2.1 g (21 mmol) of phenol in 25 mL of THF was added dropwise. After the addition, a solution of 4 g (22 mmol) of 3-chlorobenzocycloheptene (**6**) and 0.6 g (3 mmol) of 18-crown-6 ether in 250 mL of anhydrous DMSO was added dropwise. The reaction mixture was heated at 70°C overnight, after which the solution was cooled to room temperature and 250 mL of water was added. The resulting solution was extracted with Et_2O. The organic layers were dried over $MgSO_4$ and the solvent was evaporated. The residue was chromatographed on silica gel with hexane/AcOEt to give 560 mg (11%) of a white solid, mp 83–84°C, which is the compound **12**. ^1H NMR, δ($CDCl_3$): 1.93 (6H), 2.90 (2H), 5.35 (1H), 7.10 (9H); mass spectrum, calcd. for $C_{17}H_{18}O$, *M*: 238.1358; found (70 eV): 238.1369 (M^+), 145 ($M - OPh)^+$.

Characteristics of compound **13**: white solid, mp 48.5–49.5°C; ^1H NMR, δ($CDCl_3$): 1.63 (6H), 2.85 (2H), 3.70 (3H, s), 5.22 (1H), 7.13 (4H, s), 7.20 (4H); mass spectrum, calcd. for $C_{18}H_{20}O_2$, *M*: 268.1463; found (70 eV): 268.1470 (M^+), 145 ($M - OPhOCH_3)^+$.

Characteristics of compound **14**: pale yellow solid, mp 117°C; ^1H NMR, δ($CDCl_3$): 1.70 (6H), 2.91 (2H), 5.45 (1H), 7.17 (4H), AB: 7.54 (4H); mass spectrum, calcd. for $C_{17}H_{17}NO_3$, *M*: 283.1208; found (70 eV): 283.1194 (M^+), 145 ($M - OPhNO_2)^+$.

Reçu le 1[cr] août 1989

J.-P. JAY-GERIN et C. FERRADINI. Can. J. Chem. **68**, 553 (1990).

D'après les données de la littérature, nous montrons qu'une corrélation peut être établie entre le coefficient d'extinction molaire au maximum du spectre d'absorption optique de l'électron solvaté (ϵ_{max}), la largeur de celui-ci à mi-hauteur ($W_{1/2}$) et l'énergie correspondant à ce même maximum (E_{Amax}).

Mots clés : électrons solvatés, solvants polaires, spectres d'absorption optique.

J.-P. JAY-GERIN and C. FERRADINI. Can. J. Chem. **68**, 553 (1990).

On the basis of data found in the literature, it is shown that a correlation exists between the molar extinction coefficient at the maximum optical absorption of the solvated electron (ϵ_{max}), its width at half height ($W_{1/2}$), and the energy corresponding to that maximum (E_{Amax}).

Key words: solvated electrons, polar solvants, optical absorption spectra.

[Journal translation]

Les spectres d'absorption optique correspondant à des électrons en excès complètement relaxés dans un liquide polaire ont été déterminés expérimentalement pour un grand nombre de solvants, ainsi que nous l'avons déjà souligné (1). Il nous est donc apparu possible, sur la base des données disponibles actuellement, de tenter d'élargir la systématique concernant ces spectres, par exemple en essayant d'établir une corrélation entre le coefficient d'extinction molaire au maximum du spectre (ϵ_{max}), la largeur à mi-hauteur de celui-ci ($W_{1/2}$) et l'énergie (E_{Amax}) correspondant à ce même maximum. Sur le plan pratique, il serait intéressant, tout particulièrement, de pouvoir exprimer ϵ_{max} et $W_{1/2}$ en fonction de E_{Amax}. En effet, cela permettrait d'obtenir une caractérisation a priori de la forme du spectre d'électrons solvatés dans n'importe quel solvant polaire à partir de la seule détermination expérimentale de la longueur d'onde correspondant au maximum d'absorption.

Dans le tableau 1, nous avons rassemblé les données expérimentales trouvées dans la littérature pour 43 solvants de polarités diverses à la température ambiante (2–54). Les solvants sont classés par ordre des valeurs croissantes de ϵ_{max}. On peut remarquer que les valeurs de ϵ_{max} et de $W_{1/2}$ varient respectivement entre 0,6 et $5 \times 10^4\ M^{-1}\ cm^{-1}$ et entre 1,63 et 0,41 eV, alors que celles de E_{Amax} sont comprises entre 2,33 et 0,5 eV.

Nous avons tracé dans un diagramme semi-logarithmique (figure 1) la variation de ϵ_{max} en fonction de E_{Amax}. Une corrélation linéaire décrit de façon satisfaisante les données expérimentales. La relation entre ces deux paramètres peut donc s'écrire sous la forme

$$[1] \quad \epsilon_{max} = \epsilon^0_{max} \exp(-\alpha E_{Amax})$$

Un ajustement utilisant la méthode des moindres carrés conduit à $\epsilon^0_{max} = 5{,}48 \times 10^4\ M^{-1}\ cm^{-1}$ et pour la valeur de la pente de la droite à $\alpha = 0{,}81\ eV^{-1}$ avec un coefficient de corrélation égal à 0,914. Afin de mieux visualiser la relation ainsi établie, nous avons reporté sur la figure 2 quelques spectres typiques

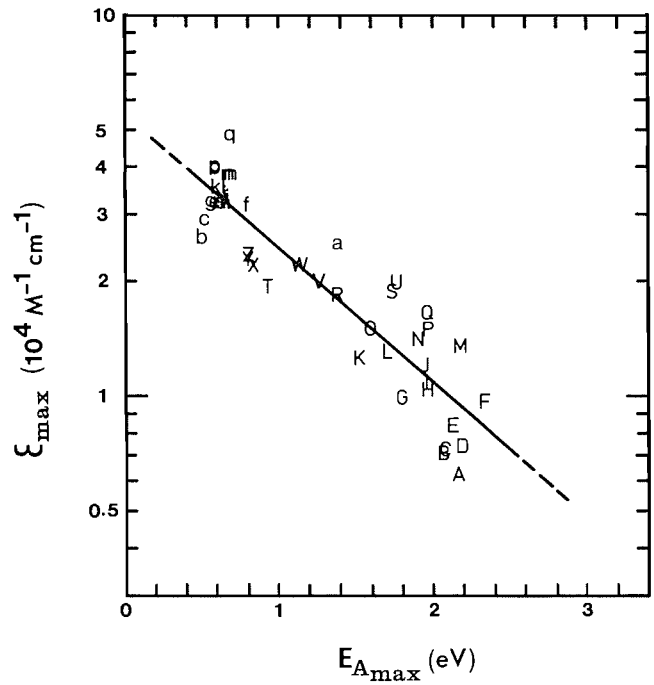

FIG. 1. Diagramme semilogarithmique montrant la variation de ϵ_{max} en fonction de E_{Amax}. La droite en trait plein a été obtenue à l'aide d'un ajustement par la méthode des moindres carrés de l'équation [1] aux données expérimentales trouvées dans la littérature pour 43 solvants de polarités diverses à la température ambiante (voir tableau 1).

d'électrons solvatés, ainsi que la courbe exponentielle représentant la relation [1].

Il est intéressant de souligner ici que l'existence d'une telle corrélation entre ϵ_{max} et E_{Amax} implique une importante conséquence. En effet, si nous appelons dN_{max} la variation de la concentration en électrons solvatés susceptibles d'absorber un

[b]Utilisé dans les figures 1, 3 et 4.
[c]Valeur estimée.
[d]Les cétones captent les électrons. Il est possible que le spectre obtenu dans le butanone-2 (point a) corresponde à celui d'un radical anion (G. R. Freeman, communication personnelle).

photon dont l'énergie est comprise entre E_{Amax} et $E_{Amax} + dE_{Amax}$ lorsqu'on passe d'un solvant au suivant,

[2] $$d\epsilon_{max} = \beta\, dN_{max} = \gamma \epsilon_{max}\, dE_{Amax}$$

le nombre d'électrons étant proportionnel à l'élément de surface sous la courbe $\epsilon_{max}(E_{Amax})$. Dans le cas général, on s'attendrait à ce que β et γ soient fonctions de la nature du solvant et donc de E_{Amax}. Il n'en est cependant rien puisque la relation [2] est identique à la relation expérimentale [1] avec $\gamma = -\alpha$. Par conséquent, la variation de ϵ_{max} avec E_{Amax} provient essentiellement de la modification concomitante de la forme des spectres, chaque électron solvaté contribuant de la même manière à la valeur de ϵ_{max} quelle que soit la nature du solvant. Ceci n'est valable que dans la mesure évidemment où la relation [1] est vérifiée. La dispersion des points expérimentaux de la figure 1 pourrait traduire la part due à l'influence de la nature du solvant.

À notre connaissance, aucun modèle théorique n'a prédit jusqu'ici une variation exponentielle de ϵ_{max} avec E_{Amax}. Il faut dire à ce sujet que la nature des transitions optiques responsables du spectre d'absorption de l'électron solvaté reste encore à ce jour relativement mal comprise. On sait en effet qu'un

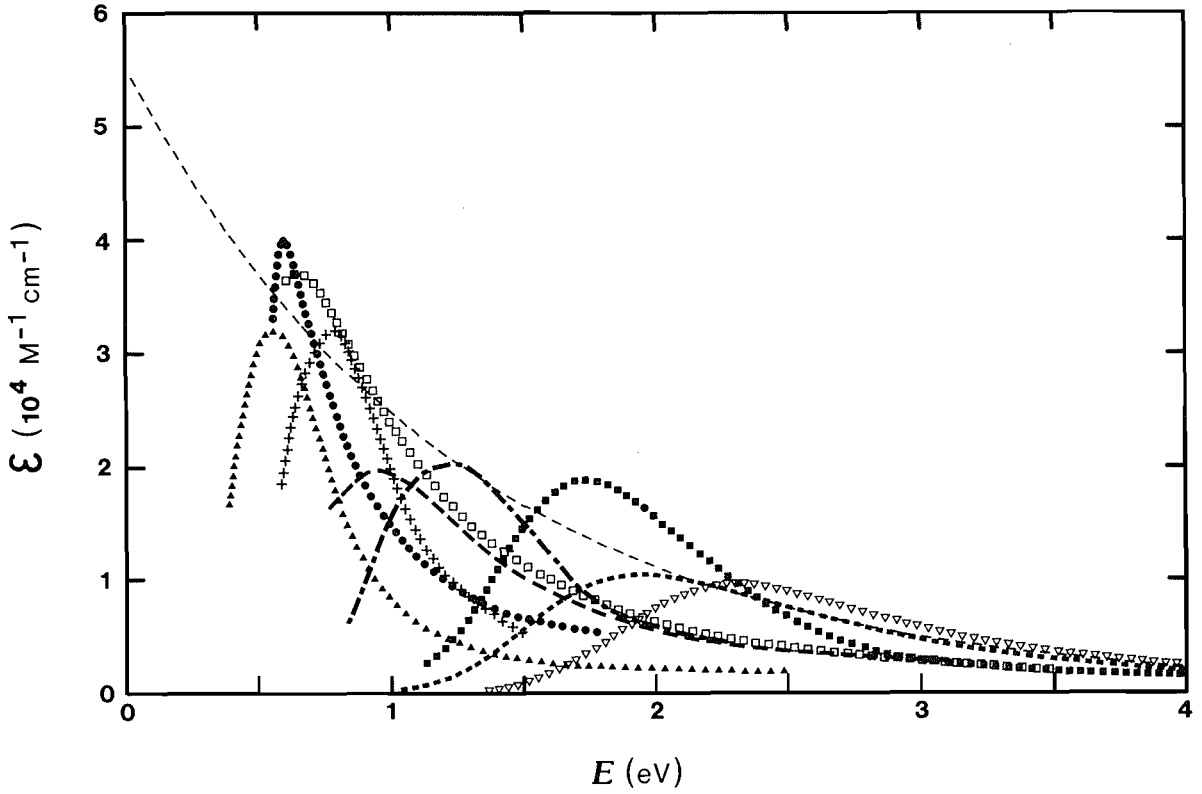

FIG. 2. Spectres typiques d'absorption d'électrons solvatés $\epsilon(E)$, à la température ambiante, dans divers solvants : ▲▲▲, hexaméthylphosphoramide; ●●●, tétrahydrofuranne; □□□, *n*-propylamine; + + +, *N*-méthylpyrrolidinone; ––, diamino-1,2 éthane; - - -, hydrazine; ■■■, H_2O; ---, méthanol; ▽▽▽, glycérol. La courbe exponentielle en tirets représente le lieu géométrique des maxima ϵ_{max} des différents spectres tel que donné par la relation [1].

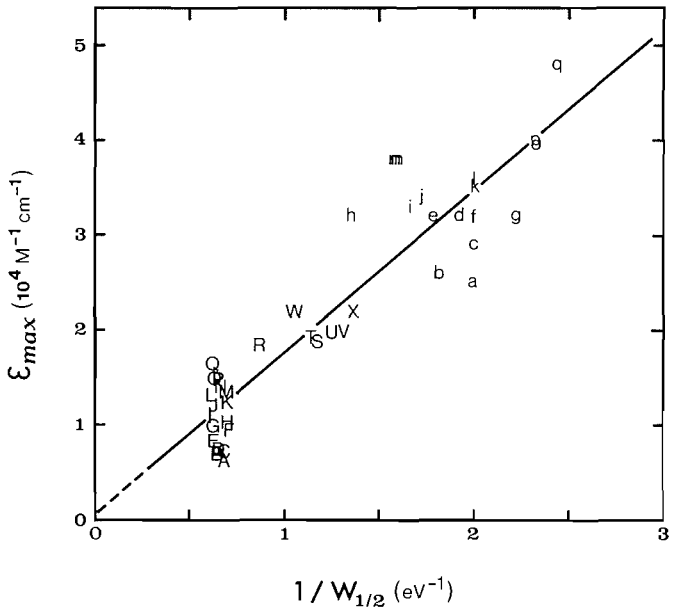

FIG. 3. Variation de ϵ_{max} en fonction de $1/W_{1/2}$. La droite en trait plein a été obtenue à l'aide d'un ajustement par la méthode des moindres carrés de l'équation [3] aux données expérimentales trouvées dans la littérature pour 41 solvants de polarités diverses à la température ambiante (voir tableau 1).

désaccord persiste entre les auteurs en ce qui concerne la nature physique des états électroniques finals, la question posée restant de savoir si les transitions mises en jeu se font vers des états liés, ou bien vers un continuum d'états délocalisés (55). Puisque ϵ_{max} reflète une mesure de la section efficace d'interaction entre un électron solvaté et un photon d'énergie E_{Amax}, la relation [1] obtenue dans ce travail, bien qu'approximative, pourrait apporter un indice utile à notre quête d'une meilleure compréhension de la nature du spectre d'absorption de l'électron solvaté.

Dans la figure 3 nous avons tracé la variation de ϵ_{max} en fonction de $1/W_{1/2}$. Une corrélation linéaire est observée, dont l'extrapolation aux faibles valeurs de $1/W_{1/2}$ passe pratiquement par l'origine. Une telle relation peut donc s'écrire sous la forme

$$[3] \quad \epsilon_{max} = \eta\left(\frac{1}{W_{1/2}}\right) + \mu$$

Un ajustement par la méthode des moindres carrés conduit à $\eta = 1{,}71 \times 10^4\ M^{-1}\ cm^{-1}\ eV$ et $\mu = 0{,}054 \times 10^4\ M^{-1}\ cm^{-1}$ avec un coefficient de corrélation égal à 0,921.

Cette corrélation linéaire entre ϵ_{max} et $1/W_{1/2}$ pouvait être attendue. En effet, de nombreux auteurs, et en particulier Freeman et coll. (4, 10, 41, 56), ont signalé que la valeur de la force d'oscillateur (f) correspondant au spectre d'absorption de l'électron solvaté varie peu lorsqu'on passe d'un solvant à l'autre. f est défini par (57)

$$[4] \quad f = 3{,}49 \times 10^{-5} \int_0^\infty \epsilon(E)\, dE$$

où $\epsilon(E)$ est le coefficient d'extinction molaire à l'énergie E (eV). L'intégrale de la relation [4], qui représente l'aire totale sous la courbe $\epsilon(E)$, peut être calculée avec une bonne approximation par l'équation

$$[5] \quad \int_0^\infty \epsilon(E)\, dE \simeq \epsilon_{max} W_{1/2}$$

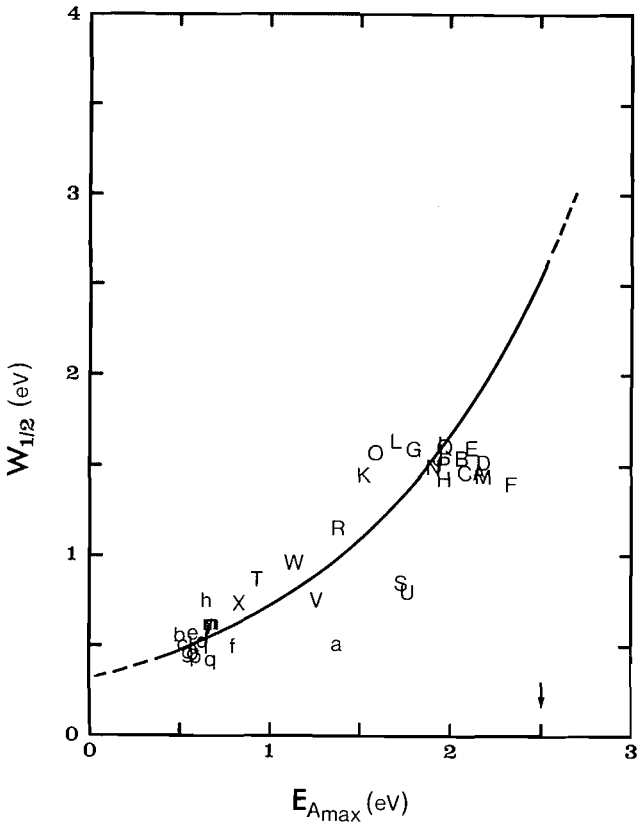

FIG. 4. Variation de $W_{1/2}$ en fonction de E_{Amax}. La courbe en trait plein illustre la relation [6]. Les données expérimentales du tableau 1 sont également représentées afin de vérifier la validité de la loi $W_{1/2}(E_{Amax})$ trouvée. La flèche indique la limite supérieure pour E_{Amax} (~2,5 eV), telle que suggérée par Freeman (58).

D'après les relations [4] et [5], on s'attend donc bien à ce que le produit $\epsilon_{max} W_{1/2}$ soit peu modifié d'un solvant à l'autre, et par conséquent à ce que ϵ_{max} varie de façon sensiblement inversement proportionnelle avec $W_{1/2}$.

On peut calculer, en utilisant les relations [3]–[5] et en prenant en compte l'ensemble des solvants considérés dans cette étude, une valeur moyenne de f. Si l'on s'en tient à la détermination précédente de η et μ, on obtient $f \simeq 0{,}62$. Une telle valeur s'accorde bien avec les données de la littérature concernant les différents solvants.

L'existence d'une corrélation, d'une part entre ϵ_{max} et E_{Amax}, et d'autre part entre ϵ_{max} et $W_{1/2}$, implique comme conséquence une corrélation entre $W_{1/2}$ et E_{Amax}. Les relations [1] et [3] donnent en effet immédiatement

$$[6] \quad W_{1/2} = \frac{1}{a \exp(-\alpha E_{Amax}) - b}$$

avec $a = \epsilon^0_{max}/\eta = 3{,}20\ \text{eV}^{-1}$ et $b = \mu/\eta = 0{,}032\ \text{eV}^{-1}$, et où $W_{1/2}$ et E_{Amax} sont exprimés en eV. La relation [6] est représentée figure 4. Afin de vérifier la validité de la loi $W_{1/2}(E_{Amax})$ ainsi trouvée, nous avons également porté sur cette même figure les données expérimentales (voir tableau 1). Comme on peut le voir, l'accord obtenu est satisfaisant.

En conclusion, nous avons montré, sur la base des données de la littérature, qu'il est possible d'établir une corrélation entre le coefficient d'extinction molaire au maximum du spectre d'absorption optique de l'électron solvaté, la largeur à mi-hauteur de celui-ci et l'énergie correspondant à ce même maximum. Cette corrélation est intéressante sur un plan pratique, car elle permet une estimation a priori de la forme du spectre d'électrons solvatés dans un solvant polaire donné. Sur un plan plus fondamental, elle pourrait apporter un élément utile à la compréhension de la nature du spectre de l'électron solvaté.

Remerciements

Les auteurs tiennent à exprimer leurs remerciements au Conseil de recherches médicales du Canada et au Programme de coopération franco-québécoise en recherche médicale pour l'aide financière qu'ils leur ont apportée.

Synthesis and substitution chemistry of some bis(dithiolate) complexes of molybdenum, $Mo(S_2C_6H_3R)_2(PMePh_2)_2$, R = H, Me

NATALIE J. LAZAROWYCH AND ROBERT H. MORRIS

Department of Chemistry and the Scarborough Campus, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received September 5, 1989

NATALIE J. LAZAROWYCH and ROBERT H. MORRIS. Can. J. Chem. **68**, 558 (1990).

The new bis(dithiolate) complexes $Mo(1,2\text{-}S_2\text{-}4\text{-}R\text{-}C_6H_3)_2(PMePh_2)_2$, R = H, Me, are readily synthesized from three different types of starting materials: *trans*-$Mo(N_2)_2(PMePh_2)_4$, $MoCl_4(PMePh_2)_2$, and $MoOCl_2(PMePh_2)_3$. The ^{31}P NMR spectra of the dithiolate complexes at low temperature are consistent with a *cis* stereochemistry of the $PMePh_2$ ligands and isomerism with respect to inversion at sulfur and relative positioning of the methyl groups on the chelating $1,2\text{-}S_2\text{-}4\text{-}Me\text{-}C_6H_3$ ligands. The singlet in the ^{31}P NMR spectrum at room temperature arises from rapid interconversion of these isomers. Substitution of one or two of the $PMePh_2$ ligands in the dithiolate complexes proceeds under mild conditions to give the complexes $Mo(S_2C_6H_4)_2(CO)(PMePh_2)$, $Mo(S_2C_6H_4)_2(CN\text{-}t\text{-}Bu)(PMePh_2)$, $Mo(S_2C_6H_3Me)_2(dppe)$, $Mo(S_2C_6H_4)_2(depe)$, $Mo(S_2C_6H_4)_2(PMePh_2)(PMe_3)$, $Mo(S_2C_6H_4)_2(PMePh_2)(P(OMe)_3)$, and $Mo(S_2C_6H_4)_2(P(OMe)_3)_2$. The ^{31}P and ^{13}C NMR spectroscopy of these bis(dithiolate) complexes suggest that they have monodentate ligands *cis* disposed.

A reversible equilibrium exists between $Mo(S_2C_6H_4)_2(PMePh_2)_2$ and $Mo(S_2C_6H_4)_2(CO)(PMePh_2)$ in the presence of carbon monoxide in solution. Isolation of $Mo(S_2C_6H_4)_2(CO)(PMePh_2)$ is facilitated by use of CH_3I as a "phosphine sponge" reagent. If the sulfur ligands are viewed as dianions, then this is the first thermally stable carbonyl complex of molybdenum(IV).

Keywords: molybdenum, dithiolate, diphenylmethylphosphine, carbonyl, NMR.

NATALIE J. LAZAROWYCH et ROBERT H. MORRIS. Can. J. Chem. **68**, 558 (1990).

De nouveau complexes bis(dithiolate), $Mo(1,2\text{-}S_2\text{-}4\text{-}R\text{-}C_6H_3)_2(PMePh_2)_2$ dans lesquels R = H ou Me, peuvent facilement être synthétisés à partir des composés suivants : *trans*-$Mo(N_2)_2(PMePh_2)_4$, $MoCl_4(PMePh_2)_2$, et $MoOCl_2(PMePh_2)_3$. Les spectres RMN du ^{31}P des complexes dithiolates, réalisés à basse température, correspondent à une stéréochimie *cis* des ligands $PMePh_2$ et à une isomérie par rapport à l'inversion au niveau du soufre et aux positions relatives des groupements méthyles sur les ligands chélatants $1,2\text{-}S_2\text{-}4\text{-}Me\text{-}C_6H_3$. Le singulet observé dans le spectre RMN du ^{31}P enregistré à la température ambiante provient d'une interconversion rapide de ces isomères. La substitution de l'un ou des deux ligands $PMePh_2$ des complexes dithiolates peut se faire dans des conditions douces pour conduire aux complexes $Mo(S_2C_6H_4)_2(CO)(PMePh_2)$, $Mo(S_2C_6H_4)_2(CN\text{-}t\text{-}Bu)(PMePh_2)$, $Mo(S_2C_6H_3Me)_2(dppe)$, $Mo(S_2C_6H_4)_2(depe)$, $Mo(S_2C_6H_4)_2(PMePh_2)(PMe_3)$, $Mo(S_2C_6H_4)_2(PMePh_2)(P(OMe)_3)$ et $Mo(S_2C_6H_4)_2(P(OMe)_3)_2$. Les spectres RMN du ^{31}P et du ^{13}C de ces complexes bis(dithiolates) suggèrent que les ligands monodentates sont disposés d'une façon *cis*.

En solution, en présence de monoxyde de carbone, il existe un équilibre réversible entre le $Mo(S_2C_6H_4)_2(PMePh_2)_2$ et le $Mo(S_2C_6H_4)_2(CO)(PMePh_2)$. Pour isoler le $Mo(S_2C_6H_4)_2(CO)(PMePh_2)$ plus facilement, on peut utiliser du CH_3I comme « éponge de phosphine ». Si l'on considère les ligands sulfurés comme des dianions, on peut alors considére ces complexes comme les premiers complexes du molybdène(IV)-carbonyle qui soient thermiquement stables.

Mots clés : molybdène, dithiolate, diphénylméthylphosphine, carbonyle, RMN.

[Traduit par la revue]

Introduction

Some important industrial chemical processes like hydrodesulfurization and biological processes like nitrogen fixation involve complexes where molybdenum is ligated primarily by sulfur donors. In the course of our studies of the properties of such complexes that also contain hydride ligands (1, 2), we identified the complexes $Mo(S_2C_6H_3R)_2(PMePh_2)_2$, R = H (**1***a* with the benzene-1,2-dithiolato ligand) and R = Me (**1***b* with the toluene-3,4-dithiolato ligand) as the products of the reaction of the hydride complexes $Mo(H)_2(S_2C_6H_3R)(PMePh_2)_3$ with excess dithiol ligand (reaction [1]).

[1] $Mo(H)_2(S_2C_6H_3R)(PMePh_2)_3 + (HS)_2C_6H_3R \rightarrow Mo(S_2C_6H_3R)_2(PMePh_2)_2 + 2\ H_2 + PMePh_2$

This is a report on the spectroscopy and chemistry of complexes **1** that have not been previously investigated.

The only directly related work is by Sellmann and Reisser (3). The complex $Mo(S_2C_6H_4)_2(PMe_3)_2$ was prepared via the dealkylation of $NaSC_6H_4S(CH_2)_2SC_6H_4SNa$ (Na_2dttd) upon reaction of this potentially tetradentate ligand with $MoCl_2(PMe_3)_4$ (reaction [2]).

[2] $MoCl_2(PMe_3)_4 + NaSC_6H_4S(CH_2)_2SC_6H_4SNa \rightarrow Mo(S_2C_6H_4)_2(PMe_3)_2 + 2\ NaCl + 2\ PMe_3 + C_2H_4$

The stereochemistry of $Mo(S_2C_6H_4)_2(PMe_3)_2$ was not elucidated. Other formally Mo(IV) complexes with four nonbridging thiolate ligands include $Mo(S\text{-}t\text{-}Bu)_4$ (4), $Mo(TIPT)_4$ (5), $Mo(TIPT)_4(RC{\equiv}CR)$ (TIPT = S-2,4,6-$C_6H_2(CHMe_2)_3$) (6), and $Mo(S_2C_6H_4)_3^{2-}$ (7). There is a wealth of chemistry associated with complexes of Mo(II) coordinated by four sulfur atoms and, usually, three other ligands like $Mo(dttd)(CO)_2(PMe_3)$ (8), $Mo(S_2PPh_2)_2(CO)_2(PPh_3)$ (9), and $Mo(S_2CNR_2)_2(CO)(PMe_3)_2$ (10).

Experimental

General

All manipulations were performed using Schlenk flasks or a glove-box filled with pure nitrogen. Literature procedures that were used to make *trans*-$Mo(N_2)_2(PMePh_2)_4$ (11–13), $Mo(H)_4(PMePh_2)_4$ (14), $MoOCl_2(PMePh_2)_3$ (15), $MoOCl_2(PEtPh_2)_3$ (15), and $1,2\text{-}(SH)_2\text{-}C_6H_4$ (16) have been described. $MoCl_5$ (resublimed) was purchased from Alfa Chemicals (Danvers) and used as such. Other ligands were purchased from Aldrich Chemical Company (Milwaukee, WI), or from Strem Chemicals (Newbury Port, MA).

Solvents other than alcohols were dried over and distilled from sodium benzophenone ketyl and were degassed before use. Alcohols were distilled from their magnesium alkoxides. Tetrahydrofuran (THF) was further dried over and vacuum distilled from $LiAlH_4$.

The infrared spectra were obtained by use of a Nicolet 5DX FTIR

spectrometer (±2 cm^{-1}) as mineral oil mulls on NaCl plates or as solutions in 0.1 mm KBr cells.

The NMR spectra were recorded by use of a Varian XL200 spectrometer operating at 80.98 MHz for ^{31}P, 200 MHz for ^{1}H, or a Varian XL400 operating at 161.98 MHz for ^{31}P and 400 MHz for ^{1}H. ^{31}P chemical shifts were recorded relative to 1% $P(OMe)_3$ in C_6D_6 in a coaxial capillary. ^{1}H chemical shifts were measured relative to residual non-deuterated solvent peaks or silicone grease (0.297 ppm in C_6D_6), and then reported relative to TMS. All resonances are singlets unless otherwise stated. All spectra were obtained at 22°C unless otherwise indicated.

Microanalyses were performed by Canadian Microanalytical Services, Vancouver, B.C.

Visible absorption spectra were recorded using a Perkin Elmer Lambda 3B UV/visible spectrophotometer and a Perkin Elmer R100 recorder.

Mass spectra were obtained using a VG 70-250S instrument. Xe atom flux was used along with nitrophenyl octyl ether (NPOE) or nitrobenzyl alcohol (NBA) as the matrices (17). The matrices were degassed before use. The compounds were stored in vials with septa under nitrogen or argon and usually added as solids to the matrix that had been applied to the target, these applications being performed as quickly as possible in air.

Preparation of cis-$Mo(S_2C_6H_3Me)_2(PMePh_2)_2$ *from* $MoOCl_2(PMePh_2)$

$MoOCl_2(PMePh_2)_3$ (0.510 g, 0.651 mmol) was suspended in benzene (20 mL) and frozen 1,2-$(SH)_2$-4-CH_3-C_6H_3 (0.203 g, 1.30 mmol) was added. The green suspension was stirred to yield a red slurry-solution within 2 min. The mixture then became a red solution as it stirred for 2.7 h. The solvent was reduced in volume, using vacuum, to 2 mL and the resulting red solid was separated by filtration (0.41 g, 0.50 mmol, 77% yield) and recrystallized from benzene/pentanes. The sample was contaminated with silicone stopcock grease. Anal. calcd. for $MoS_4P_2C_{40}H_{38}\cdot 0.2SiO(CH_3)_2$: C 59.20, H 4.82; found: C 59.09, H 4.88. FAB^+ MS (toluene/NPOE matrix): 806.2 maximum corresponding to $^{98}Mo(S_2C_6H_3Me)_2(PMePh_2)_2$ isotopomer. Superior signal-to-noise ratio spectra were obtained when a toluene slurry was dabbed onto the target, which was coated with NPOE, as opposed to using a solution of the compound in toluene/NPOE. $^{31}P\{^{1}H\}$ NMR (red-orange C_6H_6 solution) δ: −102.7. $^{31}P\{^{1}H\}$ NMR (90% toluene/10% C_6D_6, 161.98 MHz, −70°C): three sets of complex multiplets (each of approximately equal integration) having maxima at δ −98.42 (A), −98.38 (B), −101.23 (C) ppm, the most discernable peaks occurring at −98.0, −98.42, −98.60; −99.18, −99.38, −99.5, −99.71; −100.93, −101.24, −101.46; see discussion section for structures of A, B, and C.

Preparation of cis-$Mo(S_2C_6H_4)_2(PMePh_2)_2$

Method A

$MoOCl_2(PMePh_2)_3$ (0.51 g, 0.65 mmol) and 1,2-$(SH)_2$-C_6H_4 (0.20 g, 1.41 mmol) were reacted in a similar fashion to the 1,2,-S_2-4-$CH_3C_6H_3$ derivative (see above). The mixture appeared as a red slurry-solution, then a homogeneous red solution, and then a red solution with red and black precipitate. Dinitrogen purge reduced the solvent volume to 10 mL. The red solid was separated from the red liquid using filtration (0.38 g, 0.49 mmol, 75% yield). The red solid was recrystallized from benzene/pentanes. Anal. calcd. for $MoS_4P_2C_{38}H_{34}\cdot C_6H_6$: C 61.82, H 4.72; found: C 61.78, H 4.79. ^{1}H NMR (C_6D_6, 200 MHz) δ: 2.01 (br, 6H, PMe); 6.73(br), 7.081, 7.089, 7.096, 7.104, 8.347(br) (32 H (expect 28), aromatic protons of thiol and phosphine ligands). $^{31}P\{^{1}H\}$ NMR (orange-red C_6H_6 solution) δ: −102.6 ppm. $^{31}P\{^{1}H\}$ NMR (toluene, −75.5°C, lock methanol-d_4 in insert, ref. external $P(OMe)_3$ in acetone-d_6, approximate integrations in parentheses) δ: −97.98 (1), A; −98.94(1), B; −100.65(0.5), C; −100.76(0.5), C. See discussion for structures of conformers A, B, and C. λ_{max} (pale orange benzene solution, quartz cells): 421 nm, 360 nm (less intense maximum).

Method B

An orange solution of $Mo(N_2)_2(PMePh_2)_4$ (3.2 g, 3.4 mmol) in benzene (100 mL) was degassed with hydrogen (three cycles of evacuation and backfill with gas) and then left to stir under hydrogen for 45 min at 75°C. The solvent was removed from the resultant yellow solution using vacuum, leaving $MoH_4(PMePh_2)_4$ as a dirty yellow solid. Benzene (70 mL) and 1,2-$(SH)_2$-C_6H_4 (1.0 g, 7.0 mmol) were added and the yellow solution was stirred for 40 min, during which time it became a very dark red colour. The solvent was concentrated to 5 mL, using vacuum, to give a red precipitate. Recrystallization of this material from benzene/hexanes afforded a red solid (70% yield). $^{31}P\{^{1}H\}$ NMR δ: −102.82.

Crude molecular weight determination of cis-$Mo(S_2C_6H_4)_2(PMePh_2)_2$

The Signer method for molecular weight determination was employed (18, 19). The sample solution of $Mo(S_2C_6H_4)_2(PMePh_2)_2$ (0.020 g, 0.0257 mmol) in THF (2.503 g), and the reference solution of benzophenone (0.054 g, 0.296 mmol) in THF (3.007 g) were prepared. An equal volume (1.00 mL) of each of the sample and reference solutions was transferred into the appropriate compartment of the Signer apparatus. The solutions were freeze–thaw degassed three times. The initial volumes of each solution were marked on the arms of the apparatus using a fine felt-tipped glass marker. The solutions were drained from the arms into the round-bottom compartments of the apparatus and the vapours were allowed to equilibrate between compartments. After 5, 12, 13, 27, and 50 days of equilibration the solutions were drained into the arms of the apparatus, the volume marked, and the solution returned into the round-bottom compartment. The volume did not change between 27 and 50 days. On the 50th day the solutions were removed and the volume markings calibrated using microlitre syringes and dichloromethane. The approximate molecular weight, as determined by partial vapour pressure equilibration of the two solutions, is 970 ± 200 (calcd. 804).

Preparation of cis-$Mo(S_2C_6H_4)_2(CO)(PMePh_2)$

$Mo(1,2\text{-}S_2\text{-}C_6H_4)_2(PMePh_2)_2$ (1.58 g, 2.043 mmol) was partially dissolved in benzene (200 mL). The flask was evacuated and filled with carbon monoxide (1 atm (101.3 kPa)) three times. Iodomethane (320 μL, 0.73 g, 5.14 mmol) was then added to the orange-red mixture. After stirring for 10 min, the reaction solution turned deep pink. The solution was stirred under carbon monoxide for 3 days and then stored at −20°C for 3 days. The solvent was then reduced to 150 mL by N_2 purge at 20°C. Diethyl ether (200 mL) was added. The white precipitate ($[PMe_2Ph_2]I$, see below) that formed was filtered off along with a small amount of starting complex. All except a small amount of the solvent was removed from the pink filtrate using a carbon monoxide purge. The deep pink solid was then filtered off and washed with ether (0.71 g, 1.17 mmol, 57% yield). Anal. calcd. for $MoS_4POC_{26}H_{21}$: C 51.65, H 3.50; found: C 51.32, H 3.58. $^{31}P\{^{1}H\}$ NMR (benzene) δ: −95.51 ppm. ^{13}C NMR ($CDCl_3$, all resonances not assigned arise from carbons on the aromatic dithiolate ligand, or carbons of the phenyl groups on the phosphine ligand) δ: 230.3 (doublet, J_{PC} = 11.9 Hz, MoCO); 184.3 (weak); 156.0; 135.0; 134.1; 132.9 (doublet, J = 9.5 Hz); 130.4 (doublet, J = 2.2 Hz); 129.3; 128.4 (doublet, J = 10.0 Hz); 124.1; 18.3 (doublet, J_{PC} = 33.4 Hz, PCH_3). FAB^+ MS (NBA or NPOE matrix): 578 largest peak due to $^{98}Mo(S_2C_6H_4)_2(PMePh_2)$ (i.e., $M^+ - CO$). The ion current for the 578 peak (and hence the observed intensity) was much greater when NBA was used as the matrix. IR(mineral oil mull), ν_{CO}: 1977 cm^{-1}. Characterization of $[PMe_2Ph_2]I$, the white solid recovered (0.4 g, 1.2 mmol, 60% yield), was as follows. $^{31}P\{^{1}H\}$ NMR (colourless acetone/acetone-d_6 solution) δ: −114.3. ^{1}H NMR (C_6D_6) δ: 2.76 (doublet, J_{PH} = 13.9 Hz, 6H, PMe_2); 7.83–7.49 (multiplet, 10H, PPh_2).

Preparation of cis-$Mo(S_2C_6H_4)_2(CN\text{-}t\text{-}Bu)(PMePh_2)$

$Mo(S_2C_6H_4)_2(PMePh_2)_2$ (0.2 g, 0.26 mmol) and *tert*-butyl isonitrile (0.021 g, 0.25 mmol) were stirred together in 20 mL benzene for 1.5 h. The tomato-juice-red coloured slurry-solution of $Mo(S_2C_6H_4)_2(PMePh_2)_2$ became a clear dark cranberry-red coloured solution almost

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

immediately upon addition of the isonitrile. Vacuum was used to reduce the solvent volume to 2 mL and then pentanes were added to cause precipitation of a red solid. The solid, collected by filtration, was recrystallized using benzene and pentanes at room temperature. The resultant solid was dried *in vacuo* (0.04 g, 24%). Anal. calcd. for $MoS_4PNC_{30}H_{30}$: C 54.62, H 4.58, N 2.12; found: C 54.72, H 4.63, N 2.13. $^{31}P\{^1H\}$ NMR (benzene) δ: −94.0. ^1H NMR (C_6D_6, 200 MHz) δ: 0.83 (9H, *t*-Bu); 2.39 (d, J_{PH} = 7.6 Hz, 3H, PMe); 6.7–7.3 (multiplet, 10H); 7.04, 7.06, 7.07, 7.09, 8.36, 8.38, 8.39, 8.41 (8H, part of AA′XX′ pattern due to similar environments of thiol ligands). IR(mineral oil mull), ν_{CN}: 2138 cm^{-1}.

Generation of $Mo(S_2C_6H_3Me)_2(dppe)$ from $MoCl_4(dppe)$

$MoCl_4(dppe)$, dppe = $PPh_2CH_2CH_2PPh_2$, was prepared by slight modification of the method of Butcher and Chatt (15). $MoCl_4(THF)_2$ (20) was used in the preparation instead of $MoCl_4(EtCN)_2$. To a tawny-orange solution-slurry of $MoCl_4(dppe)$ (0.057 g, 0.090 mmol) in 20 mL benzene was added 1,2-$(SH)_2$-4-CH_3-C_6H_3 (0.028 g, 0.179 mmol). The reaction was allowed to sir overnight under a dynamic N_2 atmosphere during which time the solvent evaporated. The following morning a green oily solid, which was relatively insoluble, remained in the flask. $^{31}P\{^1H\}$ NMR (green C_6H_6 solution) δ: −75.6 (weak). FAB^+ MS (slurry in NPOE matrix), calcd. mass of isotopomer, relative amount: 798, 40; 799, 20; 800, 40; 801, 60; 802, 80; 803, 70; 804, 100; 805, 48; 806, 52; 807, 20; 808, 10; found: 798, 40; 799, 30; 800, 50; 801, 70; 802, 81; 803, 70; 804, 100; 805, 58; 806, 56; 807, 20; 808, 10; the maximum at 804 corresponds to $^{98}Mo(S_2C_6H_3Me)_2(dppe)$.

Generation of $Mo(S_2C_6H_3Me)_2(dppe)$ from $Mo(S_2C_6H_3Me)_2(PMePh_2)_2$

$Mo(S_2C_6H_3Me)_2(PMePh_2)_2$ (0.33 g, 0.41 mmol) was dissolved in benzene (5 mL). 1,2-Bis(diphenylphosphino)ethane (dppe, 0.18 g, 0.45 mmol) was added to this red solution and the solution turned green over 3 days. $^{31}P\{^1H\}$ NMR (benzene) δ: −76.0 ($Mo(S_2C_6H_3Me)_2$-(dppe); −168 (free $PMePh_2$).

Observation of $Mo(S_2C_6H_4)_2(depe)$ by ^{31}P NMR

$Mo(S_2C_6H_4)_2(PMePh_2)_2$ (0.20 g, 0.26 mmol) and depe, Et_2PCH_2-CH_2PEt_2 (0.053 g, 0.26 mmol), were stirred together in 20 mL benzene. The reaction mixture rapidly changed from tomato juice colour to a clear red solution within seconds. After 0.5 h of reaction time the solution turned red-brown. After 1.75 h all solvent was removed in vacuum to yield a red oily solid. $^{31}P\{^1H\}$ NMR (benzene) δ: −79.7 ($Mo(depe)(S_2C_6H_4)_2$); −168 (free $PMePh_2$).

Observation of $Mo(S_2C_6H_4)_2(PMePh_2)(PMe_3)$ by NMR

$Mo(1,2\text{-}S_2\text{-}C_6H_4)_2(PMePh_2)_2$ (0.20 g, 0.26 mmol) and PMe_3 (0.026 mL, 0.020 g, 0.26 mmol) were stirred together in 30 mL benzene. The orange-red slurry changed to a clear red solution within minutes. The reaction was stirred for 1 day and then the $^{31}P\{^1H\}$ NMR spectrum was recorded. $^{31}P\{^1H\}$ NMR (C_6H_6/C_6D_6) δ: −99.0 (br weak, Mo-$PMePh_2$); −126.1 (br weak, Mo-PMe_3); −168 (free $PMePh_2$). ^1H NMR (C_6D_6, 200 MHz) δ: 0.99 (d, J_{PH} = 9 Hz, 8H, PMe_3); 1.25 (d, J_{PH} = 9 Hz, 3H, $PMePh_2$); 3.34 (br, 2H); 6.57–7.24 (multiplet, 10H, P-Ph); 7.10, 7.11, 7.13, 7.15, 8.38, 8.39, 8.41, 8.42 (8H, part of AA′XX′ pattern of thiol ligands).

Preparation of $Mo(S_2C_6H_4)_2(PMePh_2)(P(OMe)_3)$

$Mo(S_2C_6H_4)_2(PMePh_2)_2$ (0.20 g, 0.26 mmol) and $P(OMe)_3$ (0.033 g, 0.27 mmol) were reacted as for the PMe_3 derivative. The orange-red slurry changed to a clear, deeper red solution within 40 min. The ^{31}P NMR spectrum was recorded after 1 day. The solvent was removed using vacuum to leave a red oily solid. $^{31}P\{^1H\}$ NMR (C_6H_6 solution, 80.98 MHz) δ: 23.76 (d, J_{PP} = 33 Hz, Mo-$P(OMe)_3$), −99.24 (d, J_{PP} = 33 Hz, Mo-$PMePh_2$). ^1H NMR (C_6D_6, 200 MHz) δ: 1.24 (3H, P**Me**Ph_2); 2.86 (d, J_{PH} = 15 Hz, 7H, P(O**Me**)$_3$); 6.64–7.32 (multiplet, 11 H, PMe**Ph$_2$**); 7.08, 7.10, 7.11, 7.12, 8.40, 8.42, 8.43, 8.45 (9H, part of AA′XX′ pattern of thiol ligands). FAB^+ MS (NPOE matrix): 702, M^+ for $^{98}Mo(S_2C_6H_4)_2(PMePh_2)(P(OMe)_3)$.

Observation of $Mo(S_2C_6H_4)_2P(OMe)_3)_2$ by ^{31}P NMR

$Mo(S_2C_6H_4)_2(PMePh_2)_2$ (0.200 g, 0.257 mmol) and $P(OMe)_3$ (0.12 g, 0.97 mmol) were reacted as for the PMe_3 derivative. The red solution was reduced in volume and the resultant red solid filtered off and washed with pentanes. $^{31}P\{^1H\}$ NMR (C_6H_6) δ: 30.3.

Reaction of $Mo(S_2C_6H_3Me)_2(PMePh_2)_2$ with $LiAlH_4$

$LiAlH_4$ (0.023 g, 0.605 mmol) was slowly added to the orange-red solution of $Mo(S_2C_6H_3Me)_2(PMePh_2)_2$ (0.497 g, 0.617 mmol) in 50 mL THF. After 15 min the solution had turned amber. After stirring for 21 h the solution was dark brown. The solvent was removed using vacuum, and then trituration with hexanes resulted in a clear yellow solution and a green-brown precipitate. The yellow solution was removed using a pipette and discarded, and the green-brown residue was dried *in vacuo*. ^1H NMR (amber C_6D_6 solution) δ: −2.33 ppm (quartet, J_{PH} = 55.5 Hz, Mo-H). $^{31}P\{^1H\}$ NMR (benzene, 80.98 MHz) δ: −87.93, −88.93 ppm.

Reaction of $Mo(S_2C_6H_3CH_3)_2(PMePh_2)_2$ with $LiAlH_4$ and methyldiphenylphosphine

$Mo(S_2C_6H_3Me)_2(PMePh_2)_2$ (0.84 g, 1.0 mmol) was dissolved in THF (20 mL) to give a red solution. To this solution was added $PMePh_2$ (0.21 g, 1.0 mmol) and $LiAlH_4$ (0.039 g, 1.0 mmol). The addition of $LiAlH_4$ was accompanied by gas evolution. When the gas evolution ceased the solution looked amber. The solution was stirred for 14.5 h and then the solvent was removed using vacuum. The yellow-brown residue was scraped out of the flask and into a frit using hexanes and pentanes washings. ^1H NMR (C_6D_6) δ: −0.24; −0.64; −2.29 (quartet, J_{PH} = 55.15 Hz, Mo-H of $Mo(H)_2(S_2C_6H_3Me)(PMePh_2)_3$); −2.04 (quintet, J_{PH} = 32.4 Hz, Mo-H of $Mo(H)_4(PMePh_2)_4$); −7.7 (br).

Results

Reaction of $MoOCl_2(PMePh_2)_3$ with 1,2-$(SH)_2$-4-CH_3-C_6H_3 is the preferred method of preparation of pure $Mo(S_2C_6H_3Me)_2$-$(PMePh_2)_2$ (reaction [3], R = Me; see also Scheme 1).

[3] $MoOCl_2(PMePh_2)_3$ + 2 1,2-$(SH)_2$-4-R-C_6H_3 → $Mo(S_2C_6H_3R)_2(PMePh_2)_2$ + 2 HCl + H_2O + $PMePh_2$

$Mo(S_2C_6H_3Me)_2(PMePh_2)_2$ can also be prepared from $Mo(N_2)_2(PMePh_2)_4$ (reaction [4]):

[4] $Mo(N_2)_2(PMePh_2)_4$ + 2 1,2-$(SH)_2$-4-CH_3-C_6H_3 → $Mo(S_2C_6H_3Me)_2(PMePh_2)_2$ + 2 $PMePh_2$ + 2 N_2 + 2 H_2

In fact, a mixture of $Mo(S_2C_6H_3Me)_2(PMePh_2)_2$ and $Mo(H)_2$-$(S_2C_6H_3Me)(PMePh_2)_3$ (1) was obtained as the initial crude product, but recrystallization and purification afforded only $Mo(S_2C_6H_3Me)_2(PMePh_2)_2$.

Room temperature and elevated temperature ^1H NMR spectra of $Mo(S_2C_6H_3Me)_2(PMePh_2)_2$ are consistent with the formula as proposed. However, a somewhat unusual feature, observable in the ^1H NMR spectrum of the bis(dithiolate) derivatives, is the broadness and low field position of the PCH_3 methyl resonance (*vide infra*). The ^1H NMR resonances were not useful in assigning stereochemistry. The room temperature ^{31}P NMR spectra is a simple singlet for $Mo(S_2C_6H_3Me)_2(PMePh_2)_2$, the signal occurring in the same chemical shift range as all other bis(dithiolate) complexes prepared herein (Table 1). Low temperature ^{31}P NMR spectra of this complex were much more complicated than the room temperature spectra, displaying three sets of complex multiplets due to conformers with different dithiolate ring orientations (see Discussion). This supports a *cis* stereochemistry for the complex.

Reaction [3], R = H, gave the best yield of $Mo(S_2C_6H_4)_2$-$(PMePh_2)_2$. $Mo(S_2C_6H_4)_2(PMePh_2)_2$ can also be produced by reaction of $MoH_4(PMePh_2)_4$ with 2 equivalents of 1,2-$(SH)_2$-C_6H_4 (reaction [5]):

[5] $Mo(H)_4(PMePh_2)_4$ + 2 1,2-$(SH)_2$-C_6H_4 → $Mo(S_2C_6H_4)_2(PMePh_2)_2$ + 2 $PMePh_2$ + 4 H_2

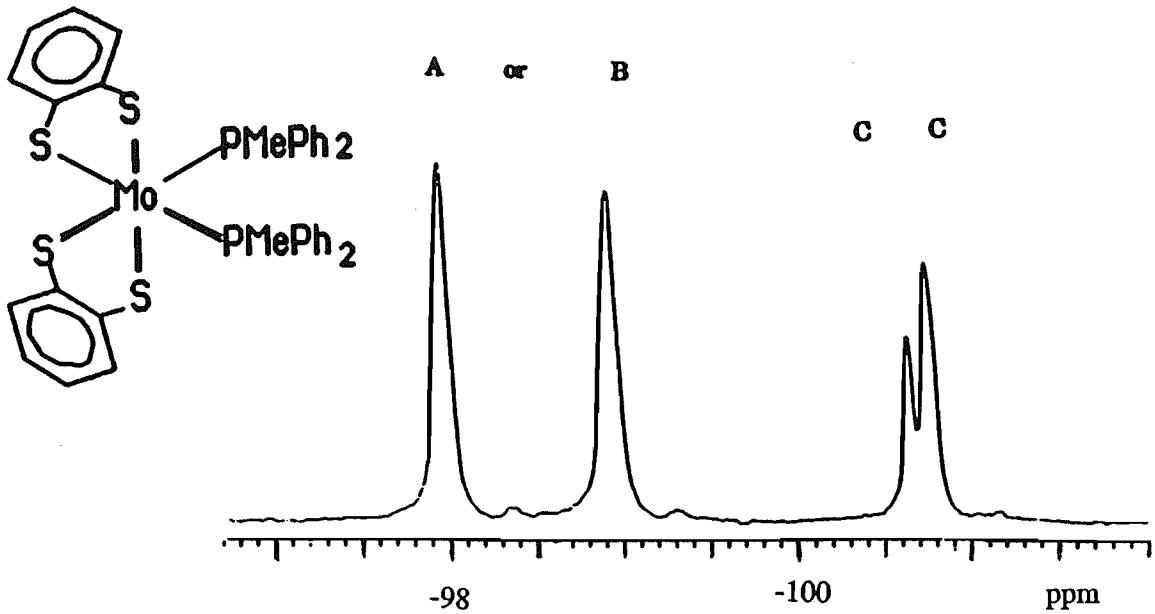

FIG. 1. $^{31}P\{^1H\}$ NMR spectrum (162 MHz) of $Mo(S_2C_6H_4)_2(PMePh_2)_2$ in toluene at −75.5°C. See Discussion for assignments of conformers A, B, and C.

TABLE 1. ^{31}P NMR resonances of bis(dithiolate) complexes

Complex	δ (ppm, vs. $P(OMe)_3$)

$Mo(S_2C_6H_3Me)_2(PMePh_2)_2$	−102.30
$Mo(S_2C_6H_4)_2(CO)(PMePh_2)$	−95.51
$Mo(S_2C_6H_4)_2(CN\text{-}t\text{-}Bu)(PMePh_2)$	−93.96
$Mo(S_2C_6H_4)_2(depe)$	−79.70
$Mo(S_2C_6H_3Me)_2(dppe)$	−75.23
$Mo(S_2C_6H_3Me)_2(PMePh_2)(PMe_3)$	−98.99[a]
	−126.08[b]
$Mo(S_2C_6H_3Me)_2(PMePh_2)(P(OMe)_3)$	−99.24[c]
	+23.76[d]
$Mo(S_2C_6H_3Me)_2(P(OMe)_3)_2$	+30.33

[a]br, weak, $PMePh_2$.
[b]br, weak, PMe_3.
[c]d, $PMePh_2$, $^2J_{PP}$ = 32 Hz.
[d]d, $P(OMe)_3$, $^2J_{PP}$ = 32 Hz.

The low temperature ^{31}P NMR of $Mo(S_2C_6H_4)_2(PMePh_2)_2$ displayed four signals (Fig. 1), again due to different conformers, which suggest a *cis* stereochemistry for the complex. The Signer method of molecular weight determination established that the compound is monomeric. This evidence indicates that the complicated low temperature spectra do not arise from some type of monomer–dimer equilibrium.

The reaction of $Mo(S_2C_6H_4)_2(PMePh_2)_2$ in benzene with CO is reversible, the CO being extremely labile in the product complex (reaction [6]).

[6] $Mo(S_2C_6H_4)_2(PMePh_2)_2 + CO \rightleftarrows Mo(S_2C_6H_4)_2(CO)(PMePh_2) + PMePh_2$

Reaction [6] proceeds to the right in 10 min, with the colour of the solution changing from orange-red to a burgundy pink. On application of vacuum to effect solvent reduction and product isolation, the colour becomes progressively more orange-red. The complex $Mo(S_2C_6H_4)_2(CO)(PMePh_2)$ was obtained (as a red solid) contaminated by $Mo(S_2C_6H_4)_2(PMePh_2)_2$ by this procedure. Repeated equilibration under a carbon monoxide atmosphere, and discarding the filtrate (without application of vacuum), resulted in incremental percentage enrichment of the product mixture along with considerable loss of product. The preparation of pure $Mo(S_2C_6H_4)_2(CO)(PMePh_2)$ in good yield may be achieved by adding iodomethane to the reaction mixture (eq. [7]):

[7] $Mo(S_2C_6H_4)_2(PMePh_2)_2 + CO + MeI \rightarrow Mo(S_2C_6H_4)_2(CO)(PMePh_2) + [PMe_2Ph_2]I$

The MeI reagent acts as a "phosphine sponge" (21) by selectively precipitating the dissociating $PMePh_2$ as its phosphonium salt. The work-up of the monocarbonyl complex must be carried out under a CO atmosphere.

The carbonyl ligand dissociates from $Mo(S_2C_6H_4)_2(CO)(PMePh_2)$ in the mass spectrometer, even with "soft" FAB ionization. Regardless of the matrix used, the highest mass peak observed does not correspond to the parent ion, but instead to $Mo(S_2C_6H_4)_2(PMePh_2)^+$. The infrared spectrum of pure $Mo(CO)(S_2C_6H_4)_2(PMePh_2)$ shows a strong, sharp absorption due to ν(CO) at 1977 cm^{-1}. No reaction was observed when H_2 instead of CO was used in eq. [7].

Preparation of high purity $Mo(S_2C_6H_4)_2(CN\text{-}t\text{-}Bu)(PMePh_2)$ may be achieved by the simple reaction of equimolar amounts of $Mo(S_2C_6H_4)_2(PMePh_2)_2$ and CN-*t*-Bu (Scheme 2). A phosphine sponge is not required to drive the reaction to the right. The formation of an isonitrile adduct is confirmed by the ν(CN) stretch at 2138 cm^{-1} of the ir spectrum and a strong singlet due to the *tert*-butyl group in the ^1H NMR spectrum.

$Mo(S_2C_6H_3Me)_2(dppe)$ may be prepared from $MoCl_4(dppe)$, reaction [8], or by substitution of the two monodentate ligands in $Mo(S_2C_6H_3Me)_2(PMePh_2)_2$ by dppe (Scheme 2).

[8] $MoCl_4(dppe) + 2\ 1,2\text{-}(SH)_2\text{-}4\text{-}CH_3\text{-}C_6H_3 \rightarrow Mo(S_2C_6H_3Me)_2(dppe) + 4\ HCl$

The FAB MS spectrum was extremely useful in the identification of this insoluble complex. The isotopomer distribution is correct with the 804 peak, due to the species with ^{98}Mo, being most intense. $Mo(S_2C_6H_4)_2(depe)$ may similarly be generated

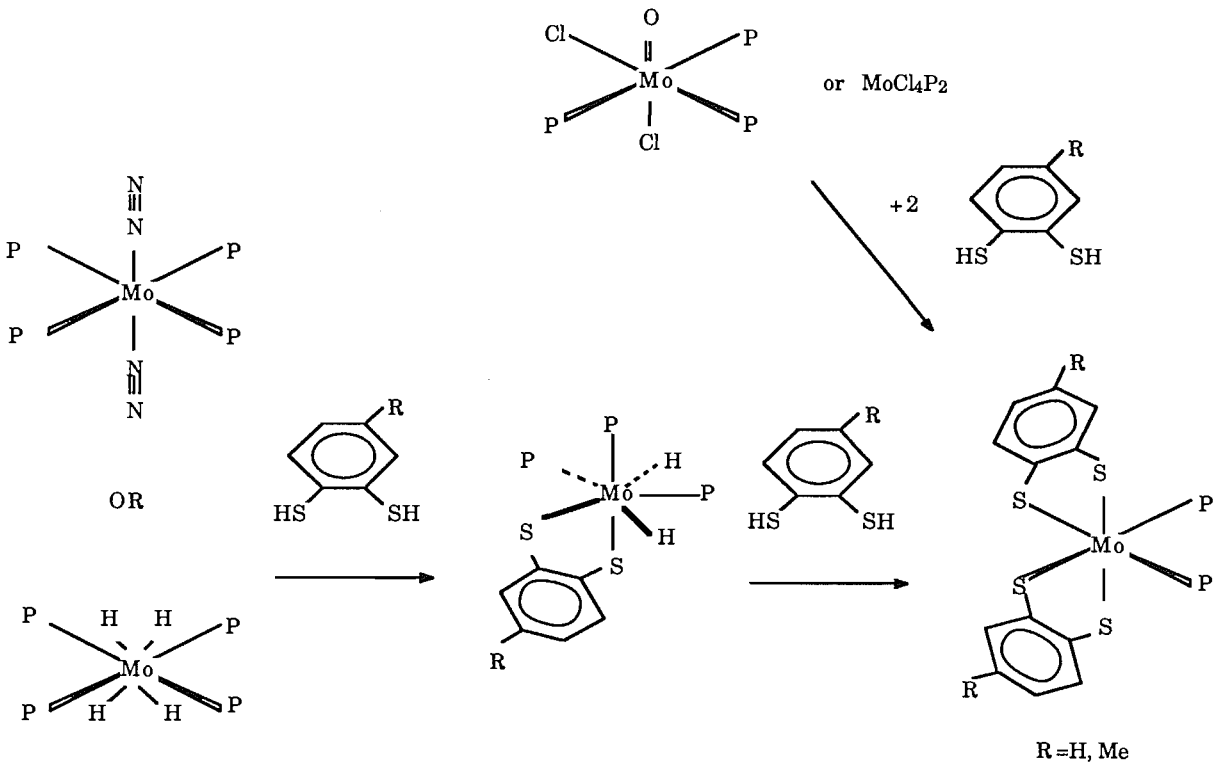

SCHEME 1. Preparation of bis(dithiolate)bis(phosphine) complexes of molybdenum.

from $Mo(S_2C_6H_4)_2(PMePh_2)_2$ and depe; depe = 1,2-bis(diethylphosphino)ethane.

When $Mo(S_2C_6H_4)_2(PMePh_2)_2$ is reacted with 1 equivalent of PR_3, R = Me, OMe, the monosubstitution product $Mo(S_2C_6H_4)_2(PR_3)(PMePh_2)$ is obtained (Scheme 2). The ^{31}P NMR spectrum of $Mo(S_2C_6H_4)_2(P(OMe)_3)(PMePh_2)$ displays two doublets with $^2J_{PP}$ = 32 Hz, while that of $Mo(S_2C_6H_4)_2(PMe_3)(PMePh_2)$ gives two broad signals (see Table 1). If 2 equivalents of $P(OMe)_3$ are reacted with $Mo(S_2C_6H_4)_2(PMePh_2)_2$ the disubstituted product, $Mo(S_2C_6H_4)_2(P(OMe)_3)_2$, is formed (Scheme 2).

The reactions of complexes $Mo(S_2C_6H_3R)_2(PMePh_2)_2$ with $LiAlH_4$ generate a mixture of hydride species, one of which is identified by ^1H and ^{31}P NMR as $Mo(H)_2(S_2C_6H_3R)(PMePh_2)_3$ (1). The ^1H and ^{31}P chemical shifts were slightly different from those of pure samples of $Mo(H)_2(S_2C_6H_3R)(PMePh_2)_3$, possibly because of interactions with unidentified aluminium-containing species. The reaction of $Mo(S_2C_6H_3Me)_2(PMePh_2)_2$ with equimolar amounts of $LiAlH_4$ and methyldiphenylphosphine yields not only $Mo(H)_2(S_2C_6H_3Me)(PMePh_2)_3$ but also $Mo(H)_4(PMePh_2)_4$ and other unidentified species.

A few other reactions were attempted. $Mo(S_2C_6H_4)_2(PMePh_2)_2$ does not react with H_2O at 22°C but does react with acetylene to give a plethora of products. It does not react with equimolar amounts of 1,2-dichloroethane or 1,3-dibromopropane, unlike the complex $[Mo(CO)_3(SC_2H_4SC_2H_4S)]^{2-}$ (22).

Discussion

Bis(phosphine)bis(dithiolate) complexes of molybdenum were initially obtained in poor yield from decomposition of the novel dihydrides, $Mo(H)_2(S_2C_6H_3R)(phosphine)_3$ with R = Me, or H (1). Once it was established that the decomposition products were not oxo-species, such as $Mo(O)(SR)_4$ (23), but instead unknown bis(dithiolate) species, high yielding routes to these complexes were sought so that their chemical properties could be investigated.

Bis(dithiolate) complexes of molybdenum were prepared using four different starting materials: bis(dinitrogen), tetrahydrido, bis(phosphine)tetrachloro, and oxo-dichloro-tris(phosphine) complexes of molybdenum (Scheme 1).

Routes involving $MoOCl_2(phosphine)_3$ and $MoCl_4(phosphine)_2$ species are superior (in terms of both yield and simplicity) for generation of bis(dithiolate)bis(phosphine) species. Routes involving dinitrogen or tetrahydride starting materials result in less tractable product mixtures since the excess phosphine that is generated impairs product crystallization and isolation. Addition of a base such as triethylamine to deprotonate and activate the thiol was not necessary.

The substitution reactions of these complexes with mono- or bidentate phosphorus donor ligands or *tert*-butyl isonitrile give either the mono- or disubstituted complexes depending on how many equivalents of donor were added (Scheme 2).

The room temperature ^{31}P NMR spectrum (Table 1) of the monosubsituted $P(OMe)_3$ derivative is most informative as to the stereochemistry of the complexes. The magnitude of the coupling constant $^2J_{PP}$ (32 Hz) observed in the ^{31}P NMR spectra of $Mo(S_2C_6H_4)_2(PMePh_2)(P(OMe)_3$ and the magnitude of $^2J_{P-CO}$ (11.8 Hz) observed in the ^{13}C NMR of $Mo(S_2C_6H_4)_2(CO)(PMePh_2)$ suggest that the complexes have *cis* monodentate ligands (24). For comparison with the above values, the complex $Mo(CO)_4(dppe)$ has a *cis* $^2J_{PC}$ coupling of 8.4 Hz and a *trans* $^2J_{PC}$ coupling of 24 Hz; the complex $Mo(N_2)_2(PMePh_2)_3(P(OMe)_3)$ has a *cis* $^2J_{PP}$ coupling of 30 Hz and a *trans* $^2J_{PP}$ coupling of 173 Hz (12). At ambient temperature, a $^2J_{PP}$ value cannot be clearly observed in the ^{31}P NMR of $Mo(S_2C_6H_4)_2(PMePh_2)(PMe_3)$.

The low temperature ^{31}P NMR spectra of the Mo(dithiolate)$_2$(PMePh$_2$)$_2$ complexes are consistent with phosphine

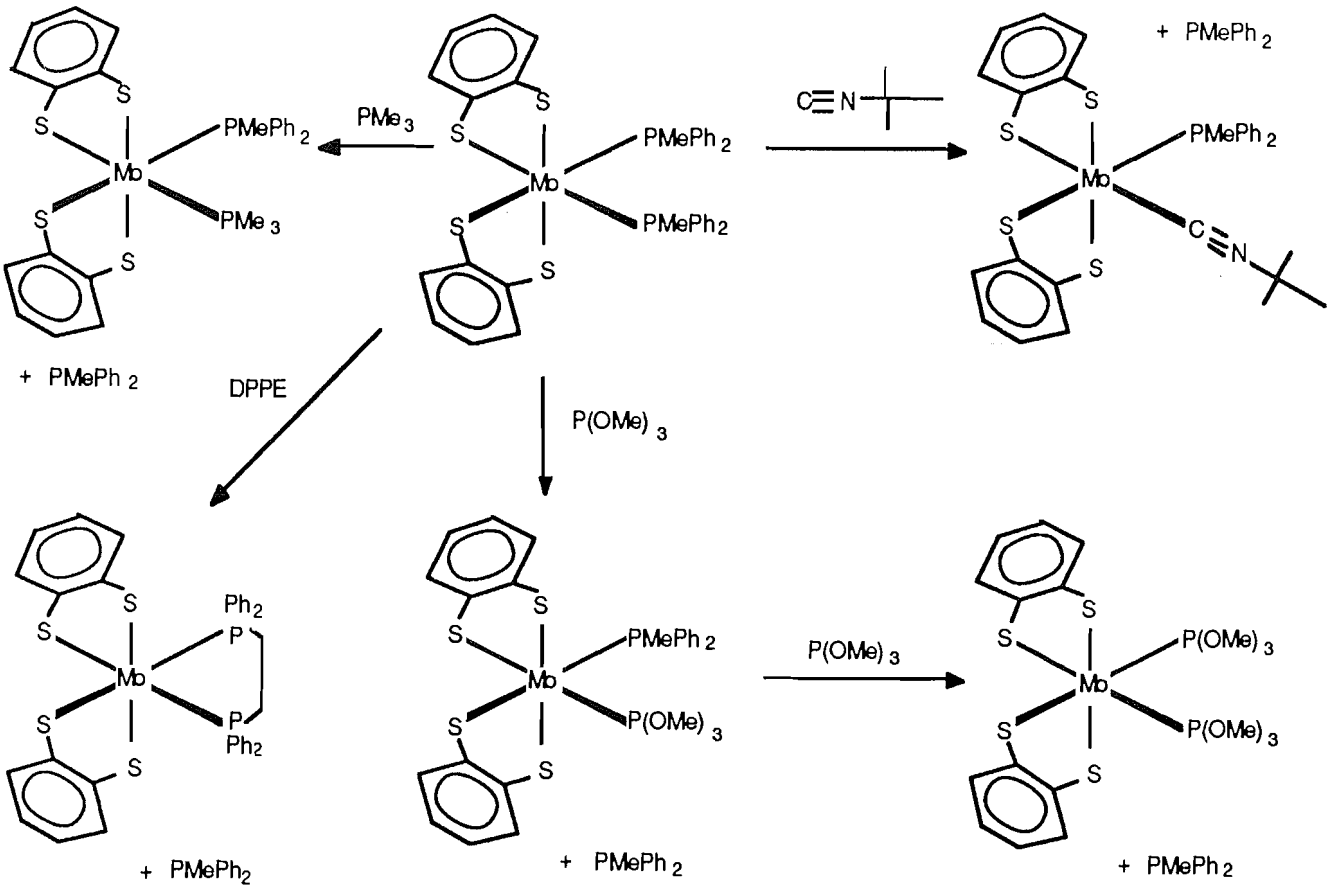

SCHEME 2. The substitution reactions of $Mo(S_2C_6H_4)_2(PMePh_2)_2$.

ligands *cis* disposed in isomers arising due to various conformations of the dithiolate ligands, as depicted in Fig. 2. Consider the low temperature ^{31}P NMR spectrum of $Mo(S_2C_6H_4)_2(PMePh_2)_2$ (Fig. 1), which consists of four signals. One phosphorus resonance arises from the isomer where both aromatic rings are flipped in towards the phosphines (and both phosphines are equivalent) (isomer A); another resonance arises from the isomer with both aromatic rings flipped away from the phosphines (and both phosphines are again equivalent; isomer B); the last two resonances arises from the other possible isomer where one ring is flipped towards the phosphorus ligands, and one away (in which the two phosphines are inequivalent; isomer C). The assignments of resonances arising from isomers A and B are tentative and may be reversed. Introduction of one methyl group in $Mo(PMePh_2)_2(S_2C_6H_3Me)(S_2C_6H_4)$ or two methyl groups in $Mo(PMePh_2)_2(S_2C_6H_3Me)_2$ gives the opportunity for geometric isomers regarding the position(s) of the methyl group(s) (almost *trans* to a phosphorus donor, or almost *trans* to a sulfur donor, and also their position relative to the other methyl group). Hence, more complicated low temperature ^{31}P spectra are obtained when the aromatic ring is substituted.

The simple one-resonance ^{31}P NMR spectra observed at room temperature for the $Mo(S_2C_6H_3R)_2(PMePh_2)_2$ complexes are the averaged signals arising from rapid interconversion of isomers by ring-flipping as the sulfur configurations invert. It is assumed that the small differences in chemical shift due to differences in position of methyl substitution are not resolved at room temperature. Otherwise a second mechanism of isomer interconversion, a Bailar twist, has to be invoked to explain the equivalence of ^{31}P resonances of isomers that differ in position of methyl substitution. Kopf and Klapotke (25) have described this type of ring-flip isomerism, which results in nonequivalence of the Cp rings at low temperatures, in the complexes $M(Cp)_2(Se_2C_6H_4)$ (where M = Ti, Zr, Hf, Mo, W). The barrier to interconversion between the isomers of $Mo(S_2C_6H_3Me)_2(PMePh_2)_2$ is expected to be much lower than $MoCp_2(Se_2C_6H_4)$, which has a barrier slightly greater than 80 kJ/mol.

The complex $Mo(S_2C_6H_4)_2(CO)(PMePh_2)$ is intriguing in that the CO can be readily removed under vacuum when $PMePh_2$ is present (cf. reaction [6]). It is not surprising that the parent ion cannot be seen in the FAB^+ mass spectrum where the sample is under vacuum; the highest mass peak corresponds to $[M - CO]^+$. Although the oxidation state of this monocarbonyl complex is ambiguous because of π delocalization in the dithiolene ligands (26, 27), an oxidation state closer to Mo(IV) than to Mo(II) is consistent with the physical properties of the complex. Thus the stretching frequency ν(CO) of 1977 cm^{-1} is higher than for comparable Mo(II) complexes such as $Mo(S_2CNC_4H_4)_2(CO)_2$ with ν(CO) = 1956, 1879 cm^{-1} (28), $Mo(S_2CNC_6H_4)_2(CO)_2(PPh_3)$ (1947, 1878 cm^{-1} (28)), and $Mo(S_2CNMe_2)_2(CO)(PMe_3)_2$ (1760 cm^{-1} (10)). The ease of displacement of CO from $Mo(CO)(PMePh_2)(S_2C_6H_4)_2$ also suggests that it can be considered as a carbonyl of Mo(IV), the first thermally stable example of its type. The other known Mo(IV) carbonyl complex, *trans*-$Mo(O)_2(CO)_4$, which was generated at 10 K, might be stable above 20 K; it has an e_u carbonyl stretching mode at 2110 cm^{-1} (29). Iodomethane can be used in reaction [7] as a phosphine sponge because the Mo(IV) complexes involved are not readily oxidized and the coordinated sulfurs are not very nucleophilic. In cases where the

For personal use only.

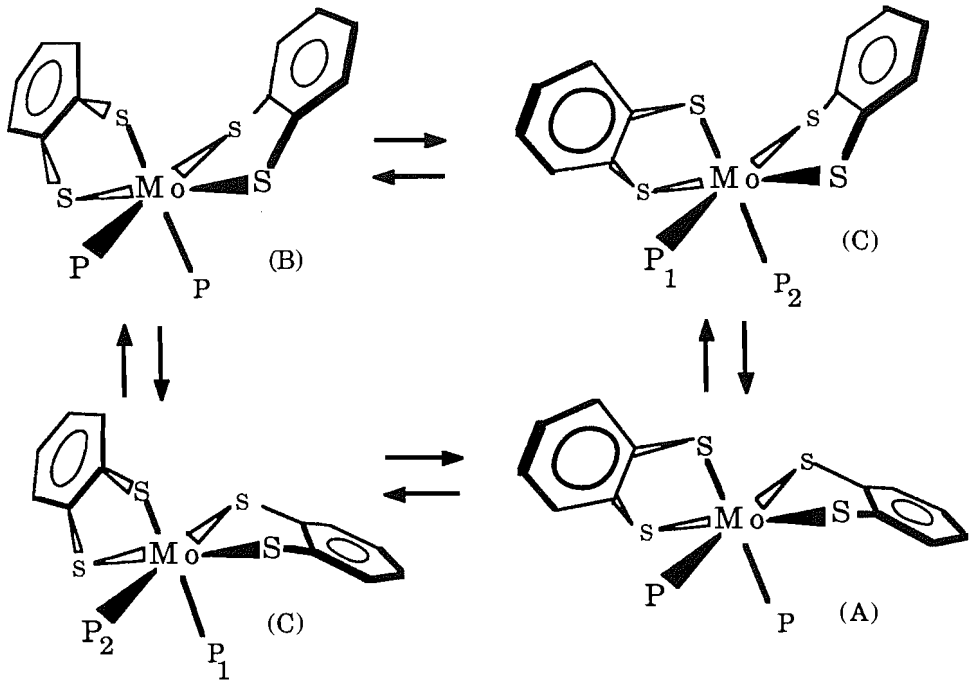

FIG. 2. Three conformations of the bis(dithiolate) complexes.

complexes are likely to be oxidized, the phosphine sponge reagent 9-BBN has been recommended (21).

The binding site of $Mo(S_2C_6H_4)_2(PMePh_2)$ has poor back-bonding capability as judged by the high ν(CO) of the monocarbonyl adduct. This explains why we were not able to isolate a dihydrogen adduct of the type $Mo(S_2C_6H_4)_2(H_2)(PMePh_2)$. Dihydrogen complexes of d^6 octahedral metals are expected to be stable when the range of ν(CO) for the corresponding carbonyl complex falls in the range 1860–1960 cm^{-1} (30). Similarly, a complex like $Mo(S_2C_6H_4)_2(N_2)(PMePh_2)$ is not expected to be stable.

Conclusions

The spectroscopic properties of the oxygen sensitive complexes $Mo(S_2C_6H_3R)_2(PMePh_2)_2$ are most consistent with an octahedral, *cis* stereochemistry. These complexes can exist as conformational isomers with respect to the MoS_2(arene) "hinges". These isomers readily interconvert at room temperature but can be observed at low temperature by ^{31}P NMR. Geometric isomerism with respect to the placement of the methyl groups on the dithiolate ligands in the complex $Mo(S_2C_6H_3Me)_2(PMePh_2)_2$ can also be detected by ^{31}P NMR at low temperature. The $PMePh_2$ ligands are labile in these complexes and are readily substituted, even by weakly coordinating carbon monoxide (in the case of Mo(IV) to give a range of products, again with *cis* stereochemistry. If the dithiolates are viewed as dianions, then $Mo(S_2C_6H_4)_2(CO)(PMePh_2)$ is the first thermally stable carbonyl complex of Mo(IV).

Rhodium induced titanium–sulfur bond cleavage: crystal and molecular structure of $((COD)Rh(\mu\text{-}SMe))_2$

TERESA A. WARK[1] AND DOUGLAS W. STEPHAN[2]

Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received September 25, 1989

TERESA A. WARK and DOUGLAS W. STEPHAN. Can. J. Chem. **68**, 565 (1990).

Reactions of Ti(III) and Ti(IV) thiolates with Rh complexes have been investigated. In the reaction of $Cp_2Ti(SMe)_2$ and $[(COD)_2Rh]BF_4$ or $[(COD)Rh(sol)_2]PF_6$, thiolate abstraction yields $((COD)Rh(\mu\text{-}SMe))_2$, **1**. Reaction of $(Cp_2Ti(\mu\text{-}SMe))_2$ with $((COD)Rh(\mu\text{-}Cl))_2$ results in ligand exchange affording $(Cp_2Ti(\mu\text{-}Cl))_2$ and **1**. The complex **1** crystallizes in the monoclinic space group $P2_1/n$, with $a = 8.551(2)$ Å, $b = 10.058(3)$ Å, $c = 22.187(4)$ Å, $\beta = 92.54(1)°$, $Z = 4$, and $V = 1906(1)$ Å^3. The structural data show a relatively short approach between the Rh centres (2.948 Å) and between the bridging sulfur atoms (2.888 Å). The implications of these structural features in terms of metal–metal and sulfur–sulfur bonding are discussed. In addition, the implications of these results with respect to the formation of thiolato-bridged, early–late heterobimetallics is considered.

Key words: thiolate abstraction, rhodium thiolate bridged dimer.

TERESA A. WARK et DOUGLAS W. STEPHAN. Can. J. Chem. **68**, 565 (1990).

On a étudié les réactions des thiolates du Ti(III) et du Ti(IV) avec des complexes du Rh. Lors de la réaction du $Cp_2Ti(SMe)_2$ avec le $[(COD)_2Rh]BF_4$ ou le $[(COD)Rh(sol)_2]PF_6$, la réaction d'abstraction du thiolate fournit du $((COD)Rh(\mu\text{-}SMe))_2$, **1**. La réaction du $((Cp_2)Ti(\mu\text{-}SMe))_2$ avec le $((COD)Ti(\mu\text{-}Cl))_2$ conduit à un échange de ligands et à la formation de $((Cp_2)Ti(\mu\text{-}Cl))_2$ et du composé **1**. Le complexe **1** cristallise dans le groupe d'espace monoclinique $P2_1/n$, avec $a = 8{,}551(2)$, $b = 10{,}058(3)$ et $c = 22{,}187(4)$ Å, $\beta = 92{,}54(1)°$, $Z = 4$ et $V = 1906(1)$ Å^3. Les données structurales montrent que les centres Rh (2,948 Å) et les atomes de soufre agissant comme ponts (2,888 Å) sont relativement rapprochés. On discute des implications de ces caractéristiques structurales en fonction des liaisons métal–métal et soufre–soufre. De plus, on considère les implications de ces résultats par rapport à la formation de pont thiolato dans les hétérobimétalliques du début et de la fin.

Mots clés : enlèvement de thiolates, dimère ponté du thiolate de rhodium.

[Traduit par la revue]

Introduction

Our interest in early–late heterobimetallics (1–14) has included an extensive investigation of synthetic routes to thiolato-bridged mixed metal species (2–7). We have recently described the utilization of titanocene dithiolates as metalloligands for Cu(I) (5) and Ni(0) (6). Analogous chemistry yielding thiolato-bridged V(IV)–Cu(I) species has been described (7); however, reaction of vanadocene dithiolates with Ni(0) species led to redox chemistry, ligand exchange, and the isolation of Ni(II) thiolate hexamers (6). In related studies, we have described the synthesis of the complex $[Cp_2Ti(\mu\text{-}SCH_2CH_2CH_2PPh_2)_2Rh]^+$ and its redox partner $[Cp_2Ti(\mu\text{-}SCH_2CH_2CH_2PPh_2)_2Rh]^0$ (3). Preliminary studies of related phosphido-bridged systems show that the Ti(III)/Rh(I) species $Cp_2Ti(\mu\text{-}PR_2)_2Rh(COD)$ form readily.[3] We have also previously shown that related bridged Zr/Rh complexes are active catalysts for hydroformylation (10). In attempting to extend the chemistry of such heterobimetallic systems towards further applications in catalysis, it seemed that an interesting system would be one in which simple thiolate bridges link Ti and Rh. In this paper, we describe our initial investigations of the reaction of $Cp_2Ti(SMe)_2$ with $[(COD)_2Rh]BF_4$ and the reaction of $((COD)Rh(\mu\text{-}Cl))_2$ with $(Cp_2Ti(\mu\text{-}SMe))_2$. Ti—S bond cleavage was evident in both cases, yielding the species $((COD)Rh(\mu\text{-}SMe))_2$, **1**. This product is also readily prepared directly from the reaction of $((COD)Rh(\mu\text{-}Cl))_2$ and NaSMe. The complex **1** was structurally characterized by X-ray crystallography. The results confirm the dimeric nature of the Rh species in which the thiolates bridge the two Rh centres. The small steric demands of the thiolate substituents apparently allow for a relatively close approach of the metal centres. The implications of these structural features in terms of metal–metal and sulfur–sulfur bonding are discussed. In addition, the implications of the results of this initial study with respect to the formation of thiolato-bridged, early–late heterobimetallics are considered.

Experimental

All preparations were done under an atmosphere of dry, O_2-free N_2. Solvents were reagent grade, distilled from the appropriate drying agents under N_2 and degassed by the freeze–thaw method at least three times prior to use. $^{31}P\{^1H\}$ NMR experiments were performed using a Bruker AC 200-MHz spectrometer employing external 85% H_3PO_4 as the reference. EPR experiments were performed with a Varian E-12 spectrometer using DPPH as the reference. PCy_3 was purchased from the Strem Chemical Co. NaSMe (6), $(Cp_2Ti(\mu\text{-}Cl))_2$ (16), $((COD)Rh(\mu\text{-}Cl))_2$ (17), and $[(COD)_2Rh]BF_4$ (18) were prepared by the literature methods.

Reaction of $Cp_2Ti(SMe)_2$ and $[(COD)_2Rh]BF_4$

To a 30 mL THF suspension of $[(COD)_2Rh]BF_4$ (149 mg, 0.37 mmol) was added PCy_3 (208 mg, 0.74 mmol) and the mixture stirred for 30 min. A 10 mL THF solution of $Cp_2Ti(SMe)_2$ (100 mg, 0.37 mmol) was added to the reaction mixture, resulting in a colour change from purple to orange over 1 h of stirring. $^{31}P\{^1H\}$ NMR (THF), δ: 10.82 (s). The solvent was removed *in vacuo* and the orange residue washed with 2 × 10 mL pentane, leaving an orange solid and an orange pentane solution.

Generation of $[(COD)Rh(sol)_2]PF_6$

To a 20 mL THF solution of $((COD)Rh(\mu\text{-}Cl))_2$ (100 mg, 0.20 mmol) was added $AgPF_6$ (103 mg, 0.40 mmol) and the solution stirred for 10 min. The silver chloride was filtered off, leaving a clear, yellow solution of the solvated rhodium cation.

Reaction of $Cp_2Ti(SMe)_2$ and $[(COD)Rh(sol)_2]PF_6$

To a 20 mL THF solution of $[(COD)Rh(sol)_2]PF_6$ (0.40 mmol) was added $Cp_2Ti(SMe)_2$ (109 mg, 0.40 mmol) and the solution immediately changed from purple to orange-red. The mixture was stirred for 1 h and then stripped to dryness. The resulting oil was washed with pentane, giving an orange solution and an oil. The pentane solution was stripped to dryness. ^1H NMR (acetone-d_6), δ: 4.04 (br s, 4H), 2.28 (br m, 8H), 1.51 (s, 3H).

Preparation of $(Cp_2Ti(\mu\text{-}SMe))_2$

To a THF solution of $(Cp_2Ti(\mu\text{-}Cl))_2$ (100 mg, 0.24 mmol) was added NaSMe (33 mg, 0.48 mmol) and the mixture stirred overnight. The reaction mixture was filtered, the solvent removed *in vacuo*, and the residue washed with 2 × 10 mL pentane. The mixture was filtered and the purple, microcrystalline solid dried under vacuum. Yield: 74 mg, 80%; EPR (THF): $g = 1.979$, $a\langle^{47}Ti/^{49}Ti\rangle = 12.5$ G.

Reaction of $(Cp_2Ti(\mu\text{-}SMe))_2$ and $((COD)Rh(\mu\text{-}Cl))_2$

To a 30 mL THF solution of $((COD)Rh(\mu\text{-}Cl))_2$ (100 mg, 0.20 mmol) was added $(Cp_2Ti(\mu\text{-}SMe))_2$ (92 mg, 0.20 mmol) and the mixture stirred for 1 h during which time the colour changed from purple to yellow-green. EPR (THF): $g = 1.979$, $a\langle^{47}Ti/^{49}Ti\rangle = 10.0$ G.

Preparation of $((COD)Rh(\mu\text{-}SMe))_2$

To a 20 mL THF solution of $(COD)Rh(\mu\text{-}Cl))_2$ (30 mg, 0.061 mmol) was added NaSMe (8.5 mg, 0.12 mmol) and the mixture was stirred for 1 h. The reaction mixture was filtered and then the yellow-orange solution stripped to dryness, yielding **1**, 35%. X-ray quality crystals were obtained by diffusion of hexane into a THF solution of **1**. ^{1}NMR (benzene-d_6), δ: 4.04 (br s, 4H), 2.29 (m, 8H), 1.52 (s, 3H). Anal. calcd.: C 41.87, H 5.86; found: C 41.50, H 5.80.

X-ray data collection and reduction

Diffraction experiments were performed on a four-circle Syntex $P2_1$ diffractometer with graphite-monochromatized Mo Kα radiation (λ = 0.71069 Å). The initial orientation matrix was obtained from 15 machine-centred reflections selected from a rotation photograph. These data were used to determine the crystal system. Partial rotation photographs around each axis were consistent with a monoclinic crystal system for **1**. The final lattice parameters and the orientation matrix were determined from 24 high-angle data measurements ($20° < 2\theta < 25°$). The observed extinctions were consistent with the space group $P2_1/n$. $\pm h, +k, +l$ data were collected ($4.5° < 2\theta < 45.0°$), with three standard reflections recorded every 197 reflections. Their intensities showed no statistically significant change over the duration of the data collection. The data were processed using the SHELX-76 program package.

Structure solution and refinement

Non-hydrogen atomic scattering factors were taken from the literature tabulations (19–21). The heavy atom positions were determined using direct methods. The remaining non-hydrogen atoms were located from successive difference Fourier map calculations. The refinement was carried out by using full-matrix least-squares techniques on F, minimizing the function $w(|F_o| - |F_c|)^2$ where the weight, w, is defined as $4F_o^2/2\sigma(F_o^2)$ and F_o and F_c are the observed and calculated structure factor amplitudes. In the final cycles of refinement, the rhodium, sulfur, and methyl carbons were assigned anisotropic temperature factors. The methyl hydrogen atom positions were calculated and allowed to ride on the carbon to which they are bonded assuming a C—H bond length of 0.95 Å; however, the cyclooctadiene hydrogens were located from a difference map. Hydrogen atom temperature factors were fixed at 1.10 times the isotropic temperature factor of the carbon atom to which they are bonded. The hydrogen atom contributions were calculated, but not refined. The residual electron densities were of no chemical significance. Crystal data and data collection parameters are summarized in Table 1. Tables of positional parameters (Table 2) and selected bond distances and angles (Table 3) are reported. Thermal parameters (Table 1A), hydrogen atom parameters (Table A2), and calculated and observed structure factors (Table A3) have been deposited.[4]

TABLE 1. Crystallographic parameters

Formula	$C_{18}H_{30}Rh_2S_2$
Crystal color, form	Orange blocks
Crystal system	Monoclinic
a (Å)	8.551(2)
b (Å)	10.058(3)
c (Å)	22.187(4)

Crystal dimensions (mm)	0.12 × 0.19 × 0.23
Absorption coefficient, μ (cm^{-1})	17.72
Radiation, λ (Å)	Mo Kα (0.71069)
Temperature (°C)	24
Scan speed (deg/min)	2.0–5.0(θ/2θ scan)
Scan range (deg)	1.0 below Kα1 1.0 above Kα2
Background scan time ratio	0.5
Data collected	2762
No. of unique data $F_o^2 > 3\sigma(F_o^2)$	1666
No. of variables	199
R (%)	3.82
Rw (%)	4.14
Largest Δ/σ in the final least-squares cycle	0.002
Maximum residual electron density (e/Å^3)	0.59
Atom associated	Rh1, Rh2

Results and discussion

Reaction of the rhodium solvated species $[(COD)Rh(sol)_2]PF_6$ with $Cp_2Ti(SMe)_2$ was the initial attempt to prepare the desired Ti/Rh heterobimetallic species. A similar route was used previously by Green and co-workers to prepare mixed metal species, $[(C_5H_4CH_2CH_2S\text{-}n\text{Pr})_2Mo(\mu\text{-}S\text{-}n\text{Pr})_2Rh(COD)]^+$ (22). Addition of $Cp_2Ti(SMe)_2$ to the yellow THF solution containing the rhodium cation caused an immediate colour change from yellow to orange. The pentane soluble species exhibited a ^{1}H NMR spectrum consistent with that of the rhodium thiolato species with the empirical formula (COD)Rh(μ-SMe). The degree of aggregation was confirmed as the dimer $((COD)Rh(\mu\text{-}SMe))_2$, **1**, by X-ray crystallography (*vide infra*).

Similarly, reactions of $[(COD)_2Rh]BF_4$ with $Cp_2Ti(SMe)_2$, in the presence of phosphine, yielded complex **1**. Despite the fact that ^{31}P NMR spectra of mixtures of $[(COD)_2Rh]BF_4$ and PPh_3 indicate the expected initial coordination of phosphine to Rh, the ^{31}P NMR spectrum of the orange reaction mixture, following addition of the $Cp_2Ti(SMe)_2$, showed only a single resonance corresponding to free phosphine. This result suggests that the phosphine is displaced by the thiolate of the metalloligand and then the thiolate is abstracted by the rhodium centre.

[4]Tables of thermal and hyrogen atom parameters and values of 10 F_o and 10 F_c have been deposited. These tables may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

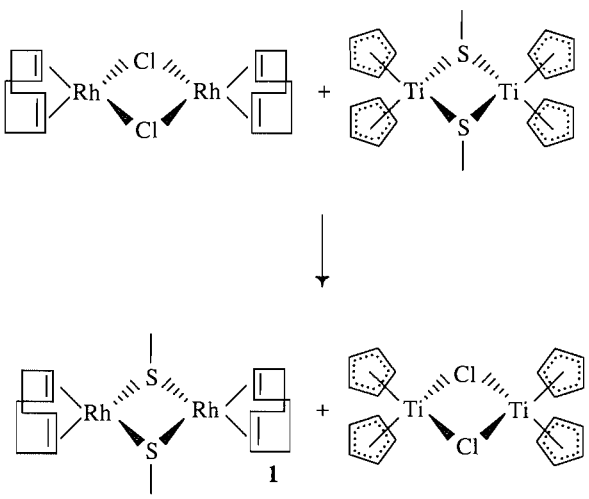
Dimerization yields **1**. This hypothesis is supported by the ability of allylic aryl sulfides to displace triphenylphosphine from $RhH(PPh_3)_4$ to give rhodium thiolate dimers and olefins (23). Abstraction of thiolate from Ti is expected to give a cationic Ti intermediate of the form $[Cp_2Ti(THF)SMe]^+$.



SCHEME 1

Jordan *et al.* have established that such Ti cations react rapidly with BF_4^- or PF_6^- to give a Ti–F species (24). Although this speculation appears consistent with known chemistry, the precise nature of the Ti containing products was not confirmed in the present reactions.

Attempts to incorporate Ti(III) and Rh(I) in a heterobimetallic complex involved the reaction of $(Cp_2Ti(\mu\text{-}SMe))_2$ with $((COD)Rh(\mu\text{-}Cl))_2$. The EPR spectrum of the reaction mixture showed a singlet with a g value of 1.980, indicative of the presence of the species $(Cp_2Ti(\mu\text{-}Cl))_2$ (25). This result implies that complete bridging ligand exchange between the titanium and rhodium dimers has occurred, affording the rhodium containing product, **1** (Scheme 1).

The compound **1** was previously prepared by heating together $((CO)_2Rh(\mu\text{-}SMe))_2$ and cyclooctadiene (26). However, a more direct route to **1** involves the reaction of $((COD)Rh(\mu\text{-}Cl))_2$ with NaSMe. Yields of **1** via this route appear quantitative by NMR.

X-ray quality crystals of $((COD)Rh(\mu\text{-}SMe))_2$ were obtained by cooling a pentane solution of **1** to −10°C. The crystallographic study showed that the crystal is made up of monoclinic unit cells containing four formula units per cell. The closest approach between any of these molecules is 2.252 Å (H1B—H27B). ORTEP drawings of the dimer appear in Fig. 1. Each

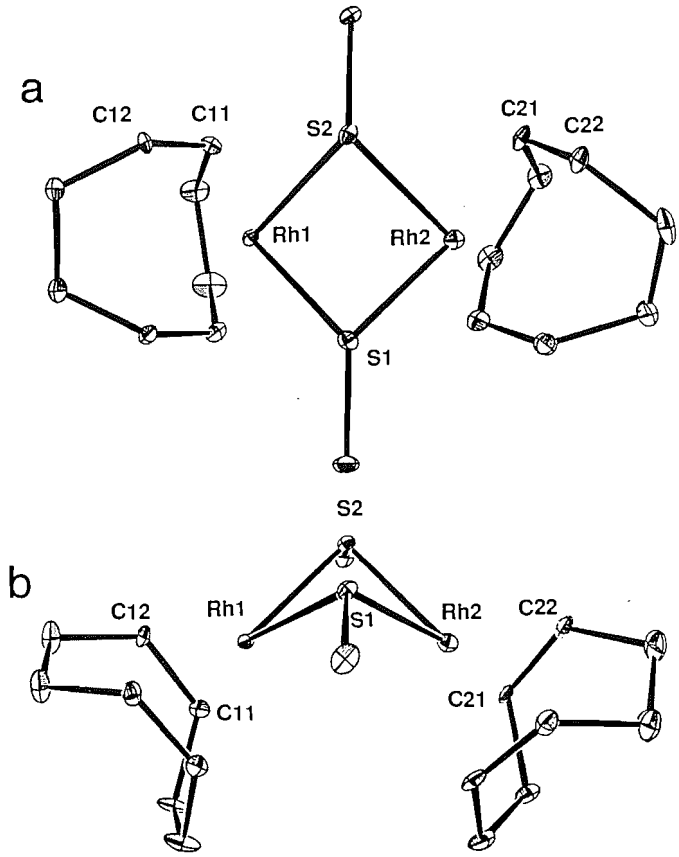

FIG. 1. (a) ORTEP drawing of molecule **1**, 20% thermal ellipsoids are shown. Hydrogen atoms are omitted for clarity; (b) ORTEP drawing of **1**; this view is rotated 90° about the Rh–Rh vector relative to the view in (a).

rhodium is π-bonded to the double bonds of a cyclooctadiene molecule and to two bridging methanethiolates in a pseudo-square-planar geometry. Each of the cyclooctadiene rings has a boat configuration, with a mean carbon–carbon double bond length of 1.366 Å, which is less than that of 1.425 Å found for $((COD)Rh(\mu\text{-}Cl))_2$ (27). In the crystal structure of the latter, the authors reported that the double and single bonds of the olefin could not be distinguished. In **1**, there is a significant difference between the single and double bond lengths, as expected. The average Rh—S distance of 2.349 Å is smaller than that found for $(Rh(SPh)(CO)(PMe_3))_2$ (2.388 Å) (28), but larger than 2.306 Å found in $(CpRh(\mu\text{-}SPh))_2$ (29). The methyl groups on the sulfurs adopt an *exo* arrangement with respect to the RhS_2Rh core. The Rh—Rh separation of 2.948 Å found in **1** is considerably shorter than the Rh—Rh distance of 3.498 Å found in $((COD)Rh(\mu\text{-}Cl))_2$ (27). It is also smaller than the Rh—Rh separation observed in $(Rh(\mu\text{-}SPh)(CO)(PMe_3))_2$ (3.061 Å) (28) or $(CO)_2Rh(\mu\text{-}SPh)_2Rh(COT)$ (3.12 Å) (26). In the related complex $(Rh(\mu\text{-}SPh)(CO)(PMe_3))_2$, a metal–metal interaction has been proposed to account for the relatively close approach of the Rh centres (28).

The S—Rh—S angles found in **1** (76.0(1)° and 75.8(1)°) are smaller than those found for $(Rh(SPh)(CO)(PMe_3))_2$ (81.0(1)° and 80.9(1)°), as are the Rh1—S—Rh2 angles of 78.1(1)° and 77.4(1)° compared to 80.2(1)° and 79.2(1)° (28). The small angle at the rhodium centres and the relatively short S—S separation of 2.888 Å in **1** suggest some degree of sulfur–sulfur interaction. Disulfide bonding character has been suggested in other metal systems where coordination of *cis* thiolato groups is present. For example, in $Cp_2Nb(SPh)_2$, the S—S distance of 3.08 Å was described as an indication of interaction between the sulfur centres (15). The existence of some degree of disulfide bonding character in **1** further suggests some degree of metal–metal interaction, thus accounting for the relatively short Rh—Rh distance. Such Rh–Rh interactions may be inhibited by the steric demands of the bridging thiophenolate groups in $(Rh(\mu\text{-}SPh)(CO)(PMe_3))_2$ (28) or $(CO)_2Rh(\mu\text{-}SPh)_2Rh(COT)$ (26).

In summary, we have described several reactions between titanium thiolate species and Rh complexes. Thiolate abstraction and ligand exchange reactions have been observed. In the present cases, the net effect has been the cleavage of Ti—S bonds and the formation of the rhodium thiolate species **1**. The inability to isolate stable Ti/Rh species is somewhat surprising in view of the numerous heterobimetallic complexes in which simple thiolates bridge divergent transition metals (1, 5, 6, 15). Apparently, the thermodynamic stability of the $Rh(\mu\text{-}SMe)_2Rh$ core is a driving force in the reactions described herein. Present research is aimed at the development of synthetic routes to stable thiolato-bridged Ti/Rh complexes.

An ICR mass spectrometry study of ion/molecule reactions in mixtures of methylamine with ethylamine, propylamine, or butylamine

GUOYING XU, JAN A. HERMAN, AND LESZEK WÓJCIK[1]

C. R. A. M. et le département de chimie, Université Laval, Québec (Qué.), Canada G1K 7P4

Received August 7, 1989

GUOYING XU, JAN A. HERMAN, and LESZEK WÓJCIK. Can. J. Chem. **68**, 570 (1990).

Ion/molecule reactions of protonated alkylamine ion species, RNH_3^+, were studied in mixtures of methylamine with ethylamine, propylamine, or butylamine by ICR mass spectrometry at 10^{-5} Torr. The occurrence of methyl group transfer from methylamine to higher protonated alkylamine ion species was observed. The rate constants of some bimolecular reactions occurring in these systems were estimated by numerical simulation.

Key words: ion/molecule reactions, methylamine, ethylamine, propylamine, butylamine, ICR mass spectrometry.

GUOYING XU, JAN A. HERMAN et LESZEK WÓJCIK. Can. J. Chem. **68**, 570 (1990).

Faisant appel à la spectrométrie de masse ICR et opérant dans des mélanges de méthylamine contenant de l'éthylamine, de la propylamine ou de la butylamine, à une pression totale de 10^{-5} Torr, on a étudié les réactions ion/molécule des espèces ioniques, alkylamines protonées, RNH_3^+. On a observé un transfert du groupement méthyle de la méthylamine vers les espèces ioniques des homologues supérieurs des alkylamines protonées. On a évalué les constantes de vitesse de quelques réactions bimoléculaires se produisant dans ces systèmes.

Mots clés : réactions ion/molécule, méthylamine, éthylamine, propylamine, butylamine, spectrométrie de masse ICR.

Introduction

The gas-phase ion chemistry of methylamine and some higher alkylamines has been studied extensively in high-pressure or ICR mass spectrometers in the pressure range 10^{-5} to 2 Torr (1–7). In this pressure range the main reaction is protonation of the molecular ion, followed only at higher gas densities by condensation processes:

[1] $RNH_2^+ + RNH_2 \rightarrow RNH_3^+ + RNH$

[2] $RNH_3^+ + RNH_2 \xrightarrow{M} (RNH_2)_2H^+ + NH_3$

Depending on the nature of the alkylamine, reaction [1] is exothermic by 20 to 50 kJ/mol in terms of the available ground state energetics (8). Condensation reaction [2] is a termolecular process. In the case of methylamine its kinetics was thoroughly analysed by Meot-Ner and Field (9), Brauman and co-workers (10), Bowers and co-workers (11), and Chang and Golden (12). For higher alkylamines the experiments were mainly focussed on the mechanism of reaction [1] (13–18). No studies on further solvation reactions of RNH_3^+ with its neutral RNH_2 (R = C_2H_5, C_3H_7, C_4H_9) were reported.

Experimental evidence suggests that ion/molecule reactions in amines proceed through an activated intermediate also called a collision or reaction complex (19). In the case of methylamine the decomposition of the chemically activated intermediate cannot proceed through a four-centered front site displacement mechanism, because the single lone electron pair of nitrogen is involved in a strong hydrogen bond. Therefore, a back attack in a nucleophilic displacement reaction is expected, but such a process should be characterized by a low rate constant

[3] $CH_3NH_3^+ + CH_2NH_2 \rightarrow [(CH_3NH_2)_2H]^{*+} \rightarrow (CH_3)_2NH_2^+ + NH_3$

If process [3] in methylamine is slow, it may be obscured by the fast proton transfer reactions from $CH_3NH_3^+$ to dimethyl- and trimethylamines, which are usually present as impurities (a few tenths of a percent) but are difficult to remove. Therefore, process [3] cannot be unambiguously studied in methylamine.

In the case of mixtures of methylamine with higher alkylamines the decomposition of the collision complexes may form product ions with alkyl groups other than the methyl group. These product ions may be distinguishable by their mass from protonated dimethyl- or trimethylamine ion species or other impurities. It is the purpose of this work to explore the processes occurred between methylamine and higher alkylamines ($C_2H_5NH_2$, $C_3H_7NH_2$, and $C_4H_9NH_2$) leading to formation of ions having the general formula $(R_xR_yNH_{3-x-y})^+$.

Experimental

The pulsed ICR mass spectrometer used in this work has been described (20). The usual pulse sequence started with a 2 ms ionizing pulse of 70 eV electrons followed by a variable delay (5–500 ms) during which ion/molecule processes take place. Then a 1.5 ms resonant RF frequency excitation pulse of 0.5 V, followed immediately by a 4 ms detection pulse, terminate the measured events. The pulse sequence ended with a quenching pulse, which swept out all remaining ions in the cell. The magnetic field was set up at 0.8 Tesla allowing ions in mass range 26 to 150 amu to be scanned within a frequency range of 80 to 450 kHz. Due to the proximity of one of the trapping plates to the emission filament the temperature of the cell cannot be uniform. We estimate the average cell temperature to be around 50°C.

The pressure at which all experiments were performed was $(1.0 \pm 0.1) \times 10^{-5}$ Torr (1.33×10^{-5} mbar). At that pressure ions can be kept in the reaction cell for about 2 s, but practical measurements of the ion intensities were limited to 0.5 s.

Methyl- and ethylamines from Matheson were of the best available purity (~99%). A gas-chromatographic analysis of methylamine showed impurities amounting to less than 1%. The propyl-, isopropyl-, and butylamines from Aldrich were better than 99% pure and were used as such.

The mixtures of alkylamines were prepared in a known ratio in a separate high vacuum manifold, which was baked each time between preparation of gaseous samples.

Results and discussion

In mixtures of methylamine with ethylamine, propylamine, or butylamines, the proton affinity of methylamine is the smallest (21). Furthermore, if the fast proton transfer processes

$C_4H_9NH_2^+ + BuNH_2 \rightarrow C_4H_9NH_3^+ + BuNH$	11.0					
$CH_3NH_2^+ + BuNH_2 \rightarrow C_4H_9NH_3^+ + MeNH$	9.0					
$CH_3NH_3^+ + BuNH_2 \rightarrow C_4H_9NH_3^+ + MeNH_2$	5.0					

in amines are taken into account, it can be expected that in a very short time the only ion species left will be the protonated alkylamine ion, RNH_3^+, where R is a C_2H_5, C_3H_7, or C_4H_9 group. Therefore, these mixtures can be used to study the reactions of protonated alkylamine ions RNH_3^+ with methylamine neutral molecules.

If the rate of formation of RNH_3^+ by charge- and proton-transfer processes in these mixtures can be measured from the rate of disappearance of primary ion species, then the subsequent slow reactions of RNH_3^+ with neutral molecules might be estimated by straightforward kinetic modeling. To that end we have used the numerical simulation written by Robichaud (22) to find solutions for a system of first, second, and/or third order kinetic differential equations. To run this program the initial concentrations (at $t = 0$) have to be known and the reaction mechanisms and rate constants have to be assumed. The initial concentrations of neutral reactants are known from the total pressure and mixture ratios. The relative initial concentrations of primary ions were obtained by extrapolating their fractional intensities to zero time. Since the total absolute initial concentration of primary ion species is not known, it was arbitrarily chosen to be 1% of the neutral concentration, which is small enough to maintain the concentration of neutral reactants constant during the experimental reaction time. If more realistic values of 0.1% or 0.01% for the initial concentration of primary ion species were used, the calculation time increases correspondingly without improving the results.

If the simulation results were reasonably close to experiment then the proposed mechanism and assumed rate constants were considered to be acceptable. An additional test for the assumed rate constants was the requirement that the experimental data agreed with calculated results at different mixture ratios. In general they agreed to within a factor of 2 for most of the product ion species, except for the less abundant ones (<6%). However, the fractional intensities of these latter ion species are also subject to more significant errors of measurement.

The rate constants of formation of protonated alkylamines from the literature and those measured in our experiments and used in the numerical simulation are reported in Table 1. It can be seen that these values often differ by nearly one order of magnitude depending on the method used for their measurements.

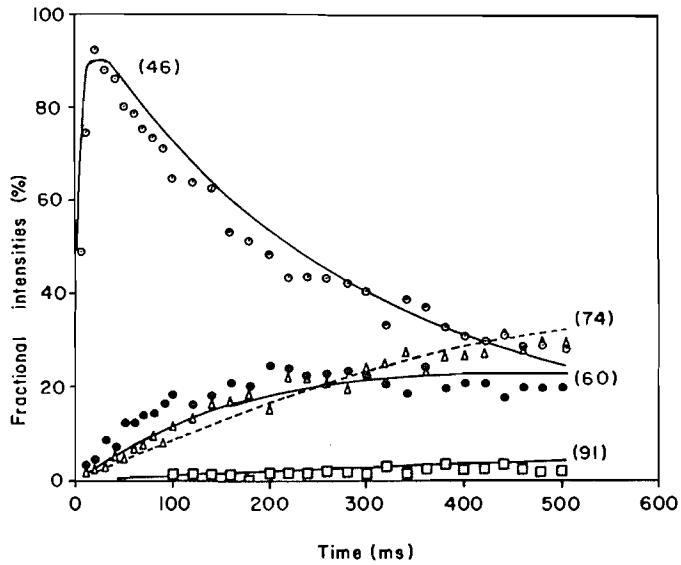

FIG. 1. Fractional intensities of ion species formed in a 8:1 mixture of $C_2H_5NH_2/CH_3NH_2$ as a function of time: (46) $C_2H_6NH_3^+$, (60) $[C_2H_5NH_2CH_3]^+$, (74) $[(C_2H_5)_2NH_2]^+$ and $[C_2H_5NH(CH_3)_2]^+$, (91) $(C_2H_5NH_2)_2H^+$. Solid lines represent simulation results.

Mixtures of ethylamine ($EtNH_2$) with methylamine ($MeNH_2$)

Mixtures of $EtNH_2$:$MeNH_2$ = 1:1, 2:1, 4:1 and 8:1, respectively, were investigated for their ion/molecule reactions occurring after ionization by 70 eV electrons.

In Fig. 1 is shown the time evolution of fractional intensities of ion species formed in ion/molecule reactions in $EtNH_2$:$MeNH_2$ = 8:1 mixture. We did not draw the disappearance of primary ions or other fragments as function of time, because all these species vanish very quickly in proton transfer processes to form the protonated ethylamine ion, $(C_2H_5NH_3)^+$, which at 30 ms is practically the sole species left in the mass spectrum.

We assume that the observed ions at longer time (>30 ms) are $[C_2H_5NH_2CH_3]^+$ at m/z = 60, $[C_4H_{10}N]^+$ at m/z = 72, $[C_2H_5NH(CH_3)_2]^+$ or $[(C_2H_5)_2NH_2]^+$ at m/z = 74, $[C_2H_5N(CH_3)_3]^+$ at m/z = 88, and $(C_2H_5NH_2)_2H^+$ at m/z = 91, respectively. The fractional intensities of ions at m/z = 72 and 88 are small and are not shown in Fig. 1. The fractional intensities of the m/z = 60 and 74 ion species are higher in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

mixtures with larger methylamine content. Even in the mixture $EtNH_2$:$MeNH_2$ = 8:1 the maximum fractional intensity of m/z = 60 ion species is larger than that in pure ethylamine.

The methyl group transfer processes may explain the formation of higher mass species:

[4] $C_2H_5NH_3^+ + CH_3NH_2 \rightarrow [CH_3NH_2..C_2H_5NH_3]^{*+} \rightarrow [C_2H_5NH_2CH_3]^+ + NH_3$

$C_2H_5NH_3^+ + C_2H_5NH_2 \rightarrow [C_2H_5NH_2...H^+...NH_2C_2H_5]^* \rightarrow$

[5] $\rightarrow [C_2H_5NH_2CH_3]^+ + CH_3NH_2$

[6] $\rightarrow [(C_2H_5)_2NH^+NH_2]^+ + NH_3$

[7] $\rightarrow C_4H_{10}N^+ + NH_3 + H_2$

[8] $\xrightarrow{M} (C_2H_5NH_2)_2H^+$

In addition the following sequence of methyl group transfers from methylamine could also contribute to the formation of m/z = 74 and 88 ion species:

[9] $[C_2H_6NH_2CH_3]^+ \xrightarrow{MeNH_2} [C_2H_5NH(CH_3)_2]^+ + NH_3$

$\xrightarrow{MeNH_2} [C_2H_5N(CH_3)_3]^+ + NH_3$

The results from these experiments allow the approximate calculation of the contribution of processes [4], [6], and [9] to the formation of the $C_4H_{12}N^+$ (m/z = 74) species.

The calculated rate constants for some of these reactions occurring in $EtNH_2$:$MeNH_2$ = 8:1 mixture are shown in Table 2.

Mixtures of propylamine ($PrNH_2$) with methylamine ($MeNH_2$)

The experimental data for all four mixture ratios of $PrNH_2$ with $MeNH_2$, 1:1, 2:1, 4:1, and 8:1, were more scattered than for the corresponding *n*-butyl- or ethylamine systems. We have no explanation for such behaviour.

The experimental results for the $PrNH_2$:$MeNH_2$ = 8:1 mixture are shown in Fig. 2. In this figure the fate of primary and their fragment ion species are not shown, because they all react very efficiently in proton transfer processes with neutral propylamine (PA = 912 kJ/mol) (20*b*), leaving in the mass spectrum at less than 50 ms only the protonated propylamine species (m/z = 60). The observed product ions are $C_4H_{12}N^+$ (m/z = 74), $C_5H_{14}N^+$ (m/z = 88), and $C_6H_{16}N^+$ (m/z = 102). We assume that the corresponding structures are $(C_3H_7NH_2CH_3)^+$ for m/z = 74, $[C_3H_7NH(CH_3)_2]^+$ or $[C_3H_7NH_2C_2H_5]^+$ for m/z = 88, and $[(C_3H_7)_2NH_2]^+$ for m/z = 102, respectively. The formation of 5 or 6 carbon cyclic structures should also be considered, the enthalpy of formation of such ions being usually lower than the corresponding acyclic species (8). Therefore, only the sequence of reactions between $C_3H_7NH_3^+$ and methyl- and propylamines have to be considered:

[10] $C_3H_7NH_3^+ + CH_3NH_2 \rightarrow [CH_3NH_2..C_3H_7NH_3]^{*+} \rightarrow [C_3H_7NH_2CH_3]^+ + NH_3$

$C_3H_7NH_3^+ + C_3H_7NH_2 \rightarrow [C_3H_7NH_2...H^+...NH_2C_3H_7]^* \rightarrow$

[11] $\rightarrow [C_3H_7NH_3CH_3]^+ + C_2H_5NH_2$

[12] $\rightarrow [C_3H_7NH_2C_2H_5]^+ + CH_3NH_2$

[13] $\rightarrow [(C_3H_7)_2NH_2]^+ + NH_3$

[14] $\xrightarrow{M} (C_3H_7NH_2)_2H^+$

[15] $(C_3H_7NH_2CH_3)^+ + CH_3NH_2 \rightarrow [C_3H_7NH(CH_3)_2]^+ + NH_3$

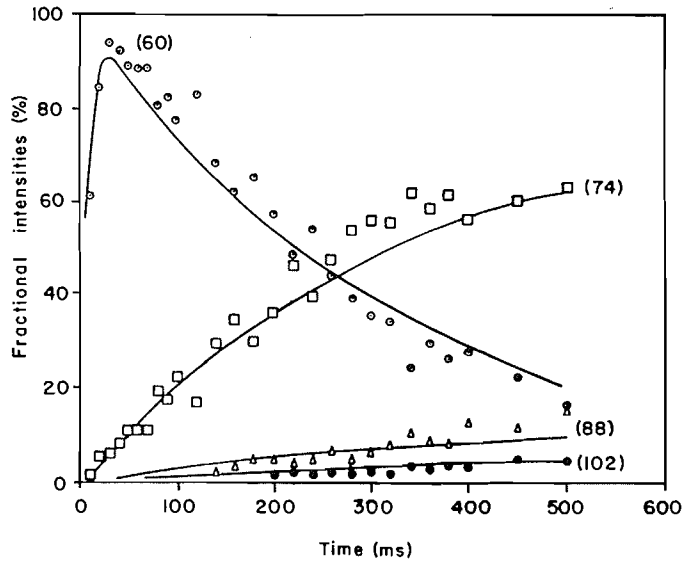

FIG. 2. Fractional intensities of ion species formed in a 8:1 mixture of $C_3H_7NH_2/CH_3NH_2$ as a function of time: (60) $C_3H_7NH_3^+$, (74) $[C_3H_7NH_2CH_3]^+$, (88) $[C_3H_7NH_2C_2H_5]^+$ and $[C_3H_7NH(CH_3)_2]^+$, (102) $[(C_3H_7)_2NH_2]^+$. Solid lines represent simulation results.

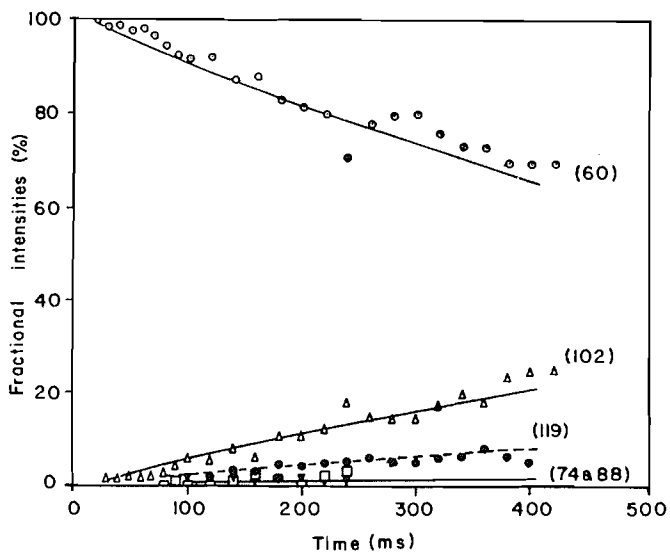

FIG. 3. Fractional intensities of ion species formed in pure propylamine as a function of time: (60) $C_3H_7NH_3^+$, (74) $[C_3H_7NH_2CH_3]^+$, (88) $[C_3H_7NH_2C_2H_5]^+$, (102) $[(C_3H_7)_2NH_2]^+$, (119) $(C_3H_7NH_2)_2H^+$. Solid lines represent simulation results.

If one compares these results with those in pure propylamine (Fig. 3), one can see that although ions with m/z = 74 and 88 are the major products in the 8:1 mixture (the same is true for 1:1, 2:1, and 4:1 mixtures), these ions occur only in small amounts in pure propylamine. The main product ions in pure propylamine are species with m/z = 102 and 119, which are assumed to be $[(C_3H_7)_2NH_2]^+$ and $(C_3H_7NH_2)_2H^+$, respectively. In contrast, at longer times, these ions account for less than 5% of the mass spectrum of the $PrNH_2$:$MeNH_2$ = 8:1 mixture and much less in methylamine-richer mixtures. These results imply that the dominant ion/molecule processes are methyl group transfer from methylamine to the protonated propylamine ion species (reactions [10] and [15]).

The calculated rate constants of some reactions for the mixture $PrNH_2$:$MeNH_2$ = 8:1 are shown in Table 2.

TABLE 2. List of rate constants

Reaction	Rate constant[a] (10^{10} cm^3 molecule^{-1} s^{-1})
$C_2H_5NH_3^+ + MeNH_2 \rightarrow [C_2H_5NH_2CH_3]^+ + NH_3$	0.28
$C_2H_5NH_3^+ + EtNH_2 \rightarrow [C_2H_5NH_2CH_3]^+ + MeNH_2$	0.03
$\rightarrow [(C_2H_5)_2NH_2]^+ + NH_3$	0.04
$\rightarrow [C_4H_{10}N]^+ + NH_3 + H_2$	0.02
$[C_2H_5NH_2CH_3]^+ + MeNH_2 \rightarrow [C_2H_5NH(CH_3)_2]^+ + NH_3$	0.31
$C_3H_7NH_3^+ + MeNH_2 \rightarrow [C_3H_7NH_2CH_3]^+ + NH_3$	0.34
$C_3H_7NH_3^+ + PrNH_2 \rightarrow [C_3H_7NHCH_3]^+ + EtNH_2$	0.05
$\rightarrow [C_3H_7NH_2C_2H_5]^+ + MeNH_2$	0.01
$\rightarrow [(C_3H_7)_2NH_2]^+ + NH_3$	0.03
$[C_3H_7NH_2CH_3]^+ + MeNH_2 \rightarrow [C_3H_7NH(CH_3)_2]^+ + NH_3$	0.06
$C_4H_9NH_3^+ + MeNH_2 \rightarrow [C_4H_9NH_2CH_3]^+ + NH_3$	0.08
$C_4H_9NH_3^+ + BuNH_2 \rightarrow [C_4H_9NH_2CH_3]^+ + PrNH_2$	0.01
$\rightarrow [C_4H_9NH_2C_2H_5]^+ + EtNH_2$	0.01
$\rightarrow [(C_4H_9)_2NH_2]^+ + NH_3$	0.007
$[C_4H_9NH_2CH_3]^+ + MeNH_2 \rightarrow [C_4H_9NH(CH_3)_2]^+ + NH_3$	0.09

[a]These rate constants are within a factor of 2.

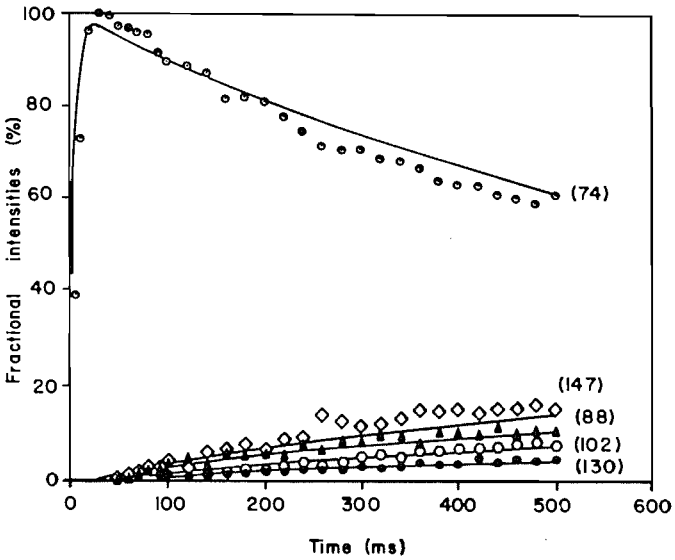

FIG. 4. Fractional intensities of ion species formed in a 8:1 mixture of n-$C_4H_9NH_2/CH_3NH_2$ as a function of time: (74) $C_4H_9NH_3^+$, (88) $[C_4H_9NH_2CH_3]^+$, (102) $[C_4H_9NH_2C_2H_5]^+$ and $[C_4H_9NH(CH_3)_2]^+$, (130) $[(C_4H_9)_2NH_2]^+$, (147) $(C_4H_9NH_2)_2H^+$. Solid lines represent simulation results.

Mixtures of butylamine ($BuNH_2$) with methylamine ($MeNH_2$)

The mixtures of $BuNH_2$:$MeNH_2$ = 1:1, 2:1, 4:1, and 8:1 respectively were investigated for their reactions occurring after ionization by 70 eV electrons.

Figure 4 shows the fractional intensities of some ion species formed in an 8:1 mixture as a function of time. The proton affinity of n-butylamine (PA = 914 kJ/mol) is larger than that of methylamine (PA = 896 kJ/mol) (21*b*) and because the proton transfer in amines is very fast (at almost collision rate) the primary ions: $CH_3NH_2^+$, CH_3NH^+, $C_4H_9NH_2^+$ ... etc., formed by electron impact quickly are transformed to protonated butylamine ions. One can see, indeed, that after 50 ms the only species practically present in the system is $(C_4H_9NH_3)^+$, and the resulting sequence of ion/molecule reactions are processes between this ion and neutral component molecules of the mixture (Fig. 4).

The observed ion products are assumed to be $(C_4H_9NH_2CH_3)^+$ at m/z = 88, $(C_4H_9NH_2C_2H_5)^+$ or $[C_4H_9NH(CH_3)_2]^+$ at m/z = 102, $[(C_4H_9)_2NH_2]^+$ at m/z = 130, and $(C_4H_9NH_2)_2H^+$ at m/z = 147. The fractional intensities of ions of m/z = 88 and m/z = 147 depends on the mixture ratio. The former dominates when the mixture ratio is $BuNH_2$:$MeNH_2$ = 1:1, whereas the latter ion dominates for a mixture ratio of 8:1 respectively. These results imply that $(C_4H_9NH_2CH_3)^+$ species are mainly formed in reaction [16]. On the other hand, the $(C_4H_9NH_2)_2H^+$ ions are apparently formed mainly in reaction [20], if we assume that the dibutylamine impurity is only in trace amounts.

The suggested mechanism is shown below:

[16] $C_4H_9NH_3^+ + CH_3NH_2 \rightarrow [CH_3NH_2..C_4H_9NH_3]^{*+} \rightarrow [C_4H_9NH_2CH_3]^+ + NH_3$

$C_4H_9NH_3^+ + C_4H_9NH_2 \rightarrow [C_4H_9NH_2...H^+...NH_2C_4H_9]^* \rightarrow$

[17] $\rightarrow [(C_4H_9)_2NH_2]^+ + NH_3$

[18] $\rightarrow [C_4H_9NH_2C_2H_5]^+ + C_2H_5NH_2$

[19] $\rightarrow [C_4H_9NH_2CH_3]^+ + C_2H_5NH_2$

[20] $\xrightarrow{M} (C_4H_9NH_2)_2H^+$

In addition the following reaction may contribute to the formation of the $C_6H_{16}N^+$ (m/z = 102) species:

[21] $(C_4H_9NH_2CH_3)^+ + CH_3NH_2 \rightarrow [C_4H_9NH(CH_3)_2]^+ + NH_3$

The apparent rate constants for these reactions are summarized in Table 2.

The comparison of rate constants for methyl group transfer reactions [4], [10], and [16] involving the three alkylamines (Table 2) indicates that butylamine is the least reactive and that ethylamine and propylamine have similar reactivities. In the case of methyl group transfer to $CH_3NH_3^+$ ion species its rate constant is estimated to be $(0.2 \pm 0.1) \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}, which is close enough to the rate constants of reactions [4] and [10], indicating that these processes proceed through a similar mechanism involving the C—N bond cleavage. The lower rate constant for methyl group transfer to protonated butylamine (reaction [16]) may reflect steric effects. On the other hand, reactions [5] to [7], [11] to [13], [17] to [19] involving a C—C bond rupture to release neutral alkylamine have rate constants one order of magnitude smaller (Table 2).

The lowest rate constants in Table 2 have to be taken

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

cautiously. If one assumes reasonable rate constants for proton transfer reactions, it requires appropriate impurities at the level of about 0.1% to account for the products in reactions [5], [7], [11], [12], [18], and [19]. However, we were unable to identify and to measure at this level the impurities contained in the available amines.

Conclusion

The present results indicate that with increasing methylamine concentration in mixtures the fractional intensities of product ions of general formula $(RNH_2CH_3)^+$ is notably increased. Therefore, it appears that methyl group transfer reactions occur from methylamine to higher protonated alkylamine ions. The calculated rate constant for these methyl group transfer processes are between 50 and 100 times smaller than the rate constants for proton transfer reactions. Therefore, the eventual presence of small amounts of dimethyl- or trimethylamines impurities can hinder very efficiently the methyl group transfer processes from methylamine. This is the reason why these processes were not observed unambiguously in the mass spectrum of methylamine.

Facile 5-*endo* ring closures to the azo group. A free radical synthesis of indazoles

CHERYL P. A. KUNKA AND JOHN WARKENTIN[1]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received August 25, 1989

CHERYL P. A. KUNKA and JOHN WARKENTIN. Can. J. Chem. **68**, 575 (1990).

Five 1-alkyl-3-methylindazoles were prepared by treatment of 1-(2-bromophenyl)-1-methoxy-1-(2-alkylazo)ethanes with tri-*n*-butyl stannane and AIBN at 80°C in benzene. Yields in the radical cyclization step ranged from 39 to 92%. 1-Phenyl-3-methylindazole was prepared by an analogous route but in very poor yield (<5%). Rate constants for the 5-*endo* radical closures ($k_{5\text{-}en}^{80°C}$), estimated by the radical clock method, were $5.2 \times 10^9\ s^{-1}$ and $9.2 \times 10^8\ s^{-1}$ for two of the alkyl systems. Rate constants for analogous 5-*endo* cyclizations of aryl radicals onto C—C double bonds are much smaller than those for cyclizations to the azo functional group.

Key words: cyclization, radical; azo group, radical closure to; indazoles, radical synthesis of.

CHERYL P. A. KUNKA et JOHN WARKENTIN. Can. J. Chem. **68**, 575 (1990).

On a préparé cinq 1-alkyl-3-méthylindazoles en faisant réagir des 1-(2-bromophényl)-1-méthoxy-1-(2-alkylazo)éthanes avec du tri-*n*-butyl stannane et du AIBN, à 80°C, dans le benzène. Les rendements obtenus au cours de la cyclisation radicalaire varient de 39 à 92%. Utilisant une voie analogue, on a aussi préparé le 1-phényl-3-méthylindazole avec un très mauvais rendement (<5%). Pour deux des systèmes alkylés, les constantes de vitesse des cyclisations radicalaires 5-*endo* ($k_{5\text{-}en}^{80°C}$), telles qu'évaluées par la méthode de l'horloge radicalaire, sont égales à $5{,}2 \times 10^9\ s^{-1}$ et $9{,}2 \times 10^8\ s^{-1}$. Les constantes de vitesse des cyclisations 5-*endo* analogues des radicaux aryles sur les doubles liaisons C—C sont beaucoup plus faibles que celles des cyclisations sur le groupement fonctionnel azo.

Mots clés : cyclisation radicalaire; cyclisation radicalaire sur un groupement azo; synthèse radicalaire d'indazoles.

Introduction

Intramolecular reaction of a free radical with a suitably placed site of unsaturation leads to the formation of a cyclic isomer of the initial radical. Such radical cyclizations now occupy a prominent place among methods for the construction of five- and six-membered rings. In the most common applications the site of unsaturation is a carbon–carbon multiple bond[2] but examples of closures to the carbonyl (8–10) and cyano groups (8, 11) as well as to imino (12) and azo (13, 14) functionality have been reported. Recently it was found (14) that cyclizations of aryl radicals onto the azo functional group are faster than corresponding alkene cyclizations and do not show the high selectivity for formation of a five-membered ring, rather than a six-membered ring, that is fairly characteristic of the latter. Very little else is known about radical cyclizations to the azo group and there are no examples of 5-*endo* closures. Therefore we decided to explore the utility of that reaction for the construction of the indazole ring system. We now report that some 5-*endo* cyclizations to azo nitrogen are facile and useful.

Methods, results, and discussion

An attractive system for studying 5-*endo* ring closures to azo nitrogen is the family of substrates **3**. They are readily available from hydrazones **2** by oxidation with lead tetraacetate (LTA) in methanol, Scheme 1. Moreover, the anticipated products (**6**) of cyclization were expected to lose methanol spontaneously to afford indazoles (**7**), (Scheme 1). Finally, authentic samples of the expected by-products (**8**) can by synthesized readily in two steps from acetophenone.

The yields of 12 hydrazones of 2-bromoacetophenone (**2**) or of acetophenone (**9**), together with their ^{1}H NMR spectra are listed in Tables 1 and 2. An interesting feature of the compounds **2** is that two isomers were observed in each case by ^{1}H NMR spectroscopy, whereas the acetophenone hydrazones (**9**) did not show isomerism. Several explanations of those phenomena are possible and discussion of them is deferred until after additional experiments are completed.

Oxidation of **2** with lead tetraacetate in methanolic solution (Scheme 1) afforded azoethers (**3**, Table 3), which were purified without difficulty by chromatography, to remove the azoacetate by-product. Reference compounds **8** (Scheme 1) were similarly prepared from the appropriate acetophenone hydrazones. Yields and spectral data of azoethers **3** and **8** are in Table 3.

Solutions of **3**, with benzene containing AIBN and excess $HSnBu_3$ in sealed tubes, were heated at 80°C to afford indazoles **7**, azoethers **8**, methanol, and products derived from **8**, including the appropriate hydrazone of acetophenone and, in some cases, acetophenone. The presumed precursors (**6**) of the indazoles could not be detected and are assumed to be short-lived under the conditions of their formation. Spectra of the indazoles **7** are in Table 4.

Control experiments, in which indazole **7** was subjected to the radical cyclization conditions, indicated that the indazole products are not affected by the other species present. Analogous experiments with **8**, however, revealed that they are not inert to the reaction conditions, but are partially converted to a mixture of products, including the parent hydrazone and acetophenone. A mechanism that could account, in part, for the disappearance of **8** is given in Scheme 2. Tributylstannyl radicals can presumably add to the azo group to form radical **10**. The latter would then afford **11** and **12** in sequence and **12** could lead to **9** during work-up. There is precedent for protiodestannylation of a vinyltin compound (16) during chromatography on silica with dichloromethane.

The initial addition of $Bu_3Sn\cdot$ (Scheme 2) could also occur with the alternative regiochemistry, leading to a regioisomer of **11** that could also afford **9** during the work-up. Acetophenone could arise during the work-up from hydrolysis of **9**, although alternative pathways, including decomposition of an azohydro-

[c]A methyl group singlet at δ ≃ 2.06 is superimposed on the multiplet corresponding to ten cyclohexyl protons.

peroxide formed from **12** by reaction with oxygen, cannot be excluded.

Analogous addition of $Bu_3Sn\cdot$ to **3** does not compete effectively with debromination, in general, as indicated by the yields of indazoles that can be obtained. However, the very poor yield of indazole from **3***f* suggests that either addition to the phenylazo functional group, to form the phenyl-conjugated hydrazyl radical, or methoxyl abstraction, is faster than abstraction of Br from **3***f*. The competition with halogen abstraction is serious, for use of the 2-iodo analogue of **3***f* did not raise the yield of indazole **7***f* significantly.

The instability of **8** under the reaction conditions made it difficult to estimate cyclization rate constants, $k_{5\text{-}en}$ (Scheme 1). Those are normally obtained from product analysis and a knowledge of the magnitude of k_H. In this case, quantitative analysis for **8**, and for numerous products derived from it, was not possible and it was necessary to resort to the assumption that all of the non-indazole material should be counted as **8**. In other words, the yield of **8** was estimated by difference, as 100 minus the yield of **7**, eq. [1]. The assumption should lead to minimum values of $k_{5\text{-}en}$, because the denominator in eq. [1] will presumably be equal to, or larger than, the percentage of **4** that went to **8**. A second problem has to do with the actual value of k_H. Although k_H for the phenyl radical has been measured directly (17), the published value ($k_H^{80°C} = 8.9 \times 10^8\ M^{-1}\ s^{-1}$) is now known to be in error and it was necessary to use a value ($k_H^{80°C} = 3.5 \times 10^8\ M^{-1}\ s^{-1}$) from a secondary source (18).

$$[1] \quad k_{5\text{-}en} = k_H \frac{[HSnBu_3]\ (\text{yield of } \mathbf{7})}{(100 - (\text{yield of } \mathbf{7}))}$$

Values of $k_{5\text{-}en}$ for the two cases that gave the best yields, and for which eq. [1] is most likely to be a good approximation, are in Table 5. In view of the way in which those values had to be obtained, the uncertainty in them is quite large, possibly as much as a factor of five. Nevertheless, there is a strong indication that cyclization of the alkylazo aryl radicals (**4***a*–**4***e*) is fast, with $k_{5\text{-}en} \geq 10^9\ s^{-1}$ at 80°C. The phenylazo-substituted aryl radical, **4***f*, either cyclizes more slowly, resulting in the very poor yield of **7***f* (Table 4), or else **4***f* is not formed efficiently, as was discussed above.

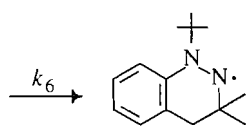
[2] 
13

Fast 5-*endo* cyclization of radicals **4***a*–**4***e* is a striking result. Analogous cyclization of *ortho* alkenylaryl radicals (**13**, eq. [2]) is very much slower,[3] with $k_{5\text{-}en}^{80°C} \simeq 1.0 \times 10^3\ s^{-1}$. In fact, the 5-*endo* cyclizations reported here are at least as fast as 5-*exo*

[3] 
14

cyclizations of **14** (eq. [3]) for which $k^{80°C} = 3.7 \times 10^8\ s^{-1}$ (18), and are comparable to the rates of 5-*exo* and 6-*endo* cyclizations of radical **15**, eq. [4].

[4] 
15



[3]The rate constant is an estimate based on the fact that ring closures of aryl radicals are some two to three orders of magnitude faster than those of alkyl radicals (19). The rate constant for 5-*endo* cyclization of 4-pentenyl at 60°C is believed to be no larger than $1.0\ s^{-1}$ (20).

For **15**, $k_5 = 1.5 \times 10^9\ s^{-1}$ and $k_6 = 2.3 \times 10^9\ s^{-1}$ at 82°C (14).

Although 5-membered rings result from radicals **4**, there are actually two ways in which **4** can rearrange to **5** (Scheme 1). Besides direct 5-*endo* closure there could be 4-*exo* cyclization followed by neophyl rearrangement, Scheme 3. Although neophyl rearrangement of hydrazyls was reported recently (21), we consider the mechanism of Scheme 3 to be unlikely. First, 4-*exo* closure of radicals **4** is unlikely to have a rate constant as large as $10^8\ s^{-1}$ at 80°C, given that cyclizations to form cyclobutylcarbinyl radicals are virtually unknown (20). Moreover, even if such a large rate constant were accepted, it is unlikely that the neophyl rearrangement could be fast enough to prevent **16** from abstracting from $HSnBu_3$ during their lifetimes. The rate constant for rearrangement of the neophyl (2-methyl-2-phenylpropyl) radical is about $1.6 \times 10^4\ s^{-1}$ at 80°C (22). Therefore, if more than 50% of **16** were to advance to **17** at $[HSnBu_3] = 3.49\ M$ (neat $HSnBu_3$), k_H for the step **16** → **18** would have to be less than $4.6 \times 10^3\ M^{-1}\ s^{-1}$ at 80°C.

We were unable to detect intermediates, such as **18**, by ^{1}H NMR spectroscopy of partially converted samples of **3**, and we are led to conclude that **18** are either not involved in the overall process or else that they are short-lived and rearrange to **7** by a mechanism such as that involving ylide **19**. In short, the probability that the rate constants in Table 5 are really those for 4-*exo* cyclization is small. That mechanism is not ruled out, however, because the properties of **16** and **18** are unknown.

Indazoles can be prepared readily by non-radical methods (23). The fact that the four indazoles **7***a*–**7***d* were unknown when this work was begun suggests that the approach based on

[b]Obtained from eq. [1] by using the initial value of $[HSnBu_3]$..

[c]From eq. [1] with $k_H = 3.5 \times 10^8$ M^{-1} s^{-1} at 80°C (17).

radical cyclization holds promise as an alternative synthetic route. However, much more important is the general promise for the construction of heterocyclic rings that is suggested by the high reactivity of the azo group in 5-*endo* as well as in 5-*exo* and 6-*endo* cyclizations (14).

Experimental

Ultraviolet spectra (hexane) were obtained with a Hewlett Packard model 8451A diode array spectrophotometer. Proton magnetic resonance spectra were recorded with a Varian EM-390 spectrometer. Deuterochloroform was the solvent and TMS was the internal reference. Carbon-13 NMR spectra were obtained with a Bruker AM-500 instrument operating at 125.76 MHz and were calibrated against the ^{13}C signal of the $CDCl_3$ solvent at 77.20 ppm. Mass spectra were obtained with a VG 70-70F, double focusing, or a VG ZAB-E, triple focusing, mass spectrometer. Samples were introduced by means of a direct insertion probe and the energy of the ionizing electrons was 70 eV.

Separations were generally carried out by means of centrifugal chromatography, with a Chromatotron (model 7924T) device fitted with a silica coated (Merck, Kieselgel 60 PF_{254}, 2 mm thickness) glass plate. The eluting solvent was ethyl acetate (2%) in low boiling petroleum ether, both distilled before use.

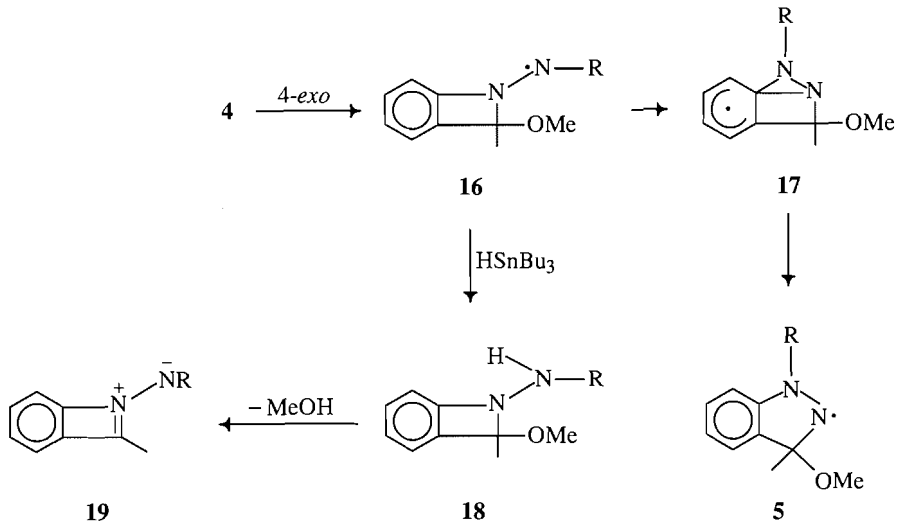

SCHEME 3

Syntheses

The straightforward syntheses of azoethers **3** are illustrated with a detailed procedure for **3***a*.

Cyclohexylhydrazine was prepared by the dropwise addition of cyclohexyl bromide (25.08 g, 0.15 mol) in 25 mL of ethanol to hydrazine hydrate (50 g, 1.0 mol) in 50 mL of ethanol. The resulting solution was heated to 74°C for 27.5 h before the ethanol was removed and the residue was extracted with ether (300 mL) for 2 days in a continuous extractor. The ether layer was dried over magnesium sulfate and the ether was evaporated to leave cyclohexylhydrazine (3.12 g, 18%), satisfactory for the next step; ^{1}H NMR (90 MHz, $CDCl_3$) δ:0.48–2.80 (m, 10H), 3.14–4.18 (m, 4H).

o-Bromoacetophenone cyclohexylhydrazone (**2***a*) was prepared by refluxing a solution of *o*-bromoacetophenone (2.13 g, 0.011 mol) and cyclohexylhydrazine (1.45 g, 0.013 mol) in 25 mL of ether, with stirring, under nitrogen for 41 h. Drying over $MgSO_4$ and evaporation of the ether yielded **2***a* (3.16 g, 82%) as a 60:40 mixture of isomers.

1-(*o*-Bromopheny)-1-cyclohexylazo-1-methoxyethane (**3***a*) was prepared by addition of a solution of **2***a* (3.16 g, 0.011 mol) in 25 mL of methanol through a dropping funnel to an ice-cold solution of lead tetraacetate (5.83 g, 0.013 mol) in 30 mL of methanol. Stirring and cooling were continued for 8 h. Most of the solvent was removed with a rotary evaporator, ice water (50 mL) and dichloromethane were added, and both phases were filtered through a bed of Celite. The organic layer was separated and the aqueous phase was extracted twice more with dichloromethane. The combined organic extract was washed sequentially with ice water, with dilute, cold bicarbonate solution, with ice water, and with cold brine before it was dried over magnesium sulfate. Evaporation of the solvent left crude **3***a*, which was purified in lots of ca. 200 mg by centrifugal chromatography. Spectral data for **3***a*, as well as for analogs prepared by similar methods, are in Tables 1–3.

Cyclizations to indazoles

The procedure described below for the case of **7***a* is representative.

A solution of **3***a* (512 mg, 1.66 mmol), tri-*n*-butyltin hydride (576 mg, 1.98 mmol), and azobisisobutyronitrile (13.5 mg, 0.08 mmol) in benzene (10 mL) was sealed into a glass tube after three cycles of freeze–pump–thaw degassing. The tube was immersed in an oil bath controlled at 80°C. After 30 h the tube was cooled and opened, and most of the benzene was distilled from the reaction products. Centrifugal chromatography of the residue afforded **7***a* (327 mg, 92%). Yields, and spectral data for all of the indazoles, are in Table 4.

Received November 14, 1989

TED SCHAEFER, CHRISTIAN BEAULIEU, RUDY SEBASTIAN, and GLENN H. PENNER. Can. J. Chem. **68**, 581 (1990).

The twofold barrier to rotation about the C_{sp^2}—C_{sp^3} bond in benzyl fluoride is deduced from the long-range $^1H,^1H$; $^1H,^{19}F$; and $^{13}C,^{19}F$ nuclear spin–spin coupling constants in solution. The barrier changes from 3.2(2) kJ/mol in the polar solvent, acetonitrile-d_3, to 0.7(2) kJ/mol in the nonpolar environment provided by cyclohexane-d_{12}. In all solutions the conformer of greatest stability has the C—F bond in a plane perpendicular to that of the phenyl group. Extrapolation of the barrier to the vapor phase, using a simple reaction field model, indicates that the most stable conformer for the free (unclustered) molecule is now that with the C—F bond in the phenyl plane and that the barrier to internal rotation is 1.1(7) kJ/mol. Molecular orbital calculations with the basis sets STO-3G, 4-21G, 4-31G, 6-31G, and 6-31G* all predict the latter conformer as that of lowest energy. However, they disagree significantly among themselves as to the height of the internal barrier. The complete geometries are given for both conformers, as computed with the 6-31G basis, and the side-chain geometries are tabulated for the planar and perpendicular conformers, as given by all the bases.

Key words: benzyl fluoride, internal rotational potential; $^{13}C,^{19}F$ spin–spin coupling constants in benzyl fluoride; benzyl fluoride, molecular orbital computations.

TED SCHAEFER, CHRISTIAN BEAULIEU, RUDY SEBASTIAN et GLENN H. PENNER. Can. J. Chem. **68**, 581 (1990).

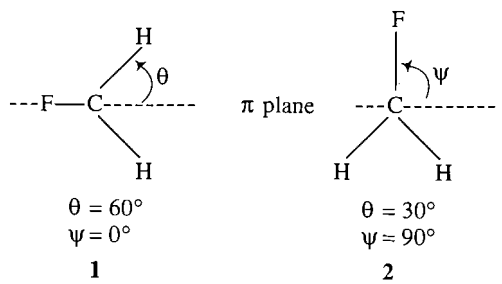
En se basant sur les constantes de couplage nucléaire spin–spin à longue distance entre ^1H et ^1H, entre ^1H et ^{19}F et entre ^{13}C et ^{19}F mesurées en solution, on a déterminé la valeur de la barrière binaire à la rotation autour de la liaison C_{sp^2}—C_{sp^3} dans le fluorure de benzyle. Cette barrière varie de 3,2(2) kJ/mol dans le solvant polaire, l'acétonitrile-d_3, à 0,7(2) kJ/mol dans l'environnement non-polaire fournit par le cyclohexane-d_{12}. Dans toutes les solutions, le conformère le plus stable est celui dans lequel la liaison C—F se trouve dans un plan perpendiculaire à celui du groupement phényle. L'extrapolation de la barrière à la phase vapeur, utilisant un modèle simple de champ de réaction, indique que le conformère le plus stable de la molécule libre (non encombrée) est celui dans lequel la liaison C—F se trouve dans le plan du groupement phényle et que la barrière à la rotation interne est de 1,1(7) kJ/mol. Des calculs d'orbitales moléculaires effectués à l'aide des bases STO-3G, 4-21G, 4-31G, 6-31G et 6-31G* prédisent tous que ce dernier possède l'énergie la plus faible. Toutefois, ces calculs diffèrent beaucoup entre eux concernant la valeur absolue de la barrière interne. On rapporte les géométries complètes des deux conformères telles que calculées avec la base 6-31G et l'on fournit des tables rapportant les géométries des chaînes latérales des conformères plans et perpendiculaires telles qu'elles ont été évaluées par chacun des ensembles.

Mots clés : fluorure de benzyle, potentiel de la rotation interne; constantes de couplage nucléaire spin–spin entre ^{13}C et ^{19}F en fluorure de benzyle; calculs d'orbitales moléculaires pour le fluorure de benzyle.

[Traduit par la revue]

Introduction

The barrier to rotation about the C_{sp^2}—C_{sp^3} bond in benzyl fluoride has been assessed theoretically and experimentally, with diverse results. Geometry-optimized STO-3G MO computations (1) indicate that the barrier is 1.4 kJ/mol in magnitude and twofold in nature, **1** being the conformation of lowest energy. Electron diffraction patterns of the vapor, together with molecular mechanics calculations (2), imply a minimum in the internal rotation potential near a ψ of 60° and a barrier height of 1.7 kJ/mol. The geminal proton coupling constant, ^2J(H,H), for a $CDCl_3$ solution suggests a conformation intermediate between **1** and **2**, with a small barrier (2), while ^5J(C,F) indicates essentially free internal rotation (3). Nuclear spin-lattice relaxation times in solution are consistent with rather different internal barriers, perhaps as large as 11 kJ/mol (4, 5). ^{19}F nuclear magnetic resonance chemical shifts, as a function of temperature in acetone solution (6), can be interpreted to mean that **2** is 1.7 kJ/mol more stable than **1**.



1 **2**

More recently (1), ^5J(C,F), ^6J(H,H), and ^6J(H,F) in benzyl fluoride, in a number of solvents, suggest strongly that, if the barrier is twofold, then **2** is stabilized by about 2 kJ/mol in passing from CS_2 to acetone-d_6 solution; in CS_2 solution the internal potential is rather flat and may be completely so at 300 K. The latest investigation, for solutions in liquid crystalline solvents (7), finds a twofold barrier of 0.3 ± 0.02 kJ/mol in one such solvent and a barrier of 1.5 ± 0.08 kJ/mol in another, more polar, liquid crystal environment. In both instances, at 300 K the stable conformer is **2** (7).

The latter work has encouraged us to reexamine our data for ^6J(H,H) and ^6J(H,F), to remeasure ^nJ(C,F) in a number of solvents, and to attempt an extrapolation of these data to the vapor phase. The results are reported below. It appears that **1** is the most stable conformer for the free molecule, and this conclusion is in agreement with a series of molecular orbital calculations, also reported below.

Experimental

Benzyl fluoride was prepared as dilute solutions in the solvents given in Table 2. The solutions were transferred to 5 mm od nmr sample

[a]At 300 K, based on ^5J(C,F) in Table 1 and a $^5J_{90}$ of 5.03(13) Hz (see text). **2** is the stable form if $\langle\sin^2\psi\rangle > 0.5$.
[b]From tables of $\langle\sin^2\psi\rangle$ as a function of V_2, computed from a hindered rotor model, although a classical average yields the same results for such barriers at 300 K. The error of 0.2 kJ/mol is given as twice that implied by the error in $\langle\sin^2\psi\rangle$.
[c]The static dielectric constant, or permittivity, estimated for the solution by assuming molar additivity of the constituents, including benzyl fluoride (see text).

tubes. The latter were degassed by the freeze–pump–thaw procedure, employing at least four cycles, and were then flame-sealed. The ^{13}C nmr spectra were obtained on an AM300 spectrometer at a probe temperature of 300 K in a manner described previously (1). The digital resolution was 0.004–0.005 Hz/point.

Molecular orbital computations with partial geometry optimization (see Table 3) were performed on benzyl fluoride as a function of the angle of rotation about the C_{sp^2}—C_{sp^3} bond. The basis sets included the STO-3G, 4-21G, 4-31G, 6-31G, and 6-31G* (5*d* orbitals on each heavy atom), as described (8). The GAUSSIAN 82 computer algorithms (9) were employed on an Amdahl 5870 system. Some STO-3G MO calculations were also done for some derivatives of benzyl fluoride (Table 3).

Results and discussion

The ^{13}C nmr chemical shifts of benzyl fluoride for six solvents are presented in Table 1, as are the values of ^nJ(C,F) for n = 1–5. The signs of all but ^4J(C,F) are known (1). That of ^4J(C,F) is almost certainly negative (1), as expected on the basis of spin correlation (10, 11).

The internal barrier in CS_2/C_6D_{12} and acetone-d_6 solutions

The following argument depends on the $\sigma-\pi$ nature of ^6J(H,H) and ^6J(H,F). This matter has been discussed in detail (1) for benzyl fluoride and it is concluded that ^6J(H,H) and ^6J(H,F) are proportional to $\sin^2\theta$ and $\sin^2\psi$, respectively. To a very good approximation, therefore, one may write that $\langle\sin^2\theta\rangle = 0.75 - 0.5\langle\sin^2\psi\rangle$, angular brackets indicating expectation values. These expectation values can be had from the measured values of ^6J if ^6J is known at its extremum, that is, when θ and ψ are 90°. In the present instance, recognizing that the polar and nonpolar solutions cause different values for the two expectation values, one has two equations in two unknowns, the extrema in ^6J(H,H) and ^6J(H,F). The former is −0.452(2) and −0.409(2) Hz in CS_2/C_6D_{12} and acetone solutions, respectively (1), whereas the latter is −1.539(2) and −1.800(2) Hz in the two solutions at 300 K. Thus, for the CS_2/C_6D_{12} solution, $\langle\sin^2\theta\rangle = -0.452(2)/^6J_{90}$(H,H) and $\langle\sin^2\psi\rangle = -1.539(2)/^6J_{90}$(H,F). The ensuing relationships yield $^6J_{90}$(H,H) as −0.941(4) Hz and $^6J_{90}$(H,F) as −2.856(4) Hz. The former number is very close to the −0.95 Hz estimated by other methods and in other connections.[2] The values of $\langle\sin^2\theta\rangle$ follow as 0.480(4) and 0.435(4) in the polar and nonpolar media, respectively, whereas those of $\langle\sin^2\psi\rangle$ are 0.538(2) and 0.630(2).

Tables of expectation values as a function of the twofold barrier, derived from a hindered rotor model (15), then yield the barrier as 0.8(2) kJ/mol in the CS_2/C_6D_{12} and as 2.7(2) kJ/mol in the acetone-d_6 solution. The $\langle\sin^2\psi\rangle$ values, of course, must yield the same estimates; formally, the error estimates, at 0.1 kJ/mol, are somewhat lower than given.

Note that the minimum in the sinusoidal potential well occurs at ψ = 90°, that is, conformer **2** is the most stable in both solutions; in the liquid crystalline solvents, **2** is also most stable (7). For a vanishing barrier the expectation values are 0.5, so that **2** immediately follows as the stable conformer from the fact that $\langle\sin^2\psi\rangle$ is larger than 0.5; for a rigid conformer, **2**, $\langle\sin^2\psi\rangle$ would be unity, of course.

The analysis of the ^1H nmr and ^{19}F nmr spectra at 300 and 282 MHz, respectively, is not an easy matter (1); for example, in CS_2 solution the internal chemical shift between the *ortho* and

[2]Thus, $^6J_{90}$ depends on the electronegativity, E_X, of the substituent, X, on the methyl group and is −1.02 Hz for X = OCH_3 (12, 13) and −1.20 Hz for X = H (14). If E_H, E_O, and E_F are 2.1, 3.5, and 4.0, respectively, then a linear dependence of $^6J_{90}$ on E_X implies $^6J_{90}$ as −0.95 Hz in benzyl fluoride.

[a]Nuclei in the phenyl group held coplanar and the ring as a hexagon, conformer **1** (text) being stable (F in plane).
[b]Hexagonal constraint is relaxed, otherwise as in footnote *a*.
[c]At 300 K.
[d]At only 0°, 30°, 60°, and 90° for ψ, unlike the 15° intervals in ψ for the other bases; ψ is zero when the C—F bond lies in plane.
[e]At ψ = 0° and 90°, only, therefore not a true V_2.
[f]For benzyl fluoride derivatives the STO-3G basis set was used.

para protons is 0.26 Hz. However, ^5J(C,F), for example, is relatively easily measured and, as a σ−π coupling constant (1), can also be used to find V_2.

^{5}J(C,F) and the solvent dependence of V_2

In Table 1, ^5J(C,F) is tabulated for solvents of varying polarity. In the CS_2 and acetone-d_6 solvent mixtures, those for which ^6J(H,H) and ^6J(H,F) were extracted from the ^{1}H nmr and ^{19}F nmr spectra (same sample tubes), ^5J(C,F) is 2.76(1) and 3.11(1) Hz, respectively. The values of $\langle\sin^2\psi\rangle$ obtained from ^6J(H,F) above then yield $^5J_{90}$(C,F) as 5.13(3) and 4.94(3) Hz for the two solutions. The mean, 5.03 ± 0.13 Hz, is in reasonable agreement with that of 5.2 ± 0.3 Hz, deducible from a rigid model compound, 1-fluorindan (3). The error in $^5J_{90}$, at less than 3%, assumes that ^5J(C,F) is a pure σ−π parameter, that is, that it is proportional to $\sin^2\psi$.

The values of $\langle\sin^2\psi\rangle$ then follow for the solutions in Table 1 and are given in Table 2, which also reports the twofold barriers. In all solutions, including that with the least polar C_6D_{12} as solvent, the most stable conformer is **2**. The internal barrier drops from 3.2(2) kJ/mol in the polar CD_3CN environment to 0.7(2) kJ/mol in C_6D_{12}.

The barrier of 0.3 ± 0.02 kJ/mol found in the liquid crystal solvent, 1-(3-fluoro-4′-ethylbiphenyl)-2-(4-*n*-pentylphenyl) ethane (7), is perhaps in reasonable congruence with that of 0.7(2) kJ/mol in C_6D_{12}, derived from ^5J(C,F).

Extrapolation to the vapor phase

The size of V_2 (Table 2) appears to be determined predominantly by the dielectric constant or polarity of the solvent, probably modified by some specific molecular interactions. Qualitatively, because the dipole moment of conformer **2** is most likely larger than that of **1** (1), the higher stability of **2** in the more polar solvents is expected on the basis of a dielectric continuum model based on the reaction field (16). The most straightforward application of that model to the present data (see eq. 13.18 and the discussion on p. 562 of ref. 16) assumes a linear dependence of V_2 on $(\epsilon - 1)/(2\epsilon + 1) \equiv x$, where ϵ is the dielectric constant of the medium. Allowing for the error of 0.2 kJ/mol in the V_2 values, the result is that V_2(kJ/mol) = $-1.14(36) + 8.77(99)x$, with a correlation coefficient of 0.976. The quantity, x, in Table 2 is estimated on the assumption of molar additivity of the dielectric constants of the solution components, including benzyl fluoride. The effective dielectric constant of the latter appears to be similar to that of chloroform, judging by the value (1) of ^5J(C,F). Actually, if the dielectric constant of the solution is taken as that of the major constituent, a very similar value, −0.97(34) kJ/mol, is obtained for V_2 in the vapor phase, that is, when $x = 0$.

For the free molecule (unclustered) one has the result that **1** is now the most stable conformer (negative sign in the linear relationship) and that the twofold barrier is 1.1(7) kJ/mol, where the doubling of the standard error is meant to allow for uncertainties in x and other small corrections (16) to the model. This result should be of interest to microwave, infrared, and other spectroscopists. It may be noted that in 3-fluoropropene the most stable conformer in the vapor phase also has the C—F bond lying *cis* to the double bond and in the plane of the molecule (17, 18) and that in the liquid the stability of this conformer decreases relative to other conformers.

^{4}J(C,F) as a check on V_2

A previous discussion (1) of ^4J(C,F) asserts that ^4J(C,F) = $^4J^\pi\langle\sin^2\psi\rangle + {}^4J^\sigma\langle\sin^2(\psi/2)\rangle$; the σ−π component, $^4J^\pi$, is negative while the σ electron component is positive. For a barrier consisting of evenfold components, the multiplier of $^4J^\sigma$ is 0.5. If the values of ^4J(C,F) for the C_6D_{12} and CD_3CN solutions are used in this equation, then $^4J^\pi$ follows as −6.37 Hz and $^4J^\sigma$ as 5.13 Hz.[3] This parametrization reproduces ^4J(C,F) for the other solutions (using again the $\langle\sin^2\psi\rangle$ values in Table 2) to within a mean deviation of 0.01 Hz. Furthermore, for 3,5-dichlorobenzyl fluoride, the ^5J(C,F) of 2.0 Hz in CS_2 solution (1) entails a ^4J(C,F) of 0.0 Hz and, indeed, this coupling constant appears to vanish (1). Hence the ^4J(C,F) numbers are consistent with the conformational conclusions based on ^6J(H,H), ^6J(H,F), and ^5J(C,F).

^{1}J(C,F), ^{2}J(C,F), and ^{3}J(C,F)

^1J(C,F) varies considerably (Table 1) and correlates reasonably well (r = 0.967) with the dielectric function, x. For unit dielectric constant, ^1J(C,F) extrapolates as −176.9(9) Hz, much different from its value of −162.3 Hz in acetonitrile

[3]It follows that ^4J(C,F) will become positive if **1** is sufficiently stable, that is, if $\langle\sin^2\psi\rangle < 0.4$, corresponding to a barrier of 2.0 kJ/mol or more.

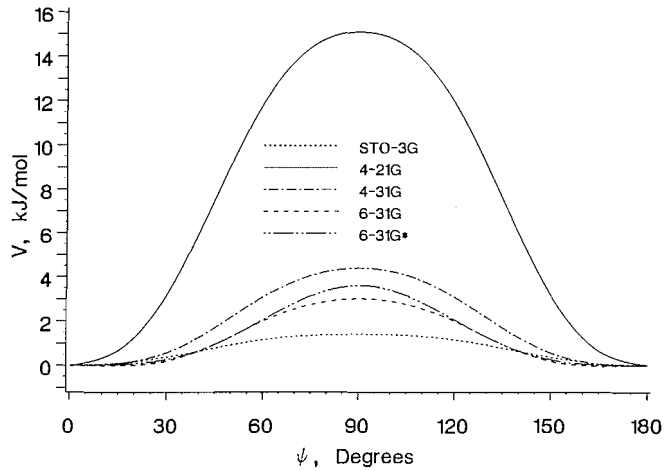

FIG. 1. The internal rotational potentials, obtained from the various basis sets (Table 3), are plotted against the angle, ψ, by which the C—F bond of benzyl fluoride twists out of the plane of the phenyl group. The minimal basis set agrees best with the experimental estimates described in the text.

solution. A possible experiment could involve the preparation of benzyl fluoride-α-^{13}C and the measurement of ^1J(C,F) in the vapor phase via ^{19}F nmr. If the vapor were dense, it would be necessary to know its dielectric constant.

^2J(C,F) correlates at least as well with x as does ^1J(C,F) and is predicted to be 18.4(1) Hz in a medium of unit dielectric constant. ^3J ($r = 0.992$) extrapolates to 6.21(2) Hz at $x = 0$ and, as a Karplus-like coupling constant, is expected to be largest in a planar conformation (1); hence its larger value in the gas phase.

Molecular orbital computations

Table 3 presents the n-fold components of the theoretical potential, V/kJ mol^{-1} = $\Sigma_n V_n \sin^2 n(\psi/2)$, where ψ is the angle by which the C—F bond twists out of the phenyl plane. The quoted errors are the standard deviations in the fits to seven computed energies, at intervals of 15° in ψ. Conformer **1**, with the C—F bond in the phenyl plane, is computed as most stable with all five basis sets. The computed relative stability of **1**, however, varies considerably from basis to basis, the minimal basis set corresponding to the lowest, essentially twofold, barrier at 1.4 kJ/mol; this value is closest to the experimental estimate above. A similar situation holds for the computations of the internal rotational potential for benzaldehyde, for which the minimal basis set agrees best with experiment (19), while the split-valence bases, including the one with polarization functions, 6-31G*, imply much too large a magnitude for the barrier; furthermore, the larger split-valence bases approach most closely the value predicted with the minimal basis. As can be seen in Table 3, relaxation of the hexagonal constraint does not drastically alter the computed potential for the STO-3G basis. The cpu time for the calculations on benzyl fluoride was over 215 h, so that the hexagonal constraint was retained for the 6-31G* optimizations.

The minimal basis set suggests a predominantly twofold barrier, equal in magnitude, within experimental error, to that obtained above by extrapolation from the solution state. The smallest barrier, obtained from the most complete geometry optimization with this basis, is 1.41 kJ/mol (V_4 does not contribute to the height of barrier whereas V_6 contributes negatively). Omission of the small fourfold and sixfold components in Table 3 alters the value of $\langle \sin^2 \psi \rangle$ at 300 K by only as much as 0.004, except for the 6-31G* results where the larger V_4 component increases it by 0.01.

The large barrier of over 15 kJ/mol at the 4-21G level of theory is rejected on the basis of the experimental results. A significant negative fourfold component, amounting to as much as 20% of the twofold in magnitude, is predicted with

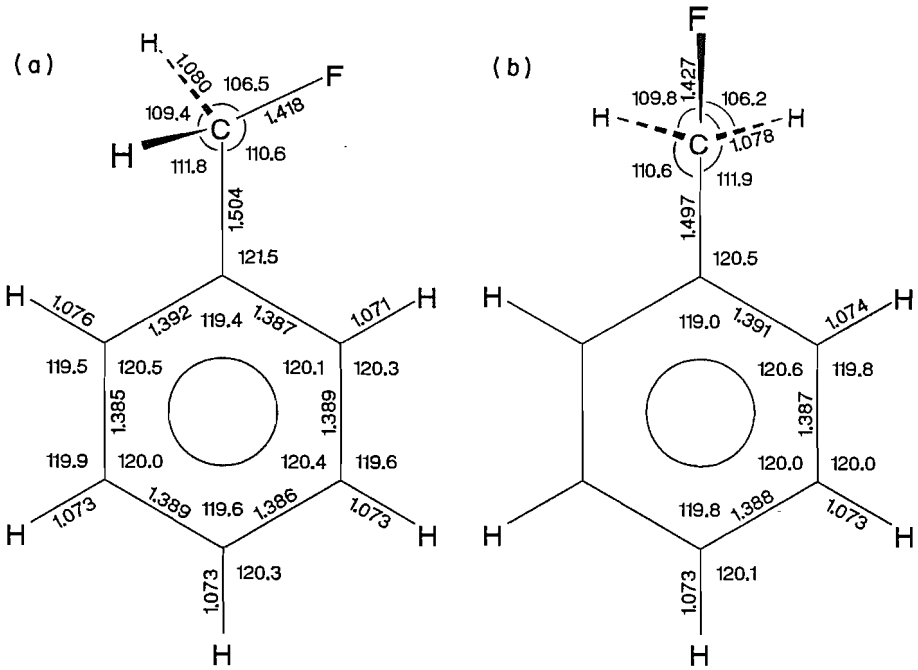

FIG. 2. The geometries of the (a) planar and (b) perpendicular conformers of benzyl fluoride are shown and were obtained with the 6-31G basis set, the largest for which the carbon atoms of the phenyl group were not constrained to a regular hexagon. The geometry of the side chain is somewhat different when computed with the 6-31G* basis, particularly the C—F bond length; see Table 4. During the geometry optimization procedures, the exocyclic C—C bond was constrained to lie in the phenyl plane.

[a]Bond lengths in angstroms, bond angles in degrees, and dipole moments in debyes.
[b]The planar conformation with the C—F bond in the phenyl plane is defined by 0°.
[c]For all but the 6-31G* basis, all bond angles and lengths are optimized. For the polarized basis, the carbon atoms of the phenyl group are constrained to a regular hexagon.
[d]As in Fig. 1.

the larger basis sets. Because $(2V_2 + 8V_4) > 0$, there is no computed barrier to planarity, that is, conformer **1** represents the minimum in the internal potential. The height of the barrier is 3.0 and 3.6 kJ/mol, respectively, according to the 6-31G and 6-31G* bases. In our opinion these magnitudes are too large and, furthermore, at present no experimental evidence exists for sizeable, higher than twofold, components of the barrier. Figure 1 displays the computed internal potential curves for the various basis sets.

It does not follow, of course, that the large basis sets do not yield reasonably reliable equilibrium geometries for the conformers of benzyl fluoride. Figure 2 displays the geometries of conformers **1** and **2**, as computed with the 6-31G basis. Table 4 displays the side-chain geometries of the planar and perpendicular conformers as obtained from the various basis sets. Judging from a recent comparison (21) of geometries from various basis sets, the geometry of the side chain in benzyl fluoride should be further refined at the MP2 level of corrections for electron correlation. Some comparisons with experimental data go as follows. It is deduced (22) from microwave data that the C—F bond length in ethyl fluoride is 1.383(7) Å, while the HCF angle is 107.3(4)°; the latter value is close to that found with the 6-31G* basis. Again, the HCH angle is 108.8°, as deduced from the nmr studies in nematic solutions (7), very close to the 6-31G* results. However, the former have the CCF angle as 105.3° (7), the latter giving 110.7°. It may be that this angle would increase from 105.3° were the C—C_α bond taken as rather shorter than the 1.54 Å assumed in the experimental work.

Of all the computed dipole moments in Table 4, those obtained from the polarized basis with the usual Mulliken procedure best fit the experimental value of 1.77(5) D; the latter refers to a benzene solution at 298 K (23).

The perturbation of the internal rotational potential by ring substituents was simulated by a limited set of computations, also presented in Table 3, employing the STO-3G basis. Substantial perturbations are predicted, the π electron donor, the amino group at the *para* position, causing a reduction in V_2 whereas the 4-nitro, electron-accepting substituent, increases V_2. The *meta* chlorine substituents also enhance V_2. The most simple rationalization is that the electrostatic stabilization of the planar conformer, **1**, by attraction of the C^+—F^- to the *ortho* C^-—H^+ bond (20), is enhanced by the electronegative chlorine and nitro substituents but reduced by the amino and methyl groups; the latter may well reduce the polarity of the C—H bond. That **1** is indeed stabilized in 3,5-dichlorobenzyl fluoride has been demonstrated for a CS_2 solution (1).

The computations imply that each benzyl fluoride derivative will have its own, significantly distinct, internal rotational potential. The experimental results for benzyl fluoride imply a medium effect on each rotational potential. Hence such compounds present a challenge to the various spectroscopies in the vapor and liquid states.

Received August 24, 1989

JAHANGIR, JIAN WANG, RICHARD W. SMITH, DAVID B. MACLEAN, and HERBERT L. HOLLAND. Can. J. Chem. **68**, 587 (1990).

The anion of 5-ethenyl-4-methyl-3-pyridinecarbonitrile **1** undergoes oxidative coupling on treatment with dibenzoyl peroxide affording 1,2-bis-(5′-ethenyl-3′-cyano-4′-pyridyl)-ethane, **2**. It is also shown that the anions of 2- and 4-methylpyridine undergo oxidative coupling. In the latter case, however, the coupling reaction is accompanied by addition to the carbonyl group of dibenzoyl peroxide. The addition products have been identified as phenacyl pyridines and dipicolyl phenyl carbinols. The ethenyl side chain of **1** has been hydrated by way of the oxymercuration–reduction process and the secondary alcohol oxidized to a ketone. Both the alcohol and ketone in protected form are potentially useful intermediates in alkaloid synthesis.

Key words: oxidative coupling, 2- and 4-methylpyridines, dibenzoyl peroxide, oxymercuration–reduction.

JAHANGIR, JIAN WANG, RICHARD W. SMITH, DAVID B. MACLEAN et HERBERT L. HOLLAND. Can. J. Chem. **68**, 587 (1990).

Sous l'action du peroxyde de dibenzoyle, l'anion du 5-éthènyl-4-méthyl-3-pyridinecarbonitrile (**1**) subit un couplage oxydant conduisant au 1,2-bis-(5′-éthènyl-3′-cyano-4′-pyridyl)-éthane (**2**). On a aussi démontré que les anions des 2- et 4-méthylpyridines subissent des couplages oxydants. Dans ces derniers cas, la réaction de couplage est accompagnée d'une addition sur le groupement carbonyle du peroxyde de dibenzoyle. On a identifié les phénacylpyridines et les dipicolylphénylcarbinols comme produits d'addition. La chaîne latérale de produit **1** a été hydratée par le biais d'une réaction d'oxymercuration suivie d'une réduction et l'alcool secondaire ainsi obtenu a été oxydé en cétone. Les formes protégées de l'alcool ainsi que la cétone sont des intermédiaires qui peuvent s'avérer utiles dans des synthèses d'alcaloïdes.

Mots clés : couplage oxydant, 2- et 4-méthylpyridines, peroxyde de dibenzoyle, oxymercuration–réduction

The synthesis of 5-ethenyl-4-methyl-3-pyridinecarbonitrile **1** was reported by Govindachari *et al.* (1) in 1957 and was used by them in the synthesis of gentianine. Some years later Kametani *et al.* (2) prepared **1** using a slightly different procedure, and converted it to gentianine and to 5-ethenyl-1-oxo-1*H*-pyrano[3,4-*c*]pyridine-3-carboxylic acid ethyl ester. The latter compound was used in the synthesis of the indole alkaloid, angustine. We have found that **1**, as its anion, is an effective intermediate for the synthesis of several benzopyridoquinolizines (3) and indolopyridoquinolizines (3*a*, 4), including a number of alkaloids of each ring system as illustrated in Scheme 1 for the former group of compounds. We describe here other transformations of **1**, namely, the oxidative coupling of its anion upon treatment with dibenzoyl peroxide to give 1,2-bis(3′-cyano-5′-ethenyl-4′-pyridyl)-ethane **2**, and the conversion of **1** to 5-(1′-hydroxyethyl)-4-methyl-3-pyridine carbonitrile **3** and to 5-acetyl-4-methyl-3-pyridinecarbonitrile **4**. We show also that the anions of 2- and 4-methylpyridine undergo oxidative coupling upon treatment with dibenzoyl peroxide and that the coupling reaction is accompanied by formation of phenacyl pyridines and dipicolyl phenyl carbinols.

Results and discussion

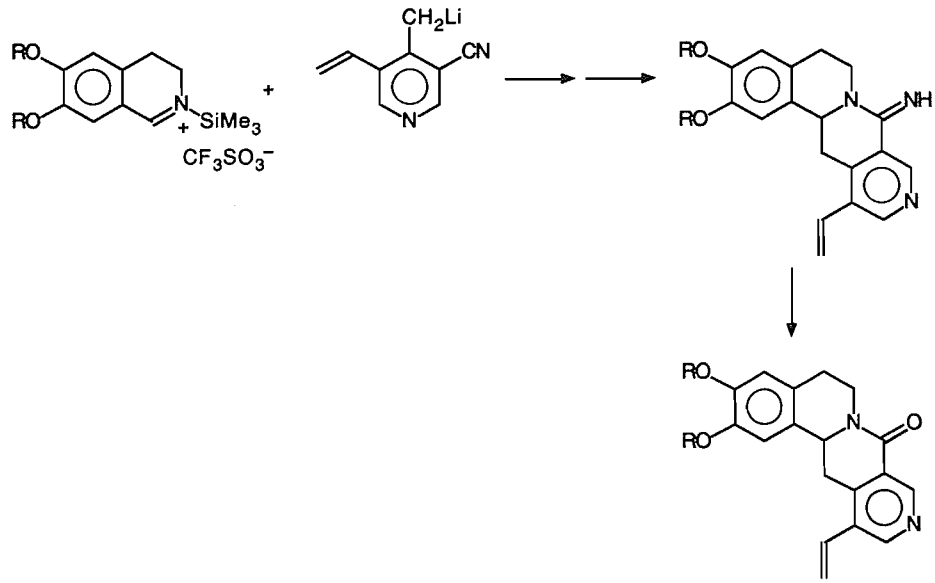
Oxidative coupling

The oxidative coupling of the lithium salt of **1** to give 1,2-bis-(3′-cyano-5′-ethenyl-4′-pyridyl)-ethane **2** upon treatment with dibenzoyl peroxide was discovered in the course of experiments directed toward the synthesis of **5**. We had investigated a variety of methods for converting the methyl group of **1** to CH_2OH in order to prepare **5**. Azaphthalides of this type were used previously to prepare the benzopyridoquinolizine ring system (5). Initially an attempt was made to prepare the alcohol by way of a halide. However, the introduction of a halogen using *N*-bromosuccinimide under a variety of reaction conditions was unsuccessful. Similarly, attempts to halogenate the lithium salt of **1** with chlorine or bromine failed. In an attempt to introduce a benzoate group we treated the lithium salt of **1** with dibenzoyl peroxide but only traces of benzoate ester were formed. Instead, the major product was the coupled product **2** formed in an overall yield of 77% based on **1**. The structure of **2** is based upon its spectroscopic properties. The mass spectrum has a molecular ion at m/z 286 at twice the mass of the starting anion. The ^{1}H nmr spectrum of **2** shows the same number of signals as the starting material **1** reflecting the symmetrical character of the product. The C-methyl signal present in the spectrum of **1** is absent in the "dimer", **2**. However, a new signal is present at δ 3.22, which is ascribed to the newly formed methylenes joining the two pyridine rings.

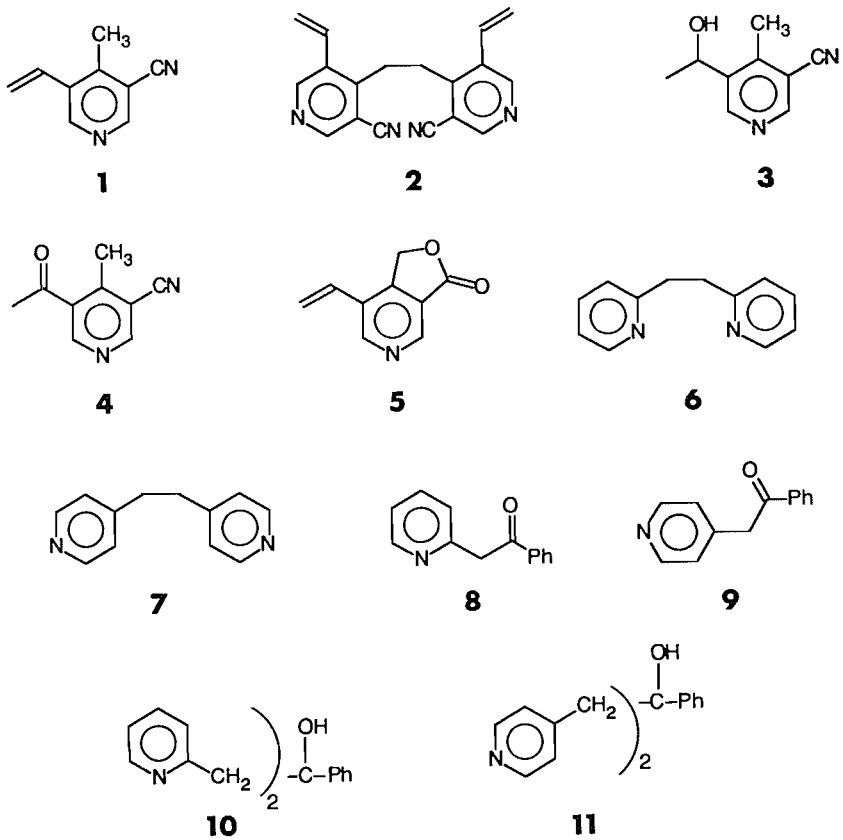
Under the same reaction conditions as those used to prepare **2** we have shown that the lithium salts of 2-methylpyridine and 4-methylpyridine also form dimeric products. The properties of the products of these reactions, namely, 1,2-bis-(2′-pyridyl)-ethane **6** (6) and 1,2-bis-(4′-pyridyl)-ethane **7** (7), agree with those described in the literature. The mechanism of the coupling reaction has not been studied but it is likely that it proceeds by a free radical mechanism.

The initial experiments were conducted using equimolar amounts of dibenzoyl peroxide and lithium salt. However, the

[1]Author to whom correspondence may be addressed.



SCHEME I



coupling reaction proceeds equally well with a molar ratio of lithium salt to dibenzoyl peroxide equal to 2:1 as shown in eq. [1]. Benzoic acid was recovered from the reaction mixtures in a yield roughly equivalent to that of the coupled products when the molar ratio of starting materials was 2:1.

[1] $2\ ArCH_2Li + C_6H_5CO_2O_2CC_6H_5 \rightarrow ArCH_2CH_2Ar + 2\ C_6H_5CO_2Li$

Ar = 2-pyridyl, 4-pyridyl, or 3-cyano-5-ethenyl-4-pyridyl

Additional products isolated from the reactions of the lithium salts of 2-methylpyridine and 4-methylpyridine with dibenzoyl peroxide were identified as the respective phenacylpyridines, **8** and **9**, and the bis-1,3-dipyridyl-2-phenyl-2-propanols, **10** and **11**. The spectroscopic properties of the compounds isolated in these reactions were identical with those of reference samples prepared here (see experimental section for details). The ketones may arise from the reaction of the lithium salts of the picolines with the lithium salts of benzoic acid (see eq. [1]) as illustrated in eq. [2].

However, the alcohols are unlikely to be derived from ketones **8** and **9**. It has been stated that intermediates of type (a) are stable and are converted to ketones only on hydrolysis (8).

[2] $C_6H_5CO_2Li + ArCH_2Li \rightarrow$ 
(a)

$\xrightarrow{H_2O}$ $C_6H_5COCH_2Ar + 2LiOH$

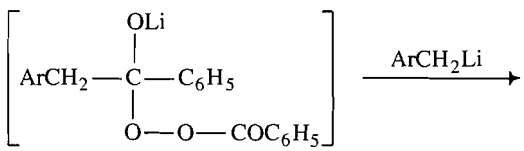
8, Ar = 2-pyridyl
9, Ar = 4-pyridyl

Moreover, if the ketones were to form in the reaction mixture it is known that they form enols with lithio reagents in preference to undergoing addition to the carbonyl group (9).

It is possible therefore that the alcohols form as a result of addition of the lithium reagent to the carbonyl group of dibenzoyl peroxide, followed by a substitution reaction as shown in eq. [3]. Such a mechanism has been proposed for the synthesis of alcohols from acid chlorides (10).

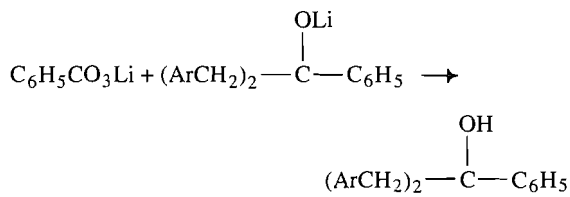
Ketones **8** and **9** might also be derived from hydrolysis of intermediate (b) of eq. [3].

[3] $ArCH_2Li + C_6H_5CO_2O_2CC_6H_5 \rightarrow$



$\xrightarrow{ArCH_2Li}$

(b)



10, Ar = 2-pyridyl
11, Ar = 4-pyridyl

The coupling of lithium salts of methyl pyridines has been previously effected with a variety of reagents. For example, coupling has been reported by treatment of solutions of lithio 2-methylpyridine with air (11), oxygen (6), bromine (12), and CuCl or $CuBr_2$ (13). Recently, it has been shown that lithio 2,6-di-*tert*-butyl-4-methylpyridine undergoes coupling upon treatment with iodine (14). The last two procedures provide coupled products in yields comparable to those obtained with dibenzoyl peroxide.

*Oxymercuration–reduction of the vinyl side chain: preparation of alcohol **3** and ketone **4***

The preparation of benzopyridoquinolizine alkaloids bearing a vinyl side chain on the pyridine ring is illustrated in Scheme 1. Alkaloids are known in which the vinyl side chain has been replaced by a CH_3CHOH- or a CH_3CO- side chain. The latter alkaloids have not been prepared by the route outlined in Scheme 1, although syntheses by other approaches have been reported (15). We have been able to effect the hydration of the vinyl group of **1** to CH_3CHOH- using the oxymercuration–reduction method developed by Brown and Geoghegan (16) and to oxidize the latter compound to the methyl ketone. In the course of this work we found that variable and often poor yields of the desired alcohol were obtained when the reduction step was carried out in a flask open to the atmosphere. Besides the desired secondary alcohol, small amounts of glycol were obtained. The replacement of the HgX group by an OH group, required for glycol formation, was reported previously and is attributed to the formation of peroxy compounds in the hydride reduction step (17, 18). The oxymercuration step is considered to proceed by an ionic mechanism but the reduction step by a radical mechanism. The carbon radicals formed in the reduction of the carbon–mercury bond will react with oxygen in the medium to generate peroxides, which are reduced to alcohols. Other more complex products were apparently formed from the radical intermediate but were not identified. Much better results were obtained by us when the reduction reaction was conducted in an argon atmosphere. Under these conditions reproducible yields of 50% of **3** were obtained and very little glycol was formed.

The ketone **4** was derived from alcohol **3** by Jones' oxidation in a yield of 77%. Therefore the way is now open to the synthesis of benzopyridoquinolizine and indolopyridoquinolizine alkaloids containing an oxygenated side chain using these two starting materials in suitably protected form. Furthermore, the opportunity now exists to prepare enantiomerically pure alcohol **3** from ketone **4**. This may open the was to enantioselective synthesis of alkaloids by the route of Scheme 1.

Experimental

Apparatus, materials, and methods

The ^1H nmr spectra were recorded on a Varian EM 390 spectrometer. Unless otherwise specified, the samples were dissolved in chloroform-*d* using tetramethylsilane (TMS) as internal standard. Chemical shifts, quoted as δ values, were measured in relation to TMS. The symbols s, singlet, d, doublet, t, triplet, q, quartet, br, broad, and m, multiplet are used in reporting spectra. The ^{13}C nmr spectra were recorded at 125.76 MHz on a Bruker WM 500 FT spectrometer at ambient temperature.

EI mass spectra were recorded at 70 eV with a source temperature of ca. 200°C on a VG Analytical ZAB-E mass spectrometer equipped with a VG 11-250J data system. High resolution mass spectra (hrms) were recorded on the same instrument. Samples were introduced with a direct insertion probe. Infrared spectra were run on a Perkin–Elmer 283 spectrometer. Melting points were determined using a Gallenkamp apparatus and are uncorrected. Thin-layer chromatography (tlc) was performed using Polygram Sil G/UV_{254} or Polygram Alox N/UV_{254} plates. For flash column chromatography Kieselgel 60 (230–400 mesh) was used.

Compound **1** was prepared using the literature procedure (1). Reference samples of **9** and **11** were prepared by a modification of the procedure of Fryer *et al.* (10) in which *n*-BuLi was used instead of phenyl lithium to generate the picolyl lithium. Compounds **8** and **10** were prepared from 2-methylpyridine in a similar manner.

*1,2-Bis(3'-cyano-5'-vinyl-4'-pyridyl)-ethane **2***

To a stirred solution of diisopropylamine (0.31 mL, 2.2 mmol) in dry THF (2 mL) at −20°C was added a solution of *n*-BuLi (1.37 mL, 1.6 M in hexane, 2.2 mmol) under an argon atmosphere; the resulting LDA solution was stirred at this temperature for a further 10 min. The LDA solution was cooled to −78°C (Dry Ice – acetone bath) and treated dropwise with a solution of compound **1** (288 mg, 2 mmol) in dry THF (3 mL), producing a red solution. The mixture was stirred at −78°C for 20 min, and then treated dropwise with a solution of dibenzoyl peroxide (484 mg, 2 mmol) in dry THF (3 mL). The red colour of the solution was completely discharged at the end of the addition, and stirring of the mixture was continued at −78°C for a further 2 h; it was then allowed to warm to room temperature and stirred overnight. The reaction mixture was then treated with 10% aqueous sodium sulphite solution (1 mL)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

and concentrated to a thick paste under vacuum. The residue was basified with saturated Na_2CO_3 solution (aqueous) and thoroughly extracted with chloroform. The combined chloroform extract was washed with saturated sodium chloride, dried over anhydrous Na_2SO_4, and evaporated to dryness. The crude product was purified by column chromatography on silica gel using hexane–CH_2Cl_2 (1:1) as eluant to give the dimeric compound **2** (220 mg, 77%), which was crystallized from acetone; mp 189–191°C; R_f 0.33 (alumina, $CHCl_3$); ^{1}H nmr (90 MHz), δ: 3.22 (4H, s, -CH_2CH_2-), 5.60 (1H, d, J = 11.5 Hz, -CH=CH_2), 5.80 (1H, d, J = 18.0 Hz, -CH=CH_2), 7.05 (1H, dd, J = 18.0 and 11.5 Hz, -CH=CH_2), 8.80 (1H, s, C-6′, or C-2′ H), and 8.90 (1H, s, C-2′ or C-6′ H); ms (EI), m/z (rel.int., %): 286 (81), 285 (76), 272 (22), 271 (100), 258 (14), 253 (13), 149 (16), 143 (46), 142 (38), and 116 (18). Anal. calcd. for $C_{18}H_{14}N_4$: C 75.52, H 4.90, N 19.58%; found: C 75.10, H 5.24, N 19.63%.

Treatment of 2-picolyl lithium with dibenzoyl peroxide

A solution of diisopropylamine (0.68 mL, 4.8 mmol) in THF (4.0 mL) was treated dropwise with stirring with *n*-BuLi (3.0 mL, 1.6 M in hexane, 4.8 mmol) at −20°C, and kept at this temperature for 10 min. The solution was then cooled to −78°C, 2-picoline (372 mg, 4 mmol) in THF (5 mL) was added dropwise, and the mixture stirred for 20 min at −78°C. A solution of dibenzoyl peroxide (484 mg, 2 mmol) in THF (5 mL) was added dropwise, the mixture was stirred at −78°C for 2 h, allowed to warm to room temperature, and stirred overnight before work-up. The reaction mixture was treated with a 10% aqueous solution of concentrated sodium sulphite, then with aqueous sodium carbonate, and extracted with dichloromethane. The extract was washed with saturated sodium chloride solution, dried over anhydrous sodium sulphate, and evaporated to give a residue, which was chromatographed on alumina (16 g). Elution with methylene chloride – cyclohexane (1:1) gave, in order of elution: compound **8**[2] (0.084 g, 11%), mp 52–54°C (lit. (9) mp 52–54°C; lit. (10) mp 59–60°C); ir (ν_{max}, $CDCl_3$): 1600, 1625, 1680 cm^{-1}; ^{1}H nmr (90 MHz) included signals at δ: 4.50 (s, CH_2), 6.06 (s, enolic -CH=), and 6.8–8.6 (m, aromatic hydrogens); ms (EI), m/z (rel.int., %): 197 (15), 196 (20), 169 (30), 168 (36), 120 (8), 105 (100), 92 (13), and 77 (68); compound **10** (0.058 g, 7%), mp 79–80°C (hexane) (lit. (19) mp 59°C); ir (ν_{max}, Nujol): 1590, 3300 cm^{-1}; ^{1}H nmr (90 MHz), δ: 3.2 and 3.4 (4H, overlapping ABq, J = 15 Hz, α-CH_2), 6.9–7.6 (11H, m, aromatic hydrogens), and 8.4 (2H, overlapping d, pyridyl α-H's); ms (NH_3CI), m/z (rel.int., %): 291 (33), 198 (100); compound **6** (0.143 g, 39%), mp 44–46°C (ethyl acetate – hexane) (lit. (6) mp 48–49°C); ^{1}H nmr (90 MHz), δ: 3.25 (4H, s, -CH_2-), 7.00–7.65 (6H, m, aromatic H's), and 8.53 (2H, d, pyridyl α-H's); ms (EI), m/z (rel.int., %): 184 (48), 183 (30), 169 (6), 106 (100), 92 (16), 91 (6), 78 (15).

Treatment of 4-picolyl lithium with dibenzoyl peroxide

The procedure described above for 2-picoline was followed and gave the following, in order of elution: compound **9** (0.026 g, 3%), mp 110–112°C (lit. (10) mp 113–115°C), ir (ν_{max}, Nujol): 1685 cm^{-1}; ^{1}H nmr (90 MHz), δ: 4.28 (2H, s, CH_2), 7.1–8.1 (7H, m, aromatic hydrogens), and 8.52 (2H, m, pyridyl α-H's); ms (EI), m/z (rel.int., %): 197 (8), 105 (100), 77 (42); compound **7** (0.15 g, 41%), mp 104–106°C (lit. (7*a*) mp 106–109°C; (7*b*) mp 110–111°C; (7*c*) mp 114.5–116°C); ^{1}H nmr (90 MHz), δ: 2.95 (4H, s, -CH_2's). 7.03–7.20 (4H, m, C-3′ H's), and 8.50–8.64 (4H, m, C-2′ H's); ms (EI), m/z (rel.int., %): 184 (100), 92 (64), 65 (33); compound **11** (0.075 g, 13%), mp 118–120°C (lit. (10) quotes various samples as melting from 92–99°C to 166–168°C, including one sample with mp 117–118°C ir (ν_{max}, Nujol): 1620, 3200 cm^{-1}; ^{1}H nmr (90 MHz), δ: 3.06, 3.28 (4H, ABq, -CH_2's), 6.86 (4H, d, pyridyl β-H's), 7.25 (5H, s, phenyl H's), and 8.28 (4H, d, pyridyl α-H's); ms (EI), m/z (rel.int., %): 290 (4), 289 (7), 198 (32), 105 (100), 92 (17), 77 (78), 65 (18).

Preparation of 5-(1′-hydroxyethyl)-4-methyl-3-pyridinecarbonitrile **3** *and 5-(1′,2′-dihydroxyethyl)-4-methyl-3-pyridinecarbonitrile*

Mercuric acetate (2.39 g, 7.5 mmol) was dissolved in water (7.5 mL) and THF (17.5 mL) was added to this solution. A solution of vinyl compound **1** (0.72 g, 5 mmol) in THF (5 mL) was added dropwise to the mercuric acetate solution over a period of 5 min and this was followed by the addition of 0.22 mL (2.5 mmol) of 70% $HClO_4$. The reaction mixture was stirred at room temperature under argon for 24 h and then cooled in an ice bath. An aqueous solution of 3 M sodium hydroxide (15 mL) was added slowly via syringe while maintaining the temperature at 0-5°C, after which the cooled solution was treated dropwise, also via a syringe, with 7.5 mL of a 0.5 M solution of sodium borohydride prepared in 3 M sodium hodroxide. The mercury formed in the reaction was separated from the supernatant solution by decantation. The solution was saturated with sodium chloride and the organic (THF) layer was separated. The remaining aqueous layer was then extracted several times with ether and the ether extract combined with the THF extract. The combined extracts were dried over Na_2SO_4 (anhydrous), filtered, and evaporated to dryness. The residual oil was chromatographed on silica (30 g) using ethyl acetate – hexane (4:6) as eluant. Starting material (0.064 g, 9%) and the alcohol **3** (0.414 g, 51%) were eluted under these conditions. An analytical sample was prepared by recrystallization from ether, mp 103–104°C; ir (ν_{max}, Nujol): 3210 (OH), 2220 (CN) cm^{-1}; ^{1}H nmr (90 MHz), δ: 1.52 (3H, d, J = 7.5 Hz, CH_3CH), 2.55 (3H, s, ArCH_3), 3.44 (1H, br s, OH), 5.15 (1H, m, CHOH), 8.66 (1H, s, H-2 or H-6), 8.89 (1H, s, H-2 or H-6); ^{13}C nmr (125.8 MHz, $CDCl_3$), δ: 16.7, 23.9, 65.1, 111.1 116.0, 140.0, 147.3, 150.0, 151.1; ms (EI), m/z, (rel.int., %): 162 (14), 147 (100), 145 (5), 144 (5), 143 (6), 119 (24), 92 (7). Exact mass (hrms). calcd. for $C_9H_{10}N_2O$: 162.0793; found: 162.0799.

Further elution of the column with ethyl acetate gave a brown oil from which the diol was obtained in low yield by crystallization from acetone, mp 140°C; ir (ν_{max}, Nujol): 3425, 3350 (sh), and 3160 (OH), 2212 (CN) cm^{-1}; ^{1}H nmr (90 MHz, DMSO-d_6 + D_2O), δ: 2.50 (3H, s, CH_3), 3.57 (2H, d, $J \approx$ 6 Hz, CH_2OH), 4.92 (1H, t, $J \approx$ 6 Hz, CHOH), 8.77 (2H, overlapping s's, H-2 and H-6); ^{13}C nmr (125.8 MHz, acetone-d_6), δ: 17.1, 67.1, 70.6, 111.5, 117.0, 138.0, 148.6, 152.1, 152.4; ms (EI) m/z (rel.int., %); 178 (4), 148 (42), 147 (100), 133 (5), 132 (4), 119 (23), 103 (4), 92 (10). Exact mass (hrms) calcd. for $C_9H_{10}N_2O_2$: 178.0742; found: 178.0746.

Preparation of 5-acetyl-4-methyl-3-pyridinecarbonitrile **4**

A solution of the alcohol **3** (0.324 g, 2 mmol) in acetone (8 mL) was treated rapidly with stirring with Jones' reagent (1.8 mL). The mixture was stirred an additional 24 h. The excess reagent was destroyed by the addition of methanol and the solution neutralized with aqueous ammonia. A precipitate of chromium compounds was removed by filtration and the filtrate heated to remove acetone. The residual solution was extracted with methylene chloride, the extract dried over Na_2SO_4 (anhydrous), the solution filtered, and the filtrate taken to dryness. The pale yellow solid residue was purified by chromatography on a silica column (10 g) using ethyl acetate – hexane (1.5:8.5) as eluant. Yield, 0.238 g, 74%; mp 64–65°C after recrystallization from hexane; ir (ν_{max}, Nujol): 2200 (CN), 1690 (C=O) cm^{-1}; ^{1}H nmr (90 MHz), δ: 2.67 (3H, s, CH_3CO), 2.76 (3H, s, Ar-CH_3), 8.90 (1H, s, H-2 or H-6), 9.05 (1H, s, H-2 or H-6); ^{13}C nmr (125.8 MHz, $CDCl_3$), δ: 19.1, 29.8, 113.2, 115.4, 133.6, 151.3, 152.3, 154.6, 198.1; ms (EI), m/z (rel.int., %): 160 (35), 145 (100), 117 (96), 90 (24), 63 (23). Exact mass (hrms) calcd. for $C_9H_8N_2O$: 160.0637; found: 160.0642.

[2]In solution in chloroform compound **8**, 2-phenacylpyridine, exists as a mixture of keto and enol forms (19). In the solid state, however, based upon ir evidence, only the enol form is present (20). We have confirmed this result using solid state ^{13}C nmr. In the solid state ^{13}C nmr spectrum of **8**, signals that might be attributed to a carbonyl carbon and a methylene carbon are absent. These signals were present in the solution spectrum at δ 196.7 and 48.2, respectively. A signal in the solid state and in solution appearing at δ 94.1 has been assigned to the enolic carbon bearing the hydrogen atom.

Intercalation of basic molecules into niobyl-vanadyl phosphate

L. García-Ponce, L. Moreno-Real, and A. Jiménez-López[1]

Departamento de Química Inorgánica, Facultad de Ciencias, Universidad de Málaga, Apartado 59, 29071 Málaga, Spain

Received September 5, 1989

L. García-Ponce, L. Moreno-Real, and A. Jiménez-López. Can. J. Chem. **68**, 592 (1990).

Mixed niobyl-vanadyl phosphate $(V_{0.14}Nb_{0.86})OPO_4 \cdot 2.7H_2O$, VNbP, is a moderately acid solid that intercalates strong basic molecules such as branched alkylamines, allylamine, cyclohexylamine, piperidine, and diethylamine, giving rise to bilayers of inclined molecules. In the case of molecules of medium basicity, such as pyridine, the intercalated amounts are small at room temperature and they present a planar orientation. A special behaviour was found with ethylenediamine and butylenediamine, strong basic diamines, which also present a planar disposition in the interlayer space.

Key words: mixed niobyl-vanadyl phosphate, layered compounds, phosphates, intercalation, pyridine.

L. García-Ponce, L. Moreno-Real et A. Jiménez-López. Can. J. Chem. **68**, 592 (1990).

Le phosphate mixte de niobyle et de vanadyle $(V_{0,14}N_{0,86})OPO_4 \cdot 2,7H_2O$, VNbP, est un solide modérément acide qui intercale des molécules fortement basiques comme des alkylamines ramifiées, de l'allylamine, de la cyclohexylamine, de la pipéridine et de diéthylamine pour donner des bicouches de molécules inclinées. Dans le cas de molécules de basicité moyenne, comme la pyridine, les quantités intercalées à la température de la pièce sont faibles et elles se présentent dans une orientation planaire. On a observé un comportement spécial avec l'éthylènediamine et la butylènediamine, des diamines fortement basiques, qui présentent aussi une disposition planaire dans l'espace entre les couches.

Mots clés : phosphate mixte de niobyle et de vanadyle, composés en couches, phosphates, intercalation, pyridine.

[Traduit par la revue]

Introduction

The phosphates of the family $MO(AO_4) \cdot nH_2O$ (M = V, Nb; A = As, P) are layered, isostructural compounds. In their tetragonal forms, the layers consist of octahedrally coordinated metal atoms, four of the coordination positions being occupied by PO_4^{3-} groups and the other two by an oxygen atom bonded to the metal via a double bond and by a water molecule. The resulting layers interact through hydrogen bonds established by the water molecules that occupy the interlayer space.

The isostructural nature of niobyl and vanadyl phosphates and the similarity between the sizes of both elements facilitate the synthesis of mixed phosphates, which are in fact solid solutions of vanadyl phosphate in its niobyl counterpart. The maximum tolerated degree of replacement of niobyl by vanadyl ion in the phosphate of the latter is 21% (1).

These mixed phosphates can undergo redox reactions similar to those of their precursors (2, 3), as well as intercalate neutral molecules of basic nature (4, 5). Thus the mixed phosphate with 14% vanadium undergoes the intercalation of *n*-alkylamines, which form a molecular bilayer at an angle of 58° with respect to the layers (6). The mechanism of this intercalation process was established to be a proton-transfer reaction between the water molecules, both coordinated to the metal and of zeolitic type, and those of the amine.

The aim of this work has been to contribute new data on the interaction of basic molecules with the aforesaid mixed phosphate in general, and to determine the influence of branched chains and the basic strength of the amines on the orientation and extent of intercalation in particular.

Experimental

The synthesis and characterization of the VNbP (14% V) used has been described elsewhere (1). All bases used were of reagent quality, without further purification. The bases to intercalate into VNbP were as follows: (a) branched amines of the same main chain length, such as *sec*-butylamine (*sec*-BA), *iso*-butylamine (*iso*-BA), neopentylamine (*neo*-PtA), and allylamine (AA); (b) a secondary amine, such as diethylamine (DEA); (c) three cyclic bases, cyclohexylamine (CHA), piperidine (Pi), and pyridine (Py); (d) two diamines with basic groups of different strength, ethylenediamine (EDA) and butylenediamine (BDA); and (e) a very weakly basic substance, dimethyl sulphoxide (DMSO).

The liquid bases were in contact with the VNbP (0.25–0.4 g in 5–10 mL of pure base) at 25°C for 24–72 h. Then the suspensions were filtered and the solids were washed with ether until the excess amine was removed. The products were vacuum dried.

Pyridine and DMSO were sorbed from the vapour phase at 25 and 60°C, respectively. Another pyridine intercalate was obtained by placing the base in contact with VNbP for 3 weeks under reflux.

Amounts of the intercalated substances were determined by CHN analysis and (or) Kjeldahl microanalysis; the water contents were calculated from TG–DTA curves. The TG–DTA analyses were carried out in air on a Rigaku Thermoflex instrument using calcined alumina as internal reference and heating from room temperature to 1273 K at a rate of 3 or 10 K/min. Platinum crucibles and Pt/Pt–Rh thermocouples were used.

Powder X-ray diffraction patterns were obtained with an automated Siemens diffractometer using graphite monochromated CuK_α radiation. IR spectra were recorded by a Perkin–Elmer 883 double beam spectrophotometer using KBr pellets containing 2% of the products. The diffuse reflectance (UV–VIS) spectra were obtained on a Kontron Uvikon 810 instrument; the UV–VIS–nIR spectra were recorded on a Shimadzu UV 3100 double beam spectrophotometer, always using barium sulphate as reference.

Results and discussion

Table 1 lists the compositions of the different intercalates prepared, their basal spacings, and the pK_a of each intercalated base. As can be seen, the amine contents of the intercalates with branched amines of the same main chain length, namely *sec*-BA, *iso*-BA, and *neo*-PtA, are lower than those found for the *n*-alkylamine of the same chain length (1.5 mol *n*-propylamine per mol of phosphate) (6), as one would expect from the more extensive "coverage" by such molecules. Nevertheless, among the three branched amines, *sec*-BA is intercalated to a lesser extent than *iso*-BA as it has a methyl group in the α position that covers a larger surface than its β counterpart. An increase in the molecular volume (*neo*-PtA) results in a

$(V_{0.14}Nb_{0.86})OPO_4$($t > 240$°C)	VNbP	—	0	4.1	

concomitant decrease in the intercalation content. On the other hand, the basal spacing for these four amines is close to that of *n*-propylamine (15.1 Å) (6). In fact, as can be seen in Table 1, the basal spacings are all of the same order, which allows one to assume that these molecules arrange themselves in an interlaminar bilayer with their main axis forming a 58° angle with respect to the layers. However, the greater steric hindrance posed by the three methyl groups of *neo*-PtA seems to result in slightly more staggered molecules and hence in a slightly wider spacing (16.4 Å).

The influence of steric hindrance is even more marked in the case of DEA, whose large extent of coverage results in a lower content compared with those of the other amines. The basal spacing of its corresponding intercalate is also indicative of the formation of a molecular bilayer in the interlayer space. Of the three cyclic bases, viz., CHA, piperidine, and pyridine, the last, on account of its special behaviour, will be discussed later. The composition of the intercalates of the other two is consistent with their similar steric hindrances: their basal spacings also suggest the formation of a bilayer, with a larger spacing for the exocyclic amine, as one would expect.

The amine content in all of the intercalates discussed above depends on the extent of coverage of the molecules, though not on their base strength as they are all strong bases. On the other hand, the X-ray diffractograms of the intercalates show a single swelling phase with various orders (001) and a clear (200) reflection, which is indicative of a preserved crystal structure.

The amine contents for the intercalates of the diamines (EDA and BDA) are clearly lower than those found for the above-mentioned amines: 0.4 and 0.3 mol per mole of phosphate, respectively. Bearing in mind that they are diamines, one should expect the formation of a monolayer of staggered molecules as a result of the simultaneous interaction of their two amine groups with the two neighbouring layers (7). On the other hand, the basal spacings found (7.0 and 7.1 Å, respectively) indicate that the molecules are oriented with the plane containing the carbon chain lying parallel to the layers and the molecules themselves occupying the structural vacancies. In addition, the amine content of these two intercalates depends on their size; thus, the ratio between the chain lengths of EDA and BDA (6.76 Å/9.28 Å) is consistent with the reciprocal of the ratio between their contents in the intercalates (0.75). The fact that these compounds form no perpendicular monolayer might be related to their base strength; their lower pK_{a2} could only allow a single protonation of the amines, so that the interaction with the upper layer would be rather weak, the energy released would be insufficient to induce the swelling, and the molecules would arrange themselves parallel to the layers. This point will be confirmed later in discussing IR and nIR spectra.

The water content of all the intercalates obtained was close to 2 mol per mol of phosphate and similar to those values found for *n*-alkylamines [6]. These water molecules play a major role in the intercalation process.

The intercalation of a weaker base, pyridine (pK_a 5.25), was effected by two methods, which resulted in two different intercalates, namely, in the vapour phase (4 months) and under reflux (3 weeks), yielding intercalates containing 0.5 mol pyridine and 1 mol water, and 0.78 mol pyridine and 2.4 mol water per mol of phosphate, respectively. Their basal spacings (8.7 and 9.9 Å, respectively) are consistent with these compositions and are larger than those obtained by other authors for the precursor phosphates (5, 8). On the other hand, the intercalate obtained under reflux, unlike that prepared by Johnson under other conditions, has a high water content, although both have similar basal spacings (8).

Taking into account that the van der Waals thickness of a pyridine ring is 3.7 Å and that the spacing of the intercalate synthesized in the vapour phase was 8.7 Å, we may assume that pyridine lies horizontally in the interlayer space. The composition is consistent with the molecular coverage (43 $Å^2$) and the area of the cell unit, $Z = 2$ (41.6 $Å^2$), so that the theoretical composition would be 0.48 mol per mol of phosphate (i.e., very close to the experimental value).

When pyridine was intercalated under more drastic conditions (e.g., under reflux), the base content was higher and the basal spacing increased up to 9.9 Å, which seems to indicate that the pyridine molecules lean slightly to accommodate themselves in the interlayer.

The DTA curves (Fig. 1) show the different thermal behaviour of these two pyridine intercalates. Thus, that obtained by the vapour reaction shows three steps in the TG curve corresponding to two endothermic effects and one exothermic effect. The first endothermic effect, between 80 and 100°C, corresponds to the partial removal of pyridine, which is weakly

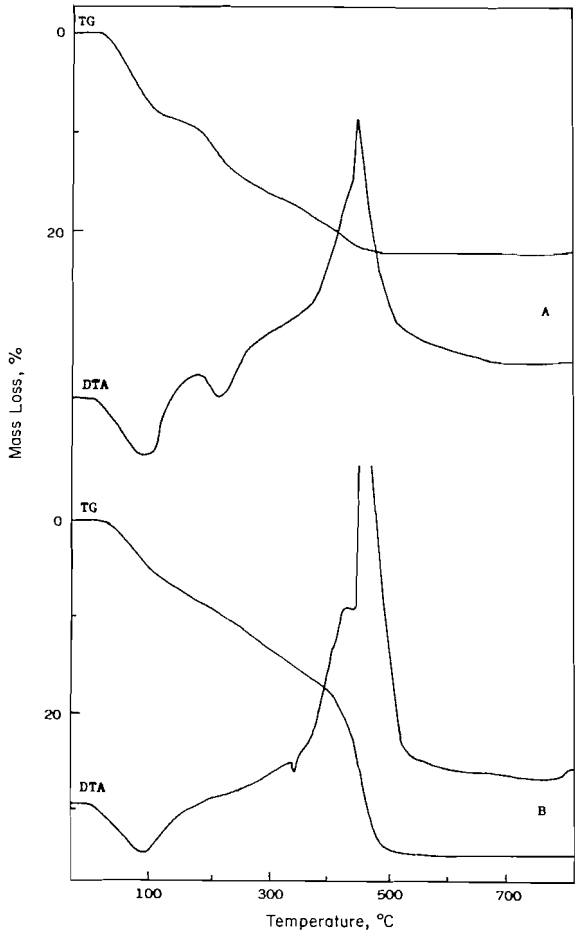

FIG. 1. DTA–TG curves for pyridine intercalates: (A) vapour phase; (B) reflux.

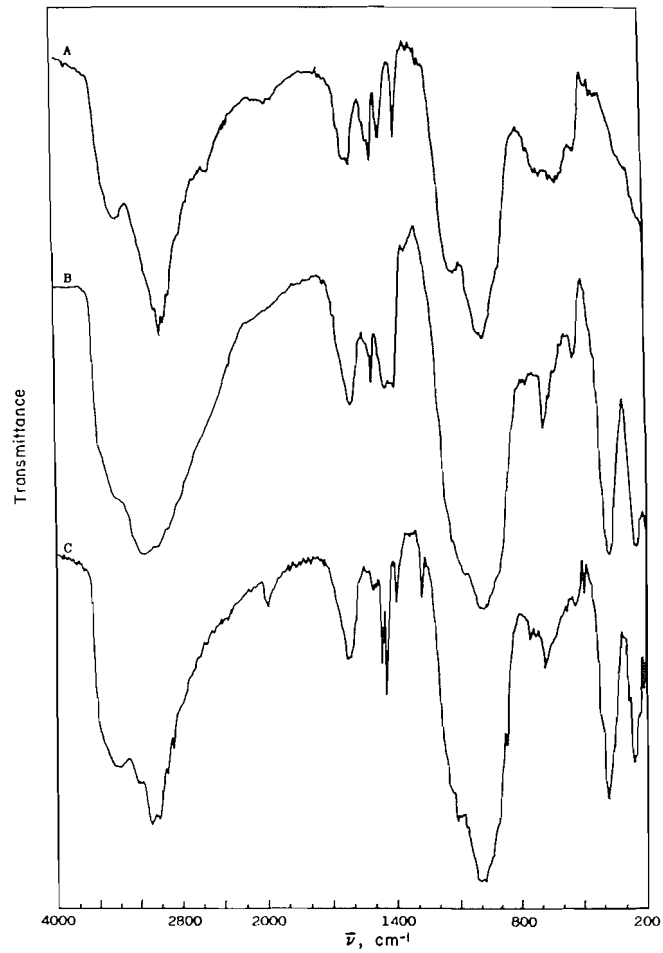

FIG. 2. Infrared spectra of intercalates of (A) *sec*-butylamine; (B) ethylenediamine; (C) butylenediamine.

retained; this is followed by the endothermic removal of coordinated water at 220°C and, finally, by a strong exothermic effect at 430°C corresponding to the combustion of the base. These results are consistent with those of the elemental CHN analysis. The steps of the intercalate obtained under reflux are not so well defined. The first, up to 170°C, corresponds to the loss of zeolitic water (1.4 mol per mol of phosphate); this stage is overlapped with the following, which corresponds to the loss of coordinated water and part of the strongly retained pyridine, which undergoes combustion at 460°C.

Finally, DMSO, very weakly basic (pK_a 0.4), is sorbed to a very small extent (0.1 mol per mol of phosphate). The composition and basal spacing of its intercalate seem to indicate that it is only retained superficially.

Infrared and nIR spectroscopy are the most useful techniques for establishing the intercalation mechanism of basic species. Table 2 gathers the most salient absorptions of the different intercalates obtained. The intercalates of all the monoamines (Fig. 2) show a typical band of symmetric deformation of the

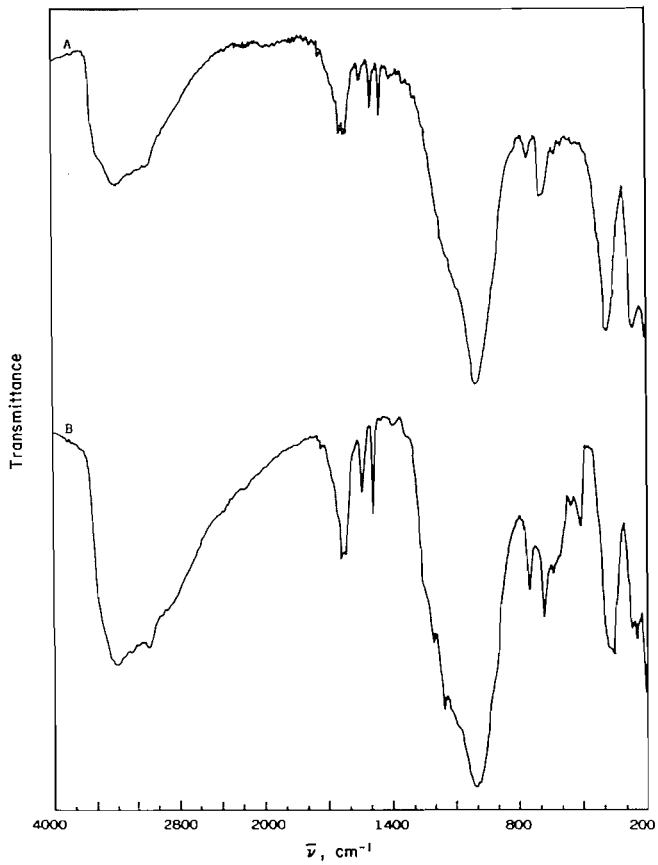

FIG. 4. Infrared spectra of pyridine intercalates: (A) vapour phase; (B) reflux.

$-NH_3^+$ group in the region 1500–1520 cm^{-1} (9), which indicates that the molecules lying in the interlayer space are protonated by the water molecules according to eq. [1]

[1] $H_2O + R\text{-}NH_2 \rightarrow R\text{-}NH_3^+ + OH^-$

The resulting *n*-alkylammonia ions interact via hydrogen bonds with the hydroxyl ions and the remaining water molecules; hence the appearance of a shoulder at 1530–1560 cm^{-1} in all cases. This protonation is also consistent with the fact that the NH stretching vibration appears at lower frequencies (3020 cm^{-1}) than that of a nonprotonated amine. The spectra of DEA and piperidine intercalates show a NH_2^+ deformation band at 1500 and 1584 cm^{-1}, respectively, which indicates that both amines are also protonated.

As far as the diamines are concerned, the IR spectrum of the BDA intercalate (Fig. 2), in addition to the above-mentioned bands at 1520–1560 cm^{-1} of the monoamines, shows other bands at 3220, 3090, and 3020 cm^{-1}, but not that at 3330 cm^{-1} corresponding to the ν(NH) of the pure amine, which seems to indicate that the BDA molecules in the interlayer space are fully protonated. This situation would make the diamine equivalent to two molecules of ethylamine, so it should arrange itself in a monolayer staggered with respect to the layers. The parallel orientation of this molecule in the interlayer space may arise from the fact that both of the amino groups may interact with polar groups of the same layer, which is the energetically most favourable arrangement. This is in contrast to the arrangement of monoamines, which are fixed to the layer by the basic group, while the hydrophobic group is directed to the center of the interlayer space. As this group cannot interact with the upper layer, the compound takes in another amine molecule, which interacts with the second water molecule, giving rise to a molecular bilayer intercalate.

The IR spectrum of the EDA intercalate, on the other hand, shows a single band in the region 3400–3200 cm^{-1}, which does not allow the bands corresponding to the ν(NH) of the nonprotonated amino groups to be clearly observed. However, the UV–VIS–nIR spectrum (Fig. 3) confirms the full protonation of EDA as it shows a combination band ($\nu(NH^+)$ + $\delta(NH_3^+)$) at 2164 nm (10). This spectrum is very similar to that of the BDA intercalate, so that this molecule also arranges itself in parallel with the layer.

Figure 3 also shows a single band at 245–255 nm for the monoamines, but not those at 335 and the shoulder at 400 nm; these two are responsible for the yellow colour of the original matrix, so the intercalates are white (1). The spectra of the intercalates with lower content of guest molecules (EDA, BDA, and DEA) exhibit a shoulder at 335 nm because of some vanadium-coordinated water molecules that do not interact with amines.

Figure 4 shows the IR spectra of the two pyridine intercalates. The spectrum obtained in the vapour phase shows a band at 1538 cm^{-1} indicative of the occurrence of protonated pyridine, and another at 1445 cm^{-1} corresponding to nonprotonated pyridine (11). The presence of these two types of pyridine molecules in the interlayer is consistent with the thermal behaviour of the intercalate, from which nonprotonated pyri-

dine was removed at a low temperature while protonated pyridine was lost at higher temperatures. The spectrum of the intercalate obtained under reflux, however, shows only the band at 1538 cm^{-1}, which indicates that all the pyridine molecules are protonated; this is also consistent with the thermal behaviour of this intercalate.

The diffuse reflectance spectra of these two intercalates between 200 and 800 nm are indicative of the same situation (Fig. 5). Thus, the spectrum of the pyridine intercalate obtained in the vapour phase shows a maximum at 330 nm that decreases until the intercalation process is completed, and is preserved as a shoulder in the 8.6 Å intercalate. However, such a shoulder completely disappears in the spectrum of the intercalate obtained under reflux, which indicates that the water molecules coordinated in the vanadium interact with pyridine, either through protonation or through hydrogen bonds.

We may conclude that the mixed VNbP is a solid of medium acidity liable to react to a great extent with monoamines, yielding molecular bilayers. The extent of intercalation of the diamines EDA and BDA is only partial and the molecules arrange themselves with their chains horizontal and parallel to the layers. Pyridine (pK_a 5.25) in the vapour phase intercalates in a ratio of 0.5 mol per mol of phosphate and its molecules lie parallel to the layers. Although the extent of intercalation under reflux is somewhat greater, the complete intercalation and a vertical arrangement of the molecules with respect to the layer (i.e., as with highly acidic solids such as uranyl hydrogen phosphate (12) or solids with a high surface charge density such as vermiculite (13)) is never reached. Finally, very weakly basic molecules (e.g., DMSO) are not intercalated at all.

Conformational analysis of 1-oxaspiro[5.5]undecanes. A powerful probe for the *endo* and the *exo* anomeric effects in acetals

PIERRE DESLONGCHAMPS[1] AND NORMAND POTHIER

Laboratoire de synthèse organique, Département de chimie, Faculté des sciences, Université de Sherbrooke, Sherbrooke (Québec), Canada J1K 2R1

Received August 1, 1989

PIERRE DESLONGCHAMPS and NORMAND POTHIER. Can. J. Chem. **68**, 597 (1990).

A ^{13}C nuclear magnetic resonance spectroscopy study of 1-oxaspiro[5.5]undecanes **1**, **4**, and **5** as a function of temperature is reported. Compound **1** exists as a rapidly equilibrating mixture of a major and a minor conformer (**1***a* and **1***b*) at room temperature that can be observed at low temperature. By comparison, 1,7-dioxaspiro[5.5]undecane **2** is conformationally rigid in a single conformation (**2***a*) at room temperature. This completely different behavior demonstrates the importance of the *endo* and the *exo* anomeric effects in the acetal function.

Key words: spiro ethers, conformational analysis, ^{13}C NMR.

PIERRE DESLONGCHAMPS et NORMAND POTHIER. Can. J. Chem. **68**, 597 (1990).

Une étude par spectroscopie de résonance magnétique nucléaire du ^{13}C en fonction de la température des 1-oxaspiro[5.5]undécanes **1**, **4** et **5** est rapportée. Le composé **1** est un mélange de deux conformères, l'un majoritaire (**1***a*) et l'autre minoritaire (**1***b*) à la température ambiante que l'on peut observer à basse température. Par comparaison, le 1,7-dioxaspiro[5.5]undécane **2** est complètement rigide existant dans une seule conformation (**2***a*) à la température ambiante. Ce comportement différent démontre clairement l'importance des effets *endo* et *exo* anomères de la fonction acétale.

Introduction

Although α- and β-glycosides can theoretically exist as three different rotamers each, they are known to exist in the crystalline state (1) as rotamers A_1 and E_1 respectively as illustrated in Scheme 1. This conformational preference, as well as the greater stability of α- over β-glycosides, is currently explained by a combination of steric and stereoelectronic effects (2) known as the *endo* and the *exo* anomeric effects (3).

The conformation of glycosides in solution (4, 5) is similar to that found in the crystalline state. It is, however, difficult experimentally to rigorously establish the relative population of the rotamers of glycosides in solution because the energy barrier between the various rotamers is too weak. The precise evaluation of the *endo* and the *exo* anomeric effects with these compounds is thus difficult. On the other hand, Kishi and co-workers (6) have recently demonstrated that the side chain in *C*-glycosides[2] exists predominantly in solution in a conformation similar to that observed in normal *O*-glycosides. In *C*-glycosides, the preference is of course due to steric effects only, and this raised the question (6) of what is the real importance of the *exo* anomeric effect in the control of population of rotamers in normal *O*-glycosides.

We have previously reported a study on 1,7-dioxaspiro-[5.5]undecane and various substituted derivatives (7). These compounds were found suitable for the estimation of the *endo* and the *exo* anomeric effects because the energy barrier associated with the conformational equilibrium is sufficiently high between each conformer that their detection and relative abundance could be determined with precision at low temperature by ^{13}C nmr spectroscopy. For instance the unsubstituted 1,7-dioxaspiro[5.5]undecane can theoretically adopt the three conformations illustrated in Scheme 2, but it was shown to exist solely in conformation **2***a* *even at room temperature*. This result was explained by the fact that conformation **2***a* is sterically and stereoelectronically more stable than conformations **2***b* and **2***c*. This study allowed us to conclude that the minimum value for the *endo* and (or) *exo* anomeric effect must be close to 1.4 kcal/mol.[3]

It appeared to us that it would be interesting to compare the conformational behavior of 1,7-dioxaspiro[5.5]undecane with spiro compounds having only one oxygen atom next to the quaternary center. This comparison should be useful to probe the importance of stereoelectronic effects because steric effects can be readily evaluated with six-membered compounds. Also, these spiro ethers can be considered good models for *C*-glycosides just as the spiro ketals are excellent models for the normal *O*-glycosides. We have therefore synthesized the 1-oxaspiro[5.5]undecanes **1** (8), **4**, and **5** (Schemes 3) (8) and have carried out their conformational analysis at room and low temperatures using ^{13}C nmr spectroscopy as the analytical technique. We wish to report this study and to compare these results with those already reported for 1,7-dioxaspiro-[5.5]undecane **2** (7) and spiro[5.5]undecane **3** (9).

Synthesis

Spiro ethers **1**, **4**, and **5** were prepared as follows (Scheme 3). The lithium acetylide derivative of acetylenic tosylate **6** was reacted with cyclohexanone to give the adduct **7**, which was hydrogenated catalytically (H_2/PtO_2) to give hydroxy-tosylate **8**. This compound was then cyclized (*n*-Buli, THF) to give spiro ether **1** (8). Using the same procedure with 4-*tert*-butylcyclohexanone as starting ketone provided a 1:9 mixture of spiro ethers **4** and **5**, which were separated by chromatography.

[2]In *C*-glycosides, the oxygen atom of the OR group at C_1 is replaced by a CH_2 group.

[3]**2***a* is energetically favored over **2***b* and **2***c* for steric and stereoelectronic reasons. *Steric*: **2***a* has two oxygens axially oriented (4 × 0.4 = 1.6 kcal/mol), while **2***b* has one oxygen and one methylene axially oriented ((2 × 0.4) + (2 × 0.9) = 2.6 kcal/mol) whereas **2***c* has two methylene groups axially oriented (4 × 0.9 = 3.6 kcal/mol). *Stereoelectronic*: **2***a* has two anomeric effects (2 × (−1.4) = −2.8 kcal/mol), **2***b* has one anomeric effect (−1.4 kcal/mol), and **2***c* has no anomeric effect (0 kcal/mol). The relative stability is therefore **2***a* = 0, **2***b* = 2.4, and **2***c* = 4.8 kcal/mol.

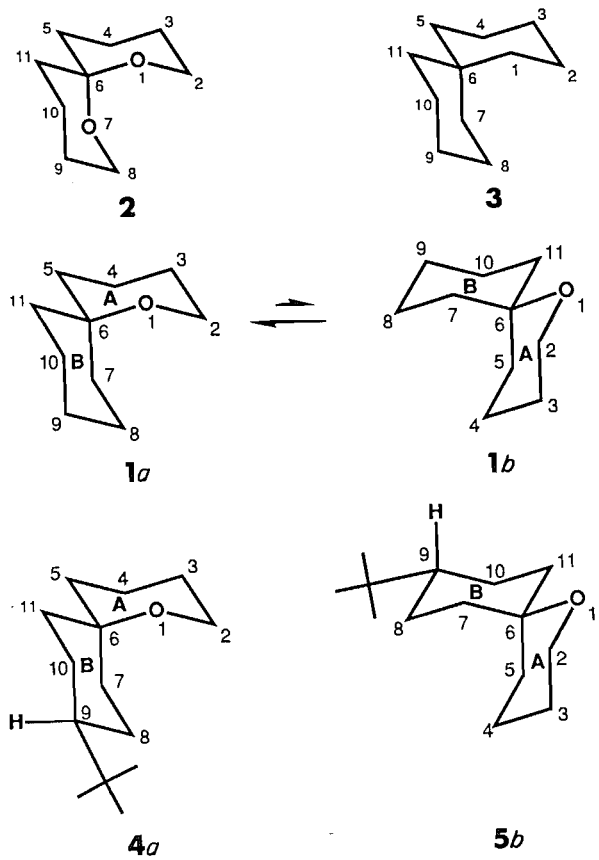
Formation of the major isomer **5** results from the preferential axial addition of acetylide **6** on 4-*tert*-butylcyclohexanone (10).

Results and discussion

The ^{13}C nmr spectrum of 1-oxaspiro[5.5]undecane **1** was obtained at room temperature (298 K). The known chemical shifts of 1,7-dioxaspiro[5.5]undecane **2** (7) and spiro[5.5]undecane **3** (Scheme 4) (9) were used as references (Table 1) for the assignment of the carbon chemical shifts of compound **1** at ring A and ring B respectively.

The correlation for the chemical shifts for C_2, C_4, C_5, C_8, C_9, and C_{10} is very good, the observed difference being <1 ppm (cf. Scheme 4 for numbering). There are larger differences for C_3, C_6, C_7, and C_{11} but those are expected since the structures of compounds **1**, **2**, and **3** are basically different, having respectively one, two, and zero oxygen atoms.

For compound **1**, the chemical shifts for C_2 and C_6 are easily assigned since both have an oxygen atom. The single frequency off-resonance decoupling spectrum (SFORD) shows a triplet (CH_2, C_2-O) at 60.7 ppm and a singlet (C quaternary, C_6-O) at 71.7 ppm. For model compounds **2** and **3**, C_6 is observed at 94.9 and 32.7 ppm respectively, in agreement with the fact that the former has two oxygen atoms while the latter has none. The chemical shifts for C_2 in **1** and **2** are essentially identical. In the spectrum of **1**, the intensity of the signals observed at 21.9 and 35.2 ppm is indicative that each corresponds to two carbon atoms. The first signal must correspond to C_8 and C_{10} while the second one corresponds to C_7 and C_{11}. At room temperature, these carbons must be equivalent since compound **1** is conformationally mobile. Indeed, rapid inversion of ring A (tetrahydropyran ring) renders ring B (cyclohexane ring) symmetrical to it. As a result, the chemical shifts for C_7 and C_{11} as well as those of C_8 and C_{10} are respectively averaged. Also, by comparison with compound **3**, where C_1 = C_5 = C_7 = C_{11} = 37.0 ppm and C_2 = C_4 = C_8 = C_{10} = 22.0 ppm because of the symmetry imposed by its conformational mobility (9), it becomes obvious that C_7 and C_{11} on one hand and C_8 and C_{10} on the other must absorb at 35.2 and 21.9 ppm respectively in compound **1**.



SCHEME 4

The two very close peaks at 26.8 ppm of **1** are assigned to C_3 and C_9 in agreement with the absorption of C_3 and C_9 in compounds **2** and **3**. For compounds **2** and **3**, C_3 and C_9 are identical by symmetry, and are observed at 25.4 and 27.5 ppm

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

respectively. The chemical shifts for C_3 and C_9 can also be compared with other compounds: for example, cyclohexane at 27.7 ppm (11), C_3 of tetrahydropyran at 26.8 ppm (11), and C_5 of 2-methyltetrahydropyran at 26.8 ppm (7).

The signal at 19.4 ppm for compound **1** is assigned to C_4 and is also in good agreement with C_4 of compound **2**, which is observed at 18.6 ppm. Finally, the chemical shifts for C_5 in compounds **1** and **2** are quite similar (35.8 and 36.5 ppm). This, a priori, is surprising since compound **2** is conformationally rigid and compound **1** is not (*vide infra*). However, it will be shown that the most stable conformer of **1** has essentially a conformation (**1***a*) identical to that observed for compound **2**, so the close chemical shift at C_5 for **1** and **2** is thus readily understood.

The ^{13}C nmr spectrum of compound **1** was obtained at low temperature (148 K). Figures 1 and 2 illustrate the 15–45 ppm region of the room and low temperature spectra. This result clearly demonstrates that compound **1** must exist as a mixture of two rapidly equilibrating conformers at room temperature, which can be observed at low temperature. Relative line intensities further indicate that one of the conformers must be predominant. Examination of molecular models suggests that these two conformers must correspond to conformers **1***a* and **1***b* (Scheme 4), which are interconvertible by inversion of ring B. Inversion of ring A is also possible and must also take place at room temperature, but that leads to the mirror image conformers of **1***a* and **1***b* and is not important for our analysis. This interconversion of course can be detected by ^{13}C nmr at low temperature (see C-7, C-8, C-10, and C-11 for **1***a*, **1***b*, **4**, and **5** in Table 1).

Using straightforward steric arguments, it can be further predicted that conformer **1***a*, which has the oxygen atom axially oriented towards ring B, must be more stable than conformer **1***b* in which the heteroatom has been replaced by the sterically more demanding C_5 methylene group in that same axial position. Thus, **1***a* and **1***b* must correspond to the major and the minor conformers. Furthermore, it is possible to assign a chemical shift for each carbon of both conformers and show that they fit with the major and minor absorptions observed in the low temperature ^{13}C nmr spectra of compound **1**. The carbon chemical shift assignments for **1***a* and **1***b* are described in Table 1.

Considering the semiempirical methods for the determination of chemical shift in ^{13}C nmr (7, 12) and the analysis of the steric effects observed in each conformer, we can predict that major differences will be observed, in terms of chemical shifts for C_5, C_7, and C_{11}. Effectively, at room temperature, C_7 and C_{11} are averaged at 35.2 as well as C_8 and C_{10} at 21.9 ppm. At low temperature, C_7 and C_{11} in **1***a* appear at 28.7 and 40.4 ppm respectively while C_7 and C_{11} in **1***b* appear at 30.9 and 41.4 ppm respectively. Similarly, C_8 and C_{10} appear at 21.2 and 21.8 pm in **1***a*, and at 23.3 and 23.8 ppm in **1***b* respectively. This indicates clearly that ring A is rigid in **1***a* and **1***b* at low temperature. The fact that C_5, which is averaged at 36.5 ppm at room temperature and shows two absorptions at 37.8 and 30.4 ppm at low temperature (assigned for C_5 in **1***a* and **1***b* respectively), indicates that ring B is also rigid at low temperature.

The chemical shift assignment for conformers **1***a* and **1***b* was rigorously confirmed by comparison with the ^{13}C nmr spectra of the *tert*-butyl spiro ethers **4** and **5**. Indeed, these two isomers are excellent rigid models for conformers **1***a* and **1***b*. Their low and room temperature ^{13}C nmr spectra are reported in Table 1.

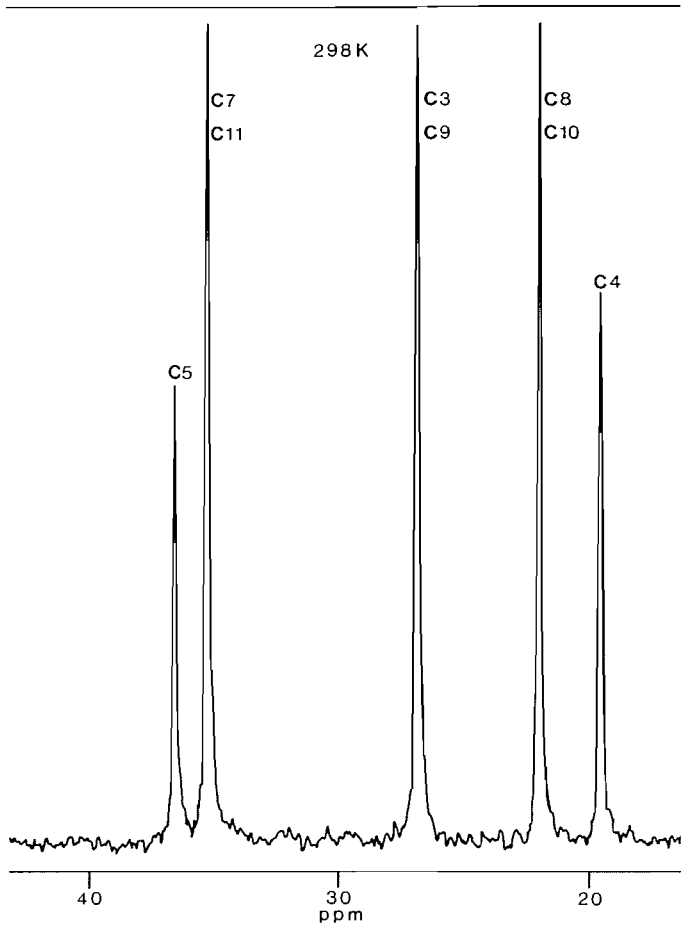


FIG. 1. The 15–45 ppm region of the ^{13}C nmr spectrum of 1-oxaspiro[5.5]undecane and chemical shift assignments in 10% CD_2Cl_2: CF_2Br_2 at 298K.

The presence of the *tert*-butyl group at C_9 renders ring B of **4** and **5** conformationally rigid at room temperature and these isomers must exist in conformations **4***a* and **5***b* respectively. However, ring A of isomers **4***a* and **5***b* must undergo rapid inversion at that temperature, which leads to the formation of the mirror image conformations of **4***a* and **5***b* respectively. The consequence of this rapid inversion is that the chemical shift at C_7 and C_{11}, on one hand, and at C_8 and C_{10} on the other, must be averaged in two single absorptions in isomer **4** as well as in isomer **5**. Of course, the chemical shift values of these carbons should differ in isomers **4** and **5**. The chemical shift assignments for C_7 and C_{11}, as described in Table 1 for the room temperature spectra of **4** and **5**, are in agreement with this discussion.

At low temperature, the rapid chair–chair interconversion of ring A in **4***a* and **5***b* is expected to slow down considerably, at least on the nmr scale. On that basis, different chemical shifts should now appear for C_7, C_8, C_{10}, and C_{11} in both isomers. Again, the exact values for these chemical shifts must be different in **4** and **5**. Furthermore, the four different signals for isomers **4** and **5** must now be very similar to those of conformers **1***a* and **1***b* respectively because **4** has a conformation (**4***a*) identical to **1***a* and the same is true for **5** (i.e., **5***b*) versus **1***b*. The spectral data described in Table 1 clearly show that with the expected exception of C_9 and the *tert*-butyl group, the low temperature spectra of **4** and **5** are indeed essentially superimposable with those of **1***a* and **1***b* respectively.

At 148 K, we have the spectra of conformers **1***a* and **1***b* as

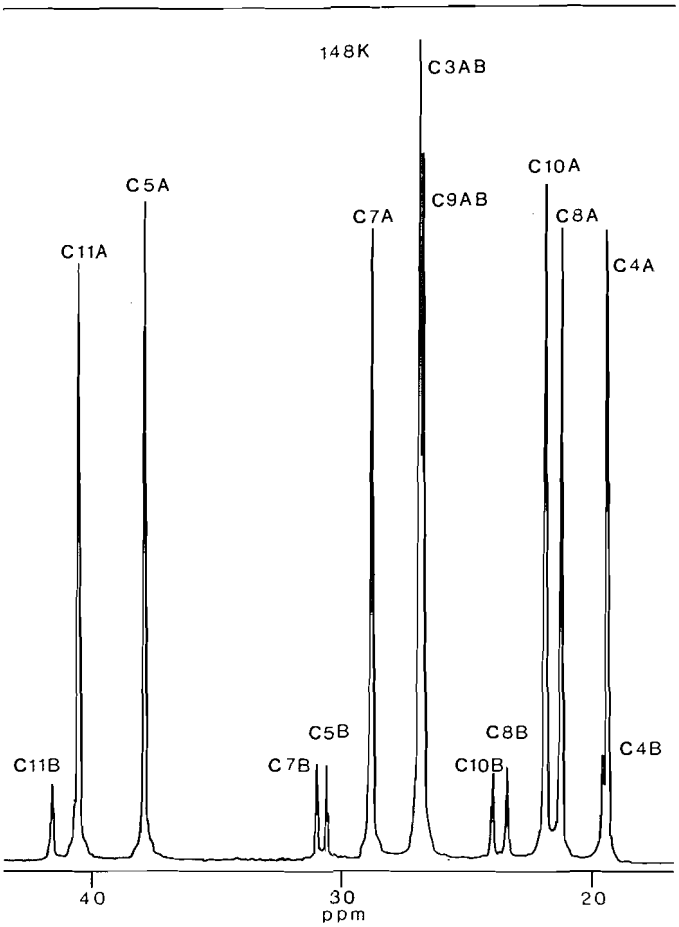

FIG. 2. The 15–45 ppm region of the ^{13}C nmr spectrum of 1-oxaspiro[5.5]undecane and chemical shift assignments in 10% CD_2Cl_2: CF_2Br_2 at 148 K.

well as the chemical shift of each carbon atom for each conformer. At 298 K, we have the average chemical shifts for the corresponding carbon atoms of the two conformers at equilibrium. The averaged chemical shifts at equilibrium depend on the chemical shifts for each carbon atom of each conformer at 148 K, and their relative population at 298 K. The relative population is related to the free energy difference, ΔG^0, between the two conformers and this can be calculated from the observed chemical shifts at 298 and 148 K using the following equation (13) where K_{298} is the population ratio of conformers **1***a* and **1***b* at 298 K.

$$K_{298} = \frac{P_{1a}^{298}}{P_{1b}^{298}} = \frac{\delta_{obs}^{298} - \delta_{1b}^{148}}{\delta_{1a}^{148} - \delta_{obs}^{298}}$$

Using the C_5 chemical shift values ($\delta_{obs}^{298} = 36.5$, $\delta_{1a}^{148} = 37.8$, and $\delta_{1b}^{148} = 30.4$ ppm), the calculated value for K_{298} is equal to 4.7. This value shows that the relative percentage of the two conformers at 298 K is 82% of **1***a* and 18% of **1***b*. ΔG_{298}^0 can be calculated from the usual equation, $\Delta G_{298}^0 = -RT \ln K_{298}$, and this gives a value of $\Delta G_{298}^0 = -0.9$ kcal/mol.

Using molecular models, we can now estimate the steric effects occurring in **1***a* and **1***b* utilizing steric parameters identical to those previously used in our analysis of the 1,7-dioxaspiro[5.5]undecane **2**. In conformer **1***b* these are two methylene groups (C_5 and C_7) oriented axially, and in conformer **1***a* there is one oxygen and one methylene group (C_7) axially oriented. When a methylene group is axially oriented, it corresponds to two *gauche* forms of butane evaluated at 0.9 kcal/mol each (14). When an oxygen is axially oriented, it corresponds to two *gauche* forms of *n*-propyl ether (O-CH_2-CH_2-CH_2) evaluated at 0.4 kcal/mol each (15). Using these values, the steric effects for conformers **1***a* and **1***b* are estimated to be 2.6 and 3.6 kcal/mol. The calculated difference in free energy, ΔG^0, between conformers **1***a* and **1***b* is thus 1.0 kcal/mol in favor of conformer **1***a*. This value is essentially identical to the experimental value of 0.9 kcal/mol. This analysis thus indicates that the values chosen for the steric effects are essentially correct. As one would expect, this also confirms that there is no need to consider parameters other than the steric one to understand the conformational behavior of compounds like spiro ethers **1**, **4**, and **5**.

The importance of the above work in relation to the *endo* and the *exo* anomeric effects stems from the completely different conformational behavior of spiro ether **1**, compared with that of spiro ketal **2**. The first compound is conformationally mobile at room temperature whereas spiro ketal **2** is not. Furthermore, spiro ether **1** exists as a mixture of a major and a minor conformer whereas spiro ketal **2** exists solely in a single rigid conformation.

First, the results obtained with **1** confirm that the steric parameters previously used for the analysis of spiro ketal **2** must be essentially correct.[4] On that basis, as discussed previously (7) (cf. footnote 3), the relative stabilities of conformers **2***a*, **2***b*, and **2***c* would be 0, 1, and 2 kcal/mol respectively, indicating that this compound could not exist in a single rigid conformation. However, if stereoelectronic effects are taken into consideration, and a value of 1.4 kcal/mol is chosen for each anomeric effect (i.e., two in **2***a*, one in **2***b*, and zero in **2***c*), the relative stabilities of conformers **2***a*, **2***b*, and **2***c* become 0, 2.4, and 4.8 kcal/mol, values that indicate that compound **2** must exist essentially in one single conformation, both at room as well as at low temperature, in accord with the experimental results.

Finally, in concluding, it is important to point out that although steric effects alone are sufficient to favor almost exclusively rotamers A_1 and E_1 in some α- and β-*C*-glycosides (6), the preferred occurrence of these rotamers in normal α- and β-*O*-glycosides *must be a result of a combination of steric and stereoelectronic effects as previously concluded.*

Experimental

All the reactions, with the exception of hydrogenation, were executed under an atmosphere of argon and were monitored by thin-layer chromatography (tlc). The intermediates were purified by flash chromatography (17) (silica gel; AcOEt in hexanes) and the final spiro ethers **1**, **4**, and **5** were purified by preparative vapor-phase chromatography (vpc). Spiro ethers **1** and **5** were obtained pure and spiro ether **4** in a mixture along with spiro ether **5**.

Vapor-phase chromatographic analysis and separations were carried out on a Varian Aerograph 920 chromatograph equipped with a thermal conductivity detector and using a 10% SE-30 on Chromosorb W column (6 ft × 3/8 in.). The infrared (ir) spectra were recorded neat or in chloroform on a Perkin–Elmer 681 spectrophotometer. Mass spectra (ms) were obtained on Micromass ZAB-1F spectrometer. Proton and carbon-13 nuclear magnetic resonance (^1H and ^{13}C nmr) spectra were recorded on a Brüker WM-250 spectrometer equipped with an Aspect 2000 computer and operating at 250 MHz for proton and 63 MHz for carbon-13. The free induction decays (FIDs) were sampled over 3000 Hz for proton and 10 000 Hz for carbon-13 using 16 384 data points. For ^1H nmr, the samples were run in deuterochloroform using the signal from residual chloroform (7.26 ppm) as an internal standard.

[4]It was suggested recently that such values might be incorrect (16).

For personal use only.

For ^{13}C nmr, spiro ether **1** was run in CD_2Cl_2 at 298 K, and the signal observed at 26.8 ppm from TMS, corresponding to the absorption for C_3, has been used as an internal standard for all the other experiments executed at room temperature or at low temperature with spiro ethers **1**, **4**, and **5** (see Table 1). Spiro ethers **4** and **5** have also been run in deuterochloroform at 293 K with the signal from solvent at 77.0 ppm being used as an internal standard. For all experiments executed in dibromodifluoromethane (CBr_2F_2) the samples were prepared as follows. Spiro ethers **1**, **4**, and (or) **5** (~125 mg) were dissolved in bidistilled CBr_2F_2 containing 10% V/V CD_2Cl_2 for locking purposes. The spectra of spiro ether **1** were recorded at 298 and 148 K, whereas those of spiro ethers **4** and (or) **5** were recorded at 298 and 163 K, the desired temperature being maintained with a precision of ±1 K. Below 160 K, spiro ethers **4** and **5** were slightly insoluble in the mixture of solvents used.

The following abbreviations are used: RT (room temperature); s (singlet); d (doublet); t (triplet); q (quartet); m (multiplet); rf (rate of flow); δ (ppm from TMS).

Acetylenic tosylate 6

To a stirred solution of *p*-toluenesulfonyl chloride (22 mmol, 4.2 g) in CH_2Cl_2 (45 mL) at RT, is added triethylamine (29 mmol, 4 mL). After 5 min stirring, commercially available 3-butyn-1-ol (20 mmol, 1.5 mL) is added dropwise and the resulting mixture is stirred overnight. After that period, the reactional mixture is diluted to 100 mL with CH_2Cl_2 and the organic phase is washed with aqueous 1 N HCl (2 × 25 mL), saturated $NaHCO_3$ (2 × 25 mL), and saturated NaCl (1 × 25 mL). The organic phase is then dried ($MgSO_4$), filtered, and the solvent is evaporated under reduced pressure. Acetylenic tosylate **6** (4.3 g, 95% yield) is obtained pure and used without further purification; ^1H nmr δ: 1.98 (1H, t, J = 2.5 Hz, H-C≡C), 2.45 (3H, s, CH_3), 2.56 (2H, t of d, J = 7.0 Hz, 2.5 Hz, $CH_2C{\equiv}C$), 4.10 (2H, t, J = 7.0 Hz, CH_2O), 7.35 (2H, d, J = 7.2 Hz, aromatic), 7.80 (2H, d, J = 7.2 Hz, aromatic); ms m/e: 224 (M^+).

Hydroxy-tosylate 8

The acetylenic tosylate **6** (20 mmol, 4.48 g) is dissolved in anhydrous THF (50 mL) and that solution is stirred during 30 min at −78°C (Dry Ice: acetone). Then *n*-butyllithium (20 mmol, 12.5 mL, solution 1.6 M in hexane) is added dropwise and, after addition, the purple solution is stirred at −78°C for a further 30 min. A solution of cyclohexanone (20 mmol, 2.07 mL) in anhydrous THF (25 mL) is then added dropwise, slowly, and after addition the reactional mixture is stirred at −78°C during 2 h. After that period, the reaction is quenched with water (1 mL) and the resulting mixture is allowed to warm to RT. The mixture is diluted with Et_2O (100 mL) and the organic phase is dried ($MgSO_4$), filtered, and the solvent is evaporated under reduced pressure. Flash chromatography (AcOEt/hexane:silica gel) of the crude oil (6.3 g) gives pure acetylenic hydroxy-tosylate **7** (5.0 g, 78% yield); ^1H nmr δ: 1.3–2.0 (11H, m, cyclohexanol ring), 2.48 (3H, s, CH_3), 2.60 (2H, t, J = 7.0 Hz, $CH_2C{\equiv}C$), 4.10 (2H, t, J = 7.0 Hz, CH_2O), 7.35 (2H, d, J = 7.2 Hz, aromatic), 7.80 (2H, d, J = 7.2 Hz, aromatic). The triple bond of the acetylenic hydroxy-tosylate **7** (15.5 mmol, 5.0 g) is then completely hydrogenated by reaction with H_2 over PtO_2 catalyst at 40 psi (1 psi = 6.9 kPa) during 4 h in dry MeOH. After hydrogenation the reactional mixture is filtered, MeOH is evaporated under reduced pressure, and flash chromatography (AcOEt/hexane:silica gel) of the resulting crude oil gives pure hydroxy-tosylate **8** (2.53 g, 50% yield); ^1H nmr δ: 1.1–1.8 (17H, m, cyclohexanol ring, 3 chain CH_2), 2.46 (3H, s, CH_3), 4.05 (2H, t, J = 6.8 Hz, CH_2O), 7.35 (2H, d, J = 8.0 Hz, aromatic), 7.80 (2H, d, J = 8.0 Hz, aromatic).

1-Oxaspiro[5.5]undecane 1

The hydroxy-tosylate **8** (3.5 mmol, 1.14 g) is dissolved in anhydrous THF (20 mL) and that solution is stirred 30 min at −78°C. Then *n*-butyllithium (3.5 mmol, 2.2 mL, solution 1.6 M in hexane) is added slowly and, after addition, the reactional mixture is allowed to warm to RT and stirred for a further 2 h. Anhydrous $NaHCO_3$ (500 mg) is then added, the mixture is filtered, and the solvent evaporated under reduced pressure. The volatile spiro ether **1** (300 mg, 55% yield) is then obtained from the residual oil and purified by preparative vpc. The purification is realized using a 10% SE-30 on Chromosorb W column (6 ft × 3/8 in.); rf: 4.5 min at 160°C; ir: 2990, 2930, 2860, 1490, 1210, and 1075 cm^{-1}; ^1H nmr δ: 1.1–1.8 (16H, m, 8 CH_2), 3.56 (2H, t, J = 8.0 Hz, CH_2O); ^{13}C nmr (in CD_2Cl_2 at 298 K) δ: 71.8 (s), 60.8 (t), 36.2 (t), 35.2 (t), 26.8 (t, two very close peaks), 22.1 (t), 19.4 (t); ms m/e: 154 (M^+).

Hydroxy-tosylates 10

The hydroxy-tosylates **10** were obtained from 4-*tert*-butylcyclohexanone and the acetylenic tosylate **6**, following exactly the same experimental procedure as the one used to obtain hydroxy-tosylate **8**, with a 33% overall yield.

Intermediate acetylenic hydroxy-tosylates **9**; ^1H nmr δ: 0.85 (9H, s, *tert*-butyl), 0.9–2.0 (10 H, m, cyclohexanol ring), 2.45 (3H, s, CH_3), 2.60 (2H, t, J = 7.0 Hz, $CH_2C{\equiv}C$), 4.10 (2H, t, J = 7.0 Hz, CH_2O), 7.35 (2H, d, J = 7.2 Hz, aromatic), 7.80 (2H, d, J = 7.2 Hz, aromatic); the ^1H nmr spectrum does not show the presence of the two possible isomers.

Hydroxy-tosylates **10**: ^1H nmr δ: 0.85 (9H, s, *tert*-butyl), 0.9–2.0 (16H, m, cyclohexanol ring, 3 chain CH_2), 2.45 (3H, s, CH_3), 4.03 (2H, t, J = 6.8 Hz, CH_2O), 7.35 (2H, d, J = 7.0 Hz, aromatic), 7.80 (2H, d, J = 7.0 Hz, aromatic); once again there is no evidence for the presence of both hydroxy-tosylates **10**.

9-tert-Butyl-1-oxaspiro[5.5]undecanes 4 and 5

The spiro ethers **4** and **5** were obtained from the hydroxy-tosylates **10**, following exactly the same experimental procedure as the one used to obtain spiro ether **1**, with a 65% overall yield, total for both isomers, with a 9:1 ratio in favor of isomer **5**.

Spiro ethers **4** and **5**, mixture ~1:1; rf: 5.1 min (**4**) and 5.8 min (**5**) at 185°C; ir: 2935, 2780, 1450, 1165, and 1090 cm^{-1}; ^1H nmr δ: 0.85 (18H, s, *tert*-butyl (**4** and **5**), 0.9–2.0 (30 h, m, 2 CH, 14 CH_2 (**4** and **5**)), 3.60 (2H, t, J = 8.0 Hz, CH_2O (**4**)), 3.70 (2H, t, J = 8.0 Hz, CH_2O (**5**)); ms m/e: 210 (M^+).

Spiro ether **4**; ^{13}C nmr (in $CDCl_3$ at 298 K), δ: 71.2 (s), 61.0 (t), 48.8 (d), 37.6 (t), 35.2 (t), 32.8 (s), 28.0 (q), 26.7 (t), 22.2 (t), 19.5 (t).

Spiro ether **5**; ^{13}C nmr (in $CDCl_3$ at 298 K), δ: 73.2 (s), 61.6 (t), 48.5 (d), 36.2 (t), 32.6 (s), 31.1 (t), 28.0 (q), 26.8 (t), 24.1 (t), 19.5 (t).

Spiro ether **5**, pure; rf: 5.8 min at 185°C; ir: 2940, 2860, 1450, 1365, and 1090 cm^{-1}; ^1H nmr δ: 0.85 (9H, s, *tert*-butyl), 0.9–2.0 (15H, m, CH, 7 CH_2), 3.70 (2H, t, J = 8.0 Hz, CH_2O); ^{13}C nmr (in $CDCl_3$ at 298 K) δ: 73.2 (s), 61.6 (t), 48.5 (d), 36.2 (t), 32.6 (s), 31.1 (t), 28.0 (q), 26.8 (t), 24.1 (t), 19.5 (t); ms m/e: 210 (M^+).

Phase transitions in solid cycloheptene

JULIAN HAINES AND D. F. R. GILSON[1]

Department of Chemistry, McGill University, 801 Sherbrooke St. W., Montreal, Que., Canada H3A 2K6

Received October 16, 1989

JULIAN HAINES and D. F. R. GILSON. Can. J. Chem. **68**, 604 (1990).

The phase transition behaviour of cycloheptene has been investigated by differential scanning calorimetry, proton spin-lattice relaxation, and vibrational spectroscopy (infrared and Raman). Two solid–solid phase transitions were observed, at 154 and 210 K, with transition enthalpies and entropies of 5.28 and 0.71 kJ mol^{-1} and 34.3 and 3.4 J K^{-1}, respectively. Cycloheptene melted at 217 K with an entropy of melting of 4.5 J K^{-1} mol^{-1}. The bands in the vibrational spectra of the two high temperature phases were broad and featureless, characteristic of highly disordered phases. The presence of other conformers, in addition to the chair form, was indicated from bands in the spectra. The ring inversion mode was highly phase dependent and exhibited soft mode type behaviour prior to the transition from the low temperature phase. The low frequency Raman spectra (external modes) of these phases indicated that the molecules are undergoing isotropic reorientation. In the low temperature phase, the vibrational bands were narrow; the splitting of the fundamentals into two components and the presence of nine external modes are consistent with unit cell symmetry of either C_2 or C_s with two molecules per primitive unit cell. A glassy state can be produced from the intermediate phase and the vibrational spectra were very similar to those of the high temperature phases, indicating that static disorder was present. The barriers to reorientation, as obtained from proton spin-lattice relaxation measurements, are 9.0 kJ mol^{-1} in both the high temperature phases, and 15.4 kJ mol^{-1} in the low temperature, ordered phase.

Key words: cycloheptene, phase transition, differential scanning calorimetry, NMR, vibrational spectroscopy.

JULIAN HAINES et D. F. R. GILSON. Can. J. Chem. **68**, 604 (1990).

Utilisant la calorimétrie à balayage différentiel, la relaxation protonique spin-réseau et la spectroscopie de vibration (infrarouge et Raman), on a étudié le comportement du cycloheptène à ses transitions de phase. On a observé deux transitions de phase solide–solide, l'une à 154 K et l'autre à 210 K; les enthalpies et les entropies de transition sont respectivement de 5,28 et 0,71 kJ mol^{-1} et de 34,3 et 3,4 J K^{-1} mol^{-1}. Le cycloheptène fond à 217 K avec une entropie de fusion de 4,5 J K^{-1} mol^{-1}. Les bandes observées dans les spectres de vibration des deux phases de température élevée sont larges et sans traits marquants, caractéristiques de phases hautement désordonnées. La présence d'autres conformères, en plus de la forme chaise, peut être déduite de la présence d'autres bandes dans les spectres. Le mode d'inversion de cycle dépend fortement de la phase et, avant la transition de la phase de basse température, il présente une comportement typique d'un mode souple. Les spectres Raman de basse fréquence (modes externes) de ces phases indiquent que des molécules subissent une réorientation isotrope. Dans la phase de basse température, les bandes de vibration sont étroites; on observe un couplage des bandes fondamentales en deux composantes ainsi que neuf modes externes qui sont en accord avec symétrie C_2 ou C_s d'une maille qui comporterait deux molécules par maille primitive. On peut produire un état vitreux à partir de l'état intermédiaire et ses spectres de vibration sont semblables à ceux observés avec les phases de température plus élevée; ces résultats indiquent qu'un désordre statique est présent. Pour chacune des deux phases de température élevée, les barrières à la réorientation, telles qu'obtenues par des mesures de relaxation protonique spin-réseau, sont égales à 9,0 kJ mol^{-1} alors que cette barrière est de 15,4 kJ mol^{-1} pour la phase ordonnée de basse température.

Mots clés : cycloheptène, transition de phase, calorimétrie à balayage différentiel, RMN, spectroscopie de vibration.

[Traduit par la revue]

Introduction

Order–disorder transitions, known to occur in saturated cyclic hydrocarbons, also occur in some of their unsaturated analogues (1, 2). A differential thermal analysis (DTA) investigation of cycloheptene (3) indicated that a phase transition occurs at 153 K, well below the melting point of 217 K. The same study also showed that cycloheptene could form a glassy crystal, which exhibits a glass transition temperature of 100 K. This behaviour is similar to that of many other cyclic hydrocarbons with ring puckering vibrations, for which glassy crystals are readily formed. These include cyclohexene, cycloheptane, and 1,3,5-cycloheptatriene (3, 4).

The infrared and Raman spectra of gaseous, liquid, and solid cycloheptene have been investigated previously, and have indicated that, in the liquid at room temperature, an equilibrium exists between the chair and boat conformations, with the chair being favoured (5). The same study also indicated that, in the low temperature solid, cycloheptene exists in the chair form. The emphasis of this investigation was to perform a normal coordinate analysis and vibrational assignment, and hence no mention was made of the solid–solid phase transitions. The solid state spectrum was obtained from samples quenched at liquid nitrogen temperature and subsequently annealed. Force field calculations (6) have indicated that the chair conformation is more stable than the boat by 3.37 kJ mol^{-1}. A recent electron diffraction study confirmed that the chair form is the favoured conformation (7).

Previous work on order–disorder transitions in solids (8–10) has demonstrated the effectiveness of various combinations of calorimetric, variable-temperature vibrational spectroscopy, and proton spin-lattice relaxation time measurements, in investigating the phase transition behaviour of a given compound. In the case of cycloheptene, very little information is available on the solid phases, and the present investigation provides a better understanding of the phase transition behaviour of this compound.

Experimental

Cycloheptene (Wiley Organics, purity 99%) was repeatedly distilled under vacuum prior to use. Cycloheptene (Aldrich Chemical Co., purity 97%), distilled under vacuum was used in some of the Raman experiments.

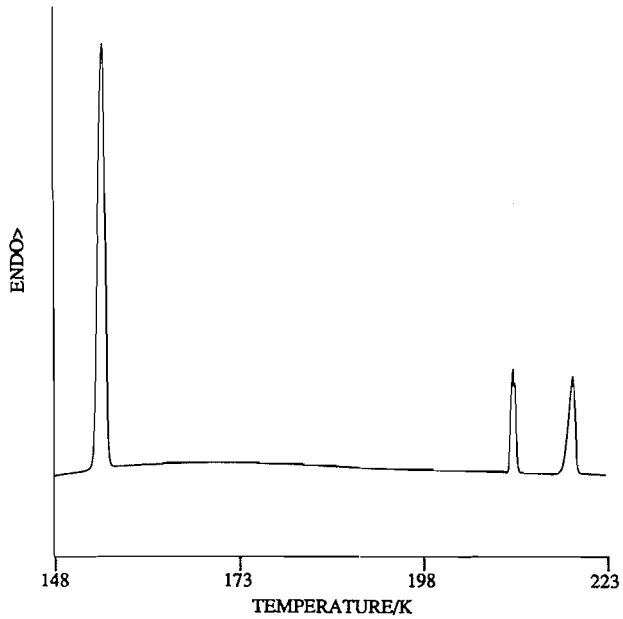

FIG. 1. DSC scan of annealed cycloheptene upon heating.

Differential scanning calorimetric (DSC) measurements down to 123 K were performed on a Perkin–Elmer DSC 7 calorimeter, which was calibrated on the solid–solid phase transition of cyclohexane (Aldrich Chemical Co. "Gold Label"). The calibration was found not to depend on the scan rate used (2.5 and 5 K min^{-1}). Samples, typically between 5 and 10 mg, were weighed on a Cahn microbalance and sealed in aluminum DSC pans. Spin-lattice relaxation times were measured by the inversion–recovery sequence using a Spin-lock CPS-2 spectrometer operating at 33 MHz. Sample temperature was varied by a stream of cold nitrogen gas.

Raman spectra were recorded on an Instruments S.A. spectrometer with a Jobin–Yvon Ramanor U-1000 1.0 m double monochromator, using a Spectra Physics model 164 argon-ion laser for excitation. The resolution was typically 1 or 2 cm^{-1}. Infrared spectra (1 cm^{-1} resolution) were acquired on a Nicolet 6199 FT-IR spectrometer. The sample temperature was controlled for both FT-IR and Raman experiments, with a Cryodyne Cryocooler model 21 cryostat (Cryogenics Technology Inc.), and measured using a silicon-diode temperature sensor attached to a Cryophysics model 4025 controller. The Raman spectra were obtained by cooling liquid samples in sealed glass capillary tubes, which were mounted onto the cold finger of the cryostat using indium foil as a conducting junction. The infrared spectra were measured on thin films sprayed on a potassium bromide window.

Results and discussion

DSC results, Fig. 1, indicate the presence of two solid–solid phase transitions in cycloheptene. Transition temperatures, enthalpies, and entropies are listed in Table 1. The phases are numbered in sequence from high to low temperature. The entropy of melting of 4.5 J K^{-1} mol^{-1} is very low, indicating that phase I is highly disordered, and the sum of the entropies of melting and the II → I transition is, in fact, very close to the values reported for the entropy of melting of cyclohexane (11) and of cycloheptane (12). Upon cooling, cycloheptene was found to supercool from the liquid down, through the melting point, to between 201 and 203 K with the I → II transition occurring 2–6 K below this temperature. The ΔS values for the freezing and I → II transitions were found to be −3.4 and −4.7 J K^{-1} mol^{-1}, respectively, the reverse of those obtained on heating. Phase II was also found to supercool well below the II → III transition temperature, and to transform irreversibly to phase III at 129 K upon heating. This supercooling and subsequent irreversible transition to phase III are consistent with previous DTA results (3). The II → I transition was found to occur reversibly with no significant thermal hysteresis.

TABLE 1. DSC results for cycloheptene

Transition	T_{onset} (K)	ΔH (kJ mol^{-1})	ΔS (J K^{-1} mol^{-1})
III → II	154	5.28	34.3
II → I	210	0.71	3.4
I → liquid	217	0.97	4.5

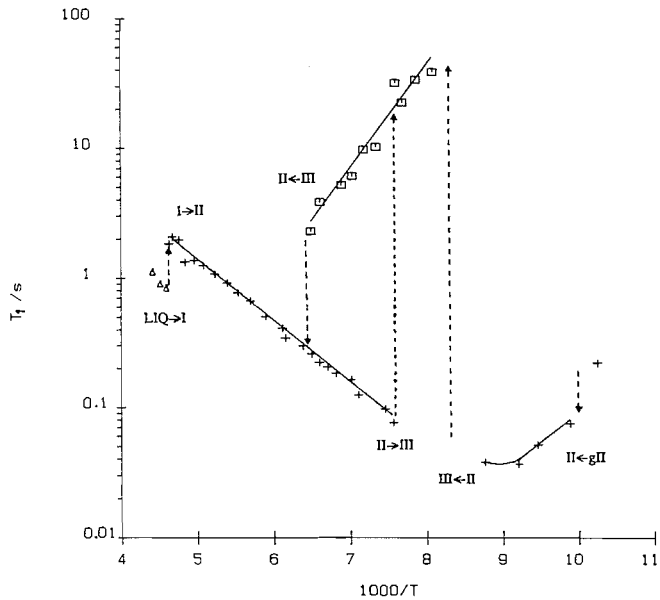

FIG. 2. Proton spin-lattice relaxation times in cycloheptene.

Transition entropies can be related to the disordering occurring at a phase transition by using the Guthrie–McCullough expression (13), $\Delta S = R \ln (N_1/N_2)$, where R is the gas constant and N_1 and N_2 are the number of distinguishable orientations in the high and low temperature phases, respectively. Applying this expression to the III → II and II → I transitions, entropy changes equivalent to $R \ln 62$ and $R \ln 1.5$ were obtained, respectively. While a 62-fold disordering process is unrealistic, the 1.5-fold or 6/4-fold disordering at the II → I transition could be due to a transition from a lattice of cubic to one of hexagonal symmetry. An alternative interpretation of the III → II transition can be made if the approach of Clarke *et al.* (14, 15) is taken, in which a contribution of approximately 10.3 J K^{-1} mol^{-1} is subtracted from the entropy of transition to account for the slackening of the lattice. This approach would produce a value of $R \ln 18$ for the configurational entropy, and hence an 18-fold disordering at the transition. This disordering contains both orientational and conformational contributions. The chair, boat, and twist-chair conformations of cycloheptene as well as the corresponding inverted structures are all of similar energy (6), and therefore interconversion between them could contribute to the total disorder.

Proton spin-lattice relaxation times, Fig. 2, were measured from just above the melting point down to 98 K, the temperature limit of the instrument. An increase in T_1 was observed at the freezing point, followed by continuous decrease in T_1 down to

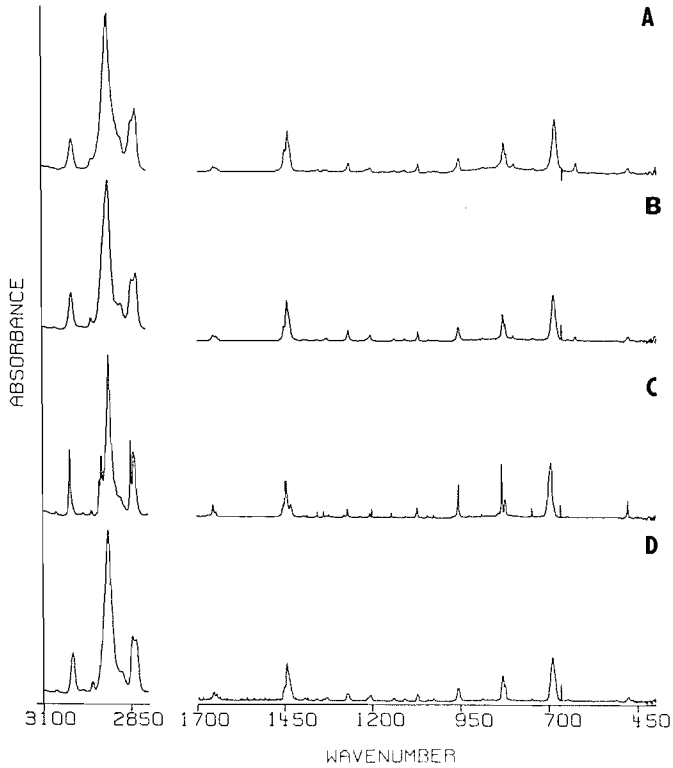

FIG. 3. Comparison of the infrared spectrum of cycloheptene: (A) phase I at 210 K; (B) phase II at 165 K; (C) phase III at 60 K; and (D) phase gII at 86 K (not to scale).

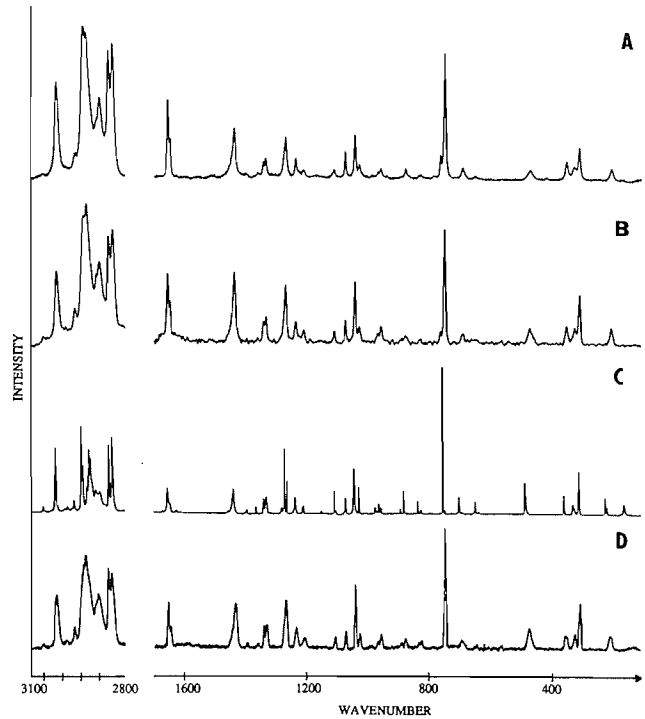

FIG. 4. Comparison of the Raman spectrum of cycloheptene: (A) phase I at 215 K; (B) phase II at 165 K; (C) phase III at 47 K; and (D) phase gII at 54 K (not to scale).

131 K. At this temperature, a sharp increase in T_1 was observed as supercooled phase II transformed to phase III. Phase III exhibited a decrease in T_1 with increasing temperature. Upon rapidly cooling phase II down to 98 K, the glassy crystal, phase gII, was formed. This phase reverted to phase II above the glass transition at 100 K, at which point the value of T_1 decreased abruptly. The supercooled phase II formed in this manner showed a decrease in T_1 with increasing temperature until the irreversible transition to phase III was observed.

Barriers to reorientation were calculated from the linear portions of the plots of ln T_1 versus reciprocal temperature. The results obtained are 15.4 kJ mol^{-1} for phase III and 9.0 kJ mol^{-1} for both phases I and II. A value of 8.7 kJ mol^{-1} was obtained for phase II below 120 K. The barrier in phase III is lower than the barrier for ring inversion of 20.9 kJ mol^{-1}, obtained in solution (16). However, ring inversion or a related motion, possibly involving interconversion between different conformers, is the most likely candidate for the motion occurring in this phase. The transition to phase II occurred before a T_1 minimum was reached, but phase II, on the other hand, appeared to reach a T_1 minimum upon heating from the glassy crystal. The value obtained, 0.035 s, corresponds to a C value, the constant from the BPP equation, of 6.3×10^9 rad^2 s^{-2}. This would be equivalent to a decrease in second moment of the resonance line of 8.8 G^2 at the III $\rightarrow$ II transition. A change of this magnitude could be the result of a transition in overall motion from ring inversion, or a related process that was not as yet fully developed, to isotropic rotation and lattice diffusion, although no definite conclusion can be made to this effect.

The vibrational spectra of phases I and II contained broad featureless bands and were characteristic of disordered solids, Figs. 3–5. Many bands were observed that were not present or were extremely weak in the low temperature phase III. These include the bands at 803 and 629 cm^{-1} in the infrared spectrum and those at 762 and 420 cm^{-1} in the Raman spectrum of phase II, Table 2. The band at 629 cm^{-1} has previously been assigned to a vibration of the boat conformation (5). The band at 327 cm^{-1} was also assigned to a vibration of the boat conformation, but no decrease in intensity was observed in the Raman spectrum upon passing to phase III. Conversely, the weak band at 420 cm^{-1}, which was not present in the Raman spectrum of phase III, was assigned as a fundamental vibration of the chair form. The present results would favor the band at 420 cm^{-1} being due to a conformation other than the chair and that at 327 cm^{-1} being due to the most stable conformation, presumably the chair form. The presence of additional bands in the spectra of these two upper phases indicated that a mixture of conformers in equilibrium with one another was present.

The spectra of the glassy crystal, phase gII, were very similar to those of phase II, with the main differences being that some of the bands had shoulders and were shifted slightly in frequency, and that there was a broad band in the low frequency Raman spectrum. In addition, the bands due to conformations other than the chair form were less intense than in phase II. This indicates that, as the temperature decreases, the equilibrium shifts in favor of the chair form. The ease with which cycloheptene supercools and forms this glassy crystal is related to the large degree of conformational disorder present in phase II.

The transformation of phase gII to phase III after passing through its glass transition can be seen from the changes in infrared linewidth of ν_{18} and ν_{45}, Fig. 6. These vibrations are both mixtures of a C—C stretch and various CH_2 vibrations. A marked decrease in the linewidth of both bands upon transition to phase III was observed, followed by an increase at the III $\rightarrow$ II transition temperature.

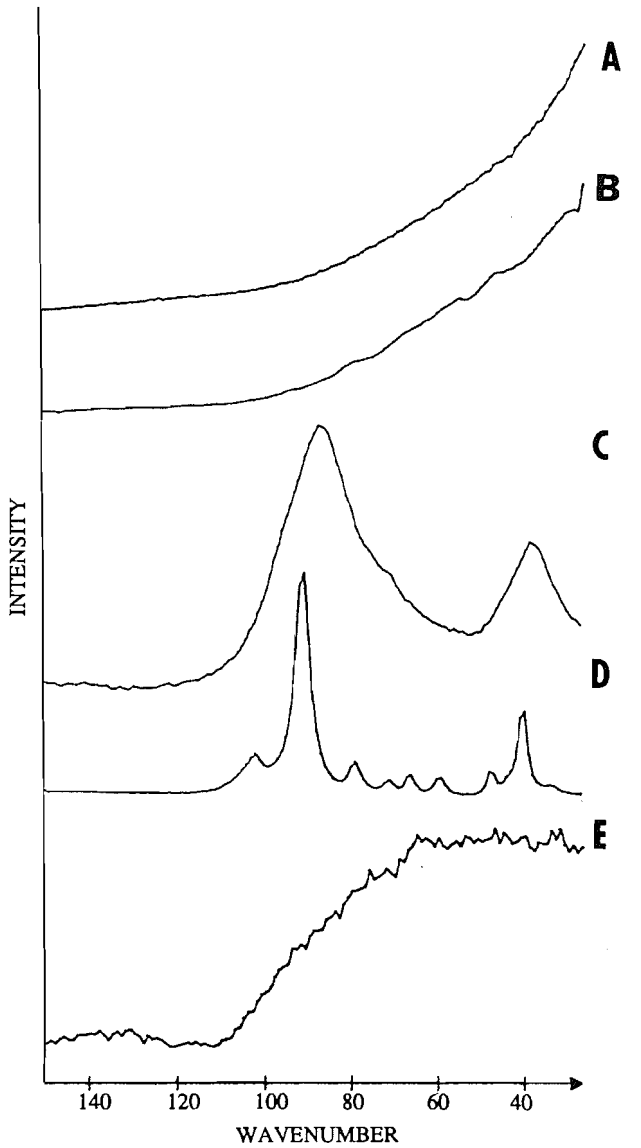

FIG. 5. Comparison of the low frequency Raman spectrum of cycloheptene: (A) phase I at 215 K; (B) phase II at 165 K; (C) phase III at 140 and (D) at 47 K; and (E) phase gII at 54 K (not to scale).

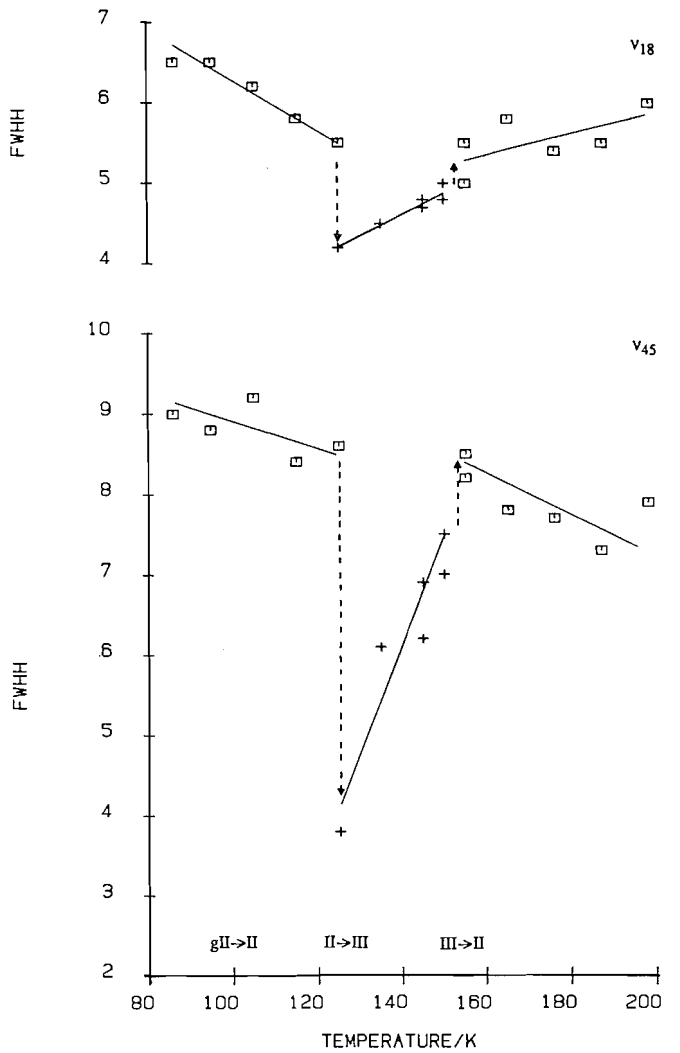

FIG. 6. Temperature dependence of the infrared linewidth (FWHH) in cm^{-1} of ν_{18} and ν_{45}.

The spectra of phase III were markedly different from those of the other phases. The bands were sharp, and the majority were split into at least two components. In particular, ν_{36} and ν_{42}, both a mixture of a CH_2 wag and a C—C stretch, split into two components in the IR and the Raman spectrum. In addition, many bands exhibited shifts in frequency, especially the out-of-plane vibrations. The lowest frequency out-of-plane vibration, ν_{28}, the ring inversion, was observed at 163 cm^{-1} in phase III, at 114 cm^{-1} in phase II, and at 132 cm^{-1} in phase gII. Such large shifts in the frequencies of the out-of-plane vibrations result from the closer packing the molecules experience in the high density, ordered phase III, which increases the barrier to the motion. In phase III, this band shifted by 8 cm^{-1} between 47 and 150 K and broadened significantly, Figs. 7 and 8; it then exhibited a decrease in frequency of more than 40 cm^{-1} at the phase transition. This behaviour is similar to that observed for the ring inversion modes in cyclohexene (9) and pentamethylene sulfide (10), except in this case the magnitude of the frequency shift is much greater. The frequency shift and broadening observed prior to the phase transition are indicative of the role played by the ring inversion vibration in the phase transition process. The linear relationship between the square of the frequency of ν_{28} and temperature, Fig. 9, is typical of soft mode type behaviour, indicating that this vibration is involved in driving the phase transition.

The infrared and Raman bands in phase III are coincident within experimental error, indicating that mutual exclusion does not apply and therefore the crystal belongs to a non-centrosymmetric space group. The point group of cycloheptene, C_s, restricts the possible site groups to C_1 and C_s. This, the observed splitting of the internal modes, and the presence of nine distinct external modes restrict the crystal to non-centrosymmetric monoclinic and orthorhombic space groups with at least two molecules per primitive unit cell. The most probable candidates are the monoclinic space groups with C_2 and C_s symmetry and two molecules located on the general positions. This presence of the molecules on the general positions prevents any further limitation of the choice of possible space groups.

The absence of external modes in the low frequency Raman spectra of phases I and II is consistent with the presence of isotropic molecular reorientation (17–19), as was proposed on the basis of the NMR results. Further evidence in support of this

conclusion is that τ, the correlation time for this motion as calculated from the proton T_1 measurements, was found to vary from 1.8×10^{-10} s at 154 K to 2.4×10^{-11} s at the melting point.

That discrete external modes were observed for phase III is indicative of an ordered crystal. These bands shifted slightly with temperature, Fig. 10, and broadened considerably. The broad band in the low frequency spectrum of phase gII indicated that static disorder was present, corresponding to a freezing-in

of the disorder in phase II. This spectrum was similar to that of glassy crystalline cyclohexanol (20), which has a disordered structure of cubic symmetry. In contrast, the low frequency Raman spectra of the glassy crystalline phases of cyclohexene were found to contain many overlapping bands, indicating that these phases are of lower symmetry (9). These phases arise from the cooling of the metastable phase III and the high temperature phase I, both of which are characterized by anisotropic disorder.

R. J. DeVoe, M. R. V. Sahyun, E. Schmidt, and D. K. Sharma. Can. J. Chem. **68**, 612 (1990).

We have compared the photooxidation of the title compound, DEA, by diphenyliodonium salts in homogeneous acetonitrile (AN) and in heptane/AOT/water reverse micelle solutions. The reaction is efficient, which we attribute to rapid (ca. 10 ps) deethylation of the DEA radical cation, initially formed by photoinduced electron transfer. In AN, the electron transfer occurs from singlet excited DEA, but in reverse micelles it is gated by intersystem crossing to triplet DEA. Under these conditions, DEA fluorescence quenching by the iodonium cation may still be observed; we infer operation of the external heavy atom effect as the primary mechanism.

Key words: anthracene, electron transfer, reverse micelle, photochemistry, picosecond.

R. J. DeVoe, M. R. V. Sahyun, E. Schmidt et D. K. Sharma. Can. J. Chem. **68**, 612 (1990).

On a comparé la photo-oxydation du composé mentionné dans le titre, le DEA, par des sels de diphényliodonium en solution homogène dans l'acétonitrile (AN) et dans des solutions micellaires inversées d'heptane/AOT/eau. La réaction est efficace et on attribue cette caractéristique à une dééthylation rapide (environ 10 ps) du cation radiocalaire DEA qui se forme originalement par un transfert d'électron photoinduit. Dans l'AN, le transfert d'électron se produit à partir d'un singulet excité du DEA; toutefois, dans les micelles inversées, cette réaction se produit par le biais d'un échange intersystème vers l'état triplet du DEA. Dans ces conditions, on peut encore observer le piégeage de la fluorescence du DEA par le cation iodonium. On en conclut que l'effet d'un atome lourd extérieur agit comme mécanisme primaire.

Mots clés : anthracène, transfert d'électron, micelle inversée, photochimie, picoseconde.

[Traduit par la revue]

Introduction

We previously (1) studied the anthracene sensitized photolyses of both diphenyliodonium and triphenylsulphonium salts in solution using both steady-state and laser flash photolysis techniques. Photoproducts, namely phenylated anthracenes along with iodobenzene or diphenylsulphide, respectively, were obtained from both salts with quantum efficiencies of ca. 0.1 at 375 nm. Accordingly we inferred the intermediacy of diphenyliodo and triphenylsulphur radicals formed by single electron transfer from the singlet excited anthracene (1), and we developed a comprehensive model of this chemistry. The overall reaction scheme is shown in Fig. 1, and the estimated rate constants for each significant step are listed in Table 1.

In the present work, we extend our observations to 9,10-diethoxyanthracene, DEA (2), as electron-transfer sensitizer for the diphenyliodonium cation. This system is not only of theoretical interest, but of technological importance as well (3). Our starting point was to make use of the reaction scheme of Fig. 1, with the goal of evaluating the corresponding rate constants when DEA substituted for anthracene. We recognized that blocking the 9- and 10-positions on the anthracene nucleus should inhibit the radical-wasting recombination pathway, which leads with anthracene, itself, principally to coupling at the 9-position (1). As will be seen, the major difference between anthracene and DEA sensitization involves active participation of the latter in the chemistry immediately consequent to the primary electron-transfer process.

The resulting highly efficient destruction of the anthracene nucleus provides a convenient monitor for electron-transfer events, which proved convenient for the study of interfacial electron transfer in a reverse micellar system. This phenomenon is of considerable current interest (4–9), particularly with respect to possibilities of enhanced efficiency of electron transfer at phase boundaries (5, 9) and the rectifying behaviour of an interface between media of differing polarity (6). In particular, we chose to make a comparative study of the photooxidation of DEA by diphenyliodonium cation in acetonitrile solution and in the heptane/Aerosol-OT/water reverse micellar system, which is well characterized (7–10).

Experimental

Diphenyliodonium hexafluorophosphate (11), mp 136°C, was purified by recrystallization from isopropanol. The DEA, mp 136–149°C, was prepared (2) by D. E. Vogel, Graphic Research Laboratory, 3M. Spectral quality, glass-distilled acetonitrile, AN (EM OmniSolv®), and glass-distilled heptane were used for solution preparation.

Reverse micelles were made using ion-exchanged, glass-distilled water and recrystallized sodium *bis*-(2-ethylhexyl)sulphosuccinate (Aldrich Aerosol-OT, AOT), which had been taken up in heptane, dried over activated molecular sieves, and recovered by removal of solvent on a rotary evaporator. The residue was dried in a vacuum oven and stored in a vacuum desiccator. No luminescent impurities were detected in either the solvents or the surfactant. The procedures for making the reverse micellar solutions were as previously described (10); DEA was incorporated 1×10^{-4} M in the heptane.

Fluorescence intensities were recorded on a Perkin Elmer MPF-44B

fluorescence spectrophotometer. The data for the Stern–Volmer plots, Figs. 3 and 4, are based on emission intensities at 450 nm of 0.3 mM anthracene solutions, excited by 370 nm radiation.

The photo-CIDNP spectra were obtained using the proton probe on a Varian XL-100 magnetic resonance spectrometer, with the probe modified to allow direct irradiation of the sample at the receiver coil. Typical sample composition was 0.0055 M 'onium salt and 0.0026 M DEA in acetonitrile-d_3. The light source was a 300-W Xe arc operating at full power, focused on the receiver coil using quartz optics on an optical rail. Heating of the sample was a problem, as infrared filtration decreased the light intensity too much to observe CIDNP. Consequently, photo-CIDNP spectra were recorded in the Fourier transform mode of the XL-100, collecting two transients over ca. 5 s exposure time, during which heating was minimal. Samples (2 mL volume) were deoxygenated by nitrogen purge, and dark spectra were taken before and after irradiation.

Quantum yields were measured with no more than 20% conversion of DEA on solutions 3×10^{-4} M in DEA and 0.005–0.10 M in the 'onium salt. The solutions were deoxygenated by dry argon purge, as required. Aliquots (3 mL) in a 1-cm quartz spectrophotometer cell were required at 366 ± 10 nm on an optical bench with light from the Xe arc lamp, passed through a monochromator with the slits adjusted to allow a 20-nm bandpass. The output of the source was calibrated by means of potassium ferrioxalate actinometry (12) and continuously monitored with a radiometer. Typical fluxes of 5×10^{-8} einstein min^{-1} resulted in ca. 20% conversion after 5 min irradiation. Ultraviolet absorption spectra were recorded on the samples in the reaction vessel before and after irradiation. For gas chromatographic analyses, the photolysis mixtures obtained after up to 10% conversion were diluted with 5 mL of 1 M aqueous sodium chloride and extracted with 1 mL cyclohexane containing 1×10^{-4} M dodecane as internal standard.

The instrumentation available at the Canadian Centre for Picosecond Laser Flash Spectroscopy has already been described in detail (13). The double-beam, mode-locked Nd-YAG laser system employed a silicon intensified target Vidicon detector. Light pulses at 355 nm were obtained by frequency-tripling; typical irradiances were ca. 2 mJ per pulse focused to a 2 mm diameter spot on the face of a 2-mm quartz sample cuvette. The pulse width was 30 ps (FWHM). Individual experiments utilized 0.6-mL aliquots of solutions 4×10^{-4} M in DEA and 0.10 M in the 'onium salt; the solutions were deoxygenated by dry argon purge prior to irradiation.

Results

Fluorescence quenching. AN solution

Like anthracene, DEA is highly fluorescent. Its absorption and fluorescence spectra are shown in Fig. 2. In carefully deoxygenated AN (but not hydrocarbon solvents), a room temperature phosphorescence spectrum may also be observed (Fig. 2). The fluorescence lifetime of DEA, determined in AN by time-correlated single photon counting, is 12.4 ns, about threefold longer than for anthracene itself. Accordingly, its fluorescence quantum yield is considerably higher, 0.68, by measurement in comparison with anthracene itself as 0.27 (14).

The quenching of DEA fluorescence, followed as the first-order fluorescence decay lifetime as a function of iodonium cation concentration in AN, is shown in Fig. 3. Quenching obeyed the Stern–Volmer relationship, with a slope of 201 ± 5 M^{-1}, close to the value expected for diffusion control.

Fluorescence quenching. Reverse micelles

The quenching of DEA fluorescence by (water-soluble) diphenyliodonium chloride in the reverse micelle system was next investigated. The water/AOT molar ratio, w, was taken as a variable in this study, and iodonium salt concentration was adjusted so that P, the average number of iodonium cations per water pool, remained within a reasonable range:

[1] $P = (nw[Ph_2I^+]/55)$

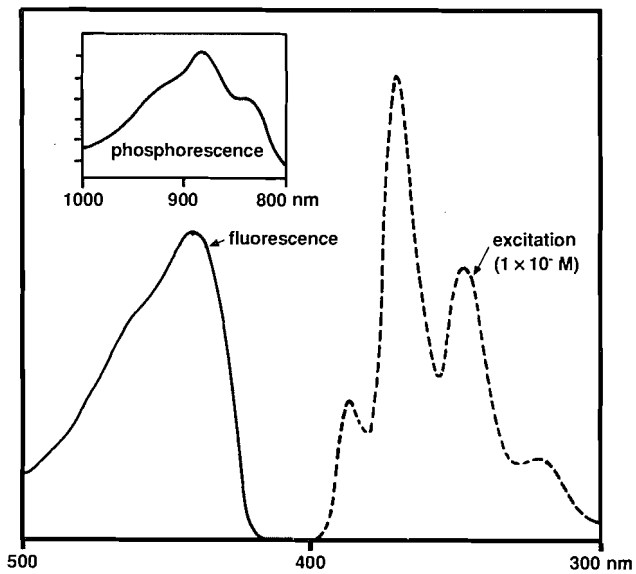

FIG. 2. Absorption and emission spectra of DEA in argon-purged AN.

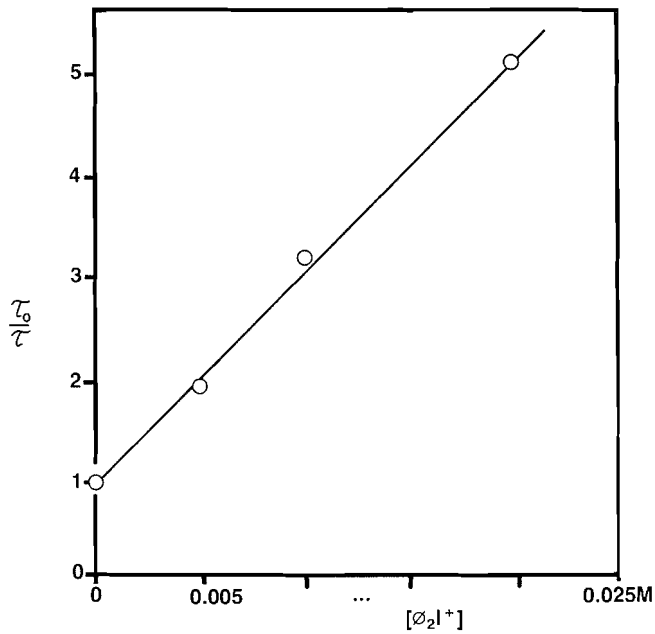

FIG. 3. Stern–Volmer plot for quenching of DEA fluorescence by diphenyliodonium hexafluorophosphate in AN.

The degree of aggregation of the AOT, n, i.e., the average number of AOT molecules associated with a typical micelle, had previously (10) been determined in luminescence probe experiments.

Under these conditions we expect that DEA would be entirely within the organic phase, while diphenyliodonium cation would be localized in the water droplets. The extent of fluorescence quenching at a given AOT concentration is accordingly

$$[2] \quad (I_0/I - 1) = k_d\Phi_q p\tau[\mathrm{AOT}]/n$$

so that the slope of the Stern–Volmer plots is given by

$$[3] \quad \mathrm{d}(I_0/I)/\mathrm{d}[\mathrm{AOT}] = k_d\Phi_q p\tau/n$$

where k_d is the rate constant for diffusional encounter of an

excited DEA molecule with a water pool, numerically taken as $1 \times 10^{10}\,M^{-1}\,s^{-1}$, one half the usual bimolecular diffusion encounter rate constant in heptane, i.e., we assume diffusion of the micelle to be negligible in comparison with the diffusion of the DEA molecule; τ is the radiative lifetime of DEA in the absence of quencher, 12.4 ns; and p is the probability that any individual micelle contains one or more iodonium cation. From the Poisson distribution

$$[4] \quad p = 1 - \exp(-P)$$

so that Φ_q, the quenching probability, can be estimated directly from experimental data.

Typical Stern–Volmer plots are shown in Fig. 4 and the appropriate experimental parameters, along with the estimates of Φ_q from eq. [3], are listed in Table 2. The overall fluorescence intensity for DEA in heptane was essentially the same as in AN; the fluorescence was not quenched by AOT alone or by AOT/water micelles in the absence of added iodonium cation. The average value of Φ_q from Table 1, 0.27 ± 0.05, indicates that electron transfer quenching is substantially *less* efficient in the biphasic system than in homogeneous solution, in contradiction to our expectations from previously published studies (7).

Quantum yields. Homogeneous solution

Quantum yield determinations on the DEA sensitized (3 ×

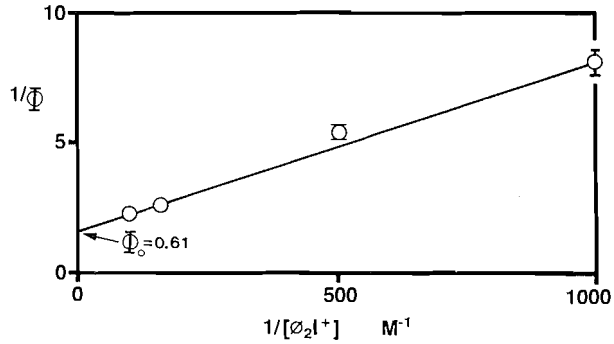

FIG. 5. Double reciprocal plot, $1/\Phi$ versus $1/[Ph_2I^+]$, for photooxidation of DEA by diphenyliodonium hexafluorophosphate in AN.

10^{-4} M in DEA) photolyses of diphenyliodonium hexafluorophosphate at 366 nm in AN were complicated by the complex mixture of reaction products detected by gas chromatographic analysis, none of which appeared to be formed stoichiometrically with iodonium salt or DEA disappearance. Iodobenzene, the principal product from diphenyliodonium cation decomposition under anthracene sensitization, did not appear in the product mixture in significant proportion, except on exhaustive photolysis.

A quantum yield for DEA photooxidation could be inferred from its spectrophotometric disappearance, e.g., at 366 nm, the irradiation wavelength. These data are shown in the form of a "double reciprocal plot" in Fig. 5. From the reciprocal of the intercept, the limiting quantum yield, Φ_0, of 0.60 is estimated. The ratio of the intercept to the slope of the plot is 240 M^{-1}, in reasonable agreement with the slope of the Stern–Volmer plot, Fig. 3, indicating mechanistic commonality of the quenching and bleaching phenomena in homogeneous solution. Determination of DEA disappearance by gas chromatographic analysis was less precise (±20%), but indicated in general that the spectrophotometric measure underestimated the extent of reaction by ca. 25%, i.e., the actual Φ_0 for the electron-transfer sensitized photolysis of the iodonium cation is better estimated as 0.75. Comparing the efficiency of fluorescence quenching, above, we conclude that essentially every quenching event leads to photochemistry in homogeneous solution.

Photo-CIDNP studies

Photochemically induced dynamic nuclear polarization (photo-CIDNP) spectra obtained with both anthracene and DEA (Fig. 6) sensitization of diphenyliodonium hexafluorophosphate photolysis in AN reveal emissions corresponding to both benzene and iodonium cation. Following the interpretation of the results with anthracene (1) in accord with Kaptein's Rules (15), we infer that benzene is a cage-escape product from a singlet radical pair while we assign the iodonium salt polarization to back electron transfer involving magnetic field induced T_-–S_0 mixing in a triplet radical pair. (There is no evidence that this occurs in the absence of the applied magnetic field, or even that triplet radical pairs form under normal circumstances.) Insofar as it competes with observable photochemistry, we expect back electron transfer entirely within the singlet manifold to be transparent to the CIDNP probe. We attribute the absence of photo-CIDNP signals corresponding to DEA and DEA-derived products to exchange broadening by interaction of the arene radical cations with the neutral hydrocarbons (16).

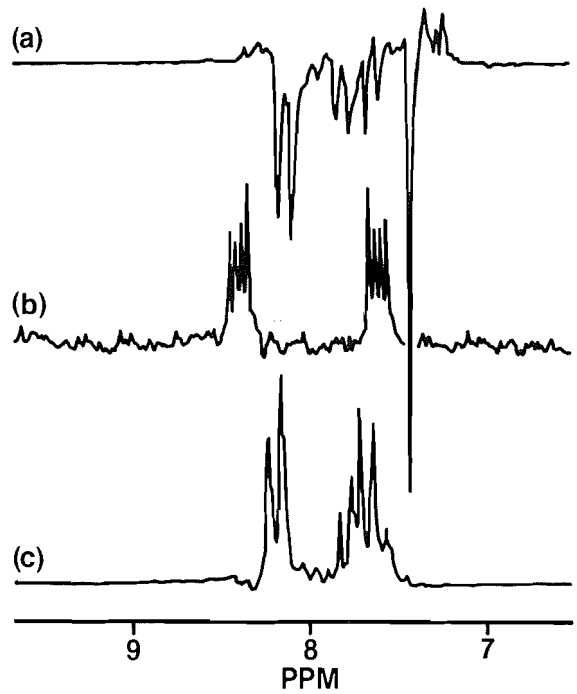

FIG. 6. (a) Photo-CIDNP spectrum for DEA, 2.6×10^{-3} M, sensitized photolysis of diphenyliodonium hexafluorophosphate, 5.5×10^{-3} M in AN-d_3; (b) reference proton nmr spectrum of DEA, 0.010 M in AN-d_3; (c) reference spectrum of diphenyliodonium cation, 0.15 M in AN-d_3.

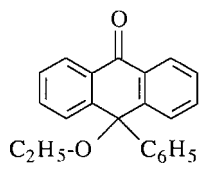
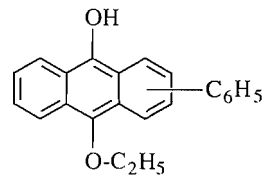
Product identification

The mixture of products from the AN photolysis was further probed by high resolution gas chromatography in tandem with mass spectrometry. On a mixture corresponding to ca. 20% conversion, based on DEA, in addition to the remaining DEA and iodobenzene, in low yield, significant products exhibiting *m/e* ratios of 314, 342, and 374 were observed. (Other peaks corresponding to fragmentation products of DEA were also observed.) The first of these, which can be observed by gas chromatography from the start of the photoreaction, corresponds to $C_{22}H_{18}O_2$, and may be represented as either the anthrone, EAO, or an anthrol:



EAO



Anthrol

We prefer the former assignment, as it readily accounts for the disappearance of the DEA chromophore, almost quantitatively, at ca. 10% conversion. Its formation represents formal loss of an ethyl group from DEA, presumably in the radical cation state, and addition of a phenyl radical, presumably from the iodonium salt.

We accordingly synthesized an authentic sample of EAO according to the procedure of Awad, Fateen, and Zayed (17); the melting point of our product agreed with that reported by these authors and its identity was confirmed by proton nmr. This material was inseparable from the 314 molecular weight photoproduct by high resolution, capillary column, gas chromatography.

The second product corresponds to 1- or 2-phenyl-DEA.

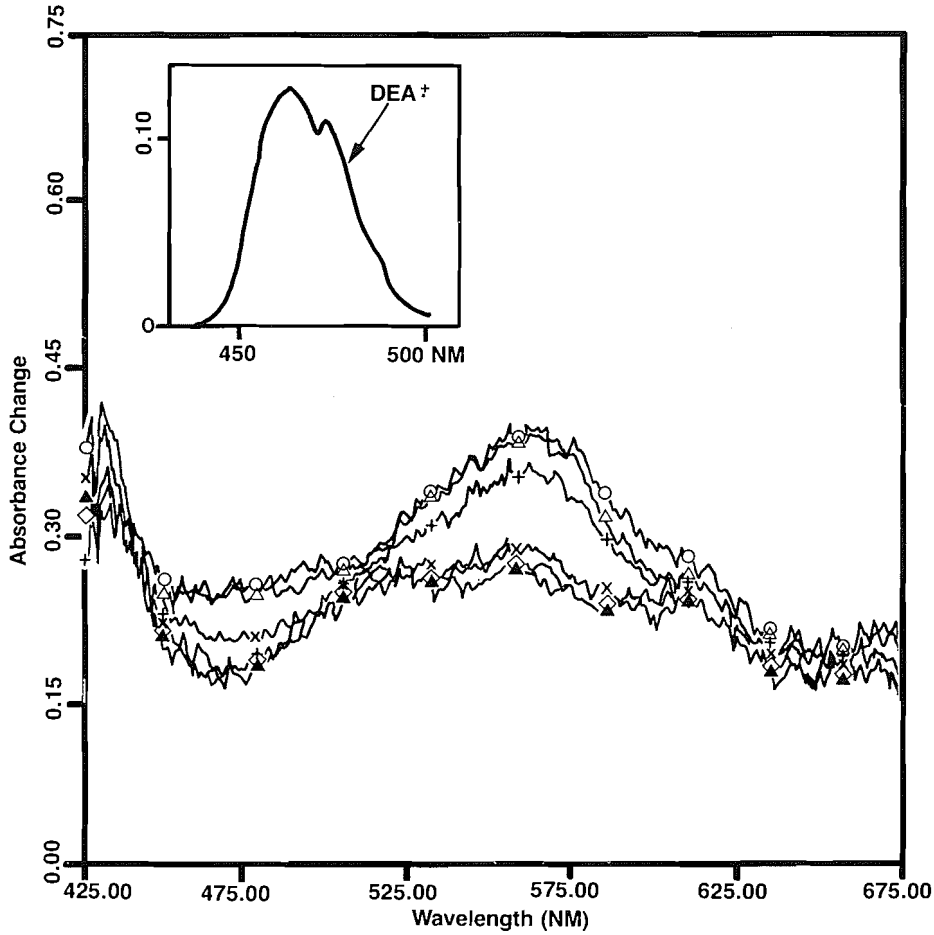

FIG. 7. Transient absorption spectra observed 50 ps (○), 200 ps (△), 500 ps (+), 2 ns (×), 5 ns (◇), and 10 ns (▲) after 355 nm laser flash photolysis of DEA in the presence of diphenyliodonium hexafluorophosphate in AN. Inset shows difference spectrum revealing weak absorption assigned to $DEA^{+\cdot}$.

The phenyl-DEA disappears on exhaustive photolysis, indicating that it also functions as a sacrificial sensitizer, undergoing similar chemistry to DEA. The third product observed in the gc/ms analysis corresponds to $C_{28}H_{22}O$, i.e., an ethoxydiphenylanthracene, most likely a secondary product, derived from phenyl-DEA. We did not attempt to identify products from the reverse micelle system.

Transient absorption spectroscopy

Absorption spectra of some of the transient intermediates observed on the 50 ps – 10 ns time scale in the DEA sensitized photolysis of the diphenyliodonium salt in AN were recorded under conditions of 355 nm laser flash photolysis. Transients observed on photolysis of a solution 3×10^{-4} M DEA and 0.1 M diphenyliodonium hexafluorophosphate in AN are shown in Fig. 7. The initially observed absorptions at 430 and 570 nm were also seen on flash illumination of DEA in the absence of the iodonium salt. In that case, the shorter wavelength absorption persisted over the lifetime of the experiment, while the longer wavelength transient decayed with a time constant comparable to the observed fluorescence lifetime for DEA (above). By analogy to similar peaks in transient absorption spectra of photoexcited anthracene, we assign them to the DEA triplet (18) and singlet (19) excited states, respectively.

We observe in Fig. 7 that the ^{1}DEA absorption decays faster than the measured radiative rate, with a time constant, in fact, of the same order of magnitude as that expected for diffusion controlled quenching by 0.1 M iodonium (2×10^9 s^{-1}). Unlike the case of anthracene, itself, the triplet absorption also decays comparably, indicating that both singlet and triplet excited states of DEA are able to enter into the electron-transfer sensitization process. This implies that the lowest triplet state of DEA is significantly more reducing than that of anthracene.

At the same time, a new absorption band emerges with an apparent maximum at ca. 475 nm. (A calculated differential absorption spectrum is shown as an inset in Fig. 7.) By analogy to anthracene and dimethoxyanthracene (20), we assign this band to $DEA^{+\cdot}$; its absorption is two- to threefold less intense than that of the anthracene radical cation observed under the same conditions (1), and the absorption maximum is, somewhat surprisingly, blue shifted relative to that for the dimethoxyanthracene radical cation (20).

Quantum yields. Reverse micelles

The lability of the DEA radical cation provides a convenient means for detecting one-electron oxidation of photoexcited DEA taking place at the water–heptane interface. When nitrogen-purged, reverse micellar solutions of similar preparation and composition to those used in the fluorescence quenching study were irradiated at 366 nm and monitored spectrophotometrically, we saw that DEA did indeed disappear. Double reciprocal plots of the quantum yields for DEA disappearance versus AOT concentration are shown in Fig. 8. Parameters for the Stern–Volmer kinetic analysis are given in Table 3. The prin-

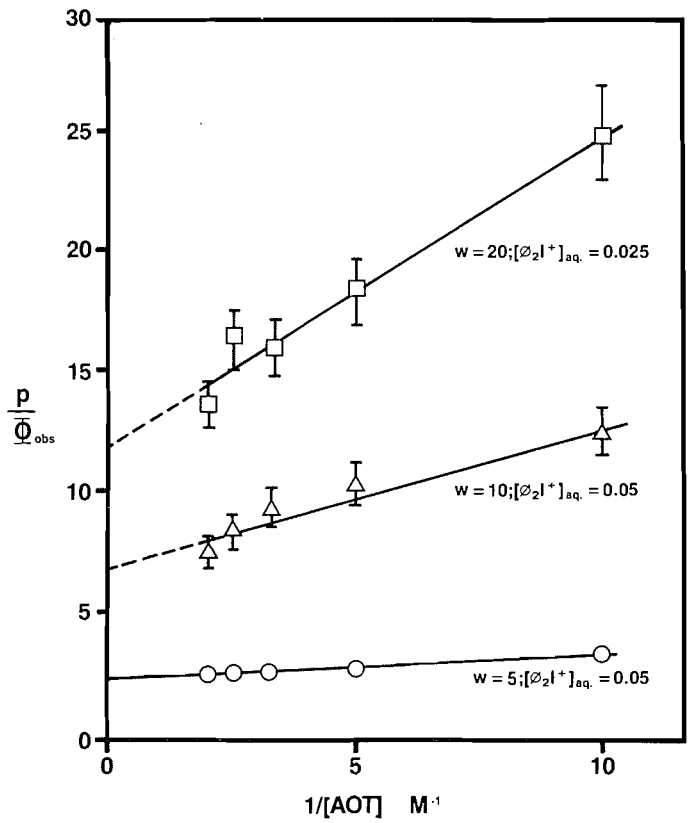

FIG. 8. Double reciprocal plots, $1/\Phi$ versus $1/[AOT]$, for photooxidation of DEA by diphenyliodonium chloride in the heptane/AOT/water reverse micelle system (see Table 3).

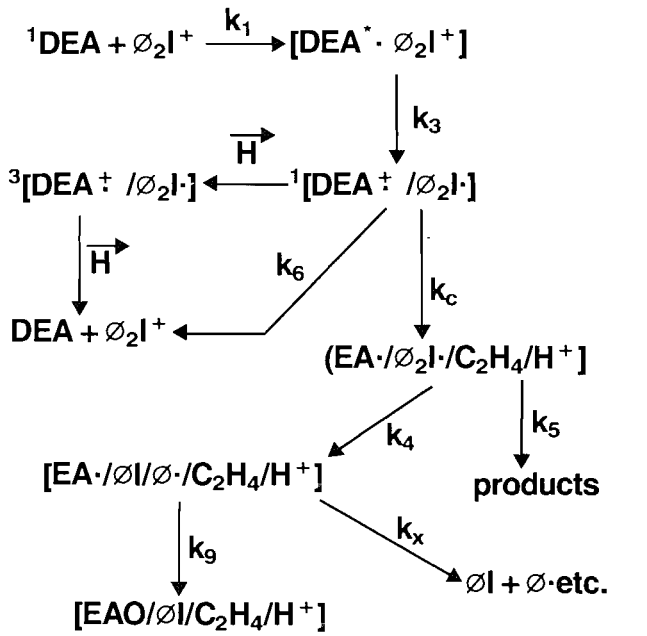

FIG. 9. Mechanistic scheme for photooxidation of DEA with diphenyliodonium cation in homogeneous solution; rate constants refer to Table 1. EA· designates the 9-ethoxy-10-anthroxyl radical.

cipal observation is that the limiting quantum yield, Φ_0, is inversely related to the average water pool size, wn; similar behaviour was *not* observed for the fluorescence quenching. A qualitatively similar inverse relationship between water pool size and efficiency of photooxidation of Mg porphyrin in a reverse micellar environment was observed by Pileni and coworkers (9).

$$[5] \quad (1/\Phi_0)\, d\{1/[AOT]\}/d(1/\Phi) = k_d\tau/n$$

When the intercept-to-slope ratios of the plots of Fig. 8 are multiplied by $p\Phi_q$, from Table 2, the products should be equal to the Stern–Volmer slopes for fluorescence quenching given in the same table, *if* the photochemistry arises from the emissive state of the DEA. Comparison of Tables 3 and 2 indicates that clearly this is not the case. The average Stern–Volmer slope for DEA bleaching (Table 3), $k_d\tau = 620 \pm 90\ M^{-1}$, requires an excited state of ca. 60 ns lifetime.

Discussion

Homogeneous solution photochemistry

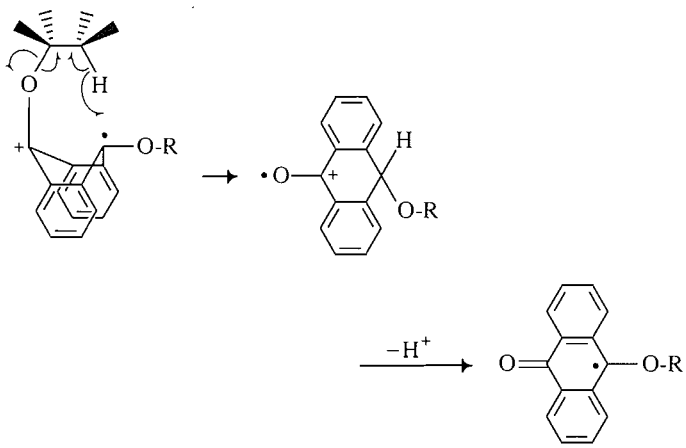
A comprehensive mechanistic scheme for the photochemistry occurring in homogenous AN solution is shown in Fig. 9. Steps corresponding to those occurring in Fig. 1 are similarly numbered. Estimates of rate constants for the various steps are listed in Table 1.

The relatively weak absorption of $DEA^{\ddagger}$ in Fig. 7 (in comparison to that observed for the anthracene radical cation under similar conditions (1)) is of significance; we infer that a correspondingly reduced concentration of $DEA^{\ddagger}$ obtains at steady state. Kinetic analysis of the formation and destruction of $DEA^{\ddagger}$ then requires that the principal pathway for decomposition of $DEA^{\ddagger}$ occurs two- to threefold faster than for the anthracene radical cation. This latter species is destroyed primarily by back electron transfer from the diphenyliodo radical, with a pseudo first-order rate constant of ca. $5 \times 10^{10}\ s^{-1}$ (see Table 1); $DEA^{\ddagger}$ thus appears to have a lifetime under our conditions of the order of only 10 ps. This estimate is also consistent with the initial cleanliness of the reaction, i.e., absence of cage-escape products, which, in turn, requires that decomposition of $DEA^{\ddagger}$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

occurs quickly in comparison to that of the diphenyliodo radical, which requires ca. 250 ps (1).

Decomposition of $DEA^{\ddagger}$ to yield EAO involves formal loss of an ethyl cation and addition of a phenyl radical, derived from the diphenyliodo radical. We hypothesize that the process occurring on the 10 ps time scale involves cleavage of a carbon–oxygen single bond in $DEA^{\ddagger}$ to yield the 9-ethoxy-10-anthroxyl radical ($EA^{\bullet}$). A similar deethylation of $DEA^{\ddagger}$ has been observed by Farid *et al.* (21) consequent to photolysis of DEA in the presence of electron-accepting aromatic hydrocarbons, e.g., 1,4-dicyanonaphthalene. This reaction may occur either by an S_E1 pathway, involving deprotonation of the ethyl group and elimination of ethylene (22), or by S_N2 reaction of an adventitious nucleophile, possibly water, at the methylene carbon. In support of operation of the S_E1 mechanism, rapid deprotonation tends to be a general fate of substituted aryl radical cations in polar media; as the rate constant for deprotonation of the toluene radical cation in water is of the order of $10^7\ s^{-1}$ (23*a*), it is doubtful that deprotonation of $DEA^{\ddagger}$ occurs with a rate of the order of $10^{11}\ s^{-1}$ (k_c). Alternatively, an 8-membered cyclic transition state, analogous to the 7-membered cyclic transition state proposed by Tolbert and Khanna (23*b*) for deethylation of the 9-ethyl-10-methylanthracene radical cation, may be involved.



As the rate of quenching approaches the diffusion controlled limit,

[6] $\Phi_0 = k_c/(k_c + k_6)$

Given that the limiting quantum yield for DEA disappearance is $\Phi_0 = 0.75$, we estimate k_6, the rate constant for back electron transfer in the encounter complex, to be no larger than $3 \times 10^{10}\ s^{-1}$, comparable to the value previously (1) estimated for the anthracene radical cation – diphenyliodo radical pair.

The cage-escape processes, k_5 and k_x, can be described by the usual value for AN cage relaxation (24); since cage escape competes with k_9 for the radical coupling process, we assign it a comparable value, although the high initial yield of EAO (above) indicates that k_9 must be somewhat greater than k_x.

Reverse micelle photochemistry

The decomposition of DEA, initiated, presumably, by one-electron oxidation, proceeds out of an excited state of at least 60 ns lifetime in the reverse micelle system. Insofar as the fluorescence lifetime of DEA is unaltered in this medium from its value in homogeneous solution, we assign this longer lived excited state as triplet DEA; this assignment is independent of, but consistent with, the observation of DEA phosphorescence (Fig. 2), and the observed quenching of DEA triplet by diphenyliodonium cation in homogeneous solution.

This assignment implies that the principal pathway for quenching of DEA fluorescence in the reverse micelle system does not involve electron transfer — otherwise it would lead to photochemistry. We propose that the fluorescence quenching observed in the reverse micelles involves the external heavy atom effect (25) and results in DEA intersystem crossing, thus providing an additional reservoir of ^{3}DEA, which can undergo interfacial oxidation. Recent results on the mechanism and distance dependence of the external heavy atom effect (26) suggest that it can operate over distances of at least 6 Å. It is thus not unreasonable to expect an enhanced rate of intersystem crossing in photoexcited DEA in contact with a water pool of up to 10 Å radius ($w = 20$) containing one diphenyliodonium cation.

This interpretation is also consistent with the quantum yields of Table 3; at least at $w = 5$, the limiting quantum yield exceeds the yield of ^{3}DEA formed by the normal intersystem crossing pathway, ≤ 0.32, based on the measured fluorescence quantum yield. Accordingly we estimate the overall limiting triplet yield where fluorescence quenching occurs by external heavy atom mediated intersystem crossing as 0.50 ± 0.04, sufficient to account for the observed values of Φ_0.

[7] $\Phi_3 = \Phi_q + (1 - \Phi_q)(1 - \Phi_f)$

We may furthermore speculate as to the basis for the apparent lack of significant electron-transfer photochemistry for singlet excited DEA in the reverse micelle environment, as it proceeds with high efficiency in homogeneous solution. This result is the opposite of our expectation from proposals for enhanced efficiency of electron transfer at interfaces (7). Pileni and co-workers (9) have also observed that photooxidation of (organic soluble) Mg porphyrin occurs efficiently in a similar reverse micellar system when the oxidant is an alkylviologen, which they expect to be part of the interfacial layer, but not with viologen sulfonate, which is freely soluble in the water pool.

A simple model is embodied in eq. [8]:

[8] $\Phi_0 = \Phi_3 k_s\tau(4\pi R^2)^{-1}/[k_s\tau(4\pi R^2)^{-1} + 1]$

so that

[8*a*] $k_s = \Phi_0 4\pi R^2/[\tau(\Phi_3 - \Phi_0)]$

We assume that diphenyliodonium cation is electrostatically bound to the anionic micellar interface but freely diffuse on this surface; ^{3}DEA is, on the other hand, immobilized in the surfactant phase, but its rate of desorption is slow compared to its lifetime; k_s is then the rate constant for diffusion of the iodonium cation on the micellar interface. We estimate the water pool radius, R, from the volume, wn, and the molecular volume of water, $3.0 \times 10^{-24}\ cm^3$, to evaluate k_s. Values of k_s, included in Table 3, are of the order of $10^{-6}\ cm^2\ s^{-1}$, a reasonable value. According to this picture, the singlet DEA is relatively unreactive at the interface owing to its shorter lifetime: for $\tau = 10$ ns and $w = 5$, eq. [8] with $k_s = 1 \times 10^{-6}\ cm^2\ s^{-1}$ predicts a contribution to Φ_0 or Φ_q of ca. 0.1. This contribution may account for the anomalously high estimate of k_s in the case of $w = 5$.

Conclusions

We have compared the mechanistic features of the photooxidation of DEA by diphenyliodonium cation in homogeneous AN solution and a heptane/AOT/water reverse micelle system. Electron-transfer photochemistry in AN proceeds out of the singlet manifold of DEA. The photoreaction differs from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

that of anthracene itself owing to the lability of the DEA radical cation, for which we estimate a lifetime under our conditions of the order of 10 ps; its principal decomposition pathway appears to involve deethylation.

In the reverse micelles, DEA fluorescence quenching does not appear to proceed primarily by electron transfer; we infer operation of the external heavy atom effect. Efficiency of this process does not depend on water pool size. Photooxidation of DEA under these conditions, on the other hand, involves a longer lived excited state, which we assign as the triplet. Efficiency of electron transfer depends inversely on water pool size. We have accommodated the experimental results with a model that assumes that diffusional encounter of electrostatically bound Ph_2I^+ with relatively immobile ^{3}DEA on the micelle interface is rate limiting.

Synthèse stéréosélective de (±) boschnialactone, (±) 7-épiteucriumlactone et (±) 7-épiisoiridomyrmécine. Étude de la stéréochimie par spectroscopie de résonance magnétique nucléaire

B. HANQUET, B. TABYAOUI, J.-C. CAILLE, M. FARNIER ET R. GUILARD[1]

Laboratoire de synthèse et d'électrosynthèse organométallique, associé au Centre national de la recherche scientifique (Unité associé n° 33), Faculté des sciences «Gabriel», 6, Bd. Gabriel, 21100 Dijon, France

Reçu le 21 décembre 1988[2]

B. HANQUET, B. TABYAOUI, J.-C. CAILLE, M. FARNIER et R. GUILARD. Can. J. Chem. **68**, 620 (1990).

Les synthèses stéréosélectives de la (±) boschnialactone **1**, la (±) 7-épiteucriumlactone **2** et la (±) 7-épiisoiridomyrmécine **3** sont décrites. Les préparations font appel à la réaction de Stetter suivie de l'addition nucléophile d'énolates de lithium d'esters convenables. L'étape de lactonisation utilise des réactifs silylés et les rendements obtenus sont compris entre 63 et 78%. L'analyse structurale proposée est en désaccord avec les résultats antérieurs. Les paramètres de résonance magnétique nucléaire sont précisés en utilisant les techniques de RMN ^1H et ^{13}C à une et deux dimensions.

Mots clés : synthèse stéréosélective, boschnialactone, 7-épiteucriumlactone, 7-épiisoiridomyrmécine, RMN ^1H et ^{13}C.

B. HANQUET, B. TABYAOUI, J.-C. CAILLE, M. FARNIER, and R. GUILARD. Can. J. Chem. **68**, 620 (1990).

The stereoselective syntheses of (±) boschnialactone **1**, (±) 7-epiteucriumlactone **2**, and (±) 7-epiisoiridomyrmecine **3** are described. Their preparation involved Stetter's reaction followed by nucleophilic addition of lithium enolates of suitable esters. Silylated reagents are used in the lactonisation step and the observed yields are between 63 and 78%. The proposed structural analysis is not in accord with the results of a previous study. The nuclear magnetic resonance data are determined using 1D and 2D proton and carbon NMR experiments.

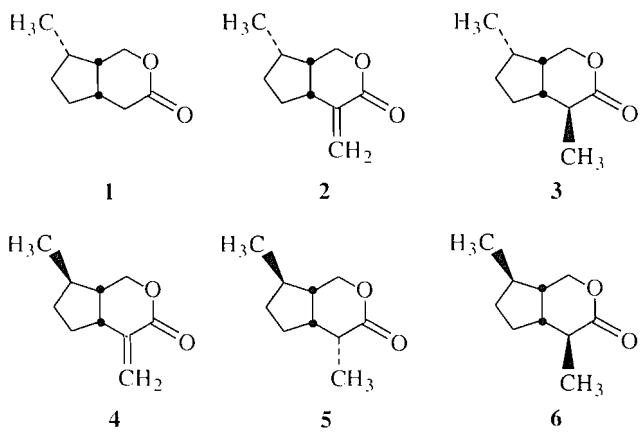
Key words: stereoselective synthesis, boschnialactone, 7-epiteucriumlactone, 7-epiisoiridomyrmecine, ^1H and ^{13}C NMR.

Introduction

Au cours des 20 dernières années, la chimie des iridoïdes a connu un essor remarquable et a suscité un nombre considérable de travaux. De nombreux iridoïdes sont des constituants des plantes (1, 2) mais leur présence a également été mise en évidence dans les secrétions de certaines fourmis du genre iridomyrmex (3). Ainsi cette classe de composés est impliquée dans diverses fonctions biologiques et joue un rôle fondamental lors de la biosynthèse d'alcaloïdes indoliques (4).

Dans ce travail, nous avons limité notre objectif à la synthèse de trois composés d'arrangement structural proche du squelette fondamental des iridoïdes : la (±) boschnialactone **1**, la (±) 7-épiteucriumlactone **2** et la (±) 7-épiisoiridomyrmécine **3**.

Si la boschnialactone **1**, ou noriridomyrmécine, et la teucriumlactone **4** n'ont suscité qu'un nombre restreint de travaux, l'iridomyrmécine **5** et l'isoiridomyrmécine **6** ont fait l'objet de nombreuses études.



1 **2** **3**

4 **5** **6**

Comme préparations originales nous pouvons citer pour l'isoiridomyrmécine **6** celle réalisée au départ du L-citronellal selon une séquence «biomimétique» (5) ou la méthode de Wender et Dreyer (6) qui opère au départ d'une cétone tricyclique. Une voie d'accès très aisée à l'iridomyrmécine **5** procède via une réaction d'hétéro Diels–Alder au départ du méthyl-5 cyclopentène-1 carboxaldéhyde (7). Le même dérivé **5** peut également être synthétisé en mettant en œuvre le diméthyl-1,5 cyclooctadiène-1,5 qui résulte de l'isomérisation de l'isoprène (8).

Sakan *et al.* (1) ont décrit une méthode de synthèse spécifique de la boschnialactone sous forme d'un mélange d'épimères mais Callant *et al.* (9) en mettant à profit la géométrie convexe de norbornanones substituées ont proposé une synthèse stéréospécifique de la boschnialactone et de la teucriumlactone.

Résultats

Dans une publication préliminaire (10), nous avons décrit une synthèse rapide et stéréosélective de la (±) boschnialactone **1** en mettant en œuvre la méthoxyméthyl-2 méthyl-3 cyclopentène-2 one-1 **7**. Ce dérivé, aisément accessible par aldocrotonisation de la méthoxy-7 heptanedione-2,5 préparée selon la méthode de Stetter (11), constitue un remarquable synthon de départ pour élaborer une méthode générale de synthèse de composés comportant le squelette octahydrocyclopenta(*c*)pyrannique. Cette méthode nous permet ainsi de proposer une préparation aisée des trois molécules cibles **1**, **2** et **3**.

L'addition nucléophile (voir schéma 1) de l'énolate de lithium de l'acétate de tertiobutyle ou de l'acétate d'éthyle sur la cétone **7** dans le tétrahydrofuranne anhydre à −78°C suivie d'une hydrolyse acide conduit respectivement et régiospécifiquement aux diènes **8***a* et **8***b* avec des rendements de 76 et 80%. Par action de l'énolate de lithium du propanoate d'éthyle sur la cétone **7**, on accède au diène **10** avec un rendement de 54%.

Le rendement relativement faible observé dans le cas du

SCHÉMA 1

propanoate nous a incité à modifier cette stratégie de synthèse pour préparer le dérivé portant un groupe méthyle en position α du reste ester. La substitution nucléophile du sel de lithium de l'ester **8***b* par l'iodure de méthyle (12) dans le tétrahydrofuranne à −20°C conduit au mélange des deux diènes **10** et **11** en proportions égales avec un rendement de 66%. En opérant dans le mélange hexaméthylphosphorotriamide–tétrahydrofuranne à 20% et dans les mêmes conditions de température, on isole spécifiquement le diène **11** avec un rendement de 76%.

L'hydrogénation des diènes **8***a*, **10** et **11**, réalisée en présence d'oxyde de platine, conduit aux cyclopentanes trisubstitués **9** et **12** sous forme de mélange de deux diastéréoisomères. La stéréosélectivité de la réaction d'hydrogénation a pu être évaluée grâce aux rapports des intégrations des signaux de résonance attribués aux protons du groupe méthyle lié au noyau cyclopentanique. Dans le cas du composé **9** le diastéréoisomère présentant la configuration souhaitée est le composé majoritaire (80%). Pour le composé **12** l'existence d'un centre chiral porteur d'un groupe méthyle (C_2) induit une plus grande stéréospécificité de la réaction d'hydrogénation et seule la formation de deux diastéréoisomères est observée. Le composé majoritaire (80%) conduit à la lactone **3** attendue.

Cette étape de lactonisation implique l'utilisation des réactifs silylés préconisés par Olah *et al.* (13) pour régénérer les fonctions acide et alcool à partir d'ester ou d'éther. L'iodure de triméthylsilyle qui représente «l'entité réactive» est généré *in situ* au départ du chlorure correspondant. La réaction de lactonisation est ainsi réalisée en une seule étape avec un rendement voisin de 63% pour **1** ou **3** en opérant au reflux de l'acétonitrile en présence d'iodure de triméthylsilyle et au départ des cyclopentanes trisubstitués **9** ou **12**. La 7-épiteucriumlactone **2** a été isolée avec un rendement de 78% par α-méthylénation de la boschnialactone selon la méthode décrite par Murray et Reid (14).

Étude structurale

À l'exception des trois lactones objet du présent article, les caractéristiques RMN des composés synthétisés sont regroupées dans la partie expérimentale.

En ce qui concerne les trois lactones synthétisées, l'étude RMN a pour but de déterminer les paramètres de glissement chimique et de couplage pour préciser la conformation privilégiée qu'adoptent ces trois molécules. Un travail déjà ancien (15) a utilisé la RMN protonique (60 MHz) et la spectroscopie infrarouge pour l'analyse conformationnelle de molécules voisines. Se basant sur les données infrarouge, les auteurs proposent une structure flexible qu'ils rattachent à deux types possibles de conformation bateau pour le cycle lactonique. Le choix de la conformation préférentielle est effectué en considérant les constantes de couplage entre le méthylène lactonique et un des protons lié à un atome de carbone commun aux deux cycles. Notre propre étude est en désaccord avec les conclusions de ces auteurs.

Nous avons procédé à une analyse très détaillée du spectre

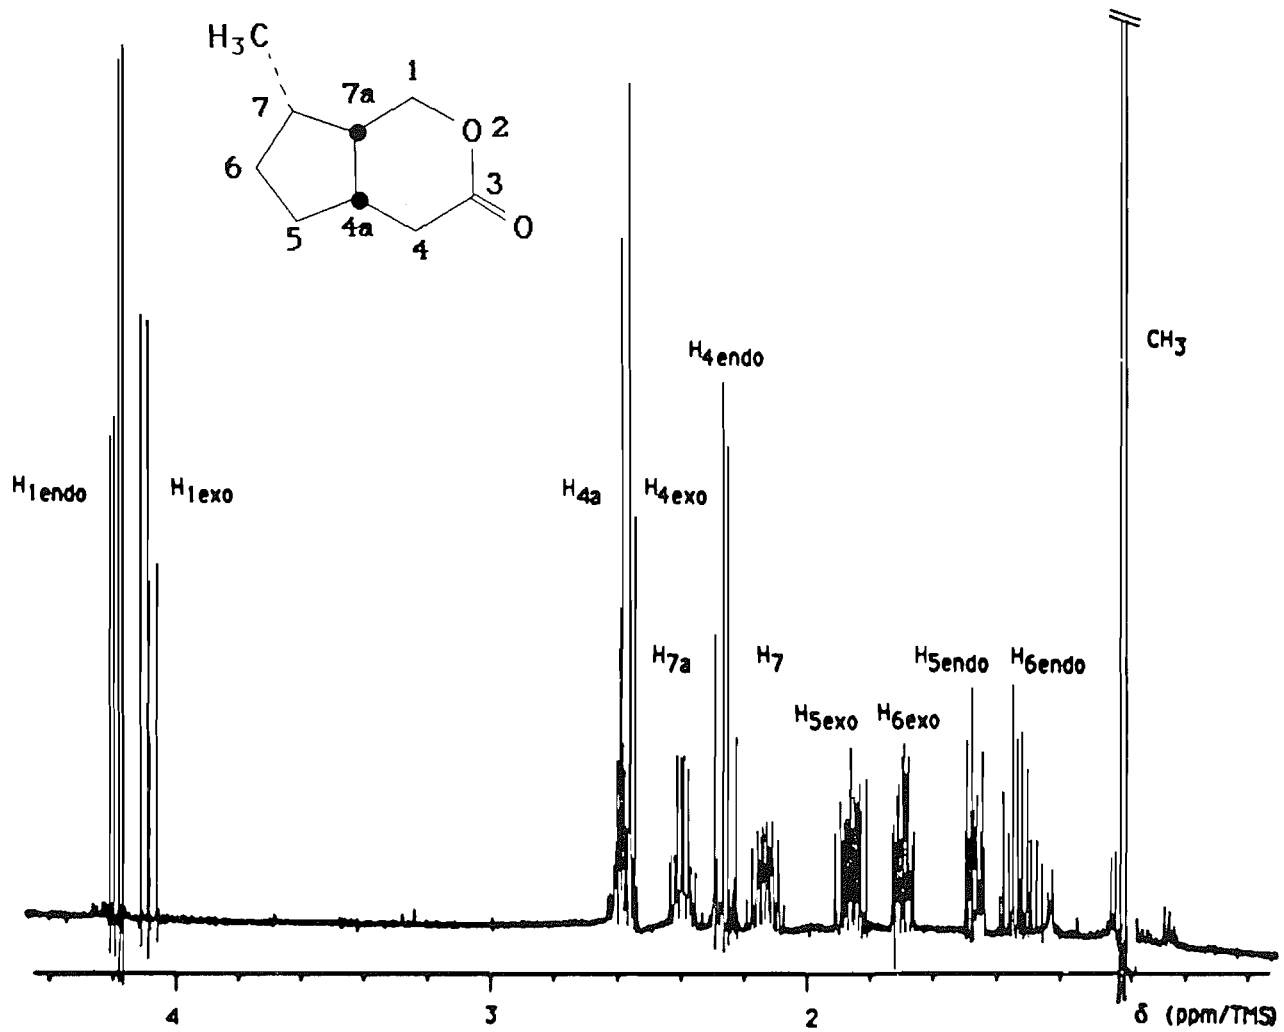

FIG. 1. Spectre de RMN ^1H (400 MHz, $CDCl_3$) de la (±) boschnialactone **1**.

de la boschnialactone et les résultats de cette étude ont servi de base à l'analyse des données concernant la 7-épiteucriumlactone et à l'analyse plus délicate de la 7-épiisoiridomyrmécine.

1. Boschnialactone

(a) Spectres à une dimension (1D)

Le spectre protonique de la boschnialactone enregistré à 400 MHz (voir figure 1) présente 14 protons répartis en 11 massifs distincts. L'examen direct du spectre ne permet d'attribuer aisément que cinq protons. Deux protons déblindés à 4,09 et 4,19 ppm correspondent au groupement méthylène $(CH_2)_1$ et les trois protons du reste méthyle apparaissent à 1,00 ppm.

Le spectre de RMN ^{13}C INEPT (16) indique la présence de neuf atomes de carbone non-équivalents. Un groupement carbonyle à 174,4 ppm, le méthylène lactonique $(CH_2)_1$ à 68,2 ppm et le reste méthyle à 15,4 ppm sont attribués sans ambiguïté. Le spectre révèle également l'existence de trois groupes méthylène voisins et de trois restes méthine entre 33,5 et 40,0 ppm. Il est à noter qu'un des restes méthine présente une constante de couplage très élevée (179 Hz) traduisant une contrainte de cycle importante (17).

Les informations fournies par les spectres à une dimension ne permettent cependant pas d'effectuer une attribution de tous les signaux en raison des forts couplages entre les protons des deux cycles. Seule l'analyse des spectres à deux dimensions conduit à une attribution certaine des différents signaux de résonance.

(b) Spectres à deux dimensions (2D)

Le spectre COSY (18) de la boschnialactone est reproduit sur la figure 2. Il montre que chacun des deux protons du groupe méthylène $(CH_2)_1$ donne une tache de connexion avec un unique proton H_{7a}. Le proton H_7 présente un couplage important avec le reste méthyle et est ainsi aisément attribué. Il reste à préciser les positions des protons géminés en 4, 5 et 6. Les protons du reste méthylène en 4 sont déblindés par suite de la proximité du groupement carbonyle et résonnent à 2,26 et 2,57 ppm. Les quatre protons portés par les atomes de carbone 5 et 6 sont tous couplés entre eux. La présence de deux taches de connexion entre deux de ces protons et H_7 permet d'attribuer ceux-ci au méthylène en 6. En revanche, les protons géminés en 5 sont seulement couplés avec H_{4a} précédemment identifié.

L'analyse complète du spectre COSY permet donc une attribution non ambigüe de l'ensemble des protons de la boschnialactone. Cette analyse va être mise à profit pour proposer une affectation des résonances carbone-13 non attribuées. Le spectre corrélé proton–carbone (19) permet de lever ces incertitudes et d'assigner les signaux de résonance aux différents atomes de carbone (voir figure 3).

$J_{H_7-(CH_3)_7} = 7,1$		

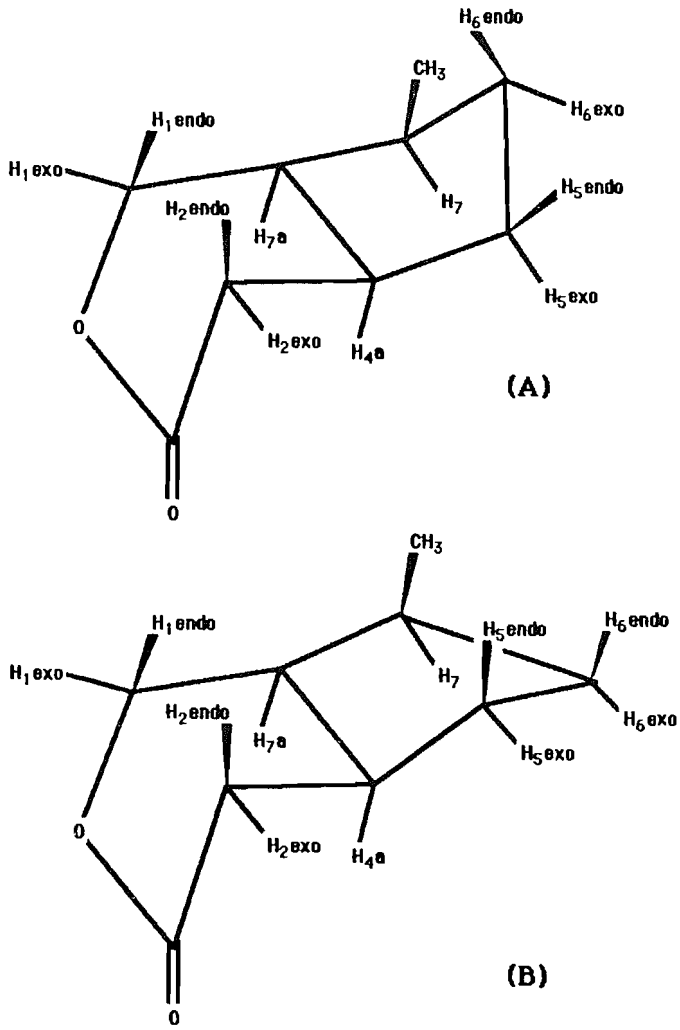

FIG. 4. Conformations enveloppe (A) ou (B) de la (±) boschnialactone **1**.

(c) Détermination de la stéréochimie de la boschnialactone

L'ensemble des paramètres RMN de la boschnialactone apparaît dans les tableaux 1 et 2. L'examen de la valeur des constantes de couplage ^3J permet, à l'aide de l'équation de Karplus (20), de déterminer la valeur de l'angle dièdre H—C—C—H et par suite de préciser la stéréochimie des différents protons.[3]

3. Sur la base de structures optimisées par des calculs théoriques, pour lesquels nous sommes redevables à Monsieur le Professeur L. D. Colebrook de l'Université Concordia, Montréal, Québec, Canada, il apparaît que la conformation (A) présente une plus grande stabilité que la conformation (B) (resp. 21,67 et 20,82 kcal/mol). La corrélation des constantes de couplage expérimentales et calculées la plus satisfaisante est donc obtenue pour la conformation (A).

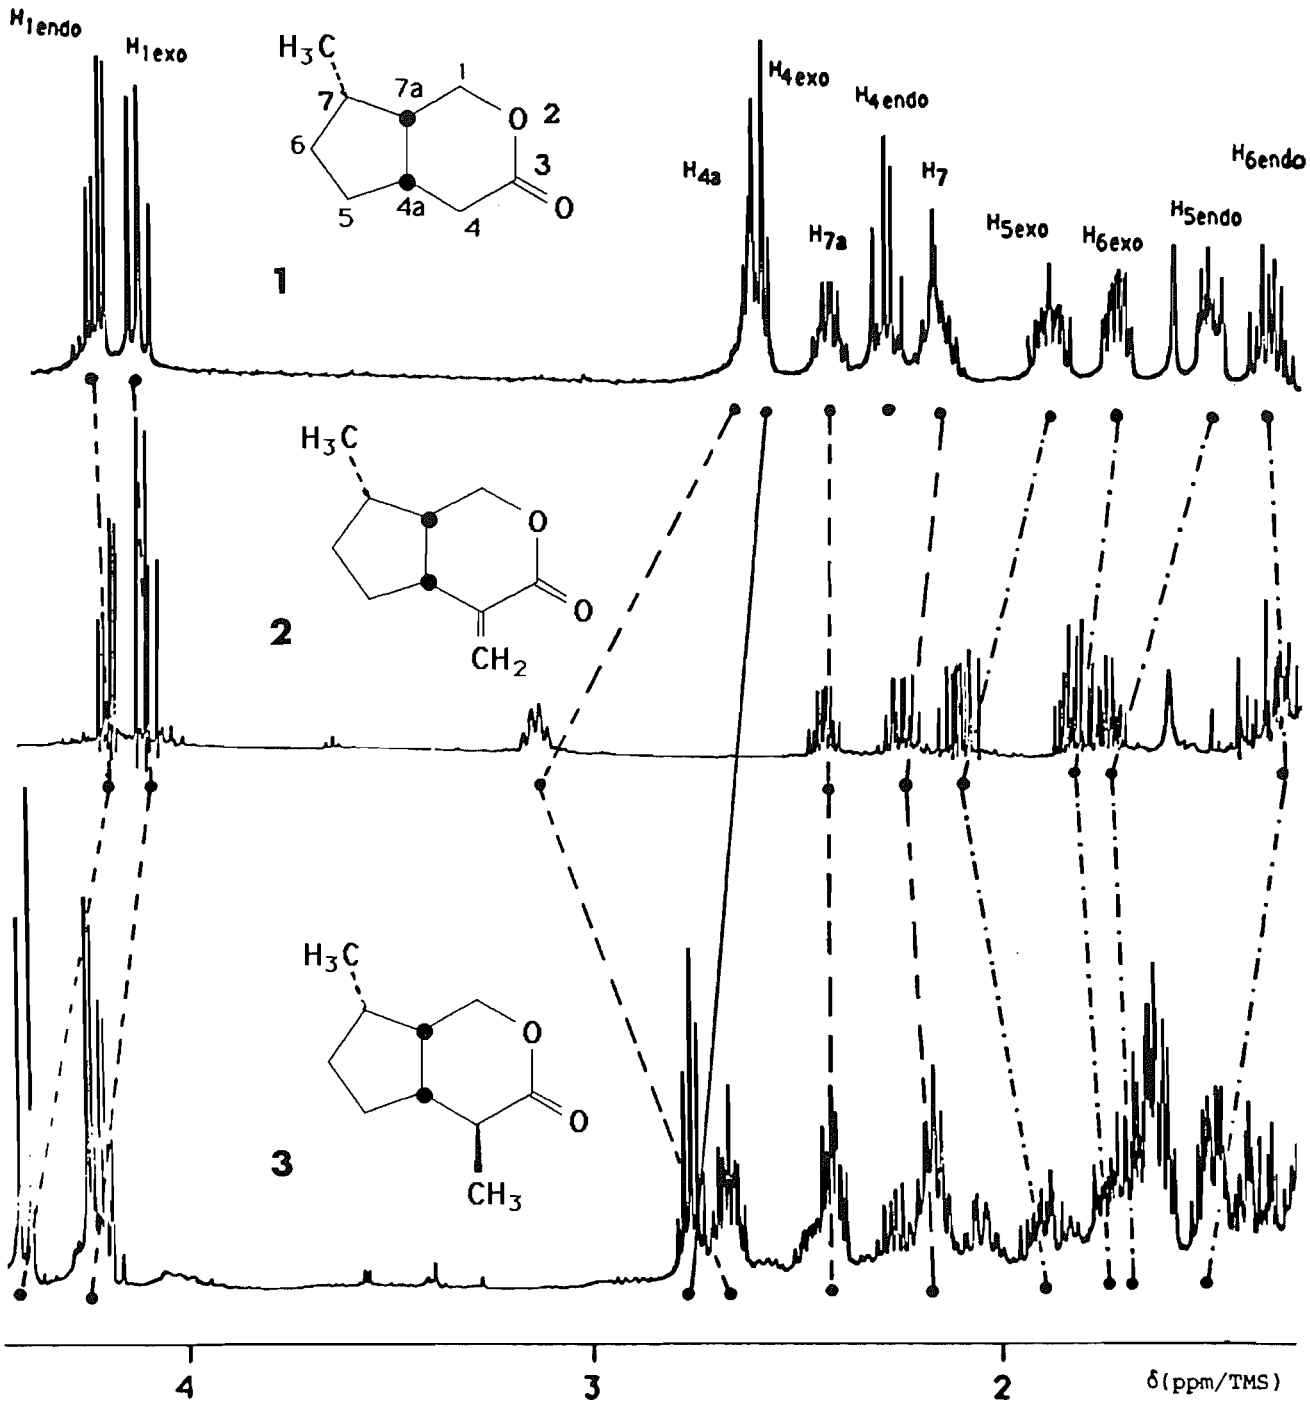

FIG. 5. Partie haut champ des spectres de RMN ^1H (400 MHz, $CDCl_3$) de la (±) boschnialactone **1**, de la (±) 7-épiteucriumlactone **2** et de la (±) 7-épiisoiridomyrmécine **3**.

La voie de synthèse de la boschnialactone fait appel à une préparation utilisant une hydrogénation catalytique et conduit ainsi à un produit de stéréochimie non ambigüe quant à la jonction des deux cycles de nature *cis* et quant à la configuration du reste méthyle en *trans* par rapport aux protons communs aux deux cycles.

L'examen des constantes de couplage ($^3J_{H_{7a}-H_{4a}}$ = 9,3 Hz et $^3J_{H_7-H_{7a}}$ = 8,6 Hz) confirme la position relative *cis*-diaxiale des protons H_{4a}–H_{7a}, H_7 et H_{7a}. La conformation de chacun des deux cycles peut également être précisée. Le carbocycle à cinq chaînons peut adopter deux conformations enveloppe (A) ou (B) (voir figure 4). Cependant l'existence d'un reste méthyle fait que l'une d'elles est privilégiée : il s'agit de celle correspondant au substituant en position équatoriale. Dans la conformation (A) seul l'un des protons en 6 présente deux fortes interactions *trans*-diaxales avec ses voisins, entraînant par là-même l'existence de deux couplages importants : $^3J_{H_{5exo}-H_{6endo}}$ = 11,3 Hz et $^3J_{H_{6endo}-H_7}$ = 11,4 Hz. Dans l'autre conformation enveloppe (B), aucun des protons en 6 ne présenterait de tels couplages. Par conséquent, H_{5exo} et H_{4a} présentent un couplage *cis*-diaxial (9 Hz). De plus, H_{5endo} et H_{4a} d'une part et H_{6exo} et H_{5endo} d'autre part ne sont que faiblement couplés (respectivement 2,4 et 2,6 Hz).

L'ensemble de ces résultats milite en faveur de l'enveloppe

$J_{H_{5endo}-H_{6endo}} = *$	$J_{H_{5exo}-H_{6exo}} = 2,7$	$J_{H_{5exo}-H_{6endo}} = 8,3$
$J_{H_{6endo}-H_{6exo}} = *$	$J_{H_{6exo}-H_7} = 5,6$	$J_{H_{6endo}-H_7} = 3,6$
$J_{H_{4a}-H_{7a}} = 9,8$	$J_{H_7-H_{7a}} = 8,8$	$J_{H_7-(CH_3)_7} = 7,1$

*Ces constantes de couplage n'ont pu être déterminées avec certitude en raison des difficultés d'attribution des signaux des protons du chaînon $(CH_2)_5$–$(CH_2)_6$.

(A) en contradiction avec l'interprétation proposé par Sisido (15).

2. Analyse comparative des paramètres RMN des trois lactones

À partir des données de RMN de la boschnialactone, il est possible d'analyser les spectres des deux molécules voisines que sont la 7-épiteucriumlactone et la 7-épiisoiridomyrmécine. La figure 5 reproduit la partie haut champ des spectres de RMN de ces trois composés et l'ensemble des paramètres RMN des lactones **2** et **3** est rassemblé dans les tableaux 1, 3 et 4. Certains motifs sont peu sensibles à la substitution : c'est le cas des protons H_7 et H_{7a}. Le proton H_{4a} est également peu modifié par la présence du groupe $(CH_3)_4$ de la 7-épiisoiridomyrmécine mais il est beaucoup plus affecté par le groupe $=CH_2$ de la 7-épiteucriumlactone. De plus pour la 7-épiisoiridomyrmécine, les signaux des protons H_{1exo}, H_{1endo}, H_{4exo} et H_{6endo} subissent un déblindage comparable, probablement dû à la présence du reste $(CH_3)_4$. En ce qui concerne le chaînon $(CH_2)_5$–$(CH_2)_6$, l'attribution des quatre protons H_{5endo}, H_{5exo}, H_{6endo} et H_{6exo} de la 7-épiisoiridomyrmécine reste incertaine. Nous proposons une attribution de ces signaux par analogie avec le spectre de RMN protonique de la boschnialactone.

Partie expérimentale

Les analyses centésimales ont été effectuées par le Service central d'analyse du C.N.R.S. Les mesures de R_f ont été réalisées après élution sur des plaques de gel de silice Merck 60 F_{254}.

Les spectres infra-rouge ont été relevés sur un appareil Perkin–Elmer 580B à partir de films d'échantillons (lames de NaCl).

Les spectres de masse ont été obtenus par bombardement électronique sur un appareil Finnigan 3300, tension d'accélération 70 eV, courant d'ionisation 0,4 mA, température de source 25–150°C.

Les spectres de RMN ^1H ont été relevés à 100 MHz (Jeol FX-100) et à 400 MHz (Bruker WM400) sur des solutions de 4–10 mg de composé dissous dans 0,4 cm^3. Les spectres ^{13}C ont été enregistrés à 100 MHz (Bruker WM400) sur des solutions de 20–30 mg de produit dans 2,5 cm^3 de solvant deutérié. Les déplacements chimiques sont donnés en partie par million (ppm) par rapport à $SiMe_4$ et les constantes de couplage en Hz. Les multiplicités sont indiquées comme suit : s (singulet), d (doublet), t (triplet), q (quadruplet), m (multiplet). Les séquences multi-impulsionnelles citées sont celles données en standard dans la bibliothèque des logiciels Bruker.

La synthèse de la méthoxyméthyl-2 méthyl-3 cyclopentène-2-one-1, **7**, a été effectuée selon la méthode citée en référence 10.

*Méthode générale de synthèse des diènes esters **8** et **10***

À une solution de diisopropylamidure de lithium (2 mmol) dans le tétrahydrofuranne anhydre (10 cm^3), on ajoute goutte à goutte à −78°C l'ester (1,5 mmol) dans 1 cm^3 de tétrahydrofuranne anhydre. On maintient le milieu réactionnel à −78°C pendant 15 min, puis on ajoute lentement la cyclopentènone **7** (1 mmol) en solution dans le tétrahydrofuranne anhydre (2 cm^3). Après addition, le milieu réactionnel est agité 1 h à −78°C puis hydrolysé par une solution d'acide chlorhydrique 1 M de façon à obtenir un pH de 1. Après retour à température ambiante puis agitation durant 15 min, le mélange est extrait par l'éther éthylique (3 × 20 cm^3) et la phase organique lavée et évaporée. Le résidu est chromatographié sur colonne de gel de silice par le mélange éther éthylique – hexane (1 : 1).

*Méthoxyméthyl-2 méthyl-1 [*tert*-butyloxycarbonylméthylène]-3 cyclopentène-1, **8**a*

On condense 0,52 g (4,5 mmol) d'acétate de tertiobutyle avec 0,42 g (3 mmol) de la cyclopentènone **7** selon le mode opératoire décrit ci-dessus. On isole après purification 0,54 g (Rdt 76%) du diène ***8a*** sous forme d'huile incolore; Eb_3 = 140°C; R_f = 0,67 (éther éthylique – hexane, 1 : 1); IR ν_{max} (film) cm^{-1} : 1698 (C=O), 1615 (C=C), 1145 (OtBu); RMN ($CDCl_3$, 100 MHz) δ : 5,74 (m, 1H, C=*CH*); 4,08 (s, 2H, CH_2—OCH_3); 3,34 (s, 3H, O—CH_3); 3,00 et 2,56 (2m, 4H, méthylènes cyclopenténiques); 1,99 (s, 3H, C—CH_3); 1,48 (s, 9H, *t*-Bu); SM *m/z* (%) : 238 (14,9), 182 (40,5), 165 (38,0), 150 (100,0), 149 (97,5). Anal. calc. pour $C_{14}H_{22}O_3$: C 70,56, H 9,30, O 20,14; tr. : C 70,34, H 9,10, O 20,24.

*Méthoxyméthyl-2 méthyl-1 [éthyloxycarbonylméthylène]-3 cyclopentène-1, **8**b*

Par condensation de 0,53 g (6 mmol) d'acétate d'éthyle sur 0,56 g (4 mmol) de cyclopentènone **7** selon le mode opératoire cité précédemment, on isole 0,76 g (Rdt 81%) du diène ***8b***, sous forme d'huile incolore; Eb_3 = 110°C; R_f = 0,53 (éther éthylique – hexane, 1 : 1); IR ν_{max} (film) cm^{-1} : 1698 (C=O), 1645 (C=C), 1151 (OEt); RMN ($CDCl_3$, 100 MHz) δ : 5,76 (m, 1H, C=*CH*); 4,16 (q, 2H, CH_2—CH_3); 4,09 (s, 2H, CH_2—OCH_3); 3,34 (s, 3H, O—CH_3); 3,00 et 2,56 (2m, 4H, méthylènes cyclopenténiques); 1,99 (s, 3H, C—CH_3); 1,28 (t, 3H, O—CH_2—CH_3); SM *m/z* (%) : 210 (15,0), 195 (29,2), 165 (40,4), 91 (100,0). Anal. calc. pour $C_{24}H_{18}O_3$: C 68,54, H 6,63, O 22,83; tr. : C 68,39, H 6,72, O 22,80.

*[(Méthoxyméthyl-3' méthyl-4') cyclopentadiène-1', 3' yl-2']-2 propanoate d'éthyle, **10***

Par condensation de 1,53 g (15 mmol) de propanoate d'éthyle sur 1,4 g (10 mmol) de cyclopentènone **7**, selon le même mode opératoire, on isole après purification 1,21 g (54%) du diène **10**, sous forme d'une huile incolore; Eb_3 = 66°C; R_f = 0,61 (éther éthylique – hexane, 1 : 1). IR ν_{max} (film) cm^{-1} : 1738 (C=O), 1638 (C=C); RMN ($CDCl_3$, 100 MHz) δ : 5,94 (s élargi, 1H, $H_{1'}$); 4,16 (s, 2H, CH_2—OCH_3); 4,13 (m, 2H, CO_2—CH_2CH_3); 3,61 (m, 1H, H_2); 3,31 (s, 3H, OCH_3); 2,91 (s élargi, 2H, $(CH_2)_{5'}$); 2,01 (s, 3H, $C_{4'}$—CH_3); 1,39 (d, 3H, C_2—CH_3); 1,21 (t, 3H, CO_2—CH_2CH_3); SM *m/z* (%) : 224 (25,3), 192 (40,4), 119 (100,0), 91 (29,2). Anal. calc. pour $C_{13}H_{20}O_3$: C 69,61, H 8,99, O 21,40; tr. : C 69,15, H 9,02, O 21,32.

*[Méthoxyméthyl-2' méthyl-3' cyclopentadiène-1', 3' yl-1']-2 propanoate d'éthyle, **11***

À une solution de diisopropylamidure de lithium (3,6 mmol) dans le mélange hexaméthylphosphorotriamide tétrahydrofuranne (20 : 80), on ajoute à −78°C et très lentement le diène ***8b*** (0,63 g, 3 mmol) dans 3 cm^3 de tétrahydrofuranne. Après agitation à −78°C pendant 30 min, on ajoute goutte à goutte 0,64 g (4,5 mmol) d'iodométhane fraîchement distillé dans 2 cm^3 de tétrahydrofuranne. À la fin de l'ajout on laisse la température s'élever jusqu'à −20°C puis on maintient le milieu réactionnel 1 h à cette même température. Après hydrolyse par une solution saturée de chlorure d'ammonium et extraction par l'éther

éthylique, la phase organique est lavée puis séchée. Le solvant est évaporé et le résidu élué sur colonne de gel de silice par le mélange éther éthylique – hexane (1 : 6). On isole 2,52 g (Rdt 76%) du cyclopentadiène **11** sous forme d'une huile incolore; Eb_3 = 68°C, R_f = 0,73 (éther éthylique – hexane, 1 : 1); IR ν_{max} (film) cm^{-1}: 1732 (C=O), 1631 (C=C); RMN ($CDCl_3$, 100 MHz) δ : 6,05 (s élargi, 1H, $H_{4'}$); 4,16 (s, 2H, CH_2—OCH_3); 4,13 (m, 2H, CO_2—CH_2CH_3); 3,61 (m, 1H, H_2); 3,31 (s, 3H, O—CH_3); 2,90 (s élargi, 2H, $(CH_2)_{5'}$); 2,02 (s, 3H, $C_{3'}$—CH_3); 1,41 (d, 3H, C_2—CH_3); 1,25 (t, 3H, CO_2—CH_2CH_3); SM *m/z* (%) : 224 (25,3), 192 (40,4), 119 (100,0), 91 (29,2). Anal. calc. pour $C_{13}H_{20}O_3$: C 69,61, H 8,99, O 21,40; tr. : C 69,96, H 9,03, O 21,18.

Méthode générale d'hydrogénation

Une solution du diène (2 mmol) dans 2 cm^3 d'acétate d'éthyle est hydrogénée à température ambiante sous pression d'hydrogène de 1 atmosphère (101,3 kPa) en présence de 0,05 g d'oxyde de platine pendant 24 h. La solution est filtrée sur Célite 545 puis évaporée et l'huile résiduelle chromatographiée sur colonne de gel de silice en utilisant l'éluant éther éthylique – hexane (1 : 1). Le produit hydrogéné est isolé avec un rendement de 98%.

[Méthoxyméthyl-2' méthyl-3' cyclopentyl-1']-2 propanoate d'éthyle, ***12***

L'hydrogénation des diènes **10** ou **11** (0,456 g, 2 mmol) est effectuée conformément à la méthode citée ci-dessus. On isole après purification 0,46 g d'une huile incolore; Eb_3 = 100°C; R_f = 0,78 (éther éthylique – hexane, 1 : 1); IR ν_{max} (film) cm^{-1}: 1735 (C=O), 1151 (OEt); RMN ($CDCl_3$, 100 MHz) δ : 4,33 (q, 2H, CH_2—CH_3); 3,33 (m, 2H, CH_2—OCH_3); 3,27 (s, 3H, O—CH_3); 2,49 (m, 1H, H_2); 2,28 (m, 1H); 2,14 et 1,80 (2m, 4H, méthylènes cyclopentaniques); 1,36 (m, 1H); 1,27 (m, 1H); 1,21 (t, 3H, O—CH_2CH_3); 1,18 et 1,12 (2d, 3H, J = 6,8 Hz et J = 7,1 Hz, CH_3—C—CO_2Et); 1,04 et 1,00 (2d, 3H, J = 6,8 Hz et J = 7,1 Hz, C—CH_3); SM *m/z* (%) : 228 (1,07), 199 (62,4), 94 (100,0). Anal. calc. pour $C_{13}H_{24}O_3$: C 68,42, H 10,52, O 21,05; tr. : C 68,40, H 10,28, O 21,36.

[Méthoxyméthyl-2' méthyl-3' cyclopentyl-1']-2 éthanoate de tert*-butyle,* ***9***

Ce composé est préparé selon le méthode citée en référence 10.

Méthode générale de lactonisation

À une suspension d'iodure de sodium (0,33 g, 2,2 mmol) dans l'acétonitrile (20 cm^3) sont ajoutés, sous courant d'azote, 0,24 g (2,2 mmol) de chlorotriméthylsilane et 1 mmol des esters **9** ou **12**. Le mélange est porté au reflux de l'acétonitrile pendant 16 h puis hydrolysé par 20 cm^3 d'eau. Après extraction par l'éther éthylique, la phase organique est lavée à l'eau puis par une solution saturée de thiosulfate de sodium. Après évaporation du solvant, le résidu est élué sur colonne de gel de silice par le mélange éther éthylique – hexane (1 : 1).

(±) Boschnialactone, ***1***

L'ester **9** (0,5 g, 2,05 mmol) est traité selon la méthode décrite ci-dessus. On récupère après purification 0,203 g (Rdt 63%) de la (±) boschnialactone; Eb_3 = 130°C; R_f = 0,36 (éther éthylique – hexane, 1 : 1); IR ν_{max} (film) cm^{-1}: 2935, 1745, 1460, 1245, 1055; SM *m/z* (%) : 154 (100,0), 136 (12,9), 124 (15,3), 111 (13,3), 108 (13,7), 95 (60,8), 81 (64,7). Anal. calc. pour $C_9H_{14}O_2$: C 70,13, H 9,09, O 20,78; tr. : C 69,98, H 9,04, O 20,70.

(±) 7-Épiisoiridomyrmécine, ***3***

L'ester **12** (0,5 g, 2,2 mmol) est traité comme décrit plus haut. On obtient après purification 0,5 g (Rdt 64%) de la lactone **3**; Eb_3 = 170°C; R_f = 0,54 (éther éthylique – hexane, 1 : 1); IR ν_{max} (film) cm^{-1}: 2930, 1745, 1458, 1147, 1117; SM *m/z* (%) : 168 (49,3), 150 (11,5), 109 (77,2), 95 (100,0), 81 (66,8). Anal. calc. pour $C_{10}H_{16}O_2$: C 71,43, H 9,52, O 19,05; tr. : C 71,23, H 9,38, O 19,01.

(±) 7-Épiteucriumlactone, ***2***

À 0,3 g d'hydrure de sodium mis en suspension dans 20 cm^3 d'éther anhydre, on ajoute goutte à goutte mais rapidement le mélange de boschnialactone (0,2 g, 1,29 mmol) et 10 cm^3 de méthanoate d'éthyle. À la fin de l'addition on ajoute 5 cm^3 d'éthanol absolu. Le mélange réactionnel est ensuite agité à température ambiante durant 1 nuit. On isole après filtration 0,26 g (Rdt 100%) du sel sodique **13** sous forme d'une poudre blanche utilisée sans aucune autre purification pour la suite de la synthèse.

À une solution du sel **13** (0,26 g, 1,29 mmol) dans 20 cm^3 de tétrahydrofuranne anhydre, sont ajoutés 10 cm^3 de formaldéhyde en solution à 30% dans l'eau. Le mélange réactionnel est porté au reflux du tétrahydrofuranne pendant 18 h. Après hydrolyse avec une solution d'acide chlorhydrique 4 M et extraction par l'éther éthylique, la phase organique est lavée à l'eau puis séchée et le solvant évaporé. Le résidu obtenu est chromatographié sur colonne de gel de silice par le mélange éther éthylique – hexane (1 : 1) pour donner 0,17 g (Rdt 78%) de la lactone **2** sous forme d'une huile; R_f = 0,78 (éther éthylique – hexane, 1 : 1); IR ν_{max} (film) cm^{-1} : 2930, 1732, 1625, 1458, 1147, 1117; SM *m/z* (%) : 166 (24,5), 167 (13,7), 150 (100,0), 138 (13,7), 109 (34,5), 95 (57,1), 81 (48,2). Anal. calc. pour $C_{10}H_{14}O_2$: C 72,29, H 8,43, O 19,28; tr. : C 72,20, H 8,23, O 19,26.

Remerciements

Received October 10, 1989

DAVID G. DICK, DOUGLAS W. STEPHAN, and CHARLES F. CAMPANA. Can. J. Chem. **68**, 628 (1990).

The disproportionation of the complex $(Et_2N)_3Ti(\mu\text{-}PCy_2)Ni(PPh_3)$ affords the coordinatively unsaturated species $Ni(PPh_3)_3$, **1**. This compound crystallizes in the triclinic space group $P\bar{1}$, with $a = 18.483(4)$ Å, $b = 16.203(3)$ Å, $c = 17.783(4)$ Å, $\alpha = 105.85(2)°$, $\beta = 117.33(3)°$, $\gamma = 92.33(3)°$, $Z = 4$, and $V = 4464(2)$ Å^3. Full-matrix least-squares refinement of 1042 variables using 6484 data ($F_o^2 > 3\sigma F_o^2$) gave $R = 0.0441$ and $R_w = 0.0438$. The two crystallographically independent molecules are essentially identical, each exhibiting a trigonal planar coordination sphere at Ni. The most interesting feature of the structure is the close approach (2.744–3.094 Å) of three *ortho* hydrogens of the PPh_3 groups to the Ni centres. The implications of the structural data regarding *ortho* metallation and the known instability of **1** are discussed.

Key words: coordinatively unsaturated, nickel phosphine complex.

DAVID G. DICK, DOUGLAS W. STEPHAN et CHARLES F. CAMPANA. Can. J. Chem. **68**, 628 (1990).

La disproportionation du complex $(Et_2N)_3Ti(\mu\text{-}PCy_2)Ni(PPh_3)$ fournit le $Ni(PPh_3)_3$, **1**, une espèce non-saturée du point de vue de la coordination. Ce composé cristallise dans le groupe d'espace triclinique $P\bar{1}$, avec $a = 18{,}483(4)$, $b = 16{,}203(3)$ et $c = 17{,}783(4)$ Å, $\alpha = 105{,}85(02)$, $\beta = 117{,}33(3)$ et $\gamma = 92{,}33(3)°$, $Z = 4$ et $V = 464(2)$ Å^3. Un affinement de 1042 variables effectué sur 6484 données ($F_o^2 > 3\sigma F_o^2$) par la méthode des moindres carrés sur la matrice entière conduit à des valeurs de $R = 0{,}0441$ et $R_w = 0{,}0438$. Les deux molécules, qui sont indépendantes d'un point de vue cristallographique, sont essentiellement identiques et chacune présente une sphère de coordination trigonale plane au niveau du Ni. La caractéristique la plus intéressante de cette structure est la close proximité (2,744–3,094 Å) des trois hydrogènes *ortho* des groupement PPh_3 attachés aux centre Ni. On discute des implications des données de la structure sur la métallation en *ortho* et sur l'instabilité bien connue du composé.

Mots clés : non-saturé d'un point de vue de la coordination, complexe du nickel avec des phosphines.

[Traduit par la revue]

Introduction

Zerovalent metals of the Ni triad readily form coordinatively unsaturated complexes with sterically demanding phosphine ligands (1–14). Structural studies have confirmed coordination numbers of two and three for several complexes of Pt and Pd including $Pt(PPh(t\text{-}Bu)_2)_2$ (1), $Pd(PPh(t\text{-}Bu)_2)_2$ (1, 2), $Pd(PCy_3)_2$ (2), $Pt(PCy_3)_2$ (3), and $Pt(PPh_3)_3$ (4). The related compound $(Cy_3P)_2Ni(\mu\text{-}N_2)Ni(PCy_3)_2$ (5) is the only example of a coordinatively unsaturated Ni(0) species where the formulation has been confirmed by crystallography. The stability of this complex was attributed to the cage of cyclohexyl rings that surrounds the bridging nitrogen molecule. Other coordinatively unsaturated Ni-phosphine complexes have been known and studied spectroscopically for years (15); however, there have been no reports of structural studies of complexes of the form $Ni(PR_3)_3$ or $Ni(PR_3)_2$. During the course of our investigation of the chemistry of heterobimetallic complexes (16–20), we isolated the complex $Ni(PPh_3)_3$, **1**. This red-brown complex was previously prepared by Tolman *et al.* (15) via the Zn reduction of $NiCl_2$ in the presence of PPh_3; however, it was reportedly extremely unstable and proved to be most difficult to characterize. In this paper, we describe the serendipitous isolation and subsequent crystallographic study of $Ni(PPh_3)_3$, **1**. This report represents the first structural study of a coordinatively unsaturated Ni-perphosphine complex. The structural data presented herein are consistent with the interactions of the Ni centre with *ortho* phenyl protons of PPh_3. Such interactions may account for the difficulty of preparation of **1** and its observed instability.

Experimental

Isolation of crystals of 1

To a solution of $Ni(COD)_2$ (0.005 g, 0.018 mmol) was added $(Et_2N)_3Ti(PCy_2)$[2] (0.018 g, 0.039 mmol) and PPh_3 (0.010 g, 0.038 mmol). The intermediate product was formulated as $(Et_2N)_3Ti(\mu\text{-}PCy_2)Ni(PPh_3)$ on the basis of $^{31}P\{^1H\}$ NMR spectroscopy. This product was extracted into pentane. On standing at 20°C over 4 days, disproportionation led to the crystallization of $Ni(PPh_3)_3$, **1**. The crystals were isolated by decantation of the solvent. The crystals were handled in an inert atmosphere glove box in an atmosphere of O_2-free N_2. The crystals were immediately mounted and sealed in 0.5-mm capillaries.

X-ray data collection and reduction

Diffraction experiments were performed on a four-circle Syntex $P2_1$ diffractometer with graphite-monochromatized Mo Kα radiation ($\lambda = 0.71069$ Å). The initial orientation matrix was obtained from 15 machine-centred reflections selected from a rotation photograph. These data were used to determine the crystal system. Partial rotation photographs around each axis were consistent with a triclinic crystal system for **1**. The final lattice parameters and the orientation matrix were determined from 58 high-angle data ($20° < 2\theta < 25°$). The diffraction data were consistent with the space group $P\bar{1}$. $\pm h, \pm k, +l$ data were collected ($4.5° < 2\theta < 45.0°$), with three standard reflections recorded every 197 reflections. Their intensities showed no statistically significant change over the duration of the data collection. The data were processed, and the solution obtained was refined using the SHELX-86 program on a Micro VAX II computer in the Siemens Analytical X-ray Laboratories in Madison, WI.

Structure solution and refinement

Non-hydrogen atomic scattering factors were taken from the literature tabulations (21–23). The heavy atom positions were deter-

mined using direct methods. The remaining non-hydrogen atoms were located from successive difference Fourier map calculations. Following the refinement of the structure in which all non-hydrogen atoms were included with isotropic thermal parameters, an empirical absorption correction was applied to the data, employing the program XABS. The final cycles of refinement were carried out by using full-matrix least-squares techniques on F, minimizing the function $w(|F_o| - |F_c|)^2$ where the weight, w, is defined as $4F_o^2/2\sigma(F_o^2)$ and F_o and F_c are the observed and calculated structure factor amplitudes. In the final cycles of refinement, all non-hydrogen atoms were assigned anisotropic temperature factors. The hydrogen atom positions were calculated and allowed to ride on the carbon to which they are bonded assuming a C—H bond length of 0.95 Å. Hydrogen atom temperature factors were fixed at 1.10 times the isotropic temperature factor of the carbon atom to which they are bonded. The hydrogen atom contributions were calculated, but not refined. Due to the large number of variables, it was necessary to employ an modified version of SHELXTL to complete the final cycles of full-matrix refinement. The residual electron densities were of no chemical significance. Crystal data and data collection parameters are summarized in Table 1. Tables of positional parameters (Table 2) and selected bond distances and angles (Table 3) are reported. Thermal parametes (Table S1), hydrogen atom parameters (Table S2), a complete listing of the bond distances and angles (Table S3), and calculated and observed structure factors (Table S4) have been deposited.[3]

[3]Tables of thermal and hydrogen atom parameters, complete listings of the bond distances and angles, and values of 10 F_o and 10 F_c may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

The tables of hydrogen atom parameters and of bond distances and angles have also been deposited with the Cambridge Crystallographic Data Centre. They can be obtained on request from the Director, Cambridge Crystallographic Data Centre, Univerity Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, UK.

Results and discussion

Conventional synthetic routes to **1** have been previously described by other authors (13, 15). Tolman *et al.* (15), in their solution study of Ni(0) bis- and trisphosphine complexes, indicated that such species were "most difficult to characterize". Furthermore they stated that as a result of their "extreme sensitivity to O_2" these complexes decomposed over several hours, even under rigorously O_2-free conditions. In the present report, crystals of **1** are formed from a solution of the species $(Et_2N)_3Ti(\mu\text{-}PCy_2)Ni(PPh_3)$[1] in pentane. $^{31}P\{^1H\}$ NMR spectra showed no evidence of free PPh_3 in the solution immediately after extraction, rather only the Ti-Ni species formulated above. This suggests that the formation of **1** occurs via disproportionation; however, the nature of the Ti containing product(s) is not known. In hindsight, it seems that the use of the ligand $(Et_2N)_3Ti(PCy_2)$ may solubilize the resulting Ni complex in pentane, permitting the ligand dissociation reaction that yields **1**. Crystallization as a result of the low solubility of **1** in pentane precludes degradation processes that could occur in solution. X-ray quality crystals of **1** were obtained on standing of the solution under strictly anaerobic conditions.

The crystallographic study showed that the crystals of **1** are made up of triclinic unit cells each containing four discrete molecules. The cell volume and centre of symmetry required by the space group $P\bar{1}$ are consistent with the presence of two independent molecules in the asymmetric unit. ORTEP drawings of the two independent molecules are shown in Fig. 1. In each molecule the pseudotrigonal coordination sphere of Ni is composed of three phosphorus atoms of the triphenylphosphine groups. The angles about the Ni centres, that is, the P—Ni—P angles, sum to 360.0 and average 120(1)° for both of the independent molecules of the asymmetric unit, consistent with a trigonal planar geometry. The Ni—P bond distances were found to range from 2.139(1) to 2.156(1) Å. This range of values presumably reflects the steric interactions between the phenyl rings on adjacent phosphine groups and the effectiveness with which the interleaving of these substituents reduces such contacts. The average Ni—P value of 2.147(6) Å is shorter than 2.17(1) Å found for $(Cy_3P)_2Ni(\mu\text{-}N_2)Ni(PCy_3)_2$ (5), 2.19(2) Å for $(Ph_3P)_2Ni(C_2H_4)$ (24, 25), 2.26(1) Å for $(Ph_3P)_3Ni(SO_2)$ (26), and the 2.222(3) Å for $(Ph_3P)_2Ni(N(SiMe_3)_2)$ (27). The shorter average Ni—P distance is consistent with the lesser steric demands of Ph_3P versus Cy_3P as well as the coordinative unsaturation of the Ni centre. The P—C and C—C bond lengths as well as the angles about the triphenylphosphine groups were typical of those found in other structural studies of compounds containing the triphenylphosphine ligand.

The disposition of the phenyl rings in each triphenylphosphine moiety appears to be guided by the approximately parallel alignment of pairs of phenyl rings on adjacent phosphine ligands. This arrangement of aromatic rings was also observed for a single pair of rings in $Pt(PPh_3)_3$ (4). The shorter metal–phosphorus distances in **1** apparently demand more effective interleaving of the phosphine substituents, thus encouraging pseudo-stacking of the phenyl rings. Comparison of the two molecules of the asymmetric unit indicates some variability in the specific orientation of the corresponding phenyl rings. This suggests that while ring stacking may be comparable in magnitude to crystal packing forces, it seems that any stabilization energy that arises from ring stacking is relatively low.

The most interesting feature of the present stuctural study is the observation of the relatively close approach of *ortho* phenyl

ring protons to the Ni atom in each of the two independent molecules. In the case of Ni(1) and H(8), H(26), and H(38), the Ni—H distances are found to be 2.93, 2.91, and 3.09 Å, respectively, while for Ni(2) and H(56), H(90), and H(108) the analogous distances are found to be 2.87, 2.74, and 2.91 Å (Fig. 2). These Ni—H distances are much longer than those attributed to "agostic" interactions (1.9–2.3 Å) (28), suggesting that the approaches observed in the present case arise from ligand–ligand repulsions and not from Ni—(CH) bonding. These close approaches of the *ortho* protons to Ni are comparable to the *ortho*-hydrogen to Pd distances of 2.73 Å seen in $Pd(PPh(t\text{-}Bu)_2)_2$ (2). In that case, the authors noted that the substituent orientation that brings about this contact is sterically favoured, although a bonding interaction between the hydrogen and the metal was also suggested. Such interactions may precede the process of *ortho* metallation, the initial step suggested in the degradation of **1** to the species $(Ph_3P)Ni(\mu\text{-}PPh_2)Ni(PPh_3)$ (15). Interestingly, such *ortho*-hydrogen – metal interactions are not seen in the more stable $Pt(PPh_3)_3$ (4). The relatively close approach of three *ortho* hydrogens to the Ni in **1** may imply that *ortho* metallation is indeed facile. These observations may account for the previously reported instability of the compound and the difficulties in preparation and characterization of the coordinatively unsaturated Ni complex **1** (15).

The present study is the first in which the structure of a coordinatively unsaturated Ni(0)-perphosphine complex has been reported. Furthermore, structural studies of three-coordinate Ni complexes are not common in general. With the exception of the several Ni-olefin complexes (27), the species $(Cy_3P)_2Ni(\mu\text{-}N_2)Ni(PCy_3)_2$ (5) and $(Ph_3P)_2Ni(N(SiMe_3)_2)$ (27) are the only truly three-coordinate Ni species that have been structurally characterized prior to this report.

The reaction of aluminum atoms with methane

HENGTAI YU[1] AND JOHN D. GODDARD[2]
Department of Chemistry and Biochemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received July 24, 1989

HENGTAI YU and JOHN D. GODDARD. Can. J. Chem. **68**, 633 (1990).

Ab initio SCF and CISD calculations with split valence and larger basis sets have been carried out for several possible reactions of ground state (^2P) aluminum atoms with methane. In particular, the barriers to insertion of Al into a CH bond to give a CH_3AlH intermediate and the abstraction of a hydrogen by Al to give AlH and CH_3 have been studied. At the SCF level, transition state structures have been located and verified by vibrational analyses. In addition, intrinsic reaction coordinates (IRC) have been followed from the transition state geometries down to reactants and to products. Calculated vibrational frequencies and lowest excitation energy for the CH_3AlH intermediate are in good agreement with matrix isolation experimental results. As anticipated on the basis of MO natural correlation symmetry arguments, the energy barrier to the insertion reaction is high (~50 kcal mol^{-1} at the CI level). The energy requirement for the abstraction reaction is similar.

$Al + CH_4 \rightarrow HAlCH_3$ Insertion
$Al + CH_4 \rightarrow HAl + CH_3$ Abstraction

Key words: Al, CH_4, $HAlCH_3$, insertion and abstraction reactions.

HENGTAI YU et JOHN D. GODDARD. Can. J. Chem. **68**, 633 (1990).

Utilisant des ensembles avec de larges bases, on a effectué des calculs *ab initio* SCF et CISD de plusieurs réactions possibles entre des atomes d'aluminium dans l'état fondamental (^2P) et du méthane. On a étudié particulièrement les barrières à l'insertion du Al dans une liaison CH pour donner un intermédiaire CH_3AlH et à l'enlévement d'un hydrogène par un Al pour donner du AlH et du CH_3. Au niveau SCF, on a localisé les structures des états de transition et on les a vérifiées par des analyses vibrationnelles. De plus, on a suivi les coordonnées intrinsèques de la réaction (CIR) des géometries de l'état de transition jusqu'aux réactifs et aux produits. Les fréquences vibrationnelles calculées ainsi que l'énergie d'excitation la plus basse pour l'intermédiaire CH_3AlH sont en bon accord avec les résultats expérimentaux obtenus avec des matrices isolées. Tel qu'on pouvait le prévoir sur la base d'arguments de symétrie des corrélations naturelles des OM, la barrière d'énergie à la réaction d'insertion est élevée (~50 kcal mol^{-1}, au niveau de IC). Les énergies requises pour les réactions d'enlévement sont semblables.

$Al + CH_4 \rightarrow HAlCH_3$ Insertion
$Al + CH_4 \rightarrow HAl + CH_3$ Abstraction

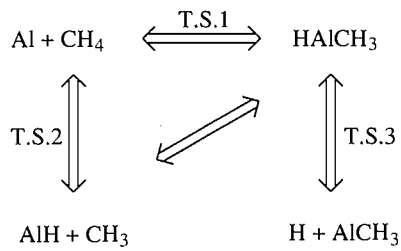
Mots clés : Al, CH_4, $HAlCH_3$, réactions d'insertion et d'abstraction.

[Traduit par la revue]

Introduction

The photochemically initiated reactions of matrix isolated aluminum atoms with methane have been the subject of a recent extensive study by Parnis and Ozin (1–4). The formation of methylaluminum hydride, CH_3AlH, from photoexcited aluminum atoms reacting with methane was conclusively demonstrated and the intermediate well characterized spectroscopically (1, 2). *Ab initio* SCF calculations on the geometry of the CH_3AlH species were reported (2) and orbital and state symmetry based discussions of possible reaction mechanisms were presented (4). A computational SCF study of the CH_3AlH molecule and of other possible reaction products, AlH and $AlCH_3$, has appeared (5). The general area of metal atom – small molecule chemistry has seen considerable activity by quantum chemists and a few references are given in ref. 6. A pioneering study of organoaluminum species is especially noteworthy (7). Interest in metal atom chemistry has been motivated both by the intrinsically fascinating problem of understanding the fine details of a chemical reaction and the view that understanding such prototypes may aid in unravelling important catalytic processes.

The present research focuses on establishing to semiquantitative accuracy the ground state potential energy surface for Al + CH_4 including transition state structures for various insertion or abstraction reactions. The features of this surface may be illustrated by the following scheme:



SCHEME 1

Such knowledge of the ground state surface is a necessary prerequisite to the study of the direct excited state chemistry of $Al^*(^2S) + CH_4$.

All geometries were optimized with modest but generally fairly reliable split valence basis sets, 3-21G* and 6-31G + d(Al). Restricted open shell SCF methods were used to eliminate any spin contamination difficulties that might be encountered with UHF. CISD calculations with ~10 000 configurations in C_1 symmetry were carried out to give preliminary indications of the effects of electron correlations on relative energies. The excited states of the Al atom and of the CH_3AlH were examined with comparable SCF + CI computations. The energies of these excited states relative to the various barrier heights on the ground state surface are crucial to the possibility of hot ground state chemistry following possible internal

conversion of initially excited species to the ground state surface.

Computational methods

Calculations were performed with the GAMESS codes (8, 9). The Celerity UNIX version was modified slightly and run on the SUN3/280 workstations of the Guelph–Waterloo Chemistry and Physics computing facility. The standard 3-21G* set and a 6-31G + *d* on Al basis (exponent = 0.325) were employed in the SCF calculations (10, 11). Restricted open shell Hartree–Fock calculations were used to describe open shell species. To examine the possibility that a diffuse basis function might be required for an adequate description of the excited states,[3] an *s*-type function of exponent 0.014 (13) was added to the 3-21G* basis to give a set denoted 3-21G* + 4*s*. Geometries were optimized at the SCF level using the methods of Schlegel or Baker (14) as implemented in GAMESS. Starting from two of the transition state structures, intrinsic reaction coordinates, IRC, were followed to reactants and products (15). Configuration interaction calculations, CISD, employed the unitary group CI codes (16) included in GAMESS. Five doubly and one singly occupied orbitals were excited from, and 11 virtuals were kept active to yield, 9972 singly and doubly excited configurations in C_1 symmetry. Dissociation limits such as Al + CH_4 or $AlCH_3$ + H were treated as super molecules in the CISD with the fragments separated by ~7 Å. Such an approach will reduce size consistency errors in comparing the CH_3AlH species to its fragments.

Results and discussion

Qualitative considerations

Parnis and Ozin (4) have presented the argument that the reaction of a ground state aluminum atom with methane is forbidden on the basis of a state symmetry correlation diagram. Figure 1 presents both a MO natural correlation diagram (17) and the more conventional MO correlation (18) for the Al + $CH_4 \rightarrow HAlCH_3$ reaction. Either approach to the symmetry character of this reaction agrees with earlier work (4) in predicting that the ground state process is forbidden. Focusing on the MO natural correlation diagram (17) in Fig. 1, the reaction is an Al atom insertion into a CH bond in methane. As the reaction proceeds, the CH bond is stretched and the σCH bonding orbital ($2a''$) increases in energy in an attempt to correlate with the σCH* antibonding orbital ($4a''$) of the CH_3AlH product. Simultaneously, the σCH* orbital decreases in energy and attempts to correlate with the $2a''$ orbital. Thus an avoided crossing point is reached since both the σCH and σCH* orbitals have the same a'' symmetry. Another avoided crossing occurs involving the $8a'$ and $9a'$ orbitals of the CH_3AlH product and the $9a'$ and $11a'$ orbitals of the Al + CH_4 reactants. Thus, orbital correlations suggest a high energy barrier to the ground state reaction.

Energies

The total SCF energies from 3-21G*, 3-21G* + 4*s*, and 6-31G + *d*(Al) calculations are given in Table 1. The energies in kcal mol^{-1} relative to the ground state of the CH_3AlH intermediate are also presented. Table 2 contains the 3-21G* + 4*s* CISD and CISD + Davidson's correlation energies along with the coefficient of the SCF reference function in the CI expansion. Figure 2 illustrates the relative energies in kcal mol^{-1} of all species examined in this study.

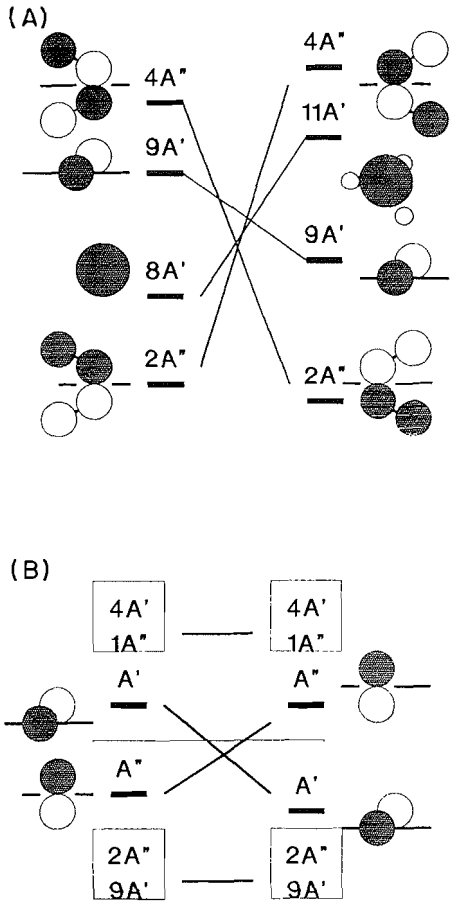

FIG. 1. The symmetry forbidden Al + CH_4 ground state reaction. A. MO natural correlation. B. Hoffmann MO correlation.

Parnis and Ozin have used the results of previous calculations (e.g., ref. 7) to suggest that the dissociation energies of both the CH_3Al—H and H_3C—AlH bonds are likely to be about 45 kcal mol^{-1}. The 3-21G* + 4*s* CISD + Davidson's correction values in Table 2 are 36.0 kcal mol^{-1} for the Al—H bond dissociation energy and 39.2 kcal mol^{-1} for the Al—C energy in methylaluminum hydride. The calculated values are 6–9 kcal mol^{-1} less than the earlier estimates (4). Certainly, the underestimation of a dissociation energy by the modest basis set and configuration interaction calculations is to be expected. Nonetheless the agreement is reasonable. It has been indicated (4) that the reaction of Al ground state (^2P) atoms with methane is 10–11 kcal mol^{-1} exothermic. The calculated exothermicity in this work is 5.4 kcal mol^{-1} or ~5 kcal mol^{-1} less. Thus, the relative energies of various minima on the potential energy surface agree within 5–10 kcal mol^{-1} with previous suggestions. (These energy quantities do *not* include corrections for zero point vibrational energy changes.)

Two energetic quantities of importance in comparison with the experimental results (1–4) are the $^2S \leftarrow {}^2P$ excitation energy of the Al atom and the excited state energy of the CH_3AlH intermediate. The experimental value for the Al $^2S \leftarrow {}^2P$ excitation energy is 72.5 kcal mol^{-1} in the gas phase. The 3-21G* + 4*s* CISD value was determined as the second root of a CI matrix built from ground state orbitals and was 82.3 kcal mol^{-1}. Thus, the calculated value is almost 10 kcal mol^{-1} too

[3]The $^2S \leftarrow {}^2P$ excitation of Al involves a transition to an *s* orbital of higher principal quantum number $3s^23p^1 \rightarrow 3s^24s^1$.

TABLE 1. Total and relative SCF energies with the 3-21G*, 3-21G* + 4s, and 6-31G + d(Al) basis sets. Calculations are at 3-21G* or 6-31G + d(Al) SCF optimized geometries. Relative energies are in kcal mol^{-1} with respect to the ground state of the CH_3AlH intermediate

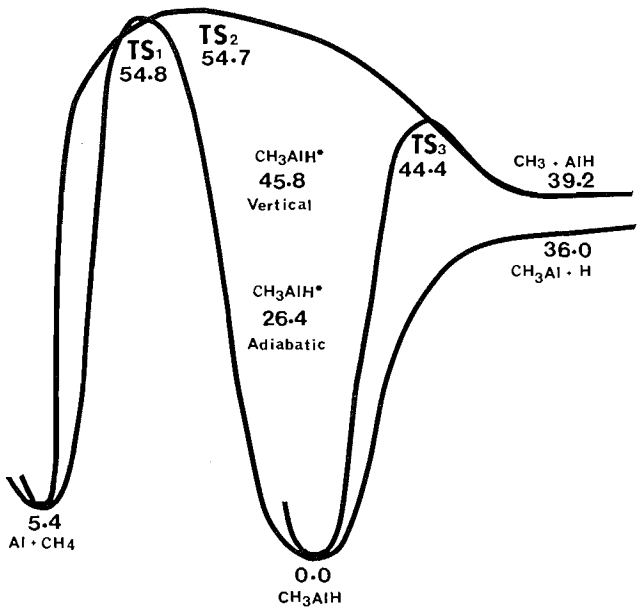

FIG. 2. A schematic illustration of the ground state potential energy surface for Al + CH_4. Energy differences shown are in kcal mol^{-1} relative to the ground state of the CH_3AlH intermediate and are from the 3-21G* + 4s CISD + Davidson's correction calculations.

large but still modestly accurate. The CISD + Davidson's correction vertical excitation energy of CH_3AlH, corresponding to $3a'' \leftarrow 10a'$, is calculated to be 45.8 kcal mol^{-1} after a separate excited state SCF before the CI. Previous computations yielded a value of 44–49 kcal mol^{-1} for this excitation energy (5). In a methane matrix, Parnis and Ozin assign an absorption at 525 nm or 54.5 kcal mol^{-1} to the $^2A'' \leftarrow {}^2A'$ energy difference in CH_3AlH. The geometry of the $^2A''$ excited state of CH_3AlH has been optimized and thus an adiabatic CI excitation energy of 26 kcal mol^{-1} can be predicted. In fact, as this excited state has the CAlH atoms essentially linear, it is degenerate (one component of an ^2E state) with the ground state at the linear structure.

The energies of the transition states at the 3-21G* + 4s CISD with Davidson's correction level will be noted here but discussed further under Reactivity. Transition state 3 (T.S. 3) represents a small barrier of ~5 kcal mol^{-1} to the reaction of H with $AlCH_3$ to form ground state methylaluminum hydride. A

similar barrier was sought for CH_3 + AlH but could not be located. The barrier to Al insertion into CH_4 to yield CH_3AlH (T.S. 1) is ~49.4 kcal mol^{-1}, which is (a) lower by 23–33 kcal mol^{-1} than Al*(^2S) + CH_4 depending on whether the experimental or calculated atomic excitation energy is used, and (b) essentially equal to the vertical excitation energy of CH_3AlH. The barrier for Al abstracting hydrogen from CH_4 to give methyl radical and aluminum hydride is ~50 kcal mol^{-1}. The reverse reaction, i.e., CH_3 abstracting H from AlH, faces a barrier of ~11 kcal mol^{-1}.

Although the energy barriers to the Al atom insertion abstraction reaction are high, the energy requirements are less than or approximately equal to the energy available upon excitation to the lowest excited state of Al or of CH_3AlH.

Structures

The geometries of the aluminum containing molecules, namely AlH, $AlCH_3$, and CH_3AlH (ground and excited state) at the 3-21G* and 6-31G + d(Al) SCF levels are shown in Fig. 3. As expected, the 3-21G* and 6-31G + d(Al) SCF geometries are quite similar. This fact promoted the use of only the 3-21G* basis in locating the transition state structures presented in Fig. 4.

The calculated AlH bond lengths of 1.649 Å (3-21G*) and 1.652 Å (6-31G + d(Al)) are within 0.006 Å of the experimental (19) r_e value of 1.6459 Å. The 3-21G* and 6-31G + d(Al) SCF predictions of the AlC bond length in $AlCH_3$ are 2.004 and

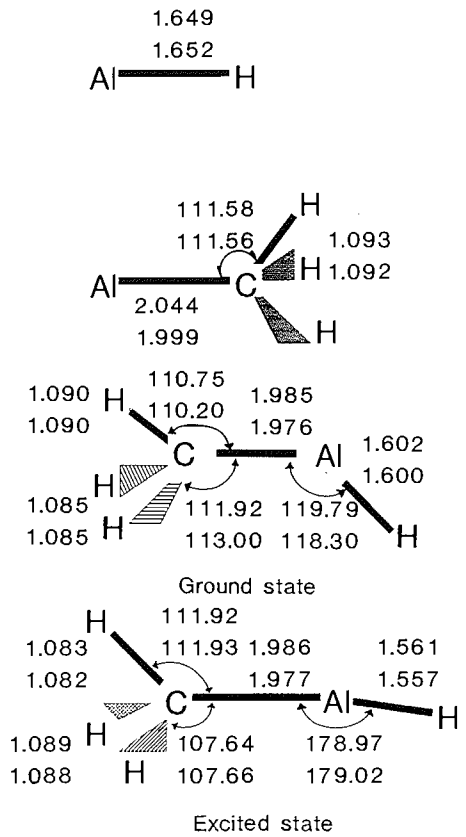

FIG. 3. Calculated geometries for AlH, $AlCH_3$, and the ground and lowest excited states of CH_3AlH at the 3-21G* and 6-31G + d(Al) SCF levels.

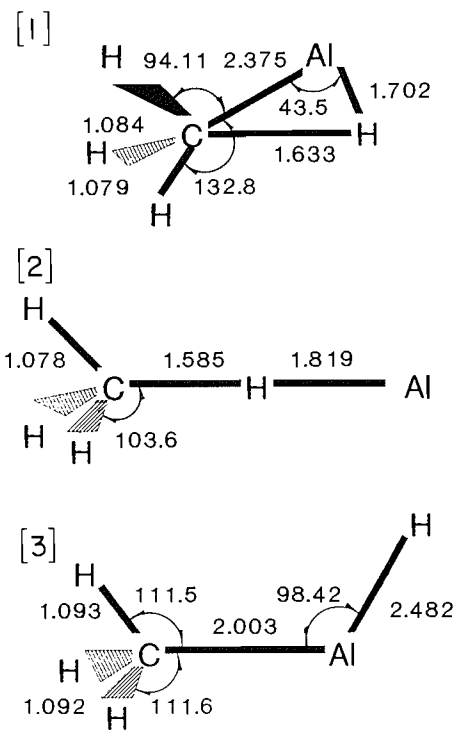

FIG. 4. Calculated transition state structures at the 3-21G* SCF level for the reactions:

[1] $Al + CH_4 \rightarrow CH_3AlH$
[2] $Al + CH_4 \rightarrow AlH + CH_3$
[3] $CH_3AlH \rightarrow CH_3Al + H$

1.999 Å, in good agreement with the previously calculated value 2.013 Å (7). In the ground electronic state of CH_3AlH both the AlC and AlH bonds are shorter than in monovalent aluminum species, $AlCH_3$ and AlH. Such a shortening of these bonds in a divalent aluminum compound may be rationalized by a "hybridization" argument (20). In AlH or $AlCh_3$ the Al uses a $3p$ orbital in bonding while in CH_3AlH sp^2 hybrids are a more appropriate qualitative description of the interactions. The 3-21G* and 6-31G + d(Al) SCF distances for the C—Al bond are 1.985 and 1.976 Å, which are close to the 6-31G** result of 1.981 Å in ref. 2 or 1.980 Å in ref. 5. The AlH distances of 1.602 Å (3-21G*) or 1.600 Å (6-31G + d(Al)) are also in excellent agreement with the previously calculated values of 1.598 or 1.600 Å (2, 5) for methylaluminum hydride. The predicted C—Al—H angles of 119.70° or 118.30° are both close to the 120° expected for sp^2 hybridization and in agreement with previous, calculated results (2, 5).

The lowest excited electronic state of CH_3AlH involves excitation from an in-plane sp^2 hybrid orbital $10a'$ to a $p\pi$ orbital $3a''$. The C—Al—H angle increases dramatically from ~120° to essentially 180° with this orbital change. The AlH distance shortens from 1.600 Å (6-31G + d(Al)) in the ground state or 1.557 Å in this excited state, while the AlC distance remains essentially unchanged. The change to a linear geometry with excitation from an a' to an a'' orbital is consistent with the Walsh diagram type arguments for a 5-valence electron AH_2-like system (21).

The 3-21G* ROHF transition state structures will be discussed briefly here, then examined further when reactivity is considered. Figure 4 illustrates T.S. 1 for the insertion of Al into a CH bond, T.S. 2 for the abstraction of a H from CH_4, and T.S. 3 for CH_3AlH fragmenting to CH_3Al and H. In the insertion transition state the Al interacts more strongly with the H at a distance of 1.702 Å as compared to the Al to C length of 2.375 Å. The CH bond into which the Al is inserting is stretched to 1.633 Å. In fact, at the transition state the reactive hydrogen is approximately equidistant from C and Al. The abstraction reaction T.S. 2 involves a head-on approach of Al to the CH bond (CHAl angle of 180°). At the transition state the CH has lengthened to 1.585 Å, which is ~45% greater than its equilibrium value. The Al to H distance of 1.819 Å is ~0.17 Å or ca. 10% greater than the equilibrium bond length in the diatomic AlH. Thus, the reaction is late in the AlH coordinate as would be expected on Hammond postulate grounds for a strongly endoergic (+33.8 kcal mol^{-1}) one.

T.S. 3 for the dissociation of CH_3AlH to CH_3Al and H has a CH_3Al moiety nearly at its equilibrium geometry with the exception of a C–Al distance slightly longer by ~0.04 Å. The hydrogen atom that is formed is ~2.5 Å removed from the Al.

Vibrational frequencies

The 3-21G* SCF level vibrational frequencies for AlH, $AlCH_3$, and CH_3AlH are collected in Table 3. Both the calculated harmonic frequencies and these values scaled by 0.9 to approximately correct both for anharmonicity and for the SCF method (22) are given. For AlH, the scaled frequency of 1621 cm^{-1} is 50 cm^{-1} lower than the experimental value (19). Previous calculated (and unscaled) frequencies for $AlCH_3$ (5) may be compared with the harmonic computed values in this study. The largest discrepancy is less than 40 cm^{-1} and the average absolute difference between the two sets of frequencies is 23 cm^{-1}.

Seven of the 12 vibrational frequencies of CH_3AlH have been

assigned on the basis of the matrix isolation experiments (2). The scaled 3-21G* values of this work differ by an average absolute value of 29 cm^{-1} from experiment. Only ν7, a CH_3 deformation, which is calculated to occur at 1272 cm^{-1} but is observed at 1162 cm^{-1}, is significantly in error. Presumably more flexibility in the C and H basis sets could resolve this difference (12). Previous calculated vibrational frequencies (5) showed the same overall good agreement with experiment.

The single imaginary frequencies for the stationary points in Table 4 verify that these are transition states. The imaginary frequency also provides information on the reaction coordinate at the transition structure. For the insertion reaction, T.S. 1, ν* is 1175i cm^{-1} and is a mode involving considerable bending of the CAlH angle. The reaction coordinate for abstraction is strongly dominated by motion of the H (CH stretching and AlH compression) and has a larger ν* of 2085i cm^{-1}. The T.S. 3 ν* of 487i cm^{-1} is consistent with the small barrier of ~5 kcal mol^{-1} relative to CH_3 + AlH.

Reactivity

Qualitative aspects of the reactions along with mention of the energies, structures, and imaginary vibrational frequencies of the transition states have already been presented. In this section, these results will be expanded upon with reference to the experiments (1–4), and the intrinsic reaction coordinates, Figs. 5 and 6, will be discussed.

The intrinsic reaction coordinates (e.g., ref. 15) shown in Figs. 5 and 6 verify that T.S. 1 connects Al + CH_4 to CH_3AlH and T.S. 2 links Al + CH_4 with CH_3 + AlH. The energy differences summarising the energetics are from the CI calculations at the 3-21G* + 4*s* CISD level although the actual points computed on the IRC were from 3-21G* SCF computations.

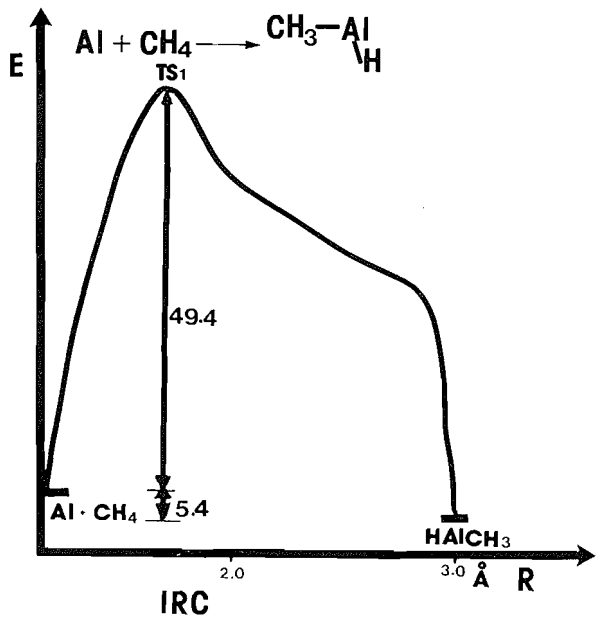

FIG. 5. The 3-21G* SCF intrinsic reaction coordinate connecting Al + CH_4 to AlH + CH_3.

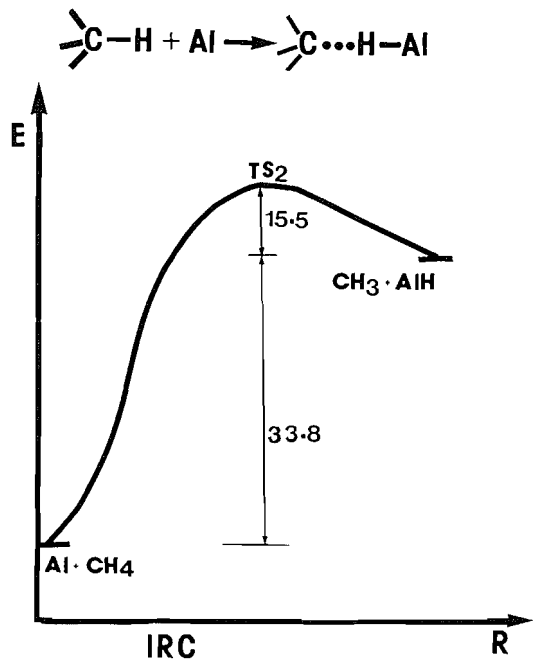

FIG. 6. The 3-21G* SCF intrinsic reaction coordinate connecting Al + CH_4 to CH_3AlH.

The high barrier of ~50 kcal mol^{-1} for the insertion provides computational confirmation of the orbital and state symmetry arguments for a forbidden ground state reaction of Al with CH_4. The abstraction reaction also faces a barrier of comparable height. These barriers are both less than the energy available once the Al is photoexcited (72.5 kcal mol^{-1} experiment or ~82 kcal mol^{-1} calculated). Thus, the possibility of hot ground state chemistry following a nonradiative relaxation from ^2S to ^2P by Al is open. Note that this "thermalization" mechanism is *not* favoured by Parnis and Ozin (4).

The prediction that the hydrogen abstraction barrier is equal to that of the insertion barrier is puzzling. Parnis and Ozin (4) presented the negative result that no evidence for formation of CH_3 was found on the Al/CH_4 system despite the high sensitivity of ESR to the detection of methyl radicals. The calculations indicate a small barrier to CH_3 and AlH recombining to yield CH_3AlH, which should inhibit the reaction and allow CH_3 to be trapped.

The regeneration of Al atoms following absorption at >450 nm by the CH_3AlH could be explained. The vertical excitation energy of the intermediate was calculated to be ~46 kcal mol^{-1} or less than 5 kcal mol^{-1} below the barriers to insertion or abstraction. Some quantum mechanical tunnelling of H may assist in the formation of Al + CH_4. Experimental evidence (4) that is at least suggestive of a role for tunnelling is the much lower yield of Al atoms in the $CD_3AlD \rightarrow Al + CD_4$ reaction.

Conclusions

The results of this study on the ground state reaction of Al atoms with CH_4 are consistent with earlier computations (1, 5) and with many of the experimental results. In particular, the high reaction barriers of ~50 kcal mol^{-1} to insertion or abstraction in the ground state verify the forbidden nature of these reactions. The possibility of hot ground state reactions following photoexcitation of Al cannot be excluded on energetic grounds. The suggestion by Parnis and Ozin (4) of a more direct excited state reaction involving a Rydberg state like Al with CH_4 will require further MCSCF or CI calculations. Such a study is planned.

Electron spin resonance detection of heterogeneous reactions of Pigment Red 122

MARY JANE WALZAK[1] AND JOHN R. HARBOUR
Xerox Research Centre of Canada, 2660 Speakman Dr., Mississauga, Ont., Canada L5K 2L1

Received April 3, 1989[2]

MARY JANE WALZAK and JOHN R. HARBOUR. Can. J. Chem. **68**, 640 (1990).

Electron spin resonance spectroscopy (ESR) has been used to investigate the electrochemical and photolytic behaviour of particulate C.I. Pigment Red 122. Heterogeneous electrochemical reduction and oxidation of the pigment resulted in different reversible ESR signals with the radical cation giving a signal of ΔH_{pp} = 2.3 G and *g*-factor of 2.0033 and the radical anion giving ΔH_{pp} = 3.2 G and *g*-factor 2.0039. On exposure to light the inherent ESR signal, which was determined to be a two-component signal, increased in intensity by a factor of 2.4 but did not change in linewidth or *g*-factor. This light-induced signal was reversible and decayed to initial levels in the dark. The mechanism of these reactions is discussed.

Key words: ESR, pigment, electrochemistry, photo effects.

MARY JANE WALZAK et JOHN R. HARBOUR. Can. J. Chem. **68**, 640 (1990).

On a utilisé spectroscopie de résonance paramagnétique électronique (RPE) pour étudier les comportements électrochimique et photolytique du pigment rouge 122 à l'état de particule. La réduction électrochimique hétérogène et l'oxydation du pigment ont conduit à des signaux réversibles différents de RPE; le cation radical donne lieu à un signal comportant un ΔH_{pp} = 2,3 G et un facteur-*g* de 2,0033 alors que l'anion radical donne lieu à un signal comportant un ΔH_{pp} = 3,2 G et un facteur-*g* de 2,0039. Lorsqu'on le soumet à la lumière, on a observé que l'intensité du signal RPE inhérent — qui est formé par la superposition de deux signaux — est augmentée par un facteur de 2,4; toutefois, la largeur de la bande ou le facteur-*g* ne changent pas. Ce signal induit par la lumière est réversible et il retourne aux niveaux initiaux lorsqu'on le place à la noirceur. On discute du mécanisme de ces réactions.

Mots clés : RPE, pigment, éléctrochimie, effets photo.

Introduction

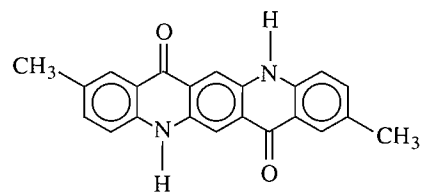
For several years we have been studying the electron transfer to and from small particles. Our goal was to demonstrate charge exchange and to gain insight into the way in which particles accept or donate electrons. We used electron spin resonance spectroscopy (ESR) to monitor electron transfer with particles as they were electrochemically reduced and oxidized. Electron spin resonance has proven to be a viable technique for detecting changes in the number of spins with these systems. These changes are of the same order of magnitude as the number of charges exchanged during triboelectrification in the xerographic development process.

Initial efforts were focussed on carbon black particles (1–4) and demonstrated that carbon blacks in dispersion can accept electrons and that these electrons are observable by ESR. From this study it was demonstrated that chemical oxidation of the carbon black creates surface sites which accept electrons on electroreduction.

ZnO particles were also found to manifest an ESR signal, due to trapped electrons, on electroreduction (5). In addition to the ESR signal there was a dielectric loss increase on electroreduction leading to a decrease in the Q of the ESR cavity. Both observations were reversible.

The redox reactions of metal-free phthalocyanine (*x*-H_2Pc) have also been investigated (6). The results show that these pigment particles can also accept and donate electrons and that they manifest different ESR signals upon electroreduction and oxidation.

We have now extended this work by studying the redox behaviour of a quinacridone pigment, C.I. Pigment Red 122 (Structure **1**; quino[2,3-*b*]acridine-7,14-dione-5,12-dihydro-2,9-dimethyl). Colour Index Pigment Red 122 is bright bluish-red in colour and is used in plastics as a colourant, in organic solar cell applications (7), as a photoconductive pigment (8), and as a pigment in coloured toners (9, 10).



1, C.I. Pigment Red 122

Experimental

The sample of Pigment Red 122 was a commercial sample obtained from Hoechst. This sample had a surface area of 71.4 m^2/g (N_2 B.E.T.) and a stated particle size of 0.2 μm. A Bruker ESP300 EPR spectrometer was used to obtain the data. DPPH was used as the standard for the determination of the number of spins. The internal standard used was the Mn^{2+} impurity in strontium oxide powder in a sealed capillary tube. This provided a reference for both *g*-factor calculations and any changes in cavity Q. The electrochemical cell employed in this work has been described previously (1) and was used with minor modifications. The cell is composed of a capillary with a glass wool plug at the bottom. Pigment Red 122 was placed on top of this plug and a thick platinum wire inserted from the top into the pigment layer. The entire electrode was inserted into an ESR tube containing the electrolyte solution (0.05 *M* tetrabutylammonium perchlorate in methylene chloride) and a thin platinum counter electrode in a separate capillary tube. Since the pigment is insoluble in methylene chloride the redox reactions are heterogeneous rather than homogeneous. The dispersion was purged of oxygen by bubbling thoroughly with nitrogen gas. There was no mechanical stirring in the system. The two electrode system was run with an applied voltage of −6 V for the electroreduction and +6 V for the electrooxidation. This system contains no reference electrode; therefore, the real potential is unknown. The reduction and oxidation were run for 2.5 to 3 h with no

[2]Revision received December 4, 1989.

plateau or saturation of the signal. The temperature dependence of the ESR spectrum was obtained in the frozen state to minimize the possibility of signal decay when the applied potential was removed. Spectra for the electrochemically generated signals were asymmetric and so a lineshape was difficult to assign. However, the signal from the oxidation was very close to Gaussian in shape. The photolytic experiments were carried out in situ by irradiating a flat cell containing a suspension of Pigment Red 122 in Isopar G, using light from a 150 W Xe lamp filtered through a Corning 3-75 filter. This filter cuts off >99.5% of the light with wavelengths shorter than 365 nm and transmits >40% of the light of wavelength longer than 405 nm.

Results and discussion

Inherent signal

Pigment Red 122 in its solid powdered form exhibits an asymmetric ESR signal of ΔH_{pp} of 8.6 ± 0.2 G at an apparent g-factor of 2.0037 ± 0.0002 measured at the crossover point. The intensity, as compared to a DPPH standard, represents a spin concentration of approximately 7.8×10^{16} spins/g or 1 spin per 20 000 molecules. This inherent signal appears to be a mixture of two components, one of narrower linewidth and lower g-factor superimposed on one of broader linewidth and higher g-factor. The g-factors are typical of an interaction of the unpaired electron with heteroatoms oxygen and nitrogen. Because of the mixed nature of the signal a power saturation study was performed. The lineshape, g-factor, and linewidth of the signal at powers from 50 μW to 200 mW were determined. The signal shape changed significantly between these two powers as did the apparent g-factor (Fig. 1). At 50 μW the signal has a g-factor of 2.0037 and a linewidth of 10.3 G, while at 200 mW the signal has a g-factor of 2.0034 and a linewidth of 4.4 G. The results show that the broader signal saturates at lower powers than the narrower signal. This is consistent with the inherent ESR signal in the Pigment Red 122 having at least two components. The ESR response is temperature dependent. At lower temperature the combined signal intensity increases and the spectrum becomes broader (approximately 13 G) and more symmetrical.

Electroreduction

Pigment Red 122 was reduced at an applied potential of −6 V; this reaction produced a slightly asymmetrical ESR signal of linewidth 3.2 G at a g-factor of 2.0039 ± 0.0002 (Fig. 2*a*). The lineshape is very nearly Lorentzian despite the slight asymmetry. The signal intensity was 21 times larger than the inherent signal, representing a spin concentration of approximately 1.6×10^{18} spins/g (Table 1) or 1 spin per 950 molecules. This increase, although significant, is well below the value of 1 spin per 4 molecules previously observed in metal-free phthalocyanine (6). The temperature dependence of the signal, which follows the Curie law (Fig. 3), suggests that it arises from localized states. An alternative explanation (as pointed out by a referee) is that the experiments were performed at temperatures above the degeneracy temperature of the semiconductor and therefore give a Curie law behaviour. Further experiments at lower temperatures would be required to differentiate between the two possibilities. The signal is unstable when the applied voltage is removed, decaying within 1 min. The observed g-factor is typical of molecules containing oxygen and nitrogen.

Electrooxidation

Electrochemical oxidation of Pigment Red 122 at +6 V applied potential resulted in a slightly asymmetrical ESR signal of nearly Gaussian lineshape (Fig. 2*b*). The signal had a linewidth of 2.3 G and a g-factor of 2.0033 ± 0.0001. The increase in signal intensity was approximately 23 times that of the inherent signal corresponding to a spin concentration of approximately 1.8×10^{18} spins/g (Table 1) or 1 spin per 870 molecules. This increase in spin concentration is similar to that observed on reduction. Since the particles are small (0.2 μm) and have a surface area of 71 m^2/g it is possible that the electrochemically generated spins can be accommodated by surface states. The nearly Gaussian lineshape is contrary to our previous experience with pigment materials where the signals due to both reduced and oxidized species were Lorentzian in shape, a result of homogeneous broadening. Furthermore, the plot of inverse intensity versus temperature has a non-zero intercept (Fig. 3). Such a non-zero intercept can be accounted for by an exchange interaction. It is therefore difficult to understand the nature of the spins giving rise to this signal. The

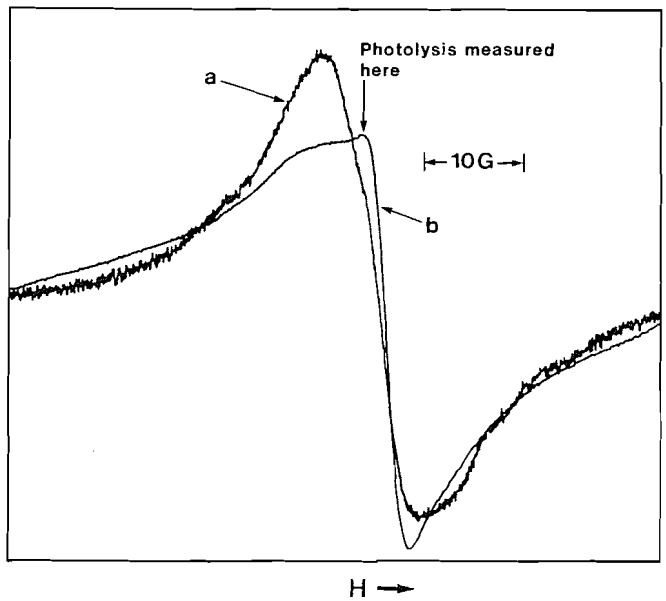

FIG. 1. Inherent ESR signal of Pigment Red 122: (*a*) gain = 1×10^6, modulation amplitude 1.6 G, power 49 μW, (*b*) gain = 1.6×10^5, modulation amplitude 1.0 G, power 200 mW.

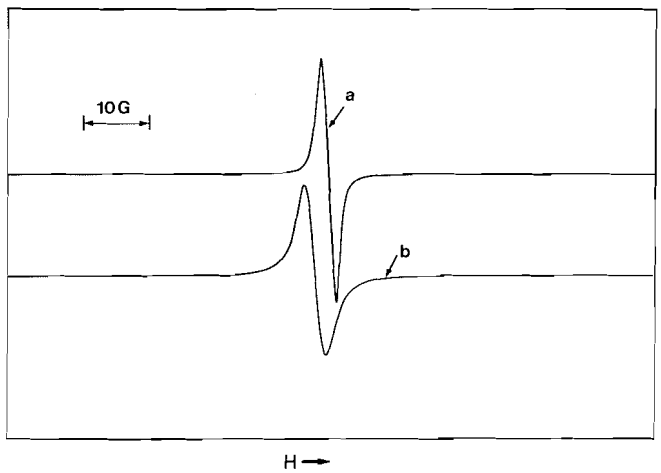

FIG. 2. Resultant ESR signals from reduction and oxidation of Pigment Red 122: (*a*) after 150 min of reduction, gain = 8×10^3, modulation amplitude = 2.8 G, power = 10 mW, (*b*) after 175 min of oxidation, gain = 5×10^3, modulation amplitude = 1.0 G, power = 10 mW.

TABLE 1. Comparison of the inherent, reduced, and oxidized signals

Signal type	Spins/g	g-factor	ΔH_{pp} (G)
Inherent	7.8×10^{16}	2.0037	8.6
Reduction	1.6×10^{18}	2.0039	3.2
Oxidation	1.8×10^{18}	2.0033	2.3

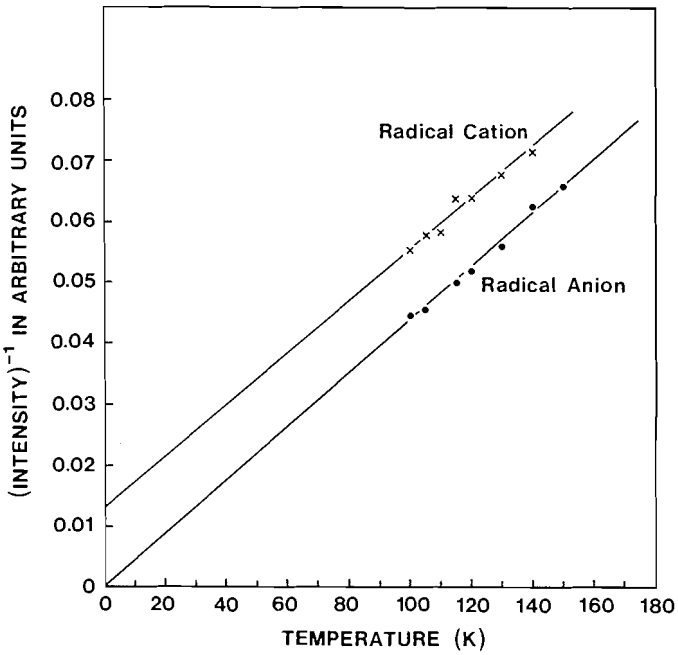

FIG. 3. Graph of inverse intensity (in arbitrary units) versus absolute temperature for the Pigment Red 122 radical anion and cation.

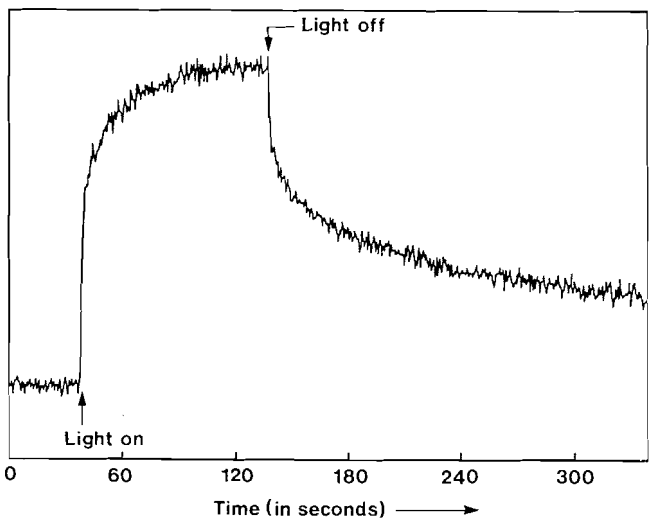

FIG. 4. Effects of irradiation on the intensity of the inherent ESR signal of Pigment Red 122 at 25°C with respect to time in seconds. Refer to Fig. 1 for the field position at which the spectrum was measured.

g-factor of the oxidized species is significantly lower than that of the reduced species. This result is consistent with the g-factors for radical ions generated from chlorophyll (2.0025 radical cation (11), 2.0028 radical anion (12)) and from soluble phthalocyanine (2.0020 radical cation (13), 2.0031 radical anion (14)). In contrast to the electroreduction signal, the electrooxidation signal is stable even 3 h after the applied voltage has been removed.

Photolysis

Pigment Red 122 has been used in a number of photolytic applications including that of a photoconductive pigment on composite electrophotographic plates (8) and as a photoactive pigment in organic solar cells (7). Consequently, the effect of light on the inherent ESR signal was investigated.

On illumination of the pigment sample ($\lambda > 365$ nm), the ESR signal increased by approximately 2.4 times with an initial sharp increase followed by a slower increase to a plateau (Fig. 4). The lineshape, apparent g-factor and linewidth obtained under illumination were identical to the values observed for the inherent signal. When the light was turned off the ESR signal initially decreased rapidly, then more slowly to the original dark level (Fig. 4). Furthermore, both the narrow and broad components of the signal grew and decayed equally in response to light.

Conclusions

C.I. Pigment Red 122 can undergo reversible electrochemical oxidation and reduction to give markedly different ESR signals. The radical anion has an ESR signal which is unstable when the voltage is removed and which follows the Curie law, indicating that it arises from localized states. Alternatively, it is possible that the experiments were performed above the degeneracy temperature of the semiconducting pigment and as a consequence the signal could arise from conduction electrons. The ESR signal from the radical cation is stable for several hours. The nature of the cation radical is difficult to determine from the present data. The non-zero intercept of the inverse temperature dependence of the signal intensity and the nearly Gaussian signal lineshape differ from our previous experiments on pigment materials. The number of spins generated in the reduction and oxidation are consistent with a surface phenomenon but a bulk effect can not be ruled out on the basis of the present evidence alone.

The inherent signal appears to be a composite of two ESR signals with g-factors similar to those of the anion and cation radicals. Photolysis of the pigment increases the composite signal intensity by a factor of 2.4. Since photoexcitation of this pigment results in charge separation, the origin of this signal is consistent with a superposition of radical cation and anion signals. However, the linewidths and temperature dependence of the inherent signal are not consistent with the linewidths and temperature dependences of the electrochemically generated anion and cation radicals. One possibility is a limited number of defect sites at which charge separation occurs. A distribution of recombination rates then accounts for the observed decay of the signal. The environment of such sites would have to be different from the sites that either donate or accept electrons electrochemically to account for the observed differences.

The significant difference in the ESR signals between the cation and anion radicals is important in our ongoing study of triboelectrifiction. These differences allow us to readily differentiate a pigment particle which has accepted an electron from a particle which has donated an electron. This will be particularly useful for experiments designed to monitor charge exchange between dry powders which have been subjected to mixing.

Received October 2, 1989

C. Robert Lucas, Shuang Liu, Michael J. Newlands, Jean-Pierre Charland, and Eric J. Gabe. Can. J. Chem. **68**, 644 (1990).

Preparations of the thiophenophane $C_{12}H_{18}S_5$ (L3), and its binuclear silver(I) complex cation $[Ag_2(L3)_2]^{2+}$ are described. The ^{13}C and ^1H nmr spectra of L3 and the ir and fast atom bombardment mass spectra of the complex are reported. X-ray structures of L3 and $[Ag_2(L3)_2](ClO_4)_2$ have been determined. For L3: space group $P2_1/n$, a = 10.8866(2), b = 9.4419(4), c = 14.9608(2) Å, β = 97.132(1)°, Z = 4, R_f = 0.057, R_w = 0.045. For $[Ag_2(L3)_2][ClO_4]_2$: space group $P2_1/n$, a = 9.2717(3), b = 19.8697(2), c = 10.2654(4) Å, β = 100.592(2)°, Z = 2, R_f = 0.036, R_w = 0.030. The effect of structure on the ligand's ability to form complexes is discussed. The centrosymmetric dinuclear cation has slightly distorted trigonal bipyramidal coordination geometry about each silver. The silver atoms are linked by one bridging thioether sulfur from each ligand. The remaining three sites on each silver are occupied by two terminal thioether sulfurs from one ligand molecule and one from the other ligand molecule. The complex is remarkably stable photochemically and chemically but under certain specific conditions reacts with loss of ligand. This stability is discussed with respect to structure.

Key words: binuclear silver(I) thiophenophane complex.

C. Robert Lucas, Shuang Liu, Michael J. Newlands, Jean-Pierre Charland et Eric J. Gabe. Can. J. Chem. **68**, 644 (1990).

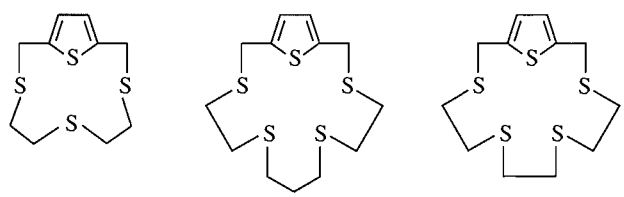
On décrit des préparations du thiophénophane, $C_{12}H_{18}S_5$ (L3), et de son complexe cationique binucléaire de l'argent(I), $[Ag_2(L3)_2]^{3+}$. On a déterminé les spectres rmn du ^{13}C et du ^1H du composé L3 ainsi que les spectres ir et de masse par bombardement avec des atomes rapides du complexe. On a déterminé les structures des composés L3 et $[Ag_2(L3)_2](ClO_4)_2$ par diffraction des rayons-X. Pour L3 : groupe d'espace $P2_1/n$, a = 10,8866(2), b = 9,4419(4) et c = 14,9608(2) Å, β = 97,132(1)°, Z = 4, R_f = 0,057, R_w = 0,045. Pour $[Ag_2(L3)_2](ClO_4)_2$: groupe d'espace $P2_1/n$, a = 9,2717(3), b = 19,8697(2) et c = 10,2654(4) Å, β = 100,592(2)°, Z = 2, R_f = 0,036, R_w = 0,030. On discute de l'effet de la structure sur la facilité qu'a le ligand à former des complexes. Le cation binucléaire centrosymétrique possède une géométrie de coordination trigonale bipyramidale déformée autour de chacun des atomes d'argent. Les atomes d'argent sont liés par un pont formé d'un soufre du thioéther de chacun des ligands. Les trois autres sites de chacun des atomes d'argent sont occupés par deux soufres de thioéthers terminaux provenant d'une molécule de ligand et d'un autre provenant de l'autre molécule de ligand. Le complexe est remarquablement stable d'un point de vue photochimique et chimique; toutefois, dans certaines conditions spécifiques, il peut réagir en perdant un ligand. On discute de cette stabilité en fonction de la structure.

Mots clés : complexe thiophénophane binucléaire de l'argent(I).

[Traduit par la revue]

Introduction

We have recently described preparations and studies of the ligands and complexes $[Cu(L1)_2]^+$, $[CuCl_2L1]_2$, and $[CuCl_2L2]_2$ (1–3).



L1 L2 L3

As a continuation of that study we now report the synthesis of thiophenophane, L3, which has a different cavity and different flexibility than L1 or L2 and of its silver(I) complex ion $[Ag_2(L3)_2]^{2+}$. This dinuclear ion contains silver(I) with a trigonal bipyramidal coordination sphere that is only slightly distorted. Until recently, examples of silver(I) with coordination numbers greater than two were relatively rare (4) and often (5–8) exhibited moderate or even severe distortions from idealized coordination geometries, in contrast to $[Ag_2(L3)_2]^{2+}$ which is only slightly distorted from trigonal bipyramidal geometry. Use of macrocyclic thioethers as ligands by several researchers has, however, led to recent preparation of new examples of silver(I) complexes with higher than usual coordination numbers. For example, Wieghardt has reported a complex salt consisting of cations $[AgL_2]^+$ and $[Ag_3L_3]^{3+}$ (L = 1,4,7-trithiacyclononane) in which the silver ions are coordinated by thioether sulfurs in distorted octahedral and tetrahedral arrays, respectively (9). In the latter, a rare example of a bridging crown thioether sulfur, like that in our $[Ag_2(L3)_2]^{2+}$, is found. Likewise, Schröder has described a distorted six coordinate complex $[AgL']^+$ (L' = 1,4,7,10,13,16-hexathiacyclooctadecane) and has studied its electrochemical and chemical oxidation to a Ag(II) species (10). In contrast, our

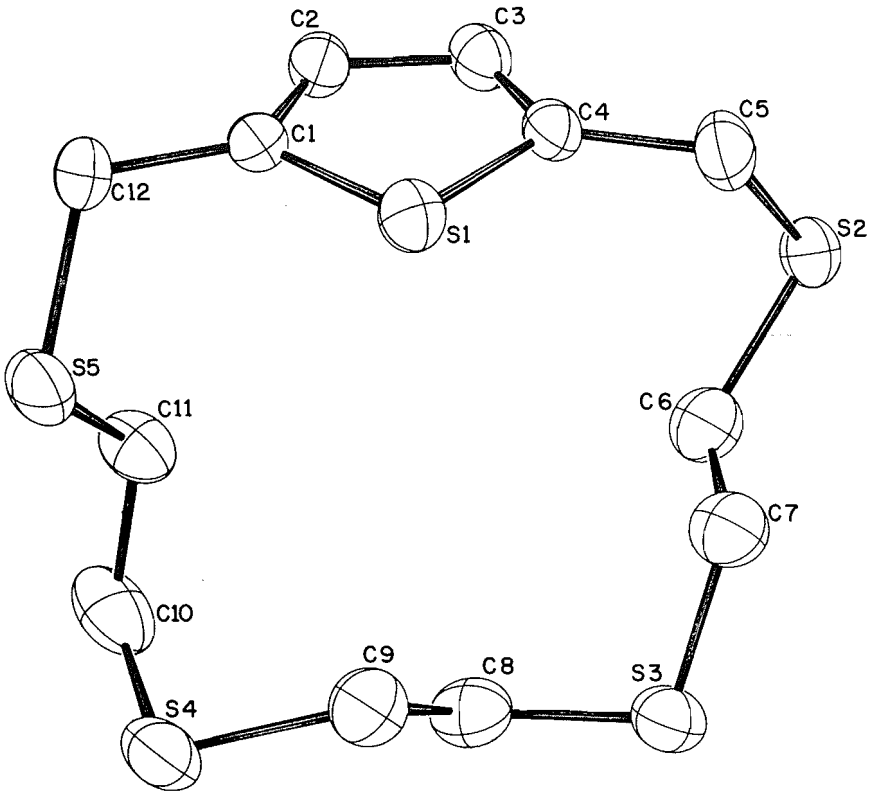

FIG. 1. ORTEP drawing of L3.

$[Ag_2(L3)_2]^{2+}$ is either unreactive or is completely decomposed under similar conditions.

Experimental

Commercially available reagents were obtained from the Aldrich Chemical Co. Inc. or from Morton Thiokol, Alfa Products Inc., and were used without further purification. Spectroscopic data were obtained using the following instruments: ir, Perkin Elmer Model 283; nmr, General Electric 300-NB; mass spectra, VG micromass 7070HS. FAB spectra were obtained using a saddle-field FAB gun on the VG 7070HS mass spectrometer equipped with a VG2035 data system. The standard VG argon atom source was operated at 8 keV and the silver salt was introduced as a mull in glycerol/*para*-toluensulfonic acid (approximately 3:1). X-ray diffraction data were collected using an Enraf-Nonius CAD-4 (L3) or a Picker ($[Ag_2(L3)_2][ClO_4]_2$), diffractometer. Analyses were performed by Canadian Microanalytical Service Ltd.

Preparative

(a) $C_{12}H_{18}S_5$ (ligand L3)

The 2,5-bis(chloromethyl)thiophene (11) used in this preparation must be purified or the overall yield of L3 will be low. Purification can be achieved by washing the crude brown liquid with saturated sodium carbonate solution and then water until the washings are neutral, drying over anhydrous $MgSO_4$, and recrystallizing from petroleum ether or by distilling under reduced pressure. Sodium (1.15 g, 50.0 mmol) was dissolved in commercial absolute ethanol (500 mL) under an atmosphere of dry nitrogen and 1,4,7,10-tetrathiadecane (12) (5.38 g, 25.0 mmol) was added slowly. The mixture was refluxed for an additional 10 min and then to the refluxing mixture a solution of purified 2,5-bis(chloromethyl)thiophene (4.53 g, 25.0 mmol) in commercial absolute ethanol (200 mL) was added dropwise over 8 h with stirring. When the addition was complete, refluxing and stirring were continued for a further 4 h. Volatiles were removed on a rotary evaporator and the residue was taken up in CH_2Cl_2, washed with water several times, dried over anhydrous $CaCl_2$, filtered, and taken to dryness. Recrystallization from benzene and then $CHCl_3$ gave white crystals. Melting point 90–91°C. Yield 4.4 g (56%). Mass spectrum: parent ion = 322 $[C_{12}H_{18}S_5]^+$. Nuclear magnetic resonance ($CDCl_3$, ppm from TMS internal standard, assignments from $^{13}C-^1H$ heteronuclear correlation and attached proton test, position identification from Fig. 1), ^{13}C: 141.9 C1—C4, 126.2 C2—C3, 32.5 C8—C9, 31.8 C7—C10, 31.0 C5—C12, 30.9 C6—C11; ^1H: 6.85 (s, 2H) C2—C3, 3.93 (s, 4H) C5—C12, 2.66 (m, 4H) C6—C11, 2.58 (m, 4H) C7—C10, 2.53 (s, 4H) C8—C9.

(b) $[Ag_2(L3)_2][ClO_4]_2$

NOTE: *Perchlorate salts are often treacherously explosive (13) and although we have been unable to cause this compound to detonate from shock or heat we recommend suitable precautions be taken whenever perchlorates are handled.*

To a solution of $AgClO_4$ (0.052 g, 0.25 mmol) in acetonitrile (10 mL) was added a solution of L3 (0.080 g, 0.25 mmol) in dichloromethane (5 mL). The resulting solution was filtered immediately and the filtrate was left in a beaker to evaporate slowly, giving eventually white crystals that were collected by filtration, washed with acetonitrile, and dichloromethane and dried in air. Yield 1.0 g (80%), mp 175–178°C (dec). Infrared: (Nujol mull) 1413 (s), 1403 (s), 1370 (s), 1302 (w), 1252 (s), 1187 (sh), 1180 (w), 1150 (w), 1080 (vs), 1028 (s), 1000 (sh), 922 (sh), 906 (w), 898 (w), 880 (w), 862 (vw), 852 (w), 838 (m), 810 (s), 743 (sh), 720 (sh), 704 (s), 685 (w), 658 (vw), 642 (m), 619 (vs), 600 (w), 580 (w), 570 (w), 480 (w), 395 (vw), 350 (vw), 275 (w), 245 (s), 225 (s) cm^{-1}. *Anal.* calcd. for $C_{24}H_{36}Ag_2Cl_2O_8S_{10}$: C 27.18, H 3.42, Ag 20.36; found: C 27.22, H 3.41, Ag 19.16.

(c) $[Ag_2(L3)_2][X]_2$ ($X = BF_4$, CF_3SO_3)

A procedure similar to that above was followed giving yields of 72% (BF_4), mp 142–145°C (dec); 89% (CF_3SO_3), mp 177–180°C (dec). *Anal.* calcd. for $C_{24}H_{36}Ag_2B_2F_8S_{10}$: C 27.85, H 3.51, Ag 20.86; found: C 27.88, H 3.50, Ag 21.29; calcd. for $C_{26}H_{36}Ag_2F_6O_6S_{12}$: C 26.94, H 3.13, Ag 18.61; found: C 27.34, H 3.21, Ag 19.50.

Infrared spectra (Nujol mulls) are similar to that of the perchlorate

X-ray studies

A summary of crystal data for L3 and $[Ag_2(L3)_2][ClO_4]_2$ is given in Table 1. The diffraction intensities were collected at 295 K using the θ/2θ scan technique with profile analysis (14) at a scan speed of 4°/min. Three standards were measured after every 100 reflections and no significant crystal decay was detected. Space groups were determined by systematic absences. Unit cell parameters in Table 1 were obtained by a least-squares refinement of the setting angles for 25 reflections (91° ≤ 2θ ≤ 96°) for L3 and 25 reflections (90° ≤ 2θ ≥ 96°) for $[Ag_2(L3)_2][ClO_4]_2$. Lorentz and polarization factors were applied. Corrections were made for absorption in L3 but not in $[Ag_2(L3)_2][ClO_4]_2$.

The structures were solved with MULTAN (15) plus a difference Fourier map and refined by full-matrix least squares with counting statistics weights. H-atom positions were calculated but their parameters were not refined. All heavier atoms were refined anisotropically. All calculations were performed with the NRC VAX Crystal Structure programs (16). Scattering factors were taken from the usual source (17). The final atomic positional parameters, the equivalent isotropic temperature factors and important bond lengths and angles are listed in Tables 2–6. Anisotropic thermal parameters, a full listing of bond lengths and bond angles and final structure factors are available as supplementary data.[3] Figures 1 and 2 show views of the structures and their atomic numbering schemes.

Results and discussion

Synthesis of L3 was achieved in 56% yield by a high dilution S_N2 cyclization. Figure 1 suggests an open cavity in the macrocycle's center and the S—S distances of 5–7 Å across the cavity (Table 3) seem to confirm that suggestion making the cavity apparently suitable to accept one or more metal atoms. The solid state conformation, however, involves an exocyclic arrangement of the thioether sulfur lone pairs as is frequently found for simple thiocrown ligands (18). The exocyclic arrangement of lone pairs in thiocrowns is presumed to be due to a preference for *anti* arrangement of S—C—C—S systems as a result of steric and electronic effects (18). In L3, only 2/3 of the S—C—C—S systems have *anti* configurations but the ring still has exocyclic thioether lone pairs. In itself, this need not

necessarily preclude complex formation since orientation of the lone pairs with respect to each other is such that a metal atom could perch above the cavity by bonding to only some of the sulfur atoms. Approach to L3's cavity in its solid state conformation is, however, largely blocked by H atoms of the methylene groups. In addition to these conformational consequences, the rigidity of the thiophene subunit and its two attached methylenes keeps S2 and S5 (Fig. 1) well separated (6.92 Å) and projecting away from the plane of the thiophene ring. These two sulfurs are thus placed appropriately to coordinate to two different metal atoms except that their lone pairs are directed towards opposite sides of the macrocycle in the solid state conformation. Clearly, this molecule has considerable latent potential as a ligand but will only form complexes in which it is binucleating, or polydentate if

conformational change first occurs in its flexible thioether chain. In this respect L3 is similar to L1 and L2 (2).

Inspection of the structure of $[Ag_2(L3)_2]^{2+}$ (Fig. 2) reveals that the dinucleating capability of the ligand has been utilized with S2 and S5 of the ligand coordinating in the equatorial positions of two separate silver atoms. Pairs of thioether sulfurs

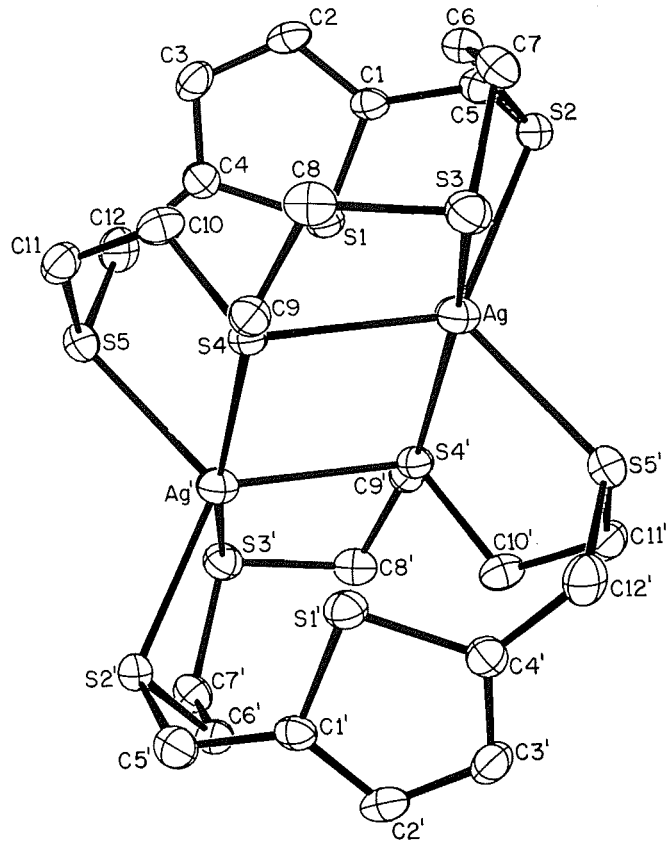

FIG. 2. ORTEP drawing of $[Ag_2(L3)_2]^{2+}$.

separated by two methylene groups are known (19) to have a tendency to form five-membered chelate rings with S—M—S bond angles close to 90°. Therefore, bearing in mind the total number of donors available the remainder of the available sulfur sites are poised for formation of trigonal–bipyramidal coordination about each silver atom. Conformational rearrangement in the thioether chain has occurred from C5 to C9 inclusive so that the lone pairs on the thioether sulfurs are oriented into the cavity towards the silver atoms. The dipositive complex cation (Fig. 2), which is centrosymmetric, consists of two silver atoms 4.082(3) Å apart (compared to 2.88 Å in metallic silver) and each is surrounded by a slightly distorted trigonal bipyramidal array of thioether sulfurs from two molecules of ligand. Neither ligand's thiophene sulfur is bonded to silver. The Ag—S (thiophene) distances are 3.7069(8) Å to the nearer thiophene and 3.9384(7) Å to the more distant one. The latter may be compared to 3.50 Å which is the sum of the van der Waals' radii (20). Sufurs S2 and S5 which hang below their thiophene's plane, bond to equatorial sites of separate silver atoms and one sulfur in each ligand (S4) bridges the two metals assuming an axial position with respect to one and an equatorial with respect to the other. The remaining two sites of a particular silver (an axial and an equatorial) are filled by adjacent sulfurs (S2 and S3) of one ligand so that a five-membered chelate ring with an S—Ag—S angle of 81.15(6)° is formed. The coordination sphere of each silver is distorted somewhat from idealized trigonal bipyramidal geometry. This is revealed most obviously by the S3—Ag—S4′ angle between axial positions which is 162.94(5)° instead of 180°. As a result, one equatorial-to-axial angle (S2—Ag—S4′) is also larger (115.79(6)°) than expected (90°). Each silver lies 0.62 Å out of the plane defined by the three equatorial S-donors and is part of three five-membered chelate rings with angles at Ag of 81.15(6), 82.31(5), and 76.35(5)°. These represent half the axial-to-equatorial angles about each silver. The other half involves a further three inter-ligand S—Ag—S angles, one of which (S4—Ag—S4′ = 86.55(5)°) is part of the Ag_2S_2 bridging system and two of which (S5′—Ag—S3 = 99.37(6); S2—Ag—S4′ = 115.79(6)°) are not part of a ring and so are relatively free to open as required to relieve any stereochemical strain.

The Ag—S lengths with an average of 2.695 Å and a range of 2.564–2.995 Å are comparable to those in other Ag(I) thioether complexes (7, 8). They show the usual slight (~11%) lengthening of average axial over average equatorial distances but the axial Ag—S4′ length is significantly longer (0.245 Å) than the other axial bond length (Ag—S3), presumably because S4′ is bridging whereas S3 is terminal and also because it reduces interaction of a hydrogen on C9 with S1′ of the other ligand.

Characterizing the cation by methods other than X-ray diffraction is difficult since most conventional spectroscopic techniques give no indication of its dinuclear nature. Fast atom bombardment mass spectroscopy has been applied to non-volatile thermally fragile organometallics (21) and we had hoped to apply it successfully to detect $[Ag_2(L3)_2]^{2+}$. The

spectrum finally obtained, however, consisted of two peaks of equal intensity with m/e = 429 and 431 corresponding to ions containing ^{107}Ag (51.8% relative abundance) and ^{109}Ag (48.2% relative abundance), respectively. These values of m/e and the relative peak intensities are consistent with $[Ag(L3)]^+$ from cleavage of the dinuclear cation into two monomer fragments. It is of interest to note that no spectrum was obtained when the matrix was glycerol and only when *p*-toluenesulfonic acid was added to the matrix was a spectrum of the complex silver cation detected. It seems reasonable to speculate, therefore, that the role of the acid is to add a proton to the anion of the silver salt, thereby freeing the complex cation so that it may be accelerated from the source into the mass-analyzing sections of the spectrometer.

Although the dimer cleaves in the mass spectrometer it is surprisingly robust under normal chemical conditions. For example, unlike macrocyclic polynitrogen ligand complexes and many other Ag(I) salts, crystalline samples or solutions in benzonitrile of the perchlorate salt can be subjected to uv radiation from a 100 W Hanovia lamp for 24 h with no sign of darkening. Stirred aqueous suspensions of the perchlorate salt containing sodium thiosulfate, ammonia or hydrochloric acid show no reaction after several hours and even a heated solution in benzonitrile of the perchlorate salt and *p*-thiocresol shows only limited reaction after 24 h. In contrast, solutions of the ion seem highly reactive in the presence of a base such as pyridine. For example, when pyridine is added to the unreactive solutions of *p*-thiocresol and $[Ag_2(L3)_2][ClO_4]_2$, a yellow precipitate of $(AgSC_6H_4CH_3)_n$ is formed rapidly in 93% yield. This insoluble mercaptide was identified by elemental analysis, and by its ir spectrum which is devoid of any bands attributable to L3 but contains bands typical of *p*-thiocresol.

It has been observed that coordinated thioethers generally stabilize low oxidation states (22). Exceptions (8) have been attributed to special geometric considerations or in complexes having large coordination numbers to high electron density on silver which should make oxidation relatively easy. Following this reasoning, we attempted unsuccessfully to oxidize the perchlorate salt by both chemical and electrochemical means. Use of ceric ammonium nitrate in methanol caused precipitation of a solid which appears to be the less soluble nitrate salt of $[Ag_2(L3)_2]^{2+}$ while electrochemical oxidation of an acetonitrile solution using a saturated calomel reference electrode gave a precipitate of silver chloride. This result stands in contrast to the inertness to chloride mentioned previously and may be a consequence of the special geometric requirements of the ligand. For example silver(II) is usually found in square or distorted octahedral environments as expected for a d^9 system. Either of these geometries would be difficult to attain from the distorted trigonal bipyramidal structure of $[Ag_2(L3)_2]^{2+}$ due to the rigidity of the thiophenophane. Thus, attempted oxidation could lead to destruction of the dinuclear complex and release of one or more silver(I) ions that would precipitate as AgCl. It would appear therefore that the special geometric requirements of L3 stabilize Ag(I). Thus, unlike cyclam which promotes disproportionation to Ag(0) and Ag(II) (23, 24) or 1,4,7-trithiacyclononane (8) which provides a coordination sphere compatible with both Ag(I) and Ag(II), leading to reversible oxidation of low electrochemical potential for its Ag(I) complex. The ligand L3 provides a coordination geometry particularly favourable to Ag(I) thereby stabilizing that oxidation state.

Synthetic applications and spectroscopic investigations of the $(NSCl)_3$–SO_2Cl_2 system

ALLEN APBLETT and TRISTRAM CHIVERS[1]
Department of Chemistry, The University of Calgary, Calgary, Alta., Canada T2N 1N4

Received June 22, 1989

ALLEN APBLETT and TRISTRAM CHIVERS. Can. J. Chem. **68**, 650 (1990).

Solutions of $(NSCl)_3$ in the presence of excess SO_2Cl_2 behave as a source of the synthetic equivalent "$NSCl_3$" in reactions with methacrylonitrile or thioacetamide to give 4-cyanoisothiazole (78%) or 5-methyl-1,3,2,4-dithiadiazolium chloride (63%), respectively. In the reaction of this reagent with thiobenzamide both 5-phenyl-1,3,2,4-dithiadiazolium chloride (42%) and 3,5-diphenyl-1,2,4-thiadiazole (51%) are produced. The treatment of the $(NSCl)_3$–SO_2Cl_2 system with 2-aminobenzenethiol yields 2,4-$C_6H_3Cl_2NSCl_2$, which is converted to 2,4-$(C_6H_3Cl_2N)_2S$ upon heating at 80°C in toluene or by reduction with Ph_3Sb or mercury. The reaction of 2-aminobenzenethiol with excess SO_2Cl_2, in the absence of $(NSCl)_3$, produces 2,4,6-$C_6H_2Cl_3NSCl_2$. Attempts to characterize the active species in the $(NSCl)_3$–SO_2Cl_2 system by ^{14}N and ^{33}S nmr, Raman and infrared spectroscopy are also described.

Key words: cyclotrithiazyl chloride, isothiazole, dithiadiazolium, arylimidosulfurous dichloride, ^{14}N nmr.

ALLEN APBLETT et TRISTRAM CHIVERS. Can. J. Chem. **68**, 650 (1990).

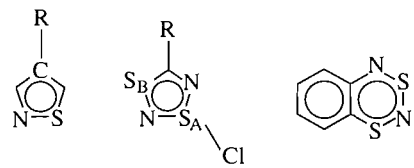
En présence d'un excès de SO_2Cl_2, les solutions de $(NSCl)_3$ se comportent comme une source de "$NSCl_3$" et elles réagissent avec le méthacrylonitrile ou le thioacétamide pour donner respectivement le 4-cyanoisothiazole (78%) et le chlorure de 5-méthyl-1,3,2,4-dithiadiazolium (63%). Lors de la réaction de ce réactif avec le thiobenzamide, il se forme du chlorure de 5-phényl-1,3,2,4-dithiadaizolium (42%) ainsi que du 3,5-diphényl-1,2,4-thiadiazole (51%). Lorsqu'on soumet le 2-aminobenzénethiol au système $(NSCl)_3$–SO_2Cl_2, on obtient du 2,4-$C_6H_3Cl_2NSCl_2$ qui se transforme en 2,4-$(C_6H_3Cl_2N)_2S$ lorsqu'on le chauffe à 80°C dans le toluène ou qu'on le réduit par le Ph_3Sb ou le mercure. La réaction du 2-aminobenzènethiol avec un excès de SO_2Cl_2, en l'absence de $(NSCl)_3$, il se forme du 2,4,6-$C_6H_2Cl_3NSCl_2$. On décrit aussi les essais qui ont été effectués pour caractériser, à l'aide de la rmn du ^{14}N et du ^{33}S ainsi que par les spectroscopies infrarouge et Raman, les espèces actives du système $(NSCl)_3$–SO_2Cl_2.

Mots clés : chlorure de cyclotrithiazyle; isothiazole; dithiazolium; dichlorure d'arylimidosulfureux; rmn du ^{14}N.

[Traduit par la revue]

Introduction

Compounds of the type NSX_3 (X = halogen) are potentially useful reagents for the synthesis of carbon–nitrogen–sulfur heterocycles in cyclocondensation reactions with appropriate organic substrates. Reactions of this type have not been reported, however, for the kinetically and thermodynamically stable molecule NSF_3 (1). We have observed that solutions of $(NSCl)_3$ in the presence of excess SO_2Cl_2 behave as the reagent "$NSCl_3$" in reactions with methacrylonitrile or thioacetamide to give 4-cyanoisothiazole, **2** (R = CN), and 5-methyl-1,3,2,4-dithiazolium chloride, **3***a*, respectively, in good yields (2).[2] This direct synthesis of **2** (R = CN) is a marked improvement over the usual four-step synthesis from the parent ring system (3). Consequently we have investigated the generality of this route to **2**. The preparation of **3***a* from "$NSCl_3$" provides an alternative to the cycloaddition of $NS_2^+AsF_6^-$ to organic nitriles (4) for the synthesis of the 1,3,2,4-dithiazolium ring and produces soluble products. We have now extended this approach to the synthesis of **3***b* from thiobenzamide and "$NSCl_3$". The reaction of 2-aminobenzenethiol with "$NSCl_3$" has also been examined as a possible route to benzo-1,3-dithia-2,4-diazine, **4**, (5). Mechanisms are proposed to rationalize the formation of **2** and **3** in cyclocondensation reactions of methacrylonitrile or thioamides, respectively, with "$NSCl_3$". Attempts to characterize the active species in "$NSCl_3$" solutions by infrared, Raman, and ^{14}N, ^{17}O, and ^{33}S nmr spectroscopies are also described.



2 **3***a* (R = Me) **4**
3*b* (R = Ph)

Experimental

Reagents and general procedures

All experimental procedures were performed under an atmosphere of dry nitrogen. Solvents were dried by heating at reflux with the appropriate drying agent and then distilled before use.

The following reagents were commercial products used as received: methacrylonitrile, methacrolein, methyl methacrylate, 2-chloropropene, thioacetamide, thiobenzamide, 2-aminobenzenethiol, and triphenylantimony (all from Aldrich) and mercury (Fisher). SO_2Cl_2 (Aldrich) was distilled before use. $(NSCl)_3$ was prepared from $S_3N_2Cl_2$ by a modification of the literature procedure (6). After the second chlorination of $S_3N_2Cl_2$, the crude $(NSCl)_3$ was ground to a powder and a third chlorination with Cl_2 was followed by the addition of sufficient SO_2Cl_2 to cover the solid product. This mixture was stirred for 12 h and then volatile products were removed *in vacuo* to give pure $(NSCl)_3$ mp 91°C (cf. lit. (7) mp 92°C).

Instrumentation

Infrared spectra (4000–400 cm^{-1}) were recorded as Nujol or Fluorolube mulls (CsI windows) on a Nicolet 5DX FT-IR spectrophotometer. Ultraviolet–visible spectra were obtained by using a Cary 219 spectrophotometer and cuvettes which were sealed with rubber septa. Mass spectra were measured on a Kratos MS80RFA instrument (EI/70 eV).

Experimental details for the measurement of Raman spectra have been described (8). In this work the spectra were obtained at *ca.* 25°C by using exciting radiation at 514.5 nm and a laser power of 300 mW.

^1H and ^{13}C nmr spectra were obtained on a Bruker ACE 200 spectrometer and chemical shifts are reported relative to Me_4Si in $CDCl_3$. All other nmr spectra were obtained on a Bruker AM-400 narrow bore nmr spectrometer operating in the FT mode at a frequency of 28.915 MHz for ^{14}N, 54.244 MHz for ^{17}O, and 30.690 MHz for ^{33}S, using a 10 mm broad-band probe. Conditions for acquisition of ^{14}N nmr spectra were a 90° pulse, a sweep width of 30 000 Hz, 4K data points and a recycle time of 0.07 s. Those for ^{17}O nmr spectra were a 90° pulse, a sweep width of 84 000 Hz, 4K data points and a recycle time of 0.025 s, while a 90° pulse, a sweep width of 50 000 Hz, 2K data points, and a recycle time of 0.02 s were utilized for ^{33}S nmr spectra. A dead time of 100 μS was used in all cases in order to negate the effects of probe ringing and all FIDs were zero filled to 16K prior to transformation. Sufficient scans were collected in order to obtain a signal-to-noise ratio of at least 100 to one. Samples were sealed under a dry nitrogen atmosphere in 10 mm Pyrex tubes equipped with Teflon-lined screw-caps. ^{14}N, ^{17}O, and ^{33}S nmr chemical shifts are reported relative to $MeNO_2$(l), H2O(l), and SO_4^{2-}(aq.), respectively.

Chemical analyses were performed by the Analytical Services Division, Department of Chemistry, The University of Calgary, and by Canadian Microanalytical Service, New Westminster, B.C.

Generation of "$NSCl_3$"

The reagent "$NSCl_3$" was generated for synthetic applications by the addition of at least a ten-fold excess of SO_2Cl_2 to a solution of $(NSCl)_3$ in CH_2Cl_2 or $CHCl_3$. This solution was stirred for at least 1 h prior to the addition of the other reactant.

Preparation of 4-cyanoisothiazole

Methacrylonitrile (0.67 g, 10 mmol) was added via syringe to a solution of $(NSCl)_3$ (0.81 g, 3.33 mmol) in chloroform (25 mL) and SO_2Cl_2 (10 mL). The reaction mixture was heated at reflux for 16 h. Volatile materials were removed under vacuum to give an orange–red residue from which colorless crystals of 4-cyanoisothiazole (0.86 g, 7.8 mmol) mp 95°C were obtained by sublimation at 50°C/0.1 Torr. *Anal.* calcd. for $C_4H_2N_2S$: C 43.62, H 1.83, N 25.44; found: C 43.74, H 1.85, N 25.51. *Mol. wt.* calcd. for $C_4H_2N_2S$: 109.9939; found (ms): 109.9930. Preparation of 5-methyl-1,3,2,4-dithiadiazolium chloride

Thioacetamide (2.66 g, 35.4 mmol) was added rapidly to a solution of $(NSCl)_3$ (2.86 g, 11.8 mmol) in $CHCl_3$ (25 mL) and SO_2Cl_2 (10 mL). An immediate reaction occurred with the slow evolution of HCl and SO_2 and the solution became orange. The reaction mixture was heated at 60°C for 16 h and then volatile materials were removed under vacuum to give an orange–red oil. The addition of acetonitrile (15 mL) produced 5-methyl-1,3,2,4-dithiadiazolium chloride (2.85 g, 18.6 mmol) as an orange solid mp 210°C (dec.). A second crop (0.58 g, 3.8 mmol) was obtained by the addition of diethyl ether (50 mL) to the filtrate. *Anal.* calcd. for $C_2H_3ClN_2S_2$: C 15.53, H 1.96, N 18.12, found: C 15.44, H 2.14; N 18.28. ^1H nmr ($CDCl_3$) δ: 1.22. ^{14}N nmr (acetone): −271, −286 ppm. Mass spectroscopy: *m/e* (relative intensity > 20%): 119(M^+ − Cl,20), 78(NS_2^+,50), 73(MeCNS$^+$,25), 46(NS^+,25). Preparation of 5-phenyl-1,3,2,4-dithiadiazolium chloride

Thiobenzamide (1.37 g, 10 mmol) was added to a stirred solution of $(NSCl)_3$ (0.81 g, 3.33 mmol) in CH_2Cl_2 (30 mL) and SO_2Cl_2 (10 mL). The solution immediately became orange and there was a slow evolution of gas. The reaction was stirred for 36 h at 23°C and then volatile materials were removed under vacuum to give a yellow–orange solid from which 3,5-diphenyl-1,2,4-thiadiazole (0.61 g, 2.55 mmol) mp 88°C (lit. (9) 90°C) was obtained by sublimation at 70°C/10^{-1} Torr. *Anal.* calcd. for $C_{14}H_{10}N_2S$: C 70.56, H 4.23, N 11.76; found: C 70.59, H 4.32, N 11.80. ^{14}N nmr (CH_2Cl_2) δ: −86, −124 ppm. Mass spectroscopy: *m/e* (%), 238(20) ($C_6H_5)_2C_2N_2S^+$, 135(100) $C_6H_5CNS^+$, 103(30) $C_6H_5CN^+$, 77(25) $C_6H_5^+$. The residue after sublimation was recrystallized from acetonitrile (20 mL) to give 5-phenyl-1,3,2,4-dithiadiazolium chloride (0.91 g, 4.2 mmol) mp 169°C. *Anal.* calcd. for $C_7H_5ClN_2S_2$: C 38.79; H 2.32; N 12.92; S 29.59; found: C 39.26; H 2.30, N 12.79, S 29.60. ^{14}N nmr (acetone) −277 ppm. Mass spectroscopy: *m/e* (relative intensity > 20%): 181 (M^+ − Cl,80), 135 ($C_6H_5CNS^+$,50), 103 ($C_6H_5CN^+$,50), 78 (NS_2^+,95), 46 (NS^+,55). Infrared (Nujol): 1599 m, 1397 s, 1151 s, 1031 m, 923 s, 889 s, 844 s, 783 s, 698 vs, 547 s cm^{-1}.

Reaction of 2-aminobenzenethiol with "$NSCl_3$"

A solution of 2-aminobenzenethiol (2.50 g, 20 mmol) in CH_2Cl_2 (10 mL) was added rapidly by syringe to a solution of $(NSCl)_3$ (1.63 g, 6.66 mmol) in CH_2Cl_2:SO_2Cl_2 (1:1, 60 mL) at −78°C. A strongly exothermic reaction occurred to give a dark red–black solution with the evolution of HCl. The reaction mixture was stirred and allowed to reach 20°C slowly (16 h). Volatile materials were removed under vacuum to give a reddish black oil, which was extracted with *n*-hexane (100 mL). The hexane solution was cooled to −30°C for 72 h to give yellow–orange needles of 2,4-dichlorophenylimidosulfurous dichloride (1.49 g, 5.6 mmol) mp 81°C (lit. (10) mp 78–80°C). A second crop (0.92 g, 2.4 mmol) was obtained by reducing the volume of the filtrate to *ca.* 25 mL and cooling this solution to −30°C. *Anal.* calcd. for $C_6H_3Cl_4NS$: C 27.40, H 1.15, N 5.53, S 12.19, Cl 53.93; found: C 27.58, H 1.20, N 5.38, S 11.85, Cl 53.51. ^{14}N nmr (CH_2Cl_2): −160 ppm, $\nu_{1/2}$ 605 Hz. Mass spectroscopy: *m/e* (relative intensity > 20%): 226(M^+ −Cl,50), 191(M^+ − 2Cl,100), 156(M^+ − 3Cl,80), 145($C_2H_3Cl_2^+$,40), 124($C_6H_3ClN^+$,95), 109($C_6H_2Cl^+$,75), 46(NS^+,60), 36(HCl^+,60). Infrared (Nujol): 1569 m, 1555 m, 1387 m, 1359 s, 1119 vs, 1102 s, 1047 m, 1018 m, 871 vs, 827 s, 813 vs, 701 m, 684 s, 634 s, 549 m, 425 vs, 400 vs cm^{-1}.

Reaction of 2-aminobenzenethiol with SO_2Cl_2

The procedure and observations were as described above for the reaction with "$NSCl_3$" except that no $(NSCl)_3$ was present and 2.00 g (16.0 mmol) of 2-aminobenzenethiol was used. The extraction of the crude product with *n*-hexane (150 mL) followed by cooling of this solution to −30°C produced yellow needles of 2,4,6-trichlorophenylimidosulfurous dichloride (1.70 g, 5.7 mmol) mp 56°C (lit. (10) mp 58°C) ^{14}N nmr (CH_2Cl_2): −167 ppm, $\nu_{1/2}$ 745 Hz. *Anal.* calcd. for $C_6H_2Cl_5NS$: C 24.23, H 0.68, N 4.71; found: C 24.30, H 0.74, N 4.77.

Preparation of bis(2,4-dichlorophenyl)sulfur diimide

(a) By reaction of 2,4-dichlorophenylimidosulfurous dichloride with mercury

Aliquots of mercury (0.25 g, 1.25 mmol) were added to a solution of 2,4-$Cl_2C_6H_3NSCl_2$ (0.66 g, 2.5 mmol) in CH_2Cl_2 (3 mL) in a 10 mm nmr tube. After each addition the tube was shaken vigorously and an ^{14}N nmr spectrum was recorded. The resonance at −160 ppm for 2,4-$Cl_2C_6H_3NSCl_2$ was gradually replaced by a new resonance at −89 ppm, $\nu_{1/2}$ 1300 Hz. The reaction was complete after the addition of four aliquots mercury (1.00 g, 5.0 mmol). The red solution was then filtered to remove Hg_2Cl_2 (1.12 g, 2.4 mmol) and the solvent was removed under vacuum to give a red solid, which was recrystallized from acetonitrile (5 mL) to give red filamentous crystals of bis(2,4-dichlorophenyl)sulfur diimide (0.40 g, 1.1 mmol) mp 133°C. *Anal.* calcd. for $C_{12}H_6Cl_4N_2S$: C 40.94, H 1.72, N 7.96, S 9.10, Cl 40.28; found: 40.42, H 1.56, N 7.92, S 9.27, Cl 41.05. Mass spectroscopy: *m/e* (relative intensity > 20%) 350(M^+,10), 315(M^+ − Cl,40), 191($C_6H_3Cl_2NS^+$,80), 159($C_6H_3Cl_2N^+$,100), 124($C_6H_3ClN^+$,35). Infrared (Nujol): 1599 m, 1300 s (ν_{as} NSN), 1150 m, 1102 vs (ν_s NSN), 1089 s, 818 vs, 722 s cm^{-1}.

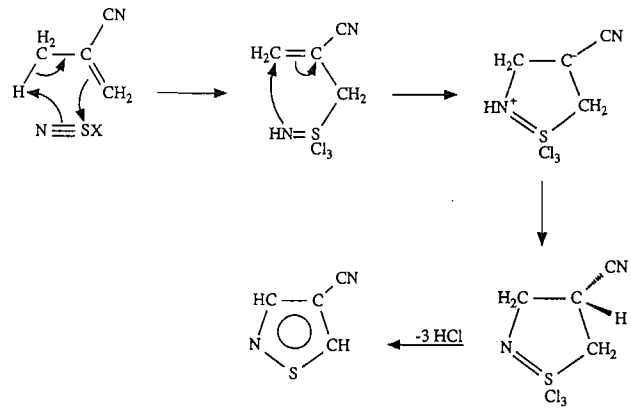

FIG. 1. Proposed mechanism for the reaction of methacrylonitrile with "$NSCl_3$".

(b) By thermolysis of 2,4-dichlorophenylimidosulfurous dichloride

A solution of 2,4-$Cl_2C_6H_3NSCl_2$ (0.50 g, 1.9 mmol) in toluene (3 mL) in a 10 mm nmr tube sealed with a Teflon-lined screwcap was heated at 80°C for 12h. The ^{14}N nmr spectrum indicated complete conversion to (2,4-$Cl_2C_6H_3$)NSN($C_6H_3Cl_2$-2,4) ($\delta(^{14}N)$ −92 ppm), which was obtained as an orange–red solid (0.32 g, 0.91 mmol) upon removal of solvent and volatile products (SCl_2 and Cl_2) under vacuum. The ir spectrum of this product was identical to that of an authentic sample prepared by procedure (*a*).

Results and discussion

Preparation of 4-cyanoisothiazole by the reaction of "$NSCl_3$" with methacrylonitrile[2]

Methacrylonitrile reacts with "$NSCl_3$" in chloroform to give 4-cyanoisothiazole, **2** (R = CN), in 78% yield. The reaction formally involves a triple cyclocondensation with the loss of three moles of HCl. The proposed mechanism in shown in Fig. 1. The first step is an ene reaction, which involves abstraction of an allylic proton with concurrent nucleophilic attack of the >C=C< bond on the sulfur atom of "$NSCl_3$"). An ene reaction has previously been postulated to explain the formation of an isothiazole from cholesteryl acetate and $(NSCl)_3$ in the presence of pyridine (11). In the present case the involvement of "$NSCl_3$" (i.e. X = Cl_3 in Fig. 1) rather than NSCl in the ene reaction is proposed because the reaction of methacrylonitrile with NSCl *in the absence of a chlorinating agent* produces mainly $[S_4N_3]Cl$. The second step is an intramolecular Michael addition to give a five-membered ring. The subsequent loss of three moles of HCl yields 4-cyanoisothiazole.

Attempts to extend this method to the synthesis of other 4-substituted isothiazoles bearing electronegative substituents were unsuccessful. The reaction of 2-chloropropene with "$NSCl_3$" gave a complex mixture of products which exhibited ^{14}N nmr resonances in the region −320 to −360 ppm indicative of amines (12). By contrast the reaction of methacrylonitrile with "$NSCl_3$" produced only a small amount of amine. The addition of methacrolein or methyl methacrylate to "$NSCl_3$" produced an exothermic reaction, but ^{14}N nmr spectroscopy indicated very little consumption of the sulfur–nitrogen reagent. Thus these alkenes appear to react preferentially with SO_2Cl_2.

Reactions of "$NSCl_3$" with thioamides

The cyclocondensation of "$NSCl_3$" with thioacetamide or thiobenzamide yields 5-methyl- or 5-phenyl-1,3,2,4-dithiadiazolium chloride, **3***a* or **3***b*, in 68% and 42% yields, respectively. The yield of **3***b* is lower due to a competing reaction between thiobenzamide and SO_2Cl_2 to give 3,5-diphenyl-1,2,4-thiadiazole, which can also be prepared by treatment of thiobenzamide with iodine (9). The cyclocondensation reaction of thioamides with "$NSCl_3$" formally involves the evolution of 2 mol of HCl and a possible reaction scheme is given in Fig. 2.

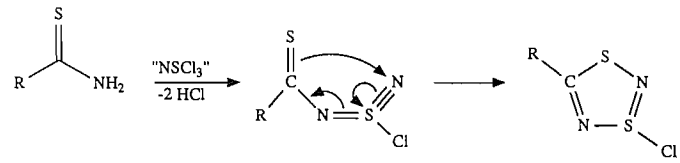

FIG. 2. Proposed mechanism for the reaction of thioamides with "$NSCl_3$".

The compounds **3***a* and **3***b* exhibit characteristic mass spectra in which the $\overline{RCNSNS}^+$ cation undergoes two major fragmentation pathways involving either the loss of NS^+ (and RCNS) or NS_2^+ (and RCN). The reverse of the second process, i.e. cycloaddition of NS_2^+ with organic nitriles, has been used for the preparation of cations of the type $\overline{RCNSNS}^+$ (4). The ir and ^{14}N nmr spectra of **3***a* and **3***b* are sufficiently different from those of the corresponding AsF_6^- salts (4) to propose a covalent structure for **3***a* and **3***b*. This contention is supported by the solubility of **3***a* and **3***b* in non-polar organic solvents and the observation of strong bands at 535 and 547 cm^{-1} in the ir spectra of **3***a* and **3***b*, respectively, attributable to ν(S—Cl). In a covalent structure the chlorine atom in **3** can be attached to either S_A or S_B. Since the sulfur atom between the two nitrogens should bear the higher positive charge in the cation, the chlorine atom is probably attached to S_A in **3***a* and **3***b*. By contrast, 4-phenyl-1,2,3,5-dithiadiazolium chloride, a structural isomer of **3***b*, is insoluble in non-polar solvents and is assumed to have an ionic structure (13). Attempts to obtain crystals of **3***a* or **3***b* suitable for an X-ray structural determination have been unsuccessful.

Reaction of 2-aminobenzenethiol with "$NSCl_3$"

Benzo-1,3-dithia-2,4-diazine, **4**, has been obtained as deep blue crystals in low yield by the reaction of $PhNSNSiMe_3$ with SCl_2 in a 1:1 molar ratio (5). We have investigated the reaction of 2-aminobenzenethiol with the trifunctional reagent "$NSCl_3$" as an alternative route to **4**. However, this approach produces an orange solid with the empirical formula $C_6H_3NSCl_4$ on the basis of C, H, N, S, and Cl analyses. ^{13}C and ^{13}C DEPT nmr spectroscopy established that the aromatic ring consists of three quaternary (δ 137.3, 134.6, and 131.0 ppm) and three tertiary carbon atoms (δ 130.0, 128.0 and 121.7 ppm). Thus the substitution of one of the hydrogen atoms on the original C_6H_4 ring has occurred. A similar electrophilic aromatic substitution takes place at the position *para* to the amino group in the reaction of aniline with S_2Cl_2 (14). Since the reduction of the orange solid with Ph_3Sb or Hg shows that only two of the chlorine atoms are labile (*vide infra*), this product is identified as 2,4-dichlorophenylimidosulfurous dichloride, **5**. This compound was previously prepared by the reaction of 2,4-$C_6H_3Cl_2NSO$ with PCl_5 (10), but the only characterization reported was the mp.

Compound **5** exhibits a single line at −160 ppm in the ^{14}N nmr spectrum (lit. (16) $\delta(^{14}N)$ $C_6F_5NSCl_2$, −112 ppm). A band at 1110 cm^{-1} in the ir spectrum of $ClSO_2NSCl_2$ has been assigned to the S=N stretching frequency and the asymmetric and symmetric SCl_2 stretching vibrations occur at 548 and 440 cm^{-1}, respectively (15). The corresponding ir absorptions for **6**

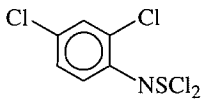
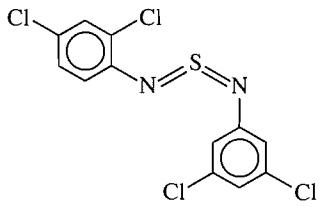
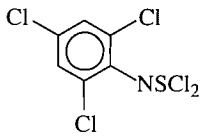
For personal use only.



5



6



7

are observed at 1119, 549, and 426 cm^{-1}. The latter two bands disappear upon reduction of **5** with Ph_3Sb or mercury to give bis(2,4-dichlorophenyl)sulfur diimide, **6**, which exhibits a singlet in the ^{14}N nmr spectrum at −89 ppm (lit. (12) $\delta(^{14}N)$ ArNSNAr, −83 to −120 ppm). It is likely that the reduction of **5** occurs via a thionitrosoarene (eq. [1]), which dimerizes with loss of sulfur in the absence of a trapping agent (16). The observed thermolysis of **5** at 80±C in toluene to give **6** is in contrast to the previously reported thermal decomposition of $RCONSCl_2$ to yield acyl chlorides and NSCl (17).

$$[1]\quad 2ArNSCl_2 \xrightarrow[-2HgCl_2]{2Hg} 2[ArNS] \xrightarrow{-S} ArNSNAr$$

The production of **5** from 2-aminobenzenethiol does not involve the incorporation of additional sulfur or nitrogen. This suggests that **5** is formed by the reaction of 2-aminobenzenethiol with SO_2Cl_2. In fact, we found that this reaction produces the known compound 2,4,6-$C_6H_2Cl_3NSCl_2$, **7**, (10) in 36% yield. The C_2 symmetry of this product is demonstrated by ^{13}C and ^{13}C DEPT nmr spectroscopy, which reveals a single resonance for the two tertiary carbon atoms at 128.7 ppm and three signals for quaternary carbons at 130.2(2C), 133.6(1C) and 135.1(1C). The ^{14}N nmr spectrum exhibits a single resonance at −167 ppm.

A possible sequence for the formation $ArNSCl_2$ from 2-aminobenzenethiol and SO_2Cl_2 is shown in Fig. 3. The initial steps involve the well known oxidation of an aromatic thiol to an arylsulfur trichloride in the presence of excess chlorinating agent (18) followed by an intramolecular cyclocondensation reaction.[3] It is not known at which point the chlorination of the aromatic ring occurs or how the presence of NSCl limits the extent of chlorination.

Spectroscopic characterization of "$NSCl_3$"

Two isomers, **1***a* and **1***b*, are possible for molecules involving a sulfur–nitrogen multiple bond and three substituents. The isomer $FNSF_2$ (**1***b*, X = Y = Z = F) has been identified (19), but it is thermodynamically less stable than NSF_3 (**1***a*, X = Y = Z = F) by *ca.* 64 kJ mol^{-1} according to *ab initio* SCF calculations (20). Surprisingly, NSF_2Cl (**1***a*, X = Cl; Y = Z = F) is unknown, but the isomer $ClNSF_2$ (**2**, X = Cl; Y = Z = F) is obtained either by the reaction of $Hg(NSF_2)_2$ with Cl_2 (21) or by the treatment of NSF with chlorine monofluoride in the gas phase (22). By contrast, the addition of ClF to NSCl gas produces NSF, presumably by elimination of Cl_2, rather than **1***a* or **1***b* (X = Y = Cl; Z = F) (22). The molecule $NSCl_3$ has not been

[3]Alternatively, the cyclocondensation could occur via an intermolecular process.

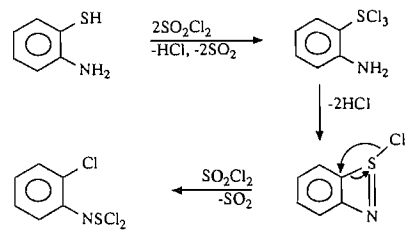


FIG. 3. The formation of an arylimidosulfurous dichloride from 2-aminobenzenethiol and SO_2Cl_2.

characterized in either of the isomeric forms, **1***a* or **1***b* (X = Y = Z = Cl), and *ab initio* SCF calculations indicate that the former isomer is thermodynamically unstable with respect to NSCl + Cl_2, but kinetically stable at low temperatures (20).

Passmore and Schriver have established by ^{14}N nmr spectroscopy that NSCl monomer is formed via dissociation of $(NSCl)_3$ in solution and that the extent of this dissociation depends on the temperature, the nature of the solvent, and the purity of $(NSCl)_3$ (7).

$$[2]\quad (NSCl)_3 \rightleftharpoons 3NSCl$$

We have used ^{14}N nmr and ir spectroscopy in an attempt to detect the formation of **1***a* or **1***b* in solutions of $(NSCl)_3$ in the presence of an excess of a chlorinating agent, e.g. SO_2Cl_2, $PhICl_2$, or Cl_2. The ^{14}N nmr spectrum of a pale green solution of $(NSCl)_3$ in $CDCl_3$ (*ca.* 0.1 *M*) at 25°C shows a dominant resonance at −261 ppm, $\nu_{1/2}$ 380 Hz (lit. (23) $\delta(^{15}N)$ $(NSCl)_3$ in $CHCl_3$, −261.5 ppm) and a very weak resonance (<5%) at 339 ppm attributed to NSCl (lit. (7) $\delta(^{14}N)$ NSCl (in CCl_4) 348–352 ppm, $\nu_{1/2}$ 70–80 Hz; $\delta(^{14}N)$ NSCl (in SO_2) 323 ppm, $\nu_{1/2}$ 60 Hz).[4] The addition of an excess of SO_2Cl_2 to this solution causes the growth of the resonance of *ca.* 339 ppm ($\nu_{1/2}$ 100 Hz) and a concomitant decrease in the intensity of the resonance due to $(NSCl)_3$. Similar behaviour was observed when $PhICl_2$ was used as the chlorinating agent. No other resonances are apparent in the ^{14}N nmr spectra except that of dissolved N_2 at −71 ppm (24). When "$NSCl_3$" solutions (*ca.* 0.005 *M* $(NSCl)_3$ in pure SO_2Cl_2 or a 50:50 mixture of SO_2Cl_2 and $CDCl_3$ or CH_2Cl_2) are cooled to −50°C the narrow resonance at 339 ppm is replaced by broader resonances at −148 and −261 ppm ($(NSCl)_3$). The former is well outside the range of chemical shifts (135–350 ppm) observed for triply bonded sulfur–nitrogen species (7, 8) but much closer to that of $ClNSF_2$, **1***b* (X = Cl; Y = Z = F) (lit. (25) $\delta(^{14}N)$ −232). Thus the −148 ppm resonance may be due to $ClNSCl_2$, **1***b* (X = Y = Z = Cl).[5] A saturated solution of $(NSCl)_3$ in liquid chlorine exhibits ^{14}N nmr spectra similar to those observed for SO_2Cl_2 solutions except for the appearance at 25°C of a weak resonance at −176 ppm in addition to the resonance for NSCl at 337 ppm. At −50°C the latter resonance disappears, while that at −176 ppm is much stronger. This resonance may be due to $ClNSCl_2$ shifted as a result of solvent effects (cf. NSCl (7)).

The ir spectrum of a solution of $(NSCl)_3$ in SO_2Cl_2 at 23°C exhibits bands at 1338 and 1331 cm^{-1}. The molecules SO_2 (ν_3 of SO_2 in H_2O occurs at 1332 cm^{-1} (27)) and NSCl (ν(SN) in CS_2 occurs at 1322 cm^{-1} (28)) are possible sources of these vibra-

[4]Although it is common practice to quote $\nu_{1/2}$ values for ^{14}N nmr signals, it should be noted that these values are dependent on factors such as temperature and solvent viscosity.

[5]A change of 135 ppm in the ^{14}N nmr chemical shift is observed in going from $C_6F_5NSF_2$ to $C_6F_5NSCl_2$ (26).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

tions, but definite assignments cannot be made. The Raman spectra of solutions $(NSCl)_3$ in SO_2Cl_2 or liquid Cl_2 did not reveal the presence of S—N species other than NSCl or $(NSCl)_3$.

Both ^{33}S and ^{17}O nmr spectroscopy provide evidence for the formation of SO_2 in solutions of $(NSCl)_3$ in the presence of an excess of SO_2Cl_2. In the ^{33}S nmr spectrum a solution of $(NSCl)_3$ in CH_2Cl_2 exhibits a signal at 252 ppm ($\nu_{1/2}$ 950 Hz) for NSCl, but the resonance for $(NSCl)_3$ is too broad to be observed. The addition of SO_2Cl_2 to this solution causes a shift of the NSCl signal to 258 ppm and the appearance of resonances of −44 ($\nu_{1/2}$ 665 Hz) and 369 ppm attributed to SO_2Cl_2 (lit. (39) −45 ppm) and SO_2 (lit. (39) 375 ppm), respectively. The latter signal is not observed in the ^{33}S nmr spectrum of liquid SO_2Cl_2. The formation of SO_2 in these solutions is confirmed by the observation of a signal at 514 ppm (lit. (30) 513 ppm) in the ^{17}O nmr spectrum in addition to the resonance at 296 ppm (lit. (30) 304 ppm) for SO_2Cl_2.

In summary, the detection of SO_2 by ^{17}O and ^{33}S nmr spectroscopy indicates that SO_2Cl_2 behaves as a chlorinating agent upon addition to $(NSCl)_3$, but convincing spectroscopic evidence for the formation of $ClNSCl_2$ or $NSCl_3$ has not been obtained.

Conclusions

Solutions of $(NSCl)_3$ in the presence of an excess of SO_2Cl_2 behave as though they contain the synthetic equivalent "$NSCl_3$" upon treatment with methyacrylonitrile or thioamides and these reactions provide useful syntheses of 4-cyanoisothiazole or 5-methyl(or phenyl)-1,3,2,4-dithiadiazolium chloride, respectively. With other substrates, however, the reaction with excess SO_2Cl_2 predominates and this is likely to be a limiting factor in the application of the "$NSCl_3$" reagent to the synthesis of S—N heterocycles. Matrix isolation experiments will be necessary to characterize the active species in "$NSCl_3$" solutions.

Thermodynamique de la solvatation d'acides protoniques et des bases conjuguées en milieux hydroorganiques riches en eau à 25°C

HENRI GILLET

Laboratoire de chimie physique des solutions, Université Blaise Pascal (Clermont-Ferrand II), Ensemble Universitaire des Cézeaux, 63177 Aubière CEDEX, France

Reçu le 9 août 1989

HENRI GILLET. Can. J. Chem. **68**, 655 (1990).

Nous avons mesuré à 25°C les enthalpies de dissolution des acides acétique, benzoïque et valérianique et de leurs sels de potassium dans les mélanges eau – alcool *tert*-butylique contenant jusqu'a 40% en masse de cosolvant organique. Nous avons aussi déterminé ces grandeurs pour le phénol, l'aniline et la pyridine dans les mêmes mélanges et pour l'acide acétique, l'aniline et la pyridine dans les mélanges eau–DMSO, eau–acétone, et eau–urée pour les mêmes teneurs en cosolvant. Nous avons, à partir de ces données, calculé les enthalpies standard de dissolution, les grandeurs de transfert correspondantes et les enthalpies de solvatation. Quand les enthalpies de dissolution sont difficiles ou impossibles à mesurer nous avons montré que les enthalpies de transfert pouvaient être calculées à partir de grandeurs de transfert judicieusement choisies obtenues à partir de mesures expérimentales, De cette manière nous avons déterminé les enthalpies de transfert du phénate de potassium et des chlorures et bromures d'anilinium et de pyridinium dans les divers mélanges. Les enthalpies de solvatation ont été séparées en enthalpies de formation d'une cavité dans le solvant et en enthalpies d'interaction. Ces dernières grandeurs ont fait l'objet d'un essai d'interprétation en rapport avec les structures des solutés et la nature des mélanges hydroorganiques.

Mots clés : enthalpies, dissolution, solvatation, acides–bases, solvants hydroorganiques.

HENRI GILLET. Can. J. Chem. **68**, 655 (1990).

We have measured at 25°C the enthalpies of solution of acetic, benzoic, and valeric acids and of their potassium salts in water – *tert*-butyl alcohol mixtures containing up to 40% by weight of organic cosolvent. We have also determined these quantities for phenol, aniline, and pyridine in the same mixtures and for acetic acid, aniline, and pyridine in water–DMSO, water–acetone, and water–urea in the zone rich in water. Using these data we have calculated the standard enthalpies of solution, the corresponding transfer quantities, and the enthalpies of solvation. When the enthalpies of solution are difficult or impossible to measure we have shown that the enthalpies of transfer can be calculated from judiciously selected transfer quantities obtained from experimental measurements. In this way we have worked out the enthalpies of transfer of potassium phenolate and of anilinium and pyridinium chlorides and bromides in the various mixtures. The enthalpies of solvation have been separated into enthalpies of formation of a cavity in the solvent and enthalpies of interaction. From these last quantities an attempt at interpretation in terms of solute and aqueous-organic media structures was made.

Key words: enthalpies, solution, solvation, acids–bases, aqueous-organic media.

I. Introduction

Dans un précédent mémoire (1) nous avons donné les valeurs des constantes de dissociation acide et des enthalpies de neutralisation des acides acétique, benzoïque et valérianique, du phénol et des ions anilinium et pyridinium dans les mélanges eau – alcool *tert*-butylique, eau–DMSO, eau–acétone et eau–urée contenant jusqu'à 40% en masse de cosolvant organique. Nous avons fait l'analyse de l'évolution des grandeurs thermodynamiques standard ΔG_d^θ, ΔH_d^θ et ΔS_d^θ relatives à la dissociation, et des grandeurs de transfert correspondantes, avec la teneur en cosolvant.

Pour accéder à l'enthalpie molaire standard de solvatation d'une molécule dans un milieu solvant déterminé il faut connaître son enthalpie molaire standard de dissolution dans ce solvant et son enthalpie de vaporisation. Les enthalpies de dissolution peuvent être obtenues par mesure calorimétrique directe pour certaines espèces ou par un processus plus complexe pour d'autres. Les enthalpies de vaporisation sont données par la littérature. La valeur de l'enthalpie de solvatation rend compte de la variation de l'énergie interne des molécules et des énergies d'interaction avec le solvant lors de la mise en solution. Les enthalpies de solvatation des ions peuvent être déduites de celles des molécules en utilisant les valeurs des enthalpies de dissociation en phase gazeuse et en solution des acides protoniques correspondants. Si l'enthalpie de solvatation du proton est connue dans le mélange considéré, on peut accéder à celle des autres ions; dans le cas contraire nous n'obtiendrons cette grandeur que pour un couple d'ions. L'enthalpie de solvatation peut être séparée en enthalpie de formation d'une cavité dans le solvant, convenable pour accueillir le soluté, et en enthalpie d'interaction. La théorie des particules calibrées (S.P.T.) nous permet d'estimer « l'enthalpie de cavité ».

Si l'on veut mettre en évidence l'influence de la nature du cosolvant organique et de la teneur du mélange sur la solvatation, il faut calculer les grandeurs de transfert pour les enthalpies d'interaction. Ces grandeurs rendent compte des variations de l'énergie interne des espèces en solution et des énergies d'interaction lors du passage de l'eau pure à un mélange hydroorganique.

En considérant à la fois la structure du soluté et la composition du solvant il est possible de faire un essai d'interprétation des enthalpies d'intéraction et des grandeurs de transfert correspondantes en essayant de déterminer les interactions existantes quand le solvant est l'eau et de voir comment se comportent ces interactions lorsqu'on ajoute un cosolvant organique.

Les chimistes organiciens sont très intéressés par l'influence du milieu solvant sur le déroulement des réactions. Dans les mélanges hydroorganiques de nombreux paramètres ont été proposés pour rendre compte de cette influence : la constante de réaction de Hammett (2), le paramètre Y du « postulat de Grunwald–Winstein » (3), le paramètre de solubilité de Hildebrand (4), le paramètre de Kosower (5), etc. Les enthalpies d'interaction peuvent aussi apporter des renseignements dans ce domaine en rendant compte de l'influence de la composition du mélange solvant et de la nature du cosolvant. On peut calculer l'enthalpie d'une réaction dans un mélange hydroorga-

Printed in Canada / Imprimé au Canada

nique si l'on connait l'enthalpie de cette réaction dans l'eau et les enthalpies de transfert des réactifs et des produits de l'eau au mélange utilisé.

II. Partie théorique

1. Enthalpie de dissolution et enthalpie de transfert des espèces

Toutes les variations d'enthalpie sont des grandeurs molaires.

L'enthalpie standard de dissolution ΔH_s^θ est la variation d'enthalpie mise en jeu lors du passage d'une molécule de soluté de l'état liquide ou solide à l'état de solution infiniment diluée dans le solvant s.

Dans le cas d'un acide non chargé, il faut tenir compte de sa dissociation en solution. Si ΔH_s est la variation d'enthalpie mesurée, nous avons

$$[1] \quad \Delta H_s^\theta(\mathrm{AH}) = \Delta H_s - \alpha \Delta H_d^\theta(\mathrm{AH})$$

α est le degré de dissociation de l'acide et $\Delta H_d^\theta(\mathrm{AH})$ son enthalpie standard de dissociation.

Dans le cas d'une base, il faut tenir compte de la dissociation de l'acide cationique conjugué ce qui donne, en négligeant la dissociation propre de l'eau :

$$[2] \quad \Delta H_s^\theta(\mathrm{B}) = \Delta H_s - \alpha[\Delta H_d^\theta(\mathrm{H_2O}) - \Delta H_d^\theta(\mathrm{BH^+})]$$

Dans le cas d'un sel AM on le suppose entièrement dissocié en solution et on peut accéder à la valeur standard :

$$[3] \quad \Delta H_s^\theta(\mathrm{AM}) = \Delta H_s - \Phi_L$$

Φ_L étant calculé par la relation donnée par Juillard et Morel (6).

Les enthalpies standard de dissolution dans les différents solvants permettent de calculer les enthalpies standard de transfert des espèces dissoutes i de l'eau (w) à ce solvant (s). En effet :

$$[4] \quad \Delta^s H_s^\theta(i) = {}^s\bar{H}^\theta(i) - H^0(i)$$

H^0 étant l'enthalpie molaire du soluté pur et $\bar{H}^\theta$ l'enthalpie molaire partielle du soluté en solution infiniment diluée. Donc :

$$[5] \quad {}^s\delta\bar{H}^\theta(i) = {}^s\delta\Delta H_s^\theta(i)$$

l'opérateur ${}^s\delta$ symbolisant le transfert.

Pour certains composés peu solubles ou difficiles à obtenir purs et anhydres, il est impossible de mesurer expérimentalement les enthalpies de dissolution, mais il est possible de calculer ces grandeurs.

Considérons deux acides A_1H et A_2H et leurs sels de potassium A_1K et A_2K. Nous pouvons facilement obtenir la relation :

$$[6] \quad {}^s\delta\bar{H}^\theta(\mathrm{A_2H}) = {}^s\delta\Delta H_d^\theta(\mathrm{A_1H}) - {}^s\delta\Delta H_d^\theta(\mathrm{A_2H}) + {}^s\delta\Delta H_s^\theta(\mathrm{A_2K}) - {}^s\delta\Delta H_s^\theta(\mathrm{A_1K}) + {}^s\delta\Delta H_s^\theta(\mathrm{A_1H})$$

Nous voyons que si nous choisissons un couple tel que toutes les grandeurs du membre de droite soient mesurables, il est possible d'accéder à ${}^s\delta\bar{H}^\theta(\mathrm{A_2H})$.

Au lieu de choisir un couple de deux acides, nous pouvons écrire :

$$[7] \quad {}^s\delta\bar{H}^\theta(\mathrm{AH}) = {}^s\delta\Delta H_s^\theta(\mathrm{A^-, K^+}) - {}^s\delta\Delta H_d^\theta(\mathrm{AH}) - {}^s\delta\Delta H_s^\theta(\mathrm{Cl^-, K^+}) + {}^s\delta\Delta H_s^\theta(\mathrm{Cl^-, H^+})$$

Si nous connaissons l'enthalpie de transfert de la réaction de dissociation de l'acide et les enthalpies de transfert de l'acide chlorhydrique, du chlorure de potassium et du sel AK, nous pouvons calculer ${}^s\delta\bar{H}^\theta(\mathrm{AH})$.

Dans le cas d'un acide cationique, nous pouvons écrire :

$$[8] \quad {}^s\delta\Delta H_d^\theta(\mathrm{BH^+}) = {}^s\delta\Delta H_s^\theta(\mathrm{B}) + {}^s\delta\Delta H_s^\theta(\mathrm{H^+, Cl^-}) - {}^s\delta\Delta H^\theta(\mathrm{BH^+, Cl^-})$$

Si nous connaissons l'enthalpie de transfert de la réaction de dissociation de l'acide, l'enthalpie de transfert de l'acide chlorhydrique et l'enthalpie de transfert de la molécule de base, nous pouvons calculer l'enthalpie de transfert du couple (BH^+, Cl^-).

2. Enthalpie de solvatation

L'enthalpie molaire standard de solvatation ΔH_{solv}^θ est l'enthalpie mise en jeu lors du passage d'une mole de soluté de l'état gazeux à l'état de solution infiniment diluée. On a la relation :

$$[9] \quad \Delta H_{solv}^\theta = \Delta H_s^\theta - \Delta H_{vap}^0$$

où ΔH_s^θ est l'enthalpie molaire standard de dissolution et ΔH_{vap}^0 l'enthalpie molaire standard de vaporisation du soluté correspondant au passage d'une mole de l'état liquide ou solide à l'état idéal gazeux monomère. Dans le cas d'un acide AH on peut écrire :

$$\Delta H_{d,g}^0(\mathrm{AH}) + \Delta H_{solv}^\theta(\mathrm{A^-, H^+}) = \Delta H_{solv}^\theta(\mathrm{AH}) + \Delta H_{d,sol}^\theta(\mathrm{AH})$$

$(\Delta H_{d,g}^0)$ est l'enthalpie molaire standard de dissociation en phase gazeuse, ΔH_{solv}^θ l'enthalpie molaire standard de solvatation et $\Delta H_{d,sol}^\theta$ l'enthalpie molaire standard de dissociation en solution. D'où la relation :

$$[10] \quad \Delta H_{solv}^\theta(\mathrm{A^-}) = \Delta H_{solv}^\theta(\mathrm{AH}) - \Delta H_{solv}^\theta(\mathrm{H^+}) + \Delta H_{d,sol}^\theta(\mathrm{AH}) - \Delta H_{d,g}^0(\mathrm{AH})$$

Si l'on connaît $\Delta H_{d,g}^0(\mathrm{AH})$ on peut accéder à $\Delta H_{solv}^\theta(\mathrm{A^-})$ dans l'eau et les mélanges où l'on connaît $\Delta H_{solv}^\theta(\mathrm{H^+})$. Dans les mélanges où cette dernière grandeur n'est pas connue, on peut seulement accéder à $\Delta H_{solv}^\theta(\mathrm{A^-, H^+})$.

Dans le cas d'un acide du type BH^+ nous pouvons écrire :

$$[11] \quad \Delta H_{d,g}^0(\mathrm{BH^+}) + \Delta H_{solv}^\theta(\mathrm{BH^+}) = \Delta H_{solv}^\theta(\mathrm{BH^+}) + \Delta H_{d,sol}^\theta(\mathrm{BH^+})$$

et

$$\Delta H_{solv}^\theta(\mathrm{BH^+}) = \Delta H_{d,g}^0(\mathrm{BH^+}) + \Delta H_{solv}^\theta(\mathrm{B}) + \Delta H^\theta{}_{solv}(\mathrm{H^+}) - \Delta H_{d,sol}^\theta(\mathrm{BH^+})$$

Là aussi, si l'on connaît $\Delta H_{d,g}^0(\mathrm{BH^+})$ on peut obtenir $\Delta H_{solv}^\theta(\mathrm{BH^+})$ dans l'eau et les mélanges où l'on connait $\Delta H_{solv}^\theta(\mathrm{H^+})$. Dans les autres mélanges on peut seulement accéder à $\Delta H_{solv}^\theta(\mathrm{BH^+}) - \Delta H_{solv}^\theta(\mathrm{H^+})$.

Pour la dissociation d'un acide AH en phase gazeuse nous avons

$$[12] \quad \mathrm{PA(A^-)} = \mathrm{D(AH)} - \mathrm{EA(A^\cdot)} + \mathrm{IP(H^\cdot)}$$

où EA(X) est l'affinité électronique de X (énergie négative), PA(X) est l'affinité pour le proton de X (énergie négative), IP(X) est le potentiel d'ionisation de X (positif) et D(AH) est l'énergie de coupure homolytique de la liaison A—H. McMahon et Kebarle (49) ont étudié par spectrophotométrie de masse des réactions d'échange du proton du type

$$\mathrm{A_1H + A_2^- = A_1^- + A_2H} \quad (1)$$

$$\mathrm{B_1H^+ + B_2 = B_1 + B_2H^+} \quad (2)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

À 600 K ils obtiennent $\delta_R\Delta G^0_{d,g}$; ils font l'hypothèse $\Delta S^0_{d,g} \simeq 0$ donc :

$$\delta_R\Delta G^0_{d,g}(600\,K) \simeq \delta_R\Delta G^0_{d,g}(298\,K) \simeq \delta_R\Delta H^0_{d,g}$$

Comme nous avons

[13] $\Delta G^0_{d,g} = \Delta H^0_{d,g} = PA(A^-) = D(AH) - EA(A^\bullet) + IP(H^\bullet)$

nous pouvons écrire pour une réaction d'échange du proton du type (1) :

[14] $\delta_R\Delta H^0_{d,g} = D(A_2H) - EA(A_2^\bullet) - D(A_1H) + EA(A_1^\bullet)$

Connaissant D(AH) et EA(A•) pour HCl et H_2S, Kebarle a évalué D(AH) − EA(A•) pour d'autres acides.

Pour la dissociation d'un acide BH^+ en phase gazeuse nous avons

[15] $PA(B) = HA(B^{\bullet+}) - IP(B) + IP(H^\bullet)$

et

[16] $PA(B) = D(BH^+) - EA(B^{\bullet+}) + IP(H^\bullet) = \Delta H^0_{d,g}(BH^+)$

HA(X) est l'affinité pour l'hydrogène de X (énergie négative).

Pour une réaction d'échange du type (2) nous pouvons écrire

[17] $\delta_R\Delta H^0_{d,g} = D(B_2H^+) - EA(B_2^{\bullet+}) - D(B_1H^+) + EA(B_1^{\bullet+})$

3. Enthalpie de cavité et d'interaction

Pour une espèce en solution, on peut écrire :

[18] $\Delta H^\theta_{solv} = \Delta H_c + \Delta H^\theta_i$

ΔH_c est l'enthalpie de formation d'une cavité dans le solvant de dimension convenable pour accueillir le soluté.

Cette grandeur peut être évaluée à l'aide de la théorie des particules calibrées (scaled-particle theory) (7, 8) :

[19] $$\Delta H_c = \frac{\alpha RT^2}{(1-\xi_3)}\left\{\xi_3 + \frac{3\xi_2}{(1-\xi_3)}\,b + \frac{3\xi_1}{(1-\xi_3)}\,b^2 + \frac{9\xi_2^2}{(1-\xi_3)^2}\,b^2\right\}$$

avec

$$\xi_k = \frac{N}{6}\,\Pi \sum_{i=1}^{m} \rho_i a_i^k$$

m est le nombre d'espèces dans le mélange solvant, ρ_i est le nombre de particules i de diamètre a_i dans l'unité de volume, b le diamètre du soluté, k prend les valeurs 1, 2 ou 3, N est le nombre d'Avogadro, R la constante des gaz parfaits, α le coefficient de dilatation isobare du mélange solvant et T la température absolue. Le terme faisant intervenir la pression est négligé.

ΔH^θ_i rend compte des interactions soluté–solvant lorsque la cavité créée est occupée par le soluté.

III. Techniques expérimentales

1. Produits utilisés

Les solvants et les solutés ont été purifiés comme nous l'avons indiqué dans des publications précédentes (1, 9, 10).

2. Mesure de l'enthalpie de dissolution des acides, des bases et des sels

Nous avons utilisé un calorimètre LKB type 8700 à dissolution. La cellule contient 100 cm^3 de solvant. L'ampoule contient le soluté en quantité telle que la concentration finale soit $0{,}02 < m < 0{,}03$.

Plusieurs cas se sont présentés :

(a) La dissolution est rapide (durée <5 min). La courbe est exploitée par la méthode de Dickinson (11). C'est la majorité des cas.

(b) La dissolution est lente (durée >5 min). La courbe est exploitée par la méthode de Regnault–Pfaundler (12). Un exemple est la dissolution de l'aniline dans l'eau ou dans les mélanges très riches en eau.

(c) Dissolution avec existence temporaire de deux phases aqueuses. Un exemple est la dissolution de l'acide *n*-valérianique dans l'eau ou dans les mélanges très riches en eau : on obtient d'abord une élévation de température et ensuite une diminution; la température finale est inférieure à la température initiale.

(d) Substance peu soluble et à dissolution très lente, l'enthalpie de dissolution ne peut pas être mesurée avec le matériel dont nous disposons. La valeur pourra être obtenue par le calcul. C'est le cas de l'acide benzoïque dans les mélanges dont la teneur en alcool *tert*-butylique est inférieure à 25%.

(e) Cas d'une substance soluble mais hygroscopique. $^s\delta\Delta H_s$ est obtenu par dilution d'une solution concentrée de cette substance. Nous avons utilisé cette méthode pour l'acétate de potassium. La cellule contenait 100 cm^3 de mélange et l'ampoule une quantité de solution du sel, de molalité $m = 4{,}579\ mol\,kg^{-1}$, telle que la molalité de la solution finale soit de l'ordre de $2 \times 10^{-2}\ mol\,kg^{-1}$. La méthode ne permet que d'atteindre directement la valeur de transfert $^s\delta\Delta H^\theta_s(AK)$ que l'on peut calculer (13) par la formule :

[20] $$^s\delta\Delta H^\theta_s(AK) = \Delta^s H - \Delta^w H - \frac{n_w}{n_i}\,\bar{L}(H_2O) + {}^w\Phi_L - {}^s\Phi_L$$

$\Delta^s H$ et $\Delta^w H$ sont les effets thermiques obtenus expérimentalement dans le mélange et dans l'eau. $\bar{L}(H_2O)$ est l'enthalpie molaire partielle relative de l'eau dans le mélange (9). n_w/n_i rapport du nombre de mole d'eau au nombre de mole d'acétate dans la solution concentrée contenue dans l'ampoule.

La connaissance de la valeur de $\Delta^w H^\theta_s(AK)$ nous permet de calculer $\Delta^s H^\theta_s(AK)$ dans les mélanges.

IV. Résultats

1. Enthalpies de dissolution des acides, des amines et des sels

Les valeurs des enthalpies molaires standard de dissolution sont données dans les tableaux 1 et 2, elles ont été déterminées à environ 200 $J\,mol^{-1}$ près.

Les molalités finales sont comprises entre 0,02 et 0,03; nous avons assimilé les enthalpies déterminées à ces concentrations aux enthalpies standard de dissolution ΔH^θ_s. Nichols et Wadsö (22) montrent que pour la dissolution dans l'eau du phénol, du *p*-crésol, de l'alcool benzylique, de l'aniline et de la benzylamine, l'enthalpie de dissolution mesurée dans le domaine $0{,}01 < m < 0{,}06$ ne dépend pas de la concentration. Avedikian *et al.* (18) ont fait la même approximation pour la dissolution d'acides carboxyliques. Les valeurs obtenues dans l'eau ont été confrontées aux valeurs de la littérature pour les acides acétique (14–18), valérianique (16), benzoïque (19), le phénol (20–22, 26), l'aniline (22–24) et la pyridine (25). Nos mesures sont en bon accord avec ces valeurs.

Dans les mélanges solvants étudiés peu de valeurs de ΔH^θ_s relatives aux solutés utilisés dans cette étude ont été publiées. Les seules valeurs à notre disposition sont celles données par Avedikian *et al.* (18) pour l'acide acétique dans les mélanges eau – alcool *tert*-butylique. Nous avons eu seulement à faire des mesures pour 35 et 40% de cosolvant. Rochester et Sclosa (27) ont publié des valeurs d'enthalpie standard de dissolution du phénol dans ces mêmes mélanges; ces valeurs sont en bon accord avec les nôtres. Rodante *et al.* (28) ont fait des mesures d'enthalpie de dissolution de l'acide benzoïque dans les mélanges eau–DMSO mais ils ne donnent qu'une seule valeur dans la zone riche en eau que nous étudions.

Pour l'acétate de potassium dans les mélanges eau – alcool *tert*-butylique nous avons utilisé la méthode exposée en III.2(e) qui nous a permis d'accéder à l'enthalpie de transfert du sel.

*Valeurs interpolées.

Pour avoir les valeurs des enthalpies de dissolution du sel dans les mélanges, nous avons utilisé la valeur de l'enthalpie de dissolution de l'acétate de potassium dans l'eau donné par Parker (29).

Pour le benzoate de potassium dans les mêmes mélanges, nous avons utilisé les valeurs données par Dollet et Juillard (30).

2. Calcul des grandeurs non mesurables

Nous avons déjà vu que certaines grandeurs thermodynamiques ne pouvaient être déterminées expérimentalement mais qu'il était possible de les calculer à partir de grandeurs mesurées.

Nous avons essayé un tel calcul sur le couple acide acétique, acide valérianique en milieu eau – alcool *tert*-butylique. Si A_2H représente l'acide valérianique, nous pouvons calculer ${}^{s}\delta\bar{H}^{\theta}(A_2H)$ par la relation [6] puisque tous les termes de droite peuvent être obtenus par l'expérience. Nous pouvons aussi calculer l'enthalpie de transfert de A_2H par la relation [7] en utilisant les enthalpies de transfert de HCl et de KCl données par Pointud *et al.* (13, 31). Les valeurs obtenues par ces deux voies sont comparées entre elles et aux valeurs expérimentales sur la figure 1. Nous voyons sur cette figure que ce sont les valeurs obtenues par la relation [7] qui concordent en général le mieux avec les valeurs expérimentales.

C'est donc cette relation que nous avons utilisée pour calculer les enthalpies de transfert de l'acide benzoïque de l'eau aux mélanges eau – alcool *tert*-butylique consignées dans le tableau 1. Nous avons d'autre part mesuré ses enthalpies de dissolution pour $X \geqq 25\%$ et avons déduit de ces résultats l'enthalpie de dissolution de l'acide benzoïque dans l'eau; la valeur trouvée, 22,5 kJ mol^{-1}, est assez différente de celle égale à 26,8 kJ mol^{-1} proposée par Fernandez et Hepler (19) et généralement utilisée. Nous avons ensuite calculé les enthalpies de dissolution pour $X < 25\%$ (tableau 1).

Pour le phénate de potassium, les difficultés rencontrées pour avoir le produit pur et en raison de son hygroscopicité nous ont fait préférer le calcul par la formule [7]. Ce calcul nous permet seulement d'obtenir l'enthalpie de transfert. Il n'existe pas à notre connaissance de valeur de l'enthalpie de dissolution dans l'eau.

De même pour les chlorures et les bromures d'anilinium et de pyridinium, nous avons calculé les enthalpies de transfert par la relation [8] en utilisant les enthalpies de transfert de HCl et de HBr données par la littérature (9, 13, 32–37). Pour pouvoir calculer les enthalpies de dissolution dans les mélanges, il faut connaître l'enthalpie de dissolution dans l'eau. Pour le chlorure d'anilinium il n'existe, à notre connaissance, que la valeur déterminée par Berthelot (38), $\Delta^{w}H_s = 11{,}43$ kJ mol^{-1}. Pour le chlorure de pyridinium nous ne connaissons aucune valeur.

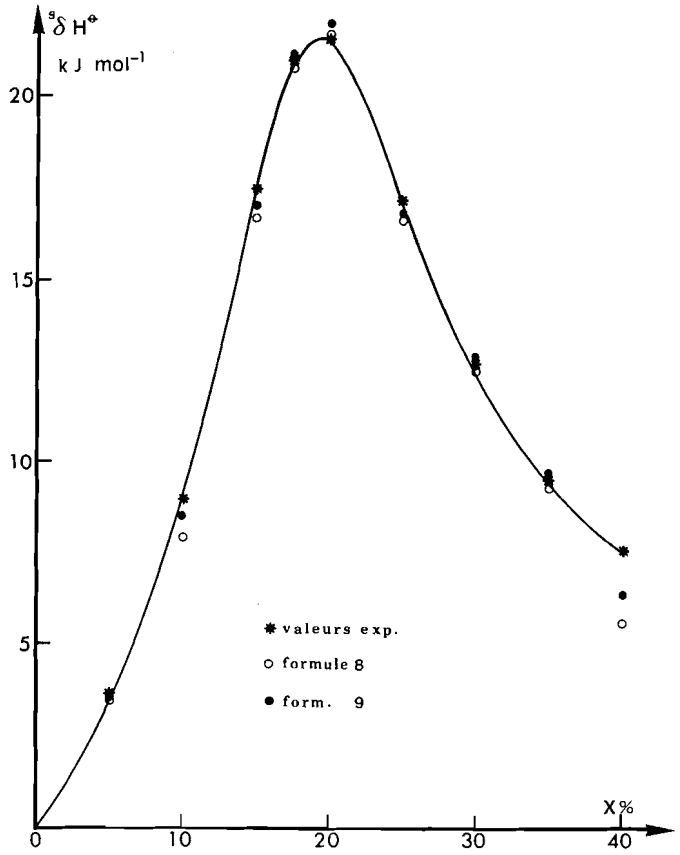

FIG. 1. Enthalpies de transfert de BuCOOH dans les mélanges eau – alcool *tert*-butylique à 25°C.

Les valeurs de transfert calculées des différentes espèces sont données dans les tableaux 3 et 4.

3. Enthalpie de solvatation, « enthalpie de cavité » et enthalpie d'interaction

Nous avons vu que la relation [9] permet de calculer l'enthalpie de solvatation si l'on connaît les enthalpies de dissolution et de vaporisation d'une espèce. L'enthalpie de solvatation peut être décomposée (voir relation [18]) en un terme ΔH_c, qui est l'enthalpie de formation d'une cavité dans le solvant, et un terme ΔH_i qui rend compte des interactions soluté–solvant.

Dans l'eau nous obtenons les résultats indiqués dans le tableau 5. Les enthalpies standard de vaporisation sont tirées de la littérature. Le terme ΔH_c a été calculé par la relation [19] sauf pour l'acide valérianique dont la structure en chaîne rend difficile le calcul de b. Pour l'eau nous avons pris $a = 2{,}73$ Å (39).

L'enthalpie de solvatation des anions est donnée par la relation [10], celle des ions BH^+ par la relation [11].

Pour les acides AH, McMahon et Kebarle (49) donnent les valeurs de D(AH) − EA(A$^\cdot$). Pour l'acide valérianique, ce terme est évalué par extrapolation à partir des valeurs données pour les acides acétique, propionique et butyrique (54, 55). On obtient PA(A^-) en ajoutant à ces valeurs IP(H$^\cdot$) comme le montre la relation [12]. La littérature donne IP(H$^\cdot$) = 1312,1 kJ mol^{-1} (49).

Pour les acides cationiques différents auteurs donnent directement la valeur de PA(B) pour NH_4^+ (50–52). Kebarle et coll. (53) donnent les valeurs de $\delta_R \Delta G^0_{d,g}$ pour les relations d'échange.

$$NH_4^+ + B = NH_3 + BH^+$$

On peut calculer $\Delta H^0_{d,g}(BH^+)$ par les relations [16] et [17] et ΔH_c pour les ions par la S.P.T. en prenant le diamètre de l'ion égal à celui de la molécule et obtenir ainsi le terme ΔH_i^θ.

Pour ce dernier calcul nous avons pris comme diamètre du cosolvant les valeurs suivantes : 5,07 Å pour l'alcool *tert*-butylique (56), 4,91 Å pour le DMSO (48), 4,76 Å pour l'acétone (48) et 4,41 Å pour l'urée (57).

Dans les solvants hydroorganiques nous pouvons calculer de la même façon les enthalpies de solvatation des molécules, les enthalpies de formation des cavités dans le solvant et les enthalpies d'interaction ΔH_i^θ.

Si l'on connaît l'enthalpie de solvatation de l'ion H^+ dans un solvant donné, on peut calculer l'enthalpie de solvatation des anions A^- par la relation [10] et celle des cations BH^+ par la relation [11]. L'enthalpie standard de solvatation du proton obtenue à l'aide de diverses hypothèses extrathermodynamiques n'est connue que dans l'eau (40, 59), dans les mélanges eau – alcool *tert*-butylique (58) et eau–DMSO (9, 33). Dans les autres mélanges nous pouvons seulement accéder aux enthalpies d'interaction $\Delta H_i^\theta(A^-, H^+)$ des couples (A^-, H^+) et aux différences $\Delta H_i^\theta(BH^+) - \Delta H_i^\theta(H^+)$.

V. Discussion

Les enthalpies standard d'interaction sont des grandeurs qui rendent compte principalement des énergies d'interaction soluté–solvant en tenant compte des modifications éventuelles de la nature des liaisons dans la molécule ou l'ion en solution. Elles

sont donc des grandeurs de choix pour l'étude de la contribution énergétique au phénomène de solvatation et la valeur de transfert correspondante nous renseigne sur les variations de ces interactions lors du passage de l'eau à un solvant mixte.

Les résultats présentés ici nous montrent que les enthalpies de solvatation sont négatives pour les molécules et les ions et que les valeurs absolues de ces enthalpies sont beaucoup plus grandes pour les ions que pour les molécules et plus grandes pour les anions que pour les cations du type BH^+.

Nous avons vu que ΔH^{θ}_{solv} peut être considéré comme la somme des deux termes ΔH_c et ΔH^{θ}_i (relation [18]). La S.P.T. donne des valeurs de ΔH_c satisfaisantes quand les solutés sont des sphères rigides qui ne donnent pas d'interactions spécifiques avec le solvant. Treiner (60) et Morel-Desrosiers (61) ont montré que ce calcul donne de bons résultats avec des solutés de taille importante tels que l'ion tétrabutylammonium (b = 7,74 Å) et l'adamantane (b = 6,36 Å). Les espèces que nous étudions ont des diamètres de l'ordre de 5–6 Å, leur taille ne semble donc pas être un obstacle à une application correcte de la théorie. Elles sont toutes peu déformables, mais n'ont pas une configuration sphérique et peuvent donner, comme nous le verrons par la suite, des interactions spécifiques du type liaison hydrogène avec les molécules du solvant. Ces deux derniers points nous permettent de penser que les valeurs de ΔH_c obtenues ne sont qu'approximatives mais donnent quand même un ordre de grandeur correct de l'enthalpie de formation de la cavité. Si l'on considère les valeurs de ces enthalpies pour les différents solutés dans les divers solvants on se rend compte que l'enthalpie de formation de la cavité a une valeur relativement faible, surtout dans le cas des ions, devant celle de l'enthalpie d'interaction, tout du moins dans l'eau et les mélanges très riches en eau. Quand la teneur en cosolvant organique augmente cette disparité diminue mais l'enthalpie d'interaction reste la grandeur prépondérante. Ceci veut dire que les interactions solutés–solvants apportent la contribution énergétique principale au phénomène de solvatation. Si maintenant nous

[a]Charges $\pi + \sigma$.
[b]Charges π.
[c]Charges σ; Charges en électrons (charges nettes).

Numérotation des carbones : 
examinons les enthalpies de transfert relatives à la solvatation nous voyons que le terme $^s\delta\Delta H_c$ prend une importance beaucoup plus grande par rapport au terme $^s\delta\Delta H_i^\theta$, il devient du même ordre de grandeur, et, comme il est positif, l'energie nécessaire à la formation de la cavité est en partie compensée pour celle qui résulte de la modification des interactions solutés–solvants (fig. 2). Dans certains cas, cette compensation est totale, c'est le cas de l'aniline et de la pyridine dans les mélanges eau–urée; l'enthalpie de solvatation reste constante quand la teneur en cosolvant croît.

Il nous a paru intéressant d'étudier le rapport existant entre la répartition électronique dans les molécules et les ions et l'enthalpie standard d'interaction ΔH_i^θ des espèces en solution. Nous avons trouvé dans la littérature de nombreuses études théoriques donnant la répartition des charges sur les différents atomes; ces données sont consignées sur le tableau 6. Les valeurs de ces charges sont difficilement comparables entre elles quand elles ne viennent pas des mêmes auteurs parce que les méthodes de calcul sont en général différentes. Par contre les rapports de ces charges peuvent être comparés d'un auteur à l'autre. Les espèces étudiées sont des solutés mixtes, c'est à dire qui possèdent des groupements polaires (hydrophiles) et non polaires (hydrophobes). L'enthalpie d'interaction d'une molécule peut être considérée comme étant la somme de trois termes (71): l'enthalpie ΔH_{VDW} due aux interactions de van der Waals entre le soluté et le solvant, le terme ΔH_{LH} qui est l'enthalpie de formation de liaisons hydrogène entre ces deux entités et enfin le terme ΔH_{MS} dû à la modification de la structure du solvant par le soluté en excluant la formation de la cavité. Ce dernier terme est presque uniquement associé aux effets des groupes non polaires du soluté sur la structure du solvant; si ce dernier est l'eau ce sont des interactions hydrophobes. Nous avons donc :

$$\Delta H_i = \Delta H_{VDW} + \Delta H_{LH} + \Delta H_{MS}$$

Les types de liaison hydrogène qui peuvent se former entre l'eau et les molécules étudiées ici (72, 73) sont consignées ainsi que les enthalpies correspondantes dans le tableau 7. Dans les mélanges hydroorganiques il y a aussi possibilité de formation de liaisons hydrogène avec les molécules de cosolvant. Les enthalpies des liaisons hydrogènes sont faibles par rapport aux liaisons covalentes normales. Par exemple pour la liaison O...HOH l'enthalpie est environ 20 fois inférieure à celle de la liaison covalente O—H. Nous pouvons ajouter que plus l'electronégativité d'un atome est élevée plus son aptitude à former des liaisons hydrogène est grande. L'oxygène dont l'électronégativité est 3,5 dans l'échelle de Pauling donne des liaisons hydrogènes plus fortes que l'azote dont l'électronégativité est 3. Les enthalpies des différentes liaisons hydrogène rencontrées dans cette étude sont données dans le tableau 7.

Les deux atomes d'oxygène de l'acide acétique portent de fortes charges négatives et l'atome d'hydrogène du groupement OH une forte charge positive. Scheraga et coll. (62) ont montré que l'acide acétique forme en solution aqueuse des liaisons hydrogène avec deux molécules d'eau; ils ont écarté la structure cyclique avec une seule molécule de solvant. Ces liaisons s'établissent entre l'oxygène du carbonyle et un hydrogène de l'eau et entre l'hydrogène du groupement OH de l'acide et l'oxygène d'une molécule d'eau. Ces auteurs signalent aussi l'existence d'une liaison hydrogène relativement faible entre l'oxygène du groupement hydroxyle et une molécule d'eau. Dans l'eau, le terme ΔH_{MS}, dû aux interactions hydrophobes du groupement CH_3, peut être évalué à $-6\,kJ\,mol^{-1}$ ce qui est l'écart entre l'enthalpie d'hydratation de l'acide acétique et

ϕ...HOH type V ϕ...OH_2 type VI	$\cong 5$[b]

[a]Référence 74.
[b]Référence 75.

celle de l'acide formique (76). La somme des enthalpies de formation des trois liaisons hydrogènes et du terme ΔH_{VDW} est donc $\Delta H = -51$ kJ mol^{-1}.

En solution aqueuse la molécule d'acide benzoïque exerce un effet hydrophobe sur les molécules d'eau. Le groupement hydrophile COOH forme des liaisons hydrogène directes avec les molécules de solvant. Peut être existe-t-il aussi des liaisons de types V et VI. À l'inverse de ce qui se produit pour l'acide acétique la charge négative sur l'oxygène du carbonyle est plus importante que sur l'oxygène du groupement OH; ceci est dû à la présence du cycle, il y a «pompage» des électrons du cycle par l'oxygène du carbonyle. Le pouvoir accepteur de proton de cet oxygène est donc augmenté. Tout ceci se traduit par une enthalpie d'interaction relativement forte $\Delta H_i^{\theta} = -76{,}1$ kJ mol^{-1}, l'acide benzoïque est la molécule la plus «hydratée» de celles étudiées ici.

Le phénol par son groupement hydroxyle est à la fois donneur et accepteur de proton, il a donc la possibilité de se lier à deux molécules d'eau par liaison hydrogène. Le noyau exerce un effet hydrophobe et l'on peut envisager un processus de solvatation analogue à celui de l'acide benzoïque.

L'aniline possède une charge négative relativement forte sur l'azote et des hydrogènes chargés positivement. On peut donc envisager pour son «hydratation» une liaison du type N...HOH, deux liaisons du type NH...OH_2 et des liaisons des types V et VI. La présence du noyau provoque aussi des interactions hydrophobes. Toutes ces liaisons correspondent bien à un ΔH_i^{θ} d'environ -60 kJ mol^{-1}.

Del Bene (cité par la réf. 77) a évalué l'enthalpie ΔH_{LH} de liaison de la pyridine avec l'eau à $-19{,}7$ kJ mol^{-1} ce qui correspond à une liaison N...HOH faible. Il y a possibilité de formation de liaisons de type V et VI (-10 kJ mol^{-1}). La valeur de ΔH_i^{θ} étant de $-55{,}7$ kJ mol^{-1}, il reste -26 kJ mol^{-1} pour les interactions hydrophobes et les interactions de van der Waals.

Lors du transfert des molécules de l'eau aux solvants hydro-organiques nous constatons qu'elles ont un comportement différent suivant le cosolvant utilisé. Dans les mélanges eau – alcool *tert*-butylique (fig. 3) elles ont le comportement déjà décrit par de nombreux auteurs (1, 9, 13, 18, 30, 32, 58). Nous constatons que $^{s}\delta\Delta H_i^{\theta}$ est positif pour $0 < X < 25\%$ et passe par un maximum pour $X = 15\%$, ce qui veut dire que les solutés ont plus de difficultés à former des liaisons hydrogène avec l'eau que dans l'eau pure à cause d'une plus grande structuration du solvant. Pour $X > 25\%$ $^{s}\delta\Delta H_i^{\theta}$ est négatif, la structure du solvant est désorganisée et les solutés ont beaucoup plus de facilité pour former des liaisons hydrogène avec l'eau et l'alcool *tert*-butylique. Pour les mélanges eau–DMSO nous avons $^{s}\delta\Delta H_i^{\theta}$ négatif et croissant en valeur absolue ce qui veut dire que la formation de liaisons hydrogène est plus facile que dans l'eau. Ceci peut être interprété par le fait que le DMSO détruit les liaisons hydrogène existant entre les molécules d'eau pour participer à la structure du solvant et empêche les solutés hydrophobes de promouvoir des liaisons hydrogène entre les molécules d'eau dans leur voisinage (78). Il y a donc plus de molécules d'eau disponibles pour former des liaisons hydrogène avec le soluté et le DMSO peut donner lui aussi de telles liaisons par son oxygène. Dans les mélanges eau–acétone on constate aussi la croissance de l'enthalpie d'interaction avec la teneur en cosolvant mais la variation est moins rapide dans le domaine où X est inférieur à 20%. Nous proposons la même explication que pour les mélanges eau–DMSO (78). Dans les mélanges eau–urée l'enthalpie d'interaction croît aussi avec la teneur en cosolvant ce qui est normal puisque l'urée détruit la structure de l'eau et empêche la solvatation hydrophobe. Les molécules d'eau sont donc disponibles pour former des liaisons hydrogène avec les solutés. L'urée peut elle même donner de telles liaisons par ses groupements NH_2 et sa fonction carbonyle.

Les enthalpies de solvatation des ions organiques en solution aqueuse sont difficiles à interpréter. Chaque ion a une structure et une répartition des charges qui lui est propre et sa structure est en général complexe. Comme nous l'avons vu pour les molécules, l'enthalpie d'interaction est la somme de plusieurs termes. Pour les ions il faut ajouter aux trois termes déjà cités un quatrième ΔH_{ES} dû à la solvatation électrostatique et dans lequel est incluse l'électrostriction du solvant c'est à dire la diminution de son volume sous l'influence du champ électrique créé par la charge de l'ion.

Les cations se comportent comme des accepteurs d'électrons

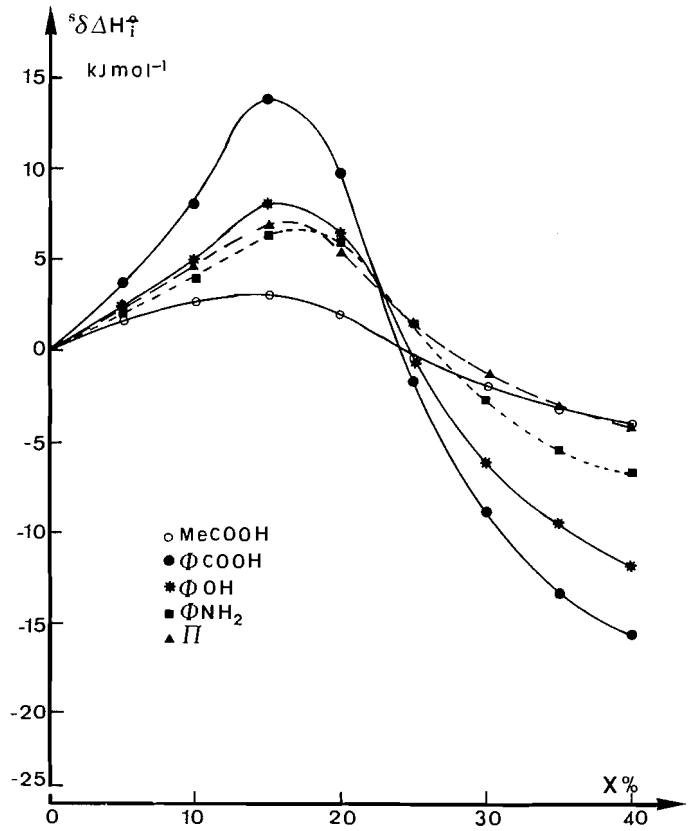

FIG. 3. Valeurs de transfert pour l'enthalpie d'interaction des acides et des amines dans les mélanges eau – alcool *tert*-butylique à 25°C.

vis à vis des atomes donneurs du solvant. Autour d'un cation BH^+ en solution aqueuse la configuration d'énergie minimum est celle dans laquelle les deux doublets électroniques libres de l'atome d'oxygène de l'eau sont orientés vers l'ion et forment une liaison «hydrogène ionique» (79) qui est plus une coordinence qu'une véritable liaison hydrogène (80). Les sphères de coordination des cations organiques sont en général mal définies. Les cations qui ont une grande variété de tailles ont des configurations qui s'adaptent elles-mêmes à la structure de l'eau environnante.

Les ions anilinium et pyridinium portent des charges positives sur les hydrogènes liés à l'azote. Ces hydrogènes peuvent donner des liaisons hydrogène ioniques avec les molécules d'eau. Dans ce cas le terme ΔH_{ES} est partagé entre l'enthalpie de formation de telles liaisons ΔH_{LHI} et l'électrostriction du solvant qui peut entrer dans le terme ΔH_{MS}. Jorgensen et Gao (81) ont évalué par la méthode de Monte Carlo l'importance des liaisons hydrogène ioniques dans l'hydratation des ions ammonium et méthylammonium. Leur étude montre que chaque hydrogène porté par l'azote est lié à 1,2 molécules d'eau et que chaque liaison hydrogène met en jeu une énergie de $-54{,}4$ kJ. Si nous faisons l'hypothèse qu'il en est de même pour les ions anilinium et pyridinium nous avons $\Delta H_{LHI} = -195{,}8$ kJ mol^{-1} pour le premier et $-65{,}3$ kJ mol^{-1} pour le second. Il reste donc pour les autres termes $\Delta H_{VDW} + \Delta H_{LH} + \Delta H_{MS}$, $-87{,}2$ kJ mol^{-1} pour l'ion anilinium et $-162{,}3$ kJ mol^{-1} pour l'ion pyridinium. Le terme ΔH_{LH} correspond ici a des liaisons entre le noyau aromatique et l'eau et peut-être aussi à des liaisons N...HOH si elles sont possibles.

Les anions ont des doublets électroniques à donner, ils sont solvatés par les solvants qui sont accepteurs de doublets. Ils forment aussi des liaisons hydrogène avec les solvants protiques. Autour des anions les hydrogènes des molécules d'eau qui portent des charges positives s'orientent vers l'ion. Dans cette situation les positions possibles des molécules d'eau les plus proches apparaissent plus étroitement dépendantes de la taille de l'ion qu'elles le sont pour les cations.

Les molécules d'eau tendent à orienter une de leur liaison O—H vers la charge négative de l'ion pour former une coordinence, elles ont ainsi la possibilité de former des liaisons hydrogène avec trois autres molécules d'eau (82). L'enthalpie d'hydratation des anions est toujours plus grande que celle des cations de même taille et de même charge. Verwey (83) explique cette différence par le fait que le centre de la charge positive du dipôle formé par la molécule d'eau est plus près de la surface que le centre de la charge négative et que l'interaction d'un ion négatif est donc plus forte que celle d'un ion positif.

L'anion acétate est un ion structuré, anisotrope, possédant deux sites négatifs équivalents, une polarisabilité et une électronégativité élevées. La structure bidentate n'existant pas en solution (81, 84) aqueuse, l'hydratation de cet ion peut être envisagée de la façon suivante (81) : liaison de molécules d'eau par coordinence sur chaque atome d'oxygène et fixation d'autres molécules d'eau par liaison hydrogène sur les précédentes. Jorgensen et Gao (81) évaluent à 3,3 le nombre de molécules d'eau liées à chacun des deux oxygènes de l'ion et l'énergie d'une liaison hydrogène ionique entre un oxygène et l'eau à $-57{,}0$ kJ. Donc pour l'ion acétate $\Delta H_{LHI} = -376{,}2$ kJ mol^{-1} et il reste $-29{,}7$ kJ mol^{-1} pour la somme des autres termes ΔH_{LH}, ΔH_{VDW} et ΔH_{MS}. Ces auteurs évaluent les interactions hydrophobes à environ -7 kJ mol^{-1}.

L'ion benzoate a aussi des charges négatives importantes équivalentes sur les oxygènes mais il est beaucoup plus gros que l'ion acétate ce qui peut géner l'approche des charges négatives par les molécules d'eau. La présence du cycle peut permettre la formation de liaisons hydrogène spécifiques et aussi provoquer un effet hydrophobe sur les molécules de solvant. L'ion benzoate est un peu moins bien «hydraté» que l'ion acétate.

L'ion phénate a une charge négative importante sur l'oxygène mais aussi une délocalisation de cette charge sur le cycle. L'enthalpie d'interaction de cet ion étant à peu près égale à celle de l'ion benzoate, nous pouvons donc penser que la diminution d'enthalpie correspondant à l'absence d'un deuxième oxygène est compensée par une plus grande importance de l'effet du cycle sur l'hydratation.

Nous voyons sur la figure 4 comment se comportent les divers ions faisant l'objet de cette étude lorsqu'on ajoute de l'alcool *tert*-butylique à l'eau. Nous pouvons séparer ce graphe en trois zones. Dans la première ($X < 12{,}5\%$) l'addition d'alcool ne produit aucun changement important dans les interactions entre l'eau et les ions. Dans la seconde ($12{,}5 < X < 30\%$) nous rencontrons les maximums (cations) et les minimums (anions) de $^s\delta\Delta H_i^\theta$ déjà rencontrés pour des systèmes chimiques voisins par de nombreux auteurs et expliqués par une structure particulière du solvant. Dans la troisième zone ($X > 30\%$) quand la teneur en alcool croît l'enthalpie d'interaction devient de plus en plus négative pour les cations et de moins en moins négative et même positive pour les anions. Le lecteur se reportera à la publication de Juillard (58) pour avoir une analyse plus complète de la solvatation dans les mélanges eau – alcool *tert*-butylique riches en eau.

Les mélanges eau–DMSO se comportent jusqu'à $X = 35\%$ comme des mélanges fortement structurés et au delà comme le

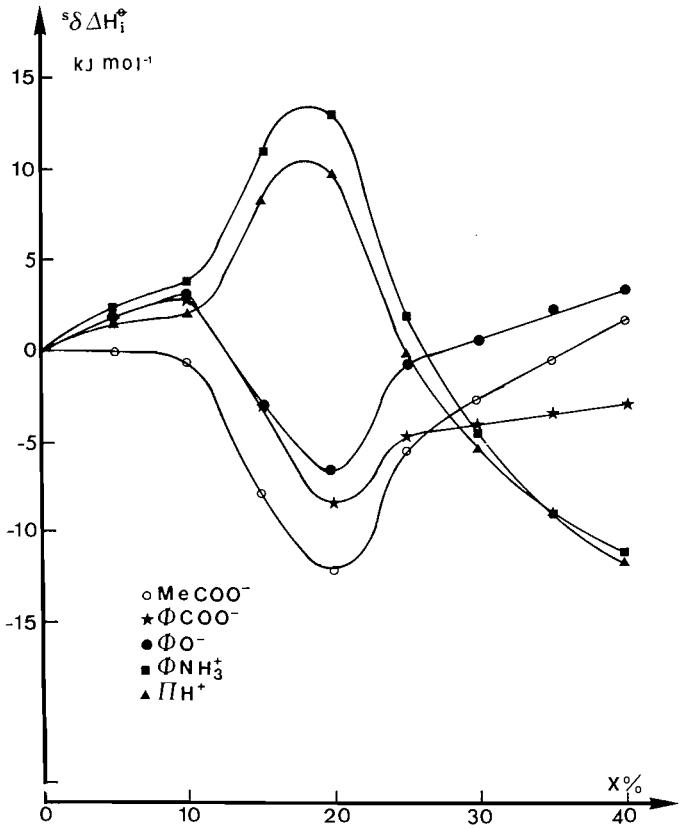

FIG. 4. Valeurs de transfert pour l'enthalpie d'interaction des anions et des cations dans les mélanges eau – alcool *tert*-butylique à 25°C.

DMSO pur, solvatant plus fortement les cations que les anions et davantage les petits cations que les gros.

Dans les mélanges eau–acétone et eau–urée nous ne pouvons étudier la solvatation que de couples d'ions. Les interactions y sont plus fortes que dans l'eau et leur force croît avec X. L'étude des couples $MeCOO^-,H^+$ et BH^+,H^+ nous montre que c'est dans les mélanges eau–urée que la force des interactions augmente le plus vite avec la teneur en cosolvant.

VI. Conclusions

Les valeurs des enthalpies d'interaction pour les molécules, les ions et les couples d'ions en solution aqueuse dépendent à la fois de la structure des espèces en solution et de la nature du solvant.

Dans le cas des molécules les interactions soluté–solvant avec un solvant protique sont en majorité des liaisons hydrogène mais il peut exister aussi des interactions hydrophobes. Les enthalpies d'interaction sont relativement faibles (−56 à −76 kJ mol^{-1}).

Pour les ions la solvatation est assurée essentiellement par des «liaisons hydrogène ioniques» qui sont des coordinences. Il peut exister aussi des liaisons hydrogène et des interactions hydrophobes. Les enthalpies d'interaction sont grandes, leurs valeurs sont situées entre −395 et −407 kJ mol^{-1} pour les anions et entre −228 et −283 kJ mol^{-1} pour les cations.

En ce qui concerne l'influence des solvants sur la solvatation, nos observations sont bien en accord avec ce que nous connaissons déjà sur eux. L'alcool *tert*-butylique organise fortement la structure de l'eau pour les teneurs comprises entre 12,5 et 25%. Le DMSO et l'acétone en participant à la structuration du solvant et en empêchant la solvatation hydrophobe permettent une solvatation plus importante des molécules par liaison hydrogène. On obtient le même résultat avec l'urée qui détruit la structure de l'eau et empêche donc aussi la solvatation hydrophobe.

Remerciements

Nous remercions Monsieur le Professeur Jean-Pierre Morel pour les conseils qu'il nous a donné pour la rédaction de ce mémoire.

Reaction mechanism of 1,2-hydrogen migration of hydrogen peroxide

ENRIC BOSCH, JOSÉ M. LLUCH,[1] AND JUAN BERTRÁN
Departament de Química, Universitat Autònoma de Barcelona, 08193 Bellaterra (Barcelona), Spain

Received July 1, 1989

ENRIC BOSCH, JOSÉ M. LLUCH, and JUAN BERTRÁN. Can. J. Chem. **68**, 666 (1990).

The 1,2-hydrogen migration of hydrogen peroxide has been investigated by *ab initio* methods and the Intrinsic Reaction Coordinate (IRC) has been constructed. An analysis of the evolution of the electron distribution along the reaction path has shown that the shifting hydrogen behaves as a proton. This transferring proton polarizes the O—O bond of the hydrogen peroxide that becomes broken at the transition state. If a water molecule is allowed to participate in the reaction, the energy barrier is noticeably lowered, this water molecule acting as a bifunctional catalyst.

Key words: 1,2-hydrogen migration, hydrogen peroxide, proton transfer, bifunctional catalyst, Intrinsic Reaction Coordinate.

ENRIC BOSCH, JOSÉ M. LLUCH et JUAN BERTRÁN. Can. J. Chem. **68**, 666 (1990).

Faisant appel à des méthodes *ab initio*, on a étudié la migration-1,2 d'hydrogène dans le peroxyde d'hydrogène et on a construit la Coordonnée Réactionnelle Intrinsèque (CRI). Une analyse de l'évolution de la distribution électronique en fonction de l'évolution de la réaction a permis de démontrer que l'hydrogène qui se déplace se comporte comme un proton. Le proton qui migre polarise la liaison O—O du peroxyde d'hydrogène et elle se brise dans l'état de transition. Si une molécule d'eau peut participer à la réaction, la barrière d'énergie est considérablement abaissée; cette molécule d'eau agit comme un catalyseur bifonctionnel.

Mots clés : migration-1,2 d'hydrogène, peroxyde d'hydrogène, transfert de proton, catalyseur bifonctionnel, Coordonnée Réactionnelle Intrinsèque.

[Traduit par la revue]

I. Introduction

Hydrogen-transfer reactions are a crucial step in many fundamental chemical and biochemical processes (1, 2). The elucidation of the actual nature of the transferring hydrogen is essential for understanding the mechanism of these reactions. As the reaction proceeds, very different electron rearrangement patterns take place depending on whether a hydride, an atomic hydrogen radical, or a proton is transferred.

Recently the 1,2-hydrogen migration of acetylene to form vinylidene has been studied theoretically (3) by an *ab initio* method and localized molecular orbital analysis. It was found that the shifting hydrogen behaves as a hydride. An interesting question is whether the nature of the migrating hydrogen depends on the identity of the hydrogen-donor and hydrogen-acceptor atoms or not. For this reason we deal in this paper with the 1,2-hydrogen migration between oxygen atoms, which are more electronegative than the carbon atoms. To this purpose we have chosen the simplest process of this type as a model: the intramolecular hydrogen transfer in hydrogen peroxide, which is in this respect an analogous system to acetylene, but involving oxygen atoms. In addition we have also investigated whether one water molecule can intervene in this process, in this way modifying the gas phase reaction mechanism. It is worthy of note that several hydrogen transfer reactions in which water molecules noticeably alter the molecular mechanism have been previously described (4–13).

From the analysis of the results obtained in this work we expect to understand how the electron reorganization takes place as the 1,2-hydrogen shift progresses. Furthermore, it is well known that H_2O_2 decomposes into water and molecular oxygen in the presence of an adequate homogeneous or heterogeneous catalyst. However, in the absence of catalyst hydrogen peroxide is stable indefinitely at room temperature (14). One can observe that the reaction proposed in this work could constitute one of the possible routes of decomposition into water and atomic oxygen, which could recombine later to form molecular oxygen. The results obtained will enable us to assess the feasibility of that process.

The organization of this paper is as follows. In the next section the theoretical method is described. The 1,2-hydrogen migration of hydrogen peroxide in the gas phase is studied in Sect. III. The effect of adding one water molecule is examined in Sect. IV. Finally, our principal conclusions are summarized in Sect. V.

II. Theoretical method

Ab initio self-consistent field (SCF) calculations have been carried out with the GAUSSIAN 86 series of programs (15), using the triply split valence basis set 3-21+G (16, 17), which contains a diffuse *sp* shell on atoms other than hydrogen.

All the geometrical parameters have been completely optimized at each stage of the hydrogen transfers. Geometry optimization and direct location of stationary points have been done with the Schlegel gradient optimization algorithm (18). Analytical second derivatives of the energy with respect to the Cartesian coordinates (19) were computed to test the nature of each stationary point: no negative eigenvalue for an equilibrium structure and one negative eigenvalue for a transition state.

Thermodynamic magnitudes were also computed by using the partition functions as provided by the statistical thermodynamic formulas within the ideal gas, rigid rotor, and harmonic oscillator models (20) as implemented in the GAUSSIAN 86 package. A pressure of 1 atm (101.3 kPa) and a temperature of 298.15 K were assumed in the calculations. The second derivatives of the energy were used for the determination of vibrational frequencies. For transition states the imaginary frequency is neglected in the thermodynamic evaluation.

To test the effect of expanding the basis sets, the energies of the stationary points were recalculated using 6-31+G and 6-31+G (D,P) basis sets, the 3-21+G geometries being kept unchanged. Moreover the influence of correlation energy was determined by using the Møller–Plesset perturbation theory to second (MP2) and third orders (MP3) (21).

Very useful information about the reaction mechanism can

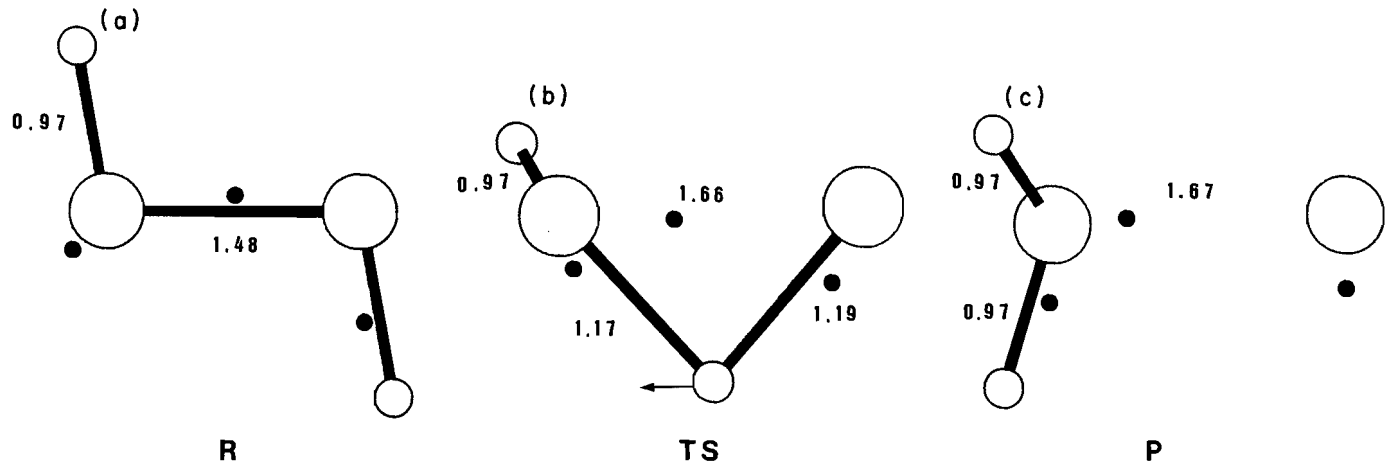

FIG. 1. Geometries of the reactant (R), transition state (TS), and product (P) for the 1,2-hydrogen migration of hydrogen peroxide in the gas phase. The arrow in the transition state structure indicates the transition vector. The positions of the three centroids of charge involved directly in the changing bonds have been marked by means of dots.

be obtained by following the evolution of the geometrical and electronic parameters of the system along the reaction path. To do this we have constructed the Intrinsic Reaction Coordinate (IRC) (22–24). The IRC has been computed with the GAMESS program (25), going downhill from the transition state in mass-weighted Cartesian coordinates (26, 27). The unique mode with imaginary frequency determines the starting direction away from the transition state. Assuming the harmonic approximation, we choose the initial step size Δs that produces the appropriate energy lowering $k(\Delta s)^2/2$, where k is the negative force constant associated with the imaginary frequency. Then the IRC is followed, taking successive very small steps in the direction of the negative gradient, which is equivalent to the Euler method. An initial energy lowering of 0.0005 hartrees and then successive steps of $\Delta s = 0.05$ amu$^{1/2}$ bohr have been used for both hydrogen transfer reactions.

III. 1,2-Hydrogen migration of hydrogen peroxide in gas phase

The geometries of the hydrogen peroxide, transition state, and product localized on the 3-21+G potential energy hypersurface are depicted in Fig. 1. The bond distances of the hydrogen peroxide agree well with the experimental values (28, 29) (1.475 and 0.95 Å for O—O and O—H bonds respectively). However, a dihedral angle of 180° corresponding to the *trans* conformation is obtained here, while it is known that in the gas phase the H_2O_2 adopts a skew configuration with a dihedral equilibration angle of 111.5° (infrared). This dihedral angle is particularly sensitive to the surroundings as values spanning the complete range from 90° to 180° have been found for various solid phases containing molecular H_2O_2 (28). Since the experimental (28, 30) *trans* barrier height is only 1.1 kcal/mol, we think that this discrepancy will not affect significantly the main results of the present work.

The transition state is nonplanar, both bond distances from the transferring hydrogen to the oxygen donor and the oxygen acceptor atoms being very similar. For this structure we have also represented the eigenvector associated with the imaginary frequency (1991i cm^{-1}), which indicates the direction of the reaction coordinate at this point. One can see that it corresponds completely to the hydrogen transfer, the rest of the atoms remaining fixed. Finally, the product is also nonplanar, both hydrogen atoms being bonded to the same oxygen atom. As will be mentioned later, the electronic distribution in this product suggests that it can dissociate to a singlet oxygen atom and a water molecule. It should be noted here that a multireference wave function would be needed to describe a free singlet oxygen atom. However, since the product of the hydrogen migration is only a precursor of a singlet oxygen atom, the RHF + MPn level of calculation is expected to be suitable to characterize the essential features of the hydrogen shift in the hydrogen peroxide.

[a]In kcal/mol.
[b]In cal/(mol K).

Table 1 presents the classical potential energy, enthalpy, entropy, and free-enthalpy barriers for the forward and backward reactions obtained at different levels of calculation. The first row shows the classical potential energy barrier obtained at the 3-21+G level, the stationary points having been localized on the 3-21+G potential energy hypersurface. The values of the classical potential energy barriers recalculated using larger basis sets and then including electron correlation, the 3-21+G geometries being kept unchanged, are exhibited in the second to the seventh rows. It should be remembered that the classical potential energy barrier does not contain the zero-point vibrational energy (ZPE). Finally, the last three rows reflect the enthalpy, entropy, and free-enthalpy barriers computed at the 3-21+G level.

The first thing one can observe in Table 1 is that the energy barrier for the forward reaction is very high at all levels of

calculation, as is also the case for the 1,2-hydrogen migration of acetylene (3). Expansion of the basis set and the introduction of electron correlation, respectively, slightly increases and decreases the barrier height. The effect of electron correlation is especially important for the backward reaction, the energy barrier being very small at the highest level of calculation. As expected, for all cases the MP2 level tends to overdo the electron correlation effect. Furthermore, it is noted that the reaction going from the hydrogen peroxide to the product is clearly endothermic. As a consequence of the trends of the energy barriers described above, the positive value of the energy reaction becomes very high at the MP3/6-31+G (D,P)//3-21+G level. Finally, regarding the thermodynamic properties, the 3-21+G enthalpy and free-enthalpy barriers for both the direct and the reverse reactions at 298.15 K are somewhat lower than the classical 3-21+G potential energy barriers at 0 K, mainly due to the fact that the ZPE at the transition state is smaller than that corresponding to both minima.

We have built up the 3-21+G IRC starting from the transition state (TS) and going to both the hydrogen peroxide (R) and the product (P) in order to follow the evolution of the reaction along the reaction path. The distance measured along the IRC is denoted by s, whose units are amu$^{1/2}$ bohr. The transition state is located at $s = 0$, and negative or positive values of s indicate the reactant or product region of the reaction respectively. The relative energies with respect to the reactant and the most relevant bond distances at selected points along the IRC are given in Table 2. The points have been numbered in both directions starting from the transition state, which is considered as point 0. Hydrogen-donor and hydrogen-acceptor oxygen atoms are respectively denoted by O and O′. Hereafter in this section H denotes the transferring hydrogen.

On the basis of the evolution of the geometrical parameters along the IRC one can say that the reaction takes place in three phases. Firstly, the O—O′ bond distance is lengthened while the O—H bond distance remains nearly fixed. The accompanying decrease in the O′—H bond distance arises from the diminution of the HOO′ angle. This phase finishes approximately at $s = -0.9$, requiring about 26 kcal/mol, one half of the energy barrier. In a second phase both oxygen atoms separate only a little more, while the O—H and O′—H bond distances are respectively lengthened and shortened in such a way that both become very similar at the transition state. One can consider that this second phase concludes at $s = 0.8$, when the new O′—H bond is almost completely formed. Finally, the third phase consists essentially in the variation of the OO′H angle so that the transferred hydrogen can attain its final position at the product. Notice that a slight OO′ bond contraction occurs in this period.

To analyze the electron-density rearrangement that takes place along the reaction path, a study of the topology of the total electronic charge density $\rho(\boldsymbol{r})$, according to Bader's methodology (31), has been performed. Figure 2 presents the isodensity contour plots of $\rho(\boldsymbol{r})$ in the plane defined by the transferring hydrogen and the oxygen atoms at selected points along the IRC. The positions of the bond critical points have been marked by means of dots. A bond critical point is a minimum along a single pair of gradient paths, which originated at the critical point and end one at each of the nuclei of the neighboring atoms, but is a maximum with respect to any orthogonal displacement. The existence of such a point indicates that the neighboring atoms are bonded to one another.

It can be seen in Fig. 2 that on going from the hydrogen peroxide to the transition state the O—O′ bond is weakened and becomes broken at the transition state, where the H atom is bonded to both oxygen atoms. Then when the H atom has been already transferred, the O—O′ bond is recovered. The product could be envisaged as an electrophilic singlet oxygen atom O nucleophilically solvated by a water molecule, the charge transfer being of 0.24 au towards the singlet O.

At this point the actual nature of the transferring hydrogen should be clarified. The net charge arising from a Mulliken population analysis on the migrating hydrogen changes from +0.47 (hydrogen peroxide) through +0.55 (transition state) to +0.52 (product). Note that the net charge peaks at the transition state. These values suggest that the moving hydrogen behaves as a proton. A localized molecular orbital analysis based on the localization method of Foster–Boys (32) confirms this idea. The localized molecular orbitals have been obtained and the positions of the centroids of negative charge associated with them have been determined. Given that the hydrogen peroxide is a closed-shell molecule containing 18 electrons, 9 centroids are found. The positions of the most relevant centroids have been marked by a dot in Fig. 1. For the sake of simplicity we have shown only the three centroids involved directly in the changing bonds. The main feature is that no centroid exists near the moving hydrogen at the transition state. In particular, one can see that the centroid related to the initial O—H bond does not follow the hydrogen atom as the reaction proceeds. Therefore one can state that, in effect, a 1,2-proton transfer takes place. This conclusion is consistent with the evolution of the $\rho(\boldsymbol{r})$ observed in Fig. 2. When the proton moves, an important polarization of the bonds that lie in the proximity of the proton trajectory occurs. As a consequence, the O—O′ bond is broken at the transition state, the electron density shifting towards the proton. Afterwards, when the proton is away from the O—O′ bond region, this bond is somewhat restored. The appearance of intense electron density redistributions accompanying a proton transfer has been already described in other works (33–36).

IV. 1,2-Hydrogen migration in the water – hydrogen peroxide complex

In the presence of a water molecule the 1,2-hydrogen migration takes place through a double proton exchange. The

reaction can be represented in Scheme 1, where we have introduced the numbering that will be used in this section. The structures of the reactant, transition state, and product localized on the 3-21+G potential energy hypersurface are shown in Fig. 3. The reactant corresponds to a hydrogen peroxide solvated by a water molecule. Only a transition state has been found, indicating that the reaction proceeds in just one step. At this transition state both hydrogen atoms 4 and 5 are being

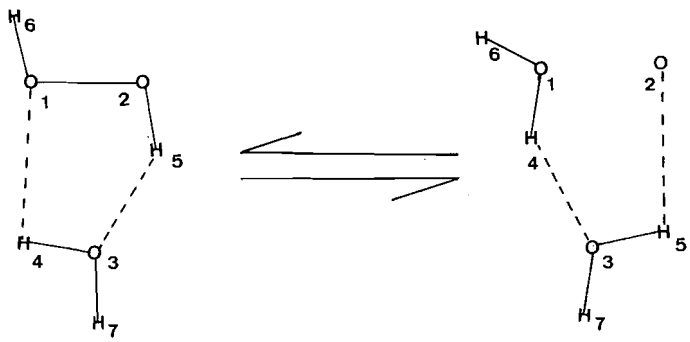

SCHEME 1

transferred, as is indicated by the eigenvector associated with the imaginary frequency (1517i cm^{-1}). The product consists of a singlet oxygen atom solvated by a chain of two water molecules.

From the energetic point of view, Table 3 displays the classical potential energy, enthalpy, entropy, and free-enthalpy values for the forward and backward processes, obtained at different levels of calculation. The most relevant point is that the intervention of a water molecule noticeably decreases the energy barriers for the forward reaction. However, these barriers remain very large, mainly due to the fact that the direct reaction is highly endothermic. On the other hand, the backward reaction occurs through a very small barrier. Finally, it can be noted that, in general, the same trends described in the gas phase, for the energy barriers when the basis set is expanded or the electron correlation is introduced and for the thermodynamic properties, are found here too.

To gain some insight into the mechanism of the double exchange, the 3-21+G IRC has been set up. The relative energies with respect to the reactant and the main bond distances

at selected points along the IRC are presented in Table 4. As mentioned above, the points have been numbered in both directions starting from the transition state, which is considered as point 0.

From the values in Table 4 several consecutive phases can be distinguished in the reaction. Firstly, a motion of the water molecule occurs in such a way that H5 and H4 approach O3 and O1 respectively, the O2H5 and O3H4 bond distances remaining almost unchanged. Then the H5 transfer from O2 to O3 begins. At the transition state both H5 and H4 are moving. Lastly, when the double exchange has nearly been completed, the water molecule corresponding to O3 goes to its final position at the product. During the process the O1O2 bond distance corresponding to hydrogen peroxide is progressively lengthened.

Let us turn our attention to the electronic aspects of the

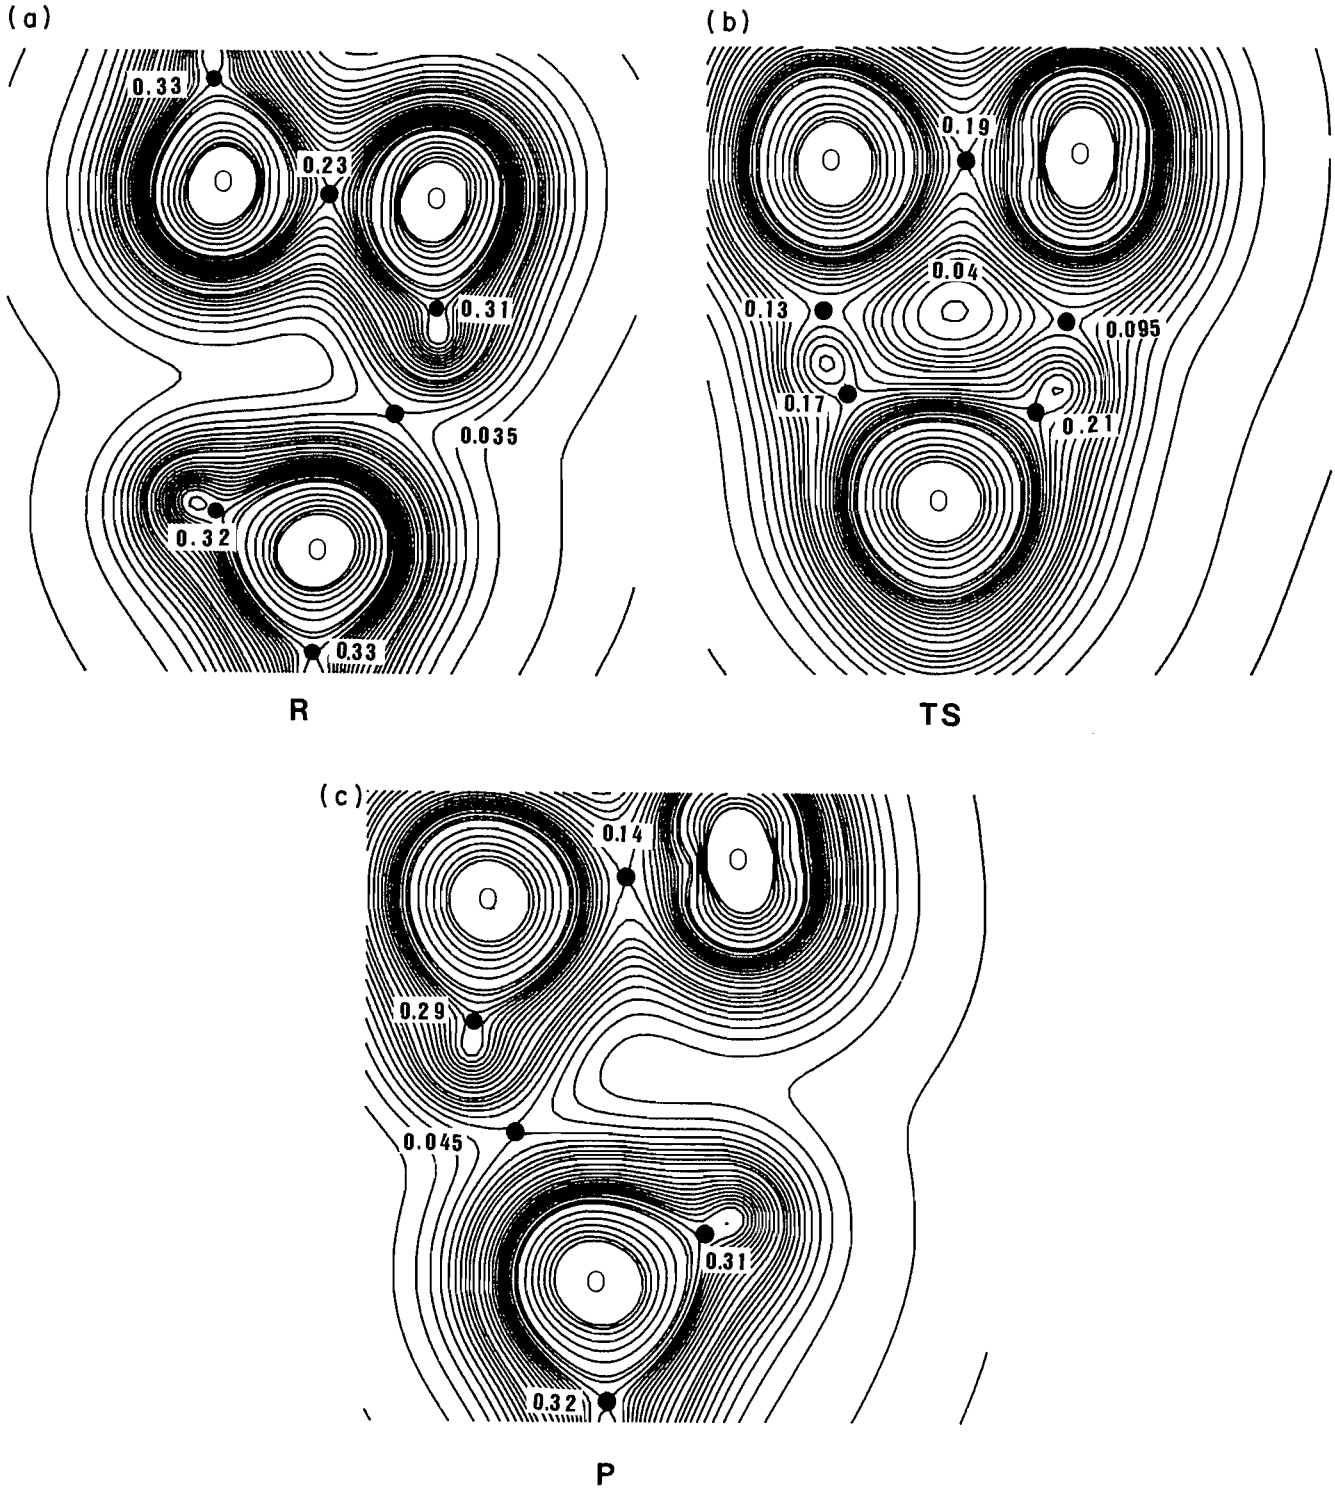

FIG. 4. Isodensity contour plots of $\rho(r)$ in the plane defined by the oxygen atoms at the reactant (R), transition state (TS), and product (P) for the water – hydrogen peroxide complex.

reaction. First of all, it should be noted that both transferring hydrogen atoms possess a net charge over +0.56 au at the transition state, which confirms their proton-like behaviour. Moreover, Fig. 4 displays the isodensity contour plots of $\rho(r)$ in the plane defined by the oxygen atoms at the reactant, transition state, and product. Two well-defined units corresponding to hydrogen peroxide and water exist at the reactant. Between them two hydrogen bonds are formed, but only the O3—H5 bond has a very weak covalent contribution. At the transition state one can see that H5 has already been transferred while H4 still "belongs" to O3. Thus, again, two structural entities can be distinguished, corresponding now to a hydronium cation and a hydroperoxide anion, with overall net charges of +0.66 and −0.66 au, respectively. A pair of covalent hydrogen bonds appears between them. H7 and H6 do not lie on the plane being considered and are not shown in the drawing. It should be emphasized that the intervention of the water molecule prevents the breaking of the O1—O2 bond of hydrogen peroxide at the

transition state. As a consequence, a ring point appears in the middle of the system. This ring point is a minimum of $\rho(\boldsymbol{r})$ on the plane considered, but a maximum in the orthogonal direction, and indicates the existence of a closed chain of bond paths linking the five nuclei around it. Finally, at the product the O2 atom is nucleophilically solvated by a water molecule and linked to the other by a hydrogen bond.

From the results presented in this section we can conclude that the water molecule intervenes very actively in the 1,2-hydrogen migration, modifying the gas phase reaction mechanism. The water molecule acts as a bifunctional catalyst, first accepting and then transferring a proton, the energy barrier being noticeably lowered. Similar behaviour has also been found for the intramolecular proton transfer in the water – hydroperoxide anion complex. In that case (36), the water molecule first gives and then takes a proton, in such a way that a hydroxide anion rather than a hydronium cation is formed.

V. Conclusions

In this paper the 1,2-hydrogen migration of hydrogen peroxide has been studied. It has been shown that the transferring hydrogen behaves as a proton. This result contrasts with the case of the 1,2-hydrogen transfer of acetylene, recently investigated by Sakai and Morokuma (3), wherein a hydride moves. The difference perhaps can be attributed to the fact that a carbon atom is a much weaker proton-donating center than the more electronegative oxygen atom.

The 1,2-hydrogen migration of hydrogen peroxide proceeds through a very high energy barrier mainly due to two factors: the reaction is clearly endothermic and the moving proton polarizes the O—O bond that becomes broken at the transition state.

If a water molecule is allowed to intervene in the reaction, the energy barrier is noticeably lowered, but it still remains high. The water molecule acts as a bifunctional catalyst, first accepting and then transferring a proton.

Finally, it should be remarked that the high values of the energy barriers obtained in this work justify why the 1,2-hydrogen migration is not a reliable route for decomposition of hydrogen peroxide into water and atomic oxygen.

Conductimetric and potentiometric investigation of effect of acidity on formation of homoconjugates in acetonitrile solvent

TURGUT GÜNDÜZ,[1] ESMA KILIÇ, GÜLEREN ÖZKAN, MUHAMMED F. AWAAD, AND MUSTAFA TASTEKIN
Department of Chemistry, Faculty of Science, University of Ankara, Ankara, Turkey

Received June 22, 1989

TURGUT GÜNDÜZ, ESMA KILIÇ, GÜLEREN ÖZKAN, MUHAMMED F. AWAAD, and MUSTAFA TASTEKIN. Can. J. Chem. **68**, 674 (1990).

In the present work, 11 aromatic and nine aliphatic carboxylic acids, namely benzoic, 2-nitrobenzoic, 3-nitrobenzoic, 4-nitrobenzoic, 2,4-dinitrobenzoic, 3,5-dinitrobenzoic, 2-aminobenzoic, 3-aminobenzoic, 4-aminobenzoic, *o*-phthalic, salicylic, formic, acetic, monochloroacetic, dichloroacetic, trichloroacetic, propionic, *n*-butyric, caprylic, and myristic acids, were titrated conductimetrically and potentiometrically with triethylamine in acetonitrile solvent, under a nitrogen atmosphere, at 25°C. Closer investigation of the conductimetric titration curves of these acids showed that the acidity of an acid, rather than the basicity of its conjugate base, plays a major part in the formation of homoconjugate ions, at least in acetonitrile solvent. If the acid is strong enough, there is a maximum before the experimental end point at about the half-neutralization point. To determine the minimum strength for an acid to show this maximum before the end point, all acids were also titrated potentiometrically. It was found that those acids which have half-neutralization potentials over −85 mV give a strong homoconjugation reaction and show a maximum before the experimental end point. Moreover, the acids that show maxima before the experimental end point in the conductimetric titration also show rather well-shaped potentiometric titration curves.

Key words: nonaqueous media, conductimetric titrations, potentiometric titrations, titration in acetonitrile, acidity and homoconjugation.

TURGUT GÜNDÜZ, ESMA KILIÇ, GÜLEREN ÖZKAN, MUHAMMED F. AWAAD et MUSTAFA TASTEKIN. Can. J. Chem. **68**, 674 (1990).

Opérant à 25°C et sous un atmosphère d'azote, utilisant de la triéthylamine dans de l'acétonitrile comme solvant et faisant appel à la conductimétrie et à la potentiométrie, on a titré 11 acides carboxyliques aromatiques et neuf acides aliphatiques, soit les acides benzoïque, 2-nitrobenzoïque, 3-nitrobenzoïque, 4-nitrobenzoïque, 2,4-dinitrobenzoïque, 3,5-dinitrobenzoïque, 2-aminobenzoïque, 3-aminobenzoïque, 4-aminobenzoïque, *o*-phtalique, salicylique, formique, acétique, monochloroacétique, dichloroacétique, trichloroacétique, propanoïque, butyrique, caprylique et myristique. Un examen plus approfondi des courbes de titrations conductimétriques a permis de démontrer que, dans l'acétonitrile, c'est l'acidité de l'acide plutôt que la basicité de son base conjugué qui est principalement responsable de la formation des ions homoconjugués. Si l'acide est suffisamment fort, il présente un maximum avant le point de virage expérimental, aux alentours du point de demi-neutralisation. Afin de déterminer quelle est la force minimale d'un acide qui donnera lieu à un maximum avant le point de virage, on a aussi titré tous les acides d'une façon potentiométrique et on a trouvé que les acides dont les potentiels de demi-neutralisation dépassent −85 mV donnent lieu à une forte réaction d'homoconjugaison et qu'ils présentent un maximum avant le point de virage expérimental. On a aussi observé que les acides qui présentent des maxima avant le point de virage expérimental dans les titrations potentiométriques présentent aussi des courbes de titrations potentiométriques qui sont plutôt bien définies.

Mots clés : milieux non-aqueux, titrations conductimétriques, titrations potentiométriques, titrations dans l'acétonitrile, acidité, homoconjugaison.

[Traduit par la revue]

Introduction

When an acid of intermediate strength is titrated conductimetrically with a base of intermediate strength, in a solvent of low or relatively low dielectric constant that is a non-hydrogen bond donor, a homoconjugation reaction takes place and homoconjugates are formed.

$$A^- + HA \rightarrow AH...A^-$$

At present it is a generally accepted fact that, in the formation of these homoconjugates, the basicity of the base rather than the acidity of the acid plays a major part (1–12). We have carried out the present work to verify this fact and to investigate it further. We selected 11 aromatic and nine aliphatic carboxylic acids, namely, benzoic, 2-nitrobenzoic, 3-nitrobenzoic, 4-nitrobenzoic, 2,4-dinitrobenzoic, 3,5-dinitrobenzoic, 2-aminobenzoic, 3-aminobenzoic, 4-aminobenzoic, *o*-phthalic, salicylic, formic, acetic, monochloroacetic, dichloroacetic, trichloroacetic, propionic, *n*-butyric, caprylic, and myristic acids, and titrated their 0.003 M solutions with a 0.100 M solution of triethylamine (an intermediate base) in acetonitrile solvent, which has a dielectric constant of 36 and is a non-hydrogen bond donor. All titrations were carried out under a nitrogen atmosphere, at 25°C.

Experimental

Apparatus

The apparatus used in this work has been described in ref. 13.

Chemicals

Triethylamine was purchased from Fluka AG in 98% purity.

Acetonitrile was purchased from Merck AG (Reinst) and purified further as follows: Anhydrous phosphorus pentoxide (5 g) was added to 1 L of solvent in a stoppered flask and, after shaking the flask for 15 min, the solvent was filtered and distilled in a tall fractionating column at atmospheric pressure. The middle distillate was collected and stored in a dark-coloured flask.

Propan-2-ol: the pure Merck product was used after distillation over CaO.

Benzoic acid was purchased from Merck AG, and was used after being sublimed.

2-Nitrobenzoic acid was prepared from 2-nitrotoluene by the method given in ref. 14.

3-Nitrobenzoic acid was prepared from 3-nitrobenzaldehyde (BDH, in 99% purity) by the method given in ref. 15.

TABLE 1. Half-neutralization potentials (hnp) of 0.003 M solutions of some aromatic and aliphatic carboxylic acids titrated with a 0.100 M solution of triethylamine in acetonitrile solvent, under a nitrogen atmosphere, at 25°C

Aromatic acids	hnp/mV	Shape	Aliphatic acids	hnp/mV	Shape
Benzoic	−180	None*	Formic	−315	None*
2-Nitrobenzoic	−30	S	Acetic	−220	None*
3-Nitrobenzoic	−85	S	Monochloroacetic	−75	S
4-Nitrobenzoic	−78	S	Dichloroacetic	80	S
2,4-Dinitrobenzoic	75	S	Propionic	−225	None*
3,5-Dinitrobenzoic	10	S	*n*-Butyric	−245	None*
2-Aminobenzoic	−190	None*	Caprylic	−235	None*
3-Aminobenzoic	−195	None*	Myristic	−255	None*
4-Aminobenzoic	−213	None*	Trichloroacetic	—	—
o-Phthalic	125	S			
Salicylic	12	S			

*Half-neutralization potentials have been found from the calculated stoichiometry.

4-Nitrobenzoic acid was purchased from Merck AG in 99% purity and was used without further purification.

2,4-Dinitrobenzoic acid was purchased from Schering Kahlbaum (pure) and was used without further purification.

3,5-Dinitrobenzoic acid was purchased from Merck AG in 99% purity and was used without further purification.

2-Aminobenzoic acid was purchased from Riedel–de Häen in 99.5% purity and was used without further purification.

3-Aminobenzoic acid was purchased from Fluka AG in 99% purity and was used without further purification.

4-Aminobenzoic acid was purchased from Riedel–de Häen in 99% purity and was used without further purification.

o-Phthalic acid was purchased from Hyden Chemical Corporation (pure).

Salicylic acid was purchased from Merck AG in 99.5% purity.

Formic acid was purchased from Merck AG in 98–100% purity and was used without further purification.

Acetic acid was purchased from Merck AG (Zur Analyse) in 99–100% purity and was used without further purification.

Monochloroacetic acid was purchased from Riedel–de Häen (pure Cryst).

Dichloroacetic acid was purchased from Schering–Kahlbaum AG.

Trichloroacetic acid was purchased from Fluka AG in 98% purity and was used without further purification.

Propionic acid was purchased from Riedel–de Häen AG and was used without further purification.

n-Butyric acid was purchased from Dr. Praenkel and Dr. Landau (Normel Gereinigt) and was used without further purification.

Caprylic acid was purchased from Schering–Kahlbaum AG (pure) and was used without further purification.

Myristic acid was purchased from BDH in 99% purity and was used without further purification.

Results and discussion

The acids titrated conductimetrically and potentiometrically with triethylamine in acetonitrile solvent are given in Table 1. One of the acids titrated in this work is benzoic acid. The initial specific conductivity of its 0.003 M solution is extremely low (1 μmho), but increases rather sharply upon addition of a 0.100 M solution of titrant, Fig. 1A.

As can be seen from the titration curve, benzoic acid shows neither a maximum at about the half-neutralization point, nor a linear increase, until the experimental end point. This clearly indicates that benzoic acid has little tendency to form homoconjugate ions with its conjugate base (benzoate ions). So its simple salt and conjugate salt remain as ion-pairs or ion-aggregates in the medium. This can be formulated as follows.

$$HA + B \rightarrow BH^+A^- \rightarrow BH^+ + A^-$$

$$BH^+A^- + HA \rightarrow BH^+HA_2^- \rightarrow BH^+ + HA_2^-$$

On the other hand, the initial specific conductivity of the 0.003 M solution of 4-nitrobenzoic acid, which is a stronger acid than benzoic acid, is also very low, but it increases more sharply than the specific conductivity of benzoic acid on addition of triethylamine (titrant). In addition, in contrast to the titration curve of benzoic acid, the titration curve of 4-nitrobenzoic acid shows a maximum at about the half-neutralization-point, Fig. 1B. The maximum is approximately symmetrical on both sides of the half-neutralization point and the end point is rather well shaped. This clearly indicates that 4-nitrobenzoic acid has a rather strong tendency to form homoconjugate ions with its conjugate base. In addition, the specific conductivity of 4-nitrobenzoic acid at any neutralization point on the titration curve is greater than the specific conductivity of the benzoic acid at the corresponding neutralization point. Possibly this is due to the higher dissociation of its homoconjugate salt ($BH^+HA_2^-$) than that of its simple salt (BH^+A^-). As is known, homoconjugate salts generally dissociate more readily than their unhomoconjugated or simple salts because the negative charge on such species is effectively dissipated over the entire larger ions, the coulombic attraction forces are reduced, and, consequently, the dissociation is increased. The titration curves of the 2-nitrobenzoic and 3-nitrobenzoic acids are very similar to the titration curve of 4-nitrobenzoic acid.

2,4-Dinitrobenzoic acid shows a very similar titration curve to the titration curve of 4-nitrobenzoic acid. But the specific conductivity of the former at any neutralization point in the titration curve is greater than the specific conductivity of the latter at the corresponding neutralization point, Fig. 1C. Moreover, 3,5-dinitrobenzoic acid gives a very similar titration curve to that of 2,4-dinitrobenzoic acid. Despite the fact that the benzoate ion is a stronger base than the mono- and dinitrobenzoate ions, it has a lesser tendency to form homoconjugate ions than the mono- and dinitrobenzoate ions, at least in acetonitrile solvent. This observation cannot be explained with the generally accepted fact that the anion of an acid plays a major part in the formation of homoconjugates. Otherwise, on the titration curve of benzoic acid a higher and sharper maximum would be observed than the maxima observed on the titration curves of mono- and dinitrobenzoic acids. In addition,

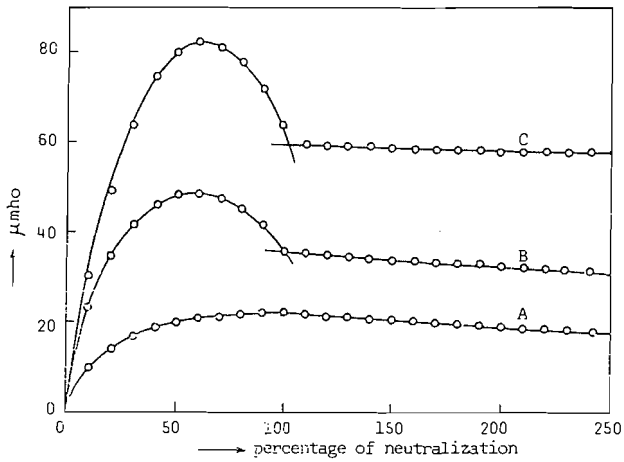

FIG. 1. Conductimetric titration curves of 0.003 M solutions of benzoic acid (A), 4-nitrobenzoic acid (B), and 2,4-dinitrobenzoic acid (C) with a 0.100 M solution of triethylamine in acetonitrile solvent. Titrations were carried out under a nitrogen atmosphere at 25°C. The specific conductivity of a 0.1000 ± 0.0005 M solution of KCl was taken as standard.

the specific conductivity of the salt of benzoic acid would be greater than the specific conductivity of the mono- and dinitrobenzoic acid salts at any point on the titration curves. As is well known, a dinitrobenzoic acid is a stronger acid than a mononitrobenzoic acid; in turn, a mononitrobenzoic acid is a stronger acid than benzoic acid. Thus anions of the nitrobenzoic acids should be weaker bases than the anion of benzoic acid. All these observations indicate that in homoconjugation reactions the acidity of an acid rather than the basicity of its conjugate base plays a major part, at least in acetonitrile solvent.

To support this observation, we also titrated aminobenzoic acids, namely, 2-amino-, 3-amino-, and 4-aminobenzoic acids. The titration curves of these acids showed a very similar pattern to that of the benzoic acid, except that their specific conductivities are relatively lower than the specific conductivity of the benzoic acid at any point in their titration curves. The anions of these are even stronger bases than the anion of benzoic acid, yet they do not undergo a homoconjugation reaction to an appreciable extent and as a result they do not show maxima before the end point owing to the weaknesses of their acids.

To further support the importance of acidity over basicity in the formation of homoconjugates, we also titrated *o*-phthalic acid and salicylic acid under the same conditions. The initial conductivity of *o*-phthalic acid solution was also low, but it increased linearly up to the end point upon addition of the titrant and then decreased very slowly, Fig. 2A. That is, it did not show a maximum at about the half-neutralization point. However, this acid is expected to show a maximum before the experimental end point because of its strong acidic character, Table 1. Such a maximum was not observed, owing to its molecular structure. Because of its special structure, *o*-biphthalate ion is very prone to give an intramolecular, rather than an intermolecular, hydrogen bond. So, up to the end point only BH^+ and intramolecular hydrogen-bonded *o*-phthalate ion are present in the medium. In addition, the experimental end point is exactly identical to the calculated or theoretical end point. The initial conductivity of the solution of salicylic acid is low; however, it increases rather sharply, but not linearly, as is the case with *o*-phthalic acid, upon addition of titrant, and gives a maximum

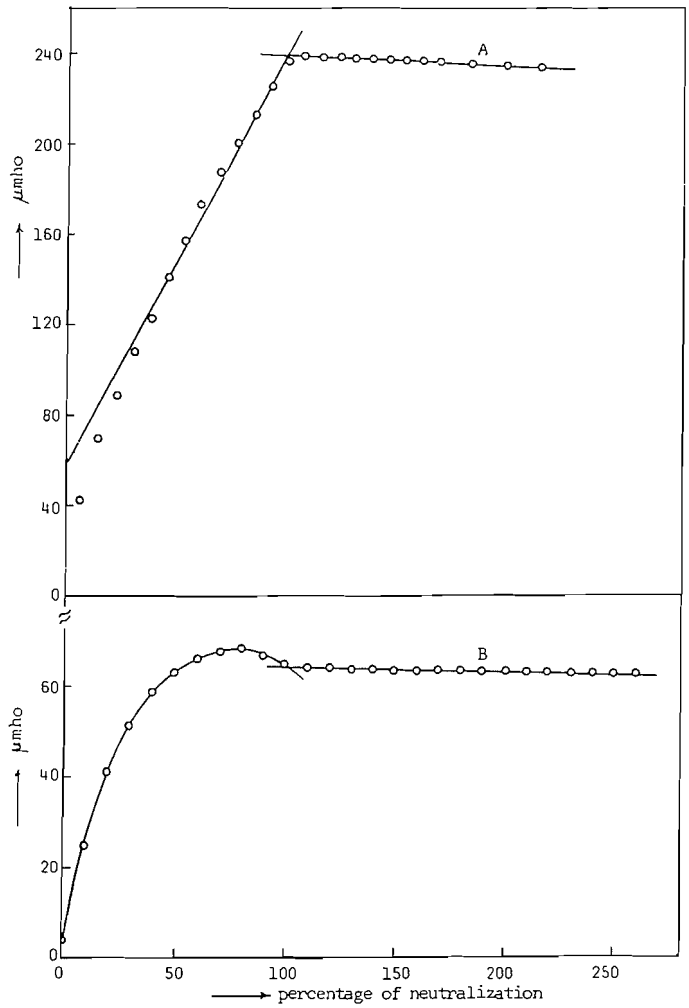

FIG. 2. Conductimetric titration of 0.003 M solutions of *o*-phthalic acid (A) and salicylic acid (B) with a 0.100 M solution of triethylamine in acetonitrile solvent. In the titrations the specific conductivity of a 0.1000 ± 0.0005 M solution of KCl was accepted as standard.

before the experimental end point, Fig. 2B. The reason that the salicylic acid shows a maximum before the end point is the weakness of the acidity of its phenolic hydroxy group. Thus, due to the weaker acidity of the hydroxy group than that of the carboxy group, salicylate ion does not give, or gives at best to a small extent, an intramolecular H-bond; instead it gives an intermolecular H-bond and consequently shows a maximum at about the half-neutralization point. The results obtained for *o*-phthalic acid and salicylic acid also supported strongly the observation given above.

To support this observation further, we also titrated some stronger and weaker aliphatic carboxylic acids, Table 1. Under the same conditions, the titration curve of acetic acid showed neither a maximum nor a conspicuous end point, Fig. 3A. On the other hand, monochloroacetic acid, a slightly stronger acid than acetic acid, showed a rather strong maximum before the end point, at about the half-neutralization point. Dichloroacetic acid behaved exactly as did monochloroacetic acid, but its specific conductivity at any point on the titration curve is greater than the corresponding specific conductivity of monochloroacetic acid, Figs. 3B and 3C. Despite the fact that the acetate ion possesses the strongest basicity among the anions of these

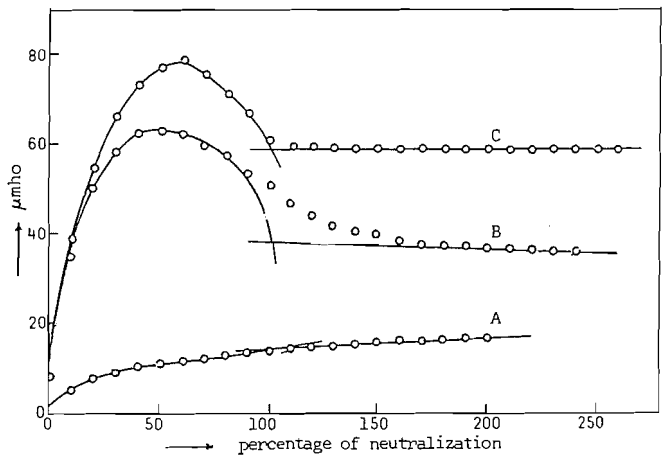

FIG. 3. Conductimetric titration curves of the solutions (0.003 M) of acetic (A), monochloroacetic (B), and dichloroacetic acids (C) with a solution (0.100 M) of triethylamine in acetonitrile solvent at 25°C. The conductivity of a 0.1000 ± 0.0005 M KCl solution was taken as standard.

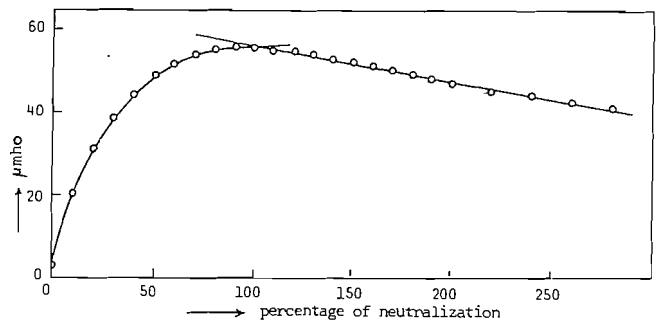

FIG. 4. Conductimetric titration curve of a 0.003 M solution of formic acid with a 0.100 M solution of triethylamine in acetonitrile solvent, under a nitrogen atmosphere at 25°C. In the titrations the specific conductivity of 0.1000 ± 0.0005 M KCl was taken as standard.

three acids, acetate ions do not form homoconjugate ions, at least to an appreciable extent, due to the weaker acidity of acetic acid than the mono- and dichloroacetic acids. This observation also strongly indicates that acidity rather than basicity of the species plays an important part in the formation of homoconjugates in acetonitrile solvent. Under the same conditions, trichloroacetic acid decomposes at the earlier stage of the titration. We also titrated formic acid, which is stronger than acetic and weaker than monochloroacetic acid, and obtained no well-defined maximum, but a rather well-defined end point, Fig. 4. The result indicates that even formic acid, though stronger than acetic acid, is not strong enough to give homoconjugate ions to an appreciable extent. Lastly, we titrated propionic, *n*-butyric, caprylic, and myristic acids, but none showed a maximum before the stoichiometric end point. These data also supported our view.

To determine the minimum acidity level for the formation of homoconjugates at appreciable concentration to give a maximum before the end point, we titrated potentiometrically all the acids given in Table 1, under the same experimental conditions, and obtained some interesting results. The acids that showed well-shaped or rather well-shaped maxima upon conductimetric

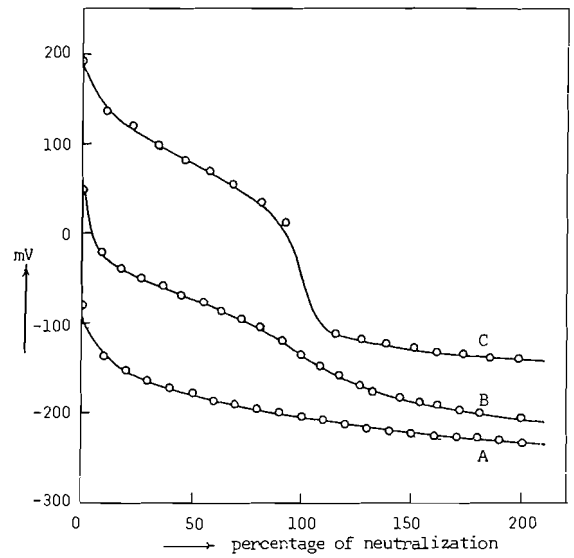

FIG. 5. Potentiometric titration curves of 0.003 M solutions of benzoic (A), 4-nitrobenzoic (B), and 2,4-dinitrobenzoic acids (C) with triethylamine in acetonitrile solvent, under a nitrogen atmosphere at 25°C.

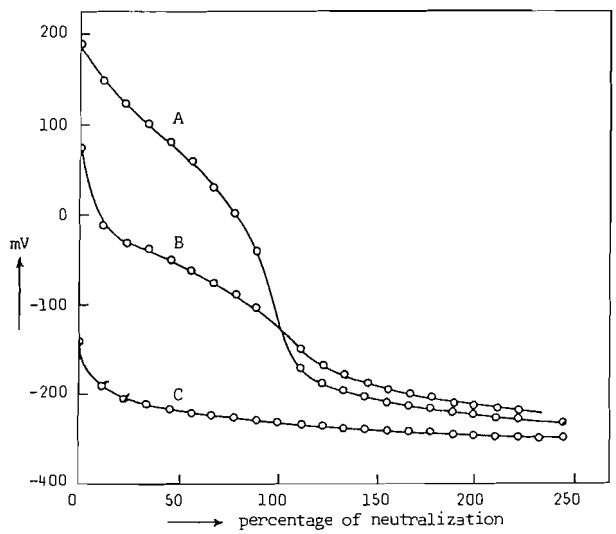

FIG. 6. Potentiometric titration curves of 0.003 M solutions of dichloroacetic (A), monochloroacetic (B), and acetic acids (C), under a nitrogen atmosphere at 25°C.

titration also gave rather well-shaped potentiometric titration curves. The rest did not even show characteristic titration curves. The half-neutralization potentials (hnp) of the acids obtained in this work have also been collected in Table 1. The acids that showed a half-neutralization potential over −85 mV gave well-shaped or rather well-shaped potentiometric titration curves, and also gave well-shaped or rather well-shaped maxima at about the half-neutralization points. To illustrate the potentiometric results, the titration curves of the benzoic, 4-nitrobenzoic, and 2,4-dinitrobenzoic acids and those of acetic, monochloroacetic, and dichloroacetic acids are given in Figs. 5 and 6.

The potentiometric titration curves of *o*-phthalic and salicylic acids are given in Fig. 7. As is easily seen from the shape of the titration curves, *o*-phthalic acid is a much stronger acid than

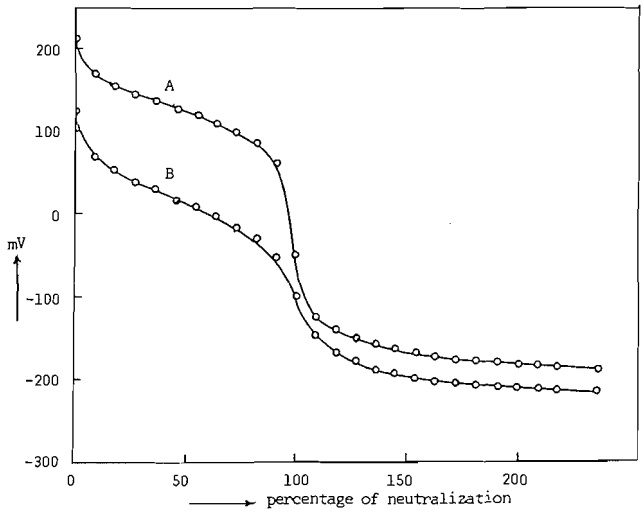

FIG. 7. Potentiometric titration of 0.003 M solutions of *o*-phthalic acid (A) and salicylic acid (B) in acetonitrile solvent, under a nitrogen atmosphere at 25°C.

salicylic acid. The half-neutralization potentials are given in Table 1. Closer examination of this table shows that the order of the acidity of certain acids, in contrast to the order of acidity in water, is as follows:

o-phthalic acid > acetic acid > formic acid

Conclusions

In the present work, we have tried to show that the acidity of an acid rather than the basicity of its conjugate base plays a major part in the formation of homoconjugates, in contrast to what has generally been believed, at least in acetonitrile solvent. The stronger the acid, the greater the concentration of homoconjugates with respect to its simple anion, at least in acetonitrile solvent, which has a relatively low dielectric constant ($\varepsilon = 36$) and is a non-hydrogen bond donor solvent.

The acids that show maxima in their conductimetric titration curves also show well-shaped or rather well-shaped potentiometric titration curves, due to their sufficiently strong acidity. For an acid to show a maximum, which is a great help in accurately determining the end point, it should have a minimum half-neutralization potential of −85 mV, under our experimental conditions.

WITOLD CIESIELSKI, ZBIGNIEW H. KUDZIN, MACIEJ TASZ, and JÓZEF DRABOWICZ. Can. J. Chem. **68**, 679 (1990).

Trifluoroacetic anhydride – sodium iodide mixture (TFAA-I) reacts with nitrones with the release of iodine. Since stoichiometrical amounts of iodine are formed with respect to starting nitrones, TFAA-I reagent can be used for analytical determination of nitrones. Two procedures for the determination of nitrones (on μmole and on nmole scale) have been described.

Key words: nitrones determination, TFAA-I reagent.

WITOLD CIESIELSKI, ZBIGNIEW H. KUDZIN, MACIEJ TASZ et JÓZEF DRABOWICZ. Can. J. Chem. **68**, 679 (1990).

Les nitrones réagissent avec un mélange d'anhydride trifluoroacétique et d'iodure de sodium pour dégager de l'iode. La quantité d'iode dégagée par rapport aux nitrones de départ étant stoechiométriques, on peut donc utiliser le réactif ATFA-I pour déterminer les nitrones d'une façon analytique. On décrit deux méthodes permettant de déterminer la présence de nitrones aux niveaux de la μmole et de la nmole.

Mots clés : détermination des nitrones; réactif ATFA-I.

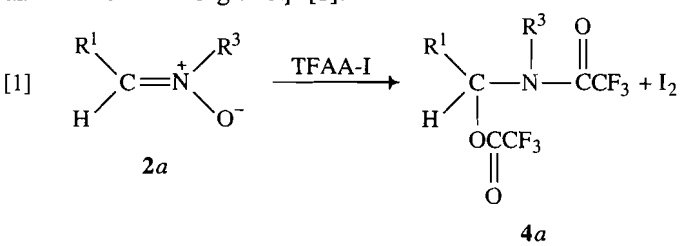
Introduction

Nitrones are useful reagents in organic synthesis (for a review of nitrone chemistry, see ref. 1) and are often used as spin trap reagents in EPR work (2). However, quantitative determination of these compounds is considered part of nitrogen analytical chemistry (3).

Recently we have published on the application of trifluoroacetic anhydride – sodium iodide (TFAA-I) system for microdetermination of sulphoxides (4) and for qualitative detection of sulphoxides and sulphimides by TLC chromatography (5). TFAA-I has also been used in the deoxygenation of quinoxalines 1,4-dioxides (6), its reactivity has been examined in reactions with other *N*-oxy compounds, including nitrones (7). Recently (8), we have established that aldonitrones react rapidly with TFAA-I, even under "analytical conditions" (0 to 20°C, approximately 5-fold excess of TFAA) forming compounds **4** and iodine according to eq. [1]:[3]



2*a* **4***a*

Reaction [1] proceeds with quantitative formation of iodine in very broad range of nitrones concentrations (10^{-1} to 10^{-6} M). Thus it can be used for quantitative determination of nitrones. The sensitivity of this procedure seems to be limited only by the method of iodine determination. Here we would like to present our approach for aldonitrones determination in which the use of TFAA-I reagent is combined with (*a*) the thiosulphate titration of released iodine with starch as an indicator and visual detection of the end point (μmole level of nitrones), and (*b*) the spectrophotometric determination of released iodine (nmole level of nitrones).

Experimental

Materials

Amine oxides — trimethylamine-*N*-oxide dihydrate, pyridine-*N*-oxide, 2-picoline-*N*-oxide, 3-picoline-*N*-oxide, and quinoline-*N*-oxide hydrate were purchased from Aldrich (Milwaukee, WI, USA). Trimethylamine-*N*-oxide, pyridine-*N*-oxide, picolines-*N*-oxide, and quinoline-*N*-oxide were dehydrated by double vacuum distillation. Quinoxaline-*N*-oxide was prepared according to ref. 6 and was of the same purity as previously reported.

Nitrones **2** were prepapred according to ref. 9 (**2***a* (9*a*), **2***b*, **2***c* (9*b*), **2***d* (9*c*), **2***e* (9*d*), **2***f* (9*e*), and **2***g* (9*f*). Nitrones **2***a–d* were purified by recrystallization to constant melting points: **2***a*: mp 85–86°C (84–86°C) (9*a*), **2***b*: mp 113–114°C (114°C) (9*b*), **2***c*: mp 115–117°C (116°C) (9*b*); **2***d*: mp 104–106°C (105°C) (9*c*). Nitrones **2***e–g* were purified by vacuum double distillation: **2***e*; bp 70–71°C/0.9 Tr, mp 29°C (66°C/0.6 Tr) (9*d*), **2***f*; bp 57–58.5°C/0.15 Tr, mp approx. 20°C, n_D^{20} = 1.4893 (9*e*), **2***g*; n_D^{22} = 1.4945 (9*f*).

Trifluoroacetic anhydride (TFAA) was purchased from Aldrich. Acetone was distilled over phosphorus pentoxide, redistilled over anhydrous potassium carbonate, and stored over molecular sieves, type 3A. Sodium iodide (Aldrich) was predried in a vacuum desiccator over phosphorus pentaoxide before use.

Solutions

NaI: 0.5 M solution of sodium iodide in anhydrous acetone.

TFAA: 0.5 M solution of trifluoroacetic anhydride in anhydrous acetone (the solution was prepared immediately before use).

Nitrones: 0.1 M solutions of nitrones **2***a–g* in anhydrous acetone. Working solutions of nitrones for spectrophotometric determinations were 5×10^{-4} *M* and were prepared immediately before use by dilution of 0.1 M solutions with anhydrous acetone.

Instruments

The absorption spectra were scanned on an instrument Specord UV-VIS, the absorbances were measured on a spectrophotometer VSU-2P (both Zeiss, Jena).

[1]To whom correspondence should be addressed.

[2]Revision received December 7, 1989.

[3]The structures of **3***a* and **4***a* were confirmed by GLC-MS measurements of corresponding reaction (TFAA-I and nitrone **2***a*) mixtures. Compounds **3***a* was also isolated from reaction mixture and compared with authentic imide **3***a*, synthesized independently. The results of mechanistic investigative reaction of TFAA-I and nitrones will be published in a separate paper.

Procedure

Iodometric titration

A known amount of nitrone (20–100 μmol contained in 200–100 μL 0.1 M solutions) is put into a 100 mL Erlenmayer flask and 1 mL of 0.5 M solution of NaI in acetone, followed by 0.8 mL of 0.5 M solution of TFAA in acetone are added. Iodine is immediately formed. After gentle mixing for 0.5 min the contents are diluted with 20 mL of 0.1 M solution of KI and titrated at once with sodium thiosulphate. At the end of titration, starch (0.5% aq. solution) is added.

Spectrophotometric determination

A known amount of nitrone (10 to 500 nmol) contained in 20 to 1000 μL of working solution is taken into a 10 mL volumetric flask and 1 mL of 0.5 M solution of NaI in acetone, followed by 100 μL of 0.5 M solution of TFAA in acetone are added. The reaction mixture is well mixed and diluted with acetone to 10 mL. Part of this solution is taken to a quartz type cuvette (for amounts of nitrone 10 to 50 nmol cuvettes with 50 mm light path and for 50 to 500 nmol cuvettes with 10 mm light path were used) and the reaction mixture absorbance (A) was measured after 2 min (since TFAA had been added), against acetone as a reference ($\lambda = 362$ nm, $t = 20$°C). The blank correction measurement (A_0) was performed also after 2 min for the reaction mixture of 1 mL of 0.5 M solution of NaI and 100 μL of 0.5 *M* solution of TFAA, diluted to 10 mL with anhydrous acetone, against acetone as a reference. The relation $A' = A - A_0$ as a function of nitrone quantity constituted the calibration line which was established on the base of nitrone **2***a* determinations (in the range of 10 to 500 nmol **2***a* — linear course) and was used in determinations of other nitrones.

Results and discussion

Apparent analytical feature of the reaction of nitrones with TFAA-I (Table 1) led to some additional investigations on the factors influencing the reaction course. One of the factors examined was the influence of the activity of acylation agents related to TFAA. Our results, summarized in Table 2, clearly reveal the change in reactivity in the following order: TFAA > AcCl > PhC(O)Cl > Ac_2O, which is in agreement with their relative acylation power. The results in Tables 1 and 2 also show that nitrones react faster than amines *N*-oxides and the reactivities of both nitrones and amines *N*-oxides are strongly dependent on the nature of the substituents. Thus, trialkylamine *N*-oxide treated with TFAA-I does not release iodine at all, whereas heterocyclic amines *N*-oxides react with nearly stoichiometric formation of iodine, showing the following reaction rate – structure dependence: quinoline *N*-oxide > quinoxaline *N*-oxide > pyridine *N*-oxide ~ picolines *N*-oxides. Similar differences are observed in reactions ot TFAA-I with nitrones: cyclic nitrones seem to be less reactive than acyclic, especially when bearing aryl substituents (Tables 1 and 2). It should be noted that the order of reagent addition strongly influences the reaction course, and consequently iodine formation. Thus, if the nitrone solution is first treated with TFAA and sodium iodide is added to this mixture later, only a small amount (approximately 10% of theoretical) of iodine is formed. This suggests that in the absence of iodide, acylated nitrone intermediate **2***A* rearranges to imide **3**, which is totally unreactive in further iodide oxidation (9) (eq. [2]).

2*a* **2***A*$_a$ **3***a*

The results of nitrones determination by iodometric titration and spectrophotometric determination are summarized in Tables 3 and 4, respectively.

The iodometric titration of the iodine released permits one to determine nitrones at the 20 to 100 μmol level with an average deviation up to ±1% (R.S.D. 0.0027 to 0.0076). Because of the relatively high molecular absorbance of triiodide, formed *in situ* from released iodine and dissolved sodium iodide (Fig. 1) ($\epsilon = 2.5 \times 10^4$ mol L^{-1} cm^{-1} at 362 nm in acetone) this system also allows spectrophotometric determination of nitrones (equivalent to released iodine) at the 500 to 50 nmol level in standard ($l = 1$ cm) and at the 50 to 10 nmol level using cuvette with path light $l = 5$ cm. The average deviation of these determinations is ±2.8% and R.S.D. ($n = 6$) 0.022 to 0.066.

In principle, eq. [1] shows the reaction of TFAA-I with nitrones should be completed when exactly 1 mol trifluoroacetic anhydride (TFAA) and 2 mol sodium iodide are consumed.[4]

[4]In the case of ketonitrones (**2***f*, **2***g*), stoichiometry and the rate of reaction with TFAA-I are different (see Tables 1, 2).

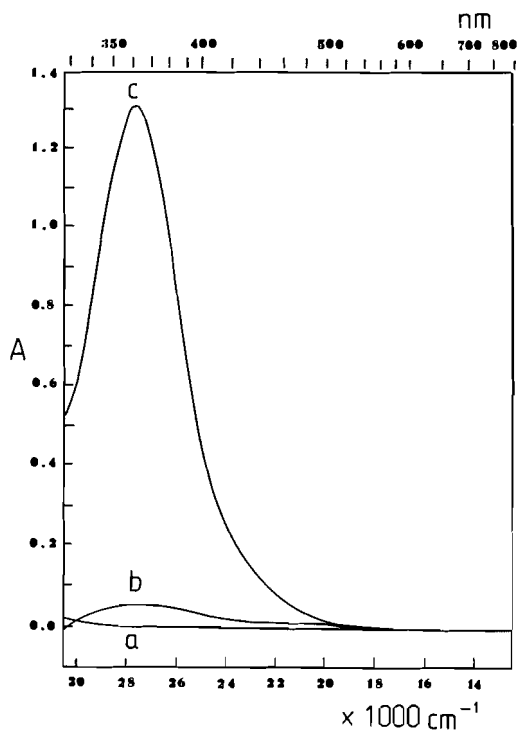

FIG. 1. Ultraviolet absorbance curves: (*a*) nitrones, (*b*) TFAA-I reagent, and (*c*) mixture of TFAA-I and nitrone. These curves were taken at standard conditions (2 min, 20°C, light path l = 1 cm) for solutions (*a*) 5 × 10^{-3} M of nitrone **2***a* or **2***b* (500 nmol nitrone in 10 mL acetone; (*b*) standard solution of TFAA-I in acetone (without nitrone); (*c*) standard reaction mixture containing 500 nmol of nitrone **2***a* (in 10 mL of acetonic solution).

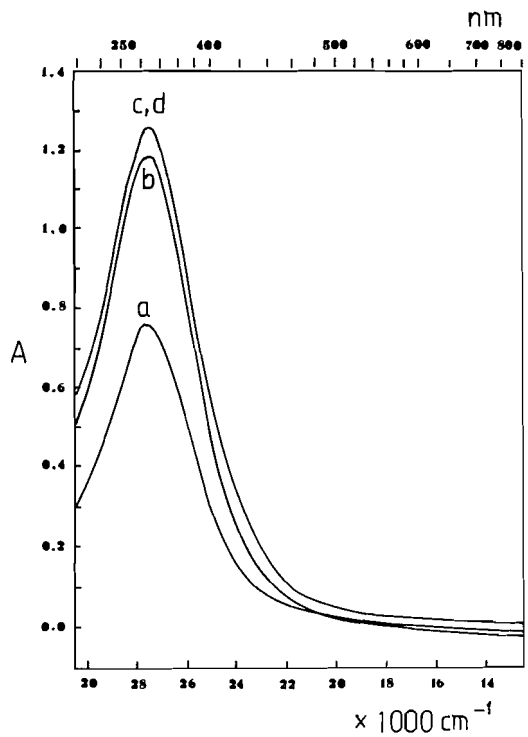

FIG. 2. The influence of sodium iodide on the uv absorbance of elemental iodine: (*a*) solution of iodine (500 nmol) in acetone (10 mL) (prepared by dilution of 50 μL of 0.01 M solution of iodine in acetone to 10 mL); (*b–d*) solutions of iodine (500 nmol) in 0.01 M (*b*), 0.05 M (*c*), and 0.1 M (*d*) acetone solutions of sodium iodide (10 mL).

However, TFAA is very easily hydrolyzed and to ensure that the reaction is completed in "analytical time" we have used at least four molar excess of TFAA and 2.5 molar excess of sodium iodide for determination on the μmole scale (with iodometric titration), and 100-fold excess of TFAA and 1000-fold excess of sodium iodide for spectrophotometric determination on nanomole level (Fig. 2). The low acidity of the reaction mixture (0.04 mmol TFAA) involves only marginal side-reaction of aerial oxidation of iodide, thus practically eliminates the

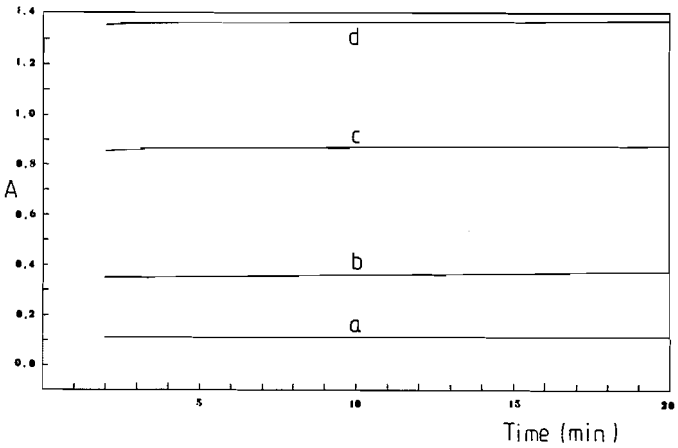

FIG. 3. The dependence of released iodine quantity as a function of the exposed time. The reaction mixture contains (*a*) standard solution of TFAA-I (without nitrone). The standard reaction mixture contains (*b*) 100 nmol, (*c*) 300 nmol, (*d*) 500 nmol nitrone **2***a*.

requirement of blank titration in titrimetric determinations of nitrones. However, in the spectrophotometric method, blank correction is needed since the iodine from aerial iodide oxidation constitutes a perceptible part of the total released iodine. Thus an examination of the course of iodine release as a function of time (Fig. 3) reveals that the reaction is completed in a few seconds after mixing the solutions, with slow gradual increase in iodine level caused by further air oxidation (A = 0.02 to A = 0.03 in 20 min). For this reason, blank correction was determined from the separate measurement of TFAA-I absorbance (standard condition: 2 min exposure, with acetone as reference) and this value was subtracted from measurements of nitrone determinations. The very low molecular absorbance of nitrones in the analytical wavelength region (Fig. 1) practically eliminates the requirement of additional correction of absorbance measurements.

Received September 13, 1989

JOANNE M. BALL, P. MICHAEL BOORMAN, and KELLY J. MOYNIHAN 1990. Can. J. Chem. **68**, 685 (1990).

Reactions of compound $Cl_3W(\mu\text{-}H)(\mu\text{-}Me_2S)_2WCl_2(Me_2S)$, **1**, and salts of derived chloro anion $[Cl_3W(\mu\text{-}H)(\mu\text{-}Me_2S)_2WCl_3]^-$, **2**, with bromide ion and with benzyl bromide are described. **1** was previously shown (1) to exist as a mixture of *meso* (C_{2v}) and DL-pair (C_1) of isomers, with the C_{2v} isomer being the more stable. Displacement of the terminal dimethyl sulfide ligand of **1** by bromide ion results in the formation of the analogous isomers of ion $[Cl_3W(\mu\text{-}H)(\mu\text{-}Me_2S)_2WCl_2Br]^-$, with retention of stereochemistry. The ^1H NMR spectra of compounds in this series are uniquely informative as to the isomers present since the two environments of the methyl groups in the bridging dimethyl sulfide ligands (axial and equatorial) provide a probe for the ion stereochemistry. This is used to show that in reactions of **2** with benzyl bromide, after replacement of μ-H by Br, Br exchanges with terminal chlorides to give a mixture of isomers. Reactions of **1** with benzyl bromide are further complicated by the fact that both terminal dimethyl sulfide and μ-H are replaced by bromides which then redistribute over all possible terminal sites.

Key words: hydride, confacial bioctahedral complexes, tungsten, bromocarbons.

JOANNE M. BALL, P. MICHAEL BOORMAN, et KELLY J. MOYNIHAN 1990. Can. J. Chem. **68**, 685 (1990).

On décrit les réactions du produit $Cl_3W(\mu\text{-}H)(\mu\text{-}Me_2S)_2WCl_2(Me_2S)$, **1**, et des sels du chloro anion $[Cl_3W(\mu\text{-}H)(\mu\text{-}Me_2S)_2WCl_3]^-$, **2**, avec l'ion bromure et avec le bromure de benzyle. Il a été démontré antérieurement (1) que le produit **1** existe sous la forme d'un mélange d'un isomère *méso* (C_{2v}) et d'une paire d'isomères-DL (C_1) et que l'isomère C_{2v} est le plus stable. Le déplacement du ligand sulfure de diméthyle terminal du produit **1** par l'ion bromure conduit à la formation des isomères analogues de l'ion $[Cl_3W(\mu\text{-}H)(\mu\text{-}Me_2S)_2WCl_2Br]^-$, avec rétention de la stéréochimie. Les spectres RMN du ^1H des composés de cette série fournissent des informations uniques sur la nature des isomères présents puisque les deux environnements des groupements méthyles des ligands sulfures de diméthyle agissant comme ponts (axial et équatorial) fournissent une sonde pour la stéréochimie de l'ion. On a utilisé ces sondes pour démontrer que, lors des réactions du composé **2** avec le bromure de benzyle suivie d'un remplacement du μ-H par un Br, le Br s'échange avec les chlorures terminaux pour donner un mélange d'isomères. Les réactions du composé **1** avec le bromure de benzyle sont encore plus compliquées par le fait que les deux sulfures de diméthyle terminaux ainsi que le μ-H sont remplacés par de ions bromures et qu'ils se redistribuent alors sur tous les sites possibles.

Mots clés : hydrure; complexes bioctaédriques confaciaux; tungtène; bromures de carbone.

[Traduit par la revue]

Introduction

The reactivity of confacial bioctahedral transition metal complexes has recently attracted considerable attention. Interconversion between edge-sharing and face-sharing bioctahedra in the presence of excess ligands is one method by which stereochemical rearrangements can take place (1). A second mechanism was recently demonstrated by Cotton and Luck (2), who showed that the interconversion between *syn* and *gauche* forms of the $[(PMe_3)Cl_2Mo(\mu\text{-}Cl)_3MoCl_2(Me_3P)]^-$ ion occurs through phosphine dissociation.

Cases involving an intramolecular exchange process between bridging and terminal ligands are less well documented; hence the observation of an example of this phenomenon in our laboratories (3) stimulated our interest in examining the factors which contribute to this kind of fluxionality. Processes of this type could be relevant to the potential catalytic properties of binuclear complexes possessing confacial bioctahedral structures, since coordinative unsaturation of one of the metal atoms can be achieved by bridge opening. The inclusion of hydride ligands in the coordination sphere of these M_2L_9 complexes would also be expected to enhance their potential reactivity. In an earlier publication (3) we reported the synthesis and characterization of the ditungsten(III) complex $Cl_3W(\mu\text{-}H)(\mu\text{-}Me_2S)_2WCl_2(Me_2S)$, **1** which, on the basis of a ^1H NMR study, was shown to exist as a mixture of two stereoisomers. As can be seen in Fig. 1, the C_{2v} isomer (*meso*) possesses just two pairs of environments (axial and equatorial) for the CH_3 groups of the two $\mu\text{-}Me_2S$ ligands whereas in the DL-pair of isomers (C_1 symmetry), the pairs of axial and equatorial CH_3 groups become inequivalent and as a result, four separate methyl resonances should be observed. However, we found that the DL-pair of enantiomers interconverted at room temperature in halocarbon solvents, via a fluxional process involving exchange of the terminal Me_2S ligand with the $\mu\text{-}Me_2S$ ligand *trans* to it. Through a different, and as yet undetermined route, the *meso* isomer was slowly produced from the C_1 isomers after extended periods in solution, and thus appears to be thermodynamically more stable. We then conducted a study of the reactivity of this compound with a variety of ligands and reagents and showed that the terminal Me_2S was readily displaced by Cl^- to yield anion $[Cl_3W(\mu\text{-}H)(\mu\text{-}Me_2S)_2WCl_3]^-$, **2** whose structure was determined crystallographically as the tetraphenylphosphonium salt (3). Subsequently, we reported (4) on the reactivity of **1** and **2** with chlorocarbons and several neutral ligands such as pyridine and MeCN, which resulted in a number of new W(III) binuclear complexes. In this paper we describe the reactivity of

1 and **2** with bromide ion and with benzyl bromide. It was anticipated that the reactivity pattern would be similar to that observed with Cl^- and with benzyl chloride (4). The latter compound reacts with the neutral complex **1** to yield the salt $[PhCH_2SMe_2][Cl_3W(\mu\text{-}Cl)(\mu\text{-}Me_2S)_2WCl_3]$, along with toluene. However, a more detailed understanding of the stereochemistry of these reactions would result from the distinction between the incoming bromide and the existing chloride ligands in the molecule.

Results

Reactions of neutral compound **1** can be divided into two types; namely, those involving displacement of the terminal dimethyl sulfide ligand and those which also involve the bridging hydride.

Initially we examined the reaction of **1** with tetraphenylphosphonium bromide in chlorocarbon solvents at ambient temperatures. It was anticipated that by analogy with the reaction of **1** with chloride ion under the same conditions the product would be the tetraphenylphosphonium salt of anion $[Cl_3W(\mu\text{-}H)(\mu\text{-}Me_2S)_2WCl_2Br]^-$. However, the stereochemistry would be distinguishable in this case since replacement of the terminal Me_2S from the C_s isomer would yield a product with C_s symmetry, whereas the C_1 isomeric pair would yield a pair of enantiomeric product ions with the same C_1 symmetry. The ^1H NMR spectra of the C_s isomer would consist of two methyl resonances of equal intensity stemming from the axial and equatorial Me groups of the $\mu\text{-}Me_2S$ groups, whereas the C_1 isomeric pair would be expected to produce four different methyl resonances (Fig. 1). The spectral data for the recrystallised product obtained from the reaction of **1** with PPh_4Br are given in Table 1. Resonances due to the phosphonium cation are not included, but the total integrations were consistent with the assignments given here. These assignments, for μ-H and axial/equatorial methyl groups of the bridging methyl sulfide ligands, are based on those reported earlier (3). As shown in Fig. 2 the spectrum is temperature dependent, and is best resolved at −70°C. Hence this is the spectrum reported in Table 1. The assignments for this bromo anion are based on those given earlier for the analogous chloro anion of **1** (3). The spectrum shows that both the more symmetric C_s isomer and the C_1 pair are produced, in approximately the same 2:1 ratio as in the starting material **1**. Thus the displacement of the terminal dimethyl sulfide ligand (confirmed by the presence of a signal due to the free ligand) occurs without significant change of configuration of the tungsten. Even in the presence of an excess of bromide there is no evidence that displacement of the terminal chloride ligands of **1** to give anions of the general formula $[W_2(\mu\text{-}H)(\mu\text{-}Me_2S)_2Cl_{6-n}Br_n]^-$ occurs. This is in contrast to the reactions of anion **2** with arylthiolate anions which rapidly displace chloride (5). In the spectral assignments given in Fig. 2 it is noteable that resonances due to μ-H ligands of the stereoisomers of bromo anion occur in the same general region of the spectrum as methyl resonances, rather than upfield of TMS. This phenomenon has been observed for other μ-hydrido complexes of tungsten (3, 6). By comparison with the ^1H NMR behavior of **1** and **2**, these hydride resonances were expected to display a temperature dependence. As shown in Fig. 2, at −70°C the C_s isomer displays a sharp hydride resonance at δ 2.77, while the C_1 pair has a hydride resonance at δ 3.31 ppm. With increasing temperature, these resonances broaden and move to lower field. This phenomenon appears to be common to all the complexes we have studied which contain the $W(\mu\text{-}H)(\mu\text{-}Me_2S)_2W$ entity. In previous work (3), we showed that $^{183}W—^1H$ coupling constants remained constant at ca. 105 Hz over the accessible temperature range, suggesting that the temperature dependence of δ was not caused by any process involving W—H bond cleavage. Chemical shifts of methyl sulfide resonances are independent of temperature, and are not involved in any exchange processes with the terminal ligand, in contrast to the behavior of C_1 isomers of precursor molecule **1** (3).

The thermodynamic stability of M—Cl bonds is, in general, greater than that of equivalent M—Br bonds. Consequently the reaction of solutions of mixed isomers of the $[BrCl_2W(\mu\text{-}H)(\mu\text{-}Me_2S)_2WCl_3]^-$ ion with tetraphenylphosphonium chloride in CD_2Cl_2 solution gave rise to a quantitative conversion to the perchloro anion, $[Cl_3W(\mu\text{-}H)(\mu\text{-}Me_2S)_2WCl_3]^-$. The characteristic ^1H NMR resonances of this anion (two singlets of equal intensity at δ 3.10 and 3.56 ppm), completely replace the group of six resonances in this region due to the two isomers of the bromoanion precursor. This helped to verify the identity of the bromo anion, but the availability of good quality crystals of tetraphenylphosphonium salt of this species prompted us to attempt to carry out an X-ray crystallographic investigation. Identity of bromo anion **3** was confirmed,[3] but the structure determination was complicated by the weighted disorder of the bromine atom among the six possible terminal ligand positions.

[3]Crystal data: formula: $[PPh_4][Cl_3W(\mu\text{-}H)(\mu\text{-}Me_2S)_2WCl_2Br]$; space group orthorhombic, $P2_1nb$; a = 12.041(3), b = 13.221(2), c = 22.782(3) Å

Since the ^{1}H NMR spectrum of the solution had indicated that the compound is a mixture of two isomers, this form of disorder in the crystal structure might have been anticipated. Because the crystal contains a mixture of two stereoisomers, bond length and bond angle data will all be averages, and therefore would provide no definitive structural comparisons with the analogous chloro anion, **2**. This structure will be reported separately (7), since its refinement is of greater crystallographic than chemical interest.

Reactions of 1 and 2 with benzyl bromide

It was shown previously that the bridging hydride in **1** and **2** was capable of reducing various chlorocarbons at elevated temperatures (i.e. ca. 80°C) to yield an alkane and the anion $[Cl_3W(\mu\text{-}Cl)(\mu\text{-}Me_2S)_2WCl_3]^-$ (4). The replacement of μ-H by μ-Cl enabled us to make direct structural comparisons between these two binuclear anions, thus affording an opportunity to examine the effect of this type of ligand substitution on the W—W bond length. It was therefore anticipated that other halide ions might be introduced into the bridging position of the binuclear framework by suitable selection of reactive halocarbon. In addition, reactions of this type would provide information on the possible exchange between bridging and terminal sites during the reaction. The simplest of these reactions is that between RX and anion **2**, which can be represented (in the absence of halide scrambling) as:

$$[1]\quad [Cl_3W(\mu\text{-}H)(\mu\text{-}Me_2S)_2WCl_3]^- + RX \xrightarrow{\Delta} [Cl_3W(\mu\text{-}X)(\mu\text{-}Me_2S)_2WCl_3]^- + RH$$

The neutral compound **1** is subject to replacement of terminal dimethyl sulfide as well as replacement of hydride. Alkylation of terminal dimethyl sulfide yields sulfonium cation:

$$[2]\quad Cl_3W(\mu\text{-}H)(\mu\text{-}Me_2S)_2WCl_2(Me_2S) + 2RX \xrightarrow{\Delta} [RMe_2S]^+[Cl_3W(\mu\text{-}X)(\mu\text{-}Me_2S)_2WCl_2X]^- + RH$$

We carried out both types of reactions for RX = benzyl bromide. First, the compound $\{[Ph_4P][Cl_3W(\mu\text{-}H)(\mu\text{-}Me_2S)_2WCl_3]\}\cdot 2CH_2Cl_2$ was dissolved in $C_2H_4Cl_2$ with an excess of benzyl bromide and refluxed for ca. 2 h (see Experimental). Toluene was identified in the reaction volatiles as expected. After removal of the solvent and recrystallization of the reaction product from dichloromethane, the ^{1}H NMR spectrum of the resulting orange–brown crystals was obtained in CD_2Cl_2. This is shown in Fig. 3(*a*). Instead of the simple pattern expected for axial and equatorial methyl group protons in $[Cl_3W(\mu\text{-}Br)(\mu\text{-}Me_2S)_2WCl_3]^-$, (i.e. two singlets of equal intensity corresponding to the two equivalent pairs of environments), a complex multiplet is observed for each site, with the pattern being identical in both multiplets. This clearly indicated that bromine scrambling in the ditungsten(III) species had occurred. The three possible isomeric forms for the ion $[W_2Cl_6Br(Me_2S)_2]^-$ are shown in Fig. 4. It is clear that these three forms are inadequate to account for the spectrum observed, and that in all probability small amounts of dibromo- and possibly more highly substituted analogs, along with perchloro anion, were formed. It would therefore appear that redistribution of the bromide among the possible sites has occurred, and that there is some further substitution of chloride by bromide. There is, however, no indication that substitution reactions displace the μ-Me_2S ligands.

A plausible mechanism for this reaction is given in Scheme 1. In view of the elevated temperature required for any of the halocarbons to react with μ-hydride, the likely first step is the cleavage of a W—H bond, thereby generating the more reactive terminal hydride ligand. In the presence of benzyl bromide, in dichloroethane solvent, this hydride will have two possible C—X bonds to react with, but that with the more labile C—Br bond will be preferred. The coordinatively unsaturated intermediate so produced could then return to a confacial bioctahedral structure by either of two the pathways shown in Scheme 1. This could occur before the hydride reacts, as depicted in the

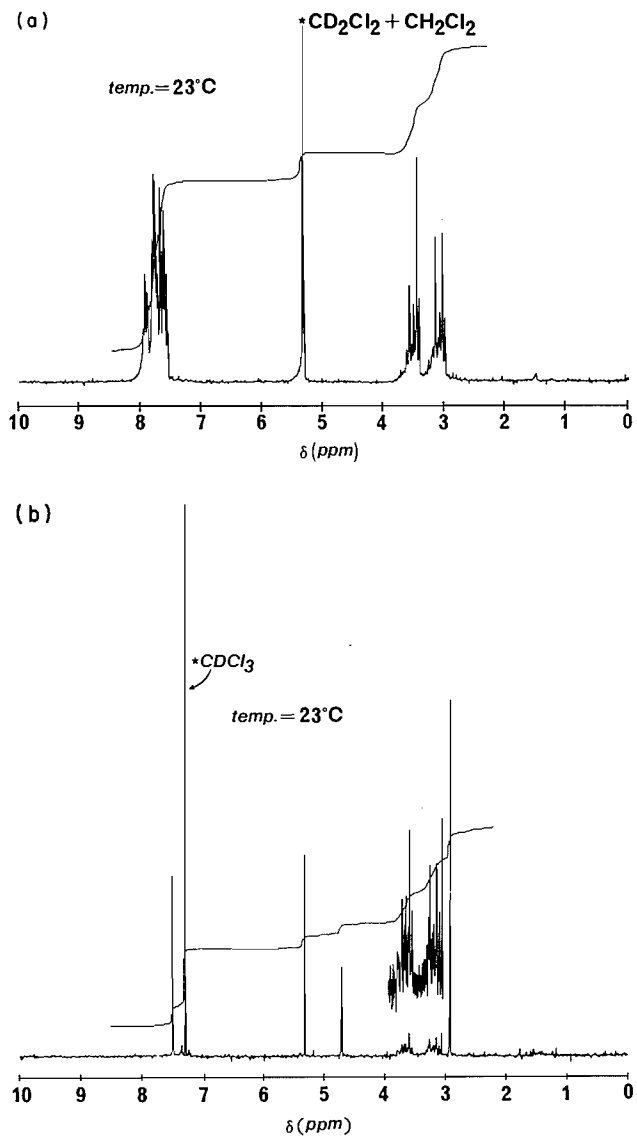

FIG. 3. (*a*) 200 MHz ^{1}H NMR spectrum (in CD_2Cl_2) of the product of reaction of **2** with benzyl bromide, $[Ph_4P][W_2Cl_{7-n}Br_n(Me_2S)_2]\cdot CH_2Cl_2$, ($n \sim 1$); (*b*) 200 MHz ^{1}H NMR spectrum (in CD_2Cl_2) of the product of reaction of **1** with benzyl bromide, $[PhCH_2SMe_2][W_2Cl_{7-n}Br_n(Me_2S)_2]\cdot CH_2Cl_2$, ($n \sim 2$). Resonances due to the axial and equatorial methyl groups of the μ-Me_2S groups have been expanded for clarity. Other signals are due to the sulfonium cation and CH_2Cl_2 of solvation.

central portion of the scheme. A similar mechanism was proposed by us earlier to account for the exchange between terminal and bridging Me_2S in **1**.[3] The interconversion between isomer **A**, **B**, and **C** could be explained on the same basis.

By analogy with this system, the spectrum of the product from the elevated temperature reaction between benzyl bromide and neutral compound 1 (as in [2] above) would be expected to possess an even more complex pattern in the methyl resonance region of the ^{1}H NMR spectrum, since a minimum of two bromines will be present in ditungsten(III) anion. A species with formula $[W_2Cl_5Br_2(\mu\text{-}Me_2S)_2]^-$ can be shown to exist as eight geometric isomers, three of which are enantiomeric. As shown in Fig. 3(*b*) the two multiplets in the μ-Me_2S region are indeed more complex, but to account for this spectrum, possible isomers of the dibromo anion alone are inadequate. Small amounts of more highly substituted isomers must also be present, along with monobromo and perchloro anions. These findings are of interest from two points of view. Firstly the binuclear anion retains its basic structural pattern even though there is a substantial change in the ligand set. This has been observed previously in confacial bioctahedral ditungsten(III) complexes by Hawkins and Garner, who studied chloride exchange in the $W_2Cl_9^{3-}$ anion and concluded that all sites were equivalent (8). More recently, it has been shown that halide ions can be replaced by chalcogenide ions in the basic octahedral cluster unit of $M_6X_8^{4+}$ (9). The second aspect worthy of comment is that, by implication, binuclear clusters might be capable of catalyzing the exchange of halide groups between benzyl molecules. This would logically ensue from the following implied reaction.

$$\text{W-Cl} + \text{Bz-Br} \leftrightharpoons \text{W-Br} + \text{Bz-Cl}$$

Small amounts of perchloro anion may be generated, a result of halide-generated exchange process in the chlorocarbon solvent.

Experimental

Starting materials **1** and **2** were prepared as described in ref. 3; a freshly prepared sample of **1** was used in each reaction, since it loses its terminal dimethyl sulfide over extended periods of time. All reactions and handling procedures were carried out in an atmosphere of pure dry nitrogen, by using standard Schlenk tube and glovebox techniques. Reagents, sources and drying procedures/agents were as follows: benzyl bromide (B.D.H.), dried over $MgSO_4$; tetraphenylphosphonium bromide (Aldrich), dried at 100°C *in vacuo*; acetonitrile (Fisher), dried over P_2O_5, then CaH_2; all other solvents and reagents were dried and degassed before use, as previously described (3, 4). Mass spectra were obtained using a Varian MAT CH-5 spectrometer, and ^{1}H NMR spectra were obtained using a Varian XL-200 or a Bruker ACE-200 MHz spectrometer.

Preparation of $[Ph_4P][BrCl_2W(\mu\text{-}H)(\mu\text{-}Me_2S)_2WCl_3]$

$Cl_3W(\mu\text{-}H)(\mu\text{-}Me_2S)_2WCl_2(Me_2S)$ (0.544 g, 0.74 mmol) and Ph_4PBr (0.31 g, 0.74 mmol) were placed in a Schlenk tube with dichloromethane (30 mL) and stirred for 30 min. A darkening in color of the reaction mixture indicated that the desired displacement of dimethyl sulfide by bromide ion had occurred, consistent with the results of an NMR study of this reaction. The solution was filtered after 12 h, and the resulting purple filtrate was reduced in volume to 15 mL. Hexane (15 mL) was slowly added to this solution. Cooling the solution to 10°C yielded a purple microcrystalline material, which after recrystallization from dichloromethane/hexane yielded crystals of X-ray quality. Yield: 0.75 g, 94% based on W. *Anal.* calcd for $W_2Cl_5BrPS_2C_{28}H_{32}$: C 30.80, H 3.05, S 5.88; found (M.H.W. Labs.): C 30.86, H 3.05, S 5.91.

Preparation of $[Ph_4P][W_2Cl_{7-n}Br_n(Me_2S)_2] \sim 1.5\ CH_2Cl_2$ (n ~ 1)

Reaction of neat benzyl bromide (ca. 1mL) with $[Ph_4P][Cl_3W(\mu\text{-}H)(\mu\text{-}Me_2S)_2WCl_3]\cdot 2CH_2Cl_2$ (0.27 g, 0.22 mmol) in $C_2H_4Cl_2$ (30 mL) at reflux temperature (~80°C) for a period of 2 h yielded an orange–red solid solution which was evaporated to dryness under vacuum. The solid product was recrystallized from a dichloromethane–hexane mixture to give the crystalline product. Yield: 0.19 g. The compound was characterized by its ^{1}H NMR spectrum as described above, but the labile nature of the CH_2Cl_2 of solvation precluded good elemental analysis. Toluene (GC analysis of the reaction volatiles) was found to be produced in the reaction, as expected.

Preparation of $[Me_2SCH_2Ph][W_2Cl_{7-n}Br_n(Me_2S)_2]\cdot CH_2Cl_2$ (n ~ 2)

1 (0.15 g, 0.20 mmol) was dissolved in $C_2H_4Cl_2$ (30 mL) and reacted with benzyl bromide (0.6 mL) at reflux temperature (~80°C) for 2 h. The orange–red solution was filtered, and the solvent removed under vacuum. The product was redissolved in CH_2Cl_2 (15 mL)

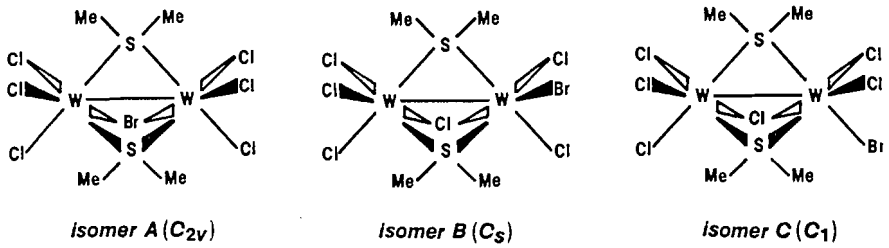

FIG. 4. Possible isomeric forms of the ion $[W_2Cl_6Br(\mu\text{-}Me_2S)_2]^-$.

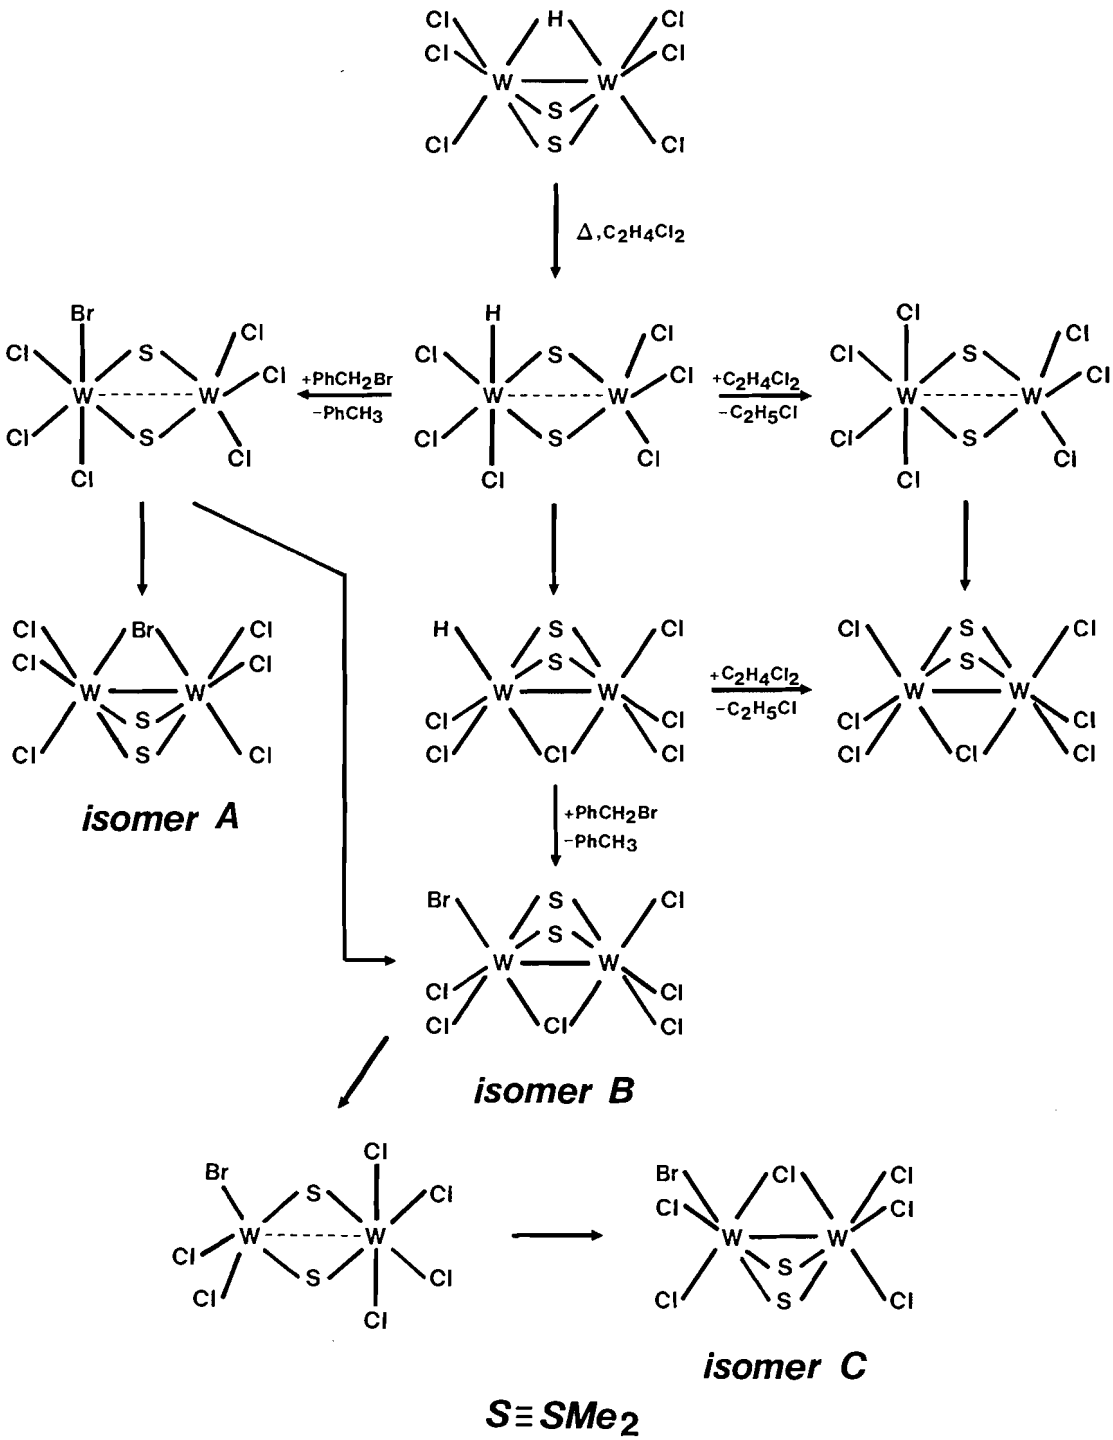

SCHEME 1. Postulated mechanism for the formation of halogenated products from anion **2**.

and hexane added (ca. 3 mL). After cooling to −20°C the solution deposited orange–red crystals which proved to be the above compound. Yield: 0.13 g. Reproducible analytical data were precluded by the labile nature of the solvent of crystallization. ^{1}H NMR data for this complex were discussed in the text.

Effect of substituents on the solvatochromism of stilbazolium merocyanines

MALGORZATA NIEDBALSKA[1] AND ILONA GRUDA[2]

Département de chimie–biologie, Université du Québec à Trois-Rivières, Trois-Rivières (Québec), Canada G9A 5H7

Received April 10, 1989[3]

MALGORZATA NIEDBALSKA and ILONA GRUDA. Can. J. Chem. **68**, 691 (1990).

The visible spectra of a series of merocyanines, derivatives of 4-[(4-oxocyclohexa-2,5-dienylidene)ethylidene]-1,4-dihydropyridine, have been investigated in a number of solvents and solvent mixtures. The effect of substituents on the solvatochromic behaviour of these compounds is described. All investigated merocyanines exhibited a strong negative solvatochromism. Inverse solvatochromism was observed in solvents of very low polarity for polar dyes, and in polar solvents for dyes containing hydrophobic substituents. This inversion of the solvatochromic behaviour is attributed to aggregation phenomena.

Key words: merocyanines, solvatochromism, betaine, aggregation.

MALGORZATA NIEDBALSKA et ILONA GRUDA. Can. J. Chem. **68**, 691 (1990).

Opérant dans un certain nombre de solvants et de mélanges de solvants, on a déterminé les spectres visibles d'une série de mérocyanines dérivées de la 4-[(4-oxocyclohexa-2,5-dièny1dène)éthylidène]-1,4-dihydropyridine. On décrit l'effet solvatochromique de ces composés. Toutes les mérocyanines étudiées présentent un solvatochromisme fortement négatif. On a observé un solvatochromisme inverse avec des solvants de très basse polarité mis en présence de colorants polaires et avec des solvants polaires mis en présence de colorants contenant des substituants hydrophobes. On attribue cette inversion dans le comportement solvatochromique à un phénomène d'agrégation.

Mots clés : mérocyanines, solvatochromisme, bétaïne, agrégation.

Introduction

Merocyanine dyes of the stilbazolium betaine type (Table 1) have attracted much attention because of the extreme sensitivity of their electronic spectra to the medium (1–3). These spectra are strongly dependent on pH and polarity of their microenvironment and also on the external electric field (4, 5). The model compound, **1***a*, exhibits a very strong negative solvatochromism. This behaviour indicates that the ground state of the dye (much more polar than its excited state) acquires extra stabilization with increased polarity of the solvent. It has been reported recently that in solvents of very low polarity (E_T < 34.6) **1***a* undergoes an inverted solvatochromism, which implies a significant structural change of **1***a* in this kind of solvent (6).

We have shown previously (7) that the introduction of alkyl substituents into the quinonoid ring of stilbazolium betaines strongly influences the solvatochromic behaviour of these compounds. However, no systematic study has been done on the effect of substituents on the spectral properties of stilbazolium betaines. In this article we report the results obtained for several stilbazolium merocyanines substituted by electron-withdrawing or electron-donating groups. To cover a large scale of polarities, we used two solvent mixtures: pyridine–water and pyridine–cyclohexane.

Experimental

Melting points were taken on a Fisher–Johns melting point apparatus and are uncorrected. All merocyanines were synthesized according to the procedure described earlier (7). Compounds **1***b*, **1***c*, **1***d*, **1***g*, and **1***h* were described previously, as shown in Table 1. IR spectra were taken on a Perkin–Elmer model 597 spectrometer. Elemental analyses were performed by Guelph Chemical Lab. Ltd., Guelph, Ontario.

*1-(6-Hydroxyhexyl)-4-[(3-nitro-4-oxocyclohexa-2,5-dienylidene)ethylidene]-1,4-dihydropyridine (***1**e**)* was synthesized from the corresponding pyridinium salt (8) and 3-nitro-4-hydroxybenzaldehyde. The solid was twice recrystallized from ethanol – aqueous ammonia, treated with 10% NaOH, and washed several times with concentrated ammonium hydroxide; 84% yield, dark red solid with metallic luster, mp 218–220°C; IR (KBr): 3400, 1640, 1590, 1520, 1460, 1420, 1330, 1260, 1230, 1160, 1060, 1040, 960 cm^{-1}; ^1H NMR (Me_2SO-d_6) δ: 1.30 (m, 8), 3.30 (t, 2), 4.35 (t, 2), 6.33 (d, 1), 6.70 (d, 1), 7.50 (d, 1), 7.80 (m, 5), 8.60 (d, 1). Anal. calcd. for $C_{19}H_{22}N_2O_4$: C 66.67, H 6.43, N 8.19; found: C 67.05, H 6.82, N 8.26.

Spectra

Absorption spectra were recorded on a Perkin–Elmer Lambda 4B spectrophotometer. Cyclohexane (Fisher) and pyridine (Aldrich) were spectrophotometric grade and were used without further purification. Solutions (10^{-5} M) of merocyanines **1***b*–**1***i* were prepared in the following solvents and solvent mixtures: cyclohexane–pyridine, v/v (90, 80, 70, 60, 50, 30, and 20%), pyridine, 0.5% aq. NaOH – pyridine, v/v (5, 10, 20, 30, 50, 80, 90, 95%). We used 0.5% NaOH in order to avoid the protonation of merocyanines that occurs in pure water (7).

Results

Table 1 shows the compounds studied in this work. Compounds **1***b*–**1***g* were dissolved in anhydrous pyridine and solutions of various polarities were prepared by adding appropriate amounts of pyridine and 0.5% NaOH or cyclohexane. Figure 1 shows the changes in λ_{max} of the long wavelength absorption band as a function of the E_T parameter, which is considered to be an appropriate measure of solvent polarity for spectral studies (11). We calculated the E_T for the mixtures of solvents assuming molar additivity of this parameter. A similar pattern of curves was obtained when dielectric constants were used as a measure of polarity.

TABLE 2. Spectral properties of merocyanines

Compound	λ_{max} I	λ_{max} II	$\Delta\lambda_{max}$
1*b*	617.5	458.7	158.8
1*c*	631.9	547.1	84.8
1*d*	655.9	506.3	149.6
1*e*	567.6	463	104.6
1*f*	508.1	408.2	99.9
1*g*	633.9	491.9	142.0

Table 2 gives the two extreme values of λ_{max} (λ_{max} I in the least polar solvent and λ_{max} II in the most polar solvent), and $\Delta\lambda_{max}$, which was considered in this work as a measure of solvatochromism. It may be seen from Table 2 and Fig. 1 that strongly electron-withdrawing substituents like NO_2 (**1***e*, **1***f*) exert two effects: (1) a hypsochromic shift of the whole spectrum and (2) a decrease in the extent of solvatochromism, as measured by $\Delta\lambda_{max}$. Electron-donating groups such as CH_3 (**1***g*) and OCH_3 (**1***d*) cause a bathochromic shift of the spectrum and affect only slightly the extent of solvatochromism. In this aspect the compound with two *t*-Bu substituents (**1***c*) is an exception, with a much lower $\Delta\lambda_{max}$.

Inverted solvatochromism was apparently observed in media of very low polarity for all compounds in Fig. 1. However, this effect must be attributed to an aggregation phenomenon rather than to a change in the structure of merocyanines. Figure 2 shows the spectra of **1***f* in mixtures of 20, 30, and 50% cyclohexane in pyridine. It is seen that the hypsochromic shift in 50% cyclohexane is related to emergence of a new absorption band, which has to be attributed to an aggregated species. **1***f* is a very polar compound; therefore, in solvents of low polarity it forms aggregated species. Dilution experiments give additional data showing that these spectral changes are related to the formation of aggregated species (Fig. 3).

We then examined the spectra of a strongly lipophilic dye, **1***h*, in very polar media. Figure 4 shows the spectra of **1***h* recorded in mixtures of 80, 90, and 95% of 0.5% NaOH in pyridine. A phenomenon similar to that in Fig. 2 was observed, i.e., emergence of a new absorption band for the aggregated species, which, in this case, is red-shifted with respect to the monomeric dye. For a still more lipophilic compound (**1***i*) we observed (Fig. 5) similar behaviour beginning in a less polar solvent (70% NaOH in pyridine).

Discussion

The extreme solvatochromism of stilbazolium merocyanines, together with electrochromism (5) and the nonlinearity of their optical properties (4, 12), makes this class of compounds very promising with respect to technical applications.

Here we show that appropriate design of molecular structure allows construction of compounds that absorb in a very broad region of the visible spectra. Additional shifts may be obtained by inducing molecular aggregation. Strongly electron-with-

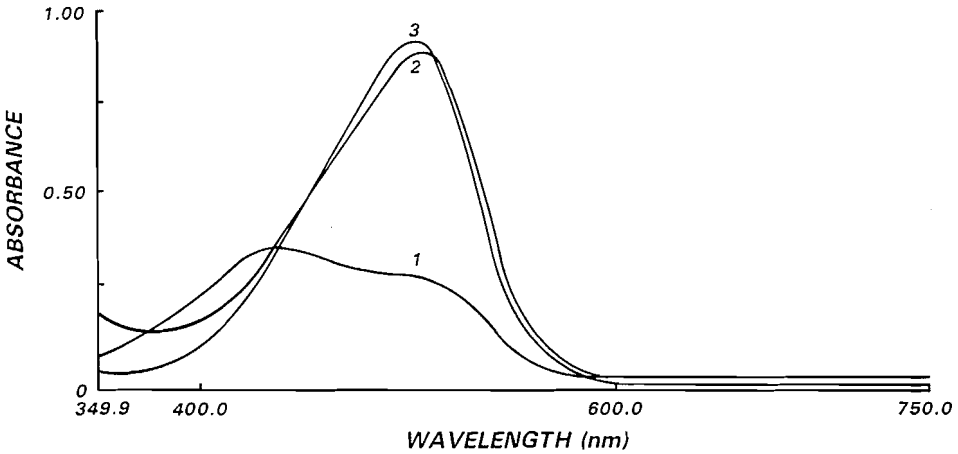

FIG. 2. Absorption spectra of merocyanine **1***f* in 50% cyclohexane–pyridine (1); 30% cyclohexane–pyridine (2); and 20% cyclohexane–pyridine (3).

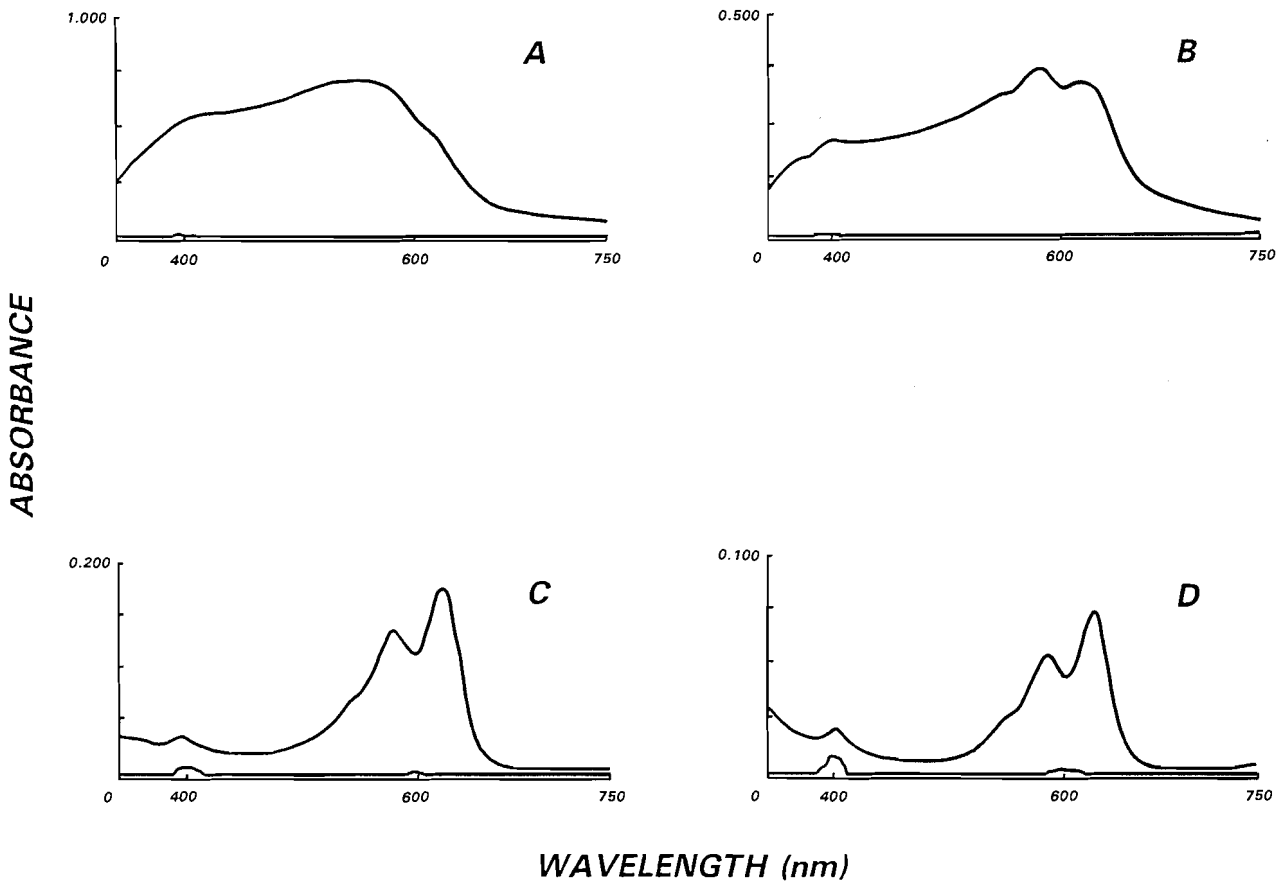

FIG. 3. Absorption spectra of merocyanine **1***b* in 70% cyclohexane–pyridine at dye concentrations of 5×10^{-5} M (A); 10^{-5} M (B); 5×10^{-6} M (C); and 10^{-6} M (D).

drawing substituents shift the absorption to shorter wavelengths, and electron-donating substituents to longer wavelengths, which is the normal contribution of substituents in conjugated systems. The extent of solvatochromy is reduced by NO_2 groups. This effect can be attributed to partial dispersion of the negative charge located on the carbonyl oxygen to the nitro groups as shown in Scheme 1.

This makes the solvation of the betaine structure B by polar solvents less efficient. Therefore the relative stability of ground and excited states is less affected by the increase in polarity of the medium.

One would expect an opposite effect, i.e., an increase of solvatochromy, by electron-donating groups, which should increase the negative charge on oxygen. It may be thought that this effect exists, but is reduced by a steric hindrance to solvation that, very important in the case of *t*-Bu substituents, is also present in the case of CH_3 and OCH_3 substituted derivatives. Therefore, for merocyanines substituted by electron-

donating groups, we can observe a shift to longer wavelengths but no increase in the $\Delta\lambda_{max}$.

Two types of aggregates were observed in this study. Aggregation of polar merocyanines in solvents of very low polarity gave rise to an absorption band hypsochromic to the monomer band. Therefore we have to envisage here a card-packing head-to-tail arrangement of monomeric units. The main attraction force between monomers in this species should be the dipole–dipole interaction, which will preferentially stabilize the ground state molecules, and hence shift λ_{max} to lower wavelengths.

Aggregation of dyes containing many hydrophobic substituents in highly aqueous solvents resulted in a bathochromic shift of the spectrum, which may be attributed to a micelle-type association of monomers. The dipolar merocyanine portions of these molecules would be held on the micellar surface in a roughly head-to-head and tail-to-tail orientation so that the ground state is destabilized. This would account for the bathochromic shift on association (13, 14).

A series of compounds containing a cyclopropyl ring adjacent to the position of oxidation during fungal biotransformation has been prepared and subjected to enzymic oxidation using *Mortierella isabellina* or *Rhizopus arrhizus*. Carbon hydroxylation and sulfoxidation reactions were observed, but in neither case did opening of the cyclopropyl ring occur. Both these reactions were subject to inhibition by carbon monoxide but not by cyanide ion, properties characteristic of cytochrome P-450 dependent mono-oxygenase enzymes. Hydroxylation at a cyclopropyl C—H bond has been studied by the use of phenylcyclopropane and phenylthiirane as substrates for the mono-oxygenase of *M. isabellina*. The former was not oxidized, but the latter was converted to phenyl glyoxylic acid in moderate yield.

Key words: biotransformation, cyclopropanes, fungi, metabolism.

HERBERT L. HOLLAND, MICHAEL J. CHERNISHENKO, MORGAN CONN, ANTHONY MUNOZ, T. SAMUEL MANOHARAN et MICHAEL A. ZAWADSKI. Can. J. Chem. **68**, 696 (1990).

On a préparé une série de composés contenant un noyau cyclopropyle adjacent de la position qui subit l'oxydation lors de la biotransformation à l'aide de champignons et on a soumis ces composés à une oxydation enzymatique à l'aide de *Mortierella isabellina* ou de *Rhizopus arrhizus*. On a observé des réactions d'hydroxylation du carbone et de sulfoxydation; toutefois, aucune de ces réactions n'a provoqué d'ouverture du noyau cyclopropyle. Les deux réactions sont sujettes à une inhibition par le monoxyde de carbone, mais non par l'ion cyanure; ces propriétés sont caractéristiques d'enzymes mono-oxydases dépendant du cytochrome P-450. On a étudié l'hydroxylation d'une liaison C—H du cyclopropyle en utilisant le phénylcyclopropane et le phénylthiirane comme substrats pour le mono-oxygénase de la *M. isabellina*. Le premier de ces composés n'est pas oxydé, mais le second est transformé en acide phénylglyoxylique avec un rendement moyen.

Mots clés : biotransformation, cyclopropanes, champignons, métabolisme.

Introduction

Biotransformation of an organic compound by a growing or resting fungal culture has been used to perform a variety of reactions, the most remarkable of which are the direct introduction of the hydroxyl group in an asymmetric fashion, particularly into the steroid nucleus (1), and the asymmetric oxidation of sulfides to sulfoxides (2). The enzymes responsible for these reactions have yet to be fully purified and characterized from fungal sources, but are thought to be cytochrome P-450 dependent mono-oxygenases (1, 2), whose mode of action involves the radical abstraction/rebound recombination process outlined in Fig. 1 for the hydroxylation reaction (3).

A possible limitation on the synthetic utility of such bio-oxidations is posed by the presence in the substrate of a functionality that may be incompatible with the requirements of Fig. 1. In particular, the presence of groups close to the reactive site whose structure or integrity can be compromised may be contraindicated. Such radical sensitive groups may include alkenes susceptible to rearrangement or cyclopropyl units that may undergo cyclopropyl–allyl or cyclopropylcarbinyl–homoallyl conversions.

Migration of double bonds adjacent to the reactive centre has been observed during enzymic hydroxylation of terpenes (4) and steroids (5), and attributed to allylic rearrangement of a carbon radical intermediate. Fungal hydroxylation or sulfoxidation adjacent to a cyclopropyl ring has not been reported, however; the cyclopropyl-containing steroids that have been used as substrates for fungal biotransformation are hydroxylated at sites remote from the cyclopropyl functionality (6).

Cyclopropyl compounds have nevertheless been used as probes for the presence of free radical intermediates in enzymic

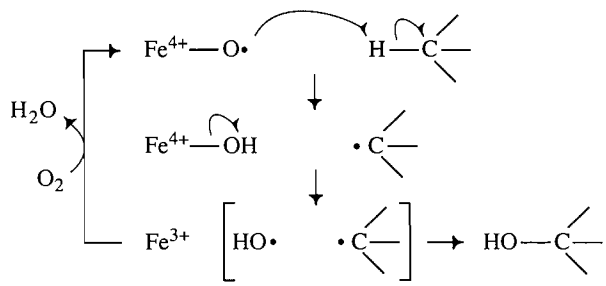

FIG. 1 Catalytic cycle of cytochrome P-450 dependent mono-oxygenases.

hydroxylation reactions (7). Dopamine β-hydroxylase, a copper-containing enzyme that catalyses the hydroxylation of dopamine at the benzylic position, is inactivated by benzylcyclopropanes analogous to **1** by a mechanism thought to involve cyclopropylcarbinyl–homoallyl rearrangement (8).

While oxidation at nitrogen (9, 10) and hydroxylation of highly strained cyclopropyl-containing substrates such as bicyclo[2.1.0]pentane (11) by cyt. P-450 dependent enzymes can involve opening of an adjacent cyclopropyl ring, other reactions such as the 7α hydroxylation of 5,6α-methanocholesterol (12) and the hydroxylation of methylcyclopropane (13) proceed without involvement of the cyclopropyl unit. These data have been rationalized by the assumption that, under normal circumstances, the rate of radical recombination of Fig. 1 (estimated as $\geq 10^9\ s^{-1}$) exceeds the rate of ring opening of a cyclopropyl methyl radical (ca. $1 \times 10^8\ s^{-1}$) (14).

Ring opening of cyclopropylbenzyl radicals, such as might be formed from **1** and **3** during benzylic oxidation by mono-

oxygenase enzymes, is slower than the opening of cyclopropyl methyl radicals by several orders of magnitude (15), so that no rearrangement is to be expected. To confirm this prediction, and the suitability of cyclopropyl compounds in general as substrates for biotransformation, we have used **1** and **3** as substrates for benzylic oxidation and sulfoxidation respectively by the fungus *Mortierella isabellina*, an efficient benzylic hydroxylating (16) and sulfoxidizing (17) microorganism; the cyclopropyl steroids **8** and **11**, with cyclopropyl functionality adjacent to C-6, as substrates for the steroid 6β hydroxylating fungus *Rhizopus arrhizus* (18); and finally, in view of the report that phenylcyclopropane (**13**) can act as a mechanistic probe[1] and inhibitor (20) of benzylic hydroxylating enzymes, we have undertaken a study of the biotransformation of this compound, and the corresponding thiirane **14**, by *M. isabellina*.

3	*M. isabellina*	**4** (58), **5** (2)
6	*M. isabellina*	**7** (4)
8	*R. arrhizus*	**9** (2), **10** (6)
11	*R. arrhizus*	**12** (38)
13	*M. isabellina*	None
13 + **16**	*M. isabellina*	**16**-sulfoxide (55)
14	*M. isabellina*	**15** (31)

Results and discussion

The results of the incubations discussed below are summarized in Table 1. The hydroxylation of **1** at the benzylic position by *M. isabellina*, giving the alcohol **2** in low yield and moderate enantiomeric enrichment, proceeded without any detectable involvement of the cyclopropyl ring. This was also the case for the sulfoxidation of phenyl cyclopropyl sulfide **3**, where the sulfoxide **4** was accompanied only by a minor amount of the sulfone **5**. In a similar vein, allyl benzene (**6**) was metabolized to give only 3-phenylpropane-1,2-diol (**7**) in low yield. This product is presumably formed by hydrolysis of an intermediate epoxide; hydroxylase enzymes are known to be capable of epoxidation of olefins located at or close to their normal site of hydroxylation (21).

The steroid substrates **8** and **11** were incubated with *R. arrhizus*. In neither case was the expected 6-hydroxy product obtained, but both substrates were hydroxylated at positions adjacent to the cyclopropyl ring (at C-2 of product **10** and C-1 of product **12**, respectively) without involvement of this functionality in the reaction. The structures of all the products formed from **8** and **11** were based on spectral analysis (see Experimental), with ^{13}C nmr being particularly diagnostic. The ^{13}C nmr data for substrates and products **8**–**12**, together with data for the product acetates, are listed in Table 2.

The ^{13}C nmr spectrum of substrate **8** in $CDCl_3$ was assigned in rings A and B by comparison with the published data for 3,5α-cyclocholestanes (22), and in rings C and D by comparison with data for 17β-hydroxyandrostanes (23). Using this spectrum of **8**, the assignments in DMSO-d_6 were then deduced and used as a basis for the determination of the sites of hydroxylation in the products **9** and **10**, which were soluble only in the latter solvent. Both products showed downfield shifts of the signals assigned to C-6 and C-8 with respect to their positions in **8**, indicating the presence of hydroxyl at C-7. The stereochemistry of substitution at C-7 (β) follows from the absence of γ *gauche* upfield effects at C-9 and C-14 present in the spectra of C-7α hydroxy steroids when compared to the unsubstituted analogues (23).

The location of the third hydroxyl group in product **9** as C-1β was apparent from its characteristic effect on the resonance position of C-19 (23), while the third hydroxyl group of product **10** is assigned to the C-2α position on the basis of the downfield shifts of C-1 and C-3, which locate the substituent at C-2, and the upfield shift at C-4, which confirms the α stereochemistry. A similar effect is caused by the C-6α hydroxy group of 6-hydroxy-3,5α-cyclocholestanes (22). The acetates of both **9** and **10** show chemical shifts that are consistent with the proposed structures.

Product **12** was assigned the 1α-hydroxy-5β,19-cycloandrostane-3,17-dione structure shown, on the basis of a comparison

of its ^{13}C nmr spectrum with that of substrate **11** (24). A downfield shift of the resonance assigned to C-10 locates the hydroxyl group at C-1 or C-9, and the observation of the shift for the latter carbon at a position 6.9 ppm upfield from its position in **11** is indicative of a *trans* diaxial substitution, suggesting the location of hydroxyl as C-1α. This is supported by the ^1H nmr spectrum, in which the signal for the hydrogen geminal to hydroxyl is located at 4.40 ppm, shifted downfield by the adjacent cyclopropyl ring current.

The final substrates used in this study were phenyl cyclopropane **13** and the thiirane **14**. As the rationale for their use was predicated on the assumption that the benzylic hydroxylating and sulfoxidizing enzyme of *M. isabellina* is a cytochrome P-450 dependent mono-oxygenase, it was first necessary to address the nature of the enzyme. Fungal hydroxylase enzymes are notoriously difficult to isolate, very few having been obtained even in crude cell-free form (25), so our experiments were perforce carried out with whole cell cultures.

We have previously demonstrated that the enzyme in *M. isabellina* responsible for sulfoxidation of thioanisole (**16**) utilizes molecular oxygen as the source of the oxygen atom (26), a feature of cytochrome P-450 dependent mono-oxygenases. We now report that this reaction, and the benzylic hydroxylation of ethylbenzene, shows the inhibition characteristics associated with P-450 catalysed reactions, namely, a susceptibility to inhibition by carbon monoxide and an insensitivity to inhibition by cyanide. For these reasons, we use as a working hypothesis the assumption that these reactions are indeed catalysed by cytochrome P-450 dependent mono-oxygenases, although in the absence of a purified enzyme preparation this cannot be definitively stated.

We were unable to isolate any products following the incubation of phenylcyclopropane (**13**) with *M. isabellina*. Cytochrome P-450 of rat liver origin is reported to convert **13** to benzoic acid in a multiple oxidation sequence in which the substrate does not leave the enzyme's active site (20, 27), but no benzoic acid was detected in the extracts following our incubations of **13**. Control extractions in which benzoic acid was added to the aqueous medium prior to treatment with methylene chloride gave excellent recoveries of the acid, confirming that the failure to isolate benzoic acid following incubations of **13** cannot be attributed to the extraction procedures employed.

To test the proposal that **13** was deactivating the enzyme following radical formation and subsequent alkylation of the haem of the enzyme's active site, one route for which is presented in Fig. 2 (20), experiments were carried out in which *M. isabellina* was incubated with **13**, followed by the addition of thioanisole as a second substrate. In this case, sulfoxidation of thioanisole proceeded in the usual manner, indicating that pre-incubation with phenylcyclopropane did not incapacitate the sulfoxidizing enzyme.

The oxidation of phenylthiirane (**14**) by *M. isabellina* proceeded to give a single product, phenylglyoxylic acid (**15**), in moderate yield. The formation of this product parallels the reported mammalian oxidation of phenylcyclopropane in that multiple oxidations have apparently taken place (20, 27). Incubations of potential intermediates such as 1-phenylethane-1,2-diol and phenyl acetic acid resulted only in recovered starting material in near-quantitative amount,[2] suggesting that, as proposed for the oxidation of phenylcyclopropane to benzoic acid (20), all the oxidative steps occur in the active site without

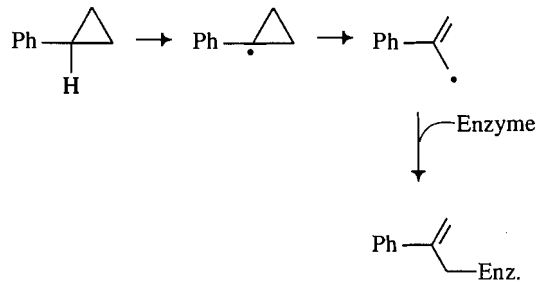

FIG. 2. Phenylcyclopropane as an irreversible inhibitor of cytochrome P-450 dependent mono-oxygenases.

dissociation of partially oxidized intermediates, but, without further information, proposal of a reaction scheme is premature.

Thiiranes may thus prove to be poor substrates for biotransformation, but from the above data it is apparent that, in spite of concerns based on mechanistic considerations, fungal oxidative biotransformation of compounds containing cyclopropyl groups can proceed with this functionality intact, even in cases where oxidation occurs adjacent to the three-membered ring.

Experimental

Melting points (uncorrected) were determined on a Kofler heating stage. Infrared spectra were recorded with an Analect 6260FX spectrometer. Proton nmr spectra were recorded at 200 MHz, and carbon nmr at 50.3 MHz (J MOD mode) with a Bruker AC200 spectrometer, using $CDCl_3$ as solvent and $CHCl_3$ as internal standard unless otherwise stated. Enantiomeric ratios were determined in CCl_4 in the presence of tris[3-(heptafluoropropylhydroxymethylene)-*d*-camphorato], europium(III). Electron impact mass spectra (eims) were obtained with an AEI MS30/Kratos DS55 system, and fast atom bombardment mass spectra (fabms) with the same machine fitted with an Ion Tech saddle field gun operating at 7 eV using a glycerol matrix. Thin-layer chromatography was performed on Merck silica gel 60F-254 and flash column chromatography on silica gel (230–400 mesh). Optical rotations were determined in 95% ethanol solution with a Rudolph Autopol III instrument, operating at 20°C. *Mortierella isabellina* NRRL 1757 (26) and *Rhizopus arrhizus* ATCC 11145 (29) were grown and maintained as previously described by us. Incubations with *M. isabellina* (26) and *R. arrhizus* (29) were also carried out as described. The incubation periods were 24 h for sulfoxidation or 72 h for hydroxylation by *M. isabellina*, and 48 h for hydroxylation by *R. arrhizus*. Products were identified following extraction, chromatography, and purification by crystallization (in the case of solid samples) or Kugelrohr distillation in the case of liquids. Microanalysis was performed by Guelph Analytical Laboratories.

Preparation of substrates

Compounds **3**, **6**, and **13** were commercial samples. The following were prepared by the published procedures and gave satisfactory spectral and analytical data: **1** (30), **8** (31), **11** (32), and **14** (33). Where relevant to product analysis, ^{13}C nmr data for substrates are presented in the tables.

Incubation of substrates

Benzylcyclopropane (1)

Incubation of **1** (1 g) with *M. isabellina* afforded (−)-cyclopropyl phenyl methanol (**2**, 0.17 g, oil), bp 140–145°C/18 Torr (1 Torr = 133.3 Pa) (lit. (30) bp 121°C/12 Torr); $[\alpha]_D$ −11.2°, ee 62% by nmr; ir (thin film) ν_{max}: 3366 cm^{-1}; ^1H nmr δ: 0.3–0.6 (4H, m, cyclopropyl CH_2's), 1.1–1.3 (1H, cyclopropyl CH), 4.0 (1H, d, J = 8.3 Hz, C*H*OH), and 7.25–7.45 (5H, m, aromatic H's) ppm; ^{13}C nmr δ: 2.8, 3.5 (cyclopropyl CH_2's), 19.2 (cyclopropyl CH), 78.5 (*C*HOH), 126.0 (2C), 127.5, 128.3 (2C), and 143.6 (aromatic C's) ppm; eims m/z (%): 148 (2), 129 (14), 120 (100), 104 (39), 91 (56), 77 (41).

Cyclopropyl phenyl sulfide (3)

Incubation of **3** (1 g) with *M. isabellina* gave the corresponding (+)-sulfoxide (**4**, 0.65 g, oil), bp 150–155°C/5 Torr (lit. (34) bp 137–138°C/1 Torr); $[\alpha]_D$ +99.2°, ee 66% by nmr, 69% by rotation (37); ^1H nmr and ir as reported (35, 36); ^{13}C nmr δ: 2.5, 3.3 (cyclopropyl CH_2's), 33.6 (cyclopropyl CH), 123.9 (2C), 129.0 (2C), 130.8 and 144.9 (aromatic C's) ppm; fabms m/z (%): 167 (M + H, 61), 150 (10), 125 (32) relative to 39 (100). Also obtained was the sulfone **5** (0.03 g), mp 34–36°C (lit. (38) mp 35–36°C); ir ν_{max}: 1148, 1291, 1315 cm^{-1}; ^1H nmr δ: 0.9–1.5 (4H, m, cyclopropyl CH_2's), 2.4–2.5 (1H, m, cyclopropyl CH), 7.5–7.7 (3H, m, aromatic *m*- and *p*-H's), 7.8–8.0 (2H, m, aromatic *o*-H's) ppm; ^{13}C nmr δ: 5.9 (cyclopropyl CH_2's), 32.9 (cyclopropyl CH), 127.5 (2C), 129.2 (2C), 133.3, and 141.5 ppm; fabms m/z (%): 183 (M + H, 10), 125 (16), 91 (8), 77 (19) relative to 39 (100).

Allyl benzene (6)

Incubation of **6** with *M. isabellina* gave, in addition to recovered starting material, *R*-(+)-3-phenylpropane-1,2-diol (**7**, 0.05 g), $[\alpha]_D$ +13.4°, ee 38% by comparison with $[\alpha]_D$ −36° reported for the *S*-(−) isomer (19), identified by comparison of spectral data with those reported for racemic material (28).

3α,5-Cyclo-5α-androstan-17β-ol (8)

Incubation of **8** (2 g) with *R. arrhizus* gave, in addition to recovered substrate, 3α,5-cyclo-5α-androstane-1β,7β,17β-triol (**9**, 35 mg), mp 254–256°C from ethyl acetate; ir ν_{max}: 3350 cm^{-1}; ^1H nmr (DMSO-d_6/$CDCl_3$) included signals at δ: −0.09 (1H, m, C-4 H), 0.65 (3H, s, C-18 CH_3), 0.84 (3H, s, C-19 CH_3), 3.06 (1H, d of t, J = 4.6, 8.9 Hz, C-7α H), 3.36 (1H, t, C-17α H), and 3.68 (1H, d, J = 6.3 Hz, C-1α H) ppm; ^{13}C nmr, see Table 2; fabms, m/z (%): 306 (M^+, 10), 305 (13), 289 (32), 271 (33), 253 (16) relative to 55 (100). Anal. calcd. for $C_{19}H_{30}O_3$: C 74.47, H 9.87%; found: C 74.56, H 9.51%; converted (pyridine/acetic anhydride) to the triacetate, oil; ir ν_{max}: 1245, 1739 cm^{-1}; ^1H nmr included signals at δ: 0.14 (1H, m) and 0.68 (1H, t), both cyclopropyl H's, 0.82 (3H, s, C-18 CH_3), 0.88 (3H, s, C-19 CH_3), 1.99, 2.01, and 2.06 (each 3H, s, $COCH_3$), 4.46–4.56 (2H, m, including t and 4.51, C-7α and -17α H's), and 5.05 (1H, d, J = 4.3 Hz, C-1α H) ppm; ^{13}C nmr, see Table 2; fabms m/z (%): 433 (M + H, 2), 373 (4), 313 (18) relative to 43 (100). Also obtained was 3α,5-cyclo-5α-androstane-2α,7β,17β-triol (**10**, 0.12 g), mp 212–215°C from ethyl acetate; ir ν_{max}: 3310 cm^{-1}; ^1H nmr (DMSO-d_6/$CDCl_3$) included signals at δ: 0.05 (1H, m, C-4 H), 0.62 (3H, s, C-18 CH_3), 0.81 (3H, s, C-19 CH_3), 3.09 (1H, d of t, J = 3.8, 8.5 Hz, C-7α H), 3.37 (1H, t, C-17α H), and 4.15–4.33 (1H, m, C-2β H) ppm; ^{13}C nmr, see Table 2; fabms m/z (%): 305 (M − H, 18), 287 (18), 271 (24), 253 (12) relative to 55 (100). Anal. calcd. for $C_{19}H_{30}O_3$: C 74.47, H 9.87%; found: C 74.72, H 9.58%; converted (pyridine/acetic anhydride) to the triacetate, oil; ir ν_{max}: 1245, 1739 cm^{-1}; ^1H nmr included signals at δ: 0.20 (d of d, J = 2.1, 5.4 Hz, C-4 H), 0.79 (3H, s, C-18 CH_3), 0.92 (3H, s, C-19 CH_3), 1.97, 2.0, and 2.03 (each 3H, s, $COCH_3$), 4.4–4.7 (2H, m, C-7α and C-17α H's), and 5.20 (d of t, J = 3.8, 7.6 Hz, C-2β H) ppm; ^{13}C nmr, see Table 2; eims m/z (%): 373 (M − acetic acid, 8), 312 (100), 297 (18).

5β,19-Cycloandrostane-3,17-dione (11)

Incubation of **11** (0.17 g) with *R. arrhizus* gave as the only detectable product 1α-hydroxy-5β,19-cycloandrostane-3,17-dione (**12**, 65 mg), mp 153–155°C from ethyl acetate; ir ν_{max}: 1705, 1738, 3340 cm^{-1}; ^1H nmr included signals at δ: 0.45 (2H, s, C-19 H's), 0.75 (3H, s, C-18 CH_3), 2.55 (2H, s, C-4 H's), and 4.40 (1H, d of d, J = 4, 3.8 Hz, C-1β H); ^{13}C nmr, see Table 2; eims m/z (%): 302 (M^+, 20), 284 (37), 269 (5), 258 (70), 241 (16), 230 (16) relative to 55 (100). Anal. calcd. for $C_{19}H_{26}O_3$: C 75.47, H 8.66%; found: C 75.27, H 8.51%.

Phenylcyclopropane (13)

Incubation of phenylcyclopropane with *M. isabellina* at substrate concentrations of 0.1–0.5 mg/mL produced no detectable products following methylene chloride extraction. Incubation of *M. isabellina* with phenylcyclopropane (0.2 mg/mL) for a period of 12 h, followed by the addition of thioanisole (0.4 mg/mL), and incubation for a further period of 24 h, produced thioanisole sulfoxide with yield and enantiomeric excess as reported (17).

Phenylthiirane (14)

Incubation of **14** (1 g) with *M. isabellina* gave an extract from which phenyl glyoxylic acid (**15**) was recovered in 31% yield. The product was identified by comparison of spectral data with those of commercial material.

Inhibitor experiments

Experiments with *M. isabellina* as fungus and thioanisole and ethylbenzene as substrates were performed as follows. Carbon monoxide inhibition was carried out in closed 1 L vessels under an atmosphere of 15% CO/85% air. No oxidation products were observed. Experiments with cyanide were carried out in aqueous medium containing 5×10^{-4} M KCN. In this case, normal yields and stereochemistries of product were obtained (16, 17).

1,1-Dihalocyclopropane derivatives and furanones were synthesized from ±α- and β-ionones using $CHCl_3$, NaOH, and triethylbenzyl ammonium chloride (TEBAC). 2D NMR and single-crystal X-ray analyses of the products are reported.

Key words: addition of 1,1-dihalocarbenes to ionones, phase transfer addition of 1,1-dihalo systems, formation of cyclopropanes.

E. Díaz, R. A. Toscano, A. Alvarez, J. N. Shoolery et K. Jankowski. Can. J. Chem. **68**, 701 (1990).

Utilisant des ± α- et β-ionones comme produits de départ et du $CHCl_3$, du NaOH et du chlorure de triéthylbenzylammonium (CTEBA) comme réactifs, on a préparé des dérivés dihalo-1,1 cyclopropanes et des furanones. On a déterminé les spectres de résonance magnétique nucléaire en 2D et les spectres de diffraction des rayons-X des produits.

Mots clés : addition de dihalo-1,1 carbènes aux ionones, addition par transfert de phase des systèmes dihalo-1,1, formation des cyclopropanes.

Discussion

A large number of C_{13} compounds formed by oxidative cleavage of carotenoids isolated from *Tobacco* (1) and marine sponges (2) or their derivatives originate from the α and β ionones (**1** and **3**) (3, 4). The synthesis of several damascones (5) and abscisic acids (6, 7), using readily available and inexpensive ionones as raw materials, encourages us to perform a new reaction leading to some new, more functionalized and useful, unsaturated compounds.

We describe here the products obtained when ionones **1** and **3** were treated with $CHCl_3$, NaOH, and triethylbenzyl ammonium chloride (TEBAC) under a phase transfer condition.

It has been reported that, in phase transfer dihalocarbene addition, stereochemistry and regioselectivity can be controlled by varying the catalyst (8–11). Accordingly ±**1** affords the expected dichlorocarbene bicycloheptane adduct **2**. Characterization of its structure and configuration were supported by NMR and X-ray analysis (Fig. 1, Table 1).

On the other hand when β-ionone (**3**) was treated under the same conditions, two new furenones (**4** and **5**) were isolated. The IR spectrum of **4** showed a signal at 1743 cm^{-1}, which clearly indicates an α,β-unsaturated γ-lactone group.

The proton NMR spectrum showed a one-proton quintet and a one-proton multiplet at 7.05 and 5.55 ppm respectively. The latter was converted to a quartet (J = 1 Hz) when the vinylic proton at 7.05 was decoupled.

A vinylic methyl group appeared at 2.0 ppm as a triplet (J = 1 Hz) instead of the methyl ketone group singlet recorded at 2.31 ppm in the spectrum of the starting ionone **3**. This triplet collapsed to a doublet (J = 1 Hz) when the proton at 5.55 ppm was decoupled. These findings suggest that a partial structure for compound **4** must contain an α,β-unsaturated γ-lactone moiety.

The mass spectrum of compound **4** shows the molecular ion at m/z 220 corresponding to the molecular formula of $C_{14}H_{20}O_2$.

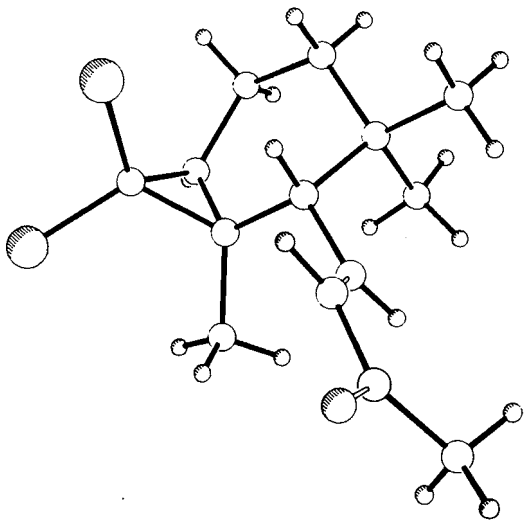

FIG. 1. X-ray structure of **2** (ORTEP plot).

TABLE 1. ^{1}H NMR spectrum of compound **2**

Proton	H	Multiplicity	(No. of protons)	J(Hz)
8	6.85	dd	(1H)	10.6, 16.5
9	6.17	dd	(1H)	1.0, 15.6
6	2.31	dd	(1H)	1.0, 10.6
11	2.28	s	(3H)	
3 ax	1.93	m	(1H)	7.92, 10.0, 14.0, 7.0
3 eq	1.83	m	(1H)	3.0, 1.0, 14.0
4	1.37	dd	(1H)	7.92, 1.0
13	1.28	s	(3H)	
2	1.18	m	(2H)	
11	0.91	s	(3H)	
12	0.74	s	(3H)	

It suggests an increase in the molecular weight of the starting ionone **3** by 28 atomic mass units.

The second compound, **5**, was identified as 3*R*,3′*S*-bis[3-methyl-5-(1′,3′,3′-trimethylcyclohex-1′-en-2′-yl)-2(1*H*)-furanone] with a molecular weight of 438 corresponding to the formula $C_{28}H_{38}O_4$. The structure was fully confirmed by 2D NMR and X-ray crystallography data.

The 400 MHz ^{1}H NMR of **5** showed methyl signals at 1.06, 1.39, and 1.71 ppm. A very well defined triplet at 2.04 ppm and a one-proton singlet at 5.59 ppm suggest the presence of one olefinic proton. The strong IR band at 1778 cm^{-1} and the ^{13}C NMR signal at 179.1 both indicate the presence of an enol lactone carbonyl.

COSY data enable us to establish the key proton vicinities. There exists a strong correlation between the methylene at δ = 2.04 and a signal at 1.68, and a weaker one between methylenes at 2.04 and the methyl at 1.71 ppm. The latter also displays a correlation with a methylene moiety at δ = 1.51 ppm.

The 1D and DEPT edited (12) spectra allowed the partial assignment of the carbon atoms (protonated carbons) and the ^{13}C spectrum enables us to assign the non-protonated carbons. The $^1J_{C-H}$ heterocorrelated spectra (13) enabled us to establish connectivities between proton-bearing carbons, and the results are shown in Table 2.

To confirm this dimeric structure we carried out an X-ray crystallographic study on compound **5** (Fig. 2).

TABLE 2. ^{1}H and ^{13}C chemical shifts for compound **5**

Carbon	n_H[b]	δ_H[a]	δ_C[a]
2	0		179.0
5	0		152.6

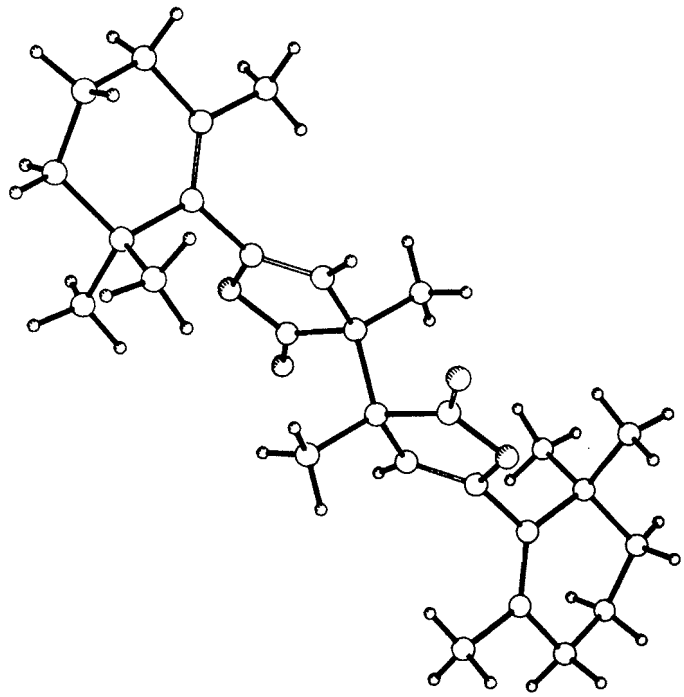

FIG. 2. X-ray structure of **5** (ORTEP plot).

The mechanism of formation of compounds is proposed in Scheme 1. For the lactone **4** one can assume an initial chemoselective adduct formation on the dienone **3** to generate the epoxide, which is rapidly transformed to an intermediate dichloroether that is hydrolysed to the γ-lactone **4**.

For the transformation of **4** into **5** we can assume that the presence of atmospheric oxygen during the reaction induces a free radical dimerization. It is supported by the fact that when the reaction was performed under a N_2 atmosphere the yield of **5** decreased dramatically and the yield of compound **4** increased. The unsaturated lactone **4** produces first a biradical that reacts with molecular oxygen, forms a tertiary radical, and finally dimerizes to compound **5**.

Finally, the sample of pure lactone **4** treated under similar conditions produced compound **5** under the N_2 oxygen-containing

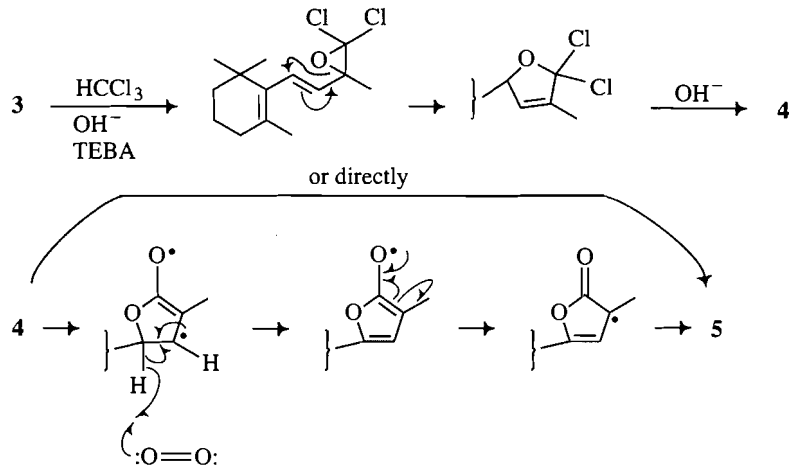

SCHEME 1

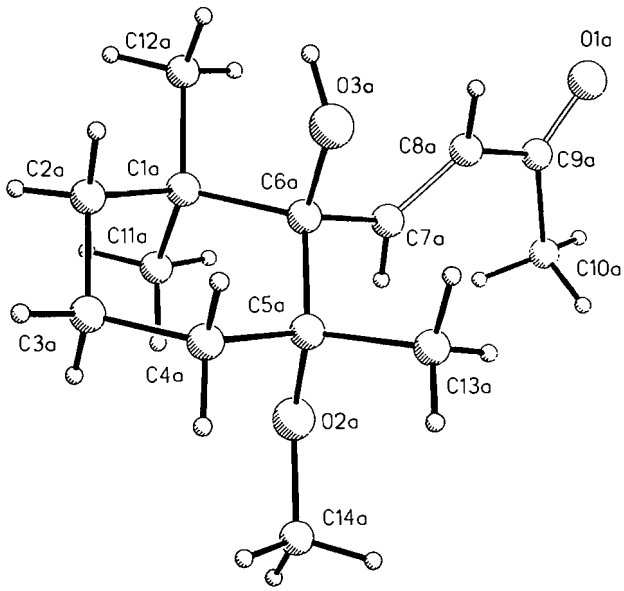

FIG. 3. X-ray structure of **6** (ORTEP plot).

atmosphere (there is no meaningful yield of **5** under the N_2 oxygen-free atmosphere).

Compound **6** was isolated in only trace amounts. The molecular weight as identified from the MS was 240 ($C_{14}H_{24}O_3$). The proton NMR presents an AX pattern (δ_A = 7.50 (H-7) and δ_x = 6.21 (H-8), J = 16 Hz), three proton singlets at 3.09 (OMe) and 2.24 (COMe), signals at 1.11, 0.92, and 0.72 for the methyls C-11, C-13, and C-12, and unresolved signals for six protons of C-2, C-3, and C-4 methylenes. The structure and configuration of compound **6** was confirmed by an X-ray crystallographic study (Fig. 3) showing the apparent diastereoselective formation of **6**.

One possible explanation for the formation of product **6** is the "normal" opening of the epoxide **7** obtained in a small quantity under phase transfer conditions with methanol (recrystallization). Similar oxidation has been observed for some sesquiterpene lactones (14).

Experimental

Infrared spectra were obtained on a Nicolet FT5X spectrometer (liquid films) and mass spectra (EI, PI) on a Hewlett–Packard 5985 A or on a VG703 high-resolution instrument. NMR spectra were recorded on Varian FT-80 (80 MHz), Varian VXR-400 (400 MHz), and Bruker 500 spectrometers. ^1H and ^{13}C spectra were run in $CDCl_3$.

X-Ray analysis

Crystals were mounted on top of a glass fiber. Intensities were collected on a Nicolet R3m automated diffractometer using graphite-monochromatized MoKα radiation. The crystal structure was solved by direct methods using the SHELXTL program package (15).

7,7-Dichloro-1,1-dimethyl-6-(3-oxo-1-butenyl)bicyclo[4,1,0]^{4,5} heptane (2)

± α-Ionone (Merck) (1) (1.92 g, 0.01 mol), 30 mL $CHCl_3$, TEBA (50 mg), and 10 mL aqueous sodium hydroxide (50%) were mixed slowly and stirred at room temperature for 24 h. The reaction product was extracted with $CHCl_3$, the organic extract was dried (Na_2SO_4), and the product was recrystallized from MeOH; mp 56–57°C; yield 52%; ^1H NMR δ: 0.74 (s, 3H), 0.91 (s, 3H), 1.37 (3H), 2.28 (s, 3H), 6.17 (d, J = 15.6, 1H), 6.85 (dd, J = 10.6, 15.6, 1H). MS m/z: 274 $M^{+\cdot}$ ($C_{14}H_{20}OCl_2$), $M^+ + 2$ 276, $M^+ + 4$ 278, 239, 241, 259, 261, 263, 109 (100%).

X-rays

Crystal size 0.2 × 0.3 × 0.4 mm. Monoclinic, spatial group $P_{2\,1/a}$. λ = 0.7071 Å (MoKα), ρ_{calc} = 1.186 g/cm^3, a = 1176(8) Å, b = 7.950(4) Å, c = 16.720(12) Å, β = 93.94(6)°, V = 1483.08 ± 1.72 Å^3, Z = 4.

Preparation of 4, 5, and 6

β-Ionone **3** (Merck) (1.92 g) in 30 mL $CHCl_3$ was added slowly to 50 mg of TEBA in 10 mL aqueous sodium hydroxide (50%) and stirred together at room temperature for 4 h. The reaction products were extracted with $CHCl_3$ and the organic extract was dried (Na_2SO_4). The solvent was removed *in vacuo* and a resulting oil showed two major spots on TLC. The oil underwent partial crystallization on addition of MeOH.

Products **4**, **5**, and **6** were separated by preparative TLC with 22, 17, and 0.1% yields. Product **4**: 3-methyl-5-(1′,3′,3′-trimethylcyclohex-1′-en-2′-yl)2(1*H*)-furanone; mp 106–107°C. IR ν_{max}: 3070, 2995, 2990, 2860, 1743, 1645, 1450, 1378 cm^{-1}; ^1H NMR δ: 1.1 (s, 3H), 1.2 (s, 3H), 1.5 (bs, 3H), 2.0 (t, J = 1.0, 3H), 5.55 (multiplet, J = 1.0), 7.0 (quintet, J = 1.0, 1H). MS m/z: M^+ 220.1490 ($C_{14}H_{20}O_2$), 105, 159, 123, 91, 97 (100%).

Product **5**: 3*R*,3′*S*-bis[3-methyl-5-(1′,3′,3′-trimethylcyclohex-1′-en-2′-yl)-2(1*H*)-furanone] was recrystallized from MeOH; mp 177–178°C; IR ν_{max}: 3010, 2960, 2925, 1778, 1665, 1450, 1380, 1200 cm^{-1}; ^1H NMR δ: 1.06 (s, 3H), 1.39 (s, 3H), 1.51 (m, 2H), 1.68 (m, 2H), 1.707 (s, 3H), 2.045 (t, 2H), 5.59 (s, 1H); also see Fig. 3. ^{13}C NMR, see Table 2. MS m/z: M^+ 438, 220, 218 (100%), 192.

Crystal data: Crystal size 0.20 × 0.28 × 0.32 mm, monoclinic crystals, spatial group P_2 13*a*; λ = 0.7071 Å (MoKα), ρ_{calc} = 1.152 g/cm^3, a = 10.297(9) Å, b = 8.163(4) Å, c = 15.069(11) Å, β = 94.60(7)°, V = 1262.39 Å^3, F(0,0,0) = 476, Z = 2.

Substituted ferrocenecarboxylic acids and esters

W. R. CULLEN AND E. B. WICKENHEISER
Chemistry Department, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received August 28, 1989

W. R. CULLEN and E. B. WICKENHEISER. Can. J. Chem. **68**, 705 (1990).

The synthesis of Fe(η-C_5H_5)(η-C_5H_3(CHMeNMe$_2$)(COOH)-1,2), **3***a*, and its methyl and ethyl esters is described. Esterification of **3***a* by using RI in DMA affords Fe(η-C_5H_5)(η-C_5H_3(CHMeOH)(COOR)-1,2), R = Me, Et, with retention of configuration at the chiral center. The variable temperature ^{1}H NMR spectrum of **3***a* reveals H-bonding between the two functional groups.

Key words: ferrocenecarboxylic acids and esters, NMR spectra, synthesis, hydrogen bonding.

W. R. CULLEN et E. B. WICKENHEISER. Can. J. Chem. **68**, 705 (1990).

On décrit la synthèse de l'acide Fe(η-C_5H_5)(η-C_5H_3(CHMeNMe$_2$)(COOH)-1,2), **3***a*, et de ses esters méthylique et éthylique. L'estérification du composé **3***a* à l'aide de RI dans le DMA conduit aux Fe(η-C_5H_5)(η-C_5H_3(CHMeOH)(COOR)-1,2), R = Me et Et, avec rétention de configuration au centre chiral. Les spectres de RMN du ^{1}H du produit **3***a*, mesurés en fonction de la température, révèlent l'existence de liaisons hydrogènes entre les deux groupements fonctionnels.

Mots clés : acides et esters ferrocènecarboxyliques, spectres de RMN, synthèse, liaisons hydrogènes.

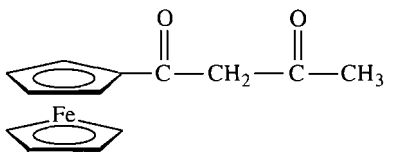
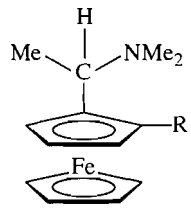
We have shown that rhodium(I) derivatives of β-diketonate ligands such as **1** are active catalysts for the hydrogenation of olefins (1) and the hydrosilylation of ketones (2). Moreover rhodium(I) derivatives of the enantiomers of **2***b* are efficient catalysts for the asymmetric hydrogenation of selected olefins (3–6). Therefore it was of interest to combine these observations and establish whether metal complexes of **2***c* would be of use as catalysts.

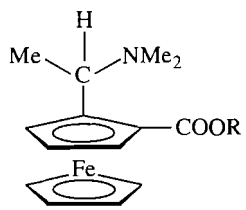


1

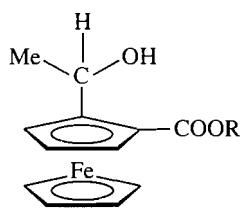


2*a* R = H
b R = PPh_2
c R = $C(O)CH_2C(O)CH_3$

The present paper outlines some unsuccessful attempts to prepare **2***c*: the properties of some esters of ferrocenecarboxylic acids, prepared as intermediates for the synthesis of **2***c*, are described.



3*a* R = H
b R = CH_3
c R = C_2H_5



4*a* R = CH_3
b R = C_2H_5

Experimental

All equipment and techniques used in this study have been described previously (2). α-*N*,*N*-Dimethylaminoethylferrocene, **2***a*, was prepared by literature methods (7).

*Preparation of 2'-(*N,N*-dimethylaminoethylferrocene)carboxylic acid, 3*a

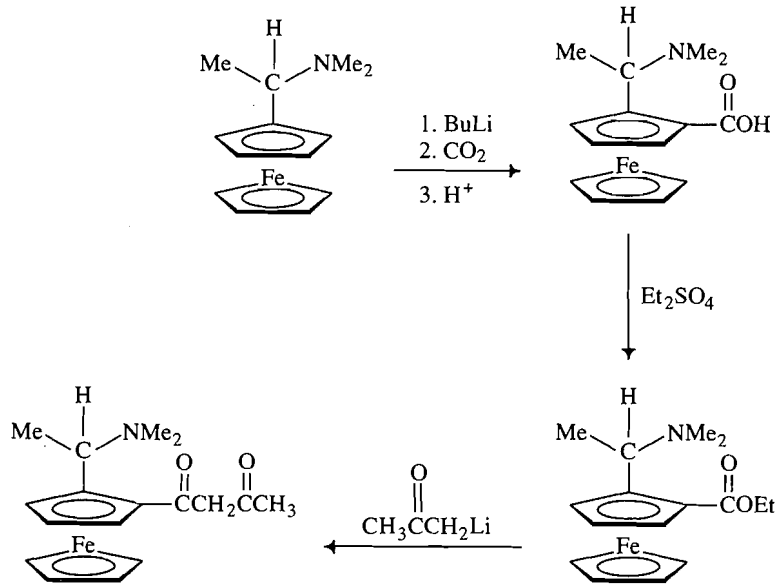
Butyllithium (12.1 mL of 1.6 M solution in hexanes, 19.4 mmol) was added to a solution of α-*N*,*N*-dimethylaminoethylferrocene (5.00 g, 19.4 mmol) in diethyl ether (100 mL). The solution was stirred overnight, and then cooled to −78°C. Solid carbon dioxide (5 g, 100 mmol) was then added in small portions, affording a light yellow precipitate. The mixture was stirred at −78°C for 2 h and allowed to warm to room temperature. The mixture was filtered under a nitrogen atmosphere and the precipitate was washed with several portions of ether. The precipitate was dissolved in methanol and chromatographed on a silica column using methanol as eluant. The product band was collected and the solvent removed under reduced pressure. The product was dissolved in dichloromethane and dried over magnesium sulfate. Removal of the solvent at reduced pressure afforded 5.15 g of a yellow glassy solid (88% yield). ^{1}H NMR spectrum ($CDCl_3$, 300 MHz) δ: 1.40 (d (J = 6.5 Hz), 3, C(CH_3)), 2.03 (s, 3, N(CH_3)), 2.54 (s, 3, N(CH_3)), 4.10 (s, 5, C_5H_5), 4.28 (m, 2, C*H*), 4.53 (q (J = 6.5 Hz), 1, C*H*(CH_3)), 5.01 (m, 1, C*H*), 17.7 (s, 1, OH). Mass spectrum *m/e* (relative intensity): 301 (36), 286 (21), 256 (100), 242 (37), 230 (20), 212 (61), 186 (12). Anal. calcd. for $C_{15}H_{19}FeNO_2 \cdot 0.5H_2O$: C 58.08, H 6.50, N 4.52; found: C 58.31, H 6.89, N 4.58.

*Preparation of 2-(*N,N*-dimethylaminoethylferrocene)carboxylic acid methyl ester, 3*b

This was prepared in a manner similar to that described by Grundy *et al.* (8) for the esterification of hindered carboxylic acids. A solution of **3***a* (0.38 g, 1.2 mmol) and potassium carbonate (0.19 g, 1.4 mmol) in 10 mL dry acetone was prepared and stirred for 30 min. Dimethyl sulfate (0.159 g, 1.26 mmol) was then added and the mixture was refluxed for 3 h. The solution was filtered, concentrated to 1 mL under reduced pressure, and chromatographed on silica. A mixture of acetone, ethyl acetate, and triethylamine (75:175:6) was used as the eluant and gave adequate separation. The major band was collected and the solvent removed at reduced pressure giving 0.195 g (50% yield) of analytically pure product. ^{1}H NMR spectrum ($CDCl_3$, 300 MHz) δ: 1.49 (d (J = 7.0 Hz), 3, C(CH_3)), 2.06 (s, 6, N(CH_3)$_2$), 3.79 (s, 3, OCH_3), 4.18 (s, 5, C_5H_5), 4.35 (m, 2, C*H*), 4.43 (q (J = 7.0 Hz), 1, C*H*(CH_3)), 4.75 (m, 1, C*H*). Mass spectrum *m/e* (relative intensity): 315 (1), 300 (2), 270 (2), 239 (1), 59 (100). Anal. calcd. for $C_{16}H_{21}FeNO_2$: C 60.96, H 6.72, N 4.44; found: C 61.13, H 6.81, N 4.61.

*Preparation of 2-(*N,N*-dimethylaminoethylferrocene)carboxylic acid ethyl ester, 3*c

The ester was also prepared using the method of Grundy *et al.* (8). A solution of **3***a* (0.96 g, 3.1 mmol) and potassium carbonate (0.48 g, 3.5 mmol) in 45 mL of dry acetone was prepared and stirred for 1 h. Diethyl sulfate (0.49 g, 3.2 mmol) was added and the mixture was



SCHEME 1

refluxed for 4 h. The mixture was filtered and the solvent removed at reduced pressure. The product was dissolved in 2 mL of methylene chloride, loaded onto a silica column, and eluted with a mixture of ethyl acetate/triethylamine (97:3). The major band was collected and the solvent removed at reduced pressure yielding 0.625 g (61% yield) of the pure ester. ^{1}H NMR spectrum ($CDCl_3$, 300 MHz) δ: 1.34 (t (J = 6.9 Hz), 3, $CH_2(CH_3)$), 1.49 (d (J = 6.9 Hz), 3, $CH(CH_3)$), 2.07 (s, 6, $N(CH_3)_2$), 4.13 (s, 5, C_5H_5), 4.08–4.36 (m, 4, CH, CH_2CH_3), 4.46 (q, 1, $CH(CH_3)$), 4.78 (m, 1, CH). Mass spectrum m/e (relative intensity): 329 (34), 314 (100), 285 (16), 263 (21), 256 (12), 239 (7), 211 (11). Anal. calcd. for $C_{17}H_{23}FeNO_2$: C 62.02, H 7.04, N 4.25; found: C 61.73, H 7.00, N 4.06.

Preparation of 2-(α-hydroxyethylferrocene)carboxylic acid methyl ester, **4**a

This was prepared using the method of esterification described by Alvarez and Watt (9); the reaction also effected replacement of the dimethylamino group with a hydroxyl group. A solution of **3***a* (213 mg, 0.687 mmol), sodium bicarbonate (131 mg, 1.56 mmol), and methyl iodide (402 mg, 283 mmol) in 1.5 mL of dimethylacetamide was prepared and stirred in the dark for 48 h. The mixture was then hydrolyzed by the addition of 30 mL of 10% aqueous sodium chloride. The product was extracted from the aqueous phase with ether and the combined extracts were dried over magnesium sulfate. The extract solution was filtered and the volume reduced to 2 mL at reduced pressure. The mixture was then chromatographed on silica using petroleum ether and triethylamine (97:3) as the eluant. The major band was collected and the solvent removed yielding 88.3 mg (44.6% yield) of the pure ester. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 1.45 (d (J = 6.7 Hz), 3, CCH_3), 3.78 (s, 3, OCH_3), 4.12 (s, 5, C_5H_5), 4.27 (m, 1, CH), 4.36 (d (J = 6.7 Hz), 1, COH), 4.40 (m, 1, CH), 4.70 (m, 1, CH), 5.00 (dq (J = 6.7 Hz), 1, $C(OH)H$). Mass spectrum m/e (relative intensity): 288 (50), 270 (26), 256 (23), 223 (16), 212 (33), 152 (16), 138 (16), 119 (100). Anal. calcd. for $C_{14}H_{16}FeO_3$: C 58.36, H 5.60, O 16.66; found: C 58.07, H 5.86, O 16.69.

Preparation of 2-(α-hydroxyethylferrocene)carboxylic acid ethyl ester, **4**b

A solution of **3***a* (0.23 g, 0.74 mmol), sodium bicarbonate (0.14 g, 1.7 mmol), and ethyl iodide (0.48 g, 3.1 mmol) in 1.5 mL of dimethylacetamide was stirred in the dark for 100 h. The reaction mixture was hydrolyzed with 30 mL of 10% aqueous sodium chloride solution. The product was then extracted from the aqueous layer with several portions of ether, and the extracts combined and dried over magnesium sulfate. The solution was filtered, concentrated to 2 mL at reduced pressure, and chromatographed on silica using ether, petroleum ether, and triethylamine (50:50:3) as the eluant. The major band was collected and the solvent removed to give 0.13 g (58% yield) of the pure ester. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 1.36 (t (J = 6.3 Hz), 3, CH_2CH_3), 1.48 (d (J = 6.3 Hz), 3, CCH_3), 4.17 (s, 5, C_5H_5), 4.43 (m, 4, CH, CH_2), 4.52 (d (J = 7.2 Hz), 1, COH), 4.76 (m, 1, CH), 4.97 (dq, 1, $CHCH_3$). Mass spectrum m/e (relative intensity): 302 (49), 284 (39), 256 (40), 237 (20), 219 (14), 212 (19), 119 (100). Anal. calcd. for $C_{15}H_{19}FeO_3$: C 59.63, H 6.00, O 15.88; found: C 59.62, H 5.95, O 16.00.

Results and discussion

Our chosen synthetic route to **2***c* is shown in Scheme 1 and is based on the stereospecific lithiation of **2***a* (7, 10). The carboxylic acid, **3***a*, was prepared by the addition of solid carbon dioxide to a solution of the lithio derivative of **2***a* and was isolated as the lithium salt (88% yield). The salt was dissolved in MeOH and subsequent chromatography on silica was used to isolate the deliquescent acid. The reaction is analogous to that used for the preparation of mono- and 1,1′-ferrocenedicarboxylic acids (11, 12). Esters of **3***a* were prepared by the reaction of the acid with dialkyl sulfates with yields of 50% (methyl **3***b*) and 61% (ethyl **3***c*). A condensation reaction between the esters and deprotonated ketones was then attempted. This reaction is similar to the one used to prepare the **1** and related ligands (1, 2). Unfortunately, no indication of any reaction (TLC monitoring) was seen after treating **3***b* and **3***c* with the lithium salts of acetophenone, acetone, and acetylferrocene in a variety of solvents and over a range of temperatures, e.g., refluxing toluene.

The analytical and spectroscopic results for **3***a* support the formulation. The mass spectrum shows a parent ion (m/e 301) and peaks associated with the loss of CH_3 (m/e 286), COOH (m/e 256), and $CHMeNMe_2$ (m/e 230). The ^{1}H NMR spectrum of **3***a* at ambient temperature shows some resonances that are broader than usual, indicating that some fluxionality is present. Part of the spectrum is shown in Fig. 1. Two broad singlets at 2.54 and 2.03 ppm are assigned to the *N*-methyl protons. These resonances coalesce at −38°C. This effect appears to be due to hindrance of the inversion at nitrogen, which otherwise would make the methyl groups equivalent. The probable cause is

For personal use only.

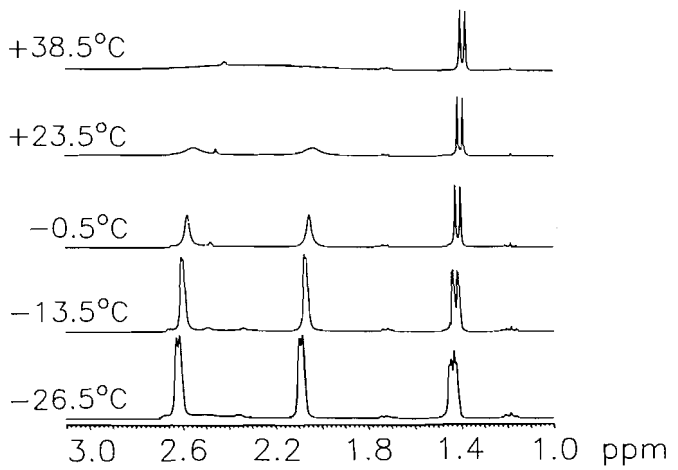

FIG. 1. The variable temperature ^{1}H NMR spectrum of **3***a* in the *N*-methyl region.

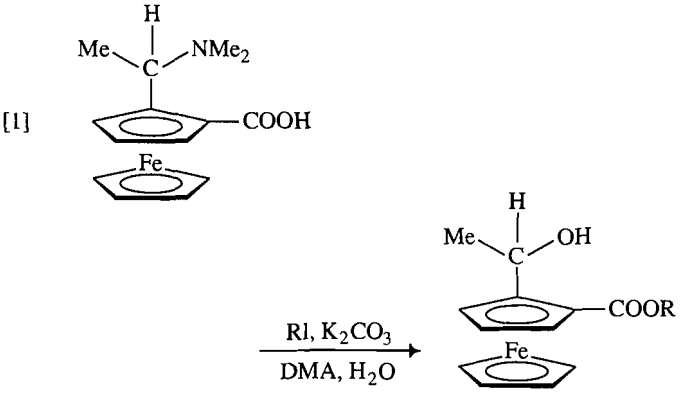
hydrogen bond formation between the COOH and the $N(CH_3)_2$ moieties. A similar effect has been noted in the NMR spectra of rhodium complexes of ligands related to **2***b* (5). The "extra" splitting seen in the resonances in the figure may be due to some long-range coupling or to the presence of frozen conformers: the latter possibility seems to be more likely. Conformers can be identified in solutions of rhodium complexes of ligands such as **2***b* (4).

The ^{1}H NMR spectra of the esters **3***b* and **3***c* show the NMe_2 groups as singlets, and the rest of the spectra are as expected and are not temperature dependent. The mass spectra show parent ions at *m/e* 315 (**3***b*) and *m/e* 329 (**3***c*).

Attempts to esterify **3***a* by using a method developed for sterically hindered carboxylic acids (9) resulted in esterification *and* replacement of the NMe_2 group by OH, eq. [1], and the



formation of **4***a* and **4***b*. (Replacement of the NMe_2 group of **2***a* can be accomplished by first replacing it with an acetate group, by reaction with acetic anhydride, followed by base hydrolysis (13).)

The analytical and spectroscopic data for **4***a* and **4***b* are consistent with the proposed structures. A doublet at 4.36 ppm in the ^{1}H NMR spectrum of **3***a* is assigned to the O*H* proton: this is coupled to the $C(CH_3)H$ proton as confirmed by shaking the samples with D_2O, which "decouples" the $C(CH_3)H$ resonance from the O*H*, converting it into the usual quartet.

Because the lithiation of **2***a* is stereospecific (7), derivatives are isolated as a pair of enantiomers of either (*R*,*R*) or (*S*,*S*) configuration due to the presence of the chiral carbon atom and the planar chirality of the disubstituted ferrocene ring. The products **4***a* and **4***b* are not mixtures of diastereomers as judged

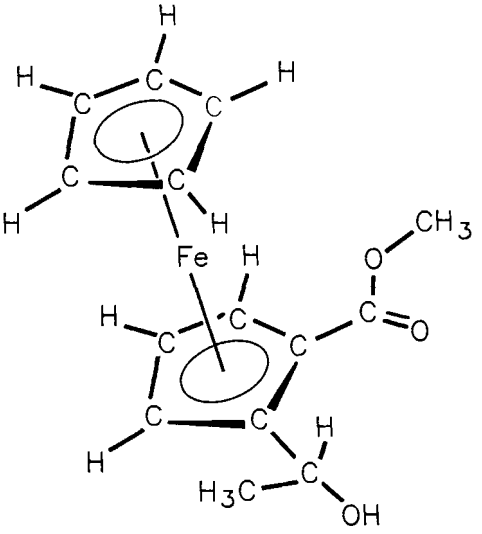


FIG. 2. The structure of **4***a*.

by their ^{1}H NMR spectra, and hence the substitution of the NMe_2 group must proceed either with complete retention of configuration, most likely (7, 14), or with complete inversion. The structure of **4***a* is shown in Fig. 2.[1] If the OH group is rotated such that it is adjacent to the substituted carbon on the cyclopentadiene ring, the CMe group is outside the rings and the CH group is between the rings. This is the conformation that would result in lithiation at the same substituted cyclopentadiene carbon atom if the OH group were replaced by NMe_2 (10). Thus the reaction of eq. [1] proceeds with overall retention of the configuration at the chiral carbon atom.

The Western Pacific Ocean sponge *Hymeniacidon* sp. was found to contain a cyclo-octapeptide designated hymenistatin 1 (**1**) active against the P388 leukemia cell line (ED_{50} 3.5 μg/mL). Structural determination was accomplished utilizing high field NMR (400 MHz) and mass spectral techniques (FAB MS/MS) followed by chiral gas chromatographic analysis to establish the absolute configuration (all *S*-amino acids).

Key words: cytostatic, *Hymeniacidon*, hymenistatin, cyclo-octapeptide, P388 leukemia.

GEORGE R. PETTIT, PAUL J. CLEWLOW, CLAUDE DUFRESNE, DENNIS L. DOUBEK, RONALD L. CERNY et KLAUS RÜTZLER. Can. J. Chem. **68**, 708 (1990).

On a trouvé que l'éponge *Hymeniacidon* sp., trouvée dans l'ouest de l'océan Pacifique, contient un cyclo-octapeptide appelé hymenistatine 1 (**1**) qui est actif contre la ligne des cellules P388 de la leucémie (ED_{50} 3,5 μg/mL). On déterminé la structure à l'aide des techniques de la RMN à 400 MHz et de la spectrométrie de masse (FAB MS/MS) et, en se basant sur une analyse par chromatographie en phase gazeuse chirale, on a pu établir que tous les acides aminés sont de configuration *S*.

Mots clés : cytostatique, *Hymeniacidon*, hymenistatine, cyclo-octapeptide, P388 de la leucémie.

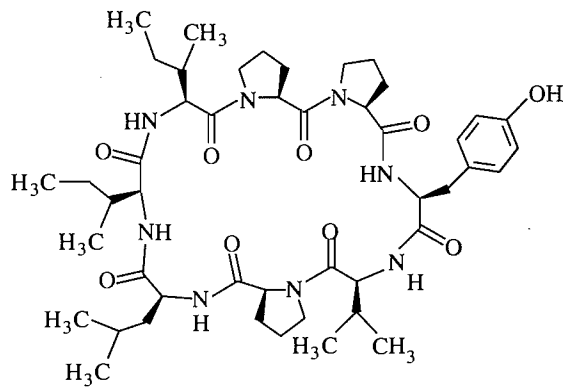
Early (2) investigations directed at isolation of marine sponge antineoplastic constituents led us initially to the geodiastatin proteins (3) and later to a series of pyrrolactams (4). Meanwhile, we have been pursuing other more promising leads in the Porifera phylum, including antineoplastic peptides. While a number of amino acids (5) have been isolated from marine sponges, only a small number of peptides (6) and antineoplastic sub- ances (7) have been isolated from these organisms. One of the *Hymeniacidon* sp. (Demospongiae Class) we collected in Palau in 1979 gave aqueous 2-propanol – methylene chloride extracts that led to a 30% life extension against the U.S. National Cancer Institute's murine P388 lymhocytic leukemia (PS system). Bioassay directed isolation using the PS leukemia led to isolation of a new cytostatic peptide designated hymenistatin (1).

After extraction and a preliminary solvent partition separation, a 1985 recollection (~ 250 kg wet wt.) of the sponge gave a PS active methylene chloride extract that was successively partitioned between 9:1 methanol–water and hexane, then diluted to 3:2 methanol–water and extracted with methylene chloride. Upon evaporation of the chlorocarbon an orange-colored solid was obtained, which significantly (PS ED_{50} 0.26 μg/mL) inhibited the PS leukemia. Initial gel-permeation chromatographic separation of the methylene chloride soluble fraction on Sephadex LH-20 and elution with 3:2 methylene chloride – methanol led to a further concentration of activity. A much better separation was achieved employing partition chromatography on Sephadex LH-20 with 3:1:1 hexane–toluene–methanol. The two principal active fractions from this chromatogram were combined and separated on a column of



Hymenistatin 1

(**1**)

Sephadex LH-20 in methanol. The nearly pure cytostatic constituent obtained by this means was chromatographed using a silica gel Lobar column. Elution with 97.5:2.5 methylene chloride – methanol afforded the cell growth inhibitory (PS ED_{50} 3.5 μg/mL) biosynthetic product we designated as hymenistatin 1 (**1**).

Mass spectral measurements of hymenistatin indicated the presence of eight nitrogen atoms, and that information combined with the eight amide carbonyls observed in the ^{13}C NMR spectrum pointed to an octapeptide. The relatively high intensity of the molecular ion (base peak) observed in the FAB-MS spectrum suggested that the presumed octapeptide might be cyclic. Extensive application of 2D NMR techniques was next used to determine the identity of the eight amino acid units. The 400 MHz ^1H NMR spectrum clearly showed the presence of only five amide protons. By following the spin systems of these protons using $^1H,^1H$-COSY, and $^1H,^1H$-relayed COSY (8),

FIG. 2. Hymenistatin 1 peptide sequence determination by FAB MS/MS.

these amino acids were determined to be valine, leucine, tyrosine, and two isoleucine units. Utilization of $^1H,^{13}C$-COSY, and $^1H,^1H,^{13}C$-RELAY (9) showed that the remaining NMR signals consisted of three independent spin systems of the type X-CH-CH_2-CH_2-CH_2-X typical of proline (10). The eight amino acid units accounted for the observed accurate-mass molecular weight. Actual sequence of the amino acids was ascertained from 1D-NOE experiments as summarized in Fig. 1.

To further corroborate the proposed structure, positive ion FAB MS/MS was pursued. As shown in Fig. 2, protonation at each proline nitrogen afforded three different linear peptide ions in the mass spectrum noted as A, B, and C. All but one of the ions predicted from their fragmentation was also observed, thereby confirming the structure assigned hymenistatin (**1**).

The absolute configuration of each chiral center was assigned using chiral GC analysis (Chirasil-Val III column) of the peptide hydrolysate following preparation of the *N*-pentafluoropropionyl/isopropyl ester derivatives (11). All of the amino acid units were found to bear the L configuration. Discovery of hymenistatin 1 (**1**), a seemingly unexceptional (12) cyclic peptide, that has cell growth inhibitory properties provides a new insight into structure requirements for such biological activity. Further biological evaluations and total synthesis are in progress.

Experimental

General methods

Solvents used for chromatographic procedures were redistilled. The Sephadex LH-20 (25-100 μm) employed for gel permeation and partition chromatography was obtained from Pharmacia Fine Chemicals AB, Uppsala, Sweden. Gilson FC-220 race track and F-80 microfractionators connected to Gilson HM UV–VIS Holochrome detectors were used for chromatographic fractionation experiments. Column chromatographic procedures with silica gel utilized the silica gel 60 prepacked "Lobar" columns supplied by E. Merck, Darmstadt, West Germany. The silica gel GF Uniplates for TLC were from Analtech Inc., Newark, Delaware. All TLC plates were viewed with UV light and (or) developed with a ceric sulphate – sulfuric acid spray (heating to approximately 150°C for 10 min).

The uncorrected melting points were observed using a Kofler-type melting point apparatus. The UV spectrum was recorded using a Hewlett–Packard 8450A UV–VIS spectrophotometer equipped with a HP7225A plotter. Optical rotation and IR spectral data were obtained using a Perkin–Elmer 241 polarimeter and a Nicolet MX-1 FTIR spectrophotometer, respectively. Mass spectra (70 eV and FAB) were recorded employing a Kratos MS-50 spectrometer. The NMR experiments were conducted with a Bruker WH-400 instrument and deuteriochloroform as solvent (TMS internal standard).

Animal collection and preliminary experiments

In early 1979, approximately 2 kg (wet wt) of the sponge *Hymeniacidon* sp. (Hymeniacidonidae family, Halichondrida Order, Ceratinomorpha Subclass, Demospongiae Class) was collected by scuba near Long Island (south side) in the Palau Archipelago, Western Caroline Islands. Taxonomic identification was conducted in the Smithsonian Institution where reference specimens are on file. The initial sample of Hymeniacidon sp. was preserved in 2-propanol. Removal of solvent gave an extract that reached a confirmed level of activity against the U.S. National Cancer Institute's murine P388 lymphocytic leukemia (PS system) with 30% life extension at 5.5 mg/kg.

Animal extraction and solvent partitioning

In March 1985, 250 kg (wet wt) of the *Hymeniacidon* sp. was recollected from the same area in Palau near the south side of Long Island and preserved in 2-propanol. The 2-propanol solution was decanted and the sponge was reextracted with the same alcohol. The extract was evaporated (*in vacuo*) to a 50 L water concentrate and found to contain a considerable amount (1.2 kg) of a pale brown suspension (PS T/C toxic at ≥ 50 mg/kg), which was removed by centrifugation (1000 *g*) and decantation. The cream-colored aqueous phase was successively partitioned between methylene chloride (90 L) and *n*-butanol (90 L). Evaporation of solvent from the chlorocarbon and *n*-butanol extracts gave, respectively, a very dark, brown, gel-like solid (180 g, PS ED_{50} 1.8 μg/mL and T/C 105 at 50 mg/kg) and a pale brown amorphous solid (300 g PS ED_{50} 6.1 μg/mL and T/C toxic at ≥ 50 mg/kg). The remaining aqueous extract was found to be PS inactive and was discarded. A solution of the methylene chloride fraction (180 g) in 9:1 methanol–water (1 L) was extracted with hexane (3 × 1 L). The methanol–water phase was diluted to 3:2 and extracted with methylene chloride. The resulting hexane (146 g), methylene chloride (20 g), and 3:2 methanol–water (14 g) fractions were concentrated and aliquots submitted for bioassay. Significant PS cytostatic activity (PS ED_{50} 0.26 μg/mL) was found to reside in the methylene chloride extract.

Isolation of hymenistatin 1 (1)

The 20 g sample of the PS active methylene chloride fraction in 3:2 methylene chloride – methanol was chromatographed on a column of Sephadex LH-20 (2.5 kg; 9 × 130 cm). While no pronounced separation of components was observed, further concentration to an active fraction designated A (elution volume 3.9 L, 18 g, PS ED_{50} 1.6 μg/mL) was realized. Further partition chromatography on Sephadex LH-20 (2.5 kg; 9 × 130 cm) and elution with 3:1:1 hexane–toluene–methanol gave active fractions B (elution vol. 500 mL, 0.50 g, PS ED_{50} 2.6 μg/mL) and C (elution vol. 480 mL, 1.64 g, PS ED_{50} 1.7 μg/mL)

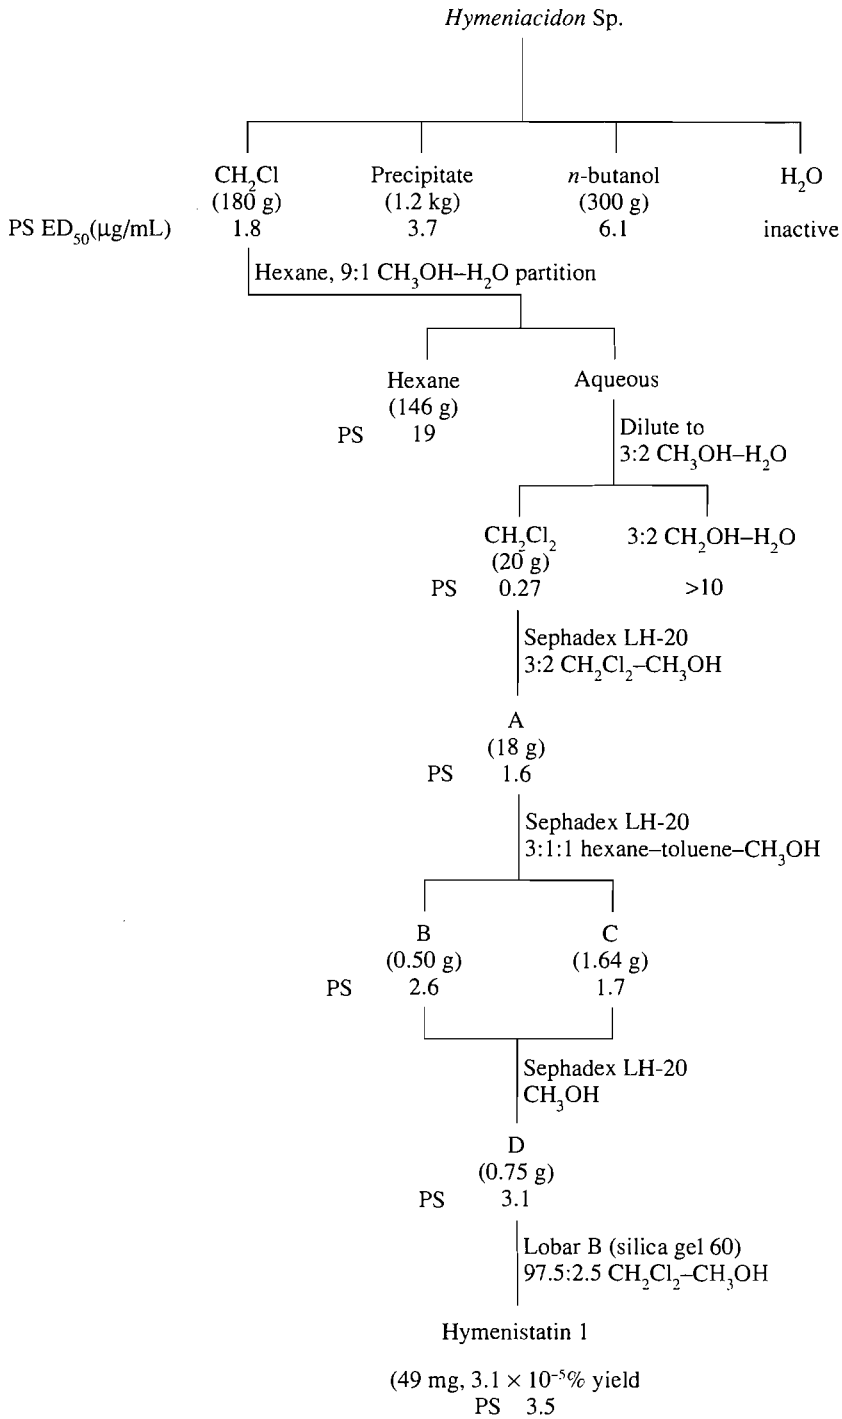

SCHEME 1

among 11 distinct composite fractions. Fractions B and C were combined and further separated in methanol on a Sephadex LH-20 column (500 g, 3.5 × 120 cm). Among the ten fraction groups obtained, a fraction labeled D (at elution vol. 60 mL, 0.75 g, PS ED_{50} 3.1 μg/mL) showed an almost single spot on tlc. Final purification was achieved utilizing a medium pressure (to 50 psi; 1 psi = 6.9 kPa) liquid chromatograhy unit with a prepacked silica gel 60 column (2.5 × 30 cm) and elution with 97.5:2.5 methylene chloride – methanol. Hymenistatin 1 was isolated as a colorless, amorphous solid (49 mg, 3.1×10^{-5} % yield) melting at 180–182°C: $[\alpha]_D$ −8.6° (*c* 1, $CHCl_3$); UV (CH_3OH) λ_{max} (log ε): 222 (3.82), 278 (3.16) nm; IR (NaCl plate): 3320, 2960, 2920, 1680, 1617, 1517 cm^{-1}; MS (HR-FAB): 893.5505 $[M + H]^+$ for $C_{47}H_{73}N_8O_9$; calcd. 893.5510; NMR ($CDCl_3$), δ, **Proline-a** unit, ^1H: 4.20 (H-2), 3.72 (H-5a), 3.38 (H-5b), 2.15 (H-3a), 2.11 (H-4a), 1.95 (H-4b), 1.93 (H-3b); ^{13}C: 60.89 (C-2), 47.35 (C-5), 31.87 (C-3), 25.06 (C-4); **Proline-b** unit, ^1H: 4.10 (dd, *J* = 9.4, 3.5; H-2), 3.28 (H-5a), 3.21 (H-5b), 2.16 (H-3a), 1.77 (H-3b), 1.60 (H-4a), 0.85 (H-4b); ^{13}C: 59.19 (C-2), 46.94 (C-5), 28.52 (C-3), 21.11 (C-4); **Proline c** unit, ^1H: 3.92 (H-5a), 3.79 (t, *J* = 7.8; H-2), 3.68 (H-5b), 2.31 (H-3a), 2.08 (H-4a), 2.06 (H-4b), 1.91 (H-3b), ^{13}C: 63.11 (C-2), 48.55 (C-5), 30.00 (C-3), 24.75 (C-4); **Tyrosine** unit, ^1H: 8.70 (br s, OH), 7.03 (d, *J* = 8.1; H-5), 6.84 (d, *J* = 8.0; H-6), 4.22 (H-2), 3.29 (H-3a), 2.90 (t, *J* = 13.0, H-3b); ^{13}C: 156.56 (C-7), 129.67 (C-5, C-9), 127.00 (C-4), 115.94 (C-6, C-8), 58.13 (C-2),

36.67 (C-3); **Valine** unit, ^{1}H: 7.58 (d, J = 8.8; NH), 4.56 (t, J = 5.9, H-2), 1.95 (H-3), 0.98 (6H; H-4, H-5); ^{13}C: 56.29 (C-2), 31.67 (C-3), 19.29 (C-4), 18.19 (C-5); **Leucine** unit, ^{1}H: 6.25 (br s, NH), 3.98 (H-2), 1.96 (H-3a), 1.82 (H-3b), 1.55 (H-4), 0.93 (3H; d, J = 6.3, H-6), 0.88 (3H, H-5); ^{13}C: 55.79 (C-2), 39.27 (C-3), 25.31 (C-4), 22.95 (C-6), 21.27 (C-5); **Isoleucine-a** unit, ^{1}H: 7.70 (d, J = 8.5, NH), 4.40 (t, J = 8.5, H-2), 1.57 (H-3), 1.50 (H-4a), 1.15 (H-4b), 0.96, (3H; H-6), 0.87 (3H; H-5); ^{13}C: 60.52 (C-2), 38.26 (C-3), 24.95 (C-4), 15.47 (C-6), 10.64 (C-5); and **Isoleucine-b** unit, ^{1}H: 7.40 (d, J = 8.5, NH), 4.69 (t, J = 9.0, H-2), 1.76 (H-3), 1.53 (H-4a), 1.05 (H-4b), 0.82 (3H; H-6), 0.80 (3H; H-5); ^{13}C: 55.01 (C-2), 36.94 (C-3), 24.79 (C-4), 16.20 (C-6), 11.87 (C-5). Eight carbonyl ^{13}C resonances appear at 172.72, 172.29, 172.10, 171.49, 171.95, 171.18, 170.41, 170.35. Where no multiplicity is indicated it could not be determined due to overlapping signals.

Assigment of the hymenistatin (1) chiral centers

The cyclo-octapeptide was hydrolyzed with 1:1 propionic acid – 12 N hydrochloric acid at 160°C for 15 min (13). The corresponding amino acids were converted to *N*-pentafluoropropionyl/isopropyl ester derivatives and configurations established by chiral capillary chromatography as reported by Shaw and Cotter (11) using a Chirasil Val III column. Each amino acid component was found to belong to the *S*(L) series.

Acknowledgments

The funds for this research were provided and received with appreciation from the Fannie E. Rippel Foundation, Grant CA-16049-05-12, and Outstanding Investigator Grant CA 44344-01A1 awarded by the Division of Cancer Treatment, NCI, DHHS, the Robert B. Dalton Endowment, the Arizona Disease Control Research Commission, Virginia G. Piper, Eleanor W. Libby, the Donald Ware Waddell Foundation, Herbert and Dianne Cummings, the Nathan Cummings Foundation, Lotte Flugel, and Polly J. Trautman. g-Values for γ-irradiated water as a function of temperature

A. JOHN ELLIOT,[1] MONIQUE P. CHENIER, AND DENIS C. OUELLETTE

System Chemistry and Corrosion Branch, Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ont., Canada K0J 1J0

Received August 14, 1989

A. JOHN ELLIOT, MONIQUE P. CHENIER, and DENIS C. OUELLETTE. Can. J. Chem. **68**, 712 (1990).

The *g*-values of primary species formed in the γ-radiolysis of water have been estimated for the temperature range 25–300°C. The *g*-values for the hydrated electron, the hydroxyl radical, and molecular hydrogen all increase approximately 50% over this temperature range. The *g*-values for the minor products, hydrogen peroxide and atomic hydrogen, probably also increase with temperature; however, there is evidence from some of the experimental data which suggests that these *g*-values may slightly decrease with increasing temperature.

Key words: radiolysis, *g*-values, temperature dependence.

A. JOHN ELLIOT, MONIQUE P. CHENIER et DENIS C. OUELLETTE. Can. J. Chem. **68**, 712 (1990).

On a évalué les valeurs-*g* des espèces primaires qui se forment lors de la radiolyse-γ de l'eau à des températures allant de 25 à 300°C. Pour cet écart de température, les valeurs-*g* de l'électron hydraté, du radical hydroxyle et de l'hydrogène moléculaire augmentent toutes d'environ 50%. Il est probable que les valeurs-*g* des produits mineurs comme le peroxyde d'hydrogène et l'hydrogène moléculaire subissent aussi des augmentations avec la température; toutefois, certaines données expérimentales suggèrent que ces valeurs-*g* diminuent légèrement avec une augmentation de la température.

Mots clés : radiolyse, valeurs-*g*, relation avec la température.

Introduction

The primary heat transport systems in both pressurized and boiling water nuclear power reactors generally operate in the 250–310°C temperature range with a 25°C pH of 7–11 (1). To computer model the water radiolysis under these conditions, the yields of the primary species (eq. [1]) are required for both the γ and the fast neutron radiation. The term "primary species" refers to the species formed by the action of the radiation as opposed to those formed by chemical reactions afterwards. The yields in radiation chemistry are generally measured in terms of *G* (or *g*)-values, which, in this paper, are defined as the number of species formed or destroyed per 100 eV of energy absorbed (2, 3). The symbol "*g*" will be used for the yield of primary species while "*G*" will be used for all other yields.

$$[1] \qquad H_2O \xrightarrow{\text{radn.}} e_{aq}^-, OH, H, H_2O_2, H_2, HO_2$$

Experimental data are available for the *g*-values up to 250–300°C for both fast neutrons (4) and γ-radiation (5–7) in 0.4 mol dm^{-3} sulphuric acid. However, for water of near-neutral pH, there are only pulse radiolysis data up to 200–250°C (8–11) and some contradictory steady-state radiolysis results (12–14) in the 250–300°C temperature range. For fast neutrons, there are only estimates for the *g*-values at room temperature (15, 16) based on the *g*-values measured using radiation with different linear energy transfer characteristics.

In this report, the literature data are combined with our recent steady-state radiolysis results to predict the *g*-values for the γ-radiolysis of water up to 300°C.

Experimental

The chemicals that were used in these experiments were AR quality or better and were used as supplied. The solutions were prepared in water that had been distilled, passed through a Millipore purification system, and then redistilled from alkaline permanganate. The solutions were degassed on a vacuum line and then transferred to and sealed in 1.5×10^{-2} dm^3 cylindrical Pyrex cells. Unless otherwise stated, for solutions to be irradiated at 300°C, the amount of solution added to the sample cell was such that, at temperature, the cell was essentially filled with liquid to minimize the proportion of water in the vapour phase. (The density of water at 300°C is 0.71 kg dm^{-3}.) At lower temperatures, there was sufficient solution in the ampoules to ensure more than 98% of the water was in the liquid phase.

The samples were heated in an autoclave and irradiated in an AECL Gamma-Cell. The dose rate as measured by Fricke dosimetry (3) was near 7.25×10^{18} eV kg^{-1} s^{-1}. Hydrogen was the only product analyzed and its yield was measured using a gas burette coupled to a gas chromatograph. At room temperature and at the highest temperature studied, the *G*-value for hydrogen was always calculated from yield–dose plots, while at intermediate temperatures it was normally calculated from the hydrogen yield from duplicate samples measured at only one dose. As the yield–dose plots were always linear within experimental error and passed through the origin, this indicated that hydrogen formed through thermal decomposition of the solutions was insignificant. This was confirmed by heating some of the solutions at 300°C without irradiation.

Two sets of experiments were carried out in ca. 8.5×10^{-2} mol kg^{-1} KOH. The concentration of KOH was determined by titration with HCl. The loss of OH^- after irradiations at 200 and 300°C was found to be only ca. 6 and 15%, respectively.

Results

(A) Estimation of $g(H_2)$

At room temperature, the hydrogen yield measured in degassed dilute solutions containing either KBr (17) or KNO_2 (18) is a good estimate of $g(H_2)$. This is because both Br^- and NO_2^- scavenge the hydroxyl radical to prevent reaction [2], which would destroy the molecular hydrogen formed in the radiolysis (eq. [1]) (2).

$$[2] \qquad OH + H_2 \rightarrow H + H_2O$$

For this study, we have irradiated both solutions over the 25–300°C temperature range.

(i) Radiolysis of 2×10^{-3} *mol* kg^{-1} *KBr solutions*

Figures 1 and 2 summarize the results obtained for γ-irradiated degassed 2×10^{-3} mol kg^{-1} KBr solutions. Also shown in Fig. 2 are the results reported by Kabakchi and Lebedeva (14), who irradiated (possibly aerated) 10^{-3} mol kg^{-1} KBr solutions in open Pyrex ampoules in an autoclave, and

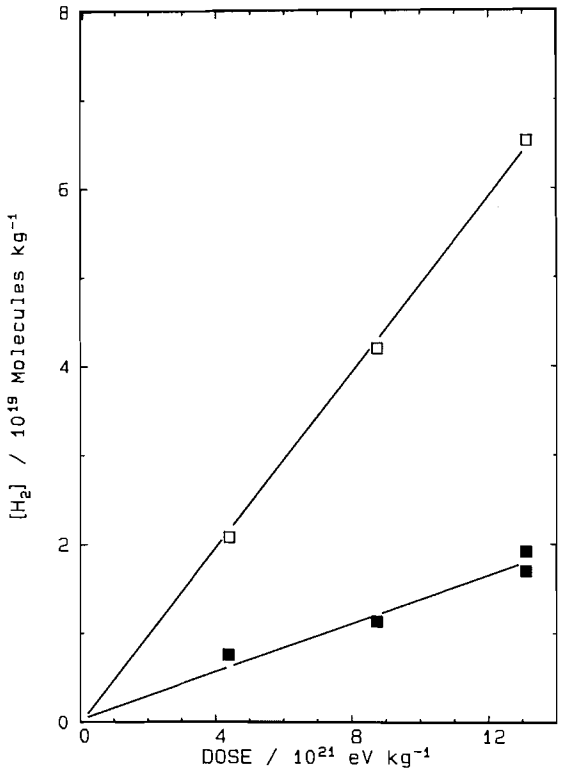

FIG. 1. The hydrogen yield from degassed 2×10^{-3} mol kg^{-1} KBr solutions irradiated at 25°C (□) and 300°C (■).

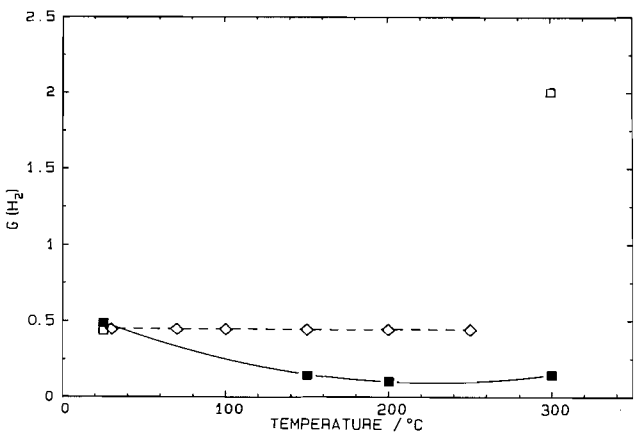

FIG. 2. $G(H_2)$ measured from (1–2) $\times 10^{-3}$ mol kg^{-1} KBr solutions as a function of temperature: this work (■), Burns and Marsh (13) (□), and Kabakchi and Lebedeva (14) (◇).

the results reported by Burns and Marsh (13), who irradiated deaerated 2×10^{-3} mol kg^{-1} KBr solutions in a stainless steel loop. While these data agree well with each other and the literature data (17) at room temperature, there is no agreement at higher temperatures.

Figure 3 shows the $G(H_2)$ obtained for a series of experiments conducted at 300°C with different proportions of water in the vapour phase. The proportion of water in the vapour phase at 300°C was calculated from the mass of the sample, the volume of the cell, and the densities of liquid water and steam (19). The line in Fig. 3 was fitted to the data using eq. [3]:

$$[3] \quad G(H_2) = (M_{gas}/M_{total})G(H_2)_{gas} + (M_{liq}/M_{total})G(H_2)_{liq}$$

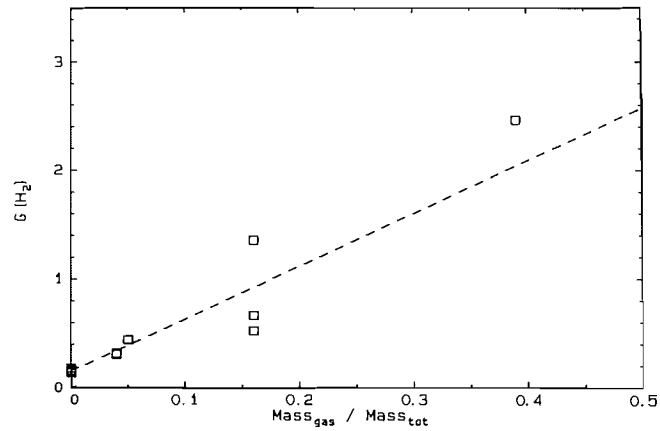

FIG. 3. $G(H_2)$ measured from degassed 2×10^{-3} mol kg^{-1} KBr solutions irradiated at 300°C as a function of the proportion of water in the gas phase.

where M is the mass of water, and $G(H_2)_{liq}$ and $G(H_2)_{gas}$ are the G-values for hydrogen formed in the liquid and steam phase, respectively. The values for $G(H_2)_{liq}$ of 0.15 and for $G(H_2)_{gas}$ of 5 were used. This $G(H_2)_{gas}$ is consistent with measurements of hydrogen yields in irradiated steam. We have measured a value of $G(H_2)$ of 4.1 at 300°C for steam under similar conditions to the above experiments. Two other groups of workers (ref. 20 and footnote 2) who have measured $G(H_2)$ in steam (at 0.5–1 atm pressure; 1 atm = 101.3 kPa) as a function of temperature have reported values of 2 at 100°C rising sigmoidally to 8 at >400°C. At 300°C, a value for $G(H_2)$ near 7 was found (ref. 20 and footnote 2). These results indicate that, depending on the proportion of water in the vapour phase, radiolysis of water vapour can contribute significantly to the measured hydrogen yield. To minimize the radiolysis of water vapour at high temperatures, the ratio of the gas to liquid volume in the sample should be minimized.

This may explain why the G-values observed by Kabakchi and Lebedeva (14) are higher than the values measured in this study. They irradiated open ampoules in an autoclave and calculated $G(H_2)$ from the gas pressure increase in the autoclave and the gas composition. Under this arrangement a large portion of the water must have been present as steam at the higher temperatures.

In the experiments by Burns and Marsh (13), corrosion of the stainless steel loop was ruled out as a source for the high $G(H_2)$ value measured at 300°C. However, in the irradiation vessel, a steam layer may have developed where the excess hydrogen could be formed by steam radiolysis, perhaps enhanced by wall effects (22).

(ii) Radiolysis of 10^{-3} mol kg^{-1} KNO_2 solutions

Figures 4 and 5 summarize the results obtained when the degassed 10^{-3} mol kg^{-1} KNO_2 solutions were irradiated. The yield–dose curves were linear at 25 and 300°C and the room temperature value of 0.42 ± 0.04 is in agreement with the literature value (18). The $G(H_2)$ of 0.62 ± 0.03 measured at 300°C is much higher than the $G(H_2)$ of 0.15 ± 0.02 measured at the same temperature from the KBr solution.

(B) Estimation of g(H_2) + g(H)

To estimate $g(H_2) + g(H)$, solutes were chosen that not only scavenged the hydrogen atoms to form hydrogen, but were also good hydroxyl radical scavengers to protect the hydrogen

[2]D. A. Armstrong and R. Ahmad. Unpublished data.

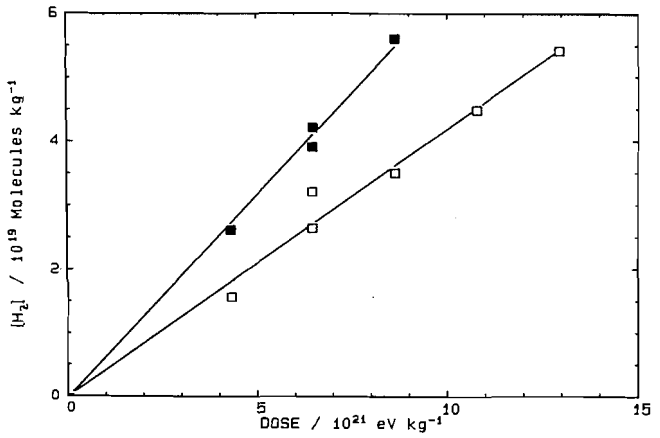

FIG. 4. The hydrogen yield from degassed 10^{-3} mol kg^{-1} KNO_2 solutions irradiated at 25°C (□) and 300°C (■).

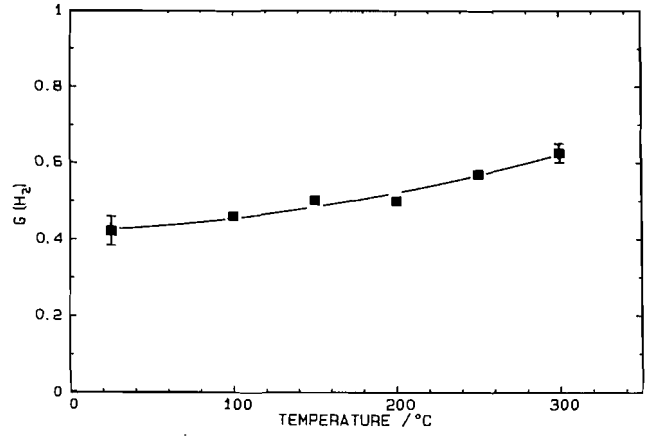

FIG. 5. $G(H_2)$ measured from degassed 10^{-3} mol kg^{-1} KNO_2 solutions as a function of temperature.

formed. The hydrated electron scavengers were selected on the basis that they were either relatively ineffective hydrogen atom scavengers or, if they did react with the hydrogen atom, molecular hydrogen was formed.

[4] $CH_3OH + OH, H \rightarrow \cdot CH_2OH + H_2O, H_2$

[5] $(CH_3)_2CHOH + OH, H \rightarrow (CH_3)_2COH + H_2O, H_2$

[6] $e_{aq}^- + Cd^{2+} \rightarrow Cd^+$

[7] $e_{aq}^- + (CH_3)_2C{=}O \xrightarrow{H^+} (CH_3)_2COH$

Three systems were studied over the 25–300°C temperature range: (a) degassed 10^{-3} mol kg^{-1} $CdSO_4$, 10^{-2} mol kg^{-1} methanol; (b) degassed 10^{-3} mol kg^{-1} acetone, 10^{-2} mol kg^{-1} methanol; and (c) degassed 10^{-3} mol kg^{-1} acetone, 10^{-2} mol kg^{-1} 2-propanol. The results are summarized in Figs. 6 and 7. At room temperature, a $G(H_2)$ of 1 was found for these systems, which is in good agreement with previously published data (23–25). Up to 200°C, all three solutions had essentially the same $G(H_2)$; above 200°C, there is a dramatic, but different, increase in $G(H_2)$ for each solution. As the yield–dose plot for each solution at 300°C was linear and passed through the origin (Fig. 6), this indicates that the hydrogen yield arose from radiation-induced processes and not thermal decomposition of the starting solution. Thermal decomposition of the stable end products of the radiolysis is also unlikely to be the source of the excess hydrogen because a $G(H_2)$ of near 1 was still found for

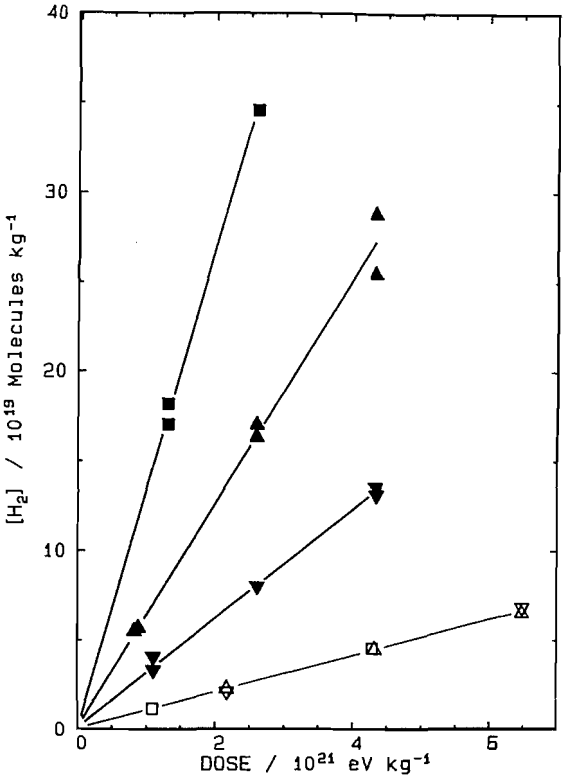

FIG. 6. The hydrogen yield from degassed solutions containing: 10^{-3} mol kg^{-1} $CdSO_4$, 10^{-2} mol kg^{-1} methanol (△, ▲); 10^{-3} mol kg^{-1} acetone, 10^{-2} mol kg^{-1} methanol (▽, ▼); and 10^{-3} mol kg^{-1} acetone, 10^{-2} mol kg^{-1} 2-propanol (□, ■). The open and solid points are solutions irradiated at 25 and 300°C, respectively.

solution (c) when it was irradiated at room temperature and then heated to 300°C.

(C) Estimation of $g(e_{aq}^-) + g(H_2) + g(H)$

Degassed solutions containing 10^{-3} mol kg^{-1} perchloric acid and 10^{-2} mol kg^{-1} methanol were irradiated to estimate $g(e_{aq}^-) + g(H_2) + g(H)$. In these solutions, the hydrated electron is converted into a hydrogen atom (reaction [8])

[8] $e_{aq}^- + H^+ \rightarrow H$

which in turn reacts with the methanol to form hydrogen (reaction [4]). The total molecular hydrogen yield is then a measure of $g(e_{aq}^-) + g(H_2) + g(H)$. Unfortunately, this system could only be studied over the 25–200°C range because at higher temperatures the acid solution reacted with the Pyrex ampoule and the pH increased. (After heating to 300°C, the room temperature pH rose from 3 to 7.) These results are given in Fig. 8. The room temperature G-value is consistent with the results of Baxendale and Dixon (25).

Increasing the acid concentration to minimize the loss of protons reacting with the Pyrex ampoule would also lead to excessive scavenging of the hydrated electron in the spur (2). To circumvent this, degassed 10^{-2} mol kg^{-1} methanol solutions containing 0.1 mol kg^{-1} KH_2PO_4 were used. The room temperature pH was adjusted to 2.4 with perchloric acid, which, at 200 and 300°C, represents pH values of 3.4 and 4.3, respectively (26). In these solutions the hydrated electron can be converted to hydrogen atoms by reactions [8] and [9] (27).

[9] $e_{aq}^- + H_3PO_4(H_2PO_4^-) \rightarrow H + H_2PO_4^-(HPO_4^{2-})$

The hydrogen atoms formed in these reactions either react with

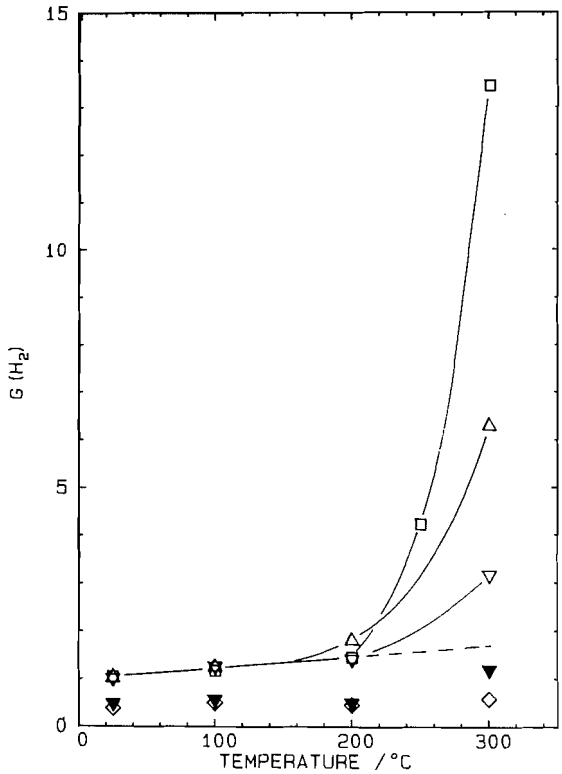

FIG. 7. $G(H_2)$ as a function of temperature as measured from degassed solutions containing: 10^{-3} mol kg^{-1} $CdSO_4$, 10^{-2} mol kg^{-1} methanol (△); 10^{-3} mol kg^{-1} acetone, 10^{-2} mol kg^{-1} methanol (▽); 10^{-3} mol kg^{-1} acetone, 10^{-2} mol kg^{-1} 2-propanol (□); 10^{-3} mol kg^{-1} acetone, 10^{-2} mol kg^{-1} methanol, 8.5×10^{-2} mol kg^{-1} KOH (▼); and 10^{-3} mol kg^{-1} KNO_2, 8.5×10^{-2} mol kg^{-1} KOH (◇).

the methanol (reaction [4]) or by reaction [10] (27).

[10] $H + H_3PO_4(H_2PO_4^-) \rightarrow H_2 + H_2PO_4(HPO_4^-)$

The $G(H_2)$ that are shown in Fig. 8 steadily increase in value with temperature over the whole temperature range but are consistently 0.92 of the $G(H_2)$ obtained from the 10^{-3} mol kg^{-1} perchloric acid and 10^{-2} mol kg^{-1} methanol solutions. The important point is that the yield smoothly increases between 200 and 300°C, which suggests that no abrupt change in yields occurred in this temperature range. The room temperature pH of the solution did not change after an irradiation at 300°C.

(D) Estimation of g(H_2) and g(H) in alkaline solutions

Because of the conflicting results for $g(H_2)$ in section (A) above, the hydrogen yields were measured from irradiated degassed 8.5×10^{-3} mol kg^{-1} KOH solutions containing either 10^{-3} mol kg^{-1} KNO_2 or 10^{-3} mol kg^{-1} acetone and 10^{-2} mol kg^{-1} methanol. In the latter solution, because of the high OH^- concentration, most of the atomic hydrogen will react by eq. [11] to form the hydrated electron (17) rather than by reaction [4] to form hydrogen.

[11] $H + OH^- \rightarrow e_{aq}^- + H_2O$

The results are summarized in Fig. 7. Up to 200°C, the hydrogen yields for the acetone–methanol solution were slightly higher than that from the nitrite solution. At 25 and 200°C, $G(H_2)$ for the nitrite solution were 0.38 and 0.45, respectively, and $G(H_2)$ for the acetone–methanol solution were 0.48 and 0.50, respectively. At 300°C, in the acetone–methanol solution, the $G(H_2)$ was 1.19, which is considerably greater than

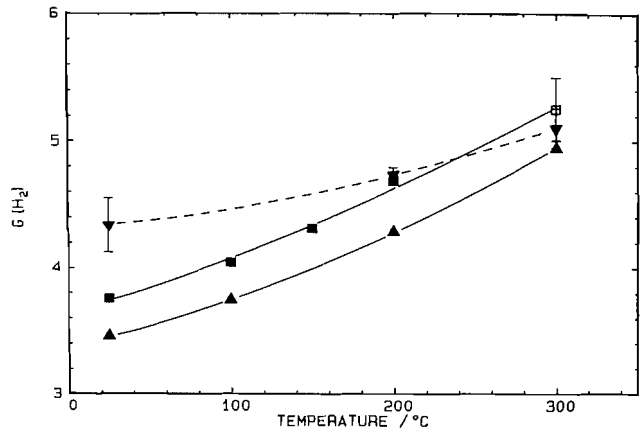

FIG. 8. $G(H_2)$ as a function of temperature as measured from degassed solutions containing: 10^{-2} mol kg^{-1} methanol, 10^{-3} mol kg^{-1} $HClO_4$ (■); value estimated at 300°C (□); 10^{-2} mol kg^{-1} methanol, 10^{-1} mol kg^{-1} KH_2PO_4, pH adjusted to 2.4 at 25°C (▲); 10^{-1} mol kg^{-1} methanol, 0.4 mol kg^{-1} H_2SO_4 (▼) (5).

the 0.57 observed in the nitrite solution. The excess hydrogen production in the acetone–methanol solution probably arises through the same process operating in this solution at neutral pH (see section D above).

The $G(H_2)$ of 0.38 for the alkaline nitrite solution at 25°C is slightly lower than the neutral pH value of 0.41 and is consistent with the hydrogen atom precursor of the molecular hydrogen reacting by eq. [11] in the spur.

The difference between $G(H_2)$ for the acetone–methanol solution at neutral pH and $G(H_2)$ from one containing 8.5×10^{-2} mol kg^{-1} KOH provides an alternative estimate of $g(H)$.

Discussion

(A) Estimation of g(H_2)

While the values of $G(H_2)$ from Br^- solutions (Fig. 2) are quite different from those obtained from NO_2^- solutions (Fig. 5), we consider the latter to best represent $g(H_2)$. At room temperature, Br^- protects the molecular hydrogen by scavenging the hydroxyl radical as shown in the following sequence of equilibria [12]–[14] (28, 29):

[12] $OH + Br^- \rightleftarrows HOBr^-$

[13] $HOBr^- \rightleftarrows Br + OH^-$

[14] $Br + Br^- \rightleftarrows Br_2^-$

At room temperature, equilibrium [14] lies well to the right ($K_{14} = 2 \times 10^5$ M^{-1} (30)). By analogy with the corresponding equilibria involving I^- and SCN^- (31, 32), as the temperature increases, K_{14} will decrease to allow intermediate species like bromine atoms and $HOBr^-$ to react with the molecular hydrogen to lower the hydrogen yield. Similar reactions involving $Br/HOBr^-$ and $SCN/HOSCN^-$ have also been observed when studying reactions of Br_2^- (33) and $(SCN)_2^-$ (34).

Further support for the assignment of $g(H_2)$ to $G(H_2)$ from the nitrite solution comes from the alkaline solution study (Fig. 7) where $G(H_2)$ was similar for both the nitrite and acetone–methanol solutions up to 200°C. As mentioned earlier, the hydrogen yield from the latter solution should represent $g(H_2)$ only as the atomic hydrogen that escaped the spur would undergo reaction [11] rather than reaction [4].

(B) Estimation of $g(H_2) + g(H)$

Up to 200°C, there is reasonable agreement between the three systems studied for the temperature dependence of $g(H_2) + g(H)$ (see Fig. 7). Above this temperature, the observed increase in $G(H_2)$ can be explained in terms of thermal reactions of the intermediates formed during the radiolyses.

In solutions containing Cd^{2+} and methanol, the principal reactions involving the primary species are given by reactions [4], [6], and [15] (2, 24, 35). From earlier studies (5) of the radiolysis of 0.4 mol kg^{-1} sulphuric acid solutions containing methanol, the hydrogen yield did not increase abruptly above 200°C (summarized in Fig. 8), which indicates that the $\cdot CH_2OH$ does not thermally decompose to form hydrogen in the 200–300°C range. It is most likely that the hydrolysis of either Cd^+, Cd_2^{2+}, or Cd^0 (reactions [6] and [15] (35))

[15] $Cd^+ + Cd^+ \rightarrow Cd_2^{2+} \rightleftarrows Cd^0 + Cd^{2+}$

gives rise to the excess hydrogen (reactions [16] or [17] followed by [4]).

[16] Cd^0 (or Cd_2^{2+}) $+ 2H_2O \rightarrow Cd^{2+}$ (or $2Cd^{2+}$) $+ H_2 + 2OH^-$

[17] $Cd^+ + H_2O \rightarrow H + Cd^{2+} + OH^-$

In the two solutions where acetone was used as the hydrated electron scavenger, the radical, $(CH_3)_2COH$, formed in reactions [5] and [7] appears to be responsible for the increase in the hydrogen yield above 200°C.

Again, it is obvious that the $\cdot CH_2OH$ radical is not the origin of the excess hydrogen. At 300°C, a $G(H_2)$ of 3.2 ± 0.3 is observed in the solutions containing acetone and methanol; here approximately equal amounts of $\cdot CH_2OH$ and $(CH_3)_2COH$ were formed. In solutions containing acetone and 2-propanol where essentially all the organic radicals were $(CH_3)_2COH$, a $G(H_2)$ of 13.5 ± 0.3 was measured. Based on the estimated g-values for water at 300°C (see later), the maximum possible G-value for $(CH_3)_2COH$ is 10.7 and this assumes that all the hydrogen peroxide thermally decomposes to form two hydroxyl radicals (reaction [18]) (36).

[18] $H_2O_2 \rightarrow 2OH$

This suggests a chain reaction must be occurring, but, unfortunately, under the present experimental arrangement the dose rate cannot be varied to screen for a chain reaction. One possible mechanism is the thermally induced reaction [19] to form atomic hydrogen

[19] $(CH_3)_2COH \xrightarrow{\text{heat}} (CH_3)_2C{=}O + H$

followed by reaction [5] to form the excess molecular hydrogen and another $(CH_3)_2COH$ radical to propagate the chain. When methanol is present, reaction [4] produces some extra molecular hydrogen but, as $\cdot CH_2OH$ does not thermally decompose at these temperatures, the chain reaction cannot occur.

Also consistent with the above mechanism is the much lower increase in hydrogen yield observed at 300°C in the acetone–methanol solution containing 8.5×10^{-2} mol kg^{-1} KOH compared to the same solution at neutral pH (Fig. 7). In this alkaline solution at 300°C, $(CH_3)_2COH$ will probably exist largely as the acetone radical anion (equilibrium [20]) based on the measured pK_a of 12.2 at 25°C and 11.7 at 64°C (41).

[20] $(CH_3)_2COH + OH^- \rightleftarrows (CH_3)_2C{-}O^- + H_2O$

The radical anion, $(CH_3)_2C{-}O^-$, is unlikely to undergo a reaction similar to [19].

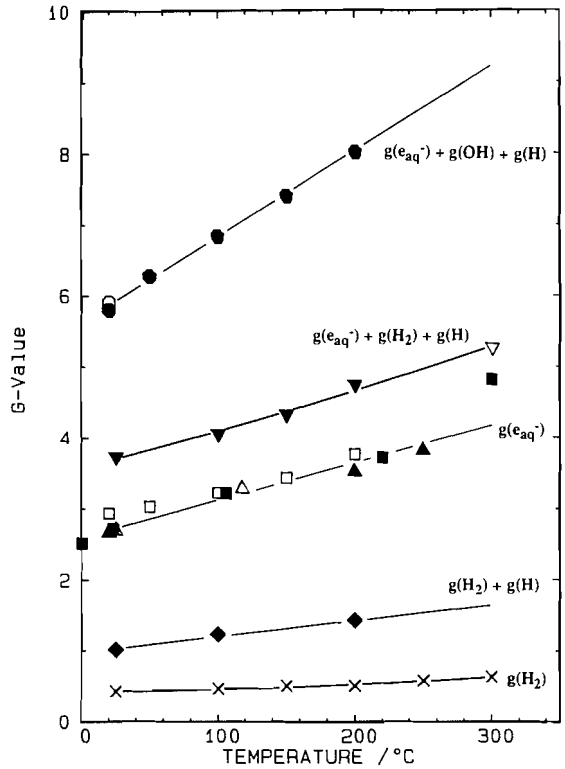

FIG. 9. The data used to calculate the g-values for the primary species as a function of temperature. $g(H)$ (X), $g(H_2) + g(H)$ (◆); $g(e_{aq}^-) + g(H_2) + g(H)$ (▼, ▽) (this work). $g(e_{aq}^-)$: (■) (12), (▲) (11), (□) (10), and (△) (40). $g(e_{aq}^-) + g(OH) + g(H)$: (●) (see text, 9, 10) and (○) (8). The values used in the calculations are given by the solid lines.

Since the marked increase in $G(H_2)$ above 200°C appears to arise from thermally initiated processes involving the intermediates and not the primary species, the data up to 200°C were extended to 300°C in a linear fashion, as shown in Fig. 7.

(C) Estimation of $g(e_{aq}^-) + g(H_2) + g(H)$

The values of $G(H_2)$ from solutions containing 10^{-2} mol kg^{-1} methanol and 0.1 mol kg^{-1} KH_2PO_4 increase smoothly over the 25–300°C temperature range. Although these data are 8% lower than the $G(H_2)$ from the solutions containing 10^{-3} mol kg^{-1} perchloric acid and 10^{-2} mol kg^{-1} methanol, we have used this temperature dependence to extrapolate the G-values for the perchloric acid – methanol solution from 200 to 300°C (Fig. 8).

Also shown in Fig. 8 is the $G(H_2)$ obtained in an earlier study of 0.1 mol kg^{-1} methanol in 0.4 mol kg^{-1} sulphuric acid (5). The increase of $G(H_2)$ with temperature for the 0.4 mol kg^{-1} sulphuric acid solution is less than with the 10^{-3} mol kg^{-1} perchloric acid. In general, it appears that the increase in G-value with temperature is less, the more acidic the solution. Further evidence of this comes from pulse radiolysis studies: Elliot (37) has observed at pH 2 that $g(e_{aq}^-) + g(H)$ was constant over the temperature range 20–80°C; and studies where G(radical) was measured at different pH's using HO_2/O_2^- yields in solutions containing formate ions (8) or saturated with hydrogen (38) also showed the same effect.

(D) g*-Values for the primary species as function of temperature*

The data used to estimate the g-values for the primary species in γ-irradiated near-neutral water are shown in Fig. 9. The yields for $g(e_{aq}^-) + g(OH) + g(H)$ were taken from Fig. 6 in ref. 9 and corrected by the recently published (10) extinction

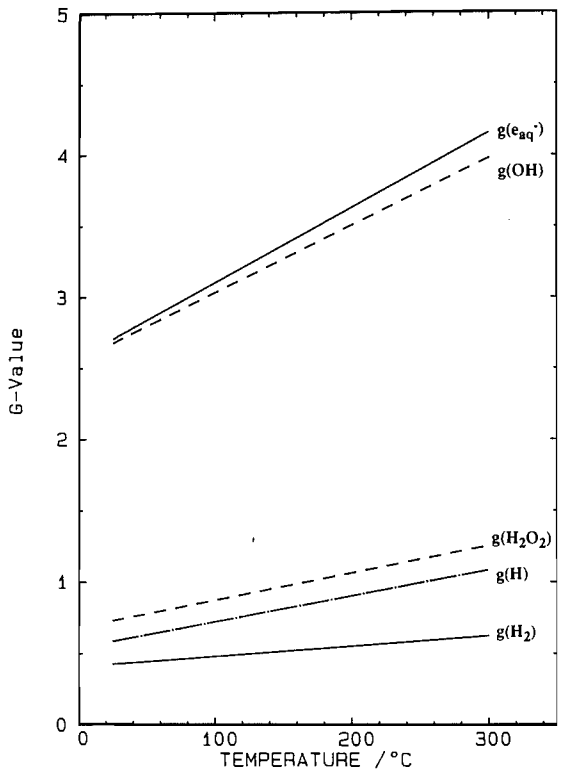

FIG. 10. The temperature dependence of the g-values for the primary species based on $g(H_2) + g(H)$ data (see text).

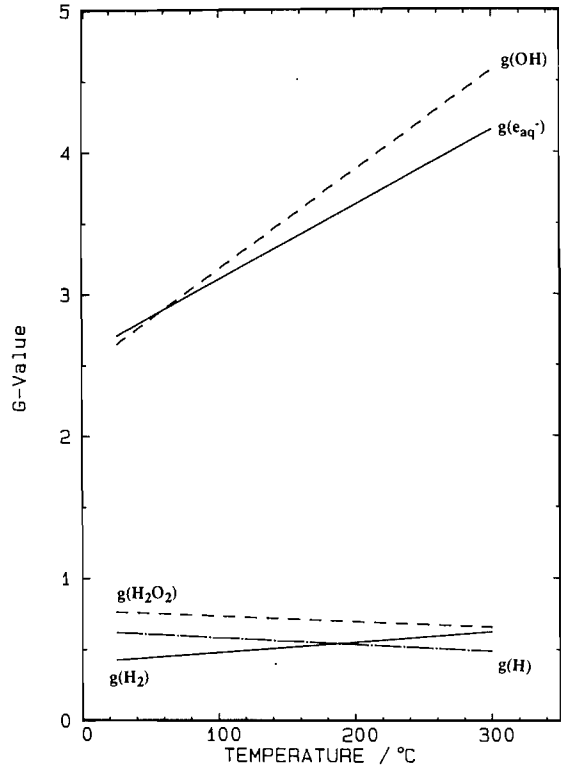

FIG. 11. The temperature dependence of the g-values for the primary species based on $g(e_{aq}^-) + g(H_2) + g(H)$ data (see text).

coefficients for the mono-cation, MV^+, formed by the one-electron reduction of the methyl viologen (1,1′-dimethyl-4,4′-bipyridylium) di-cation. In general, the data selected from the literature were chosen because there was little ambiguity associated with the value. There are pulse radiolysis experiments where the absorptions of e_{aq}^-, O_2^-, and HO_2 were followed as a function of temperature but, because their extinction coefficients at different temperatures are not known, the results were not used (8, 38, 39). The lines in Fig. 9 represent the actual values used in the calculations. In choosing the line for $g(e_{aq}^-)$, data obtained with the least spur scavenging were used.

The data in Fig. 9, as they stand, are not altogether self-consistent. Different values for $g(H)$ are calculated from $g(H_2) + g(H)$ and from $g(e_{aq}^-) + g(H_2) + g(H)$ using $g(H_2)$ and $g(e_{aq}^-)$. This can be seen in Fig. 10, where the primary g-values based on $g(H_2) + g(H)$ are given, and in Fig. 11, where the primary g-values based on $g(e_{aq}^-) + g(H_2) + g(H)$ are shown.

For both figures, the g-values for hydrogen peroxide were calculated using the mass balance eq. [21]:

$$[21] \quad g(H_2O_2) = (g(H) + g(e_{aq}^-) + 2g(H_2) - g(OH))/2$$

The g-values at 25°C in Figs. 10 and 11 are essentially the same and agree with the accepted values for the γ-radiolysis of water (2, 3). However, as the temperature increases, the $g(H)$ difference becomes apparent and, as a consequence of this, $g(H_2O_2)$ (eq. [21]) also differs. Figure 10 probably best represents the g-values for γ-irradiated water of near-neutral pH for a number of reasons. Firstly, the values of $g(H_2) + g(H)$ were derived from *three* experimental systems at near-neutral pH whereas the values of $g(e_{aq}^-) + g(H_2) + g(H)$ were measured from one acidic solution, and G-values from acidic solutions do appear to have a lower temperature dependence than in near-neutral solutions. Secondly, the $g(H)$ calculated from the difference in the $G(H_2)$ value for the acetone–methanol solution at neutral pH and 8.5×10^{-2} mol kg^{-1} KOH is consistent with the $g(H)$ in Fig. 10 over the 25–200°C range. Thirdly, an independent estimate of $g(H)$ over the temperature range 20–200°C, from pulse radiolytic estimates of $G(CO_3^-)$ (which equals $g(e_{aq}^-) + g(OH)$) from N_2O-saturated 9.2×10^{-2} mol kg^{-1} sodium bicarbonate solutions (42) and from the $g(e_{aq}^-) + g(OH) + g(H)$ data given in Fig. 9, gave values of $g(H)$ equal, within experimental error, to those shown in Fig. 10.

At the present time there are probably not enough experimental data available to say whether the g-values reported here for 300°C conform with the currently accepted views of water radiolysis. However, certain observations can be made.

At 25°C the radiation chemistry of water at 1 ps, before any of the spur reactions occur, can be written as (43):

$$[22] \quad 5.70H_2O \xrightarrow{100\ eV} 4.78e_{aq}^- + 4.78H^+ + 0.62H + 5.7OH + 0.15H_2 + 0.0H_2O_2$$

At 300°C, the radiation chemistry, after all the spur reactions are complete, can be written, based on Fig. 10, as:

$$[23a] \quad 6.47H_2O \xrightarrow{100\ eV} 4.15e_{aq}^- + 4.15H^+ + 1.08H + 3.97OH + 0.62H_2 + 1.25H_2O_2$$

or, based on Fig. 11, as:

$$[23b] \quad 5.87H_2O \xrightarrow{100\ eV} 4.15e_{aq}^- + 4.15H^+ + 0.48H + 4.57OH + 0.62H_2 + 0.65H_2O_2$$

For both reactions [23*a*] and [23*b*], the amount of water

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

decomposed at the end of the spur reactions at 300°C is equal to or greater than the 1 ps 25°C value (reaction [22]). However, the $g(-H_2O)$ at 1 ps for 300°C water radiolysis will be greater than that at the end of the spur reactions. We have some evidence for this from ongoing work on the effect of scavenger concentration on g-values at 300°C where, at nitrite concentrations of 0.05 and 0.5 mol kg^{-1}, $g(H_2)$ was 0.52 and 0.37, respectively. The fact that nitrite, a hydrated electron and hydroxyl radical scavenger, lowers the molecular hydrogen yield implies it is being formed, at least in part, by free radical processes (reaction [24]),

[24] $e_{aq}^-, H \rightarrow H_2$

which, in turn, implies that some recombination (reaction [25]) to reform water must also have occurred (2).

[25] $H, e_{aq}^- + OH \rightarrow H_2O, OH^-$

While the overall decomposition of water is higher at 300°C, this could be due in part to increases in the yield of excitation rather than ionization processes (43).

Recently it was found that the temperature dependence of rate constants of a number of reactions that were near-diffusion-controlled at 25°C was less than that of diffusion in water (44). As most of the important spur reactions are near-diffusion-controlled at 25°C (2), this means that, as the temperature is raised, more free radical species will diffuse out of the spur than will react in the spur to form water, molecular hydrogen, and hydrogen peroxide, i.e., the yield of free radicals relative to molecular products should increase with temperature. Furthermore, as the density of the solution decreases with increased temperature, this should lead to an expanded spur, which also should facilitate the escape of the radicals from the spur.

The fast neutron radiolysis of 0.4 mol dm^{-3} sulphuric acid is consistent with this model as the g-values for radicals do show a marked increase with temperature while the molecular product yields decrease (4). However, the γ-radiolysis g-values do not follow the above prediction. In Fig. 10, the yield of all the primary species increases, while in Fig. 11 all the yields increase except that for the free radical, H, and the molecular product, hydrogen peroxide.

Focusing on Fig. 10, the increase in the molecular products, hydrogen and hydrogen peroxide, might be accounted for by an increase in the yield arising from excitation processes alluded to above (reaction [26]) (43).

[26] $H_2O^* \rightarrow H_2O + O$

The oxygen atom can lead to peroxide formation through recombination of hydroxyl radicals formed in reactions [22] and [27] or the dismutation of the hydroperoxy radical formed in reaction [28].

[27] $O + H_2O \rightarrow 2OH$

[28] $O + OH \rightarrow HO_2$

Obviously more experimental data are required before any comprehensive mechanism for the radiolysis of water at 300°C can be given. In particular, scavenger studies are needed, both steady state and pulse radiolysis. Other systems that are thermally stable at 300°C need to be found with which to determine both yields and kinetics. The role of reactions that occur in steam but not in liquid water at lower temperatures needs to be assessed.

Conclusions

The g-values for the primary species formed in the γ-radiolysis of water at 250–300°C in near-neutral pH are similar in distribution to, but 50% greater than, those observed at room temperature. Furthermore, these g-values are quite different from those used recently in computer simulations (45–47) based on the 300–400°C results reported by Burns and Marsh (13). However, because the present results are derived from a broad spectrum of experimental data from different sources, it is felt that the g-values reported here are a more realistic set.

TEIJI CHIHARA, TAMIE WAKABAYASI, KAZUO TAYA, and HARUO OGAWA. Can. J. Chem. **68**, 720 (1990).

The less reactive carbonyl group of a mixture of reducible groups of carbonyl compounds was preferentially reduced with diborane on silica gel by first forming an adduct of the more reactive carbonyl group with sodium bisulfite. For example, 4-acetylbenzaldehyde could be converted to 4-(1-hydroxylethyl)benzaldehyde in 93% selectivity; in a mixture of 4-phenylacetophenone and 4-phenylbenzaldehyde, biphenylethanol was preferentially formed in 95% yield with 16% yield of 4-phenylbenzyl alcohol. Silica gel and sodium bisulfite were essential for this selective reaction. Aliphatic and aromatic aldehydes and unhindered cyclohexanones could be selectively protected by this method.

Key words: sodium bisulfite, silica gel, carbonyl compound, selective reduction, diborane.

TEIJI CHIHARA, TAMIE WAKABAYASI, KAZUO TAYA et HARUO OGAWA. Can. J. Chem. **68**, 720 (1990).

Lorsqu'un mélange de divers groupements carbonyles pouvant être réduits est soumis à l'action du diborane déposé sur du gel de silice, il est possible de ne réduire que le groupement carbonyle le moins réactif en procédant à la formation préalable d'un adduit bisulfitique avec le groupement carbonyle le plus réactif. Par exemple, le 4-acétylbenzaldéhyde peut être transformé en 4-(1-hydroxyéthyl)benzaldéhyde avec 93% de sélectivité; dans un mélange de 4-phénylacétophénone et de 4-phénylbenzaldéhyde, le biphényléthanol se forme préférentiellement avec un rendement de 95% alors que le rendement d'alcool 4-phénylbenzilique n'est que de 16%. Le gel de silice et le bisulfite de sodium sont tous les deux essentiels pour réaliser cette réaction sélective. Les aldéhydes aliphatiques et aromatiques ainsi que les cyclohexanones qui ne sont pas encombrées peuvent être protégées d'une façon sélective par cette méthode.

Mots clés : bisulfite de sodium, gel de silice, composés carbonylés, réduction sélective, diborane.

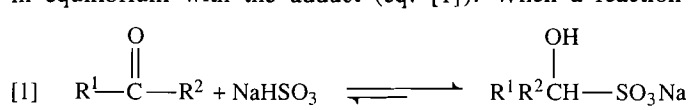
It is known that sodium bisulfite (SBS) gives adducts, α-hydroxysulfonic acids, with some carbonyl compounds (1), especially with aliphatic and aromatic aldehydes. With ketones, SBS gives adducts with acetone, cyclohexanone, and cycloheptanone, but not with diethyl ketone, 2-methylcyclohexanone, or cyclooctanone (2). Thus SBS exhibits specific adduct formation with carbonyl compounds; however, it has never been used for the purpose of protecting carbonyl groups. Selective reductions of ketones in the presence of aldehydes by cerium trichloride with $NaBH_4$ (3) and selective carbonylalkylation of ketones in the presence of aldehydes by methylaluminium bis(2,6-di-*tert*-butyl-4-methylphenoxide) (4) have been reported. In addition to the specific differentiation between aldehyde and ketone, SBS makes it possible to get specific selectivity among ketones.

Because of the limited stability of the adduct with SBS, it has been used only to isolate or purify carbonyl compounds. Usually the adducts are produced in aqueous natural solution and are stable as crystalline solids. In aqueous solution, a small quantity of unreacted carbonyl compound still exists in equilibrium with the adduct (eq. [1]). When a reaction



[1] $R^1R^2C{=}O + NaHSO_3 \rightleftharpoons R^1R^2CH{-}SO_3Na$

consuming the carbonyl compound proceeds under these conditions, the successional regeneration of the carbonyl compound by dissociation of the adduct will occur readily.

Solid adsorbents such as silica gel and alumina have been used as media for controlling organic reactions (5). Examples include terminal ozonation and chlorination of a methyl or methylene group remote from the adsorbed amino, carbonyl, or carboxyl group (6, 7), ozonation of olefin to normal ozonide with the suppression of complete dissociation of the intermediate (8), regioselective photocycloaddition of alkenes or allene to steroidal enones (9), and monomethyl esterification of dicarboxylic acids (10, 11).

The solid adsorbents have a large surface area and the solvent can be easily removed by evacuation (12). The well-dispersed and supported adduct of SBS is a good candidate for protection of the carbonyl groups. This is because the equilibrium expressed by eq. [1] is quenched by lack of solvent, and water-sensitive reagents can be used. We have reported briefly on the selective reduction of 4-acetylbenzaldehyde to 4-(1-hydroxyethyl)benzaldehyde (**2**) in an earlier paper (13). This paper presents details of this reaction and its application to a mixture of carbonyl compounds.

Results and discussion

Selective reduction of 4-acetylbenzaldehyde (1)

Compound **1** (100 mg) and SBS (145 mg) were allowed to react in a dioxane–water solvent (3.2 mL). To the resulting solution was added silica gel (2.5 g) and the solvent evaporated under reduced pressure. The supported sample contained 76–78% of the amount of **1** added, accompanying the formation of the adduct with SBS. Reduction of the supported sample with diborane (30 molar excess), followed by hydrolysis, afforded 4-(1-hydroxyethyl)benzaldehyde (**2**) selectively: the selectivity for **2** showed 87% at 65% conversion of **1**.

The reaction profile is illustrated in Fig. 1. This shows that **2**, produced by the reduction of the acetyl group of **1**, was formed

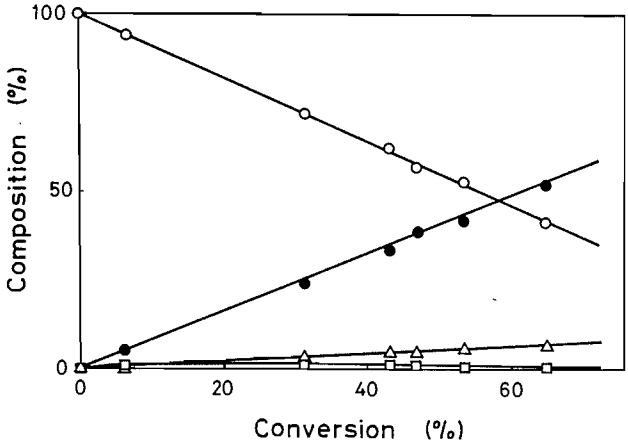

FIG. 1. Selective reduction of carbonyl group of 4-acetylbenzaldehyde (**1**) with sodium bisulfite (SBS) on silica gel. SBS:**1** = 2:1 (mol/mol), (SBS + **1**):SiO_2 = 1:10 (w/w), at 0°C; **1** (○); 4-(1-hydroxyethyl)benzaldehyde (**2**) (●); 4-acetylbenzyl alcohol (**3**) (□); 1-{4-(hydroxymethyl)phenyl}ethanol (**4**) (△).

predominantly with decrease in **1**. In contrast, 4-acetylbenzyl alcohol (**3**), produced by the reduction of the formyl group of **1**, was formed at early stages of the reaction with the maximum 0.9% selectivity; it disappeared and was converted to 1-[4-(hydroxymethyl)phenyl]ethanol (**4**) as the reaction progressed. Compound **4** was produced in a maximum 13% selectivity.

The necessity for both sodium bisulfite (SBS) and silica gel

Figure 2(a) shows the reduction profile of **1** in bis(2-methoxyethyl) ether with diborane in the absence of both SBS and silica gel. The formyl group was more reactive than the acetyl group: only after almost quantitative reduction of the formyl group was the acetyl group reduced.

The reduction profile of **1** on silica gel with diborane in the absence of SBS is represented in Fig. 2(b). Compound **3** was the main product in the first half of the reaction and **4** in the latter half. Compound **2** was not detected in this reduction. The profile was similar to that of the reduction in bis(2-methoxyethyl) ether solution (Fig. 2(a)). The preferential reduction of the acetyl group of **1** was not achieved unless SBS was used.

The adduct was then reduced with sodium borohydride (SBH) in an aqueous solution without silica gel. The reduction profile is illustrated in Fig. 2(c). The selective reduction of the acetyl group of **1** did not proceed: the amount of **2** produced was only half as much as that of **3**. The maximum yield of **2** was only 16%, and **4** was the main product of the reaction.

In the presence of water the equilibrium expressed by eq. [1] is established. The non-selective reduction in an aqueous system appears to be a consequence of the equilibrium. Thus both SBS and silica gel were essential for the selective reduction.

Dependence of amounts of SBS and silica gel on selectivity

The effect of the amount of SBS on the formation of **2** was examined (Table 1). The selectivity increased with increasing amounts of SBS (entries 1–3 and 5), but decreased with increasing the amount of available silica gel (entries 4–6).

The maximum selectivity (93%) for the formation of **2** was obtained with a 5:1 ratio of silica gel to the combined amount of **1** and SBS (entry 4), but the reduction did not proceed further than 60% conversion in spite of the addition of a large excess of diborane. On the other hand, when large quantities of silica gel were used (entry 6), the reduction proceeded in 84% conversion and afforded **2** in 70% selectivity. Multilayer deposition of the adduct with small quantities of the silica gel probably prevented complete reduction. Alumina was also an effective solid support for this reaction (entry 7), but the selectivity is lower than that using the silica gel. Interestingly, the same tendency appeared in the former study of Girard's reagent for the protection of carbonyl groups (12).

*The preferential reduction of 4-phenylacetophenone (**5**) in the presence of 4-phenylbenzaldehyde (**6**)*

Upon adding a 40 molar excess of diborane, 95% of the acetyl group of **5** was reduced; in contrast, only 16% of the formyl group of **6** was reduced. Further addition of diborane (120 molar excess) led to reduction of 99% of the acetyl group of **5** and 22% of the formyl group of **6**, before the reaction ceased. The formyl group of **6** (Fig. 3) was effectively protected with SBS, while the acetyl group of **5** was thoroughly reduced.

On the other hand, in a THF solution in the absence of SBS and silica gel the more reactive formyl group in **6** was reduced first followed by the acetyl group in **5** (open circles, Fig. 3). On silica gel in the absence of SBS both carbonyl groups were evenly and completely reduced. These results clearly demonstrate that SBS functions as a protecting agent to the more highly reactive carbonyl group.

In the presence of SBS in aqueous ethanol, the mixture of **6**

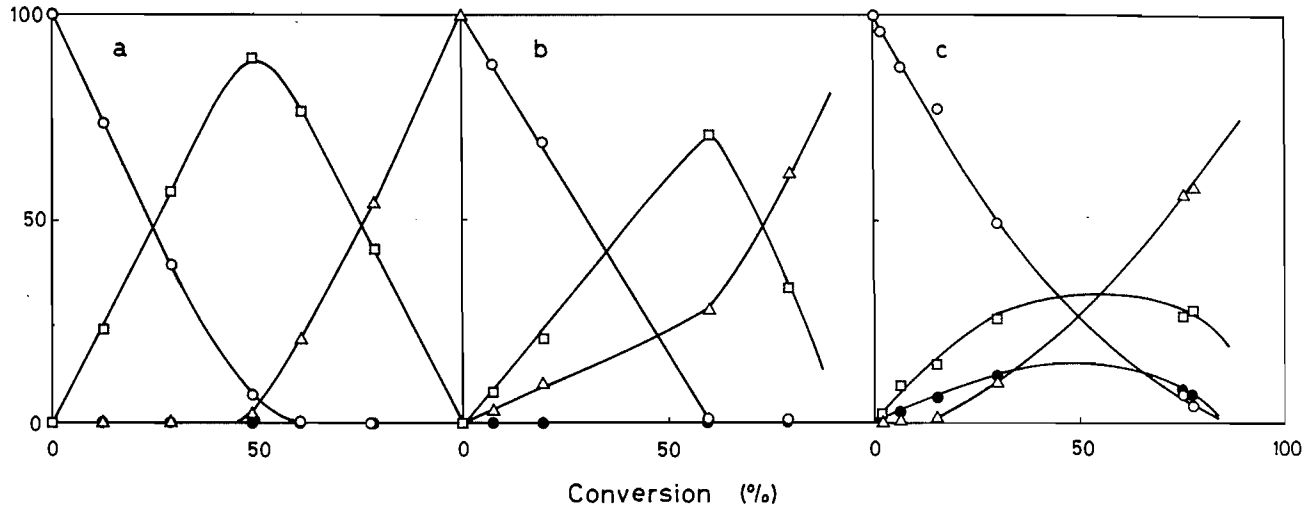

FIG. 2. Reduction profiles of 4-acetylbenzaldehyde (**1**); **1** (○); 4-(1-hydroxyethyl)benzaldehyde (**2**) (●); 4-acetylbenzyl alcohol (**3**) (□); 1-{4-(hydroxymethyl)phenyl}ethanol (**4**) (△) at 0°C. (a) With diborane in 2,2′-dimethoxydiethyl ester in the absence of both sodium bisulfite (SBS) and silica gel. (b) With diborane on silica gel in the absence of SBS, **1**:SiO_2 = 1:10 (w/w). (c) With sodium borohydride (SBH) in aqueous solution in the presence of SBS, SBS:**1** = 1:5 (mol/mol), water:ethanol = 1:1 (w/w).

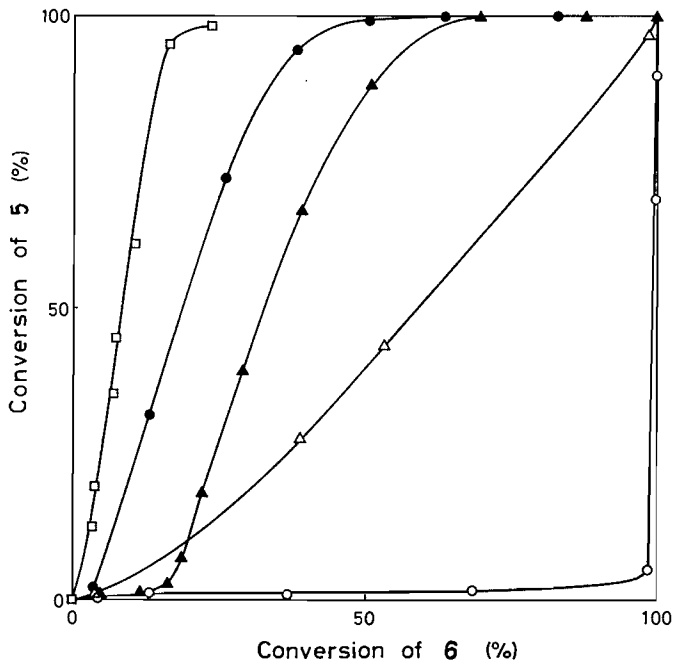

FIG. 3. Competitive reduction of 4-phenylbenzaldehyde (**6**) and 4-phenylacetophenone (**5**). Equal moles of **6** and **5** were used, at 0°C. □: With diborane on SiO_2 in the presence of sodium bisulfite (SBS), SBS:**6** = 1:2 (mol/mol), **6**:SiO_2 = 1:20 (w/w). ○: With diborane in THF solution in the absence of both silica gel and SBS. △: With diborane on silica gel in the absence of SBS, **6**:SiO_2 = 1:20 (w/w). ▲: With sodium borohydride (SBH) in aqueous solution in the presence of SBS, SBS:**6** = 2:1 (mol/mol), water:ethanol = 1:1 (v/v). ●: With SBH in aqueous solution in the presence of SBS, SBS:**6** = 5:1 (mol/mol), water:ethanol = 1:1 (v/v).

and **5** was allowed to react with SBH (Fig. 3). The formyl group of **6** was predominantly reduced to give 4-phenylbenzyl alcohol in up to about 20% yield, with only 5% yield of 1-(4-phenylphenyl)ethanol at the initial stages of the reduction, when using a twofold molar excess of SBS. The acetyl group of **5** was reduced at about twice the rate of the formyl group. After the complete reduction of the acetyl group, the remaining formyl group was reduced. When a fivefold molar excess of SBS was used, a little improvement was observed (Fig. 3). However, the protection of the formyl group was inadequate. Thus, combination of SBS and silica gel was necessary for preferential reduction in a mixture of the carbonyl compounds.

Selectivity in protection by SBS

The selective reduction of pairs of different kinds of carbonyl compounds was examined, and the results are listed in Table 2. Less than 16% of undecanal (**7**) or of **6** was reduced, so both aliphatic aldehyde **7** and aromatic aldehyde **6** were sufficiently protected (entries 1–5); the counter pairs **5**, 2-undecanone (**8**), and 3-undecanone (**9**) were readily reduced to the corresponding alcohols.

On the other hand, methyl ketone **8** was largely unprotected by using a twofold molar excess of SBS (entry 4). A mixture of **8** and **9** gave nearly as effective selectivity, if a twofold molar excess of SBS was used (entry 6), but the selectivity was raised to 1.9 with a tenfold molar excess of SBS (entry 7). On the whole, aldehydes were selectively protected in the presence of ketone but only a low selectivity could be observed in the competitive reduction of methyl ketone and ethyl ketone (Table 2).

4-Phenylcyclohexanone (**10**), an unhindered derivative of cyclohexanone (**11**), was effectively protected in competitive reduction with 2-methyl-4-phenylcyclohexanone (**12**) (entries 8–10).

The selective protection of the carbonyl groups of alicyclic ketones was also studied (Table 2). The selectivity in protection was high in the competition between **11** and cyclooctanone (**13**) or cycloheptanone (**14**) (entries 12, 13). In contrast, the selectivity was low in the competition between **11** and cyclopentanone (**15**) (entry 11). A similar tendency in the reactivity of the ketones was reported in liquid phase hydrogenation with metal catalysts in which **11** was shown to be the most reactive alicyclic ketone (14).

Carbonyl compounds contained in the adsorbed sample could be recovered before reduction. In a few cases, the recovery was lower than 80% because of evaporation of the unprotected

carbonyl compounds. For example, in the case of alicyclic ketones, the values of recovery of **13**, **14**, and **15** were low and decreased in the order of entries 11–18. Interestingly, the order was the reverse of their vapor pressure. On the other hand, the recovery of **11** shown was as high as that of **10**, in spite of the high vapor pressure of **11**. These results implied that those three ketones, not forming the adducts, were lost from the system, probably because of their high vapor pressure. High mass compounds, which generally have low vapor pressure, are suitable for this method.

Selective reduction with other reagents

A supported sample was prepared by using the mixture of **6** and **5**, which was then allowed to react with a THF solution containing a 100 molar excess of each reducing agent. Sodium hydrotrimethoxyborate, lithium aluminum hydride, and SBH were used for the reduction. More than 96% of **5** was reduced to the corresponding alcohol in every run. On the contrary, the reactivity of the counter component **6** was suppressed and only 29% of **6** was reduced by sodium hydrotrimethoxyborate, while about 70% of **6** was reduced by lithium aluminum hydride or SBH. Sodium hydrotrimethoxyborate was the most effective reagent, but less selective results were observed with this reducing agent than with diborane in the absence of solvent. Trace amounts of water, which could not be removed completely from the supported sample, may have caused the dissociation of the adduct.

We conclude that aliphatic and aromatic aldehydes are selectively protected in the presence of ketones by SBS in combination with silica gel, and that unhindered cyclohexanones are also selectively protected. This selectivity has not been achieved by any other method. The selectivity for protection by SBS differs from that of Girard's reagent, which protected relatively reactive carbonyl groups in spite of the nature of these carbonyl groups (12).

Experimental

Materials

4-Acetylbenzaldehyde (**1**, bp 155°C/15 Torr; 1 Torr = 133.3 Pa) (15), 4-phenylacetophenone (**5**, mp 121–122°C) (16), 4-phenylcyclohexanone (**10**, mp 78°C) (17), 2-methyl-4-phenylcyclohexanone (**12**, mp 139°C) (18), diborane (19), and sodium hydrotrimethoxyborate (20) were obtained according to the literature procedures. Silica gel and alumina were Wakogel C-200 and activated alumina, 200 mesh, respectively (Wako Pure Chemical Industries, Ltd.), and were used as received; it is certified that Merck Silica Gel 60 for column chromatography gives substantially the same results. Other materials were also commercial products. Solvents were dried over synthetic zeolite 3A or calcium hydride.

Methods

Typically, 100 mg (0.67 mmol) of **1** and 145 mg (1.38 mmol) of sodium bisulfite (SBS) were added to 3.2 mL of a dioxane–water mixture (1:2 (v/v)). The resulting solution was stirred well for 1 h at 30°C to produce the adduct and then 2.5 g of silica gel was added. The solvent was evaporated under reduced pressure (10 Torr) for 40 min at 40°C and then for 30 min at 70°C. About 76–78% of **1** could be recovered from this supported sample. Compound **1** was partially lost through the evaporation procedure. The supported sample contained less than 10% solvent by weight.

The supported sample (500–1000 mg) was packed into a glass column (5 mm i.d.) maintained at 0°C by iced water, and a 30 molar excess of diborane was introduced from the bottom of the column in a stream of dry nitrogen for 15 min. The reaction column was allowed to stand for 20 min, then the hydroborated adduct was decomposed by the addition of an aqueous solution of sodium hydroxide. The resulting mixture was then extracted with benzene. After concentration of the extract under reduced pressure, the residue was analyzed by gas–liquid chromatography (GLC). The unreacted **1** and the products 4-(1-

hydroxyethyl)benzaldehyde (**2**) (51.9%), 4-acetylbenzyl alcohol (**3**) (0.5%), and 1-[4-(hydroxymethyl)phenyl]ethanol (**4**) (5.0%) were recovered in high mass balance: the loss was less than 2% based on the initial quantity of **1** on the supported sample.

A mixture of water and 2-propanol or water alone could be used as alternative solvents for the preparation of the supported sample. The quantity of solvent was adjusted to the minimum volume necessary to wet the silica gel.

In competitive reactions, equimolar quantities (0.34 mmol) of two carbonyl compounds were used.

Analysis

The recovery of the substrates from the supported samples before the reduction was determined by means of GLC and (or) UV spectroscopy. For example, the supported sample of **1** was decomposed by the addition of an aqueous solution of sodium hydroxide and then the mixture was extracted with ether followed by evaporation of the solvent. The amount of **1** extracted was determined by Shimazu model GC-7A GLC equipped with a polyethylene glycol 20 000 column, using 1,2-diphenylbenzene as an internal standard. The amount of **1** recovered was also determined by dissolving the extract with 1,4-dioxane followed by UV absorption measurement at 254 nm (ε 2.22 $\times$ 10^4). A Hitachi model 124 spectrophotometer with 1 cm quartz cells was used. The results obtained from the measurements by these two methods agreed with a difference of less than 2%.

The progress of reaction was followed by GLC analysis of aliquot samples. Shimazu model GC-7A and GC-4BPTF gas chromatographs with columns of polyethylene glycol 20 000, bis(2,3-dihydroxypropyl) ether, and Apiezone Grease L were used. Naphthalene, 1-methylnaphthalene, anthracene, 1,2-diphenylbenzene, or *trans*-stilbene was used as internal standard. All the products were identified by comparison of authentic samples obtained independently.

Partial molar volumes of some dipolar ions in water at 35°C

M. IQBAL[1] AND M. MATEEULLAH
Department of Chemistry, Bahauddin Zakariya University, Multan, Pakistan 60800

Received May 24, 1989[2]

M. IQBAL and M. MATEEULLAH. Can. J. Chem. **68**, 725 (1990).

This work reports partial molar volumes, V^0, of eight peptides and three other dipolar ions (glycine, diglycine, triglycine, *dl*-alanyl-*dl*-valine, glycyl-*dl*-alanine, glycyl-*dl*-leucine, glycyl-tyrosine dihydrate, *dl*-alanyl-glycyl-glycine, *l*-valyl-glycyl-glycine, *l*-lysine-*l*-aspartate, *l*-lysine-*l*-glutamate) in water, calculated from density data obtained at 35°C. V^0 data are interpreted in terms of solute–solvent interactions. In some cases where V^0 data at 25°C were available from the literature, a comparison indicates that partial molar volumes of these solutes at 35°C are higher than their respective volumes at 25°C by about 2–3 $cm^3\ mol^{-1}$. Partial molar expansibilities, E^0, were also estimated in such cases. Expansibility data appear to show a trend indicating dependence of E^0 values on the chain length of the solute molecules. Some plausible modes of solute–solute interactions are also discussed.

Key words: hydration of dipolar ions, partial molar volumes of peptides, solute–solvent interactions, electrostriction, solute–solute interactions.

M. IQBAL et M. MATEEULLAH. Can. J. Chem. **68**, 725 (1990).

Utilisant des données de densités obtenues à 35°C, on a calculé les volumes molaires partiels, V^0, de huit peptides et des trois autres ions dipolaires (glycine, diglycine, triglycine, *dl*-alanyl-*dl*-valine, glycyl-*dl*-alanine, glycyl-*dl*-leucine, dihydrate de glycyl-tyrosine, *dl*-alanyl-glycyl-glycine, *l*-valyl-glycyl-glycine, *l*-lysine-*l*-aspartate, *l*-lysine-*l*-glutamate) en solution dans l'eau. On interprète les données de V^0 en fonction d'interactions soluté–solvant. Dans quelques cas pour lesquels les valeurs de V^0 à 25°C sont disponibles dans la littérature, une comparaison indique que les volumes molaires partiels des solutés à 35°C sont plus élevés que les volumes respectifs à 25°C et que la différence est d'environ 2 à 3 $cm^3\ mol^{-1}$. On a aussi évalué les dilatabilités molaires partielles, E^0, et les données relatives à cette propriété présentent une tendance qui semble indiquer que les valeurs de E^0 varient avec la longueur de la chaîne des molécules de soluté. On discute aussi des quelques modes plausibles pour les interactions soluté–soluté.

Mots clés : hydratation d'ions dipolaires, volumes molaires partiels de peptides, interactions, soluté–solvant, électrostriction, interactions soluté–soluté.

[Traduit par la revue]

Introduction

Hydration of dipolar ions is a concept of particular significance in chemistry and biology. Among the dipolar ions frequently studied, amino acids, peptides, proteins, certain types of hormones, and antibiotics are common. In physiological media such as blood, membranes, cellular fluids, etc., where water happens to be involved in an important manner, the dipolar character of these compounds has an important bearing on their biological function. The study of zwitterions in aqueous solutions, therefore, offers an opportunity for investigating the molecular phenomenon occurring in physiological media.

The study of some of the thermodynamic properties of proteins can be facilitated by investigating the behaviour of their constituents, viz., amino acids and peptides. Some of these properties are found to be implicated in several biochemical processes, such as protein hydration (1, 2), aggregation (3, 4), denaturation (5, 6), antigen–antibody reactions (7), etc. The property of partial specific volume of proteins is believed to be implicated in the phenomenon of anaesthesia. According to the concept of "critical volume of anaesthesia" (8, 9), the reversal of anaesthesia under applied pressure has been viewed as important evidence in favor of this concept (8). Expansion of membrane proteins is believed to be the key factor in the mechanism (9). Experimental evidence for the concept, however, remains sketchy and highlights the importance of data concerning volumetric behaviour of proteins, particularly those found in the membranes.

Several important works on volumetric investigations of amino acids and peptides have been reported in the past, at normal laboratory temperature (25°C) (10–19). These studies have contributed significantly toward an understanding of water – dipolar ion interactions. Volume contributions of the glycyl residue and of various side groups are now known with a greater degree of accuracy, and have been used in additivity schemes for computing improved volumetric data for proteins (20).

This work focusses on the determination of partial molar volumes of 11 dipolar ions in water at 35°C. The choice of temperature (35°C) was made to (a) obtain greater relevance of the present data for macromolecules in certain biological systems (such as mammals), operating near physiological temperatures, and (b) to assist in estimating expansibility behaviour of selected compounds by comparing present and previous data (reported at 25°C). The expansibility data for biological macromolecules are believed to be beneficial for the study of living systems under different physiological conditions such as fever or hypothermia.

Experimental

The compounds studied in this work were of reasonably good purity. Glycine (Merck lot no. 721K 118690), diglycine (Sigma lot no. 102F-5037), triglycine (Sigma lot no. 87C-0417), *dl*-alanyl-*dl*-valine (Sigma lot no. 73F-0078), glycyl-*dl*-alanine (Sigma lot no. 20F-0103), glycyl-*dl*-leucine (Sigma lot no. 111F-0297), glycyl-tyrosine dihydrate (Sigma lot no. 41F-0130), *dl*-alanyl-glycyl-glycine (Sigma lot no. 114C-0163), *l*-valyl-glycyl-glycine (Sigma lot no. 119C-0187), *l*-lysine-*l*-aspartate (Sigma lot no. 98B-06801), *l*-lysine-*l*-glutamate (Sigma lot no. 59B-1270) were further purified by recrystallizing from ethanol–water mixtures. After recrystallization, compounds were dried under vacuum at room temperature. Water used in the experiments was doubly distilled, deionized, and degassed.

Density measurements were carried out at 35°C using 20-mL

pyknometer flasks (Pyrex) and a Lauda RC3 thermostat bath providing a temperature control accurate within better than ±0.01°C. Calibration of pyknometers was done using water (21) and NaCl (Merck Art 6400) (22, 23). All weighings were carried out on a Sartorious 2434 balance (±0.01 mg). Reproducible Δd values were obtained through careful and refined experimentation providing an accuracy of $\pm 0.5 \times 10^{-4}\ g\ cm^{-3}$ in the density data.

Results and discussion

Apparent molal volumes (ϕ_v, $cm^3\ mol^{-1}$) were calculated using the following equation

$$[1] \quad \phi_v = 1000/mdd_0(d_0 - d) + M/d$$

where d and d_0 are the densities of solution and solvent respectively, m the solution molality, and M is the relative molar mass of the solute.[3] ϕ_v data obtained from eq. [1] were fitted to the following equation using a weighted least-squares fit program.

$$[2] \quad \phi_v = \phi_v^0 + S_v m$$

Values of ϕ_v^0, i.e., the apparent molal volume at infinite dilution, were taken as the partial molar volumes at 35°C, V_{35}^0, and are shown in Table 1, along with the values of coefficient S_v, the pair interaction parameter, indicative of solute–solute interactions. Table 1 also shows values of partial molar volumes at 25°C, V_{25}^0, for six of these compounds (glycine, diglycine, triglycine, glycyl-alanine, glycyl-leucine, alanyl-glycyl-glycine), reported by previous workers, for comparison.

Due to the limited accuracy of density data obtained in this work ($\pm 0.5 \times 10^{-4}$ g cm^{-3}), the errors associated with parameters V^0 and S_v are larger than those achieved from current state-of-the-art techniques such as vibrating-tube electronic densimetry (24), where the level of accuracy is higher by at least an order of magnitude. Errors in the apparent molal volumes ($\Delta\phi_v$) were computed using a differentiated form of eq. [1] (with respect to density and molality), and were employed as weighting parameters in the least-squares fit computations of V^0 and S_v.

Solute–solvent interactions

Previous studies on dipolar ions have shown that, in aqueous systems, these types of solutes represent unique hydration characteristics, which can be described briefly as follows.

(i) In amino acids and peptides, NH_3^+ and CO_2^- terminals, being charged ends, are hydrated in an electrostrictive manner while the intervening backbone is hydrated in accordance with its character, which may be hydrophilic, hydrophobic, amphiphilic, or that involving hydrogen bonding, etc. (10–18).

(ii) The electrostriction of the NH_3^+ group is known to be greater than that of the CO_2^- group by about a factor of 10 (25).

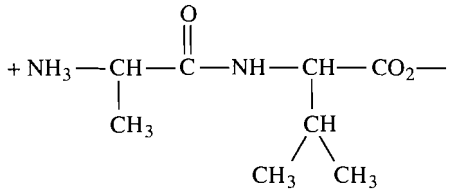
(iii) The change in volume occurring from the overlapping of hydration shells (of the terminals and of the groups adjacent to them) is believed to be due to the net result of two opposing effects (26): (a) an increase in V^0 due to the reduction in electrostriction at the terminal; (b) a decrease in V^0 due to the disruption of side-group hydration by that of the charged end.

[3]Tables of molality and density data for the compounds studied, at 35°C, have been deposited, and may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

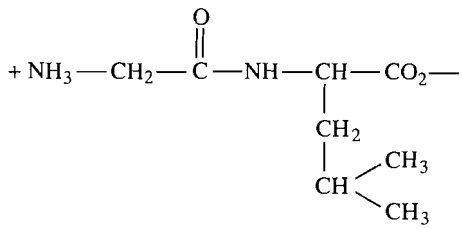
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

(iv) As a consequence of (ii), a side group falling near the N-terminal effects a relatively larger volume release from the electrostricted region than is produced in the case of a C-adjacent group. Present V^0 data, obtained at 35°C, appear to support these observations.

For instance, a comparison between the V^0 values of two isomeric peptides, viz., *dl*-alanyl-*dl*-valine and glycyl-*dl*-leucine, both having a relative molar mass of 188.2 g mol^{-1}, indicates a higher V^0 value for the former (145.94 cm^3 mol^{-1}) than for the latter (141.31 cm^3 mol^{-1}). A glance at the molecular structure of these peptides (shown below) reveals that a relatively freer N-terminal in glycyl-leucine appears to contribute toward greater volume contraction than an obstructed N-terminal in alanyl-valine.



Alanyl-valine



Glycyl-leucine

Comparison of these two compounds with triglycine highlights this effect rather more conspicuously. Triglycine, despite having a slightly greater relative molar mass (189.2), shows a smaller V^0 value (114.93 cm^3 mol^{-1}) than those of the above named isomers, which can be ascribed to a more independent $-NH_3^+$ group.

Partial molar expansibilities

Comparison between V_{35}^0 and V_{25}^0 values for six of the above compounds shows that V_{35}^0 values are greater than the respective V_{25}^0 values by about 2–3 cm^3 mol^{-1}. Assuming that a linear variation of V^0 occurs within this temperature range, partial molar expansibility, E^0 $(= (\partial V^0/\partial T)_p)$, of these compounds can be calculated by taking ∂V as $(V_{35}^0 - V_{25}^0)$ and $\partial T = 10$°C. E^0 values obtained in this manner are included in Table 1. Given the magnitude of errors associated with the V^0 data, values of expansibilities do not appear to be very significant. Nevertheless, these may be regarded as indicative of a trend showing correlation between E^0 and the chain length of a solute molecule. Further studies involving high precision data are needed to test the trend.

Solute–solute interactions

S_v values shown in Table 1 represent quantitative estimates of solute–solute (pairwise) interactions for the compounds studied. It is seen that all S_v values are positive except that for glycyl-tyrosine, where this value is found to be negative (-2.08 ± 1.21 cm^3 mol^{-2} kg). Studies conducted on a variety of hydrophilic, hydrophobic, and amphiphilic solutes in the past have shown that positive S_v values are generally associated with solutes showing an overall hydrophilic character while negative values are found to be associated with hydrophobic solutes. Amphiphilic solutes are found to show little or no concentration dependence of V^0 data.

In the context of solute–solute interactions, the Cosphere overlap model proposed by Gurney (27) is also a frequent reference used and is often employed in interpreting S_v data. Using this model and the generalizations obtained from the study of a variety of model compounds, it appears that all of the present compounds exhibit hydrophilic character in aqueous environments except glycyl-tyrosine, which shows an overall hydrophobic character. This may be due to the nonpolar tyrosyle residue whose presence appears to affect the dipolar character of this molecule. Gurney's model describes the overlapping of hydrated solutes using spherical shapes for hydrated species. In the case of solutes having nonspherical shapes (oblong, cylindrical, rod shaped, etc.), e.g., the peptides under study, the overlapping of hydrated entities may not be exactly in the spherical manner. Instead, the overlaps may preferably be direction oriented such that the N-terminal of one hydrated peptide may prefer to align with the C-terminal of the other, particularly in cases where side chains are smaller and do not offer any hindrance to these anisotropic overlaps. In cases where side chains happen to be larger in size, this kind of alignment, however, may not be possible due to obstruction caused by the side group.

Photodissolution of iron oxides II: The lack of efficiency of thiocyanate

MARTA I. LITTER AND MIGUEL A. BLESA[1]

Departamento de Química de Reactores, Comisión Nacional de Energía Atómica, Avenida del Libertador 8250, 1429 Buenos Aires, Argentina

Received August 3, 1989

MARTA I. LITTER and MIGUEL A. BLESA. Can. J. Chem. **68**, 728 (1990).

Thiocyanate does not enhance, and even inhibits, the photochemical dissolution of iron oxides at 254 nm. At low SCN^- concentrations, surface complexes $\rangle Fe^{III}—SCN^-$ are formed only to a small extent due to the low affinity for the surface by the monovalent anion, and electron-hole pairs essentially recombine. At higher ligand concentrations, only the homogeneous photolysis of SCN^- is observed. At 450 nm, there is no appreciable light absorption by the oxide but homogeneous photolysis of $Fe^{III}—SCN^-$ complexes produces Fe^{II}, which dissolves the oxide by a reductive mechanism.

Key words: iron oxides photodissolution, thiocyanate heterogeneous photochemistry, metal oxides surface complexation.

MARTA I. LITTER et MIGUEL A. BLESA. Can. J. Chem. **68**, 728 (1990).

Le thiocyanate loin d'augmenter, inhibe plutôt, la dissolution photochimique des oxydes de fer, à 254 nm. À des concentrations faibles de SCN^-, la quantité de complexes superficiels de $\rangle Fe^{III}—SCN^-$ qui se forme est faible à cause de la faible affinité de l'anion monovalent pour la surface et du fait que les paires de trous électroniques ne font essentiellement que se recombiner. À des concentrations plus élevées de ligand, on n'observe que la photolyse homogène du SCN^-. À 450 nm, l'oxyde n'absorbe pas beaucoup la lumière; toutefois, la photolyse homogène des complexes $Fe^{III}—SCN^-$ conduit à la formation de Fe^{II} qui dissout l'oxyde par un mécanisme réducteur.

Mots clés : photodissolution d'oxydes de fer, photochimie hétérogène du thiocyanate, complexation superficielle d'oxydes métalliques.

[Traduit par la revue]

Introduction

Reductive dissolution of iron oxides in the presence of a variety of complexing agents has been the subject of a number of papers (1–7). The proposed mechanisms involve an interfacial electron transfer, and it is therefore not surprising that light absorption by the oxide may substitute for the reducing agent in thermal dissolutions, in the presence of adequate complexants and hole scavengers (8–14). In fact, organic carboxylate anions may play the role of both complexing agents and hole scavengers, and it is only because of kinetic factors that the implicit reducing power does not give rise to fast thermal dissolution at room temperature. Reductive thermal dissolution does, however, take place at higher temperatures (4, 5). In this view there is a close parallel between the thermal and photochemical behaviour of aqueous and surface $\rangle Fe^{III}—L$ complexes (15). Electron transfer, either thermal or photochemical, may take place, generating $Fe^{II} + L^\bullet$ pairs that may either revert to $Fe^{III} + L^-$, or further evolve to Fe_{aq}^{2+} + oxidation products of L.

In this context, thiocyanate appears almost as a paradigmatic case. It is a very simple species, which forms well-characterized complexes with iron(III) (16–19), and these complexes are known to exhibit both the thermal (20) and photochemical (21) reactivity mentioned above. Furthermore, another study from our laboratory[2] showed its ability to promote thermal dissolution of iron oxides through a reductive mechanism.

In this paper, the photochemical behaviour of γ-Fe_2O_3 suspended in thiocyanate solutions is described, and shown not to correspond to the expectations mentioned above.

The photochemistry of thiocyanate ion in aqueous solutions has been explored in several papers. Ultraviolet irradiation of SCN^- solutions results in the production of cyanide, sulfur, and lesser amounts of sulfate. Two main reaction paths have been proposed (23–25):

[1] $SCN^- \rightarrow SCN^\bullet + e_{aq}^-$

[2] $SCN^- \rightarrow S + CN^-$

followed by complex reactions in which cage recombination and further reaction with SCN^- are central:

[3] $SCN^\bullet + SCN^- \rightleftharpoons (SCN)_2^{\dot{-}}$

[4] $2(SCN)_2^{\dot{-}} \rightarrow (SCN)_2 + 2SCN^-$

[5] $3(SCN)_2 + 4H_2O \rightarrow 7H^+ + 5SCN^- + HCN + SO_4^{2-}$

[6] $S + SCN^- \rightarrow S_2 + CN^-$

The photochemistry and thermal decomposition of iron(III)–thiocyanate complexes has also been much studied (20, 21). At 436 nm, absorption of light in the charge-transfer band of the complex produces Fe^{2+} and $SCN^\bullet$, which then reacts with SCN^- according to eq. [3] (21). The same intermediate $(SCN)_2^{\dot{-}}$ was proposed in the thermal dark reaction (20).

The photooxidation of thiocyanate by semiconducting oxides has also been described (26–28). In the case of colloidal titanium dioxide, band-gap excitation by a laser leads to electron-hole pair formation (26); the hole migrates to the semiconductor interface and is transferred to SCN^-, producing $SCN^\bullet$. In this system, Kamat (28) was able to observe directly the association of SCN^- with the TiO_2 surface from an absorption band at 295 nm. SCN^- anions complex with TiO_2 with an association constant of 350 $mol^{-1}\,dm^3$.

In the case of iron oxides, Schumacher *et al.* (27) report an increase in the photocurrent of thin film electrodes after boiling in 0.5 mol dm^{-3} KSCN. They suggest that the complexing agent stabilizes surface Fe^{2+} ions on the oxide surface, thereby enhancing the charge-transfer step at the interface.

Experimental

Materials and instrumentation

Potassium thiocyanate (analytical grade) from Mallinckrodt was dried at reduced pressure and 50°C and used without further purification. Maghemite (γ-Fe_2O_3) was a commercial sample (Hercules HHO), and was characterized by X-ray diffractometry, chemical analyses, scanning electronic microscopy (SEM), and surface area measurements. It was composed of acicular particles, of average length 0.5 μm, aspect ratio 7:1, and specific surface area 25 $m^2\ g^{-1}$. All other reagents were analytical grade, and used without further purification. Water was bidistilled in a quartz apparatus.

pH adjustments were made with 0.05 mol dm^{-3} H_2SO_4 or NaOH.

The reaction cell was a 10-mm path-length quartz tube of rectangular section fitted with a PTFE stopcock. The cell was thermostatted by a water circulating holder connected to a thermostatic bath.

The sources of light were a low-pressure mercury germicidal lamp for 254 nm and a 200-W tungsten filament lamp with an interference filter for 450 nm.

Procedures

The suspensions were irradiated in the closed cell at the chosen wavelength during different periods of time, with magnetic stirring. After the irradiation, the cell content was transferred to a beaker containing 20 cm^3 0.25% Na_2CO_3 (to prevent HCN loss) by inverting the cell, immersing the outlet in the beaker solution, and opening the stopcock. The iron oxide was filtered off through a 0.45-μm pore-size membrane. Cyanide was analyzed colorimetrically in the filtrate with sodium picrate (29), and iron by the thioglycolate method (30). Actinometry was performed at 254 nm by the ferrioxalate method (31); the Reineckate salt method was used at 450 nm (32). The reported quantum yields are apparent, calculated on the assumption of total absorption of incident light.

Results and discussion

The results obtained in this study can be essentially described as negative: not only is photodissolution not observed, but in some cases the oxide protects thiocyanate from homogeneous photodecomposition. In spite of being negative, the results are of interest because they shed light on the conditions favouring the photocorrosion of iron oxides.

Tables 1 and 2 compare the quantum yield at 254 nm for cyanide, ϕ_{CN^-}, with and without maghemite for various photolysis times. In homogeneous solutions (Table 1), there is a steady decrease in ϕ_{CN^-} with irradiation time, in agreement with previous reports (23, 24). This effect is due to precipitated sulfur (observed visually), which filters incident radiation and (or) back-reacts with cyanide.

In the presence of maghemite, ϕ_{CN^-} drops (see Table 2), becoming essentially zero when the mass concentration of particles is ca. 10 g dm^{-3}. This effect is obviously due also to a filter effect that reduces absorption of light by dissolved SCN^- (ε = 14 $mol^{-1}\ dm^3\ cm^{-1}$). In the more concentrated dispersions, at least 0.9 I_0 is therefore absorbed by the oxide. Under these conditions, no detectable photochemistry is observed, indicating that electron-hole recombination is far more efficient than any other reaction. The two conditions that favor the photodissolution of iron oxides are (*i*) that surface states corresponding to electron traps within the band gap are created by surface complexation of iron(III) centers with dissolved ligands; (*ii*) that adequate hole scavengers are available. In the case of thiocyanate solutions, neither condition is fulfilled under accessible experimental conditions. Surface complexation is characterized by a low affinity constant: we have found K_s = 0.87 $mol^{-1}\ dm^3$ at pH 2 and 80°C;[2] appreciable complexation takes place therefore only when thiocyanate concentration is 1 mol dm^{-3} or higher. At these high concentrations, light is essentially absorbed by dissolved SCN^-, and the observed photochemistry is that of homogeneous solutions. Even the best set of conditions ([SCN^-] = 5×10^{-2} mol dm^{-3}, 10 g dm^{-3} dispersed solid) is insufficient: although light is absorbed by the solid, the density of surface states is too low to produce noticeable photocorrosion.

Thiocyanate is also a poor hole scavenger both because of the low affinity for the surface and the reversibility of its oxidation process; a very likely fate of SCN$^\bullet$ or $(SCN)_2^{\dot{-}}$ is to recombine with electrons, without any net photochemical transformation. Only at very high light intensities (i.e., laser flash photolysis experiments) and in the presence of oxygen to scavenge electrons has it been possible to observe the heterogeneous photooxidation of thiocyanate (26, 28), proceeding through the dismutation of $(SCN)_2^{\dot{-}}$ (eq. [4]).

The crux of the very low quantum yields of thiocyanate-assisted dissolution resides therefore in its low surface affinity. By now, several pieces of evidence indicate that chemisorption of simple mononegative anions on iron oxides is low, even if the corresponding solution complexes are well known. This assertion is especially true for the case of anions of strong (or moderately strong) acids, such as SCN^-.

This behavior is appreciably different from that of TiO_2, on which an appreciable chemisorption and photooxidation of SCN^- have been reported (26, 28). The reasons for the

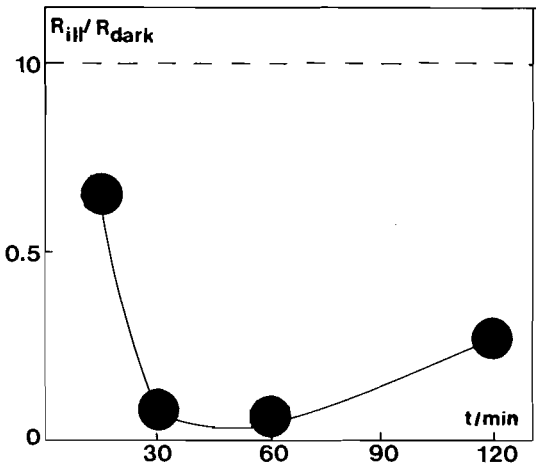

FIG. 1. Photolysis of KSCN at 254 nm. Ratio of iron dissolution rate under illumination to rate in the dark, R_{ill}/R_{dark}, vs. irradiation time (c_{KSCN} = 2 mol dm^{-3}; $c_{\gamma\text{-}Fe_2O_3}$ = 1 g/L; pH 2).

difference are not clear, although they may be related to a higher affinity of Ti^{IV} for SCN^- in homogeneous solution. Also, it is possible that chemisorption may not always be a reversible process; the findings of Schumacher *et al.* (27) may reflect the presence of irreversibly bound SCN^-.

Figure 1 shows that the ratio of the rate of iron dissolution under illumination to the rate in the dark, R_{ill}/R_{dark}, varies with irradiation time, showing a minimum at ca. 60 min. The initial decrease can be assigned to the filter effect already described; the rise in the ratio at longer times is a simple consequence of the thermal reaction between Fe^{II} (formed by homogeneous photolysis of dissolved Fe^{III}—SCN^-) and the oxide. This type of thermal reaction is well known in iron oxides (22). At 450 nm, only photochemistry associated with light absorption by Fe^{III}—SCN^- complexes is possible. It is, however, impossible to demonstrate any effect associated with surface complexes because there is always a modest leach of iron(III) to solution prior to irradiation, and observed effects may be simply attributed to photolysis of aqueous Fe^{III}—SCN^-: at short irradiation times R_{ill}/R_{dark} is, within experimental error, close to one. At longer times, however, the ratio grows (e.g., 1.36 at 120 min) because Fe^{II} species build up in solution and promote the thermal dissolution of the oxide.

Energetics of intra- and intermolecular bonds in ω-alkanediols. III. Thermochemical study of 1,6-hexanediol, 1,7-heptanediol, 1,8-octanediol, 1,9-nonanediol, and 1,10-decanediol at 298.15 K

P. KNAUTH AND R. SABBAH[1]

Centre de thermodynamique et de microcalorimétrie du Centre national de la recherche scientifique 26, rue du 141è R.I.A., 13003 Marseille, France

Received November 21, 1989

P. KNAUTH and R. SABBAH. Can. J. Chem. **68**, 731 (1990).

The enthalpies of combustion and sublimation or vaporization of the title compounds were determined on milligram samples and used to derive, at 298.15 K, the enthalpies of formation in the gaseous phase and the enthalpies of atomization. The previous conclusions drawn from the investigation of the lower ω-alkanediols were confirmed: the enthalpy of a hydrogen bond in solid ω-alkanediols amounts to 27 kJ mol^{-1} and the intramolecular C—C and C—OH bond enthalpies to 343.2 and 819.5 kJ mol^{-1}, respectively. The enthalpies of fusion and the triple point temperatures of the ω-alkanediols ($2 \leqslant n \leqslant 10$) are reported and discussed.

Key words: ω-alkanediols, enthalpies of formation, triple point temperatures, differential thermal analysis, calorimetry.

P. KNAUTH et R. SABBAH. Can. J. Chem. **68**, 731 (1990).

Ce travail concerne l'étude thermochimique à 298,15 K des ω-alcanediols de formule générale HO—$(CH)_n$—OH pour lesquels $6 \leqslant n \leqslant 10$. Elle a été réalisée principalement par calorimétrie de combustion et de sublimation sur de faibles quantités de substance (quelques milligrammes par essai), ce qui a permis la détermination des fonctions thermodynamiques correspondantes à partir desquelles ont été calculées d'abord les enthalpies de formation à l'état gazeux puis d'atomisation. Les résultats acquis montrent l'existence de liaison hydrogène dans les alcanediols solides dont l'énergie aurait pour valeur 27 kJ mol^{-1}. À partir de l'enthalpie d'atomisation ont pu être déterminées les valeurs des enthalpies des liaisons intramoléculaires C—C (343, 2 kJ mol^{-1}), et C—OH (819,5 kJ mol^{-1}). Toutes ces valeurs sont en bon accord avec celles qui ont précédemment été obtenues à partir de l'étude des premiers membres de cette série ($2 \leqslant n \leqslant 5$). Sont aussi consignées et discutées dans ce mémoire, les températures du point triple ainsi que les enthalpies de fusion des ω-alcanediols ($2 \leqslant n \leqslant 10$) obtenues expérimentalement.

Mots clés: ω-alcanediols, enthalpies de formation, températures du point triple, analyse thermique différentielle, calorimétrie.

1. Introduction

The ω-alkanediols are compounds with important technical applications, especially as intermediates for polyester resins. Their thermodynamic properties have been only partly investigated. We previously reported the thermochemical properties of the lower ω-alkanediols HO—$(CH_2)_n$—OH ($2 \leqslant n \leqslant 5$) and discussed the inter- and intramolecular bond enthalpies (1–3). The same type of investigation remains to be done for the higher homologues, for which only sparse information is available: Gardner and Hussain (4) reported the enthalpies of combustion, sublimation, and formation of 1,6-hexanediol; Parks and Mosher (5) determined the enthalpy of combustion of 1,10-decanediol. In the present work, we have studied the higher homologues ($6 \leqslant n \leqslant 10$) by combustion and vaporization or sublimation calorimetry and tested the validity of the previously derived equations for the whole series. Furthermore, the triple point temperatures and the enthalpies of fusion of the ω-alkanediols ($2 \leqslant n \leqslant 10$) have been determined.

2. Experimental

2.1. Substances

The pure commercial products 1,8-octanediol (>98%, Fluka), 1,9-nonanediol (97%, Fluka), 1,10-decanediol (99%, Aldrich) were purified by sublimation at 313 K under a residual pressure of 10^{-2} Torr (1 Torr = 133.322 Pa). 1,6-Hexanediol (99+%, "Gold Label", Aldrich) was used without further purification. The liquid 1,7-heptanediol (purum, Fluka) was purified by rectification over a rotating band column (Büchi, type Dr. Abegg). The purified hygroscopic samples were then stored in a glove box over diphosphorus pentoxide.

[1]Author to whom correspondence may be addressed.

2.2 Differential thermal analysis

The purities of the investigated samples were determined by differential thermal analysis using the freezing-point method (6). The mean-temperature version of our differential thermal analyzer used for the investigation of 1,8-octanediol and 1,10-decanediol has been described previously (6). The low-temperature version used for the other compounds is described elsewhere (7). The mole fraction purities of the investigated samples were as follows: 1,6-hexanediol, 0.9938 ± 0.0002; 1,7-heptanediol, 0.9920 ± 0.0003; 1,8-octanediol, 0.9991 ± 0.0001; 1,9-nonanediol, 0.9981 ± 0.0001; and 1,10-decanediol, 0.9933 ± 0.0003. The triple point temperatures and the enthalpies of fusion of the ω-alkanediols ($2 \leqslant n \leqslant 10$) were determined after calibration of the apparatuses with standard reference substances (7).

2.3. Vaporization and sublimation calorimetry

A Tian–Calvet calorimeter equipped with a Knudsen effusion cell was used to determine the enthalpies of sublimation or vaporization of the investigated substances. The method of operation has been described in detail elsewhere (8). The calorimeter was calibrated electrically. The temperature T of the calorimeter and the diameter of the effusion cell orifice were adapted to the volatility of the compounds. The substance with the highest saturated vapour pressure, 1,6-hexanediol, was investigated at 298 K with an effusion cell orifice diameter of 3 mm. The enthalpies of sublimation of 1,8-octanediol and 1,10-decanediol were determined respectively at 323 K (effusion cell orifice: 1 mm) and 342 K (effusion cell orifice: 0.5 mm). The enthalpies of vaporization at 323 K of 1,7-heptanediol and 1,9-nonanediol, both liquid at this temperature, were measured with an effusion cell orifice of 0.5 mm. The correction to the standard temperature of 298.15 K required knowledge of the molar heat capacities of the substances in the condensed and the gaseous phases. The molar heat capacities in the gas phase at 298.15 K and T K were calculated from the group increments tabulated by Benson (9). The enthalpy differences $H(T) - H$

10	345.4±0.1	41.7±0.3

(298.15 K) of the condensed phase were measured with a Tian–Calvet calorimeter using the drop method. The calorimeter was calibrated with standard α-alumina samples from the National Bureau of Standards, and the accuracy of the results was checked with naphthalene, the enthalpy difference $H(342\text{ K}) - H(298.15\text{ K})$ of which is well known (10).

The saturated vapour pressures P of the ω-alkanediols can be calculated according to eq. [1], if Knudsen effusion conditions are fulfilled during the experiment.

$$[1] \quad P \approx \Delta P = \mathrm{d}m/\mathrm{d}t\,(1/aF)\,(2\pi RT/M)^{1/2}$$

ΔP is the difference of pressure between the inside and the outside of the effusion cell, $\mathrm{d}m/\mathrm{d}t$ the effusion rate, a the surface of the effusion cell orifice, F the Clausing factor, R the ideal gas constant, T the absolute temperature, and M the molar mass of the substance (11).

2.4. Combustion calorimetry

The enthalpies of combustion were determined on milligram samples with a CRMT calorimeter equipped with a stainless-steel microbomb. The apparatus and the method of operation for liquid ω-alkanediols have been described elsewhere (2). The solid samples were investigated with an original container technique using polythene foil of 0.05 mm thickness (12). The calorimeter was calibrated using benzoic acid standard reference sample 39i of the National Bureau of Standards. The Washburn and buoyancy corrections to the weighings were performed with computer programs.

3. Results

The triple point temperatures and the molar enthalpies of fusion of the ω-alkanediols studied ($2 \leqslant n \leqslant 10$) are summarized in Table 1. In Table 2, the experimental molar enthalpies of vaporization or sublimation of the title compounds and their saturated vapour pressures are reported. Since the saturated vapour pressures of the ω-alkanediols are relatively low, the identity $\Delta_{vap\text{ or }sub}H_m(T) \equiv \Delta_{vap\text{ or }sub}H^0_m(T)$ is assumed.

In Table 3, the enthalpy differences $H(T) - H(298.15\text{ K})$ for ω-alkanediols in condensed and gaseous phases are tabulated. For 1,9-nonanediol, which was studied at 323 K, the main part of the enthalpy difference for the condensed phase is due to the melting of the substance ($T_{tp} = 319.5$ K). The uncertainties of the enthalpy differences for the gas phase are estimated from the last digit given by Benson. The values are used to determine the molar enthalpies of sublimation and vaporization at 298.125 K (Table 4).

The standard molar enthalpies of combustion and formation in the condensed phase at 298.15 K of the ω-alkanediols have been reported in detail elsewhere (12). Using the standard molar enthalpies of vaporization (1,7-heptanediol) or sublimation (other compounds) at 298.15 K, the standard molar enthalpies of formation in the gaseous phase were calculated (Table 4). The standard molar enthalpies of the dissociation reaction of the molecules in the ideal gas phase into the atoms in the ideal gas phase, the so-called enthalpies of atomization, were then calculated using the standard molar enthalpies of formation of the gaseous ω-alkanediols and gaseous carbon, hydrogen, and oxygen atoms taken from the literature (13) (Table 4). The accompanying experimental uncertainties are standard deviations of the mean.

4. Discussion

4.1. Triple point temperatures, enthalpies and entropies of fusion

The triple point temperatures of the even-membered chain alkanediols are always higher than those of the next higher odd-membered. Within the class of the odd- and the even-membered compounds, the triple point temperatures and the molar enthalpies of fusion increase regularly. The molar entropy of fusion can be calculated by dividing the molar enthalpy of fusion by the temperature of fusion (or by the triple point temperature, which is nearly identical). The molar entropy of fusion is particularly sensitive to the existence of ordering phenomena in the liquid state, reducing free rotation of the molecules. The most consistent effects are due to hydrogen bonds. Bondi (14) pointed out that the presence of hydrogen bonds in liquid *n*-alkanols resulted in a decrease of $\Delta_{fus} S_m/R$ of about 1.1, compared with isoelectronic *n*-alkanes. In the case of ω-alkanediols, the difference (Table 5) amounts to about 3.4, reflecting a high order in the liquid state due to the existence of two hydrogen bonds per diol molecule. This is in agreement with earlier conclusions drawn from a discussion of the enthalpies of vaporization (1). On the other hand, intramolecular hydrogen bonds, which permit free rotation in the liquid state and therefore enhance the entropy of fusion (14), can be excluded, with the exception of 1,2-ethanediol. In the case of 1,2-ethanediol, the molar entropy of fusion is nearly identical to that of *n*-butane; this result indicates the possibility of an intramolecular hydrogen bond in 1,2-ethanediol.

4.2. Enthalpies of sublimation

In a previous paper (1), we showed that the contributions of London-type interactions, dipolar interactions, and hydrogen bonds to the enthalpies of vaporization can be separated and calculated by comparison with the enthalpies of vaporization of isoelectronic *n*-alkanes and ethers. In the same manner, we compared the molar enthalpies of sublimation at 298.15 K of the ω-alkanediols with the sum of the molar enthalpy of vaporization at 298.15 K (15) and the molar enthalpy of fusion at the melting temperature (16) of isoelectronic *n*-alkanes (Table 6). In a first approximation, the temperature variation of the enthalpy of melting is neglected. The comparison with ω-alkanediols reveals that the mean difference amounts to about 56 kJ mol^{-1}, which corresponds to the contributions of dipolar interactions and of hydrogen bonds to the enthalpy of sublimation. The contribution of dipolar interactions is rather small and should amount, as shown previously (1), to only about 1 kJ

mol^{-1}. A structural study of 1,6-hexanediol (17) showed that two hydrogen bonds are formed by each molecule; the enthalpy of a hydrogen bond is thus about 27 kJ mol^{-1}. This value is slightly higher than the value previously found in liquid ω-alkanediols (23 kJ mol^{-1} (1)), in accordance with the lower intermolecular distance in the solid state.

4. 3. Enthalpies of combustion, formation, and atomization

The standard molar enthalpies of combustion and formation at 298.15 K of the solid ω-alkanediols can, as was previously reported, be expressed as a linear function of the number n of methylene groups.

$$\Delta_c H^0_m \text{ (s, 298.15 K) / (kJ mol}^{-1}) = 129.0 - 652.7n$$

$$\Delta_f H^0_m \text{ (s, 298.15 K) / (kJ mol}^{-1}) = -414.7 - 26.6n$$

The standard molar enthalpies of formation in the gaseous phase at 298.15 K (Table 4) can be used together with the previously reported values (3) to derive an equation valid for all members of the compound family.

$$\Delta_f H^0_m \text{ (g, 298.15 K) / (kJ mol}^{-1}) = -361.4 - 16.2n$$

Furthermore, we can express the standard molar enthalpies of atomization of the ω-alkanediols ($2 \leqslant n \leqslant 10$) as a linear relation of n.

$$\Delta_{a,\,exp} H^0_m \text{ (298.15 K) / (kJ mol}^{-1}) = 1295.8 + 1168.9n$$

Both equations are in excellent agreement with the equations previously derived for the lower ω-alkanediols ($2 \leqslant n \leqslant 5$). The conclusions drawn in ref. 3 are thus reinforced: the enthalpy of the C—OH bond amounts to 819.5 kJ mol^{-1}, the mean enthalpy of the C—C bonds to 343.2 kJ mol^{-1}. The mean C—C bond enthalpy is lower than in other aliphatic compounds, because the bond is weakened by the electron-attracting effect of the hydroxyl groups. The low CH_2-group contribution to the enthalpy of formation in the gaseous phase can thus be explained.

Elemental analysis of the marine biological reference material LUTS-1 by instrumental neutron activation, graphite furnace atomic absorption spectroscopy, and anodic stripping voltammetry

NORINE MOTKOSKY, ANGELO RANSIRIMAL FERNANDO, AND BYRON KRATOCHVIL
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received October 27, 1989

NORINE MOTKOSKY, ANGELO RANSIRIMAL FERNANDO, and BYRON KRATOCHVIL. Can. J. Chem. **68**, 735 (1990).

Marine biological reference material LUTS-1, lobster heptopancreas, was analyzed for elemental homogeneity using graphite furnace atomic absorption, anodic stripping voltammetry, and neutron activation analysis. Analysis of samples taken from 12 bottles of LUTS-1 bottled on two different days showed no statistical differences at the 95% confidence level for within-bottle variance for a large number of elements. Differences were observed for between-day variances for aluminum, iron, cobalt, sodium, chlorine, bromine, and iodine, but not at a level sufficient to affect utility as a reference material.

Key words: neutron activation analysis, graphite furnace atomic absorportion spectroscopy, anodic stripping voltammetry, elemental analysis, marine biological reference material.

NORINE MOTKOSKY, ANGELO RANSIRIMAL FERNANDO et BYRON KRATOCHVIL. Can. J. Chem. **68**, 735 (1990).

Afiin de déterminer l'homogénéité élémentaire de l'hepatopancréas de homard, le produit de référence de biologie marine LUTS-1, on a fait appel à l'absorption atomique avec fournaise de graphite, à la voltamétrie anodique et à des analyses par activation neutronique. Des analyses d'échantillons provenant de 12 bouteilles de LUTS-1 embouteillées à deux jours différents démontrent qu'il n'y a pas de différences statistiques, au niveau de confiance de 95%, pour des variations d'un grand nombre d'éléments à l'intérieur d'une même bouteille. On a toutefois observé des variations entre échantillons provenant de jours différents pour l'aluminium, le fer, le cobalt, le sodium, le chore, le brome et l'iode; ces différences sont suffisamment faibles pour qu'elles n'affectent pas l'utilité de ces échantillons comme produits de référence.

Mots clés : analyse par activation neutronique, spectroscopie d'absorption atomique avec fournaise de graphite, voltamétrie anodique, analyse élémentaire, produit de référence de biologie marine.

[Traduit par la revue]

Introduction

The marine biological reference material LUTS-1 has recently been prepared under the Canadian Marine Analytical Standards program. Unlike most other materials developed for monitoring and evaluating analytical procedures, LUTS-1 is a slurry obtained through mechanical homogenization of lobster heptopancreas tissue. Since no pretreatment such as acetone extraction of fatty matter has been carried out, this material is closer in nature and properties to the original matrix, thereby allowing more realistic scrutiny of analytical procedures.

As in any reference material, establishing homogeneity is of prime importance. In view of the trend toward smaller and smaller analytical test portions to satisfy instrumental requirements such as direct solid insertion for atomic or mass spectroscopic techniques, and to assess localized distribution of elements within substances such as biological tissues, homogeneity of reference samples can be expected to become more important in the future.

This study was undertaken to assess the homogeneity of LUTS-1. Three different analytical techniques were used: atomic absorption spectroscopy using graphite furnace atomization for lead, cadmium, and aluminum; anodic stripping voltammetry employing mercury electrodes with differential pulse stripping for lead, and instrumental neutron activation analysis using the SLOWPOKE II reactor facility of the University of Alberta for 17 additional elements.

Experimental

Apparatus

Atomic absorption measurements were made on a Perkin Elmer model 5000 spectrophotometer with background correction, an HGA 2200 furnace, and an AS-1 autosampler. Injected volumes were 20 μL. Pyrolytic graphite tubes with platforms were used. Operating conditions are given in Table 1. The argon purge gas flow was stopped during atomization of lead but was continued using the normal (40 mL/min) setting for the first 3 s for cadmium and 6 s for aluminum. Peak areas were recorded on a Perkin Elmer PRS-10 printer sequencer.

Differential pulse anodic stripping analyses were done using a Princeton Applied Research (PAR) model 174 polarographic analyzer coupled to a PAR model 315 automated electroanalysis controller and a PAR model 303 stationary mercury drop electrode. A Hewlett Packard 7045A *xy* recorder was used for data recording. Some of the solutions were analyzed with a PAR model 303 operating in the hanging mercury drop mode (HMDE). Others were analyzed using a thin mercury film deposited on a glassy carbon electrode (PAR model GO197) mounted on the PAR 303 electrode assembly (MTFE). All solutions were deaerated for 5 min by bubbling nitrogen. All analyses were done using differential pulse stripping. Typical parameters for a run are listed in Table 2. When the MTFE was used, each deposition/stripping operation was preceded by a conditioning step (−0.3 V for 1.5 min). Mercury deposition was carried out from a 500 ppm Hg^{2+} solution, with a −0.1 V applied potential for 50 s.

Instrumental neutron activation analyses studies were carried out at the SLOWPOKE II reactor facility of the University of Alberta. For those elements producing useful short-lived radioisotopes upon irradiation, two irradiation–decay–count schemes were used. The first was 120 s irradiation, 10 s decay, and 180 s count, which gave satisfactory counting statistics for radioisotopes of Al and V. This set was irradiated in site 5 of the reactor at a flux of 1×10^{12} n cm^{-2} s^{-1} and was counted at a sample-to-detector distance of 10 cm. The second was 120 s irradiation, 45 s decay, and 600 s counting, which gave satisfactory results for Na, Cl, Mn, Ca, Br, I, Mg, and Cu. These irradiations were carried out in site 1 of the reactor at the same flux but were counted at a sample-to-detector distance of 6 cm within a 10-cm lead cave with graded shield to reduce natural background. For those elements that only produce longer-lived ($T_{1/2} > 1$ day) radioisotopes, irradiation for 4 h at a flux of 1×10^{12} n cm^{-2} s^{-1} was carried out. Following a 6-day decay period the samples and standards were counted for 2.5 h at a distance of 1 cm from the detector to determine As, La, Sb, Na, Br, Co, Zn, and Fe. The

	Scan rate	2 or 5 mV/s
	Modulation	50 mV
	Clock	0.5 s
	Final potential	−0.3 V (vs. Ag/AgCl)

samples were then counted again after about 21 days for 10 h to determine Ag, Co, Fe, Sb, and Zn. The long counts were performed 1 cm from the detector in a 10-cm lead cave.

Counting was carried out on three different systems. For the 180-s counts an Ortec 86 cm^3 active volume WIN-15 coaxial Ge (Li) detector with an Ortec 472A amplifier and a Nuclear Data (ND) 575 ADC was used. Detector specifications include a relative efficiency of 18.5%, a measured FWHM of 2.1 keV, and a peak-to-Compton ratio of 53:1 for the 1332-keV photopeak of ^{60}Co. For the 600-s counts a GEM 20180 hyperpure Ge detector coupled to a ND 660 multichannel analyzer with an Ortec 572 amplifier and ND 575 ADC was used. Detector specifications include a relative efficiency of 22.4%, a measured FWHM of 1.7 keV, and a peak-to-Compton ratio of 59:1. For the 2.5- and 10-h counts a GEM 18180 hyperpure Ge detector coupled to a Canberra Series 80 multichannel analyzer with a Canberra 8622 amplifier and ADC was used. Detector specifications include a relative efficiency of 19.7%, a FWHM of 1.68 keV, and a peak-to-Compton ratio of 58:1. Signals were stored on floppy discs for later analysis.

The specific activities (counts/microgram for each radionuclide) were determined for each counting period, and the masses of the elements in the NRC standards were determined via an adaptation of the comparator (semi-absolute) method for INAA (1), that is, by dividing the photopeak areas of the unknowns by the specific activities of the relevant radionuclides. Deadtime corrections (2) for the decay of short-lived radioisotopes in the presence of active, long-lived isotopes such as ^{14}Na and ^{38}Cl were applied to each peak. In addition, a correction factor for random summing effects was calculated and applied following the procedure of Wyttenbach (3).

Measurements of photopeak areas and associated computations were carried out using standard Nuclear Data software (with modifications made by personnel at the SLOWPOKE Facility) and the University of Alberta Amdahl mainframe computer or an IBM personal computer. Statistical analysis procedures were performed on an Apple Macintosh computer using the statistical package StatWorks by Data Metrics, Inc.

Reagents

Distilled deionized water was obtained either from a modified Barnsted Bantam still or from a column of mixed-bed strong acid–strong base ion exchange resins (Amberlite MB-3, Rohm and Haas). Nitric and perchloric acids of ultra pure grade produced via subboiling distillation were used (Seastar Chemicals, Sidney, B.C., Canada). All other chemicals were reagent grade. Certified standard metal ion solutions (Fisher Scientific) were used as stock solutions for calibrations and standard additions, except in DPASV analysis where a 1000 ppm stock solution prepared by dissolving analytical grade $Pb(NO_3)_2$ was used to prepare working standards. For checking purposes, certified reference materials TORT-1 from the National Research Council of Canada and NBS 1566 Oyster Tissue from the U.S. National Institute for Standards and Technology were also analyzed.

Sample preparation

Atomic absorption analyses

Twelve bottles of LUTS-1, six labelled Day 1 and six labelled Day 2, were obtained from the Marine Standards Analytical Program, Division of Chemistry, National Research Council of Canada, Ottawa, Canada. The bottles were sonicated for 30 min prior to opening and before removal of subsequent samples. Appropriate amounts were pipetted directly from the bottles and weighed to ±0.01 mg on a Mettler H-51 semimicro balance into Savillex 60-mL Teflon PFA digestion vessels (Savillex Corp., Minnetonka, Minn.). After adding acids in amounts listed below the vessels were closed and placed on a turntable in a Sears Kenmore microwave oven and heated for 2 min at 100% power, followed by 10 min at 15% power.

For aluminum analysis 500-μL portions of LUTS-1 were treated with 2 mL of concentrated HNO_3 and 0.25 mL of concentrated HF in the above manner. After cooling, the samples were transferred to 30-mL Teflon bottles containing 0.232 g of H_3BO_3 dissolved in 5 mL of water and were diluted to about 15 g by weight. The final volume of solution was obtained by dividing the weight by the density, the density being determined by weighing a 1-mL portion. For the standard additions procedure 2 mL of the above solution, 1 mL of 0.547 M $Mg(NO_3)_2$, and from 0 to 600 μL of 1 μg/mL Al standard were added to 60-mL pothyethylene bottles and diluted to about 10 g. The volume of solution was again determined by dividing the weight of the solution by its density. The value of the Al concentration was determined by least-squares calculations on the standard additions plots.

For cadmium, approximately 100-μL portions were weighed and digested with about 2.5 mL of concentrated nitric acid as described above. After cooling, the samples were transferred to 10-mL volumetric flasks and diluted to volume with deionized water. For the standard additions, 200 μL of this solution and 0–60 μL of a solution containing 1 μg Cd per mL were added to 2-mL volumetric flasks and diluted to volume with deionized water. The value of the Cd concentration was determined by a least-squares calculation on the standard additions plot as for aluminum.

[a]Not available. Value obtained earlier in this laboratory by INAA and GFAAS on 300-mg portions of TORT-1 was 43±3 μg/g (5).

For lead, approximately 1-mL portions were weighed and digested as above using about 3 mL of concentrated nitric acid. After cooling, the samples were transferred to 10-mL volumetric flasks and diluted to volume with water. For analysis, 0.36 mL of sample and 0.06 mL of 2% $NH_4H_2PO_4$ were placed in sample cups and mixed before being injected by the auto sampler. Each solution was run at least four times.

Anodic stripping voltammetry

LUTS-1 solutions obtained by digestion with nitric acid for the analysis of lead by graphite furnace atomic absorption spectrophotometry were further treated according to the following procedure.

A 1-mL portion of HNO_3 digested solution was placed in a Teflon PFA voltammetric cell (Princeton Applied Research GO 174) with 1 mL of $HClO_4$ and heated under cover (Teflon TFE cover plates) for about 2 h at approximately 200°C. The covers were then removed and the solution was allowed to evaporate to dryness (2–3 h) at a temperature near 240°C. Heating was done on a sandbath covered with aluminum foil to prevent contamination and adherence of sand particles to the hot Teflon. The evaporation procedure was carried out in a stainless steel fumehood designed to handle perchloric fumes. (**Caution**: The usual precautions must be taken when working with hot, concentrated $HClO_4$.)

Residue from the above procedure was dissolved in 5 mL of 0.01 M HNO_3 pipetted directly into the cell. After addition of a Teflon-coated stirbar the cell was placed in the electrode assembly for subsequent anodic stripping analysis.

All solutions were analyzed at least three times with and without added standard. The addition was of standard Pb solution with a micropipet in volumes corresponding either to a 2 or a 2.5 ppb increase in Pb content. For samples where interferences from residual organics were suspected, as indicated by the appearance of foreign peaks, five or six measurements were made on each solution. In one or two cases a second standard addition was used.

Measured peak heights were evaluated by least squares after a Q test on each set to reject outliers. The resulting estimates for the lead concentrations, along with corresponding standard deviations, were used with the sample weight and dilution factors to estimate the lead levels in the sample. These evaluations were performed using a standard addition data treatment program (4).

Instrumental neutron activation analysis

Samples were taken from each of 12 bottles of LUTS-1 provided by the National Research Council of Canada. The bottles were sonicated for 30 min before opening and before removal of subsequent samples. One-millilitre portions were pipetted into small, acid-washed polyethylene irradiation vials. The vials were heat sealed and enclosed in large irradiation vials that were also heat sealed.

Standards were prepared from commercial atomic absorption standard solutions (Spex, Fisher, Custom Std., and NBS) and from standard compounds (Fisher, Anachemia, and Aldrich). For both long and short irradiations multielement standards were prepared by pipetting 100 μL of a multielement standard solution onto Whatman no. 2 filter paper cut to fit the inside walls of a small irradiation vial. The multielement standard solution was prepared by micropipetting aliquots of individual standard solutions into a 10-mL volumetric flask and diluting to volume. The treated filter papers, except for those containing arsenic, were dried slowly under an infrared lamp. All vials were then heat sealed.

For the short irradiations certified reference materials were irradiated as a slurry by combining solid material with water and mixing by sonication. For the 4-h irradiations the reference materials were irradiated as solids because of possible problems with leakage from the vials.

Results and discussion

Results of the atomic absorption and anodic stripping determinations are listed in Table 3. The procedure for aluminum used here was checked by analysis of TORT-1, for which a value had been determined earlier in our laboratories (5). The graphite furnace AA technique described here allows convenient quantification of aluminum in these materials, although sample contamination must be guarded against. Because of lack of agreement among various laboratories and methods neither LUTS-1 nor TORT-1 have been certified for aluminum. This is also the situation for a number of other reference materials.

In the GFAAS work done here the absolute standard

deviations of the determinations were found to depend largely on the amount of analyte injected into the furnace. This amount in turn depends on the material being analysed as well as on the sample preparation technique, and should be given consideration during data interpretation.

An analysis of variance procedure was used to check the homogeneity of the material. No significant bottle-to-bottle variations were observed for aluminum within either the Day 1 or Day 2 sets of bottles. Between-day variations appeared to be high enough to reject the null hypothesis of no significant difference between Day 1 and 2 at the 95% confidence level; the null hypothesis is not rejected, however, at the 99% confidence level. Average values for the two sets of samples were 3.4 ± 0.4 μg/g for Day 1 and 3.1 ± 0.4 μg/g for Day 2. Thus the homogeneity between these two sets of samples with respect to aluminum is borderline in a statistical sense at the 0.5-mL test portion level. In view of this, a practical value for the aluminum content reported in Table 3 was established by calculating the overall average for all samples.

An analysis of variance of the data for LUTS-1 did not indicate any between-bottle variability for cadmium content at the 95% confidence level for 0.1-mL test portions. No difference was observed in cadmium levels at the 95% confidence level for the bottles labeled Day 1 and Day 2. Therefore this material can be considered homogeneous with respect to cadmium for subsampling at the 0.1-g level. Our best estimate for the cadmium level, reported in Table 3, was obtained by calculating the overall average.

Relative standard deviations associated with individual values for lead in LUTS-1 samples by atomic absorption covered a wide range: 2–19% with an average of 7%. Ranges for the other certified reference materials were narrower. On the other hand, as mentioned before, a correlation was observed between the relative standard deviation and the amount of lead injected into the graphite furnace. For LUTS-1 the amount of lead injected was roughly 83 pg, with an observed relative standard deviation of 7%. For Dogfish Muscle the amount of lead was approximately 116 pg, giving a relative standard deviation of 4%, for TORT-1 about 134 pg of lead gave a relative standard deviation of 2.4%, and for Dogfish Liver about 321 pg of lead gave a relative standard deviation of 1.6%. Considering the differences in the composition of these four materials, the results cannot be considered as evidence for deterioration of the quality of the analyses. Rather, the lower precision observed may be related to the lower lead level in the sample.

An analysis of variance for the LUTS-1 lead data does not reject the homogeneity assumption for between-bottle variation or between-day variation. The lower precision of the analytical procedures for lead, however, makes the degree of homogeneity less certain than for more precise measurements for other elements. It should be noted, though, that the relative standard deviations for the individual measurements of lead in LUTS-1 by DPASV averaged 7.6% and for TORT-1 8.3%. These values agree well with each other and with literature values for comparable analytical systems (4, 6, 7).

Most of the imprecision in the DPASV analyses can be traced to errors in Hg drop reproducibility and to poor reproducibility of flow conditions during the deposition step. Data points with very high relative standard deviations were associated with the analyses done using the hanging mercury drop electrode. Considering the low lead level and the organic matrix of the samples, precision and analytical control of the analysis can be viewed as satisfactory for the equipment used. Anodic stripping data does not offer any significant improvement in precision for the determination of lead relative to graphite furnace atomic absorption analysis, and homogenity conclusions based on

GFAAS work were not, as expected, affected by the DPASV data.

Correlation diagrams for the graphite furnace and anodic stripping data indicated random scatter. Since both analyses were done on the same sample solutions, any differences during the subsampling stage can be ruled out as the origin of high uncertainty. This puts the burden on instrumental performance, allowing one to accept sufficient homogeneity of LUTS-1 for the analysis of lead using 1-g subsamples.

The overall average estimate for lead by anodic stripping for LUTS-1 is 0.052 ± 0.018 μg/g, the uncertainty being one standard deviation. On the basis of a *t*-test assuming unequal and unknown variances (8), this value is not significantly different from the value obtained from graphite furnace atomic absorption (0.049 ± 0.013). Therefore the mean of these two values, 0.050 μg/g, is proposed as our best estimate for the lead content in LUTS-1, with a standard deviation calculated by combining the variances for the two data sets of ± 0.011 μg/g. This lead value is approximately 0.04 μg/g higher than the certified value. The reason for this discrepancy is unknown; the most likely explanation is contamination in some way of the original sample bottles.

A summary of the analytical results obtained by instrumental neutron activation analysis on 1-g samples of LUTS-1 is given for the major elements in Table 4 and for the trace elements in Table 5. The NRC certified reference materials TORT-1 and DOLT-1 and the NBS standard reference materials SRM 1566 (Oyster Tissue) and SRM 1577 (Bovine Liver) were run as controls. The results for these materials, along with the accepted values, are included in Tables 4 and 5.

The INAA data were tested for differences in within- vs. between-bottle and for within- vs. between-day homogeneity for each element by a one-way analysis of variance. Prior to running of the ANOVA program the data were tested for outliers by the Dean and Dixon *Q* test (9) and values falling outside the Dean and Dixon criteria at the 90% confidence level (Q_{90}) were deleted.

An ANOVA study of the data from 2.5- and 10-h counts for between- vs. within-bottle variability did not indicate significant heterogeneity at the 95% confidence level except for silver (658 keV) and zinc on Day 1. The silver and zinc data are affected by two relatively high values coming from the same bottle, which markedly increase the average of that bottle. On the other hand, data for 3- and 10-min counts did not allow rejection of the homogeneity assumption for any of the elements determined. Therefore we conclude that within-bottle homogeneity is satisfactory for all elements listed in Tables 4 and 5 at the 95% confidence level for 1-mL test portions.

When tested in a between- vs. within-day format, the 2.5- and 10-h count data did not show significant differences for any of the elements except iron (1099 and 1291 keV) and cobalt (1173 keV). The iron counts at both energies were consistently higher in the Day 1 samples than in those from Day 2. The cobalt data were affected by two high values occurring in the Day 2 data.

When tested in the same format, data for the 3- and 10-min counts indicate significant between-day differences for sodium (1368 and 2754 keV), chlorine (1643 and 2167 keV), bromine (617 and 666 keV), and iodine at the 95% confidence level. For these elements Day 1 values were consistently higher than Day 2 values.

Aluminum count data were also obtained by INAA, but could not be corrected for either phosphorus or silicon interferences because concentration values for these elements were not determined. As P and Si data become available our results can be corrected and an aluminum value obtained.

In summary, the results obtained in this work agree well with certified values except for magnesium and copper, both of which are low. Other elements for which further investigation might be warranted are iron and possibly cobalt. Lower values of Na, Cl, Br, and I were found for material bottled on Day 2, which may indicate either loss of soluble salts from the solution phase between days, or an increase in water content between days. The variation is not sufficiently large, however, to cause a discrepancy in the overall values reported at the tolerance levels established by the NRC.

Photochromic systems. Part 1. Structural and spectroscopic study of photochromically active products of Stobbe condensation. 2,3-Dibenzylidenesuccinic acid and its anhydride

P. ADRIAAN DAVIDSE, JAN L. M. DILLEN, ANTON M. HEYNS, TOMASZ A. MODRO,[1] AND PETRUS H. VAN ROOYEN
Department of Chemistry, University of Pretoria, Pretoria 0002, South Africa

Received December 19, 1988[2]

P. ADRIAAN DAVIDSE, JAN L. M. DILLEN, ANTON M. HEYNS, TOMASZ A. MODRO, and PETRUS H. VAN ROOYEN. Can. J. Chem. **68**, 741 (1990).

E,E-2,3-Dibenzylidenesuccinic acid (**2**) and its anhydride (**1**) were synthesized, their crystal structures and ^1H and ^{13}C nuclear magnetic resonance spectra were determined, and electron charge densities of carbon atoms were calculated. These results were related to the corresponding data available for *E*-cinnamic acid (**3**) in order to evaluate the effect of structural changes in a series **3** → **2** → **1** on the molecular parameters and spectroscopic properties of the cinnamic system. In the molecule of **2** most of the steric strain is released by the rotation about the C(α)—C(α′) bond giving rise to a structure consisting of two, approximately independent, cinnamic acid moieties. In **1**, severe steric strain is introduced, as demonstrated by the unusually large values of the CCC bond angles exocyclic with respect to the anhydride ring, as well as by significant deviations from the plane of the cinnamic skeleton. The geometry of **1** results in an intramolecular shielding of the aromatic hydrogen atoms due to the proximity of the two benzene rings; this shielding effect for the *ortho*, *meta*, and *para* hydrogen atoms correlates well with the intramolecular distances between the corresponding positions of both rings. The common linear relationship between ^{13}C chemical shifts and the electron charge densities on the given carbon atom has been obtained for compounds **1**, **2**, and **3**.

Crystal data. Anhydride (**1**): space group $P2_1/c$ with a = 13.536(3), b = 14.391(3), c = 7.159(1) Å; β = 98.69(1)°; R_w = 0.029 and R = 0.055. Succinic acid (**2**): space group $P\bar{1}$ with a = 8.881(3), b = 9.786(1), c = 11.355(3) Å; α = 85.56(1), β = 88.76(2), γ = 69.46(2)°; R_w = 0.048 and R = 0.081. This compound cocrystallizes with one molecule of the solvent (acetic acid).

Key words: photochromic, cinnamic, succinic.

P. ADRIAAN DAVIDSE, JAN L. M. DILLEN, ANTON M. HEYNS, TOMASZ A. MODRO et PETRUS H. VAN ROOYEN. Can. J. Chem. **68**, 741 (1990).

On a synthétisé l'acide *E,E*-2,3-dibenzylidènesuccinique (**2**) et son anhydride (**1**), on a déterminé leurs structures cristallines et leurs spectres de résonance magnétique nucléaire du ^1H et du ^{13}C et on a calculé les densités des charges électroniques des atomes de carbone. En comparant ces données avec les données correspondantes disponibles pour l'acide *E*-cinnamique, on a évalué l'effet des changements structuraux reliés à la série **3** → **2** → **1** sur les paramètres moléculaires et sur les propriétés spectroscopiques du système cinnamique. Dans la molécule **2**, on peut éliminer complètement les contraintes stériques en effectuant une rotation autour de la liaison C(α)—C(α′) pour obtenir une structure comportant deux portions pratiquement indépendantes d'acide cinnamique. Dans le cas de la molécule **1**, des contraintes stériques importantes sont introduites; elles sont mises en évidence par des valeurs exceptionnellement élevées pour les angles des liaisons CCC exocycliques par rapport aux valeurs correspondantes du cycle anhydride ainsi que par des déviations importantes par rapport au plan du squelette cinnamique. Le géométrie de la molécule **1** est le résultat d'un blindage intramoléculaire des atomes d'hydrogène aromatiques provenant de la proximité des deux noyaux benzéniques; il existe une corrélation entre cet effet de blindage sur les atomes d'hydrogène en *ortho*, en *meta* et en *para* et les distances intramoléculaires entre les positions correspondantes des deux cycles. Pour les composés **1**, **2** et **3**, on a obtenu le relation linéaire habituelle entre les déplacements chimiques du ^{13}C et les densités des charges électroniques sur les atomes de carbones donnés.

Données cristallographiques. Anhydride (**1**) : groupe d'espace $P2_1/c$, avec a = 13,536(3), b = 14,391(3) et c = 7,159(1) Å, β = 98,69(1)°; R_w = 0,029 et R = 0,055. Acide succinique (**2**) : groupe d'espace $P\bar{1}$, avec a = 8,881(3), b = 9,786(1) et c = 11,355(3) Å; α = 85,56(1), β = 88,76(2) et γ = 69,46(2)°; R_w = 0,048 et R = 0,081. Ce composé co-cristallise avec une molécule de solvant (acide acétique).

Mots clés : photochromique, cinnamique, succinique.

[Traduit par la revue]

Introduction

Fulgides (**1**) represent a well-known photochromic system investigated since the early 1900's (1), and their photochemical and thermal transformations still attract considerable attention (2). Anhydrides (**1**), prepared by the Stobbe condensation (3) of aromatic aldehydes with succinic acid derivatives, are formed almost exclusively as *E,E* isomers (4), i.e., compounds with the maximum steric interactions between the aromatic groups.

This stereoselectivity was explained by Johnson *et al.* (5), as well as by Heller and co-workers (6), who proposed the mechanism involving "overlap control", according to which the maximum overlap of the developing *p*-orbitals is achieved in the transition state with no eclipsing effects between the aryl and ester groups. The *E,E*-diacid (**2**) is thus formed in two successive condensations, and suffers no serious steric congestion because of the free rotation about the α,α′ carbon–carbon bond. It is only when the diacid **2** is converted into the anhydride **1** that severe steric interactions between aromatic rings are introduced (9). Systems **2** and **1** are formally derived from *E*-cinnamic acid (**3**) by α,α′ coupling and then closure to the anhydride ring.

The first (and only) structural study on fulgides (**1**) was carried out by Cohen *et al.* (7), who demonstrated, using X-ray diffraction and ^1H nmr spectroscopy, the *E,E* configuration of the di-*p*-anisylidenesuccinic anhydride prepared from *p*-methoxybenzaldehyde via Stobbe condensation. In this paper, which is the first of a series aimed at the comprehensive study of

the structural and chemical properties of **1**, we focussed our attention on the effect of the sequence of the structural changes **3** → **2** → **1** on the molecular parameters and spectroscopic properties of these compounds. We report here the crystal and molecular structures of **1** and **2** (Ar = Ph) together with the detailed interpretation of their nmr (^{1}H, ^{13}C) spectra, and relate these data to the corresponding characteristics available for *E*-cinnamic acid. Whenever possible, our results are related to the literature data (7) for the *p*-anisyl system in order to reaffirm the structural assignments. MNDO calculations were also performed (8) on all three compounds and the electron densities determined for each atom are correlated with the ^{13}C chemical shift data.

Results and discussion

Molecular structures

Selected molecular parameters relevant for the discussion of the structural relationship of compounds **1**, **2**, and **3** are listed in Table 1, and the projections of molecules of **1** and **2** are given in Figs. 1 and 2.

Compound **2** incorporates, in the solid state, a molecule of solvent (acetic acid). Each molecule of **2** is involved in four hydrogen bonds forming a cluster of two acid **2** and two solvent molecules. The conformation of the succinic acid part of the molecule is, however, similar to that found in the *Z*,*E* isomer of **2**, recently synthesized in this laboratory, and which crystallizes without solvent molecules.

It is clear that coupling of two molecules of cinnamic acid, which yields diacid **2**, as well as dehydrating the latter to form **1**, has a profound effect on the geometry of the system. The compound of reference (**3**), can be considered as an unhindered, fully conjugated system as indicated by almost identical C(2)—C(3) and C(8)—C(9) distances, as well as by the almost ideal planarity of the molecule (the values of the torsion angles of **3** based on the numbering of **2** are as follows: C(2)—C(3)—C(8)—C(9) −178.2°, O(1)—C(2)—C(3)—C(8) −1.5°, O(7)—C(2)—C(3)—C(8) 178.1°, C(3)—C(8)—C(9)—C(10) 0.9°, and C(3)—C(8)—C(9)—C(14) 179.6°). (*Note*: for the numbering of atoms in **3** see numbering of atoms O(1A)—C(14) in **2**, Fig. 2.) This structure gives rise to an extensive chromophore, characterized by the λ_{max} value of 287.5 nm and by the molar extinction coefficient, ε, of 19 500 (10). Fusion of two molecules of **3** through the C(α)—C(α′) bond to yield **2** introduces significant intramolecular steric interactions. Most of this strain can be released by the rotation about the C(α)—C(α′) bond, as can be seen by the value (104.2° (7)) of

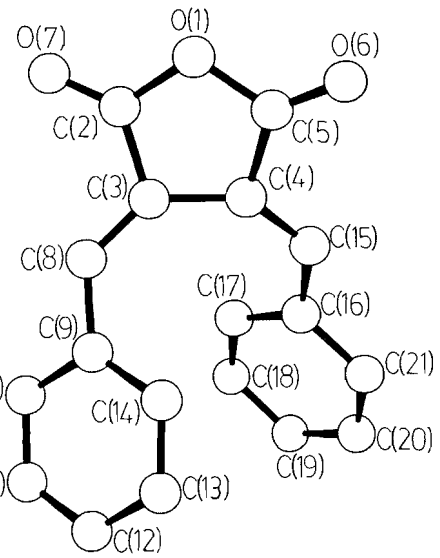

FIG. 1. A perspective view of **1** with atomic numbering.

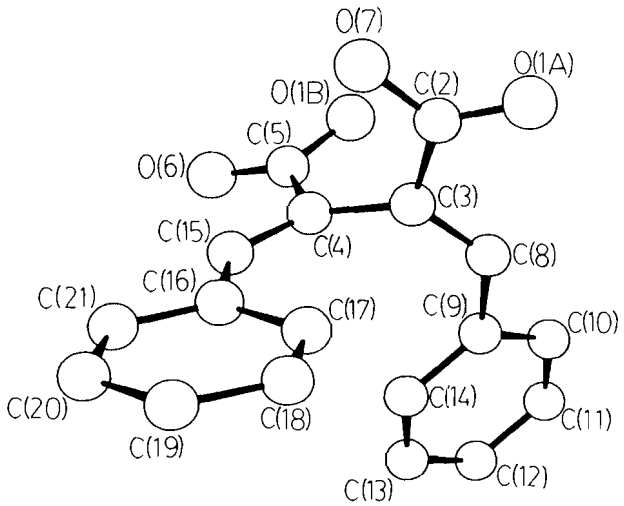

FIG. 2. A perspective view of **2** with atomic numbering.

the C(8)—C(3)—C(4)—C(15) torsion angle. As a result of this rotation, the molecule of **2** should be considered as consisting of two independent cinnamic acid moieties, without any electronic feature of the 1,4-diphenyl-1,3-butadiene molecule (**2** is a colorless substance). Moreover, the close proximity of two skeletons of **3** in the molecules of **2** results in the deviation of the individual halves of the system from the cinnamic acid geometry. The C(2)—C(3) (and C(4)—C(5)) bond distances are different from C(8)—C(9) (and C(15)—C(16)) distances, and both phenyl rings deviate significantly (22° and 39°) from the plane of the olefinic group. This deviation, aiming to minimize intramolecular interactions between two aromatic rings, is paralleled by the hypsochromic effect and the decrease of intensity in the electronic spectrum. Compound **2** exhibits the absorption maximum at 272.5 nm with an ε value of 27 000, i.e., of 13 500 per single cinnamic acid unit.

In the molecule of **1**, the anhydride ring imposes severe steric strain upon the whole cinnamic system. In this case, however, any rotation about the C(3)—C(4) bond is prohibited, so the relief of the strain can be achieved via changes of the bond angles at these two carbon atoms. This is demonstrated by the dramatic *increase* of the exocyclic bond angles C(3)—C(4)—

[a]Taken from ref. 9.
[b]Calculated (8).
[c]In all cases the phenyl rings together with atoms C(8), C(15) form planes with all torsion angles of ca. 180°.

C(15) (in **1** 135.5(2)° and **2** 127.4(5)°) and C(4)—C(3)—C(8) (in **1** 137.0(2)° and **2** 126.0(5)°) and a *decrease* of the endocyclic angles C(2)—C(3)—C(4) (in **1** 105.6(2)° and **2** 115.8(4)°) and C(3)—C(4)—C(5) (in **1** 105.5(2)° and **2** 116.9(4)°). The corresponding exo- and endocyclic bond angles in the bis-*p*-anisyl analogue (**1***a*) are very similar (7) (average 137.8° and average 106.2° respectively), but since the molecular structure of the corresponding diacid has not been determined, no direct effect of structural change on molecular parameters could be assessed for this system. For (*Z*)-veratrylidene succinic acid (11) the corresponding exo- and endocyclic bond angles are 129.0° and 107.7°. This trend indicates that the increase in exocyclic bond angles results from the steric interactions experienced by the phenyl groups. In addition, individual atoms in **1** deviate more from the plane of the cinnamic acid system than corresponding atoms in **2**. Consideration of two planes in **1**, each determined by ten atoms (O(6)—C(5)—C(4)—C(15)—[C(16) to C(21)], and O(7)—C(2)—C(3)—C(8)—[C(9) to C(14)]), reveals that both carbonyl oxygens (O(6) and O(7)) deviate by −0.4(2) and 0.4(2) Å respectively from these planes, and both α carbons (C(4) and C(3)) deviate by 0.5(2) and −0.5(2) Å respectively from these planes. Similar deviations from planarity have been reported (7) for the bis-*p*-anisyl compound. The deviation of the phenyl rings from the plane of the olefinic groups is 21° and 25° in **1** and approximately 30° for di-*p*-anisylidenesuccinic anhydride (7).

3	6.50(d)	7.80(d)	7.55(d of d)	7.41(m)	7.41(m)
4	6.54(d)	7.87(d)	7.55(d of d)	7.40(m)	7.40(m)
Δδ(**2**/**3**)	—	+0.14	0.00	−0.11	−0.11
Δδ(**1**/**4**)	—	+0.02	−0.74	−0.59	−0.28

[a]Δδ(**i**/**j**) corresponds to the chemical shift for **i** relative to that for **j**; positive values of Δδ indicate deshielding.

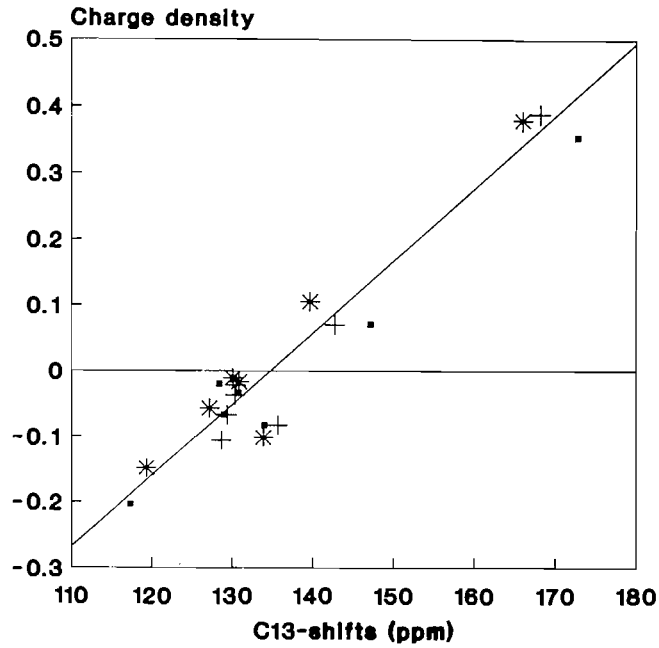

FIG. 3. The correlation between observed ^{13}C shifts and calculated electron charge densities. The points marked * are the values for **1**; +, values for **2**; and ■, values for **3**.

In contrast, the alignment of the phenyl ring in (*Z*)-veratrylidene succinic acid is virtually parallel (6°) to the enone π-system (11). The structure of **1** does not affect significantly the spectroscopic properties of the cinnamic moiety, as shown by the similarity of the section of the uv spectrum of **1** (λ_{max} 290 nm; ε, 34 000) to the spectrum of cinnamic anhydride, (λ_{max} 290 nm; ε, 49 000) (12). In addition to the π electron system of the cinnamic acid derivative, **1** is also a derivative of 1,4-diphenyl-1,3-butadiene, as indicated by the shift of the electronic spectrum of **1** to the visible region (yellow substance, λ_{max} 360 nm; ε, 12 600). The most obvious structural feature of **1**, illustrated in Fig. 1, is the tendency of the aromatic rings to maximize their mutual intramolecular distance. As will be seen from the analysis of the ^1H nmr spectrum of **1**, the intramolecular relation of the phenyl groups has a strong effect on the shielding of aromatic hydrogen atoms. The angle between the vectors normal to the phenyl rings is −76° in **2**, 35° in **1**, and 19° in the bis-*p*-anisyl compound.

^1H nuclear magnetic resonance spectra

Table 2 lists chemical shift values, as well as relative chemical shifts, for all hydrogen atoms in compounds **1**, **2**, and **3**.

The diacid **2** can be viewed as consisting of two independent cinnamic acid moieties linked through the C(α)—C(α′) bond. At the temperature of the measurements the rotation about this bond seems to be completely free, as the two olefinic protons in **2** are magnetically equivalent and give rise to a sharp singlet at δ 7.94 (the corresponding olefinic protons in the diacid derived from **1***a* also give rise to a singlet (7)). Slight deshielding of H(β) in **2** relative to **3** can be easily attributed to the effect of the 2-cinnamyl group substituted for the hydrogen atom at carbon α. The aromatic hydrogen atoms in **2** have chemical shifts similar to those in **3**, except for a weak shielding of *meta* and *para* positions, suggesting some long-distance mutual interactions between two aromatic rings. Much more significant changes in the shielding of the individual hydrogen atoms are, however, observed upon closing the diacid **2** into the anhydride **1**. Olefinic hydrogens, H(β), H(β′), which belong to the planar, rigid bis-methylenesuccinic anhydride system, have an almost identical chemical shift to that of the equivalent hydrogen atoms in **2**. For the aromatic rings, on the other hand, steric constraint of the *E,E* geometry of system **1** requires significant rotation around the C(8)—C(9) and C(15)—C(16) bonds. However, this effect locates the benzene rings in the near-parallel planes, hence results in repulsive interactions between the two sets of aromatic π electrons. As a result of this, aromatic rings increase their intramolecular distance. In consequence of this geometry, aromatic hydrogen atoms of one ring are located in the shielding section of the magnetic field induced by the second ring. The shielding effects decrease in the order *ortho* > *meta* > *para*, as the distances between the corresponding positions in the rings increase. This correlation can be easily demonstrated by comparing chemical shifts of aromatic hydrogen atoms in **1** with the corresponding values for the strain-free *E*-cinnamic anhydride **4**, whose ^1H nmr data have been also included in Table 2. The relative shielding of ring hydrogens in **1**, as compared with **4**, decreases from −0.74 to −0.59 to −0.28 ppm for the *ortho*, *meta*, and *para* hydrogen atoms, respectively.

^{13}C nuclear magnetic resonance spectra

Chemical shift data, together with the net atomic charges (calculated by the MNDO method (8)) for individual carbon atoms in compounds **1**–**3** are given in Table 3. Assignment of ^{13}C resonances was based on the comparison of chemical shifts with the literature data for similar derivatives, on the relative peak intensities, and on the INEPT experiments, which allowed the identification of all CH carbon atoms. In *E*-cinnamic acid the C(β) atom is strongly deshielded relative to the C(α) atom, the difference being Δδ = 30.1 ppm. This difference indicates strong polarization of the olefinic bond, which effectively transmits the conjugation between the (donor) phenyl and the

[c]In $CDCl_3$.
[d]In acetone-d_6.

(acceptor) carboxylic group. The presence of the β-phenyl group is necessary for such polarization to occur since the chemical shifts for olefinic carbons in a molecule of ethyl acrylate are almost identical ($\Delta\delta$ = 0.7 ppm) (13). The transmission of the conjugative effects is, for steric reasons, diminished in the diacid **2**. Consequently, the relative deshielding of C(β) vs. C(α) decreases in compound **2** ($\Delta\delta$ = 14.1 ppm), paralleling the effects of the deviation of **2** from planarity on its uv spectrum (*vide supra*). In agreement with the known fact that shieldings of vinyl carbons are more sensitive to polar effects than those of aromatic carbons (14), the only significant changes in chemical shifts for a series **1**, **2**, **3** are observed for the C(carbonyl), C(α), and C(β) atoms. The strongest effects operate at C(α); attachment of a second moiety of cinnamic acid results in strong deshielding of this atom (for **3** → **2**, $\Delta\delta$ = 11.3 ppm), as expected from the electronic effects of the 2-cinnamyl substituent relative to the hydrogen atom. Interestingly, this deshielding effect is almost completely lost upon the closure of the diacid **2** into the anhydride **1**, the deshielding of C(α) in **1** relative to that in **3** being only $\Delta\delta$ = 2.0 ppm. This loss could possibly be a compensation effect brought about by the delocalization in the more planar diphenylbutadiene system in **1**.

The most common assumption made in the interpretation of ^{13}C nmr chemical shifts is that there is a linear correlation between shifts and the electron density on the given carbon atom (15). Although this assumption has been frequently questioned, the chemical shift – charge density linear correlation has been used for the determination of unknown compounds (16). We have tested this assumption by plotting the observed ^{13}C chemical shifts for compounds **1**, **2**, and **3** vs. net atomic charges calculated by the MNDO method (Fig. 3). The plot, involving 21 carbon atoms, is reasonably linear (r = 0.955) and the carbon atoms of all three substrates follow the same relationship. This common dependance of the chemical shifts on the electron densities for these three configurationally different structures suggests that shielding parameters of a given carbon atom are mainly determined by the electronic state of an atom (a diamagnetic and a paramagnetic shielding term) with negligible contribution from anisotropy effects of neighbouring atoms and groups.

Experimental

Melting points are uncorrected. The nmr spectra were recorded on a superconducting FT Bruker AC 300 spectrometer with TMS as internal standard. The uv spectra were recorded on a Beckman Acta MIV spectrophotometer. All solvents and reagents were purified by conventional methods immediately before use. *E*-cinnamic acid (**3**) (Aldrich, Gold Label, mp 133–134°C) was used as supplied. Anhydride (**1**) was prepared directly from crude acid (**2**), which was synthesized following the procedure given in the literature (3). Crude **2** was added to acetyl chloride (20 mL per 1 g of **2**) and the mixture was heated under reflux for 2 h. After evaporation of the excess of acetyl chloride under reduced pressure, crude **1** was first crystallized from ethyl acetate, and then from benzene. Yield 22%; yellow crystals, mp 210–211°C (from benzene; lit. (17) mp 203°C); ^1H and ^{13}C nmr spectra are given in Tables 2 and 3. Diacid **2** was prepared from **1** in the following manner: **1** (0.5 g, 1.8 mmol) was dissolved in dioxane (20 mL), water (1 mL, 55 mmol) and concentrated hydrochloric acid (ca. 5 drops) were added, and the solution was heated under reflux until it became colourless. Solvent was removed under reduced pressure and crude **2** was recrystallized from glacial acetic acid. Yield 0.51 g (95%); colourless prisms; mp ca. 217°C (varies with the rate of heating); ^1H and ^{13}C nmr spectra are given in Tables 2 and 3.

Crystal structure determination

Diffraction quality crystals of **1** (0.21 × 0.23 × 0.29 mm) and **2** (0.32 × 0.25 × 0.27 mm) were obtained by crystallization from benzene and glacial acetic acid respectively. Crystals of $C_{18}H_{12}O_3$ (**1**) are monoclinic, space group $P2_1/c$, a = 13.536(3), b = 14.391(3), c = 7.159(1) Å, β = 98.69(1)°, Z = 4, V = 1378.5 Å^3, μ = 0.52 cm^{-1}, $F(000)$ = 576, MW = 276.1 g mol^{-1}, D_c = 1.33 g cm^{-3}, D_{obs} = 1.32 g cm^{-3}.

Crystals of $C_{18}H_{14}O_4$ (**2**) cocrystallize with one acetic acid molecule and are triclinic, space group $P\bar{1}$, a = 8.881(3), b = 9.786(1), c = 11.355(3) Å, α = 85.56(1), β = 88.76(2), γ = 69.46(2)°, Z = 2, V = 921.4 Å^3, μ = 0.57 cm^{-1}, $F(000)$ = 372, MW = 354.4 g mol^{-1}, D_c = 1.28 g cm^{-3}, D_{obs} = 1.27 g cm^{-3}.

Diffraction data were collected at room temperature with an Enraf Nonius CAD4 diffractometer using graphite monochromated MoKα (λ = 0.71073 Å) radiation. For both crystals an ω:2θ scan method was employed, where the ω angle changed as (0.60 + 0.34 tan θ)° for **1** and (0.65 + 0.34 tan θ)° for **2**. For **1**, 4154 reflections with h(0:19), k(0:20), l(0:10) and 3 ≤ θ ≤ 30° were measured, and for **2** 4022 reflections with h(0:11), k(−12:12), l(−14:14) and 3 ≤ θ ≤ 27°. The horizontal aperture was fixed at 1.3 mm and the vertical slit at 4 mm. Variable scan speed was used, with a maximum of 5.49° min^{-1} and a minimum corresponding to 50 s reflection^{-1}. Data were corrected for Lorentz and polarization effects, and for decay (13%) in the case of **2**. Both structures were determined by direct methods (MULTAN80) (18) and the non-hydrogen atoms were refined with anisotropic thermal parameters (SHELX76) (19). Compound **2** cocrystallizes with one acetic acid solvent molecule. All hydrogen atoms for **1** were refined in experimentally determined positions with a common isotropic thermal parameter that refined to U = 0.071(2) Å^2. The hydrogen atoms of the methyl group of the solvent molecule in **2** were placed in calculated positions (C—H = 1.08 Å, H—C—H = 109.5°) and refined as a rigid group. Distance constraints (r(O—H) = 0.9 Å, r(CO..H) = 2.4 Å, σ_r = 0.05 Å) were applied to HIB and HS. The common isotropic temperature factor refined to U = 0.126(6) Å. All other hydrogen atoms in (**2**) were refined in experimentally determined positions.[3]

The final residuals were R_w = 0.029 and R = 0.055 using $\sigma^{-2}(F)$ weights and 1981 reflections ($I > 2\sigma(I)$) for 227 parameters for **1**,

[3]Tables of fractional atomic coordinates, bond lengths, bond angles, anisotropic temperature parameters, and structure factors have been deposited as supplementary material, and may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

The tables of atomic coordinates, bond lengths, and bond angles have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, UK.

and $R_w = 0.048$, $R = 0.081$ for 2222 reflections ($I > \sigma(I)$) and 284 variables for **2**, using $\sigma^{-2}(F)$ weights (19). The maximum shift/esd for **1** was <0.2 Å and <0.34 Å for **2**, and the residual electron density ranges are (−0.24, 0.18) and (−0.26, 0.28) e Å^{-3} for **1** and **2**, respectively.

Each molecule of **2** is involved in four hydrogen bonds to molecules at $(-x, -y, 2 - z)$ acting as both a donor (O1A...OS1 = 2.620 Å and O1B...O6 = 2.606 Å) and an acceptor (O6...O1B = 2.606 Å and O7...OS2 = 2.672 Å).

The photoelectron spectra and electronic structure of 2-carbonyl furans

DIETER KLAPSTEIN,[1] CHARLES D. MACPHERSON, AND ROBERT T. O'BRIEN
Department of Chemistry, St. Francis Xavier University, Antigonish, N.S., Canada B2G 1C0

Received November 23, 1989

DIETER KLAPSTEIN, CHARLES D. MACPHERSON, and ROBERT T. O'BRIEN. Can. J. Chem. **68**, 747 (1990).

The He(I), $\lambda = 58.4$ nm, photoelectron spectra of a series of six 2-carbonyl furans and 2-furonitrile have been measured in the gas phase. The low ionization energy bands are assigned to photoionizations from π orbitals of the furan ring, orbitals localized on the carbonyl group, and orbitals of the carbonyl substituents. Changes in ionization energies within the series can be rationalized in terms of the relative conjugative and inductive effects of the substituents. Substituent inductive effects were found to be dominant. The relatively broad vibrational fine structure on the low IE bands of the carbonyl furans could result from the presence of rotational isomers of the species.

Key words: photoelectron spectra, 2-carbonyl furans, molecular orbitals.

DIETER KLAPSTEIN, CHARLES D. MACPHERSON et ROBERT T. O'BRIEN. Can. J. Chem. **68**, 747 (1990).

Opérant en phase gazeuse, on a mesuré les spectres photo-électroniques (He(I), $\lambda = 58{,}4$ nm) d'une série de six 2-carbonyl furanes et de 2-furonitrile. On a attribué les bandes aux basses énergies d'ionisation aux photo-ionisations des orbitales-π du noyau furane, des orbitales localisées sur le groupement carbonyle et des orbitales des substituants du groupement carbonyle. On peut rationaliser les changements observés dans les énergies d'ionisation des composés formant la série en fonction des effets relatifs de conjugaison et d'induction des substituants. On a trouvé que les effets inductifs des substituants prédominent. On a observé une structure fine vibrationnelle relativement importante dans les bandes de basse énergie d'ionisation des carbonyl furanes; ces observations pourraient être attribuées à la presence d'isomères de rotation des espèces.

Mots clés : spectres photo-électroniques, 2-carbonyl furanes, orbitales moléculaires.

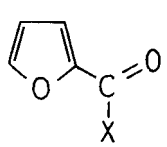
[Traduit par la revue]

Introduction

The five-membered furan ring is an important building block in organic and natural product chemistry. As well, furan itself is a model compound of heteroaromatic systems. In contrast to benzene, the π-electron distribution over the furan ring is not homogeneous due to the presence of the oxygen atom. The higher nuclear charge of the heteroatom and the concomitant higher electron density results in the appreciable dipole moment of furan and the inequality of the 2- and 3-positions towards electrophilic substitution (for a review, see ref. 1).

A method for obtaining information on the electronic structure of molecules is photoelectron spectroscopy (PES), wherein monochromatic photons are used to photoeject electrons from the occupied molecular orbitals, followed by kinetic energy analysis. Within the approximation of Koopmans' Theorem, equating the experimental vertical ionization energy (IE) with the negative of the orbital eigenvalue, the PE spectrum then gives an energy mapping of the occupied molecular orbitals. While the electronic structure of furan itself has been the subject of several PES investigations (2–7), very little has been done on substituted furans (8). Extending our earlier work on the electronic structure of carbonyl ethynes (9), propynes (10), and ethenes (11), this work presents the photoelectron spectra of a series of substituted 2-carbonyl furans **1** with X = H, F, Cl, Br, OH, and CH_3, and 2-furonitrile, and their interpretation to yield information on the electronic structures of the species.

1



Experimental

The gas-phase photoelectron spectra were obtained with an instrument incorporating a high-voltage helium discharge lamp and a 127° cylindrical sector electrostatic deflection analyzer. Data acquisition and spectral scanning were handled by a Nicolet 1170 signal averager/Apple IIe microcomputer data system. The spectral ionization energies were calibrated with nitrogen, argon, or iodomethane as internal calibrants; the ionization energies for well-resolved bands have an uncertainty of ± 0.02 eV while for broad maxima it is ± 0.1 eV.

Commercially available (Aldrich) samples of 2-furaldehyde, 2-furoic acid, and 2-furonitrile were used. 2-Furoyl chloride (Aldrich) was used following vacuum distillation. 2-Furoyl fluoride was prepared by reacting the corresponding chloride with spray-dried potassium fluoride (12), distilling off the resulting acid fluoride, and purifying by fractional distillation. 2-Furoyl bromide was prepared by reacting the acid with thionyl bromide and hexamethylphosphoramide (13) (HMPA) at −40°C, followed by vacuum distillation. In all cases the samples were checked by infrared and ^{13}C NMR spectroscopies.

Semi-empirical MO calculations were carried out using the MNDO method (14) adapted for use on a PC, and by the HAM/3 method (15) on a VAX 11/780 minicomputer. As few structural parameters are available for this series of molecules, the full geometry optimization of the MNDO program was used. The derived geometries were then used for the HAM/3 calculation. The MNDO program is not parameterized for Br, while the HAM/3 program is not parameterized for Cl or Br.

Results and discussion

The He(I) photoelectron spectra are shown on a common energy scale in Figs. 1 and 2. Also included in Fig. 1 is the spectrum of furan, which is important to the assignment of the spectra of this work. The experimental ionization energies (IEs) and observed vibrational structure are summarized in Tables 1–7. The spectrum of 2-furaldehyde has been presented elsewhere (16) but without discussion; the ring π-orbital ionization energies of 2-furoic acid and 2-furonitrile have also been reported previously (8). The results of this work are in agreement with these earlier reports.

The C_s symmetry of these planar species allows orbital classifications of only in-plane (a') or out-of-plane (a''). However, in this analysis a composite molecule approach will be taken: the occupied molecular orbitals will be assumed to be localized to a large degree on specific atoms or functional groups and will be described as such. This will allow trends in

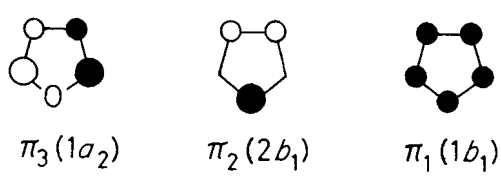
localized orbital energy changes within the series to be discussed and also allow comparison with the appropriate (π) orbital energies of furan itself.

Furan

Furan has been the subject of many studies with regards to its electronic structure. Of special interest have been the relative energies of the three occupied π molecular orbitals of the aromatic ring. These molecular orbitals (17) can be depicted by the appropriate linear combinations of atomic orbitals, the symmetries in the point group C_{2v} being given in parentheses:



The photoelectron spectrum shows that the first two ionization events give rise to sharply structured bands at 8.87 and 10.38 eV ionization energy. These are undoubtedly due to electron photoejection from the highest two occupied orbitals π_3 and π_2, respectively (2, 3). The assignment of the π_1 band is, however, less certain. Early workers (2–4) assigned the well-structured band at 17.77 eV to ionization from π_1, but subsequent molecular orbital calculations (5, 18) seem to indicate it should be found in a congested part of the spectrum at about 15.5 eV. This seems to be confirmed by a comparison of band intensity ratios of the spectra taken with He(I), 21.22 eV, and He(II), 40.8 eV, photon sources (7).

2-Furaldehyde

Substitution of an aldehyde functional group at the 2-position of the ring gives 2-furaldehyde, the PE spectrum of which is shown in Fig. 1. The aldehyde functionality has, in general, two characteristic photoelectron bands (19): ionization from the carbonyl oxygen in-plane lone-pair orbital n'_O in the region 9.5–11 eV, while the π_{CO} band is found in the region 14–15 eV. Thus for the spectrum of 2-furaldehyde, the low ionization energy region shows three distinct bands corresponding to ionization from π_3 and π_2, still mainly ring orbitals, and n'_O.

The ordering of the first three bands can be rationalized by considering the photoelectron results for similar systems. The doubly degenerate HOMO of benzene, $1e_{1g}$, has its degeneracy lifted and the two orbitals are stabilized by about 0.45 eV in benzaldehyde (20), relative to benzene. Applying this same magnitude of stabilization to the 8.87 and 10.38 eV bands of

furan leads to the prediction that the ring π orbitals of furaldehyde should give rise to bands at about 9.3 and 10.8 eV. This is in good agreement with the observed positions of the first and third bands in the furaldehyde spectrum, 9.22 and 10.76 eV, which are thus assigned to ionizations from the ring orbitals π_3 and π_2, respectively. The stabilization of these orbitals, relative to furan, reflects the inductive effect of the carbonyl group. The second band of the spectrum, 9.94 eV, is assigned to ionization from the in-plane orbital centered mainly on the carbonyl oxygen ("lone pair", n'_O). The corresponding band of acetaldehyde is found at 10.26 eV (19), that of propenal at 10.11 eV (11), that of propynal at 10.70 eV (9), and that of benzaldehyde at 9.69 eV (20).

An alternative scheme would have the band assignments, in order of increasing ionization energy, $n'_O < \pi_3 < \pi_2$. This ordering is not favoured for several reasons. Firstly, it would give the n'_O orbital an anomalously low ionization energy relative to benzaldehyde and other substituted carbonyl compounds. Secondly, substitution at the carbonyl carbon by halides and hydroxyl produces much greater IE shifts for the second band than for the first and third (*vide infra*); the n'_O orbital IE should be much more sensitive to these electronegative substituents than the more delocalized ring π orbitals. Thirdly, if the second and third bands were both assigned as ring π-orbital bands, the small energy separation, 0.8 eV, does not compare favourably with that of other monosubstituted furans (8) where the separation is ca. 1.5 eV. The preferred assignment order is $\pi_3 < n'_O < \pi_2$. This ordering, at first glance, is at odds with the results from the ultraviolet absorption spectrum of 2-furaldehyde (21), in which the singlet–singlet $\pi^* \leftarrow n$ absorption band is at lower energy than the $\pi^* \leftarrow \pi$ band. This would imply $n'_O < \pi_3$ in terms of ionization energy. However, a CNDO MO treatment (22) has shown that the relative energies of the $\pi^* \leftarrow n$ and $\pi^* \leftarrow \pi$ transitions are a result of configuration interaction in the excited state. As well, the CNDO calculation (22) of the neutral ground state gave the ordering of the orbital eigenvalues as $\pi_3 < n'_O < \pi_2$, in agreement with this work.

The carbonyl π orbital is expected to give rise to a band at about 13–14 eV, a heavily congested part of the spectrum. However, that the ring π orbitals π_3 and π_2 are both shifted to higher ionization energy by about the same amount, relative to furan, implies that any conjugation between π_{CO} and π_3 and π_2 (all of a'' symmetry in C_s) is quite small on this energy scale.

The MO calculation results are listed in Table 1. Both the HAM/3 and MNDO methods predict IEs in good agreement with the experimental vertical IEs for the out-of-plane orbitals. The calculations predict very little interaction between the ring π orbitals and the carbonyl π system. The atomic orbital coefficients also show that π_3, π_2, and π_1 of substituted furans correlate well with the $1a_2$, $2b_1$, and $1b_1$ orbitals, respectively, of furan itself. The MO calculations do not predict the carbonyl oxygen lone pair (n'_O) IE very well: the MNDO value is about 1 eV too high, while the HAM/3 value is 0.6 eV too low.

2-Furoyl fluoride

Substitution of fluorine for hydrogen at the carbonyl position introduces a heteroatom that is able to cause significant changes in the orbital energies, on account of both its high electronegativity and the favourable overlap of the fluorine orbitals with other orbitals. The low IE region of the spectrum shows only two distinct bands, but the second is probably due to two separate bands overlapping. The first band, at 9.72 eV, and the maximum of the second, at 11.10 eV, are assigned to ionizations from π_3 and π_2, respectively. This energy separation is again characteristic of substituted furans (8). The shift towards higher IEs relative to furan is indicative of the strong influence of the electronegative fluorine atom. This influence is shown even better by the shift of the n'_O band, assigned as the broad maximum at about 11.6 eV, a shift of 1.7 eV from its position in the spectrum of 2-furaldehyde. Although heavily overlapped by the π_2 band, the n'_O band probably has quite a broad profile; for acyl fluorides the n'_O description of this orbital loses some of its meaning since the MO calculations show that the in-plane carbonyl oxygen and fluorine orbitals mix to a considerable extent. This mixing in of some fluorine AO character also tends to stabilize the MO and gives the band a broader shape (more bonding character). The MO calculations, Table 2, again predict IEs in agreement with the experimental values for π_3 and π_2 but not for n'_O, although the inductive effect of fluorine, relative to the aldehyde, is clearly predicted.

2-Furoyl chloride

The spectrum is dominated by the intense band at 11.70 eV

due to ionization from the in- and out-of-plane chlorine lone-pair orbitals. These orbitals are not degenerate by symmetry but their energies are rather similar in this case, interaction of the n''_{Cl} orbital with the other out-of-plane orbitals being small. The broadness of the band is due to the slight inequivalency of the orbitals.

Ionization from the ring orbitals π_3 and π_2 gives rise to the bands at 9.56 and 10.93 eV, respectively. These are intermediate to the corresponding values for the aldehyde and the acyl fluoride, reflecting the relative electronegativities of the carbonyl substituents. The n'_O IE is much more sensitive to the carbonyl substituent than π_3 and π_2, the n'_O band shifting to lower IE by about 0.9 eV whereas π_3 and π_2 shift by less than 0.2 eV on going to the chloride from the fluoride.

2-Furoyl bromide

The lowest IE band of the spectrum is clearly due to ionization from the π_3 ring orbital. The IE is essentially unchanged relative to that of the chloride, any change in heteroatom electronegativity having a negligible effect on the ring π electrons. With this in mind the π_2-orbital band is assigned to the maximum at 10.78 eV (cf. 10.93 eV for the chloride). There is a slight destabilization which might result from interaction of π_2 with n''_{Br}, which is energetically very close. Such an interaction would also tend to stabilize n''_{Br} relative to n'_{Br}; the former is assigned to the band at 11.26 eV while the 11.04 eV maximum is assigned as n'_{Br}. The remaining band in the low IE region, at 10.36 eV, is assigned to the carbonyl n'_O orbital.

2-Acetyl furan

With reference to the molecules discussed thus far, 2-acetyl furan represents a furoyl unit with an electron-donating group attached at the carbonyl site. This results in the photoelectron bands being generally shifted to lower IEs relative to the aldehyde and the furoyl halides.

The π_3 and π_2 ring orbital bands are found at 9.02 and 10.61 eV, respectively, a modest shift of 0.2 eV or less from the corresponding values for the aldehyde. However, the carbonyl oxygen lone-pair band is more strongly affected, the n'_O band at 9.64 eV being 0.3 eV lower ionization energy than for the aldehyde. These shifts are also predicted by the MO calculations, Table 5, although the absolute value of the n'_O ionization energy does not agree well with either calculation. The broad band observed at 12.27 eV is associated with an out-of-plane

MO, which the calculations predict to be a combination of the π''_{CH_3} and π''_{CO} orbitals.

2-Furoic acid

The carboxylic acid is predicted to have four bands with IEs less than 13 eV, π_3, π_2, n'_O, and n''_O, the last one being centered on the hydroxyl oxygen. The spectrum shows three distinct bands in this region but the intensity of the second band leads to the conclusion that it is composed of two overlapping bands. The first band, at 9.32 eV, is due to ionization from the ring π_3 orbital. The second, intense, band at 10.74 eV is due to overlap of the ring π_2-orbital band (again a $\pi_2 - \pi_3$ band separation of about 1.5 eV) and the n'_O band of the carbonyl group. The latter band is shifted to higher IE relative to the aldehyde and methyl ketone, but not as much as for the acyl fluoride. This trend nicely reflects the relative electron-withdrawing abilities of the carbonyl substituents. The out-of-plane lone-pair orbital on the hydroxyl oxygen, n''_O, gives rise to the band at 11.70 eV. Conjugation of this a'' orbital with the other a'' orbitals on the furan ring (π_3, π_2) appears to be small since (i) the π_3, π_2 band separation is not noticeably different than for the other members of this series, and (ii) the n''_O band position is not substantially changed from that of (unconjugated) carboxylic acids (ref. 19, pp. 164–165): the n''_O band of acetic acid is found at 12.05 eV and for propionic acid at 12.04 eV. The MO calculations, Table 6, predict the a'' orbital IEs quite well and reinforce the preceding arguments. The IE of the in-plane n'_O orbital of the carbonyl group is again distinctly different from the predicted values: the MNDO value is 0.9 eV too high while the HAM/3 result is 0.7 eV too low.

2-Furonitrile

The nitrile substituent on the furan ring provides an interesting contrast to the carbonyl substituent in terms of the photoelectron spectra. The -CN group has both in- and out-of-plane π orbitals, as well as an in-plane lone pair centered on the nitrogen atom. The nitrogen lone pair has a substantially higher IE than the carbonyl lone pair, usually rationalized in terms of the larger *s*-atomic character of the nitrogen pair (*sp* "hybridization" versus sp^2). Thus the two lowest IE bands, at

[a]Vertical values.

9.45 and 10.98 eV, are assigned as the ring π_3- and π_2-orbital bands, respectively. The π_3 and π_2 IEs are predicted well by the MO calculations, Table 7. The group of bands in the region of 12–14 eV ionization energy belong to the nitrile orbitals. For simple alkyl nitriles (ref. 19, pp. 178–182) the ordering of the band IEs is π'_{CN}, $\pi''_{CN} < n'_N$; thus the high IE band in this group, at 12.98 eV, is assigned as n'_N. The corresponding bands for acetonitrile and propionitrile are found at 13.14 and 12.83 eV, respectively (ref. 19, pp. 178–182). The nitrile π-orbital bands here are found at 12.35 eV (π'_{CN}) and 12.58 eV (π''_{CN}). The splitting of 0.23 eV is due to the stabilization of π''_{CN} by interaction with the lower IE π_3 ad π_2 orbitals and (or) destabilization of π'_{CN} by interaction with the higher IE, in-plane, σ-type orbitals. The ordering and energies of the nitrile group orbitals are confirmed by the MO calculations.

General trends

Comparison of the spectra and band assignments to ionizations from specific orbitals brings out several trends. Figure 3 shows the experimental ionization energies of the lower IE bands. Within the approximation of Koopmans' Theorem (23), equating the experimental vertical IE with the negative of the orbital eigenvalue, the correlation diagram shows how the energies of the higher, occupied, orbitals change as a function of ring or carbonyl substituent.

For all members of this series the HOMO is a furan ring π orbital correlating with the π_3 orbital of furan. The ionization energy of the HOMO varies slightly with the electron-withdrawing ability of the substituent. The penultimate occupied out-of-plane orbital has also been identified for all species and correlates with the π_2 orbital of furan. The energy separation of π_3 and π_2 of furan has been conserved in the substituted compounds. This implies that interactions between any a'' orbitals centered on the substituents and the ring a'' orbitals are rather small, on the photoelectron energy scale; otherwise one might expect the π_3, π_2 separation to vary as a result of unequal interactions with π_3 and π_2 due to energy or proximity considerations. This is borne out by the MNDO and HAM/3 MO calculations, which predict the π_3 and π_2 orbital ionization energies quite well and also show, by way of the atomic orbital coefficients, that the source orbitals are essentially the same as those of furan itself in terms of nodal characteristics. However, this does not imply that conjugation of the out-of-plane orbitals is negligible, only that the observed π_3, π_2 band separation does not seem to reflect them. This could be due to the delocalization of the ring electrons. That conjugation of the out-of-plane orbitals can be measured by PES is shown by the splitting of the π_{CN} bands of 2-furonitrile. Unfortunately, such an indicator is not available for the carbonyl compounds.

The substituent inductive effect arguments are further exemplified by the energies of the n'_O orbitals of the carbonyl compounds, which show large variations in accord with the electronegativities of the carbonyl substituents, e.g., F versus H. The magnitudes of the n'_O band shifts parallel those found for other substituted carbonyls (9–11).

For carbonyl substituents with loosely bound lone pairs, the low IE regions of the spectra show the corresponding bands. Interaction of the lone-pair orbitals with the ring π orbitals

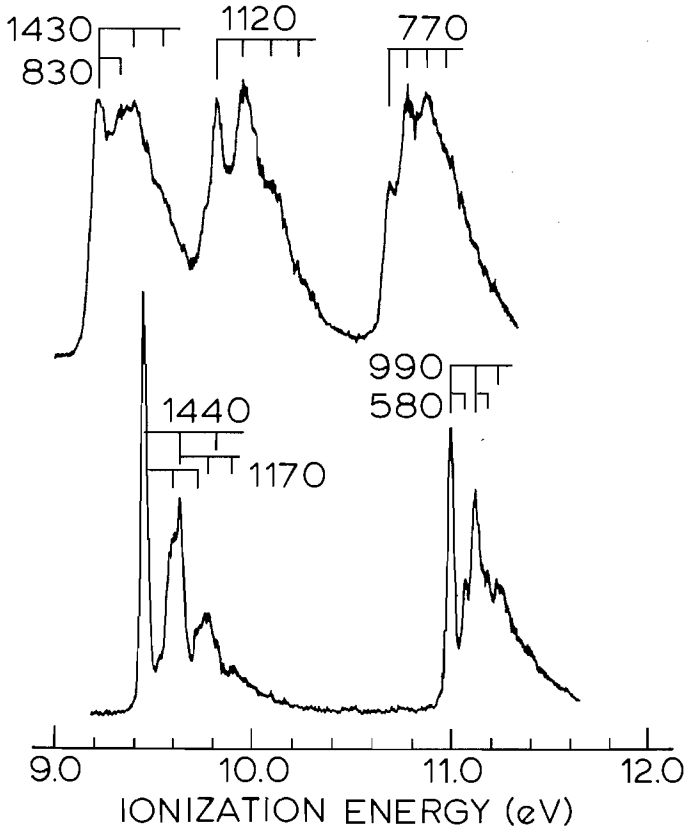

FIG. 4. Vibrational structure on the low ionization energy bands of 2-furaldehyde (top) and 2-furonitrile (bottom). Vibrational intervals are in wavenumbers.

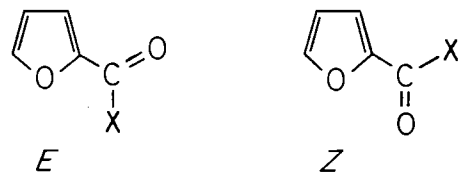
is small. For similarly substituted acetylenic and ethylenic carbonyl compounds (9–11) the strongest interaction of the substituent lone-pair orbitals was found to be with the carbonyl π system. Unfortunately in this series the carbonyl π-orbital bands are found in the heavily congested part of the spectra and could not be identified. However, comparison of the spectra of the furan carbonyl species with that of furonitrile suggests that for the carbonyl species the π_{CO} band is one of the bands in the region of 13–14 eV ionization energy.

The semiempirical MO calculations predict ionization energies that, in general, agree well with the experimental values where the PES bands are resolvable. Within the series of compounds the calculations confirm that the effect of the carbonyl group and its substituents on the ring π orbitals is mainly of an inductive nature, and justify our interpretation of the photoelectron spectra in terms of orbitals localized on the ring and on the carbonyl group. However, neither MO method satisfactorily predicts the ionization energies of the in-plane lone-pair orbital (n'_O) of the carbonyl oxygen or the lone-pair orbitals of other heteroatom substituents. The cause is undoubtedly the choice of initial atomic parameters used in the calculations. This series of molecules could be treated by more rigorous MO methods to investigate these problems. Nevertheless, the calculations do correctly predict the relative changes in the n'_O IE as a function of carbonyl substituent changes. It is also of interest that the MO calculations predict the most tightly bound π orbital of the furan ring, π_1, to have IEs in the range 15.5–16.5 eV, in agreement with previous arguments for furan itself (5, 7, 18).

The experimental ionization energies give directly the energies of the doublet ground and excited states of the molecular radical cations. These, along with the observed vibrational structure, may be used in identifying and characterizing the electronic states of the molecular ions.

The lower IE bands of all species show some vibrational fine structure (Tables 1–7). The π_3 bands exhibit cationic vibrational intervals in the range 1000–1400 cm^{-1}, probably excitation of the cationic ring $\nu_{C=C}$ mode (1486 cm^{-1} in the neutral ground state of furan). The π_2 bands usually exhibit a smaller vibrational interval and a broader Franck–Condon envelope, both in accord with the increased bonding character of π_2 relative to π_3. The vibrational structure of the furan bands has already been discussed elsewhere (2, 3). The structures of the 2-furaldehyde and 2-furonitrile bands are shown in Fig. 4. Assignment of the vibrational intervals to specific cationic modes is difficult due to the large number of vibrational modes possible and the lack of specific experimental vibrational data. The π_3 band shows a progression of 1440 cm^{-1}, probably the ring C=C stretch corresponding to the 1486 cm^{-1} mode of furan. The π_2 band shows progressions of 1000 cm^{-1} and 570 cm^{-1}. Possible vibrational progressions are indicated for the π_{CN} bands but they are only tentative due to the considerable overlap of the bands. Clearly evident from a comparison of the spectra is that the π_3 and π_2 bands of all the carbonyl compounds are considerably less resolved than the corresponding bands of furan itself and 2-furonitrile, all spectra being run with the same instrumental resolution.

The cause of the broadness of the vibrational fine structure of the carbonyl furans could be the rotational isomerism of the species, two planar conformations being possible:



The notation *E* and *Z* indicates the relative orientations of the oxygen atoms. Existence of two rotamers has been known for some time from other spectroscopic measurements. Interpretation of the data has been hampered by the strong dependence of the rotational equilibrium on the medium and the low energy barrier to interconversion.

From IR and variable-temperature NMR studies it appears that the *Z* isomer of 2-furaldehyde is the more stable in the gas phase and in nonpolar solvents (24, 25), with the *E* isomer being about 4 kJ/mol higher in energy (26). Thus appreciable quantities of both rotamers should exist in the gas phase at room temperature. Similar rotational isomerism has been observed for 2-furoyl fluoride (25, 27) and chloride (28), and 2-acetyl furan (29). As well, MO calculations on the relative stabilities of the rotamers of 2-furaldehyde (30) and other substituted carbonyl furans (31) have been reported. Both experimental and theoretical results indicate that for all species the energy difference between the two planar configurations is small, with a low barrier to interconversion. Even though the total electronic energies of the two rotamers are similar, the energies of individual orbitals might vary slightly between the two forms, superimposition leading to the observed broad structure of the photoelectron bands. To investigate this possibility MNDO MO calculations were carried out for 2-furaldehyde and 2-furoyl fluoride, in which the carbonyl group orientation relative to the plane of the five-membered ring was varied. For the aldehyde, Fig. 5 shows the variation of the orbital eigenvalues as a function of the angle of rotation ϕ. It can be seen that the

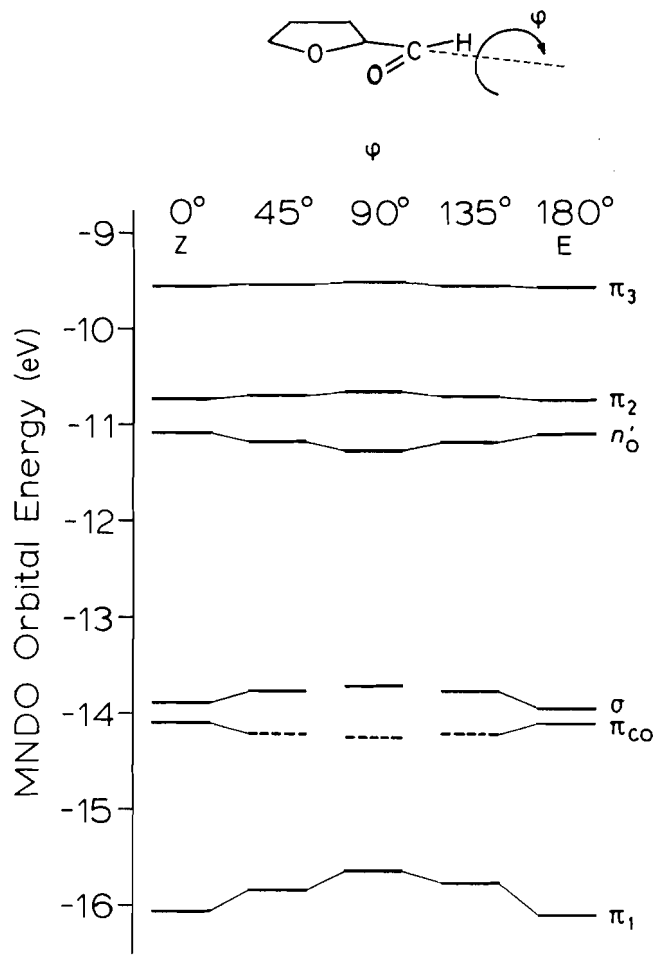


FIG. 5. MNDO calculated orbital eigenvalues for conformations of 2-furaldehyde as a function of the angle of rotation. The calculated heats of formation are -178.955 kJ mol^{-1} for the Z isomer and -178.603 kJ mol^{-1} for the E isomer.

presence of the two conformers, and their free interconversion, could lead to broadening of the associated photoelectron bands and their vibrational fine structure. Furthermore, the calculation results again predict very little delocalization energy between the ring π orbitals and the carbonyl π system since the eigenvalues of the planar configurations differ only slightly from those of the nonplanar configurations. The conclusions from the 2-furoyl fluoride calculations are similar.

Conclusions

The 58.4 nm photoelectron spectra of 2-furaldehyde and a series of substituted carbonyl furans, as well as 2-furonitrile, have been interpreted by comparison within the series and by reference to the relative inductive effects of the substituents. Assignments were made for the low ionization energy bands, which result from ionization out of the ring π orbitals and lone-pair orbitals centered on the substituents. Interaction between the furan ring π orbitals and the carbonyl and substituent groups is mainly of an inductive nature. The qualitative trends of ionization energy changes within the series are supported by the semiempirical HAM/3 and MNDO molecular orbital calculations. As well, the calculations show that rotational isomerism could result in the broad vibrational fine structure observed in the photoelectron spectra of the 2-carbonyl furan compounds.

In slightly acidic aqueous solutions, malvin essentially exists, in a stable form, as a fast equilibrating reaction between a ring structure, the hemiacetal B, and a chain structure, the *cis*-chalcone C_E. The temperature-jump technique has been used for the determination of the relaxation time τ characterizing this equilibrium. At 20°C τ-values were found to be in the range 1s (for the more acidic solutions) to 2×10^{-4} s (for the neutral solutions). Both buffered and unbuffered solutions were investigated. It was found that τ is largely dependent upon pH and upon the concentration of the buffer. For instance, at constant pH, a plot of the observed first-order rate constant τ^{-1} versus the acetic acid – sodium acetate buffer concentration shows a nonlinear variation that can only be interpreted as a change in the proton transfer rate-limiting step with the buffer concentration. At 20°C, the constant $K = [C_E]/[B]$ is 0.25 (±0.05) and the enthalpy change ΔH associated with this equilibrium is 20.7 (±2) kJ mol^{-1}. Therefore, increasing the temperature greatly enhances the stability of the open *cis*-chalcone isomer. Possible implications arising from the existence of a fast chemical ring-closure reaction, in the case of natural anthocyanins, for the biosynthesis of flavonoids are discussed. In particular, it is suggested that, along with the main biosynthetic pathway to flavonoids, a minor pathway involving the anthocyanin *cis*-chalcone C_E could also occur under favorable circumstances. Physico-chemical conditions in the plant organelles containing flavonoids (vacuoles) make this alternative plausible.

Key words: flavonoids, malvin, chalcone, catalysis, temperature jump.

RAYMOND BROUILLARD et JACQUES LANG. Can. J. Chem. **68**, 755 (1990).

En solution aqueuse légèrement acide, la malvine existe essentiellement, et de manière stable, sous forme d'un équilibre rapide entre la forme cyclique hémiacétal B et la forme ouverte *cis*-chalcone C_E. En utilisant la technique de saut de température par effet Joule, nous avons mesuré pour cet équilibre des temps de relaxation d'environ 1s (milieux les plus acides proches de pH 1) à environ 2×10^{-4} s (milieux proches de la neutralité), à 20°C. Les mesures ont été réalisées avec des solutions tamponnées (acide acétique – acétate de sodium ou acide phosphorique – acétate de sodium) et des solutions sans tampon. Le temps de relaxation est influencé par le pH et aussi par la concentration du tampon. On trouve par exemple, qu'à pH constant, la relation entre l'inverse du temps de relaxation (constante cinétique d'ordre 1), et la concentration du tampon n'est pas linéaire. Ce phénomène peut être interprété par un changement de l'étape de transfert de proton limitant la vitesse de la réaction avec l'augmentation de la concentration du tampon. La constante $K = [C_E]/[B]$, vaut, à 20°C, 0,25 (±0,05) et la variation d'enthalpie ΔH de l'équilibre est égale à 20,7 (±2) kJ mol^{-1}. Une élévation de température favorise donc la formation de l'isomère *cis*-chalcone C_E. On discute aussi de la possibilité de l'existence, chez les flavonoïdes, d'une voie mineure de biosynthèse basée sur la formation chimique rapide de l'hétérocycle oxygéné central à partir de la fermeture de la *cis*-chalcone C_E. Cette forme est probablement abondante dans les milieux vacuolaires contenant des anthocyanes.

Mots clés : flavonoïdes, malvine, chalcone, catalyse, saut de température.

Introduction

Ten years ago, one of us published a series of articles essentially devoted to the structural transformations that occur when a natural anthocyanin is dissolved in an aqueous medium (1). The existence, in the case of these natural molecules, of a ring–chain isomeric equilibrium leading to an open chalcone structure, previously unknown, was demonstrated (eq. [1]). The stereostructure of the chalcone, however, could not be established, and it is now believed that it is the *trans*-chalcone C_Z. In particular, relaxation times for the interconversion between the ring form (hemiacetal B), and the chain form (*trans*-chalcone C_Z), were found to be larger than 1 h at room temperature.

More recently, McClelland and co-workers (2) convincingly

[2] 
demonstrated that, in the case of some synthetic, non-natural flavylium cations, the ring-opening – ring-closure equilibrium is fast and is characterized by a relaxation time, in slightly acidic buffered aqueous solutions, lower than 1 s. They attributed this relaxation process to a rapid, base-catalyzed reaction between the hemiacetal ring structure and the *cis*-chalcone chain structure (eq. [2]). This interesting finding prompted us to check whether such a reaction also occurs for natural anthocyanins. As will be seen in the following, the existence of such a fast reaction has indeed been evidenced from temperature-jump (T-jump) experiments, in the case of malvin. The reaction between the hemiacetal form and the *cis*-chalcone form of malvin has been found to occur over a large pH range in aqueous solution at room temperature. Malvin is an anthocyanin frequently found in colored organs of higher plants (3). Moreover, our kinetic results completely agree with the proposed mechanism given in ref. 2*d* for the interconversion shown in eq. [2]. Thus, the originality of our work essentially lies in the extension to natural anthocyanins of the existence of this fast ring–chain isomeric equilibrium, as well as in a detailed treatment of the temperature-jump spectroscopic relaxation amplitudes. Finally, since anthocyanins belong to a large group of the biosynthetically related flavonoids, it may be worth asking whether the fast spontaneous chemical ring-closure reaction is of some biological importance.

Experimental

Materials

Solutions were prepared using distilled water. The purity of malvin chloride (Roth) was checked both by HPLC and by recording its ^{1}H NMR and UV–visible absorption spectra according to published procedures (4). Acetic acid, sodium acetate, potassium chloride, hydrochloric acid, sodium hydroxide, and phosphoric acid were all purchased from Merck (Suprapur). Aqueous solutions, most frequently with a 0.20 M ionic strength adjusted by means of KCl, were prepared in the following way: 1.50 mg of malvin chloride was added, at room temperature, to 5 mL of a buffer (acetic acid – sodium acetate or phosphoric acid – sodium acetate) with a known amount of KCl. After vigorous stirring or sonication, the solution was allowed to stand for about half an hour, in order for it to reach equilibrium before running the temperature-jump experiment. A given aliquot (3.0 mL) of the solution was then transferred to the T-jump cell and the pH was recorded, before and after the T-jump run, by means of a Metrohm 654 pH-meter fitted with a small combined glass electrode (EA 125). Experiments where pH values had shifted by more than 0.05 were discarded. Malvin solutions without buffer were also investigated.

Temperature-jump relaxation measurements

Absorbance changes, induced by small temperature jumps, were recorded using a Joule-heating double beam spectrometer described previously (5). Most of the relaxation transient signals were obtained for temperature jumps going from 16.5 to 20°C and were detected at a wavelength of 325 nm, which corresponds to the best signal-to-noise ratio obtainable with our system. The initial temperature was controlled within ±0.1°C, using a Haake thermo-cryostat, in the temperature range 2–20°C. The bandwidth of the spectrometer was set to a value close to 2.5 nm. For each solution investigated, several runs (usually 3–6) were undertaken. For each run, the resulting data (absorbance changes versus time) were stored on a transient recorder (Datalab). The 3–6 runs were added using a computer (Computer Automation Inc.) and the relaxation amplitude Amp as well as the relaxation time τ were obtained by fitting the equation: Amp $\times$ exp $(-t/\tau)$, where t is time, to the data, with Amp and τ as adjustable parameters, using a nonlinear least-squares procedure (6). Relaxation amplitudes (Amp) reported in the following are expressed in arbitrary absorbance units. No attempt was made to calibrate the temperature-jump spectrometer in absorbance units.

Equilibrium measurements

Ultraviolet–visible absorption spectra of malvin chloride solutions, at different temperatures and different pH values, were recorded with a Perkin Elmer Lambda 5 spectrophotometer equipped with a thermostated quartz cuvette. Stopped-flow equilibrium measurements were run using a commercial apparatus (Durrum–Gibson D-110).

Results and discussion

When an acidic malvin chloride solution, previously equilibrated, is submitted to a fast transient temperature jump from 16.5 to 20°C, a fast change in the absorbance of the solution is observed in the spectral range 250–400 nm. Figure 1 shows that the change in the amplitude of the relaxation process obtained from the T-jump experiment, as a function of wavelength, parallels the change in the absorbance obtained when the solution is submitted to the same temperature variation and the absorbance recorded with a conventional spectrometer. UV–visible absorption spectra, at two different temperatures for a pH 3.46 malvin solution, are shown in Fig. 2. It is usually admitted that the strong absorption band close to 275 nm is characteristic of the hemiacetal cyclic B structure, whereas the shoulder, visible in the neighbourhood of 330 nm, is likely to correspond to a chalcone structure (1). Another structure, resulting from the addition of water to the C-4 position of the malvin flavylium cation (see Scheme 1), may well contribute slightly to the absorption in the 275 nm region. However, this species is only a minor one, and its presence does not actually affect the relaxation process investigated in this study. As long as the pH is not too low (pH > 3), the very small amounts of the colored flavylium cation AH^+ and the colored neutral bases A (Scheme 1) produce some absorption, not only in the visible, but also in the UV range. As will be shown later, they have no effect on the kinetics of the hemiacetal B – *cis*-chalcone C_E reaction (Scheme 1); it is only the relaxation amplitude which diminishes when the flavylium cation becomes stable, that is, in the more acidic solutions (pH < 3). At room temperature and below, the *trans*-chalcone C_Z (Scheme 1) only appears in negligible quantity (1). Inspection of Figs. 1 and 2 shows that increasing the temperature favors the C_E open form at the expense of the B ring form. Increasing the temperature well above room temperature would significantly increase the quantity of the malvin *trans*-chalcone C_Z (1).

In the pioneering chemical relaxation work on anthocyanins (1), no evidence for the existence of a fast ring–chain hemiacetal B – *cis*-chalcone C_E equilibrium was reported for the following reasons: (i) experiments were made in the visible

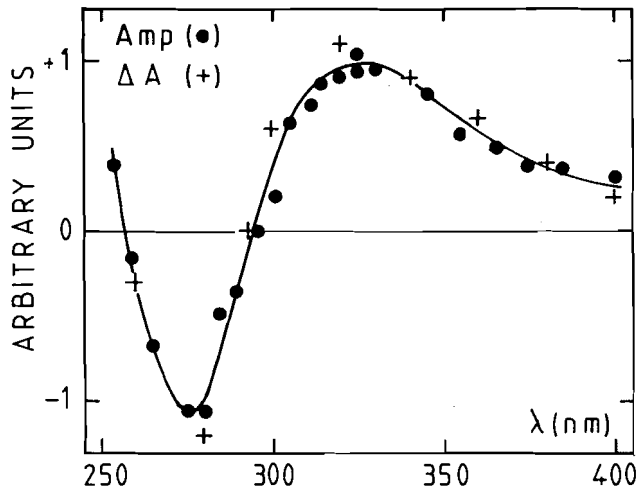

FIG. 1. (●): Plot of the hemiacetal–*cis*-chalcone relaxation amplitude, Amp, of malvin (1.50×10^{-4} M) versus wavelength. T_i = 16.5°C; T_f = 20°C; pH = 4.57; I = 0.20 M. (+): Difference in the absorbance, ΔA, of a pH 4.57 malvin solution (1.50×10^{-4} M), initially at 16.5°C and finally at 20°C, as a function of wavelength.

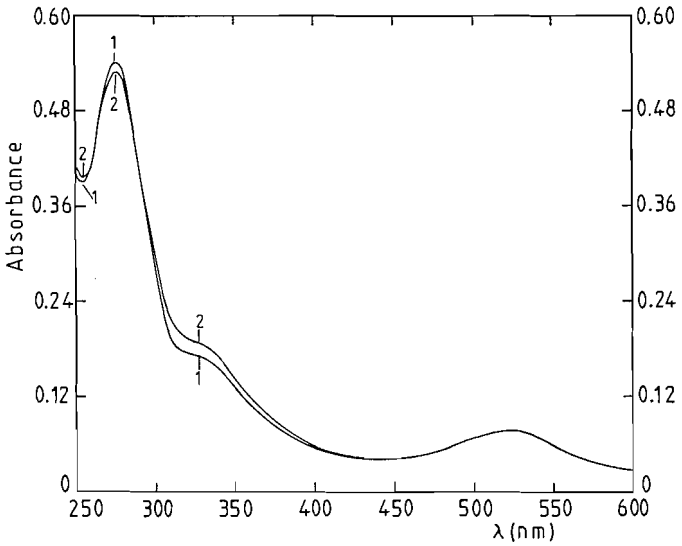

FIG. 2. Ultraviolet–visible absorption spectra of malvin (5.40×10^{-4} M) in aqueous solution at pH 3.46 and 0.20 M ionic strength; l = 1 mm. (1): T = 6.2°C; (2): T = 20.5°C.

range where the flavylium cation AH^+ and the neutral bases A are the only absorbing species (Fig. 2); (ii) at pH > 1, the $B \rightleftharpoons C_E$ equilibrium is much faster than the $AH^+ \rightleftharpoons B + H^+$ equilibrium and therefore optical detection, in the visible range, is only sensitive to the second equilibrium. This also means that the hydration equilibrium constant K_h, previously written as $([B] \times a_{H^+})/[AH^+]$, corresponds in fact to the expression $([B] + [C_E]) \times a_{H^+}/[AH^+]$, where [B], $[C_E]$, and $[AH^+]$ are the equilibrium concentrations of species B, C_E, and AH^+, respectively, and a_{H^+} is the activity of the hydronium ion (7).

From a kinetic viewpoint, the situation encountered in Scheme 1 is interesting and rather unusual. Since the equilibrium between the hemiacetal B and the *cis*-chalcone C_E is coupled to two equilibria ($AH^+ \rightleftharpoons B + H^+$ and $C_E \rightleftharpoons C_Z$), which are slow compared to the $B \rightleftharpoons C_E$ equilibrium, the observed first-order rate constant $k_{obs} = \tau^{-1}$ associated with this equilibrium is unaffected by their presence. Such a result is illustrated by the great similarity between our kinetic results on malvin and the results reported in ref. 2*d* in the case of the 4′-methoxy-3-methylflavylium cation (eq. [2]), which had been precisely selected for the absence of a quinonoidal base A and a *trans*-chalcone C_Z. One can conclude that, whatever the structural complexity of the anthocyanin or the synthetic flavylium salt under study, the hemiacetal–*cis*-chalcone equilibrium will be characterized by a kinetic first-order relaxation law identical to the one that would be obtained in the absence of all or any one of the other structures drawn in Scheme 1. However, as will be seen in the following, the variation of k_{obs}, as a function of $[H^+]$ or of the concentration of the buffer, does not conform to any simple rate law but can be understood using the model established by McClelland *et al.* (2*d*) for the 4′-methoxy-3-methyl flavylium cation.

Relaxation amplitudes

The relaxation amplitude Amp associated with the $B \rightleftharpoons C_E$ equilibrium can be affected by the presence of the other species shown in Scheme 1. For instance, when B and C_E become minor species, the relaxation signal disappears. This occurs at both low and high pH values. The lower limit is in the pH range 1–2 (Fig. 3), and the upper limit is close to neutrality. In fact, for pH values above 7, a new absorption band, with a maximum of absorption close to 400 nm, appears. We attribute this spectral feature to the presence of the ionized C_E^- chalcone form. Therefore, at pH > 7, our system transforms into a new one. In this work, investigations were limited to the acidic pH range where no ionized chalcone form could be found to occur in measurable amount. It is remarkable that the hemiacetal–*cis*-chalcone relaxation exists in the pH range usually found in vacuoles. Vacuoles are the organelles where flavonoids are stored if not synthesized. Effectively, in the case of the vacuoles of epidermal cells of many flowers, pH values have been demonstrated to range from 2.5 to 7.5 (8).

The amplitude for the relaxation process of a two-species equilibrium, as monitored by absorption spectroscopy, was previously derived for the case of the tautomerism of adenine and cytosine (9). The relaxation amplitude for the $B \rightleftharpoons C_E$ equilibrium is given therefore by eq. [3],

$$[3] \quad \text{Amp} = \frac{\Delta H}{RT^2} \times \Delta T \times \frac{K}{(1+K)^2} \times l \times (\varepsilon_{C_E} - \varepsilon_B)([B] + [C_E])$$

where ΔH is the molar enthalpy, K the equilibrium constant, l the optical pathlength, ΔT the magnitude of the temperature jump, ε_{C_E} and ε_B are the molar absorption coefficients, and $[C_E]$ and [B] are the equilibrium concentrations of C_E and B at temperature T, respectively. If one neglects the small amounts of the ionized quinonoidal base A^-, of the C-4 hydration product as well as of the *trans*-chalcone C_Z, eq. [3] transforms into eq. [4],

$$[4] \quad \text{Amp} = \frac{\Delta H}{RT^2} \times \Delta T \times \frac{K}{(1+K)^2} \times l \times (\varepsilon_{C_E} - \varepsilon_B) \times \frac{K_h(1+K)C_0}{K_a + K_h(1+K) + a_{H^+}}$$

where K_h is the hydration constant, K_a the acid–base constant defined as $[A] \times a_{H^+}/[AH^+]$, a_{H^+} the activity of the hydronium ion, and C_0 the concentration of malvin. At pH 4.55 and λ = 325 nm with T_i = 16.5°C and T_f = 20°C, we have observed that a plot of the relaxation amplitude, as a function of the

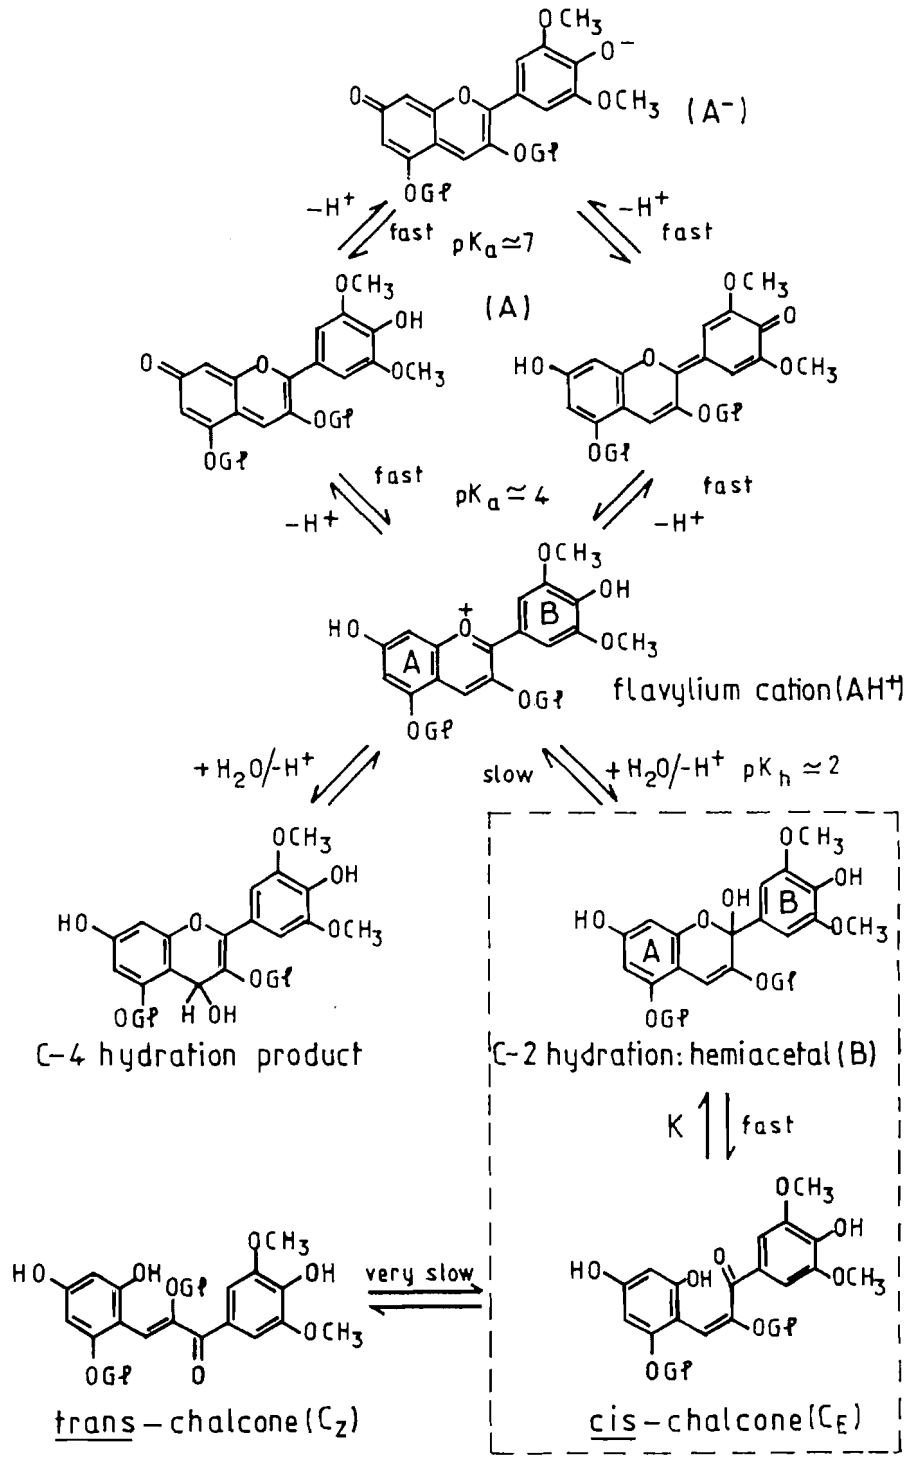

SCHEME 1

concentration of malvin (up to $C_0 = 7.2 \times 10^{-4}$ M), gives a straight line passing through the origin. The change in the amplitude versus the wavelength of observation is reported in Fig. 1. Due to so many interchanging malvin forms, it was not possible to seriously determine either the separate values of ε_{C_E} and ε_B or their difference. The results in Fig. 1 only permit us to conclude that, at a wavelength larger than 295 nm, $\varepsilon_{C_E} > \varepsilon_B$, and that at wavelengths between 255 and 295 nm the reverse is true. Equation [4] shows that Amp should increase as a_{H^+} decreases, i.e., as the pH increases, and should level off for $a_{H^+} \ll K_a + K_h(1 + K)$. This has indeed been found, as shown in Fig. 3, the levelling off of Amp (Amp_{max}) occurring at pH > 3.5, approximately. Equation [4] also predicts that, for sufficiently acidified solutions (pH < 1), the relaxation amplitude should become vanishingly small and this is indeed seen in Fig. 3. This can be understood on the basis of the formation of large quantities of the flavylium cation AH^+, which is the only stable species in the lowest pH range (Scheme 1). Another interesting feature appears in Fig. 3. Since $K_a/K_h \cong 10^{-2}$ (1), the a_{H^+} value at $Amp_{max}/2$ equals $K_h(1 + K) = 7 \times 10^{-3}$ M at 20°C. This gives $p(K_h(1 + K)) = 2.15$, a value in good agreement with previous estimates of

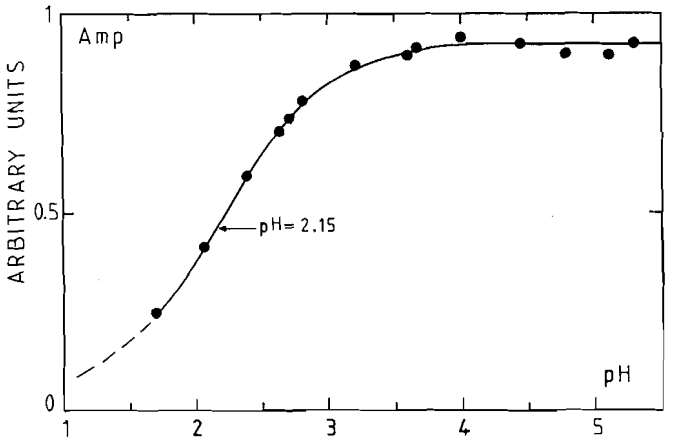

FIG. 3. Plot of the hemiacetal–*cis*-chalcone spectroscopic relaxation amplitude as a function of pH. Concentration of malvin chloride: 4.4×10^{-4} M; T_i = 16.5°C; T_f = 20°C; λ = 325 nm; I = 0.20 M (KCl).

the equilibrium constant for the hydration reaction of malvin chloride (10).

The value of K was obtained by performing a suitable stopped-flow experiment according to a procedure described previously (2). A slightly acidic aqueous solution containing malvin is mixed, at 20°C, with an equal volume of a strongly acidic aqueous solution of perchloric acid (0.58 M). After complete rapid mixing of the two solutions, the decrease in the transmittance is recorded at 540 nm, a value close to the maximum of absorption of the flavylium form AH^+. One observes that the flavylium cation is regenerated according to a two-step mechanism. This time the fastest step corresponds to the acid-catalyzed dehydration reaction of the hemiacetal B, whereas the slower step is now characteristic of the base-catalyzed ring closure of the *cis*-chalcone to the hemiacetal. Indeed, for pH values lower than 1, the first-order rate constant for the ring closure becomes smaller than the pseudo-first-order rate constant for the dehydration process. It is demonstrated that the ratio of the amplitude of the slow step to the amplitude of the fast step gives K = 0.25 (±0.05) at 20°C. It should be noticed that this value is very similar to the one measured, at 25°C, in the case of the 4′-methoxy-3-methylflavylium cation (K = 0.25) (2*d*). In eq. [4], K is defined as the ratio of the concentration of the minor isomer (C_E) to the concentration of the major isomer (B). In ref. 2*d* the reverse definition has been adopted. Since $K_h(1 + K)$ is 7×10^{-3} M and K = 0.25, a rough estimate of K_h gives 5.6×10^{-3} M (pK_h = 2.25).

Assuming that ΔH and $(\varepsilon_{C_E} - \varepsilon_B)$ do not vary with temperature and also that ln $(1 + K)$ can be approximated by K, one obtains eq. [5] (9).

$$[5] \qquad \frac{d[\ln (\text{Amp} \times T^2)]}{dT} = (1 - 2K)\frac{d \ln K}{dT}$$

A plot of ln (Amp × T^2) as a function of the reciprocal of the temperature should therefore be linear with a slope equal to $-(\Delta H/R)(1 - 2K)$. Such a linear relationship has indeed been found and it is expressed by $\ln (\text{Amp} \times T^2) = 20.6 - 1243/T$ (r = −0.996). ΔH is found to be 20.7 (±2) kJ mol^{-1}. The ring-opening reaction is endothermic and raising the temperature will greatly favor the open isomer. The somewhat large value for ΔH can, at least, partly explain the excellent signal-to-noise ratios that were obtained for the relaxation curves.

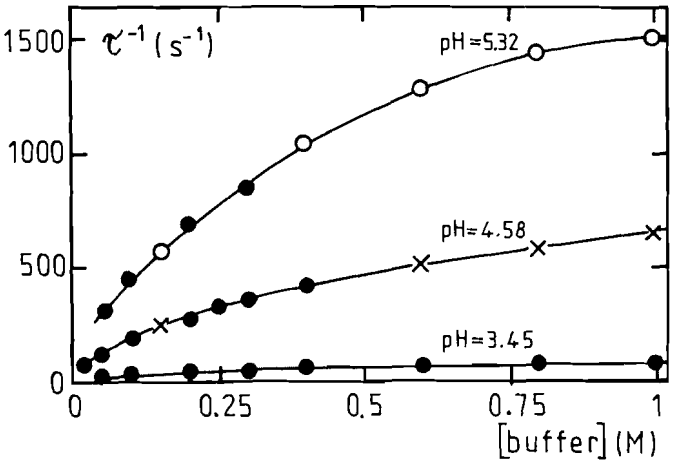

FIG. 4. Plot of the reciprocal of the relaxation time as a function of the acetic acid – sodium acetate buffer concentration at different pH values. (●): I = 0.20 M; (×): I = 0.50 M; and (○): I = 1.00 M. λ = 325 nm. Concentration of malvin chloride: 4.3×10^{-4} M. T_i = 16.5°C. T_f = 20°C.

Relaxation kinetics

From pH 1 to 7, relaxation times were found to range, approximately, between 1s and 2×10^{-4} s at 20°C. In the absence of buffer, relaxation times were observed to decrease as the pH increased. At constant pH, relaxation times became smaller as the concentration of the buffer increased. Typical results are shown in Fig. 4. The reciprocal of the relaxation time τ^{-1} is the first-order rate constant usually measured for acid- and base-catalyzed reactions. One can see that τ^{-1} is not affected by the ionic strength of the medium (Fig. 4). However, the most striking feature of Fig. 4 is the curvature exhibited by the change in τ^{-1} as a function of the concentration of the buffer. Such a result seems to indicate a reduction in the strength of the catalyst as its concentration increases. It is, however, difficult to admit this hypothesis since no change in the molecular structure (as, for example, self-association) of either acetic acid or sodium acetate occurs in the concentration range used in the present work (Fig. 4). A variation of τ^{-1} with the acid form of the buffer concentration, analogous to that shown in Fig. 4, was previously observed by McClelland *et al.* (2*d*), in the case of the hemiacetal–*cis*-chalcone system of the artificial 4′-methoxy-3-methylflavylium cation (eq. [2]). It was assumed to be related to a change in the rate-limiting step with the increase in the concentration of the buffer. The same conclusion probably applies to our own results. The mechanism given in ref. 2*d* is shown in eq. [6]. In dilute buffer, the rate-limiting step

$$[6] \qquad B \underset{k_3^0 + k_3^H[H^+] + k_3^{HA}[HA]}{\overset{k_{-3}^{OH}[OH^-] + k_{-3}^0 + k_{-3}^A[A^-]}{\rightleftharpoons}} B^- + H^+ \overset{k_{-2}}{\underset{k_2}{\rightleftharpoons}} C_E^- + H^+ \underset{k_1^{OH}[OH^-] + k_1^0 + k_1^A[A^-]}{\overset{k_{-1}^0 + k_{-1}^H[H^+] + k_{-1}^{HA}[HA]}{\rightleftharpoons}} C_E$$

is the proton transfer of the third step, and in more concentrated buffer it is the proton transfer of the first step, whereas in fairly concentrated buffer it is the ring-closure and ring-opening equilibrium occurring between the two anions which limits the rate. A detailed kinetic analysis of eq. [6] has been given (2*d*). It takes into account all the base and acid catalytic effects brought about by the species present in the aqueous medium. Rate constants in eq. [6] are those defined by McClelland *et al.* (2*d*). They have been shown (2*d*) to be related according to

TABLE 1. Rate constants for the hemiacetal–chalcone isomerization in the case of malvin

Constant	Expression	Value[a]
$k_1^0(s^{-1})$	$k_{-1}^{H}K_C$	32
$k_{-1}^0(s^{-1})$	$k_1^{OH}K_W/K_C$	2.6×10^4
$k_{-3}^0(s^{-1})$	$k_3^{H}K_B$	5×10^{-3}
$k_3^0(s^{-1})$	$k_{-3}^{OH}K_W/K_B$	1.6×10^8
$k_1^A(M^{-1}\,s^{-1})$	$k_{-1}^{HA}K_C/K_{HA}$	1×10^6
$k_{-3}^A(M^{-1}\,s^{-1})$	$k_3^{HA}K_B/K_{HA}$	1.6×10^2
$k_1^{OH} = k_{-3}^{OH}(M^{-1}\,s^{-1})$	Measured	1.3×10^{10}
A	$k_1^{OH}K_W$	$1.6\times10^{-4}(2\times10^{-4})$
B	$k_1^{A}K_{HA}$	32(32)
C	$K_{HA}k_1^Ak_3^{HA}/k_3^0$	$10^3(1.3\times10^3)$
D	$(K^{-1}/(1+K^{-1}))K_{HA}k_1^A/K_CK^-k_3^0$	$3.8\times10^4(1.6\times10^4)$
E	$(K^{-1}/(1+K^{-1}))K_{HA}k_1^Ak_3^{HA}/K_Ck_2k_3^0$	$2.1\times10^4(2.8\times10^4)$

[a]Values in parentheses are those obtained from the solid line in Fig. 5 using eq. [9]. K^- is 6.3×10^{-4} and k_2 has been taken from ref. 2*d* ($6\times10^6\ s^{-1}$).

eqs. [7] and [8], where K_C, K_B, K_W, and K_{HA} are the acidity constant of the *cis*-chalcone C_E, the acidity constant of the hemiacetal B, the dissociation constant of water, and the acidity constant of the buffer, respectively.

$$[7]\quad K_C = \frac{k_1^0}{k_{-1}^H} = \frac{k_1^{OH}K_W}{k_{-1}^0} = \frac{k_1^AK_{HA}}{k_{-1}^{HA}}$$

$$[8]\quad K_B = \frac{k_{-3}^0}{k_3^H} = \frac{k_{-3}^{OH}K_W}{k_3^0} = \frac{k_{-3}^AK_{HA}}{k_3^{HA}}$$

k_1^{OH}, k_{-3}^{OH}, k_{-1}^H, k_3^H, k_{-1}^{HA}, and k_3^{HA} are diffusion-controlled rate constants whose values are close to $5\times10^9\,M^{-1}\,s^{-1}$. At 20°C and I = 0.20 M, K_W and K_{HA} are $10^{-13.9}$ and $10^{-4.50}$, respectively. At the same temperature and ionic strength, K_C has been measured by us and found to be $10^{-8.20}$. K_B could not be measured and its value (10^{-12}) has been taken from ref. 2*d*. Values of the rate constants k_1^0, k_{-1}^0, k_1^A, k_3^0, k_{-3}^0, and k_{-3}^A are reported in Table 1. Strong experimental support was given to the mechanism in eq. [6] by the existence of a curved relationship between the product $\tau^{-1}\times[H^+]$ and the HA concentration (2*d*). It was also shown that this relationship does not depend on the free acidity of the medium. A similar plot is found in the case of the hemiacetal–*cis*-chalcone equilibrium of malvin (Fig. 5). Therefore the assumption made by McClelland and co-workers (2*d*) to interpret their results can basically also be used in our case. Since B^- and C_E^- are highly unstable species under our experimental conditions (acidic pH range), only one relaxation process is observable in the case of eq. [6]. The reciprocal of the relaxation time has been derived by McClelland *et al.* (2*d*) and demonstrated to correspond to eq. [9], where A, B, C, D, and E are composite constants

$$[9]\quad \tau^{-1} = \frac{1}{[H^+]}\frac{A + B[HA] + C[HA]^2}{1 + D[HA] + E[HA]^2}$$

obtained in the relaxation treatment. Values of these constants according to their expressions in ref. 2*d* are reported in Table 1 as well as the values of the same constants based on the best fit of eq. [9] to the experimental data as shown in Fig. 5. Agreement between the two series of values is interpreted as good evidence for the validity of the mechanism shown in eq. [6]. However, only one change in the slope is apparent in Fig. 5, whereas two slope changes were observed in the $\tau^{-1}\times[H^+]$ versus [HA] plot for the 4′-methoxy-3-methylflavylium cation. Two explanations can be put forward for this difference: (i) Our work has been performed at pH values lower than those used for the study of the 4′-methoxy-3-methylflavylium compound, and it could happen that the base catalysis of the proton transfer between B and B^- is not efficient enough so that the ring-closure – ring-opening equilibrium would become rate determining. Or (ii) due to the existence of a better nucleophilic leaving group (ring A of malvin, eq. [1]), as compared to the less substituted A ring of the compound in eq. [2], the B^- species cannot form and eq. [6] reduces to a two-step system (11). It can also be admitted that B^- and C_E^- are non-classical resonant anions. In this case, the interconversion between B^- and C_E^- will always be referred to as extremely fast.

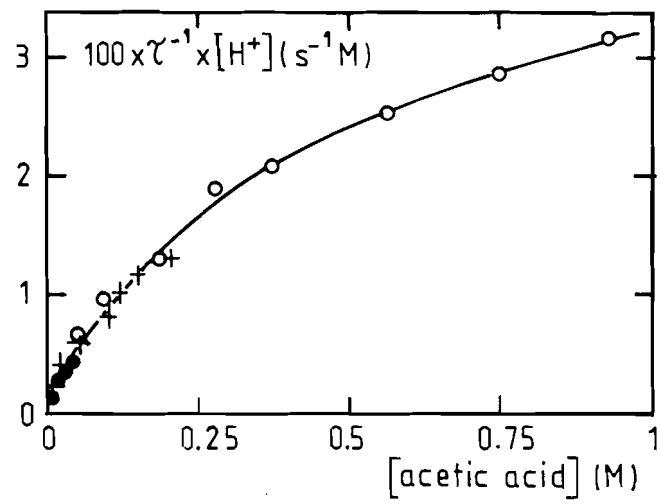

FIG. 5. Reciprocal of the relaxation time multiplied by the proton concentration as a function of the concentration of acetic acid. T_i = 16.5°C; T_f = 20°C; I = 0.20 M; (○): pH = 3.45; (+): pH = 4.58; (●): pH = 5.32. The solid line corresponds to eq. [9] using parameters A, B, C, D, and E shown in parentheses in Table 1.

Chalcones previously detected in the case of malvin and malvidin 3-glucoside (1) are *trans*-chalcones (see eq. [1]). In the acidification experiments reported elsewhere (1), what was observed is their slow conversion, via the *cis*-chalcone, to the flavylium cation, the rate-limiting step being the isomerization process. Therefore, previously reported chalcone contents in anthocyanins relate to the ratio $[C_Z]/([B] + [C_E])$, since B

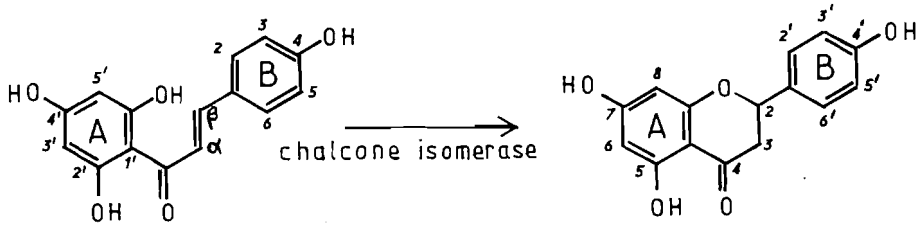
[10]



a regular chalcone (special numbering of the carbon atoms)

a flavanone (usual numbering of the carbon atoms)

and C_E rapidly revert to the flavylium ion and not to the ratio $[C_Z]/[B]$ as estimated in ref. 1. This remark also applies to the work done on the preparation of natural anthocyanin chalcones using high performance liquid chromatography (12).

Biological implication

Now that we have demonstrated the existence, for a natural anthocyanin, of a fast ring-closure reaction, the question is whether this feature is important in the biosynthesis of flavonoids. The key step in the biosynthesis of flavonoids is the formation of a regular chalcone whose isomerization to a cyclic flavanone is catalyzed by a chalcone isomerase (13). This type of chalcone, however, differs from the anthocyanin type of chalcone (retrochalcone) by the location of the carbonyl group and the ethylenic double bond with respect to the A and B phenolic rings as exemplified in eq. [10]. The flavanones thus formed are at the origin of many of the flavonoids, i.e., flavones, isoflavones, proanthocyanidins, anthocyanins, etc. (14). Since the chalcones formed from anthocyanins (retrochalcones) transform so easily into hemiacetals, it is worth asking whether there is a possibility of a second, minor, biosynthetic pathway to flavonoids, avoiding the chalcone isomerase catalyzed ring-closure step. Moreover, and as far as anthocyanins are concerned, generation of the strongly colored A^-, A, and AH^+ forms (Scheme 1), starting from the *cis*-chalcone C_E, only proceeds through fast, acid- or base-catalyzed steps. Natural physico-chemical conditions in vacuoles do provide such acid and base catalysts in good amounts.

Evidence has been given for the existence of a few rare natural regular chalcones with the structural requirement necessary to a fast chemical ring-closure reaction (15). Such rarely identified regular chalcones possess a 2-hydroxyl group in the B ring and, therefore, fast chemical ring closure takes place by the attack of the 2-hydroxyl on the carbonyl group leading to a hemiacetal form (16). This corresponds to an exchange of the roles played by the A and B rings with respect to the ring-closure process. Until now, such molecules were not shown to play an important role in the biosynthesis of flavonoids. It should also be mentioned that only a very limited number of natural retrochalcones (the anthocyanin type of chalcone) have previously been identified (17). To this group one could now add the anthocyanin retrochalcones. Their number is probably as large as the number of the anthocyanins themselves. However, one should not forget that the retrochalcones are difficult to detect, not only in their natural environment but also in model solutions.

The optimized structures, bond orders, and electrostatic potentials for both transoid and cisoid fluoronitrosoethylenes and nitrosoethylene have been calculated by *ab initio* self-consistent-field molecular orbital procedure. The transoid structures are found to be of lower energy than the cisoids. Analyses of the calculated bond orders show that the C—C bond energy compares well with that of ethylene and the C—N bond energy with that of ethylamine, and therefore the contributions from ionic resonance structures are predicted to be small. The calculated electrostatic potential contour maps show that the presence of the nitroso group completely eliminates the negative potential region associated with the C—C double bond, thus rendering it less susceptible to electrophilic attack. Analyses of the values and relative locations of positive electrostatic potentials correctly predict that the nucleophilic addition to β-carbon is favoured when in the transoid conformation.

Key words: conformation, charge distribution, fluoronitrosoethylenes, nitrosoethylenes.

CECILIA SARASOLA, FERNANDO P. COSSÍO et JESUS M. UGALDE. Can. J. Chem. **68**, 762 (1990).

Utilisant une procédure *ab initio* d'orbitales moléculaires en champ auto-cohérent, on a calculé les structures optimisées, les ordres des liaisons ainsi que les potentiels électrostatiques des formes tant transoïdes que cisoïdes des fluoronitrosoéthylènes et nitrosoéthylène. On a évalué que l'énergie des structures transoïdes est plus faible que celle des formes cisoïdes. Une analyse des ordres de liaison calculées montre que l'énergie de la liaison C—C se compare bien à celle de l'éthylène alors que l'énergie de la liaison C—N se compare bien à celle de l'éthylamine; on en conclut que les contributions des structures ioniques de résonance doivent être faibles. Les cartes des contours des potentiels électrostatiques calculés montrent que la présence du groupement nitroso élimine complètement la région de potentiel négatif associée à la double liaison C—C; cette liaison est donc moins susceptible à une attaque nucléophile. Une analyse des valeurs et des positions relatives des potentiels électrostatiques positifs permet de prédire correctement que, lorsque la conformation est transoïde, l'addition nucléophile sur le carbone β est favorisée.

Mots clés : conformation, distribution de charge, fluoronitrosoéthylènes, nitrosoéthylènes.

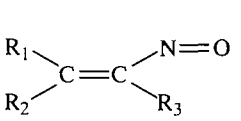
[Traduit par la revue]

1. Introduction

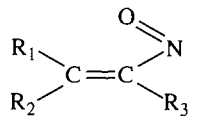
Interest in the chemistry of conjugated nitroso compounds has been renewed in recent years. Although the nitroso group has been recognized for many years as a powerful activating group for nucleophilic substitution in benzenoid aromatics (1), and nitrosocarbonyl compounds (RCONO) have been generated and shown to participate, through the nitroso group, in Diels–Alder and ene reactions (2), it is only recently that the chemistry of conjugated nitrosoalkenes has been reviewed (3). Only a few conjugated nitrosoalkenes have been isolated so far. The first of such compound, the trifluoronitrosoethylene, was reported in 1960 (4). Since then a few others, usually with bulky alkyl or halo substituents at the β-carbon atom, have been described (3). There is, however, substantial evidence for the existence of a wide range of conjugated nitrosoalkenes in solution as transient intermediates (5).

Conjugated nitrosoalkenes are potentially very useful synthetic intermediates because of the presence of a double bond in conjugation with a powerful inductive electronic charge withdrawer such as the nitroso group (6). Thus the β-carbon should be expected to be highly electrophilic, and indeed reactions with nucleophiles are the best-known features of their chemistry (3).

This paper reports the results of a study using *ab initio* molecular orbital theory of the fluoronitrosoethylenes and nitrosoethylene. We have completely optimized all the transoid (**I**) and cisoid (**II**) structures, for R_1, R_2, R_3 = F or H; and then carried out an analysis of the conformations and electronic charge distributions by means of the relative bond strengths and molecular electrostatic potentials.



I



II

2. Methods

All results presented in this paper are based upon *ab initio* self-consistent-field molecular orbital theory, using the GAUSSIAN-86 (7) series of programs. Complete geometry optimizations were carried out at the 4-21G* level of theory. This particular basis set has been selected because earlier calculations (8) on molecules containing the nitroso group have shown that the inclusion of *d*-type polarization functions has a substantial effect on the optimimzed geometries. On the other hand, larger basis sets such as 6-31G* has been shown to have little effect on the optimized geometries. For instance, the optimized HF/6-31G* and the HF/4-21G* geometries of the *cis*-1,2-dinitrosoethylene never differ more than 0.6% (9). To improve energies, MP2/4-21G* single point calculations were carried out on the previously 4-21G* optimized structures. The size of the molecules involved in the calculation prevented us to go further in the perturbation expansion. Along with the geometrical characteristics we have focused attention upon relative bond orders (10), calculated as

$$[1] \quad \text{Bond order} = 0.55747\,(k/R_e)^{1/2}$$

where R_e is the 4-21G* equilibrium bond length (in Å) and k is the force constant of the bond under study. Politzer *et al.* have shown (10) that experimentally measured bond dissociation

energies correlate well with bond orders calculated using eq. [1]. Hence it represents a practical means for predicting the relative strengths of chemical bonds, particularly when it is a given type of bond in different environments.

We have also studied the electrostatic potential $V(\boldsymbol{r})$ on the previously 4-31G* optimized geometries as

[2] $V(\boldsymbol{r}) = \Sigma_A Z_A |\boldsymbol{r} - \boldsymbol{R}_A|^{-1} - \mathrm{tr}(\boldsymbol{P}\cdot\boldsymbol{V})$

$V(\boldsymbol{r})$ was computed using eq. [2] with the STO-5G basis set, which has been shown to be generally reliable for determining this property (11–13). In particular, it has been shown to be superior to the standard STO-3G minimal basis set (13), while keeping the computational cost still affordable. In eq. [2], Z_A is the charge on nucleus A, located at $\boldsymbol{R}_A$, $\mathbf{P}$ is the total density matrix and $V_{\mu\nu} = \langle\mu||\boldsymbol{r} - \boldsymbol{r}'|^{-1}|\nu\rangle$ is the matrix element of the coulombic potential operator $|\boldsymbol{r} - \boldsymbol{r}'|^{-1}$ and $\{\phi_\mu|\mu = 1, 2,\ldots\}$ is the basis functions set. The electrostatic potential is a real physical property, which can be determined experimentally as well as computationally, and is related to the electronic charge distribution. Therefore it can be used to study the approaching channels of molecules, and since at this stage the interactions are weak, the frozen charge distribution approximation is valid. For instance, electrostatic calculations are in substantial agreement with SCF calculations performed by keeping the internal geometries of the partners unaltered. The latter approximation allows for mutual polarization effects, the non-classical exchange contributions to the energy, and to some extent the charge transfer effects. The accord between the two approximations is of course better at larger distances, but it is also present at intermediate values of the approach coordinate (11), in such a way that the electrostatic potential has proven to be an effective means for interpreting and predicting the initial reactive sites of molecules (12, 13). Other methods, such as the Bader type of analysis of molecular electron density distribution (14), have also proven to be useful for predictions of reactivity patterns. In particular, we would like to mention that reactivities of a series of molecules in a Michael addition reaction have been analyzed on the basis of properties expressed in terms of the Laplacian of charge density distribution (15). However, since electrostatic potentials are directly available from the GAUSSIAN-86 program package, we will focus on the $V(\boldsymbol{r})$ function.

Our calculated 4-21G* optimized structures for all the fluoronitrosoethylenes and the nitrosoethylene are shown in Table 1. Figures in square brackets belong to the transoid conformer and those in parentheses belong to the cisoid. Using the same notation, the HF/4-21G* and the MP2/4-21G*//HF/4-21G* energies have been collected in Table 2, and the bond orders in Table 3. Finally in Table 4 are reported the magnitudes and locations of the planar electrostatic potential maxima that are associated with each molecule.

3. Discussion

3.1 Structures

All HF/4-21G* optimized structures were found to be planar. Subsequent harmonic vibrational frequencies, calculated at the same level of theory, confirm that all but the monofluoronitrosoethylenes were true minima. We were unable to find true minima structures for the monofluoronitrosoethylenes for all attempts converged to the geometries given in Table 1. These structures were found to have three imaginary frequencies at the HF/4-21G* level of theory. Table 1 shows that the N—O bond lengths remain almost constant around a value of 1.18 Å all through the series of molecules under study. Changes affect at most the third decimal figure. The differences between the corresponding transoid and cisoid conformers are kept within a maximum value of 0.001 Å. Earlier calculations on related molecules like nitrosoacetylene (16), and nitrosomethanol (17, 18), with basis sets including no polarization functions report N—O bond lengths of 1.208 Å for nitrosoacetylene (6-31G basis set was employed) and 1.21 Å for nitrosomethanol (standard DZ (17), and 3-21G (18) basis sets). The discrepancy between these data and our calculated N—O bond lengths should be attributed to the electron donation from the $2p$ orbitals of the nitroso oxygen into d-type orbitals on nitroso nitrogen (19). For instance, we have found that the 4-31G* bond length has been reduced by 0.041 Å in the transoid nitrosoethylene with respect to the corresponding 4-31G optimized bond length (see Table 1 in ref. 8). Clearly basis sets including polarization functions are needed to take into account the effect of the back donation into the d-type orbitals on nitrogen, which bring about this N—O bond length reduction.

The differences found for the carbon–carbon optimized bond lengths are worthy of mention. Inspection of Table 1 reveals that the C—C bond distances are always slightly larger for the cisoid than for the corresponding transoid structure. The calculated mean bond distance of 1.31 Å appears to be underestimated with respect to the experimental average carbon–carbon double bond length of 1.34 Å (20). The latter is typical of SCF calculations, with extended sets (19). The C—N bond lengths are slightly larger in the cisoid conformers than in their corresponding transoid ones. The carbon–nitrogen HF/4-21G* equilibrium distance decreases as the number of fluorine substituents increases.

The C—F bond lengths vary slightly around a value of 1.31 Å, which compares well with the experimental bond lengths of 1.325 Å in 1-chloro-1-fluoroethylene (21) and 1.323 Å in 1,1-difluoroethylene (22). A remarkable point from Table 1 is that the C—F bond lengths appear to be slightly larger in the transoids than in the cisoids.

3.2 Energies

For all the molecules under study the transoid conformations are calculated to be more stable than their corresponding cisoid conformations, at both HF/4-21G* and MP2/4-21G* levels of theory, see Table 2. However, as the energy differences are less than 5 kcal/mol, a word of caution should be put on whether larger basis sets and more particularly higher level correlation energy treatments will not reverse the calculated MP2/4-21G* stability order. We would also like to point out that the average relative transoid/cisoid stability increase, due to the inclusion of electron correlation via Moller–Plesset perturbation theory up to the second order at the 4-21G* level of theory, is approximately 1 kcal/mol, in favour of the transoid conformation.

3.3 Bond orders

As discussed earlier the bond orders in Table 3, calculated using eq. [1], will be taken as measures of relative bond strengths of bonds of a given type. Thus we can see that the C—H bond orders, and therefore the bond energy, appears to be larger when the hydrogen atom is attached to the α-carbon than when it is attached to the β-carbon. The β-C—H bond energies are very similar. However, we would like to point out that all C—H bonds of molecules studied are stronger than the more typical methyl C—H bonds (4), because of the well-known strengthening effect that strong inductive withdrawers of electronic charge have on adjacent single bonds (23, 24). The behavior of the C—F bond energies parallels that of the C—H

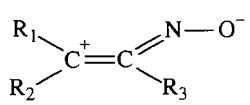
[a]Figures in square brackets correspond to the transoids and those in parentheses to the cisoids.

bonds. From Table 3 one may observe that the C—F bonds are stronger on the α-carbon than on the β-carbon, and do not vary significantly between the *cis* and *trans* dispositions of the fluorine atom on the β-carbon, with respect to the nitroso group. Also the data in Table 3 reveal that both C—H and C—F bonds are a little stronger for the cisoid than for the transoid conformers. This is fully consistent with the optimized C—H bond lengths, which appear to be shorter for the cisoid conformers than for their corresponding transoids.

The C—C bond orders of the transoid conformers fluctuate between 1.67 and 1.609. These values compare well with the 4-21G* C—C bond order of 1.637 in ethylamine (24). Therefore one should expect no significant contribution from ionic resibabce structures like **III**.



III

The calculated C—N bond orders further confirm this point. The values for the transoid structures go from a maximum value of 1.334 to a minimum of 1.285, and those of the cisoids from 1.094 to 1.007. These figures compare well with the 4-31G* bond order of 1.266 in ethylamine (24), where the C—N bond is a single bond, and differ markedly from the 4-31G* C—N bond order of 1.952 in methylenamine (24), and 1.730 in 1,2-dinitrosoethylene (25), where the C—N bond has a significant double bond character. These values suggest that there is little conjugation of the electrons in C=C and N=O.

3.4 Electrostatic potentials

Figures 1 to 3 show the electrostatic potential contour maps for some of the molecules under study, at the conventional (13) 1.75 Å above the molecular plane. To save space we do not present the plots of the other molecules, though they are available upon request.

Figures 1 to 3 clearly show that the strong inductive electron withdrawing power of the nitroso group completely eliminates the large negative electrostatic potential region associated with the carbon–carbon double bond (26). As a consequence of this effect one should expect a less nucleophilic olefinic double bond. For instance, the trifluoronitrosoethylene has been reported to react smoothly with chlorine in the dark to give 1,2-dichlorotrifluoro-1-nitrosoethene (4). Major negative electrostatic potentials are now associated with the nitroso nitrogen,

which has a relatively localized lone pair and corresponding strong negative potential. It can be regarded as a likely initial reaction site for nucleophilic attack.

The positive electrostatic potential regions of these molecules are also of considerable interest for they determine the initial reaction stages for nucleophilic attack, which are the best-known reactions for compounds of this type.[4] Inspection of Figs. 1 to 3 indicates the existence of a number of positive buildups of electrostatic potential. As pointed out by Politzer and Bar-Adon (16), positive buildups of electrostatic potential are generally associated with nuclei, and it is rather unusual, and noteworthy, to find them elsewhere, especially above bonds. The magnitudes and approximate locations of these maxima are given in Table 4. Thus we see that the cisoid trifluoronitrosoethylene has a unique positive buildup on the C—N—O angle (see Fig. 1*a*), but the transoid conformer has two positive buildups, one above the C—N—O angle and the other, which

[4]For a recent review about nucleophilic addition to conjugated nitrosoalkenes, see ref. 3 section 4B.

turns out to be the largest one, above the F—β-C—F angle. Figures 2*a* and 2*b* show that major positive values of the electrostatic potential in the cisoid β-difluoronitrosoethylene are located above the α-C—H bond. This positive buildup disappears and a new larger one arises above the F—β-C—F angle in the transoid conformer. Consistent with this, it has been reported that conjugated nitroso-alkenes preferentially add nucleophiles to the β-carbon atom when in the transoid conformation (27). Two positive electrostatic potential buildups in the transoid conformer have been found for all the molecules except for the nitrosoethylene (see Table 4). These molecules present positive electrostatic potential regions above the C—N—O angle irrespective of whether their conformation is cisoid or transoid (see Fig. 3, Table 4). Similar buildups of positive potential have been found on other molecules like nitro- and nitrosoacetylene (16), and related to the tendencies of these species to undergo nucleophilic attack upon the C—NO_2 and C—NO bonds (28).

4. Summary

We have computed the optimized geometries, bond orders, and the electrostatic potentials for both transoid and cisoid fluoronitrosoethylenes and nitrosoethylene, with an objective of gaining insight into the nature of intramolecular interactions of the nitroso group with the carbon—carbon double bond, and determining the initial reactive interaction sites of these molecules. Calculations at the single determinant Hartree–Fock level of theory demonstrate that the transoid conformers are more stable than the cisoids. Inclusion of electron correlation via Moller–Plesset theory up to the second order does not vary this trend. Analyses of the bond orders show that all the C—H bonds are found to be stronger than more typical aliphatic C—H bonds, due to the strong inductive withdrawing effect by the nitroso group. It is also of interest to note that the C—C bond and C—N bond orders, and consequently their bond

TABLE 4. Summary of calculated electrostatic potentials

Molecule	Approximate location of planar maxima	Values of maxima (kcal/mol)
$R_1 = R_2 = R_3 = F$		Cisoid *a*:19.56 Transoid *a*:13.04 *b*:20.22
$R_1 = H$ $R_2 = R_3 = F$		Cisoid *a*:15.00 Transoid *a*:12.39 *b*:16.30
$R_2 = H$ $R_1 = R_3 = F$		Cisoid *a*:16.00 Transoid *a*:13.10 *b*:15.93
$R_3 = H$ $R_1 = R_2 = F$		Cisoid *a*:18.36 Transoid *b*:20.31
$R_1 = R_2 = R_3 = H$		Cisoid *a*:8.34 Transoid *a*:8.37

energies, compare well with those of ethylene and ethylamine, respectively, and therefore contributions from ionic resonance structures should be small.

Examining the electrostatic potential contour maps we have observed that introduction of the nitroso group completely eliminates the negative potential region associated with the C—C double bond. Consequently, the carbon–carbon double bond should be regarded to be less nucleophilic than olefinic double bonds, in agreement with earlier experimental studies (4). The values and relative locations of the positive electrostatic potential maxima clearly show that nucleophilic addition to the β-carbon occurs preferentially when the molecule is in the transoid conformation.

Finally positive potential buildups that are found above the C—N—O angle and in some of the molecules also above the α-C—H bond are other remarkable features of these molecules.

The audio frequency conductances of magnesium, manganese II, and barium malonates in aqueous medium at 25°C

ANIS A. AL-NAJAR AND AWATIF M. IBRAHIM
Department of Chemistry, College of Science, University of Basrah, Basrah, Iraq

Received April 10, 1989[1]

ANIS A. AL-NAJAR and AWATIF M. IBRAHIM. Can. J. Chem. **68**, 770 (1990).

The conductance of aqueous solutions of magnesium, manganese II, and barium malonates has been measured at 1.59 kHz, using a conventional audio frequency bridge. Conductance data were evaluated using different modern theoretical conductance equations, each a three-parameter equation in K_A, Λ_0, and a. These are the complete and expanded forms of both the Fuoss–Hsia (F/H) and Pitts (P) equations and the Lee–Wheaton (L/W) equation. Our results show that the Lee–Wheaton equation is the most satisfactory.

Key words: conductance, aqueous medium, magnesium malonate, manganese malonate, barium malonate.

ANIS A. AL-NAJAR et AWATIF M. IBRAHIM. Can. J. Chem. **68**, 770 (1990).

Utilisant un pont à fréquence audio conventionnel et opérant à 1,59 kHz, on a mesuré les conductivités de solutions aqueuses de malonates de magnésium, de manganèse(II) et de baryum. On a évalué les données de conductivité à l'aide de diverses équations théoriques modernes de la conductivité; chacune de ces équations implique trois paramètres, soit le K_A, le Λ_0 et le a. Les équations utilisées sont : les formes complètes et étendues de l'équation de Fuoss–Hsia (F/H), celle de Pitts (P) ainsi que celle de Lee–Wheaton (L/W). Les paramètres de conductivité obtenus à l'aide d'une analyse faisant appel à ces théories indique que l'équation de L/W reproduit les données mieux que les autres équations.

Mots clés : conductivité, milieu aqueux, malonate de magnésium, malonate de manganèse, malonate de baryum.

[Traduit par la revue]

Introduction

Within experimental uncertainty, Onsager's limiting equation (1) agrees with the data for numerous uni–univalent salts in water up to 0.001 M. Agreement with experiment is also found for most uni–bivalent and uni–tervalent salts, but when the valency product increases to four the equation no longer holds. A much steeper slope of the experimental points than the theoretical Onsager value is usually obtained when the equivalent conductance of a bi–bivalent is plotted against the square root of the concentration. The increase in divergence with increasing concentration of the experimental data from the theoretical conductance data in these cases can be attributed to ion-pair formation of an essentially electrostatic and non-specific kind, described by K_A. K_A may be derived if it is assumed that the free ions obey the limiting equation, that the ion-pair is non-conducting, and that its activity coefficient in dilute solution is unity (2). Under these conditions, the conductance equation chosen for representing the phoreogram of a given salt in a particular solvent is a function of the three parameters K_A, Λ_0, and a.

On the other hand, the conductance behaviour of 2:2 electrolytes has received relatively little attention. This is largely due to the difficulty encountered in analysing such data since the usual methods require an arbitrary choice for some of the parameters needed in the analysis. In this paper we report conductance measurements of magnesium, manganese II, and barium malonates in aqueous medium. Five currently used conductance equations, the complete and expanded forms of both the Fuoss–Hsia (3, 4) and the Pitts (5, 6) equations and a recent equation Lee–Wheaton (7) describing charge transport in electrolyte solutions, based on a new and specifically chemical model for ions in solution (7, 8) have been used to analyse conductance data for these malonate salts.

Experimental

Measurements were made at 25°C with Wayne–Kerr B331 audio frequency bridge of admittance in all four quadrants of complex plane. It combines speed and simplicity of operation with 0.01% accuracy.

The cell used for measuring conductances has been described elsewhere (9).

The cell constant (as determined by standard solutions (10) of potassium chloride) was 0.20261 ± 0.00002 cm^{-1}. The method used for measuring conductances has been described (11).

Materials

The KCl used in this work was purified and used according to the literature (9).

Magnesium malonate was prepared by the addition of clean and dried magnesium metal to a solution of malonic acid. The pH of the solution was continuously tested until the solution became neutral. The mixture was then filtered to remove excess added metal, after which the solvent was evaporated on a water bath. The product was recrystallised twice from conductivity water and air-dried at room temperature. The final product was a white crystalline material, a dihydrate. Manganese malonate was prepared as described by Vogel (12) for calcium malonate but with some modification. AnalaR grade manganese chloride solution was added to a solution of sodium malonate. The mixture was heated on a water bath for a few minutes with continuous stirring. The light pink precipitate formed was allowed to cool to room temperature. The mixture was filtered off and the filtrate tested for chloride ions. The product was washed with cold conductivity water until chloride-ion free, after that the final product, a dihydrate was air-dried at room temperature. Barium malonate was prepared the same way as manganese malonate. The product was a white crystalline salt in the form of a dihydrate. The magnesium and manganese malonates were analysed for Mg and Mn contents by titration with EDTA, while the analysis for barium content was carried out using the method described by Vogel (13). The compositions of the three salts were determined by thermogravimetric analysis for hydration.

All stock solutions were prepared by weight, and all measurements were done using the weight dilution technique.

Results and discussion

The measured molar conductances Λ_{exp} and the corresponding concentrations C in moles per liter at 298 K are given in Table 1. These data were analyzed using the complete and modified forms of both F/H and P equations as well as using the L/W equation. For the interpretation of the characteristic parameters of an electrolyte solution from conductance data, a

minimisation technique has been used (14) in terms of K_A, Λ_0, and a. For analysis of each set of data points C_j, Λ_j ($j = 1, \ldots, N$), an Algol computer program has been written. All calculations were performed on an ICL. 1905 F computer using Λ_0, a, and K_A which produce a theoretical curve giving the best fit to the measured conductance. The results of the minimisation technique for the best fit values of the three parameters Λ_0, K_A, and a are listed in Table 2 together with the corresponding values of the standard deviation σ, given by

$$[1] \quad \sigma = (S^2/N)^{1/2}$$

where S^2 is defined by

$$[2] \quad S^2 = \sum_{j=1}^{N} (\Lambda_{calc} - \Lambda_j)^2$$

The results from other workers are listed in Table 3.

From the association constants given in Table 2, it can be

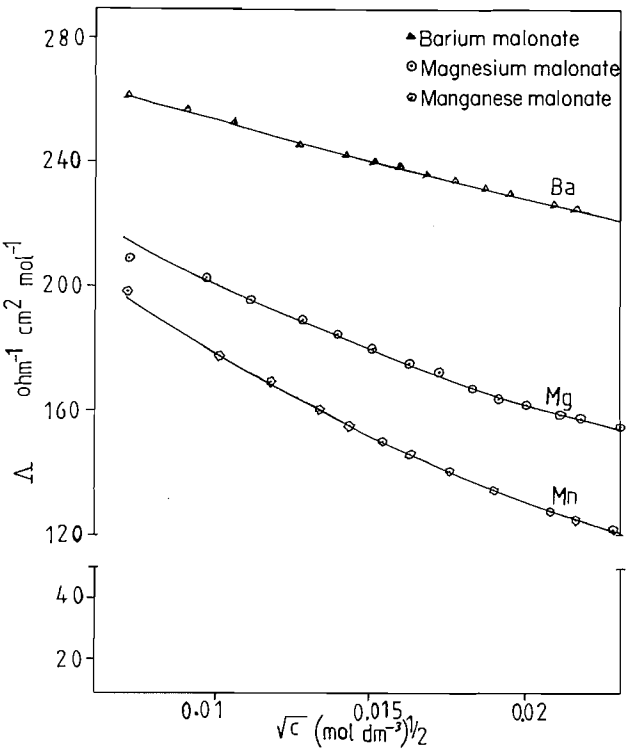

FIG. 1. Experimental molar conductances versus square root of concentration.

deduced that these salts do not behave as "strong" electrolytes, and their dissociations are far from complete. It can also be seen that manganese malonate undergoes more ion-pair formation according to the quantitative conductance data. The same conclusion was given by Riley and Fisher (15) who predicted that the degree of dissociation fluctuates significantly from one to another.

The malonate ion is less of a donor compared to the oxalate ion (15), thus it can also be emphasized that magnesium and manganese malonates are more highly dissociated than the oxalates (21).

The values obtained in this work for K_A, Λ_0, and a are satisfactory, providing a particularly good example of typical incompletely dissociated electrolyte the thermodynamic association constants of which conform to the law of mass action. The abnormally low conductances of these electrolytes (Fig. 1) are not due to the presence of electrically neutral molecules but to the ion-pair formation. This was indicated by measurements at high frequency (22).

It is of interest to note from Table 2 that the values of parameter a are small for all salts studied. This agrees with the previous results obtained by Stock and Davies (16) that a = 2.9 Å for magnesium malonate, a = 2.4 Å for manganese malonate, but a = 10 Å for barium malonate. Their explanation for these results is that the small a values indicate that the linkage is largely covalent (16, 17) and not merely due to "coulomb" ion association. The large a value for barium malonate was explained (16) by the fact that the assumption of spherical symmetry and a central charge is far from the truth for the malonate ion. The idea of ionic radii from Gane and Ingold (23) was used by Jones and Stock (17), who suggested that the molecules of the malonate salts acquire a coiled configuration as an explanation for the small a values they have obtained for the malonate salts.

Later (18), it was found that the hydrated radii for Mg^{2+} and Ba^{2+} ions are 4.1 Å and 4.2 Å respectively as calculated from the dissociation constants.

The small a values obtained in the present work agree with Prue's (24) point of view, Justice's suggestion (25) and Beronius' results (26).

Unfortunately, no recent determinations of Λ_0 at 298 K for magnesium, manganese, and barium malonates have been found. Moreover, Λ_0 was only found (15) to be 223.72 $ohm^{-1}\,cm^2\,mol^{-1}$ for magnesium malonate. Thus in comparison with ionic mobilities at infinite dilution at 298 K taken from ref. 27: $\lambda_0(Mg^{2+})$ = 106.12, $\lambda_0(Mn^{2+})$ = 106.20 and $\lambda_0(Ba^{2+})$ = 127.28 together with the value of 129.4 for malonate ion (20), good agreement has been shown in Table 2 for both magnesium and manganese malonates. The value obtained in this work for barium malonate is much higher than that given by direct combination of λ_0 values of ionic mobilities.

It was noted that the minimisation Λ_0 values for the complete and modified F/H equation were always greater than those values obtained using the complete form of the Pitts equation. The reason for this has been discussed briefly by Fernandez Prini and Prue (4, 6) and in detail by Pitts *et al.* (28). The Brownian terms in the velocity of the ion was neglected by Pitts. Also, Pitts equation does not allow for the kinetic (osmotic) terms which contributed to the increase in velocity of the ion. Another feature of the minimisation results is that the modified Pitts equation yields values of a lower than those given by other equations.

It was obvious from the minimisation techniques that the parameter Λ_0 had the greatest effect on the values of S^2 during the variation of the three parameters K_A, Λ_0, and a. This is to be expected, in so far as Λ_0 is the leading term in all the conductance equations. However, Λ_0 was relatively insensitive to the values of K_A and a at the corresponding minima of S^2.

However, it was shown that the L/W equation, relative to the other four equations, is preferable for the analysis of conductance data (as indicated by σ) for our present system. This may be due to the inclusion of third order terms (7, 8) in the plasma parameter (ϵK) of their equation. The same behaviour was found in another system (29).

Chemistry Department, Faculty of Education, Ain Shams University, Roxy, Cairo, Egypt

Received February 14, 1989[3]

MOHAMED S. ABDEL-MOEZ, SHAKER L. STEFAN, MOSTAFA M. EL-BEHAIRY, MOHAMED M. MASHELY, and BASHEIR A. EL-SHETARY. Can. J. Chem. **68**, 774 (1990).

The stepwise stability constants of VO(II), Mn(II), Cu(II), Ni(II), Co(II), Zn(II), Fe(III), and UO_2(II) metal ions with 2-(2-acetylphenylhydrazone)-5,5-dimethyl-1,3-cyclohexane dione (2-APHDm), 3-(2-acetylphenylhydrazone)pentane-2,4-dione (2-APHA), 2-(2-acetylphenylhydrazone)-1-phenyl-1,3-butane dione (2-APHB), 2-(2-acetylphenylhydrazone)-1,3-diphenyl-1,3-propane dione (2-APHDB), and 3-(2-acetylphenylhydrazone)-1,1,1-trifluoropentane-2,4-dione (2-APHTA) were determined at 30°C by pH titrations in 75% (v/v) dioxane–water solvent. In addition, metal complexes of three related β-diketones, 2-APHA, 2-APHB, and 2-APHDB have been synthesized and characterized by elemental analysis, uv–visible, ir spectra, and conductance in DMF and magnetic susceptibility measurements. The structure of the complexes have been proposed.

Key words: transition metal complexes of hydrazone-β-diketone ligands.

MOHAMED S. ABDEL-MOEZ, SHAKER L. STEFAN, MOSTAFA M. EL-BEHAIRY, MOHAMED M. MASHELY et BASHEIR A. EL-SHETARY. Can. J. Chem. **68**, 774 (1990).

Opérant à 30°C, dans un mélange à 75% (v/v) de dioxane–eau et faisant appel à des titrations par pH, on a déterminé les constantes de stabilité des ions VO(II), Mn(II), Cu(II), Ni(II), Co(II), Zn(II), Fe(III) et UO_2(II) avec la 2-(2-acétylphényl-hydrazone)-5,5-diméthylcyclohexane-1,3-dione (2-APHDm), 3-(2-acétylphénylhydrazone)-pentane-2,4-dione (2-APHA), 2-(2-acétylphénylhydrazone)-1-phényl-butane-1,3-dione (2-APHB), 2-(2-acétylphénylhydrazone)-1,3-diphényl-propane-1,3-dione (2-APHDB) et 3-(2-acétylphénylhydrazone)-1,1,1-trifluoropentane-2,4-dione (2-APHTA). On a aussi synthétisé des complexes métalliques de trois β-dicétones apparentées et on les a caractérisés par analyse élémentaire, par spectroscopie uv et ir et par des mesures de susceptibilité magnétique et de conductivité dans le DMF. On propose des structures pour les complexes.

Mots clés : complexes de métaux de transitions avec des ligands d'hydrazones β-cétoniques.

[Traduit par la revue]

Introduction

β-Diketone as well as hydrazone compounds have been used widely as chelating agents with transition elements (1, 2). However, the combination products of the two classes of chelating agents form new interesting compounds which act as very good bi- or tridentate ligands (3). The present study investigates the physicochemical properties of the complexes of chelating agents with transition metals in both solution and solid states. The structure and basicity effects of the ligands on the stability of the formed complexes are discussed and some correlations attempted.

The hydrazone structure of the five related ligands **I** to **V** is given in Scheme 1.

Experimental

(i) Materials and methods

Solutions of Cu(II), Co(II), Ni(II), Fe(III), Zn(II) and UO_2(II) were prepared from their nitrate salts. Solutions of Mn(II) and VO(II) were prepared from the sulphates. The exact concentration was determined by titration with EDTA in the presence of a suitable indicator (4). The concentration of UO_2(II) was determined gravimetrically as uranium oxide U_3O_8 (4).

(ii) Preparation of solid complexes

The organic ligands were prepared by coupling the diazonium salt of 2-aminoacetophenone with the following diketones: **1**, pentane-2,4-dione (2-APHA); **II**, 1-phenyl-1,3-butane dione (2-APHB); **III**, 1,3-diphenyl-1,3-propane dione (2-APHDB); **IV**, 1,1,1-trifluoropentane-2,4-dione 2-APHTA; and **V**, dimedone (2-APHDm) in sodium acetate medium.

The solid complexes were prepared by adding equimolar amounts of aqueous solutions of the metal salts and ethanolic solution of the respective ligands in 1:1 molar ratio. The pH of the mixture was adjusted between 3.5–4.0 by addition of KOH with continuous stirring. The mixture was refluxed for about 4.0 h. The solid complexes were separated on cooling, then filtered, washed with water and alcohol, and dried under vacuum. The purity of the ligands (5) and their solid complexes was checked by elemental analysis, melting points, uv–visible and ir spectra.

3-(2-Acetylphenylhydrazone)pentane-2,4-dione (2-APHA)

This compound was obtained as yellow crystals from acetic acid, mp 159.0–159.5°C; λ_{max} (nm) in DMF: 365 1st band, 255 2nd band; ir (KBr) ν: 3050–3020(NH) (mb), 1663(C=O) (s), 1563(C=N) (s) cm. *Anal.* calcd. for $C_{13}H_{14}N_2O_3$: C 63.41, H 5.69, N 11.38; found: C 63.60, H 5.80, N 10.67.

[Mn(2-APHA)] complex

This compound was obtained as yellowish green crystals, decomposed at 182–182.5°C; λ_{max} (nm) in DMF: 362 1st band, 252 2nd band; ir (KBr) ν: 1660(C=O) (s), 1565(C=N) (s), 550(M—N) (m), 470(M—O) (w) cm^{-1}. *Anal.* calcd. for $[Mn(C_{13}H_{13}N_2O_3)_2]$: C 57.24, H 4.77, N 10.27; found: C 57.30, H 5.20, N 10.00.

[Fe(2-APHA)] complex

This compound was obtained as orange crystals, decomposed at 178–175.5°C; λ_{max} (nm) in DMF: 375 1st band, 250 2nd band; ir (KBr) ν: 1660(C=O) (s), 1565(C=N) (s), 550(M—N) (w), 450(M—O) (m) cm^{-1}. *Anal.* calcd. for $[Fe(C_{13}H_{13}N_2O_3)_3]$: C 59.16, H 4.93, N 10.61; found: C 60.09, H 4.90, N 10.89.

[Co(2-APHA)] complex

This compound was obtained as deep yellow crystals, decomposed

at 196–196.5°C: λ_{max} (nm) in DMF: 362 1st band, 250 2nd band; ir (KBr) ν: 1660(C=O) (s), 1565(C=N) (s), 550(M—N) (w), 455(M—O) (w) cm^{-1}. *Anal.* calcd. for $[Co(C_{13}H_{13}N_2O_3)_2]$: C 56.83, H 4.73, N 10.20; found: C 57.16, H 4.99, N 10.25.

[Ni(2-APHA)] complex

This compound was obtained as yellow crystals, decomposed at 191–191.5°C; λ_{max} (nm) in DMF: 370 1st band, 252 2nd band; ir (KBr) ν: 1660(C=O) (s), 1565(C=N) (s), 550(M—N) (w), 460(M—O) (w) cm^{-1}. *Anal.* calcd. for $[Ni(C_{13}H_{13}N_2O_3)_2]$: C 56.83, H 4.73, N 10.20; found: C 56.60, H 5.01, N 10.50.

[Cu(2-APHA)] complex

This compound was obtained as yellowish green crystals, decomposed at 181–181.5°C, λ_{max} (nm) in DMF: 360 1st band, 250 2nd band; ir (KBr) ν: 3515–3400(OH) (b), 1660(C=O) (s), 1565(C=N) (s), 810 (m) coordinated H_2O, 550(M—N) (w), 460(M—O) (m) cm^{-1}. *Anal.* calcd. for $[Cu(C_{13}H_{13}N_2O_3)(H_2O)(OH)]$: C 45.41, H 4.66, N 8.15; found: C 44.91, H 4.77, N 8.40.

2-(2-Acetylphenylhydrazone)-1-phenyl-1,3-butane dione (2-APHB)

This compound was obtained as yellow crystals from acetic acid, mp 114.0–114.5°C; λ_{max} (nm) in DMF: 370 1st band, 256 2nd band; ir (KBr) ν: 3060(NH) (mb), 1642(C=O) (s), 1570(C=N) (s) cm^{-1}. *Anal.* calcd. for $C_{18}H_{16}N_2O_3$: C 70.12, H 5.19, N 9.09; found: C 69.96, H 5.42, N 8.89.

[Mn(2-APHB)] complex

This compound was obtained as yellowish green crystals, decomposed at 178–178.5°C; λ_{max} (nm) in DMF: 368 1st band, 253 2nd band; ir (KBr) ν: 1645(C=O) (s), 1575(C=N) (s), 565(M—N) (m), 430(M—O) (m) cm^{-1}. *Anal.* calcd. for $[Mn(C_{18}H_{15}N_2O_3)_2]$: C 64.57, H 4.48, N 8.37; found: C 64.31, H 4.72, N 8.30.

[Fe(2-APHB)] complex

This compound was obtained as deep orange crystals, decomposed at 180–180.5°C; λ_{max} (nm) in DMF: 367 1st band, 252 2nd band; ir (KBr) ν: 1645(C=O) (s), 1575(C=N) (s), 565(M—N) (m), 468, 430(M—O) (w) cm^{-1}. *Anal.* calcd. for $[Fe(C_{18}H_{15}N_2O_3)_2NO_3]$: C 59.0, H 4.09, N 9.56; found: C 58.75, H 4.30, N 9.30.

[Co(2-APHB)] complex

This compound was obtained as reddish brown crystals, decomposed at 194–194.5°C; λ_{max} (nm) in DMF: 365 1st band, 250 2nd band; ir (KBr) ν: 1645(C=O) (s), 1575(C=N) (s), 565(M—N) (m), 430(M—O) (w) cm^{-1}. *Anal.* calcd. for $[Co(C_{18}H_{15}N_2O_3)_2]$: C 64.19, H 4.46, N 8.32; found: C 64.70, H 5.00, N 7.93.

[Ni(2-APHB)] complex

This compound was obtained as orange crystals, decomposed at 187–187.5°C; λ_{max} (nm) in DMF: 368 1st band, 252 2nd band; ir (KBr) ν: 1645(C=O) (s), 1575(C=N) (s), 565(M—N) (m), 435(M—O) (w) cm^{-1}. *Anal.* calcd. for $[Ni(C_{18}H_{15}N_2O_3)_2]$: C 64.19, H 4.46, N 8.33; found: C 64.70, H 4.60, N 8.43.

[Cu(2-APHB)] complex

This compound was obtained as yellowish green crystals, decomposed at 165–165.5°C; λ_{max} (nm) in DMF: 365 1st band, 252 2nd band; ir (KBr) ν: 1645(C=O) (s), 1575(C=N) (s), 560(M—N) (w), 430(M—O) (w) cm^{-1}. *Anal.* calcd. for $[Cu(C_{18}H_{15}N_2O_3)_2]$: C 63.76, H 4.43, N 8.26; found: C 63.38, H 4.50, N 8.28.

2-(2-acetylphenylhydrazone)-1,3-phenyl-1,3-propane dione (2-APHDB)

This compound was obtained as yellow crystals from acetic acid, mp 78.0–78.5°C; λ_{max} (nm) in DMF: 368 1st band, 252 2nd band; ir (KBr) ν: 3130(NH) (mb), 1625(C=O) (s), 1567(C=N) (s) cm^{-1}. *Anal.* calcd. for $C_{23}H_{18}N_2O_3$: C 74.59, H 4.86, N 7.56; found: C 74.52, H 5.17, N 7.58.

[Mn(2-APHDB)] complex

This compound was obtained as yellowish green crystals, decomposed at 179–179.5°C; λ_{max} (nm) in DMF: 355 1st band, 250 2nd band; ir (KBr) ν: 1630(C=O) (s), 1570(C=N) (s), 590(M—N) (m), 515(M—O) (m) cm^{-1}. *Anal.* calcd. for $[Mn(C_{23}H_{17}N_2O_3)_2]$: C 69.60, H 4.28, N 7.06; found: C 69.20, H 4.10, N 6.80.

[Fe(2-APHDB)] complex

This compound was obtained as red crystals, decomposed at 182–182.5°C; λ_{max} (nm) in DMF: 380 1st band, 254 2nd band; ir (KBr) ν: 1634(C=O) (s), 1576(C=N) (s), 550(M—N) (m), 490, 440(M—O) (w) cm^{-1}. *Anal.* calcd. for $[Fe(C_{23}H_{17}N_2O_3)_2NO_3]$: C 64.48, H 3.97, N 8.17; found: C 64.50, H 3.90, N 8.23.

[Co(2-APHDB)] complex

This compound was obtained as deep yellow crystals, decomposed at 198–198.5°C; λ_{max} (nm) in DMF: 370 1st band, 250 2nd band; ir (KBr) ν: 1629(C=O) (s), 1570(C=N) (s), 560(M—N) (m), 510, 435(M—O) (w) cm^{-1}. *Anal.* calcd. for $[Co(C_{23}H_{17}N_2O_3)_2]$: C 69.28, H 4.26, N 7.20; found: C 69.33, H 4.70, N 7.17.

[Ni(2-APHDB)] complex

This compound was obtained as yellowish green crystals, melted above 234°C; λ_{max} (nm) in DMF: 352 1st band, 250 2nd band; ir (KBr) ν: 1629(C=O) (s), 1570(C=N) (s), 565(M—N) (m), 440(M—O) (m) cm^{-1}. *Anal.* calcd. for $[Ni(C_{23}H_{17}N_2O_3)_2]$: C 69.28, H 4.27, N 7.03; found: C 69.81, H 4.50, N 7.09.

[Cu(2-APHDB)] complex

This compound was obtained as yellowish green crystals, melted above 235°C; λ_{max} (nm) in DMF: 340 1st band, 250 2nd band; ir (KBr) ν: 1635(C=O) (s), 1575(C=N) (s), 570(M—N) (m), 510, 440(M—O) (m) cm^{-1}. *Anal.* calcd. for $[Cu(C_{23}H_{17}N_2O_3)_2]$: C 68.87, H 4.24, N 6.98; found: C 68.70, H 4.20, N 6.78.

(iii) Measurements

Titrations of 5×10^{-3} M free ligand as well as mixtures of the free ligand with 1×10^{-3} M metal ion were carried out against standard KOH in 75% dioxane–water (v/v) to avoid precipitation. Dilute solutions (10^{-3} M) were used to reduce the possibility of formation of polynuclear species. pH titrations were carried out using a WTW 520 digital pH meter fitted with a combination electrode at 30°C and ionic strength of 0.1 M in 75% (v/v) dioxane–water solvent in an inert atmosphere (nitrogen).

The dissociation constants pK_H as well as the stability constants were calculated as mentioned before (5). The method of Irving and Rossotti was employed to determine the parameters $\bar{n}$ and pL (6), where $\bar{n}$ is the average number of molecules of ligand bound by one metal atom and L is the concentration of the free ligand.

Infrared spectra were obtained using a Perkin-Elmer 598 spectrophotometer in the range of 200–4000 cm^{-1}, using the KBr disk technique. Ultraviolet and visible spectra in pure DMF solvent were obtained using a recording Perkin-Elmer 550 S spectrophotometer.

The conductance of 1×10^{-3} M solutions of the solid complexes in purified DMF were measured using a WTW, D-812 Weilheim conductivity meter, Model LBR, fitted with a cell model LTA 100.

Magnetic measurements were carried out at 28.5°C using the Gouy method.

(iv) Organic solvent

Dioxane was purified by refluxing with sodium metal, lithium aluminium hydride and pure dioxane was collected between 100.5 to 101°C (7). Dimethyl formamide was purified as mentioned by Verlag (8). The DMF fraction was collected under vacuum at about 53°C in a dark bottle (9).

Results and discussion

1. pH-metric studies

Titration curves of metal ion and organic ligand mixtures of ratio 1:5 at 30°C ± 0.5 were greatly different from those of the free ligands (Fig. 1) as a result of complex formation.

The titration curve of 2-APHDm ligand in the presence of Cu^{2+} ion showed distinct inflections at m = 1 and m = 2, where m = moles of base per mole of ligand, which indicated the stepwise formation of ML and ML_2 species. The same behaviour was obtained for the VO^{2+}–2-APHDm mixture whereas in the case of the Mn^{2+}–2-APHDm mixture, the titration curve showed an inflection at m = 1, which suggested the formation of 1:1 (ML) species. Titration curves obtained in the presence of the bivalent metal ions (Co^{2+}, Ni^{2+}, Zn^{2+}, UO^{2+}) and the trivalent Fe^{3+} ion showed an inflection at m = 2 corresponding to the formation of the bischelate represented by the equilibrium

$$M^{2+} + 2HL \rightleftharpoons ML_2 + 2H^+$$

transition metal ions with hydrazone-β-diketone ligands in 75% dioxane–water*

constants ranged between 0.01 to 0.05 and the correlation coefficient (r) ranged between 0.95 to 0.98.

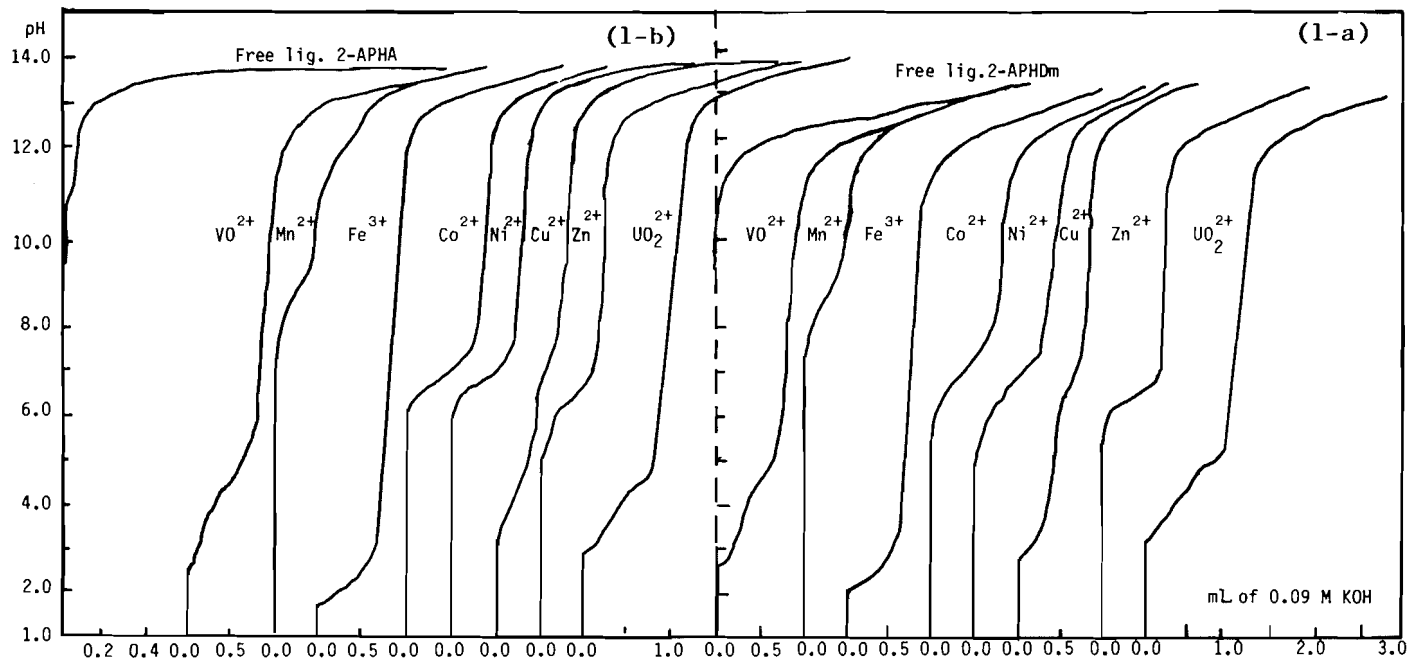

FIG. 1. pH-metric titration curves for 5 × 10^{-3} M ligand and 1 × 10^{-3} M metal ion at 30°C in 75% (v/v) dioxane–water and V_0 = 40 mL.

Titration curves of the 2-APHTA and 2-APHDB ligands obtained in the presence of the divalent VO^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, and UO_2^{2+} ions and the trivalent Fe^{3+} ion showed an inflection at m = 2 corresponding to the formation of bischelates. In the case of the Mn^{2+} ion, an additional weak inflection was observed at m = 1, corresponding to the formation of an ML species as well as ML_2 chelate compounds. Titration curves of metal–2-APHTA mixtures were characterized by the appearance of a weak inflection at pH values higher than eleven which may be attributed to the neutralization of the excess ligand present in the mixture by the alkali or due to the formation of hydroxo complexes. Titration curves of 2-APHB and 2-APHA ligands obtained in the presence of VO^{2+}, Co^{2+}, Ni^{2+}, Zn^{2+}, and Fe^{3+} metal ions showed an inflection at m = 2, indicating the formation of bischelates. Titration curves obtained in the presence of both Cu^{2+} and Mn^{2+} ions showed a distinct inflection at m = 1 in addition to that at m = 2 which accounted for the stepwise formation of ML and ML_2. The stepwise formation constants log K_1 and log K_2 were evaluated as given in Table 1. The formation constants of Fe^{3+} complexes had higher observed values than the other metal complexes which may be attributed to increased covalency of the bond. The stability of the complex formed generally increased with increasing oxidation number of the metal ion (9).

The formation constants of the divalent oxygenated cation complexes (VO^{2+} and UO_2^{2+}) had higher values than the other divalent cations. This may be attributed to the bonded oxygen atoms which may increase the electrostatic attraction between the metal ion and the coordinated ligands and overcome any steric hindrance offered by the oxygen of the oxygenated cation. Moreover, high chelate stability values of oxygenated cations were observed for the complexes of β-diketones themselves (10–12).

The order of increasing formation constants of metal complexes for a series of similar divalent metal ions with the different complexing agents under investigation were as follows

$$Mn < Co < Ni < Cu > Zn$$

This order is in good agreement with that of formation constants reported by Irving and Williams (13).

$[Cu(C_{23}H_{17}N_2O_3)_2]$	5.00	1.731	340	250

The order largely reflects the change in heat of complex formation across the series, and arises from a combination of the influence of both polarising ability of metal ion, which varies in the sequence Mn < Fe < Co < Ni ~ Co > Zn (14) and crystal-field stabilization energies which vary in the oder (15)

Mn < Fe < Co < Ni > Zn

More bulky entering ligands will obviously suppress the stability constant, whereas less bulky ligands will enhance the stability constant (14). Accordingly, metal ions that are susceptible to large crystal-field stabilization effects form stronger complexes with less bulky ligands (16, 17).

In the selected series of the complexing agents two important factors were considered, i.e., steric and basicity effects. Considering the substitution effects, the ligands were arranged according to decreasing basicity in the following order:

2-APHDm < 2-APHA > 2-APHB > 2-APHDB > 2-APHTA

The pK values (see Table 1) of these ligands appear to be high, but this can be explained by the higher pK's in 75% dioxane and also the effect of hydrogen bonding with acetyl-carbonyl which retards deprotonation of hydrazo hydrogen. Thus orthohydroxyacetophenone has a very high pK (14.0) compared to phenol (12.0) (18).

The most basic ligands form the most stable complexes. In addition, the role of the steric effect due to the bulky phenyl group is quite clear in the stability order of complexes for the three ligands 2-APHA, 2-APHB, and 2-APHDB. The two factors, i.e., basicity and steric effects of ligands together influence the order in the same direction (Table 1).

2-APHA > 2-APHB > 2-APHDB

Chelating agents may be classified according to whether the skeleton of the molecule is flexible or rigid. In the present study, 2-APHA represents the most flexible molecule and 2-APHDm represents the most rigid one. Rigid chelating agents exhibit less loss of configurational entropy on complex formation. Therefore the complex stability values of the complexing agent 2-APHA are found to be higher than that of the rigid complexing agent 2-APHDm.

The ratio of successive stability constants is affected by ligand and metal ion. The effect of ligands can be subdivided into their electrostatic and steric effects. The electrostatic effect accounts for the charges on the ligand and the metal ion. The effect of steric size on the ratio of successive constants depends on whether the entering ligand is more bulky or less bulky than the ligand it is replacing.

Table 1 shows that for all systems studied here, log K_1 − log K_2 is positive. The different log K values of the complexes of the studied compounds (**I–V**) may be explained by the difference in the basicity of these ligands. Calculated values show that they depend on the nature of the substituent on the hydrazone moiety, indicating that the complexation of the studied ligands is increased by increasing electron density at the reaction site, thus explaining the higher stability in electron-repeling substituents. The lower stability of ligand **V** compared to ligand **I** complexes may be attributed to both the cyclic structure and the distant location of the methyl groups from the hydrazone moiety.

In Fig. 2 both the electronegativity (19) (X_m) and second ionisation potentials (2nd I_p) of metal ions were plotted against log K_1 (first formation constant) for the ligands under investigation. Straight lines were obtained for all the divalent metal ions indicating that the stability constants decrease in the following order for different metal ligand complexes:

Zn < Cu > Ni > Co > Mn

This trend indicates that the stability of chelate compounds increases with increase of both electronegativity (X_m) and second ionization potential (2nd I_p) of the metal ion.

2. Solid complexes studies

The ultraviolet spectra of the organic ligands were recorded in pure DMF. Two maxima were observed in all of the ligands investigated. These bands may be assigned to $\pi-\pi^*$ transitions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.85.125.76 on 09/07/12
For personal use only.

of the hydrazone and carbonyl groups. The electronic absorption spectra of the free ligands compared to the spectra of their complexes in DMF reveals a shift of maxima (Table 2) which, produces evidence for sharing of both hydrazone and carbonyl groups in the complexation process.

The comparison of ir spectra of the solid organic ligands and their solid metal complexes may be helpful in identifying the structure of the solid complexes.

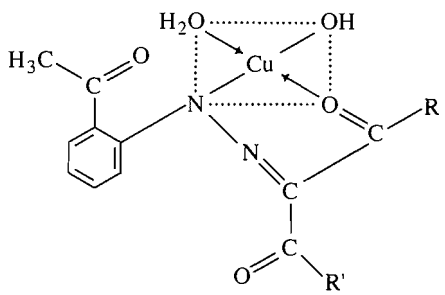
The studied ligands exhibit a stretching vibration band due to >NH at 3050, 3060, and 3130 cm^{-1} for 2-APHA, 2-APHB, and 2-APHDB ligands, respectively. Disappearance of the >NH stretching frequency was observed on chelate formation, which may be caused by coordination of hydrazone nitrogen to the metal atom upon complexation.

The only exception observed was the appearance of new medium intensity composite broad bands at 3515 and 3400 cm^{-1} in the spectrum of Cu(II)–2-APHA complex. These bands may be attributed to the ν_{H_2O} vibration of a coordinated water molecule. The appearance of a new medium intensity band at 810 cm^{-1} in the spectrum may be attributed to π_{H_2O} modes of coordinated water (20, 21). Elemental analysis is also consistent with the presence of coordinated water. Furthermore, the nonelectrolytic nature indicated by the molar conductance of the solid complex suggests that the complex has a 1:1 composition with the formula $[CuLH_2O(OH)]$.

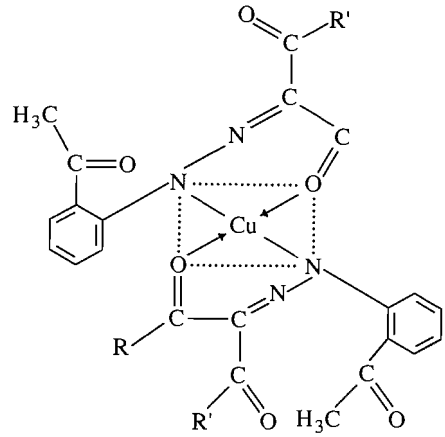
A very interesting feature in the infrared spectra is the appearance of new bands at lower frequencies due to metal–nitrogen and metal–oxygen interactions. The interaction is closely related to the stability of the chelates and provides information about the ligand–metal bond. In the metal complexes, there are new medium to weak intensity bands at lower frequencies (590–530 cm^{-1}) which may be assigned to ν_{M-N} modes of vibration (22–24). The metal–oxygen (22) interaction is observed at frequencies of 515–435 cm^{-1} for different metal complexes of 2-APHA, 2-APHB, and 2-APHDB ligands, depending upon both the metal ion and organic ligand.

The observed values for molar conductance of the complexes in DMF solution are shown in Table 2. All the measured complexes have molar conductance values which are indicative of a nonelectrolytic nature. In the case of Fe(III) nitrate complexes for both 2-APHB and 2-APHDB ligands, the molar conductance values indicate that the nitrate ion is not affected by DMF and is still present in the inner coordination sphere (Table 2).

The magnetic moment values for Cu^{2+}–2-APHA and Cu^{2+}–2-APHDB are 1.468 and 1.731 BM, respectively, indicating one unpaired electron. The complex may be square-planar and it is possible to propose the following structures for the Cu^{2+} complexes:



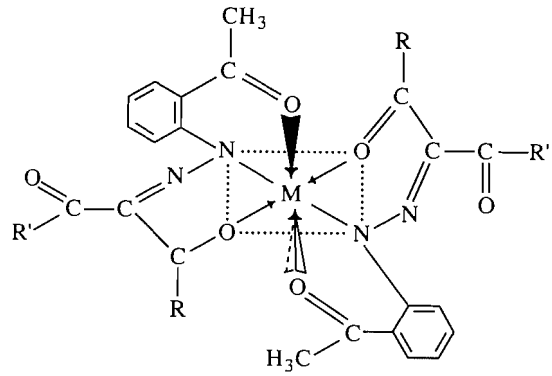
$[CuL\,H_2O(OH)]$, 1:1 complex



$[CuL_2]$, 1:2 complex

The magnetic moment for Fe(III)–2-APHDB complexes is 5.423 BM, indicating a spin-free configuration which may have octahedral structure.

The magnetic moment for Ni^{2+}–2-APHA and Ni^{2+}–2-APHDB complexes are 2.719 and 2.963 BM, respectively, indicating spin-free configurations. These magnetic moments are consistent with the assignment of octahedral configurations (25, 26). Consequently, the proposed structure of the octahedral M^{2+} complexes is as follows:



$[M^{2+}:L_2]$, 1:2 complex

Received August 22, 1989

This paper is dedicated to Professor G. B. Marini-Bettòlo on the occasion of his 75th birthday

GEORGE M. STRUNZ, CHAO-MEI YU, LI YA, PETER S. WHITE, and E. A. DIXON. Can. J. Chem. **68**, 782 (1990).

2-Acetonyl-2-methylsuccinic anhydride, **3**, the major product from base-catalysed reaction of 3-methyltricarballylic acid with acetic anhydride, was converted by simple manipulation of functional groups into 1,5-dimethyl-2,7-dioxabicyclo[3.2.1]octane. This bicyclic ketal (**6**) is isomeric with frontalin, **7**, an aggregation pheromone for *Dendroctonus* bark beetles. It elicited electroantennogram responses in *D. ponderosae* and *D. rufipennis*. Besides **3** and the known compounds, **4** and **5**, two new minor products, **8** and **9**, were identified from base-catalysed acylative decarboxylation of 3-methyltricarballylic acid.

Key words: pheromone analogue, *Dendroctonus*, bark beetles.

GEORGE M. STRUNZ, CHAO-MEI YU, LI YA, PETER S. WHITE et E. A. DIXON. Can. J. Chem. **68**, 782 (1990).

L'anhydride 2-acétonyl-2-méthyl succinique, **3**, le produit majeur provenant de la réaction de l'acide 3-méthyl tricarballylique avec l'anhydride acétique sous catalyse basique, a été transformé en 1,5-diméthyl-2,7-dioxobicyclo[3.2.1]octane. Cet acétal bicyclique (**6**) est isomère avec la frontaline, **7**, une phéromone d'agrégation des *Dendroctonus*. L'électroantennogramme indique une réaction de *D. ponderosae* et *D. rufipennis* à ce composé. De plus **3** et les composés connus **4** et **5**, on a identifié deux nouveaux produits mineurs, **8** et **9**, provenant de la décarboxylation acylative de l'acide 3-méthyl tricarballylique.

Mots clés : analogue de phéromone, *Dendroctonus*, scolytes.

Acylative decarboxylation of tricarballylic acid (3-carboxyglutaric acid) by the action of acid anhydrides under basic catalysis produces the Fittig bislactones **1** (1). These compounds have been found to be convenient precursors for the synthesis of certain 1,4-diketones, hence of substituted cyclopentenones (2, cf. 3). Tricarballylic acids that are fully substituted at C-3 undergo acylation at one or both of the methylene carbons, and decarboxylation of the resulting β-keto acids results in a different array of products (4, 5). Thus, when 3-methyltricarballylic acid, **2**, was heated under reflux with an excess of acetic anhydride in the presence of 4-dimethylamino pyridine (6), the keto-anhydride **3** and the bridged bislactone **4** were isolated in yields of 42 and 7.4% respectively (4, cf. 5). A minor product (~1%) was identified as the enol-lactone **5** (4).

We recognized that **3** and **4** offered ready access to the bicyclic ketal **6**, which has an interesting structural relationship to frontalin **7** (7, cf. 8), an aggregation pheromone for several species of *Dendroctonus* bark beetles. Frontalin has been detected in various *Dendroctonus* species, including *D. adjunctus* (9), *D. brevicomis* (10, 11), *D. frontalis* (7, 12), *D. pseudotsugae* (13), *D. rufipennis* (14), and *D. vitei* (15). It was detected in male *D. ponderosae* fed on Ponderosa pine but, somewhat surprisingly, not in the females (16). Structure–activity relationships of frontalin isomers and analogues may shed some light on the interaction between the pheromone and its receptors (8).

In this paper we report the conversion of **3** to **6** by straightforward manipulation of functional groups, and the results of some preliminary electrophysiological bioassays[2] of **6** using two *Dendroctonus* species. The characterization of two novel minor products, **8** and **9**, from the base-catalysed reaction of **2** with acetic anhydride is also recorded.

11

Both the keto-anhydride **3** and the bridged bislactone **4**, which are interconvertible via the corresponding keto-diacid (4), are suitable precursors of the frontalin isomer **6**. Acid-catalysed methanolysis of **3**, selected because of its greater abundance, afforded dimethyl 2-acetonyl-2-methylsuccinate in excellent yield. The ketone functionality was then protected as its ethylene ketal to allow the selective reduction of the ester groups using an excess of sodium bis(2-methoxyethoxy) aluminum hydride (19). Work-up of the latter reaction under acidic conditions resulted in removal of the protecting group, and the bicyclic ketal **6** was obtained in an overall yield of 48% from **3**.

Bioassays of the frontalin isomer **6**, which has a characteristic "camphor-like" odour, involved measuring the electroantennogram (EAG) responses which it elicited in *D. rufipennis*, the spruce bark beetle, and *D. ponderosae*, the mountain pine beetle. Frontalin is an aggregation pheromone for *D. rufipennis* (14), but has not been proven to play the same role for *D. ponderosae* (16, cf. 13). Racemic frontalin was used as a standard for comparison. It was observed that the shapes of the dose–response curves for **6** and (±) frontalin are quite similar. They differ in the threshold concentration that elicits an EAG signal: with both *Dendroctonus* species tested, the threshold concentration is 10–100 times higher than **6** than for racemic frontalin. At the 10 μg level (see Experimental) the response to **6** was 75% that produced by frontalin for *D. rufipennis*, and 67% for *D. ponderosae*. There were no significant differences in the relative responses of male and female insects.

To provide starting materials **3** and **4**, for the synthesis of **6** in sufficient quantity for field studies, the reaction of 3-methyltricarballylic acid with acetic anhydride was conducted on a larger scale than in the exploratory study (4). From the scaled-up process, which required a longer reaction time, besides **3** (42% yield), **4** (3.4%), and **5** (3.1%), two new minor products were obtained. The more abundant of these (4.5% yield) was a crystalline solid, $C_9H_{12}O_3$, identified as **8** on the basis of its spectroscopic characteristics and mechanistic considerations. Infrared absorption at 1787 cm^{-1} is consistent with the presence of a strained lactone system, and the mass spectrum shows loss of carbon dioxide as a prominent feature. In the ^1H nmr spectrum, singlets at δ 1.33 and 1.71, each corresponding to three protons, are assigned to the methyl groups on C-5 and C-1 respectively. A three-proton doublet (J 1.2 Hz) at δ 1.78 represents the allylic methyl hydrogens that are coupled with the C-4 olefinic proton. The latter is manifested as a narrow multiplet at δ 4.62. The olefinic hydrogen also exhibits long-range W-coupling (1.7 Hz) (17, cf. 4) with the low-field component of an AB quartet at δ 1.97 (J_{AB} 11.2 Hz, $\Delta\nu_{AB}$ 25.5 Hz) assigned to the geminal hydrogens on C-8. The bridged lactone **8** is isomeric with **5**, and may similarly be derived from the double acylation–decarboxylation product 4-carboxy-4-methylheptane-2,6-dione or an acid anhydride thereof.

The other new product, $C_{10}H_{10}O_4$, also a crystalline solid, was isolated in about 1% yield. Its structure, **9**, was deduced from spectroscopic evidence and confirmed by a single crystal X-ray analysis. A notable feature of its ^1H nmr spectrum is an AB quartet at δ 4.83 (J_{AB} 3.4 Hz, $\Delta\nu_{AB}$ 85.3 Hz) that clearly signals the presence of a terminal methylene group. A singlet at δ 2.16 indicates an allylic methyl group. The spectrum also includes an AB quartet at δ 2.80 (J_{AB} 15.7 Hz, $\Delta\nu_{AB}$ 48.3 Hz) whose upfield component displays long-range coupling with a methyl group (three-proton doublet at δ 1.42, J 0.6 Hz). Enol-lactone functionality is suggested by the infrared absorption at 1804 cm^{-1}, with shoulders at 1795 and 1787 cm^{-1}. Considering the origins of the product, these data are best accommodated by structures **9** or **10**. Formulations such as **11**, which are mechanistically plausible, can be excluded by the absence of any sign of allylic coupling of the terminal methylene protons. Of the proposed alternative representations, **9** or **10**, the former was favored on the basis of its ultraviolet chromophore. Thus, absorption at 252 nm (ε 8600) is consistent with a system containing two double bonds in conjugation and exocyclic to a five-membered ring (18) as in **9**.

Since this evidence was considered less than totally compelling, the product was subjected to a single crystal X-ray analysis that has provided rigorous proof for structure **9**. An ORTEP representation of **9** is shown in Fig. 1, and atomic coordinates, bond lengths, and bond angles are presented in Tables 1–3.

Experimental

Melting points were determined on a hot-stage apparatus and are uncorrected. Infrared spectra were recorded on a Philips Pye Unicam PU 9516 infrared spectrophotometer, and ultraviolet spectra on a Philips PU 8800 uv/vis spectrophotometer. Proton and carbon magnetic resonance spectra were run on a Varian XL-200 instrument. The gc/ms analysis was performed on a Finnigan 3200F-100 coupled with a 6110 data system (35 eV, SP 1000 capillary column, split, 220°C). Accurate mass measurements were provided through the courtesy of Dr. A. Hogg, University of Alberta. Microanalysis was performed by Spang Microanalytical Laboratory, Eagle Harbor, MI.

Reaction of 3-methyltricarballylic acid with acetic anhydride (cf. ref. 4)

A solution of 3-methyltricarballylic acid (4.0 g; 21.0 mmol) and 4-dimethylaminopyridine (337 mg; 2.76 mmol) in freshly distilled acetic anhydride (50 mL) was heated under reflux. After 16 h, evolution of CO_2 had almost ceased, and the mixture was evaporated to dryness on a rotary vacuum evaporator.

The major (and most polar) product **3** was isolated by flash chromatography (20) on silica gel using chloroform – ethyl acetate (9:1, then 4:1) as eluent. The yield of **3**, after crystallization from ethyl acetate, was 1.49 g (42%). Physical and spectroscopic characteristics are described in ref. 4.

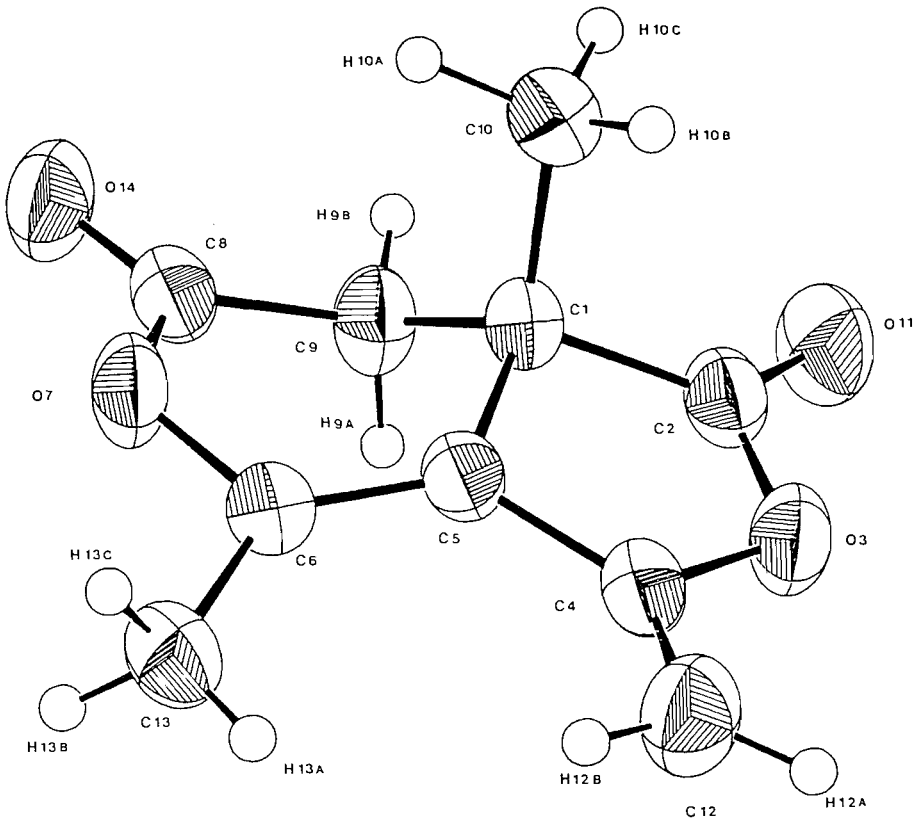

FIG. 1. ORTEP representation of compound **9**.

The less polar fractions were combined and separated by flash chromatography on silica gel employing hexane – ethyl acetate (9:1, then 3:1) as eluent. In order of decreasing chromatographic mobility the products isolated were **8**, **9**, **5**, and **4**.

The yield of bislactone **4** (4) after crystallization from ethyl acetate – hexane was 3.4%, and **5** (4) was obtained in 3.1% yield as an oil.

The bridged lactone **8**, after crystallization from ethyl acetate – hexane, was obtained as colorless crystals (160 mg, 4.5%), mp 75–78°C; ir ($CHCl_3$), *inter alia*: 1787, 1662, 1450, 1395, 1385, 1320, 1165, 1142, 1080, 1000, 910, and 880 cm^{-1}; ^1H nmr ($CDCl_3$, 200 MHz), see text; mass spectrum (*inter alia*), *m/e* (relative intensity) (ion): 168.0784(28) $(C_9H_{12}O_3)^{\ddagger}$ $(M^{\ddagger})$, 125.0603(47) $(C_7H_9O_2)^+$, 124.0886(36) $(C_8H_{12}O)^{\ddagger}$ $(M - CO_2)^{\ddagger}$, 123.0813(50) $(C_8H_{11}O)^+$ $(M - CO_2 - H)^+$, 111.0455(29) $(C_6H_7O_2)^+$, 83.0505(100) $(C_5H_7O)^+$.

The bis enol-lactone **9**, following crystallization from ethyl acetate – hexane, was obtained in 1% yield (40 mg) as colorless crystals, mp 123–124°C; ir ($CHCl_3$), *inter alia*: 1804, 1795 (sh), 1787 (sh), 1702, 1655, 1148, 1120, 1040, and 975 cm^{-1}; ^1H nmr ($CDCl_3$, 200 MHz), see text; mass spectrum (*inter alia*), *m/e* (relative intensity) (ion): 194.0573 (100) $(C_{10}H_{10}O_4)^{\ddagger}$ $(M^{\ddagger})$, 179.0329(2) $(C_9H_7O_4)^+$ $(M - CH_3)^+$, 166.0627(9) $(C_9H_{10}O_3)^{\ddagger}$ $(M - CO)^{\ddagger}$, 152.0470(68) $(C_8H_8O_3)^{\ddagger}$, 149.0236(24) $(C_8H_5O_3)^+$, 138.0680(20) $(C_8H_{10}O_2)^{\ddagger}$ $(M - CO - CO)^{\ddagger}$, 124.0523 (78) $(C_7H_8O_2)^{\ddagger}$ $(M - CO - CO - CH_2)^{\ddagger}$, 123.0447(24) $(C_7H_7O_2)^+$, 109.0305(56) $(C_6H_5O_2)^+$, 96.0573(31) $(C_6H_8O)^+$, 81.0342(24) (C_5H_5O). X-ray crystallography, see below.

Dimethyl 2-acetonyl-2-methylsuccinate

A solution of keto-anhydride **3** (400 mg; 2.35 mmol) in dry methanol (15 mL) containing concentrated sulfuric acid (10 drops) was heated at reflux under anhydrous conditions. After 12 h, the solution was concentrated to near dryness on a rotary vacuum evaporator. The residue was redissolved in chloroform and the solution was washed successively with saturated $NaHCO_3$ and water before being dried over anhydrous $MgSO_4$. Removal of solvent under reduced pressure afforded dimethyl 2-acetonyl-2-methylsuccinate as a colorless oil (480 mg, 94%) that was sufficiently pure to be used directly in the next step without further purification; ir ($CHCl_3$): 1730 cm^{-1}; ^1H nmr ($CDCl_3$, 200 MHz) δ: 1.32 (3H, s), 2.13 (3H, s), 2.78 (2H, s), 2.98 (2H, AB_q, J_{AB} 18.0 Hz, $\Delta\nu_{AB}$ 29.5 Hz), 3.65 (3H, s), 3.69 (3H, s); mass spectrum (*inter alia*), *m/e* (relative intensity) (ion): 216.1000(18) $(C_{10}H_{16}O_5)^{\ddagger}$ $(M^{\ddagger})$, 201.0767(6) $(C_9H_{13}O_5)^+$ $(M - CH_3)^+$, 185.0816(55) $(C_9H_{13}O_4)^+$ $(M - OCH_3)^+$, 159.0661(44) $(C_7H_{11}O_4)^+$ $(M - CH_2COCH_3)^+$, 157.0867(19) $(C_8H_{13}O_3)^+$ $(M - COOCH_3)^+$, 143.0705(13) $(C_7H_{11}O_3)^+$ $(M - CH_2COOCH_3)^+$, 141.0555(45) $(C_7H_9O_3)^+$, 127.0398(39) $(C_6H_7O_3)^+$, 125.0605(100) $(C_7H_9O_2)^+$ $(M - COOCH_3, OCH_3,$ and $H)^+$, 114.0682(51) $(C_6H_{10}O_2)^{\ddagger}$ $(M - COCH_3$ and $COOCH_3)^{\ddagger}$, 111.0447(31) $(C_6H_7O_2)^+$, 73.0657(40) $(C_4H_9O)^+$, 55.0566(34) $(C_4H_7)^+$.

Ethylene ketal of dimethyl 2-acetonyl-2-methylsuccinate

A solution of dimethyl 2-acetonyl-2-methylsuccinate (477 mg; 2.21 mmol) in dry benzene (25 mL) containing ethylene glycol (2.1 g, 33.8 mmol) and *p*-toluenesulfonic acid (50 mg) was heated under reflux for 10 h. The apparatus was then fitted with a Dean–Stark water separator containing molecular sieves and reflux was continued for an additional 2 h. When cool, the solution was diluted by addition of benzene (25 mL), washed successively with saturated $NaHCO_3$ solution and brine, and dried over $MgSO_4$. Removal of solvent *in vacuo* then afforded the ethylene ketal of dimethyl 2-acetonyl-2-methylsuccinate (555 mg, 96%) as a colorless oil, sufficiently pure to be used directly in the next step without further purification; ir ($CHCl_3$): 1730 cm^{-1}; ^1H nmr ($CDCl_3$, 200 MHz) δ: 1.26 (3H, s), 1.37 (3H, s), 2.21 (2H, AB_q, J_{AB} 14.9 Hz, $\Delta\nu_{AB}$ 36.9 Hz), 2.68 (2H, AB_q, J_{AB} 16.4 Hz, $\Delta\nu_{AB}$ 36.5 Hz), 3.65 (3H, s), 3.68 (3H, s), 3.89 (4H, narrow m); mass spectrum (*inter alia*), *m/e* (relative intensity) (ion): 260.1258(2) $(C_{12}H_{20}O_6)^{\ddagger}$ $(M^{\ddagger})$, 245.1029(7) $(C_{11}H_{17}O_6)^+$ $(M - CH_3)^+$, 229.1074(7) $(C_{11}H_{17}O_5)^+$ $(M - OCH_3)^+$, 216.0995(10) $(C_{10}H_{16}O_5)^{\ddagger}$, 215.0921(12) $(C_{10}H_{15}O_5)^+$, 189.0765(9) $(C_8H_{13}O_5)^{\ddagger}$, 185.0816(45) $(C_9H_{13}O_4)^+$, 171.0658(13) $(C_8H_{11}O_4)^+$, 159.0662(12)

Frontalin isomer: 1,5-dimethyl-2,7-dioxabicyclo[3.2.1]octane

To a stirred solution of sodium bis(2-methoxyethoxy) aluminum hydride (2.3 g of 60% solution, 6.83 mmol) (Red-Al^R) in dry benzene (11 mL) under nitrogen was added by syringe the ketal diester prepared above (700 mg, 2.69 mmol) in dry benzene (7 mL). The mixture was heated under reflux for 3 h, and was then cooled in an ice bath. Excess reagent was decomposed by cautious addition of water (8 mL), then the mixture was poured into cold aqueous sulfuric acid solution (25 mL of 20% solution) in a 125-mL Erlenmeyer flask. The mixture was stirred with ice-cooling for 30 min, then extracted with 4 × 50 mL ether.

The combined extracts were washed successively with saturated $NaHCO_3$ solution and brine, and then dried over $MgSO_4$. The solvent was removed *in vacuo*, and the residue distilled. A fraction, bp 82°C/30 Torr (1 Torr = 133.3 Pa), was characterized as the frontalin isomer **6** (201 mg, 53%); ir ($CHCl_3$) (*inter alia*): 2970, 2940, 2880, 1455, 1390, 1330, 1325, 1170, 1125, 1075, 1050, 1015, and 980 cm^{-1}; ^{1}H nmr ($CDCl_3$, 200 MHz) δ: 1.07 (3H, s, C(5)Me), 1.29 (3H, s, C(1)Me), 1.3 (1H, m, C(4)H_{eq}), 1.52 (2H, s, C(8)H_2), 1.6 (1H, m, C(4)H_{ax}), 3.44 (1H, dd, J 7.6, 2.3 Hz (W coupling), C(6)H_{exo}), 3.6–3.85 (3H, m, C(3)H_2, C(6)H_{endo}); ^{13}C nmr ($CDCl_3$) δ: 22.1 (Me on C(5)), 23.9 (Me on C(1)), 36.4 (C(4)), 39.8 (C(5)), 48.9 (C(8)), 60.7 (C(3)), 77.9 (C(6)), 106.2 (C(1)); gc/ms (*inter alia*): 142 (28) $(C_8H_{14}O_2)^{+\cdot}$ ($M^{+\cdot}$), 98 (100).

X-ray crystallography

The crystal data and X-ray diffraction conditions were as follows:

$C_{10}H_{10}O_4$ Formula weight 194.12

Triclinic, $P\bar{1}$, a = 6.7661(9) Å, b = 7.9960(5) Å, c = 9.8676(12) Å, α = 73.808(8)°, β = 76.237(12)°, γ = 65.748(8)°, V = 462.8 Å^3, Z = 2, ρ_{calc} = 1.394 Mg m^{-3}, $F(000)$ = 204e, MoKα radiation (λ = 0.71073 Å), μ = 0.10 mm^{-1}, $2\theta_{max}$ = 50°, crystal dimensions 0.74 × 0.30 × 0.15 mm, temperature 293 K.

Intensity data were collected on an Enraf–Nonius CAD-4 diffractometer equipped with graphite-monochromated MoKα radiation, using the NRCCAD control routines (21). The cell dimensions were obtained by a least-squares fit to the coordinates of 25 reflections, in the range 30° < 2θ < 35°, which were obtained by centering each reflection at four equivalent positions. An ω/2θ scan with profile analysis was used for the intensity data, 1623 reflections were measured of which 1197 had $I_{net} > 2.5\sigma(I)$ and were included in subsequent calculations. Three standard reflections measured every hour during data collection showed no significant deviation from their mean values. No correction was made for absorption.

The structure was solved by direct methods using the MULTAN-80 suite of programs (22). All subsequent computations were performed using the PC version of NRCVAX (23). Hydrogen atom positions were located from a difference synthesis. The structure was refined using least squares and minimizing $\Sigma\omega(|F_o| - |F_c|)^2$, with weights derived from counter statistics. In the final cycles all non-hydrogen atoms were

assigned anisotropic thermal parameters; the hydrogen atoms were permitted to refine with isotropic thermal parameters. Scattering factors were taken from ref. 24 and corrected for anomalous dispersion. The final agreement factors were $R = 0.051$ and $R_w = 0.071$ (0.071 and 0.077 for all reflections). The number of parameters refined was 167 and the largest shift/error was 0.10. A final difference synthesis showed no recognizable features and varied from -0.18 to 0.23 e $Å^{-3}$.[3]

An ORTEP (25) representation of the molecule is shown in Fig. 1, and final atomic coordinates are given in Table 1.

Bioassay

Electroantennograms (EAG's) indicating the response of the entire olfactory antennal club of the bark beetles to the stimulant vapor were recorded. The details of the technique have been described previously (26) and are based on the procedure reported by Dickens *et al.* (27). EAG's were recorded with Ag/AgCl capillary electrodes filled with insect saline. The recording electrode was placed in the distal end of the antennal club following prepuncture with an electrolytically sharpened tungsten needle. The indifferent electrode was placed in the beetle's head in the mouth region. The response signals were amplified by a Grass P-16 amplifier and plotted. The magnitude of the EAG response was measured as a percentage of the mean of two bracketing standards, 10 μg racemic frontalin.

The test compounds were diluted in *n*-pentane in decade steps. A 10-μL sample on a 20 × 6 mm filter-paper strip in a 80 × 5 mm glass chamber held about 1 cm away from the insect preparation was puffed towards the beetle by passing air at 1.7 L/min through the chamber for 1 s. Samples were presented from lowest to highest concentration for six different dilutions. Five replicates with different beetles and for both sexes were made at each concentration. A minimum interval of 4 min was allowed between stimuli, except at higher concentrations when 6 min was allowed. Racemic frontalin (10 μg on filter paper) was used as the standard for comparison, and this stimulus was presented between every set of two stimulations. Responses for *n*-pentane, but not for air, were subtracted from all responses. Generally, the response to air was either minor or absent.

Acknowledgements

We thank Mr. See-Hua Tan, Research and Productivity Council, for the gc/ms study. The EAG bioassays were conducted in the laboratory of Dr. A. T. Whitehead, Brigham Young University, and we thank him for his hospitality and assistance.

Raman spectroscopy and electrochemistry of water-soluble porphyrins at a silver electrode

HIDEO ORITA,[1] MASAO SHIMIZU, CHIZUKO NISHIHARA, TAKASHI HAYAKAWA, AND KATSUOMI TAKEHIRA
National Chemical Laboratory for Industry, Tsukuba, Ibaraki 305, Japan

Received February 21, 1989[2]

HIDEO ORITA, MASAO SHIMIZU, CHIZUKO NISHIHARA, TAKASHI HAYAKAWA, and KATSUOMI TAKEHIRA. Can. J. Chem. **68**, 787 (1990).

Cyclic voltammetry and laser Raman spectroscopy were applied to investigate *in situ* the properties and structures of metal *meso*-tetrakis (*p*-sulfonatophenyl)porphyrins (MeTPPS, Me = Co, Fe, Mn, Cu, Ni) adsorbed on a silver electrode in 0.05 M H_2SO_4 aqueous solution. The cyclic voltammograms for O_2 reduction were investigated by changing the metal cations in the porphyrin ring. Among the porphyrins examined, only CoTPPS shows catalytic behavior for O_2 electrochemical reduction. The Raman spectra of MeTPPS in aqueous solution are very similar to those of metal tetraphenylporphyrins (MeTPP), and the band assignments were carried out on the basis of the results for $[FeTPP]_2O$. The Raman spectra of MeTPPS on a silver electrode were measured under a N_2 or O_2 atmosphere, changing the applied potentials and the metal cations in the porphyrin ring. Their spectra are very sensitive to metal cations, but not so to applied potential.

Key words: porphyrin, SERS, electrochemistry, dioxygen, silver electrode.

HIDEO ORITA, MASAO SHIMIZU, CHIZUKO NISHIHARA, TAKASHI HAYAKAWA et KATSUOMI TAKEHIRA. Can. J. Chem. **68**, 787 (1990).

On a fait appel à la voltamétrie cyclique et à la spectroscopie Raman au laser pour étudier *in situ* les propriétés et les structures de *méso*-tétrakis(*p*-sulfonatophényl)porphyrines métalliques (MeTPPS, Me=Co, Fe, Mn, Cu, Ni) adsorbées sur une électrode d'argent, dans une solution aqueuse de H_2SO_4, à 0,05 M. On a examiné les voltamogrammes cycliques de la réduction de O_2 par des porphyrines contenant divers cations métalliques. Parmi les porphyrines étudiées, seule la CoTPPS présente un comportement catalytique pour la réduction électrochimique de O_2. Les spectres Raman des MeTPPS en solutions aqueuses sont très semblables à ceux des tétraphénylporphyrines (MeTPP) et l'on a procédé à l'attribution des bandes en se basant sur les résultats obtenus avec le $[FeTPP]_2O$. On a déterminé les spectres Raman des MeTPPS déposées sur une électrode d'argent sous des atmosphères de N_2 et de O_2, en faisant varier les potentiels appliqués ainsi que les cations métalliques du cycle de la porphyrine. Ces spectres sont très sensibles à la nature des cations métalliques, mais non au potentiel appliqué.

Mots clés : porphyrine, SERS, électrochimie, dioxygène, électrode d'argent.

[Traduit par la revue]

Introduction

Transition metal porphyrins and phthalocyanines catalyze the electrochemical reduction of O_2 when they are present either in solution or on electrode surfaces (1–10). Recently, water-soluble porphyrins and phthalocyanines have been introduced in order to identify the chemical species and understand the mechanism of O_2 electroreduction in aqueous solution (1–9).

In situ Raman spectroscopy is a very useful technique in studying electrochemical reactions in aqueous solutions because it provides a large amount of information about structures of adsorbates from their vibrational spectra. On the other hand, infrared spectroscopy usually cannot be applied to these systems, since strong absorption of infrared radiation of water makes it difficult to observe weak band intensities of adsorbates. Furthermore, surface enhanced Raman scattering (SERS) provides a means for detecting small amounts of adsorbates because of its large enhancement of the Raman signal.

The SERS spectra of water-soluble *meso*-tetrakis(*p*-sulfonatophenyl)porphyrin (TPPS) have already been reported by Cotton *et al.* (11) and Itabashi *et al.* (12). They studied the dependence of the spectra upon potential and found that the adsorbed porphyrins undergo partial incorporation of Ag from the electrode during the anodization step. However, neither of the two research groups investigated the effect of metal cations other than Ag, in a porphyrin ring, on the SERS spectra. In the present work, we selected MeTPPS (Me=Co, Fe, Mn, Cu, Ni) as a catalyst of O_2 reduction, and silver as electrode. We investigated the effect of metal cations on properties of water-soluble porphyrins during electrochemical reduction of O_2 in aqueous solution by the use of cyclic voltammetry and laser Raman spectroscopy and found that the cyclic voltammograms for O_2 reduction and the SERS spectra are very sensitive to metal cations.

Experimental

A silver rod (Furu-Uchi Chemicals, 99.99%, 5 mm in diameter, its side walls covered by a heat-shrinkable tube) was polished to a mirror finish with a suspension of alumina (Baikalox, 0.05 μm) and used as a working electrode after ultrasonic cleaning. A saturated calomel electrode (SCE) and a platinum wire were used as reference electrode and counter electrode, respectively. The potential of the electrode was controlled by the combination of a potentiogalvanostat (Hokuto Denko HA-501 or PAR M273) and a function generator (Hokuto Denko HB-105) or a personal computer (NEC PC-9801 VX2). The rotating ring-disk electrode (RRDE) apparatus used has been described before (13). An Au(ring)–Ag(disk) electrode was employed after the final polishing with alumina suspension. The measurements of Raman spectra using the 488.0 nm line of an argon ion laser (Coherent Radiation CR-8, ca. 50 mW) and a double dispersion Raman spectrometer (JASCO R-800) were carried out during electrochemical reduction of O_2 at a given potential. The incident angle was about 60° and the scattered light was collected in the perpendicular direction.

meso-Tetrakis(*p*-sulfonatophenyl)porphyrin was synthesized (14) and its metallation was carried out (15) by the published procedure. The sample solutions were prepared by dissolving porphyrins (10^{-2}–10^{-5} M) and H_2SO_4 (0.05 M) in distilled water.

Results and discussion

Cyclic voltammograms for O_2 reduction in 0.05 M H_2SO_4 aqueous solution are given in Fig. 1. Before the oxidation–reduction cycle (ORC) was applied, between −0.4 and +0.6 V

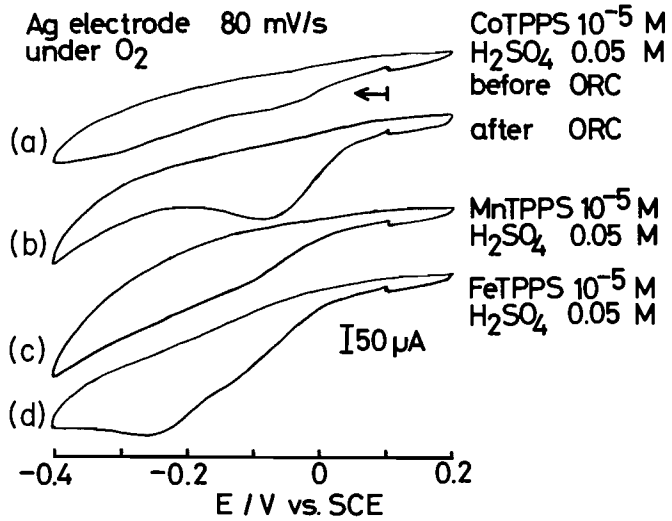

FIG. 1. Cyclic voltammograms for O_2 reduction in 0.05 M H_2SO_4 aqueous solution on a silver electrode at 80 mV/s: (a) CoTPPS 10^{-5} M, before oxidation–reduction cycles (ORC) between −0.4 and +0.6 V; (b) CoTPPS 10^{-5} M, after ORC; (c) MnTPPS 10^{-5} M, after ORC; (d) FeTPPS 10^{-5} M, after ORC.

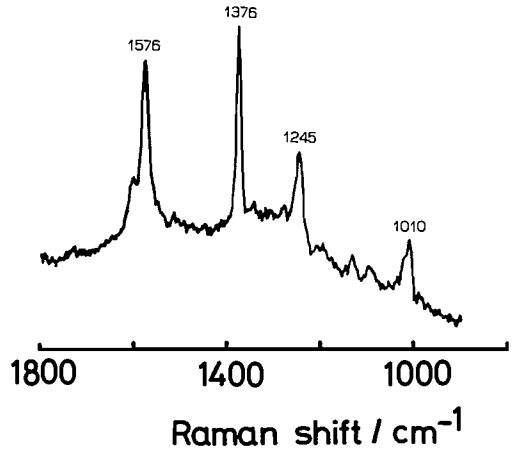

FIG. 2. Raman spectrum of CoTPPS in aqueous solution (10^{-2} M) with 488.0 nm excitation.

vs. SCE, the peak of the O_2 reduction wave was not clearly observed between −0.4 and +0.2 V in any of the cases investigated in this work (e.g., Fig. 1a). After ORC (usually ORC was applied in aqueous acidic solutions of MeTPPS), the peak of the O_2 reduction wave was distinctly observed at ca. −0.1 V in the presence of CoTPPS (Fig. 1b), suggesting that special sites involving an interaction of CoTPPS with the Ag electrode were created by ORC. When the same experiment was carried out for aqueous acidic solutions of MnTPPS, FeTPPS, CuTPPS, or NiTPPS, the peak of the reduction wave at −0.1 V did not appear (e.g., Figs. 1c and d). There was some increase in current for MnTPPS and a peak at ca. −0.25 V for FeTPPS. For CuTPPS, NiTPPS, or in absence of MeTPPS, only a small increase in the O_2 reduction current was observed at ca. −0.3 V after ORC. The electrode that was used after ORC in the solutions of MeTPPS other than CoTPPS was washed with water, and when the solution was changed to that of CoTPPS, the peak of the O_2 reduction wave at −0.1 V appeared clearly as is the case in Fig. 1b. Therefore, the cyclic voltammograms for O_2 reduction are very sensitive to metal cations, and CoTPPS clearly shows catalytic behavior for O_2 reduction. In neutral or alkaline solution, the effect of porphyrins on O_2 reduction was not observed. To check the presence of H_2O_2 as a product of O_2 reduction, RRDE experiments were carried out (Ag disk, 6 mm diameter, 0.2 mm gap width; Au ring, 1 mm ring width, calculated collection efficiency=0.4, 1000 rpm, 80 mV/s, ring potential=0.6 or 1.0 V). The formation of H_2O_2 generated by two-electron reduction of O_2 was not observed by RRDE in the present work. Consequently, it is considered that O_2 reduction mainly proceeds through a four-electron pathway (O_2 to H_2O). Ozer *et al.* (6) have studied the electrochemical reduction of O_2 by using cobalt tetra(4-N,N′,N″-trimethylanilinium) porphyrin and a glassy carbon electrode. They reported that dioxygen reduction proceeds mostly through a four-electron reduction in acidic solutions in the presence of adsorbed (or dissolved) porphyrin. Collman *et al.* (10) have also reported that cobalt derivatives of particular cofacial porphyrin dimers catalyze the overall four-electron reduction of O_2 while adsorbed on graphite electrodes in acidic solution, and that a Lewis-acid center facilitates the four-electron path.

Surface enhanced Raman scattering was applied to the present electrochemical system in order to obtain information about structures of MeTPPS at the electrode–solution interface and to investigate the effect of metal cations on O_2 electroreduction. At first, the spectra of MeTPPS in aqueous solution were measured; a typical result for CoTPPS is shown in Fig. 2. As the 488.0 nm line of the argon ion laser was not in resonance with the absorption bands of CoTPPS, spectra could be measured only when the concentration of CoTPPS was higher than 10^{-3} M. The spectrum in Fig. 2 is very similar to the spectrum of cobalt tetraphenylporphyrin (CoTPP) (16) or $[FeTPP]_2O$ (17). Therefore we have the following assignments based on the results obtained for $[FeTPP]_2O$, assuming D_{4h} symmetry: 1576, $\nu(C_\beta–C_\beta) + \delta(C_\beta–H)$; 1376, $\nu(C_\alpha–N) + \delta(C_\beta–H)$; 1245, $\nu(C_m–Ph)$; 1010, $\nu(C_\alpha–C_m)$. Here, ν and δ denote the stretching and in-plane bending mode, respectively, and all the numbers are given in cm^{-1}. All the bands that appeared strongly are assigned to the totally symmetric (A_{1g}) modes.

Figure 3a shows the Raman spectrum of CoTPPS on a silver electrode at −0.3 V under a N_2 atmosphere after ORC. In spite of low concentration (10^{-5} M), a spectrum of CoTPPS was obtained with a good S/N ratio. Compared with the solution-phase spectrum in Fig. 2, the bands were shifted to the lower wavenumber, and the relative intensity of bands at 1572 and 1193 cm^{-1} increased. These facts indicate that the observed Raman spectrum with the silver electrode is associated with adsorbed CoTPPS rather than with the solution-phase species. The solution-phase concentration during these experiments was too low to detect Raman signals under the conditions of the present work. The dependence upon potential of the Raman spectrum was examined by changing the electrode potential between −0.5 and +0.2 V. No significant shifts of bands were observed, within experimental accuracy. At potentials more positive than −0.1 V, all the peaks rapidly decreased in intensity as the potential was increased, suggesting that this phenomenon could be due to the desorption of CoTPPS from the electrode.

No change in the Raman spectrum of the adsorbed CoTPPS was observed with introduction of O_2, compared to N_2 saturation in the O_2 reduction region between −0.1 and −0.4 V, in spite of the effect of CoTPPS on the O_2 reduction wave for

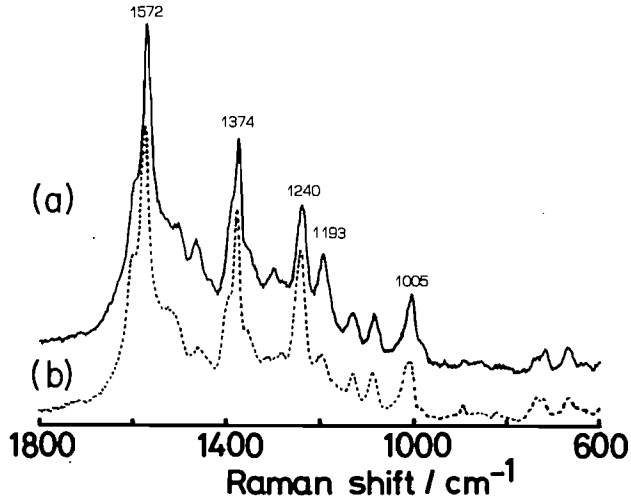

FIG. 3. Raman spectrum of MeTPPS on a Ag electrode with 488.0 nm excitation (10^{-5}, 0.05 M H_2SO_4, −0.3 V vs. SCE): (a) CoTPPS, N_2 atmosphere; (b) NiTPPS, O_2 atmosphere.

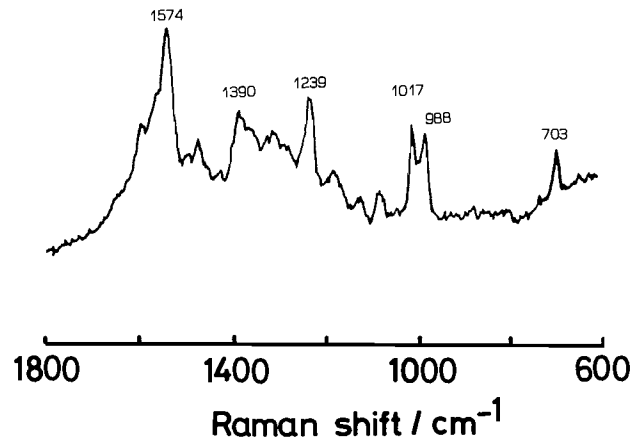

FIG. 4. Raman spectrum of MnTPPS on a Ag electrode with 488.0 nm excitation (10^{-5} M, 0.05 M H_2SO_4, −0.3 V vs. SCE, N_2 atmosphere).

the cyclic voltammogram. On the other hand, it is well known that cobalt porphyrins can form 1:1 O_2/Co adducts, and Bajdor *et al.* (18) reported that the O_2 stretching vibration ($\nu(O_2)$) of the dioxygen adduct of CoTPP with proper ligands and higher pressures of O_2 (ca. 4 atm; 1 atm = 101.3 kPa) was observed at 1144 cm^{-1} by the use of resonance Raman spectroscopy. Two possible explanations for no change in the Raman spectrum with introduction of O_2 can be considered. One is that at the quite negative potential used in the present study (at potentials more positive than −0.1 V, the Raman signal decreased rapidly and a spectrum with a good S/N ratio was not obtained), the O_2 was reduced easily and the concentration of O_2 in solution at the electrode surface, as well as the surface concentration of any O_2 adduct, was reduced effectively to zero. The other is that the residual O_2 in solution, even after prolonged N_2 bubbling, was sufficient to saturate the surface completely with respect to the formation of O_2 adduct (at a rough estimation, only ca. 10^{-9} moles per cm^2 of Ag surface were required to cover the Ag electrode as a monolayer). For CuTPPS and NiTPPS, which did not show any effect on O_2 reduction, similar spectra were obtained except that the band intensity at 1193 cm^{-1} was much weaker (Fig. 3b). The second explanation suggests that the band at 1193 cm^{-1} might arise from the interaction between CoTPPS and O_2, but the precise assignment of this band cannot be done at the present stage. More detailed and careful experiments by the use of isotopes (deuterated TPPS, $^{18}O_2$) and various laser lines (resonance Raman effect) will be necessary.

The Raman spectrum of MnTPPS on a silver electrode is shown in Fig. 4. The spectrum of MnTPPS is somewhat different from that of CoTPPS: the band at ca. 1000 cm^{-1} is split into two bands; the band at ca. 1200 cm^{-1} was very weak; the band at 1390 cm^{-1} broadened, shifted to higher wavenumber, and decreased in intensity, indicating that the adsorbed state of MnTPPS is a little different from that of CoTPPS. The spectrum of FeTPPS could not be measured because FeTPPS was decomposed to unknown compounds by laser radiation. No spectrum of MeTPPS on Ag could be obtained in alkaline solution. As no effects of MeTPPS on O_2 reduction were observed in alkaline solution, the adsorption of MeTPPS on a Ag electrode in alkaline solution may be hindered. Although the above-mentioned SERS measurements did not give definitive evidence with respect to the mechanism of O_2 reduction for CoTPPS because of experimental restrictions, they have revealed that Raman spectra of MeTPPS adsorbed on a Ag electrode are very sensitive to metal cations, but not so to applied potential.

Conclusions

The Raman spectra of MeTPPS were obtained on a Ag electrode and in aqueous solution. The spectra are similar to that of MeTPP, and the band assignments were carried out on the basis of the results for $[FeTPP]_2O$. All the bands that appeared strongly are assigned to totally symmetric modes. The cyclic voltammograms for O_2 reduction and SERS spectra are sensitive to the metal cations of MeTPPS. The band at 1193 cm^{-1} was clearly observed only when the electrochemical reaction was carried out using CoTPPS, which showed the highest activity of O_2 reduction among the porphyrins examined.

Acknowledgments

The authors wish to thank Dr. H. Shindo for use of the Raman apparatus and for advice on surface enhanced Raman scattering. The authors also thank the reviewers, whose valuable advice greatly helped to improve the discussion in this paper.

Received October 10, 1989

ANGEL GUZMÁN, MOISES ROMERO, and JOSEPH M. MUCHOWSKI. Can. J. Chem. **68**, 791 (1990).

It is shown that the reaction of *N*-alkylsuccinamidals (**2**) with the Vilsmeier–Haack reagent derived from DMF and phosphorus oxychloride can be controlled to preferentially produce either 5-chloropyrrole-2-carboxaldehydes (**8**) or 5-chloropyrrole-2,4-dicarboxaldehydes (**9**). The corresponding *N*-unsubstituted aldehydes are obtained when *N*-*tert*-butoxycarbonylsuccinamidal (**11**) is the substrate in the above reactions.

Key words: Vilsmeier–Haack reaction, succinamidals, 5-chloropyrrole-2-carboxaldehydes, 5-chloropyrrole-2,4-dicarboxaldehydes.

ANGEL GUZMÁN, MOISES ROMERO et JOSEPH M. MUCHOWSKI. Can. J. Chem. **68**, 791 (1990).

On a démontré que la réaction des *N*-alkylsuccinamidals (**2**) avec le réactif de Vilsmeier–Haack, obtenu à partir du DMF et de l'oxychlorure de phosphore, peut être contrôlée afin qu'elle produise préférentiellement soit des 5-chloropyrolle-2-carboxyaldéhydes (**8**) ou des 5-chloropyrolle-2,4-dicarboxyaldéhydes (**9**). Lorsque le substrat des réactions mentionnées plus haut est le *N*-*tert*-butoxycarbonylsuccinamidal (**11**), on obtient les aldéhydes correspondants qui ne sont pas substitués sur l'azote.

Mots clés : réaction de Vilsmeier–Haack, succinamidals, 5-chloropyrolle-2-carboxaldéhydes, 5-chloropyrolle-2,4-dicarboxaldéhydes.

[Traduit par la revue]

In connection with other studies in progress in these laboratories, it became necessary to develop a synthesis of 5-chloropyrrole-2-carboxaldehydes that was more convenient than those in existence. Such compounds have been prepared by the action of Vilsmeier–Haack reagents on 2-chloropyrrole derivatives (1) or 3-pyrroline-2-ones (2, 3). The first method does provide the aldehydes in good yields but the notorious instability of 2-chloropyrroles (1) makes this process distinctly unattractive. The second method possesses some degree of generality but 3-pyrrolin-2-ones are often not trivial to prepare (4–11).

It has been known for some time that succinimides are reduced to succinamidals by sodium borohydride (12). Dehydration of these reduction products under acidic conditions leads to 3-pyrrolin-2-ones but because of competing side reactions the process is usually not a useful one. It occurred to us that succinamidals might undergo dehydration under the conditions of the Vilsmeier–Haack reaction. The *in situ* generated 3-pyrrolin-2-ones would be expected to react rapidly with the Vilsmeier–Haack reagent, thus reducing potential competing acid-promoted side reactions. This paper describes results that demonstrate that this does indeed constitute a viable route to 5-chloropyrrole-2-carboxaldehyde derivatives.

Reaction of *N*-methylsuccinamidal (**2***a*, Scheme 1) with dimethylformamide (DMF) and phosphorus oxychloride (1:3:6 molar ratio)[4] in dichloromethane, at room temperature, gave the known (1) 5-chloro-1-methylpyrrole-2-carboxaldehyde (**8***a*, 33% yield, Table 1), after hydrolysis with aqueous sodium carbonate solution. Application of these conditions to other *N*-substituted succinamidals produced the expected 5-chloropyrrole-2-carboxaldehyde derivatives in modest yields (Table 1), but only a small amount (2%) of 5-chloropyrrole-2-carboxaldehyde (**8***d*) was obtained from succinamidal itself. In addition, in every case, except when succinamidal was the starting material, trace amounts of a second product, subsequently shown to be the 5-chloropyrrole-2,4-dicarboxaldehyde derivative **9**, were formed. This material doubtless stemmed from further reaction of the primary product **6** with the Vilsmeier–Haack reagent. The dialdehyde could be made the major or exclusive product by effecting the reaction at 50°C in the presence of 5 molar equivalents of the Vilsmeier–Haack reagent though, under these conditions, 5-chloropyrrole-2,4-dicarboxaldehyde (**9***d*) was isolated in only 2% yield from succinamidal.

The synthesis of 5-chloropyrrole-2-carboxaldehyde (**8***d*) was

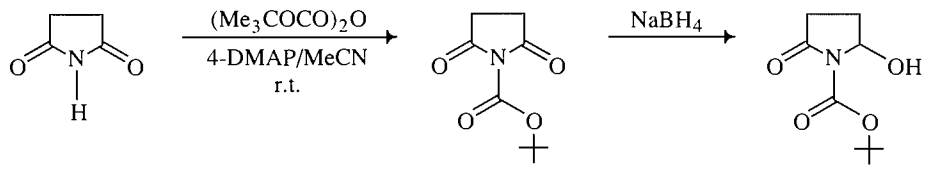
SCHEME 1



2*d* 10 11

SCHEME 2

dramatically improved by utilization of *N-tert*-butoxycarbonylsuccinamidal (**11**, Scheme 2) in the Vilsmeier–Haack reaction. This compound, upon reaction with 3 equivalents of the Vilsmeier–Haack reagent, gave rise to **8***d* in 46% yield, after hydrolysis with aqueous sodium acetate.[5,6] The loss of the protecting group must have occurred during the course of the reaction[7] since *N-tert*-butoxycarbonyl-5-chloropyrrole-2-carboxaldehyde (**12**) was stable to the hydrolysis conditions. The *N*-protected succinamidal **11** was prepared in the usual manner from *N-tert*-butoxycarbonylsuccinimide (**10**), which in turn was synthesized by the 4-dimethylaminopyridine-catalysed reaction of di-*tert*-butyldicarbonate with succinimide (14).

In conclusion, 5-chloropyrrole-2-carboxaldehydes or 5-chloropyrrole-2,4-dicarboxaldehydes are readily synthesized by reaction of the Vilsmeier–Haack reagent with succinamidals. Although the aldehyde yields, in most cases, are modest, the simplicity and brevity of the process as well as the low cost of the starting material(s) make this a particularly attractive route to such pyrrole derivatives.

In view of the observations of von Dobeneck and co-workers (2, 3), it is highly probable that the methodology described herein will be applicable to the synthesis of 5-brominated pyrrole mono- or dicarboxaldehyde derivatives and to 5-halo-2-acetylpyrroles (15).

Experimental

The melting points were determined in a Mel-Temp melting point apparatus and are not corrected. The infrared spectra were measured in chloroform solution, unless stated otherwise, with a Perkin–Elmer model 1420 infrared spectrophotometer or a Nicolet 5 PC FT infrared spectrophotometer. The ^{1}H nmr spectra were obtained in deuteriochloroform with a Varian EM-390 or a Bruker WM 300 nmr spectrometer and are expressed as parts per million (δ) from internal tetramethylsilane. When exchangeable protons were present, the data are given for deuterium oxide exchanged spectra.

[5]Much lower product yields resulted when the hydrolysis of the reaction products of **11** was effected with aqueous sodium carbonate.

[6]The chlorination of pyrrole-2-carboxaldehyde with sulfuryl chloride or *tert*-butyl hypochlorite is known (13) to produce a mixture of 4-chloropyrrole-2-carboxaldehyde, compound **8***d*, and 4,5-dichloropyrrole-2-carboxaldehyde.

[7]This is not unreasonable since 3 equiv. of hydrogen chloride are produced in the reaction.

The terms "worked up in the usual manner" or "the usual work-up" signify that the extract was dried over sodium sulfate and evaporated *in vacuo*.

Succinimide and the *N*-alkyl congeners thereof were obtained from commercial sources or synthesized by literature methods.

N-tert-*Butoxycarbonylsuccinimide (**10**)*

Di-*tert*-butyldicarbonate (13.1 g, 60 mmol) and 4-dimethylaminopyridine (0.610 g, 5 mmol) were added to a magnetically stirred solution of succinimide (5.0 g, 50 mmol) in reagent grade acetonitrile (100 mL). Carbon dioxide evolution began immediately. After 3 h, the solvent was removed *in vacuo* and the residue was subjected to column chromatography on silica gel (80 g). The product (8.8 g, 88%), eluted with hexane – ethyl acetate (4:1), was obtained as a solid that, after crystallization from hexane–dichloromethane, had mp 86°C; ir: 1806, 1767, 1709 cm^{-1}; nmr δ: 1.58 (s, 9H, *t*-Bu), 2.77 (s, 4H, CH_2CH_2). Anal. calcd. for $C_9H_{13}NO_4$: C 54.26, H 6.57, N 7.03; found: C 53.98, H 6.61, N 7.01.

Synthesis of the succinamidals

Succinamidal and *N*-methylsuccinamidal were prepared by the method of Speckamp and co-workers (12) in 60–65% yields.

(a) N-n-*Pentylsuccinamidal (**2**b)*

Powdered sodium borohydride (4.0 g, 106 mmol) was added in portions to a stirred, cooled (−20°C) solution of *N*-*n*-pentylsuccinimide (12.0 g, 71 mmol) in methanol (50 mL). After 2 h, a saturated aqueous solution of ammonium chloride (50 mL) was added and the reaction mixture was stirred for 1 h at ambient temperature. The mixture was filtered, the solids were washed well with ethyl acetate, and the washings and filtrate were evaporated *in vacuo*. The residue was extracted with dichloromethane and, after the usual work-up, the crude product was purified by column chromatography on silica gel (150 g). The product was eluted from the column with 1:1 hexane – ethyl acetate and was obtained as an oil (7.0 g, 60%); ir: 3350, 1685, 1680 cm^{-1}; nmr δ: 0.90 (t, 3H, J = 6.0 Hz, Me), 1.20 (m, 6H, $(CH_2)_3$), 1.86–2.69 (m, 4H, CH_2CH_2), 2.96–3.72 (m, 2H, NCH_2), 4.92–5.30 (m, 1H, CH). Anal. calcd. for $C_9H_{17}NO_2$: C 60.15, H 7.06, N 7.01; found: C 60.40, H 7.18, N 6.96.

(b) N-*Benzylsuccinamidal (**2**c)*

Powdered sodium borohydride (2.0 g, 43 mmol) was added portionwise to a stirred solution of *N*-benzylsuccinimide (4.0 g, 20 mmol) in 1:1 tetrahydrofuran (THF) – 95% ethanol (60 mL) at 0°C. After 3 h, the reaction was quenched by the addition of 10% aqueous hydrochloric acid (10 mL) and the mixture was worked up as described above for **2***b*. The crude product was diluted with water, extracted with ethyl acetate, and, after the usual work-up, the material obtained was purified as described for **2***b*. A solid (2.6 g, 50% yield) was obtained, which had mp 105–107°C after crystallization from ethyl acetate; ir: 3355, 1685 cm^{-1}; nmr δ: 1.74–2.72 (m, 4H, CH_2CH_2), 4.15 (d, 1H, J_{AB} = 15.1 Hz, H_A of NCH_2), 4.84 (d, 1H, J_{AB} = 15.1 Hz, H_B of NCH_2), 5.07 (dd, 1H, J_{AX} = 2.1 Hz, J_{BX} = 4.2 Hz, CH), 7.30 (s, 5H, C_6H_5). Anal. calcd. for $C_{11}H_{13}NO_2$: C 69.09, H 6.85, N 7.32; found: C 69.12, H 6.78, N 7.17.

(c) N-tert-*Butoxycarbonylsuccinamidal (**11**)*

This compound was synthesized in the same manner as **2***c* except that the reduction was effected at −50°C for 5 h. The reaction was quenched with 5% hydrochloric acid, the mixture was filtered, the solids were washed well with ethyl acetate, and the washings and filtrate were evaporated *in vacuo*. After the usual work-up, the crude product was purified by column chromatography on silica gel (350 g for a 47 mmol reaciton). Elution of the column with hexane – ethyl acetate (3:7) gave a solid (70% yield), which on crystallization from hexane – ethyl acetate had mp 78–79°C; ir: 3510, 1767, 1709 cm^{-1}; nmr δ: 1.57 (s, 9H, *t*-Bu), 1.93–2.97 (m, 4H, CH_2CH_2), 5.71 (dd, 1H, J_{AX} = 2.1 Hz, J_{BX} = 4.2 Hz, CH). Anal. calcd. for $C_9H_{15}NO_2$: C 53.72, H 7.51, N 6.86; found: C 53.88, H 7.73, N 6.85.

*Synthesis of 5-chloropyrrole-2-carboxaldehydes (**8**)*

*(a) 1-Methyl-5-chloropyrrole-2-carboxaldehyde (**8**a)*

The Vilsmeier–Haack reagent was prepared by slow addition of anhydrous DMF (1 mL, 0.94 g, 13 mmol) to phosphorus oxychloride (2.4 mL, 4.0 g, 26 mmol) with stirring at 0°C in a nitrogen atmosphere. The reaction mixture was left at room temperature for 3 h and then a solution of *N*-methylsuccinamidal (0.500 g, 4.34 mmol) in anhydrous 1,2-dichloroethane (10 mL) was added and the reaction mixture was stirred for 15 h at room temperature. A solution of sodium carbonate (4.6 g, 43 mmol) in water (20 mL) was added and the mixture was stirred for 2–3 h at room temperature. The products were extracted into dichloromethane and, after the usual work-up and purification by column chromatography on silica gel (60 g), using hexane – ethyl acetate (7:3) as the eluting solvent, the aldehyde **8***a* was obtained as an oil (0.205 g, 33% yield), which had spectroscopic properties identical to those reported (1).

*(b) 1-*n*-Pentyl-5-chloropyrrole-2-carboxaldehyde (**8**b)*

This compound was synthesized in the same manner as described for **8***a* except that hexane – ethyl acetate (95:5) was used in the column chromatographic purification. The product was obtained as an oil; ir: 1678 cm^{-1}; nmr δ: 0.87 (t, 3H, J = 6.1 Hz, Me), 1.23–1.47 (m, 4H, CH_2CH_2), 1.55–1.86 (m, 2H, CH_2), 4.37 (t, 2H, J = 7.3 Hz, NCH_2), 6.21 (d, 1H, J = 4.3 Hz, H-4), 6.90 (d, 1H, J = 4.3 Hz, H-3), 9.44 (s, 1H, CHO). Anal. calcd. for $C_{10}H_{14}ClNO$: C 60.15, H 7.06, N 7.01; found: C 60.40, H 7.18, N 6.96.

*(c) 1-Benzyl-5-chloropyrrole-2-carboxaldehyde (**8**c)*

Prepared in the same way as described for **8***a* except that hexane – ethyl acetate (9:1) was used for the column chromatographic purification. Compound **8***c* was obtained as an oil; ir: 2715, 1695 cm^{-1}; nmr δ: 5.66 (s, 2H, CH_2), 6.25 (d, 1H, J = 4.1 Hz, H-4), 6.93 (d, 1H, J = 4.1 Hz, H-3), 7.04–7.40 (m, 5H, C_6H_5), 9.46 (s, 1H, CHO). Anal. calcd. for $C_{12}H_{10}ClNO$: C 65.61, H 4.58, N 6.37; found: C 66.00, H 4.71, N 6.13.

*(d) 5-Chloropyrrole-2-carboxaldehyde (**8**d)*

This compound was prepared from compound **11** as described for **8***a* except that 3 molar equivalents of DMF and of phosphorus oxychloride were used. At the end of 15 h, sodium acetate (6 g for a 2.5 mmol scale reaction) in water (10 mL) was added to the reaction mixture and, after stirring for 3 h at room temperature, the reaction mixture was processed exactly as described for **8***a*. After crystallization from dichloromethane–hexane, compound **8***d* had mp 110°C (lit. (1) mp 110–111°C).

*Synthesis of 5-chloropyrrole-2,4-dicarboxaldehydes (**9**)*

*(a) 1-Methyl-5-chloropyrrole-2,4-dicarboxaldehyde (**9**a)*

The Vilsmeier–Haack reagent was prepared as described for **8***a* except that 5 molar equivalents of DMF and 10 molar equivalents of phosphorus oxychloride were used. The amidal was added in 1,2-dichloroethane solution (10 mL for a 4.34 mmol reaction) and the reaction mixture was maintained at 50°C for 15 h. The reaction mixture was cooled to 0°C, sodium carbonate (9.4 g for a 4.34 mmol reaction) in water (45 mL) was added, and the mixture was stirred for 2–3 h at room temperature. The reaction mixture was processed in the same manner as described for **8***a*, to give the desired product as well as a small amount (5%) of **8***a*. After crystallization from hexane–dichloromethane, the dialdehyde **9***a* had mp 153–154°C; ir: 2810, 1676 cm^{-1}; nmr δ: 4.00 (s, 3H, Me), 7.39 (s, 1H, H-3), 9.62 (s, 1H, CHO), 9.97 (s, 1H, CHO). Anal. calcd. for $C_7H_6ClNO_2$: C 49.00, H 3.52, N 8.16; found: C 48.83, H 3.50, N 8.03.

*(b) 1-*n*-Pentyl-5-chloropyrrole-2,4-dicarboxaldehyde (**9**b)*

Prepared in the same manner as described for **9***a* except that hexane – ethyl acetate (9:1) was used in the column chromatographic purification. The dialdehyde **9***b* and a small amount (4%) of **8***b* were obtained. After crystallization from hexane–dichloromethane, compound **9***b* had mp 70°C; ir: 1674, 1663 cm^{-1}; nmr δ: 0.91 (t, 3H, J = 7.0 Hz, Me), 1.35 (m, 4H, CH_2CH_2), 1.73 (m, 2H, CH_2), 4.44 (t, 2H, J = 7.6 Hz, NCH_2), 9.53 (s, 1H, CHO), 9.90 (s, 1H, CHO). Anal. calcd. for $C_{11}H_{14}ClNO_2$: C 58.02, H 6.14, N 6.15; found: C 57.94, H 6.17, N 5.83.

*(c) 1-Benzyl-5-chloropyrrole-2,4-dicarboxaldehyde (**9**c)*

Prepared in the same way as described for **9***a* except that hexane –

ethyl acetate (4:1) was used in the column chromatographic purification. After crystallization from hexane–dichloromethane, the dialdehyde **9***c* had mp 103–104°C; ir: 2720, 1680 cm^{-1}; nmr δ: 5.73 (s, 2H, CH_2), 7.17 (m, 2H), 7.33 (m, 3H), 7.42 (s, 1H, H-3), 9.54 (s, 1H, CHO), 9.92 (s, 1H, CHO). Anal. calcd. for $C_{13}H_{10}ClNO_2$: C 63.04, H 4.06, N 5.65; found: C 63.08, H 4.11, N 5.68.

*(d) 5-Chloropyrrole-2,4-dicarboxaldehyde (***9**d*)

Prepared in the same manner as described for **8***d* except that 5 molar equivalents each of DMF and $POCl_3$ were used and the reaction was left at room temperature for 40 h. The dialdehyde **9***d* was obtained in 9% yield together with the monoaldehyde **8***d*. After crystallization from methanol, **9***d* had mp 180°C; ir (KBr): 3440, 2722, 1650 cm^{-1}; nmr δ: 7.30 (s, 1H, H-3), 9.55 (s, 1H, CHO), 9.93 (s, 1H, CHO). Anal. calcd. for $C_6H_4ClNO_2$: C 45.93, H 2.50, N 8.88; found: C 46.10, H 2.72, N 8.70.

*1-*tert*-Butoxycarbonyl-5-chloropyrrole-2-carboxaldehyde (**12**)*

Di-*tert*-butyldicarbonate (0.335 g, 1.54 mmol) was added to a solution of 5-chloropyrrole-2-carboxaldehyde (0.100 g, 0.57 mmol) and 4-dimethylaminopyridine (0.010 g, 0.07 mmol) in reagent grade acetonitrile (5 mL). The solution was stirred at room temperature for 2 h, the solvent was then removed *in vacuo*, and the residue was purified by column chromatography on silica gel (15 g) using hexane – ethyl acetate (3:1) as the eluting solvent. The product (0.124 g, 70%) was obtained as a pale yellow oil; ir: 1767, 1678 cm^{-1}; nmr δ: 1.50 (s, 9H, *t*-Bu), 6.25 (d, 1H, J = 4.1 Hz, H-4), 6.95 (d, 1H, J = 4.1 Hz, H-3), 9.60 (s, 1H, CHO). Anal. calcd. for $C_{10}H_{12}ClNO_3$: C 52.29, H 5.27, N 6.10; found: C 52.37, H 5.28, N 5.99.

New macrocycle polyether 18-crown-6 complexes of stoichiometry $[(H_3O^+ \cdot 18\text{-crown-}6)_2(MCl_4^{2-})]$ have been synthesized for M = Zn and Mn. The two complexes are isostructural and crystallize in the monoclinic system, space group $C2/c$. The unit cell dimensions are as follows: a = 16.229(9), b = 11.535(3), c = 20.134(8) Å, β = 97.55(4)° and a = 16.255(6), b = 11.625(3), c = 20.122(8) Å, β = 96.54(3)° for the Zn and Mn complexes respectively. In both crystal structures (final R_w = 0.048 with 1817 reflections for Zn and R_w = 0.074 with 728 reflections for Mn), the crown ether molecule and the H_3O^+ cation to which it is hydrogen-bonded are disordered over two sites. The MCl_4^{2-} anions, which have tetrahedral coordination, are on crystallographic twofold axes of rotation. The Mn—Cl and Zn—Cl distances average 2.270 and 2.361 Å respectively. The hydronium cation, H_3O^+, has pyramidal coordination. Of the two disordered crown ether molecules in the Zn and the Mn complexes, one has a slightly deformed $(ttg)_6$ conformation while the other one may be described as having the distorted $(ttg)_5(ttc)$ conformation. These observations are in agreement with the infrared analyses of the complexes.

Key words: 18-crown-6 complexes, hydronium ion, $ZnCl_4^{2-}$, $MnCl_4^{2-}$, crystal structure.

ROBERT CHÊNEVERT, DANIEL CHAMBERLAND, MICHEL SIMARD et FRANÇOIS BRISSE. Can. J. Chem. **68**, 797 (1990).

On a synthétisé de nouveaux complexes de polyéthers macrocycliques 18-couronne-6 de stoechiométrie $(H_3O^+ \cdot 18\text{-couronne-}6)_2(MCl_4^{2-})$ dans lesquels M = Zn et Mn. Les deux complexes sont isostructuraux et ils cristallisent dans le système monoclinique, groupe d'espace $C2/c$ avec a = 16,229(9), b = 11,535(3) et c = 20,134(8) Å, β = 97,55(4)° et a = 16,255(6), b = 11,625(3) et c = 20,122(8) Å, β = 96,54(3)° respectivement pour les complexes du Zn et du Mn. Dans chacune des structures cristallines (valeurs finales de R_w = 0,048 avec 1817 réflexions pour le Zn et R_w = 0,074 avec 728 réflexion pour Mn), la molécule d'éther couronne et le cation H_3O^+ auquel elle est attachée par liaisons hydrogène est désordonnée sur les deux sites. Les anions MCl_4^{2-} qui possèdent une coordination tétraédrique se retrouvent sur des axes cristallographiques binaires. Les distances moyennes Mn—Cl et Zn—Cl sont respectivement 2,270 et 2,361 Å. La coordination du cation hydronium, H_3O^+, est pyramidale. Des deux molécules d'éthers couronnes désordonnées qui sont présentes dans les complexes du Zn et du Mn, l'une possède une conformation légèrement déformée $(ttg)_6$ alors que l'on peut décrire la conformation déformée de l'autre par $(ttg)_5(ttc)$. Ces observations sont en accord avec les analyses infrarouges de ces complexes.
