Stable doubly charged negative ions exist in crystals, because of the surrounding environment. To simulate such an environment for the doubly charged negative ions in the crystals and to ensure a bound solution to the Schrödinger equation, Watson proposed a sphere of charge +1 or +2 with a defined radius surrounding the free singly or doubly charged negative ion. The charged sphere forces the asymptotic form of the potential to be negative and the Schrödinger equation to give a bound solution.

The extra potential generated by a Watson sphere with charge +1 or +2 (the environment of the doubly charged negative ion in the crystal) is combined within LSD–GX–SIC theory. The details of this theory and VWM correlation energy functional can be found in the literature (9, 23–25).

III. Results and discussion

The calculation of the doubly charged negative ion of oxygen, O^{2-}, was carried out using LSD–GX–SIC theory with the VWN correlation energy functional, the Gopinathan, Whitehead, and Bogdanovic (GWB) (26) Fermi-hole parameters, and a Watson sphere of charge +1 and +2. The calculated LSD–GX–SIC statistical total energy (including the energy contribution of the Watson sphere but excluding the VWN correlation energy correction) for O^{2-} was −156.2137 Ry for the +1 Watson sphere and −163.5574 Ry for the +2 Watson sphere, compared to Watson's HF calculation (14) in which the total ionic energy (including Watson sphere energy) was −156.1194 Ry for the +1 Watson sphere and −163.4968 Ry for the +2 Watson sphere. The same radius (1.4 Å or 2.66 au) of Watson sphere (14) was used in both calculations. The excellent agreement of the total energies for the doubly charged negative ion from LSD–GX–SIC theory and from HF theory parallels that for the neutral atoms, positive ions, and the singly charged negative ions (8, 27). Therefore LSD–GX–SIC theory predicts doubly charged negative ions as reliably as HF theory.

The statistical total energy of a negative ion from Watson-sphere-aided LSD–GX–SIC theory is dependent on the charge on the Watson sphere. There are several choices for this charge, +2, +1, or 0 for singly and doubly charged negative ions. Calculation shows that there is no difficulty in getting convergent results for singly and doubly charged negative ions with a Watson sphere of charge +1 and +2, but, as mentioned in Sect. II, it is impossible to obtain a convergent value for a doubly charged negative ion using a Watson sphere of charge 0, which is equivalent to a calculation without a Watson sphere.

Table 1 summarizes the VWN correlation energy corrected statistical total energies without and with the energy contribution of the Watson sphere for the singly and doubly charged negative ions of oxygen, O^- and O^{2-}, in LSD–GX–SIC theory with the Watson sphere of charge +2, +1, and 0 and radius 2.66 au. The last line gives the corresponding energy differences of the singly and doubly charged negative ions, that is,

$$[3] \quad \mathrm{EA} = E_{\mathrm{tot}}{}^{-} - E_{\mathrm{tot}}{}^{2-}$$

the second electron affinity of O, where $E_{\mathrm{tot}}{}^{-}$ and $E_{\mathrm{tot}}{}^{2-}$ are the statistical total energy excluding the Watson sphere energy (corresponding to columns 2, 3, and 4 in Table 1) or the statistical total energy including the Watson sphere energy (columns 5, 6, and 7), respectively. Compared to the experimental second electron affinity, −0.61 Ry for O, it is clear that the difference of the statistical total energies (excluding the Watson sphere energy) with both +1 and +2 charges for the singly and doubly charged negative ions (columns 2 and 3) can be used to fit the experimental value of the second electron affinity for O by slightly adjusting the radius of the Watson sphere. However, the difference of the statistical total energy including the Watson sphere energy (columns 5 and 6) cannot be fitted to experiment. The best prediction of the second electron affinity for O is with the Watson sphere of charge +2.

The difference in the statistical total energies between the singly charged negative ion O^- with the Watson sphere of charge +1 and the doubly charged negative ion O^{2-} with the Watson sphere of charge +2 is −0.6629 Ry, close to experiment. It can be used to fit the experimental value by adjusting the radius of the Watson sphere. However, this method was not used to predict any other second electron affinity because (i) the best fit of the second electron affinity is obtained from the

difference of the statistical total energies, with Watson spheres of charge +2 and radius 2.66 au (which is interestingly close to the lattice distance); (ii) physically, the second electron affinity should be the total energy difference between the singly and doubly charged negative ions in the same environment; it is possible to obtain a positive second electron affinity for an atom by using a different environment for the singly and doubly charged negative ions.

The statistical total energy of the negative ion in Watson-sphere-aided LSD–GX–SIC theory depends on the Watson sphere radius. Therefore the difference between the statistical total energies of the singly and doubly charged ions, eq. [3], depends on the choice of Watson sphere radius. Watson suggested using the ionic radius of the doubly charged negative ion for the artificial charged sphere. This suggestion was tested in the present work for O, S, and Se using a Watson sphere of charge +2. The second electron affinity in LSD–GX–SIC theory with VWN correlation energy correction is −0.6655 Ry for O, −0.3858 Ry for S, and −0.3462 Ry for Se, compared to the averaged experimental values, which are −0.595 Ry for O, −0.45 Ry for S, and −0.39 Ry for Se. Obviously, the agreement between the calculated and experimental values is not consistent for these three elements; the second electron affinity is underestimated for O and overestimated for S and Se using the ionic radii of the doubly charged negative ions for the Watson spheres.

To find the Watson sphere radius that is best for calculating the second electron affinity of an atom, the second electron affinities, the difference of the statistical total energies (including the VWN correlation energy correction but excluding the

Watson sphere energy) between the singly and doubly charged negative ions, with a Watson sphere of charge +2 are plotted in Fig. 1 against the radius of Watson sphere for O, S, and Se in LSD–GX–SIC theory with VWN correlation energy functional and GWB Fermi-hole parameters. Figure 2 has a Watson sphere of charge +1. The experimental values of the second electron affinities for O (16, 21), S, and Se (15, 21) are also marked on the corresponding curves of these figures. From Figs. 1 and 2, it is obvious that the calculated second electron affinities of O, S, and Se are much less negative with a Watson sphere of charge +1 than with a sphere of charge +2 for the same Watson sphere radius. Physically, a Watson sphere of charge +2 is more reasonable, because the net charge provided by the remainder of a crystal would be +2 for an equilibrium situation. The Watson sphere has to be very small to give an acceptable second electron affinity with a +1 charge sphere so that it is far from the lattice distance found in the crystal.

Figure 1 illustrates the calculated second electron affinity for O equal to experiment at a Watson sphere radius of approximately 3.0 au: approximately 2.8 au for S and 2.6 au for Se or 4.37 au, since two different experimental values of the second electron affinity for Se are given (15, 21). The "best" Watson sphere radius, suitable for the three doubly charged negative ions to give correct second electron affinities, compared to experiment, is approximately 3.0 au.

Table 2 lists the negative of the second electron affinities for atoms helium to krypton calculated using eq. [3], in which the total energies are the statistical total energies (including VWN correlation energy correction and excluding the energy generated by the Watson sphere) with a Watson sphere of charge +2 and radius 3.0 au using LSD–GX–SIC theory with VWN correlation energy functional and GWB Fermi-hole parameters. These results are compared with other estimations (15, 21), for which extrapolation was used, and with experiment (15, 16, 21). Columns 3 and 4 give the electron configurations of the singly and doubly charged negative ions, chosen according to the ground-state electron configuration of the atom, in which the total number of electrons is the same as in the negative ion. Columns 5 and 6 give the present results without and with VWN correlation energy correction.

Table 2 shows that all the doubly charged negative ions are unstable (the negative values of the second electron affinities), which supports the physical fact that they exist only in crystals (Sect. II). The statistical total energy of the singly charged negative ion is lower than that of the doubly charged negative ion for all these elements.

It may be seen that the second electron affinities for the same group elements become less negative as the atomic number Z increases, except for the first row elements, H and He, where the average Watson sphere radius of 3.0 au is too far from the ideal for these atoms. The second electron affinities, EA(2), of the same row elements in which the outermost orbitals are $2p$ also become less negative as the occupation number of their spin quantum number m_s increases, that is,

$$\mathrm{EA(2)_{Li}} < \mathrm{EA(2)_{Be}} < \mathrm{EA(2)_{B}}$$

and

$$\mathrm{EA(2)_{C}} < \mathrm{EA(2)_{N}} < \mathrm{EA(2)_{O}}$$

etc., as is true for the elements in which the outermost orbitals are $3p$ and $4p$. The calculated results parallel experiment. These trends are reasonable; as the total number of electrons increases, the exchange correlation, which is approximately proportional to the number of electrons, also increases. The existence of stable negative ions of atoms in nature is mainly caused by the quantum effect, which is the negative contribution of the exchange-correlation effect of the electrons to the energy functional; therefore the results should parallel the exchange correlation.

Conclusion

It has been shown that the Watson sphere is an effective technique for calculating the doubly charged negative ions, which normally cause non-convergent problems (28, 29). The second electron affinities of atoms are acceptable when a correct radius of Watson sphere is chosen; the method has been illustrated and the trends established using a fairly accurate average Watson sphere radius of 3.0 au. Specific choice of radius would yield slightly more accurate numerical results but would not alter the trends. This method can be extended to estimate values for the high-Z atoms.

Radical clocks as probes of 1,4-biradical intermediates in the photochemical cycloaddition reactions of 2-cyclopentenone with alkenes[1]

ANDREAS RUDOLPH AND ALAN C. WEEDON[2]

The Photochemistry Unit, Department of Chemistry, The University of Western Ontario, London, Ont., Canada N6A 5B7

Received February 28, 1990

ANDREAS RUDOLPH and ALAN C. WEEDON. Can. J. Chem. **68**, 1590 (1990).

The products of the photochemical reaction of 2-cyclopentenone with 1,6-heptadiene and with vinylcyclopropane have been examined. With 1,6-heptadiene the products were cyclobutanes, which arise from 2 + 2 photocycloaddition between the cyclopentenone carbon–carbon double bond and one of the two terminal double bonds of the heptadiene. The 1,4-biradical that is an intermediate in this reaction contains a derivative of a 1-hexenyl radical; no products derived from cyclization of this intermediate to a cyclopentylmethyl radical were observed. With vinylcyclopropane some of the products isolated also arose from 2 + 2 photocycloaddition; in addition, comparable quantities of products resulting from rearrangement of the intermediate 1,4-biradical were obtained. In this case the initially produced intermediate 1,4-biradical contains a cyclopropylmethyl radical that can rearrange to a homoallylic radical; the products isolated were derived from intramolecular disproportionation in the new 1,7-biradical containing the homoallylic radical. The rate constant for the rearrangement of the cyclopropylmethyl radical to the homoallylic radical is known and was used as a clock to estimate the lifetime of the initially produced 1,4-biradical. The value estimated is of the order of 50 ns. The structures of the products indicate that the initial bonding between the excited cyclopentenone and vinylcyclopropane takes place at both the α-position and the β-position of the enone and not exclusively at the α-position as a recent report claims.

Key words: enone photocycloaddition, 1,4-biradicals, radical clocks.

ANDREAS RUDOLPH et ALAN C. WEEDON. Can. J. Chem. **68**, 1590 (1990).

On a examiné la nature des produits de la réaction photochimique de la cyclopent-2-ènone avec l'hepta-1,6-diène et avec le vinylcyclopropane. Avec l'hepta-1,6-diène, les produits sont des cyclobutanes qui proviennent d'une photocycloaddition 2 + 2 entre la double liaison carbone–carbone de la cyclopenténone et l'une des deux doubles liaisons terminales de l'heptadiène. Le 1,4-diradical intermédiaire dans cette réaction contient un dérivé d'un radical hex-1-ènyle; on n'a pas observé la formation de produits provenant de la cyclisation de cet intermédiaire en un radical cyclopentylméthyle. Avec le vinylcyclopropane, quelques produits isolés provenaient aussi d'une photocycloaddition 2 + 2; de plus, on a obtenu des quantités comparables de produits provenant d'une transposition du 1,4-biradical intermédiaire. Dans ce cas, l'intermédiaire 1,4-biradical qui se forme initialement contient un radical cyclopropylméthyle qui se transpose en un radical homoallylique; les produits isolés proviennent d'une disproportionation intramoléculaire en un nouveau 1,7-biradical qui contient le radical homoallylique. La constante de vitesse pour la transposition du radical cyclopropylméthyle en radical homoallylique est connue et on l'a utilisée comme horloge pour évaluer le temps de vie du 1,4-biradical produit initialement. La valeur estimée est de l'ordre de 50 ns. Les structures des produits indiquent que la liaison initiale entre la cyclopenténone excitée et le vinylcylopropane se produit autant en position α qu'en position β de l'énone et non pas uniquement en position α comme il avait été suggéré récemment.

Mots clés : photocycloaddition d'énone, 1,4-biradicaux, radicaux agissant comme horloge.

[Traduit par la revue]

Introduction

The photochemical cycloaddition reaction of enones with alkenes to give cyclobutane products (e.g., Scheme 1) has been the subject of many reports over the last 30 years and numerous examples of the application of this reaction to the synthesis of natural products and of novel carbon skeletons have appeared (1). The synthetic application of the reaction has made necessary an understanding of the factors that control the stereochemistry and regiochemistry of the alkene addition and this has stimulated a large amount of work aimed towards the determination of the reaction mechanism. It has been proposed by Loutfy and de Mayo (2) that the reaction proceeds as shown in Scheme 2. In this scheme the triplet excited state of the enone, $^3E^*$, forms an exciplex, $^3EA^*$, with the alkene, A. Bond formation in the exciplex between one terminus of the alkene and either the α-position or the β-position of the enone leads to a triplet 1,4-biradical species, BIR. The major fates of the biradical are reversion to ground state enone and alkene, or closure to the

cyclobutane-containing product **1**, although intramolecular disproportionation is occasionally competitive (1).

Elements of this cycloaddition mechanism remain controversial; for example, there is still no general agreement concerning the site of initial bonding of the alkene to the enone and hence the structure of the intermediate 1,4-biradical (see for, example, ref. 3). Thus for the reaction of cyclopentenone with ethylene to give **1** the biradical could, in principle, have either structure **2** or structure **3**, which correspond to initial bonding to the enone

α-position or β-position, respectively. In addition, while the intermediacy of biradicals in the photocycloaddition reaction is well established from indirect kinetic evidence (1, 2) and from product studies (1), it has not yet been observed directly and no value of the biradical lifetime has been determined.

The work described here was designed to allow an estimate to be made of the biradical lifetime and also to determine whether the initial bonding between the enone and the alkene in the biradical is via the α-position or the β-position of the enone. The approach adopted was to perform the photocycloaddition reaction using alkenes that yield biradicals that, in competition with ring closure to normal cyclobutane products, are capable of undergoing a rearrangement leading to alternative products. The rearrangement reaction can then be used as a probe of both the structure of the biradical and, if the rate of the rearrangement reaction is known, as a clock (4) to measure its lifetime.

The alkenes chosen for this study were 1,6-heptadiene and vinylcyclopropane.

Scheme 3 shows the anticipated outcome of the reaction between cyclopentenone and vinylcyclopropane. Interaction of the triplet excited enone and the alkene can in principle lead to the biradicals **4**–**7**, although **4** and **7** might be expected to dominate over **5** and **6** because the latter pair contain primary radical centres. Biradicals **4** and **5** can cyclize to **8** while **6** and **7** can close to **9**. The biradicals **4** and **7** contain a cyclopropylalkyl radical that is known (5) to ring open rapidly to a homoallylic radical as shown for the formation of **10** and **11** from **4** and **7**, respectively. If double bond geometry is correct in **10** and **11** then they can close to **12** and **13**, respectively. The rate of the rearrangement of the cyclopropyl methyl radical to the homoallylic radical is known (5); therefore, the quantities of **12** and **13** formed relative to the amounts of **8** and **9** can be used to infer the rate of formation of **8** and **9** from **4** and **7**, and hence the lifetime of **4** and **7**. In addition, since **13** is only formed from **7**, and **12** is only formed from **4**, the question of whether the products are formed by initial bonding between the alkene and either the α-position or the β-position of the enone can be answered by determining which of **12** and **13** is produced.

In Scheme 4 the expected outcome of the reaction between cyclopentenone and 1,6-heptadiene is shown. The expected biradicals are **14**–**17**, although **14** and **17** may dominate since **15** and **16** contain primary radical centres. Cyclization of **14** and **15** gives **18** while cyclization of **16** and **17** gives **19**. However, **14** and **17** contain derivatives of 1-hexenyl radicals, which are known (6) to be capable of cyclization to cyclopentylmethyl radicals. If this occurs here then species **20** and **21** will be formed, which can proceed to the various stereoisomers of **22**. Since the rate of the cyclization of 1-hexenyl radicals to cyclopentylmethyl radicals is known (6), the proportions of **18** and **19** relative to **22** formed can be used to define the lifetime of the biradicals **14** and **17**.

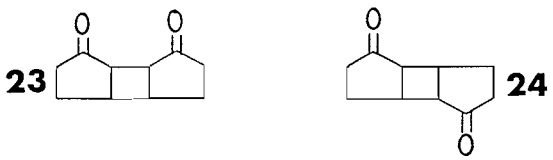
Irradiation of cyclopentenone with vinylcyclopropane

Irradiation with UV light of a cyclohexane solution of cyclopentenone and vinylcyclopropane gave the previously described



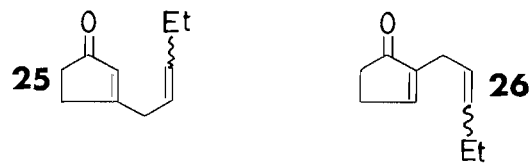
cyclopentenone dimers **23** and **24** (7) along with a mixture of four 1:1 adducts of the cyclopentenone and vinylcyclopropane.

The ^{1}H NMR spectrum of the product mixture after removal of solvent and excess reactants indicated the presence of compounds possessing cyclopropyl rings (signals at 0.1–0.8 ppm). In addition, olefinic signals (at 5.5 ppm) were observed, indicative of non-conjugated 1,2-dialkyl substituted alkenes. This was in accord with expectations since it was anticipated that the mixture would contain adducts of the type **8** and **9**, and **12** and **13**. However, the ^{1}H NMR spectrum of the reaction mixture also contained signals corresponding to the olefinic protons on a cyclopentenone ring (resonances at 6.1 and 7.2 ppm) even though all unreacted cyclopentenone had been removed.

It was possible to separate the adducts from the cyclopentenone dimers by preparative thin-layer chromatography (PLC) and this technique also allowed partial separation of the adducts into two groups. The ^{1}H NMR spectrum of the more polar group of adducts indicated the absence of olefinic signals and the presence of signals in the region 0.1–0.8 ppm. Consequently it was tentatively concluded that this fraction contained the expected 2 + 2 cycloadducts **8** and **9**. The ^{1}H NMR spectrum of the less polar material revealed that this contained the species possessing the olefinic hydrogens and none of the cyclopropyl ring containing species.

The more polar fraction (i.e., that containing the 2 + 2 adducts **8** and **9**) was further separated by preparative gas chromatography. We were not able to obtain the separate adducts entirely free from each other and so full characterization of the structures was not possible. Consequently no conclusions could be drawn as to the stereochemistry and regiochemistry of these compounds. The general structures **8** and **9** were, however, confirmed by the ^{1}H NMR and mass spectra of the partially separated components.

The mixture of compounds present in the less polar fraction from PLC was further separated by preparative GC and yielded comparable amounts of two major components each consisting of a single compound, and a very minor component consisting mainly of a mixture of two compounds. The two major components were identified as single geometrical isomers of the pentenyl substituted cyclopentenones **25** and **26**. The mixture of minor components was identified as the two alternative geometrical isomers of **25** and **26**. No trace of the expected rearrangement products **12** and **13** was found.



The structures of the two major isomers of **25** and **26** were deduced primarily from their ^{1}H NMR spectra. The ethyl group of both compounds appeared as a three-proton triplet at ca. 0.9 ppm coupled to two protons at 2 ppm, which appeared as a pentuplet showing evidence of further allylic coupling. The allylic coupling and part of the vicinal coupling in the latter signal arose from the adjacent pair of olefinic protons that appeared at ca. 5.3 and 5.5 ppm; these in turn were coupled to the adjacent methylene, which was found at 2.9 ppm. The single cyclopentenone olefinic proton in these compounds appeared in

one at 6.05 and in the other at 7.29 ppm. The chemical shifts of these protons allowed the point of attachment of the pentenyl side chain to be established since the α and β hydrogens of cyclopentenone come at 6.22 and 7.76 ppm, respectively; thus the product with a signal at 7.29 was identified as one of the geometrical isomers of **26** and that with the signal at 6.05 was identified as one of the geometrical isomers of **25**. The results of two-dimensional homonuclear ^{1}H correlation experiments showed the expected coupling between all the protons in the spectra of the two major isomers and confirmed the assignments. An attempt was made to assign the stereochemistry of the double bond of the pentenyl side chain by measurement of the coupling constants of the olefinic protons. However, in both compounds the olefinic protons were at very similar chemical shifts and this, along with the fact that they are further coupled both vicinally and allylically, made measurement of the coupling constants difficult. However, in the case of **25** it was possible to measure the desired coupling constant by recording the two-dimensional *J*-resolved ^{1}H NMR spectrum, from which a value of 9 Hz was obtained, indicative of *cis* stereochemistry (8).

The assignment of structure to the two minor geometrical isomers of **25** and **26**, which were isolated as a mixture in very small amounts, was based upon the mass spectral and ^{1}H NMR spectral data, which appeared as a composite of spectra very similar to those of the purified major isomers. In view of the very small amounts of these minor reaction products obtained, no further attempts were made to separate and characterize this mixture.

Comparison of the ^{1}H NMR spectra of the isolated samples of **8** and **9**, and **25** and **26**, with that of the crude reaction mixture indicated that these were the major components of the mixture and that no further products, such as **12** and **13**, had escaped notice. This was confirmed by GC comparison, which also allowed the ratio of (**8** + **9**) to (**25** + **26**) in the reaction mixture to be estimated as approximately 3.7:1.

Irradiation of cyclopentenone with 1,6-heptadiene

The reaction mixture obtained from irradiation of cyclopentenone (0.08 M) with 1,6-heptadiene (0.17 M) in cyclohexane was found to contain five major products by GC. The molecular ions in the mass spectra of the five products obtained by GC–MS of the reaction mixture indicated that two of them were dimers of cyclopentenone while the other three were 1:1 adducts of cyclopentenone with the diene. The fragmentation patterns of the three adducts were similar and showed characteristic $M^+ - 41$ peaks assigned to cleavage of an allyl fragment. This suggested that the adducts are stereoisomers of the expected cyclobutane products **18** and **19**, as did the observation of fragments corresponding to retro 2 + 2 cleavage of the cyclobutane ring. The cyclopentenone/1,6-heptadiene adducts were separated from the other components of the reaction mixture by PLC, although the adducts could not be separated from one another. The ^{1}H NMR spectrum of the adduct mixture contained the expected signals at 4.9 and 5.7 ppm corresponding to the terminal alkene of **18** and **19**. To confirm that none of the rearranged adduct **22** was present but masked by **18** and **19**, the entire reaction mixture was hydrogenated to reduce all alkene double bonds present. Inspection of the hydrogenated mixture by GC-MS revealed that while the cyclopentenone dimers were unchanged, all the other products, assigned to **18** and **19**, had moved to longer retention time and had increased in mass by two units. Thus it was concluded that none of the rearranged adduct **22** had been formed.

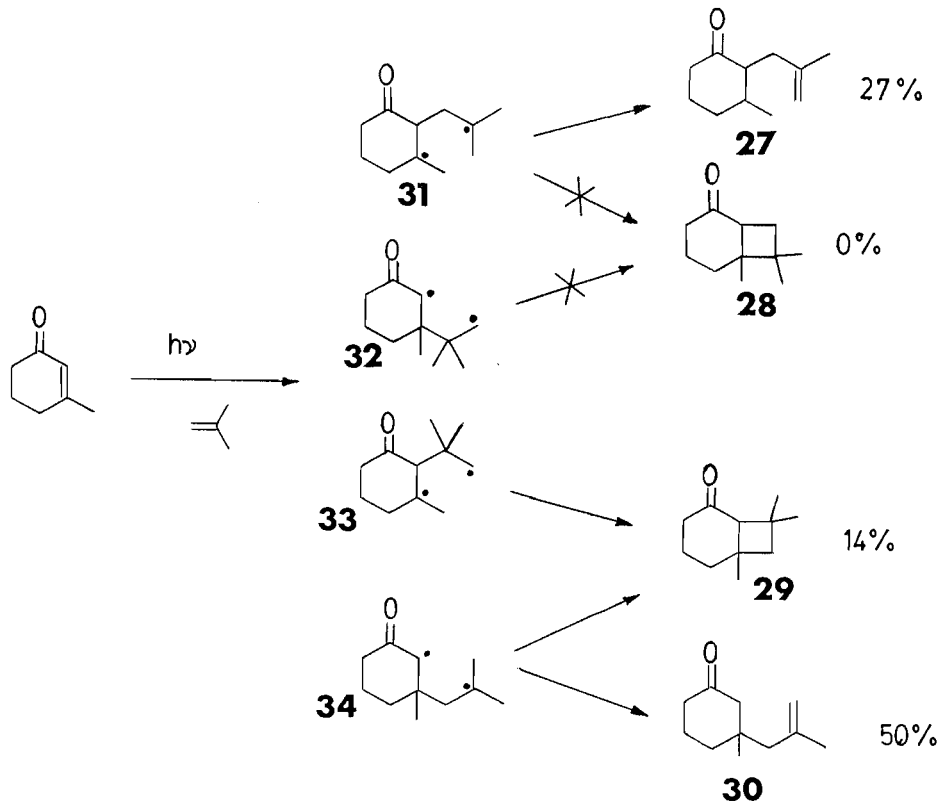
Discussion

Irradiation of cyclopentenone with 1,6-heptadiene gave none of the rearranged adduct **22** and no other products derived from the rearranged biradicals **20** or **21** were found. Apart from cyclopentenone dimers, only adducts assigned structures **18** and **19** were found. This must mean that the biradicals **14** and **17** close to the products **18** and **19** much faster than rearrangement of the 1-hexenyl radical to a cyclopentylmethyl radical. The rate constant for the latter rearrangement is at most 1.0×10^5 s^{-1} (6) and so it can be concluded that the biradicals **14** and **17** have lifetimes substantially shorter than 10 μs.

Irradiation of cyclopentenone with vinylcyclopropane gave a mixture of the 2 + 2 adducts **8** and **9** along with comparable amounts of the products **25** and **26**, which presumably result from disproportionation of the biradicals **10** and **11**. The latter are formed by opening the cyclopropyl alkyl radicals **4** and **7**. The cyclopropyl methyl radical has been estimated to open with a rate constant of 2.1×10^8 s^{-1} at room temperature (4, 5). If the methyl group is substituted, as in the cyclopropylethyl radical, then the extra stabilization slows the rate of opening to a value estimated as 2×10^7 s^{-1} (9, 10). If **4** and **7** open at a similar rate to the latter then the sum of their rate constants for ring closure to the cyclobutane products **8** and **9** plus their rate constants for reversion to the starting materials must be comparable with the rate constant for rearrangement of the secondary cyclopropylethyl radical. Hence the lifetimes of the biradicals **4** and **7** must be of the order of 50 ns.

The above arguments assume that none of the products **8**, **9**, **18**, and **19** are formed from biradicals **5**, **6**, **15**, and **16**, respectively, and that the observed products are predominantly derived from **4**, **7**, **14**, and **17**. While reaction via **5**, **6**, **15**, and **16** may represent a minor reaction pathway it is highly unlikely that the enone triplet excited state would react with the more hindered terminus of the mono-substituted alkenes to give the less stable biradical intermediates.This assumption is supported by the observed regioselectivity of the reaction of alkyl radicals with non-symmetrically substituted alkenes where the major product of addition is always that derived from attack at the less substituted end of the alkene (11). However, alkyl radicals are not perfect models of enone triplet excited states and better evidence for the regiochemistry of addition of an enone to an alkene can be found in the observed products of photoaddition between cyclohexenones and 2-methylpropene (12). In addition to cyclobutane-containing products, this reaction yields substantial quantities of compounds derived from intramolecular disproportionation of the intermediate biradicals. For example, the photochemical reaction between 3-methylcyclohexene and 2-methylpropene (Scheme 5) gives **27**–**30** in the yields shown (12*a*–*c*). These must be formed from the biradicals **31**–**34**, with **27** derived exclusively from **31**, and **30** exclusively from **34**. Of the isolated products, at most 14% (i.e., **29**) can have their origin in a biradical resulting from addition of the enone triplet excited state to the more substituted end of the alkene (i.e., **33**).

The value of 50 ns estimated for the lifetime of the 1,4-biradicals produced in the cycloaddition of cyclopentenone to vinylcyclopropane is towards the lower end of the range of lifetimes reported for other 1,4-biradicals such as those generated in the Norrish Type II reaction (13) and the Paterno–Buchi reaction (13c, 14), which have been reported to have lifetimes anywhere in the range of 1–2000 ns. It has been proposed that the lifetime of these biradicals at room temperature depends largely upon the rate of inter-system crossing from the triplet biradical to the singlet biradical, and less upon structural effects in the biradical



SCHEME 5

(15). The fact that the estimated lifetimes of **4** and **7** are in this range supports this idea.

The formation of similar quantities of **25** and **26** in the reaction between cyclopentenone and vinylcyclopropane indicates that the initial bond formation between the enone and the alkene occurs at both the α-position and the β-position of the cyclopentenone. This has not previously been demonstrated for cyclopentenones, although for cyclohexenones the same would also seem to apply since the products of biradical disproportionation in the reaction between 2-methylpropene and cyclohexenones (e.g., **27** and **30** in Scheme 5) must also be derived from initial bonding to both the α-position and the β-position of the enone (12).

The formation of disproportionation products **25** and **26** rather than the expected bicyclic adducts **12** and **13** requires some comment. Biradicals and radical pairs that contain cyclopropyl alkyl radicals have been generated in a number of photochemical reactions but these mainly involve intermediates produced from the excited states of cyclopropyl ketones. Examples include Norrish Type II reactions (9, 16) and intermolecular hydrogen abstraction reactions (17) of cyclopropyl ketones, as well as Norrish Type I reactions of α-cyclopropyl ketones (18). In general, because of the structures of the biradicals or radical pairs that are formed as intermediates in these reactions, the disproportionation process implicated in the production of **25** and **26** from **10** and **11** is not usually observed. The use of vinylcyclopropane derivatives as precursors of cyclopropyl alkyl radicals in photochemical reactions has been applied to the Paterno–Buchi reactions of aryl ketones and aldehydes (19). The triplet excited states of these carbonyl compounds interact with vinylcycloproprane (19*a*) to give a 1,4-biradical that contains a cyclopropyl alkyl radical capable of rearranging to a homoallylic radical. The isolated products are the unrearranged 2 + 2 adducts **35** (or their decomposition products) and the tetrahydro-oxepins **36** derived from closure of the biradicals formed from ring openings of the intermediate cyclopropyl alkyl radicals, as shown in Scheme 6. Two aspects of this reaction are especially pertinent to the results described in this paper. First, only the adducts with the regiochemistry exhibited by **35** are formed and none of the regioisomers **39** are obtained. This is consistent with the formation of a 1,4-biradical by bonding of the ketone oxygen to the terminus of the alkene to give the more stable secondary radical **37** rather than the primary radical **38**. This supports the argument given above for the preferential formation of biradicals **4** and **7** rather than **5** and **6** in the reaction between vinylcycloproprane and cyclopentenone. Second, the biradical **40** closed to the tetrahydro-oxepin **36** rather than undergoing an intramolecular disproportionation reaction analogous to that observed here for **10** and **11**, which gave **25** and **26**. The preference for closure over disproportionation shown by **40** presumably reflects the absence of an abstractable hydrogen atom adjacent to the ketyl radical in **40**.

Following the completion of this manuscript we became aware of a recent preliminary report describing the intramolecular addition of a 1,6-diene and a vinylcyclopropane to a cyclohexenone (20). The compounds examined were **41** and **42**. The former gave a mixture of compounds identified as cyclobutane-containing adducts while the latter also gave a mixture of species identified as cyclobutane-containing adducts along with a mixture of products assigned structures **43**. The latter are presumed to be formed by rearrangement of the intermediate **44** (which contains a cyclopropylmethyl radical) to **45** and subsequent closure to **43**. No disproportionation products corresponding to **25** and **26** were isolated, presumably because a suitable hydrogen is not present for abstraction by the terminal methylene radical in **45**.

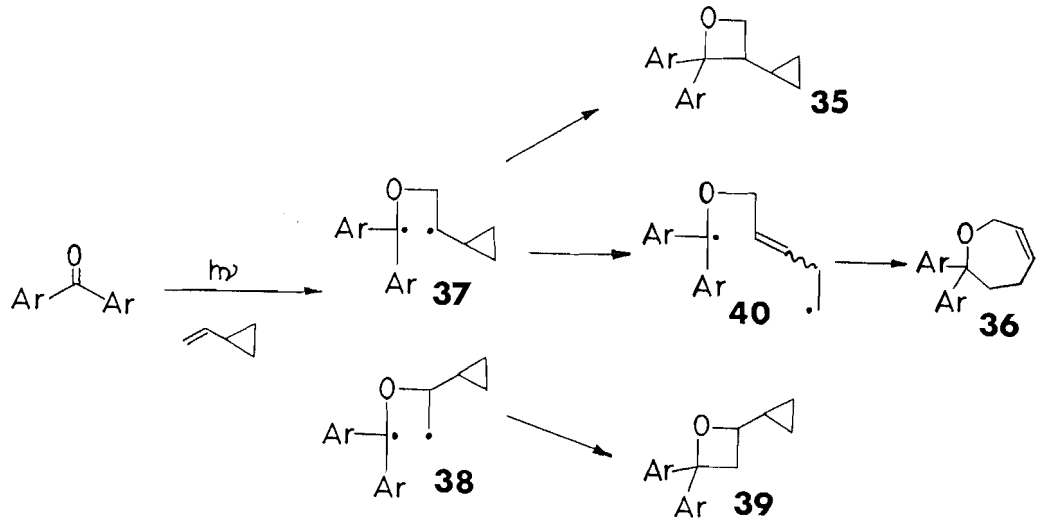
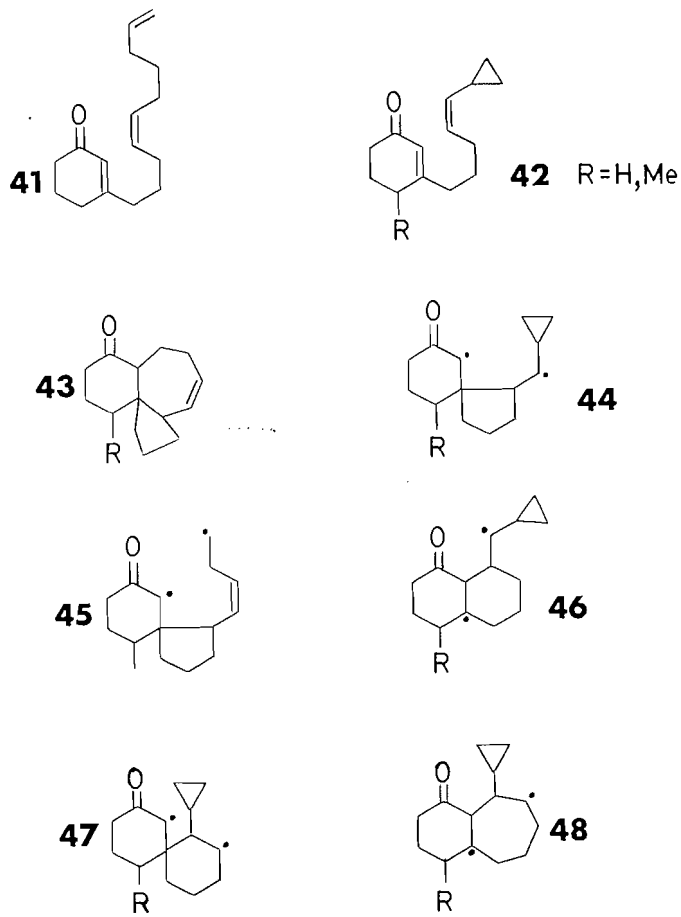


SCHEME 6

These results for the intramolecular 2 + 2 addition to a cyclohexenone complement ours for the intermolecular 2 + 2 addition to cyclopentenone. They imply that the intermediate 1,4-biradicals have similar lifetimes in both systems and decay with rate constants comparable with that of the cyclopropylmethyl radical ring-opening reaction. However, the results obtained for **42** are also used to support the idea that the first-formed bond in enone–alkene 2 + 2 photo-cycloaddition is formed between the alkene and the β-position of the enone. Our results suggest otherwise since we observe rearrangement products from both of the regioisomeric biradicals **4** and **7**. In fact, **42** is not a good probe of the site of initial bonding since the well-known "rule of five" (1) predicts that none of the alternative biradicals **46–48** should be formed in the intramolecular cycloaddition reaction of **42**, but rather that product formation via **44** should be favoured. Indeed, in a yet more recent report from the same laboratory (21) the products of intramolecular photochemical cycloaddition of 2-(4-pentenyl)-2-cyclohexenone and 3-(4-pentenyl)-2-cyclopentenone have been examined and the authors find no conclusive evidence that initial bonding occurs exclusively at any one position.



Conclusions

Two conclusions about the mechanism of enone photocycloaddition with alkenes can be drawn from the work described here. First, the formation of a product mixture containing the rearranged adducts **25** and **26** from the photochemical reaction of vinylcyclopropane with 2-cyclopentenone is good evidence that the initial bonding between the alkene and the enone is to both the α-position and the β-position of the enone and not exclusively at the β-position as recently proposed (20). Second, the formation of the rearranged adducts **25** and **26** in addition to the 2 + 2 adducts **8** and **9** suggests that cyclopropane ring opening in the initially formed biradicals occurs at a similar rate to their ring closure to cyclobutane-containing adducts. Using the known rate of the ring-opening reaction as a clock it is possible to assign a rate constant to cyclobutane formation and so arrive at a value of the biradical lifetime that is of the order of 50 ns.

Experimental

Cyclopentenone was prepared from singlet oxygen oxidation of cyclopentene using the method of Mihelich and Eickhoff (22). Vinylcyclopropane was most conveniently prepared in larger quantities by Bamford Stevens reaction of the tosyl hydrazone of cyclopropyl methyl ketone using a modification of a method described by Kirmse *et al.* (23) as outline below. A commerical sample of 1,6-heptadiene was used. ^{1}H NMR spectra were recorded at 200 MHz in $CDCl_3$ on a Varian XL 200 instrument. Coupled gas chromatography–mass spectroscopy (GC–MS) was performed using a Varian 3400 gas chromatograph equipped with a 30-m DB-5 capillary column attached to a Finnegan MAT 8230 mass spectrometer. ^{13}C NMR spectra were recorded at 75 MHz in $CDCl_3$ on a Varian XL 300 instrument. Routine GC was performed on a Hewlett-Packard 5880 instrument equipped with an 18-m methyl silicone capillary column using one of the following temperature programs: (a) 3 min at 35°C then 10°/min to 150°C; (b) 90°C to 150°C at 1°/min.

Preparation of vinylcyclopropane

Cyclopropyl methyl ketone was prepared from acid hydrolysis of α-acetyl-γ-butyrolactone and was converted to its tosyl hydrazone by the literature procedures (24). A suspension of sodamide in liquid ammonia was prepared by dissolution of sodium (6.6 g, 287 mmol) in liquid ammonia (200 mL) containing ferric nitrate (0.6 g). Decalin (200 mL) was added and the ammonia was allowed to evaporate. The tosyl hydrazone of cyclopropyl methyl ketone (10 g, 40 mmol) was added and the mixture heated to 190°C. The colourless liquid that distilled out of the reaction mixture was collected using an efficient Dry Ice condenser and redistilled (bp ca. 40°C) to give a mixture of vinylcyclopropane and 1-methylcyclobutene (1.38 g, 50%) in a ratio of 97:3 as determined by ^{1}H NMR spectroscopy. Attempts to use sodium hydride as the base, as described in the literature, gave much higher (up to 28%) proportions of 1-methylcyclobutene. For vinylcyclopropane, ^{1}H NMR: 0.38 (m, 2H), 0.68 (m, 2H), 1.38 (m, 1H), 4.76 (dd, 1H, J = 10, 2 Hz), 4.97 (dd, 1H, J = 17, 2 Hz), 5.25 (ddd, 1H, J = 17, 10, 2 Hz) ppm; ^{13}C NMR: 6.67, 14.76, 111.50, 142.61 ppm. For 1-methylcyclobutene, ^{1}H NMR: 1.64 (m, 3H), 2.27 (m, 2H), 2.36 (m, 2H), 5.55 (m, 1H) ppm; ^{13}C NMR: 16.88, 26.45, 32.67, 146.47 ppm.

Irradiation of cyclopentenone

A solution of cyclopentenone (43 mg) in cyclohexane (4 mL) was purged with nitrogen to remove oxygen and irradiated at room temperature for 5 h with Pyrex and water filtered light from a medium pressure mercury lamp. Gas chromatography showed the formation of three major products in the ratio 1:3:6, which were shown to be cyclopentenone dimers by GC–MS: 164 (M^+, 90%) 82 (100%), 54 (70%). Other minor products were cyclopentanone and a photoreduction product of the dimers (M^+ 166).

Irradiation of cyclopentenone with 1,6-heptadiene

A solution of freshly distilled cyclopentenone (303 mg, 3.7 mmol) and 1,6-heptadiene (730 mg, 7.6 mmol) in cyclohexane was deoxygenated by purging with nitrogen and irradiated at room temperature using water and Pyrex filtered light from a medium pressure mercury lamp for 7 h at which time GC indicated almost 100% conversion of the cyclopentenone. Five products were observed by GC in relative amounts in order of increasing retention time of 1:6:6.5:2.3:2.5. GC–MS indicated the first three of these to be adducts of cyclopentenone and the diene (M^+ = 178) and the latter two to be dimers of cyclopentenone. The retention times and mass spectra of the dimers were identical with those obtained by irradiation of a cyclohexane solution of cyclopentenone in the absence of alkene. The solvent and excess reactants were removed under reduced pressure to give a colourless oil (297 mg) whose ^{1}H NMR spectrum showed multiplets at 4.9 and 5.7 ppm. A portion of the mixture was separated by preparative thin-layer chromatography on silica gel (2 elutions with ether–hexanes, 1:9) to give three major fractions; the most polar was identified as the dimers **23** and **24** (20.5 mg) and the two less polar (23 mg and 5.3 mg) were identified by ^{1}H NMR and mass spectroscopy as mixtures of the adducts **18** and **19**. The ^{1}H NMR spectra of the adducts showed the expected signals in the range 1–2 ppm as well as olefinic signals at 4.9 and 5.7 ppm. The mass spectrum showed : 178 (M^+, 6%), 149 (3%), 137 (5%), 121 (5%), 95 (16%), 83 (100%).

A portion of the reaction mixture was hydrogenated in methanol at atmospheric pressure using PtO_2 as catalyst, as were the isolated adducts. GC indicated loss of all of the adducts and their replacement by peaks at slightly longer retention times but no loss of the dimer products. GC–MS of the hydrogenated reaction mixture and MS of the hydrogenated adducts showed that the adducts had increased in mass by two units, while the ^{1}H NMR spectra showed the loss of olefinic signals. The mass spectrum of the adducts showed: 180 (M^+, 10%), 151 (2%), 123 (6%), 83 (100%).

Irradiation of cyclopentenone with vinylcyclopropane

A procedure was adopted in which the reaction was interrupted at partial conversion, and unconverted starting material was recycled following its separation from photoadducts. This procedure was followed in order to avoid secondary photochemistry of the adducts and yet to ensure maximum conversion of the cyclopentenone and vinylcyclopropane. A solution of cyclopentenone (556 mg, 6.8 mmol) and vinylcyclopropane (1.38 g, 20 mmol) in cyclohexane (40 mL) was deoxygenated by purging with nitrogen and irradiated at room temperature with water and Pyrex filtered light from a medium pressure mercury lamp for 2 h. The solvent and unconverted starting materials were distilled off under reduced pressure to leave a residue containing the photoadducts. The distillate was irradiated for a further 2 h; the solvent and unconverted starting materials were again distilled off under reduced pressure to give a residue containing adducts. More cyclopentenone (202 mg) was added to the distillate and the irradiation was resumed; after 2 h unconverted starting materials were removed by distillation under reduced pressure leaving a third residue containing adducts. The distillate was irradiated for a further 2 h and again distilled; the four residues containing adducts were combined to give a product mixture (1.18 g) that was shown by GC-MS to be predominantly a mixture of four 1:1 adducts of cyclopentenone and vinylcyclopropane (M^+ = 150) in the ratio (in order of elution) 1:0.7:1:2, along with a small amount of cyclopentenone dimers (M^+ = 164). Treatment of a portion of the mixture with bromine resulted in strong depletion of the adduct eluted first and slight depletion of the last adduct eluted. The mixture was separated by PLC on silica gel (two elutions with ether:hexanes, 1:6, one elution with ether:hexanes 1:9) to give three major fractions, I, II, III, in order of increasing polarity. Fraction III contained the cyclopentenone dimers.

Fraction I was further separated by preparative GC (5% SE30 on Chromosorb W: column length 8 ft, diameter 0.25 in., temperature 125°C: carrier gas, helium; flow rate 50 mL/min) to give three fractions, Ia, Ib, and Ic.

Fraction Ia was identified as 3-(*cis*-2-pentenyl)-2-cyclopentenone, **25**. ^{1}H NMR: 0.94 (3H, t, J = 7.4) 1.96 (2H, m), 2.11 (2H, m), 2.40 (2H, m), 2.85 (2H, m), 5.30 (1H, m), 5.45 (1H, m), 6.05 (1H, m); MS: 150 (M^+, 2%), 122 (1%), 121 (1%), 107 (1%), 91 (10%), 82 (100%), 60 (30%), 53 (22%).

Fraction Ic was identified as a single geometrical isomer of 2-(2-pentenyl)-2-cyclopentenone, **26**. ^{1}H NMR: 0.99 (3H, t, J = 7.4), 2.05 (2H, m), 2.43 (2H, m), 2.58 (2H, m), 2.88 (2H, m), 5.50 (2H, m), 7.29 (1H, m); MS: 150 (M^+, 64%), 135 (30%), 121 (62%), 106 (21%), 96 (38%), 93 (40%), 91 (48%), 79 (100%).

Fraction Ib was a mixture of the remaining geometrical isomers of **25** and **26** and possessed ^{1}H NMR and mass spectra that were composites of those given for fractions Ia and Ic.

Fraction II was further separated by preparative GC (10% SE30 on Chromosorb W: column length 8 ft, diameter 0.25 in., temperature 90°C: carrier gas, helium; flow rate 50 mL/min) to give three fractions all of which contained stereo- and regioisomers of adducts **8** and **9**. Their ^{1}H NMR spectra contained multiplets in the range 0.1–0.5 ppm (cyclopropyl) and 1.7–2.8 ppm (cyclobutane and cyclopentenone) and no olefinic protons. The MS showed: 150 (M^+, 8%), 121 (16%), 91 (20%), 79 (38%), 68 (100%), 53 (78%).

The direct electrochemical synthesis of some metal derivatives of 3-hydroxy-2-methyl-4-pyrone

THEODORE A. ANNAN, CLOVIS PEPPE,[1] AND DENNIS G. TUCK

Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received January 30, 1990

THEODORE A. ANNAN, CLOVIS PEPPE, and DENNIS G. TUCK. Can. J. Chem. **68**, 1598 (1990).

The electrochemical oxidation of a metallic sacrificial anode (M = Zn, Cd, Sn, In, Cu) in a non-aqueous solution of 3-hydroxy-2-methyl-4-pyrone (= HL) yields the ML_n complexes (M = Zn, Cd, Sn, Cu, $n = 2$; M = In, $n = 3$). Adducts of the type $ML_2.B$ (M = Zn, Cd, B = *N,N,N′,N′*-tetramethylethylenediamine (tmen); M = Cu, B = triphenylphosphine) were obtained by the reaction between the appropriate ligand (B) and the previously synthesized complexes (M = Zn, Cd), or by arranging for the initial electrolytic phase to include the base (M = Cu). The tin(II) compound shows the typical reactions of such low oxidation state species by reacting with iodine and *ortho*-quinones by oxidative addition. All compounds were characterized by elemental analysis and by IR, ^1H and ^{13}C nmr spectroscopy. The structure of CdL_2.tmen was determined by X-ray crystallography, which identified the CdO_4N_2 kernel, and partial electron delocalization within the pyronate ring.

Key words: electrochemical synthesis, cadmium complexes, zinc complexes, tin(II) oxidation, 3-hydroxy-2-methyl-4-pyrone.

THEODORE A. ANNAN, CLOVIS PEPPE et DENNIS G. TUCK. Can. J. Chem. **68**, 1598 (1990).

L'oxydation électrochimique, dans une solution non-aqueuse de 3 hydroxy-2-méthyl-4-pyrone (= HL), d'une anode métallique qui est sacrifiée (M = Zn, Cd, Sn, In, Cu) fournit des complexes ML_n (M = Zn, Cd, Sn, Cu avec $n = 2$; M = In avec $n = 3$). On a pu obtenir les adduits du type $ML_2.B$ (M = Zn, Cd avec B = *N,N,N′,N′*-tétraméthyléthylènediamine (tmen); M = Cu avec B = triphénylphosphine) en faisant réagir les ligands (B) appropriés avec les complexes (M = Zn et Cd) synthétisés antérieurement ou en s'assurant que la phase initiale de l'électrolyse contenait de la base (M = Cu). Le composé de l'étain(II) présente les réactions typiqués des espèces dont l'état d'oxydation est faible; il réagit donc avec l'iode et les *ortho*-quinones par des réactions d'additions oxydatives. Tous les composés ont été caractérisés par analyse élémentaire et par spectroscopies IR et rmn du ^1H et du ^{13}C. La structure du complexe CdL_2.tmen a été déterminée par diffraction des rayons-X; il a été possible d'identifier la noyau de CdO_4N_2 et la délocalisation partielle des électrons dans le cycle pyronate.

Mots clés: synthèse électrochimique, complexes du cadmium, complexes du zinc, oxydation du Zn(II), 3-hydroxy-2-méthyl-4-pyrone.

[Traduit par la revue]

Introduction

A number of papers from this laboratory have demonstrated that the method of direct electrochemical synthesis is a simple, efficient one-step route to the preparation of a wide range of metal complexes, including metal thiolates (1–5), diphenylphosphides (6), carboxylates (7), catecholates (8, 9), and dipyridylamides (10). The method consists simply in the reduction of the selected substrate at an inert platinum cathode in a non-aqueous solution, followed by the oxidation of a sacrificial metal anode. The desired metal complex frequently precipitates in the electrochemical cell, or is readily isolated from the solution phase.

We have recently investigated the application of this method to the preparation of complexes of anionic bidentate oxygen donors, beginning with substrates containing a carbonyl group *ortho* to a phenolic OH group. These experiments resulted in the one-step synthesis of metallic acetonaphthonates and flavonates (11). We now report the successful application of this method to the direct high yield synthesis of metal pyronates.

Experimental section

General

Zn, Cd, Sn, In, and Tl were in the form of rods (Aldrich); Cu shot was flattened to give discs, ca. 1 cm diameter and 1 mm thick. All metals were washed with nitric acid, distilled water, and acetone, dried, and then abraded with fine sandpaper and polished with tissue. 3-Hydroxy-2-methyl-4-pyrone (maltol, HL) tetrachloro-*ortho*-benzoquinone and di-*tert*-butyl-*ortho*-benzoquinone were used as supplied (Aldrich). Acetonitrile and methylene chloride were freshly distilled from calcium hydride; toluene and diethyl ether were dried over sodium and distilled before use. All other reagents were used as supplied.

Analysis and spectroscopy

Metal analyses were by atomic absorption spectrophotometry, using an IL-251 instrument. Iodine was determined by the Volhard method. Microanalysis was by Guelph Chemical Laboratories Ltd. Infrared spectra were recorded on a Nicolet 5 DX instrument, using KBr discs; ^1H and ^{13}C nuclear magnetic resonance spectra were run on a Bruker AC 300L instrument.

Electrochemical procedures

The electrochemical procedures were essentially those described in earlier papers (1–11). The electrochemical cell was a 100 mL round-bottomed flask with a Schlenk arm containing the solution phase; the sacrificial metal electrode suspended by a platinum wire through the rubber septum was the anode of the cell and a second platinum wire similarly supported was the cathode. All operations were carried out under dry nitrogen, using standard vacuum line techniques. The details of cell composition, electrical conditions, and electrochemical efficiency are given in Table 1.

The solution phase was degassed by pumping on a vacuum line for 3 min with continuous stirring, and the cell was purged with dry nitrogen gas throughout the electrolysis. As soon as current flowed in the cell, bubbles of H_2 gas were visible at the cathode, and the colourless solution began to turn yellow. The electrolysis was conducted for a period of 1–2 h, after which the anode was removed, washed, dried and weighed to obtain the quantity dissolved (and hence the electrochemical efficiency (see below)). The electrode was re-introduced into the cell, and the electrolysis continued until ca. 80–90% of the initial quantity of pyrone was consumed; we frequently observed a significant drop in the current towards the end of the electrolysis. At this stage some small deposition of metal occurred at

[b]Solid incompletely digested for atomic absorption analysis; found C 24.3, H 1.88, I 38.0; Calcd. C 25.5, H 2.29, I 38.5.

the cathode, and this was followed by mechanical separation which resulted by small quantities of metal contaminating an insoluble ML_n product. These difficulties can be eliminated either by restricting the period of electrolysis or by placing a small beaker (1 cm diameter, 1 cm height) under the electrode to collect any solid residue, since the desired insoluble product tends to fall well away from the electrode. Details of the synthesis and isolation of the compounds investigated are given below.

Zinc(II) derivarives

The electrochemical oxidation of zinc in a solution of HL occurred smoothly, with the solution becoming yellow, and finally yellow–red, in colour. After ca. 1 h of electrolysis, ZnL_2 began to precipitate in the cell as an amorphous yellow powder, which was subsequently collected and dried under vacuum; ZnL_2 is insoluble in common organic solvents (e.g., acetone, chloroform, or acetonitrile) but soluble in strong donors such as dimethylsulphoxide. This is undoubtedly due to solvation, and in keeping with this, ZnL_2 complexes with other donor ligands, as demonstrated by its reaction with *N,N,N′,N′* -tetramethylethylenediamine (tmen). A suspension of ZnL_2 (246 mg, 0.78 mmol) in CH_3CN (15 mL) was treated with tmen (0.5 mL, 385 mg, 3.31 mmol). The reaction was brought to the boiling point of CH_3CN (82°C) and the resultant solution quickly filtered; the filtrate deposited 295 mg (0.68 mmol) of ZnL_2.tmen spontaneously on cooling, in the form of yellow crystals (yield: 88%). Analytical results for these and other products are given in Table 2.

Cadmium(II) derivatives

The oxidation of cadmium to produce CdL_2 followed the same course as for zinc. The solubilities of CdL_2 are also similar to those of ZnL_2, and it reacts with tmen under essentially identical conditions, to produce CdL_2.tmen as a yellow crystalline material in 86% yield.

Tin derivatives

The electrolysis proceeded as above, except that in this case the product (SnL_2) is soluble in the electrochemical phase, and also that towards the end of the electrolysis, a small amount of Sn metal deposited at the cathode. After filtration, the solution was reduced in volume by ca. 10%, and cooled in the freezer, when 232 mg of SnL_2 precipitated in the form of yellow crystals, which lost their crystallinity when filtered and dried *in vacuo*. The residual solution was taken to dryness, and the yellow solid so obtained washed with absolute ethanol (2 × 15 mL) to remove excess HL and the supporting electrolyte; the additional SnL_2 (450 mg) was collected and dried *in vacuo*. This substance is soluble in CH_2Cl_2, $CHCl_3$, and dimethylsulphoxide. There is no reaction between SnL_2 and tmen in CH_2Cl_2 under the conditions used for ZnL_2, since unreacted SnL_2 was isolated quantitatively.

This tin(II) compound can be oxidized to SnI_2L_2 by I_2. A solution of I_2 (392 mg, 1.54 mmol) in diethyl ether (20 mL) was added to a suspension of SnL_2 (569 mg, 1.54 mmol) in the same solvent (15 mL) over a period of 30 min. The colour of I_2 was discharged after the addition of each drop. When all the I_2 had been added, the reaction mixture was stirred at room temperature for 4 h, after which the solid was collected, washed with diethyl ether, dried, and recrystallized from CH_2Cl_2/Et_2O to give $SnI_2L_2.0.5Et_2O$ (904 mg, 1.37 mmol) in 89% yield. This compound is soluble in CH_2Cl_2, $CHCl_3$, acetone, or dmso. SnL_2 can also be oxidized to a tin(IV)-catecholate complex by either tetrachloro-*ortho*-benzoquinone or 3,5-di-*tert*-butyl-*ortho*-benzoquinone. A solution of $Cl_4C_6O_2$-*o* (472 mg, 1.92 mmol) in CH_3CN (20 mL) was added dropwise to a suspension of SnL_2 (709 mg, 1.92 mmol) in the same solvent (20 mL) over a period of 30 min. The red colour of the quinone was discharged, giving a clear yellow solution. When the volume was reduced to ca. 5 mL, a yellow solid was thrown down, and further solid appeared on leaving the mixture overnight at 0°C; this solid was collected and dried *in vacuo*. The yield of bis(3-hydroxy-2-methyl-4-pyronato)-tetrachlorocatecholato-tin(IV), $L_2Sn(O_2C_6Cl_4)$, was 925 mg (78%). The same procedure lead to the synthesis of the analogous di-3,5-*tert*-butylcatecholato compound as the acetonitrile solvate, $L_2SnO_2C_{14}H_{20}.CH_3CN$, in 90% yield from SnL_2 and 3,5-di-*tert*-butyl-*ortho*-benzoquinone.

Indium(III) derivative

As soon as the current flowed in a cell with an indium anode, metal deposited below the anode, and the solution assumed the characteristic yellow–red coloration. At the end of the electrolysis, the deposited metal was collected and weighed (215 mg, 1.87 mmol). The mass of indium lost from the anode was 446 mg (3.88 mmol). The solution was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

pumped to dryness, and the resultant solid collected, washed with ethanol (3 × 10 mL), and dried under vacuum; yield of InL_3 743 mg (1.51 mmol). The compound is soluble in CH_2Cl_2, $CHCl_3$, acetone and dimethylsulphoxide. Like SnL_2, InL_3 is coordinatively saturated, and attempts to coordinate it with tmen in CH_3CN lead to the eventual recovery of unreacted InL_3.

Copper(II) derivative

As in the electrochemical oxidation of indium just described, the oxidation of copper leads to a disproportionation reaction. During the electrolysis, a solid precipitates at the anode, and metallic copper deposited in the cell, mainly on the walls. The green–grey solid formed during electrolysis was collected by filtration, but attempts to extract a pure product with hot CH_3CN, toluene, methanol, or ethanol all failed. The electrolysis was then conducted with triphenylphosphine in the solution, when the same disproportionation to copper metal was observed; in this case we observed only metallic copper precipitating in the cell, which at the end of the experiment contained a dark green–brown solution. The metal was collected (104 mg, 1.64 mmol), and compared to an amount of Cu dissolved from the electrode of 241 mg (3.79 mmol); $CuL_2.PPh_3$ was isolated as a green solid by concentrating the solution phase.

Thallium

An attempt to prepare TlL_n complexes by using solutions of HL in CH_3CN in the usual way was unsuccessful. No current flow was observed, and we attribute this to the formation of insoluble $TlClO_4$ on the anode surface. When solutions containing Et_4NPF_6 were used, thallium was simply transported from anode to cathode, and these systems were not invesigated further.

Crystallographic analysis

A single crystal of CdL_2.tmen was sealed in a capillary tube and mounted in a Syntex $P2_1$ diffractometer along its largest dimension. The cell parameters were obtained from 35 strong reflections in the range $15<2\theta<30°$. The data were collected following the procedures described previously (12). The intensities of three reference reflections were measured every 200 reflections to monitor stability and crystal decomposition, and it was found that the intensity of these reflections did not change significantly during the data collection. The results were then corrected for Lorentz and polarization effects; no absorption corrections were applied because of the low absorption coefficient. The systematic absences suggested the space group *Ibca*, which was later confirmed by the successful refinement. The unit cell contains 16 molecules of CdL_2.tmen, with the asymmetric unit containing two crystallographically non-equivalent molecules. Details of the cell parameters, data collection, and structural refinement are given in Table 3. The positions of the two cadmium atoms were obtained from a sharpened Patterson synthesis, using the SHELX-76 program, and Fourier synthesis gave the positions of the remaining non-hydrogen atoms. Refinement was carried out using full matrix least squares methods, with scattering factors taken from ref. 13.

The initial identification of two non-equivalent molecules appeared to arise from disorder in the tmen ligand of one of these structures, and mainly from the carbon atom C(29). The position of this atom was therefore fixed, with a thermal parameter equal to the average value of the neighbouring carbons. The refinement then proceeded smoothly; in the final cycles of the least-squares refinement, the Cd, O, and N atoms were refined with anisotropic thermal coefficients, while all the remaining carbon atoms were refined isotropically. This refinement converged on a pair of closely related structures at $R = 0.0562$ and $R_w = 0.0658$. All hydrogen atoms were then included in idealized positions (r(C–H) = 0.95A°; ∠CCH = ∠HCH = 109.5°), and their isotropic thermal parameters were assigned values 0.01 U(Å^2) greater than those for the bonded carbon atoms. The structure was further refined until convergence was achieved with the final $R = 0.0428$ and $R_w = 0.0514$. The final atomic coordinates for non-hydrogen atoms are given in Table 4, and the bond distances and angles for the two molecules are in Table 5. Tables of structure factors, anisotropic

Results and discussion

Preparative electrochemistry

Complexes of the type ML_n involving 3-hydroxy-2-methyl-4-pyrone and various d^{10} metal ions can now be readily prepared in high yield by the electrochemical technique in a convenient single step process. This work extends some earlier investigations of such synthetic methods (14). The preparation of ZnL_2, a potential agent for the treatment of anaemia, has been carried out via the reaction of $ZnCl_2$ with maltol in chloroform (15); InL_3 has also been synthesized from $InCl_3$ and maltol in acetone–methanol (16), and other boron, aluminum, and gallium analogues were obtained in a similar manner (17–19), but there seem to be no reports of the preparation of these pyronates starting from the metallic element other than by this electrochemical route.

[2]A complete set of material may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A OS2.

Following our standard procedure, we measured the electrochemical efficiency, E_f, defined as moles of metal dissolved per Faraday of charge, for each system (see Table 1). For Zn, Cd, and Sn, for which ML_2 complexes were obtained, the value of ca. 0.5 mol F^{-1} corresponds to the reaction sequence

Cathode
[1] $2HL + 2\,e^- \rightarrow 2\,L^- + H_2(g)$

Anode
[2] $2\,L^- + M \rightarrow ML_2$

For copper, the value of 1.01 mol F^{-1} indicates the formation of CuL as the primary product, which disproportionates to the element and CuL_2 according to

[3] $2\,CuL \rightarrow Cu + CuL_2$

In keeping with this, we isolated 105 mg (1.64 mol) of metallic copper from an experiment in which 241 mg (3.79 mol) of copper was lost from the electrode, corresponding to a yield of 87% on the basis of the above reaction.

When indium was used as a sacrificial anode, we observed an irreproducible electrochemical efficiency, with values in the range 0.50–0.73 mol F^{-1}. No direct reaction between maltol and indium metal was detected, establishing the absence of any competing chemical reaction at the anode, but we did observe that some of the metal which was thrown down in the cell during electrolysis could become mechanically reattached to the anode when the reaction mixture was shaken, and such processes may account for the observed non-reproducibility in E_F. The product recovered from the solution was identified as InL_3, and in terms of the known chemistry of this element, one would predict the sequence

Cathode
[4] $HL + e \rightarrow 1/2\,H_2(g) + L^-$

Anode
[5] $In + L^- \rightarrow InL + e$

Solution phase
[6] $3InL \rightarrow 2\,In^\circ + InL_3$

so that the overall stoichiometry is

[7] $3In \rightarrow 2\,In + InL_3$: observed (mmol) 3.88, 1.87, 1.51

In view of the experimental observations reported above, we suspect that the loss of indium from the anode is underestimated, and that the quantity of indium metal collected at the end of the experiment is also too low, partly because of adherence to the anode and partly because of the difficulty of quantitatively recovering this finely divided material.

Adduct formation

The reaction between the ML_n complexes and the bidentate ligand tmen were investigated. The results indicate that adduct formation

[8] $ML_n + B \rightarrow ML_n.\,B$

occurs only in the case of M = Cd and Zn. Attempts ro react SnL_2 and InL_3 with tmen resulted in the complete recovery of the unreacted ML_n compounds. As demonstrated below, the pyrone ligand acts as a bidentate donor, and expansion of the coordination numbers beyond five (Sn) or six (In) in these complexes is not expected to occur.

We should also note here that in the case of copper, the only product which could be isolated from electrochemical experiments was the copper(II) adduct $CuL_2.PPh_3$. The reasons for the apparent instability of the uncomplexed CuL and CuL_2 are not clear at this point.

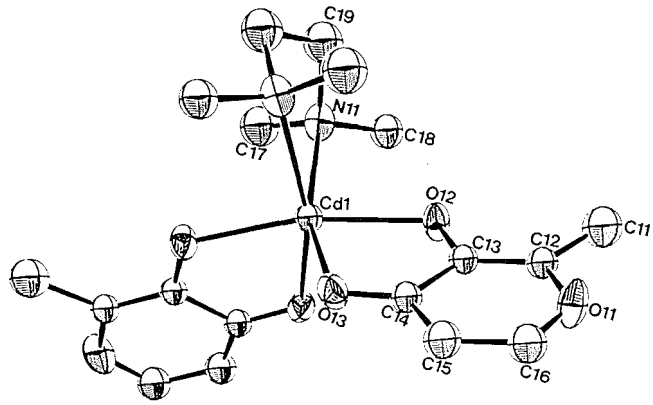

FIG. 1. The molecular structure of one of the forms of $Cd(O_3C_3H_5)_2$.tmen as an ORTEP diagram with 50%-probability ellipsoids. Hydrogen atoms have been omitted for clarity. The second molecular form has essentially the same stereochemistry.

*The structure of $Cd(O_3C_6H_5)_2$.tmen (**1**)*

The structure of the tmen adduct of CdL_2 (Fig. 1) confirms the suggestion that this is a six-coordinate complex with a pseudo-octahedral CdO_4N_2 kernel, in which the cadmium atom is constrained by symmetry requirements to occupy a special position on a two-fold axis. There are a number of interesting features about the structure of this molecule. The Cd–tmen interaction involves a crystallographically imposed symmetrical CdN_2C_2 ring, with Cd—N bond distances similar to those ina number of related molecules (20). The C—C and C—N distances and angles are close to those recently reported for a zinc(II)–tmen adduct (11), except that the N—CH_3 bonds appear to be significantly shorter in that species (1.450(2), 1.462(2) Å) than in **1** (1.482(15), 1.468(15) Å).

The Cd—O bond distances to the γ-pyronate ligand establish a significant difference between that to the keto-oxygen (Cd—0(13), 2.312(9), 2.346(10) Å) and the Cd-hydroxo oxygen (Cd—O(12), 2.237(8), 2.198(8) Å). These values are similar to those reported recently for $Cd(O_2C_{12}H_9)_2$.bpy (**2**) ($C_{12}H_9O_2^-$ = 1′-hydroxo-2′-acetonaphthonate anion) (11), and to relevant compounds discussed in that context. The bite angle at the cadmium atom (O(12)—Cd—O(13)) of 74.2(3)° is also close to those reported for **2** (76.8(2), 78.8(2)°).

There are some closely related molecules with which the present results can be compared, and especially Ph_2BL (18) and AlL_3 (17, 18). The first point is that as the ligated atom increases in size, so the M—O bond becomes longer and the bite angle decreases accordingly (B, 99.49(13)°; Al, 90 ± 5.5°; Cd, 74.2(3)°). There are concomitant changes in the MO_2C_2 ring, in that both the M—O—C and O—C—C angles increase as the bite angles decrease, but the sum of the angles within the MO_2C_2 ring is remarkably constant at 539°. Another interesting and almost constant factor is that although the M—O and C—O distances depend on M, as would be expected, the differences between these bond lengths within the ring do not vary substantially. The actual values, expressed as r(M—O(13)) − r(M—O(12)) are 0.067 (B), 0.055 (Al), and 0.059 Å (Cd); the values for A1 are for the two non-disordered ligands (17). The r(O(12)—C(13)) − r(O(13)—C(14)) differences are 0.055 (B). 0.060 (Al), and 0.067 Å (Cd). Given that the C(13)—C(14) distances also depend on the central atom, in the order B

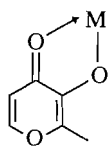
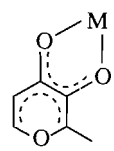
(1.394(3)) < Al (1.423(9)) < Cd (1.472(15) Å), it is clear that this five-membered ring has a remarkable facility to accommodate different metals by internal adjustment of both bond distances and angles.

The question of the C—C and C—O bond distances within the C_5O ring has been discussed in detail for Ph_2BL and AlL_3 (18). Given the changes in r(C(13)—C(14)) discussed above, one would expect minor differences in the other distances in the planar ring, as are found, but the conclusion for each of these three compounds is that C(15)—C(16) and C(12)—C(13) are in the range 1.31–1.37 Å, indicating significant double bond character. Together with the differences in length for C(14)—O(13) (1.249(12)) and C(13)—O(12) (1.306(14) Å). it is clear that the metal–ring interaction involves a substantial contribution from form **I** rather than the delocalized structure **II**.



I



II

Spectroscopic studies

Both nmr and infrared spectroscopy provide useful confirmation that the structure of each of the compounds prepared is the same as CdL_2.tmen as far as the M—L interaction is concerned.

Table 6 gives the nmr spectra (^1H and ^{13}C) for the derivatives of 3-hydroxy-2-methyl-4-pyrone, except for the copper(II) complex, which is paramagnetic. The assignment of the proton spectra follows earlier work on the HL and InL_3 (16), and more recent studies by Orvig and co-workers (19) on aluminum and gallium tris(3-hydroxy-2-methyl-4-pyronates), and does not require detailed comment. The broad-band decoupled ^{13}C spectra of 3-hydroxy-2-methyl-4-pyrone and its metallic complexes show in every case a number of peaks corresponding to the number of non-equivalent carbons required by the molecular formulae, but the assignment of the carbon resonances from the pyrone ring is not a simple matter. The pattern observed for the ring carbons is a set of two intense peaks, one at 109.7–113.2 ppm and the second at lower field (149.6–154.6 ppm), plus two very weak signals which appear in the range 143.3–156.1. Carbon atoms 15 and 16 would be expected to have shorter relaxation times than carbons 12 and 13, and should therefore be more easily detected and give rise to the most intense peaks. Following this argument, we assign the peak at higher field (ca. 110 ppm) to C(15), and that at low field (149.6–154.6 ppm) to C(16). This leaves the two weak resonance signals at 143.3–156.1 ppm, which we attribute to carbons 12 and 13. Other resonances from tmen and diethyl ether are readily assigned in Table 3, and call for no further comment. The most striking feature of the ^{13}C nmr spectra of these complexes is the significant shift of the carbonyl resonance of the pyrone ligand, found at 173.1 ppm in HL, to lower field in the ML_n complexes, in agreement with the coordination of the carbonyl oxygen to the metal, as observed in the crystallographic studies discussed above.

The important features of the ir spectra of HL and its ML_n complexes are given in Table 7. The tentative assignments follow the general work by Katritzky and Jones (21) on γ-pyrone derivatives, and more recent studies on ML_3 compounds (M = Al, Ga, In) (16, 19). The first important point is that ν(O—H), found at 3262 cm^{-1} in 3-hydroxy-2-methyl-4-pyrone, is absent in the spectra of all the complexes prepared. Other absorptions of the pyronate ligand, such as ν(CH)(ring), ν(CH(CH_3)) and δ(CH)(ring) are almost unaffected on complex formation. The most prominent feature in the spectra of HL and its complexes is the set of four strong absorptions in the region 1660–1460 cm^{-1}, attributed to mixed C=O and C=C stretching modes of the pyrone, with the higher frequency band at 1656 cm^{-1} in the parent compound involving mainly ν(C=O) (21). This pattern of strong absorptions is retained in the spectra of the complexes, with a significant bathochromic shift of the order 40–70 cm^{-1} in the two higher frequency absorptions. The weakening of these C=O and C=C bonds is clearly associated with electron donation from the ring to the metal, and we conclude from these results that the coordination of the pyrone ligand to the metal

involves the same bidentate mode in all the compounds examined.

The oxidation of $Sn(O_3C_6H_5)_2$

As reported in the Experimental section, SnL_2 is readily oxidized by iodine to SnI_2L_2. This reaction, which is clearly similar to that recently reported for a number of tin(II) derivatives of aromatic 1,2-diols (22), causes only minor quantitative changes in the nmr or infrared spectra (see Tables 6 and 7). Following this work, and other studies in this laboratory of the oxidation of tin(II) compounds by *ortho*-quinones (23, 24), we also established that the reaction

$$SnL_2 + Q \rightarrow L_2Sn(Cat)$$

(Q = $Cl_4C_8O_2$-*o*, *t*-$Bu_2H_2C_6O_2$-*o*; Cat^{2-} = corresponding 1,2-diolate dianion) occurs smoothly to give six-coordinate tin(IV) compounds with SnO_6 kernels.

The nmr spectra of these two compounds gave the following resonances (in ppm from Me_4Si = 0):

$L_2Sn(O_2C_6Cl_4)$ (in d_6-dmso)

^{1}H: 2.56(s, 3H). 7.35(d,1H), 8.73(d,1H).

^{13}C: 15.6, 110.0, 116.4, 118.2, 145.6, 147.2, 158.4, 158.9, 171.9.

$L_2Sn(O_2C_{14}H_{20}).CH_3CN$ (in $CDCl_3$)

^{1}H: 1.97(s. 3H), 1.29(s, 9H), 1.40(s, 9H), 2.50(s, 6H), 6.64(d, 1H), 6.82(d, 2H), 6.90(d, 1H), 7.60(d, 2H).

^{13}C: 1.76, 15.6, 29.6, 31.8, 34.2, 34.9, 109.8, 110.3, 110.7, 111.9, 134.1, 138.5, 145.9, 147.6, 149.0, 155.3, 156.7, 173.4.

The proton nmr spectrum of $L_2Sn(O_2C_6Cl_4)$ is analogous to those of other pyronates (see Table 6) and calls for no comment. In the proton spectrum of $L_2Sn(O_2C_{14}H_{20}) \cdot CH_3CN$, the resonances at 6.82, 7.60 and 2 50 ppm are assigned to H(15), (16) and (11) respectively (see Table 6) of the pyronate ligand, so that the resonances of the catecholate ligand are at 1.29 and 1.40 (*t*-C_4H_9) and 6.64 and 6.90 ppm (aromatic protons); the signal at 1.97 ppm is due to the acetonitrile. Certain resonances in the ^{13}C spectra of these compounds are readily assigned. The methyl group of the pyronate ligand appears at 15.6 ppm in both derivatives, and the C(14) resonances are at 171.9 and 173.4 ppm, respectively. Resonances from the *tert*-butyl substituent groups are at 29.6 and 31.8 (CH_3 groups), and 34.2 and 34.9 ppm (CMe_3), and the signal at 1.76 ppm is assigned to the methyl carbon of the acetonitrile. The correct assignment of the resonances in the aromatic region of either catecholate is a difficult matter because of the presence of pyronate resonances in the same region, but we certainly detect resonances corresponding to the number of carbons required by the molecular formulae. Finally, we note that the C=O resonances in the parent quinones, at 168.8 ppm ($Cl_4C_6O_2$-*o*), and 180.5 and 179.7 ppm ($Bu_2H_2C_6O_2$-*o*), disappear following the formation of the tin(IV) catecholates, evidence which unambiguously supports the reduction of the quinones.

The vibrational spectra of the tin(IV) catecholato derivatives also show evidence of the reduction of the quinone to the corresponding catecholate. The strong absorptions at 1670 and 1641 cm^{-1} ($Cl_4C_6O_2$-*o*), and 1661 and 1662 cm^{-1} ($Bu_2H_2C_6O_2$-*o*) disappear. One would expect to find new C—O stretching modes, as were observed in earlier work (23, 24) on tin(IV) catecholates, in the region 1414–1468 cm^{-1}, but unfortunately this region is obscured in the present compounds by the strong absorptions from 1460–1660 cm^{-1} due to mixed C=O and C=C, and C—O stretching modes of the pyronate ligand.

Received August 29, 1989[2]

VLADIMIR KOCMAN and JAN T. SZYMAŃSKI. Can. J. Chem. **68**, 1606 (1990).

The crystal structure of the α-modification of the "red salt" of trisilver amidoselenate, Ag_3NSeO_3 has been determined from Mo$K\alpha$ X-ray diffraction data, and refined to $R = 3.19\%$ from 337 unique absorption-corrected observed reflections. The structure is rhombohedral, $R3c$ (No. 161), with (hexagonal) $a = 8.462(4)$, $c = 11.372(6)$ Å. The formula unit has point symmetry 3 (C_3), with Se and N on the threefold axis, each approximately tetrahedrally coordinated; Se by three oxygen atoms (at 1.651(8) Å) and N (at 1.70(2) Å), and N by Se and three silver atoms (at 2.164(8) Å). The bond of 1.70(2) Å between Se and N is particularly short. The Ag_3NSeO_3 structural unit bridges to three adjacent units via short Ag...O contacts of 2.23(1) Å to form a three-dimensional network.

Key words: trisilver amidoselenate, selenium–nitrogen bond, X-ray structure.

VLADIMIR KOCMAN et JAN T. SZYMAŃSKI. Can. J. Chem. **68**, 1606 (1990).

La structure cristalline de la modification α du «sel rouge» d'amidosélénate d'argent, Ag_3NSeo_3 a été déterminée et affinée à un résidu de $R = 3{,}19\%$ utilisant 337 réflections uniques mesurées à l'aide de la radiation Mo$K\alpha$. La structure est rhomboédrique de groupe spatial $R3c$ (No. 161) avec a (hex.) = 8,462(4) Å, c = 11,372(6) Å. L'unité structurale possède une symétrie d'ordre 3 (C_3), Se et N étant situés sur l'axe ternaire, chacun d'eux ayant une coordination approximativement tétraédrique. Le Se est lié à 3 atomes d'oxygène à 1,651(8) Å et un atome d'azote à 1,70(2) Å, et l'azote est lié à 3 atomes d'argent à 2,164(8) Å et un Se. La liaison de 1,70(2) Å entre Se et N est particulièrement courte. Le groupe Ag_3NSeO_3 est relié à trois autres groupes adjacents par des contacts courts de 2,23(1) Å entre Ag et O, et forme un réseau tridimensionnel.

Mots clés : amidosélénate d'argent, liaison sélénium–azote, structure cristalline.

Introduction

The formation of an orange–red precipitate, during the reaction of ammonium amidoselenate $NH_4SeO_3NH_2$ with silver nitrate in dilute NH_4OH, was first observed by Dostál and Krejčí (1) in 1958. Later, Engelbrecht and Clementi (2) described this reaction in their work on Se—N compounds. They suggested that the formation of the title compound most probably proceeds via substitution of the amino-group hydrogens by silver. Further studies of the compounds of the type Ag—N—X (where X is S or Se) were carried out by Dostál and Růžička (3), Růžička (4), and Paetzold, Dostál, and Růžička (5). It was Dostál and Růžička (3) who first confirmed the existence of two different modifications of Ag_3NSeO_3, and named them α and β. The α-modification results from the reaction given in ref. 3, while the β-modification results when the orange–red precipitate is kept at room temperature in the mother liquor for several days. The β-form can also be obtained as a product of the hydrolysis of $Ag_3NSeO_3.3NH_3.2H_2O$. Both modifications are highly explosive, and can be distinguished easily by their different X-ray powder patterns.

Paetzold, Růžička, and Dostál (5) studied a number of silver compounds containing NXO_3 groups (X = S, Se) by means of IR spectroscopy. They proposed possible structural models for the α and β forms of Ag_3NSeO_3. For the α form, the authors suggested a chain polymer structure with $NSeO_3$ groups bridged through linear O...Ag—N bonds, and a point symmetry C_{3v} for the Ag_3NSeO_3 structural unit. Although many other compounds containing Se—N bonds have been synthesized and characterized in the past (1–7), the structures of only a few compounds with Se—N bonds have been determined by single-crystal diffraction. Among these is the subject of a preliminary short communication by one of us (8) on the title compound, and the full structural report on potassium triselenylimide $K_3(NSeO_3)_3$ by Kocman and Rucklidge (9). The latter compound contains cyclic anions in a "chair" configuration, where the ring consists of three $NSeO_3$ units with Se—N bond lengths ranging from 1.75 to 1.79 Å. Structural studies have been done on nitrogen-containing organic molecules bonded to selenium; in all cases the Se—N bonds are in the range 1.80–1.85 Å. A review of these compounds was done by Roesky *et al.* (10), including the X-ray structural investigations of four selenium-containing compounds by the same authors. Two other X-ray structural determinations of novel compounds with Se—N, S—N, and Se—N—P rings have been recently completed by Chivers *et al.* (11, 12). As structural evidence for a Se—N double (or triple) bond is not available for Se—N acyclic compounds (as opposed to the extensive data available on S—N multiple bonds), we decided to complete the X-ray crystal structure analysis of α-Ag_3NSeO_3.

The original brief communication on the title compound (8) was based on Cu$K\alpha$ data, and had some shortcomings in the refined thermal parameters, probably as a result of inaccuracies in the very large absorption corrections performed on the data ($\mu = 1120\ cm^{-1}$). The present structure determination is based on Mo$K\alpha$ data ($\mu = 198.3\ cm^{-1}$), and will serve to establish the short Se—N bond in this compound.

Experimental

Crystals of the title compound were obtained as described above; they are dark-red, transparent, and quite hard. They crystallize as regular hexagonal prisms $\{11\bar{2}0\}$, capped on one end with a trigonal pyramid of form $\{10\bar{1}1\}$. They are insoluble in water, but dissolve

TABLE 1. Crystal data and refinement

Formula	Ag_3NSeO_3
Formula weight	464.6 daltons
Crystal system	Rhombohedral (hexagonal axes)
Space group	$R\bar{3}c$ or $R3c$ from systematic absences $R3c$ determined from structure analysis
Cell dimensions	a = 8.462(4) Å c = 11.372(6) Å Z = 6
Crystal dimensions	0.154 mm between $\{11\bar{2}0\}$ faces, 0.20 mm between {0001} faces
Absorption coefficient	μ(Mo$K\alpha$) = 198.3 cm^{-1} D_{measd} = 6.63 g cm^{-3} D_{calcd} = 6.56 g cm^{-3}
X-ray data	collected with Mo$K\alpha$ ($\lambda(K\alpha_1)$ = 0.70932 Å) to 2θ = 70°, 360 reflections measured, 337 observed with $I > 3\sigma(I)$
Collection mode	θ–2θ scan at 1°(2θ)/min, 2 × 20 background counts, 2 standards every 30 reflections, no decay, variation < 1%
Absorption correction	Gaussian, with 24 × 24 × 24 grid
Refinement	Full matrix least-squares, anisotropic thermal parameters, extinction coefficient, chirality parameter (to define enantiomorph)
Residual	R = 3.19%, R_w = 4.65%

TABLE 2. Positional and anisotropic thermal parameters (×100)[a]

readily in aquaeous ammonia and acids. The crystal selected was cut with a scalpel parallel to (0001) to remove the pyramidal faces, and this resulted in a hexagonal prism, 0.154 mm between faces, and 0.2 mm long. Weissenberg and precession photographs indicated rhombohedral symmetry, and absences that conformed to space groups $R3c$ and $R\bar{3}c$. The former (non-centric) was selected on the basis of previous IR studies (5), morphology, and the E-distribution.

The cell dimensions and their standard deviations were obtained by a least-squares fit of 15 high-angle carefully centred reflections. A total of 360 unique reflections were collected to a limit of 2θ = 70°, using Mo$K\alpha$ radiation with a scan rate of 1°/min in 2θ, and 20 s background counts on either side of the peak. Standard reflections were monitored, but showed no decay and less than 1% variation. The data set contained 337 observed reflections with $I > 3\sigma(I)$, and these were corrected for absorption using a Gaussian integration procedure and a grid of 24 × 24 × 24 points. The crystal data are summarized in Table 1.

X-ray structure refinement

The earlier structure determination of this compound by Kocman *et al.* (8) using copper radiation provided starting parameters for the refinement. Real $\Delta f'$ and imaginary $\Delta f''$ components of the scattering factors were included for all atoms; the scattering curves for the neutral atomic species were taken from International Tables, Vol. IV (13). Anisotropic thermal parameters were refined, as was an extinction parameter and a chirality parameter. The latter defines the enantiomorph in a non-centric molecular structure (14). The final full-matrix residual was R = 3.19%. The programs used were the PC version of the NRCVAX system (15). The positional and thermal parameters are included in Table 2. All the thermal parameters refined to acceptable values, although the spheroids for Se and especially N are somewhat prolate with the major axis along z. This may be a coupled (riding) motion on the part of the N atom, as there is really no reason for the larger thermal parameter in this direction. There was no evidence of disorder around the N sites, nor any reason to suspect partial interchange between O and N atoms between their assigned positions. However, to confirm this, the population parameters of O and N were varied simultaneously at the end of the refinement. The population parameters of O and N refined to 1.09(10) and 1.02(5) respectively; the differences from unity are not significant, and with *both* increasing, this seems to rule out any possibility of O–N interchange. The list of observed and calculated structure factors has been deposited, and is available from the Depository of Unpublished Data.[3]

[3]Photocopies of the structure factor tables may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

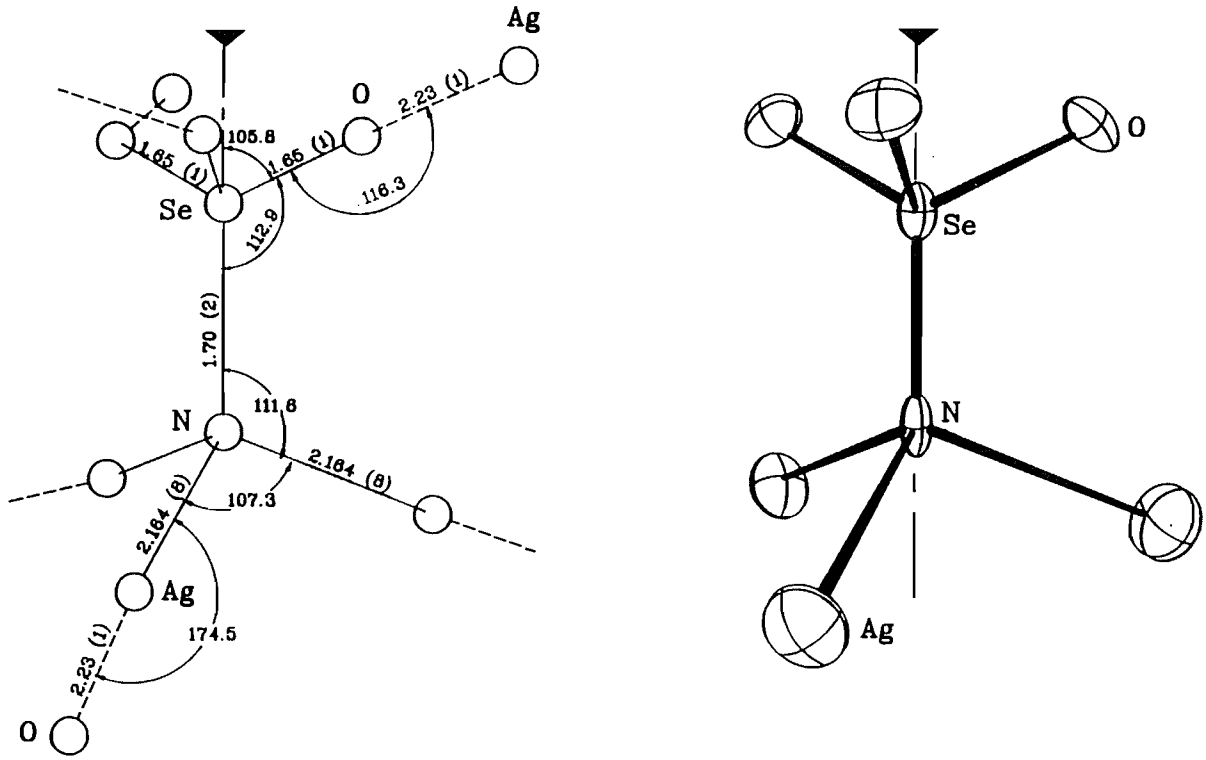

FIG. 1. (*left*) Selected bond lengths and angles in α-Ag_3NSeO_3; (*right*) the structural unit drawn with thermal vibration ellipsoids at 50% probability.

Results and discussion

Figure 1 shows one Ag_3NSeO_3 unit of the polymeric network, with selected bond lengths and angles. The right side of the figure shows a perspective view of the same unit with thermal vibration ellipsoids. Major interatomic distances and angles are summarized in Table 3.

The threefold symmetry of the monomeric unit within the structure is a consequence of the space group. The symmetry of the unit is close to the C_{3v} point group originally predicted for this compound by Paetzold *et al.* (5). Within the monomeric repeat unit, the Se and N atoms (1.70(2) Å apart) are located on a threefold axis, and each atom is approximately tetrahedrally coordinated. The Se atom is bonded to three O atoms and N to three Ag atoms. The Se—O and N—Ag bonds are nearly eclipsed in projection, there being a rotational offset of 11° between the two (Fig. 2). The intermolecular packing is helical, each monomer being bonded via N...Ag...O bridges to three other units. In these bridges, the Ag^+ ion is linearly coordinated, with the N...Ag distances of 2.164(8) Å being slightly shorter than the O...Ag distance of 2.23(1) Å. The polymeric units are arranged in double helices, coaxial with the 3_1 screw axis of the $R3c$ space group. The separation between the helices is $\frac{1}{2}$ in the z-direction as shown in Fig. 3, where two strands of the helices are depicted in perspective. In the polymeric structure, the nearly tetrahedral $NSeO_3$ group acts as a hexadentate bridging group, with N coordinated to three and each O to one Ag-metal centre.

The bonding within this unit and the relatively short Se—N bond length of 1.70(2) Å in this compound is of primary interest. Based on the sum of the single-bond radii (16) of 1.87 Å for Se—N and 1.83 Å for Se—O bonds, it is apparent that appreciable multiple-bond character is suggested for both the Se—N and Se—O bonds in the bridging $NSeO_3$ moiety. The latter with d = 1.651 Å is well within the range reported for metal selenates of 1.60 to 1.70 Å (17), while the slightly longer Se—N bond of 1.70 Å reflects almost precisely the difference in the covalent single-bond radii for N and O of 0.70 and 0.66 Å, respectively (16). This suggests approximately identical

TABLE 3. Bond lengths (Å) and angles (deg)[a]

Bond	Length	Bond	Length
Ag—N	2.164(8)	Se—O(c)	1.651(8)
Ag—O(a)	2.229(12)	N—Ag(b)	2.164(8)

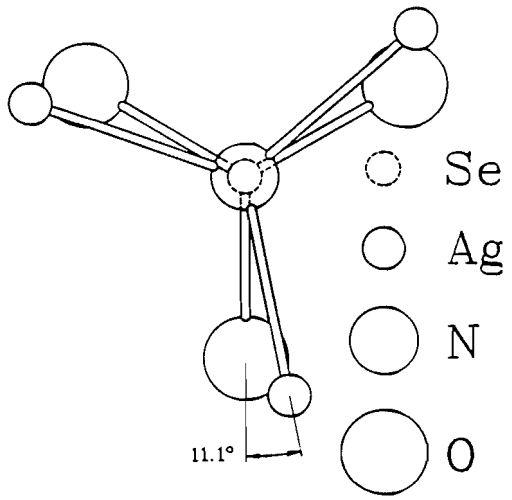

FIG. 2. The almost eclipsed Ag and O atoms of α-Ag_3NSeO_3 viewed down the hexagonal *c*-axis.

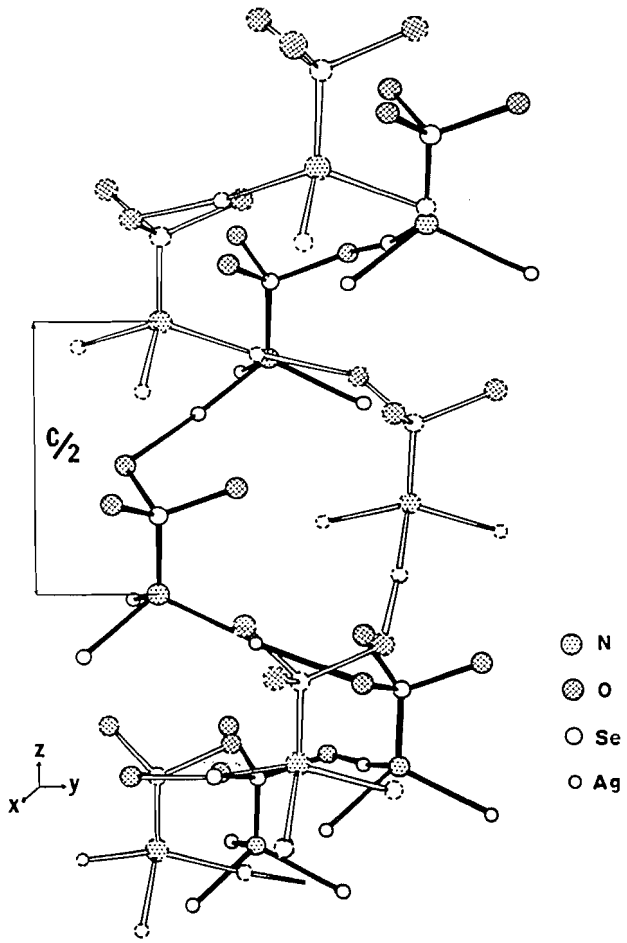

FIG. 3. Two independent strands of helices which represent the dense packing of α-Ag_3NSeO_3 in the hexagonal unit cell.

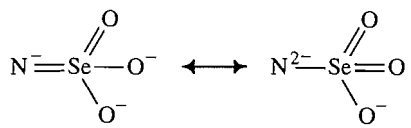
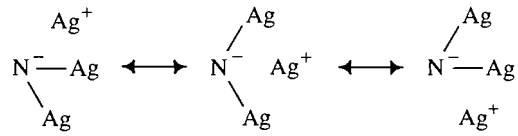
π-contributions to all four bonds formed by selenium(VI) in this compound. Hence, it seems appropriate to describe the bonding within the approximately tetrahedral $NSeO_3$ group by the three permutations of each of the following two resonance forms



which make identical contributions to the overall structure, resulting in an average bond order of 1.5 for all four bonds, and a π-bond order of 2.0 for this group. This approach follows closely similar ideas developed some time ago by Cruickshank (18) for sulphur–oxygen compounds, invoking $p\pi \rightarrow d\pi$ bonding. The average formal charge on nitrogen of −1.5, suggested by the two resonance forms above, can also explain readily the slightly shorter Ag—N distances compared to the Ag...O contacts: N coordinates to three Ag^+, while O coordinates to one Ag^+ each. The average formal charge on oxygen of −0.5 suggests a lower donor ability towards Ag^+ in agreement with general observations (19). The Ag—N distances of 2.164 Å are slightly longer than distances observed for the linear cation $[Ag(NH_3)_2]^+$, where depending on the type of counter-anion, values of 2.11 and 1.89 Å are reported (19). This in turn suggests a bonding description for the NAg_3 moiety in terms of ionic-covalent resonance



rather than in terms of three distinct N—Ag coordinate bonds, which would certainly imply pentacovalent nitrogen in at least two of the resonance forms. A similar approach is applicable to the description of the Ag—O contacts. It is apparent, in particular from the short Se—N bond observed here, that the bonding in the Se—N moiety is distinctly different from that observed in the zwitterion form of sulfamic acid $[H_3N^+\ SO_3^-]$ studied by Sass (20), and the approach described above appears to be more appropriate for interpreting the bonding in Ag_3NSeO_3.

Other aspects of the structure, its bond lengths and angles conform to values found by X-ray methods in other similar compounds (9, 21, 22). The Ag—N bond length of 2.164(8) Å and the Ag—O distance of 2.229(12) Å do not show any unusual departures from values found in the literature (23). In summary, it appears that the "red salt" of α-trisilveramido-selenate is best viewed as a "coordination polymer", with a double-helix structure, weakly and near-linearly coordinated Ag(I) centres and bridging $NSeO_3$ moieties, with strong Se—N and Se—O bonds and tetrahedrally coordinated N and Se atoms. Even though the amido-selenate anion $H_2NSeO_3^-$ is known (17), there appears to be no precedent for the $NSeO_3^{3-}$ anion, which is isoelectronic with the well-known selenate anion SeO_4^{2-}. Finally, it should be pointed out that the interpretation presented here is totally consistent with the IR absorption spectrum of α-Ag_3NSeO_3 (5), and that the crystal structure confirms most of the structural predictions reported in the same publication.

Only very recently (February 1990), we have obtained information on the newly-completed single-crystal structure determination of the "parent compound" related to the "red salt", namely $Ag_3NSeO_3.3NH_3.2H_2O$ (24). Although full details are not yet available, it appears that the $NSeO_3$ moiety has a very similar geometry to that reported here for α-Ag_3NSeO_3. There is a non-crystallographic pseudo-threefold axis along the Se—N bond, although in this case the Ag_3N and SeO_3 groups appear to be staggered by about 30°. For comparison, the bond lengths are Se—N = 1.73 Å, Se—O = 1.64 Å, Ag—N = 2.11 Å.

Tracer diffusion in aqueous sucrose and urea solutions

ALLAN J. EASTEAL
Department of Chemistry, University of Auckland, Auckland, New Zealand

Received November 30, 1989[1]

ALLAN J. EASTEAL. Can. J. Chem. **68**, 1611 (1990).

Tracer diffusion coefficients for water (as HTO), methanol ($^{14}CH_3OH$), and acetonitrile (CT_3CN) in aqueous sucrose (10–25% w/w) and urea (0.25–4 mol L^{-1}) solutions at 298 K have been determined using the diaphragm cell technique. For sucrose solutions tracer diffusion coefficients vary with the 2/3 power of the relative viscosity and the viscosity dependence is the same for the above tracers as for sucrose and oxygen. In urea solutions tracer diffusion coefficients appear to have a solute-specific viscosity dependence, but the solute specificity is largely removed when the effects of proton exchange and urea dimerisation are considered.

Key words: diffusion, water, methanol, acetonitrile, sucrose, urea.

ALLAN J. EASTEAL. Can. J. Chem. **68**, 1611 (1990).

Opérant à 298 K et utilisant la technique de la cellule à diaphragme, on a déterminé les coefficients de diffusion des marqueurs de l'eau (sous la forme de HTO), du méthanol ($^{14}CH_3OH$) et de l'acétonitrile (CT_3CN) dans des solutions aqueuses de sucrose (de 10 à 25% p/p) et d'urée (0,25 à 4 mol L^{-1}). Pour les solutions de sucrose, les coefficients de diffusion des marqueurs varient avec les 2/3 de la puissance de la viscosité relative; la relation avec la viscosité est la même pour les marqueurs mentionnés plus haut. Il semble que, dans les solutions d'urée, la variation des coefficients de diffusion des marqueurs avec la viscosité soit spécifique pour chaque soluté; toutefois, cette spécificité disparaît lorsque les effets de l'échange de proton et de la dimérisation de l'urée sont pris en considération.

Mots clés : diffusion, eau, méthanol, acétonitrile, sucrose, urée.

[Traduit par la revue]

Introduction

The effect of the viscosity (η) on tracer- and self-diffusion coefficients (D) for species in liquid media has been a matter of considerable interest. For example, there is a substantial body of experimental diffusion data for volatile components in concentrated carbohydrate solutions. The dependence of D on carbohydrate concentration and hence medium viscosity simulates the variation in D of "flavour constituents", to be expected in the course of the water content decrease which occurs in spray drying of liquid foods. In another context, the effect of viscosity on diffusion coefficients is central to the correlation between solvent viscosity and the rates of diffusion-controlled reactions. The viscosity dependence of D for a wide variety of solutes in numerous aqueous and non-aqueous solvents has been investigated; the results of such studies (prior to 1973) have been discussed at length by Hiss and Cussler (1).

The Stokes–Einstein equation, in the form

$$[1] \quad D\eta/T = \text{constant}$$

(T = temperature) has been used as the starting point for most attempts to develop predictive methods for D, based on correlations of known values of D with solvent properties. Empirical correlations of that kind have been critically reviewed by Reid and co-workers (2) who concluded that over wide temperature or viscosity ranges simple empirical correlations are inadequate and the viscosity dependence of (tracer- or self-) diffusion coefficients is expressed by (at constant temperature)

$$[2] \quad D \propto \eta^{\alpha}; \; -1 \leq \alpha \leq -0.5$$

According to Hiss and Cussler (1), α in eq. [2] depends on the solute/solvent size ratio (R_D). They postulated that $\alpha = -1$ for $R_D > 5$; α tends to the value $-2/3$ for $R_D < 5$ in high viscosity solvents; $\alpha = 0$ in extremely high viscosity media. The situation regarding diffusion of a variety of solutes in a given solvent is unclear. Oosting and co-workers (3) concluded that α may change for one solute in different carbohydrate solutions or for different solutes in the same carbohydrate solution. However, they found that for 1-hexanol and 2-butanone diffusing in a carbohydrate solution at 60, 75, and 90°C, the single value $\alpha = -0.5$ gave an acceptable representation of the experimental data.

The objective of the present study was to obtain accurate tracer diffusion data for a variety of solutes in aqueous solvents with varying viscosity, to (*a*) investigate the applicability of a relationship of the form of eq. [2]; (*b*) determine the extent to which α varies with solute. Aqueous solutions of sucrose and urea at 298 K were selected as solvents because the diffusion coefficients of sucrose (4) and urea (5) in their solutions have been accurately measured, and the viscosities are known as functions of concentration for both sucrose (6) and urea (7–9) solutions. Furthermore, sucrose and urea provide a contrast in their effects on the viscosity of water. Whereas a very large increase in viscosity can be achieved at small sucrose concentrations, high concentrations of urea are needed to significantly increase the viscosity of water. The solutes (tracers) chosen for initial study were water, methanol, and acetonitrile, all of which were available in suitably labelled form (HTO, $^{14}CH_3OH$ and CT_3CN).

Experimental

Sucrose solutions containing 10, 15, 20, and 25% w/w were made up from AnalaR grade sucrose. Urea solutions of concentration 0.25, 0.5, 1, 2, 3, and 4 mol L^{-1} were made up from AnalaR grade urea.

Tracer diffusion coefficients were measured at 298.15 ± 0.01 K for HTO, $^{14}CH_3OH$ and CT_3CN in each sucrose and urea solution using the (glass) diaphragm cell technique and associated procedures (10). In several cases, diffusion coefficient measurements for a particular tracer and solution were replicated with two independently calibrated diaphragm cells, in order to check that systematic errors in the cell constants were not significant. In all such cases replicated determinations agreed to within a few tenths %, and the accuracy of the values of D is believed to be ±0.5% for the measurements with $^{14}CH_3OH$ and ±1% for the HTO and CT_3CN data.

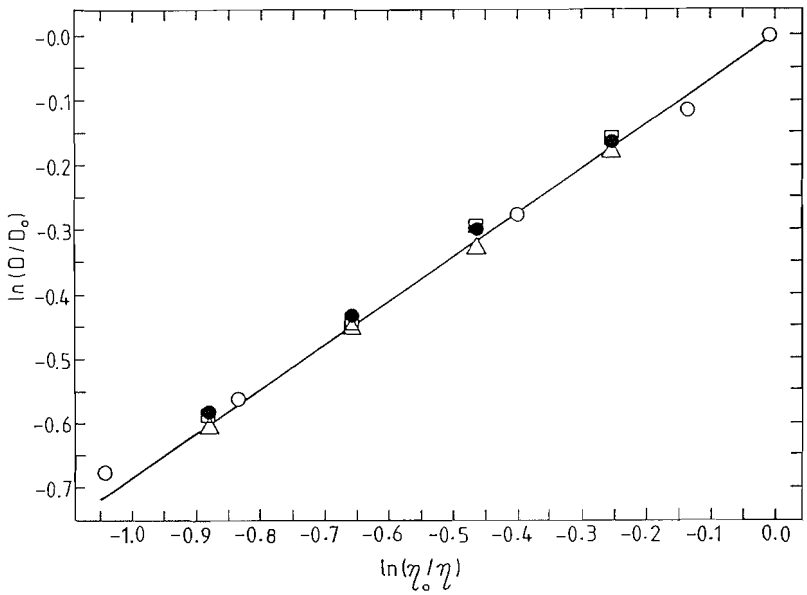

FIG. 1. Viscosity dependence of tracer diffusion coefficients in sucrose solutions at 298.15 K. ○, sucrose; ●, HTO; △, CT_3CN; □, $^{14}CH_3OH$.

Density (ρ) and relative viscosity (η/η_0, where η_0 is the viscosity of water) data were obtained from the literature. The source of data for the sucrose solutions was the critical compilation by Stokes and Mills (6). For urea solutions the density data of Gucker and co-workers (11) were used to interconvert molarities and molalities, and the viscosity data of Dunstan and Mussell (7), Chadwell and Asnes (8), and Jones and Talley (9) combined into a single data set were interpolated at the concentrations of interest.

Results and discussion

1. *Sucrose solutions*

The experimental data are given in Table 1 which includes the values of η/η_0 for the solutions investigated. For a constant temperature eq. [2] can be written in the form

$$[3] \quad D/D_0 \propto (\eta_0/\eta)^{\alpha}$$

where D_0 is the limiting tracer diffusion coefficient at vanishingly low concentration of tracer in water. Figure 1 shows the variation of D/D_0 with η_0/η in the form of a log–log plot, and includes the tracer data for sucrose (4). It is apparent that to within the experimental uncertainty the four solutes obey a relationship of the form of eq. [3]. The values of α which fit the data for the individual tracer molecules are sucrose, 0.65; CH_3OH, 0.66; HTO, 0.66; CT_3CN, 0.69; and the whole data set can be represented to within the experimental uncertainty by eq. [3] with $\alpha = 0.67$. In Fig. 2, the tracer data are compared with data for oxygen diffusion (12) in sucrose solutions. The $D(O_2)$ values plotted were measured at atmospheric pressure and about 300 K, and sucrose concentrations up to 1.96 mol L^{-1}. They can be fitted with a function of the form of eq. [3] with $\alpha = 0.69$ and are collinear within uncertainty with the data for sucrose, HTO, CH_3OH, and CT_3CN.

Also shown in Fig. 2 are tracer data (13) at 298 K for esters (CH_3COOR, where R = ethyl, *n*-propyl, *n*-butyl, and *n*-pentyl) diffusing in 15% w/w and 30% w/w sucrose. The D/D_0 (ester) values for the less concentrated sucrose solution are in accordance with the other tracer data plotted. For the more concentrated sucrose solution, however, the ester data are in substantial disagreement with the other tracer data. Even though the precision of the ester data is not high (±10% at the higher sucrose concentration, according to the authors) the ca. 25% discrepancy is difficult to account for. If all of the D/D_0 values (including ester data at 318 K (13)) are plotted against % w/w sucrose, the data lie close to a smooth curve except for the ester values for 30% sucrose at 298 K. It is possible, therefore, that the latter data are significantly in error. On the other hand, it may be the case that at 298 K in 30% w/w sucrose the esters have a tendency to form clusters. If that were so, the ester diffusion coefficient should be significantly smaller than for non-clustered molecules, leading to an apparent discrepancy qualitatively similar to that in Fig. 2, in the ester diffusion coefficient under these conditons.

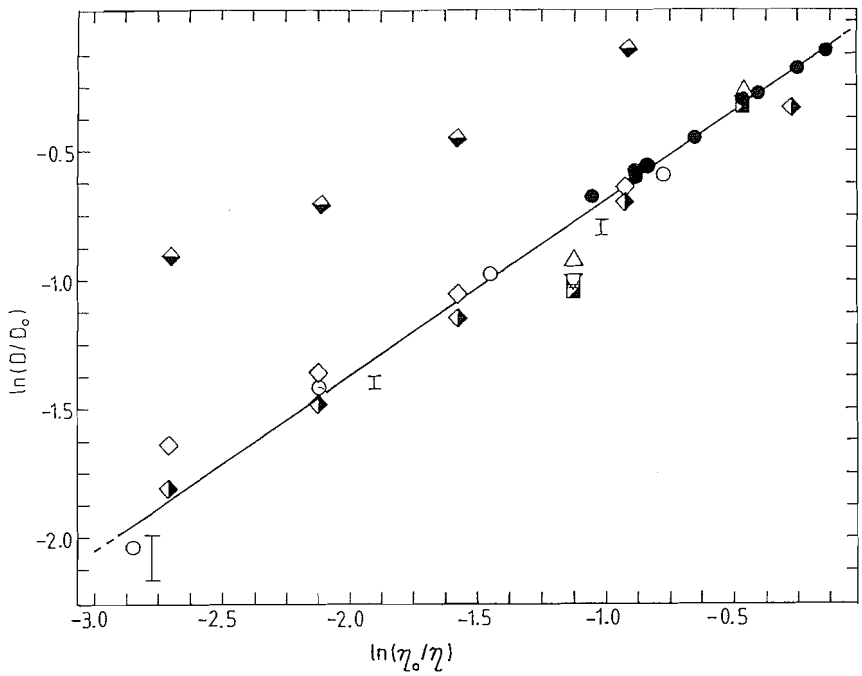

FIG. 2. Viscosity dependence of tracer and mutual diffusion coefficients in sucrose solutions at 298.15 K. Tracer diffusion coefficients are denoted by ●, sucrose, HTO, CH_3OH, CT_3CN; ○, O_2; △, ethylacetate; □, *n*-propylacetate; ▽, *n*-butylacetate; ◪, *n*-pentylacetate. The vertical bars denote ester data at 318 K. Mutual diffusion coefficients are denoted by ◆, uncorrected; ◇, including an activity coefficient correction (eq. [4]); ◈, using eq. [5].

With the exception of the ester data at the higher sucrose concentration at 298 K, the diffusion coefficients for a variety of different solutes with a range of molecular sizes (the extremes being O_2 and sucrose) have virtually identical ($D \propto \eta^{-2/3}$) dependence. This observation is contrary to the selective diffusion concept postulated by Thijssen (14). The $D \propto \eta^{-2/3}$ dependence was also found by Hiss and Cussler (1) for tracer diffusion of *n*-hexane and naphthalene in liquid hydrocarbons with a four decade range of viscosities. Evans and co-workers (15, 16) have observed, on the other hand, for a variety of tetraalkyltins, rare gases, methanes, and substituted methanes diffusing in hydrocarbons, acetone, and alcohols at 298 K, that while eq. [2] is obeyed with $\alpha > -1$ the exponent varies inversely with the solute radius. It is interesting to note that relative tracer diffusion coefficients for esters at 318 K (13) (shown in Fig. 2 as vertical bars) have the same viscosity dependence, to within experimental uncertainty, as that of the tracers at 298 K. The exponent α in eq. [3] is evidently independent of the tracer species, and is temperature invariant within the restricted temperature range for which data are available for sucrose solutions.

Since sucrose contains hydroxylic protons which can exchange with water protons, the effect of tritium exchange between HTO and sucrose on the diffusion coefficient of HTO should be considered. For a solute with p exchangeable protons per molecule, provided that tritium exchange between the solute and HTO is sufficiently rapid, a statistical distribution of the tritium label between solute and solvent water will be attained. The observed diffusion coefficient for tritium (in all forms) is then given by the weighted average, D_T, defined by

$$D_T = (pcD + 2c_W D_W)/(pc + 2cw)$$

where c and D are the concentration and diffusion coefficient of the solute, and c_W and D_W are the corresponding quantities for water. Since c_W is of the order 55 mol L^{-1}, the equation for D_T reduces to

$$[4] \quad D_T = (pcD + 110D_W)(pc + 110)$$

Sucrose has at most eight exchangeable protons per molecule. Substitution in eq. [6] for the values of D_T, c, and D for the most dilute and most concentrated sucrose solutions studied, and solving for D_W gives $D_W = 1.93 \times 10^{-9}$ m^2 s^{-1} for $c = 0.27$ mol L^{-1}, and $D_W = 1.31 \times 10^{-9}$ m^2 s^{-1} for $c = 0.81$ mol L^{-1}. The correction to D_T for tritium exchange is thus no larger than between about 2% and 4% over the concentration range investigated, and does not significantly affect the viscosity dependence of D_T.

The viscosity dependence of mutual diffusion coefficients in sucrose and other solutions has been a matter of interest for a considerable time. Mutual diffusion coefficients, D_{12}, reported by Henrion (17) for sucrose solutions at 298 K are shown in Fig. 2. The values of D_{12} have been reduced by the limiting tracer diffusion coefficient of sucrose (0.523×10^{-9} m^2 s^{-1}) (4, 18, 19) but are othewise unadjusted, and they have a very different viscosity dependence from that of the tracer diffusion coefficients. If the relative mutual diffusion coefficients are divided by the thermodynamic factor

$$[5] \quad Q = \mathrm{d} \ln a / \mathrm{d} \ln x$$

(x = mol fraction of sucrose) as suggested by the Gordon equation (20), they lie close to the line representing the tracer values for concentrations up to about 1.8 mol kg^{-1}. If the values of D_{12} are reduced by the limiting diffusion coefficient given by

$$[6] \quad D_0 = x_W D_{0,S} + x_S D_W$$

where x_W and x_S are mol fractions of water and sucrose, $D_{0,S}$ is

[a]For limiting values of D see footnotes to Table 1.

the limiting tracer diffusion coefficient for sucrose in water and D_W is the self-diffusion coefficient of water (2.299×10^{-9} m^2 s^{-1}) (21) and divided by Q, as in the Hartley–Crank equation (22), they lie close to the line representing the tracer diffusion coefficients up to about 3 mol kg^{-1}. The implication is that up to moderate concentrations corrected relative mutual diffusion coefficients show to a good approximation the same dependence on viscosity as do the tracer diffusion coefficients.

2. Urea solutions

The experimental data are given in Table 2, which includes the values of η/η_0 for the solutions investigated. In marked contrast to sucrose solutions for which the concentration dependence of relative tracer diffusion coefficients can be represented by a single (almost linear) function, for urea solutions D/D_0 for urea (5) and HTO, $^{14}CH_3OH$ and CT_3CN cannot be represented by a single function of concentration.

The viscosity dependence of D/D_0 is shown in Fig. 3. At one extreme, the behaviour of CH_3OH is well represented by a function of the form of eq. [3] with $\alpha \approx 3/4$. At the other extreme, the graph for urea is linear at low concentrations, with slope $\approx 4/3$, but the slope decreases with increasing concentration above about 1 mol L^{-1} to ca. 3/4 at 4 mol L^{-1}. CT_3CN and HTO behave similarly to each other, and approach CH_3OH-type behaviour at low concentrations and urea-type behaviour at high concentrations of urea.

Urea has at most four exchangeable protons per molecule. Calculation of corrected values of D_T, using eq. [4], reveals a correction which is negligibly small at the lowest concentration, increasing to about 5% for the most concentrated solution. The effect of tritium exchange between urea and HTO is therefore to lessen the viscosity dependence of D_T, and the correction gives values of D/D_0 for HTO which are close to those for CH_3OH in Fig. 3.

It should be noted that urea is partially dimerised in aqueous solution, and the effect of dimerisation on the tracer diffusion coefficient of urea has been analyzed in detail by Stokes (24). Stokes concluded that the viscosity dependence of the tracer diffusion coefficient could be accounted for using values for the degree of dimerisation calculated from experimental activity coefficient data, a relationship of the form of eq. [3] with $\alpha = 0.8$, and the value of 0.615 for the ratio, D_R^0, of the limiting tracer diffusion coefficients of dimer to monomer. (It must be borne in mind, however, that other combinations of values of α and D_R^0 are also satisfactory (24).)

When the effects of (*a*) tritium exchange between HTO and urea and (*b*), dimerisation of urea are taken into account, therefore, in the urea solutions the tracer diffusion coefficients of CH_3OH, HTO, and urea have approximately the same viscosity dependence, and the viscosity dependence is consistent with eq. [3] with $\alpha \sim 0.75$. The remaining tracer in the urea solutions, CT_3CN, exhibits qualitatively similar behaviour except that the value of α is close to 1. The different behaviour of CT_3CN cannot be accounted for by tritium exchange with urea or water because the tritium atoms in CT_3CN are non-exchangeable (under the conditions of the diffusion coefficient measurements). It is possible that the diffusive motion of CT_3CN is slowed by a weak association of CT_3CN with urea, since although CT_3CN does not have a hydrogen bond acceptor site it has, like urea, a large dipole moment, and dipole–dipole interactions may be strong enough to lead to the observed viscosity dependence of D.

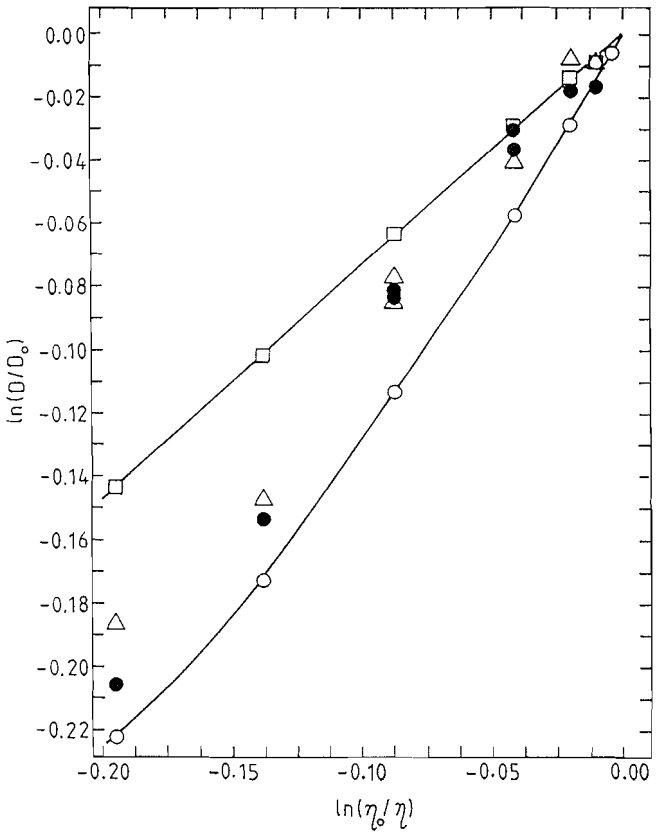

FIG. 3. Viscosity dependence of tracer diffusion coefficients in urea solutions at 298.15 K. ○, urea; ●, HTO; □, CH_3OH; △, CT_3CN.

Mutual diffusion coefficients for urea solutions, relative to the limiting tracer diffusion coefficient for urea (5, 23) and either unadjusted or adjusted as per the Gordon equation, lie

For personal use only.

between the curves for urea and CH_3OH in Fig. 3, and likewise if the mutual diffusion coefficients are reduced according to the Hartley–Crank equation. The viscosity dependence of D_{12} cannot be described by an equation of the form of eq. [3] with a concentration-independent exponent. However, the effect of dimerisation of urea on the mutual diffusion coefficient has not been taken into account. Aspects of the general problem of the effect of solute association on mutual diffusion coefficients have been discussed by several authors (25–28). In particular, Schönert (28) has extended Stokes' analysis (24) of tracer diffusion in urea solutions to mutual diffusion, and concluded, in effect, that the experimental diffusion coefficients can be accounted for using a relative viscosity exponent (α in eq. [3]) of 1.

Intercalation of cations into niobyl-vanadyl phosphate by redox reactions

A. JIMENEZ-LOPEZ,[1] A. L. GARCIA-PONCE, AND L. MORENO-REAL

Departamento de Química Inorgánica, Cristalografía y Mineralogía, Facultad de Ciencias, Universidad de Málaga, Ap. 59, 29071 Málaga, Spain

Received January 31, 1990

A. JIMENEZ-LOPEZ, A. L. GARCIA-PONCE, and L. MORENO-REAL. Can. J. Chem. **68**, 1616 (1990).

Mixed niobyl-vanadyl phosphate, $Nb_{0.86}V_{0.14}OPO_4 \cdot 2.7H_2O$, intercalates various alkali, NH_4^+ alkaline earth, Zn^{2+}, Cd^{2+}, transition metal, and H^+ cations by topotactic redox reactions. All the intercalates thus obtained are tetragonal ($a = b = 6.44$ Å, c lower than in the precursor solid). The degree of hydrolysis of the mixed phosphate in the intercalate in the redox reactions is always lower than 1%. Upon reduction, the cation exchange capacity (CEC) of the intercalates is 71 mequiv. per 100 g of solid calcined at 1000°C.

Key words: mixed niobyl-vanadyl phosphate, layered compounds, redox intercalation.

A. JIMENEZ-LOPEZ, A. L. GARCIA-PONCE et L. MORENO-REAL. Can. J. Chem. **68**, 1616 (1990).

Utilisant des réactions rédox topotactiques, il est possible d'intercaler les ions H^+ ou NH_4^+ ainsi que des ions de divers métaux alcalins, alcalino-terreux (Zn^{2+}, Cd^{2+}) ou de transition dans un phosphate mixte de niobyle et de vanadyle, $Nb_{0,86}V_{0,14}OPO_4$. Tous les produits intercalés ainsi obtenus sont tétragonaux ($a = b = 6,44$ Å alors que c = est plus courte que dans le solide précurseur). Le degré d'hydrolyse du phosphate mixte présent dans le produit intercalé des réactions rédox est toujours inférieur à 1%. Après réduction, le CEC des produits intercalés est égal à 71 mequiv. par 100 g de solide calciné à 1000°C.

Mots clés : phosphate mixte de niobyle et de vanadyle, composés en couches, intercalation rédox.

[Traduit par la revue]

Introduction

Vanadyl phosphate, α-$VOPO_4 \cdot 2H_2O$, is a layered substance typically undergoing two types of reaction: (a) intercalation of neutral species such as amines, amides, pyridine, etc. (1–3), and (b) electron transfer between the lattice and a reductant, in the presence of a guest species, resulting in the reduction of vanadium to V(IV) (4, 5). This second type of reaction is subject to the high degree of hydrolysis of the reduced phases obtained, so that some authors use small volumes of hydroalcoholic mixtures (4) or acetone (5) as reaction media. The search for a phase that would withstand hydrolysis led to the synthesis of mixed niobyl-vanadyl phosphates, which proved to be solid solutions of the two phosphates of formula $(Nb_{1-x}V_x)OPO_4 \cdot 2.7H_2O$, where x can take a maximum value of 0.21 (6). The mixed phosphates also intercalate neutral substances such as amines (7), pyridine (8), and amides (9) in reactions evidencing the mild acidic nature of the water molecule coordinated to the metal.

This paper reports a study on the intercalation of alkali, alkaline earth, transition, and other cations such as Zn^{2+}, Cd^{2+}, and H^+ into the mixed phosphate of formula $(Nb_{0.86}V_{0.14})OPO_4 \cdot 2.7H_2O$ (NbVP) by a redox reaction from the corresponding iodides in aqueous medium. The redox reaction of NbVP was also carried out with isobutyl alcohol. Each experiment involved the determination of the extent of reaction and the degree of hydrolysis undergone by the intercalates isolated.

Experimental

The intercalation of the inorganic cations into NbVP was carried out by a method reported elsewhere (4) and based on reacting the solid with a solution of the iodide of the cation. To optimize the reaction conditions, we studied the influence of the reaction time and reductant concentration on the extent of reduction. This involved performing two preliminary experiments. In the first, 0.1 g of NbVP was brought into contact with 25 mL of KI solution so that $[I^-] = 5[V^{5+}]$. The suspensions obtained were centrifuged at preset intervals, after which the potassium concentration in the supernatants was measured. The reaction was quite fast: the extent of reduction was 70% after 30 min and 90% after 1 h. Nevertheless, all the intercalation reactions were allowed to develop for 24 h.

The second of the above-mentioned experiments involved studying the influence of the iodide concentration on the intercalation reaction. Thus, 0.3 g of NbVP was suspended at 25°C in 25 mL of solution with $[I^-]/[V^{5+}]$ ratios between 0.1 and 10. After 24 h, the solids were isolated by centrifugation and washed with deionized water. The supernatants and the solids were analyzed for potassium and V^{4+}, respectively. The maximum extent of reduction was reached at a $[I^-]/[V^{5+}]$ ratio of 5, which was chosen for all subsequent experiments.

The different ions intercalated into NbVP phosphate were as follows: alkali (Li^+,Na^+, K^+, and Cs^+) and ammonium; alkaline earth (Mg^{2+} and Ca^{2+}); post-transition (Zn^{2+} and Cd^{2+}), and transition (Mn^{2+}, Fe^{2+}, Co^{2+} and Ni^{2+}). All the reactions were conducted under the above-described conditions. The metallic iodides used were either commercially available or synthesized by the authors. The extent of reduction was measured from the cation content of the isolated solids. In most cases, these values are in good agreement with those found by V^{4+} redox titration.

The synthesis of the H^+ intercalates involved two experiments. In the first, NbVP was brought into contact with an HI solution under the same conditions used in preparing the intercalates of the metal ions; in the second, 0.4 g of NbVP was suspended in 25 mL of isobutyl alcohol and refluxed for 10 days. The resultant solid product was then isolated and washed with acetone.

Finally, as the reduction potential of the Fe^{3+}/Fe^{2+} pair is lower than that of the V^{5+}/V^{4+} pair, the redox intercalation of Fe^{2+} ions was effected by bringing the solid into contact with 25 mL of a $FeSO_4$ solution with an $[Fe^{2+}]/[V^{5+}]$ ratio of 5.

The solids obtained in these reactions were characterized by chemical and TD–TG analyses, X-ray diffraction, and IR and UV–vis–nIR spectroscopy.

The extent of hydrolysis undergone by NbVP in the redox intercalation reaction was determined by measuring the phosphorus content in the supernatants. It was always very low (below 1% in all cases).

Thermogravimetric and differential thermal analyses were carried out on a Rigaku Thermoflex instrument using calcined alumina as internal reference and heating at a rate of 10 K/min. Platinum crucibles and Pt/Pt–Rh thermocouples were used throughout.

Powder X-ray diffraction patterns were recorded on a Siemens

D-501 automatic diffractometer using graphite-monochromated CuK_α radiation.

Infrared spectra were obtained on a Perkin–Elmer 883 spectrophotometer using KBr pellets (2%), while UV–vis–nIR spectra were recorded on a Shimadzu UV 3100 spectrophotometer using pressed $BaSO_4$ tablets as references.

Results and discussion

Niobyl-vanadyl phosphate, NbVP, is highly stable to hydrolysis; in fact, after undergoing a redox reaction, the degree of hydrolysis of the resultant product is never higher than 1%; in contrast, vanadyl phosphate is hydrolyzed to an extent of 20% under the same conditions. This high hydrolytic stability allowed us to use aqueous solutions to study the intercalation reactions.

Redox intercalation of monovalent ions

The monovalent cations intercalated into NbVP were Li^+, Na^+, K^+, Cs^+, and NH_4^+. Table 1 lists the chemical composition, extent of reduction of V^{5+}, and basal spacings of the compounds isolated. As a rule, and despite the high $[I^-]/[V^{5+}]$ ratios used, the extent of reduction of V^{5+} was not too great; in fact, the maximum was 87%. On the other hand, the extent of reduction increased with the atomic number of the alkali cation. This might be related to the hydrated radii of these ions; as the $Li(H_2O)_n^+$ cation features the largest radius, the narrowing of the basal space brought about by the reduction–intercalation hinders the uptake of further ions.

The smallest extent of intercalation of the Li^+ into NbVP contrasts with the findings of other authors (4) for vanadyl phosphate, which was found to be reduced by 100%. On the other hand, this intercalate features the highest water content, which decreases with decreasing ionic potential along the series. The composition and basal spacing of the NH_4^+ intercalate are similar to those of the K^+ intercalate on account of the similarity of their sizes.

The Li^+ intercalate has the largest basal spacing, consistent with its highest water content; the other intercalates have d_{002} spacings of about 7 Å, smaller than that of the original matrix (7.90 Å) as a result of the electrostatic interactions between the charged layers and the intercalated cations, and lower water contents. The diffractograms of these solids resemble that of the original matrix, although they contain fewer reflections; however, they show higher degrees of crystallinity than organic intercalates (7–9). The (200) reflection appears quite sharp at 3.22 Å, thereby indicating the preservation of the layered structure. The reflections can be indexed in the tetragonal system, with $a = b = 6.44$ Å and c between 13.94 and 14.78 Å, although the corresponding basal spacings (6.99–7.35 Å) are half the value of the c parameter (6). Only a single phase is observed under the experimental conditions used ($[I^+]/[V^{5+}] = 5$);

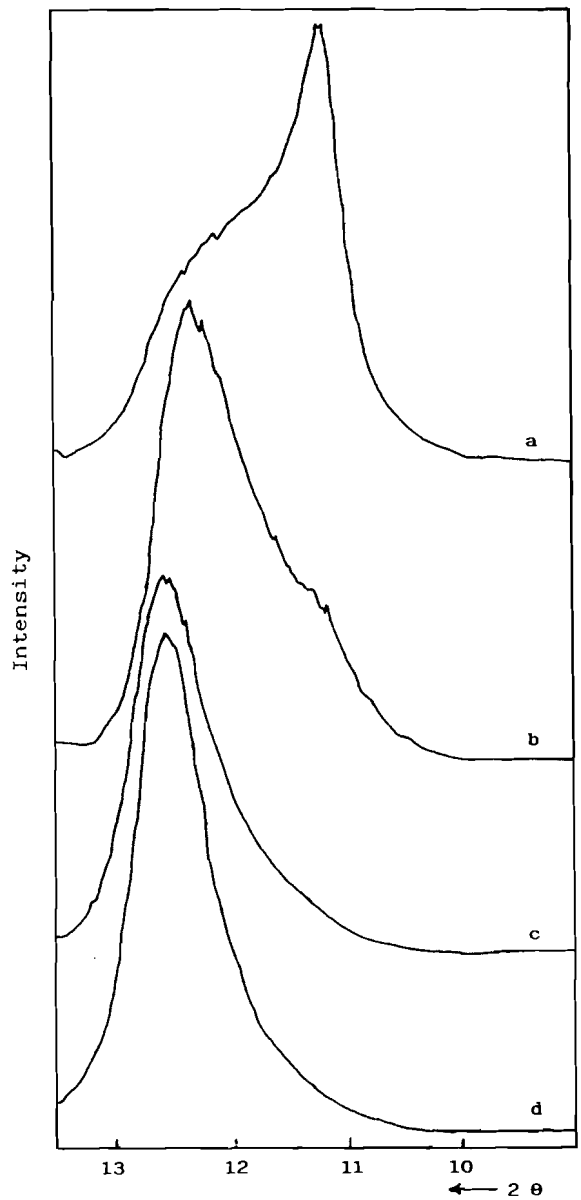

FIG. 1. Basal spacing evolution with the degree of reduction of vanadium of the potassium–NbVP intercalates: (a) 7%, (b) 21%, (c) 43%, (d) 64%.

however, extents of reduction below 43% result in a mixture of the reduced phase with others arising from partial dehydration of the original matrix (Fig. 1).

The thermograms of the intercalates of the monovalent ions are very similar to one another and to that of NbVP, with the exception of that of NH_4^+, which also shows two small exothermal effects at 305 and 435°C, corresponding to the elimination of intercalated ammonium. Figure 2 shows the diagrams of various K^+ intercalates and that of NbVP. As can be seen, all show two endothermal effects similar to NbVP, with two corresponding weight losses in the TG curves that can be assigned to two dehydration stages. The first effect is centred between 83 and 90°C and corresponds to the loss of 1.2 mol of water weakly retained by the solid. The second is influenced by the extent of reduction, as it tends to split with increase in this variable, as does the interval over which coordinated water is removed (1 mol per mol of phosphate); thus, the peak is centred

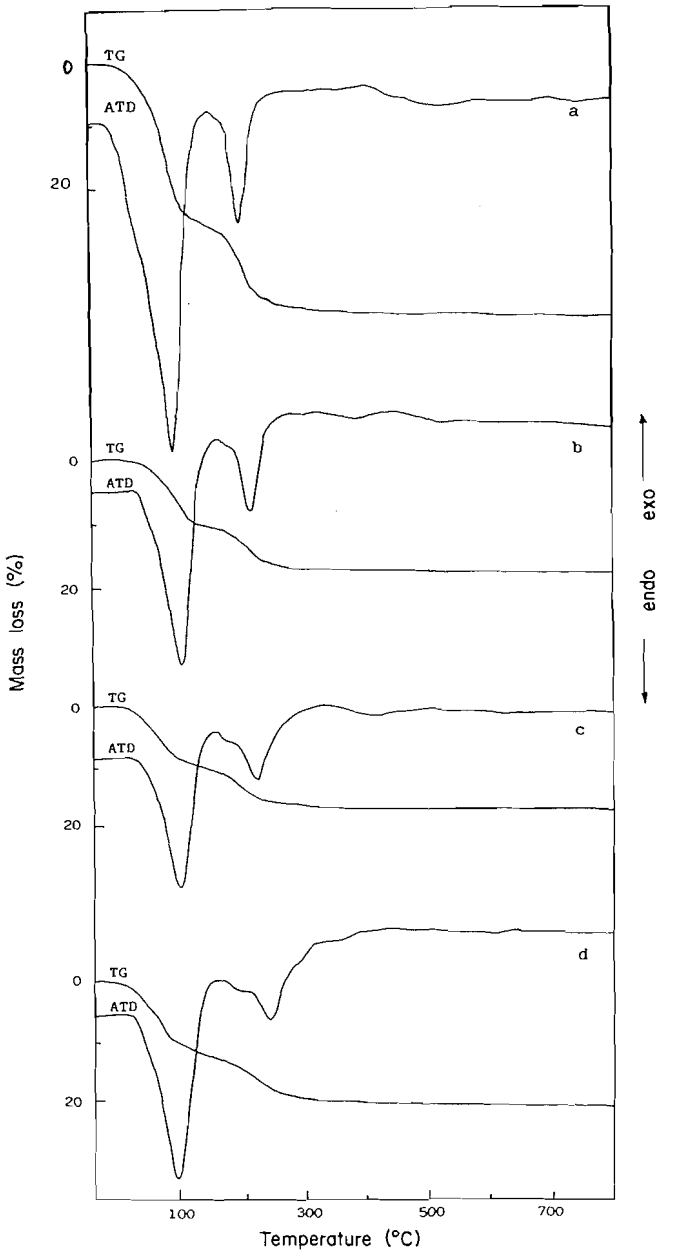

FIG. 2. DTA curves of potassium–NbVP intercalates with different degrees of reduction of vanadium: (a) NbVP, (b) 7%, (c) 43%, (d) 79%.

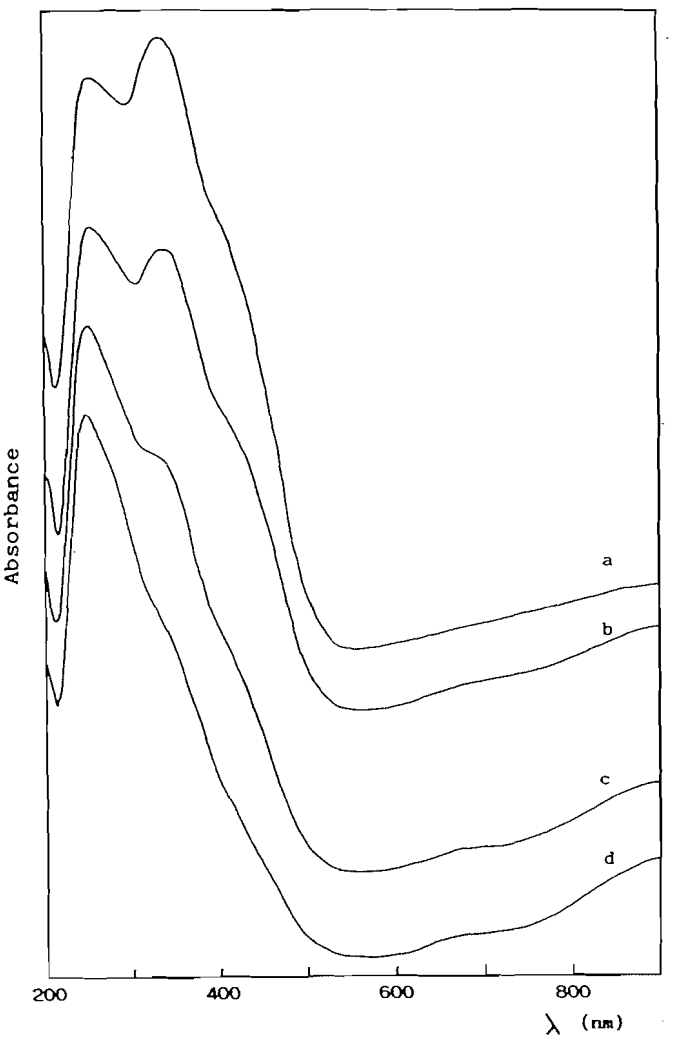

FIG. 3. Diffuse reflectance spectra of potassium–NbVP intercalates with different degrees of reduction of vanadium: (a) 7%, (b) 43%, (c) 64%, (d) 79%.

at 196°C and 228°C for an extent of reduction of 9% and 79%, respectively. This shift appears to arise from the negative charge localized in the $(O_5VH_2O)^-$ octahedron, which exerts a strong attraction on the K^+ ion, so that the water molecule lying between both ion species is strongly retained and hence more difficult to remove.

This phenomenon rules out the possibility of the intercalation taking place via the same mechanism as that proposed by other authors (10) for the intercalation of Na^+ into vanadyl phosphate; the water content and extent of intercalation of the Na^+ ions are supposed to be interrelated as the (O_5VH_2O) octahedron becomes an (O_5V) square pyramid and the Na^+ ion occupies the former position of water. Obviously, if this were also the case with our intercalates, the remaining coordinated water would not be affected by the extent of intercalation as stated above.

The diffuse reflectance spectra of the intercalates of these ions also vary with the extent of reduction as the charge transfer bands of vanadium at 335 nm and the shoulder at 400 nm are shifted to the UV region (where the charge transfer band of niobium is observed (6)) with increasing reduction. Figure 3 is illustrative of this behaviour. The reduction results in a concomitant adoption of a d^1 configuration by V^{4+}, which yields three absorptions, namely $E \leftarrow B_2$ (930–840 nm), $B_1 \leftarrow B_2$ (660 nm), and $A_1 \leftarrow B_2$ (overlapped with the charge transfer bands) in its distorted octahedral environment. The UV–vis–nIR of the K^+ intercalate is presented in Fig. 4, which also shows the bands at 1424 nm corresponding to combinations of ν(OH) and $\delta(H_2O)$, and at 1925 nm, corresponding to the first harmonic of ν(OH).

Redox intercalation of divalent ions

The chemical composition, extent of reduction of vanadium, and basal spacings of the intercalates of divalent ions obtained are listed in Table 2.

The extent of reduction of V^{5+} in these intercalates is greater than in those of the monovalent cations; in some cases, the host matrix was almost completely reduced. The Mg^{2+} intercalate was an exception in this respect since, as a result of its higher

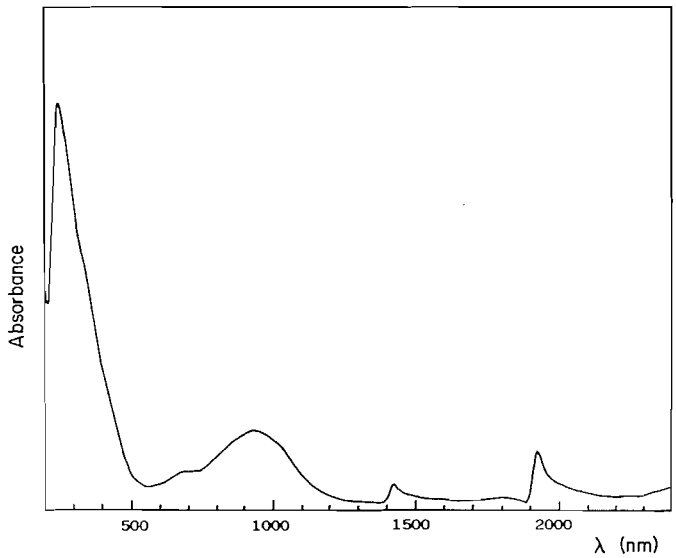

FIG. 4. Diffuse reflectance spectrum (UV–vis–nIR) of potassium–NbVP intercalate (79% reduction).

TABLE 2. Chemical composition, degree of reduction of vanadium, and basal spacing (Å) of the divalent cation intercalates M_x ($V_{0.14}$ $Nb_{0.86}$) $OPO_4 \cdot y\ H_2O$

Cation	% Reduction	x	y	d_{002}
Mg^{2+}	74.3	0.052	2.8	7.76
Ca^{2+}	91.4	0.064	2.3	7.14
Zn^{2+}	94.3	0.066	2.4	7.17
Cd^{2+}	95.7	0.067	2.4	7.17
Mn^{2+}	100	0.070	2.4	7.17
Fe^{2+}	95.7	0.067	2.5	7.47
Co^{2+}	92.8	0.065	2.3	7.30
Ni^{2+}	98.6	0.069	2.5	7.50

ionic potential, it behaved similarly to Li^+: it showed the highest water content as a result of the hindered intercalation of so strongly hydrated a cation, which in turn resulted in the smallest extent of reduction.

As far as the transition metal cations are concerned, the vanadium in the host is reduced in virtually 100% in all cases; their extents of reduction were thus greater than those found by other authors (4, 11) for $VOPO_4 \cdot 2H_2O$.

As one would expect, the water content was higher for the intercalates of these divalent cations than for those of the monovalent ions, so much so that the content of the Mg^{2+} intercalate was equal to or even higher than that of the host matrix.

The unit cell volumes calculated for $Li_{0.10}$ $NbVP \cdot 2.5H_2O$ and $Mg_{0.05}$ $NbVP \cdot 2.8H_2O$ with equivalent extents of reduction were 610 and 644 Å^3, respectively. The difference in the volumes results from the uptake of $4 \times (2.8-2.5)$ water molecules per unit cell ($Z = 4$). This results in a volume of 28.3 Å^3 per water molecule, i.e., very close to that calculated for a liquid water molecule (30 Å^3), which indicates that the interlayer space is fully occupied by the cations and water molecules.

The DTA diagrams of these intercalates are all equivalent and show two endothermal effects, the first centred between 90 and 100°C, depending on the cation, and corresponding to the

removal of water not coordinated to vanadium-niobium, and the second, at a higher temperature (213–227°C), corresponding to the loss of that coordinated water.

The diffuse reflectance spectra of the intercalates of the divalent transition metals show none of their typical bands in the visible regions as they are masked by those of V(IV), which is also present at higher concentrations.

Redox reactions with other reductants

A number of reductants have been used by other authors (4) to reduce V^{5+} to V^{4+}; we chose Fe^{2+} to obtain the intercalate of a trivalent metal. On the other hand, some authors have prepared intercalates of the H^+ ion (12, 13) by using 2-propanol or 2-butanol under reflux to reduce vanadyl phosphate to an orthorhombic compound of formula $VO(HPO_4) \cdot 0.5H_2O$ (14). This method has also been used with NbVP, as has the reduction with HI under the same conditions used with the metal ions. Table 3 lists the chemical composition, extent of reduction of vanadium(V), and basal spacings of the intercalates obtained.

The reaction with Fe^{2+} is quite fast, and the extent of reduction is identical with that found in the intercalation with FeI_2, which leads us to think that, although Fe^{2+} is oxidized to Fe^{3+}, the cation actually compensating for the layer charge is Fe^{2+}. In addition to the fact that the layer charge is markedly localized, it would be rather difficult to neutralize by trivalent ions. Moreover, both iron intercalates have the same magnetic susceptibility at 290°C, namely 3.5×10^{-6} μcgs.

The intercalate prepared from HI was only reduced by 85.7%; in this respect, the H^+ ion behaved in much the same way as the more polarizing Li^+ and Mg^{2+} ions. However, the intercalate obtained under reflux with isobutyl alcohol was reduced by 100%. The diffractograms of the two intercalates are identical and can be indexed in the tetragonal system ($a = b = 6.44$ Å; $c = 14.2$ Å), which indicates the preservation of the *ab* plane. The fact that the V^{5+} is evenly distributed throughout the

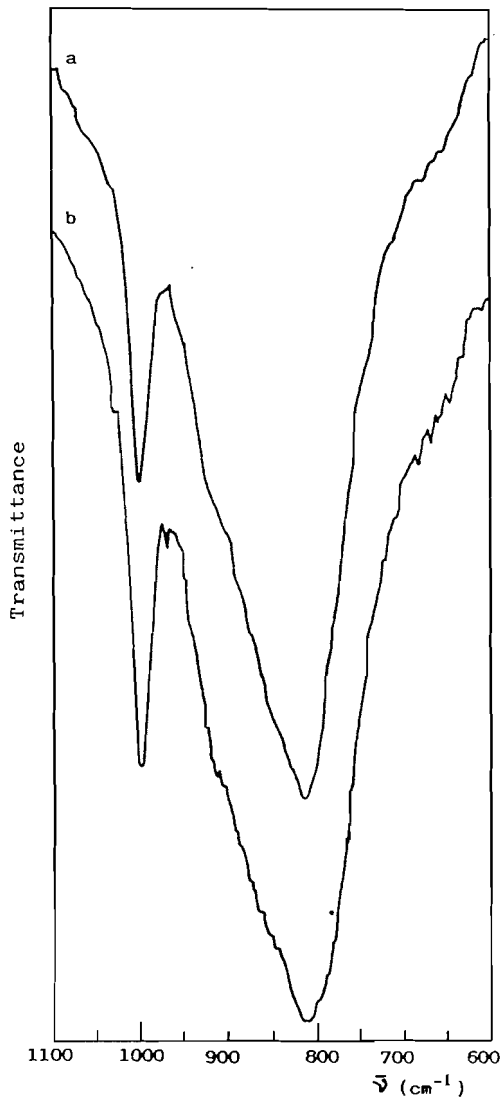

FIG. 6. IR spectra of mixed niobium–vanadium arsenate (a) and its reduced intercalate of potassium (b).

$NbOPO_4$ lattice prevents the reduction from yielding the orthorhombic compound found in reducing $VOPO_4$ with the same reductant.

The IR spectra of the H^+ intercalates (Fig. 5) show small bands at 1700 and 1730 cm^{-1} corresponding to the $\delta_a(H_3O^+)$ of the hydrated protons occurring at the interlayer (15), although their symmetric and asymmetric vibration bands (2940 and 2870 cm^{-1}, respectively) are masked by the broad absorption band of the OH stretching vibrations of the water contained in these compounds.

The reduction of vanadium is also evidenced by the IR spectrum, where the ν(VO) band is shifted to lower frequencies as a result of the relaxation of the double bond. As this band is masked in NbVP by the broad bands of the phosphate groups, it was studied in a mixed arsenate, NbVAs containing only 7% vanadium and prepared by the same method as the mixed phosphate (6). Figure 6 shows a band centred at 998 cm^{-1} and corresponding to the ν(MO) vibration of the mixed arsenate; the reduction yields a small band at 970 cm^{-1} corresponding to the V^{IV}=O stretching vibration (4, 5).

Conclusions

Mixed niobyl-vanadyl phosphate undergoes topotactic redox reactions by intercalating various alkali, alkaline earth, post-transition and transition cations and protons, with preservation of the tetragonal structure of the host solid. Because vanadyl phosphate forms a 14% solid solution in niobyl phosphate, it is substantially stabilized against hydrolysis; the maximum degree of hydrolysis found was only 1%. The intercalates obtained have a cation exchange capacity (CEC) for the maximum reduction of 71 mequiv. referred to 100 g of phosphate calcined at 1000°C.

On a trouvé que les éponges du genera *Axinella* et du *Hymeniacidon* des iles Caroline occidentale (Palau) et orientale (État de Truk) ainsi que de la Nouvelle Guinée contiennent des pyrrologuanidines **1***a* et **1***b* qui sont des cytostatiques (PS ED_{50} 2,5 et 2,0 μg/mL) et des antinéoplasiques (PS T/C 143 à 3,6 mg/kg et T/C 138 à 3,6 mg/kg). À partir d'un *Axinella* sp., on a aussi isolé l'hydantoïne apparentée **2**, appelée axinohydantoïne, et on a déterminé sa structure à l'aide de la diffraction des rayons-X. L'expérience acquise avec les éponges de l'*Axinella* et de l'*Hymeniacidon* genera suggère que l'hyménialdisine (**1***b*), qui était connue antérieurement, ainsi que les dérivés imidazoles analogues sont peut-être très répandus dans ces éponges et dans les Porifera apparentés de couleur orange.

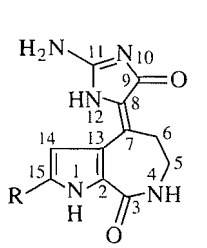
Mots clés : axinohydantoïne, hyménialdisine, *Axinella, Hymeniacidon,* cytostatique.

[Traduit par la revue]

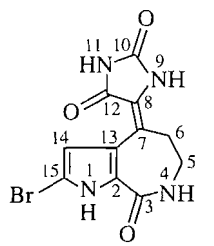
Introduction

Early (2) in our evaluation of marine animals as new sources of potentially useful anticancer drugs, good leads were uncovered among the Porifera, and this initial (1966–1968) promise is now being amply realized (3, 4). In 1979 in Palau we collected a *Hymeniacidon* species (at −40 m) and an *Axinella* sp. that provided extracts with confirmed levels of activity against the U.S. National Cancer Institute's (NCI) murine P388 lymphocytic leukemia (PS system). Other PS active sponge collections were completed in 1981 (Papua New Guinea) and 1985 (Truk, Federated States of Micronesia) that included *Axinella carteri* (Dendy) and a *Hymeniacidon* species.

Initial extracts of each sponge were found to provide a confirmed level of activity against the PS system. By means of PS (*in vitro*) bioassay guided separation procedures, these sponge species led to two cytostatic and antineoplastic alkaloids (**1***a*,*b*) accompanied in the case of *Axinella* sp. by a closely related, but marginally (PS ED_{50} 18 μg/mL) inactive, component (**2**). The PS active marine alkaloids proved to be identical[6] with the known (5–7) hymenialdisine (**1***b*, ref. 6, PS ED_{50} 2.0 μg/mL and T/C 138 at 3.6 mg/kg)[7] and its debromo derivative **1***a* (refs. 5–7, PS ED_{50} 2.5 μg/mL and T/C 143 at 3.6 mg/kg).



1*a*, R = H debromohymenialdisine
1*b*, R = Br hymenialdisine



2
axinohydantoin

The unequivocal X-ray crystal structure of hymenialdisine was nicely established by Cimino *et al.* (5) and reconfirmed in the following year by the Kitagawa group (6). In turn, these advances simplified characterization of the companion substance from *Axinella* sp., herein named axinohydantoin (**2**), as a closely related compound. But establishing the exact geometrical configuration for its hydantoin–lactam sp^2 bond required the following crystal structure determination.

Axinohydantoin (**2**) crystallized from methanol as yellow prisms, which corresponded to $C_{11}H_9BrN_4O_3$ (by hreims) and with one mole of methanol. The structure was solved using

[5]Revision received March 27, 1990.

[6]By comparison with authentic specimens provided by Dr. I. Kitagawa (see ref. 6).

[7]Interestingly, hymenialdisine was previously active in the KB cell line, but *in*active employing the P388 leukemia: cf. ref. 5. Perhaps the initial negative results were due to the sparingly soluble properties of this pyrrologuanidine.

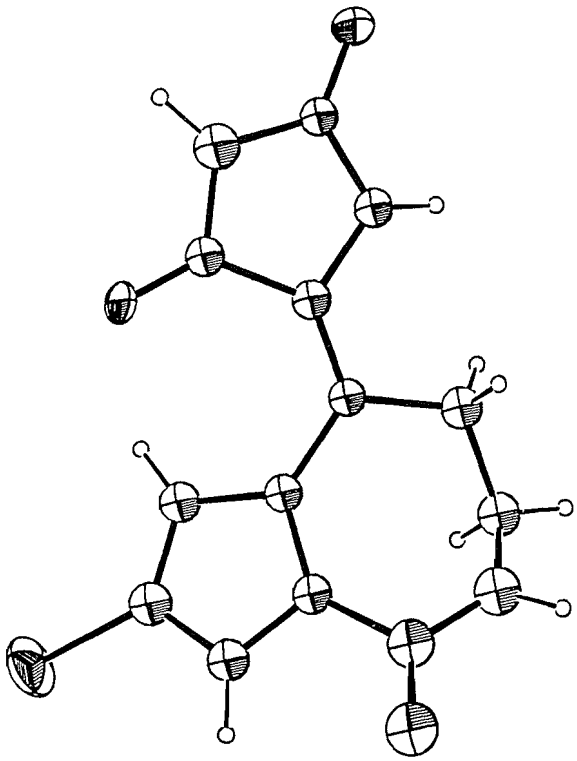

FIG. 1. ORTEP view of a single molecule of **2**, with 50% thermal ellipsoids.

MULTAN (8) and refined to $R = 0.054$ using anisotropic temperature factors for Br and oxygens other than O-3, and isotropic temperature factors for the other non-hydrogens and for hydrogens (unrefined) in calculated positions. HN-1, HN-11, and HN-9 were calculated to be 0.95 Å along a line to the respective oxygen. These positions differed very little from those calculated assuming bonding to trigonal atoms. HN-4 has been shown at the calculated position assuming a trigonal N-4 that is too far (2.4 Å) from the closest O-10 for significant hydrogen bonding; it may actually bend somewhat toward this O-10.

The structure deduced for axinohydantoin (**2**, Fig. 1) was found to be closely related to that of hymenialdisine (**1***b*), with reversal of configuration at the C7—C8 double bond being the most interesting difference. In turn, this suggested that axinohydantoin was not simply a hydrolysis product of guanidine **1***b*. The most prominent bond length difference between the two structures occurs at C10—O10, with 1.23 Å in hydantoin **2** compared to 1.33 Å for C11—N11 in **1***b*. No significant differences in bond angles were observed. An angle of 36° was observed between the least-squares planes of the two nearly planar five-membered rings in hydantoin **2**, compared to 43.8° in guanidine **1***b*. In both cases, the seven-membered ring has adopted a boat conformation with C-5 at the prow, and similar torsion angles except for C2—C3—N4—C5 expanding from −10.5° in **1***b* to −15° in **2**, and C2—C13—C7—C6 contracting from 41.1° in **1***b* to 31° in **2**. The twist angle C13–C7—C8—C12 about the carbon–carbon double bond increases from 0.5° in **1***b* to 10° in **2**, presumably to relieve the steric interaction between O-12 and HC-14.

The arrangement of intermolecular hydrogen bonds governing the packing in hydantoin **2** (see supplementary material)[8] was found to be completely different than that in guanidine **1***b* (6). The hydantoin ring in each molecule was found linked to the hydantoin rings of two other molecules via base-pairing interactions across centers of symmetry. The pyrrole NH proved to be hydrogen bonded to the methanol solvate oxygen and in turn to O-3. Only a few substances (9–12) with a hydantoin system have been isolated from sponges, and one of these, midpacamide, found by Scheuer and co-workers (9) in an unidentified Marshall Island sponge, may be biogenetically related to axinohydantoin. From evidence now in hand, pyrroles **1** and **2** and related substances may prove to be ubiquitous Porifera biosynthetic products.

Experimental

General methods

Marine sponge taxonomic identification was performed in the Smithsonian Institution where voucher specimens are deposited in the collections of the Department of Invertebrate Zoology, National Museum of Natural History. All solvents employed were redistilled. Size exclusion chromatography was accomplished with Sephadex LH-20 (particle size: 25–100 μm) suppled by Pharmacia Fine Chemicals, Uppsala, Sweden. Thin-layer chromatography was carried out with silica gel GHLF Uniplates (Analtech Inc.) and with RP-8 precoated plates (layer thickness: 0.25 mm) from E. Merck, Darmstadt, Germany. High-speed countercurrent chromatography was accomplished with an Ito multilayer coil extractor–separator (P.C. Inc., Potomac, MD) using 2.6 mm i.d. tubing, and an FMI Lab Pump.

Melting points are uncorrected and were determined on a Kofler-type hot-stage apparatus. Ultraviolet spectra were recorded employing a Hewlett–Packard model 8450 uv/vis spectrophotometer and ir spectra with a Nicolet ft-ir model MX-1 instrument. The nmr spectra were measured in DMSO-d_6 using a Bruker AM-400 instrument and are recorded in ppm downfield to TMS (assignments bearing the same superscript may be reversed). The ^{13}C nmr multiplicities were determined with APT experiments based on an average coupling constant of 135 Hz. The eims spectra were recorded with a Kratos AEI 5076 spectrometer at the NSF Regional Facility, University of Nebraska, Lincoln, Nebraska.

Palau Porifera (Axinella *sp. and* Hymeniacidon *sp.) collection and extraction.*

The initial collection of *Axinella* sp. (Demospongiae class, Axinellida order, Axinellidae family) in Palau, Western Caroline Islands, was conducted in May, 1979. The sponge displayed a brownish-yellow exterior of irregular mass. A 2-propanol–$CHCl_3$ extract gave confirmatory in vivo activity with PS T/C 201 at 100 mg/kg, PS ED_{50} = 2.5 μg/mL. A scale-up re-collection (220 kg wet wt.) of this sponge was completed in March, 1985, and preserved in 2-propanol. The preserving solution was separated from the sponge, concentrated to an aqueous slurry, and extracted with CH_2Cl_2 (13). The remaining sponge material was re-extracted with 2-propanol–CH_2Cl_2 (1:1); the extract was separated, solvent removed, and the residue partitioned between CH_2Cl_2 and H_2O. At this early stage a solid precipitate appeared at the CH_2Cl_2–H_2O interface. The precipitate was separated and amounted to

[8]Tables of observed and calculated structure factor amplitudes, calculated hydrogen coordinates, isotropic temperature factors, bond lengths and angles, torsion angles, and a packing diagram may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Tables of positional parameters and bond distances have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

For personal use only.

1.8 kg (PS T/C 227 at 294 mg/kg, ED_{50} 2.8 μg/mL). Analogous solid fractions were also obtained at this initial CH_2Cl_2 step during separations of the sponge extracts summarized below.

The orange sponge *Hymeniacidon* sp. (Demospongiae class, Halichondrida order, Hymeniacidonidae family) was collected (1979), re-collected (in 1985, 218 kg wet wt.), and extracted (2-propanol extract showed PS T/C 130 at 5.5 mg/kg and ED_{50} 27 μg/mL) as summarized above. Removal of solvent from the initial 2-propanol extract led to an aqueous concentrate that contained 1.2 kg of a solid fraction with PS ED_{50} = 3.7 μg/mL.

*Isolation of hymenialdisine (**1**b) and axinohydantoin (**2**)*

A 10 g aliquot from the 1.8 kg of solid precipitate noted above was dissolved in CH_3OH (400 mL) and separated by size exclusion chromatography on a column of Sephadex LH-20 (100 × 10 cm) to yield two major marine alkaloid fractions. When fraction 1 (elution volume: 12.0–12.6 L) was allowed to stand for 24 h at room temperature, axinohydantoin (**2**) slowly crystallized as yellow needles (30 mg): mp >350°C; tlc on silica gel R_f = 0.83, 1-BuOH–AcOH 50% (95:5); tlc on RP-8 R_f = 0.51, CH_3OH–AcOH 5% (1:1); uv (CH_3OH) λ_{max}: 264sh (log ε = 3.88), 345 (log ε = 4.16) nm; ir (KBr) ν_{max}: 1740, 1702, 1638, 1480, 1425, 1407 cm^{-1}; ^1H nmr (DMSO-d_6) δ: 2.67 (2H, m, H-6), 3.22 (2H, m, H-5), 6.66 (1H, s, H-14), 7.89 (1H, t, HN-4), 9.83, 10.91 (2 × 1H, s, HN-9, HN-11), 12.35 (1H, s, HN-1); ^{13}C nmr (DMSO-d_6) δ: 36.2 (t, C-6), 38.5 (t, C-5), 101.6 (s, C-15), 113.9 (d, C-14), 120.0 (s, C-13), 121.2 (s, C-7), 125.5 (s, C-2), 126.5 (s, C-8), 153.8 (s, C-10), 162.7 (s, C-3), 163.3 (s, C-12); hreims *m/z*: 325.9842 and 323.9834 ($C_{11}H_9N_4O_3Br$ requires 325.9836).

Fraction 2 (elution volume: 12.9–13.5 L) yielded a crystalline precipitate (100 mg), which was identified as hymenialdisine (**1***b*) by comparison (uv, ir, ^1H nmr, eims) with an authentic sample (6).

*Truk Porifera (*Axinella carteri*) collection and extraction*

In May 1985, approximately 1 kg of an orange-yellow sponge subsequently identified as *Axinella carteri* (Dendy), was collected in the Truk Lagoon, Federated States of Micronesia, at −13 to −24 m. The preserving solution (2-propanol) was removed and this extract proved toxic down to 50 mg/kg against the PS leukemia. The 2-propanol extract was partitioned between CH_2Cl_2 and H_2O and the resulting CH_2Cl_2 extract was successively partitioned (13) between 9:1–4:1–1:1 MeOH:H_2O with hexane–CCl_4–CH_2Cl_2. The final CH_2Cl_2 extract showed PS T/C 135 at 100 mg/kg and PS cell line ED_{50} = 1.2 μg/mL.

In October 1985, approximately 148 kg (wet wt.) of the sponge was recollected and preserved in MeOH. The MeOH solution was decanted, and the sponge was ground and extracted with MeOH:CH_2Cl_2 (1:1). The original MeOH solution was concentrated to an aqueous phase and extracted with CH_2Cl_2 (3×) followed by 1-BuOH. Study of this 1-BuOH fraction was discontinued when PS results showed minimal activity.

When the ambient temperature extraction of the sponge with MeOH:CH_2Cl_2 was completed, the aqueous MeOH phase was separated and concentrated to an aqueous phase, which was extracted with 1-BuOH (15 L). The 1-BuOH phase was concentrated, redissolved in MeOH (1.5 L), and dried to give a 232 g fraction (PS ED_{50} 1.4 μg/mL). A 97 g aliquot of the MeOH soluble fraction was treated with 1-BuOH (800 mL, 50°C, 12 h) and the relatively insoluble part (50 g, PS ED_{50} 1.5 μg/mL) was collected. The MeOH (600 mL) sparingly soluble portion weighed 4.26 g (PS ED_{50} 0.11 μg/mL).

*Papua New Guinea Porifera (*Hymeniacidon *sp.) collection and extraction*

The collection (May 1981, near Motapure Island, Papua New Guinea) and recollection (October 1983, 44 kg wet wt.) of an orange *Hymeniacidon* sp. as well as the large scale extraction (crude extract PS T/C 136 at 100 mg/kg and ED_{50} 24 μg/mL) and solvent partitioning were performed as described above for *A. carteri*. In this case, when the 934 g initial CH_2Cl_2 fraction was subjected to further separation by MeOH:H_2O with the hexane → CCl_4 → CH_2Cl_2 sequence, a total of 135 g (PS ED_{50} 14 μg/mL) of a solid interfacial fraction was collected and used to isolate hymenialdisines **1***a* and **1***b*.

*Starred atoms were refined isotropically.

Anisotropically refined atoms are given in the form of the isotropic equivalent thermal parameter, defined as $8\pi^2(U_{11} + U_{22} + U_{33})/3$.

*Isolation of hymenialdisines **1**a and **1**b—Procedure A*

An aliquot (250 mL) of the preceding *Axinella carteri* MeOH (600 mL) solution was applied to a column of Sephadex LH-20 (1.9 kg in MeOH). A total of 460 fractions of 20 mL each were collected and a fraction weighing 0.73 g (PS ED_{50} 2.2 μg/mL) was further separated using high speed countercurrent distribution with an Ito coil. A 50 mg aliquot was applied (6 mL) in 1-BuOH:HOAc:H_2O (4:1:5) to the coil with the 1-BuOH phase as stationary (upper) and the aqueous part as mobile (lower) phase. Fractions (120) of 6.5 mL each were collected; fractionation was monitored with ultraviolet detection (254 nm). The fractions were neutralized (pH 7) with aqueous NaOH and refrigerated. Debromohymenialdisine **1***a*, 9 mg, PS ED_{50} = 3.0 μg/mL, crystallized from fractions 28–33 and was identical (tlc, ms, nmr) with an authentic sample (6).

The MeOH less soluble fraction (4.26 g) described above was extracted with MeOH (5 × 25 mL) at 40°C and the solution filtered to give 3.73 g of residue. A 0.90 g portion was triturated with DMSO (10 mL). The soluble portion (0.25 g) was chromatographed on a column of Sephadex LH-20 in MeOH to provide 0.13 g of hymenialdisine (**1***b*) as yellow crystals (PS ED_{50} 0.62 μg/mL), identical (tlc and ms comparisons) with an authentic sample (6).

Procedure B

The 1.2 kg fraction (see above) from the Palau *Hymeniacidon* sp. was further separated by successive Soxhlet extraction (20 g aliquot) with CH_2Cl_2 (6 × 5 L), EtOH (6 × 5 L), and 1-BuOH (6 × 5 L) to give respectively 35 g (PS ED_{50} 26 μg/mL), 500 g (PS ED_{50} 8.6 μg/mL), and 106 g (PS ED_{50} 2.6 μg/mL) fractions. A 10 g sample of the 1-BuOH fraction in MeOH was subjected to chromatography on a column of Sephadex LH-20 (500 g) to give 26 individual (by tlc comparisons) fractions using 4:1 CH_2Cl_2:MeOH. Of these, 56 mg proved to be largely debromohymenialdisine **1***a* (PS ED_{50} 1.4 μg/mL) and hymenialdisine (5.5 mg, **1***b*, PS ED_{50} 7.5 μg/mL) by comparison nmr and tlc.

Procedure C

The 135 g fraction from the Papua New Guinea *Hymeniacidon* sp.

was extracted (Soxhlet procedure with two stainless steel 1-gallon extractors) with EtOH to yield a 22 g alcohol soluble fraction. Treatment of this fraction with CH_2Cl_2:CH_3OH (1:1) yielded a precipitate (4.3 g, PS ED_{50} 8.5 μg/mL), which was extracted with hot 1-BuOH. The 1.5 g 1-BuOH soluble fraction was preabsorbed onto silica gel and separated by chromatography on a column (3 × 62 cm) of silica gel (180 g). Gradient elution with 95:5 CH_2Cl_2:CH_3OH with increments of MeOH provided fractions that yielded (0.17 g and 0.06 g respectively) debromohymenialdisine (**1***a*, PS T/C 143 at 3.6 mg/kg and ED_{50} 2.5μg/mL) and hymenialdisine (**1***b*, PS T/C 138 at 3.6 mg/kg and ED_{50} 2.7 μg/mL). Both **1***a* and **1***b* were identified by direct comparison with authentic samples (6) employing tlc, ^{13}C and ^1H nmr, ms, uv, and ir spectral data.

X-ray structure of axinohydantoin (2)

$C_{11}H_8BrN_4O_3 \cdot CH_3OH$ fw = 357.17

The thermal isomerization of bicyclic oxazines into epoxyepimines. A preliminary theoretical study

MICHEL SANA,[1] GEORGES LEROY, JEAN-LUC VAERMAN, AND HEINZ GUNTER VIEHE

Laboratoire de Chimie Quantique et Laboratoire de Chimie Organique, Université Catholique de Louvain, Bâtiment Lavoisier, Place Louis Pasteur, 1, Bte 35, B-1348 Louvain-la-Neuve, Belgium

Received September 20, 1989[2]

MICHEL SANA, GEORGES LEROY, JEAN-LUC VAERMAN, and HEINZ GUNTER VIEHE. Can. J. Chem. **68**, 1625 (1990).

The thermal isomerization of bicyclic oxazines **1** to epoxyepimines **2** depends on the *N*-substituent. BDE calculations on model systems agree with the mechanistic picture. The rate-determining step in N—O bond homolysis is facilitated by *N*-vinyl substituents.

Key words: oxazines, BDE, NO bond, substituent effect.

MICHEL SANA, GEORGES LEROY, JEAN-LUC VAERMAN et HEINZ GUNTER VIEHE. Can. J. Chem. **68**, 1625 (1990).

L'isomérisation thermique des oxazines bicycliques **1** en époxyépimines **2** dépend de la nature des substituants présents sur le N. Des calculs de BDE réalisés sur des systèmes modèles sont en accord avec ce mécanisme réactionnel. L'homolyse de la liaison N—O qui se produit dans l'étape déterminante de la réaction est facilitée par la présence de substituants *N*-vinyles.

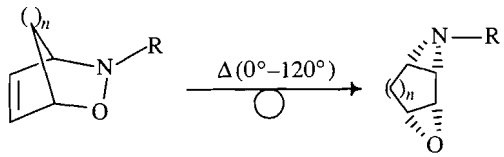
Mots clés : oxazines, BDE, liaison NO, la effet de substituant.

[Traduit par la revue]

Introduction

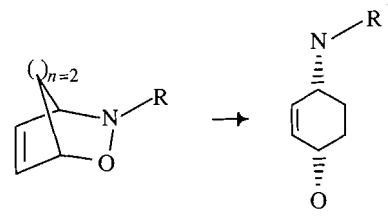
The nature of the *N*-substituent as well as the size of the bicyclic system of substituted oxazines **1** affect their thermal reactivity (1). Thus some oxazines decompose by cycloreversion reaction (2) whereas others isomerize via Cope rearrangement (3). Generally they are comparatively thermally stable.

We have found that bicyclic oxazines **1** with vinylic captodative substitution (4) isomerize into epoxyepimines **2** (5). Mechanistic studies suggest that this "epoxyepimination" reaction proceeds by a biradical pathway (6) with the rate-determining step being the homolytic cleavage of nitrogen–oxygen bond in oxazine.



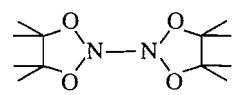
1 **2**

Homolytic breaking of the N—O bond is an endothermic process. According to Hammond's postulate, the structure of the epoxyepimination transition state must be closer to the intermediate biradical **3** than to the starting oxazine **1**. Therefore, knowledge of the energy difference between oxazine and its corresponding biradical (which is the bond dissociation energy: BDE(N—O)) would be an indication of the activation energy for the rate-determining step.

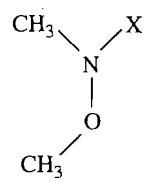


1 **3**

In this preliminary theoretical study we calculate the influence of *N*-substituents on the N—O bond strength in a simple model system without the cyclic structure. According to Leffler's relation (7) (also known as Marcus's relation (8)), a connection exists between the heat of reaction and the activation energy for any chemical process. In some cases, the quadratic Leffler's relation (in ΔH_r) is approximated by a simple linear expression (9, 10): $E_a \approx a + b\Delta E_r$. According to this very simple relationship, the smallest activation energies should correspond to the largest heats of reaction (BDE). Therefore one can modify the bond strengths by using appropriate substituents; large variations in BDE are possible depending on the nature of the groups considered (see Fig. 1): CC bonds with BDE between 22 [$(NC)_3C—C(CN)_3$] and 121 ($CH_3—CN$) kcal mol^{-1} are known. As BDE's are heats of reaction, they can be negative as well as positive. Negative BDE's occurs when bond breaking involves very unstabilized molecules (11)



and (or) largely stabilized radicals ($(NH_2)_2N\cdot$ (12)). Thus BDE(NN) varies from −5 [$(NH_2)_2N—N(NH_2)_2$] to 70 ($NHF—NH_2$) kcal mol^{-1} (Fig. 1). Accordingly, the study of the weakness points in a molecule corresponds to an evaluation of BDE's. Unfortunately, thermochemical data (especially for radicals) are not often available for this evaluation. However, quantum chemical calculations are now accurate enough to give reliable heats of formation. The isodesmic procedure of Pople *et al.* (13) attains this goal even for large molecules (14). To estimate the effect of substituents on bond strength (independent of ring nature) we have chosen to apply this procedure to the following model molecules:



where X stands for CH_3, $CH=CH_2$, CH=O, NH_2, or $CH=C(CN)(NH_2)$.

Methods of calculation

The equilibrium geometry of these molecules and related

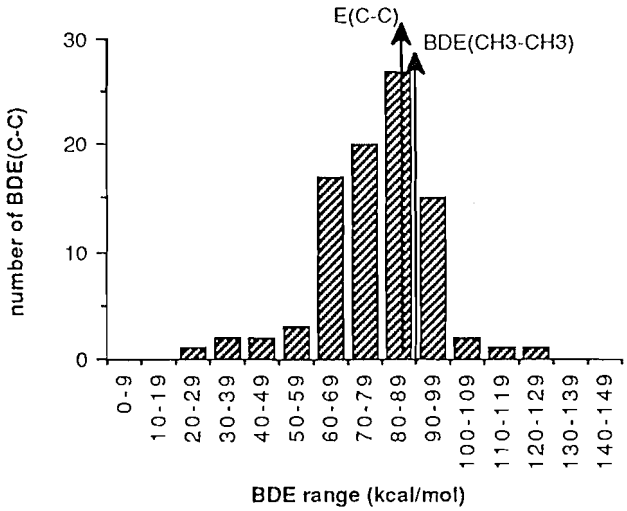

FIG. 1. C—C bond as an example of the domain of variation for bond dissociation energies.

radicals has been determined at the Hartree–Fock level (LCAO-SCF-MO RHF and UHF) (15), using the 6-31G basis set of Pople and co-workers (16). In Table 1 we report their total energies and heats of formation. The chosen isodesmic reactions and other necessary data are commonly available in the literature or can be obtained on request from the authors.

Results and discussion

Figure 2 shows rather large variations in BDE depending on the *N*-substituent. It is interesting to note that the order in BDE's does not correspond to the standard bond energies (standard bond energies are selected from ref. 17). The following sequences are normal (in kcal mol^{-1}):

E(C—O)	$\gg$	E(C—N)	$\gg$	E(N—O)	$>$	E(N—N)	
91	$\gg$	77	$\gg$	52 (ref. 18)	$>$	48	

and

BDE(CH_3—OH)	$>$	BDE(CH_3—NH_2)	$\gg$	BDE(NH_2—NH_2)	$>$	BDE(NH_2—OH)	
93	$>$	86	$\gg$	68	$>$	64	

In CH_3—NX—O—CH_3 compounds, we find unusually weak C—O bonds (53 to 68 kcal mol^{-1} depending on X). Nevertheless, in all cases, the N—O bond is the weakest one. Its strength is particularly small in *N*-vinyl derivatives, but larger in *N*-formyl species. Comparison of BDE modification in various cases is shown in Fig. 3. The first line shows that even methyl groups have a non-negligible effect on the NO single bond energy; substitution on oxygen in particular produces an important lowering of BDE. It is also seen that the substituents considered here produce similar but smaller effects on C—O as well as on O—O bonds.

For analysing bond strengths in terms of stabilization energies (SE), we use the definition of SE introduced by one of us (20): the SE is simply the deviation between the atomization energy (ΔH_a) and the sum of standard bond energies: $\Delta H_a = \Sigma E_b$ + SE. This means that the BDE is mainly dependent on the standard energy of the breaking bond on the one side and on the difference in SE between the radicals and the parent molecule on the other side. For lowering a bond strength, one may destabilize (SE < 0) the parent molecule and/or stabilize (SE > 0) the radicals derived from the homolytic dissociation. As shown in Table 1, one observes negligible SE's for vinilic parent molecules. In these cases, the lowering of BDE can only be induced by large stabilization energies of the radicals

TABLE 1. Total energies (au), heats of formation (kcal mol^{-1}), and stabilization energies (SE) (kcal mol^{-1}) for the compounds of interest

Compounds	E(6-31G)	ΔH_f	SE

(±13 kcal mol^{-1}). With CHO and NH_2 substituents, the radicals remain stabilized but the parent molecules now also become stabilized. For $NH_2N(CH_3)OCH_3$ the stabilization of the aminyl radical is larger than that of the molecule. It follows a global lowering of the BDE(N—O). For $CHON(CH_3)OCH_3$ the parent molecule has so large an effect the BDE is increased. Nevertheless, in conjunction with the parent molecules, one finds large lowering in the BDE(N—O) only with the vinyl substituents. In the case of formyl derivatives, one has an increase in BDE(NO). An another interesting point, which appears in Fig. 2, is the very low BDE for the C—O bonds (50–70 kcal mol^{-1} compared to the standard value of 93 kcal mol^{-1}). The large stabilization energies of the nitroxide radicals (in the range 28–33 kcal mol^{-1}) lead to these weak C—O bonds. As explained below, the origin of the stabilization energy can be found in the electronic structure of the nitroxyl radicals. The methoxy aminyl radicals have SE values between 14 and 23 kcal mol^{-1}. If we take into account the stabilization energies of the parent molecules, one obtains, except for the formyl derivatives, BDE values ten or more kcal mol^{-1} lower than the usual standard C—N energy. Let us now summarize our observations: one has to retain that the N—O bond is significantly modified by the vinyl substituent. The BDE(N—O) decreases to 34 kcal mol^{-1}. The C—N bonds exhibit small to

For personal use only.

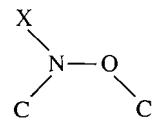
medium weakening of strength. The remaining C—O bonds are always weak, but their minimum values remain equal to or larger than 53 kcal mol^{-1}. The



frame exhibits weak bonds. Ring structure connecting the two carbon atoms can enhance the weakness of this frame, as is observed experimentally. The variations in the heats of formations are large enough compared to the usual reliability of the calculations that our conclusions are at least not qualitatively suspicious. The theoretical method we use is known to give heats of formations with a target accuracy of 3 kcal mol^{-1} (21).

Large stabilization energies correspond to the occurrence of non-standard electronic organization or to long range interaction (21) (through the molecular chain or with some polysubstitution). The large SE within the parent molecules (in the case of NH_2 and CHO substitution) are of the second type. For the radicals considered in this work, the first explanation is the only valid one. All the heavy atoms in the radicals lie in the same plane, thus avoiding the usual tetrahedral electronic organization. The Boys' localization of the wave function allows the generation of conventional electronic pictures of any chemical compound (22). Using this technique, one can represent the electron distribution in radicals of interest. Figure 3 shows in a conventional manner the Boys' electronic pictures of some radicals. In those Linnett formulas for the aminyl radicals we have three electrons on the nitrogen atom. Distinction between σ and π type electrons represents a more formal than a physical view. Those electrons or part of them can be delocalized when appropriate groups are attached to the nitrogen atom: i.e. CH_2=CH, CHO, or NH_2. This stabilizes the radical. The large stabilization energies in the nitroxide radicals (and consequently the small BDE of the C—O bonds) can be explained in terms of an electronic description of the compounds. As shown in Fig. 4, the N—O bond in nitroxide derivatives appear as a three-electron two-center bond. This electronic delocalization gives stronger NO bond in the radical which becomes stabilized.

Conclusion

The stabilization energies of radicals and in a lesser way of parent molecules gives large variation in bond dissociation energies depending on the nature of the substituent in $XN(CH_3)OCH_3$ compounds. In each case the BDE(N—O) is the smallest; the vinyl group (with captodative substitution or without) leads to BDE(N—O) close to 30 kcal mol^{-1}. This is not the largest observed variation, but it gives the lowest BDE in those compounds. Those stabilization energies can be explained in terms of electronic Boy's picture. Although the relationship between BDE and E_a is still unknown for such type of bonds,

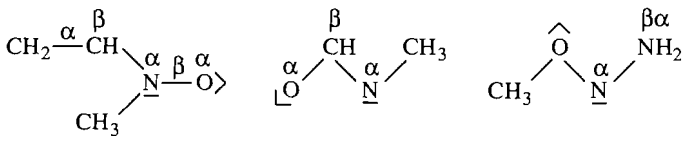


FIG. 4. Conventional representation of the map of charge centroids obtained using the Boys' localization procedure.

one can suppose that these values are small enough for easy bond breaking, especially in bicyclic compounds such as **1** which must be destabilized due to a non-negligible ring strain.

Carbocationic polymerization in the gas phase: polymerization of acetylene induced by BF_2^+

LEONARD FORTE, MIN H. LIEN, ALAN C. HOPKINSON, AND DIETHARD K. BOHME
Department of Chemistry, York University, North York, Ont., Canada M3J 1P3

Received August 30, 1989[1]

LEONARD FORTE, MIN H. LIEN, ALAN C. HOPKINSON, and DIETHARD K. BOHME. Can. J. Chem. **68**, 1629 (1990).

Gas-phase measurements for the primary reaction of BF_2^+ with acetylene and the ensuing higher-order reactions with acetylene have been performed at 296 ± 2 K in helium at 0.35 torr using the Selected-Ion Flow Tube (SIFT) technique. The primary reaction was observed to be rapid and to produce two species which both initiated rapid polymerization of acetylene. The major primary product, C_2HBF^+, was observed to initiate the sequential addition of four molecules of acetylene, most likely by termolecular association reactions. The first few steps in this polymerization were also followed using *ab initio* molecular orbital theory. The calculations and measurements provide structural, energetic, and kinetic information and, in combination, reveal several intrinsic features of the initial steps of the cationic polymerization of acetylene initiated by BF_2^+.

Key words: polymerization, acetylene, aromaticity.

LEONARD FORTE, MIN H. LIEN, ALAN C. HOPKINSON et DIETHARD K. BOHME. Can. J. Chem. **68**, 1629 (1990).

Opérant à 296 ± 2 K, à une pression de 0,35 torr d'hélium et faisant appel à la technique du tube à écoulement ionique sélectif (SIFT), on a effectué des mesures en phase gazeuse sur la réaction primaire du BF_2^+ avec l'acétylène et sur les réactions subséquentes d'ordre plus élevées avec l'acétylène. On a observé que la réaction primaire est rapide et qu'elle conduit à deux espèces qui initient chacune une polymérisation rapide de l'acétylène. On a observé que le produit primaire majeur, le C_2HBF^+, initie une addition séquentielle de quatre molécules d'acétylène qui se produisent probablement par des réactions d'association termoléculaires. On a aussi suivi les premières étapes de cette polymérisation à l'aide de la théorie des orbitales moléculaires *ab initio*. Les calculs et les mesures fournissent des informations sur la structure, sur les énergies et sur le cinétique de la réaction et, lorsqu'on les combine, ils révèlent plusieurs caractéristiques intrinsèques des étapes initiales de la polymérisation cationique de l'acétylène initiée par le BF_2^+.

Mots clés : polymérisation, acétylène, aromaticité.

[Traduit par la revue]

Introduction

Our recent observations of the "clean" gas-phase polymerization of ethylene and other olefinic monomers initiated by BF_2^+ (1, 2) prompted us to study the related ion-induced gas-phase polymerization of acetylene. Acetylene has been polymerized in solution by Friedel–Crafts or Lewis acid catalysts such as $AlCl_3$ and BF_3 (3), but the mechanism of the initiation of polymerization remains a matter of speculation.

For the polymerization of olefins in solution, one theory attributes initiation to the ionized form of the initiator resulting from self-dissociation (4, 5). For example, in the polymerization of isobutene by $AlCl_3$, the $AlCl_2^+$ cation formed by self-dissociation could add to the double bond to give an equivalent concentration of propagating carbenium ions (4, 5). Indirect evidence for such a mechanism has been given (5, 6), but direct identification of the initiating and propagating species in solution is lacking. However, we have recently shown that the intrinsic nature and reactivity of these species can be revealed with measurements of the polymerization of isobutene induced by BF_2^+ in the gas phase (2). The gas-phase polymerization of several other olefinic monomers was also investigated (2).

It is reasonable to assume that a similar initiation mechanism can apply to the polymerization of alkynes by Lewis acids. To test this assumption we chose to investigate the polymerization of acetylene initiated by the BF_2^+ cation in the gas phase, both experimentally and theoretically. In our experimental study, mass-selected BF_2^+ ions were allowed to react with acetylene in a flowing helium buffer gas and the primary and higher-order ions evolving in the polymerization chemistry were monitored downstream with a second mass spectrometer. The first few steps of this polymerization also were followed theoretically using *ab initio* molecular orbital calculations. In combination, the measurements and the calculations reveal a number of the intrinsic features of this cationic polymerization by providing kinetic, energetic, and structural information. Such insight is not accessible to measurements made in solution.

Experimental

The selected-ion flow tube (SIFT) apparatus was used to perform the measurements. The apparatus and technique have been described in detail elsewhere (7). BF_2^+ was generated from a mixture of BF_3 (Matheson C.P. grade) and helium (about 30 mol%) by electron impact at 55–80 eV. BF_2^+ was then selected using a quadrupole mass filter and injected into a flow tube containing helium at ca. 0.33 torr. We have seen that $FBOH^+$ arises from the reaction of BF_2^+ with water vapour impurity in the carrier gas (2). All measurements were performed at a room temperature of 296 ± 2 K and a total pressure of ca. 0.33 torr. Helium (Matheson, high purity 99.995 mol%) was used as the carrier gas and acetylene (Matheson, prepurified 99.6 mol%) as the reactant gas.

Table 1 includes a summary of the measured rate coefficients. At least two measurements were made for each determination of a rate coefficient. Sources of uncertainty have been discussed previously (7). The rate coefficient for the reaction for BF_2^+, which was determined from 11 measurements, was derived from a fit to the semilogarithmic decay of this ion and has an estimated accuracy of less than ±30%. The rate coefficients for the secondary and higher-order reactions were derived from a double-exponential computer fit to the profile of the corresponding reactant ion and have an estimated accuracy of less than ±40%.

Figure 1 shows that BF_2^+ reacts rapidly with acetylene to produce two primary products according to reaction [1]. The semilogarithmic

TABLE 1. Effective bimolecular rate coefficients (in units of 10^{-10} cm^3 molecule^{-1} s^{-1}) for initiating and propagating reactions in the BF_2^+-induced gas-phase polymerization of acetylene at 296 ± 2 K in helium buffer gas at 0.35 torr

Reactant ion	k_{exp}[a]	k_c[b]	k_{exp}/k_c
BF_2^+	4.5	11.0	0.41
C_2HBF^+	3.8	10.8	0.35
$C_4H_3BF^+$	5.5	10.2	0.54
$C_6H_5BF^+$	3.2	9.9	0.32
$C_8H_7BF^+$	0.92	9.7	0.09
$C_2H_2 \cdot BF_2^+$	8.4	10.3	0.82
$C_4H_4 \cdot BF_2^+$	0.57	10.0	0.06

[a]Deduced from data of the type shown in Fig. 1 with computer-fitting techniques using single (for BF_2^+) or double exponentials (for the remaining ions). The estimated accuracies are less than ±30% for the reaction of BF_2^+ and less than ±40% for the remaining reactions.

[b]Collision-rate coefficients were derived using the Average Quadrupole Orientation theory (8) with $\alpha(C_2H_2) = 3.3$ Å^3 (9) and $Q = 3.6 \times 10^{-26}$ esu cm^2 (10).

decay of BF_2^+ provides a rate coefficient of (4.1 ± 1.6) × 10^{-10} cm^3 molecule^{-1} s^{-1}. The adduct ion presumably is formed in a termolecular reaction with helium as the stabilizing third body. The C_2HBF^+ product ion was seen to undergo a rapid sequential addition of four acetylene molecules as shown in reaction [2], again presumably in a termolecular fashion.

$$[2]\quad C_2HBF^+ \xrightarrow[k_2]{C_2H_2} C_4H_3BF^+ \xrightarrow[k_3]{C_2H_2} C_6H_5BF^+ \xrightarrow[k_4]{C_2H_2} C_8H_7BF^+ \xrightarrow[k_5]{C_2H_2} C_{10}H_9BF^+$$

Figure 1 also shows clearly the occurrence of the first three propagation steps indicated by reaction [2]. The fourth was observed in a separate experiment.

Table 1 shows that the acetylene additions in reaction [2] proceed with a slight overall decrease in efficiency, where efficiency is defined as the ratio of the experimental reaction rate coefficient, k_{exp}, to the computed collision rate coefficient, k_c. Collision rate coefficients were computed with the Average Quadrupole Orientation theory (8) taking the polarizability and rotation-averaged quadrupole moment (one-half of the static quadrupole moment) to be 3.33 Å^3 (9) and 3.6 × 10^{-26} esu cm^2 (10)), respectively. The effective bimolecular rate coefficients for the addition reactions were found to be 3.8, 5.5, 3.2, and 0.92 × 10^{-10} cm^3 molecule^{-1} s^{-1}. It is interesting to note that the rate coefficient and efficiency maximize for the addition of the second molecule of acetylene.

The adduct ion, $C_2H_2 \cdot BF_2^+$, also reacted further with two sequential additions of acetylene being observed, as shown in Fig. 1 and reaction [3], with helium presumably acting as the stabilizing third body.

$$[3]\quad C_2H_2BF_2^+ \xrightarrow[k_2']{C_2H_2} C_4H_4BF_2^+ \xrightarrow[k_3']{C_2H_2} \text{products}$$

The effective bimolecular rate coefficients for reaction [3] were found to be 8.4 and 0.57 × 10^{-10} cm^3 molecule^{-1} s^{-1} (Table 1). Here we note a sharp decrease in rate coefficient for the addition of a second molecule of acetylene.

Theory

The reaction sequences for the first three reactions with acetylene were examined using *ab initio* molecular orbital calculations at the HF 3-21G level of theory (11) and for the smaller ions also at the HF 6-31G* level (12). All Hartree–Fock calculations were performed with the MONSTERGAUSS program (13) and single-point MP2 calculations (14) were performed with the Gaussian 82 program (15).

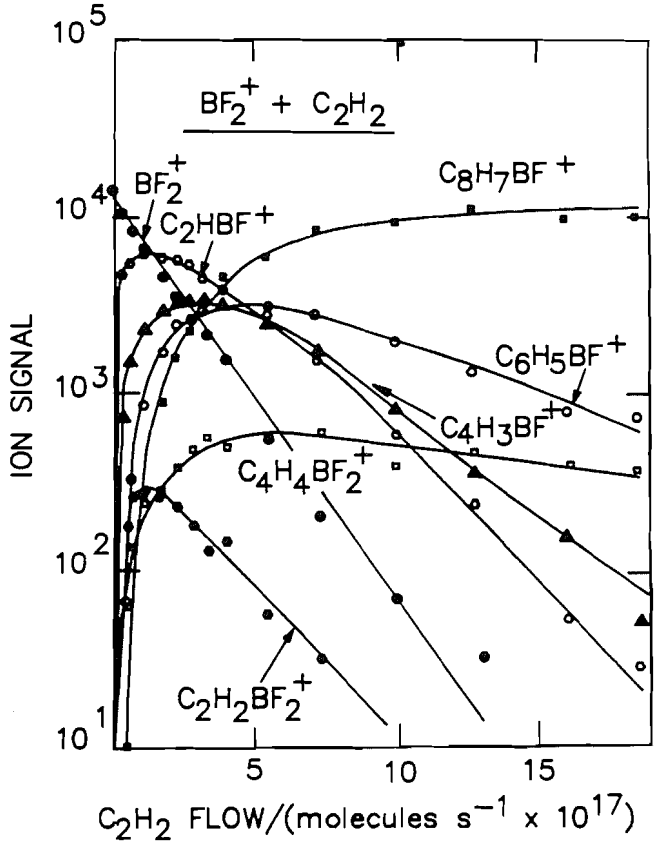

FIG. 1. Observed variation in ion signals upon addition of C_2H_2 into the reaction region in which the reacting ion BF_2^+ has been established with the SIFT technique. $P = 0.35$ torr, $T = 295$ K, [He] = 1.13 × 10^{16} atoms cm^{-3}, $\bar{v} = 6.6 \times 10^3$ cm s^{-1}, $L = 46$ cm.

The energy differences as calculated at the HF 3-21G level for the first three reactions of BF_2^+ with acetylene are shown in Fig. 2. Structures for the small ions, **1**, **3**, **5**, **6**, **7**, **8**, and **9** were optimized at both the HF 3-21G and HF 6-31G* levels of theory and the results of the higher level calculations are given in Fig. 3. For the larger ions, **4**, **10**, **11**, **12**, and **13**, several conformers were optimized at the HF 3-21G level and for each ion the main structural features of the lowest energy conformer are given in Fig. 4. The total energies as calculated at the HF 3-21G//3-21G and HF 6-31G*//6-31G* levels are recorded in Tables 2 and 3.

Reaction profile at the 3-21G level of theory

(a) The major channel

The gas-phase addition of BF_2^+ to acetylene has a large exothermicity, and in the dominant channel, much of this excess energy is used to fragment the initial complex into HF and C_2HBF^+ (**1**). The calculated ΔE for this reaction is −9.9 kcal mol^{-1}. Ion **1** can be represented by two valence tautomers, **1***a* and **1***b*. At the 3-21G level the C—C bond is 1.199 Å

$$F—B^+—C{\equiv}C—H \leftrightarrow F—B{=}C{=}C^+—H$$
$$\mathbf{1}a \qquad\qquad \mathbf{1}b$$

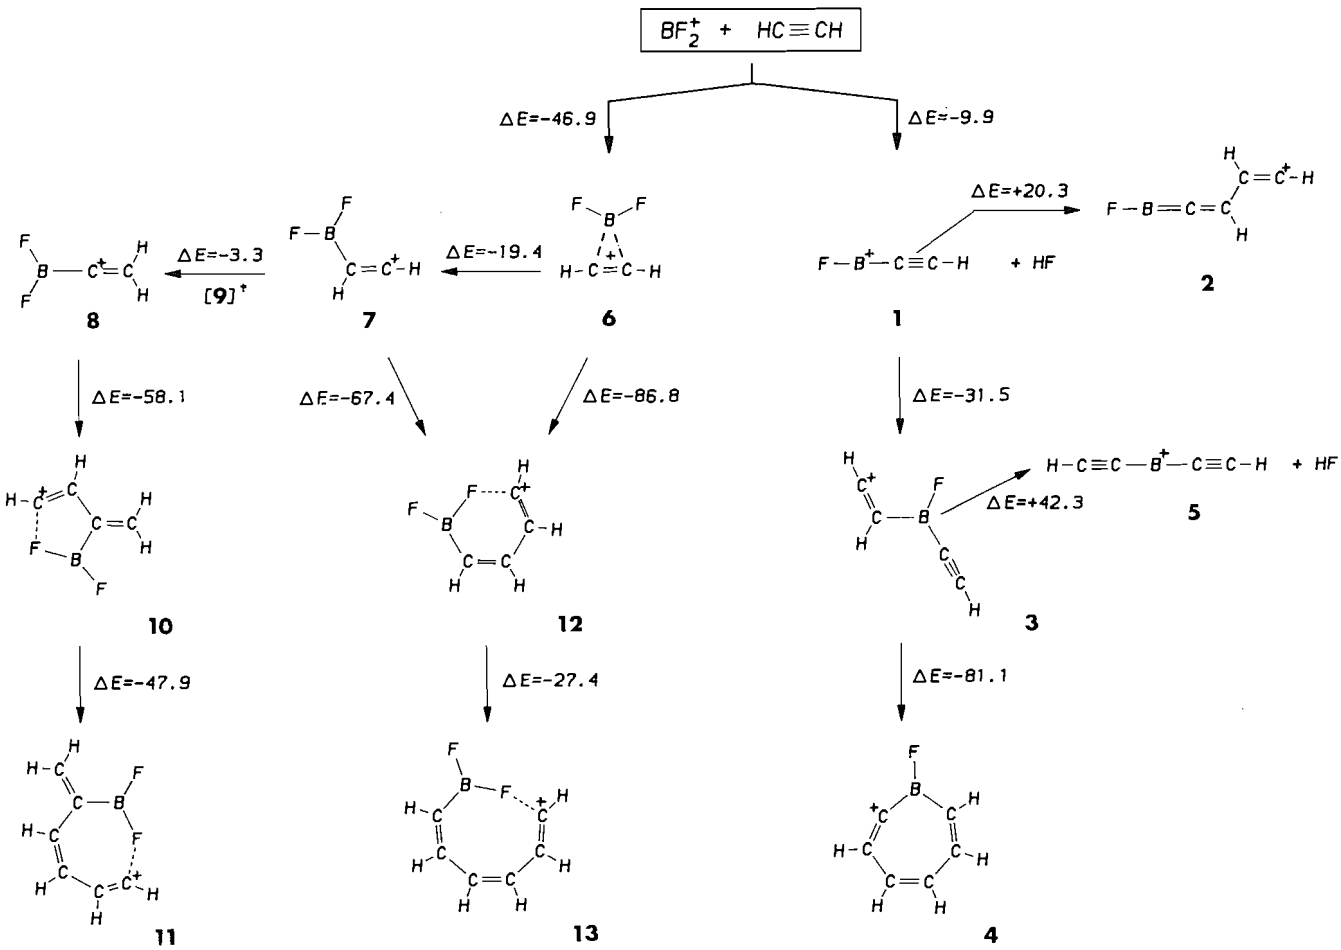

FIG. 2. Differences in total energy, ΔE (in kcal mol^{-1}), computed at 3-21G, for the first three steps in the reaction of BF_2^+ with C_2H_2.

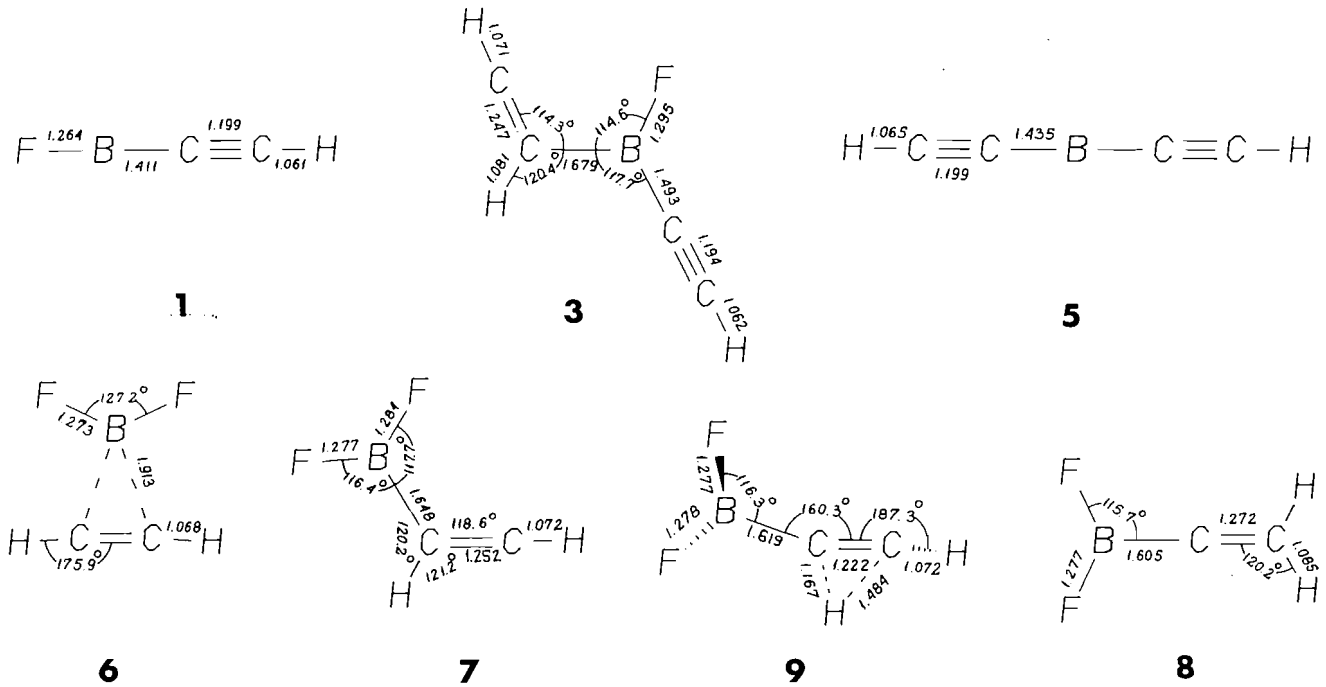

FIG. 3. Structures from HF 6-31G* optimization studies on ions **1**, **3**, **5**, **6**, **7**, **8**, and **9**. Bond lengths are in Ångstroms and bond angles in degrees. Based on the results of optimizations at the HF 3-21G level, ions **1** and **5** were assumed to be linear ($C_{\infty v}$ and $D_{\infty h}$), **6** and **8** were taken to have C_{2v} symmetry, and angles in acetylenes and at cationic carbons in vinyl cations were assumed to be 180°. In transition structure **9** both fluorines and both hydrogens are out of the plane defined by BCC, but all dihedral angles are less than 2°.

and C—B bond is 1.411 Å, indicating that structure **1***a* is the better representation. Structures **1***a* and **1***b* formally localize the positive charge on boron and the terminal carbon, respectively, and, in principle, nucleophilic attack by acetylene could occur at either of these atoms. However, addition at the carbon leads to ion **2** which is higher in energy than the initial reactants and the only energetically allowed pathway results in formation of **3**, a vinyl cation with a substituent on the β-carbon atom. We studied the profile to rotation about the C—B bond and found the conformation with the fluorine eclipsing the double bond (Figs. 2 and 3) to have the lowest energy. In this structure the positive charge is localized on the cationic carbon, with little participation from the substituent. Rotation by 180° about the C—B bond results in the triple bond eclipsing the double bond, a structure which might be expected to be stabilized by through-space π-donation from the triple bond to the cationic carbon (**3***a*). However, the product formed by collapsing this internal complex is a five-membered ring, **3***b*, which has anti-aromatic character (4π electrons in the ring) and is a vinyl cation with badly distorted geometry at the cationic carbon (bending at the α carbon of vinyl cations is a high energy process (16)). These destabilising interactions result in the structure with fluorine eclipsing the double bond being 2 kcal mol^{-1} lower in energy than **3***a*.

TABLE 2. Total energies of ions and relative energies of products shown in Fig. 2

Products	Total energy of ion[a]	Relative energy[b]
1 + HF	−199.03755	−9.9
2 + HF	−275.40120	+10.4
3 + HF	−275.48363	−41.4
4 + HF	−352.00849	−122.2
5 + 2HF	−175.95598	+0.9
6	−298.55678	−46.9
7	−298.58772	−66.4
8	−298.59292	−69.6
9	−298.55944	−48.6
10	−375.08150	−127.7
11	−451.55376	−175.6

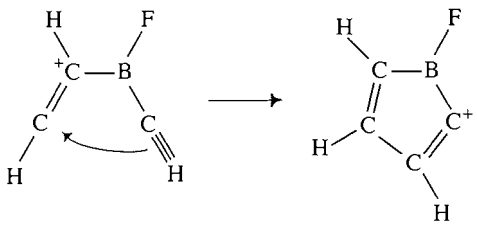
[a]Total energy in hartrees computed at the HF/3-21G//HF/3-21G level.

[b]Energy (in kcal mol^{-1}) relative to the reactants $BF_2^+ + nC_2H_2$. Total energies for BF_2^+, C_2H_2, and HF are −222.08601, −76.39596, and −99.46022 hartrees, respectively.

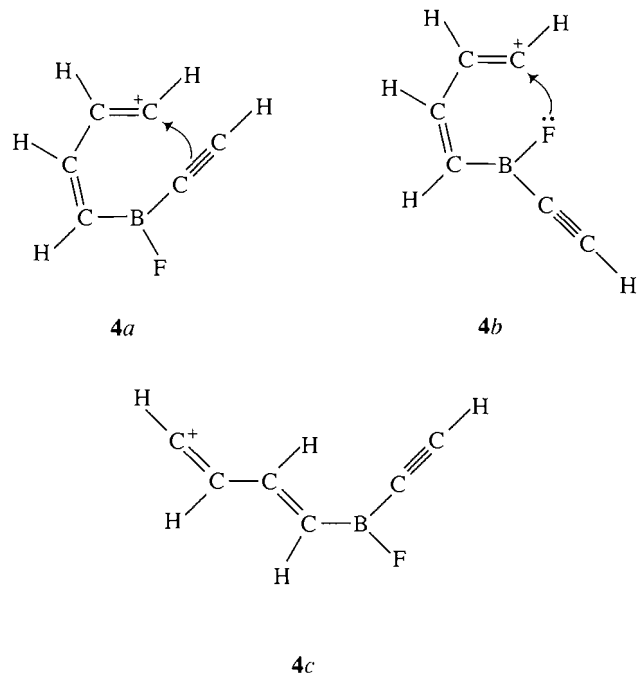


3a *3b*

Addition of a further acetylene molecule to the cationic carbon of **3** results in the vinyl cation

$$HC^+{=}CH{-}CH{=}CH{-}B(F){-}C{\equiv}C{-}H$$

Assuming that this ion is planar, then rotation about the HC—B, HC=CH, and HC—CH bonds lead to eight possible structures. Two of these structures permit formation of cyclic ions both with 6π electrons and these two aromatic ions have the lowest energies. The *trans,cis,cis* arrangement, **4***a*, permits stabilization of the cationic carbon by through-space π-donation from the alkynyl group. This structure, which is the lowest energy conformer, has a distance of 1.443 Å between the terminal carbon atoms, and is best regarded as a seven-membered ring with alternating single and double C—C bonds (Fig. 4, structure **4**). The bond angle of 156° at the α-carbon is far from ideal, but is similar to that calculated for the 1-cyclohexenyl cation (16).



4a *4b*

4c

The *cis,cis,cis* structure **4***b* permits through-space donation from fluorine to the cationic carbon. The $^+$C—F distance is 1.506 Å and the ∠C—C—H at the cationic carbon is 139.7°, showing considerable $^+$C—F interaction. This structure is 16 kcal mol^{-1} higher in energy than **4***a*. All other structures are higher in energy and the *trans,trans,trans* structure **4***c*, where the positive charge is further from the unsaturated bonds and lone pairs, is 47 kcal mol^{-1} above **4***a*. Addition of acetylene to **3** gives the aromatic ion **4** in the most exothermic reaction in the major pathway (ΔE is −80.8 kcal mol^{-1}). Elimination of HF from **3** to form **5**, an analogous reaction to the major pathway

in the initial step, requires 10.8 kcal mol^{-1} more energy than the maximum available in the formation of **3** from **1**, and does not occur.

(b) The minor channel

Adduct $C_2H_2BF_2^+$ is a minor product in the gas-phase addition of BF_2^+ to acetylene. As BF_2^+ and acetylene approach, the initial long-range interaction is expected to be π-donation from the triple bond to the empty *p*-orbital on the boron atom. Similar π-complexes are believed to be intermediates in electrophilic addition to alkynes in solution (17). π-Complexes are stabilized by two interactions, π-donation from the alkyne to a vacant orbital on X^+ and back-donation usually from a lone pair on the electrophile to π* of the alkyne. In the reaction between BF_2^+ and acetylene, the electrophile is a good acceptor but back-donation is minimal and the C—B bonds are effectively one-electron bonds. The π-complex, **6**, has the anti Van't Hoff planar structure and is 19.5 kcal mol^{-1} higher in energy than the β-substituted vinyl cation, **7**. By analogy with profiles to interconversion between the open and cyclic $C_2H_2X^+$ ions (18), there is likely to be little or no barrier to interconversion of **6** and **7**. The planar α-substituted ion, **8**, has the lowest energy 3.2 kcal mol^{-1} below **7** and the barrier to interconversion of **7** and **8** via transition structure **9** is 17.8 kcal mol^{-1} above **7** (Table 1). Structure **8** is 69.6 kcal mol^{-1} below the reactants, C_2H_2 and BF_2^+, and structures **6** to **9** are all easily accessible on this reaction path.

We have calculated structures for the polymerization of acetylene starting with structures **6**, **7**, and **8**. For the larger ions where a multiple carbon–carbon bond or a fluorine atom is at one end of the molecule and the other terminus is a vinyl cation, there is a through-space interaction between the terminal groups and the ion is cyclic. Addition reactions which produce cyclic ions formally containing π electrons in the ring (ions **11** and **12**) are highly exothermic, a fact which we attribute to the aromaticity of the product.

Addition of acetylene to **8** occurs at the cationic carbon and gives ion **10**. This is formally a vinyl cation but there is considerable through-space interaction with the fluorine atom, as shown by the C...F distance of 1.635 Å, the long B—F bond and the bending at the cationic carbon (Fig. 4). Further addition yields the cyclic ion, **11**, in which the C—F distance of 1.589 Å is approximately 0.2 Å longer than a normal C—F bond. Formally there are six π electrons in the cross-conjugated ring in structure **11** and this ion is 14.4 kcal mol^{-1} lower in energy than the isomeric eight-membered ring, **12**, which formally contains eight π electrons in the ring.

Addition of acetylene to **6** and **7** is highly exothermic and leads to structure **12**, a six-membered ring which formally contains six π electrons. Ion **12** is 6.0 kcal mol^{-1} lower in energy than the isomeric ion, **10**. The aromaticity of **12** is destroyed by addition of a further acetylene molecule and ΔE for formation of **13**, which is an eight-membered ring formally carrying eight π electrons in the ring, is small.

Higher level calculations

Ab initio calculations with small gaussian basis sets favour classical structures like **7** and **8** over bridged structures like **6** and transition states like **9**. These ions are sufficiently small that inclusion of polarisation functions in the basis set used in structure optimisation is feasible. We have used the HF/6-31G* level of theory to reoptimize some of the smaller structures and have then used these structures to test the effect of inclusion of correlation energy on the calculated ΔE for the initial step of the reaction sequence. The results of these calculations are included in Table 3 and Fig. 3.

For the major channel, addition followed by elimination of HF, ΔE is −0.8 kcal mol^{-1} at the HF/6-31G* level and −2.2 kcal mol^{-1} at the MP2/6-31G*//HF/6-31G* level. These are much closer to thermoneutral than ΔE calculated at the HF/3-21G level (−9.9 kcal mol^{-1}). The subsequent addition reaction of acetylene to form the adduct **3** is calculated to have ΔE = −26.9 kcal mol^{-1} at the HF/6-31G* level, i.e. it is slightly less exothermic than at the HF/3-21G level. Formation of $B(C{\equiv}CH)_2^+$ by loss of HF from **3** is calculated to require 12.3 kcal mol^{-1} more energy than is available in the initial reactants. To summarise, then, for the major reaction pathway, increasing the basis set size has the effect of decreasing the relative energies of the products but does not change the overall mechanistic conclusions.

For the initial ions in the minor channel, extension of the basis set and inclusion of correlation energy both result in significant stabilisation of the cyclic ions **6** and **9**. At the HF/6-31G* level the non-classical bridged ion, **6**, has the highest energy but is only 5.6 kcal mol^{-1} above the open ion **7**, and the transition structure **9** is only 5.3 kcal above **7**. Inclusion of correlation energy at the MP2 level (valence electrons only) has the dramatic effect of making the bridged ion **6** the lowest energy isomer, with structures **7**, **8**, and **9** all having similar energies 5 kcal mol^{-1} higher than **6**. The highest level calculations then show that, although BF_2^+ is ineffective as a back-donor, nevertheless $C_2H_2BF_2^+$ is a symmetrically bridged ion. Previous theoretical studies have found that the parent vinyl cation to have the open $H_2C{=}C^+H$ structure at the Hartree–Fock level but to have the symmetrically bridged structure when correlation is included (19, 20). A recent experimental study has shown the vinyl cation to be symmetrically bridged (21).

Discussion and conclusions

We have characterized the intrinsic chemistry of the initial steps in the polymerization of acetylene by BF_2^+ in the gas phase experimentally using the SIFT technique. The measurements provide a quantitative measure of the intrinsic reaction kinetics. The initiation reaction is quite rapid (k = 4.1×10^{-10} cm^3 $molecule^{-1}$ s^{-1}) with the major channel being the formation of C_2HBF^+ ion and the elimination of HF. Some addition product is also formed, most likely in a termolecular reaction at our operating pressures. Polymerization occurs mainly via the C_2HBF^+ ion followed by four additions of acetylene. The rate coefficient exhibits a maximum early in the reaction sequence. Two sequential addition reactions were observed with the addition product, $C_2H_2 \cdot BF_2^+$.

The *ab initio* molecular orbital calculations provide insight into the structures and energetics of several of the intermediates in the polymerization chemistry. The energetics of the first few steps in the polymerization reaction involving the major initial product ion, C_2HBF^+, are of interest. Formation of C_2HBF^+ is fast, but the reaction of this ion to form **3** is somewhat slower and is less exothermic than most of the addition reactions in Fig. 2. Ion **3** is unusual in that, unlike other vinyl cations containing unsaturated linkages, it does not adopt the s-*cis* conformation which permits delocalization of the charge through space onto the triple bond. This may be attributed to the antiaromatic character of such a five-membered ring containing four π electrons. The reaction of **3** to form **4** is the fastest reaction in this channel and the product is a seven-membered

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

ring with six π electrons (excluding the lone pair on fluorine). It therefore appears that the rates and energetics of reactions in the gas-phase polymerization are dictated by the aromaticity of the product ion.

In solution the major reaction pathway might be addition rather than elimination of HF since solvation of BF_2^+ would make it less reactive. Assuming that the solvent does not act to prevent ring formation, then structure **13** and probably **11** are likely to be major intermediates in the solution-phase polymerization. The highest level calculations show the adduct $C_2H_2BF_2^+$ to have the planar bridged structure **6**. Reaction of ion **6** with acetylene produces cyclic ion **12** which has six π electrons in the ring. This reaction has the largest calculated exothermicity in the two reaction schemes in Fig. 2 and the observed rate constant is the largest in Table 1. Further reaction of **12** with acetylene produces an eight-membered ring with eight π electrons. ΔE for this last step is small (-27.4 kcal mol^{-1}) and the experimental rate coefficient (5.7×10^{-11} cm^3 molecule^{-1} s^{-1}) is the smallest in Table 1. Here again the rates of formation and reaction of the aromatic ion **12** correlate with their calculated exothermicities.

The π-bonds of acetylene are stronger than that of ethylene (the ionization energies are 11.4 and 10.5 eV, respectively) (22). In general then, in reactions in which π-donation is dominant (e.g. electrophilic addition and formation of π-complexes with metals) alkenes react faster than alkynes. Previous results have been for solution reactions, but now we find that the gas-phase reaction of BF_2^+ with ethylene has a larger rate coefficient (7.3×10^{-10} cm^3 molecule^{-1} s^{-1}) than that for the reaction of BF_2^+ with acetylene (4.5×10^{-10} cm^3 molecule^{-1} s^{-1}). In both gas-phase reactions the major pathway is elimination of HF to produce the propagating species $C_2H_3BF^+$ in the ethylene reaction and C_2HBF^+ in the acetylene reaction. In the reaction with ethylene, loss of HF is the only reaction channel. In the reaction with acetylene some addition product is observed (5%) but the dominant pathway is loss of HF. The observation of an addition product in the reaction with acetylene and non-observation in the reaction with ethylene may be explained by the difference in the exothermicity of HF elimination. Elimination of HF in the ethylene reaction is more exothermic (5 kcal mol^{-1} at HF/6-31G*) than elimination in the acetylene reaction (1 kcal mol^{-1} at HF/6-31G*). Thus the initial acetylene adduct can persist for a longer time and can be more easily deactivated by collision with helium buffer atoms before HF is eliminated.

With the SIFT experiments in combination with theoretical calculations we have characterized the intrinsic features of the initial steps of the BF_2^+ ion induced polymerization of acetylene in the gas phase. Such a combined approach should have general applications in the elucidation of intrinsic features of cationic polymerization in the gas phase.

The consecutive cyclization–elimination reaction of a radical generated from an epoxide: stereospecific formation of an exocyclic alkene

TIMOTHY B. LOWINGER AND LARRY WEILER[1]

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received March 23, 1990

TIMOTHY B. LOWINGER and LARRY WEILER. Can. J. Chem. **68**, 1636 (1990).

A titanium(III) mediated radical cyclization–elimination reaction is reported, which allows for the efficient generation of functionalized cyclopentane derivatives. The reaction is highly stereospecific, giving excellent control over the geometry of the resulting exocyclic alkene. In addition, functionality at both reacting termini is retained for subsequent transformations.

Key words: stereospecific, radical cyclization–elimination, exocyclic alkene.

TIMOTHY B. LOWINGER et LARRY WEILER. Can. J. Chem. **68**, 1636 (1990).

On rapporte l'observation d'une réaction radicalaire de cyclisation/élimination promuée par le titane(III) qui permet une génération efficace de dérivés cyclopentaniques fonctionnalisés. La réaction est hautement stéréospécifique et elle permet un contrôle efficace sur la géométrie des alcènes exocycliques qui en résultent. De plus, les fonctions présentes aux deux extrémités de la chaîne sont conservées et permettent d'effectuer des transformations subséquentes.

Mots clés : stéréospécifique, cyclisation/élimination radicalaire, alcène exocyclique.

Following the pioneering work of Beckwith and Schliesser on radical cyclizations (1), the application of these reactions in synthesis has been well established, as illustrated in several recent reviews (2–4). In particular, 5-hexenyl radical cyclizations have emerged as a powerful method for the construction of cyclopentane derivatives. The usual synthetic procedure involves the reaction of a radical precursor, typically an alkyl halide, with tri-*n*-butyltin hydride to generate an alkyl radical that then adds to the alkene in a 5-*exo* fashion. However, one significant drawback of this procedure is the concomitant loss of two functional groups — the halide and the alkene. A novel partial solution to this problem, which allows the synthesis of cyclopentane derivatives, has recently been reported by Nugent and RajanBabu (5). They showed that the reaction of an epoxide with a titanium(III) reagent results in the homolytic cleavage of the C—O bond, resulting in the formation of a secondary carbon-centered radical. This radical undergoes cyclization in the usual fashion and, after hydrolytic work-up, a cyclopentane derivative bearing a hydroxymethylene unit is obtained. We would like to report the extension of this methodology to the stereospecific formation of exocyclic alkenes.

Recently, we reported a stereospecific synthesis of exocyclic alkenes by a radical cyclization in which only the alkene unit of the product is functionalized (6). In 1985, Russell and Ngoviwatchai demonstrated that radicals can undergo a stereospecific vinyl substitution by an addition–elimination sequence (7*a*). In a later study, it was shown that the stereospecificity depends on the substituents on the alkene and the attacking radical (7*b*). In these studies, the radical addition–elimination reactions occur with retention of the geometry of the alkene. Curran and van Elberg have reported a radical annulation, also involving an addition–elimination step, which occurs with inversion of geometry about the alkene (8). The stereochemical outcome of the reaction appears to be controlled by the substituents α to the alkene (8).

The ω-alkenyl acetylenic esters **1** and **2** were prepared as illustrated in Scheme 1. These compounds were then converted to the corresponding *E* and *Z* vinyl stannanes **3**–**6** with high stereoselectivity following the procedure of Piers *et al.* (9). Epoxidation of **3**–**6** with *meta*-chloroperbenzoic acid (MCPBA) in dichloromethane afforded the ω-epoxy vinylstannanes **7**–**10** in good yield. The compounds **7**–**10** were then reacted with chlorobis(η^5-cyclopentadienyl)titanium(III) (10). In a typical reaction, 1.2 molar equivalents of chlorobis(η^5-cyclopentadienyl)titanium(III) in THF were added dropwise to a THF solution of the ω-epoxy vinylstannane at room temperature under argon. When thin-layer chromatography indicated an absence of starting material the reaction was quenched. The crude product was extracted and purified by centrifugal chromatography.

The results of the cyclizations of compounds **7** and **8** are summarized in Table 1. These cyclizations were found to be highly stereospecific, and result from an addition–elimination sequence that involves "retention" of the stereochemistry of the double bond. The reactions proceed smoothly at room temperature and are typically complete in 30 min. In contrast, reaction of compounds **9** and **10** under identical conditions did not yield any of the desired cyclic compounds, even after prolonged reaction times. Instead, the only product obtained at room temperature was the corresponding acyclic alcohol resulting from reduction of the intermediate secondary radical. In an effort to promote cyclization, the reaction was performed in refluxing benzene. However, no cyclic products were formed under these conditions. Instead, the product obtained from reaction at higher temperature was the corresponding alkene (**5** or **6**), resulting from deoxygenation.

These later results are not completely unexpected. Beckwith has shown that the rate of 6-heptenyl radical cyclization is considerably slower than that of 5-hexenyl radical cyclization (1). Consequently, the intermediate radical generated from **9** or **10**, being slow to cyclize, preferentially follows a different, competing reaction pathway.

The intramolecular cyclization–elimination reaction of radicals generated from epoxides is a useful method to synthesize cyclopentane derivatives, offering excellent control over the geometry of the exocyclic alkene. In this cyclization functional groups at both termini are retained for subsequent transformations. The use of other radical precursors to form different functionalized exocyclic alkenes, as well as methods to improve cyclization of 6-heptenyl systems via an addition–elimination pathway, is being investigated.

Evidence for stereoregulation in the polymerization of phenylsilane by bis(indenyl)dimethylzirconium complexes

F. GAUVIN AND J. F. HARROD

Chemistry Department, McGill University, 801 Sherbrooke Street West, Montreal, P.Q., Canada H3A 2K6

Received April 11, 1990

F. GAUVIN and J. F. HARROD. Can. J. Chem. **68**, 1638 (1990).

Bis(indenyl)dimethylzirconocene, **1**, and [1,2-bis(indenyl)ethane]dimethylzirconocene, **2**, both catalyze the dehydropolymerization of phenylsilane to a mixture of low molecular weight cyclic oligosilanes $(PhSiH)_n$ (n = 6–9). The limited number of sharp resonances in the ^{29}Si and ^1H NMR spectra of the polymer produced with **2** as catalyst indicates that the catalyst exerts a significant stereoregulating influence on the polymerization.

Key words: polysilanes, catalytic dehydrocoupling, stereoregulation, bis(indenyl)zirconium complexes.

F. GAUVIN et J. F. HARROD. Can. J. Chem. **68**, 1638 (1990).

Le bis(indényl)diméthylzirconocène, **1**, ainsi que le [1,2-bis(indényl)éthane]diméthylzirconocène, **2**, catalysent tous les deux la déshydropolymérisation du phénylsilane pour donner un mélange d'oligosilanes cycliques de bas poids moléculaire $(PhSiH)_n$ (n = 6–9). Le nombre restreint de résonances fines que l'on observe dans les spectres RMN du ^{29}Si et du ^1H du polymère produit sous l'influence du catalyseur **2** indique que ce dernier exerce une grande influence sur la polymérisation et donne naissance à un produit hautement stéréorégulier.

Mots clés : polysilanes, déshydrocouplage catalytique, stéréorégularité, complexes du bis(indényl)zirconium.

Polyorganosilanes have recently attracted a great deal of attention because of their unusual electronic and optical properties (for an excellent review, see ref. 1). These properties are strongly dependent on polymer backbone conformation and, consequently, control of backbone conformation in tactic polyorganosilanes is an important objective. Such control is not likely to be achieved using the Wurtz–Fittig type coupling, which presently is the only synthetic route to high molecular weight polysilanes. In principle, such control could be achieved using syntheses based on coordination catalysis.

In earlier reports we have described the use of a variety of bis(cyclopentadienyl) complexes of titanium and zirconium as catalysts for the polymerization of primary silanes by dehydrocoupling (2–6). Other workers have since made important contributions to our understanding of the mechanisms of such reactions and to extending their scope (7–9).

One of the interesting aspects of primary silane dehydrocoupling is the tactic character of the resulting polymers. With bis(cyclopentadienyl) catalysts there seems to be no stereoregulation in the polymer chain propagation step and the products are essentially atactic. Since chiral bis(indenyl) complexes of titanium and zirconium have been used with considerable success for the stereoregular polymerization of olefins (10), we have also used them for silane polymerization.

Bis(indenyl)dimethyltitanium(IV) proved to be ineffective as a catalyst for the dehydrocoupling of phenylsilane beyond dimer and trimer. On the other hand, the zirconium analogue, **1**, was quite active and, at catalyst concentrations of 1–5 mol%, converted phenylsilane quantitatively to an oligomer in about 24 h. A similar activity was observed for [1,2-bis(indenyl)ethane] dimethylzirconium, **2**. The catalysts were prepared as racemic mixtures by modifications of a literature procedure (11) involving reaction of two equivalents of methyl lithium with the dichloro complexes in diethyl ether. The dichloro precursor to **1** was prepared by the method of Rausch *et al.* (12) and that of **2** by the method of Collins *et al.* (13). Typical polymerization reactions were run at room temperature in toluene with a catalyst concentration of 0.10 M and an initial phenylsilane concentration of 3.2 M.

The ^1H NMR spectra (see Fig. 1) of the polymers, particularly that of the polymer produced with **2** as catalyst, were significantly different from those of similar polymers produced with bis(cyclopentadienyl) complexes. The latter polymers give spectra resembling the lower spectrum in Fig. 1, but without any sign of fine structure. The difference was even more evident in ^{29}Si NMR spectra using a DEPT pulse sequence (see Fig. 2). These spectra show the products to be free of SiH_2 units, i.e., to be entirely free of linear species. Since complete methanolysis of the polymers gives phenyltrimethoxysilane as the sole product, the polymers only contain PhSiH units.

The sharp, relatively well-resolved, resonances for the polymer produced with **2** indicate a dramatic reduction in the number of magnetically distinct stereocenters relative to polymers produced with other catalysts. This could be due to the selective production of a single ring size (e.g., the cyclohexasilane has 9 isomers with a total of 23 different stereocenters). Alternatively, it could be due to stereoselection. Since the mass spectra of the oligomers produced with both **1** and **2** are very similar (see Table 1), and clearly show the presence of Si_n rings (n = 6–9) in both cases, the evidence is strongly in favour of stereoselection. The presence of some fine structure, albeit an extremely complicated one, in the polymer produced with **1** is attributable to the statistical distribution of stereocenters of a mixture of rings. Addition of the further resonances of linear species would result in the relatively featureless massifs typically observed with the bis(cyclopentadienyl) catalysts.

The mechanism whereby stereoselection occurs in these systems is not evident from the present results. Growth of a chain at a single chiral center by repetitive addition of monomer could lead to stereoregulation in a similar manner to Ziegler–Natta type polymerization of olefins. However, since primary silanes are not prochiral, the stereochemistry of the entering silicon atom must be determined entirely by interactions between the chiral metal center and the polymer chain end.

$(PhSiH)_4$	420	12	10	4H
$(PhSiH)_5$	372	40	10	$2C_6H_6$, 2H
$(PhSiH)_4$	343	18	3	C_6H_6, 3H
Ph_3Si	259	100	95	—

[a]The cited masses are the major peaks in a given cluster.
[b]Any peak corresponding to $(PhSiH)_n$ may contain contributions from species of higher n that have lost PhSiH units.

Since the rate of catalytic dehydrocoupling is known to be very sensitive to steric effects (4), an alternative mechanism involving diastereoselection between a chiral catalyst complex and an approaching chiral oligomer could lead to stereoregulation in a stepwise growth mechanism.

Further studies involving bis(tetrahydroindenyl) complexes and enantiomerically pure **2** are presently in progress.

		Ave.	3.29×10^3

[a]In aqueous solution at 25°C, ionic strength 1.0 M (KCl). Hydroxide concentrations determined by titration (trifluoro) or calculated from the pH of buffers (acetate, phosphate, or carbonate) using $pK_w = 14$. k_ψ is the observed pseudo-first-order rate constant.

[b]Initial rate, assuming the same absorbance change as for reaction at 1 M hydroxide with the same initial concentration of ketone.

is very rapid in solution[2] but can be slow if the trihaloacetophenone is simply added to aqueous base because of the insolubility and slow dissolution of the ketone (1).

We now wish to report rate contants for the alkaline cleavage of trifluoro-, trichloro-, and tribromoacetophenone: see Table 1. There is a dramatic effect of the nature of the halogen, which demonstrates quite vividly that electronegativity can be far less important than size-related factors in determining the carbanion stabilizing power of an atom.

For trifluoroacetophenone, 1 N NaOH solution was used to get reasonable reaction rates for the slow cleavage; for the other two it was necessary to use buffer solutions to give reactions slow enough to be followed conveniently. The kinetics are interpreted in terms of the mechanism shown in Scheme 1, for which the pseudo-first-order rate constant, k_ψ, is given by:

$$[1] \quad k_\psi = (k_1K_hK_{a1}K_w[OH^-] + k_2K_{a1}K_{a2}K_h[OH^-]^2)/(K_{a1}K_w + K_hK_w^2 + K_{a1}K_hK_w[OH^-] + K_{a1}K_{a2}K_h[OH^-]^2)$$

Trifluoroacetophenone is fully hydrated in water (4) and is completely converted to its hydrate anion in 1 N NaOH: the pK_a of the ketone hydrate is 10.00 (4). In 0.1 N NaOH the reaction was 0.15 as fast as in 1.0 N NaOH. Since the observed rate constant is approximately proportional to [OH^-], reaction is mainly occurring via the dianion. On the other hand, the rate in 0.1 N NaOH is clearly faster than one tenth the rate in 1.0 N NaOH. It is most likely that what is observed is the beginning of the levelling off corresponding to conversion of trifluoroacetophenone hydrate to its dianion, with $k_2 = 2.1 \times 10^{-5}$ s^{-1}, and $pK_{a2} = 14.2$.[3] Pauling's rules (5) suggest that the second pK_a of trifluoroacetophenone hydrate should be approximately 15, so this is plausible. The monoanion rate would then be an unknown amount slower. A reasonable model would be cleavage of phenyl propargaldehyde (6) for which the leaving group is a localized carbanion of basicity ($pK_a = 20$ (7)) similar to that of CF_3^- ($pK_a = 27$ (8)). For phenylpropargaldehyde, Hine and Koser (6) suggest $k_2/k_1 = 2.0 \times 10^6$ M^{-1}. If a similar ratio

[2]An organic cosolvent is required to increase the solubility of the trihaloketone.

[3]If the term in the numerator and the first two terms in the denominator of eq. [1] are negligible, then k_2 and K_{a2} can be evaluated from the observed rate constants.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

applies to trifluoroacetophenone, k_1 would be 1.33×10^{-11} s^{-1}, and the apparent second-order rate constant at pH 7 would be 1.3×10^{-7} M^{-1} s^{-1}. We note that this is only two orders of magnitude slower than the apparent second-order rate constant at pH 14. Experimental confirmation will be difficult because of the very slow reactions involved.

For the trichloro and tribromo derivatives the observed rates are first order in hydroxide, and the pH used is less than any plausible value for the pK_a of the adduct, so this must be reaction via the monoanion.

There is also a problem of rate-determining step, since it is possible that the trichloro and (or) tribromo compounds react with rate-determining hydroxide addition; if this were the case then the actual rate constants for cleavage would be even larger. This is particularly so for tribromoacetophenone, for which the second-order rate constant is 3.3×10^6 M^{-1} s^{-1}. This value is larger than the rate constant for hydroxide-catalyzed hydration of trifluoroacetophenone, log $k = 5.70$ in 10:1 water/acetonitrile (9). That the rate constant for attack of hydroxide on tribromoacetophenone would be much larger than 10^6 M^{-1} s^{-1} seems highly unlikely. This argument implies that attack of hydroxide is rate limiting, and that the actual cleavage step is much faster. Thus our measures for the effect of halogen on the rate constants for haloform cleavage may be lower limits.

In nmr experiments in partly aqueous solvent[4] (CD_3CN–D_2O) we found that trifluoroacetophenone was completely hydrated, trichloroacetophenone was partly hydrated, and tribromoacetophenone was completely in the carbonyl form.

The breakdown of chloral is much slower than that of trichloroacetophenone, the apparent second-order rate constants at low pH being 2.19 M^{-1} s^{-1} and 7.9×10^3 M^{-1} s^{-1} respectively. This can reasonably be ascribed to the less favorable equilibrium for expulsion to generate formaldehyde vs. acetophenone, by analogy with dehydration of the covalent hydrates for which the equilibrum constants are 0.024 M and 8.3×10^6 M respectively (10).

Our results to date suggest that the relative rates for cleavage of the monoanions are in the ratio $PhCOCF_3$: $PhCOCCl_3$: $PhCOCBr_3$ = 1 : 5.3×10^{10} : 2.2×10^{13}. Although these results appear surprising if one relies on electronegativity arguments to estimate the stability of the trihalomethylcarbanions, they are quite in line with the results of studies of exchange in trihalomethanes. The rate constants for hydroxide-catalyzed reaction at 0°C for CF_3H (8), CCl_3H (11), and CBr_3H (11) are in the ratio 1 : 2.1×10^6 : 2.6×10^8.

[4]The organic cosolvent was needed to get sufficiently concentrated solutions for nmr spectroscopy.

Concertedness and E2 elimination reactions: prediction of transition state position and reaction rates using two-dimensional reaction surfaces based on quadratic and quartic approximations

J. PETER GUTHRIE

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received November 14, 1989

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

J. PETER GUTHRIE. Can. J. Chem. **68**, 1643 (1990).

An analytical expression for the two-dimensional reaction surface appropriate for discussing a concerted reaction has been derived for the quartic approximation to a reaction coordinate, and shown to be consistent with Marcus theory. By analysis of literature data for S_N1 solvolyses and carbanion formation we have been able to reproduce the qualitative behavior of eliminations involving *t*BuBr, *i*PrBr, and EtBr in EtOH/EtO^-, and to predict the rates of these reactions within the uncertainties of the input data.

Key words: concerted reactions, Marcus theory, eliminations, reaction surfaces.

J. PETER GUTHRIE. Can. J. Chem. **68**, 1643 (1990).

On a développé une expression analytique pour la surface réactionnelle bidimensionnelle qui est appropriée pour discuter une réaction concertée et qui peut être utilisée pour l'approximation quartique d'une coordonnée réactionnelle; on a démontré que cette expression est en accord avec la théorie de Marcus. En se basant sur une analyse des données de la littérature pour des solvolyses S_N1 et pour la formation de carbanions, on a été capable de reproduire le comportement qualitatif des éliminations impliquant le *t*BuBr, *i*PrBr et EtBr dans EtOH/EtO^- et de prédire les vitesses de ces réactions à l'intérieur des limites d'incertitude des données utilisées.

Mots clés : réactions concertées, théorie de Marcus, éliminations, surfaces réactionnelles.

Introduction

We have recently reported an equation for the energy surface for the situation where two reaction progress variables are required to describe a reaction (1). The equation, which was a generalization of the inverted parabola model for the reaction coordinate of a simple reaction, was shown to be consistent with Marcus theory (2–4) for the edge reactions. It provides a basis for predicting when a reaction will be concerted and when it will be stepwise in terms of the thermodynamics and intrinsic barriers of the edge reactions. A logical consequence of the simple theory used is that the intrinsic barriers are the same for each pair of parallel edge reactions.

There has been considerable interest in the use of various energy surfaces to analyze concerted reactions (1, 5–18). We wish now to report that, using information from the literature, it is possible to predict which of a set of simple β-elimination reactions are concerted, and to make semiquantitative predictions of the rate constants, with no adjustable parameters.

We (8) and others (19, 20) have discussed the advantages of a quartic equation as an approximation to a reaction coordinate diagram, since it has the correct shape at the extrema. We have now devised an analogous equation with two reaction coordinate dimensions, which provides the simplest generalized surface in the quartic approximation with the correct behavior for the edge reactions, and which satisfies Marcus theory for all sections through it.

Results

The equation which we used (1), eq. [1], is based on a hyperbolic paraboloid, which gives an inverted parabola for each edge reaction:

$$[1] \quad G = \alpha x + \beta x^2 + \gamma y + \delta y^2 + \epsilon xy$$

This equation can be solved analytically to give the conditions for the transition state

$$x^{\ddagger} = (2\alpha\delta - \gamma\epsilon)/(\epsilon^2 - 4\beta\delta)$$

$$[2] \quad y^{\ddagger} = (2\beta\gamma - \alpha\epsilon)/(\epsilon^2 - 4\beta\delta)$$

$$\Delta G^{\ddagger} = (\alpha^2\delta + \beta\gamma^2 - \alpha\gamma\epsilon)/(\epsilon^2 - 4\beta\delta)$$

If the edge reactions are described by a quartic reaction profile, then the analogous energy surface is given by eq. [3], which provides a basis for examining questions of concertedness. In this equation, as in eq. [1], we have chosen to express all free energies relative to the level of the $x = 0$, $y = 0$ corner of the reaction coordinate diagram, in order to avoid having an additional constant term. This corner corresponds to the reactive encounter complex, at an energy higher than the free reagents by the "work term". We estimate the work term following Hine (21) by assuming that the equilibrium constant for encounter complex formation in the absence of special interactions is the probability of the reactive atom of a second molecule being in a sphere of radius 1.5 Å adjacent to the first molecule. This works out to be $0.0085n$ where n is the number of equivalent positions.[1,2] Corrections for desolvation or electrostatic interactions must be made where appropriate.

$$[3] \quad G = a_1x^2 + a_2y^2 + a_3x^3 + a_4y^3 + a_5x^4 + a_6y^4 + a_7x^2y^3 + a_8x^3y^2 + a_9x^3y^3 + a_{10}x^2y^2$$

We will first show that this equation has the minimum number of terms needed to satisfy the constraints placed upon it. We must first interpret the one-dimensional quartic equation in terms of Marcus theory. For the quartic

[1] See Appendix for details.

[2] Copies of the Supplementary Tables may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

$$G = ax^4 + bx^3 + cx^2$$

it may be shown (20) that:

$$c = -2a - 3b/2$$

$$\Delta G^0 = -a - b/2$$

$$x^{\ddagger} = -1 - 3b/4a$$

We observe that when $\Delta G^0 = 0$, $x^{\ddagger} = 0.5$, and $\Delta G^{\ddagger} = a/16$. By definition, the intrinsic barrier is the free energy of activation when the thermodynamic barrier is zero. Thus we can define "a" in terms of the intrinsic barrier, $\tilde{G}$, as

$$a = 16\tilde{G}$$

and it then follows that

$$b = -32\tilde{G} - 2\Delta G^0$$

$$c = 16\tilde{G} + 3\Delta G^0$$

[4] $$\Delta G^{\ddagger} = \tilde{G}(1 + 8y + 18y^2 - 27y^3)$$

where $y = \Delta G^0/16\tilde{G}$. This expression for $\Delta G^{\ddagger}$ is very closely analogous to the corresponding expression for $\Delta G^{\ddagger}$ derived from the quadratic approximation to the reaction profile, namely

[5] $$\Delta G^{\ddagger} = \tilde{G}(1 + 8y + 16y^2)$$

which is equivalent to the more usual form of the Marcus equation,

$$\Delta G^{\ddagger} = \tilde{G}(1 + \Delta G^0/\tilde{G})^2$$

and leads to the commonly employed expression (22) for the intrinsic barrier $\tilde{G}$ in terms of the equilibrium free energy change and the free energy of activation

[6] $$\tilde{G} = \tfrac{1}{2}\{\Delta G^{\ddagger} - \tfrac{1}{2}\Delta G^0 + [(\Delta G^{\ddagger})^2 - \Delta G^{\ddagger}\Delta G^0]^{1/2}\}$$

It is not feasible to derive a corresponding analytical expression for $\tilde{G}$ based on eq. [4], but numerical solution is straightforward.

For the quartic surface, the pairs of edge reactions ($x = 0$ and $x = 1$, $y = 0$ and $y = 1$) must have different equations, thus at least some cross terms are essential. A logical consequence of eq. [1] was that the intrinsic barriers for both of a pair of edge reactions had to be the same. This condition could be relaxed in the quartic approximation, but we will in general have no means to evaluate the intrinsic barriers for some of the edge reactions; to be able to evaluate intrinsic barriers for two reactions is generally difficult enough. Consequently for the moment we continue to impose the constraint that both of a pair of edge reactions must have the same intrinsic barrier. This immediately demands that there be no cross terms involving x^4 or y^4, because the coefficients of these terms are dependent only on the intrinsic barriers; thus any cross terms would imply different intrinsic barriers. Let us rewrite eq. [3] to express the section through the surface at some arbitrary value of x

$$G_x = (a_1x^2 + a_3x^3 + a_5x^4) + (a_2 + a_8x^3 + a_{10}x^2)y^2 + (a_4 + a_7x^2 + a_9x^3)y^3 + a_6y^4$$

The y^2 and y^3 coefficients depend on the intrinsic barrier, which we assume is independent of x, and on the thermodynamic barrier, which will in general be a function of x. Thus at least some of the cross terms must be non-zero.

For this section through the surface, the equilibrium free energy change is

$$\Delta G_x^0 = a_2 + a_4 + (a_{10} + a_7)x^2 + (a_8 + a_9)x^3$$

So long as not all of a_7, a_8, a_9, and a_{10} are zero, then the coefficients of y^2 and y^3 in the expression for G_x, and the coefficients of x^2 and x^3 in the analogous expression for G_y, must include three terms, one independent of the fixed coordinate, one second order, and one third order, or the expressions will not be self-consistent. The parameters can be solved for in terms of the thermodynamic and intrinsic barriers as:

$$a_1 = 16\tilde{G}_x + 3(G_{10} - G_{00})$$

$$a_2 = 16\tilde{G}_y + 3(G_{01} - G_{00})$$

$$a_3 = -32\tilde{G}_x - 2(G_{10} - G_{00})$$

$$a_4 = -32\tilde{G}_y - 2(G_{01} - G_{00})$$

$$a_5 = 16\tilde{G}_x$$

$$a_6 = 16\tilde{G}_y$$

$$a_7 = a_8 = -6(G_{11} - G_{10} - G_{01} + G_{00})$$

$$a_9 = 4(G_{11} - G_{10} - G_{01} + G_{00})$$

$$a_{10} = 9(G_{11} - G_{10} - G_{01} + G_{00})$$

The condition for a transition state that represents a maximum along both coordinates is:

$$\partial G/\partial x = 0 = \partial G/\partial y$$

$$0 = \{2a_5\}(x^{\ddagger})^2 + (3/2)\{a_3 + a_8(y^{\ddagger})^2 + a_9(y^{\ddagger})^3\}x^{\ddagger} + \{a_1 + a_{10}\{y^{\ddagger})^2 + a_7(y^{\ddagger})^3\}$$

$$0 = \{2a_6\}(y^{\ddagger})^2 + (3/2)\{a_4 + a_7(x^{\ddagger})^2 + a_9(x^{\ddagger})^3\}y^{\ddagger} + \{a_1 + a_{10}\{x^{\ddagger})^2 + a_8(x^{\ddagger})^3\}$$

Unfortunately, these equations are intractably difficult to solve analytically, although they could readily be solved numerically. We have found that in many cases the transition state for a concerted reaction is not at a maximum for one of the coordinates; it is more general to find the transition state by calculating contour maps of the reaction surface, and by calculating more detailed maps of the region containing the transition state.

For the quadratic approximation we can use error analysis to deduce the sensitivity of the value assigned to $\tilde{G}$ to errors in ΔG^0, which will be the most uncertain value in the cases of interest here.

$$\partial\tilde{G}/\partial\Delta G^0 = (1/4)(1 + 1/\sqrt{(1 - \Delta G^0/\Delta G^{\ddagger})}$$

$$\sigma_{\tilde{G}} = |\partial\tilde{G}/\partial\Delta G^0|\sigma_{\Delta G^0}$$

For ionization of *t*BuBr, this leads to $\sigma_{\tilde{G}} = 0.8\sigma_{\Delta G^0}$.

Test of the approach

We will consider the examples of ethoxide-induced eliminations of *tert*-butyl bromide, isopropyl bromide, and ethyl bromide in ethanol.

The first example to be considered is the elimination reaction of *tert*-butyl bromide with ethoxide in ethanol. The edge reactions are the ionization of an encounter complex of *tert*-butyl bromide and ethoxide to the ethoxide *tert*-butylium bromide ion triplet, and the reaction of ethoxide ion with *tert*-butyl bromide to give 2-bromo-2-methylpropyl anion hydrogen bonded to ethanol. We must evaluate the free energy change for each edge reaction, and the intrinsic barrier for it.

Thermodynamics of ion triplet formation

For the ionization of *tert*-butyl bromide to the ion pair in ethanol, Abraham gives a value for the equilibrium free energy

change (by a careful estimation procedure) as 20.1 kcal/mol (23).

The free energy change for the dissociation of *tert*-butyl bromide to free ions estimated by Abraham (23) is consistent with recent estimates of tertiary carbocation stability by Kresge and co-workers (24, 25). Kresge (24) estimated that for *tert*-butylium ion the rate constant for nucleophilic attack by water at 25°C was $6 \times 10^9\ s^{-1}$. The rate constant for protonation of isobutylene is known to be $3.7 \times 10^{-4}\ M^{-1}\ s^{-1}$ (26, 27). The reaction of *tert*-butylium ion with water as nucleophile is 29 times faster than loss of a proton (28), so the rate constant for deprotonation is $2.1 \times 10^8\ s^{-1}$. Thus the equilibrium constant for deprotonation of the tertiary carbocation to give the alkene is $K_a = 5.6 \times 10^{11}$ M, or $\Delta G^0 = -16.0$ kcal/mol. Abraham (23) gives −16.5 kcal/mol for the same process, in excellent agreement.

We assume that the free energy of ionization of *t*BuBr is only affected by the presence of an EtO^- next to *t*BuBr by the additional electrostatic interaction of ion triplet formation. A crude estimate of the magnitude of this interaction can be calculated by using an oversimplified model where a cation is symmetrically disposed between two anions, with all three ions in a line. The electrostatic energy for a point charge arrangement:

$$-\frac{r}{} + \frac{r}{} -$$

will be given by $E_{el} \propto 2/r_{-+} - 1/r_{--}$. Now $r_{--} = 2r_{+-}$, so $E_{el} \propto 3/2r_{+-}$, while for a simple ion pair, $E_{el} \propto 1/r_{+-}$. The stabilizing electrostatic interaction for this arrangement will be 1.5 times that for an ion pair of two opposite charges at the same distance. We used an ion pair interaction energy based on an estimated ion pair association constant of −2.9 kcal/mol. This will be the sum of the non-electrostatic contribution, +2.8 kcal/mol, and the electrostatic contribution, which is then −5.7 kcal/mol. For the ion triplet, the electrostatic contribution would be $1.5 \times (-5.7) = -8.6$ kcal/mol, and the non-electrostatic contribution would be $+2.2 + 2.8 = 5.0$ kcal/mol. (There are three possible sites for association of the EtO^-, but only one for Br^-). The expected free energy change on formation of the ion triplet is then −3.6 kcal/mol. The free energy for encounter complex formation from EtO^- and *t*BuBr, allowing for loss of one hydrogen bonded solvent molecule, is estimated below (in the section on Equilibria for C—H ionization) as 8.3 kcal/mol.

For the formation of the ion triplet from an ethoxide – *tert*-butyl bromide encounter pair, we calculate:

$t\text{BuBr} \rightleftharpoons t\text{Bu}^+ + \text{Br}^-$	$\Delta G = 23.0$ (23)
$\text{EtO}^-, t\text{BuBr} \rightleftharpoons \text{EtO}^- + t\text{BuBr}$	$\Delta G = -8.3$
$t\text{Bu}^+ + \text{Br}^- + \text{EtO}^- \rightleftharpoons \text{EtO}^-, t\text{Bu}^+, \text{Br}^-$	$\Delta G = -3.6$
$\text{EtO}^-, t\text{BuBr} \rightleftharpoons \text{EtO}^-, t\text{Bu}^+, \text{Br}^-$	$\Delta G = 11.1$

The free energy changes upon ion triplet formation from the encounter complexes of EtO^- and *i*PrBr or EtBr are calculated analogously, following Abraham (23). The calculations are summarized in Tables 1 and 2.

For all of the alkyl bromides we assign an uncertainty of ±5 kcal/mol in the free energy level of the ion triplet corner.[1]

Intrinsic barrier for S_N1 solvolysis

Abraham gives a value for the free energy of activation as 24.7 kcal/mol (23, 29, 30). From this value and the equilibrium free energy change for ionization we can derive the intrinsic barrier as 12.66 kcal/mol in terms of the quadratic model, or 12.39 in terms of the quartic model.

Initially we assume, for lack of information allowing a different estimate, that the intrinsic barriers for ionization of *i*PrBr and EtBr to the contact ion pairs are the same as for *t*BuBr.

We will now attempt to estimate the intrinsic barrier for the ionization process in *t*BuBr in an encounter complex with EtO^-. A possible way to do this is to assume that there is a linear change in the interaction energy along the reaction coordinate as the C—Br bond cleaves. The initial state then has an interaction energy of +8.3 kcal/mol, while the free energy cost of bringing an EtO^- into contact with the $t\text{Bu}^+\text{Br}^-$ ion pair is 2.2 (for encounter) + (−2.9) (for electrostatics) = −0.7 kcal/mol. Thus the interaction energy at the transition state (which is at $x^* = 0.65$ in the quartic approximation) would be $2.2 + 0.65 \times (-2.9) = 0.31$ kcal/mol. This leads to an activation energy of $24.7 + 0.3 - 8.3 = 16.7$ kcal/mol relative to the encounter complex of EtO^- and *t*BuBr. These values lead to an intrinsic barrier of 10.5 in the quadratic approximation, and 10.38 in the quartic approximation, i.e., somewhat smaller than the value derived from the data for the process without EtO^-.

For the simple solvolysis of *t*BuBr, the free energy of ionization is reasonably well defined, as shown by the agreement of estimated (23) and quasi-experimental values (24, 25), and the rate is known (23, 29, 30) so the intrinsic barrier should also be reasonably well defined, and the uncertainty should be $0.8\sigma_{\Delta G^0}$. The free energy changes for the special ionization process of interest here, which take place in the presence of a perturbing EtO^-, are clearly less well defined. We have assigned an uncertainty of ±5 kcal/mol to the free energies of ionization, and clearly the uncertainty in the intrinsic barrier is at least 0.8 times this, as indicated by simple error analysis, leading to an uncertainty of ±4 kcal/mol.

Equilibria for C—H ionization

For the proton transfer reaction we must first estimate the equilibrium free energy change. One possible set of starting points are the acidities of methane and isobutane reported by Breslow and co-workers, based on electrochemical measurements (31). The value which they calculated for methane, by a reasonable extrapolation procedure, was $pK_a = 60.3$–62, which we will take as 61. This value refers to THF as solvent, with some added HMPA, and 0.2 M $LiClO_4$. Very similar electrode potentials were reported by Griller and co-workers (32, 33), who used acetonitrile with 0.1 M tetrabutylammonium perchlorate as the solvent. These solvents are both of enhanced polarity because of the supporting electrolyte. Since the potentials are very similar for both systems we will assume the same potentials, and hence the same relative pK_a values in DMSO. It has been suggested (33) that $\Delta G_{tr}(R^-)$ for benzylic carbanions is small for transfer from acetonitrile to DMSO. Absolute pK_a values are available for triphenylmethane and diphenylmethane in DMSO as 30.6 and 32.2 respectively (34). Following Breslow's procedure, but using the absolute pK_a for triphenylmethane in DMSO as an anchor, we obtain a pK_a of 43.9 for toluene in DMSO. Then by extrapolating a plot of pK_a vs. BDE ($r = 0.9987$) we estimate $pK_a = 60.5$ for methane. Table S2 summarizes our calculations.[2]

For isobutane in acetonitrile containing 0.1 M tetrabutylammonium perchlorate, Breslow and Grant have reported a pK_a of 71 (35). This was based on Streitwieser's pK_a for triphenylmethane, which referred to cesium ion pair equilibria in cyclohexylamine solution (36). If we assume as before that the

[g]Calculated as described in ref. 23. Raoult's law coefficient for methanol as solvent is $\gamma^\infty = (P/P_0N)_{N\to 0} = 13$; $P_0 = 135.3$ Torr (70); ΔG_t^x (g→MeOH) = 0.50; ΔG_t^x (MeOH→water) = 4.55 (71); ΔG_t^x (g→water) = 5.05; ΔG_t^c (g→water) = 2.67; from the data in ref. 71, ΔG_t^x (w→EtOH) = −4.94, and ΔG_t^c (water→EtOH) = −4.24; hence ΔG_t^c (g→EtOH) = −1.63 kcal/mol.

electrode potential would be the same in DMSO, and use the absolute pK_a of triphenylmethane in DMSO as anchor value, we obtain a pK_a value of 69.1. These calculations are also summarized in Table S2.

Given values for methane and a tertiary alkane, we estimate a pK_a for a primary alkane by linear interpolation, assuming the effect of each methyl on the pK_a is the same. We further assume that all simple primary alkanes will be the same and take the pK_a of a primary hydrogen in isobutane as 60.5 + (69.1 − 60.5)/3 = 63.4 in DMSO.

The problem with these values is that the solvent is ill defined, and the extrapolation procedure employed to get a pK_a for methane uses triphenylmethane, which is clearly a delocalized anion, and toluene, which will be semilocalized, to extrapolate to methane where the anion is fully localized. The ion pairing is unlikely to be equivalent over this series.

An alternative starting point is the set of kinetic acidities determined by Streitwieser. These values refer to cesium ion pairs in cyclohexylamine as solvent. The anchor is the equilibrium ion pair acidity for benzene determined as 43.0 (37). Cyclohexane was shown to exchange at a rate 1.1×10^{-8} times that of benzene, and isotope effects showed that internal return is not important (38). Finally, the exchange rate for methane was shown to be 2.2×10^3 times as large as that for

cyclohexane, which in turn means that methane is 2.4×10^{-5} times as reactive as benzene (39). If it is assumed that the Brønsted slope is unity, then the pK_a for methane is 48. Streitwieser has argued that for localized carbanions the cesium ion pair pK values in cyclohexylamine should be very close to pK_a values in methanol, and has shown that for a series of compounds giving localized carbanions the Brønsted slope is approximately unity (40). Streitwieser states that ethane and other compounds with only primary hydrogens are 10^2–10^3 times less reactive than methane (39); this would lead to a pK_a for a primary hydrogen of about 50 in methanol.

A third starting point is the value estimated by Bordwell and Algrim (41) by extrapolation based on measured pK_a values of hydrocarbons in DMSO. The estimate so obtained was pK_a = 56 for methane in DMSO. Following the procedure used above, we estimate that the pK_a for a primary hydrogen of isobutane on this scale would be 59 in DMSO.

A fourth starting point is the theoretical pK_a for ethane in aqueous solution reported by Jorgensen and Briggs (42). This value is based on *ab initio* molecular orbital calculations for gas phase energies and intermolecular potentials, and Monte Carlo calculations for solvation energies. The value so obtained is pK_a = 52 ± 2.

The effect of the neighboring bromine on the pK_a of the primary CH will be estimated by assuming that polar effects have the same magnitude as for the analogous alcohols, i.e., the linear free energy relation for X-CH_2-OH will be used for X-C-CH_2-H. ρ^* for alcohols is −1.32 (43). σ^* for Br^- is 2.84 (44). Thus ΔpK_a for introducing a bromine is 3.75. The pK_a predicted for *tert*-butyl bromide is therefore 63.4 − 3.75 = 59.6 in DMSO on Breslow's scale, 59 − 3.75 = 55 in DMSO on Bordwell's scale, 50 − 3.75 = 46 in methanol on Streitwieser's scale, and 52 − 3.75 = 48 in water on Jorgensen's scale.

For an acid with a simple localized anion the major effect on the pK_a upon transfer from water to DMSO is expected to be the loss of hydrogen bonding solvation (45). The effect of this hydrogen bonding can be estimated from the pK_a differences observed for simple oxygen acids from water to DMSO; using the data in Table 3, we plot $\Delta pK_a/n_{hb}$ vs. pK_a^{DMSO} and obtain $\Delta pK_a/n_{hb} = -0.222 \pm 0.100 + (0.161 \pm 0.005)pK_a^{DMSO}$, which predicts a hydrogen bond effect of 9.4 pK units for an acid with $pK_a^{DMSO} = 59.6$. This leads to a predicted pK_a for *tert*-butyl bromide, on the Breslow scale, of 50.2 in water. From water to ethanol the pK_a difference for simple oxygen acids, where dispersion effects are likely to be small, is 5.7; see Table S3.[2] This leads to a pK_a for *tert*-butyl bromide of 55.7 in ethanol. Similarly we estimated pK_a values for *tert*-butyl bromide, on the Bordwell scale, of 45 in water and 51 in ethanol. Based on measurements in aqueous solution, Stahl and Jencks (46) found $\alpha = 0.15$ and $\beta = 0.10$ for hydrogen bond formation between phenoxide ions and ammonium ions; these values are in approximate agreement with the slope suggested here for the effect of pK_a on hydrogen bond strength.

The net result of our estimations is an increase in acidity of 4 pK_a units for *t*BuBr on transfer from DMSO to ethanol. Highly delocalized carbanions are more basic in methanol or ethanol than in DMSO (47). This is attributed to the effects of dispersion interactions. In the present case the dominating effect is that of hydrogen bond formation, which should be very strong for the highly localized and strongly basic carbanions.

The change in pK_a from water to methanol for a series of OH acids was 4.9 ± 0.2 (48). The change in pK_a from water to ethanol is 5.7 ± 0.5 based on the data in Table S3. The change in pK_a from methanol to ethanol for a series of acids is then +0.82; thus the pK_a for *tert*-butyl bromide in ethanol, on Streitwieser's scale, is 47. The pK_a for *tert*-butyl bromide in ethanol, on Jorgensen's scale, is 48 + 5.7 = 54.

Our four estimates of the pK_a for *tert*-butyl bromide in ethanol are: 56, 54, 51, and 47. We will work principally with the value based on Streitwieser's scale, which is based most directly on measurements on the compounds of interest, but will use the other values to test the sensitivity of our conclusions to the assumptions made.

The ion product of ethanol in ethanol as solvent is 19.1 (49). Thus for the proton transfer reaction:

$$t\text{BuBr} + \text{EtO}^- \rightleftharpoons \text{Me}_2\text{BrC—CH}_2^-\text{,HOEt}$$

log K = −37 and ΔG = 51 kcal/mol (Breslow scale), or log K = −33 and ΔG^0 = 45 kcal/mol (Bordwell scale), or log K = −28 and ΔG = 38.2 kcal/mol (Streitwieser scale), or log K = −35 and ΔG = 48 kcal/mol (Jorgensen scale). Since we take the hydrogen bonding effect on pK_a for ROH as 4.5 pK_a units per hydrogen bond, the cost of desolvating an EtO^- is log K = −4.5, ΔG = 6.1 kcal/mol. The equilibrium constant for bringing a desolvated EtO^- up to one of the antiperiplanar hydrogens of *t*BuBr will then be $3 \times 0.0085 = 0.026\ M^{-1}$, for ΔG = 2.2 kcal/mol. Then the total ΔG for encounter complex formation will be 6.1 + 2.2 = 8.3 kcal/mol. Then:

$$t\text{BuBr} + \text{EtO}^- \rightleftharpoons t\text{BuBr,EtO}^- \qquad \Delta G = 8.3$$

$$t\text{BuBr,EtO}^- \rightleftharpoons \text{Me}_2\text{BrC—CH}_2^-\text{,HOEt} \qquad \Delta G = 30 \text{ (or 43 or 42 or 40)}$$

For lack of any information allowing us to estimate the effect of the methyl groups on the neighboring carbon, we will assume that the acidity of the methyl C—H bonds of isopropyl bromide and ethyl bromide are the same as for *tert*-butyl bromide.

Although the various estimates for the pK_a of *tert*-butyl bromide vary by 9 pK_a units, and we have chosen the more acidic of the four, we feel that the Streitwieser scale is the most directly tied to experiments on the class of compounds of interest. As we will argue in the discussion, it is also consistent with patterns of substituent effects on pK_a. We assign an uncertainty of ±5 kcal/mol to the free energy level of the solvated carbanion.[1]

Intrinsic barrier for proton transfer

A possible starting point for estimating the intrinsic barrier for C—H ionization is the investigation by Bednar and Jencks (50) of proton transfer rates for HCN, which is a carbon acid and seems to give a hydrogen bonded species with HCN hydrogen bonded to the base that is to abstract the proton. They give the rate for no thermodynamic barrier as log $k = 9.1$, using a three-step model for the proton transfer reaction, with diffusional encounter and separation (51). This leads to an intrinsic barrier, $\tilde{G} = 5.0$. However HCN is not an ideal model because there may be a considerable change in solvation at N upon ionization. One would expect hydrogen bonding to N of cyanide to be far superior to hydrogen bonding to N of HCN because of

$$^-{:}C{\equiv}N \leftrightarrow {:}C{=}N{::}^-$$

This means that the observed intrinsic barrier for proton transfer to HCN may be an upper limit on the desired barrier for proton abstraction to give a simple alkyl carbanion. From studies with $CHCl_3$, admittedly for conditions well away from $\Delta pK = 0$, Kresge and Lin (52) concluded that these were "normal" acids, with any deviations from "normal" behavior being due to the cost of desolvating strong bases before proton abstraction could take place. This implies a *small* intrinsic barrier.

As we have argued above, the value of 5 kcal/mol for the intrinsic barrier derived from studies of HCN may be an upper bound. Following Kresge (53) we use 1 kcal/mol, the value appropriate to a diffusion controlled proton transfer involving O or N, as the lower bound, and assign an uncertainty of ±4 kcal/mol to this intrinsic barrier. We will use both 5 and 1 kcal/mol in our calculations.

Free energy change for the overall reaction

The overall free energy change for the elimination will be calculated from the standard free energies of reactants and products in ethanol solution. The quantities needed are found in Table 4. From these values we calculate that for

$$t\text{BuBr} \rightleftharpoons Me_2C{=}CH_2 + H^+ + Br^- \qquad \Delta G = 2.86$$

for

$$i\text{PrBr} \rightarrow MeCH{=}CH_2 + H^+ + Br^- \qquad \Delta G = 6.13$$

and for

$$\text{EtBr} \rightarrow CH_2{=}CH_2 + H^+ + Br^- \qquad \Delta G = 7.72$$

From the free energy change for the neutral species and the ion product of ethanol we calculate

$$EtO^- + t\text{BuBr} \rightleftharpoons Me_2C{=}CH_2 + Br^- \qquad \Delta G = -23.2$$
$$EtO^- + i\text{PrBr} \rightleftharpoons CH_3CH{=}CH_2 + Br^- \qquad \Delta G = -20.0$$
$$EtO^- + \text{EtBr} \rightleftharpoons CH_2{=}CH_2 + Br^- \qquad \Delta G = -18.4$$

and allowing for desolvation and product complex formation as described above,

$$EtO^-,t\text{BuBr} \rightleftharpoons Me_2C{=}CH_2,Br^- \qquad \Delta G = -29.3$$
$$EtO^-,i\text{PrBr} \rightleftharpoons CH_3CH{=}CH_2,Br^- \qquad \Delta G = -26.1$$
$$EtO^-,\text{EtBr} \rightleftharpoons CH_2{=}CH_2,Br^- \qquad \Delta G = -24.5$$

Observed rate constants

The rate of the E2 elimination of *t*BuBr with ethoxide in ethanol at 25°C is 3×10^{-5} M^{-1} s^{-1} (54, 55); $\Delta G^{\ddagger} = 23.63$ kcal/mol; the analogous activation energy calculated starting from the EtO^-,*t*BuBr complex is 17.5 kcal/mol. The rate of the E2 elimination of *i*PrBr with ethoxide in ethanol at 25°C is 2.4×10^{-6} M^{-1} s^{-1} (54); $\Delta G^{\ddagger} = 25.13$ kcal/mol starting from separate reagents, and 19.0 starting with the encounter complex. The rate of the E2 elimination of EtBr with ethoxide in ethanol at 25°C is 2.5×10^{-7} M^{-1} s^{-1} (54); $\Delta G^{\ddagger} = 26.46$ kcal/mol starting from separate reagents, and 20.3 kcal/mol starting with the encounter complex.

Calculated rate constants

The energies for the three-dimensional diagram for ethoxide-catalyzed reactions are now as shown in Fig. 1. Calculations using eq. [2], with $\tilde{G} = 5$ kcal/mol, lead to predicted transition state parameters as follows:

*t*BuBr/OEt^-	$x^* = 0.63 \pm 0.25$,	$y^* = 0.00$,	$\Delta G^* = 16.7 \pm 4.9$	edge
*i*PrBr/OEt^-	$x^* = 0.40 \pm 0.14$,	$y^* = 0.42 \pm 0.19$,	$\Delta G^* = 24.3 \pm 5.7$	
EtBr/EtO^-	$x^* = 0.25 \pm 0.12$,	$y^* = 0.65 \pm 0.19$,	$\Delta G^* = 26.8 \pm 5.3$	

For *t*BuBr and *i*PrBr the calculated free energies of activation are within their uncertainty limits of the experimental values.

If we examine the effect of assuming an intrinsic barrier of 1 for the C—H bond breaking, then we obtain:

*t*BuBr/OEt^-	$x^{\ddagger} = 0.46 \pm 0.17$,	$y^{\ddagger} = 0.20 \pm 0.23$,	$\Delta G^{\ddagger} = 15.7 \pm 5.1$
*i*PrBr/OEt^-	$x^{\ddagger} = 0.37 \pm 0.06$,	$y^{\ddagger} = 0.46 \pm 0.11$,	$\Delta G^{\ddagger} = 20.4 \pm 5.7$
EtBr/EtO^-	$x^{\ddagger} = 0.31 \pm 0.06$,	$y^{\ddagger} = 0.60 \pm 0.11$,	$\Delta G^{\ddagger} = 23.0 \pm 5.5$

With this assumed intrinsic barrier for proton abstraction, all three reactions have calculated free energies of activation within their uncertainty limits of the experimental values.

Similarly, using the quartic model, we find, for $\tilde{G}_{C-H} = 5$:

*t*BuBr/OEt^-	$x^{\ddagger} = 0.60$,	$y^{\ddagger} = 0.00$,	$\Delta G^{\ddagger} = 16.8 \pm 4.9$
*i*PrBr/OEt^-	$x^{\ddagger} = 0.44$,	$y^{\ddagger} = 0.44$,	$\Delta G^{\ddagger} = 24.4 \pm 5.7$
EtBr/EtO^-	$x^{\ddagger} = 0.35$,	$y^{\ddagger} = 0.58$,	$\Delta G^{\ddagger} = 27.0 \pm 5.5$

	$y^{\ddagger}$	0.47	0.55		0.40	0.48	0.52

[a]In ethanol at 25°C; all energies in kcal/mol.

and for $\tilde{G}_{C-H} = 1$:

*t*BuBr/OEt$^-$	$x^{\ddagger} = 0.48$,	$y^{\ddagger} = 0.29$,	$\Delta G^{\ddagger} = 15.7 \pm 5.2$
*i*PrBr/OEt$^-$	$x^{\ddagger} = 0.42$,	$y^{\ddagger} = 0.46$,	$\Delta G^{\ddagger} = 20.4 \pm 5.7$
EtBr/EtO$^-$	$x^{\ddagger} = 0.37$,	$y^{\ddagger} = 0.56$,	$\Delta G^{\ddagger} = 23.2 \pm 5.6$

These values are very similar to those obtained with the quadratic model. We consider this reassuring because the quadratic model has been extensively used. The present results show that the quartic model, which seems intuitively to be a better approximation to what we believe to be the true shape of the reaction profile, gives results very similar to the quadratic model. The quartic model is less easily worked with but should have advantages in that it can model more complex behavior. We plan to continue the investigation of both models.

Although we consider it very important that we have been able to calculate, at least approximately, the free energies of activation of these concerted reactions using only input parameters for the edge reactions, it is of interest to ask what values for the intrinsic barriers would give exact matches to each of the experimental values. It is also of interest to explore the effect of using the highest of the pK_a values for alkyl bromides, which we deduced above from literature data. We have carried out a series of such calculations, leading to the results in Table 5.

These numerical explorations show that: (1) for the highest pK_a values for the alkyl bromides that could be derived from literature results, it is possible to fit the data, but only if the intrinsic barrier for proton abstraction is very low, and then only with quite low intrinsic barriers for C—Br bond breaking in EtBr. (2) For the lower pK_a values for the alkyl bromides, which we prefer, the best fit is obtained if the intrinsic barrier for C—Br bond cleavage is significantly lower for EtBr than for *t*BuBr.

Discussion

The key result of the present investigation is that a simple model for concertedness, based on analytical expressions for the energy surface, gives qualitative predictions in accord with our expectations for these simple model reactions and semiquantitative predictions of the rates of the concerted reactions, even when these are quite significantly faster than the rates of the simple edge reactions used as inputs. We have also shown that the quartic approximation to the reaction profile can be extended to two reaction coordinate dimensions, and that it can be simply interpreted in terms of Marcus theory.

There has been criticism directed at the use of Marcus theory for electrophile–nucleophile combination reactions (56), but there is a strong empirical basis for using the equation because so many reactions are described by it (21, 57, 58).

A source of concern might be that we have used the lowest of the possible pK_a estimates for CH ionization of the simple alkyl bromides in order to carry out our calculations. The higher values that have been proposed give the same qualitative results,

of transition states changing from essentially S_N1-like for *t*BuBr to highly concerted and rather carbanion-like for EtBr. They do not give calculated $\Delta G^{\neq}$ values matching the experimental values unless very low intrinsic barriers for both processes are postulated. As a justification for the relatively high acidity for methane that we recommend, we point out that there is a consistent pattern to the effects of replacing H by phenyl in RXH_n, as shown by the data in Table 6. There seems to be no basis for concluding that the pK_a of methane proposed by Streitwieser is out of line relative to toluene, which has a generally accepted pK_a of about 41.

The intrinsic barriers for ionization of *i*PrBr and EtBr are not experimentally accessible because the solvolyses of these molecules are S_N2 processes (23, 59). There is a basis for expecting $\tilde{G}$ to be less for the less substituted alkyl bromides. Mitchell *et al.* (60) have reported that $\tilde{G}$ is proportional to the deformation energy for CH_3—X. They were considering S_N2 reactions but it appears likely that similar effects would apply to S_N1 reactions. A crude calculation supports the conclusion that the deformation energy would be less for EtBr than for *t*BuBr, so that $\tilde{G}$ would be smaller as well. It is not possible to estimate how much less the intrinsic barrier should be.

Bordwell (61) challenged the generality of the concerted E2 mechanism for β-eliminations, and proposed that a large fraction of such eliminations proceed by a stepwise path. Saunders (62) reviewed the evidence that there are indeed concerted E2 reactions for suitable reactants. In the present investigation, our calculations led to the conclusion that the elimination reaction of *t*BuBr has a transition state essentially the same as that for solvolysis, although there is no barrier at any stage after the transition state to the proton transfer component of the elimination. For *i*PrBr and EtBr, which would lead to less desirable carbocations, the reactions are predicted to be concerted with significant progress along both coordinates at the transition states.

Clearly the method described in this paper gives only very crude predictions of rates, but it does allow a qualitative prediction of when a reaction will be concerted, and semi-quantitative predictions of rate constants.

The major limitations on the use, or even the thorough testing, of the model is the lack of information about the intrinsic barriers of simple "edge" reactions. We hope that reaction surfaces may prove to be a general way of interpolating

For personal use only.

from simple edge reactions to the wide range of concerted reactions possible for modest changes in structure or conditions.

One major virtue of the equations we have used for surfaces of reaction energy diagrams is that once the input data (corner energies and intrinsic barriers) are specified, the energy surface is unambiguously specified, so that cleaner and more explicit statement and testing of mechanistic hypotheses becomes possible.

Appendix

Details concerning various calculations

Free energy for encounter complex formation

Hine (21) defined the encounter complex as having the nucleus of the basic atom within either of two spherical regions with the van der Waals radius of oxygen (1.5 Å) on either side of a planar carbon acid. We have generalized this to apply to n spherical regions in contact with the carbon acid. Following Hine, we assume that the basic atom is equally likely to be anywhere in solution, and so calculate the equilibrium constant for encounter formation as the ratio of the volume of the region(s) defining the encounter complex for one molar reagent to the total volume of solution (1 L). This calculation gives $K = 0.0085$ for $n = 1$.

Uncertainty in the free energy of ion triplet formation

Abraham (23) suggests an uncertainty of 3–4 kcal/mol for free energies of ionization estimated by his method. We will use the larger value as a conservative estimate of absolute uncertainty. For the desolvation and encounter we estimate an uncertainty of ±2 kcal/mol; although we believe that the estimation procedure that we used for this process is plausible, to assume anything better than 20% errors in free energy seems rash. The free energy of formation of the ion triplet from the three ions is the small difference between two larger contributions; a prudent estimate of uncertainty begins with 20% uncertainties in both the electrostatic and non-electrostatic contributions. Standard error propagation calculations (63) lead to an overall uncertainty in the free energy of ion triplet formation of 2 kcal/mol. These values for the three contributory processes lead to an uncertainty of ±5 kcal/mol for ionization of an encounter complex of ethoxide and *tert*-butyl bromide to the ion triplet.

$t\text{BuBr} \rightleftharpoons t\text{Bu}^+ + \text{Br}^-$	$\Delta G = 23.0 \pm 4$ (23)
$\text{EtO}^-, t\text{BuBr} \rightleftharpoons \text{EtO}^- + t\text{BuBr}$	$\Delta G = -8.3 \pm 2$
$t\text{Bu}^+ + \text{Br}^- + \text{EtO}^- \rightleftharpoons \text{EtO}^-, t\text{Bu}^+, \text{Br}^-$	$\Delta G = -3.6 \pm 2$
$\text{EtO}^-, t\text{BuBr} \rightleftharpoons \text{EtO}^-, \text{Br}^-$	$\Delta G = 11.1 \pm 5$

Uncertainty in the free energy level of the solvated carbanion

For reasons given in the text, we believe that the estimate based on Streitwieser's approach (37–40) is the most likely to be correct, and have used this value. Prudence dictates that our error estimates should include all current plausible estimates within the 95% confidence bounds. Assigning an estimated standard deviation of ±5 kcal/mol achieves this, since the highest pK_a is then within two standard deviations of our preferred value.

Received December 8, 1989

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

Y. CHIANG, A. J. KRESGE, R. A. MORE O'FERRALL, B. A. MURRAY, N. P. SCHEPP, and J. WIRZ. Can. J. Chem. **68**, 1653 (1990).

Rates of ketonization of the enol of acetophenone, generated by flash photolytic photohydration of phenylacetylene, were measured in aqueous sulfuric and perchloric acid solutions over the concentration range 1–50 wt.% acid; rates of enolization of acetophenone, monitored by bromine scavenging, were also measured in aqueous perchloric acid solutions over the same concentration range. The results suggest that the curvature observed in a previous *X* acidity function correlation of the rate of enolization in sulfuric acid solutions was an artifact produced by insufficiently efficient scavenging, and that introduction of the activity of water in the correlating expression, used previously to eliminate the curvature and believed to reflect covalent involvement of water in the enolization reaction, is unnecessary. The present results also show that the keto–enol equilibrium constant for acetophenone decreases with increasing acidity in these concentrated sulfuric and perchloric acid solutions.

Key words: acetophenone, enolization, ketonization, keto–enol equilibrium, concentrated acid solutions.

Y. CHIANG, A. J. KRESGE, R. A. MORE O'FERRALL, B. A. MURRAY, N. P. SCHEPP et J. WIRZ. Can. J. Chem. **68**, 1653 (1990).

Opérant dans des solutions aqueuses d'acides perchlorique et sulfurique, à des concentrations allant de 1 à 50%, on a mesuré les vitesses de cétonisation de l'énol de l'acétophénone produit par unc photohydratation (par photolyse éclair) du phénylacétylène; opérant dans des solutions aqueuses d'acide phosphorique aux mêmes concentrations, on a aussi mesuré les vitesses d'énolisation de l'acétophénone, telles que détectées par un piégeage avec du brome. Les résultats obtenus suggèrent que la courbe observée antérieurement dans la corrélation entre la fonction d'acidité *X* et la vitesse d'énolisation des solutions d'acide sulfurique (a) était le produit d'un artefact résultant d'un piégeage qui n'était pas suffisamment efficace et (b) que, contrairement à ce qui a été suggéré antérieurement, il n'est pas nécessaire d'introduire l'activité de l'eau dans l'expresssion de la corrélation pour éliminer la courbe qui avait été considérée comme un reflet d'une implication covalente de l'eau dans la réaction d'énolisation. Les résultats actuels démontrent aussi que, dans ces solutions concentrées d'acides sulfurique et perchlorique, la constante d'équilibre céto–énol de l'acétophénone diminue avec une augmentation de l'acidité.

Mots clés : acétophénone, énolisation, cétonisation, équilibre céto–énol, solutions concentrées d'acides.

[Traduit par la revue]

Introduction

The enolization of acetophenone is one of the reactions used by Hammett in his pioneering investigation of reaction rates in concentrated acid solutions (1), and that work stimulated much other study of strong acids that eventually led to our present-day good understanding of phenomena in these media. A more recent examination of the enolization of acetophenone in concentrated sulfuric acid solutions (2) found that the rate data gave a curved rather than linear correlation with the *X* acidity function (3), but that linearity could be achieved by including the activity of water in the correlating relationship, consistent with the expected mechanistic role of water in the enolization process.

Curvature of the kind observed in this more recent study might also be induced by a change in rate-determining step from enolization, eq. [1], to reaction of enol with the bromine

[1] 
scavenger used to monitor the process, eq. [2]. This scavenging reaction is not catalyzed by acids, whereas reketonization of the enol is (4). As the acidity of the medium is increased, reketonization will therefore speed up while bromination will not, and the two processes might then begin to occur at comparable rates. This would produce a progressive lowering of observed rate constants and lead to a curved acidity function correlation.

[2] 
To determine whether or not this was so, we have measured rates of ketonization of acetophenone enol in concentrated acid solutions, using enol generated by flash photolytic hydration of phenylacetylene (5), eq. [3]. Comparison of these rates with rates of enol bromination calculated using the recently determined specific rate of this reaction (6) suggests that such a

change in rate-determining step did indeed take place. Our results, in combination with the enolization data, also provide keto–enol equilibrium constants that show a marked reduction in the enol content of acetophenone with increasing medium acidity.

Experimental

Materials

Phenylacetylene and acetophenone were purified by distillation. All other materials were best available commerical grades and were used as received. Acid solutions were prepared with distilled water and concentrations were determined by titration of weighed amounts.

Kinetics

Ketonization

Two different flash photolysis systems were used: (1) a conventional apparatus with excitation flash produced by capacitor discharge through a pair of xenon flash lamps, 50 μs pulse width, and (2) a laser system using a KrF excimer laser, λ_{excit} = 248 nm, 25 ns pulse width, 200 mJ/pulse. The enol transient was monitored at λ = 270 nm; its decay adhered well to the first-order rate law, and rate constants were calculated by least-squares fitting to a single-exponential function.

Enolization

Rates of enolization were measured by bromine scavenging under zero-order conditions using a ca. 100-fold excess of acetophenone over bromine. Initial bromine concentrations were ca. 1×10^{-4} M. The solutions also contained 0.2 M Br^-, which complexed 77% of the Br_2 as Br_3^-. Reactions were monitored at λ = 320 nm using the operational extinction coefficient ε = 3600 M^{-1} cm^{-1} determined here. Traces of absorbance vs. time were linear over most of their course, and zero-order rate constants were calculated from the slopes of these linear portions.

Results and discussion

Ketonization

Rates of ketonization of acetophenone enol were measured in aqueous solutions of perchloric and sulfuric acid over the concentration range 1–50 wt.% acid. The results are summarized in Table 1.

Figure 1 shows that the data give linear correlations with the X acidity function; least-squares analysis gives $\log(k/C_{H^+}) = (3.08 \pm 0.02) + (0.668 \pm 0.014)X$ for perchloric acid solutions and $\log(k/C_{H^+}) = (3.20 \pm 0.01) + (0.833 \pm 0.008)X$ for sulfuric acid solutions. The intercept of the perchloric acid correlation corresponds to $k_{H^+} = (1.20 \pm 0.05) \times 10^3$ M^{-1} s^{-1}, which agrees well with the catalytic coefficient $k_{H^+} = (1.25 \pm 0.02) \times 10^3$ M^{-1} s^{-1} determined previously in dilute hydrochloric acid solutions (4*a*).

The intercept of the sulfuric acid correlation gives a somewhat greater rate constant, $k = (1.58 \pm 0.03) \times 10^3$ M^{-1} s^{-1}, but this reflects catalysis by bisulfate ion in addition to hydronium ion. A bisulfate ion catalytic coefficient may be estimated on the assumption that the X correlation obtained in perchloric acid solution, where hydronium ion is the only catalytic species, can be used to calculate hydronium ion contributions to observed rates in sulfuric acid solutions. Excess rate constants, k_{xs}, equal to the difference between observed rate constants and these hydronium ion contributions, are a reasonably good linear function of bisulfate ion concentrations for the six least concentrated sulfuric acid solutions used here (Fig. 2). Least-squares analysis gives the relationship $k_{xs} = (5.26 \pm 5.67) \times 10^1 + (5.42 \pm 1.18) \times 10^2[HSO_4^-]$. The intercept of this relationship is zero within its experimental uncertainty, as expected since bisulfate ion is the only catalytically active species present in these solutions in addition to hydronium ion, and the slope gives a bisulfate-ion catalytic coefficient, $k_{HSO_4^-} = 540$ M^{-1} s^{-1}, whose value is reasonable in relation to the hydronium ion catalytic coefficient, $k_{H^+} = 1250$ M^{-1} s^{-1}.

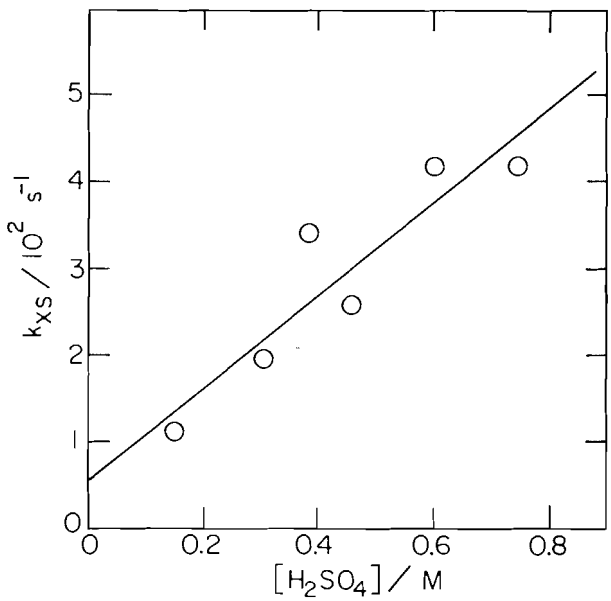

FIG. 2. Relationship between excess rate constants, k_{xs} (= $k_{obs} - k_{H^+}[H^+]$) for the ketonization of acetophenone enol and bisulfate ion concentration in moderately concentrated sulfuric acid solutions.

In the more concentrated sulfuric acid solutions, on the other hand, k_{xs} increases much more rapidly with increasing $[HSO_4^-]$ than required by this correlation. Such differences have been observed before in analyses of rates of other reactions in concentrated sulfuric acid solution (7); they might be the result of salt effects on the bisulfate-ion catalyzed reaction or incursion of catalysis by undissociated sulfuric acid.

Enolization

The rate law that governs the enolization of acetophenone when the process is monitored by bromine scavenging is given by eq. [4]. Here k^E_{obs} is the observed rate constant for the overall process and k^E, k^K, and k^{Br} are rate constants for the enol-forming step (eq. [1], forward direction), the reketonization step (eq. [1], reverse direction), and the enol-bromination step (eq. [2]) respectively. These rate constants are all defined as first-order specific rates, i.e., they contain the effect of acid catalyst or bromine reactant concentration. When bromination is sufficiently more rapid than reketonization, this expression reduces to eq. [5], and observed rate constants provide a true measure of rates of enolization. On the other hand, when bromination and reketonization occur at comparable rates, the full expression applies, and rearrangement of eq. [4] into eq. [6] shows that observed rate constants are reduced from rates of enolization by the fraction $1/(1 + k^K/k^{Br})$.

$$[4]\quad k^E_{obs} = k^E k^{Br}/(k^K + k^{Br})$$

$$[5]\quad k^E_{obs} = k^E$$

$$[6]\quad k^E_{obs} = k^E/(1 + k^K/k^{Br})$$

The critical quantity is therefore the ratio of reketonization to bromination rate constants, k^K/k^{Br}: only when this is small does eq. [5] apply. This ratio may be evaluated for the conditions of the study described in ref. 2 by using the X acidity function correlation established here for rates of ketonization of acetophenone enol in sulfuric acid solutions and the recently determined rate constant for the reaction of acetophenone enol with bromine, $k = 3.3 \times 10^9\ M^{-1}\ s^{-1}$ (6).[2] Evaluation of this ratio also requires knowledge of the bromine concentrations employed. This is not known with certainty, inasmuch as ref. 2 as well as the thesis upon which this reference is based (8) specify only that the range $[Br_2] = 10^{-2}$–10^{-3} M was used for acetophenone and several other substrates. The ratio k^K/K^{Br} was therefore evaluated here using both ends of this range. The results for $[Br_2] = 10^{-3}$ M are listed in Table 2; those for $[Br_2] = 10^{-2}$ M are a factor of 10 less.

It may be seen that k^K/k^{Br} is negligibly small at low acidities, but at higher acidities, especially in the most concentrated acid solution used, it does become significant. Observed rate constants were therefore corrected, i.e., converted into values of k^E, by multiplication by $(1 + k^K/k^{Br})$. The results for $[Br_2] = 10^{-3}$ M are listed in Table 2 and are also displayed in Fig. 3 (open circles) along with the values for $[Br_2] = 10^{-2}$ M (triangles).

Figure 3 shows that, whereas the X function correlation using values of K^E based upon $[Br_2] = 10^{-2}$ M is still curved, the one using values based on $[Br_2] = 10^{-3}$ M is linear. It is likely that the latter is the better representation of the true situation, inasmuch as it provides better agreement with rates of enolization of acetophenone measured by Hammett using iodine scavenging (1); these are shown in Fig. 3 as filled circles. Hammett realized that iodine was not a sufficiently efficient scavenger in the more acidic solutions that he used, and he allowed for this in calculating his rate constants; his results therefore pertain to the enolization step only. The combined data, those of Hammett plus those of ref. 2 corrected using $[Br_2] = 10^{-3}$ M, provide the relationship $\log(k^E/C_{H^+}) = -(4.66 \pm 0.01) + (0.328 \pm 0.008)X$.

These arguments suggest that rates of enolization of aceto-

[2]This reaction is a very nearly diffusion-controlled process whose rate will be independent of medium acidity.

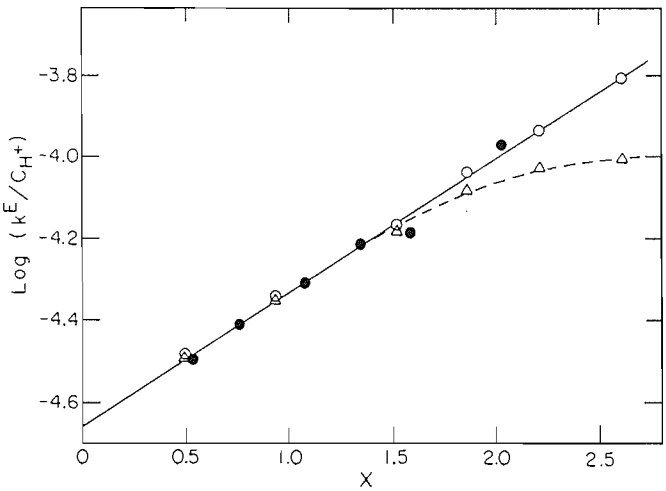

FIG. 3. Acidity function correlation of rates of enolization of acetophenone enol in aqueous sulfuric acid solutions: ○ and △, ref. 8 corrected as described in text using $[Br_2] = 10^{-3}$ and 10^{-2} M respectively; ●, ref. 1.

phenone could give a linear X function correlation without the incorporation of the activity of water in the correlating expression. Water is undoubtedly involved in the enolization process, as the base that receives the proton being transferred from carbon, but to a good approximation this covalent involvement would then already be reflected in a normal, linear X function dependence, and it would not need to be included explicitly. We will return to the role of water in a later paper.

Keto–enol equilibrium

Keto–enol equilibrium constants may be evaluated as ratios of enolization to ketonization rate constants, $K^E = k^E/k^K$. Combination of the X function correlations for enolization and ketonization described above therefore gives an expression relating K^E to X for acetophenone in sulfuric acid solutions: log $K^E = -(7.86 \pm 0.02) - (0.506 \pm 0.012)X$. The intercept of this relationship is consistent with the value determined previously in dilute solution, log $K^E = -7.96 \pm 0.04$ (4*b*), and the slope shows that enol content decreases with increasing acidity.

It is of interest to determine whether this decrease in K^E is specific to sulfuric acid or whether it also occurs in other concentrated acids as well, and we therefore measured rates of enolization of acetophenone in perchloric acid solutions in order to combine these with the ketonization data and provide a K^E–X relationship for this medium also. Enolization was again monitored by bromine scavenging and allowance was made for insufficiently efficient scavenging wherever necessary. The results are summarized in Table 3; it may be seen that only minor adjustments to k^E_{obs} were on the whole necessary.

Hammett also measured rates of enolization in perchloric acid solutions (1), and his values of k^E, again obtained allowing for insufficiently efficient scavenging, are in good agreement with ours. The combined data give the linear correlation: $\log(k^E/C_{H^+}) = -(4.86 \pm 0.01) + (0.086 \pm 0.001)X$. The intercept of this relationship corresponds to the hydronium-ion catalytic coefficient, $k_{H^+} = (1.38 \pm 0.04) \times 10^{-5}\ M^{-1}\ s^{-1}$, which is in reasonable agreement with the value measured previously in dilute acid solutions, $k_{H^+} = (1.21 \pm 0.01) \times 10^{-5}\ M^{-1}\ s^{-1}$ (4*b*).

TABLE 3. Rate data for enolization of acetophenone monitored by bromine scavenging in aqueous perchloric acid solutions at 25°C

Wt.% $HClO_4$	$k_{obs}/10^{-6}\ s^{-1}$	$k^E/10^{-6}\ s^{-1}$
0.40	0.576, 0.589	0.576, 0.589
1.18	1.81	1.81
3.17	5.34	5.35
3.49	5.01	5.02
7.92	11.3, 13.0	11.4, 13.1
20.0	39.5	40.7
29.3	58.2	63.5
37.9	127.	133.
46.3	140.	145.

Combination of the enolization and ketonization correlations for perchloric acid solutions gives log $K^E = -(7.94 \pm 0.02) - (0.581 \pm 0.013)X$. The intercept of this relationship agrees very well with the previously determined value, log $K^E = -7.96 \pm 0.04$ (4*b*), and the slope shows that the enol content decreases with increasing acidity in concentrated perchloric acid solution just as it does in concentrated sulfuric acid.

It is interesting that this change in K^E with increasing medium acidity may be modelled using phenol as a substitute for acetophenone enol. Activity coefficient measurements show that phenol is salted out of concentrated sulfuric acid quite markedly whereas acetophenone is not affected very much at all (9). The ratio of activity coefficients of acetophenone to phenol in 50% H_2SO_4 relative to pure water, $f(PhCOCH_3)/f(PhOH) = 11$, is in fact remarkably similar to the change in keto–enol equilibrium constant for acetophenone in going from water to 50% H_2SO_4, $\delta K^E = 12 \pm 1$.

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

MIROSLAW DWORNICZAK and KENNETH T. LEFFEK. Can. J. Chem. **68**, 1657 (1990).

3,3,6,9,9-Pentamethyl-2,10-diazabicyclo[4.4.0]dec-1-ene has been synthesized and its proton transfer reactions, together with those of the bases 2,2,6,6-tetramethylpiperidine and 1,2,2,6,6-pentamethylpiperidine, have been studied with the carbon acids 4-nitrophenylphenylcyanomethane and 2-methyl-4-nitrophenylphenylcyanomethane. Equilibrium constants, rate constants, primary deuterium isotope effects, and activation parameters are reported for the reactions in acetonitrile solvent. Values of the pK_a in acetonitrile have been measured for the conjugate acid of each base and the Brønsted β value of 0.56 in acetonitrile has been determined for the proton transfer from 4-nitrophenylphenylcyanomethane.

Key words: proton transfer reactions, kinetic isotope effects, cyclic nitrogen bases.

MIROSLAW DWORNICZAK et KENNETH T. LEFFEK. Can. J. Chem. **68**, 1657 (1990).

On a synthétisé le 3,3,6,9,9-pentaméthyl-2,10-diazabicyclo[4,4,0]déc-1-ène et, utilisant les acides carbonés 4-nitrophénylphénylcyanométhane et 2-méthyl-4-nitrophénylphénylcyanométhane, on a étudié ses réactions de transfert de proton avec ceux des bases 2,2,6,6,-tétraméthyl- et 1,2,2,6,6-pentaméthyl-pipéridines. On a déterminé les constantes d'équilibre, les constantes de vitesse, les effets isotopiques primaires du deutérium et les paramètres d'activation de ces réactions dans l'acétonitrile. On a mesuré la valeur du pK_a, dans l'acétonitrile, pour chaque acide conjugué de chaque base et on a déterminé que, dans l'acetonitrile, la valeur β de Brønsted pour le transfert de proton à partir du 4-nitrophénylphénylcyanométhane est égale à 0,56.

Mots clés : réactions de transfert de proton, effets isotopiques cinétiques, bases cycliques d'azote.

[Traduit par la revue]

Introduction

This work continues the study of proton transfer reactions and primary deuterium isotope effects in the reactions of cyanomethane carbon acids and nitrogen bases in acetonitrile solvent. Previous studies have investigated the effects of substituents in the carbon acid with respect to electronic effects (1) and steric effects (2). In this paper, structural changes in the nitrogen base are studied using two carbon acids, 4-nitrophenylphenylcyanomethane **1** and 2-methyl-4-nitrophenylphenylcyanomethane **2**. The base 3,3,6,9,9-pentamethyl-2,10-diazabicyclo[4.4.0]dec-1-ene (PMDBD) **3** has been synthesized in order to study the steric effect on the reactivity of the basic centre and its relation with the isotope effects on deuteron transfer. For comparison, the bases 2,2,6,6-tetramethylpiperidine (**4**) and 1,2,2,6,6-pentamethylpiperidine (**5**) were also studied.

5

The proposition put forward by Sugimoto and Sasaki (3) that increased steric hindrance at the basic centre decreases the extent of proton tunnelling in the proton transfer reaction could also be tested, if the reactions exhibit a significant tunnelling contribution.

[1]Postdoctorate Fellow 1988–1989.

Directly measured pK_a values for the conjugate acids of these bases in acetonitrile solvent allows the determination of the Brønsted β value for the proton transfer reactions. Previously most β values were determined in water or in other mixed solvents using pK_a values measured in water, although some β values based on pK_a measurements in nonaqueous solvents, e.g., DMSO, have been reported (4).

carbon acid **2**, in accordance with eq. [1].

[1] $AH + B \rightleftharpoons A^-BH^+$

In acetonitrile solvent these reactions gave a product with a single broad strong absorption band at 580 nm for acid **1** and 597 nm for acid **2**. The absorbance values for a series of base concentrations at a constant acid concentration were fitted to eq. [2] for an ion-pair product, where a and b are the initial concentrations of acid and base respectively and A is the equilibrium absorbance

[2] $$a/A = \frac{1}{Kb\varepsilon} + \frac{1}{\varepsilon}$$

The equilibrium constant K and the molar absorptivity ϵ were derived from a plot of a/A vs. $1/b$. A good linear fit, correlation coefficients 0.997–0.9999, verified that the product was an ion-pair. The results are summarized in Table 1, together with those for TMG and DBU from earlier work (2).

The pK_a values of the conjugate acids of the bases **3**, **4**, and **5** were determined by the method described by Leffek *et al.* (6), based on the methods of Coetzee and Padmanabhan (7, 8) and Kolthoff and Chantooni (9, 10), and are included in Table 1.

Despite the good correlation coefficients found for the fit to eq. [2], the values of K are derived from the intercept and the slope of the plot and are subject to larger errors than those indicated by the standard deviations. However, the logarithms of these equilibrium constants correlate with the pK_a except for DBU, which gives an equilibrium constant for the abstraction of the proton from carbon acid **2** about 10 times larger than would be expected from the other equilibrium constants in Table 1. The Hildebrand-Benesi method does not yield highly precise equilibrium constants, particularly when they are large. However, even when a minimum value of 2100 $dm^3\ mol^{-1}$ is assumed for DBU, i.e., 3500 $dm^3\ mol^{-1}$ minus twice the standard deviation, which is close to the equilibrium constant of 2000 ± 200 $dm^3\ mol^{-1}$ determined (2) from the kinetics of the reaction between DBU and carbon acid **2**, the discrepancy between this value and the other equilibrium constants in Table 1 is still well beyond experimental error. Thus DBU is acting as a stronger base in this proton transfer reaction than would be expected from pK_a of 23.9 in acetonitrile (6).

Kinetic measurements

Using the base in large excess, pseudo-first-order rate constants, k_{obs}, were fitted to eq. [3], which may be derived for an equilibrium yielding a single ion-pair product as in eq. [1]. The results obtained at 25°C are shown in Table 2, together with those from previous work (2, 11) with TMG and DBU bases for comparison.

[3] $k_{obs} = k_2[\text{Base}] + k_b$

The equilibrium constants calculated from k_2/k_b in Table 2 are in satisfactory agreement with those listed in Table 1 and, again, log K values from the kinetic data correlate with the pK_a of the conjugate acid of the base, with the exception of DBU noted above.

A Brønsted plot of log k_H against the pK_a of the base for 4-nitrophenylphenylcyanomethane reacting with the four bases listed in Table 2 gives $\beta = 0.53 \pm 0.07$. This is the first β value determined in acetonitrile solvent using pK_a values measured in that solvent and it is remarkably similar to the β value of 0.55 reported by Bordwell and Boyle (12) for several arylnitromethane acids reacting with similar bases in water. The log k_D vs. pK_a plot shows a very similar correlation, with $\beta = 0.50 \pm 0.07$. However, the k_H/k_D values, being much more sensitive measures of the transition state structure, show a reversal in the magnitude of the effect for the two piperidine bases. The smallest isotope effect of 7.1 ± 0.2 at 25°C is found with 2,2,6,6-tetramethylpiperidine **4**, and the *N*-methyl analogue **5**, which is a slightly weaker base, gives $k_H/k_D = 8.4 \pm 0.2$ at 25°C. This difference, well beyond the experimental error of ±(twice the standard deviations), is attributed to the increased steric hindrance in **5** relative to **4**, even though the steric effect is not large enough to be apparent in the Brønsted plots.

For the reaction with the 2-methyl-4-nitrophenylphenylcyanomethane **2** the rate constants are much smaller due to the inhibition of the reaction by the *ortho*-methyl group. The PMDBD base reacts about nine times more slowly at 25°C with the acid **2** than with acid **1**, and the kinetic isotope effect is also smaller although the difference is not much larger than the experimental error. This base is less sensitive to the *ortho*-methyl group than is TMG, which reacts about 18 times more slowly with acid **2** than it does with acid **1**, and the isotope effects with TMG are again diminished slightly from 10.7 to 10.0. The absence of an increase in the isotope effect when the steric hindrance to proton transfer is increased indicates that proton tunnelling is not an important contributor to the rate of this reaction.

The isotope effects on the activation parameters are summarized in Table 3. None of the isotope effects on the enthalpies of activation are beyond the semiclassical limit of 1.1–1.2 kcal mol^{-1}, confirming that there is no significant contribution from proton tunnelling to the reaction rate. These results show that the larger isotope effect found when the nitrogen atom of the piperidine base is methylated results from an entropy of activation effect rather than an enthalpy effect. This indicates that the difference in the isotope effect between the piperidine **4** and the *N*-methylpiperidine **5** probably lies in the difference between the solvent–base interactions for the =N—H and =N—CH_3 groups.

The isotope effects on the activation parameters for PMDBD reacting with the *ortho*-substituted acid **2** are very similar to those for DBU reacting with the same acid (2), i.e., enthalpy isotope effects at about the semiclassical limit of 1.2 kcal mol^{-1} and entropy isotope effects close to zero. Thus, there is no evidence of proton tunnelling and, although PMDBD is a

$(\Delta S_D‡ - \Delta S_H‡)$		−0.3±0.8	

weaker base than DBU and more sterically hindered, the width of the barrier to proton transfer must be very similar for both bases.

In general, the results show that there is no direct relationship between extensive steric hindrance and proton tunnelling and that isotope effects may be increased beyond the semiclassical limit of $k_H/k_D = 7$ at 25°C by entropy of activation effects, so that rate ratios alone may not be used as evidence for proton tunnelling.

Experimental

Materials

4-Nitrophenylphenylcyanomethane and (2-methyl-4-nitrophenyl)-phenylcyanomethane and their deuterated analogues were prepared following the procedure previously described (11).

3,3,6,9-Pentamethyl-2,10-diazabicyclo[4.4.0]dec-1-ene was synthesized according to the procedure described by Heinzer *et al.* (13) with minor modifications.

A mixture of 21 mL 10 M BuLi solution in hexanes and 250 mL of dry ether was cooled to −65°C. To this solution, 28.3 mL of freshly distilled diisopropylamine was added dropwise with stirring. The temperature remained below −60°C. After about 5 min 7.2 mL (5.5 g) of freshly distilled propionitrile was added dropwise. The resulting mixture was stirred for another 30 min. Then 30 g of isoprene hydrobromide was added, keeping the temperature below −50°C. The reaction mixture was stirred for 1.5 h at −65°C followed by an additional 1 h of stirring at room temperature. The flask contents were poured onto ice and acidified with 100 mL of 10% H_2SO_4.

The organic phase was separated, and the water phase was extracted three times with 80-mL portions of diethyl ether. The combined ethereal extracts were washed with $NaHCO_3$ and NaCl and dried overnight with $MgSO_4$. After evaporating the solvent, the product, 5-cyano-2,5,8-trimethylnona-2,7-diene, was used for the next step of synthesis without further purification.

This compound (20 g) was dissolved in 75 mL of dry benzene (distilled from calcium hydride) and 28 mL of a 50% suspension of sodium amide in toluene was added at once. The resulting mixture was refluxed and the progress of the reaction checked by TLC (eluent hexanes:ether 9:1, silica gel). The reaction was completed after 8 h. Then, small portions of ice were added to decompose the remaining $NaNH_2$, and the mixture was stirred with gentle heating to cause liberation of ammonia. This could be facilitated by passing nitrogen through the mixture.

The organic layer was separated and the water phase extracted three times with ether. The combined organic extracts were acidified with four portions of 2 N H_2SO_4. The acidic water was cooled in an ice bath and made alkaline with NaOH pellets to reach pH > 12. The liberated base was separated and the water phase extracted three times with 50-mL portions of ether. The combined extracts were dried over anhydrous K_2CO_3. The purity of the product, 5-amidino-2,5,8-trimethylnona-2,7-diene, was checked by means of NMR and GC-MS.

Ten grams of the product were dissolved in 80 mL of freshly distilled methylene chloride and cooled to 0°C. Gaseous dry HCl was passed through the solution until the pH reached 2. Then the solvent was evaporated and remaining oily substance dried *in vacuo* until a constant mass was reached. A round-bottom flask containing the hydrochloride was provided with a $CaCl_2$ drying tube and heated at 200°C. After the evolution of gaseous HCl had stopped, the flask was closed with a stopcock and heated for an additional 20 h. After cooling, the mixture was dissolved in 100 mL of water and acidified with 30 mL of 2 N H_2SO_4.

The water phase was extracted three times with ether, cooled to 0°C, and NaOH pellets added to reach pH > 12. The alkaline solution was then extracted with ether and the combined extracts dried overnight with anhydrous K_2CO_3. The product was vacuum-distilled to give a dense colourless oil (bp 110°C/3 Torr (1 Torr = 133.3 Pa) (lit. (13) bp 65°C/0.07 Torr). The NMR spectrum of 3,3,6,9,9-pentamethyl-2,10-diazabicyclo[4.4.0]dec-1-ene (CCl_4/TMS) showed 1.06/1.12 (s/s, 6H), 1.19 (s, 3H), 1.21–2.0 (m, 8H), 3.38 (s, NH). The latter signal

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12

disappeared when the NMR spectrum was run in $CDCl_3$. Picrate: mp 233–234°C.

2,2,6,6-Tetramethylpiperidine and 1,2,2,6,6-pentamethylpiperdine (Aldrich) were dried over KOH and distilled fractionally under vacuum immediately before use. Picrate mp's: 230–231°C and 239–241°C respectively.

Reagent grade acetonitrile was purified by the method of O'Donnell (14) followed by distillation from calcium hydride and final fractional distillation from P_2O_5.

pK_a measurements

These measurements were made using the potentiometric procedure described by Leffek *et al.* (6).

Equilibrium measurements

The absorbance at equilibrium was measured using a Cary 219 spectrometer with a thermostating device. Acid concentrations of 1×10^{-5} and 2×10^{-5} M were used; base concentrations were in excess by factors ranging from 20 to 2000.

Kinetic measurements

Pseudo-first-order rate constants were measured using a Durrum–Gibson stopped-flow spectrometer. Acid and base concentrations are shown in Table 2. Calculations of the rate constants were made using the Guggenheim method (15). The activation parameters were calculated by a least-squares fit to the transition state theory equation.

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

DENNIS D. TANNER, ABDELMAJID KHARRAT, and H. OUMAR-MAHAMAT. Can. J. Chem. **68**, 1662 (1990).

The reduction of *p*-benzoquinone (BQ) by 1-benzyl-1,4-dihydronicotinamide (BNAH) proceeds by a free-radical chain mechanism initiated by single electron transfer (SET). In dry deoxygenated acetonitrile, the chain, whose propagation steps contain a SET–hydrogen atom transfer sequence, could be inhibited by dinitrobenzene and initiated by di-*tert*-butylperoxyoxalate. The reduction does not follow second-order reaction kinetics. The fractional order of each reactant was found to be 0.80 and 1.36 for BNAH and BQ, respectively. The ΔG^0 values for both the initiation and the propagation steps were evaluated electrochemically (CV) and were found to be of a reasonable magnitude to sustain a free-radical chain process.

Key words: 1-benzyl-1,4-dihydronicotinamide, *p*-benzoquinone, free radical, reduction.

La réduction de la *p*-benzoquinone (BQ) par la 1-benzyl-1,4-dihydronicotinamide (BNAH) se produit par un mécanisme radicalaire en chaîne qui est initié par un transfert d'électron unique (TEU). Dans de l'acétonitrile désoxygéné, la chaîne, dont les étapes de propagation comportent une séquence de transfert d'atome d'hydrogène par un TEU, peut être inhibée par le dinitrobenzène et initiée par le peroxyoxalate de di-*tert*-butyle. La réduction ne suit pas une cinétique d'ordre deux. On a trouvé que l'ordre fractionnaire pour chacun des réactifs est de 0,80 et de 1,36 respectivement pour la BNAH et la BQ. Faisant appel à des méthodes électrochimiques (CV), on a évalué les ΔG^0 des étapes d'initiation et de propagation et on a trouvé qu'ils sont d'une amplitude telle qu'ils permettent un processus radicalaire en chaîne.

Mots clés : 1-benzyl-1,4-dihydronicotinamide, *p*-benzoquinone, radical libre, réduction.

Introduction

A recent communication (1) has prompted us to report the results of our investigation of the mechanism of the reduction of benzoquinone by the NADH model compound, 1-benzyl-1,4-dihydronicotinamide (BNAH). Previously we reported that the reductions by BNAH and a series of substituted dihydronicotinamides (DHN's) reacted with a variety of substrates via a free-radical chain process (2–4). Both the initiation and propagation sequences contained an electron transfer reaction, see Scheme 1. The mechanistic path followed during these reductions, however, is substrate specific, since under the same reaction conditions the reduction of *N*-methyl acridinium iodide proceeds by a hydride transfer process (Scheme 2) (3).

During the course of our studies the electron transfer initiation process was substantiated for substrates with high electron affinities by the observation that 2,6-di-*tert*-butyl benzoquinone gives strong EPR signals for the 2,6-di-*tert*-butyl benzoquinone radical anion. Since a rate-limiting step in the chain reduction of the quinone would be the single electron transfer (SET) initiation (3), it was suprising to learn from the report of the studies of the BNAH reduction of benzoquinone, a substrate that is more reactive than 2,6-di-*tert*-butylbenzoquinone, that the authors had concluded that the reduction proceeds by a hydride transfer mechanism (1).

Results

Several mechanisms have been proposed to rationalize the reduction reactions of a hydride equivalent acceptor with BNAH. Besides a heterolytic hydride transfer, three homolytic processes have been suggested: SET–proton–SET (5) or a SET – hydrogen atom transfer, both from a geminate caged pair (6), and a SET – hydrogen atom abstraction radical chain (2–4). A kinetic analysis of the progress of the reaction requires second-order kinetics for both the heterolytic process and the homolytic reactions involving caged species. In the case of the radical chain process initiated by SET, only a chain terminated solely by cross termination shows second-order kinetics (3), eq. [11] (Scheme 3).

The reduction of *p*-benzoquinone (BQ) with BNAH was carried out in dry acetonitrile (23°C). Contrary to the previous report by Tanaka and co-workers (7), when equal concentrations (10^{-3} M) of each reactant are used, a plot of the second-order reaction rate ($1/(A_\infty - A)$ vs. time) is not found to be linear (see Fig. 1).

The kinetics of the reduction reaction with DHN's have been studied in water or in a mixed aqueous–organic solvent (6, 8–10). In the reduction of methyl acridinium iodide by NADH models (3) we had observed that the addition of a small amount of water (1–5%) increased the curvature of the second-order plot with a decrease in the instantaneous rate at $t = 0$. In this study the addition of small amounts of water (1%) produced a linear second-order plot, see Fig. 2, but with an increase in the rate of reaction. Since the presence of a small amount of water changed the kinetics, and undoubtedly the mechanism of the reaction, the solvent of choice was dry acetonitrile.

The rate of reduction in dry acetonitrile could be inhibited by the addition of small amounts of DNB (5–10%) and initiated by di-*tert*-butylperoxyoxalate, see Fig. 3.

The kinetic behaviour of the BQ reduction is consistent with a free-radical chain mechanism. As proposed previously (2–4), the electron transfer takes place in both the initiation and propagation steps (Scheme 4).

Tanaka and co-workers (7) reported a kinetic isotope effect for the reduction of BQ with 4-deutero-*N*-benzyldihydronicotinamide. The isotope effect indicates that the rate-determining

SCHEME 3

step is the hydrogen atom abstraction, eq. [13]. The hydrogen atom abstraction mechanism had been discarded by Tanaka (11) since it was thought to be inconsistent with their linear kinetic data. Carlson and Miller (10) conceded that the hydrogen atom abstraction mechanism process proposed was possible; however, this was not investigated further.

The kinetic expression for the free-radical chain processes when cross termination is not the sole termination step can be formulated as

[18] $$\text{rate} = k_{obs}[BQ]^a[BNAH]^b$$

where a and b are the fractional order of BQ and BNAH, respectively.

To evaluate a and b in eq. [18], the difference in the log of the initial rate of reaction was determined at several values of ratios of concentration for the reactants (r):

[19] $$a \text{ or } b = \left[\log\left(\frac{dx}{dt}\right)_{0,I} - \log\left(\frac{dx}{dt}\right)_{0,II}\right] \Big/ \log r$$

where $(dx/dt)_0$ is the initial rate at concentration I or II, which can be evaluated graphically using the plot of absorbance versus time (12). Table 1 summarizes the results.

We have reported (3) that the kinetic expression for a free-radical chain process depends upon the termination step. Equation [11] can be transformed into the general expression for a kinetic chain, in which cross termination may not be the sole termination process:

[20] $$\begin{aligned}\text{rate} = &\left(2+\left(\frac{k_1k_2}{k_4k_i}\right)^{1/2}\right)k_i[BNAH][BQ] \\ &+ \frac{k_1k_i}{(2k_ik5)^{1/2}}[BNAH][BQ]\frac{[BNAH]^{1/2}}{[BQ]^{1/2}} \\ &+ \frac{k_4k_i}{(2k_3k_i)^{1/2}}[BNAH][BQ]\frac{[BQ]^{1/2}}{[BNAH]^{1/2}} \\ &= k_1[BNAH][BQ] + k_2[BNAH]^{3/2}[BQ]^{1/2} \\ &+ k_3[BNAH]^{1/2}[BQ]^{3/2}\end{aligned}$$

From the initial rate data we have shown that the reaction has a

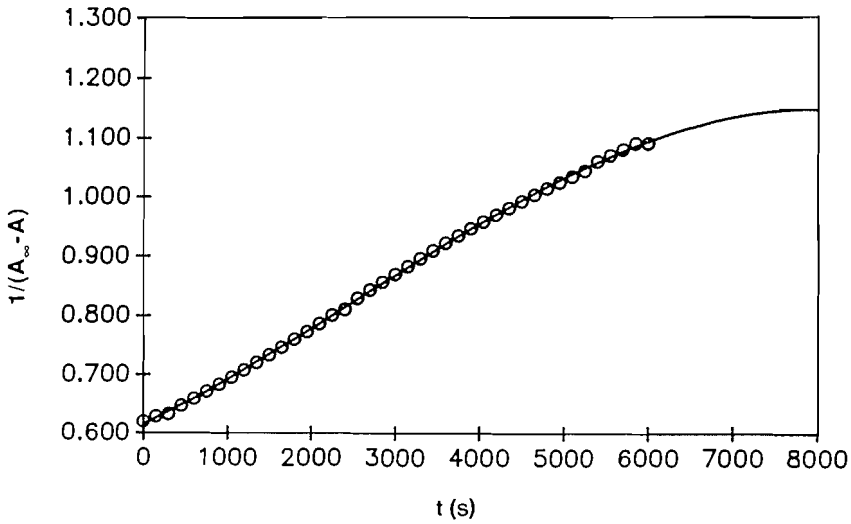

FIG. 1. Plot of the second-order rate of reaction; [BQ] and [BNAH] = 1.00×10^{-3} M.

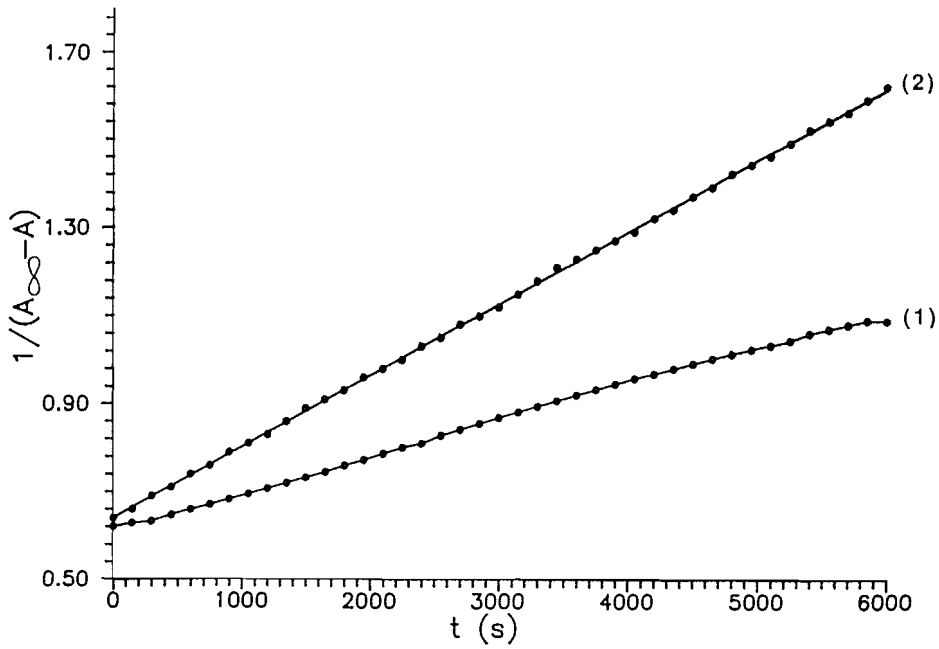

FIG. 2. Comparison plots of second-order rates of reaction [BQ] and [BNAH], 1.00×10^{-3} M, in dry acetonitrile (1), and in 1% water–acetonitrile (2).

fractional order (rate = k_{obs}[BNAH]$^{0.80}$[BQ]$^{1.36}$). The rate expression suggests that several termination steps are involved, and that cross termination, eq. [16], is not the dominant process.

The plots for the pseudo first-order reaction of either reactant are not linear; however, when the solutions were not deoxygenated a straight line was observed and the second-order rate constant obtained was similar to the value reported by Tanaka (7). The radical chain appears to be inihibited by atmospheric oxygen.

Tanaka and co-workers (7) reported that plots of the observed rate constant versus the concentration of [BQ] or [BNAH] are linear, and that the [BNAH] plot had a larger slope than the plot of [BQ] vs. k_{obs}. They argued that the difference in the slopes was due to the stoichiometry of the reaction. When our data were plotted in this manner two curves were obtained (Fig. 4), and although the BNAH plot does have the larger slope at concentrations $>1.5 \times 10^{-3}$, neither plot was linear.

Thermochemical aspects for the reduction

The value of the redox potential of *p*-benzoquinone (−0.50 V vs. SCE in acetonitrile) has previously been reported (1). For BNAH, several values for the redox potential in acetonitrile have been reported (13).[4] We have chosen +0.57 V vs. SCE (13) because the CV technique used in these studies was similar to those used to determine the E^0 for *p*-benzoquinone. The ΔG^0 for the initiation step using these redox potentials is equal to 24.7 kcal mol^{-1}, and although it is rather high it is not an unreasonable value for the initiation of a free-radical chain process. Supporting evidence was obtained for the electron transfer initiation reaction when solutions of [BQ], 3×10^{-3} M, and [BNAH], 3×10^{-3} M, were degassed and mixed in an EPR tube, and the ESR spectrum was taken. The spectrum appeared

[4]A value by the same authors (13) using a fluorescence quenching technique gave quite similar results, 0.60 V vs. SCE.

immediately, showing the five lines of the *p*-benzoquinone radical anion. The spectrum observed is completely consistent with the observed formation of the charge transfer complexes between BNAH and *p*-benzoquinone derivatives reported by Tanaka and co-workers (7, 11, 14).

The feasibility of the electron transfer step in the propagation sequence could be evaluated electrochemically. The redox potential for BNA^+ is determined to be −0.94 V vs. SCE in acetonitrile (glassy carbon electrode). ΔG^0 for the electron transfer, in eq. [14], is evaluated to be exergonic, −10.1 kcal mol^{-1}. The thermochemical data are consistent with the proposed free-radical chain mechanism.

Conclusion

The *N*-benzyl-1,4-dihydronicotinamide used as a biomimetic model for enzyme-controlled reductions by NADH reduces *p*-benzoquinone by a free-radical chain mechanism in dry and deoxygenated acetonitrile. Kinetic studies show that the reduction is not a second-order reaction.

Since a free-radical chain process could not take place in the enzyme-controlled reaction, the model studies when run under these conditions cannot be extended to the biological systems.

Experimental

Materials

Reagent acetonitrile (Caledon, HPLC grade) was purified by successive distillations over potassium permanganate and sodium carbonate. The distillate was treated with several drops of concentrated sulfuric acid and redistilled. Finally it was distilled again from calcium hydride.

1-Benzyl-1,4-dihydronicotinamide was described in an earlier paper (2). *p*-Benzoquinone (Matheson Coleman and Bell) was dried under vacuum over P_2O_5, mp 113°C (lit. (15) mp 113–115°C). *m*-Dinitrobenzene (Fisher) was recrystallized from ethanol, mp 89°C (lit. (16) mp 80–90°C). Di-*tert*-butyl peroxyoxalate was prepared according to the literature procedure (17).

General procedure for determination of the kinetics of the reduction p-*benzoquinone by BNAH*

Acetonitrile solution containing 3×10^{-3} M of *p*-benzoquinone or 3×10^{-3} M BNAH was deoxygenated by bubbling dry argon for 15 min through each solution, protected from the atmosphere with a septum. After the solutions were deoxygenated the concentration of each solution was readjusted by the syringe addition of a few drops of previously deoxygenated acetonitrile.

An aliquot of each solution with the corresponding concentration (with or without additives) was transferred by syringe to the ultraviolet cell, protected by a septum at room temperature. When the reaction was initiated a stop-flow apparatus was used.

The kinetics were investigated as described in the literature (7) using an ultraviolet HP 8450A diode array spectrophotometer connected to an HP 7470A plotter and an HP 82901 M flexible disc drive.

The pseudo first-order rates were investigated by using 10-fold excess BNAH or *p*-benzoquinone. For the determination of the fractional order of each reactant, three ratios (r) of concentration were used: 1.5, 1.8, and 2. The order given is the mean value of three determinations (see text).

The kinetic data were investigated by least-squares curve fitting.

ESR spectroscopy

The ESR spectra were obtained for the radical anion of *p*-benzoquinone by mixing a 3×10^{-3} M solution of the quinone and 3×10^{-3} M BNAH in acetonitrile at room temperature. A Brucker ER 200 E/D spectrometer was used to record the spectra.

Cyclic voltammetry

The electrochemistry of BNA^+ was studied as previously described (18), using a glassy carbon electrode. The reversible wave was observed at a scan rate equal to 50 V/s.

Received January 26, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

YU-HUANG ZHANG, MING-HUA DONG, XI-KUI JIANG, and YUAN L. CHOW. Can. J. Chem. **68**, 1668 (1990).

The photoinitiated bromination of 1-chloropentane with *N*-bromosuccinimide (NBS) in the presence of Br_2 is compared with that of NBS and 1,1-dichloroethene to generate the succinimidyl radical (S$^\bullet$) and with that of $Br_2 + K_2CO_3$ to generate the bromine atom (Br$^\bullet$) as the chain carriers. The relative reactivities of intermolecular H-abstraction (*r*-values) shown by the NBS + Br_2 system decrease to levels lower than those shown by either S$^\bullet$ or Br$^\bullet$ chain propagations at lower temperatures under appropriate conditions: these observations indicate the presence of a new chain propagating species that is assumed to be the bromine radical complex (BRC) modified from S$^\bullet$ or Br$^\bullet$ reversibly under the experimental conditions. Supporting evidence for the equilibria of S$^\bullet$, Br$^\bullet$, and BRC in the photodecomposition of NBS + Br_2 is discussed. The unusual H-abstraction reactivity of Br$^\bullet$ toward the methyl hydrogens of 1-chloropentane was noted; this serves as independent support for the presence of a new radical propagation species.

Key words: *N*-bromosuccinimide, succinimidyl radical, photobromination, bromine radical complex.

YU-HUANG ZHANG, MING-HUA DONG, XI-KUI JIANG et YUAN L. CHOW. Can. J. Chem. **68**, 1668 (1990).

On a comparé la bromation photoinitiée du 1-chloropentane par la *N*-bromosuccinimide (NBS) en présence de Br_2 avec celles réalisées par la NBS et le 1,1-dichloroéthène pour générer les radicaux succinimidyles (S$^\bullet$) et par le $Br_2 + K_2CO_3$ pour générer l'atome de brome (Br$^\bullet$) comme propagateur de la chaîne. On a démontré que les réactivités relatives d'enlèvement intermoléculaires d'hydrogène (valeurs-*r*) pour le système NBS + Br_2 diminue jusqu'à des valeurs qui sont plus basses que celles observées avec les propagations de chaîne à l'aide de S$^\bullet$ ou de Br$^\bullet$, à des températures plus basses et des conditions appropriées : ces observations suggèrent l'apparition d'une nouvelle espèce pour propager la chaîne et on fait l'hypothèse qu'il s'agit d'un complexe radicalaire de brome (CRB) qui a été modifié d'une façon réversible à partir du S$^\bullet$ ou du Br$^\bullet$, dans les conditions expérimentales. On discute des données suggérant l'existence de l'équilibre S$^\bullet$, Br$^\bullet$ et CRB dans la photodécomposition du NBS + Br_2. On a noté la réactivité inhabituelle du Br$^\bullet$ dans l'enlèvement d'hydrogènes des groupements méthyles du 1-chloropentane; ce résultat sert de support indépendant pour la présence d'une nouvelle espèce pour la propagation des radicaux.

Mots clés : *N*-bromosuccinimide, radical succinimidyle, photobromination, complexe radicalaire de brome.

[Traduit par la revue]

Introduction

Mechanistic studies of the photodecomposition of *N*-bromosuccinimide (NBS) under various conditions have caused many controversies over the number and nature of the chain propagating species (1–8). The claim (4–7) of "the generation and identification of excited state and ground state Σ–Π succinimidyl radicals" appears to arise from experimental artefacts and has been withdrawn (3). Recently it was shown (9, 10) that the photoexcitation of NBS in the presence of 1,1-dichloroethene (DCE) causes the enhanced ring-opening reaction to form extra amounts of β-bromopropionyl isocyanate (BPI) from the excited state *NBS directly or via a vibrationally "hot" succinimidyl radical (†S$^\bullet$) (Scheme 1); this observation has led to the discussion of probable sources of previous controversies (1–8). Reviews of the NBS photodecomposition and details of the controversies are described in recent publications (1–3) and will not be repeated here.

There exists another controversy, namely the type of chain carriers involved in photobromination with NBS in the presence of Br_2. In a recent paper Skell *et al.* (3) reiterated the previous claim that the photodecomposition of 2,2-dimethyl-*N*-bromosuccinimide (or NBS) in the presence of bromine must involve a third propagating radical in addition to Br$^\bullet$ and the succinimidyl radicals (S$^\bullet$). While this paper (3) reports some evidence for the claim, the line of arguments has been questioned since it compares the percentage yields of the ring-opened product under different photolysis conditions as a criterion for judging the reaction pattern; such comparisons may cause serious errors because of the presence of two parallel channels for the formation of the ring-opened product in direct excitation of NBS. Results from Tanner's and Walling's groups (1, 2, 8) indicate that simple competing S$^\bullet$ and Br$^\bullet$ propagation processes can adequately explain this photobromination system with the exception of some experiments that imply the presence of a third propagating radical. Indeed in the photodecomposition of NBS + Br_2, using either neopentane (1, 4, 8) or cyclohexane (9) as a substrate in CH_2Cl_2, the patterns of relative reactivities (*r*-values) do not require proposing a third chain propagating intermediate in intermolecular H-abstraction. Controlled photolysis of the NBS + Br_2 system or of NBS without the addition of DCE to scavenge Br_2 or Br$^\bullet$ shows that these photobromination systems can be explained by reactions involving S$^\bullet$ and Br$^\bullet$ as the chain propagating species, which are interrelated by the fast equilibria (9, 11, 12) shown in Scheme 2. A crucial question in the radical equilibria of Scheme 2 is whether the bromine radical complex (BRC), the intermediate formed either from Br$^\bullet$ + NBS or from S$^\bullet$ + Br_2, will be stable enough to act independently as a chain propagating radical to show its own reactivity (11). In other words, the reactivity of the S$^\bullet$ and $Br_2^\bullet$

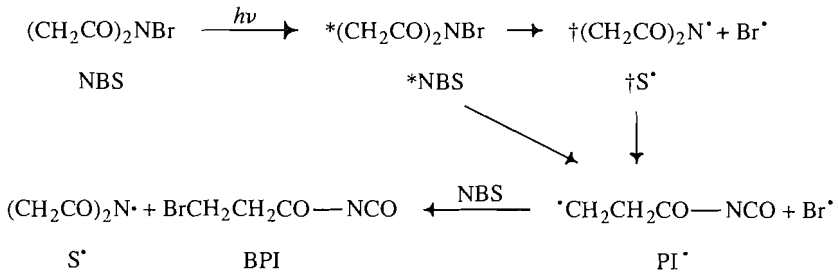
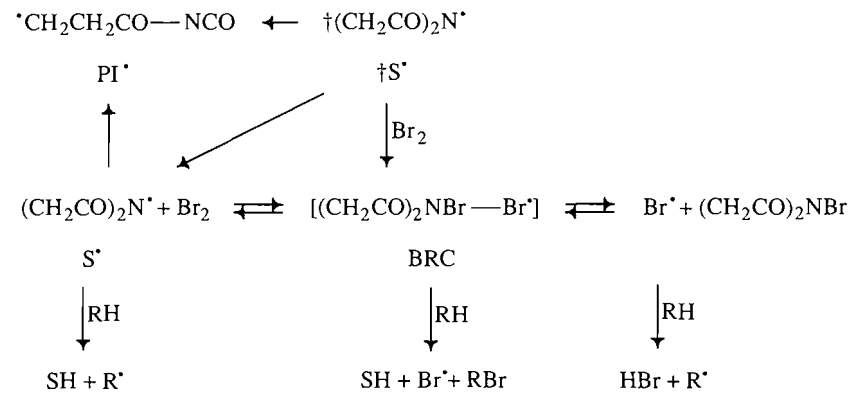


SCHEME 1



SCHEME 2

propagation species might be modified somewhat under the NBS + Br_2 conditions. In a photodecomposition of a tricyclic *N*-bromoimide, it is demonstrated that such a BRC exists, acting as a distinctive intermediate in intramolecular H-abstraction and bromination (12).

Simple radicals form complexes, most commonly with those electron-donating solvent molecules (13), and modify the reactivity of the radicals significantly (13–15) as recently shown in a selective chlorination of steroidal molecules (16). In this report, we wish to provide more evidence in support of the presence of the equilibria and BRC, as shown in Scheme 2, that modify the propagating species in the photodecomposition of NBS and its tetrafluoro derivative.

Results

The photodecomposition of NBS was carried out in CH_2Cl_2 in the presence of 1-chloropentane as the substrate, under four types of conditions that have evolved over the years through contributions from various groups (1–9); in this study the experimental conditions described in ref. 9 were adapted in order to avoid ambiguity on the excited species. Firstly, a solution of NBS in CH_2Cl_2 is photolysed through a Pyrex filter in the presence of DCE to scavenge Br_2 and Br• (Type I); these are the typical conditions in which the succinimidyl radical is the only chain carrier, as has been agreed by various groups (1–9). Secondly, NBS is photolysed under the same conditions without the presence of DCE (Type II); it is known that Br_2 is generated as the photodecomposition progresses (9). Thirdly, a mixture of NBS + Br_2 is decomposed by irradiation of Br_2 using a filter transparent >400 nm (Type III); photolytically generated Br• initiated the decomposition of NBS as shown in Scheme 2. Finally, Br_2 and K_2CO_3 are photodecomposed to generate Br• under the same conditions as above in the absence of NBS (Type IV); this system is designed to examine the reactivity of Br•, and K_2CO_3 is present to scavenge HBr generated as the by-product in the system (5, 6).

The bromination of 1-chloropentane in CH_2Cl_2 was carried out at 20°C to a low monobromination yield (5–8%) according to the procedures defined for the four types of conditions. From these photolysates the brominated products, 1-chloro-*x*-bromopentanes and $CHBrCl_2$, were isolated and their corresponding factors with respect to bromobenzene (the internal standard) in GC peaks were determined. These factors were used to do quantitative determinations of the brominated products by GC analysis. The structures of these chlorobromopentanes were determined from their MS and NMR spectra (Table 4). Since the yield of 1-chloro-5-bromopentane was low, this compound was identified by direct comparison with an authentic sample obtained from a commercial source by GC–MS. The percentages of β-bromopropionyl isocyanate (BPI) were determined by ^1H NMR spectroscopy using the intensity of the triplet at 3.63 and 2.81 ppm according to the method described by Tanner's and Walling's groups (1, 8). From the photolysate of NBS + DCE, we isolated the addition product **1**, $(CH_2CO)_2NCH_2CCl_2Br$, which was characterized from its spectroscopic data; the percentage yield of this compound was determined from the intensity of ^1H NMR singlets at 2.9 (4H) and 3.85 ppm (2H). This adduct has been detected in comparable reactions in the presence of high DCE concentrations (8).

In each series, two or more experiments were carried out under the same bromination conditions and the yields of the products were determined using bromobenzene as the internal standard; the average yields of these experiments were used to represent the series. The yields were used to calculate the

[a]Experiments were carried out in an NMR tube containing the amounts of reagents indicated, in CH_2Cl_2 (0.4 mL) and 1-chloropentane (0.11 mmol) in a thermostated bath. For Types I and II conditions, a Pyrex filter was used; for Types III and IV conditions, a JB-400 filter (cutoff <400 nm) was used. The duration of irradiation was 10 min at 17 ± 1°C, 45 minutes at 10 ± 1°C, and 58 minutes at 0 ± 3°C.

[b]The yields were determined by GC analysis.

[c]These data contain the percentage of the addition product to DCE, compound **1**; the values of which are 26.5% in expt. 1 and 30.2% in expt. 2.

[d]The % yield is low.

relative reactivities per hydrogen of each group of chemically identical hydrogens in 1-chloropentane with respect to the hydrogen of CH_2Cl_2 as shown in eqs. [1] and [2]; this is defined as the r-value (Table 1). In eq. [2], $[C_5H_{10}ClBr]_t$ represents the yield of the all monobrominated products, which is used to calculate the overall relative reactivity of 1-chloropentane (r_t) with respect to CH_2Cl_2.

$$[1] \quad r_x = \frac{[CH_2Cl_2][1\text{-Cl-}x\text{-Br-}C_5H_{10}]}{[1\text{-}ClC_5H_{11}][CHBrCl_2]}$$

$$[2] \quad r_t = \frac{2[CH_2Cl_2][C_5H_{10}ClBr]_t}{11[1\text{-}ClC_5H_{11}][CHBrCl_2]}$$

$$[3] \quad q_x = \frac{[1\text{-Cl-}x\text{-Br-}C_5H_{10}]}{[1\text{-Cl-1-Br-}C_5H_{10}]}$$

Alternatively, the relative reactivity of H-abstraction for each position with respect to the first position in 1-chloropentane, defined as the q-value, could be calculated as in eq. [3]; calculated q-values of typical experiments for each type of condition are given in Table 2. For the calculation of r_5 and q_5, the multiplication of a factor of 2/3 in eqs. [1] and [3] is required. All the experiments in Table 1 used the same apparatus and a set of standard conditions.

Similar experiments were carried out using *N*-bromotetrafluorosuccinimide (4F-NBS) as the brominating agent under the four types of reaction conditions. Both tetrafluorosuccinimide (4F-SH) and 4F-NBS were sensitive to moisture and light; reactions with water led to the rapid formation of tetrafluorosuccinic acid as the final product. Therefore, the preparation of the starting solutions was carried out inside a darkened dry box. While the bromination products, 1-chloro-*x*-bromopentane and $CHBrCl_2$, were the same as those obtained above, $BrCF_2CF_2CONH_2$ (**2**) was isolated in the photolysis of 4F-NBS alone, and $Br(CCl_2CH_2)_nCF_2CF_2CONH_2$ (**3**), where n = 1 and 2, was obtained in the photolysis of 4F-NBS + DCE. It should be mentioned that the addition product of 4F-NBS and DCE, the compound corresponding to **1**, was not obtained. The latter products **3** were obtained as a mixture of the products with n = 1 and 2 and were derived (17) from the reaction of the ring-opened radical $^{\bullet}CF_2CF_2CONCO$ (4F-PI$^{\bullet}$) (see eq. [5]). Both amides **2** and **3** were isolated since the corresponding isocyanates rapidly underwent hydrolysis and decarboxylation. The structures of these new products were assigned on the basis of their MS and ^{19}F NMR spectra (Table 5). By analogy with the NBS cases, the same apparatus and processes were maintained and the yields of the products were determined from several experiments in each series; their q-values and r-values were calculated (Tables 2 and 3).

It should be noted that 1-chloro-5-bromopentane was formed in insignificant amounts except in the bromination by Br$^{\bullet}$ atom chain processes (Br_2 + K_2CO_3) under Type IV conditions as

in expts. 7, 8 and 19, 20; the r_5-values in these experiments are small but reproducible. In view of reports (3, 8) that the corresponding r-value of the Br$^\bullet$ chain process toward neopentane and CH_2Cl_2 is 0.02–0.1, the r_5-value of about 1.1 must indicate an unusual reactivity of the methyl group of 1-chloropentane toward Br$^\bullet$; this anomaly is worthy of investigation in future. The pattern of r-values obtained at 20°C (except that of r_5-values) is characteristically similar to those of the previous publications using other substrates (1–3, 9); the relative reactivities are highest with the S$^\bullet$ reaction (Type I conditions) and lowest with the Br$^\bullet$ reactions (Type IV conditions), and those from the NBS + Br_2 system (Type III or II conditions) are in between these two extremes but closer to the latter (9). Previously this reactivity pattern was interpreted as a simple

competition of S• and Br• propagation processes (1, 2), and led to the suspicion that an additional propagating radical in the NBS + Br_2 system is not required. The relative reactivities (Tables 1–3) show that S• preferentially abstracts hydrogens from the methylene groups, but not from the terminal methyl group, of 1-chloropentane over those of CH_2Cl_2, and does so more selectively from the CH_2 at the C4 and C3 (in that order) positions than does Br•.

The brominations with Br_2 + K_2CO_3 (Type IV) and with NBS (or 4F-NBS) + Br_2 (Type III) were also investigated at 10° and 0°C. The data were treated as usual to give the *r*-values and *q*-values that are shown in Tables 1 and 2 for NBS experiments and in Tables 3 and 2 for 4F-NBS experiments. It is noteworthy that at 10°C the *r*-values of the NBS + Br_2 system under Type III conditions dramatically decrease to levels below the *r*-values of the Br• reaction, although the corresponding *q*-values do not show such drastic changes. However, at 0°C the decrease of the *r*-values is abruptly attenuated and they even show slight increases in some cases, although all *r*- and *q*-values are still far below these levels at 20°C. This trend hints that a counterbalancing factor starts to operate at 0°C; this factor is believed to arise from rapid changes of viscosity around this temperature range. The experiments at 10°C and 0°C were repeated several times and average values are shown in Tables 1 and 3.

Discussion

The results shown in Tables 1–3 for the photodecomposition of either NBS or 4F-NBS in the presence of 1-chloropentane as a substrate under four different types of conditions at 20°C are generally comparable with those using neopentane or cyclohexane as a substrate (1–9) but differ somewhat in the pattern of the reaction with DCE. As the percentage yields of 4F-BPI are higher than those of BPI under comparable conditions in the corresponding reactions (Tables 1 and 3), undoubtedly 4F-S• ring-opens to form 4F-PI• considerably faster than does S• to give PI•. Thus, **3** is derived from the addition of 4F-PI• to DCE (17) as in eq. [5], but **1** is formed from that of S• to DCE as in eq. [4]. The addition of PI• to DCE is probably much slower

4F-PI•
$\rightarrow {}^{\bullet}CCl_2CH_2CF_2CF_2CONCO \rightarrow \mathbf{3}$

than the reaction of PI• with Br_2 or NBS. In the present cases, the formation of **1** and **3** is undoubtedly facilitated by a high concentration of DCE. The low %BPI in expts. 1 and 2 (Table 1) under Type I conditions no doubt shows that S• is efficiently scavenged by DCE at a concentration >0.25 M; this pattern is analogous to the scavenging of S• with a high concentration of benzene (10, 18).

The results (Tables 1 and 3), however, share a number of similarities with those of NBS photodecompositions using cyclohexane as the substrate (9). First of all, the photolysis of NBS or 4F-NBS in the presence of a Br_2 and Br• scavenger (Type I conditions) yields the highest amount of ring-opened products, obviously arising from the enhanced ring opening upon direct excitation (9, 10) of NBS (or 4F-NBS). It should be mentioned that the %BPI in expts. 1 and 2 is considerably higher if **1** is not formed. Secondly, the direct photolysis of NBS (or 4F-NBS) in the absence of DCE (Type II conditions) yields a lesser amount of BPI (or 4F-BPI) than that in the presence of DCE (Type I conditions). This has been shown to arise from the formation of Br_2 during the photolysis (9) of NBS alone, in which Br_2 intercepts S• to prevent the ring opening. Thirdly, Br• induces decomposition of NBS (or 4F-NBS) under Type III conditions (expts. 5, 6 and 17, 18), to cause the formation of BPI (or 4F-BPI), indicating the generation of S• (or 4F-S•) and subsequent ring-opening in the process. The last two conclusions both support the previous proposal, of equilibria (9–12) that can be approached either from S• + Br_2 or Br• + NBS as shown in Scheme 2. In the ensuing discussion, NBS, SH, S•, PI•, and BPI are used on the understanding that they also represent their tetrafluoro analogues, unless specified otherwise.

The examination of the relative reactivities per hydrogen, *r*-values, provides information on the nature of propagation processes under different conditions; in particular, those in the presence of Br_2 are of great interest to us. The r_1–r_4 values in the Br• initiated photodecomposition of NBS under Type III conditions at lower temperatures (expts. 9, 11, 21, and 22) exhibit levels lower than the corresponding *r*-values of Br• H-abstraction under Type IV conditions (expts. 10 and 12). The observations clearly rule out the propagation by simple competition of S• and Br• chain processes, and *indicate the presence of another propagating radical in addition to S• and Br• radicals under Type III conditions*. Secondly, the anomalous bromination reactivity of Br• at the C5 position of 1-chloropentane under Type IV conditions provides independent support for this claim. The insignificant r_5-values under Type III conditions in comparison to low but reproducible r_5-values under Type IV conditions (Tables 1 and 3) *unambiguously show that Br• is not the major propagating radical under Type III conditions, and that the* r_1–r_4*-values in the cases under Type III conditions do not represent the Br• reactivities*; this conclusion is significant since only Br• is generated by the photoexcitation of Br_2 under Type III conditions. Thirdly, in the photolysis of NBS alone under Type II conditions, in spite of the fact that both S• and Br• are generated by photoexcitation, the *r*-values in expts. 3, 4 and 15, 16 are clearly inconsistent with those arising from a mixture of S• and Br• chain propagations determined under Type I and IV conditions respectively. A simple competition of propagation processes by S• and Br•, even after subtraction of the S• ring-opening reaction, would give higher estimated *r*-values than these observed values. A similar trend of *r*-values has been noted in the photodecomposition of NBS in the presence of cyclohexane under Type II conditions during which the formation of Br_2 has been established (9).

The three conclusions drawn from the *r*-values in Tables 1 and 3 uniquely indicate that S• and Br• generated in the photobromination with NBS in the presence of Br_2 under Type II and III conditions must be rapidly modified in their nature and reactivities, leading to the appearance of a new radical chain carrier. We advocate the equilibria and reactions proposed previously (9) as shown in Scheme 2, and suggest that the modified chain carrier is BRC derived from either S• or Br• in the equilibria under these conditions. It should be mentioned that the basic concept of the equilibria has been proposed before (11, 12) and that in the NBS + Br_2 reaction system a simple competition of Br• and S• processes was shown to pose difficulties in explaining certain experiments, in recent publications from Walling's and Tanner's groups (1, 8).

It follows that the *r*-values under Type II and III conditions (Tables 1 and 3) consist mainly of the intermolecular relative reactivities of BRC toward 1-chloropentane and CH_2Cl_2; the *r*-values of expts. 9, 11, 21, and 23 should closely represent those of BRC at these same temperatures. It is noted that these

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

r-values of BRC are very similar to those of Br• H-abstraction under Type IV conditions. We assume that the structure of BRC is somewhat similar to that proposed by Walling *et al.* (8) in having two non-equivalent bromine atoms, one of which may have a pentavalent configuration. The bromination of a substrate (RH) by BRC may be represented by an overall reaction as shown in Scheme 2. It is reasonable to expect that a BRC is more stabilized and possesses a longer lifetime in which to show its reactivities at a lower temperature; at a higher temperature, the dissociation of BRC is faster, to show more of S• and Br• reactivities. It is very fortunate indeed that the *r*-values of the intermolecular H-abstraction by BRC from 1-chloropentane under the present conditions are lower than those by Br• under comparable conditions, and the inversion of *r*-values occurs in the experimentally readily accessible region of 0–20°C. In the photobromination of cyclohexane with NBS + Br_2 in CH_2Cl_2, it is shown that such an *r*-value inversion does not occur even at −20°C. In an intramolecular H-abstraction, the corresponding BRC reactivities can be detected even at room temperature (12) because an activation energy for such intramolecular reactions is generally small and is probably much smaller than the barriers of BRC dissociations.

As shown by its *r*-values (expts. 13 and 14), the tetrafluorosuccinimidyl radical (4F-S•) abstracts H-atoms more vigorously from 1-chloropentane than does S• (expts. 1 and 2). However, 4F-S• is undoubtedly more electrophilic than S•, as shown by the higher q_2/q_3 ratio (expts. 1, 2 and 13, 14 in Table 2). It appears that the electron-withdrawing properties of fluorine atoms may also contribute to the facile ring opening of 4F-S•; undoubtedly, it is these same properties that make 4F-PI• attack DCE more vigorously. The present results have clearly established the presence of a new chain carrier derived from a modification of Br• or S• in intermolecular H-abstraction; an analogous case in intramolecular H-abstraction has been published by us (12). Indeed, such phenomena appear to be fairly common in radical reactions (13). In the present case, no doubt both NBS and Br_2 can participate in the complex formations that make the reactions of this system unusually complicated. Even in simple radical reactions, one should be aware of a possible participation of solvent molecules, in a complex formation, that may not be totally innocent in terms of mechanistic effects.

Experimental

General conditions and chemicals

The ultraviolet spectra were taken with a Perkin–Elmer 559 spectrophotometer and GC–MS with a Finigan 4021 or a Shimadzu QP 1000 mass spectrometer; GC analysis was carried out with a Shangfen model 102GD gas chromatograph equipped with a glass column (0.3 cm × 300 cm) with a packing of 10% polyethylene glycol (PEG). ^1H NMR spectra were taken with a Varian EM-360 (at 60 MHz) or a Varian XL-200 (at 200 MHz) using TMS as the internal standard, and ^{19}F NMR spectra with a Perkin–Elmer R-32 (at 90 MHz) using CF_3CO_2H as the internal standard.

NBS was recrystallized from hot water and kept in a desiccator over P_2O_5. Br_2 was redistilled. 1-Chloro-5-bromopentane was purchased from Aldrich Chemical Co., Milwaukee, U.S.A. Both CH_2Cl_2 and 1-chloropentane were purified according to the published method (19). Argon was successively passed through 5A molecular sieves, Ag molecular sieves, and Pd molecular sieves to remove O_2 and moisture.

Preparation of N*-bromotetrafluorosuccimide (4F-NBS)*

Tetrafluorosuccinic diamide, $NH_2COCF_2CF_2CONH_2$ ((9.6 g, Fluorocarbon Group, Shanghai Institute of Organic Chemistry), mp 258–260°C (lit. (20) mp 259.8–260.3°C); ^{19}F NMR −42 ppm (s)), and concentrated H_2SO_4 were treated according to Henne's method (20) to give tetrafluorosuccinimide (4F-SH, 5 g). The crude product was redistilled at bp 82°C/15 Torr (1 Torr = 133.3 Pa) to afford a white solid; mp 66°C in a capillary tube (lit. (20) mp 66.0–66.5°C); ^{19}F NMR −49 ppm. This product (7.5 g) was brominated with bromine (10 g) and AgO (8 g) according to the published method (21) to give 4F-NBS (79% yield), which was sublimed; mp 51–52°C in a capillary tube; UV λ_{max} 231.2 nm (log ε, 3.2); ^{19}F NMR −45 ppm. Owing to the great sensitivity to light and moisture, both 4F-NS and 4F-NBS were handled in a darkened dry box.

Photobromination

CH_2Cl_2 or its solution containing a suitable concentration of Br_2 or DCE, followed by 1-chloropentane, was added to an NMR tube containing the desired amount of NBS (or 4F-NBS). The tube was wrapped with aluminum foil and capped with a septum. The solution was purged with deoxygenated and dried argon through a needle inserted through the septum; the use of either a stainless steel needle or a Teflon needle caused no difference in the results. The light source was a Hanovia medium pressure mercury lamp (200 W) filtered through a Pyrex filter or a JB-400 filter (cutoff <400 nm, Shanghai Color Glass Works). The lamp was placed in a cooling sleeve, which was placed in a thermostated bath. The NMR spectrum of the solution was recorded at 200 MHz before and after photolysis and the % yields of NBS (singlet at 3.0 ppm), SH (singlet at 2.80 ppm), BPI (triplet at 3.20 ppm), and **1** (singlet at 2.9 ppm) were calculated from the integration of the characteristic peaks according to the method described by Walling's and Tanner's groups (1, 8). To the photolysate was added an exact amount of a solution containing bromobenzene as the internal standard in CH_2Cl_2. The solution was treated with an aqueous $NaHSO_3$ solution (5%) and was washed with water twice. The CH_2Cl_2 solution was dried over Na_2SO_4 for GC analysis. At least three injections were made under comparable GC conditions and the ratios of peak area to internal standard area were averaged to give the yields of the particular experiments. For each series, two or more tubes were photolysed, and the average yields were used to calculate *r*-values as shown in Tables 1 and 3.

For experiments using 4F-NBS, ^{19}F NMR spectra were recorded with a Perkin–Elmer R-32 spectrophotometer in a different type of NMR tube and the characteristic ^{19}F peaks at δ −45 ppm (s, 4F-NBS), −49 ppm (s, 4F-SH), −36.86 ppm (t, **2**), and −43.04 ppm (t, **3**) were used to determine the % yields before and after the photolysis. Both 4F-NBS and 4F-SH decomposed rapidly during washings with $NaHSO_3$ solution to give tetrafluorosuccinic acid, which was washed with water; the products, chlorobromopentanes, in the organic phase were analysed by GC.

Isolation of products

For the preparative run, photolysis was carried out in a test tube without NMR monitors. For the photolysis of Br_2 + K_2CO_3 in the presence of 1-chloropentane, the solution, after treatment with $NaHSO_3$ solution, was injected into a preparative GC to separate chlorobromopentanes. 1-Chloro-5-bromopentane was produced in too small yield and was not isolated; it was identified by coinjection into GC analysis with an authentic sample from the commercial source. In the photolysis of NBS in the presence of DCE (0.5 M), the crude products in pentane were filtered through a silica gel column to give fractions containing **1** contaminated by some succinimide. In the photolysis of 4F-NBS in CH_2Cl_2, the photolysate was washed with 5% aqueous $NaHSO_3$ solution and twice with water to decompose 4F-BPI, 4F-NBS, and 4F-SH. Pure β-bromotetrafluoropropionamide (**2**) derived from 4F-BPI was obtained from the organic phase after evaporation of solvent. In the photolysis of 4F-NBS in the presence of DCE (0.5 M), the photolysate was treated as above and the crude product was chromatographed on a silica gel column; **3** was obtained as a mixture of the compounds with n = 1 and 2 and was contaminated with a trace amount of **2**. Both **2** and **3** were derived from the hydrolysis and decarboxylation of the corresponding isocyanates.

Received October 23, 1989

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

VETKA RACHINA, IVA B. BLAGOEVA, IVAN G. POJARLIEFF, and KEITH YATES. Can. J. Chem. **68**, 1676 (1990).

The pK_{BH^+} values for protonation of the ureido groups of the title acids, and for protonation at the 2-carbonyl groups of the product hexahydropyrimidine-2,4-diones, have been determined by standard UV and NMR methods. A bell-shaped dependence of the observed rate constants on H_2SO_4 concentration was found for both the ring-closure and ring-opening directions. This medium dependence is satisfactorily reproduced by means of rate equations based on the excess acidity treatment, providing account is taken of unproductive protonation equilibria. The derived slope parameters (m^+) for the ring-closure direction indicate that the slow step involves proton transfer from nitrogen rather than to oxygen. For the ring-opening or hydrolysis reactions, the corresponding slope parameters (m^+m^*) are characteristic of similar reactions known to proceed with slow C—N scission concerted with proton transfer.

Key words: mechanism, hydrolysis, cyclization, acid catalysis.

VETKA RACHINA, IVA B. BLAGOEVA, IVAN G. POJARLIEFF et KEITH YATES. Can. J. Chem. **68**, 1676 (1990).

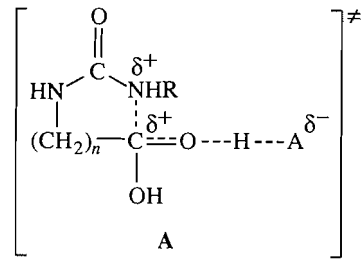
Faisant appel à des méthodes RMN et UV standard, on a déterminé les valeurs de pK_{BH^+} pour la protonation des groupements uréido des acides mentionnés dans le titre ainsi que pour la protonation des groupements carbonyles en position 2 des hexahydropyrimidine-2,4-diones. Tant pour la fermeture que pour l'ouverture du cycle, on a observé une relation en forme de cloche entre les constantes de vitesse et la concentration en H_2SO_4. Si on tient compte de l'équilibre de protonation qui n'est pas productif, on peut assez bien reproduire cette relation avec le milieu à l'aide d'équations de vitesse basées sur un d'excès d'acidité. Les paramètres de pente (m^+) que l'on dérive pour la direction de la fermeture de cycle indiquent que l'étape lente implique un transfert de proton à partir de l'azote plutôt qu'à l'oxygène. Pour les réactions d'hydrolyse ou d'ouverture de cycle, les paramètres de pente correspondants (m^+m) sont caractéristiques de réactions semblables qui sont connues et qui procèdent avec une scission lente de la liaison C—N, concertée avec un transfert de proton.

Mots clés : mécanisme, hydrolyse, cyclisation, catalyse acide.

[Traduit par la revue]

Introduction

The ring closure of 3-ureidopropanoic acid to dihydrouracil was found previously (2) to be reversible to aqueous HCl solutions, and from acidity function criteria (3) and other evidence it was concluded that the reverse, ring-opening reaction proceeds with slow attack of water on the protonated form of the dihydrouracil. This is analogous to the currently accepted mechanism of acid-catalyzed amide hydrolysis (4). Subsequently, a similar conclusion was drawn for the closely related reactions of acetylthiourea and thiohydantoin (4). More recently, however, Guler and Moodie (5), on the basis of ^{18}O-exchange experiments, have shown that the slow step in the cyclization of 5-methylhydantoic acid to the corresponding hydantoin is the formation of the C—N bond and not the breakdown of the tetrahedral intermediate, which is inconsistent with the above conclusions with respect to the ring-opening step in related systems. In the pH region, these authors (5) observed general acid catalysis and proposed a concerted mechanism, illustrated by the transition state **A**.



A

Subsequent studies (6) with strained hydantoic acids, which react rapidly at room temperature, also demonstrated general acid catalysis with Brønsted α values of 0.3 and 0.6 for 5-methyl and 5-phenyl substitution respectively, thus confirming the concertedness of heavy atom reorganization with proton transfer. Considerations of the effect of structure on the basicity of the nitrogen atom, in terms of its effect on Jencks – More O'Ferrall type diagrams (7), were all in agreement with the direction of change of α with structure expected for transition state **A**, and that which was observed experimentally (6).

However, for cyclization reactions in H_2SO_4 solutions, where a similar mechanism presumably operates, the m^+m^*

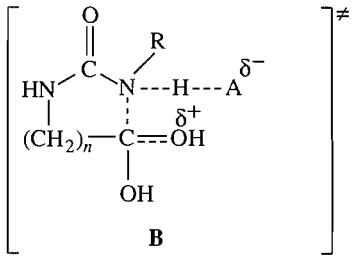
values obtained from an X-function treatment (5, 8) were 0.64 and 0.4 for the 5-methyl- and 5-phenylhydantoic acids respectively. If these parameters are interpreted in a similar way to Brønsted α values, this indicates the alternative and kinetically equivalent process of specific acid – general base catalysis, going through the more likely transition state **B**, especially where a very weakly basic ureido nucleophile is involved.



B

The above discrepancy posed a number of questions as to its origin, particularly: is the same mechanism operative in moderately concentrated H_2SO_4 solutions as in HCl, and can acidity function treatments be successfully applied to differentiate between possible concerted reactions where slow proton transfers between heteroatoms are involved? We now wish to report on ring-closure reactions of β-ureido acids in dilute to 70% sulfuric acid solutions, as shown in Scheme 1. The ring

closures of 3-ureidopropanoic acids such as **1** and **3** have the advantage of being measurably reversible, unlike hydantoic acids where the equilibria lie far on the hydantoin side, and hence can be studied kinetically in both directions. Also the hydrolysis reactions of **2** and **4** can be compared with the better

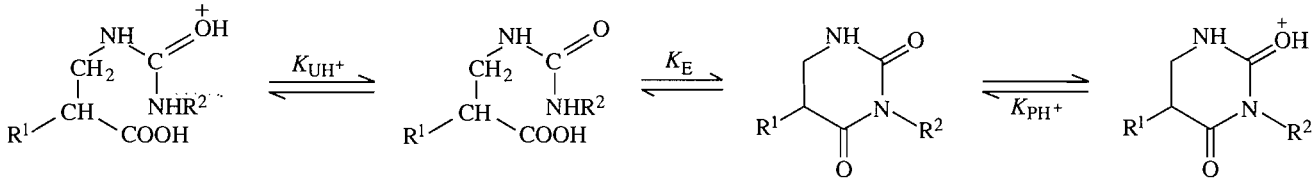
known amide hydrolysis mechanism. The effect of changing the N-substitution from methyl to phenyl was again intended to give information on the effect of N-basicity on transition-state structure. The 2-methyl derivatives **3** and **4** were chosen because the apparent equilibrium constant for this reaction is close to unity.

Results

Rate measurements

Plots of the observed first-order rate constants for both ring closure (k_f) and ring opening (k_r) versus % H_2SO_4 (w/w) are shown in Fig. 1. In the acidity range studied (0–70% H_2SO_4), both reactions are accompanied by the unproductive (and thermodynamically favoured) protonations shown in Scheme 2.



UH^+ U P PH^+

SCHEME 2

Therefore the observed rates of cyclization (V_f) and ring opening (V_r), and overall equilibrium constant are given by

$$V_f = k_f^{obs}([U] + [UH^+])$$

$$V_r = k_r^{obs}([P] + [PH^+])$$

$$K_e^{obs} = \frac{([P] + [PH^+])}{([U] + [UH^+])}$$

Thus corrections are needed for these unproductive ionizations.

pK determinations

The pK values of **1**–**4** listed in Table 1 were obtained using the excess acidity treatment of Cox and Yates (9). This has recently been shown (10) to be equivalent to the Bunnett–Olsen method (11), provided correct values of C_{H^+} are used in the latter treatment. The pK values are the thermodynamic values extrapolated to $X = 0$, obtained from the expression

$$\log [BH^+]/[B] - \log C_{H^+} = m^*X + pK_{BH^+}$$

These pK values, because of the extrapolation involved, are frequently sensitive to errors in determining m^* and the ionization ratio terms $[BH^+]/[B]$. However, the bases studied here are not very weak, so that the extrapolations involved are not that long. The *N*-methyl compounds **1** and **2** were studied via ^1H and ^{13}C NMR spectroscopy since the only changes observed in UV spectra with acidity were at the short wavelength (ca. 200 nm) end of the spectrum where accurate measurements are difficult. The variation in ^{13}C chemical shift of the 2-carbon gave reasonable sigmoidal behaviour with acidity, and thus was used to determine pK (see experimental section).

The *N*-phenyl compounds **3** and **4** were studied by standard UV measurements (see experimental section), using the procedure of Katritzky *et al.* (12) to account for spectral solvent dependencies, as described in detail in ref. 8.

We have used three criteria for the reliability of the pK values obtained: linearity of the Cox–Yates plots; the derived statistical parameters for m^*; and the fit of the recalculated to the observed spectral changes with acidity. In addition, the changes in basicity shown in Table 1 as a function of structure are very reasonable, either in terms of *N*-methyl versus *N*-phenyl substitution, or acyclic urea versus uracil formation.

Acidity dependence of the rate constants

The reactions (cyclization and ring opening) were sufficiently slow that they could be conveniently followed kinetically at 70°C. The observed rate constants were corrected for the unproductive ionizations discussed in the previous section, as in

$$k_{corr} = k_{obs}(1 + [BH^+]/[B])$$

where

$$[BH^+]/[B] = \text{antilog}\,(m^*X + pK_{BH^+} + \log C_{H^+})$$

The X-function and pK_{BH^+} values were temperature corrected to 70°C as recommended by Cox *et al.* (13). Values of log C_{H^+} at 25°C were used unchanged, since it has been shown that temperature corrections over the range studied would be very small or negligible (9).

The rate constants for the cyclization direction (k_f), which are the more important in terms of the present mechanistic comparisons, were treated by both the Cox–Yates (C–Y) (14) and Bunnett–Olsen (B—O) (15) treatments, as in eqs. [1] and [2] respectively.

[1] $\log k_f^{corr} - \log C_{H^+}$

[2] $\log k_f^{corr} + H_0 = \phi(H_0 + \log C_{H^+})$

In both cases linear plots were obtained (see Fig. 2), without including any water activity terms as is reasonable in terms of

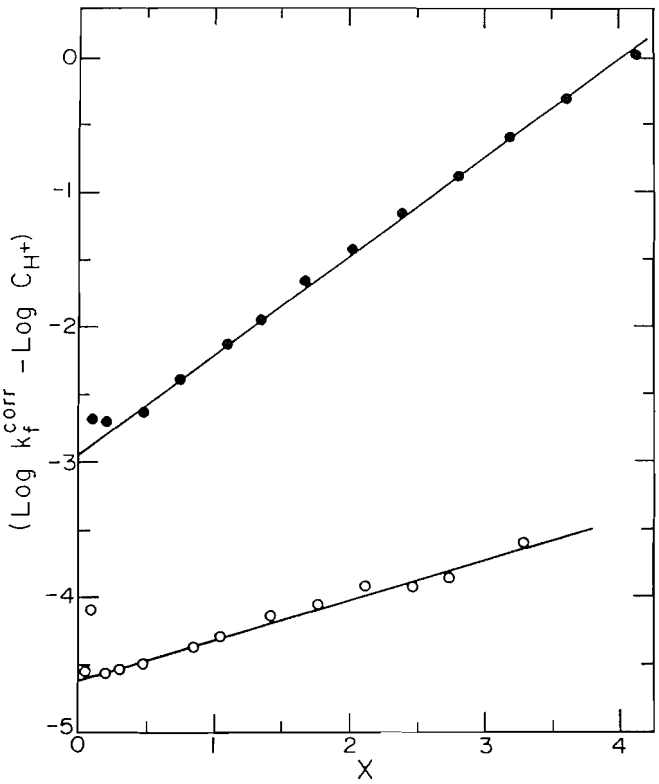

FIG. 2. Plots of (log k_f^{corr} − log C_{H^+}) versus the X-function for the ring closure of **1** (●) and **3** (○).

Scheme 1 for reaction in the forward direction. The medium-independent rate constants k_2^0 and the slope parameters ($m^*m^\ddagger$ or ϕ) are given in Table 2, along with the appropriate statistical parameters. Given the previously demonstrated (14) equivalence between $m^*m^\ddagger$ and $(1 - \phi)$, the two kinetic treatments give essentially the same results for both k_f and k_r. Since the former is somewhat easier to interpret mechanistically, only $m^*m^\ddagger$ will be used in subsequent discussion.

The rate constants in the ring-opening direction (k_r) were also treated by both the C–Y and B–O approaches, but the correlations were less clear-cut. The unmodified eqs. [1] and [2] led to downward curving plots, which is not reasonable either in terms of the negative $m^*m^\ddagger$ values implied or in terms of the stoichiometry of Scheme 1. Incorporation of explicit water activity terms as in eqs. [3] or [4]

[3] $\log k_+^{corr} - \log C_{H^+} + n \log aH_2O = m^*m^\ddagger X$

[4] $\log k_r^{corr} + H_0 + n \log aH_2O = \phi(H_0 + \log C_{H^+})$

improved the fit in some, but not all, cases. Also, although the

slope parameters $m^*m^{\neq}$ became positive using eq. [3], there was no significant difference in linearity[2] between the cases of $n = 1$ and $n = 2$, as shown in Table 2. It therefore seems to be the case that, although a water activity term should be included, there is no clear-cut answer as to the molecularity of the ring-opening reaction in terms of water, unlike the situation found with ester and related hydrolysis reactions. The problem can be illustrated using the Yates r-parameter (17) modification of the original Bunnett w-parameter treatment (18) as shown in Fig. 3, where (log $k_r - H_s$) is plotted against log α_{H_2O}. The plots are again curved, as found in r-plots for amide hydrolysis (17*b*, 19), and there is a clear indication of a sharp break in water–activity dependence between reactions in dilute ($r \sim 4$) and more concentrated ($r \sim 1.5$) acid solutions. This again is reminiscent of amide hydrolysis, where, as the availability of water is strongly decreased in more concentrated acids, the mechanism changes from $r = 3$ to $r = 1$ in terms of its water dependence. Since the emphasis in the present paper is on comparisons of five- and six-membered ureido derivatives, and k_r cannot be studied kinetically in the former case, the kinetic treatment of these hydrolysis rate constants was not pursued further.

Acidity dependence of the equilibrium constants

The effect of changing acidity on the observed equilibrium constants is not very pronounced, as shown in Fig. 4. The equilibrium between the *N*-methyl compounds (**1** ⇄ **2**) shifts towards **1** with increasing acid concentration, as observed previously for dihydrouracil itself (2), and is explainable in terms of the protonation of the relatively basic methylureido group. A similar effect is observed for the equilibrium **3** ⇄ **4**, but is only exhibited at higher acidity because of the weaker basicity of the phenyl-ureido group. However, in both cases log K_{obs} changes by less than one unit over the entire range 0–70% H_2SO_4. The problem is that the equilibria of interest (Scheme 1) are complicated by the two unproductive protonations of Scheme 2. Taking these into account leads to the following expression for K_{obs}:

[2]This is due in part to the approximate linearity of the excess acidity function, X, with log aH_2O (slope ca. 0.3) in the region of acidities studied.

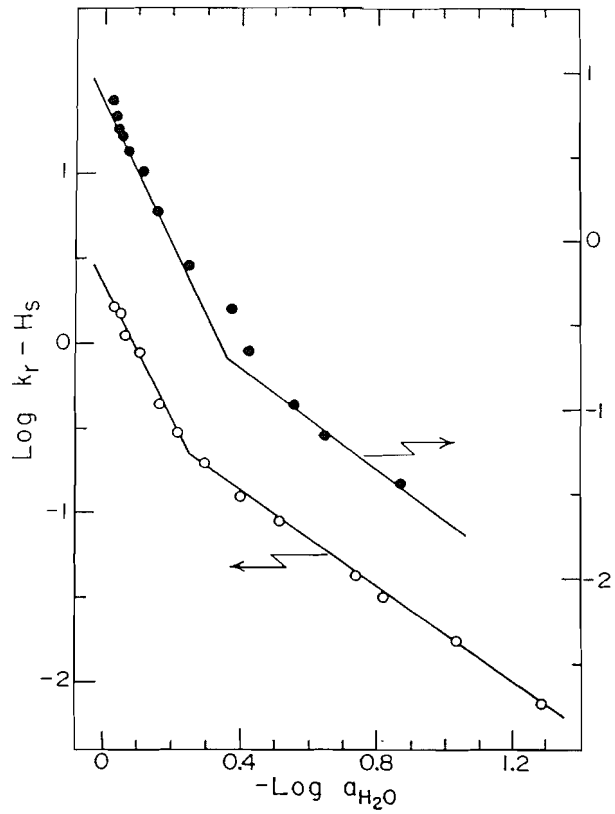

FIG. 3. Yates r-plots for the hydrolysis of **2** (●) and **4** (○).

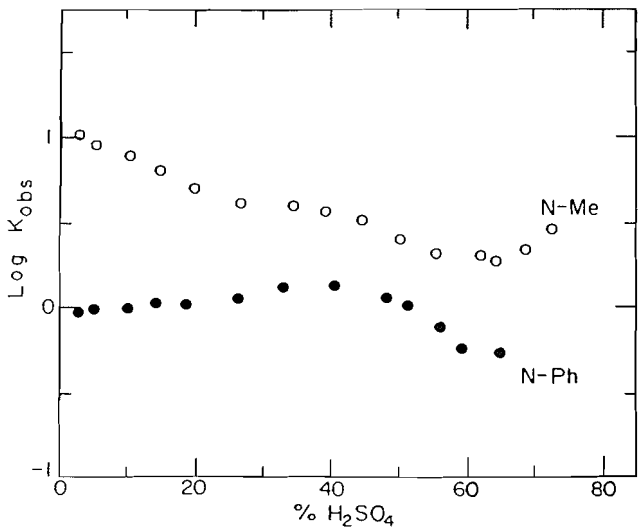

FIG. 4. Medium dependence of the equilibrium constants (log k_{obs}) on acid concentration. **1** ⇄ **2** (○); **3** ⇄ **4** (●).

$$[5] \quad K_{obs} = \left(\frac{(h_3{}^{P} + K_{PH^+})K_{UH^+}}{(h_s{}^{u} + K_{UH^+})K_{PH^+}}\right) \cdot \left(\frac{K_e f_u}{f_p a_{H_2O}}\right)$$

where the h and f terms refer to the relevant acidity functions and activity coefficients for the neutral species. The last term on the right of eq. [5] is the apparent equilibrium constant for the unprotonated species (as shown in Scheme 1), i.e., U ⇄ P, as given by eq. [6].

$$[6] \quad K_{app} = K_{obs}\frac{(1 + I_p)}{(1 + I_u)} = \frac{K_e f_u}{f_p a_{H_2O}}$$

Thus a plot of (log K_{app} + log aH_2O) versus X should give as slope the acidity dependence of log f_u/f_p and as intercept log K_e. The correlations are reasonable, as shown in Table 3. The slopes, which are equal to m_e, are positive in both cases, as expected because of the greater hydration requirements of the ureido acids than the uracils. The m_e values obtained should be equal to the difference between the kinetic $m^*m^{\ddagger}$ values for k_f and k_r given in Table 1, which is found to be the case.

Discussion

The pK_{BH^+} value of **1** (−0.85) is close to that reported for 5-methylhydantoic acid (5), if the latter is corrected by 0.3 units because of the mis-anchoring of the original H_A scale (20) (−1.06). Both values are significantly lower than the kinetically determined pK value of −0.25 reported for 3-ureidopropanoic acid (2), which is probably due to some loss of planarity in 1,3-disubstituted ureas. A similar effect is found when the pK_{BH^+} of the phenylureido acid **3** (−1.83) is compared with that for phenylurea (−1.22) (21). No reliable pK_{BH^+} values have been reported for the corresponding uracil derivatives. An H_0 value of −4.7 for the half-protonation of dihydrouracil has been reported (26) in $HClO_4$, and from somewhat uncertain ionization ratio determinations the Bunnett–Olsen treatment had given a pK_{BH^+} value of −2.54 (ϕ = 0.55) (2). The latter values are close to the values obtained in this work for **2** (pK_{BH^+} = −2.6, ϕ = 0.48). The value for **4** is significantly more negative (pK_{BH^+} = −3.56), as expected for the base-weakening effect of *N*-phenyl, rather than *N*-methyl substitution. It is interesting that effects of ring closure on the basicity of **1** and **3** are practically identical, as shown in Table 1. In addition, the decreases in $m^{\ddagger}$ for both **1** → **2** and **3** → **4** are in the expected direction, because of the higher hydration requirements of the ureido acid form. The m^* values for the protonation of the pyrimidinediones **2** and **4** fall in the usual range observed for amides (22).

Because of their structural similarities to amides and ureas, it is instructive first to consider possible hydrolysis mechanisms for pyrimidinediones (such as **2** and **4**) before examining the reaction in the ring-closure direction. The overall scheme including all reasonable intermediates is shown in Scheme 3.

Currently it is considered that in $A_{AC}2$ type ester (13) and amide hydrolysis (3), although T_0^+ can be formed by rate-determining attack of water on the protonated substrate, its presence can be avoided in dilute to moderately concentrated acids by the further participation of water (as a base) in a one-step process leading directly to T_0.

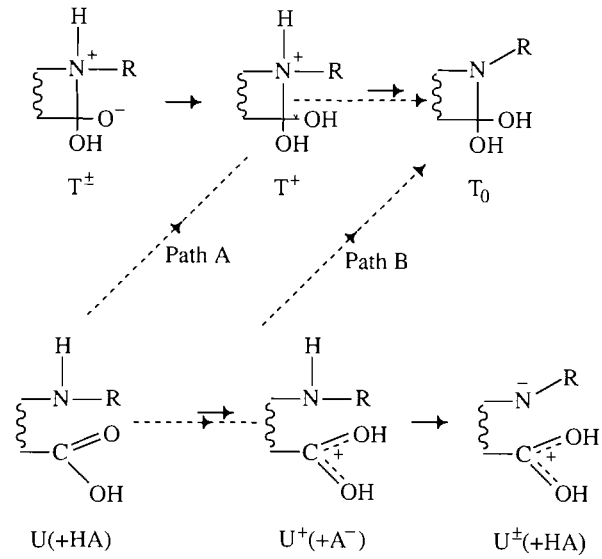
The parameters obtained from acidity function treatment of **2** and **4** are not very different from those observed for acid-catalyzed amide hydrolysis ($A_{AC}2$) (3) and, as previously mentioned, dihydrouracil (2) and acylthiourea (4) hydrolyses also behave similarly: with the latter, the interpretation of rate-determining water attack on the protonated substrate was consistent with other evidence, such as high negative $\Delta S^{\neq}$ values, inverse solvent isotope effect, and substituent effects in the acyl moiety (2, 4).

However, there is evidence for an alternate mechanism in the case of 3-methylhydantoin, where Guler and Moodie (5) observed that ^{18}O-exchange is at least 10 times faster than ring opening.[3] This strongly supports the idea that C—N bond breaking or formation is involved in the rate-determining steps of acid-catalyzed ring opening and ring closing. Furthermore, the same authors (5) observed general acid catalysis, whereas typical $A_{AC}2$ amide hydrolysis is specific acid catalyzed (3). In addition, one of us (2) has found that cyclization of sterically strained hydantoic acids showed general acid catalysis with Brønsted coefficients $0 < \alpha < 1$. This is generally believed to indicate proton transfer concerted with heavy atom reorganization.

An important question at this point is, how likely is it that the above five-membered ring compounds (hydantoins) hydrolyse by a different mechanism from the six-membered rings (uracils) of the present study? Five-membered rings are usually more difficult to open, and this can make ring formation rate determining on changing from six- to five-membered ring compounds, as shown previously for 3-(2′-aminophenyl) propanoic (24) and 2-aminophenylacetic acids (25). However, decreased basicity of the amino group in the hydrolysis direction tends to shift the rate-determining step in Scheme 3 from formation of T_0 or T_0^+ to one of the subsequent steps. Since anilines are a borderline case (26), then the much more weakly basic amino group of the present ureido systems is most unlikely to be affected by ring size.

Hydrolysis of **2** in ^{18}O-enriched 0.5 M HCl solutions showed that its rate of ^{18}O-exchange is 7.85 times faster than the rate of hydrolysis (**2** → **1**). This demonstrates that the process T → U occurs about 16 times faster than T → P, thus proving that C—N bond scission is also rate determining for the six-membered ring compounds.

Since the mechanism of hydrolysis of both hydantoin and uracil derivatives involves rate-determining C—N bond breaking, as opposed to the standard $A_{AC}2$ mechanism for amide hydrolysis, then are the acidity function parameters $m^*m^{\neq}$ or ϕ able to distinguish between such processes? The answer is certainly no, since the $m^*m^{\neq}$ or ϕ parameters listed in Table 2 fall within the range observed (3) for various types of amide hydrolysis, as do the m^* for the protonation step itself (see Table 1). A major problem, alluded to earlier, is that amide-type hydrolyses are more complex in terms of their medium dependence than other types of hydrolysis, as shown earlier by Cox and Yates (3*a*), and as illustrated by Fig. 3. One thing seems clear, however, from all the evidence; that is, in Scheme 3 the transition state in the ring-opening direction is almost certainly at T_0 or to the right of T_0. Therefore the transition state in the ring-closure direction must lie between T_0 and the starting ureido acid.



SCHEME 4

The possible pathways for ring closure are as shown in Scheme 4, since this approach will allow clearer consideration of alternate route diagrams of the Albery–Jencks – More O'Ferrall type (7).

First of all, pathways leading through $T^{\pm}$ can be neglected. Since the ureido nitrogen is very weakly, and the O^- group very strongly basic, this will represent a very high energy species. Similarly, the species $U^{\pm}$ will probably be even higher in energy than $T^{\pm}$ and can also be neglected. This means that the only two viable pathways will be paths A and B (see Scheme 4). Path A represents true general acid catalysis, and path B specific acid – general base catalysis, both being concerted with C—N bond formation. Since these two pathways are kinetically indistinguishable, there are two approaches to try to resolve the problem. One is to consider the effects of N-substitution on the basicity or acidity of the various intermediates. It is clear from Fig. 2 that the ring closure of the *N*-methyl derivative **1** has a substantially higher value of $m^*m^{\neq}$ than that of the *N*-phenyl derivative **3** (0.7 versus 0.3), similar to the situation reported (8) for five-membered ring analogues. On the highly probable assumption that N-substitution will have very little effect on the m^* value for proton transfer to the remote carboxyl group, this means that the $m^{\neq}$ value for proton transfer, following Kresge's interpretation (29) of the slope parameters obtained from the rate–acidity profiles, corresponds to the Brønsted α. This means that **1** will have a higher α, or later transition state, than **3**. As can be seen from Scheme 4 for path A, decreased basicity of N-Ph versus N-Me will increase the degree of proton transfer to nitrogen at the transition state and hence increase α, which is opposite to what is observed. For path B, a similar decrease of N-basicity (or increase of NH-acidity) will increase proton transfer from nitrogen to H_2O at the transition state and hence increase β for this step. Experimentally, this will be detected as a decrease in the observed α, which is what is observed experimentally. Thus path B is clearly favoured by this argument.

A second approach is to construct a three-dimensional Albery–Jencks – More O'Ferrall diagram (7) as shown in Fig. 5. This shows both pathways A and B as in Scheme 4, with the

[3]Dr. Moodie has kindly drawn attention to an error of 4 in the published estimate.

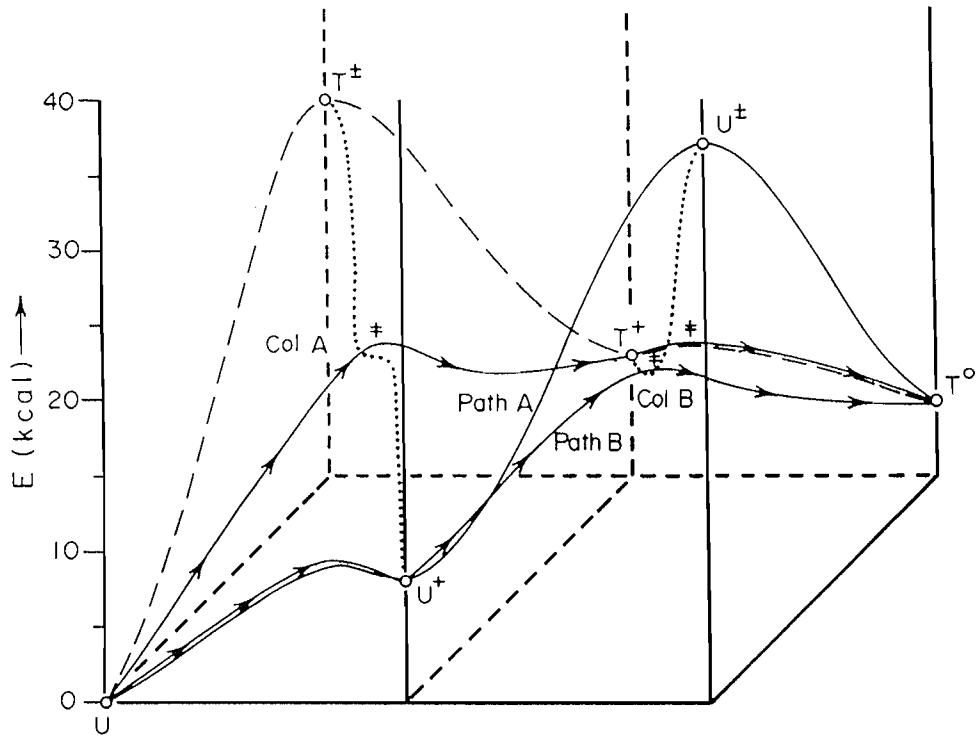


FIG. 5. Energy–reaction coordinate profiles for the ring closure of ureido acid (**U**) to form the neutral tetrahedral intermediate ($\mathbf{T_0}$). See text for description of intermediates and pathways.

heights of the various intermediates in energy terms, relative to that of the substrate, taken as the zero reference point. Estimates of these relative energies were based on p*K* values for related model compounds and on standard bond energy values, as described in the experimental section. It seems clear from the diagram that the saddle-point for path B (denoted Col. B) will be close in energy to, and probably lower than, that of the intermediate T^+, which lies on path A. As far as the saddle-point on path A is concerned (denoted by Col. A), this will either be higher than T^+ (and hence higher than Col. B), which would mean simple general acid catalysis, or it is lower than T^+, which would mean that the transition state for path A would lie between T^+ and T_0. The latter would imply that proton transfer from nitrogen would be rate determining, *after* the acid-catalyzed formation of the C—N bond, which seems most improbable, although it would lead to observed general acid catalysis. In the former, more probable case, if Col. A is higher than T^+, which in turn is equal to or higher in energy than Col. B, this indicates that path B would be the favoured mechanism, as already concluded from comparison of the *N*-methyl and *N*-phenyl derivatives' response to changing acidity. It should be emphasized that the conclusions based on Fig. 5 do not depend on the precise energy values calculated for the various intermediates, but only on the general features of the diagram.

Thus, overall, it seems probable that both six- and five-membered ring formation take place by rate-determining proton transfer from nitrogen, concerted with C—N bond formation, and not slow proton transfer to oxygen as previously assumed. As already mentioned, the variation of Brønsted α values observed for buffer catalysis with strained hydantoic acids, upon replacing N-Me for N-Ph, favour the alternate mechanism, path A. The reasons for this difference are at the present not clearly understood.

Experimental

Spectra

UV spectra were taken on a Carl Zeiss, Jena, Specord UV–VIS spectrophotometer and the NMR spectra on a Bruker WM 250 instrument.

Materials

3-(3[1]-Methylureido)-propanoic acid, **1**, was prepared by adding 0.033 mol of methyl isocyanate to an ice-cooled solution of 0.03 mol of 3-aminopropanoic acid in 15 mL of 2 M NaOH under vigorous stirring. The mixture was heated to ambient temperature for 5–10 min and, after a further 5 min, the pH of the solution was brought to 2 by adding cation-exchanger Dowex W in H^+-form. The resin was filtered and the filtrate evaporated to dryness to yield 1.68 g (38%) of **1**. The pure compound was obtained after repeated crystallization from acetone, mp 132–134°C (dec.). Anal. calcd. for $C_5H_8N_2O_2$: C 41.69, H 6.90, N 19.17; found: C 40.86, H 6.64, N 18.87%. 3-Methylhexahydropyrimidine-2,4-dione was obtained by evaporating to dryness a solution of **1** in 1:1 HCl at 100°C, extracting the residue with hot dioxane, and recrystallizing from ethanol; mp 128.5–129°C (lit. (30) mp 128–129°C). 3-(Phenylureido)-2-methylpropanoic acid, **3**, and 5-methyl-3-phenylhexahydropyrimidine-2,4-dione have been described previously (31).

Sulfuric acid solutions were prepared from analytical grade H_2SO_4 (Riedel de Haen) and distilled water, and the concentrations determined by titration.

pK_{BH^+} determinations; NMR measurements

These were carried out at 19°C and 30°C for **1** and **2** respectively. The p*K* value of **1** was determined from the changes in the ^1H chemical shifts at 250 MHz of the methyl protons with the concentration of the sulfuric acid. The shifts varied from 1.917 to 2.013 ppm for the unprotonated and protonated form respectively. Solutions (2%) of **1** in aqueous H_2SO_4 were used with acetone-d_6 and TMS as external lock and standard respectively. Care was taken to use the same capillaries throughout the series of measurements. The p*K* value of **2** was determined from the changes in the ^{13}C chemical shifts of the 2-CO carbon at 62.7 MHz, using 2% (w/v) solutions of **2** in aqueous H_2SO_4

and D_2O and TMS as external lock and standard respectively. The shifts varied from 135.7 for the unprotonated form to 159.3 for the protonated form.

UV measurements

The pK values of **3** and **4** were determined from the changes in absorbance at 238 nm with sulfuric acid concentration (24 solutions from 2.5 to 78%) at 25.0°C in a temperature controlled cell holder. Stock solutions of **3** and **4** (2×10^{-3} M) in ethanol were used and the final solutions prepared by adding 0.085 mL of **3** or 0.17 mL of **4** to 2.75 mL of the sulfuric acid solution. The changes in the total spectra did not show isosbestic points and were treated as described in Calculations.

Kinetic runs

In the case of **1** and **2** these were carried out in the temperature-controlled cell holder of the spectrometer at 70.0 ± 0.1°C in 10-nm stoppered cells. The reaction was initiated by adding 0.05–0.1 mL of a 2.2×10^{-2} M ethanolic solution of **1** or **2** to 2.75 mL of the H_2SO_4 solution at 70.0°C and monitored at 232 nm where **2** has a higher absorbance than **1**. The reaction of **3** or **4** was carried out in sealed ampoules in a thermostat bath at 70.0°C. The solutions were prepared by making up to 100 mL, 3 mL of an ethanolic 2×10^{-3} M solution of the substrate, with the sulfuric acid solution. The reaction was monitored at 238 nm by the decrease of the absorbance of **3** or the increase of that of **4**. In all cases good isosbestic points were obtained. With all sulfuric acid concentrations the reactions were carried out in both directions and the spectra obtained at $10t_{1/2}$, A_∞, were found to be identical within experimental error. The observed first-order rate constants $k^{obs} = k_f + k_r$, where k_f and k_r are the rate constants for the forward and reverse reactions, were calculated by the least-squares procedure from the linear dependence of $\ln(A_t - A_\infty)$ or $\ln(A_\infty - A_t)$ against time. The apparent equilibrium constant, $K_e^{obs} = k_f/k_r$ was obtained from

$$K_e^{obs} = \frac{A_\infty - A^0_u}{A^0_p - A_\infty}$$

where A^0_u and A^0_p are the initial absorbances of the ureido acid or pyrimidine, respectively, at a particular sulfuric acid concentration. The rate and equilibrium constants were obtained as averages from 2–3 runs. The differences between separate determinations did not exceed 5%. k_f and k_r were derived from the two equations above.

Kinetics of ^{18}O-exchange of 2

These were carried out in 0.5 M HCl at 50.0°C. In a separate experiment, K_e^{obs} and k^{obs} were determined as described above, to be 15.3 and 2.20×10^{-4} s^{-1}, respectively, yielding $k_f = 2.06 \times 10^{-4}$ s^{-1} and $k_r = 1.35 \times 10^{-5}$ s^{-1}.

A 0.5 M solution of HCl in water 20% enriched in ^{18}O was prepared by volume with concentrated HCl and the concentration checked by titration; 11.6 mg (10^{-4} mol) of **2** was dissolved in 0.9 mL of the HCl solution in a stoppered UV cell at 50.0°C in the temperature controlled cell holder. Aliquots of 0.1 or 0.05 mL were withdrawn and quenched in a small flask containing 0.5 mL of water and 0.4 (or 0.2) mL of 0.1 M KOH. The pH was adjusted to 7 with KOH solution and the contents evaporated to dryness. The residue was extracted three times with a total of 4 mL of methylene chloride. The extract was filtered and evaporated and the dry residue analysed on a JEOL JMS-D300 mass spectrometer, electron impact mode, ionization potential 70 eV, ionization current 300 μA, and ion source temperature 170°C. A separate experiment showed that no ureido acid is extracted under these conditions. The extent of exchange was monitored by the ratio of the M^+ to ($M^+ + 2$) peaks, averaged from several determinations and corrected for the natural content of ^{18}O. The rate constant of exchange, $k = 1.06 \times 10^{-4}$ s^{-1}, was calculated from the integrated first-order rate equation after accounting for rapid exchange via the ureido acid.[4]

[4]The hydrolysis of **2** is appreciably reversible, $K_e = 15.3$, so that the exchange can occur via the free acid. From the data in ref. 28 on ^{18}O-exchange in acetic acid, a rate of 0.002 s^{-1} can be calculated at the temperature at which the exchange rate of **2** was measured. Because of this rather high estimate for the exchange of the free carboxy group, the exchange data for **2** were corrected by assuming that every molecule of **1** exchanged before recycling. The ratio P*/P, for the exchange along this pathway, was found by means of the integrated rate equation for consecutive irreversible first-order reactions. The results obtained indicated that this was probably an "over-correction"; plots of ln (% of exchange) against time of the uncorrected data were linear for ca. 70% conversion; however, the rate constants before and after correction differed by less than 20%.

Calculations

*p*K *values*

These were obtained using the Cox–Yates (9) treatment outlined in the results section. In the case of **1** this method was applied in a straightforward fashion to the variation of ^1H chemical shift of the *N*-methyl group with acidity. For compound **2** the ^{13}C chemical shifts of the 2-CO group varied in the expected way up to 79% H_2SO_4, then decreased slightly (i.e., points at 83.5 and 88% H_2SO_4). That this is not due to a medium effect but rather is due to the onset of a second protonation at 4-CO was evidenced by the chemical shift behavior of the latter carbon. The chemical shifts decreased in parallel to the protonation of 2-CO (ca. 70 Hz up to $H_A = -3.5$), and then increased rapidly (by ca. 110 Hz up to $H_A = -5$). Since too few data were available in the high acidity region, no quantitative treatment of this second protonation was attempted. The ionization ratios for the first protonation were obtained by assuring that the maximum chemical shift is ΔBH^+. For compound **3**, the variation in UV spectra with acidity showed no isosbestic point, similar to the cases of arylureas (21, 32) and 5-arylhydantoic acids (8). Following previous experience the ionization ratios were obtained by assuming (12, 33) linear dependence of A(B) and $A(BH^+)$ on H_A. The latter values were obtained by plotting the absorbance (A) at 238 nm versus H_A, and extrapolating the linear portions of each end of the sigmoid curve obtained.

The 3-phenyldihydrouracil **4** showed only end UV absorption, which increased with acid concentration, but did not level off at high acidity. When plotted against H_0, however, an inflection point around $H_0 = -7$ was observed, indicating the completion of the first protonation and beginning of the second, as indicated by the ^{13}C NMR spectra of **2**. Usually with weaker bases, only A(B) is significantly medium dependent (33), and thus the ionization ratios for **4** were calculated by assuming linear dependence of A(B) on H_0 and by adjusting $A(BH^+)$ iteratively until the best fit was obtained for the total variation of A.

Rate constants

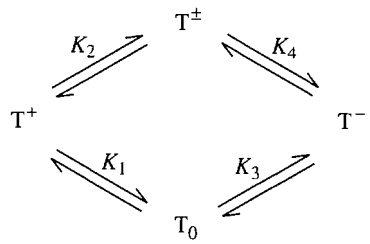
The medium independent bimolecular rate constants and equilibrium constants were obtained by means of eqs. [1]–[6] (see Results). The values for X and pK were corrected as recommended (13); log C_{H^+} values for 25°C were used. In the Bunnett–Olsen treatment H_0 values interpolated for 70°C from the data in ref. 34 were used together with log C_{H^+} instead of the acid molarity. The log aH_2O values at 70°C are from ref. 35; values for solutions more concentrated than 63% H_2SO_4 were obtained by extrapolation of a plot log aH_2O^{25} vs. log aH_2O^{70} (36).

Energy–reaction coordinate profiles

For the change in free energy for $U^+ \rightarrow U$, a pK value of approximately −4 was used, based on values obtained (37) for aromatic and α,β-unsaturated acids, using the Bunnett–Olsen

treatment. To the best of our knowledge, no pK values have been reported for simple aliphatic carboxylic acids. Recently, however, Edward and Wong (38) have determined $pK_{BH^+} = -4.7$ ($m^* = 0.56$) for benzoic acid. For the change $U^+ \rightarrow U^{\pm}$, we have used the reported pK values of 18.3 (39) for the equilibrium $H_2NCONHCH_3 \rightleftarrows H_2NCON^- CH_3 + H^+$, and 16.3 and 16.6 for the ionizations of $PhNHCONHCH_2COO^-$ and $PhNHCON(CH_3)CH_2COO^-$ respectively (40).

For the tetrahedral intermediates shown below, the following pK values are estimated using the approach of Fox and Jencks (41): $pK_1 = -8.1$, $pK_2 = 8.2$, $pK_3 = 12.8$, $pK_4 = -3.3$. These are based on a pK_{BH^+} of -3.9 reported (39) for the *N*-methyl nitrogen in methylurea and a suitable LFER recommended by Fox and Jencks (41), assuming that a unit charge changes the pK by 4.8 units.



The most difficult term to estimate reliably was the energy difference between U and T_0. Using representative average bond energies (16), T_0 was estimated to be only 2 kcal higher in energy than U. However, using group contributions from two sources (16, 23), based on somewhat dubious analogies, higher values of 9.5–11.8 kcal were obtained. Finally, heats of formation for U and T_0 based on AM1 calculations (27) gave $\Delta\Delta H_f$ of 7.2 kcal. We have therefore used an average value of ~6 kcal for this difference. The absolute accuracy is not, however, critical in comparing the relative energy changes of paths A and B from U to T_0.

Acknowledgements

The continued financial support of NSERC of Canada and the Committee of Science of Bulgaria is acknowledged. We are also very grateful to Dr. Alexander Dyulgerov for carrying out the mass-spectral measurements for the ^{18}O-exchange studies, and to Dr. Jose Kaneti for the AM-1 calculations.

The mechanism of the photochemical cycloaddition reaction of *N*-benzoylindole with cyclopentene[1]

BIMSARA W. DISANAYAKA AND ALAN C. WEEDON[2]

The Photochemistry Unit, Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received March 28, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

BIMSARA W. DISANAYAKA and ALAN C. WEEDON. Can. J. Chem. **68**, 1685 (1990).

The mechanism of the photochemical cycloaddition reaction between *N*-benzoylindole, **1**, and cyclopentene to give cyclobutane adducts **2** and **3** has been examined. The triplet excited state lifetime and quantum yield of intersystem crossing were determined for **1** as $(2.8 \pm 0.3) \times 10^{-8}$ s and 0.39 ± 0.01, respectively, using the triplet counting procedure. In addition, the dependence of the quantum yield of cycloadduct formation upon the concentration of cyclopentene and upon the concentration of excited state quenchers has been determined. The results are used to propose a mechanistic model in which the triplet excited state of **1** reacts with cyclopentene to give a triplet 1,4-biradical intermediate. Following spin inversion the biradical intermediate reverts to the ground state starting materials or proceeds to the products **2** and **3**; this partitioning, along with the quantum yield of intersystem crossing, gives rise to a limiting quantum yield of cycloaddition at infinite alkene concentration of 0.061. It is calculated that 84% of the biradical intermediates revert to the starting materials and 16% proceed to cycloadducts. The quantum yield data are also used to calculate two independent values of the rate constant for reaction of the triplet excited **1** with alkene; the values are $(1.8 \pm 0.1) \times 10^7\ M^{-1}\ s^{-1}$ and $(4.0 \pm 0.8) \times 10^6\ M^{-1}\ s^{-1}$. Some evidence for self quenching of the triplet excited state of **1** by ground state **1** was also observed. The quantum yield of intersystem crossing and the triplet excited state lifetime of **1** were found to vary with the solvent used; this is discussed in terms of the possible existence of a charge transfer triplet excited state.

Key words: indole, photocycloaddition, mechanism.

BIMSARA W. DISANAYAKA et ALAN C. WEEDON. Can. J. Chem. **68**, 1685 (1990).

On a étudié le mécanisme de la réaction de cycloaddition photochimique entre le *N*-benzoylindole, **1**, et le cyclopentène qui conduit aux adduits cyclobutaniques **2** et **3**. Utilisant la technique de comptage des états triplets, on a établi que le temps de vie de l'état triplet excité et le rendement quantique du croisement intersystème du composé **1** sont respectivement de $(2,3 \pm 0,3) \times 10^{-9}$ s et $0,39 \pm 0,01$. De plus, on a déterminé la relation qui existe entre le rendement quantique pour la formation du cycloadduit et, d'une part, la concentration de cyclopentène et, d'autre part, la concentration des pièges des états excités. On a utilisé les résultats obtenus pour proposer un modèle mécanistique dans lequel l'état triplet excité du produit **1** réagit avec le cyclopentène pour donner un intermédiaire triplet 1,4-biradicalaire. Après une inversion de spin, l'intermédiaire biradicalaire retourne à l'état fondamental des produits réactionnels ou il se transforme pour donner les produits **2** et **3**; cette répartition prise de concert avec le rendement quantique du croisement intersystème placent à 0,061, la limite du rendement quantique de la cycloaddition à une concentration infinie d'alcène. On a calculé que 84% des intermédiaires biradicalaires retournent aux produits de départ et que 16% donnent des produits de cycloadditions. On a aussi utilisé les rendements quantiques pour calculer deux valeurs indépendantes de la constante de vitesse de la réaction du triplet excité du produit **1** avec l'alcène; ces valeurs sont $(1,8 \pm 0,1) \times 10^7\ M^{-1}\ s^{-1}$ et $(4,0 \pm 0,8) \times 10^6\ M^{-1}\ s^{-1}$. On a aussi obtenu quelques données suggérant l'existence d'un auto-piégeage de l'état triplet excité du produit **1** par l'état fondamental du produit **1**. On a trouvé que le rendement quantique du croisement intersystème ainsi que le temps de vie de l'état triplet excité du produit **1** varient avec le solvant utilisé; on discute de ces données en fonction de l'existence possible d'un état triplet excité de transfert de charge.

Mots clés : indole, photocycloaddition, mécanisme.

[Traduit par la revue]

Introduction

The indole chromophore is a common component of alkaloids and also of proteins where it occurs as part of the amino acid tryptophan. The latter is one of the few naturally occurring amino acids that absorbs light in the near uv region and is responsible for the major part of the accessible absorption spectra of proteins. Possibly because of its ubiquitous presence in living organisms the photophysics of the indole system has received much attention (1). Fortunately for those life-forms exposed to sunlight the simple indole chromophore has relatively low photochemical reactivity and fluorescence is a major fate of the excited state initially formed by light absorption (2). The few photochemical reactions that have been reported include the formation of 3-(1-cyanoethyl)indole from irradiation of indole in the presence of acrylonitrile (3), and the photoaddition of alkynes across the indole 2,3 double bond to give cyclobutenes, which then open thermally to give benzazepines (4). The low photochemical reactivity of the indole chromophore contrasts with the properties of the analogous heterocycles benzofuran and benzothiophene, which have an extensive photochemistry (5). This includes photodimerization by 2 + 2 addition of the 2,3 double bond of an excited heterocycle to the same bond in a ground state partner. The 2 + 2 addition of alkenes across the 2,3 double bond of the excited states of these heterocycles to form cyclobutanes is also well known (5).

The photochemical and photophysical properties of the indole chromophore are dramatically altered if the nitrogen atom is substituted by an electron-withdrawing group such as acetyl, benzoyl, or toluenesulfonyl (6–9). It has been shown in this laboratory for various *N*-benzoylindoles that the excited state initially formed by light absorption is non-fluorescent; rather it undergoes intersystem crossing to the triplet excited state in competition with relaxation to a charge transfer singlet

excited state that is weakly fluorescent (9). It has also been reported that ultraviolet irradiation of these N-substituted indoles in the presence of ketones and alkenes can lead to the formation of good chemical yields of oxetanes (7) and cyclobutanes (6, 8), respectively, by addition of the ketone or alkene π-system across the 2,3 double bond of the indole derivative. If the nitrogen substituent is absent then no cycloaddition occurs. The reaction with alkenes offers a potentially powerful route for the preparation of 2- or 3-substituted indoles if selective methods for the cleavage of the cyclobutane ring can be developed, and if the limitations of the photochemical cycloaddition reaction are known. The latter requires a knowledge of the mechanism of the cycloaddition reaction so that the stereochemistry and regiochemistry of the reaction can be understood and predicted. This paper describes a study in which the mechanism of the photochemical cycloaddition reaction between *N*-benzoylindole, **1**, and cyclopentene was investigated.

Results

Spectroscopic properties of N-*benzoylindole, 1, in the presence and absence of cyclopentene*

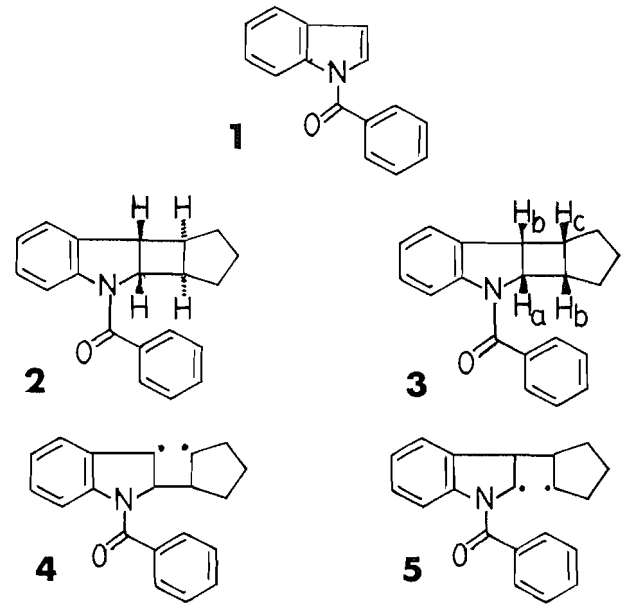
The ultraviolet absorption spectrum of indole shows two maxima, one at 225 nm (extinction coefficient 25 000) and the other at 270 nm (extinction coefficient 6000). The latter possesses vibrational structure and the position of the whole spectrum is somewhat dependent upon solvent polarity (1). In contrast, the absorption spectrum of *N*-benzoylindole possesses maxima at 247 nm (extinction coefficient 24 000) and 302 nm (extinction coefficient 8000), neither of which has any obvious vibrational structure. The position of these bands is not affected by changes in solvent polarity (9). At room temperature weak fluorescent emission from **1** has been observed (9) with a quantum yield in hexanes of 0.041. This emission is structureless and occurs with a very large Stokes' shift. The magnitude of the Stokes' shift increases with increasing solvent polarity and this has been used to assign the emission to a charge transfer singlet excited state that is formed from the initially produced singlet excited state (9).

The absorption spectrum of **1** suggests that the first singlet excited state formed from direct excitation has an energy of 95 kcal/mol, while the charge transfer state formed from it has an energy varying from 65 kcal/mol in hexane to 53 kcal/mol in acetonitrile. Time-resolved fluorescence measurements obtained by the single photon counting technique indicate that the lifetime of the fluorescing state is ca. 0.5 ns. At 77 K *N*-benzoylindole was found to phosphoresce strongly and this completely masked the weak fluorescence. The position of the O–O band of the phosphorescence (422 nm) was not solvent dependent and corresponds to a relaxed triplet excited state energy of 68 kcal/mol.

The positions and intensities of the absorption and emission spectra of **1** were not affected by the presence of high concentrations of cyclopentene.

Characterization of photoadducts from ultraviolet irradiation of N-*benzoylindole with cyclopentene*

Ultraviolet light irradiation of a benzene solution of *N*-benzoylindole containing cyclopentene resulted in the apparent formation of a single product, as indicated by gas chromatography. At low conversions the rate of formation of this product and the rate of disappearance of *N*-benzoylindole were zero order; however, at high conversions the formation of insoluble matter became evident and the reaction slowed down. The insoluble matter is assumed to be cyclopentene polymers and it is light scattering by these which is the most likely cause of the slowing of the reaction. The ^{13}C NMR and ^{1}H NMR spectra of the isolated product indicated the presence of two compounds in approximately equal amounts, even though both gas and liquid chromatography indicated the presence of a single component. One of the two products was crystalline and this allowed their separation. Mass spectroscopy confirmed that the two compounds were 1:1 adducts of *N*-benzoylindole and cyclopentene, and the ^{1}H NMR spectra were consistent with the structures **2** and **3**. The stereochemistries of the cyclopentane–cyclobutane and indoline–cyclobutane ring fusions were assumed to be *cis* in each compound, and the coupling constants of cyclobutane methine protons support this assignment. Thus J_{ab} and J_{cd} were ca. 8 Hz for both compounds. The crystalline isomer was assigned the *cis-anti-cis* stereochemistry shown in **2**, which results from *exo* addition of the alkene to the indole. This assignment was made on the basis of the coupling constants observed between protons a and d (J = 2.9 Hz) and between protons b and c (J = 2.9 Hz). The non-crystalline isomer was assigned the *cis-syn-cis* stereochemistry shown in **3**, which results from *endo* addition, and the coupling constants observed support this (J_{ad} = 7.7 Hz; J_{bc} = 8.0 Hz). Further details of the assignment of stereochemistry to these and other alkene adducts will be described elsewhere.[3]



Relative quantum yields of formation of adducts 2 and 3 in the presence of varying concentrations of quenchers and cyclopentene

Qualitative experiments revealed that the rate of the photochemical cycloaddition reaction between *N*-benzoylindole and cyclopentene was diminished when the alkene concentration was lowered or when typical triplet excited state quenchers such as cyclohexadiene, *trans*-piperylene, or isoprene were present in the solution during the irradiation. This was quantified by measurement of the relative amounts of the adducts **2** and **3** formed when *N*-benzoylindole (0.02 M in benzene) was irradiated in the presence of varying concentrations of cyclopentene and cyclohexadiene in a merry-go-round apparatus (10). Under these conditions the relative amounts of the adducts produced are a direct measure of their relative quantum yields of

formation. Conversions were kept low so that the yields were recorded in the region where the reaction followed zero-order kinetics. The results are given in Table 1 and are shown graphically in Fig. 1 as Stern–Volmer plots in which the quantum yield of adduct formation in the absence of quencher, ϕ^0, relative to the quantum yield of adduct formation in the presence of cyclohexadiene quencher, ϕ, is plotted against quencher concentration for various values of cyclopentene concentration.

Absolute quantum yield of N-*benzoylindole cycloaddition in the presence of varying concentrations of cyclopentene and* N-*benzoylindole*

The absolute quantum yields of adduct formation were determined for benzene solutions containing various concentrations of cyclopentene. The results are shown in Table 2 and indicate a nonlinear increase in quantum yield with increasing cyclopentene concentration. The quantum yield of adduct formation was found to decline very slightly with increasing *N*-benzoylindole concentration when the cyclopentene concentration was held constant; these data are shown in Table 3.

Quantum yield of intersystem crossing and triplet excited state lifetime of N-*benzoylindole from triplet counting*

The quantum yield of intersystem crossing of *N*-benzoylindole, ϕ_{isc}, was determined in three solvents utilizing the triplet counting method of Lamola and Hammond (11). In this procedure *trans*-piperylene is used to quench *all* of the *N*-benzoylindole triplet excited states produced by a known number of photons; the amount of *cis*-piperylene produced by relaxation of the triplet excited state of piperylene is then determined and this yields an apparent value of the quantum yield for *trans* → *cis* isomerization of piperylene, $\phi_{t\rightarrow c}$. This is used to count the number of triplet excited states of *N*-benzoylindole quenched by comparison with the actual value of the quantum yield of *trans* → *cis* isomerization of piperylene via the triplet excited state. To ensure that the value of $\phi_{t\rightarrow c}$ determined corresponds to the condition that all *N*-benzoylindole triplet excited states are quenched, the apparent piperylene

isomerization quantum yield is measured as a function of piperylene concentration and fitted to eq. [1] (11). In eq. [1],

$$[1] \quad \frac{0.44}{\phi_{t\rightarrow c}} = \frac{1}{\phi_{isc}}\left\{1 + \frac{1}{k_q\tau[Q]}\right\}$$

k_q is the rate constant for quenching of the triplet excited state of **1** by piperylene, τ is the lifetime of the *N*-benzoylindole triplet excited state, and [Q] is the concentration of the quencher piperylene. The quantity 0.44 is the experimentally determined value of $\phi_{t\rightarrow c}$ for complete quenching when benzophenone (for which ϕ_{isc} is known to be unity) is used as a sensitizer instead of **1**.

The fit of the data to eq. [1] gives the quantum yield of intersystem crossing, ϕ_{isc}, for **1** as well as a value of the triplet excited state lifetime of **1** if the quenching rate constant k_q is assumed to be equal to the rate constant for diffusion, k_{diff}. This assumption is based upon the fact that energy transfer from triplet excited **1** (triplet excited state energy 68 kcal/mol) to piperylene (triplet excited state energy 59 kcal/mol) is sufficiently exothermic for every collision to result in energy transfer. The values obtained are shown in Table 4 and the data plotted to fit eq. [1] are shown in Fig. 2.

Discussion

In their paper on the photochemical cycloaddition of alkenes to *N*-benzoylindole Julian and Foster reported qualitative results which indicated that the reaction could be sensitized by acetophenone and quenched by naphthalene (6), and they interpreted this to mean that the reaction proceeded via the triplet excited state of *N*-benzoylindole. Their results do not, however, exclude the possibility that the singlet excited state

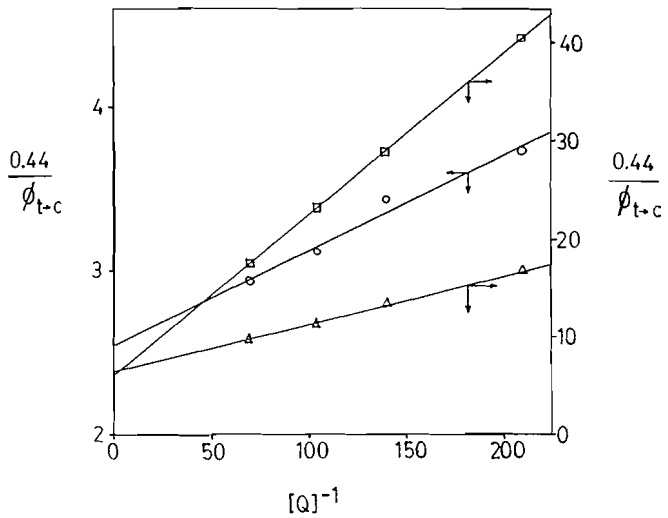

FIG. 2. Plot of $0.44/\phi_{t\rightarrow c}$ against reciprocal piperylene concentration, where $\phi_{t\rightarrow c}$ is the apparent quantum yield of *trans* to *cis* isomerization of *trans*-piperylene in benzene solvent (○), acetonitrile solvent (□), and dichloromethane solvent (△).

can also undergo cycloaddition. In the work reported here it was found that the fluorescence of the charge transfer singlet excited state of **1** was not quenched when high concentrations of cyclopentene were present. This indicates that the charge transfer singlet excited state of **1** is unreactive with cyclopentene and also indicates that the singlet excited state formed initially by light absorption, from which the charge transfer state is derived, is also unreactive with cyclopentene and so is not involved in the cycloaddition reaction. In addition, the Stern–Volmer plots shown in Fig. 1 are linear; if more than one excited state were involved in the cycloaddition reaction then the plots would be curved unless the lifetimes of the states were identical, which is unlikely.

If it is assumed that the singlet excited state of **1** is unreactive and that photocycloaddition occurs through the triplet excited state exclusively, then the simplest reaction mechanism that can be envisaged is as shown in Scheme 1. In the scheme, light absorption (rate I_a einstein/s) and intersystem crossing lead to the triplet excited state of **1**, which either decays to the ground state (rate constant k_d) or reacts with alkene to give the adducts (rate constant k_a).

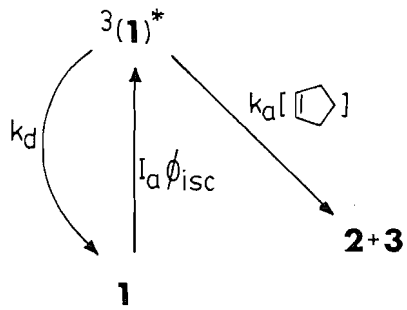
The efficiency of population of the triplet excited state of **1** is given by the quantum yield of intersystem crossing, ϕ_{isc}, which was determined in this work by triplet counting to be 0.39 ± 0.1 in benzene. The triplet counting procedure leads to a value of the triplet excited state lifetime for **1** in benzene of $(2.8 \pm 0.3) \times 10^{-8}$ s, which corresponds to a triplet decay rate constant, k_d, of $(3.6 \pm 0.4) \times 10^7\ s^{-1}$. The value of the triplet excited state lifetime is extracted from the gradient of the plot for benzene solvent in Fig. 2 assuming that k_q is equal to k_{diff} and adopting a value of $1.6 \times 10^{10}\ M^{-1}\ s^{-1}$ for the latter.

Application of the steady state approximation to the sequence shown in Scheme 1 yields an expression relating the quantum yield of adduct formation, ϕ, to the rate constants defined in the scheme and to alkene concentration; this expression is shown in eq. [2], where [A] is the alkene concentration. Equation [2]

$$[2] \quad \phi = \frac{k_a[A]\phi_{isc}}{k_a[A] + k_d}$$

predicts that at high alkene concentrations the value of k_d

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.



SCHEME 1

becomes negligible and that ϕ becomes identical to ϕ_{isc}. This corresponds to interception of all of the triplet excited states of **1** by the alkene and their conversion into the product. In addition, eq. [2] predicts a linear relationship between $1/\phi$ and $1/[A]$ with an intercept at high [A] equal to $1/\phi_{isc}$. The plot of the data obtained in this work (Table 2) is shown in Fig. 3 and is linear, although the intercept yields a value of ϕ_{isc} of 0.061, which is in very poor agreement with the value of 0.39 determined by triplet counting (Table 4). The value of 0.061 should represent the limiting quantum yield of photocycloaddition at infinite alkene concentration, under which circumstances the triplet excited state of **1** is completely intercepted by alkene. Therefore, to account for the inefficient quantum yield there must be a step following interception that prevents the formation of the products and regenerates the starting materials.

A similar state of affairs has been found to obtain in the photochemical cycloaddition of alkenes to 2-cyclopentenones and 2-cyclohexenones (12). In these cases the intermediacy of a triplet 1,4-biradical intermediate between the triplet excited state and the products has been demonstrated. This biradical intermediate partitions between the products and the starting materials and accounts for a quantum yield of product formation that is lower than the quantum yield of intersystem crossing at infinite alkene concentration (12).

For the reaction between *N*-benzoylindole and cyclopentene the appropriate biradical intermediates would be stereoisomers of **4** and **5**; these are the triplet 1,4-biradicals produced by bonding of the alkene to either the 2-position or 3-position of the indole nucleus, respectively. Such biradicals are logical intermediates in a triplet excited state reaction. If the production of the adducts **2** and **3** were a singlet excited state process then the two new bonds of the cyclobutane rings could be formed concertedly. However, for a triplet reaction, spin inversion must occur at some point along the reaction pathway and, since this is normally a relatively slow process, a biradical intermediate in which only one of the new cyclobutane bonds has been formed provides an opportunity for spin inversion to take place.

If it is assumed that a biradical species is an intermediate in the formation of **2** and **3** then the mechanism shown in Scheme 1 can be modified to that shown in Scheme 2. In this scheme a biradical intermediate is introduced which partitions to the starting materials (rate constant k_r) and the adducts (rate constant k_c); also two additional processes for decay of the triplet excited state have been incorporated. These are self quenching of the triplet by ground state **1** (rate constant k_{sq}) and quenching of the triplet by an added quenching species Q (rate constant k_q). The introduction of these species will be discussed further below. Adaptation of eq. [2] to take into account the extra processes in Scheme 2 gives eq. [3], which

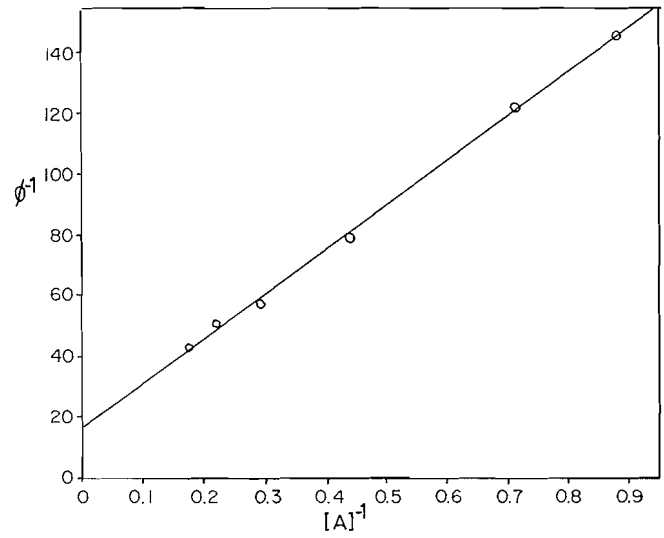


FIG. 3. Plot of reciprocal quantum yield of cycloadduct formation against reciprocal of alkene concentration ([A]) for the photochemical cycloaddition of cyclopentene to **1** in benzene solution.

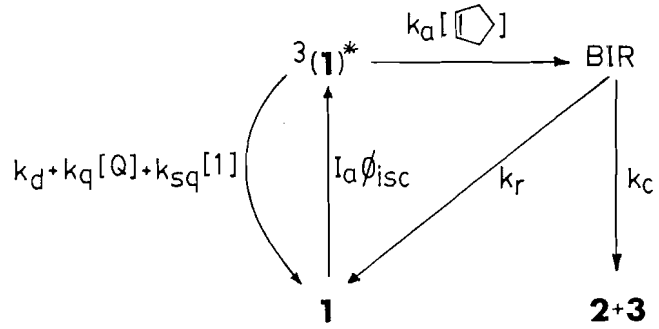

SCHEME 2

can be cast into reciprocal form to give eq. [4].

$$[3]\quad \phi = \left\{\frac{k_c}{k_r + k_c}\right\}\left\{\frac{k_a[A]\phi_{isc}}{k_a[A] + k_d + k_q[Q] + k_{sq}[\mathbf{1}]}\right\}$$

$$[4]\quad \frac{1}{\phi} = \frac{1}{\phi_{isc}}\left\{\frac{k_c}{k_r + k_c}\right\}^{-1}\left\{1 + \frac{(k_d + k_q[Q] + k_{sq}[\mathbf{1}])}{k_a[A]}\right\}$$

Equation [4] predicts that the inverse of the quantum yield of adduct formation should vary linearly with the inverse of the alkene concentration, as did eq. [2]; however, eq. [4] requires that the intercept corresponding to infinite alkene concentration should have a value equal to the reciprocal of $\phi_{isc}k_c/(k_c + k_r)$ where $k_c/(k_c + k_r)$ is the fraction of biradical intermediates that proceed to the adducts. From the plot of the data obtained in this work (Table 2, Fig. 3), combination of the intercept with the value of ϕ_{isc} in benzene (determined by triplet counting as 0.39 ± 0.01) gives a value of $k_c/(k_c + k_r)$ of 0.16 ± 0.02, indicating that 84% of the biradicals revert to the starting materials and only 16% close to the products.

It was found in this work that the quantum yield of adduct formation was reduced when the concentration of **1** was increased. This can be ascribed to self quenching of the triplet excited state of **1** by ground state **1** and is the reason for the incorporation of the k_{sq} term in eqs. [3] and [4]. Self quenching of triplets has been observed previously in photocycloaddition chemistry (13). To determine the importance of self quenching, the inverse of the quantum yield of adduct formation, ϕ, was

plotted against [**1**] to get the line predicted by eq. [4]. The result is shown in Fig. 4; the gradient, M, of this line is 13.6 ± 1.7 and is given by eq. [5] if [Q] is put to zero. Using the values

$$[5]\quad M = \frac{1}{\phi_{isc}}\left\{\frac{k_c}{k_c + k_r}\right\}^{-1}\frac{k_{sq}[\mathbf{1}]}{k_a[A]}$$

already determined for ϕ_{isc} and $k_c/(k_c + k_r)$ gives a value for $k_{sq}/k_a[A]$ of 0.8 ± 0.4. The concentration of alkene used in this experiment was 2.276 M. Therefore, k_{sq}/k_a is estimated to be 1.8 ± 0.4. The more accurate values of k_a estimated in this work are described below and are (1.8 ± 0.1) × 10^7 M^{-1} s^{-1} and (4.0 ± 0.8) × 10^6 M^{-1} s^{-1}; consequently, k_{sq} is estimated to be (3.2 ± 0.9) × 10^7 M^{-1} s^{-1} or (7 ± 3) × 10^6 M^{-1} s^{-1}, depending upon which number is chosen for k_a. In the experiments in which the data in Tables 1 and 2 were determined, the concentration of **1** used was 0.02 and 0.027 M, respectively. Therefore, the value of $k_{sq}[\mathbf{1}]$ is small compared with the value of k_d and so can be ignored in eq. [4]. In effect this means that self quenching does not contribute greatly to triplet excited state decay under the conditions used in this work for the determination of ϕ as a function of alkene concentration.

The intercept in Fig. 4 is given by eq. [6], which can be used

$$[6]\quad C = \frac{1}{\phi_{isc}}\left\{\frac{k_c}{k_r + k_c}\right\}\left\{1 + \frac{(k_d + k_q[Q])}{k_a[A]}\right\}$$

for the estimation of a very inaccurate value for k_a, the rate constant for reaction of the triplet excited state of **1** with the alkene, if the value of k_d obtained from the triplet counting experiments is used and if $k_q[Q]$ is set to zero. The value of k_a so calculated is (10 ± 7) × 10^7 M^{-1} s^{-1}.

A more accurate estimate of k_a can be obtained from the data for the variation of ϕ with cyclopentene concentration (Table 2). Assuming that no triplet quencher is present then the plot of this data fitted to eq. [4] (Fig. 3) yields a line whose gradient, $M^{\mathbf{1}}$, should be given by eq. [7]. Using the value of

$$[7]\quad M^{\mathbf{1}} = \frac{1}{\phi_{isc}}\left\{\frac{k_c}{k_r + k_c}\right\}^{-1}\left\{\frac{(k_d + k_{sq}[\mathbf{1}])}{k_a}\right\}$$

$\phi_{isc}k_c/(k_c + k_r)$ obtained from the reciprocal of the intercept of the line in Fig. 3 along with the value of k_{sq} just determined and the value of k_d obtained from triplet counting gives a value of k_s of (4.0 ± 0.8) × 10^6 M^{-1} s^{-1}.

Independent values of k_a and k_d were obtained from the relative quantum yield data given in Table 1. The quantum yield of adduct formation in the absence of a quencher can be represented by ϕ^0 and is defined by eq. [3] if the validity of Scheme 2 is assumed and if [Q] is put to zero. Division of ϕ^0 by ϕ (as defined by eq. [3]) then gives the Stern–Volmer expression shown in eq. [8], which relates the relative quantum

$$[8]\quad \frac{\phi^0}{\phi} = 1 + \frac{k_q[Q]}{(k_a[A] + k_d + k_{sq}[\mathbf{1}])}$$

yield ϕ^0/ϕ to the concentration of quencher, [Q], in a linear manner if the concentration of alkene **1** is held constant.

The plots of the data in Table 1 are shown for various [A] in Fig. 1; the concentrations of A and Q were held approximately constant by keeping conversions low. If the gradients of the lines in Fig. 1 are denoted by M^{II}, then the inverse of M^{II} can be obtained from eq. [8] and is given by eq. [9]. This equation

$$[9]\quad \frac{1}{M^{II}} = \frac{k_a}{k_q}[A] + \frac{(k_d + k_{sq}[\mathbf{1}])}{k_q}$$

predicts that a plot of $1/M^{II}$ against [A] should be linear and

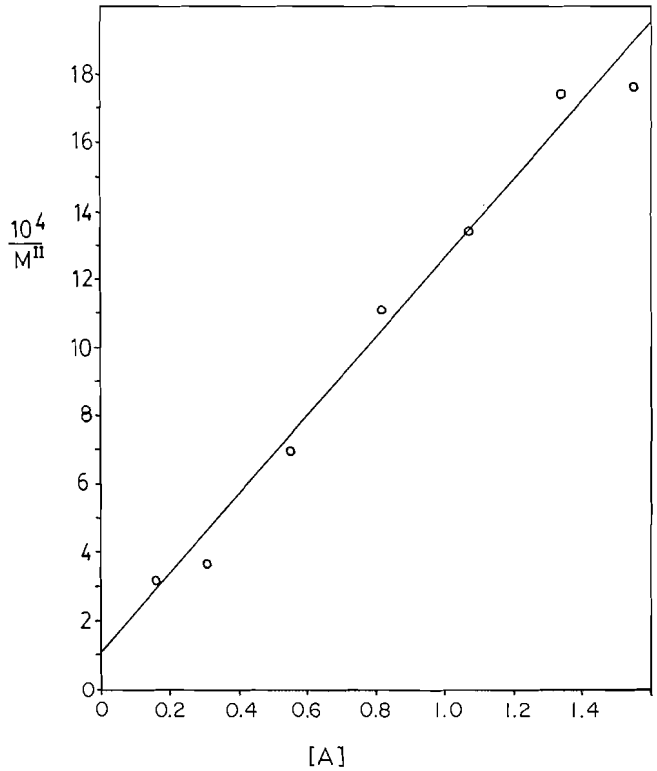

FIG. 5. Plot of reciprocal of the gradients of the lines in Fig. 1 against cyclopentene concentration ([A]).

yield a value of k_a if k_q is known. As long as quenching is appreciably exothermic then the quenching rate constant k_q can be equated with the rate constant for diffusion, which can be calculated from the Debye equation. In benzene at 25°C this value is $1.6 \times 10^{10}\ M^{-1}\ s^{-1}$ (10). The plot of $1/M^{11}$ against [A] is shown in Fig. 5. The gradient of the line is $(1.15 \pm 0.06) \times 10^{-3}$ and this yields a value of k_a of $(1.8 \pm 0.1) \times 10^7\ M^{-1}\ s^{-1}$. The intercept of the plot is equal to k_d/k_q if self quenching is ignored. This yields a new but inaccurate value of k_d of $(1.6 \pm 0.9) \times 10^6\ s^{-1}$.

The value of the rate constant for triplet excited state decay of $(1.6 \pm 0.9) \times 10^6\ s^{-1}$ obtained from the Stern–Volmer plot is appreciably different from that obtained by the triplet counting procedure, which gave $k_d = (3.6 \pm 0.4) \times 10^7\ s^{-1}$. Similarly, the value of k_a obtained by measurement of relative quantum yields in the Stern–Volmer determination of $(1.8 \pm 0.1) \times 10^7\ M^{-1}\ s^{-1}$ is different from that obtained from the plot of reciprocal quantum yield against reciprocal alkene concentration, which was $(4.0 \pm 0.8) \times 10^6\ M^{-1}\ s^{-1}$. These differences may reflect the greater magnitude of the errors in the Stern–Volmer determination. An additional and likely major source of the differences is that some of the rate constants are estimated using the assumption that the rate constant for quenching by piperylene in the triplet counting experiment and by cyclohexadiene in the Stern–Volmer experiments can be equated with the calculated rate constant for diffusion in benzene. While both quenching rate constants are expected to approach the value for diffusion, the value of one or the other may fall slightly below it.

The triplet counting procedure was used to measure the triplet excited state lifetime and quantum yield of intersystem crossing of **1** in several solvents. The results are given in Table 4

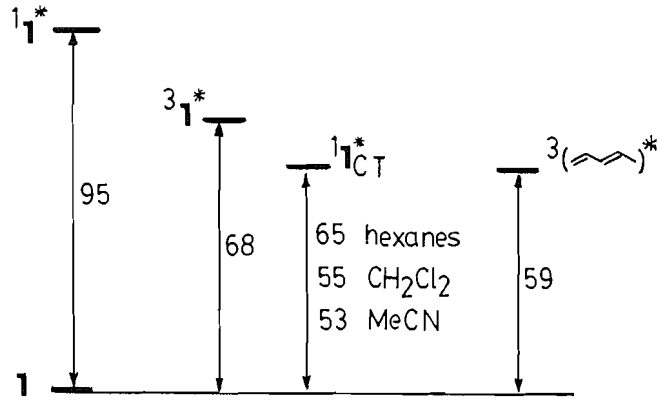

FIG. 6. Diagram showing relative energies of various electronic states of **1** and 1,3-pentadiene. All energies are in kcal mol^{-1}.

and indicate a remarkable solvent effect that translates into a lowering of the values of ϕ_{isc} and the triplet excited state lifetime, τ, in the more polar solvents dichloromethane and acetonitrile, as compared with benzene. To explain this unusual effect we postulate the existence of a lower energy triplet excited state possessing charge transfer character. It was mentioned above that we have previously shown that the singlet excited state of **1** produced by light absorption relaxes to a weakly fluorescent state possessing charge transfer character (9) in competition with intersystem crossing. The energy of this state is highly solvent dependent and varies from 65 kcal mol^{-1} in nonpolar solvents such as pentane or hexanes to 55 kcal mol^{-1} in dichloromethane and 53 kcal mol^{-1} in acetonitrile. The energy of the state in these solvents was determined from the wavelength of the fluorescent emission. It could not be determined in benzene because this solvent absorbs and fluoresces too efficiently; however, the state's energy depends largely upon solvent polarity and the value in benzene is not expected to be very different from that in alkane solvents. The energies of the known states of **1** are shown diagrammatically in Fig. 6 along with the energy of the triplet excited state of *trans*-pentadiene; if it is assumed that the triplet excited state of **1** can also relax to a charge transfer state of similar energy to the singlet analogue, then it can be seen that energy transfer from this state to the pentadiene will become endergonic in the more polar solvents. The consequence of this will be that in polar solvents the pentadiene will be able to quench only the non-charge transfer triplet state and the latter will have a shorter lifetime because it has an extra mode of decay (to the charge transfer triplet). If the charge transfer triplet excited state is not populated from the singlet excited state, then the number determined for ϕ_{isc} should be unaffected by the existence of a charge transfer triplet state. Consequently, the lower values of ϕ_{isc} determined in the more polar solvents must reflect less efficient intersystem crossing in singlet excited **1**. This is reasonable since in polar solvents relaxation of singlet excited **1** to the charge transfer singlet excited state becomes more exergonic and hence possibly faster, thus reducing the efficiency of intersystem crossing.

Conclusions

The work described indicates that the photochemical cycloaddition of cyclopentene to *N*-benzoylindole in benzene solution proceeds via a short-lived triplet excited state of the indole derivative (τ = 28 ns by triplet counting), which reacts with

For personal use only.

cyclopentene (rate constant in the range of 4×10^6 to 1.8×10^7 M^{-1} s^{-1}) to give biradical intermediates, 16% of which proceed to cycloadducts with the remainder returning to the starting materials.

Experimental

Irradiation of N-*benzoylindole,* **1**, *in benzene containing cyclopentene*

N-Benzoylindole (1.63 g) was dissolved in benzene (300 mL) and purged with nitrogen. Cyclopentene (7.8 g) was added and the solution was irradiated with light from a Pyrex and water filtered medium pressure mercury lamp for 89 h. The reaction solution was evaporated to yield 2.13 g of a brown oil, which was purified by column chromatography to yield unreacted **1** (0.53 g) and a yellow oil (0.49 g), which partially crystallized. The crystals were separated from the oil by washing with hexanes to yield the *cis-anti-cis* adduct **2** (0.3 g), mp 123–126°C. The hexanes solution was evaporated to yield the *cis-syn-cis* adduct **3** (0.18 g) contaminated with small amounts of **2**. For **2**: ^{1}H NMR ($CDCl_3$, 200 MHz): 8.3 (br s, 1H), 7.44 (m, 5H), 7.4–7.0 (m, 3H), 3.94 (br s, 1H), 3.32 (dd, J = 7.5, 2.9 Hz, 1H), 2.84 (m, 1H), 2.66 (m, 1H), 1.80 (m, 2H), 1.62 (m, 2H), 1.31 (m, 2H) ppm; ^{13}C NMR ($CDCl_3$) CH_2 signals: 25.4, 30.9, 32.4; CH signals: 45.1, 46.2, 47.9, 63.7; aryl signals: 110.5, 118.3, 124.7, 126.4, 126.8, 127.6, 128.3, 128.4, 130.0, 137.5; carbonyl: 193.8. MS *m/e*: 289 (4.1%), 221 (46), 105 (100%), 77 (20). Exact Mass calcd. for $C_{20}H_{19}NO$: 289.14666; found: 289.14654. For **3**: ^{1}H NMR ($CDCl_3$, 200 MHz): 8.3 (br s, 1H), 7.44 (m, 5H), 7.4–7.7 (3, 5H), 4.70 (br s, 1H), 4.05 (br dd, J = 7.5, 8.0 Hz, 1H), 3.08 (br m, 2H), 1.80 (m, 2H), 1.31 (m, 2H) ppm; ^{13}C NMR ($CDCl_3$) CH_2 signals: 27.1, 27.9, 28.9; CH signals: 42.2, 43.4, 45.5, 61.7; aryl signals: 110.5, 118.3, 125.7, 126.4, 126.8, 127.3, 128.3, 128.4, 130.5, 137.5; carbonyl signal: 195.0. Exact Mass calcd. for $C_{20}H_{19}NO$: 289.14666; found: 289.14656.

Procedure for determination of relative quantum yields

A series of nitrogen-purged benzene solutions containing **1** (0.0156 M), octacosane (2.74 mg/mL), cyclopentene (0.156–1.55 M), and 1,3-cyclohexadiene ($(0–2.5) \times 10^{-3}$ M) were prepared, and identical volumes (4.0 mL) placed in Pyrex tubes. These were then irradiated in a merry-go-round apparatus using light from a Pyrex and water filtered medium pressure mercury lamp. This apparatus ensures that all of the tubes receive the same dose of ultraviolet light. After the irradiation the amount of cycloadducts formed in each sample relative to the internal standard octacosane was determined by GC. For a given concentration of cyclopentene, the relative amount of cycloadduct formed in each tube containing cyclohexadiene divided by the relative amount of cycloadduct formed in the tube containing no cyclohexadiene is equal to the ratio of quantum yields ϕ^0/ϕ. The results for each concentration of cyclopentene are given in Table 1 and shown graphically in Fig. 1.

Procedure for the determination of absolute quantum yields

The quantum yield of cycloaddition between **1** and cyclopentene in nitrogen-purged benzene solution was determined for various concentrations of **1** and cyclopentene by measuring the total amount of cycloadducts produced following the absorption of a known quantity of photons. Light from a high pressure mercury lamp was used and a wavelength of 313 ± 2 nm was selected using a monochromator. Its intensity was determined by potassium ferrioxalate actinometry. The conversions were kept low (<5%) and the total amount of cycloadducts produced in the irradiations was determined by GC relative to a previously calibrated octacosane internal standard. The results are shown in Tables 2 and 3.

Determination of the quantum yield of intersystem crossing and the triplet excited state lifetime of **1** *by triplet counting*

The quantum yield of isomerization of *trans*-piperylene to *cis*-piperylene sensitized by benzophenone was determined in benzene, acetonitrile, and dichloromethane by measuring the amount of *cis*-piperylene produced when a known number of photons were absorbed by the benzophenone. The concentrations used were *trans*-piperylene, 0.0144 M; benzophenone, 0.0247 M. Under these conditions all of the benzophenone triplets should be quenched by the piperylene. Light of wavelength 213 ± 2 nm was used and its intensity was determined by potassium ferrioxalate actinometry. Conversions were kept low (<4%) and the amount of *cis*-piperylene produced was determined by GC relative to a previously calibrated cycloheptane internal standard. The value of $\phi_{t\rightarrow c}$ determined was 0.440 ± 0.003.

The above procedure was repeated using 0.0267 M **1** as the sensitizer instead of benzophenone, and various concentrations of *trans*-piperylene ranging from 0.0048 to 0.0144 M. The apparent values of $\phi_{t\rightarrow c}$ determined were used to give the data shown in Table 4 and Fig. 2. Values of ϕ_{isc} and the triplet lifetime are extracted from these data as described in the results and discussion sections above.

Phosphorescence quenching studies of bromoacetonaphthones in solution

ZDENEK HRUSKA,[1] MARK C. PITON, AND MITCHELL A. WINNIK[2]

Department of Chemistry and Erindale College, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received April 3, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

ZDENEK HRUSKA, MARK C. PITON, and MITCHELL A. WINNIK. Can. J. Chem. **68**, 1693 (1990).

4′-Bromo-1′-acetonaphthone (BAN) and 4′-bromo-1′-(1-dodecano)naphthone (BLN) exhibit strong phosphorescence in degassed solutions in benzene. We report rate constants (k_q) for phosphorescence quenching determined by phosphorescence quenching measurements for the following series of quenchers: pyrene, anthracene, tetracyanoethylene, *p*-dicyanobenzene, *N,N*-dimethylaniline (DMA), and *N,N*-dimethylamino-4-toluidine (DMAT). The first three quenchers quench at the diffusion-controlled rate. DMAT is 20-fold more effective as a quencher than DMA ($k_q = 1.4 \times 10^6$ M^{-1} s^{-1}), but what is noteworthy is that both activation energies are very small, and quenching by DMAT is favoured over DMA mainly by entropic effects ($\triangle S^{\neq} = -105$ vs. -120 J mol^{-1} K^{-1}, respectively).

Key words: aromatic ketone photochemistry, triplet exciplex.

ZDENEK HRUSKA, MARK C. PITON et MITCHELL A. WINNIK. Can. J. Chem. **68**, 1693 (1990).

En solution dans du benzène dégazé, les 4′-bromo-1′-acétonaphtone (BAN) et 4′-bromo-1′-(1-dodécano)naphtone (BLN) présentent une forte phosphorescence. On a mesuré l'extinction de la phosphorescence par des pièges comme le pyrène, l'anthracène, le tétracyanoéthylène, le *p*-dicyanobenzène, la *N,N*-diméthylaniline (DMA) et la *N,N*-diméthylamino-4-toluidine (DMAT) et on en a déduit les constantes de vitesse (k_q) de l'extinction de la phosphorescence. Avec les trois premiers pièges, les constantes de vitesse d'extinction de la phosphorescence sont limitées par la diffusion. La DMAT est un piège 20 fois plus efficace que la DMA ($k_q = 1{,}4 \times 10^6$ M^{-1} s^{-1}); il est toutefois remarquable que les énergies d'activation de ces réactions sont toutes les deux très faibles et que l'efficacité de la DMAT par rapport à celle de la DMA est principalement due à des effets entropiques ($\triangle S^{\neq} = -105$ vs. -120 J mol^{-1} K^{-1}, respectivement).

Mots clés : photochimie de cétones aromatiques, triplet exciplex.

[Traduit par la revue]

Introduction

For many years we have been interested in the reactivity of the triplet states of aromatic ketones as measured by phosphorescence quenching in solution (1, 2). Our own particular interest stems from the idea that when such chromophores are attached to flexible molecules (or polymers) the quenching kinetics can be used as a tool to study issues of conformation and dynamics in these molecules (3, 4). Such applications require a rather detailed understanding of chromophore reactivity and quenching kinetics. As a consequence we have expended a significant effort studying these processes for the particular chromophores of interest to us, and paid considerable attention to the large and ever-growing body of literature on triplet quenching processes in general. Lissi and Encinas have recently done a tremendous service for the entire photochemistry community with an excellent review of this field (5).

Our early experiments involved benzophenone derivatives (1–3). To enlarge the scope of our experiments we needed a different chromophore with easily detected phosphorescence in solution, with a triplet lifetime τ on the order of 100–300 μs, and with very low reactivity toward hydrogen abstraction. A useful candidate is 4′-bromo-1′-acetonaphthone as well as its longer chain alkylnaphthone homologues. These derivatives have been cleverly exploited by Turro and co-workers (6) in their study of aqueous surfactant micelles. Since little has been reported on the triplet reactivity of this chromophore in solution in isotropic solvents, we undertook a study of the phosphorescence quenching kinetics of 4′-bromo-1′-acetonaphthone itself, and 4′-bromo-1′-(1-dodecano)naphthone in benzene solution.

Experimental

Sample preparation

The quenchers *N,N*-dimethylaniline and *N,N*-dimethylamino-*p*-toluidine were purchased from Eastman. Pyrene (PY), *p*-dicyanobenzene (DCB), tetracyanoethylene (TCNE), and anthracene (ANT) were purchased from Aldrich. The quenchers were further purified just prior to use by the following methods: *N,N*-dimethylaniline and *N,N*-dimethylamino-*p*-toluidine by refluxing several hours with an excess of acetic anhydride, and then fractional distillation; *p*-dicyanobenzene by recrystallization from methanol; tetracyanoethylene, pyrene, and anthracene by vacuum sublimation. Benzene, 99+ %, thiophene free (Aldrich), was distilled prior to use. For the synthetic work, lauroyl chloride, acetyl chloride, and aluminum trichloride were purchased from Aldrich, 1-bromonaphthalene and carbon disulfide from Eastman.

The ketones were prepared by a standard Friedel-Crafts reaction of 1-bromonaphthalene with the appropriate acyl chloride in carbon disulfide in the presence of aluminum trichloride.

4′-Bromo-1′-acetonaphthone (BAN) was prepared according to ref. 7. The crude product was isolated in 75% yield as a pale yellow oil that crystallized on standing for several days at 0°C. The ketone was further purified by recrystallization from hexane, mp 47–48°C (lit. (7) mp 47–47.5°C).

4′-Bromo-1′-(1-dodecano)naphthone (BLN), to the best of our knowledge, has not been reported previously. It was prepared according to the following procedure. Into a 250-mL flask were placed 20.7 g (0.1 mol) of 1-bromonaphthalene, 24.1 g (0.11 mol) of lauroyl chloride, and 80 mL of carbon disulfide. The solution was cooled to 0°C and 17.3 g (0.13 mol) of aluminum trichloride was added in small portions. The reaction was maintained at this temperature for 5 h and stirred overnight at room temperature. The reaction mixture was then decomposed with concentrated hydrochloric acid and extracted with ether. The organic layer was washed with water until neutral, dried over $MgSO_4$, and the ether evaporated. Recrystallization of the residue from isopropanol yielded 22.2 g (57%) of white crystals, mp 41°C. 200 MHz proton NMR ($CDCl_3$) δ (ppm): 0.85 (t, 3H, CH_3, J =

6.35 Hz), 1.23 (m,18H, $9CH_2$), 2.99 (t, 2H, $COCH_2$, J = 7.8 Hz), 7.59–8.50 (m, 6H, aromatic). Mass spectrum: 390 and 388 (M^+), 309, 250, 248, 235, 233, 207, 205, 126.

UV–VIS absorption spectra were obtained using a Hewlett Packard 8465A diode array spectrophotometer. Acquisition and analysis were performed using an IBM XT personal computer running software purchased from Hewlett Packard.

Steady-state Stern–Volmer analyses were performed for BAN and BLN using the quenchers listed above. The results are summarized in Table 1. Phosphorescence spectra were recorded on a Spex Fluorolog 2 spectrometer controlled by an AT-type personal computer using Spex DMB 3000 acquisition software. Sample excitation was at 340 nm, and the emission spectra were measured between 400 and 670 nm using a right-angle alignment. The slit openings were 0.5 mm on both the excitation and emission monochromators in all cases.

Ketone phosphorescence is notoriously sensitive to the presence of oxygen. To minimize this effect, freeze–pump–thaw techniques have classically been employed to eliminate the bulk of the dissolved oxygen from solution. To avoid this tedious procedure, which typically takes several hours for a species of samples, we employed a special technique for preparing samples for the purposes of obtaining preliminary results. A quartz fluorescence cell equipped with Teflon stopcock and rubber septum was filled with 2–3 mL of sample solution and then, using a 22-gauge syringe needle, was vigorously purged with nitrogen (Canox, less than 3 ppm of oxygen) presaturated with solvent, for 15 min. Quencher was added by injection of small volumes (10–50 μL) of concentrated solution (prepurged with nitrogen) through the septum cap and stopcock. After each addition the stopcock was closed, the cell shaken, and the spectrum recorded. Volume changes due to quencher addition were assumed to be additive, but in fact were negligible in calculating final concentrations.

For the lifetime measurements, solutions containing 1×10^{-3} M of the ketones with the varying concentrations of quenchers in benzene were prepared by serial dilution. The range of concentrations for each quencher was chosen so that the highest concentration reduced the observed lifetimes of the ketones by a factor of 10–20. The samples were placed in Pyrex cells constructed from 6.1 mm o.d. tubing (approx. 0.5 mL), thoroughly degassed by five freeze–pump–thaw cycles, and sealed under vacuum. Sample temperatures for Arrhenius studies were controlled using a circulating water/ethylene glycol bath and monitored using a copper–constantan thermocouple.

Lifetimes were measured by monitoring phosphorescence decays using a conventional laser flash-photolysis apparatus. Samples were placed in a temperature-controlled cell holder and allowed to attain the desired temperature prior to analysis. Sample excitation was performed using 355-nm pulses from a Quanta-Ray DCR3 Nd:YAG laser fitted with a harmonic generator and separator. Pulses were attenuated using neutral density filters, thereby eliminating distortions in the shape of the observed decay traces due to triplet–triplet annihilation.

The emission from the samples was monitored using a Schott 530-nm cutoff filter in front of a gated photomultiplier tube (PMT) (8). Decay signals were acquired using a Tektronix 7912AD transient digitizer interfaced to an AT-type personal computer. The PMT was gated on 150 ns after the laser pulse to protect it from short bursts of intense light (possibly scattered light and prompt fluorescence), which was a recurring problem in these experiments. Signal averaging of 64 traces and the addition of three signal-averaged "files" gave decays that were exponential over at least two decades. These yielded lifetime values with a precision better than 3% from duplicate samples.

Steady-state spectra

In steady-state experiments, the emission intensities at 570 nm were recorded from the spectra. The ratios $(I_o/I)_{570}$ were calculated, where I_o represents the emission intensity at 570 nm prior to the addition of any quencher. The intensities at 540 nm (first peak) were not reliable enough. The Stern–Volmer plots were constructed according to eq. [1].

$$[1] \quad (I_o/I)_{570} = 1 + k_q\tau_o[\text{quencher}]$$

Here we assume no singlet quenching. With estimated or measured values of τ_o, approximate values of k_q for each quencher allowed us to calculate the best concentration of the quencher for lifetime measurements, where sample preparation by vacuum degassing is more reproducible but much more time consuming.

Lifetime measurements

The rate constants for quenching of the triplet ketone, k_q, were obtained from the slope of the linear Stern–Volmer relation between the measured lifetime and the quencher concentration (eq. [2]).

$$[2] \quad 1/\tau = 1/\tau_o + k_q[\text{quencher}]$$

Here τ and τ_o are the observed lifetimes obtained in the presence and absence of quencher, respectively. Stern–Volmer plots constructed from these results provided k_q with correlation coefficients better than 0.99. The quenching rate constants, determined at various temperatures between 5 and 90°C and corrected for solvent density changes at each temperature (9), were analyzed using the Arrhenius equation

$$[3] \quad k_q = A \exp(-E_a/RT)$$

The activation energy (E_a) and preexponential factor A were calculated from the plot of log k_q versus $1/T$. The activation parameters such as molar enthalpy of activation ($\Delta H^{\neq}$) and molar entropy of activation ($\Delta S^{\neq}$) were obtained directly from Eyring plots of $\ln(k_q/T)$ versus $1/T$

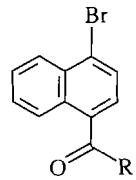
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

according to relationship [4]. Here, k_B and h are the Boltzmann and Planck constants respectively.

$$[4] \quad \ln(k_q/T) = \ln(k_B/h) + \Delta S^{\neq}/R - \Delta H^{\neq}/RT$$

Results and discussion

BAN and BLN have identical UV–VIS absorption spectra. These in turn are essentially the same as in the similar molecule 10-(4-bromo-1-naphthoyl)decyltrimethyl-ammonium bromide, BND-10, reported by Turro (6). All 4-bromo-1-naphthoyl



R	Name
$CH_2(CH_2)_9N^+(CH_3)_3Br^-$	BND-10
CH_3	BAN
$CH_2(CH_2)_9CH_3$	BLN

spectra exhibit a broad absorption from approximately 265 nm to 355 nm. For BLN the maxima occurs at 304 nm with an extinction coefficient of 8500 M^{-1} cm^{-1} in cyclohexane. Our studies confirm previous work (*6a*) on the effect of solvent polarity on the position of this maxima. These show a bathochromic shift with increasing solvent polarity. This, together with the observed magnitude of the extinction coefficient, is consistent with the assignment of this band as a π,π^* transition.

The excitation and emission spectra for BAN in benzene at room temperature are shown in Fig. 1. The emission spectrum is characterized by a broad intense peak with maxima at 540 and 570 nm. A minor emission occurs in the region 360–400 nm for all samples. In aerated solutions, the 540/570 nm peak is quenched while the 360–400 nm emission remains. This is consistent with the assignment of phosphorescence to the former and fluorescence to the latter. To further confirm these assignments, spectra of BAN in CCl_4 show little or no emission around 400 nm and enhanced phosphorescence emission (540 and 570 nm).

The emission spectra of BAN in the presence of TCNE and DMA are presented in Figs. 2a and 2b, respectively. Both quench BAN^{3*}, but the quenching by DMA is accompanied by a new broad emission in the 400–500 nm region. We are currently examining this quenching behaviour in the presence of DMA, and hope to be able to assign this emission in a future publication.

All phosphorescence decay measurements gave exponential decay profiles, whose lifetimes fit very well to eq. [3]. For example, in the case of pyrene as a quencher, we show in Fig. 3 a series of plots of reciprocal phosphorescence lifetimes versus pyrene concentration at various temperatures. Excellent linearity is observed, allowing the rate constants to be calculated from the slopes. Values of k_q at various temperatures were used to construct Arrhenius plots for the quenching of BAN^{3*} and BLN^{3*} phosphorescence (Figs. 4 and 5). The diffusion-controlled rate constant, k_{diff}, was calculated from the Debye equation [5] as a function of T using literature values (10) for viscosity η.

$$[5] \quad k_{diff} = 8\pi RT/3000\eta$$

Diffusion-controlled processes

4′-Bromo-1′-acetonaphthone triplets (BAN^{3*}) are quenched by pyrene, anthracene, and tetracyanoethylene with rate constants near the diffusional limit (see Table 1). For anthracene at 25°C ($k_q = 9.0 \times 10^9$ M^{-1} s^{-1}) and for pyrene at 25°C ($k_q = 7.3 \times 10^9$ M^{-1} s^{-1}) the rate constants are very similar in magnitude to other examples reported by Lissi (5) involving triplet energy transfer from $\pi-\pi^*$ triplet states to lower energy acceptors. In the case of tetracyanoethylene, the rate constant is somewhat smaller, and the quenching mechanism may well involve electron transfer.

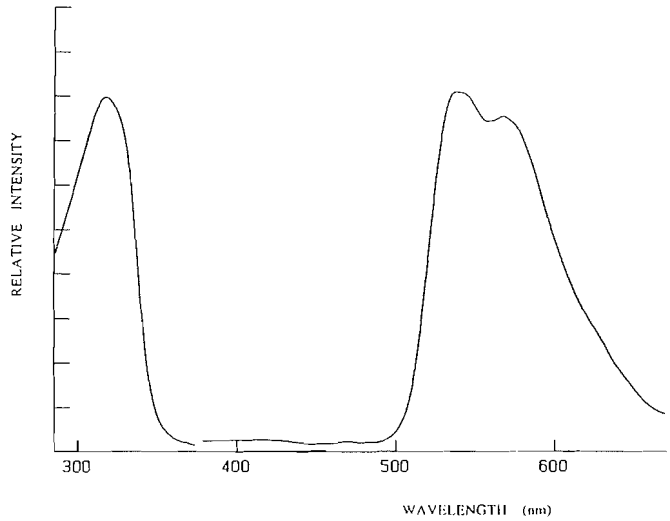


FIG. 1. Phosphorescence excitation (λ_{em} = 570 nm) and emission (λ_{exc} = 318 nm) spectra of 4′-bromo-1′-acetonaphthone for concentrations of 1×10^{-4} M in benzene at room temperature.

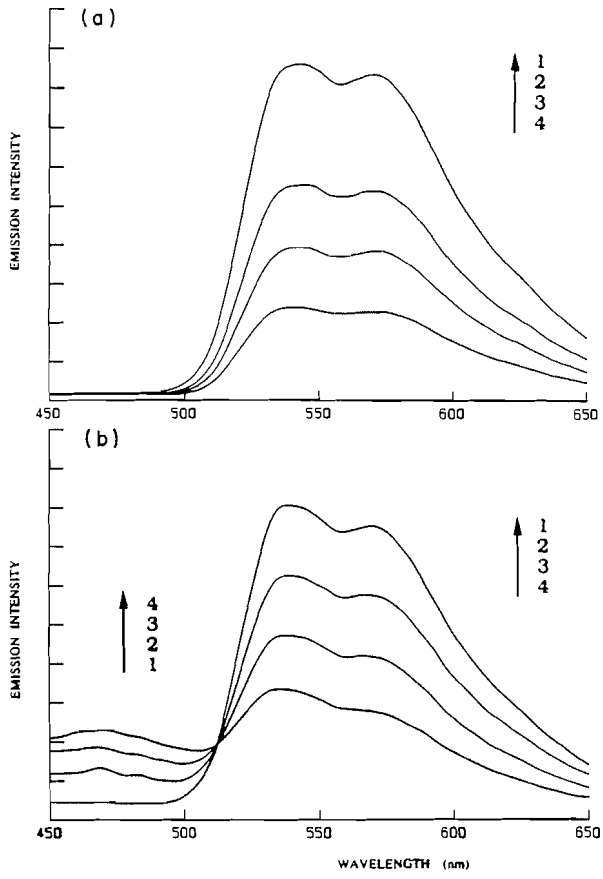

FIG. 2. Emission spectra of BAN^{3*} quenched by TCNE (a) and by DMA (b). Concentration of TCNE: (1) 0; (2) 8.8×10^{-7} M; (3) 2.2×10^{-6} M; (4) 4.8×10^{-6} M; concentration of DMA: (1) 0; (2) 0.001 M; (3) 0.01 M; (4) 0.0192 M. λ_{exc} = 340 nm.

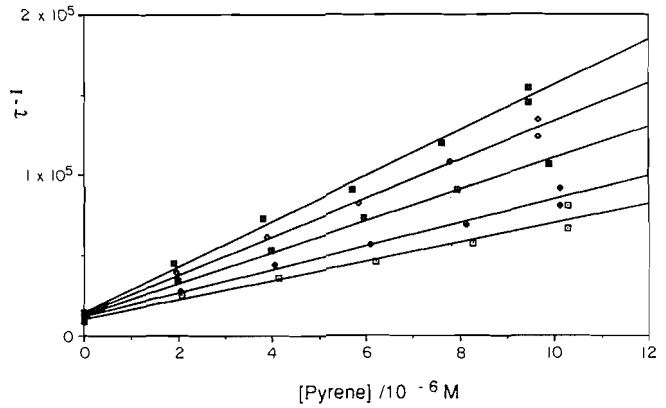

FIG. 3. Pyrene quenching of phosphorescence of BAN^3*, 1×10^{-3} M in benzene. Decay rate, τ^{-1} (s^{-1}), versus pyrene concentration at five different temperatures: (⊡) 9.9°C; (◆) 24.6°C; (■) 44.6°C; (◇)61.8°C; (■) 81.4°C.

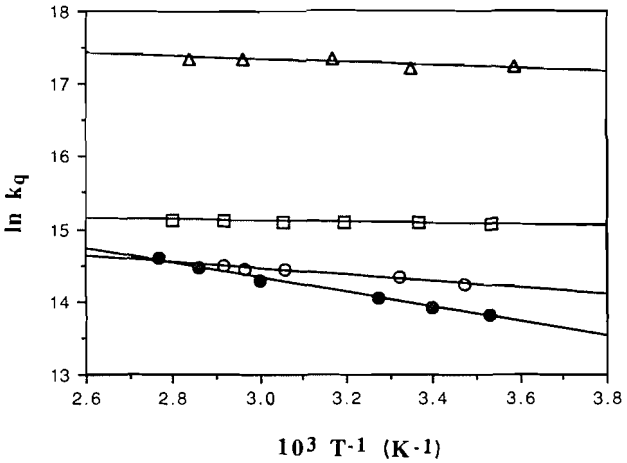

FIG. 4. Arrhenius plots of the quenching of aromatic ketones by various quenchers: BAN^3* quenched by DMA (○); DMAT (△); and DCB (●); BLN^3* quenched by DMA (□).

Non-diffusion-controlled processes

N,N-Dimethylaniline, *N,N*-dimethylamio-*p*-toluidine, and *p*-dicyanobenzene quench the BAN and BLN triplets with considerably lower rate constants. Observed values of k_q were in these cases almost four orders of magnitude lower than in diffusion-controlled processes. These molecules all have triplet energies much larger than that of BAN. Here the quenching mechanism almost certainly involves charge transfer interactions (11).

Table 1 also presents some important thermodynamic parameters for the quenching of bromonaphthoyl triplets in benzene. For pyrene, anthracene, and tetracyanoethylene, the Arrhenius parameters are entirely consistent with diffusion-controlled quenching, i.e., A values on the order of $(4–5) \times 10^{11}$ M^{-1} s^{-1} and apparent activation energies (10–12 kJ mol^{-1}) close to that for diffusion in benzene (12.8 kJ mol^{-1}).

This situation is very different for DCB, DMA, and DMAT. Here we find very low activation energies. In the case of the aromatic amines, the E_a values are close to zero, corresponding to quenching rate constants that do not increase significantly with temperature (Fig. 4). The activation entropies, on the other hand, are typical for bimolecular reactions. Relatively slow quenching, coupled with very low apparent activation energies,

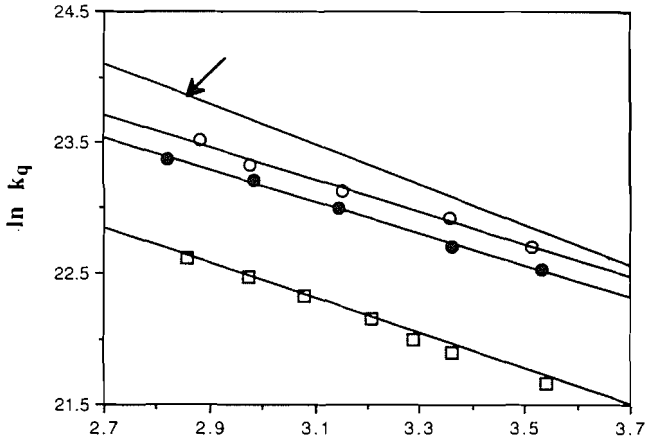

FIG. 5. Arrhenius plots of the quenching of BAN^3* phosphorescence by TCNE (□); ANT (○); and PY (●). Arrow denotes the curve for the diffusion-controlled rate constant.

often points to involvement of a bound complex (an exciplex) along the reaction pathway. Increasing temperature promotes dissociation of the complex to regenerate the excited state, compensating in part for the true activation energy for the quenching reaction. The photoreduction of ketones by amines has been studied extensively (11). In these reactions there is good evidence that the triplet ketones form an exciplex with the amine and that the quenching mechanism has charge transfer character. This explains, for example, very low E_a and negative $\Delta H^{\neq}$ values for quenching BLN by DMA.

There are two particular results that require special comment. One is that DMAT is almost 20 times more efficient as a quencher than is DMA. In one sense, this result is not so surprising, since it is well known (11) that triplet quenching by electron-rich species is sensitive to the presence of additional electron-donating substituents on the quencher. For fluorenone, for example, introduction of a methyl group to an aromatic amine increases the quenching efficiency by a factor of six. What is special here is that the difference in quenching efficiency between DMA and DMAT is almost entirely entropic in origin.

The final point concerns the remarkable difference in activation parameters for DMA quenching BAN^3* and BLN^3*. Here the activation entropies are rather similar, but E_a for BLN reactivity is nearly 3 kJ mol^{-1} lower than that for BAN. In absolute terms, the effect is small, but because the E_a values are so close to zero, this difference seems to be well outside experimental error. We have no unambiguous explanation for this difference. Further experiments are in progress. We hope to be able to comment further on these differences in a future publication.

Received March 16, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

JAMES P. KUTNEY, KRYSTYNA PIOTROWSKA, YONG-HUANG CHEN, KWOK-PING NORMAN CHENG, ZHENYONG GAO, and STEVEN J. RETTIG. Can. J. Chem. **68**, 1698 (1990).

Utilizing thujone-derived intermediates, efficient routes to the natural polygodial family of antifeedants as well as novel analogues within this family are described. One of the key features of this study involves the insertion of an oxygen function into a tertiary carbon center adjacent to a cyclopropane ring system thus providing convenient intermediates for subsequent elaboration. An interesting ring expansion of five-membered to six-membered ring systems by means of tri-*n*-butyltin hydride is also described.

Key words: antifeedants, polygodial, thujone.

JAMES P. KUTNEY, KRYSTYNA PIOTROWSKA, YONG-HUANG CHEN, KWOK-PING NORMAN CHENG, ZHENYONG GAO et STEVEN J. RETTIG. Can. J. Chem. **68**, 1698 (1990).

Utilisant des intermédiaires dérivés de la thujone, on a développé des méthodes efficaces pour préparer les produits de la famille du polygodial, un anti-nutrition naturel, ainsi que de nouveaux analogues de cette famille. L'une des caractéristiques principales de cette étude implique l'insertion d'une fonction oxygénée sur un carbone tertiaire adjacent d'un système cyclopropanique; cette méthode fournit des intermédiaires précieux pour le reste de la synthèse. On décrit aussi une intéressante extension d'un cycle à cinq chaînons en système à six chaînons qui se produit sous l'influence de l'hydrure de tri-*n*-butyl-étain.

Mots clés : anti-nutrition, polygodial, thujone.

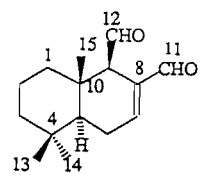
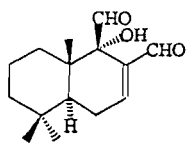
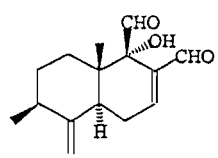
The naturally occurring sesquiterpenoid dialdehydes of the drimane series exemplified by polygodial (**1**), warburganal (**2**), and cinnamodial (**3**) have been thoroughly investigated for



1



2



3

their strong antifeedant activities, and considerable efforts have been devoted to syntheses of these compounds. Extensive reviews (2, 3) summarize the various studies in this area. In our program directed at the utilization of the readily available and inexpensive chiral monoterpene thujone (**7**) in the synthesis of biologically active substances, we became interested in developing a versatile route to this family of compounds. The utilization of a chiral starting material would afford chiral end products, an obvious advantage in any subsequent commercial application *if* evaluation of antifeedant activity should reveal that only one optimal isomer possesses optimum activity. Hopefully the developed strategy would also entail the synthesis of polygodial analogues, not previously studied, so as to establish a proper structure–activity relationship within this area. This publication presents results that satisfy a number of these objectives.

It was clear from the previously published syntheses (2, 3) that bicyclic intermediates such as **4** and **5** were most ideal for our further studies, the former providing a route to novel ring A monomethyl analogues of polygodial while **5** would allow an entry directly to the natural products. With ready access to tricyclic intermediates such as **6**, via Robinson annelation of thujone (4), it was now appropriate to develop methods for converting the "cyclopropyl ring – isopropyl side chain component" of **6** into the ketone functionality portrayed in **4** and **5**. The overall strategy for this process is summarized in the sequence **7** → **8** → **9** → **10**. Thujone (**7**) was used in the initial studies, with X representing a leaving group and N an appropriate nucleophile.

It is known that ozone reacts slowly with saturated hydrocarbons with oxygen insertion into the C—H bond. Insertion occurs preferentially at the tertiary carbon atoms, resulting in alcohols and ketones. This type of reaction had been little

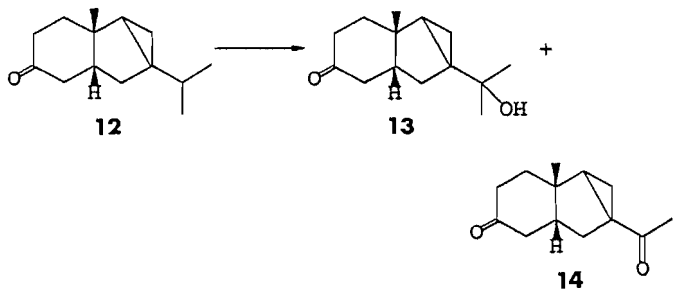
used until 1975 when it was reported (5) that a dry ozonation method allows introduction of hydroxyl groups into saturated compounds. The main idea was to use silica gel as the reaction matrix based on the fact that silica gel absorbs ozone efficiently at low temperature (its concentration being about 4.5% by weight at −78°C). In practice, the silica gel is preabsorbed with the organic substrate, cooled to −78°C, and then saturated with ozone; it is then allowed to warm slowly to room temperature and the product is eluted in the normal fashion. It has also been observed (6) that ozone cleaves not only C—H bonds, but also C—CH_3 bonds, the reaction involving a direct insertion of ozone into these bonds. Application of this reaction to thujone (**7**) afforded a mixture of the alcohol **8** (X = OH) and the ketone **11** in a 3:1 ratio respectively, and an overall combined yield of 70% based on recovery of starting material. Since **11**, after hydride reaction, can also afford the necessary functionality for the ring-opening process (**8** → **9**), *both* compounds (**8** and **11**) could be useful for our objective. Extension of this ozonation process to the tricyclic ketone **12**, available from other studies in our laboratory, similarly provided **13** and **14**. Although this



method offered some potential in our overall strategy, the difficulties with scale-up and substantial recovery of starting materials discouraged further development. However, these results stimulated the approach to perform ozonation reactions in solution with thujone and other thujone-derived intermediates. Indeed when **7**, dissolved in anhydrous ethyl acetate at −25°C, is treated with a stream of ozone over a 10 h period, the alcohol **8** (X = OH, 50% yield) and ketone **11** (20% yield) were obtained. As will be seen later, both types of products are indeed useful in the cyclopropyl ring-opening reaction (e.g., **8** → **9**) and this reaction became sufficiently attractive for future applications.

With the above data on hand, the synthetic route to novel ring A monomethyl polygodial analogues was undertaken. For this purpose, the previously synthesized tricyclic ketone **15** (4) (Scheme 1) was reduced, in quantitative yield, to the saturated ketone **16**. The stereochemistry of **16** at C4 and C5 was first investigated by a detailed proton nmr study. The C4 and C5 methine protons appeared as multiplets at 2.59 and 1.70 ppm respectively, while the C4 methyl group revealed a doublet at 0.94 ppm. These assignments were established from the following decoupling studies. There are three multiplets, each integrating for one proton, resonating at 2.15, 2.42, and 2.59 ppm in the spectrum. On the basis of their chemical shifts, they must be attached to C2 and C4. Irradiation of the signal at 2.59 ppm resulted in the three-proton doublet at 0.94 ppm collapsing into a singlet, thereby implying that the multiplet at 2.59 ppm was due to the proton at C4, and the doublet at 0.94 ppm was, in turn, due to the C14 methyl group. Conversely, irradiation of the signal at 0.94 ppm changed the splitting pattern at 2.59 ppm from a multiplet to a poorly resolved doublet. Also as a result of irradiation of the C4 proton signal at 2.59 ppm, the multiplet at 1.70 ppm, integrating for one proton, became a doublet of doublets, thereby allowing assignment of the multiplet at 1.70 ppm to be that of the C5 proton. The C15 methyl signal was then easily recognized at 1.23 ppm since it is the only three-proton singlet in the spectrum.

Having located these key protons in the nmr spectrum, the stereochemistry at C4 and C5 could be investigated in a nuclear Overhauser effect (nOe) difference experiment. Examination of a molecular model of **16** showed that the distances between the C14 methyl group and the C5 proton, and also the C15 methyl group and the C5 proton are small if these nuclei are on the same side of the molecule. Therefore irradiation of the β-oriented C15 methyl or C14 methyl signals should enable determination of the configurations at C4 and C5.

Irradiation at 1.23 ppm (C15 methyl) resulted in the enhancement of the multiplet at 2.59 ppm due to the C4 proton, but revealed no effect on the multiplet at 1.70 ppm due to the C5 proton. Irradiation at 0.94 ppm (C14 methyl) gave only a very small enhancement at 1.70 ppm. These observations indicated that the C4 proton is on the same side as the C15 methyl group, namely, the C14 methyl group is α-oriented; however, the nature of the ring A/B fusion (*cis* or *trans*) remained unclear.

To settle this question and to allow assignments in subsequent synthetic intermediates, as outlined in Scheme 1, a suitable crystalline compound for X-ray analysis was required. Fortunately compound **26**, obtained from ozonation of **16**, provided satisfactory crystals and the subsequent X-ray analysis of **26** clearly revealed the C14α-methyl orientation and *cis* A/B ring fusion as shown in Scheme 1 and Fig. 1. As a result, it is possible to assign *cis* A/B ring fusion to all compounds arising from **16**.

Employing the classical Huang–Minlon modification of the Wolff–Kishner reduction, **16** was converted to the required intermediate **17** (87% yield) for subsequent ozonation studies according to the earlier developed conditions. Treatment of a cooled (−40°C) ethyl acetate solution of **17** with a stream of ozone over a 10 h period provided a 1:1 ratio of the expected products **18** and **19** (combined yield 70%), which were easily separated by silica gel chromatography. Control of temperature during ozonization was important in that a complex mixture was obtained if the reaction was conducted at 0°C while only a slow reaction was noted with **17** at −50°C.

The ketone **19**, upon reduction with sodium borohydride, yielded the expected alcohol **24** (93% yield). Both alcohols **18** and **24** can be utilized to provide the crucial intermediate **25** (see Scheme 1).

Cyclopropyl ring opening of **18** was then evaluated under acidic conditions similar to those employed in our earlier study (4). Thus treatment of **18** with concentrated hydrochloric acid at 0°C afforded a highly unstable oily product with spectroscopic properties consistent with the structure **20**. The mass spectrum with fragments at *m/z* 240 and 242 was consistent with the formulae $C_{15}H_{25}{}^{35}Cl$ and $C_{15}H_{25}{}^{37}Cl$ respectively, and the ^1H nmr spectrum was particularly informative, revealing a typical ABX coupling pattern, that is, two well-resolved doublets of doublets at 3.45 ppm (1H, dd, J = 11 Hz) and 3.61 ppm (1H, dd, J = 11 Hz), consistent with methylene protons on a carbon atom attached to the chlorine. It was thus clear that cyclopropyl ring opening to the five-membered ring intermediate **20** was occurring, in contrast to the mode of cyclopropyl ring opening to a six-membered ring B intermediate observed in another series studied previously (4). Further studies of the ring opening of **18** were performed with 48%

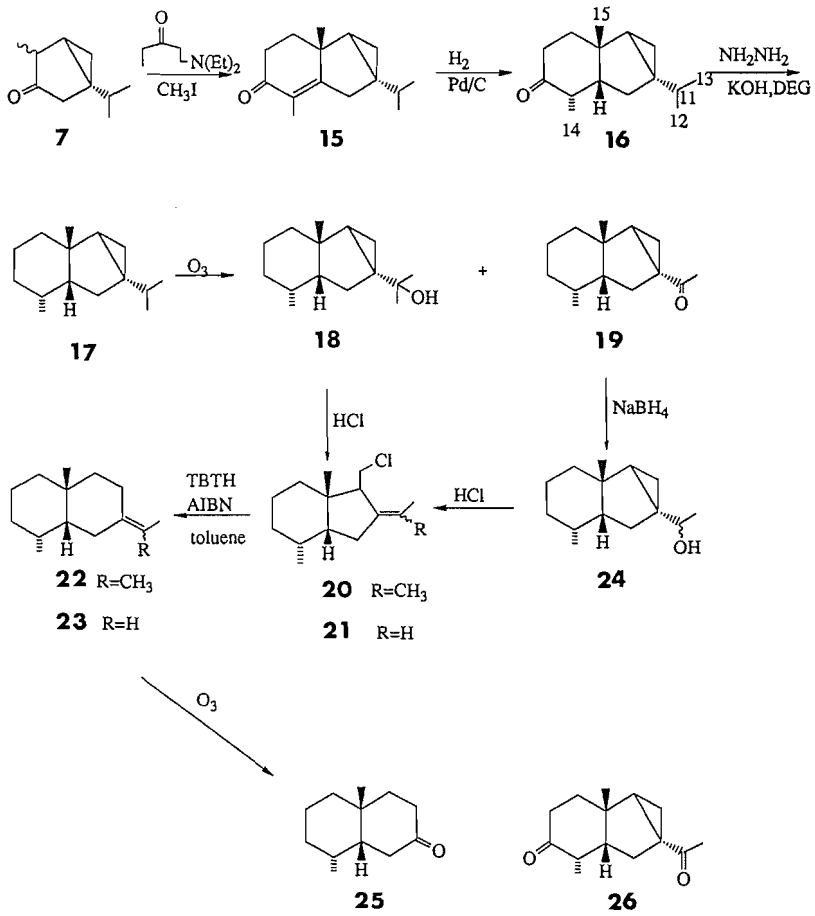


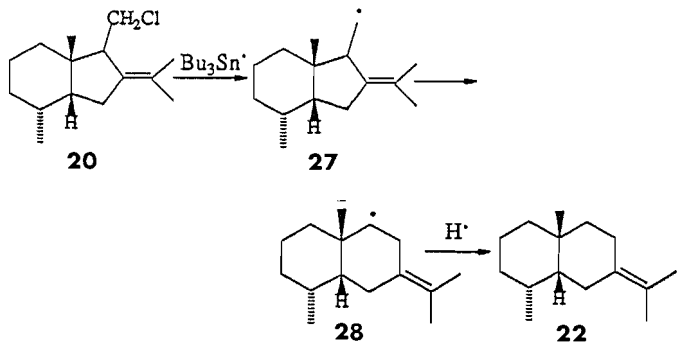
SCHEME 1. Conversion of thujone to the carbonyl intermediate **25**.

hydrobromic acid and magnesium bromide or iodide in refluxing anhydrous ether employing the conditions of McCormick *et al.* (7, 8) and a combination of magnesium and zinc halides (9), but, in each instance, more complex reaction mixtures and lower overall yields of products were obtained.

Interestingly the five-membered ring intermediate **20** was converted to the desired bicyclic intermediate **22** when **20** was treated with an excess of tri-*n*-butyltin hydride in refluxing toluene employing azobisisobutyronitrile as radical initiator. In similar fashion, the chloride **21**, obtained after acid treatment of **24**, afforded **23**. In fact, for preparative purposes, the entire sequence **17** → **18** + **19** → → **20**, **21** → **22**, **23** could be conducted without isolation of intermediates. Thus the reaction mixture containing **18** and **19** resulting from ozonolysis of **17** is treated directly with borohydride to afford a mixture of alcohols **18** and **24**, and the latter, without purification, is subjected to the acidic treatment. The resulting mixture of **20**, **21** is treated with the tin hydride to afford **22**, **23** in an overall yield ot 45%. As is noted below, a mixture of **22** and **23** can be subsequently converted to the common intermediate **25**.

The six-membered ring structure of **22** was supported by the ^{1}H nmr spectrum, which clearly revealed four methyl signals at 0.88 (3H, d, J = 6.6 Hz, C14-CH_3), 0.94 (3H, s, C15-CH_3), 1.65 (3H, s, C12-CH_3), and 1.66 ppm (3H, s, C13-CH_3). If ring B in the structure was five-membered, one more methyl signal, occurring as a doublet, would be observed.

There is little doubt that the above conversion of **20** to **22** involves a radical process. Thus homolytic fission of the carbon–halogen bond, initiated by the tri-*n*-butyltin radical,



generates intermediate **27**. Rearrangement of **27** affords **28**, which is finally converted to **22**. It is logical to assume that the rearrangement, **27** → **28**, could involve a concerted 1,2-shift although mechanistic studies were not performed here.

With the alkenes **22** and **23** in hand, the important intermediate decalone **25** was readily available. Alkene **22** or **23** (or the mixture) was treated with ozone at −60°C, followed by decomposition of the resultant intermediate ozonide under reductive conditions employing dimethyl sulfide, and decalone **25** was thus obtained in 90–93% yield. In summary, the majority of the reactions outlined in Scheme 1 can be conducted without isolation of intermediates, thereby affording an overall efficient route to **25** from thujone.

For the functionalization of ring B in decalone **25** so as to provide a synthetic route to ring A monomethylated A/B *cis* fused drimane dialdehydes (see **38**, Scheme 2) for subsequent evaluation as antifeedants, it was considered appropriate to

34 II R^1= R^2=CN R^3=H

consider methodology developed earlier by de Groot and co-workers (10) for a related series of compounds. Thus introduction of the C8 aldehyde function was attempted initially with ethyl formate and sodium hydride in the manner described (10) but no reaction occurred. However, the use of stronger base (KH) was successful and a high yield (89%) of **29** was obtained. The latter compound, although easily purified by silica gel chromatography, was somewhat unstable and it was best to perform the next reaction without delay.

The olefinic bond in **30** was introduced via a selenylation–deselenylation reaction with **29**. Liotta *et al.* reported (11) that the rate of selenation with PhSeCl/pyridine can be roughly correlated with the percent enolic character of the starting β-dicarbonyl compound. When the substrate in question exists to a substantial extent in its enol form, selenation is instantaneous at room temperature. In our case, **29** exists entirely in the enol form, as supported by two singlets shown in the ^{1}H nmr spectrum at 8.56 and 14.29 ppm. Compound **29** was therefore readily converted to the corresponding unsaturated derivative **30** by (a) selenation using a 1:1 complex of phenylselenenyl chloride/pyridine and (b) *in situ* oxidation with 30% H_2O_2. The isolated yield of **30** was 86%.

The unsaturated keto aldehyde **30** was reacted with cyanide to afford the expected nitrile **31** as an unstable yellow oil that could not be purified due to rapid decomposition. However, the characteristic nitrile absorption (2236 cm^{-1}) in its infrared spectrum and the ^{1}H nmr spectrum with singlets at 4.01, 8.98, and 15.04 ppm clearly supported the assigned structure. Further characterization could be achieved, however, when the crystalline *n*-butylthio derivative **32**, obtained by treatment of **31** with 1-butanethiol under acidic conditions, was obtained. The stereochemistry of the nitrile group in **32** is uncertain and NMR data (see below) were inconclusive.

Borohydride reduction of **32** followed by treatment of the product (not isolated) with mercuric chloride and hydrochloric acid afforded the unsaturated aldehyde **33** as a crystalline product. For preparative purposes, isolation of intermediates **31** and **32** was not essential and the overall yield in the conversion **30** → → **33** was 52%.

To convert the nitrile function in **33** to the required aldehyde, initial protection of the aldehyde group in **33** by ketalization was considered. Thus, reaction of **33** with ethylene glycol catalyzed by *p*-toluenesulfonic acid afforded, somewhat surprisingly, a mixture of the expected ketal **34** (71% yield, one olefinic proton at 6.05 ppm) and the isomeric ketal **35** (18% yield, two olefinic protons at 5.53 and 6.62 ppm). Since it was expected that the double bond in **35** would migrate into conjugation with the aldehyde function on subsequent deprotection, it could be also utilized in the preparation of **38** (see Scheme 2).

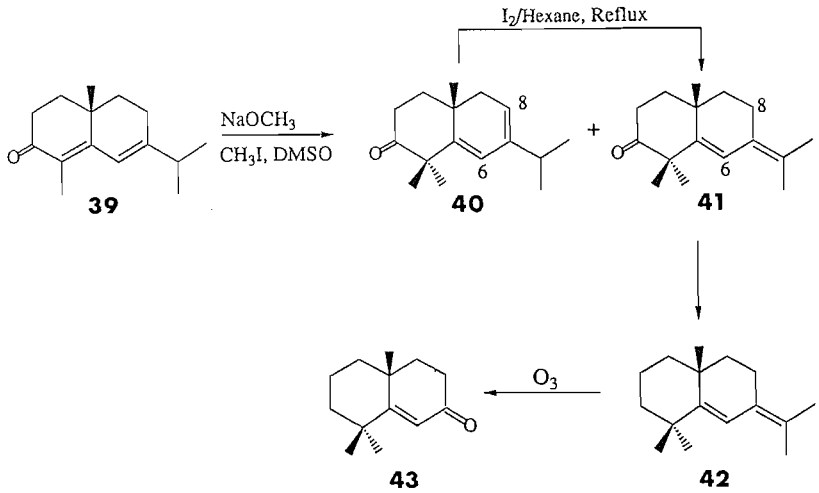
A comment concerning the stereochemistry of the nitrile function at C9 in **34** is appropriate and nmr data were considered for this purpose. Examination of the ^{1}H nmr spectrum of **34** revealed a one-proton singlet (2.79 ppm) for the C9 proton and a three-proton singlet at 1.24 ppm for the methyl group at C10. Irradiation of this methyl proton resonance resulted in an nOe enhancement of the C9 proton signal thereby establishing their close proximity to each other. However, conformational analysis suggests that in the most stable conformation (I) for the two possible C9 epimers (**34**I and **34**II), the distances between the C9 protons and the corresponding methyl protons are very similar, thereby preventing a definitive conclusion to be drawn from the nOe experiment.

Nitrile **34** was conveniently reduced to the corresponding aldehyde **36** (85% yield) by treatment with diisobutyl aluminum hydride at low temperature. In a similar manner, **35** was also converted to **37**.

Removal of the ketal group in **36** was achieved under acidic conditions to afford the target compound **38** in 93% yield. As was expected, deketalization of the minor isomer **37** also afforded **38**. Again, for preparative purposes, the cyano compounds **34** and **35** obtained as a mixture in the ketalization reaction of **33** can be directly reduced to **36** and **37** and the mixture then treated directly with acid. In this manner, the overall yield in the conversion **34**, **35** → → **38** is 77%. The dialdehyde functionality in **38** was clearly established by infrared (1718 and 1665 cm^{-1}) and ^{1}H nmr (9.44 and 9.79 ppm) spectroscopy.

Another nOe difference experiment was applied to **38**. Irradiation at the C14 methyl protons resonance (1.26 ppm) resulted in the enhancement of the C9 proton (3.33 ppm) and the C9 aldehyde proton (9.79 ppm). Similar arguments to those presented above for **34**, concerning nOe results and stereochemistry at C9, apply in this case and therefore nOe data cannot conclusively establish the C9 configuration in the final product **38**. However, it is logical to assume that the acidic treatment employed in the deketalization process leading to **38** may well provide the C9β orientation (equatorial) for the aldehyde function in **38**.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.



In conclusion, the sequence of reactions as summarized in Schemes 1 and 2, particularly since many of them can be conducted without isolation of intermediates, affords efficient routes to novel polygodial analogues. Subsequent evaluation will determine their antifeedant properties, if any.

As was noted earlier, the naturally occurring drimane antifeedants possess a *trans* A/B ring fusion and a *gem* dimethyl functionality in ring A. It was therefore desirable to establish an efficient route to the natural series employing thujone-derived intermediates. For this purpose, the previously synthesized β-cyperone molecule (**39**) (4) was considered as an appropriate starting material. Alkylation of **39** with methyl iodide and sodium methoxide in dimethyl sulfoxide yielded an inseparable mixture of the dienes **40** (5.38, m, C8-H; 5.80, s, C6-H) and **41** (6.41, s, C6-H) in an approximate ratio of 2:1 respectively, as determined by the relative intensity ratios of the olefinic signals in the ^{1}H nmr spectrum. Direct treatment of this mixture with iodine in refluxing hexane afforded pure **41** for further elaboration.

Wolff–Kishner reduction of **41** provided **42**, and the latter on low temperature ozonolysis (−78°C) afforded the conjugated ketone **43**. Since the latter, synthesized previously in racemic form by de Groot and co-workers (10), has been converted to (±)-polygodial (**1**) and (±)-warburganal (**2**), the present study with thujone-derived intermediates allows a synthetic entry to the natural series of antifeedants.

Experimental

Melting points were determined on a Nalge melting point apparatus and are uncorrected. The infrared spectra were recorded on Perkin–Elmer 710B and 1710 (Fourier Transform IR) spectrometers either in chloroform solution (using sodium chloride cells of 0.1-mm path length) or as a neat liquid film. The ultraviolet spectra were recorded on a Cary 15 spectrometer, the extinction coefficients (log ε_{max}) are given in parentheses, and the wavelength(s) of the maxima in nanometers. The mass spectra were recorded on AEI-MS-9 (low resolution) or Kratos-MS-50 (high resolution) spectrometers. The ^{1}H nmr spectra were recorded on either Bruker WH-400 or Varian XL-300 spectrometers in $CDCl_3$ solution and the chemical shifts are reported in ppm relative to tetramethylsilane (internal standard). The optical rotations were recorded on a Perkin–Elmer 141 automatic polarimeter in a 10-cm cell at ambient temperature using the solvent and concentrations (g/100 mL) indicated in parentheses following the recorded rotation values. The elemental analyses were determined by Mr. P. Borda, Microanalytical Laboratory, The University of British Columbia. The X-ray diffraction analysis was performed by Dr. S. Rettig on a Rigaku AFC6 diffractometer. Column chromatography was performed using 230–400 mesh silica gel supplied by E. Merck Co. Gas–liquid chromatography was performed on a Hewlett Packard model 5890 gas chromatograph, using a flame ionization detector and a 25 m × 0.21 mm fused silica capillary column: DB1701.

"Wet" ozonation of thujone

A solution of thujone **7** (10 g, 66 mmol) in ethyl acetate (100 mL) was cooled to −25°C and a stream of ozone was passed through with the employment of a gas dispersion tube for 10 h. While the ozonizer was turned off, the oxygen flow was continued for the next 15 min to remove an excess of ozone and the reaction mixture was allowed to warm up slowly to room temperature. Then 5 mL of dimethyl sulfide was added and stirred for 15 min. The reaction mixture was washed with a saturated solution of sodium bicarbonate and water and dried with sodium sulfate. After evaporation of solvent, the resulting oil was chromatographed on 250–400 mesh silica gel with the employment of a mixture of isopropanol and hexane (2:8) to yield alcohol **8** (4.7 g, 47%) and ketone **11** (2.3 g, 23%) with a combined yield of 70%.

"Dry" ozonation of thujone

To the solution of thujone **7** (350 mg, 2.3 mmol) in 50 mL of methyl chloride, 35 mg of silica gel was added and the solvent was removed under vacuum. The flask containing silica gel impregnated with thujone was equipped with a rotating mechanism, placed in a cooling bath (−78°C), and the stream of ozone was passed continuously for the period of 8 h. Then the mixture was allowed to warm up slowly from −78°C to room temperature. The elution with an organic solvent followed by chromatographic separation of the crude product yielded 195 mg of unreacted thujone and 115 mg (70% yield) of a mixture of alcohol **8** and ketone **11** in 3:1 ratio. Repeated column chromatography gave pure **8** and **11**.

Alcohol **8**: ir ν_{max} (neat): 3500, 1730 cm^{-1}; ^{1}Hmr δ: 0.11 (1H, t, J = 4.8), 1.13 (1H, m), 1.18 (3H, d, J = 7.6), 1.22 (3H, s), 1.32 (3H, s), 1.35 (1H, dd, J = 4.0, 8.0), 1.60 (1H, bs, OH), 2.19 (1H, d, J = 16.4), 2.29 (1H, q, J = 7.6), 2.79 (1H, dm, J = 16.4); ms m/z: 168 (M^+, 10%), 150 (4%), 107 (69%), 43 (100%). High resolution molecular weight determination calcd. for $C_{10}H_{16}O_2$: 168.1150; found: 168.1146.

Ketone **11**: ir ν_{max} (neat): 1740, 1685 cm^{-1}; ^{1}Hmr δ: 0.75 (1H, t, J = 4.8), 1.22 (3H, d, J = 8.4), 1.86–1.98 (2H, m), 2.09 (3H, s), 2.30–2.41 (2H, m), 3.25 (1H, m); ms m/z: 152 (M^+, 35%), 137 (11%), 124 (32%), 109 (100%). High resolution molecular weight determination calcd. for $C_9H_{12}O_2$: 152.0837; found: 152.0839.

*Dry ozonation of (5β)-7α-isopropyl-10β-methyltricyclo[4.4.0^{5,10}.0^{7,9}]-dec-3-one (**12**)*

To the solution of ketone **12** (500 mg, 2.5 mmol) in methylene dichloride (100 mL), silica gel (50 g) was added. After evaporation of solvent, the flask containing silica gel impregnated with ketone **12** was

For personal use only.

equipped with a rotating mechanism, placed in a cooling bath, and a stream of ozone was passed continuously for 8 h at the temperature of −78°C. Then the mixture was allowed to warm up slowly to room temperature. Silica gel was washed with methylene chloride and ethyl acetate. Evaporation of solvents gave 470 mg of oil, which after first chromatography yielded 310 mg of unreacted starting material and 132 mg of a 3:1 mixture of alcohol **13** and ketone **14** respectively. Repeated chromatography yielded pure **13** and **14**.

Alcohol **13**: ir ν_{max} (neat): 3459, 1690 cm^{-1}; ^{1}Hmr δ: 0.45 (1H, m), 0.63 (1H, m), 1.14 (3H, s), 1.15 (1H, m), 1.21 (3H, s), 1.24 (3H, s), 1.41 (1H, s, b, OH), 1.57–1.83 (5H, m), 2.09–2.25 (2H, m), 2.31–2.52 (2H, m); ms *m/z*: 222 (M^+), 204, 189.

Ketone **14**: ir ν_{max} (neat): 1705, 1680 cm^{-1}; ^{1}Hmr δ: 1.06 (1H, t), 1.25 (3H, s), 1.39 (1H, d, d), 1.69–1.89 (5H, m), 2.05 (3H, s), 2.12–2.25 (3H, m), 2.36–2.48 (2H, m); ms *m/z*: 206 (M^+), 191, 147.

*(5β)-4α,10β-Dimethyl-7α-isopropyltricyclo[4.4.0^{5,10}.0^{7,9}]dec-3-one (**16**)*

A mixture of tricyclic enone **15** (8.00 g, 36.7 mmol), potassium hydroxide (1 g, 17.8 mmol), and 10% palladium on active charcoal (2 g) in ethanol (800 mL) was hydrogenated at room temperature and atmospheric pressure. Hydrogen absorption ceased after 3.5 h. The mixture was filtered through a Celite plug and the filtrate evaporated. Water (100 mL) was added to the residue, and the mixture was extracted with methylene chloride (2 × 100 mL) and dried over sodium sulfate. Evaporation of the solvent at reduced pressure afforded the saturated ketone **16** as a colorless oil (7.99 g, 99%); ir ν_{max} (neat): 2942, 2846, 1702 cm^{-1}; ^{1}Hmr δ: 0.20 (1H, dd, *J* = 9, 4, C8), 0.43 (1H, dd, *J* = 6, 4, C8), 0.85 (3H, d, *J* = 8), 0.91 (3H, d, *J* = 8), 0.94 (3H, d, *J* = 7), 1.18 (1H, t, *J* = 11), 1.23 (3H, s), 1.33 (1H, h, *J* = 8), 1.61–1.83 (5H, m), 2.15 (1H, m, C2), 2.42 (1H, m, C2), 2.59 (1H, m, C4); ms *m/z*: 220 (M^+, 8%), 205 (5%), 177 (25%), 136 (32%), 124 (35%), 105 (51%), 93 (75%), 86 (100%), 82 (32%), 67 (26%), 55 (41%), 41 (54%). *(5β)-4α,10β-Dimethyl-7α-isopropyltricyclo[4.4.0^{5,10}.0^{7,9}]decane (**17**)*

A mixture of **16** (30 g, 136.4 mmol) and hydrazine (21.8 g, 681.8 mmol) in diethylene glycol (300 mL) was heated from 100 to 130°C for 1.5 h (water and excess hydrazine were distilled). After cooling, potassium hydroxide (45.8 g, 818.4 mmol) was added to the reaction mixture and heating was continued at 200–210°C for 6 h. The cooled reaction mixture was added to water (300 mL), extracted with ether (2 × 250 mL), washed with brine, and dried over sodium sulfate. The solvent was removed and the residue was purified on a silica gel column using petroleum ether as eluant to give the ketone-free compound **17** (24.5 g, 87%) as a colorless oil; ir ν_{max} (neat): 3035, 2995, 2925, 2860, 1470, 1385 cm^{-1}; ^{1}Hmr δ: 0.07 (1H, dd, *J* = 8, 5, C8), 0.40 (1H, dd, *J* = 10, 5, C8), 0.81 (3H, d, *J* = 7), 0.89 (3H, d, *J* = 7), 0.96 (3H, d, *J* = 7, C13), 0.95 (3H, s), 1.10–1.63 (12H, m); ms *m/z*: 206 (M^+, 15%), 191 (35%), 163 (100%), 123 (40%), 110 (24%), 95 (32%), 81 (41%), 55 (60%). *(5β)-4α,10β-Dimethyl-7α-isopropinoltricyclo[4.4.0^{5,10}.0^{7,9}]decane (**18**) and (5β)-7α-acetyl-4α,10β-dimethyltricyclo[4.4.0^{5,0}.0^{7,9}]-decane (**19**)*

Ozone was bubbled through a solution of **17** (24 g, 116.5 mmol) in ethyl acetate (500 mL) containing sodium bicarbonate (9.8 g) at −40°C (acetonitrile/Dry Ice bath) for 8 h. The excess ozone was removed under a stream of argon and then dimethyl sulfide (5 mL) was added to the solution. The reaction mixture was allowed to warm to room temperature and stirred for 1 h. Filtration and concentration, followed by flash chromatography on a silica gel column (hexanes–ethyl acetate as eluant, 17:3, v/v), provided alcohol **18** (10 g, 38.7%), ketone **19** (7.7 g, 32.3%), and starting material **17** (6.9 g, 28.7%). The total yield was 71% based on the recovered starting material. Alcohol **18**: ir ν_{max} (neat): 3405, 3050, 2903, 2850, 1140 cm^{-1}; ^{1}Hmr δ: 0.43 (1H, dd, *J* = 5, 4, C8), 0.48 (1H, dd, *J* = 6, 4, C8), 0.83 (3H, d, *J* = 6), 0.98 (3H, s), 1.18 (3H, s), 1.27 (3H, s), 1.00–1.51 (10H, m), 1.62 (1H, O-H), 1.75 (1H, t, *J* = 12); ms *m/z*: 222 (M^+, 2.1%), 204 ($M^+ - H_2O$, 17%), 189 (18%), 161 (28%), 133 (30%), 119 (13%), 105 (49%), 95 (100%), 91 (57%), 81 (59%), 67 (37%), 59 (27%), 55 (37%), 41 (63%), 32 (30%). *(5β)-4α,10β-Dimethyl-7α-(1'-hydroxyethyl)-tricyclo[4.4.0^{5,10}.0^{7,9}]-decane (**24**)*

To a solution of ketone **19** (5.2 g, 25 mmol) in methanol (70 mL) was added sodium borohydride (0.58 g, 15 mmol) at 0°C. The reaction mixture was stirred at 0°C for 20 min, then the methanol was evaporated. Ether was added to the residue and the solution was washed with water and brine. The solvent was removed under reduced pressure and the residue was purified by chromatography on a silica gel column (ether/pet. ether as eluant, 1:1, v/v) to afford alcohol **24** (4.8 g, 93%) as a colorless oil; ir ν_{max} (neat): 3325, 3050, 2900, 1100 cm^{-1}; ^{1}Hmr δ: 0.24 (1H, dd, *J* = 9, 5, C8), 0.56 (1H, dd, *J* = 6, 5, C8), 0.82 (3H, d, *J* = 7), 0.98 (3H, s), 1.21 (3H, d, *J* = 7), 0.88–1.67 (11H, m), 1.72 (1H, t, *J* = 11), 3.42 (1H, q, *J* = 7).

*(5β)-8-Chloromethyl-4α,9β-dimethyl-7α-isopropylidenebicyclo-[4.3.0^{5,9}]nonane (**20**)*

Compound **18** (6.08 g, 27.4 mmol) was dissolved in dichloromethane (150 mL) and added to ice-cold concentrated hydrochloric acid (150 mL). The mixture was stirred rapidly at 0°C for 2 h. The mixture was poured into water (200 mL), and the aqueous layer was extracted with dichloromethane (3 × 70 mL). The combined organic extracts were washed with saturated aqueous sodium bicarbonate solution (2 × 70 mL), dried over sodium sulfate, and the solvent was evaporated. The yellow oil was carried over to the next step without purification; ir ν_{max} (neat): 2905, 2850, 1654, 718 cm^{-1}; ^{1}Hmr δ: 0.87 (3H, d, *J* = 7), 1.14 (3H, s), 1.65 (3H, s), 1.73 (3H, s), 0.89–1.59 (7H, m), 1.90 (1H, m), 2.11 (2H, d, *J* = 10, C6), 2.50 (1H, m, C8), 3.45 (1H, dd, *J* = 11, 4, C10), 3.61 (1H, dd, *J* = 11, 8, C10); ms *m/z*: 242/240 (M^+, 3/11%), 227/225 (1/5%), 204 (45%), 197 (20%), 189 (52%), 161 (100%), 147 (25%), 133 (44%), 119 (60%), 105 (52%), 95 (57%), 91 (58%), 83 (24%), 79 (35%), 61, 55 (45%), 41 (84%). High resolution molecular weight determination calcd. for $C_{15}H_{25}{}^{35}Cl$: 240.1656; found: 240.1650.

Compound **21** was prepared from **24** as described for **20**. The crude oily product was carried over to the next step without purification.

*(5β)-4α,10β-Dimethyl-7-isopropylidenebicyclo[4.4.0^{5,10}]decane (**22**)*

To a solution of crude **20** in dry toluene (250 mL) under argon was added tri-*n*-butyltin hydride (11.9 g, 41.1 mmol). AIBN (300 mg, 1.9 mmol) was then added and the reaction mixture was heated at reflux under argon for 2 h. A further portion of AIBN (300 mg) was added and the reaction maintained at gentle reflux for an additional 6 h. The solvent was evaporated and the residue chromatographed on silica gel with hexanes to give **22** (3.16 g, 56%, calculated from **18**), as a colorless oil; ir ν_{max} (neat): 2920, 1660 cm^{-1}; ^{1}Hmr δ: 0.88 (3H, d, *J* = 7), 0.94 (3H, s), 1.11–1.62 (10H, m), 1.65 (3H, s), 1.66 (3H, s), 1.83–1.98 (2H, m), 2.41 (2H, m); ms *m/z*: 206 (M^+, 3%), 191 (2%), 163 (6%), 109 (9%), 95 (7%), 81 (22%), 67 (10%), 55 (11%), 41 (17%), 17 (100%). High resolution molecular weight determination calcd. for $C_{15}H_{26}$: 206.2034; found: 206.2037. Anal. calcd. for $C_{15}H_{26}$: C 87.30, H 12.70; found: C 87.05, H 12.60.

Compound **23** was prepared from **21** as described for **22**. The total

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

yield from **24** to **23** was 53%; ir ν_{max} (neat): 2950, 2930, 2859, 1660, 829 cm^{-1}. Partial ^{1}Hmr (1:1 C11 isomer) δ: 0.83, 0.87 (3H, two sets, d, J = 6), 0.95 (3H, two sets, s), 1.56 (3H, two sets, d, J = 4, C12), 5.13 (1H, two sets, m, C11); ms m/z: 192 (M^+, 42%), 177 (28%), 163 (39%), 109 (100%), 95 (41%), 81 (58%), 67 (38%), 55 (27%), 41 (34%). High resolution molecular weight determination for $C_{14}H_{24}$: 192.1878; found: 192.1870.

(5β)-4α,10β-Dimethyl-octahydro-7-(6H)-naphthalenone (25)

Ozone was bubbled through a solution of **22** (2.30 g, 11.2 mmol) in ethyl acetate (70 mL) at −60°C. After 20 min, the system was flushed with argon until there was no blue color in the solution, and dimethyl sulfide (1.12 mL, 15.2 mmol) was added. The solution was then allowed to warm up slowly to 0°C in 1 h, then stirred at ice bath temperature for 1 h, and finally at room temperature for 1 h. The solvent was removed and the residue was purified by flash chromatography (ether/pet. ether, 2:8, v/v) to give decalone **25** (1.83 g, 91%) as a colorless oil.

23 provided **25** in the same way to give a yield of 90%; $[\alpha]_D^{18}$ +12.9° (*c* 0.940, methanol); ir ν_{max} (neat): 2900, 2845, 1705 cm^{-1}; ^{1}Hmr δ: 0.80 (3H, d, J = 7, C11), 1.05 (3H, s, C12), 1.06–2.03 (10H, m), 2.12–2.56 (4H, m); ms m/z: 180 (M^+, 10%), 123 (9%), 109 (23%), 95 (17%), 81 (14%), 69 (14%), 55 (13%), 41 (15%), 31 (100%). High resolution molecular weight determination calcd. for $C_{12}H_{20}O$: 180.1514; found: 180.1514. Anal. calcd. for $C_{12}H_{20}O$: C 79.94, H 11.18; found: C 80.00, H 11.30.

(5β)-7α-Acetyl-4α,10β-dimethyltricyclo[4.4.0^{5,10}.0^{7,9}]dec-3-one (26)

Diketone **26** was obtained in the process of "wet" ozonation as described earlier ("wet" ozonation of thujone); ir ν_{max} ($CHCl_3$): 1713, 1680 cm^{-1}; ^{1}Hmr δ: 0.98 (3H, d, J = 6.4), 1.06 (1H, t, J = 4.8), 1.33 (3H, s), 1.38 (1H, dd, J = 4.8, 8.0), 1.65–2.00 (6H, m), 2.07 (3H, s), 2.46 (1H, m), 2.64 (1H, m); ms m/z: 220 (M^+, 15.3%), 205 (3.2%), 177 (10.4%), 43 (100%). *4α,10β-Dimethyl-*cis*-perhydro-7-oxonaphthalene-8-carboxaldehyde (29)*

The formylation of **25** was performed by suspending potassium hydride (1.33 g, 33.3 mmol) in dry THF (120 mL). To this suspension was added a mixture of **25** (6.00 g, 33.3 mmol) and ethyl formate (5.00 g, 66.6 mmol) in dry THF (10 mL) over 5 min. After stirring at room temperature for 20 min, the solvent was evaporated and ether (100 mL) was added to the residue. The ethereal solution was extracted twice with 4 N potassium hydroxide (50 mL). The combined alkaline solution was acidified with concentrated hydrochloric acid and extracted with ether. The ethereal solution was washed with brine and dried. Evaporation of ether gave **29** (6.17 g, 89%) as a light yellow liquid; $[\alpha]_D^{23}$ 0.575° (*c* 1.980, methanol); ir ν_{max} (neat): 3350, 2920, 2850, 1650, 1600 cm^{-1}; ^{1}Hmr δ: 0.85 (3H, d, J = 6), 1.09 (3H, s), 0.88–1.63 (8H, m), 2.05 (2H, d, J = 15, C9), 2.28 (2H, dd, J = 8.4, C6), 8.56 (1H, s, olefin-H), 14.29 (1H, s, O-H); ms m/z: 208 (M^+, 31%), 190 (5%), 178 (6%), 110 (50%), 95 (100%). High resolution molecular weight determination calcd. for $C_{13}H_{20}O_2$: 208.1463; found: 208.1462.

4α,10β-Dimethyl-1,2,3,4,5β,6,7,10-octahydro-7-oxonaphthalene-8-carboaldehyde (30)

To an ice-cooled solution of benzene selenenyl chloride (5.68 g, 29.7 mmol) in dichloromethane (300 mL) were added pyridine (2.58 g, 32.6 mmol) and **29** (6.17 g, 29.7 mmol) in dichloromethane (25 mL). The reaction mixture was stirred for 1 h and washed with 4 N hydrochloric acid (25 mL) and brine (25 mL). The dichloromethane solution was cooled to 0°C, 30% hydrogen peroxide (4.5 mL) was added in three portions with intervals of 20 min, and the reaction was stirred at 0°C for another 30 min. The solvent was then evaporated and the residue was purified by column chromatography on silica gel using pet. ether/ether (4:1 v/v) as eluant to give **30** (5.26 g, 86%) as a colorless oil; $[\alpha]_D^{20}$ 96.16° (*c* 1.016, methanol); uv λ_{max}: 238, (3.836); ir ν_{max} (neat): 2920, 2856, 1680, 1617 cm^{-1}; ^{1}Hmr δ: 0.91 (3H, d, J = 7), 1.21 (3H, s), 1.07–2.05 (8H, m), 2.42 (2H, m, C6), 7.45 (1H, s, C9), 10.09 (1H, s, aldehyde-H); ms m/z: 206 (M^+, 26%), 191 (29%), 178 (70%), 110 (87%), 95 (100%), 55 (13%), 41 (20%). High resolution molecular weight determination calcd. for $C_{13}H_{18}O_2$: 206.1307; found: 206.1303. Anal. calcd. for $C_{13}H_{18}O_2$: C 75.67, H 8.79; found: C 75.55, H 8.94.

*4α,10β-Dimethyl-8-(hydroxymethylene)-*cis*-perhydro-7-oxonaphthalene-9-carbonitrile (31)*

To a solution of **30** (3.00 g, 14.6 mmol) in dioxane (43 mL) and water (4.3 mL) was added a solution of potassium cyanide (0.949 g, 14.6 mmol) in dioxane (4.3 mL) and water (1 mL). The reaction mixture was stirred at room temperature for 30 min, and then the dioxane was evaporated. The residue was treated with 4 N potassium hydroxide (20 mL) and extracted with ether. The basic solution was acidified with concentrated hydrochloric acid (5 mL) and washed with ether. The ethereal solution was washed with brine and dried. The ether was evaporated to give crude **31** (2.41 g, 71%) as a yellow oil; ir ν_{max} (neat): 3621, 3019, 2964, 2933, 2236, 1220 cm^{-1}. ^{1}Hmr δ: 0.91 (3H, d, J = 5), 1.15 (3H, s), 1.22–2.00 (8H, m), 2.53 (1H, d, J = 20, C6), 2.56 (1H, dd, J = 20, 5, C6), 4.01 (1H, s, C9), 8.98 (1H, s, olefin-H), 15.04 (1H, s, O-H); ms m/z: 233 (M^+, 8%), 215 (1%), 206 (5%), 178 (21%), 110 (78%), 95 (100%), 81 (26%), 77 (30%), 67 (31%), 53 (36%), 41. High resolution molecular weight determination calcd. for $C_{14}H_{19}NO_2$: 233.1415; found: 233.1415.

*8-[(Butylthio)methylene]-4α,8aβ-dimethyl-*cis*-perhydro-7-oxonaphthalene-9-carbonitrile (32)*

A solution of **31** (2.41 g, 10.4 mmol), 1-butanethiol (1.0 mL), and *p*-toluenesulfonic acid (14 mg) in dry benzene (60 mL) was refluxed for 3 h in a Dean–Stark apparatus. After cooling, the reaction mixture was washed with saturated sodium bicarbonate solution (10 mL), water (10 mL), and brine (10 mL), and dried. The benzene was evaporated and the residue was purified by column chromatography on silica gel using ether/pet. ether (3:7 v/v) as eluant to give compound **32** (2.77 g, 88%) as white crystals; mp 85–86°C, ir ν_{max} ($CHCl_3$): 2990, 2950, 2933, 2852, 2220, 1660, 1545 cm^{-1}; ^{1}Hmr δ: 0.85 (3H, d, J = 6), 0.95 (3H, t, J = 8), 1.38 (3H, s), 1.02–2.25 (12H, m), 2.32 (1H, dd, J = 20, 10, C6), 2.43 (1H, dd, J = 20, 8, C6), 2.94 (2H, t, J = 8, S-CH_2), 3.37 (1H, s, C9), 7.89 (1H, s, olefin-H); ms m/z: 305 (M^+, 17%), 248 (38%), 217 (20%), 109 (100%), 89 (32%), 67 (29%), 55 (50%), 44 (12%). High resolution molecular weight determination calcd. for $C_{18}H_{27}NOS$: 305.1805; found: 305.1809. Anal. calcd. for $C_{18}H_{27}NOS$: C 70.77, H 8.91, N 4.59, S 10.50; found: C 70.63, H 8.72, N 4.41, S 10.39.

4α,10β-Dimethyl-8-formyl-1,2,3,4,5β,6,9,10-octahydronaphthalene-9-carbonitrile (33)

To a solution of **32** (1.623 g, 5.3 mmol) in methanol (15 mL) was added sodium borohydride (62 mg, 1.6 mmol) at 0°C. The reaction mixture was stirred for 15 min, and then the methanol was evaporated. Ether was added to the residue, and the solution was washed with water and brine. The ether was evaporated and the residue was dissolved in methanol (25 mL). Mercuric chloride (2.44 g, 9.0 mmol) and 4 N hydrochloric acid (7.5 mL) were added to this solution. The reaction mixture was stirred at room temperature for 16 h, and then filtered. The methanol was evaporated, and ether (100 mL) was added. The ethereal solution was washed with saturated sodium bicarbonate solution and with brine, and dried. The ether was evaporated, and the residue was purified by column chromatography on silica gel using ether/pet. ether (3:7 v/v) as eluant to give **33** (0.712 g, 84%) as white crystals; mp 103–104.5°C; $[\alpha]_D^{15}$ 149.8° (*c* 0.990, methanol); uv λ_{max}: 224, (4.129); ir ν_{max} ($CHCl_3$): 2915, 2850, 2220, 1683, 1659 cm^{-1}; ^{1}Hmr δ: 0.91 (3H, d, J = 5), 1.36 (3H, s), 1.05–2.13 (8H, m), 2.31 (1H, ddd, J = 20, 9, 4, C6), 2.45 (1H, ddd, J = 20, 8, 4, C6), 3.30 (1H, s, C9), 7.05 (1H, dd, J = 4, 4, C7), 9.51 (1H, s, aldehyde-H); ms m/z: 217 (M^+, 12%), 200 (10%), 190 (30%), 146 (21%), 110 (98%), 105 (39%), 95 (100%), 81 (23%), 77 (21%), 55 (31%), 41 (50%). *4α,10β-Dimethyl-8-(1,3-dioxolan-2-yl)-1,2,3,4,5β,6,9,10-octahydronaphthalene-9-carbonitrile (**34**) and 4α,10β-dimethyl-8-(1,3-dioxolan-2-yl)-1,2,3,4,5β,8,9,10-octahydro-naphthalene-9-carbonitrile (**35**)*

A solution of **33** (712 mg, 3.3 mmol), ethylene glycol (0.83 mL), and *p*-toluenesulfonic acid (5 mg) in benzene (9 mL) was refluxed for 3 h in a Dean–Stark apparatus. The reaction mixture was cooled, ether (50 mL) was added, and the solution was washed with saturated sodium bicarbonate solution and dried. The solvent was evaporated and the residue was purified by column chromatography on silica gel using ether/pet. ether (3:7 v/v) as eluant to give **34** (615 mg, 71%) and **35** (156 mg, 18%).

Compound **34**: $[\alpha]_D^{15}$ 109.6° (*c* 0.920, methanol); ir ν_{max} (neat): 2950, 2900, 2220, 1680 cm^{-1}; ^{1}Hmr δ: 0.79 (3H, d, *J* = 7), 1.24 (3H, s), 0.85–2.14 (10H, m), 2.79 (1H, s, C9), 3.85–4.04 (4H, m), 5.19 (1H, s), 6.05 (1H, dd, *J* = 4, 4, C7); ms *m/z*: 261 (M^+, 12%), 246 (6%), 221 (3%), 138 (21%), 110 (47%), 95 (73%), 86 (100%), 73 (84%), 55 (18%), 41 (23%). High resolution molecular weight determination calcd. for $C_{16}H_{23}NO_2$: 261.1729; found: 261.1724. Anal. calcd. for $C_{16}H_{23}NO_2$: C 73.53, H 8.87, N 5.36; found: C 73.31, H 8.98, N 5.36.

Compound **35**: ^{1}Hmr δ: 0.84 (3H, d, *J* = 7), 1.30 (3H, s), 1.19–2.32 (9H, m), 2.85 (1H, d, *J* = 4, C9), 3.83–4.05 (4H, m), 5.14 (1H, d, *J* = 6, C8), 5.53 (1H, dd, *J* = 10, 2, olefin-H), 6.02 (1H, dd, *J* = 10, 2, olefin-H).

*4α,10β-Dimethyl-8-(1,3-dioxolan-2-yl)-1,2,3,4,5β,6,9,10-octahydronaphthalene-9-carboxaldehyde (**36**) and 4α,10β-dimethyl-8-(1,3-dioxolan-2-yl)-1,2,3,4,5β,8,9,10-octahydronaphthalene-9-carboxaldehyde (**37**)*

A solution of **34** (250 mg, 0.96 mmol) in dry toluene (19 mL) was cooled to −60°C under argon, and a solution of diisobutylaluminum hydride (1.0 M, hexane solution) (1.80 mL) was added. The reaction mixture was stirred at −60°C for 3 h and then poured into saturated ammonium chloride solution (15 mL). The layers were separated and the aqueous layer was extracted 5 times with ether (100 mL). The combined organic solutions were dried, and the solvent was evaporated. The residue was purified by column chromatography on silica gel using ether/pet. ether (3:7 v/v) as eluant to give **36** (215 mg, 85%) as a colorless oil; $[\alpha]_D^{21}$ 311° (*c* 0.820, methanol); ir ν_{max} (neat): 2900, 2835, 2690, 1705, 1655 cm^{-1}; ^{1}Hmr δ: 0.84 (3H, d, *J* = 7), 1.10 (3H, s), 0.93–2.25 (10H, m), 2.67 (1H, d, *J* = 5, C9), 3.80–4.10 (4H, m), 5.16 (1H, s, C11), 6.20 (1H, dd, *J* = 4, 4, C7), 9.50 (1H, d, *J* = 5, aldehyde-H); ms *m/z*: 264 (M^+, 1%), 249 (0.5%), 235 (44%), 73 (100%), 55 (23%), 45 (40%), 41 (34%). High resolution molecular weight determination calcd. for $C_{16}H_{24}O_3$: 264.1726; found: 264.1723. Anal. calcd. for $C_{16}H_{24}O_3$: C 72.70, H 9.15; found: C 73.00, H 9.30.

Compound **35** (188 mg, 0.72 mmol) in toluene (15 mL) was reduced by DIBAH (toluene solution, 1.5 M) (1.3 mL) at −78°C in 2 h by the above procedure to give **37**. The crude product was hydrolyzed in the next reaction without further purification.

*4α,10β-Dimethyl-1,2,3,4,5β,6,9,10-octahydronaphthalene-9,8-dicarboxaldehyde (**38**)*

A solution of **36** (92 mg, 0.35 mmol) and *p*-toluenesulfonic acid (8 mg) in acetone (7 mL) and water (1.7 mL) was stirred for 2 h at room temperature. The acetone was evaporated, and water/ether were added. The aqueous layer was extracted with ether, and the combined ethereal solution was washed with saturated sodium bicarbonate solution, with water, and brine, and then dried. The ether was evaporated and the residue was chromatographed on silica gel using ether/pet. ether (3:7 v/v) as eluant to give **38** (71 mg, 93%) as a colorless oil; $[\alpha]_D^{16}$ 393° (*c* 0.700, methanol); uv λ_{max}: 229 (4.026); ir ν_{max} (neat): 2920, 2860, 2820, 2715, 1718, 1665, 1300 cm^{-1}; ^{1}Hmr δ: 0.86 (3H, d, *J* = 7), 1.26 (3H, s), 1.05–2.50 (10H, m), 3.33 (1H, d, *J* = 3, C9), 7.09 (1H, dd, *J* = 4, 4, C7), 9.44 (1H, s, C8-aldehyde-H), 9.79 (1H, d, *J* = 3, C9-aldehyde-H); ms *m/z*: 220 (M^+, 1%), 202 (2%), 192 (70%), 177 (20%), 121 (42%), 109 (44%), 95 (100%), 91 (67%), 81 (56%), 77 (57%), 67 (45%), 55 (46%), 41 (50%). High resolution molecular weight determination calcd. for $C_{14}H_{20}O_2$: 220.1461; found: 220.1462. Anal. calcd. for $C_{14}H_{20}O_2$: C 76.33, H 9.15; found: C 76.38, H 9.20.

Crude **37** from last step in acetone (15 mL), water (3.6 mL), and 1 N hydrochloric acid (2 mL) was refluxed for 6 h to give **38** (121 mg, 77% from **35**).

*7-Isopropyl-4,4,10β-trimethyl-1,4,9,10-tetrahydro-3-(2H)-naphthalenone (**40**) and 7-isopropenyl-4,4,10β-trimethyl-1,4,7,8,9,10-hexahydro-3-(2H)naphthalenone (**41**)*

To a mixture of β-cyperone (11.7 g) and dry DMSO (90 mL) at room temperature and under argon atmosphere, was added sodium methoxide (8.5 g). After stirring for 1 h, methyl iodide (15 mL) was added. The reaction mixture was stirred for 0.5 h. It was then poured into 1 N HCl (400 mL) and extracted with ether (3 × 500 mL). The combined ethereal layers were washed with water, dried over sodium sulfate, filtered, and evaporated to give an oil, which was chromatographed on silica gel to give a mixture of **40** and **41** (4.82 g, 39% isolated yield or 61% based on recovered starting material) and starting material **39** (4.22 g, 36%).

Analytical samples of **40** and **41** were obtained by subjecting the mixture to preparative tlc (2% ethyl ether in petroleum ether as eluting solvent, eight developments). In this manner, pure **40** was isolated as the more mobile compound. Compound **40**: ir ν_{max} ($CHCl_3$): 1710, 1660 (w), 1605 (w) cm^{-1}; uv (methanol) λ_{max}: 266 nm (ε 5 600); ^{1}Hmr δ: 1.01 (3H, s), 1.02 (3H, d, *J* = 7.2), 1.03 (3H, d, *J* = 7.2), 1.31 (6H, s), 5.38 (1H, br d, *J* = 5.8), 5.80 (1H, s); ms *m/z*: 232 (M^+, 58%), 217 (13%), 189 (35.5%), 175 (100%). High resolution molecular weight determination calcd. for $C_{16}H_{24}O$: 232.1829; found: 232.1827. Anal. calcd. for $C_{16}H_{24}O$: C 82.71, H 10.41; found: 82.91, H 10.40.

Compound **41**: ir ν_{max} ($CHCl_3$): 1710, 1605 (w) cm^{-1}; uv (methanol) λ_{max}: 251 nm (ε 18 000); ^{1}Hmr δ: 1.04 (3H, s), 1.31 (6H, s), 1.77 (3H, s), 1.82 (3H, s), 6.40 (1H, s); ms *m/z*: 232 (M^+, 100%), 217 (64%), 189 (78%), 175 (19%). High resolution molecular weight determination calcd. for $C_{16}H_{24}O$: 232.1829; found: 232.1828. Anal. calcd. for $C_{16}H_{24}O$: C 82.71, H 10.41; found: C 82.90, H 10.45.

*7-Isopropenyl-4,4,10β-trimethyl-1,4,7,8,9,10-hexahydro-3-(2H)-naphthalenone (**41**) by isomerization of a mixture of **40** and **41***

A mixture of **40** and **41** (5.38 g), iodine (550 mg), and hexane (110 mL) was heated under reflux for 1 h. The mixture was poured into saturated sodium thiosulfate (300 mL) and then extracted with ether (3 × 500 mL). The combined organic layers were washed with water, dried over sodium sulfate, filtered, and evaporated to give an oil, which was purified on a silica gel column to afford **41** (4.6 g, 86%) as a slightly yellow oil.

*7-Isopropenyl-4,4,10β-trimethyl-1,2,3,4,7,8,9,10-octahydronaphthalene (**42**)*

A mixture of **41** (4.94 g), hydrazine monohydrate (5 mL), potassium hydroxide (3.2 g), and diethylene glycol (40 mL) was heated under reflux at 135°C for 1 h. Then the temperature of the reaction mixture was slowly raised to 205–210°C. Volatile materials were removed with a Dean–Stark trap. After stirring for 1 h at 205–210°C, the mixture was cooled, poured into water (200 mL), and extracted with petroleum ether (3 × 200 mL). The combined organic layers were washed with water, dried over sodium sulfate, filtered, and evaporated to leave an oil, which was chromatographed on a silica gel column to afford **42** (3.94 g, 85%) as a colorless oil; uv (methanol) λ_{max}: 250 nm (ε 20 000); ^{1}Hmr δ: 1.13 (3H, s), 1.15 (3H, s), 1.16 (3H, s), 1.73 (3H, s), 1.81 (3H, d, *J* = 2.0), 6.35 (1H, s); ms *m/z*: 218 (M^+, 100%), 203 (96%), 175 (21%). High resolution molecular weight determination calcd. for $C_{16}H_{26}$: 218.2035; found: 218.2037. Anal. calcd. for $C_{16}H_{26}$: C 88.00, H 12.00; found: 87.99, H 12.10.

*4,4,10β-Trimethyl-1,2,3,4,9,10-hexahydro-7-(8H)-naphthalenone (**43**)*

Diene **42** (3.94 g) in a mixture of dichloromethane–methanol (9:1, 500 mL) was ozonized at −78°C for 20 min. Then dimethyl sulfide

(20 mL) was added. The reaction mixture was allowed to warm up to room temperature and stirred at room temperature for 3 h. Removal of solvents followed by chromatography on a silica gel column afforded recovered starting material (475 mg) and enone **43** (2.14 g, 70% based on recovered starting material) as a yellow oil; ir ν_{max}: 1660, 1600 cm^{-1}; uv (methanol) λ_{max}: 241 nm (ε 13 200); ^{1}Hmr δ: 1.15 (3H, s), 1.19 (3H, s), 1.34 (3H, s), 5.96 (1H, s); ms *m/z*: 192 (M^+, 86%), 177 (14%), 164 (30%), 149 (51%), 136 (75%), 123 (100%). High resolution molecular weight determination calcd. for $C_{13}H_{20}O$: 192.1514; found: 192.1507.

Appendix

X-ray crystallographic analysis of ***26***

A crystal ca. 0.10 × 0.25 × 0.33 mm in size was mounted in a general orientation. Unit-cell parameters were refined by least squares on setting angles for 25 reflections (2θ = 50.1–94.2°) measured on a diffractometer with Cu-K_α radiation (λ = 1.54178 Å). Crystal data at 21°C are as follows:

$C_{14}H_{20}O_2$ f.w. = 220.31

Orthorhombic, a = 6.165(2), b = 12.649(1), c = 15.997(1) Å, V = 1247.5(4) Å^3, Z = 4, ρ_c = 1.173 Mg m^{-3}, $F(000)$ = 480, μ(Cu-K_α) = 5.70 cm^{-1}. Absent reflections ($h00$, h odd; $0k0$, k odd; and $00l$, l odd) uniquely indicate the space group $P2_12_12_1$.

Intensities were measured with graphite-monochromated Cu-K_α radiation on a Rigaku AFC6S diffractometer. An ω–2θ scan at 8° min^{-1} over a range of (1.25 + 0.30 tan θ)° in ω (with up to eight rescans, background/scan time ratio = 0.5) was employed. Data were measured to 2θ = 150°. The intensities of three check reflections, measured every 150 reflections throughout the data collection, showed only small random fluctuations. After data reduction,[3] an empirical absorption correction, based on azimuthal scans for three reflections, was applied, which resulted in transmission factors ranging from 0.95 to 1.00. Of the 1307 independent reflections measured, 1083 (82.9%) had intensities greater than or equal to $3\sigma(F^2)$ above background where $\sigma^2(F^2) = [S^2(C + 4B) + (0.04F^2)^2]/(Lp)^2$ with S = scan rate, C = scan count, B = total background count, and Lp = Lorentz polarization factor.

The structure was solved by direct methods, the coordinates of all 16 non-hydrogen atoms being determined from an E-map. Hydrogen atoms were positioned from a subsequent difference Fourier synthesis. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms with isotropic thermal parameters. Scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from ref. 12. The weighting scheme $w = 4F_o^2/\sigma^2(F_o^2)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix least-squares refinement of 226 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.032 and R_w = 0.047 for 1083 reflections with $I \geq 3\sigma(I)$. The

function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the maximum parameter shift corresponded to 0.04σ. The mean error in an observation of unit weight was 1.95. The final difference map showed maximum fluctuations of $-0.09 - +0.12$ e Å^{-3}. The absolute configuration was based on that known for C(10). A parallel refinement of the opposite enantiomer resulted in marginally higher residuals (R_w ratio = 1.002). The final positional and (equivalent) isotropic thermal parameters for the non-hydrogen atoms appear in Table 1. Bond lengths and angles are given in Tables 2 and 3. Hydrogen atoms parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, least-squares planes, bond lengths and angles involving hydrogen, and structure factors have been deposited.[4]

Discussion

Compound **26** has the structure and absolute configuration shown in Fig. 1. Both ring junctions are *cis*. The six- and five-membered rings have chair and flattened C(5)-envelope conformations, respectively. Bond lengths and angles (Tables 2 and 3) are normal. All intermolecular distances correspond to normal van der Waals interactions, the shortest intermolecular distance between non-hydrogen atoms being O(2)···C(12) = 3.383(5) Å.

Formation and reactivity of 1-pyrrolyl-2,2,2-trifluoroethyl cations[1]

ANNETTE D. ALLEN, JEAN-MARC KWONG-CHIP, WING CHEUNG LIN, PAUL NGUYEN, AND THOMAS T. TIDWELL[2]

Department of Chemistry, University of Toronto, Scarborough Campus, Scarborough, Ont., Canada M1C 1A4

Received March 14, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

ANNETTE D. ALLEN, JEAN-MARC KWONG-CHIP, WING CHEUNG LIN, PAUL NGUYEN, and THOMAS T. TIDWELL. Can. J. Chem. **68**, 1709 (1990).

1-(1-Methyl-2-pyrrolyl)-2,2,2-trifluoroethyl *p*-nitrobenzoate (**3**) reacts by carbocation formation with an *m* value for the dependence of rate on the solvent polarity parameter Y_{OTs} of 0.56, and a rate 41 times slower than (1-methyl-2-pyrrolyl)methyl *p*-nitrobenzoate. The products from **3** include significant amounts of material derived from solvent attack at the 5-position of the pyrrole ring. The results indicate a high degree of charge delocalization by the strongly donating pyrrolyl group, resulting in a low $k(H)/k(CF_3)$ rate ratio and nucleophilic attack on the ring. 1,1,1-Trifluoro-2-(1-methyl-2-pyrrolyl)propan-2-ol (**10**) reacted with CF_3CO_2H via a tertiary carbocation, which led to dimeric products resulting from electrophilic substitution on the pyrrole ring.

Key words: pyrrole, trifluoromethyl substituents, carbocations.

ANNETTE D. ALLEN, JEAN-MARC KWONG-CHIP, WING CHEUNG LIN, PAUL NGUYEN et THOMAS T. TIDWELL. Can. J. Chem. **68**, 1709 (1990).

Le *p*-nitrobenzoate de 1-(1-méthyl-2-pyrrolyl)-2,2,2-trifluoroéthyle (**3**) réagit par formation de carbocation avec une valeur *m*, pour la dépendance de la vitesse de réaction sur le paramètre de polarité du solvant Y_{OTs}, de 0,56 et avec une vitesse de réaction qui est 41 fois moindre que celle du *p*-nitrobenzoate de (1-méthyl-2-pyrrolyl)méthyle. Les produits obtenus à partir du composé **3** comprennent des quantités importantes de matériaux provenant d'une attaque de la position 5 du noyau pyrrole par le solvant. Les résultats indiquent que le groupement pyrrolyle fortement donneur provoque une grande délocalisation de charge qui a comme conséquence que le rapport des vitesses $k(H)/k(CF_3)$ est faible et qu'il se produit une attaque nucléophile sur le cycle. Le 1,1,1-trifluoro-2-(1-méthyl-2-pyrrolyl)propan-2-ol (**10**) réagit avec le CF_3CO_2H par le biais d'un carbocation tertiaire qui conduit à la formation de produits dimères provenant d'une substitution électrophile sur le noyau pyrrole.

Mots clés : pyrrole, substituants trifluorométhyles, carbocations.

[Traduit par la revue]

Introduction

The CF_3 group ordinarily has a powerful destabilizing effect on the formation of an adjacent carbocation, resulting in rate ratios $k(H)/k(CF_3)$ of 10^6 or more (2). In certain circumstances the ratio can be significantly less, in particular the values of 1.4–2.8 for 2-trifluoromethyl-2-adamantyl tosylate (2*b*), those of 2.4–5.2 for the doubly destabilized system 4-$CH_3OC_6H_4$-$CR(CF_3)$OTs (2*c*), and that of 4×10^3 for 4-$CH_3OC_6H_4CH$-(OTs)R (2*d*). These reduced ratios are attributed (2) to delocalization of the positive charge away from the CF_3 group in every case, and also to steric effects in the adamantyl derivative.

The pyrrolyl group is known to be an extraordinarily strong electron donor, as shown by the high reactivity of pyrrole in electrophilic aromatic substitution (3) and by the facility of side-chain carbocation formation adjacent to the pyrrolyl group (4). The present report deals with the generation and further reactions of carbocations substituted with both the strongly electron-withdrawing CF_3 group and the strongly donating 1-methyl-2-pyrrolyl group.

Results

Reaction of 1-methylpyrrole with trifluoroacetic anhydride gave 1-methyl-2-trifluoroacetylpyrrole **1** (5), which was reduced with $NaBH_4$ to the alcohol **2**, which was converted to the *p*-nitrobenzoate **3** by reaction with triethylamine and *p*-nitrobenzoyl chloride.

Solvolysis rates for the reaction of **3** in various solvents were measured by uv, and the derived rate constants are given in Table 1. For the correlation of the reactivity of **3** with solvent polarity the Y_{OTs} scale (6*a*) was used, as there is no reported scale of solvent polarities for carbocation generation based on the *p*-nitrobenzoate leaving group. The correlation obtained, $\log k = 0.56\ Y_{OTs} - 3.36$, $r = 0.990$, is surprisingly good considering that scales of solvent polarity are generally leaving group dependent (6). Other examples of the successful correlation of carbocation-forming reactions of *p*-nitrobenzoates have been reported (2*c*).

The products of the reaction of **3** in CH_3OH and EtOH at 40°C were mixtures of a 1-(1-methyl-2-pyrrolyl)-2,2,2-trifluoroethyl

ether (**4** or **5**) and a 1-methyl-2-(2,2,2-trifluoroethyl)-5-alkoxypyrrole (**6** or **7**), with product ratios **4**/**6** and **5**/**7** of 2:1 and 3:2, respectively. The reaction of **3** in acetic acid gave the acetate **8** while reaction in 70% acetone/30% H_2O at 25°C gave the alcohol **2** and 1-methyl-5-(2,2,2-trifluoroethylidene)-2-pyrrolidinone (**9**). The structures of **4**–**9** follow from their ^1H nmr, ir, and mass spectral properties. Reported data (7) for similar compounds are particularly helpful in establishing the structure of **9**.

Reaction of **1** with methylmagnesium iodide gave the alcohol **10**, which on reaction with 0.1 M CF_3CO_2H in CCl_4 for 18 h gave a complex mixture of products from which **10**–**14** were isolated by gas chromatography, with relative peak heights of 7, 4, 7, 8, and 74, respectively. A proposed mechanism for formation of these products is shown in Scheme 1. The structures were readily established by their ^1H nmr, ir, and mass spectral properties. The mass spectrum of the crude reaction product also showed peaks corresponding to trimeric and tetrameric products, but these were not isolated and positively identified.

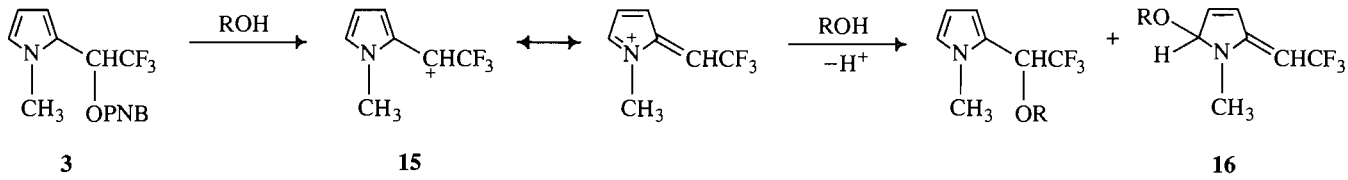


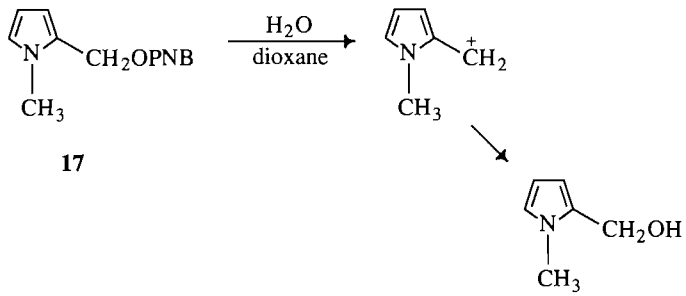
SCHEME 2

Discussion

The reactivity of **3** and the formation of mixtures of ring and side-chain substitution products for the reactions in methanol, ethanol, and aqueous acetone are strong evidence for the occurrence of reactions proceeding through carbocation intermediates with a high degree of positive charge delocalization, as shown in Scheme 2. In the case of methanol and ethanol the intermediate **16** rearranges to the alkoxypyrroles **6** and **7**, respectively, whereas for H_2O the pyrrolidinone **9** is favored. The *m* value of 0.56 for the correlation of the reactivity of **3** with Y_{OTs} is significantly less than unity, and this is typical of the behaviour we have observed for highly delocalized benzylic cations (2*a*, *c*, *d*; 8*a*).

Nucleophilic attack on the aromatic ring of benzylic carbocations with α-CF_3 substituents has been observed before (2*c*, 8), and appears to reflect the high degree of charge delocalization into the ring induced by the electron-withdrawing group.

Further evidence for the carbocationic nature of the reaction of **3** comes from the results of Noyce and Fraser[3] on the solvolysis of (1-methyl-2-pyrrolyl)methyl *p*-nitrobenzoate (**17**) and ring-substituted analogues. These compounds showed high reactivity in carbocation formation with a strong dependence of the rate on the electron-donor ability of the ring substituent, and were interpreted[3] as proceeding through carbocations as shown.



The value of k_{obs} for **17** in 70% H_2O/dioxane was 1.82×10^{-2} s^{-1} at 25°C. The Y_{Cl} parameter for this solvent is 0.01 (6*a*), which is essentially the same as that of 0.00 defined for 80% ethanol. Thus the rate constant of 4.40×10^{-4} s^{-1} observed here for **3** in 80% ethanol can be compared to that for **17** to give a rate ratio $k(H)/k(CF_3) = 41$. This ranks with other low values that have been observed for this ratio as cited in the introduction (2*b*,*c*,*d*). In the 1-aryl-2,2,2-trifluroethyl systems these ratios are attributed to diminution of the effect of the CF_3 group due to delocalization of the charge to a remote location in the ring (2*a*).

The value of σ^+_{Ar} for the 1-methyl-2-pyrrolyl group has been measured as −1.90 (4*a*) from a correlation of the reactivity of 1-arylethyl acetates in 30% ethanol. Such σ^+_{Ar} constants consider the aryl group as equivalent to a substituted phenyl ring. The rate ratio k(1-methyl-2-pyrrolyl)/k(4-$Me_2NC_6H_4$) in the above series was 9.0 (4*a*), whereas the value of $k_{obs} = 8.56 \times 10^{-4}$ for 4-$Me_2NC_6H_4CH_2OPNB$ in 70% aqueous dioxane at 25°C[3] leads to a comparable value of 21 for the same ratio. Thus the substituent effect of the 1-methyl-2-pyrrolyl group on carbocation formation in these two systems is mutually consistent, and the value of −1.90 proposed (4*a*) for σ^+_{Ar} for the 1-methyl-2-pyrrolyl group is reasonable in view of the value of −1.74 for σ^+_p for Me_2N derived from solvolytic data (9).

The reaction of (1-methyl-2-pyrrolyl)methyl *p*-nitrobenzoate (**17**) in 70% dioxane leads to the carbinol as the only observed product,[3] together with polymeric material. The apparent greater propensity of **3** to form ring-substituted products is expected on the basis of the known (2*a*) barriers to substitution in 2,2,2-trifluoroethyl systems.

The formation of the products from the reaction of **10** with CF_3CO_2H may be readily rationalized by the pathway shown in Scheme 1. The details of this pathway have not been tested and variants of this scheme may be equally plausible.

The oligomerization of pyrroles by electrophilic attack on the α-ring carbons of pyrroles by the side-chain carbon of 2-pyrrolylcarbinyl derivatives is well documented (10). There was evidence for the presence of trimeric and tetrameric products in the mass spectra of the crude reaction products from **10** so this type of chemistry promises to serve as a preparative route to such materials and to fluorinated porphyrin-like materials.

In summary, the side-chain carbocations generated from the pyrrolyl derivatives **3** and **10** both dislay the consequences of extensive charge delocalization into the strongly electron-donating pyrrolyl ring. The formation of 2,5-substituted pyrrole systems occurs in each series, with the formation of fluorinated dipyrrolylmethanes in the latter.

Experimental

Fluorinated solvents and reagents were obtained from Aldrich, and the solvent purification was described previously (2*c*). All reactions were carried out under N_2 in dry glassware. Liquid chromatographic separations were carried out using a Chromatotron centrifugal radial thin-layer chromatograph from Harrison Research. Spectra were measured using Varian T-60 and Gemini 200 nmr spectrometers and a Nicolet Ftir spectrometer.

1-Methyl-2-trifluoroacetylpyrrole (1)

To a stirred solution of 12.2 mL (0.0864 mol) of trifluoroacetic anhydride in 23 mL ether cooled in an ice bath was added dropwise *N*-methylpyrrole (7.00 g, 0.0863 mol) in 25 mL ether over 2 h. After 4 h further stirring, water was added and the aqueous layer extracted twice with ether. The combined ether layers were extracted three times each with saturated $NaHCO_3$ and NaCl solutions and dried over $MgSO_4$. The solvent was evaporated and the product distilled at 59°C and 6.5 Torr (1 Torr = 133.3 Pa) to give **1** (9.58 g, 0.0541 mol, 63%) as a colorless liquid; ir (CCl_4): 1680 (C=O) cm^{-1}; ^1H nmr (CCl_4) δ: 3.96 (s, 3, CH_3), 6.18 (m, 1, H-4), 6.92 (m, 1, H-5), 7.12 (m, 1, H-3); ms, *m*/*z* (rel. intensity): 177 (69, M^+), 163 (7), 108 (100, $M^+ - CF_3$), 94 (13), 80 (23, $M^+ - CF_3CO$), 69 (17, CF_3^+); hrms, *m*/*z* calcd. for $C_7H_6F_3NO$ (M^+): 177.0401; found: 177.0408.

1-(1-Methyl-2-pyrrolyl)-2,2,2-trifluoroethanol (2)

To a stirred solution of **1** (4.0 g, 0.023 mol) in 15 mL methanol

cooled in an ice bath was carefully added $NaBH_4$ (2.0 g, 0.053 mol). After 4 h stirring, saturated $NaHCO_3$ was added and the solution was extracted three times with ether, and the combined ether layers were extracted twice each with saturated $NaHCO_3$ and NaCl and dried over $MgSO_4$. Evaporation of the solvent gave a thick oil that crystallized on standing. Distillation at 60°C (2 Torr) gave **2** (2.89 g, 0.016 mol, 70%); ir (CCl_4): 3200–3550 (associated OH) cm^{-1}; ^1H nmr (CCl_4) δ: 2.35 (s, 1, OH), 3.63 (s, 3, CH_3), 4.82 (q, 1, J_{HF} = 7 Hz, $CHCF_3$), 5.96 (m, 1, H-4), 6.14 (m, 1, H-3), 6.52 (m, 1, H-5); ms, *m/z* (rel. intensity): 179 (100, M^+), 162 (47, M^+ −OH), 110 (89, $M^+ - CF_3$), 82 (69); hrms, *m/z* calcd. for $C_7H_8F_3NO$ (M^+): 179.0558; found: 179.0542.

1-(1-Methyl-2-pyrrolyl)-2,2,2-trifluoroethyl p*-nitrobenzoate (**3**)*

To a solution of **2** (2.89 g, 0.0161 mol) and 3 mL triethylamine in 25 mL ether cooled in an ice bath was slowly added *p*-nitrobenzoyl chloride (3.1 g, 0.0167 mol) dissolved in 25 mL ether. After 3 h stirring at room temperature water was added and, after extraction and drying as previously, **3** was obtained as a yellow solid (3.19 g, 0.0097 mol, 60%) that, after recrystallization from pentane, gave mp 78–79°C; ir (CCl_4): 1741 (C=O) cm^{-1}; ^1H nmr (CCl_4) δ: 3.78 (s, 3, CH_3), 6.0 (m, 1, H-4), 6.4 (m, 2, H-3 and $CHCF_3$), 6.6 (m, 1, H-5), 8.19 (s, 4, $C_6H_4NO_2$); ms, *m/z* (rel. intensity): 328 (66, M^+), 259 (25, $M^+ - CF_3$), 178 (28, M^+ − PNB), 162 (97, M^+ − OPNB), 150 (100, PNB^+), 104 (26); hrms, *m/z* calcd. for $C_{14}H_{11}F_3N_2O_4$ (M^+): 328.0670; found: 328.0677.

Solvolysis studies of 3

A solution of **3** (0.50 g, 1.5 mmol) in 65 mL CH_3OH was kept 14 h at 40°C, then was poured into H_2O and extracted as above. Separation of the crude product by gc (20% OV-17 column, flow rate 110 mL/min, 130°C) gave two significant peaks in the ratio 1:2. The peak at 6.6 min was identified as 1-(1-methyl-2-pyrrolyl)-2,2,2-trifluoroethyl methyl ether (**4**) by its spectral properties; ir (CCl_4): 2800–3015 (C—H) cm^{-1}; ^1H nmr (CCl_4) δ: 3.34 (s, 3, OCH_3), 3.68 (s, 3, NCH_3) 4.53 (q, 1, J_{HF} = 7 Hz, $CHCF_3$), 5.9 (m, 1, H-4), 6.1 (m, 1, H-3), 6.45 (t, 1, $J_{4,5}$ = 2 Hz, H-5); ms, *m/z* (rel. intensity): 193 (48, M^+), 179 (20, $M^+ - CH_2$), 162 (68, $M^+ - OCH_3$), 124 (100, $M^+ - CF_3$); hrms, *m/z* calcd. for $C_8H_{10}F_3NO$ (M^+): 193.0714; found: 193.0725.

The smaller peak at 8.2 min was a yellow solid identified as 1-methyl-2-(2,2,2-trifluoroethyl)-5-methoxypyrrole (**6**); ir (CCl_4): 3015–2800 (CH) cm^{-1}; ^1H nmr (CCl_4) δ: 3.20 (q, 2, J_{HF} = 10 Hz, CH_2CF_3), 3.32 (s, 3, OCH_3), 3.78 (s, 3, NCH_3), 5.02 (d, 1, $J_{3,4}$ = Hz, H-4), 5.78 (d, 1, $J_{3,4}$ = 4 Hz, H-3); ms, *m/z* (rel. intensity): 193 (73, M^+), 179 (20, $M^+ - CH_2$), 178 (100, $M^+ - CH_3$), 124 (50, $M^+ - CF_3$), 67 (17, $M^+ - C_4H_5F_3O$); hrms, *m/z* calcd. for $C_8H_{10}F_3NO$ (M^+): 193.0714; found: 193.0708.

Ethanolysis of **2** was carried out similarly to give a product that showed two components collected by gc with a 2:3 ratio of peak heights. The larger peak at 9.8 min was an oil identified as 1-(1-methyl-2-pyrrolyl)-2,2,2-trifluoroethyl ethyl ether (**5**); ^1H nmr (CCl_4) δ: 1.24 (t, 3, *J* = 7 Hz, OCH_2CH_3), 3.50 (q, 2, *J* = 7 Hz, OCH_2CH_3), 3.68 (s, 3, NCH_3), 4.62 (q, 1, J_{HF} = 7.5 Hz, $CHCF_3$), 5.98 (m, 1, H-4), 6.10 (m, 1, H-3), 6.52 (m, 1, H-5). The ms showed a major peak at *m/z* 207 as expected for M^+ but also signals at higher *m/z*, and had apparently decomposed. The smaller peak at 12.8 min was identified as 1-methyl-2-(2,2,2-trifluoroethyl)-5-ethoxy pyrrole (**7**); ir (CCl_4): 2800–3000 (CH) cm^{-1}; ^1H nmr (CCl_4) δ: 1.40 (t, 3, *J* = 7 Hz, OCH_2CH_3), 3.22 (q, 2, J_{HF} = 10 Hz, CH_2CF_3), 3.34 (s, 3, NCH_3), 3.97 (q, 2, *J* = 7 Hz, OCH_2CH_3), 5.04 (d, 1, $J_{4,5}$ = 4 Hz, H-4), 5.82 (d, 1, $J_{4,5}$ = 4 Hz, H-3); ms, *m/z* (rel. intensity): 207 (46, M^+), 179 (18, $M^+ - C_2H_4$), 178 (100, $M^+ - C_2H_5$), 110 (31, $M^+ - C_3H_4F_3$); hrms, *m/z* calcd. for $C_9H_{12}F_3NO$ (M^+): 207.0871; found: 207.0881.

Acetolysis of **3** (0.60 g, 1.83 mmol) in 5 mL acetic acid for 20 h at 25°C was followed by removal of precipitated *p*-nitrobenzoic acid by filtration, partitioning between water and ether, drying, and evaporation. Radial chromatography (10% ethyl acetate/petroleum ether) gave **8**; ir (CCl_4); 1757 (C=O) cm^{-1}; ^1H nmr (CCl_4) δ: 2.10 (s, 3, $COCH_3$), 3.68 (s, 3, NCH_3), 6.1 (m, 2, $CHCF_3$ and H-4), 6.30 (m, 1, H-3), 6.53 (m, 1, H-5); ms, *m/z* (rel. intensity); 221 (78, M^+), 162 (93, M^+ − AcO), 110 ($M^+ - CF_3$, C_2H_2O); hrms, *m/z* calcd. for $C_9H_{10}F_3NO_2$ (M^+): 221.0663; found: 221.0662.

Hydrolysis was carried out with **3** (1.0 g, 3 mmol) in 33 mL of 30% H_2O/acetone for 16 h at 25°C. The mixture was worked up as before and separated by gc (30% Carbowax 20 M, 120 mL/min, 200°C) to give two peaks in a 1:1 ratio. The peak at 4.2 min was identified as **2** by a comparison of spectral properties, whereas that at 2.8 min was identified as *1-methyl-5-(2,2,2-trifluoroethylidene)-2-pyrrolidinone* (**9**): ir (CCl_4); 1749 (C=O), 1666 (C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 2.57 (m, 2, H-4), 2.96 (s, 3, NCH_3), 2.96 (m, 2, H-3), 4.89 (q, 1, *J* = 8 Hz, $CHCF_3$); ms, *m/z* (rel. intensity): 179 (78, M^+), 160 (15), 150 (38), 123 (27), 104 (27), 82 (28), 68 (23); hrms, *m/z* calcd. for $C_7H_8F_3NO$ (M^+): 179.0558; found: 179.0542.

*1,1,1-Trifluoro-2-(1-methyl-2-pyrrolyl)propan-2-ol (**10**)*

A solution of 1-methyl-2-trifluoroacetylpyrrole (**1**, 0.50 g, 3.0 mmol) in 10 mL ether was added dropwise to methylmagnesium iodide (6.0 mmol) in 20 mL ether. After stirring overnight 25 mL of saturated NH_4Cl solution was added, the layers were separated, and the aqueous layer was extracted with ether. The combined ether layers were extracted with water followed by saturated NaCl, dried over Drierite, and evaporated. The residue was purified on the Chromatotron (10% ethyl acetate in petroleum ether) to yield **10** (0.385 g, 2.1 mmol, 70%); ir (CCl_4): 3480 (OH) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.80 (s, 3, CCH_3), 2.40 (s, 1, OH), 3.83 (s, 3, NCH_3), 6.07 (q, 1, $J_{3,4}$ = 3.8 Hz, $J_{4,5}$ = 2.7 Hz, H-4), 6.20 (m, 1, H-3), 6.63 (t, 1, $J_{3,5}$ = 1.8 Hz, $J_{4,5}$ = 2.6 Hz, H-5); ms, *m/z*: 193 (93, M^+), 176 (13, M^+ − OH), 124 (100, $M^+ - CF_3$), 69 (13, CF_3^+); hrms, *m/z* calcd. for $C_8H_{10}F_3NO$ (M^+): 193.0714; found: 193.0718.

*Reaction of 1,1,1-trifluoro-2-(1-methyl-2-pyrrolyl)propan-2-ol (**10**) with trifluoroacetic acid*: To a solution of **10** (1.47 g, 7.62 mmol) in 40 mL carbon tetrachloride was added 0.6 mL of trifluoroacetic acid. The reaction mixture was stirred at room temperature 18 h, was then poured over 40 mL of saturated $NaHCO_3$ solution and extracted three times with ether. The combined ethereal solution was washed successively with water and saturated NaCl solution, then dried over anhydrous $CaSO_4$. Evaporation of the solvent gave 0.9 g of a brown, sticky oil. The sample was tested with tlc using petroleum ether (40–60°C) – ethyl acetate (97:3) as the solvent, and gave R_f values of 0.27, 0.38, 0.52, 0.45, and 0.18; it was separated by gc (OV-17, 165°C) with retention times 3.0, 0.5, 18.4, 21.2, and 68 min for **10**–**14**, respectively.

Separation of the reaction products by gc gave **10**–**14** in 7, 4, 7, 8, and 74% relative yields as determined by the relative areas of the gc peaks. The compounds were identified by their spectral properties:

*3,3,3-Trifluoro-2-(1-methyl-2-pyrrolyl)propene (**11**)*: ir (CCl_4): 1740 (C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 3.60 (s, 3, NCH_3), 5.47 (d, 1, *J* = 1.3 Hz, *syn*-CF_3C=CH), 6.00 (t, 2, *anti*-CF_3C=CH and H-4), 6.20 (m, 1, H-3), 6.55 (t, 1, $J_{3,5}$ = 2.2 Hz, H-5); ms, *m/z* (rel. intensity): 175 (100, M^+), 156 (13, M^+ − F), 106 (96, $M^+ - CF_3$); hrms, *m/z* calcd. for $C_8H_8F_3N$ (M^+): 175.0609; found: 175.0611.

*1,1,1-Trifluoro-2,2-bis(1-methyl-2-pyrrolyl)propane (**12**)*: ir (CCl_4): 2960–3000 (aromatic C—H) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.89 (s, 3, CCH_3), 2.98 (s, 6, NCH_3), 6.10 (q, 2, $J_{3,4}$ = 3.8 Hz, $J_{4,5}$ = 2.7 Hz, H-4), 6.30 (m, 2, H-3), 6.55 (t, 2, $J_{4,5}$ = 2.7 Hz, H-5); ms, *m/z* (rel. intensity): 256 (81, M^+), 187 (100, $M^+ - CF_3$), 106 (34, $C_7H_8N^+$), 94 (17, $C_3HF_3^+$); hrms, *m/z* calcd. for $C_{13}H_{15}F_3N_2$ (M^+): 256.1187; found: 256.1202.

*3,3,3-Trifluoro-2-(1-methyl-5-[1,1,1-trifluoro-2-(1-methyl-2-pyrrolyl)propyl]-2-pyrrolyl)propene (**13**)*: ir (CCl_4): 2960–3000 (aromatic C-H) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.92 (s, 3, CCH_3), 2.92 (s, 3, NCH_3), 2.98 (s, 3, NCH_3), 5.57 (d, 1, *J* = 1.3 Hz, *syn*-CF_3C=CH), 6.10 (q, 1, $J_{3',4'}$ = 3.2 Hz, $J_{4',5'}$ = 2.2 Hz, H-4'), 6.15 (d, 1, *J* = 1.3 Hz, *anti*-CF_3C=CH), 6.24 (d, 1, $J_{3,4}$ = 3.3 Hz, H-4), 6.35 (m, 2, H-3, H-3'), 6.56 (t, 1, *J* = 2.2 Hz, H-5'); ms, *m/z* (rel. intensity): 350 (62, M^+), 281 (100, $M^+ - CF_3$), 200 (12, $C_{10}H_9F_3N^+$), 106 (16, $C_7H_8N^+$), 94 (17, $C_3HF_3^+$); hrms, *m/z* calcd. for $C_{16}H_{16}F_6N_2$ (M^+): 350.1217; found: 350.1215.

*1,1,1-Trifluoro-2-(1-methyl-5-[1,1,1-trifluoro-2-(1-methyl-2-pyrrolyl)propyl]-2-pyrrolyl)propan-2-ol (**14**)*: ir (CCl_4): 3600 (O-H) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.79 (s, 3, CCH_3), 1.91 (s, 3, CCH_3), 2.27 (s, 1, OH), 2.96 (s, 3, NCH_3), 3.23 (s, 3, NCH_3), 6.09 (m, 1, H-4'), 6.19 (d, 1, $J_{3,4}$ = 3.8 Hz, H-4), 6.27 (m, 2, H-3, H-3'), 6.53 (m, 1, H-5'); ms, *m/z* (rel. intensity): 368 (32, M^+), 299 (65, $M^+ - CF_3$),

218 (20, $M^+ - C_6H_7F_3N$); hrms, m/z calcd. for $C_{16}H_{18}F_6N_2O$ (M^+): 368.1323; found: 368.1315.

Kinetic studies were carried out by injecting 4-mL aliquots of 0.03 M solutions of **3** into 1.2 mL of the solvent in 1 cm pathlength quartz cells and observing the decrease in uv absorption with time. Wavelengths used were 264 nm (HFIP), 236 nm (TFE), and 240 nm (EtOH). Constant final absorbances were obtained, and plots of log ($A - A_\infty$) versus time gave good first-order rate constants (correlation coefficients greater than 0.999 in all cases), which were reproducible to ±2%.

Acidities and homolytic bond dissociation energies of the α C—H bonds in ketones in DMSO

FREDERICK G. BORDWELL[1] AND JOHN A. HARRELSON, JR.
Department of Chemistry, Northwestern University, Evanston, IL 60208-3113, U.S.A.

Received March 28, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

FREDERICK G. BORDWELL and JOHN A. HARRELSON, JR. Can. J. Chem. **68**, 1714 (1990).

Equilibrium acidities in DMSO are reported for nine cycloalkanones, acetone, acetophenone, and 19 of their α-substituted derivatives. Oxidation potentials in DMSO for the conjugate bases of most of these ketones are also reported. Combination of these $E_{OX}(A^-)$ and pK_{HA} values gives estimates of the homolytic bond dissociation energies (BDEs) of the acidic C—H bonds in the ketones. The ΔBDEs, relative to the BDE of CH_3-H, or a parent ketone, provide a measure of the radical stabilization energies (RSEs) of the corresponding radicals. The effects of successive α-Me and α-Ph substitutions on RSEs, relative to those of CH_3COCH_2-H or $PhCOCH_2$-H, are similar to those reported in the gas phase for methane. The RSE for the $MeCHCOPh$ radical, relative to CH_3• is 17 kcal/mol, which is smaller than the sum of the RSEs of the $MeCH_2$• and $PhCOCH_2$• radicals relative to CH_3• (7 + 12 = 19), contrary to the prediction of the captodative postulate. When G in $PhCOCH_2G$ is PhCO, CH_3CO, or CN the ΔBDEs (relative to $PhCOCH_2$-H) are 0, 1, and 3 respectively; for $MeCOCH_2SO_2Ph$, $PhCOCH_2SO_2Ph$, and $PhCOCH_2NMe_3^+$ the ΔBDEs are −5, −2, and −4, respectively. The BDEs in C_5, C_6, C_7, C_8, C_{10}, and C_{12} cycloalkanones are within ±2.5 kcal/mol of that of 3-pentanone. Acetophenones bearing *meta* or *para* substituents all have BDEs of 93–94 kcal/mol. Ketone radical cations, $[RCOR']^{+\bullet}$, appear to be superacids with estimated $pK_{HA}{}^{+\bullet}$ values below −25.

Key words: acidities, bond dissociation energies, ketones.

FREDERICK G. BORDWELL et JOHN A. HARRELSON, JR. Can. J. Chem. **68**, 1714 (1990).

On a déterminé les acidités à l'équilibre dans le DMSO de neuf cycloalcanones, de l'acétone, de l'acétophéone et de 19 de leurs dérivés substitués en α. On a aussi déterminé les potentiels d'oxydation dans le DMSO des bases conjuguées de la plupart de ces cétones. En combinant les valeurs de ces E_{OX} (A^-) et de ces pK_{HA}, on a évalué les énergies de dissociation homolytique des liaisons (EDL) C—H acides de ces cétones. Les valeurs des ΔEDL, relatives à l'EDL du CH_3-H ou d'une cétone parente, sont des mesures des énergies de stabilisation radicalaire (ESR) des radicaux correspondants. Les substitutions successives de la CH_3COCH_2-H ou de la $PhCOCH_2$-H par des α-Me ou des α-Ph provoquent des effets sur les ESR qui sont semblables à ceux qui sont observés avec le méthane en phase gazeuse. L'ESR du radical $MeC•HCOPh$, relative à celle du radical CH_3•, est égale à 17 kcal/mol; celle valeur est inférieure à la somme des ESR, relatives au CH_3•, des radicaux $MeCH_2$• et $PhCOCH_2$• (7 + 12 = 19) et ce résultat est contraire à ce que prédit le postulat captodatif. Lorsque le groupement G de la molécule $PhCOCH_2G$ est égal à PhCO, CH_3CO ou CN, les valeurs des ΔEDL (relatives à celle de la $PhCOCH_2$-H) sont respectivement 0, 1 et 3; pour les composés $MeCOCH_2SO_2Ph$, $PhCOCH_2SO_2Ph$ et $PhCOCH_2NMe_3^+$, les valeurs de ΔEDL sont respectivement −5, −2 et −4. Les valeurs des EDL des cycloalcanones en C_5, C_6, C_7, C_8, C_{10} et C_{12} sont égales à celle de la 3-pentanone, à ±2,5 kcal/mol. Les EDL des acétophénones portant des substituents en positions *méta* ou *para* sont toutes égales à 93–95 kcal/mol. Il semble que les cations radicaux des cétones, $[RCOR']^{+\bullet}$, sont des superacides; les valeurs de leurs $pK_{HA}{}^{+\bullet}$ seraient inférieures à −25.

Mots clés : acidités, énergies de dissociation de liaison, cétones.

[Traduit par la revue]

Introduction

Although ketonic functions abound in nature, and base-catalyzed condensation reactions with ketones are commonly used in syntheses, relatively little information on the acidity of ketones occurs in the literature. The reason is, of course, that ketones are too weakly acidic for direct measurements of their acidities to be made in hydroxylic solvents. Numerous measurements of the rates of deuterium exchange have been made, however, and equilibrium acidities for a few ketones have been determined therefrom, or by other methods. For example, numerous indirect determinations of the equilibrium acidity of acetone in aqueous solution have been made, the most accurate of which gives the pK_a as 19.16 ± 0.04 (1).

Establishment of an acidity scale in dimethyl sulfoxide (DMSO) solution has provided a large number of pK_{HA} values of weak acids, including ketones, in that solvent (2). Furthermore, combination of these pK_a values with ketone oxidation potentials and those of their conjugate bases has made possible estimates of (a) the acidities of the radical cations formed by removing an electron from the parent acids (3), and (b) the homolytic bond dissociation energies (BDEs) of their acidic C—H bonds (4). Equations [1] and [2] are used to estimate these $pK_{HA}{}^{+\bullet}$ and BDE values.

$$[1]\quad pK_{HA}{}^{+\bullet} = pK_{HA} + [E_{OX}(A^-) - E_{OX}(HA)]\ 23.06/1.37$$

$$[2]\quad BDE = 1.37\ pK_{HA} + 23.06\ E_{OX}(A^-) + 56$$

In eqs. [1] and [2], both of which are based on thermodynamic cycles, the factors 1.37 and 23.06 are used to convert pK_{HA} units and oxidation potential eV units to kcal/mol. The number 56 is a constant made up of the free energy of formation of the hydrogen atom, $\Delta G_f^0(H•)_g$, together with estimates of $\Delta G_{sol}^0(H•)$, $\Delta G_{tr}^0(H^+)$, and $T\Delta S^0$, which are needed to relate the free energies in solution to gas phase $\Delta H°$ values. The constant used (56) is semiempirical in the sense that some of these conversion factors are difficult to evaluate. Nevertheless, the BDEs obtained by use of eq. [2] agree to within ±3 kcal/mol, for the most part, with the best gas phase values that have been obtained for six hydrocarbons, phenol, thiophenol, aniline, and acetone (4*a*). In a family of compounds such as the ketones, the relative BDEs are believed to be accurate to about ±1 kcal/mol

In this paper we will present pK_{HA} data for a variety of ketones in DMSO, and compare the effects of structural changes on their acidities, BDEs, and radical cation acidities.

[a]Measured in DMSO against two or more indicators as described in earlier papers.
[b]Measured by X.-M. Zhang.
[c]Measured by cyclic voltammetry under the conditions previously described and referenced to the standard hydrogen electrode (3, 4).
[d]Estimated by eq. [2].

Results and discussion

Acidities of ketones

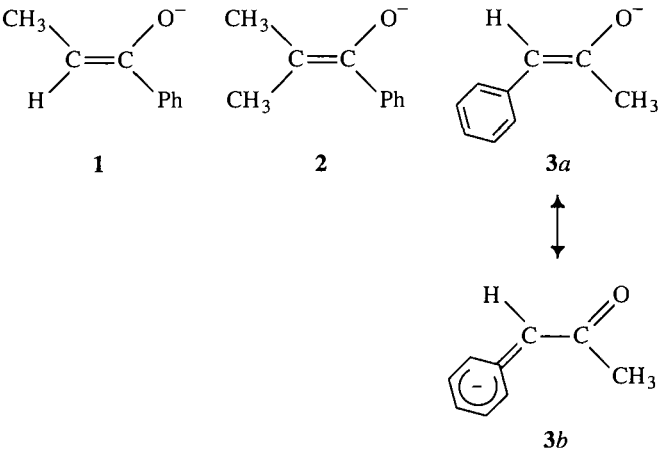
Table 1 presents data that allow one to discern the effects on acidities (pK_{HA}) and BDEs of substitution of alkyl, phenyl, or electron-withdrawing groups for α-hydrogen atoms in acetone and acetophenone.

In DMSO, acetone has a pK_{HA} of 26.5, which is 7.3 units higher than the value determined in aqueous solution (1). This difference in DMSO vs. aqueous acidities (ΔpK_{HA}) is almost the same as for the CH_3NO_2 ($\Delta pK_{HA} = 7.2$), where the negative charge in the anion is also delocalized to oxygen, but is much greater than those for carbon acids wherein the negative charge in the anion is localized primarily on carbon, such as malononitrile ($\Delta pK_{HA} = 0$) or $(Me_2SO)_2CH_2$ ($\Delta pK_{HA} = 2.3$).[2]

Substitution of an α- and an α′-hydrogen atom in acetone by methyl groups causes a 0.4 unit decrease in acidity (statistically corrected for the number of acidic hydrogen atoms). A second such substitution causes a further 0.8 decrease in acidity (Table 1). These small decreases in acidity can be attributed to increases in steric inhibition of solvation in the anion, which overshadow the stabilizing effect of Me on the C=C bond in the enolate ion. Note in this connection that replacement of one of the methyl groups in acetone by a *tert*-butyl group also causes a small (0.9 unit) decrease in acidity. On the other hand, replacement of one of the methyl groups by phenyl causes a 1.5 unit increase in acidity because the field/inductive (*F*) effect of the phenyl group on the anion overshadows the steric effect.

[2]Table I in ref. 2.

Substitution of a methyl group for an α-hydrogen atom in acetophenone causes a 0.1 unit *increase* in acidity, but a second methyl substitution causes a 1.6 unit decrease. Two effects are evidently operative here, namely, an acid-strengthening stabilization of the π-bond in the enolate ion by methyl, which is dominant in **1**, and an acid-weakening steric inhibition of solvation by methyl in the enolate ion, which is dominant in **2**. We have seen previously that α-OR and α-NR_2 groups cause slight increases in acidity (4*c*). For these, the acidifying *F* and *R* effects in the enolate ions are opposed by lone pair – lone pair repulsions (Z-isomer) (5) and (or) steric inhibition of solvation.



1 **2** **3*a***

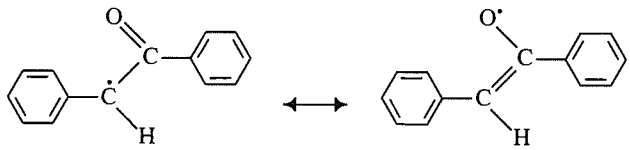
3*b*

Substitution of a phenyl group for an α-hydrogen atom in acetone causes a 6.4 pK_a unit increase in acidity. A similar effect is observed for phenyl substitution into acetophenone (a 6.8 increase) (6). Extensive delocalization of the negative charge in the anion (*R* effect), as illustrated in **3*b***, is responsible for these changes. Introduction of a second α-phenyl group into acetone and into acetophenone causes a 0.7 unit acidity *increase* and an 0.8 unit acidity *decrease*, respectively. Evidently the second phenyl substituent introduces severe steric inhibition of resonance and of solvation effects, which are sufficient to cause the acidity decrease in $Ph_2CHCOPh$.

Homolytic bond dissociation energies (BDEs) for open-chain ketones

The BDE estimated from eq. [2] for the C—H bond in acetone of 94 kcal/mol (4*a*) is 4 kcal/mol below the "best" gas phase value (7), but is 2 kcal/mol higher than a more recent corrected value (8). The only other estimates of BDEs for the acidic C—H bonds in ketones of which we are aware is that for $PhCOCH_2$-H of 95 kcal/mol[3] and that for the secondary C—H bond in $CH_3CH_2COCH_3$ of 92 kcal/mol (9). In the series $(CH_3)_2C{=}O$, $(MeCH_2)_2C{=}O$, $(Me_2CH)_2C{=}O$, the first α-Me substitution lowers the BDE of the α C—H bonds by 6 kcal/mol, and the second by an additional 3 kcal/mol (Table 1). These ΔBDE values are close to those reported for the gas phase ΔBDEs for successive methyl substitution into CH_4 (7 and 3.5 kcal/mol, respectively (7)), as are those for α-methyl substitution into acetophenone (5 and 2 kcal/mol, respectively). On the other hand, the decrease in BDE caused by substituting an α-phenyl substituent into acetone or acetophenone, although large (10–11 kcal/mol), is much smaller than that into methane (17 kcal/mol). The smaller effect in the ketones is probably due primarily to a larger steric effect (**4*a*** ↔ **4*b***).

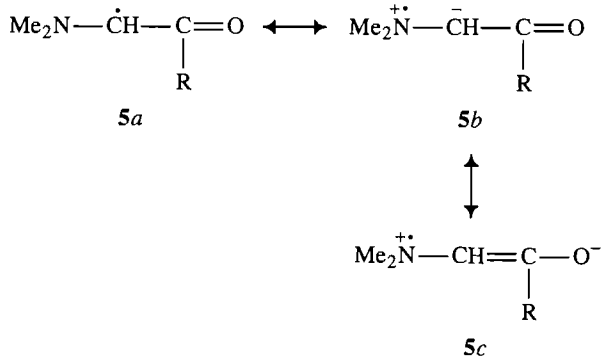
[3]From the thermodynamic cycle $DH(HA) = \Delta H_{HA} + IP(H\cdot) - EA(A^-)$ given in a list compiled by J. E. Bartmess.



4a 4b

The effect on BDE of a second α-phenyl substitution into either acetone or acetophenone is negligible, whereas a second α-Ph substitution into methane causes a further 14 kcal/mol decrease in BDE (7). The zero decrease in BDE for the second α-Ph substitution into acetone or acetophenone should be compared, however, with the *third* α-Ph substitution into methane (ΔBDE = 1 kcal/mol (4*a*)). Steric effects have also been found to cause sizable decreases in ΔBDEs in other trisubstituted systems (4*d*).

In substituted acetophenones $PhCOCH_2G$, where G is a donor group, Me, MeO, or Me_2N, the ΔBDE (or RSEs) are 5, 12, and 21 kcal/mol, respectively, relative to G = H. In terms of RSEs, we can account for the effects of the methyl group as a hyperconjugative interaction with the orbital holding the odd electron, and for MeO and Me_2N groups as lone pair conjugative interactions (**5***a* ↔ **5***b* ↔ **5***c*). Since extended



5a 5b 5c

conjugation is possible between the donor and acceptor groups in these radicals, e.g., as in **5***c*, several authors have suggested that extra (more than additive) stabilization should be present (10). The effects with COR acceptors and MeO or Me_2N donors are no more than additive, however (4*c*). The same is true for the $MeCHCOCH_3$ and MeCHCOPh radicals where the observed RSEs (or ΔBDEs), relative to CH_3-H (BDE = 105 kcal/mol) (7) are 17 and 16 kcal/mol, respectively, compared to (7 + 12 = 19) and (7 + 11 = 18), respectively, for the individual effects. Also, the combined RSE for $PhCH_2$• and $PhCOCH_2$• is 29 (17 + 12) whereas the RSE for the PhCHCOPh radical is only 22.5 (Table 1). These data support our recent conclusion that the presence of both donor and acceptor functions attached to a carbon or nitrogen-centered radical results in little or no synergism (11).

Examination of Table 1 shows that, when G in $PhCOCH_2G$ is PhCO, MeCO, or CN, the ΔBDEs are 0, 1, and 3 kcal/mol, respectively. Apparently electron acceptor groups play a dual role toward the radical, stabilizing it by virtue of their delocalizing ability, but destabilizing it by virtue of their *F* effects. When G is SO_2Ph or Me_3N^+ the *F* effects on the radical are dominant, and are destabilizing by 2 and 4 kcal/mol, respectively, in the $PhCOCH_2G$ systems. Radical destabilizing (bond strengthening) effects by these electron-withdrawing groups have been observed previously in other systems (3*d*, 3*e*).

Acidities and BDEs for cyclic ketones

In Table 2 we present acidity and oxidation potential data for a number of cyclic ketones and open-chain analogues.

Examination of Table 2 shows that the acidities of the cycloalkanones in DMSO are remarkably similar to that of the open-chain analogue, 3-pentanone. Cyclobutanone, cyclopentanone, and cyclohexanone are 1–2.5 kcal/mol more acidic than 3-pentanone, and the C_7, C_8, C_{10}, and C_{12} cycloalkanones have acidities within ±0.4 kcal/mol of 3-pentanone. The peaks for the cyclic voltammograms (CVs) for the enolate ions derived from cycloalkanones, as well as from open-chain ketones, are relatively narrow and are reproducible. For the cycloalkanones and 3-pentanone the BDEs estimated for the acidic C—H bonds are all identical (88 kcal/mol). For comparison, the C—H bonds in C_4, C_5, C_6, and C_7 cycloalkanes are all 94.5 ± 2 (7).

1-Indanone was found to be 1.9 kcal/mol more acidic than its open-chain analogue, propiophenone, and its BDE is estimated to be 1 kcal/mol higher. 2-Indanone is 2.5 kcal/mol more acidic than its open-chain analogue 1,3-diphenylacetone, and its BDE is estimated to be 3 kcal/mol lower. The pK_{HA} and BDE of 2-indanone are 8 and 10 kcal/mol lower, respectively, than that of 1-indanone, as expected for benzylic vs. non-benzylic α-hydrogens.

Radical cation acidities of ketones

Radical cation acidities for the acidic C—H bonds in fluorene, cyclopentadiene, phenylacetonitrile, benzyl phenyl sulfone, and a number of their derivatives have been estimated previously by eq. [1] (3). The validity of this method has been supported by the observation of a linear plot for $pK_{HA^{+\cdot}}$ in the gas phase vs. $pK_{HA^{+\cdot}}$ in DMSO solution for radical cations derived from $PhCH_2CN$, Ph_2CH_2, $PhCH_3$, cylopentadiene, fluorene, thiophenol, phenol, and aniline (3*h*). There appears to be no previous report of the radical cation acidity of a ketone. Examination of Table 2 shows that the ketone radical cations are all super acids with $pK_{HA^{+\cdot}}$ values in the −24 to −31 range. There is no obvious trend in acidity caused by structural changes in the ketones. The oxidation potentials of the ketones are all strongly positive, which necessitated a change in the solvent from DMSO to CH_3CN. (DMSO itself has an E_{OX} (HA) of about 1.5.) The radical cation acidities of *p*-substituted acetophenones in the series H, *p*-Me, *p*-MeO (−24, −20, −12) follow the same trend as in the series $GC_6H_4CH_2SO_2Ph$ (−25, −18, and −12) (12*a*) and in the series $GC_6H_4CH_2CN$ (−32, −28, −19) (12*b*). This suggests that in all three series the electron is being removed from the GC_6H_4 moiety to form the radical cation.

Remote substituent effects on acidities and BDEs of acetophenones

In an earlier paper we presented a Hammett plot for the acidities in DMSO of 14 *m*- and *p*-substituted acetophenones with a ρ = 3.55 and a correlation coefficient, R^2 = 0.998 (13). Oxidation potentials for ten of these acetophenones and their conjugate bases, along with their pK_{HA}'s are given in Table 3.

Examination of Table 3 shows that remote electron-accepting groups (*p*-CN, *p*-Cl, *m*-Cl, and *m*-Br) acidify acetophenone by 2–3.7 kcal/mol, but these effects on BDE are offset in eq. [1] by shifts of E_{OX} (A^-) to more positive potentials by 1.1–3.9 kcal/mol. As a consequence, there is no change in BDE. On the other hand, the donor groups (*p*-CH_3, *m*-CH_3, *p*-NH_2, *p*-MeO) decrease the acidity of acetophenone by 0.4–1.37 kcal/mol, and these effects are for the most part *augmented* by small positive shifts in E_{OX} (A^-) values in eq. [2]. The result is about

a 1 kcal/mol increase in BDE for the acidic C—H bonds in these acetophenones. The E_{OX} (A^-) values for remote *p*-donor substituents in arylacetonitriles (12*b*, 14), and benzyl phenyl sulfones (12*a*), have been shown to become more negative as their donor properties increase along the series *p*-Me, *p*-MeO, *p*-NH_2. Although these effects are offset in eq. [2] to some extent by small increases in pK_{HA}, the net result for *p*-Me and *p*-NH_2 groups is a small *decrease* in BDE, relative to G = H. The difference in the present instance is that the acidic site is separated from the ring by the carbonyl group and the donor groups such as *p*-Me and *p*-NH_2 cannot interact directly to stabilize the incipient radical. Their major effect is apparently to stabilize the parent acetophenone. The lowered ground state energy raises the pK_{HA} and also leads to a small increase in BDE.

Experimental

The ketones were for the most part commercial samples that were carefully purified prior to pK_{HA} or oxidation potential measurements.

Strongly basic indicators, such as 9-phenylxanthenide ion (pK_{HA} = 27.9) have been shown to add to the carbonyl group of ketones lacking α-hydrogen atoms, such as benzophenones. Addition of acetone to a DMSO solution containing fluorenide ion (pK_{HA} = 22.6) caused no change in absorbance, other than that caused by dilution, however. Experiments such as this, together with the consistency of the E_{OX} (A^-) measurements, indicate that addition to the carbonyl group does not compete with proton transfer reactions in the formation of these enolate ions.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

Equilibrium acidities in DMSO were measured by an overlapping indicator method (2). Cyclic voltammograms were measured by the method described earlier (4*b*). The oxidation potentials of the enolate ions gave irreversible waves that were, however, narrow and reproducible. Some gave small shoulders at more negative potentials, prior to the much stronger main peak. The oxidation peaks for the ketones themselves were strong and broad, but not so readily reproduced.

Acknowledgments

We are grateful to Craig A. Wilson for some of the cyclic voltammetric measurements on *m*- and *p*-substituted acetophenone enolate ions, and to Frederick J. Cornforth, Walter S. Matthews, and Noel R. Vanier for the pK_{HA} measurements of the ketones. This work was supported by the National Science Foundation.

Isotope effects in solution: contrasts between muonium and hydrogen in reactions with acetone

DAVID C. WALKER
Chemistry Department and TRIUMF, University of British Columbia, Vancouver, B.C., Canada V6T 1C6

Received March 7, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

DAVID C. WALKER. Can. J. Chem. **68**, 1719 (1990).

Munonium atoms are hydrogen isotopes with positive muons rather than protons, deuterons, or tritons as nuclei. Thus, they have one ninth the mass of ^{1}H, and microsecond lifetimes. By using nuclear physics counting techniques, muonium can be studied in a wide variety of media and its chemical and physical properties used to appraise hydrogen. Results are described for the interaction of muonium with acetone, showing two types of kinetic isotope effects, formation of free radicals, evidence for intermolecular "muonium bonding", and micelle-induced enhancements of reaction rate constants.

Key words: isotope effects, muonium atoms, muonium bonding, thiyl radicals, micelles.

DAVID C. WALKER. Can. J. Chem. **68**, 1719 (1990).

Les atomes de muonium sont des isotopes de l'hydrogène incorporant des muons positifs pluôt que des protons, des deutérons ou des tritons comme noyaux. Ils ont donc une masse qui est neuf fois plus faible que celle du ^{1}H et des temps de vie de l'ordre de la microseconde. Utilisant des techniques de comptage issues de la physique nucléaire, on peut étudier le muonium dans un grand nombre de milieux et on peut utiliser ses propriétés physiques et chimiques pour évaluer l'hydrogène. On décrit les résultats obtenus lors de l'interaction entre le muonium et l'acétone; ces résultats permettent de mettre en évidence deux types d'effets isotopiques cinétiques, la formation de radicaux libres, des données suggérant l'existence de liaisons muonium intermoléculaires ainsi que des accélérations des constantes des vitesses de réactions induites par des micelles.

Mots clés : effets isotopiques, atomes de muonium, liaisons muonium, radicaux thiyles, micelles.

Introduction

(a) Muonium

The proton is a unique chemical species (1), being a bare nucleon, while the positive muon is unique in being a lepton acting as a nucleus. When given orbital electrons these two "elementary" particles form a pair of atoms whose comparisons show some of the best isotope effects, and some surprises.

Muons are formed as decay products of pions (lifetime 26 ns) and live for 2 μs before decaying to positrons, as in [1].

[1] $\pi^+ \rightarrow \mu^+ + \nu_\mu \qquad \mu^+ \rightarrow e^+ + \nu_e + \bar{\nu}_\mu$

Table 1 gives the basic physical properties of ^{1}H, ^{2}H(D), ^{3}H(T) compared to muonium (Mu, the atom with a positive muon as its nucleus). Mu has virtually the same size and shape of electron orbital as the others, therefore it has almost the same ionization energy, van der Waals radius, polarizability, etc. Any "chemical" difference between Mu and the other H-isotopes should arise primarily from their diverse atomic masses, which differ by factors of 9, 18, and 27. They also differ from each other in nuclear magnetic moments, so this confers on them distinguishable hyperfine interactions and magnetic resonance phenomena.

(b) Kinetic isotope effects, k_M/k_H

For bimolecular reactions in solution, there are three mass-dependent factors that enter into the simple empirical analysis of a rate constant: (i) the encounter frequency, (ii) the activation barrier, and (iii) the quantum mechanical tunneling coefficient.

For (i), the muonium rate constant, k_M, should be greater than that of H, k_H, by a factor of three, the inverse ratio of the square roots of the masses, based on mean thermal velocities. This seems to apply for simple gas phase reactions (2), but not for Mu reactions in solution (3). In water, both Mu and H reactions reach the same maximum rate constants at the diffusion-controlled limit, and show a temperature dependence characteristic of water's viscosity ($E \sim 17$ kJ/mol, as in the top line of Fig. 1(b)). Consequently, the diffusion of both Mu and H must be governed by the structure of water rather than by their intrinsic velocities (4). This was a surprise, but it has been rationalized by simulation studies that indicate the atoms are significantly clathrated in water (5).

For (ii), the popular rule-of-thumb "lighter isotope reacts faster" does not apply when the isotopes react as atoms. This is because only the isotopic differences in the zero point energies of the transition states affect the activation barrier (see Fig. 1(a)), whereas the "rule" applies to the breaking of C—H compared with C—D, where zero point energy differences are larger in the reactants than in the transition states. Thus, for reactions with large energy barriers, Mu is expected to be slower that H if this term dominates, and there are examples in both gaseous (2, 6) and liquid phases (3) where it evidently applies. For example, the reaction of Mu with HCO_2^- in water (lowest line of Fig. 1(b)) has an activation energy of 33 kJ/mol and k_M/k_H is 0.03 (3), so it looks like a zero point energy effect on the transition states.

For (iii), muonium is so light that even at room temperature there is evidence of significant tunneling. This should strongly favour Mu over H, even though the width and height of the barriers are somewhat larger, because quantum mechanical barrier penetration has an inverse exponential mass dependence. The best example here is Mu + $F_2 \rightarrow$ MuF + F (7), and is confirmed by theory (8). An example in water seems to be the Mu + NO_3^- reaction, where the measured pre-exponential factor ($A = 7 \times 10^{10}$ M^{-1} s^{-1}) and activation energy ($E_a = 6$ kJ/mol) are both remarkably small (3). These data suggest the type of behaviour indicated by the middle line of Fig. 1(b), where an activation-controlled reaction is subsumed by its tunneling component in the lower temperature range.

Kinetic isotope effects have been found to range from >100 to <0.01 for Mu versus H, in water, as seen in the sample of data quoted in Table 2. Dividing them up into various combina-

TABLE 1. Basic physical properties of Mu compared with H, D, and T

Property	Mu	^{1}H	^{2}H(D)	^{3}H(T)

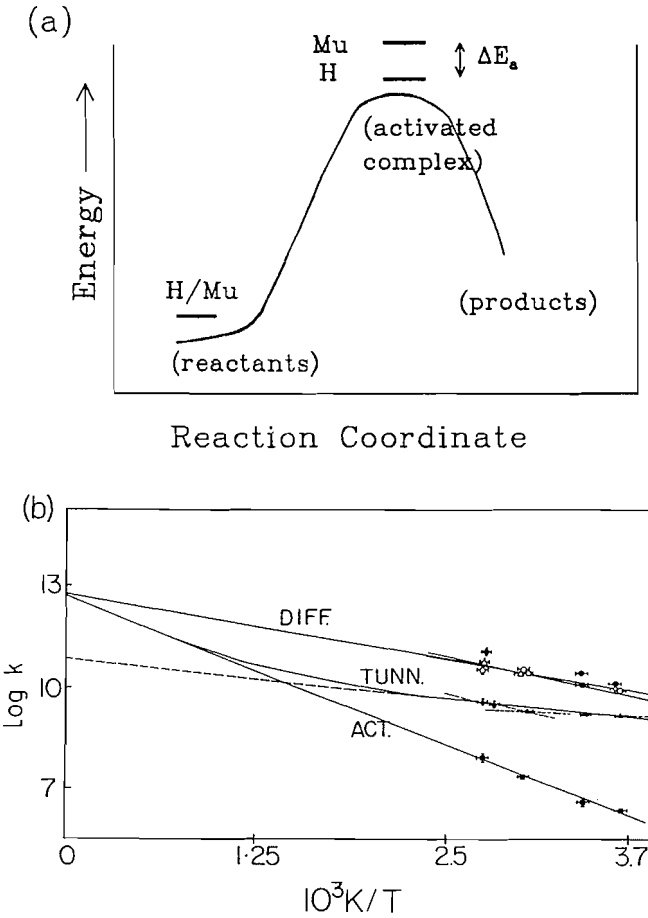

FIG. 1. Schematic illustrations of (a) zero point energy effects for reactions of atoms, showing the origin of the difference in activation barriers (ΔE_a) of Mu compared to H, and (b) Arrhenius plots with quantum mechanical tunneling (TUNN) contributing significantly to an activation-controlled reaction (ACT) so that its rate approaches that of a diffusion-limited rate (DIFF). The right-hand side of this figure shows actual data obtained in water (3, 4). The middle line represents reaction of Mu with NO_3^-. Its slope and intercept, obtained from the region of observation, both *appear* to be much smaller than the others. This is characteristic of tunneling.

tions of the above three components is impossible, and there are solvation and "cage" effects to include as well. Thus, at best, one can suppose that tunneling makes a substantial contribution when Mu is strongly favoured, and that transition state energy differences dominate when H is favoured. For the two reactions of Mu with acetone both extremes may be present (see later).

Muonium may not be the physical-organic chemists' choice reagent, but it readily attacks the benzene ring to form muonated cyclohexadienyl radicals (which live for at least a microsecond),

TABLE 2. Sample of observed kinetic isotope effects (k_M/k_H) in water at ~295 K

Solute	$k_M/M^{-1}\,s^{-1}$	k_M/k_H^a	Type of reaction (conjectured)
NO_3^-	1.5×10^9	150	?
Acetone	9×10^7	34	Addition (to O)
CH_3CSNH_2	3×10^{10}	5	Addition (to C)

[a]Muonium rate constants, k_M, taken from tables in refs. 4 and 11; hydrogen rate constants, k_H, taken from tables in ref. 12.

and the tools available for studying it reveal how much addition actually occurs at each *ortho, meta,* and *para* position, for any substituent or pairs of substituents. It means one can calculate *absolute* rate constants for each directional isomer. This has been done for single substituents and for substituted benzoic acids in water (9). When plotted against Hammett σ-parameters, these results show muonium to be weakly nucleophilic, with $\rho \sim +0.3$. This is opposite to H, which is reported to be electrophilic for ring additions, with $\rho \sim -0.5$ (10).

Perhaps ρ is more often used in conjunction with equilibrium data than with absolute rate constants (as here) but, regardless of whether it is kinetic or thermodynamic in orgin, the question arises as to whether the difference between Mu and H stems primarily from their small differences in atomic ionization energies (see Table 1). Another question raised is whether this nucleophilic character of Mu may have bearing on the fact that (i) it adds to a carbonyl group much faster than does H, and (ii) that Mu adds to the O of a C=O group but to the C of a C=S group (as discussed below).

2. Experimental

Reaction rate constants are most directly measured by using a short impulse of energy to produce the reactive species, and then following its concentration by kinetic spectrometry. H-atoms can be produced from hydrated electrons by pulse radiolysis of strongly acidic water, and have their concentrations monitored by ESR spectroscopy or VUV photometry. Substantial tables of k_H values have become available by these techniques (12). Muonium, on the other hand, needs a muon beam, such as is available at the TRIUMF cyclotron, and fast nuclear

physics counting equipment. Given those facilities, however, Mu can be studied with better time resolution, without the need for an acidified water medium, and with greater versatility than can H.

The basic principles of the two techniques used for Mu studies will be outlined briefly here. They were both developed for physics but quickly applied in chemistry. Muon Spin Rotation (μSR) is used for muonium rate constants, fractional muon yields (P-values), and muon hyperfine coupling constants ($A\mu$), whereas Level Crossing Resonance (LCR) provides information on muonated free radicals, their structure, yields, and occasionally their rate and mode of formation.

(a) Muon spin rotation (μSR) studies

Details of this technique are available elsewhere (13). It is a single particle counting method in which each muon is timed as it arrives at the sample and its decay position is timed when it is emitted. A lifetime histogram is then composed from 5–50 million such events.

It transpires that there is a breakdown of the parity-invariance principle in both steps of eq. [1], which results in the muon being formed as a spin-polarized particle, then decaying by emitting its positron along its instantaneous spin direction. Use is made of both these asymmetries in the spin rotation method. The sample is placed in a fixed transverse magnetic field so that each muon's spin precesses at a frequency characteristic of that muon's chemical state. A small detector for positrons in the plane of precession sees an oscillation at this frequency superposed on its ordinary muon lifetime histogram. In pure water the oscillation that corresponds to muonium lasts for several microseconds, but as a reactive solute is added it is damped accordingly. Figure 2 shows typical histograms in a field of 8 G with muonium observable as the small ripple. An eight-parameter MINUIT χ^2- minimization fitting procedure gives the munonium relaxation as one of these parameters. The experiment is repeated at different solute concentrations, so that a plot of relaxation against solute concentration produces the bimolecular rate constant k_M.

Muonium-containing free radicals can also be detected at precession frequencies related to their hyperfine coupling constants and split by the various protons present. In the high field limit, as used in ENDOR, these merge to just a pair of frequencies whose sum equals A_μ (14). In all μSR studies the state to be observed has to be formed rapidly enough that there is no precession in a prior muon state, in order for the spins to all precess coherently. For radical formation in solution this is a serious disadvantage.

The μSR technique allows different initial types of chemical states of muons to be determined. These are presented as fractional yields (P) and appear in four forms: as muonium atoms, P_M, as free radicals, P_R, and as diamagnetic species, P_D. When these sum to less than 1.0 the deficit is described as the missing fraction and designated P_L.

(b) Level crossing resonance (LCR) studies

In the LCR technique (15), the sample is held in a longitudinal magnetic field and the total number of muons emitting their positrons in the forward direction is compared with those going backwards. The integrated forward-to-backward difference is studied as a function of field. There are resonance fields (B_R) where the Zeeman-split levels of the muon and a proton of the radical cross. At this field, spin polarization is transferred from muon to proton via their mutual hyperfine couplings in the radical. This results in some loss of the intrinsic polarization of the muon, and hence a decrease of the forward-to-backward asymmetry. A small modulation field of ~50 G is usually applied to maximize the signal-to-noise ratio, and this gives the plots a "differential" appearance. Figure 3 shows typical LCR spectra. Fitting programs allow for the "best" values to be obtained for B_R, and for intensity. The former is related to A_μ and to any proton hyperfine coupling constants of the radical, A_H, by eq. [2] (15)

$$[2] \qquad B_R = \frac{1}{2}\left[\frac{A_\mu - A_H}{\gamma_\mu - \gamma_H} - \frac{A_\mu^2 - 2MA_H^2}{\gamma_e(A_\mu - A_H)}\right]$$

where the γ's are magnetogyric ratios of muon, proton, and electron and M is the sum of the quantum numbers at the resonance.

The intensity can be used to evalutate the yield of that particular radical (P_R) by eq. [3] (16)

$$[3] \qquad P_R = \frac{(\Delta B)^2 \mathrm{ampl}(\gamma_\mu - \gamma_H)^2}{A_{bf}\nu_R^2}$$

where ΔB and "ampl" are the fitted width and amplitude of the LCR spectra, A_{bf} is the experimental asymmetry, and ν_R the LCR frequency.

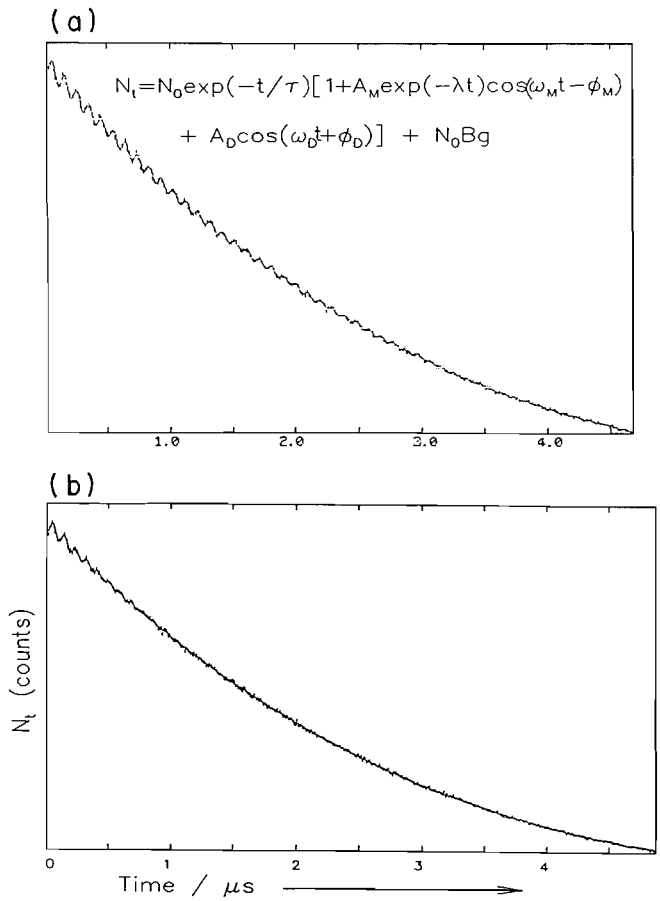

FIG. 2. Typical μSR lifetime histograms in transverse fields of 8 G for (a) pure water, showing a long-lived muonium signal as the ~10 MHz oscillation, and (b) a dilute aqueous solution of a reactive solute like acetone, showing damping of the superposed muonium oscillation due to chemical reaction. (The μSR "fitting" equation is given in (a), with λ as the muonium relaxation parameter.)

(c) Reactions in micelles

Addition of amphiphilic "surfactant" molecules to water at concentrations above their critical micelle concentration causes them to coalesce into micelles. These have hydrocarbon cores capable of solubilizing organic molecules that would otherwise be insoluble in water. This micellization of a solute can change k_M markedly (17). Such changes have been interpreted through a kinetic model (18) that is based on steady-state and pre-equilibrium conditions, arising from the much shorter mean residence time of Mu at a micelle (~2 ns (19)) than either its lifetime (2 μs) or the time to diffuse between micelles ($1/k_d$[micelle]). In the presence of added micelles the muonium rate constant is designated k_M(mic), and the ratio k_M(mic)/k_M changes markedly with *type* of reaction (17).

LCR can be used to observe the free radicals produced by reaction of Mu with unsaturated organic solutes solubilized in water by micelles. For benzene, styrene, vinyl acetate, acrylonitrile, and others, in dilute aqueous micelles, the same Mu radical is found as in these pure organic liquids, with its yield corresponding to the yield of muonium in water (20). But for acetone it is different.

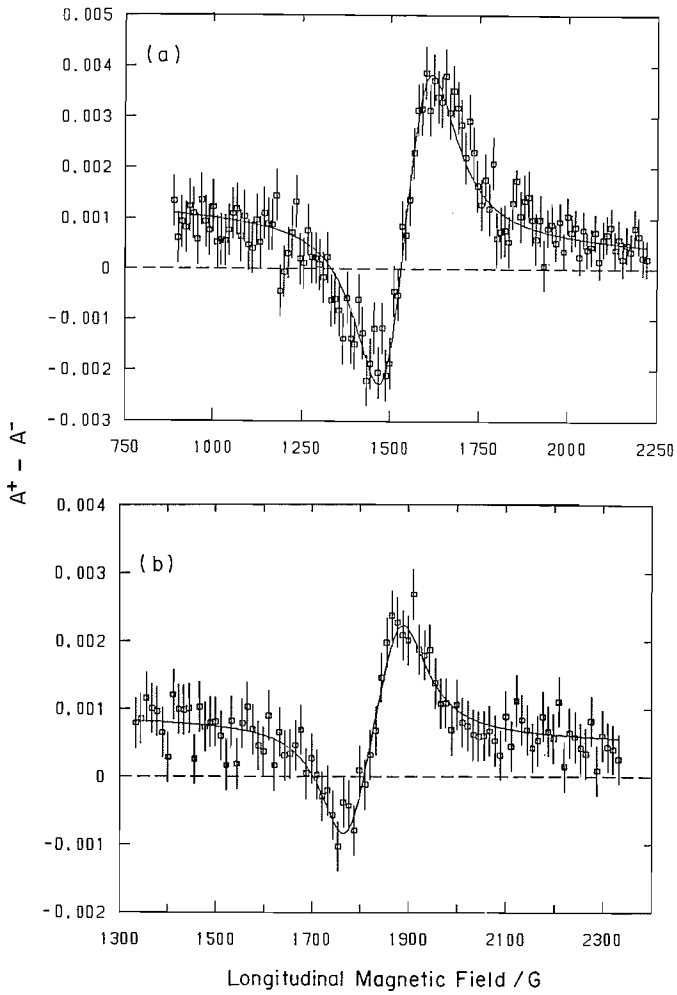

FIG. 3. The LCR spectra of (a) pure acetone, and (b) 0.1 M acetone in water, given as $A^+ - A^-$ (ordinate) against applied longitudinal magnetic field (abscissa) in gauss. A^+ is the normalized difference between forward-to-backward count rates with a positive modulation field, and A^- with the modulation field negative. These are typical LCR plots, showing transfer of muon spin polarization from the muon to a proton at a resonant level crossing field. In (a) the resonance field is centred at 1.540 kG, in (b) at 1.820 kG.

3. Results obtained for acetone

Table 3 summarizes most of the LCR and μSR data obtained for acetone, both as a solute in solution and as a pure liquid. Interactions between muons and acetone show quite a variety of results.

When a pure liquid is studied by either of these techniques, the high-energy charged particle (μ^+) may undergo chemical reactions in that state before reaching thermal energy, so that the muonated products observed can have *ionic* or *hot* precursors. These are "direct" effects. When acetone is present as a dilute solute in an inert solvent like water or hexane, however, the muon initially interacts mainly with solvent and some of them form muonium. Such Mu-atoms then undergo "secondary" reactions with solutes. It is in these dilute solutions that contrasts with reactions of H-atoms are evident.

The extent to which acetone's overall muon chemistry is representative of compounds containing carbonyl groups remains to be fully explored, but it certainly reacts much faster than acetamide and much slower than thioacetamide (see Table 2).

(a) Reaction rate constants in water

From the measured rates of disappearance of Mu and H in dilute acetone solutions at pH = 1 the overall isotope effect is seen to favour Mu by a factor of 34. There is almost no pH dependence on the Mu reaction, so it can probably also be ignored for the H reaction. Product analysis of the H reaction has shown there are two channels (21), with addition via reaction [3] being only half as fast as abstraction via reaction [4].

[3] $(CH_3)_2CO + H \rightarrow (CH_3)_2\dot{C}OH, \quad k_3 = 9 \times 10^5$ (21)

[4] $(CH_3)_2CO + H \rightarrow CH_3C\dot{O}CH_2 + H_2, \quad k_4 = 1.9 \times 19^6$ (21)

Mu, on the other hand, reacts predominantly via the addition pathway [5].

[5] $(CH_3)_2CO + Mu \rightarrow (CH_3)_2\dot{C}OMu, \quad k_5 = 9 \times 10^7$ (22)

The reason for this conclusion is that the yields of radicals show complete conversion of all muonium to radicals, and the fact that k_M equals the radical formation rate constants, k_f. Both are detailed below. It means that an abstraction reaction analogous to [4] involving Mu (reaction [6])

[6] $(CH_3)_2CO + Mu \rightarrow CH_3C\dot{O}CH_2 + MuH, \quad k_6 < 9 \times 10^6$

cannot be detected, though it could easily be there at the 10% level.

With two reaction paths we have two kinetic isotope effects. (a) For the addition reaction, $k_{M[5]}/k_{H[3]}$ equals $9 \times 10^7/9 \times 10^5$, i.e., 100. (b) For the abstraction of a hydrogen atom from acetone, $k_{M[6]}/k_{H[4]}$ must be less than $9 \times 10^6/1.9 \times 10^6$, i.e., <5. The latter is based on the presumption that the abstraction reaction [6] with Mu is *at most* 10% of the addition reaction [5]. In fact, most abstraction reactions favour H over Mu by about 10^2 (4), as with 2-propanol and formate (Table 2), so this may well be too large, even by two or three orders of magnitude.

(b) Muonated free radicals in acetone

The LCR spectra obtained in pure acetone and in 0.1 M acetone in water are shown in Figs. 3 (a) and (b). They undoubtedly arise from the same radical, but there is a shift in B_R of 280 MHz and a large change in amplitude.

The spectral shift can be attributed to a change in A_μ, rather than to the A_H of eq. [2], because a similar shift was found in A_μ by transverse field μSR (23). It is interpreted as a change in the degree of hydrogen bonding, here muonium bonding, between the Mu of the free radical and O-atoms of the molecules composing its microenvironment (23). In a pure acetone environment hydrogen bonding will be much weaker than it will be in an aqueous medium. The shift is such that A_μ is smaller when Mu has more restricted rotation around the C—O bond axis (the C—O—Mu angle is expected to be ~120 degrees). This corroborates an earlier suggestion that the hyperfine coupling constant of -O-Mu relative to -O-H is much larger than normal isotope effects, due to it being a difference in moments of inertia, rather than simply differences in vibrational modes (24). Acetone was the first example in which there was an isotope effect greater than twice the ratio of nuclear magnetic moments, and it differs from other radicals in having Mu attached to O. Table 3 gives the ratio of muon-to-proton hyperfine coupling constants for this radical formed by addition of Mu and H to the C=O group of acetone, and the ratio of 9 has already been compensated for the factor of 3.18 in nuclear magnetic moments.

The muonated free radical yield in pure acetone has been

TABLE 3. μSR and LCR data for acetone as the reactive ingredient

Parameter	Values and conditions	Reference
k_M	9×10^7 at pH = 1; 1.1×10^8 at pH = 7	4, 27
k_f[a]	8.5×10^7 (±25%)	22
k_M/k_H	34 (overall); 100 (for addition)	
k_M(mic)	2.5×10^{10} in CTAB (3 solutes/micelle)	27
k_M(mic)/k_M	290 (overall); >2700 (for abstraction)	
B_R	1.540 kG in pure acetone	22
	1.425 kG in hexane	22
	1.820 kG in water	22
A_{H_β}[b]	55.5 MHz in all three media	22
A_μ	26.1 MHz in pure acetone	14
	29.4 MHz in hexane	22
	22.0 MHz in water	23
A_μ/A_p[c]	9.1[d]	11
P_R	0.41 (in pure acetone)	24
	0.27 (in 5 M acetone in water)	22
	0.16 (at 0.1 M); 0.11 (at 0.01M)	22

[a] k_f is the rate constant for the formation of radicals.
[b] This is the hyperfine coupling constant of the six hydrogens in the $(CH_3)_2COMu$ radical.
[c] The muon-to-proton isotope ratio of hyperfine coupling constants for the radicals formed when Mu and H add to the O of acetone.
[d] Actual ratio is 29; but this is divided by 3.18, due to the muon's nuclear magnetic moment being that much bigger, in order to separate out the genuine isotope effect.

estimated from transverse field μSR to be 0.45 ± 0.03 (24). Also, the diamagnetic yield is known to be 0.54 (4), so all muons in acetone are accounted for. They either form diamagnetic species directly or they produce the radical of reaction [5]. Therefore there is no "missing fraction" on the μSR timescale, as there would have been with a slow abstraction reaction, because Mu would be dephased in the transverse field of a P_D measurement. This is the first of the reasons leading us to conclude that reaction [5] completely dominates over reaction [6].

For the 0.1 M acetone solution in water the free radical yield is much smaller than in pure acetone, and has been evaluated using eq. [3] to be 0.16 (22) (equal to the scavengable muonium yield in water for those conditions). In experiments with 0.01 M acetone, the yield was found to be smaller still (0.11) (22), as given in Table 3. This difference is due to significant radioactive decay of the muon in muonium *prior* to it being scavenged by acetone, particularly at the lowest concentration. (One can see this from the *overlap* of the timescale for reaction ($1/k_M(0.01)$ = 1.1 μs) with the intrinsic muon lifetime (2 μs).) From the ratio of these yields (0.16/0.11) one then calculates a rate constant for the *formation* of radicals in reaction [5] to be $8.5(\pm 2) \times 10^7$. This is indistinguishable from k_M, as determined for the total rate of loss of muonium by μSR, and therefore is a second reason why reaction [5] can be taken as the dominant reaction path.

(c) Micelle-mediated muonium reactions

No free radicals were found for acetone solutions in water to which micelles were added, even after scanning 500 G both sides of the signal shown in Fig. 3. The implication is that muonium undergoes reaction [6] rather than reaction [5] *when* it is within the micelle. If this is so, it is an example in which one reaction, the abstraction, is enhanced much more than the other, the addition, with the result that micelles have actually changed the dominant reaction channel. It means that the abstraction reaction has been enhanced from $<9 \times 10^6$ to 2.5×10^{10} M^{-1} s^{-1}, an enhancement factor of >2700. This is not inconsistent with enchancement factors specific to abstraction, which were found to be as high as 20 000 for molecules like 2-propanol and ethyl formate (17).

(d) Comparison with thiocarbonyls

Because of the instability of thioacetone, it was not possible to directly compare the exchange of acetone's C=O for C=S; however, in thioacetamide (and dimethylthioformamide) an LCR study produced a radical that had muonium attached to the C, and which was therefore a thiyl radical R-S• (25). Such radicals are not seen by ESR because of line-broadening effects. This one is quite evident here, however, at least on the LCR and μSR timescales. It is positively identified as an S• radical, and not C•, by its enormous muon hyperfine coupling (380 MHz) (26) compared with acetone (26 MHz) and non-aromatic C-centred radicals (100–150 MHz) (4, 14).

Muonium reacts with thioacetamide on first encounter (k_M = 3×10^{10} M^{-1} s^{-1} (27), which is the diffusion-controlled limit (4)). This is 3000 times more efficient than the acetone reaction. It is also faster than the corresponding H-atom reaction (12), but only by a factor of ~6. There was no micelle-induced enchancement of the Mu + thioacetamide reaction, but this is not surprising since it is already diffusion limited, and is an addition reaction rather than an abstraction (17).

Summary

Muonium is proving to be a probe of hitherto hidden kinetic isotope effects. Just from these studies with acetone as solute in water it has shown a number of surprises. It adds across a carbonyl group 100 times faster than does H, but it probably

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

abstracts a hydrogen from a methyl group more slowly than H does. It attaches to the oxygen atom when it adds to a carbonyl, but to the carbon of a thiocarbonyl. It reacts with thiocarbonyls three orders of magnitude faster than with carbonyls. Its abstraction reaction seems to be enhanced more than its addition reaction when incorporated in micelles, so there is a switch in the dominant reaction channel. Its thiyl radicals are sufficiently stable to be observed, and have large coupling constants. Hyperfine coupling constants can be determined for all protons, and for other nuclei with non-zero magnetic moments, in radicals produced from muonium; for the six β hydrogens of acetone the value is 55.5 MHz. There is intermolecular muonium bonding, analogous to hydrogen bonding, seen as a decrease in the muon coupling constant when water is exchanged for acetone as the radical's microenvironment. Mu shows the opposite directional effect to H when adding into substituted benzene rings, which is its major reaction path with most aromatics. Yet it diffuses in water at the same rate as H, despite its mass being only one ninth that of H.

Accordingly, if muonium is to usurp H as the leading hydronium isotope, there is still much to be learned about isotope effects!

Acknowledgments

The author is most grateful to his colleagues in the work reviewed here: particularly Drs. Mary Barnabas, Krishnan Venkateswaran, John Stadlbauer, Bill Ng, and Mr. Zhennan Wu. Many enjoyable "working" lunches with Ross Stewart also contributed to these studies. NSERC provided some of the funds needed.

Photosolvolysis of 11*H*-benzo[*b*]fluoren-11-ol in aqueous solution

ERIK KROGH AND PETER WAN[1]

Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received March 14, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

ERIK KROGH and PETER WAN. Can. J. Chem. **68**, 1725 (1990).

The photosolvolysis of 11*H*-benzo[*b*]fluoren-11-ol (**2**), a 9-fluorenol derivative, has been studied in aqueous solution to test the hypothesis of enhanced photosolvolytic reactivity of these compounds. It is found that compared to the model compound, α-phenyl-2-naphthalenemethanol (**3**), **2** exhibited enhanced photosolvolytic reactivity. Quantum yields for photosolvolysis in aqueous alcohol solutions and steady-state and transient fluorescence studies are reported in neutral and acid solutions. The results further support the notion that an intrinsically accelerated *photo*dehydroxylation step is associated with the formation of a 9-fluorenyl type carbocation intermediate (formally $4n\pi$ electrons).

Key words: photosolvolysis, photodehydroxylation, carbocation.

ERIK KROGH et PETER WAN. Can. J. Chem. **68**, 1725 (1990).

Afin de vérifier l'hypothèse selon laquelle ces composés présentent une réactivité photosolvolytique accrue, on a étudié la photosolvolyse du 11*H*-benzo[*b*]fluorèn-11-ol (**2**), un dérivé du 9-fluorénol, en solution aqueuse. On a trouvé que, si on compare sa réactivité avec celle du composé modèle, le α-phényl-2-naphtalèneméthanol (**3**), le composé **2** présente une réactivité photosolvolytique accrue. On rapporte les rendements quantiques pour les photosolvolyses en solutions aqueuses d'alcool; on a aussi étudié la fluorescence des états stationnaires et de transition dans des solutions neutres et acides. Les résultats obtenus apportent un nouveau support à l'hypothèse selon laquelle une étape de *photo*déhydroxylation intrinsèquement accélérée est associée à la formation d'un carbocation intermédiaire de type 9-fluorényle qui contient formellement $4n\pi$ électrons.

Mots clés : photosolvolyse, photodéhydroxylation, carbocation.

Continued interest in photosolvolytic reactions stems partly from the fact that these reactions generate ion pairs, which are much less common intermediates than radicals or radical pairs in organic photochemistry (1). In addition, recent studies by McClelland *et al.* (2–6) have utilized these types of reactions for photogenerating carbocation intermediates for study by flash photolysis, from which new insights into structure–reactivity of the *photogenerated* carbocations in aqueous solutions have been obtained. We have been exploring structure–reactivity effects of the *initial* photochemical step for a number of systems (7–11) and have discovered that 9-fluorenols **1** are particularly prone to photosolvolyze (10, 11). It has been proposed (10, 11) that the reaction proceeds from the singlet state via primary benzylic C—OH bond heterolysis (photodehydroxylation), to generate a 9-fluorenylium ion intermediate, which is rapidly trapped by nucleophiles in the system. The 9-fluorenylium ion is an antiaromatic species in the ground state (12, 13) and is therefore very difficult to generate and characterize thermally. This instability, compared to $4n + 2$ π systems or molecules lacking the cyclic array altogether, is commonly employed to explain the marked reduced solvolytic reactivity of fluorenol derivatives in the ground state. The photochemical method is therefore significant by providing $\mathbf{1}^+$ and related cations. In particular it provides a potential means of studying these elusive antiaromatic cations via laser flash photolysis. That a 9-fluorenylium ion is an intermediate in these reactions is supported by recent flash photolysis studies (14, 15). We proposed (11) that photodehydroxylation leading to a 4π electron cation in the Internal Cyclic Array (ICA; defined as the carbocyclic array immediately surrounding the cation on solvolysis) is a favourable arrangement, suggesting that such species have an enhanced stability in the excited singlet state, when compared to similar systems lacking the 4π ICA (11). Calculations by us[2] and others (16) support the suggestion that $4n\pi$ systems adopt pseudo-aromatic characteristics in the S_1 state. Several features of the original 9-fluorenol system (11) made the study of its photochemical reaction mechanism difficult. Most notably, 9-fluorenols, **1**, are very weakly fluorescent ($\Phi_f < 0.01$) and have very short fluorescence lifetimes (typically $\tau < 100$ ps) (11) in aqueous solution. Secondly, they failed to exhibit acid-catalyzed photosolvolysis, a feature that we have used often (7, 9) to rule out electron transfer and homolytic pathways. We report here a study of the photosolvolysis of a benzannelated derivative of 9-fluorenol, 11*H*-benzo[*b*]fluoren-11-ol (**2**). Like 9-fluorenol, **2** is very reactive towards photosolvolysis. We have also studied a reference compound, α-phenyl-2-naphthalenemethanol (**3**), and find it to be much less reactive with respect to photosolvolysis. Furthermore, **2** allows us to probe steady-state and transient fluorescence behaviour in detail, as well as providing the first example of acid catalysis in the photosolvolysis of 9-fluorenol type systems.

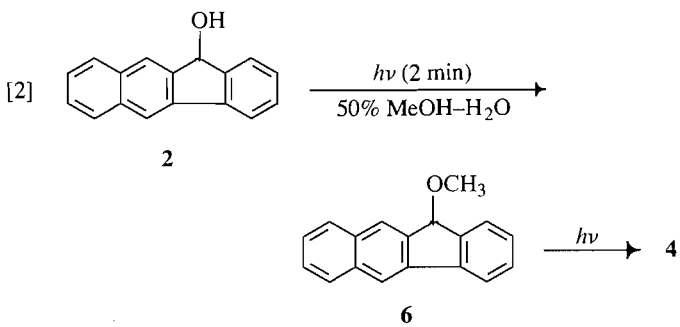
densation of 1-indanone with *o*-phthaldehyde, according to the procedure of Streitwieser *et al.* (17) (eq. [1]). The reference alcohol **3** was studied because it lacks an ICA, but possesses a chromophore similar to **2**. It was made via the addition of phenyllithium to 2-napthaldehyde. The corresponding hydrocarbon **4** was of interest for comparison purposes (steady-state and transient fluoresence studies) since it is known to be inert to photosolvolysis and other photochemical pathways in the absence of oxygen. It was made via reduction of **5** using $LiAlH_4/AlCl_3$ (eq. [1]).

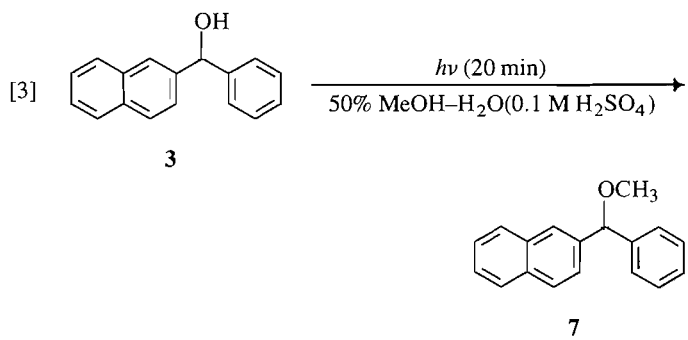
Product studies

Photolysis of either **3** or **4** (typical conditions: 10^{-3} M substrate, 50% (v/v) MeOH–H_2O, neutral water; Rayonet RPR 100 photochemical reactor; 254-nm lamps; argon-purged solutions; 5–60 min irradiation) resulted in no observable photoreaction. However, a 2 min photolysis of **2** under the same conditions resulted in high yields (>50%) of the corresponding methyl ether product **6** (eq. [2]). Extended photolysis results in



the formation of **4**, which arises from the secondary photolysis of **6**. This was confirmed by independent photolysis of **6** in the same solvent, and from the dependence of product formation on the photolysis time as shown in Fig. 1. The efficient photoreduction of **6** to **4** is analogous to the photoreduction of 9-methoxyfluorene to fluorene, which we (11) and Tomioka *et al.* (18) have shown to occur via initial C—OMe homolysis, to give the radical pair, followed by disproportionation. Photolysis of **2** in a variety of alcohol–water mixtures also gave the corresponding ethers in good yields (Table 1). However, photolysis (10–60 min) in either 0.25 M NaCN or NaBr (50% acetonitrile cosolvent) failed to produce significant quantities of the corresponding cyano or bromo derivatives. This may in part be due to the inherent photolability of the initially formed products. In all of the above reactions control experiments showed no reaction in the absence of irradiation.

To investigate the possibility of acid catalysis in the photosolvolysis reaction, **2** and **3** were irradiated in methanol – aqueous sulfuric acid mixtures. When **3** was photolyzed in a 50% MeOH–H_2O (0.1 M H_2SO_4) solution for 20 min, it was converted to its corresponding methyl ether, **7**, in 25% yield (eq. [3]). Furthermore, **2** demonstrated an increased reactivity under acidic conditions. The conversion to methyl ether, after a 1 min photolysis, rose from 20% in neutral solution to 35% when the water portion was replaced by 0.1 M H_2SO_4. In both cases, no reactions were observed in the absence of light, thus clearly indicating that acid catalysis of photosolvolysis was taking place (*vide infra*). Compounds **2** and **3** will thermally solvolyze under the reaction conditions at sulfuric acid concentrations above 1.5 M and 0.5 M, respectively. Photolyses were not studied at these higher acidities.



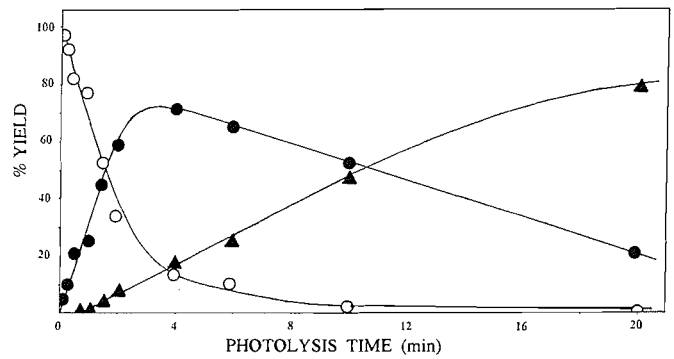


FIG. 1. Time-dependent product formation for the photosolvolysis of **2** in 50% MeOH–H_2O. Open circles represent **2**, filled circles represent primary photoproduct **6**, and triangles represent secondary photoproduct **4**.

Product quantum yields

Quantum yields for product formation (Φ_p) were measured using GC to analyze the extent of conversion and potassium ferrioxalate actinometry (19) for light intensity measurements. Photolyses were carried out under a stream of argon in quartz cuvettes (10^{-3} M substrate) and irradiated on an optical bench with an Oriel 200-W Hg source and an Applied Photophysics monochromator (λ_{ex} = 280 nm, 5-nm band width). Table 1 summarizes quantum yields of ether formation in different solvent systems. Quantum yields in MeOH–H_2O solution as a

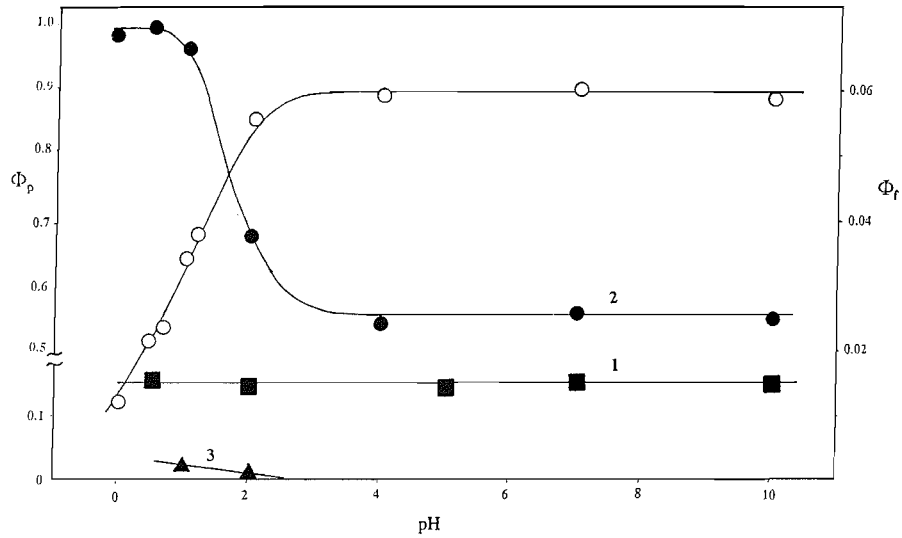

FIG. 2. Plot of product quantum yield for methyl ether formation (Φ_p) for compounds **1** (R = H), **2**, and **3** as a function of pH (or H_0), solid points. Also included is the pH dependence of fluorescence quantum yield (Φ_f) for **2** (open circles). The quoted pH (or H_0) value is for the aqueous portion of the solvent mixture.

2-PrOH–H_2O[b]	0.22±0.1[c]

[a]Measured using an optical bench setup at λ_{ex} = 280 nm; substrate concentration, 10^{-3} M; conversions determined by GC analysis and light intensity measurements by potassium ferrioxalate actinometry (19).

[b]Experiments were carried out using 50 mg of substrate dissolved in 60 mL ROH and 40 mL H_2O (pH 7) and photolyzed at 254 nm for 4 min.

[c]Quantum yields were calculated by ^{1}H NMR integration using the value in 50% MeOH–H_2O as a secondary standard.

function of acidity of the *aqueous portion* are plotted in Fig. 2, with the results for the parent 9-fluorenol (**1**, R = H) shown for comparison purposes. It is evident from this plot that **3** has appreciable reactivity only in the presence of acid, with measurable Φ_p only below pH 2. From a previous study (11), the parent 9-fluorenol (**1**, R = H) did not display acid catalysis. However, it is clear that the reactivity of **2** is enhanced below pH 2, with Φ_p reaching a limit close to unity below pH 1.

Steady-state and transient fluorescence studies

The fluorescence excitation and corrected emission spectra of **2–4** are shown in Fig. 3. The absorption spectra of **2** and **4** are similar, with a long wavelength band $\lambda_{max} \approx 340$ nm. On the other hand, **3** does not possess this longer wavelength absorption, and its absorption spectrum resembles that of naphthalene. The emission intensity of **2** showed a marked solvent dependence whereas the intensity of **4** was invariant with a change in solvent, consistent with a similar trend in the fluorescence lifetimes (*vide infra*). The reference alcohol **3** displayed a reduced emission intensity only in acidic MeOH–H_2O solutions, concurrent with its increased reactivity in this solvent system. Fluorescence quantum yields in aqueous CH_3CN and 50% MeOH–H_2O are shown in Table 2. The nonreactive parent compound **4** was the most strongly fluorescent, with $\Phi_f \approx 0.85$ in either solvent; **2** has a fluorescence quantum yield of 0.26 in the inert solvent CH_3CN, and 0.06 in MeOH–H_2O solutions where efficient photosolvolysis occurs. The fluorescence quantum yield was further diminished with decreasing pH (H_0) (Fig. 2). Fluorescence lifetimes of **2–4** were measured using time-correlated single photon counting, on a Photon Technology instrument, using a hydrogen spark lamp as the excitation source. All lifetimes were obtained using fresh samples and a minimum exposure to the excitation source light. Solutions were exhaustively purged with a stream of a argon prior to data collection. The results are shown in Table 3, and are consistent with the above observations of the fluorescence emisison intensity. The decrease in the fluorescent lifetime of **2** with increasing acid concentration is consistent with the interception of the excited state by protons. A Stern–Volmer plot for **2** (Fig. 4) displays the linear dependence of (τ_0/τ) on the proton concentration at moderate acidities ($\leq$0.2 M). The slope provides a measure of k_q, the quenching rate constant, which can be equated with the acid-catalyzed rate coefficient, k_H, assuming a dynamic quenching mechanism. We calculate values of k_H for **2** to be $(4.0 \pm 0.3) \times 10^9$ M^{-1} s^{-1} and $(3.4 \pm 0.4) \times 10^9$ M^{-1} s^{-1}, in 20% CH_3CN–H_2O and 50% MeOH– H_2O, respectively. A similar treatment of the steady-state quenching (Φ^0_f/Φ_f), 20% CH_3CN–H_2O, also gave a value of $(3.7 \pm 0.2) \times 10^9$ M^{-1} s^{-1}.

The fact that the values in the different mixed solvent systems are in relative agreement suggests that a simple treatment of correcting the proton concentration by a dilution factor is adequate at these low proton concentrations. Plots of the fluorescence (Φ_f) and product (Φ_p) quantum yields as a function of pH are shown in Fig. 2 for **2** (open and solid circles respectively). The complementary behaviour of the acid-catalyzed photosolvolysis and the acid quenching of fluorescence strongly suggests a reactive singlet excited state for these substrates.

Solvent isotope effects

Solvent isotope effects for the quantum yield of photosolvoly-

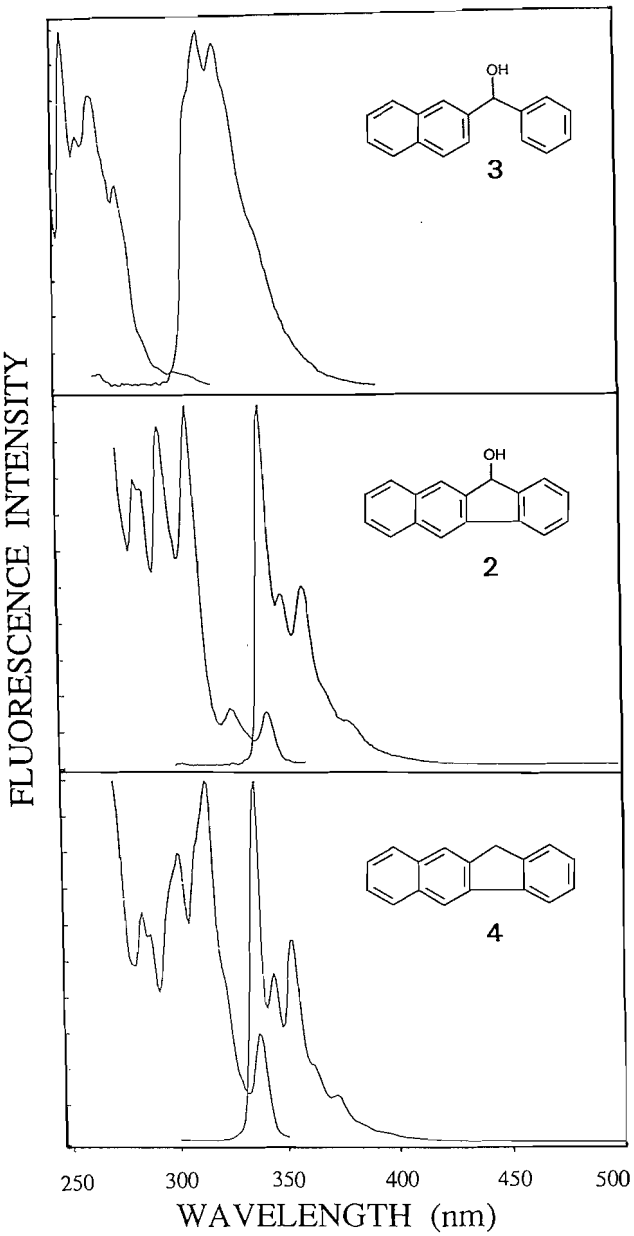

FIG. 3. Overlay of the fluorescence excitation and corrected emission spectra of **2**–**4** in 100% CH_3CN (λ_{ex} = 300 nm for **2** and **4**, λ_{ex} = 260 nm for **3**).

sis of **2** were measured in 50% MeOH–H_2O (Φ_{H_2O}) and compared to 50% MeOD–D_2O (Φ_{D_2O}). The observed value was $\Phi_{H_2O}/\Phi_{D_2O} = 1.1 \pm 0.1$. The fluorescence lifetimes of **2** were also measured in the deuterated solvents and the values of τ_{D_2O}/τ_{H_2O} are 1.24 ± 0.04 and 1.21 ± 0.04 for 50% MeOL–L_2O and 20% CH_3CN–L_2O, respectively. The unreactive compounds **3** and **4** displayed no solvent isotope effect. Using the relation, $k = \Phi_p/\tau$, the ratio of the rate constant k_{H_2O}/k_{D_2O} was determined to be 1.3 ± 0.1. This value is consistent with a mechanism involving a solvent-assisted bond cleavage step, and supports our mechanism of heterolytic bond cleavage as the primary photochemical event.

Triplet sensitization

Both steady-state and transient fluorescence studies indicate that the photosolvolysis of **2** and **3** occurs via the excited single state. Triplet sensitization experiments, carried out for **2**, in

TABLE 2. Fluorescence quantum yields (Φ_f) for **2**–**4**[a]

Solvent	Φ_f		
	2[b]	**3**[c]	**4**[b]
CH_3CN	0.26±0.03	0.10±0.01	0.82±0.06
50% MeOH–H_2O	0.06±0.01	0.10±0.01	0.85±0.06

[a]Determined by comparing the integrated emission areas of absorbance matched solutions using a Photon Technologies LS-1 spectrofluorimeter with recommended standards (25).
[b]Secondary standard was 2-aminopyridine in 0.05 M H_2SO_4, Φ_f = 0.60 (25).
[c]Secondary standard was naphthalene in cyclohexane, Φ_f = 0.23 (25).

TABLE 3. Fluorescence lifetimes (τ) for **2**–**4** in various solvent systems

Solvent system	Lifetime τ (ns)[a]		
	2[b]	**3**[b]	**4**[b]
100% CH_3CN	19	39	26
100% MeOH	13	36	27
20% CH_3CN–H_2O	3.8	36	25
50% MeOH–H_2O	4.6	36	26
50% MeOD–D_2O	5.7	36	26
10% MeOH–H_2O	1.5	36	26
50% MeOH–H_2O (pH 1)	2.6	35	26
50% MeOH – 20% H_2SO_4	0.25	26	24

[a]Errors are estimated to be less than 4% of the quoted value, except for lifetimes less than 1 ns, where they may be larger. The absorbance at the excitation wavelength was less than 0.3 in all cases.
[b]Excitation wavelength was 295 nm for **2** and **4** and 265 nm for **3**. Monitoring wavelength was 355 nm for **2** and **4** and 340 nm for **3**.

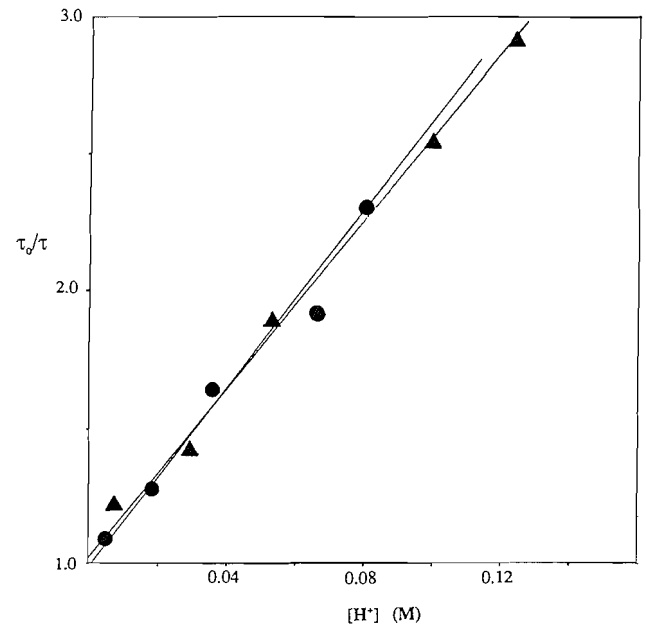

FIG. 4. Stern–Volmer plot of (τ_0/τ) versus [H_3O^+] for **2**. Triangles represent measurements in 20% CH_3CN–H_2O, slope = 15.3 ± 0.4 M^{-1}; circles represent measurements in 50% MeOH–H_2O, slope = 15.6 ± 0.8 M^{-1}.

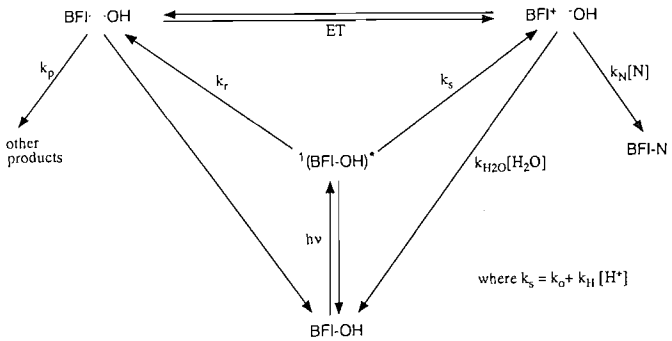

SCHEME 1

60% MeOH–H_2O (pH ≈ 10, λ_{ex} = 350 nm) using sodium benzophenone-2-carboxylate (100 molar excess) as the sensitizer lead to no photosolvolysis products. Thus, the photodehydroxylation appears to be an exclusively singlet state reaction. It was not possible to carry out the same sensitization studies with **3** since this compound had measurable solvolytic reactivity only at low pH, a solvent system where insufficient amounts of the sensitizer could be dissolved. However, the similar behaviour observed so far between **2** and **3** would suggest that **3** also reacts exclusively via S_1.

Discussion

Mechanism and rate constants

The photosolvolytic behaviour of **2** and **3** closely resembles that observed for other benzylic alcohols studied in our laboratory, all of which are known to proceed via heterolysis (photodehydroxylation) from S_1 to generate ion pairs. Our working mechanism of photosolvolysis of dibenzannelated systems has been proposed previously (11) and is shown in Scheme 1 (where BF1-OH represents **2**). Preparatory photolysis and laser flash photolysis studies of 9-fluorenol (11, 14, 15) have shown that a competing homolytic reaction pathway, k_r, contributed to the loss of the excited state, particularly in low dielectric solvents. The possibility of radical intermediates and electron transfer processes has therefore been included in this scheme, although we have no evidence that these steps are important in the present study. The very high product quantum yields for **2** necessarily relegate competing pathways to minor processes. The solvent isotope effect, k_{H_2O}/k_{D_2O} = 1.3, and the observed acid catalysis provide convincing evidence for the heterolytic bond cleavage step. The rate constant associated with this step, k_s, can be separated into two components: one, k_0, associated with the solvent assisted cleavage that is dominant in neutral solution, and another, k_H[H^+], associated with acid catalysis that contributes at higher proton concentrations. Use of the Stern–Volmer relation above established a value of $k_H = (3.7 \pm 0.4) \times 10^9\ M^{-1}\ s^{-1}$, for **2**. Because the other alcohols **1** and **3** did not display significant acid catalysis in a suitable pH region, they could not be treated in a similar manner to yield comparative values. However, the overall rate constants, k_s, could be evaluated in all cases using the relation $k_s = (\Phi_p/\tau)\cdot\{(k_{H_2O}[H_2O] + k_N[N])/k_N[N]\}$, where the term in brackets arises from the competition for the intermediate cation by the two nucleophiles in mixed solvent environments. These values are summarized in Table 4 under neutral and acid conditions. The rate constant for the heterolysis of **2**, leading to the 4π intermediate, is at least three orders of magnitude greater than that for **3**, which does not contain the ICA. This order of reactivity is the opposite to that observed in the ground state. The rate constant, k_s, for **2** is about an order of magnitude less than the value we estimated for **1** in neutral MeOH–H_2O. The annelation effect of the added benzene ring understandably decreases the reactivity of benzofluorenol by reducing the electron density in the vicinity of the incipient cyclopentadienyl cation. Thus, in terms of their rate constants, the 9-fluorenols are still the most photosolvolytically reactive molecules of which we are aware to date. Presumably, the lack of acid catalysis for 9-fluorenol can be explained by its very high reactivity in neutral solution, which would necessitate the use of much stronger acid media to observe the onset of catalysis. Our attempts to trap the photogenerated cations of **1** and **2** with added nucleophiles (i.e., Br^-, CN^-) in aqueous solvents have been unsuccessful. We have attributed this observation to an extremely short lifetime associated with the intermediate cation, which would therefore preclude cage escape and ensuing bimolecular reaction. Recent assignments by Mecklenburg and Hilinski (15) confirm this proposal. They have estimated the lifetime of $\mathbf{1}^+$ to be around 20 ps in aqueous methanol solutions.

TABLE 4. Values of k_s for **1–3** in 50% MeOH–H_2O

Solvent system	k_s[a] (s^{-1}) **1**[b]	**2**	**3**
50% MeOH–H_2O (pH 7)	$\approx 5 \times 10^9$	1.2×10^8	$\leq 5.5 \times 10^4$[c]
50% MeOH–H_2O (pH 1)	—	3.6×10^8	5.7×10^5

[a]Rate constants calculated by the relation $k_s = \Phi_p/\tau$.
[b]Based on a lifetime of ≈30 ps in this solvent (11).
[c]Estimated upper limit.

Quantum yields

The surprisingly high product quantum yields for **2** seem to indicate a strong preference for methanol attack. In the absence of quantitative data to the contrary (at least for excited states), we have previously assumed the rates of MeOH and H_2O attack to be similar. The results of this study severely question this assumption. Ritchie (20) has reported relative nucleophilicity values, $N+$, for H_2O and MeOH of 0.0 and 0.5, respectively. These are log values, so MeOH sould be ≈3.2 times more reactive than H_2O. When this reactivity difference is combined with the fact that the mole fraction of MeOH in a 50% (v/v) solution is 0.31, we are still unable to accommodate quantum yields approaching unity. The unusually high selectivity of the intermediate carbocation is not fully understood at this time. We provide two possible explanations here. Firstly, the $N+$ values measured with relatively stable ground state cations may not be appropriate for short-lived photogenerated intermediates. However, based on reactivity–selectivity arguments one might expect even less of a difference in the nucleophilic properties of MeOH and H_2O. A second possibility is that the arrangement of the solvent cage predisposes the MeOH molecules to solvolyze the incipient cation once it is formed. We know that the solvolytic step is very rapid, probably involving little more than the collapse of the solvent cage once the cation is formed. 11*H*-Benzo[*b*]fluoren-11-ol (**2**) is quite hydrophobic and it may not be unreasonable to expect that the microscopic environment immediately surrounding it is methanol enriched. We await laser flash photolysis studies to comment further on this phenomena.

Conclusion

The study of the photosolvolysis of **2** has brought additional insights into the details of the reaction pathway for these types of compounds. Since **2** has a close structural resemblance to the parent 9-fluorenol systems, its photochemical behaviour was expected to parallel that of 9-fluorenol. This indeed was observed, as demonstrated by the high reactivity of **2**, compared to a closely related compound **3** that lacks a 4π ICA. However, unlike the situation encountered in **1** (11), it was possible to measure several important experimental parameters, which strengthens the proposed mechanism offered in the previous study (11). In addition, the availability of measurable fluorescence lifetimes and acid catalysis observed in **2** allows for the calculation of primary rate constants of reaction.

Experimental

General

^{1}H NMR spectra were recorded on a Perkin–Elmer R32 instrument in $CDCl_3$ or acetone-d_6 (TMS internal standard). UV spectra were obtained on a Perkin–Elmer Lamda 4B or a Pye–Unicam 800 spectrophotometer. Fluorescence spectra were taken on a Perkin–Elmer MPF66 spectrofluorimeter or the Photon Technologies LS-1 in steady-state mode. Fluorescence lifetimes were measured using time-correlated single photon counting on a Photon Technologies LS-1 instrument in lifetime mode. Mass spectra were taken on a Finnigan 3300 instrument. Melting points were obtained on a Koefler hot stage microscope and are uncorrected. Gas chromatography (GC) was performed on a Varian 3700 instrument with a Hewlett–Packard 3390A integrator. Photolyses were carried out in Suprasil quartz cuvettes or 100-mL quartz tubes using a Rayonet RPR 100 photochemical reactor. An Oriel 200-W Hg light source and an Applied Photophysics monochromator on an optical bench were used for the quantum yield determinations.

Materials

Naphthalene and 2-aminopyridine (99%+) were purchased from Aldrich Chemical Co. The naphthalene sample was recrystallized twice from ethanol and then sublimed before use as a secondary quantum yield reference. 2-Aminopyridine was used as received. All solvents were of spectral grade and checked for spurious emission prior use. β-Napthylaldehyde, 1-indanone, and *o*-phthaldehyde were used as received from Aldrich Chemical Co. in the synthesis of **2** and **3**.

11H-Benzo[b]fluorenone (5)

This compound was synthesized in 53% yield according to the method in ref. 17; mp 153°C (lit. (21) mp 153–154.5°C).

11H-Benzo[b]fluoren-11-ol (2)

A solution of 5.0 g (22 mmol) of benzo[*b*]fluorenone in 100 mL of MeOH and 50 mL of THF was cooled while a suspension of 0.80 g (11 mmol) of $NaBH_4$ in 20 mL of MeOH was added dropwise. The reaction was warmed to ambient temperature and then refluxed for 12 h. The product was worked up by concentrating the mixture of 20 mL, diluting with CH_2Cl_2, and then washing with aqueous NH_4Cl and H_2O. The organic fraction was dried over $MgSO_4$, and evaporated to yield 4.6 g (90% yield) of a light yellow solid, which was recrystallized from ligroin to give white plates; mp 184°C (lit. (22) mp 185°C); ^{1}H NMR δ: 1.9 (d, J = 6 Hz, 1H), 5.75 (d, J = 6 Hz, 1H), 7.3–8.1 (arom., 10H); mass spectrum (EI) (m/z): 232 (M^+).

11H-Benzo[b]fluorene (4)

To a stirred suspension of 0.30 g (8 mmol) $LiAlH_4$ in 150 mL of dry THF was added 2.4 g (18 mmol) of $AlCl_3$ in small portions. The mixture was heated to reflux and 1.0 g (4.4 mmol) of **5** was extracted from the thimble of a Soxhlet extractor into the reaction vessel over a 6 h period. The reaction was worked up by reducing the THF to 10 mL, diluting with 100 mL CH_2Cl_2, and pouring onto 50 g of ice acidified with 5% H_2SO_4. The organic layer was separated, washed with H_2O, dried over $MgSO_4$, and evaporated to yield 0.88 g of a white solid (90% yield), which was recrystallized from MeOH and sublimed; mp 209–211°C (lit. (23) mp 208.5–209.5°C); ^{1}H NMR δ: 4.05 (s, 2H), 7.3–8.2 (arom., 10H); mass spectrum (EI) (m/z): 216 (M^+).

α-Phenyl-2-naphthalenemethanol (3)

To a solution of 5.0 g (32 mmol) of β-napthaldehyde (32 mmol) in dry THF was added via syringe 20 mL of PhLi (1.8 M, 35 mmol), under nitrogen. The solution was refluxed for 4 h and worked up as follows. The solution was concentrated to about 20 mL, diluted with 200 mL CH_2Cl_2, and washed with H_2O (2 × 200 mL). The combined organic fractions were dried over $MgSO_4$, and evaporated to yield 6.5 g (85% yield) of a white solid, which was recrystallized from petroleum ether; mp 87–88°C (lit. (24) mp 87–88°C); ^{1}H NMR δ: 2.45 (d, J = 5 Hz, 1H), 5.92 (d, J = 5 Hz, 1H), 7.2–7.9 (arom., 12H); mass spectrum (EI)(m/z): 232 (M^+).

Product studies. Dark reactions

The photosolvolytic behaviour of alcohols **2** and **3** was investigated at acidities (0.10 M H_2SO_4) where there were no concurrent dark reactions. In more concentrated sulfuric acid solutions, 1.5 M for **2** and 0.5 M for **3**, thermal solvolysis reactions became significant. A typical experimental procedure for a preparative dark reaction follows. A solution of 50 mg of compound in 50 mL of MeOH was diluted with 50 mL of aqueous sulfuric acid. The solution was stirred in the dark with a cold water circulator (≈12°C) for the appropriate irradiation time (usually 5–30 min). The reactions were worked up by saturating the aqueous solution with NaCl and extracting with CH_2Cl_2. The isolated materials were then analyzed by ^{1}H NMR spectroscopy.

Preparatory photolysis

In a typical photolsysis, 50 mg of substrate was dissolved in 50 mL of MeOH and diluted with 50 mL of H_2O. (Due to its low solubility in aqueous solutions, 60% MeOH–H_2O was often employed in the preparatory photolysis of **2**.) The solution was placed in a quartz tube fitted with a cold finger (≈12°C) and deaerated with a continuous stream of argon. The solution was then irradiated at 254 nm. After photolysis, the solution was worked up by saturating with NaCl, followed by extraction (2 × 100 mL) with CH_2Cl_2. The identity and yields of the photosolyate products were determined by ^{1}H NMR and gas chromatography. Product mixtures were separated by preparative TLC. The ethers of **2** and **3** were characterized by ^{1}H NMR and mass spectroscopy, as presented below.

11-Methoxy-11*H*-benzo[*b*]fluorene (**6**): mp 90–92°C; ^{1}H NMR δ: 3.05 (s, 3H), 5.75 (s, 1H), 7.3–8.1 (arom., 10H); mass spectrum (EI) (m/z): 246 (M^+).

α-(Methoxy)-α-(phenyl)-2-methylnapthalene (**7**): ^{1}H NMR δ: 3.38 (s, 3H), 5.38 (s, 1H), 7.2–7.5 (m, 8H), 7.7–7.9 (m, 4H); mass spectrum (EI) (m/z): 248 (M^+).

11-Ethoxy-11*H*-benzo[*b*]fluorene: ^{1}H NMR δ: 1.18 (t, 3H), 3.35 (q, 2H), 5.85 (s, 1H), 7.2–8.1 (arom., 10H).

11-(*n*-Propyloxy)-11*H*-benzo[*b*]fluorene: ^{1}H NMR δ: 0.90 (t, 3H), 1.56 (sextet, 2H), 3.20 (t, 2H), 5.85 (s, 1H), 7.2–8.1 (arom., 10H).

11-(2-Propyloxy)-11*H*-benzo[*b*]fluorene: ^{1}H NMR δ: 1.24 (d, 6H), 3.94 (septet, 1H), 5.80 (s, 1H), 7.2–8.1 (arom., 10H).

Steady-state fluorescence and lifetime measurements

Fluorescence spectra and lifetimes were recorded on a Photon Technologies LS-1 instrument in 1.00-cm Suprasil quartz cuvettes at 10^{-5} M. Solutions were purged with argon for 10 min prior to measurement.

Quantum yields and pH effects

Quantum yields for methyl ether formation of **2** and **3** were carried out in a variety of solvent systems. In a typical experiment, 0.50 mL of a stock solution of substrate in MeOH (4×10^{-3} M) was transferred to a quartz cuvette, and diluted with 1.0 mL of MeOH followed by 1.5 mL of H_2O. The solutions were argon purged for 10 min prior to and during the photolysis (usually 2–20 min, at 280 nm). After irradiation the photosolyate was transferred to a test tube, saturated with NaCl, and extracted with CH_2Cl_2 (3 × 3 mL). The organic fractions were separated using a pipette, and then dried over $MgSO_4$, filtered, and evaporated to ca. 100 μL before being injected onto a capillary column

(220°C) for analysis. Control experiments indicated that material is not lost during the work-up procedures. Conversions were determined by the relative peak areas of ether and alcohol, using a Hewlett–Packard integrator. Conversions determined this way are in agreement with those obtained from integration of ^{1}H NMR signals. Light intensity measurements were determined by irradiating a 0.006 M aqueous solution of potassium ferrioxalate under identical conditions and working up according to the method of Hatchard and Parker (19).

Fluorescence quantum yields

Fluorescence quantum yields for **2**–**4** were obtained on a Photon Technologies LS-1 instrument using secondary standards and recommended procedures (25). Naphthalene was the standard of choice for **3** whereas 2-aminopyridine provided a better overlap of the emission bands for **2** and **4**.

Registry No.: **2**, 110334-50-4; **3**, 35060-38-9P; **4**, 243-17-4; **5**, 96575-40-5P.

A distorted anilide (3,4-dihydro-2-oxo-1,4-propanoquinoline (**3**)) has been synthesized, its structure determined by X-ray diffraction, and its hydrolysis profile from pH 0–13 investigated. The amide unit in **3** is distorted in that the N lone pair is twisted 35° and tilted 15° out of optimum conjugation with the C=O Π system. Due to this distortion, **3** hydrolyses rapidly in H_2O at 25°C. The pH/rate constant profile exhibits domains consistent with OH^- attack on **3** (k_{OH^-} = 17.2 M^{-1} s^{-1}) and H_2O attack on a protonated form of **3** ($k_{H_3O^+}$ = 8.26 s^{-1}; pK_a (**3**-H^+) = 0.56). The kinetic pK_a is most consistent with an N-protonated form. It is also shown that this mechanism of hydrolysis is common to the series of bridged anilides consisting of **3**, 3,4-dihydro-2-oxo-1,4-ethanoquinoline (**1**), and 2,3,4,5-tetrahydro-2-oxo-1,5-ethanobenzazepine (**2**).

Key words: distorted amide, hydrolysis, X-ray structure.

QINGPING WANG, A. J. BENNET, R. S. BROWN et B. D. SANTARSIERO. Can. J. Chem. **68**, 1732 (1990).

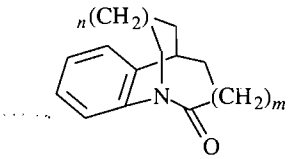
On a synthétisé un anilide déformé (3,4-dihydro-2-oxo-1,4-propanoquinoléine (**3**)), on a déterminé sa structure par diffraction des rayons-X et on a étudié son profil d'hydrolyse en fonction du pH (de 0 à 13). L'unité amide du composé **3** est déformée; la paire d'électrons non partagée forme un angle de torsion de 35° et une inclinaison de 15° par rapport au plan de conjugaison optimale du C=O avec le système Π. À cause de cette distorsion, l'hydrolyse du produit **3** se fait rapidement dans l'eau, à 25°C. Le profil de la constante de vitesse vs. le pH est en accord avec une attaque d'un OH^- sur le composé **3** (k_{OH^-} = 17,2 M^{-1} s^{-1}) et d'une attaque de H_2O sur la forme protonée du composé **3** ($k_{H_3O^+}$ = 8,26 s^{-1}; pK_a (**3**-H^+) = 0,56). Le pK_a cinétique est principalement en accord avec une forme N-protonée. On démontre aussi que ce mécanisme d'hydrolyse est commun dans la série d'anilides pontés formée du produit **3**, de la 3,4-dihydro-2-oxo-1,4-éthanoquinoléine (**1**) et de la 2,3,4,5-tétrahydro-2-oxo-1,5-éthanobenzazépine (**2**).

Mots clés : amide déformé, hydrolyse, structure par rayons-X.

[Traduit par la revue]

Introduction

As part of an ongoing program in understanding the detailed mechanism of hydrolysis of strained amides (1) we have embarked on the syntheses and physicochemical studies of a series of anilides **1**–**4**. The synthesis and hydrolysis of amide



1 $n = m = 0$
2 $n = 0$; $m = 1$
3 $n = 1$; $m = 0$
4 $n = m = 1$

1 had originally been reported by Blackburn *et al.* (2) and molecular models indicate that the N "lone pair" of the N-C=O unit is essentially orthogonal to the C=O Π-system. This geometric constraint leads to a large hydrolytic reactivity of **1** in both acid and base (1, 2). Amide **2**, in which the geometry allows more conjugation of the N-C=O system (3), is similarly prone to accelerated hydrolysis. Moreover, **2** shows a remarkable activation toward attack by bifunctional nucleophiles such as β-aminoalcohols (3–5) and diacids capable of forming cyclic anhydrides (6, 7) in a way that is reminiscent of the serine proteases and aspartate proteinases respectively.

To probe more completely the manner in which amide hydrolytic reactivity can be influenced by distortion within the anilide series, we have synthesized **3**. Herein we report the synthetic procedure as well as the hydrolytic profile and details of the crystal structure.

Experimental

(a) Synthesis

The synthesis of 3,4-dihydro-2-oxo-1,4-propanoquinoline (**3**) was accomplished according to the route outlined in Scheme 1 starting with the known keto *N*-tosylate **5** (8).

*5-(Ethoxycarbonylmethyl)-5-hydroxy-*N*-tosyl-2,3,4,5-tetrahydrobenzazepine (**6**)*

To a 500-mL 3-necked flask equipped with a 250-mL dropping funnel (charged with 16.6 g (0.053 mol) of 5-oxo-*N*-tosylbenzazepine (**5**, (8)), 6.45 mL (0.058 mol, d = 1.506) of ethyl-α-bromoacetate, and 210 mL of dry benzene), a reflux condenser, and magnetic stir bar, was added 4.56 g (0.070 mol) of zinc powder and 210 mL of dry ether. The contents of the dropping funnel were added dropwise to the stirred Zn suspension, after which time the mixture was heated at reflux overnight under an Ar atmosphere. By morning a white suspension had formed and the mixture was cooled (ice bath) and treated with 210 mL of 10% H_2SO_4. The phases were separated and the organic phase washed with 5 × 140 mL of 10% H_2SO_4, the combined extracts being saved. The organic layer was then extracted with 5 × 100 mL of 5% KOH and 5 × 100 mL of saturated NaCl, and subsequently dried ($MgSO_4$), filtered,

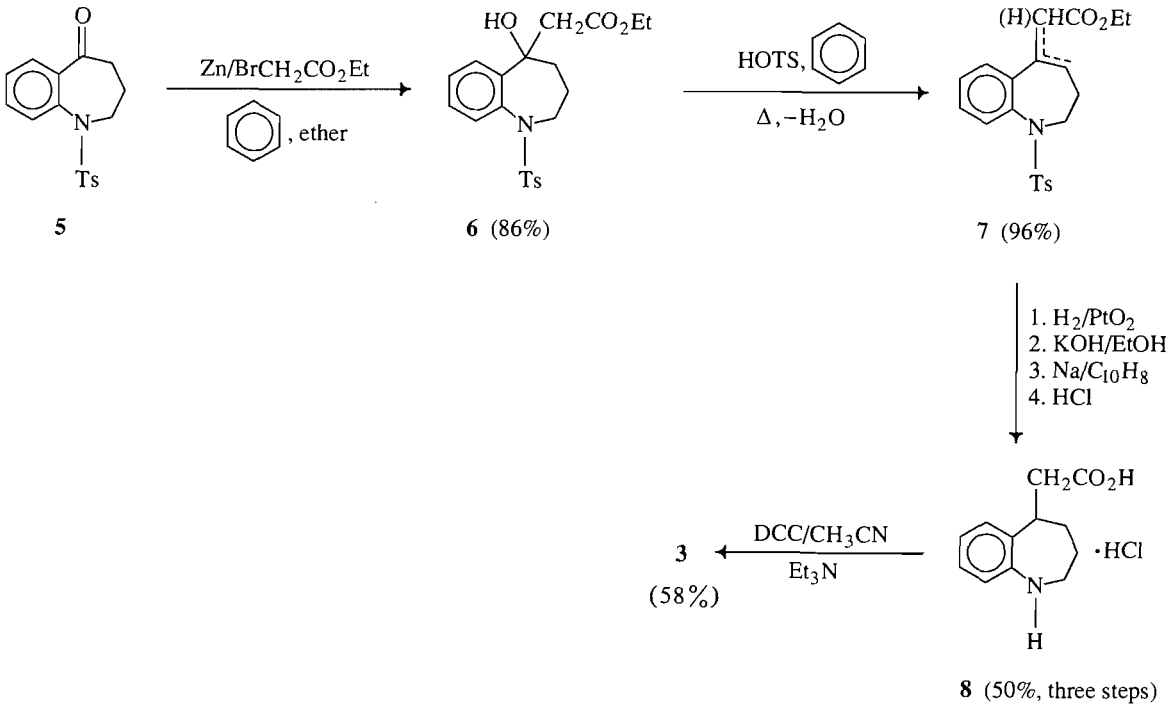

SCHEME 1

and stripped of volatiles to give crude **6**. The combined acid extracts were reextracted with 3 × 100 mL of $CHCl_3$, these extracts being combined, dried ($MgSO_4$), filtered, and stripped of volatiles. The crude product thus obtained was combined with that above, and recrystallized from 95% EtOH to yield 18.3 g (86.3%) of pure **6**, mp 149.0–150.0°C; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.80 (2H, m), 6.9–7.35 (6H, m), 4.08 (4H, q, J = 7 Hz), 3.15 (2H, s), 2.90 (1H, br t), 2.45 (3H, s), 2.15 (2H, br), 1.80 (2H, br t), 1.20 (3H, t, J = 7 Hz). Exact mass calcd. for $C_{21}H_{25}NO_5S$: 403.1453; found: 403.1445. Anal. calcd. for $C_{21}H_{25}NO_5S$: C 62.51, H 6.25, N 3.47; found: C 62.24, H 6.44, N 3.44.

*(5-Ethoxycarbonylmethyl)-2,3-dihydro-*N*-tosylbenzazepine and (5-ethoxycarbonylmethylidene)-2,3,4,5-tetrahydro-*N*-tosylbenzazepine (7)*

Into a 500-mL round-bottom flask was placed 250 mL of benzene, 0.7 g of *p*-toluenesulfonic acid, and 36.0 g (0.0892 mol) of alcohol **6**. The mixture was heated at reflux for 16 h and 1.5 mL of H_2O was removed via a Dean–Stark apparatus. The benzene was extracted with 2 × 200 mL of saturated $NaHCO_3$ and 2 × 200 mL of H_2O, after which it was dried ($MgSO_4$), filtered, and the volatiles removed by rotary evaporation. The crude residue was recrystallized from 95% EtOH after it had been decolorized with charcoal to yield 33.0 g (96%) of 7 as a mixture of isomers, mp 126.5–128.5°C; ^{1}H NMR (200 MHz, $CDCl_3$) of the *exo* methylene derivative, δ: 7.6–7.4 (8H, m), 5.28 (1H, s), 4.06 (2H, q, J = 7 Hz), 3.77 (2H, t, J = 5 Hz), 2.75 (2H, br t), 2.35 (3H, s), 1.80 (2H, m), 1.28 (3H, t, J = 7 Hz); of the ethoxycarbonylmethyl isomer, δ: 7.64–7.12 (8H, m), 5.75 (1H, t, J = 6 Hz), 4.08 (2H, q, J = 7 Hz), 3.93 (2H, m), 2.78 (2H, s), 2.35 (3H, s), 2.20 (2H, m), 1.22 (3H, t, J = 7 Hz). Exact mass calcd. for $C_{21}H_{23}NO_4S$: 385.1348; found: 385.1351. Anal. calcd. for $C_{21}H_{23}NO_4S$: C 65.43, H 6.01, N 3.63; found: C 65.39, H 6.22, N 3.58.

(5-Ethoxycarbonylmethyl)-2,3,4,5-tetrahydrobenzazepine

This was made by catalytic hydrogenation (30 psi; 1 psi = 6.9 kPa) of 17.4 g (0.045 mol) of 7 in 150 mL THF containing 0.5 g of PtO_2. After 36 h, the mixture was filtered and the volatiles removed to yield 17.4 g (100%) of hydrogenated product, mp 97.5–98.5°C; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.65 (2H, m), 7.10 (6H, m), 4.05 (2H, q, J = 7 Hz), 3.2–3.0 (2H, br), 2.64 (2H, br), 2.34 (3H, s), 1.4–1.8 (4H, br m), 1.18 (3H, t, J = 7 Hz). Exact mass calcd. for $C_{21}H_{25}NO_4S$: 387.1504; found: 387.1504. Anal. calcd. for $C_{21}H_{25}NO_4S$: C 65.09, H 6.50, N 3.62; found: C 65.12, H 6.51, N 3.56.

2[5'(2,3,4,5-Tetrahydrobenzazepinyl)]acetic acid (8)

To a 100-mL round-bottom flask containing 16 mL of 20% KOH and 24 mL of 95% EtOH was added 3.614 g (9.33 mmol) of the hydrogenated ester (above). The contents were heated at reflux for 5 h, and then the mixture was poured into an ice–HCl mixture at pH 1. The mixture was then extracted with 3 × 50 mL of $CHCl_3$, and the combined extracts dried ($MgSO_4$), filtered, and the volatiles removed. The acid so obtained was not purified further, but taken immediately on to the next step. Removal of the *N*-tosyl protecting group was effected by a modification of a reported (9) procedure. Into a 500-mL 3-necked round-bottom flask equipped with serum stoppers, magnetic stirbar, and Ar inlet was placed the crude acid product from above, 10 mL of dry DME, and 720 mg (30 mmol) of NaH (prepared from 1.2 g of 60% NaH in oil, which was freed from the oil by washing with heptane).

In a separate 200-mL 3-necked round-bottom flask equipped with serum stoppers, magnetic stirbar, and Ar inlet was placed 16.8 g (0.13 mol) of naphthalene and 40 mL of dry DME. To this solution was added 2.7 g (0.12 mol) of Na^0, upon which the solution turned deep green. This was allowed to stir at room temperature for 15 min and then it was taken up via syringe, and injected into the first flask. As the $Na/C_{10}H_8$ solution was injected, the green colour immediately disappeared, and enough was then added so that the colour persisted. This resulting mixture was allowed to stir at room temperature overnight. In the morning, the DME was removed by rotary evaporation, and H_2O/benzene was added to the residue. The H_2O layer was extracted with 3 × 100 mL of benzene and then the pH of the aqueous layer was adjusted to 1 by addition of concentrated HCl. Solid Na_3PO_4 was added to adjust the pH to 5–6, and then the solution was extracted with 50 mL of EtOAc, followed by 2 × 25 mL of CH_2Cl_2. The organic layers were combined, dried ($MgSO_4$), filtered, and the volatiles removed to yield 1.5 g of crude product **8**. Purification was effected by dissolving this material in a small amount of 95% EtOH containing a few drops of concentrated HCl and then adding ether to turbidity. After refrigeration, a yellow crystalline material was removed by filtration. This was dissolved in H_2O, treated with charcoal to decolorize it, filtered, and the H_2O removed to give a solid. The solid was dissolved

again in the above EtOH/HCl solution and ether added to turbidity. Refrigeration yielded 1.1 g (50%) of the HCl salt of **8**, mp >200°C (dec.). ^{1}H NMR (200 MHz, DMSO-d_6) δ: 6.75 (1H, m), 6.30–6.40 (3H, m), 3.70 (1H, m), 3.50 (1H, m), 2.70–3.10 (3H, m), 2.55 (2H, m), 1.90–2.22 (3H, br m), 1.4–1.6 (1H, br). Exact mass calcd. for $C_{12}H_{15}NO_2$: 205.1103; found: 205.1099. Anal. calcd. for $C_{12}H_{15}NO_2 \cdot HCl$: C 59.63, H 6.67, N 5.79, Cl 14.67; found: C 59.53, H 6.66, N 5.76, Cl 14.76.

3,4-Dihydro-2-oxo-1,4-propanoquinoline (3)

To a 500-mL 3-necked round-bottom flask was added 220 mL of dry CH_3CN (distilled from P_2O_5), 1.0 g of the HCl salt of **8** (4.14 mmol), and 0.58 mL (d = 0.726, 4.17 mmol) of triethylamine. The mixture was stirred under a blanket of Ar until everything dissolved, and then 0.86 g (4.17 mmol) of dicyclohexylcarbodiimide in 4.2 mL of dry CH_3CN was added via syringe. The solution was periodically monitored by IR to observe the progress by the appearance of a 1711 cm^{-1} C=O bond. The mixture was allowed to stand overnight, filtered, and the volatiles removed by rotary evaporation. The solid residue was redissolved in dry benzene, filtered to remove traces of the dicyclohexyl urea, and evaporated to dryness with a vacuum pump. The solid so obtained was recrystallized from octane to give 0.45 g (58%) of **3**, which was filtered in a cold room (4°C); mp 36.0–37.0°C; IR ($CHCl_3$): 1711.50 cm^{-1}; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.15 (4H, m), 3.90 (1H, m), 3.15 (2H, m), 2.68 (2H, d, J = 2 Hz), 2.05 (1H, br), 1.3–1.7 (3H, m); ^{13}C NMR (40 MHz, $CDCl_3$) δ: 200.5, 129.7, 128.7, 127.8, 126.9, 125.4, 54.9, 44.6, 33.7, 28.4, 24.8. Exact mass calcd. for $C_{12}H_{13}NO$: 187.0997; found: 187.1001. Anal. calcd. for $C_{12}H_{13}NO$: C 76.98, N 7.48, H 7.00; found: C 76.62, N 7.37, H 6.99.

(b) Kinetics

Triply distilled water was used throughout. Kinetic data at 25°C were obtained by monitoring the rate of change of absorbance of 3×10^{-4} M aqueous solutions of **3** at the wavelength of maximum change (260 nm, pH <5; 280 nm, pH >5) with an HP8451A diode array UV–VIS spectrophotometer. Buffered solutions at four concentrations from 0.05 to 0.20 M were employed, μ = 1.0 KCl. The buffers used were HCl (pH ≤2); formate (3.0–4.0); acetate (4.0–5.0); MES (2-(*N*-morpholino)ethane sulfonic acid) (5.1–6.5); MOPS (3-*N*-(morpholino)propanesulfonic acid) (6.7–7.6); EPPS (*N*-(2-hydroxyethyl)-piperazine-*N'*-(3-propanesulfonic acid) (8.0–8.7); CHES (2-(*N*-cyclohexylamino)-ethanesulfonic acid) (9.0–9.8); CAPS (3-(cyclohexylamino)-1-propanesulfonic acid) (9.8–11.1); NaOH (>11). Slower reactions were initiated by injecting 10 μL of a stock solution of **3** (0.015 g (0.080 mmol) in 1.0 mL CH_3CN) into 3.0 mL of the buffer in a 10-cm quartz cuvette that had thermally equilibrated in the spectrophotometer cell holder for 30 min at 25.0 ± 0.2°C. All reactions were followed in triplicate and monitored for at least three half-lives. Pseudo-first-order rate constants were evaluated by non-linear least-squares fitting of the absorption vs. time data to a standard exponential model. Plots of k_{obsd} data vs. buffer concentration for a given pH were extrapolated back to zero buffer concentration in order to yield the k_{hyd} values given in the text. Primary data are given as Supplementary Material.[2]

Faster reactions (k_{obsd} > 0.1 s^{-1}) were obtained using a Durrum–Gibson 115 stopped-flow kinetics system thermostated at 25°C. Into one drive syringe was placed the main buffer solution, μ = 1.0 (KCl), while the second syringe contained a 2.7×10^{-4} M solution of **3** in 10 mL of 1 M KCl along with one drop of a MOPS buffer (0.05 M) to set the pH at the value corresponding to the slowest hydrolysis. Both solutions were thermostated at 25°C for 20 min, and then rapidly mixed. Four runs were made at each pH. pH measurements were made on the effluent from the mixing chamber and it is assumed that the pH was instantly equilibrated on mixing. When the pH was <2 or >12, $[H_3O^+]$ or $[OH^-]$ was determined by titration using bromothymol blue as the indicator. In general, pH measurements were made with a Radiometer TTT2 titration unit and Radiometer GK-2321C combination electrode. The electrode was standardized prior to use using Fisher Certified pH 4.00, 7.00, and 10.00 buffers.

TABLE 1. Experimental details of the crystal of **3**

$C_{12}H_{13}NO$
FW = 187.24
Crystal dimensions: 0.13 × 0.13 × 0.35 mm
Monoclinic space group $P2_1/c$
a = 6.686(4) Å
b = 10.508(4) Å
c = 28.397(9) Å
β = 102.80(5)°
V = 1945 Å^3
D_c = 1.278 g cm^{-3}
μ = 0.50 cm^{-1}

(c) Product analysis

Into a 3.0-mL sample of pH 7.93 CHES buffer was injected 20 μL of 20 mM **3** in CH_3CN. The UV spectrum (330–250 nm) was continuously scanned using a Cary 210 UV–VIS spectrophotometer. An isosbestic point at λ = 265 nm was observed during the run. At the completion of the kinetic event the spectrum indicated a λ_{max} of 278 nm (ε = 1015 M^{-1} cm^{-1}), which was superimposable upon the spectrum of a solution of authentic amino acid at the same concentration in a pH 7.93 CHES buffer.

(d) Crystal structure

Crystals were grown by dissolving **3** in a small amount of pentane, and placing the solution in a sealed disposable pipette in the freezer compartment of a refrigerator.

(i) Data collection

A clear, colorless crystal of $C_{12}H_{13}NO$, with the approximate dimensions of 0.13 × 0.13 × 0.35 mm, was mounted on a glass fiber with a thin coat of viscous oil, and placed in a stream of cold air. The crystal was cooled to roughly −80°C, and all measurements were made at this temperature. The crystal was optically centered in the X-ray beam of an Enraf–Nonius CAD4 automated diffractometer with graphite monochromator and Mo radiation (λ = 0.7107 Å).

The automatic peak search and reflection indexing programs[3] suggested a unit cell with monoclinic symmetry. The systematic absences of $h0l$, l odd and $0k0$, k odd and the magnitude of the unit cell volume led to the unique choice of space group as $P2_1/c$ (No. 14 (ref. 10)), with two independent molecules in the asymmetric unit. The cell constants and orientation matrix were obtained from a least-squares refinement of the setting angles of 25 reflections in the range 11.8 < θ < 19.9°. The unit cell parameters and other crystallographic information are given in Table 1.

The intensity data were collected with θ–2θ scans of fixed speed, 5.0° min^{-1} (in θ) for the low-angle shell (θ <20°) and 2.0° min^{-1} for the remaining data. The scan range was varied as a function of θ to compensate for α_1–α_2 wavelength dispersion: ω scan width = 0.800 + 0.347 tan θ. The backgrounds for the peaks were measured by extending the scan 25% on each side of the calculated range; this gave a peak-to-background counting time ratio of 2:1. Intensity measurements were made out to a maximum 2θ of 50°. One reflection was chosen as a standard reflection and was remeasured after every 120 min of exposure time to check on crystal and electronic stability over the course of data collection. There was no unusual variation in the intensities of this standard reflection. A total of 8277 reflections, (h, ±k, ±l), was collected and reduced to intensities.

[2]These data may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[3]The diffractometer programs are those supplied by Enraf–Nonius for operating the CAD4F diffractometer with some local modifications made by Dr. R. G. Ball.

(ii) Structure solution and refinement

All of the non-hydrogen atoms of the two molecules were evident in an electron density map calculated from a set of phases generated by the direct methods program MITHRIL (11). Adjustment[4] of atomic parameters was carried out by full-matrix least-squares refinement on F_o minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, where $|F_o|$ and $|F_c|$ are the observed and calculated structure factor amplitudes and the weight w is $4F_o^2/\sigma^2(F_o^2)$. The neutral atom scattering factors were calculated from the analytical expression for the scattering factor curves (12). The f' and f'' components of anomalous dispersion (13) were included in the calculations of all non-hydrogen atoms.

The hydrogen atoms were generated at idealized calculated positions by assuming a C—H bond length of 1.00 Å and the appropriate sp^2 or sp^3 geometry. These atoms were then included in the calculations with an isotropic U = 0.013 Å^2 and constrained to "ride" on the attached atom.

The refinement of the coordinates and isotropic U's for all non-hydrogen atoms was continued to convergence. At that stage the data were corrected for absorption using an empirical scheme based on the absorption surface (Fourier filtering) method of Walker and Stuart (14). The maximum and minimum correction factors applied to F_o were 1.4617 and 0.7850. After averaging over $2/m$ symmetry (R-merge on F is 0.148, high due to the dominance of weak intensities) and deleting the systematic absences, there were 3590 averaged observations, 1212 with $I > 3\sigma(I)$. The refinement was continued with use of anisotropic Gaussian displacement parameters for the non-hydrogen atoms. In the final cycle, 253 parameters were refined using the 1212 reflections with $I > 3\sigma(I)$, and the largest and average shift/error ratio was less than 0.01. As a result, the final goodness-of-fit was 1.66, and

$$R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.065$$

$$R_2 = (\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2)^{1/2} = 0.070$$

An analysis of R_2 in terms of F_o, $\sin\theta/\lambda$, and various combinations of (h, k, l) indicated no unusual trends. No substantial differences in the model were evident from a refinement with more of the intensity data; there were 1871 reflections with $I > \sigma(I)$, and the resultant goodness-of-fit was 1.52. Adjustment of the hydrogen atom coordinates with the other variables also indicated no substantial differences, resultant goodness-of-fit to 1.59. The highest peak in the final difference Fourier map has a density of 0.26(7) e Å^{-3}.[2,5] A listing of atomic coordinates and isotropic Gaussian parameters is given in Table 2.

[4]The computer programs used in this analysis include the Enraf–Nonius Structure Determination Package, Version 3 (1985, Delft, The Netherlands) adapted for a Sun Microsystems 3/160 computer, and several locally written programs by Dr. R. G. Ball.

Results and discussion

Amide **3** can be prepared in 24% purified yield in six steps (Scheme 1) from the known ketone **5** (8). The most notable spectroscopic feature of **3** is its C=O stretch appearing at 1711 cm^{-1}, which can be compared with values of 1755 cm^{-1} and 1705 cm^{-1} for **1** and **2** respectively (1).

(a) Molecular and crystal structure of 3

Similar views of the two independent molecules are given in Fig. 1a,b. Because it is the source of the enhanced hydrolytic reactivity, the distortion imposed by the bridged structure on the amidic N-C=O unit is the unique feature of interest in these molecules. The geometrical details of the amide section in each are not significantly different ($>3\sigma$) from those found for amide **2** (Tables 3–5).[2,5] The degree of pyramidalization at N and C(=O) is also similar for amides **2** and **3**. For amide **2**, the displacement of C1 from the NCO (N1—O1—C2) plane is 0.064 Å, and the displacement of N1 from the attached-carbon-atom (C1—C9—C12) plane is 0.436 Å. The corresponding values for amide **3** are 0.079 and 0.408 Å in molecule 1, and 0.048 and 0.430 Å in molecule 2. It is important to note that the environment around molecules 1 and 2 is substantially different. Very roughly, there are eight molecules in contact with molecule 1, but only six molecules in contact with molecule 2. This is somewhat evident from the stereoview of the unit cell projection shown in Fig. 2. One effect of this different packing

[5]A full summary of crystallographic information, the complete listings of anisotropic Gaussian displacement parameters for the non-hydrogen atoms, hydrogen atom coordinates, interatomic bond lengths, angles, and least-squares plane information, and a listing of structure factor amplitudes have been deposited as Supplementary Material. These data may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

The crystallographic data, hydrogen atom coordinates, and interatomic bond lengths and angles have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

TABLE 3. Table of selected bond lengths (Å)[a]

Molecule 1	Length	Molecule 2	Length	Average[b]	Amide **2**[c]
N1—C1	1.413 (10)	N2—C21	1.419 (11)	1.416	1.401 (2)

N1—C1—C2	116.9 (5)	N2—C21—C22	117.0 (7)	116.1 (1)
O1—C1—C2	122.9 (7)	O2—C21—C22	123.6 (8)	123.4 (2)

[a]Corresponding values determined for molecular structure of **2** (3).

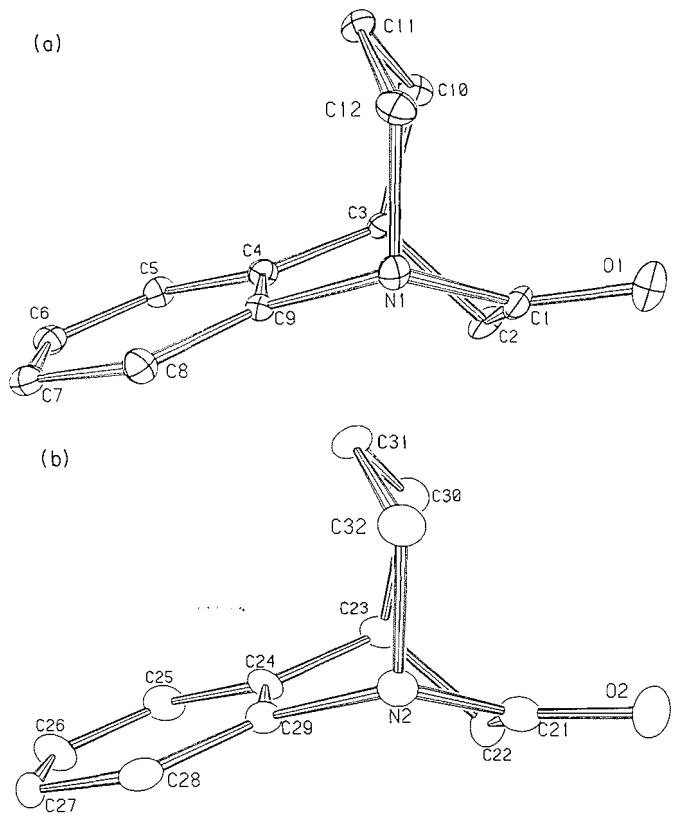

FIG. 1. Perspective view of (a) molecule 1 (atoms N1–C14) and (b) molecule 2 (atoms N2–C32) showing the labelling scheme. Atoms are represented as Gaussian ellipsoids at the 30% probability level.

arrangement is that the U_{eq}'s for the non-hydrogen atoms in molecule 1 are approximately 50% smaller than the corresponding values in molecule 2; the average U_{eq} of the 14 atoms is 0.025 Å^2 in molecule 1 and 0.038 Å^2 in molecule 2. Surprisingly, the conformations of the two molecules are not significantly different (*vide infra*), suggesting that the observed conformation in each represents a ground state configuration unperturbed by crystal packing forces.

TABLE 5. Table of torsional angles (degrees)

Atom 1	Atom 2	Atom 3	Atom 4	Angle (°)	Amide **2**[a]
C9	N1	C1	O1	−174.1 (6)	177.5 (2)
C29	N2	C21	O2	−169.7 (6)	
C9	N1	C1	C2	16.9 (8)	−11.5 (2)
C29	N2	C21	C22	17.0 (9)	
C12	N1	C1	O1	58.8 (8)	−59.7 (2)
C32	N2	C21	O2	65.4 (8)	
C12	N1	C1	C2	−110.3	111.3 (2)
C32	N2	C21	C22	−107.9 (7)	

[a]Corresponding values for amide **2** (3). Difference in sign arises from amide **2** being originally reported in the opposite absolute configuration to **3**.

We have previously described the distortion in amide **2** in terms of a twist angle (ϕ) and tilt angle (θ) of the N "lone pair" away from optimum conjugation with the C=O Π system (1, 3). For **2**, the N pair of electrons was located as a peak in the difference Fourier map lying ~1.2 Å away from the N in a position expected on geometric grounds. Using the centre of this electron density, the respective twist and tilt angles are ϕ = 30–35° and θ = 18° (3). In **3**, the corresponding peak cannot be located, so a geometric position for the N lone pair was assigned on the basis of a perpendicular drawn through N1 from the plane defined by C1, C9, and C12. On this basis, the twist and tilt angles (visualized in Fig. 3) are 35° and 15° respectively. With reference to the deformation of the amide group, we note that Winkler and Dunitz (15) have studied the distortions of amides in closed-ring systems. For **3**, the values of the bending and twisting coordinates are χ_C = 11.0°, χ_N = 52.8°, and τ' = 75.6°. Although the N-C=O units in **2** and **3** are nearly superimposable, there is a substantial difference in the disposition of the aromatic ring, evident from a comparison of the lone pair–N1—C9—C4 torsion angle in **3**, 27°, and the corresponding angle in **2**, −3°.

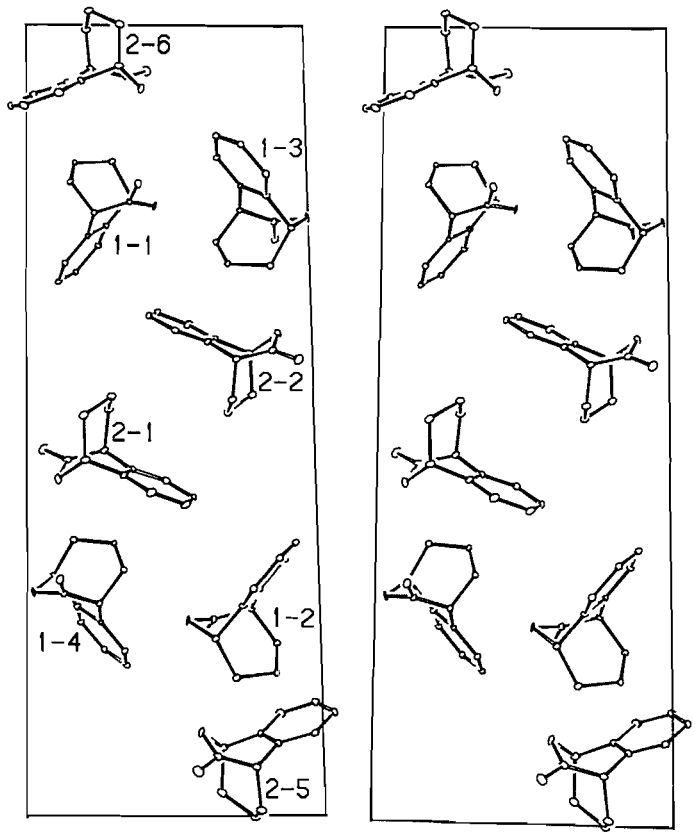

FIG. 2. Stereoview of the unit cell viewed up a with b to the left and c down the page. The labels identify the specific molecule, with the first digit indicating molecule 1 or 2, and the second digit indicating the symmetry operation (1–6). The symmetry operation, $\boldsymbol{Rx} + \boldsymbol{t}$, is described by use of a rotation matrix $\boldsymbol{R}$ and a translation matrix $\boldsymbol{t}$, and operates on the atomic coordinates $\boldsymbol{x}$. The specific symmetry operations are:

$$R_1 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \; t_1 = \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}; \quad R_2 = \begin{pmatrix} -1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & -1 \end{pmatrix}, \; t_2 = \begin{pmatrix} 0 \\ 1 \\ 1 \end{pmatrix}$$

$$R_3 = \begin{pmatrix} -1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1 \end{pmatrix}, \; t_3 = \begin{pmatrix} 0 \\ \frac{1}{2} \\ \frac{1}{2} \end{pmatrix}; \quad R_4 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \; t_4 = \begin{pmatrix} 0 \\ \frac{1}{2} \\ \frac{1}{2} \end{pmatrix}$$

$$R_5 = \begin{pmatrix} -1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1 \end{pmatrix}, \; t_5 = \begin{pmatrix} 0 \\ \frac{1}{2} \\ \frac{3}{2} \end{pmatrix}; \quad R_6 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \; t_6 = \begin{pmatrix} 0 \\ \frac{1}{2} \\ -\frac{1}{2} \end{pmatrix}$$

(b) Kinetics of hydrolysis

Given in Table 6 are the pseudo-first-order rate constants (k_{hyd}) for hydrolysis of **3** at 25°C, μ = 1.0 (KCl), extrapolated to zero buffer concentration. Given as Supplementary Material[2] are the primary kinetic constants for each buffer concentration. The pH/rate profile given in Fig. 4 shows three domains: one first order in $[OH^-]$, and a second, first order in $[H_3O^+]$, which gives way at low pH to a pH-independent domain. The appearance of the profile is consistent with the mechanism given in eq. [1] from

$$[1] \quad \mathrm{P} \underset{H_2O}{\overset{k_{H_3O^+}}{\longleftarrow}} \mathbf{3}\text{-}H^+ \overset{K_a}{\rightleftharpoons} H_3O^+ + \mathbf{3} \xrightarrow{k_{OH^-}[OH^-]}$$

for which can be derived the kinetic expression in eq. [2].

$$[2] \quad k_{hyd} = k_{H_3O^+}[H_3O^+]/(K_a + [H_3O^+]) + k_{OH^-}K_w/[H_3O^+]$$

Non-linear least-squares (NLLSQ) fitting of the k_{hyd} and

$[H_3O^+]$ data of Table 5 to eq. [2] yields values of $k_{H_3O^+}$ = 8.26 (1.7) s^{-1}, k_{OH^-} = 17.2 (1.7) M^{-1} s^{-1}, and K_a = 0.28 (0.07) (pK_a = 0.56), assuming $K_w = 10^{-14}$: the line drawn through the data points in Fig. 4 is that computed on the basis of the NLLSQ fit. Also given in Fig. 4 are the hydrolytic profiles for amides **1** and **2** (1).

The kinetic profile for **3** invites comparison with those for **1** and **2**. The base domains for **1–3** show a striking similarity, which suggests that in this region, **3**, like **1** and **2** (1), suffers rate-limiting irreversible attack of OH^-. Normal acetanilides (16), trifluoromethyl acetanilides (17, 18), and formanilides (19) show base domains for log k_{hyd} vs. pH of slopes 1, >1, and 1 in passing from low to high pH. This is analyzable in terms of eqs. [3] and [4] where the intermediate (Tl^-), in competition

[3] $$OH^- + R{-}\overset{\overset{O}{\|}}{C}NRAr \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} R{-}\overset{\overset{O^-}{|}}{\underset{\underset{OH}{|}}{C}}{-}NRAr \quad (Tl^-)$$

$$\xrightarrow[k_3'[OH]]{k_2} P$$

[4] $$k_{hyd} + k_1[OH^-](k_2 + k_3[OH^-])/(k_{-1} + k_2 + k_3[OH^-])$$

with reversion to starting materials or uncatalyzed breakdown to product, can be intercepted by a second OH^- and driven forward. The inherent distortion in anilides **1–3** obviously facilitates the forward pathway since the corresponding Tl^-, once formed, has little tendency to reverse because amidic resonance (which accelerates k_{-1} in the normal anilides (16–19) is substantially eliminated in **1–3**.

By way of comparison, the values of the second-order rate constants for OH^- attack on **1**, **2**, and **3** are 262 (1), 60 (1), and 17.2 M^{-1} s^{-1} respectively at 25°C while the apparent ones for acetanilide (0.957 M, NaOH) and *N*-methylacetanilide (0.89 M NaOH) are 7.55 × 10^{-6} M^{-1} s^{-1} (16)[6] and 1.5 × 10^{-5} M^{-1} s^{-1} respectively. Although the structure of **1** is unknown, its amide unit must certainly be more strained (with respect to orthogonality of the N: and C=O Π system arising from rotation around the C—N bond) than those of **2** (3) and **3** (*vide infra*). On the surface, it would be anticipated that the attack rate constant would be related to the carbonyl electrophilicity, which by these simple geometric arguments is anticipated to be **1** > **2** ≈ **3**. Surprisingly, the rate constant differences for OH^- attack are small (16:4:1 respectively), suggesting that beyond a certain point, rotation about the O=C—N bond produces little additional kinetic benefit. We note that each of **1–3** has an additional nearly equivalent distortion, namely that of N pyramidalization, which has also been shown to accelerate dramatically nucleophilic OH^- attack (20). Perhaps that distortion dominates the kinetics in this series, but in the absence of activation parameter studies with **1–3** (currently in progress), little additional comment on the relationship between OH^- attack and twisting can be offered at this time.

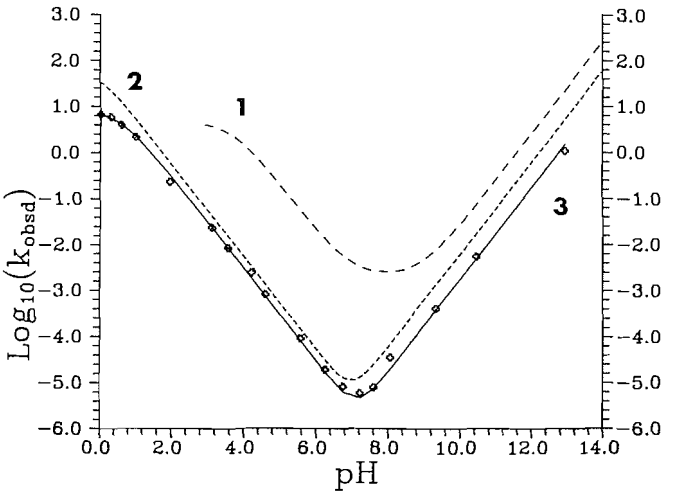

FIG. 4. A plot of log k_{hyd} vs. pH for the hydrolysis of amide **3**, T = 25°C, μ = 1.0 (KCl); line through the data points calculated on the basis of eq. [2]; kinetic profiles for amide **1** (———) and **2** (- - -) (1). Data for **2** from pH 0–2 determined in present study.

The observation of kinetic pK_a values of 3.7 (1) for **1** and 0.6 for **3** prompted a reinvestigation of the hydrolysis kinetics for **2** at low pH. We had originally failed to detect the onset of plateauing for **2**, but the structural similarity to **3** suggested that both might hydrolyze by common mechanisms. Indeed, as shown in Fig. 4 the new data[7] from pH 0–2 give evidence of plateauing for **2** and NLLSQ fitting provides a K_a of 1.8 (pK_a −0.28 ± 0.03) and $k_{H_3O^+}$ of 101 ± 7 s^{-1}. These latter values are considered as less accurate than the corresponding ones for **1** and **3** since at the lowest pH (0) attainable,[7] substantially less than half of the material is protonated.

The distinction between N- and O-protonation sites can be made by comparison of the kinetic pK_a's of **1–3** with those for normal amides. Typical amides have N-H^+ and O-H^+ pK_a values of −6 to −8 (21) and 0 to −2 (21*b–e*) respectively. In **1**, and to a lesser extent **2** and **3**, favorable resonance effects that stabilize the O-protonation of amides are precluded. Thus, the N and C=O in **1** should tend to behave independently, as amino and ketonic units, but exert mutual inductive effects that destabilize the other's protonated form. Thus, the pK_a of the C=O—H^+ unit in **1** is anticipated to be even lower than that of a ketone (normally −7 to −5 for acetone, cyclohexanone, etc. (21*d*)) so that the observed kinetic pK_a must be attributable to the N-H^+ form. By way of comparison, the pK_a of 3.7 for the conjugate acid of **1** (1) is ~4 units lower than the pK_a of benzoquinuclidine (7.79 (22)), in line with the inductive destabilization of N-H^+ by an adjacent orthogonal C=O.

As pointed out above, the structures of **2** and **3** do not completely inhibit N-C=O delocalization, and this leads to a drop in the N-H^+ pK_a relative to **1**. Correspondingly, the N-C=OH^+ forms of **2**, **3** are more stable than O-protonated **1**,

[6]It is known that acetanilide exhibits a large amount of ^{18}O-exchange concurrent with its hydrolysis in base and that reversal of Tl^- tends to slow the hydrolysis markedly. The second-order rate constants quoted above are termed apparent ones because in the NaOH concentration range used (16), the kinetics contain terms second order in [NaOH]. From a graphical analysis of the exchange/hydrolysis ratios vs. $[OH^-]$ values quoted in ref. 16 it can be shown that k_2/k_{-1} = 0.047; k_3/k_{-1} = 0.097. On this basis, one can calculate that for acetanilide at 25°C, the true rate constant for OH^- attack, namely, $k_1 = (1.3 \pm 0.2) \times 10^{-4}$ M^{-1} s^{-1}.

[7]k_{hyd}(pH) data for **2** at T = 25°C, μ = 1.0 KCl in units of s^{-1}: 0.59 ± 0.1 (1.95); 5.78 ± 0.04 (1); 14.50 ± 0.18 (0.60); 26.15 ± 0.22 (0.30); 42.8 ± 1.1 (0.01). These data were fit to a standard titration model to yield the values quoted in the text. Unfortunately, $[H_3O^+]$ in excess of 1 M was not accessible due to the timescale of the reaction and problems in stopped-flow mixing of solutions of widely different ionic strengths.

but they cannot be as stable as that of a normal amide where full delocalization is permitted. Thus we are forced to conclude that the observed kinetic pK_a values of -0.3 (**2**) and 0.6 (**3**) are most consistent with the N-H^+ forms. It must be pointed out that the kinetics do not provide information as to which of the N-H^+ or O-H^+ forms is attacked by H_2O although we favor the former. Thus although the N-H^+ form is arguably the most thermodynamically stable, it could be kinetically less reactive toward nucleophilic attack than the O-H^+ form. In that event, the N-H^+ form would be not considered to be on the reaction pathway.

Conclusions

The strained amides **1–3** hydrolyze rapidly in both acid and base. X-ray crystallographic structural comparison can be made between **2** and **3**, and the amidic unit in each is structurally similar with respect to bond lengths and angles. In both cases, the N is essentially sp^3 hybridized with the N "lone pair" being twisted some 30–35° out of optimum alignment with the C=O Π system.

Observations on cation-binding characteristics and nuclear magnetic resonance spectra of the *N*-carboxymethyl and *N*-acetyl analogs of heparin

RABINDRA N. REJ, KEVIN R. HOLME, AND ARTHUR S. PERLIN
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2A7

Received March 30, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

RABINDRA N. REJ, KEVIN R. HOLME, and ARTHUR S. PERLIN. Can. J. Chem. **68**, 1740 (1990).

Based on the observed paramagnetic relaxation effects of Cu^{2+} and Fe^{3+} ions and the chemical shift displacements induced by Ca^{2+} ions, nuclear resonance spectroscopy has been used to compare cation-binding characteristics of heparin with those of its *N*-carboxymethyl and *N*-acetyl analogs and related polyanions. Heparin is unique in exhibiting a high affinity for all three cations. Among the other polymers, binding selectivities differ notably. Such factors as the incidence and distribution of anionic charges are discussed. The preparation of the *N*-carboxymethyl analog of heparin is described, and ^1H and ^{13}C nuclear magnetic resonance spectroscopic data are reported for it, as well as for the *N*-acetyl analog.

Key words: heparin, *N*-carboxymethyl analog, *N*-acetyl analog, cation binding, ion-selectivity, anionic charge distribution.

RABINDRA N. REJ, KEVIN R. HOLME et ARTHUR S. PERLIN. Can. J. Chem. **68**, 1740 (1990).

En se basant sur les effets de relaxation paramagnétique observés pour les ions Cu^{2+} et Fe^{3+} ainsi que les variations des déplacements chimiques induite par les ions Ca^{2+}, on a utilisé la résonance magnétique nucléaire pour comparer les caractéristiques de capture de cation de l'héparine avec celles de ses analogues *N*-carboxyméthyle et *N*-acyle et celles des polyanions apparentés. L'héparine est le seul produit à présenter une grande affinité pour les trois cations. Parmi les autres polymères, les sélectivités de capture diffèrent beaucoup. On discute de fracteurs comme l'incidence et la distribution des charges anioniques. On décrit la préparation de l'analogue *N*-carboxyméthyle de l'héparine et on rapporte des données relatives à ses spectres de résonance magnétique nucléaire du ^1H et du ^{18}C ainsi qu'à ceux de son analogue *N*-acétylé.

Mots clés : héparine, analogue *N*-carboxyméthyle, analogue *N*-acétyle, affinité pour les cations, sélectivité ionique, distribution des charges ioniques.

[Traduit par la revue]

Introduction

The binding of cations by heparin, which has been studied extensively (1, 2) in relation to its clinical importance as a blood anticoagulant, is attributable to the polymer's strongly anionic character, as represented in the major disaccharide repeating unit (**1**→**2**) shown. Not only are there marked differences among cations (3–10) in their affinity for heparin, depending upon such factors as the valence of the cation and (or) its ionic radius, but also in their specificity for modified forms of the polymer (11–15) that contain fewer negative charges and differing distributions of those residual charges.

Recently, we reported (16) that the binding of cupric ion (Cu^{2+}) by heparin is detectable by nmr spectroscopy through highly sensitive paramagnetic relaxation effects. The effects on ^1H and ^{13}C nuclei were observed even when the proportion of the cation was several orders of magnitude lower than that of the polymer. By contrast, no comparable interaction was detected between Cu^{2+} and a variety of other anionic polymers, including the chondroitin sulfates and several modified forms of heparin. As these non-binding substances contain fewer anionic charges than does heparin, total charge density is likely to be a highly important factor. Nevertheless, a single exception was encountered. That is, the 2-acetamido-2-deoxy (*N*-acetyl) analog of heparin (**1**→**3**), which also is less strongly anionic, does respond to the paramagnetic relaxation influence of Cu^{2+} ion. This appeared to be consistent with an earlier suggestion (14) that although an overall high charge density may be necessary for binding, the geometric arrangement of the anionic groups is critical as well.

Results and discussion

The N-*carboxymethyl analog of heparin*

In this context, we have prepared the *N*-carboxymethyl analog (**1**→**4**) of heparin, which, to our knowledge, has not previously been described.[1] In addition to having the three anionic groups that the *N*-acetyl derivative contains, this derivative carries a total of four negative charges per disaccharide unit, as does heparin itself, and, at least superficially, the spatial distribution of the anionic groups is similar in both polymers. The *N*-carboxymethyl substituent of **4** was introduced by the reaction of selectively *N*-desulfated heparin (**1**→**5**) with bromoacetic acid in aqueous sodium carbonate, conditions analogous to those conventionally used for selective *N*-sulfation of residues of **5**. The ^1H nmr spectrum (Fig. 1C), following two successive treatments with bromoacetic acid, indicated that >80% of *N*-substitution had occurred, and had not been accompanied by other detectable modifications. That is, there is a major H-2 signal (δ 2.70) attributable to the *N*-carboxymethylated residue (**4**), although the minor peak at δ ~3.0 suggests that a small proportion of amine **5** remained unsubstituted. A high level of conversion into **4** was confirmed by the ^{13}C spectrum of the new polymer, which is composed essentially of the 14 resonances expected (Table 1). It is noteworthy that both the ^1H-1 and ^{13}C-1 resonances of residue **4** are well upfield of the corresponding signals in heparin, whereas ^1H-2 and ^{13}C-2 are, respectively, upfield and downfield (δ 2.7 vs. δ 3.3, and δ 63.3 vs. δ 60.0).

To test for the effect of Cu^{2+} on the *N*-carboxymethyl derivative, the solution of the derivative was adjusted to pD ~5.8, at which heparin has been found (16) to respond to the paramagnetic effect of the cation more strongly than at neutrality. This change in pD, in the absence of the metal ion, caused (Fig. 1B) several resonances of the aminohexose residue (**4**) to be displaced downfield relative to those in Fig. 1C, most strikingly A-1, A-2, and the methylene doublets of the carboxymethyl

[1]As determined by assays of anti-XA potency, neither this polymer nor the *N*-acetyl analog of heparin exhibits significant anticoagulant activity.

[b]Data from ref. 27.

[c]Data in parentheses are for the corresponding 2-sulfamino analog (**6**→**2**), from ref. 19.

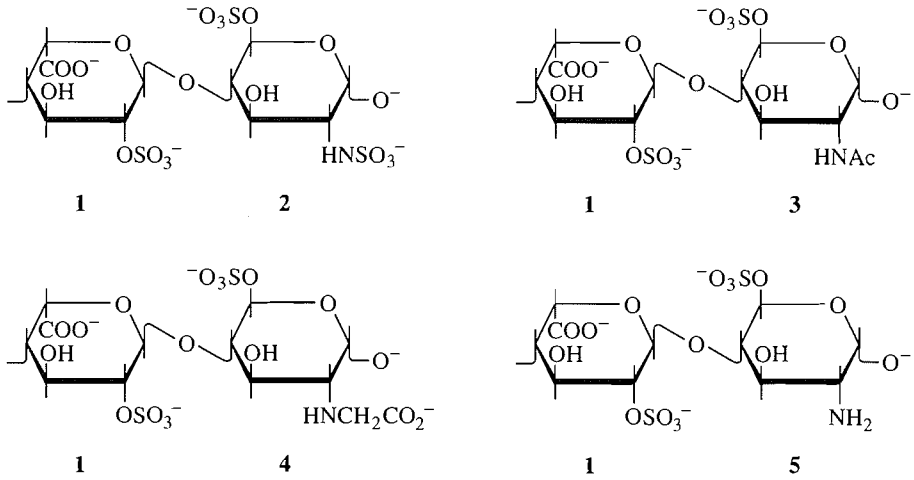
group. By comparing these spectra and the accompanying spectrum of heparin itself (Fig. 1A), the signals (I-1 and I-5) for H-1 and H-5 of the uronic acid residue (**1**) are found to remain largely unaffected throughout, which suggests that this conformationally unstable (2, 17) type of residue is not appreciably altered by the changes to the aminodeoxyhexose residues (**2** and **4**). The I-1 and I-5 nuclei of **1** are of particular concern in copper binding because, in the ^{1}H nmr spectrum of heparin, their resonances undergo (16) the most marked broadening in the presence of Cu^{2+} (as also do the signals for ^{13}C-1, ^{13}C-5, and ^{13}COOH). However, the introduction of Cu^{2+} (10^{-3} moles/disaccharide unit) into the solution represented by Fig. 1B caused essentially no change, and this evidence of unreactivity persisted when the cation level was increased threefold.

Hence, despite the high charge density of the *N*-carboxymethyl derivative, and its (seemingly) closer structural resemblance to heparin than all of the other polymers tested, it showed no paramagnetic response to Cu^{2+} analogous to that exhibited by heparin and its *N*-acetyl analog. The possible influence of varying the pD of the measurements, so as to allow for pK_a differences between this polyanion and heparin, was not examined, nor was the possibility that binding may occur when the proportion of Cu^{2+} is *equal* to that of the polymer (or higher), i.e., conditions that others (5, 18) have described in detail for heparin itself.

Many studies already mentioned, including some of our own, have dealt with characteristics of complex formation between heparin and calcium ion (Ca^{2+}). Consequently, the *N*-carboxymethyl derivative was tested with this cation as well, under conditions similar to those used previously (13, 14, 16) with the parent polymer. In this instance, evidence for the binding of Ca^{2+} is given by the ^{1}H nmr spectrum in Fig. 1D, which shows the changes occurring relative to Fig. 1C, following the introduction of 2 moles of Ca^{2+} per mole of disaccharide. The displacements in chemical shift for resonances A-1, I-1, and I-5, respectively, attributable to the binding of the cation, are compared in Table 2 with values of the corresponding resonances of heparin. There also is a large downfield displacement of the doublet of one of the diastereotopic methylene protons by 21 Hz. It is worth noting that although the *N*-carboxymethyl derivative interacts with Ca^{2+}, which leads to ^{1}H chemical shift displacements not unlike those (13, 14) exhibited by heparin, the amino derivative (**1** plus **5**) from which it was derived is incapable of binding either Ca^{2+} or Cu^{2+}.

The N*-carboxymethyl analog of modified heparin* (**6**→**2**)

A second *N*-carboxymethyl derivative based on heparin was prepared from a recently described (19) modified form of the polymer, represented by the disaccharide sequence, **6**→**2**. This material was obtained from heparin by a selective base-catalysed displacement of the 2-*O*-sulfo group of its L-iduronic acid residue (**1**). In the absence of this sulfate group, the anomeric proton of **6** resonates ~0.2 ppm upfield of that of **1** (see Fig. 2A). By selective hydrolysis of the *N*-sulfo group of the pyridinium salt of the polymer in 19:1 dimethyl sulfoxide/water, the procedure (20) employed to generate residue **5** (above), the corresponding amine derivative (**6**→**5**) was prepared, and analogously converted into the *N*-carboxymethyl derivative (**6**→**4**). That the latter was of relatively high purity was evident from the structural homogeneity implicit in its ^{1}H nmr spectra at pD 5.8 and 7.0, respectively (Figs. 2B and 2C), as well as the fact that its ^{13}C spectrum consisted essentially of the 14 resonances (Table 1) required by the formula shown.



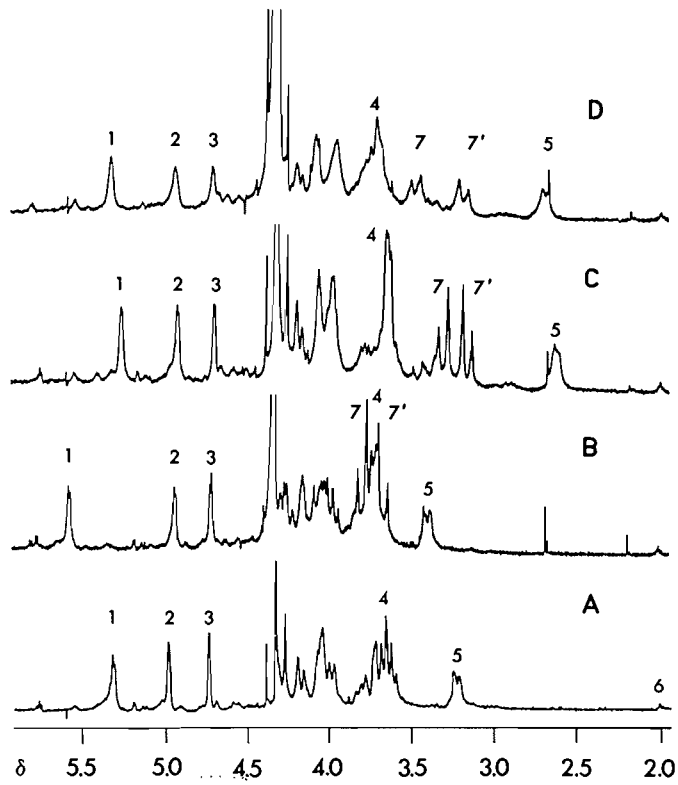


FIG. 2. The ^{1}H nmr spectra (300 MHz; 65°C) of (A) modified heparin (**6**→**2**, sodium salt) in D_2O; (C) the *N*-carboxymethyl analog (**6**→**4**, sodium salt) in D_2O; (B) solution in (C) adjusted to pD ~5.8; (D) solution in (C) following the introduction of 2 moles of Ca^{2+} per mole (541) of disaccharide. Signal designations: 1, 4, and 5 are for H-1, H-3 and (or) H-4, and H-2, respectively, of both residues **2** and **4**; 2 and 3 are for H-1 and H-5, respectively, of residue **6**; 7 and 7′ are for the methylene (CH_2) protons of residue **4**.

[b]At 65°C.
[c]The values in parentheses are those obtained (16) for heparin under comparable conditions.
[d]The values in parentheses are those obtained (16) for the corresponding 2-sulfamino analog (**6**→**2**).

A close correspondence in the chemical shifts of protons 1–4 and CH_2 of residue 4, in this *N*-carboxymethyl derivative and that of heparin, is seen by comparing Figs. 2B and 2C with Figs. 1B and 1C, including the marked downfield displacements of the H-1, H-2, and CH_2 signals of residue 4 that accompanied the drop in pD. Data for the ^{13}C spectrum are listed in Table 1.

As polymer **6**→**2** does not bind Cu^{2+} (16), perhaps it is not surprising that this *N*-carboxymethyl derivative was also found to be unreactive towards Cu^{2+} at pD 5.8. That is, in the presence of the cation its spectrum was virtually indistinguishable from that in Fig. 2B. It proved to be highly sensitive, however, to Ca^{2+} (at pD 7.0), as shown in Fig. 2D from the occurrence of major alterations with respect to the spectrum in Fig. 2C; the most substantial displacement (Table 2) was the downfield shift by 50 Hz of the methylene doublet at δ 3.3. Nevertheless, the influence of the cation appears to be more selective for the *N*-carboxymethyl aminodeoxyhexose than the uronic acid residue, whereas the data for heparin (13, 14) and its *N*-carboxymethyl analog correspond to a relatively greater impact by Ca^{2+} on their L-iduronic acid 2-sulfate residues. The 2-*O*-sulfo substituent cannot account solely for the differences in signal displacement, because the modified heparin precursor (**6**→**2**) lacking this substituent shows Ca^{2+}-binding nmr characteristics (see Table 2) similar to that of heparin itself. Hence, it is apparent that a simple replacement of one anionic function (SO_3^-) on the amino group by another (CH_2COO^-), although maintaining a total negative charge of three, cannot ensure a retention of metal-binding characteristics.

The 2-acetamido-N-acetyl) analog of heparin

As already mentioned, and now supplemented by the *N*-carboxymethyl examples just described, the only glycosami-

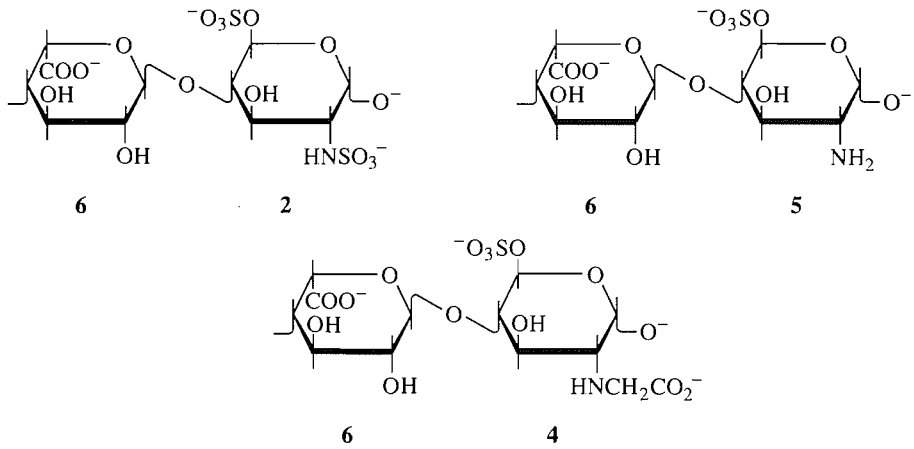

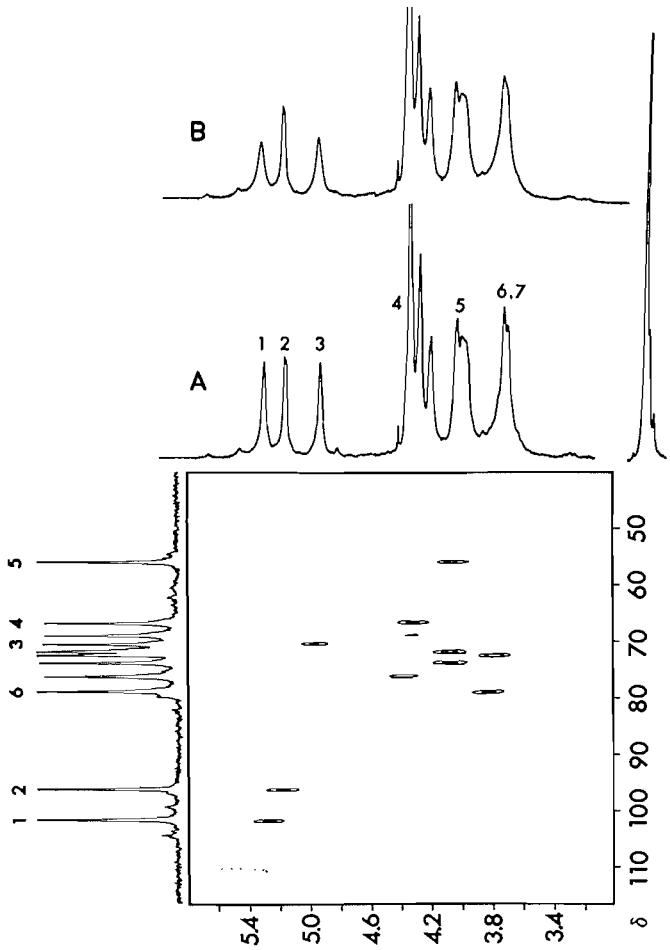

FIG. 3. (A) The ^1H and ^{13}C nmr heterocorrelation spectrum (300/75 MHz) of the *N*-acetyl analog (**1**→**3**, sodium salt) in D_2O; although the correlation data were obtained at 25°C, the ^1H spectrum shown was actually recorded at 65°C. Signal designations: 1 and 3 are for H-1 and H-5, respectively, of residue **1**; 2, 4, 5, 6, and 7 are for H-1, H-6, 6′, H-2, H-3, and H-4, respectively, of residue **3**; (B) the ^1H nmr spectrum (300 MHz; 65°C) of the *N*-acetyl analog (**1**→**3**) in D_2O (pD ~5.8) following the introduction of 1×10^{-3} moles of Cu^{2+} per mole (605) of disaccharide.

noglycan-type polymer that we have found (16), similar to heparin in its ability to bind Cu^{2+}, is the *N*-acetyl derivative (**1**→**3**). In the present study, nmr spectra of this derivative have been examined in greater detail than previously, and are more fully described. Also, the strong paramagnetic effect of Cu^{2+} on

[c]Data from ref. 16, for solutions 0.8 M with respect to NaCl.

spin-lattice relaxation times is now illustrated (Fig. 3), and described quantitatively by the data in Table 3. By analogy with the response of heparin to the cation, the T_1 values for resonances I-1 and I-5 of the uronic acid residue (**1**) (Fig. 3A) are notably broadened in the presence of the cation (Fig. 3B), whereas the other signals are less strongly perturbed. These differences are a reflection of the fact that the T_1 values for I-1 and I-5 are reduced by a value of ~4, whereas those of A-1 and A-2 of the aminodeoxyhexose residue (**3**) are affected to a lesser extent, i.e., by a factor of 2–3 (Table 3).

In marked contrast to this rare capacity it shares with heparin in binding Cu^{2+}, the *N*-acetyl derivative does not (11) form a complex with Ca^{2+}, despite the fact that most other modified forms of heparin bind that cation to a greater or lesser extent. Hence, the *N*-acetyl analog possesses a unique combination of characteristics, which further emphasizes the wide range of selectivities found among the interactions of anionic polymers with cations.

Although we previously described (13) a preparation of the *N*-acetyl derivative, that particular material has been found in the interim to have been incompletely *N*-acetylated. A newly synthesized specimen (see Experimental), which was used in the cation-binding tests, has the characteristics of a far more fully *N*-substituted derivative. This follows from its ^1H and ^{13}C spectra, shown in Fig. 3A together with the corresponding ^{13}C–^1H correlation (HETCOR) spectrum; the ^1H signal assignments were confirmed by reference to a COSY version of the ^1H spectrum. One striking difference between the present data and those reported earlier is the location of the A-2 signal for residue **3**. Here it is far downfield of its location in the spectrum (13) of the incompletely *N*-acetylated sample, its chemical shift (δ 3.95) being close to that (δ 3.92) reported (21, 22) for the A-2 signal of residues of **3** in the spectra of hog mucosal heparin. It is

Heparin (**6**→**4**)	–	+	[b]

[a]Weak response.
[b]Not tested.

noteworthy that the chemical shift (δ 5.1) of the anomeric proton (A-1) of the *N*-acetyl analog shows it to be more strongly shielded than is that of the aminodeoxyhexose residue of all other heparin-derived polymers of which we are aware. Also unaccounted for is the fact that in the ^{13}C spectrum (Fig. 3A) the I-4 signal for residue **1** of the *N*-acetyl analog is substantially upfield from that of ^{13}C nucleus I-4 in heparin, i.e., δ 74.0 as compared with δ 78.2, respectively. Contributing factors may be the magnetic anisotropy of the *N*-acetyl group and orientational differences about the glycosidic bonds. As to the latter possibility, however, infrared spectroscopic data (23) emphasize a similarity, rather than a difference, between conformational states of the two polymers.

Paramagnetic effect of ferric ion on the nmr spectra of heparin and its analogs

In addition to Cu^{2+} (16) and Gd^{3+} (24), other metal ions may be utilized (25) as paramagnetic probes. Among these is ferric ion (Fe^{3+}), which has now been tested for effects that it may have on the nmr spectra of heparin and derivatives. At the very low metal/polymer ratio used with Cu^{2+}, it was found (Fig. 4) that Fe^{3+} makes an equally marked impact on the relaxation characteristics of the L-iduronic acid residue (**1**) of heparin, as shown by the pronounced line-broadening of its I-1 and I-5 signals (Fig. 4A). The *N*-acetyl analog is affected to a lesser extent (Fig. 4B) and, in addition, its response is noticeably weaker than that observable (Fig. 3) in the binding of Cu^{2+}. Under comparable conditions, *N*-carboxymethyl heparin showed no interaction with Fe^{3+}. Hence, the degree of sensitivity of heparin towards the paramagnetic relaxation effects of transition metal ions appears to be uniquely high among the various glycosaminoglycan-type polymers examined.

Overall, for the group of polymers dealt with here, the variations in cation-binding selectivity are summarized in Table 4.

Summary

The current study supplements earlier observations designed to identify structural elements of the heparin molecule that determine its properties as a polyanion. Its high charge density readily accommodates strong interactions with a host of cations, including proteins. Many of these cations show little or no affinity for the other glycosaminoglycans and various modified forms of heparin, which contain fewer anionic groups per disaccharide unit than the four present in sequence **1** → **2**. Consistent with this comparison is the finding that whereas both the *N*-desulfated polymer (**1**→**5**), and that produced by acetylation of its amino group (**1**→**3**), do not interact with Ca^{2+}, binding does occur with the *N*-carboxymethyl analog (**1**→**4**), which represents the restoration of a *total* of four anionic groups. An appropriate spatial configuration of the negative charges must also be highly significant because polymer **6**→**2**, for example, formed by selective removal of the 2′-*O*-sulfo group of heparin, has the capacity to bind Ca^{2+} despite its reduced overall charge density. As this is also true for its *N*-carboxymethyl analog (**6**→**4**), prepared for comparison with that of heparin, it appears that the $N\text{-}SO_3^-$ and $N\text{-}CH_2COO^-$ functions are (qualitatively) interchangeable as anionic components when Ca^{2+} is the counterion.

Cupric ion does not elicit the same response, however, because heparin binds this cation whereas its *N*-carboxymethyl analog does not. That a fourth negative charge does not ensure binding is confirmed by the fact that the *N*-acetyl analog of heparin also binds Cu^{2+} — the only other polymer to do so under the experimental conditions used. It appears that if the total charge density is not the preponderant factor, neither is there an obvious relationship as to how the charges are distributed. That is, all three polymers contain the two anionic groups of the residue of L-iduronic acid 2-sulfate (**1**), *plus* that of the 6-sulfate group of the aminodeoxyhexose residue (**2**, **3**, or **4**), whereas only two of the polymers bind Cu^{2+}. Furthermore, the paramagnetic effects observed are largely confined to the uronide residues, which, based on their similar chemical shifts, appear to have analogous conformations. As noted for the *N*-acetyl analog, however, such parameters as the torsion angles of the various inter-residue linkages may differ significantly. This is suggested by the chemical shift data in Table 1, showing that the change from $N\text{-}SO_3^-$ to $N\text{-}CH_2CO_2^-$ (or $N\text{-}COCH_3$) has a greater impact on the shielding of ^{13}C nuclei of the neighbouring uronic acid residue **1** than those of **6** (i.e., compare the values for the I nuclei in column 1 with those in 2 (or 5), and 3 with 4).

Overall, many more of the polyelectrolytes in this series bind Ca^{2+} than Cu^{2+}. This suggests that the types of interaction are different. The binding of Ca^{2+} by heparin is a delocalized process (14), involving relatively long-range electrostatic interactions that are characterized by the counterion condensation model of Manning (26). Although this requires a charge density value that exceeds some substantial minimum value, it appears that the Ca^{2+} ion is able to accommodate a relatively broad

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

range of spatial dispositions among the anionic groups. By contrast, the restricted selectivity of Cu^{2+}, as well as its localized effects on relaxation, suggests that the interaction of this cation with a polyelectrolyte entails a more specific type of complex formation. The binding of Fe^{3+} by heparin may be categorized in the same way.

Experimental

Beef lung heparin was furnished by the Upjohn Company of Canada. Modified heparins **1→5** and **6→2** were available from earlier studies. Nuclear magnetic resonance spectra were recorded with a Varian XL-300 spectrometer operating at 300 MHz for ^1H and 75 MHz for ^{13}C, or with a Varian XL-200 spectrometer (^1H at 200 MHz). Chemical shifts are given with respect to the signal for internal sodium 4,4-dimethyl-4-silapentane-1-sulfonate (δ 0.0). The poylsaccharide solutions consisted of approximately 20 mg per 0.5 mL of D_2O, and the appropriate quantity of a given cation was introduced into the nmr tube as a solution (generally 2–10 μL) of either $CuSO_4 \cdot 5H_2O$, $FeCl_3$, or $CaCl_2 \cdot 2H_2O$ of the required molarity in D_2O. The adjustment of pH was carried out initially with an aqueous solution of the polymer sample, which was then evaporated. Deuterium exchange was carried out subsequently by repeatedly dissolving the residue in D_2O, followed by distillation of the solvent under reduced pressure.

N-Carboxymethyl analog of heparin

A sample (40 mg) of polymer **1→5**, prepared from beef lung heparin by selective hydrolysis (20) of the 2-*N*-sulfo group, was dissolved in water (9 mL). Sodium carbonate (70 mg) was introduced, followed by bromoacetic acid (60 mg); the mixture was held at 55–60°C for 20 h, then neutralized with acetic acid, and the solution was dialysed against water for 18 h. Chelex ion-exchange resin was added to the solution, then filtered off, and the filtrate was concentrated and subjected to D_2O exchange. As the ^1H nmr spectrum of the powdery residue indicated that *N*-substitution was incomplete (from the presence of a strong residual signal for $CHND_2$ at δ 3.0, at pD 9), the reaction with bromoacetic acid was repeated (as above). The 300 MHz ^1H nmr spectrum (Figs. 1B, C) of the solid product (32 mg), recovered following dialysis, indicated that >80% *N*-carboxymethylation had been effected. In a second experiment, which involved two successive additions of the bromoacetic acid without interruption, the product was indistinguishable (nmr evidence) from the initial one; $[\alpha]_D$ +34° (*c* 1.5, D_2O) (in comparison with +40° for the beef lung heparin).

N-Carboxymethyl analog of modified heparin (**6→2**)

A sample (50 mg) of modified heparin (**6→2**) was converted into the pyridium salt form by dissolution in water (5 mL), by acidification with Amberlite IR-120 ion-exchange resin, neutralization with pyridine, followed by concentration to dryness. A solution of the residue in 1:19 water/methyl sulfoxide (20) (5 mL) was heated at 60°C for 2h, diluted with water (10 mL), adjusted to pH 9 with 0.1 N sodium hydroxide, dialysed against water, and concentrated. The powdery residue (44 mg) was found by ^1H nmr spectroscopy (δ 3.0, $CHND_2$ at pD 9) to consist essentially of the 2-amino derivative (**6→5**). By reaction of the product (40 mg) in water (9 mL) with bromoacetic acid (85 mg) and sodium carbonate (100 mg) at 55–60°C for 22 h, and recovery as above, the *N*-carboxymethyl derivative (**6→4**) (25 mg) was obtained, as evidenced by its 300 MHz ^1H nmr spectrum (Figs. 2B, C).

N-Acetyl analog of heparin

A sample (120 mg) of polymer **1→5**, prepared from beef lung heparin by selective hydrolysis of the 2-*N*-sulfo group (also see preceding paragraph), was dissolved in sodium bicarbonate solution (5%, 10 mL). Acetic anhydride (0.2 mL) and methanol (0.2 mL) were added with stirring, and successive additions were made at 4 and 16 h, respectively. Following each addition of these reagents, the pH of the solution was monitored for 1 h and, when necessary, 5% sodium bicarbonate solution was introduced to ensure that the pH did not fall below 7. After 24 h the solution was dialysed exhaustively against distilled water, and lyophilized, giving a white solid (130 mg); $[\alpha]_D$ +41° (*c* 1.5, D_2O). The ^1H and ^{13}C nmr spectra of the product are shown, and correlated, in Fig. 3.

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday.

ALESSANDRO BAGNO, VITTORIO LUCCHINI, and GIANFRANCO SCORRANO. Can. J. Chem. **68**, 1746 (1990).

The protonation (m^* and pK_{BH^+}) and thermodynamic ($\Delta G°$, $\Delta H°$, $\Delta S°$) parameters of ionization of four thioamides $RCSNMe_2$ (R = Me, Et, *i*-Pr, *t*-Bu) have been determined in aqueous sulfuric acid in the 25–60°C temperature range with a UV technique. The title compounds are relatively strong bases; 100% protonation is reached in 47% H_2SO_4. Their solvation is lower than for primary thioamides and sulfides, as indicated by the higher values of m^*, and close to the range of carbon bases. Base strengths are discussed in terms of the competition between internal and external stabilization.

Key words: basicity, protonation, solvation, thermodynamics, thioamides.

ALESSANDRO BAGNO, VITTORIO LUCCHINI et GIANFRANCO SCORRANO. Can. J. Chem. **68**, 1746 (1990).

Faisant appel à une technique UV et opérant dans de l'acide sulfurique aqueux, à des températures allant de 25 à 60°C, on a déterminé les paramètres de protonation (m^* et pK_{BH^+}) et thermodynamiques ($\Delta G°$, $\Delta H°$ et $\Delta S°$) pour l'ionisation de 4 thioamides $RCSNMe_2$ (R = Me, Et, *i*-Pr, *t*-Bu). Les composés mentionnés dans le titre sont des bases relativement fortes; on atteint 100% de protonation dans du H_2SO_4 à 47%. Comme l'indique leurs valeurs plus élevées de m* qui se rapprochent de celles des bases carbonées, leur solvatation est plus faible que celle des thioamides primaires ou des sulfures. On discute des forces des bases en fonction de la compétition entre les stabilisations interne et externe.

Mots clés : basicité, protonation, solvatation, thermodynamique, thioamides.

[Traduit par la revue]

Introduction

In contrast to the widely studied acid–base properties of the carbonyl group (1–5), analogous thiocarbonyl compounds have received little attention. While this is in part due to the lack of stability of many such derivatives, there are nonetheless some which exhibit sufficient stability towards acids. Among these, thioamides R—CS—NR_2' are probably the best suited, and have been the object of a number of studies (6–8). An acidity function (H_T) for thiocarbonyl bases has been constructed (7, 8*a*, 9) and protonation data for a wide variety of the same have been reported (7, 8). p*K* data obtained by the Hammett acidity function, Bunnett–Olsen and Marziano–Cimino–Passerini methods have been compared (7, 8) and found to be rather similar. Moreover, the values of the φ parameter (8) indicate that the solvation requirements of these compounds are low (1) and little dependent on structure. Thus, unlike their oxygen analogs (1), thiocarbonyl bases from a homogeneous family of bases, well suited for defining an acidity function. The above data, and studies in superacid media (10), indicate that thioamides are *S*-protonated.

The comparison between analogous families of bases with *O* or *S* as the basic site has proved very informative in other cases (11). Thus a comparison with amides, whose acid–base properties are well established (1, 2, 12), is certainly interesting. In order to completely characterize the acid–base behavior of thioamides, we undertook the study of the protonation equilibria of four *N,N*-dimethylthioamides $RCSNMe_2$ (R = Me (**1**), Et (**2**), *i*-Pr (**3**), *t*-Bu (**4**)) at various temperatures. This enabled us to obtain enthalpies and entropies (as well as free energies) of ionization in solution, which contributes information for the eventual determination of their hydration energies.

Experimental

The thioamides **2, 3** and **4** were prepared from the corresponding acid chlorides and dimethylammonium chloride with P_2S_5 in anhydrous pyridine; **1** was prepared directly from the corresponding amide (13). **1** and **4** were purified by vacuum sublimation or recrystallization from toluene/ligroin; **2** and **3** by distillation. Physical constants and spectral data for **1** (14*a*), **2** (14*a, b*), **3** (14*c*), **4** (14*d*) agreed with literature values.

Preparation of sulfuric acid solutions and data processing were carried out as previously described (3). Ultraviolet spectra were run on a Varian Cary 214A instrument with a thermostatted cell compartment; the actual temperature in the cell was measured with a thermocouple. NMR spectra were run on a Bruker WP-60 operating at 1.4 T.

Results

We have studied the protonation equilibria of the thioamides **1–4** in aqueous sulfuric acid at 25, 40, and 60°C. All compounds had strong UV absorptions in a convenient spectral range (see Table 1). The spectra defined good isosbestic points, thus indicating a very small solvent effect. This was probably due to the narrow acidity range in which these bases are protonated. Ultraviolet spectra were subjected to Principal Component Analysis (PCA), as suggested by Edward and Wong (15); this treatment should enable one to separate the spectral changes due to protonation from those due to other (including solvent) effects into orthogonal components (vectors) (3, 15). In all cases, the spectra were reproduced to >99.5% accuracy with a single vector, thus ensuring that no relevant phenomenon other than protonation was taking place. The spectra were recalculated from that vector, and absorbances at a single

[a]Wavelengths in nm; log ϵ = 4.2 for B and 4.0 for BH^+. Data for B were determined in water or 5% H_2SO_4, and those for BH^+ in 50% H_2SO_4. For all compounds, an additional weaker band of the free base was present at 211 nm (log ϵ = 1.5).
[b]See eq. [2].
[c]Errors (in parentheses) from linear weighted least-squares fitting.
[d]Energies in kcal mol^{-1}; entropies in cal mol^{-1} K^{-1}.

wavelength were used for calculating ionization ratios; as implied by the method, the results were within experimental error at any wavelength (15).

Ionization ratios I were calculated as

$$[1] \quad I = [BH^+]/[B] = (A - A_B)/(A_{BH^+} - A)$$

The protonation parameters were obtained using an excess acidity function (X) (1, 16) based on nitroaniline indicators, for which $X = -(H_0 + \log c_{H^+})$ and $m^* = 1 - \varphi$ (1, 9, 16, 17). log I values were fitted to eq. [2] (1, 3, 16):

$$[2] \quad \log I - \log c_{H^+} = m^*X + pK$$

where log c_{H^+} and X for the H_2SO_4/H_2O system were calculated as previously described (3). Ultraviolet absorbances *vs.* the H_0 acidity function defined very good sigmoid plots with random differences from the calculated curve from eqs. [1] and [2]; the values of m^* and pK at the various temperatures are reported in Table 1.

Enthalpies and entropies of ionization were obtained as slopes and intercepts, respectively, of pK *vs.* $10^3/T$ plots (see Table 1).

The protonation of **4** was also followed by NMR, monitoring the chemical shift changes with acidity of the *t*-Bu and *N*-Me protons relative to trimethylammonium sulfate (3). The resulting sigmoid curves showed a very small chemical shift change ($\nu_{BH^+} - \nu_B$ = 7–10 Hz at 60 MHz), even lower than for carboxamides (12); protonation occured in a very narrow acidity range (15–40% H_2SO_4). Some peculiar features were observed: (*a*) at acidities below *ca.* 36% H_2SO_4, the *N*-methyl groups were observed as a single sharp resonance; above this value, the rotation around the C—N bond slowed down, until above 57% acid two sharp distinct resonances were observed. The line broadening occurring in this range introduces some inaccuracy in the chemical shifts measurements. (*b*) Within the same acidity range (about a half of the extremely steep protonation curve), a medium effect amounting to *ca.* 10% of the total shift was present, thus making measurements questionable in a large portion of the acidity range in which protonation takes place (unlike carboxamides, for which points affected by medium effects can be safely eliminated (12)).

The dynamic NMR data are consistent only with *S*-protonation, thus confirming earlier observations. On the other hand, a detailed analysis is prevented by the very low accuracy of chemical shifts. The apparent protonation parameters so obtained (m^* = 2.43, pK = −2.91) will obviously need correction for the other processes (rotation and medium effect). For these reasons, in this paper we will only discuss UV data, which do not appreciably suffer from medium effects and yield very accurate protonation parameters.

Discussion

An examination of the available data for primary thioamides (7, 8, 18) indicates that m^* values for a wide variety of compounds containing the —$CSNH_2$ group (and also some thioureas, thioesters, and related compounds) span only a very limited range (1.4 ± 0.1), so that these bases meet the suggested requirements for constructing an acidity function (16*a*).

On the other hand, our values for *N,N*-dimethyl derivatives (1.6–1.8) are higher by an amount outside the experimental error, thus showing that m^*'s for thiocarbonyl bases show a structural dependence if appropriately substituted. Consequently, these compounds may not be used for the building of H_T, nor is their protonation accurately described by that acidity function.

While the need for individual acidity functions can be overcome by the Bunnett–Olsen, Marziano–Cimino–Passerini, or Cox–Yates methods (1, 9), the use of an excess acidity function based on nitroanilines allows one to give a physical meaning to the slope parameter m^* (1). In fact, with the excess acidity function being defined as $X = \log (\gamma_{B^*}\gamma_{H^+}/\gamma_{B^*H^+})$ (1, 9, 16,

17), where B* is the nitroaniline taken as reference, the activity coefficient term for another base B will be linearly related to X according to eq. [3] (1):

[3] $\log (\gamma_B\gamma_{H^+}/\gamma_{BH^+}) = m^* \log (\gamma_{B^*}\gamma_{H^+}/\gamma_{B^*H^+})$

Such activity coefficients represent free energies of transfer from the standard state to the non-ideal acidic solutions, and are dominated by solvation effects (1). It is easy to show that, if $\gamma_{BH^+}/\gamma_B \gg 1$, then $0 < m^* < 1$ and, conversely, $m^* > 1$ when $\gamma_{BH^+}/\gamma_B \approx 1$. The first case applies when there is a large difference of solvation between B and BH^+, on a scale referred to B^*/B^*H^+ (an aniline), and the second when the solvation of B and BH^+ are similar (1, 18, 19). However, since solvation energies of charged species are higher than for neutrals (1, 20), m^* essentially measures the hydrogen bonding solvation of the protonated base. Thus, as we might expect, m^* increases in the series $ROH < R_2O < R_2CO < R_2SO < ArNH_2 < R_2S < Ar_3C^+$ (1).

Both the m^* values and the dynamic NMR behavior confirm that thioamides are sulfur bases. The solvation requirements of thioamides are lower than those of sulfides, as shown by the m^* of the latter (*ca.* 1.3) (1). In fact, charge stabilization in protonated thioamides is provided by the polarizable sulfur atom and by delocalization into the amide group, which effectively reduces the interactions with the solvent; the latter accounts for the decreased solvation relative to sulfides. It is then evident that this parameter is directly affected by *N*-substitution, as in amides (2, 12), and will increase with alkyl substitution. For example, CH_3CSNH_2 and *t*-$BuCSNH_2$ studied by Edward *et al.* (8*b*) ($m^* = 1.44$ and 1.49, respectively) can be compared with their *N,N*-dimethyl derivatives (1.67 and 1.78).

These values are among the highest known, being only lower than those for carbon bases (1). These bases are also peculiar in that, unlike most others (1), they feature a rather high aqueous basicity accompanied by a very low solvation, which corresponds to a very steep protonation curve (3). These two factors make thioamides readily protonated; in fact, 100% protonation is reached at *ca.* 47% H_2SO_4 (amides are fully protonated at *ca.* 55% H_2SO_4, despite their pK's being *ca.* 2 units higher (12)).

Within many families of bases in which substituents change around the basic site, substitution with electron-releasing groups usually causes an increase in m^* and a decrease in pK (1, 3–5). This has been explained with the consideration that the substituent stabilizes the protonated base, thus decreasing the interactions with the solvent (higher m^*) and therefore its overall stabilization in water (lower pK). For thioamides, there is very little stabilization by solvation; since internal stabilization is the major factor involved, we might expect a better electron-releasing substituent to increase the aqueous basicity. However, while changing from Me to *t*-Bu does increase m^*, as expected, the pK's remain practically identical suggesting that the two effects are compensating.

Because of the very small range spanned by these thermodynamic parameters, it is pointless to discuss their values in detail. However, we can compare these values with those for other classes of bases, and attempt an investigation of the origin of the relative basicities of thioamides and their oxygen analogues carboxamides, which behave rather differently (see Table 2). The order of basicity in water is $MeCSNMe_2 < MeCONMe_2$. This difference arises from both enthalpic and entropic effects; amide protonation is less endothermic and entropically more favored. The trend for enthalpies is consistent with the expectation that protonation on a less solvated site gives rise to a weaker hydrogen bonding stabilization and therefore makes protonation more endothermic. With regard to the entropy change for the process $BH^+ \rightarrow B + H^+$, besides the purely statistical term (positive), the other major contribution comes from the difference in solvation of H^+ and BH^+, which causes an ordering of the water molecules involved in hydrogen bonding and thus makes a negative contribution depending on the solvation of BH^+. The balance between these two factors determines the size of $\Delta S°$, if the solvation of B makes a minor contribution.

Despite the large difference in solvation, the two bases have very similar entropies of ionization. This discrepancy probably stems from a negative contribution coming from the strong hydrogen bonds existing in the free amide, thus making $\Delta S°$ for $MeCONMe_2$ more negative than expected. A similar situation is found in the dimethyl derivatives listed in Table 2; dimethyl sulfoxide has a lower $\Delta S°$ than expected because of a peculiar solvation of the free base (19).

Received January 2, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

PAUL M. SHIUNDU, ADRIAN P. WADE, and S. B. JONNALAGADDA. Can. J. Chem. **68**, 1750 (1990).

Precise and accurate knowledge of peroxydisulfate ion concentration is critical in industrial polymer production, where it is extensively used as an activator. Its ability to oxidize in either acidic, neutral, or alkali media also makes it widely applicable in many other areas of chemistry.

In this paper we present an optimized spectrophotometric flow injection method for determination of peroxydisulfate. The analyte oxidizes *o*-dianisidine to form a stable product which has a convenient absorbance maximum at 450 nm. This provides a simple and sensitive alternative to present methods which are more costly, tedious, or complex.

Key words: spectrophotometric method, peroxydisulphate.

PAUL M. SHIUNDU, ADRIAN P. WADE et S. B. JONNALAGADDA. Can. J. Chem. **68**, 1750 (1990).

Une connaissance exacte et précise de la concentration en ions peroxydisulfates est critique dans la production industrielle de polymères où il est utilisé d'une façon extensive comme activant. Comme il peut provoquer des oxydations en milieux acide, basique ou neutre, on peut l'utiliser dans plusieurs autres domaines de la chimie.

Dans ce travail, on présente une méthode spectrophotométrique optimisée pour déterminer la concentration en ion peroxydisulfate. Le produit à analyser oxyde l'*o*-dianisidine pour former un produit stable qui possède une bande d'absorption maximale à 450 nm. Cette procédure fournit une alternative simple et sensible aux méthodes actuelles qui sont plus couteuses, plus embêtantes ou plus complexes.

Mots clés : méthode spectrophotométrique, peroxydisulfate.

[Traduit par la revue]

Introduction

The peroxydisulphate (persulphate) ion is a strong two-electron oxidizing agent

$$S_2O_8^{2-} + 2e^- \rightarrow 2SO_4^{2-}$$

with a standard redox potential of -2.01 V in either neutral or alkaline solution (1). Its utility as an oxidizing agent for various substrates is derived from its ability to oxidize in acidic, neutral, and alkaline media (2). It has industrial importance as a polymerization activator, e.g., in production of polystyrene (3).

The literature provides a number of methods for the determination of persulphate. Kolthoff and Carr (4) reported several reductometric methods for the volumetric determination of persulphate ions. Of these, the iodometric and ferrometric (titrimetric) methods were the most practicable from the points of view of rate of reaction, accuracy, and simplicity (4). However, both procedures involve a back-titration step after the redox reactions with persulphate and thus are tedious to perform in any number. They also require reaction times of at least 15–30 min. Amin and Hareez (5) reported a procedure using a combination of titrimetry with alternating current (a.c.) polarography. This method is likewise tedious and complex. Amin (6) later reported an indirect amplification method by a.c. polarography which enabled measurement of persulphate concentrations as low as 2.6×10^{-6} M with reasonable accuracy. This method, however, involves an extraction step followed by a back-titration. Ion-exchangers are also required to remove metal ions which form water-insoluble iodides that would otherwise interfere. Kolthoff and Woods (7) reported an alternating-current polarographic method by which persulphate concentrations in the range (10^{-4}–10^{-3} M) could be measured. This method was found to be highly temperature dependent. Substances that have wave potentials close to that of the iodate are known to interfere (6) (for example, Zn(II) in alkali media or Mo(IV), Cu(II), and Bi(II) under acidic conditions). These examples show that development of rapid selective methods for determination of persulphate has proven a difficult analytical problem.

The reaction between persulphate ions and aromatic amines, now known as the Boyland–Sims oxidation, was first reported in 1953 (8). A literature survey found that the reaction of persulphate with the substituted aromatic amine, *o*-dianisidine (ODA) has not previously been used for quantitative analysis of persulphate. However, persulphate ion has been used as a spray reagent for detection of aromatic amines and related compounds in thin layer chromatography (9), and the kinetics of the reaction of ODA with oxidizing agents such as H_2O_2 are well known (10, 11).

This paper reports the automated development of a simple flow injection procedure to determine persulphate ions at low concentrations, and is based on reaction with ODA. Flow injection (FI) is a versatile form of microflow analysis (12). Typical FI methods are fast, dependable, semi-automated, and use colorimetric or electrochemical detection in low volume flow-through cells. Samples are typically 30–100 μL in volume and throughput rates of 120 samples h^{-1} are commonly reported.

Many manual procedures have been adapted to flow injection (12). Advantages of this include decreased reagent consumption and improved precision.

The present work has been carried out on an automated flow injection methods development system, which has been reported elsewhere (13). Such computer-controlled units have much to offer analytical chemistry. Reaction conditions may be specified from the keyboard and automatically adjusted. This is achieved by mixing streams of the required composition (reagent(s), solvent(s), buffer, diluent) using variable speed pumps and stock solutions. Sample introduction is via computer-controlled injection valves or stream switching valves. Optimization of such systems requires that operating conditions be found which maximize some measure of performance (e.g. extent of reaction) whilst limiting unnecessary sample dispersion. This is typically a highly multivariate problem, as flow conditions must be optimized in addition to the chemical parameters.

Simplex optimization (14–16) and automated response surface mapping (13, 17) have been implemented on these systems. The former provides a rapid means to find the optimum conditions for analysis. The latter seeks to establish the effects of system variables such as flow rates, sample size, pH, and ionic strength. Together or separately these facilitate essentially operator-unassisted methods development, in a matter of a few hours.

Experimental

Reagents

A stock solution of persulphate (1.00×10^{-2} M) was prepared by dissolving 0.676 g of potassium persulphate (Fisher Scientific, Fairlawn, NJ), in 250 mL of distilled water. Standard solutions were prepared from this by appropriate dilution. A 1.0×10^{-2} M ODA solution (2.443 g L^{-1}) (Aldrich, Milwaukee, WI) was freshly prepared daily in a 40% v/v mixture of acetone in water. Solutions of ODA were freshly prepared every day. A buffer solution was prepared from 100 mL of 0.1 M 3,3-dimethylglutaric acid (Aldrich, Milwaukee, WI) in 1 M sodium chloride (18). Sodium chloride was present to minimize the effect of changes in ionic strength of the reaction media. Various reaction pHs for the batch method experiments were obtained by adding appropriate volumes of 0.1 M sodium hydroxide to the buffer.

Apparatus

The automated flow injection analyzer used was the same as in previous methods development (16, 17) and is discussed in detail elsewhere (13). The options used in this work included a custom-built variable speed peristaltic pump unit containing five independent pump heads, a high precision variable speed peristaltic pump (Models C-4V or C-6V, Alitea USA, Seattle, WA), and a six-port air-driven solenoid-actuated injection valve (Rheodyne 5020P, Cotati, CA) equipped with a 100 μL sample loop. A diode array spectrophotometer (Hewlett Packard 8452A) with a standard 1 cm quartz cell was used for absorption measurements. This was interfaced to the control computer, an IBM PC/AT compatible computer (NORA Systems, Vancouver, B.C.), via an IEEE-488 instrumentation interface. All the other units were controlled by the same microcomputer as described elsewhere (13). For the flow injection studies, a 30 μL, 1 cm path length quartz flow cell was used. The pH of reaction mixtures was determined on-line using a flow through electrode cell, a Ag/AgCl electrode (Radiometer America Electrodes Inc., GK473901), and a laboratory pH meter (Model 119, Fisher Scientific, Richmond, B.C.). Polytetrafluoroethylene (PTFE) tubing of 0.5 mm i.d. was used throughout. Software was written in Microsoft QuickBASIC^R version 4.0, as was the code used for nonlinear curve fitting and other data processing tasks. The optimization algorithm used was the composite modified simplex method (14, 19, 20). Response surface plots were generated using a commercial scientific graphics program (SURFER^R v. 3.0, Golden Software, Golden, CO).

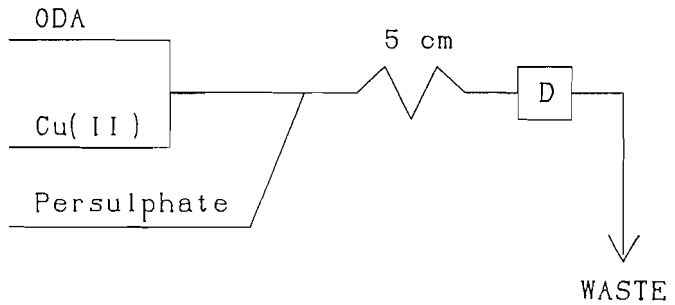

FIG. 1. Continuous flow manifold used for stopped flow kinetic studies for the reaction between ODA and persulphate. The reagent stream was of ODA in 40% v/v acetone in DMGA buffer at pH 7.0. A 1.0×10^{-4} M Cu(II) stream was used to catalyze the reaction. Absorbance measurements were made using the spectrophotometer, D.

Procedures

Batch kinetics studies

A series of preliminary batch kinetics experiments were performed to investigate the suitability of ODA as a reagent for the determination of persulphate ions.

A standard reaction was first obtained by adding 5.0 mL of 1.0×10^{-4} M persulphate solution to a mixture containing 5.0 mL of 1.0×10^{-2} M ODA solution and 10.0 mL distilled water. After thorough mixing an appropriate reaction mixture volume was transferred to a standard 1 cm cell in the spectrophotometer. Absorbance measurements at 450 nm were initiated 30 s after the start of the reaction and acquired at 10 s intervals for a period of 900 s. The effect of pH on this reaction for the above ODA concentration was then established by adding 10.0 mL of buffer solution at a known pH in place of the distilled water. The pH was varied from 3.00 to 9.00.

Stopped flow kinetic studies

Once the optimum reaction pH was identified, stopped-flow experiments were conducted to determine the kinetic parameters (i.e. final amount of product formed, order of reaction, and rate constant, K'). The flow configuration used for the stopped flow experiments is as shown in Fig. 1. A single Alitea pump was run at maximum speed to merge the reagents and then rapidly transport the reaction mixture to the cell (in less than $\frac{1}{2}$ s from the tee to observation window). The flow was then stopped and absorbance measurements were made at 1 s intervals at 450 nm for a period of 400 s.

The effect of various metal ions on the kinetics at pH 7 was then established by adding dilute metal ion solutions in place of the 10.0 mL distilled water. A similar procedure was followed using neutral salts to determine the effect of ionic strength on the reaction. Finally, the effect of other possible solvents and solvent mixture composition on the ODA solution and product stability was determined.

Flow injection studies

The flow injection configuration used for both the automated simplex optimization and response surface mapping studies is shown in Fig. 2*a*. The reagent stream, R, consisted of ODA merged with distilled water to give a total flow rate of 1.00 mL min^{-1} and maximum ODA concentration of 1.0×10^{-2} M. The buffer stream, B, comprised 0.10 M 3,3-dimethylglutaric acid in 0.10 M NaCl merged with a 0.10 M sodium hydroxide stream to give a total flow rate of 1.0 mL min^{-1} and a maximum NaOH concentration of 0.10 M. The carrier stream was made up of 5.00×10^{-4} M Cu(II) solution as a catalyst, flowing at a fixed rate of 2.00 mL min^{-1}. By allowing the NaOH flow rate to vary from (0.00–1.00) mL min^{-1}, the pH was varied from about 3.50–10.00. The flow at the detector was kept at a constant total rate of 3.00 mL min^{-1}. This ensured a constant sample residence time in the system. Separate pumps were used for each solution. The internal diameter (i.d.) of reaction coils was 0.5 mm for all sets of experimental conditions. Before any sample injection was made, the system was allowed to equilibrate to a steady baseline reading.

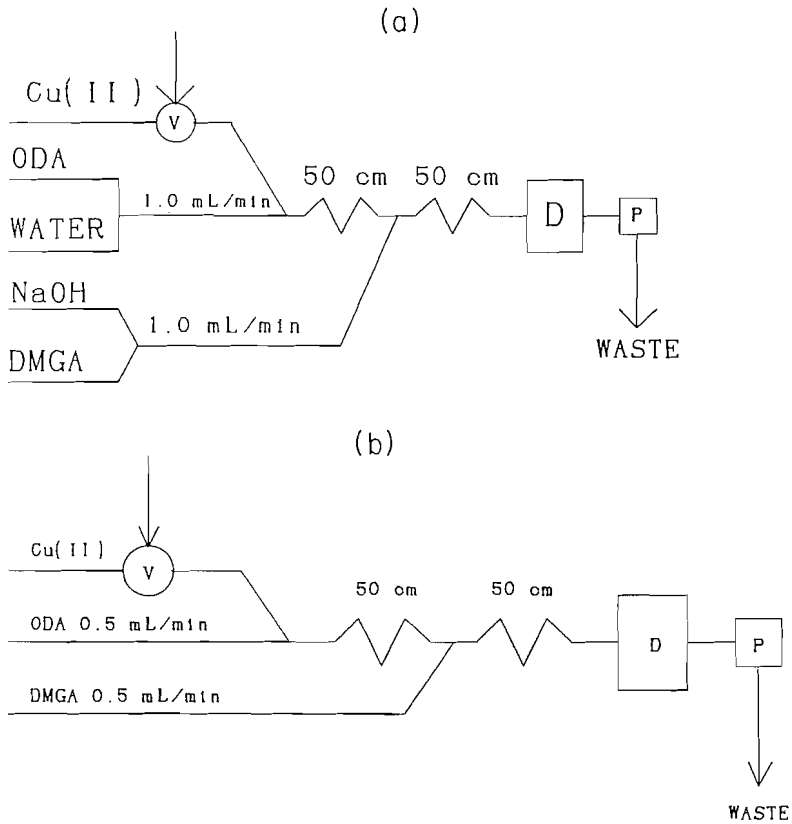

FIG. 2. (*a*) Flow injection manifold used for automated optimization and response surface mapping studies. This comprised a 5.0×10^{-4} M Cu(II) carrier stream flowing at a constant flow rate of 2.0 mL min^{-1}, an injection valve with 100 μL loop (V), reagent and water streams buddied at 1.0 mL min^{-1}, a buffer stream consisting of NaOH and DMGA buddied at 1.0 mL min^{-1}, a spectrophotometer (D), and a pH electrode cell (P). (*b*) Flow injection manifold used for the calibration studies and investigation of the effect of organic substances. This is comprised of a 5.0×10^{-4} M Cu(II) carrier stream flowing at a constant flow rate of 1.5 mL min^{-1}, an injection valve with 100 μL loop (V), an 1.0×10^{-2} M ODA reagent stream flowing at 0.5 mL min^{-1}, a DMGA buffer stream at pH 7.0 flowing at a constant 0.5 mL min^{-1}, a spectrophotometer (D), and a pH electrode cell (P).

TABLE 1. The response, pH, and the relative standard deviation (RSD) of the initial (expt. #1) and the five best simplex experimental conditions (total number of experimental points, 20)

Expt. #	Variable #1 (ODA)/mL min^{-1}	Variable #2 NaOH/mL min^{-1}	Response[a]	pH	(RSD)/%
1	0.400	0.400	0.071	4.42	1.5
4	0.840	0.672	0.198	5.75	0.3
5	1.000	0.807	0.198	7.5	1.6
7	1.000	0.664	0.211	6.67	0.7
8	0.763	0.775	0.190	7.12	1.0
12	1.000	0.585	0.189	5.26	0.6

[a]Responses were measured as peak absorbance.

A 100 μL sample of 1.00×10^{-4} M persulphate was then injected into the carrier stream and absorbances measured at 450 nm. The pH of the reaction mixture was measured simultaneously in a simple-flow through cell placed 5 cm after the spectrophotometric detector.

Automated simplex optimization

During automated simplex optimization, the flow rates of all streams save for the carrier stream were automatically adjusted. This was to determine the optimum flow rates for the reagent and NaOH streams (optimum pH from flow rate of NaOH and the buffer stream).

The initial experimental conditions and the best experimental conditions established during the simplex optimization procedure are summarized in Table 1. The best conditions obtained correspond to those of experimental point number 7, i.e. ODA and NaOH flow rates of 1.00 and 0.66 mL min^{-1} respectively, with the pH of the reaction mixture equal to 6.67 as recorded by the pH meter.

Once the optimum conditions were established, these were implemented on a simpler flow injection system shown in Fig. 2*b*, comprising two pumps, three pump tubes, and a single injection valve. This was used for subsequent routine analysis, calibration, and studies on the effect of organic substances. Alternatively, a single pump could have been employed with the carrier stream channel having a pump tubing which could provide a flow rate that is three times higher than that of the other channels.

Automated response surface mapping

A more thorough investigation of the ODA–persulphate response surface was then achieved by carrying out triplicate experiments at

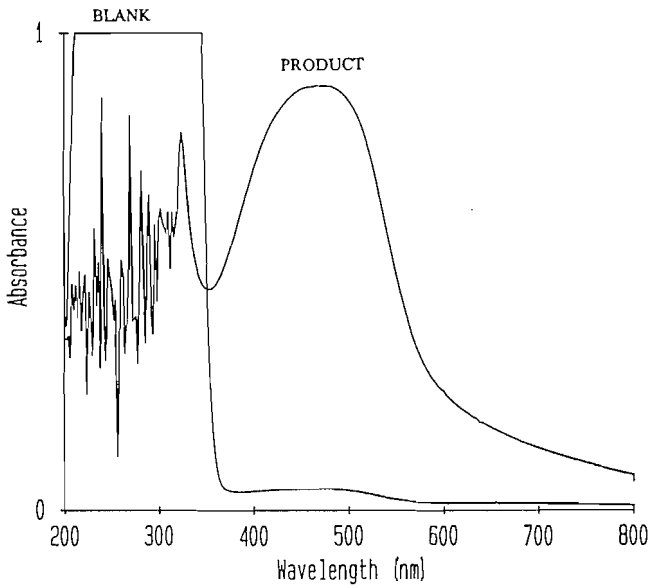

FIG. 3. UV–visible absorption spectra of the ODA–persulphate reaction product: (*1*) reagent blank with water as reference; (*2*) ODA–persulphate mixture after 300 s with the reagent blank as reference.

TABLE 2. Effect of metal ions on the ODA–persulphate reaction; absorbance measurements taken 5 min after initiation

M^{n+}	$[M^{n+}]$/mol L^{-1}	Absorbance	Enhancement factor[a]
Blank	—	0.747	0.63 (300 s)
Mo^{6+}	1×10^{-3}	0.779	0.66 (300 s)
Mn^{2+}	1×10^{-3}	0.946	0.80 (300 s)
Ni^{2+}	1×10^{-3}	1.040	0.88 (215 s)
Co^{2+}	1×10^{-3}	1.038	0.88 (200 s)
Zn^{2+}	1×10^{-3}	1.108	0.94 (245 s)
Pb^{2+}	1×10^{-3}	1.133	0.96 (245 s)
Cu^{2+}	1×10^{-3}	1.181	1.00 (85 s)
Fe^{3+}	1×10^{-3}	Interferes	—
Ag^{+}	1×10^{-3}	Interferes	—

[a]Enhancement factor is calculated relative to 10^{-3} M Cu^{2+} ions and the values in brackets show the times at which maximum absorbance were recorded with [ODA] = 5.0×10^{-3} M, $[S_2O_8^{2-}] = 1.0\times10^{-4}$ M, buffered at pH = 7.0.

each of the 64 sets of reaction conditions. These were regularly spaced across the search space in the pattern of an 8 × 8 square lattice. The average absorbance at each set of conditions was taken as the height of the response surface at that point.

Results and discussion

Selection of analytical wavelength

The absorption spectra of 5.0×10^{-3} M ODA in 40% v/v acetone–water mixture and that of the reaction product formed from the reaction between 5.0×10^{-3} M ODA in 40% v/v aqueous acetone and 1.0×10^{-4} M persulphate after 5 min as reaction time are shown in Fig. 3. This reveals that absorbance measurements due to formation of product can be made at 450 nm without interference from the reagent matrix.

Batch kinetic studies

Effect of metal ions

A number of metal ions are known to catalyze reactions involving persulphate ions. The metal ions studied are given in Table 2. Most showed catalytic activity to varying degrees.

TABLE 3. Effect of neutral salts on rate of formation of product; reaction conditions: [ODA] = 1.0×10^{-3} M, $[S_2O_8^{2-}] = 5.0\times10^{-5}$ M

Salt	Concentration mol L^{-1}	Absorbance after 600 s	Relative increase (%)
Blank	0.0	0.0932	0
NaCl	1.0×10^{-4}	0.1479	58.69
	4.0×10^{-3}	0.1488	59.66
KCl	1.0×10^{-4}	0.1401	50.32
	4.0×10^{-3}	0.1495	60.41
KNO_3	1.0×10^{-4}	0.1040	11.59
	4.0×10^{-3}	0.1323	41.95

Both Fe(II) and Cu(II) showed remarkable catalytic activity even at concentrations as low as 10^{-5} M. Reactions catalyzed by Fe(II), however, yielded very unstable products. This was not surprising since the reaction mechanism is thought to be via a free radical species (4) producing Fe(III), which in itself formed a colored complex with ODA. A substantial catalytic effect was also observed for Pb(II). The catalytic activities of Mn(II), Co(III), Ni(II), Zn(II), and Mo(VI) were much less than that of Cu(II). About a 100-fold concentration (10^{-1} M) of these metal ions had a comparable catalytic effect as that of the Cu(II) (10^{-3} M). Both Ag(I) and Fe(III) formed colored complexes with ODA and thus interfered.

Further investigation of the suitability of Cu(II) as a catalyst in the ODA–persulphate reaction was then performed. The concentration of Cu(II) was varied from 10^{-7} to 10^{-1} M. At concentrations below 10^{-6} M, the reaction rate was slightly increased relative to the uncatalyzed reaction. For concentrations between 10^{-6} and 10^{-4} M, equilibrium of the reaction mixture was reached between 240 and 90 s, respectively, while with concentrations between 5.0×10^{-4} and 10^{-1} M, equilibrium was attained within 60 s. A Cu(II) concentration in the range 10^{-3} to 10^{-2} M is recommended. This is a compromise between the rate of attaining equilibrium and product instability, since at concentrations above 10^{-2} M Cu(II) instability became more apparent.

Effect of neutral salts

Ionic strength often varies from sample to sample and so the effects of NaCl, KCl, and KNO_3 concentrations on the ODA–persulphate reaction was investigated. Table 3 summarizes the effect of various concentrations of these neutral salts on the rate of reaction. The reported absorbances were measured 300 s after initiating the reactions. All these neutral salts showed a positive effect on the rate of the reaction with increase in concentration. KCl and NaCl showed approximately equal effects which were greater than that observed with KNO_3 (Table 3).

Effect of % v/v composition of acetone in water as solvent

The % v/v composition of acetone in water was varied from 20 to 100%. The lower limit was chosen because of the limited solubility of ODA in water. The results showed a general increase in rate of the reaction with increase in mole fraction of acetone, but product stability decreased. In the presence of 10^{-4} M Cu(II) as catalyst, equilibrium was attained in less than 60 s with compositions above 40%. Product stability, however, decreased with increase in % composition above 40%. Under similar conditions with 20–40% acetone, equilibrium was achieved between 60 and 90 s, respectively, with product stability times greater than 300 s (product stability times = time

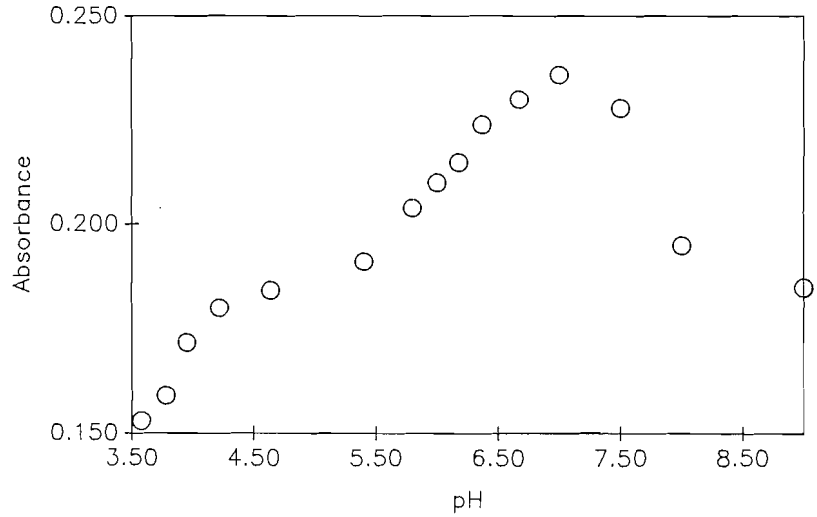

FIG. 4. Absorbance at 450 nm for the ODA–persulphate reaction mixture as a function of pH.

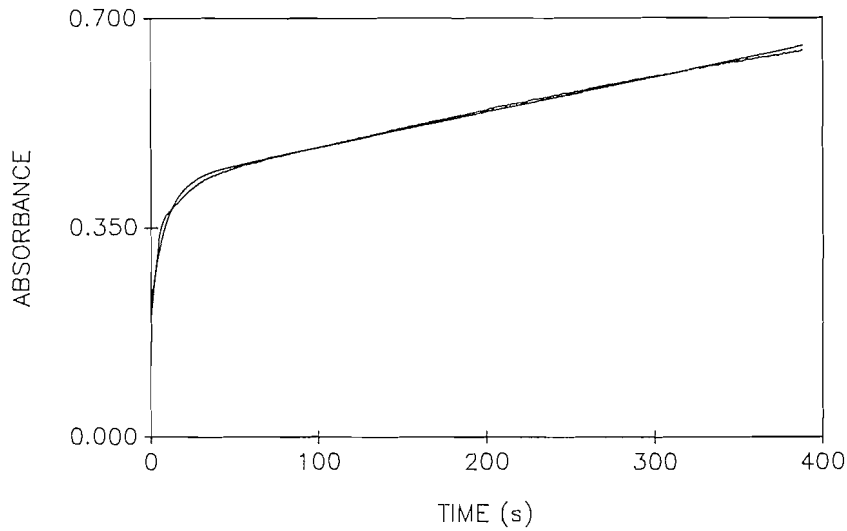

FIG. 5. Fit of a pseudo-first order reaction model to data collected for the reaction between ODA and persulphate at pH 7.0.

period over which absorbance readings were recorded within ±0.05 absorbance units). Thus a composition of between 20 and 40% is recommended.

Effect of reaction mixture pH

3,3-Dimethylglutaric acid (0.1 M) in 1 M NaCl and 0.1 M NaOH was used to vary the pH of the reaction mixtures from 3.5 to 10.0. A high concentration of NaCl was employed to keep the ionic strength of reaction medium constant. Figure 4 shows the responses obtained from reaction mixtures at various pH values. Absorbance was measured after 300 s of reaction time. From these batch reactions, the maximum response obtained corresponded to neutral conditions; however, acceptable sensitivity was obtained between pH 6.5 and 7.5.

Reaction kinetics studies

Reaction kinetics were investigated at neutral pH conditions under pseudo-first order conditions, with ODA in excess. Expressing the reaction as

$$S_2O_8^{2-} + n\text{ODA} \rightarrow \text{Product}$$

the reaction rate can be written as

$$\text{Rate} = K'[S_2O_8^{2-}]$$

where K' is the pseudo-first order rate constant.

A non-linear curve fitting program was used to extract the pseudo-first rate constant from the stopped-flow experimental data. The equation fit to the data was

$$A_t = A_0[1 - \exp(-K't)] + C$$

where A_t is the absorbance at time t, A_0 is the final solution absorbance due to product, and C is a constant background term. The flow through cell was thermostated at 25°C. Figure 5 is representative of the fits of the model to the data. Excellent fits were obtained for each of the solutions tested. The pseudo-first order rate constant obtained from the fitting routine was 0.06 ± 0.01 s^{-1}. The final equilibrium absorbance due to the product remained unchanged within ±0.01 absorbance units for ODA concentrations in the range 0.001 to 0.01 M, an indication that reaction was going to completion. The reaction is essentially finished in less than 90 s.

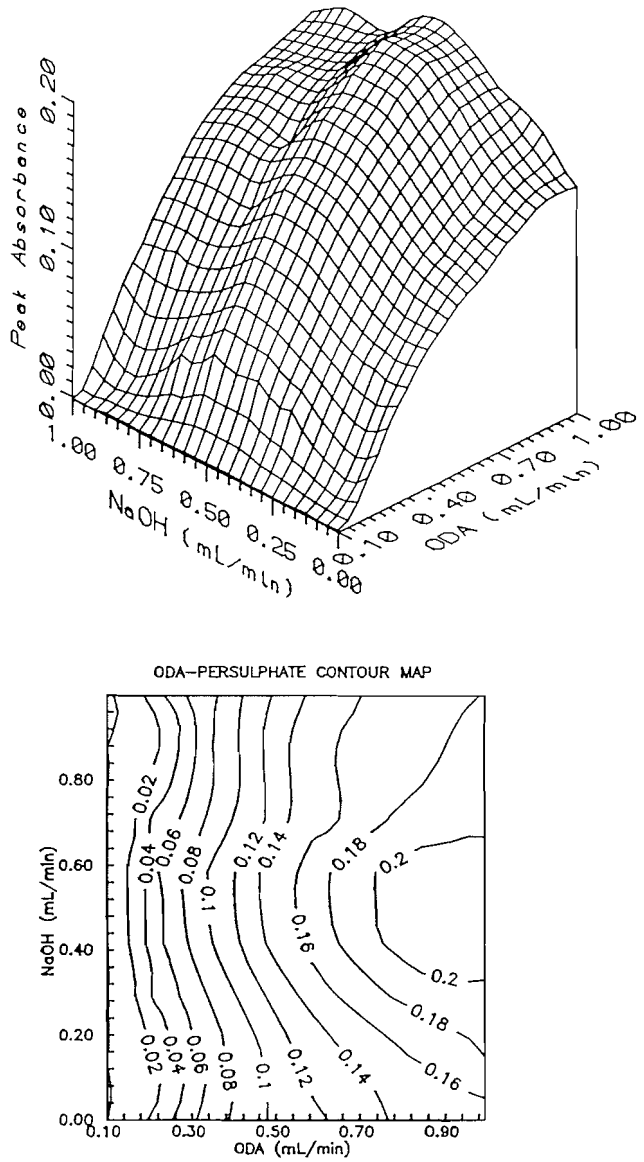

FIG. 6. The ODA–persulphate response surface shown as a 3D plot and its corresponding contour map. The response shown is the peak absorbance at 450 nm. ODA and NaOH flow rates are in mL min^{-1}.

Automated optimization of the flow injection system

Both simplex optimization and response surface mapping were employed. The results are compared. Simplex optimization was chosen as an optimization procedure because it rapidly optimizes chemical and flow conditions in flow injection systems (12). While this approach adequately locates the maximum, it gives little information about the global nature of the response surface (13). Some workers have advocated carrying out an additional set of experiments around the best conditions found by an experimental optimization to confirm that the true optimum has indeed been located and establish the effect of changes in experimental variables in this region (21). This provides the experimentalist with evidence of the stability and therefore experimental repeatability of the analytical method. This was not done here as the same function was achieved globally by the response surface mapping experiments.

With three replicate runs at every experimental condition, the total time taken to achieve the optimum conditions by simplex optimization was 2.0 h. This was for about 20 sets of experimental conditions. For the automated response surface mapping, a factorial design consisting of 64 experiments each with three replicates, was used. This optimization process took about 4 h.

TABLE 4. Optimization of coil length for ODA–$S_2O_8^{2-}$ reaction

Coil length/cm	Peak maximum (AU)	Relative performance (%)
55	0.391	77.4
60	0.423	83.8
80	0.466	92.3
90	0.477	94.5
100	0.505	100
110	0.477	94.5
120	0.446	88.3

The results of the response surface mapping study are shown in Fig. 6. The ideal pH for this reaction was established as 7.0, however the pH range 6.0 to 7.5 could be used without great loss in sensitivity. This range corresponded to NaOH stream flow rates in the range 0.30–0.80 mL min^{-1} for the FIA manifold of Fig. 2*a*. Thus the whole pH range 6.0–7.5 is recommended. These results were in good agreement with those from the simplex optimization procedure. As shown in Table 1, the optimum flow rate conditions obtained from simplex experiments fall in the region considered optimum from the response surface studies. Also the pH's corresponding to the five best simplex experimental conditions are within the pH range established as optimum from the response surface studies. The optimum conditions established by the simplex procedure were thus confirmed by the automated response surface mapping studies at the expense of more experiments and somewhat less information about the region of the optimum.

The effect of reaction coil length on the sensitivity of the system was determined by performing 10 replicate experiments under the optimum conditions obtained from the first simplex optimization experiment with different reaction coil lengths. A 100 cm coil length was established as optimum. Results of these studies are summarized in Table 4. Since this value was (fortuitously) as used in the previous automated chemical flow optimization, no further optimization experiments were warranted. The automated analyzer used does not presently have the capability of automatically adjusting coil length.

Interference studies

In polymerization studies with persulphate as activator, persulphate must often be determined in the presence of various organic substances. Thus the effect of methanol, ethanol, allyl acetate, formaldehyde, ethyl acetate, and allyl alcohol on the ODA–persulphate reaction was investigated. Of these substances, methanol and ethanol showed the least effect even at concentrations as high as 1.0 M. Solutions containing 2.5 M methanol and 1.0 M ethanol caused an error of about +0.22% in the determination of 2.0×10^{-4} M persulphate ions. At 0.25 M concentrations of both allyl alcohol and allyl acetate errors of +0.50% and −6.98% respectively were recorded. The worst acceptable interference was obtained with 0.5 M ethyl acetate which gave an error of +11.80. Reaction in the presence of formaldehyde resulted in a turbid mixture which then formed a pinkly colored precipitate. Formaldehyde thus strongly interferes, and should not be present.

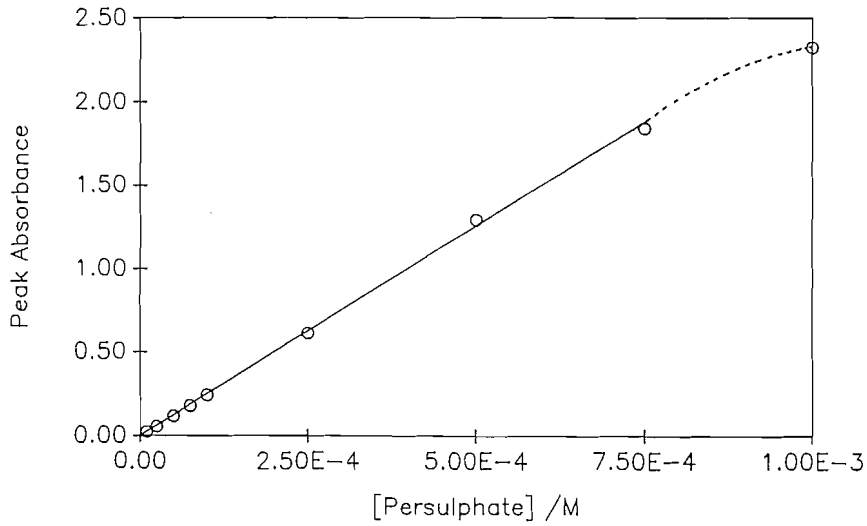

FIG. 7. Calibration curve for developed method of persulphate determination. The solid line represents the linear dynamic range.

Analytical implications

The calibration curve obtained with the flow geometry of Fig. 2*b* is shown in Fig. 7. This indicates a linear dynamic range of 2.50×10^{-5} M to 7.5×10^{-4} M, with a sensitivity of 2.4×10^3 Abs M^{-1}. The detection limit (3 × standard deviation of the baseline noise) with this system was 5.0×10^{-7} M. The lower limit of the linear dynamic range was detected with a relative standard deviation of 1.5% from 10 replicates.

Conclusions

The analytical method developed is both simple and sensitive. Other advantages generic to flow injection techniques include high precission, high sample throughput rate, and low sample and reagent consumption rates. Together these give the analytical procedure reported here many advantages over previous classical (4, 9), titrimetric (4), and the polarographic methods (6, 7). While a few organic species and metal ions do interfere, either the extent of their effects is tolerable, or the interference is usually obvious in the reaction mixture.

Evaluation of K_{BH^+} constants for weak organic bases

W. David Chandler and Donald G. Lee
Department of Chemistry, University of Regina, Regina, Sask., Canada S4S 0A2

Received February 9, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

W. David Chandler and Donald G. Lee. Can. J. Chem. **68**, 1757 (1990).

A non-linear regression procedure has been developed to analyze simgoidal plots even when data at or near the plateaus are missing. The method was used to fit relative C-13 nmr chemical shifts (Δ) of five alcohols to sigmoidal functions of the excess acidity (X). With two of the functions, the regression gives Δ_{BH^+}, the relative chemical shift of the protonated alcohol. That parameter permits calculation of the ratio, $[BH^+]/[B]$, necessary for an additional linear regression to determine pK_{BH^+} and m^*. With a third function, regression gives Δ_{BH^+}, pK_{BH^+} and m^* directly. Comparison of pK_{BH^+} values obtained from these methods with those estimated previously suggests that the sigmoidal regressions are reliable, and can be of considerable use in handling titration-type curves generally.

Key words: basicities, alcohols, regression, sulfuric aid.

W. David Chandler et Donald G. Lee. Can. J. Chem. **68**, 1757 (1990).

On a mis au point une proédure de régression non-linéaire qui permet d'analyser des courbes sigmoïdales, même lorsqu'il manque des données près de ou au niveau des plateaux. On a utilisé cette méthode pour ajuster les déplacements chimiques relatifs (Δ) de la rmn du ^{13}C de cinq alcools avec les fonctions sigmoïdales de l'excès d'acidité (X). Avec deux de ces fonctions, la régression fournit la valeur de Δ_{BH^+}, le déplacement chimique relatif de l'alcool protoné. Ce paramètre permet de calculer la valeur du rapport $[BH^+]/[B]$ qu'il est nécessaire de connaître pour effectuer une régression linéaire additionnelle dans le but de déterminer les valeurs de pK_{BH^+} et de m^*. Avec une troisième fonction, la régression fournit directement les valeurs de Δ_{BH^+}, pK_{BH^+} et m^*. Une comparaison des valeurs de pK_{BH^+} obtenues par ces méthodes avec celles évaluées antérieurement suggère que les régressions simoïdales sont fiables et qu'elles peuvent être très utiles pour traiter d'une façon générale des courbes du type "titration".

Mots clés : basicités, alcools, régression, acide sulfurique.

[Traduit par la revue]

Introduction

An ability to accurately measure dissociation constants (K_{BH^+}, eq. [1]) for the conjugate acids, BH^+, of weak bases, B, is essential to a quantitative understanding of reactions that are subject to acid catalysis. Because of the number and importance of such reactions in organic chemistry and biochemistry it is not surprising that the literature contains descriptions of attempts that have been made to estimate K_{BH^+} values for many weak bases including alcohols (1–4), ketones and aldehydes (3–9), carboxylic acids and esters (7–11), ethers (3, 4, 12, 13), and sulfur-containing compounds (3, 13, 14).

$$[1] \quad BH^+ \overset{K_{BH^+}}{\rightleftharpoons} B + H^+$$

In the absence of a reliable value for the dissociation constant it is impossible to quantitatively analyze the kinetics of reactions that are catalyzed by acid (15).

Three requirements must be met before K_{BH^+} values can be determined accurately: (*i*) a suitable acidity function must exist (15); (*ii*) it must be possible to measure some physical property that accurately determines the ratio $[BH^+]/[B]$ (16), and (*iii*) methods must be available to analyze a plot of a function of $[BH^+]/[B]$ against the acidity of the solution.

Extensive studies based on the pioneering work of Hammett led, eventually, to the development of acidity functions that can be used with confidence (17). The most general of these (the excess acidity function, X) utilizes a plot of $\log [BH^+]/[B] - \log [H^+]$ vs. X (eq. [2]) (18).

$$[2] \quad \log [BH^+]/[B] - \log [H^+] = m^*X + pK_{BH^+}$$

Two physical properties have been used extensively to measure the ratio $[BH^+]/[B]$ – UV absorption intensities (18) and nmr chemical shifts (2, 3, 12). The former is useful if the base contains a chromophore that undergoes a change of either position or intensity on protonation. If ϵ_B and ϵ_{BH^+} are extinction coefficients of the base and its conjugate acid at a particular wavelength and ϵ is the observed extinction coefficient at the same wavelength when the base is dissolved in an acidic solution, $[BH^+]/[B]$ is equivalent to $(\epsilon_B - \epsilon)/(\epsilon - \epsilon_{BH^+})$ (16). The reliability of this method rests on the assumption that the extinction coefficients are not subject to solvent effects and that no other reactions are occurring. Figure 1 illustrates a typical curve that may be obtained when ultraviolet spectroscopy is used to monitor the protonation of a weak base.

The use of nuclear magnetic resonance to estimate $[BH^+]/[B]$ relies on the *position* of the chemical shifts rather than the intensities of the signals (2, 12). If Δ_B and Δ_{BH^+} are the proton or carbon-13 chemical shifts for particular atoms of the base and its conjugate acid and Δ is the observed chemical shift when the base is dissolved in an acidic solution, $[BH^+]/[B]$ is equivalent to $(\Delta_B - \Delta)/(\Delta - \Delta_{BH^+})$ (2, 12). This method has the advantage that the occurrence of side reactions does not necessarily invalidate the measurement. It suffers, however, from the disadvantage that high concentrations of base, which are often required in order to obtain a measurable signal, may alter the properties of the solution. Figure 2 illustrates a curve typical of those that may be obtained by using nmr signals.

While it is usually quite straightforward to analyze the plots obtained when all of the properties (ϵ_B, ϵ_{BH^+}, and ϵ, or Δ_B, Δ_{BH^+}, and Δ) can be accurately measured, it is unfortunately true that for some of the most interesting and important reactions reliable direct measurements of either ϵ_{BH^+} or Δ_{BH^+} are impossible to obtain. For example, if the base is sufficiently weak, conditions may not exist under which it is both fully protonated *and* stable. In such cases one is faced with the challenge of analyzing a partial curve as in Fig. 3.

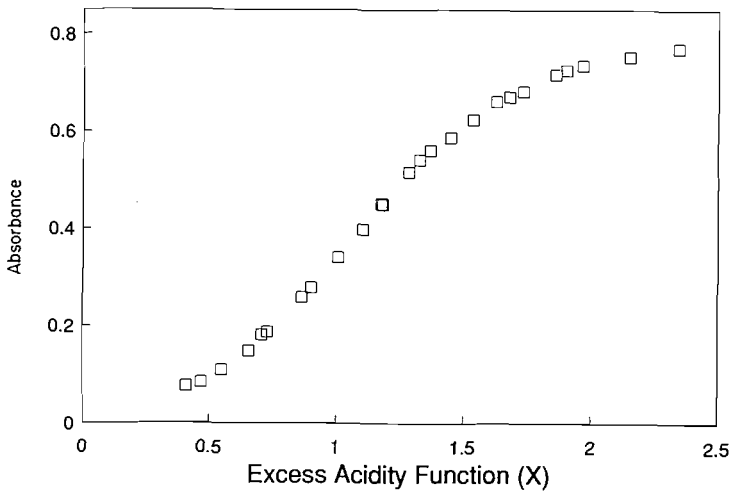

FIG. 1. Absorbance of a weak base as a function of the acidity of the medium.

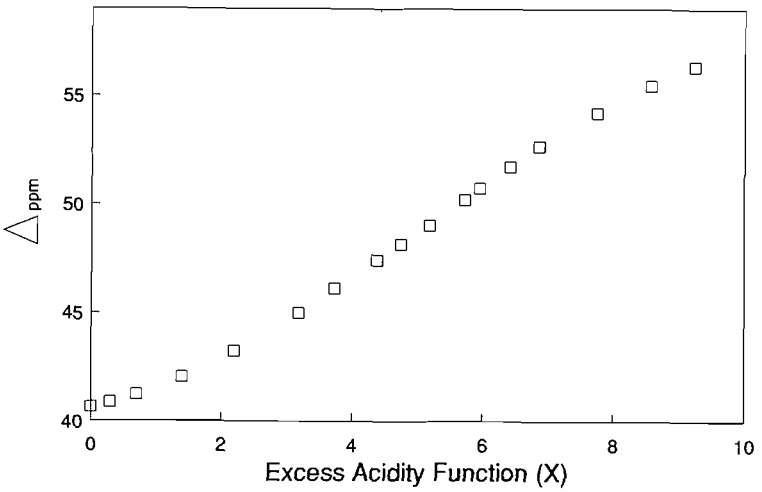

FIG. 2. Difference in C-13 chemical shifts (Δ) at C1 and C2 of an alcohol as a function of the acidity of the medium. Data up to near Δ_{BH^+} are available.

Several approaches may be considered when complete sigmoidal curves are not available. For example, attempts have been made to estimate Δ_{BH^+} by selecting the value that gives the best straight line when log $(\Delta_B - \Delta)/(\Delta - \Delta_{BH^+})$ is plotted against a known acidity function (2, 3, 6, 13). Alternatively, one may attempt to fit experimental values of Δ or absorbance to a known function of acidity and then determine the position of the inflection point (which will correspond to the situation where $[BH^+] = [B]$). If the sigmoidal curve is symmetrical, the vertical distance from the inflection point to Δ_{BH^+} should then be the same as that from Δ_B to the inflection point. In theory, the inflection point may be obtained by setting the second derivative of the function equal to zero and solving for acidity.

The most obvious type of function to use is a polynomial in excess acidity, X (eq. [3]). Such a function

$$[3] \quad \Delta = a_0 + a_1X + a_2X^2 + a_3X^3 + \cdots + a_nX^n$$

is easily fitted to experimental data and, for orders three or four, produces a simple second derivative (20).

An alternative is a function that is known to be sigmoidal. Examples are the hyperbolic tangent of [4] and the exponential ratio of [5].

$$[4] \quad \Delta = A \tanh (BX - C) + D$$

$$[5] \quad \Delta = \frac{A + BX\exp(CX + D)}{1 + X\exp(CX + D)}$$

Both of these can give Δ_{BH^+}) directly without the necessity of finding an inflection point. With [4], $\Delta_{BH^+} = A + D$, $\Delta_B = D - A$, and $\Delta_{inf} = D$. In the case of [5], $\Delta_{BH^+} = B$ and $\Delta_B = A$. Fitting these functions to the data is more complex than fitting [3] since they are not linear in the variable parameters A, B, C, and D. However, gradient techniques are available so that, with modern microcomputers, regression analysis is achievable (20, 21).

The principal goal of finding Δ_{BH^+} (or ϵ_{BH^+}) in this and earlier work was to find K_{BH^+} for a weak base such as an alcohol. With Δ_{BH^+} in hand, log $[BH^+]/[B]$ may be calculated, and the linear regression of [2] carried out. Determining K_{BH^+} and m^* then requires two regressions; one produces Δ_{BH^+} while the second gives pK_{BH^+} as the intercept of a straight line (eq. [2]). It would seem preferable to combine the two regressions into one.

Recognizing that $[BH^+]/[B]$ is equivalent to $(\Delta_B - \Delta)/(\Delta - \Delta_{BH^+})$, [2] can be rewritten in exponential form, [6],

$$[6] \quad \Delta = \frac{A + B[H^+]\exp(CX + D)}{1 + [H^+]\exp(CX + D)}$$

where $A = \Delta_B$, $B = \Delta_{BH^+}$, $C = 2.303m^*$, and $D = 2.303pK_{BH^+}$. All four of the desired basicity parameters are readily extractable from a regression involving only the experimental or derivable quantities Δ, X, and $[H^+]$.

This paper describes the successes we have had using the various functions to fit previously reported C-13 nmr data for some alcohols in sulphuric acid (2) and to obtain pK_{BH^+} values.

Experimental

The C-13 chemical shift (Δ) data for a series of aliphatic alcohols have been correlated with the excess acidity (X) using four functions (eqs. [3]–[6]). Values of X and $[H^+]$ for H_2SO_4 were taken from the work of Cox and Yates (18). Using gradient, least-squares algorithms (20, 21) discussed previously, computer programs were written in BASIC, C, or Pascal to handle all regressions on an MS-DOS computer; the basic gradient technique proved to be far faster and more reliable than simplex algorithms (6). Aside from the experimental data, only a preliminary guess for pK_{BH^+} was required. Initial values for the other variable parameters were then calculated from the appropriate equations using two data parts. Output included the final values of each variable and its uncertainty. While an 80×87 math coprocessor was not necessary its presence greatly accelerated the non-linear calculations.

Results

A fourth-order polynomial (eq. [3]) was successful in locating Δ_{BH^+} only if data were available well past the inflection point and nearly up to the Δ_{BH^+} plateau. Since such a function is useful only within the region of X spanned by experimental data; extrapolation is not possible. In several cases the second derivative either found a false inflection point or was unable to locate one at all. As a result the polynomial turned out to be an unreliable function when applied to real data of the type available.

Better success accompanied the use of the two sigmoidal functions (eqs. [4] and [5]). As Table 1 shows, these two give values for Δ_{BH^+} that are comparable with each other as well as with previously published results. Moreover, not only are the sigmoidal regressions faster than for other methods (2), the reported Δ_{BH^+} values are expected to be more reliable; plots of correlation coefficients vs. Δ_{BH^+} values usually have imprecise broad maxima. The hyperbolic tangent does not equate Δ_B to Δ ($X = 0$) since tanh is symmetric about the inflection point, and Δ_{BH^+} is between 2 and 5% lower than that obtained from the regression using [5]. Figure 4 illustrates how well the two functions correlate with experimental data, and how they can be extrapolated to give Δ_{BH^+}. Both regressions work even when experimental data are available only up to (or nearly up to) the inflection point, provided these data are reliable. Some of the alcohols reported earlier did not have enough sufficiently good data to allow analysis by either sigmoidal function (2).

Using the Δ_{BH^+} values obtained, the relationship defined by [2] was used to determine pK_{BH^+} and m^* (Table 2). Within the estimated error, the results of this and previous work are identical. The errors quoted for this work in Table 2 include both the uncertainty in Δ_{BH^+} and the error inherent in the linear regression. Those quoted by Lee and Demchuk (2) are for the linear regression alone.

The use of [6] obviates the need to estimate Δ_{BH^+} before obtaining m^* and pK_{BH^+}. In addition, there is less reason to limit data to $\log [BH^+]/[B] < 1.0$, or to use only acidity data below 84% H_2SO_4 where the dramatic decrease in $[H^+]$ at high acid concentration is avoided. To test this particular sigmoidal

regression, absorbance data for 2,5-dichloro-4-nitroaniline were used (18, 19). The results shown in Table 3 indicate that, even without calculating $[BH^+]/[B]$, quite acceptable values of pK_{BH^+} are obtained. As an added bonus, absorbances for the aniline and anilinium ion become available in spite of their not being measured directly.

Table 4 presents results from the use of [6] to analyze nmr data for seven alcohols. Of these, five — ethanol, 1-propanol,

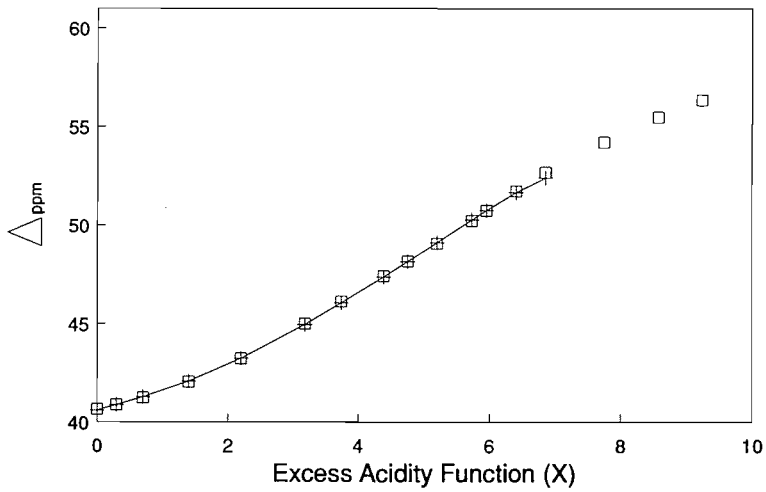

FIG. 5. Difference in C-13 chemical shifts (Δ) at C1 and C2 of ethanol as a function of the acidity of the medium. (□) Experimental data. (+) Regression curve from eq. [6].

2-propanol, 2-phenoxyethanol, and 2-nitroethanol — have values for Δ_{BH^+}, pK_{BH^+} and m^* that are virtually identical to those of previous work and those reported earlier in this paper. The apparently low errors quoted by Lee and Demchuk (2) are misleading because they refer only to the linear regression part of the analysis and assign no uncertainty to Δ_{BH^+}. 2-Chloroethanol and 2-bromoethanol did not give good regressions although they did not fall as when using the hyperbolic tangent (eq. [5]).

Conclusions

K_{BH^+} constants for weak bases such as alcohols and amines can be evaluated from nmr chemical shifts or from absorbance data for the bases in a strong acid if a non-linear regression is used to fit the data to the sigmoidal function of [6]. Alternatively, the property of the fully protonated conjugate acid (ϵ_{BH^+} or Δ_{BH^+}) can be obtained from sigmoidal functions like those of [4] or [5], and that property used in the standard way (eq. [2]) to calculate pK_{BH^+}. Sigmoidal regression offers a straightforward way of analyzing titration curves in general. It is especially useful when data are unavailable over the complete curve.

Rate constants for the addition of the enolate ion of acetone to quinolinium and acridinium cations

JOHN W. BUNTING, CYNTHIA FU,[1] AND JAMES W. TAM[2]

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received February 16, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

JOHN W. BUNTING, CYNTHIA FU, and JAMES W. TAM. Can. J. Chem. **68**, 1762 (1990).

The reaction of acetone with four heteroaromatic cations (10-methylacridinium (**1**), 3-aminocarbonyl-1-methylquinolinium (**2***a*), 3-cyano-1-methylquinolinium (**2***b*), and 3-bromo-1-methylquinolinium (**2***c*)) has been investigated in basic aqueous solutions (pH 9–12, ionic strength 0.1, 25°C). For each of **2***a* and **2***b*, the kinetically controlled product is a 35:65 mixture of the C-2 and C-4 enolate ion adducts; the C-2 adduct subsequently isomerizes to give the C-4 adduct as the only observable species under thermodynamic control. For **2***c*, the C-2 enolate adduct appears to be favoured both kinetically and thermodynamically. Under kinetic control, the pH-dependence of adduct formation from each cation is consistent with rate-determining attack of the enolate ion upon the heterocyclic cation. Comparisons of regiochemical control of acetone enolate ion attack with hydroxide ion attack upon these same cations indicate that acetone enolate ion shows a more pronounced preference for C-4 attack over C-2 attack than does hydroxide ion. The thermodynamically controlled regiochemistry is similar for each of these two nucleophiles.

Key words: nucleophilic addition, regioselectivity, kinetic control, thermodynamic control, quinolinium cations.

JOHN W. BUNTING, CYNTHIA FU et JAMES W. TAM. Can. J. Chem. **68**, 1762 (1990).

Opérant dans des solutions aqueuses basiques (pH de 9 à 12, force ionique de 0,1 et température de 25°C), on a examiné la réaction de l'acétone avec quatre cations hétéroaromatiques (10-méthylacridinium (**1**), 3-aminocarbonyl-1-méthylquinolinium (**2***a*), 3-cyano-1-méthylquinolinium (**2***b*) et 3-bromo-1-méthylquinolinium (**2***c*)). Pour les cations **2***a* ainsi que **2***b*, le produit de contrôle cinétique est un mélange 35:65 des adduits des ions énolates C-2 et C-4; l'adduit C-2 s'isomérise ultérieurement pour donner l'adduit C-4, la seule espèce observée sous contrôle thermodynamique. Pour le cation **2***c*, il semble que l'adduit énolate C-2 est favorisé tant d'un point de vue cinétique que thermodynamique. Sous contrôle cinétique, la relation entre le pH et la nature de l'adduit qui se forme à partir de chaque cation est en accord avec une étape déterminant la vitesse de la réaction qui implique l'attaque de l'ion énolate sur le cation hétérocyclique. Des comparaisons du contrôle régiochimique de l'attaque de ces cations par l'ion énolate de l'acétone avec celui de l'attaque par l'ion hydroxyde permet de montrer que, par comparaison avec ce qui est observé avec l'ion hydroxyde, l'ion énolate de l'acétone offre une nette préférence pour une attaque en C-4 plutôt qu'en C-2. Sous contrôle thermodynamique, la régiochimie des réactions de ces deux nucléophiles est très semblable.

Mots clés : addition nucléophile, régiosélectivité, contrôle cinétique, contrôle thermodynamique, cations quinolinium.

The addition of carbanionic nucleophiles to cationic heteroaromatic species is commonly used as a synthetic method for the introduction of side chains onto heterocyclic rings (1–5). Such additions to quinolinium cations are influenced by the usual C-2 vs. C-4 regiochemical considerations that complicate all such nucleophilic additions to these cations. Substituent effects, and considerations of kinetic and thermodynamic control, also constrain attempts to reliably predict the regiochemical outcomes of such processes. Quantitative investigations (6) of the addition of hydroxide ion to quinolinium cations in aqueous solutions have clarified these latter considerations for this one nucleophile. However, the general applicability of the results for hydroxide ion to other nucleophilic species remains an area of uncertainty.

We have demonstrated (7) that the rates and equilibria for the addition of the enolate ion of acetone to the 2-methyl-5-nitroisoquinolinium cation can be readily measured in aqueous solution. As a follow up, we have now investigated the addition of this nucleophile to the 10-methylacridinium cation (**1**) and also to several C-3 substituted 1-methylquinolinium cations (**2**). These data allow the first quantitative insight into many of the regiochemical considerations mentioned above for the reaction of a carbanionic nucleophile with quinolinium cations. In addition, these data, together with our earlier studies, provide further insight into the relative reactivities of acridinium, quinolinium, and isoquinolinium cations in their reactions with nucleophilic addends.

c: W = Br

Experimental

Bromide salts of the *N*-methyl quinolinium cations (**2**.Br^-) and 10-methylacridinium chloride (**1**.Cl^-) were available from earlier studies in our laboratories (6, 8). Acetone was HPLC Grade (99.9 + %) supplied by Aldrich Chemical Co. Buffer solutions were prepared using $NaHCO_3/Na_2CO_3$ for pH 9.0–10.8 and standard solutions of KOH adjusted to ionic strength 0.1 with KCl for pH ≥ 11.0. The pH values of all solutions were measured at the end of each kinetic run with a Radiometer PHM82 pH meter equipped with a GK2401B combination electrode.

All kinetic studies were done in buffered aqueous solutions of ionic strength 0.1 at 25°C. All reactions were followed spectrophotometrically under pseudo-first-order conditions on a Varian Cary 210 spectrophotometer, with digitized absorbance data being recorded on a Commodore 4048 computer. Data were collected for at least 95%

[1]Recipient of a 1988 NSERC Summer Bursary for Undergraduate Research.

[2]Recipient of a 1985 NSERC Summer Bursary for Undergraduate Research.

of each reaction, and were accurately first-order for at least three half-times. Pseudo-first-order rate constants were calculated by fitting the absorbance (A) at time (t) to the relationship:

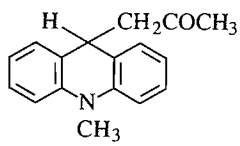
$$A = A_f + (A_i - A_f) \exp(-k_{obs}t)$$

via the Marquardt algorithm, treating the initial absorbance (A_i), the final absorbance (A_f), and the pseudo-first-order rate constant as parameters to be evaluated. Data at each pH were collected for at least five acetone concentrations in the range 0.09–0.50 M. Analytical wavelengths and concentrations used for kinetic studies on each cation were: **1** — 420 nm, 0.17 mM; **2***a* — 355 nm, 0.060 mM; **2***b* — 345 nm, 0.05 mM; **2***c* — 370 nm, 0.40 mM.

Results

*10-Methylacridinium cation (**1**)*

We have isolated a colourless oil upon prolonged treatment of an aqueous solution (pH 8.5) of 10-methylacridinium chloride with a large excess of acetone. This product displayed an ^{1}H nmr spectrum that is consistent with the structure of the adduct (**3**) from the addition of the enolate ion of acetone to C-9 of the 10-methylacridinium cation: δ 1.87 (s, 3H, CH_3CO), 2.64 (d, J = 7 Hz, 2H, CH_2), 3.40 (s, 3H, N-CH_3), 4.42 (t, J = 7 Hz, 1H, C(9)—H), 6.7–7.4 (m, 8H, aromatic H) (in $CDCl_3$). The electronic absorption spectrum of this product showed an intense maximum at 284 nm (log ε = 4.09) (in acetonitrile) which is similar to the spectrum of related 9,10-dihydroacridine derivatives (9–11); e.g., 9,10-dihydroacridine, itself, has λ_{max} = 289 nm (log ε = 4.14) (in ethanol (9)).



3

The conversion of the 10-methylacridinium cation into its acetone adduct could be conveniently monitored from the time-dependence of the characteristic absorption spectrum of this cation in the range 320–450 nm. The spectrum of this cation in the presence of a large excess of acetone gradually decayed in the vicinity of pH 9–10, and was replaced by an intense increase in absorption in the vicinity of 290 nm. The strong background absorption from the relatively high concentrations of acetone required in these experiments prevented the direct observation of the absorption maximum of the adduct produced. The time-dependence of the absorbance at 420 nm proved to be cleanly first-order in acridinium cation concentration. Pseudo-first-order rate constants (k_{obs}) were evaluated at a number of acetone concentrations in the range 0.1–0.5 M at pH 9.13, 9.57, and 10.12. In less basic solutions, the addition reaction became too slow for convenient rate measurements, while experiments in more basic solutions were precluded by the competition from C-9 pseudobase formation by hydroxide ion addition to the 10-methylacridinium cation (pK_{R^+} = 10.01 at 25°C, ionic strength 0.1 (12)).

The pseudo-first-order rate constants proved to be linear in acetone concentration with ordinate intercepts being zero within experimental error. Apparent second-order rate constants (k_f), calculated from the slopes of k_{obs} vs. [acetone], are given in Table 1.

*3-Aminocarbonyl-1-methylquinolinium cation (**2**a)*

The electronic absorption spectrum of this cation in aqueous base (pH 9–12) undergoes a dramatic time-dependent change in the presence of acetone (0.05–0.5 M). The major observation is the growth of an absorption maximum at 348 nm which is accompanied by a much less intense shoulder in the vicinity of 410 nm. This long wavelength absorbance eventually reaches a maximum value having an apparent extinction coefficient of ≈1000, which is independent of both pH and acetone concentration. At this stage, the apparent extinction coefficient at λ_{max} = 348 nm is ≈10000. The shoulder near 410 nm subsequently disappears in a much slower process, and this change is accompanied by a further intensifying of the absorption maximum at 348 nm which approaches a final ε ≈ 15000.

We have investigated the rates of the initial reaction described above as a function of both pH and acetone concentration, but have not attempted a quantitative investigation of the second, much slower, reaction in the present work. The rate of initial increase in absorbance at 348 nm proved to be cleanly first-order in quinolinium cation concentration. Pseudo-first-order rate constants were linear in acetone concentration with ordinate intercepts that were experimentally indistinguishable from zero. Second-order rate constants (k_f) were evaluated from the slopes of such plots, and are included in Table 1 at various pH.

Several 3-aminocarbonyl-1,4-dihydroquinolines have been well characterized and in general have intense absorption maxima in the vicinity of 340 nm (13–17); for instance, 3-aminocarbonyl-1-benzyl-1,4-dihydroquinoline has λ_{max} = 343 nm (ε = 13100) in water (15). The assignment of the product species displaying λ_{max} = 348 nm (ε ≈ 15000) as the adduct (**4**) that is formed by the addition of the enolate ion of acetone to C-4 of **2***a* appears quite reasonable. The shoulder appearing near 410 nm is most likely due to the presence of the isomeric C-2 adduct (**5**). We have been unable to locate a well characterized example of a 3-aminocarbonyl-1,2-dihydroquinoline in the literature for comparison, however it is known that related 3-ethoxycarbonyl- and 3-cyano-1,2-dihydroquino-

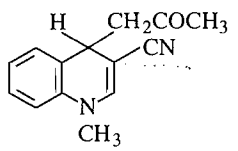
lines do display absorption maxima in the 400–420 nm range (13, 18).

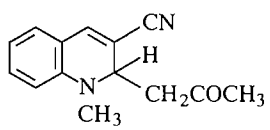
3-Cyano-1-methylquinolinium cation (2b)

In basic aqueous solutions, this cation exists in equilibrium with a mixture of its C-2 and C-4 pseudobases, with the C-4 hydroxide adduct (λ_{max} = 304 nm) predominating in a 26:1 ratio over its C-2 isomer (6). Addition of acetone to basic solutions (pH 8–11) of this cation produces a species which has maximum absorbance at 402 nm. The increasing concentration of this species can be readily followed in successive spectrophotometric scans (Fig. 1). The absorbance in this region reaches a maximum value with an apparent extinction coefficient ≈ 1000. The intensity of this maximum value is independent of pH and acetone concentration (0.1–0.5 M). At much longer reaction times, this long wavelength absorbance slowly decays. The initial increase in absorbance in the vicinity of 400 nm is accompanied by a significant decrease in the range 300–320 nm, while the following decrease in absorbance near 400 nm is accompanied by an increase in the region 300–320 nm. Unfortunately, the background absorption due to the high concentrations of acetone that are required in these reactions obscures accurate spectral observations in the vicinity of 300 nm.

The long wavelength absorption of λ_{max} = 402 nm is typical of that of a 3-cyano-1,2-dihydroquinoline derivative; for instance, 3-cyano-1,2-dihydro-1-methylquinoline is reported to have λ_{max} = 410 nm in ethanol (13) and 416 nm in 4:1 2-propanol–water (16). We therefore assign the species having λ_{max} = 402 nm as the product (7) of the addition of the acetone enolate ion to C-2 of the 3-cyano-1-methylquinolinium cation. The isomeric 3-cyano-1,4-dihydroquinoline (**6**) is expected to have λ_{max} in the vicinity of 320–330 nm as do related species bearing this same chromophore; e.g. 3-cyano-1,4-dihydroquinoline has λ_{max} = 325 or 327 nm in ethanol (13, 19), while its N-methyl derivative displays λ_{max} = 333 nm in methanol (19) and 334 nm in 4:1 2-propanol–water (18).



6



7

Rates of the reaction of acetone with **2***b* were most conveniently monitored at 345 nm. In the presence of excess acetone (0.1–0.5 M), these reactions were strictly first-order in quinolinium cation concentration, and values of k_{obs} and k_f (see Table 1) were evaluated as described above for **2***a*.

3-Bromo-1-methylquinolinium cation (2c)

This cation reacts with acetone in aqueous base to give a product having an absorption maximum near 330 nm. Successive spectral scans of this ongoing reaction show a clean isosbestic point at 333 nm. There is no increase in absorbance in the vicinity of 400 nm as reported above for **2***a* and **2***b*. These

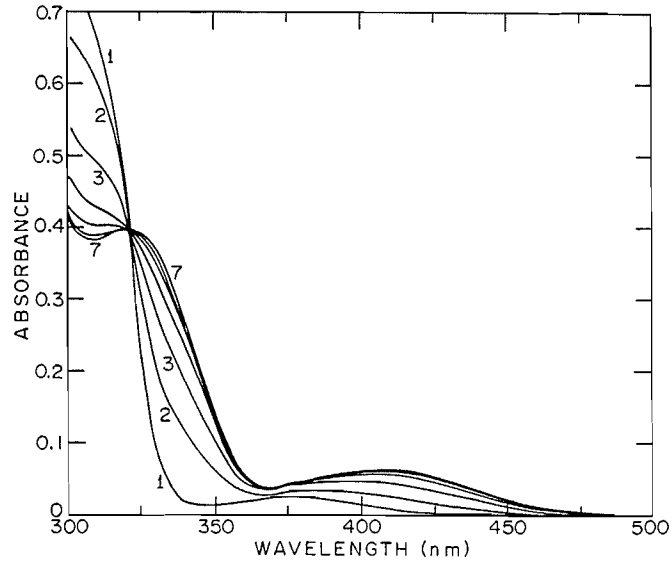


FIG. 1. Time-dependence of the electronic absorption spectrum of **2***b* (0.05 mM) in the presence of acetone (0.55 M) at pH 11.55 (cell path = 1 cm). Curves 1–7 are at 0, 2, 6, 12, 18, 24, and 36 min, respectively after mixing. The subsequent much slower decay of the absorbance in the vicinity of 400 nm is not shown.

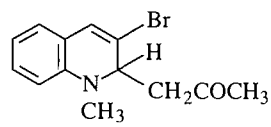
observations indicate a simple equilibration of **2***c* with a single acetone enolate adduct in this case. We assign this product as the C-2 adduct (**8**) by analogy with absorption maxima in the range 333–344 nm for other 3-bromo-1,2-dihydroquinolines (6).



8

The 3-bromo-1-methylquinolinium cation (**2***c*) was unique in the current study in that plots of k_{obs} vs. [acetone] display significant ordinate intercepts at low pH (Fig. 2). Such plots are described by eq. [1]. Values of k_f and k_d for **2***c* are included in Table 1. Cation **2***c* was also the only cation in the current study to display an equilibrium absorbance which increased with both acetone concentration and solution pH. Such observations are consistent with equilibrated solutions of **2***c* with acetone containing significant amounts of both **2***c* and **8**.

$$[1] \quad k_{obs} = k_f[\text{acetone}] + k_d$$

Extensive attempts to characterize the acetone adducts from **2***a*, **2***b*, and **2***c* by ^{1}H nmr spectroscopy were unfruitful. Complex multi-component spectra were obtained both for isolated products, and also for in situ observations (in D_2O + CD_3COCD_3 containing Na_2CO_3), from the reactions of these cations with acetone in aqueous base. The presence of pseudobase species, and also disproportionation products of these pseudobase species, extensively contaminated the acetone adducts from reactions at high concentrations of these quinolinium cations in aqueous base. The presence of time-dependent ratios of the isomeric 1,2-dihydro- and 1,4-dihydro-quinoline acetone adducts, which are indicated by electronic absorption spectroscopy for **2***a* and **2***b*, even further complicates attempts at ^{1}H nmr spectral observations in these systems.

No reaction between acetone and the 1-methylquinolinium cation (**2**: W = H) was observed by electronic absorption

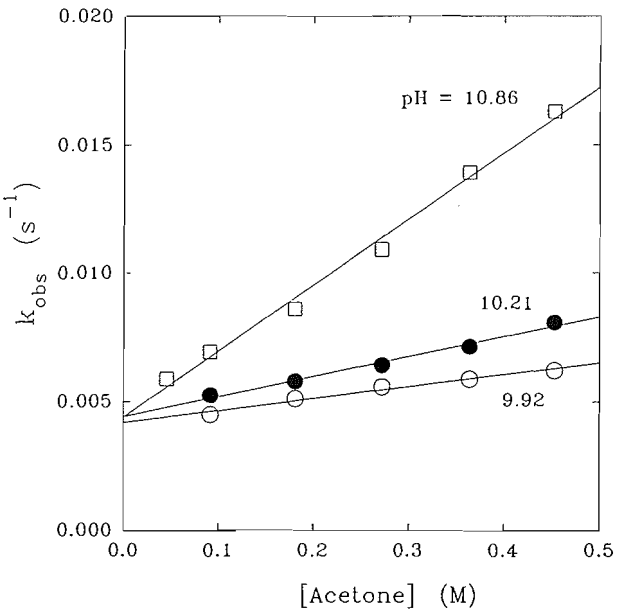

FIG. 2. The dependence of k_{obs} upon acetone concentration for the reaction of **2***c* at various pH (ionic strength 0.1, 25°C).

spectroscopy in basic aqueous solutions. We attribute this result to an unfavourable equilibrium constant under the current experimental conditions.

Discussion

There are many claims in the literature for the isolation of addition products from the reaction of nitrogen heteroaromatic cations with acetone and related carbon acids (20–41). However, there do not seem to have been any attempts to investigate such reactions in a systematic manner, and in cases where isomeric adducts are possible, such as for pyridinium and quinolinium cations, it is usually unclear whether the reported products are obtained under kinetic or thermodynamic control. In such cases, even the structure assignments are sometimes uncertain. We have been unable to locate any report of a quantitative study of rate or equilibrium constants for such reactions, other than our own earlier report (7) for the addition of the acetone enolate ion to the 2-methyl-5-nitroisoquinolinium cation.

The addition of the anionic conjugate bases of many carbon acids to C-9 of acridinium cations has been reported (26, 27). Although we could find no report of the addition of the enolate ion of acetone to the *N*-methyl acridinium cation, the 9,10-dihydroacridine addition products have been isolated from the reaction of the enolate ion of acetophenone and related ketones with this acridinium cation in basic media (27). Interestingly, acetone and many related ketones have been added to acridine, itself, in basic methanol to give 9-substituted 9,10-dihydroacridines in good yield (10, 11). The adduct (**3**) has been isolated in the current work, and was unambiguously characterized by ^{1}H nmr spectroscopy as the product from the reaction of **1** with acetone in aqueous base.

Products have been isolated from the addition of the conjugate bases of many carbon acids to a number of *N*-substituted quinolinium cations (20–22, 25, 28–33). The structures of these products have usually been assumed to be 1,2-dihydroquinolines, although 1,4-dihydroquinoline structures have occasionally been established. The products obtained from the reactions of the *N*-(2,6-dichlorobenzyl) quinolinium cation in basic ethanol have been unambiguously established as the C-2 adduct from the addition of the enolate ion of acetone, but the C-4 adduct from the enolate ion of 4-nitroacetophenone (31). The addition of the enolate ion of acetone to the *N*-methyl quinolinium cation in basic ethanol has been claimed (30) to occur at C-4, however, the reported λ_{max} = 350 nm for this product clearly indicates (42, 43) that it must be a 1,2-dihydroquinoline rather than a 1,4-dihydroquinoline.

We could locate no previous reports of the addition of the conjugate base of a carbon acid to **2***a*, **2***b*, or **2***c*. The C-4 adducts have been isolated from reactions of the conjugate bases of a variety of strongly activated carbon acids with the 1-methyl-3-nitroquinolinium cation (32). It seems likely that these C-4 adducts are the thermodynamic products of these reactions since the C-4 hydroxide adduct of this same cation predominates over its C-2 isomer at equilibrium by 180:1 (6). We have shown above that the electronic absorption spectra of the equilibrium products from the reaction of both **2***a* and **2***b* with acetone enolate ion are predominantly 1,4-dihydroquinolines, and this observation is also consistent with the thermodynamic preference that is found for hydroxide ion addition to these two cations (6). 3-Cyano-1,2-dihydro-1-methylquinoline has also been shown to be thermodynamically less stable than its 1,4-dihydro isomer (18). The C-2 addition of the enolate ion to **2***c* is also similar to the observed thermodynamic preference for hydroxide ion addition at C-2 of the 3-bromoquinolinium cation.

The uv–visible spectral observations for the reactions of each of **2***a* and **2***b* with acetone are consistent with the competitive addition of the enolate ion at C-2 and C-4 under the initial kinetic control, with the C-2 adduct being subsequently slowly converted into its C-4 isomer. The general appearance of the spectra of the kinetic products is somewhat misleading as a guide to the relative amounts of C-2 and C-4 addition products, because of the very large difference in magnitude of the extinction coefficients of these isomeric species. For instance, 3-cyano-1,4-dihydro-1-methylquinoline has ϵ = 12000 at 334 nm whereas its 1,2-dihydroquinoline isomer has ϵ = 2800 at 416 nm (18). Thus the absorption maximum in the vicinity of 400 nm for the 3-substituted 1,2-dihydroquinolines has only about 25% of the intensity of the long wavelength maximum near 350 nm for their 1,4-dihydro isomers.

The observations reported in the Results section allow at least an approximate estimation of the ratio of the concentrations of the C-2 and C-4 adducts from each of **2***a* and **2***b* when the initial addition is complete. This ratio will represent the kinetically controlled product mixture, and can be used as described below to estimate individual rate constants for nucleophilic attack by the enolate ion at C-2 and C-4 from the observed second-order rate constants.

On the assumption that ϵ = 2800 at λ_{max} = 416 nm that was reported (18) for 3-cyano-1-methyl-1,2-dihydroquinoline is typical of the intensity of the long wavelength absorption maximum of such species, we can use $\epsilon \approx 1000$ at λ_{max} = 402 nm to estimate that the kinetically controlled product mixture from **2***b* and acetone contains 35% of the C-2 adduct (**7**) and 65% of the C-4 adduct (**6**). The initial decrease in absorbance that we report in the vicinity of 300–320 nm at the start of this reaction then represents the conversion of some of the predominant C-4 hydroxide adduct of **2***b* into the C-2 acetone adduct. The subsequent increase in absorbance at 300–320 nm that is concomitant with the decay in absorbance at 402 nm then represents the increase in concentration of **6** at

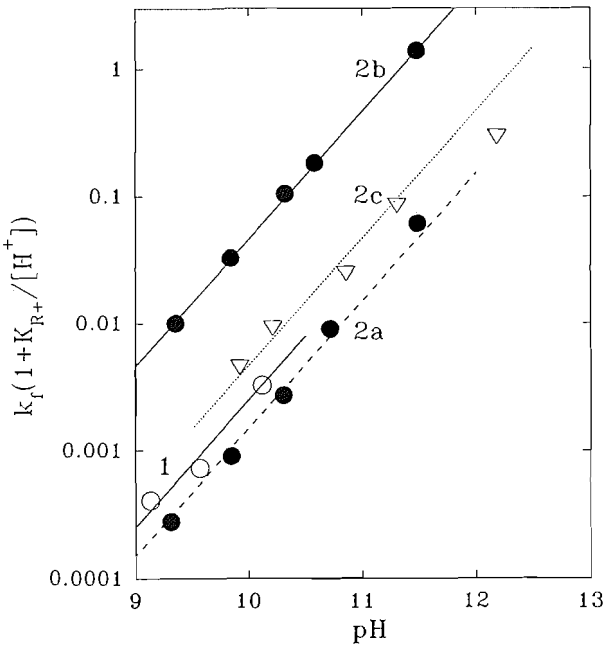

FIG. 3. pH dependence of $k_f(1 + K_{R^+}/[H^+])$ for each of **1**, **2***a*, **2***b*, and **2***c*. Lines are drawn with slope = 1.

the expense of **7** as the final equilibrium mixture is reached. A similar ratio of 35% of the C-2 adduct (**5**) and 65% of **4** in the kinetically controlled product from **2***a* may also be made from the kinetic product and final product absorbances at 348 nm, if it is assumed that **5** does not make a large contribution to the absorbance at this wavelength. We have been unable to locate accurate extinction coefficients for any 3-aminocarbonyl-1,2-dihydroquinolines in the literature. However, this approximate estimate of the product ratio is also supported by the similar intensity of the shoulder at 410 nm in the kinetic product from **2***a* to that of the maximum at 402 nm in the spectrum of the kinetic product from **2***b*.

Kinetic analysis

The equilibration of the cations (R^+) with their acetone enolate ion adducts (RC) can be represented by eq. [2].

[2] $R^+ + CH \rightleftharpoons RC + H^+$

Kinetic studies of all cations, with the exception of **2***c*, were under conditions in which this equilibrium heavily favours the adduct. Under these conditions, the experimentally measured rate constants, k_{obs} and k_f, are defined by eqs. [3] and [4], where ROH is the hydroxide adduct (pseudobase) which is in equilibrium with R^+ in these basic solutions.

$$[3]\quad \frac{d[RC]}{dt} = k_{obs}([R^+] + [ROH])$$

$$[4]\quad = k_f[CH]([R^+] + [ROH])$$

$$[5]\quad = k_f[CH][R^+](1 + K_{R^+}/[H^+])$$

The pH-dependence of the second-order rate constant, k_f, after correction for the presence of ROH, is shown for each cation in Fig. 3. From this figure, it is clear that $k_f(1 + K_{R^+}/[H^+])$ is proportional to hydroxide ion concentration, and eq. [5] can be rewritten as eq. [6]. Values of k_3 were evaluated for each cation from the data in Fig. 3, and are listed in Table 2. The third-order rate constants were converted to second-order rate constants (k_2 in Table 2) for the attack of the enolate ion on the heterocyclic cation according to eq. [7], where $pK_a = 19.16$ for acetone in aqueous solution (44), and K_w is the ionic product of water.

TABLE 2. Values of k_3 and k_2 for the reaction of heterocyclic cations with acetone[a]

Cation	k_3 (M^{-2} s^{-1})	k_2 (M^{-1} s^{-1})
1	25 (±5)	3.6×10^6
2*a*	15 (±3)	2.2×10^6
2*b*	460 (±50)	6.6×10^7
2*c*	47 (±10)	6.8×10^6
9[b]	38	5.5×10^6

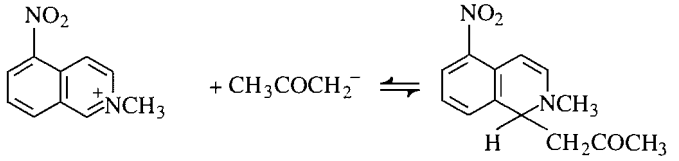
[a]In aqueous solution at 25°C, ionic strength 0.1. k_2 and k_3 are defined by eqs. [6] and [7].
[b]Data from ref. 7.

$$[6]\quad \frac{d[RC]}{dt} = k_3[^-OH][CH][R^+]$$

$$= (k_3K_w/K_a)[C^-][R^+]$$

$$[7]\quad = k_2[C^-][R^+]$$

For **2***a* and **2***b*, k_2 is the sum of the individual second-order rate constants for enolate ion attack at C-2 and C-4 to give the kinetically controlled product mixture. For these two cations, k_2 can be apportioned using the ratio of 35% of C-2 adduct to 65% of C-4 adduct that is estimated above for these two cations. The true second-order rate constants (k_{Nu}) for enolate ion attack at individual sites in each of the cations under study are listed in Table 3, along with literature data for the related hydroxide ion reactions, and also data from our earlier study (7) of acetone addition to the 2-methyl-5-nitroisoquinolinium cation (**9**).



9

The 3-bromo-1-methylquinolinium cation is the only electrophile in the current study for which we were able to observe an equilibrium mixture containing significant amounts of both RC and R^+. In this case the pH-independent (see Table 1) k_d of eq. [1] represents the first-order rate constant for the uncatalyzed expulsion of the enolate ion from adduct **8**. This value $k_d = 0.0043\ s^{-1}$ allows the calculation of the pH-independent equilibrium constant $K_{HNu} = [H^+][RC]/[R^+][CH] = k_2K_a/k_d = 1.1 \times 10^{-10}$ for reaction [2]. The values of k_{Nu}, k_d, and K_{HNu} that are found in the current study for C-2 attack of acetone enolate ion on **2***c*, are all quite similar to the values of these parameters that were found (7) for the same reaction at C-1 of (**9**) ($k_{Nu} = 5.5 \times 10^6\ M^{-1}\ s^{-1}$, $k_d = 1.9 \times 10^{-3}\ s^{-1}$, $K_{HNu} = 2.0 \times 10^{-10}$). These observations seem to be a reflection of the similar pK_{R^+} values for hydroxide ion addition to these two cations ($pK_{R^+} = 12.34$ for **2***c* (6) and 11.7 for **9** (45)).

Table 3 presents detailed comparisons of the rate constants for hydroxide ion and acetone enolate ion attack upon the five heteroaromatic cations for which quantitative data are now available. The k_{Nu}/k_{OH} ratio is similar for C-2 attack in quinolinium cations (**2**) and C-1 attack in the isoquinolinium cation (**9**). We suspect that the somewhat smaller values for this ratio for **2***a* and **2***b* are possibly influenced by steric interactions

between the enolate ion and the C-3 substituents in **2***a* and **2***b*. Of particular interest are the enhanced k_{Nu}/k_{OH} ratios that are observed for C-4 attack on quinolinium cations and C-9 attack on the acridinium cation in comparison with these ratios for C-2 attack upon the quinolinium cations. This 100-fold enhancement in the relative rates of formation of 1,4-dihydro derivatives when compared with the formation of their 1,2-dihydro isomers is reminiscent, at least qualitatively, of similar rate enhancements for C-4 attack over C-2 attack that are found (16, 46) in the formal hydride transfer from 1,4-dihydronicotinamides to quinolinium cations.

These regiochemical differences in relative rates of hydroxide ion and acetone enolate ion attack upon quinolinium cations are determined by different regioselectivities for these two nucleophiles in the formation of C-2 and C-4 adducts under kinetic control. Whereas reactions of hydroxide ion with **2***a* and **2***b* show approximately a 40-fold preference for C-2 attack over C-4 attack under kinetic control, the nucleophilic attack of the acetone enolate ion upon these two cations occurs approximately twice as fast at C-4 as at C-2. With both nucleophiles, thermodynamic control favours the 1,4-dihydro derivatives from both **2***a* and **2***b*.

Although in principle the acetone enolate ion is an ambident nucleophile, it is clear from the data in Table 3 that the formal oxyanion is unlikely to be able to compete effectively with the carbanionic centre as the attacking nucleophile. In all cases the enolate ion is more reactive than hydroxide ion ($k_{Nu} > k_{OH}$). This observation can only be interpreted as nucleophilic attack by carbon, since the oxyanion of the enolate ion is less basic than hydroxide ion ($pK_a = 10.96$ for the enol of acetone in aqueous solution (44)) and should therefore also be less nucleophilic than hydroxide ion.

The current study provides the first quantitative data of which we are aware for the regiochemical preferences of a carbanion in its nucleophilic addition to quinolinium cations. These data should provide a reasonable guide for the analysis of reactions of related carbanionic species with these cations until such time as a more comprehensive rate and equilibrium analysis of such reactions becomes available.

Kinetics and mechanism of the bromination of phenols in aqueous solution. Evidence of general base catalysis of bromine attack

OSWALD S. TEE[1] AND N. RANI IYENGAR

Department of Chemistry and Biochemistry, Concordia University, Montreal, P.Q., Canada H3G 1M8

Received April 5, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

OSWALD S. TEE and N. RANI IYENGAR. Can. J. Chem. **68**, 1769 (1990).

The reactions of bromine with phenol, 4-bromophenol, and 4-methylphenol (*p*-cresol) in aqueous solution are catalyzed by carboxylate anions, confirming the suggestions of earlier work. The results are consistent with deprotonation of the phenol hydroxyl group by a general base occurring at more or less the same time as electrophilic attack by molecular bromine. Possible origins of the general base catalysis are discussed. Combined with earlier results, the present findings suggest that a *protonated* cyclohexadienone is not a mandatory intermediate in phenol bromination; it can be avoided in both the formation of and enolization of the cyclohexadienone intermediate by general catalysis.

Key words: bromination, phenol, mechanism, catalysis, kinetics.

OSWALD S. TEE et N. RANI IYENGAR. Can. J. Chem. **68**, 1769 (1990).

Les réactions du brome avec le phénol, le 4-bromophénol et le 4-méthylphénol (*p*-crésol), en solution aqueuse, sont catalysées par les anions carboxylates; cette observation confirme les suggestions faites antérieurement. Les résultats sont en accord avec un mécanisme impliquant une déprotonation du groupement hydroxyle du phénol par une base générale qui se produirait pratiquement en même temps que l'attaque électrophile par le brome moléculaire. On discute des origines possible de la catalyse basique générale. Si l'on combine les résultats actuels avec ceux obtenus antérieurement, on peut suggérer qu'une cyclohexadiènone *protonée* n'est pas un intermédiaire nécessaire dans la bromation du phénol; cet intermédiaire peut être évité par la formation et par l'énolisation de l'intermédiaire cyclohexadiènone par une catalyse générale.

Mots clés : bromation, phénol, mécanisme, catalyse, cinétique.

The importance of acid–base catalysis for a large number of reactions occurring in aqueous solution is firmly established (1). Many reactions which are sluggish or non-existent in other media are facilitated by the ease of proton transfers in water, thereby allowing highly unfavorable intermediates to be stabilized or avoided (1, 2). As reported herein, such may be the case with phenol bromination in aqueous solution.

Several recent studies in this laboratory have been concerned with the mechanism of bromination of phenol derivatives in aqueous solution (3–9). Some of these studies dealt mainly with electrophilic bromine attack (3, 4), while others were devoted to the enolization or debromination of transient bromocyclohexadienones (5–9). Three studies, in particular, suggested that bromine attack may be catalyzed by general bases.

Firstly, we found that salicylate (*o*-hydroxybenzoate) anions (**1**) have an enhanced reactivity towards bromine and a reduced selectivity (less negative ρ^+), when compared to analogous, monosubstituted phenols (3*b*). As a result, we argued that the attack of bromine on salicylate anions is intramolecularly catalyzed by their *ortho* carboxylate groups (reaction [1]).

[1] 
1 **2**

Secondly, it was observed that the bromide ion-induced debromination of labile 4-bromo-4-alkyl-2,5-cyclohexadienones (*ipso*-dienones) (**3**, reaction [2]) is catalyzed by general acids (6). This observation, through the Principles of Microscopic Reversibility and of Detailed Balance (10*a*), implies that the reverse reaction, bromine attack *ipso* to the alkyl group of the *p*-alkylphenol (**4**), is catalyzed by general bases (reaction [2]).

[2] 
3 **4**

Complementary to these conclusions, we also found that debromination of the *ipso*-dienone **5** by bromide ion is strongly catalyzed by the internal carboxyl group (reaction [3]) (3*b*, 6, 9).[2]

[3] 
5

Since three, quite distinct studies strongly suggested that the attack of bromine on phenols is catalyzed by general bases, we have looked for buffer catalysis in the aqueous bromination of phenol and two derivatives.

Results

The fast reactions of phenols with bromine in aqueous

[1]Author to whom correspondence may be addressed.

[2]Debrominations of the *ipso*-dienones **3** are also strongly catalyzed by α-cyclodextrin (7), as is that of the salicylate derivative **5** (9). In the latter case, the combination of the two types of catalysis results in an overall rate enhancement of about 12 million (9).

TABLE 2. Effect of buffers on the rate of the bromination of phenol[a,b]

[Buffer], M		k_1^{obsd}, s^{-1}	
Acetate:	pH = 4.26	4.86	5.36
0.025	28.2	34.7	53.8
0.050	28.7	35.8	57.3
0.075	30.8	38.6	61.0
0.100	32.6	40.7	63.7
Slope (M^{-1} s^{-1}) =	61 ± 9	83 ± 9	134 ± 6
r =	0.9752	0.9878	0.9979
Propionate:	pH = 4.28	4.53	5.06
0.010	25.6	27.1	38.5
0.025	26.8	29.1	39.6
0.050	28.9	31.3	43.2
0.075	31.5	35.3	
0.100	34.1	37.8	50.3
Slope (M^{-1} s^{-1}) =	95 ± 3	120 ± 6	135 ± 7
r =	0.9984	0.9963	0.9971

[a]At 25°C, [phenol]$_0$ = 0.50 mM, [Br_2]$_0$ = 0.05 mM, and total I = 1.00 M = [NaCl] + [buffer salt] + 0.50 M KBr. The "slope" is from a least squares analysis of k_1^{obsd} vs. [buffer], its error is its standard deviation; r is the correlation coefficient.
[b]The data for acetate buffers are presented in Fig. 1. Buffer catalysis was also observed with succinate, methoxyacetate, and chloroacetate buffers.

solution follow second-order rate laws: first-order in substrate and in bromine (3, 4, 11, 12). For the present work rates were measured as the first-order disappearance of bromine, in the presence of an excess of the substrate and a large excess of bromide ion.[3] In some cases observed first-order rate constants (k_1^{obsd}) were converted to second-order constants (k_2^{obsd}), assuming there is no reaction with tribromide ion (13), which is true for phenols but not always true for very reactive phenoxide anions (4). For comparative purposes, we also studied the rates of bromination of anisole (methoxybenzene) and of 2-pyridone, which also show second-order kinetics in their reactions with bromine (14, 15). Depending on the pH of the medium, phenols react with bromine either as such or by way of their anions (3, 4, 11, 12); the same is true of 2-pyridone (15). Therefore, in order to maximise our chances of observing general base catalysis,

[3]The practical reasons for using high concentrations of bromide ion have been given previously (13).

TABLE 3. Effect of buffers on the rate of bromination of 4-methylphenol and 4-bromophenol[a]

Buffer	pH	[Buffer], M	r	Slope, M^{-1} s^{-1}
4-Methylphenol:				
cyanoacetate	2.52	0.025–0.10	0.9997	59 ± 1
chloroacetate	3.11	0.025–0.10	0.9975	51 ± 4
acetate	4.83	0.025–0.10	0.9968	92 ± 5
acetate	5.35	0.025–0.10	0.9998	104 ± 2
4-Bromophenol:[b]				
chloroacetate	2.65	0.050–0.20	0.9822	0.5 ± 0.06
succinate	4.29	0.025–0.10	0.9971	2.6 ± 0.2
acetate	4.85	0.025–0.10	0.9997	20 ± 0.5

[a]As in Table 2.
[b][Substrate]$_0$ = 0.1 mM; [Br_2]$_0$ = 0.01 mM.

we carried out experiments at pHs near the changeover between the two reaction modes (e.g. see Fig. 1, ref. 4*b*).

The rates of bromination of anisole and of 2-pyridone are *not* affected by the concentration of an acetate buffer, at fixed pH (Table 1). In sharp contrast, the values of k_1^{obsd} for the bromination of phenol, 4-methylphenol (*p*-cresol), and 4-bromophenol all show linear dependences on the concentration of several carboxylate buffers (Tables 2 and 3). Some examples are plotted in Fig. 1. Note that the slopes of the plots in Fig. 1 (and Table 2) increase with pH, so that the active form of the buffer is the anion, implying that bromine attack occurs with general base catalysis. From the buffer slopes, and assuming that water functions in the same way, we estimate a Brønsted β (1) of ~0.4 for this catalysis.[4]

Discussion

The absence of any buffer catalysis in the case of the bromination of anisole and of 2-pyridone (Table 1) rules out the possibility that bromine reacts with the buffer anion to produce another, more reactive electrophile. Such has been postulated from time to time in the literature, and has been cited by some textbooks and reviews. In particular, it has been proposed that an acyl hypobromite, formed from bromine and the buffer anion [4], might be the brominating agent.[5] Certainly, on the basis

[4] $RCCO^- + Br_2 \rightleftharpoons RCOOBr + Br^-$

of leaving group abilities, one expects Br—Br to be a much more reactive brominating agent than an acyl hypobromite, RCOO—Br (16).[6]

The bromination of the three phenols studied here (Tables 2 and 3) show catalysis by buffer anions. This is *not* due to the known buffer catalysis of the enolization of bromocyclohexadienone intermediates (5). Under the chosen reaction conditions,

[4]From the slopes in Table 2 the estimated catalytic coefficients are acetate, 185 M^{-1} s^{-1}; propionate, 290 M^{-1} s^{-1}. Converting these to third-order rate constants gives 3.7 × 10^6 and 5.8 × 10^6 M^{-2} s^{-1}, respectively. Using these and a value of 7400 M^{-2} s^{-1} (= 4.1 × 10^5 M^{-1} s^{-1}/55.5 M) for water (4*b*) leads to β ~ 0.43.

[5]The observations which led to such proposals may well have been due to buffer catalysis in a later stage of the reaction. Such is not the case in the present work, as discussed later.

[6]The involvement of the equilibrium [4] is ruled out on other grounds also: it would lead to an inverse dependence on [Br^-], over and above that due to the formation of tribromide ion, which is not observed in any of the large number of brominations that we and others have studied (3, 4, 11, 12, 14–16).

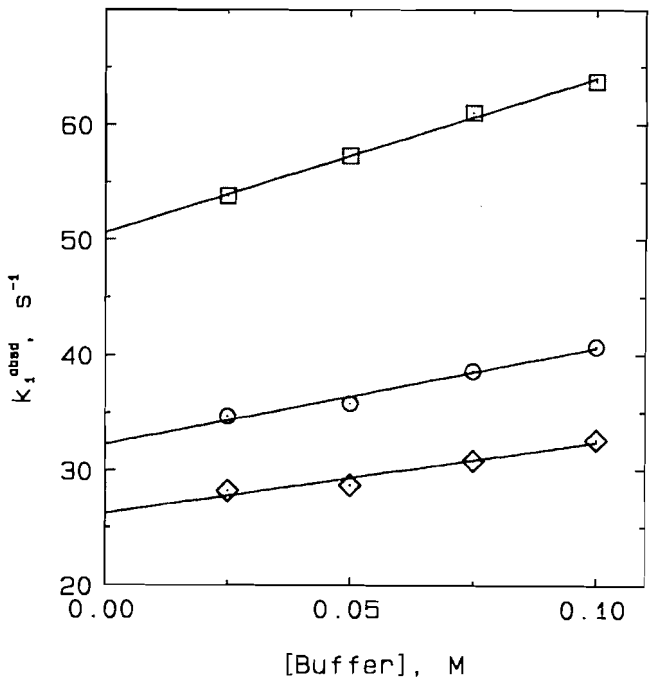

FIG. 1. Effect of acetate buffers on the rate of bromination of phenol. Data taken from Table 2, as follows: diamonds, pH 4.26; circles, pH 4.86; squares, pH 5.36. Note the slopes increase with pH. The intercepts also increase with pH due to the onset of reaction on phenoxide ion (4*b*).

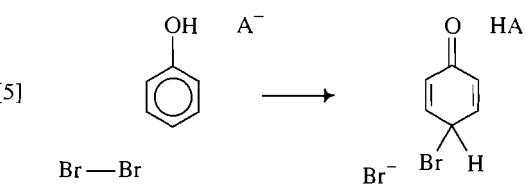
enolization of the intermediate in the *para* bromination of phenol is slower than bromine attack (5), as is debromination of the *ipso*-dienone derived from 4-methylphenol (5–7).[7] In any event, we monitored bromine disappearance at a wavelength longer than that where the enolizations are observable. Further, the Brønsted β values for cyclohexadienone enolization is 0.54 (5*b*), higher than the value of 0.4 suggested by the present data. In the case of 4-bromophenol no cyclohexadienone is observable (5*b*). We conclude, therefore, that the attack of bromine on phenols is subject to general base catalysis, as presaged by earlier work (3*b*, 6, 9).

The simplest interpretation of the anion catalysis is that a general base abstracts the phenolic proton more or less in synchrony with the electrophilic attack by bromine [5]. As to the origins of this catalysis, they probably lie in the instability and high reactivity of potential intermediates (2), such as the bromocyclohexadienone conjugate acid, the phenoxide anion, or the phenol cation-radical.

[5]



Electrophilic attack by bromine on phenol would lead to the protonated cyclohexadienone ($BrCh{=}OH^+$) [6]. The oxygen-bound proton of this intermediate must be very acidic ($pK_a < -3$ (3*b*, 5*b*)), so that proton transfer to an adjacent water molecule would be favorable and quite fast. If bromine attack took place within an encounter complex (10*b*, 17) also containing a carboxylate anion (A^-),[8] proton transfer would be even more favorable, so much so that it could occur faster than diffusional departure (18) of the bromide ion [7]. In this event,

[6] $Br_2 + Ph{-}OH \rightarrow Br^- + BrCh{=}OH^+ \rightarrow Br^- + BrCh{=}O + H^+(H_2O)$

[7] $\{Br_2.Ph{-}OH.A^-\} \rightarrow \{Br^-.BrCh{=}OH^+.A^-\} \rightarrow \{Br^-.BrCh{=}O.HA\}$

the reaction would exhibit catalysis by the buffer anion.

A possibility which does not involve actual proton transfer is that the protonated dienone and the transition state leading to it are stabilized by the buffer anion through hydrogen-bonding. However, such a mechanism should give rise to a fairly small Brønsted β value 0.1–0.2 (19), smaller than the value suggested by the present data.

A quite different mechanism to that shown in [7] reverses the sequence of bromine attack and proton transfer; it recognizes the high reactivity of Br_2 towards phenoxide ions. The attack of molecular bromine on simple phenoxide ions is diffusion-controlled (3, 4, 11, 12), and so the reaction of Br_2 with the phenoxide ion within the encounter complex $\{Br_2.Ph{-}O^-\}$ must be much faster than diffusional separation of the two reactants ($\sim 10^{10}\ s^{-1}$) (18). Thus, one can imagine that proton transfer within the encounter complex $\{Br_2.Ph{-}OH.A^-\}$

[8] $\{Br_2.Ph{-}OH.A^-\} \rightarrow \{Br_2.Ph{-}O^-.HA\} \rightarrow \{Br^-.BrCh{=}O.HA\}$

leads to a highly reactive ternary complex $\{Br_2.Ph{-}O^-.HA\}$ in which bromine and phenoxide ion react to give Br^- and the bromocyclohexadienone ($BrCh{=}O$) faster than diffusional separation of any of the partners. Estimation of a value of β for this mechanism is difficult since it would be composite, being due to the formation of the initial complex and to the proton transfer step. However, as a referee has rightly pointed out, mechanism [8] should have a positive ρ value (due to the substituent effect on phenol acidity), whereas the observed value is −5.21 (3*a*). Also, for the bromination of salicylate ions, where the proton transfer is intramolecular, ρ is −2.7 (3*b*). These observations strongly militate against the operation of mechanism [8].

In recent years, evidence has been accumulating for the involvement of charge-transfer (CT) complexes in aromatic halogenation carried out in non-aqueous solution (20). From such CT complexes reaction may ensue by single electron transfer (SET) rather than by conventional electrophilic attack, a two-electron process. In the present case, an SET process within the encounter complex formed between Br_2 and phenol would led to the phenol cation-radical.

[9] $\{Br_2.Ph{-}OH\} \rightarrow \{Br^-.Br\cdot.Ph{-}OH\cdot^+\} \rightarrow \{Br^-.BrCh{=}OH^+\}$

Combination of the bromine atom with the cation-radical would give the dienone conjugate acid, $BrCh{=}OH^+$ [9]. However, bearing in mind the high acidity of cation-radicals (21), it is unlikely that the phenol cation-radical would survive very long, particularly adjacent to a buffer anion: thermodynamically favorable proton transfer should be very rapid. If this proton transfer is faster than the Br atom/cation-radical combination, a phenoxy radical will be formed adjacent to the bromine atom;

[7] Thus, in these two cases intermediates build up significantly (5–7). In no cases have the bromocyclohexadienones involved in *ortho* bromination been observed in aqueous solution; apparently, they enolize too rapidly (5–9).

[8] How this ternary encounter complex might arise is considered later.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

these should rapidly combine to give the dienone (BrCh=O), without the prior formation of its conjugate acid. Operation of this mechanism, [10], would also explain the observed buffer catalysis.

[10] $\{Br_2.Ph—OH.A^-\} \rightarrow \{Br^-.Br\cdot.Ph—OH\cdot^+.A^-\}$
$\rightarrow \{Br^-.Br\cdot.Ph—O\cdot.HA\} \rightarrow \{Br^-.BrCh=O.HA\}$

The ternary complex $\{Br_2.Ph—OH.A^-\}$ is implicated in all of the mechanisms outlined above. This complex would most likely arise from the encounter of $Br_2$with a hydrogen-bonded complex of phenol and the buffer anion, [11]:

[11] $Br_2 + Ph—OH + A^- \rightleftharpoons Br_2 + Ph—OH.A^- \rightleftharpoons \{Br_2.Ph—OH.A^-\}$

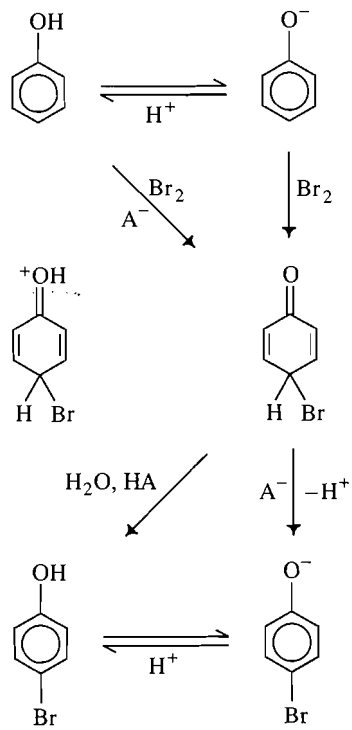
For the hydrogen-bonded complex between phenol and acetate ion Stahl and Jencks (19) have estimated a formation constant of $0.06\ M^{-1}$ implying very weak hydrogen-bonding. Nevertheless, it could be kinetically significant.

Without much more extensive data from a range of substrates and several buffers distinguishing between the mechanisms for bromine attack (above) is not possible.

Conclusions

The combination of the present findings and those from earlier studies (3–9) provide a reasonably detailed picture of the course of bromination of simple phenols, as it occurs in aqueous solution (Scheme 1).

Previous work has shown that bromocyclohexadienones can be observed in phenol bromination (5–9). The general acid-catalyzed enolization of these intermediates does not appear to involve the dienone conjugate acid (5*b*, 8*a*). If, through general base catalysis, the protonated bromocyclohexadienone is also avoided in bromine attack (*vide supra*), then this putative intermediate is not mandatory in the aqueous bromination of phenol (4*b*).



SCHEME 1

Experimental

The phenols used were obtained from commercial sources and purified by distillation or recrystallization, where necessary. All buffer components and inorganic reagents were of the highest purity available. In the main, the procedures for making up solutions and measuring the kinetics followed normal practice (3–9). *Fresh* stock solutions of bromine (0.1 M in 1.0 M aqueous KBr) were made up by weight and then a small volume was diluted with the desired electrolyte solution, just before use. For the phenols stock solutions were prepared in HPLC grade methanol and small volumes of these were diluted with the desired buffer medium. The actual concentrations of the phenols used in the experiments are given in the tables. Final solutions had a total ionic strength of 1.0 M (= [KBr] + [NaCl] + buffer salt).

Rates were measured at 25.0 ± 0.1°C by monitoring the disappearance of bromine using an Aminco-Morrow stopped-flow apparatus + Aminco DW-2 spectrophotometer interfaced to an Apple II microcomputer (22). Normally, bromination reactions are monitored at the tribromide ion maximum at 265 nm (13). In the present case, we used 275 nm to minimize any interference from the enolization of bromocyclohexadienones, which is apparent at shorter wavelengths (5–7).

For a ten (or more)-fold excess of substrate over bromine the absorbance decrease exhibited good first-order behavior. From the traces pseudo first-order rate constants (k_1^{obsd}) were calculated from data covering about 90% reaction. Reported values were the averages of 4–5 determinations. In some cases values of k_1^{obsd} was converted to second-order constants (k_2^{obsd}) by correction for the substrate concentration and the fraction of free bromine in equilibrium with tribromide ion (13). The dissociation constant of tribromide ion was taken as 0.0625 M (I = 1.0 M) (23).

Kinetics and mechanism of the oxidation of alcohols by ruthenate and perruthenate ions

DONALD G. LEE AND LIGAYA N. CONGSON
Department of Chemistry, University of Regina, Regina, Sask., Canada S4S 0A2

Received February 8, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

DONALD G. LEE and LIGAYA N. CONGSON. Can. J. Chem. **68**, 1774 (1990).

In addition to being important synthetic reagents, ruthenate and perruthenate are of interest because they are representative of a number of high valent transition metal ions that can be used as oxidants in organic chemistry. In their reactions with alcohols both ions exhibit several striking similarities — concave Hammett plots, primary deuterium isotope effects, small enthalpies of activation, and large negative entropies of activation. The most likely explanation of the concave upward Hammett plots is the involvement of free radical-like transition states that could be formed by the decomposition of organometallic intermediates.

Key words: oxidation, ruthenate, perruthenate, alcohols, mandelic acid.

DONALD G. LEE et LIGAYA N. CONGSON. Can. J. Chem. **68**, 1774 (1990).

En plus d'être des réactifs de synthèse importants, le ruthénate et le perruthénate présentent de l'intérêt parce qu'ils sont représentatifs d'un certain nombre d'ions de métaux de transition polyvalents qui peuvent être utilisés comme oxydants en chimie organique. Dans leurs réactions avec les alcools, ces deux ions présentent plusieurs similarités frappantes — courbes de Hammett concaves, effets isotopique primaires du deutérium, petites enthalpies d'activation et importantes entropies négatives d'activation. La cause la plus probable de la concavité des courbes de Hammett serait une implication d'états de transition ressemblant à des radicaux libres qui se formeraient par la décomposition d'intermédiaires organométalliques.

Mots clés : oxydation, ruthénate, perruthénate, alcools, acide mandélique.

[Traduit par la revue]

Introduction

Ruthenate (RuO_4^{2-}) and perruthenate (RuO_4^-) ions have both been employed as oxidants in various synthetic procedures. Ruthenate, because it reacts very slowly with carbon–carbon double bonds (1), has found extensive use as a selective oxidant for unsaturated alcohols (2), while perruthenate has been used for the oxidative cleavage of carbon–carbon double bonds (3), the oxidation of secondary alcohols to ketones (4), and the conversion of primary alcohols to carboxylic acids (4). Ruthenate also oxidizes saturated secondary alcohols to ketones in good yields (5). Both ions are stable only under basic conditions (6), thus limiting their use as oxidants to organic compounds that are both stable *and* soluble in aqueous solutions of high pH.

Burke and Healy at one time suggested that ruthenate oxidations actually proceed via perruthenate (7). However, a careful study of the reactions of these two oxy-anions has shown this contention to be false (8). Perruthenate is not involved when ruthenate is used as an oxidant.

In addition to being important synthetic reagents, ruthenate and perruthenate are of interest because of their possible involvement as intermediates in ruthenium tetroxide oxidations and the fact that they are representative of a number of high valent transition metal ions that are used as oxidants in organic chemistry. It is likely that knowledge of the mechanisms of these reactions will also aid in an understanding of the reactions of other more common high valent transition metal oxidants such as permanganate which has been investigated extensively by Stewart and co-workers (9).

Experimental

Reagents and substrates

Sodium ruthenate and perruthenate were prepared by the reduction of ruthenium tetroxide in sodium hydroxide solutions. Sodium perruthenate solutions were obtained when ruthenium tetroxide (prepared by the oxidation of hydrated ruthenium dioxide with periodate (10)) was distilled on a stream of nitrogen into 0.3 M NaOH at 0°C. After standing at 5°C overnight this solution exhibited an absorption spectrum that was identical with that previously reported for sodium perruthenate (11).

Sodium ruthenate was obtained by the reduction of ruthenium tetroxide in 1 M NaOH at 23°C for 24 h. Spectroscopic analysis of the resulting solution showed that it did not contain detectable amounts of either RuO_4 or RuO_4^-.

2-Propanol, obtained commercially, was distilled from calcium oxide and a middle fraction (bp 81–82°C) was collected for use in the kinetic experiments.

2-Propanol-2-*d* was prepared following the procedure of Leo and Westheimer (12). Dry acetone (86 mmol) in 20 mL of anhydrous ether was added dropwise to a stirred solution of lithium aluminum deuteride (25 mmol) in 50 mL of anhydrous ether at −80°C. The mixture was allowed to warm slowly to room temperature and the complex decomposed with dilute sulfuric acid. The heterogeneous reaction mixture was then distilled and an azeotrope of 2-propanol-2-*d* and water collected at 70–90°C. The azeotrope was dissolved in ether, dried over anhydrous magnesium sulfate and after evaporation of the ether, the resulting clear solution was distilled from calcium oxide to give 2-propanol-2-*d* (bp = 81–82°C). The purity of the compound was further verified by means of gas chromatographic analysis and the deuterium incorporation was checked by proton NMR spectroscopy.

THF was refluxed over LAH and fractionally distilled just prior to use. The mandelic acids were obtained commercially and purified by Soxhlet extraction using benzene as the solvent (13). When the hot benzene extract was allowed to cool, crystallization occurred. The product was then collected on a Buchner funnel and air dried. Melting points (14) and NMR spectra were used to verify the purity of these acids. The observed melting points were: *p*-methoxymandelic acid, 108–109°C (lit. 108–111°C); *p*-methylmandelic acid, 139–140°C; mandelic acid, 119–120°C (lit. 120–122°C); mandelic acid-α-*d*, 119–121°C; *p*-fluoromandelic acid, 137–138°C; *p*-chloromandelic acid, 119–120°C (lit. 119–122°C); *p*-bromomandelic acid, 118–120°C (lit. 118–120°C).

Kinetic methods

All kinetic measurements were done under pseudo first order conditions with a substrate concentration at least ten times that of the oxidant. A minimum of three kinetic measurements were performed for each experiment.

The kinetics of the oxidations by sodium perruthenate were studied

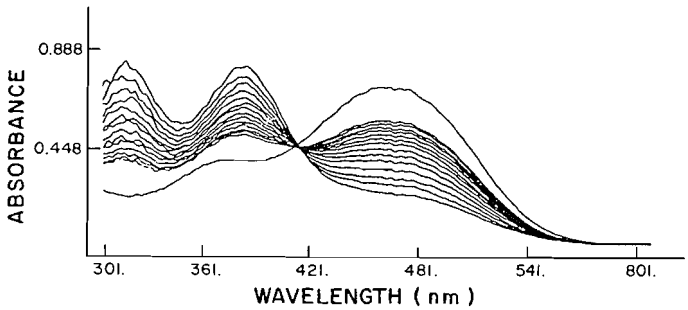

FIG. 1. Sequential scans for the oxidation of 2-propanol by sodium perruthenate. Spectra taken at 30 ms intervals, top to bottom at 385 nm. The lowest trace at this wavelength was obtained about 1 min after completion of the reaction.

using a Tracor Northern System 777 Rapid Scanning Stopped-Flow Spectrophotometer. Stock solutions of RuO_4^- and reductant, both in 0.3 M NaOH, were first thermostated at 25.0°C for 15 min. The sample syringes were then filled, one with perruthenate and the other with reductant solution, and equal volumes of the two reactants forced into the observation cell. Spectra of the reaction solutions were collected at preset intervals (5 to 200 ms), stored in a multichannel analyzer, displayed on a CRT as smooth curves, and recorded as shown in Fig. 1. The reaction rate was followed by monitoring the disappearance of the absorption band at 385 nm ($\epsilon = 2275\ M^{-1}\ cm^{-1}$).

Pseudo first order rate constants were then obtained from plots of $-\ln(A - A_\infty)$ against time (which exhibited good linearity through at least two half lives).

For ruthenate oxidations, stock solutions of RuO_4^{2-} and 2-propanol, THF, or mandelic acid in 1.0 M NaOH were first thermostated at 25°C for 30 min. Then 2.0 mL of the oxidant solution was transferred to a quartz cuvette which was in turn placed in the thermostated cell compartment of the HP 8450A spectrophotometer. An excess of reductant solution (100 μL) was added using a microlitre syringe and the progress of the reaction monitored by following the formation of RuO_2 spectrophotometrically.

Under these conditions it is impossible to directly measure the concentration of ruthenate remaining in solution. However, if the reaction is carried out in a flask and aliquots are centrifuged to remove suspended ruthenium dioxide, a transparent solution of sodium ruthenate is obtained. The concentration of this solution can then be determined by measuring the absorbance at 464 nm ($\epsilon = 1960\ M^{-1}\ cm^{-1}$). A plot of ln (Absorbance) versus time was linear, thus indicating that the reaction is first order in ruthenate.

Measuring the reaction rates by this method is slow, cumbersome, and susceptible to error because the solutions cannot be thermostated during centrifugation. Consequently, the rates of reaction were usually determined by following the increase in absorbance at 320 nm as the reaction progressed. This approach, based on the assumption that the rate of formation of RuO_2 is equal to the rate of disappearance of RuO_4^{2-}, is consistent with previous work which indicated ruthenate is a two-electron oxidant (15). Both kinetic methods gave very similar values for the rate constants.

When the increase in absorbance at 320 nm is monitored, the concentration of ruthenate ion can be calculated using eq. [1], where A is the absorbance at time t, A_∞ is the final absorbance, and $\Delta\epsilon$ is the difference in the extinction coefficients of ruthenium dioxide and ruthenate ion (16).

$$[1] \quad [RuO_4^{2-}] = (A_\infty - A)/\Delta\epsilon$$

The general rate law is then given by eq. [2], or by eq. [3] under pseudo first order conditions.

$$[2] \quad -d(A_\infty - A)/dt = k_2[RuO_4^{2-}]^x[ROH]^y$$

$$[3] \quad -d(A_\infty - A)/dt = k_1[RuO_4^{2-}]^x$$

TABLE 1. Order of perruthenate oxidations with respect to reductants[a]

[Reductant] (M)	k_1 (s^{-1})	k_2 ($M^{-1}\ s^{-1}$)
2-Propanol		
4.64×10^{-3}	1.88 ± 0.04	405 ± 9
1.28×10^{-2}	5.21 ± 0.04	407 ± 3
1.69×10^{-2}	7.14 ± 0.29	422 ± 18
3.39×10^{-2}	13.4 ± 0.4	395 ± 12
Mandelic acid		
4.95×10^{-3}	3.67 ± 0.06	741 ± 12
7.23×10^{-3}	5.49 ± 0.09	759 ± 12
1.03×10^{-2}	7.74 ± 0.09	751 ± 9

[a]Temperature = 25.0 ± 0.1°C, [NaOH] = 0.30 ± 0.01 M.

TABLE 2. Kinetic isotope effects[a]

Reductant	Oxidant	k_2 ($M^{-1}\ s^{-1}$)	k_H/k_D
2-Propanol	Perruthenate	404 ± 11	
2-Propanol-2-*d*	Perruthenate	155 ± 12	2.6 ± 0.3
2-Propanol	Ruthenate	0.11 ± 0.01	
2-Propanol-2-*d*	Ruthenate	0.048 ± 0.004	2.4 ± 0.3

[a]Temperature = 25.0 ± 0.1°C; perruthenate oxidations in 0.31 M NaOH; ruthenate oxidations in 1.02 M NaOH.

Since A_∞ is a constant, the rate, $-d(A_\infty - A)/dt$, is equivalent to dA/dt and the rate law can then be rewritten in its simplest form:

$$[4] \quad dA/dt = k_1[RuO_4^{2-}]^x$$

In order to obtain dA/dt, the absorbance/time data was first fitted to eq. [5] using a program described in a previous publication (17).

$$[5] \quad A = a_0 + a_1t + a_2t^2 + a_3t^3 + a_4t^4 + a_5t^5$$

Differentiation of eq. [5] with respect to time gives eq. [6] from which the initial reaction rate, $(dA/dt)_i$, can be obtained by setting $t = 0$.

$$[6] \quad dA/dt = a_1 + 2a_2t + 3a_3t^2 + 4a_4t^3 + 5a_5t^4$$

Products

Acetone, isolated as the 2,4-dinitrophenylhydrazone, was the only product obtained from the oxidation of 2-propanol. The oxidation of mandelic acid by sodium perruthenate in 0.3 M NaOH or by sodium ruthenate in 1.0 M NaOH gave benzoic acid (isolated by acidification, extraction with ether, and evaporation of the solvent) in 98–99% yields. This result, however, does not preclude the involvement of an intermediate such as phenylglyoxylic acid that would be susceptible to oxidative decarbonylation under these conditions.

Results

Perruthenate oxidations

Linear plots of $-\ln(A - A_\infty)$ against time indicated that these reactions are first order with respect to oxidant. Since the pseudo first order rate constants so obtained are proportional to the concentrations of 2-propanol or mandelic acid (Table 1) it is clear that the reaction is also first order with respect to reductant.

Primary kinetic isotope effects were observed when the rate of oxidation of 2-propanol-2-*d* was compared with the corresponding unlabelled compound (Table 2).

TABLE 3. Rate constants for the oxidation of substituted mandelic acids by ruthenate and perruthenate ions[a]

Substituent	Oxidant	k_2 (M^{-1} s^{-1})
p-Methoxy	Ruthenate	4.67 ± 0.43
p-Methyl	Ruthenate	3.97 ± 0.53
Hydrogen	Ruthenate	3.65 ± 0.34
p-Fluoro	Ruthenate	3.93 ± 0.22
p-Chloro	Ruthenate	5.85 ± 0.38
p-Bromo	Ruthenate	6.44 ± 0.52
p-Methoxy	Perruthenate	943 ± 24
p-Methyl	Perruthenate	816 ± 7
Hydrogen	Perruthenate	750 ± 14
p-Fluoro	Perruthenate	765 ± 8
p-Chloro	Perruthenate	856 ± 10
p-Bromo	Perruthenate	865 ± 18

[a]Temperature = 25.0 ± 0.1°C; ruthenate oxidations in 1.02 ± 0.01 M NaOH, perruthenate in 0.30 ± 0.01 M NaOH.

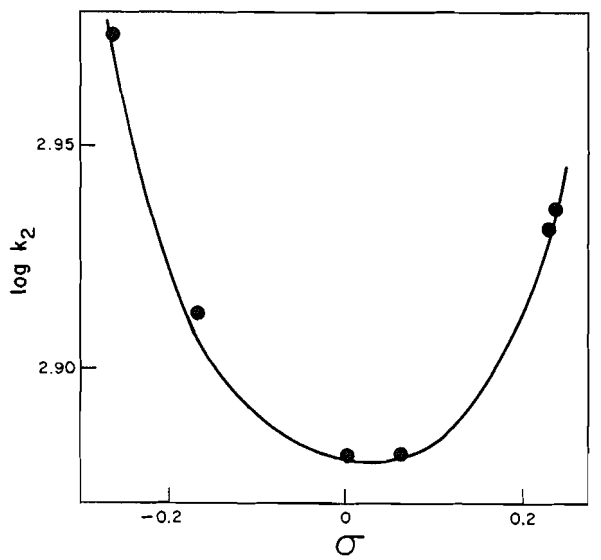

FIG. 2. Hammett plot for the oxidation of substituted mandelic acids by perruthenate. Substituents are (from left to right) *p*-methoxy, *p*-methyl, hydrogen, *p*-fluoro, *p*-chloro, *p*-bromo.

The rate constants for the oxidation of a series of substituted mandelic acids (Table 3) gave a concave Hammett plot (Fig. 2). Activation parameters calculated from plots of ln (k_2/T) against $1/T$, are summarized in Table 4.

Ruthenate oxidations

As indicated by the typical plots in Figs. 3 and 4, the orders of the reaction with respect to oxidant and reductant are both unity.

Primary isotope effects were observed for the oxidation of 2-propanol-2-*d* (Table 2) and the activation parameters were calculated from rate constants obtained at different temperatures (Table 4). A concave Hammett plot was obtained when the rate constants for the oxidation of substituted mandelic acids (Table 3) were plotted against the corresponding σ values (18) as in Fig. 5.

The rate of oxidation of 2-propanol decreases as the basicity of the solution increases (Table 5). This decrease in rate could be a consequence of reaction [10] since it is expected that

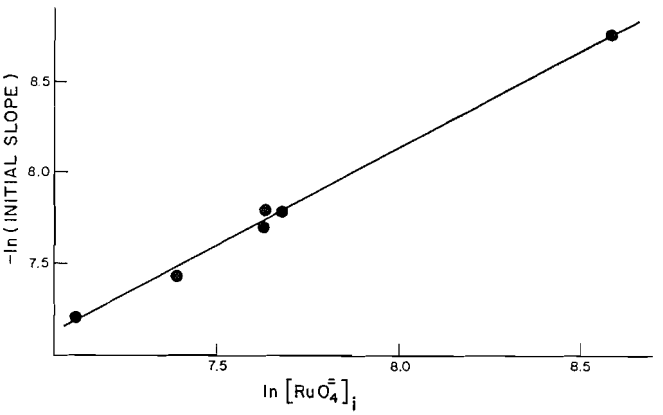

FIG. 3. Determination of the order with respect to ruthenate. [2-Propanol] = 5.15×10^{-3} M; [NaOH] = 1.02 M; T = 25.0 ± 0.1°C; r = 0.999; slope = 1.0.

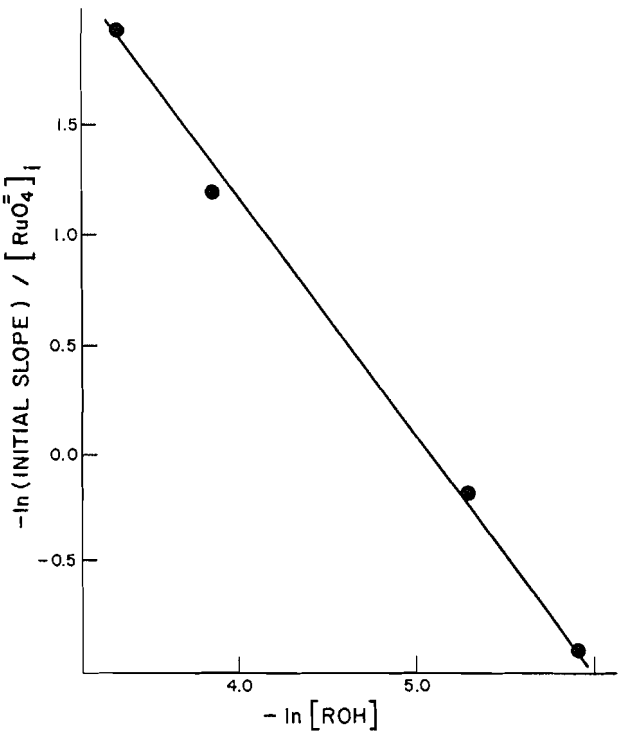

FIG. 4. Determination of the order with respect to 2-propanol for ruthenate oxidations. [NaOH] = 1.02 M; T = 25.0 ± 0.1°C; r = 0.999; slope = 1.0.

hydrogen ruthenate ion ($HRuO_4^-$) would be a more reactive oxidant than ruthenate ion (RuO_4^{2-}) (9, 19).

[10] $HRuO_4^- + OH^- \rightleftharpoons RuO_4^{2-} + H_2O$

Discussion

The reactions of ruthenate and perruthenate exhibit several striking similarities — concave Hammett plots, primary deuterium isotope effects, small enthalpies of activation, and large negative entropies of activation — that suggest some common mechanistic features. However, it must also be remembered that the two reagents give different products with certain substrates. For example, the oxidation of cyclobutanol by ruthenate gives quantitative yields of cyclobutanone, but the use of perruthenate produces only acyclic products (8).

Concave upward Hammett plots have previously been observed when the introduction of substituents caused a change in mechanism (20, 21) or when free radicals were formed in the rate-limiting step (20, 22). It may be noted, however, that a change of the rate-limiting step of a multi-step mechanism causes a concave downward Hammett plot and is, therefore, not a possible explanation for the substituent effects observed in these reactions (20, 21).

An explanation based on a change in reaction mechanism would require the oxidants to be ambiphilic — reacting as electrophiles when electron-donating substituents are present and as nucleophiles when electron-withdrawing substituents are present. This seems unlikely, especially in light of the most recent theoretical studies which suggest that all transition metal oxides are electrophiles (23).

The involvement of free radicals seems more likely. It is known, for example, that perruthenate effects single electron-transfer oxidations (8), and free radicals have been detected by use of esr during ruthenium tetroxide oxidations (24). Consequently, the most likely explanation for the concave upward Hammett plots is the formation of free radical-like transition states which can be stabilized by both electron-withdrawing and electron-donating substituents (20, 21).

Ruthenate oxidations

The most direct way in which neutral free radicals could be formed would be by transfer of a hydrogen atom to the oxidant as in reaction [11].

[11] $RCH_2OH + RuO_4^{2-} \rightarrow R\dot{C}HOH + HRuO_4^{2-}$

However, this mechanism, despite its apparent simplicity, is not consistent with recent theoretical predictions. Molecular orbital calculation by Goddard and Rappe' (23) indicate that the reactions between alcohols and transition metal oxides are initiated by an oxidative addition of an O—H or C—H bond to an oxo metal bond (M=O) to give intermediate products as indicated in reactions [12] and [13].

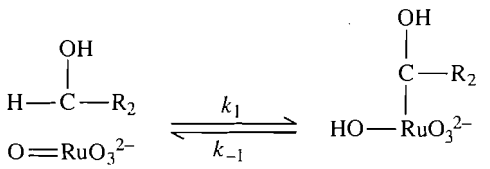
[12] 
[13] 
Addition to an O—H bond (as in reaction [12]) leads to formation of esters, intermediates that have been proposed for several reactions, the most well known being the oxidation of alcohols by chromic acid (25).

Addition to a C—H bond (the α-C—H being most reactive) as in reaction [13] leads to formation of an organometallic compound. These intermediates are most likely for those elements that form strong metal–carbon bonds (26).

Fortunately it is possible to experimentally distinguish between the possibilities shown in reactions [12] and [13]. If a reaction occurs by addition to an O—H bond it is expected that the oxidant would not react as readily with ethers as with alcohols. For example, chromic acid reacts about 1500 times faster with isopropyl alcohol than with isopropyl ether (27), thus confirming (along with other evidence (28)) that esters are intermediates in chromic acid oxidations. However, if the reaction proceeds by way of reaction [13] it is to be expected

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

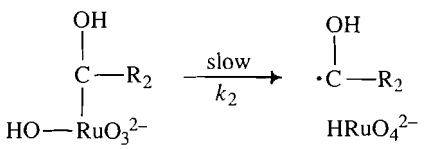
that alcohols and ethers would be oxidized with approximately equal ease. Such an observation has been made for ruthenium tetroxide (29) and it is also the case for ruthenate as indicated by the data in Table 4. Consequently, it appears likely that ruthenate reacts with 2-propanol by addition to the α-C—H bond giving the intermediate depicted in reaction [14].



[14]

1

In agreement with these theoretical predictions, Behari *et al.* (30) have shown that the kinetics obtained when cyclohexanol is oxidized by RuO_4^{2-} (using hexacyanoferrate(III) ion as a cooxidant) indicate the reaction mechanism involves formation of an alcohol/RuO_4^{2-} "complex" in a rapid equilibrium step, followed by a rate-limiting decomposition of the complex to give products. Although these authors did not speculate on a possible structure for the intermediate, it seems clear from the aforementioned theoretical calculations that their "complex" is likely the adduct, **1**. A rate-limiting decomposition of this intermediate by homolytic cleavage of the Ru—C bond (reaction [15]) would then be consistent with the observation of a concave Hammett plot.



[15]

1

Since the oxo-ruthenium species formed in reaction [15] ($HRuO_4^{2-}$) is in the reactive 5+ oxidation state, a subsequent single electron transfer (reaction [16]) would probably occur before the radical could diffuse out of the solvent cage.

[16]

Because the products of this reaction, ruthenium(IV) and a resonance stabilized α-hydroxycarbocation, are both stable moieties it is not unreasonable to expect that its rate would be rapid.

Deprotonation of the carbocation and hydrolysis of the ruthenium(IV) ion (reactions [17] and [18]) would give the observed products — a ketone and RuO_2.

[17]

[18]

Application of the steady-state approximation (31) to the intermediate **1** in reactions [14] and [15] indicates why the reaction mechanism would produce an isotope effect in spite of the fact that the α-C—H bond is cleaved prior to the rate-limiting step.

$$[19]\quad -d[RuO_4^{2-}]/dt = k_1[R_2CHOH][RuO_4^{2-}] - k_{-1}[\mathbf{1}]$$

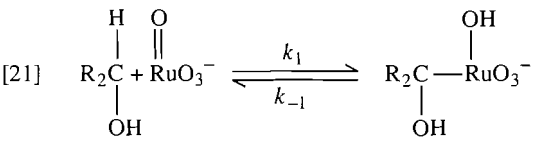
$$[20]\quad = k_1k_2/(k_{-1}+k_2)[R_2CHOH][RuO_4^{2-}]$$

Because the values of the observed rate constant depend directly on the magnitude of k_1 (which would, in turn, be reduced by deuterium substitution at the α-hydrogen) a primary isotope effect results.

The negative entropy of activation, $\Delta S^{\ddagger} = -23 \pm 1$ eu, observed for the oxidation of 2-propanol by ruthenate, indicates that the rate-limiting step, in common with most second order reactions, involves an increase in organization of the transition state as compared to the ground state.

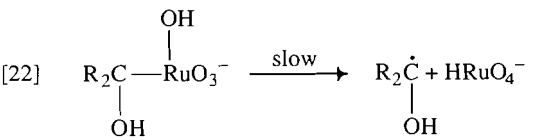
Perruthenate oxidations

A concave Hammett plot suggests that perruthenate oxidations also involve the formation of free radical intermediates which, if the MO calculations of Goddard and Rappe' (23) are correct, would be formed by the homolytic decomposition of the complex **2** as in reactions [21] and [22].



[21]

2



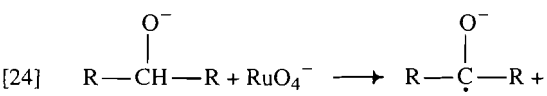
[22]

The very negative entropy of activation for this reaction ($\Delta S^{\ddagger} = -40 \pm 1$ eu) is consistent with a highly organized transition state.

There appears to be one substantial difference between this reaction and the one previously described for ruthenate. Because the hydrogen ruthenate(VI) ion formed in reaction [22] would be less reactive than the hydrogen ruthenate(V) ion formed in reaction [15], it is more likely that the products of reaction [22] will move out of the solvent cage before undergoing further reaction. It is to be expected, therefore, that the radicals will diffuse into the bulk of the solution and undergo further reaction with a second molecule of perruthenate (reaction [23]). Reaction within the solvent cage would undoubtedly result in the eventual formation of RuO_2, a possibility that is not consistent with the experimental evidence.

[23]

The greater reactivity of alkoxide ions in these reactions is likely related to the increased stability of the radical anion, **3** in reaction [24], as compared to an uncharged radical (9).



[24]

3

This understanding of the reaction mechanism also accounts for the different products obtained when cyclobutanol is oxidized by ruthenate and perruthenate ions. As indicated in Scheme 1, transfer of a second electron (to the ruthenium(V) ion, $HRuO_4^{2-}$) would likely occur very rapidly when ruthenate is used as an oxidant. Assuming that the free radical never escapes the solvent cage, it is to be expected that the product will be cyclobutanone. However, in the case of perruthenate ion (Scheme 2), transfer of a second electron would be much slower (because of the lower reactivity of $HRuO_4^-$) and the free radical

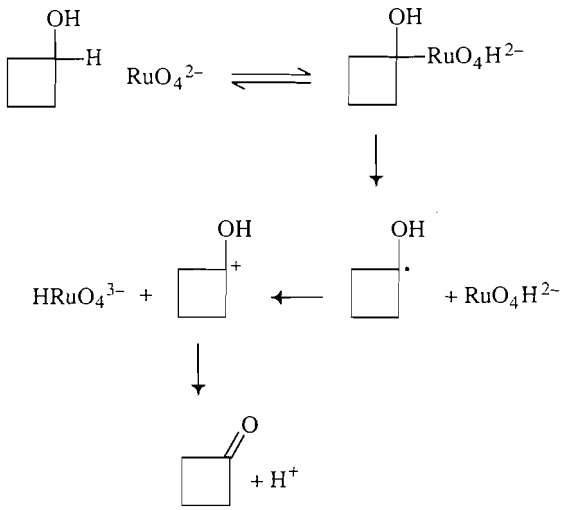
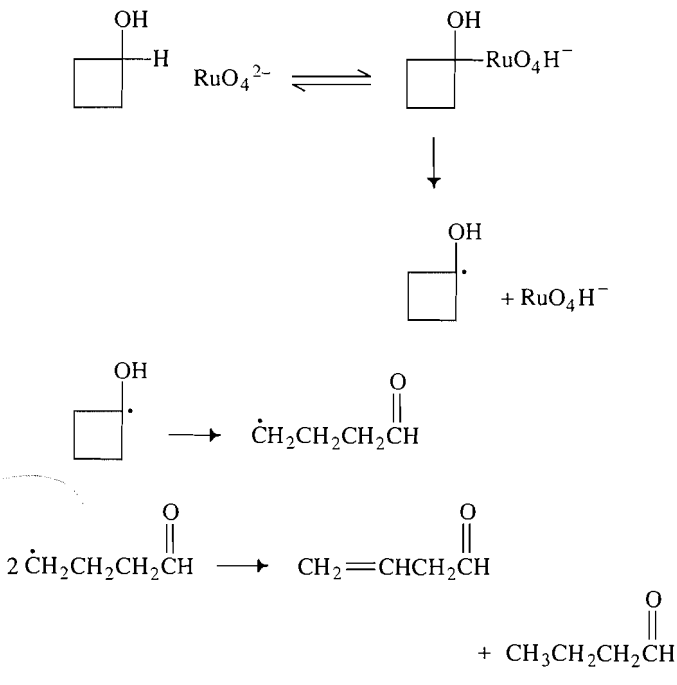


SCHEME 1



SCHEME 2

could diffuse into the solution and undergo α-scission with the consequent formation of acyclic products (32).

Received March 30, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

COLIN M. BRENNAN, IAN HUNT, TERENCE C. JARVIS, C. DAVID JOHNSON, and PETER D. MCDONNELL. Can. J. Chem. **68**, 1780 (1990).

The 2′-hydroxychalcone (2-$HOC_6H_4COCH{=}CHC_6H_4X$)–flavanone equilibrium in trifluoroacetic acid (TFA) has been examined. The influence of substituents X on the rate of attainment of equilibrium shows that the 6-*endo*-trig mode of ring closure by Michael addition is disallowed, by demonstrating a negative ρ value for the reaction rate when X is varied. Reaction therefore proceeds either on the carbonyl-protonated form, which allows twisting about the 2,3 bond, its double bond character being reduced by resonance, or through direct rate-limiting protonation on the 2,3 double bond. Either pathway permits the allowed 6-*exo*-trig mode of ring closure to be followed. Alternative mechanisms involving intermolecular Michael addition of trifluoroacetate, followed by intramolecular 6-*exo*-tet displacement are considered. Such Michael adducts can be detected in the ring closures of 2-crotonyl-4-methylphenol and 4,4-dimethyl-1-(2-hydroxyphenyl)-2-penten-1-one in TFA, but they do not appear to lie on the main pathway, because the reactions proceed with equal facility in methanesulphonic acid/chloroform medium, which does not contain a suitable nucleophile for such a mechanism. Further important mechanistic information is given by studying the reactions in TFA-*d*, together with measurements on the (*E*)-2-methyl-3-oxo-5-arylpent-4-en-2-ol and 3′-methoxychalcone systems. These isotope effect studies, which yield k_H/k_D values of about 3, indicate that the proton is in flight during the rate-limiting step, and provide evidence against the mechanism involving a preequilibrium carbonyl protonation, such as in the Nazarov rearrangement of 3′-methoxychalcones, where k_H/k_D is ca. 0.7. Some results are also reported for ring closure of the 2-aminochalcones in TFA.

Key words: 2′-hydroxychalcones, flavanones, 3′methoxychalcones, 3-aryl-6-methoxyindanones, 2′-aminochalcones, 2-aryl-1, 2, 3, 4-tetrahydroquinolines, Baldwin's rules.

COLIN M. BRENNAN, IAN HUNT, TERENCE C. JARVIS, C. DAVID JOHNSON et PETER D. MCDONNELL. Can. J. Chem. **68**, 1780 (1990).

On a étudié l'équilibre de la 2′-hydroxychalcone (2-$HOC_6H_4COCH{=}CHC_6H_4X$)–flavone dans l'acide trifluoroacétique (TFA). L'influence des substituants X sur le temps qu'il faut pour atteindre l'équilibre, exprimée par la valeur négative de ρ sur la vitesse de la réaction, démontre que le mode 6-*endo*-trig de fermeture du cycle par addition de Michael n'est pas permis. La réaction se produit donc soit par une attaque sur la forme protonée du carbonyle, qui permet une torsion autour de la liaison 2,3 puisque son caractère de liaison double est réduit par résonance, soit par une protonation directe de la double liaison 2,3 qui limite la vitesse. On considère aussi d'autres mécanismes impliquant une addition de Michael intramoléculaire de l'ion trifluoroacétate, suivie par des déplacements 6-*exo*-tet. On peut détecter de tels adduits de Michael dans les cyclisations du 2-crotonyl-4-méthylphénol et de la 4,4-diméthyl-1-(2-hydroxyphényl)-2-pentèn-1-one dans l'acide TFA; toutefois, ils ne semblent pas faire partie du mécanisme principal puisque les réactions se produisent avec une facilité similaire dans un milieu comme l'acide méthanesulfonique/chloroforme qui ne contient pas de nucléophile susceptible de participer à un tel mécanisme. On a obtenu d'autres informations importantes d'un point de vue mécanistique en étudiant les réactions dans le TFA-*d* et en faisant des mesures sur les systèmes (*E*)-2-méthyl-3-oxo-5-aryl pent-4-ène-2-ol et 3′-méthoxychalcone. Ces études d'effets isotopiques, qui nous permettent d'évaluer le k_H/k_D à environ 3, indiquent que le proton se déplace au cours de l'étape qui détermine la vitesse de la réaction; ces données s'opposent à un mécanisme impliquant un prééquilibre pour la protonation du carbonyle puisque dans la transposition de Nazarov des 3′-méthoxychalcones k_H/k_D = environ 0,7. On rapporte aussi quelques données relatives à la cyclisation des 2-aminochalcones dans l'acide TFA.

Mots clés : 2′-hydroxychalcones, flavanones, 3′-méthoxychalcones, 3-aryl-6-méthoxyindanones, 2′-aminochalcones, 2-aryl-1,2,3,4-tétrahydroquinolines, règles de Baldwin.

[Traduit par la revue]

Introduction

Baldwin's rules offer assistance to the rationalisation of organic synthesis (1). As an added bonus, they also provide valuable signposts to important perspectives in physical and mechanistic organic chemistry, and it is this aspect of the rules that has taken our attention (2–6). Experiments on (*E*)-2-methyl-3-oxo-5-phenylpent-4-en-2-ol and its phenyl substituted derivatives **1** were interpreted as showing that the ring closure to give 2,2-dimethyl-5-aryltetrahydro-3-furanone **2** in TFA proceeds via the protonation form **3**, in which the double bond character of the 4,5 linkage is reduced by the participation of canonical form **4** in the resonance hybrid. This permits more facile twisting to allow the 5-*exo*-trig mode to occur (2, 4, 7). Such a process can be detected by a "reverse substituent effect" (2, 4), in which the usual role of electron-withdrawing groups (EWG's) substituted in the phenyl ring of compounds (2–6), in accelerating the rate of reaction for a Michael addition, is not observed. Instead, a reverse effect, whereby electron-donating substitutents (EDG's) speed the reaction, is found.

According to Baldwin's rules, 6-*endo*-trig reactions are allowed (8), but are slower than the corresponding *exo* process when a choice is available (9). In such a critical case, the "allowedness" of the 6-*endo*-trig reaction may be further reduced by the nature of the connection between the two reacting centres.

A suitable case to investigate this situation appears to be the biologically important (10, 11) 2′-hydroxychalcone **5** – flavanone **6** system. Here models reveal the hydroxyl group to be

well off-line for a 109° approach of its lone pairs in the plane of the *p*-orbitals of the double bond, the optimum trajectory for the fastest reaction (12). This arises, in part at least, from the increased bond angle of the sp^2 hybridised connecting chain compared to that of a chain of sp^3 hybridised carbons, and must be accentuated by the tendency of conjugated systems to stay in plane.

Results and discussion

Table 1 gives the results of rate and equilibrium studies on the 2-hydroxychalcone **5** – flavanone **6** system in TFA and TFA-*d*, and Table 2 gives the corresponding results for ring closure of compounds **1** in TFA and TFA-*d*.

e X = *p*-F *j* X = *m*-F

The logarithmic rates for the ring closure of compounds **5** using log k_{obs} values give the ρ value of −2.55 against σ^+ values[2] (correlation coefficient 0.991). Measurements on a more extended series (**5***a–j*) give ρ = −2.43 (0.963). Plots using log k_f give essentially the same result. Thus in this latter case ρ becomes −2.42 (0.960). The similar size and sign of ρ to that for the closures of **1** in the same media suggest that the two systems go via the same mechanism, i.e., through *exo* closure onto the protonated forms **3** and **7** utilising canonical forms **4** and **8**. A complicating factor in our studies of compounds **1** was the reversible formation of trifluoroesters (4). With the phenolic hydroxy group in compounds **5**, however, no such esterification can be seen.

Another possible mechanism involves the nucleophilic attack of trifluoroacetic acid on protonated systems **3** and **7**, in an intermolecular Michael type addition, to yield **9** and **10** followed by *exo*-tet displacement to give the ring-closed products. The substituent effect for such a process would be expected to be positive if the attack of the nucleophile is rate determining, but the possibility exists that this step might be fast, and the subsequent displacement the slow step. Examination of the nmr spectra used to determine the rates of conversion of **1** to **2** and **5** to **6** showed no indication of any buildup of detectable quantities of **9** or **10**. Moreover, we found that the initial nmr spectra of 2′-methoxychalcone, 2′-methoxy-4-methylchalone, and 2′,4-dimethoxychalcone in TFA, indicative of these compounds, remained unchanged over several weeks: no evidence for formation of double bond addition compounds could be seen. We were, however, able to show that aliphatic derivatives **11** did give, in TFA, appreciable amounts of such adducts, judging from the appearance of the nmr spectra as they changed with time. A relevant spectrum is shown in Fig. 1. It was thus necessary to find out if such adducts could lie on the reaction pathway. We therefore examined the reactions in a 3% v/v solution of methanesulfonic acid in $CDCl_3$. These results are recorded in Table 3. This solution contains a weaker nucleophile than TFA. If no reaction occurred, a reasonable assumption might be that the nucleophilic addition–displacement mechanism did particpate to a significant or predominant extent in TFA. If, however, the rates were not significantly reduced, this fact, together with the substituent effect observed, would serve to suggest the absence of such a mechanism to any significant degree. Comparison of the results given in Tables 1 and 2 with

[2]All substituent constants were taken from ref. 13.

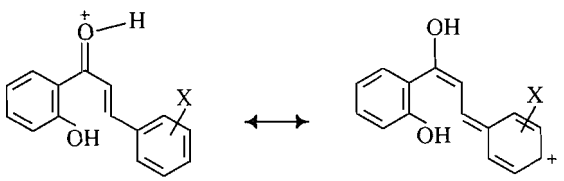
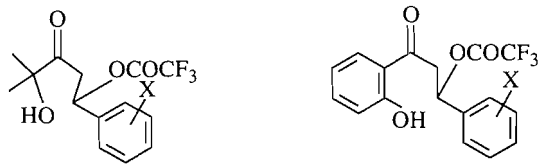
those in Table 3 show that in the $MeSO_3H$ medium, the rates observed are very similar to those in TFA and, further, that in both media EDG's X accelerate the reaction.

We therefore consider it unlikely that the intermolecular nucleophilic addition pathway plays a large part in the overall mechanism. A further mechanistic variation must also be considered as a possibility. In this, protonation occurs directly on the carbon–carbon double bond conjugated with the carbonyl group



7 ⟷ **8**



9 **10**

in structures **1** and **5** to give the carbocations **12**↔**13** and **14**↔**15**, which are tautomers of carbonyl protonated forms **3** and **7** respectively. To shed some light on this possibility, we measured the solvent kinetic isotope effect (SKIE) observed in going from TFA to TFA-*d* as solvent. The results are given in Table 1. We do not believe that the variation of k_H/k_D is experimentally significant (see discussion of errors in the experimental section), but the values are considerably greater than unity, and in the range that suggests the proton is in flight in the rate-limiting step. Similarly, SKIE values have been reported for rate-limiting proton addition to CC double and triple bonds (6, 14), and these suggest the predominant mechanism is the rate-limiting protonation of the carbon–carbon double bond.

The alternative mechanism involving a preequilibrium protonation on the carbonyl group is predicted to have a value of k_H/k_D of less than unity (15–18). The situation in TFA has not been experimentally verified, however, and to our knowledge results confirming this are not readily found in the literature. We therefore examined the solvent isotope effect on the TFA-catalysed rates of ring closure reaction of 3′-methoxychalcones **16** to give 1-indanones **17**, a reaction believed to go via an electrocyclic Nazarov reaction initiated by a preequilibrium carbonyl protonation (19, 20). The results are given in Table 4. The logarithmic rates afford a ρ value of −0.7 using σ^+ values, and the k_H/k_D values are all consistently less than unity. This supports the notion that if compounds **1**, **5**, and **11** had cyclised in TFA by a preequilibrium protonation at the carbonyl group, k_H/k_D would also be less than unity. We therefore favour a mechanism for ring closure of these compounds in which the proton is in flight in the rate-limiting step, that is, rate-determining protonation of the carbon–carbon double bond. Usually, however, ρ values for such reactions are much more negative than the −2.4 observed for cyclisation of **1** and **5**; values observed are usually about double this for acid-catalysed hydration involving rate-limiting proton transfer to CC double or triple bonds (6, 21). It may be that in these cases the attack of the intramolecular nucleophile commences before carbocation formation is complete, so that it intrudes to a certain extent in the rate-limiting step, and therefore the substituents are not called upon to stabilise the positive charge to the same extent that they are in the case of intermolecular attack.

We also investigated the ring closure of 2′-aminochalcones **18** to 2-aryl-1,2,3,4-tetrahydroquinolines **19**, which appears to be a closely analogous case to the 2′-hydroxychalcone ring closure. The pseudo-first-order rate constants ($k/10^{-6}$ s^{-1}) were as follows: **18***a*, 25; **18***b*, 41; **18***c*, 127; **18***d*, 4.9. The final nmr spectrum in all cases showed no indication of residual 2′-aminochalcone. Cyclisation of **18***e* was observed in TFA, but the nmr was complicated by the formation of what appeared to

more complex than that for the 2′-hydroxychalcone–flavanone system: we are in the course of further experimental investigations, and full details will be reported later.

The ring closure of **5** and **18** in TFA to give flavanones and 2-aryl-1,2,3,4-tetrahydroquinolines respectively appears to be a good method for the preparation of such compounds in reasonable yields (22). We are currently preparing a paper to describe these synthetic routes in detail.

Conclusion

The evidence presented here makes it seem more likely that ring closure of **1** and **5** involves rate-limiting protonation at carbon rather than a carbonyl preequilibrium protonation. In other words the reaction proceeds via **12** and **14** rather than through the alternative tautomeric systems **3** and **7**, respectively. The extent to which these systems eschew the intramolecular Michael addition on the majority species free base forms **1** and **5** because of operation of Baldwin's rules is a matter for debate: base catalysis might be very different (11), and Baldwin's rules could be more important here.

Experimental

TFA and TFA-*d* were reagent grade and used as received. Proton nmr spectra were recorded on a Perkin–Elmer R12 60-MHz instrument. Methanesulphonic acid was dried and distilled as described by Schofield and co-workers (23). (*E*)-2-Methyl-3-oxo-5-arylpent-4-en-2-ols were prepared as described previously (4).

2′-Hydroxy-, 2′-methoxy-, and 2′-aminochalcones were prepared by condensation of 2-hydroxy-, 2-methoxy-, or 2-aminoacetophenone with the appropriately substituted benzaldehydes in aqueous ethanolic sodium hydroxide. 3′-Methoxychalcones were prepared in the same manner using 3-methoxy acetophenone. Melting points agreed with literature values.

Flavonones were prepared in good yield by refluxing the appropriate 2′-hydroxychalcone in TFA, evaporating the bulk of the solvent under vacuum, chromatographing the residue on alumina, and recrystallising. 2-Aryl-1,2,3,4-tetrahydroquinolin-4-ones and 6-methoxy-3-arylindan-1-ones were prepared similarly. Melting points agreed with literature values. Where the compounds had not been prepared before (**6***c*, **6***g*, **6***h*, **17***b*, **17***c*, **17***d*, and **17***e*, **18***b–e*, **19***b–e*), satisfactory elemental analyses were obtained (22). These procedures form an efficient mode of synthesis of these compounds, in reasonable to high yields, and their description will form a further publication.

2-Crotonyl-4-methylphenol **11***a* was prepared by the procedure of von Auwers and Lammerhirt (24), which involves a Friedel–Crafts reaction between *p*-methylanisole and crotonyl chloride.

4,4-Dimethyl-1-(2-hydroxyphenyl)-2-penten-1-one **11***b*: Pivaldehyde (4.31 g, 50 mmol) was added to a solution of *o*-hydroxyacetophenone (6.8 g, 50 mmol) in dry THF (20 mL) under nitrogen, and then, portionwise, sodium hydride (4.0 g, 60% dispersion in mineral oil, washed with hexane, 100 mmol). The mixture was stirred at room temperature for 36 h, acidified to pH 3 with 5% v/v hydrochloric acid, diluted with water (100 mL), and extracted with ether (addition of water before acidification gives high yields of the cyclised product **12***b*). The combined ethereal extract was washed three times with water and dried with $MgSO_4$. The solvent was removed *in vacuo* to give an orange oil, which on distillation under reduced pressure gave **11***b* as a mobile yellow oil (5.85 g, 57%); bp 106°C/0.6 Torr (1 Torr = 133.3 Pa); H nmr δ($CDCl_3$): 1.15 (s, 9H, $C(CH_3)_3$, 6.62–7.80 (m, 6H, aromatic and vinyl); ms, *m/z*: 204 (M^+, 4%), 147 (M^+ ^tBu, 100%). Anal. calcd. for $C_{13}H_{16}O_2$: C 76.42, H 7.91; found: C 76.12, H 8.08.

Kinetic measurements

The kinetics of ring closure of enones **1** were measured by monitoring the change in proton nmr spectra with time as described previously (4).

The kinetics of cyclisation of 2′-hydroxy- and 2′-aminochalcones **5** and **18** respectively were determined using nmr integral measurements for the ABX signals due to the C-2 and C-3 protons of the flavonones **6** and the tetrahydroquinolones **19**. Solutions of the chalcones were prepared as 10% w/v solutions in TFA or TFA-*d*, tetramethylsilane was added, and the tubes stoppered or, in cases of longer reactions, sealed, then shaken, and maintained at 35°C in a water bath when not being measured.

Integrals were usually measured three times in each direction and the mean value calculated for the AB and X proton signals. Similar measurements were made on an internal methyl peak for normalisation purpose or, where no such peak was available, on 1,4-dioxan added as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

an internal standard, which gives a sharp singlet close to δ 4.0 in TFA and thus falls between the AB and X resonances. The 1,4-dioxan is nonvolatile and no decomposition was observed in the stock solution in TFA over 4 months. In the case of the 2′-aminochalcones, cyclohexane was used, because the dioxan peak overlapped with other peaks.

A representative treatment of data is given in Table 5. The kinetics of cyclisation of the 3′-methoxychalcones were examined in an analogous fashion, by following the appearance of the ABX peaks.

Kinetics for cyclisation of the 2′-hydroxychalcones in 3% methanesulphonic acid were also measured in this fashion. This approach gave good first-order kinetics for the results in Table 3; however, for less reactive compounds, increasing decomposition with the passage of time was observed.

Errors

The accuracy of nmr integrals on a 60-MHz machine is not very high, probably at best within ±5%. Consequently, in some of the longer kinetic runs, some scatter is observed in the calculated concentration terms. This is because of the problems associated with measuring small integrals or small changes in integrals at the start and end of a run.

This means that evaluation of the [**6**]/[**5**] ratios is particularly dependent on this variation. The ratios in TFA vary between 5.6 and 7.2 (Table 1), which implies that the percentage of flavonone **6** varies from 85 to 88% respectively, indicating that the variation is within the limits of the accuracy of the nmr integrals. As a consequence, it appears that [**6**]/[**5**] ratios are approximately constant across the series. In TFA, determination of the rate constants is based upon the ABX pattern in the nmr, using the integrals of these two sets of peaks to obtain an average value. In TFA-*d* this is not possible due to incorporation of deuterium at C3, α to the carbonyl group. This suggests that the results in TFA-*d* will be more susceptible to accuracy of the integrals and hence *k* in TFA-*d* are probably less reliable than those in TFA. We are, however, convinced that the accuracy of our measurements is amply sufficient to draw the mechanistic conclusions given in the discussion.

Received January 26, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

A. J. KRESGE, M. LEIBOVITCH, and K. R. KOPECKY. Can. J. Chem. **68**, 1786 (1990).

The acid-catalyzed hydrolysis of tetramethoxyethene to methyl dimethoxyacetate in aqueous solution at 25°C was found to occur with the hydronium-ion catalytic coefficient $k_{H^+} = 0.454\ M^{-1}\ s^{-1}$, to give the solvent isotope effect $k_{H^+}/k_{D^+} = 3.15$, and to provide a Brønsted relation based upon six carboxylic acids with the exponent $\alpha = 0.42$. These data indicate that the reaction proceeds via rate-determining proton transfer from the catalyzing acid to an olefinic carbon atom of the substrate. They also show tetramethoxyethene to be 1.0×10^6 times less reactive than 1,1-dimethoxyethene (ketene dimethyl acetal), a rate retardation 600 times greater than that expected from initial state stabilization by the two additional methoxy groups in tetramethoxyethene; possible causes of this disparity are discussed.

Key words: tetramethoxyethene, carbon–carbon double bond reactivity, ketene acetal, vinyl ether hydrolysis.

A. J. KRESGE, M. LEIBOVITCH et K. R. KOPECKY. Can. J. Chem. **68**, 1786 (1990).

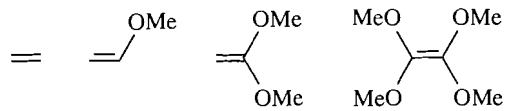
On a trouvé que l'hydrolyse acido-catalysée du tétraméthoxyéthène en diméthoxyacétate de méthyle, en solution aqueuse, à 25°C, se produit avec un coefficient catalytique de l'ion hydronium $k_{H^+} = 0{,}454\ M^{-1}\ s^{-1}$ et un effet isotopique du solvant $k_{H^+}/k_{D^+} = 3{,}15$ et qu'elle donne lieu à une relation de Brønsted, basée sur six acides carboxyliques, avec un exposant $\alpha = 0{,}42$. Ces données indiquent que la réaction se produit par le biais d'un transfert de proton du catalyseur acide avec un atome de carbone oléfique et que ce transfert limite la vitesse de la réaction. Ces données démontrent aussi que le tétraméthoxyéthène est $1{,}0 \times 10^6$ fois moins réactif que le 1,1-diméthoxyéthène (diméthyl acétal du cétène); ce ralentissement est 600 fois plus grand que celui attendu sur la base d'une stabilisation de l'état initial du tétraméthoxyéthène par deux groupements méthoxyles additionnels: on discute des causes possibles de cette disparité.

Mots clés: tétraméthoxyéthène, réactivité de la double liaison carbone-carbone, acétal du cétène, hydrolyse de l'éther vinylique.

[Traduit par la revue]

Introduction

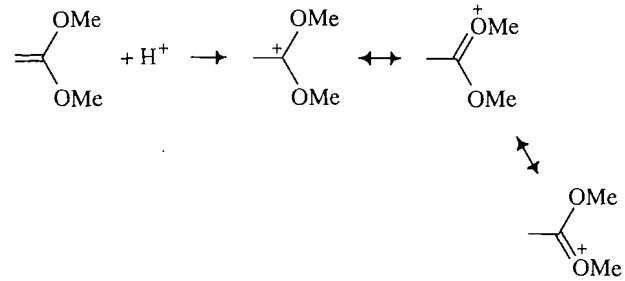
Alkoxy substituents raise the reactivity of carbon-carbon double bonds to electrophilic addition by impressively large amounts. Methyl vinyl ether (1), **2**, for example, is protonated on carbon fifteen orders of magnitude more rapidly than is ethylene (2), **1**, and ketene dimethyl acetal, **3**, is another five orders of



1 **2** **3** **4**

magnitude more reactive than the mono-ether (3). These rate accelerations can be understood in terms of resonance stabilization of the alkoxy carbocation product of these reactions, as shown for example in reaction [1].

[1]



Further methoxy substitution, however, as in tetramethoxyethene, **4**, is likely to lead to a decrease rather than to a further increase in reactivity. This is because the additional substituents will be unable to interact conjugatively with the positive charge being generated on the substrate in the reaction's transition state, but they will be able to lower the energy of the initial state of the reaction by stabilizing the substrate through the well-known carbon–carbon double bond stabilizing effect of methoxyl (4), and this will raise the reaction barrier and exert a retarding effect on the reaction rate.

We have now substantiated this expectation by measuring rates of acid-catalyzed hydrolysis of tetramethoxyethene.

Experimental section

Materials

Tetramethoxyethene was prepared by treating dimethoxy-*p*-chlorophenoxymethane with sodium hydride (5) and was purified by recrystallization from isopentane followed by distillation. All other materials were best available commercial grades. Solutions were prepared using deionized H_2O purified further by distillation or D_2O (Merck, Sharp & Dohme 99.8%) as received.

Kinetics

Rates of hydrolysis of tetramethoxyethene were measured spectroscopically by monitoring the decrease in absorbance at $\lambda = 205$ nm (mineral acid solutions) or $\lambda = 225$ nm (carboxylic acid buffers). Measurements were made with Cary Model 118 and Model 2200 spectrophotometers whose cell compartments were thermostatted at 25.0 ± 0.1°C. Reactions were initiated by injecting 5 μL of a solution of tetramethoxyethene in tetrahydrofuran into a cuvette containing 3 mL

of acid or buffer solution which had been allowed to come to temperature equilibrium with the spectrometer cell compartment; the concentration of tetramethoxyethene in the reaction mixture was *ca.* 1×10^{-3} M. The reactions followed the first-order rate law accurately, and observed first-order rate constants were calculated from slopes of appropriate linear expressions and/or by least-squares fitting to an exponential function.

Results

Rates of hydrolysis of tetramethoxyethene were measured in dilute solutions of perchloric acid in H_2O and in D_2O over a range of acid concentrations; the data are summarized in Table 1. Observed first-order rate constants obtained in both solvents were accurately proportional to acid concentration (Fig. 1), and linear least-squares analysis gave the catalytic coefficients k_{H+} = 0.454 ± 0.006 M^{-1} s^{-1} and k_{D+} = 0.144 ± 0.002 M^{-1} s^{-1}; these provide the solvent isotope effect k_{H+}/k_{D+} = 3.15 ± 0.06.

Rates of hydrolysis of tetramethoxyethene were also measured in buffer solutions of six different carboxylic acids. These data are summarized in Table 2. It may be seen that measurements were made in sets of solutions of varying buffer concentrations but constant buffer ratio and constant ionic strength. This served to keep hydronium-ion concentrations constant in the less acidic buffers (acetic and hydroxyacetic acids) and thus facilitated assessment of catalysis by buffer species by keeping hydronium-ion contributions to observed rates constant. In the more acidic buffers, however, "buffer failure" (6*a*) occurred and hydronium ion concentrations dropped significantly with decreasing buffer concentration. These changes were compensated for by adjusting observed rate constants where necessary using the hydronium-ion catalytic coefficient measured in perchloric acid solutions. Hydronium-ion concentrations needed for this purpose were obtained by calculation using literature pK_a values for the buffer acids and activity coefficients recommended by Bates (7).

Strong buffer catalysis was found in all of the buffer systems examined, with rates of disappearance of tetramethoxyethene accurately proportional to buffer concentration. Measurements made in acetic acid buffers at two different buffer ratios showed this catalysis to be of the general acid type. The data were therefore fitted by linear least-squares analysis to the rate law given in eq. [2]; the general acid catalyic coefficients so evaluated are listed in Table 3.

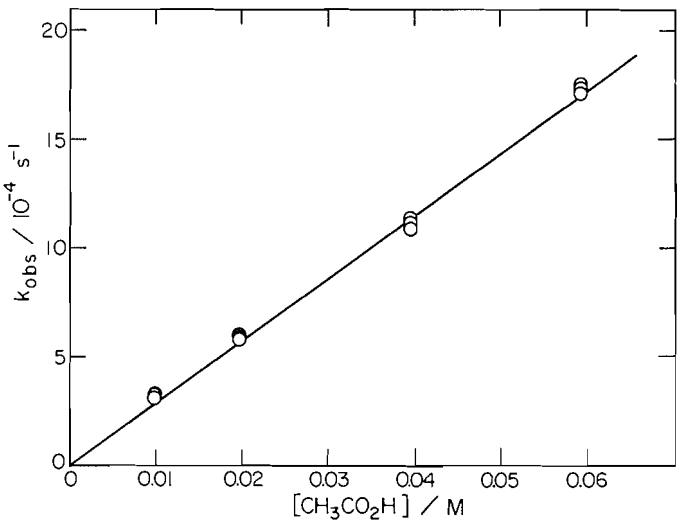

FIG. 1. Relationship between acid concentration and observed first-order rate constants for the hydrolysis of tetramethoxyethene in aqueous solution at 25°C; ○, H_2O; △, D_2O.

$$[2] \quad k_{obs} = k_{H+}[H^+] + k_{HA}[HA]$$

Hydronium-ion catalytic coefficients were also determined from the buffer solution data using the terms $k_{H+}[H^+]$ of the rate law (eq. [2]) and the known hydrogen ion concentrations of the buffers. These results are also listed in Table 3. It may be seen that, whereas all k_{H+} values so obtained are consistent with k_{H+} = 0.454 measured directly in perchloric acid solutions, uncertainties in these results increase with decreasing buffer solution acidity and eventually become greater than the values of k_{H+} themselves. This is because general acid catalysis in these solutions is very strong and hydronium-ion contributions to observed rates are correspondingly small, as seen, for example, in Fig. 2. Situations such as this arise in reactions with small Brønsted exponents and/or hydronium-ion catalytic coefficients that fall markedly below the Brønsted line (6*b*); both of these factors were operative in the present case (*vide infra*).

[a]Ionic strength = 0.10 M ($NaClO_4$).

The Brønsted plot constructed with the seven carboxylic acid catalytic coefficients determined here is shown in Fig. 3. Linear least-squares analysis gave the exponent $\alpha = 0.42 \pm 0.05$ and predicted a value for the hydronium-ion catalytic coefficient which is greater than the experimentally determined value, $k_{H+} = 0.454$ M^{-1} s^{-1} by a factor of 45. The presently determined Brønsted exponent is similar to values obtained before for

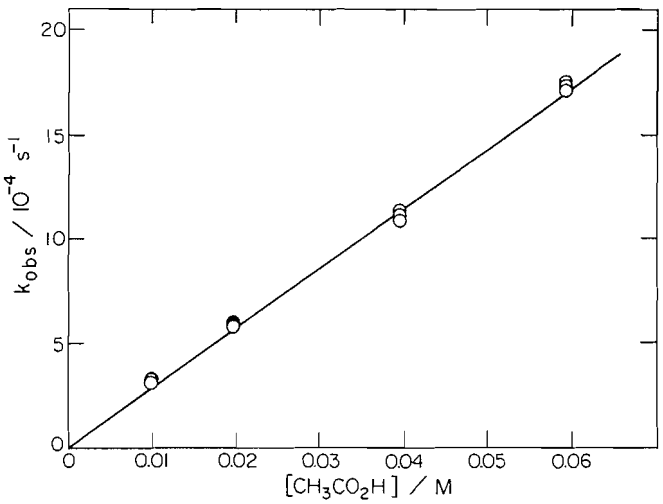

FIG. 2. Relationship between buffer acid concentration and observed first-order rate constants for the hydrolysis of tetramethoxyethene in aqueous acetic acid buffer solutions at 25°C; buffer ratio ([HA]/[NaA]) = 0.99, ionic strength = 0.10 M.

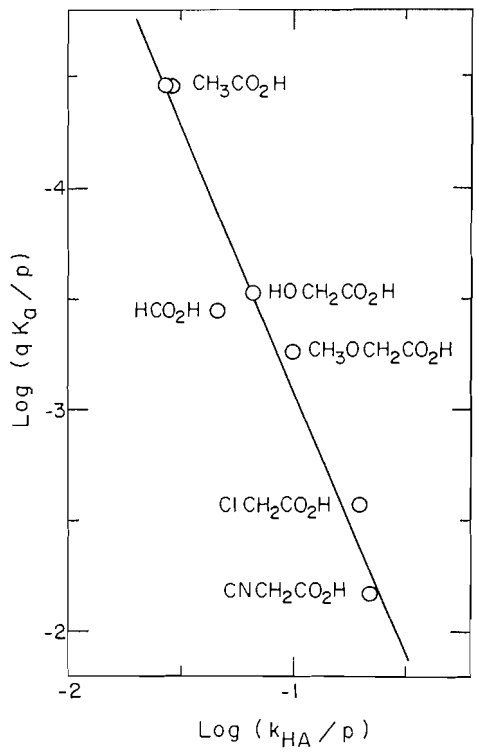

FIG. 3. Brønsted relation for the hydrolysis of tetramethoxyethene catalyzed by carboxylic acids in aqueous solution at 25°C.

the hydrolysis of ketene acetals (8), and the present hydronium-ion deviation is typical of reactions undergoing rate-determing proton transfer to carbon (9). The present Brønsted relation also shows carboxylic acid deviations which are strikingly similar to characteristic deviations for individual carboxylic acids found before in other ketene acetal hydrolysis reactions (8): formic acid is consistently low and chloro- and methoxyacetic acid are consistently high, while cyano-, hydroxy-, and acetic acid itself lie on the Brønsted line. It was pointed out before (8) that these deviations seem to be related to the size of the catalysts involved and may therefore be caused by London dispersion interactions between catalyst and substrate.

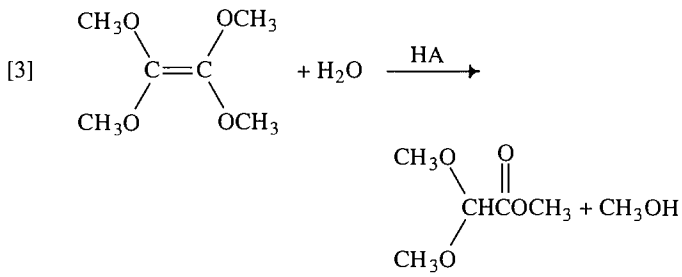
Discussion

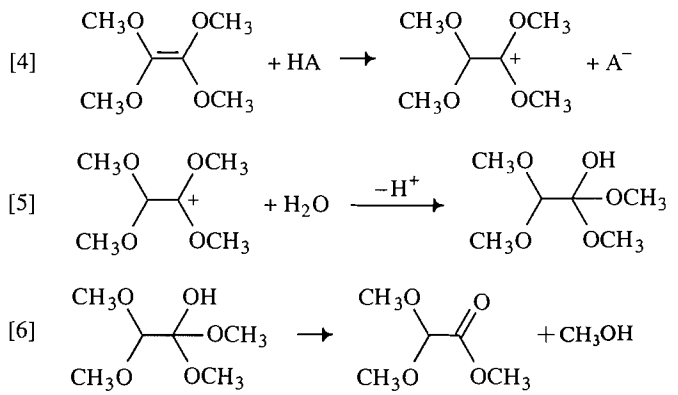
Reaction mechanism

The product of hydrolysis of tetramethoxyethene in dilute aqueous acid is reported to be methyl dimethoxyacetate, reaction [3] (10).



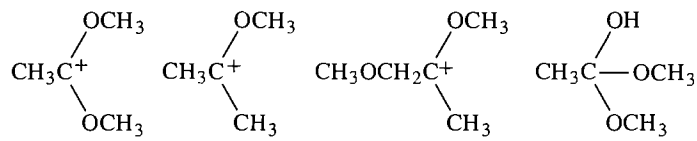
This was confirmed in the present study by the changes that occurred in the proton NMR spectrum of a reacting solution tetramethoxyethene in D_2O containing approximately 0.1 M DCl: the signal of tetramethoxyethene at δ = 3.42 ppm quickly diminished as three new peaks, at δ = 3.61, 3.22, and 3.13 ppm in the intensity ratio 1:2:1, grew in; the first two of these new resonances are consistent with expectation for the methyl proton signals of the ester and acetal groups of methyl dimethoxyacetate, respectively, and the third was identified as the signal from the methyl group of methanol by adding a small sample of this alcohol to the reaction mixture. These changes were complete in 10 min, and they were then followed by very much slower decreases of the ester and acetal signals and increase of the methanol signal as further hydrolysis of methyl dimethoxyacetate took place.

The analog of the accepted mechanism for vinyl ether or ketene acetal hydrolysis (8, 11) which applies in the present case consists of protonation of tetramethoxyethene on carbon, reaction [4], followed by hydration of the dialkoxycation so formed, reaction [5], and decomposition of the ensuing hydrogen ortho ester, reaction [6]. This reaction scheme is consistent



with all of the evidence presented here. The large hydrogen ion isotope effect found, moreover (k_{H+}/k_{D+} = 3.15), indicates that the first step is rate-determining, for reversible carbon protonation with some subsequent step rate-determining would have produced an inverse isotope effect, $k_{H+}/k_{D+} < 1$ (6c). This assignment is supported by the observation of general acid catalysis, though such catalysis is also consistent with rate-determining hydration of the dialkoxy cation, reaction [5], assisted by general-base promoted removal of a proton from the attacking water molecule.

This assignment of a rate-determining, non-reversible role to the carbon protonation step is also consistent with the fact that the subsequent steps are expected to be very fast. A rate constant of $3 \times 10^6\ s^{-1}$ can be estimated for the hydration reaction [5] from $k = 1.8 \times 10^5\ s^{-1}$ for the hydration of the α,α-dimethoxyethyl cation (12), **5**, plus an accelerating effect of 4 for each of the β-methoxy substituents introduced in going from **5** to the substrate of reaction [5]; this accelerating effect is based upon the difference in hydration rate constants for the α-methyl-α-methoxyethyl cation, **6**, $k = 1 \times 10^9\ s^{-1}$, and the α-methoxymethyl-α-methoxyethyl cation, **7**, $k = 4 \times 10^9\ s^{-1}$ (13). Decomposition of the hydrogen ortho ester, reaction [6], will also be rapid inasmuch as such processes are well-known to be fast reactions (14); for example, the hydronium-ion catalytic coefficient for decomposition of dimethyl hydrogen orthoacetate, **8**,



5 **6** **7** **8**

has been estimated to be greater than $7 \times 10^4\ M^{-1}\ s^{-1}$ (15).

Reactivity

The hydronium-ion catalytic coefficient determined here for tetramethoxyethene, k_{H+} = 0.454 $M^{-1}\ s^{-1}$, is considerably smaller than that for 1,1-dimethoxyethene (ketene dimethyl acetal, **3**), $k_{H+} = 2.3 \times 10^5\ M^{-1}\ s^{-1}$ (3). The two additional methoxy groups introduced in going from 1,1-dimethoxyethene to tetramethoxyethene thus decrease rather than increase the reactivity of the carbon–carbon double bond to electrophilic addition of a proton. This, of course, is consistent with expectation based upon the double-bond stabilizing effect of methoxy groups.

Some additional insight into the nature of this retarding effect may be gained from a quantitative comparison of the rate reduction observed with that expected from the double-bond stabilizing effect of the additional methoxy groups. This effect has been evaluated as $\delta\Delta G$ = 5.2 kcal mol^{-1} per methoxy

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

group (4). If all of this stabilization were present in the initial state of the reaction and were absent from its transition state, a rate retardation corresponding to $2 \times 5.2 = 10.4$ kcal mol^{-1} would be realized. However, some of the stabilizing effect will still be present in the transition state because this state still contains a partial double bond. On the assumption that the Brønsted exponent, α, for the system measures the resemblance of the transition state to the final state, and $1 - \alpha$ therefore measures its resemblance to the initial state, $(1 - \alpha)$ $(5.2) = (1 - 0.42)$ $(5.2) = 3.0$ kcal mol^{-1} double-bond stabilization should still be present in the transition state. Two methoxy groups will contribute twice this amount, and the difference between that and the initial state stabilization corresponds to a rate retardation of 1.7×10^3. The experimentally observed value, based on the difference in rate between 1,1-dimethoxyethene and tetramethoxyethene, calculated taking into account the fact that tetramethoxyethene has two equivalent carbon-protonation sites, is 1.0×10^6. Tetramethoxyethene is thus 600 times less reactive than it should be on the basis of the effect of double bond stabilization by methoxy groups estimated in this way.

A similar disparity between an estimate made in the same way and the experimental value for the hydronium-ion catalyzed hydrolysis of dihydro-1,4,-dioxin, **9**, has been ascribed to an

9

additional, destabilizing inductive effect of the second oxygen on the positive charge being generated on the substrate in the transition state (16). This explanation could apply here, but there is also another possibility: the disparity might be due to imperfect synchronization of the changes that occur as the system moves from initial state through the transition state to the final state (17). If, for example, changes in conjugation of the methoxy groups with the carbon–carbon double bond run ahead of proton transfer, then $1 - \alpha$ will overestimate the methoxy-group double-bond stabilization left at the transition state, and the rate retardation calculated on this basis will consequently be too low. Such a disparity between changes in conjugation and the extent of proton transfer is believed to occur in the ionization of nitroalkanes (18).

Reaction of *N,N'*-1,2-ethanediylidenebis(2,2-diethoxyethanamine)-*N,N'*-dioxide and phenylboronic acid yields the title compound. Crystals of 1,4-bis(2,2-diethoxyethyl)-6,8-diphenyl-5,7,9-trioxa-4-aza-1-azonia-8-bora-6-boratabicyclo[4.3.0]-nonane are triclinic, $a = 12.625(2)$, $b = 13.962(2)$, $c = 9.273(1)$ Å, $\alpha = 104.81(1)$, $\beta = 98.61(1)$, $\gamma = 106.52(1)°$, $Z = 2$, space group $P\bar{1}$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to $R = 0.058$ and $R_w = 0.081$ for 3677 reflections with $I \geq 3\sigma(I)$. The molecule has a bicyclo[4.3.0]nonane structure containing one transannular N—B bond. Important bond lengths are sp^3-boron, N—B = 1.759(3), O—B = 1.435(3) and 1.454(3), C—B = 1.579(4); sp^2-boron, O—B = 1.335(3) and 1.404(3), C—B = 1.557(4) Å. The (sp^3)B—C(phenyl) bond is the shortest yet reported for this type of compound.

Key words: crystal structure, boron compound, organoboron compound.

HENNING AMT, WOLFGANG KLIEGEL, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **68**, 1791 (1990).

La réaction de la *N,N'*-dioxyde de *N,N'*-1,2-éthanediylidène bis(2,2-diéthoxy-éthanamine) avec l'acide phénylboronique fournit le composé mentionné dans le titre. Les cristaux du 1,4-bis(2,2-diéthoxyéthyl)-6,8-diphényl-5,7,9-trioxa-4-aza-1-azonia-8-bora-6-boratabicyclo[4.3.0]nonane sont tricliniques avec $a = 12,625(2)$, $b = 13,962(2)$ et $c = 9,273(1)$ Å, $\alpha = 104,81(1)$, $\beta = 98,61(1)$ et $\gamma = 106,52(1)°$, $Z = 2$, groupe d'espace $P\bar{1}$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés jusqu'à des valeurs respectives de $R = 0,058$ et $R_w = 0,081$ pour 3677 réflexions avec $I \geq 3\sigma(I)$. La molécule possède une structure bicyclo[4.3.0]nonane contenant une liaison transannulaire N—B. Les longueurs de liaisons importantes sont : sp^3-bore, N—B = 1,759(3), O—B = 1,435(2) et 1,454(3), C—B = 1,579(4); sp^2-bore, O—B = 1,335(3) et 1,404(3), C—B = 1,557(4) Å. La longueur de la liaison (sp^3)B—C(phényle) est la plus courte à avoir été observée jusqu'à maintenant pour ce type de composé.

Mots clés : structure cristalline, composé du bore, composé du organobore.

[Traduit par la revue]

Introduction

Reduction of glyoxalbisnitrone **1** with potassium tetrahydroborate gives the *N,N'*-dihydroxy-1,2-ethanediamine derivative **2** which was then reacted with phenylboronic acid. We expected a condensation leading to the tricyclo[5.4.0.$0^{3,9}$]undecane **3** with the "4-homotwistane" ring skeleton which has recently been structurally characterized for the *N*-methyl derivative **2** (R = Me) (1). Surprisingly the crystalline reaction product of **2** (R = $CH_2CH(OEt)_2$) and phenylboronic acid showed the quantitative elemental analysis and nmr spectral data consistent with a 1:2 condensate, regardless of the molar ratio of the reactants (1:3 or 1:2). Chemical and spectroscopic data were not sufficient to allow for an unambiguous decision between the possible isomeric structures of **4** which include structures having both bicyclic (**A–C**) and tricyclic ring systems (**D**, **E**). The cyclononane **A** with transannular N—B coordination represents a ring-enlarged homolog of bicyclic compounds of the type **5** (2) which have been structurally characterized by X-ray crystallographic analysis (3). Similar ring systems, containing a pyroboronate —OB(Ph)OB(Ph)O— partial structure cyclized with one hydroxylamine function to form a BOBON ring, have already been found for the compounds **6** (4) and **7** (5). The bicyclo[3.3.0]octane type structure **B** would also possess a transannular N—B bond but would have an *N*-oxide function with its nitrogen atom bound to tetracoordinated boron, an unstable grouping expected to rearrange to the more stable structure **A**. The third bicyclic variation **C** could be formed by an N—O—B bridge within an isomeric cyclononane system.

All three transannular mono-coordinated ring systems, **A**, **B**, and **C**, could undergo fluxional intramolecular coordination exchange because of the additional sp^2-boron atom and electron-donating N/O groups present in each of these systems. As an alternative, in the structures **D** and **E**, two transannular coordinative interactions could give rise to the tricyclic systems, **D** being formed from **A** by an additional N—B bond and **E** being formed from **B** or **C** by additional O—B or N—B bonds, respectively. Structures **D** and **E** represent symmetric heterocyclanes with "nortwistane" and "norisotwistane" skeletons, respectively.

An X-ray crystallographic analysis has been carried out to determine the solid state structure of **4** definitively.

6 mmol; procedure [*b*]: 0.49 g, 4 mmol) are heated in 80 mL absolute ethanol under reflux for 1 h. After evaporation of the solvent *in vacuo* the remaining oil is diluted with ether/petroleum ether (1:1) and cooled 24 h for crystallization. Yields: procedure [*a*]: 0.71 g (69%), procedure [*b*]: 0.68 g (66%). Melting point: 95°C (ether/petroleum ether). *Anal.* calcd. for $C_{26}H_{40}B_2N_2O_7$: C 60.73, H 7.84, B 4.21, N 5.45; found: C 60.74, H 8.07, B 4.34, N 5.24. Infrared (KBr): 1605 cm^{-1} (phenyl C=C). ^1H nmr ($CDCl_3$/TMS): δ (ppm) = 0.90 and 1.09 (t, t, J = 7 Hz, 4 CH_3), 2.79 (d, J = 5 Hz, 2 $CH_2C(O)O$), 3.08–3.62 (m, 4 O—CH_2), 4.61 (t, J = 5 Hz, 2 CH(O)O), 7.20–7.42 (m, 6 aromatic H), 7.70–7.89 (m, 4 aromatic H). Crystals suitable for X-ray analysis were obtained by recrystallization from absolute diethylether.

X-ray crystallographic analysis of 1,4-bis(2,2-diethoxyethyl)-6,8-diphenyl-5,7,9-trioxa-4-aza-1-azonia-8-bora-6-boratabicyclo-[4.3.0]nonane

A crystal *ca.* 0.24 × 0.25 × 0.35 mm in size was mounted in a general orientation. Unit-cell parameters were refined by least-squares on setting angles for 25 reflections (2θ = 54–80°) measured on a diffractometer with Cu-$K\alpha$ radiation (λ = 1.54178 Å). Crystal data at 21°C are as follows:

$C_{26}H_{40}B_2N_2O_7$ f.w. = 514.23

Triclinic, a = 12.625(2), b = 13.962(2), c = 9.273(1) Å, α = 104.81(1), β = 98.61(1), γ = 106.52(1)°, V = 1470.8(4) $Å^3$, Z = 2, ρ_c = 1.161 Mg m^{-3}, $F(000)$ = 552, μ(Cu-$K\alpha$) = 6.36 cm^{-1}. Absent reflections: none, space group $P\bar{1}$ (reduced cell, Donnay convention) from structure analysis.

Intensities were measured with graphite-monochromated Cu-$K\alpha$ radiation on a Rigaku AFC6S diffractometer. An ω–2θ scan at 32° min^{-1} over a range of (1.25 + 0.30 tan θ) degrees in ω (with up to eight rescans, background/scan time ratio = 0.5) was employed. Data were measured to 2θ = 151.6°. The intensities of three check reflections, measured every 150 reflections throughout the data collection, showed only small random variations. After data reduction,[2] an empirical absorption correction based on azimuthal scans for four reflections was applied, resulting in relative transmission factors ranging from 0.94 to 1.00. Of the 6200 reflections measured, 5811 were unique (R_{int} = 0.009) and 3677 (63.3%) of these had intensities greater than or equal to $3\sigma(F^2)$ above background where $\sigma^2(F^2) = (S^2(C + 4B) + (0.04(F_o^2))^2)/Lp^2$ with S = scan speed, C = scan count, B = total background count, and Lp = Lorentz-polarization factor.

The structure was solved by direct methods, 29 of the 37 non-hydrogen atoms being positioned from an E-map. The remaining non-hydrogen atoms were positioned from subsequent difference Fourier syntheses. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms were fixed in calculated positions (C—H = 0.98 Å, $B_H = 1.2B_{bonded\ atom}$). The peripheral atoms C(9) and C(10) show a high degree of thermal motion that results in anomalous bond lengths and angles. The fact that the thermal motion of atom C(9) is nearly isotropic suggested that a simple disordered model would not be adequate in this case, thus no attempt to refine a disordered model for this ethyl group was made. Scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from ref. 7. The weighting scheme $w = 4F_o^2/\sigma^2(F_o^2)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix refinement of 335 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. An extinction correction was applied, the final value of the extinction parameter being 1.63 × 10^{-5}. Convergence was reached at R = 0.058 and R_w = 0.081 for

3677 reflections with $I \geq 3\sigma(I)$. For all 5811 reflections $R = 0.094$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the maximum parameter shift corresponded to 0.11σ. The mean error in an observation of unit weight was 3.04. The final difference map showed maximum fluctuations of -0.29 to 0.37 e $Å^{-3}$. The final positional and equivalent isotropic thermal parameters for the non-hydrogen atoms appear in Table 1. Bond lengths and angles are listed in Tables 2 and 3, and intra-annular torsion angles in Table 4. Hydrogen parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, least-squares planes, and structure factors have been deposited.[3]

Results and discussion

The structure analysis confirms the bicyclic formulation **4***A*, with one transannular N—B bond dividing the heterononane system into a six-membered BONCCN ring and a five-membered BOBON ring containing the pyroboronate moiety. The BOBON ring is axially fused to the side of the BONCCN boat, while the *N*- and *B*-substituents (—$CH_2CH_2(OEt)_2$ and phenyl groups, respectively) occupy equatorial positions (see Fig. 1).

The B(2) phenyl group is not exactly coplanar with the O(2)—B(2)—O(3) plane of the BOBON ring (dihedral angle between normals to the mean planes = 9.2°), but the shortened B(2)—C(21) distance is indicative of some π-interaction between the phenyl group and the sp^2-boron atom. The bond length of 1.557(4) Å is comparable to similar bond distances in

TABLE 4. Intra-annular torsion angles (deg) standard deviations in parentheses

the related bicyclic systems **5** (1.548 Å) (3), **6** (1.557 Å) (4), and **7** (1.555 Å) (5). As in compounds **5–7** there is evidence of O—B $pp(\pi)$ back-donation in the O—(sp^2)B—O portion of the BOBON ring, the partial π-bond character causing short O—B bonds, especially at the anhydridic O(3)—B(2) bond. The bond lengths of 1.454(3), 1.335(3), and 1.404(3) Å in the (sp^3)B—O—(sp^2)B—O moiety are similar to corresponding distances of 1.466, 1.339, 1.406 Å in **5** (3); 1.467, 1.334, 1.404 Å in **6** (4); 1.458, 1.331, 1.404 Å in **7** (5); 1.487, 1.329, 1.422 Å in **8** (8); and 1.495, 1.332, 1.418 Å in **9** (9).

The (sp^3)B—phenyl distance (B(1)—C(15) = 1.579(4) Å) is the shortest yet observed for a compound having a "$PhBO_2N$" ligand set; the bonds in **3** (1), **5** (3), **6** (4), **7** (5), and **10–12**

(10–13) range from 1.582 Å in **5** to 1.633 Å in **12** with an average value of 1.601 Å. The B(1)—phenyl bond in **4***A* is nearly as short as some (sp^2)B—phenyl bond lengths such as one of the (sp^2)B—C bonds in the phenylboroxin ring of **12** (13) at 1.575 Å and the (sp^2)B—C bond length of 1.574 Å in **3** (1). It is possible that some degree of π-interaction may be occurring between the phenyl substituent and the boron atom involved in the transannular coordinative bond. The shortening of the (sp^3)B—phenyl bond is balanced by the relatively long transannular N(2)—B(1) bond (1.759(3) Å), similar in length to those observed for compounds **5** (1.742 Å) (3) and **7** (1.754 Å) (5). While weaker basicity of the hydroxylamine function could be invoked as a possible cause of the lengthening of the N—B coordinative bond, the most important factor is steric with the

For personal use only.

ring fusion forcing an eclipsed configuration about the N—B bond as noted earlier for **5** and **7**. The N—B bonds in **3** are about 1.66 Å in length (1) and that in **11** is only 1.59 Å (12) in spite of the low basicity at the oxime nitrogen atom. The intramolecular contact N(1)···B(2) = 2.981(4) Å is shorter than the sum of the van der Waals radii (~3.15 Å), but not short enough to form the second intramolecular N—B coordinative interaction required to produce the "nortwistane" structure ***4D***.

Within the ethylenediamine portion of the ring system, the difference between the N(2)—C(2) and N(1)—C(1) distances is striking: the bond at the quaternized nitrogen atom is about 0.03 Å longer than that at the trivalent nitrogen atom (1.484(3) vs. 1.450(3) Å, the latter being a very short N—C single bond). The difference between the other N—C bonds, N(2)—C(5) = 1.487(3) Å and N(1)—C(3) = 1.466(3) Å, is close to that normally observed between N—C bonds at tetravalent and trivalent nitrogen, e.g. compound **5** N—C(methyl): 1.476 and 1.465 Å (3). Surprisingly the two N—O bond lengths are equal to within experimental error (1.458(3) and 1.453(2) Å). In compound **5** a difference of 0.015 Å between the N—O bonds was noted (3).

The five-membered BOBON ring containing the trigonal planar (sp^2)-boron atom has a nearly planar, flattened B(1)—envelope conformation (see Table 4). The geometry of this ring is very similar to that observed for **5** (3) and is comparable to that observed for corresponding BOBON rings in compounds **6–9** (4, 5, 8, 9) which exhibit varying degrees of non-planarity (most pronounced in **8** (8)).

Received March 13, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

HENNING AMT, WOLFGANG KLIEGEL, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **68**, 1797 (1990).

The synthesis of 4,7-dicyclohexyl-2,2,5,6-tetraphenyl-1,3-dioxa-4-aza-7-azonia-2-boratacycloheptane is reported. Crystals of the compound are orthorhombic, $a = 10.893(1)$, $b = 28.072(1)$, $c = 10.596(1)$ Å, $Z = 4$, space group $P2_12_12_1$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to $R = 0.036$ and $R_w = 0.043$ for 2480 reflections with $I \geq 3\sigma(I)$. The molecule has a seven-membered chelate structure. The seven-membered ring, which has a twisted chair conformation, is stabilized by an intramolecular N—H···O hydrogen bond. Bond lengths O—B = 1.468(4) and 1.554(4), C—B = 1.621(5) and 1.626(4) Å are consistent with moderately strong binding of the diphenylboron moiety by the *O,O*-chelating ligand.

Key words: crystal structure, organoboron compound, boron compound.

HENNING AMT, WOLFGANG KLIEGEL, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **68**, 1797 (1990).

On décrit la synthèse du 4,7-dicyclohexyl-2,2,5,6-tétraphényl-1,3-dioxa-4-aza-7-azonia-2-boratacycloheptane. Les cristaux de ce composé sont orthorhombiques et ils appartiennent au groupe d'espace $P2_12_12_1$, avec $a = 10,893(1)$, $b = 28,072(1)$, $c = 10,596(1)$ Å et $Z = 4$; on a résolu la structure par les méthodes directes et on l'affiné par la méthode des moindres carrés jusqu'à des valeurs respectives de $R = 0,036$ et $R_w = 0,043$ pour 2480 réflexions avec $I \geq 3\sigma(I)$. La molécule possède une structure chélatée à sept chaînons. Le cycle à sept chaînons, qui possède une conformation chaise déformée, est stabilisé par une liaison hydrogène intramoléculaire N—H...O. Les longueurs des liaisons O—B = 1,468 (4) et 1,554(4), C—B = 1,621(5) et 1,626(4) Å sont en accord avec une liaison relativement forte de la portion diphénylbore par le ligand *O,O*-chélatant.

Mots clès : structure cristalline, composé du organobore, composé du bore.

Introduction

The addition of 2 mol of phenylmagnesium bromide to glyoxalbisnitrone **1** led to the substituted bishydroxylamine **2** which was reacted with diphenylborinic acid anhydride in ethanol at room temperature. The crystalline reaction product was shown to be a mono-acylation product of the reaction of bishydroxylamine with diphenylborinic acid using quantitative elemental analysis. The presence of an intact diphenylboron moiety was substantiated by the color reaction with diphenylcarbazone (1). The ^{1}H nmr spectrum confirmed the elemental analysis but no signal for an exchangeable proton (OH or NH) was detectable up to $\delta = 20$ ppm. The OH protons of **2**, for instance, give a broad singlet at 4.70 ppm. In the infrared spectrum of the diphenylborinic acid derivative a distinct absorption band at 3100 cm^{-1} is conspicuous, this could correspond to the N—H stretching frequency of an ammonium grouping. Similar values (3050–3150 cm^{-1}) have been reported for N—H vibrations in hydroxylamine derivatives with quaternized nitrogen (2). The O—H absorption of **2** is found as a broadened band between 3200 and 3600 cm^{-1} with a sharp peak at 3580 cm^{-1}. Thus an open-chain acylation derivative **3** or its BONBON-cyclic dimer seemed less reasonable than chelate structures like the seven-membered species **4** or its intramolecular hydrogen bridged variants **4***A* and **4***B*. Although seven-membered boron chelates are rare in the literature (3–6), both the fact that they can be stable compounds and the high affinity of oxygen ligands to boron strongly support a type **4** structure. The six-membered isomer **5** resembles the diphenylboron chelates of 3-aminoalkanols (7, 8) or 2-aminooxyalkanols (9) and could not be definitely precluded, nor could we preclude the hydrogen-bridged derivatives **5***A* and **5***B*. The least probable isomer considered is the five-membered chelate **6** and its hydrogen-bridged derivative **6***A*. Even though five-membered boron chelates with two nitrogen atoms are well known (10) the molecular arrangement of an N—B coordinated *N*-oxide function seems very unfavorable even if stablized by an intramolecular hydrogen bond as in **6***A*. Formally, an intramolecular exchange of the *O,O*-chelated proton in **6***A* for the *N,N*-chelated diphenylborenium (Ph_2B^+) ion would lead to structure **4***A*. The same relationship exists between **5***B* and **4***B*. For clarity an X-ray crystallographic analysis has been undertaken.

Experimental

Synthesis

N,N′-*Dicyclohexyl*-N,N′-*dihydroxy-1,2-diphenyl-1,2-ethanediamine, 2*

N,N′-1,2-Ethanediylidenebis(cyclohexanamine)-*N,N′*-dioxide, **1**[2] (5.05 g, 20 mmol) is suspended in 150 mL dry ether. Under vigorous stirring a Grignard solution of bromobenzene (25.12 g, 160 mmol) and magnesium (3.89 g, 160 mmol) in 150 mL dry ether is added over a period of 10 min. After refluxing for 1 h, the solution is cooled and hydrolysis carried out by the addition of water and then 2 N hydrochloric acid until the magnesium hydroxide is dissolved. The aqueous phase

[1]Previous paper in this series: ref. 22.

[2]Compound **1** has been synthesized by condensation of glyoxal and *N*-cyclohexylhydroxylamine. Melting point 214°C (from ethanol) (11).

for recrystallization but loss of material still occurs.[3] Melting point (decomp.): 114°C (from ether). *Anal.* calcd. for $C_{38}H_{45}BN_2O_2$: C 79.71, H 7.92, B 1.89, N 4.89; found: C 79.72, H 7.83, B 1.96, N 4.88. Infrared (KBr): 3100 cm^{-1} (N—H). ^1H nmr ($CDCl_3$/TMS): δ(ppm) = 0.74–2.20 (m, 2 —$(CH_2)_5$—), 2.40 and 2.56 (m, m, 2 N—CH(cyclohexyl)), 4.40 and 4.58 (s, s, N—CH—CH—N), 7.1–8.0 (m, 4 C_6H_5).

The substance gave a blue color reaction (1) with diphenylcarbazone in methanolic solution, indicating the presence of a diphenylboron moiety. Crystals suitable for X-ray analysis were obtained by recrystallization from ethanol after 14 days at −18°C.

X-ray crystallographic analysis of ***4***

A crystal ca. 0.20 × 0.20 × 0.25 mm in size was mounted on a glass fiber. Unit-cell parameters were refined by least-squares on setting angles for 25 reflections (2θ = 50.2–91.9°) measured on a diffractometer with Cu-K_α radiation (λ = 1.54178 Å). Crystal data at 21°C are as follows:

$C_{38}H_{45}BN_2O_2$ f.w. = 572.60

Orthorhombic, a = 10.893(1), b = 28.072(1), c = 10.596(1) Å, V = 3240.0(5) $Å^3$, Z = 4, ρ_c = 1.174 Mg m^{-3}, $F(000)$ = 1232, μ(Cu-K_α) = 5.16 cm^{-1}. Absent reflections: $h00$, h odd, $0k0$, k odd, and $00l$, l odd, uniquely indicate the space group $P2_12_12_1$ (No. 19).

Intensities were measured with graphite-monochromated Cu-K_α radiation on a Rigaku AFC6S diffractometer. An ω–2θ scan at 16° min^{-1} over a range of (1.05 + 0.30 tan θ)° in ω (with up to eight rescans, background/scan time ratio = 0.5) was employed. Data were measured to 2θ = 155°. The intensities of three check reflections, measured every 150 reflections throughout data collection, showed only small random variations. After data reduction,[4] an empirical absorption correction based on azimuthal scans for three reflections was applied. Transmission factors range from 0.98 to 1.00. Of the 3807 independent reflections measured, 2480 (65.1%) had intensities greater than or equal to 3σ(F^2) above background where $\sigma^2(F^2) = [S^2(C + 4B) + (0.035F^2)^2]/Lp^2$ with S = scan rate, C = scan count, B = total background count, and Lp = Lorentz-polarization factor.

The structure was solved by direct methods, the coordinates of all non-hydrogen atoms being determined from an E-map. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms (with the exception of the N—H hydrogen atom which was refined with an isotropic thermal parameter) were fixed in idealized positions (C—H = 0.98 Å, $B_H = 1.2B_{bonded\ atom}$). A correction for secondary extinction was applied, the final value of the extinction coefficient being 1.73 × 10^{-4}. Scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from ref. 13. The weighting scheme $w = 4F_o^2/\sigma^2(F_o^2)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix least-squares refinement of 393 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.036 and R_w = 0.043 for 2480 reflections with $I \geq 3\sigma(I)$. A parallel refinement of the mirror-image structure gave slightly higher residuals, the R_w ratio being 1.002. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the maximum parameter shift corresponded to 0.01σ. The mean error in an observation of unit weight was 1.44. The final difference map showed maximum fluctuations of −0.12 +0.14 e $Å^{-3}$. The final positional and (equivalent) isotropic thermal parameters for the non-hydrogen atoms appear in Table 1. Bond lengths and angles are given in Tables 2 and 3 and intra-annular torsion angles in Table 4. Hydrogen atom parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, least-squares planes, bond lengths and angles involving hydrogen, and structure factors have been deposited.[5]

Results and discussion

The X-ray analysis confirms a seven-membered chelate structure having a twisted chair conformation (see Fig. 1 and Table 4). If an idealized C_2 symmetry, distorted in ***4B***, is taken as a basis for the twisted chair conformation of the seven-membered chelate ring the boron atom would lie on the two-fold axis to offer the most favorable position for geminal disubstitution. The conformation of the seven-membered ring along with the substitution pattern — the C(1) phenyl group is positioned (pseudo)axial while the C(2)—phenyl and the N-cyclohexyl residues occupy (pseudo)equatorial positions — forces H(1) into a (pseudo)axial position at the quaternized nitrogen atom N(1). This particular arrangement only allows the formation of

an intramolecular N—H···O(2) hydrogen bond, resulting in the H-bridged structure **4***B*. The N(1)···O(2) distance (2.612(3) Å) is shorter than the alternative N(2)···O(1) distance (3.002(3) Å). The H(1)···O(2) contact of 2.18(3) Å is similar to those reported for intermolecular N—H···O hydrogen bonds in the solid state structures of compounds **7** (2.11(5) Å) (14), **8** (1.97(2) Å) (2*a*), and **9** (2.15(4) Å) (15). These types of *N*-monoprotonated boron chelate compounds all show relatively sharp N—H stretching frequencies at about 3100 cm^{-1} in their infrared spectra (2, 16, 17), indicating weak N—H···O hydrogen bonding, as does the bent (102(2)°) intramolecular N(1)—H(1)···O(2) hydrogen bridge in **4***B* with an infrared band at 3100 cm^{-1}. A strong intramolecular N—H···N hydrogen bond, as proposed in formula **4***A*, cannot be formed for steric reasons (ring conformation). The presence of such a hydrogen bridge would be indicated by broad association bands in the infrared spectrum and signals in the ^1H nmr spectrum such as those reported for "proton cryptates" or "proton sponges" (18).

The mono-protonation and H-bridging in **4***B* introduces asymmetry into the basically symmetric ring skeleton. The N—C bonds of the ethylenediamine portion of the ring differ by about 0.06 Å: N(1)—C(1) = 1.543(3) Å and N(2)—C(2) = 1.482(4) Å. The O(1)—B bond (1.554(4) Å) is markedly longer than the O(2)—B bond (1.468(4) Å). This difference is larger than that between the O—B bonds in the asymmetric six-membered diphenylboron chelate **10** with values of 1.552 and 1.493 Å (19). The N—O bond length within the quaternized hydroxylamine group (N(1)—O(1) = 1.412(3) Å) is about 0.05 Å shorter than that involving the trivalent nitrogen atom (N(2)—O(2) = 1.464(3) Å). A similar, but less pronounced, difference has been observed for the N—O bonds in compound **11** (20) which also contains both tri- and tetravalent hydroxylamine nitrogen atoms. The asymmetry of **4***B* is also reflected by the ^1H nmr spectrum which displays separate signals for the methine protons of C(1) and C(2), and also for those of C(3) and C(9). Both geminal *B*-phenyl substituents display nearly equal C—B distances of normal magnitude (1.621(5) and 1.626(5) Å), comparable to those in **10** which average 1.623 Å (19).

The mean C—B/mean O—B bond length ratio of 1.074 for **4***B* is indicative of fairly strong overall binding of the *O,O*-chelating ligand to the diphenylboron moiety (21). The two cyclohexane rings have essentially undistorted chair conformations (see Table 4). The remaining molecular geometry (Tables 2 and 3) is as expected. Molecules are well separated in the crystal lattice, the shortest intermolecular contact between non-hydrogen atoms being C(6)···C(35) (1 + *x*, *y*, *z*) = 3.587(5) Å.

Structural studies of organoboron compounds. XLI. (3-Hydroxy-2-methyl-1-(*p*-tolyl)-4-pyridinonato)diphenylboron

CHRIS ORVIG, STEVEN J. RETTIG, JAMES TROTTER, AND ZAIHUI ZHANG
Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received March 26, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

CHRIS ORVIG, STEVEN J. RETTIG, JAMES TROTTER, and ZAIHUI ZHANG. Can. J. Chem. **68**, 1803 (1990).

(3-Hydroxy-2-methyl-1-(*p*-tolyl)-4-pyridinonato)diphenylboron has been prepared in high yield by the reaction of 3-hydroxy-2-methyl-1-(*p*-tolyl)-4-pyridinone with diphenylborinic acid. Crystals of the hemi-acetone solvate are triclinic, a = 15.119(2), b = 16.528(1), c = 9.5802(9) Å, α = 98.721(6), β = 93.344(8), γ = 102.443(6)°, Z = 4, space group $P\bar{1}$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to R = 0.050 and R_w = 0.065 for 4330 reflections with $I \geq 3\sigma(I)$. The five-membered chelate rings in both of the two crystallographically independent molecules have flattened *B*-envelope conformations (maximum deviations from the mean planes = 0.114(4) and 0.065(5) Å). Mean bond lengths O—B = 1.553 and C—B = 1.599 Å are consistent with intermediate strength binding of the diphenylboron moiety by the *O,O*-chelating ligand.

Key words: crystal structure, organoboron compound.

CHRIS ORVIG, STEVEN J. RETTIG, JAMES TROTTER et ZAIHUI ZHANG. Can. J. Chem. **68**, 1803 (1990).

On a préparé le (3-hydroxy-2-méthyl-1-(*p*-tolyl)-4-pyridinato)diphénylbore avec un excellent rendement en faisant réagir de la 3-hydroxy-2-méthyl-1-(*p*-tolyl)-4-pyridinone avec de l'acide diphénylborinique. Les cristaux solvatés par une demi-molécule d'acétone sont tricliniques et ils appartiennent au groupe d'espace $P\bar{1}$ avec a = 15,119(2), b = 16,528(1), et c = 9,5802(9) Å, α = 98,721(6), β = 93,344(8), et γ = 102,443(6)°, et Z = 4. On a résolu la structure par les méthodes directes et on l'a affinée par la méthode des moindres carrés jusqu'à des valeurs respectives de R = 0,050 et R_w = 0,065 pour 4330 réflexions avec $I \geq 3\sigma(I)$. Les cycles chélatés à cinq chainons des deux molécules cristallographiquement indépendantes possèdent une conformation enveloppe-B (déviations maximales du plan moyen = 0,114(4) et 0,065(5) Å). Les longueurs moyennes des liaisons O—B et C—B (1,553 et 1,599 Å) sont en accord avec une liaison de force moyenne entre la portion diphénylbore et le ligand chélatant-*O,O*.

Mots clés : structure cristalline, composé du organobore.

Introduction

The title compound **1** has been prepared as part of a continuing investigation of the structures of organoboron compounds (1) (including 3-hydroxy-4-pyrone **4** (2) and 3-hydroxy-4-pyridinone (3) complexes **2** and **3**) and in parallel with chemical and biological studies of neutral 3-hydroxy-4-pyridinone complexes (of variable lipophilicity) of the other group 13 metal ions Al^{3+}, Ga^{3+}, and In^{3+} (4, 5).

Experimental

*(3-Hydroxy-2-methyl-1-(*p*-tolyl)-4-pyridinonato)diphenylboron*

A solution of diphenylborinic acid was prepared by the acid hydrolysis (60 mL 0.10 *M* HCl) of (2-aminoethanolato)diphenylboron (0.658 g, 2.92 mmol, Aldrich Chemical) and was extracted with diethyl ether (4 × 50 mL). To the organic layer was added a solution of (3-hydroxy-2-methyl-1-(*p*-tolyl)-4-pyridinone (0.620 g, 2.88 mmol, prepared according to ref. 5) in 50 mL ethanol. The solution was stirred for 1 h, reduced in volume to 120 mL, and kept at 4°C overnight. A white crystalline product was isolated by filtration and dried *in vacuo* (yield 0.892 g, 82%). Analytically pure flakes were obtained by recrystallization from acetone/water, mp 160–161°C (uncorrected). *Anal.* calcd. for $C_{25}H_{22}BNO_2$: C 79.13, H 5.85, N 3.69; found: C 79.31, H 5.83, N 3.62. Infrared (KBr, all strong, cm^{-1}): 1635 ($\nu_{C=O}$); 1580, 1570, 1530, 1480 ($\nu_{C=C}$, pyridinone ring). ^1H NMR (d_6-acetone, 25°C, 300 MHz): δ 2.19 (s, 3H, NC(CH_3)); 2.48 (s, 3H, $C_6H_4(CH_3)$); 6.82 (d, 6.7 Hz, 1H, C*H*C(O)); 7.1–7.5 (m, 14H, $2C_6H_5$ and C_6H_4); 7.83 (d, 6.7 Hz, 1H, CHC*H*N).

The infrared spectrum was recorded on a Perkin-Elmer 783 from 4000–200 cm^{-1} and the ^1H NMR spectrum on a Varian XL-300. Crystals used for the X-ray analysis were obtained by slow evaporation of an acetone solution.

X-ray crystallographic analysis

A crystal *ca.* 0.12 × 0.15 × 0.35 mm in size was mounted on a glass fiber. Unit-cell parameters were refined by least-squares on setting angles for 25 reflections (2θ = 50.1–82.8°C) measured on a diffractometer with Cu-K_α radiation (λ = 1.54178 Å). Crystal data at 21°C are as follows:

$C_{25}H_{22}BNO_2 \cdot (1/2)\ C_3H_6O$ f.w. = 408.30

Triclinic, a = 15.119(2), b = 16.528(1), c = 9.5802(9) Å, α = 98.721(6), β = 93.344(8), γ = 102.443(6)°, V = 2300.4(4) Å^3, Z = 4, ρ_c = 1.179 Mg m^{-3}, $F(000)$ = 864, μ(Cu-K_α) = 5.53 cm^{-1}. Absent reflections: none, space group $P\bar{1}$ (reduced cell, Donnay convention) from structure analysis.

Intensities were measured with graphite-monochromated Cu-K_α radiation on a Rigaku AFC6S diffractometer. An ω–2θscan at 16° min^{-1} over a range of (1.00 + 0.25 tan θ)° in ω (with up to eight rescans, background/scan time ratio = 0.5) was employed. Data were measured to 2θ = 155°. The intensities of three check reflections, measured every 200 reflections throughout the data collection, re-

mained essentially constant. After data reduction,[1] an empirical absorption correction (based on azimuthal scans for four reflections) was applied. Transmission factors range from 0.96 to 1.00. Of the 10304 reflections measured, 9377 were unique ($R_{int} = 0.020$) and 4330 (46.2%) of these had intensities greater than or equal to $3\sigma(F^2)$ above background where $\sigma^2(F^2) = [S^2(C + 4B) + (0.045F^2)^2]/Lp^2$ with S = scan rate, C = scan count, B = total background count, and Lp = Lorentz-polarization factor.

The structure analysis was initiated in the centrosymmetric space group $P\bar{1}$ on the basis of the E-statistics, the choice being verified by the subsequent successful solution and refinement of the structure. The structure was solved by direct methods, the coordinates of all non-hydrogen atoms being determined from the E-map or from subsequent difference Fourier syntheses. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms were fixed in idealized positions (methyl group orientations based on difference Fourier peaks, C—H = 0.98 Å, $B_H = 1.2B_{bonded\ atom}$). A correction for secondary extinction was applied, the final value of the extinction coefficient being 3.68×10^{-4}. Scattering factors for all atoms

and anomalous disperson corrections for the non-hydrogen atoms were taken from ref. 6. The weighting scheme $w = 4F_o^2/\sigma^2(F_o^2)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix least-squares refinement of 560 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at $R = 0.050$ and $R_w = 0.065$ for 4330 reflections with $I \geq 3\sigma(I)$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the maximum parameter shift corresponded to 0.003σ. The mean error in an observation of unit weight was 1.80. The final difference map showed maximum fluctuations of -0.22 to $+0.21$ e Å^{-3}. The final positional and (equivalent) isotropic thermal parameters for the non-hydrogen atoms appear in Table 1. Bond lengths and angles are given in Tables 2 and 3 and intra-annular torsion angles in Table 4. Hydrogen atom parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, least-squares planes, bond lengths and angles involving hydrogen, and structure factors have been deposited.[2]

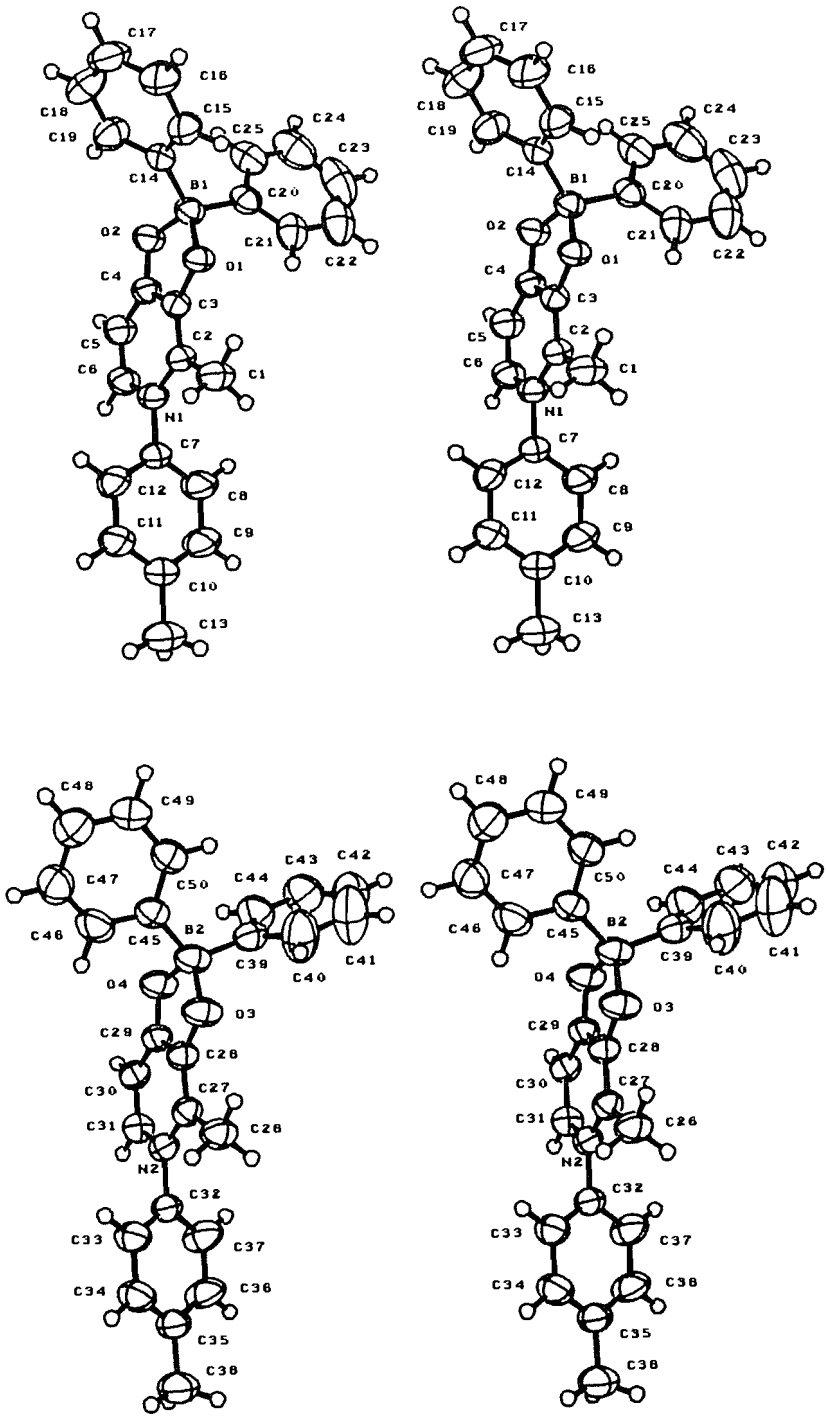

FIG. 1. Stereoviews of the two crystallographically independent (3-hydroxy-2-methyl-1-(*p*-tolyl)-4-pyridinonato)diphenylboron molecules; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

Results and discussion

The crystal structure of **1**·0.5 Me_2CO consists of molecules of **1** and acetone separated mainly by van der Waals distances. There is one weak C—H···O interaction between molecules of **1** (C(30)—H(26)···O(1)(1 − *x*, 1 − *y*, −*z*), C···O = 3.419(4), H···O = 2.45 Å). The shortest contact between non-hydrogen atoms occurs between a pair of acetone molecules (O(5)···C(51) (2 − *x*, −*y*, 1 − *z*) = 3.205(8) Å). The two crystallographically independent molecules of **1** are shown in Fig. 1. The central fused-ring systems are planar to within 0.150(4) and 0.085(5) Å in the two independent molecules, these deviations from planarity being larger than the corresponding values of 0.067, 0.015, and 0.054 Å for **2, 3**, and **4** respectively (2, 3). The C_2O_2B five-membered rings in both molecules of **1** are significantly non-planar and have flattened *B*-envelope conformations (see Table 4), that containing B(1) showing a greater deviation from planarity (deviations of the boron atoms from the mean planes = 0.114(4) Å for B(1) and 0.065(5) Å for B(2)). The six-membered heterocyclic rings are both slightly but significantly non-planar (maximum deviations from the mean

TABLE 4. Intra-annular torsion angles (deg) with estimated standard deviations in parentheses

Atoms	Value
B(1)—O(1)—C(3)—C(4)	−9.4(3)
O(1)—C(3)—C(4)—O(2)	2.7(4)
C(3)—C(4)—O(2)—B(1)	5.2(3)
C(4)—O(2)—B(1)—O(1)	−9.9(3)
O(2)—B(1)—O(1)—C(3)	11.3(3)
B(2)—O(3)—C(28)—C(29)	−5.5(4)
O(3)—C(28)—C(29)—O(4)	1.7(4)
C(28)—C(29)—O(4)—B(2)	2.8(4)
C(29)—O(4)—B(2)—O(3)	−5.5(3)
O(4)—B(2)—O(3)—C(28)	6.5(3)

planes = 0.012(3) and 0.013(3) Å for the two independent molecules), as noted earlier for compounds **2**–**4** (2, 3) as well as for the free ligands 3-hydroxy-2-methyl-4-pyridinone and 3-hydroxy-1,2-dimethyl-4-pyridinone (7). The *B*-phenyl and *N*-tolyl rings are all planar to within experimental error and show normal geometry (8).

The mean C—B/mean O—B bond length ratios, indicative of the overall binding strength of the *O,O*-chelating ligand with respect to the diphenylboron moiety (9), are 1.029 and 1.030 for the B(1) and B(2) molecules of **1**, respectively. These values are consistent with intermediate ligand binding strength. The bond length ratios for other "Ph_2BO_2" compounds containing five-membered chelate rings range from 1.016 to 1.066 with an average value of 1.033 (ref. 2 and references therein, refs. 3, 10). The average bond length ratio of 1.030 for **1** is intermediate between the values of 1.016 for **2** and 1.034 for **3**, and greater than the value of 1.023 for **4**. The slightly stronger ligand binding in **3** relative to **1** is consistent with the fact that the chelate ring in the former is more nearly planar than that in the latter. It has been noted that the O—B binding in diphenylboron complexes having unsaturated five-membered chelate rings is strongest when these rings are planar (3, 11). The differing values of the ligand binding strength for compounds **1**–**3** reflect both the electronic effects of *N*-substitution and packing forces for this system.

The pattern of bond lengths within the pyridinone ring of **1** differs from those observed for the complexes **2**–**4**. The most noticeable feature is the fact that in each of compounds **2**–**4** the longest bond in the six-membered heterocyclic ring is C(4)—C(5) while in the present structure the C(3)—C(4) (C(28)—C(29)) bond is the longest (see Table 2). The significant bond length alternation observed for **2**–**4** (most pronounced for **3**) gives way to a more delocalized structure which also involves the oxyen atoms in **1**. The average difference between the C—O bond lengths in each molecule of **1** is 0.030 Å compared to corresponding values of 0.051, 0.081, and 0.055 Å for **2**–**4** respectively. The C=O stretching frequency of 1635 cm^{-1} for **1** in the solid state is consistent with the longer C=O bond in **1** than in **3** ($\nu_{C=O}$ = 1640 cm^{-1}). A combination of steric and inductive effects is probably responsible for the differences in pyridinone ring geometry. In the other *N*-substituted molecule, **3**, the N—C(2) bond is short (1.349 Å), but a shortening of the same bond in **1** is sterically unfavorable due to the bulk of the *N*-*p*-tolyl substituent. The tolyl rings are oriented roughly at right angles to pyridinone rings (the angles between the normals to the mean planes are 85.0 and 73.7° for the two molecules) to minimize steric interactions with the adjacent C(1) and C(26) methyl groups. There is no evidence for any conjugative interaction between the ring nitrogen atom and the tolyl substituent, the difference between the N–C(tolyl) distances in **1** (mean 1.455 Å) and the N—Me distance in **3** (1.465 Å) being explicable in terms of hybridization effects alone; thus the electronic differences between the substituents must be inductive in nature.

Ruthenium(III) complexes containing dimethylsulfoxide or dimethylsulfide ligands, and a new route to *trans*-dichlorotetrakis(dimethylsulfoxide)ruthenium(II)

JASWINDER S. JASWAL, STEVEN J. RETTIG, AND BRIAN R. JAMES

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received March 19, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

JASWINDER S. JASWAL, STEVEN J. RETTIG, and BRIAN R. JAMES. Can. J. Chem. **68**, 1808 (1990).

The new Ru(III) complex *trans*-$[(dmso)_2H]^+[RuCl_4(dmso)_2]^-$ (**1**) (dmso = S-bonded dimethylsulfoxide) has been synthesized. New synthetic routes are reported for *mer*-$RuX_3(dms)_3$ complexes (dms = dimethylsulfide, X = Cl (**2**) and Br (**3**)) and for *trans*-$RuCl_2(dmso)_4$ (**4**). The complexes have been studied spectroscopically while **1**, **2** and **4** have also been characterized crystallographically. Crystals of **1** are monoclinic, $P2/n$, $a = 9.280(3)$, $b = 16.518(4)$, $c = 14.034(3)$ Å, $\beta = 100.78(2)°$, $Z = 4$, $\rho_c = 1.75$ g cm^{-3}. Crystals of **2** are orthorhombic, $Pca2_1$, $a = 10.764(2)$, $b = 11.375(1)$, $c = 12.243(1)$ Å, $Z = 4$, $\rho_c = 1.74$ g cm^{-3}. Crystals of **4** are tetragonal, $I4/m$, $a = 9.1256(8)$, $c = 11.184(2)$ Å, $Z = 2$, $\rho_c = 1.73$ g cm^{-3}. The structures were determined by heavy atom methods and were refined by full-matrix least-squares procedures to R (R_w) values of 0.030 (0.036), 0.025 (0.032), and 0.051 (0.071) for 3051, 3354, and 1205 reflections with $I \geq 3\sigma(I)$, respectively. The ionic complex **1** contains the protonated dmso cation $[(dmso)_2H]^+$, with the proton asymmetrically bonded between the two O atoms (O(3)—H(1) = 1.30(6); O(4)—H(1) = 1.12(6) Å), and the $[RuCl_4(dmso)_2]^-$ octahedral anion with *trans*-disposed S-bonded dmso ligands. The structure determined for **4** duplicates one reported recently in the literature (E. Alessio *et al.* Inorg. Chem. **27**, 4099 (1988)), and reveals all S-bonded dmso ligands; the Ru—Cl distance, 2.432(1) Å, is significantly longer than that reported, 2.402(2) Å. The dms complexes **2** and **3** were isolated unexpectedly from reaction of Ru salts with acidic dmso solutions.

Key words: ruthenium complexes, dimethylsulfoxide, dimethylsulfide, hydrogen bonding.

JASWINDER S. JASWAL, STEVEN J. RETTIG et BRIAN R. JAMES. Can. J. Chem. **68**, 1808 (1990).

On a synthétisé un nouveau complexe du Ru(III), le *trans*-$[(dmso)_2H]^+[RuCl_4(dmso)_2]^-$ (**1**) (dmso = diméthylsulfoxyde lié par le S). On a développé de nouvelles voies de synthèse des complexes *mer*-$RuX_3(dms)_3$ (dms = diméthylsulfure, X = Cl (**2**) et Br (**3**) et *trans*-$RuCl_2(dmso)_4$ (**4**). On a étudié les complexes par diverses méthodes spectroscopiques alors que l'on a caractérisé les composés **1**, **2** et **4** par diffraction des rayons-X. Les cristaux du produit **1** sont monocliniques et ils appartiennent au groupe d'espace $P2/n$, avec $a = 9,280(3)$, $b = 16,518(4)$, et $c = 14,034(3)$ Å, $\beta = 100,78(2)°$, $Z = 4$, et $\rho_c = 1,75$ g cm^{-3}. Les cristaux du produit **2** sont orthorhombiques et ils appartiennent au groupe d'espace $Pca2_1$ avec $a = 10,764(2)$, $b = 11,375(1)$, et $c = 12,243(1)$ Å, $Z = 4$, $\rho_c = 1,74$ g cm^{-3}. Les cristaux du produit **4** sont tétragonaux et ils appartiennent au groupe d'espace $I4/m$ avec $a = 9,1256(8)$, et $c = 11,184(2)$ Å, $Z = 2$, $\rho_c = 1,73$ g cm^{-3}. On a déterminé les structures par la méthod des atomes lourds et on les a affinées par la méthode des moindres carrés jusqu'à des valeurs de R (R_w) de 0,030 (0,036), 0,025 (0,032) et 0,051 (0,071) pour respectivement 3051, 3354 et 1205 réflexions avec $I \geq 3\sigma(I)$. Le complexe ionique **1** contient le cation du dmso protoné $[(dmso)_2H]^+$ dans lequel le proton est lié d'une façon asymétrique entre les deux atomes de O [O)3)—H(1) = 1,30(6); O(4)—H(1) = 1,12(6) Å] et l'anion octaédrique $[RuCl_4(dmso)_2]^-$ portant des ligands dmso liés par le S et disposés en *trans*. La structure du composé **4** une réplique de celle rapportée récemment dans la littérature (E. Alessio *et al.* Inorg. Chem. **27**, 4099 (1988)) et elle révèle tous les ligands dmso liés par le S; la distance Ru—Cl, 2,432(1) Å est beaucoup plus longue que celle rapportée, 2,402(2) Å. On a été surpris de pouvoir isoler les complexes **2** et **3** du dms provenant de la réaction de sels du Ru avec des solutions acides de dmso.

Mots clés : complexes de ruthénium, diméthylsulfoxide, diméthylsulfure, liaison hydrogène.

[Traduit par la revue]

Introduction

Earlier studies from this laboratory focussed on the potential of sulfoxide complexes of ruthenium(II) as catalysts for homogeneous hydrogenation, including asymmetric catalysis using chiral sulfoxides (1). Some years later, Italian workers from Trieste (Alessio, Mestroni, Monti-Bragadin, and co-workers) reported that *cis*-$RuCl_2(dmso)_4$ possesses mutagenic properties, exhibits antitumour activity, and interacts with nucleobases of DNA (2); and recently, the Trieste group has reported on the synthesis of *trans*-$RuCl_2(dmso)_4$ and its antitumour activity (3), while its interaction with nucleic acid components has also been studied (4). Concurrent with developments in the antitumour properties of Ru(II)–dmso complexes, a joint program between this laboratory and the B.C. Cancer Research Centre in Vancouver (Skov and co-workers) has led to the effective use *in vitro* and *in vivo* of Ru(II)–sulfoxide-nitroimidazole complexes as radiosensitizers, the work also requiring complementary studies on genotoxicity and DNA-binding (5); these nitroimidazole complexes are formed via Ru(II)–sulfoxide precursors.

A potentially important parameter in all of the applications outlined above is the oxidation state of the metal, although the chemistry described thus far is restricted to that of Ru(II). Extension of the synthetic methods for the isolation of Ru(III)–sulfoxides was an obvious goal and, during our attempts to accomplish this using chemical oxidants with $RuX_2(dmso)_4$ precursors (X = Cl, Br) (6), reports by Poddar and co-workers (7, 8) appeared, describing apparently simple routes to Ru(III)–dmso complexes via the commercially available $RuCl_3 \cdot 3H_2O$; some of the complexes reported were *fac*- and *mer*-$RuCl_3(dmso)_3$,[1] $RuBr_3(dmso)_3$, and a chloro-bridged dimer $Ru_2Cl_6(dmso)_4$. We repeated the synthetic procedures reported for these four complexes, but isolated instead, following the respective recipes, *trans*-$[(dmso)_2H]^+[RuCl_4(dmso)_2]^-$ (**1**), *mer*-$RuCl_3(dms)_3$ (**2**), *mer*-$RuBr_3(dms)_3$ (**3**) (**2** and **3** both containing coordinated *dimethylsulfide*), and *trans*-$RuCl_2(dmso)_4$ (**4**).[2]

[1] A complex of formula $RuCl_3(dmso)_3$ was first reported by Wilkinson's group (J. Chem. Soc. A. 2765 (1970)), but the work was later retracted by the same group (J. Chem. Soc. Dalton Trans. 204 (1973)).

[2] dmso and dmso refer to S- and O-bonded dmso, respectively.

This present paper reports on the isolation and characterization of **1**–**4**, including crystallographic analyses of **1**, **2** and **4**, and comments on the uncertainties in the literature regarding Ru(III) sulfoxide complexes. An account of this work, dedicated to Ross Stewart, seems particularly appropriate in that it incorporates data on the protonated dmso cation $[(dmso)_2H]^+$, and Ross has done pioneering research on acidity function measurements in dmso, even though his interests have focussed on the acidic properties of this solvent.

Experimental

Materials and methods

Analytical grade dmso (BDH), acetone, *n*-hexane, and CCl_4 were used without further purification; CH_2Cl_2 was refluxed for 3 h over P_2O_5, and MeOH over Mg powder for 2 h, prior to distillation, Ruthenium was obtained as $RuCl_3 \cdot 3H_2O$ (43.96% Ru) on loan from Johnson, Matthey Ltd.

Electronic and ir spectra (KBr) were recorded on Perkin Elmer 552A and Nicolet 5DX-FT spectrometers, respectively. ^1H nmr spectra were recorded in $CDCl_3$ on a Varian XL-300 (FT mode) instrument, with shifts in ppm relative to internal TMS, downfield shifts being positive. Equivalent conductivities were measured at 25°C at $\sim 10^{-3}$ M concentration using a Thomas Serfass conductivity bridge and a cell from Yellow Springs Instrument Co.

The synthesis reactions, including isolation of the complexes, did not require inert atmosphere techniques and the procedures described below were all carried out in air; complexes **1**–**4** are not air-sensitive in the solid state or in solution, and physical measurements on the complexes were also carried out in air. TLC was done using Merck Kieselgel 60 F254 plates/CH_2Cl_2, and for column chromatography Merck silica gel 60 (mesh 70-230) was used.

Bis(dimethylsulfoxide)hydrogen trans*-tetrachlorobis(S-dimethylsulfoxide)ruthenate(III), $[(dmso)_2H]^+[RuCl_4(dmso)_2]^-$ (1)*

Concentrated HCl (5 mL) was added to a solution of $RuCl_3 \cdot 3H_2O$ (0.25 g, 1.0 mmol) in dmso (1.5 mL), and the mixture heated at 85°C for 30 min; the solution was then concentrated to ~1 mL under reduced pressure at 85°C, and left at room temperature. Orange–yellow needle-like crystals, suitable for X-ray analysis, separated out over 2 days. **1** could be isolated in powder form by adding acetone (5 mL) to the concentrated solution. Yield 0.30 g, 55%. *Anal.* calcd. for $C_8H_{25}Cl_4O_4RuS_4$: C 17.27, H 4.49; found: C 17.25, H 4.4. λ_{max} nm (log ϵ), MeCN: 485 (2.76), 408 (3.67). Infrared: ν_{SO} 1082 cm^{-1}, and see text. Λ_0, in MeOH 115, in MeCN 9 ohm^{-1} cm^2 mol^{-1}.

mer*-Trichlorotris(dimethylsulfide)ruthenium(III), $RuCl_3(dms)_3$ (2)*

Concentrated HCl (5 mL) was added to a solution of $RuCl_3 \cdot 3H_2O$ (0.25 g, 1.0 mmol) in dmso (1.5 mL), and the mixture refluxed at 130–140°C for 1.5 h. The red complex that separated out on cooling the solution to room temperature was collected, washed 3 times with CCl_4, and dried *in vacuo*. TLC revealed a minor impurity that was removed by column chromatography using CH_2Cl_2/MeOH (100:1 v/v); the major component was collected and solvent removed by Rotovap. Yield 0.31 g (80%). *Anal.* calcd. for $C_6H_{18}Cl_3RuS_3$: C 18.29, H 4.82; found: C 18.3, H 4.6. λ_{max} nm (log ϵ), MeCN: 433 (3.20), 377 (3.26); $CHCl_3$: 433 (3.36), 377 (3.39). Needle-like crystals for X-ray analysis were obtained by recrystallization from acetone/*n*-hexane (1:1 v/v).

mer*-Tribromotris(dimethylsulfide)ruthenium(III), $RuBr_3(dms)_3$ (3)*

$RuCl_3 \cdot 3H_2O$ (0.25 g, 1.0 mmol) was dissolved in concentrated HBr (5 mL) containing LiBr (1 g). The mixture was warmed to give a clear solution to which dmso (1.5 mL) was added. The solution was then refluxed for 5 min at ~130°C, and left to cool at room temperature. The dark violet crystals that separated out were collected, washed 3 times with small amounts of water followed by ethanol, and dried *in vacuo*. Yield 0.45 g (86%). *Anal.* calcd. for $C_6H_{18}Br_3RuS_3$: C 13.66, H 3.42; found: C 13.7, H 3.4. λ_{max} nm (log ϵ), $CHCl_3$: 620 (3.0), 540 (3.44), 395 (3.00).

trans*-Dichlorotetrakis(S-dimethylsulfoxide)ruthenium(II), $RuCl_2(dmso)_4$ (4)*

$RuCl_3 \cdot 3H_2O$ (0.25 g, 1.0 mmol) was dissolved in dmso (1.5 mL) by warming the mixture to 70°C for ~15 min. The solution was cooled to room temperature and acetone (30 mL) added with continuous stirring until a red complex separated out. This red solid was collected, washed with acetone, and dried *in vacuo*, while the mother liquor on standing for 3 days deposited orange crystals (60 mg) that were shown by X-ray diffraction and elemental analysis to be pure *trans*-$RuCl_2(dmso)_4$, **4**. *Anal.* calcd. for $C_8H_{24}Cl_2O_4RuS_4$: C 19.83, H 4.99; found: C 19.8, H 4.9. λ_{max} nm (log ϵ), $CHCl_3$: 441(2.39), 286(3.13). Infrared: ν_{SO} 1086 cm^{-1}. TLC of the red solid revealed two components, one being **4** but the major one was not identified; recrystallization of the red solid from dmso/acetone (1:10 v/v) yields further crystals of **4**. Total yield of **4** was 0.35 g (75%).

X-ray crystallographic analyses of 1, 2 and 4

Crystallographic data for the three compounds appear in Table 1. The final unit-cell parameters were obtained by least-squares on the setting angles for 25 reflections with 2θ = 35.8–40.5° for **1**, 53.0–62.8° for **2**, and 40.5–50.3° for **4**. The intensities of three standard reflections, measured every 200 reflections throughout the data collections, decayed uniformly by 29.0% for **1** and were essentially constant for **2** and **4**. The data were processed[3] and corrected for Lorentz and polarization effects, decay (for **1**), and absorption (empirical, based on azimuthal scans for four reflections).

The structure analysis of **1** was initiated in the centrosymmetric space group $P2/n$ on the basis of *E*-statistics and the Patterson function, the choice being confirmed by subsequent calculations. The structure analyses of **2** and **4** were initiated in the noncentrosymmetric space groups $Pca2_1$ and $I4$, respectively, based on *E*-statistics. The choice of space group $Pca2_1$ for **2** was confirmed by the subsequent successful solution and refinement of the structure. In the case of **4**, originally thought to be a different complex, both the presence of additional symmetry elements and the identification of the material as *trans*-$RuCl_2(dmso)_4$ verified the space group $I4/m$, as reported for the earlier structure analysis of this compound (3). The structures were solved by conventional heavy atom methods, the coordinates of the Ru, Cl, and S atoms being determined from the Patterson functions and those of the remaining non-hydrogen atoms from subsequent difference Fourier syntheses. The asymmetric unit of **1** contains two crystallographically distinct *trans*-$[RuCl_4(dmso)_2]^-$ anions, both situated on crystallographic two-fold rotation axes, and a $[(dmso)_2H]^+$ cation. The chlorine atoms of one of the anions in **1** were found to be disordered, a (1:1) two-fold disordered model being refined. All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were fixed in idealized positions (d_{C-H} = 0.98 Å, B_H = 1.2 $B_{bonded\ atom}$) except for the bridging hydrogen atom of the cation in **1** which was refined with an isotropic thermal parameter. Neutral atom scattering factors and anomalous dispersion corrections for the non-hydrogen atoms were taken from the International tables for X-ray crystallography (9). A parallel refinement of the structure of **2** having the opposite polarity gave higher residuals, the R_w factor ratio being 1.037. Final atomic coordinates and equivalent isotropic thermal parameters ($B_{eq} = 4/3\Sigma_i\Sigma_j\beta_{ij}(\mathbf{a}_i \cdot \mathbf{a}_j)$), bond lengths, and bond angles appear in Tables 2–4, respectively. Hydrogen atom parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, least-squares planes, and measured and calculated structure factor amplitudes for the three structures are included as supplementary material.[4]

Values given for R, R_w, and gof are based on those reflections with $I \geq 3\sigma(I)$.

Results and discussion

Synthetic procedures, and characterization of the Ru-containing species, excluding crystallographic data

The synthetic procedures used for obtaining **1–4** follow as closely as possible those given by Poddar and co-workers (7, 8) for reported isolation, respectively, of *fac*-$RuCl_3(dmso)_3$, *mer*-$RuCl_3(dmso)_3$, $RuBr_3(dmso)_3$ (of unspecified configuration) and $Ru_2Cl_6(dmso)_4$. In each case, we isolate a different complex and, of the four **1**, **2** and **4** are identified crystallographically. No crystal data were given in Poddar's reports.

Complex 1

We isolate $[(dmso)_2H]^+[RuCl_4(dmso)_2]^-$ (**1**) after heating $RuCl_3 \cdot 3H_2O$ in dmso in the presence of concentrated HCl for 30 min at 85°C, and then concentrating the solution and cooling (or by precipitation with acetone). The two procedures were described by Poddar's group (7) to give correspondingly yellow needle-like crystals or a powder, respectively, the material being characterized as *fac*-$RuCl_3(dmso)_3$ with all S-bonded sulfoxides; the ν(S=O) of *S*-bonded dmso was seen at 1087 cm^{-1}, close to that (1082 cm^{-1}) of **1** which does have all S-bonded sulfoxides, and the Poddar complex, like **1**, is a Ru(III) species (μ_{eff} = 1.7 BM). The major distinction is in elemental analyses: $RuCl_3(dmso)_3$ requires C 16.3, H 4.1, Cl 24.6; while **1** requires C 17.27, H 4.43, Cl 25.5, and Poddar's reported data are closer to those of the neutral compound (the *fac*- geometry was inferred from ν(Ru-Cl) ir data).

Of interest, **1** is conducting in MeOH, but is weakly conducting in MeCN, Λ_0 9 = ohm^{-1} cm^2 mol^{-1} (Poddar's group reported a Λ_0 value of 8 in MeCN for this compound). It seems likely that the H-bonded cation "breaks down" in MeCN, and that HCl is formed, with concomitant generation of $RuCl_3(dmso)_3$ and a molecule of dmso. Corresponding behavior has been noted for the rhodium(III) complex $[(dmso)_2H]^+[RhCl_4(dmso)_2]^-$ (10). Complex **1** in MeCN shows electronic absorption maxima at 485 and 408 nm; Poddar's group report maxima at 468 and 405 nm for "*fac*-$RuCl_3(dmso)_3$". The ir data for the cation of **1** will be discussed following consideration of the crystallographic data. The $[RuCl_4(dmso)_2]^-$ anion has been isolated previously as the Na^+ and Bu_4N^+ salts using as precursor $[Ru(dmso)_6]Cl_3$ (11, 12).

Complexes 2 and 3

The synthetic procedure for *mer*-$RuCl_3(dms)_3$ (**2**) follows that for **1** except that a higher temperature (130–140°C) is required, and the product separates out merely on cooling. The observations appear identical to those noted by Poddar and co-workers (7), although this group formulates the product as *mer*-$RuCl_3(dmso)_2(dmso)$, the arrangement and types of ligands being inferred from ir data (ν(S=O): S-bonded, 1113, 1093;

O-bonded, 981 cm^{-1}. ν(Ru—Cl): 340, 326, 313 cm^{-1}). Complex **2** shows strong ir bands at 1030 and 973 cm^{-1}, both of which can be attributed to CH_3 rocking modes (13), strong and medium bands at 340, 320 cm^{-1}, respectively, which are likely due to ν(Ru–Cl), and also a medium band at 270 cm^{-1} which could be the third required ν(Ru—Cl) band for a *mer*-configuration. The electronic spectrum of **2** in $CHCl_3$ (see Experimental section) is close to that reported by Poddar's group: λ_{max} nm (log ϵ), 435 (3.41), 380 (3.46). It seems more probable that the complex reported by Poddar's group is, in fact, the tris(dimethylsulfide), although their analytical data (C 16.6, H 4.3, Cl 24.0) are much closer to those required for the sulfoxide complex (C 16.3, H 4.1, Cl 24.1). Complex **2** that initially separated out did contain a minor impurity that we removed by chromatography on silica gel.

That the structure revealed coordinated thioether certainly surprised us, but the formulation accommodated our analytical data well. A corresponding higher temperature procedure, but using a concentrated HBr/LiBr medium, again identical to that used by Poddar and co-workers (8), generated a dark violet

[a]Distances are in angstroms. Estimated standard deviations in the least significant figure are given in parentheses.

crystalline compound that we formulate as *mer*-RuBr$_3$(dms)$_3$, **3**, again a thioether complex. Poddar's group formulate the complex as RuBr$_3$(dmso)$_3$ containing only *O*-bonded dmso (ρ_r(CH$_3$) 1030, ν(S=O) 970 cm^{-1}), but could not assign the *mer*- or *fac*-geometry. The ir of **3** showed strong ir bands at 1028 and 968 cm^{-1}, which we believe are both due to ρ_r(CH$_3$). Further, the electronic spectrum of **3** in CHCl$_3$ (see Experimental section) corresponds to that reported in Poddar's paper (8). The analytical data given by Poddar's group, however, again match better those required for the sulfoxide (C 12.5, H 3.1, Br 41.7). We assign the *mer*-configuration to **3** based on its almost superimposable ir spectrum (from 3000–450 cm^{-1}) with that of **2**.

It appears that strongly acidic solutions of RuCl$_3$·3H$_2$O containing dmso, when heated to ~130°C, generate dms species. Indeed, this provides a convenient route to the Ru(III)-dms complexes and avoids the use of the obnoxious thioether itself; the RuCl$_3$(dms)$_3$ complex, synthesized previously by refluxing RuCl$_3$·3H$_2$O with dms in alcohol (14, 15), has been assigned the *mer*-configuration based on esr (14) and ν(Ru—Cl) data (15), the latter (345, 330, 280 cm^{-1}) agreeing well with those found for **2**. The bromo analogue, **3**, to our knowledge, has not been reported previously, although both RuX$_3$(Et$_2$S)$_3$ complexes (X = Cl, Br), tentatively assigned the *fac*-configuration based on ν(Ru—X) data, have been made previously, again using the thioether ligand as a reactant (16, 17). Whether use of the sulfoxide at higher temperatures in acid solution provides a general preparative method for the sulfide complexes needs to be explored. The complex RuCl$_3$(^{n}Bu$_2$SO)$_3$ is reportedly formed on refluxing RuCl$_3$·3H$_2$O with the sulfoxide in MeOH, although the characterization data are minimal (17); the analytical data are poor, and are only marginally more satisfactory for the sulfoxide than for a corresponding tris-(dibutylsulfide) complex. We have found recently that use of tetramethylenesulfoxide (tmso) instead of dmso, under acid conditions similar to those used for the synthesis of RuBr$_3$(dms)$_3$, also gives generation of the corresponding thioether complex RuBr$_3$(tms)$_3$ (6).

The redox chemistry of Ru in sulfoxides deserves comment. It should be noted first that the commercially available compound RuCl$_3$·3H$_2$O consists, in fact, of a mixture of Ru(III) and Ru(IV), the latter probably being present as a hydroxo species (18). Work from this laboratory first reported the synthesis of *cis*-RuCl$_2$(dmso)$_4$ from the commercial trichloride in a method where H$_2$ was used as the reductant (1*a*, 19). Wilkinson's group later synthesized the same Ru(II) complex by simply refluxing RuCl$_3$·3H$_2$O in dmso under N$_2$ (20), and this method has been widely used since (2–5, 11). However, whether the reductant is dmso (itself being oxidized to the sulfone Me$_2$SO$_2$) or perhaps dms impurity (giving dmso as oxidized product) has not been determined. The former has been implied by Ledlie *et al.* (17) but with no evidence, for example reaction [1], while the same group has presented evidence for the reversible equilibrium shown in reaction [2] (17)

[1] $2\,Ru^{III} + Me_2SO + H_2O \rightarrow 2\,Ru^{II} + Me_2SO_2 + 2\,H^+$

[2] $2\,Ru^{III} + {}^nBu_2S + H_2O \rightleftharpoons 2\,Ru^{II} + {}^nBu_2SO + 2\,H^+$

Further, more careful studies are required on the dmso redox chemistry of well-defined Ru(III) and Ru(II) complexes (rather than RuCl$_3$·3H$_2$O) before our new route to thioether complexes is understood mechanistically. However, the dms almost certainly comes via reduction of dmso in acid solution (*cf.* the reverse of reaction [2]); the reductant is probably Ru(II) formed via reaction [1], although the ligand sets coordinated at Ru(II) and Ru(III) are ill-defined. A relative lower solubility of the RuX$_3$(dms)$_3$ (X = Cl, Br) complexes at lower temperatures could shift the relevant equilibria and allow for isolation of these species.

The isolation of the thioether complexes is important in that Poddar and co-workers (7, 8) have used their complexes formulated as *mer*-RuCl$_3$(dmso)$_2$(dmso) and RuBr$_3$(dmso)$_3$ as precursors for the synthesis of a range of other Ru(III) species, which includes: RuCl$_3$L$_2$(dmso) (L = MeCN, py; L$_2$ = phen, bipy), RuCl$_2$(acac)(dmso)$_2$, RuBr$_3$L(dmso)$_2$ (L = py, 4-Mepy), RuBr$_3$L$_2$(dmso) (L = PPh$_3$, AsPh$_3$), [RuBr$_2$(pda)$_2$(dmso)$_2$]Br, RuBr$_2$(pda)(dmso)$_2$, and RuBr$_2$(Et$_2$NCS$_2$)(dmso)$_2$; where py = pyridine, phen = *o*-phenanthroline, bipy = 2,2′-bipyridyl, Hacac = acetylacetone, and pda = *o*-phenylenediamine. The theoretical elemental analyses for the corresponding dms complexes are little different from those of the sulfoxides and, as noted above, ir data, the other major criteria used by Poddar's group, are not unequivocal.

Complex 4

The *trans*-RuCl$_2$(dmso)$_4$ complex (**4**) was isolated in good yield as orange crystals by addition of acetone to a dmso solution of RuCl$_3$·3H$_2$O, the dissolution of the trichloride being effected by warming. The initially precipitated solid contained a red, major component that was converted to **4** during recrystallization from dmso/acetone. The method follows closely that reported by Poddar *et al.* for synthesis of a brown–red compound formulated as Ru$_2$Cl$_6$(dmso)$_4$, which from elemental analysis and ir data was considered to be a chloride-bridged dimer containing both O- and S-bonded dmso (7); their reported dimer, which was obtained following a simple washing of the precipitated solid with acetone, is clearly different from **4** in

[a]Angles are in degrees. Estimated standard deviations in the least significant figure are given in parentheses. Primes and double primes refer to the symmetry operations: $1/2 - x$, y, $1/2 - z$; and $1/2 - x$, y, $3/2 - z$; respectively.

terms of analytical and ir data, and solubility characteristics (e.g. **4** does not dissolve in MeCN whereas the dimer does). The dimer was also paramagnetic, consistent with a Ru(III) formulation (7). Of interest, Poddar's group were actually attempting to prepare RuCl$_3$(dmso)$_3$ species following a route reported earlier by Antonov *et al.* (21)!

The identity of **4** was established by crystallographic analysis as well as ir data: ν(S=O) 1086 cm^{-1}, ^{1}H nmr data ($CDCl_3$): δ 3.4 (S-bonded dmso), 2.62 (free dmso), and UV/vis spectra ($CHCl_3$): λ_{max} 441, 286, 246 nm. During the course of our studies, a paper by Alessio *et al.* reported the synthesis and structure of **4**, made via photolysis, under an inert atmosphere, of the thermodynamically more stable *cis*-RuCl$_2$(dmso)$_4$ compound (3); our spectroscopic and structural data are generally in good agreement with those of the Italian workers (see below). Our synthesis of **4** is remarkably simple, and may be of benefit considering its promising pharmacological properties (3).

Crystallographic data on the Ru moieties

The relevant bond lengths and angles for complexes **1**, **2**, and **4** are given in Tables 2 and 3.

The complex *trans*-[(dmso)$_2$H]$^+$[RuCl$_4$(dm*so*)$_2$]$^-$ (**1**) is isomorphous and isostructural with the corresponding rhodium complex *trans*-[(dmso)$_2$H]$^+$[RhCl$_4$(dm*so*)$_2$]$^-$, synthesized earlier in this laboratory (10).[5] Both complexes contain in the asymmetric unit two essentially octahedral anions (both having exact C_2 symmetry), one of which is disordered and exists in two possible orientations of a square planar arrangement of chlorides, and in **1**, one is related to the other by a 17.6° rotation about the S—Ru—S axis (see Fig. 1). If there were substantial double bond character in the Ru—S bonds due to Ru $d_\pi \rightarrow S$ d_π backbonding, only one mutual orientation of dmso and chloride

[5]The space group in ref. 10 was incorrectly given as $P2_1/n$, instead of $P2/n$.

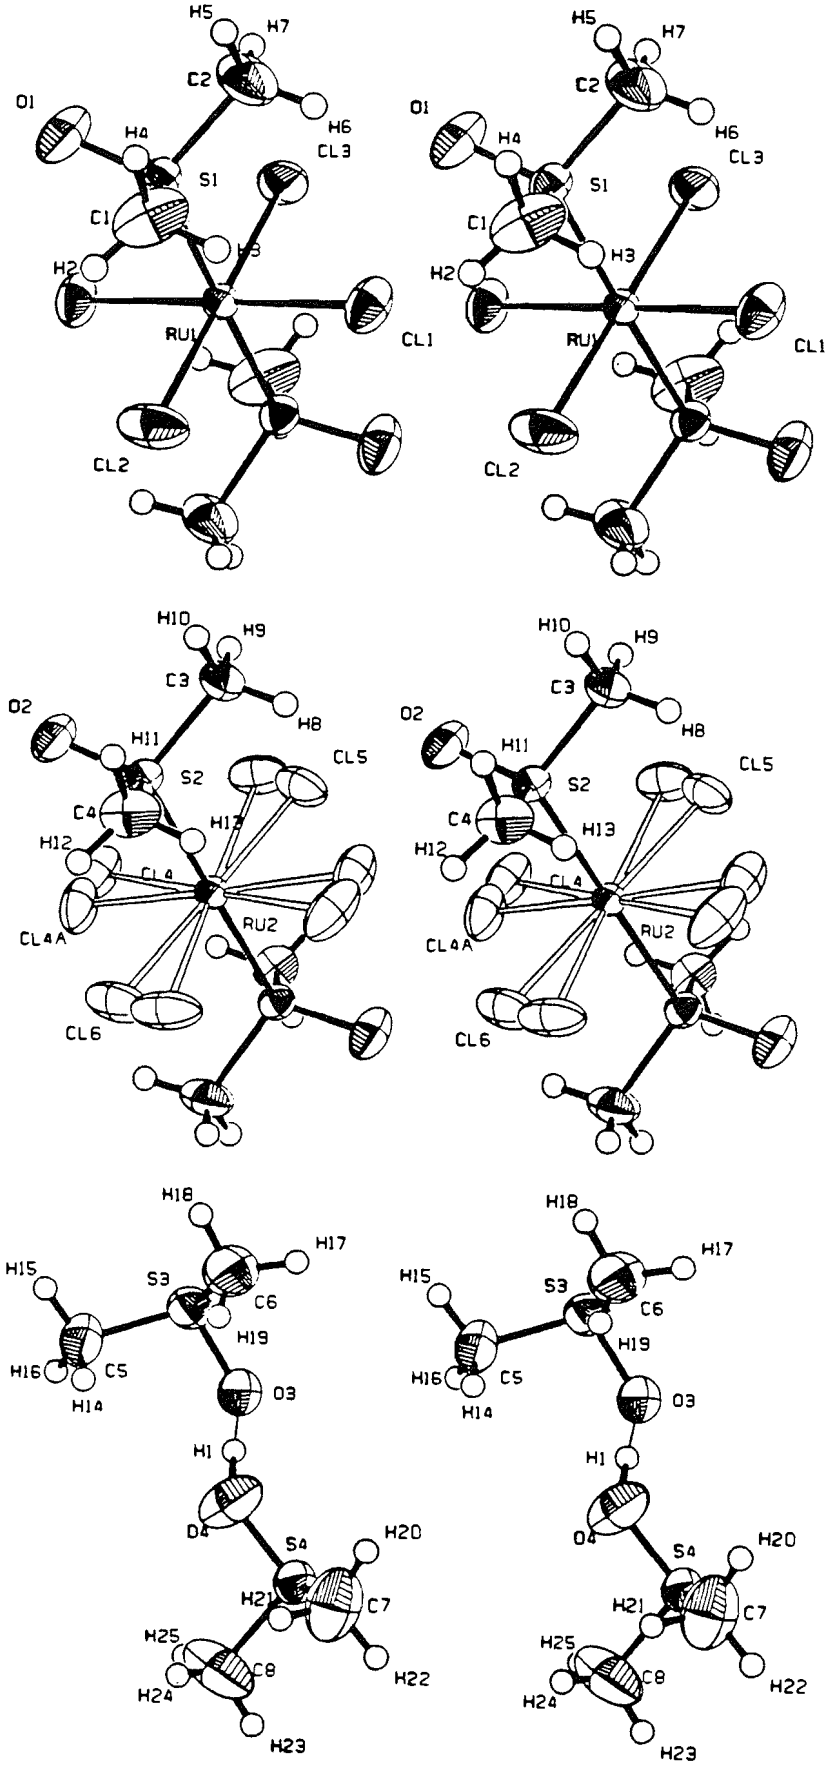

FIG. 1. Stereoviews of the two independent *trans*-$[RuCl_4(dmso_2]^-$ anions (top, middle) and the $[(dmso)_2H]^+$ cation (bottom) in **1**; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

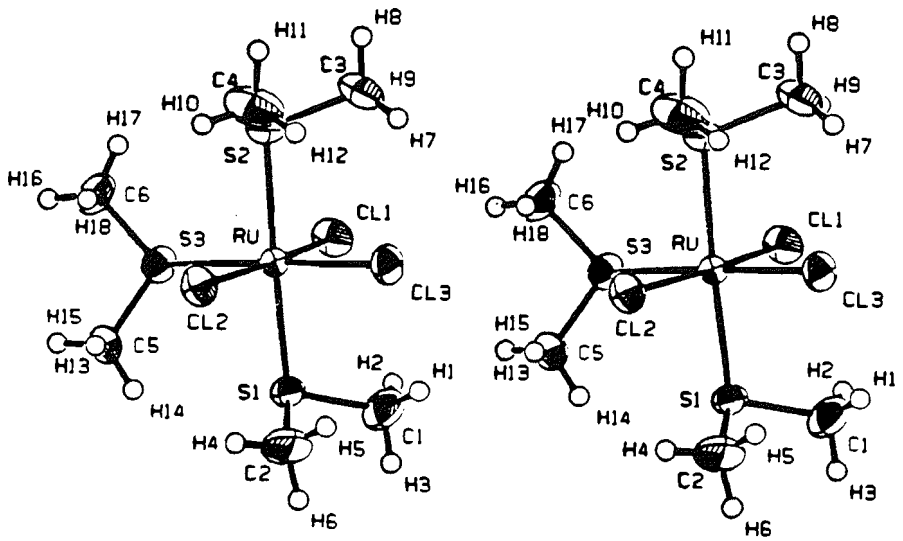

FIG. 2. Stereoview of *mer*-$RuCl_3(dms)_3$, **2**; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

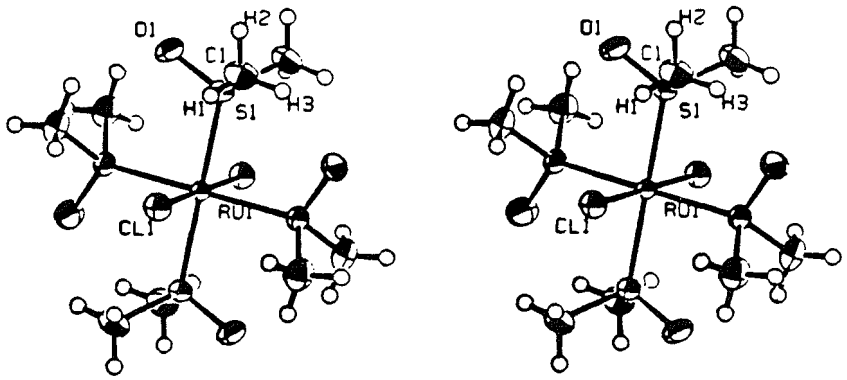

FIG. 3. Stereoview of *trans*-$RuCl_2(dmso)_4$, **4**; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

ligands might be expected, this giving optimum overlap of such orbitals. Thus, any *trans* influence (see below) of the mutually *trans* dmso ligands is possibly exerted by way of σ-bonding orbitals (22). Alternatively, intermolecular forces in the crystal might prevail over the rotational barrier of a partial Ru—S double bond and determine the observed disorder. The *trans* dmso ligands in the non-disordered and disordered anions are related by a C_2 axis of symmetry along a Cl—Ru—Cl axis, or along a line bisecting the two Cl—Ru—Cl orientations, respectively.

The average Ru—Cl distance in **1** is 2.35 Å which is shorter than that found (2.43 Å) for the *trans*-chlorides in *trans*-$RuCl_2(dmso)_4$ (**4**, Fig. 3) or that found (2.42 Å) for the *cis*-chlorides in *cis*-$RuCl_2(dmso)_4$ (3). The shorter bond length seems reasonable for the low-spin d^5 Ru(III) complex compared to the low-spin d^6 Ru(II) species. The average Ru—Cl bond length of 2.34 Å in *mer*-$RuCl_3(dms)_3$ (**2**), again close to octahedral, also follows this trend. Of note, however, the average Ru—S bond lengths within **1** and **4**, both for mutually *trans* sulfoxide ligands, are essentially the same (2.35 Å); the significant increase compared to those in *cis*-$RuCl_2(dmso)_4$ (ave 2.27 Å. with two sulfurs being *trans* to chloride, and one being *trans* to O-bonded sulfoxide) is attributed to the *trans* influence of the S ligands and, although this is usually thought to result from π-backbonding competition between the *trans* dmso ligands (1*a*, 1*d*, 3), the disorder effect discussed above perhaps argues for a σ-directed *trans* influence. This must dominate over any decrease in Ru—S bond length that might arise from a change to the higher oxidation state. The average S—O bond lengths within the anions of **1** (1.46 Å) — as for the Rh analogue (10) — and within **4** (1.46 Å) are, as usually in S-bonded dmso metal complexes, shorter than in crystalline dmso, 1.51 Å (23), because of a resonance contribution from $M \leftarrow S^- \equiv O^+$ (24).

The structure of **1** has been mentioned in a review but no crystal data were presented by the authors (25).[6] The same group has recently published structural data on **4** (3); the data are in good agreement generally although our Ru—Cl distance of 2.432(1) Å is significantly longer than that reported, 2.402(2) Å. The Italian group rationalized the shortness of this bond relative to that of the Ru—Cl bond in the three forms of *cis*-$RuCl_2(dmso)_4$ (2.435(1), 2.42(1), 2.422(3) Å) in terms of the greater *trans* influence of S-bonded dmso compared to chloride (3). Our structural data imply that such an effect is not evidenced within the Ru—Cl bond lengths of these *cis* and *trans* isomers. It should be noted that although the published *R* factors for structure **4** (3) are somewhat smaller than in the

[6]We have learned from this group via M. Calligaris (private communication) that the determined cell parameters are in excellent agreement with those reported in Table 1.

present work, we collected significantly more data over a wider 2θ angle range and obtained, for example, more accurately determined cell parameters.

The Ru—S bond lengths in *mer*-$RuCl_3(dms)_3$ (**2**, Fig. 2) are 2.40 Å for S *trans* to Cl, and 2.38 and 2.40 Å for the mutually *trans* S atoms; the "constant" values imply the absence of any significant *trans* influence of the thioether ligand. We have been unable to find any literature data on Ru(III) thioether complexes, while structural data on Ru(II) saturated thioether complexes first appeared in 1982 (26), and now appear with increasing frequency, particularly for systems with multidentate ligands including crown thioethers (e.g. refs. 27–34); incidentally, a paper published in 1988 (30) incorrectly claims the first structurally characterized Ru(II) thioether complex. The Ru(II)—S bond lengths are in the range 2.26–2.40 Å, most commonly 2.32–2.37 Å, and in the higher range 2.37–2.40 Å when the thioether links are mutually *trans* (33, 34). The generally shorter distances compared to those found in **2** could be rationalized in terms of some π-backbonding to S from the strongly π-basic Ru(II) (26).

*The $[(dmso)_2H]^+$ cation of complex **1** (and the Rh analogue)*

To our knowledge, the only other report describing crystallographic data on the hydrogen-bonded cation (Fig. 1) is that noted above on the analogous $[(dmso)_2H]^+[RhCl_4(dmso)_2]^-$ complex (10); a somewhat more detailed discussion, taken also in part from ref. 35, is presented here.

The short O···O distance of 2.42 Å is observed in both **1** and the Rh analogue, consistent with the presence of a strong hydrogen bond (36, 37); within **1**, the H position is now somewhat better defined: O(3)—H(1), 1.30(6); H(1)—O(4), 1.12(6) Å, and perhaps implies an asymmetric H position with a closely spaced double minimum potential for the proton (36). The average S—O bond length (1.539 Å) is somewhat larger than the corresponding value in crystalline dmso (see above), and is consistent with protonation at oxygen; similar, small increases in S—O bond length are seen on coordination of metals to the oxygen of dmso (1*d*, 3, 24). The asymmetry of the O(4)···H···O(3) is more convincingly reflected by the two sets of C—S—O angles: 102.5° (ave) on the O(4) side, and 105.5° (ave) on the O(3) side. The significant decrease in the C—S—O angles from those in free dmso, 107° (23), is observed also in O-bonded dmso at transition metal centres (1*d*, 3, 24, 38). The C—S—C angles and C—S bond lengths are typical of those in free or coordinated dmso (100°, 1.78 Å, respectively).

The ir spectrum of the $[(dmso)_2H]^+$ cation has been discussed previously in some detail in our earlier papers describing the $[RhCl_4(dmso)_2]^-$ complex (10, 13), and the data obtained for the new ruthenate(III) complex are essentially identical: there is a "background", medium intensity, broad band from 1600–1100 cm^{-1}, and an intense broad band at 900–600 cm^{-1} centered at 730 cm^{-1}. This type of spectrum is typical of O···H···O systems (10, 36), and indeed the correct structure of protonated dmso was first predicted in 1967 from ir data on dmso containing methanesulfonic acid (39).

Attempts to detect by ^1H nmr in $CDCl_3$ or D_2O the proton of the $[(dmso)_2H]^+$ cation within **1** were unsuccessful; the dmso associated with the cation appeared at the chemical shift for free dmso in the respective solvents (δ 2.6–2.7), suggesting that the HCl is eliminated when the tetrachloro salt is dissolved. The same phenomenon was observed with the Rh system, the product being *mer*-$RhCl_3(dmso)_3$ which, being diamagnetic, was readily detected in the ^1H nmr spectrum (10, 13). The expected *in situ* Ru product would be the "elusive" paramagnetic $RuCl_3(dmso)_3$; several weak, broad resonances were observed in the ^1H nmr, and such solutions might well provide a source of this Ru(III) complex.

Received January 26, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

JOHN R. JONES, DAVID A. WICKENDEN, CAREL W. FUNKE, and FRANS M. KASPERSEN. Can. J. Chem. **68**, 1818 (1990).

A recently developed procedure (Buist *et al.*, J. Chem. Soc. Perkins II, 169 (1990)) has been used to study the kinetics of detritiation of [10,10-^3H] mianserin and two other structurally related compounds in highly basic media. Over the H_- range 16–20 the stereoselectivity of the exchange process k_{eq}/k_{ax} for all three compounds is virtually constant (5 ± 1). The apparent increase at still higher basicities is associated with distinct curvature in the log k vs. H_- plots, indicating the onset of another mechanism. Partial detritiation studies at higher levels of radioactivity, when combined with ^3H nmr spectroscopic analysis, confirms the greater lability of the C-10 (or C-9) equatorial hydrogen.

Key words: detritiation, high basic media, mianserin.

JOHN R. JONES, DAVID A. WICKENDEN, CAREL W. FUNKE et FRANS M. KASPERSEN. Can. J. Chem. **68**, 1818 (1990).

On a utilisé une méthode développée récemment (Buist *et al.*, J. Chem. Soc. Perkins II, 169 (1990)) pour étudier la cinétique de la détritiation, dans des milieux fortement basiques, de la [10,10-^3H] miansérine et de deux autres composés de structures apparentées. À des H_- allant de 16 à 20, la stéréosélectivité du processus d'échange, k_{eq}/k_{ax}, pour les trois composés est virtuellement constante (5 ± 1). L'augmentation apparente qui est observée à des basicités encore plus élevées est associée à une inflexion distincte dans les courbes de log k vs. H_- qui indique le début d'un autre mécanisme. Lorsqu'on combine des études de détritiation partielle à des niveaux plus élevés de radioactivité avec des analyses spectroscopiques par rmn du ^3H, on peut confirmer la labilité plus grande de l'hydrogène équatorial en C-10 (ou C-9).

Mots clés : détritiation, milieux fortement basiques, miansérine.

The challenge of designing organic compounds with unusual reactivity can only be tackled when one has a good appreciation of the many factors that affect reactivity. One of the least well understood is stereoelectronic in nature (2) and so far most of the studies in this area have been concerned with the hydrolysis of esters, acetals, and amides. It is clearly desirable to widen the range of compounds that can be investigated and this can only be done when one can apply another widely encountered reaction; hydrogen isotope exchange is ideal for such a purpose.

In the few examples of base-catalysed hydrogen isotope exchange reactions so far studied the emphasis has been on using ketones. Thus in one of the earliest cases, that of 4-*t*-butylcyclohexanone (3) $k_{ax}/k_{eq} \sim 5$, but *ab initio* calculations (4) suggest that much higher selectivities should be possible. This has been borne out in some recent results, e.g., for 4′,1″-dimethyl-1,2,3,4-dibenzcyclohepta-1,3-diene-6-one (**1**) hydrogen–deuterium exchange (5) of the methylene protons in MeOD–OMe^- proceeds with a stereoselectivity of 73:1 whilst a kinetic selectivity of 290:1 was witnessed (6) in the base-catalysed exchange of the diastereotopic protons α to the carbonyl group in twistan-4-one (**2**).

There are many other types of carbon acids of lower acidity than these ketones and for which highly basic media need to be employed in order that hydrogen isotope exchange takes place at a measurable rate. Such an example is mianserin (1,2,3,4,10,14*b*-hexahydro-2-methyldibenzo[*c.f*]pyrazino-[1,2-*A*]azepine (**3**)), a tetracyclic antidepressant initially developed as an antihistamine and antiserotonin compound. Although it has been the subject of extensive pharmacological studies (7) its chemistry has received scant attention. Various deuterated mianserins (8) have been prepared as part of a project to assign the ^1H nmr spectra; the C-10 hydrogens were found to undergo deuteration when sodium deuteroxide was used in hexamethylphosphoric triamide.

One of the many advantages of using mianserin as a model for studying the importance of stereoelectronic effects is the ready availability of structurally similar compounds. We have therefore taken advantage of this in the present study by carrying out parallel investigations on two other compounds, 1,2,3,4,10,14*b*-hexahydro-2-methylpyrazino[2,1-*A*]pyrido-[2,3-*C*](2)benzazapine (**4**, or Org 3770) and 1,2,3,13*b*-tetrahydro-2-methyl-9*H*-dibenzo[*c.f*]imidazo[1,5-*A*]azepine (**5**, or Org 2249).

Experimental

Synthesis and purification of compounds

Compounds **4** and **5** were supplied chromatographically pure. Mianserin itself was provided as the hydrochloride of which 200 mg was dissolved in approximately 20 mL of distilled water and the solution saturated with anhydrous Na_2CO_3. The precipitated mianserin was extracted into diethyl ether (3 × 50 mL), the solution dried over anhydrous Na_2SO_4 before the solvent was removed by rotary evaporation to give the crude product. The latter was further purified by preparative thin layer chromatography (silica gel plates 200 × 200 × 1 mm, solvent system ethyl acetate – methanol 4:1).

Tritiation procedure

Typically some 150–200 mg of compound was dissolved in the minimum amount of freshly distilled hexamethylphosphoric triamide and transferred to a thick-walled glass tube containing a small quantity of powdered solid sodium hydroxide. Tritiated water (5 μL, 50 Ci mL^{-1}) was added and the tube sealed under vacuum before being

kept in a thermostat at 95°C for 2 days. The tritiated substrate was then extracted into diethyl ether, the solution washed with water to remove any labile tritium, and dried over anhydrous Na_2SO_4; after further filtration the solvent was removed by rotary evaporation to give a product which typically had a specific activity in the range 16–45 mCi mmol^{-1}.

^3H nmr analysis

The procedure was the same as that described previously (1).

Kinetic procedure

To a mixture of dimethyl sulphoxide in water (of known mole fraction) was added a few crystals of the tritiated substrate. Some 100 mL of this solution was transferred to a round-bottom flask and thermostatted at 95°C. A 2 mL portion was withdrawn, added to 5 mL of scintillator and 5 mL of water, shaken and allowed to settle before pipetting off most of the non-aqueous layer, drying over anhydrous Na_2SO_4, and counting 2 mL to give the N_0 value. The reaction was initiated by adding an aliquot of a stock sodium hydroxide solution to give a solution of known H_. Samples were subsequently withdrawn at fixed time intervals so as to cover over 90% of the reaction. As well as some 30 N_t values a value of N_∞ was also obtained in order to calculate the experimental extent of detritiation P_{obs} ($= (N_0 - N_t)/(N_0 - N_\infty)$), which increases from $0 \rightarrow 1$ as the detritiation proceeds.

The theoretical extent of detritiation is given by

$$P_{cal} = x_{ax}[1 - \exp(-k_{ax}t)] + x_{eq}[1 - \exp(-k_{eq}t)]$$

where x_{ax} and x_{eq} are the tritium atom fractions and k_{ax} and k_{eq} the unknown first-order rate constants for exchange from the axial and equatorial positions, respectively. The ^3H nmr results give values of x_{ax} and x_{eq} and a computer programme allows one to determine the optimum values of k_{ax} and k_{eq} when the "least squares error" criterion

$$S\left[= \sum_i^n (P^i_{cal} - P^i_{obs})^2 \right]$$

is employed. The results can be supplemented by a graphical procedure when the ratio k_{eq}/k_{ax} are very high, e.g., >10.

Partial detritiation experiments

On at least one occasion for each of the three compounds studied an experiment was carried out using much higher levels of radioactivity (usually 7–10 mCi) than usual so that a partially detritiated sample could be withdrawn and its ^3H nmr spectrum recorded. In this way one was able to confirm that for all three compounds the equatorial triton exchanged faster than the axial triton.

Results and discussion

The kinetic data are summarised in Table 1 and, taken together with the nmr results, give a consistent picture for all three compounds. Previous nmr studies (9) have shown that mianserin has the same conformation in solution as in the solid state (10) — the piperazine ring is chair formed, with an equatorial N—CH_3 and the piperazine–dihydroazepine junction is *trans*. The difference between H(14b) and the N(5) lone pair results in both sides of the dihydroazepine ring being non-equivalent: the C(10) bridge twists to the side of the N(5) lone pair. Selective irradiation experiments of the H(10) signal at δ 4.82 and 3.30 followed by nOe experiments allows one to identify the former as axial and the latter as equatorial. The ^3H nmr (^1H decoupled) spectrum of tritiated mianserin merely gives rise to these two signals and the results for the partially detritiated compound shows that the equatorial triton is the more reactive of the two.

This stereoselectivity can be rationalised in terms of stabilisation of the intermediate carbanions. β-Halocarbanions have been shown to be stabilised by through-bond interaction (11), the lone pair of the carbanion being delocalised to the anti-bonding σ* (C—X) orbital. This delocalisation is maximal for conformations with a planar lone-pair —C—C—C—X path. In mianserin (and Org 2249 and 3770) a similar situation exists: abstraction of the equatorial ^3H (10) yields a carbanion with a planar lone-pair —C—C—N (5) path, *i.e.*, with optimal through-bond stabilisation. Abstraction of the axial ^3H (10) yields a carbanion in which the lone-pair is roughly perpendicular to the C(10)—C—C—C—N (5) plane, *i.e.*, with less stabilisation.

Table 1. Kinetic data for the detritiation of [10,10-^3H] mianserin, [10,10-^3H] Org 3770, and [9,9-^3H] Org 2249 in highly basic media (CH_3SOCH_3–H_2O–OH^-) at 95.0°C

Although the pK_a of the benzylic protons of mianserin (or Org 3770 and 2249) has not been measured, the fact that one has to use highly basic media and an elevated temperature to induce hydrogen isotope exchange to proceed at a measurable rate suggests that it is in the 27–30 range. For such compounds the log k – H_ plots are usually linear with slopes approaching unity and this is the case for all three compounds studied here (Fig. 1) with the difference that at the higher basicities deviations from linearity occur. For mianserin itself in the H_ range 18–21 the stereoselectivity is effectively constant ($k_{eq}/k_{ax} = 5 \pm 0.5$) with a log k – H_ slope of 0.94. For Org 3770 in the H_ range 16–19 $k_{eq}/k_{ax} = 4.6 \pm 1$ with a log k – H_ slope of 0.65 and for Org 2249 in the H_ range 16–20.5 $k_{eq}/k_{ax} = 4.6 \pm 0.8$ with a log k – H_ slope of 0.90. The stereoselectivity for all three compounds is therefore effectively constant. This of course assumes that internal return is either absent or its contribution to the rates is effectively constant.

The deviation in the linearity of the log k – H_ plots for all three compounds suggests that at the higher basicities we are witnessing the onset of another mechanism. Three possibilities emerge, namely demethylation of the N-methyl group, hydroxide-ion addition to the substrate or oxidation of the

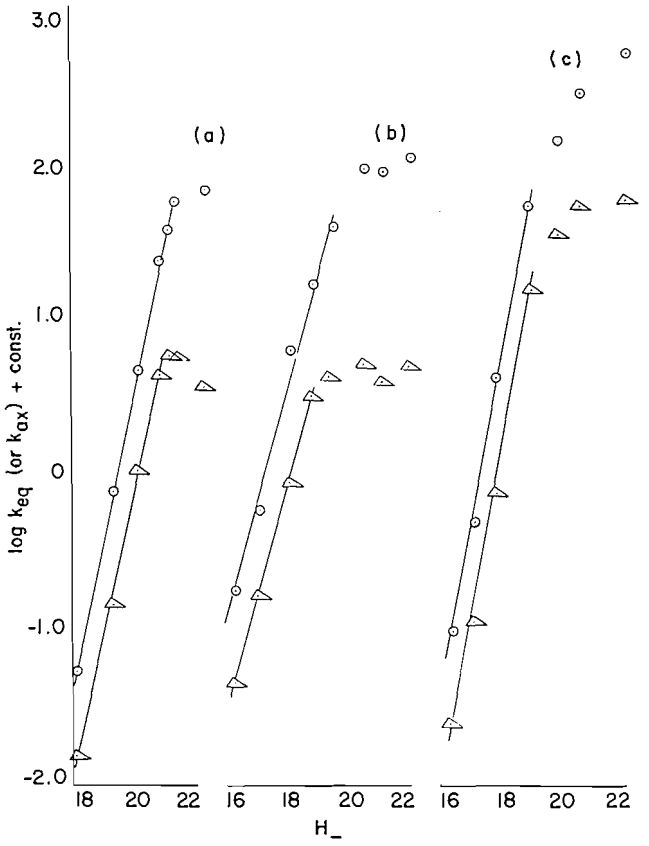

FIG. 1. Plot of log k_{eq} (or log k_{ax}) against H_ for (*a*) mianserin, (*b*) Org 3770, and (*c*) Org 2249. ○ k_{eq}, △ k_{ax}.

benzylic methylene hydrogens by dimethyl sulphoxide, the latter being the more likely (as illustrated by the isolation of 10-hydroxymianserin); however, more work is required before firmer conclusions can be drawn.

We may therefore conclude that studies of hydrogen isotope exchange processes in highly basis media, besides providing a route to stereospecifically tritiated (or deuterated) compounds, also allow one to determine the true stereoselectivity especially in circumstances where the onset of another mechanism can introduce an element of uncertainty.

Formation of synthetically useful camphor derivatives: mechanistic aspects

WILLIAM M. DADSON, JOHN H. HUTCHINSON,[1] AND THOMAS MONEY[2]

Chemistry Department, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received March 21, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

WILLIAM M. DADSON, JOHN H. HUTCHINSON, and THOMAS MONEY. Can. J. Chem. **68**, 1821 (1990).

Evidence is presented to support the occurrence of a 3,2-*endo*-methyl shift during the C(8)-bromination of 3,3-dibromocamphor. The mechanism proposed for the rearrangement of (+)-3-bromocamphor to (−)-6-bromocamphor is also supported by experimental evidence.

Key words: 8-bromocamphor, 6-bromocamphor, 3,2-*endo* methyl shifts.

WILLIAM M. DADSON, JOHN H. HUTCHINSON et THOMAS MONEY. Can. J. Chem. **68**, 1821 (1990).

On présente des données qui supportent le mécanisme selon lequel il se produit un déplacement 3,2-*endo* de groupement méthyle au cours de la bromation en C(8) du 3,3-dibromocamphre Le mécanisme proposé pour la transposition du (+)-3-bromocamphre en (−)-6-bromocamphre est aussi supporté par les données expérimentales.

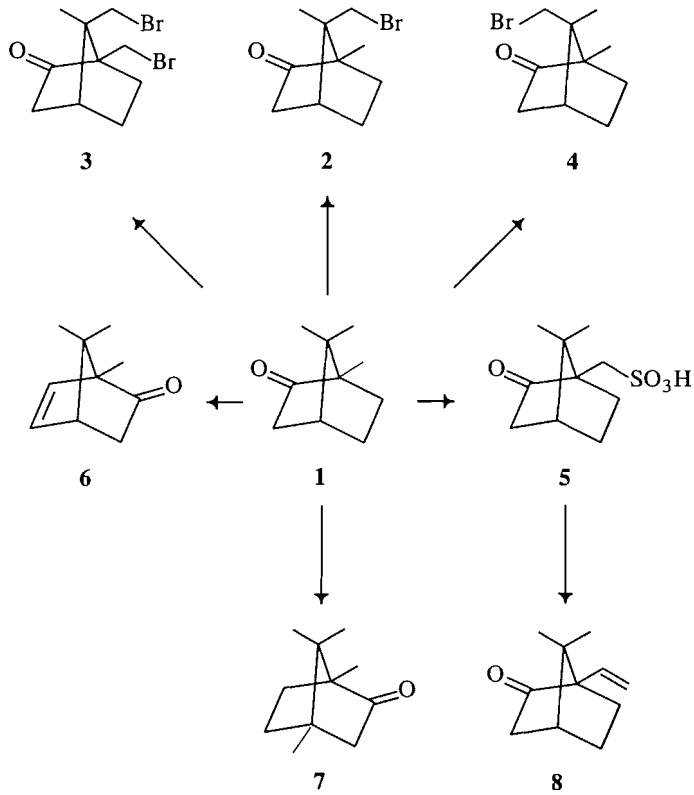
Mots clés : 8-bromocamphre, 6-bromocamphre, transposition 3,2-*endo* de groupements méthyles.

[Traduit par la revue]

Introduction

A variety of camphor derivatives (**2**–**5**, Scheme 1) have been used successfully as optically pure intermediates in natural product synthesis (1). Other interesting derivatives, **6** (2*a*), **7** (2*b*), and **8** (2*c*, *d*), are currently being evaluated. In all cases these camphor derivatives have been prepared by reactions in which the basic camphor framework undergoes rearrangement to provide intermediates that react with electrophiles (SO_3, Br_2) and then rearrange to the original camphor framework or its enantiomer. The rearrangements that form the basis of the transformations outlined in Scheme 1 can be considered as extensions or modifications of the fundamental rearrangement mechanism (Scheme 2), which has been proposed (3) to explain the acid-catalysed partial racemization of camphor. As shown in Scheme 2 this involves Wagner–Meerwein rearrangements, 3,2-*exo*-methyl shifts, and 6,2-hydride shifts and provides intermediates (e.g., **9***b*, **10***b*) in which the original C(10) and C(9) methyl groups have become electrophilic *exo*-methylene groups. Thus to explain C(10) sulfonation of (+)-camphor (**1**) it is assumed that intermediate **9***b* reacts with SO_3 or equivalent to provide an intermediate that can then undergo Wagner–Meerwein rearrangement to regenerate the camphor framework and provide (+)-camphor-10-sulfonic acid (**5**). Similarly, to explain C(9) bromination of camphor, it is assumed that bromine reacts with intermediates **10***b* and *ent*-**10***b* to provide brominated intermediates, which can then undergo Wagner–Meerwein rearrangement to regenerate the camphor framework and provide a mixture of (+)-9-bromocamphor and (−)-9-bromocamphor (cf. references 1*a*, *b* for a detailed description of these transformations).

To explain the C(9)-bromination reaction that converts (+)-*endo*-3-bromocamphor (**12**) to (+)-*endo*-3,9-dibromocamphor (**17**) (4) (Scheme 3), it is assumed that the *exo*-methylene intermediate (**14**) reacts with bromine to provide a carbocation (**15**) (or bromonium ion) intermediate, which then rearranges back to the camphor framework. The product of this reaction, (+)-*endo*-3,9-dibromocamphor (**17**), can then be debrominated regioselectively to provide optically pure (+)-9-bromocamphor



SCHEME 1

(**2**). The mechanism outlined in Scheme 3 is supported by appropriate labelling experiments using 3-bromo-[8-^{2}H]-camphor (**19**) as substrate (5*b*). The results of this investigation (5*b*) demonstrated that, during the C(9)-bromination process, the methyl groups retain their positional integrity.

Synthesis of 8-bromocamphor (4): evidence for 3,2-*endo* methyl shifts

Examination of the mechanism proposed (Scheme 3) for the C(9) bromination of (+)-*endo*-3-bromocamphor (**12**) (or (+)-camphor) led us to conclude (6) that C(8)-bromination could

WM = Wagner–Meerwein rearrangement; 3,2-Me-*exo* = 3,2-*exo*-methyl shift; 6,2-H = 6,2-hydride shift

SCHEME 2

only occur if an intermediate similar to **15** (Scheme 3) underwent a 3,2-*endo*-methyl shift. Authentic examples of 3,2-*endo*-methyl shifts are exceedingly rare (7, 8), and indeed, in the absence of special structural features, molecules will tend to rearrange by a circuitous route involving 3,2-*exo*-methyl shifts rather than by a more direct route involving *endo*-methyl shifts (cf. transformation of longifolene to isolongifolene (9) and albene structure and synthesis (10)).

In spite of these reservations, we considered (6) the possibility of reversing the normal preference (9–17) for 3,2-*exo*-methyl over 3,2-*endo*-methyl shifts in bicyclo[2.2.1]heptyl systems by having a bulky group (i.e., a bromine atom) in the 7-*syn*-position of intermediate **15** (Scheme 3). This led us previously (6) to synthesize (+)-3,3-dibromocamphor (**27**) (Scheme 4) and subject it to the conditions ($Br_2/ClSO_3H$) that are used normally to accomplish C(9)-bromination. The product of this reaction was (+)-3,3,8-tribromocamphor (**42**) and subsequent regiospecific debromination provided optically pure (+)-8-bromocamphor (**4**).[3] In spite of its poor overall yield (30–40%) (1*c*) the simplicity of our route (1*c*, 6) compared to the 12-step procedures previously used (3*b*, 18) makes it the most convenient way of preparing optically pure 8-bromocamphor. However, the successful outcome of these previous synthetic studies (6) could not be considered as evidence for the occurrence of a 3,2-*endo*-methyl shift. Evidence in support of the C(8)-bromination mechanism outlined in Scheme 4 was obtained by using 9-deuterio-3,3-dibromocamphor[4] (**28**; 99 mol% deuterium) and 8-deuterio-3,3-dibromocamphor[4] (**29**; 94–

[3]The optical purity of (+)-8-bromocamphor (**4**) was established (6) by hydrogenolysis (Bu_3SnH) to (+)-camphor (**1**).

[4]9-Deuteriocamphor (**26**) (16, 19, 24–26) and 8-deuteriocamphor (**18**) (19, 26, 27) were synthesized by reducing 9-bromocamphor (**2**) and 8-bromocamphor (**4**), respectively, with Bu_3SnD/AIBN. Subsequent bromination (1*c*) then provided the corresponding 3,3-dibromo derivatives.

47 *ent*-**47**

FIG. 1

96 mol% deuterium) as substrates in the C(8)-bromination reaction (19). The ^{1}H nmr spectrum (δ ($CDCl_3$, 250 MHz): 0.90 (3H,s), 1.13 (2H, t), 3.08(1H, d, J = 11.0 Hz), and 3.14 (1H, d, J = 11.0 Hz)) of the deuterated 8-bromocamphor (**45**) (Scheme 4) derived from 9-deuterio-3,3-dibromocamphor (**28**) indicated that the deuterium was exclusively located in the C(9) position and this was confirmed when hydrogenolysis (Bu_3SnH) provided 9-deuteriocamphor (**26**; 98 mol% deuterium) (δ (CCl_4, 250 MHz): 0.83 (3H, s), 0.87 (3H, s), 0.94 (2H, t, J = 2 Hz); δ (^{13}C, $CDCl_3$, 20 MHz): 9.3, 18.9 (t, J = 19 Hz), 19.8). In a similar fashion the ^{1}H nmr spectrum (δ (CCl_4, 400 MHz): 0.90 (3H, s) 1.14 (3H, s), and 3.12 (1H, m)) of deuterated 8-bromocamphor (**46**) derived from 8-deuterio-3,3-dibromocamphor (**29**; 94–96 mol% deuterium) (Scheme 4) indicated that the deuterium was located in the C(8) position. This was confirmed by subsequent transformation of **46** to 8-deuteriocamphor (**18**; 84–86 mol% deuterium) (δ ($CDCl_3$, 250 MHz): 0.82 (2H, t, J = 2 Hz), 0.84 (s), 0.91 (3H, s), 0.96 (3H, s); δ (^{13}C, $CDCl_3$, 20 MHz): 9.2, 19.1, and 19.4 (t, J = 19 Hz)). The lower deuterium content revealed by mass spectroscopic analysis and the presence of a weak sharp singlet at δ 0.84 in the ^{1}H nmr spectrum clearly indicated that there was some undeuterated camphor in this product. The partial loss of deuterium from the C(8) position of 8-deuterio-3,3-dibromocamphor (**29**) during its conversion to 3,3,8-tribromocamphor (**44**) provides some additional support for the intervention of intermediates **35** and **38** (Scheme 4) in the C(8) bromination process.[5]

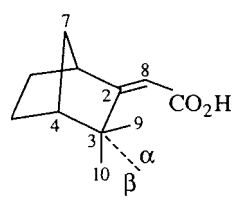
The almost exclusive occurrence of 3,2-*exo* rather than 3,2-*endo* methyl shifts in rearrangements involving bornyl or norbornyl carbocations has been thoroughly documented by several research groups (9–17), and a stereoelectronic effect (8, 20, 21) has been proposed to account for this stereoselectivity. The stereoelectronic effect can be illustrated in the case of camphene (**47**) racemization (cf. **47** = *ent*-**47**, Fig. 1) where it has been proposed (8, 20) that the preferred migration of the *exo*-methyl group could possibly be due to unequal dihedral angles (α and β; cf. Fig. 1) between the C(3)—C(9), C(3)—C(10) bonds and the C(2)—C(8) bond. If α > β, the *exo*-methyl group will be closer than the *endo*-methyl group to the ideal coplanar relationship with the developing *p*-orbitals at C(2) and will therefore migrate preferentially. The converse, β > α, would of course result in a 3,2-*endo*-methyl shift.

Although this proposal has not been tested with camphene, an X-ray cyrstallographic analysis of camphene-8-carboxylic acid (**48**), (20*b*, *c*) has shown that this molecule is twisted and that the dihedral angle α is greater than β (see Table 1). This distortion is also reflected in a decreased C(3)—C(9)/C(4)—C(7) dihedral angle and a corresponding increase in the C(3)—C(10)/C(4)—C(5) angle (Table 1).

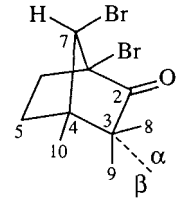
[5]In addition, the complete retention of deuterium during the conversion of 9-deuterio-3,3-dibromocamphor (cf. **28**; Scheme 4) to 9-deuterio-8-bromocamphor (**45**) indirectly supports intervention of intermediates **30**–**41** in the C(8) bromination process.

If a 3,2-*endo*-methyl shift is occurring during the formation of 3,3,8-tribromocamphor (**42**) (cf. Scheme 4), then according to the Sorensen–Vaughan proposal (8, 20) this could be due to distortion of the postulated intermediates **30** and **36** (Scheme 4) in such a way as to increase the dihedral angle β at the expense of α. This explanation could not be tested directly, but indirect evidence for its validity was obtained from the structure of dibromoketone **49**, a compound that could be regarded as a reasonably close structural analog of the hypothetical intermediate, **30**. Dibromoketone **49** (6) is formed during the bromination of 3,3-dibromocamphor (**27**) and reexamination of the previously reported X-ray crystallographic data (22) for this compound revealed that the dihedral angle C(3)—C(8)/C(2)—O (α) is less than the angle C(3)—C(9)/C(2)—O (β) (cf. Table 1). In addition the expected relationship between the angles C(3)—C(8)/C(4)—C(7) and C(3)—C(9)/C(4)—C(5) is also evident (cf. Table 1).

However, the small difference in α and β angles in **49** is not a



48



49

sufficiently convincing explanation for the exclusive occurrence of 3,2-*endo*-methyl shifts in **30** and **36**. Indeed it seems more likely that our original explanation (6) for the occurrence of 3,2-*endo*-methyl shifts during the C(8)-bromination of 3,3-dibromocamphor (**27**) has greater validity, i.e., the C(7)-*syn* bromine substituents in the proposed intermediates, **30** and **36**, sterically inhibit 3,2-*exo*-methyl shifts and, hence, the alternative 3,2-*endo*-methyl shifts occur.

Synthesis of 6-bromocamphor: mechanistic aspects

Recent investigations (2*a*) in our laboratory have established that (+)-5,6-dehydrocamphor (**6**) has considerable potential as an optically pure intermediate in terpenoid synthesis. One of the routes (Scheme 5) we have developed to this compound involves acid-catalysed rearrangement of (+)-*endo*-3-bromocamphor (**12**) to (−)-*endo*-6-bromocamphor (**63**) followed by dehydrohalogenation with base. The remarkable transformation of **12** to **63** is an extension of a previous report by Nishikawa and co-workers (23), which described the rearrangement of (+)-3,9-dibromocamphor (**17**) to (−)-6,9-dibromocamphor (**65**) in fuming sulfuric acid (Scheme 5). It was also reported (23) that the corresponding reaction with (+)-3-bromocamphor (**12**) resulted only in C(9)-sulfonation.

Our investigations have shown that treatment of (+)-*endo*-3-bromocamphor (**12**) with chlorosulfonic acid at 55°C for 15 min produces (−)-*endo*-6-bromocamphor (**63**) in 35–40% yield. The structure of this product was established by its ^{1}H nmr

spectrum (400 MHz) and by reduction (Bu_3SnH) to optically pure (−)-camphor (*ent*-**1**) ($[\alpha]_D$ −44.75 (c 0.4, EtOH)). Later studies revealed that (+)-3,9-dibromocamphor (**17**), under similar conditions, rearranges to (−)-6,9-dibromocamphor (**65**) in ~50% yield.

During the transformation of (+)-*endo*-3-bromocamphor (**12**) to (−)-*endo*-6-bromocamphor (**63**) the basic camphor framework is inverted and this probably occurs by a mechanism (Scheme 5) that is analogous to that proposed for the acid-catalysed transformation of (+)-camphor (**1**) to (−)-camphor (*ent*-**1**) (Scheme 2). Experimental support for the proposed mechanism (Scheme 5) is provided by the fact that (+)-*endo*-3-bromo-10-deuteriocamphor (**50**) rearranges to (−)-*endo*-6-bromo-8-deuteriocamphor (**64**). The structure of the latter

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12

compound was confirmed by hydrogenolysis (Bu_3SnH/C_6H_6) to (−)-8-deuteriocamphor (*ent*-**18**; Scheme 5).

Experimental

Low resolution mass spectra were determined on a Varian MAT CH-4B spectrometer and high resolution spectra on a Kratos MS-50 spectrometer. Mass spectroscopic deuterium analyses were determined by Dr. Jim Yergey (Merck Frosst, Canada Inc., Pointe Claire – Dorval, Quebec). Infrared spectra were recorded on a Perkin–Elmer 710B spectrometer and ^1H nmr spectra were taken on Bruker WH-400 and Bruker AM-250 spectrometers. Elemental analyses were performed by Mr. P. Borda, Microanalytical Laboratory, Chemistry Department, U.B.C.

*8-Deuteriocamphor (**18**) (19, 26, 27)*

A solution of 8-bromocamphor (**4**) (1*c*) (1.0 g, 4.3 mmol), tri-*n*-butyltin deuteride (2.0 mL, 7.4 mmol), and AIBN (100 mg, 0.43 mmol) in dry benzene (10 mL) was heated to reflux under nitrogen. After 3 h the solution was cooled, the solvent removed, and the residue chromatographed (silica gel; hexane/ethyl acetate 19:1) to yield 8-deuteriocamphor (**18**) (19, 26, 27) (560 mg, 85%) as a waxy solid; δ ($CDCl_3$, 250 MHz): 0.82 (2H, t, J = 1.8 Hz), 0.90 (3H, s), 0.94 (3H, s), 1.30–1.46 (2H, m), 1.68 (1H, m), 1.83 (1H, d, J = 18 Hz) 1.94 (1H, m), 2.07 (1H, dd, J = 4.5 Hz, 4.5 Hz), 2.33 (1H, ddd, J = 18 Hz, 5 Hz, 4.5 Hz); δ (^{13}C, $CDCl_3$, 20 MHz): 9.2, 19.1, 19.4 (t, J = 19 Hz). Mass spectroscopic analysis[6] showed this material to contain 94–96 mol% deuterium. Exact mass calcd. for $C_{10}H_{15}DO$: 153.1264; found: 153.1265.

*8-Deuterio-3,3-dibromocamphor (**29**)*

Hydrogen bromide was passed through a solution of 8-deuteriocamphor (**18**) (433 mg, 2.8 mmol) and bromine (1.25 mL, 24 mmol) in acetic acid (3 mL). The solution was heated to 100°C for 5 h, then cooled and poured into water. After extraction with ether (3×) the combined organic layers were washed with saturated $NaHCO_3$ solution, then twice with water, dried, and evaporated. The crude product was purified by flash chromatography (hexane/ethyl acetate 19:1) to yield 8-deuterio-3,3-dibromocamphor (**29**) (565 mg, 65%), mp 57.5–59°C; δ ($CDCl_3$, 250 MHz): 1.01 (3H, s), 1.10 (3H, s), 1.22 (2H, bs), 1.60–1.68 (2H, m), 2.08 (1H, m), 2.32 (1H, m), 2.81 (1H, d, J = 4.2 Hz). Exact mass calcd. for $C_{10}H_{13}Br_2DO$: 308.9473/310.9453/312.9433; found: 308.9423/310.9449/312.9416.

*8-Bromo-8-deuteriocamphor (**46**)*

8-Deuterio-3,3-dibromocamphor (**29**) (550 mg, 1.77 mmol) was added to a solution of bromine (0.3 mL) and chlorosulfonic acid (1.2 mL). The mixture was stirred at room temperature for 3 h, then poured onto ice and solid $NaHSO_3$. Water was added and the mixture was extracted with ether (3×). The combined ether layers were washed with saturated $NaHCO_3$ solution, then with water (2×), and dried. Removal of the solvent gave impure 8-deuterio-3,3,8-tribromocamphor (**44**) as a brown oil, which was dissolved in ether (2.0 mL) and acetic acid (2.0 mL) and cooled in a water bath. Zinc dust (170 mg, 2.6 mmol) was added (vigorous reaction) and after 30 min the solution was poured into water. After extraction with ether (3×) the combined ether extracts were washed with saturated $NaHCO_3$ solution, water (2×), dried, and evaporated. Column chromatography of the resulting oil (hexane/ethyl acetate 20:1) gave 8-bromo-8-deuteriocamphor (**46**) (127 mg) as a waxy solid; δ ($CDCl_3$, 250 MHz): 0.92 (3H, s), 1.14 (3H, s), 1.39 (1H, m), 1.58 (1H, m), 1.82 (1H, m), 1.95 (1H, m), 1.96 (1H, d, J = 18 Hz), 2.30–2.47 (2H, m), 3.15 (~1H, m). Exact mass calcd. for $C_{10}H_{14}BrDO$: 231.0369/233.0349; found: 231.0364/233.0331.

*Conversion of 8-bromo-8-deuteriocamphor (**46**) to 8-deuteriocamphor (**18**)*

A solution of 8-bromo-8-deuteriocamphor (**46**) (109 mg, 0.47 mmol), tri-*n*-butyltin hydride (0.19 mL, 0.7 mmol), and AIBN (10 mg, 0.047 mmol) in dry benzene (3 mL) was heated at reflux under a nitrogen atmosphere for 1.5 h. The solution was cooled, solvent removed, and the resulting oil purified by flash chromatography (hexane/ethyl acetate 20:1) to give 8-deuteriocamphor (**18**) (37 mg, 51%) as a waxy solid. Mass spectroscopic analysis showed this material to contain 85–87 mol% deuterium. Comparison of the ^1H nmr spectrum (δ ($CDCl_3$, 250 MHz): 0.82 (2H, t, J = 2 Hz), 0.84 (s), 0.91 (3H, s), 0.96 (3H, s)) of this compound with that of authentic 8-deuteriocamphor (prepared, as described above, from 8-bromocamphor by reduction with tri-*n*-butyltin deuteride) also indicated that approximately 10–20% loss of deuterium had occurred.

*9-Deuteriocamphor (**26**) (16, 19, 24–26)*

A solution of 9-bromocamphor (**2**) (4) (1.0 g, 4.3 mmol), tri-*n*-butyltin deuteride (2.0 mL, 7.4 mmol), and AIBN (200 mg, 0.86 mmol) in dry benzene (20 mL) was heated to reflux under nitrogen. After 8 h the solution was cooled, the solvent removed, and the residue chromatographed (silica gel; hexane/ethyl acetate 19:1) to yield 9-deuteriocamphor (**26**) (480 mg, 73%; 99 mol% deuterium) as a waxy solid; δ ($CDCl_3$, 250 MHz): 0.82 (3H, s), 0.90 (3H, s), 0.93 (2H, t, J = 2 Hz), 1.30–1.47 (2H, m), 1.68 (1H, m), 1.83 (1H, d, J = 18 Hz), 1.94 (1H, m), 2.07 (1H, dd, J = 4.5 Hz, 4.5 Hz), 2.33 (1H, ddd, J = 18 Hz, 5 Hz, 4.5 Hz); δ (^{13}C, $CDCl_3$, 20 MHz): 9.3, 18.9 (t, J = 19 Hz), 19.8. Exact mass calcd. for $C_{10}H_{15}DO$: 153.1264; found: 153.1272.

*9-Deuterio-3,3-dibromocamphor (**28**)*

Hydrogen bromide was passed through a solution of 9-deuteriocamphor (**26**) (373 mg, 2.4 mmol) and bromine (1.1 mL, 20.7, mmol) in acetic acid (2 mL). The solution was heated to 100°C for 5 h, then cooled and poured into water. After extraction with ether (3×) the combined organic layers were washed with saturated $NaHCO_3$ solution, water (2×), dried, and evaporated. The crude product was purified by flash chromatography (hexane/ethyl acetate 19:1) to yield 9-deuterio-3,3-dibromocamphor (**28**) (512 mg, 69%), mp 57–58°C; δ ($CDCl_3$, 250 MHz): 1.01 (3H, s), 1.08 (2H, t, J = 2 Hz), 1.23 (3H, s), 1.60–1.68 (2H, m), 2.08 (1H, m), 2.32 (1H, m), 2.81 (1H, d, 4.2 Hz). Exact mass calcd. for $C_{10}H_{13}Br_2DO$: 308.9473/310.9453/312.9433; found: 308.9491/310.9445/312.9412.

*8-Bromo-9-deuteriocamphor (**45**)*

9-Deuterio-3,3-dibromocamphor (**28**) (470 mg, 1.51 mmol) was added to a solution of bromine (0.3 mL) and chlorosulfonic acid (1.2 mL). The mixture was stirred at room temperature for 3 h, then poured onto ice and solid $NaHSO_3$. Water was added and this was then extracted with ether (3×). The combined ether layers were washed with saturated $NaHCO_3$ solution, then with water (2×), and dried. Removal of the solvent *in vacuo* gave a brown oil, which was used without purification. The impure 9-deuterio-3,3,8-tribromocamphor (**43**) was dissolved in ether (1.5 mL) and acetic acid (1.5 mL) and cooled in a water bath. Zinc dust (160 mg, 2.5 mmol) was added in one lot (vigorous reaction) and after 30 min the solution was poured onto water. After extraction with ether (3×) the combined ether layers were washed with saturated $NaHCO_3$ solution, then twice with water, dried, and evaporated. Column chromatography of the resulting oil (hexane/ethyl acetate 20:1) gave 8-bromo-9-deuteriocamphor (**45**) (80 mg, 23%) as a waxy solid; δ ($CDCl_3$, 250 MHz): 0.93 (3H, s), 1.14 (2H, t, J = 2 Hz), 1.39 (1H, m), 1.58 (1H, m), 1.82 (1H, m), 1.94 (1H, m), 1.95 (1H, d, J = 18 Hz), 2.31–2.48 (2H, m), 3.10 and 3.17 (AB quartet; 2H, J = 11 Hz). Exact mass calcd. for $C_{10}H_{14}BrDO$: 231.0369/233.0349; found 231.0367/233.0325.

*Conversion of 8-bromo-9-deuteriocamphor (**45**) to 9-deuteriocamphor (**26**)*

A solution of 8-bromo-9-deuteriocamphor (**45**) (77 mg, 0.33 mmol), tri-*n*-butyltin hydride (0.13 mL, 0.5 mmol), and AIBN (7 mg, 0.033 mmol) in dry benzene (2 mL) was heated to reflux under a nitrogen atmosphere for 1.5 h. The solution was cooled, solvent removed, and the resulting oil purified by flash chromatography (hexane/ethyl acetate 20:1) to give 9-deuteriocamphor (**26**) (32 mg, 635) as a waxy solid. Mass spectroscopic analysis showed this material to contain 98–100 mol% deuterium. This compound was identical to

[6]We are grateful to Dr. Jim Yergey (Merck-Frosst Inc.) for the quantitative deuterium analyses.

9-deuteriocamphor (**26**) prepared, as described above, by reduction of 9-bromocamphor with tri-*n*-butyltin deuteride.

*Rearrangement of (+)-3-*endo*-bromocamphor (**12**) to (−)-*endo*-6-bromocamphor (**63**)*

(+)-3-*endo*-Bromocamphor (**12**) (7.5 g) (Aldrich Chemical Co.) in chlorosulfonic acid (30 mL) was stirred at 50°C for 15 min, then poured onto ice. After extraction with ether (3×), the ether layers were washed with sodium bicarbonate solution, then twice with water, and finally dried over $MgSO_4$. Removal of the solvent under reduced pressure gave a light yellow crystalline solid (3.51 g). Column chromatography (silica gel; petroleum ether/ether 9:1) gave the 7-*anti*-bromofenchone (75 mg, 1%) as a cyrstalline solid, mp 49–50°C (sealed tube); $[\alpha]_D$ −133.15° (*c* 0.19, CH_2Cl_2); ν_{max} (film): 1745 cm^{-1}; δ ($CDCl_3$, 400 MHz): 1.09 (3H, s), 1.13 (3H, s), 1.16 (3H, s), 1.38 (1H, m), 1.75–1.90 (2H, m), 2.22 (1H, m), 2.34 (1H, br d, J = 4 Hz; C-4 proton), 4.26 (1H, br s; C-7 *syn* proton); *m/e* (relative intensity): 232/230 (M^+, 1/0.6), 151 (8), 123 (60), 81 (100). Exact mass calcd. for $C_{10}H_{15}OBr$: 232.0286/230.0306; found: 232.0291/230.0312.

Further elution provided a mixture of unidentified compounds (186 mg) that decomposed spontaneously and this was followed by (−)-*endo*-6-bromocamphor (**63**) (34), (2.67 g, 36%) as a white crystalline solid, $[\alpha]_D$ −51.77° (*c* 4.96, CH_2Cl_2); ν_{max} ($CHCl_3$): 1745 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.92 (3H, s), 0.97 (3H, s), 1.00 (3H, s) 1.90 (1H, dd, J = 15 Hz, 3.5 Hz; C-5 *endo* proton), 2.05 (1H, d, J = 18 Hz; C-3 *endo* proton), 2.22 (1H, dd, J = 4 Hz, 4 Hz; C-4 proton), 2.44 (1H, ddd, J = 18 Hz, 4 Hz, 4 Hz; C-3 *exo* proton), 2.85 (1H, dddd, J = 15 Hz, 10 Hz, 4 Hz, 4 Hz; C-5 *exo* proton), 4.22 (1H, dd, J = 10 Hz, 3.5 Hz; C-6 *exo* proton); *m/e* (relative intensity): 232/230 (M^+, 1.2/1.8), 167 (11), 151 (39), 149 (30), 109 (100), 108 (34), 107 (43). Exact mass calcd. for $C_{10}H_{15}$ OBr: 232.0286/230.0306; found: 232.0274/230.0303. Anal calcd. for $C_{10}H_{15}OBr$: C 51.97, H 6.54, Br 34.57: found: C 51.93, H 6.45, Br 34.68.

*Conversion of (−)-*endo*-6-bromocamphor (**63**) to (−)-camphor (*ent*-**1**)*

To a solution of (−)-6-*endo*-bromocamphor (**63**) (107 mg, 0.46 mmol) and azobisisobutyronitrile (20 mg) in benzene (4 mL) was added tri-*n*-butyltin hydride (29) (0.2 mL, 0.74 mmol) and the mixture refluxed under argon for 16 h. After cooling the solution, it was poured into 10% aqueous potassium fluoride solution (28) and extracted twice with ether. The ether layers were washed twice with the postassium fluoride solution, dried ($MgSO_4$), and evaporated to yield a colourless oil (377 mg). Column chromatography (silica gel; petroleum ether/ether 20:1), gave (−)-camphor (*ent*-**1**) (33.4 mg, 47%), $[\alpha]_D$ −44.75° (*c* 0.40, 95% EtOH); authentic (−)-camphor (Aldrich Chemical Co.) had $[\alpha]_D$ −40.15° (*c* 0.396, 95% EtOH) and authentic (+)-camphor (Aldrich Chemical Co.) had $(\alpha]_D$ +44.80° (*c* 0.386, 95% EtOH). The synthetic (−)-camphor was identical (ir; ^1H nmr, tlc, glc) to authentic material.

*(+)-*endo*-3-Bromo-10-deuteriocamphor (**50**)*

Bromination of (+)-10-deuteriocamphor (24, 30–33) with bromine/acetic acid according to the procedure reported by Meyer *et al.* (5) provided (+)-*endo*-3-bromo-10-deuteriocamphor (**50**), mp 74.5–76°C; δ ($CDCl_3$, 400 MHz): 0.93 (3H, s), 0.96 (2H, t, J = 2 Hz), 1.08 (3H, s), 1.43 (1H, ddd, J = 14 Hz, 9 Hz, 5 Hz), 1.69 (1H, m), 1.88 (1H, m), 2.09 (1H, ddd, J = 13 Hz, 9 Hz, 4 Hz), 1.30 (1H, dd, J = 4.5 Hz, 4.5 Hz; C-4 proton), 4.62 (1H, br d, J = 4.5 Hz). Exact mass calcd. for $C_{10}H_{14}DOBr$: 233.0349/231.0369; found: 233.0348/231.0369.

*Rearrangement of (+)-*endo*-3-bromo-10-deuteriocamphor (**50**) to (−)-6-endo-*bromo-8-deuteriocamphor (**64**)*

Rearrangement of (+)-*endo*-3-bromo-10-deuteriocamphor (**50**), as described above for *endo*-3-bromocamphor, provided (−)-*endo*-6-bromo-8-deuteriocamphor (**64**), mp 55–56°C; δ ($CDCl_3$, 400 MHz): 0.90 (2H, bs), 0.97 (3H, s), 0.99 (3H, s), 1.90 (1H, dd, J = 14.5 Hz, 3 Hz), 2.05 (1H, d, J = 18.5 Hz), 2.21 (1H, dd, J = 4.5 Hz, 4.5 Hz), 2.44 (1H, ddd, J = 18.5 Hz, 5 Hz, 4.5 Hz), 2.85 (1H, m), 4.22 (1H, dd, J = 10 Hz, 3.5 Hz). Exact mass calcd. for $C_{10}H_{14}DOBr$: 233.0349/231.0369; found: 233.0346/231.0374.

*Conversion of (−)-*endo*-6-bromo-8-deuteriocamphor (**64**) to (−)-8-deuteriocamphor (*ent*-**18**)*

(−)-*endo*-6-Bromo-8-deuteriocamphor (**64**) was reduced by the tri-*n*-butyltin hydride method (above) to provide (−)-8-deuteriocamphor (*ent*-**18**) (19, 25–27) in 60% yield; ν_{max} ($CHCl_3$): 1740 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.83 (2H, t, J = 1.8 Hz; C-8 methyl), 0.93 (3H, s; C-10 methyl), 0.97 (3H, s; C-9 methyl); *m/e* (relative intensity): 153 (M^+, 49), 109 (72), 96 (100), 84 (44), 81 (84). Exact mass calcd. for $C_{10}H_{15}DO$: 153.1264; found: 153.1264. This compound was identical (400 MHz ^1H nmr) to an authentic sample prepared from (+)-8-bromocamphor (1*c*).

*Rearrangement of (+)-*endo*-3,9-dibromocamphor (**17**) to (−)-*endo*-6,9-dibromocamphor (**65**)*

(+)-*endo*-3,9-Dibromocamphor (**17**), (4) (2.13 g) was stirred in chlorosulfonic acid (7.5 mL) at 55°C for 45 min. The mixture was carefully added to ice-cold brine and extracted with ether (3×). The combined ether layers were washed with aqueous postassium hydroxide/brine (emulsion formed), then twice with brine before being dried over $MgSO_4$. Removal of the solvent gave a waxy orange solid (1.73 g), which was recrystallized from ether to yield (−)-*endo*-6,9-dibromocamphor (**65**) (23) (1.01 g). Chromatography (silica gel; petroleum ether/ether 13:1) of the mother liquors provided a further quantity (144 mg) of **65** (total yield, 54%); mp 153.5–154°C (lit. (23) mp 152°C); $[\alpha]_D$ −98.3° (*c* 0.402, CH_2Cl_2) (lit. (23) $[\alpha]_D$ −81° (EtOH)); δ ($CDCl_3$, 270 MHz): 1.02 (3H, s), 1.07 (3H, s), 1.99 (1H, dd, J = 14 Hz, 3 Hz; C-5 *endo* proton), 2.13 (1H, d, J = 19 Hz; C-3 *endo* proton), 2.46 (1H, ddd, J = 19 Hz, 5 Hz, 4 Hz; C-3 *exo* proton), 2.64 (1H, dd, J = 4 Hz, 4 Hz; C-4 proton), 2.83 (1H, m), 3.26 (1H, d, J = 10 Hz), 3.54 (1H, d, J = 10 Hz), 4.27 (1H, dd, J = 10 Hz, 3 Hz; C-6 *exo* proton); *m/e* (relative intensity): 312/310/308 (M^+, 2/5/2), 231/229 (67/67), 217/215 (24/24), 175/173 (24/25), 149 (34), 121 (26), 107 (100). Exact mass calcd. for $C_{10}H_{14}OBr_2$: 311.9371/309.9391/307.9411; found: 311.9381/309.9393/307.9422. Anal. calcd. for $C_{10}H_{14}OBr_2$: C 38.74, H 4.55, Br 51.55; found: C 38.68, H 4.54, Br 51.49.

Acknowledgement

A simple synthetic route to 4-methylcamphor: mechanistic aspects

J. Andrew Clase, Diana L. F. Li, Linda Lo, and Thomas Money[1]

Chemistry Department, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received March 28, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

J. Andrew Clase, Diana L. F. Li, Linda Lo, and Thomas Money. Can. J. Chem. **68**, 1829 (1990).

A mechanism proposed for the rearrangement of (+)-2-methylenebornane (**8**) to a mixture of (+)-4-methylisobornyl acetate (**5**) and its enantiomer (*ent*-**5**) is supported by evidence obtained by investigating the rearrangement of deuterated 2-methylenebornane.

Key words: 4-methylcamphor, Wagner–Meerwein rearrangement, 6,2-hydride shift, 9-bromo-4-bromomethylcamphor.

J. Andrew Clase, Diana L. F. Li, Linda Lo et Thomas Money. Can. J. Chem. **68**, 1829 (1990).

En examinant la transposition du 2-méthylènebornane deutéré, on a obtenu des données supportant le mécanisme qui a été proposé antérieurement pour la transposition du (+)-2-méthylènebornane (**8**) en un mélange d'acétate de (+)-4-méthylisobornyle (**5**) et de son énantiomère (*ent*-**5**).

Mots clés : 4-méthylcamphre, transposition de Wagner–Meerwein, déplacement 6,2 d'hydrure, 9-bromo-4-bromométhylcamphre.

In connection with our general synthetic objective of using camphor derivatives as enantiomerically pure intermediates in terpenoid synthesis (1), we required an enantiospecific procedure for the conversion of camphor to 4-methylcamphor. Literature procedures (2) (Scheme 1) for the synthesis of (−)-4-methylcamphor (**7**) generally involve initial conversion of (+)-camphor (**1**) to (−)-2-methylisoborneol (**2**) or 1-methylcamphene (**3**) followed by acid-catalysed rearrangement to (+)-4-methylisoborneol (**4**) (2*c*,*g*), (+)-4-methylisobornyl acetate (**5**) (2*h*,*i*), or (+)-4-methylisobornyl nitrate (**6**) (2*d*,*f*). In no case was the optical purity of these products or the derived (−)-4-methylcamphor (**7**) determined and, hence, only an estimate of relative enantiomeric purity can be gauged from literature values of specific rotations listed in Table 1.

Since the conversion of (+)-camphor (**1**) to (−)-2-methylisoborneol (**2**) does not occur in high yield (3), we recently devised an alternative and potentially enantiospecific route to 4-methylcamphor that involves direct acid-catalysed rearrangement of (+)-2-methylenebornane (**8**) (Scheme 1) or its enantiomer (*ent*-**8**). The latter compounds are readily prepared (4, 5) in high yield (>90%) from (+)- and (−)-camphor, respectively, and we have discovered that treatment of **8** with $HOAc/H_2SO_4$ (conc.) (40:1 v/v) for 30 min at room temperature provides (+)-4-methylisobornyl acetate (**5**) ($[\alpha]_D^{20}$ +39.2 (*c* 2.20, EtOH)) in ~70% yield. Subsequent conversion of **5** to (+)-4-methylisoborneol (**4**) ($[\alpha]_D^{30}$ +19.5 (*c* 10.00, EtOH)) and (−)-4-methylcamphor (**7**) ($[\alpha]_D^{21}$ −16.0 (*c* 2.00, EtOH)) was then accomplished in ~90% overall yield.

Although the specific rotations (see above) of 4-methylisobornyl acetate, 4-methylisoborneol, and 4-methylcamphor prepared in this way were comparable to those recorded in the literature (cf. Table 1), the optical purity of our compounds or those described in the literature had not been established. Accordingly, the optical purity of our synthetic 4-methylisobornyl acetate was determined by measuring the ^1H nmr spectrum in the presence of a chiral shift reagent (6), $Eu(hfc)_3$. Three methyl groups in **5** (presumably C(8), C(10), and C(11)) appeared as a pair of signals, and their integration indicated that the enantiomeric ratio (**5**: *ent*-**5**) was ~4.5:1, i.e., an optical purity of ~64%. Authentic (±)-isobornyl acetate and (−)-isobornyl acetate were used as standards to establish the accuracy of this method of estimating optical purity. In a similar fashion, the optical purity of (−)-4-methylcamphor (**7**), derived from (+)-4-methylisobornyl acetate (**5**), was also estimated by recording the ^1H nmr spectrum in the presence of $Eu(hfc)_3$. In this case, one of the methyl groups (presumably C(10), see below) was clearly discernible as two signals with relative area ~4.3:1. Attempts to determine the optical purity of our synthetic (+)-4-methylisoborneol (**5**, or **5** + *ent*-**5**), by measuring the ^{31}P nmr spectrum (121.421 MHz) in the presence of Anderson–Shapiro reagent (7), clearly showed that the compound was not enantiomerically pure. However, the difference in chemical shift (0.04 ppm) between the two diastereomeric phosphate esters was too small to provide a reliable estimate of optical purity.

A comparison of the specific rotations quoted in the literature (cf. Table 1) and those recorded in our laboratory (*vide infra*) leads to the conclusion that all of the current methods of preparing 4-methylisobornyl acetate (**5**) provide material that is not enantiomerically pure. A plausible mechanism for the conversion of 2-methylisoborneol (**2**) (2*f*,*i*), 1-methylcamphene (**3**) (2*g*,*h*,*j*,*k*), and (+)-2-methylenebornane (**8**) to (+)-4-methylisobornyl acetate (**5**) and its enantiomer (*ent*-**5**) is shown in Scheme 2 and involves a combination of Wagner–Meerwein rearrangements, 3,2-*exo*-methyl shifts, and 6,2-hydride shifts. The validity of this mechanism can be evaluated by tracing the fate of deuterium when deuterated 2-methylenebornane (**8**) is rearranged to deuterated 4-methylisobornyl acetate (**5**). To accomplish this objective, however, it was necessary to assign chemical shifts to each of the four methyl groups in 4-methylcamphor (**7**).

The assignment of chemical shifts to the C(8), C(9), and C(10) methyl groups in camphor (**1**) was made by Connolly and McCrindle (8) by comparing the nmr spectra recorded in deuteriochloroform and benzene. Benzene-induced upfield shifts were noted for the C(8) and C(9) methyl groups ($\Delta\delta$ 0.23 and 0.32 ppm) while the C(10) methyl group absorption had almost the same chemical shift in deuteriochloroform and benzene ($\Delta\delta \sim 0.02$ ppm). Connolly and McCrindle suggested (8) that benzene-induced shifts of methyl group nmr absorptions

TABLE 1. Literature values of the specific rotation of 4-methylisoborneol (**4**), 4-methylisobornyl acetate (**5**), and 4-methylcamphor (**7**)

Compound	Specific rotation $[\alpha]_D^{20}$	Reference
4	+14.8°	2*a*
	+22.69° (EtOH)	2*g*
	+25.20° (*c* 10.0, EtOH)	2*c*,*f*
5	+18.90°	2*a*
	+35.84°	2*g*,*i*
7	−14.5° (*c* 10.0, EtOH)	2*c*,*f*

in cyclic ketones could be predicted by considering the position of the methyl group with respect to a reference plane passing through the carbon of the carbonyl group and perpendicular to its axis. Methyl groups that lie close to but behind this plane experience small upfield benzene-induced shifts (>0.1 ppm) while those some distance behind the plane show larger upfield shifts (~0.25–0.55 ppm).

Comparing the nmr spectra of 4-methylcamphor (**7**) in $CDCl_3$ (δ 0.71, 0.83, 0.92, and 1.04) and benzene-d_6 (δ 0.47, 0.51, 0.70, and 0.92) clearly reveals that one methyl group signal (δ 0.92) does not undergo an upfield shift in benzene-d_6 and, by analogy with camphor, this absorption (δ 0.92) was assigned to the C(10) methyl group. The assignment of chemical shifts to the C(9) and C(11) methyl groups (δ ($CDCl_3$) 0.83 and 1.04) was deduced from the nmr spectrum of 9-deuterio-4-deuteriomethylcamphor (**30**) (δ: 0.71 (s), 0.85 (t, J = 2 Hz), 0.92 (s), and 1.02 (t, J = 2 Hz)). This compound was prepared (Scheme 3) by reduction (Bu_3SnD) of 9-bromo-4-bromomethylcamphor (**29**) (9) and, since this structure has been confirmed by X-ray crystallographic analysis[2] of its synthetic precursor (**28**), the assignment of signals to C(9) and C(11) methyl groups rests on secure experimental evidence. The assignment of the signal at 0.83 ppm to the C(9) methyl group was deduced from an nOe difference experiment; irradiation at this frequency results in enhancement of the signals for the C(5) and C(6) *exo*-protons (δ 1.59–1.77). Thus the signal at δ 1.04 ppm was assigned to the C(11) methyl group protons. The remaining unassigned signal at δ 0.71 in the spectrum of 4-methylcamphor (**7**) was, of course, assigned to the C(8) methyl group and confirmatory evidence for this assignment was obtained from nOe difference experiments. Thus, irradiation at the C(8) methyl group resonance frequency resulted in enhancement of the C(3)-*exo*-hydrogen signal (δ 2.08, dd, J = 18 and 3 Hz).

General support for the mechanism outlined in Scheme 2 was obtained by rearranging 2-(dideuteriomethylene)bornane (**21**), derived from (+)-camphor (**1**), to deuterated 4-methylisobornyl acetate (**25** + *ent*-**25**). The ^1H nmr spectrum (δ ($CDCl_3$, 400 MHz): 0.69 (3H, s, C(8) methyl), 0.83 (3H, s, C(9) methyl), 0.86 (3H, s, C(10) methyl), 0.88 (m, C(11) deuteriomethyl + C(11) dideuteriomethyl), 0.90 (3H, s, C(11) methyl), 2.01 (3H, s, CH_3CO), 4.65 (1H, dd, J = 9 and 3.5 Hz, C(2) H)) of this compound demonstrated that considerable loss of deuterium had occurred during its formation from 2-(dideuteriomethylene)bornane (**21**). When the rearrangement of 2-(dideuteriomethylene)bornane (**21**) was carried out in CH_3CO_2D/H_2SO_4 (catalytic) the ^1H nmr (400 MHz) spectrum (δ: 0.71 (3H, s, C(8) methyl), 0.83 (3H, s, C(9) methyl), 0.92 (3H, s, C(10) methyl), 1.01 (m, C(11) dideuteriomethyl)) of the derived 4-methylcamphor (**26**) indicated that the C(11) methyl group signal was very weak and weak multiplets appeared at δ 0.82 and 0.90, upfield from the normal C(9) and C(10) methyl signals. According to the mechanism outlined in Scheme 2, the C(9) and C(10) methyl groups (but not the C(8) methyl group) of 2-methylenebornane (**8**) can become *exo*-methylene groups and, hence, incorporate deuterium.

SCHEME 3

Support for the operation of a 6,2-hydride shift[3] (Scheme 2) to explain the formation of *ent*-**5** was obtained by converting 8-deuterio-2-methylenebornane (**12**) (Scheme 2), derived from 8-deuteriocamphor (10), to deuterium-labelled 4-methylisobornyl acetate (**16** + **19**). The ^1H nmr spectrum (δ ($CDCl_3$, 400 MHz): 0.70 (2H, 1:1:1 t, J = 2 Hz, C(8) dideuteriomethyl), 0.71 (s, C(8) methyl), 0.81 (sh, C(9) dideuteriomethyl), 0.83 (3H, s, C(9) methyl), 0.92 (3H, s, C(10) methyl), 1.04 (3H, s, C(11) methyl)) of 4-methylcamphor (**17** + **20**) derived from this sample of 4-methylisobornyl acetate (**16** + **19**) showed that deuterium was located primarily in the C(8) methyl group with a small amount present in the C(9) methyl group. This evidence is consistent with the proposal (Scheme 2) that partial racemization is due to the occurrence of a 6,2-hydride shift, and the relative amount of deuterium present in the C(8) and C(9) methyl groups, although not estimated accurately, is consistent with the ratio of enantiomers, (**5** + *ent*-**5**) or (**7** + *ent*-**7**), determined by the chiral shift reagent method (cf. above).

From the mechanism proposed for the conversion of (+)-2-methylenebornane (**8**) to (+)-4-methylisobornyl acetate (**5**) and its enantiomer (*ent*-**5**) (Scheme 2), it is obvious that optically pure 4-methylisobornyl acetate can only be obtained if intermediate **11** reacts exclusively with solvent (HOAc) rather than undergoing a 6,2-hydride shift. Suppression of the 6,2-hydride shift could be accomplished perhaps by introducing a removable functional group into an appropriate position (e.g., C(3) or C(5)) in 2-methylenebornane, and we are currently investigating this possibility.

[3]It is worth noting that the intermediate **11** in Scheme 2 could be converted to *ent*-**11** by the occurrence of a 3,2-hydride shift rather than (or in addition to) the proposed 6,2-hydride shift. In general, however, 6,2-hydride shifts are generally preferred over 3,2 hydride shifts in bicyclo[2,2,1]heptyl carbocations (11). Also, it has been established (12) that when hydride shifts occur in carbocations of this type they are almost exclusively *exo* (12) and, hence, the product would be 4-methylbornyl acetate, i.e., the C(2) epimer of **5**. The chemical shift (δ 4.65) and multiplicity of the C(2) hydrogen of **5** formed by rearrangement of 2-methylenebornane (**8**) is almost identical to that of isobornyl acetate (δ 4.67) and, therefore, inconsistent with the *endo* epimer.

Experimental

Infrared (ir) spectra were recorded on a Perkin–Elmer model 710B spectrophotometer and were calibrated using the 1601 cm^{-1} band of polystyrene. Optical rotations ($[\alpha]_D$) were measured on a Perkin–Elmer 141 polarimeter at room temperature. The proton nuclear magnetic resonance spectra were recorded in deuteriochloroform at 400 MHz on a Bruker WH-400 spectrometer. The ^{31}P nmr spectra were recorded in benzene at 121.421 MHz using a Varian XL-300 spectrometer. Signal positions are given in ppm downfield from H_3PO_4 (used as an external reference standard) with an internal benzene-d_6 lock. Low-resolution mass spectra were obtained using a Varian MAT CH-4B spectrometer, and exact masses were obtained by high-resolution mass spectroscopy on a Kratos MS-50 mass spectrometer. All compounds characterized by high-resolution mass spectrometry exhibited one spot on a tlc (thin-layer chromatography) plate. Low-resolution gas liquid chromatography/mass spectra (gc/ms) were obtained on a Carlo Erba 41 60/Kratos MS 80 RFA instrument using a 0.25 mm × 15 m column with helium as the carrier gas. Gas–liquid chromatography (glc) was performed on either a Hewlett Packard model 5830A gas chromatograph with a 6 ft × 1/8 in. column of 3% OV-17 (carrier gas nitrogen) or a Hewlett Packard model 5880A gas chromatograph using a 50 m or 12 m × 0.2 mm column of Carbowax 10 M or a 12 m × 0.2 mm column of OV-101 (carrier gas helium). X-ray crystallographic analysis was carried out by Dr. S. Rettig and microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia.

All reactions involving moisture-sensitive reagents were performed under an atmosphere of dry argon using either oven- or flame-dried glassware. All reaction products were dried by allowing the solutions to stand over anhydrous magnesium sulfate. The solvents and reagents used were purified as follows: tetrahydrofuran (THF) was distilled from calcium hydride, lithium aluminum hydride (LAH), and sodium/benzophenone. Diethyl ether was distilled from LAH. Benzene, dichloromethane, triethylamine, and pyridine were distilled from

calcium hydride. Methanol was distilled from dry magnesium and iodine following reflux. Petroleum ether (bp 30–60°C) was distilled prior to use.

Flash chromatography was performed using Merck silica gel 60, 230–400 mesh, and tlc using Merck silica gel 60 F_{254} sheets.

(−)-2-Methylenebornane (8) (4, 5b)

(i) Method A (4)

Methyltriphenylphosphonium bromide (154.73 g, 0.43 mol) was vacuum pumped for 3 h to remove any trace of moisture before it was dissolved in dry THF (400 mL). *n*-Butyllithium (0.43 mol, 270.7 mL of a 1.6 M solution) was added dropwise at room temperature and the resultant mixture was stirred at 50°C for 2 h under argon. (+)-Camphor (**1**) (41.21 g, 0.27 mol) in dry THF (160 mL) was then added dropwise to the Wittig reagent and the reaction mixture was refluxed for 15 h under argon. Upon completion of the reaction, the THF solution was reduced to half volume by rotary evaporation, diluted with water, and extracted with pentane. The pentane extracts were combined, washed with water, and dried over anhydrous magnesium sulfate. Evaporation of the solvent yielded a viscous yellow oil that was purified by column chromatography (230–400 mesh silica; elution with 100% petroleum ether) to provide (−)-2-methylenebornane (**8**) as a white crystalline solid (35.5 g, 87%), mp 70–71°C (sealed tube) (lit. (4*a*) mp 68–70°C); $[\alpha]_D^{23}$ −52.88 (*c* 2.67, benzene) (lit. (4*c*) $[\alpha]_D^{26}$ −48.5 (*c* 2.12, benzene)); ν_{max} ($CHCl_3$): 1650, 885 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.76 (3H, s, C(8)H_3), 0.89 (3H, s, C(10)H_3), 0.92 (3H, s, C(9)H_3), 1.16–1.30 (2H, m, C(5) and C(6) *endo* protons), 1.64 (1H, ddd, *J* = 12, 12, and 4 Hz, C(6) *exo* proton), 1.73 (1H, dd, *J* = 8 and 4 Hz, C(4) proton), 1.78 (1H, m, C(5) *exo* proton), 1.91 (1H, bd, *J* = 16 Hz, C(3) *endo* proton), 2.38 (1H, bd, *J* = 16 Hz, C(3) *exo* proton), 4.63 (d) and 4.69 (d) (2H, AB quartet, *J* = 22 Hz, *exo*-methylene protons); *m/e* (relative intensity): 150 (M^+, 10.2), 135 (8.6), 69 (80.6), 55 (26.9), 41 (52.4). Exact mass calcd. for $C_{11}H_{18}$: 150.1409; found: 150.1413. Anal. calcd. for $C_{11}H_{18}$: C 87.93, H 12.07; found: C 87.71, H 12.10.

(ii) Method B (5)

Titanium tetrachloride (0.48 mL, 4.37 mmol) was added dropwise to a stirred suspension of zinc dust (1.18 g, 18.0 mmol) and dibromomethane (1.04 g, 0.42 mL, 6.0 mmol) in THF (20 mL) at −40°C. The reaction mixture was allowed to warm to 5°C and kept in the refrigerator for 3 days to give a thick brown slurry (5*a*). The ice-cold slurry was added portionwise to a stirred solution of (+)-camphor (**1**) (0.30 g, 2.0 mmol) in dichloromethane (2.0 mL) and the resultant mixture was stirred at room temperature for 18 h under argon. The reaction mixture was then quenched with saturated sodium bicarbonate solution, extracted with ether, the combined ether extracts washed with water, and dried over anhydrous magnesium sulfate. Evaporation of the solvent yielded pure (−)-2-methylenebornane (**8**) as a white crystalline solid (0.30 g, 99%) exhibiting spectral data comparable to those above.

(+)-Methylisobornyl acetate (5) (2)

Concentrated sulfuric acid (1.31 mL, 0.016 mol) was added dropwise to (−)-2-methylenebornane (**8**) (12.64 g, 0.084 mmol) in glacial acetic acid (54.4 mL). The reaction mixture was stirred at 0°C for 30 min, quenched in water, and extracted with ether. The ether extracts were combined, washed with saturated sodium bicarbonate solution, then with water, and dried over anhydrous magnesium sulfate. Evaporation yielded a light-yellow oil (12.58 g) that was purified by column chromatography (silica gel 230–400 mesh). Elution with petroleum ether/ether (98:2) provided pure (+)-4-methylisobornyl acetate (**5**) as a clear colorless oil (9.54 g, 73%); $[\alpha]_D^{20}$ +39.2 (*c* 2.20, 95% ethanol) (lit. (2*j*) $[\alpha]_D$ +35.84); ν_{max} (film): 1740, 1250, 1040 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.69 (3H, s, C(9)H_3), 0.83 (3H, s, C(8)H_3), 0.86 (3H, s, C(10)H_3), 0.90 (3H, s, C(11)H_3), 1.10–1.19 (2H, m, C(5) and C(6) *endo* protons), 1.36–1.54 (3H, m, C(6) *exo*, C(3) *endo*, and C(5) *exo* protons), 1.82 (1H, dd, *J* = 14 and 8 Hz, C(3) *exo* proton), 2.01 (3H, s, CH_3CO), 4.65 (1H, dd, *J* = 9 and 3.5 Hz, C(2) proton); *m/e* (relative intensity): 210 (M^+, 2.0), 150 (50.9), 135 (48.3), 109 (82.3), 43 (100.0). Exact mass calcd. for $C_{13}H_{22}O_2$: 210.1620; found: 210.1622. Anal. calcd. for $C_{13}H_{22}O_2$: C 74.24, H 10.54; found: C 74.82, H 10.70.

(+)-4-Methylisoborneol (4) (2)

Lithium aluminum hydride (3.1 g, 0.082 mol) was added to a solution of (+)-4-methylisobornyl acetate (**5**) (9.54 g, 0.045 mol) in dry THF (160 mL) and the reaction mixture was stirred at 0°C for 4 h. The reaction mixture was then quenched in water, extracted with ether, and the ether extracts washed with 1 M HCl solution, brine, and water, and dried over anhydrous magnesium sulfate. Evaporation of the ether yielded (+)-4-methylisoborneol (**4**) as white needles (7.56 g, 99%), mp 193–194°C (sealed tube) (lit. (2*f*) mp 195–196.5°C; lit (2*i*) mp 193–194°C); $[\alpha]_D^{30}$ +19.5 (*c* 10.0, 95% ethanol) (lit. (2*f*) $[\alpha]_D$ +25.2 (*c* 10.0, EtOH); lit. (2*j*) $[\alpha]_D$ +22.69 (EtOH); lit. (2*b*) $[\alpha]_D$ +18.9° (EtOH)); ν_{max} ($CHCl_3$): 3600, 1210 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.67 (3H, s, C(9)H_3), 0.87 (3H, s, C(8)H_3), 0.90 (3H, s, C(10)H_3), 0.93 (3H, s, C(11)H_3), 0.94–1.11 (2H, m, C(5) and C(6) *endo* protons), 1.34–1.46 (2H, m, C(6) *exo* and C(3) *endo* protons), 1.51 (1H, ddd, *J* = 8, 8, and 4 Hz, C(5) *exo* proton), 1.74 (1H, dd, *J* = 14 and 8 Hz, C(3) *exo* proton), 3.52 (1H, dd, *J* = 8 and 4 Hz, C(2) proton); *m/e* (relative intensity): 168 (M^+, 2.1), 150 (14.4), 109 (100.0), 41 (70.6). Exact mass calcd. for $C_{11}H_{20}O$: 168.1514; found: 168.1514. Anal. calcd. for $C_{11}H_{20}O$: C 78.51, H 11.98; found: C 78.57, H 11.99.

(−)-4-Methylcamphor (7) (2)

(+)-4-Methylisoborneol (**4**) (7.50 g, 0.045 mol) was dissolved in dichloromethane (150 mL) and the solution was added dropwise to pyridinium chlorochromate (PCC) (14.4 g, 0.067 mol) in methylene chloride (150 mL). After stirring at room temperature for 3.5 h, the reaction mixture was filtered through a layer of silica gel and anhydrous magnesium sulfate and washed with ether. Evaporation of the solvent provided (−)-4-methylcamphor (**7**) as a white crystalline solid (7.45 g, 99%), mp 150–151°C (sealed tube) (lit. (2*c*,*f*) mp 167–168°C); $[\alpha]_D^{21}$ −16.0 (*c* 2.04, 95% ethanol) (lit. (2*c*,*f*) $[\alpha]_D$ −14.50 (*c* 10.0, EtOH)); ν_{max} ($CHCl_3$): 1730 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.71 (3H, s, C(8)H_3), 0.83 (3H, s, C(9)H_3), 0.92 (3H, s, C(10)H_3), 1.04 (3H, s, C(11)H_3), 1.35–1.43 (2H, m, C(5) and C(6) *endo* protons), 1.57–1.75 (2H, m, C(5) and C(6) *exo* protons), 1.87 (1H, d, *J* = 18 Hz, C(3) *endo* proton), 2.08 (1H, dd, *J* = 18 and 3 Hz, C(3) *exo* proton); δ (C_6D_6, 400 MHz): 0.48 (3H, s, C(8)H_3), 0.51 (3H, s, C(9)H_3), 0.71 (3H, s, C(11)H_3), 0.92 (3H, s, C(10)H_3); *m/e* (relative intensity): 166 (M^+, 39.8), 138 (13.9), 109 (94.8), 83 (19.6), 82 (100.0). Exact mass calcd. for $C_{11}H_{18}O$: 166.1358; found: 166.1360. Anal. calcd. for $C_{11}H_{18}O$: C 79.47, H 10.91; found: C 79.67, H 11.03.

Determination of optical purity using tris[3-(heptafluoropropylhydroxymethylene)-d-camphorato]europium(III), Eu(hfc)$_3$

(i) (+)-4-Methylisobornyl acetate (**5**) (21.03 mg, 0.10 mmol) was dissolved in $CDCl_3$ (1 mL) and a series of four 400-MHz ^1H nmr spectra were recorded in the presence of different amounts of $Eu(hfc)_3$ (cf. Table 2).

(ii) (−)-4-Methylcamphor (**7**) (16.63 mg, 0.10 mmol) was dissolved in $CDCl_3$ (1 mL) and a series of ^1H nmr spectra (400 MHz) were recorded before addition of $Eu(hfc)_3$ and after sequential addition of 11.94 mg (0.01 mmol), 23.87 mg (0.02 mmol), and 35.81 mg (0.03 mmol) of $Eu(hfc)_3$ (cf. Table 3).

Determination of optical purity using the Anderson–Shapiro reagent (7)((4R,5R)-2-chloro-4,5-dimethyl-1,3,2-dioxaphospholane-2-oxide)

Anderson–Shapiro reagent (7) (358 mg, 2.10 mmol) was added to (+)-4-methylisoborneol (**4**) ($[\alpha]_D^{30.5}$ +19.47 (*c* 10.0, 95% ethanol) (334.5 mg, 2.0 mmol)), dry triethylamine (0.42 mL, 0.20 mmol), and 4-(dimethylamino)pyridine in dry benzene (2.0 mL). After 15 min a small amount of C_6D_6 was added and the mixture was filtered through a cotton plug. The ^{31}P nmr spectrum of this solution was recorded at 121.4 MHz using H_3PO_4 as internal standard; δ: 13.667, 13.628 (relative intensity ~2:1, Δδ 4.86 Hz).

8-Deuterio-2-methylenebornane (12)

Methylenation of 8-deuteriocamphor (10) by the method B described

above provided 8-deuterio-2-methylenebornane (**12**) as a white solid, mp 170–171°C; ν_{max} ($CHCl_3$): 3075, 1660, 880 cm^{-1}; δ (400 MHz, $CDCl_3$): 0.74 (2H, t, J = 2 Hz, C(8)H_2D), 0.88 (3H, s, C(10)H_3), 0.91 (3H, s, C(9)H_3), 1.15–1.30 (2H, m, C(5) and C(6) *endo*-H), 1.63 (1H, td, J = 11.5, 4 Hz, C(6) *exo*-H), 1.71–1.83 (2H, m, C(4) H and C(5) *exo*-H), 1.93 (1H, dt, J = 16, 2 Hz, C(3) *endo*-H), 2.40 (1H, dm, J = 16 Hz, C(3) *exo*-H), 4.65 (1H, bs) and 4.70 (1H, bs) (=CH_2); *m/e* (relative intensity): 151 (M^+, 22.9), 136 (42.6), 79 (100.0). Exact mass calcd. for $C_{11}H_{17}D$: 151.1470; found: 151.1470.

Rearrangement of 8-deuterio-2-methylenebornane (12)

Rearrangement of 8-deuterio-2-methylenebornane (**12**) by the procedure described above provided 8-deuterio-4-methylisobornyl acetate (**16**) as a colourless mobile oil; ν_{max} (neat): 2195, 1740, 1240, 1025 cm^{-1}; δ (400 MHz, $CDCl_3$): 0.68 (3H, s, C(9)H_3), 0.81 (2H, br s, C(8)H_2D), 0.86 (3H, s, C(10)H_3), 0.90 (3H, s, C(11)H_3), 1.11–1.21 (2H, m, C(5) and C(6) *endo*-H), 1.37–1.47 (2H, m, C(5) and C(6) *exo*-H), 1.50 (1H, dt, J = 14, 3.5 Hz, C(3) *exo*-H), 1.84 (1H, dd, J = 14, 8.5 Hz, C(3) *endo*-H), 2.03 (3H, s, CH_3CO-), 4.65 (1H, dd, J = 8.5, 3.5 Hz, CHOAc). The spectrum also shows a small broad peak at 0.67 ppm, and a small sharp singlet at 0.83 ppm, which are assigned respectively to C(9)H_2D and C(8)H_3 of 9-deuterio-4-methylisobornyl acetate (**19**), a minor coproduct. Mass spectrum, *m/e* (relative intensity): 211 (M^+, 7.7), 169 (16.5), 151 (85.5), 43 (100.0). Exact mass calcd. for $C_{13}H_{21}DO_2$: 211.1681; found: 211.1681.

8-Deuterio-4-methylcamphor (17)

Conversion of 8-deuterio-4-methylisobornyl acetate (**16**) to 8-deuterio-4-methylcamphor (**17**) was accomplished by reductive removal of the acetyl group followed by oxidation as described above. This afforded 8-deuterio-4-methylcamphor (**17**) as white crystals; 54%; mp 150–151°C; ν_{max} ($CHCl_3$): 3020, 2980, 2900, 1740 cm^{-1}; δ (400 MHz, $CDCl_3$): 0.70 (2H, 1:1:1 t, J = 1.8 Hz, C(8)H_2D), 0.83 (3H, s, C(9)H_3), 0.92 (3H, s, C(10)H_3), 1.04 (3H, s, C(11)H_3), 1.35–1.45 (2H, m, C(5) and C(6) *endo*-H), 1.59–1.77 (2H, m, C(5) and C(6) *exo*-H), 1.88 (1H, d_{AB}, J = 18 Hz, C(3) *endo*-H), 2.09 (1H, dd_{AB}, J = 18, 3 Hz, C(3) *exo*-H). The spectrum also exhibits a small singlet at 0.71 ppm and a shoulder at 0.81 ppm that were assigned respectively to C(8)H_3 and C(9)H_2D of 9-deuterio-4-methylcamphor (**20**). δ (C_6D_6): 0.45 (2H, 1:1:1 t, J = 7 Hz, C(8)H_2D), 0.51 (3H, s, C(9)H_3), 0.71 (3H, s, C(11)H_3), 0.91 (3H, s, C(10)H_3), 1.03 (1H, br t, J = 10 Hz, C(5) *endo*-H), 1.20 (1H, td, J = 10, 5 Hz, C(6) *endo*-H), 1.24–1.40 (2H, m, C(5) and C(6) *exo*-H), 1.62 (1H, d_{AB}, J = 18 Hz, C(3) *endo*-H), 1.81 (1H, br d_{AB}, J = 18 Hz, C(3) *exo*-H); *m/e* (relative intensity): 167 (M^+, 95.0), 152 (3.2), 139 (47.8), 110 (100.0). Exact mass calcd. for $C_{11}H_{17}DO$: 167.1420; found: 167.1425.

2-(Dideuteriomethylene)bornane (21)

Methylenation of (+)-camphor (**1**) with freshly distilled dideuteriomethylene bromide using method B described above provided a pale yellow liquid, which was purified by column chromatography (70–230 mesh SiO_2), eluting with petroleum ether to provide 2-(dideuteriomethylene)bornane (**21**) as a white solid, mp 69–71°C; ν_{max} ($CHCl_3$): 2300, 1610, 700 cm^{-1}; δ (400 MHz, $CDCl_3$): 0.76 (3H, s, C(8)H_3), 0.89 (3H, s, C(10)H_3), 0.92 (3H, s, C(9)H_3), 1.15–1.30 (2H, m, C(5) and C(6) *endo*-H), 1.64 (1H, td, J = 13, 5 Hz, C(6) *exo*-H), 1.74 (1H, m, C(4)H), 1.78 (1H, m, C(5) *exo*-H), 1.92 (1H, d, J = 16 Hz, C(3) *endo*-H), 2.40 (1H, dt, J = 16, 4 Hz, C(3) *exo*-H); *m/e* (relative intensity): 152 (M^+, 14.6), 137 (25.8), 41 (100.0). Exact mass calcd. for $C_{11}H_{16}D_2$: 152.1532; found: 152.1541.

Rearrangement of 2-(deuteriomethylene)bornane (21)

Concentrated sulfuric acid (1 drop) was added to a solution of 2-(dideuteriomethylene)bornane (**21**) (39.2 mg, 0.257 mmol) in CH_3CO_2D (1 mL) and the solution was stirred for 4 h at 25°C. The mixture was diluted with ether and water and the aqueous layer was extracted with ether. The combined organics were washed with water, saturated $NaHCO_3$, and brine, and dried over anhydrous magnesium sulfate. Evaporation of the solvent produced a colourless oil that was purified by column chromatography (230–400 mesh SiO_2). Elution with petroleum ether provided 4-(trideuteriomethyl)isobornyl acetate (**25**) as a colourless mobile liquid; ν_{max} (neat): 2220, 1740, 1220, 1020 cm^{-1}; δ (400 MHz, $CDCl_3$): 0.69 (3H, s, C(9)H_3), 0.83 (3H, s, C(8)H_3), 0.86 (3H, s, C(10)H_3), 1.11–1.20 (2H, m, C(5) and C(6)

endo-H), 1.37–1.55 (3H, m, C(5) and C(6) *exo*-H, and C(3)-*exo*-H), 1.83 (1H, dd, J = 14, 8.5 Hz, C(3)-*endo*-H), 2.02 (3H, s, CH_3CO), 4.66 (1H, dd, J = 8.5, 3.5 Hz, CHOAc). The ^{1}H nmr spectrum also exhibits small peaks at 0.67 and 0.85 ppm due respectively to deuterium exchange into the C(9) and C(10) methyl groups. Mass spectrum, m/e (relative intensity):[4] 213 (M^+, 0.8), 170 (2.4), 153 (29.2), 43 (100.0). Exact mass calcd. for $C_{13}H_{19}D_3O$: 213.1808; found: 213.1777.

*4-(Trideuteriomethyl)camphor (**26**)*

Sequential reduction and oxidation of 4-(trideuteriomethyl)isobornyl acetate (**25**) by the procedures described above provided 4-(trideuteriomethyl)camphor (**26**) as white crystals, mp 150–151°C; ν_{max} ($CHCl_3$): 2210, 1735 cm^{-1}; δ ($CDCl_3$).[5] 0.71 (3H, s, C(8)H_3), 0.83 (3H, s, C(9)H_3), 0.92 (3H, s, C(10)H_3), 1.35–1.45 (2H, m, C(5) and C(6) *endo*-H), 1.58–1.77 (2H, m, C(5) and C(6) *exo*-H), 1.88 (1H, d_{AB}, J = 18 Hz, C(3) *endo*-H), 2.08 (1H, dd_{AB}, J = 18, 3 Hz, C(3) *exo*-H); m/e (relative intensity):[6] 169 (M^+, 20.8), 141 (9.2), 85 (100.0). Exact mass calcd. for $C_{11}H_{15}D_3O$: 169.1546; found: 169.1543.

endo-*3-Bromo-4-methylcamphor (**27**)*

A solution of (−)-4-methylcamphor (**7**) (6.37 g, 0.038 mol) in glacial acetic acid (28 mL) was warmed to 80°C, and bromine (2.29 mL, 6.87 g, 76.6 mmol) in glacial acetic acid (2.29 mL) was added dropwise. The mixture was stirred at 80°C for 24 h, then cooled, and poured into ice-water. The resulting solid was filtered and washed with water to yield *endo*-3-bromo-4-methylcamphor (**27**) as a white crystalline solid (9.30 g, 99%), mp 119.5–120.5°C (sealed tube); ν_{max} ($CHCl_3$): 1700 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.81 (3H, s, C(8)H_3), 0.98 (3H, s, C(9)H_3), 1.00 (3H, s, C(10)H_3), 1.06 (3H, s, C(11)H_3), 1.40 (1H, m, C(6) *endo* proton), 1.55–1.67 (2H, m, C(5) *endo* and C(6) *exo* protons), 2.07 (1H, m, C(5) *exo* proton), 4.31 (1H, d, J = 1.5 Hz, C(3) proton); m/e (relative intensity): 246/244 (M^+, 5.0/4.9), 165 (48.1), 137 (52.1), 123 (45.0), 109 (75.7), 83 (100.0). Exact mass calcd. for $C_{11}H_{17}OBr$: 246.0442/244.0462; found: 246.0439/244.0467. Anal. calcd. for $C_{11}H_{17}OBr$: C 53.89, H 6.99, Br 32.59; found: C 53.81, H 6.86, Br 32.80.

endo-*3,9-Dibromo-4-(bromomethyl)camphor (**28**)*

endo-3-Bromo-4-methylcamphor (**27**) (7.36 g, 0.030 mol) and bromine (3.47 mL, 0.069 mol) were added to a single-neck flask. Chlorosulfonic acid (5.48 mL, 0.082 mol) was added slowly to the reaction mixture. After being stirred at room temperature for 19 h, the reaction mixture was added to ice-cold bisulfite solution and extracted with ether. The ether extracts were combined, washed with saturated sodium bicarbonate solution and water, and dried over anhydrous magnesium sulfate. Evaporation of the solvent yielded a yellow solid, which was triturated with ice-cold ether to provide *endo*-3,9-dibromo-4-(bromomethyl)camphor (**28**) as a white crystalline solid (6.20 g, 51%), mp 142.5–143.5°C (sealed tube); ν_{max} ($CHCl_3$): 1750 cm^{-1}; δ ($CDCl_3$, 400 MHz): 1.07 (3H, s, C(8)H_3), 1.27 (3H, s, C(10)H_3), 1.53 (1H, ddd, J = 14, 9, and 4 Hz, C(6) *endo* proton), 1.72 (1H, td, J = 14 and 4 Hz, C(5) *endo* proton), 1.85 (1H, tdd, J = 14, 4, and 2.5 Hz, C(5) *exo* proton), 2.22 (1H, ddd, J = 14, 9, and 4 Hz, C(6) *exo* proton), 3.45 and 3.74 (2H, AB quartet, J = 11 Hz, C(9) methylene), 3.52 and 4.05 (2H, AB quartet, J = 11.5 Hz C(11) methylene), 4.92 (1H, d, J = 2.5 Hz, C(3) proton); m/e (relative intensity): 406/404/402/400 (M^+, 0.4/1.8/2.0/0.7), 325/323/321 (17.1/41.7/18.8), 245/243 (14.0/18.8), 201/199 (28.7/22.2), 163 (16.9), 121 (36.3), 107 (50.8), 105 (37.8), 93 (66.7), 91 (69.2). Exact mass calcd. for $C_{11}H_{15}OBr_3$: 405.8612/403.8632/401.8652/399.8672; found: 405.8605/403.8637/401.8667/399.8675. Anal. calcd. for $C_{11}H_{15}OBr_3$: C 32.79, H 3.75, Br 59.49; found: C 33.05, H 3.78, Br 59.22. The structure of this compound was confirmed by X-ray analysis.[2]

*9-Bromo-4-(bromomethyl)camphor (**29**)*

A solution of 3,9-dibromo-4-(bromomethyl)camphor (580 mg, 1.44 mmol) in 1:1 Et_2O/AcOH was cooled to 0°C. While stirring vigorously, zinc (294 mg, 4.50 mmol) was added in portions over 30 min. Stirring was continued for a further 15 min before Celite (500 mg) was added and the mixture was filtered. The solution was diluted with ether and washed with water, saturated sodium bicarbonate, and brine, and dried over magnesium sulfate. Evaporation of the solvents yielded a pale yellow slushy solid, which was recrystallized from methanol to afford 9-bromo-4-(bromomethyl)camphor as white crystals; yield: 283 mg, 61%; mp 53–55°C.

The mother liquor was concentrated and the residue purified by column chromatography (230–400 mesh SiO_2), eluting with 19:1 petroleum ether/ether to provide a further 146 mg; total yield: 429 mg, 92%; ν_{max} ($CHCl_3$): 3025, 2980, 1745 cm^{-1}; δ (400 MHz, $CDCl_3$): 0.99, 1.03 (3H each, 2 s, C(8)H_3 and C(10)H_3), 1.50–1.59 and 1.70–1.79 (1H each, 2 m, C(5) and C(6) *endo*-H), 1.87–2.03 (2H, m, C(5) and C(6) *exo*-H), 2.32 (1H, d_{AB}, J = 18 Hz, C(3) *endo*-H), 2.35 (1H, dd_{AB}, J = 18, 3 Hz, C(3) *exo*-H), 3.36 and 3.66, 3.62 and 4.02 (2H each, $2q_{AB}$, J = 11, 10 Hz, C(9)H_2Br and C(11)H_2Br); m/e (relative intensity): 326/324/322 (M^+, 11.4/23.9/12.7), 245/243 (56.2/56.2), 217/215 (35.5/35.2), 201/199 (83.9/76.6), 163 (50.3), 135 (85.8), 121 (77.8), 107 (69.6), 93 (90.0), 81 (97.4), 41 (100.0). Exact mass calcd. for $C_{11}H_{16}OBr_2$: 325.9527/323.9547/321.9567; found: 325.9532/323.9543/321.9585. Anal. calcd. for $C_{11}H_{16}Br_2O$: C 40.77, H 4.98, Br 49.31; found: C 40.99, H 5.04, Br 49.09.

*9-Deuterio-4-(deuteriomethyl)camphor (**30**)*

9-Bromo-4-(bromomethyl)camphor (**29**) (384 mg, 1.25 mmol) was dissolved in dry benzene (7 mL) and AIBN (cat.) and tributyltin deuteride (1.0 mL, 1.1 g, 3.7 mmol) were added. The solution was refluxed for 18 h. The solvent was evaporated to provide a yellow oil, which was purified by column chromatography (70–230 mesh SiO_2), eluting with petroleum ether and increasing polarity to 9:1 petroleum ether/ether to afford a mixture of 9-deuterio-4-(deuteriomethyl)camphor (**30**) and tributyltin bromide. Further purification by sublimation provided pure 9-deuterio-4-(deuteriomethyl)camphor (**30**) as a white crystalline solid; yield: 121 mg, 58%; mp 149–150°C; ν_{max} ($CHCl_3$): 2200, 1735 cm^{-1}; δ ($CDCl_3$): 0.71 (3H, s, C(8)H_3), 0.82 (2H, 1:1:1 t, J = 2 Hz, C(9)H_2D), 0.92 (3H, s, C(10)H_3), 1.03 (2H, 1:1:1 t, J = 2 Hz, C(11)H_2D), 1.35–1.43 (2H, m, C(5) and C(6) *endo*-H), 1.57–1.77 (2H, m, C(5) and C(6) *exo*-H), 1.88 (1H, d_{AB}, J = 18 Hz, C(3) *endo*-H), 2.08 (1H, dd_{AB}, J = 18, 3.5 Hz, C(3) *exo*-H); δ (C_6D_6): 0.48 (3H, s, C(8)H_3), 0.495 (2H, br s, C(9) H_2D), 0.69 (2H, br s, C(11) H_2D), 0.92 (3H, s, C(10) H_3), 1.03 (1H, br t, J = 10 Hz, C(5) *endo*-H), 1.15–1.40 (3H, m, C(6) *endo*-H, C(5) and C(6) *exo*-H), 1.62 (1H, d_{AB}, J = 18 Hz, C(3) *endo*-H), 1.86 (1H, dd_{AB}, J = 18, 3 Hz, C(3) *exo*-H); m/e (relative intensity): 168 (M^+, 62.0), 140 (23.9), 84 (100.0). Exact mass calcd. for $C_{11}H_{16}D_2O$: 168.1483; found: 168.1483.

[4]The masses listed are only those for the trideuterio compound. The low resolution ms also exhibits peaks at m/e (%) = 216 (0.5), 215 (0.8), 214 (0.5), and 212 (0.1), presumably due to the picking up of up to three additional deuterons or, in the latter case, a proton during the rearrangement. The measured masses support these assignments.

[5]The signals quoted are only those for 4-(trideuteriomethyl)camphor. The ^{1}H nmr also exhibits a broad shoulder at 0.82 ppm, a 1:1:1 triplet at 0.90 ppm, and a multiplet at 1.01 ppm, corresponding to C(9)H_2D, C(10)H_2D, and C(11)HD_2 respectively.

[6]The masses quoted are only those for the trideuterated compound. The low resolution ms also exhibits peaks at m/e (%) = 172 (28.2), 171 (33.6), 170 (30.6), and 168 (8.7), corresponding to the uptake of up to three more deuterons or, in the latter case, a proton during the rearrangement. The exact masses measured for these peaks support this assignment.

The reactions of *p*-nitrophenyl diphenylphosphinate (**1**) with lithium, sodium, potassium, and benzyltrimethylammonium phenoxides (BTMAOPh) have been studied by spectrophotometric techniques in anhydrous ethanol at 25°C. The reactivity (k_{obs}) of the alkali metal phenoxides increases in the order BTMAOPh < KOPh < NaOPh < LiOPh. The rate of reaction of **1** with LiOPh is enhanced when lithium salts (LiSCN, $LiNO_3$, $LiClO_4$, LiOAc) are added to the reaction media. The addition of the alkali metal complexing agents dicyclohexyl-18-crown-6 ether or [2.2.2]cryptand for Na^+, and [2.1.1]cryptand for Li^+, to each of the alkali metal phenoxide reactions resulted in a decrease in rate, indicating catalysis by the alkali metal ions. The kinetic data are analyzed to obtain specific rate coefficients of reactions of phenoxide and ethoxide as the dissociated ions and as alkali metal – phenoxide ion pairs. Reactivities follow the order $k_{PhOM} > k_{PhO^-}$; $k_{EtOM} > k_{EtO^-}$; $k_{EtO^-} > k_{PhO^-}$; $k_{EtOM} > k_{PhOM}$. A mechanism is proposed in which the ion-paired metal phenoxide is more reactive towards the substrate than is the dissociated phenoxide. Analysis of the data in terms of initial state and transition state interactions with metal ions indicates that the increased reactivity of the ion-paired species results from greater stabilization of the negatively charged transition state relative to stabilization of the ion-paired nucleophile.

Key words: nucleophilic displacement at phosphorus by phenoxide, alkali-metal-ion catalysis.

EDWARD J. DUNN, ROBERT Y. MOIR, ERWIN BUNCEL, J. GARFIELD PURDON et ROBERT A. B. BANNARD. Can. J. Chem. **68**, 1837 (1990).

Faisant appel à des techniques spectrophotométriques et opérant dans de l'éthanol anhydre, à 25°C, on a étudié les réactions du diphénylphosphinate de *p*-nitrophényle (**1**) avec les phénolates de lithium, de sodium, de potassium et de benzyltriméthylammonium (BTMAOPh). La réactivite (k_{obs}) des phénolates des métaux alcalins augmente dans l'ordre : BTMAOPh < KOPh < NaOPh < LiOPh. Lorsqu'on ajoute des sels de lithium (LiSCN, $LiNO_3$, $LiClO_4$, LiOAc) au milieu réactionnel, il y a une augmentation de la vitesse de réaction du composé **1** avec le LiOPh. Lorsqu'on ajoute des agents complexants des métaux alcalins, comme l'éther dicyclohexyl-18-couronne-6 ou le cryptand[2.2.2] pour le Na^+ et le cryptand[2.1.1] pour le Li^+, à chacune des réactions des phénolates de métaux alcalins, les vitesses de réaction sont abaissées; ces résultats indiquent qu'il y a catalyse par les ions des métaux alcalins. On a analysé les données cinétiques pour obtenir les coefficients spécifiques des vitesses de réactions du phénolate et de l'éthylate comme ions dissociés ainsi que sous la forme de paires l'ions phénolate – métal alcalin. Les réactivités sont dans l'ordre suivant : $k_{PhOM} > k_{PhO^-}$; $k_{EtOM} > k_{EtO^-}$; $k_{EtO^-} > k_{PhO^-}$; $k_{EtOM} > k_{PhOM}$. On propose un mécanisme selon lequel, par rapport à chaque substrat, chaque phénolate existant sous la forme d'une paire d'ions est plus réactif que le phénolate qui n'est pas dissocié. Une analyse des données en fonction de l'état initial et des interactions avec les ions métalliques dans l'état de transition indique que la réactivité accrue des espèces existant sous la forme de paires d'ions provient d'une plus grande stabilisation de l'état de transition portant une charge négative par rapport à la stabilisation du nucléophile existant sous la forme de paire d'ions.

Mots clés : déplacement nucléophile à phosphore par phenoxide, catalyse par les ions des métaux alcalins.

[Traduit par la revue]

Introduction

A number of cases demonstrating catalysis of nucleophilic displacement reactions by divalent metal ions have been reported for substrates containing phosphoryl centers (1–4). In our own studies we have shown previously (5) that the reaction of *p*-nitrophenyl diphenylphosphinate (**1**) with ethoxide ion in ethanol at 25°C is catalysed by alkali metal ions (Li^+, Na^+, K^+). Catalysis by the alkali metal ions in this system is believed to result from lowering of the free energy of activation for formation of a negatively charged transition state, which is stabilized by association with the alkali metal cation. It was not clear, however, if this stabilization occurred by interaction of dissociated ions with the substrate in a pre-equilibrium step, or whether alkali metal ion pairs were involved. the ion-paired species was chosen as the more probable explanation of these observations.

To gain more information regarding metal ion catalysis in this and related systems, it was desirable to extend the study to other nucleophiles and substrates. The results of a study of the reaction of **1** with lithium, sodium, potassium, and benzyltrimethylammonium phenoxides in ethanol are presented herein.

Results

The kinetic data for the reaction of *p*-nitrophenyl diphenylphosphinate (**1**) with lithium phenoxide (LiOPh), sodium phenoxide (NaOPh), potassium phenoxide (KOPh), and benzyltrimethylammonium phenoxide (BTMAOPh) in ethanol at 25°C are given in Table 1. It can be seen from the plots of k_{obs} vs. $[MOPh]_0$ (Fig. 1) that the apparent reactivity of these nucleophiles towards **1** increases in the order BTMAOPh < KOPh < NaOPh < LiOPh. These results imply that the reaction of **1** with PhO^- in EtOH is catalysed by the alkali metal ions.

In our study of metal ion catalysis in the reaction of *p*-nitrophenyl diphenylphosphinate with ethoxide ion in ethanol at 25°C (5), the plots of k_{obs} vs. [EtO^-] displayed an *upward* curvature, which was attributed to differences in reactivities of the free ethoxide and the metal–ethoxide ion pair. However, the observed rate constants for the reaction of **1** with KOPh, NaOPh, LiOPh, and BTMAOPh in EtOH give rise to plots with a *downward* curvature (Fig. 1), that is, opposite to the behaviour observed with the ethoxide ion.

Catalysis by metal ions in the present system is also evident in that addition of Li^+ ions, in the form of an unreactive salt, to the reaction of **1** with LiOPh causes an initial increase in rate (Table 2). However, after the initial rapid increase the plots level off at a value of ca. 1.0 M^{-1} s^{-1} (Fig. 2).

Further evidence of catalysis by metal ions is observed through addition of macrocyclic complexing agents to the reaction system (Table 3). Figure 3 demonstrates that addition of

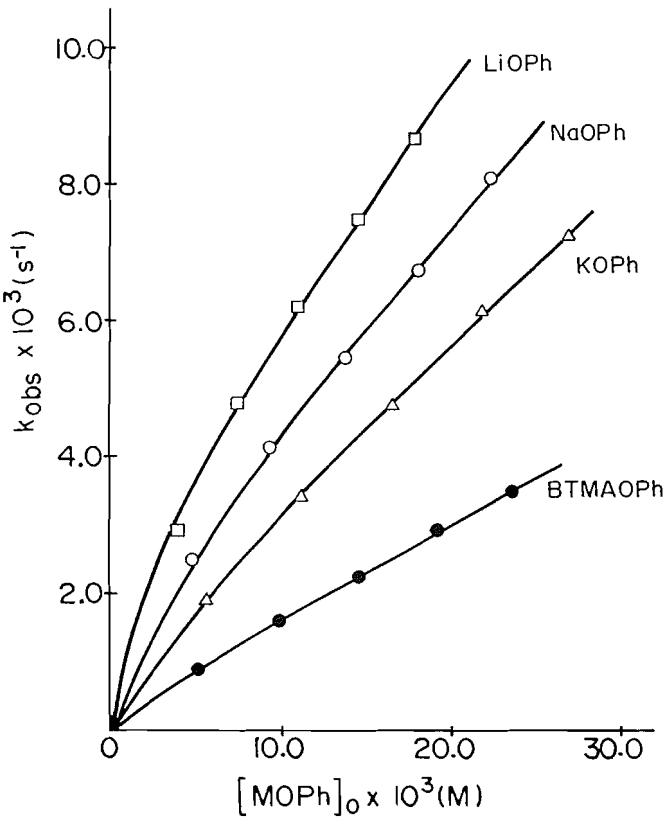

FIG. 1. Reaction of *p*-nitrophenyl diphenylphosphinate (**1**) with LiOPh (□), NaOPh (○), KOPh (△), and BTMAOPh (●) in EtOH at 25°C.

complexing agent causes a rapid initial decrease in reaction rate to a value of ca. 0.19 M^{-1} s^{-1}. The plots, however, do not level off at a minimum value, as was observed in the reaction of **1** with MOEt (5). Instead, after the initial decrease, the rates began to increase slowly as the concentration of complexing agent was increased. The reason for this rate increase is not clear at present. It can be concluded, however, that the initial decrease in the rate with added complexing agent is consistent with catalysis of nucleophilic displacement by the metal ions.

Discussion

Metal ion catalysis

It can be seen from Fig. 1 that the alkali metal phenoxides and benzyltrimethylammonium phenoxide (BTMAOPh) all have different reactivities towards **1**. The observation that the observed rate constants are greater for the alkali metal phenoxides, relative to BTMAOPh, implies involvement of the metal ion in the nucleophilic displacement. The decrease in rate constants with added complexing agent, and their increase on addition of metal ions, also supports a mechanism in which the nucleophilic displacement reaction of **1** by phenoxide ion is catalysed by the alkali metal ions. Possible mechanisms to account for catalysis by alkali metal ions have been described in some detail previously (5) and will be reviewed only briefly here.

First, one can consider the basic reaction of the substrate with phenoxide as proceeding by rate-determining attack of the free nucleophile at the phosphorus center of **1** to form a pentacoordinate intermediate, **2**, followed by expulsion of the leaving group in a subsequent fast step, eq. [1].

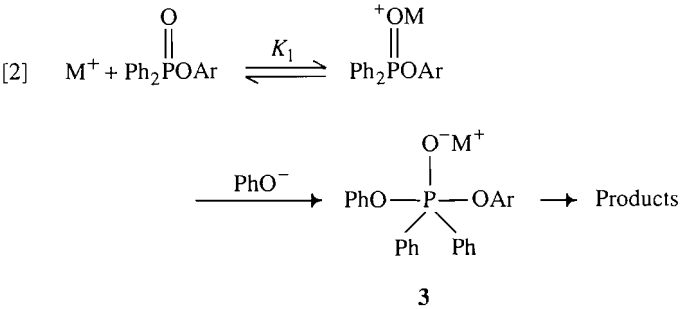
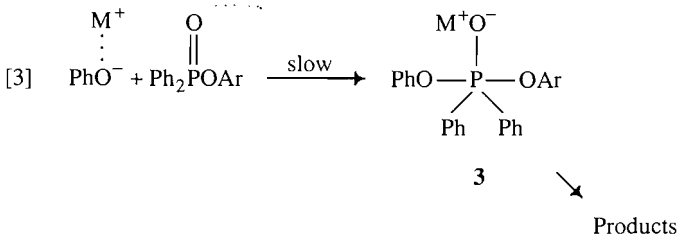
Formation of a pentacoordinate intermediate has been proposed in the alkaline hydrolysis reaction of aryl diphenylphosphinothioates, based on the correlation of rate constants with Hammett σ values rather than σ^- values, and on the magnitude of the Hammett ρ value (6). We have studied the reaction of substituted aryl diphenylphosphinates with ethoxide, phenoxide, and other nucleophiles and, based on the observed Hammett ρ values and correlation of rates with σ^0 constants, similarly propose the formation of a pentacoordinate intermediate. The results of these experiments will be presented subsequently in this series.

Explanations for rate accelerations by metal ions include the situation in which the metal ion coordinates to the substrate, likely at the phosphoryl oxygen, making the phosphorus atom more electrophilic, eq. [2]. This gives rise to an intermediate (**3**), which is stabilized by association with the metal ion. Preassociation of M^+ with the oxygen of the aryloxy leaving group is considered to be less likely since cleavage of the P—OAr bond does not occur to a significant extent in the rate-determining step.



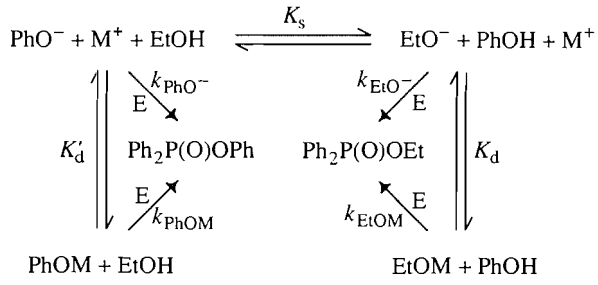
Alternatively, the metal ion may be associated with the base as an ion pair, which would react with the substrate giving rise to intermediate **3**. The rate law for the mechanisms according to eqs. [2] and [3] would be identical.



Assuming that ion pairs and free ions are both capable of reacting with the substrate gives rise to a kinetically complex system. Thus, there is the possibility of four species capable of reacting with the substrate, namely free and ion-paired phenoxide, and free and ion-paired ethoxide, generated through solvolysis of phenoxide. The overall pseudo-first-order rate equation, which would describe reaction by all species, can be given as eq. [4].

$$[4]\quad k_{obs} = k_{PhO^-}[PhO^-] + k_{PhOM}[PhOM] + k_{EtO^-}[EtO^-] + k_{EtOM}[EtOM]$$

These reactive species are related by a number of equilibria as shown in Scheme 1, where E refers to the ester **1**. In this scheme there are four rate constants and three equilibrium constants that must be reconciled. These are k_{EtO^-}, the rate constant for the reaction of free ethoxide; k_{EtOM}, the rate constant for the reaction of the ethoxide ion pair; k_{PhO^-}, the rate constant of the free phenoxide; k_{PhOM}, the rate constant of the phenoxide ion pair; K_d, the dissociation constant of the ethoxide ion pair; K'_d, the dissociation constant of the phenoxide ion pair; and K_s, the solvolysis constant of phenoxide in ethanol.



SCHEME 1

The rate constants for the reactions of free ethoxide (k_{EtO^-}) and the ion pair (k_{EtOM}) with **1** have been determined previously (5), while the value of K_d is known from conductivity studies (7). K_s and k_{PhO^-} can be determined from the reaction of **1** with BTMAOPh in EtOH, by dissecting the rate data into contributions by EtO^- and PhO^- as described below.

Phenoxide ion reactivity

In the reaction of **1** with the benzyltrimethylammonium salt of phenoxide, it is assumed that the large benzyltrimethylammonium ion has no effect on the reaction, that is, the ammonium ion acts neither as catalyst nor as rate inhibitor. In the absence of alkali metal ions to influence the reaction, a simple pseudo-first-order rate equation can be written:

$$[5]\quad k_{obs} = k_{EtO^-}[EtO^-]_{eq} + k_{PhO^-}[PhO^-]_{eq}$$

The equilibrium concentrations of phenoxide and ethoxide are related via K_s (eq. [6], which is a combination of the dissociation constant of PhOH in EtOH (eq. [7]) and the autoprotolysis constant of EtOH (eq. [8]), from which eq. [9] follows:

$$[6]\quad PhO^- + EtOH \overset{K_s}{\rightleftharpoons} PhOH + EtO^-$$

$$[7]\quad PhOH + EtOH \overset{K_{PhOH}}{\rightleftharpoons} PhO^- + EtOH_2^+$$

$$[8]\quad EtOH + EtOH \overset{K_{auto}}{\rightleftharpoons} EtO^- + EtOH_2^+$$

$$[9]\quad K_s = \frac{[EtO^-]_{eq}[PhOH]_{eq}}{[PhO^-]_{eq}} = \frac{K_{auto}}{K_{PhOH}}$$

A value for K_s (5.01×10^{-4} M) can be determined using the literature values of 15.8 for pK_{PhOH} (8, 9) and of 19.1 for pK_{auto} (9, 10). The equilibrium concentrations of phenoxide ($[PhO^-]_{eq}$) and ethoxide ($[EtO^-]_{eq}$) can then be calculated from eq. [10],

noting that $[PhOM]_0$ is the initial stoichiometric concentration of phenoxide and that the initial concentrations of phenoxide and phenol are equivalent ($[PhOM]_0 = [PhOH]_0$).

$$[10]\quad [EtO^-]_{eq} = -\{([PhOM]_0 + K_s) + (([PhOM]_0 + K_s)^2 + 4K_s[PhOM]_0)^{1/2}\}/2$$

$$[11]\quad [PhO^-]_{eq} = [PhOM]_0 - [EtO^-]_{eq}$$

The equilibrium concentration of EtO^- can be calculated according to eq. [10] and since k_{EtO^-} is known from the previous study ($k_{EtO^-} = 0.980\ M^{-1}\ s^{-1}$) (5), the ethoxide term of eq. [5] ($k_{EtO^-}[EtO^-]$) can be evaluated and subtracted from k_{obs} to give a modified pseudo-first-order rate constant k_ψ:

$$[12]\quad k_\psi = k_{obs} - k_{EtO^-}[EtO^-]_{eq} = k_{PhO^-}[PhO^-]_{eq}$$

The values of k_ψ and $[PhO^-]_{eq}$ for the reaction of **1** with BTMAOPh are presented in Table 4. The rate constant for the phenoxide ion ($k_{PhO^-} = 0.14\ M^{-1}\ s^{-1}$: $r = 0.9998$) was calculated from these data by linear regression analysis. The rate constant for the phenoxide ion was also determined from a non-linear differential least-squares (DLS) fitting of the experimental data to eq. [5].[3] This treatment yields a value for k_{PhO^-} of $0.13\ M^{-1}\ s^{-1}$. Two-parameter DLS fitting of the BTMAOPh data gave a value for k_{PhO^-} of $0.14\ M^{-1}\ s^{-1}$ and a value for K_s of 3.0×10^{-4} M, which is in good agreement with the value of K_s derived from the literature pK_a values. It follows that phenoxide ion is approximately an order of magnitude less reactive than ethoxide ion, since $k_{EtO^-} = 0.980\ M^{-1}\ s^{-1}$ (5).

[3]A description of the DLS treatment has been deposited as supplementary material. Copies may be purchased from the Depository of Unpublished Data, CISTI, National Research Council, Ottawa, Ont., Canada K1A 0S2.

Phenoxide ion-pair reactivity

Having determined the rate constant for the reaction of **1** with free phenoxide ion, two constants in Scheme 1, i.e., K'_d and k_{PhOM}, still require evaluation. These constants were determined for the reaction of **1** with LiOPh, NaOPh, and KOPh using differential least-squares (DLS) curve fitting of the experimental data to eq. [4]. The calculated plots are shown in Fig. 1 as solid lines, while the experimental points are shown as open symbols. It can be seen from Fig. 1 that the DLS fitting produces a good simulation of the experimental data with very little deviation from the curve. The values of k_{PhOM} and K'_d determined by this method are given in Table 5. It follows that the rate constants for the alkali metal phenoxides increase in the order $k_{PhOK} < k_{PhONa} < k_{PhOLi}$. These results are similar to those obtained for the reaction of **1** with alkali metal ethoxides (5) where rate constants increased in the order $k_{EtO^-} < k_{EtOK} < k_{EtONa} < k_{EtOLi}$ (Table 5).

The values of K'_d calculated using the DLS fitting (Table 5) similarly show that association of the metal ion with phenoxide ion decreases on going from LiOPh to KOPh. This again corresponds to the trend in dissociation constants (K_d) observed for the alkali metal ethoxides (Table 5), indicating that the smaller metal cations are associated more strongly with the anions than are the larger cations (5).

The accuracy of the values of k_{PhOM} and K'_d derived from the DLS fitting is difficult to assess since they are derived using constants from various sources. While the standard deviation of the experimental points from the calculated curves may be very small, the true error in the calculated constants will be a combination of all errors associated with all of the parameters used in their derivation. For this reason the equilibrium and rate constants determined by the DLS fitting for the reaction of **1** with PhOM are reported only to two significant figures.

The main conclusion of the DLS treatment is that the qualitative trends and the relative magnitudes of k_{PhOM} and K_d' values can be considered as valid and are in fact mutually supportive of the behaviour observed in our previous study (5). The derived values are also fully consistent with the observed experimental kinetic data, i.e., $k_{LiOPh} > k_{NaOPh} > k_{KOPh}$ (Fig. 1).

Dissection of nucleophilic reactivities of free ions and ion pairs

It is now possible to calculate the relative contribution of each nucleophile to the overall rate (Table 6) using the calculated values for the rate constants, k_{EtO^-}, k_{PhO^-}, k_{EtOM}, and k_{PhOM}, and the equilibrium solvolysis constant, K_s.

First, consider only the reaction of **1** with BTMAOPh. It can be shown that at the lowest concentration studied the contributions of EtO^- and PhO^- to the overall reaction are 41.6 and 58.4% respectively. However, at the highest concentration studied the contributions of EtO^- and PhO^- change to 13.6 and 86.4% respectively. This change, coupled with the fact that EtO^- is ca. 10 times more reactive than PhO^-, leads to the downward curvature observed in Fig. 1. In dilute solutions of base, a large fraction of phenoxide ion will be converted to ethoxide ion; as the initial base concentration is increased, the amount of ethoxide ion produced, as a fraction of the total amount of base present, becomes relatively small. Since $k_{EtO^-} > k_{PhO^-}$, the reaction of **1** with EtO^- will predominate at low initial phenoxide concentration ($[PhOM]_0$). As the PhO^- concentration ($[PhO^-]_{eq}$) increases relative to that of $[EtO^-]_{eq}$, the reaction of **1** with PhO^- will take precedence. In this region the rate will exhibit a decrease and become proportional to the initial BTMAOPh concentration, thus giving rise to the observed downward curvature.

Proceeding to the reactions of **1** with the alkali metal phenoxides, downward curvature is similarly observed in the plots of k_{obs} vs. LiOPh, NaOPh, and KOPh (Fig. 1). This is in contrast to the upward curvature observed in similar plots for the reaction of **1** with KOEt, NaOEt, and LiOEt (5). The upward curvature in these plots was explained as arising from an increase in ion pairing of the nucleophile at higher base concentrations, leading to an increase in rate due to the reaction of the more reactive ion-paired species.

Table 6 shows the percentage contribution of each nucleophile to the overall rate calculated using the derived rate and equilibrium constants for each nucleophile system. For the reaction **1** with LiOPh it is seen that the relative contributions of EtO^- and PhO^- remain relatively constant. In contrast, the contribution of EtOM decreases while that of PhOM increases over the range of base concentrations studied. This situation is similar to that of the benzyltrimethylammonium phenoxide system described above, where the change from nucleophilic attack of the more reactive EtOLi to the less reactive PhOLi results in downward curvature of the plots. This also holds true for the reaction of **1** with PhONa, though the change is more gradual and the curvature less pronounced. In the PhOK system the situation is a little different. The contributions of EtOK and PhO^- remain constant and dominant while the downward curvature arises from a decrease in EtO^- contribution and increase in PhOK contribution.

Transition state vs. ground state stabilization

The above analysis of the kinetic data has led to the conclusion that the alkali metal ion paired nucleophile is more reactive than the corresponding free nucleophile. This conclusion may seem contrary to the conventional wisdom that predicts a decrease in reactivity due to stabilization of the anion by pairing to the cation. This apparent contradiction can be resolved, however, if one considers that the metal ion catalysis can occur in this system as a result of either an interaction of M^+ with the ground state of the nucleophile, the substrate, or with the transition state of reaction. Since no appreciable

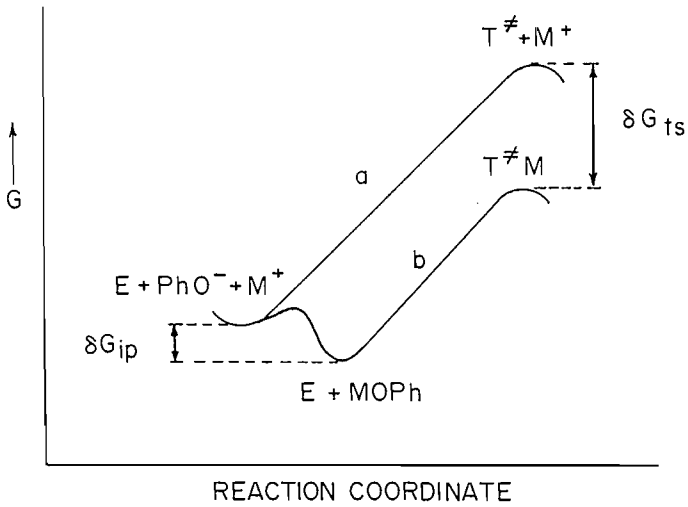

FIG. 4. Reaction coordinate diagram illustrating the uncatalysed reation of the phosphinate ester (E) with PhO^- (path a) and the alkali metal ion catalysed reaction of E with MOPh (path b).

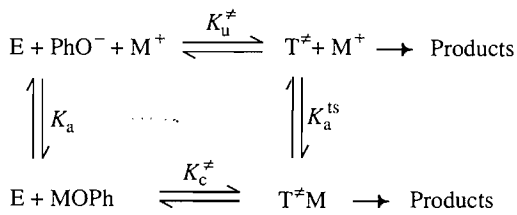
interaction between M^+ and the substrate has yet been observed, the interaction of M^+ with the ground state of the nucleophile and the transition state of the reaction remain to be considered as the main interactions.

These two interactions can be illustrated in Fig. 4. Path a illustrates the uncatalysed reaction of **1** (E) with PhO^-, whereas path b describes the reaction of E with the ion-paired phenoxide. Since the association constants ($K_a = 1/K_d'$) for the ion-paired phenoxides are greater than unity, the ion-paired nucleophile must lie at a lower free energy than the free nucleophile, the difference being shown as δG_{ip} in Fig. 4.

Similarly, it is expected that the ion pairing of the transition state ($T^{\neq}$) will result in a lowering of its free energy. This stabilization is shown as δG_{ts} in Fig. 4. Therefore, if the difference in free energy between $T^{\neq}M$ and $T^{\neq}$ (δG_{ts}) is greater than the stabilization of the ion-paired nucleophile (δG_{ip}), catalysis will be observed in the system.

Association constants for the interaction of M^+ with the transition state (Scheme 2) were determined as described by Kurz (11) and are given in Table 5.



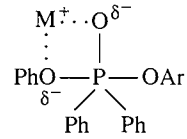
SCHEME 2

Here, E is the phosphinate ester, $K_u^{\neq}$ and $K_c^{\neq}$ are the equilibrium constants for the formation of the uncatalysed and catalysed transition states ($T^{\neq}$ and $T^{\neq}M$), while K_a and K_a^{ts} are the equilibrium association constants of M^+ with PhO^- and the transition state, respectively. From transition state theory eq. [13] can be derived.

$$[13] \quad K_a^{ts} = \frac{k_{PhOM}\, K_a}{k_{PhO^-}} = \frac{k_{EtO^-}}{k_{PhO^-}\, K_d'}$$

These equilibrium constants are given in Table 5.

The trend in K_a^{ts} values follows the same order for the reaction of **1** with EtOM and with PhOM in that the constants increase in the order $K^+ < Na^+ < Li^+$. It can also be seen from the data in Table 5 that the magnitude of K_a^{ts} is typically much greater than that of K_a. The larger values of K_a^{ts} relative to K_a find explanation in a chelation effect of the metal ion by nucleophile and substrate, as illustrated in structure **4**. The greater association of the metal ion with the transition state resulting from this chelation effect would account for its increased stability relative to the ground state, and hence the observed catalysis by the metal ion.



4

Although the kinetic data cannot distinguish between pre-association and the ion-pair mechanism, the latter is more attractive since the rate increases with increasing base concentration and hence with increasing ion-pair concentration. A mechanistic model for the transfer of the metal ion from the ion pair to the transition state, with the inclusion of solvent molecules, has been proposed for the reaction of **1** with the EtOM ion pair (5). A similar model can be proposed for the reaction of **1** with the PhOM ion pair.

It is also interesting to note that the magnitudes of the K_a^{ts} values for the phenoxide reactions are substantially lower than the corresponding values for the ethoxide reactions. This may be due to an increase in delocalization of negative charge in the transition state on the phenoxy moiety. The net overall charge on the phosphoryl oxygen for reaction with phenoxide may therefore be less than that in the reaction with the charge-localized ethoxide ion. Further studies concerning the association of M^+ with the transition state of nucleophilic displacement reactions of different carbon, phosphorus, and sulfur systems will be reported in subsequent papers in this series (12).

Experimental

The *p*-nitrophenyl diphenylphosphinate, ethanol, alkali metal ethoxides, and lithium salts used in this study were prepared as described previously (5). The preparation of solutions and the kinetic methods have also been described previously (5). No attempt was made to isolate and analyze the reaction products due to the complexity of the system, since the phenoxide product is capable of reacting further to give the ethoxide product. This reaction will be reported on subsequently. Also, no correction of the data was made for ionic strength effects. The equilibrium constants used in this study can therefore be considered as apparent equilibrium constants that change nominally over the relatively small range of concentrations used.

Preparation of LiOPh, NaOPh, and KOPh solutions

The alkali metal phenoxide solutions were prepared by addition of the corresponding alkali metal ethoxide solution in ethanol of known concentration to solid phenol in the inert atmosphere of a Dri-Lab (Vacuum Atmospheres Co.) glove box. Generally, 10 mL of a ca. 0.05 M ethoxide solution was added to 0.01 mol of PhOH. This produced a solution in which the initial concentrations of phenoxide and phenol were equivalent.

Preparation of BTMAOPh solutions

Benzyltrimethylammonium phenoxide (BTMAOPh, mp 114–116°C) was prepared by the following general method. Benzyltrimethylammonium hydroxide (57.7 g of a 40% methanolic solution) was added to sublimed phenol (13.0 g) dissolved in methanol. The mixture

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

was stirred for 3 h at room temperature, the bulk of the solvent removed on a rotary evaporator, and the residue dried overnight under high vacuum (< 0.001 Torr; 1 Torr = 133.3 Pa). The resulting solid was dissolved in acetone, filtered to remove impurities, and the product was precipitated with ether.

A solution containing equimolar proportions of BTMAOPh and phenol was obtained by first preparing a solution of PhOH in EtOH in the Dri-Lab. The BTMAOPh was then weighed into a volumetric flask, again in the Dri-Lab, and diluted to the mark with the phenol solution.

Metal ion catalysis in nucleophilic displacement reactions at carbon, phosphorus, and sulfur centers.[1] III. Catalysis vs. inhibition by metal ions in the reaction of *p*-nitrophenyl benzenesulfonate with ethoxide

MARKO J. PREGEL, EDWARD J. DUNN, AND ERWIN BUNCEL[2]

Received March 16, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

MARKO J. PREGEL, EDWARD J. DUNN, and ERWIN BUNCEL. Can. J. Chem. **68**, 1846 (1990).

The rate of the nucleophilic displacement reaction of *p*-nitrophenyl benzenesulfonate (**1**) with alkali metal ethoxides in ethanol at 25°C has been studied by spectrophotometric techniques. For lithium ethoxide, sodium ethoxide, potassium ethoxide, and cesium ethoxide, the observed rate constants increase in the order LiOEt < NaOEt < CsOEt < KOEt. The effect of added crown ether and cryptand complexing agents was also investigated. Addition of complexing agent to the reaction of KOEt results in the rate *decreasing* to a minimum value corresponding to the reaction of free ethoxide. Conversely, addition of complexing agent to the reaction of LiOEt results in the rate *increasing* to a maximum value that is identical to the minimum value seen in the reaction of KOEt in the presence of excess complexing agent. In complementary experiments, alkali metal ions were added in the form of unreactive salts. Addition of a K^+ salt to the reaction of KOEt increases the reaction rate, while addition of a Li^+ salt to the reaction of LiOEt decreases the rate. The involvement of metal ions in the reaction of **1** is proposed to occur via reactive alkali metal – ethoxide ion pairs. The kinetic data are analyzed in terms of an ion pairing treatment that allows the calculation of second-order rate constants for free ethoxide and metal–ethoxide ion pairs; the rate constants increase in the order LiOEt < EtO^- < NaOEt < CsOEt < KOEt. *Thus, Li^+ is an inhibitor of the reaction of ethoxide with **1**, while the other metals ions studied are all catalysts.* Equilibrium constants for the association of the various metal ions with the transition state are calculated using a thermodynamic cycle, and are compared to association constants in the ground state. Consistent with the observed kinetic results, Li^+ is found to stabilize the ground state more than the transition state, while Na^+, K^+, and Cs^+ all stabilize the transition state more than the ground state. The trend in the magnitude of the transition state stabilization is interpreted in terms of interactions of the transition state with bare or solvated metal ions. It is concluded that the transition state for the reaction of **1** with ethoxide forms solvent separated ion pairs with alkali metal ions. Analogous data were available for the reaction of *p*-nitrophenyl diphenylphosphinate (**2**) with ethoxides, where Li^+, Na^+, K^+, and Cs^+ all function as catalysts, and the results are analyzed as above. In contrast to the sulfonate system, it is proposed that the phosphinate transition state forms contact ion pairs with alkali metal ions. The difference is attributed to a greater localization of negative charge in the phosphinate transition state, leading to stronger interactions with metal ions, which overcome metal ion – solvent interactions.

Key words: nucleophilic substitution at sulfur, alkali metal ion catalysis.

MARKO J. PREGEL, EDWARD J. DUNN et ERWIN BUNCEL. Can. J. Chem. **68**, 1846 (1990).

Utilisant des techniques spectrophotométriques et opérant à 25°C, on a déterminé les vitesses de réactions nucléophiles du benzénesulfonate de *p*-nitrophényle avec les alcoolates des métaux alcalins, en solution dans l'éthanol. Pour les éthylates de lithium, de sodium, de potassium et de césium, les constantes de vitesse observées augmentent dans l'ordre LiOEt < NaOEt < CsOEt < KOEt. On a aussi examiné l'effet de l'addition d'éther couronne et de cryptand comme agents complexants. L'addition d'agents complexants à la réaction avec le KOEt provoque une diminution de la vitesse jusqu'à une valeur minimale correspondant à la réaction de l'alcoolate libre. Par ailleurs, l'addition d'un agent complexant à la réaction avec le LiOEt provoque une augmentation de la vitesse jusqu'à une valeur maximale qui est identique à la valeur minimale observée dans la réaction du KOEt en présence d'un excès d'agent complexant. Au cours d'expériences complémentaires, on a ajouté des ions métalliques sous la forme de sels non-réactifs. L'addition d'un sel de K^+ à la réaction du KOEt provoque une augmentation de la vitesse alors que l'addition d'un sel de Li^+ à la réaction de LiOEt provoque une diminution de la vitesse. On suggère que l'implication des ions métalliques dans la réaction du composé **1** se produit par le biais de paires d'ions formées de métal alcalin et d'éthylate. On a analysé les données cinétiques en fonction d'un traitement de couplage ionique qui permet de calculer les constantes de vitesse du deuxième ordre pour l'éthylate libre et pour les paires d'ions métal–éthylate; les constantes de vitesse augmentent dans l'ordre LiOEt < EtO^- < NaOEt < CsOEt < KOEt. *Le Li^+ est donc un inhibiteur de la réaction de l'éthylate avec **1** alors que les autres ions métalliques étudiés sont des catalyseurs.* Utilisant un cycle thermodynamique, on calcule les constantes d'équilibre pour l'association des divers ions métalliques avec l'état de transition et on les compare avec les constantes d'association de l'état fondamental. En accord avec les résultats cinétiques observés, on a trouvé que le Li^+ stabilise plus l'état fondamental que l'état de transition alors que le Na^+, le K^+ et le Cs^+ stabilisent tous plus l'état de transition que l'état fondamental. On interprète cette variation de l'amplitude de la stabilisation de l'état de transition en fonction d'interactions de l'état de transition avec des ions métalliques nus ou solvatés. On en conclut que l'état de transition pour la réaction du produit **1** avec l'éthylate forme des paires d'ions où les ions des métaux alcalins sont séparés par le solvant. Des données analogues sont disponibles pour la réaction du diphénylphosphinate de *p*-nitrophényle (**2**) avec les éthylates où Li^+, Na^+, K^+ et Cs^+ agissent tous comme catalyseurs et pour lesquels on a analysé les résultats comme précédemment. Par opposition avec ce qui a été observé avec le système sulfonate, on propose que l'état de transition du phosphinate forme des pairs d'ions de contact avec les ions des métaux alcalins. La différence est attribuée à une plus grande localisation de la charge négative dans l'état de transition du phosphinate qui provoquerait de plus grandes interactions avec les ions métalliques et permettrait de surmonter les interactions ion métallique–solvant.

Mots clés : substitution nucléophile à soufre, catalyse par les ions des métaux alcalins.

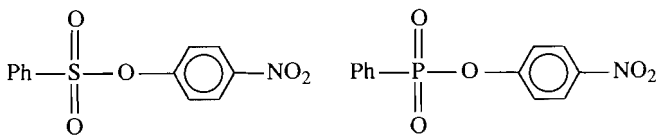
Introduction

Subtle differences in the physical and chemical properties of alkali metal ions, particularly Na^+ and K^+, have been exploited in living systems to discriminate between the various ions and to develop markedly different roles for each (2). Studies of the mechanism of discrimination between alkali metal ions in organic reactions would provide a bridge between observations on selectivity between alkali metal ions in biological and nonbiological systems and bring further evidence to bear on the underlying mechanism. However, this area has not been extensively investigated.

We have initiated systematic studies into the influence of alkali metal ions on nucleophilic substitution/addition reactions at carbon, phosphorus, and sulfur centers. The present study deals with the effects of alkali metal ions on nucleophilic substitution reactions of sulfonate esters, specifically, the reaction of alkali metal ethoxides with *p*-nitrophenyl benzenesulfonates (**1**). Alkali metal ions are expected to behave similarly, but surprisingly, we have found that in this case, *the ions Na^+, K^+, and Cs^+ cause a rate acceleration, while Li^+ causes a rate retardation.* A previous report outlined the observation of alkali metal ion catalysis in the reaction of ethoxide with *p*-nitrophenyl diphenylphosphinate (**2**), in which *Li^+, Na^+, K^+, and Cs^+ all acted as catalysts* (1*c*).



1 **2**

The alkaline hydrolysis reactions of benzenesulfonate and tosylate esters have been studied in a number of different media: water (3), aqueous ethanol (4), aqueous DMSO (4), aqueous acetonitrile (5), aqueous DME (5), aqueous dioxane (6), and aqueous acetone (6). However, no studies have used single solvent systems other than water. In particular, no studies of the reaction in anhydrous ethanol have been reported.

Ion pairing is important to the understanding of the behavior of alkali metal ethoxides in ethanol, as it is for the behaviour of other ionizable species in solvents of moderate polarity (7, 8). In ethanol, stabilization of the metal ion through electrostatic interactions with anions becomes significant and ion pairs are formed to an appreciable extent. Ion pairing of alkali metal ethoxides is well known and can have interesting effects on reactivity. For instance, downward plots of rate constant versus base concentration were obtained in the reaction of ethoxides in ethanol with benzyl chloride (9), methyl iodide (10), and phenyl acetate (11) and were attributed to ion pairing effects. Consequently, ion pairing will be considered in relation to the experimental results on the effects of alkali metal ions on the reaction of **1** with ethoxide ion in ethanol.

The kinetic data will be analyzed in terms of stabilization/destabilization of the ground state and transition state by metal ions. In the ground state, the metal ion is known to ion pair to the ethoxide ion and may also complex the ester. In the transition state, chelation of the sulfonyl oxygens is conceivable. Thus, ground state and transition state interactions will be the focus of our discussion (12).

Results

Reactions of alkali metal ethoxides

We have studied the reactions of *p*-nitrophenyl benzenesulfonate (**1**) with lithium ethoxide, sodium ethoxide, potassium ethoxide, and cesium ethoxide in anhydrous ethanol at 25°C. Reaction rates were measured spectrophotometrically by following the appearance of the absorption due to released *p*-nitrophenoxide ion. Plots of $\log(A_\infty - A_t)$ versus time were linear for more than three half-lives, the slopes yielding the pseudo-first-order rate constants, k_{obs}.

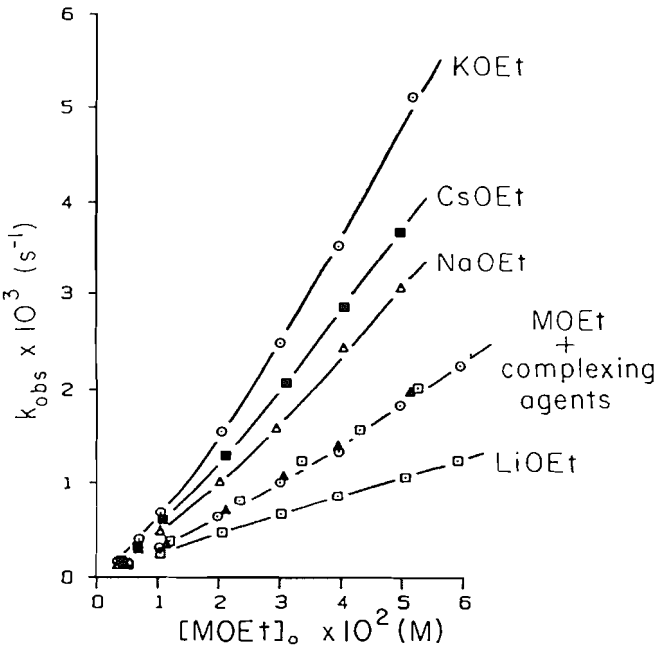


FIG. 1. Kinetic data for reaction of **1** with LiOEt, NaOEt, KOEt, CsOEt, and MOEt in the presence of excess complexing agents in EtOH at 25°C in the 10^{-2} M concentration range. The line labelled "MOEt + complexing agents" is made up of data for KOEt in the presence of excess 18C6 (⊙), KOEt with excess 2.2.2 (▲), and LiOEt with excess 2.1.1 (⊡).

The variation of k_{obs} with the concentration of alkali metal ethoxide is shown in Fig. 1 and Table 1. It is significant that the ethoxides appear to have different reactivities, which follow the order LiOEt < NaOEt < CsOEt < KOEt. Furthermore, the dependence of k_{obs} on $[MOEt]_0$, the total base concencentration, is nonlinear in some cases. Sharp upward curvature is seen for KOEt, while CsOEt and NaOEt display slight upward curvature, and the plot for LiOEt is apparently linear.

Effect of added complexing agents

Complexing agents such as crown ethers and cryptands eliminate interactions between metal ions and their counterions (13, 14). Consequently, coronate and cryptate formation has been a powerful tool in the determination of the role of metal ions in reaction mechanisms (13, 15).

The effects of added cryptands on the reactions of KOEt and LiOEt with **1** are shown in Fig. 2. As increasing amounts of 2.2.2 cryptand are added to the KOEt reaction, the rate *decreases* until one equivalent of complexing agent has been added, at which point further addition of cryptand has no effect. When 2.1.1 is added to the reaction of LiOEt with **1**, the rate constant *increases* until one equivalent of cryptand has been added, then levels off to a constant value. The plots for KOEt + 2.2.2 and LiOEt + 2.1.1 reach a common plateau. This is assumed to correspond to the reaction of free ethoxide since all metal ions should be complexed at these concentrations of added cryptands.

The dependence of k_{obs} on the ethoxide concentrations for the reaction of KOEt in the presence of excess 18C6 is shown in Fig. 1, which also shows that the kinetic behavior for KOEt in the presence of excess 18C6 is identical to the behavior of KOEt

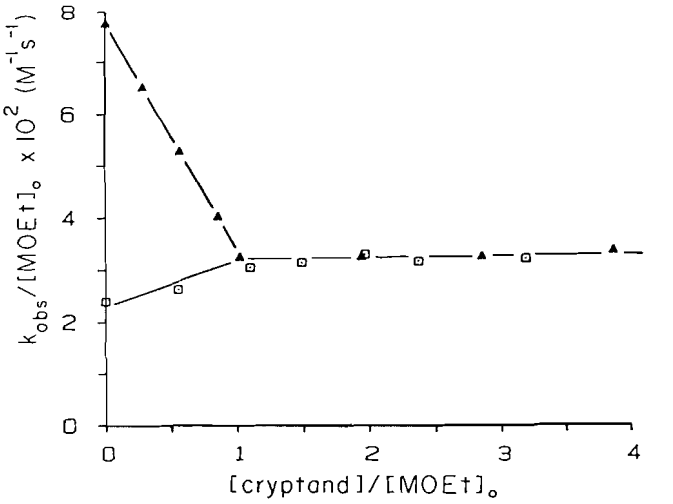

FIG. 2. Effects of added 2.2.2 on the reaction of **1** with KOEt (▲), and of added 2.1.1 on the reaction of **1** with LiOEt (⊡) in EtOH at 25°C at constant base concentration.

in the presence of excess 2.2.2, and LiOEt in the presence of excess 2.1.1, i.e., all of the data points fall on a common line. These data are also found in Table 1. Reactions in the presence of excess complexing agents are thought to represent the reaction of free ethoxide, so it is evident that EtO^- is more reactive than LiOEt, but less reactive than NaOEt. The order of reactivity is: LiOEt < EtO^- < NaOEt < CsOEt < KOEt.

Effect of added metal ions

Since removal of metal ions by complexation had a marked effect on the rate of reaction, it was also of interest to look at the effect of the addition of metal ions in the form of unreactive salts.

The effect of added potassium iodide on the reaction of potassium ethoxide with **1** is shown in Fig. 3. When the K^+ salt is added at a constant concentration of KOEt, the observed rate constant *increases* asymptotically to a maximum value.

The effect of added LiCl on the reaction of LiOEt with **1** is shown in Fig. 4. Addition of a Li^+ salt to a constant concentration of LiOEt causes a *decrease* in rate, with the rate constant approaching a minimum value asymptotically. Similarly, when $LiNO_3$ is added to the reaction of LiOEt with **1**, the rate decreases, approaching a limiting minimum value.

It should be noted that when increasing amounts of $NaBPh_4$ are added to the reaction of NaOEt with **1** at a constant concentration of NaOEt, the reaction rate increases, approaching a limiting maximum value. However, further additions cause a significant decrease in rate. The reasons for the rate decrease after the maximum are not fully understood at present.

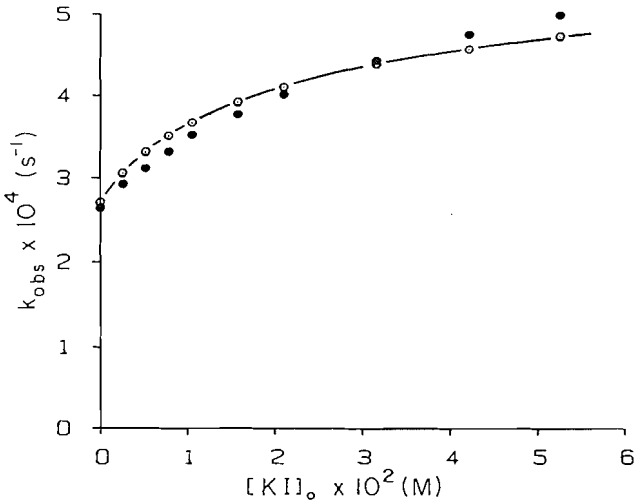

FIG. 3. Effect of added KI on the reaction of **1** with KOEt in EtOH at 25°C at constant base concentration and comparison of calculated (⊙) and observed (●) rate constants.

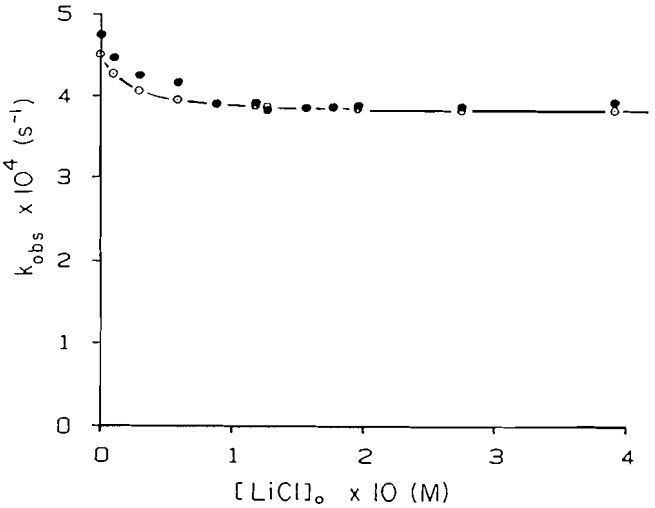

FIG. 4. Effect of added LICl on the reaction of **1** with LiOEt in EtOH at 25°C at constant base concentration and comparison of calculated (⊙) and observed (●) rate constants.

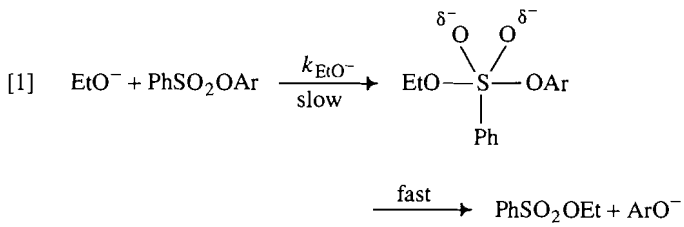
Kinetic data on the effect of added salts have been deposited as Supplementary Material.[3] The effects of added KI on the reaction of KOEt, of added $LiNO_3$ and LiCl on the reaction of LiOEt, and of added $NaBPh_4$ on the reaction of NaOEt are reported. The Supplementary Material also includes data on the effects of increasing amounts of added 18C6 and 2.2.2 on the reaction of KOEt and the effects of increasing amounts of added 2.1.1 on the reaction of LiOEt with **1**.

Discussion

The behaviour of the observed rate constants for the reaction of **1** with alkali metal ethoxides, and the effects of both added complexing agents and added metal salts, indicate significant and differing involvement of metal ions in the reaction mechanism. Certain metal ions, e.g., K^+, act as *catalysts*, i.e., the rate increases when they are added as inert salts and decreases when they are removed by complexing agents. One metal ion studied, Li^+, acts as an *inhibitor*, i.e., the rate decreases when it is added and increases when it is complexed.

In the following discussion, we consider the involvement of alkali metal ions via association with either the ester or the ethoxide ion. Interaction with the transition state will be considered subsequently. The reaction is depicted as an addition–elimination mechanism with nucleophilic attack as the rate-limiting step. This is consistent with the results of our investigations into the mechanism of these reactions, which include Hammett σ–ρ treatment of leaving group effects. These results will be reported subsequently in this series of articles. However, a concerted $S_N2(S)$ mechanism is also conceivable, and the discussion would apply equally to this mechanism.[4]

In the absence of metal ions, the mechanism in eq. [1] is assumed, i.e., the nucleophile attacks the substrate in a slow step, forming a pentacoordinate intermediate, and the leaving group is expelled in a subsequent fast step. The rate law in eq. [2] will apply (E denotes the substrate ester).



[2] rate = k_{EtO^-}[EtO$^-$][E]

Catalysis via alkali metal ethoxide ion pairs

Ion pairing is known to occur in solutions of alkali metal ethoxides in ethanol. Other associated species, such as dimers and aggregates, may also exist. Zavada and co-workers have measured the degree of association in lithium, sodium, and potasium ethoxide solutions by ebulliometry (17), and concluded that at relatively low concentrations (<0.1 M), the main species present were free ions and ion pairs. Because the present study involves lower total base concentrations, only free ions and ion pairs will be considered in the following discussion.

The association of alkali metal ions with ethoxide ion is governed by an ion pair association constant, K_a (eq. [3]). Since free ions and ion pairs are in equilibrium, two reaction pathways should be possible. The substrate can in principle react with either free ethoxide or an alkali metal – ethoxide ion pair, as shown in eq. [3]. Therefore, the overall rate law and the observed pseudo-first-order rate constant will both be sums of terms corresponding to reaction of free ions and ion pairs (eqs. [4], [5]).

[3]This material may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[4]In further studies, Hammett treatment of leaving group effects in the reaction of substituted aryl benzenesulfonates with ethoxide was found to yield a best correlation with σ^0 substituent constants.[5] These results imply that the transition state is characterized by well-advanced EtO—S bond formation, but negligible S—OAr bond breakage. However, this conclusion is at variance with that of Williams concerning the reaction of aryloxides with substituted 2-hydroxyphenylmethanesulfonic acid sultones (16), in which a concerted process and a symmetrical transition state were inferred. Efforts are currently underway to address the origin of this variance.

$$M^+ + EtO^- + PhSO_2OAr \xrightarrow{k_{EtO^-}} \text{products}$$

[3] K_a

$$MOEt + PhSO_2OAr \xrightarrow{k_{MOEt}} \text{products}$$

[4] $\text{rate} = k_{EtO^-}[EtO^-][E] + k_{MOEt}[MOEt][E]$

[5] $k_{obs} = k_{EtO^-}[EtO^-] + k_{MOEt}[MOEt]$

As the total base concentration increases, the ion pair equilibrum shifts, leading to a greater proportion of ion pairs to free ions. This is consistent with the curvature observed in plots of k_{obs} versus $[MOEt]_0$ (Fig. 1). If the ion pair model applies, upward curvature for NaOEt, KOEt, and CsOEt would imply that for these bases, *the ion pair is more reactive than the free anion*. The absence of observable curvature for LiOEt may be due to changes in activity coefficients with concentration. A small accelerating activity coefficient effect could counterbalance downward curvature due to ion pairing effects.

The ion pair model has been applied to the reactions of alkali metal ethoxides in ethanol with various substrates. Kinetic data for the attack of sodium ethoxide on benzyl chloride (9) and methyl iodide (10), and the attack of lithium, potassium, and cesium ethoxides on phenyl acetate (11) were all analyzed in terms of the reactivity of free ions and ion pairs *only*. In the case of the S_N2 reactions, ion pairs had measurable reactivity and were less reactive than free ions (9, 10), but in the reaction of phenyl acetate, ion pairs were found to be more reactive than free ions (11), as in the present case.

The idea that ion pairs could be more reactive than free ions seems to be contrary to chemical intuition. Association of a metal ion to an anionic nucleophile would result in neutralization of negative charge, producing a less basic nucleophile, which would be expected to have lesser reactivity. In fact, this is just what is observed in the case of typical S_N2 reactions, such as the examples given above and the exchange reaction of alkali metal iodides and methyl iodide in ethanol (18). In all three cases, ion pairing to the nucleophile caused a *decrease in rate* and plots of the observed rate constant versus concentration of nucleophile curved *downwards*. This behavior is expected when the metal ion interacts with the nucleophile predominantly in the ground state. In S_N2 reactions, this occurs because the charges in the transition state are delocalized over the nucleophile, reacting center, and leaving group, leading to weak interactions of the transition state with metal ions.

However, when the charge on the transition state is localized (or if effective chelation of the transition state by the metal ion is possible), the metal ion may be able to stabilize the transition state to a greater extent than the ground state, and if metal ion involvement occurs through ion pairing to the nucleophile, then ion pairs could be more reactive than free ions. This is seen in the reaction of alkali metal ethoxides with phenyl acetate in ethanol, where ion pairs are more reactive than free ethoxide (11). Reactive ion pairs have also been proposed to account for metal ion involvement in the reaction of KOEt and LiOEt with aryl diphenylphosphinates in anhydrous ethanol (1*c*), and in the reaction of barium and strontium methoxides with phenyl acetates in methanol (19). As well, attack of a metal–methoxide ion pair on a metal-complexed ester has been inferred in the reaction of lithium methoxide with phenyl acetate in methanol (20). Therefore, a number of literature precedents support the application of the ion pair model to the present work: ion pairs are known to be present and are known to be reactive in reactions of alkali metal alkoxides with esters.

Catalysis by preassociation of metal ion with substrate

It is also conceivable that metal ions may be involved in the reaction by complexing the substrate in a pre-equilibrium step (21, 22). Coordination to the sulfonate oxygen(s) of the substrate would polarize the S—O bond(s), making the sulfur center more electrophilic. The possibility of metal ion catalysis by preassociation is inferred from infrared spectroscopic studies of carboxylic acid esters, which have demonstrated the existence of Li^+ and Ba^{2+} complexes in methanol (23), as well as kinetic studies of the reactions of alkoxides with carboxylate esters which were interpreted in terms of a preassociation mechanism (19, 23). There are no reports, to our knowledge, of significant interactions between sulfonate esters and alkali metal ions in alcoholic solution.

Preassociation would result in the reaction pathway shown in eq. [6]. Since ethoxide can in principle react with both free and metal-complexed substrates as well as in the form of an ion pair, as illustrated below, the observed rate law would be eq. [7]. The observed pseudo-first-order rate constant is now given by eq. [8], which is identical in form to eq. [4] in the discussion of the ion pair model.

$$MOEt + PhSO_2OAr \xrightarrow{k_{MOEt}} \text{products}$$

K_a

[6] $$EtO^- + M^+ + PhSO_2OAr \xrightarrow{k_{EtO^-}} \text{products}$$

K_c

$$EtO^- + PhSO_2OAr \,.\, M^+ \xrightarrow{k_{M^+}} \text{products}$$

[7] $\text{rate} = k_{EtO^-}[EtO^-][E] + k_{M^+}[EtO^-][E.M^+] + k_{MOEt}[MOEt][E]$

[8] $k_{obs} = k_{EtO^-}[EtO^-] + (k_{MOEt} + (k_{M^+}K_c)/K_a)[MOEt]$

If ion pairs are assumed to be unreactive, eq. [8] simplifies to:

[9] $k_{obs} = k_{EtO^-}[EtO^-] + ((k_{M^+}K_c)/K_a)[MOEt]$

Comparing eq. [9] to eq. [5], one observes that the equations are identical except that the coefficient for [MOEt] is k_{MOEt} in eq. [5], while the coefficient is $(k_{M^+}K_c)/K_a$ in eq. [9]. The following section assumes the ion pair mechanism (eq. [5]) and calculates k_{MOEt}. However, if the preassociation mechanism is assumed instead, the product $k_{M^+}K_c$ can be calculated ($k_{M^+}K_c = k_{MOEt}K_a$) since K_a values are known. This results in $k_{M^+}K_c$ values of 3.82, LiOEt; 8.16, NaOEt; 12.3, KOEt; and 11.7, CsOEt. Since K_c is expected to be much less than unity (esters are poor ligands), k_{M^+} can be calculated using fixed values of K_c (1, 0.1, and 0.01 M^{-1}). The results are summarized in Table 2.

When these values are compared to the free ion rate constant ($k_{EtO^-} = 0.0287\ M^{-1}\ s^{-1}$), it is clear that for the preassociation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

TABLE 2. Values of k_{M^+} (M^{-1} s^{-1}) derived from fixed values of K_c (M^{-1}) if the preassociation mechanism of eq. [6] is assumed

	K_c	k_{M^+}		K_c	k_{M^+}
KOEt			LiOEt		
	1	12.3		1	3.82
	0.1	123		0.1	38.2
	0.01	1230		0.01	382
NaOEt			CsOEt		
	1	8.16		1	11.7
	0.1	81.6		0.1	117
	0.01	816		0.01	1170

model to apply, the complexed ester must be extraordinarily reactive when compared to the uncomplexed ester, which does not appear to be reasonable. This suggests that *p*-nitrophenyl benzenesulfonate does not react via the preassociation mechanism. Unfortunately, rate constants or association constants for sulfonate ester – metal ion complexes are not available for comparison to the values presented above and this conclusion must therefore be a tentative one at present.

In summary, metals ions may in principle be involved in reactions of **1** with ethoxide either via metal ethoxide ion pairs or by preassociation to the ester. Kinetic experiments cannot distinguish between the two possibilities since the two mechanisms give rate laws with identical forms. In this respect, the present study illustrates a drawback inherent in all kinetic studies, which can give information on the composition of a transition state, but not its structure.

Following previous treatments (1*c*, 9–11, 19), the results are discussed below in terms of the ion pair mechanism. This is done because ion pairs are known to be present, while there is no evidence for the existence of sulfonate ester – metal ion complexes. The ion pair model is the simplest mechanism that at the same time involves only those species known to be present and completely accounts for all of the kinetic data. Also, fitting of the kinetic data to the preassociation mechanism with reasonable values of K_c implied that the putative complexed ester must be extraordinarily reactive, and this is considered unlikely, as discussed above.

Reactivities of free ions and ion pairs

The discussion in this section is based on the assumption that free ions and ion pairs are the only reactive species in reactions of alkali metal ethoxides with *p*-nitrophenyl benzenesulfonate. When both free ions and ion pairs can react with the substrate, the observed rate is the sum of the rates of reaction of the free and associated ions (24), as shown by eq. [5]. The equilibrium concentrations of free and ion-paired ethoxide can be calculated if the association constant, K_a, is known since the total base concentration, $[MOEt]_0$, is known and $[M^+] = [EtO^-]$ at equilibrium. Once the concentration of free ethoxide has been calculated, the observed rate constants can be dissected into rate constants for the reaction of free ethoxide and alkali metal – ethoxide ion pairs using eq. [10].

$$[10] \quad \frac{k_{obs}}{[EtO^-]} = k_{EtO^-} + k_{MOEt}K_a[EtO^-]$$

It is apparent from eq. [10] that a plot of $k_{obs}/[EtO^-]$ vs. $[EtO^-]$ should be linear with slope $k_{MOEt}K_a$ and intercept k_{EtO^-}. Therefore, the second-order rate constants for the reaction of

TABLE 3. Second-order rate constants (at 25°C) for various ethoxide species from ion pairing treatment of kinetic data

Ethoxide	$k_2 \times 10^2$ ($M^{-1}s^{-1}$)
KOEt	13.7
CsOEt	9.7
NaOEt	8.0
LiOEt	1.80
EtO^-	2.87

free and ion-paired ethoxide can be calculated from the kinetic data. K_a values for alkali metal ethoxides in anhydrous ethanol at 25°C have been determined by Barthel *et al.* (25). They are as follows: LiOEt, 212 M^{-1}; NaOEt, 102 M^{-1}; KOEt, 90 M^{-1}; CsOEt, 121 M^{-1}. Plots of $k_{obs}/[EtO^-]$ vs. $[EtO^-]$ were linear for all ethoxide species, and yielded k_{MOEt} and k_{EtO^-} values. However, better values for k_{EtO^-} were obtained by taking the intercept of a plot of $k_{obs}/[KOEt]_0$ vs. $[KOEt]_0$ for the reaction of KOEt in the presence of excess 18C6. These results generally had smaller error limits than the values of k_{EtO^-} that were obtained from the intercept of plots of $k_{obs}/[EtO^-]$ vs. $[EtO^-]$. k_{EtO^-} was not obtained from the slope of plots of k_{obs} vs. $[KOEt]_0$ in the presence of excess 18C6 because of the slight curvature in these plots. Data for ion pairing treatment plots of $k_{obs}/[EtO^-]$ vs. $[EtO^-]$ for KOEt and LiOEt, as well as data used in the calculation of k_{EtO^-} are given in the Supplementary Material.[3]

The ion pair rate constants of the various species that resulted from the calculations described above are listed in Table 3. Consistent with the observed kinetic results, these follow the order LiOEt < EtO^- < NaOEt < CsOEt < KOEt. The values range from LiOEt, which is 1.6 times less reactive than free ethoxide, to KOEt, which is 4.8 times more reactive.

The curvature in plots of k_{obs} vs. $[KOEt]_0$ in the presence of excess 18C6 may have its origin in weak ion pairing between the complexed metal ions and ethoxide ion. According to Lehn, the crown-complexed cation is accessible from above and below the plane of the crown ether in alkali metal – crown ether complexes (15). Ion pairing of the complexed cation to an anion is considered to be possible. Similarly, alkali metal – cryptand complexes may interact with anions through a face of the cryptand, especially when the face is an 18-membered ring, as in 2.2.2 (15).

Abraham *et al.* have studied the conductivity of 2.2.2 complexes of alkali metal halides in methanol and obtained evidence for association of halide ions with complexed cations (eq. [11]) with ion pair association constants ranging from 20 to 68 for the various halide ions (26).

$$[11] \quad [M.2.2.2]^+ + X^- \rightleftarrows [M.2.2.2]^+X^-$$

There are numerous other examples of formation of crown- and cryptand-complexed ion pairs in nonpolar (27) and dipolar aprotic solvents (28), as well as in the solid state (29).

Given that weak ion pairing of ethoxide ion to the complexed metal ion may be occurring, the complexed ion pair thus formed could be slightly more reactive than free ethoxide due to interaction of the complexed metal ion with the substrate or transition state, leading to slight upward curvature in plots of observed rate constant versus base concentration. Alternatively, changes in activity coefficients with base concentration could be

TABLE 4. Ion pair association constants for alkali metal salts in ethanol at 25°C

Salt	K_a (M^{-1})	Reference
KI	68.4	30
$NaBPh_4$	31	31
$LiNO_3$	19.2	32
LiCl	27	33

exerting a slight rate-accelerating effect which could be responsible for the observed curvature.

Since the ion pair association constants for both alkali metal ethoxides and alkali metal salts are known, the equilibrium concentrations of free ions and ion pairs can be calculated as follows. Values of the association constants for the various salts are presented in Table 4, and the kinetic scheme for reactions in the presence of added metal salts is presented below:

[12] $$M^+ + X^- \underset{}{\overset{K_a(MX)}{\rightleftharpoons}} MX$$

$$MOEt + PhSO_2OAr + X^- \xrightarrow{k_{MOEt}} \text{products}$$

$$K_a(MOEt) \uparrow\downarrow$$

[13] $$EtO^- + M^+ + X^- + PhSO_2OAr \xrightarrow{k_{EtO^-}} \text{products}$$

$$K_a(MX) \uparrow\downarrow$$

$$EtO^- + MX + PhSO_2OAr$$

K_a(MOEt), K_a(MX), k_{EtO^-}, and k_{MOEt} are all known, so the rate constant can be predicted from the pseudo-first-order rate equation (eq. [5]) once the equilibrium concentrations of EtO^- and MOEt are calculated. These concentrations were obtained through combining expressions for K_a(MOEt), K_a(MX), charge balance, and mass balance. Details of the calculation and the equilibrum concentrations of free ions and ion pairs, as well as a comparison of calculated and observed rate constants are reported in the Supplementary Material.[3]

Thus, the results for the effect of added salts can be predicted since k_{EtO^-} and k_{MOEt} are known. The agreement between calculated and observed rate constants is good for KI and LiCl, as shown in Figs. 3 and 4, as well as for $LiNO_3$. $NaBPh_4$ shows very poor agreement, but this salt also shows unusual downward curvature in plots of k_{obs} vs. [added salt]. Therefore, factors such as salt effects, ionic strength effects, and changes in activity coefficients apparently do not significantly affect the reaction rate, at least for KI, LiCl, and $LiNO_3$, and the ion pair mechanism adequately describes the observed behavior.

Interaction of metal ions with ground state and transition state

The kinetic data can be dissected into ground state and transition state contributions to catalysis and inhibition to give greater insight into the roles of metal ions in the reaction. As above, involvement of metal ions is assumed to occur through ion pairing to the nucleophile, rather than the alternative preassociation mechanism, because this is the simplest explanation consistent with all of the data.

Catalysis results from greater stabilization of the transition state by the metal ion relative to stabilization of the ground state. Conversely, inhibition is due to greater stabilization of the ground state relative to the transition state. The degree of transition state stabilization can be evaluated using a method developed by Kurz (34), and applied subsequently by Wolfenden (35) and Lienhard (36).

In the present system, the reaction mechanism is described as a set of equilibria among the various reactants and transition states for catalyzed and uncatalyzed pathways (Scheme 1):

$$E + EtO^- + M^+ \underset{}{\overset{K^{\neq}}{\rightleftharpoons}} A^{\neq} + M^+ \longrightarrow \text{products}$$

$$K_a \uparrow\downarrow \qquad\qquad K_a' \uparrow\downarrow$$

$$E + EtOM \underset{}{\overset{K^{\neq\prime}}{\rightleftharpoons}} A^{\neq} M^+ \longrightarrow \text{products}$$

SCHEME 1

In this scheme, $K^{\neq}$ and $K^{\neq\prime}$ are the equilibrium constants for formation of the uncatalyzed and catalyzed transition states; K_a and K_a' are the association constants for ion pairing of M^+ with EtO^- and the transition state, respectively.

If the transition states are assumed to be in equilibrium with their respective reactants, the equilibrium constant for the association of M^+ with the transition state, K_a', can be calculated even though there is no direct equilibrium between the two transition states (34). This value is obtained from the kinetic data using eq. [14].

[14] $$K_a' = \frac{k_{MOEt} K_a}{k_{EtO^-}}$$

K_a' values for the various metal ions were calculated and are presented in Table 5. Analogous data were available for the reaction of *p*-nitrophenyl diphenylphosphinate, **2**, with alkali metal ethoxides in anhydrous ethanol at 25°C (1*d*). K_a' values for this system are also included in Table 5. These data clearly show that Li^+, an inhibitor in the reaction of **1**, has a stronger association with the ground state than the transition state. Conversely, the other metal ions, which are all catalysts, have values of K_a' greater than K_a. In the phosphinate system, all metal ions act as catalysts. It is interesting and significant to note that the trends in K_a' values are different in the two systems, and, with the exception of Cs^+, are inverted relative to each other. This observation will be discussed in the following section.

The effects of metal ions on the ground and transition states can be discussed with reference to the free energies shown in Fig. 5 (37). In this diagram, $\Delta G_u^{\neq}$ and $\Delta G_c^{\neq}$ are the free energies of activation of the uncatalyzed and catalyzed reactions, respectively. δG_{ip} and δG_{ts} refer to the free energies for association of a metal ion to ethoxide ion and the transition state, respectively. The net catalytic effect of the metal ion is given by ΔG_{cat}, the difference in free energies of activation between the catalyzed and uncatalyzed reactions. From the diagram, the following relationships can be written:

[15] $$\Delta G_u^{\neq} = G_u^{ts} - G_u^{gs}$$

[16] $$\Delta G_c^{\neq} = G_c^{ts} - G_c^{gs}$$

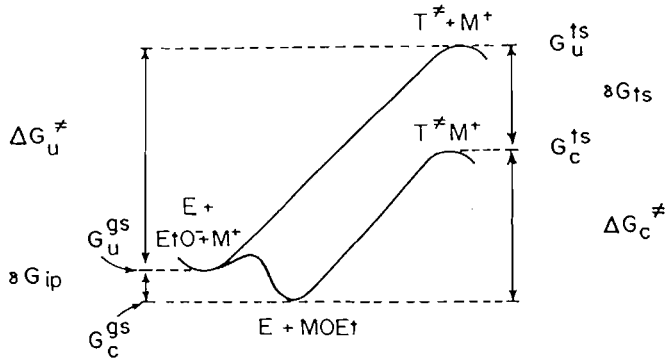

FIG. 5. Free energies involved in the uncatalyzed and metal ion catalyzed reactions of an ester, E, with an alkali metal ethoxide, MOEt. $\Delta G_u^{\neq}$ and $\Delta G_c^{\neq}$ are the activation energies for the uncatalyzed and catalyzed reactions, respectively. δG_{ip} and δG_{ts} refer to the stabilization of the ground state and transition state of the reaction by the metal ion, respectively.

TABLE 5. Association constants for the interaction of various metal ions with the transition states (K_a') and ground state (EtO^-, K_a) of the reaction of EtO^- with **1** and **2** at 25°C (K_a values from ref. 25). All values are in M^{-1}

Ion	K_a	K_a' (**1**)	K_a' (**2**)
Li^+	212	133	5188
Na^+	102	284	1207
K^+	90	430	347
Cs^+	121	409	266

$$\delta G_{ip} = G_c^{gs} - G_u^{gs} \quad [17]$$

$$\delta G_{ts} = G_c^{ts} - G_u^{ts} \quad [18]$$

$$-\delta G_{ip} + \Delta G_u^{\neq} = \Delta G_c^{\neq} - \delta G_{ts} \quad [19]$$

$$\Delta G_{cat} = \Delta G_c^{\neq} - \Delta G_u^{\neq} = \delta G_{ts} - \delta G_{ip} \quad [20]$$

The previously calculated association constants are presented as free energies of association in Table 6. Comparing δG_{ts} and δG_{ip} values helps explain the variation in catalytic efficiency among metal ions. Thus, δG_{ts} measures the stabilization of the transition state by the metal ion (which is its maximum catalytic potential), while δG_{ip} measures the stabilization of the nucleophile by the metal ion (which detracts from its catalytic effect) (37). ΔG_{cat} is the difference between δG_{ts} and δG_{ip} and is a measure of the net catalytic effect of the metal ion. A positive value of ΔG_{cat} implies that the transition state stabilization is a smaller negative number than the ground state stabilization and the net effect of the metal ion is to act as an *inhibitor*. A negative value of ΔG_{cat} means that the metal ion is acting as a *catalyst*.

Thus, it is seen from the data that Li^+ associates more strongly with the ground state than with the transition state, so the net effect is inhibition of the reaction ($\Delta G_{cat} > 0$). The other metal ions all stabilize the transition state to a greater extent than the ground state, and act as catalysts ($\Delta G_{cat} < 0$). Since K^+ has the strongest association with the transition state and the weakest association with the ground state, it is the best catalyst and has the largest negative value of ΔG_{cat}.

Given this quantitative description of catalysis and inhibition, some chemical insight into how and why metal ions bind the ground state and transition state more or less strongly is required. In particular, an explanation of how metal ions could bind to the transition state more strongly than to ethoxide ion, which has a more localized negative charge, is needed. Structure **3** depicts a *proposed* structure for the transition state for the attack of ethoxide on the sulfonate ester, which resembles the intermediate in the addition–elimination mechanism. The negative charge is therefore expected to reside predominantly on the sulfonyl oxygens, with only a small charge on the ethoxide oxygen.

TABLE 6. Free energies of metal ion stabilization of ethoxide (δG_{ip}) and the transition states (δG_{ts}) for the reaction of ethoxide with **1** at 25°C. The net catalytic effect of the metal ion (ΔG_{cat}) is also given. All values are in kJ mol^{-1}

Ion	δG_{ip}	δG_{ts}	ΔG_{cat}

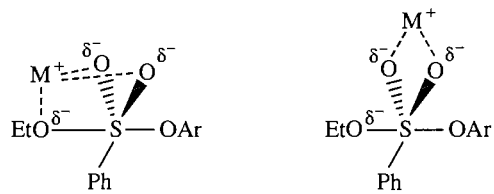
3 **5**

Chelation of the metal ion to two or three negatively charged oxygens, as shown in structures ***4a*** and ***4b***, may result in the transition state binding the metal ion more strongly than ethoxide. Chelation, therefore, would allow the sulfonate transition state to bind metal ions more strongly than ethoxide ion.



4a ***4b***

Interactions of metal ions in the phosphinate system will be considered subsequently.

Trends in the degree of transition state stabilization by metal ions

Data on the interactions of metal ions with the phosphinate and sulfonate transition states can now be compared. Table 7 summarizes the degree of stabilization of the sulfonate and phosphinate transition states by various metal ions. In the case of the phosphinate transition state, the ordering of δG_{ts} values is $Li^+ < Na^+ < K^+ < Cs^+$. For the sulfonate transition state, the order is $K^+ < Cs^+ < Na^+ < Li^+$. The two sets of reactions were carried out under identical conditions and the two esters are believed to react by similar mechanisms. However, the way in which the metal ion interacts with the transition state is apparently not the same in both cases. It is expected that the explanation underlying these differing results arises from

Li^+	−13.3	−12.1	−21.2
Na^+	−11.5	−14.0	−17.6
K^+	−11.2	−15.0	−14.5
Cs^+	−11.9	−14.9	−13.8

differences in the geometric and electronic structures of the two transition states.

One obvious difference between the two transition states is that they do not contain the same number of potential ligand oxygens. Assuming that both transition states are intermediate-like, the sulfonate transition state contains two ligand oxygens with a significant negative charge (structure **3**), while the phosphinate has only one (structure **5**). With a single oxygen, simple cation–anion electrostatic interactions are expected to result in stronger association for smaller cations for the phosphinate transition state, as observed.

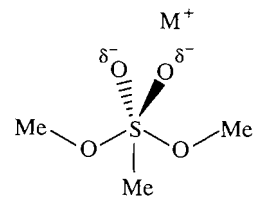
In the sulfonate transition state, the situation is more complex. Attractive interactions with two negatively charged oxygens as well as repulsive interactions with a positively charged sulfur center are possible. If the oxygens are far enough apart, chelation of a small metal ion to the sulfonyl oxygens may be possible, but this would be counterbalanced in part by repulsive interactions with the sulfur center. Larger cations would be further from the sulfur, but would be less effective at chelating the sulfonyl oxygens. The optimum balance between attractive forces to the negatively charged oxygens and repulsive forces from the positively charged sulfur may be achieved by metal ions of intermediate size, accounting for the observed size selectivity of the sulfonate transition state.

As a test of the above hypothesis, electrostatic metal ion – transition state interactions were modeled in a preliminary manner using MNDO calculations. The limitations of the application of semiempirical calculations to compounds containing SO and SO_2 groups have been noted for MNDO (38). However, these drawbacks can be reduced by fixing the geometry of the sulfonate and by considering relative energies only.

A model for the pentacoordinate intermediate resulting from the attack of methoxide on methyl methanesulfonate was constructed (structure **6**). Bond lengths and angles about the sulfur center from the crystal structure of pentacoordinate sulfur compound (39) were used to define a reasonable starting geometry for the intermediate, whose structure was then optimized using MNDO, giving a structure with partial negative charges on oxygens and a substantial positive charge on the sulfur center (as expected).

The optimized geometry of the intermediate was then fixed and the energies of complexes with alkali metal ions (Li^+-, Na^+-, and K^+-like sparkles in MNDO) were minimized. The resulting complexes had similar geometries, with the metal ion interacting with the equatorial sulfonyl oxygens, but with one sulfonyl oxygen to a greater extent than with the other, as shown in **6**. The sparkles in MNDO do not have an intrinsic heat of formation, so the heats of formation of the complexes give the heat of association. These fell in the order $Li^+ < Na^+ < K^+$, i.e., Li^+ gave the largest heat of association, which is opposite to the observed ordering in the experimental data for **1**.

Therefore, calculations on the interaction of the modelled intermediate with metal-ion-like "sparkles" suggested that a simple electrostatic model involving interactions of the metal ion, negatively charged oxygens, and a positively charged sulfur probably does not account for the observed ordering in the association constants for the various metal ions.



6

Another difference between the two transition states is the extent of charge delocalization. In the phosphinate transition state (**5**), the charge is localized mainly on the phosphoryl oxygen. There is evidence to suggest that the P=O bond is highly polarized, resembling $P^+—O^-$, even in the ground state (40). This means that a relatively strong interaction with metal ions is possible since the negative charge is highly localized. In a solvent of moderate polarity, such as ethanol, the stabilizing effect of solvent on metal ions, i.e., solvation, is reduced in comparison to solvation in water, so it is reasonable to suppose that the energy of the electrostatic interaction of M^+ with the transition state ($M^+ + ts^- \rightarrow M^+ts^-$) could be greater than the energy of solvation of the metal ion ($M^+ + n.\text{solvent} \rightarrow M(\text{solvent})_n^+$) in certain instances. This being the case, contact ion pairing between the transition state and the metal ion would be the result. Here, association would involve the interaction of the transition state with bare metal ions, which increase in size in the order $Li^+ < Na^+ < K^+ < Cs^+$ (41). Since the smaller cations should interact more strongly with the anionic transition state, this would lead to δG_{ts} values increasing in the order $Li^+ < Na^+ < K^+ < Cs^+$, which is identical to the observed ordering for reactions with **2** (Table 7). Furthermore, contact ion pairing is known to cause spectral shifts that show a correlation with the reciprocal of the cation crystal radius (42, 43). This is because the metal ion affects the energy levels of its counterion in inverse relation to its electrostatic potential. We observe that the stabilization of the phosphinate transition state by metal ions (δG_{ts}) does in fact increase with the reciprocal of the cation crystal radius (r_c). Thus, a plot of δG_{ts} versus $1/r_c$ is linear and has a negative slope (Fig. 6), as expected for contact ion pairs.

In contrast, the sulfonate transition state, which has its charge delocalized over two (or more) oxygens, is expected to have weaker interactions with metal ions and may not be able to displace a solvent molecule from the coordinate sphere of the metal ion. Hence, the transition state would interact with solvated metal ions. The magnitudes of solvated radii now follow a trend opposite to crystal radii ($Cs^+ > K^+ > Na^+ > Li^+$) because the metal ions with smaller crystal radii, having a greater electrostatic potential, attract more solvent molecules. Values of crystal and solvated radii are listed in Table 8. The solvated radii of the alkali metal ions in ethanol were calculated using the Stokes equation from the data of Kay and Evans (44). Since it is known that the Stokes equation underestimates the solvated radii of ions, the values were corrected by the method of Della Monica and Senatore (45) using data from ref. 46. These calculations are described in the Supplementary Material.[3]

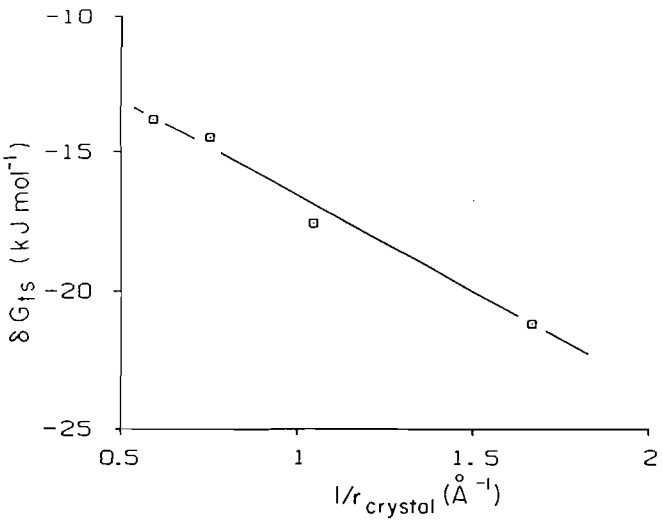


FIG. 6. Plot of δG_{ts} versus the reciprocal of the crystal radius of the metal ion for the reaction of *p*-nitrophenyl diphenylphosphinate with alkali metal ethoxides in EtOH at 25°C ($r = -0.9920$).

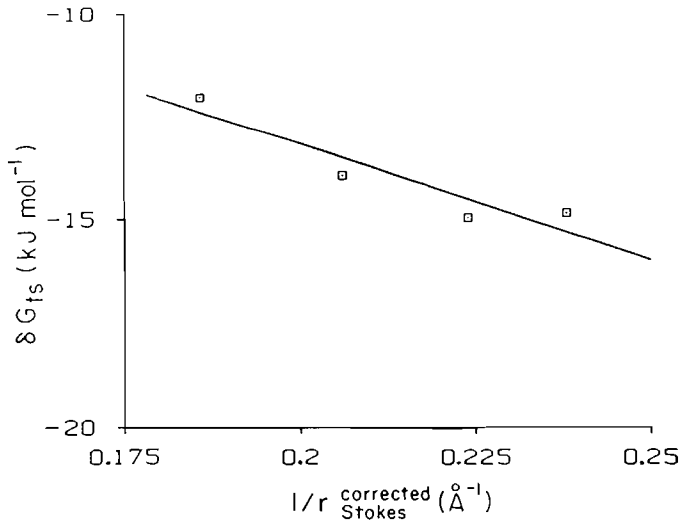

FIG. 7. Plot of δG_{ts} versus the reciprocal of the corrected Stokes radius of the metal ion for the reaction of *p*-nitrophenyl benzenesulfonate with alkali metal ethoxides in EtOH at 25°C ($r = -0.9334$).

TABLE 8. Crystal radii, Stokes radii, and corrected Stokes radii for alkali metal ions in ethanol (in Å). See text for details on calculation of Stokes and corrected Stokes radii

Radius	Li^+	Na^+	K^+	Cs^+
Cation crystal radius (Pauling)	0.60	0.95	1.33	1.69
Stokes radius	4.43	3.73	3.21	2.86
Corrected Stokes radius	5.39	4.86	4.47	4.20

Association with solvated metal ions would result in δG_{ts} values increasing in the order $Cs^+ < K^+ < Na^+ < Li^+$, which is similar to the observed order, $K^+ \leq Cs^+ < Na^+ < Li^+$ for **1** (Table 7). In this situation, one might still expect a relationship between the free energy of association and the size of the metal ion, but now the size of the ion is given by its solvated or Stokes radius. A plot of δG_{ts} versus the reciprocal of the corrected Stokes radius gives a linear relationship that shows that the free energy of association increases with the electrostatic potential of the metal ion, as given by its solvated radius (Fig. 7). However, the plot is not as linear as in the case of the phosphinate transition state. One of the reasons for this may be that the solvated ions are probably not exactly spherical, so the corrected Stokes radii are only an approximate measure of their sizes. Furthermore, it is worth noting that the δG_{ts} values in the sulfonate system are, in general, smaller than in the phosphinate system. This is consistent with the present explanation because the solvated radii are all much greater than the crystal radii of the ions. The larger ions have a lesser electrostatic potential, which results in lower association constants.

Parallel arguments have been advanced by Eisenman to explain selectivity among alkali metal ions by ion exchange resins (47). As above, two types of interaction were considered: (a) electrostatic interaction between the anionic group and its alkali metal counterion, and (b) rearrangement of solvent molecules to permit the anion and counterion to come into direct contact. The anion and solvent are said to compete for the metal ion (48). Anionic groups with high electric strengths win the contest and attract cations away from solvent. The smallest cations are attracted most strongly, so the affinity sequence is $Li^+ > Na^+ > K^+ > Cs^+$. This ordering is found in practice for carboxylate ion exchange resins and is consistent with the small size and high field strength of the carboxylate group (47). This ordering is also seen in δG_{ts} values for the phosphinate transition state, indicating a high electric field strength.

Conversely, anionic groups with low electric field strengths lose the contest with solvent for association with the metal ion. The cations remain solvated, leaving the ions with the smaller solvated radii to be bound most strongly (48). The affinity sequence in this case is $Cs^+ > K^+ > Na^+ > Li^+$. The sulfonate group is believed to have a low field strength and, in fact, many different types of ion exchange resins containing sulfonate groups have displayed the affinity sequence described above (47).

From the above arguments, it is clear that, as the field strength of the anion is increased, the affinity sequence must change from $Cs^+ > K^+ > Na^+ > Li^+$ (the order of solvated radii) to $Li^+ > Na^+ > K^+ > Cs^+$ (the order of crystal radii) with a number of different sequences as intermediates. Eisenman's theory predicts that the first change will be from $Cs^+ > K^+ > Na^+ > Li^+$ to $K^+ > Cs^+ > Na^+ > Li^+$ (47). Thus, the observed ordering of δG_{ts} values for the sulfonate transition state is quite consistent with an anion with low to intermediate field strength as the transition state.

The discussion presented here can be summarized in a scheme which is an extension of the Kurz approach and is reminiscent of solvolysis schemes involving different types of ion pairs (Fig. 8) (49). In the ground state, free ions, solvent separated ion pairs, and contact ion pairs are all in equilibrium. It is not known whether alkali metal ethoxides prefer to form contact or solvent separated ion pairs. However, each species has the potential to react with the substrate to form a transition state, which may not be associated with metal ions, or, alternatively, which may form a contact or solvent separated ion pair with a metal ion, as in the ground state. Because it is possible for solvent reorganization to occur along the reaction coordinate (50), a contact ion paired ethoxide, for example, need not react with substrate to form a contact ion paired transition state. In this scheme, solvent separated ion pairs

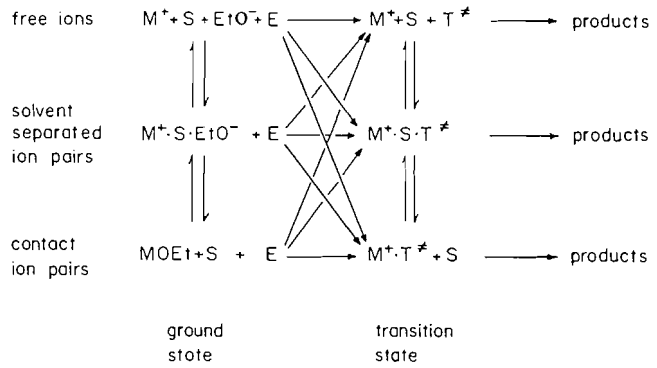

FIG. 8. Scheme showing equilibria between free ions, solvent-separated ion pairs, and contact ion pairs in the ground state and transition state for the reaction of alkali metal ethoxides with an ester, E. $T^{\neq}$ represents the transition state formed by reaction of ethoxide ion with the ester.

would be favoured for the sulfonate transition state, while contact ion pairs would be favored for the phosphinate transition state.

The above discussion has omitted consideration of differences in solvation of the two transition states in the absence of metal ions. The phosphinate transition state, with a greater charge density on oxygen, is expected to benefit more from solvation than the sulfonate transition state. Thus, stronger solvation of the transition state might be expected to result in a greater tendency to form solvent separated ion pairs with metal ions for the phosphinate, in opposition to the predictions above. However, since the experimental results show that the phosphinate transition state prefers to form contact ion pairs with alkali metal ions, it follows that electrostatic interactions of metal ions with these transition states are stronger than solvation effects.

Therefore, the trends in δG_{ts} values can be rationalized by considering differences in solvation of ion pairs of the transition states of the two systems studied. An alternative explanation based on a simple electrostatic model appears less likely. Consequently, it is concluded that the effects of alkali metal ions on nucleophilic displacement reactions are determined in part by the extent of charge delocalization in the transition state for the reaction. It is proposed that the transition state for reaction of alkali metal ethoxides with *p*-nitrophenyl benzenesulfonate exists as a species analogous to a solvent separated ion pair. On the other hand, the transition state for the reaction of *p*-nitrophenyl diphenylphosphinate forms a species that may be described as a contact ion pair with alkali metal ions. The difference in behavior between the two systems is consistent with a greater delocalization of charge in the sulfonate transition state.

To investigate the influence of the degree of charge delocalization on the association of the transition state with metal ions, further work is in progress on metal ion effects in related systems, including other esters containing phosphoryl and carbonyl centers. The results of these studies as well as investigations of the mechanisms of these reactions will be presented in subsequent papers.

Conclusions

These studies have allowed significant insight into the role of alkali metal ions in nuleophilic displacement reactions of sulfonate and phosphinate esters (**1** and **2**, respectively). Some of the main conclusions that we have reached are as follows:

1. In the reaction of **1**, certain metal ions, e.g., K^+, act as *catalysts*, i.e., the rate increases when they are added as inert salts and decreases when they are removed by complexing agents. One metal ion studied, Li^+, acts as an *inhibitor*, i.e., the rate decreases when it is added and increases when it is complexed.

2. Metal ions are assumed to be involved in the reaction of **1** via reactive alkali metal – ethoxide ion pairs. Metal–ethoxide ion pairs are known to be present in ethanol solutions of alkali metal ethoxides and assumption of the alternative mechanism involving preassociation of metal ions to the ester led to unrealistically large rate constants for reaction of the putative ester – metal ion complexes.

3. The catalytic or inhibitory effects of metal ions have been discussed in terms of ground state (δG_{ip}) and transition state (δG_{ts}) stabilizations. The overall catalytic effect (ΔG_{cat}) has also been calculated for each metal ion. ΔG_{cat} values quantitate the catalytic or inhibitory effects. The values are -3.8, -3.0, -2.5, and $+1.2$ kJ mol^{-1} for K^+, Cs^+, Na^+, and Li^+, respectively, indicating that K^+ is the best catalyst, Cs^+ and Na^+ are less effective catalysts, and that Li^+ is an inhibitor of the reaction of **1**.

4. Trends in δG_{ts} values for systems **1** and **2** were compared and the results rationalized in terms of the extent of charge delocalization in the two transition states and the role of metal ion solvation. It is concluded that the negative charge in the sulfonate transition state is significantly delocalized and that consequently solvent separated ion pairs are formed with alkali metal ions. The phosphinate transition state, with a more localized negative charge, forms contact ion pairs. These conclusions are supported by the linear relationships between δG_{ts} and $1/r_{Stokes}^{corrected}$ and $1/r_{crystal}$ in the case of reactions of **1** and **2**, respectively.

5. The balance in equilibrium between contact and solvent separated ion pairs is governed by two competing effects. The cation and anion can be stabilized by organization of solvent molecules around themselves (solvation) and by electrostatic interaction with each other. When the energy gained by solvation is greater than the energy of cation–anion electrostatic interaction, solvent separated ion pairs are favored (sulfonate transition state). When the reverse is true, contact ion pairs are favored (phosphinate transition state).

Experimental

Materials

Anhydrous ethanol was obtained by refluxing absolute ethanol (2 L) with magnesium turnings (10 g, BDH) and iodine (1 g, BDH) followed by fractional distillation (51).

18-Crown-6 (Parish and Aldrich) was recrystallized from acetonitrile, then dried over P_2O_5 under vacuum (<1 Torr (133.3 Pa)) before use. 2.2.2 Cryptand (Fluka) was recrystallized from hexanes, then dried over P_2O_5 under vacuum; 2.2.2 and 2.1.1 cryptands (E. Merck) were used without further purification; 2.2.2 was dried over P_2O_5 *in vacuo*.

Sodium tetraphenylborate (Aldrich, Gold label) was dried at 76°C under vacuum before use. Anhydrous lithium chloride (Aldrich, Gold label) was used as received. Lithium nitrate (Merck, Suprapur) and potassium iodide (BDH, Analar) were dried under vacuum with P_2O_5 before use.

Sodium, potassium, and cesium ethoxides were prepared as follows. Dry ethanol (200 mL) was collected in a round-bottom flask equipped

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

with a nitrogen inlet and magnetic stirrer. The solvent was cooled under nitrogen using an ice-water bath. The alkali metal (0.2 mol of Na (BDH Assured ACS), K (BDH or Alfa 99.95%), or Cs (Alfa, 99.95%)) was cut under petroleum ether and added in small portions to the stirred, cooled ethanol under nitrogen. Liquid Cs was added to ethanol that had been cooled in a Dry Ice – isopropanol bath and the solution allowed to warm slowly. When the reaction was complete, the flask was stoppered, sealed, and stored in a freezer.

Lithium ethoxide was prepared by adding lithium hydride (Aldrich, 95% or Alfa, 98%) to dry ethanol. The powder was added gradually from a glass bulb to a stirred, ice-cooled ethanol solution under nitrogen. In some cases, all of the LiH did not react and the excess was filtered off in a Vacuum Atmospheres Co. dry box. The LiOEt solution was sealed and stored in a freezer. Ethoxide solutions were standardized against 0.1 M HCl, which was in turn standardized against trishydroxymethylaminomethane (THAM, Fisher primary standard) (52).

p-Nitrophenyl benzenesulfonate was prepared following the procedure of Davy *et al.* (53).

Kinetic measurements

Reaction rates were measured by following ultraviolet–visible absorbance changes using Beckman DU-8 and Perkin–Elmer λ-5 spectrophotometers. All reactions were carried out under pseudo-first-order conditions with the base concentration usually at least 20 times greater than the substrate concentration. UV cells were equilibrated to 25.0°C in the thermostatted cell block of the spectrophotometer.

Rate constants were measured by following the appearance of the product continuously at fixed wavelength. Absorbance readings were made at the λ_{max} of the product, *p*-nitrophenoxide (400 nm).

Rate constants were calculated from at least 30 absorbance readings spanning three half-lives. An infinity absorbance reading was taken after at least 10 half-lives. Rate constants were calculated as the slope of a plot of $\ln(A_\infty - A_t)$ vs. time. It is estimated that the measured rate constants have errors of no more than ±3% (95% confidence interval).

The base-catalysed anomerization of dinitrophenyl glycosides: evidence for a novel reaction mechanism

LEISE A. BERVEN, DAVID DOLPHIN, AND STEPHEN G. WITHERS[1]

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received April 17, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

LEISE A. BERVEN, DAVID DOLPHIN, and STEPHEN G. WITHERS. Can. J. Chem. **68**, 1859 (1990).

The mechanism of base-catalysed anomerization of per-*O*-acetylated 2,4-dinitrophenyl-β-D-glucopyranoside in dimethylsulfoxide has been investigated using a variety of techniques. A mechanism involving proton abstraction at C-1 was eliminated by the absence of proton exchange at that center and the measurement of a secondary deuterium kinetic isotope effect for the 1-deuterio substrate. A mechanism involving phenolate departure and recombination is rendered unlikely on the basis of remote substituent effects on the reaction rate and by the absence of any exchange of the phenyl moiety with added phenolate. A mechanism involving nucleophilic aromatic substitution initiated by an attack of the dimethylsulfinyl anion to generate a glucosyl oxyanion intermediate that anomerizes and recombines with the reactive aryl intermediate is consistent with the observations. This mechanism is further supported by the observation of a purple Meisenheimer complex intermediate and by the observed exchange between the substrate containing a labelled sugar moiety and added unlabelled 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranose.

Key words: glycoside, anomerization, reaction mechanism.

LEISE A. BERVEN, DAVID DOLPHIN et STEPHEN G. WITHERS. Can. J. Chem. **68**, 1859 (1990).

Faisant appel à diverses techniques, on a examiné le mécanisme de l'anomérisation catalysée par les bases du β-D-glucopyranoside de 2,4-dinitrophényle per-*O*-acétylé en solution dans le diméthylsulfoxyde. En se basant sur le fait qu'il n'y a pas d'échange de proton dans cette position et sur la mesure d'un effet isotopique cinétique secondaire du deutérium pour le substrat 1-deutéré on a éliminé un mécanisme impliquant l'enlèvement d'un proton de la position C-1. En se basant sur l'existence d'effets des substituants éloignés sur la vitesse de la réaction et sur l'absence de tout échange de la portion phénylée lorsqu'on ajoute des ions phénolates, on peut déduire qu'un mécanisme impliquant un départ et une recombinaison du phénolate est improbable. Un mécanisme impliquant une substitution aromatique nucléophile, initiée par une attaque de l'anion diméthylsulfinyle pour générer l'intermédiaire oxyanion glucosyle qui s'anomérise et se recombine avec l'intermédiaire aryle réactif, est en accord avec les données expérimentales. Ce mécanisme est aussi supporté par l'observation d'un complexe intermédiaire de Meisenheimer violet et par l'observation d'un échange entre le substrat contenant une portion sucrée marquée et du 2,3,4,6-tétra-*O*-acétyl-β-D-glucopyranose qui n'est pas marqué.

Mots clés : glycoside, anomérisation, mécanisme de réaction.

[Traduit par la revue]

Introduction

There are many examples of acid-catalysed glycoside anomerization and their mechanisms are reasonably well understood (1–7). In all cases studied to date, including simple alkyl glycosides (1–3), protected alkyl glycosides (4), or fully acetylated sugars (5–7), the mechanism has involved oxocarbonium ion intermediates, whether catalysed by a Lewis or a Brønsted acid. Usually, reaction proceeds via cleavage of the exocyclic carbon–oxygen bond, though in some cases it is suggested that the preferred mode involves endocyclic bond cleavage. Base-catalysed reactions involving the glycosidic linkage are less common and, consequently, little is known about the mechanisms of such reactions. The anomerization of 1,2,3,4,6-penta-*O*-acetyl-β-D-glucopyranose and 2′,4′-dinitrophenyl 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranoside (β-2,4-DNPG)[2] has been reported using sodium hydroxide in anhydrous pyridine (8). Although yields were low, this reaction was one of the first methods used to transform a β- to the α-phenyl glycoside. Interestingly, anomerization of the β-glucosides of phenol, 2-nitrophenol, and 4-nitrophenol were unsuccessful. More recent studies (9) have shown that treatment of β-2,4-DNPG with potassium carbonate in dimethylsulfoxide (DMSO) afforded an equilibrium mixture of the α and β anomers (80:20, respectively) in good yield. Reaction of 2′,4′-dinitrophenyl 2,3,4,6-tetra-*O*-benzyl-β-D-glucopyranoside, however, was found to proceed approximately 70 times more slowly than the acetylated glycoside, leading to the suggestion that the acetyl group at C-2 may participate in the reaction.

Very little is known concerning the mechanism of this base-catalysed anomerization. The only published suggestion for a mechanism is that (10) involving initial abstraction of the proton from the anomeric centre, generating a glycoside anion that can then reprotonate from either side. However, there has been no published evidence in support of this, or any other mechanism. We have considered four possible mechanisms for the carbonate catalysed anomerization of 2′,4′-dinitrophenyl 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranoside (Scheme 1). The first (i) involves proton abstraction at C-1 as suggested by Ferrier (10), forming a carbanion intermediate that can reprotonate from either face. The second (ii) is initiated by phenolate departure, forming an oxocarbonium ion intermediate with possible neighboring group assistance of the C-2 acetoxy group. The phenolate and oxocarbonium ions then recombine to give α or β product. The third mechanism (iii) also involves phenolate departure, but is in this case an elimination reaction initiated by proton abstraction from C-2 with formation of an acetoxyglucal intermediate that subsequently recombines with phenolate. The

fourth mechanism (iv) involves an initial nucleophilic substitution reaction at C-1′ of the aromatic ring by an added, or generated, nucleophile (most likely dimethylsulfinyl anion in the present work), displacing a glycosyl oxyanion and forming an activated aromatic intermediate. This glycosyl oxyanion then anomerizes by the usual mechanism (1, 2) under the basic conditions and subsequently recombines with the reactive aromatic species (see also Scheme 2 for mechanism (iv)). Each of these mechanisms has some attractive and unattractive features. Mechanism (i) is certainly consistent with the basic conditions of the reaction, but involves a most unusual deprotonation of the anomeric carbon. However, this would be consistent with the earlier observations (8) that only glycosides of extremely electron-deficient phenols undergo the anomerization. Mechanism (ii) is consistent with known carbohydrate chemistry and with the requirement for electron-deficient phenol leaving groups, and with the greater reaction rate for glycosides with potential participating groups at C-2. However, it is difficult to envisage a role for the base in such a reaction. Mechanism (iii) is also reasonably consistent with known carbohydrate chemistry and with the requirement for reactive leaving groups. In addition, it does suggest a clear role for the base. However, it seems doubtful that the glycal intermediate would be reactive enough to recombine with such a poor nucleophile as dinitrophenolate. Additional problems also arise concerning retention of stereochemistry at C-2 in the product. Mechanism (iv) is consistent with the requirement for an electron-deficient aromatic ring and suggests a role for the base either as the nucleophile or in generating the dimethylsulfinyl anion nucleophile. However, it suffers from a paucity of precedence since nucleophilic aromatic substitution reactions are rare in aryl glycoside chemistry. Nonetheless, an important precedent for this exists in the base-catalysed hydrolysis of nitrophenyl glycosides (11, 12). In this case reaction is initiated by base-catalysed intramolecular attack of the sugar 2-hydroxyl upon C-1′ of the aromatic moiety, resulting in migration of the nitrophenyl group to O-2. Subsequent further migration of the aromatic group to O-3 is followed by elimination, yielding nitrophenolate and saccharinic acids.

This paper describes our approaches to identifying the mechanism through a combination of kinetic and product identification studies. A preliminary account of this work has been published previously (13).

Results and discussion

Investigation of solvents, catalysts, and substrates

The first factors to be investigated were the solvents and the catalysts capable of effecting the transformation. This was of particular interest not only in terms of providing clues to the mechanism itself, but also in terms of finding a totally homogeneous system that would be suitable for kinetic studies. For these initial investigations β-2,4-DNPG was used as the substrate and potassium carbonate as the catalyst while thin-layer chromatography was used to determine whether or not reaction had occurred. The substrate, β-2,4-DNPG, was soluble in all the solvents tested, while the potassium carbonate was, at best, only sparingly soluble. Reaction failed to occur only in the least polar of the solvents tested, namely toluene, diethyl ether, and dichloromethane, while reaction was successful in a range of more polar solvents including dimethylsulfoxide, *N*,*N*-dimethylformamide, propylene carbonate, tetrahydrofuran, pyridine, chloroform, and acetonitrile. The reaction does not therefore appear to be especially solvent dependent. Indeed, the absence of reaction in the least polar solvents may simply reflect poor solubility of the catalyst. On the basis of these results dimethylsulfoxide (DMSO) was chosen as the solvent for subsequent studies due to the ease of reactions therein and due to its stability to bases.

A variety of other bases was tested for their ability to catalyse the anomerization of β-2,4-DNPG in DMSO. All the carbonate salts tested (potassium, barium, cesium, tetramethyl-, tetraethyl-, and tetrabutyl-ammonium) were effective, along with

other dianions or trianions such as trisodium phosphate and bis-tetramethylammonium hydrogen phosphate. The very weakly basic dianion potassium sulfate and the monoanion potassium perchlorate were ineffective. Neutral bases of comparable basicity[3] to carbonate (triethylamine and 1,8-bis(dimethylamino)naphthalene) were unable to support the reaction. However, relatively strong monoanionic bases such as potassium *tert*-butoxide, dimethylsulfinyl anion, and sodium hydride were quite effective at promoting anomerization. These observations were initially confusing since there appeared to be no clear correlation with base strength until it was realized that anionic bases, and particularly dianionic bases, are *much* stronger bases in DMSO than in water (14–16) while neutral bases are of comparable basicity in the two solvents. Indeed potassium *tert*-butoxide was shown previously (14) to be capable of generating a high concentration of dimethylsulfinyl anion when dissolved in DMSO, and it is probable that the carbonate dianion has a comparable basicity. It therefore appears that a strong base is required to bring about anomerization, possibly strong enough to generate significant quantities of dimethylsulfinyl anion. The fact that dimethylsulfinyl anion itself promotes anomerization supports this contention. The search for different catalysts also revealed several that were soluble in DMSO, these being the bis(tetra-alkylammonium) carbonates and dimethylsulfinyl anion. This finding is particularly relevant not only in terms of providing a completely soluble homogeneous system for kinetic studies, but also because it disproves an earlier hypothesis (8) that the reaction requires heterogeneous catalysis.

The previous assertion (8) that the only aryl glycosides to undergo this transformation are those with aglycone moieties of low pK_a was investigated further by synthesis and testing of a series of protected aryl glycosides to see which underwent anomerization. Thus the per-*O*-acetylated β-D-glucopyranosides of the following phenols were synthesized: phenol, 4-nitrophenol, pentafluorophenol, 3,4-dinitrophenol, 2,3-dinitrophenol, 2,5-dinitrophenol, 2,6-dinitrophenol, and 2,6-dichloro-4-nitrophenol. These glycosides were dissolved in DMSO containing potassium carbonate and stirred for several days. Analysis of reaction products by tlc and nmr revealed that only the 2,6-dinitrophenyl and 2,6-dichloro-4-nitrophenyl glucosides anomerized at a comparable rate to β-2,4-DNPG. These are the only three phenols that have pK_a's less than 4.0 (17, 18), confirming that the reaction depends on the electron-withdrawing effects of substituents on the aryl ring.

The search for intermediates. Exchange reactions

All four possible mechanisms proposed for the anomerization reaction occur via bond cleavage at either C-1—H-1 (proton abstraction), C-1—O-1 (phenolate departure), or O-1—C-1′ (nucleophilic aromatic substitution). In all cases, the intermediates generated by bond cleavage should be exchangeable with appropriate equivalent substances added to the reaction mixture. Therefore a series of exchange reactions was performed to determine which bond is cleaved during anomerization.

Proton abstraction (mechanisms (i) or (iii)) was investigated by anomerizing [1-^{2}H]-β-2,4-DNPG (19) in DMSO-d_6 containing tetramethylammonium carbonate in the presence of *tert*-butanol as a proton source (100-fold mole excess). The ^{1}H nmr analysis of the isolated product mixture indicated that although complete anomerization had occurred, there had been no exchange of the deuteron at C-1 since no resonance due to an anomeric proton was observed. Similarly, anomerization of non-labelled β-2,4-DNPG in the presence of a deuteron source (^{2}H-*tert*-butanol) showed no exchange at either C-1 or C-2. These observations are strong evidence against mechanisms (i) or (iii).

Demonstration of a dinitrophenolate intermediate was attempted by looking for exchange of added dinitrophenolate anion with that which might be generated during the reaction. Ideally this could be achieved using appropriately labelled (e.g., deuterated), 2,4-dinitrophenolate in the presence of β-2,6-DNPG. However, since such material was not readily available, and since β-2,6-DNPG had also been shown to undergo anomerization, experiments were performed in which β-2,4-DNPG was anomerized in the presence of added potassium 2,6-dinitrophenolate and β-2,6-DNPG in the presence of potassium 2,4-dinitrophenolate. In both cases, ^{1}H nmr analysis of the product mixture indicated that no exchange had occurred. The lack of phenolate exchange is significant evidence against mechanisms (ii) and (iii). However, it is just possible, though unlikely, that exchange might not occur if the phenolate was not released from the immediate solvent shell before recombining with the sugar moiety.

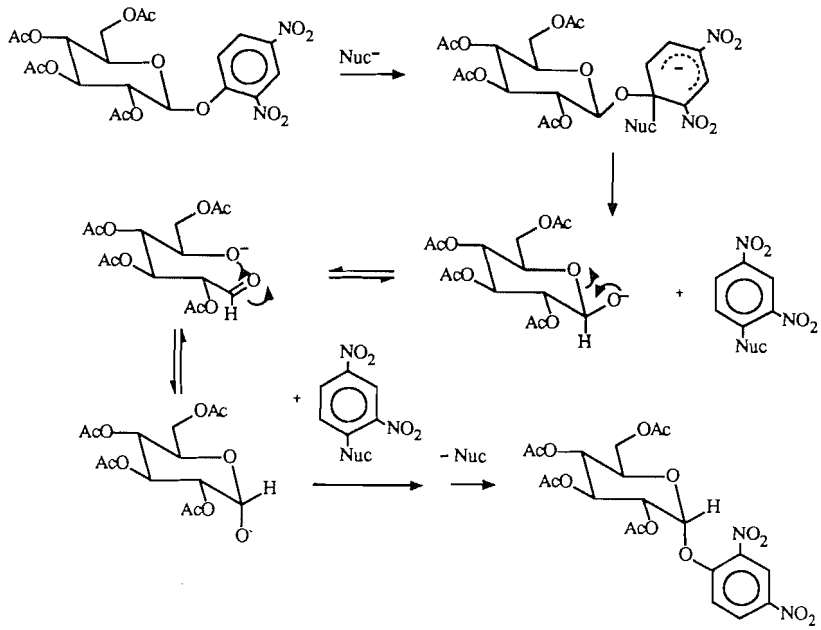
To test mechanism (iv), a third exchange reaction was performed in which [1-^{2}H]-β-2,4-DNPG was anomerized in the presence of one equivalent of 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranose. In the presence of base, 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranose is deprotonated to produce the glycosyl oxyanion intermediate proposed in the nucleophilic aromatic substitution mechanism (Scheme 2). If this is indeed an intermediate in the reaction, then the added, unlabelled, 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranose should be capable of exchanging with the deuterated species generated from the substrate during reaction. The ^{1}H nmr spectrum of the isolated α-2,4-DNPG revealed that exchange had indeed occurred since an anomeric proton resonance integrating to approximately half a proton was evident in the spectrum (Fig. 1). Had there been no exchange, no anomeric proton resonance whatsoever would have been seen. The glycosyl oxyanion must therefore be an intermediate in the reaction mechanism, and this strongly supports mechanism (iv).

A final experiment performed to probe mechanism (iii) involved the independent synthesis of 2,3,4,6-tetra-*O*-acetyl-D-glucal, the postulated intermediate, and attempted reaction of this with potassium 2,4-dinitrophenolate in DMSO in the presence of potassium carbonate. No dinitrophenyl glycoside product was observed, providing additional evidence against mechanism (iii).

Kinetic studies

Two kinds of kinetic studies were performed to attempt to distinguish between mechanisms. One of these involved measurement of the kinetic isotope effect associated with the anomerization of 1-[^{2}H]-β-2,4-DNPG in an attempt to distinguish between the anomeric proton abstraction mechanism (i), which should show a primary kinetic isotope effect, and the other mechanisms, which would likely be subject to a secondary deuterium kinetic isotope effect. The second study involved comparison of the rates of anomerization of a series of remotely substituted 2′,4′-dinitrophenyl glycosides in an attempt to distinguish between cationic and anionic mechanisms. At-

[3]Basicity in H_2O.



SCHEME 2

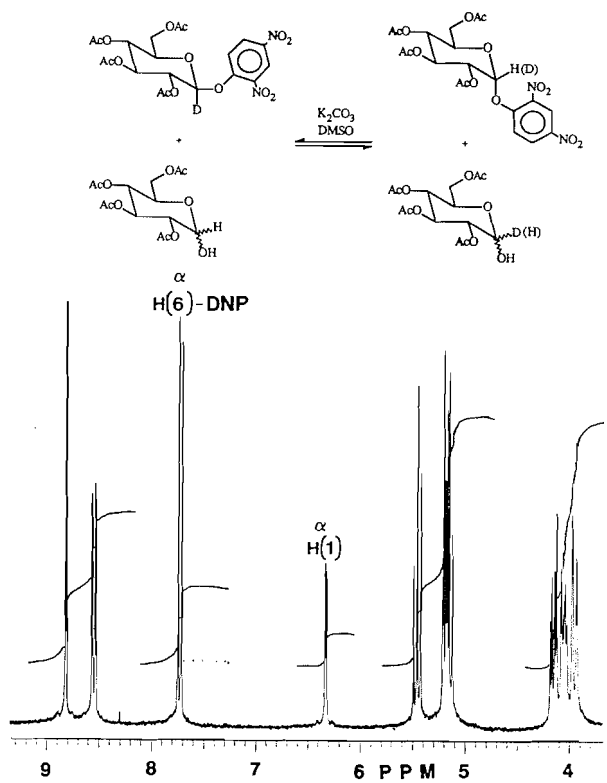


FIG. 1. The ^{1}H nmr spectrum of α-2,4-DNPG isolated from the reaction mixture shown. Integration of the anomeric proton resonance reveals that exchange has occurred.

tempts were made initially to monitor the reaction by use of a polarimeter since there is a significant difference in optical rotation between β-2,4-DNPG and α-2,4-DNPG. Unfortunately all such attempts were unsuccessful because of the relatively rapid appearance of small amounts of a highly chromophoric by-product, identified as 2,4-dinitrophenolate, even under anhydrous conditions. This rendered the use of polarimetry unreliable and forced the use of ^{1}H nmr to follow the reaction. This was more suitable since the reaction could be followed directly using sealed tubes under scrupulously anhydrous conditions. The quantity of 2,4-dinitrophenolate formed was too small to be observable by ^{1}H nmr, and hence it did not interfere with this technique. Direct monitoring by ^{1}H nmr allowed determination of the amounts of product and starting materials at any time by careful integration of the appropriate resonances. It should also allow the observation of any intermediate species generated if they are formed at significant concentrations.

Deuterium kinetic isotope effects

The deuterium kinetic isotope effect measured for the anomerization of 1-substituted β-2,4-DNPG was $k_H/k_D = 1.09 \pm 0.06$. This is a small, but real, isotope effect, but is clearly not a primary kinetic isotope effect since much larger values (up to 7) might have been expected. This finding argues strongly against the proton abstraction mechanism (i) since it is reasonable to assume that the initial proton abstraction step would be rate determining for this mechanism, and thus a primary kinetic isotope effect would be expected. The value measured is, however, in the range expected for a secondary (α or β) deuterium kinetic isotope effect. Either of the other three mechanisms (ii, iii, or iv) could be expected to show such an effect.

Remote substituent effects

It has long been known that substitution of sugar ring hydroxyl groups by hydrogen or other substituents can have a pronounced effect upon the rate of hydrolysis of such substituted glycosides when reaction proceeds via an oxocarbonium ion mechanism (2, 20–22). These changes in rate have generally been considered to be the result of some combination of steric and electronic effects that affects the stability of the transition state. More recent studies on the hydrolysis rates of a complete series of deoxy- and deoxyfluoro-α-D-glucopyranosyl phosphates (23, 24) have suggested that, in these cases at least, the effect is entirely electronic in origin, with the deoxysugars hydrolysing faster than the parent compound and the deoxyfluorosugars hydrolys-

TABLE 1. Substituent effects on anomerization rate

β-2,4-DNPG Substrate	[DNPG] (M)	$[(Me_4N)_2CO_3]$ (M)	Rel. Rate (disappearance of β-anomer)
β-2,4-DNPG	0.0138	0.0167	1.00*
2,3,6-Tri-*O*-acetyl-4-deoxy	0.0138	0.0167	0.13
2,3,4-Tri-*O*-acetyl-6-deoxy	0.0153	0.0167	0.40
2,3,6-Tri-*O*-acetyl-4-deoxy-4-fluoro	0.0136	0.0167	1.05
β-2,4-DNPG	0.0121	0.0182	1.00
3,4,6-Tri-*O*-acetyl-2-deoxy-2-fluoro	0.0134	0.0182	0.90

*Apparent first-order rate constant at 25°C = 3.63×10^{-3} min^{-1}.

ing more slowly. It should therefore be possible to measure anomerization rates for several deoxy- and deoxyfluoro-β-2,4-DNPG substrates and determine whether the reaction proceeds via an anionic mechanism or a cationic mechanism. Such data are presented in Table 1. As can be seen, the two deoxy-β-2,4-DNPG substrates anomerize considerably more slowly than the parent substrate while the two fluorinated substrates anomerize at comparable rates to β-2,4-DNPG. This supports an anionic rather than a cationic mechanism and is therefore inconsistent with mechanism (ii) involving phenolate departure from an oxocarbonium ion.

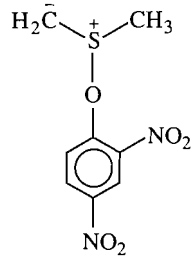
Conclusion

The only mechanism to emerge unscathed from this investigation is the nucleophilic aromatic substitution mechanism (iv), Scheme 2. The kinetic studies are consistent with a mechanism such as this, which involves anionic intermediates and exhibits a secondary deuterium kinetic isotope effect. In this case the isotope effect would be a β-kinetic isotope effect if the nucleophilic attack is rate limiting (most likely) and an α-kinetic isotope effect if the anomerization of the hemiacetal anion is rate limiting. Either could be consistent with the observed effect of $k_H/k_D = 1.09$. The best evidence, however, is the observation of exchange between [1-^{2}H]-β-2,4-DNPG and added unlabelled 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranose. This provides unequivocal evidence for the intermediacy of the protected sugar oxyanion. Additional support for this mechanism comes from the observation that when the anomerization is performed under scrupulously anhydrous conditions a deep purple coloration ($\lambda_{max} = 574$ nm) is observed initially in the reaction mixture. Similar observations have been described previously in nucleophilic aromatic substitution reactions and attributed to the formation of Meisenheimer complexes (25); thus it seems likely that the colored species generated in this reaction is the initial adduct formed upon attack o sthe nucleophile onto β-2,4-DNPG.

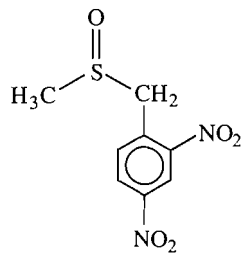
The identity of the nucleophile and therefore of the activated aryl intermediate is, as yet, unproven. Likely candidates are the added nucleophile itself (carbonate or phosphate) or dimethylsulfinyl anion generated in the solution by addition of the anionic base. Clearly, in the reaction where dimethylsulfinyl anion is used as the base, there is no other candidate. In all the other cases studied, as stated previously, it is either known, or at least probable, that the bases employed are strong enough to generate significant quantities of dimethylsulfinyl anion *in situ*.

The possibility that phosphate is the nucleophile was eliminated by independent synthesis (26) of 2,4-dinitrophenyl phosphate, the putative intermediate in that case, and reacting it with 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranose in DMSO in the presence of trisodium phosphate. No dinitrophenyl glucoside product was observed. Attempts to synthesize 2,4-dinitrophenyl carbonate were, not surprisingly, unsuccessful. Such an intermediate would be extremely unstable and subject to rapid spontaneous decarboxylation, liberating 2,4-dinitrophenolate. This could explain formation of dinitrophenolate, even under strictly anhydrous conditions. Such an intermediate therefore remains a possibility.

There are two likely candidates for the intermediate if dimethylsulfinyl anion is the nucleophile, either **1** or **2**.



1



2

Compound **2** was synthesized by an independent route involving oxidation of the methyl dinitrobenzyl thioether formed by reaction of methane thiol with 2,4-dinitrobenzyl chloride (27, 28). Reaction of this with 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranose in DMSO in the presence of bis(tetramethylammonium) carbonate yielded no dinitrophenyl glucoside product, thus eliminating compound **2** as a possible candidate.

All of our attempts to synthesize compound **1** have been unsuccessful. The most promising approach, involving direct substitution of fluoro-2,4-dinitrobenzene with dimethylsulfinyl anion in DMSO failed as the reaction proved difficult to control and products formed decomposed upon work-up and purification. Interestingly, the same compound was suggested to be an intermediate in the reaction of chloro-2,4-dinitrobenzene with DMSO at high temperature (29), as well as in the reaction of 2,4-dinitrophenol with dicyclohexylcarbodiimide and DMSO in the presence of acid/base catalysts (30, 31). Considerable effort was expended by these authors in attempts to isolate and characterize this intermediate, but without success. Suggestive evidence for the identity of the intermediate as compound **1** is provided by the observation that, even under anhydrous conditions, some 2,4-dinitrophenolate by-product is formed in these reactions. This could be explained readily by the collapse of **1**, yielding 2,4-dinitrophenolate and the sulfonium derivative. It was of concern to us initially that the generation of this type of intermediate had previously been shown to be accompanied by *ortho*-alkylation of the aromatic ring, yet no such reaction has been observed in our hands. However, it has

been shown (31) that no such reaction occurs with the 2,4-dinitrophenyl derivative, presumably because of the electron-deficient nature of the system.

In summary, the anomerization of protected 2,4-dinitrophenyl-β-D-glucopyranosides has been shown to proceed via a novel mechanism involving an initial nucleophilic aromatic substitution reaction. The identity of the aromatic intermediate involved has not been proven, but is in all likelihood the aryldimethylsulfinyl species generated by attack of dimethylsulfinyl anion on the substrate. It also suggests that a likely mechanism for the pyridine-catalysed anomerization of per-*O*-acylated sugars (8) involves initial attack of the pyridine on the acyl carbon of the anomeric substituent, resulting in formation of the acyl pyridinium species and the protected sugar oxyanion. This could then mutarotate and react with the acyl pyridinum salt by an entirely analogous process to that described in this work.

Experimental

Thin-layer chromatography (tlc) was performed on Merck Silica Gel 60 F_{254} aluminum backed plates using a solvent system of 1:1 (v/v) ethyl acetate/petroleum ether unless otherwise stated. Chromatograms were visualized by uv irradiation or by charring with 10% sulfuric acid in methanol. Flash chromatography was carried out on Merck Silica Gel (180–230 mesh). The ^{1}H nmr spectra were recorded on a 300 MHz Varian XL-300 instrument using $CDCl_3$ solutions and tetramethylsilane as an internal standard. Chemical shifts are expressed in ppm and coupling constants (J) are given in hertz (s = singlet, d = doublet, t = triplet, m = multiplet). Kinetic measurements were carried out in DMSO-d_6 solutions using residual proton resonances from DMSO (δ = 2.49) as a reference.

Syntheses

With the exception of the 2,4-dinitrophenyl glycosides, commercially unavailable acetylated phenyl glycosides were prepared by condensation of the sodium salt of the phenol with 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide (32). Protected 2,4-dinitrophenyl glucosides were prepared from the corresponding protected glycoside hemiacetals using fluoro 2,4-dinitrobenzene according to the method of van Boom *et al.* (9). Physical properties were in agreement with those previously reported (32, 33).

The following new compounds were prepared.

*Pentafluorophenyl 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranoside:* mp 144–145°C; ^{1}H nmr data: δ ($CDCl_3$) 5.34–5.12 (m, 3H, H-2, H-3, H-4), 4.97 (d, 1H, $J_{1,2}$ 8 Hz, H-1), 4.25–4.10 (2 dd, $J_{6,5}$ 4, $J_{6',5}$ 2, $J_{6,6'}$ 12 Hz, H-6, H-6'), 3.70 (m, 1H, H-5), 2.10–2.02 (4 s, 12H, 4 × CH_3CO). Anal. calcd. for $C_{20}H_{17}F_5O_{10}$: C 46.71, H 3.72; found: C 45.90, H 3.56.

*2'3'-Dinitrophenyl 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranoside:* mp 191–192°C; ^{1}H nmr data: δ ($CDCl_3$) 7.96 (dd, 1H, $J_{4',5'}$ 8, $J_{4'6'}$ 2 Hz, H-4), 7.68 (dd, 1H, $J_{6',5'}$ 8, $J_{6',4'}$ 2 Hz, H-6), 7.62 (dd, 1H, $J_{5',4'}$ 8, $J_{5',6'}$ 8 Hz, H-5), 5.32–5.05 (m, 4H, H-1, H-2, H-3, H-4), 4.24 (d, 2H, $J_{6,5'} = J_{6',5}$ 4 Hz, H-6, H-6'), 3.86 (dt, 1H, $J_{5,4}$ 10, $J_{5,6'}$ 4 Hz, H-5), 2.14–2.03 (4 s, 12H, 4 CH_3CO). Anal. calcd. for $C_{20}H_{22}N_2O_{14}$: C 46.69, H 4.31, N 5.47; found: C 46.32, H 4.51, N 5.42.

*2'5'-Dinitrophenyl 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranoside:* mp 145–147°C; ^{1}H nmr data: δ ($CDCl_3$) 8.23 (d, 1H, $J_{6',4'}$ 2 Hz, H-6), 8.06 (dd, 1H, $J_{4',3'}$ 9, $J_{4',6'}$ 2 Hz, H-4'), 7.89 (d, 1H, $J_{3',4'}$ 9 Hz, H-3'), 5.37–5.06 (m, 4H, H-1, H-2, H-3, H-4), 4.30 (dd, 1H, $J_{6',6}$ 12, $J_{6',5}$ 3 Hz, H-6'), 4.19 (dd, 1H, $J_{6,6'}$ 12, $J_{6,5}$ 6 Hz, H-6), 4.02 (m, 1H, H-5), 2.13–2.02 (4 s, 12H, 4 CH_3CO).

*2'6'-Dichloro-4'-nitrophenyl 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranoside:* mp 181–182°C; ^{1}H nmr data: δ $CDCl_3$) 8.20 (s, 2H, H-3', H-5'), 5.46–5.13 (m, 4H, H-1, H-2, H-3, H-4), 4.18 (dd, 1H, $J_{6,6'}$ 11 Hz, H-6), 4.07 (dd, 1H, $J_{6',6}$ 11, $J_{6',5'}$ 2 Hz, H-6'), 3.65 (m, 1H, H-5), 2.09–2.02 (3 s, 12H, 4 CH_3CO). Anal. calcd. for $C_{20}H_{21}Cl_2NO_8$: C 44.62, H 3.93, N 2.61; found: C 44.39, H 4.06, N 2.79.

*2'6'-Dinitrophenyl 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranoside:* mp 190–191°C; ^{1}H nmr data: δ ($CDCl_3$) 7.98 (d, 2H, $J_{3',5'}$ 8 Hz, H-3', H-5'), 7.47 (t, 1H, $J_{4',5'} = J_{4',3'}$ 8 Hz, H-4'), 5.36–5.08 (m, 4H, H-1, H-2, H-3, H-4), 4.03 (d, 2H, $J_{6,5} = J_{6',5}$ 4 Hz, H-6'), 3.62 (dt, 1H, $J_{5,4}$ 10, $J_{5,6} = J_{5,6'}$ 4 Hz, H-5), 2.13–2.00 (4 s, 12H, CH_3CO). Anal. calcd. for $C_{20}H_{22}N_2O_{14}$: C 46.69, H 4.31, N 5.47, found: C 46.45, H 4.23; N 5.29.

*2',4'-Dinitrophenyl 2,3,6-tri-*O*-acetyl-4-deoxy-4-fluoro-β-D-glucopyranoside*

A solution of 1,2,3,6-tetra-*O*-acetyl-4-deoxy-4-fluoro-β-D-glucopyranose (23) (0.100 g, 0.29 mmol) in 45% HBr/HOAc (3.0 mL) and acetic anhydride (0.30 mL) was stirred for 2 h at room temperature, then cooled to 0°C, diluted with dichloromethane (30 mL), washed five times with ice-cold water, and the organic phase dried with sodium sulfate. Removal of the solvent produced 2,3,6-tri-*O*-acetyl-4-deoxy-4-fluoro-α-D-glucopyranosyl bromide as a colourless syrup, which was crystallized from diethyl ether/hexanes; 90 mg, 0.24 mmol, 85%.

A solution of 2,3,6-tri-*O*-acetyl-4-deoxy-4-fluoro-α-D-glucopyranosyl bromide (90 mg, 0.24 mmol) was dissolved in acetone (0.20 mL) and cooled to 0°C. Water (10 μL) was added, followed by addition of silver carbonate (0.10 g, 0.36 mmol) in small portions. The solution was stirred for 20 h at room temperature in the dark, warmed to 50°C, filtered, and washed with two portions of warm acetone. The solvent was removed from the combined filtrates to produce a brown syrup of 2,3,6-tri-*O*-acetyl-4-deoxy-4-fluoro-D-glucopyranose (64 mg, 0.21 mmol).

Derivatization of 2,3,6-tri-*O*-acetyl-4-deoxy-4-fluoro-D-glucopyranose was performed according to van Boom *et al.* (9) giving the title compound as yellow needles (45 mg, 0.091 mmol); mp 171–173°C; ^{1}H nmr data: δ ($CDCl_3$) 8.72 (d, 1H, $J_{3',5'}$ 3 Hz, H-3'), 8.44 (dd, 1H, $J_{5',6'}$ 10, $J_{5',3'}$ 3 Hz, H-5'), 7.47 (d, 1H, $J_{6',5'}$ 10 Hz, H-6'), 5.50–5.23 (m, 3H, H-1, H-2, H-4), 4.68 (dt, 1H, $J_{F,4}$ 50, $J_{3,4} = J_{4,5}$ 9 Hz, H-4), 4.55 (dd, 1H, $J_{6,6'}$ 12 Hz, H-6), 4.28 (dd, 1H, $J_{6',6}$ 12 Hz, H-6'), 4.20 (m, 1H, H-5), 2.14 (s, 6H, 2CH_3CO), 2.09 (s, 3H, CH_3CO). Anal. calcd. for $C_{18}H_{19}FN_2O_{12}$: C 45.57, H 4.04, N 5.93; found: C 45.50, H 3.82, N 6.01

*2',4'-Dinitrophenyl 2,3,6-tri-*O*-acetyl-4-deoxy-β-D-glucopyranoside*

To a suspension of methyl 2,3,6-tri-*O*-benzoyl-4-deoxy-α-D-glucopyranoside (24) (0.20 g, 0.41 mmol) in methanol (1.0 mL) was added 1 M sodium methoxide in methanol (0.010 mL). The mixture was stirred for 2 days at room temperature, neutralized with Dowex 50W-X8 (H^+) ion exchange resin, and the suspension filtered. The filtrate was concentrated *in vacuo* and the concentrate was purified by column chromatography (9:1 v/v ethyl acetate/methanol). The resulting syrup (72 mg, 88%) was immediately acetylated by addition of a cold (0°C) solution of acetic anhydride (0.37 mL, 3.9 mmol) and pyridine (0.47 mL), warmed to room temperature, and stirred overnight. This was cooled to 0°C, then quenched by addition of methanol and stirred at 0°C for 1 h. The solution was diluted with dichloromethane, washed three times with ice-cold water, and the organic phase was dried with sodium sulfate. Removal of the solvent *in vacuo* afforded methyl 2,3,6-tri-*O*-acetyl-4-deoxy-α-D-glucopyranoside as a colourless syrup, which was crystallized from diethyl ether (87 mg, 0.29 mmol, 71%).

Methyl 2,3,6-tri-*O*-acetyl-4-deoxy-α-D-glucopyranoside was dissolved in dichloromethyl methyl ether (0.40 mL) and a catalytic amount of freshly fused zinc chloride was added. The solution was stirred at 65–70°C for 1 h, then concentrated *in vacuo*, diluted with chloroform, and washed twice with 10 mL of cold saturated aqueous sodium bicarbonate. The organic phase was dried with sodium sulfate and removal of the solvent produced a brown syrup of 2,3,6-tri-*O*-acetyl-4-deoxy-α-D-glucopyranosyl chloride (65 mg).

2,3,6-Tri-*O*-acetyl-4-deoxy-α-D-glucopyranosyl chloride was hydrolysed exactly as described previously for the 4-fluoro derivative to yield a yellow syrup, which was reacted directly with fluoro-2,4-dinitrobenzene according to van Boom *et al.* (9) to yield the title compound as a yellow crystalline solid; mp 180–181°C; ^{1}H nmr data:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12

δ ($CDCl_3$) 8.71 (d, 1H, $J_{3',5'}$ 3 Hz, H-3'), 8.42 (dd, 1H, $J_{5',6'}$ 10, $J_{5',3'}$ 3 Hz, H-5'), 7.48 (d, 1H, $J_{6',5'}$ 10 Hz, H-6'), 5.32–5.05 (m, 3H, H-1, H-2, H-3), 4.22 (d, 2H, $J_{6,6'}$ 7 Hz, H-6, H-6'), 4.40 (m, 1H, H-5). Anal. calcd. for $C_{18}H_{20}N_2O_{12}$: C 47.36, H 4.42, N 6.16; found: C 47.27, H 4.40, N 6.18.

*2',4'-Dinitrophenyl 2,3,4-tri-*O*-acetyl-6-deoxy-β-*D*-glucopyranoside*

1,2,3,4-Tetra-*O*-acetyl-6-deoxy-D-glucopyranose (24) (0.40 g, 1.2 mmol) was brominated at the anomeric centre as described previously for the 4-deoxy sugar. The product was isolated as a white solid (420 mg, 1.06 mmol, 99%), and directly hydrolysed as described previously, using silver carbonate, yielding 2,3,4-tri-*O*-acetyl-6-deoxy-D-glucopyranose as a colourless gum (306 mg, 1.05 mmol). This was derivatized using fluoro-2,4-dinitrobenzene by the general method to afford 2'4'-dinitrophenyl 2,3,4-tri-*O*-acetyl-6-deoxy-β-D-glucopyranoside as white needles (424 mg, 0.93 mmol); mp 198–199°C (lit. (34) mp 152–156°C); ^{1}H nmr data: δ ($CDCl_3$) 8.70 (d, 1H, $J_{3',5'}$ 3 Hz, H-3'), 8.43 (dd, 1H, $J_{5',6'}$ 10, $J_{5',3'}$ 3 Hz, H-5'), 7.45 (d, 1H, $J_{6',5'}$ 10 Hz, H-6'), 5.46–5.20 (m, 3H, H-1, H-2, H-3), 4.95 (m, 1H, H-5), 2.12, 2.08, 2.05 (3 s, 9H, CH_3CO), 1.35 (d, 3H, $J_{6,5}$ 4 Hz, 3 × H-6). Anal. calcd. for $C_{18}H_{20}N_2O_{12}$: C 47.36, H 4.42, N 6.16; found: C 47.34, H 4.35, N 6.10.

*2',4'-Dinitrophenyl 3,4,6-tri-*O*-acetyl-2-deoxy-2-fluoro-β-*D*-glucopyranoside*

3,4,6-Tri-*O*-acetyl-2-deoxy-2-fluoro-α-D-glucopyranosyl bromide (35) (1.4 g) was hydrolysed using silver carbonate, as described previously, yielding 3,4,6-tri-*O*-acetyl-2-deoxy-2-fluoro-D-glucopyranose as a colourless gum. This was dissolved in DMF (10 mL) containing DABCO (1.5 g), stirred over 4A molecular sieves for 15 min, then a solution of fluoro-2,4-dinitrobenzene (0.9 g) in DMF (5 mL) added. After 1.5 h the solution was filtered, and the solvent removed by evaporation under vacuum. The residual oil was redissolved in chloroform, washed twice with saturated aqueous sodium bicarbonate, then twice with water, and dried over sodium sulfate. Evaporation of the solvent yielded an oil, which crystallized spontaneously upon addition of ethanol giving a mixture of the α(20%)- and β(80%)-glycosides (0.99 g). This solid was dissolved in a minimal volume of hot ethyl acetate and, upon cooling to room temperature, the pure α-glucoside crystallized out. After filtration, petroleum ether was added to induce crystallization of the β-glycoside. This process was repeated twice, giving a mixture of the α(5%)- and β(95%)-glycosides as a crystalline solid. Pure β-glycoside was obtained by preparative thin-layer chromatography (silica; 1.2:1 ethyl acetate/petroleum ether) and recrystallized from ethyl acetate/petroleum ether; mp 145–147°C; ^{1}H nmr data: δ ($CDCl_3$) 8.77 (d, 1H, $J_{3',5'}$ 2.6 Hz, H-3'), 8.50 (dd, 1H, $J_{5',6'}$ 9.3, $J_{5',3'}$ 2.5 Hz, H-5'), 7.41 (d, 1H, $J_{6',5'}$ 9.3 Hz, H-6'), 5.52–5.39 (m, 2H, H-3, H-1), 5.15 (t, 1H, $J_{4,3} = J_{4,5}$ 9.7 Hz, H-4), 4.73 (ddd, 1H, $J_{2,F}$ 49.5, $J_{2,3}$ 8.9, $J_{2,1}$ 7.4 Hz, H-2), 4.28 (dd, 1H, $J_{6,6'}$ 14.6, $J_{6,5}$ 5.4 Hz, H-6), 4.20 (dd, 1H, $J_{6',6}$ 14.6, $J_{6',5}$ 2.9 Hz, H-6'), 3.95 (ddd, 1H, $J_{5,4}$ 9.7, $J_{5,6}$ 5.4, $J_{5,6'}$ 2.9 Hz, H-5), 2.14 (s, 3H, CH_3CO), 2.08 (s, 6H, CH_3CO). Anal. calcd. for $C_{18}H_{19}N_2O_{12}F$: C 45.48, H 4.04, N 5.91; found: C 45.10, H 4.18, N 5.69.

2,4-Dinitrobenzylchloride

A mixture of nitric acid (7 mL) and sulfuric acid (12 mL) was added with stirring to a suspension of 4-nitrobenzylchloride (11.4 g, 55 mmol) in sulfuric acid (52 mL) at 0°C, stirred at 0°C for 30 min, then at room temperature for 1 h. The mixture was poured onto ice and extracted with chloroform; the combined chloroform extracts were washed with cold water until the aqueous layer was neutral to pH paper, then dried with sodium sulfate and the chloroform removed *in vacuo*, producing a red oil. The oil was purified by flash chromatography (silica; 3:1 petroleum ether/ethyl acetate) to afford the product as a yellow oil, which solidified upon cooling (11.6 g, 43 mmol, 81%); ^{1}H nmr data: δ ($CDCl_3$) 8.91 (d, 1H, H-3), 8.53 (dd, 1H, H-5), 8.05 (d, 1H, H-6), 5.10 (s, 2H, $-CH_2-$).

2,4-Dinitrobenzylmethyl sulfide

The sulfide was prepared by the method of Russell and Pecoraro (27) as follows. 2,4-Dinitrobenzylchloride (8.02 g, 37 mmol) in methanol (100 mL) was added slowly, under nitrogen, to a 2.5 M solution of sodium (70 mmol) and methyl mercaptan in methanol (28 mL) at 0°C (28). After stirring for 15 min, the mixture was acidified with 1 M hydrochloric acid, diluted with water, and extracted with ether. The combined ether extracts were washed with water until the aqueous layer was neutral, dried with magnesium sulfate, and concentrated *in vacuo* to produce a red solid. Purification by flash chromatography (silica; 5:1 petroleum ether/ethyl acetate) afforded 2,4-dinitrobenzylmethyl sulfide as yellow crystals (5.78 g, 25 mmol, 68%); ^{1}H nmr data: δ ($CDCl_3$) 8.83 (d, 1H, H-3), 8.41 (dd, 1H, H-5), 7.72 (d, 1H, H-6), 4.11 (s, 1H, $-CH_2-$), 2.05 (s, 3H, $-CH_3$).

2,4-Dinitrobenzylmethyl sulfoxide

2,4-Dinitrobenzylmethyl sulfide (0.830 g, 3.64 mmol) in methylene chloride (1.0 mL) was cooled to −20°C and a solution of *m*-chloroperbenzoic acid (0.628 g, 3.64 mmol) in methylene chloride (6.0 mL) was added under nitrogen. The mixture was stirred for 20 h, at which time tlc (silica; ethyl acetate) showed one major product (R_f = 0.14) plus a very small amount of a component later identified as 2,4-dinitrobenzylmethyl sulfone (R_f = 0.54). The sulfoxide product was separated by flash chromatography, eluting first with ethyl acetate to remove the sulfone by-product and any residual starting material, then with methanol. The sulfoxide was isolated as a yellow solid, which was crystallized from warm ethanol (0.650 g, 2.66 mmol, 73%); mp 125–127°C; ir data: (KBr pellet) 1049 cm^{-1} (S=O stretch); ^{1}H nmr data: δ ($CDCl_3$) 9.02 (d, 1H, H-3), 8.54 (dd, 1H, H-5), 7.80 (d, 1H, H-6), 4.48 (m, 2H, $-CH_2-$), 2.73 (s, 3H, $-CH_3$); ms data: *m/z* 244, M^+ for $C_8H_8N_2O_5S$. Anal. calcd. for $C_8H_8N_2O_5S$: C 39.32, H 3.31, N 11.52; found: C 39.85, H 3.28, N 11.40.

Anomerization reactions

Tests for anomerization of substrates were performed by dissolving the aryl β-glycoside (0.036 mmol) over 3A molecular sieves in anhydrous DMSO (0.2 mL) containing anhydrous potassium carbonate (0.10 mmol). Reaction was monitored by tlc (1:1 ethyl acetate/petroleum ether) and product composition was confirmed by ^{1}H nmr of the isolated product mixture. Typically, anomerization was complete in approximately 20 h. Exchange reactions were also carried out by this method, but with the addition of appropriate potentially exchangeable compounds.

Isolation of the product α-2,4-DNPG, when necessary, was achieved by the following method. The reaction mixture was diluted with chloroform, filtered, and concentrated *in vacuo* to a red syrup, which was redissolved in chloroform, washed twice with 10% aqueous sodium bicarbonate, and twice with water. The organic phase was dried over magnesium sulfate, concentrated to a yellow syrup, dissolved in warm 95% ethanol, and allowed to cool to room temperature when the α-2,4-DNPG crystallized out. Further cooling yielded a mixture of α and β anomers. If necessary, separation of the anomers could be achieved readily by flash chromatography (silica; 97:3 chloroform/acetone).

Kinetic studies

All kinetic studies were performed by using ^{1}H nmr to follow the reaction. Reactions were performed in DMSO-d_6 solutions containing bis(tetramethylammonium) carbonate as catalyst. Solutions of both the aryl glycoside and the carbonate catalyst were prepared separately under anhydrous conditions. The solution of carbonate was introduced into the 5-mm nmr tube and frozen at −70°C, then the solution of glycoside was layered on top and frozen. Samples were stored in sealed tubes at −70°C until needed, then reaction initiated by warming to 25°C and mixing. The ^{1}H nmr spectra were recorded at 25°C at appropriate time intervals. Rates of disappearance of the β-glycoside and appearance of the α-glycoside were estimated by integration of both the anomeric proton resonances and the aromatic proton H-6' resonance. The total integral measured for the acetate resonances (δ 2.2–2.0) was used for standardization. Rate constants were calculated using a plot of log ($B_t - B_e$) against time, where B_t is the con-

centration of β anomer remaining at time t and B_e is the concentration of β anomer at equilibrium. Such plots were linear ($p > 0.98$) for at least two half-lives. A linear regression analysis was used to extract rate constants. Errors in reported values are ± 5% on single runs. The kinetic isotope effect reported was measured in the same manner, using four pairs of substrates (protiated and deuterated). The value reported is calculated from the average of the four rate constants determined for protiated material and the four rate constants for the deuterated material.

An efficient route to vinylporphyrins

PAUL YON-HIN, TILAK WIJESEKERA, AND DAVID DOLPHIN[1]

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received April 3, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

PAUL YON-HIN, TILAK WIJESEKERA, and DAVID DOLPHIN. Can. J. Chem. **68**, 1867 (1990).

The use of 1-bromo-19-methylbiladienes-ac in the synthesis of vinylporphyrins is described. The effect of the vinyl precursors on the reactions of the dipyrromethene intermediates and the construction of the linear tetrapyrrole are discussed. High-yield syntheses of a methylvinylporphyrin, an H-vinyl analogue, as well as two A,C-divinylporphyrins are presented.

Key words: pyrrole, dipyrromethene, acetoxyethylpyrrole, chloroethylpyrrole, biladiene-ac, porphyrin, vinylporphryin, benzoporphyrin, decarboxylation, transesterification.

PAUL YON-HIN, TILAK WIJESEKERA et DAVID DOLPHIN. Can. J. Chem. **68**, 1867 (1990).

On décrit l'utilisation des 1-bromo-19-méthylbiladiènes-ac dans la synthèse des vinylporphyrines. On discute de l'effet des précurseurs vinyles sur les réactions des intermédiaires dipyrrométhènes et sur la construction du tétrapyrrole linéaire. On rapporte des synthèses avec rendements élevés d'une méthylvinylporphyrine, d'un analogue H-vinyle ainsi que de deux A,C-divinylporphyrines.

Mots clés: pyrrole, dipyrrométhène, acétoxyéthylpyrrole, chloroéthylpyrrole, biladiène-ac, porphyrine, vinylporphyrine, benzoporphyrine, dicarboxylation, transesterification.

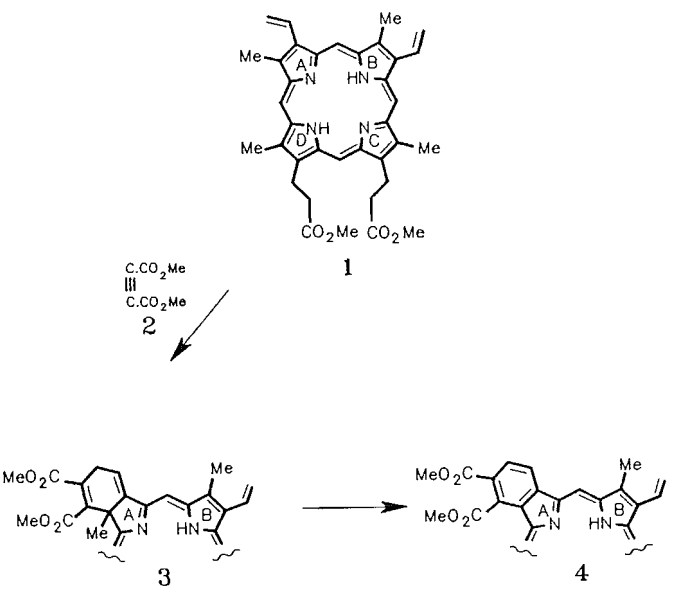
Introduction

Porphyrins and related macrocycles bearing peripheral vinyl substituents play an important role in the vital functioning of living organisms (1). Of particular interest is heme, the iron(II) complex of protoporphyrin IX (**1**), which is the prosthetic group of hemoglobin, myoglobin, and several heme enzymes. Because of their biological significance, synthesis of vinylporphyrins has received special attention, particularly in structure/function (2–6) and isotopic labelling studies (7–9). In addition, the vinyl and cross-conjugated porphyrinic β,β′ double bonds of protoporphyrin IX (**1**) have been shown (10, 11) to undergo [4+2] cycloaddition reactions with electron-deficient dienophiles to give compounds (**3**) having essentially a *chlorin* chromophore (Scheme 1). With alkynes (**2**), the initially formed cycloadducts, under certain reaction conditions, undergo aromatization (12) with the concomitant loss of the angular methyl group to give benzoporphyrins (**4**). To study this cycloaddition reaction further, we have developed, and describe here, an efficient synthesis of vinylporphyrins.

Although peripheral substituent manipulations of protoporphyrin IX have been used to prepare several useful porphyrins (13), synthesis of a totally unsymmetrical porphyrin involves the stepwise coupling of individual pyrroles, leading to a linear tetrapyrrole, which is cyclized in the final step. Two of the most commonly used tetrapyrrolic precursors are 1,19-dimethylbilenes-b and 1,19-dimethylbiladienes-ac (14), which are converted to the porphyrin using cupric salts in refluxing solvents (e.g., dimethylformamide). This method, originally developed by Johnson and Kay (15), has since been successfully modified for the synthesis of several vinylporphyrins (2–9) and other unsymmetrically substituted porphyrins. However, the varying yields (20–50%) of porphyrin produced and the harsh acidic conditions required (H_2SO_4–CF_3CO_2H) to remove coordinated Cu after cyclization are notable disadvantages of this method.

Our approach to unsymmetrical porphyrins has been via 1-bromo-19-methylbiladienes-ac (**7**), which are prepared by the stannic chloride mediated coupling of a 5′-unsubstituted



SCHEME 1

5-methyldipyrromethene (**5**) with a 5-bromo-5′-bromomethyldipyrromethene (**6**) and cyclized to the porphyrin (**8**) in DMSO–pyridine at room temperature, each reaction producing a greater than 80% yield (Scheme 2). This method, originally described by Johnson and co-workers (16, 17), suffered from a major drawback, viz. the traditional preparation of dipyrromethene **6** by the bromination of dipyrromethene **5** in hot anhydrous acetic or formic acid produced varying results, with yields of 50% being considered exceptional. However, the mild room temperature bromination procedure developed by us (18) (bromine in 10–15% TFA–1,2-dichloroethane) increased the accessibility of this important dipyrrolic intermediate and thereby made this route more versatile (19). We report here the syntheses of four vinylporphyrins using this method: a methylvinyl and an H-vinyl analogue (**8***a* and **8***b*), which have been used to study the regio- and stereochemistry of Diels–Alder additions as well as transformation to benzoporphyrins, and, in

addition, ring A,C-divinylporphyrins (**8***c* and **8***d*) have been prepared and used for a high yield synthesis of bacteriochlorins via two simultaneous Diels–Alder reactions.

Results and discussion

The sensitive nature of the vinyl substituent requires that a two-carbon vinyl precursor be carried through most of the synthetic sequence, with generation of the vinyl group being delayed until the final stages. The two most commonly used precursors are the 2-chloroethyl group (20) (derived from methoxycarbonylmethyl) and the acetyl group (21), the latter being transformed to the vinyl via the 1-hydroxyethyl moiety. Scheme 3 outlines the synthesis of the unsymmetrical porphyrins **8***a* and **8***b*; the cycloaddition reactions of the latter leading to benzoporphyrins have already been reported (22). Retrosynthetic analysis of the target porphyrins clearly indicated that the northern half carrying the reactive centres should constitute the 5′-unsubstituted 5-methyldipyrromethene components **20** and **21**. Of the two monopyrrolic precursors required for each synthesis, the common 5-unsubstituted 2-formylpyrrole (**19**) was prepared in high yield as reported earlier (23). The dipyrromethene **20** was obtained in 90% yield by coupling pyrrole **19** with 4-(methoxycarbonyl)methyl-3,5-dimethylpyrrole-2-carboxylic acid (**10**) (24) in the presence of 48% aqueous hydrobromic acid, the decarboxylation occurring *in situ*.

The α,β-diunsubstituted pyrrole **18** necessary for the synthesis of the dipyrromethene **21** was obtained from pyrrole **11** (Scheme 3), which in turn was prepared from benzyl acetoacetate and diethyl 3-oxopentanedioate as described earlier (25). Following catalytic debenzylation using 10% Pd–C, the resulting pyrrole-4-carboxylic acid (**12**) was decarboxylated by an indirect iodinative–deiodinative procedure (the electron-withdrawing 2-ethoxycarbonyl group prevents direct decarboxylation) to give the β-unsubstituted pyrrole (**14**) in 60% overall yield (from **11**). To manipulate the α-ester for pyrrole coupling, compound **14** was transbenzylated to the bis-benzyl ester **15** and preferentially transmethylated with sodium methoxide in methanol–THF at room temperature to give benzyl 3-(methoxycarbonyl)methyl-5-methylpyrrole-2-carboxylate (**16**) in 77% overall yield. Debenzylation of **16** to pyrrole-2-carboxylic acid **17** and coupling with the formylpyrrole **19** in the usual manner resulted in a low yield of the dipyrromethene **21**, suggesting that the replacement of an alkyl group at the 4-position by a hydrogen atom deactivated the ring towards electrophilic substitution. To overcome this problem, **17** was first decarboxylated to the diunsubstituted pyrrole **18** with trifluoroacetic acid at room temperature. Removal of the electron-withdrawing carboxyl group increased the nucleophilicity of the ring system and the coupling with **19** proceeded smoothly.

The dipyrromethenes **20** and **21** in dichloromethane were condensed separately with the 5-bromo-5′-bromomethyldipyrromethene **22** (18) using stannic chloride as the catalyst to give the biladienes **23** and **24** respectively in over 90% yield. They in turn, when treated with DMSO–pyridine, cyclized to the porphyrins **25** and **28** in over 80% yield. The transformation of the methoxycarbonylmethyl to the required vinyl substituent was effected via 2-hydroxyethyl and 2-chloroethyl groups. For best results, the porphyrins **25** and **28** were metalated (Zn) prior to reduction with lithium aluminum hydride and subsequently demetalated; this avoids any complications that may arise due to the possible irreversible insertion of aluminum. The porphyrins **26** and **29** so obtained (>95% yield) were converted to the 2-chloroethyl analogs **27** and **30** using thionyl chloride (95% yield) and dehydrochlorinated (aqueous NaOH in pyridine) to the vinylporphyrins **8***a* and **8***b* in 85% yield.

The substituents in the ring A,C-divinylporphyrins **8***c* and **8***d* (Scheme 2) were arranged to give the molecules a twofold axis of symmetry so that the 5-bromo-5′-bromomethyldipyrromethene (**6**) could be obtained by the direct bromination of 5′-unsubstituted 5-methyldipyrromethene (**5**). However, bro-

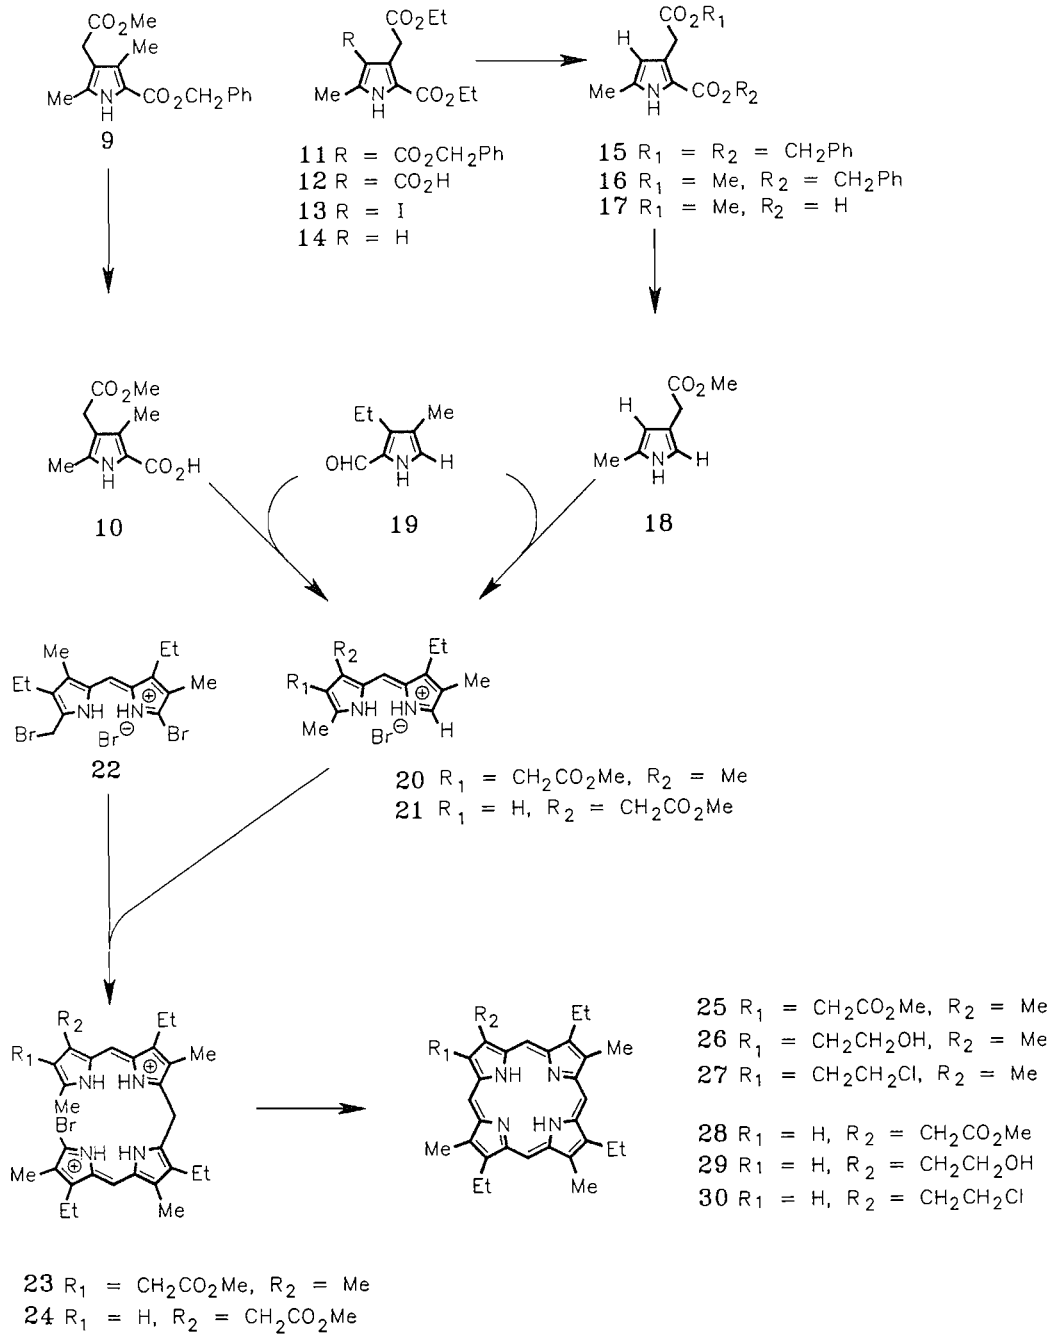

SCHEME 3

mination of the dipyrromethene **20** (Scheme 3), using bromine in 10–15% trifluoroacetic acid/1,2-dichloroethane turned out to be rather slow, giving at best a 70% yield of the bromomethyl derivative in 2 weeks. This required that the vinyl precursor be modified prior to bromination.

Scheme 4 outlines the synthetic sequence used. The common monopyrrolic precursor **33** was prepared starting from 4-(methoxycarbonyl)methylpyrrole **9**, by diborane reduction to 4-(2-hydroxyethyl)pyrrole **31**, protecting as the 4-(2-acetoxyethyl) derivative (**32**) followed by catalytic debenzylation of the α-ester group. 2-Formyl-3-ethyl-4-methylpyrrole (**19**) (23) and 2-formyl-3-(2-methoxycarbonyl)ethylpyrrole (**38**) (25) were synthesized according to literature procedures. Acid-catalyzed condensation of the pyrrole pairs **19, 33** and **38, 33** afforded the dipyrromethenes **39** and **40** in high yield. The former was successfully brominated (85% yield) with bromine in 10–15% TFA–1,2-dichloroethane, and the product, 5-bromo-5′-bromomethyldipyrromethene (**41**), coupled with **39** itself in the presence of anhydrous stannic chloride to give the biladiene-ac **43** in 79% yield. However, the bromination of the 2-(methoxycarbonyl)ethyl analog **40** under the same conditions was incomplete after 1 week, with the isolated material exhibiting approximately 80% reaction at the α-methyl group. To maximize the yield of the biladiene-ac **44**, the brominated product **42** was coupled, *without isolation* (after removal of excess bromine), with the α-unsubstituted dipyrromethene **40** to give an overall yield of 59% (from **40**). The biladienes **43** and **44** were subsequently cyclized in DMSO–pyridine to give the bis(2-acetoxyethyl)porphyrins **45** and **48** in over 85% yield. Removal of the acetoxy protection using 5% H_2SO_4 – methanol,

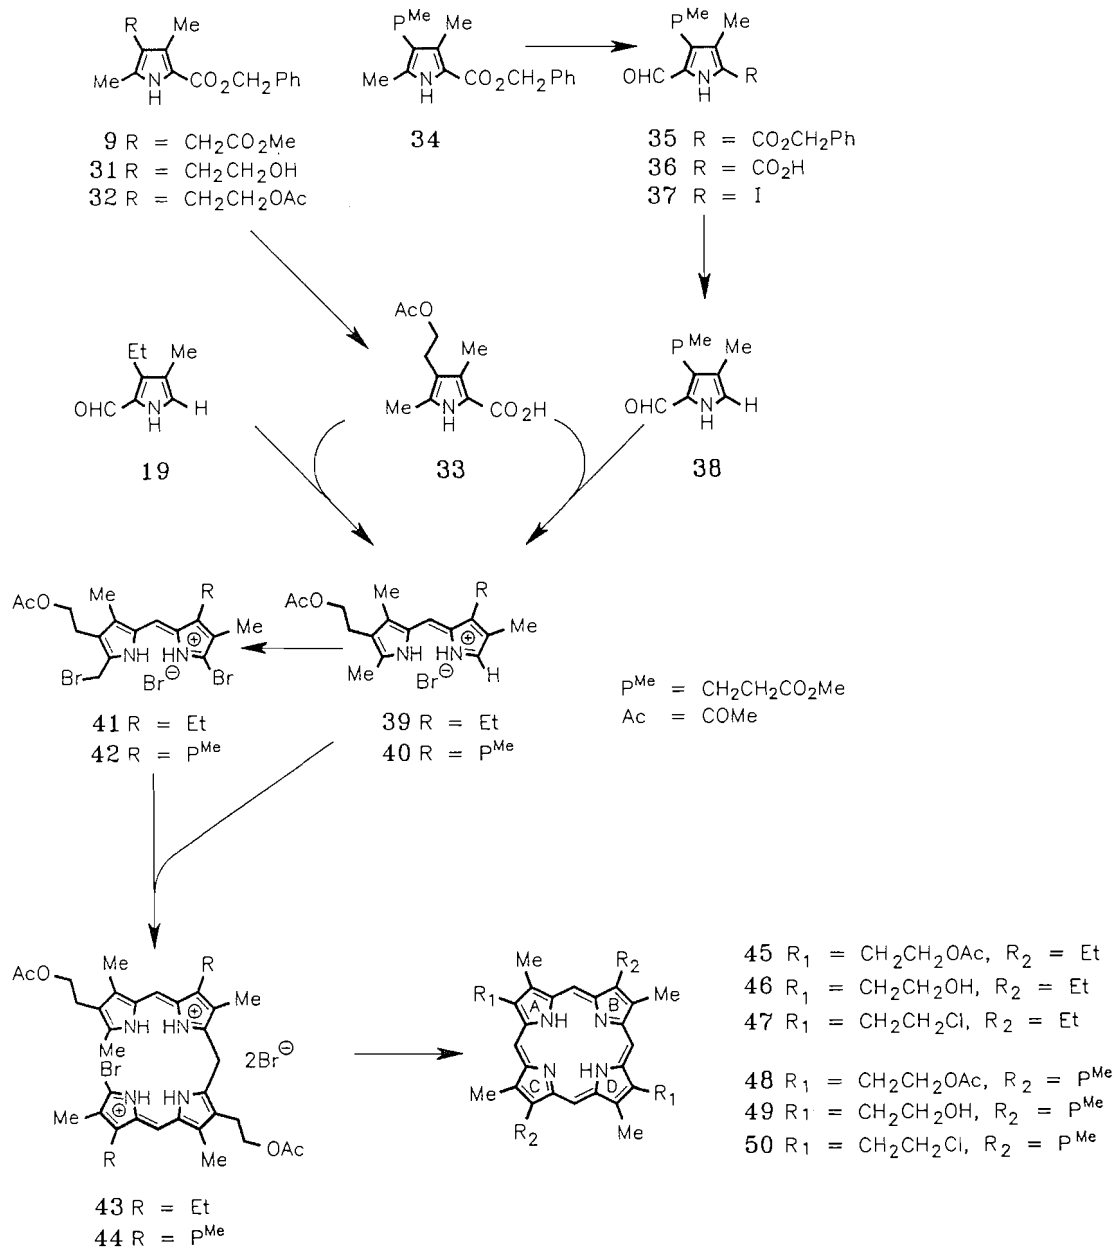

SCHEME 4

chlorination with thionyl chloride, and dehydrochlorination with aqueous NaOH in pyridine afforded the ring A,C-divinyl porphyrins **8***c* and **8***d* in high yield.

Experimental

The ^{1}H nmr spectra were recorded in the indicated solvents on a Varian XL-300 or a Bruker WH-400 spectrometer. Low resolution mass spectra were recorded on either a Varian MAT CH4B or a Kratos-AEI MS-50 instrument while high resolution measurements were obtained on the latter instrument. Melting points were determined using a Thomas Kofler Micro Hot Stage apparatus (dipyrromethenes and biladienes decompose rather than melt cleanly).

*Ethyl 4-carboxy-3-(ethoxycarbonyl)methyl-5-methylpyrrole-2-carboxylate (**12**)*

Ethyl-4-benzyloxycarbonyl-3-ethoxycarbonylmethyl-5-methylpyrrole-2-carboxylate (**11**) (37.3 g, 0.10 mol) in THF (500 mL) containing triethylamine (5 drops) and 10% Pd–C (1.5 g) was hydrogenated to completion at room temperature and atmospheric pressure. The catalyst was filtered, the filtrate evaporated to dryness, and the residue redissolved in hot ethanol (300 mL) and crystallized by the addition of water. The product, a white powder, was collected by filtration, washed with water, and dried. Yield 25.0 g (88%), mp 244–246°C; ^{1}H nmr (DMSO-d_6) δ: 1.25 (t, 3H, OCH_2CH_3), 1.32 (t, 3H, OCH_2CH_3), 4.10 (q, 2H, OCH_2CH_3), 4.15 (s, 2H, $CH_2CO_2C_2H_5$), 4.30 (q, 2H, OCH_2CH_3), 8.00 (s, 1H, NH), 11.80 (s, 1H, CO_2H); ms (*m/z*); 283 (M^+), 265, 236. Anal. calcd. for $C_{13}H_{17}NO_6$: C 55.12, H 6.05, N 4.94; found: C 55.07, H 6.10, N 4.85.

*Ethyl 3-(ethoxycarbonyl)methyl-4-iodo-5-methylpyrrole-2-carboxylate (**13**)*

To a hot solution of $NaHCO_3$ (35.0 g) in water (150 mL) was added the carboxypyrrole **12** (23.0 g, 81.3 mmol), and 1,2-dichloroethane (150 mL) added with stirring. A solution of I_2 (25 g) and NaI (30 g) in water (150 mL) was carefully added over 5 min and the reaction mixture refluxed for 15 min. The excess I_2 was destroyed by cautious

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

addition of aqueous $NaHSO_3$ and the reaction mixture extracted with dichloromethane. The organic phase was filtered, the solvent removed under reduced pressure, and the residual yellowish-brown oil dissolved in warm ethanol. Water was added until the solution turned turbid and, on cooling, the iodopyrrole crystallized out as pale yellow crystals that were filtered, washed with 65% aqueous ethanol, and air dried. Yield 25.6 g (86%), mp 110–111°C; ^{1}H nmr ($CDCl_3$) δ: 1.30 (2t, overlapping, 6H, 2 × OCH_2CH_3), 2.30 (s, 3H, CH_3), 3.80 (s, 2H, $CH_2CO_2C_2H_5$), 4.20 (q, 2H, OCH_2CH_3), 4.30 (q, 2H, OCH_2CH_3), 9.50 (br s, 1H, NH); ms (*m/z*): 365 (M^+), 320, 319, 292. Exact mass calcd. for $C_{12}H_{16}NO_4I$: 365.0123; found: 365.0123.

*Ethyl 3-(ethoxycarbonyl)methyl-5-methylpyrrole-2-carboxylate (**14**)*

The iodopyrrole **13** (21.3 g, 58 mmol) was dissolved in boiling methanol (150 mL) and treated with a solution of NaI (18 g) in water (20 mL), followed immediately by concentrated HCl (10 mL). The solution turned dark brown with liberation of iodine. The mixture was refluxed for 10 min, cooled to room temperature, and solid $NaHSO_3$ was added to destroy the iodine. Water (150 mL) was added to dissolve the excess bisulfite and the mixture extracted with dichloromethane (3 × 100 mL). The combined organic layers were washed with saturated $NaHCO_3$ (2 × 200 mL) and water (200 mL), dried over anhydrous $MgSO_4$, and concentrated to give a pale yellow oil. The oil was dissolved in ether (30 mL) and *n*-hexane added dropwise to induce crystallization. The white crystals were collected by filtration, washed with *n*-hexane, and air dried. Yield 11.0 g (79%), mp 80–81°C; ^{1}H nmr ($CDCl_3$) δ: 1.28 (t, 3H, OCH_2CH_3), 1.35 (t, 3H, OCH_2CH_3), 2.30 (s, 3H, CH_3), 3.82 (s, 2H, $CH_2CO_2C_2H_5$), 4.18 (q, 2H, OCH_2CH_3), 4.30 (q, 2H, OCH_2CH_3), 5.95 (s, 1H, pyr-H), 8.92 (br s, 1H, NH); ms (*m/z*): 239 (M^+), 193, 166. Exact mass calcd. for $C_{12}H_{17}NO_4$: 239.1158; found: 239.1155.

*Benzyl 3-(benzyloxycarbonyl)methyl-5-methylpyrrole-2-carboxylate (**15**)*

The pyrrole (**14**) (6.0 g, 25.2 mmol) in refluxing benzyl alcohol (150 mL) was treated, under nitrogen, with 1-mL portions of a concentrated solution of sodium benzyloxide (prepared from freshly cut sodium in benzyl alcohol) until no further evolution of ethanol vapors occurred. The hot solution was poured into a stirred solution of methanol (100 mL) and acetic acid (10 mL), diluted with water, and cooled. The precipitated solid was collected by filtration, washed with 50% aqueous methanol, then with water, and air dried to give the desired product as colourless crystals. Yield 7.78 g (85%), mp 92–93°C; ^{1}H nmr ($CDCl_3$) δ: 2.24 (s, 3H, CH_3), 2.86 (s, 2H, $CH_2CO_2CH_2C_6H_5$), 5.08 (s, 2H, $CH_2C_6H_5$), 5.21 (s, 2H, $CH_2C_6H_5$), 5.92 (s, 1H, pyr-H), 7.32 (m, 10H, 2 × C_6H_5), 8.70 (br s, 1H, NH); ms (*m/z*): 363 (M^+), 228, 91. Exact mass calcd. for $C_{22}H_{21}NO_4$: 363.1471; found: 363.1470.

*Benzyl 3-(methoxycarbonyl)methyl-5-methylpyrrole-2-carboxylate (**16**)*

A solution of the pyrrole **15** (6.0 g, 17 mmol) in dry tetrahydrofuran (20 mL) and anhydrous methanol (25 mL) was stirred at room temperature under argon with a solution of sodium methoxide (63.3 mg of sodium in 5 mL of methanol). When tlc indicated that no starting material remained, the reaction was quenched with acetic acid (10 mL) and the solution concentrated to a pale yellowish-brown oil, which was dissolved in a minimum of methanol and treated with water to afford a precipitate of tan crystals. The solid was recrystallized from ether–hexane to give the product as colourless crystals (4.30 g, 91%), mp 82–84°C; ^{1}H nmr ($CDCl_3$) δ: 2.25 (s, 3H, CH_3), 3.65 (s, 3H, CO_2CH_3), 3.82 (s, 2H, CH_2CO_2CH3), 5.30 (s, 2H, $CH_2C_6H_5$), 5.95 (s, 1H, pyr-H), 7.40 (m, 5H, C_6H_5), 8.90 (br s, 1H, NH); ms (*m/z*): 287 (M^+), 196, 153, 91. Anal. calcd. for $C_{16}H_{17}NO_4$: C 66.89, H 5.96, N 4.88; found: C 66.69, H 5.95, N 4.84.

*3-(Methoxycarbonyl)methyl-5-methylpyrrole-2-carboxylate (**17**)*

The pyrrole **16** (4.0 g, 14 mmol) in THF (400 mL) containing triethylamine (0.1 mL) and 10% Pd–C (0.4 g) was hydrogenated as described earlier and the resulting pale yellow oil was crystallized from THF–hexane to give the desired product as a white powder (2.6 g, 95%), mp 190°C (dec.); ^{1}H nmr (DMSO-d_6) δ: 2.10 (s, 3H, CH_3), 3.60 (s, 3H, OCH_3), 3.76 (s, 2H, $CH_2CO_2CH_3$), 5.80 (s, 1H, pyr-H), 11.22 (br s, 1H, NH), CO_2H too broad to be observed; ms (*m/z*): 153 ($M^+ - CO_2$), 94. Exact mass calcd. for $C_8H_{11}NO_2$: 153.0790; found: 153.0791.

*4-Methoxycarbonylmethyl-2-methylpyrrole (**18**)*

The foregoing pyrrolecarboxylic acid **17** (2.50 g, 12.7 mmol) was stirred in trifluoroacetic acid (20 mL) under nitrogen for 30 min (reaction monitored by tlc). The trifluoroacetic acid was evaporated *in vacuo*, the residual oil dissolved in dichloromethane (50 mL), washed twice with aqueous $NaHCO_3$, and dried ($MgSO_4$). The filtered solution was evaporated to a yellow oil, which was purified by column chromatography (silica gel 60, dichloromethane eluent) to give the product as a colourless oil (1.85 g, 95%) that could not be induced to crystallize; ^{1}H nmr ($CDCl_3$) δ: 2.30 (s, 3H, CH_3), 3.50 (s, 2H, $CH_2CO_2CH_3$), 3.70 (s, 3H, CO_2CH_3), 5.85 (s, 1H, 4-H), 6.56 (s, 1H, 2-H), 7.86 (br s, 1H, NH); ms (*m/z*): 153 (M^+), 94. Exact mass calcd. for $C_8H_{11}NO_2$: 153.0790; found: 153.0796.

*3′-Ethyl-4-(methoxycarbonyl)methyl-3,4′,5-trimethyl-2,2′-dipyrromethene hydrobromide (**20**)*

3-Ethyl-2-formyl-4-methylpyrrole (**19**) (23) (3.01 g, 21 mmol) and 2-carboxy-4-methoxycarbonylmethyl-3,5-dimethylpyrrole (**10**) (25) (4.22 g, 20 mmol) were dissolved in THF (110 mL) and treated with aqueous HBr (48%, 5 mL). The colour of the solution changed from yellow to dark orange. The solvent was replaced under reduced pressure by adding methanol at regular intervals. The reaction mixture was cooled in an ice bath, the precipitated product filtered, washed with 10% methanol – ether, then with ether, and air dried. Yield 5.15 g (90%), mp 160°C (dec.); ^{1}H nmr ($CDCl_3$) δ: 1.17 (t, 3H, J = 7.5 Hz, CH_2CH_3), 2.10 (s, 3H, CH_3), 2.35 (s, 3H, CH_3), 2.70 (q, 2H, CH_2CH_3), 2.75 (s, 3H, CH_3), 3.67 (s, 3H, OCH_3), 3.71 (s, 2H, CH_2CO), 7.17 (s, 1H, bridge CH), 7.57 (d, 1H, J = 4.0 Hz, pyr-H), 13.23 (br s, 2H, 2 × NH); ms (*m/z*): 286 ($M^+ - HBr$), 271. Exact mass calcd. for $C_{17}H_{22}N_2O_2$: 286.1681; found: 286.1685.

*3′-Ethyl-3-(methoxycarbonyl)methyl-4′,5-dimethyl-2,2′-dipyrromethene hydrobromide (**21**)*

3-Ethyl-2-formyl-4-methylpyrrole (**19**) (1.66 g, 12.1 mmol) and 4-(methoxycarbonyl)methyl-2-methylpyrrole (**18**) in methanol were cooled to 0°C and treated with aqueous HBr (48%, 2 mL). The mixture was stirred for 30 min, when the solution darkened and the product crystallized. The crystals were collected, washed successively with cold methanol, ether, and hexane, and air dried. Yield 3.22 g in three crops (75%), mp 120–121°C; ^{1}H nmr ($CDCl_3$) δ: 1.22 (t, 3H, CH_2CH_3), 2.15 (s, 3H, CH_3), 2.76 (q, 2H, CH_2CH_3), 2.80 (s, 3H, CH_3), 3.80 (s, 3H, OCH_3), 3.82 (s, 2H, CH_2CO), 6.40 (s, 1H, 4-H), 7.30 (s, 1H, bridge CH), 7.62 (d, 1H, J = 3.0 Hz, 5-H), 13.50 (br s, 2H, 2 × NH); ms (*m/z*): 272 ($M^+ - HBr$), 257, 243. Exact mass calcd. for $C_{16}H_{20}N_2O_2$: 272.1725; found: 272.1728.

*4-(2-Acetoxyethyl)-3′-ethyl-3,4′,5-trimethyl-2,2′-dipyrromethene hydrobromide (**39**)*

Benzyl-4-(2-acetoxyethyl)-3,5-dimethylpyrrole-2-carboxylate (**32**) (20 g, 63 mmol) in THF (300 mL) containing triethylamine (5 drops) and 10% Pd–C (2.0 g) was hydrogenated at room temperature and atmospheric pressure. The catalyst was filtered, and the filtrate treated with a solution of pyrrole **19** (9.6 g, 70 mmol) in THF (75 mL) followed by aqueous HBr (48%, 70 mL). The solvent was slowly replaced with methanol under reduced pressure until crystallization occurred. The orange crystals were filtered, washed with methanol, and air dried. Yield 19 g in two crops (79%), mp 146°C (dec.); ^{1}H nmr ($CDCl_3$/TFA) δ: 1.18 (t, 3H, J = 7.5 Hz, CH_2CH_3), 2.00 (s, 3H, CH_3), 2.04 (s, 3H, CH_3), 2.35 (s, 3H, $COCH_3$), 2.65 (s, 3H, CH_3), 2.75 (m, overlap, 4H, CH_2CH_3 and CH_2CH_2O-), 4.10 (t, 2H, J = 6.5 Hz, CH_2CH_2O-), 6.80 (s, 1H, bridge CH), 7.45 (d, 1H, J = 3.2 Hz, pyr-H), 12.80 (br s, 1H, NH), 13.00 (br s, 1H, NH). Anal. calcd. for $C_{19}H_{27}N_2BrO_2$: C 57.22, H 6.88, N 7.09; found: C 57.68, H 6.85, N 7.05.

*4-(2-Acetoxyethyl)-3'-[(methoxycarbonyl)ethyl]-3,4',5-trimethyl-2,2'-dipyrromethene hydrobromide (**40**)*

The pyrrole **32** (25), (1.35 g, 4.3 mmol) in THF (35 mL) containing triethylamine (5 drops) and 10% Pd–C (140 mg) was hydrogenated as described above. The 2-formylpyrrole **38** (24) (0.85 g, 4.4 mmol) was added, the catalyst filtered, and the volume reduced to 15 mL. Methanol (35 mL) was added, the solution warmed on a water bath and treated with aqueous HBr (1 mL). Following 5 min of heating, trimethyl orthoformate (1 mL) was added and heating was continued for a further 5 min. The solution was concentrated *in vacuo* (ca. 15 mL), diluted with diethyl ether (50 mL), and cooled. The solid was collected by filtration, washed with 5% methanol – diethyl ether, then with ether, and dried in air. Yield 1.67 g (89%), mp 157–159°C; ^{1}H nmr ($CDCl_3$/TFA) δ: 2.05 (s, 3H, CH_3), 2.11 (s, 3H, CH_3), 2.40 (s, 3H, $COCH_3$), 2.57 (t, 2H, CH_2), 2.75 (s, 3H, CH_3), 2.79 (t, 2H, CH_2), 3.02 (t, 2H, CH_2), 3.63 (s, 3H, OCH_3), 4.13 (t, 2H, OCH_2), 7.43 (s, 1H, bridge CH), 7.61 (d, 1H, pyr-H), 13.17 (br s, 1H, NH), 13.35 (br s, 1H, NH); ms (*m/z*): 358 ($M^+ - HBr$), 284, 223, 211. Exact mass calcd. for $C_{20}H_{26}H_2O_4$: 358.1892; found: 358.1891.

*4-(2-Acetoxyethyl)-5'-bromo-5-bromomethyl-3'-ethyl-3,4'-dimethyl-2,2'-dipyrromethene hydrobromide (**41**)*

4-(2-Acetoxyethyl)-3'-ethyl-3,4',5-trimethyl-2,2'-dipyrromethene hydrobromide **39** (1.5 g, 4 mmol), trifluoroacetic acid (1.5 mL), and bromine (1.9 g, 12 mmol) were stirred in 1,2-dichloroethane (12 mL) at room temperature with exclusion of moisture for 1 week. The solution was cooled and ether (20 mL) added with stirring until crystallization occurred. The crystals were collected, washed with ether, redissolved in dichloromethane (70 mL), and treated with cyclohexene (6 mL). The dichloromethane was replaced by ethyl acetate under reduced pressure, the resulting red crystals were collected, washed with ethyl acetate, then with hexane, and air dried. Yield 1.81 g (85%), mp 175°C (dec.); ^{1}H nmr ($CDCl_3$/TFA) δ: 1.25 (t, 3H, J = 7.5 Hz, CH_2CH_3), 2.10 (s, 3H, CH_3), 2.18 (s, 3H, $COCH_3$), 2.40 (s, 3H, CH_3), 2.75 (q, 2H, J = 7.5 Hz, CH_2CH_3), 3.00 (t, 2H, J = 6.5 Hz, CH_2CH_2O-), 4.50 (t, 2H, J = 6.5 Hz, CH_2CH_2O-), 4.95 (s, 2H, CH_2Br), 7.20 (s, 1H, bridge CH), 13.00 (br 2s, 2H, 2 × NH). Anal. calcd. for $C_{18}H_{23}N_2Br_3O_2$: C 40.10, H 4.30, N 5.20; found: C 39.45, H 4.15, N 4.85.

*1-Bromo-3,8,13-triethyl-18-(methoxycarbonyl)methyl-2,7,12,17,19-pentamethylbiladiene-ac dihydrobromide (**23**)*

The dipyrromethenes **20** (917 mg, 2.5 mmol) and **22** (1.202 g, 2.5 mmol) in dichloromethane (200 mL) were treated with stannic chloride (4 mL) and the mixture stirred for 1.5 h with exclusion of moisture. The reaction was quenched with aqueous HBr (4 mL of 48% HBr in 50 mL of water), the organic phase was poured into a mixture of methanol (100 mL) and aqueous HBr (48%, 25 mL), concentrated *in vacuo*, and allowed to stand in the refrigerator. The desired biladiene was collected by filtration, washed with ethyl acetate, then with *n*-hexane, and air dried. Yield 1.92 g (99%), mp 190°C (dec.); ^{1}H nmr ($CDCl_3$) δ: 0.67, 1.12, 1.22 (3t, 3H each, 3 × CH_2CH_3), 1.98, 2.09, 2.29, 2.35 (4s, 3H each, 4 × CH_3), 2.52 (q, 2H, CH_2CH_3), 2.64 (q, 2H, CH_2CH_3), 2.75 (s, overlap, 3H, CH_3), 2.75 (q, overlap, 2H, CH_2CH_3), 3.48 (s, 2H, CH_2CO), 3.72 (s, 3H, OCH_3), 5.25 (s, 2H, bridge CH_2), 7.12, 7.15 (2s, 1H each, 2 × bridge CH), 13.35, 13.52, 13.70, 13.92 (4 br s, 1H each, 4 × NH); ms (*m/z*): 522 (M^+; cyclized porphyrin product). Exact mass calcd. for $C_{33}H_{38}N_4O_2$: 522.2995; found: 522.2996.

*1-Bromo-3,8,13-triethyl-17-(methoxycarbonyl)methyl-2,7,12,19-tetramethylbiladiene-ac dihydrobromide (**24**)*

This biladiene was similarly prepared from the dipyrromethenes **21** (1.26 g, 3.56 mmol) and **22** (1.72 g, 3.56 mmol) and afforded 2.41 g (90%) of dark reddish-brown crystals, mp 182°C (dec.); ^{1}H nmr ($CDCl_3$) δ: 0.75, 0.92, 1.14 (3t, 3H each, 3 × CH_2CH_3); 1.99, 2.30, 2.31 (3s, 3H each, 3 × CH_3) 3.50 (q, 2H, CH_2CH_3), 2.65 (s, 3H, CH_3), 2.75 (2q, overlap, 2H each, 2 × CH_2CH_3), 3.59 (s, 3H, OCH_3), 3.95 s, 2H, CH_2CO), 5.18 (s, 2H, bridge CH_2), 7.14, 7.15 (2s, 1H each, 2 × bridge CH), 7.32 (s, 1H, β-H), 13.57, 13.65, 13.73, 13.79 (4 br s, 1H each, 4 × NH); ms (*m/z*): 508 (M^+; cyclized porphyrin product). Exact mass calcd. for $C_{32}H_{36}N_4O_2$: 508.2828; found: 508.2838.

*1-Bromo-8,18-bis(2-acetoxyethyl)-3,13-diethyl-2,7,12,17,19-pentamethylbiladiene-ac dihydrobromide (**43**)*

This biladiene was similarly prepared from the dipyrromethenes **39** (0.9 g, 2.4 mmol) and **41** (1.3 g, 2.4 mmol) to give 1.60 g (79%) of product, mp 195°C (dec.); ^{1}H nmr ($CDCl_3$) δ: 1.20 (2t, overlap, 6H, 2 × CH_2CH_3), 2.15 (s, 3H, CH_3), 2.16 (s, 3H, CH_3), 2.37 (s, 6H, 2 × $COCH_3$), 2.60–3.00 (m, overlap, 4H, 2 × CH_2CH_3), 2.65, 2.68, 2.70 (3s, 3H each, CH_3), 3.80 (2t, overlap, 4H, 2 × CH_2CH_2O-), 4.40 (2t, overlap, 4H, 2 × CH_2CH_2O-), 4.50 (s, 2H, bridge CH_2), 7.20, 7.26 (2s, 1H each, bridge CH), 11.70–12.60 (4s, 1H each, 4 × NH); ms (*m/z*): 594 (M^+; cyclized porphyrin product). Exact mass calcd. for $C_{32}H_{42}N_4O_4$: 594.3206; found: 594.3208.

*1-Bromo-8,18-bis(2-acetoxyethyl)-3,13-bis[(methoxycarbonyl)ethyl]-2,7,12,17,19-pentamethylbiladiene-ac dihydrobromide (**44**)*

The dipyrromethene **40** (355 mg; 0.81 mmol), trifluoroacetic acid (2.5 mL), bromine (390 mg; 2.4 mmol), and dichloromethane (10 mL) were stirred at room temperature for 2 weeks, protected from moisture. The solvent was removed *in vacuo*, the residue taken into dichloromethane and treated with cyclohexene. The solution was evaporated to dryness, redissolved in dichloromethane (20 mL), stirred in the dipyrromethene **40** (290 mg; 0.66 mmol), and treated with $SnCl_4$ (1 mL) in dichloromethane (1 mL). The solution was allowed to stand at room temperature for 2.5 h and quenched with a mixture of methanol (10 mL) and 48% aqueous HBr (1.5 mL). Dichloromethane (60 mL) was added, the solution extracted with water (2 × 30 mL) and concentrated to ca. 15 mL. Slow addition of diethyl ether resulted in the crystallization of the product, which was filtered, washed with 10% methanol – diethyl ether, and dried in air. Yield 456 mg; 59% overall for 2 steps; ^{1}H nmr ($CDCl_3$) δ: 1.86, 2.00, 2.06, 2.09, 2.37, 2.40 (6s, 3H each, 6 × CH_3), 2.53 (t, 2H, CH_2), 2.60 (t, 2H, CH_2), 2.75 (s, 3H, CH_3), 2.80 (t, 2H, CH_2), 2.96 (2t, overlap, 4H, 2 × CH_2), 3.07 (t, 2H, CH_2), 3.52 (t, 2H, CH_2), 3.62, 3.65, (2s, 3H each, 2 × OCH_3, 4.13 (t, 2H, CH_2), 5.25 (s, 2H, bridge CH_2), 7.35, 7.37, (2s, 1H each, bridge CH), 13.41, 13.54, 13.88, 14.12 (4s, 1H each, NH); ms (*m/z*): 710, (M^+; cyclized porphyrin product), 696, 651, 637. Exact mass calcd. for $C_{40}H_{46}N_4O_8$: 710.3316; found: 710.3322.

*7,12,17-Triethyl-2-(methoxycarbonyl)methyl-3,8,13,18-tetramethylporphyrin (**25**)*

The biladiene **23** (1.60 g, 2.08 mmols) dissolved in DMSO (200 mL) was treated with pyridine (10 mL) and allowed to stand in the dark at room temperature for 5 days. The porphyrin crystals were collected by filtration, washed with methanol, and air dried. Yield 0.89 g in two crops (82%), mp 289–290°C; visible spectrum (CH_2Cl_2) λ_{max} (nm) (relative intensities): 400 (18.5), 498 (2.00), 534 (1.57), 568 (1.08), 620 (1.00); ^{1}H nmr ($CDCl_3$) δ: −3.73 (br s, 2H, 2 × NH), 1.86 (3t, 3H each, 3 × CH_2CH_3), 3.60 (s, 3H, CH_3), 3.65 (s, 9H, 3 × CH_3), 3.76 (s, 3H, OCH_3), 4.03–4.14 (3q, overlap, 2H each, 3 × CH_2CH_3), 5.05 (s, 2H, CH_2CO), 10.07 (s, 2H, 2 × *meso*-H), 11.01, 11.04 (2s, 1H each, 2 × *meso*-H; ms (*m/z*): 522 (M^+). Anal. calcd. for $C_{33}H_{38}N_4O_2$: C 75.83, H 7.33, N 10.72; found: C 75.67, H 7.39, N 10.68.

*7,12,17-Triethyl-2-(2-hydroxyethyl)-3,8,13,18-tetramethylporphyrin (**26**)*

A solution of the porphyrin **25** (200 mg, 0.38 mmol) in dichloromethane (60 mL) was stirred with a saturated solution of zinc acetate in methanol (2 mL) and the metal insertion was monitored by ultraviolet–visible spectroscopy. More dichloromethane (100 mL) was added, the organic phase washed twice with water, and the solvent removed to afford the zinc complex (0.20 g, 90%), which was dried and used without further purification.

In a cooled 250-mL two-necked round-bottomed flask equipped with a magnetic stirring bar and an argon gas inlet was placed a slurry of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

lithium aluminum hydride (49.0 mg, 1.28 mmol) in THF (30 mL), which was treated, dropwise, with a solution of the zinc complex (150 mg, 0.26 mmol) in THF. The reaction mixture was allowed to warm to room temperature and stirred for 2 h (progress monitored by tlc). Cold water was carefully added to quench the reaction (H_2 evolved), the mixture was extracted with dichloromethane, and the organic phase shaken with trifluoroacetic acid (3 mL) to demetalate the zinc complex. The excess acid was removed by washing the dichloromethane solution with 5% aqueous $NaHCO_3$, followed by water, and dried ($MgSO_4$). Evaporation of the solvent *in vacuo* afforded the desired porphyrin. Yield 122 mg (95%). A sample was recrystallized from chloroform–ether to give fine purple crystals, mp 275°C (dec.); visible spectrum (CH_2Cl_2) λ_{max} (nm) (relative intensities): 400 (25.2), 498 (2.78), 532 (2.24), 566 (1.65), 620 (1.00); ^{1}H nmr ($CDCl_3$) δ: −3.76 (br s, 2H, 2 × NH), 1.87 (3t, overlap, 9H, 3 × CH_2CH_3), 3.61, 3.64, 3.65, 3.66 (4s, 3H each, 4 × CH_3), 4.10 (3q, overlap, 6H, 3 × CH_2CH_3), 4.35 (t, 2H, CH_2CH_2OH), 4.48 (t, 2H, CH_2CH_2OH), 10.08 (s, 1H, *meso*-H), 10.09, (s, 2H, 2 × *meso*-H), 11.01 (s, 1H, *meso*-H); ms (*m/z*): 494 (M^+), 463. Exact mass calcd. for $C_{32}H_{38}N_4O$: 494. 3046; found: 494.3051.

*2-(2-Chloroethyl)-7,12,17-triethyl-3,8,13,18-tetramethylporphyrin (**27**)*

A mixture of the porphyrin (**26**) (200 mg, 0.405 mmol), dichloromethane (100 mL), DMF (20 mL), and K_2CO_3 (6 g) was stirred at room temperature and treated with thionyl chloride (6 mL). On completion of the reaction (monitored by tlc), water was added, the organic phase washed with $NaHCO_3$, followed by water, and dried ($MgSO_4$). After filtration, removal of solvent under reduced pressure gave a purple-brown solid, which was purified by chromatography (silica gel 70–230 mesh, dichloromethane eluent) and recrystallized from chloroform–methanol. Yield 180.4 mg (86%), mp 250°C (dec.); visible spectrum (CH_2Cl_2) λ_{max} (nm) (relative intensities): 398 (34.1), 498 (2.35), 534 (1.82), 566 (1.35), 620 (1.00); ^{1}H nmr ($CDCl_3$) δ: −3.75 (br s, 2H, 2 × NH), 1.88 (2t, overlap, 9H, 3 × CH_2CH_3), 3.61 (s, 3H, CH_3), 3.66 (s, 9H, 3 × CH_3), 4.04–4.14 (3q, overlap, 6H, 3 × CH_2CH_3), 4.32 (t, 2H, CH_2CH_2Cl), 4.52 (t, 2H, CH_2CH_2Cl), 10.01, 10.08, 10.09, 10.11 (4s 1H each, 4 × *meso*-H); ms (*m/z*): 512 (M^+), 497, 478, 463. Exact mass calcd. for $C_{32}H_{37}N_4Cl$: 512.2707; found: 512.2715.

*7,12,17-Triethyl-3,8,13,18-tetramethyl-2-vinylporphyrin (**8**a)*

The porphyrin **27** (150 mg, 0.293 mmol) in pyridine (100 mL) was heated at reflux under nitrogen for 10 min and treated with a 10% aqueous NaOH solution (10 mL). Heating was continued for an additional 2 h (completion of reaction shown by tlc), 50% aqueous acetic acid (40 mL) was added, and the mixture was extracted with dichloromethane (200 mL). The organic layer was washed with 5% aqueous $NaHCO_3$ (3 × 200 mL), followed by water (2 × 200 mL), dried ($MgSO_4$), and evaporated to dryness. The residue was chromatographed (silica gel 60, dichloromethane eluent) to give a pink residue after solvent evaporation. Recrystallization from chloroform–methanol gave the title porphyrin as purple prisms. Yield 121.3 mg (87%), mp 220°C (dec.); visible spectrum (CH_2Cl_2) λ_{max} (nm) (relative intensities): 400 (18.6), 502 (2.04), 538 (1.93), 570 (1.40), 624 (1.00); ^{1}H nmr ($CDCl_3$) δ: −3.68 (br s, 2H, 2 × NH), 1.90 (3t, overlap, 3H each, 3 × CH_2CH_3) 6.15 (dd, 1H, J = 1.5, 11.5 Hz, CH=CH_2), 6.36 (dd, 1H, J = 1.5, 17.5 Hz, CH=CH_2), 8.32 (dd, 1H, J = 11.5, 17.5 Hz, CH=CH_2), 10.07 (s, 2H, 2 × *meso*-H), 10.15, 10.23 (2s, 1H each, 2 × *meso*-H); ms (*m/z*): 476 (M^+), 461, 446. Exact mass calcd. for $C_{32}H_{36}H_4$: 476.2940; found: 476.2940. Anal. calcd. for $C_{32}H_{36}N_4$: C 80.63, H 7.61, N 11.76; found: C 80.54, H 7.63, N 11.74.

*7,12,17-Triethyl-3-(methoxycarbonyl)methyl-8,13,18-trimethylporphyrin (**28**)*

The biladiene **24** (2.00 g, 2.66 mmol) was cyclized in DMSO (300 mL) and pyridine (10 mL) as described earlier to afford 1.12 g (83%) of the pure product after chromatography and recrystallization; mp 228–230°C; visible spectrum (CH_2Cl_2) λ_{max} (nm) (relative intensities): 398 (29.9), 498 (3.00), 534 (2.37), 566 (1.80), 620 (1.00); ^{1}H nmr ($CDCl_3$) δ: −3.88 (br s, 2H, 2 × NH), 1.85 (3t, overlap, 9H, J = 7.5 Hz, 3 × CH_2CH_3), 3.55, 3.58, 3.62 (3s, 9H, 3 × CH_3), 3.85 (s, 3H, OCH_3), 3.97–4.11 (3q, overlap, 6H, J = 7.5 Hz, 3 × CH_2CH_3), 5.16 (s, 2H, $CH_2CO_2CH_3$), 9.24 (s, 1H, β-H), 10.00–10.12 (4s, 1H each, 4 × *meso*-H); ms (*m/z*): 508 (M^+), 493, 478, 449. Anal. calcd. for $C_{32}H_{36}N_4O_2$: C 75.56, H 7.13, N 11.01; found: C 75.40, H 7.25, N 10.86.

*7,12,17-Triethyl-3-(2-hydroxyethyl)-8,13,18-trimethylporphyrin (**29**)*

This was prepared in 95% yield from the porphyrin **28** as described earlier; mp 273–274°C; visible spectrum (CH_2Cl_2) λ_{max} (nm) (relative intensities): 400 (28.17), 498 (2.29), 532 (2.05), 568 (1.78), 620 (1.00); ^{1}H nmr ($CDCl_3$) δ: −3.75 (br s, 2H, 2 × NH), 1.88 (2t, overlap, 9H, 3 × CH_2CH_3), 3.62, 3.65, 3.69 (3s, 3H each, 3 × CH_3), 4.10 (3q, 6H, 3 × CH_2CH_3), 4.45 (t, 2H, CH_2CH_2OH), 4.62 (t, 2H, CH_2CH_2OH), 9.19 (s, 1H, β-H), 10.08–10.16 (4s, 1H each, 4 × *meso*-H); ms (*m/z*): 480 (M^+), 465, 449. Exact mass calcd. for $C_{31}H_{36}N_4O$: 480.2889; found: 480.2892.

*3-(2-Chloroethyl)-7,12,17-triethyl-8,13,18-trimethylporphyrin (**30**)*

This was prepared in 95% yield from 2-hydroxyethylporphyrin **29** as described earlier; mp 230–232°C; visible spectrum (CH_2Cl_2) λ_{max} (nm) (relative intensities): 400 (30.1), 502 (2.52), 542 (2.42), 570 (1.73), 626 (1.00); ^{1}H nmr ($CDCl_3$) δ: −3.80 (br s, 2H, 2 × NH), 1.08 (3t, overlap, 9H, 3 × CH_2CH_3), 3.61, 3.65, 3.69 (3s, 3H each, 3 × CH_3), 4.02–4.17 (3q, overlap, 6H, 3 × CH_2CH_3), 4.51 (t, 2H, CH_2CH_2Cl), 4.67 (t, 2H, CH_2CH_2Cl), 9.20 (s, 1H, β-H), 10.10–10.14 (4s, 1H each, 4 × *meso*-H); ms (*m/z*): 498 (M^+), 483, 462. Exact mass calcd. for $C_{31}H_{35}N_4Cl$: 498.2550; found: 498.2552.

*7,12,17-Triethyl-8,13,18-trimethyl-3-vinylporphyrin (**8**b)*

This was prepared in 88% yield by the dehydrochlorination of porphyrin **30** as described earlier; mp 221–222°C; visible spectrum (CH_2Cl_2) λ_{max} (nm) (relative intensities): 402 (22.35), 504 (2.27), 544 (2.51), 570 (1.69), 630 (1.00); ^{1}H nmr ($CDCl_3$) δ: −3.66 (s, 2H, 2 × NH), 1.90 (2t, overlap, 9H, 3 × CH_2CH_3), 3.60, 3,64, 3.66 (3s, 9H, 3 × -CH_3), 4.15 (2q, overlap, 6H, 3 × CH_2CH_3), 6.40 (d, 1H, J = 12.0 Hz, CH=CH_2), 6.63 (d, 1H, J = 17.0 Hz, CH=CH_2), 8.47 (dd, 1H, J = 12.0, 17.0 Hz, CH=CH_2), 9.44 (s, 1H, Ar-H), 10.06, 10.07, 10.10, 10.26 (4s, 1H each, 4 × *meso*-H); ms (*m/z*): 462 (M^+), 447, 432. Exact mass calcd. for $C_{31}H_{34}N_4$: 462.2783; found: 462.2784.

*2,12-Bis(2-acetoxyethyl)-7,17-diethyl-3,8,13,18-tetramethylporphyrin (**45**)*

The biladiene **43** (1.55 g, 1.85 mmol) was cyclized in DMSO–pyridine as described earlier to afford the title porphyrin in 81% yield. A pure sample was obtained for characterization by column chromatography (silica gel 60, 95:5, dichloromethane–methanol eluent); mp 320°C; visible spectrum (CH_2Cl_2) λ_{max} (nm) (relative intensities): 398 (26.81), 498 (2.66), 534 (2.10), 568 (1.52), 620 (1.00); ^{1}H nmr ($CDCl_3$) δ: −3.80 (br s, 2H, 2 × NH), 1.90 (t, 6H, J = 8.0 Hz, 2 × CH_2CH_3), 2.10 (s, 6H, 2 × C(=O)CH_3), 3.65 (s, 6H, 2 × CH3), 3.70 (s, 6H, 2 × CH_3), 4.15 (q, 4H, J = 8.0 Hz, 2 × CH_2CH_3), 4.38 (t, 4H, J = 8.0 Hz, 2 × CH_2CH_2O-), 4.90 (t, 4H, J = 8.0 Hz, 2 × CH_2CH_2O-), 10.10 (s, 2H, 2 × *meso*-H), 10.15 (s, 2H, 2 × *meso*-H); ms (*m/z*): 594 (M^+), 552, 536, 521. Anal. calcd. for $C_{26}H_{42}N_4O_4$: C 72.70, H 7.12, N 9.42; found: C 72.52, H 7.69, N 9.08.

*7,17-Diethyl-2,12-bis(2-hydroxyethyl)-3,8,13,18-tetramethylporphyrin (**46**)*

The bis(acetoxyethyl)porphyrin **45** (600 mg, 1.01 mmol) was dissolved in methanol (150 mL) containing 5% (w/v) concentrated H_2SO_4 and stirred in the dark for 16 h (reaction monitored by tlc). The mixture was poured onto ice (150 g) and the product extracted with dichloromethane. The organic phase was washed with 5% aqueous $NaHCO_3$, dried ($MgSO_4$), and evaporated to dryness to give a purple-red solid, which was recrystallized from chloroform–ether to give the bis(hy-

droxyethyl)porphyrin (505 mg, 98%), mp 240°C (dec.); visible spectrum (CH_2Cl_2) λ_{max} (nm) (relative intensities): 394 (18.41), 496 (2.14), 530 (1.65), 564 (1.28), 618 (1.00); ^{1}H nmr ($CDCl_3$) δ: −3.40 (br s, 2H, 2 × NH), 1.75 (t, 6H, 2 × CH_2CH_3), 3.66 (s, 6H, 2 × CH_3), 3.71 (s, 6H, 2 × CH_3), 4.16 (q, 4H, 2 × CH_2CH_3), 4.56 (t, 4H, 2 × CH_2CH_2OH), 5.04 (t, 4H, 2 × CH_2CH_2OH), 10.65 (s, 2H, 2 × *meso*-H), 10.70 (s, 2H, 2 × *meso*-H); ms (*m/z*): 510 (M^+), 495, 479, 448. Exact mass calcd. for $C_{32}H_{38}N_4O_2$: 510.2995; found: 510.2999.

*2,12-Bis(2-chloroethyl)-7,17-diethyl-3,8,13,18-tetramethylporphyrin (**47**)*

Porphyrin **46** was converted to its bis(chloroethyl) analog **47** in 85% yield as described earlier; mp 324–325°C; visible spectrum (CH_2Cl_2) λ_{max} (nm) (relative intensities): 398 (17.53), 498 (1.69), 534 (1.43), 570 (1.16), 620 (1.00); ^{1}H nmr ($CDCl_3$) δ: −3.75 (br s, 2H, 2 × NH), 1.88 (t, 6H, J = 7.5 Hz, 2 × CH_2CH_3), 3.65 (s, 6H, 2 × CH_3), 3.68 (s, 6H, 2 × CH_3), 4.13 (q, 4H, J = 7.5 Hz, 2 × CH_2CH_3), 4.32 (t, 4H, J = 8.0 Hz, 2 × CH_2CH_2Cl), 4.50 (t, 4H, J = 8.0 Hz, 2 × CH_2CH_2Cl), 10.03 (s, 2H, 2 × *meso*-H), 10.13 (s, 2H, 2 × *meso*-H); Exact mass calcd. for $C_{32}H_{36}N_4Cl_2$: 546.2307; found: 546.2307. Anal. calcd. for $C_{32}H_{36}N_4Cl_2$: C 70.19, H 6.63, N 10.23; found: C 70.25, H 6.58, N 10.20.

*7,17-Diethyl-3,8,13,18-tetramethyl-2,12-divinylporphyrin (**8**c)*

Dehydrochlorination of the porphyrin **47** was carried out as described earlier to afford the title compound in 84% yield; mp 225°C (dec.); visible spectrum (CH_2Cl_2) λ_{max} (nm) (relative intensities): 402 (19.2), 506 (2.05), 546 (2.68), 572 (1.80), 626 (1.00); ^{1}H nmr ($CDCl_3$) δ: −3.66 (br s, 2H, 2 × NH), 1.90 (t, 6H, 2 × CH_2CH_3), 3.68 (s, 6H, 2 × CH_3), 3.72 (s, 6H, 2 × CH_3), 4.15 (q, 4H, 2 × CH_2CH_3), 6.15 (dd, 2H, J = 2.0, 12.0 Hz, CH=CH_2), 6.34 (dd, 2H, J = 2.0, 18.0 Hz, CH=CH_2), 8.32 (dd, J = 12.0, 18.0 Hz, 2H, CH=CH_2), 10.15 (s, 2H, 2 × *meso*-H), 10.23 (s, 2H, 2 × *meso*-H); ^{13}C nmr (10% TFA – $CDCl_3$) δ: 11.71, 12.61 (4C, 4 × -CH_3), 16.18 (2C, 2 × CH_2CH_3); 20.07 (2C, 2 × CH_2CH_3), 99.09, 99.48 (4C, 4 × *meso* carbons); 127.59 (2C, 2 × CH=CH_2), 128.23 (2C, 2 × CH=CH_2), 138.34, 138.60, 140.52, 141.54, 142.82, 145.00, (16C, α- and β-pyrrolic carbons); ms (*m/z*): 474 (M^+) 459, 444. Anal. calcd. for $C_{32}H_{34}N_4$: C 80.98, H 7.22, N 11.80; found: C 80.41, H 7.38, N 11.65.

*2,12-Bis(2-acetoxyethyl)-7,17-[(methoxycarbonyl)ethyl]-3,8,13,18-tetramethylporphyrin (**48**)*

The biladiene **44** (370 mg, 0.39 mmol) dissolved in DMSO (25 mL) was treated with pyridine (1.5 mL) and allowed to stand in the dark at room temperature for 6 days. Methanol (15 mL) was added followed by water (6 mL), the solution was cooled to 0°C, and the porphyrin crystals were filtered and washed with methanol. Yield 194 mg (71%); mp 238–240°C; visible spectrum (CH_2Cl_2) λ_{max} (nm) (relative intensities): 400 (25.6), 498 (2.53), 532 (1.79), 568 (1.35), 620 (1.00); ^{1}H nmr ($CDCl_3$) δ: −3.76 (br s, 2H, 2 × NH), 2.09 (s, 6H, 2 × $COCH_3$), 3.29 (t, 4H, 2 × CH_2CO), 3.67, 3.68, 3.69 (3s, 6H each, 2 × OCH_3, 4 × CH_3), 4.36–4.48 (m, 8H, 2 × CH_2CH_2CO, 2 × CH_2CH_2O), 4.89 (t, 4H, 2 × CH_2O), 10.10, 10.15 (2s, 2H each, 2 × *meso*-H); ms (*m/z*): 710 (M^+), 696, 637, 577. Exact mass calcd. for $C_{40}H_{46}N_4O_8$: 710.3316; found: 710.3320.

*2,12-Bis(2-hydroxyethyl)-7,17-bis[(methoxycarbonyl)ethyl]-3,8,13,18-tetramethylporphyrin (**49**)*

The bis(acetoxyethyl)porphyrin **48** (190 mg, 0.27 mmol) was dissolved in 5% H_2SO_4 – methanol (40 mL) and allowed to stand in the dark for 20 h. Dichloromethane (50 mL) and dilute aqueous sodium acetate (100 mL) were added, the organic phase separated, and was washed with 5% aqueous $NaHCO_3$, then with water, and dried ($NaSO_4$). The product was crystallized by the addition of *n*-hexane. Yield 165 mg (99%); mp 253–255°C; visible spectrum (CH_2Cl_2) λ_{max} (nm) (relative intensities): 400 (20.5), 498 (2.19), 532 (1.63), 568 (1.27), 620 (1.00); ^{1}H nmr ($CDCl_3$/TFA) δ: −3.25 (br s, 2H, 2 × NH), 3.18 (t, 4H, 2 × CH_2CO), 3.66, 3.70, 3.74 (3s, 6H each, 2 × OCH_3, 4 × CH_3), 4.48 (t, 4H, 2 × CH_2CH_2CO), 4.56 (t, 4H, 2 × CH_2CH_2OH), 5.05 (t, 4H, 2 × CH_2OH), 10.73, 10.86 (2s, 2H each, 2 × *meso*-H); ms (*ms/z*): 626 (M^+), 595, 564, 553. Exact mass calcd. for $C_{36}H_{42}N_4O_6$: 626.3104; found: 626.3113.

*2,12-Bis(2-chloroethyl)-7,17-bis[(methoxycarbonyl)ethyl]-3,8,13,18-tetramethylporphyrin (**50**)*

The bis(hydroxyethyl)porphyrin **49** (152 mg, 0.24 mmol) was chlorinated as described earlier. The crude reaction mixture was chromatographed on neutral alumina (4% water added), using dichloromethane as eluent. The product was isolated by crystallization from dichloromethane–*n*-hexane. Yield 143 mg (89%); mp 265–267°C; visible spectrum (CH_2Cl_2) λ_{max} (nm) (relative intensities): 400 (26.8), 498 (2.62), 534 (1.87), 568 (1.40), 622 (1.00); ^{1}H nmr ($CDCl_3$/TFA) δ: −3.15 (t, 4H, 2 × CH_2CO), 3.60, 3.67 3.72 (3s, 6H each 2 × OCH_3, 4 × CH_3), 4.17 (t, 4H, CH_2CH_2CO), 4.43 (t, 4H, CH_2CH_2Cl), 4.56 (t, 4H, CH_2Cl), 10.55, 10.74 (2s, 2H each, 2 × *meso*-H), NH protons not observed; ms (*m/z*): 662 (M^+), 628, 613, 589. Exact mass calcd. for $C_{36}H_{40}N_4O_4Cl_2$: 662.2427; found: 662.2429.

*7,17-Bis[(methoxycarbonyl)ethyl]-3,8,13,18-tetramethyl-2,12-divinylporphyrin (**8**d)*

The bis(chloroethyl)porphyrin **50** (143 mg, 0.22 mmol) in pyridine (30 mL) was heated to reflux and treated with 10% aqueous NaOH (5 mL). Heating was continued for 3 h, the reaction mixture was cooled, 25% aqueous acetic acid (50 mL) and water (25 mL) were added, and the solution concentrated *in vacuo*. The precipitated solid was filtered onto a Celite pad, washed with water, and dried in a vacuum desiccator over KOH.

The product was dissolved in 5% H_2SO_4 – methanol (100 mL), the Celite removed by filtration, and the solution allowed to stand overnight. Dichloromethane (100 mL) was added to the above solution, the organic layer was washed with 5% aqueous $NaHCO_3$, then washed and dried (Na_2SO_4). After filtration, the solution was evaporated to dryness, redissolved in dichloromethane, chromatographed on neutral alumina (4% water added), and the product crystallized from *n*-hexane. Yield 101 mg (79%); mp 268–270°C (lit. (4) mp 270–272°C); visible spectrum (CH_2Cl_2) λ_{max} (nm) (relative intensities): 402 (27.6), 506 (2.57), 544 (2.90), 572 (1.89), 630 (1.00); ^{1}H nmr ($CDCl_3$/TFA) δ: −3.75 (br s, 2H, 2 × NH), 3.27 (t, 4H, 2 × CH_2CO), 3.65, 3.68, 3.71 (3t, 6H each, 2 × OCH_3, 4 × CH_3), 6.18 (dd, 2H, J = 2.0, 12.0 Hz, -CH=CH_2), 6.36 (dd, 2H, J = 2.0, 18.0 Hz, -CH=CH_2), 8.28 (dd, J = 12.0, 18.0 Hz, -CH=CH_2), 10.07, 10.17 (2s, 2H each, *meso*-H); ms (*m/z*): 590 (M^+), 531, 517. Exact mass calcd. for $C_{36}H_{38}N_4O_4$: 590.2893; found: 590.2894.

Received March 27, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

ROBIN A. COX, EWART GRANT, TODD WHITAKER, and THOMAS T. TIDWELL. Can. J. Chem. **68**, 1876 (1990).

The excess acidity method has been used to analyse the hydration kinetics of the phenylacetylenes Y-C_6H_4-C≡C-Z in aqueous sulfuric acid mixtures; Z = CF_3 (**1**), H (**2**), COC_6H_4-X (**3**), and CO_2H (**4**). All substrates gave acetophenone-type products consistent with the normal hydration mechanism involving rate-determining vinyl cation formation. Standard-state log k_0 intercepts, and $m^{\neq}m^*$ slopes, were both used in linear free energy relationship plots against the substituent σ^+ values. Solvent isotope effects and activation parameters were obtained in some cases. The deactivating Z substituents in **1**, **3**, and **4** all cause reaction to be some 100 times slower than that of the parent phenylacetylene **2**. Compounds **2**, **3**, and **4** all have ρ^+ values of about −3.8, but **1** is more substituent sensitive, with a ρ^+ of −5.3. A σ^+ value of 0.38 is calculated for the $CF_3C{\equiv}C$ substituent. The ρ^+ values were found to be acidity independent for **1** and **2**, and probably for **3**, but not for **4**. Proton transfer at the transition state was found to be most advanced for the fastest reaction, that of **2**, contrary to intuition.

Key words: alkyne hydration, excess acidity, phenylacetylenes, vinyl cations, deactivated carbocations.

ROBIN A. COX, EWART GRANT, TODD WHITAKER et THOMAS T. TIDWELL. Can. J. Chem. **68**, 1876 (1990).

On a utilisé la méthode d'acidité en excès pour analyser la cinétique d'hydratation des phénylacétylènes, Y-C_6H_4-C≡C-Z (Z = CF_3 (**1**), H (**2**), COC_6H_4-X (**3**) et CO_2H (**4**)), dans des solutions aqueuses d'acide sulfurique. Tous les substrats ont donné naissance à des produits du type acétophénone qui correspondent au mécanisme normal d'hydratation impliquant la formation d'un cation vinylique dans l'étape qui détermine la vitesse de la réaction. Dans le but d'obtenir des courbes relation linéaire d'énergie libre, on a utilisé les ordonnées à l'origine du log k_0 ainsi que les pentes $m^{\neq}m^*$ de l'état standard vs. des valeurs σ^+ des substituants. Dans quelques cas, on a aussi obtenu les effets isotopiques du solvant ainsi que les paramètres d'activation. Les vitesses de réaction des composés **1**, **3** et **4** portant des substituants désactivants Z sont environ 100 fois plus lentés que celle du phénylacétylène parent, **2**. Les valeurs de ρ^+ des composés **2**, **3** et **4** sont toutes égales à environ −3,8; toutefois, le composé **1** est plus sensible aux substituants et sa valeur de ρ^+ est égale à −5,3. On a calculé que la valeur σ^+ du substituant $CF_3C{\equiv}C$ est égale à 0,38. On a trouvé que les valeurs de ρ^+ des composés **1** et **2** et probablement du composé **3** sont indépendantes de l'acidité; ce n'est toutefois pas le cas avec le composé **4**. Contrairement à ce que l'on pouvait croire d'une façon intuitive, on a trouvé que le transfert de proton dans l'état de transition est le plus avancé avec la réaction la plus rapide.

Mots clés : hydratation des alcynes, acidité en excès, phénylacétylènes, cations vinyliques, carbocations désactivés.

[Traduit par la revue]

Introduction

The effect of deactivating substituents like CF_3 upon carbocations has become a subject of considerable recent interest (1, 2). The work reported in this paper was initiated as a study of the influence of the β-CF_3 substituent on vinyl cation formation (3). This is conveniently studied by following the rates of hydration of suitably substituted phenylacetylenes in aqueous sulfuric acid, the well-known (4–10) mechanism of which is shown below, Z being CF_3 (3).

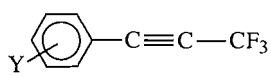
[1] $Y{-}C_6H_4{-}C{\equiv}C{-}Z \xrightarrow[\text{slow}]{+H^+}$

$Y{-}C_6H_4{-}\overset{+}{C}{=}CHZ \xrightarrow[\text{fast}]{+H_2O,\ -H^+}$

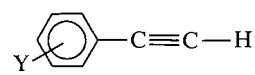
$Y{-}C_6H_4{-}\overset{OH}{\overset{|}{C}}{=}CHZ \xrightarrow{\text{tautomerization}}$

$Y{-}C_6H_4{-}\overset{OH}{\overset{\|}{C}}{-}CH_2Z$

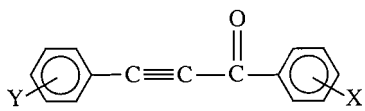
For comparison purposes, existing hydration rate data for the parent phenylacetylenes (Z = H) (6–14), and for compounds with the deactivating substituents Z = COC_6H_4-X (15) and Z = CO_2H (16), were also analysed, along with those for some aliphatic alkynes (4–6, 13, 17). The major compounds in the study, **1**–**4**, are shown below.



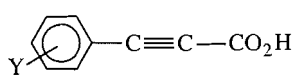
1*a*, Y = 4-OMe
1*b*, Y = 4-Me
1*c*, Y = 3-Me
1*d*, Y = H
1*e*, Y = 4-Cl
1*f*, Y = 3-Cl
1*g*, Y = 4-$CF_3C{\equiv}C$
1*h*, Y = 4-CF_3CH_2CO



2*a*, Y = 4-OMe
2*b*, Y = 4-Me
2*c*, Y = 3-Me
2*d*, Y = H
2*e*, Y = 4-Cl
2*f*, Y = 4-Br
2*g*, Y = 3-Cl
2*h*, Y = 3-NO_2
2*i*, Y = 4-NO_2



3*a*, Y = 4-OMe, X = H
3*b*, Y = 4-Me, X = H
3*c*, Y = H, X = H
3*d*, Y = H, X = 4-Me
3*e*, Y = H, X = 4-NO_2



4*a*, Y = 4-OMe
4*b*, Y = 4-Me
4*c*, Y = H
4*d*, Y = 4-Cl
4*e*, Y = 3-Cl
4*f*, Y = 3, 4-Cl_2

[c]Not directly comparable with the other table entries; see text.

The rate data were analysed using the excess acidity method (18), which was successfully used previously in the analysis of alkenyl ester hydration data (19). It has also been used in the analysis of rate data for enolizations and aldol condensations (20), acylhydrazine hydrolyses (21), amide hydrolyses (22), and many other reactions (18) in aqueous sulfuric acid. The excess acidity equation applicable to the rate-determining proton transfer of eq. [1] is eq. [2] (18). In eq. [2] the k_ψ are the

$$[2] \quad \log k_\psi - \log C_{H^+} = m^{\neq}m^*X + \log k_0$$

observed pseudo-first-order rate constants. C_{H^+} is the proton concentration and X is the excess acidity; these take the place of an acidity function in the excess acidity method (18, 23). The slope parameter m^* refers to equilibrium protonation of the substrate; $m^* = 1.0$ for primary aromatic amines, 0.6 for carbonyl compounds, 1.3 for tertiary aromatic amines, etc. (23). The term $m^{\neq}$ refers to the transition state; $m^{\neq} > 1$ for A-1 reactions, $m^{\neq} < 1$ for A-S_E2 reactions, such as the one in eq. [1], and $m^{\neq} \cong 1$, with additional water activity terms, etc., necessary in eq. [2], for A-2 reactions (18). The intercept gives k_0, the medium-independent rate constant for the reaction, i.e., the value in the hypothetical ideal 1 M acid solution which is the standard state (18, 23); these are directly comparable with values obtained in aqueous buffer media. For the mechanism of eq. [1] these are rate constants for proton transfer from the acid "H^+", commonly symbolized k_{H^+}.

Experimental

The 1-aryl-3,3,3-trifluoropropyne substrates **1***a–g* were synthesized by a Wittig procedure (24*a*), purified by GLC (all but **1***g* are oils), and their purity and identity confirmed by comparison of their spectra with published spectral data (24*a–e*).

Compound **1***g* is new: colourless needles, mp 92–93°C; IR (CCl_4): 2256 (C≡C) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 7.60 (s, 4); ^{19}F NMR (C_6D_6) δ: −54.3 (6); ^{13}C NMR (C_6D_6) δ: 78.0 (q, 2, J_{CCF} = 52.7 Hz, CCF_3), 85.6 (q, 2, J_{CCCF} = 6.4 Hz, $CCCF_3$), 115.4 (q, 2, J_{CF} = 257.2 Hz, CF_3), 120.5 (2, quarternary C), 132.4 (4); MS *m/z* (rel. intensity): 262 (100, M^+), 243 (55, $M^+ - F$), 193 (35, $M^+ - CF_3$), 69 (49, CF_3^+); HRMS *m/z*: 262.0208 (M^+), $C_{12}H_{14}F_6$ requires 262.0217. Preparation according to ref. 24*a* gave a yield of 10%.

Compounds **1***c*, **1***f*, and **1***h* are also new. **1***c*: IR (CCl_4): 2266, 2233 (C≡C) cm^{-1}; ^1H NMR (CCl_4) δ: 2.34 (s, 1, CH_3), 7.1 (m, 4, Ar). **1***f*: IR (CCl_4): 2261 (C≡C) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 7.3–7.5 (m, 4); MS *m/z* (rel. intensity): 206 (46, M^+), 204 (100, M^+), 185 (46, $M^+ - F$), 169 (69), 154 (21), 125 (38); HRMS *m/z*: 203.9954, $C_9H_4ClF_3$ requires 203.9954. Compound **1***h* was not isolated but was generated *in situ* from the reaction of **1***g* in acid.

The 3,3,3-trifluoropropiophenone products Y-$C_6H_4COCH_2CF_3$ have been reported previously (24*f*) for Y = 4-OMe, 4-Me, H, and 4-Cl.

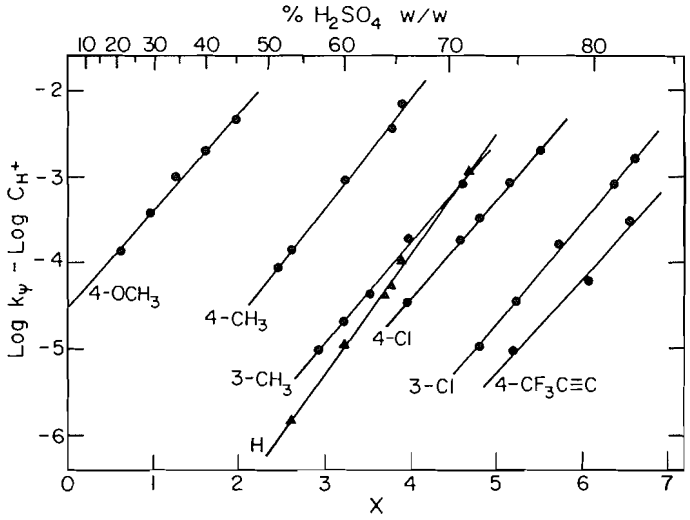

FIG. 1. Excess acidity plots according to eq. [2], for the hydration of various 1-aryl-3,3,3-trifluoropropynes **1** in aqueous sulfuric acid mixtures.

The formation of the ketone from **1***c*, Y = 3-Me, was confirmed by neutralizing the product of the reaction of 5 mg of **1***c* in 2 mL of concentrated H_2SO_4 with 10% aqueous KOH. After extraction into CCl_4 and evaporation, the product showed the characteristic propiophenone IR absorption at 1694 cm^{-1}.

The hydration kinetics were studied at 25°C using a Cary 210 UV–VIS spectrophotometer, following the disappearance of the aryl-acetylene peak at 230–240 nm. Runs were performed in duplicate; agreement was within ±5%. Reaction was initiated by injecting stock substrate solutions in acetonitrile into the aqueous sulfuric acid mixtures. The latter were analysed by titration. The measured rate constants are in Table S1, available from the Depository of Unpublished Data,[3] along with those literature values for **2** which are not readily available otherwise, Table S2.

The rate constants obtained for **1**, and those available in the literature for **2**, **3**, and **4**, were analysed according to the excess acidity procedure as previously described (18–22), using linear regression on eq. [2]. The values of X and log C_{H^+} used are from Cox and Yates (23). In those cases where rate constants at several different temperatures were available they were analysed using standard multiple linear regression or curve-fitting techniques (25) as described in the literature (22, 26), taking into account the variation of X and log C_{H^+} with temperature (25*a*). Rate constants obtained in D_2SO_4 enabled the calculation of solvent isotope effects; Noyce's assumption (27) that medium acidities are equal at equal mole fractions of H_2SO_4 and D_2SO_4 was used so that X and log C_{D^+} could be calculated in D_2SO_4 media, since there are at present no measured values.

All of the derived information, $m^{\neq}m^*$ slopes, log k_0 values and the aqueous standard-state k_{H^+} values that are their antilogs, activation parameters, solvent isotope effects, and certain other information, is collected in Table 1–8. The errors reported in the tables are standard deviations. The σ and σ^+ values used for the LFER's in Figs. 2–5 are from Hammett (28).

Results

The rate constants obtained for **1**, with the exception of those for **1***h*, are plotted according to the excess acidity equation [2] in Fig. 1. As can be seen, the plots are nicely linear and all roughly parallel, with that for the parent phenyl compound **1***d* being somewhat deviant. The slopes, intercepts, and derived k_{H^+}

[3]Tables S1 and S2 are on deposit and may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

values are listed in Table 1. Linear free energy relationships (LFER's) for both the log k_0 intercepts and the $m^{\neq}m^*$ slopes as functions of σ^+ are shown in Fig. 2; ρ^+ is −5.28. No σ^+ value is known for the 4-$CF_3C\equiv C$ substituent, but based upon the LFER for the others a value of 0.38 can be calculated from this work. Rate constants obtained for the 4-CF_3CH_2CO substituent, compound **1***h* in Table 1, are not directly comparable with the others because this compound appears to protonate on the substituent carbonyl oxygen (e.g., see the highly deviant slope in Table 1), and as sufficient information to allow for this is not available, the actual reaction rate could not be calculated, as it could be for **3**, see below.

The results of applying eq. [2] to the plenitude of literature information available for **2** (6–14) are listed in Tables 2 and 3. Results obtained by different authors are in complete agreement, and so all data for the same compound were treated together, regardless of source. Table 2 lists the basic $m^{\neq}m^*$, log k_0 and k_{H^+} information, and Table 3 has the activation parameters and solvent isotope effects obtainable for some of

[f]$m^* = 1$ (assumed).

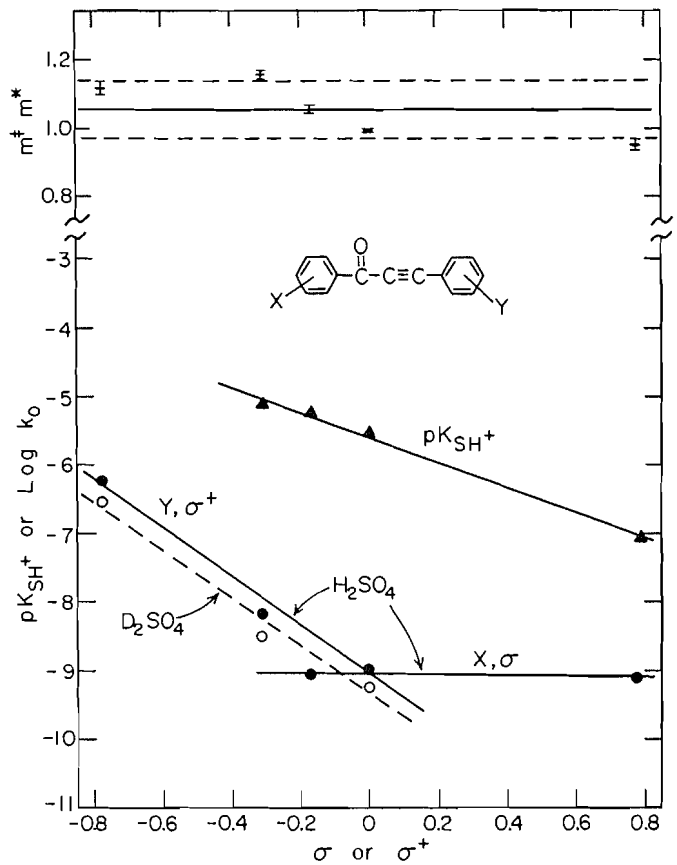

FIG. 4. LFER plots for **3**. Data from Tables 4 and 5. See Fig. 2. The pK_{SH^+} values are carbonyl group basicities; see text. For the remote substituents X, σ values are used; for the ones nearest the vinyl cation centre, Y, σ^+ values.

the phenylacetylenes. An LFER for the Table 2 information is given as Fig. 3; ρ^+ is −4.03.

Compound **3** (15) also protonates on the carbonyl oxygen, and plots according to eq. [2] curve downward because of this. However, the curvature can be accounted for by adding an additional $\log(C_S/(C_S + C_{SH^+}))$ term to eq. [2] (18), and curve-fitting the entire equation to obtain slope, intercept, and pK_{SH^+} (25). Sufficient rate constant data were available to also enable calculation of m^* for carbonyl protonation in two cases; in two more $m^* = 1$ was assumed, based upon the two known ones (Table 5). For **3***a* carbonyl protonation was not a complication. Table 4 lists the basic eq. [2] information, and Table 5 has the pK_{SH^+} values, with activation parameters and solvent isotope effects. Figure 4 has the LFER's; changing Y directly affects the vinyl cation, ρ^+ being −3.54, but changing X on the benzoyl group does not, ρ being essentially zero. The benzoyl pK_{SH^+} values also form a reasonable LFER, the ρ for this being -1.8 ± 0.1.

The phenylpropiolic acids **4** give β-ketoacids as first-formed products, which subsequently decarboxylate (16). However, this is not a problem in obtaining the hydration rates (16), and the excess acidity analysis results are given in Table 6. Figure 5 has the LFER's; ρ^+ is −3.85. Here for the first time it is apparent that the $m^{\neq}m^*$ slopes also vary with substituent; for **1**–**3** (Figs. 2–4) they are invariant.

In Table 7 we have collected together the results of applying eq. [2] to some other 25°C alkyne hydration rate constants, which we had obtained previously (4, 5) or which are available in the literature (6, 13, 17), for comparison and completeness. Table 8 is a summary table, containing the ρ^+ values for **1**–**4**, the intercepts of the LFER's in Figs. 2–5 (the most convenient data for relative rate comparisons), averaged solvent isotope effects, and, except for **4**, averaged $m^{\neq}m^*$ slopes.

Discussion

All of the evidence in the previous section is in favour of the rate-determining vinyl cation formation mechanism for this reaction, given in eq. [1]: the fact of linearity according to eq. [2] (18); the magnitudes of most of the entropies of activation (29); the magnitudes of the $m^{\neq}m^*$ slopes. These latter are all less than the 1.8 that is typical of carbocation formation m^* values (30); unfortunately no m^* value is available for vinyl cation formation. However, it seems likely that all of the $m^{\neq}$ values will be less than 1, the mechanistic criterion for an A-S_E2 process (18).

Having said that, some of the individual numbers are puzzling. The magnitudes of all of the solvent isotope effects lie between the values of 2 and 4, but it is by no means obvious why that for **2** should be 3, intermediate between the value of 2 obtained for **3**, with its deactivating benzoyl group, and the value of 4 obtained for **4**, with its deactivating CO_2H group. There are wide discrepancies between the entropies of activation for **3***a*, **3***b*, and **3***c* in Table 5; however, since these are derived from rate constants obtained at only two temperatures (15) they may not be too reliable. Typical protonation m^* values for the carbonyl group are around 0.6 (23), considerably lower than those of around 1.0 found for **3**.

All of the deactivating substituents do in fact slow the reac-

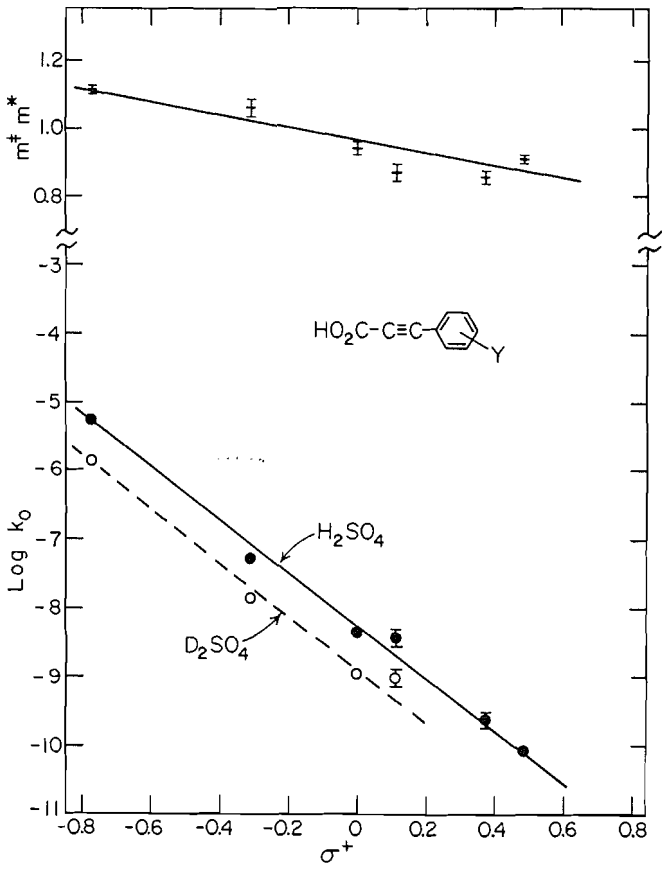

FIG. 5. LFER plots for **4**. Data from Table 6. See Fig. 2.

tion down. Table 8 shows that log k_0 for **2** (Z = H) is at least two log units more positive (factor of 100 times faster) than that for **1** (Z = CF_3), **3** (Z = COC_6H_4-X), and **4** (Z = CO_2H). However, **1** is far more substituent sensitive ($\rho^+ = -5.3$) than **3** ($\rho^+ = -3.5$) and **4** ($\rho^+ = -3.8$); **2** lies between, at −4.0. Electron demand in the transition state must be stronger with a non-polarizable CF_3 substituent present.

Dividing the $m^{\neq}m^*$ slopes in Table 8 by 1.8 should give some idea of the degree of proton transfer at the transition state (18, 31). The fastest reaction is that of **2**, followed by those of **4**, **1**, and **3**; the extents of proton transfer calculated this way are 76%, about 54%, 67%, and 59%. (If m^* for a vinyl cation is not 1.8, the absolute magnitudes will be different, but it is unlikely that the relative magnitudes will change.) Thus the fastest reaction may well have the most advanced transition state. To explain this counter-intuitive result a two-dimensional reaction surface such as the one drawn by Chokotho and Johnson (10) is undoubtedly necessary, rather than a linear reaction profile.

Previously, in a study of acylal and thioacylal hydrolyses (32), we found that the reaction ρ values were dependent upon the acidity at which they were measured. When using the excess acidity method, this is most easily expressed as a variation of the $m^{\neq}m^*$ slopes with substituent; if these are in fact independent of substituent, ρ will not vary with acidity (32). This is the case in this work for **1** and **2**, and probably for **3** (see Figs. 2–4), which agrees with Johnson's conclusion for **2** (9, 10). However, compound **4** certainly does not have a substituent-independent slope (see Fig. 5); in this case ρ^+ measured at high acidities will be *more negative* than the value reported here, extrapolated to the standard state. This is in contrast to the acylal/thioacylal study, which found that ρ at high acidity is usually *more positive*

for those compounds (32). The reason for the difference is, at present, obscure; the slope of the Fig. 5 line is difficult to interpret since $m^{\neq}m^*$ is already an LFER slope parameter (33) and, plotting these in another LFER, while a useful visual illustration, has no readily interpretable theoretical meaning.

We reemphasize here that derived quantities like ρ and $\Delta S^{\neq}$ have maximum mechanistic meaning if obtained in the standard state, as is done in this work by extrapolation to $X = 0$, rather than at some arbitrary acidity. Studies like this have a bearing on the incompatibility of the Hammett equation with the reactivity–selectivity principle (RSP) discussed by Johnson (9, 10, 34), even if this bearing is hard to interpret. The effect for **4** found here would be categorized by Johnson as an anti-RSP effect, whereas **1**, **2**, and **3** show no evidence for the operation of the RSP at all.

The *N*-formyl-serineamide (For-Ser-NH_2), a model diamide for the conformational behaviour of the protein backbone at serine residue, has been gradient optimized for selected conformations at the *ab initio* 3-21G level. Previous molecular mechanics ECEPP/2 calculations suggested that the optimal side-chain (χ_1, χ_2) and backbone (ϕ, ψ) conformations are strongly coupled, due to intramolecular H-bonding formed between the side-chain hydroxyl group and the amide moiety. Four different side-chain geometries (I–IV) were considered at each of the four backbone conformations (α, β, β', γ) giving a total 16 different critical points on the coupled (ϕ, ψ)–(χ_1, χ_2) surface. The very fact that upon changing the (ϕ, ψ) values the global minimum of (χ_1, χ_2) surface was shifted indicated clearly that the two subspaces are strongly coupled. The present theoretical results were compared to experimental peptide and protein geometries taken from the Cambridge Structure Database and from the Brookhaven Protein Data Bank, respectively.

Key words: conformation of a serinediamide, backbone side-chain interactions, topological analysis of potential energy surfaces, *ab initio* calculations.

ANDRÁS PERCZEL, RAYMOND DAUDEL, JÁNOS G. ÁNGYÁN et IMRE G. CSIZMADIA. Can. J. Chem. **68**, 1882 (1990).

Opérant au niveau 3-21G et faisant appel à des calculs *ab initio*, on a optimisé des conformations choisies de la *N*-formyl-sérinamide (For-Ser-NH_2), une diamide utilisée comme modèle pour étudier le comportement conformationnel du squelette protéinique au niveau des restes de sérine. Des calculs antérieurs au niveau ECEPP/2 avaient suggéré que les conformations optimales de la chaîne latérale (χ_1, χ_2) et du squelette (ϕ, ψ) sont fortement couplées à cause d'une liaison hydrogène intramoléculaire entre le groupement hydroxyle de la chaîne latérale et la portion amide. On a considéré quatre géométries différentes (I–IV) pour la chaîne latérale, pour chacune des quatre conformations (α, β, β', γ) du squelette, soit 16 points critiques différents sur la surface de couplage (ϕ, ψ)–(χ_1, χ_2). Le fait qu'un changement dans les valeurs de (ϕ, ψ) provoque un déplacement global de la surface (χ_1, χ_2) indique clairement que les deux sous-surfaces sont fortement couplées. On a comparé les résultats géométriques obtenus ici avec les géométries expérimentales de peptides et de protéines telles qu'on peut extraire respectivement de la base de donnée de structures de Cambridge et de la banque de donnée sur les protéines de Brookhaven.

Mots clés: conformation d'une sérindiamide, interactions du squelette avec la chaîne latérale, analyse topologique des surfaces de l'énergie potentielle, calculs *ab initio*.

[Traduit par la revue]

1. Introduction

The quantum chemical study of the conformational behaviour of diamide model systems has been the subject of continuous interest since Pullman's pioneering work at the semiempirical PCILO level (1). During the 80's several papers (2–9) had been published on *ab initio* studies of such systems. Recent calculations on the simplest case (i.e. on *N*-methyl-glycineamide) have raised the question about the reliability of earlier molecular mechanics (10, 11), and semiempirical (1) studies for predicting peptide conformations.

The smallest chiral system, *N*-acetylalanine *N'*-methylamide, is another important model case. *Ab initio* 4-21G calculations by Schäfer and co-workers (6, 7) demonstrated the possibility of interconversion of the most important α, β, and γ conformations through low-energy pathways (7). They found that the β and γ conformations are stabilized by intramolecular H-bonding, which is characteristic to these specific backbone structures. The "intra-backbone" H-bonding may be perturbed by the presence of polar side-chains with H-bonding donor/acceptor ability and a new side-chain/backbone H-bond may eventually be formed. The simplest system modelling this feature is the serine diamide. In the recent calculations by Schäfer and co-workers (6) on the *N*-acetyl-*N'*-methylserineamide, the side-chain conformation was kept fixed in + *syn-clinial* conformation ($\chi_1 = 60°$, $\chi_2 = 60°$) as suggested by their previous studies on the *N*-acetyl-*N'*-methylserineamide (9). This strategy was based on the hypothesis that perturbations coming from different (χ_1, χ_2) side-chain structures can be neglected on the two dimensional (ϕ, ψ) cross-section of the conformational potential energy surface. Unfortunately this assumption is not confirmed by X-ray, NMR, and CD-spectroscopical evidences (12, 13). In effect, the "side-chain/backbone interaction" is a key concept in the interpretation of experimental data (12, 13).

The four possible structures involving H-bonding between the backbone and the serine side-chain have been discussed in a molecular mechanics study by Scheraga and co-workers on

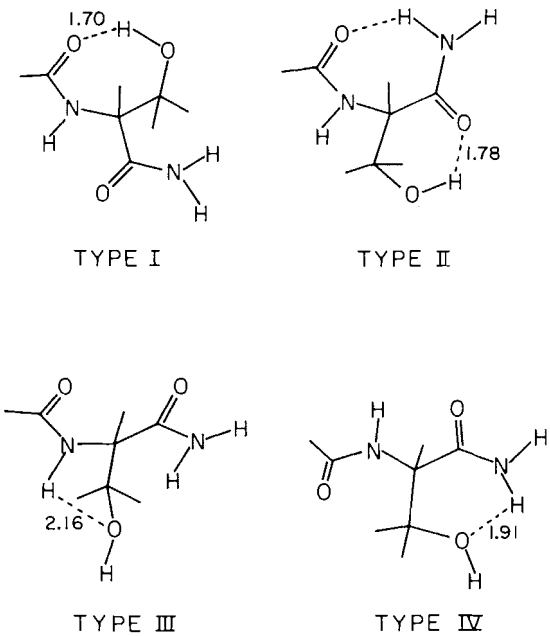

FIG. 1. The four hydrogen bonded conformations of FSA used as starting point for the ab initio SCF-MO computions. The gradient optimized torsional angles are given below in degree: type **I** has $\phi = 174, \psi = 169, \chi_1 = -89, \chi_2 = 52$; type **II** has $\phi = -83, \psi = 72, \chi_1 = 53, \chi_2 = 66$; type **III** has $\phi = -76, \psi = -36, \chi_1 = 49, \chi_2 = 178$; type **IV** has $\phi = -171, \psi = -172, \chi_1 = -172, \chi_2 = 173$. The hydrogen bond distances are given in Angström.

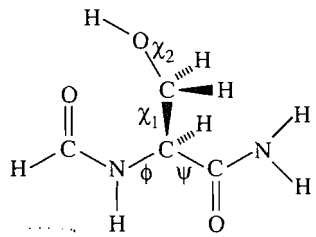
N-acetyl-*N'*-methylserineamide (10). These structures, labelled as **I, II, III,** and **IV,** are illustrated in Fig. 1.

In the present work a systematic study of the coupling between the serine side-chain and the peptide model system was undertaken by calculating the various cross-sections as well as selecting the critical points of the four-dimensional conformational hypersurface $E(\phi, \psi, \chi_1, \chi_2)$. The variables were torsional angles defined according to the IUPAC-IUB convention for peptides.



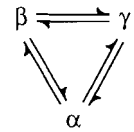
This four-dimensional space has been subdivided into two subspaces:

$$(\phi, \psi, \chi_1, \chi_2) \rightarrow \begin{cases} (\phi, \psi) \\ (\chi_1, \chi_2) \end{cases}$$

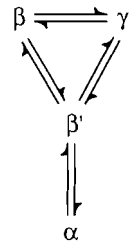
Such a subdivision leads to two (regular) potential energy surfaces each having two independent variables. These two variables are parametrically dependent on the other two variables as well as an ensemble of the remaining internal coordinates of the molecules.

$$E(\phi, \psi, \chi_1, \chi_2 \rightarrow \begin{cases} E_{\chi_1, \chi_2}(\phi, \psi) \\ E_{\phi, \psi}(\chi_1, \chi_2) \end{cases}$$

The $E(\phi, \psi)$ surface is expected to have several minima, and some of these should correspond to traditional backbone conformations: α-helix, β-pleated sheet, γ-turn, (i.e. α, β, γ). The interconnection between the three classical conformations (α, β, γ) that exists in peptides and in proteins may be depicted by the following scheme:



Another possibility is that a common transient structure may be considered. This transient structure was labeled as β' by Schäfer *et al.* (4), and its involvement is illustrated by



This transient structure, β' has turned out to be a first-order saddle point. To each of the minima (α, β, γ), as well as to the transient structure β' of the $E(\phi,\psi)$ surface one may associate a separate $E(\chi_1, \chi_2)$ surface, with its own minima labelled as **I, II, III, IV** (Fig. 1).

2. Computational method

Due to the large dimensionality of the problem, peptide and protein conformations are usually studied by empirical methods. ECEPP/2 calculations (11) were performed on twenty backbone geometries of various (φ, ψ) values, selected on low-energy pathways, interconnecting the α, β, and γ structures of the model diamide. For each of these backbone conformations a separate $E(\chi_1, \chi_2)$ surface was generated consisting of a 25 × 25 grid.

Four typical backbone conformations (α, β, β', γ) were computed using an *ab initio* SCF-MO method. For each of these four possible backbone structures four side-chain conformations (**I, II, III, IV**) were included in the study yielding a total of sixteen rotamers of FSA. These sixteen structures were gradient-optimized using the MONSTERGAUSS program (14) at the 3-21 G basis set level. All internal degrees of freedom, including bond lengths, bond angles, and torsion angles were optimized, thus energies reported in this paper are for totally relaxed geometries. The extent of optimization was such that the total gradient length was reduced to at least a few hundredths of a mdyn. However, most of the individual gradients were no more than a few thousandths of a mdyn. Further geometry optimization at this level, due to the length of the calculation, can only be performed with an excessive use of computer time.

3. Results and discussion

3.1. Molecular mechanics calculation

The ECEPP/2 potential energy surface is shown in Fig. 2. It can be seen that the low energy paths going from the β-pleated sheet conformation to α may occur via two pathways: either on the way of crossing through γ and β' or via passing directly through β' (see Fig. 2).

One of the reaction coordinates on the $E(\phi, \psi)$ surface is a path connecting points from β (−150, 150) through β' (−150, 80) to α (−50, −50). The other reaction coordinate connects

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12

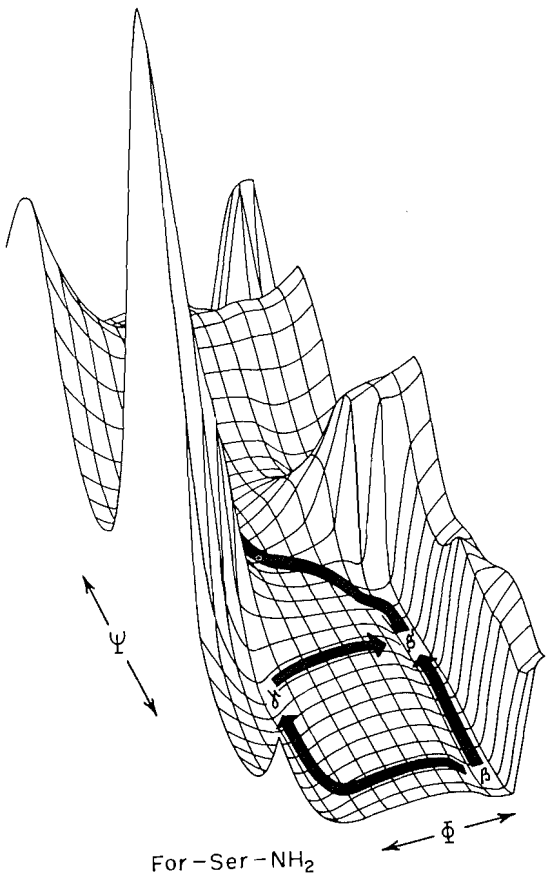

FIG. 2. An enlarged detail of $E(\phi, \psi)$ surface of FSA computed with ECEPP/2 in the range of $-180 < \phi < -50$ and $-180 < \psi < 180$ where the low energy pathways are indicated as $\beta \rightarrow \gamma \rightarrow \beta' \rightarrow \alpha$. (The position of the α conformation is hidden by the high maximum).

points from β through γ $(-75, 75)$ toward β' $(-150, 80)$ with a destination to α $(-50, 50)$. On these paths the β' is a saddle point. At several (ϕ, ψ) points, on or near the path, we performed (χ_1, χ_2) grid searches and obtained $E(\chi_1, \chi_2)$ surfaces with similar general features, as shown in Fig. 3.

3.1.1. The topology of $E(\chi_1, \chi_2)$ *surfaces*

The critical points of cross-sections of the conformational potential energy surfaces $E(\chi_1, \chi_2)$ at all (ϕ, ψ) points were found and the index (λ) of the critical points was evaluated using numerical methods to determine the second derivatives of the energy. The minima ($\lambda = 0$) were labelled as 0_i, the saddle points ($\lambda = 1$) as 1_i and the maxima ($\lambda = 2$) as 2_i. The $E(\chi_1, \chi_2)$ surface, given in Fig. 4, is regarded as "ideal" (15), since the alternating sum rule (16).

$$N_0 + N_1 + N_2 = 0$$

is such that it follows the "κ- rule" (17, 18)

$$N_\lambda = \kappa \binom{n}{\lambda}$$

Note that $N\lambda$ is the total number of critical points of a given type (λ) on the whole surface: $(9 - 18 + 9 = 0)$. The value of κ is the product of the two three-fold rotational axes: $3^2 = 9$ and $n = 2$ is the dimensionality of the conformational space.

Due to the presence of internal attraction or repulsion, all other $E(\chi_1, \chi_2)$ surfaces are more or less distorted but they still could be considered as "ideal". Detailed analysis of the $E(\chi_1, \chi_2)$ surface shows that at all $E(\phi,\psi)$ minima the number of

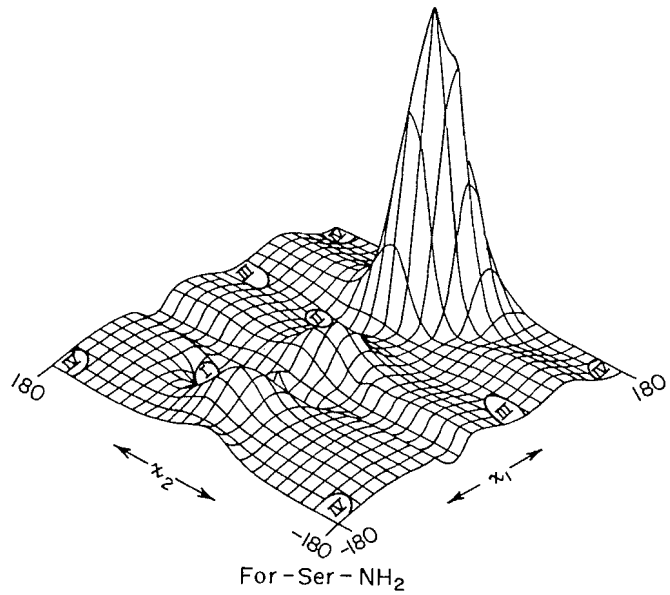

FIG. 3. A typical $E(\chi_1, \chi_2)$ surface of FSA computed with ECEPP/2. Roman numbers indicate the labeled minima associated with the —CH_2OH side-chain conformation.

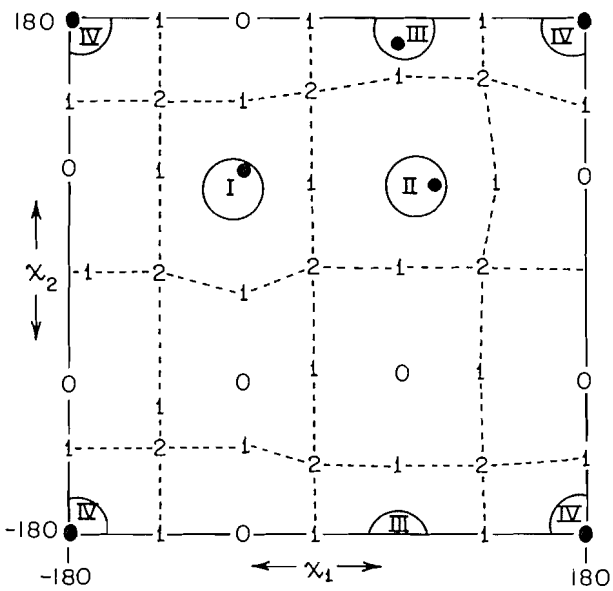

FIG. 4. The topology of an $E(\chi_1, \chi_2)$ surface, where 0's indicate the various minima, 1's symbolize the different saddle points, and 2's are positioned at all the maxima. Roman labeled black spots are the most important minima. The catchment regions associated with each of the minima are located with the four broken lines that are forming the various rectangles. The black spots around the most important minima denote the regions where the actual side-chain minima (**I-IV**) of the four backbone conformations ($\alpha, \beta, \beta', \gamma$) are located (see Table 1 for details).

critical points in $E(\chi_1, \chi_2)$ surfaces are the same. In other words, a displacement on the $E(\phi, \psi)$ surface leaves $E(\chi_1, \chi_2)$ always identical in a topological sense; only the values of the position and height of the critical points are changing but not the overall feature of the $E(\chi_1, \chi_2)$ surfaces. From the given nine minima of the $E(\chi_1, \chi_2)$ surface only four of the minima are stabilized by different types of intramolecular hydrogen bonding (**I, II, III, IV**) as shown in Fig. 3. These four critical points have more significance than the others, as any one of these conformations

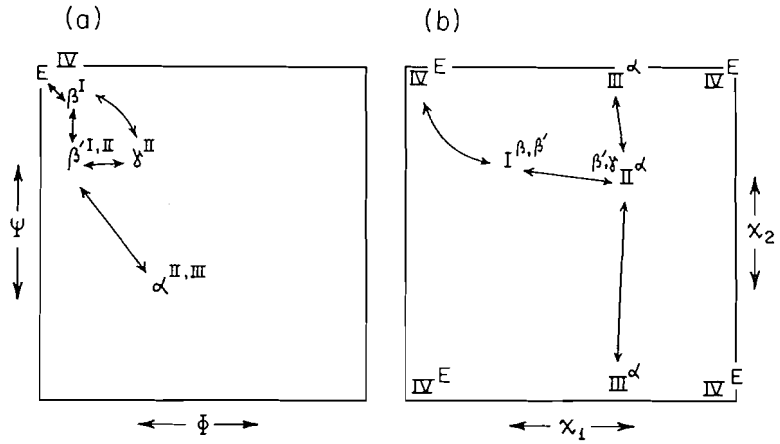

FIG. 5. Coupling effects of the $E(\phi, \psi)$ and $E(\chi_1, \chi_2)$ surfaces. The torsion angles (ϕ, ψ) of backbone and the torsion angles (χ_1, χ_2) of the side-chains mutually determine each other. Each of the symbols used consists of two characters. The main symbol characterizes the critical point on a given surface and its superscript characterizes the minimum on the associated coupled surface.

could be candidates for global minimum in the course of changing (ϕ, ψ) values, corresponding to different backbone conformations (e.g. $\beta \rightarrow \beta' \rightarrow \alpha$ or $\beta \rightarrow \gamma \rightarrow \beta' \rightarrow \alpha$).

3.1.2. Coupling of the (ϕ, ψ) and (χ_1, χ_2) subspaces

It has been already demonstrated (6) that there are several minima both on the $E(\phi, \psi)$ and on the $E(\chi_1, \chi_2)$ surfaces. The most important of them are labelled as α, β, β', γ and **I, II, III, IV**, respectively. The present study of FSA showed that minima on the $E(\phi, \psi)$ and an $E(\chi_1, \chi_2)$ are intimately related to each other. A rigorous interdependence can be demonstrated in the sense that displacement along the minimum energy pathway on $E(\phi, \psi)$ involves a shift of the global minimum on the $E(\chi_1, \chi_2)$ potential energy surface. This is also illustrated in Fig. 5*a* and *b*. The most favourable side-chain conformation can be found at the upper left corner of the $E(\phi, \psi)$ surface, labelled as extended (E) backbone geometry, *i.e.* structure **IV**. In this structure (E–**IV**) all torsion angles are *trans*-like and the six-membered ring involves a hydrogen bond between the side-chain hydroxy group and the amino group of the C-terminal amide (O...HN distance is 1.91 Å). The (E–**IV**) $\rightarrow$ (β-**I**) transition is also illustrated in Fig. 6.

The β-pleated sheet, labelled as the β conformation ($\phi = -150$, $\psi = 150$), slightly differs from the extended (*E*) one ($\phi = -180$, $\psi = 180$) and involves a side-chain conformation participating in a seven-membered intramolecular hydrogen bond. The HO...HN distance has a favourable 1.70 Å value (Fig. 1). Following the pathway from β to β' (Fig. 5*a*) one observes a displacement on the $E(\chi_1, \chi_2)$ surface (Fig. 5*b*) in the horizontal direction from **I** to **II**. The γ backbone conformation ($\phi = -78$, $\psi = 78$) is associated with a $+syn$ clinal ($\chi_1 = 68$, $\chi_2 = 56$) side-chain conformation resulting in two hydrogen bonds. The rigidity of the geometry in structure γ-**II** is produced by locking of the all four tension angles due to the presence of the two hydrogen bonds (Fig. 1). One of these forms a seven-membered ring, where the proton donor is the NH of the *C*-terminal amide and the carbonyl of the *N*-terminal formyl group is the proton acceptor. In the same structure there is also a six-membered hydrogen-bonded ring in which the proton is donated by the hydroxy-methyl group of the side-chain and accepted by the carbonyl group of the serine—CONG—moiety.

Following the pathway from β or from γ towards α through the saddle point β' induced a displacement of the global minimum on the $E(\chi_1, \chi_2)$ surface from **I** or **II** to **III**. On the way from **II** towards **III** there is a saddle point. As it may be seen from Fig. 5*b*, it is only 3 kcal/mol higher in energy than the adjacent minimum previously occupied. Conformation **III** is a five-membered ring resulting from the H-bonding between the serine NH group and the serine hydroxyl group, with an interatomic NH...O distance of 2.16 Å.

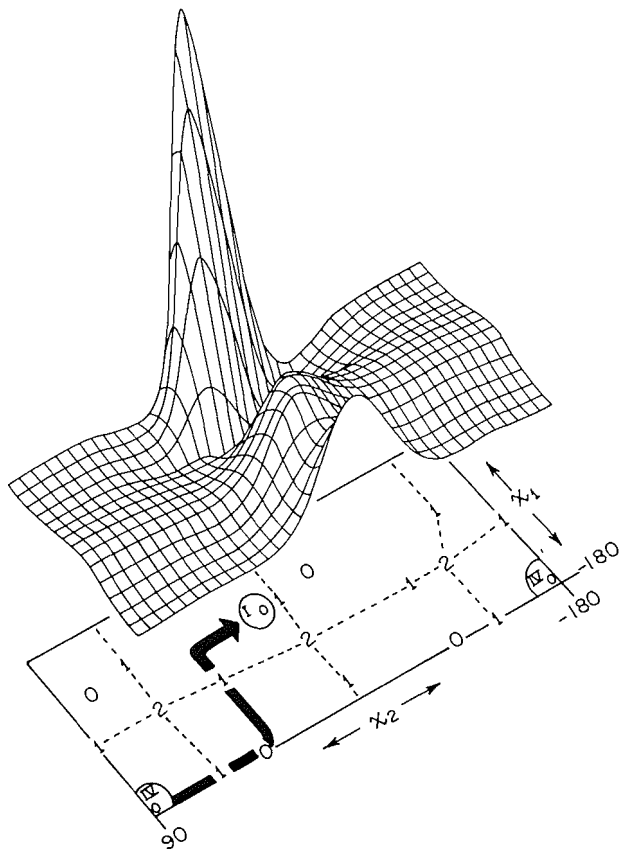

FIG. 6. The low energy pathway related **IV** with **I** on the $E(\chi_1, \chi_2)$ surfaces. The path is directed from minimum **IV** to minimum **I** through an unlabeled minimum and two unlabeled saddle points.

In order to prove thoroughly the hypothesis of "coupling phenomenon" between the (ϕ, ψ) and (χ_1, χ_2) subspaces, *ab initio* calculations were performed on the above sixteen selected geometries. In agreement with the conclusions drawn from the

molecular mechanics computations (Table 1) the *ab initio* results (Table 2) confirm the hypothesis and demonstrate clearly that the backbone torsional angles (ϕ, ψ) and the optimal side-chain dihedral angles (χ_1, χ_2) mutually dependent on each other. Thus this coupling enables one to predict the optimum (χ_1, χ_2) values from a given pair of (ϕ, ψ) values and vice versa. Details of this phenomenon are given in the next section.

3.2. *Ab initio SCF results and their comparison with molecular mechanics*

Tables 1 and 2 demonstrate the qualitative agreement of the results obtained by the two methods. In β′ and γ conformations both methods predict the same dihedral angle combinations for the side-chain. Moreover, all conformations having β′ or γ like backbones have the same relative energetic order (ΔE_{ref}).

Note that for the *ab initio* results (Table 2) the minimum, labelled as β-**IV** structure has a backbone conformation ($\phi = -171$, $\psi = -173$), which is in fact quite close to the extended geometry ($\phi = -180$, $\psi = -180$). If we disregard this structure (β-**IV**), we find that the remaining three conformations obtained in molecular mechanics (Table 1) and *ab initio* (Table 2) results are in qualitative agreement in as far as the order of stability is the same.

As far as the α-like backbone torsion angles are concerned one can see that there is only a few tenths of kcal/mol difference between type **II** and type **III** conformations. This means that both minima on the $E(\chi_1, \chi_2)$ surface can be populated approximately to the same extent. However, the *ab initio* calculation predicted a slightly lower energy for type **II** in contrast with ECEPP/2 method. Figure 5 schematically illustrates the topology of the two surfaces. The topology is the same, irrespective of the fact that it is generated by molecular mechanics or by the *ab initio* methods. Consequently the two methods are in good qualitative agreeesnt.

3.3. *Computed conformations versus crystal structures*

X-ray data concerning serine containing peptides and proteins can be obtained from the Cambridge Structural Data Base (19) and from Brookhaven Protein Data Bank (20). It was the pioneering work by Dunitz and co-workers (2) that first

[a]Torsion angles($\phi, \psi, (\chi_1, \chi_2)$ in degrees and energy differences (ΔE_{rel}, ΔE_{abs}) in kcal/mol units, BB = backbone, SC = side-chain.

indicated that the maximum population of a given geometrical arrangement for a particular fragment in various molecular environments, as deduced from crystallographic data bases, outlines the domain, where a minimum lies. This leads to the possibility of a meaningful comparison between experimental and theoretical results. This type of procedure has, for example, been applied recently in our laboratory to the case of pyrrolidone ring puckering (22).

The application of a procedure similar to that suggested by Dunitz and co-workers seemed to be desirable here as well. Due to the relatively small number of serine diamide fragments in CCDB, a statistically significant analysis of the data was difficult. We also have to emphasize that the crystal-phase conformation of a peptide is not necessarily the best choice of a primary standard to be compared with theoretical results. This is

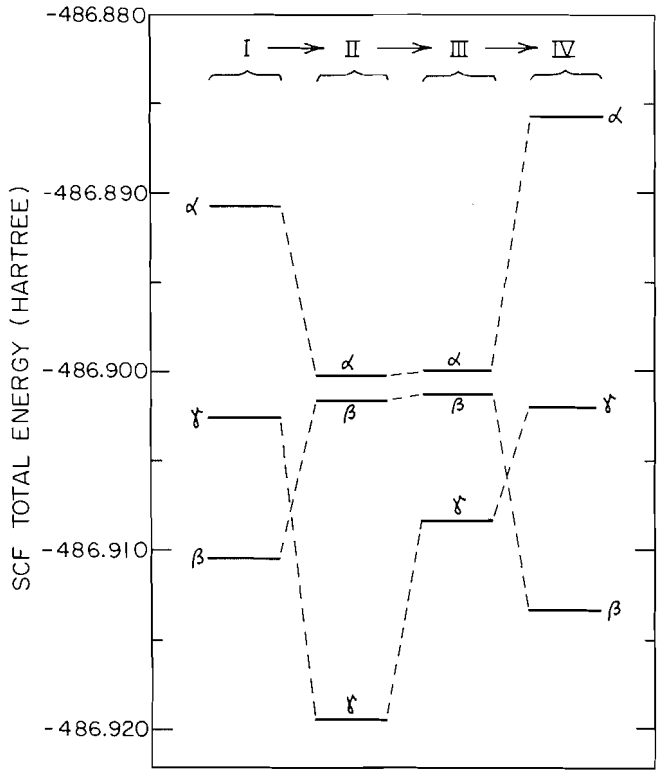

FIG. 7. Energy levels of α, β, and γ backbone conformations (ϕ, ψ) associated with changing sidechain (χ_1, χ_2) conformations: **I → II → III → IV.**

due to the almost always presence of external hydrogen bonds or hydrophobic attractions (23). Nevertheless, a comparison of experimentally determined conformations with surrounding-dependence and the computed environment-free geometries might lead to certain conclusions.

From the few serine-containing structures found in the Cambridge Structure Data Bank only six molecules have features reminiscent of the FSA structure. There are two cyclo-dioxopiperazines (cyclo-(Ser-Ser) and cyclo-(Ser-His)) with distorted backbones due to the six-membered diamide ring that have (ϕ,ψ) torsion angles close to 0 degree. Whereas it is not a typical backbone conformation, it is on a low pathway (Fig. 2) and the coupling correlation predicts type **II** or type **III** side-chain conformation, which happened to be the observed crystallographic combinations of χ_1 and χ_2.

In cyclio(Gly-Pro-Dêr-(D)Ala-Pro) the serine torsion angles are $\phi = -167.4$, $\psi = 114.7$, $\chi_1 = 179.5$, $\chi_2 = 172$, strongly resembling the type E-**IV** which is in good agreement with the present predictions. Furthermore, *t*-butylcarbonyl-L-prolyl-*N*-methyl-L-serine amide represents a conformation of the type α-**III** ($\phi = -75$, $\psi = -11$, $\chi_1 = 50.8$, $\chi_2 = -168.3$) just as well as *t*-butylcarbonyl-L-prolyl-L-serine-*N'*-methylamide fits in the class labeled as type α-**III** ($\phi = -75$, $\psi = -11$, $\chi_1 = 50.9$, $\chi_2 = -167$). The prediction based on FSA stereochemistry is generally good, the only exception is *t*-butylcarbonyl-L-serine-*N'*-methylamide. In this case the side-chain conformation is type **III** ($\chi_1 = 69.7$, $\chi_2 = -88.2$) which does not harmonize with the backbone conformation ($\phi = -90.8$, $\psi = 153.4$) and with the rule deduced from the FSA results. However, we can explain this discrepancy if we allow for geometrical variations due to the strong intermolecular interactions detected in the experimentally determined crystal conformations.

Instead of analyzing the whole set of data coming from several hundred proteins provided by the Brookhaven Protein Data Bank, attention has been paid to a randomly chosen subset consisting of eight proteins: SUBSTILISIN/BPN (E.C.3.4.21.14), LYSOZYME (E.C.3.2.1.17), RIBONUCLEASE (E.C.3.1.4.22), CYTOCHROME C, FERROCYTOCHROME C, TOSYLE-LASTASE (E.C.3.4.21.11), MYOGLOBINE, and ACID PROTEASE (E.C.3.4.23.9). A comprehensive utilization of the information contained in the Brookhaven PDB for the present purposes is difficult because of the lack of hydrogen coordinates, i.e., the absence of χ_2 angles.

The above eight proteins analyzed contained 116 serine units. About 22% of these was α-helix like, 9% was γ-turn like, and 16% was β-pleated sheet like conformations. The remaining 53% belonged to other backbone conformations. In the β backbone conformation only two third of the side-chain geometry was of type **I** or **IV** that obeyed the present coupling rule. In the γ backbone conformation only a tenth was of type **II** and nine tenth was of type **I**. On the other hand, all γ backbone conformations were distorted toward the β conformation, for α-like backbone geometry one fourth was of the expected type **II** or type **III**. These discrepancies can be regarded as a result of long-range intermolecular interactions. In effect, the serine residue are most probably situated in hydrophylic regions of the protein, *i.e.*, where the intramolecular H-bonding is competing with external H-bondings caused by other side-chains or solvent molecules.

4. Conclusions

The present analysis demonstrae s that a strong correlation (coupling rule) exists between the (ϕ, ψ) and the (χ_1, χ_2) subspaces in the four dimensional conformational space (ϕ,ψ, χ_1, χ_2) associated with the stereochemistry of For-Ser-NH. This coupling enables one to predict the optimum χ_1 and χ_2 from a given pair of (ϕ, ψ) values and *vice versa*, as illustrated by Fig. 6. If the energy levels shown on Fig. 6 would reduce or increase along the reaction coordinate associated with the side-chain conformation (**I → II → III → IV**) in a parallel fashion then the $E(\phi, \psi)$ and $E(\chi_1, \chi_2)$ surfaces would be completely independent. A small deviation from such a parallelism would indicate a modest interaction between the (ϕ, ψ) and (χ_1, χ_2) subspaces but the crossing of levels, as shown in Fig. 7, is a clear indication of strong coupling of the two subspaces.

It is found that internal hydrogen bonding is an important feature which influences the overall conformation of the serine-containing peptides as demonstrated by both theoretical calculations and experimental findings.

A study of the observable axial- and equatorial-2,4-dimethyl-2-adamantyl cations. Further examples of equilibrating nonclassical structures in "ordinary" tertiary carbocations

D. J. BUFFAM, T. S. SORENSEN,[1] AND S. M. WHITWORTH
The Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received April 3, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

D. J. BUFFAM, T. S. SORENSEN, and S. M. WHITWORTH. Can. J. Chem. **68**, 1889 (1990).

The title cations have been prepared *in situ* from the corresponding tertiary alcohols, using three different superacid systems. The ^{13}C NMR spectra were measured at a number of different temperatures, using the structurally related ^{13}C peaks of internal 2-methyl-2-adamantyl cation as a reference. Using this protocol, one finds that the ^{13}C chemical shifts of the four β carbons are quite temperature dependent, two of them shifting to higher field and the other two on the opposite face shifting to lower field, or vice versa, as the temperature is increased or decreased. This behavior is uniquely ascribed to a rapid equilibration between two "structures" for each cation system. The two structures in question involve selective C–C hyperconjugative delocalization on one face or the other of the 2-adamantyl skeleton. In the case of the 4-equatorial-methyl isomer, a structure with C–C hyperconjugation on the methyl-substituted face is most stable, while for the 4-axial-methyl cation, the structure with delocalization from the face opposite the substituent is favored. The former preference is regarded as stereoelectronic in origin while the latter is ascribed to steric effects.

Key words: non-planar carbocations, temperature dependent NMR shifts, stereoelectronic effects.

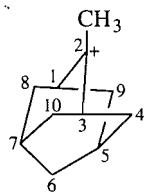
D. J. BUFFAM, T. S. SORENSEN et S. M. WHITWORTH. Can. J. Chem. **68**, 1889 (1990).

Utilisant trois systèmes différents de superacides, on a préparé les cations mentionnés dans le titre *in situ* à partir des alcools tertiaires correspondants. On a mesuré leurs spectres RMN du ^{13}C à diverses températures; comme référence, on a utilisé les bandes internes du cation 2-méthyl-2-adamantyle. Utilisant cette méthode, on trouve que, en RMN du ^{13}C, les déplacements chimiques des quatre carbones β dépendent beaucoup de la température; lorsqu'on augmente la température, deux des déplacements dérivent vers les hauts champs alors que les deux autres qui correspondent aux carbones qui se trouvent sur la face opposée se déplacent vers les bas champs et l'inverse se produit lorsqu'on diminue la température. Ce comportement est attribué uniquement à un équilibre rapide entre deux «structures» pour système cationique. Les deux «structures» en question impliquent une délocalisation sélective par hyperconjugaison C—C sur une face ou l'autre du squelette 2-adamantyle. Dans le cas de l'isomère portant un groupement méthyle en position 4-équatoriale, une structure avec une hyperconjugaison C–C de la face substituée par un méthyle est la plus stable; pour le cation portant un groupement méthyle en position 4-axiale, la structure favorisée est celle avec une délocalisation de la face opposée au substituant. On considère que la première préférence est d'origine stéréoélectronique alors que la dernière est attribuée à des effets stériques.

Mots clés : carbocations non-plans, déplacements RMN qui dépendent de la température, effets stéréoélectroniques.

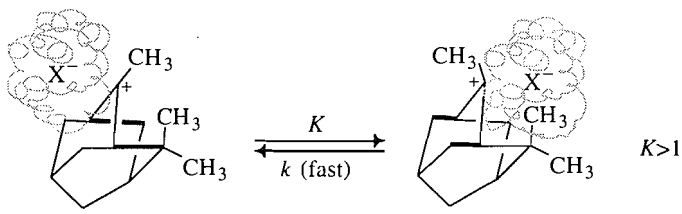
[Traduit par la revue]

Most tertiary alkyl carbocations, as a class, have been regarded as planar, sp^2-hybridized structures, and there is of course much solvolysis and stable ion work to support this generalization. Increasingly, however, as one looks in more detail at individual systems, one begins to find behavior at odds with this generalization and, furthermore, this often has some chemical reactivity or selectivity considerations. The 2-methyl-2-adamantyl cation **1** is a case in point.

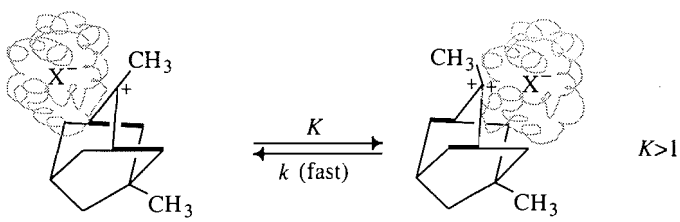


1

The ^1H and ^{13}C NMR spectral data for **1** are normal (1); however, we have recently suggested from a more detailed analysis (2, 3) that **1**, in superacid media, is in fact two structures, degenerate in energy in this case, and each involving C–C hyperconjugation with only one face of the molecule. These conclusions were derived from a study of two substituted derivatives of **1**, the 2,5-dimethyl- and the 2,4,4-trimethyl-2-adamantyl cations **2** and **3**. In each case, the evidence suggested that one had two populated structures for each cation, as shown below:



3*a* **3***b*



2*a* **2***b*

The heavy lines in these structures are meant to signify C–C hyperconjugative delocalization.

The evidence for these equilibria was indirect, in the sense that one does not see separate NMR peaks for each "*a*" and "*b*"

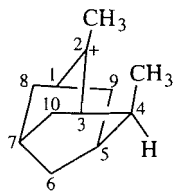
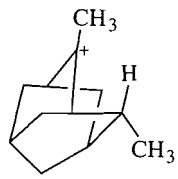
structure. However, the NMR spectra of cations **2** and **3** each showed several ^{13}C NMR peaks whose chemical shift positions had unusual temperature dependences. These observations were interpreted in terms of a rapid equilibrium of two structures **2***a* ⇄ **2***b* or **3***a* ⇄ **3***b*, resulting in averaged peaks whose positions are temperature dependent because the magnitude of K can change with a change in temperature. However, the interpretation of such temperature dependent chemical shifts is not an easy matter, as Lambert *et al.* (4) have pointed out, and in this paper we would like to report the results of a second study, in which several experimental improvements have been made. As well, the study involves two new unsymmetrical derivatives of **1**: the 2, axial-4- and the 2, equatorial-4-dimethyl-2-adamantyl cations, **4** and **5**, respectively (both depicted at this stage in a traditional way).



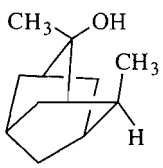
4



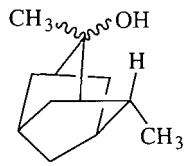
5

Results

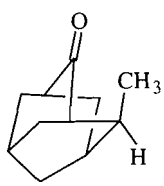
Cations **4** and **5** were generated from the corresponding tertiary alcohols **6** and **7**, which were in turn prepared from the known ketones **8** and **9**. Alcohol **6** was essentially a single stereoisomer from ^1H or ^{13}C NMR, whereas **7** was an approximate 60:40 mixture of the two epimers.



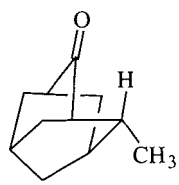
6



7



8



9

In the previous study involving cations **2** and **3**, ^{13}C NMR peaks were referenced relative to internal standards such as $CFCl_3$ or TMS, and in such instances one has to be concerned with the temperature dependence of both the substrate peaks and the reference peaks. In this study, we have used the internal 2-methyl-2-adamantyl cation **1** as a temperature reference, each peak in **4** or **5** being referenced to the corresponding peaks in **1** (except for the 4-methyl peak). In addition, the previous study involving **2** and **3** was carried out at 22.6 MHz and involved only 8K data points (4K real). The present study was carried out at 100 MHz, and up to 512K data points were used, giving a much improved digital resolution in determining the chemical shift positions. In addition, the added chemical shift dispersion at 100 MHz lessens the chances for peak overlaps. The studies were also carried out in three different acid–solvent systems, ROH in 1:1 FSO_3H–SbF_5 and SO_2ClF solvent, ROH in 4:1 FSO_3H–SbF_5, and ROH in 1:1 FSO_3H–SbF_5 and 3:1 SO_2ClF–SO_2F_2 solvent, giving in each case virtually identical results in the temperature regions where there was an overlap.

*Chemical shift assignments for **4** and **5***

At 400 MHz, both **4** and **5** show nearly resolved ^1H NMR spectra. Coupling networks were traced from COSY spectra, although the abundance of W-couplings makes this procedure tricky. The ^{13}C $\{^1H\}$ data were obtained at 100 MHz, and a DEPT spectrum was used to assign the carbon multiplicities. A HETCOR (cation **5**) or an INVERSE HETCOR (cation **4**) was then used to make the more detailed ^{13}C NMR assignments. In the end, the only ambiguity involves the C8–C10 carbons in **4**, where the two peaks have a chemical shift separation of only ca. 0.3 ppm. and the corresponding proton peaks overlap. However, the exact assignment of C8–C10 is immaterial for our purposes. The end result of these assignments is entirely consistent, i.e., the 4-methyl group has the usual effect on nearby ^{13}C resonances, including a significant shielding for carbons δ to an axial methyl group (C2 and C9 in **4**, C6 and C10 in **5**). The NMR assignments for **4** and **5** are listed in the experimental section and these are also entirely consistent with carbon assignments for the related ketones **8** and **9**.

*Temperature dependence of the ^{13}C shifts in **4** and **5***

In 1:1 FSO_3H–SbF_5 in SO_2ClF, usable data were obtained from 157 to 237 K (six temperatures) and in 4:1 FSO_3H–SbF_5, data were obtained from 198 to 280 K (five temperatures). With the mixed 3:1 SO_2ClF–SO_2F_2 solvent, data were obtained from 143 to 183 K (three temperatures), but at 143 K, some of the peaks were rather broad so these data do not in fact usefully extend the temperature range. Only the first two data sets were used in the detailed analysis. At or above 280 K, both **4** and **5** are rapidly transformed into a mixture of the 1,2-dimethyl- and 2,5-dimethyl-2-adamantyl cations (2), the latter the predominant species. The 2-methyl-2-adamantyl cation **1** reference peaks were clear of interference from **4** or **5** peaks, and in fact all three cations can be made up in a single solution and at most temperatures all 30 peaks are base-line resolved.

At each individual temperature, the chemical shift of each carbon was corrected for "intrinsic" temperature effects by using the temperature behavior of the corresponding carbon peak of **1**. There is some arbitrariness in reporting the corrected ^{13}C NMR chemical shifts for **4** and **5** since the corrections can be made in several ways. We have used the data at 200 K as uncorrected, all chemical shifts for higher or lower temperatures being adjusted by the quantity $\delta_1{}^{200}C_X - \delta_1{}^{T}C_X$, i.e., the chemical shift change for an X-type carbon in **1** measured at a temperature T(K), relative to the same measurement at 200 K. The main point is simply that one now has a set of ^{13}C shift vs. T data for which intrinsic temperature effects are hopefully corrected (or partially corrected) for. The validity of this procedure is best evaluated by looking at the resulting data. In Table 1, the temperature-induced changes in the corrected ^{13}C chemical shifts are shown, assuming a linear relationship between temperature and the δ shift change. One notes several things from this table:

1. Carbons 4, 8, 9, and 10 show large chemical shift changes in both cations **4** and **5**.

2. In both cations, several carbons, such as the C2 methyl group and the C6 carbon, show very small chemical shift changes.

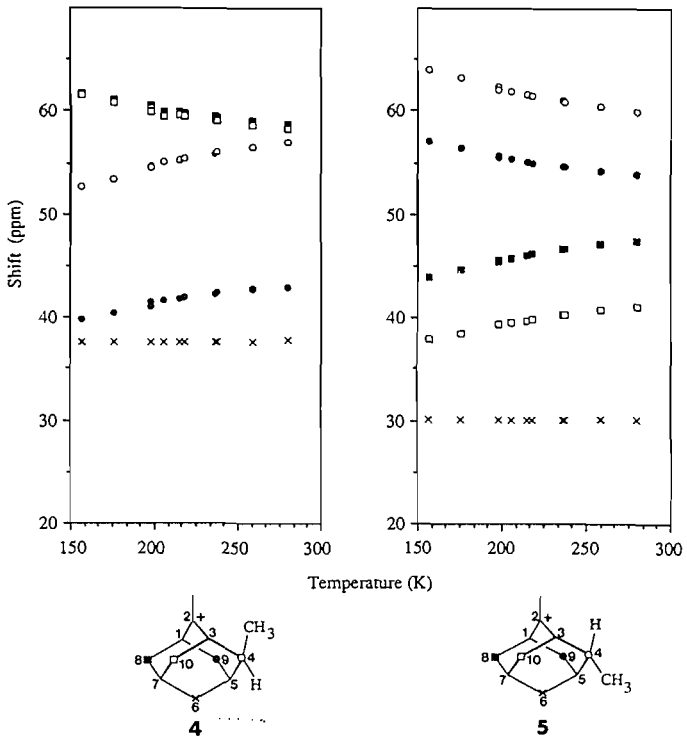
TABLE 1. Corrected temperature shifts[a] of ^{13}C NMR peaks

Carbon	Cation **4**	Cation **5**
1	+24	+13
2	+60	+61
3	−19	+10
4	+409	−390
5	+50	−35
6	+14	−11
7	−38	+31
8	−285 or −298	+333
9	+308	−300
10	−298 or −285	+313
11	~0	~0

[a]Corrected as defined in the text using data from 157 K to 237 K in 1:1 SbF_5–FSO_3H in SO_2ClF solvent, in units of ppm × 10^4/°C. The units are positive when the chemical shifts move upfield with decreasing temperature.



4 5

FIG. 1. Temperature dependence of ^{13}C chemical shifts for carbons 4(○), 6(X), 8(■), 9(●), and 10(□) in cations **4** and **5**.

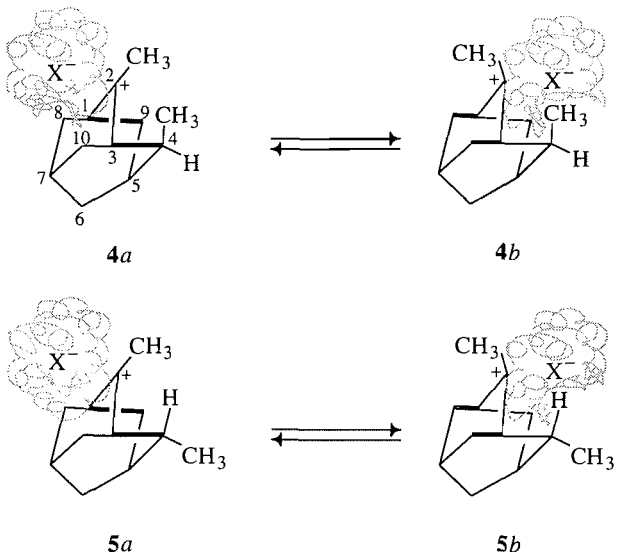
3. In both cations, the behavior of carbons 4 and 9 is similar, as is the behavior of carbons 8 and 10. Furthermore, these carbon pairs show nearly equal and opposite temperature-induced chemical shift changes.

4. Comparing cations **4** and **5**, one sees completely opposite temperature-induced chemical shift behavior for C4–C9 and for C8–C10.

In Fig. 1, we have plotted the corrected ^{13}C chemical shifts for carbons 4, 8, 9, and 10, as well as for C6, vs. temperature, for both **4** and **5**. It is readily apparent that most of these curves are not strictly linear, as assumed in Table 1. If this data is replotted as a function $1/T$ (K), one still does not see linearity.

Discussion

The temperature-induced chemical shift data for cations **4** and **5**, reported in Table 1, can only be rationalized if one proposes that each is a pair of structures, i.e., consistent with the previous interpretation involving **2** and **3**. Thus, **4** should be written as a rapid equilibrium of two structures **4***a* and **4***b*, and likewise for **5**, **5***a* and **5***b*, where the heavy lines again refer to structures with predominant hyperconjugation on that face of the molecule. Because of this hyperconjugation, carbons 4 and 9 in **4***a* are quite deshielded compared to those on the opposite face (C8 and C10), and an opposite situation applies for **4***b*. The interpretation of structures **5***a* and **5***b* is similar. The large chemical shift difference of carbons 4 and 9 collectively in **4***a* and **4***b*, or for carbons 8 and 10 in these same two structures allows the averaged ^{13}C peaks for these carbons to have unusually large temperature dependences (the van't Hoff equation). A similar situation applies to **5***a*–**5***b*. This analysis uniquely rationalizes why C4–C9 or C8–C10 act in concert, and why one pair shows a positive temperature effect and the other a negative one (or vice versa).



4*a* **4***b*

5*a* **5***b*

For both **4** and **5**, the data require that $\Delta\Delta H = \Delta H_b - \Delta H_a \neq 0$, i.e., that one isomer forms a dominant population in each case. For **4**, the isomer **4***b* is dominant, while for **5**, **5***a* is dominant (as one goes from low to high temperature, $K \rightarrow 1$, so the averaged chemical shift changes observed reflect an increase in the minor isomer in each case).

Besides the temperature dependent ^{13}C shifts observed, one should also note that if **4** or **5** were really a single structure in each case, one would expect C8 to have a virtually identical δ value in both **4** and **5**, as is found in the ketones **8** and **9** (δ 39.5 and 39.4, respectively). In fact, at low temperatures, this C8 carbon is nearly 20 ppm different in **4** and **5**.

The rationale for using 2-methyl-2-adamantyl cation **1** as a reference can now be expanded upon. One presumes that **1** is also an equilibrium of two degenerate structures, for which $K = 1$, $\Delta\Delta H = 0$, and, necessarily, no van't Hoff type temperature dependent chemical shifts would be observed. However, intrinsic temperature dependent chemical shifts for like carbons can be expected to be similar in **1** and **4** or **5**, so one hopes to cancel these out. The results shown in Table 1 bear this out. Thus C6 in both **4***a* and **4***b*, or in **5***a* and **5***b*, is far from the cation centre and is symmetrically located with respect to the distortion on either face. Hence δ C6 should be similar in **4***a* and **4***b* and, since we

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

have corrected for intrinsic temperature-derived shifts, this carbon should be fairly insensitive to temperature changes, as is indeed observed. Note also that carbons 1 and 3 in **4***a* and **4***b*, or in **5***a* and **5***b*, also have a nearly identical local environment so that once again one would not expect the respective δ values for these carbons in **4***a* and in **4***b* (or **5***a*–**5***b*) to be very different. Hence, like C6, population changes should not have a large effect on the δ_{AV} value for C1 or C3, again as experimentally observed.

The 4-methyl substituent effect

In work involving simple cyclohexyl cations (3), it was found that equatorial β-alkyl substituents favor C–C hyperconjugation, while γ-alkyl substitution has an opposite effect. In previous work with the adamantyl cations **2** and **3**, one finds in **2** that a 5-methyl substituent (γ) favors C–C hyperconjugation on the unsubstituted face, in agreement with the cyclohexyl cation work, but this same preference is also found for the 4,4-dimethyl substituents (β,β) in ion **3**, in disagreement. In the present work, the equatorial 4-methyl (β) substituent in **5** favors C–C hyperconjugation on the substituted face, also in agreement with the cyclohexyl cation results. However, the axial 4-methyl substituent in **4** causes the opposite behavior. Combined with the previous results for the 4,4-dimethyl cation **3**, one can now show that this axial-4-methyl substituent result in **4** is not a stereoelectronic effect, and is almost certainly steric in origin.

Since the axial and equatorial 4-methyl cations **4** and **5** show opposite population preferences (see next section), one would predict on stereoelectronic grounds that the 4,4-dimethyl cation **3** would show some intermediate behavior. In fact, cation **3** shows an even greater population preference for C–C hyperconjugation on the face opposite the substituents, consistent with a further steric buttressing of the axial 4-methyl group by the equatorial 4-methyl group.

In recently published high level *ab initio* computations, the secondary 2-adamantyl cation has been shown (5) to adopt an unsymmetrical, non-planar C^+ centre, structure (two degenerate structures separated by a very small barrier). We believe that a similar kind of geometric distortion is probable in the case of **4***a* and **4***b* (or **5***a* and **5***b*). Such distortion would in fact enhance the steric interaction between the C2 methyl group and the axial C4 methyl group in **4***a* and help explain why this isomer is not favored in the **4***a*–**4***b* equilibrium.

Possible quantitative treatment of the data

For two species X and Y in rapid equilibrium in an NMR spectrometer, the equilibrium constant K is given by:

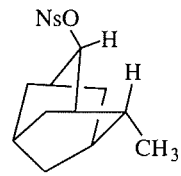
$$K = \frac{\delta_X - \delta_{AV}}{\delta_{AV} - \delta_Y} = \frac{[Y]}{[X]}$$

where δ_{AV} is the experimental chemical shift and δ_X and δ_Y are the positions of a given atom in the pure compounds X and Y. In the case at hand, δ_X and δ_Y are unknown. In theory, one can use the van't Hoff equation to solve for these but in practice the linearity of a van't Hoff relationship is fairly insensitive to the choice of δ_X and δ_Y. In the previous work (2), values of δ_X and δ_Y for a carbon such as C8 in **4** or **5** was estimated as δ ca. 65.5 in isomer **4***b* or **5***b*, and δ ca. 36.5 in **4***a* or **5***a*. Our van't Hoff analysis of the present data show that these numbers are still reasonable choices. Using these values gives a K for cation **4**, **4***b*/**4***a* = 3.8, and for **5**, **5***b*/**5***a* = 0.45.

We previously noted that the Fig. 1 data are not linear for δ_{AV} vs. T, nor are they linear for δ_{AV} vs. $1/T$(K). This negative result is consistent with the van't Hoff equation, where δ_{AV} and T involve a more complex relationship.

Significance of the present results

There is a good correlation between solvolysis results involving 5-methyl- or 2,5-dimethyl-2-adamantyl esters (or ethers) (6) and our previous stable ion results (2) for cation **2**. The rate of equilibration of the isomers **2***a* and **2***b* in solvolysis solvents appears to be competitive with the rates for nucleophilic capture, so that one gets both net retention and net inversion of configuration depending upon which stereoisomer is being solvolyzed and the particular solvent being used.



10

Unfortunately, there are no comparable solvolysis data for either the 2,4-dimethyl- or the 4-methyl-2-adamantyl systems. Grob *et al.* (7) have reported that equatorial-4-methyl-2-adamantyl nitrobenzenesulfonate **10** solvolyzes slightly faster than the parent adamantyl compound and shows predominant retention of configuration in the alcohol product (76% vs. 24% inversion). These results are certainly consistent with our results for cation **5**, but they are relatively meaningless without comparison data for the stereoisomeric (at C2) nitrobenzenesulfonate ester. Grob has described the solvolysis intermediate in this reaction as a weakly σ-delocalized, bridged, cation. The C–C hyperconjugative delocalization description given in our work bears some relationship to their ideas. We also note that our structures shown for **4***a*, or for **5***a*, suggest equal C–C delocalization from both the C1—C9 and C3—C4 bonds. If one looks in detail at Table 1, one notes that the substituted C4 carbon is more temperature dependent, suggesting perhaps that the C3—C4 bond contributes slightly more to the cation C–C stabilization than does the C1—C9 bond. If the C4 substituent were a group such as cyano, one can predict that isomer *b* will now dominate the *a* ⇄ *b* equilibrium, and that in the isomer *a*, if present, C–C hyperconjugation will probably predominate from the unsubstituted C1—C9 bond.

The present work concerns a somewhat esoteric dimethyl 2-adamantyl system, but the real significance is that it shows some rather ordinary looking tertiary carbocations to have a detailed structure that is not "classical". In fact, as Schleyer *et al.* (8) have pointed out, at a detailed level of study, whether computational or experimental, there are probably very few classical cations. Moreover, these structural details concern cation properties that lead to chemical reactivity and (or) stereoelectronic consequences.

One would still like to know more about the dynamics of the interconversion of isomers such as **5***a* and **5***b*, since all one can do at present (via NMR spectroscopy) is to put an upper limit of ca. 5 kcal/mol on the transition-state barrier.

Conclusions

In cases such as the present, where one cannot "freeze-out" the equilibrium pair, or even see dynamic NMR line-broadening, one has to be cognizant of alternative interpretations. However, in the present work there are two key experimental observations that do not fit any other explanation:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

1. The temperature dependences of similarly substituted and positioned carbons, such as C8 and C9 in **4** or **5**, show totally opposite shift behavior.

2. For a given carbon, such as C8, the temperature – chemical shift behavior is completely reversed in comparing cation **4** to cation **5**.

We feel therefore that the evidence for two populated structures in both cation **4** and cation **5** is unambiguous.

Experimental

NMR spectra were recorded on a Bruker AM-400 or ACE-200 spectrometer. Preparative GLC was carried out with a Hewlett–Packard model 5890 gas chromatograph, employing a thermal conductivity detector.

Axial-4-methyl- and equatorial-4-methyl-2-adamantanones **8** and **9**, respectively, were prepared as a ca. 60:40 mixture, as described (9). They were separated by preparative GLC, using a 3% OV225-Chromosorb W (80/100) column, 0.4 (i.d.) × 244 cm. The axial isomer elutes first.

2-Equatorial-methyl, 4-axial-methyl-2-adamantanol ***6***

The ketone **8** (13.2 mg, 0.080 mmol) was treated dropwise, under nitrogen, with an excess of methyl lithium solution (1.5 M in ether) at 0°C. After ca. 1 h, the excess methyl lithium was destroyed with water, the phases separated, and the aqueous phase extracted (4 × 5 mL) with ether. After drying ($MgSO_4$), the combined ether layers were evaporated to yield 14.5 mg (0.080 mmol) of a single oily alcohol, assigned the title structure for obvious steric reasons, and which was used without further purification. ^{1}H NMR shows characteristic peaks at δ 1.32 (s, 3H, the C2 methyl), and a doublet at δ 1.26, J = 7, the C4 methyl. ^{13}C NMR: 75.37, 44.61, 41.42, 40.26, 39.17, 37.12, 35.49, 33.15, 29.36, 27.97, 27.29, and 21.67.

Mixture of 2-equatorial-methyl,4-equatorial-methyl- and 2-axial-methyl,4-equatorial-methyl-2-adamantanol ***7***

This preparation was carried out in the same way as for tertiary alcohol **6**, employing 11.9 mg (0.072 mmol) of ketone **9**. ^{1}H NMR spectroscopy shows clearly that the two isomeric alcohols were formed in about a 60:40 ratio; however, the spectra permit no specific assignments. ^{1}H NMR; δ 1.375 (major) and 1.360 (minor), both s, the epimeric C2 methyl group, δ 1.055, d, J = 7 (major), and 1.090, d, J = 7 (minor), the C4 methyl group. The alcohol mixture was used for the cation preparations since the alcohol stereochemistry at C2 is immaterial.

Carbocation preparations and NMR spectra

The cation solutions were made up at −80°C (or lower) directly in 5-mm NMR tubes. Typically, about 13 mg of alcohol **6** or **7** and 7 mg of 2-methyl-2-adamantanol was dissolved in the minimum amount of CD_2Cl_2 and slowly stirred into the pre-prepared superacid solvent mixture (0.4 mL) using syringe techniques. A large molar excess of superacid to alcohol (>5:1) was used. ^{1}H NMR spectra at various low temperatures were measured at 400 MHz for both **4** and **5**, and COSY 2D ^{1}H–^{1}H spectra were also obtained. These ^{1}H NMR spectra were only used for verification of the ^{13}C assignments, via a HETCOR spectrum for **5** and an INVERSE HETCOR for **4**. The ^{1}H NMR data are available on request. The ^{13}C NMR spectra[2] were measured at 100 MHz, employing sweep widths of ca. 36 000 Hz (32K FID) and transforming over 128K data points (up to 512K data points were used in several trial instances to even better define peak shapes, but the end result did not differ significantly from the 128K data). The individual peaks are characterized by data points every 0.0055 ppm. Since chemical shift comparisons are being made to an internal reference with the same uncertainty, the overall uncertainty in chemical shifts should be of the order ±0.01 ppm. DEPT 90 and 135 spectra were used to assign ^{13}C multiplicities.

The ^{13}C NMR shifts for **4** and **5** can be listed in two ways: (1) the actual temperature dependences, given in Table 1, which, as defined in the text, are independent of the actual ^{13}C chemical shifts themselves; and (2) the data in Fig. 1, which were corrected as defined in the text. The absolute ^{13}C chemical shifts at 200 K were referenced to internal CD_2Cl_2, taken as δ 53.80 (middle peak). The data at 200 K are as follows: cation **4**, 325.42 (C2), 72.94 (C3), 66.51 (C1), 60.45 and 60.19 (C8 and C10), 54.46 (C4), 43.70 (C2 methyl), 41.10 (C9), 37.62 (C6), 32.99 (C5), 29.57 (C7), 21.15 (C4 methyl). Cation **5**, 318.21 (C2), 71.19 (C1), 64.44 (C3), 62.35 (C4), 55.70 (C9), 45.45 (C8), 41.22 (C2 methyl), 39.24 (C10), 33.82 (C5), 30.08 (C6), 27.62 (C7), 18.60 (C4 methyl). Cation **1**, 322.33 (C2), 66.07 (C1, 3), 52.32 (C4, 8, 9, 10), 41.15 (C2 methyl), 36.34 (C6), 28.83 (C5, 7).

The temperature of the probe was calibrated using a standard methanol sample (^{1}H), or for temperatures below 173 K, neat 2-chlorobutane (^{13}C) was used for the calibration (10). Internal CD_2Cl_2 was used as a lock and ^{1}H decoupling of the ^{13}C spectra employed the WALTZ procedure.

[2]Tables of chemical shift data for cations **1**, **4**, and **5**, as a function of temperature, have been deposited and may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

The 1:1 and 2:1 adducts of cyclopentadiene with *p*-benzoquinone

PETER YATES AND KRZYSZTOF SWITLAK

Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada, M5S 1A1

Received April 17, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

PETER YATES and KRZYSZTOF SWITLAK. Can. J. Chem. **68**, 1894 (1990).

The *exo-cis* isomer (**8**) of the well-known *endo-cis* 1:1 adduct (**4**) of cyclopentadiene and *p*-benzoquinone has been obtained by heating the *endo-cis-anti-cis-endo* 2:1 adduct (**13**) with *p*-benzoquinone and also by heating **4** alone. The *exo-cis* isomer of the 1:1 adduct (**11**) of cyclopentadiene and *p*-toluquinone has also been obtained for the first time. Heating of the 2:1 adduct **13** gives a mixture containing the *endo-anti-exo* isomer **15**, the *exo-anti-exo* isomer **16**, and **13**. The structures of these two new isomers are assigned on the basis of (i) spectroscopic comparison with **13** and the known *endo-syn-endo* and *endo-syn-exo* isomers, **12** and **14**; (ii) spectroscopic comparison of the corresponding tetrahydro compounds; and (iii) the conversion of tetrahydro **15** by oxidation and acetylation to the *syn*-hydroquinone diacetate **28**, which is stereoisomeric with the *anti*-hydroquinone diacetate **25**, prepared by similar treatment of tetrahydro **13**, **14**, and **16**. It is proposed that interconversion of the 1:1 adducts occurs via dissociation–recombination, interconversion of the tetrahydro 2:1 adducts occurs via enolization, while interconversion of the 2:1 adducts themselves can occur by both routes.

Key words: Diels–Alder, benzoquinone, cyclopentadiene, stereoisomerism, cycloaddition.

PETER YATES et KRZYSZTOF SWITLAK. Can. J. Chem. **68**, 1894 (1990).

En faisant chauffer de l'adduit 2:1 *endo-cis-anti-cis-endo* (**13**) en présence de *p*-benzoquinone, on a obtenu l'isomère *exo-cis* (**8**) de l'adduit 1:1 bien connu *endo-cis* (**4**) du cyclopentadiène et de la *p*-benzoquinone; on a aussi obtenu l'isomère **8** par chauffage de l'adduit **4**. On a aussi préparé pour la première fois l'isomère *exo-cis* de l'adduit 1:1 (**11**) du cyclopentadiène et de la *p*-toluquinone. Par chauffage, l'adduit 2:1 (**13**) fournit un mélange contenant l'isomère *endo-anti-exo* (**15**), l'isomère *exo-anti-exo* (**16**) et le produit **13**. On a attribué les structures de ces deux nouveaux isomères en se basant : (i) sur un comparaison de leurs spectres avec ceux du produit **13** et des isomères bien connus *endo-syn-endo* (**12**) et *endo-syn-exo* (**14**); (ii) sur un comparaison spectroscopique des composés tétrahydrogénés correspondants; et (iii) par la conversion du dérivé tétrahydrogéné **15**, par oxydation et acétylation, en diacétate de la *syn*-hydroquinone (**28**) qui est un stéréoisomère du diacétate de l'*anti*-hydroquinone **25**, préparé par une méthode semblable à partir des dérivés tétrahydrogénés **13**, **14** et **16**. On suggère que l'interconversion des adduits 1:1 se produit par une dissociation–recombinaison, que l'interconversion des adduits 2:1 tétrahydrogénés se produit par le biais d'une énolisation et que l'interconversion des adduits 2:1 peut se produire par les deux voies.

Mots clés : Diels–Alder, benzoquinone, cyclopentadiène, stéréoisomérie, cycloaddition.

1:1 Adducts

The reaction of cyclopentadiene and *p*-benzoquinone to give a 1:1 adduct was first reported in 1906 by Albrecht (1). Although the reaction was initially considered to involve Michael addition to give **1** or 1,2-cycloaddition to give **2** (2), it was later shown by Diels and Alder (3) to be a 1,4-cycloaddition reaction giving **3**, and is one of the first reported examples of the reaction that now bears their names.

The stereochemistry of this adduct was established to be *cis-endo* as in **4** on the basis of its photoconversion to the pentacyclic isomer **5** (4); its preferred conformation in solution is considered to be the "open" form **6** rather than the "closed" form **7** (5). The preferred formation of the *cis-endo* stereoisomer under conditions of kinetic control in Diels–Alder reactions is now generally recognized and is enshrined in the *Alder rules* (6). However, in this case, unlike many others (7),[1] the formation of the *cis-exo* isomer, **8**, has not been reported previously. We describe now the preparation of this compound; its availability is of interest because it permits spectroscopic comparison of the two isomers, assists in the assignment of stereochemistry to the 2:1 adducts of cyclopentadiene and *p*-benzoquinone (*vide infra*), and provides a stereochemical variant of **4** for application in synthesis.

Compound **8** was obtained by heating the *initially formed* isomer of the 2:1 adduct of cyclopentadiene and *p*-benzoquinone (**13**: *vide infra*) with *p*-benzoquinone in boiling

[a]The coupling patterns were not analyzed and the multiplicites and numerical values given in parentheses (apparent coupling constants) are phenomenological and not analytical, except in the case of the one-carbon bridge protons. Pentet (p) is used rather then quintet to avoid confusion with quartet.

xylene for 20 min, when thin-layer chromatography showed that no **13** remained; a 7:3 mixture of the *endo* and *exo* 1:1 adducts, **4** and **8**, was formed. The *exo* isomer **8** was obtained by chromatographic separation of this mixture. It was also formed, but more slowly, by heating the *endo* isomer alone in boiling toluene.

The structure of **8** follows from its elemental composition and its spectra. Its ir spectrum in the 1650 cm^{-1} region is very similar to that of **4** and confirms the presence of the 2-ene-1,4-dione system in **8**. The ^{1}H nmr spectra of **4** and **8**, which are compared in Table 1, resemble one another, but are readily distinguishable, the most striking difference being in the chemical shifts of the C-4a(8a) protons (for numbering, see **3**). The upfield shift ($\Delta\delta$ −0.68) of the signal for the *exo* isomer **8**, where these protons are *endo*, relative to that for the *endo* isomer **4**, where they are *exo*, is in accord with the previously observed upfield shifts of the signals of the corresponding protons in the spectra of other norbornenes and norbornanes (9). Both signals appear as apparent doublets, which are attributable to C-4a(8a) *endo* – C-9 *anti* proton coupling in the *exo* isomer and to C-4a(8a) *exo* – C-1(4) proton coupling in the *endo* isomer. In accord with this interpretation is the relationship of the coupling patterns of the signals assigned to the C-9 *anti* protons, the greater multiplicity shown by the *exo* isomer being attributable to the coupling of the C-9 *anti* proton with the *endo* protons at C-4a and C-8a.

The ^{13}C nmr spectra of **4** and **8** (Table 2) are very similar except for an upfield shift ($\Delta\delta$ −4.5) of the C-9 signal in the *exo* isomer **8** and a downfield shift ($\Delta\delta$ 4.3) of the C-2(3) signal. These differential shifts are interpretable in terms of a γ-effect of C-5(8) at C-9 in **8** and at C-2(3) in **4**. It is unlikely that the effect at C-2(3) stems from electronic interaction between the two ethylenic bonds in **4** (5).

Ultraviolet irradiation of **8** under conditions that convert **4** to the pentacyclic compound **5** does not lead to cyclization, and **8** is recovered largely unchanged. This is to be expected, and provides further evidence favoring assignment of the *cis-endo* structure **4** to the initially formed adduct on photochemical grounds, since it allays the possible fear (10) that this adduct is **8** and undergoes photoisomerization to **4** prior to photocyclization to **5**.

[a]The assignments are in accord with APT spectra.
[b]For each compound the assignments of the signals marked with an asterisk are interchangable.

We have also found that the *cis-endo* 1:1 adduct, **10**, of cyclopentadiene and *p*-toluquinone, which is formed exclusively at room temperature or below (11, 12), is converted to a mixture of **10** and its *cis-exo* isomer **11** on being heated in boiling xylene. The structure of the latter follows from its composition and spectra; the latter are compared with those of **10** in Tables 1 and 2. Exclusive formation of *cis-endo* 1:1 adducts from methylcyclopentadiene and *p*-benzoquinone at room temperature has also been reported, although reaction of cyclopentadiene with nitro-*p*-benzoquinone gives a mixture of *endo* and *exo* 1:1 adducts (12). However, it cannot be excluded that formation of the *exo* isomer was catalyzed by species associated with the *in situ* generation of nitro-*p*-benzoquinone from the corresponding hydroquinone and silver oxide.

cyclopentadiene have the gross structure **9**. If it is assumed that all are formed by *cis* addition, as has been observed for other 1,4 cycloaddition reactions of cyclopentadiene, six stereoisomers of **9** are possible, viz. compounds **12–17**.

A compound of type **9**, mp 155°C, was first isolated by Albrecht (1) from the reaction of the *endo* 1:1 adduct **4** with cyclopentadiene. It was initially assigned the *endo-syn-endo* structure **12** (13, 14), but was later proved to be the *endo-anti-endo* isomer **13** (11, 15, 16), as confirmed by X-ray crystallography (10). A second stereoisomer, mp 186°C, was prepared by isomerization of **13** with alkali, and was assigned the *endo-syn-exo* structure **14** (15, 16). Very recently the synthesis of a third stereoisomer, mp 184°C, was reported; this is assigned the *endo-syn-endo* structure **12** on the basis of its method of preparation and its reactions (17).

We now report the preparation of two additional stereoisomers, the *endo-anti-exo* compound **15**, mp 153–154°C, and the *exo-anti-exo* isomer **16**, mp 163–164°C. These were obtained by heating the initially formed isomer **13** in xylene in a sealed tube at 120°C; this gave a mixture of **13**, **15**, and **16**, together with the hydroquinone **18**, which was obtained previously (18). The structures of the newly discovered isomers have been established by spectroscopic and chemical means.

Qualitative comparisons of the ^{1}H and ^{13}C nmr spectra of the isomers **12–14** and those of the two newly obtained isomers (Tables 3 and 4) show that these compounds are all compounds of type **9**. As expected, the nmr spectra of the *endo-exo* isomer **14** are more complex than those of the *endo-endo* isomers **12** and **13** because of the lower degree of symmetry of **14**. The nmr spectra of the new isomer, mp 153–154°C, resemble those of **14** in complexity and thus it follows immediately that it is the *endo-anti-exo* compound **15**, since this is the only remaining structure with a degree of symmetry corresponding to that of **14**. It further follows that the new isomer, mp 163–164°C, must have either the *exo-anti-exo* structure **16** or the *exo-syn-exo* structure **17**. This is confirmed by the fact that the nmr spectra of this compound are analogous in complexity to those of **12** and **13**. The choice of the *exo-anti-exo* structure **16** for this compound follows from studies of the chemistry of the tetrahydro derivatives **19** of the compounds of type **9** (*vide infra*).

We next discuss quantitative aspects of the ^{1}H nmr spectra of compounds **12–16** and interpret them in structural terms, an exercise whose validity is not compromised by the use of qualitative aspects of these spectra in the structural assignments. The proton signals in the δ 0.5–1.7 and 5.9–6.1 regions (Table 3) can immediately be assigned to the bridge protons at C-11 and C-12 and to the ethylenic protons at C-2(3) and C-6(7), respectively. Distinction can be made between the signals of the two remaining types of protons, the bridgehead protons at C-1(4) and C-5(8) and the ring-fusion protons at C-4a(9a) and C-8a(10a), on the basis of the relative broadness of the signals. The former type are broader than the latter because of the more extensive coupling of the bridgehead protons (19) (cf. the analogous signals in the ^{1}H nmr spectra of the *endo* and *exo* adducts of cyclopentadiene and maleic anhydride, **20** and **21** (20), and of **4** and **8**). The assignments in the case of **13** were confirmed by a COSY spectrum and by the fact that treatment with potassium deuteroxide in deuterium oxide/tetrahydrofuran at room temperature for 0.5 h led to a 65% reduction of the intensity of the δ 2.88 signal relative to all other signals.

The bridgehead proton signals occur in a narrow range (δ 3.3–3.4) and in this respect resemble the ethylenic proton signals with a range of δ 5.9–6.2. The ring-fusion proton signals occur in the much broader range δ 2.1–3.5. This wide variation can be interpreted in terms of the interplay of two factors. First, the variance in the shielding of *endo* vs. *exo* protons in norbornene systems (cf., for example, the cases of the *endo* and *exo* 1:1 adducts discussed above), and second, the shielding of the ring-fusion protons in one norbornene system by the ethylenic group in the other when this group is *syn* with respect to the ring-fusion protons. The latter effect we refer to as interannular ("inter-ann") shielding, in contrast to the intraannular shielding involved in the *endo* vs. *exo* effect. It can be operative only in *anti-endo* isomers (cf. **22**). These effects are codified in Table 5, which it is hoped may serve predictive purposes.

With one exception, the signals of the C-11 and C-12 protons fall in the range δ 1.2–1.6. It is possible to associate these in pairs on the basis of the magnitudes of the geminal coupling constants, but unambiguous assignments to *syn* and *anti* protons are not possible with the data currently available. The exception

TABLE 5. Factors affecting the chemical shifts of C-4a(9a) and C-5a(8a) in the ^{1}H nmr spectra of the 2:1 adducts **12–16**

Factor(s)	Compound	Chemical shift	Range
exo	**12**	3.24	3.2–3.5
exo	**15**	3.54	
exo	**16**	3.19	
exo + *inter-ann*	**13**	2.83	
endo	**14**	2.63	2.5–2.6
endo	**16**	2.51	
endo + *inter-ann*	**15**	2.09	

is a one-proton signal of **14** that appears at δ 0.51. This effect could be associated with interannular shielding in the preferred conformation by either the ethylenic or carbonyl π electrons. The latter source is more probable since a similar effect is shown in the spectrum of the corresponding tetrahydro compound (see Experimental).

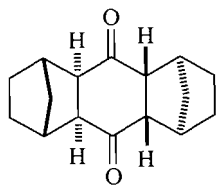
The ^{13}C nmr spectral assignments are given in Table 4. These are based on APT spectra, which distinguish all types of signal other than those of C-1,4(5,8) and C-4a,9a(8a,10a). A HETCOR spectrum in the case of **13** permitted this distinction to be made; assignments for corresponding carbons in the spectra of the other compounds were made by analogy. The ^{13}C nmr spectra are in accord with the gross structural assignments, but are not very useful for making stereochemical distinctions.

Tetrahydro 2:1 adducts

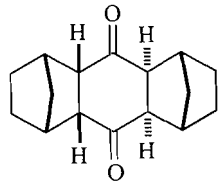
Hydrogenation of the original 2:1 adduct **13** gives a tetrahydro compound **23**, mp 255°C; similar treatment of the isomer **14** gives a tetrahydro compound **24**, mp 188°C (13, 15, 16). Compound **24** could also be obtained by alkaline treatment of **23** in the same fashion that **13** was converted to **14**, or by heating **23** above its melting point (ca. 240°C). More vigorous basic treatment of **23**, e.g., with aluminum *tert*-butoxide at 250°C, gives a mixture of **23** and a third isomer, mp 165°C, in comparable amounts; a similar mixture is formed on analogous treatment of the third isomer. All three of these tetrahydro compounds give the same hydroquinone diacetate **25** on oxidation with bromine in carbon tetrachloride followed by acetylation. The structure of this product follows from its formation from **23** and **24**, which both have an *anti* relationship of their one-carbon bridges. It further follows that the third tetrahydro isomer must possess an analogous *anti* relationship of its one-carbon bridges and must be the *exo-anti-exo* compound **26**, the only remaining isomer with this relationship (16).

Hydrogenation of the two newly obtained stereoisomers **16** and **15** gives **26** and a fourth tetrahydro isomer, mp 200–202°C, respectively. The formation of the former leads to the assignment to **16** of a structure with an *anti* relationship between the one-carbon bridges and thus completes the proof that it is the *exo-anti-exo* isomer. The fourth tetrahydro isomer must have the *endo-anti-exo* structure **27** and, as expected, gives with bromine followed by acetylation the *syn* hydroquinone diacetate **28**, which is different from, although very similar to, the *anti* hydroquinone diacetate **25**.

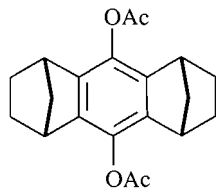
As expected, the ^{1}H nmr spectra of compounds **24** and **27** are more complex than those of **23** and **26** because of the lower symmetry of the former compounds (see Experimental). However, quantitative comparisons of these four spectra are of less diagnostic value than those for compounds **12–16** because the bridgehead and ring-fusion proton signals overlap in the



26 (*exo-anti-exo*)



27 (*endo-anti-exo*)



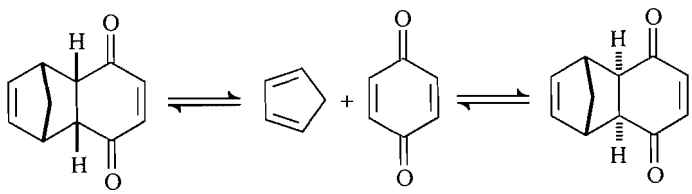
28

narrow range δ 2.5–2.9 and the signals of the one-carbon bridge protons and those of the *exo* and *endo* protons on the two-carbon bridges overlap in the similarly narrow range of δ 1.2–1.6.

Discussion

A number of pathways have been considered for the interconversion of the *endo* and *exo* forms of Diels–Alder adducts related to those investigatged here. These include enolization, dissociation to diene and dienophile followed by recombination, formation of a complex of the diene and dienophile, cleavage of one bond of the adduct followed by rebonding or followed by hydrogen transfer and then rebonding (refs. 21–23 and refs. quoted therein). In most cases the initially formed adduct is the *endo* isomer, formed under kinetic control, and subsequent thermal treatment results in its conversion to the more stable *exo* isomer, with subsequent isomerization leading to the eventual formation of an equilibrium mixture when the reactions are under full thermodynamic control. Thus the formation of the *exo* adduct **8** from the *endo* 1:1 adduct **4** can be represented as in Scheme 1 (the position of equilibrium was not established).

We consider that the present observations can be most simply interpreted in the following terms. The isomerization of the 1:1 adducts occurs via dissociation–recombination as in Scheme 1 (the position of equilibrium was not established). In the cases of **23**, **24**, **26**, and **27**, the tetrahydro derivatives of the 2:1 adducts, the dissociation–recombination pathway is not available for the interconversion of stereoisomers, but such interconversion can occur. This has usually been effected under basic conditions, and in at least one case thermal interconversion has also been observed (**23** → **24**), albeit at a considerably higher temperature than that used for the formation of **8** from **4**. We subscribe to the proposal of Cookson *et al.* (15) that the changes in the tetrahydro series involve enolization of the two carbonyl groups, although the detailed pathway cannot at present be defined. Thus the reaction of **23** to give **24** may proceed via the enolate or enol **30** or via the dienolate or dienol **31** and may or may not involve the



4 **8**

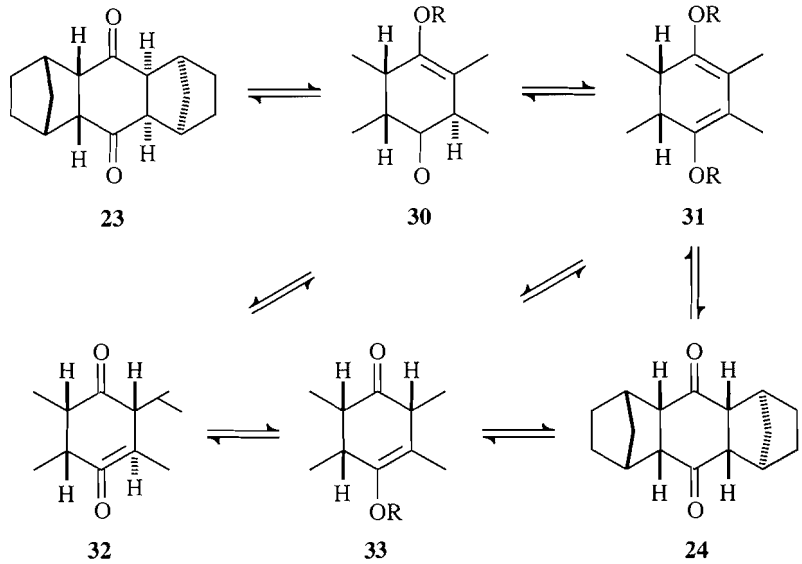
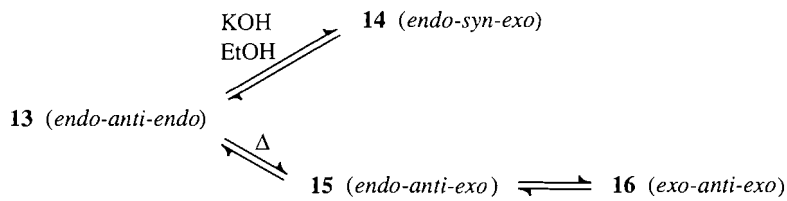


SCHEME 2



SCHEME 3

transitory formation of the *trans*-fused intermediate **32** (Scheme 2). It may be noted that, whatever the details of the mechanism, each such conversion of an *endo* to an *exo* system, or vice versa, must be accompanied by a change from an *anti* to a *syn* system, or vice versa. This is not the case for interconversion via retro-Diels–Alder reaction and recombination.

A similar type of enolization mechanism is not applicable in the case of the 1:1 adducts, for enolization leads to irreversible aromatization. However, for the 2:1 adducts **12–16** both retro-Diels–Alder and enolization routes are viable and we propose that this duality accounts for our observations in the present work as shown in Scheme 3.

Experimental

Melting points (mp) were measured on a Fisher-Johns melting point apparatus and are uncorrected. Infrared spectra were recorded in chloroform solutions or on potassium bromide discs. ^1H and ^{13}C nuclear magnetic resonance spectra (nmr) were recorded in deuteriochloroform solutions with a Varian Gemini 200 or XL-200 spectrometer.

endo-cis-*1,4,4a,8a-Tetrahydro-1,4-methanonaphthalene-5,8-dione (4)*

Compound **4** was prepared by the procedure of Marchand and Allen (24); mp 76–77°C (lit. (19) mp 75.8–76.2°C, (24) mp 76.0–78.5°C); ν_{max} (CCl_4): 1666 (br, vs), 1650 (infl, m), 1605 (m) cm^{-1} (cf. ref. 15).

exo-cis-*1,4,4a,8a-Tetrahydro-1,4-methanonaphthalene-5,8-dione (8)*

(*i*) *p*-Benzoquinone (3.05 g, 27.8 mmol) was added to a boiling solution of compound **13** (*vide infra*; 4.50 g, 18.7 mmol) in xylene (70 mL). Boiling was continued under reflux for 20 min, when tlc (silica with ethyl acetate/hexanes) showed that all of the **13** had been consumed. The mixture was cooled to room temperature and hexanes (500 mL) were added. The black suspension was filtered and the filtrate was cooled in a Dry Ice/acetone bath. A yellow solid (0.6 g) separated, which was shown by ^1H nmr spectroscopy to contain compounds **4** (95%) and **8** (5%). The mother liquor was stripped of solvent to give a 65:35 mixture of compounds **4** and **8** (3.0 g). Flash chromatography on silica with 1:4 ethyl acetate/hexanes led first to the elution of the oxidation product, 1,4-dihydro-1,4-methanonaphthalene-5,8-dione (11), followed by compound **8** and then **4**. Compound **8** was recrystallized from methanol; mp 80.5–81.5°C; ν_{max} (CCl_4): 1778 (vs), 1667 (s), 1657 (infl, s), 1608 cm^{-1}. Anal. calcd. for $C_{11}H_{10}O_2$: C 75.84, H 5.78; found: C 75.61, H 5.94.

(*ii*) A solution of compound **4** (1.00 g) in toluene (50 mL) was boiled under reflux under argon for 36 h. The product consisted of a 1:9 mixture of compounds **8** and **4** (50%), hydroquinone **18**, and *p*-benzoquinone.

endo-cis-*1,4,4a,8a-Tetrahydro-6-methyl-1,4-methanonaphthalene-5,8-dione (10)*

Compound **10** was prepared by the procedure of Marchand and Allen (24); mp 62–63°C (lit. (11) mp 62°C); ν_{max} (CCl_4): 1675 (s), 1667 (vs), 1652 (s), 1625 (m) cm^{-1}.

exo-cis-*1,4,4a,8a-Tetrahydro-6-methyl-1,4-methanonaphthalene-5,8-dione (11)*

A solution of compound **10** (5.00 g, 26.6 mmol) in xylene (50 mL) was boiled under reflux for 15 h. Removal of the solvent gave a residue that was shown by ^1H nmr spectroscopy to contain compounds **10** (80%) and **11** (15%). Compound **11** (0.60 g) was separated by flash chromatography on silica with 1:4 ethyl acetate/hexanes and recrystallized from methanol; mp 59–60°C; ν_{max} (CCl_4): 1666 (br, vs), 1648 (s), 1627 (m) cm^{-1}. Anal calcd. for $C_{12}H_{12}O_2$: C 76.57, H 6.42; found: C 76.42, H 6.49.

endo-cis-anti-cis-endo-*1,4,4a,5,8,8a,9a,10a-Octahydro-1,4:5,8-dimethanoanthracene-9,10-dione (13)*

Compound **13** was prepared by the method of Alder and Stein (13); mp 153–154°C (dec.) (lit. (13) mp 157–158°C (dec.)).

Base-catalyzed stereoisomerization of ***13****. Formation of its* endo-cis-syn-cis-exo *isomer* ***14***

Compound **13** was treated with ethanolic potassium hydroxide to give compound **14** (5); mp 184–185°C (lit. (13) mp 186°C).

Thermal stereoisomerization of compound ***13****. Formation of its* endo-cis-anti-cis-exo *and* exo-cis-anti-cis-exo *isomers* ***15*** *and* ***16***

A solution of compound **13** (10.0 g, 0.42 mmol) in xylene (3 mL) in a sealed tube was heated at 120°C for 15 h. The mixture remaining after removal of the xylene was flash chromatographed on silica with 1:4 ethyl acetate/hexanes and gave five fractions, each ca. 20%.

Crystallization of the first fraction from acetone gave compound **16**, mp 163–164°C; ν_{max}: 1687, 1681 cm^{-1}. Anal. calcd. for $C_{16}H_{16}O_2$: C 79.97, H 6.71; found: C 79.84, H 6.95.

Crystallization of the second fraction from methanol gave compound **15**, mp 153–154°C; ν_{max}: 1686 cm^{-1}. Anal. calcd. for $C_{16}H_{16}O_2$: C 79.97, H 6.71; found: C 79.68, H 6.79.

Crystallization of the third fraction gave compound **13**. The fourth fraction was an unstable mixture, which was not further investigated. The fifth fraction contained the aromatization product, 1,4-dihydro-1,4-methanonaphthalene-5,8-diol (**18**) (25).

Hydrogenation of compounds ***13–16****. Formation of 1,2,3,4,4a,5,6,7,-8,8a,9a,10a-dodecahydro-1,4:5,8-dimethanoanthracene-9,10-diones* ***23****,* ***24****,* ***27****, and* ***26***

The octahydroanthracenedione was dissolved in ethanol (50 mL), 5% palladium/carbon was added, and hydrogenation was carried out at atmospheric pressure and temperature for 2 h. The catalyst was filtered and the solid residue obtained after removal of the solvent was recrystallized from methanol.

Compound **13** gave the *endo-cis-anti-cis-endo* isomer **23**, mp 222–223°C (lit. (13) mp 225°C); ν_{max}: 1686 cm^{-1}; $^{H}\delta$: 2.83 (m, 4H), 2.75 (m, 4H), 1.2–1.6 (m, 12H).

Compound **14** gave the *endo-cis-syn-cis-exo* isomer **24**, mp 250–252°C (lit. (13) mp 255°C); $^{H}\delta$: 3.15 (m, 2H), 3.01 (m, 2H), 2.81 (m, 2H), 2.66 (m, 2H), 1.1–1.6 (m, 11H), 0.71 (m, 1H).

Compound **15** gave the *endo-cis-anti-cis-exo* isomer **27**, mp 200–202°C (dec.); ν_{max}: 1681, 1687 cm^{-1}; $^{H}\delta$: 2.87 (m, 2H), 2.71 (m, 2H), 2.62 (m, 2H), 1.2–1.6 (m, 12H). Exact Mass calcd. for $C_{16}H_{20}O_2$: 244.1463; found: 244.1451.

Compound **16** gave the *exo-cis-anti-cis-exo* isomer **26**, mp 156–157°C; (lit. (16) mp 165–166°C); ν_{max}: 1692 cm^{-1}; $^{H}\delta$: 2.69 (m, 4H), 2.63 (m, 4H), 1.2–1.6 (m, 12H).

Thermal stereoisomerization of compound 23 to 24

Compound **23** was heated at ca. 240°C for 5 min and the resulting mixture, which consisted mainly of compounds **23** and **24**, was flash chromatographed on silica with 1:4 ethyl acetate/hexanes. Compound **24** was isolated in ca. 15% yield; mp 251–252°C (lit. (13) mp 255°C).

*Oxidation of compounds 23, 24, and 26 followed by acetylation. Formation of 9,10-diacetoxy-*anti-1,2,3,4,5,6,7,8-*octahydro-1,4:5,8-dimethanoanthracene (25)*

Compounds **23**, **24**, and **26** were oxidized with bromine in carbon tetrachloride by the procedure of Alder and Stein (13) to give *anti*-1,2,3,4,5,6,7,8-octahydro-1,4:5,8-dimethanoanthracene-9,10-diol. Treatment of the hydroquinone (0.50 g, 2.06 mmol) with acetic anhydride (10 mL) and pyridine (2 mL) at room temperature overnight gave the diacetate **25**, which was purified by chromatography on silica with 1:4 ethyl acetate/hexanes; mp 222–224°C (lit. (13) mp 226°C); ν_{max} (KBr): 1752 cm^{-1}; $^{H}\delta$: 3.27 (m, 4H), 2.30 (m, 6H), 1.7–1.8 (m, 6H), 1.4 (m, 2H), 1.2 (m, 4H); $^{C}\delta$: 169.8 (e), 138.9 (e), 136.3 (e), 49.3 (e), 41.2 (o), 26.3 (e), 20.9 (o).

*Oxidation of compound 27 followed by acetylation. Formation of 9,10-diacetoxy-*syn-*1,2,3,4,5,6,7,8-octahydro-1,4:5,8-dimethanonthracene (28)*

Compound **27** was oxidized and the resulting *syn* hydroquinone was acetylated as above to give compound **28**, mp 206–207°C; mixture mp with **25**, 202–204°C; ν_{max} (KBr): 1757 cm^{-1}; $^{H}\delta$: 3.25 (m, 4H), 2.27 (m, 6H), 1.7–1.8 (m, 6H), 1.4 (m, 2H), 1.2 (m, 4H); $^{C}\delta$: 169.7 (e), 138.9 (e), 136.2 (e), 49.9 (e), 41.0 (o), 26.3 (e), 20.9 (o). Exact Mass calcd. for $C_{20}H_{22}O_4$: 326.1518; found 326.1513.

Received April 6, 1990

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

TOM OTIENO, STEVEN J. RETTIG, ROBERT C. THOMPSON, and JAMES TROTTER. Can. J. Chem. **68**, 1901 (1990).

The complexes $CuL_2(CF_3SO_3)$ where L is pyrazine and 2,5-dimethylpyrazine have been prepared by the reaction of copper(I) triflate with the neutral ligand in methanol. Single crystal X-ray diffraction studies on the 2,5-Me_2pyz complex are reported. Crystals of the compound are triclinic, a = 9.424(4), b = 12.103(4), c = 9.113(4) Å, α = 110.97(3), β = 117.20(3), γ = 80.26(3)°, Z = 2, space group $P\bar{1}$. The structure was solved by heavy atom methods and was refined by full-matrix least-squares procedures to R = 0.033 and R_w = 0.039 for 3326 reflections with $I \geq 3\sigma(I)$. The structure is similar to that of the pyz analogue involving chains of copper ions linked by bridging 2,5-Me_2pyz ligands and monodenate triflate and terminal 2,5-Me_2pyz ligands completing a distorted tetrahedral CuN_3O chromophore. Mono-pyrazine and -2,5-dimethylpyrazine complexes of the type $CuL(CF_3SO_3)$ were obtained by thermolysis of the corresponding bis-ligand complexes. These compounds are assigned a polymeric structure involving bridging neutral ligands and monodenate triflate groups on the basis of infrared spectroscopy studies. Electronic spectroscopy and differential scanning calorimetry studies are also reported.

Key words: pyrazine and 2,5-dimethylpyrazine complexes, copper(I) triflate, crystal structure.

TOM OTIENO, STEVEN J. RETTIG, ROBERT C. THOMPSON et JAMES TROTTER. Can. J. Chem. **68**, 1901 (1990).

On a préparé les complexes $CuL_2(CF_3SO_3)$, dans lesquels L représente la pyrazine et la 2,5-diméthylpyrazine, en faisant réagir le triflate de cuivre(I) avec le ligand neutre, dans le méthanol. On rapporte des études de diffraction des rayons-X sur des cristaux uniques du complex 2,5-Me_2pyz. Les cristaux son tricliniques, avec a = 9,424(4), b = 12,103(4) et c = 9,113(4)Å, α = 110,97(3), β = 117,20(3) et γ = 80,26(3)°, Z = 2 et groupe d'espace $P\bar{1}$. On a résolu la structure par la méthode des atomes lourds et on l'a affinée par la méthode des moindres carrés jusqu'à des valeurs de R = 0,033 et R_w = 0,039 pour 3326 réflexions avec $I \geq 3\sigma(I)$. La structure est semblable à celle de l'analogue pyz impliquant des chaînes d'ions cuivres liés par des ligands 2,5-Me_2pyz qui servent de ponts alors que le triflate monodentate et les ligands 2,5-Me_2pyz complètent un chromophore CuN_3O tétraédrique déformé. On a obtenu les complexes de monopyrazine et de la 2,5-dimethylpyrazine du type $Cu(CF_3SO_3)$ par thermolyse des complexes correspondants portant deux ligands. Sur la base d'études de spectroscopie infrarouge, on a attribué à ces composés une structure polymérique comportant des ligands neutres servant de ponts ainsi que des groupments triflates monodentates. On rapporte aussi des études de spectroscopie électronique et de calorimétrie à balayage différentiel.

Mots clés : complexes de la pyrazine et de la 2,5-diméthylpyrazine, triflate de cuivre(I), structure cristalline.

[Traduit par la revue]

Introduction

The first and, until recently, only reported pyrazine-bridged compounds of copper(I) were some bimetallic complexes of composition Cu_2LX_2 (where L is pyrazine or a methylpyrazine and X is Cl, Br, I, or CN) (1, 2). Recently we reported the serendipitous isolation of a polymeric complex $[Cu(pyz)_2(CF_3SO_3)]_x$, **1**, from the reaction of copper(II) trifluoromethanesulfonate (copper(II) triflate) with pyz in a 1:2 mole ratio in methanol (3). The reaction involves the reduction of copper(II) to copper(I), presumably by the solvent. The present work was aimed primarily at developing a synthetic route to this compound starting with a copper(I) salt and, in addition, at obtaining and characterizing analogous complexes containing substituted pyrazine ligands.

We describe here the synthesis of **1** by the direct reaction of copper(I) triflate (4) with pyz, and the isolation by a similar route, and X-ray crystallographic analysis of the 2,5-dimethylpyrazine analogue, $[Cu(2,5\text{-}Me_2pyz)_2(CF_3SO_3)]_x$, **2**. The structure of **2** is similar to that of **1** in that it is polymeric and contains both bridging and terminal 2,5-Me_2pyz ligands. Compounds **1** and **2** are found to undergo ready thermal dissociation of one mole of neutral ligand to produce materials of composition $Cu(pyz)(CF_3SO_3)$, **3**, and $Cu(2,5\text{-}Me_2pyz)(CF_3SO_3)$, **4**. Spectroscopic studies on **3** and **4** suggest polymeric structures with bridging neutral ligands and monodentate triflate groups.

Experimental

Syntheses

Poly-μ-pyrazine-(pyrazine)(trifluoromethanesulfonato-O)-copper(I), $Cu(pyz)_2(CF_3SO_3)$, 1

Copper(I) trifluoromethanesulfonate, $Cu(CF_3SO_3)$, was prepared by a method similar to that described by Dines (5). To 16.0 g (112 mmol) of red copper(I) oxide was added 50 mL of *n*-octane and 20 mL (~226 mmol) of trifluoromethanesulfonic acid. The mixture was refluxed under nitrogen at about 110°C overnight, filtered, and the precipitate washed with *n*-octane and dried *in vacuo* at room temperature for 6 h, then at 135°C for 6 h. Subsequent reactions involving this copper(I) triflate and manipulation of the products of its reactions were performed using standard dry-box and vacuum-line techniques. To 1.07 g (~5 mmol) of copper(I) triflate was added 10 mL of methanol containing 10% v/v 2,2-dimethoxypropane, and the resulting slurry was stirred for 0.5 h. A solution of 1.63 g (20.4 mmol) of pyrazine in 5 mL of the above solvent was then added and the slurry stirred for an additional 2 h. On filtering and washing with a small amount of solvent, the solid product was found to consist of a mixture of an orange compound and copper(I) oxide. The presence of the latter, which was identified by infrared spectroscopy, indicated incomplete conversion of copper(I) oxide to copper(I) triflate in the initial reaction. The presence of this oxide impurity did not adversely affect subsequent reactions. The orange compound and the oxide were separated by

mixing with acetonitrile, in which only the former is soluble, followed by filtration. The filtrate was evaporated to dryness, *in vacuo*, to give an orange powder that was further dried at room temperature *in vacuo*, for about 0.75 h. Anal. calcd. for $CuC_9H_8N_4F_3SO_3$: C 29.00, H 2.16, N 15.03; found: C 28.73, H 2.22, N 15.23. Yield: 82%.

Poly-μ-2,5-dimethylpyrazine-(2,5-dimethylpyrazine)(trifluoromethanesulfonato-O)copper(I), Cu(2,5-Me$_2$pyz)$_2$(CF$_3$SO$_3$), 2

A slurry of copper(I) triflate (1.09 g, ~5 mmol), prepared as above, in methanol containing 10% v/v 2,2-dimethoxypropane (10 mL) was stirred for 0.5 h and then 2,5-dimethylpyrazine (3.0 mL, 27 mmol) was added and the slurry stirred for an additional 2 h. The solid produced was separated by filtration, washed with a small amount of solvent, then treated with acetonitrile to separate insoluble copper(I) oxide from the soluble complex as above. After filtration, the filtrate was allowed to evaporate slowly in a nitrogen atmosphere glove box, yielding a crystalline yellow product. Anal. calcd. for $CuC_{13}H_{16}N_4F_3SO_3$: C 36.41, H 3.76, N 13.06; found: C 36.60, H 3.79, N 12.96. Yield: 55%.

Pyrazinecopper(I) trifluoromethanesulfonate, Cu(pyz)(CF$_3$SO$_3$), 3

A sample of **1** was heated, *in vacuo*, at 140°C for 3.5 h during which time the color changed from orange to yellow. Anal. calcd. for $CuC_5H_4N_2F_3SO_3$: C 20.52, H 1.38, N 9.57; found: C 20.58, H 1.36, N 9.60.

2,5-Dimethylpyrazinecopper(I) trifluoromethanesulfonate, Cu(2,5-Me$_2$pyz)(CF$_3$SO$_3$), 4

A sample of **2** was heated, *in vacuo*, at 85°C for 0.5 h and then at 135°C for a further 6 h to yield the desired product as a yellow powder. Anal. calcd. for $CuC_7H_8N_2F_3SO_3$: C 26.21, H 2.52, N 8.73; found: C 26.32, H 2.59, N 8.84.

Physical measurements

Differential scanning calorimetry (DSC) studies were made using a Mettler DSC20 cell and TC10 TA processor. Infrared spectra in the range 4000–250 cm^{-1} were recorded on a Perkin–Elmer model 598 spectrometer using samples mulled in Nujol and hexachlorobutadiene and pressed between KRS-5 plates (Harshaw Chemical Co.). Calibration was achieved using polystyrene and frequencies are considered accurate to ±3 cm^{-1}. Electronic spectra (360–800 nm) of samples mulled in Nujol and smeared on filter paper were obtained on a Shimadzu UV-2100 spectrometer. Magnetic susceptibilities were measured using a P.A.R. model 155 vibrating sample magnetometer as described previously (6). X-ray powder diffraction patterns were recorded in the range 2θ = 5–60° using a Rigaku Rotaflex rotating anode X-ray powder diffractometer (Ni filtered Cu-K_α radiation). Carbon, hydrogen, and nitrogen were determined by P. Borda of this department.

X-ray crystallographic analysis of 2

A crystal ca. 0.25 × 0.30 × 0.45 mm in size was mounted in a glass capillary. Unit-cell parameters were refined by least squares on setting angles for 25 reflections (2θ = 35.8–40.7°) measured on a diffractometer with Mo-K_α radiation (λ = 0.71069 Å). Crystal data at 21°C are

$C_{13}H_{16}CuF_3N_4O_3S$ f.w. = 428.90

Triclinic, a = 9.424(4), b = 12.103(4), c = 9.113(4) Å, α = 110.97(3), β = 117.20(3), γ = 80.26(3)°, V = 863(1) Å^3, Z = 2, ρ_c = 1.650 Mg m^{-3}, $F(000)$ = 436, μ(Mo-K_α) = 14.32 cm^{-1}. Absent reflections: none, space group $P\bar{1}$ (reduced cell, Donnay convention) from structure analysis.

Intensities were measured with graphite-monochromated Mo-K_α radiation on a Rigaku AFC6S diffractometer. An ω–2θ scan at 32° min^{-1} over a range of (0.94 + 0.35 tan θ)° in ω (with up to 8 rescans, background/scan time ratio = 0.5) was employed. Data were measured to 2θ = 60°. The intensities of three check reflections, measured every 150 reflections throughout the data collection, showed a uniform decay of 3.6%. After data reduction,[2] an empirical absorption correction, based on azimuthal scans for three reflections, and a linear decay correction were applied. Transmission factors range from 0.87 to 1.00. Of the 5320 reflections measured, 5035 were independent (R_{merge} = 0.029) and 3326 (66.1%) of these had intensities greater than or equal to $3\sigma(F^2)$ above background where $\sigma^2(F^2) = [S^2(C + 4B) + (0.03F^2)^2]/Lp^2$ with S = scan speed, C = scan count, B = total background count, and Lp = Lorentz-polarization factor.

The structure was solved by conventional heavy atom methods, the coordinates of the Cu and S atoms being determined from the Patterson function. The remaining atoms (including hydrogen) were positioned from subsequent difference Fourier syntheses. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms with isotropic thermal parameters. Scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from ref. 7. The weighting scheme $w = 4F_o^2/\sigma^2(F_o^2)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix least-squares refinement of 290 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.033 and R_w = 0.039 for 3326 reflections with $I \geq 3\sigma(I)$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the maximum parameter shift corresponded to 0.19σ. The mean error in an observation of unit weight was 1.57. The final difference map showed maximum fluctuations of −0.23 to +0.42 e Å^{-3}. The final positional and (equivalent) isotropic thermal parameters for the non-hydrogen atoms appear in Table 1. Bond lengths and angles are given in Tables 2 and 3. Hydrogen atom parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, least-squares planes, bond lengths and angles involving hydrogen, and structure factors have been deposited.[3]

Results and discussion

Syntheses and thermal studies

$[Cu(pyz)_2(CF_3SO_3)]_x$, **1**, was obtained by the direct reaction of copper(I) triflate with excess pyrazine in methanol. The compound is soluble in acetonitrile, from which it may be obtained in pure form by the removal of the solvent under vacuum. The 2,5-dimethylpyrazine analogue, **2**, was prepared in the same manner; slow evaporation of an acetonitrile solution yielded **2** in crystalline form suitable for X-ray diffraction studies. Attempts to obtain a 2-methylpyrazine complex by the same route failed. Whereas in the preparation of **1** and **2** immediate formation of yellow/orange precipitates was noted on mixing $Cu(CF_3SO_3)$ with ligand in methanol, no such precipitate was obtained with the 2-Mepyz ligand. In this case the reaction produced a mixture of brown and pink solids and a dark brown solution, the latter giving a dark green solid on standing. C, H, and N analysis indicated the green material is non-stoichiometric and a room temperature magnetic susceptibility measurement showed it to be paramagnetic. No further characterization of this material was attempted. These observations suggest that in this reaction the copper(I) complex is not stabilized by polymer formation and in solution disproportionation occurs. This indicates the need for a symmetrically bridging ligand in order to obtain stable copper(I) polymers such as **2**.

Compound **1** prepared as described here exhibits three endothermic events in its DSC thermogram at 80, 107, and 217°C. ΔH for the first two events is 24 kJ mol^{-1} each and for the third event, 55 kJ mol^{-1}. Weight measurements before and after the first two events show a loss of ~6% and corresponding measurements for the third show an additional 15% weight loss. The total loss for the three events agrees well with the 21% loss expected for the dissociation of one mole of pyz. The thermal behavior of this material differs from that of crystalline samples of **1** prepared as described previously (3). In the latter case a single endothermic event occurs at 204°C (ΔH = 61 kJ mol^{-1}) and weight loss measurements confirm the loss of one mole of pyz. We interpret these results as follows. The synthetic procedure described here produces analytically pure samples of composition $Cu(pyz)_2(CF_3SO_3)$. This material, however, consists of a mixture of the extended chain polymer present in the crystalline form of **1**, plus lower oligomers. The latter dissociate pyrazine at lower temperatures than the former. Both types of sample show the onset of exothermic decomposition at temperatures immediately above the ~200°C endothermic event. The presence of the extended chain polymer in the sample of **1** prepared here was confirmed by an X-ray powder diffraction study. A simulated powder X-ray diffraction pattern for **1** was generated using the single crystal data from ref. 3 and the computer program LAZY PULVERIX (8). All of the observed peaks in the powder sample prepared here could be assigned as arising from the polymer and the absence of peaks assignable to other species suggests the lower oligomers are present in an amorphous phase.

The bis(2,5-dimethylpyrazine) complex, **2**, exhibits two closely spaced endothermic events at 182 and 221°C (total ΔH for the two events = 104 kJ mol^{-1}). The weight loss of 24% measured over the two events compares favorably with the value of 25% expected for the loss of one mole of ligand. The onset of exothermic decomposition is observed at temperatures immediately above the 221°C endothermic event.

The thermal analysis results for both **1** and **2** suggested the possibility of obtaining, on a preparative scale, $Cu(pyz)(CF_3SO_3)$, **3**, and $Cu(2,5\text{-}Me_2pyz)(CF_3SO_3)$, **4**, by the thermolysis route. As described in the experimental section, the syntheses of **3** and **4** were achieved by preparative thermolysis by heating **1** and **2** at ~140 and ~135°C respectively, *in vacuo*. The technique of employing, in preparative thermolysis, temperatures well below DSC peak temperatures for ligand dissociation has been used previously (9) and avoids significant thermal decomposition of the product. The DCS thermogram of **3** shows the onset of exothermic decomposition above 200°C with no events below this temperature, thus indicating that the complex does not lose neutral ligand prior to decomposition. The thermogram of **4** shows a small, reversible, endothermic event at 137°C (ΔH ~ 4 kJ mol^{-1}) of unknown origin. This complex also does not dissociate neutral ligand prior to decomposition, the onset of which occurs at about 205°C.

Crystal structure of 2

The crystal structure analysis shows that the structure of the bis(2,5-Me_2pyz) complex **2** is very similar to that of its pyrazine analogue **1** (3). A stereoview of the unit cell is shown in Fig. 1 while the geometry around each copper is given in Fig. 2 together with the atom numbering scheme. The structure consists of spiral chains of copper atoms linked by bidentate bridging 2,5-Me_2pyz ligands. Monodentate neutral ligand and triflate groups complete the coordination around each copper to yield a distorted tetrahedral CuN_3O chromophore.

The triflate anion in **2** is very similar, in regard to internal bonding parameters, to that in **1** (Table 4): it adopts a staggered-ethane configuration about the C—S bond; the O—S—O angles are greater than 109°C while the C—S—O angles are less than this angle, indicating that repulsions between adjacent oxygen atoms are greater than those between oxygen atoms and the trifluoromethyl group; the S—O bond involving the coordinated oxygen atom is longer than those involving the non-coordinated ones.

The 2,5-dimethylpyrazine moieties in **2** are planar to within experimental error and the internal bonding parameters for the three attached to a given copper atom are presented in Table 5. For comparison, data obtained for $Ni(2,5\text{-}Me_2pyz)Br_2$ (10) are included in Table 5. Even though the corresponding parameters for all the 2,5-dimethylpyrazines listed in the table are comparable (indicating lack of substantial distortion of all the rings), it is noteworthy that those for the two bridging ligands in $Cu(2,5\text{-}Me_2pyz)_2(CF_3SO_3)$ are identical within experimental

error. The terminal 2,5-dimethylpyrazine ligand is the least symmetrical.

A detailed comparison of the structures of **1** and **2** reveals some interesting differences, however. Attention was drawn previously (3) to the long Cu—O bond in **1** and the fact that the triflate–metal interaction is weak in this compound. The Cu—O distance in **2** is, in fact, ~0.06 Å longer than in **1** (Table 4), indicating even weaker metal–anion interactions in **2**. The observation that the S—O bond associated with the bridging oxygen atom is slightly shorter in **2** than in **1** is also consistent with weaker metal–anion interaction in **2**.

In **1**, two bridging pyrazine groups distinguished by different Cu–N bond distances are present. In contrast, although there are also two crystallographically different bridging ligands in **2**, the two Cu–N bridging distances are equal within experimental error. The mean bridging Cu—N distance of 2.006 Å in **2** is slightly longer than the corresponding value of 1.999 Å in **1**, while the terminal Cu—N distance in **2** (2.033(2) Å) is significantly longer than that in **1** (1.985(2) Å). It is interesting that on average both Cu—O and Cu—N distances are greater in **2** than in **1**, a consequence, presumably, of steric effects imposed by the methyl substituents on the pyrazine ligands of the former.

Steric interactions involving the methyl substituents of the 2,5-Me_2pyz ligand in **2** are responsible for the most obvious structural differences between this compound and the unsubstituted analogue **1**. These differences involve bond angles

[e]2,5-Me_2pyz absorbs in this region (1255 w, in liquid) and possibly accounts for the shoulders at 1264 and 1254 cm^{-1} in **2** and **4** respectively.
[f]2,5-Me_2pyz absorbs in this region (1165 w, in liquid) and probably accounts for the bands at 1175 and 1165 cm^{-1} in **2** and **4** respectively.

about the copper atom and the relative orientations of the bridging ligands. The N—Cu—N angle involving the bridging pyrazine ligands is substantially larger (126.28(8)°) for the 2,5-Me_2pyz derivative than for the unsubstituted complex (110.6(1)°). In compound **1** the normals to the mean planes of the μ-pyz ligands lie roughly in the plane of the copper atoms of the polymeric chain, while in **2** one μ-2,5-Me_2pyz ligand is oriented as in **1** and the other (that in the center of the unit cell, see Fig. 1) is oriented approximately at a right angle to the first (the normal to the mean plane being roughly orthogonal to the plane of the Cu atoms). Thus adjacent μ-2,5-Me_2pyz ligands along the polymer **2** are mutually orthogonal, minimizing steric interactions between methyl groups on neighboring μ-2,5-Me_2pyz ligands. The orientation of the terminal 2,5-Me_2pyz ligand in **2** also differs from that of the corresponding pyz ligand in **1**, as a result of the rearrangement of the bridging ligands and the more stringent steric requirements of the substituted pyrazine ligands in **2**.

Spectroscopic studies

The electronic spectra of **1, 2, 3**, and **4** show the presence of a single band at 19.0, 21.9, 19.8, and 20.4 kK, respectively. No d–d transitions are expected for these d^{10} complexes. The diamagnetism of **2** was, in fact, confirmed by magnetic susceptibility studies over the temperature range 4.2–80 K. The spectra are assigned to a metal to ligand π^* charge transfer transition. Methyl substituents on the pyrazine ring may be expected to increase the charge density on the ring, making it a poorer π-acceptor (11). This may account for the fact that the charge transfer transition for each of the 2,5-Me_2pyz complexes is higher in energy than that of the corresponding pyz complex.

The bands observed in the infrared spectra of these complexes may be separated as described previously (3) into those due to the triflate anion vibrations and those due to neutral ligand vibrations. Infrared frequencies with assignments are given in Tables 6 and 7. As mentioned previously (3), assignments for the pyrazine complexes in the 1150–1230 cm^{-1} range are tentative due to overlap of anion and pyz bands in this region. A similar problem arises with the 2,5-dimethylpyrazine complexes in this region, as noted in Table 6 and 7.

The infrared spectrum of $Cu(pyz)_2(CF_3SO_3)$ prepared in this work differs only slightly from that of the crystalline form reported earlier (3). The weak band at 774 cm^{-1} is absent and probably arose from an impurity in the earlier sample; in addition, the bands at 1247 and 1279 cm^{-1} assigned to the antisymmetric SO_3 stretching mode are broadened somewhat in the spectrum observed here, resulting in a less distinct splitting. This band broadening may well be a consequence of the presence of lower oligomers in addition to the extended chain polymer in this sample, as suggested above. The remainder of the spectrum agrees within error (±3 cm^{-1}) with that reported previously.

The infrared spectrum of $Cu(pyz)(CF_3SO_3)$, **3**, is, in general, similar to that of its bis(pyrazine) analogue, **1**, with the following notable differences. While **1** exhibits two bands of medium intensity at 452 and 472 cm^{-1}, assigned to terminal and bridging pyrazine respectively (3), **3** exhibits only one band in this region, at 473 cm^{-1}, which we assign to bridging pyrazine. In addition a medium intensity pyz band at 1051 cm^{-1} in **1** (3) is not observed in **3** and is likely a vibration associated with terminal pyz moieties. The anion spectra of **1** and **3** (Table 6) are virtually identical, suggesting that in **3** the mode of anion coordination is the same as in **1**, monodentate via oxygen. The splitting of the antisymmetric SO_3 stretching vibration (E symmetry in C_{3v}) is only slighter greater in **3** than in **1** (41 versus 32 cm^{-1}), suggesting, as discussed previously (3), a similar degree of anion distortion and therefore similar metal–anion bonding interactions in the two compounds. The vibrational spectra, therefore, are consistent with a polymeric structure for **3** involving three-coordinate copper(I) ions bridged by pyz ligands with the coordination around each copper completed by monodentate triflate groups to produce a CuN_2O chromophore.

Considering the 2,5-Me_2pyz complexes, **2** and **4**, it is evident from the data in Table 7 that most of the bands in free 2,5-Me_2pyz are present in the spectra of the complexes, with most bands shifting by a few wavenumbers to higher frequencies on coordination. In addition, band splitting is generally evident in **2** as a consequence, in part at least, of the presence of both bridging and terminal 2,5-Me_2pyz ligands in this compound. The band at 419 cm^{-1} in free 2,5-Me_2pyz, like that at 417 cm^{-1} in liquid pyrazine (3), is of potential diagnostic value to distinguish between monodentate and bidentate ligand coordination. In **2** the band is replaced by two medium intensity bands at 430 and 451 cm^{-1} and in **4** it is replaced by one band at 461 cm^{-1}. Assigning the higher frequency vibrations to bridging ligands would be consistent with the assignments made previously for the pyz analogues and would support the assignment of bridging 2,5-Me_2pyz in **4**. The close correspondence between the spectral bands assigned to triflate vibrations in compounds **1** and **2** (Table 6) is consistent with the X-ray diffraction studies which, as described above, reveal very similar internal bonding parameters for the anions in the two compounds. Apart from the fact that the splitting of the antisymmetric SO_3 stretching vibration in **4** is slightly, but significantly, greater than the corresponding splitting observed for the other three compounds, the anion spectrum of **4** is comparable to those of the other compounds and is consistent with monodentate triflate coordination. We conclude the structure of **4** to be polymeric, and similar to that of its pyz analogue **3**. Finally, we note that for both the pyz and the 2,5-Me_2pyz pairs of complexes the splitting of the infrared band assigned to the antisymmetric SO_3 stretching vibration is slightly, but significantly, greater in the three-coordinate complex than in the corresponding four-coordinate complex. This possibly reflects

stronger metal–triflate interactions in the former complexes due to fewer steric repulsions associated with a CuN_2O chromophore than with a CuN_3O chromophore.

^{1}H NMR studies of proton transfer in Schiff base and carboxylic acid systems

HOA LE-THANH AND D. VOCELLE[1]

Département de chimie, Université du Québec à Montréal, C.P. 8888, succ. A, Montréal (Québec), Canada H3C 3P8

Received February 6, 1990

HOA LE-THANH and D. VOCELLE. Can. J. Chem. **68**, 1909 (1990).

When the unconjugated Schiff base, isobutylidene isopropylamine (**2**), reacts with acids such as the mineral acids HCl, HBr, and HI, or the carboxylic acids trichloroacetic, monochloroacetic, and propionic acid, in $CDCl_3$, several complexes are formed. In this study, ^{1}H NMR allows us to differentiate between several possibilities. With the mineral acids, only 1:1 structures are seen and the chemical shift of the N---H---X proton varies according to the strength of the hydrogen bond between the protonated Schiff base and its counterion. With the carboxylic acids, 1:1 and 1:2 structures are present in rapid equilibrium. In the presence of an excess of acid, protonation of the Schiff base increases considerably. Extrapolation of the results is given in terms of the molecular mechanism of vision.

Key words: protonation, proton nuclear magnetic resonance, proton transfer, rhodopsins, Schiff base.

HOA LE-THANH et D. VOCELLE. Can. J. Chem. **68**, 1909 (1990).

Quand la base de Schiff non conjuguée, l'isobutylidène isopropylamine (**2**), réagit dans le $CDCl_3$ avec différents acides tels que les acides minéraux HCl, HBr et HI ou les acides carboxyliques comme trichloroacétique, monochloroacétique et propionique, plusieurs complexes sont formés. Dans cette étude, la RMN du proton permet de différencier plusieurs possibilités. Avec les acides minéraux, seules les structures 1:1 sont observées et le déplacement chimique du proton N---H---X varie selon la force de la liaison hydrogène entre la base de Schiff protonée et son contre-ion. Avec les acides carboxyliques, les structures 1:1 et 1:2 sont présentes dans un équilibre rapide. En présence d'un excès d'acide, la protonation de la base de Schiff augmente considérablement. La discussion de ces résultats en fonction du mécanisme moléculaire de la vision est abordée.

Mots clés : protonation, résonance magnétique nucléaire du proton, transfert du proton, rhodopsines, bases de Schiff.

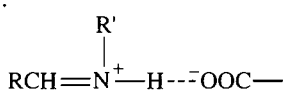
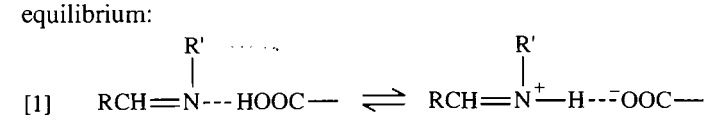
Introduction

In visual pigments such as rhodopsins, or in related bacterial pigments such as bacteriorhodopsins, the retinylidene Schiff base is protonated or deprotonated depending upon the stage in the photocyclic mechanism of vision, or proton pumping, at which the chromophore is located. As an example, the large blue shift occurring during the formation of metarhodopsin II (or at M_{412} in bacteriorhodopsin) is explained in terms of deprotonation of the preceding intermediate metarhodopsin I (L_{550} for bacteriorhodopsin) (1–5). One is tempted to believe that in such systems there exists an easily polarizable hydrogen bond such as this one:



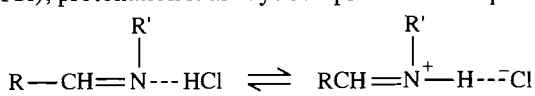
This has been advocated by Zundel and Merz (6, 7) on the basis of continua in IR spectra of model systems of rhodopsins and bacteriorhodopsins. Consequently, protonation or deprotonation of a Schiff base can be summarized by the following equilibrium:



[1]

In such systems, the equilibrium would be quite sensitive to the nature of the environment (in model systems, it will be the solvent) and to a variety of other well-known effects in vision research such as the presence of water molecules (8–10) and of a local electrical field surrounding the chromophore (11).

Most model systems of rhodopsins and bacteriorhodopsins use a mineral acid (usually HCl) as the proton donor. With this acid (HCl), protonation is always complete and the equilibrium:



is strongly shifted to the right. For some years now, we have investigated the effects of carboxylic acids on Schiff bases (SB) since aspartic or glutamic acids[2] are reputed to be the proton donor in the pigments (6). This has been done using UV, FTIR at room temperature and at low temperature, and by ^{13}C and ^{15}N NMR spectroscopy (see refs. 5 and 14). Some interesting facts emerged from these studies. In particular, protonation in nonpolar solvents by weak carboxylic acids is incomplete and acids having pK_a's near to those of aspartic and glutamic acids (pK_a's of 3.9 and 4.2 respectively in water) need some additional stabilizing factors to effect 100% protonation. These factors could be of different natures but we are especially interested in the effects of water molecules near the SB and in the presence of several carboxylic acids, which may act as a proton relay transfer (4, 5).

In the present study, we intend to investigate the effects of excess acid on the proton transfer capability of three carboxylic acids of quite different pK_a's: trichloroacetic acid (TCA, pK_a 0.66), monochloroacetic acid (MCA, pK_a 2.85), and propionic acid (PRO, pK_a 4.9). Also, steric effects around the SB will be studied with the help of three different imines: neopentylidene *n*-butylamine (**1**), isobutylidene isopropylamine (**2**), and isobutylidene *tert*-butylamine (**3**).

^{1}H NMR spectroscopy was chosen for this investigation since it is not affected by the presence of excess acid, as is the case for IR studies (because of the proximity of $-CO_2H$, $-CO_2^-$, $-C{=}N^+H$, $-C{=}N$ bands in the 1600–1750 cm^{-1} region). By looking at the behavior of the $-N^+{-}{-}{-}H{-}{-}{-}{}^-O$ proton we can gain a good idea of how much proton transfer has occurred when excess acid is used.

[2]Quite recently, Sakmar *et al.* (12) and Zhukovsky and Oprian (13) in a most elegant experiment using site-directed mutagenesis of opsin genes were able to show quite convincingly that the protonating agent of the retinyl Schiff base chromophore is glutamic acid-113 in bovine rhodopsin.

Experimental

The imines **1**, **2**, and **3** were prepared according to a method previously described (15). Their purity was assessed by IR and ^{1}H NMR spectroscopy. The imines were freshly distilled before use. The acids TCA and MCA were dried in a desiccator under vacuum and in the presence of P_2O_5. Propionic acid was dried over activated molecular sieves (3Å). Preparation of the mineral salts has also been described (15). Deuterated chloroform was used as received (Merck, Sharp & Dohme). The concentration of the imines and their salts in $CDCl_3$ was always 0.1 M. All operations concerning the preparation of the samples for NMR spectra were carried out under dry nitrogen atmosphere in a glovebox and the spectra were recorded immediately after. The NMR spectra were taken on a Bruker WH-400/DS (400 MHz) at 293 K and in some cases at 233 K (−40°C).

Results and discussion

To our knowledge, no ^{1}H NMR study of the N---H---O bonds of SB/carboxylic acid systems has been reported before. However, N---H---O bonds in other systems have already been studied. For instance, *syn* and *anti* isomers of di-α-pyridyl ethylene (16), homoconjugated and heteroconjugated amines and amine oxides (17), diamine monosalts (18), trimethylamine oxide and carboxylic acids (19), pyridine dicarboxylic acid *N*-oxide (20), pyridine and several substituted acetic acids (21, 22), 4-methyl pyridine and dichloroacetic acid (23), substituted pyridines and trifluoroacetic acid complexes (24), some Mannich bases and alcohols (25, 26), a phenol derivative with triethylamine (27) and with a disubstituted aniline (28), both at low temperatures, have been studied by NMR.

It is a known fact that proton transfer can be assisted through the participation of solvent molecules (29) and that it is linearly correlated with the difference between the pK_a's of the base (proton acceptor) and the acid (proton donor), ΔpK_a (29, 30). In our study, it is expected that with mineral acids full protonation occurs because of the large ΔpK_a. Full protonation means that the equilibrium (eq. [1]) is shifted completely to the right and consequently implies that 100% proton transfer is also present. From our previous studies carried out in deuterated chloroform (5, 15), imines and acids are expected to form ion pairs and neutral associated species (as in the left hand of eq. [1]). In all the spectra, concentrations of the SB were held constant at 0.1 M while the concentrations of the acids vary from 0.05 M to 1.0 M (2.0 M for PRO). The chemical shift of the OH of the carboxylic acids is sensitive to changes in concentration. Therefore the measurements for the acids alone and for the SB/carboxylic acid systems were done under exactly the same experimental conditions. Results will be first discussed for the mineral acids, then followed by the carboxylic acids.

Schiff bases/mineral acids systems

For isobutylidene isopropylamine (**2**), all three mineral acids were used. That full protonation (and proton transfer) has occurred is indicated by the fact that the N---H---X proton (where X = Cl, Br, I, henceforth abbreviated H_{NX}) is coupled with the α and α′ protons of the SB (Fig. 1) and by IR data (15) that leave no doubt on its state of protonation (presence only of the $\nu_{C=N^+H}$ band).

The chemical shift of the α protons (Table 1) is greater for HI than for HBr than for HCl. It follows the strength of the acids (HI > HBr > HCl). On the contrary, for the H_{NX}, results of Table 2 show an increase in the chemical shifts while going from HI to HBr and to HCl. This indicates that the strength of the hydrogen bonding between the protonated SB and its counterion increases following this order:

$$N^+\text{-H---}Cl^- > N^+\text{-H---}Br^- > N^+\text{-H---}I^-$$

[a]Expressed in molar ratio of **2**:acids.

[b]The H_d values at 293 and 233 K refer to the acid alone, in solution, at the same concentrations as those containing SB/acid; see text.

These observations are in good agreement with the previous results obtained in FTIR spectroscopy (15).

It is obvious also that the chemical shifts of H_{NX} taken alone do not indicate full protonation. The variation in the chemical shifts of the three salts indicates that the counterion (X^-) exerts a strong influence on the N^+-H proton. Again this signifies that ion pairs are formed in deuterated chloroform. Because of this, their chemical shifts cannot be used to evaluate the degree of protonation in systems where protonation is incomplete. As we

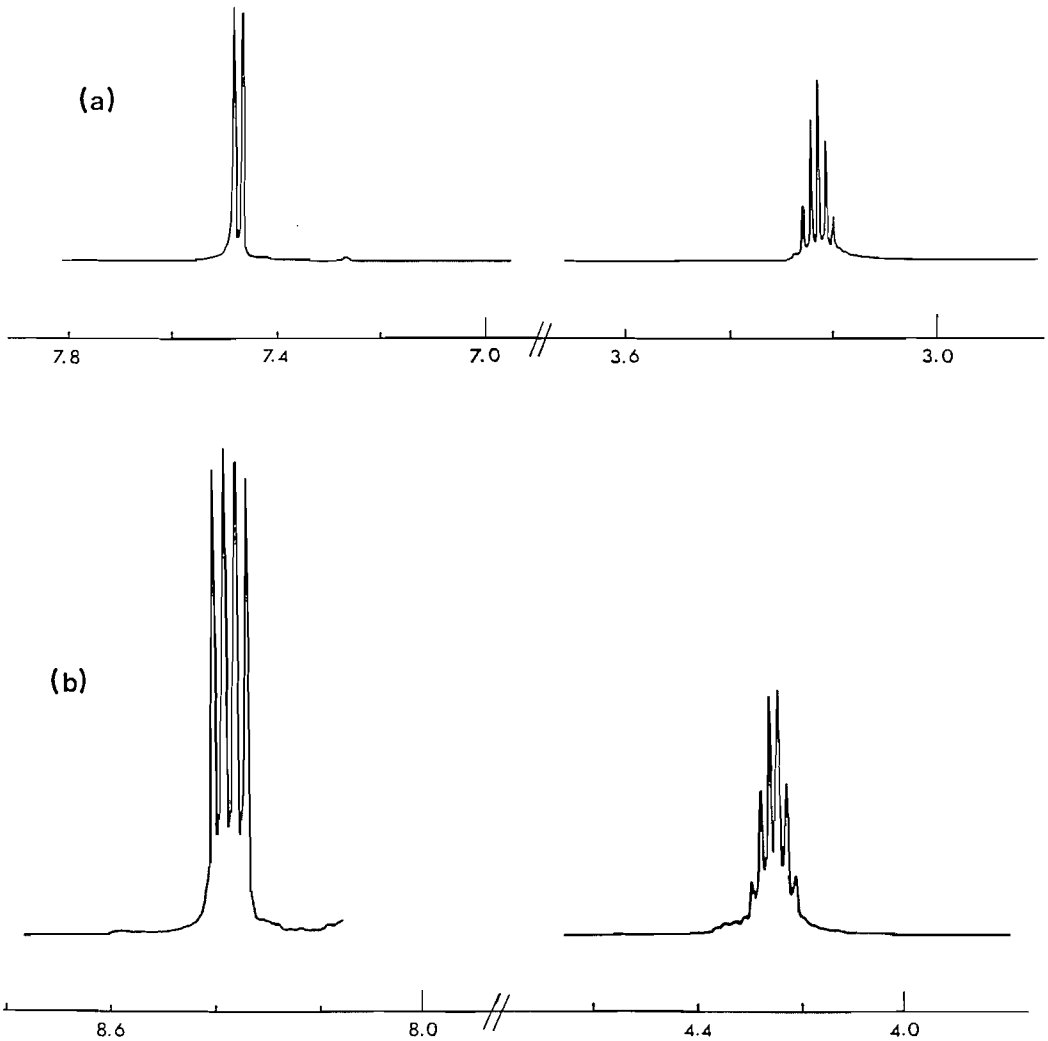

FIG. 1. A part of ^{1}H NMR spectra showing the spin–spin coupling of α and α′ protons, at 293 K: (a) SB **2**; (b) SB **2** + HBr 1:1.

have demonstrated for ^{13}C and ^{15}N NMR (31, 32), chemical shifts for some judiciously chosen nuclei could be used to evaluate the degree of protonation of SB. The data in Table 1 indicate that the β′ protons for **2** and possibly for **3** could be used for that purpose since they are well deshielded upon protonation of the SB but are somewhat insensitive to the presence of the counterion. A value of 1.52 ppm was retained for these protons and will serve later as the 100% protonation reference point. The β′ protons of **1** are more deshielded than those of **2** and **3** since they are methylene protons rather than methyl protons.

Tables 2–4 also show that the chemical shifts of H_{NX} vary according to the degree of branching of the amine residue. Upon branching, H_{NX} is shifted to low field while the aldimine proton is shifted to high field. This could be explained by steric hindrance caused by the bulky isopropyl and *tert*-butyl groups.

Schiff bases/carboxylic acids systems

Let us recall that one of the principal aims of this study is to show the presence and effects, if possible, of several carboxylic acid molecules acting simultaneously on the SB. By stabilizing the negative charge on the carboxylate anion, the presence of two or more molecules of acid should make the acid appear stronger. This resembles the so-called proton relay transfer often mentioned in enzyme chemistry (33). That such complexes do exist has been demonstrated by Barrow (34) and Denisov and Golubev (35) for related systems. In an attempt to show the presence of these complexes, the molar ratios of SB to carboxylic acid were varied from 1:0.5 to 1:10 (1:20 for PRO). The chemical shifts of the N--H--O protons are shown in Tables 2–4.

At first glimpse, inspection of these tables shows that the data appear rather similar for the three SB. As was the case for the mineral acids, imine **1** is the most deshielded by the carboxylic acids, as seen for H_α, while for N--H--O protons it is the most shielded (systems 1:1), and this is true for all the acids used. Furthermore, while spectra for TCA show two peaks in the 10–17 ppm region for molar ratios of 1:2 and up (see Fig. 2c, f and Fig. 4a, b), spectra for MCA present two peaks only for molar ratio 1:5 and up (see Figs. 3, 4c, d), and only one broad peak appears in that same region for PRO (see Fig. 5a–f). Also, the chemical shifts obtained with MCA (as is also the case for TCA) decrease from 16.5 to 12.6 ppm (17.1 to 12.7 ppm for TCA) upon increase in the acid concentration, while for propionic acid the contrary is observed: the chemical shifts increase from 11.65 to 12.24 ppm upon addition of acid. Because of these facts, each acid will be discussed separately.

Trichloroacetic acid

IR results show (15) that this acid is able to protonate SB to a large extent. Data of Table 1 for compound **2** only allow the evaluation of the degree of protonation by considering that when **2** is fully protonated the β′ proton should have a mean value of

1.52 ppm (see before) while, as observed, the value is 1.12 ppm for 0% protonation. With a found value of 1.46, the degree of protonation is calculated to be 85%. With acid concentrations of 0.05 and 0.1 M, only one peak is present at 293 K and the chemical shifts have values near 17 ppm (see Fig. 2a, b). When excess acid is present and the molar ratio changes to 1:2, two rather broad peaks are seen at 293 K (Fig. 2c) while one is sharper than the other at 233 K (Fig. 2f). To assign proper structures for these two N--H--O protons, the possibility of the simultaneous presence of several complexes must be considered and one also cannot forget that, in systems like these, fast

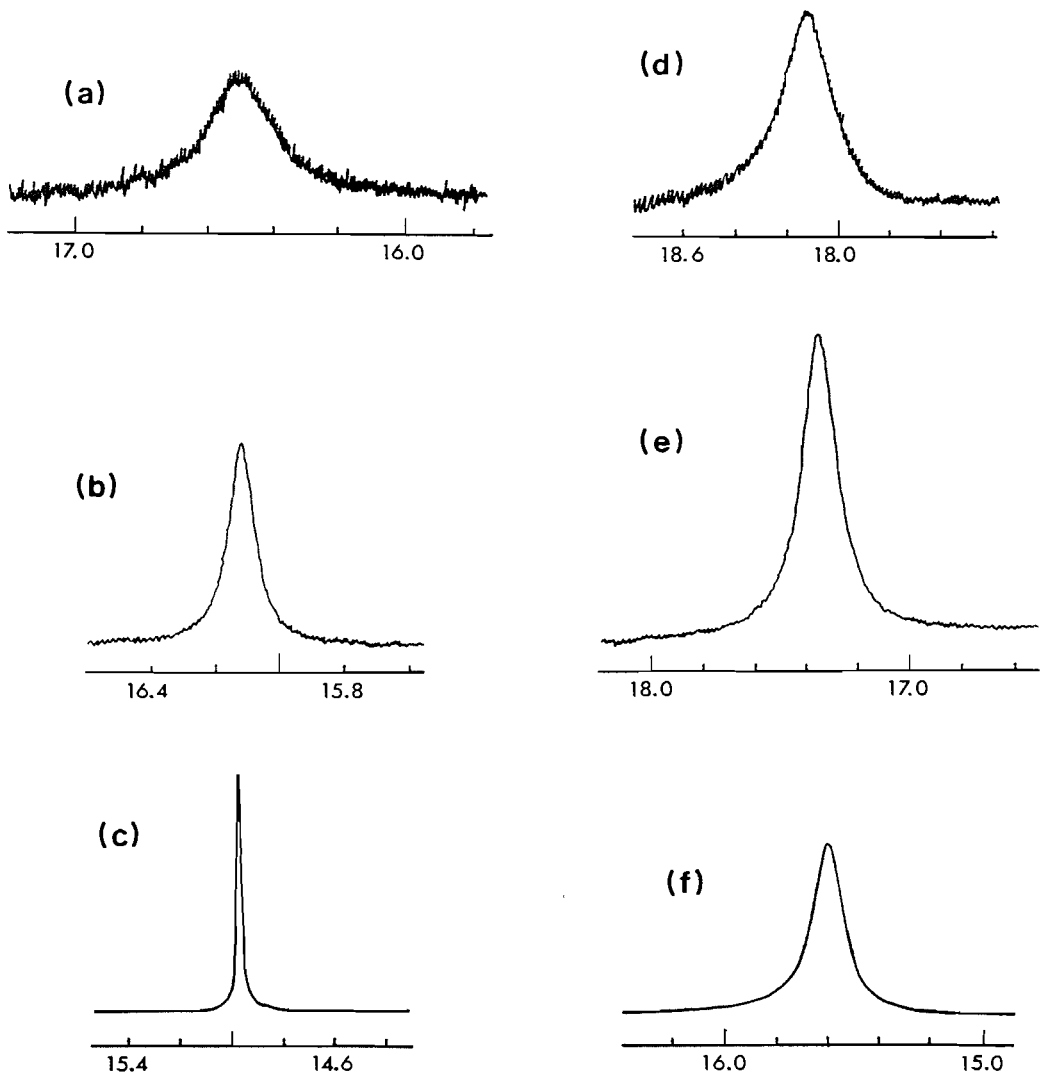

FIG. 3. ^{1}H NMR spectra for N---H---O protons at 293 and 233 K and for different molar ratios of **2**:MCA: At 293 K (a) 1:0.5; (b) 1:1; (c) 1:2. At 233 K (d) 1:0.5; (e) 1:1; (f) 1:2.

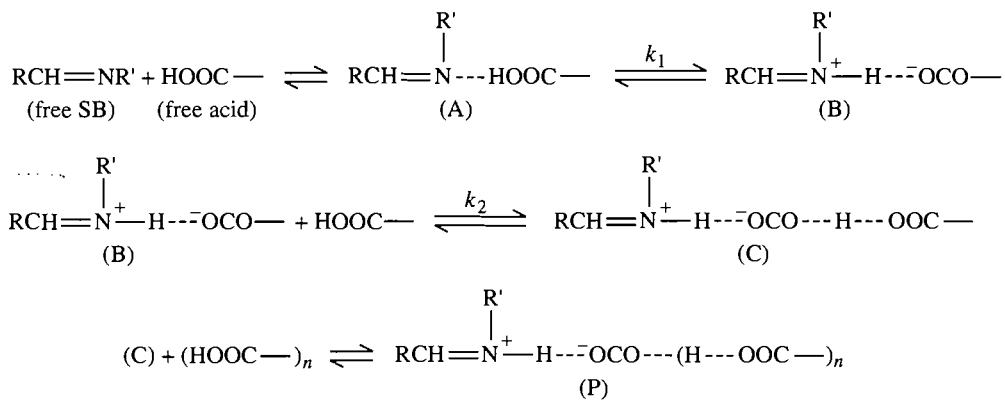

SCHEME 1

intermolecular exchanges could always be present. Scheme 1 (see below) shows some of the complexes that could reasonably be occurring. In this scheme, we see the solvated SB and acid interacting first to form the molecular adduct A, which equilibrates rapidly with the ionic species B. By the addition of more acid, a 1:2 complex (C) can be formed, followed by a polymeric structure such as P. All these structures are in equilibrium.

Also, the presence of an acid dimer cannot be excluded. The RCOOH proton will be abbreviated H_d. It is shown below.

A 2:1 complex is not shown in Scheme 1 since such a structure would only be possible when the amount of acid is low compared to the Schiff base concentration, as for the ratio 1:0.5. However, no peak assignment could be related to such a structure in this work and, furthermore, review of the literature on related systems as discussed before (13–23) shows that such

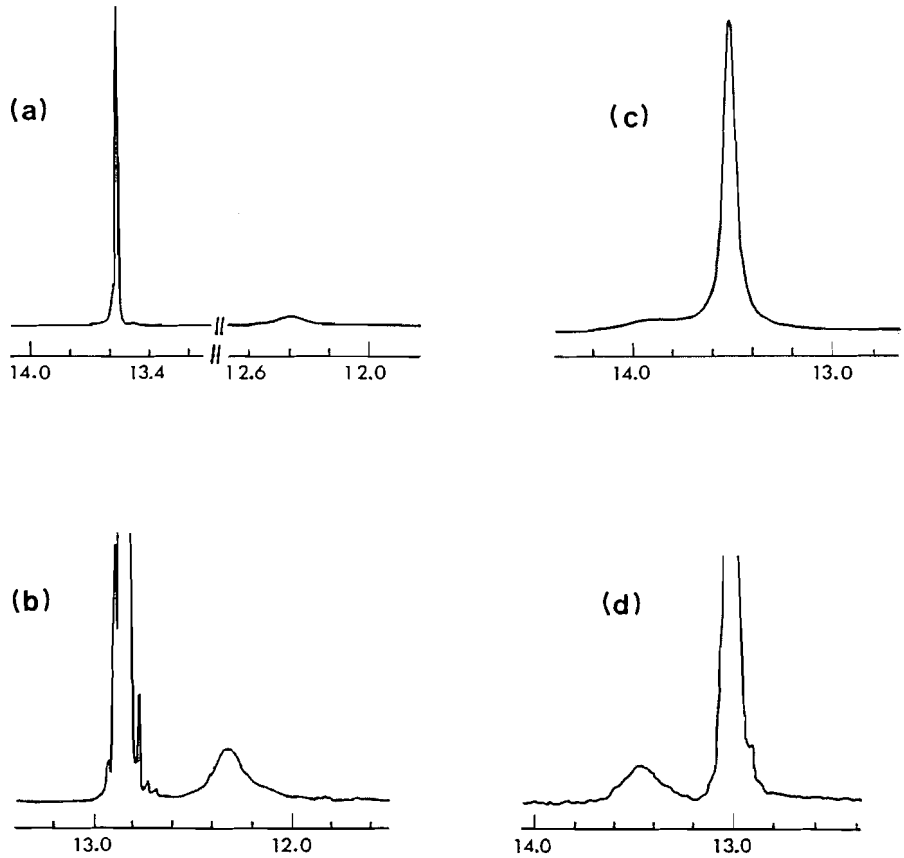

FIG. 4. ^{1}H NMR spectra for N---H---O protons at 233 K and for two molar ratios of **2**:TCA and **2**:MCA. System **2**:TCA (a) 1:5; (b) 1:10. System **2**:MCA (c) 1:5; (d) 1:10.

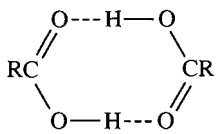

H_d

structures are rarely invoked. Since the location of the peak for samples having molar ratios of 2:1 can readily be explained with 1:1 structures, in this work 2:1 structures will be omitted.

In Scheme 1, the free forms of SB and the acid are probably present only at very low concentration for an acid as strong as TCA, which means that at the rather high concentrations used here (0.1 M) it could be considered absent. This has been confirmed by UV spectroscopy.[3] Furthermore, structures A and B are expected to be in a fast equilibrium (26) and their N--H--O protons are not expected to be differentiable at room temperature. These protons will be abbreviated as H_A and H_B (or H_{AB}). The 1:2 complex must also be in equilibrium with the 1:1 complex and it is reasonable to expect that the equilibrium would not be as fast as between A and B since a second molecule of acid must be added, which is obviously not the case for A and B. Another possibility could arise for the formation of structure C: this could not only be formed as described before but also, conceivably, by direct reaction of the free Schiff base with the dimer complex of the acid as shown in eq. [2]:

[2] $RCH{=}NR' + (HOOC\text{-})2 \rightleftharpoons C$

This is a distinct possibility and it shows the complexity of the question. Nevertheless, in this work it will be neglected on the basis that since 1:1 structures are present, it seems logical to think that the cyclic dimer would be broken in the presence of the Schiff base.

In C, however, there are two highly deshielded protons (N--H--O and O--H--O); they are not expected to be differentiable either at room temperature or at 233 K. These two protons will be abbreviated H_C. Finally, polymeric complexes (n = 2, 3, etc.) might also be present, especially when large excesses of acid are used, but these complexes will be quite difficult to differentiate from C since their structures appear similar.

With molar ratios of 1:0.5 and 1:1 only one broad peak is present and is quite deshielded (Fig. 2a, b). This can be explained in terms of a fast equilibrium between the molecular (A) and the ionic species (B) of Scheme 1 since it is known that protonation is incomplete and that the free forms are unlikely with a strong acid like TCA, as previously discussed. The chemical shifts must represent the mean values of the proportions of each of the two entities. At 233 K no second peak is present and the peak appears more shielded by some 0.3 ppm. At 233 K and with an equimolar concentration of SB and acid (Fig. 2e), the N--H--O proton is now coupled with the α and α' protons of the SB. On the other hand, one can see that H_α appears now as a doublet of doublets and that the coupling of $H_{\alpha'}$ with the N--H--O proton results in an overlapped doublet of a multiplet, similar to those observed in the systems of SB and halogenated mineral acids, as shown in Fig. 1b. This can be explained on the basis that the free energy between the free forms (even at very low concentration) and B is, at 233 K, large enough that the rate of exchange is now sufficiently slow to

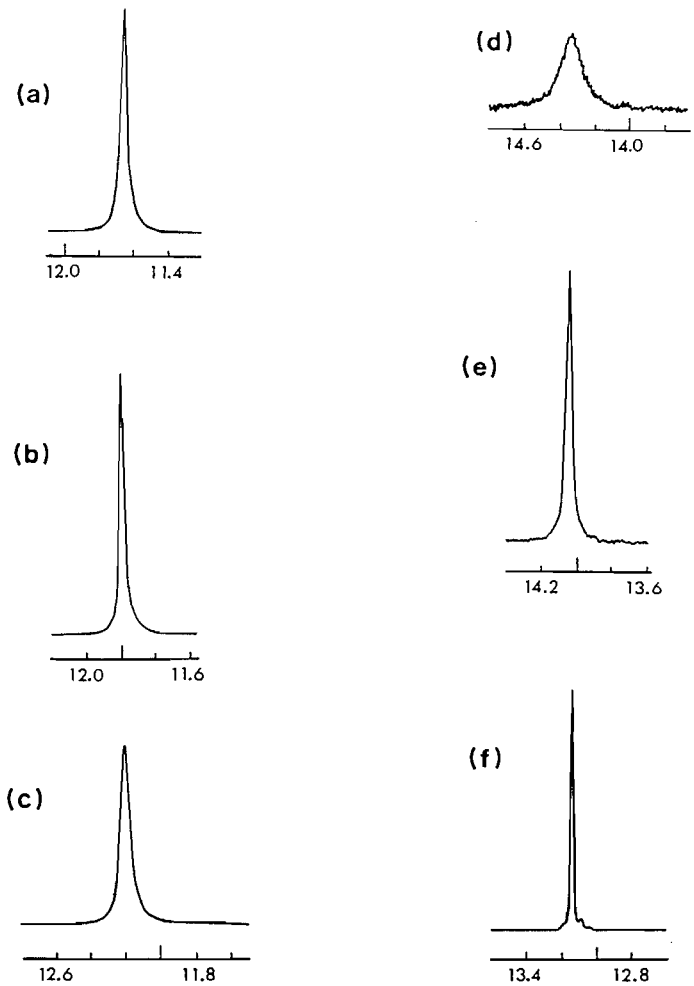

FIG. 5. ^{1}H NMR spectra for N---H---O protons at 293 and 233 K and for different molar ratios of **2**:PRO: At 293 K (a) 1:0.5; (b) 1:1; (c) 1:5. At 233 K (d) 1:0.5; (e) 1:1; (f) 1:5.

make the α protons appear as a doublet of doublets. All these observations signify as expected that, as the concentration of acid increases and with a lowering of the temperature, the equilibrium k_1 is shifted to the right.

When excess acid is added as in the molar ratio of 1:2 at 293 K, the spectrum reveals two peaks located at 14.84 and 14.27 ppm (Fig. 2c). According to Denisov and Golubev (35), the more deshielded peak could be attributed to the two protons of C, which are interchanging rapidly, and the more shielded peak could come from the averaging of the N---H---O protons in A and B, this latter being preponderant for the reasons already stated. This assignment is also supported by the shape of the peaks obtained when the temperature is lowered. This will be discussed later. The proton at 14.27 ppm will then be referred to as H_{AB}. H_{AB} experiences a large shielding effect of more than 2 ppm compared to the value obtained previously at a molar ratio of 1:1. This can be explained by a strong shift of the equilibrium to the right, that is, towards protonation or proton transfer. The presence of a second peak in the NMR spectrum signifies that C is slowly equilibrating with B (compared to the timescale of NMR). How can this be rationalized? Compared to a 1:1 structure, a 1:2 complex is a trimeric structure, which should be quite different in energy from a dimeric one. With TCA, this is the case. (For MCA and PRO, as will be shown, the situation is somewhat different.) At 233 K and with a molar ratio of 1:2 (Table 2 and Fig. 2f), the shapes of the two peaks obtained differ: one is sharper (at 15.89 ppm) than the other (at 13.53 ppm). Peak integration indicates that they are in a 1:1 ratio. As said before, the broader and more shielded one is assigned to the N---H---O proton in A and B (or H_{AB}), which is thought to be in a slower equilibrium than at 293 K, but still fast compared to the NMR timescale. The sharper peak at 15.89 ppm comes from the two protons in C. The peak H_{AB} is broad because of some couplings with the vicinal protons (not always resolved due to the fast equilibria between the different structures) and also because of the nitrogen quadrupolar effect. The more deshielded peak H_C is sharper due to the influence of the O---H---O proton in rapid exchange with the proton N---H---O in structure C (Scheme 1). Incidentally, the H_d peak of the carboxylic acid (that is, the peak of the carboxylic acid taken alone in the solvent: see Experimental) is always sharper than those of B and C. The chemical shift of H_{AB} moves to higher field at 233 K while H_C parallels H_d and goes to lower field. This is not too surprising since H_C must have much in common with H_d (same O---H---O bond). In conclusion then, with a molar ratio of 1:2, the results can be explained in terms of

$$A \overset{k_1}{\rightleftharpoons} B \overset{k_2}{\rightleftharpoons} C$$

where $k_1 \gg k_2$.

For molecular ratios of 1:5 and 1:10, again two peaks are obtained at room temperature as well as at 233 K (Fig. 4a, b). This time the assignments are easy since, for instance, at a molar ratio of 1:5 the peak at 12.81 ppm (see Table 2) integrates for a ratio of 1:5 compared to the aldimine proton. The same situation as described before is maintained except that the proportion of C increases while that of B decreases. At a ratio of 1:10, B now represents around 25% of the mixture while it was 50% for a molar ratio of 1:2 (at 293 K). Also, the N--H--O proton of B has its coupling with adjacent protons resolved, which means that A is not contributing in the overall picture. Furthermore, it is probable that complexes formed by one molecule of imine and several molecules of carboxylic acid (as in P of Scheme 1) do exist, along with the three complexes already proposed (A, B, and C), but NMR is not expected to be able to differentiate C from P since they have quite similar structures. It is interesting also to note that the chemical shift of H_C now approaches that of H_d: at a molar ratio of 1:10, the chemical shifts are at 12.20 and 12.05 ppm respectively (Table 2).

Monochloroacetic acid

With this acid of medium strength, all the spectra at room temperature show only one peak whatever the molar ratio used (Fig. 3a, b, c). At 233 K, one broad peak is present for molar ratios of 1:0.5, 1:1, and 1:2 (Fig. 3d, e, f). Only at molar ratios of 1:5 and 1:10 (Tables 2 and 3) is there a second peak present (Fig. 4c, d). However, the behavior of MCA as judged by the peak's chemical shifts and shapes in Fig. 3 is rather similar to that obtained with TCA (compare Figs. 2a, b and 3a, b), so that MCA seems to act much like TCA except for ratios of 1:2 (compare Figs. 2c and 3c). This difference can be explained by the fact that because MCA is a weaker acid, complexes B and C must have closer free energies so that B and C are rapidly equilibrating (faster than the timescale of NMR). Also, since the SB is now only 40% protonated, structure A is expected to play a more important role. With MCA then, the results can be explained as with TCA, that is, in terms of $A \rightleftharpoons B \rightleftharpoons C$ but where A and B are more populous.

Another fact must be pointed out. When the temperature is lowered to 233 K, the chemical shift of the N--H--O proton varies in a different way depending on the acids used. For

example, with TCA and a molar ratio 1:1, the chemical shift was seen to decrease from 293 to 233 K; with MCA, the contrary is observed, but the values of the chemical shift for the two acids are similar (16–17 ppm). According to Rospenk and Sobczyk (26), these results could suggest that, in the system of SB and TCA, the proton transfer form (B) prevails, while in the system of SB and MCA, the hydrogen-bonding complex (A) is preponderant and, in complex A, the lowering of the temperature enhances the strength of the hydrogen bond, affording an increase of the chemical shift.

Propionic acid

PRO is a very weak acid and data from Table 1 indicate that **2** is only 10% protonated. Data from Tables 2 and 3 show that only one peak is present whatever the molar ratios or temperatures used (Fig. 5a–f). When the temperature is decreased, the chemical shift of H_{AB} increases, similar to the system SB + MCA. This again characterizes the usual behavior of the protons involved in the hydrogen-bonding complexes. Furthermore, the chemical shifts are quite different from those of the other acids: they resemble more the chemical shifts of H_d than anything else. These facts can be explained by now proposing that the free SB and acid are in fast equilibrium with A and B as in the first part of Scheme 1. With a large excess of acid, structure C is probably present but, as with MCA, it must be in rapid equilibrium with B. Since PRO is such a weak acid, C is probably in very low concentration.

Finally, all the results and discussion already presented used data obtained with compound **2**. For imines **1** and **3**, the NMR spectra closely resemble those shown for **2** except that the chemical shifts are somewhat different. Tables 3 and 4 present these results. The chemical shift changes can be attributed to the differences in the branching of the molecules. In point of fact, both **1** and **3** served to double-check our results.

Conclusion

This study demonstrates that two or more carboxylic acid molecules can act simultaneously and that, in consequence, the equilibrium that exists between N--H-O $\rightleftharpoons$ N^+-H---$^-$O is shifted to the right. This means that proton transfer is induced by the cooperative presence of several molecules of acid. Of course, our system is somewhat remote from being a proper model of rhodopsins or bacteriorhodopsins since our SB are not conjugated and the acids are not part of a protein. Notwithstanding these points, our study still indicates that aspartic or glutamic acid, in a nonpolar environment, could not protonate a SB completely without some additional stabilizing factors. This study does indicate that one of these factors could be the presence of several molecules of acid acting simultaneously on the SB, thereby causing a proton transfer.

Acknowledgements

The authors wish to thank Professor C. Sandorfy of the Université de Montréal for very helpful discussions. The NMR spectra were obtained at the Centre régional de RMN de haut champ of the Université de Montréal, whose help we acknowledge here. Synthesis of 14-hydroxy steroids. Total synthesis of methyl 14β-hydroxy-1,7,17-trioxo-5β,8-androstene-10β-oate and related compounds

RÉJEAN RUEL[1] AND PIERRE DESLONGCHAMPS[2]

Laboratoire de synthèse organique, Département de chimie, Faculté des sciences, Université de Sherbrooke, Sherbrooke (Québec), Canada J1K 2R1

Received April 24, 1990

RÉJEAN RUEL and PIERRE DESLONGCHAMPS. Can. J. Chem. **68**, 1917 (1990).

The total synthesis of the title compound **22** and methyl 14α-hydroxy-5β,13α,8-androstene-1,7,17-trioxo-10β-oate **21** isomer is reported. We also describe the 1,6-Michael addition of 2-methyl-1,3-cyclopentanedione on dienone **14** and the protic ammonium salt catalyzed intramolecular Michael addition of cyclic β-ketoester on the conjugated acetylenic ketone **13**.

Key words: cardenolides, steroid synthesis, aldol, Michael addition.

RÉJEAN RUEL et PIERRE DESLONGCHAMPS. Can. J. Chem. **68**, 1917 (1990).

On rapporte la synthèse totale des isomères 13α,14α **21** et 13β,14β **22** du 14-hydroxy-5β,8-androstene-1,7,17-trioxo-10β-oate de méthyle. Nous décrivons l'addition de Michaël-1,6 de la 2-méthyl cyclopentane-1,3-dione sur la diènone **14** de même que l'addition de Michäel intramoléculaire du β-cétoester cyclique sur la cétone acétylénique conjuguée **13**, cette dernière addition étant catalysée par un sel d'ammonium protique.

Mots clés : cardénolides, synthèse des stéroïdes, aldol, addition de Michaël.

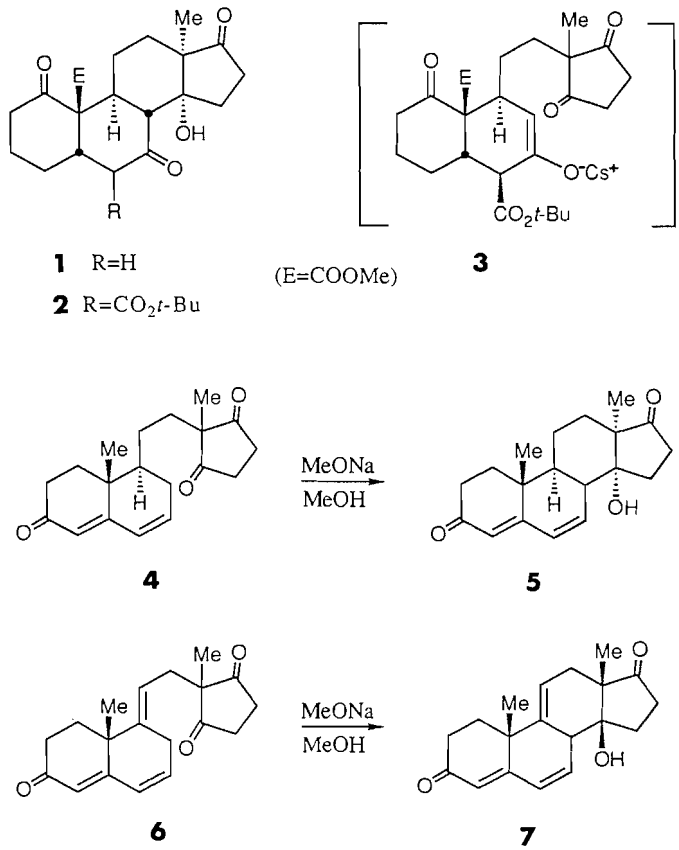
Introduction

We have previously reported the synthesis of 14α-hydroxy steroid **1** (Scheme 1) using a new stereocontrolled anionic polycyclization method (1). Base-catalyzed aldol condensation involving the cesium enolate **3** led to bis-β-ketoester **2**, which was transformed to steroid **1** upon selective decarboxylation of the *tert*-butyl ester (PTSA, C_6H_6, 80°C). A single-crystal X-ray analysis revealed that the 14-hydroxy substituent in steroid **1** had an α configuration. This configuration was, however, opposite to the 14β-hydroxy substituent normally found in cardioactive steroids (2).

It then came to our attention that in Valenta's modified Torgov sequence (3) the closure of ring C effected by base-catalyzed aldol condensation on dienone **4** led to the 14α-hydroxy steroid **5**. On the other hand, when the aldol condensation involved the anion formed from the trienone system in **6** bearing a C9–C11 (steroid numbering) olefin, the 14β-hydroxy steroid **7** was the only product formed. Based on these results, we expected the preferential formation of a 14β-hydroxy steroid from the aldol condensation that would involve an enolate related to **3** but bearing a conjugated double bond between carbons C9 and C11. This account describes the synthesis of this aldol precursor as well as the results observed during the aldol condensation.

Results and discussion

The synthesis of *cis*-bicyclic dienone **14** is depicted in Scheme 2. The β-ketoester **8** was first obtained by treatment of 2-carbomethoxy-2-cyclohexenone (4) with allyltrimethylsilane and titanium tetrachloride (5). The dimethyl ketal **9** was then formed by treatment of **8** with methanol containing *p*-toluenesulfonic acid and methyl orthoformate. Subsequent ozonolysis led to the aldehyde **10** and, like its olefinic precursor **9**, this aldehyde **10** existed as a 2:1 *trans/cis* mixture of isomers that was used without separation. These isomers could be separated and were in fact isolated as pure compounds for the purpose of characterization (see Experimental). The acetylide formed from *n*-butyllithium (THF, −78°C) and the *O*-tosyl derivative of commercially available 3-butyn-1-ol was then added to



SCHEME 1

aldehyde **10** and the resulting propargylic alcohol **11** was oxidized with Jones reagent (5 min, 0°C, Me_2CO) to the ynone **12**. It should be pointed out here that in these conditions the dimethyl ketal protecting group was not hydrolyzed. Transacetalization of dimethyl ketal **12** (12 h, 23°C, Me_2CO, PTSA) then yielded β-ketoester **13**.

Previous reports from this laboratory described in a systematic study the intramolecular Michael addition of cyclic β-ketoesters on conjugated acetylenic (6) and olefinic (7) ketones. Cesium carbonate was the base used for these stereocontrolled

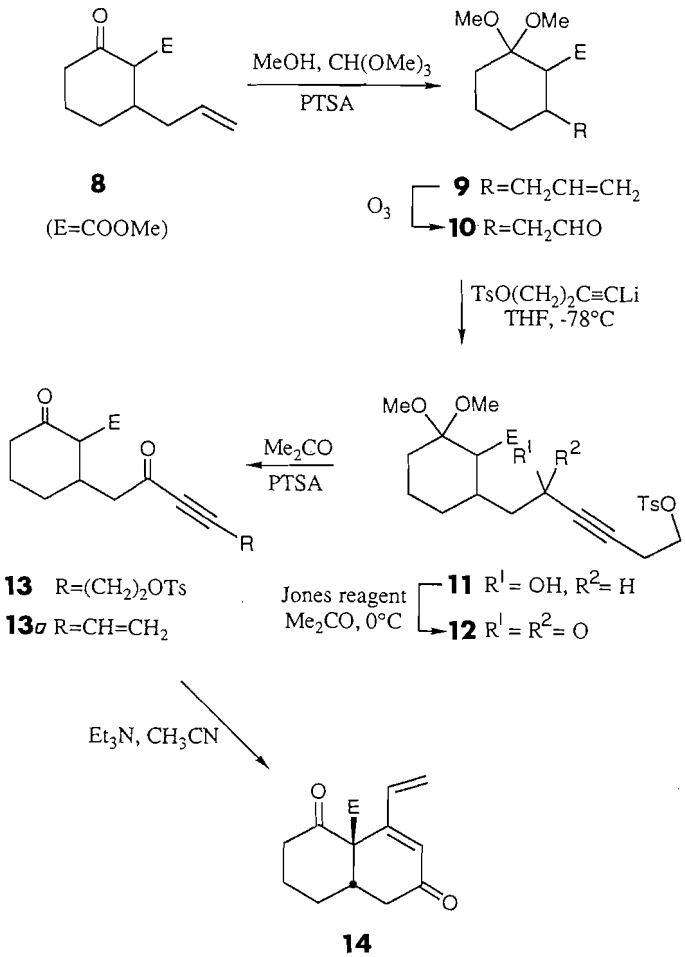
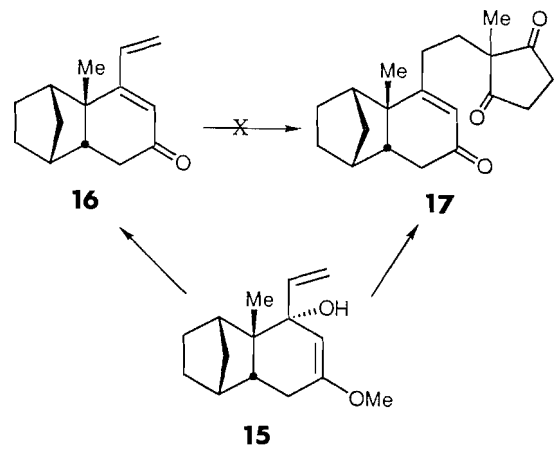


SCHEME 2



SCHEME 3

processes, which yielded specifically *cis*-decalin products. Using the conditions described (6, 7), we were, however, unable to achieve the Michael addition on acetylenic ketone **13** and obtained mainly decomposition products. This problem was solved when we found complementary experimental conditions very effective for the desired intramolecular Michael addition. When triethylamine (3 equiv.) was indeed added to a solution of β-ketoester **13** in acetonitrile, the *cis*-decalin dienone **14** (74%) was obtained after completion of the reaction. The first intermediate formed in the reaction was the elimination product **13***a*. This β-ketoester **13***a* was in fact spontaneously produced in the reaction mixture and transformed, after 3 h in acetonitrile at room temperature, to the Michael addition product **14**. If, however, acetonitrile was replaced by the less polar solvent methylene chloride (8), only the elimination product **13***a* was obtained from tosylate **13** after the same period of time. This elimination process generated a triethylammonium salt that catalyzed the intramolecular Michael addition, as the following results clearly indicate. When the elimination product **13***a* was submitted to the reaction conditions (Et_3N, CH_3CN) but without any protic ammonium salt, the Michael adduct **14** was formed, but with a modest 50% yield, while completion of the reaction required 2 days. On the other hand, when triethylammonium hydrochloride (1 equiv.) was added to a solution of **13***a* and triethylamine (2 equiv.) in acetonitrile, the formation of the Michael adduct **14** was completed after only 3 h and proceeded with better yield (74%). The synthesis of dienone **14** thus required seven steps and the overall yield was 30%.

Having the dienone **14** in our hands, only the 1,6-Michael addition of 2-methyl-1,3-cyclopentanedione (for a related 1,8-Michael addition, see ref. 9) remained to be done in order to get the requisite aldol condensation precursor of the steroid. Dienone **14** resembles Yates' bridged-ring dienone **16** (Scheme 3), which arose upon attempted purification on silica gel of allylic alcohol **15** (10). Yates *et al.* also reported the synthesis of enone **17**, through their modified Torgov sequence, from allylic alcohol **15**, but attempts to synthesize enone **17** from the Michael addition of 2-methyl-1,3-cyclopentanedione on dienone **16** were uniformly unsuccessful (10). Bearing this in mind, we were pleased to find that the Michael addition of 2-methyl-1,3-cyclopentanedione on our dienone **14** (in CH_3CN) took place cleanly and efficiently (80% yield) to give enone **18** (Scheme 4) when triethylamine was used as the base. It should be pointed out here that since the experimental conditions used (Et_3N, CH_3CN) for this Michael addition are essentially the same as required for the previously described intramolecular Michael addition (**13** → **14**), enone **18** could be synthesized in a "one pot" procedure from ynone tosylate **13** in 65% yield. We have investigated here again whether a protic ammonium salt would enhance the efficiency of this Michael addition, that is, if the reaction **14** → **18** would be also catalyzed by the protic salt as was the case for intramolecular Michael reaction **13***a* → **14**. For the 1,6-Michael addition leading to enone **18**, however, we found no appreciable effect when a protic ammonium salt ($Et_3NH^+Cl^-$) was added to the reaction mixture. The absence of catalysis by the protic ammonium salt may not be surprising if one considers the inherent acidity of the nucleophile 2-methyl-1,3-cyclopentanedione ($pK_a \sim 9$), which could itself catalyze the Michael reaction.

Hydrogenation of enone **18** gave the dihydro compound **19** where hydrogen has approached the less-hindered β face of the cyclohexenone ring. Aldol condensation (*t*-BuOK, *t*-BuOH–THF) of tetraketone **19** then gave 14β-hydroxy steroid **20**. The structure of **20** was predicted, based on related work reported in Professor Yates' elegant synthesis of 1,4-methano bridged steroids (10), and was later confirmed by a single crystal X-ray analysis (11). One should note that steroid **20** has an "unnatural" *syn* relationship between the carbomethoxy group (at C-10) and the C-9 hydrogen atom. Base-catalyzed aldol condensation of enone **18** then led to interesting results. When enone **18** was treated with cesium carbonate in refluxing acetonitrile for 48 h, a 3:2 mixture of 14α- and 14β-hydroxy steroids **21** and **22** was obtained (54% yield). Structures **21** and **22** were also confirmed by single crystal X-ray analysis.[3] No trace of the $\Delta^{9(11)}$-7-keto

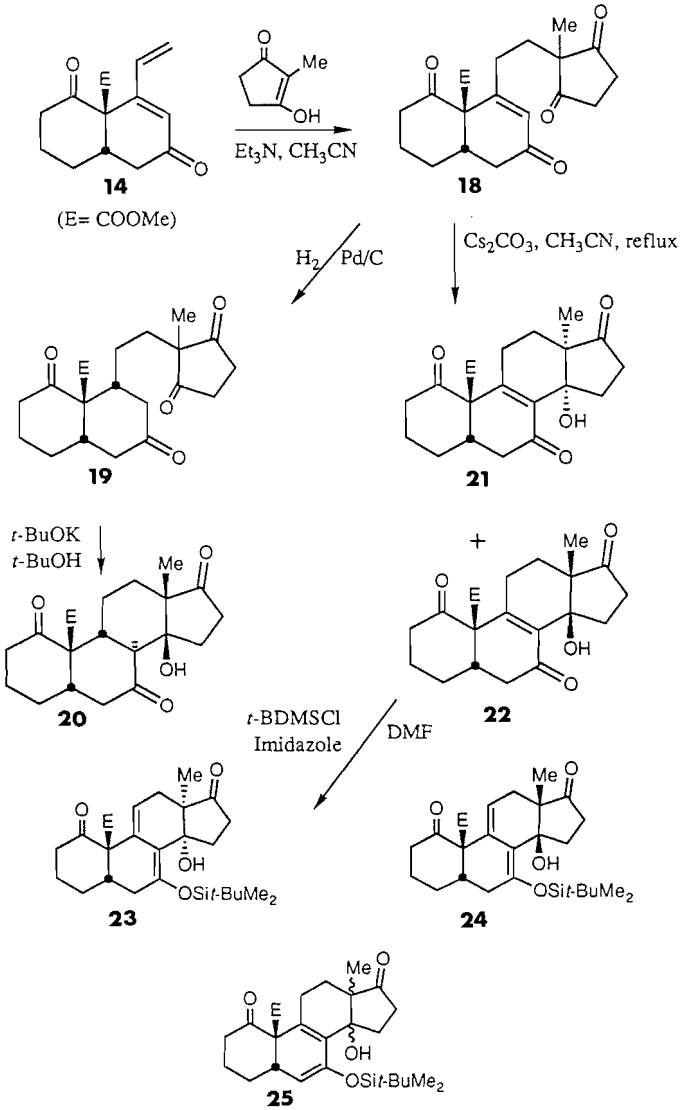

SCHEME 4

steroids corresponding to steroids **21** and **22** could be isolated since, after the aldol condensation, the C9—C11 double bond must rapidly isomerize to the more stable C9—C8 conjugated double bond in **21** (or **22**). This isomerization obviously makes this aldol condensation irreversible.

The 14-hydroxy steroids **21** and **22** could not, however, be separated using low or medium pressure flash chromatography techniques. We could, however, later obtain pure 14-hydroxy steroids **21** and **22** since other quite interesting and unexpected results emerged upon attempted *tert*-butyldimethylsilylation of the tertiary alcohol in **21** or **22**. For example, when *tert*-butyldimethylsilyl chloride was added to a dimethylformamide solution of the 3:2 mixture of steroids **21** and **22** and imidazole, a 19:13:1 mixture of silyl enol ethers **23**, **24**, and **25** was isolated. Whether these silyl enol ethers were formed via an internal S_N2 migration of the "normally expected" silyl ether is not known but none of that silyl ether could be isolated. Technically, this reaction (**21**/**22** → **23**/**24**/**25**) could never be driven to completion but proceeded nevertheless in 67% yield (based upon recovered starting material). We were also pleased to find that 14-hydroxy silyl enol ethers **23** and **24** were easy to separate using flash chromatography techniques. Once the isomers **23** and **24** were separated, regeneration of enone steroids **21** and **22** was the only thing that remained to be done in order to obtain pure steroids. The use of tetrabutylammonium fluoride in THF at −78°C, even for a reaction time as low as 30 s, uniformly led to extensive decomposition. The reasons for this behavior are not quite understood. Among other things, unavoidable traces of hydroxide ions in the ammonium fluoride reagent may, for example, induce retro-Claisen type opening of A-ring β-ketoester. If that process operates, the generated ester enolate would be conjugated with the $\Delta^{8(9)}$-7-keto system of enones **21** and **22** and a complex cascade of reactions could follow. Fortunately, the use of cesium fluoride proved successful. Thus, when silyl enol ether **23** or **24** was treated with cesium fluoride in acetonitrile, the pure hydroxy steroid **21** or **22** was obtained in good yield (73%).

In summary, the enolate derived from the aldol condensation precursor **18** led, although with low selectivity, to the expected 14β-hydroxy steroid **22**. We also found new conditions (Et_3N, $Et_3N^+HCl^-$) for the intramolecular Michael addition of cyclic β-ketoester on acetylenic ketone. Furthermore, our work describes the successful 1,6-Michael addition of 2-methyl-1,3-cyclopentanedione to bicyclic dienone **14** bearing a 9-vinyl-$\Delta^{8(9)}$-7-keto system (steroid numbering).

Experimental

All reactions were carried out under an argon atmosphere unless otherwise noted. Melting points are uncorrected. R_f values were determined by using 5 × 20 cm^2 plates and an equilibrated solvent chamber. Chromatographic separations were made using Merck Kieselgel 60 (230–400 mesh ASTM). The infrared (ir) spectra were taken on a Perkin–Elmer 681 spectrophotometer. The ultraviolet (uv) spectra were registered on a Varian Tecktron 635 spectrophotometer. Mass spectral assays (ms, *m/e*) and peak matching were obtained using a VG Micromass ZAB-1F spectrometer. Proton nmr and carbon nmr spectra were recorded on a Bruker WM-250 instrument. Chemical shifts are reported in δ values relative to chloroform as internal standard. Abbreviations used are m: multiplet, s: singlet, d: doublet, t: triplet, q: quartet, dd: double doublets.

Allyl β-ketoester 8

To a stirred solution of 2-carbomethoxy-2-cyclohexenone (4.13 g, 26.8 mmol) in methylene chloride (55 mL) at −78°C is added titanium tetrachloride (2.8 mL, 28.1 mmol) followed by allyltrimethylsilane (5.8 mL, 37.5 mmol). After stirring for 20 min, aqueous sodium carbonate (20%) is added to the mixture. The aqueous layer is extracted with methylene chloride (3 × 50 mL) and the combined organic layers are washed with brine, dried ($MgSO_4$), filtered, and evaporated to yield 5.3 g of an oil. Flash chromatography of the residue (ethyl acetate/hexane,1:3) yields 4.7 g (90%) of **8** as a colorless oil; R_f 0.26–0.43 (ethyl acetate/hexane,1:4); ir (neat, ν cm^{-1}): 3070, 2935, 2860 (CH), 1745 (C=O ester), 1710 (C=O, ketone) cm^{-1}; ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 5.80–5.68 (1H, m, CH_2=C*H*-), 5.15–4.90 (2H, m, CH_2=CH-), 3.76 (3H, s, CO_2CH_3), 3.16 (1H, d, J = 11.0 Hz, -CO-C*H*-CO_2CH_3), 2.60–1.40 (9H, m, -$(CH_2)_3$-C*H*-CH_2-). Enol form (characteristic signals): 12.36 (>1H, s, enolic H), 3.75 (>3H, s, CO_2CH_3).

Allyl dimethyl ketal 9

To a stirred solution of ketoester **8** (5.1 g, 26.0 mmol) and trimethyl orthoformate (3.7 mL, 33.7 mmol) in methanol (50 mL) at 23°C is added *p*-toluenesulfonic acid (247 mg, 1.3 mmol). After 12 h at 23°C, saturated sodium bicarbonate is added and the mixture is extracted with methylene chloride. The separated aqueous layer is extracted with methylene chloride (3 × 50 mL) and the combined organic layers are washed with brine, dried ($MgSO_4$), filtered, and evaporated to yield 6.3 g of an oil. Flash chromatography of the residue (ethyl acetate/hexane,1:4) yields 5.25 g (84%) of a 2:1 *trans/cis* mixture of dimethyl ketal **9**; R_f 0.36 (**9**-*cis*) and 0.28 (**9**-*trans*) (ethyl acetate/hexane,1:4); ir (neat, ν cm^{-1}): 3070, 2940 (CH), 1740 (C=O ester); ^1H nmr (250 MHz, $CDCl_3$) δ ppm (**9**-*cis*): 5.83–5.72 (1H, m, CH_2=C*H*-), 5.03–4.96 (2H, m, CH_2=CH-), 3.67 (3H, s, -CH_2CH_3),

Aldhyde ***10***

Ozone is bubbled into a cold (−78°C) solution of olefin **9** (5.0 g, 20.7 mmol) in methylene chloride (200 mL) until a blue color persists. Argon is then passed through the solution to lower the concentration of ozone, and triphenylphosphine (7.0 g, 26.9 mmol) is added at −78°C. The resulting mixture is stirred for 2 h at room temperature. Concentration under reduced pressure yields the aldehyde **10**, which can be used without purification in the next step. Pure material may be obtained by means of flash chromatography (ethyl acetate/hexane, 7:13), which yields 4.5 g (89%) of aldehyde **10**; R_f 0.13 (**10**-*cis*) and 0.10 (**10**-*trans*) (ethyl acetate/hexane,1:4); (**10**-*cis*): white needles; mp 124–126°C (heptane); (**10**-*trans*): oil; ir (CH_2Cl_2, ν cm^{-1}): 2940, 2830, 2720 (CH), 1740 (C=O ester), 1720 (C=O aldehyde); ^{1}H nmr (250 MHz, $CDCl_3$) δ ppm: (**3**-*cis*): 9.74 (1H, t, J = 1.4 Hz, -CHO), 3.67 (3H, s, -CO_2CH_3), 3.19 (6H, s, 2 × -OCH_3), 3.07 (1H, dd, J = 4.3, 1.7 Hz, -CH-CO_2CH_3), 2.42–1.39 (9H, m, -(CH_2)$_3$-CH-CH_2-), (**3**-*trans*): 9.71 (1H, t, J = 1.5 Hz, -CHO), 3.69 (3H, s, -CO_2CH_3), 3.20–3.19 (6H, 2s, 2 × -OCH_3), 2.70 (1H, d, J = 6.5 Hz, -CH-CO_2CH_3), 2.63–1.15 (9H, m, -(CH_2)$_3$-CH-CH_2-); ms, *m/e*: 229 ($M^+ - CH_3$), 213 ($M^+ - OCH_3$), 201 ($M^+ - CH_2CHO$). *14-Hydroxy enone steroids **21** and **22***

Cesium carbonate (63.2 mg, 0.2 mmol) is added to a solution of enone **18** (350 mg, 0.97 mmol) in acetonitrile (15 mL). The mixture is heated at reflux for 48 h and cooled down to 23°C before filtration on silica gel. Evaporation and flash chromatography of the residue yields 189 mg (54%) of a 3:2 mixture of 14-hydroxy steroids **21** and **22**; R_f 0.22 (ethyl acetate/hexane,1:1); uv (CH_3CN) λ_{max}: 246 nm (ε 6700); ir (CH_2Cl_2, ν cm^{-1}): 3500 (OH), 2950 (CH), 1740 (C=O ester), 1715 (C=O ketone), 1660 (C=O enone). For **21**: mp 151–153°C ($CHCl_3$–heptane); ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 4.27 (1H, s, -O*H*), 3.80 (3H, s, -CO_2-CH_3), 3.12 (1H, m, -CH_2-C*H*-CH_2-), 2.69–1.47 (16H, m, 8 × -CH_2), 1.10 (3H, s, -CH_3). For **22**: mp 168–170°C (MeO*t*-Bu); ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 4.39 (1H, s, O*H*), 3.85 (3H, s, -CO_2CH_3), 3.24 (1H, m, -CH_2-C*H*-CH_2-), 2.90–1.20 (16H, m, 8 × -CH_2), 1.05 (3H, s, -CH_3); ms, *m/e*: 360 (M^+), 342 ($M^+ - H_2O$). Exact mass calcd. for $C_{20}H_{24}O_6$ (M^+): 360.1573; found: 360.1568.

*14-Hydroxy silyl enol ether steroids **23, 24, 25***

To a solution of a 3:2 mixture of enones **21** and **22** (100 mg, 0.28 mmol) and imidazole (47 mg, 0.69 mmol) in freshly distilled dimethylformamide (300 μL) is added *tert*-butyldimethylsilylchloride (58 mg, 0.39 mmol). The mixture is stirred at 23°C for 52 h, quenched with saturated ammonium chloride, and diluted with water (5 mL). The mixture is extracted with 1:1 ether–hexane (5 × 10 mL). The combined organic layers are washed with brine, dried ($MgSO_4$), filtered, and evaporated to yield 107 mg of an oil. Flash chromatography of the residue (ethyl acetate/hexane,1:3) yields **23** (25.0 mg) and **24** (16.7 mg) (37% yield, 67% yield based on recovered starting material) as well as **25** (1.3 mg) and recovered starting material (52.4 mg). For **23**: R_f 0.22 (ethyl acetate/hexane,3:7); ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 5.17 (1H, dd, J = 6.3, 2.5 Hz, -C=C*H*-CH_2-), 4.84 (1H, s, -O*H*), 3.73 (3H, s, -CO_2CH_3), 2.80 (1H, m, -CH_2-C*H*-CH_2-), 2.75–1.65 (14H, m, 7 × CH_2), 1.12 (3H, s, -CH_3), 0.97 (9H, s, -Si-C(CH_3)$_3$, 0.27, 0.20 (6H, 2s, 2 × Si-CH_3). For **24**: R_f 0.19 (ethyl acetate/hexanes,3:7); uv (CH_3CN) λ_{max}: 250 nm (ε 20 800); ir ($CHCl_3$, ν cm^{-1}): 3500 (OH), 2930, 2860 (CH), 1740 (C=O ester), 1705 (C=O ketone); ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 5.18 (1H, dd, J = 6.4, 2.5 Hz, -C=C*H*-CH_2-), 4.61 (1H, s, -O*H*), 3.76 (3H, s, -CO_2CH_3), 2.85 (1H, m, -CH_2-C*H*-CH_2-), 2.75–1.60 (14H, m, 7 × -CH_2), 1.11 (3H, s, -CH_3), 0.99 (9H, s, -Si-C(CH_3)$_3$), 0.29 (6H, s, -Si(CH_3)$_2$); ms, *m/e*: 474 (M^+), 456 ($M^+ - H_2O$), 417 ($M^+ - C_4H_9$). Exact mass calcd. for $C_{26}H_{38}SiO_6$ (M^+): 474.2437; found: 474.2444. For **25** (unseparated mixture of isomers): R_f 0.13 (ethyl acetate/hexane,3:7); ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 5.58 (1H, d, J = 6.4 Hz, -CH-C*H*=C-OSi*t*BDM), 5.27 (1H, d, J = 5.0 Hz, -CH-C*H*=C-OSi*t*BDM), 3.92 (1H, s, -O*H*), 3.87 (1H, s, -O*H*), 3.74 (3H, s, -CO_2-CH_3), 3.70 (3H, s, -CO_2CH_3), 3.44 (1H, m, -C*H*-CH=C-OSi*t*BDM), 3.25 (1H, m, -C*H*-CH=C-OSi*t*BDM), 2.90–1.60 (14H, m, 7 × -CH_2), 1.21 (3H, s, -CH_3), 1.18 (3H, s, -CH_3), 0.99 (9H, s, -SiC(CH_3)$_3$), 0.98 (9H, s, -SiC(CH_3)$_3$, 0.28, 0.26 (6H, 2s, 2 × -Si-CH_3), 0.28 (6H, s, -Si(CH_3)$_2$).

*Cleavage of 14-hydroxy silyl enol ether **23** or **24**. Formation of pure 14-hydroxy steroids **21** and **22***

To a solution of silyl enol ether **23** (35.8 mg, 0.08 mmol) in acetonitrile at 23°C is added cesium fluoride (23.0 mg, 0.15 mmol). The mixture is stirred vigorously at 23°C for 15 min, quenched with saturated ammonium chloride, and diluted with water. The mixture is extracted with ethyl acetate and the combined organic layers are washed with brine, dried ($MgSO_4$), filtered, and evaporated to yield 25 mg of an oil. Flash chromatography of the residue (ethyl acetate/hexanes,1:1) yields 19.6 mg (73%) of 14-hydroxy steroid **21**. The same procedure applies for the reaction **24** → **22**.

Carbanion sources (organolithium and Grignard reagents) react with $[(mesitylene)_2Fe]^{2+}$ and $[(mesitylene)(Ch)Fe]^{+}$ cations (Ch = cyclohexadienyl) to afford neutral Ch_2Fe and ChCh'Fe ("pseudoferrocene") complexes, respectively. Addition of R^- (R^- = methyl, phenyl, benzyl, and *t*-butyl) occurs stereospecifically via *exo* addition at an unsubstituted carbon atom of the arene ring. The synthesis and characterization of these complexes is detailed and the structure of bis(η^5-*exo*-6-phenyl-1,3,5-trimethylcyclohexadienyl)iron(II), **3***b*, has been determined by single crystal X-ray diffraction analysis. **3***b* crystallizes in the triclinic space group $P\bar{1}$, with a = 11.947(2), b = 12.784(1), c = 8.865(2), α = 108.59(1)°, β = 108.19(1)°, γ = 84.91(1)°, and D_{calcd} 1.227 g cm^{-3} for Z = 2. Least-squares refinement gave a conventional R value of 0.0452 for 2080 independent observed reflections. The structure reveals that the complex adopts a *gauche*-eclipsed conformation. The variable temperature (vt) ^{1}H NMR spectra of pseudoferrocenes are interpreted in terms of restricted ring rotation around the ligand—metal—ligand axis.

Key words: arene, cyclohexadienyl, pseudoferrocene, variable temperature NMR, X-ray diffraction.

MICHAEL D. CLERK, MICHAEL J. ZAWOROTKO, BOZENA BORECKA, T. STANLEY CAMERON, DONALD L. HOOPER et ANTHONY LINDEN. Can. J. Chem. **68**, 1923 (1990).

Les réactifs pouvant conduire à des carbanions (organolithiens et réactifs de Grignard) réagissent avec les cations $[(mésitylène)_2Fe]^{2+}$ et $[(mésitylène)(Ch)Fe]^{+}$ (dans lesquels Ch = cyclohexadiényl) pour fournir respectivement les complexes neutres ("pseudoferrocène") Ch_2Fe et ChCh'Fe. Les additions des radicaux R^- (R^- = méthyl, phényl, benzyl et *tert*-butyl) se produisent d'une façon stéréospécifique par le biais d'une addition exo sur un atome de carbone non-substitué du noyau arène. On décrit la synthèse et la caractérisation de ces complexes et on a déterminé la structure du bis(η^5-exo-6-phényl-1,3,5-triméthylcyclohexadiényl)fer(II), **3***b*, grâce à une analyse du spectre de diffraction des rayons-X réalisée sur un cristal unique. Les cristaux du produit **3***b* cont tricliniques et ils appartiennent au groupe d'espace $P\bar{1}$, avec a = 11,947(2), b = 12,784(1) et c = 8,865(2) Å, α = 108,59(1), β = 108,19(1) et γ = 84,91(1)°, D_{calcd} = 1.227 g cm^{-3} et Z = 2; on a affiné la structure par la méthode des moindres carrés jusqu'à une valeur de R de 0,0452 pour 2080 réflexions indépendantes observées. La structure révèle que le complexe adopte une conformation *gauche*-éclipsée. Les spectres rmn du ^{1}H à température variable des pseudoferrocènes ont été interprétés en fonction d'une restriction à la rotation du cycle autour de l'axe ligand—métal—ligand.

Mots clés : arène, cyclohexadiényl, pseudoferrocene, rmn à température variable, diffraction des rayons-X.

Introduction

Attention has recently concentrated upon cyclohexadienyl (Ch) ligands as possible reaction intermediates for bifunctionalized arenes (1–5), for synthetically applicable cyclohexadienes (6), or for highly substituted arenes (7). However, progress has been impeded by the lack of facile, high yield routes to cyclohexadienyl intermediates via inexpensive and readily available substrates. For example, traditional alkylating reagents such as organolithiums, Grignards, and organocuprates often react to yield undesirable products (5). However, recent work in our laboratory (8, 9) has shown that C—C bond formation in the series $[(arene)_2Fe]^{2+}$ (arene = benzene, *p*-xylene, mesitylene, pentamethylbenzene, and hexamethylbenzene) occurs readily when AlR_3 (R = Me, Et) is employed as the carbanion source. The possibility of synthesizing a wide range of Ch_2Fe and ChCh'Fe "pseudoferrocene" complexes therefore becomes apparent as Ch_2Fe complexes may be prepared from $[(mesitylene)_2Fe]^{2+}$ (10, 11).

There are several reasons for studying pseudoferrocene complexes: (*i*) They have attracted very little attention from organometallic chemists even though they are analogues of ferrocene and bispentadienyl (pd_2Fe), "open ferrocene" complexes, which have received considerable attention in recent years (12). (*ii*) They are potentially useful synthetically, particularly as precursors to substituted cyclohexadienes (6) or arenes (7). (*iii*) It has been shown (11) that Ch_2Fe complexes exhibit temperature dependent ^{1}H NMR spectra with the explanation of the occurrence of a "rocking" of the two rings with respect to the iron atom (Fig. 1). However, a crystallographic paper subsequently published by Palenik and Mathew (13) showed a solid state conformation different from that assumed for the lowest

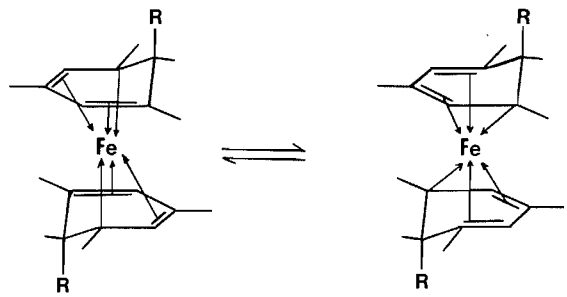

FIG. 1. Proposed "rocking" effect in pseudoferrocenes.

energy conformation in solution by Helling and Braitsch. Furthermore, temperature dependent spectra of pd_2Fe complexes were recently explained in terms of electronically controlled restricted rotation (12).

We have therefore undertaken synthesis of several new pseudoferrocene compounds and report an investigation of their dynamic behaviour in solution via variable temperature ^1H NMR studies.

Experimental

General

The following chemicals were purchased from Aldrich Chemical Company, Inc. and used as supplied: acetone-d_6, ammonium hexafluorophosphate, benzene-d_6, benzylmagnesium chloride, decahydronaphthalene, 1,2-dichloroethane, mesitylene, methyllithium, phenyllithium, *tert*-butyllithium, toluene-d_8. Acetone, hexanes, and tetrahydrofuran were purchased from BDH Chemicals, and were distilled over calcium hydride under a dinitrogen atmosphere prior to use. Anhydrous iron (III) chloride and anhydrous aluminum chloride were purchased from Johnson-Matthey Inc. and stored in desiccators prior to use. Calcium hydride, purchased from the Eastman Kodak Company, potassium iodide, purchased from Fisher Scientific Company, Ltd, and triethylaluminum, purchased from Texas Alkyls Inc., were used as supplied. All manipulations involving neat triethylaluminum were performed in a Vacuum Atmospheres' glove box equipped with a HE-493 dritrain under an argon atmosphere. Manipulations involving lithium reagents and the Grignard reagent were conducted using standard Schlenk and vacuum line techniques under a dinitrogen atmosphere.

Spectroscopy

^1H NMR spectra (60 MHz) were recorded on a Varian EM-360 spectrometer while 360 MHz ^1H NMR, variable temperature ^1H NMR, and 91 MHz ^{13}C NMR studies were conducted on a Nicolet 360NB spectrometer. Infrared spectra were obtained on a Perkin-Elmer 1600 Fourier Transform Infrared Spectrophotometer equipped with a diffuse reflectance accessory. Infrared samples were prepared as 5% mixtures of the compounds in KBr.

$[(\eta^6\text{-mesitylene})_2Fe]^{2+}$

(i) PF_6^- salt, **1***a* — 10.00 g (0.0616 mol) of anhydrous $FeCl_3$ and 24.64 g (0.1848 mol) of anhydrous $AlCl_3$ were stirred in 150 mL of dried, distilled mesitylene for 24 h under ambient conditions. The reaction flask was cooled at 0°C and the contents quenched with 200 mL of H_2O. After filtration the aqueous phase was separated from the organic phase and washed several times with hexanes, affording an orange aqueous solution. The dication was precipitated with saturated aqueous $NH_4^+PF_6^-$ and the resulting orange solid washed with hexanes and dried *in vacuo* yielding 19.16 g (32.69 mmol, 53%) of **1***a*. ^1H NMR ($(CD_3)_2CO$): δ 2.64(s, 9H), 6.50(s, 3H); ^{13}C NMR ($(CD_3)_2CO$): δ 19.7q, 92.0d, 113.3s. Infrared (cm^{-1}): 3117m, 3076m, 2930w, 1548m, 1459s, 1388m, 1036m, 1016m, 842s. In addition to NMR and IR data, **1***a* has been characterized via X-ray crystallography (14).

(ii) I^- salt, **1**b — Prepared as for **1***a* but the dication was precipitated with saturated aqueous K^+I^-. Yield: 16.96 g (30.83 mmol, 50%) of **1***b*. Nuclear magnetic resonance data could not be obtained on the solid due to its limited solubility, however, **1***b* has been characterized via X-ray crystallography (15). Infrared (cm^{-1}): 3078m, 2970s, 2894s, 2827s, 1535s, 1452s, 1429s, 1389s, 1034m, 1013m.

[(mesitylene)(Ch)Fe]$^+$

(i)(η^5-exo-6-Ethyl-1,3,5-trimethylcyclohexadienyl)(η^6-mexitylene)iron(II) hexafluorophosphate, **2**a — 7.00 g (0.0119 mol) of **1***b* was stirred in 150 mL of 1,2-dichloroethane in a 250 mL Erlenmeyer flask to which was added 6.53 mL (0.0476 mol) of neat $AlEt_3$. This resulted in the formation of a deep red reaction mixture within 30 s, which was then stirred at room temperature for 24 h. The mixture was cooled to 0°C and quenched with 50 mL of water. After filtration, the organic phase was separated and concentrated under reduced pressure. The red–orange solid was recrystallized from acetone/H_2O (4.41 g, 9.38 mmol, 77%). ^1H NMR spectroscopy (360 MHz) revealed the crude product to be a mixture of two compounds: **2***a* (80%) and [(η^5-*exo*-6-$CH_2CH_2ClC_6H_3Me_3$)(η^6-$C_6H_3Me_3$)Fe]PF_6 (20%). For **2***a*, ^1H NMR ($(CD_3)_2CO$): δ 5.86(s, 3H), 4.37(s, 2H), 2.76(s, 3H), 2.61(t, 1H), 2.47(s, 9H), 1.70(s, 6H), 0.56(q, 2H), 0.46(t, 3H); ^{13}C NMR ($(CD_3)_2CO$): δ 102.0s, 94.8s, 92.5d, 84.0d, 63.0s, 49.0d, 29.8t, 23.3q, 18.7q, 11.3q, 5.3q. Infrared (cm^{-1}): 3056w, 2975m, 2929m, 1540m, 1452m, 1383m, 1037m, 1012m, 875m, 840s. **2***a* has also been characterized via X-ray crystallography (8).

(ii) (η^5-exo-6-Ethyl-1,3,5-trimethylcyclohexadienyl)(η^6-mesitylene)iron(II) iodide, **2**b — A similar procedure was carried out for the idodide salt affording 2.20 g (4.87 mmol, 38%) of the pure product, **2***b*. ^1H NMR ($(CD_3)_2CO$): δ 5.74(s, 3H), 4.27(s, 2H), 2.74(s, 3H), 2.44(s, 9H), 1.67(s, 6H), 0.51(m, 5H). Infrared (cm^{-1}): 3056w, 3008s, 2954s, 1910s, 1540s, 1540s, 1458s, 1382s, 1169w, 1033s, 1011s.

Ch_2Fe complexes

These complexes were prepared in a manner similar to that described previously (11).

(i)Bis(η^5-1,3,5-exo-6-tetramethylcyclohexadienyl)iron(II), **3**a 1.00 g (1.71 mmol) of **1***b* was suspended in 50 mL of dried, distilled THF in a 150 mL Schlenk tube, and cooled to −95°C via an acetone slush bath. Under a stream of dinitrogen gas, 3.66 mL (5.12 mmol) of a 1.4 M solution of methyllithium in diethyl ether was added via syringe yielding a red–brown reaction mixture within seconds. After removing the acetone slush bath, the reaction mixture was stirred until it came to room temperature, at which point it was quenched with 10 mL of H_2O to remove excess MeLi. The mixture was subsequently filtered and concentrated under reduced pressure to give an orange aqueous suspension. Extraction with distilled hexanes afforded an orange solution which gave an orange oily solid following rotoevaporation. Recrystallization of the solid from hexanes at −20°C afforded 0.36 g (1.10 mmol, 61%) of red–orange crystals of **3***a*. Melting point 72–74°C. ^1H NMR (toluene-d_8, 30°C): δ 3.37(s, 4H), 2.33(q, 2H), 2.06(s, 6H), 1.61(br s, 12H), 0.43(d, 6H).

(ii) Bis(η^5-exo-6-phenyl-1,3,5-trimethylcyclohexadienyl)iron(II), **3**b — 1.00 g (1.82 mmol) of **1***b*, 3.64 mL (7.27 mmol) of a 2.0 M PhLi solution in cyclohexane/diethyl ether, 0.40 g (0.89 mmol, 49%) of orange crystals. Melting point 134–135°C. ^1H NMR (acetone-d_6, 30°C): δ 7.29(m, 10H), 3.71(s, 4H), 3.51(s, 2H), 2.16(s, 6H), 1.57(s, 12H).

(iii) Bis(η^5-exo-6-benzyl-1,3,5-trimethylcyclohexadienyl)iron(II), **3**c — 1.00 g (1.71 mmol) of **1***a*, 5.12 mL (5.12 mmol) of a 1.0 M solution of benzylmagnesium chloride in diethyl ether, 0.74 g (1.55 mmol, 91%) of orange solid. Melting point 82–84°C. ^1H NMR (toluene-d_8, 30°C): δ 6.89(m, 10H), 3.22(s, 4H), 2.52(t, 2H), 1.86(s, 6H), 1.76(d, 4H), 1.29(s, 12H).

(iv) Bis(η^5-exo-6-t-butyl-1,3,5-trimethylcyclohexadienyl)iron(II), **3**d — 1.00 g (1.82 mmol) of **1***b*, 4.28 mL (7.27 mmol) of a 1.7 M *t*-BuLi solution in pentane, 0.63 g (1.53 mmol, 84%) of orange crystals. Melting point 201–203°C. ^1H NMR (toluene-d_8, 70°C): δ 3.57(br s, 2H), 2.96(br s, 2H), 2.19(br s, 6H), 2.16(s, 2H), 1.83(s, 6H), 1.06(br s, 6H), 0.65(s, 18H).

ChCh'Fe complexes

(i) (η^5-exo-6-Ethyl-1,3,5-trimethylcyclohexadienyl)(η^5-1,3,5,exo-6-tetramethylcyclohexadienyl)iron(II), **4**a — 0.500 g (1.11 mmol) of **2***b* was dissolved in 50 mL of THF in a 150 mL Schlenk tube, and cooled to −95°C via an acetone slush bath. Under a stream of dry dinitrogen gas, 3.16 mL (4.42 mmol) of a 1.4 M MeLi solution in diethyl ether was added via syringe affording a red–brown reaction mixture within 1 min. After removing the acetone slush bath, the reaction mixture was stirred until it came to room temperature, at which point it was quenched with 10 mL of H_2O to eliminate excess MeLi. The mixture was filtered and concentrated under reduced pressure to an orange aqueous suspension. Extraction with hexanes afforded an orange solution which was concentrated under reduced pressure yielding 0.28 g (0.82 mmol, 74%) of an orange solid, **4***a*. Melting point 65–67°C. ^1H NMR (toluene-d_8, 20°C): δ 3.22(br s, 4H), 1.87(s, 3H), 1.83(s, 3H), 1.47(s, 6H), 1.42(s, 6H), 0.60(m, 5H), 0.20(d, 3H).

X-ray crystallography

The crystal used for X-ray diffraction studies was an orange cube obtained by cooling a concentrated hexanes solution of **3***b* to −20°C. The single crystal was sealed in a thin-walled capillary and placed on an Enraf-Nonius Cad-4 four circle diffractometer (graphite-monochromated Mo K_α radiation). Cell dimensions were calculated from 25 reflections with 2θ angles in the range 26–30° and are listed along with other pertinent crystallographic parameters in Table 1. The structure was solved by heavy-atom methods and refined using the SHELX Crystal Structure System (16). Refinement was based on $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = [\Sigma(w(F_o - F_c)^2)/\Sigma wF_o^2]^{1/2}$. It converged at $R = 0.0452$ and $R_w = 0.0429$ with all non-hydrogen atoms refined with anisotropic thermal parameters and hydrogen atoms placed geometrically and refined with individual isotropic thermal parameters. Weights were given by $w = 1.3994/[\sigma^2(F) + 0.000375F^2]$. No corrections were made for extinction but an absorption correction was applied (17). Atomic scattering factors and corrections for anomalous dispersion for Fe, C, and H were taken from International tables for X-ray crystallography, Vol. IV (18). Final fractional coordinates and interatomic distances and angles are presented in Tables 2 and 3, respectively.[3]

Since anisotropic vibrations of the atoms in the two organic portions of the molecule showed clear indications of concerted motion, the rigid body motion of the molecule (19) was analyzed with routine "tls" (20) calculations. The results of these calculations are seen in Fig. 2 and the salient details are given in Table 4.

The two organic portions of the molecule are both librating with independent motions and it is not clear from the calculations whether the motion of the two portions is linked or not (see below). In each of the two portions there is little or no concerted translation or screw motion, and the librations of both parts adopt a broadly similar motion which differs more in detail than type.

Both phenyl rings have a major libration about an axis which runs close to the axis of the ring from the *p* carbon through the C—C bond joining the ring to the pseudoferrocene moiety. This libration has an amplitude of 8.9° for ring 1 and of 10.2° for ring 2 (Fig. 2 *a* and *c*) and operates about a centre close to the carbon atoms, C(11) and C(31) respectively, which form the bond to the rest of the molecule. There are smaller, but significant librations which operate at right angles to this major motion and these two have centres close to C(11) or C(31).

There is a second libration of the pseudoferrocene rings and these

[3] Supplementary tables providing hydrogen atom positional parameters for bis(phenylmesitylene)iron, anisotropic temperature factors (Å^2) for bis(phenylmesitylene)iron, torsional angles (deg) for bis(phenylmesitylene)iron, and observed and calculated structure factors for bis(phenylmesitylene)iron may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K2A 0S2.

have a distinctive difference from one to the other. Both have the major libration about an axis running perpendicular to the general plane of the ring (4.7° for ring 3 and 6.0° for ring 4), but in one case (ring 3) the centre of libration is close to the centre of the ring (Fig. 2*e*) and in the other (ring 4) the centre of libration is close to the end of the ring where the phenyl group is bonded (Fig. 2*f*). Thus in one case (ring 1 + ring 3), the pseudoferrocene moiety is librating about an axis joining the iron atom with the centre of the ring and thus through the connection of C(1)—C(11) causing the phenyl group to librate from side to side about a centre somewhat "above" C(11) (Fig. 2*b*). While independently this phenyl group is librating approximately about the C(11)—C(14) axis. In the other case (ring 2 + ring 4) the pseudoferrocene portion is librating from "side to side" in the general plane of the ring, but about an axis close to the carbon atom bonded to the phenyl group (Fig. 2*f*). This reduces the consequent motion of the bonded phenyl group (ring 2) when it is compared with ring 1. Ring 2 has its own major libration approximately about the C(31)—C(34) axis.

The "tls" calculations for the rigid body motion of the phenyl groups show good correlation between the observed and calculated anisotropic thermal parameters, R = 4.4% and 4.9%, respectively, with rms deviations of the same order as the esd's calculated from the full X-ray structure refinement. The "tls" calculations for the pseudoferrocene fragments are not so good. The "tls" R is 7.5% and 7.7%, respectively and the rms deviations are at least 50% greater than the esd's

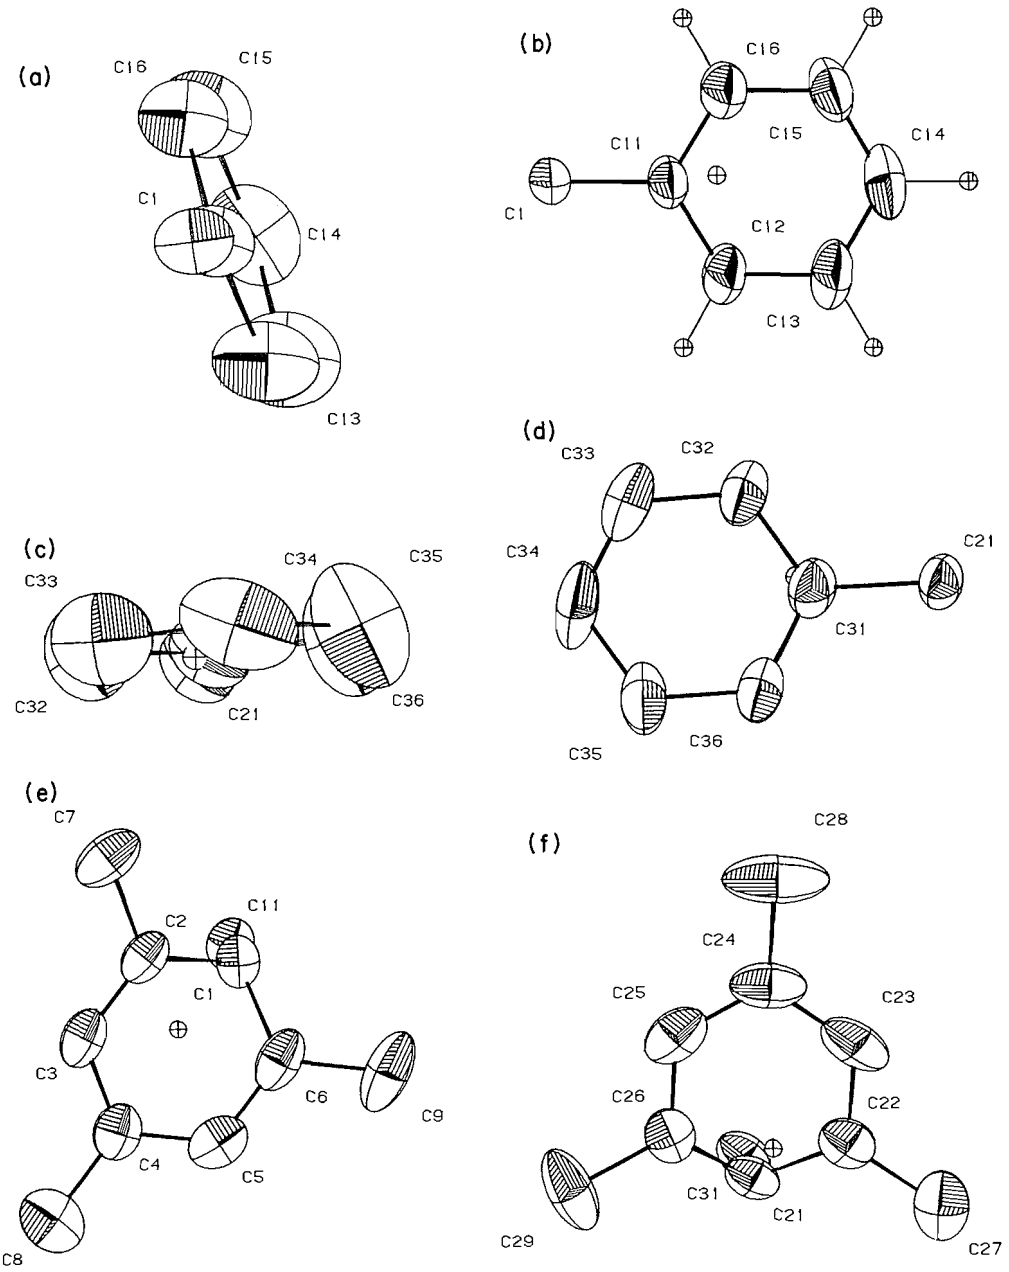

FIG. 2. Libration axes. ⊕ indicates the centre of librations. In (*a*), (*c*), (*e*), and (*f*) the principal libration axis (*Z*″) is perpendicular to the page and the third axis (*X*″) down the page. (*a*) Libration axes for ring 1 (note the centre of libration is hidden between C(11) and C(14) and cannot be seen from either end of the axis). (*b*) Location of the centre of libration for ring 1. (*c*) Libration axes for ring 2. (*d*) Location of the centre of libration for ring 2. (*e*) Libration axes for ring 3. (*f*) Libration axes for ring 4.

determined from the X-ray data refinement. It seems probable that these two groups are more flexible and are not the strictly rigid bodies that have been assumed in the calculation.

Thus the two organic portions of the molecule have broadly similar librations. From the perspective of conservation of angular momentum, it is tempting to suggest that the two systems are linked with one pseudoferrocene librating to the left while the opposite ring is rotating to the right. However, the demonstration of such a motion is beyond the limit of the current structure determination.

Results and discussion

The dications **1***a* and **1***b* and the monocations **2***a* and **2***b* react with excess R^- (R^- = methyl, phenyl, benzyl, *t*-butyl) to afford neutral Ch_2Fe (**3***a*–*d*) and ChCh′Fe (**4***a*–*d*) pseudoferrocene complexes, respectively.

Varible temperature (VT) ^1H NMR studies demonstrate that **3***a*–*d* and **4***a*–*d* are fluxional. Representative spectra for the ChCh′Fe complex, **4***d*, are presented in Fig. 3. The spectra are consistent with the proposed structure of the complex, and, as expected (11), only the peaks corresponding to the 1,5-methyl groups and the 2,4-protons are temperature dependent.

Coalescence temperatures (T_c) and the free energy of rotational barriers, $\Delta G^{\neq}$, were calculated for the 1,5-methyl groups and the 2,4-protons of all compounds and are tabulated in Table 5. An interesting trend evident in Table 5 is that as the R

*The centroid is given in crystal fraction units with respect to the real crystal axes. In the diagram (Fig. 2), the largest libration occurs around the Z'' axis which is perpendicular to the page and passes through the centroid. The X'' and Y'' axes, perpendicular to the Z'' axis, are down and across the page respectively, but do not necessarily intersect either with the Z'' axis or with themselves.

substituents increase in size, both T_c and $\Delta G^{\neq}$ increase. This observation indicates that the dynamic behaviour of pseudoferrocene complexes is not purely an electronic effect, as has been suggested for pd_2Fe complexes (12).

The earlier study of pseudoferrocenes conducted by Helling and Braitsch (11) attributed the temperature dependent spectra of Ch_2Fe complexes to a "rocking" effect of the two rings with respect to the iron atom (see Fig. 1). It was suggested that the NMR spectra could be explained by free rotation or lack of rotation but not by restricted rotation. This conclusion was reached assuming the preferred conformation of **3***b* and **3***d* at low temperature to be anti-eclipsed, **I**. However, the possibility of other low energy conformations taking precedence in solution at low temperature or in the solid state was not considered. Two other conformations are, of course, possible: *gauche* (either eclipsed or staggered), **II**, and *syn*-eclipsed, **III**. Subsequent X-ray crystallographic (Ch_2Fe (13), pd_2Fe (12)) and theoretical studies (pd_2Fe (21)) suggest that *gauche*-eclipsed conformations are favoured by $(dienyl)_2Fe$ complexes. This is very important, as a feature of conformation **II** is that a C_2-axis bisecting the angle between the two R groups is present as the Ch_2Fe complexes possess C_2 point-group symmetry, which is observed crystallographically in the case of **3***d*. Adoption of conformation **II** by Ch_2Fe complexes would therefore put the methyl group at position 3 on one ring in the same chemical environment as the symmetry related 3-methyl group on the other ring. One would therefore expect the two methyl groups to appear as a sharp singlet with a relative area of 6, independent of temperature. However, the 1,5-methyl substituents and the 2,4-protons should not be equivalent in conformation **II** and would be expected to split into two peaks each at the low temperature limit. In the case of the ChCh′Fe complexes the C_2 axis is no longer present so at both low and

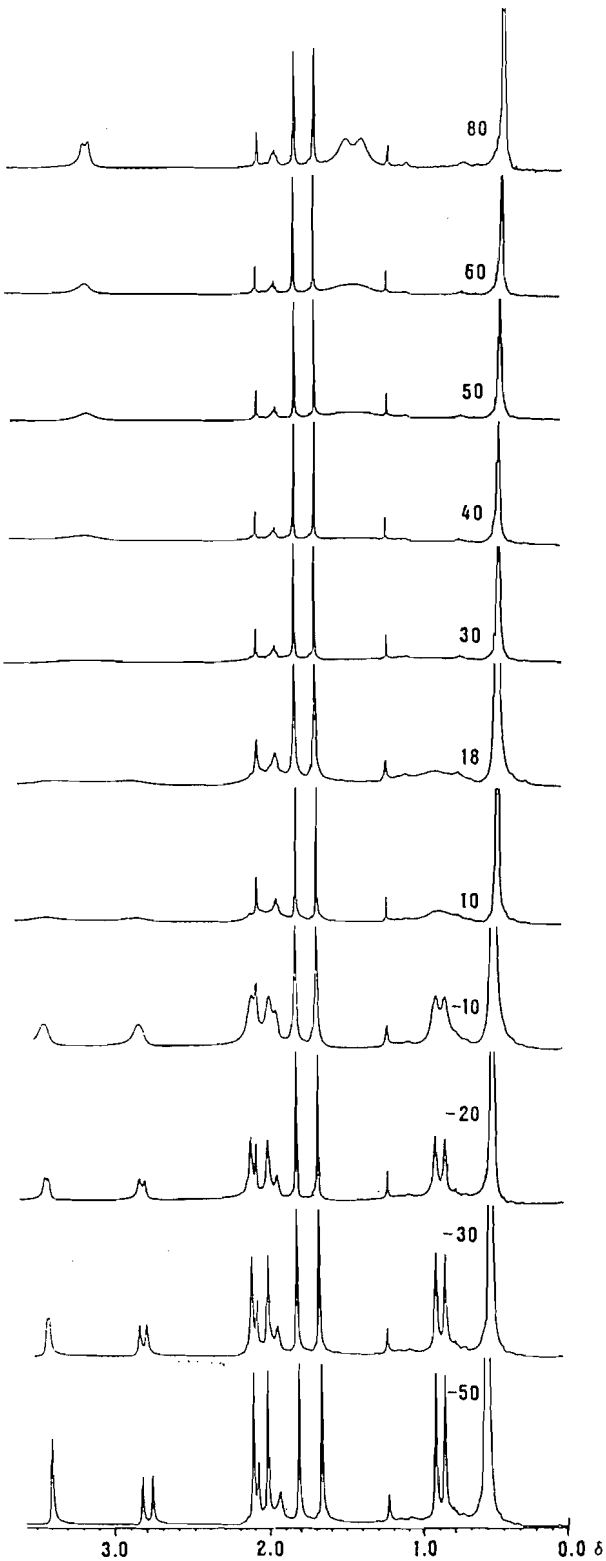

FIG. 3. Representative spectra of ChCh′Fe complex, **4***d*.

high temperature limits the spectra should be more complex. This, of course, corresponds to the observed spectra for both Ch_2Fe and ChCh′Fe complexes. Explanation of the spectra by assuming restricted rotation with adoption of conformation **II** at low temperature therefore appears a reasonable interpretation of our observations; however, they do not fully explain the effect.

TABLE 5. $\Delta G^{\neq a}$ values in kJ/mol, for complexes **3***a–d* and **4***a–d*

Complex	Protons	Coalescence temperature (°C)	$\Delta G^{\neq}$
3*a*	1,5-Me's	−25	46.3

Electronic and steric factors that favour conformation ***II***

Calculations of rotational barriers for pd_2Fe complexes by Ernst *et al.* (21) suggested two energy minima, one at $\alpha = 0$ (*anti*) and the other at $\alpha \approx 70°$ (*gauche*) ($\Delta G^{\neq}$ = 22 kJ/mol, 29 kJ/mol calculated by the EH and INDO methods, respectively). The X-ray structures of **3***b* and **3***d* reveal torsion angles of 63.0° and 63.2°, respectively, close to the electronic minimum calculated and indeed observed (12) in the solid state for pd_2Fe compounds. According to the calculations this particular minimum should be higher in energy than *anti*-eclipsed, **I**.

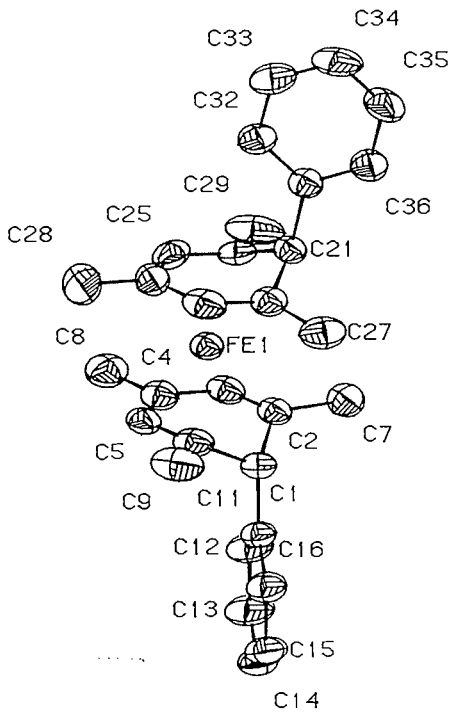

FIG. 4. Perspective view of bis(η^5-exo-6-phenyl-1,3,5-trimethylcyclohexadienyl)iron(II), **3***b*.

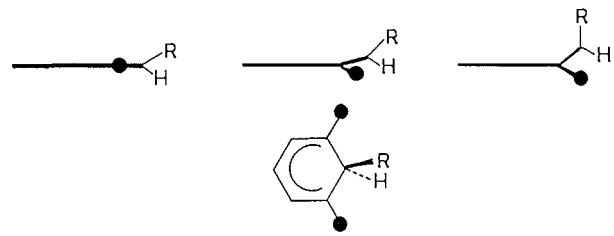

FIG. 5. Steric effect of R group on 1,5-methyl groups.

However, steric factors would be expected to favour the *gauche* conformation, particularly for the compounds described herein, which possess 1,5-methyl substituents that orient down towards the metal atom (see later).

That the size of the R group on carbon 6 of the Ch ring affects the values of $\Delta G^{\neq}$ and T_c suggests that a steric component to the rotational barrier exists. A possible rationalization is that the R group influences the two adjacent methyl groups at positions 1 and 5 by forcing them out of the plane of the ring towards the iron moiety. In order to test this hypothesis and check the apparent anomaly with the data in Table 5 (i.e. **3***b* having lower $\Delta G^{\neq}$ and T_c values than **3***a*) the crystal structure of complex **3***b* was determined.

A perspective view of **3***b* is given in Fig. 4. It reveals that the phenyl groups have added in the expected *exo* fashion and that the Ch rings adopt a *gauche* conformation. The two ligands are not identical in the solid state as the phenyl groups are oriented differently from each other. The deviation from planarity of the 1-methyl and 5-methyl groups averages 0.12 Å, which may be compared with the considerably larger 0.25 Å deviation observed for **3***d*. Indeed, the deviation in **3***b* is small even compared with a range of Ch complexes (Table 6).

The small deviation could be a simple manifestation of the fact that carbon 6 is sp^3 hybridized. Steric pressure from the iron atom forces C6 above the plane of the dienyl fragment of the Ch ring, a feature common to coordinated cyclohexadienyl moieties (8, 9, 13) but not to uncoordinated cyclohexadienylium cations (22–24). The other five carbons atoms in the ring maintain their sp^2 hybridization and planarity, hence the 1,5-methyls are forced below the plane of the ring. The size of R is expected to influence the magnitude of this effect as steric repulsions would increase with the size of R (see Fig. 5).

Summary

Synthesis and characterization of a series of pseudoferrocene complexes has been achieved. Temperature dependent ^{1}H NMR spectra were observed for all compounds studied, restricted rotation about the ring—Fe—ring axis instead of a "rocking" effect being the probable cause of the dynamic behaviour. Both

steric and electronic factors support this claim and a crystal structure of **3***b* has been presented in support.

A study of the Ca^{2+} – Arsenazo III system and its application to the spectrophotometric determination of free calcium in solution

BYRON KRATOCHVIL[1] AND XI-WEN HE[2]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received February 13, 1990

BYRON KRATOCHVIL and XI-WEN HE. Can. J. Chem. **68**, 1932 (1990).

A two-wavelength method was applied to the determination of free, ionic calcium with Arsenazo III in solutions containing calcium-binding ligands. By this procedure impurities in the indicator can be corrected for, thereby allowing the use of commercial indicator preparations with purities as low as 80%. Only a 1:1 complex with a conditional log stability constant of 4.28 ± 0.13 at pH 4.6 and ionic strength 0.1 was found under the conditions studied.

Key words: free metal ion determination, calcium ion speciation, spectrophotometry, arsenazo III, ion increment method for speciation.

BYRON KRATOCHVIL et XI-WEN HE. Can. J. Chem. **68**, 1932 (1990).

On a utilisé une méthode faisant appel a deux longueurs d'onde pour déterminer le calcium ionique libre dont Arsenazo III dans des solutions contenent des ligands pouvant lier le calcium. Cette procédure permet de corriger la présence d'impuretés dans l'indicateur; on peut ainsi utiliser des préparations d'indicateurs commerciaux dont la pureté ne dépasse pas 80%. Dans les conditions utilisées, on n'a observé que la formation d'un complexe 1:1 dont le log (conditionnel) de la constante de stabilité est égal à 4,28 ± 0,13 à un pH de 4,6 et à une force ionique de 0,1.

Mots clés : détermination d'ions métalliqueslibres, spéciation de l'ion calcium, spectrophotométrie, Arsénazo III, méthode d'augmentation d'ionique pour la spéciation.

The determination of free calcium in solution is important in many biological, clinical, environmental, and agricultural systems. Methods that have been studied include ion selective electrode potentiometry (1), spectrophotometry with indicator dyes (2, 3), and equilibrium calculations (4, 5). When the bound species is chemically inert the free calcium can be separated for measurement by techniques such as filtration (6), solvent extraction (7), chromotography (8), or ion exchange (9). A related specialized problem, the measurement of free calcium in biological cells and tissues, has also received intensive study (10). All these methods suffer interferences from other species or from limited applicability in terms of pH or calcium concentration range.

One of the more widely used techniques is that employing the chelating indicator dye Arsenazo III. This dye is a sensitive and selective reagent for calcium, and has been studied for the determination of calcium both in solution (10*a*, 11–21) and in cells and tissue (10*a*,*b*,*c*, 11). A problem with the system has been uncertainties in combining ratios of calcium with Arsenazo III, which have been measured variously as 1:1 (12, 14); 2:1 (10*d*, 13); 2:2 and 1:1, 1:2, or 2:1 (17). Also, the purified, low-calcium reagent is costly, and interferences from sodium and potassium have been reported (14, 18). Accordingly, we have investigated the effects of pH, ionic strength, and sodium and potassium ion concentrations on the calcium – Arsenazo III system. We have also measured the protonation constants for the dye in water, and the conditional stability constant of the calcium-dye complex at pH 7.25 and 4.60. Finally, we have applied the sample ion increment method to the measurement of free calcium with Arsenazo III in the presence of citrate, and in several urine samples.

Sample ion increment method

Direct spectrophotometric measurements of free calcium ion concentrations have several limitations. The most severe restriction is that only a small fraction of the ionic calcium, usually less than 1%, may be allowed to complex with the indicator if the equilibria existing in the original sample solution are not to be significantly perturbed. This requires a relatively small value for the conditional formation constant(s) of the calcium–indicator complex(es), which limits sensitivity.

These limitations can be overcome by the approach described by Fulton and Kratochvil (21), the Sample Ion Increment Method (SIIM). In this method, a known amount of indicator is added to the sample and the absorbance is measured. Then an accurately known amount of the sample ion to be determined is added and the absorbance is remeasured. The second measurement determines the sample ion buffering capacity of the original solution and permits a correction for the amount of sample ion complexed by the indicator. With this approach close to 100% of the sample ion can be complexed by the indicator before adding the sample ion increment without introducing appreciable determinate error, thereby reducing previous stringent requirements on the magnitude of the conditional formation constant and of the molar absorptivity of the sample ion – indicator complex. It is still necessary that the indicator be of either high or accurately known purity; this requirement may be overcome by measuring the difference between absorbance values of a solution at two wavelengths (22, 23).

Experimental

Reagents and solutions

Stock 1×10^{-3} M solutions of Arsenazo III, either free acid (Aldrich) or the sodium salt (Fluka), were prepared in water. For the free acid three different levels of purity were purchased and assessed. The first was labelled as containing 1 to 5% calcium, the second less than 0.1% calcium, and the third as 98% pure. The degree of purity was screened by measuring the ratio of absorbance at the wavelength of maximum absorbance for the uncomplexed dye, 646 nm, to that for the calcium complex, 548 nm. The first material gave a ratio of 3.0, the second 5.0, and the third 15. For the disodium salt the ratio was 21. Photometric titrations of the first and third free acid material with standard calcium solution at pH 4.6 gave purities of 80% and 98%; the

[1]Author to whom correspondence may be addressed.

[2]On leave from Department of Chemistry, Nankai University, Tianjin, People's Republic of China.

disodium salt also gave a purity of 98%. Stock 5×10^{-3} M solutions of calcium nitrate ($Ca(NO_3)_2 \cdot 4H_2O$) (Baker Analyzed Reagent) were prepared by weight. The purity of the calcium nitrate was determined by titration with EDTA standardized against pure calcium carbonate. A purity of 100.8% was found; this value was used to calculate the concentrations of all calcium solutions. All solutions were prepared with distilled, demineralized water. Other chemicals were analytical or reagent grade.

Instrumentation

All pH measurements were made with a Fisher Accumet Model 525 pH meter and a glass–SCE pair that was calibrated with commercial buffers (Fisher). Spectrophotometric measurements were made on a Hewlett-Packard Model 8451A diode array spectrophotometer in 1-cm silica cells in a constant temperature room held at 25 ± 1°C.

Procedure for calibration plots and spectrophotometric measurements

A series of solutions were prepared in 25-mL volumetric flasks. Varying amounts of calcium and/or Arsenazo III stock solution were added to each flask by Mohr pipet. The ionic strength was adjusted, usually with NaCl but in a few cases with KNO_3, as required, then the solution diluted to near volume and the pH adjusted to the desired value by addition of concentrated HCl. Dilution to volume was then completed. All solutions were measured spectrophotometrically the same day they were prepared.

Results and discussion

Purity of commercial arsenazo III

Spectrophotometric titrations of commercial Arsenazo III as free acid and as the sodium salt with standard calcium solution gave purities ranging from 81% for the lowest grade of free acid to 98% for both the highest grade of free acid and the sodium salt. All subsequent work was done using the less expensive sodium salt.

Dual wavelength method

The difficulty in obtaining Arsenazo III and reagents such as NaOH, NaCl, and KNO_3 with sufficiently low levels of calcium led us to use a dual wavelength procedure (22, 23) to compensate for this contamination. In this method absorbance readings are taken at two wavelengths, chosen so that the absorbance difference changes in a major way with concentration. The advantage of this procedure is that the precise calcium contamination of the dye and reagents need not be known. Wavelengths selected for this work were 458 and 598 nm in water, 458 and 600 nm in NaCl solutions, and 458 and 602 nm in KNO_3 solutions; 458 nm is an isosbestic point.

Effect of pH and ionic strength on absorbance of Arsenazo III (ArIII) and Ca^{2+}–ArIII complex

Plots of absorbance difference as a function of pH for 1×10^{-4} M ArIII (Fluka, sodium salt) with and without 5×10^{-5} M Ca^{2+} present are shown in Fig. 1. The ΔA value ($A_{598} - A_{458}$) for free ArIII is 0 in water and in 0.1 M NaCl over the pH range 4 to 6. THe ΔA value for the Ca^{2+}–ArIII complex is higher in pure water than in 0.1 M sodium chloride because of the effect of ionic strength on the conditional stability constant, K_{cond}, of the Ca^{2+}–ArIII complex over the pH range studied:

$$K_{cond} = \frac{[CaArIII^{2-x}]}{[Ca^{2+}][ArIII^{x-}]}$$

$$K_{th} = \frac{a_{CaArIII}{}^{2-x}}{a_{Ca^{2+}} a_{ArIII}{}^{x-}} = K_{cond} \frac{\gamma_{CaAr}{}^{2-x}}{\gamma_{Ca^{2+}} \gamma_{Ar}{}^{x-}}$$

where x is predominately 3 to 4 over the pH range of 4 to 6 (24). The increase in ΔA with pH is expected if calcium is competing with hydrogen ion for sites on the indicator. Since absorbance changes appeared smallest in the pH range 4.6 to 4.8 in both water and 0.1 M NaCl, a value of 4.6 was arbitrarily chosen for subsequent work. Figure 2 shows spectra of ArIII and the Ca^{2+}–ArIII complex at pH 4.6 for varying concentrations of NaCl. The effect of increasing ionic strength on complex formation is clearly evident.

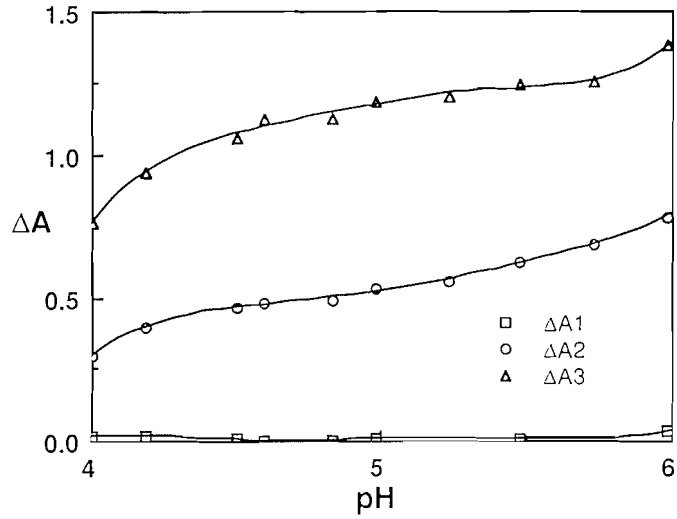

FIG. 1. Plot of ΔA against pH for (*1*) 1×10^{-4} M Arsenazo III in H_2O ($\Delta A = A_{598} - A_{458}$) and in 0.1 M NaCl ($\Delta A = A_{600} - A_{458}$), (*2*) 1×10^{-4} M Arsenazo III + 5×10^{-5} M Ca^{2+} in 0.1 M NaCl ($\Delta A = A_{600} - A_{458}$), and (*3*) same as *2*, but in H_2O ($\Delta A = A_{598} - A_{458}$). H_2O used as reference.

Effect of Na^+ and K^+ on Ca^{2+}–ArIII complex formation

It has been reported that both Na^+ and K^+ interfere with the Ca^{2+}–ArIII reaction (14, 18). This was checked by recording spectra for free ArIII and the Ca^{2+}–ArIII complex as a function of cation at constant ionic strength. Spectra in the presence of Na^+, K^+, and NH_4^+ are shown in Fig. 3. The spectra in NH_4Cl and KNO_3 are superimposable, thereby showing that none of the ions in these salts have a discernible effect upon the absorbance spectrum of the Ca^{2+}–ArIII system. The spectrum in NaCl indicates slightly more Ca^{2+}–ArIII complex formation than in KNO_3 or NH_4Cl; this may be the result of small differences between activity coefficients for Na^+ and K^+ or NH_4^+. We conclude that the effect of Na^+ or K^+ upon Ca^{2+}–ArIII complex formation is not species specific for these ions, but is a function of ionic strength. We also find no specific interaction with chloride, in contrast to the report of Minganti *et al.* (25). Their results also appear to be due to ionic strength changes. The effect of ionic strength is significant, as can be seen from the calibration curves in Fig. 4. Our results confirm the findings of Brown and Rydquist (19).

Determination of combining ratio for Ca^{2+}–ArIII system at pH 4.6

As mentioned in the Introduction, several combining ratios have been reported for the Ca^{2+}–ArIII system. Therefore we remeasured this ratio at pH 4.6 by both the molar ratio and Job methods. A molar ratio plot at 648 nm showed only a break at a 1:1 ratio, and Job's plots of ΔA ($A_{600} - A_{458}$) and of A at 648 nm directly also both showed a maximum at a 1:1 ratio only. Thus at pH 4.6, under the conditions used we observe only a 1:1 combining ratio for Ca^{2+} with ArIII.

A 1:1 ratio does not differentiate between 1:1 and 2:2 species. To determine which was present the method of He and Poe (26)

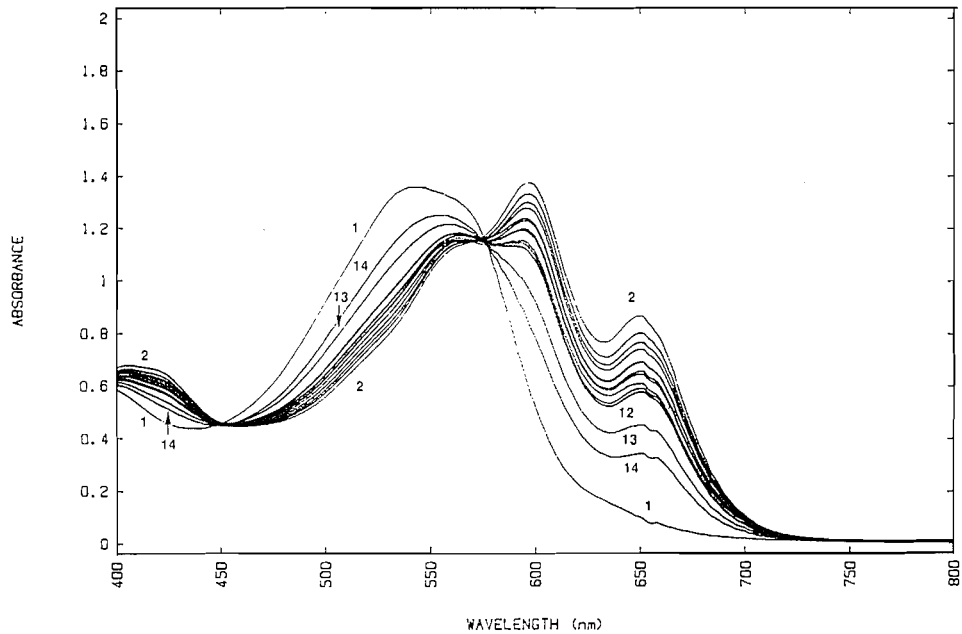

FIG. 2. Effect of ionic strength on spectrum of mixture of Ca^{2+} and ArIII: (*1*) Spectrum of 5×10^{-5} M ArIII in 0.5 M NaCl. Remaining spectra are of 5×10^{-5} M ArIII + 2.5×10^{-5} M Ca^{2+} in (*2*) H_2O, and in NaCl at (*3*) 0.01, (*4*) 0.02, (*5*) 0.03, (*6*) 0.04, (*7*) 0.05, (*8*) 0.06, (*9*) 0.07, (*10*) 0.08, (*11*) 0.09, (*12*) 0.10, (*13*) 0.2, and (*14*) 0.5 M. pH = 4.6 throughout; H_2O used as reference.

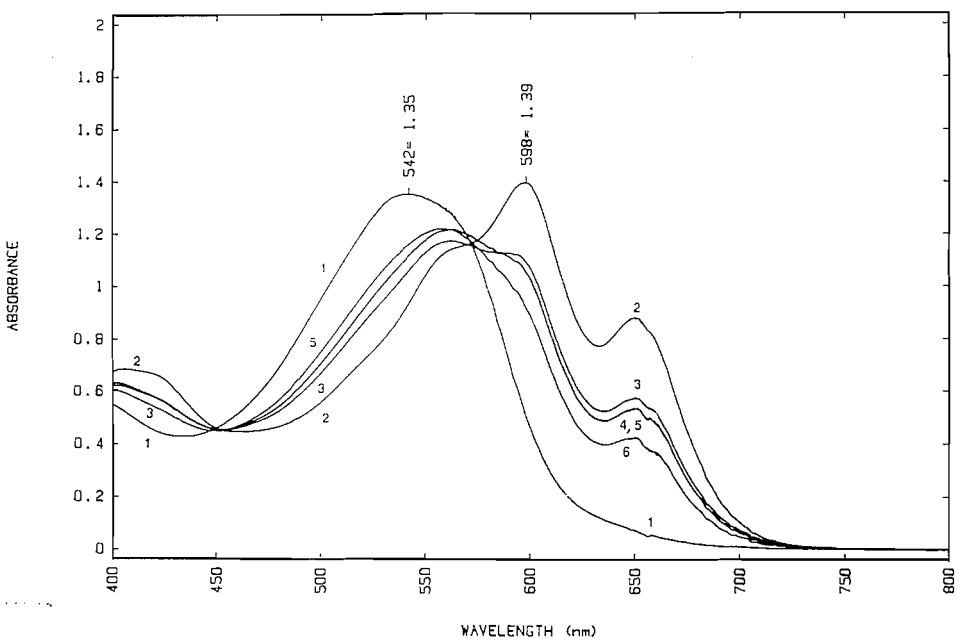

FIG. 3. Spectra of (*1*) 5×10^{-5} M ArIII in H_2O, (*2*) same as (*1*) but 2.5×10^{-4} M Ca^{2+} present, (*3*) same as (*2*) but in 0.1 M NaCl, (*4*) same as (*2*) but in 0.1 M NH_4Cl, (*5*) same as (*2*) but in 0.1 M KNO_3, and (*6*) same as (*2*) but in 0.05 M Na_2SO_4. pH = 4.6 throughout; H_2O used as reference.

was used, with slight changes. Following their procedure, for

$$m\mathrm{Ca}^{2+} + m\mathrm{ArIII} \rightleftharpoons \mathrm{Ca}_m\mathrm{ArIII}_m$$

if $C_{Ca^{2+}} = C_{ArIII}$ initially, then the stability constant expression can be written as

$$[1] \quad K_{cond} = \frac{C_{Ca^{2+}}\alpha_C}{m[C_{Ca^{2+}}]^{2m}(1-\alpha_C)^{2m}}$$

where

$$\alpha_C = \frac{m[Ca_m^{2+}\,ArIII_m]}{C_{Ca^{2+}}} = \frac{\Delta A}{\Delta A_{max}}$$

In this work $\Delta A = A_{598} - A_{458}$.

Taking the logarithm of eq. [1] gives

$$[2] \quad \log \frac{\alpha_C}{(1-\alpha_C)^{2m}} = (2m-1)\log C_{Ca^{2+}} + \log mK_{cond}$$

By plotting $\log (\alpha_C/(1-\alpha_c)^{2m})$ against $\log C_{Ca^{2+}}$, a slope of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

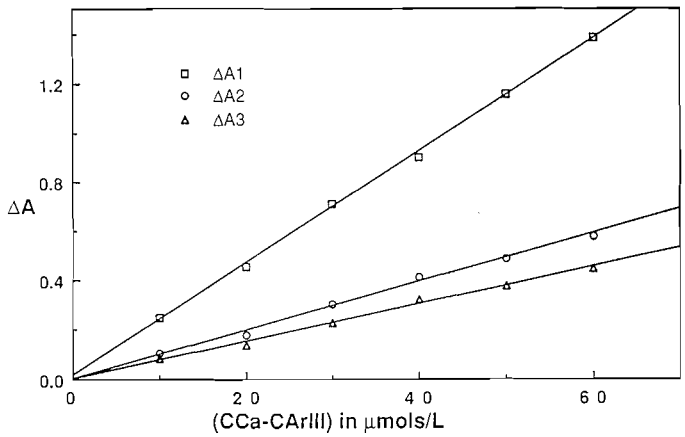

FIG. 4. Calibration plots for Ca^{2+}–ArIII in water and in 0.1 M NaCl and 0.1 M KNO_3 at pH 4.6. Concentration of ArIII = 1×10^{-4} M, H_2O used as reference. Absorbances are ΔA values: (*1*) $\Delta A = A_{598} - A_{458}$ in H_2O; (*2*) $\Delta A = A_{600} - A_{458}$ in 0.1 M NaCl; (*3*) $\Delta A = A_{602} - A_{458}$ in 0.1 M KNO_3.

$(2m - 1)$ and an intercept of log mK_{cond} is obtained. Selection of different integer values of m will yield straight lines with different slopes, but only the true value of m will yield a slope equal to the value predicted by the equation.

For this system, insertion of 1, 2, and 3 for m into eq. [2] gave predicted slope values of 1, 3, and 5, respectively, and experimental slopes from the plots of 1.4, 2.1, and 3.1. Since the experimental value of 1.4 for m is the closest to the corresponding predicted value, we conclude that only a 1:1 complex is present under the conditions studied.

Determination of K_{cond} for the Ca^{2+}–ArIII complex at pH 4.6

The intercept of eq. [2] gives the value of log mK_{cond}. Using $m = 1$, a value for log K_{cond} in water of 6.43 ± 0.08 is obtained by a least-squares fit. This value was measured at a low but variable ionic strength.

A second estimation of K_{cond} at $\mu = 0.1$ (adjusted with NaCl) was made using absorbance data from a series of solutions for which $C_{ArIII} = C_{Ca^{2+}}$ in the range of 3 to 6 × 10^{-5} M. A log K_{cond} value of 4.28 ± 0.13 was obtained for four measurements (Table 1). This value compares reasonably well with literature values, which range for 1:1 complex formation from 3.5 by Thomas (15) to 4.77 by Onishi (14). The sensitivity of the conditional constant to pH and ionic strength is great because of the large number of weak protons on Arsenazo III and the high charge on the ligand anion. This sensitivity may account in part for the range of stability constant values reported in the literature (14–19).

Test of the SIIM method for measurement of free Ca^{2+} in the presence of citrate

To evaluate the applicability of ArIII to the determination of free Ca^{2+} by the SIIM method (21), a series of solutions containing varying amounts of Ca^{2+} and citrate were prepared and the free Ca^{2+} calculated using literature values for the Ca–citrate complex. The experimental conditions and results are given in Table 2. The conventional spectrophotometric indicator method gives good agreement with calculated values of pCa at lower citrate concentrations, but begins to deviate at higher levels. Under these conditions the SIIM may be used to advantage, as can be seen from Table 2.

TABLE 1. Conditional stability constants of the 1:1 calcium-arsenazo III complex at ionic strength 0.1 in NaCl and pH 4.6

$C_{Ca^{2+}} = C_{ArIII}$, M	ΔA $(A_{600} - A_{458})$	ΔA_{max}	α_C	log K_{cond}[a]

Determination of free Ca^{2+} in urine with ArIII and the SIIM

Several urine samples were analyzed for free Ca^{2+} by the SIIM. The original pH of the urine, about 5.8, was adjusted to 4.6 before measurement. This shift could change the free Ca^{2+} in solution by shifting the equilibria; to avoid this would require K_{cond} to be known at each sample pH. Table 3 gives results along with total calcium values as measured by atomic absorption spectroscopy and some preliminary values obtained on two samples by an ion exchange method under development in this laboratory. It can be seen that the values fall within a reasonable range. We were not able to obtain stable readings on these samples with a calcium ion selective electrode.

In summary, we have found the SIIM method with ArIII as indicator to be useful for the determination of free calcium in solutions containing calcium bound as metal–ligand complexes. The major disadvantage of the method is that the metal-indicator conditional stability constant must be known precisely, otherwise significant error is introduced into the value obtained for the free metal. Also, since K_{cond} varies with ionic strength in all systems, and with pH in most, the scope of applicability is limited to cases where the pH and ionic strength can be adjusted to specified values without shifting the original equilibria to an unacceptable extent. If necessary the pH and ionic strength of the samples under study could be matched, but this would involve additional time and work.

The dual wavelength method was found to be satisfactory over the range of calcium concentrations investigated here. The importance to medicine of knowing free as compared to

MADALENA S. DIONÍSIO, JOAQUIM J. MOURA RAMOS, and RAQUEL M. GONÇALVES. Can. J. Chem. **68**, 1937 (1990).

A new method to calculate the enthalpy and entropy of cavity formation in liquids is proposed. The reference cavity formation process is identified with the vaporization of liquid in the absence of order and Corresponding States Principle is used to eliminate the order contribution to vaporization enthalpy. The proposed method agrees very well with Claverie's modification of the Pierotti's method but strongly disagrees with the Sinanoglu's method, particularly in the context of entropy of cavity formation.

The new method is checked by applying it to the description of solution process in alkane binary mixtures at infinite dilution and is used to study the solvent effect on the solvolysis of *t*-butyl chloride and bromide.

Key words: cavity formation, enthalpy and entropy of cavity formation, Corresponding States Principle, alkanes, intermolecular interactions, acentric factor, solvent effect.

MADALENA S. DIONÍSIO, JOAQUIM J. MOURA RAMOS et RAQUEL M. GONÇALVES. Can. J. Chem. **68**, 1937 (1990).

Dans ce travail nous proposons une rouvelle méthode pour calculer l'enthalpie et l'entropie de formation de cavités microscopiques dans les liquides. Le processus de formation de la cavité de référence est identifié au processus de vaporisation du liquide en absence d'ordre; le Principle des États Correspondants est utilisé pour éliminer de l'enthalpie de vaporisation cette contribution due à l'ordre. La méthode proposée conduit à des résultats qui sont en bon accord avec ceux obtenues par la méthode de Pierotti modifiée par Claverie mais sont en désaccord avec la méthode de Sinanoglu particulièrement en ce qui concerne l'entropie de formation de la cavité.

La nouvelle méthode est testée en l'utilisant pour décrire le processus de dissolution à dilution infinie en mélanges binaires d'alcanes et utilisée pour étudier l'effect de solvent sur la solvolyse d'halogénures de tertio-butyle.

Mots clés : formation de cavité, enthalpie et entropie de formation de cavité, Principle des États Correspondants, alcanes, interactions intermoleculaires, facteur acentrique, effect de solvent.

Introduction

During the past years considerable progress has been made in the theory of liquid mixtures of non-electrolytes. If molecular properties of component molecules are known it is possible to predict the thermodynamic equilibrium properties of mixtures by using appropriate statistical mechanical theories. This is certainly an interesting scientific subject with several important practical applications (1). Nevertheless, the case is less straightforward for mixtures whose components are polyatomic molecules interacting through non-spherically symmetric potentials and several molecular conformations are possible. The latter is usually the case for mixtures of practical importance in chemical engineering or in biochemistry. The major difficulties are associated with insufficient knowledge of many-body effects including short-range molecular order and medium effects on conformational equilibria, and also with the uncertainty of intermolecular potential between unlike molecules. Moreover, these theoretical treatments are very time-consuming, even in the era of supercomputers, so that there is still a need for simple models which, in some cases, can overcome the difficulties of rigorous treatment. The cavity model which has been extensively used to interpret solvent effects on chemical processes (2–6) is an example. In this model it is possible to calcualte the enthalpy, H_c the entropy, S_c, and the Gibbs energy, G_c, needed to create a microscopic (molecular sized) cavity in a pure liquid. The calculated quantities, together with the experimental dissolution thermodynamic quantities, enable us to obtain (without calculation) the solute–solvent interaction energy.

One of the main problems associated with the calculation of the energetics of cavity formation in liquids is a thermodynamic description of the *reference* cavity formation process. A reference cavity is one that has same size and shape as the space occupied by a single molecule in a pure liquid. This reference cavity corresponds to the absence of a molecule in the bulk of the liquid and it is thus characterised by the same correlations with its neighbouring molecules as the "absent" molecule. The calculation of the energetics of formation of a reference cavity was based on the identification of its formation process with that of vaporization of the liquid (3, 5). In recent works (7, 8) we pointed out that these two processes cannot be identified with each other because we have emphasized on their differences. In fact, the formation of a reference cavity is not associated with the changes in molecular order of the liquid, as is the case for vaporization. An alternative method was thus proposed to calculate the enthalpy of formation of a reference cavity and this method was tested using solution enthalpy data at infinite dilution for *n*-alkane binary mixtures. It has also been shown that this method is potentially better than other methods proposed in the literature, namely that based on the Scaled Particle Theory.

In the present work we wish to present a new formulation of this problem. In this new formulation the reference cavity formation process is viewed again as physically different from a vaporization process (it does not imply the destruction of the molecular order of a liquid) and now we will be able to calculate

its energetics from different physical properties of the liquid. We will propose a set of equations to calculate the enthalpy, the entropy, and the Gibbs energy of cavity formation and show that these equations are thermodynamically consistent in that they are related to each other by the Gibbs-Helmholtz relationship. This new semi-empirical method will be used to describe the dissolution of alkane solutes at infinite dilution in alkane solvents and to study the solvent effect on the solvolysis of *t*-butyl halides.

The vaporization of a liquid in the absence of order

Let us first consider simple liquids (monoatomic or apolar and spherical molecular liquids) that comply with the two-parameter Corresponding States Principle (CSP) (9). For these liquids the reduced saturated pressure varies with the reduced temperature in a way that is approximately described by Rowlinson equation:

$$[1] \qquad \ln p_r = 5.365\left(1 - \frac{1}{T_r}\right)$$

If eq. [1] holds in low saturated pressure region, by applying the Clapeyron–Clausius equation,[2] it can be shown that the vaporization enthalpy, H^0_{vs}, is independent of temperature:

$$[2] \qquad H^0_{vs} = 5.365RT_c$$

where T_c is the critical temperature.

For liquids complying with the three-parameter CSP, so-called normal liquids (9, 11), the following equation applies:

$$[3] \qquad \ln p_r = 5.365(1 + \omega)\left(1 - \frac{1}{T_r}\right)$$

where ω is the Pitzer acentric factor. For normal liquids of weak polarity and/or small shape anisotropy, the vaporization enthalpy is also independent of temperature in the low pressure region and is represented by

$$[4] \qquad H^0_{vn} = 5.365(1 + \omega)RT_c$$

Complex liquids composed of polar, associated, and/or anisotropic and flexible molecules deviate from the three-parameter CSP and have temperature-dependent vaporization enthalpies. These liquids show a temperature-dependent molecular order and temperature-dependent molecular degrees of freedom which are changed in the vaporization process and are at the origin of the temperature dependence of vaporization enthalpy. There are different qualitative explanation on their deviations from CPS (12): (*1*) interactions between molecular peripheries; (*2*) non-central forces arising from electric moments (long-range forces) and/or anisotropic shape (short-range forces), leading to ordered local structures at low temperatures; and (*3*) density-dependent rotational and librational degrees of freedom (internal rotation in flexible molecules, hindered overall rotation in anisotropic molecules).

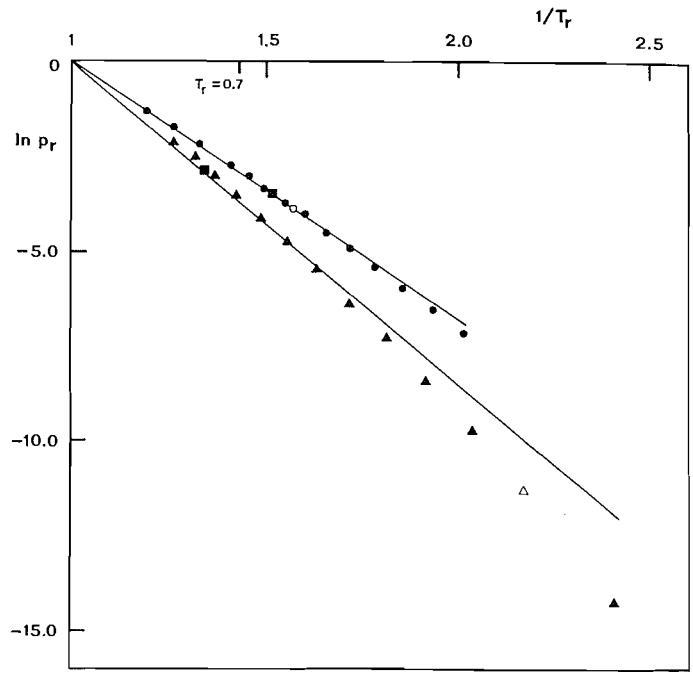

FIG. 1. Reduced saturated vapor pressure as a function of the inverse of reduced temperature for *n*-pentane (circles) and *n*-dodecane (triangles). Empty symbols indicate values at room temperature (25°C). Squares are values at normal boiling point. These data are taken from ref. 24.

For complex liquids we have a bending in the $\ln p_r$ *vs.* $1/T_r$ curve in the low pressure region as shown in Fig. 1 (for pentane and dodecane), 2 (for acetone and methanol), and 3 (for water). Between the critical point and normal boiling point (shown as squares) these curves are nearly linear or have a very elongated S-shape (13). With decreasing temperature the reduced saturated vapor pressure curve shows an increased curvature for ordered liquids. For *n*-pentane the curve is almost linear even at temperatures far below room temperature (empty circle), the deviation from the linearity being apparent only for temperatures lower than -10°C ($1/T_r > 1.78$). On the other hand, the curve for *n*-dodecane, as well as curves for methanol and water, show that deviation from linearity starts near T_b and is quite strong at room temperature. Since the deviation from linearity of the reduced vapor pressure curve is a consequence of the liquid order which decreases rapidly with increasing temperature (14, 15), at normal boiling point liquid order is destroyed and the liquid is expected to obey the three-parameter CSP (in fact, one can eliminate the contribution of order using behaviour at high temperatures). If so, the same must be true for temperature $T_r = 0.7$ at which the acentric factor is measured. In fact, as shown in Table 1, this temperature is generally higher than the normal boiling temperature except for long *n*-alkanes. Even in this case, the temperature $T_r = 0.7$ is not very different from normal boiling temperature and is higher than room temperature. Moreover, we can see from Figs. 1–3 that the points at $T_r = 0.7$ and at normal boiling point are inside the linear region of the curves. This is true for alkanes, acetone, methanol, and even for water. We can thus assume that the straight line defined by the

[2]The fact that the $\ln p_r$ *vs.* $1/T_r$ curve is linear between the critical point and the normal boiling point (high pressure region) does not mean that the vaporization enthalpy is constant and independent of temperature in this region. The Clapeyron–Clausius equation in reduced variables can be written as

$$\frac{d \ln p_r}{d\, 1/T_r} = -\frac{H^0_v}{RT_c}$$

if we assume an ideal gas behaviour. The linearity in the high pressure region is then the result of compensation of errors from assuming a constant vaporization enthalpy and an ideal gas behaviour. Below the normal boiling point, on the other hand, the saturated vapor pressures are small and so are the deviations from the ideal gas behaviour. Thus the linearity of the $\ln p_r$ *vs.* $1/T_r$ curve in this low pressure region indicates that the vaporization enthalpy is independent of the temperature.

TABLE 1. A comparison between normal boiling temperature (T_b) and the temperature at which acentric factor is measured ($0.7T_c$)

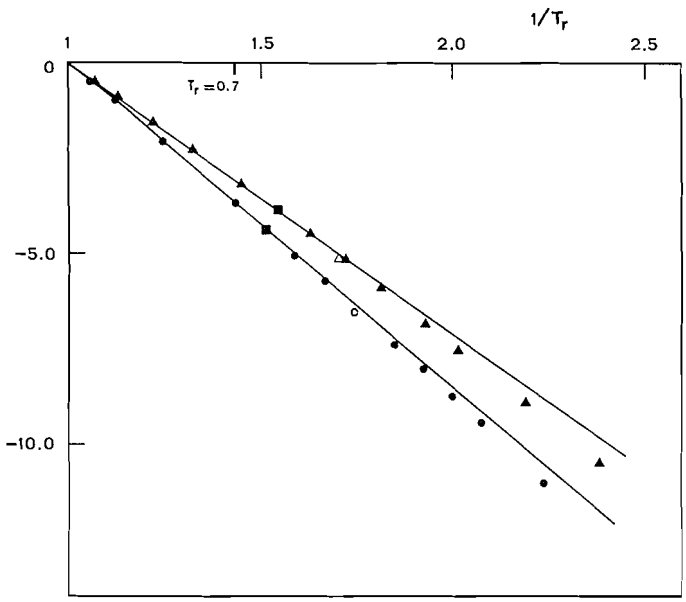

FIG. 2. Reduced saturated vapor pressure as a function of the inverse of reduced temperature for acetone (triangles) and methanol (circles). Empty symbols indicate values at room temperature (25°C). Squares are values at normal boiling point. These data are taken from ref. 24.

critical point and the point at $T_r = 0.7$, or alternatively at normal boiling point, will represent the saturated vapor pressure curve a liquid would have in the absence of order.

We will now show that both definitions are similar. Equation [3] is the straight line which passes through the critical point and the point at $T_r = 0.7$, its slope is $-5.365\,(1 + \omega)$. On the other hand, the equation of the straight line which passes through the critical point and normal boiling point ($p_b = 1$ atm) can be written as:

$$[5] \qquad \ln p_r = \frac{\ln p_c}{T_c/T_b - 1}\left(1 - \frac{1}{T_r}\right)$$

where p_c, critical pressure, is expressed in atmospheres. The slope of $\ln p_r$ *vs.* $1/T_r$ is $-\ln p_c/(T_c/T_b - 1)$. Equations [3] and [5] will be equivalent if their slopes are the same or if

$$[6] \qquad \omega = \frac{T_b}{5.365(T_c - T_b)} \ln p_c - 1$$

for different liquids. In Table 2 experimental values of the

Water	0.344	0.367

[a]Experimental acentric factors, normal boiling temperatures, and critical data are taken from ref. 16.

acentric factor are compared with those calculated from the right-hand side of eq. [6]. That these values are similar, even for complex liquids (alcohols and water), shows that eqs. [3] and [5] are equivalent and suggests that eq. [6] can be used to predict acentric factor values. We can thus assume eq. [3] and eq. [5] both represent the saturated vapor pressure curve a complex liquid would have if order was absent. From eq. [5] we can also obtain the vaporization enthalpy of a normal liquid in the low pressure region:

$$[7] \qquad H^0_{vn} = R\frac{T_c T_b}{T_c - T_b} \ln p_c$$

Since eqs. [3] and [5] are equivalent as indicated by their similar slopes (Table 2), so are eqs. [4] and [7].

The enthalpy of the reference and of the solute cavity formation

We emphasized previously (7, 8) that the reference cavity formation process does not imply molecular order changes in the

liquid and that the internal molecular degrees of freedom are maintained in this process. In this context the enthalpy of formation of the reference cavity, H_{c0}, can be identified with the vaporization enthalpy a liquid would have if it was a normal liquid (if it obeyed the three-parameter CSP), i.e., if temperature-dependent contributions to the vaporization enthalpy were absent. From eq. [4] we can thus write

$$[8] \quad H_{c0} = 5.365(1 + \omega)RT_c$$

or, alternatively, from eq. [7]

$$[9] \quad H_{c0} = R\frac{T_cT_b}{T_c - T_b} \ln p_c$$

The enthalpy of the reference cavity, calculated using eqs. [8] and [9] can be compared with the values obtained by our previously proposed method (7) which was based on

$$[10] \quad H_{c0} = \frac{H_v^0}{1 + \omega} - T\Delta C_v$$

where H_v^0 is vaporization enthalpy at working temperature (25°C) and ΔC_v the difference, at the same temperature, between the specific heat at constant volume of gas and that of liquid. Table 3 shows a comparison between the H_{c0} values calculated from eqs. [8] and [10] and we can observe that the two sets of values show, except for water, a similar behaviour. We can also see that the H_{c0} value obtained for water from eq. [10] is greater than the vaporization enthalpy of water at 25°C (44.0 kJ mol^{-1}). For an ordered liquid H_{c0} must always be smaller than the vaporization enthalpy at room temperature since in the reference cavity formation process there is no order destruction as occurs in the vaporization process. The value of H_{c0} obtained for water from eq. [10] is thus inconsistent and we think that the method of calculating H_{c0} from eqs. [8] and [9] has a deeper physical foundation and a clearer physical meaning when compared with that based on eq. [10]. In fact, eq. [10] is the sum of two terms whose physical significance is not very clear. On the one hand, the ΔC_v contains an order contribution; and $H_v/(1 + \omega)$ does not represent, as previously shown, the vaporization enthalpy of a liquid in the absence of order which is most correctly described by eq. [4] or [7]. Equation [10] is thus a semi-empirical equation in which the sum $H_v/(1 + \omega) - T\Delta C_v$ has no overall physical significance. Moreover, the method based on eqs. [8] or [9] is easier to use since the physical properties needed for calculation are easily available in the literature (in particular this method avoids the use of ΔC_v values which are not always available).

It is also interesting to note that the quantity H_{c0}/S_0, where H_{c0} is calculated from eq. [8] or [9] and S_0 is the exposed molecular area (surface of the reference cavity), shows similar values for liquids composed of molecules of similar chemical nature. This was expected since H_{c0} is related to the interaction energy of a molecule with its whole surroundings. Alkane liquids are composed by molecules with similar contact energies and so the molar interaction energy per unit of exposed surface area must be identical for different alkanes. Table 4 shows the H_{c0}/S_0 values for different *n*-alkanes (S_0 was calculated as indicated in the table). The close similarity of these values supports the idea of similar contact energies of those molecules. This behaviour was not observed for other properties such as cohesive energy density or internal pressure which have been used extensively in the theories of solutions (17, 18). The quantity H_{c0}/S_0 is thus potentially a useful property of liquids in liquid–solution thermodynamics and is to be explored in the quantitative study of intermolecular forces.

TABLE 3. A comparison between two different methods of calculating enthalpy of the reference cavity; the third column (the enthalpy of vaporization at 25°C) can be compared with the first column to estimate the order of contribution to the enthalpy of the liquid

The entropy and the Gibbs energy of the reference cavity

From eq. [1] it can be shown that the standard vaporization entropy of a simple liquid is given by

$$[11] \quad S_{vs}^0 = 5.365R + R \ln p_c$$

For a normal liquid, from eq. [3] we will have

$$[12] \quad S_{vn}^0 = 5.365(1 + \omega)R + R \ln p_c$$

and from eq. [5]

$$[13] \quad S_{vn}^0 = R\frac{T_b}{T_c - T_b} \ln p_c + R \ln p_c$$

We recall that the critical pressure in eqs. [11]–[13] must be expressed in atmospheres, and that eqs. [12] and [13] are equivalent as are eqs. [4] and [7].

We will now focus our attention on the entropy of formation of the reference cavity. For a simple liquid (composed of spherical and non-polar molecules) this entropy must be zero since there are no correlations between the reference cavity and the neighbouring molecules. The entropy of cavity formation in those liquids is a configurational entropy (the ideal entropy of mixing) or a cratic entropy in the language of Gurney (19), as opposed to the unitary or contact entropy which reflects contacts or correlations, at the molecular level, between movements and orientations of the reference cavity and those of the neighbouring molecules.[3] The cratic contribution to entropy (or to Gibbs energy) is not measurable, i.e., it is not included in experimental thermodynamic properties such as solution entropies or Gibbs energies. For a normal liquid (complying with the three-parameter CSP), on the other hand, the reference cavity will

[3]Cratic entropy does not depend on the chemical nature of particles taking part in the process. It is only a function of composition. As pointed out by Ben-Naim (20) the unitary entropy, on the other hand, may also depend on the composition of non-ideal solutions of intermediate concentration. In this situation the unitary entropy is not a characteristic of the particles only. We are considering, however, the infinite dilution situation and in this context the unitary entropy is really a characteristic of the contact between particles, and is independent of composition.

n-Tetradecane	265.4[c]
n-Pentadecane	262.5[c]
n-Hexadecane	261.8[c]

[a] H_{c0} calculated from eq. [8].

[b] S_0 calculated assuming spherical approximation by using the equation $S_0/\text{cm}^2\ \text{mol}^{-1} = 4.084 \times 10^8 V_0^{2/3}$, where V_0 is the molar volume in cm^3 mol^{-1}. In fact, it is known that long *n*-alkane molecules in the liquid state are in extended conformations so that the cavity occupied by each molecule is much more like cylinders than spheres. For smaller alkane molecules, however, the shape anisotropy is small and the spherical approximation must be used.

[c] S_0 calculated assuming the molecules are cylindrical with $r = 3.5$ Å (see ref. 7) by using the equation $S_0/\text{cm}^2\ \text{mol}^{-1} = 10^8 (46.358 + 0.571\ V_0)$, where V_0 is the molar volume in cm^3 mol^{-1}.

[d] Mean value from footnotes *b* and *c*. As explained in footnote *b* it is logical to consider intermediate sized *n*-alkane molecules as ellipsoidal, a shape which is intermediate between a sphere and a cylinder.

have orientational correlations with neighbouring molecules and so the reference cavity will have a non-zero entropy. This entropy, S_{c0} (which must be negative since the presence of those correlations lowers the entropy), will thus be given by the difference between the entropy of the liquid if it was normal and the entropy of the simple liquid. Otherwise stated, the entropy of the reference cavity will be the difference between the vaporization entropy of the simple liquid (eq. [11]) and the vaporization entropy the liquid under consideration would have if it was a normal liquid (eq. [12] or [13]). For eqs. [11] and [12] we thus have

$$[14] \quad S_{c0} = -5.365\omega R$$

and from [11] and [13]

$$[15] \quad S_{c0} = R\left[5.365 - \frac{T_b}{T_c - T_b} \ln p_c\right]$$

Hence, Gibbs energy of the reference cavity will be given by

$$[16] \quad G_{c0} = 5.365R\,[\,T_c + \omega(T_c + T)]$$

from eqs. [8] and [14] or, alternatively, from eqs. [9] and [15]

$$[17] \quad G_{c0} = R\left[\frac{T_b(T_c + T)}{T_c - T_b} \ln p_c - 5.365\,T\right]$$

where T is the working temperature. We recall again that the critical pressure, p_c, in eqs. [15] and [17] must be expressed in atmospheres.

We thus have two different sets of equivalent equations ([8], [14], and [16] on the one hand — method 1 — and eqs. [9], [15], and [17] on the other — method 2) which enable us to calculate the energetics of the reference cavity from different macroscopic properties of liquids. To use method 1 the experimental values of ω and T_c are needed. To use method 2 we need to know T_c, p_c, and T_b. Since the knowledge of the acentric factor implies the knowledge of the critical pressure, method 2 can be more useful if the critical pressure is known but not the acentric factor (or the vapor pressure at $T_r = 0.7$). Nevertheless in the case where all the experimental data are available, the two methods are equivalent and there is no reason to prefer one or the other. The fact that these properties are generally available in the literature is one advantage of the present method over methods proposed before (the Sinanoglu method (5) needs saturated vapor pressure at 25°C, a statistic not available for liquids of very low volatility, such as hexadecane, and our previous method for calculating H_{c0} (7, 8) needed ΔC_v, the difference between the specific heats at constant volume of the gas and liquid at 25°C, a value not easily available in the literature for many organic liquids). The most important point, however, is that we have now a thermodynamically consistent method to obtain the different quantities associated with the formation of the reference cavity.

Table 5 shows the values of H_{c0}, S_{c0}, and G_{c0} for different liquids and calculated by different methods (the Sinanoglu method (5), the modified SPT (6), and the method we presented based on eqs. [8], [14], and [16]). Table 5 shows that (*a*) the H_{c0} values calculated by all three methods are relatively close for most liquids; (*b*) the S_{c0} values are large and positive when calculated by the Sinanoglu method and are always negative and generally small when calculated by the two other methods. A relatively good agreement exists between the S_{c0} values calculated by Claverie's modification (6) of the Pierotti method and those calculated by the method we propose in the present work (eq. [14]). As argued (6), these values are compatible with the negative values obtained by Ben-Naim (21) for "insertion" entropy, since the cavity contributes most to that entropy. This is not the case with the values obtained by the Sinanoglu method; (*c*) there is a good agreement between the G_{c0} values calculated by modified SPT (6) and by eq. [16]. The Sinanoglu values are substantially lower as a consequence of the large and positive S_{c0} values obtained by this method.

It seems to us that the high S_{c0} and low G_{c0} values obtained by the Sinanoglu method are the result of an incorrect treatment of G_{c0} which is taken as

$$[18] \quad G_{c0} = -RT \ln p + RT \ln (V_g/V)$$

where p is the saturated vapor pressure at 25°C (in atmospheres), V_g the molar volume of the ideal gas at 25°C and 1 atm, and V the volume accessible to the translational motions of the molecules in the liquid (taken as the molar volume of the liquid). We must realize that both terms on the right-hand side of eq. [18] are "purely" entropic terms. In the first one $R \ln p$ describes the entropy change of the vapor when it is compressed from the saturated vapor pressure at 25°C to the standard pressure ($p^0 =$ 1 atm) and is thus a gas phase term. The second term accounts for the change in positional entropy of the molecules as they go from an accessible volume V to the volume of one mole of ideal gas. Since in the cavity formation process all molecules remain

TABLE 5. Enthalpy, H_{c0}, entropy, S_{c0}, and Gibbs energy, G_{c0}, of the reference cavity for different liquids calculated following the Sinanoglu method (line *1*), the modified SPT (line *2*)[a], and eqs. [8], [14], and [16] (line *3*)

[a]Values taken from ref. 6.

in the liquid phase (they do not undergo any phase transition), it is hard to understand how the terms in eq. [18] are able to describe this process. Another criticism to the Sinanoglu method is that we cannot identify H_{c0} with the vaporization enthalpy of the liquid at 25°C. This does not dramatically affect the liquids presented in Table 5 but is, as previously shown (7, 8), very important when we are dealing with long-chain alkanes where the deviations from the three-parameter CSP are very large at 25°C. These are strong enough arguments which lead us to consider that the Sinanoglu method is not a good method to calculate the energetics of cavity formation, particularly on the entropy and Gibbs energy of cavity formation.

Energetics of the solute cavity formation

From the thermodynamic parameters associated with the formation of the reference cavity in a given solvent we can calculate those parameters for any solute cavity in the same solvent. The method has already been described (7, 8) and we will just briefly refer to it to clarify the text which follows.

If we describe the cavity formation process as work done against the surface forces of the solvent we will have, for molar Gibbs energy of cavity formation,

$$[19] \quad G_c = N_A \sigma_0 S k_g$$

and for molar enthapy

$$[20] \quad H_c = N_A \sigma_0 A_0 S k_h$$

where A_0 is given by

$$[20a] \quad A_0 = 1 - T\left(\frac{1}{\sigma_0}\frac{d\sigma_0}{dT} + \frac{2}{3}\alpha_0\right)$$

In these equations N_A is the Avogadro's constant, σ^0 the solvent surface tension, α_0 the isobaric thermal expansion coefficient of the solvent, S the surface area of the cavity, k_g a correction factor to take into account the influence of the curvature of the cavity surface on its surface tension, and k_h a similar correction factor for the enthalpy part of surface tension. k_g and k_h depend on the size and shape of the cavity and we will consider, as before, (7, 8) two different significant situations. (*1*) *the curvature of the solute cavity is the same as that of the reference cavity* (see ref. (7) for a detailed explanation of the significance of this situation); in this case we will have

$$[21] \quad k_g = k_{g0} \quad \text{and} \quad k_h = k_{h0}$$

where the subscript zero denotes the reference cavity. For this cavity eqs. [19] and [20] take the form

$$[22] \quad G_{c0} = N_A \sigma_0 S_0 k_{g0}$$

and

$$[23] \quad H_{c0} = N_A \sigma_0 A_0 S_0 k_{h0}$$

where S_0 is the surface area of the reference cavity.

Comparing [22] with [19] and [23] with [20] we conclude that

$$[24] \quad G_c = \frac{S}{S_0} G_{c0}$$

and

$$[25] \quad H_c = \frac{S}{S_0} H_{c0}$$

(*2*) *The solute and the reference cavities are spheres of different radii*. In this case k_g and k_h will depend on the size of the cavity according to

$$[26] \quad k = 1 + \frac{S_0}{S}(k_0 - 1)$$

and we obtain

$$[27] \quad G_c = N_A \sigma_0 (S - S_0) + G_{c0}$$

$$[28] \quad H_c = H_A \sigma_0 A_0 (S - S_0) + H_{c0}$$

It is most useful to express eqs. [24]–[27] in terms of the cavity volume instead of its surface area. For spherical cavities we have $S = 4\pi r^2$ and if we consider $V = N_A 4\pi r^3/3$ where V is the molar volume of the liquid, we have

$$[29] \quad S = (4\pi)^{1/3}\left(\frac{3V}{N_A}\right)^{2/3}$$

and substituting [29] in [27] and [28] we will obtain

$$[30] \quad G_c/\text{J mol}^{-1} = 40.840\sigma_0(V^{2/3} - V_0^{2/3}) + G_{c0}$$

and

[31] $$H_c/\text{J mol}^{-1} = 40.840\sigma_0 A_0(V^{2/3} - V_0^{2/3}) + H_{c0}$$

where the factor 40.840 contains constants and unit conversion factors to give G_c and H_c in J mol^{-1} if V is expressed in cm^3 mol^{-1} and σ_0 in dyn cm^{-1}. We would recall that eqs. [30] and [31] can be used if both solute and reference cavities are spherical, in which case k varies according to [26]. If the curvature of those cavities are similar we must use eqs. [24] and [25]. As shown in ref. 7, the quantity S/S_0 in these equations may take different forms according to the shape of the cavities. We will consider here only two kinds of cavity shape: cylindrical cavities of radius 3.5 Å (see footnote 8 in ref. 7) and spherical cavities. We will thus have the following different situations:

(*a*) cylindrical cavity in a cylindrical solvent

[32] $$\frac{S}{S_0} = \frac{0.140V + 11.3509}{0.140V_0 + 11.3509}$$

(*b*) cylindrical cavity in a spherical solvent

[33] $$\frac{S}{S_0} = \frac{0.140V + 11.3509}{V_0^{2/3}}$$

(*c*) spherical cavity in a cylindrical solvent

[34] $$\frac{S}{S_0} = \frac{V^{2/3}}{0.140V_0 + 11.3509}$$

(*d*) spherical cavity in a spherical solvent

[35] $$\frac{S}{S_0} = \left(\frac{V}{V_0}\right)^{2/3}$$

Figure 4 shows qualitatively how S/S_0 depends on the size of the cavity according to eqs. [32]–[35]. Equations [32] and [35] are nearly equivalent, leading to S/S_0 values which never differ more than 5% in the whole V/V_0 range. The results for these two equations are thus presented as a single curve (curve *2*). From Fig. 4 we can see that eq. [33] leads to higher S/S_0 values (curve *1*) and eq. [34] leads to lower values (curve *3*). We can also see that the difference between the S/S_0 values obtained by the different equations is significant and increases when the solute is large compared with the solvent molecule. These conclusions show the need for a realistic description of the shape of the solute and the reference cavities. The appropriate S/S_0 value must thus be introduced in eqs. [24] and [25] in order to calcuate the Gibbs energy and the enthalpy of solute cavity when its curvature is similar to that of the reference cavity. In Table 6 the physical properties for a large number or organic solvents needed for the calculations are presented.

Application to *n*-alkane binary mixtures and discussion

The difficulty with any model for calculating cavity properties is that we cannot verify its validity experimentally. The most straightforward method of verifying the validity of a cavity model is to apply it to the description of the dissolution process of a liquid solute in a solvent at infinite dilution (7). In fact, under such conditions there are no solute–solute interactions and the thermodynamic properties, X_d, associated with the solution process ($X_d = G_d, S_d, H_d$) can be factorized as

[36] $$X_d = X_v + X_{solv} = X_s + X_c + X_i$$

where X_v is the vaporization energy of the solute, X_{solv} is the solvation energy of the solute in the solvent, X_s describes the separation or dispersion of the solute molecules in the solvent, X_c describes the formation of the solute cavity in the solvent, and X_i describes the solute–solvent interaction. For structured solvents a fourth term should be added to eq. [36] to describe the change of the solvent structure around the solute molecule. Nevertheless, as pointed out by Friedman (22) this term would be zero for Gibbs energy since the solute cosphere is in equilibrium with the bulk. Equation [36] can be used to evaluate a cavity model if we calculate the solute–solvent interaction energy and the cavity energy and compare with the experimental solvation energy. This was done by Pierotti (23) to test the method based on the Scaled Particle Theory. Nevertheless, as pointed out in the Introduction, the calculation of the interaction term is a difficult task for complex systems, precisely where the different cavity models diverge. In fact, for simple systems (composed of molecules with moderate shape anisotropy and polarity and without strong directional interactions) the different methods proposed in the literature to calculate the energetics of cavity formation are nearly equivalent. On the other hand, one advantage of the cavity models is, as stated before in the Introduction and in ref. 7, the possibility of obtaining the interaction term and thus avoiding the complex and uncertaint task of its calculation. This is why we prefer to check our cavity model by applying it to systems in which the solute and solvent molecules have similar chemical nature or similar contact energies. In this situation we have $X_c = -X_i/2$, so eq. [36] becomes

[37] $$X_s - X_d = X_c$$

The *n*-alkane molecules have very similar chemical nature, the only difference being the fraction of molecular surface covered by methyl and methylene groups. Since these groups are thermodynamically very similar, the *n*-alkane binary mixtures are certainly the systems most likely to satisfy eq. [37]. As shown before (7, 8), X_s is equivalent to the energy of the solute

reference cavity formation, so that we have $X_s = X_{c1}$, where the subscript 1 refers to the solute and [37] takes the form

[38] $$X_{c1} - X_d = X_c$$

To evaluate the validity of the method we propose to calculate the enthalpy and entropy of cavity formation by applying eq. [38] to *n*-alkane binary mixtures. Table 6 shows some physical properties of liquids needed for the calculations. The solution enthalpies at infinite dilution for *n*-alkane binary systems are shown in Table 3 of ref. 7. Table 7 shows a comparison between the quantity $H_{c1} - H_d$ (first member of eq. [38]) and H_c calculated by the method we propose in this work. Our H_c values are also compared with those calculated using the Scaled Particle Theory. From this table we can see that our values are in good agreement with the $H_{c1} - H_d$ values. Moreover, our results show an interesting feature we wish to emphasize. If we consider a given solute in different solvents we would expect to obtain the same H_c value if the interaction potential is the same for different solvents. This is the case for different *n*-alkanes solvents where molecules contain identical segments. In fact, from Table 7 we can see that the *n*-hexane cavity, for example, has nearly the same enthalpy in all *n*-alkane solvents, from *n*-heptane (30.3 kJ mol^{-1}) to *n*-hexadecane (31.0 kJ mol^{-1}). This interesting feature is not observed if we look at the H_c values obtained from the Scaled Particle Theory. We can also conclude that these H_c values are different from those obtained by our model, particularly for systems in which the solute and solvent molecules have different sizes.

The results in Table 7 are graphically presented in Fig. 5. To represent these results we transform eq. [38] by subtracting X_{c0} (a thermodynamic quantity associated with solvent reference cavity formation) to both sides of the equation. We thus have

[39] $$X_{c1} - X_{c0} - X_d = X_c - X_{c0}$$

[a]Reference numbers of solutes and solvents are given in Table 6.
[b]Dissolution enthalpy, H_d, for these systems have been tabulated in ref. 7.
[c]The method used in the calculations was that based on eq. [9].
[d]Unless otherwise stated, eq. [32] was used to describe the molecular shape of both solute and solvent.
[e]H_c values calculated from the SPT using hard spheres diameters from Wilhelm and Battino (Table 4 in ref. 7).
[f]Equation [34] was used to describe the molecular shape of both solute and solvent.

The rationale for the modification is that eq. [39] is more discriminative than eq. [38], since it enables us to distinguish clearly systems composed of a large solute in a small solvent (positive values for both sides of eq. [39]) from those composed of a small solute in a large solvent (negative values for both sides). In Fig. 5 the ordinate represents the right hand side in eq. [39], the abcissa the left hand side, and the straight line means that both sides of eq. [39] are equal. We can see that the calculated points are reasonably close to the line. This observation is not a proof or a demonstration of the correctness of our model but shows that it enables us to make a consistent description of the solution process in terms of enthalpy. We have stated that there are no experimental methods to verify the validity of the model. However, the fact that our model allows for a consistent description of the solution process is a strong indication of its validity.

We will now use eq. [38] to check the validity of our model for Gibbs energy. In Table 8 the experimental Gibbs energies of dissolution for different alkane solutes at infinite dilution in alkane solvents as well as the results of calculations of G_c according to the model based on eq. [16] are presented. From

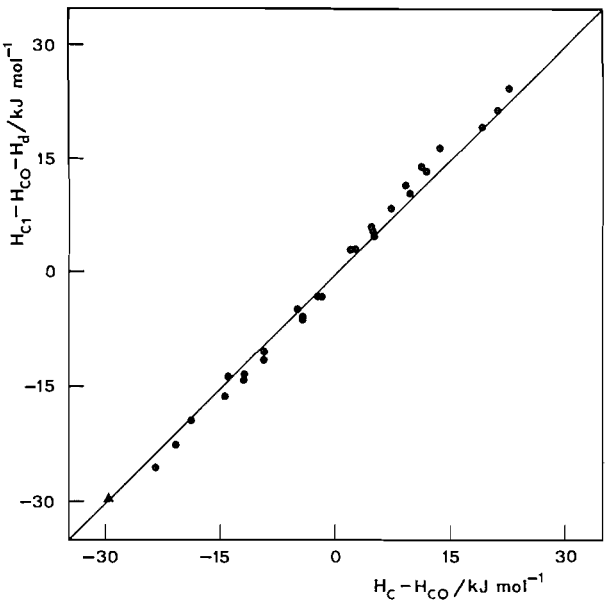

FIG. 5. Comparison between the parameters in eq. [39] for enthalpy. The points correspond to the systems presented in Table 7. To calculate H_c eq. [32] was used for all systems except for system 1/12 (triangle) where eq. [34] was used.

this table we can see that our G_c values compare reasonably well with $G_{c1} - G_d$. This agreement is not so good when the Sinanoglu method is used, as also shown in Table 8. The G_c values obtained using the Sinanoglu method are substantially lower than those obtained using our method. This is expected since, as discussed before, the Sinanoglu method gives high and positive values for the cavity entropy. Moreover, the same interesting feature we pointed out for enthalpy is observed again for Gibbs energy. Indeed we obtain for the cyclohexane cavity a G_c value which is similar in hexane and in hexadecane. The same is observed for the *n*-hexane solute for which G_c is identical in decane, dodecane, and hexadecane (32 kJ mol^{-1}) and also similar to the *n*-hexane reference cavity Gibbs energy, G_{c0} (33 kJ mol^{-1}). This interesting feature is not so clearly observed when the Sinanoglu method is used (the systems containing hexadecane are lacking because its saturated vapor pressure at 25°C is not available), as is not observed at all when the Pierotti method is used to calculate G_c.

As stated before, the fact that our G_c values are close to the $G_{c1} - G_d$ values is not a demonstration of the correctness of our method of calculation of the energetics of cavity formation in liquids. However, the fact that the calculated results follow eq. [38] means that our method allows for a consistent description of the solution process both for enthalpy and Gibbs energy.

The solvent effect on the solvolysis of *tert*-butyl chloride and bromide

To study the influence of solvent on reaction rates two main methods have been developed. One is to make use of multiple linear correlation analysis between rate constants (or Gibbs energies of activation) and a number of solvent parameters. In the second method, the solvent effect, generally in terms of Gibbs energy, is divided into initial-state and transition-state contributions. Further the resulting energies of transfer of the transition-state from one solvent to another are compared with corresponding values from a suitable model of the activated complex. In what concerns the solvolytic reactions of *tert*-butyl

halides, pertinent properties of the transition state were deduced using the latter method (10, 34).

Some years ago, a different approach to the treatment of solvent effect on the rate of chemical reactions was proposed (4) and illustrated with a study of the solvent effect on the solvolysis of *tert*-butyl chloride. According to this approach the Gibbs energy of transfer of a solute from one solvent to another, δG, can be described as the sum of two contributions:

$$[40] \quad \delta G = \delta G_c + \delta G_i$$

where δG_c is related to energies required to create cavities in the solvents and δG_i is associated with solute–solvent interaction. The Gibbs energies of reorganization of the solvent molecules around the solute was neglected because of the enthalpy–entropy compensation which exists in those phenomena as pointed out before in this paper. Since charge separation in a given solute will only be reflected in δG_i, the calculated δG_i terms, instead of δG, were used as a sensitive probe for charge separation.

In a previous paper (4) the Sinanoglu method was used to give the related cavity terms for the *tert*-butyl chloride transition-state and for the model compound, the $Me_4N^+Cl^-$ ion-pair, in twelve solvents. A good linear correlation between these values was observed and the slope, 0.73, was taken as charge separation in the solvolytic reaction activated complex. The estimated value of δG_i, however, depends on the adopted model to calculate the energetics of cavity formation. Therefore, a comparison of the results from different methods plays an important part in rational selection. To perform comparative analysis we chose the solvolyses of *tert*-butyl chloride (in sixteen solvents) and *tert*-butyl bromide (in eight solvents). Methanol was taken as the reference solvent. The cavity terms were then calculated

[a]The same set of solvents are used in analysing *t*-BuBr solvolysis.

using different methods: the original Pierotti method, the Sinanoglu method, and the new approach proposed here (eq. [16]). Tables 9 and 10 give the relative Gibbs energies of interaction with the solvent of the activated complex and the model for the two mentioned solvolytic reactions. The corresponding linear plots are shown in Figs. 6 and 7. The results confirm the poor results using the Pierotti method in these systems. Not only are correlation coefficients smaller than those obtained by other methods, but the slope for *t*-BuCl solvolysis is only 0.47. Several independent studies give 0.70–0.80 as charge separation in the transition state of this reaction (10, 34).

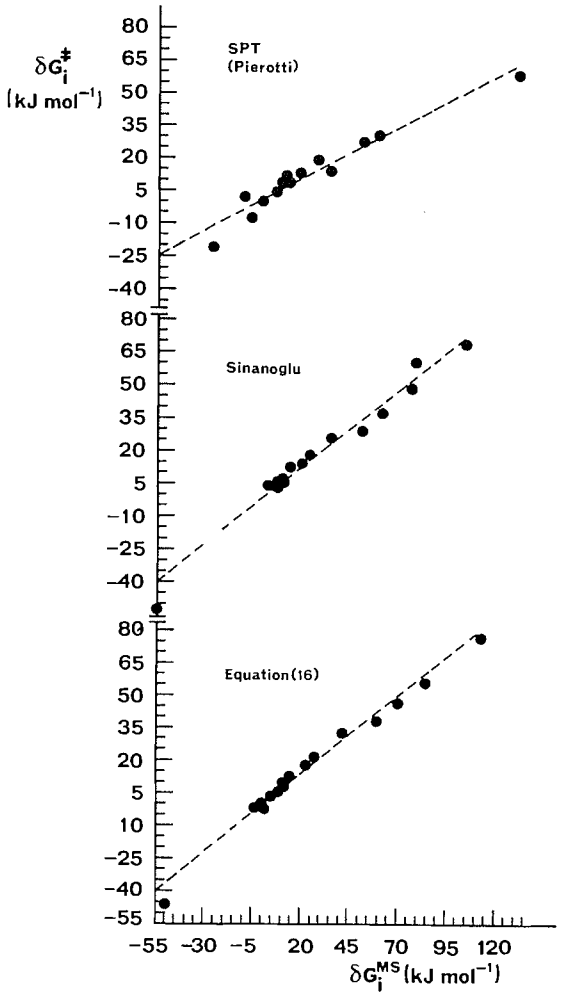

FIG. 6. Correlation between the differential solute–solvent interaction Gibbs energy for the activated complex (‡) and the model solute (MS) in solvolysis of *tert*-butyl chloride.

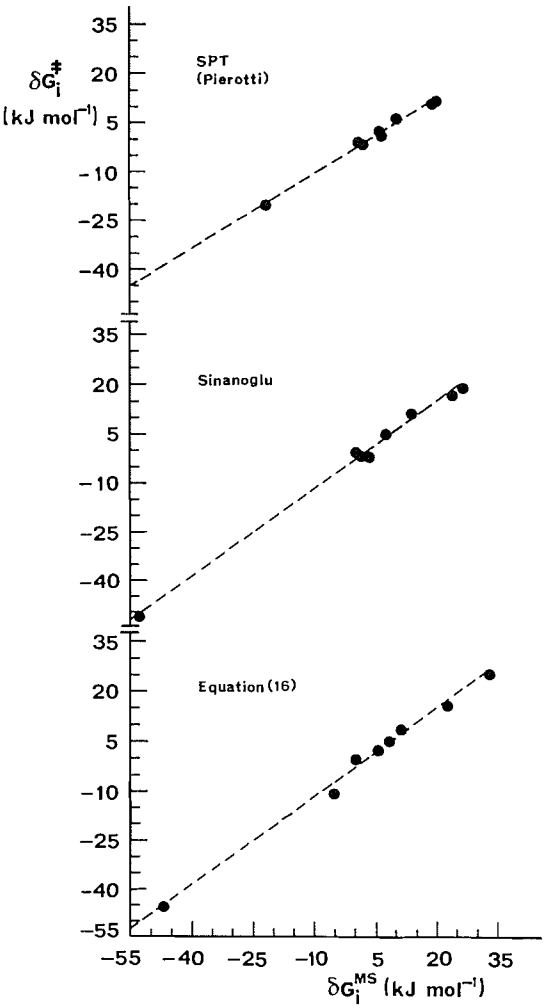

FIG. 7. Correlation between the differential solute–solvent interaction Gibbs energy for the activated complex (‡) and the model solute (MS) in the solvolysis of *tert*-butyl bromide.

On the other hand, the other two approaches give consistent charge separation values. Excellent linear correlations are observed, particularly for the method we proposed in this work. Thus we may conclude that, whatever the structure of the transition-state, charge separation is always quite high.

Although the same straight line is found to be adequate to characterize in general the polar nature of the transition state of the *t*-BuCl solvolysis over all solvents studied, the slope of the line for a smaller set of very polar and associated solvents increases to 0.87. This agrees with previous results when data for the more polar solvents are used: 0.81–0.94 (34). The same set of solvents was also used to analyse the solvolytic reaction of *t*-BuBr (Table 11). No significant differences can be assigned to the solvolysis of both substrates, except that the transition state in *t*-BuBr solvolysis is even more ion-pair like in nature.

Conclusions

In this work we proposed a new method for calculating the energetics of cavity formation in liquids. This method enables the calculation of different thermodynamic properties associated with the cavity formation process. It is consistent from a thermodynamic point of view in the sense that we can relate those properties by using the Gibbs–Helmholtz relationship.

We believe that the proposed method is better than others previously proposed in the literature, namely the Pierotti method and the Sinanoglu method, and several features were pointed out to support this statement. The fact that our method allows a consistent description of the dissolution process of alkane solutes at infinite dilution in alkane solvents (for Gibbs energy as well as for enthalpy and obviously for entropy) is probably the most important feature. Other features to validate our method have been stated in our previous works (7, 8). Our calculated energy of cavity formation is the same for same solute in different alkane solvents. This feature, which has been observed for enthalpy and for Gibbs energy, reinforces the idea of similar contact energies in different *n*-alkane molecules.

Our method of calculating the energetics of cavity formation has been applied to the study of solvent effect on the solvolytic reactions of *tert*-butyl halides. We obtain very good correlations between the relative Gibbs energy of interaction with the solvent for the activated complex and for its ion-pair model. From these correlations the charge separation in the transition state was deduced and our results are in very good agreement with independent studies.

The products, plausible intermediates, and their mechanisms of formation in the aprotic diazotization of 2-[(2-acetoxyethyl)-sulfinyl (and sulfonyl)]anilines with isoamyl nitrate have been investigated by experimental and quantum chemical methods. Oxidation of 1,2,3-benzthiadiazole with hydrogen peroxide in acetic acid affords 1,2,3-benzthiadiazole-1-oxide, **13**. The thermal stability of **13** up to 135°C, together with EPR evidence which disfavors an aryldiazenyl radical precursor, discount **13** as an intermediate in the formation of benzoxathiete **14** or its valence tautomer **17** during aprotic diazotization of the sulfinylanilines. Electron paramagnetic resonance evidence in conjunction with spin trapping indicates an intermediate arylaminyl radical. This evidence, taken together with *ab initio* calculations of optimized geometries energies and energy differences for biradical intermediate **15**, favors a mechanism of formation of benzoxathiete **14** via aryldiazoate anhydride **5** thence to rapid ring closure of carbon-centered radical **8**. Further oxidation of 1,2,3-benzthiadiazole-1-oxide, **13**, with hydrogen peroxide in methanol – acetic acid affords biphenylene and dibenzo-1,4-oxathiane-*S*-oxide, **38**. Rose bengal sensitized photooxidation of 1,2,3-benzthiadiazole affords **13**, biphenylene, and **38**. Formation of the latter, in which one of the original S—O bonds has been broken, requires the formation of benzoxathiete-*S*-oxide, **34**, and its rapid valence tautomerism to ketosulfine **36** and (2+4) cycloaddition of **36** to the simultaneously generated dehydrobenzene to give **38**. Both ring closure of singlet biradical **35** to **34** and valence tautomerism of the latter to **36** are predicted by *ab initio* calculations to be facile and exothermic. In contrast to the aprotic diazotization of 2-[(2-acetoxyethyl)sulfinyl]anilines, the reaction of isoamyl nitrite with the corresponding sulfonyl anilines may plausibly follow a mechanism via 1,2,3-benzthiadiazole-1,1-dioxide **33** owing to the thermal instability of the latter and supported by *ab initio* treatments of the energetics of the processes involved. In addition EPR evidence, in conjunction with spin trapping of carbon centered radicals, support the viability of the pathway via **23**, **25**, **28**, and **16** to biphenylene **20**. The *ab initio* calculations of the energy differences between the reaction intermediates and estimates of the activation energies elucidated several aspects of these novel reactions.

Key words: benzoxathiete, *ab initio* calculations, valence tautomerism.

ALI NAGHIPUR, KRZYSZTOF RESZKA, J. WILLIAM LOWN et ANNE-MARIE SAPSE. Can. J. Chem. **68**, 1950 (1990).

Utilisant des méthodes expérimentales et des méthodes de la chimie quantique, on a étudié la nature des produits, des intermédiaires possibles ainsi que de leurs mécanismes de formation lors de la diazotation aprotique des 2-[(2-acétoxyéthyl)sulfinyl (et sulfonyl)]anilines avec du nitrite d'isoamyle. L'oxydation du 1,2,3-benzthiadiazole par le peroxyde d'hydrogène dans l'acide acétique fournit le 1,2,3-benzthiadiazole-1-oxyde (**13**). La stabilité du produit **13** jusqu'à une température de 135°C ainsi que les données de la rpe qui défavorisent un radical aryldiazényle comme précurseur permettent d'éliminer le produit **13** comme intermédiaire possible dans la formation du benzoxathiète **14** ou de son tautomère de valence **17** lors de la diazotation aprotique des sulfinylanilines. Les données de la rpe et celles du piégeage de spin suggèrent plutôt le radical arylaminyle comme intermédiaire. Ces données, utilisées de concert avec des calculs *ab initio* d'énergies de géométries optimisées et de différences d'énergie de l'intermédiaire biradicalaire **15**, favorisent un mécanisme de formation du benzoxathiète **14** impliquant l'anhydride d'aryldiazoate **5**; ceci expliquerait la fermeture rapide du radical **8** qui est centré sur le carbone. L'oxydation subséquente du 1,2,3-benzthiadiazole-1-oxyde **13** par le peroxyde d'hydrogène dans un mélange de méthanol et d'acide acétique fournit du biphénylène et du dibenzo-1,4-oxathiane-*S*-oxyde, **38**. La photooxydation du 1,2,3-benzthiadiazole, photosensibilisée par le rose du bengale, fournit du produit **13**, du biphénylène et du produit **38**. La formation de ce dernier produit, dans lequel les liaisons S—O originales ont été brisées, implique la formation du benzoxathiète-*S*-oxyde **34** et de sa tautomérie de valence rapide vers la cétosulfine **36** et une cycloaddition (2+4) subséquente du composé **36** sur le déhydrobenzène qui est généré simultanément pour donner le produit **38**. Les calculs *ab initio* prédisent que la cyclisation du biradical singulet **35** en **34** ainsi que la tautomérie de valence de ce dernier en **36** sont deux processus faciles et exothermiques. Par opposition à la diazotation aprotique des 2-[(2-acétoxyéthyl)sulfinyl]anilines, il est possible que la réaction du nitrite d'isoamyle avec les sulfonyl anilines correspondantes puisse se produire par un mécanisme impliquant le 1,2,3-benzthiadiazole-1,1-dioxyde **33**; en effet, ce dernier composé est instable d'un point de vue thermique et ce mécanisme est supporté par les traitements *ab initio* des énergies des processus impliqués. De plus, les données de la rpe, prises de concert avec le piégeage de spin des radicaux centrés sur le carbone, supportent la viabilité d'une voie réactionnelle impliquant les composés **23**, **25**, **28** et **16** pour obtenir le biphénylène **20**. Les calculs *ab initio* des différences d'énergie entre les intermédiaires réactionnels et des évaluations des énergies d'activation ont permis d'élucider plusieurs aspects de ces nouvelles réactions.

Mots clés : benzoxathiète, calculs *ab initio*, tautomérie de valence.

Introduction

1,2-Oxathietanes and their derivatives have been identified as intermediates in the spontaneous decomposition of anticancer (2-chloroethyl)sulfinyl nitrosoureas under physiological conditions (1–3). Subsequently means were developed to prepare and isolate these novel reactive heterocycles (2, 4, 5) which are of practical and theoretical interest in their structural similarity to the extensively studied 1,2-dioxetanes (6). Some of the characteristic chemical reactions of 1,2-oxathietanes have been explored (1–3) and, recently, the formation and some reactions of benzoxathiete were examined both experimentally (4) and by quantum chemical methods (5). Among the novel reactions of benzoxathiete uncovered was its valence tautomerism to monothio-*o*-benzoquinone (4) which, while being formally disallowed under thermal conditions (5), nevertheless proceeds under the experimental conditions used and, by trapping with the simultaneously generated dehydrobenzene, affords dibenzo-1,4-thioxane.

A number of questions concerning the alternative mechanisms of formation of benzoxathiete as well as the stability and reactivity of plausible intermediates arose from the previous communications (4, 5). The present report addresses these questions and our results serve to clarify several aspects of the chemical reactivity of these novel heterocycles as well as to uncover some novel chemistry of benzoxathiete-*S*-oxide and its valence tautomer. Since many of the intermediates are amenable to *ab initio* calculations the application of quantum chemical methods (5) permitted greater insight into several aspects of stability, reactivity, and orbital symmetry considerations.

Experimental section

Melting points were determined on a Fisher-Johns apparatus and are uncorrected. IR spectra were recorded on a Nicolet 7199 F.T. spectrophotometer, and only the principal sharply defined peaks are reported. NMR spectra were recorded on Varian HA-100, Bruker WH-200, or WH-400 spectrometers. The spectra were recorded on approximately 5–15% (w/v) solutions, depending upon the spectrometers, in appropriate deuterated solvents with tetramethylsilane as internal standard. EI mass spectra were determined on an Associated Electrical Industries (AEI) MS-9 double focusing high-resolution mass spectrometer with ionization energies at 70 eV. Peak measurements were made by comparison with perfluorotributylamine at a resolving power of 15000 on an AEI-MS-50 mass spectrometer. GC analyses were performed on a Hewlett-Packard 5840A analytical gas chromatograph equipped with a flame ionization detector. GC/MS analyses were performed on an AEI-MS-12 spectrometer. Samples were injected onto a 6–ft, 10% Carbowax 20M 80-100 WAW-DMCS a5830 column with a helium flow rate of 20 mL/min. The column was heated at 60°C for 20 min and was heated further at a rate of 10°C/min up to 150°C for 1 h.

1,2,3-Benzothiadiazole-1-oxide

To a stirred solution of 1,2,3-benzothiadiazole (7) (0.45 g, 3 mmol) in 1:1 methanol – acetic acid (20 mL) was added a 30% solution of hydrogen peroxide (3 g, 88 mmol), and the mixture was stirred at room temperature for 45 days, at which time TLC analysis showed complete disappearance of starting material. The solvent and excess of the reagent were removed *in vacuo*, and the residual solid was purified by column chromatography (silica gel, hexane) to afford first biphenylene as a light yellow solid: mp 110°C (lit. (7) mp 110°C); MS, *m/z* (rel. int.) 153 (12.90), 152 (M^+, 100), 151 (18.77), 126 (7.11), 125 (1.45), 76 (11.87), 51 (3.03). Further elution with hexane – ethyl acetate (2:1) afforded 1,2,3-benzothiadiazole-1-oxide as a yellow crystalline solid: mp 132–134°C; 0.3 g (60% yield); MS, *m/z* (rel. int.) 152 (M^+, 100), 136 ($M^+ - 16$, 9.69), 124 ($M^+ - 28$, 2.63), 122 (40.31), 108 (27.15), 76 (26.55), 75 (13.03), 74 (14.53), 51 (23.55).

Thermal stability of 1,2,3-benzothiadiazole-1-oxide in solution

A solution of 1,2,3-benzothiadiazole-1-oxide (0.1 g, 0.65 mmol) in freshly distilled dry ethylene glycol and dimethyl ether (10 mL) was heated under reflux under a nitrogen atmosphere for 5 h. TLC analysis indicated no decomposition and the solvent was removed *in vacuo*. Recrystallization of the solid residue from 1:1 dichloromethane/hexane afforded only pure unreacted 1,2,3-benzothiadiazole-1-oxide. Similar experiments were performed using successively toluene, *o*-xylene, and *o*-dichlorobenzene as solvents. In no case was any thermal decomposition of 1,2,3-benzothiadiazole-1-oxide detected.

Photooxidation procedure

Photooxidation reactions were carried out in a 20 cm water-cooled square quartz reaction vessel equipped with a gas bubbler which was driven from above the vessel. A slow stream of oxygen gas was passed into the solution during the course of irradiation. The light source consisted of a medium pressure Hanovia mercury lamp with a UV cutoff filter (7910) and the sensitizer was rose bengal polymer supported 0.12 mmol/g.

Photosensitized oxidation of 1,2,3-benzothiadiazole

To a stirred solution of 1,2,3-benzothiadiazole (0.2 g, 1.47 mmol) in dry dichloromethane (100 mL) was added rose bengal, polymer supported ca. 0.12 mmol/g (0.5 g). The reaction mixture was irradiated for 60 h, at which time TLC analysis showed complete disappearance of the starting material. The solution was filtered through celite and washed with methanol. The solvents were removed *in vacuo* and the residual solid was subjected to column chromatography (silica gel, pentane) to afford biphenylene as a light yellow solid, mp 110°C (lit. (8) mp 110°C) trace, MS, *m/z* (rel. int.) 153 (12.27), 152 (M^+, 100), 151 (22.19), 150 (11.95), 126 (4.69), 125 (1.10), 76 (12.98), 51 (1.50).

Further elution with hexane:ethyl acetate (2:1) afforded 1,2,3-benzothiadiazole-1-oxide as a yellow crystalline solid: mp 132–134°C, 0.15 g (67% yield); MS, *m/z* (rel. int.), 153 (7.57), 152 (M^+, 130), 136 (2.70), 122 (39.06), 104 (3.49), 76 (11.38), 51 (9.66).

Further elution with hexane:ethyl acetate (1:1) afforded dibenzo-1,4-oxathiane-*S*-oxide, **38**, as a white crystalline solid mp 153–154°C (lit. (9) mp 152–153°C); MS, *m/z* (rel. int.) 217 (13.96), 216 (M^+, 100), 200 ($M^+ - 16$, 16.64), 188 (19.14), 187 (69.61), 168 ($M^+ - 48$, 86.52), 139 (23.64), 115 (7.31), 79 (2.07), 76 (2.09), 63 (11.04), 51 (5.01).

General procedure for analysis of the products of aprotic diazotization of substituted arylalkylsulfoxide or substituted arylalkylsulfones

A solution of substituted arylalkylsulfoxide (4) or corresponding sulfone (4) (2.5 mmol) and isoamyl nitrite (1 mL, 7.5 mmol) each in glyme (3 mL) were added simultaneously in 1 h to a refluxing solution of trapping agent (1.25 mmol) in glyme (7 mL). After the addition was completed, the mixture was refluxed for 20–30 min and then allowed to cool. Dichloromethane (40 mL) was added and the mixture was evaporated to dryness. The residual solid was purified by column chromatography as described previously (4) to separate the products.

EPR spectroscopy

Isoamyl nitrite, 5,5-dimethyl-1-pyrroline *N*-oxide (DMPO), and benzene were purchased from Aldrich (Milwaukee, WI). Arylalkyl thioethers (**1***a–c*) and sulfoxides (**11***a–b*) were synthesized as previously described (4). DMPO was purified by distillation under reduced pressure. All other compounds were used as received.

Stock solutions of the amines (0.1 M and 0.2 M) of iAmONO (70 mM and 100 mM) and ND (10 mM) were prepared in benzene. Samples were prepared adding 10, 20, or 50 μL of iAmONO to 450 μL of the amine solutions containing DMPO (usually 10–100 mM) or ND (5 mM) in quartz EPR tubes (internal diameter 3 mM). Solutions were saturated with argon of 25 min and sealed tightly. EPR spectra were measured using a Bruker ER-400 spectrometer operating at 9.3 GHz with 100 kHz modulation frequency. The following instrumental settings were generally employed; microwave power, 20 mW; modulation amplitude, 0.5 G; time constant, 0.2 or 0.5 s; scan rate 500 or 1000 s and the appropriate gain level. Magnetic field calibration was

achieved using the known distance between the hf components of the EPR spectrum of Fremy salt in 50 mM K_2CO_3. All measurements were performed at room temperature.

Results and discussion

Synthetic and product isolation studies

Attempted oxidation of 1,2,3-benzthiadiazole with *m*-chloroperbenzoic acid, with 30% aqueous hydrogen peroxide, hydrogen peroxide in methylene chloride – acetic acid mixtures, sodium metaperiodate in aqueous dioxane or prolonged photosensitized oxidation using rose bengal on silica gel were unsuccessful. However, treatment of 1,2,3-benzthiadiazole with 30% hydrogen peroxide in a mixture of acetic acid and methanol afforded a product, the physical and spectral data of which are consistent with 1,2,3-benzthiadiazole-1-oxide, **13**, in 60% yield. Compound **13** is a stable pale yellow solid, mp 132–134°C. Solutions of **13** heated under reflux in the following progressively higher boiling solvents were indefinitely stable; 1,2-dimethoxyethane, toluene, *o*-xylene, and *o*-dichlorobenzene.

In the aprotic diazotization of 2-[(2-acetoxyethyl)sulfonyl]-anilines (**21**, X = OAc), analogy with the observed behavior and product distribution from the corresponding 2-[(2-acetoxyethyl)sulfinyl]anilines (**1**, X = OAc), would suggest the possible intermediacy of 1,2,3-benzthiadiazole-1,1-dioxide, **33** (Scheme 2). Although the latter compound has been reported (10), the availability of the novel compound **13** suggested attempted conversion of **13** to **33** by selective oxidation so as to explore the relationship between the two species.

Accordingly further oxidation of **13** was attempted under a variety of conditions. Finally prolonged oxidation of **13** with hydrogen peroxide in acetic acid afforded evidence of conversion to the corresponding 1,1-dioxide in that biphenylene, derived from the dimerization of the intermediate dehydrobenzene and dibenzo-(1,4)-oxathiane-*S*-oxide **38** were identified among the products. Further oxidation of 1,2,3-benzthiadiazole was also effected by rose bengal photosensitized oxidation which afforded **13**, biphenylene, and **38**. Formation of the latter product requires formation of benzoxathiete-*S*-oxide, **34**, its ketosulfine valence tautomer **36**, and cycloaddition of the latter to dehydrobenzene (*vide infra*).

Spin trapping EPR detection of free radical intermediates

The involvement of free radical species in the reaction of 2-[(2-acetoxyethyl)sulfinyl]aniline (**1**, X = OAc) with isoamyl nitrite under aprotic conditions (11) was proven by spin trapping experiments (4, 12*a*, *b*) in conjunction with EPR spectroscopy. However, since EPR spectra are seldom diagnostic for particular species (12*c*, *d*) a more detailed examination was undertaken with a series of model compounds to attempt to delineate the actual types of radicals involved. Treatment of amines **I***a* or **II***a* (Table 1) (0.1 M) with iAmONO (2–7 mM) in the presence of spin trap DMPO (0.1 M) in deaerated benzene at room temperature generated strong and persisted EPR spectra assigned to DMPO adducts of arylaminyl radicals **39** (4, 12*a*, *b*).

Spin adducts can be formed either by trapping arylaminyl radicals by DMPO (reaction [1]), or by oxidation of hydroxylamines (**40**), formed via nucleophilic addition of an amine to DMPO (reaction [2]).

[1] DMPO + $ArNH^{\cdot}$ → 
39

[2] DMPO + $ArNH_2$ →  $\xrightarrow{[O_2]}$ **39**

40

For example, *n*-butyl amine is known to add to the nitrone and form a nitroxide radical according to reaction [2] (13*a*). The question, which of these two alternative pathways (or both) contribute to formation of radical **39**, has been discussed separately (12*a*, *b*). Nevertheless, arylaminyl radicals, if formed, do not participate in the main pathways of processes **1** → ... → **12** (Scheme 1) and **21** → ... → **28** (Scheme 2). Treatment of amines such as **21**, or **III***a* (Table 1) (0.1 M) with iAmONO (2–7 mM) in the presence of DMPO (ca. 20 mM) in deaerated benzene produced the spin adduct of a carbon-centered radical assigned to a DMPO–Ar species (12*a*, *b*)

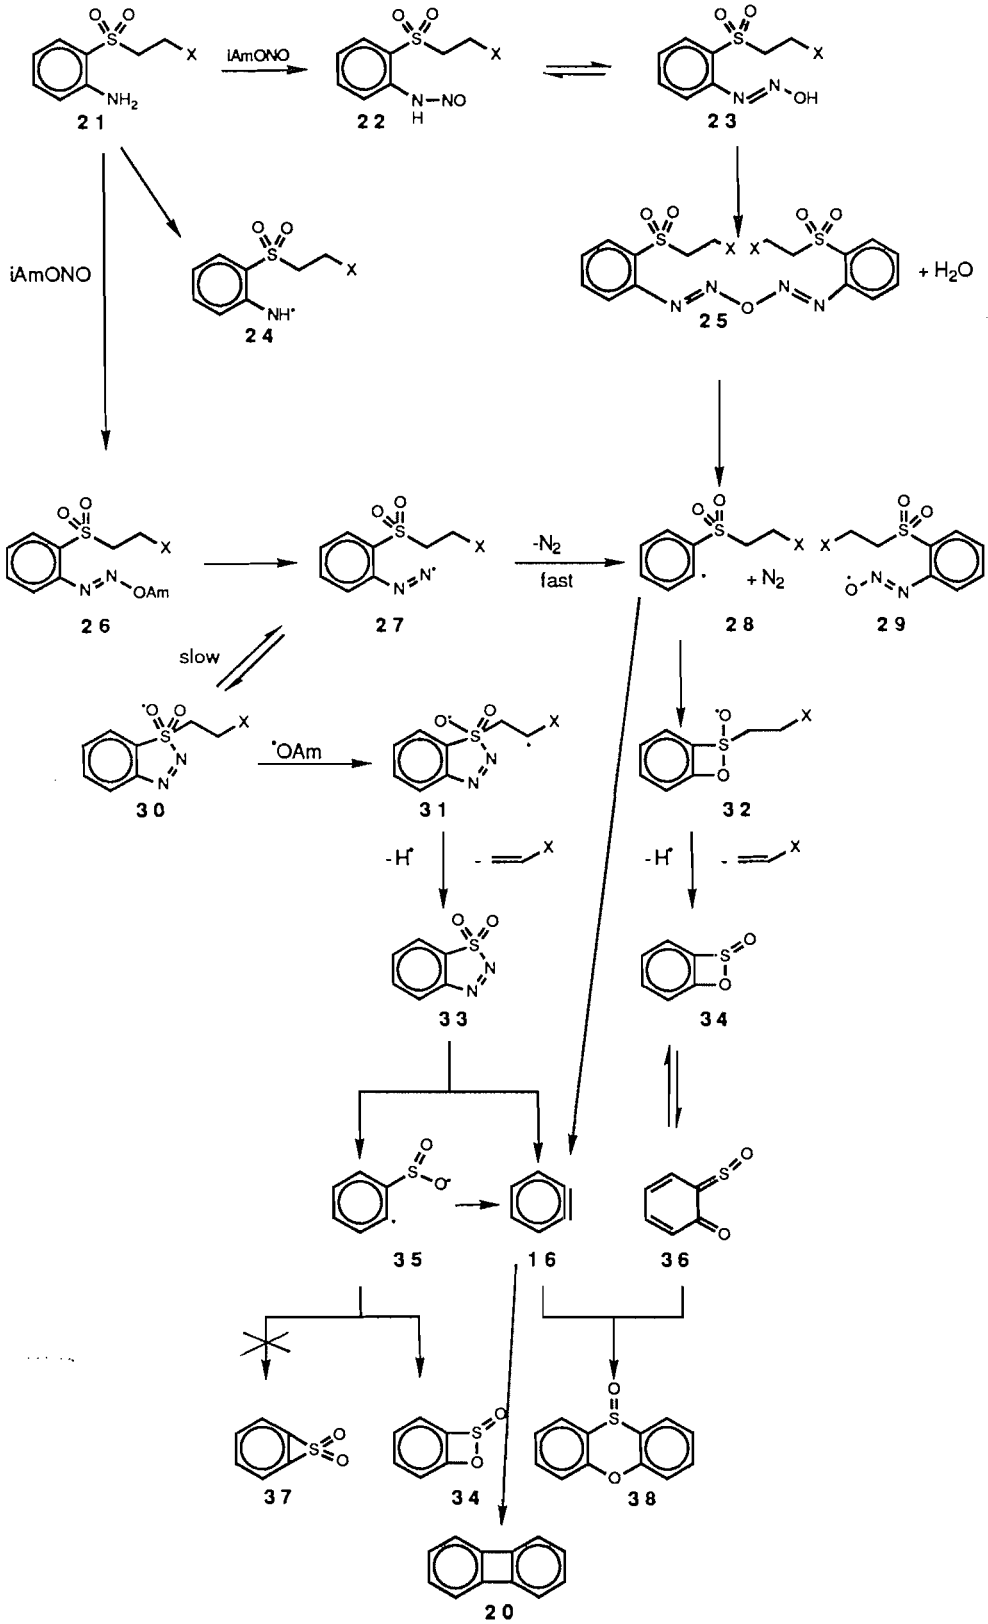

SCHEME 2. Products and alternative pathways of aprotic diazotization of 2-[(2-acetoxyethyl)sulfonyl]aniline with isoamyl nitrite.

where Ar = **28**, *vide infra*) (EPR spectrum is shown in Fig. 1). A similar spectrum was recorded with **III***b*. Evidently, amines **III***a* and **III***b* do not form the intermediate hydroxylamine, similar to **40**, otherwise, upon its oxidation, an EPR spectrum typical for radical **39** would be recorded.

The EPR spectrum of the spin adduct depicted in Fig. 1 does not provide sufficient information to identify the trapped radical unambiguously. This is because hf coupling constants of DMPO adducts with various carbon-centered radicals are very close (13*a*). However, additional evidence in support of the intermediacy of radical species **28** and its discrimination from species **42** was obtained by further spin trapping experiments

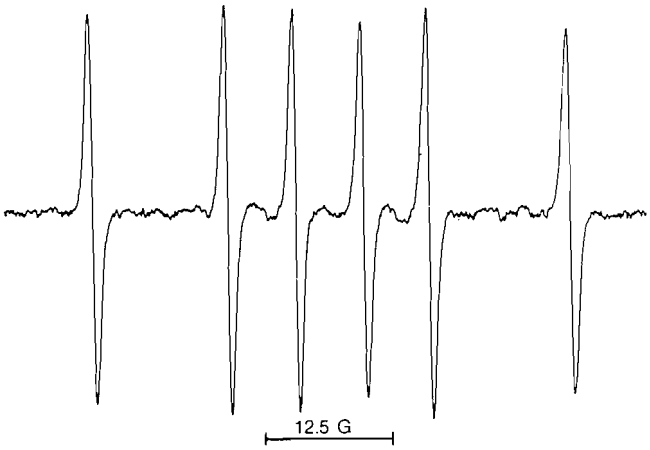

FIG. 1. EPR spectrum derived from a solution of 2-[(2-acetoxyethyl)sulfonyl]aniline (0.1 M), DMPO (10 mM), and isoamyl nitrite (3.5 mM) in deaerated benzene at room temperature. Hyperfine coupling constants are a_N = 14.1 G and $a_{\beta H}$ = 21.2 G.

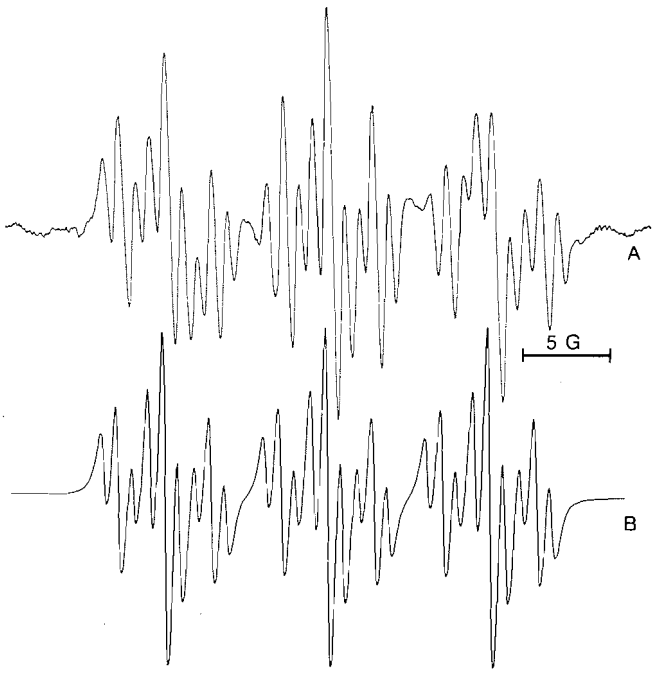

FIG. 2. (*A*) EPR spectrum derived from a solution containing 2-[(2-acetoxyethyl)sulfonyl]aniline (0.1 M), nitrosodurene (5 mM), and isoamyl nitrite (3.5 mM) in deaerated benzene at room temperature. (*B*) Simulated EPR spectrum using the hyperfine coupling constants a_N = 9.6 G, a_H = 2.7 G (2H), a_H = 0.75 G (2H).

using nitrosodurene (ND). In this case the reaction between **21** (**III***a*,*b* Table 1) and iAmONO gave rise to a well resolved and strong EPR signal of an ND adduct with an aryl radical (Fig. 2A). Analysis of the EPR spectrum yielded the following hyperfine splittings: a_N = 9.6 G, a_H = 2.7 G (two equivalent protons), and a_H = 0.75 G (two equivalent protons). Coupling to two pairs of equivalent protons can only arise from the aromatic ring radical **28**. This observation provides support for the assignment of the carbon-centered radical trapped by DMSO to species **28** (*vide supra*). Reaction of **1** with isoamyl nitrite in the presence of ND in benzene produced an EPR spectrum similar to that shown in Fig. 3*A* and was assigned to the ND—Ar (Ar = **8**) spin adduct, for which the following hyperfine coupling constants were determined: a_N = 9.7 G, a_H = 2.99 G (2H), a_H = 1.01 G (2H).

In a control experiment without isoamyl nitrite no spin adduct was obtained. An additional control experiment was performed with aniline, and isoamyl nitrite in benzene which in the presence of nitrosodurene afforded the well resolved EPR spectrum of the phenyl radical spin adduct (12*b*) with hf splittings in agreement with literature reports (12*d*).

Ab initio *calculations of optimized geometries and energies of species implicated in the formation and reactions of benzoxathiete*

Self-consistent field (SCF) *ab initio* calculations were made with full geometry optimization of the energies of relevant species. The *ab initio* calculations at the Hartree–Fock level were performed on products and intermediates using the 3-21G* Gaussian basis set, as implemented in the Gaussian-82 (14) and Gaussian-86 programs (15). The geometry optimizations were performed using the Berny optimization techniques (16). As in our previous studies (4, 5) the inclusion of *d* orbitals is particularly necessary for a good theoretical description of sulfur (17). It may be seen that 1,2,3-benzthiadiazole-1-oxide, **13**, is predicted to be stable relative to the 1,1-dioxide, **33** (Table 2).

Bicyclic species

The energy differences for certain reactions of 1,2,3-benzthiadiazole-1-oxide, **13**, and related structures are given in Table 2. The parent 1,2,3-benzthiadiazole is predicted to be more stable than the *S*-oxide with respect to the oxidation reaction by about 62.8 kJ/mol. Reaction of **13** to give biphenylene **20**, the dimerization product of dehydrobenzene, **16**, nitrogen, and singlet sulfur monoxide is predicted to be mildly exothermic (ΔE = −86.6 kJ/mol). However, the high energy of the transition states (largely due to the high energy of ^{1}SO, as well as of dehydrobenzene) would make **13** very stable relative to this decomposition reaction as is found experimentally. In a related example the high energy of singlet sulfur monoxide resulted in the highly endothermic nature (178.6 kJ/mol) of the orbital symmetry allowed (18) formyl [σ_{2s} + σ_{2a}] cycloreversion of benzoxathiete to singlet sulfur monoxide and the dimer of dehydrobenzene biphenylene (4) (see Table 3). Similar energetic considerations apply to the alternative decomposition of **13** via biradical **15** and thence to dehydrobenzene **16** and biphenylene **20**. Although biradical species **15** (17) may be implicated in alternative pathways (q.v.), its generation via **13** may be discounted since **13** is demonstrably stable under the reaction conditions. The biradical **15**, is, however, a viable intermediate in the pathway from **8** to **16** and **15** is predicted to have substantial stability relative to its decomposition products. The calculated energy of **15** is somewhat artificially low since the triplet also has some quintuplet character mixed in, *i.e.* the spin which has to be perpendicular, so $(\sqrt{s(s+1)})^2 = 2$ is approximately 2.3 for $s(s+1)$.

In contrast the comparable decomposition reaction of 1,2,3-benzthiadiazole-1,1-dioxide, **33**, to biphenylene, sulfur dioxide, and nitrogen is predicted to be highly exothermic with an estimated ΔE = −200 kJ/mol. In this case estimates of the transition state energy are much lower (~148.5 kJ/mol) and may be even lower owing in large part to the stability of SO_2, compared with **13**. This result is in accord with the observed facile generation of biphenylene from **33** formed by further oxidation of the otherwise stable **13**.

In contrast to the situation with **13** where its great stability

[a]Difference in energy between products and reactants.
[b]Estimate of transition state energy for the preceding reaction via intermediate dehydrobenzene.

precludes generation of biradical **15** (at least by this pathway) the facile thermolysis of **33** renders generation of the corresponding biradical **35** quite likely. Since **33** is observed experimentally to decompose to dehydrobenzene and biphenylene (10) it is useful to consider alternative pathways. Energy differences predict a highly exothermic conversion of **35** to biphenylene **20** and sulfur dioxide. In this reaction the transition state energy is estimated to be very low (ca. 18.8 kJ/mol) as in the corresponding reaction of **33**, rendering this pathway quite feasible. Compound **18** was predicted not to be stable and there is no experimental evidence for its contribution in the overall reaction scheme.

Biradical species

Free radical species generated in these reactions have been detected and their structures and reactivities investigated by EPR. In addition, certain biradical species are implicated in the alternative pathways of aprotic diazotization of aryl sulfinyl amines and in the generation of benzoxathiete and related structures (1–5). The results of the *ab initio* calculations permit an examination of their properties and an assessment of the contributions. The consensus of opinion following extensive experimental and theoretical studies of dioxetane decomposition favors a biradical intermediate corresponding to cleavage of the O—O bond (6, 19). Similarly experimental and *ab initio* studies favor biradical intermediates in the formal cycloreversion of 1,2-oxathietane (5) and in the valence tautomerism of benzoxathiete **14** to monothio-*o*-benzoquinone **17** (4). Ring closure of biradical **15**, involved in the latter process, to **14** is predicted to be exothermic.

Although the isomeric biradical **15** is not generated from **13**, at least under the present mild experimental conditions, it

is quite likely to be generated from radical **8**. Therefore its characteristics were examined theoretically. Biradical **15** is surprisingly stable quite close in energy to **14** (Table 4, Fig. 3). The conversion of **15** to biphenylene and ^{1}SO would be highly endothermic. If one considers the high transition state energy for this process via dehydrobenzene (ΔE = 513.1 kJ/mol, endothermic), this pathway is even less likely. While the alternative conversion of **15** to biphenylene and ^{3}SO overall is slightly exothermic, consideration of the high transition state energy (ΔE = 341.6 kJ/mol) indicates this is also not a feasible reaction pathway. In contrast the energy difference for ring closure of biradical **15** to benzoxathiete predicts a facile and slightly exothermic process.

Products of aprotic diazotization of 2-[(2-acetoxyethyl)sulfonyl]-anilines benzoxathiete-S-oxide and its valence tautomer

The situation with the aprotic diazotization of 2-[(2-acetoxyethyl)sulfonyl]anilines is somewhat different in that, in contrast to the very stable compound **13**, 1,2,3-benzthiadiazole-1,1-dioxide (**33**) and the attendant species are plausible intermediates en route to the isolated biphenylene, **20**. Azosulfones are generally in equilibrium with diazonium sulfinates and on

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12
For personal use only.

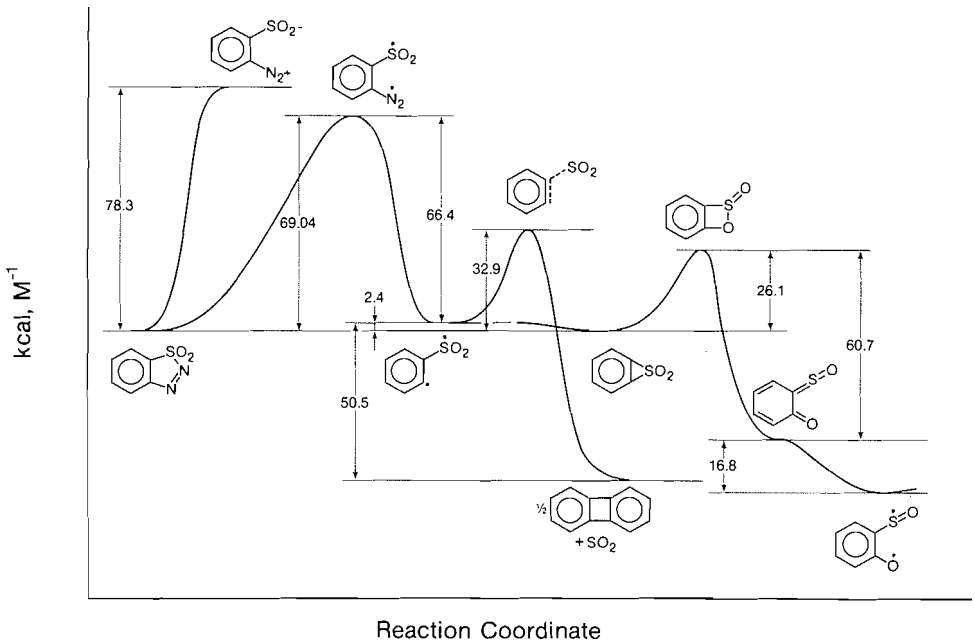

FIG. 4. Depiction of relative energies (derived from *ab initio* calculations) of intermediates and transition states along the reaction coordinate involved in aprotic diazotization of 2-[(2-acetoxyethyl)sulfonyl]aniline and leading to benzoxathiete-*S*-oxide, **34**, and its valence tautomer *o*-benzketosulfine, **36**.

this basis it has been suggested that 1,2,3-benzthiadiazole-1,3-dioxide, **35**, is in equilibrium with *o*-benzenediazonium sulfinate or equivalent biradical species (20). The principle of microscopic reversibility applied to these equilibria provides support for the suggested processes **27** $\rightleftharpoons$ **30** thence to **33**. In addition the isolation of dibenzo-1,4-oxathiane-*S*-oxide, **38**, from further oxidation of **13** and which requires intermediate formation of benzoxathiete-*S*-oxide **34** and its valence tautomer **36** required theoretical examination. Therefore the energetics of these species were examined using quantum chemical methods. Reaction of **33** to give triplet biradical **35** and sulfur dioxide predicts an endothermic reaction with ΔE = 31 kcal/mol. The estimate of the energy of triplet biradical **35** is somewhat low since there is quintuplet character mixed in. However, it is evident that triplet biradical **35** has significant stability.

Alternatively decomposition of **33** to give singlet **35** and sulfur dioxide predicts an even more endothermic process with $\Delta E = 27.8 \times 10^4$ J/mol and, as such, the reaction would not be spontaneous. While generation of biradical **35** is therefore energetically disfavored, compared with spontaneous decomposition of **33** to biphenylene and SO_2 (10), species **35** could reasonably arise by side chain elimination from **28** by analogy with the reaction **8** to **15**. For this reason the energetics of the processes arising from **35** were examined and are summarized in Fig. 4. The behavior of **35** is quite different from that of **15**. Thus the conversion of **35** to biphenylene and SO_2 is predicted to have a ΔE value of -211.3 kJ/mol and the process is expected to be highly exothermic owing largely to the high stability of SO_2. When consideration is taken of the energy of the transition state via dehydrobenzene an estimated activation energy is found to correspond to ΔE = 137.6 kJ/mol.

The corresponding ring closure of biradical **35** to benzoxathiete-*S*-oxide **34** is predicted, like the ring closure of **15** to **14** to be favorable both energetically ($\Delta E = -10.0$ kJ/mol) and entropically. Despite the energetically favored cleavage of **35** to dehydrobenzene and sulfur dioxide, dibenzo-1,4-oxathiane-*S*-oxide, **38**, is obtained from the further oxidation of **13** to **33** and the spontaneous decomposition of the latter. This requires formation of ketosulfine **36** by valence tautomerism of **34** and therefore strongly suggests that ring closure of biradical **35** is rapid.

In view of the precedent of valence tautomerism of benzoxathiete, **14**, to monothio-*o*-benzoquinone, **1** (4), the properties of **34** were examined by *ab initio* treatment. The photochemical generation of the isomeric thiobenzpropiolactone in a solid matrix has been described and its photoelectron spectrum reported and interpreted theoretically (21). Upon optimization, benzoxathiete-*S*-oxide, **34**, has not been found to represent a minimum in energy. A single-point calculation which keeps the SCC and OCC angles frozen at values that insure the formation of the ring leads to an energy value of -772.6064 au (Table 5). An analogy for the suggested valence tautomerism of **14** to **15** and **34** to **36** is that involved in the decomposition of benzenediazonium carboxylate. In this case participation to the incipient unsaturated center gives benzoxetone which is suggested to be in equilibrium with *o*-quinone methide ketene (22). More closely related analogies are those between thiobenzpropiolactone and the corresponding thioketoketene (23), between benzthietekene and the corresponding valence tautomer thioketocumulene (24), and between benzothiete and *o*-quinonemethide (25).

The valence tautomer, **36**, could be optimized to a much lower energy of -772.7012 au, therefore more stable than **34** by 251 kJ/mol. This difference is due to the relief of ring strain (26). As such, valence tautomerism should take place readily (Fig. 5). Species **34** represents a transition state between **35** and **36** since, when SCC and OCC are allowed to relax, **34** reverts to **36**. According to reaction conditions, **34** can revert to biphenylene and SO_2 in a reaction which is predicted to be exothermic. It can be seen from Table 5 that reaction **36** $\rightarrow$ biphenylene and SO_2 is also exothermic. However, a factor that may render observation of **34** or its valence tautomer **36** strongly

dependent on reaction conditions is that cycloreversion of **34** to biphenylene and SO_2 is predicted to be highly exothermic and thus favored energetically. This is in complete contrast to the energetically highly disfavored (though orbital symmetry allowed) reaction of benzoxathiete, **14**, to biphenylene and SO (4). The fact that **34** is not a stable species might explain why compound **38** was not detected in the aprotic diazotization of 2-[(2-acetoxyethyl)sulfonyl]aniline.

Conclusions

1,2,3-Benzthiadiazole-1-oxide, **13**, previously considered an intermediate in one pathway of formation of benzoxathiete via the aprotic diazotization of 2-[(2-acetoxyethyl)sulfonyl]anilines (4), has been synthesized by an unambiguous method. This previously unreported compound proved to be indefinitely stable at ambient temperatures so that the possibility of its giving rise to dehydrobenzene spontaneously in solution must be discounted. The marked thermal stability of **13** (up to the temperature of refluxing *o*-dichlorobenzene) is fully in accord with the *ab initio* calculation of its energy and in relation to its putative decomposition products. The more extensive EPR experiments described herein also tend to favor the pathway **1** → **2** → **3** → **5** → **8** → **12** as the principal route to benzoxathiete and disfavor the intermediacy of radical **7**, the logical precursor to **13**. The energetics of the processes from species **15** (derived from **8**) are depicted in Fig. 3. Literature precedents exist for each of the key steps: (*i*) step **1** → **2** (27–29); (*ii*) equilibrium **2** ⇌ **3** (28, 29); (*iii*) formation of the anhydride of diazohydroxide **5** (30); (*iv*) formation of diazotate ester **6** (31); (*v*) generation of the carbon centered radical **8** via rapid dediazionation of **7** (31–34) or homolysis of a diazoanhydride **5** (30); (*vi*) facile ring closure of radical **8** to **12** (13*b*,*c*); (*vii*) free radical abstraction of hydrogen atom from alkyl side chain, e.g., **28** → **42** (13*b*,*c*).

The synthesis of compound **13** afforded an opportunity to attempt further selective oxidation to the corresponding 1,2,3-benzthiadiazole-1,1-dioxide, **33**, which is a possible intermediate in the generation of dehydrobenzene during comparable aprotic diazotization of 2-[(2-acetoxyethyl)sulfonyl]aniline with isoamyl nitrite. 1,2,3-Benzothiadiazole-1,1-dioxide is conventionally generated by treatment of sodium salt of 2-aminobenzenesulfinic acid with sodium nitrite in aqueous sulfuric acid at −15°C (10). It is not normally isolated because of its great instability and tendency to explode spontaneously in the solid state (10).

In the event prolonged treatment of 1,2,3-benzthiadiazole-1-oxide, **13**, with hydrogen peroxide in acetic acid at ambient temperatures or rose bengal sensitized photooxidation afforded, among the products, biphenylene and dibenzo-1,4-oxathiane-*S*-oxide, **38**. Since the monooxide **13** is stable at this temperature this result implies selective S-oxidation to the 1,1-dioxide, **33**, and spontaneous decomposition of the latter with formation of dehydrobenzene **16** and concomitant generation of biradical **35** by loss of nitrogen. Rapid ring closure of **35** gives benzoxathiete-*S*-oxide, **34**, which reverts immediately via valence tautomerism to the ketosulfine **36**. Thus the chemical behavior and products derived from **33** are sensitive to reaction conditions. This may explain why **38** was not detected among the products of the aprotic diazotization of 2-[(2-acetoxyethyl)sulfonyl]anilines. Conceivably radical **28** may decompose directly to **16**, thereby preventing the formation of species **32**. Trapping of **36** from **34** by dehydrobenzene gives **38** and dimerization of **16** affords biphenylene.

EPR evidence in conjunction with spin trapping experiments employing both DMPO and nitrosodurene unambiguously identify an aryl radical intermediate, corresponding to **28**. Since the major product of aprotic diazotization is biphenylene **20** derived from dimerization of dehydrobenzene **16** the experimental evidence suggests radical **28** converts to **35** or **16**

in preference to species **32**. The energetics of the processes following from the biradical species **35** (and derived from either **28** or **33**) are depicted in Fig. 4.

The solution-phase photochemistry of 2-trifluoromethylnorbornene

N. NGUYEN, B. E. HARRIS, K. B. CLARK,[1] AND W. J. LEIGH[2]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received March 28, 1990

N. NGUYEN, B. E. HARRIS, K. B. CLARK, and W. J. LEIGH. Can. J. Chem. **68**, 1961 (1990).

The photochemistry of 2-trifluoromethylnorbornene in pentane solution has been investigated. Direct photolysis with 193 nm light yields 1-trifluoromethyl-2-norcarene in 90% yield, due to formal [1,3]-sigmatropic rearrangement, in addition to three other minor products. Chlorobenzene-sensitized photolysis affords photoreduction products, principally *exo*- and *endo*-2-trifluoromethylnorbornane and decane isomers, in addition to several products of higher molecular weight. On the basis of comparisons of the photochemistry of this compound to that previously reported for norbornene and 2-cyanonorbornene, as well as spectroscopic evidence, it is suggested that the lowest excited singlet state (the photoreactive state in solution) in 2-trifluoromethylnorbornene is the π,π^* state. The results indicate that trifluoromethyl substitution has the effect of significantly raising the energy of the π,R(3*s*) Rydberg state in simple alkenes, without altering the high energy (*ca.* 6.5 eV) or the localized character of the alkene π,π^* state. Furthermore, they lend additional support to the view that the carbene-derived products typically formed upon photolysis of alkenes in solution are derived from π,R(3*s*) excitation.

Key words: Rydberg, photolysis, far-uv, alkene, solution phase, singlet, triplet.

N. NGUYEN, B. E. HARRIS, K. B. CLARK et W. J. LEIGH. Can. J. Chem. **68**, 1961 (1990).

On a étudié la photochime du 2-trifluoromethylnorbornene, en solution dans le pentane. La photolyse directe avec de la lumière à 193 nm fournit du 1-trifluorométhyl-2-norcarène avec un rendement de 90%, en plus de trois autres produits qui sont présents en quantités mineures; le produit principal se forme par le biais d'une transposition formelle [1,3]-sigmatropique. La photolyse sensibilisée par le chlorobenzène fournit des produits de photoréduction, principalement les isomères *exo*- et *endo*-2-trifluorométhylnorbornanes et décanes, en plus de plusieurs produits de poids moléculaires élevés. En se basant sur des données spectroscopiques ainsi que sur une comparaison de la photochimie de ce composé avec celles rapportées antérieurement pour le norbornène et pour le 2-cyanonorbornène, on suggère que l'état excité singulet de plus basse énergie (l'état photoréactif en solution) du 2-trifluorométhylnorbornène est l'état π,π^*. Les résultats indiquent que la substitution par un groupement trifluorométhyle a pour effet d'augmenter considérablement l'énergie de l'état Rydberg π,R(3*s*) des alcènes simples sans toutefois altéré l'énergie élevée (environ 6,5 eV) ou le caractère localisé de l'état π,π^* de l'alcène. De plus, ces résultats ajoutent un poids additionnel à la théorie selon laquelle les produits dérives des carbènes, qui se forment d'une façon typique par photolyse des alcènes, sont dérivés d'une excitation π,R(3*s*).

Mots clés : Rydberg, photolyse, UV lointain, alcène, solution, singulet, triplet.

[Traduit par la revue]

Introduction

The photochemistry of simple alkenes in solution has been a subject of intense interest over the past three decades (1–5). The complex photobehaviour that is frequently observed on direct irradiation of aliphatic olefins in solution has been attributed to the involvement of two singlet excited states of comparable energies, the π,π^* valence and the π,R(3*s*) Rydberg states (1). The π,π^* state is thought to lead to *cis,trans*-isomerization in acyclic and larger-ring cyclic (*i.e.*, $\geq C_6$) alkenes, and hydrogen-abstraction reactions. The π,R(3*s*) Rydberg state has been proposed to be responsible for the products of carbene intermediates derived from [1,2]-hydrogen or -alkyl shifts and in alcohol solvents, the products of nucleophilic addition to the C=C bond (1). Products attributable to formal [1,3]-H or -alkyl migration are also frequently observed in alkene photochemistry (1–4), and their origin has been subject to some discussion (6). In general, these products may arise from either concerted pathways or stepwise ones involving carbene intermediates, and thus may derive from either the π,π^* or π,R(3*s*) state. Inoue and co-workers have suggested that yet a third singlet excited state may in fact be responsible for the formation of [1,3]-hydrogen migration products in solution-phase alkene photolysis, on the basis of their observation of wavelength-dependence in the photochemistry of 2,3-dimethyl-2-butene and *cis*-2-octene (6). In our view, however, the evidence in support of this proposal is not compelling.[3]

The assignment of carbene-derived products as due to π,R(3*s*) excitation in simple alkenes has been made largely on the basis of gas-phase uv absorption (7, 8*a*) and (solution-phase) fluorescence emission studies (9), which indicate that this state is lower in energy than the spectroscopic π,π^* state in most cases. In tri- and tetraalkyl-substituted olefins, the π,R(3*s*) is thought to be lower in energy than the twisted π,π^* singlet state. These studies have further shown that the energy of the π,R(3*s*) state is markedly more sensitive to alkyl substitution than the π,π^* state; increasing the degree of alkyl substitution at the C=C bond results in a lowering of energies of both the π,R(3*s*) and π,π^* states, the former more than the latter (7, 8*a*). A similar effect is observed on alkene π-ionization potentials (IP's) (8*a*, 10). Since the relative yield of carbene- versus π,π^*-derived products from alkene photolysis

[3]The evidence for the third photoreactive state in simple alkenes is that longer excitation wavelengths result in reduced yields of 1,3-H migration products relative to carbene-derived (π,R(3*s*)) ones in the photolysis of 2,3-dimethyl-2-butene, and to $E \rightleftarrows Z$ isomerization (π,π^*) in the photolysis of *cis*-2-octene. Strictly speaking though, these experiments demonstrate only that [1,3]-H migration is not Rydberg-derived in the case of 2,3-dimethyl-2-butene, and not π,π^*-derived in the case of *cis*-2-octene. The indication that it is not π,π^*-derived in the latter compound does not preclude it from being so in the former compound. In the case of 2-octene, these products could result from carbenes derived from the π,R(3*s*) state.

in solution also increases with increasing alkyl substitution on the double bond (1), the identification of the $\pi,R(3s)$ state as that responsible for the formation of carbene-derived products seems to be a logical one. In addition, the product distribution from solution-phase photolysis of tetramethylethylene is wavelength dependent, with the yields of carbene-derived products increasing relative to [1,3]-migration product at longer excitation wavelengths (6).

[1,2]-Migrations are also common in the photochemistry of β-alkylstyrene derivatives (11, 12). Hixson and co-workers have demonstrated that these products, as well as those of formal [1,3]-H or -alkyl migration, are in fact formed by complex pathways involving carbenes (12). The state responsible for carbene formation in phenylated alkenes has not been identified, however. In benzenoid systems, the $\pi,R(3s)$ state is higher in energy than the lowest π,π^* state (8*b*).

The photochemistry of simple alkenes is thus often complex, even in monosubstituted systems. As a further aid to the assignment of alkene photoproduct types to the involvement of specific excited states, it is desirable to be able to selectively excite one state or the other. This is usually not possible by simple variation of the excitation wavelength (*cf.* ref. 6, however), so it is necessary to alter the state-separation through substitution on the alkene. As mentioned above, increasing alkyl substitution at the C=C bond can be employed to lower the Rydberg state energy at the expense of that of the π,π^* state. Conjugative substituents can of course be used to lower the energy of the π,π^* state at the expense of the Rydberg, but this also changes the basic character of the chromophore. We wished to develop a means of *raising* the energy of the $\pi,R(3s)$ state so that the π,π^* state would be rendered lower in energy, but still maintain the high energy and localized character of the basic system.

The $\pi,R(3s)$ state can be considered to have radical–cation character at the double bond (7), since the 3*s* orbital is quite diffuse and is approximately of *molecular* size for small alkenes such as tetramethylethylene. With this simple picture in mind, we reasoned that substitution at the C=C bond with nonconjugative electron-withdrawing groups such as trifluoromethyl might have the desired effect of raising the energy of the $\pi,R(3s)$ state without substantially affecting the energy or localized nature of the ethylenic π,π^* singlet state. In this paper, we describe the results of a study of the photochemistry of 2-trifluoromethylnorbornene (**1**) in hydrocarbon solution. This compound was chosen for our initial study because it is easily synthesized and the photochemistry of norbornene (**2**) and 2-cyanonorbornene (**3**) have both been reported (13–15). Compounds **2** and **3** are excellent model compounds with which to compare the behaviour of **1**; direct photolysis of **2** yields predominantly carbene-derived products upon photolysis in solution (13, 14), while **3** affords only products consistent with π,π^* photochemistry (15). We have coupled this study with gas-phase spectroscopic studies of **1**, **2**, and 2-methylnorbornene (**4**), which are reported in a separate paper (16).

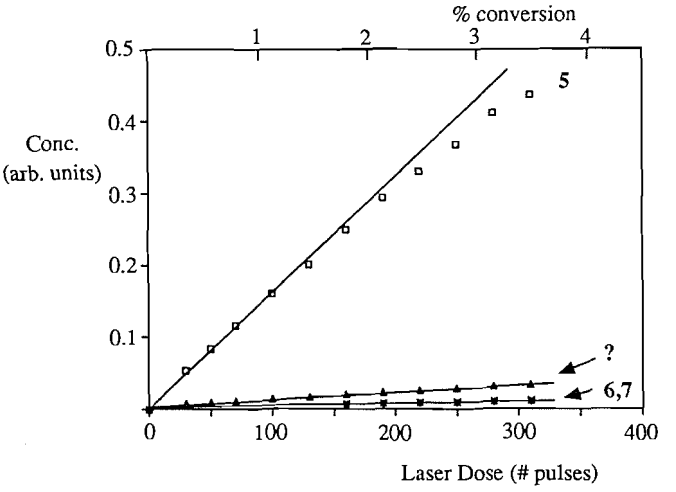

FIG. 1. Plots of product concentration vs. excitation dose from 193 nm photolysis of **1** as a deoxygenated, 0.02 M pentane solution.

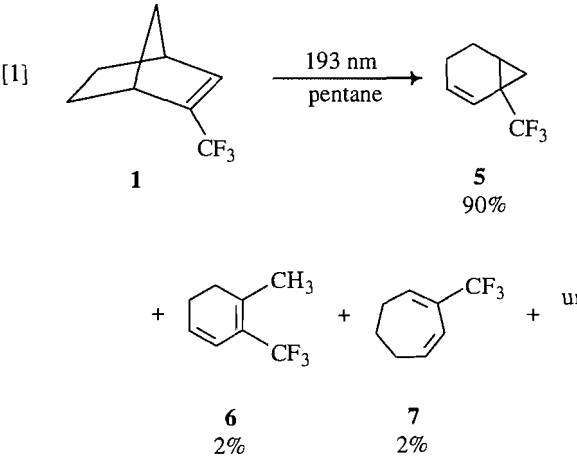
Results

Compound **1** was synthesized by free radical addition of trifluoromethyl iodide to norbornene (17), followed by base-catalysed elimination with potassium *tert*-butoxide (18). It was purified by preparative vapour-phase chromatography (vpc) to >99.5% purity.

Photolysis of a deoxygenated, 0.02 M pentane solution of **1** with the pulses (193 nm, *ca.* 40 mJ) from an Ar/F_2 excimer laser led to the product mixture shown in reaction [1].



1 → **5** 90%

+ **6** 2% + **7** 2% + 6%

Products **5–7** were isolated by preparative vpc from semi-preparative runs (*ca.* 300 mg scale) carried to *ca.* 40% conversion, and were identified on the basis of their ^1H, ^{13}C, and ^{19}F nmr, infrared, uv absorption, and mass spectra. The photolysate also contained one other component (*ca.* 6%) for which quantities adequate for its identification could not be obtained. A major factor in the identification of **5** was the fact that its ^1H and ^{13}C nmr spectra show very marked similarities to

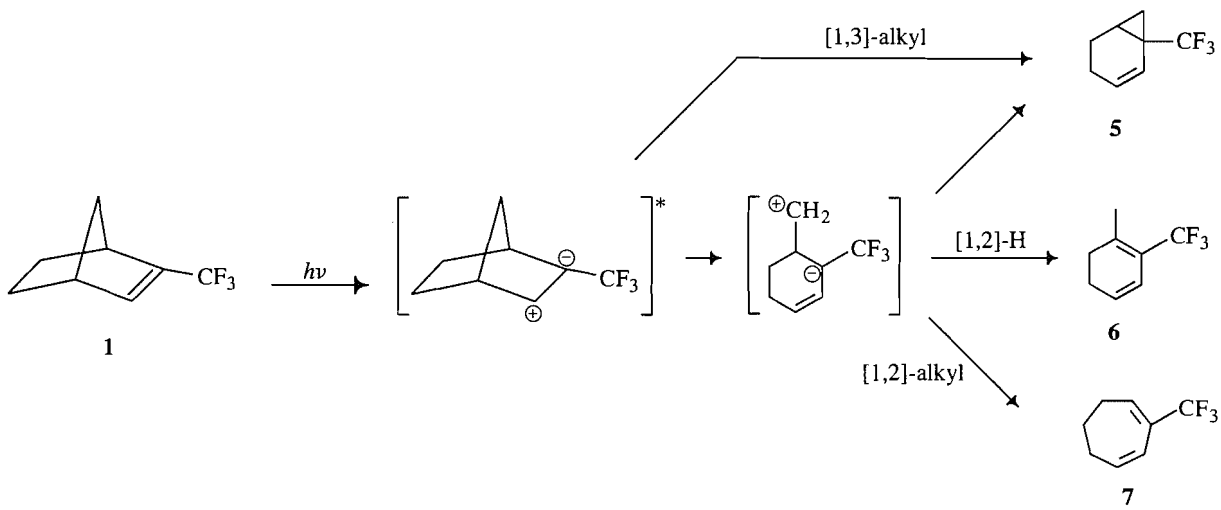


SCHEME 1

those reported for the analogous cyano-substituted derivative (*vide infra*), which is the major product from direct photolysis of **3** in solution (15). The structure of this compound was proven by X-ray crystallography of a derivative.

Product yields listed in reaction [1] were obtained from the slopes of plots of product concentration versus excitation dose, constructed from small scale runs that were monitored between 0.3 and 4% conversion. Typical plots of this type are shown in Fig. 1. The material balance is estimated to be at least 98% at 4% conversion.

To verify that **6** and **7** are primary products from photolysis of **1** and do not arise from secondary photolysis of **5** (products of this type are known to result from direct photolysis of 2-norcarene derivatives (19)), a deoxygenated pentane solution of the latter (0.02 M) was photolysed at 193 nm under similar conditions to those used for the photolysis of **1**. As expected, **6** and **7** are formed from photolysis of **5**, but only as minor products. The major products in this photolysis were not identified, but could not be detected as products from the photolysis of **1** at low (<10%) conversions, within the accuracy limits of our analytical method.

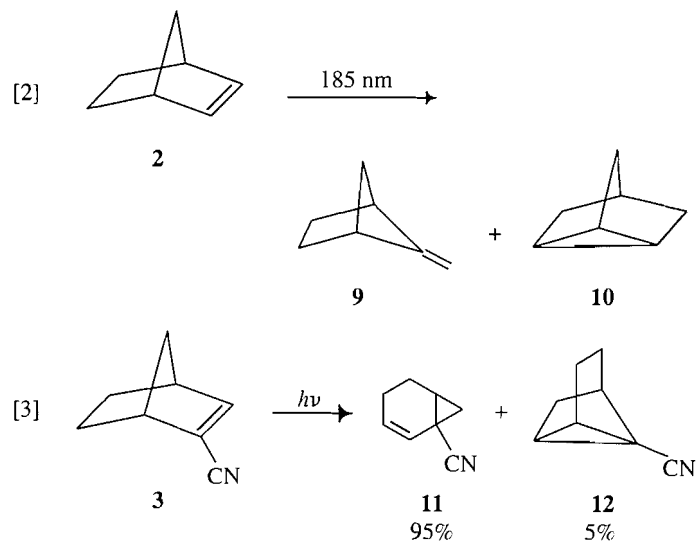
Chlorobenzene- or toluene-sensitized photolysis of a deoxygenated 0.01 M solution of **1** in pentane (containing 0.02 M sensitizer) afforded similar, complex mixtures of products. The major volatile products of chlorobenzene-sensitized photolysis are *exo*- and *endo*-2-trifluoromethylnorbornane (**8**) (formed in roughly equal yields) and three isomers of decane (due presumably to coupling of 2- and 3-pentyl radicals). The structures of *exo*- and *endo*-**8** were assigned on the basis of their ^{1}H nmr, ir, and mass spectra, after isolation from the crude photolysate by semi-preparative vpc. Several products of higher molecular weight were also formed in these photolyses. Gas chromatographic/mass spectroscopic (gc/ms) analysis indicated three of these to have parent ions of 234 amu, corresponding to addition products of **1** with the solvent. In addition, a product of parent ion mass 274 amu was formed in minor yield, and is presumably a cycloaddition product between **1** and the sensitizer. None of the products formed in the direct photolysis of this compound could be detected in the sensitized photolysis.

Discussion

The major product from direct photolysis of **1** is formally the product of a [1,3]-sigmatropic shift, although the formation of all three identified products can be rationalized as arising from a common mechanistic pathway which involves initial heterolytic cleavage of the C_4—C_7 bond in **1** (Scheme 1). Such a cleavage would be expected to be facilitated by zwitterionic character in the singlet excited state of **1**, as depicted in Scheme 1. The zwitterionic intermediate so formed can then collapse to form **5**, undergo [1,2]-H migration to yield **6**, or ring expansion to yield **7**. Naturally, it is not possible to define whether **5** is formed by one or both of these two possible routes.

The products of chlorobenzene- and toluene-sensitized photolysis of **1** are analogous to those observed in the toluene- or xylene-sensitized photolyses of norbornene and other substituted derivatives, and presumably involve the alkene triplet state (20). The absence of **5**–**7** as products of the sensitized photolysis of **1** suggests that in the direct photolysis, these products are formed exclusively via the singlet excited state(s). This is not surprising, since intersystem crossing in alkenes is generally relatively inefficient (1).

The photochemistry of **1** is to be compared to that reported previously for norbornene (**2**; reaction [2] (13, 14)) and 2-cyanonorbornene (**3**; reaction [3] (15)). The main products from



photolysis of **2** (*i.e.*, **9** and **10**) are thought to derive from carbenes formed via [1,2]-alkyl and [1,2]-H migrations, respectively, in the π,R(3*s*) state (reaction [4]). Norbornane,

[4]

norbornyl dimers, solvent-addition products, and solvent-derived dimers formed as minor products in the photolysis of **2** presumably arise from H-abstraction from the solvent (14). Carbene-derived products are also the main ones in the photolyses of monocyclic (C_5–C_7) alkenes in solution (1, 13, 14, 21–24). Gas-phase uv absorption studies have identified the π,R(3*s*) state as the lowest energy (vertical) excited singlet state in these systems (8*a*). While the oscillator strengths of Rydberg transitions drop dramatically in the condensed phase and the band is slightly blue-shifted (8), photochemical (6) and spectroscopic (9) results indicate that Rydberg state population in solution is most efficient by direct excitation of the absorption band (as opposed to internal conversion from more intensely absorbing upper states).

In the gas phase, the lowest energy (vertical) excited singlet state of norbornene (**2**) is the π,R(3*s*) state (7, 8*a*, 16), but the 0,0 level appears to be similar in energy to that of the π,π^* state. In solution, the Rydberg levels are shifted to slightly higher energies compared to the valence levels (Rydberg absorptions are not visible in the solution phase uv spectrum of **2** (16)) (7, 8*a*, 16). In the case of **1**, gas-phase optical and energy loss spectroscopies demonstrate that the π,R(3*s*) absorption maximum is shifted to much higher energies than it is in **2** (by *ca.* 0.4 eV), placing it slightly higher in energy than the π,π^* absorption maximum. Thus, the *absence* of carbene-derived products in the direct photolysis of **1** provides additional support for the notion that in the case of **2** and other simple alkenes, such products result from π,R(3*s*) excitation.

The lowest energy singlet excited state in **3** is the π,π^* state (15), which is lowered below the π,R(3*s*) state due presumably to the conjugative effect of the —CN substituent. Furthermore, this substituent should raise the energies of the Rydberg manifold relative to the situation in **2** because of the correlation between Rydberg state energies and π-ionization potential of the alkene (8*a*). Accordingly, the photochemistry of **3** is markedly different from that of **2**, the major product (**11**) being derived from formal (*supra, supra*) [1,3]-migration of the bridgehead carbon from C_4 to C_2. The minor product from photolysis of **3** (*i.e.*, **12**) was formalized by McCullough and co-workers as arising from a ($\sigma_{2a} + \pi_{2a}$) [1,2]-migration pathway analogous to that postulated to account for the photochemistry of β-alkylstyrene derivatives (11, 12).

The main product from photolysis of **1** is the [1,3]-migration product analogous to that obtained from **3**. This suggests that the configuration of the lowest excited singlet states (or at least, the photoreactive singlet states) in these two compounds are identical, although they are very different in energy. It is interesting that the formation of **12** can be viewed in terms of a zwitterionic rearrangement pathway similar to that shown for **1** in Scheme 1, invoking C5-to-C3 migration in the excited state of **3** (instead of C7—C6 bond cleavage). On the basis of our spectroscopic studies of **1** (16), the π,π^* state is very strongly implicated as the primary photoreactive state in the solution-phase photolyses of **1** and **3**.

Conclusions

Trifluoromethyl-substitution has profound effects on the ordering of the lowest Rydberg and π,π^* singlet excited states in simple alkenes. In di-, tri-, and tetraalkyl substituted olefins, the π,R(3*s*) state is similar or lower in energy than the π,π^* state, and the photochemistry in solution is dominated by [1,2]-alkyl and -hydrogen migrations leading to carbene intermediates. Trifluoromethyl-substitution raises the energies of states in the Rydberg manifold due to the strong inductive electron-withdrawing power of the —CF_3 group, without altering the energy or localized character of the π,π^* state. Accordingly, the photoreactivity of such alkenes can be viewed as typical of π,π^* state excitation, and provides a further indication that carbene-derived products from photolysis of simple alkenes result from π,R(3*s*) excitation. The use of trifluoromethyl substituents to delineate "true" π,π^* state reactivity should prove to be of considerable mechanistic value in other simple olefinic systems that exhibit complex photobehaviour. Studies of this type are in progress.

Experimental

The ^{1}H, ^{13}C, and ^{19}F nmr spectra were recorded in $CDCl_3$ solution on a Bruker AM500 (500 MHz) spectrometer and are reported in ppm downfield from tetramethylsilane (^{1}H and ^{13}C) or external fluorotrichloromethane (^{19}F). Infrared spectra were recorded on a Perkin-Elmer 283 spectrometer in $CDCl_3$ solution; spectra are reported in wavenumbers, calibrated against polystyrene. Mass spectra were recorded on a Finnigan 4000 mass spectrometer (Model 4500 ion source), interfaced with a Finnigan gas chromatograph, equipped with a 60 m × 1.0 μm DB1-30W fused silica capillary column (Chromatographic Specialties, Inc.), or a VG7070 mass spectrometer coupled with a Varian 3700 gas chromatograph, equipped with a 60 m × 0.25 mm DB-1701 fused silica capillary column (Chromatographic Specialties, Inc.). Exact masses were determined on a VGH ZABE mass spectrometer, and employed a mass of 12.000 000 for carbon. Ultraviolet absorption spectra were recorded in pentane solution using a Perkin-Elmer Lambda 9 spectrometer equipped with a Model 3600 data station.

Analytical vpc separations were carried out using a Hewlett-Packard 5890 gas chromatograph equipped with a flame ionization detector, a Hewlett-Packard 3396 recording integrator, and a 1.0 μm SPB-1 wide-bore capillary column (30 m × 0.75 mm id borosilicate; Supelco, Inc.). Semi-preparative vpc separations employed a Hewlett-Packard 5750B gas chromatograph equipped with a thermal conductivity detector and one of the following stainless steel columns: (*a*) 3% OV-17 on 80/100 Chromosorb WAW (6′ × 0.25″; Supelco, Inc.); (*b*) 15% Carbowax 20M on 60/80 Chromosorb W (5′ × 0.25″; Supelco, Inc.); (*c*) 3.8% UCW 982 on 80/100 Supelcoport (24′ × 0.25″; Supelco, Inc.); (*d*) 20% tris(cyanoethoxy)propane (TCEP) on 80/100 Chromosorb PNAW (6′ × 0.25″; Supelco, Inc.).

n-Pentane (Baker Photrex), 2,2,4-trimethylpentane (isooctane; Baker Photrex), trifluoromethyl iodide (Columbia), dimethylsulfoxide (Fisher), chlorobenzene (Fisher Reagent), toluene (Fisher Reagent), and potassium *tert*-butoxide (Aldrich) were used as received from the suppliers. Norbornene (Aldrich) was vacuum distilled before use.

2-Trifluoromethylnorbornene (**1**) was prepared using the following typical procedure (17, 18). In a thick-walled Pyrex tube (6″ × 1″ o.d.) fitted at one end with a Rotaflo stopcock was placed norbornene (10 g, 0.106 mmol). The tube was attached to a vacuum line via a rubber hose,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/07/12

and degassed twice by the freeze–pump–thaw method. It was then placed on a balance in a Dewar containing liquid nitrogen, and trifluoromethyl iodide (40.0 g, 0.2 mol) was introduced through a separate stopcock on the vacuum line. The stopcock was closed, and the tube was removed from the vacuum line. After allowing the contents to melt and the norbornene to dissolve, the tube was placed in a quartz Dewar containing Dry Ice/isopropanol at *ca.* −30°C in a Rayonet reactor. The solution was then irradiated with twelve 300 nm Rayonet lamps until it turned yellow (*ca* 6 h), periodically adding Dry Ice to the Dewar to maintain a temperature below *ca.* −30°C. The tube was reattached to the vacuum line and excess trifluoromethyl iodide was separated from the product by distillation into another sealable Pyrex tube (cooled with liquid nitrogen). The slightly yellow liquid that remained (30.5 g) was used without further purification in the following step. On the basis of its 90 MHz ^{1}H nmr spectrum (Varian EM390; $CDCl_3$; δ (ppm) = 1.27 (t, 2H), 1.4–1.9 (m, 4H), 2.1–2.5 (m, 3H), 4.14 (m, 1H)), the major component of the liquid was identified as 2-iodo-3-trifluoromethylbicyclo[2.2.1]heptane (17).

In a large Pyrex tube containing deoxygenated dimethyl sulfoxide (25 mL) and potassium *tert*-butoxide (1.5 g) was placed a portion of the product from the above reaction (2.0 g; 6.8 mmol), resulting in a yellow solution. The tube was placed in a Dry Ice/isopropanol bath, evacuated and sealed, and then heated at 60°C for 12 h. The tube was opened and the deep red reaction mixture was placed in a separatory funnel. Water (25 mL) was added and the resulting mixture was extracted with *n*-pentane (4 × 15 mL). The combined extracts were washed thrice with water, dried over anhydrous sodium sulfate, and filtered. Careful removal of the solvent by distillation afforded a yellow liquid. This was bulb-to-bulb distilled under vacuum to yield a colourless liquid that was shown to consist of 2-trifluoromethylnorbornene (**1**; 0.44 g, 2.7 mmol, 40%) contaminated with a small amount (<5%) of residual *n*-pentane and dimethyl sulfoxide (by vpc analysis). Compound **1** was purified by semi-preparative vpc, using one pass through column a to remove residual DMSO followed by two passes through column b, after which it was > 99.8% pure by vpc. Compound **1** has the following spectral properties:

*2-Trifluoromethylbicyclo[2.2.1]hept-2-ene (**1**).* ^{1}H nmr: δ (ppm) = 1.07 (m, 1H), 1.19 (m, 2H), 1.53 (m, 1H), 1.73 (m, 2H), 2.98 (br s, 1H), 3.08 (br s, 1H), 6.46 (br s, 1H); ^{13}C nmr: δ (ppm) = 24.4, 24.7, 41.3, 42.5, 49.1, 124.2, 137.8, 138.7; ^{19}F nmr: δ (ppm) = −65.3; ir (neat): 3010 (sh, w), 2982 (s), 2881 (m), 1626 (m), 1450 (w), 1356 (s), 1299 (s), 1269 (m), 1233 (m), 1150 (s), 1101 (s), 1037 (s), 876 (m), 843 (m), 831 (w), 730 (w), 688 (m); ms (m/e (I)): 162 (6), 134 (93), 135 (7), 127 (8), 115 (9), 114 (10), 93 (4), 91 (4), 84 (6), 65 (6); Mass calcd. for $C_8H_9F_3$: 162.0656. found: 162.0664; uv (λ_{max} (ε)): 194 nm (3190).

Analytical and preparative-scale photolysis experiments used pulses (193 nm, *ca.* 15 ns, *ca.* 40 mJ) from a Lumonics TE-861M excimer laser filled with an argon/fluorine/helium mixture. Analytical photolyses were carried out at ambient temperature (*ca.* 22°C) in rectangular cells constructed from 10 × 20 mm rectangular Suprasil tubing (Vitro Dynamics), using a 0.5–1 Hz laser pulse repetition rate. Solutions of **1** and isooctane (as internal standard) in *n*-pentane were deoxygenated with argon prior to irradiation, and the sample was agitated during photolysis with a magnetic stirrer. The course of photolysis was monitored between 0.2 and 4% conversion, with aliquots being removed periodically for vpc analysis. Relative product yields were determined from the slopes of concentration vs. laser dose constructed for all components of the mixture relative to the internal standard. The vpc detector was not calibrated for variations in response towards the different products.

Preparative scale (*ca.* 300 mg) photolyses were carried out in 2″ × 2″ cylindrical cells with Suprasil windows (*ca.* 50 mL volume), using a 6 Hz laser pulse repetition rate and vigorous stirring of the predeoxygenated solutions during photolysis to *ca.* 40% conversion (monitoring by vpc). After photolysis, the pentane was carefully distilled from the mixture through a long Vigreux column. The residue from the distillation was bulb-to-bulb distilled under vacuum, and the products were separated by preparative vpc using column *a*. One product (*ca.* 6% yield) could not be isolated in pure form since it eluted just slightly before **1** on all three vpc columns employed in this work. The photolysis products, listed in order of vpc retention time on column, a, had the following spectral characteristics.

*1-Trifluoromethylbicyclo[4.1.0]hept-2-ene (**5**).* ^{1}H nmr: δ (ppm) = 0.92 (t, 1H), 1.21 (m, 1H), 1.57 (m, 1H), 1.74 (m, 2H), 1.93 (m, 1H), 2.03 (m, 1H), 5.64 (m, 1H), 6.02 (dd, 1H); ^{13}C nmr: 14.7, 17.1, 18.1, 20.0, 122.7, 125.7, 127.7 (q); ^{19}F nmr: −65.3; ir: 3050 (w), 2940 (m), 2870 (w), 1442 (w), 1412 (m), 1394 (m), 1354 (s), 1334 (s), 1318 (s), 1181 (m), 1162 (s), 1147 (s), 1134 (s), 1067 (m), 927 (w), 689 (m); ms (*m/e* (I)): 162 (36), 147 (22), 141 (7), 127 (64), 114 (6), 115 (5), 93 (100), 83 (6), 77 (54), 65 (23); Mass calcd. for $C_8H_9F_3$: 162.0656; found: 162.0665; uv (λ_{max} (ε)): 200 nm (830).

*1-Methyl-2-trifluoromethyl-1,3-cyclohexadiene (**6**).* ^{1}H nmr: δ (ppm) = 1.95 (br s, 3H), 2.14 (m, 2H), 2.21 (m, 2H), 5.78 (dt, 1H), 6.00 (tt, 1H); ^{13}C nmr: 20.3, 21.6, 30.7, 120.7, 124.9 (quaternary carbons not detected); ^{19}F nmr: −60.3; ir: 2940 (s), 2880 (w), 2840 (w), 2340 (w), 1650 (w), 1600 (w), 1420 (w), 1410 (w), 1360 (s), 1305 (s), 1160 (s), 1120 (s), 1030 (s), 887 (w), 704 (w), 636 (m); ms (*m/e* (I)): 162 (24), 147 (17), 141 (4), 134 (10), 127 (60), 93 (100), 91 (40), 77 (50), 69 (8), 65 (16); Mass calcd. for $C_8H_9F_3$: 162.0656; found: 162.0662; uv (λ_{max}) = 263 nm (ε unknown).

*2-Trifluoromethyl-1,3-cycloheptadiene (**7**).* ^{1}H nmr: δ (ppm) = 1.86 (m, 2H), 2.37 (m, 4H), 5.84 (d, 1H), 6.04 (dt, 1H), 6.46 (t, 1H); ^{13}C nmr: 25.1, 29.9, 31.5, 119.9, 134.9, 137.0 (quaternary carbons not detected); ^{19}F nmr: −68.0; ir: 2940 (m), 1360 (w), 1305 (s), 1180 (s), 1120 (s); ms (*m/e* (I)): 162 (65), 147 (43), 134 (22), 127 (47), 101 (8), 93 (100), 91 (31), 77 (35), 69 (8), 65 (17); Mass calcd. for $C_8H_9F_3$: 162.0656; found: 162.0651; uv (λ_{max}) = 243 nm (ε unknown).

Chlorobenzene-sensitized photolysis of a deoxygenated pentane solution (70 mL) containing **1** (0.01 M), chlorobenzene (0.02 M), and isooctane (0.001 M) was carried out in a quartz tube with a Rayonet reactor fitted with twelve 253.7 nm lamps. The photolysis was continued until *ca* 60% conversion of **1**, with periodic monitoring by vpc, and final analysis by gc/ms. These analyses showed that the photolysate consisted of four main volatile (C_{10} or less) products, in addition to several products that eluted only at relatively high column temperatures. Gas chromatographic/mass spectroscopic analysis of the volatile components showed that two of the products had molecular weights of 164 amu, while the other two had molecular weights of 142 amu and were tentatively identified as decane isomers on the basis of their fragmentation patterns. The major higher molecular weight products had parent ions of 234 amu, corresponding to the free radical addition product of pentane to **1** (three isomers). A relatively small peak with parent ion mass of 274 eluted at even longer time. This is the correct mass for a cycloaddition product of **1** with chlorobenzene. The first two volatile products were isolated from the photolysate, after removal of the solvent and bulb-to-bulb distillation of the residue under vacuum, by semi-preparative vpc (columns c and d). The structures of the two products, listed below in order of their elution from the SPB-1 megabore capillary column, were identified primarily on the basis of their ^{1}H nmr spectra (25). They exhibit the following spectral characteristics.

*exo-2-Trifluoromethylnorbornane (exo-**8**).* ^{1}H nmr: δ (ppm) = 1.17 (m, 2H), 1.22 (m, 1H), 1.50 (m, 2H), 1.55 (m, 3H), 2.07 (m, 1H), 2.30 (br s, 1H), 2.43 (br s, 1H); ir ($CDCl_3$): 2960 (s), 2880 (w), 1315 (w), 1275 (s), 1265 (w), 1220 (w), 1110 (s), 1040 (w); ms (*m/e* (I)): 164 (11), 149 (30), 136 (40), 122 (13), 103 (8), 95 (50), 77 (21), 68 (96), 67 (100), 55 (19), 44 (77).

*endo-2-Trifluoromethylnorbornane(endo-**8**).* ^{1}H nmr: δ (ppm) = 1.27 (m, 2H), 1.34 (br s, 2H), 1.37 (m, 1H), 1.57 (m, 1H), 1.73 (m, 2H), 2.30 (br s, 1H), 2.44 (br s, 1H), 2.47 (m, 1H); ir ($CDCl_3$): 2960 (s), 2920 (w), 2880 (w), 1380 (br, w), 1320 (m), 1275 (s), 1260 (w), 1220 (w), 1180 (w), 1160 (s), 1130 (m), 1100 (br, w), 1050 (w); ms (*m/e* (I)): 164 (26), 149 (42), 136 (34), 122 (18), 103 (6), 95 (73), 85 (6),77 (23), 68 (90), 67 (86), 55 (23), 44 (100).

Acknowledgements

We thank Dr. D. Hughes (McMaster University) for acquiring the high field ^{1}H, ^{13}C, and ^{19}F nmr spectra, Dr. R. E. Hill (McMaster University) for some of the gc/ms analyses, and the McMaster University Regional Mass Spectrometry Facility for gc/ms analyses and exact mass determinations. Valence and inner-shell (C_{1s}) electronic excitation spectra of norbornene, 2-methylnorbornene, and 2-trifluoromethylnorbornene have been measured by electron energy loss spectroscopy. These data have been complemented with gas- and solution-phase UV absorption spectra in the 5–6.7 eV range, HeI UV photoelectron spectra, and AM1 semi-empirical calculations for the three compounds. The valence shell energy loss and UV absorption spectra show marked variations throughout the series of compounds, suggesting the presence of at least three low-lying electronic excited states. The spectral bands have been assigned as due to π,R($3s$), π,π^*, and π,R($3p$) excitations on the basis of their term values and the differences between their intensities in the solution and gas phase absorption spectra. The valence shell spectra indicate that while the vertically-excited π,R($3s$) state is substantially lower in energy than the (vertically-excited) π,π^* state in norbornene and the 2-methyl derivative, they are nearly isoenergetic in 2-trifluoromethylnorbornene. This difference in excited state manifolds is reflected in profound differences between the solution phase photochemistry of norbornene and the 2-trifluoromethyl derivative.

The carbon 1s spectra are even more sensitive to substituent than the valence shell energy loss spectra. An interpretation is proposed which reflects the spatially localized character of inner-shell excitation and a "group orbitals" picture of the unoccupied MO's as accessed by C_{1s} excitation.

Key words: Rydberg, electron energy loss, UV absorption, UV photoelectron spectroscopy, alkene, gas-phase.

Faisant appel à la spectroscopie de la perte d'énergie électronique, on a mesuré les spectres d'excitation électronique de valence et de couche interne (C_{1s}) du norbornène, du 2-methylnorbornène et du 2-trifluorométhylnorbornène. On a complété ces données en déterminant aussi les spectres d'absorption UV en solution (énergies de 5 à 6, 7 eV), les spectres photo-électroniques UV HeI et en effectuant des calculs semi-empiriques AM1 pour les trois composés. Pour toute la serie des composés, on a noté d'importantes variations dans les spectres de perte d'énergie de la couche interne et des spectres d'absorption UV; ces résultats suggèrent qu'il existe au moins trois états électroniques excités de basses énergies. En se basant sur les valeurs de leurs termes ainsi que sur les différences entre les intensities de leurs spectres d'absorption en solution et en phase gazeuse, on a attribué les bandes spectrales aux excitations π,R($3s$), π,π^* et π,R($3p$). Les spectres des couches de valences internes indiquent que, même si l'énergie de l'état excité verticalement (π,R($3s$)) du norbornène et de son dérivé méthylé en position 2 est beaucoup plus faible que celle de son état π,π^* (excité verticalement), ils sont pratiquement isoénergétiques dans le 2-trifluorométhylnorbornène. Cette différence dans les états excités se reflète par des différences importantes entre les photochimies en solution du norbornène et du 2-trifluorométhylnorbornène.

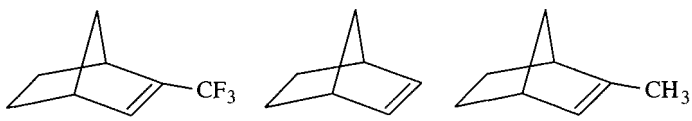
Les spectres 1s du carbone sont encore plus sensibles aux substituants que les spectres de perte d'énergie de la couche interne. On propose une interprétation qui est le reflet du caractère orienté dans l'espace de l'excitation de la couche interne ainsi que d'une représentation des orbitales de groups des OM qui ne sont pas ocupées telles qu'elles sont influencées par l'excitation C_{1s}.

Mots clés : Rydberg, perte d'énergie électronique, absorption UV, spectroscopie photo-électronique UV, alcènes, phase gazeuse.

[Traduit par la revue]

Introduction

The far-UV solution phase photochemistry of 2-trifluoromethylnorbornene (**1**) (1) shows significant differences compared to that reported previously for norbornene (**2**) under similar conditions (2). These differences are consistent with a dramatic alteration in the ordering of the lowest electronic excited states that are accessible in the far-UV (6.5–6.7 eV) region in solution, presumably induced by the effects of trifluoromethyl-substitution at the C=C bond. For most simple alkenes (*e.g.* **2**), direct photolysis in solution results in predominant formation of carbene-derived rearrangement products (3). Such products are thought to result from π,R($3s$) excitation, since the π,R($3s$) state is lower in energy than the π,π^* valence excited state in most simple alkenes (4, 5). The photochemical results for **1**, when compared to those previously reported for **2**, are consistent with an inversion of the ordering of the π,R($3s$) and the π,π^* singlet states in these two compounds (1). To investigate this point further, we have recorded the valence electronic excitation spectra of **1, 2**, and 2-methylnorbornene (**3**) by electron energy loss and gas- and solution-phase UV absorption spectroscopy, along with the HeI UV photoelectron spectra (PES) of each compound.



1 **2** **3**

In addition to the valence spectra in the 2–40 eV range, electronic spectra in the region of C_{1s} excitation (275–325 eV) have been recorded. Inner-shell excitation emphasizes the more compact valence component of virtual orbitals. Since the bonding/non-bonding character of photoactive orbitals is dictated by the valence component (6), it is possible that the C_{1s} spectra might also give useful insight into the origins of the differences in the photochemistry of **1** and **2** in solution.

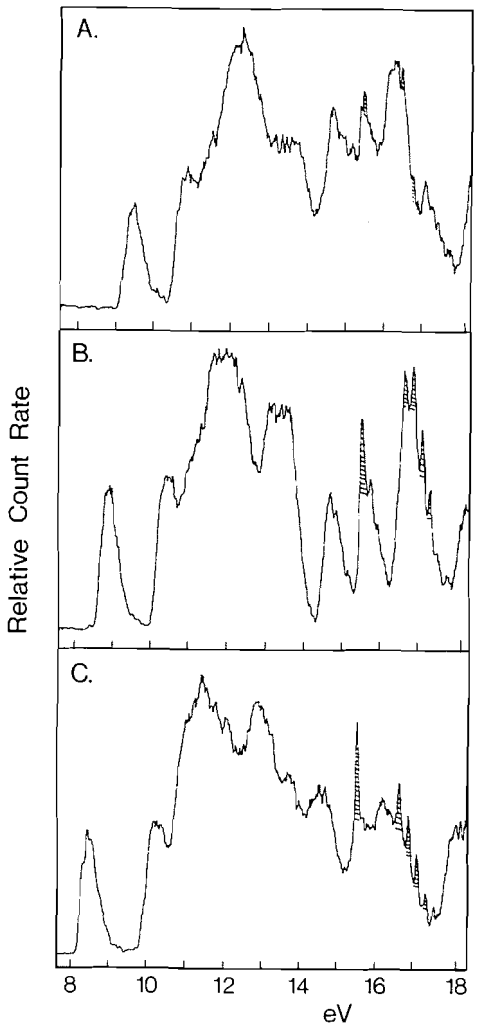

FIG. 1. HeI UV photoelectron spectra of (*A*) 2-trifluoromethylnorbornene (**1**); (*B*) norbornene (**2**); and (*C*) 2-methylnorbornene (**3**). The shaded peaks correspond to N_2 of air, which was used as a calibrant.

Results and discussion

HeI ultraviolet photoelectron spectra

HeI photoelectron spectra (PES) of **1–3** are shown in Fig. 1, and the two lowest vertical ionization potentials, as obtained from the spectra, are listed for each compound in Table 1. The PE spectra reveal the expected trend in π-IP throughout the series, and are more or less unexceptional. The spectrum of **2** is similar to the one reported previously by Heilbronner and co-workers (7). Methyl substitution results in a (0.7 eV) decrease in the π-IP, while trifluoromethyl substitution results in an increase of 0.4 eV. AM1 semi-empirical calculations were carried out for **1–3**, and the calculated π- and σ-eigenvalues are shown in Table 1 along with the experimental ionization energies from PES. These calculations qualitatively reproduce the substituent effect on the experimental π-IP's. Quantitatively though, AM1 underestimates the absolute effects of methyl substitution on the π-IP of norbornene, and overestimates that of trifluoromethyl substitution. AM1 does not reproduce the known effects of methyl substitution on π^*-MO energies (*i.e.*, electron affinities (8)) even on a qualitative level (9), so these eigenvalues have not been included in Table 1.

Optical spectra

Gas-phase UV absorption spectra of **1–3**, recorded on a conventional UV spectrometer with samples of pressures in the 1.5–2 torr range, are presented in Fig. 2. Figure 2 also contains spectra recorded for each compound in deoxygenated *n*-pentane solution with the same system and under identical conditions.

TABLE 1. Ionization energies (PES) and eigenvalues of substituted norbornenes **1–3**

Compound	Ionization energy (eV)[a]		ϵ^b	
	π	σ	π	σ
1	−9.6	−11.1	−10.4	−11.5
2	−9.2	−10.6	− 9.6	−10.9
3	−8.5	−10.3	− 9.2	−10.9

[a]Error estimated at ±0.1 eV.
[b]Computed using AM1.

The optical spectrum of **2** reported here (Fig. 2*b*) can be compared to the vacuum ultraviolet optical absorption spectra previously reported for the same compound (10). The previously reported spectra of **2** show three prominent bands in the region below 7.5 eV, centred at 5.97 eV (208 nm), 6.34 eV (196 nm), and 7.10 eV (175 nm) (10). These have been assigned as due to the π,R(3*s*), π,π^*, π,R(3*p*) transitions, respectively, by Robin and co-workers (4, 10*b*, 11). The Rydberg transitions in the optical spectra are quite sharp and well-defined compared to the valence (π,π^*) transition. The gas-phase spectrum shown in Fig. 2*b* exhibits absorption bands centred at 6.02 and 6.30 eV, in satisfactory agreement with the somewhat better-resolved spectra reported previously for the region below 6.7 eV (the upper energy limit of our spectrometer). The noise appearing in our spectra in the 6.6–6.7 eV region is due to background absorption by oxygen. As expected (4, 5), the 6.02 eV Rydberg absorption is absent in the solution-phase spectrum of **2**, which shows only the valence transition centred at 198 nm (6.26 eV).

The gas-phase optical spectrum of **3** shows weak, but sharp absorption bands centred at 5.62 eV (220.5 nm) and 6.43 eV (193 nm), which can be assigned to the π,R(3*s*) and π,R(3*p*) transitions on the basis of their term values (*vide infra*) and the fact that they are quenched in the solution-phase spectrum (4, 5). The latter is a standard "test" for Rydberg transitions — these bands are severely reduced in intensity and blue-shifted in the condensed phase compared to the gas phase at low pressure (4, 5). The prominent band centred at 6.16 eV (201 nm) is also present in the solution spectrum and can thus be assigned to the π,π^* transition.

The gas-phase spectrum of **1** in the 5.5–6.7 eV region shows a single, symmetrical absorption band centred at 6.46 eV (192 nm) that can be assigned as due to the π,π^* transition. The slight shift of the absorption maximum (to 195 nm) in the solution-phase spectrum is probably due to background absorption by the solvent. The weak feature that appears at 6.37 eV in the gas-phase spectrum may be due to π,R(3*s*) absorption. Because it is so poorly resolved from the prominent, underlying π,π^* absorption, we consider this assignment to be more tentative than the others.

The energies and proposed assignments for the various bands in the gas-phase optical spectra are listed in Table 2. Table 2 also contains term values (*T*) calculated for each transition as the difference between the spectral band maxima and the lowest vertical (π) ionization potentials of the three compounds from PES (4). The term values support our assignments for the various bands in the spectra of **1–3** based on Mulliken's (4) and

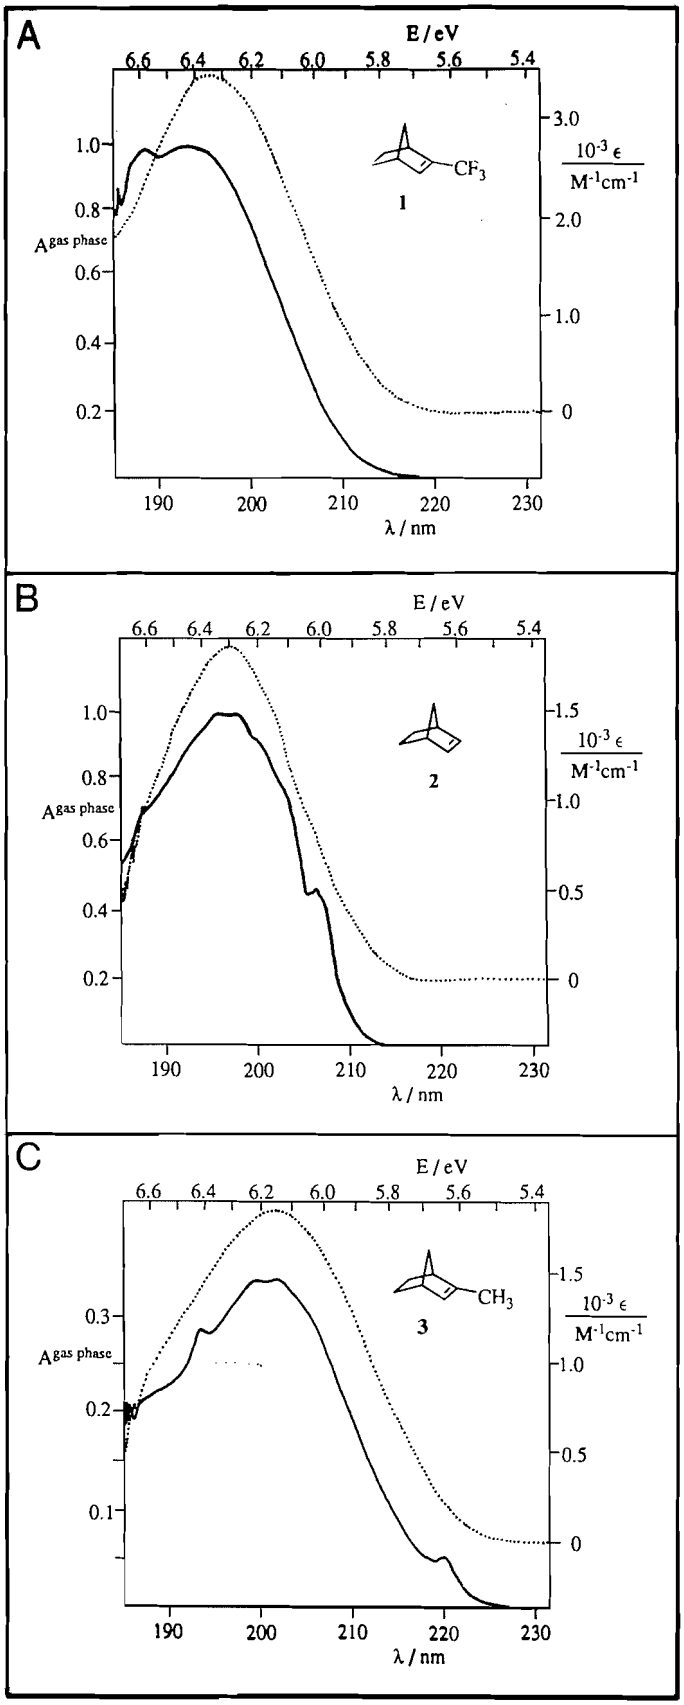

FIG. 2. Ultraviolet absorption spectra of **1–3** in gas phase (——) and in deoxygenated pentane solution (····). Gas phase spectra were recorded at pressures of 1,4, 1.7, and 1.5 torr for **1**, **2**, and **3**, respectively. The left axes refer to gas-phase spectra and right axes refer to solution phase spectra.

TABLE 2. Energies (E; eV), term values (T; eV),[a] and possible assignments for features in the gas-phase UV absorption spectra of **1–3**

	E/eV (T/eV)			
Feature	**1**	**2**	**3**	Assignment
1	6.37(3.2)	6.02(3.2)	5.62(2.9)	π,R(3*s*)
2	6.46(3.1)	6.30(2.9)	6.16(2.3)	π,π*
3	—	—	6.43(2.1)	π,R(3*p*)

[a]Term values calculated as the difference between absorption maxima and the vertical ionization potentials for **1–3**, determined by PES (Table 1).

Robin's (5) extensive generalizations on valence and Rydberg assignments in the optical spectra of alkenes, and the variations in term values with substituent. It is well-known that in alkylethylenes, increasing methyl substitution at the C=C bond results in decreases in the Rydberg transition energies (π,R(3*s*) and especially π,R(3*p*)) that are comparable to those in the π-ionization potentials (4, 5). This is reasonable to the extent that Rydberg excitation can be viewed as involving partial ionization of the molecule. Furthermore, the larger and more diffuse the Rydberg orbital, the better the correlation should be between transition energy and ionization potential. The π,π* transition energies also decrease with increasing alkyl substitution in the same way, but much less dramatically. Thus, the π,π* transitions in **1–3** are assigned as those bands whose term values vary the most with substituent throughout the series (*i.e.*, whose energies are least sensitive to variations in the π-IP), and the π,R(3*s*) transitions as those whose term values vary the least (*i.e.*, whose energies are most senstitive to variations in π-IP).

Valence-shell electron energy loss spectra

The valence-shell energy loss spectra of **1–3** are presented in Fig. 3. Figure 3 also includes expansions of the 4–10 eV region, which is of greatest interest to the solution phase photochemistry of these molecules. The energies, term values, and proposed assignments of the various features in these spectra are listed in Table 3.

The energy loss spectrum of **2** reported by Kupperman and co-workers (12) has been included for comparison with the present one in Fig. 3*b*. The qualitative features of the two spectra agree quite closely. The main difference is in resolution, which is three to four times lower in our spectrometer than in that used for the previously reported spectrum. Also, Kupperman's spectrum exhibits a shoulder at 6.6 eV which is not resolved in ours. The intensity of this feature was found to increase very rapidly with increasing momentum transfer (*i.e.*, scattering angle) relative to the 6.3 eV feature (12). Since the momentum transfer is much smaller under our experimental conditions, it is likely that the relative intensity of the 6.6 eV feature is reduced to the point where we are unable to detect it.

As in the case of Kupperman *et al.* (12), we are not able to resolve the lowest energy Rydberg transition which is observed at 6.02 eV in the optical spectrum of **2**. This band is presumably obscured in the low energy tail of the prominent π,π* absorption centred at 6.53 eV, and our failure to observe it as a discrete feature is due simply to inadequate spectral resolution. We observe a second band, occurring as a shoulder at 7.5 ± 0.1 eV on the rising edge of the diffuse, higher energy absorption above 10 eV. A corresponding feature is also evident in the spectrum of Kupperman *et al.* This band has not been previously assigned, unless it coincides with the 7.10 eV

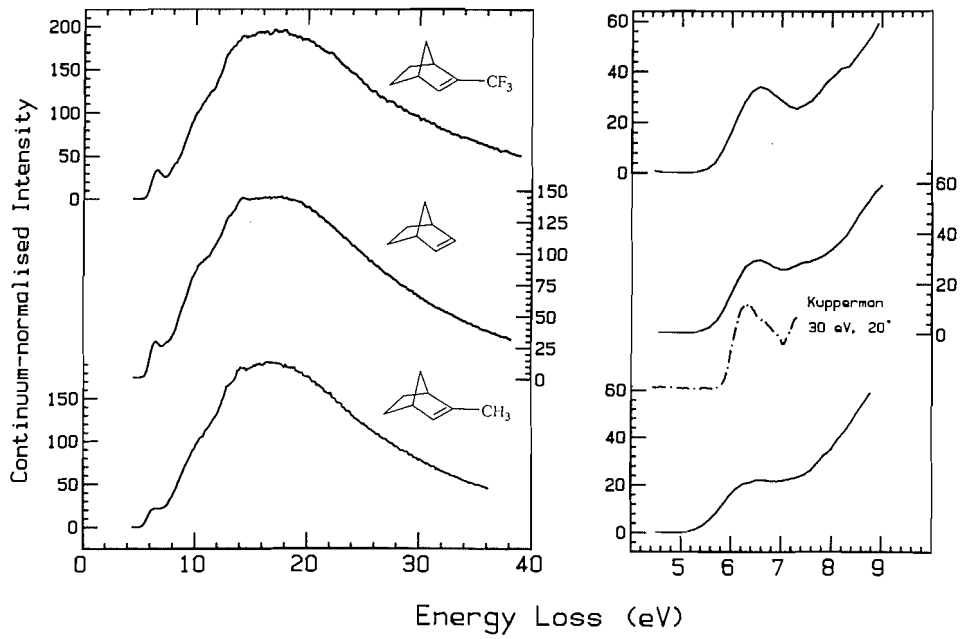

FIG. 3. Energy loss spectra of substituted norbornenes **1**–**3** in the region of valence electronic excitation. For each spectrum, the 4–10 eV region, normalized at 30 eV to an intensity proportional to the total number of electrons in the molecule, has been expanded (left). The previously reported energy loss spectrum of **2** (12) has been superimposed on the present one in (*b*).

TABLE 3. Energies (E; eV),[a] term values (T; eV),[b] and possible assignments for features in the valence shell energy loss spectra of **1**–**3**

	E/eV (T/eV)			
Feature[c]	**1**[d]	**2**[e]	**3**[f]	Assignment
2	6.52(3.0)	6.50(2.7)	6.15(2.3)	π,π^*
3	7.90(1.7)	7.50(1.7)	6.62(1.9)	π,3R(3p)

[a]From absorption band maxima in valence shell energy loss spectra. The uncertainty in the absolute energy is estimated at ±0.05 eV.

[b]Term values calculated as the difference between E-values and the vertical ionization potentials for **1**–**3** determined by PES (Table 1).

[c]Spectral features numbered so as to allow comparison with optical spectra (see Fig. 2 and Table 2).

[d]Additional bands occur at 8.24, 11.53, 13.40, 14.29, and 16.99 eV (see Fig. 3).

[e]Additional bands occur at 10.37, 13.08, and 14.32 eV (see Fig. 3). These can be compared with the high energy features reported previously at 8.25, 8.97, 10.3, 11.9, and 12.8 eV (12).

[f]Additional bands occur at 7.90, 10.65, 13.04, 14.23, and 16.75 eV (see Fig. 3).

(π,R(3p) (5, 10b, 11)) absorption band in the optical spectrum (10). We tentatively assign this band to the π,R(3p) transition on the basis of its term value (*vide infra*).

The energy loss spectra of **1** and **3** show distinct differences compared to that of **2**. The low energy band of **3** is distinctly broader than the corresponding absorption in **2**, and appears to consist of two overlapping transitions with maxima at *ca.* 6.2 and 6.6 eV. Again, we see no discrete evidence for the low energy (5.62 eV) π,R(3s) transition which is observed in the optical spectrum of this compound. In contrast, the low energy region in the spectrum of **1** seems to have a rather symmetric first absorption band, similar to that of **2**. While all three compounds show absorption bands centred at 6.5–6.6 eV, the 7–8 eV regions exhibit distinct shoulder absorptions whose positions vary dramatically throughout the series.

The energy loss spectra of these compounds complement the optical spectra in that they provide evidence for π,R(3p) excitations, which are of too high energy in **1** and **2** to be observed with our absorption spectrometer. We assign the 7.9, 7.5, and 6.6 eV features in the energy loss spectra of **1**, **2**, and **3**, respectively, as due to this transition, since their term values are essentially independent of substituent. The 6.6 eV transition in the energy loss spectrum of **3** is also observed in the optical spectrum at 6.43 eV. The latter energy should be considered more accurate because better resolution is obtained in optical experiments. In fact, the π,R(3p) transition energies from the energy loss spectra of all three compounds should probably be considered to have uncertainties of 0.2–0.3 eV because of the resolution of our spectrometer, which results in the appearance of these bands as shoulders on more intense excitations.

The combination of optical and energy loss spectroscopies bolster our assignment of the weak feature at 6.37 eV in the gas-phase optical spectrum of **1** as due to π,R(3s) absorption, or at least suggest that the π,R(3s) transition should occur at roughly this energy in **1**. It is possible to estimate a probable range of energies for the π,R(3s) transition in **1**, using the term values for the π,R(3p) excitations in **1**–**3** and by taking into account the trends in the *differences* between term values for the two Rydberg transitions in **2**, **3**, and other alkyl-substituted olefins (4, 5). The extensive published data for alkenes show that depending on the structure and the degree of alkyl substitution, the π,R(3s) state is situated between 0.3 and 1.2 eV below the π,R(3p) state (4, 5). For **2**, the reported optical absorption data (10) places the π,R(3s)–π,R(3p) energy gap at *ca.* 1.1 eV, in satisfactory agreement with the 1.0 eV gap given by our energy loss spectrum of this compound. This is similar to the value obtained for **3** (0.8 eV) from its optical spectrum (Fig. 2*c* and Table 2). Assuming a similar π,R(3s)–π,R(3p) energy gap for **1**, we thus estimate the π,R(3s) energy to be in the 6.4–6.9 eV range. The suggestion that the π,R(3s) transition is superposed on the intense π,π^* band is thus a reasonable one, and it can be concluded that the vertically-excited π,R(3s) state

is of similar or even higher energy than the vertically-excited π,π^* state in this compound. This difference in the vertical energies of the two states is expected to be magnified in the 0,0 levels, since Rydberg transitions are much sharper than valence transitions (4, 5). Assuming the normal shift to higher energies of Rydberg states in the condensed phase (4, 5), the present data suggest that the π,π^* state should be the lowest energy singlet excited state in solution.

This lowest state assignment for **1** is consistent with its solution-phase 193 nm (6.5 eV) photochemistry (1). Far-UV photolysis of **2** affords carbene-derived rearrangement products consistent with Rydberg state excitation (2, 3). Photolysis of **1** under similar conditions, on the other hand, affords products that are most consistent with valence (π,π^*) excitation; analogous products are formed upon photolysis of 2-cyanonorbornene whose lowest excited state is very clearly of π,π^* configuration (13). While it has been proposed that there may be yet a third photoactive alkene excited singlet state accessible in solution, presumably underlying the intense π,π^* absorption (14), we observe no evidence for such a state in the optical and energy loss spectra of **1**–**3**.

Carbon 1s spectra

The oscillator strengths for C_{1s} excitation of **1**–**3** are presented in Fig. 4 while energies, term values (the differences between the excitation energies and the average CH_xIP) and proposed assignments are summarized in Table 4. The average CH_x C_{1s} ionization potential has been estimated as 290.5 ± 0.4 eV from the measured XPS of similar molecules (15). The C_{1s} IP of the CF_3 carbon is estimated as 299.0 ± 0.5 eV while that of the sp^2 carbon to which the CF_3 group is attached has an estimated IP of 292.0 ± 0.5 eV. These estimates are derived from data for 3,3,3-trifluoropropene, which has IP's of 291.6, 292.0, and 298.7 eV for the 1-, 2-, and 3-carbons, respectively (15).

The C_{1s} spectra exhibit much larger variation with substituent than the valence spectra. This can be attributed to the spatially-localized character of core electronic excitation, which makes these excitations much more sensitive to differences in the structure of these molecules than spatially-delocalized valence excitations. In particular, the second and third peaks in the spectrum of **3**, corresponding to σ(C—H) and σ(C—C) resonances, are more intense than their counterparts in the spectrum of **2**, due simply to the higher carbon-number of **3**. The spectrum of **1** consists of the overlap of transitions originating at the CF_3 and CH_x carbons, which are well-isolated because of the large C_{1s} chemical shift associated with the electronegative fluorines. Thus the CF_3 component of the spectrum of **1** is composed of strong σ*(C—F) and σ*(C—C) resonances, while the CH_x component is similar to that seen in the spectra of the other two molecules. The term values for corresponding transitions in the three compounds are generally similar (see Table 4); indeed the constancy of the term values, based on the similarity of the energies of corresponding virtual orbitals, has guided our assignments.

The C_{1s},π^* excitation energies and term values are of particular interest, from the point of view of comparisons with the π,π^* excitation energies, term values, and the π-IP's discussed earlier. The variation in π,π^* and $C_{1s}\pi^*$ term values and π-ionization potentials throughout the three compounds is depicted in Fig. 5. The slight decrease in the π,π^* term value for **3** relative to **2** is consistent with a slight destabilization of the π^* MO as a result of methyl substitution. The same trend is observed in the electron affinities of simple alkenes (8). In the

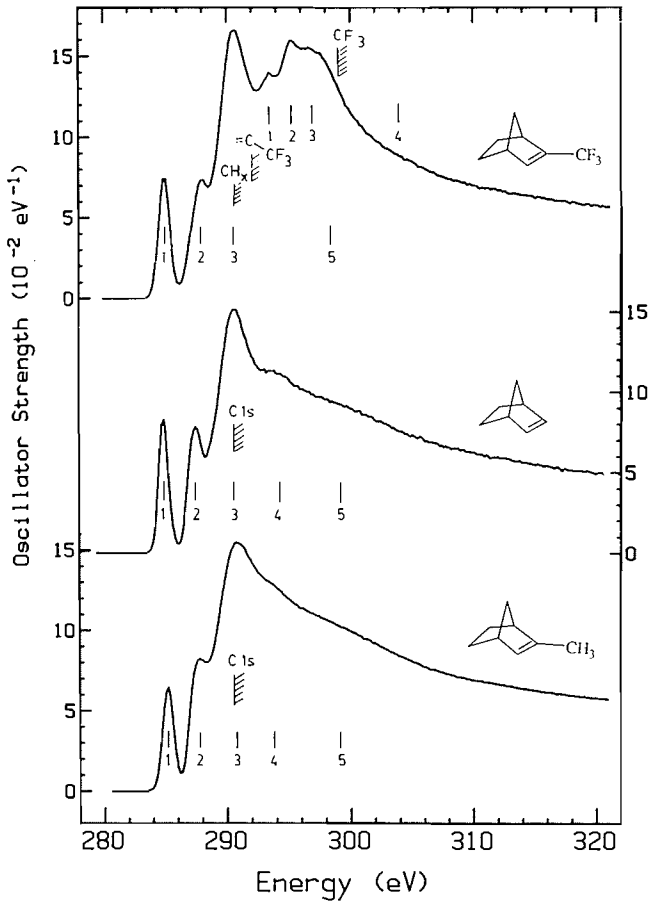

FIG. 4. Oscillator strengths for C_{1s} excitation of substituted norbornenes **1**–**3**, derived from electron energy loss spectra recorded with 2.5 keV final electron energy, 2° scattering angle and 0.6 eV FWHM resolution. The indicated C_{1s} IP's are estimated from XPS values of similar molecules (14).

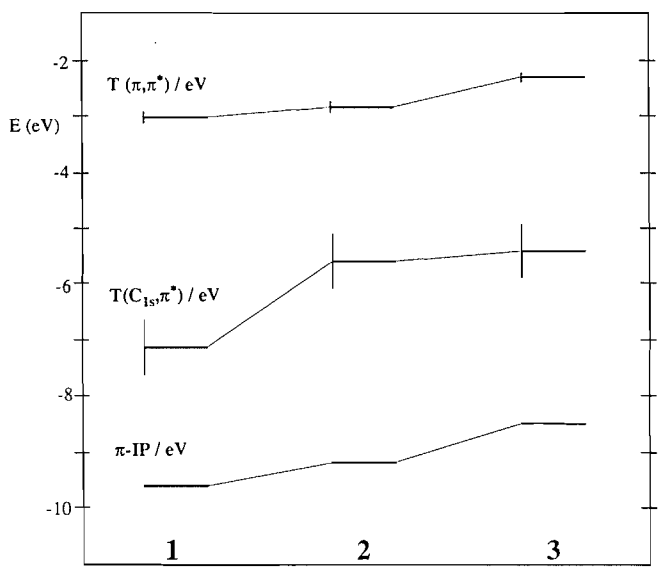

FIG. 5. Histograph showing the variation in π,π^* and C_{1s},π^* term values and π-IP's with substituent in **1**–**3**, from the electron energy loss spectra. Error bars are due to the uncertainty in the associated IP's.

[a]T = IP − E, where IP is the appropriate C_{1s} ionization energy, estimated from the IP's of similar species (14). Note that there will be at most a 0.2 eV chemical shift between the sp^3 and sp^2 carbons in **2** and **3** . The sp^2 carbons in **1** will have significantly higher IP's than the sp^3 carbons. Bracketed term values indicate that there is likely to be only a small contribution to intensity from this core level.

[b]Entries labelled "F" are features associated with $C_{1s}(CF_3)$ excitation.

[c]Calibration relative to $CO_2(C_{1s},\pi^* = 290.74\,eV)$; $\Delta E = -5.82_4$ (**1**), -5.83_4 (**2**), and -5.59_4 (**3**).

case of **1**, the π-IP and π,π* excitation energies predict that trifluoromethyl substitution should result in stabilization of the π*-MO by *ca.* 0.3 eV relative to **2**. The fact that the C_{1s},π* transition is observed at 285.1 eV in the low energy region of the spectrum of **1**, even though the C_{1s} IP of the 2-carbon (═*C*—CF_3) is clearly going to be 1–2 eV higher in energy than that of the sp^2 carbons in **2** or **3**, indicates that the C_{1s},π* state has an appreciably larger term value. Thus one sees that the C_{1s} spectrum also senses the stabilization of the π*-MO that is reflected in the valence shell π,π* transition energy. In fact, the C_{1s} spectrum appears to predict a stabilization of more than twice that predicted from the valence electronic spectra, although the larger error bars associated with the $C1_s$ (due to the uncertainty in the estimated $C1_s$ IP's) make this a tentative statement.

Conclusions

Previous work has shown that the lowest electronic excited state of norbornene (**2**) is the π,R(3s) Rydberg state (4, 10), which is consistent with the photochemical behaviour of this molecule in solution (2, 3). The present study demonstrates that the valence shell optical and energy loss spectra of **1–3** show significant differences throughout the series. These differences are suggested to be the result of a dramatic substituent effect on the energies of the π,R(3s) and π,R(3p) excited states. Trifluoromethyl substitution at the C═C bond has little effect on the energy of the π,π* state relative to the unsubstituted derivative, but destabilizes the π,R(3p) and π,R(3s) Rydberg states considerably. The effect is large enough that in **1**, the (vertical) π,π* state is *ca.* 1.3 eV lower in energy than the π,R(3p) state, and slightly lower in energy than (or at most, isoenergetic with) the π,R(3s)) Rydberg state. These differences are expected to be magnified in the 0,0 levels so that for **1**, the π,π* valence state appears to be the lowest energy excited singlet state that is accessible in solution. This is consistent with the solution phase photochemistry of this molecule, which leads to products attributable to π,π* excitation exclusively (1).

Experimental

The gas- and solution-phase UV absorption spectra were recorded in single beam mode on a Perkin-Elmer Lambda 9 spectrophotometer equipped with a Model 3600 Data Station. The spectrometer sample compartment was continuously flushed with dry nitrogen. Samples were contained in 1 cm Suprasil UV cells (Hellma) which were fitted with a glass stopcock for gas-phase spectra. Gas-phase samples were prepared by introducing the compound into the cell from a cold finger on a vacuum line whose pressure was measured by a Varian 801 vacuum gauge. A background spectrum, recorded under identical conditions with the empty cell (evacuated to 30 mtorr), was electronically subtracted from the sample spectra. Reference and sample solutions for the solution-phase spectra were deoxygenated with a stream of argon for 10 min prior to recording the spectrum.

The valence and inner-shell energy loss spectra were obtained by inelastic electron scattering with a high velocity incident electron beam (E_0 = 2.5 keV plus the energy loss), using an instrument that has been described in detail previously (16). The valence spectra were recorded with a 0° average scattering angle while the $C1_s$ spectra were obtained using a small scattering angle (~2°) to eliminate an instrumental background associated with scattering of the incident electron beam inside the electron energy analyser. The instrumental resolution was 0.6 eV fwhm. Under these electron scattering conditions only electric dipole transitions are excited, with intensities that are very similar to those in the corresponding optical absorption spectra (17).

The valence energy loss spectra were calibrated with the $1s \rightarrow 2p$ transition of He (21.22 eV). A semiquantitative comparison of the intensities has been achieved by normalizing at 30 eV in the valence ionisation continuum to a value proportional to the number of valence electrons in each molecule. The $C1_s$ spectra were calibrated with the π* feature of CO_2 at 290.74 eV (17), and were converted to absolute optical oscillator strengths (f values) using a procedure described and tested previously (18).

Ultraviolet photoelectron spectra were recorded in conventional mode using a spectrometer which has been described in detail elsewhere (19), and are the averages of 50–100 scans. The spectra were calibrated relative to the peak at 15.67 eV corresponding to the ionization of nitrogen.

Semi-preparative gas chromatographic (vpc) purifications were carried out with a Hewlett-Packard 5750B gas chromatograph, fitted with a thermal conductivity detector and one of the following stainless steel columns: (*a*) 3% OV-17 on 80/100 Chromosorb WAW (6′ × 0.25″ stainless steel; Supelco, Inc.); (*b*) 15% Carbowax 20M on 60/80 Chromosorb W (5′ × 0.25″ stainless steel; Supelco, Inc.); (*c*) 3.8% UCW982 on 80/100 Supelcoport (24′ × 0.25″ stainless steel; Supelco, Inc.).

Analytical vpc separations were carried out with a Hewlett-Packard

5890 gas chromatograph equipped with a flame ionization detector, a borosilicate megabore capillary column (30 m × 0.75 mm SPB-1; Supelco, Inc.), and a Hewlett-Packard 3396 recording integrator.

2-Trifluoromethylnorbornene (**1**) was prepared by a modification (1) of a reported procedure (20) and purified by semi-preparative vpc (columns b, c). Norbornene (**2**; Aldrich) was purified by distillation followed by semi-preparative gas chromatography (column a). 2-Methylnorbornene was available from an earlier study (21) and was purified by vacuum distillation, followed by semi-preparative vpc (column a). The samples of **1**–**3** used in this work were all of > 99.9% purity as estimated by vpc.

Computational studies were carried out using AM1, Version 2.1, of the general purpose molecular orbital computational package AMPAC (22). Optimizations were carried out using the AM1 default parameters.

Received February 5, 1990

DAVID A. ARMSTRONG, MOHSEN FARAHANI, and PARMINDER S. SURDHAR. Can. J. Chem. **68**, 1974 (1990).

Spectrophotometric titration of tetrahydropterins with incremental amounts of $^{\bullet}N_3$ showed that 6,7-dimethyl-7,8-dihydropterin was an intermediate in the oxidation of 6,7-dimethyltetrahydropterin at the two electron-equivalent oxidation point. The eventual end product at four electron equivalents was 6,7-dimethylpterin. In the case of unsubstituted tetrahydropterin, the dihydro form was clearly not an exclusive product at the two electron equivalent point, and this was attributed to the disproportionation of different forms of dihydropterin to tetrahydropterin and pterin.

The azide radical oxidized tetrahydropterins to trihydropterin radicals, $^{\bullet}PnH_3$, with overall second-order rate constants at pH 7 of 4.1, 3.8, and 2.9×10^9 M^{-1} s^{-1} for tetrahydropterin, 6,7-dimethyltetrahydropterin, and 6-carboxylated tetrahydropterin, respectively. At pH 10 the rate constants are slightly larger due to the presence of the deprotonated enolate forms of tetrahydropterins. Spectra vary somewhat with substitution in the pterin molecule, but all species have a strong peak ($\epsilon \sim 9000$ M^{-1} cm^{-1}) near 320 nm and lower absorption above this, with a tail extending to 580 nm.

Key words: tetrahydropterin oxidation, tetrahydropterin, trihydropterin radical, azide radical, trihydropterin spectrum.

DAVID A. ARMSTRONG, MOHSEN FARAHANI et PARMINDER S. SURDHAR. Can. J. Chem. **68**, 1974 (1990).

Le titrage spectrophotométrique des tétrahydroptérines avec des quantités croissantes de $^{\bullet}N_3$ a permis de démontrer que, au niveau de l'oxydation par deux équivalents d'électron, la 6,7-diméthyl-7,8-dihydroptérine est un intermédiaire dans l'oxydation de la 6,7-diméthyltétrahydroptérine. La 6,7-diméthylptérine est le produit qui se forme éventuellement au niveau de l'oxydation par quatre équivalents d'électron. Dans le cas de la tétrahydroptérine qui n'est pas substituée, il est clair que la forme dihydro n'est pas le produit exclusif au niveau de l'oxydation par deux équivalents d'électron; ce résultat est attribué à la disproportionation des diverses formes de la dihydroptérine en tétrahydroptérine et en ptérine.

A un pH de 7, le radical azoture oxyde les tétrahydroptérines en radicaux trihydroptérines, $^{\bullet}PnH_3$; les constantes de vitesse du deuxième ordre sont respectivement 4,1, 3,8 et $2,9 \times 10^9$ M^{-1} s^{-1} pour la tétrahydroptérine, la 6,7-diméthyltétrahydroptérine et la tétrahydroptérine portant un groupement carboxyle en position 6. A un pH de 10, les constantes de vitesse sont légèrement supérieures à cause de la présence des formes énoliques déprotonées des tétrahydroptérines. Les spectres varient légèrement avec les substituants présents sur la molécule de ptérine; toutefois, toutes les espèces présentent une forte bande ($\epsilon = 9000$ M^{-1} cm^{-1}) près de 320 nm et une absorption moins intense à une longueur d'onde plus grande avec une queue allant jusqu'à 580 nm.

Mots clès : tétrahdroptérine oxidation, tétrahydroptérine, radical trihydroptérine, radical azoture, spectre trihydroptérine.

Introduction

Reduced derivatives of folic acid are carriers of activated one-carbon units in the synthesis of nucleic acids (1), and the related unconjugated pterins act as cofactors in the enzymically-catalyzed conversion of phenylalanine to tyrosine and of tyrosine to dihydroxyphenylalanine (1–3). In addition, knowledge of the mechanisms of oxidation of reduced pterin coenzymes is important for the preservation of vitamin activity during the course of food processing (4). For these reasons, there has been extensive interest in the oxidation–reduction reactions by which the biologically relevant di- and tetrahydro forms of folic acid are interconverted. Important studies (5–9) have been conducted with the structurally simpler pterin analogues, PnH_2 and PnH_4 (as shown in Scheme 1) which still posess the heterocyclic ring system essential to the redox chemistry and biological functions.
