The ^2H nuclear magnetic resonance spectrum of mollisin from cultures of the fungus *Mollisia caesia* supplemented with [2-$^2H_3$]acetate was consistent with biosynthesis of the metabolite via a single-chain polyketide. The presumption that chain scission accompanies dichlorination of a reactive methylene group in such a polyketide was supported by the detection of chloroperoxidase activity with monochlorodimedone as a substrate, and failure to detect chlorinating activity when the substrate was acetoacetyl coenzyme A. However, a decisive choice between single-chain and two-chain polyketide intermediates cannot be made with information provided by the techniques used so far.

Key words: biosynthesis, mollisin, deuterium labelling and NMR; deuterium labelling and NMR, mollisin biosynthesis; labeling of mollisin by deuterium, NMR analysis; mollisin biosynthesis, deuterium, labeling and NMR; NMR deuterium, mollisin biosynthesis.

A. GAVIN MCINNES, JOHN A. WALTER, JEFFREY L. C. WRIGHT, LEO C. VINING, NEELING RANADE, RONALD BENTLEY et EDWARD P. MCGOVERN. Can. J. Chem. **68**, 1 (1990).

Les spectres en résonance magnétique nucléaire du ^2H de la mollisine provenant de milieux de cultures du champignon *Mollisia caesia* auxquels on a ajouté du [2-$^2H_3$]acetate sont en accord avec ceux auxquels on pourrait s'attendre sur la base d'un mécanisme de biosynthèse du métabolite impliquant une chaîne unique de polycétide. L'hypothèse d'après laquelle une scission de la chaîne accompagne la dichloration d'un groupement méthylène réactif d'un polycétide est en accord avec la détection d'une activité de la choroperoxydase sur la monochlorodimédone comme substrat et le fait que l'on ne peut dètecter de chloration lorsque le substrat est l'acétoacétyl coenzyme A. Toutefois, sur la base des résultats obtenus avec les techniques utilisées jusqu'à maintenant, on ne peut choisir entre les mécanismes impliquant des intermédiaires polycétides à chaînes uniques ou doubles.

Mots Clés: biosynthèse, mollisine, marquage au deutérium et RMN; marquage au deutérium et RMN, biosynthèse de la mollisine; marquage de la mollisine par du deutérium, analyse par RMN; biosynthèse de la mollisine, marquage au deutérium et RMN; RMN, deutérium, biosynthèse de la mollisine.

[Traduit par la revue]

Early experiments with ^{14}C-labeled acetate and malonate indicated that mollisin (**1**, Fig. 1) was formed in the fungus *Mollisia caesia* by condensation of acetate and malonate (1). Subsequently it was shown (2) by measuring the increase in intensity of ^{13}C-H satellite resonances in the proton magnetic resonance spectrum of mollisin that [2-^{13}C]acetate enriched C-3, C-6, C-11, C-12, and C-14 to equal extents with ^{13}C. When cultures were supplemented with [1,2-$^{13}C_2$]acetate and the metabolite was examined by ^{13}C nmr spectrometry, the labelling pattern obtained was consistent with biosynthetic pathways (a) or (b) in Fig. 1, and excluded several other possibilities (3–5).

In an attempt to distinguish between the one-chain (a) and two-chain (b) polyketide pathways, we have grown *M. caesia* in cultures containing [2-$^2H_3$]acetate and determined the isotopic enrichment in mollisin by using ^2H nmr spectrometry. Figure 2 shows the ^1H and ^2H nmr spectra of the product displayed on the same ppm scale by assuming that the chemical shift for natural abundance C^2HCl_3 (relative to TMS-$^2H_{12}$) in the ^2H spectrum corresponds to that for $CHCl_3$ (referred to TMS) in the ^1H spectrum (6). The ^2H spectrum contains resonances only for C^2HCl_3 and ^2H-12; from the relative intensities of the two signals and the weight of chloroform used as solvent, the ^2H-enrichment at C-12 was estimated to be 0.27 ± 0.05% (cf. 0.015% natural abundance).

The integral of the ^2H-12 resonance was more than 12 times that of the ^2H-11 region, confirming that the two methyl groups, although both ultimately derivable from the methyl group of acetate, have different biosynthetic histories. The integral of the ^2H-12 resonance was at least 25 times greater than the noise level of the integrals over the regions corresponding to ^2H-3 and ^2H-14. After correction for the number of hydrogens at each position, the ^2H-enrichment at C-12 was, therefore, at least eight times that at C-14. The results are consistent with the single-chain pathway (a) for mollisin biosynthesis.

Within the single envelope for ^2H-12, isotopically shifted peaks corresponding to the species $C^1H_2{}^2H$, $C^1H^2H_2$, and C^2H_3 were resolved ($\Delta\delta(^2H)$ 0, 0.048 ± 0.010, and 0.093 ± 0.010, respectively). The resonance displacements indicated that the three species were present in the proportions 2.5:2.7:1.0 (error ±0.3). A mixture of partially and fully deuterated methyl groups has also been found in other fungal metabolites biosynthesized in the presence of [$^2H_3$]acetate (10–12). Activation of [2-$^2H_3$]-acetate to acetyl coenzyme A is not accompanied by exchange of deuterium with water, or with hydrogens at enzyme reaction centres (7). However, acetyl coenzyme A is reversibly converted to malonyl coenzyme A by the action of acetyl coenzyme A carboxylase, and the methylene hydrogens of malonyl coen-

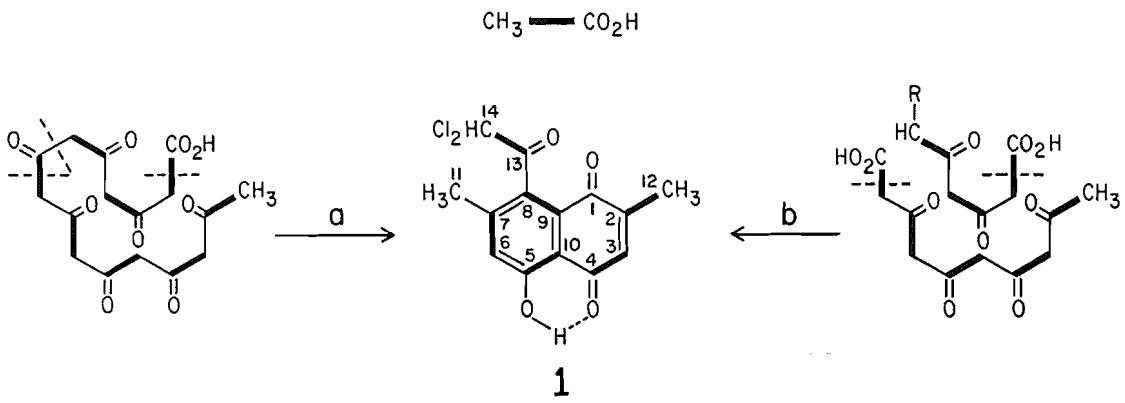

FIG. 1. Potential routes for the biosynthesis of mollisin.

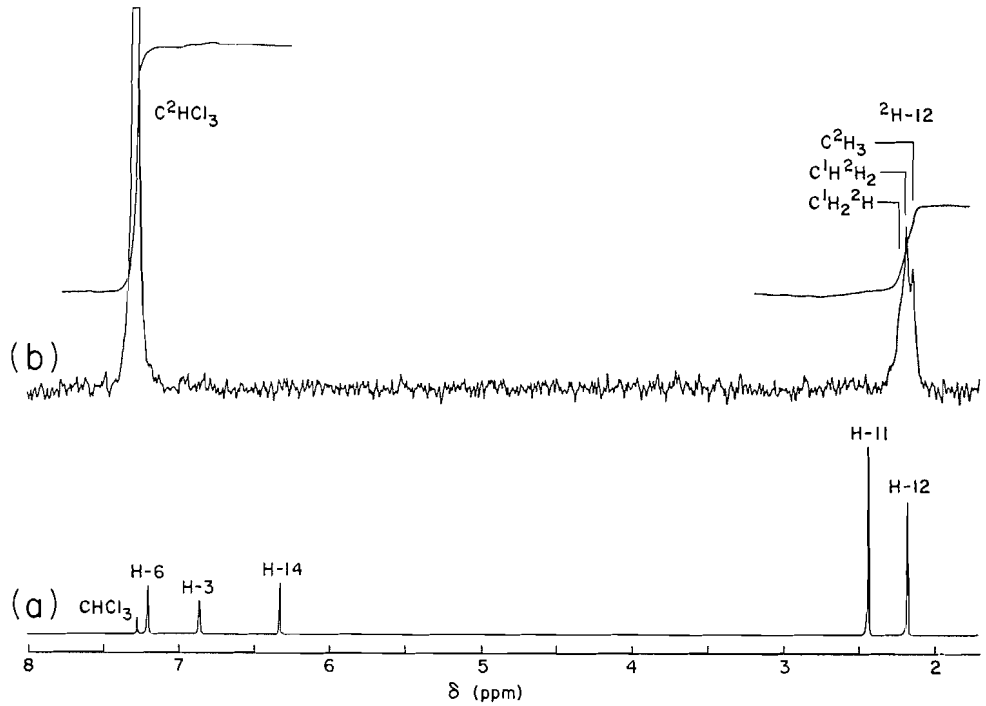

FIG. 2. (a) Portion of the ^1H spectrum of mollisin biosynthesized in the presence of [2-$^2H_3$]acetate (99%; ^2H); (b) ^2H spectrum and integral.

zyme A are known to undergo stereospecific exchange (8, 9). This could account for the observed distribution of isotopic species at C-12 of mollisin. Since some exchange of deuterium in methyl groups derived from [2-$^2H_3$]acetate can be anticipated, survival of the C^2H_3 species along with partially exchanged forms of the precursor is considered to be useful evidence in locating the starter unit of a polyketide chain (13, 14).

If the labelling at H-12 is accounted for by interconversion of acetyl coenzyme A and malonyl coenzyme A, mono- and dideuteromalonate must have been present in the malonate pool drawn upon for polyketide chain extension during mollisin biosynthesis. However, no peaks could be detected at positions expected for ^2H-3, ^2H-6, ^2H-11, or ^2H-14 in the ^2H nmr spectrum. The absence of deuterium at sites other than C-12 in the labeled metabolite implies that further exchange of deuterium occurred during or after the biosynthesis of mollisin. To determine whether hydrogens in mollisin could have exchanged after formation of the metabolite, an unlabeled sample recrystallized from benzene–isooctane was spread in agar containing ^2H_2O. After 3 weeks the mollisin was recovered and its ^1H nmr spectrum was compared with that of the original sample. No change in peak integration values was detected, indicating that the absence of label at methylene-derived carbons is more likely due to exchange at activated positions of enzyme-bound polyketide intermediates during mollisin biosynthesis. Similar examples of deuterium loss during the biosynthesis of other polyketide-pathway aromatic compounds from ^2H-labeled acetate have been reported, and have been attributed to exchange of labile hydrogens in biosynthetic intermediates or in the product (10, 11, 15). The degree of ^2H retention at positions derived from the malonate methylene group appears to be quite unpredictable (14), and can vary from complete loss to almost complete retention (16).

Since the introduction of chlorine into metabolites such as mollisin is catalyzed by chloroperoxidases that require a strongly nucleophilic target site (17, 18), a two-chain pathway in which both chains have acetate starter units (Fig. 1; path b; R = H_2) can be discounted on the grounds that the methyl of a chain-initiating acetate group is not sufficiently acidic to have furnished the nucleophilic enol required as the substrate for a

chlorination reaction. However, a two-chain pathway remains feasible if the chlorinated chain-initiating unit were to be generated from a more appropriate precursor. One possibility is for the dichloroacetyl unit to be synthesized from a suitable acetate-derived substrate before being used to initiate a polyketide chain (Fig. 1; path b; R = Cl_2). Such a starter unit might exchange deuterium with its environment during formation or after serving as a chain initiator.

To ascertain whether dichloroacetic acid itself might function as a precursor of mollisin, the deuterated compound was included in a medium used to grow *M. caesia*. At the concentration used, the supplement did not inhibit mollisin production, and ^2H nmr examintaion of broth extracts verified that excess [2-^2H]dichloroacetic acid was present throughout metabolite biosynthesis. Neither in the ^2H nmr spectrum nor in the gas chromatography – mass spectrum of mollisin extracted from the cultures was any evidence of ^2H enrichment detected. The upper limits for detection of the isotope, estimated to be approximately 1% and 0.6%, respectively, were higher than those for the experiment with [2-$^2H_3$]acetate because of the smaller sample size. Because of the more limited opportunities for metabolism of the chlorinated substrate, however, higher specific incorporations might also have been expected if it were a precursor of mollisin.

While the foregoing result suggests that free dichloroacetic acid is not incorporated, it is not conclusive. The absence of isotopic enrichment might have been due to cellular impermeability or to the inability of thiokinase to activate this substrate. Endogenous synthesis from an acetate-derived progenitor metabolite would likely furnish the chain-initiating precursor in an activated form. By analogy with biosynthesis of the dichloroacetyl moiety of chloramphenicol in *Streptomyces venezeulae* (Ranade and Vining, unpublished), a plausible precursor candidate would be acetoacetyl coenzyme A. To ascertain whether a chloroperoxidase that catalyzes formation of dichloroacetyl coenzyme A from acetoacetyl coenzyme A was present in *M. caesia*, extracts of the mycelium from cultures producing mollisin were assayed for this enzyme. No activity could be detected. In contrast, chloroperoxidase activity could be demonstrated when the assay was carried out with monoclorodimedone as the substrate. Since this compound is widely accepted as an analogue of the natural substrate by chloroperoxidases that introduce chlorine at the methylene group of β-diketones (18), activity under these conditions suggests that the natural substrate is an extended polyketide, perhaps constrained in a cyclic conformation.

A second way in which a dichloroacetyl chain-initiating group might be formed is through generation *in situ* from a longer polyketide (Fig. 1; path b, R = CH_3CO- or multiples). This could serve as a chloroperoxidase substrate by providing the necessary β-diketone grouping in a manner similar to that postulated for the single-chain polyketide precursor. Thus although the enzyme assay results are consistent with the single-chain polyketide pathway of biosynthesis, they do not exclude the possibility of two chains if the second chain were processed in this way. Clearly it is difficult to decide between such alternatives by the type of isotopic labeling and enzyme experiments described above, since both involve similar chain scission reactions that remove the distinguishing features of the progenitor polyketide (or polyketides). Answers to questions of this kind will probably require enzyme isolation and characterization of substrate specificities.

Experimental

Cultures and labeled substrates

"[1,2-$^2H_4$]Acetic acid" (99 at.% ^2H) and "[1,2-$^2H_2$]dichloroacetic acid" (98 at.% ^2H) were from MSD Isotopes, Pointe Claire, Que. Aqueous solutions were neutralized before filter sterilization.

In labeling experiments with deuterated acetate, ten 25 × 150 mm culture tubes, each containing 10 mL of malt extract agar plus NaCl (1), were inoculated with *M. caesia* and incubated at 22°C. To each tube, 100 μL of a 0.3 M sterile aqueous solution of sodium [2-$^2H_3$]acetate was added on the fifth day; a further 50 μL was added on the eleventh day. After 26 days mollisin was extracted as described (1) and purified by recrystallization.

When deuterated dichloroacetic was used, cultures of *M. caesia* were grown in five 100 × 15 mm Petri plates, each containing 20 mL of potato dextrose agar (BBL) supplemented with a sterile solution of sodium [2-^2H]dichloroacetate (0.1 mmol). After 16 days incubation at 22°C, mollisin was extracted with chloroform and purified by preparative thin-layer chromatography (silicia gel Sil 60, Merck; chloroform as solvent). Mollisin (bright-yellow zone, R_f 0.56) was the main component in the extract. It was eluted with acetone as a yellow solid (4.8 mg), mp 203°C, with an absorption maximum at 420 nm, as reported (1). Unused [2-^2H]dichloroacetate was transferred from the chloroform culture extract into bicarbonate solution and recovered as the free acid with chloroform. Its presence in the extract was established by ^2H nmr.

For enzyme assays, an inoculum was first prepared by transferring mycelium from 8-day-old slant cultures on 2% malt agar to Sabouraud's broth (50 mL/250-mL Erlenmeyer flask) and incubating the culture without agitation at 22°C for 10 days. The mycelium was washed, resuspended in 0.1 M phosphate buffer, pH 7.0, homogenized, and added (10 mL/200 mL) to 2% malt extract (200 mL/l-L Erlenmeyer flask). These cultures were grown in the same way as the inoculum for 19 days.

Enzyme assays

Mycelium from the 19-day cultures was collected and washed with 0.1 M phosphate buffer, pH 7.0, by centrifugation. It was resuspended in twice its volume of buffer and disrupted with a sonic oscillator (8 × 30 s). After clarification (10 000 × *g*, 30 min), the cell homogenate was assayed for chloroperoxidase activity and its protein content was measured.

Chloroperoxidase activity was determined by two procedures: the first used monochlorodimedone as the substrate and was based on the increase in absorbance at 278 nm accompanying formation of dichlorodimedone (17). The second depended upon the formation of a ^{36}Cl-labeled organic product from $^{36}Cl^-$ and acetoacetyl coenzyme A; it was performed by incubating 10 μL of 0.5 M K^{36}Cl (0.8 μCi/mmol), 0.5 μmol of acetoacetyl coenzyme A, 2 μL of 30% (v/v) aqueous H_2O_2, 84 μL of 0.1 M acetate buffer, pH 4.5, and 100 μL of cell extract. After agitation for 1 h at 22°C, the reaction was stopped and coenzyme A esters were hydrolyzed by adding 1 M NaOH. The mixture was acidified, and the radioactivity in an ethyl acetate extract was measured.

Nuclear magnetic resonance spectra

The ^2H nmr spectra were recorded at 46.075 MHz without lock or ^1H decoupling on a Bruker MSL-300 spectrometer. The experimental parameters were as follows: 10 mg of mollisin enriched from [2-$^2H_3$]-acetate in 0.40 mL of chloroform; 5-mm sample tube; spectral width 2000 Hz; one pulse sequence with flip angle ca. 40° (6 μs); repetition time 2.5 s; data size 8 K. Spectra were collected in six lots of 12 000 transients, each lot being zero-filled to 32 K and Fourier transformed before addition to allow for small field drifts, which were correctable from the position of the natural abundance C^2HCl_3 peak. The ^1H spectrum (300.13 MHz) was recorded after the sample was dried and redissolved in C^2HCl_3; the spectral width was 4505 Hz; data size 16 K zero-filled to 32 K; flip angle 45° (6 μs); repetition time 6.8 s.

Similar conditions were adopted to record the ^2H and ^1H nmr spectra

of mollisin from cultures supplemented with [2-^{2}H]dichloroacetate; for the ^{2}H spectrum, a 0.5 mg sample in 0.5 mL of C^2HCl_3 was used and approximately 80 000 transients were accumulated. Chemical shifts in the spectrum for mollisin have been assigned (2).

Mass spectra

A Finnigan model 4500 gc/ms was used with a DB5 chromatographic column. The sample was examined by chemical ionization with isobutane at 0.7 Torr (1 Torr = 133.3 Pa); ion source at 230°C.

Acknowledgements

The mass spectra were obtained by Dr. R.K. Boyd and Mr. D.J. Embree, and technical assistance was provided by Mr. J. Van Ingen, Atlantic Research Laboratory. The research was supported by a grant to L.C.V. from the Natural Sciences and Engineering Research Council of Canada.

Solvatation et complexation des métaux dans les mélanges eau – fluorure d'hydrogène. Sn, Cd, Pb et Tl

RÉJEAN BEAUDOIN ET HUGUES MÉNARD

Département de chimie, Faculté des sciences, Université de Sherbrooke, Sherbrooke (Québec), Canada J1K 2R1

Reçu le 17 mai 1989

RÉJEAN BEAUDOIN et HUGUES MÉNARD. Can. J. Chem. **68**, 5 (1990).

Le comportement électrochimique de l'étain et du thallium dans les mélanges eau–HF a été étudié sur toute la gamme de concentration. Le thallium ne forme pas de complexes fluorés. L'étain Sn^{2+} forme deux complexes fluorés, SnF_2 et SnF^+, dans les mélanges contenant moins de 60% en HF. Le complexe SnF_2 est suffisamment fort pour empêcher la formation de complexes chlorés. La formation de SnF_6^{2-} et SnF_5^- a aussi été démontrée pour l'étain Sn^{4+}. La force relativement grande des complexes fluorés de l'étain se réflète bien sur la fonction R_0 (M). Tous les métaux étudiés, Sn, Cd, Pb et Tl, sont soins solvatés dans les mélanges eau–HF que dans l'eau, sauf là où la complexation par l'ion fluorure est importante, c.-à-d. l'étain. Aux hautes concentrations en HF, l'espèce HF_2^- semble devenir l'expèce complexante.

Mots clés : polarographie, thallium, étain, cadmium, plomb, fluorure d'hydrogène.

RÉJEAN BEAUDOIN and HUGUES MÉNARD. Can. J. Chem. **68**, 5 (1990).

The behavior of tin and thallium has been studied in water–HF mixtures. The formation of thallium fluoride complexes was not observed. Tin Sn^{2+} forms two complexes, SnF_2 and SnF^+, in mixtures containing less than 60% in HF. SnF_2 is strong enough to prevent the formation of chloride complexes. SnF_6^{2-} and SnF_5^- have been determined for Sn^{4+} in the same solutions. The relatively high strength of the tin fluoride complexes is reflected in the R_0 (M) function. In fact, all the metals studied, Sn, Cd, Pb, and Tl, are less solvated in water–HF mixtures than in water, except for the case where the fluoride complex is strong, i.e., tin. HF_2^- seems to be the complexing species at high HF concentrations.

Key words: polarography, thallium, tin, cadmium, lead, hydrogen fluoride.

[Journal translation]

Introduction

Les mélanges eau – fluorure d'hydrogène ont été largement utilisé pour la solubilisation de divers matériaux et pour le décapage de semi-conducteurs. Le comportement électrochimique des ions métalliques dans ces mélanges a été étudié surtout pour des applications analytiques. Les variations des propriétés d'oxydoréduction en fonction de la composition en HF méritent néanmoins d'être mieux définies.

Le comportement du mélange eau–HF lui-même est relativement bien défini, soit au niveau de l'acidité avec les fonctions H_0 (1, 2) et R_0(H) (3, 4), au niveau de l'activité en ions fluorure libres R_0(F) (4, 5) de même qu'au niveau de l'association moléculaire grâce aux études par spectroscopie infrarouge (6–9).

La fonction R_0(M) a été utilisé de façon à obtenir les variations d'activité des ions métalliques en fonction de la composition du mélange eau–HF (10). Il a cependant été démontré que la solvatation de l'ion F^- est beaucoup plus importante dans les mélanges eau–HF que dans l'eau (5), principalement dû à la formation de la paire d'ions ($H_3O^+ \ldots F^-$) (6–8). Il est donc évident que les ions métalliques seront moins solvaté dans les mélanges eau–HF que dans l'eau. De récentes études ont montrées que le cadmium et le plomb sont complexés par l'ion fluorure aux basses concentrations en HF mais que cette complexation diminue avec la concentration en HF (11, 12).

Le comportement de l'étain et du thallium sera discuté et des conclusions générales pourront étre tirées sur la solvatation sur tout le domaine de concentration en HF.

Partie expérimentale

Le potentiel de réduction du métal a été mesuré par polarographie. Un capillaire recouvert de polyéthylène (13) résistant au HF a été utilisé comme électrode de mercure. Aux concentrations de HF inférieures à 60%, une électrode de référence au calomel a été utilisée alors qu'aux hautes concentrations en HF, le système Cu/CuF_2 (14) offre une meilleure stabilité. Les mesures ont été effectuées à 25 ± 1°C pour les concentrations en HF inférieures à 60% et à 0°C pour les concentrations supérieores à 60%.

Les polarogrammes ont été enregistrés à une concentration de 10^{-3} M pour l'espèce ionique considérée. Pour l'étude des complexes fluorés, le potentiel de réduction du système de référence indépendant du solvant (4, 10, 15) Fc^+/Fc est mesuré dans la même solution que celle du métal étudié. La précision sur le potentiel de demi-vague est de ±5 mV. Pour les mesures de complexes chlorés, la concentration du métal est de 10^{-3} M, auquel du KCl est ajouté en quantité voulue. Une description complète du système de mesure de la cellule et les données expérimentales sont présentées aux références 16 et 17.

Résultats

L'étain dans les mélanges eau–HF

L'évolution des complexes fluorés en fonction de la concentration en HF dépend de l'activité en ions fluorure libres. Un déplacement du potentiel de demi-vague ($E_{1/2}$) mesuré par rapport au potentiel d'une électrode réversible aux ions fluorure est donc indicatif du type de complexe fluoré en solution. Il faut noter ici que la réduction des complexes étudiés présentent des vagues polarographiques réversibles. Il est donc possible de calculer, à partir de l'équation de Nernst, les pentes du déplacement de $E_{1/2}$ en fonction de l'activité en ions fluorure libres que l'on devrait mesurer pour des complexes fluorés d'ordre croissant (11, 12). Les pentes théoriques calculées en fonction de l'activité en ions fluorure libres sont les suivantes : SnF^+, +0,029; SnF_2, 0; SnF_3^-, −0,029 volt. La figure 1 illustre l'évolution du $E_{1/2}$ de réduction de l'étain et la figure 2 illustre le comportement du $E_{1/2}$ de l'oxydation de même métal en fonction de l'activité en ions fluorure libres R_0 (F). Les pentes mesurées sur ces graphiques, et présentées aux tableaux 1 et 2, permettent de déterminer l'ordre des complexes fluorés en solution. Les complexes déterminés pour la réduction de l'étain, soit le SnF_3^-, le SnF_2 et le SnF^+, sont utilisés comme complexe de départ pour déterminer les complexes de l'étain oxydés vers l'état Sn^{4+}.

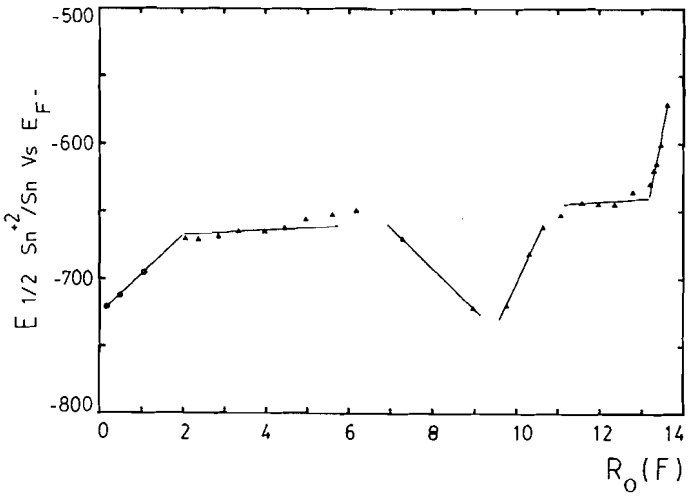

FIG. 1. Potentiel de réduction de l'étain vs. E_{F^-} en fonction de R_0(F). (Chaque point sur les figures représente la moyenne de 5–10 mesures.) Les pentes ont été calculées par régression linéaire.

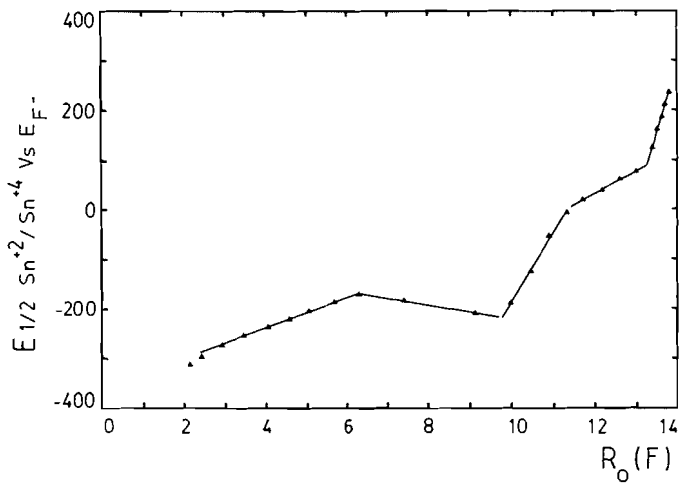

FIG. 2. Potentiel d'oxydation de l'étain vs. E_{F^-} en fonction de R_0(F).

L'étain en présence d'ions chlorure

La présence d'ions chlorure dans une solution eau–HF contenant de l'étain (Sn^{2+}) cause un déplacement du $E_{1/2}$ de réduction à partir d'une concentration en HF supérieure à 30% et ce pour des concentrations en ions chlorure de l'ordre d'un molaire. La figure 3 montre le déplacement du potentiel de demi-vague pour quelques concentrations en HF en fonction de la concentration en ions chlorure. Le tableau 3 donne les constantes de formation successives des complexes chlorés de l'étain calculées selon la théorie de DeFord et Hume (19).

Le thallium dans les mélanges eau–HF

L'étude de la réduction du thallium dans les mélanges eau–HF nous donne une pente de $E_{1/2}$ vs. E_{F^-} en fonction de R_0 (F) (fig. 4) près de 0,059 V, ce qui indique que le thallium n'est pas complexé par l'ion fluorure dans les mélanges eau–HF. Aux très hautes concentrations en HF, c.'à'd. plus de 80%, la vague de réduction du thallium se confond avec la réduction de l'hydrogène, mais la tendance semble toujours être la même au niveau de la pente.

Le thallium en présence d'ions chlorure

La figure 5 montre le déplacement de $E_{1/2}$ en présence d'ions

chlorure à plusieurs concentrations en HF. Le déplacement de $E_{1/2}$ est relié à la formation de complexes chlorés en solution mais la faible amplitude du déplacement montre une complexation relativement faible. Le tableau 4 donne les constantes de formation successives pour les complexes chlorés du thallium.

Le cadmium et le plomb dans les mélanges eau–HF

Les vagues de réduction du cadmium et du plomb ont été mesurées à haute concentration en HF de façon à compléter les résultats déjà publiés (11, 12).

Discussion

L'étain

L'étain en solution aqueuse contenant l'ion fluorure a été étudié par plusieurs auteurs. Schaap *et al.* (18) puis Bond et Taylor (20) ont déterminé les constantes de formation des complexes fluorés en milieu acide et neutre. Le pourcentage de distribution montre que le complexe SnF_3^- est prédominant jusqu'à 10^{-7} M en ions fluorure libres. Hall et Slater (21) ont calculé les relations thermodynamiques ΔG, ΔH et ΔS pour la réaction [1] et ils concluent que le complexe fluoré est plus stable, en solution aqueuse, que les complexes avec le chlore et le brome.

[1] $Sn^{2+} + 3F^- \rightleftarrows SnF_3^-$

Donc on considère que le complexe d'étain formé à faible concentration en HF sera le SnF_3^-. Le tableau 1 montre une pente de −0,034 volt pour des concentrations en HF jusqu'à 2%, ce qui confirme que le complexe en solution est le SnF_3^-.

Dans le domaine de 2 à 60% en HF, il y a formation de deux complexes fluorés différents de celui qui prédomaine dans les solutions inférieures à 2% en HF. Les pentes mesurées sur la figure 1 permettent de dire qu'on a le complexe SnF_2 dans le domaine de 2 à 45% en HF et le complexe SnF^+ dans la région de 45 à 55% en HF. L'évolution des complexes dans les mélanges eau–HF s'explique bien puisque l'activité en ions fluorure libres diminue lorsque la proportion de HF augmente dans la solution.

Schaap *et al.* (18) ont proposé l'équilibre suivant pour l'oxydation de l'étain dans les solutions aqueuses d'ions fluorure :

[2] $SnF_3^- + 3F^- \rightleftarrows SnF_6^{2-} + 2é$

Leblond-Routhier (17) a démontré que la vague d'oxydation due à la réaction [3] est réversible (pente de 29 mV) dans les solutions aqueuses

[3] $Sn^{2+} \rightleftarrows Sn^{4+} + 2é$

de HF, quoiqu'aucune vague n'apparaît pour la réduction de l'étain au degré d'oxydation plus quatre vers plus deux. Même en voltamétrie à balayage rapide, on n'observe pas la réduction de Sn(IV). On peut donc exprimer l'équation de Nernst sous la forme suivante :

$$[4] \quad (E_{Sn}) = (E^0_{Sn}) + \frac{0{,}059}{2} \log \frac{[SnF_6^{2-}]}{[SnF_3^-][F^-]^3}$$

Au potentiel de demi-vague $[SnF_3^-] = [SnF_6^{2-}]$ et l'équation [4] devient

$$[5] \quad (E_{Sn}) = (E^0_{Sn}) - \frac{0{,}059}{2} \log [F^-]^3$$

$$[6] \quad E_{F^-} = E^0_{F^-} - 0{,}059 \log [F^-]$$

$$[7] \quad \Delta E_{1/2} = (E_{Sn}) - (E_{F^-}) = \text{cte} + 0{,}059 \log [F^-] - \frac{3 \times 0{,}059}{2} \log [F^-]$$

$$[8] \quad \Delta E_{1/2} = \text{cte} - 0{,}029 \log [F^-]$$

La pente du potentiel versus le logarithme de l'activité en ions fluorure devrait donc être de −0,029 volt pour l'équilibre [2]. La pente mesurée à moins de 2% en HF est de −0,034 volt, ce qui permet donc de considérer le complexe SnF_6^{2-} en solution. L'écart mesuré entre la valeur théorique et les valeurs mesurées pour les concentrations inférieures à 2% est dû à la vague

TABLEAU 5. Constantes d'equilibre et de formation successives des complexes fluorés de l'étain dans les mélanges eau–HF

	log K	log β
SnF_2	9.5	16.0
SnF^+	6.5	9.5

d'oxydation qui n'est pas totalement réversible pour ce domaine de concentration par rapport aux hautes concentrations en HF où la vague d'oxydation est réversible (17).

En solution aqueuse, on peut considérer le complexe SnF_3^- pour Sn(II) et SnF_6^{2-} pour Sn(IV) comme exprimé aux équations [1] et [2].

Les résultats obtenus pour l'oxydation de Sn(II) à Sn(IV) dans les mélanges eau–HF de 2 à 55% en HF montrent la présence de deux complexes selon la concentration en HF. Si on applique le même raissonnement que dans les solutions diluées de HF et la même façon de calculer la pente, on peut établir l'équilibre suivant:

[9] $SnF_2 + 3F^- \rightleftarrows SnF_5^- + 2é$

pour les mélanges de 2 à 45% en HF. La pente est de −0,030 volt, ce qui correspond au complexe SnF_5^-.

Dans les mélanges de 45 à 55% en HF, la pente est plus difficile à mesurer avec précision. On peut seulement proposer le complexe SnF_3^+. Les complexes de coordination 5 et 6 sont relativement commun pour les éléments du groupe IV. La possibilité d'utiliser les orbitales d pour la complexation rend difficile la prédiction du nombre de coordination à cause de la faible différence d'énergie entre les deux états (22). Un complexe chargé comme le SnF_3^+ a cependant peu de chance d'exister à moins d'être largement stabilisé par une autre espèce en solution.

Aux concentrations en HF de plus de 60%, l'évolution des $E_{1/2}$ de réduction et d'oxydation permet de conclure que l'espèce complexante en solution n'est plus l'ion fluorure.

Il est possible d'évaleur les constantes de formation à partir du changement de pente du potentiel de demi-vague réversible aux ions fluorure en fonction de l'activité en ions fluorure R_0(F) (10, 11). Aux points d'inflection à la figure 1, le logarithme des constantes de formation peut être considéré égal à R_0(F). Le tableau 5 montre les valeurs ainsi obtenues et la figure 6 présente la distribution des divers complexes fluorés en fonction de l'activité en ions fluorure dans le mélange eau–HF. Le complexe SnF_3^- se retrouve seulement en solution où la concentration en HF est moins de 2%.

En solution aqueuse, l'étain donne trois complexes chlorés. D'autre part, dans les mélanges eau–HF sans chlorure, l'étain donne deux complexes fluorés. Le complexe SnF_2 existe de façon majoritaire dans les mélanges jusqu'à 30% en HF. En présence de KCl à la figure 3, on constate qu'il n'y a pas de déplacement du potentiel de demi-vague de l'étain aux concentrations inférieures à 30% en HF. On peut donc supposer que le complexe fluoré est suffisamment fort pour empêcher la formation de complexes chlorés. Dans HF 47% on observe un déplacement rapide du potentiel de demi-vague avec la concentration en KCl. L'espèce fluorée en solution eau–HF est le SnF^+. Il semble qu'il soit possible dans ce mélange d'ajouter des ligands sur l'étain. L'espèce en solution est probablement

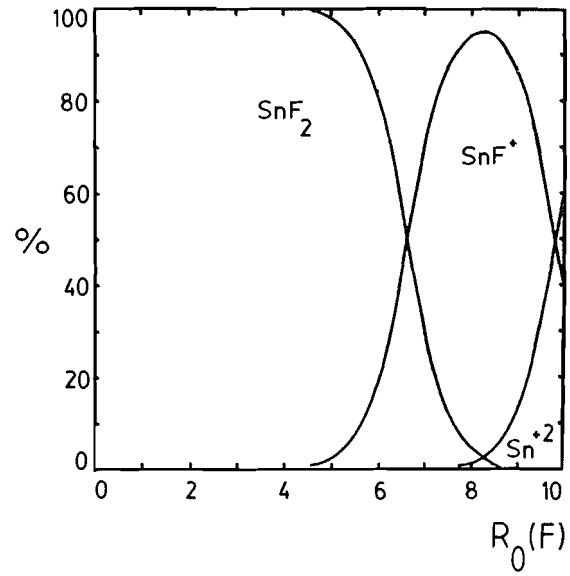

FIG. 6. Distribution des complexes fluorés de l'étain en fonction de R_0(F).

SnClF, un complexe mixte qui n'implique pas le remplacement d'un ion fluorure sur le métal. Le complexe $SnCl_2$ n'apparaît qu'à très grande concentration en ions chlorure. Le tableau 3 montre que les constantes de formation des complexes chlorés de l'étain augmentent avec la concentration en HF. Dans HF 56 et 65%, la diminution de la force des complexes fluorés permet la formation de complexes chlorés de degré supérieur.

Le thallium

Les solutions aqueuses de thallium contenant l'ion fluorure ont été étudié par plusieurs auteurs. Bond (23) a étudié le thallium en présence d'ions fluorure par polargraphie et par potentiométrie. Les complexes du thallium sont en général très faibles. À partir de résultats potentiométriques, il apparaît concevable que l'ion perchlorate soit plus complexant pour le thallium que l'ion fluorure. La constante de stabilité pour le complexe TlF est très faible, de l'ordre de 0,4 ou moins. Les complexes chlorés sont relativement faibles avec β_1 et β_2 de 1,00 et 0,36 respectivement. $TlCl_2^-$ est d'ailleurs observé seulement à force ionique élevée. Notre graphique du potentiel de demi-vague en fonction de l'activité en ions fluorure donne une pente de −0,056 V. Cette valeur est près de la valeur théorique de −0,059 V et indique donc que le thallium n'est pas complexé par l'ion fluorure dans les mélanges eau–HF.

En solution aqueuse contenant des ions Cl^-, le thallium n'est que faiblement complexé par ces ions. Selon la force ionique, Bond (23) a observé soit un complexe ou deux complexes chlorés. Dans les mélanges eau–HF, la force ionique est élevée et en présence d'ions Cl^- on devrait donc s'attendre à obtenir deux complexes chlorés comme c'est le cas en solution aqueuse à force ionique élevée. Dans HF 5%, nous observons deux complexes chlorés, une diminution du courant de diffusion a été relié à la précipitation du chlorure de thallium. Le précipité a été identifié par diffraction des rayons-X. Dans HF 26 et 47%, nous observons aussi deux complexes chlorés. L'évolution du courant de diffusion montre bien qu'il y a précipitation du chlorure de thallium suivi d'une resolubilisation à plus haute concentration en ions chlorure.

Le thallium ne forme pas de complexes fluorés dans les mélanges eau–HF. Par contre, en présence des ions Cl^-, on

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

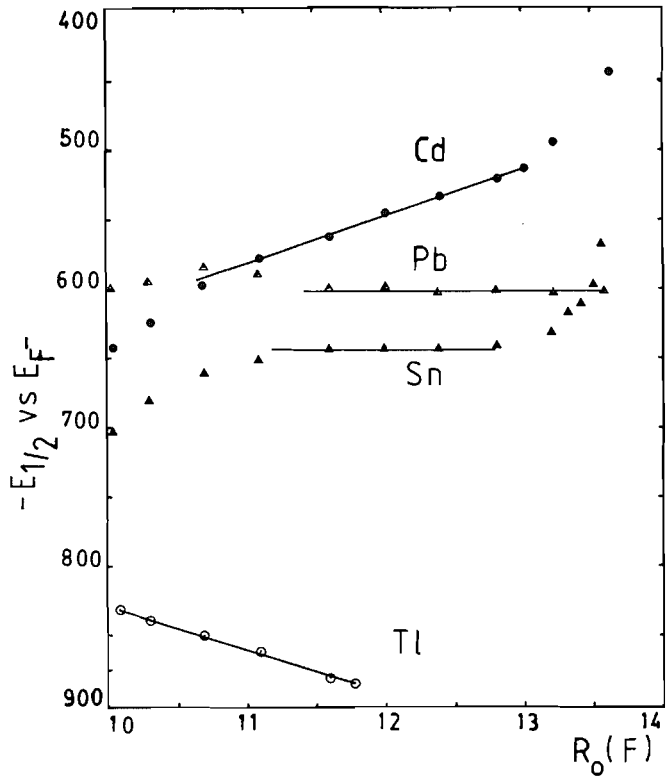

FIG. 7. Potentiel de réduction des métaux vs. E_{F^-} dans la région des hautes concentrations en HF.

forme des complexes chlorés faibles dans les mêmes mélanges. Il est donc raisonnable, en présence d'ions Cl^- de supposer la présence des complexes chlorés faibles dans les mélanges eau–HF et une distribution de la même façon que dans l'eau. La principale distinction entre les deux milieux, c'est la force ionique élevée pour les mélanges eau–HF.

Les hautes concentrations en HF

L'état d'ionisation dans les mélanges eau–HF a été établi par voie électrochimique (3–5) et spectroscopique (6, 7, 9). Les équations suivantes résument les équilibres en solution :

[10] $H_2O + HF \rightleftarrows [H_3O^+ \cdot F^-]$

[11] $[H_3O^+ \cdot F^-] \rightleftarrows H_3O^+ + F^-$

Les mesures de $R_0(F)$ montrent que l'équilibre [13] est largement porté vers la gauche.

[12] $[H_3O^+ \cdot F^-] + HF \rightleftarrows H_3O^+ + HF_2^-$

[13] $HF + F^- \rightleftarrows HF_2^-$

Des mesures spectroscopiques ont mis en évidence la présence de HF_2^- à haute concentration en HF et la formation de polymères de HF (9).

Pour les faibles concentrations en HF, nous avons établi la présence de complexes fluorés. À des concentrations en HF supérieures à 60%, l'évolution du potentiel de demi-vague, tel que présenté à la figure 7, ne peut pas être expliqué en terme de complexes fluorés.

L'apparition de l'espèce HF_2^- en solution peut venir expliquer le déplacement important du potentiel de réduction du Cd^{2+}/Cd et de Sn^{2+}/Sn. Il n'y a pas de techniques électrochimiques qui permettent de mesurer l'activité ou la concentration de l'espèce HF_2^- mais, sur une base purement qualitative, on peut estimer que la concentration en HF_2^- suit la concentration en H_3O^+ dans le domaine de 70 à 80% en HF. Si on calcule la molarité de H_3O^+ à 70% et à 80% en poids de HF, on obtient respectivement 21 et 14 molaires. La variation est de 7 moles et la variation de $R_0(F)$ est de 0,9 dans ce domaine. La variation est donc comparable, log 7 = 0,85.

La pente du potentiel de réduction réversible aux ions fluorure des quatre métaux étudiés est linéaire dans le domaine de 70 à 80% en HF. On peut donc considérer que la pente mesurée en fonction de $R_0(F)$ ($-\log a_{F^-}$) est comparable à celle qu'on pourrait tracer en fonction de $-\log [HF_2^-]$, les deux fonctions ayant une variation parallèle.

Dans la région de 70 à 80% en HF nous mesurons les pentes suivantes : thallium, +0,040 V; plomb, +0,010 V; étain, −0,010 V; cadmium, −0,027 V. Si on introduit la concentration de HF_2^- à la place de a_{F^-} dans les équations de Nernst, il est possible de définir les complexes présents dans les mélanges eau–HF concentrés.

Le thallium ne forme pas de complexes fluorés. Il est donc raisonnable que celui-ci ne forme pas de complexe avec HF_2^-. La pente mesurée est la même que pour les solutions peu concentrées en HF. Le comportement particulier du thallium est très bien illustré à la figure 4. Il n'y a pas de changement notable en passant du système eau plus ions complexants aux mélanges de solvants eau–HF plus ions complexants, contrairement aux autres métaux qui eux forment des complexes fluorés à divers degrés.

Le plomb et l'étain forment des complexes contenant deux ions fluorure à faible concentration en HF. Il apparaît raisonnable que ces métaux forment des complexes avec HF_2^- du même ordre qu'avec l'ion fluorure. Les pentes mesurées sont près de zéro. Si on considère les approximations faites précédemment on peut conclure à la formation de complexes selon les équilibres suivants :

[14] $Pb^{2+} + 2HF_2^- \rightleftarrows Pb(HF_2)_2$

[15] $Sn^{2+} + 2HF_2^- \rightleftarrows Sn(HF_2)_2$

Le cadmium forme un complexe contenant trois ions fluorure à faible concentration en HF. Comme pour le plomb et l'étain, on peut considérer la formation d'un complexe contenant trois ions HF_2^- à haute concentration en HF. La pente de −0,027 V nous permet de déduire le complexe $Cd(HF_2)_3^-$.

[16] $Cd^{2+} + 3HF_2^- \rightleftarrows Cd(HF_2)_3^-$

Conclusion

L'analyse du comportement électrochimique des ions métalliques en milieu eau–HF montre que l'énergie de solvatation y est plus faible qu'en solution aqueuse, c'est-à-dire que le potentiel de réduction mesuré par rapport à une référence independante (Fc^+/Fc) du solvant y est moins négatif qu'en milieu aqueux. L'ion thallium qui ne forme que de très faibles complexes avec l'ion fluorure illustre bien ce comportement. Dans certains cas, comme pour l'étain, la formation d'un complexe fluoré fort compense la perte de solvatation dans le domaine des faibles concentrations en HF. Le fait qu'il n'y ait pas de complexes chlorés formés en présence du complexe SnF_2 démontre bien la force de ce dernier.

Le déplacement important du potentiel de réduction de certain ions métalliques aux hautes concentrations en HF a été relié à la présence de l'ion HF_2^- qui devient l'espèce complexante. L'ordre de ces complexes ne peut cependent qu'être proposé car l'activité de l'espèce HF_2^- n'est pas mesurable.

The isolation and characterization of a novel triterpene glycoside from the sea cucumber *Cucumaria frondosa*, collected from the Gulf of St. Lawrence, are described. Physico-chemical data obtained on the underivatized saponin are presented in support of structure **1** for frondoside A. The structure is characterized by the presence of a branched oligosaccharidic chain composed of five units. The holostane-type aglycone features an endocyclic double bond at position C-7,8 and a β-acetoxy group at C-16.

Key words: triterpene glycoside; *Cucumaria frondosa* saponins; saponins, triterpene from holothurians; holothurian saponins; echinoderm triterpene saponins.

MICHEL GIRARD, JACQUELINE BÉLANGER, JOHN W. APSIMON, FRANÇOIS-XAVIER GARNEAU, CHRISTIAN HARVEY et JEAN-ROBERT BRISSON. Can. J. Chem. **68**, 11 (1990).

On décrit l'isolation et l'élucidation structurale d'un nouveau triterpène-glycoside, obtenu de l'holothurie *Cucumaria frondosa* provenant du golfe du St-Laurent. En se basant sur les données physico-chimiques du produit intact, on propose la structure **1** pour le frondoside A. Le composé est caractérisé par la présence d'une chaîne oligosaccharidique branchée, de cinq unités. L'aglycone de type holostane possède une insaturation en position C-7,8 et un groupement acétoxy-β en C-16.

Mots clés : triterpènes, glycosides; *Cucumaria frondosa*, saponines; saponines triterpénique des holothuries; saponines des holothuries; saponines des échinodermes.

Introduction

Sea cucumber saponins, commonly referred to as holothurins, are triterpene glycosides of the lanosterol type, with a distinctive D-ring fused γ-lactone (1). Traditionally, structural studies of these saponins have involved degradation into the various components and formation of derivatives, hence requiring large amounts of material and, in many cases, leading to the formation of artifacts. The development in the last two decades of high resolution NMR techniques, and more specifically ^{13}C NMR spectroscopy, alleviates the need for large quantities of material, and also permits the first studies of intact saponins. The advent of modern high-field two-dimensional (2D) NMR techniques now provides an extremely useful tool for the characterization of complex molecules since these techniques allow for the unambiguous assignment of most signals observed in conventional unidimensional ^{1}H and ^{13}C NMR spectra. Findlay *et al.* (2, 3) have recently demonstrated the usefulness of these techniques by deducing the complete structure of several starfish saponins. In our continuing investigation of marine species of the Atlantic Coast of Canada, we have isolated a novel triterpene glycoside from the holothurian *Cucumaria frondosa* that we have successfully characterized using several of these NMR techniques, and without the need to derivatize the product.

Results and discussion

The brown-colored sea cucumbers were collected off the north coast of the Gulf of St. Lawrence (near Sept-Isles and Port-Cartier, Québec). Frondoside A (**1**) was one of the major constituents separated from the 70% aqueous ethanol extract, and purified by the previously described chromatographic methods (4).

Frondoside A was obtained as a colorless crystalline solid, mp 234–236°C (dec.), $[\alpha]_D$ −13° (H_2O), with no UV absorption maximum above 210 nm. The infrared spectrum (KBr) showed strong hydroxyl absorption at 3400 cm^{-1} (broad) as well as a carbonyl absorption band at 1750 cm^{-1} (broad) indicating the presence of the characteristic γ-lactone and an acetate group. The two bands at 1230 and 825 cm^{-1} suggested the presence of a sulfate moiety; this observation was substantiated by a positive rhodizonate test (5). The location of the sulfate group on C-4 of the xylose unit directly attached to the aglycone was determined by spectroscopic methods (*vide infra*).

Aglycone portion

The assignments for the NMR signals associated with the aglycone moiety (Table 1) showed a close similarity to those reported for cucumariogenin acetate (**2**) (6). The ^{13}C NMR spectrum (Fig. 1) featured signals at 120.41 and 145.80 ppm in the downfield region, indicative of the presence of an endocyclic double bond at the 7,8 position, and two low-field

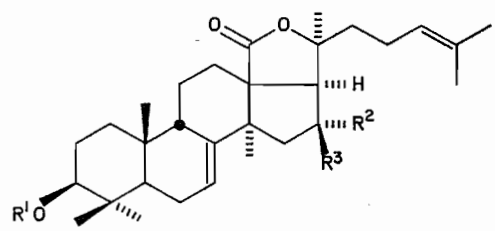
resonances at 180.58 and 171.00 ppm, assigned to the γ-lactone carbonyl and acetoxy carbonyl carbons respectively. The 500-MHz ^1H NMR spectrum (pyridine-d_5:D_2O/5:1) showed a pattern characteristic of most holothurins in the high-field region, and which featured many overlapping signals. In this instance, the use of the COSY experiment allowed the establishment of the connectivities within the framework and thus permitted the assignments of the chemical shifts for the overlapping proton signals.

Assignments were completed using two-dimensional nuclear Overhauser effect (2D-NOE) (Fig. 2a–i). Such an effect only occurs between resonances whose protons are in close proximity to each other and is dependent on interproton distance to the inverse sixth power. Then, the ^{13}C resonances were assigned by a ^{13}C–^1H correlation analysis. Using this information it was possible to complete the elucidation of the aglycone structure.

Of particular interest, the C-9Hβ configuration was confirmed by (a) the presence of a broad doublet at 3.423 ppm, the downfield shift of which had been previously attributed to the anisotropic effect of the γ-lactone carbonyl (7), and (b) a strong NOE between C-9Hβ and C-19H_3 (Fig. 2e), due to the close proximity of these protons.

The presence of an acetoxy group at C-16 was deduced from



2 R^1 = Ac; R^2 = H; R^3 = OAc

3 R^1, R^3 = H; R^2 = OAc

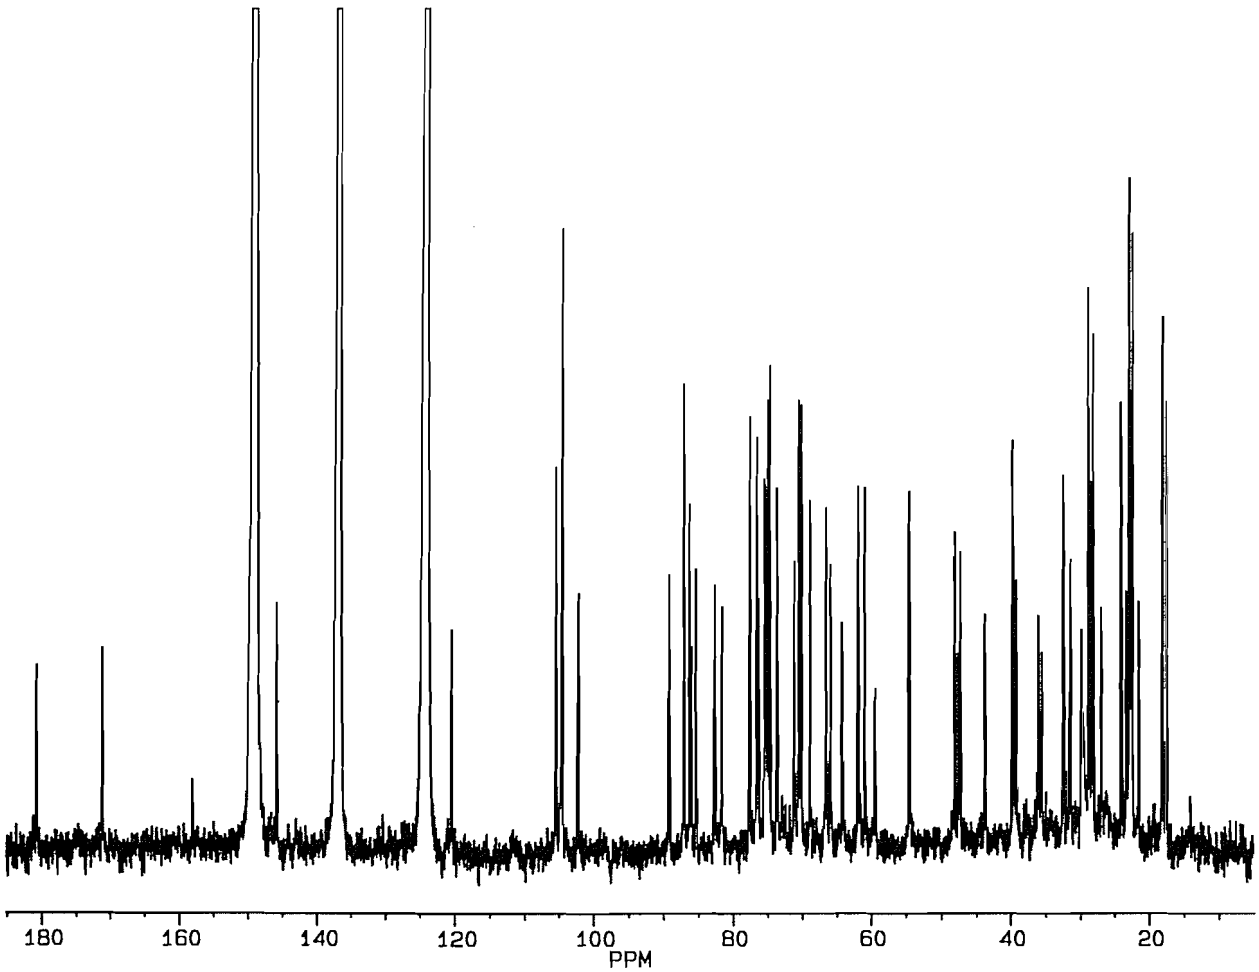


FIG. 1. ^{13}C NMR spectrum of frondoside A in C_5D_5N:D_2O/5:1.

the chemical shift of the C-16H signal (5.963 ppm) (6, 8), which showed coupling to signals at 2.792 (C-17H), 2.672 (C-15Hα), and 1.731 (C-15Hβ) ppm in the 2D-COSY spectrum. The assignments for the two C-15 protons were made here based on a clearly visible long-range coupling (W-coupling) of the C-28H_3 resonance to the C-15Hβ resonance, and its absence at C-15Hα since only the C-15β proton is geometrically well positioned for the known W coupling path (9, 10).

The β configuration of the C-16 acetoxy group was deduced primarily from the 2D-NOE trace of the C-16H signal (Fig. 2f) and the C-17H signal (Fig. 2g). Enhancements were detected between the C-16H resonance (5.963 ppm) and the C-17Hα, the C-15Hα, and the C-28H_3 resonances. An NOE between the C-17Hα and the C-28H_3 resonances was also observed, indicating that the latter group is on the α face of the molecule. Thus, since all the enhancements for C-16H arose for protons that are α, C-16H must also be assigned as α. Coupling constant calculations (11) for the C-16 proton with C-17Hα and the C-15 protons, based on a distorted envelope conformation for the D-ring, again supported the β configuration for the C-16 acetoxy group (Table 2). Therefore, it appears that the presence of the pseudo-equatorial (β) C-16 substituent induces larger downfield shifts on the pseudo-equatorial C-15α and C-17α vicinal protons, a situation analogous to the reported effect of substituents in cyclohexanoid systems (9).

In a recent report on the hydrolysis products from *C. frondosa*, Findlay and Daljeet (8) proposed the epimeric C-16α acetoxy structure for frondogenin (**3**) while reporting spectroscopic data similar to ours. Their assignment of the C-16 OAc configuration was based solely on a presumed, and as yet unconfirmed, deshielding effect on C-17Hα and C-15Hβ, due to the presence of a *syn* substituent, in contrast to our observations supported by the NOE results.

The α configuration of the C-21H_3 group was also confirmed by the presence of an NOE between the C-21H_3 singlet and the C-12 proton resonances (Fig. 2i) and an NOE between the C-21H_3 and C-17Hα resonances (Fig. 2g), indicating the close proximity of C-21H_3 to the C-12 and C-17Hα protons.

Oligosaccharide chain

The constitution of the oligosaccharide chain was studied by gas-chromatographic (GC) analysis of the trimethylsilylated methyl glycosides obtained from mild anhydrous acid methanolysis. Three units of xylose and one unit each of 3-*O*-methyl glucose and quinovose (6-deoxyglucose) were detected while glucose, a sugar usually present in holothurins containing more than two sugar units, was not found. This unusual situation has also been observed in neothyonidioside, the major holothurin from *Neothyonidium magnum* (12).

The sugar sequence and the position of the interglycosidic linkages were determined mainly using a combination of COSY, relay COSY, ^{13}C–^{1}H correlation, and 2D-NOE experiments, and confirmed by fast-atom bombardment (FAB) mass spectrometry. The chemical shift assignments for the proton

15α, 16β		1.2	270

[a]Based on a distorted envelope conformation. For calculations see ref. 8.

and carbon signals are summarized in Table 3 and the spin simulation of the sugar chain is shown in Fig. 3. Using the data from the ^{13}C–^{1}H correlation experiment, it was possible to determine the position of the interglycosidic linkages by comparison of the carbon chemical shifts observed with those of the corresponding methyl glycopyranoside (13) and taking into account the downfield shift resulting from glycosidation (Table 3).

The presence of five sugar units was confirmed in the ^{1}H NMR spectrum where the signals for the five anomeric protons appeared as doublets in the 4.8–5.4 ppm region. The large coupling constants observed for these signals and the intra-residue NOE between their respective C-1H, C-3H, and C-5H resonances (Fig. 4) confirmed the β configuration.

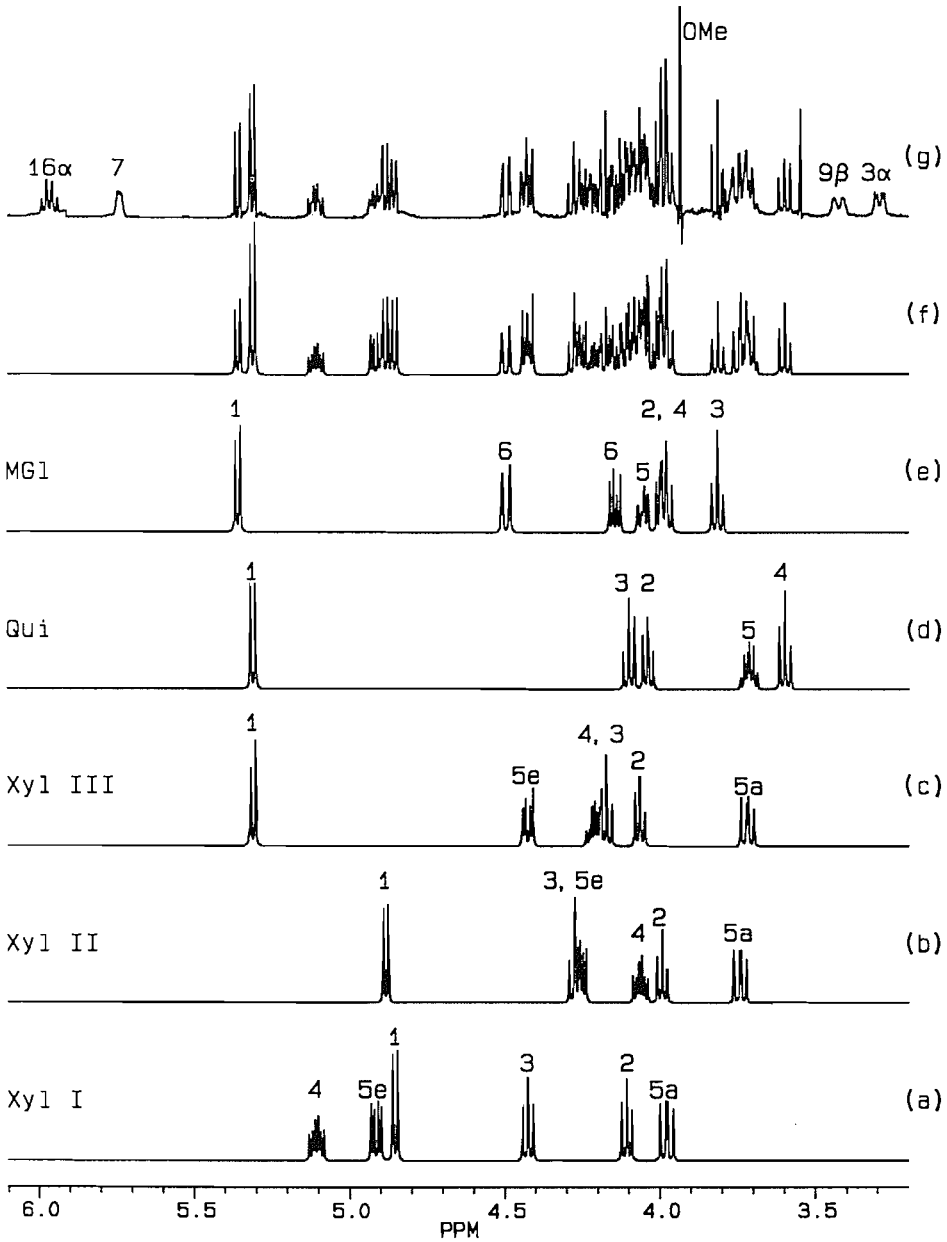

FIG. 3. Downfield region of the ^{1}H NMR spectrum with HOD peak removed, and spin simulation of the pentasaccharide moiety of frondoside A in C_5D_5N:D_2O/5:1.

Xylose I must be linked to the aglycone C-3 due to the strong NOE observed between C-1H of xylose I and the C-3α proton of the aglycone (Fig. 4a). The interglycosidic position of attachment of Xyl I was assigned at C-2 based on the significant downfield shift (7.0 ppm) observed for this carbon resonance. Another important downfield shift (5.4 ppm) was observed at C-4 and was attributed to the presence of a sulfate group at that position. This shift could not be the consequence of a glycosidic linkage since no inter-residue NOE involving C-4H of Xyl I was observed. The FAB mass spectrum also showed evidence of the presence of the sulfate group in the xylose unit directly attached to the aglycone (*vide infra*).

The 3-*O*-methyl glucose (MG1) and one xylose (Xyl III) were terminal units as suggested by the absence of any ^{13}C glycosidation shifts for these sugars. An enhancement between C-1H of MG1 and C-3H of Xyl II (Fig. 4b), as well as a large glycosidation shift on C-3 of Xyl II (8.2 ppm), confirmed that MG1 was β1–3 linked to Xyl II. Similarly, the presence of an inter-residue NOE between C-1H of Xyl II and C-4H of Qui (Fig. 4c), the NOE between the C-6H$_3$ resonance of Qui and C-1H of Xyl II (Fig. 4d), and the downfield shift of C-4 of Qui (8.0 ppm), were indicative that Xyl II was β1–4 linked to Qui. Hence, by deduction, the downfield shift of the C-2 of Qui (6.0 ppm) further suggested that the terminal xylose unit must be attached at this position, and therefore that the quinovose unit is linked at C-2 on the xylose (Xyl I) attached to the aglycone. The 2D-NOE trace for the coincidental doublets (5.308 ppm), corresponding to the anomeric proton signals of Xyl III and Qui (Fig. 4e), showed enhancements on C-2H of Xyl I and C-2H of Qui consistent with the above deductions. Hence, the oligosaccharide moiety of frondoside A consists of a pentasaccharide having the following structure:

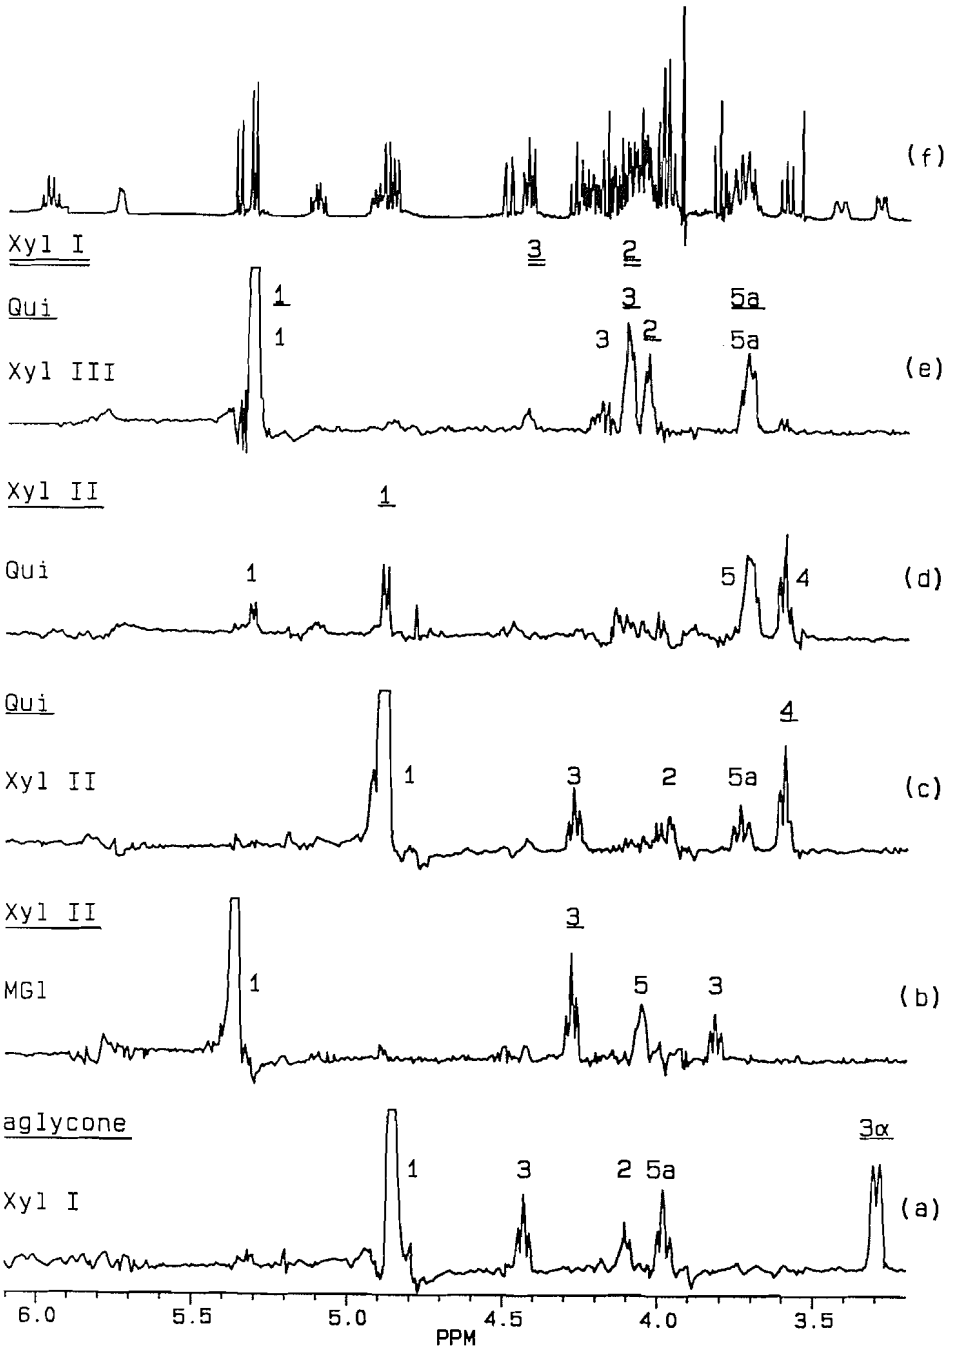

FIG. 4. Downfield region of the ^{1}H NMR spectrum and cross sections of the 2D-NOE contour map for frondoside A in C_5D_5N:D_2O/5:1. Cross section through (a) H-1 of xylose I; (b) H-1 of 3-*O*-methyl glucose; (c) H-1 of xylose II; (d) H-6 of quinovose; (e) H-1 of xylose III and H-1 of quinovose; and (f) normal spectrum with the HOD peak removed.

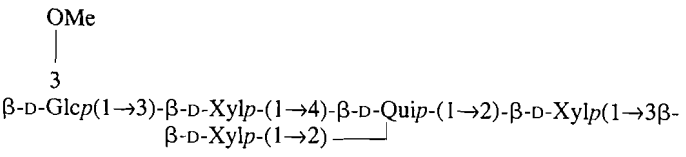

The FAB mass spectra, obtained in the positive and negative ion modes (Fig. 5), are in good agreement with the assigned structure. Molecular weight information was obtained from peaks at *m/z* 1351 $[M_K + H]^+$ and *m/z* 1311 $[A]^-$ in the positive and negative modes respectively.

Therefore, based on the above results, frondoside A possesses structure **1**, that is, 3β-*O*-{3-*O*-methyl-β-D-glucopyranosyl (1→3)-*O*-β-D-xylopyranosyl (1→4)-*O*-[β-D-xylopyranosyl (1→2)]-*O*-β-D-quinovopyranosyl (1→2)-*O*-β-D-4-sulfonato-xylopyranosyl}-16β-acetoxy-holost-7-ene, sodium (or potassium) salt. This is the first example of a naturally occurring holothurin containing an odd number of sugar units (five), and it is the first complete structure reported for a holothurin from the Cucumaridae family.

Experimental

All NMR measurements were performed on a Bruker AM500 spectrometer at ambient temperature with 50 mg of frondoside A dissolved in 0.5 mL of pyridine-d_5/D_2O (5:1) and tetramethylsilane

[a]Difference from corresponding methyl glycopyranoside (12).

as the internal reference. Proton assignments were made using homonuclear shift correlation (COSY) and relay COSY as previously described (2, 3). The two-dimensional nuclear Overhauser experiment (2D-NOE) was done according to Bodenhausen *et al.* (14). The ^{13}C–^1H correlation was performed using a least-squares analysis of the ^{13}C intensity as a function of four proton evolution times of 0.16, 1.0, 2.4, and 3.2 ms (15). Spectral simulations with a linewidth of 1 Hz were done using Bruker's program PANIC.

Melting points were determined on a Fisher–Johns hot stage melting point apparatus or on a Buchi SMP-20 using capillary tubes, and are uncorrected.

Infrared spectra were recorded on a Perkin–Elmer 237-B grating spectrophotometer. Ultraviolet spectra were recorded on a Perkin–Elmer Coleman 124 "double beam" UV–visible spectrophotometer in ethanol solutions. Optical rotations were measured on a Perkin–Elmer 141 polarimeter using a sodium lamp operating at 589 nm. Fast atom bombardment mass spectra (FAB-MS) were recorded on a glycerol support in the positive ion mode on a VG Analytical 7070E instrument.

Gas–liquid chromatography experiments were performed on a Hewlett–Packard 5730-A gas chromatograph equipped with a flame ionization detector. Stainless steel columns (1.8 m long) packed with 3% OV-17 support were used. Thin-layer chromatographic analyses were carried out on precoated silica gel GF-254 (Merck) and reverse-phase KC-18 (Whatman) glass plates. Glycoside fractions were developed in the solvent mixtures $CHCl_3$–MeOH–H_2O: 60-15-2, 60-20-2.5, and 60-25-4. Detection was accomplished by spraying a

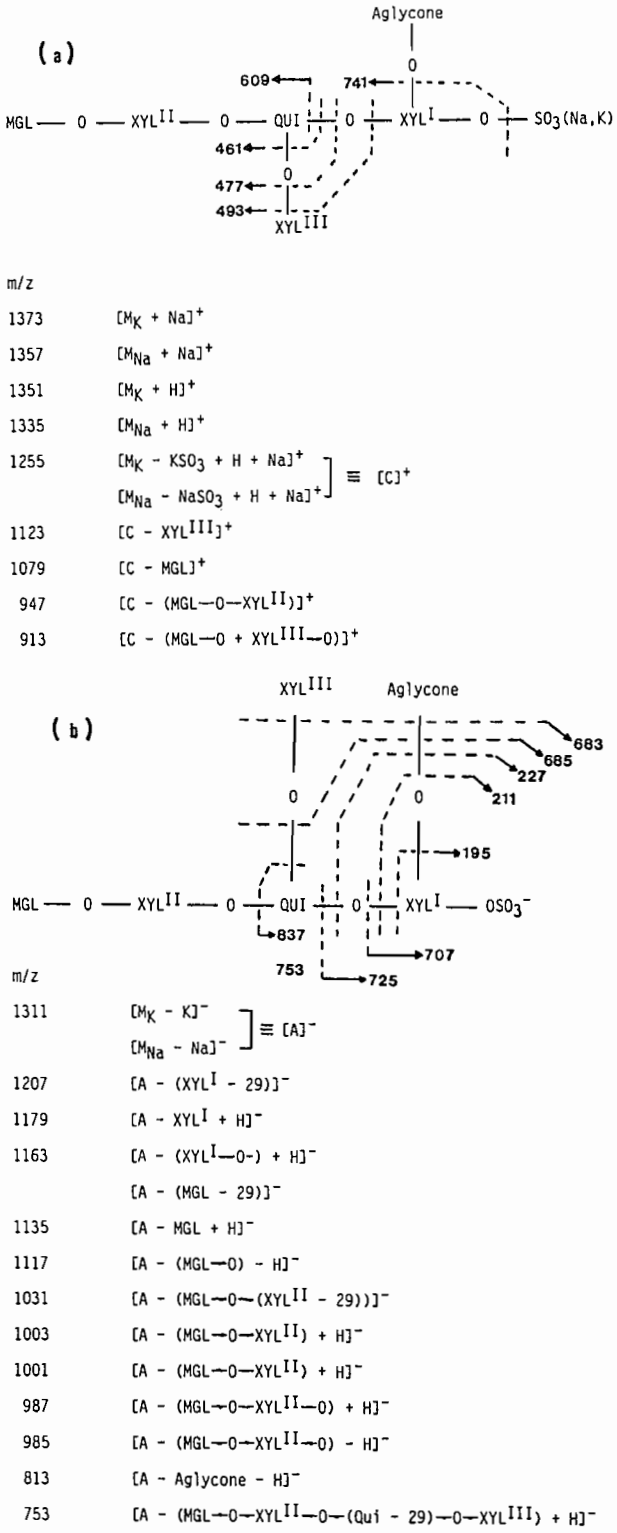

FIG. 5. (a) FAB^+ fragmentation and (b) FAB^- fragmentation of frondoside A.

1% ceric ammonium nitrate in 50% sulfuric acid solution followed by heating at 100–120°C. Low pressure column chromatography separations were carried out on silica gel 60H (Merck), or Whatman silica gel LPS-1 (13–24 μm) and LPS-2 (37–53 μm). Columns were prepared as a slurry in $CHCl_3$. HPLC separations were performed on a column (1 × 25 cm) of Spherisorb ODS, 10 μm (C18), using a Waters-244 chromatograph linked to a Kratos SF-770 UV detector.

All solvents were glass-distilled before use.

Extraction and purification of frondoside A (1)

Fifty-one specimens of the sea cucumber *Cucumaria frondosa* were collected at the Iles de Mai, Port-Cartier, Québec, Canada and at the Matamek Research Station of the Woods Hole Oceanographic Institution, Québec, Canada.

The body walls were treated with 1.5 L of acetone (residue after evaporation: 21 g) and ground to a fine powder (0.78 kg; 15.3 g/specimen). The powder was successively extracted several times with benzene and methanol to remove the residual pigments and lipids. The 70% ethanol extracts were combined and evaporated under reduced pressure to give the crude frondosides (19.3 g). Part of this extract (4.6 g) was then subjected to an Amberlite XAD-2 resin (Mallinckrodt, 20–50 mesh) column chromatography. This gave a salt-free, partially purified, glycoside mixture (350 mg). Low pressure column chromatography (silica gel LPS-2, 199 g; 4 × 30 cm; bed volume: 390 mL; elution at 12 psi (1 psi = 6.9 kPa); flow rate 6 mL/min; eluting solvents: $CHCl_3$–MeOH–H_2O, 60-15-2, 60-20-2.5, and 60-25-4) of the mixture furnished **1** (32 mg) along with other constituents.

Frondoside A (**1**) ($C_{60}H_{95}O_{29}SNa$), mp 234–236°C; $[\alpha]_D$ −13° (*c* 26, H_2O); UV λ_{max} (H_2O): transparent above 210 nm; IR ν_{max} (KBr): 3400 (OH, br), 1750 (γ-lactone), 1230 (S=O), 825 (C—O—S); FAB-MS: see Fig. 5; ^1H and ^{13}C NMR (pyridine-d_5:D_2O/5:1): see Tables 1 and 3; potassium rhodizonate test: positive (yellow coloration); CD (*c* = 0.18, H_2O): $[\Theta]_{303}$ 0, $[\Theta]_{247}$ −4293 (neg. max.), $[\Theta]_{238}$ 0, $[\Theta]_{224}$ +5075 (pos. max.), $[\Theta]_{213}$ 0, $[\Theta]_{211}$ −1168!

Methanolysis of frondoside A (1)

Carbohydrate constituents

A solution of frondoside A in anhydrous 1% HCl–MeOH was refluxed for 5 h. After cooling, the solution was evaporated to dryness under reduced pressure to afford a mixture of methyl glycosides quantitatively analysed by GC of the TMS derivatives.

The retention times were identical to those of the authentic methyl-D-glycosides of the following sugars: xylose (14.5), quinovose (16.5), and 3-*O*-methyl glucose (18.3, 19.5). The relative quantities were determined to be 3:1:1 respectively (peak area/mass of TMS derivatives).

Desulfatation of frondoside A

A solution of frondoside A (2 mg in 1 mL of 0.04 M anhydrous HCl in methanol) was stirred at room temperature for 20 min. The solution was then neutralized with silver carbonate, filtered on a small pad of Celite, and evaporated under reduced pressure. The desulfated glycoside was separated from the accompanying salts on a reverse-phase Sep-Pak (Waters) by elution with water (1 mL), 50% aqueous methanol (2 mL), and methanol (2 mL). The FAB-MS of the mixture showed fragments corresponding to the desulfated glycoside at *m/z* 1255 $[M + Na]^+$ and the deacetylated analogue at *m/z* 1213 $[M + Na]^+$.

Isolation and structure of sporidesmolide V from cultures of *Pithomyces chartarum*[1]

H. A. GILLIS,[2] D. W. RUSSELL,[3] A. TAYLOR,[4] AND J. A. WALTER

National Research Council of Canada, Atlantic Research Laboratory, Halifax, N.S., Canada B3H 3Z1

Received June 16, 1989

H. A. GILLIS, D. W. RUSSELL, A. TAYLOR, and J. A. WALTER. Can. J. Chem. **68**, 19 (1990).

The total sporidesmolide fraction from cultures of *Pithomyces chartarum* contains at least five cyclodepsipeptides. Four of these are known compounds but the fifth, cyclo-2-oxyisovaleryl-D-alloisoleucyl-D-leucyl-2-oxyisocaproyl-L-valyl-L-*N*-methylleucyl, appears to be new. Its isolation, physical properties, and structure determination are reported.

Key words: *Pithomyces chartarum*, sporidesmolide II, sporidesmolide V, sporidesmolic acid D.

H. A. GILLIS, D. W. RUSSELL, A. TAYLOR et J. A. WALTER. Can. J. Chem. **68**, 19 (1990).

La fraction totale de sporidesmolide provenant de cultures de *Pithomyces chartarum* contient au moins cinq cyclodepsipeptides. Quatre d'entre eux sont des composés connus; toutefois, le cinquième, le cyclo-2-oxyisovaléryl-D-alloisoleucyl-D-leucyl-2-oxyisocaproyl-L-valyl-L-*N*-méthyl-leucyl, semble être nouveau. On rapporte son isolement, ses propriétés physiques ainsi que la détermination de sa structure.

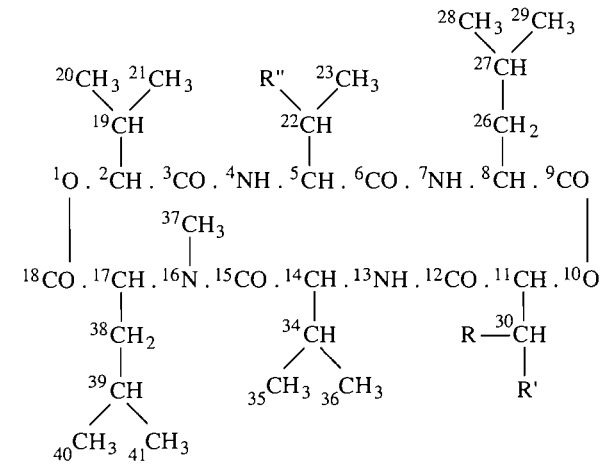
Mots clés : *Pithomyces chartarum*, sporidesmolide II, sporidesmolide V, acide sporidesmolic D.

[Traduit par la revue]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

The production of sporidesmolides I (1), II (2), and III (1) by *Pithomyces chartarum* has been reported. Examination of the total sporidesmolide fraction (3) of isolates of this fungus from Brazil, Colombia, Texas, and Nova Scotia has revealed the presence of two more congeners. One of these proved to be the known sporidesmolide IV (4), while the other, named sporidesmolide V, appears to be new.

Sporidesmolide V was purified by repetitive reversed phase partition chromatography and finally by vacuum sublimation. Elemental analysis and high resolution mass spectroscopy indicated that its molecular formula was $C_{35}H_{62}N_4O_8$, confirmed by ^1H and ^{13}C NMR data. The compound is therefore a higher homologue of sporidesmolide II (ref. 2, $C_{34}H_{60}N_4O_8$), here isolated for the first time from cultures of *Pithomyces chartarum* unenriched with isoleucine. It was possible to separate the synthetic sporidesmolides II (5) with residues of D-alloisoleucine and D-isoleucine and thus show that this residue in the natural product was D-alloisoleucine. Acid hydrolysis of sporidesmolide V gave one mole each of L-valine, D-leucine, D-alloisoleucine, and L-*N*-methylleucine. Mild alkaline hydrolysis gave two sporidesmolic acids (1), *m/z* 344 and *m/z* 358. Dakin–West degradation showed that leucine and *N*-methylleucine were, respectively, the C-terminal amino acids of these two sporidesmolic acids, and chromatography of their hydrazides in solvent *a* (see experimental) showed that one had R_f identical to the hydrazide of sporidesmolic acid C (4) and the other to either sporidesmolic acid B (1) or D (one of the two alkaline hydrolysis products of sporidesmolide II). In solvent *b*, sporidesmolic acids B and D were resolved and it was shown that one of the acids from the new metabolite had the same R_f as the latter. Thus the structure of one of these degradation products was 2-hydroxyisovalerylisoleucylleucine and the other was probably 2-hydroxyisocaproylvalyl-*N*-methylleucine. This conclusion was confirmed by mass spectroscopic analysis of individual molecular ions of the two acids, the fast-atom bombardment fragments corresponding to the suggested sequences. It was also confirmed by comparative analysis of the ^1H and ^{13}C NMR spectra of sporidesmolides II, IV, and V. In the case of



Sporidesmolide II, R'' = $^{24}CH_2\,^{25}CH_3$; R = R' = $^{31(32)}CH_3$

Sporidesmolide IV, R'' = $^{24}CH_3$; R = H, R' = $^{31}CH(^{32}CH_3)(^{33}CH_3)$

Sporidesmolide V, R'' = $^{24}CH_2\,^{25}CH_3$; R = H, R' = $^{31}CH(^{33}CH_3)(^{32}CH_3)$

sporidesmolide IV, most of the ^{13}C signals and many of the ^1H signals could be assigned by heteronuclear correlation, DEPT, and COSY experiments. In particular there were three CH_2 groups in the spectrum of sporidesmolide IV at δ_C 37.81, 39.28, and 40.75, but the three CH_2 groups in sporidesmolide II had δ_C 26.47, 37.79, and 39.38. A COSY experiment showed that the CH_2 group at 40.75 ppm was coupled to two CH groups, the chemical shift of one (δ_C 79.66) indicating it to have an oxygen substituent. It follows that this methylene group is part of a 2-oxyisocaproyl residue. In the ^{13}C spectrum of sporidesmolide V, resonances at δ_C 26.43, 37.43, 39.72, and 40.68 were shown by a DEPT experiment to be CH_2 groups. Thus, by analogy with the spectra of sporidesmolides II and IV, the resonance at 40.68 ppm can be assigned to an isocaproyl CH_2 group and that at 26.43 ppm to an isoleucyl CH_2 group.

The mass spectrum of sporidesmolide V was closely similar

to those of all other sporidesmolides from the genus *Pithomyces*, i.e., the main ion reactions in the electron impact source involved loss of butene or propene from the amino/hydroxy acid side chains, and three protons were exchanged with ^2H_2O in the source of the mass spectrometer (6). However, there were also ions of low abundance that indicated the sequence of residues in the macro-ring. Thus the ion *m/z* 227 contained no exchangeable protons and corresponded to $C_{12}H_{21}NO_3$ = MeN.CH(C_4H_9)CO_2.CH(C_3H_7)CO (because of relative abundances the protonated ion at *m/z* 228 was mass measured), establishing that the *N*-methylleucine residue was esterified to the 2-hydroxy-3-methylvaleric acid moiety and hence the sequence of the residues in the depsipeptide. From the close similarity of the ^{13}C NMR spectra of sporidesmolides II, IV, and V it may be inferred that the stereochemistries of the three depsipeptides are the same. Hence, the structure of the new metabolite is established.

Experimental

Melting points are not corrected. Specific optical rotations were measured on a Perkin–Elmer 141 polarimeter. Mass spectra were obtained on a VG Analytical ZAB-EQ mass spectrometer with a VG 11-250 data system. Accurate mass measurements were made by the peak-matching method using an appropriate ion in the spectrum of perfluorokerosene as a reference. NMR spectra at 20°C were obtained in chloroform (C^2HCl_3) and were recorded on a Bruker MSL-300 instrument at 300 MHz for proton spectra and at 75.5 MHz for ^{13}C spectra. All chemical shifts are given in ppm downfield from the signal of tetramethylsilane. Coupling connectivity was determined by ^1H COSY and $^{13}C/^1H$ heterocorrelation experiments. Assignments were based on this coupling information, DEPT experiments, known chemical shifts of amino acid nuclei (7), and comparison of spectra of compounds of known structure. Chemical shifts and coupling constants are presented with reference to the arbitrarily numbered formula given in the text. Depsipeptides (1 mg) were hydrolysed in a solution (0.2 mL) of hydrochloric acid (*d* = 1.2) and acetic acid (0.2 mL) in an atmosphere (0.1 Torr; 1 Torr = 133.3 Pa) of nitrogen at 120°C. Analysis of amino acids was performed on a Beckman amino-acid analyser model no. 6300, and of *N*-methylleucine by paper chromatography (8). Analytical reversed phase partition chromatography was done using the equipment described (9). Elution volumes were (sporidesmolide, volume in mL): I, 12.2; II (natural and synthetic), 13.5; II (synthetic, D-isoleu), 14.8; III, 10.2; IV, 14.0; V, 15.5. Thin-layer chromatograms were run on silica gel plates (0.25 mm, Macherey–Nagel, Doren, FGR) using acetonitrile–triethylamine (500:1, *a*) or ethyl acetate – ethyl alcohol – triethylamine (1000:250:1, *b*) as the developing solvents. Sporidesmolides or methyl sporidesmolates were treated with a solution (10 mL) of hydrazine (1 g) in ethyl alcohol (0.1 mL per mg of sample) for 30 min at 75°C. The reaction mixtures were evaporated, the residues dissolved in ethyl alcohol at the same concentration, and portions applied as spots to the tlc plates. The plates were thoroughly dried in air and were developed 3 times with solvent *a*, or once with solvent *b*. The hydrazides were detected by spraying the plates with ethanolic picryl chloride (0.5%).

Isolation of sporidesmolides II, IV, and V from spores of Pithomyces chartarum

Spores (460 g) from rye-grain cultures of *P. chartarum* (3) were dried for 48 h at 20°C/0.2 Torr and then stirred with chloroform (1 L) for 40 min. The mixture was filtered through an alumina pad (5 mm) and the spores washed with three portions of chloroform (1 L). The filtrate and washings were combined and evaporated. The residue (28.7 g) was dissolved in dichloromethane (28 mL), carbon tetrachloride (560 mL) added, and the solution concentrated to 50 mL. The mixture was kept at 4°C for 18 h and the resulting gel broken up under carbon tetrachloride (100 mL) and filtered. The filtrate was evaporated, the residue (5.5 g) was digested with diethyl ether (110 mL), and the insoluble material (4 g) was applied to a radially packed reversed phase (C_{18}) column (4 × 25 cm). The column was developed with methyl alcohol – water (17:3) and the first 4.5 L of eluate were discarded. The following 3 L were collected and evaporated. The material soluble in carbon tetrachloride and insoluble in ether (1.05 g; sporidesmolides I:II:IV:V = 43:32:18:7) was dissolved in ethyl alcohol (5 mL) and dichloromethane (15 mL) was added. The filtered solution (2 mL) was evaporated, the residue taken up in dichloromethane (2.5 mL), ethyl alcohol (0.2 mL) added, and the solution (50 μL) chromatographed as before (10). The column was eluted with methyl alcohol – water (41:9) and the sporidesmolides were collected separately as they eluted from the column in the following order: sporidesmolide II (72 mL), sporidesmolide IV (75 mL), and sporidesmolide V (82 mL). Like fractions from about 40 chromatograms were combined. Analysis of the material (16 mg) from the sporidesmolide II band indicated that it contained about 4% of sporidesmolide I (1), which was removed by recrystallization from 70% acetic acid, 95% ethyl alcohol, and finally from 70% aqueous acetic acid, as needles, mp 233–234°C, $[\alpha]_D^{24}$ −216° (*c* 0.268, $CHCl_3$); δ_C: 173.97, 171.79 (3C), 169.43, 169.27, 79.50, 78.36, 65.72, 63.97, 54.40, 51.44, 40.08, 39.28, 37.79, 34.21, 30.09, 29.94, 29.36, 26.47, 25.34, 24.90, 23.05, 22.40, 22.24, 22.19, 19.54, 19.43, 18.97, 18.85, 17.06, 16.59, 16.10, 11.05; *m/z*: 652.4411 ($C_{34}H_{60}N_4O_8$ requires 652.4411). The combined sporidesmolide IV fractions contained ca. 5% sporidesmolide I and 34% sporidesmolide II. A solution (30 μL) of this material (3 mg) in methyl alcohol – water (41:19) was applied to the reversed phase column (10), and the fraction eluting at 75 mL was collected. These fractions from 17 runs were combined and evaporated. The residue (30.2 mg), which still contained 6% of sporidesmolide I, was rechromatographed in the same way and fractions from the apex of the elution profile were collected. The residue (20 mg) from the combined (evaporated) fractions was triturated with ether (0.2 mL) and the insoluble material (18.8 mg) sublimed to give sporidesmolide IV, R_v 75 mL, mp 227–229°C; $[\alpha]_D^{24}$ −207° (*c* 0.1, $CHCl_3$); δ_H: 7.91 (e, $J_{H_4H_5}$ 6.5 Hz), 7.83 (e, $J_{H_7H_8}$ 6.6 Hz), 7.14 (e, $J_{H_{13}H_{14}}$ 9.8 Hz), 5.12 ($J_{H_{11}H_{30}}$ 9.9 Hz), 4.86 ($J_{H_2H_{19}}$ 3.7 Hz), 4.56 ($J_{H_{14}H_{34}}$ 10.2 Hz), 4.35 (m, H8), 3.57 ($J_{H_{17}H_{38}}$ 5.8 Hz), 3.40 (3H37), 3.27 ($J_{H_5H_{22}}$ 11.45 Hz), 2.92 (m, H22), 2.3 (m, H2 and H34), 2.0 (m, H38), 1.9 (m, H31), 1.6 (m, H27, 2H26), 1.05–0.8 (m, 36H); δ_C: 173.97, 171.81 (2C), 171.6, 170.3, 169.43, 79.66 (C_{11}), 73.24 (C_2), 67.18 (C_5), 64.04 (C_{17}), 54.27 (C_{14}), 51.54 (C_8), 40.74 (C_{30}), 40.20 (C_{37}), 39.30 (C_{26}), 37.82 (C_{38}), 29.97 (C_{19}), 29.65 (C_{34}), 27.93 (C_{22}), 25.38 (C_{39}), 24.99 (C_{27}), 24.73 (C_{31}), 23.28, 23.05, 22.40, 22.27, 22.23, 21.17, 20.21, 19.97, 19.45, 19.41, 18.57, 19.07 (12 Me groups). The material (23 mg, sporidesmolides I:II:IV:V = 7:10:8:72) from the combined fractions eluting at 82 mL was rechromatographed using the same solvent and column, and the sporidesmolide V band (11.4 mg) was collected from about 10 chromatograms. This fraction was washed with diethyl ether and sublimed at 185–190°C/0.01 Torr, and the sublimate resublimed under the same conditions gave *sporidesmolide V*, 5.27 mg, mp 215–216°C; $[\alpha]_D^{24}$ −198° (*c* 0.26, $CHCl_3$); δ_C: 174.09, 171.83, 171.73, 171.64, 170.3, 169.52 (6 *C*O), 79.64 (C_{11}), 73.19 (C_2), 65.55 (C_5), 63.93 (C_{17}), 54.23 (C_{14}), 51.57 (C_8), 40.68 (C_{30}), 40.19 (C_{37}), 39.17 (C_{26}), 37.72 (C_{38}), 29.95 (C_{19}), 29.59 (C_{34}), 26.43 (C_{24}), 25.33 (C_{27}), 24.96 (C_{39}), 24.73 (C_{31}), 23.32, 23.11, 22.23 (2C), 21.08, 19.47, 18.56, 17.12, 16.17 (C_{23}), 10.98 (C_{25}); *m/z*: 666.4577 ($C_{35}H_{62}N_4O_8$ requires 666.4567); 228.1599 ($C_{12}H_{22}NO_3$ requires 228.1600). *Anal.* calcd. for $C_{35}H_{62}N_4O_8 \cdot 0.5H_2O$: C 62.2, H 9.4, N 8.3; found: C 62.1, H 8.9, N 8.4%.

Sporidesmolic acid D

Sporidesmolide II (84 mg) in boiling ethyl alcohol (95%, 10 mL) was treated with sodium hydroxide solution (2 N, 2 mL) and the solution concentrated to 3 mL. Hydrochloric acid (6 N, 1 mL) was added, the solution evaporated, and the residue digested with chloroform (10 mL) and water (10 mL). The insoluble material was collected and was recrystallized from dilute acetic acid as needles, 16 mg, mp 199–200°C. *Anal.* calcd. for $C_{17}H_{32}N_2O_5$: C 59.3, H 9.4, N 8.1%; found: C 59.1, H 9.4, N 8.4%.

Dakin–West reaction on sporidesmolic acids from sporidesmolide V

Sporidesmolide V (1.8 mg) was dissolved in methyl alcohol (0.25 mL) and sodium hydroxide solution (2 N, 70 μL) added. After 1 h at room temperature the solution was treated with hydrochloric acid (6 N, 35 μL) and then was evaporated to dryness. The residue after mass spectroscopic analysis was extracted with ethyl alcohol (3 × 0.25 mL), the combined extracts (= A, 0.38 mL) were evaporated, and the residue was treated with pyridine (0.2 mL) and acetic anhydride (0.3 mL). The reaction mixture was heated in a sealed tube at 110°C for 2.5 h after which time it was evaporated and the residue treated with hydrochloric acid (6 N, 0.5 mL) at 110°C for 24 h. The hydrolysis mixture was cooled and evaporated. The residue was dissolved in water (0.1 mL) and 10 μL was chromatographed on Whatman 3MM paper, with marker chromatograms (of val, leu, allo-isoleu, and N-Meleu) to its left and right. The chromatograms were developed with *tert*-butyl alcohol – ammonium hydroxide (4.25 N, 4:1). The marker strips showed the presence of valine and isoleucine, which were recovered from the paper by the method described in the next paragraph.

Determination of chirality of amino acids in acid hydrolysates of sporidesmolic acids

The remaining ethanolic extract (= A, see above, 0.37 mL) was evaporated and the residue treated with hydrochloric acid (6 N, 0.5 mL). The mixture was heated at 110°C for 24 h, evaporated to dryness, and the residue dissolved in water (0.1 mL) and chromatographed on Whatman 3MM paper as described for the hydrolysis products of the Dakin–West reaction. The bands of amino acids were cut out, rolled longitudinally, saturated with water, and centrifuged. The amino acid solutions obtained were concentrated to 0.1 mL and were applied to silica gel plates containing a chiral Cu^{2+} reagent (Macherey–Nagel, "Chiralplate"). The plates were developed with methyl alcohol – water–acetonitrile (1:1:4). In all cases the L isomers had the greatest R_f (L in the range 0.53–0.57; D, 0.45–0.50). The R_f values for the four amino acids were as follows: valine, 0.53 (L); isoleucine, 0.45 (D); leucine, 0.45 (D); and *N*-methylleucine, 0.56 (L).

Identification of isodomoic acid D and two new geometrical isomers of domoic acid in toxic mussels[1]

JEFFREY L. C. WRIGHT,[2] MICHAEL FALK, A. GAVIN MCINNES, AND JOHN A. WALTER
National Research Council, Atlantic Research Laboratory, 1411 Oxford Street, Halifax, N.S., Canada B3H 3Z1

Received April 28, 1989

JEFFREY L. C. WRIGHT, MICHAEL FALK, A. GAVIN MCINNES, and JOHN A. WALTER. Can. J. Chem. **68**, 22 (1990).

Isodomoic acids E and F, two new geometrical isomers of the neurotoxin domoic acid, have been found to occur with domoic acid and isodomoic acid D in extracts of toxic mussels. The entire set of geometrical isomers can be prepared in the laboratory by photolysis.

Key words: amnesic shellfish toxin, domoic acid, isodomoic acid, neurotoxin.

JEFFREY L. C. WRIGHT, MICHAEL FALK, A. GAVIN MCINNES et JOHN A. WALTER. Can. J. Chem. **68**, 22 (1990).

Dans les extraits de moules toxiques, on a trouvé que les acides neurotoxiques, domoïque et isodomoïque D, sont accompagnés des acides isodomoïques E et F, deux nouveaux isomères géométriques de l'acide domoïque. Faisant appel à la photolyse, il est possible de préparer au laboratoire l'ensemble des isomères géométriques.

Mots clés : toxine amnésique du testacé, acide domoïque, acide isodomoïque, neurotoxine.

[Traduit par la revue]

Introduction

We recently isolated and identified the neurotoxin domoic acid **1** as the toxic agent in an outbreak of shellfish poisoning traced to cultured mussels *Mytilus edulis* L. from a localized area of eastern Prince Edward Island, Canada (1). This compound was originally isolated from the red macroalga *Chondria armata* Okamura some 30 years ago (2, 3). Based on its toxic properties and its discovery in shellfish, it has been proposed[3] that **1** be termed an amnesic shellfish poison (ASP). As **1** is the most potent known activator of the kainate receptors in the central nervous system[4] it is of interest from a chemical and neurophysiological standpoint that domoic acid isomers or derivatives be characterized as fully as possible. We report here the isolation of isodomoic acid D **2** (4) and two new geometrical isomers, isodomoic acids E **3** and F **4**, obtained in small quantities during further studies of these toxic mussels.[5]

Results and Discussion

In the original identification of **1** in toxic mussels (1) the chemical and physical properties were identical with published data (5) and the optical rotation of an anhydrous sample of **1** (α_D^{24} −120°) showed that the enantiomeric form was the same as that previously reported from *Chondria armata*. Our NMR experiments (1) confirmed the ^1H assignments and spin–spin coupling constants of ref. 5 and led to minor reassignment of ^{13}C resonances compared to those of ref. 4. Additional homonuclear NOE experiments confirmed the (*Z*, *E*) configuration of double bonds in the side chain and the conformation of the prolyl ring (1).

During subsequent large-scale extraction and purification of domoic acid, additional peaks displaying essentially the same ultraviolet spectra as the toxin were observed. These compounds were obtained pure by repeated reversed-phase chromatography.

The UV spectrum (λ_{max} 244 nm) of the major isomer **2** (MH^+ 312.1448, $C_{15}H_{22}NO_6$, α_D^{25} −72°) indicated the presence of conjugated double bonds, although the IR spectrum showed no absorption in the region 955–980 cm^{-1} characteristic of a *trans*-disubstituted double bond. The NMR data (Tables 1 and 2) show this compound to be isodomoic acid D **2**, previously isolated as a minor component of extracts of *C. armata* (4). Values of δ(H) and *J*(H, H) (Tables 1 and 2) from our spectra are close to the published values, recorded at unspecified pH (4). They indicate that the conformation of the prolyl ring is virtually identical with **1**. Our NOE measurements, showing the proximity of H-2′ and 1′-CH_3, H-2′ and H-5′, H-3′ and H-4′, H-4′ and H_3-6′, confirm the (*Z*, *Z*) configuration of the two conjugated double bonds.

The (*E*, *E*) isomer structure was consistent with the UV absorption (241 nm) and IR spectrum (960 cm^{-1}) of isodomoic acid E **3** (MH^+ 312.1430, $C_{15}H_{22}NO_6$, α_D^{25} −19.5°), which eluted after **2**, and was confirmed by the NOE data showing the proximity of H-3′ to H-5′, H_3-6′ and 1′-CH_3, and of H-4′ to H-5′, H_3-6′ and H-2′. The values of δ(H) and *J*(H, H) (Tables 1 and 2) show similarity of the prolyl ring protons to **1** and **2**, except that a reduction in *J*(2, 3) indicates that the average conformation of the ring reduces the (H-2)—C—C—(H-3) angle, from ca. 143° to ca. 120°, if Karplus-type parameters for proline (6) are applied to this case. Closer proximity of these protons seems to be indicated by NOE between H-2 and H-3, which is not observed in **1** and **2**. Similarly, *J*(4, 5α) shows an increase in the relative angle of the 4-H and 5-αH bonds, also reflected in the occurrence of NOE between H-4 and H-5β.

The last compound to elute (MH^+ 312.1444, $C_{15}H_{22}NO_6$,

[a]Error ca. ±0.2 Hz unless stated. Coupling connectivity confirmed by ^1H COSY spectra. Some couplings determined by simulation using Bruker PANIC program. Data previously reported (1) for domoic acid are included for comparison. pH as for ^1H data in Table 1.

α_D^{25} −85°) was identified as isodomoic acid F **4**. The UV (243 nm) spectrum confirms the presence of two conjugated double bonds. The IR spectrum (no band in the region 955–980 cm^{-1}) shows there is no *trans*-disubstituted double bond. Occurrence of NOE between H-3′ and H-4′, as well as between H-2′ and H-5′, and H-3′ and 1′-CH_3, confirms the (*E*, *Z*) configuration of the double bonds. The reduction in *J*(2, 3) and increase in *J*(4, 5α) compared to **1** and **2**, and the occurrence of NOEs between H-2 and H-3, and H-4 and H-5β, indicate that the ring conformation is more similar to **3**. In this regard it is noteworthy that **3** and **4** both possess a (1′*E*) configuration. In all the isomers, the coupling constants (Table 2) and ^{13}C chemical shifts (Table 1) were consistent with the proposed structures. The chirality at C-5′ and the enantiomeric form of each isomer remain to be established.

The isomers are only available in small amounts following tedious and repetitive chromatography. However, more material was required for toxicological studies so alternative methods for their production were investigated. Exposure of dilute aqueous solutions of domoic acid to ultraviolet light (250 nm) resulted in the rapid conversion to the geometrical isomers. Maximum yield of the isomers **2**–**4** was reached after 9–12 min, at which time the proportions of **1**–**4** were respectively 0.28:0.12:0.27:0.13 relative to an initial unit amount of **1**.

It is now well established that domoic acid is produced by the diatom *Nitzschia pungens* (7, 8). Traces of the isomers **2**, **3**, and **4** have been observed in laboratory cultures of *N. pungens* using sensitive analytical techniques (M. Quilliam, personal communication), but these isomers are much more obvious in extracts of various shellfish, suggesting that further conversion of domoic acid occurs within the digestive system of the mollusc. Optical rotations for the isomers produced by photolysis were identical within error (±2°) to those for the corresponding isomers from mussels.

As the isomers have been observed in essentially the same proportions in both steamed and uncooked mussels, it appears that the steaming process does not contribute significantly to isomer production. Another popular recipe is to heat mussels in a solution of vinegar and white wine for several minutes. When domoic acid was warmed (80°C) in aqueous solutions containing acetic acid (3%; 15%; 60%) or trifluoracetic acid (10%) no trace of the isomers was observed by HPLC–DAD analysis, even after prolonged periods (up to 3 h).

Domoic acid is the most potent member of a family of glutamate agonists that includes kainic acid **5**. A portion of these molecules (C2-CO_2H, C-2, C-3, C-6, and C-7) can mimic glutamic acid and bind to glutamate receptors in the brain (9–14). The nature of the side chain has obvious implications with respect to the efficacy of binding to these receptors located in the membrane, and to the potency of the compound as a neuro-excitatory amino acid. Work on the relationship between biological activity and chemical structure of the four geometrical isomers is in progress.

Experimental

HPLC–DAD analysis and all NMR, MS, IR, and UV spectra were obtained with the instruments and conditions previously described (1).

Isolation of isomers

The aqueous methanol extract of blended steamed mussel tissue was concentrated and partially purified by flash chromatography using a C_{18} reversed-phase support (55–105 μm; Waters Prep Pak) and elution with acetonitrile–water mixtures containing 1% acetic acid. The fraction (20% acetonitrile/water) containing domoic acid and the isomers was further purified by Lobar chromatography (C_8 reversed-phase support) and elution with the same mixtures. Finally, fractions enriched in domoic acid and the isomers were separated into various components by repeated reversed-phase HPLC (10 μm; Vydac 201TP 1010; 8% acetonitrile–water containing 0.1% trifluoracetic acid) runs using diode-array detection. Domoic acid **1** was the major component (>90% of the mixture) and the isomers eluted at relative retention times (RRT) **2** (0.84), **3**(0.90), and **4**(1.34) (Vydac 201TP52, 250 mm × 2 mm). The isomers were obtained as oils in the proportions indicated: **2** (ca. 5%), **3** (ca. 2%), **4** (ca. 1%).

The physical and spectroscopic properties of the isomers are described in Results and discussion and in Tables 1 and 2.

Photolysis of domoic acid

Photochemical reactions were carried out at 30°C in a quartz tube (35 × 5 cm diameter) using an ultraviolet photoreactor (Southern New England Ultraviolet Company, Middletown, Conn.) equipped with eight ultraviolet tubes (253.7 nm Rayonet photochemical reactor lamp). Dilute aqueous solutions (500 mL) of domoic acid (100 μg/mL) were degassed by filtration followed by purging with argon. Initially, to set up optimum reaction conditions, the isomerisation was followed by HPLC–DAD analysis. In a typical production run the photolysis reaction was halted after 15 min, the solution concentrated *in vacuo*, and the isomers collected by repeated reversed-phase HPLC runs as described above. The ratio of isomers **1**–**4** was 1:0.42:0.96:0.46. Isomers prepared in this way had identical spectroscopic properties (UV, IR, NMR, $[\alpha_D]$) to those obtained from cooked mussels.

Determination of the charge density of acrylamide/acrylate copolymers by tensammetry

TRUIS SMITH-PALMER AND BYRON R. WENTZELL
Chemistry Department, St. Francis Xavier University, Antigonish, N.S., Canada B2G 2E2

Received January 23, 1989

TRUIS SMITH-PALMER and BYRON R. WENTZELL. Can. J. Chem. **68**, 26 (1990).

The charge densities of acrylamide/acrylate copolymers can be determined using tensammetry. The tensammograms were run using 20 ppm solutions of polymer in 0.1 *M* tetraethylammonium chloride. A standard curve of desorption peak height versus mol% anionicity was useful in the range 10–50%. A second standard curve of the potential at which the capacitive current measured 1 μA versus mol% anionicity allowed the determination of charge density in the range 0–15%.

Key words: tensammetry, polyacrylamide, charge density, tetraethylammonium, desortion peaks.

TRUIS SMITH-PALMER et BYRON R. WENTZELL. Can. J. Chem. **68**, 26 (1990).

On peut déterminer la densité de charge du copolymère acrylamide/acrylate par tensammétrie. On a obtenu les tensammogrammes à partir de solutions de chlorure de tétraéthylammonium 0.1 *M* contenant 20 ppm de polymère. Une courbe standard de la hauteur du pic de désorption en fonction du % molaire d'anionicité s'est avérée utile dans l'intervalle allant de 10 à 50%. Une deuxième courbe standard d potentiel auquel le courant capacitif mesure 1 μA en fonction du % molaire d'anionicité permet de déterminer la densité de charge dans l'intervalle allant de 0 à 15%.

Mots clés : tensammétrie, polyacrylamide, densité de charge tétraéthylammonium, pic de désorption.

[Traduit par la revue]

Introduction

Acrylamide/acrylate copolymers (pams) have many industrial applications, particularly in coal and oil processing. Their usefulness is often a function of their charge density. Charge density refers to the percentage of the monomers which contain charged functional groups, i.e., acrylate rather than acrylamide. For example, in pure polyacrylamide, all the monomers contain the amide functional group and it is considered to be non-ionic. However, as more of the monomers are acrylic acid, the charge density increases. Charge density affects things such as solubility, conformation, and electrostatic interaction, and itself is sensitive to pH.

A number of methods have been used to determine charge density, including conductimetric and potentiometric titrations (1), nmr (1), ir (2), differential scanning calorimetry (1), and thermogravimetric methods (3). The titrations are tedious and time-consuming (1), while the latter three methods require preparation of a pure sample in the solid state. The nmr method is absolute, but not all labs are equipped with a suitable instrument. We have previously shown that the concentrations of solutions of pams can be determined by tensammetry (4) and by the suppression of polarographic maxima (5), and when using either of these methods, it would be convenient if one could further use the same apparatus to determine the charge density of pams of interest.

We had observed that the shapes of tensammograms changed as the charge density of the pams changed and this suggested a means by which the charge density of pams might easily be determined. In this study we choose to use a set of pams of the same molecular weight but varying charge density to see if we could establish a relationship between capacitive current and charge density at one or more potentials.

Experimental

Tensammograms were recorded, as described previously (4), using a Princeton Applied Research (PAR) Model 174A Polarographic Analyzer and a Model 303 static mercury drop electrode (SMDE) in conjunction with a PAR Model 174A/50 AC Polarographic Analyzer Interface and a PAR Model 122 Lock-In Amplifier. The analog output of the polarograph was digitized using an Apple IIe microcomputer with Interactive Microware software (Lab Data Manager, Scientific Plotter) and hardware (ADALAB Interface card, ADA-AMP Instrumentation Amplifier). A modulation amplitude of 10 mV (p-p) at 200 Hz was used. The phase was adjusted to be 135 degrees away from the phase of the reference modulation to minimize faradaic currents. The HMDE (small) and a scan rate of 5 mV/s were used. Scans in the positive and negative direction were started at −600 mV after a 2 min hold time. All potentials reported are relative to a silver – silver chloride reference electrode containing KCl (saturated).

Infrared spectra were run on an FT IR microscope (A.R.L., Halifax, N.S.) on thin films obtained by evaporation of solutions at room temperature.

The Magnifloc pams (Table 1) used as standards were obtained from the American Cyanamid Corp. Other pams (Table 1) were obtained from Energy, Mines and Resources, Edmonton. Alkylammonium salts were obtained from Aldrich. Standard deviations were determined using 12 measurements.

TABLE 1. Properties of pams used in this paper

Results and discussion

As a check on the charge densities of the standard samples supplied by Cyanamid, their ir spectra were run and ratios of the peaks at 1569 and 1670 cm^{-1} (COO^- and $CONH_2$, respectively) were plotted versus charge density (2). A straight line was obtained with a correlation of 0.991 (Fig. 1).

Tensammograms of the Magnifloc standards in 0.25 *M* KCl (as used previously for the determination of concentration) were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

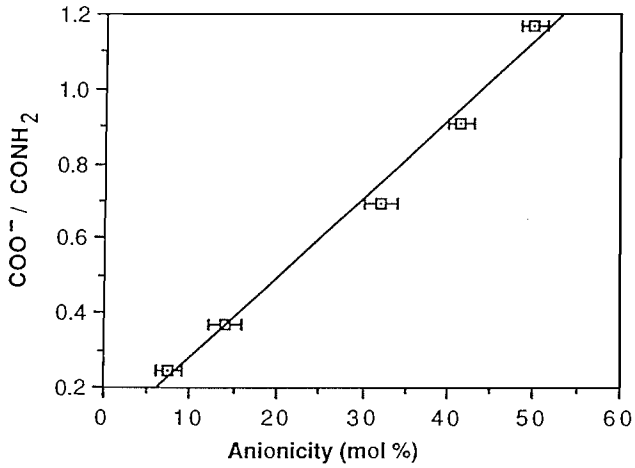

FIG. 1. Standard curve of the ratio of the IR absorbances at 1569 and 1670 cm^{-1} (COO^- and $CONH_2$, respectively) versus the charge density, for a series of films of known Magnifloc polymers of the same molecular weight.

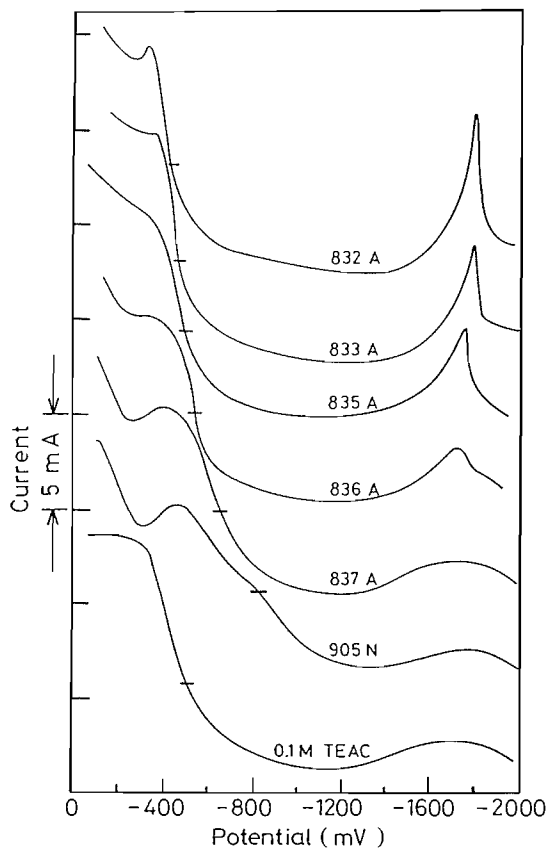

FIG. 2. Tensammograms of 0.1 *M* tetraethylammonium chloride (TEAC) and 20 ppm solutions of various Magnifloc pams in 0.1 *M* TEAC. Each tensammogram is composed of a negative and a positive scan, each beginning at −600 mV. A dash (—) is drawn through each tensammogram at the potential at which the capacitive current is 1 μA.

then run. The shape of the tensammograms obtained differed with charge density, but there was no potential at which the capacitive current was a simple function of the charge density. However, when tensammograms of the standard polymers in 0.1 *M* tetraethyl ammonium chloride (TEAC) were run, desorption peaks appeared at potentials around −1750 mV (Fig. 2). The exact peak potential became more negative as the charge density of the polymer increased. Previously such desorption peaks have been used to determine the concentration of various small surface-active species (6). The heights of the desorption peaks on our tensammograms were a function of the charge density of the pam used. The best (most reproducible) results were obtained when pam concentrations of 20 ppm were used. At lower concentrations, the tensammetric curves are affected by concentration (4). Higher concentrations can be used and give similar results, but are slightly less reproducible, perhaps because of the greater viscosities of the pam solutions involved. Figure 2 also shows the tensammograms for 0.1 *M* TEAC and for the non-ionic pam 905N in 0.1 *M* TEAC. They are very similar in the region where the desorption peaks occur and results were compared using each as the baseline for peak height. The standard curve plotted using the peak heights read with respect to the capacitive current for a nonionic pam in 0.1 *M* TEAC (Fig. 3) gave a slightly better correlation coefficient than the curve plotted using peak heights read with respect to the capacitive current for TEAC alone (0.992 compared to 0.988). In other respects the curves were not very different. The maximum charge density of a polymer used was 50%, reflecting the fact that acrylamide/acrylate copolymers of 0–50% charge density are the most widely used industrially — Magnifloc pams of higher charge density were not available.

The potential was held at −600 mV for 2 min before a scan in either the positive or negative direction. The hold time allowed the capacitive current to stabilize. If the potential was held at −600 mV (close to the potential of zero charge (7)), the current dropped in the first 20–30 s during which the voltage was applied and then increased again. This occurred with or without the pam present. After 2 min the drift in each was steady and would cancel out.

No desorption peaks were found for pams in 0.1 *M* tetramethylammonium chloride, and 0.1 *M* tetrabutylammonium chloride gave a desorption peak at −1990 mV which was not affected by the addition of pams. The latter suggests that the tetrabutylammonium ion adsorbs more strongly than do pams (8). Tetraalkylammonium ions are known to be strongly adsorbed at a mercury surface, with the tetramethylammonium ion being less strongly adsorbed than the tetraethylammonium (9). Normally, anionic pams are not adsorbed on a negatively charged mercury surface (10), as is evidenced by their tensammograms being identical to those of the electrolytes at negative potentials (4). Thus the tetraethylammonium ion presumably complexes with the pams. Desorption peaks for other complexes with tetraethylammonium ion have previously been reported (11). The complex may hold together by both electrostatic and dispersion type bonds. Thus the greater charge density of the tetraethylammonium ion in comparison with tetrabutylammonium, and its greater organic character in comparison with tetraethylammonium, may be important deciding factors in the stability of the complex. As the height of the desorption peak is usually a function of concentration (6), we suggest that the more highly charged pams are able to complex with more tetramethylammonium ions and thus produce higher desorption peaks. Desorption peaks have previously been found in differential capacity – voltage curves of copolymers of methacrylic and methylmethacrylic acid at ~ −0.3 V in 0.1 *N* NaF, with the copolymers of higher charge density giving higher peaks (12), and differential capacity – voltage curves are the same shape as corresponding tensammograms (13). Our pams showed no peaks when run under these conditions, presumably because of the much higher molecular weights involved.

The charge densities of some other pams of nominal charge

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

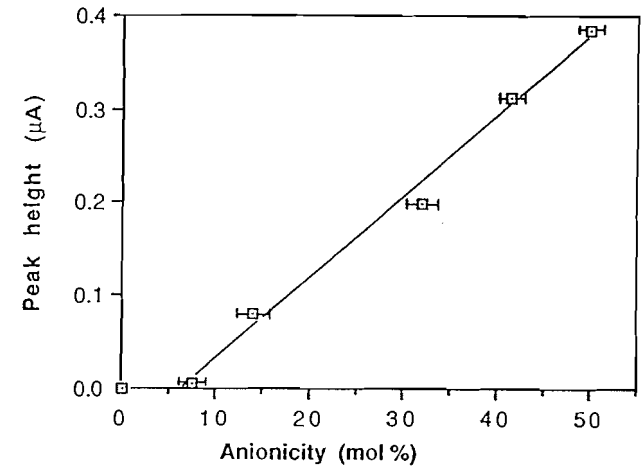

FIG. 3. Standard curve of height of desorption peak (with respect to the capacitive current of a nonionic pam in 0.1 *M* TEAC at the same potential) versus the charge density for a series of 20 ppm solutions of known Magnifloc pams of the same molecular weight.

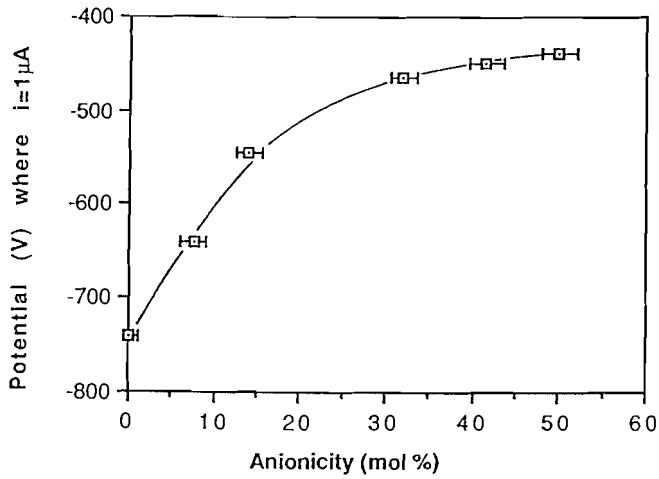

FIG. 4. Standard curve of potential at which the capacitive current is 1 μAmp versus the charge density for a series of 20 ppm solutions of known Magnifloc polymers of the same molecular weight.

densities 5, 12.5, 25, and 37.5% (Table 1) were read from the standard curve (Fig. 3) to demonstrate its general applicability. Values of 10, 12, 26, and 34%, respectively, were found using non-ionic pam in TEAC as blank. This standard curve is obviously not useful for determining low charge densities, as it is flat until just under 10% charge density. However, using the same tensammograms (Fig. 2) we found that we could construct another standard curve which was most sensitive in the region of low charge density. To do this, we plotted the potential at which the capacitive current read 1 μA versus the charge density (Fig. 4). Non-ionic pams and those of low negative charge density stay adsorbed on the mercury surface at potentials where pams of higher charge density have little affect and the capacitive current in this region is sensitive to the charge density up to a limiting value which would cause all pam to be desorbed. Thus the curve was not reliable at charge densities above ~15% (pams of nominal charge density 5, 12.5, and 25% were analyzed as having values of 5, 13, and 18.5%, respectively) and is complementary to our other standard curve. Charge densities of 10–15% should give the same answer on either curve. Standard deviations of 1.3% and 0.33% were found for repeat analyses of Magnifloc 832A (50%) and Magnifloc 837A (7.5%), respectively.

In determining such as this, it is very likely that clean samples would be used, but if this is not the case some interferences may be present. Other surface active substances, especially if negatively charged, can interfere with the peak height, and also some salts. For example, 10 ppm humic acid decreases the peak height for 832A by over 60%. However, most interferences, including humic acid, can be removed by the various chromatographic processes we developed for cleaning up pam solutions prior to determining concentrations. The procedures are fairly quick and typical interferences and appropriate removal procedures have been described in detail in previous papers (4, 5).

Conclusions

The charge density of pams can be determined by means of standard curves using parameters obtained from tensammograms of the pams in TEAC. The method uses solutions and is not critically dependent on pam concentration. Thus pure, dry samples are not strictly necessary.

Chromic oxidation of lactic acid in very strong acid media

MARÍA PIEDAD ALVAREZ-MACHO AND MARÍA ISABEL MONTEQUI-MARTIN
Departamento de Química-Física, Facultad de Ciencias, Universidad de Valladolid, 47005 -Valladolid, Spain

Received April 5, 1989

MARÍA PIEDAD ALVAREZ-MACHO and MARÍA ISABEL MONTEQUI-MARTIN. Can. J. Chem. **68**, 29 (1990).

The oxidation of lactic acid by chromic acid was studied at high concentrations of $HClO_4$, HNO_3, and H_2SO_4. It was observed that the reaction rate depends not only on the acidity of the medium, but also on the nature of the mineral acid. The use of the Bunnett and Bunnett–Olsen criteria and the excess acidity concept allows us to propose a reaction mechanism of the A-2 type, the rate-determining step being a bimolecular process in which water participates as a nucleophile. The enthalpy and entropy of activation were determined; the decrease of the magnitude of these parameters when the acidity of the medium was increased suggests the existence of a compensation effect.

Key words: chromic acid, oxidation, lactic acid, acidic media.

MARÍA PIEDAD ALVAREZ-MACHO et MARÍA ISABEL MONTEQUI-MARTIN. Can. J. Chem. **68**, 29 (1990).

Opérant à des concentrations de $HClO_4$, HNO_3 et H_2SO_4 élevées, on a étudié l'oxydation de l'acide lactique par l'acide chromique. On a observé que la vitesse de la réaction ne dépend pas seulement de l'acidité du milieu mais aussi de la nature de l'acide minéral. L'utilisation des critères de Bunnett et de Bunnett–Olsen ainsi que du concept d'acidité en excès nous permet de proposer un méchanisme réactionnel de type A-2 dans lequel l'étape déterminante de la vitesse de la réaction est un processus bimoléculaire où l'eau agit comme nucléophile. On a détermine l'enthalpie et l'entropie d'activation de la réaction; le fait que l'amplitude de ces paramètres diminue avec une augmentation de l'acidité du milieu suggère qu'il existe un effet de compensation.

Mots clés : acide chromique, oxydation, acide lactique, milieu acidique.

[Traduit par la revue]

Introduction

The functional group of the lactic acid molecule that is attacked by Cr(VI) species depends upon both the acidity and the temperature used (1). If the oxidant attacks the alcohol group, a reaction mechanism of the Westheimer type (2) is suggested, with the modification given by Kwart and Francis (3). In this case, the rate-determining step is the intermolecular decomposition of a cyclic ester, giving the corresponding ketoacid (pyruvic acid) due to the breaking of the C—H bond in the α position (4–7).

On the other hand, when the oxidant attacks the carboxyl group it breaks the C—C bond, giving aldehyde and CO_2 as a result of this decarboxylation (8, 9).

In this work, the chromic oxidation of lactic acid in very strong acid media has been studied, and a reaction mechanism is proposed, in agreement with the results obtained when different correlations of rate constant with acidity of the medium were analyzed.

Experimental

Materials

Lactic acid (Merck) and potassium dichromate (Merck) were used without further purification. The acid solutions were prepared from perchloric, nitric, and sulfuric acids (Panreac) in bidistilled water.

Kinetic measurements

The oxidation of lactic acid by chromic acid was followed at 350 nm with a Perkin–Elmer spectrophotometer, model Coleman 55, equipped with a thermostatted cell holder. All oxidation experiments in these studies were carried out with a large excess of substrate over oxidant concentration ($\sim 10^{-4}$ M). Thus, pseudo-first-order rate constants for the disappearance of chromium(VI), k_{exp}, could be determined by plotting log absorbance vs. time.

Results and discussion

The influence of the concentration of lactic acid on the reaction rate at different concentrations of perchloric acid was studied (Table 1). Linear variations of log k_{exp} vs. log [lactic acid] were found, with slope values of 0.98 ($r_{xy} = 0.9996$), 0.94 ($r_{xy} = 0.9992$), and 0.99 ($r_{xy} = 0.9961$) respectively for the three acidities studied, which indicates that the kinetic order for the lactic acid was one.

1.0	3.77	9.37	21.97

$[K_2Cr_2O_7] = 4.6 \times 10^{-4}$ M; $T = 25$°C.

Studies on the variation of rate constant with acidity (Table 2) show that the reaction rate is influenced not only by the acidity of the medium but also by the nature of the mineral acid used as solvent.

To establish a relationship between k_{exp} and the acidity of the medium, the criterion proposed by Zucker and Hammett (10) was first taken into consideration. Good linear correlations were found between log k_{exp} and $-H_0$. However, it was necessary to consider treatments given by other authors (11) because the slope was not one.

Bunnett (12) considered that the water activity had a very important role in acid-catalysed processes and he proposed the following correlation:

$$[1] \quad \log k + H_0 = w \log a_{H_2O} + \text{const.}$$

In which the w parameter is much more sensitive to changes of

reacting substrate than the slopes of the conventional Zucker–Hammett plots.

Later Bunnett and Olsen (13) obtained very satisfactory results by using linear free energy relationships:

[2] $$\log k + H_0 = \Phi (H_0 + \log[H^+]) + \text{const.}$$

The parameters defining the slopes of these criteria (eqs. [1] and [2]) can be associated for substrates protonated on the oxygen atom as follows:

Water role	w	Φ
Not involved	$-2.5 < w < 0.0$	$\Phi < 0.0$
Nucleophile	$1.2 < w < 3.3$	$0.22 < \Phi < 0.56$
Proton transfer agent	$w > 3.3$	$\Phi > 0.58$

Our findings (Table 3) show that the water participates in the rate-determining step as a nucleophile, allowing us to propose a reaction scheme of the A-2 type, as follows:

[3] $S + H \rightleftharpoons SH^+$ (fast)

[4] $SH^+ + H_2O \rightarrow$ Prod. (slow)

in which "S" represents a 1:1 complex between lactic acid and Cr(VI) species.

Recently Cox and Yates (14) have recommended the use of the excess acidity function X instead of the traditional acidity functions, because it gives important mechanistic information (15). The corresponding correlation equation for an A-2 scheme is

[5] $$\log k - \log[H^+] - n \log a_{H_2O} = m^* m^{\neq} X + \text{const.}$$

In practice, it is necessary to test different values for the factor n ($n = 1,2,...$) until a linear fit of the left side of eq. [5] vs. X is obtained. Our findings indicate that, in a perchloric medium (Fig. 1), two water molecules in the transition state will participate, while in a sulfuric medium (Fig. 2) only one participates. It was not possible to consider the case of nitric acid, because the values of X are not available for this solvent.

The slope of these plots correspond to $m^* m^{\neq}$, where m^* is a parameter that depends only upon the medium (~0.7 in perchloric and ~1.0 in sulfuric) while the value of the $m^{\neq}$ parameter depends upon the mechanism through which the reaction takes

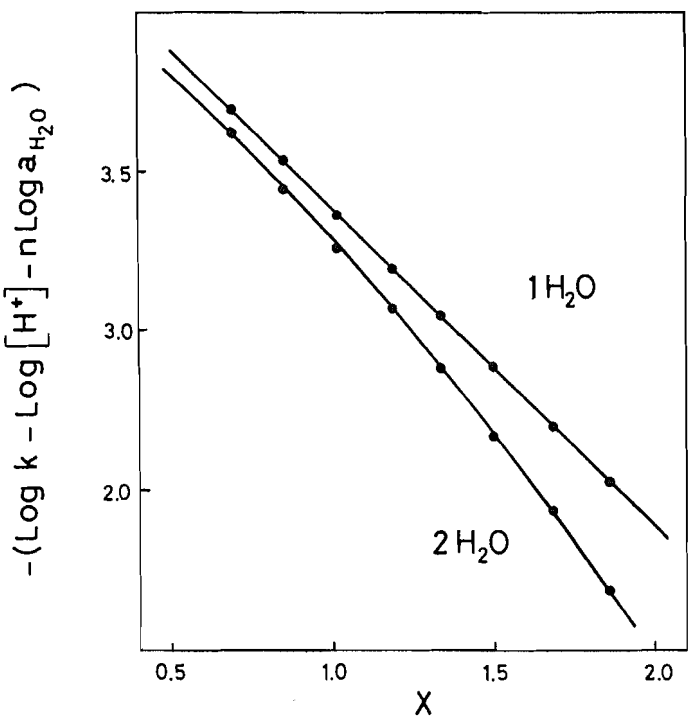

FIG. 2. Plot according to eq. [5] for the chromic oxidation of lactic acid in sulfuric acid medium, assuming the involvement of one or two water molecules.

place. The values obtained for $m^* m^{\neq}$: 0.63 ($r_{xy} = 0.9993$) in perchloric acid and 1.00 ($r_{xy} = 0.9994$) in sulfuric acid, give a value $m^{\neq} \simeq 1$, characteristic of an A-2 type mechanism (15, 16).

The influence of the temperature on the reaction rate at different acidities of the medium was studied and the activation parameters determined (Table 4). The decrease in the magni-

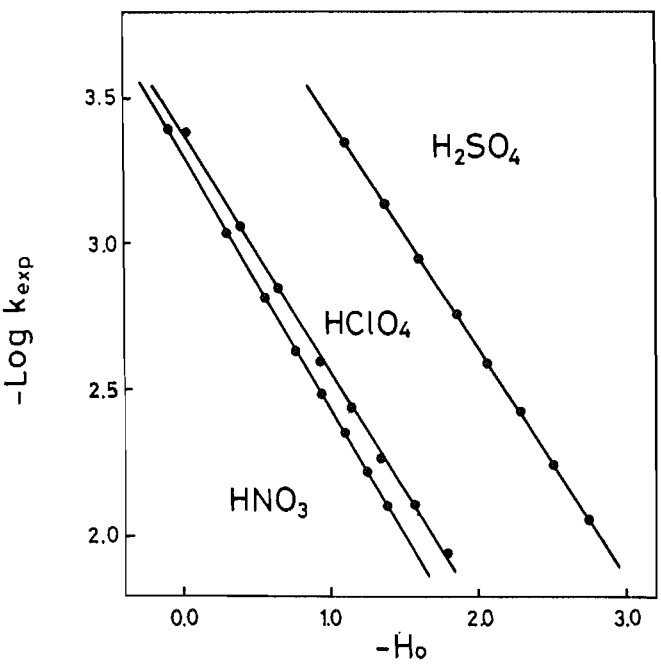

FIG. 3. Variation of rate constant with H_0 for the chromic oxidation of lactic acid.

tude of these parameters, as a consequence of the nucleophilic attack of water, suggests the existence of a compensation effect.

An isokinetic relationship between the activation parameters was found ($\Delta H^{\neq} = \Delta H_0^{\neq} + \beta \Delta S^{\neq}$), the isokinetic temperature being β = 915 K. However, the verification of this isokinetic relationship and the estimation of β involved difficult statistical problems, since $\Delta H^{\neq}$ and $\Delta S^{\neq}$ were determined simultaneously from the same set of experimental data and hence are mutually dependent (17, 18). This problem was avoided by a statistical method (19, 20), which on the one hand permits a reliable estimation of the isokinetic temperature (β = 909 K) and on the other hand vouches for the validity of the isokinetic relationship.

In this work, it was found (Table 2) that the reaction rate depends on the nature of the mineral acid used as solvent. Therefore, in agreement with other authors (19–22), it is possible that the protonation of the acid chromate ion will be accompanied by the incorporation of the anion form of the mineral acid used as solvent, which will considerably affect the subsequent oxidant capability of the new species of Cr(VI), according to the following equilibrium:

$$HCrO_4^- + A^- + 2H^+ \rightleftharpoons HCrO_3A + H_2O$$

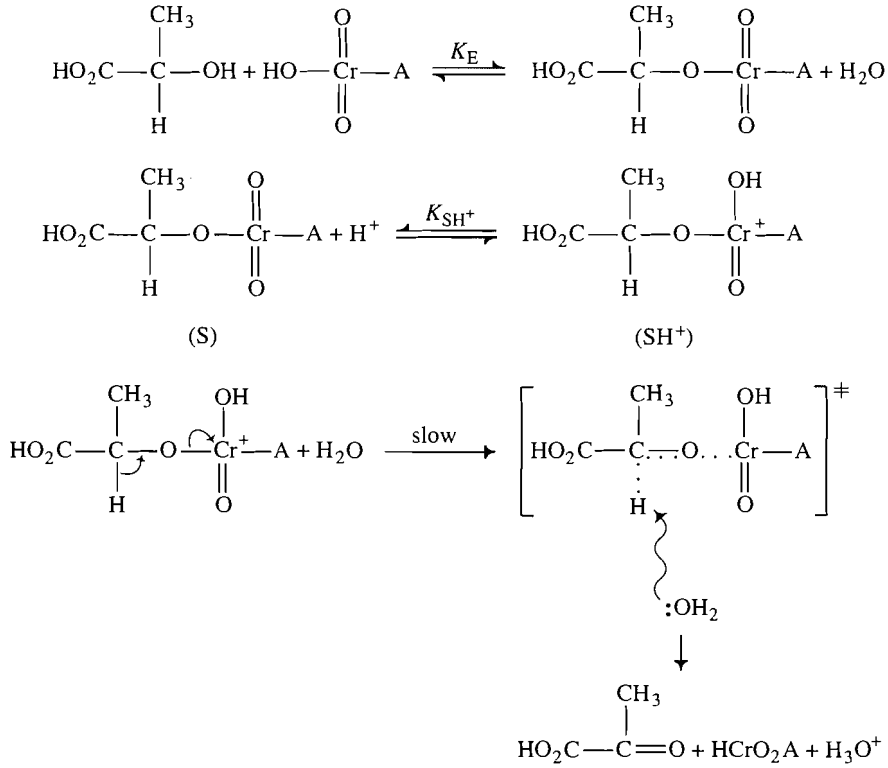
From the pK_a values (22), the oxidant ability of these species (for a given value of the Hammett function, H_0) varies in the order:

$$HCrNO_6 > HCrClO_7 > H_2CrSO_7$$

This sequence coincides with that experimentally observed for the values of k_{exp} in different media (Fig. 3). Therefore it is likely that the Cr(VI) will mainly act as $HCrO_3A$, although it is not possible to completely discard the participation of the $HCrO_4^-$ species, especially for low values of the acidity (23).

All the results mentioned above, together with the isotopic effect (7) that indicates the breaking of the α C—H bond in the

rate-determining step, allow us to propose the following mechanism:



in which "S" represents a chromic ester similar to that proposed by other workers (5–7) for this type of oxidation. The subsequent protonation of the ester will probably take place in the chromate part, which increases the capability of the chromium to accept electrons (22). The results obtained using different criteria of acidity allow us to propose, as the rate-determining step, a bimolecular process in which water acts as a nucleophile and, therefore, represents our formulation of the mechanism for the chromic oxidation of lactic acid at high values of the solvent acidity of the Westheimer type.

Coupled diffusion of butanol solubilized in aqueous sodium dodecylsulfate micelles

DEREK G. LEAIST
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received May 11, 1989

DEREK G. LEAIST. Can. J. Chem. **68**, 33 (1990).

Ternary interdiffusion coefficients have been measured for ten compositions of the system sodium dodecylsulfate (NaDS) + 1-butanol (BuOH) + water at 25°C. The diffusivity of BuOH in this system is lower than in pure water because about one half of the alcohol is solubilized in the slowly-diffusing NaDS micelles. Yet, surprisingly, diffusion of the NaDS component transports only minor amounts of BuOH. Diffusion of the BuOH component, however, produces a substantial coupled flow of NaDS. Although added BuOH increases the solution viscosity and the size of the micelles, the diffusivity of the NaDS component does not change significantly. The Harned restricted diffusion method for the determination of electrolyte diffusivities is extended to electrolyte + nonelectrolyte solutes.

Key words: micelles, ionic; solubilization; diffusion, coupled.

DEREK G. LEAIST. Can. J. Chem. **68**, 33 (1990).

On a mesuré les coefficients d'interdiffusion ternaire pour dix compositions du système dodécylsulfate de sodium (DSna) + 1-butanol (BuOH) + eau, à 25°C. La diffusivité du BuOH dans ce système est plus faible que dans l'eau pure parce qu'environ la moitié de l'alcool est solubilisé dans des micelles de DSNa qui diffusent lentement. Malgré tout et d'une façon surprenante, la diffusion de la composante DSNa ne transporte que de faibles quantités de BuOH. La diffusion de la composante BuOH provoque un flux couplé important du DSNa. Même si l'addition de BuOH provoque une augmentation de la viscosité de la solution et de la grosseur des micelles, la diffusivité de la composante DSNa ne change pas beaucoup. On a étendu la méthode de la diffusion restreinte, développée par Harned pour la détermination des diffusivités électrolytiques, à des solutions du type électrolyte + non-électrolyte.

Mots clés : micelles, ionic; solubilization, diffusion, couplée.

1. Introduction

Organic molecules that do not dissolve appreciably in pure water can often be solubilized by aqueous micelles (1, 2). The research reported here was undertaken to study the coupled diffusion of ionic micelles + solubilizate. To supplement the analysis, ternary interdiffusion coefficients are reported for aqueous sodium dodecylsulfate (NaDS) + 1-butanol (BuOH). Since about one half of the total alcohol is solubilized (3–5) and therefore transported in the NaDS micelles, this system should provide an interesting exception to the rule that diffusion of electrolytes and nonelectrolytes is weakly coupled (6–8). Aqueous NaDS and BuOH were chosen because accurate binary interdiffusion data (9–12) are available for comparison with the ternary results, and because the distribution of BuOH between micellar and aqueous environments has been reported (3, 4).

There have been a number of studies of intradiffusion in micelle + solubilizate solutions (1, 3, 13–15). This type of diffusion refers to the interchange of magnetically- or isotopically-tagged species with untagged species in chemically uniform solutions (6). The interdiffusion coefficients (also known as mutual diffusion coefficients) reported here, by contrast, describe mass transport during the interchange of solute and solvent driven by gradients in chemical composition. Interdiffusion of micelles + solubilizate finds important applications in detergency, tertiary oil recovery and the controlled release of drugs and pesticides. Ternary interdiffusion coefficients are required, for example, to describe the rate of diffusion of aqueous micelles to an oil/water interface, and the subsequent diffusion of the oil-laden micelles back into the aqueous phase. No interdiffusion coefficients for micelles + solubilizate have been reported previously.

2. Experimental

NaDS (BDH specially pure grade) was dried in a vacuum oven at 60°C. 1-Butanol (Fisher reagent grade) was used as received. Solutions were prepared with distilled deionized water in calibrated volumetric flasks.

A simplified version of Harned's restricted diffusion technique (16, 17) was used to measure diffusion of the solutes. The initial concentration gradients were prepared by injecting solutions into the lower end of a short (3.05 cm) column of less dense solution. At each mean cell composition, three runs were performed with the initial gradient in NaDS, and another three with an initial BuOH gradient. The rate of decay of the concentration gradients was followed by measuring changes in electrical conductance across pairs of small platinum electrodes located at 1/6 and 5/6 of height of the solution column. Each run lasted about one week. Ternary interdiffusion coefficients were computed by moments analysis of the conductance versus time data (16). Details of the equipment and procedure have been reported (16, 17).

It might seem inappropriate to use a conductimetric procedure to monitor diffusion of a nonelectrolyte, such as BuOH. But in aqueous NaDS solutions, provided the concentration of NaDS is above the critical micelle concentration, added BuOH increases the conductance (18, 19) by displacing bound Na^+ counterions from the micelles. This gives BuOH a partial molar conductance about one tenth as large as that of the NaDS component, which is sufficiently large for the successful employment of Harned's method.

3. Results

Interdiffusion of aqueous NaDS + BuOH is a complicated process involving the coupled flow of several rapidly-equilibrating solute species: charged micelles (composed of aggregated DS^- ions together with bound Na^+ counterions and solubilized BuOH), free BuOH molecules, and monomeric Na^+ and DS^- ions. A detailed treatment of the diffusion behavior

would have to include interactions between the species (such as electrophoresis), nonideal solute activities, polydispersity of the micelles, and possible changes in micelle shape or structure with composition. These and other complications are included implicitly in the multicomponent diffusion equations (6–8)

$$[1] \quad -J_i = \sum_{k=1}^{2} D_{ik} \nabla C_k \qquad i = 1, 2$$

$$[2] \quad \partial C_i/\partial t = \sum_{k=1}^{2} \nabla (D_{ik} \nabla C_k)$$

J_1 and J_2 denote the molar flux densities of the neutral solute components: 1. total NaDS (micellar + nonassociated electrolyte); 2. total BuOH (solubilized + free alcohol). C_i denotes the total concentration of component i, and coefficient D_{ik} gives the flux of component i produced by the gradient in the concentration of component k. Cross-coefficients D_{12} and D_{21} are included to allow for interactions between the diffusing solutes.

Although multicomponent diffusion equations have not been used in previous studies of micelle + solubilizate transport, they provide a concise but accurate description of the diffusion. No assumptions are made concerning the number or the composition of the various diffusing species. Since the transport equations are written in terms of known total solute concentrations, the D_{ik} values can be determined by experiment (6), using optical or diaphragm–cell methods, or the conductimetric method used here.

Interdiffusion coefficients of aqueous NaDS(1) + BuOH(2) were measured at 25.00 ± 0.05°C and concentrations of each solute from 0.05 to 0.3 M. The results are given in Table 1. D_{11} and D_{12} which describe transport of the NaDS component were reproducible within $\pm 0.01 \times 10^{-9}$ m^2 s^{-1}. The reproducibility of D_{21} and D_{22}, $\pm 0.03 \times 10^{-9}$ m^2 s^{-1}, was poorer due to the lower partial molar conductance of BuOH which meant that its diffusion could not be followed as precisely.

Table 1 includes values of D_{11}, the interdiffusion coefficient of aqueous NaDS, interpolated from an earlier binary conductimetric study on aqueous NaDS in BuOH-free solutions (11). D_{11} might reasonably be expected to decrease with C_2 due to the viscosity increase and the increase in effective micelle diameter with the solubilization. Comparison of the binary data with the present results, however, indicates that added BuOH appears to have little effect on D_{11}, the diffusivity of NaDS. In the most concentrated solution that was studied ($C_1 = 0.3\,M$, $C_2 = 0.3\,M$), however, a drop in D_{11} is noted. This behavior may reflect a breakdown of the micelles structure in favor of a microemulsion (19, 20).

Lyons and Sandquist (12) have used Gouy interferometry to measure accurate binary interdiffusion coefficients for aqueous BuOH. As the concentration of the alcohol increased from 0 to 0.3 M, D_{22} dropped from 0.97×10^{-9} to 0.88×10^{-9} m^2 s^{-1}. The values of the diffusivity of BuOH in NaDS solutions listed in Table 1 are 20–30% lower, no doubt because of the portion of the alcohol that is solubilized is transported in the slowly-diffusing micelles. As the ratio of BuOH to NaDS increases, the solubilized fraction of the total alcohol drops and D_{22} increases.

The ratio D_{12}/D_{22} takes values as large as 1/4, indicating that each mole of diffusing BuOH cotransports up to 1/4 mole NaDS. On the other hand, the relatively small values of D_{21} suggests that NaDS does not co-transport significant amounts of BuOH. This is surprising since the diffusing NaDS micelles carry up to about one-half of the total alcohol (3–5). Consider

the solutions containing equimolar amounts of total NaDS and BuOH, for example. It would seem that each mole of the total NaDS should cotransport on the order of 1/2 mole BuOH, and hence the value of D_{21} should equal approximately $D_{11}/2$, about 0.25×10^{-5} m^2 s^{-1}, which is considerably larger than the measured D_{21} values.

4. Discussion

The experimental results suggests that NaDS micelles do not co-transport large amounts of BuOH. This puzzling behavior can be understood by noting that the solubilized fraction of BuOH increases with the concentration of NaDS. Once a gradient in the concentration of NaDS is formed, the region with excess NaDS becomes deficient in free BuOH molecules. Free BuOH molecules then diffuse "up" the NaDS gradient, countercurrent to the solubilized BuOH carried "down" the NaDS gradient by the micelles. Since the diffusivity of free BuOH is about one order of magnitude larger than the diffusivity of the micelles, the rapidly-diffusing free alcohol effectively "levels" the total concentration of BuOH before significant cotransport of micellar alcohol can occur.

By what mechanism does BuOH cotransport relatively large amounts of NaDS? As mentioned earlier, added BuOH releases bound Na^+ counterions from the NaDS micelles. As a result, a gradient in the concentration of total BuOH produces a gradient in the same direction in the concentration of free Na^+ ions. The Na^+ ions, the most mobile solute species, diffuse rapidly down the BuOH gradient. To maintain electroneutrality, negatively-charged micelles are dragged along by the diffusion-induced electric field. The freed Na^+ ions have the additional effect of increasing the diffusivity of the NaDS component, D_{11}. The flow of NaDS is more strongly coupled to the flow of NaDS than expected for typical electrolyte–nonelectrolyte pairs because transport of BuOH produces both an electric field and ionic gradients in the present system.

In the present work, diffusion with solubilization is described by using coupled diffusion equations for the total solute components. However, the diffusion of associating solutes is more frequently described by using pseudobinary transport equations (8, 21–29)

$$[3] \quad j_i = -D_i \nabla c_i$$

$$[4] \quad \partial c_i/\partial t = D_i \nabla c_i^2 + r_i$$

for each solute species. Since the individual species that constitute the total solute components are not conserved, eqs. [4] include the reaction rate of species i per unit volume, r_i. It is often overlooked that unlike the multicomponent diffusion equations [1] and [2], eqs. [3] and [4] are accurate only for dilute solutions in which solute–solute interactions are negligible. Moreover, for many systems, including the one under discussion, the identity of the various species and their concentrations (c_i), diffusion coefficients (D_i), and reaction rates are not known accurately, nor are they easily measured. For charged solute species, there is the additional complication that eqs. [3] and [4] should include terms for the transport driven by the electric field that is generated whenever the diffusing ions have different mobilities (30, 31).

Despite their limitations, the pseudobinary transport equations can be used to help interpret multicomponent diffusion (32). With this goal in mind, attempts were made to predict the multicomponent diffusion coefficients using estimates of the concentrations and the diffusion coefficients of the various transported solute species. As a first approximation, three major solute species were assumed: mixed micelles (DS_nNa_q-$BuOH_s)^{q-n}$; free alcohol molecules, BuOH; and free counterions, Na^+. (The concentration of free dodecylsulfate ions is negligible provided the concentration of total NaDS is well above the critical micelle concentration (0.008 M at 25°C (33)). Unfortunately, it was not possible to obtain estimates of the D_{ik} coefficients in reasonable agreement with experiment. A more successful treatment of the problem could be formulated by using the stepwise aggregation model.

$$nDS^- + qNa^+ + sBuOH = (DS_nNa_qBuOH_s)^{q-n} \qquad K_{nqs}$$

It would be necessary, however, to determine the values of a large number of association constants K_{nqs}. The stepwise aggregation models that have been reported for ionic micelles + solubilizate (34–37) do not include variable degrees of counterion binding, an important feature for diffusion. Even with a better description of the speciation, the problem of evaluating the diffusivities of the various species remains. In view of these difficulties, it is likely that multicomponent diffusion experiments will be required for a quantitative description of micelle + solubilizate transport for some time to come.

Enhanced polymerization of molybdate ions in the presence of antimonic acid

M. KONE, P. COURTIN, AND J. LEMERLE

Laboratoire de chimie des polymères inorganiques, Unviersité Pierre et Marie Curie, 75252 Paris Cedex 05, France

Received July 31, 1989

M. KONE, P. COURTIN and J. LEMERLE. Can. J. Chem. **68**, 36 (1990).

Polymer compounds including both antimony and molybdenum were formed by mixing freshly prepared solutions of antimonic and molybdic acid. These acids were formed through an ion exchange process. When antimony is in excess, molybdenum is included in the high polymers having the ccp structure of β antimonic acid. When molybdic acid is in excess in the starting mixture, molybdenum-rich polymers with a larger molecular weight than molybdic acid were formed. In GPC experiments the behaviour of the compounds is related to their Mo and Sb content. The elution volume is only related to the molecular weight of the compound when Sb is the main component and imposes its structure.

Key words: molybdoantimonic acids, inorganic polymers, ultracentrifugation, GPC.

M. KONE, P. COURTIN et J. LEMERLE. Can. J. Chem. **68**, 36 (1990).

Des polymères composés d'antimoine V et de molybdène VI sont élaborés par mélange d'acides molybdiques et antimoniques fraîchement préparés. Ceux-ci sont eux-mêmes préparés par échange d'ions. La nature des composés obtenus dépend de l'élément en excès dans le milieu. Quand l'antimoine est en excès, le molybdène est inclus dans des hauts polymères ayant la structure pyrochlore de l'acide antimonique β. Quand le molybdène est en excès, des polymères riches en molybdène incluent de l'antimoine. Leur nombre d'atomes de molybdène est nettement supérieur à celui de l'acide molybdique. Quand les polymères sont riches en molybdène le fractionnement par GPC est fortement perturbé par l'adsorption sur le gel. Cet artéfact peut être utilisé pour caractériser la nature des polymères formés.

Mots clès : acides molybdoantimoniques, polymères inorganiques, ultracentrifugation, GPC.

Introduction

Polymerization of some transition or post-transition metals occurs spontaneously upon acidification. For example, acidification results in the formation of polymer built up from MO_6 octahedra (M = W, V, Mo, Sb...) (1). The nature of the polymers depends not only on the experimental conditions (e.g. pH) but also on the history of the sample since some of the conversions are slow (2).

If the protonation goes through an ion exchange process, tungstate solutions lead to α tungstic acid (polymerization degree $n = 24$) which spontaneously polymerizes to form a gel and then WO_3 (3). Molybdate solutions lead to molybdic acid ($n = 48$) but this acid does not age to form polymers with a higher molecular weight (4). Nevertheless, polymerization of molybdic acid can be enhanced by mixing with polytungstic acids even with the less reactive ones (5). Antimonic acid spontaneously ages to form high polymers which sedimentate (6). Before its polymerization it reacts with α tungstic acid to form suluble mixed compounds (7). In this paper we study the formation of polymerized anions, including both molybdic and antimonic acids.

Experimental

The solutions were prepared by mixing solutions of antimonic and molybdic acids. The antimonic acid was prepared by ion exchange in a resin (DOWEX 50 WX2 100–200 mesh) from potassium hexahydroxoantimonate solutions (Merck, analytical grade). Just after the exchange, turbid solutions were obtained. They became clear after aging (1 h) and α antimonic acid was formed (6). The molybdic acid was also prepared by ion exchange in a resin (DOWEX 50 WX8 100–200 mesh) from sodium molybdate solutions (Prolabo analytical grade). In this paper we use x_i for the initial molar fraction of molybdenum in the mixtures of the two acids. To prepare mixtures whose x_i lies from 0 to 1, two series of samples were prepared: Samples A with a constant antimony concentration (6×10^{-2} mol L^{-1}) and a variable molydbenum concentration ($0 \leq x_i \leq 0.64$); samples B with a constant molybdenum concentration (8×10^{-2} mol L^{-1}) and a variable antimony concentration ($0.65 \leq x_i \leq 1$).

To study the influence of the total concentration of the reactants, samples with the same x_i as samples A but with lower antimony concentration (3.45×10^{-2} mol L^{-1}) were prepared (samples C).

All mixtures were allowed to age. Measurements were carried out after 2 and 15 months.

The concentrations of antimony and molybdenum were measured after alkaline degradation of the compounds. The samples were heated for 1 day in an excess of potassium hydroxide. The resulting solution was adjusted to pH 8 in a volumetric flask and aliquot reactions were used for titrations. Antimony was titrated by atomic absorption with an air–acetylene flame with a Perkin-Elmer 373 spectrophotometer. Molybdenum was colorimetrically titrated using the molybdenum–pyrocatechol complex formed at pH 7 (8). Measurements were carried out at $\lambda = 400$ nm with a Beckman spectrophotometer.

Analytical ultracentrifuge experiments were carried out with a Beckman model E ultracentrifuge equipped with schlieren and absorption optics. Double sector cells manufactured in Kel F were used. The rotation speed ranges from 8000 to 56000 rpm depending on the sample. To avoid the effects of electric charges, an electrolyte (LiCl 5×10^{-2} mol L^{-1}) was added to the sample just before the run. Specific volumes were measured from density measurements carried out with a PAAR automatic densimeter.

Preparative ultracentrifugations were carried out with a Beckman microfuge at 10000 rpm for 1 h. In this centrifuge the tube axis is colinear with the centrifugal field.

The ultrafiltration of the sample was carried out in a Millipore assembly using Pellicon PTGC membranes under a nitrogen flow (NMWL tested for similar compounds 15000 daltons (9)). Polyacrylamide gel manufactured by Bio-Rad was used for gel permeation chromatography (GPC). This gel has been standardized with known antimonic polymers and has an exclusion limit corresponding to 16000 daltons (10).

Results

The aged samples corresponding to small x_i (low molybdenum content) were turbid, but they do not precipitate even after several months at rest. When x_i increases, the turbidity decreases and a yellow colour appears. For x_i values higher than 0.3 the samples were limpid and yellow colored.

The ultracentrifugation measurements exhibit three types of

compounds according to their behaviour in the centrifugal field. The low speed experiments ($\leq$ 8000 rpm) exhibit free sedimenting species when $x_i < 0.50$ (samples A and C). Their sedimentation coefficients S range from 2000 to 8000 Svedberg (Tables 1 and 2). In these experimental conditions, only one sedimentation peak was observed for samples A and two for samples C. The S value decreases with decreasing antimony concentration (x_i constant) or increasing x_i. Moreover, the S values are enhanced when the samples age (Table 2). All sedimenting species having an S value greater than 2000 are labelled "high polymers."

The high speed experiments (56000 rpm) exhibit free sedimenting species when $0.38 < x_i < 0.64$ (samples A only). Their sedimentation coefficient range from 6.9 to 17.3 (Table 1). At the same speed non-sedimenting species were observed for most samples. Their molecular weight is calculated by the Archibald's method (11, 12) assuming the compounds to be in equilibrium at the meniscus of the cell (Tables 1 and 2). According to the x_i value, two types of patterns were observed on the photographic plates and one of them ($x_i > 0.65$) corresponds to a mixture of two species. The heavier species has a molecular weight near 7000 and would freely sedimentate if it was alone in the medium. These compounds (M = 7000) and the free sedimenting species ($6.9 < S < 17.3$) are considered to have the same range of molecular weight; and are labelled "small polymers." Nevertheless, we will distinguish the small polymers obtained from samples A (small polymers A) and those from samples B (small polymers B). The compounds

having the smaller molecular weight ($M < 2000$) are labelled "oligomers." Each type of polymer (high polymers, small polymers, and oligomers) was isolated using a technique which splits the samples according to their molecular weight: preparative ultracentrifugation, ultrafiltration, and GPC.

In preparative ultracentrifugation the high polymers were packed down to the bottom of the centrifugation tube and the small polymers and oligomers remain in the supernatant solution. Mo and Sb were titrated in the supernatant solution and by difference with the initial concentrations, we obtain the high polymers composition. This composition was also obtained by direct titration. The two values are in good agreement. When x_i increases, the amount of high polymer decreases and the Mo content increases (Table 3). The composition of high polymers is only dependant on x_i. Their abundance increases when the sols age (Table 4).

Powder patterns of solid high polymers exhibit the same cubic close packing (ccp) structure (pyrochlore type) as the β antimonic acid (6). The length of the unit cell decreased slightly as in other mixed compounds with antimonic acid (7, 9) (a = 10.35 Å). The diffraction patterns obtained with a sol containing high polymers and those obtained with solid high polymers isolated from this sol were the same. Thus we can expect that the crystals exist in the aqueous phase with the same size as in the solid state.

The supernatant solutions and the samples which do not contain high polymers were splitted by ultrafiltration ($x_i < 0.52$) and high speed ultracentrifugation ($x_i > 0.52$). When $0.30 < x_i < 0.52$, one compound does not pass through the membrane. These samples correspond to those which exhibit free sedimenting species ($S \simeq 17$ Svedberg). The compounds which were stopped by the membrane were dissolved in water. This solution was analysed with the ultracentrifugation technique and Mo and Sb were titrated. The ultracentrifugation exhibits a free sedimenting compound ($S \simeq 17$ Svedberg). Therefore these compounds were the small polymers A. Their composition is reported in Table 5. The high speed ultracentrifugation experiments lead to the composition of small polymers B (Table 5).

TABLE 5. Composition and relative abundance of small polymers

x_i	Name of small polymers	Mo/Sb	%*
0.23	A		0
0.30	A	0.65	11.5
0.41	A	0.60	33.5
0.47	A	0.69	51.7
0.52	A	0.76	15
0.56	B	1.38	81
0.60	B	1.56	85
0.64	B	1.76	89

*%: ratio of antimony concentration in the small polymers to the antimony concentration (expressed in %).

All samples were studied by GPC. If they contain high polymers, a preparative centrifugation was done before chromatography to remove the high polymers. Some compounds containing Mo and Sb in a constant ratio Mo/Sb = 2/3 were excluded when $0.30 < x_i < 0.52$ (samples A). All samples exhibit one or several elution peaks for the following volumes:

$1.5v_m$, $x_i > 0.65$

$2.25v_m$, $x_i < 0.52$

$3.75v_m$, $x_i > 0.4$ (these fractions were yellow coloured)

$5.25v_m$, $x_i > 0.8$

where v_m = the outer volume of the gel.

The composition of the various fractions corresponding to these peaks are reported in Table 6. Pure molybdic acid was eluated for a volume corresponding to $5.25v_m$. Molybdenum-rich samples (samples B) were also passed through a column containing an ion exchange resin (Amberlite CG 400 100–200 mesh Cl^- form). Molybdic acid was fixed. The remaining solution was studied with GPC technique in the same conditions as previously. The elution peak located at $5.25v_m$ does not exist.

Discussion

Upon aging α antimonic acid transforms into insoluble β antimonic acid (6). In previous works (7, 9) it has been seen that mixed polymers can be formed with antimonic acid by substitution of a SbO_6 octahedron by another octahedral group MO_6 if the size substituting atoms are close to that of antimony atoms. The amount of mixed compound formed decreases when the ratio of substituting atoms increases. These MO_6 groups limit the extent of the β antimonic structure formed by polymerization (9). The aged samples A, B, or C never exhibit any precipitate. Thus in each sample all the antimony combines with the molybdenum to form new mixed compounds, thus preventing antimony precipitation. From the experimental

results the composition and the relative abundance of different compounds can be calculated (Tables 5 to 7).

When x_i reaches to 0.5, high polymers including molybdenum in the ccp structure of antimonic acid are formed. The other compounds formed are oligomers ($x_i < 0.28$) or oligomers and small polymers A ($0.28 < x_i < 0.5$).

The compositions (Mo/Sb) of the small polymers A and the oligomers are in the same range. Therefore small polymers can be formed from oligomers through a condensation process.

In a previous work (9) the formation process of mixed polymers has been described. In such a process the chemical element in excess impose its "structure." The formation of high polymers with a ccp structure ($x_i < 0.5$) agrees with this rule. When $x_i < 0.5$, the GPC experiments give fraction whose composition agrees with that of small polymers A and oligomers. The molecular weight of these compounds are in good agreement with the volume of eluent used for these fractions. Thus in the GPC experiments, the antimony-rich compounds have the same behaviour as the α antimonic acid or its derivatives (10, 13, 14). When $x_i > 0.5$ the compounds eluted for $v = 1.5v_m$ and $3.75v_m$ have the same composition as small polymers B and oligomers, respectively. Molybdic acid is eluted for $5.75v_m$. All these elution volumes are abnormal: elution occurs for larger volumes than the volume of the gel and molybdic acid whose molecular weight is greater than oligomers (4) is eluted for these largest elution volumes. One factor to be considered is the adsorption of molybdenum-rich compounds onto the gel. For antimony-rich compounds the splitting of the sols by gel chromatography is based upon the difference in molecular weight and for molybdenum-rich compounds, the splitting is based upon the difference in chemical reactivity between gel and molybdic compounds. This reactivity can be related to the structure of the compounds due to the excess of molybdenum in these mixed compounds.

For a given x_i only the molecular weight and the amount of high polymer depend on the sol concentration, but the samples do not have the same behaviour in a centrifugal field. With samples C, two peaks are observed and for a given aging time the sedimentation coefficients are smaller than the corresponding ones for samples A and B. We can therefore assume that the particles can associate or dissociate into large units without change in chemical composition if the molecular weight of high polymer is large enough. When the concentration of the sols increases an association equilibrium between high polymers particles is displaced towards the formation of associated particles, and only one sedimentation peak is seen. When the sols age, the high polymer particles grow through a water elimination process involving particles having the same composition.

In mixtures of α tungstic acid and α antimonic acid only two types of mixed compounds are formed for a given initial ratio of W/Sb (7). In their formation process, the first step is the depolymerization of both α antimonic and α tungstic acids. The second step is the polymerization of the monomer units of each element including monomer units of the other element. With molybdenum, the starting material (molybdic acid) can not be considered a monomer unit to stop the polymerization of antimony. However, it does not polymerize enough to form particles with more than 48 atoms per molecule (4). Moreover, molybdic acid exists in two forms according to the concentration and the pH of the solution (4). In the concentration range used in this paper the molybdic acid always exists under its two forms. As a result the number of mixed compounds is enhanced.

Conclusion

Stable aqueous sols of mixed compounds including both antimony and molybdenum can be made by mixing freshly prepared solutions of antimonic and molybdic acids. Depending on the composition of the inital mixture, different types of polymers can be formed. The element (Mo or Sb) in excess imposes its structure and the properties of the compounds. Gel chromatography can be used to split the sols. The elution volume is related to the molecular weight of the species if antimony is the main constituent. On the other hand, if molybdenum is the main constituent the chemical reactions between the gel and the mixed compounds control the splitting.

Received April 11, 1989

GEORGE B. RICHTER-ADDO, ALLEN D. HUNTER, and NADIA WICHROWSKA. Can. J. Chem. **68**, 41 (1990).

The bimetallic complexes $(\eta^6\text{-}1,4\text{-}C_6H_4XFp)Cr(CO)_3$ (where X = H, Me, Cl, or OMe; Fp = $(\eta^5\text{-}C_5H_5)Fe(CO)_2$) were synthesized in 32–80% yields by the reaction of NaFp with $(\eta^6\text{-}1,4\text{-}C_6H_4XF)Cr(CO)_3$ (where X = H, Me, or OMe) or $(\eta^6\text{-}1,4\text{-}C_6H_4Cl_2)Cr(CO)_3$. They were fully characterized by conventional spectroscopic techniques. In these complexes, the arenes are σ bound to the Fp group and π bound to the $Cr(CO)_3$ group. The ^{13}C NMR data suggest that a synergic substituent–arene–Fp π interaction is occurring. Cyclic voltammetric studies of these complexes in CH_2Cl_2 show that they are oxidized reversibly to give stable radical cations, and confirm that the Fp substituents are strong net electron donors to the $Cr(CO)_3$ fragments.

Key words: bimetallic, iron, chromium, arene, oxidation.

GEORGE B. RICHTER-ADDO, ALLEN D. HUNTER et NADIA WICHROWSKA. Can. J. Chem. **68**, 41 (1990).

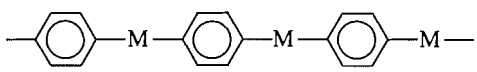
Faisant appel à la réaction du NaFp avec le $(\eta^6\text{-}1,4\text{-}C_6H_4XF)Cr(CO)_3$ (dans lesquels X = H, Me ou OMe) ou $(\eta^6\text{-}1,4\text{-}C_6H_4Cl_2)Cr(CO)_3$, on a réalisé la synthèse des complexes bimétalliques $(\eta^6\text{-}1,4\text{-}C_6H_4XFp)Cr(CO)_3$ (dans lesquels X = H, Me, Cl ou OMe et Fp = $(\eta^5\text{-}C_5H_5Fe(CO)_3)$ avec des rendements allant de 32 à 80%. On les a pleinement caractérisés grâce aux techniques spectroscopiques conventionnelles. Dans ces complexes, les arènes sont liés au groupement Fp par une liaison σ et au groupement $Cr(CO)_3$ par une liaison π. Les données de la RMN du ^{13}C suggèrent qu'il existe une interaction π substituant–arène–Fp. Des études de voltamétrie cyclique réalisées sur ces complexes en solution dans le CH_2Cl_2 montrent qu'ils s'oxydent d'une façon réversible pour donner des cations radicaux stables et elles confirment que les substituants Fp sont de forts donneurs nets d'électrons aux fragments $Cr(CO)_3$.

Mots clés : bimétallique, fer, chrome, arène, oxydation.

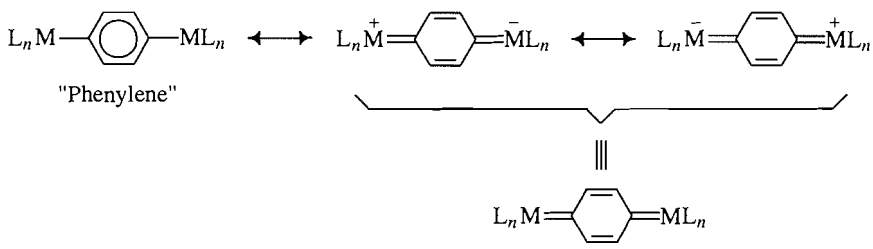
[Traduit par la revue]

Introduction

Organic ligands having delocalized π systems can act as electronic bridges between adjacent metal centers. This property should allow the synthesis of linear-chain organometallic polymers exhibiting one-dimensional electronic conductivity, i.e.,



Our initial studies in this area have focussed on the synthesis of model complexes containing arenes as the bridging ligands (e.g., $C_6H_{6-n}(ML_m)_n$, where ML_m = Fp, $Mn(CO)_5$, etc., and Fp = $(\eta^5\text{-}C_5H_5)Fe(CO)_2$) (1). Particular emphasis has been placed on the elucidation of the factors controlling the degree and nature of electronic linkage in such species. During the course of these studies, we have shown that the strongest electronic interactions occur when the organometallic groups are arranged *para* to one another. A consequence of this 1,4 interaction is that the bonding in such complexes develops significant dimetalloquinone character (1*b*), i.e.,



which may be related to the mode of electrical transmission in any phenylene-bridged polymers to be synthesized in the future. An additional effect of polymetallic substitution is that the arene bridges in these species are likely to be very electron rich (due to σ and π donation from the organometallic fragments) and should thus form π complexes with 12-electron fragments such as $Cr(CO)_3$. Such species would be expected to exhibit significantly different electronic properties than do their uncomplexed precursors (e.g., giving better conductors or photoconductors). We are therefore interested in elucidating the nature of any such perturbations of the σ,σ metal–arene–metal interaction. To this end, we have prepared a series of σ,π model complexes $((\eta^6\text{-}C_6H_{6-n}Fp_n)Cr(CO)_3$, n = 2 or 3) and have investigated their various metal–arene–metal interactions. We have found that their Cr centers are very electron rich and that substantial transfer of electron density from Fe to Cr is observed (1). In addition, our studies have shown that the nature of the Fe–

arene–Fe π-bonding interactions are not dramatically altered upon η^6 complexation (1*c*). However, the separation of the σ,σ and σ,π components of the bonding interactions in these species is difficult due to the complexities inherent when dealing with complexes containing three or four metal centers.

To overcome these difficulties and to help in the elucidation of the nature of this σ,π interaction, we decided to synthesize a series of simpler complexes containing only a single σ-bound Fp group. At the time of this study,[3] only a single member of this class of complexes had been reported (i.e., $(\eta^6\text{-}C_6H_5Fp)Cr(CO)_3$) and it was prepared by the reaction of the parent Fp–phenyl complex with $Cr(CO)_6$ (2), i.e., eq. [1].

[1] $C_6H_5Fp + Cr(CO)_6 \xrightarrow{\Delta} (\eta^6\text{-}C_6H_5Fp)Cr(CO)_3$

Given the high nucleophilicity of the Fp^- anion (3) and facility with which strong organic nucleophiles substitute for halides in $(\eta^6\text{-}C_6H_{6-n}Y_n)Cr(CO)_3$ complexes (where Y = F, Cl, etc.) (4), we felt a more promising and interesting route to such species would be nucleophilic displacement of halide by the Fp^- anion, e.g., eq. [2].

[2] $(\eta^6\text{-}C_6H_5Y)Cr(CO)_3 + Fp^- \rightarrow (\eta^6\text{-}C_6H_5Fp)Cr(CO)_3$

This approach proved successful and produces the desired complexes in high yields. In this paper, we would like to report the complete results of our studies of these complexes including syntheses and spectroscopic and electrochemical characterization of the resultant σ,π products. These data will be compared to the analogous polysubstituted complexes (1) and, in particular, our ^{13}C NMR and cyclic voltammetric data will be discussed with reference to the nature of the Fe–arene–Cr interaction in these complexes.

Experimental

Unless otherwise noted, all reactions and subsequent manipulations were performed under anaerobic and anhydrous conditions using conventional techniques for the manipulation of air-sensitive compounds as described in detail previously (1*b*). The chemicals used were of reagent grade or comparable purity and where necessary were purified before use and had their purity ascertained by elemental analyses and (or) other suitable methods (6). Solvents used were dried and deaerated by standard procedures and stored under N_2 or Ar (6). The (arene)$Cr(CO)_3$ and Fp_2 reagents were prepared and purified by the standard procedures (7, 8). Unless specified otherwise, the chemical reactions described below were effected at ambient temperatures (≈25°C).

Infrared spectra were recorded on a Pye Unicam PU9522 infrared spectrophotometer calibrated with the 1601 cm^{-1} band of polystyrene. Nuclear magnetic resonance spectra were recorded on a Bruker WH-300 spectrometer with reference to the deuterium signal of the solvent employed. The ^1H and ^{13}C chemical shifts are reported in parts per million downfield from external Me_4Si and were obtained with the assistance of the departmental NMR staff. The low- and high-resolution and the fast atom bombardment (FAB) mass spectra were recorded as previously described (1*b*).

The analytical, mass-spectral, IR, and NMR data for the complexes synthesized during this work are collected in Tables 1 and 2. Synthetic procedures and yields are recorded below.

Preparation of $(\eta^6\text{-}1,4\text{-}C_6H_4XFp)Cr(CO)_3$ (where X = H, Me, OMe, or Cl; Fp = $(\eta^5\text{-}C_5H_5)Fe(CO)_2$)

All these complexes were synthesized in a similar fashion. The procedure for $(\eta^6\text{-}1,4\text{-}C_6H_4MeFp)Cr(CO)_3$ is described in detail as a representative example.

An excess of solid sodium amalgam (1*b*) (18.0 g, 18.0 mmol Na) was liquified by the addition of mercury (≈3 mL), and then THF (60 mL) and Fp_2 (1.45 g, 4.10 mmol) were added. The resultant dark red solution was vigorously stirred for 1 h to produce a solution of NaFp (8). Excess amalgam was drained from the reaction through a sidearm of the reaction flask and the solution was then filtered through Celite (2 × 3 cm) supported on a medium porosity frit (2 × 10 mL THF wash) and the resulting orange-red solution was cooled to −78°C (Dry Ice/acetone). To this stirred solution was added $(\eta^6\text{-}1,4\text{-}C_6H_4MeF)Cr(CO)_3$ (1.08 g, 4.39 mmol) and the resultant mixture was held at −78°C for 4 h and then allowed to warm to ambient temperature overnight. The solution was taken to dryness *in vacuo* and the resultant red solid was washed with hexane (7 × 15 mL). The hexane wash contained Fp_2 and unreacted $(\eta^6\text{-}1,4\text{-}C_6H_4MeF)Cr(CO)_3$ (by IR) and was discarded. Crystallization of the residue from CH_2Cl_2 (100 mL) and hexanes (15 mL) at −30°C resulted in the formation of a yellow precipitate. This crystalline material was collected by filtration and washed with hexanes (30 mL) to give the desired product, $(\eta^6\text{-}1,4\text{-}C_6H_4MeFp)Cr(CO)_3$, in good yield (1.77 g, 62%).

The other products (where X = H, OMe, and Cl) were produced in a similar manner from $(\eta^6\text{-}C_6H_5F)Cr(CO)_3$, $(\eta^6\text{-}1,4\text{-}C_6H_4(OMe)F)Cr(CO)_3$, and $(\eta^6\text{-}1,4\text{-}C_6H_4Cl_2)Cr(CO)_3$ in 52, 32, and 80% yields, respectively.

The related reaction of NaFp with $(\eta^6\text{-}1,4\text{-}C_6H_4FNH_2)Cr(CO)_3$ did not proceed as cleanly as those described above; however, the presence of traces of $(\eta^6\text{-}1,4\text{-}C_6H_4(NH_2)Fp)Cr(CO)_3$ was confirmed by mass-spectral analysis. Attempts to react NaFp with $(\eta^6\text{-}C_6H_6)Cr(CO)_3$ or $(\eta^6\text{-}C_6H_5OMe)Cr(CO)_3$, even at ambient temperature, gave no new products on work-up, *vide supra*. Instead, the (arene)$Cr(CO)_3$ starting materials were recovered unchanged.

Electrochemical analysis of the products

A standard three-electrode cell (9) of approximately 40 mL volume was used for the cyclic voltammetry experiments. The working electrode was a small (≈1 mm diameter) Pt bead sealed in soft glass. A coiled Pt wire (≈15 cm in length) was used as the auxiliary electrode. The aqueous SCE reference electrode was separated from the working electrode compartment by a fine frit and a Luggin probe. The $[n\text{-}Bu_4N]PF_6$ support electrolyte (10) and the cell parts were dried in an oven at 130°C overnight just prior to use. The working electrode was cleaned by placing the electrode tip over boiling HNO_3 (reagent grade) for 0.5 h, rinsing with distilled water (2 L), and then soaking it in a saturated ferrous ammonium sulphate solution (made up in 1 M H_2SO_4) for 0.5 h. Finally, it was rinsed with distilled water (2 L) and reagent acetone (1 L) and then was dried with a hot air gun just prior to use. Dichloromethane (Spectrograde, BDH) was stirred over alumina (5 g, Woelm neutral, W200 Super 1) while simultaneously being purged with prepurified nitrogen for 20 min. The solvent with some entrained alumina (≈0.5 g) was then transferred by cannula to the electrochemical cell, which had been previously set up on a vacuum line under dinitrogen.

The potentials were supplied by a BAS CV27 voltammograph, and the resulting cyclic voltammograms were recorded on a Hewlett–Packard 7090A X–Y recorder. The formal oxidation potential ($E^{0\prime}$) for reversible couples is defined as the average of the anodic ($E_{p,a}$) and cathodic ($E_{p,c}$) peak potentials. ΔE is defined by $|E_{p,c} - E_{p,a}|$, and the cathodic to anodic peak current ratio is defined by $i_{p,c}/i_{p,a}$ (11). Diffusion control was established for the redox processes by the observation of a linear plot of i_p versus the square root of scan rate ($v^{1/2}$) over at least one order of magnitude of scan rate. The oxidation of ferrocene is reported to be highly reversible in many solvents (10). After each experiment, ferrocene was added as an internal reference (12). Under our experimental conditions, ferrocene is reversibly oxidized ($E^{0\prime}$ = +0.47 V vs. SCE; $i_{p,c}/i_{p,a}$ = 1.0; ΔE = 60 mV at 0.1 V s^{-1}). Occasionally the ferrocene/ferricinium redox couple was obscured by the redox couple of the analyte, and in these cases cobaltocene was used as the internal reference ($E^{0\prime}$ = −0.86 V vs.

[3]After the completion of our synthetic and spectroscopic studies, a related report was published (5). A complete comparison of the two sets of independent results will be presented in the results and discussion section.

For personal use only.

SCE; $i_{p,a}/i_{p,c} = 1$; $\Delta E = 74$ mV at 0.10 V s^{-1}). In general, reversible oxidations were exhaustively studied before irreversible waves, since the irreversible oxidations lead to extensive coating of the electrode surface. However, when electrode coating was observed, cleaning of the working electrode with facial tissues and its replacement into the cell often appeared to remedy the problem (although no quantitative data for publication were used after such operations).

Electrochemical data for the complexes synthesized during this work are collected in Table 4.

Results and discussion

Synthesis of the complexes

The reaction of NaFp (where Fp = $(\eta^5\text{-}C_5H_5)Fe(CO)_2$) with (haloarene)$Cr(CO)_3$ complexes produces the desired bimetallic products, i.e.,

[3] NaFp + $(\eta^6\text{-}1,4\text{-}C_6H_4XY)Cr(CO)_3$ $\xrightarrow[-78°C]{THF}$ $(\eta^6\text{-}1,4\text{-}C_6H_4XFp)Cr(CO)_3$

(where X = H, Me, or OMe, Y = F; X = Y = Cl). The use of a small excess of Fp^- anion (10–20%) ensures complete consumption of the starting material; however, a larger excess should be avoided since it will simply be converted to Fp_2 in the work-up. In addition, this reaction should be carried out at low temperature to minimize the formation of the Fp_2 dimer, *vide infra*. Using this method, the yields (nonoptimized) of these products vary from 32 to 80%, which is two to four times higher than those reported earlier from an analogous reaction using $[Et_4N]Fp$ at ambient temperatures (5), i.e., eq. [4]

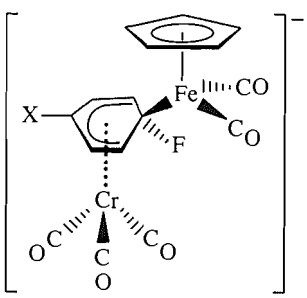
[4] $[Et_4N]Fp + (\eta^6\text{-}1,4\text{-}C_6H_4XY)Cr(CO)_3 \xrightarrow[RT]{THF}$

$(\eta^6\text{-}1,4\text{-}C_6H_4XFp)Cr(CO)_3 + (\eta^6\text{-}C_6H_5X)Cr(CO)_3 + Fp_2$

This increased yield is probably due to the suppression of an ambient temperature side reaction, which has been ascribed to single electron transfer reactions, SET (5), and which produces $(\eta^6\text{-}C_6H_5X)Cr(CO)_3$ as a major product. In our low temperature syntheses, no evidence for such SET-derived products was observed.

The IR spectra of the reaction solutions after 3 h at −78°C indicate that the desired bimetallic species are formed cleanly and in very high yield under these conditions even in the presence of excess NaFp. However, when the solution is allowed to warm to room temperature, a number of new IR bands between 1840 and 1960 cm^{-1} are observed. The new species responsible for these bands have not been isolated but it is tempting to speculate that they may be due to a reversible addition (4) of Fp^- to the complexes.

The detailed mechanism of these syntheses is not known but, by analogy with the related reactions with organic nucleophiles (4), they probably proceed through an S_NAr nucleophilic displacement reaction involving a $Cr(CO)_3$ stabilized Meisenheimer intermediate, i.e.,



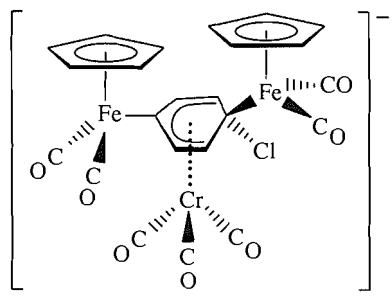
Interestingly, when an excess of NaFp is added to solutions of $(\eta^6\text{-}1,4\text{-}C_6H_4ClFp)Cr(CO)_3$, even at ambient temperatures, we see no evidence for the formation of the expected product $(\eta^6\text{-}1,4\text{-}C_6H_4Fp_2)Cr(CO)_3$, **2***a*, i.e., eq. [5]

[5] xsNaFp + $(\eta^6\text{-}1,4\text{-}C_6H_4ClFp)Cr(CO)_3$ $\xrightarrow{\cancel{THF}}$ $(\eta^6\text{-}1,4\text{-}C_6H_4Fp_2)Cr(CO)_3$

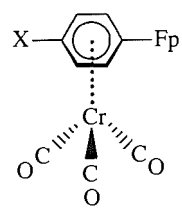
This is in accord with previous reports (5) but is somewhat surprising given the stability of the desired products (1) and the fact that weaker organic nucleophiles (3) readily give disubstituted products in high yields under these conditions (4*a*), i.e.,

[6] 2NaSR + $(\eta^6\text{-}1,4\text{-}C_6H_4Cl_2)Cr(CO)_3$ $\xrightarrow{THF}$ $(\eta^6\text{-}1,4\text{-}C_6H_4(SR)_2)Cr(CO)_3$ $\xrightarrow{I_2}$ 60–90% $C_6H_4(SR)_2$

(where R = Me, *n*-Bu, and *t*-Bu, for 1,2-, 1,3-, and 1,4-$C_6H_4Cl_2$ complexes). This difference is probably due to a combination of the greater electron-donating ability and steric bulk of the Fp groups. The more strongly electron-donating Fp group (1*b*, *c*) would make the monosubstituted complex, $(\eta^6\text{-}1,4\text{-}C_6H_4ClFp)Cr(CO)_3$, less prone to nucleophilic attack (and would perhaps destabilize the transition state). This monosubstituted complex is also much more sterically crowded and thus the formation of the Meisenheimer intermediate would probably be inhibited, i.e.,



These new 18-electron complexes, $(\eta^6\text{-}1,4\text{-}C_6H_4XFp)Cr(CO)_3$ (where X = H, Me, OMe, or Cl), i.e.,



X = H (**1***a*), Me (**1***b*), OMe (**1***c*), or Cl (**1***d*)

are yellow crystalline solids that are sufficiently air stable to be handled in air as solutions, for short periods of time, without the occurrence of noticeable decomposition. In fact, these complexes are sufficiently air stable that we have been able to store them as solids in air for up to a year without noticeable decomposition occurring. They are more soluble in common organic solvents than are the complexes $(\eta^6\text{-}C_6H_{6-n}Fp_n)Cr(CO)_3$, (where n = 2 or 3 (1)), i.e.,

TABLE 1. Analytical, mass-spectral, and infrared data for the complexes

but are less soluble than are their halo-arene precursors and are almost totally insoluble in nondonor solvents such as hexanes at ambient temperature. The analytical and spectral data for these complexes (Tables 1 and 2) confirm the proposed formulations as σ,π clusters with three-legged piano-stool geometries, as do the X-ray crystal structures, previously reported, of the CH_2Cl_2 solvate of **2***c* (1*a*, *c*) and of **1***d* (5).

Spectroscopic characterization of the complexes and the nature of the σ,π metal–arene–metal interactions

It is well established that many substituents (e.g., OMe, NMe_2, Fp, etc.) act as π donors in both uncomplexed and $Cr(CO)_3$ complexed arenes (1*b*,*c*, 13–17). In addition, the Fp group also acts as a σ donor (1*b*,*c*, 13). When two Fp groups are bonded to the same arene in a 1,4 fashion, we have shown that for both $1,4\text{-}C_6H_4Fp_2$ and $(\eta^6\text{-}1,4\text{-}C_6H_4Fp_2)Cr(CO)_3$ a synergic metal–arene–metal interaction occurs giving these complexes significant dimetalloquinone resonance character (1*b*,*c*). In $(arene)Cr(CO)_3$ complexes, the substituents may interact with one another through both the σ- and π-bonding frameworks. In comparison to noncomplexed arenes, the σ interactions are sharply attenuated but the π interactions remain largely unchanged (1, 14*d*,*e*, 15*a*,*c*). Thus, our observation that the magnitude of the 1,4-dimetalloquinone interactions is not changed significantly upon complexation by $Cr(CO)_3$ indicates that this interaction occurs through the arene's π system (1*c*). Of particular relevance to the present study, the IR spectra of the Fp complexes, $(\eta^6\text{-}C_6H_{6-n}Fp_n)Cr(CO)_3$, clearly indicated that substantial transfer of electron density from Fe to Cr is occurring in these species (1); however, elucidating the exact nature of this Fe–arene–Cr interaction is difficult for these species because of the presence of the Fe–arene–Fe interactions.

Four IR bands are observed in solution that may be attributed to the carbonyl ligands of our σ,π complexes (Table 1, Fig. 1). These complexes all exhibit two bands below 1960 cm^{-1}, the lower energy band being broader. The positions of these bands are all lower than those of the parent $(\eta^6\text{-}C_6H_6)Cr(CO)_3$ complex (i.e., ν_{CO} (CH_2Cl_2) 1973 (s), 1893 (s, br) cm^{-1}) but are higher than those of the polysubstituted species (i.e., $(\eta^6\text{-}C_6H_{6-n}Fp_n)Cr(CO)_3$, **2***a*–*c*, ν_{CO} (CH_2Cl_2) 1937, 1854 and 1919, 1835 cm^{-1} for n = 2 and 3, respectively (1*a*,*c*)). They are also quite dependent on the identity of the organic substituents, X (varying by 10–15 cm^{-1} between **1***b* and **1***d*). In addition, their relative intensities are somewhat greater than those of the higher energy bands but lower than those found in the corresponding bands of polysubstituted complexes. Those bands above 1970 cm^{-1} have positions that show only a weak dependence (3–7 cm^{-1}), as expected (13*a*), on the arene

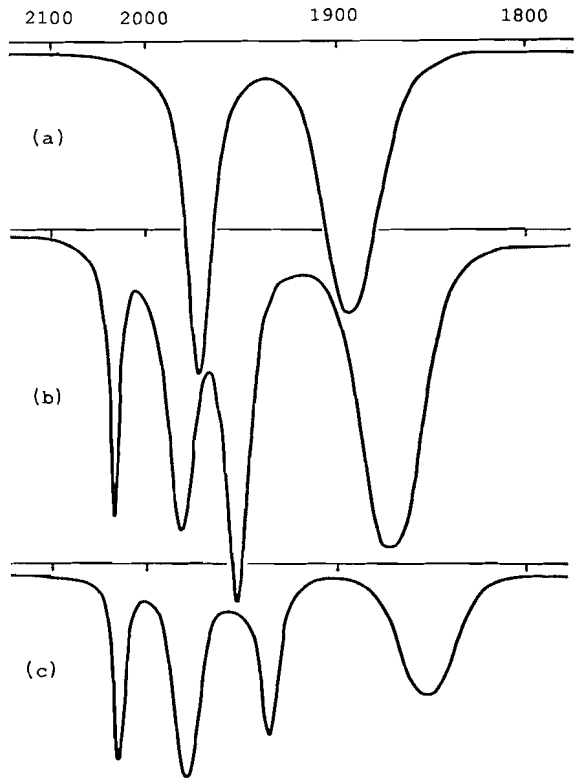

FIG. 1. The IR spectra in the carbonyl region of the complexes (a) $(\eta^6\text{-}C_6H_6)Cr(CO)_3$, (b) $(\eta^6\text{-}C_6H_5Fp)Cr(CO)_3$, and (c) $(\eta^6\text{-}1,4\text{-}C_6H_4Fp_2)Cr(CO)_3$ in CH_2Cl_2 are shown. Note the shifts in the low-frequency bands due to the $Cr(CO)_3$ group, the invariance in the Fp bands, and the changes in relative intensities.

substituents. They are also similar in position to those in **2***a–c* (i.e., ν_{CO} (CH_2Cl_2) 2030, 1980 cm^{-1} (1*a*,*c*)). These facts conclusively indicate that the lower energy pair of bands are due to the $Cr(CO)_3$ fragment and that the higher energy pair are due to the Fp fragments. Thus, these data can be entirely explained without having to invoke vibrational mixing[4] and the assignments are most consistent with those of related species (1) and other Fp and $Cr(CO)_3$ complexes (13–16). We therefore believe that each set of carbonyl bands can be uniquely assigned to either the Fe or the Cr fragments and that any vibrational mixing between these fragments is negligible in solution.

The trends in IR stretching frequencies as a function of the organic substituents, X, are as expected for the Fe (13*a*,*b*) and Cr (14*f*) carbonyls. The decrease observed in the Cr-carbonyl stretching frequencies upon the replacement of the halogens of the starting materials by the Fp group confirms that this substituent is a net electron donor to the $Cr(CO)_3$ center. This suggestion of substantial electron transfer is confirmed by the electrochemical data, *vide infra*, and by the ^{13}C NMR data of these complexes (Table 2). Thus, the Fp carbonyls are shielded by about 2 ppm compared to uncomplexed Fp-phenyls (i.e., δ_{CO} of 1,4-$C_6H_4Fp_2$, **3***a*, at 217.47 ppm in $(CD_3)_2SO$ (1*b*)) while the Cr carbonyls are deshielded by 1–2 ppm compared to those in (η^6-C_6H_6)$Cr(CO)_3$ (i.e., δ_{CO} at 234.00 in $(CD_3)_2SO$). These changes are in the direction that would be predicted (on the basis of the expected changes in the paramagnetic screening of the carbonyls) and confirm that electron density is transferred from Fe to Cr (1*c*, 13*b*, 15*b*). The ^1H and ^{13}C NMR signals attributable to the cyclopentadienyl rings of our complexes are also as expected (1, 13) and confirm that the Fp groups in these complexes retain their three-legged pianostool geometries in solution.

The NMR spectral data for the phenyl groups in these complexes are listed in Table 2 and may be compared with those of the related uncomplexed and $Cr(CO)_3$ complexed Fp-phenylenes (1*b*,*c*). The ^1H and ^{13}C NMR spectra of the phenyl groups are relatively simple due to the high symmetry of these molecules and were assigned using the peak multiplicities, chemical shifts, and homo- and heteronuclear coupling constants of the signals. In addition, the ^{13}C assignments were confirmed by consideration of the characteristic substituent effects of the pendant metal fragment, *vide infra*, and by heteronuclear decoupling and NOE difference experiments on **1***c*. As expected, the ^1H NMR signals of the Fp-phenyl groups are shielded by about 2 ppm compared to the uncomplexed Fp-phenyls (i.e., for **3***a* in $(CD_3)_2SO$, $\delta(C_6H_4)$ is 6.95 ppm (1*c*, 14, 15)) and exhibit the expected AB quartet structures for **1***b–d*. The J_{CH} and the J_{HH} coupling constants are also as expected (13–15).

The ^{13}C NMR chemical shifts of arene carbons are particularly useful since they are related to the arene-carbon electron density. For this reason, they have been used to elucidate the nature of arene–substituent bonding interactions of both complexed and uncomplexed arenes (1*b*,*c*, 15, 17). They are best understood in terms of the substituent constants, Δ (which measure the effect that a particular substituent will have on the chemical shift of each arene carbon), which are generally linearly additive (15, 17). The Δ_π values are the most useful and may be interpreted in terms of the π-donor and π-acceptor properties of the substituents (1*b*,*c*, 15*a*, 17). Using the

[4]The solid state IR spectra (KBr) of some of these complexes were assigned differently (5) and vibrational mixing was invoked to explain the observed trends in stretching frequencies.

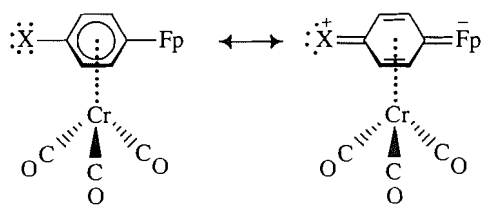
[b]The Δ_{π} values are the substituent chemical shifts, $\Delta_{\pi} = \delta_{\text{arene carbon}} - \delta_{(C_6H_6)Cr(CO)_3}$ and $\Delta_{\pi} = \Delta_{para} - \Delta_{meta}$.

[c]This work ($(CD_3)_2SO$).

[d]This work and reference 1*c*, derived to give the most consistent set of values from the data for all the Fp–phenylene π complexes ($(CD_3)_2SO$).

substituent constants of Fp, Me, OMe, and Cl (Table 3), the ^{13}C spectra of the complexes (Table 2) can be assigned with an average error of less than 1 ppm (with the exception of the *ipso* carbons of **1***b–d*, *vide infra*).

The carbon atom *ipso* to Fp in $(\eta^6\text{-}1,4\text{-}C_6H_4(OMe)Fp)Cr(CO)_3$ is shielded by about 8.1 ppm *more* than would be predicted on the basis of linear additivity. This implies that when these substituents are arranged 1,4 to each other on the benzene ring the OMe group (which is the stronger π donor substituent, i.e., $\Delta_{\pi} = -10.1$ vs. -5.0 for Fp) experiences an increase in its *para* substituent constant, Δ_{para}, from its usual value of −7.7 to −15.8 ppm. Similar, although less pronounced, effects are observed for the Me and Cl substituted complexes. These apparent increases in Δ_{para} are probably (15*a*, 17*a–c*) due to an increase in the π donor ability of the "organic" substituents, X. This suggests that a synergic interaction is occurring between the Fp and X substituents. We have observed similar synergic interactions for $(\eta^6\text{-}1,4\text{-}C_6H_4Fp_2)Cr(CO)_3$ (1*c*) and they are well established for uncomplexed 1,4-disubstituted arenes (1*b*, 17*b*). It seems tempting to speculate that (in valence bond terms and by analogy with these systems) such synergic interactions are due to a quinoidal contribution to the resonance structure of the complexes, e.g., for **1***c*,



(where X = OMe). However, with the data at hand we cannot entirely rule out the possibility that these unexpected chemical shift changes are due to an anomalous *ipso* sensitization (17*b*) by Fp. Experiments to eliminate this and related difficulties are currently in progress and preliminary results (using the methods of Bromilow, Brownlee, *et al.* (17*b*)) indicate that an anomalous sensitization is not involved and that such a synergic interaction is occurring.[5] Indeed, such a resonance effect is somewhat analogous to the conjugation observed in complexes such as $(\eta^6\text{-}1,4\text{-}C_6H_4(CHO)(NMe_2))Cr(CO)_3$ (in which one substituent acts as a π donor and the other as a π acceptor (18)). However, confirmation of this proposal must await the crystallographic characterization of a number of such species and a detailed molecular orbital analysis of the bonding in these unusual complexes.

Electrochemical characterization of the complexes

To the best of our knowledge, the electrochemistry of complexes containing σ-bound transition-metal substituents on (arene)$Cr(CO)_3$ complexes has not been reported (19*b*). We therefore decided to investigate the electrochemical behavior of our σ,π complexes since such studies should provide evidence for the nature of the metal–metal interactions in these species.[6]

The complexes **1***a–d* undergo diffusion-controlled, reversible one-electron oxidations in CH_2Cl_2 (0.1 M $[n\text{-}Bu_4N]PF_6$) to give the corresponding radical cations. In general, these oxidations may be represented as

[7] $(\eta^6\text{-}1,4\text{-}C_6H_4XFp)Cr(CO)_3 \underset{+e^-}{\overset{-e^-}{\rightleftharpoons}} [(\eta^6\text{-}1,4\text{-}C_6H_4XFp)Cr(CO)_3]^{\cdot+}$

(where X = H, Me, Cl, or OMe) and the electrogenerated radical cations persist in dichloromethane solution, as judged by the high $i_{p,c}/i_{p,a}$ values. The electrochemical data for the oxidations of the complexes are summarized in Table 4. As can be seen from the table, all these complexes exhibit similar electrochemical behavior. Diffusion control in these oxidations was established by obtaining linear plots of $i_{p,a}$ vs. (scan rate)$^{1/2}$ over at least one order of magnitude of scan rate. Cyclic voltammograms of a representative example (i.e., $(\eta^6\text{-}C_6H_5Fp)Cr(CO)_3$) are shown in Fig. 2. As may be noted in Fig. 2a, this compound undergoes a reversible oxidation at $E^{0\prime} = +0.64$ V. Comparison of CV peak separations and anodic peak current heights with those of ferrocene established this process as involving one electron. As is observed in Fig. 2b, when the anodic scan is taken out to the solvent limit (≈2 V), a second oxidation is observed at +1.38 V. The magnitude of the current in this process is similar to that of the first, and indicates the transfer of one electron. This second oxidation peak occurs in the range for the irreversible oxidations of many Fp–alkyl (or –aryl) complexes (20), as well as the range for the second oxidation

[6]Some of these results have been communicated previously, see: G. B. Richter-Addo and A. D. Hunter. Inorg. Chem. In press.

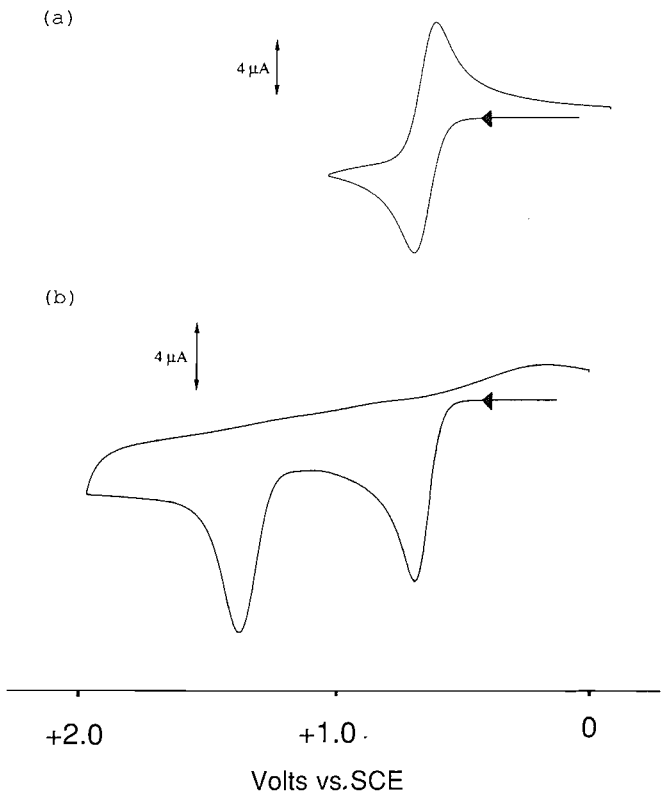

FIG. 2. The cyclic voltammograms of $(\eta^6\text{-}C_6H_5Fp)Cr(CO)_3$ in CH_2Cl_2 at a Pt-bead electrode (0.1 M $[n\text{-}Bu_4N]PF_6$, scan rate of 0.1 V s^{-1}).

of (arene)$Cr(CO)_3$ species (21). Therefore, it cannot be conclusively assigned to either metal center. Unlike the first oxidation process, which is reversible, this second oxidation is irreversible, indicating a very rapid decomposition of the electrogenerated dication. In addition, extensive electrode coating occurs after this second oxidation wave is passed, and subsequent waves become ill-defined. Indeed, all of the title complexes exhibit second (irreversible) waves (at $\geq$1.37 V) which lead to a similar degradation of the electrode surface. As such, these secondary oxidations were not investigated further. Moreover, the observation of somewhat lower $i_{p,c}/i_{p,a}$ values for the first redox couple at lower scan rates indicates that secondary chemical reactions (leading to decomposition of the radical cations) are occurring.

The formal potentials ($E^{0\prime}$) for these oxidations show a marked dependence on the arene substituents. As expected on the basis of the trends in the IR and ^{13}C NMR data for the carbonyl ligands in these complexes, *vide supra*, the $E^{0\prime}$ values are more cathodic (by about -0.22 to -0.24 V) than those found in the analogous complexes without Fp substituents (i.e., $E^{0\prime}$ in dichloromethane for the complexes $(\eta^6\text{-}C_6H_5X)Cr(CO)_3$ is observed at +0.97, +0.87, +0.84, +0.78 V for X = Cl, H, Me, and OMe, respectively). This is consistent with our hypothesis that the Fp groups in these complexes are transferring substantial electron density to the Cr center since the magnitude of these shifts is similar to that caused by six methyl groups (-0.26 V) or an NH_2 group (-0.27 V).

Conclusions

The IR, NMR, and electrochemical data obtained in this study confirm the substantial transfer of electron density from Fe to Cr in these complexes. The observed trends are in accord with what one might expect if this electron-density transfer were proceeding through the σ and π frameworks of the arene bridge. We therefore find no evidence to support any direct Cr–Fe interaction. However, some evidence for a synergic Fp–arene–substituent interaction is observed. We are currently extending our investigations of related complexes to confirm or deny the existence of such interactions. Finally, the derivative chemistry of these unusual complexes (especially as applied to organic synthesis) is also being explored.

Received May 23, 1989

G. W. BUCHANAN, R. A. KIRBY, and J. P. CHARLAND. Can. J. Chem. **68**, 49 (1990).

For the *cis–anti–cis* isomer of dicyclohexano-13-crown-4 ether, disorder has been detected in the crystal structure, with two conformations being present in the ratio of ca. 3:2. Crystal structures for two Li^+ complexes of the *cis–syn–cis* isomer have also been determined. Representative ^{13}C solid phase NMR spectra are presented and discussed for these systems and the related dibenzo substituted compounds.

Key words: crown ethers, solids, NMR, conformation.

G. W. BUCHANAN, R. A. KIRBY et J. P. CHARLAND. Can. J. Chem. **68**, 49 (1990).

Dans la structure cristalline de l'isomère *cis–anti–trans* de l'éther dicyclohexano-13-couronne-4, on a détecté du désordre; deux conformations sont présentes dans un rapport d'environ 3:2. On a aussi déterminé les structures cristallines de deux complexes du Li^+ de l'isomère *cis–syn–cis*. On présente et on discute des spectres RMN du ^{13}C en phase solide qui sont représentatifs de ces systèmes et de composés apparentés substitués par deux groupements benzo.

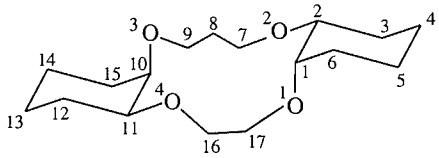
Mots clés : éthers couronne, solides, RMN, conformation.

[Traduit par la revue]

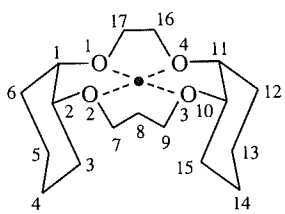
Introduction

Recent publications from these laboratories have reported the use of X-ray crystallography and ^{13}C NMR (solution and solid phase) to describe the stereochemical features of substituted 14-crown-4 (1–3) and 12-crown-4 ethers (4, 5) and their complexes with Li^+. In contrast to the now well-documented behaviour of these molecules and 12-crown-4 itself (6), rather little is known regarding the analogous 13-crown-4 systems. The only 13-crown-4 that has been studied in any detail is the benzo derivative (7, 8), for which results indicate effective and selective Li^+ complexation.

Herein we present results for two dicyclohexano-13-crown-4 ethers, specifically the *cis–anti–cis* (**1**) and *cis–syn–cis* derivatives. In the structures depicted below for **1** and the LiNCS (**2**) and $LiClO_4$ (**3**) complexes of the *cis–syn–cis* isomer, the dispositions of the cyclohexane rings are consistent with the X-ray crystallographic data (*vide infra*).



1



• ≡ Li

2, 3

An interesting feature of these compounds is that **1** lacks any element of symmetry and thus is potentially resolvable into the structure as depicted and as its nonsuperimposable mirror image.

In addition, ^{13}C CPMAS spectra are presented for two materials where X-ray data are not available, these being dibenzo-13-crown-4 ether **4** (below) and its LiNCS complex **5**. Stereochemical influences on ^{13}C chemical shifts are examined along with the utility of these techniques for the detection of conformational disorder in solids.

• ≡ Li

5

Results and discussion

The ORTEP drawings of the *cis–anti–cis* isomer **1** are presented in Fig. 1 while those for the LiNCS complex (**2**) of the *cis–syn–cis* isomer and the $LiClO_4$ complex (**3**) of the *cis–syn–cis* isomer are depicted in Figs. 2 and 3 respectively. The ^{13}C CPMAS NMR spectra are illustrated in Fig. 4. In Table 1 are listed refinement details for structures **1**, **2**, and **3** while the refined coordinates of the non-H atoms for all materials are presented in Table 2. Bond lengths and angles involving all non-H atoms are collected in Table 3 while torsional angles involving only C and O atoms are given in Table 4. Table 5 contains the ^{13}C NMR chemical shifts. Lists of anisotropic temperature factors, hydrogen atomic parameters, all torsional angles, and calculated, observed, and unobserved structural factors are available as Supplementary Material.[2]

X-ray crystallographic structures

The crystal structure of **1** is disordered. The disordered positions are carbons 8, 9, and 17, which show occupancy factors in a 60:40 ratio. The conformation with the 60% occupancy is depicted in Fig. 1a while that occupied to the extent of 40% is illustrated in Fig. 1b. The disordered positions are centrosymmetrically related from a positional but not an occupancy standpoint and represent nonsuperimposable mirror image sites.

The presence of the ethylene and propylene chains induces asymmetry in the structure of **1**. However, since the material was prepared and recrystallized as a racemic mixture, there will be equal amounts of each enantiomer present. The unit cell composition is consistent with this expectation despite the 60:40 conformer ratio present, since mirror related sites in the crystal contain these same forms in a 40:60 ratio.

In the cases of **2** and **3**, the Li^+ is pentacoordinated to the four ethereal oxygens of the crown ether and to the anions (SCN^- in **2** and ClO_4^- in **3** respectively). The four oxygens are not coplanar; the mean deviations from the least-squares plane connecting them are 0.20 and 0.24 Å in **2** and **3** respectively.

The macrocyclic ring conformation of **1** is almost identical with that found for the *cis–anti–cis* isomer of dicyclohexano-14-crown-4 (2). The only differences are found in the torsional networks involving C17′ and C17″ of **1**, which are anticipated since one of the propano bridges of the 14-crown-4 system has been replaced by an ethano bridge in the 13-crown-4 cases.

The more abundant conformer of **1** has a fairly regular geometry while the minor form shows some geometrical distortions centered at the disordered positions C9″ and C17″ (Table 3). The O–O diagonal distances in **1** are 4.2 and 4.3 Å for the O1–O3 and O2–O4 diagonals respectively. These, as expected, are somewhat smaller than in the corresponding 14-crown-4 molecule (2), where these distances are 4.4 and 4.7 Å. The O–O distances between equatorial oxygens are more affected than those involving axial oxygens when the macrocyclic ring size is decreased.

Comparison of bond lengths, angles, and torsional angles in the Li^+ complexes **2** and **3** shows that they are basically the same except for a small variation in the torsional angle about the O2—C2 bond. This difference is one of steric hindrance related to the different nature and orientation of the coordinating anion. In **3**, the ClO_3 base of the bonded anion is located over the six-membered O1—C7—C8—C9—O2—Li portion of the molecule. O7, one of the noncoordinating ClO_4^- oxygens, is 3.8 Å away from C8, a distance that is slightly longer than the sum of the van der Waals radii of CH_2 and O, ~3.6 Å (9).

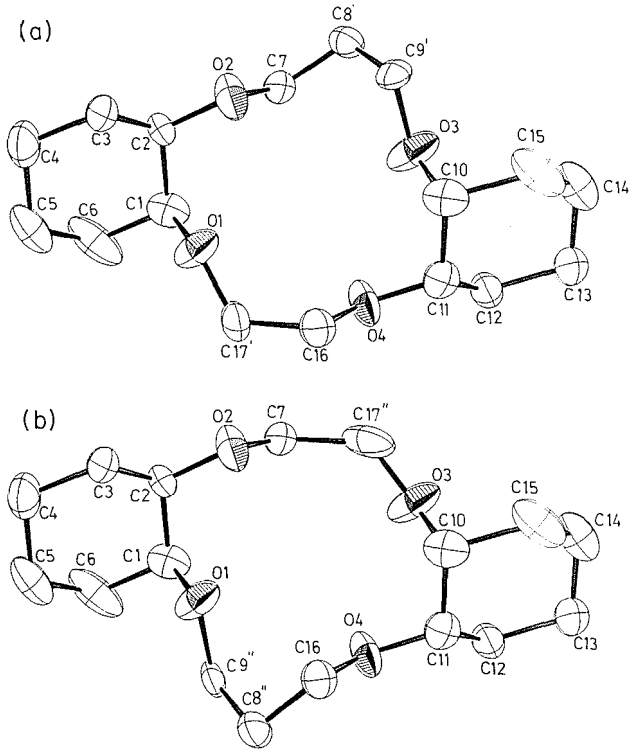

FIG. 1. (a) ORTEP diagram of **1** (60% isomer), (b) ORTEP diagram of **1** (40% isomer).

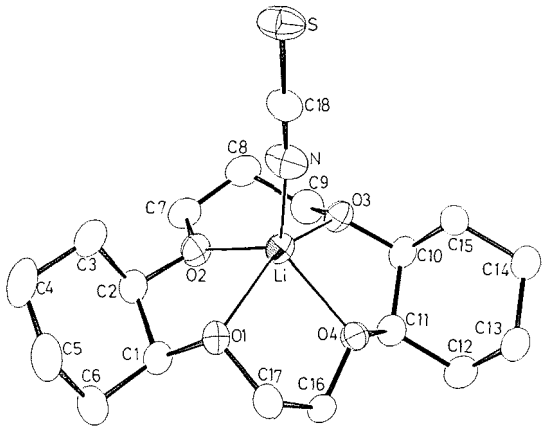

FIG. 2. ORTEP diagram of **2**.

To minimize possible repulsive interactions, a rotation of ca. 12° about the C2—O2 bond in **3** has the effect of pushing the whole propano chain away from O7. The overall orientation of the anion relative to Li^+ and the macrocyclic crown is subsequently different in **2** and **3**. The differences are most evident from comparison of the two pairs of corresponding angles O2—Li—N (116°) and O4—Li—N (125°) in **2** with O2—Li—O4 (123°) and O4—Li—O5 (112°) in **3**. Thus in **2**, the binding of the N atom of the linear NCS^- is located on the propano side of the crown while in **3**, for the steric reasons mentioned above, the binding O atom of the tetrahedral ClO_4^- is located on the ethano side but the ClO_3 moiety is bent towards the propano bridge of the 13-membered ring.

In the $O_{eq}—(CH_2)_3—O_{eq}$ portions of **2** and **3**, there are substantial conformational differences relative to the corresponding LiNCS complex of dicyclohexano-14-crown-4 (2), most

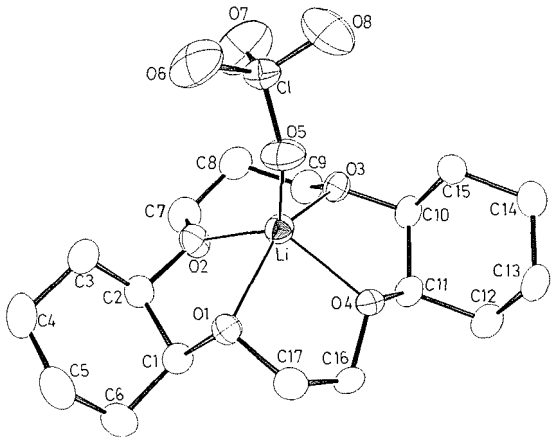

FIG. 3. ORTEP diagram of **3**.

notably in the C9—O3—C10—C11 and C7—O2—C2—C1 networks. In the 14-crown-4 system (2), these angles are near 180°, which is the common "relaxed" conformation in larger ring crown systems (10, 11). By contrast, in **2** and **3**, the C9—O3—C10—C11 angles are 95.0 and 93.6° respectively while the C7—O2—C2—C1 networks have torsion angles of 146.9 and 134.6° respectively.

In the $O_{ax}—(CH_2)_2—O_{ax}$ portions of **2** and **3** additional torsional strain is evident, especially in the C1—O1—C17—C16 network where the angles are 80.6 and 77.9° respectively. Hence the O1 and O3 regions appear to account for most of the strain present in **2** and **3**.

An additional interesting feature of **2** and **3** relative to the corresponding 14-crown-4 system (2) is the overall geometry of complexation. In the present cases, the four ethereal oxygens are directed towards the "concave" side of the molecule, with Li^+ and the anion coming in from this side. In the 14-membered system, the four oxygens are directed towards the "convex" side of the crown and hence the Li^+ complexes preferentially from the convex direction.

With respect to the lithium environment, some comparison with the known (8) X-ray structure of the LiNCS complex of benzo-13-crown-4 can be made. In **2** and **3**, the diagonal distances, O1–O3 and O2–O4, are 4.05 and 3.54 Å respectively, which result in an adjusted cavity diameter of 0.74–1.25 Å, a value nearly identical to that present in the benzo-13-crown-4 system. This diameter is small compared to the effective diameter of the Li^+ ion (1.18–1.52 Å) (12), and thus favours, as expected, five-coordinate lithium complexation. In **2** and **3**, the Li is lying 0.75 Å out of the least-squares plane going through the four binding oxygen atoms. For the related benzo system (8), the Li^+ lies slightly farther (distance ~0.80 Å) out of the plane of the four complexing oxygens, a result consistent with the anticipated increase in flexibility of the dicyclohexano substituted molecules relative to benz-annelated crowns.

It appears that the 13-crown-4 cavity size is less ideal for Li^+ complexation than was the case in the related 14-crown-4 molecules (2). For the LiNCS complex of *cis–syn–cis*-dicyclohexano-14-crown-4, the Li^+ lies less far (0.55 Å) out of the plane of the four coplanar oxygens. This distance is still sufficient, however, to leave the other side of the lithium ion open for anion coordination (2).

The $Li—O_{crown}$ distances listed in Table 3 are shorter for equatorial than for axial oxygens, a trend similar to that noted in the related 14-crown-4 case (2). On the average, these bond lengths are 2.07 Å, which is nearly identical to those in the

benzo-13-crown-4 complex (8), but substantially longer than those in the 14-crown-4 analog (2.02 Å). Notably, the Li—O1 bonds in both **2** (2.149 Å) and **3** (2.170 Å) are significantly longer than the others.

In summary, the coordination geometry around the lithium in both **2** and **3** is a distorted intermediate between square pyramid and trigonal bipyramid, in contrast to the related 14-crown-4 case where an essentially square pyramid exists (2). Also it is evident that no major conformational changes are induced in the 13-membered ring in the presence of differing anions.

Solid phase ^{13}C NMR spectra

The ^{13}C NMR spectrum of solid **1** (Fig. 4) reflects the disorder present in the crystal. Although the spectrum is rather complex, there are ten resolved resonances in the range of 60–80 ppm indicative of oxygenated carbons. If an ordered racemic mixture were present, only eight resonances would be observed in this region. Regarding detailed peak assignments, a number of these can be made based on analogy with earlier work (2) and are indicated in Table 5. The effects are in accord with the well-established steric shifts in ^{13}C NMR spectra of molecules in which cyclohexane functions are present bearing axial and equatorial oxygenated functions (13, 14).

In contrast to the situation in solution ^{13}C NMR, methods of unambiguous signal attribution in solid state spectra are relatively few. The most common technique is interrupted decoupling, alternatively known as dipolar dephasing (15, 16), a method that allows discrimination between immobile protonated carbons and nonprotonated or very mobile protonated carbon sites. Unfortunately this method does not effectively discriminate between methine and methylene carbons, which is the major problem in the ^{13}C CPMAS spectrum of **1**, especially in the 68–80 ppm range. Consequently, many of the assignments in Table 5 must be regarded as being interchangeable as indicated.

One method was, however, of some utility. It was observed that the low temperature (173 K) solution ^{13}C spectrum of **1** (major conformer) is remarkably similar to that of the solid in the 68–80 ppm range.[3] The APT test (17) was subsequently performed on the low temperature sample to identify the CH vs. CH_2 resonances in this region and the results were utilized to aid in partial assignment of the solid state spectrum. Hopefully, recent advances in assignment methods, such as that based on separated local field methods (18), will become applicable to the solution of such problems.

No isolable Li^+ complexes of **1** could be prepared. This observation is consistent with that found in related 12-crown-4 and 14-crown-4 ethers (2, 3, 5), where stable complexes of the *cis–syn–cis* dicyclohexano system could be prepared, but not for the configurationally isomeric *cis–anti–cis* cases. Presumably the conformational distortions required to allow the four oxygen atoms to become coplanar (as is preferred for complexation) are too extreme in the *cis–anti–cis* isomers.

The LiNCS and $LiClO_4$ complexes of the *cis–syn–cis* isomer (an oil in the uncomplexed form) gave essentially identical ^{13}C CPMAS spectra and thus only that for the LiNCS case is shown in Fig. 4. In contrast to the spectrum of **1**, the relatively sharp resonances for **2** indicate an ordered situation in the crystal. In fact seven out of eight possible oxygenated carbon resonances in the range of 64–80 ppm are resolved.

With the X-ray data in hand, some interesting stereochemical aspects of the ^{13}C chemical shifts can be explored. The cyclohexyl carbons, which are γ–gauche to the axial oxygens (i.e., C5 and C13), will resonate at highest field (1–5, 13, 14). Since the X-ray structure of **2** indicates no symmetry, separate resonances are anticipated and, indeed, observed for these carbons (at 18.6 and 20.3 ppm). An examination of the torsional environments for C5 and C13 in **2** reveals one significant difference as delineated below.

Ignoring hydrogens, C5 and C13 are each involved in five torsional networks. With respect to their environments relative to the other cyclohexyl carbons, there is little difference between these two sites. For C5, the average of four torsional

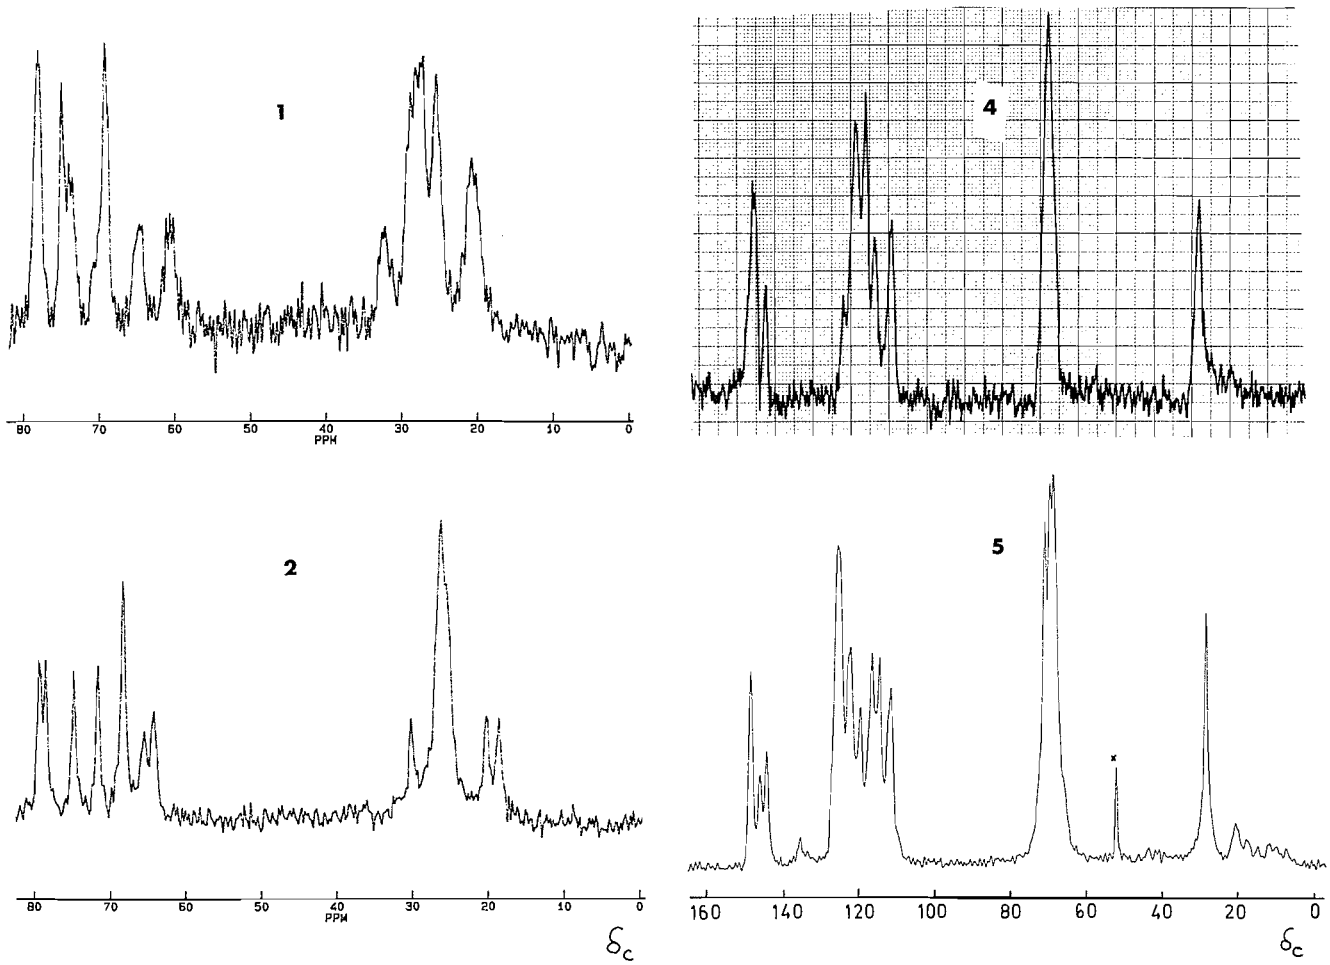

FIG. 4. 45.3 MHz ^{13}C CPMAS NMR spectra.

angles is 55.7° while for C13, the value is 56.1°. The most significant difference in their environments occurs in the networks O1—C1—C6—C5 vs. O4—C11—C12—C13. Whereas the former has a dihedral angle of 60.6°, this expands to 64.6° in the latter. Although no theoretical ^{13}C chemical shift calculations have appeared for the O—C—C—C network, results for the geometrically similar C—C—C—C network (19) indicate that expansion of a torsional angle above that of a pure *gauche* interaction would be expected to lead to a deshielding of the terminal carbon atom. On this basis, we assign the resonance at 20.3 ppm to C13 and that at 18.6 ppm to C5.

In the methine carbon region of the spectrum (72–80 ppm), the resonances for the carbons bearing equatorial oxygen (C2 and C10) are separated by less than 1 ppm and hence no attempt will be made to provide separate assignments. On the other hand, there is a 3.2 ppm difference between the resonances for C1 and C11, the carbons bearing axial oxygen, (appearing at 74.7 and 71.5 ppm). Each of these carbons is involved in twelve torsional networks if one ignores the hydrogen atoms. Examination of the data in Table 4 reveals that two torsional networks show large differences in dihedral angles involving these two sites in the crystal as depicted below.

C16—C17—O1—*C1* θ = 168.1° vs. C17—C16—O4—*C11* θ = 81.0°

C1—C2—O2—C7 θ = 95.1° vs. *C11*—C10—O3—C9 θ = 147.0°

Unfortunately no experimental ^{13}C chemical shift data exist for these particular torsional networks in either solution or the solid phase. One can, however, theoretically model these networks using the simple aliphatic ether CH_3—O—CH_2—CH_3 and employing INDO MO calculations of the ^{13}C chemical shifts.[4] In the case of a C—C—O—*C* network, the results indicate that the designated carbon in the situation in which θ = 81.0° will be more shielded (i.e., lower δ_C), by ca. 4 ppm, than that for θ = 168.1°. For the *C*—C—O—C situation, the calculations[4] indicate nearly identical chemical shifts for the torsion angles of 95.1° and 147.0°. On the basis of these considerations, we assign the 71.5 ppm resonance to C11 and the line at 74.7 to C1.

The final points of interest in the ^{13}C CPMAS spectrum of **2** concern the CH_2-O resonances at 68.2 ppm (intensity two) and the single intensity resonances at 65.4 and 64.2 respectively. In view of the discussion of the chemical shifts of C1, 5, 11, and 13 in terms of their torsional environments, it is instructive to carry out the same type of analysis for C7, 9, 16, and 17 of **2**. The results, however, do not lead to any clear arguments for one set of assignments being more valid than any other. Part of the problem with these carbons is the present lack of theoretical shift calculations for the C—C—C—O network. An additional complicating factor is the unknown influence of the spatially proximate lithium ion on the ^{13}C shieldings.

For dibenzo-13-crown-4, **4**, and its LiNCS complex, **5**, no

[a–n]Indicate possible interchange of resonance assignments.

X-ray crystallographic data are available. In the case of **4**, a single broad resonance for the oxygenated carbons is observed at 67.9 ppm, whereas in **5**, there are three resolved resonances in this region of the spectrum. This suggests that there may be less mobility in the LiNCS complex than in the free crown ether, which is intuitively reasonable. In view of the number of observed aromatic carbon resonances, it appears that neither **4** nor **5** possesses any elements of symmetry. Of course in the absence of X-ray data, one cannot rule out crystal packing phenomena or the existence of different molecules in the crystal as the cause of spectral multiplicity (20), but the occurrence of such phenomena is relatively rare.

To conclude, attempts are presently underway to resolve the enantiomeric forms of **1** via complexation with optically pure α-methylbenzylammonium salts. Results of these investigations, as well as the detailed low temperature solution NMR behaviour of these materials, will be the subject of a future report.

Experimental

Spectra

The ^{13}C CPMAS NMR spectra were recorded at 45.3 MHz on a Bruker CXP-180 spectrometer using techniques described previously (2). Chemical shifts were measured relative to external solid hexamethylbenzene (HMB) and converted to the TMS scale via the factor of 16.9 ppm, which is the chemical shift of the CH_3 group of HMB.

Crystallographic measurements and structure solution and refinement

Single crystals of **1**, **2**, and **3** were mounted on glass fibres and transferred and studied on a Picker 4-circle diffractometer. Accurate cell parameters and intensity data were obtained at room temperature using graphite-monochromatized CuKα radiation. Crystal data are provided in Table 1.

The space group $P2_1/a$ was uniquely defined from the systematic absences noted in the data sets of **2** and **3**. The intensity data for **1** showed systematic absences consistent with the space groups *Pbcm* and $Pbc2_1$. The space group $Pbc2_1$ was selected for **1** based on the Z value of four molecules per unit cell (Table 1) and the lack of symmetry in the expected structure of **1**. **1** was solved and refined successfully in this space group and inspection of the structure rules out any possibility of describing it in the centrosymmetric space group *Pbcm*. The data were corrected in the standard fashion for Lorentz and polarization ratio factors but not for absorption. Other details pertaining to the data reduction step are listed in Table 1.

The structure of **1** is disordered and will be discussed in the following paragraph. The positions of the non-hydrogen atoms of the three structures were determined by direct methods with MULTAN (21). At this stage, isotropic refinement of all non-hydrogen atoms was carried out by full-matrix least squares. Subsequent difference maps revealed the positions of the H atoms of **2** and **3**. They were included and refined isotropically while non-H atoms were refined anisotropically. The three structures were refined to convergence by full-matrix least squares; $\Sigma w(|F_o|-|F_c|)^2$ was minimized with $w = 1$ for **1** and $w^{-1} = {}^2(F_o) + 0.0003F_o{}^2$ for **2** and **3**. Details related to the structure refinements and final D-maps are given in Table 1.

After isotropic refinement of all non-H atoms of **1** and close inspection of the refined positions, some carbon atoms of the ethano and propano bridges had large isotropic thermal parameters and dis-

torted geometries, suggesting possible disorder and (or) the presence of highly mobile bridging units. Refinement was resumed with the ethano and propano C atoms having U_{iso} values fixed at 0.07 Å^2 (based on the average U_{iso} value from a Wilson plot) and varying occupancies. A subsequent *D*-map gave split peaks for three of the ethano and propano carbon atoms. These were included and refined also on occupancy with fixed thermal parameters. At convergence, the disordered positions showed occupancy factors in a 60:40 ratio.

Despite the 60:40 conformer ratio (*vide supra*), the unit cell of **1** contains equal amounts of each enantiomer. Refinement was pursued and H atoms of the two cyclohexyl rings were located on the next *D*-map. Non-H atoms were refined anistropically and H atoms of the rings isotropically. H atoms of the ethano and propano bridges were introduced at calculated positions (sp^3 hybridized; C—H distances of 1.08 Å) and taking into account the two disordered orientations. They were included in the next least-squares cycles but not refined. Refinement details for **1** are listed in Table 1. All computations were performed with the NRCVAX crystal structure package (22). The scattering curves were from standard sources (23).

Materials

Dibenzo-13-crown-4 (**4**) was prepared from the previously described (5) 1,2-bis(*o*-hydroxyphenoxy)ethane via the following procedure. In 1.5 L 1-butanol were dissolved 50.0 g (0.20 mol) of 1,2-bis(*o*-hydroxyphenoxy)ethane and 19.0 g (0.44 mol) $LiOH \cdot H_2O$. This solution was refluxed for 1 h. To this dark solution was added slowly 40.0 g (0.20 mol) of 1,3-dibromopropane, with agitation and reflux being continued for 27 h. After removal of the butanol by rotary evaporation, a solid residue remained, which was dissolved in methylene chloride and washed with water. Subsequent to drying, evaporation of the organic phase yielded 27.1 g of crude product. Recrystallization from methylene chloride – hexanes mixture gave 19.3 g (33% yield) of pure **4**, mp 134–136°C; *ms* (CI) *m*/e 287 (M + 1), base peak *m*/e 121.

Hydrogenation of **4** to a mixture of **1** and the *cis–syn–cis* isomer was accomplished using an American Instrument Co. 50 000 psi (1 psi = 6.9 kPa) maximum pressure high pressure apparatus. In 60 mL of 1-butanol were dissolved 2.0 g (0.007 mol) of **4** and 0.40 g of 5% ruthenium on alumina catalyst. A pressure of 1200 psi was used and the reaction was continued for 12 h at a temperature of 120°C. The catalyst was removed via filtration and the butanol by rotary evaporation at 70°C, to yield 1.9 g of a clear yellow oil. From ^{13}C NMR, there appeared to be two configurational isomers present in the ratio of ca. 2:1. Separation of these isomers was accomplished via column chromatography on activated silica gel of mesh size 100–200. Initially the mixture (1.9 g) was applied to the column (30 g of solid phase) in 50:50 methylene chloride – hexanes. Subsequent to the collection of 100 mL of eleunt, 100-mL aliquots were employed containing 3, 5, 10, 15. and 20% of diethyl ether respectively. Initial fractions contained pure **1** only, while the latter fractions were essentially pure *cis–syn–cis* isomer, the major isomer formed in the hydrogenation (as later determined via X-ray of its complexes). Recrystallization from hexanes yielded crystalline **1**, mp 78–80°C, while the other isomer remained an oil. The complexes **2** and **3** were prepared according to the following procedures. Equimolar amounts of the oil from the chromatographic column and LiNCS or $LiClO_4$ were mixed and dissolved in a minimum quantity of dry methanol. After allowing these mixtures to stand for 2–3 h, the solvent was removed by rotary evaporation. Following recrystallization from a hexane – methylene chloride solvent pair, **2**, mp 210–212°C, and **3**, mp 225–228°C, were obtained. For the preparation of **5**, solid **4** was dissolved in a minimum volume of methanol, to which an equimolar quantity of LiNCS was added. After 3 h, the methanol was removed. Recrystallization from hexane – methylene chloride yielded **5**, mp 239–241°C.

Pyrazagaboles, pyrazolyl-bridged heterocycles containing boron and gallium

STEVEN J. RETTIG, MARK SANDERCOCK, ALAN STORR, and JAMES TROTTER
Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received June 7, 1989

STEVEN J. RETTIG, MARK SANDERCOCK, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **68**, 59 (1990).

The synthesis and structural characterization of representative and novel pyrazagaboles, boron- and gallium-containing compounds with a central six-membered heterocyclic B—(N—N)$_2$—Ga ring feature, are detailed. Crystals of dimethylgalliumbis(μ-pyrazolyl)dimethylboron are orthorhombic, a = 7.6135(5), b = 16.2917(5), c = 22.331(1) Å, Z = 8, space group *Pbca*, and those of hydroxy(methyl)galliumbis(μ-pyrazolyl)dimethylboron are orthorhombic, a = 7.6197(3), b = 16.2184(7), c = 22.190(1) Å, Z = 8, space group *Pbca*. Both structures were solved by conventional heavy atom methods and were refined by full-matrix least-squares procedures to R = 0.054 and 0.040 for 1243 and 1272 reflections with $I \geq 1.5$ and $3\sigma(I)$, respectively. The crystal structures are isomorphous and both feature six-membered B—(N—N)$_2$—Ga rings having highly asymmetric boat conformations, unlike those observed for the majority of the homobinuclear analogs previously reported. The mean Ga—N and B—N distances in the two compounds are 1.977 and 1.61 Å.

Key words: pyrazagaboles, pyrazolyl-bridged heterocycles, crystal structures, synthesis of pyrazagaboles.

STEVEN J. RETTIG, MARK SANDERCOCK, ALAN STORR et JAMES TROTTER. Can. J. Chem. **68**, 59 (1990).

On rapporte les détails relatifs à la préparation et à la caractérisation de la structure de nouveaux pyrazagaboles représentatifs, des composés contenant du bore et du gallium dans un hétérocycle central à six chaînons B—(N—N)$_2$—Ga. Les cristaux du diméthylgalliumbis(μ-pyrazolyl)diméthylbore sont orthorhombiques avec a = 7,6135(5), b = 16,2917(5) et c = 22,331(1) Å, Z = 8 et groupe d'espace *Pbca* alors que ceux de l'hydroxy(méthyl)galliumbis(μ-pyrazolyl)diméthylbore sont orthorhombiques avec a = 7,6197(3), b = 16,2184(7) et c = 22,190(1) Å, Z = 8 et groupe d'espace *Pbca*. On a résolu les deux structures par les méthodes usuelles aux atomes lourds et on les a affinées par la méthode les moindres carrés jusqu'à des valeurs de R de 0,054 et 0,040 pour 1243 et 1272 réflexions avec respectivement $I \geq 1{,}5$ et $3\sigma(I)$. Les structures cristallines sont isomorphes et chacune présente des cycles à six chaînons B—(N—N)$_2$—Ga possédant des conformations bateaux hautement asymétriques; ces conformations sont très différentes de celles observées; pour la majorité des analogues homobinucléaires rapportés antérieurement. Les distances Ga—N et B—N moyennes dans les deux composés sont 1,977 et 1,61 Å.

Mots clés : pyrazagaboles; hétérocycles pyrazolyles pontés; structures cristallines; synthèses de pyrazagaboles.

[Traduit par la revue]

Introduction

Pyrazaboles, $R_2B(pz)_2BR_2$ (where R = H, alkyl, Cl, or aryl and pz = pyrazolyl, $N_2C_3H_3$) were first described some time ago by Trofimenko (1) and consist of two "R_2B" moieties bridged by pyrazolyl groups to give heterocyclic six-membered B—(N—N)$_2$—B ring systems. The first structural characterization of this class of compound came with the introduction of the pyrazolylgallane analogs, namely the structure of $D_2Ga(pz)_2GaD_2$ (2). Since these early reports numerous other derivatives of these symmetrical six-membered ring systems involving B, Al, or Ga have been detailed (3). The present account describes the synthesis and characterization of the first examples of pyrazagaboles, six-membered heterocycles containing both B and Ga moieties bridged by two exobidentate pyrazolyl ligands. The crystal structures of two of these compounds are described.

Experimental

Air-sensitive materials were handled in a glove box under oxygen-free dry nitrogen or on a high-vacuum line. Diethyl ether was dried by refluxing over Na/benzophenone and benzene by refluxing over molten potassium. Both solvents were distilled under N_2 before use. Trimethylgallium (4), $Na^+Me_2Bpz_2^-$ (5), and $K^+H_2Bpz_2^-$ (6) were prepared as described previously.

Preparation of $Me_2GaCl.OEt_2$ (7)

Trimethylgallium (2.828 g, 24.66 mmol) was transferred into a vessel containing diethyl ether (~30 mL). The mixture was cooled to −196°C and the vessel evacuated. Hydrogen chloride gas (24.65 mmol) was condensed into the reaction vessel which was then flame sealed and allowed to warm to room temperature. After ~24 h, the reaction mixture was again cooled to −196°C and the methane evolved was measured (24.65 mmol). The product solution was then transferred to a 250 mL volumetric flask to give a standard solution (0.0986 mmol/mL) for subsequent reactions.

*Preparation of $Me_2Gapz_2BMe_2$, **1***

$Na^+Me_2Bpz_2^-$ (0.780 g, 3.94 mmol) was reacted in Et_2O with an aliquot of the above standard solution of $Me_2GaCl.OEt_2$ (40.0 mL, 3.94 mmol). The reaction mixture was stirred for 2 days after which time the precipitated NaCl was removed by filtration. The solvent was then removed from the filtrate under vacuum and the solid product recrystallized from benzene in ~80% yield. *Anal.* calcd. for $Me_2Gapz_2BMe_2$: C 43.71, H 6.60, N 20.39; found: C 43.43, H 6.54, N 20.32. ^{1}H nmr (C_6D_6; 80, 270 MHz; $\delta(C_6H_6)$ = 7.16 ppm): δ = 0.10 (s, $GaMe_2$), 0.51 (s, BMe_2), 5.88 (t, pzH^4, J = 2.2 Hz), 7.15 (d, pzH^5, J = 2.2 Hz), 7.45 (dd, pzH^3, J = 2.2 and 0.75 Hz). The mass spectrum of the compound displayed a strong signal due to the parent − methyl ion, P − Me^+, in addition to the expected fragment ion signals.

A single crystal of the compound $Me(OH)Gapz_2BMe_2$, **2**, was isolated as a by-product of the above reaction and was characterized by a crystal structure analysis (see below). The formation of **2** probably resulted from an accidental use of wet solvent on the first attempt to prepare compound **1**. In all subsequent preparations, no trace of **2** could be detected.

Preparation of $Me_2Gapz_2BH_2$

This compound was prepared by reacting $K^+H_2Bpz_2^-$ (0.732 g, 3.94 mmol) in Et_2O with an aliquot of the standard solution of $Me_2GaCl.OEt_2$ (40.0 mL, 3.94 mmol). Recrystallization of the product from benzene afforded white crystals of the desired compound in ~75% yield. *Anal.* calcd. for $Me_2Gapz_2BH_2$: C 38.94, H 5.72, N 22.71; found: C 39.12, H 5.42, N 22.71. ^{1}H nmr (C_6D_6; 80, 270 MHz; $\delta(C_6H_6)$ = 7.16 ppm): δ = 0.53 (s, $GaMe_2$), 5.77 (t, pzH^4, J = 2.2 Hz), 7.07 (d, pzH^5, J = 2.2 Hz), 7.41 (dd, pzH^3, J = 2.2 and 0.75 Hz). The mass spectrum again displayed a strong signal due to the P − Me^+ ion and the ir spectra (Nujol, KBr disk) showed ν_{BH_2} vibrations at ~2430 cm^{-1}.

[a]Temperature 294 K, Enraf-Nonius CAD4-F diffractometer, Cu-K_α radiation ($\lambda_{K\alpha_1}$ = 1.540562, $\lambda_{K\alpha_2}$ = 1.544390 Å), nickel filter, takeoff angle 2.7°, aperture (2.0 + tan θ) × 4.0 mm at a distance of 173 mm from the crystal, scan range extended by 25% on both sides for background measurement, $\sigma^2(I) = C + 2B + [0.04(C - B)]^2$ (C = scan count, B = normalized background count), function minimized: $\sum w(|F_o| - |F_c|)^2$ where $w = 1/\sigma^2(F)$, $R = \sum||F_o| - |F_c||/\sum|F_o|$, $R_w = (\sum w(|F_o| - |F_c|)^2/\sum w|F_o|^2)^{1/2}$, $S = (\sum w(|F_o| - |F_c|)^2/(m - n))^{1/2}$. Values given for R, R_w, and S are based on those reflections with $I \geq 3\sigma(I)$.

*X-ray crystallographic analyses of dimethylgalliumbis(μ-pyrazolyl)dimethylboron, **1**, and hydroxy(methyl)galliumbis(μ-pyrazolyl)dimethylboron, **2***

Crystallographic data for the two compounds are presented in Table 1. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 45–70° for **1**, 60–80° for **2**) measured with Cu-$K\alpha_1$ radiation. Data were corrected[1] for Lp and absorption. The structure of **2** was solved by conventional heavy atom methods. The coordinates of the gallium atom being determined from the Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference Fourier synthesis. Compound **1** is isomorphous with **2**, the analysis of **1** being initiated with the coordinates of the non-hydrogen atoms of **2**.

The hydroxy compound **2** was initially believed to be compound **1**, thus the oxygen atom was refined as a carbon atom. The anomalously small equivalent isotropic thermal parameter which resulted from this atom prompted us to refine this atom as an oxygen (the only reasonable alternative). The agreement factors improved by about 0.5% and the thermal parameter for the oxygen atom was consistent with those of the methyl carbon atoms. The subsequent structure analysis of a genuine sample of **1** provided additional evidence for the formulation of **2**. The lattice constants, unit-cell volumes, and calculated densities (Table 1) for the isoelectronic species **1** and **2** are significantly different. The crystal of **2** chosen for data collection from the first batch of compound **1** was selected simply because it was of higher quality than the crystals of **1** which formed the bulk of the sample.

For both structures, **1** and **2**, the non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms were fixed in idealized positions (staggered methyl groups, OH based on observed position, O—H = 0.874 Å, C—H = 0.98 Å, $U_H \propto U_{bonded\ atom}$). Neutral atom scattering factors and anomalous dispersion corrections were taken from ref. 8. An isotropic Type I extinction correction (Thornley–Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied for **2** (9–11), the final value of g being 0.45(6) × 10^4. Final positional and anisotropic thermal parameters are given in Tables 2 and 7,[2] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2] Bond lengths, bond angles, and intra-annular torsion angles appear in Tables 3–5, respectively. Hydrogen atom parameters and a complete listing of torsion angles (Tables 6 and 8) have been deposited.[2]

Results and discussion

The pyrazagaboles, $Me_2Gapz_2BMe_2$ and $Me_2Gapz_2BH_2$ (Fig. 1), have been synthesized from $Me_2GaCl.OEt_2$ and the bispyrazolyl borate anions $Me_2Bpz_2^-$ and $H_2Bpz_2^-$, respectively. Crystalline samples were obtained from benzene solution.

[1]The computer programs used include locally written programs for data processing and locally modified versions of the following: AGNOST, absorption corrections, by J. A. Ibers; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

The ^{1}H nmr spectra of the two compounds can be rationalized on the basis of either planar six-membered Ga—(N—N)$_2$—B heterocycles or rapidly inverting boat conformations for these ring systems. Thus the spectrum of $Me_2Gapz_2BMe_2$ consists of singlets for both the —$GaMe_2$ and —BMe_2 groups and a doublet–doublet–triplet pattern for the three different C—H protons of the pyrzolyl rings. Similarly the $Me_2Gapz_2BH_2$ complex gave a singlet for the —$GaMe_2$ protons and the expected doublet–doublet–triplet pattern for the pyrazolyl ring protons in its ^{1}H nmr spectrum.

Previous X-ray crystallographic studies on pyrazagallole derivatives containing the central six-membered Ga—(N—N)$_2$—Ga heterocycle, have shown that all of the complexes possess a central boat conformation for the Ga—(N—N)$_2$—Ga ring in the solid state with the one exception of $Me_2Ga(3,5\text{-}Me_2pz)_2GaMe_2$ where steric requirements force a planar arrangement on the central ring (2, 12, 13). Similarly, extensive structural studies on pyrazabole compounds, with the central B—(N—N)$_2$—B feature, reveal that the large majority of the solid state structures exhibit a boat conformation for this heterocyclic ring (14–16). However, steric effects can again dictate alternate structural arrangements in some complexes and indeed the first structure of this class of compound reported, the bis-3,5-dimethyl-

pyrazolyl borane dimer, exhibited a slightly chair-shaped B—(N—N)$_2$—B ring (17), whilst others have displayed a planar B—(N—N)$_2$—B ring system (18, 19). The present study reports the first hybrid compounds of the pyrazaboles and pyrazagalloles with both a B and a Ga atom incorporated into the six-membered heterocyclic ring system, B—(N—N)$_2$—Ga. It was of obvious interest to determine the solid state structure of this type of compound for comparison with the wealth of structural data available on the parent species. Interestingly, whilst this work was in progress two reports on related structures have appeared. Cowley et al. have reported the structure of a cation containing a central gallium atom octahedrally coordinated by two tridentate pyrazolyl borate ligands, [HB(3,5-Me$_2$pz)$_3$]$_2$Ga$^+$ (20), and also that of the neutral three-coordinate complex [HB(3,*t*-Bupz)$_3$]Tl(I) (21).

The present structures, **1** and **2**, both display the B—(N—N)$_2$—Ga rings in asymmetric boat conformations. The four nitrogen atoms are planar within 0.008 Å in **1** and 0.002 Å in **2**. The angles θ_1 and θ_2 are defined (14) as the dihedral angles between the N_4 and NNE (E = B or Ga), and the N_4 and pyrazolyl mean planes respectively. The θ_1(Ga) angles of 15.8 and 16.0° in **1** and **2** lie within the range observed for pyrazagalloles (2, 12, 13) while the θ_1(B) values of 42.5 and 42.0° in **1** and **2** are larger than any yet reported for pyrazaboles (14, and references therein). The large difference between the θ_1(Ga) and θ_1(B) values highlights the asymmetry of the present B—(N—N)$_2$—Ga rings, a feature not observed in any of the homobinuclear analogs. The θ_2 values (22.3 and 23.9° in **1**, 22.3 and 24.0° in **2**, mean 23.1°) are consistent with the average θ_1 value of 29.1° in **1** and **2** (from a plot of θ_1 vs. θ_2 for pyrazabole structures (14)).

The Ga—N distances in **1** and **2** average 1.977 Å, shorter than the average Ga—N bond length of 1.993 Å for the four pyrazagallole molecules having Me$_2$Ga— groups (12, 13) but similar to the mean Ga—N distance of 1.974 Å in D$_2$Gapz$_2$GaD$_2$ (2). The short Ga—N distances in **1** and **2** are balanced by a lengthening of the B—N distances to an average of 1.61 Å compared to average B—N distances of 1.521–1.567 Å reported for all pyrazabole structures (14–19) except that of Et$_2$B(4-Brpz)$_2$BEt$_2$ (22) which has an unusually long average B—N distance of 1.69 Å. The long B—N distances in **1** and **2** may be a result of the large deviations of the boron atoms from the N_4 mean planes (0.68 and 0.65 Å in **1** and **2**). Remaining features of the molecular geometries are as expected (Tables 3–5). Both crystal structures consist of well-separated molecules, all intermolecular

For personal use only.

distances corresponding to van der Waals interactions. The O—H group in **2** is not hydrogen-bonded. The shortest intermolecular contact involving the O atom in **2** is O···C(9) = 3.652(8) Å and, as expected, the corresponding C(1)···C(10) distance in **1** is longer at 3.72(1) Å. Since the structures of **1** and **2** are isomorphous, it is likely that the potential H-bonding in compound **2** is precluded by other aspects of the molecular packing.

Condensation of equimolar amounts of salicylaldehyde, *N*-hydroxypiperidine, and phenylboronic acid yields the title compound. Crystals of 8,8-pentamethylene-6-phenyl-6,9-epoxy-5,7-dioxa-8-azonia-6-borata-6,7,8,9-tetrahydro-5*H*-benzocycloheptene are monoclinic, $a = 12.773(1)$, $b = 11.9600(7)$, $c = 10.6411(6)$ Å, $\beta = 103.786(7)°$, $Z = 4$, space group $P2_1/c$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to $R = 0.039$ and $R_w = 0.047$ for 2420 reflections with $I \geq 3\sigma(I)$. The compound has a bridged heterocyclic *B,N*-betaine structure with a $PhB(OR)_3$ anionic centre. Bond lengths (corrected for libration) include: B—O(aryl C) = 1.481(2), B—O(alkyl C) = 1.488(2), B—O(N) = 1.539(2), and B—C = 1.591(2) Å.

Key words: organoboron, boron compounds, crystal structure.

La condensation de quantités équimoléculaires de salicylaldéhyde, de *N*-hydroxypipéridine et d'acide phénylboronique fournit le composé mentionné dans le titre. Les cristaux du 8,8-pentaméthylène-6-phényl-6,9-époxy-5,7-dioxa-8-azonia-6-borata-6,7,8,9-tétrahydro-5*H*-benzocycloheptène sont monocliniques, groupe d'espace $P2_1/c$, avec $a = 12,773(1)$, $b = 11,9600(7)$ et $c = 10,6411(6)$ Å, $\beta = 103,786(7)°$ et $Z = 4$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de $R = 0,039$ et $R_w = 0,047$ pour 2420 réflexions avec $I \geq 3\sigma(I)$. La molécule possède une structure *B,N*-bétaïne hétérocyclique pontée comportant un centre anionique $PhB(OR)_3$. Les longueurs des liaisons (corrigées pour la libration) incluent : B—O(C aryle) = 1,481(2), B—O(C alkyle) = 1,488(2), B—O(N) = 1,539(2) et B—C = 1,591(2) Å.

Mots clés : organobor, composés du bor, structure cristalline.

[Traduit par la revue]

Introduction

The reaction of equimolar amounts of salicylaldehyde, *N*-hydroxypiperidine, and phenylboronic acid leads to a 1:1:1 condensation product, the elemental analysis of which shows that 2 mole equivalents of water have been eliminated. This is consistent with the fact that the infrared and ^1H nmr spectra show no evidence of free hydroxyl groups. On the basis of the elemental analysis and spectroscopic data several structures are possible for this compound. The absence of a C=O absorption in the infrared spectrum (solid state, KBr pellets) implies that the aldehyde function is involved in an intra- or intermolecular addition reaction resulting in the loss of the C=O double bond. The result could be a zwitterionic condensate **1** with a five-membered cyclophenylboronate structure, or a six-membered phenylboronate ring system such as that in the *N*-oxide **2** or its rearrangement product **3** (which could also be formed directly by condensation of the three reactants).

Both isomers, **1** and **2**, could also be transformed by intramolecular O → B coordination into the bridged heterocyclic *B,N*-betaine **4**, whereas **3** would give the isomeric bridged heterocycle **5** by intramolecular N → B coordination. All of the structures **1**–**5** are consistent with the appearance of a singlet in the ^1H nmr spectrum of the compound at $\delta = 6$ ppm, a typical shift value for the resonance of methine protons of *O,O*- or *N,O*-acetals. This signal, however, only accounts for about 90% of the expected peak area for the methine proton. The remaining 10% appears as a singlet at about $\delta = 10$ ppm which can be ascribed to the methine proton of a free aldehyde group in the open-chain isomers **4′** and **5′**. The appearance of this downfield signal, the peak area of which varies only slightly upon changing the solvent, demonstrates the existence of **4′** or **5′**, at least in solution, and is also consistent with the formation of the bridged ring forms **4** or **5** containing tetracoordinated boron via the open chain forms **4′** and **5′**, respectively. An X-ray crystallographic analysis was undertaken in order to establish unambiguously which of the most probable structures, **4** or **5**, is correct.

Experimental

*8,8-Pentamethylene-6-phenyl-6,9-epoxy-5,7-dioxa-8-azonia-6-borata-6,7,8,9-tetrahydro-5*H*-benzocycloheptene*

Five millimoles each of salicylaldehyde, *N*-hydroxypiperidine, and phenylboronic acid were dissolved in 10 mL ethanol and refluxed for 15 min. Colorless crystals are obtained upon cooling of the solution. Yield: 80%. Melting point 161°C (recrystallized from ethanol). *Anal.* calcd. for $C_{18}H_{20}BNO_3$: C 69.93, H 6.52, B 3.50, N 4.53; found: C 69.93, H 6.53, B 3.46, N 4.53. Infrared (KBr): 1580, 1610 cm^{-1}

(aromatic C=C). ^{1}H nmr ($CDCl_3$/TMS): δ (ppm) = 1.4–3.9 (m, $(CH_2)_5$), 5.69 (s, N—CH—O [86%]), 6.6–7.8 (m, C_6H_4 and C_6H_5), 9.79 (s, CH=O [14%]); (d_6-DMSO/TMS): δ (ppm) = 6.07 (s, N—CH—O [94%]), 10.17 (s, CH=O [6%]). Crystals suitable for X-ray analysis were obtained by very slow recrystallization from ethanol at room temperature.

X-ray crystallographic analysis

A crystal bounded by the six faces (followed by the distances in mm between parallel faces): {0 1 1}, 0.46, and {1 0 0}, 0.32 was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 37–44°) measured on a diffractometer with Mo-$K\alpha$ radiation ($\lambda(K\alpha_1)$ = 0.70930, $\lambda(K\alpha_2)$ = 0.71359 Å). Crystal data at 22°C are:

$C_{18}H_{20}BNO_3$ f.w. = 309.17

Monoclinic, a = 12.773(1), b = 11.9600(7), c = 10.6411(6) Å, β = 103.786(7)°, V = 1578.8(2) Å^3, Z = 4, ρ_c = 1.301 Mg m^{-3}, $F(000)$ = 656, μ(Mo-$K\alpha$) = 0.81 cm^{-1}. Absent reflections: $0k0$, k odd, and $h0l$, l odd, uniquely indicate the space group $P2_1/c$ (C_{2h}^5, No. 14).

Intensities were measured with graphite-monochromated Mo-$K\alpha$ radiation on an Enraf-Nonius CAD4-F diffractometer. An ω-2θ scan at 1.1–10.0° min^{-1} over a range of (0.95 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of three check reflections, measured every 4000 s throughout the data collection, remained constant to within 3.5%. Of the 3615 independent reflections measured and processed,[2] 2420 (67.0%) had intensities greater than or equal to $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The structure was solved by direct methods. The non-hydrogen atoms were positioned from an E-map and the hydrogen atoms from a subsequent difference Fourier synthesis. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms with isotropic thermal parameters. Scattering factors for all atoms were taken from ref. 1. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix refinement of 288 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.039 and R_w = 0.047 for 2420 reflections with $I \geq 3\sigma(I)$. For all 3615 reflections R = 0.070. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.001 and 0.009σ, respectively. The mean error in an observation of unit weight was 2.081. The largest peak on the final difference map was 0.24 e Å^{-3}. The final positional and thermal parameters appear in Tables 1 and 6,[3] respectively. Measured and

calculated structure factors have been placed in the Depository of Unpublished Data.[3]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (2). The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0008 Å^2. Four structural subunits were separately analysed: the two aromatic rings, the piperidine ring, and the bicyclo[3.2.1]octane system, plus non-hydrogen atoms directly bonded to these moieties (rms ΔU_{ij} = 0.0013–0.0021, mean 0.0016 Å^2). The appropriate bond distances have been corrected for libration (2, 3), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 2 along with the uncorrected values; bond angles appear in Table 3 and intra-annular torsion angles in Table 4. Hydrogen atom parameters (Table 5), bond lengths and angles involving hydrogen and a complete listing of torsion angles (Tables 7–9) have been deposited.[3]

Results and discussion

The X-ray analysis shows that the molecule (Fig. 1) adopts the bridged heterocyclic *B*,*N*-betaine structure **4** in the solid state. The polycyclic chelate system with a tridentate ligand and a tetrahedrally coordinated boron atom within an arylboronate function is composed of a bicyclo[3.2.1]octane skeleton with a fused benzene component and a spiro piperidine ring. Similar bridged heterocyclic arylboronates with an $ArB(OR)_3$ anionic centre in a *B*,*N*-betaine structure containing bicyclo[3.3.1]-octane (4), tricyclo[3.3.1.1^{3,7}]decane (5), and bicyclo[2.2.2]-octane (6) ring skeletons have been reported. A crystal structure has been reported for an example of the latter, namely compound **6** (7). In this series, compound **4** represents a new ring system.

The sum of B—O distances[4] in **4** (4.508 Å) is essentially equal to the corresponding sum for **6** (4.510 Å) (7) and the B—C(phenyl) bond lengths in **4** and **6** are both 1.591 Å. The B(sp^3)—C bond, as expected, is longer than in trigonal planar phenylboronates where the B(sp^2)—C distances range from 1.548 Å (8, 9) to 1.566 Å (10), consistent with at least partial loss of π-interaction between the boron atom and the aromatic system.

Compound **4** contains a five-membered ring system which can be synthesized from an *N*-hydroxydialkylamine, a carbonyl compound, and a chelate-forming boron reagent such as phenylboronic acid (and derivatives thereof). Crystal structures have been reported for two examples of the BONCO ring system **7**: **7***a*, R = Me, R^1 = R^2 = H (11); and **7***b*, R = R^1 = R^2 = Me (12). The BONCO ring in **4** has a distorted half-chair conformation (see Table 4), similar to those observed in **7***a* and **7***b*. The N—O, (N)O—B, B—O(C), and O—C bond lengths

[4]Libration corrected bond lengths (esd's assumed equal to those of the uncorrected values) are employed in the discussion and are compared with similarly treated (2) distances unless otherwise stated.

of 1.424, 1.539, 1.488, and 1.382 Å in the BONCO ring of **4** are similar to the corresponding values of 1.409, 1.556, 1.506, and 1.378 Å in **7***a* (11) and 1.410, 1.534, 1.507, and 1.387 Å in **7***b* (12). The acetal carbon – nitrogen distance in **4** (C(7)—N = 1.569 Å) lies between the corresponding distances of 1.505 Å in **7***a* and 1.591 Å in **7***b*, the latter bond being an extremely long (sp^3)N—C bond resulting from steric interactions (12). The long N—C(7) bond in **4** is consistent with evidence of dissociation (ring-chain isomerism) in solution indicated by nmr studies.

The six-membered BOCCCO ring in **4** originates from the salicylaldehyde. Comparison with the structure of the diphenylboron chelate of salicylaldehyde, **8** (13), shows, of course, the dramatic change in the carbonyl C=O bond length from 1.263 Å in **8** to 1.382 Å in **4** associated with the sp^3 hybridization of C(7) in **4**. The bond between C(7) and the aromatic ring also lengthens considerably with the change in hybridization at C(7): from 1.413 Å in **8** to 1.494 Å in **4**. Both B—O bonds are shorter in **4** than in **8**, the most notable difference involving the dative interaction between the carbonyl oxygen atom and boron in **8** (1.574 Å) and the corresponding single bond in **4** (1.488 Å). The O(2)—C(1)—C(6)—C(7) ring fragment in **4** is planar to within experimental error. The six-membered BOCCCO ring has a distorted semi-planar (O(3)-envelope) conformation.

The seven-membered BONCCCO ring in **4** may be compared with those observed in diphenylboron chelates of salicylaldehyde nitrones (14, 15) and certain salicylohydroxamic acid derivatives (16) having the general structure **9**. The main

difference between these seven-membered rings in **9** and **4**, apart from substantial conformational differences, is the longer C(7)—N distance in **4** (1.569 Å) relative to the corresponding C=N double bond in **9** (1.291 Å for the salicylaldonitrone with X = H and R = Me) (15). The N—O and C(6)—C(7) bonds are also longer in **4**. The sum of bond lengths in the BONCCCO ring of **4** (10.275 Å), when compared with the corresponding value of 9.907 Å for **9** (X = H, R = Me), is consistent with the higher degree of saturation in the seven-membered ring of **4**.

The piperidine ring in **4** has an essentially undistorted chair conformation (see Table 4). The oxygen substituent at the nitrogen atom occupies an axial position, and the carbon substituent is equatorial. The same positioning of substituents has been observed for other cyclic *N*-oxide derivatives such as ethylenebis(piperidine *N*-oxide) salts (17) and hydrates (18). The N—O distance in **4** (1.424 Å) is similar to those in *N*-alkylpiperidine *N*-oxide perchlorates (1.411–1.412 Å) (17).

The crystal structure of **4** consists of well-separated molecules, the most significant intermolecular contact (O(1)···C(4) ($2 - x$, $y - \frac{1}{2}$, $\frac{3}{2} - z$) = 3.307(2) Å and O(1)···H(4) = 2.57(2) Å) corresponding to a normal van der Waals interaction. Features of the molecular geometry (Tables 2–4) not discussed above are normal.

Reaction of oxybis(diphenylborane) with the condensation product of salicylohydroxamic acid and cyclopentanone gives the title compound in good yield. Crystals of 2,2-diphenyl-4,4-tetramethylene-1,3,5-trioxa-3*a*-azonia-2-borata-2,3,4,5-tetrahydro-1*H*-cyclopenta[*a*]naphthalene are monoclinic, $a = 12.521(1)$, $b = 12.409(1)$, $c = 12.975(1)$ Å, $\beta = 93.784(8)°$, $Z = 4$, space group $P2_1/n$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to $R = 0.043$ and $R_w = 0.044$ for 1502 reflections with $I \geq 2\sigma(I)$. The molecule has a typical diphenylboron hydroxamate structure featuring a five-membered COBON chelate ring. The *O*,*O*-chelating ligand is weakly bound to the diphenylboron moiety. Bond lengths (corrected for libration) include: (N)O—B = 1.558(4), (C=)O—B = 1.578(4), and C—B = 1.589(5) and 1.603(5) Å.

Key words: crystal structure, boron compound, organoboron compound.

WOLFGANG KLIEGEL, MAHMOOD TAJERBASHI, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **68**, 69 (1990).

La réaction de l'oxybis(diphénylborane) avec le produit de condensation de l'acide salicylehydroxamique et la cyclopentanone conduit au composé mentionné dans le titre, avec un bon rendement. Les cristaux du 2,2-diphényl-4,4-tétraméthylène-1,3,5-trioxa-3a-azonia-2-borata-2,3,4,5-tétrahydro-1*H*-cyclopenta[*a*]naphtalène sont monocliniques, groupe d'espace $P2_1/n$, avec $a = 12{,}521(1)$, $b = 12{,}409(1)$ et $c = 12{,}975(1)$ Å, $\beta = 93{,}784(8)°$ et $Z = 4$. On a résolu la structure par des méthodes directes et on l'a affinés par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de $R = 0{,}043$ et $R_w = 0{,}044$ pour 1502 réflexions avec $I \geq 2\sigma(I)$. La molécule possède une structure hydroxamate de diphénylbore typique comportant un cycle chélate COBON à cinq chaînons. Le ligand chélatant-*O*,*O* est faiblement lié à la portion diphénylbore. Les longueurs des liaisons (corrigées pour la libration) incluent: (N)O—B = 1,558(4), (C=)O—B = 1,578(4) et C—B = 1,589(5) et 1,603(5) Å.

Mots clés : structure cristalline, composé du bore, composé du organobore.

[Traduit par la revue]

Introduction

The condensation of salicylohydroxamic acid and aldehydes (1, 2) or ketones (2) gives crystalline compounds which were formulated as cyclic *N*,*O*-acetals **1**. Structure **1** is a cyclic *N*-(α-phenoxyalkyl)hydroxamic acid and, as such, is of interest to us as a ligand for boron chelation in the course of our investigation of *N*-substituted hydroxamic acids (3–8). Compound **1** ($R^1 + R^2 = -(CH_2)_4-$) was synthesized from salicylohydroxamic acid and cyclopentanone and was reacted with oxybis(diphenylborane).

The resulting diphenylboron chelate was expected to possess the molecular structure **2** by analogy with the general structure **3** found for other boron chelates of *N*-substituted hydroxamic acids (3–7). If there had been another mode of reaction between salicylohydroxamic acid and the carbonyl compound, the five-membered *O*,*O*-acetal **4** could have been formed as in the acid-catalysed cyclization of 3-hydroxycarbohydroxamic acids with cyclohexanone (9). The 1,4,2-dioxazole partial structure of **4** is well documented in the literature (10). Compound **4** would lead to a diphenylboron chelate of structure **5** with a six-membered chelate ring, the formation of which is demonstrated by the known diphenylboron chelate **6** (11). Infrared and ^{1}H nmr data do not allow an unambiguous choice between the structures **2** and **5**. This also applies for the less probable structure **7** which contains a seven-membered chelate ring iden-

tical to that observed for compound **8** (12). The formation and stability of the 1,3-oxazetine ring system in **7**, however, seems unlikely.[2] An additional structural isomer that has to be considered would have a seven-membered cyclic *O,O*-acetal structure with *N*-diphenylboryl substitution, **9**. Simple amidoboranes are reported to exist as monomers or cyclic dimers (16). To decide definitively between the structures **2**, **5**, **7**, and **9** an X-ray crystallographic analysis was undertaken.

Experimental

2,3-Dihydro-3-hydroxy-2,2-tetramethylene-4H-1,3-benzoxazin-4-one, 1 ($R^1 + R^2 = -(CH_2)_4-$)

Salicylohydroxamic acid (1.22 g, 8 mmol) and cyclopentanone (0.67 g, 8 mmol) are dissolved in benzene (100 mL) and, after addition of *p*-toluenesulfonic acid (0.15 g), refluxed for 80 min using a Dean–Stark trap for the continuous removal of water. After partial evaporation of the solvent and addition of petroleum ether, colorless needles were obtained upon cooling. Yield: 1.51 g (86%). Melting point: 114°C (benzene/petroleum ether). *Anal.* calcd. for $C_{12}H_{13}NO_3$: C 65.74, H 5.97, N 6.39; found: C 65.87, H 5.99, N 6.35. The substance gives a red-to-violet solution upon reaction with $FeCl_3$ in ethanol. Infrared (KBr): 1650 (C=O / C=N), 2200–3600 cm^{-1} (broad, OH). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ(ppm) = 1.70–2.73 (m, $(CH_2)_4$), 6.75–7.90 (m, C_6H_4), 9.55 (s, exchangeable, OH).

2,2-Diphenyl-4,4-tetramethylene-1,3,5-trioxa-3a-azonia-2-borata-2,3,4,5-tetrahydro-1H-cyclopenta[a]naphthalene, 2 ($R^1 + R^2 = -(CH_2)_4-$)

A solution of **1** (1.10 g, 5 mmol) and oxybis(diphenylborane) (0.87 g, 2.5 mmol) in 20–30 mL ethanol is refluxed for 15 min. After partial evaporation of the solvent, colorless needles crystallize upon cooling. Yield: 1.63 g, (85%). Melting point: 163°C (absolute ethanol). *Anal.* calcd. for $C_{24}H_{22}BNO_3$: C 75.22, H 5.78, N 3.65; found: C 75.24, H 5.95, N 3.72. Mass spectrum (70 eV, 120°C): m/z = 306 (100%, $M^+ - C_6H_5$), 121 (14%). Infrared (KBr): 1615 cm^{-1} (C=O / C=N). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ(ppm) = 1.69–2.78 (m, $(CH_2)_4$), 6.85–7.80 (m, C_6H_4 and BPh_2). ^{13}C nmr (400 MHz, $CDCl_3$): δ(ppm)[3] = 23.57 (C(10),C(11), 34.93 (C(9),C(12)), 104.17 (C(7)), 110.06 (C(1)), 117.53–136.03 (C(3)—C(6), C(13)—C(18), C(19)—C(24)). The substance gives a blue-colored solution upon addition of diphenylcarbazone in ethanol, indicating the chelated diphenylborenium ion in **2** (17).

X-ray crystallographic analysis

A crystal bounded by the six faces (followed by the distances in mm between parallel faces): ±(−1 0 1), 0.22, ±(1 0 1), 0.48, {0 1 0}, 0.54, was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 20–31°) measured on a diffractometer with Mo-Kα radiation (λ($K\alpha_1$) = 0.70930, λ($K\alpha_2$) = 0.71359 Å). Crystal data at 22°C are as follows:

$C_{24}H_{22}BNO_3$ fw = 383.25

Monoclinic, a = 12.521(1), b = 12.409(1), c = 12.975(1) Å, β = 93.784(8)°, V = 2011.5(3) Å^3, Z = 4, ρ_c = 1.265 Mg m^{-3}, F(000) = 808, μ(Mo-Kα) = 0.77 cm^{-1}. Absent reflections: 0k0, k odd, and h0l, $h + l$ odd, uniquely indicate the space group $P2_1/n$ (C_{2h}^5, No. 14).

Intensities were measured with graphite-monochromated Mo-Kα radiation on an Enraf-Nonius CAD4-F diffractometer. An ω-2θ scan at 0.7–6.7° min^{-1} over a range of (0.65 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 50°. The intensities of three check reflections, measured every 4000 s throughout the data collection, showed only small random fluctuations. Of the 3525 independent reflections measured and processed,[4] 1502(42.6%) had intensities greater than or equal to 2σ(I) above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The structure was solved by direct methods, the coordinates of the non-hydrogen atoms being determined from an *E*-map. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms were fixed in idealized positions (C(sp^2)—H = 0.97, C(sp^3)—H = 0.98 Å, and $U_H \propto U_{\text{bonded atom}}$). Scattering factors for all atoms were taken from ref. 18. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix refinement of 262 variables. Reflections with $I < 2\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.043 and R_w = 0.044 for 1502 reflections with $I \geq 2\sigma(I)$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.001 and 0.006σ, respectively. The mean error in an observation of unit weight was 1.598. The largest peak on the final difference map was 0.19 e Å^{-3}. The final positional and thermal

[2]The 2*H*-1,3-oxazet-1-ine ring system is reported sporadically in the literature: as an intermediate salt (13), SO_3-adduct (14), or mass spectral fragment (15).

[3]Shifts relative to TMS; numbering of the C atoms is as shown in Fig. 1.

[4]The computer programs used include locally written programs for data processing and locally modified versions of the following: MULTAN 80, multisolution program by P. Main, S. J. Fiske, S. E. Hull, L. Lessinger, G. Germain, J. P. Declercq, and M. M. Woolfson; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

parameters appear in Tables 1 and 6,[5] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[5]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (19). The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0025 Å^2. Five structural subunits were separately analysed: 2 PhB, O(1)C(2–7), O(1)NC(1)C(9–12), and the central fused-ring system (rms ΔU_{ij} = 0.0029–0.0051, mean 0.0036 Å^2). The appropriate bond distances have been corrected for libration (19, 20), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 2 along with the uncorrected values; bond angles appear in Table 3 and intra-annular torsion angles in Table 4. Hydrogen atom parameters (Table 5) and a complete listing of torsion angles (Table 7) have been deposited.[5]

[5]The structure factor table, Table 6 (anisotropic thermal parameters) and other material mentioned in the text may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Results and discussion

The structure of **2**, deriving from the cyclic *N*-alkyl hydroxamic acid **1**, is verified by the X-ray analysis (Fig. 1). The molecule has a typical diphenylboron hydroxamate structure featuring a five-membered COBON chelate system, also realized in similar hydroxamates of the general type **3** (3, 4) and in the diphenylboron chelates of *N*-hydroxy-2-pyridinones (7). The six-membered *N*,*O*-acetal ring system of **1** is retained in the chelate **2**.

The C=O bond of the hydroxamate group (1.288(3) Å) has lost some of its double bond character compared to that in free salicylohydroxamic acid (1.258(3) Å, uncorrected[6]) (21), but a π-bond order of 0.53 can be estimated from a plot of bond length versus π-bond order (22). The C—N bond of salicylohydroxamic acid (1.316(4) Å, uncorrected) (21), which already exhibits considerable double bond character, gains even more in the chelate **2** (1.309(3) Å). The latter C—N distance corresponds to an estimated π-bond order of 0.70 (22). The formulation of the chelate ring in **2** as a cyclic *B*,*N*-betaine is thus justified, this being reflected by the nomenclature employed to describe the chelate **2** (which is similar to boron chelates of the type **3**).

Compared to the boron chelates of *N*-methylacethydroxamic acid (3, 4) and *N*-hydroxy-2-pyridinone (7), which have C=O bond lengths of about 1.34 Å, the hydroxamate C=O bond in **2** is shorter (1.309(3) Å). More double bond character is retained upon chelate formation in the present structure than in the above mentioned hydroxamate complexes. This could be attributed to the influence of the (conjugated) aryl substituent at the hydroxamate function. Similar dimensions within the hydroxamate group are found in a MoO_2 complex of salicylohydroxamic acid (23): C=O = 1.288 and 1.265, C=N = 1.304 and 1.317, N—O = 1.374 and 1.380 Å (uncorrected).

Enhanced π-interaction between the hydroxamate system and the adjacent aryl group is also manifested by shortening of the C(7)—C(8) bond (1.438(4) Å) in **2** relative to that in free salicylohydroxamic acid (1.489(5) Å, uncorrected) (21). This effect is more pronounced in **2** than in the MoO_2 complex (23), so the alkylation of the phenol group in **2** by cycloacetal formation may contribute to the shorter C(7)—C(8) bond. The angle between the normals to the C(2)—C(7) and hydroxamate group mean planes is 8.8°.

The phenolic C(2)—O(1) bond in **2** (1.386(4) Å) is 0.03 Å longer than the corresponding C(ar)—O bond in salicylohydroxamic acid (1.355(4) Å, uncorrected) (21). Lengthening of C(ar)—O bonds by alkylation is well known: aryl alkyl ethers show an average uncorrected C(ar)—O distance of 1.370 Å (24). The somewhat longer bond in **2** could reflect an influence of the α-iminoalkyl substituent at the phenolic oxygen atom and/or the cyclic alkylation mode.

The average O—B and C—B distances in **2** are 1.568 and 1.596 Å, respectively. The mean C—B/mean O—B ratio, which is a good indicator of the overall binding strength of the *O*,*O*-chelating ligand with respect to the diphenylboron moiety (25), of 1.018 for compound **2** lies at the low end of the range 1.017–1.066 (mean 1.035) observed for Ph_2BO_2 compounds

[6]Libration corrected bond lengths (esd's assumed equal to those of the uncorrected values) are employed in the discussion and are compared with similarly treated (19) distances unless otherwise stated.

having five-membered chelate rings (ref. 26 and references therein). Only the diphenylboron chelates of *N*-hydroxy-2-pyridinone (7) and 3-hydroxy-2-methyl-4-pyridinone (26), which both have C—B / O—B ratios of 1.017, have average O—B distances longer than compound **2**.

The cyclopentane ring in **2** has a distorted C(11)-envelope comformation (see Table 4) with the phenol ether group in a pseudo-axial and the chelate ring in a pseudo-equatorial position. The 1,3-oxazine ring (cyclic *N,O*-acetal) has a "semi-planar" (envelope-like) conformation with O(1)—C(2)—C(7)—C(8)—N qualitatively planar. The five-membered COBON ring has a flattened N-envelope conformation, the ring being planar to within ±0.032(3) Å. The hydroxamate group itself is non-planar, the angle between normals to the N and C(8) coordination planes being 19.7°. The crystal structure consists of molecules separated by normal van der Waals distances, the shortest intermolecular contact between non-hydrogen atoms being O(1)···C(6) = 3.461(4) Å.

Topological investigations of the volumetric and enthalpic effects in some binary mixtures of non-electrolytes

PREM P. SINGH AND MEENU BHATIA
Department of Chemistry, Maharshi Dayanand University, Rohtak-124001, India

Received January 30, 1989[1]

PREM P. SINGH and MEENU BHATIA. Can. J. Chem. **68**, 74 (1990).

Volumetric and enthalpic effects have been measured at 308.15 K for pyridine (A) + aniline, *o*-toluidine, formamide, or *N*,*N*-dimethylformamide (B) mixtures and the same have been rationalized by graph–theoretical arguments to suggest that while aniline in the pure state exists as an equilibrium mixture of monomers and dimers, *o*-toluidine exists mainly as dimers. This analysis has further yielded information about the state of association in formamide and *N*,*N*-dimethylformamide that is consistent with the existing views on their nature of association. This analysis has further yielded information about the molecular entities in these mixtures that has been supported by their infrared spectral studies. The energetics of the various interactions that result in the formation of these A + B mixtures have also been investigated and the results have been rationalized by graph–theoretical arguments.

Key words: topological, association, solvation, energetics, volumetric, enthalpic effects.

PREM P. SINGH et MEENU BHATIA. Can. J. Chem. **68**, 74 (1990).

Opérant à 308,15 K, on a mesuré les effets volumétriques et enthalpiques de mélanges de pyridine (A) avec les composés suivants (B) : l'aniline, l'*o*-toluidine, la formamide et la *N*,*N*-diméthylformamide; en se basant sur la théorie des graphes, on suggère que l'aniline à l'état pur existe sous la forme d'un équilibre entre des monomères et des dimères alors que l'*o*-toluidine existe principalement sous la forme de dimères. Cette analyse a aussi fourni des informations concernant l'état d'association dans la formamide et la *N*,*N*-diméthylformamide et ces informations sont en accord avec les vues généralement acceptées concernant la nature de l'association qui existe dans ces composés. Cette analyse a aussi fourni de l'information concernant les entités moléculaires présentes dans ces mélanges; ces informations sont en accord avec les données obtenues en se basant sur les spectres infrarouges de ces mélanges. On a aussi examiné les énergies impliquées dans les diverses interactions qui conduisent à la formation de ces A + B mélanges et on a rationalisé les résultats à l'aide d'arguments basés sur la théorie des graphes.

Mots clés : topologie, association, solvatation, énergies, effets enthalpiques, effets volumétriques.

[Traduit par la revue]

Introduction

In view of the two well known resonance structures of the amide group (1), it is reasonable to assume that like alkanols (2–5), the lower amides in the pure state exist as dimers, trimers, or higher *r*-mers. Davies (6), however, maintains that the association of amides in solution is limited to dimer formation. On the other hand, while Bellamy and Williams (7) maintain that aniline in the pure state exists as monomers, Wolff and Mathias (8) and Kreglewski and Wilhoit (9) favour the associated structure of aniline and suggest that only one of the hydrogen of its NH_2 group is free to form hydrogen bond and the other hydrogen atom is involved in weak interactions with the π-electron cloud of another aniline molecule. Further *ab initio* molecular orbital calculations on the structural, energetic, and electronic properties of substituted pyridine have suggested (10) that the π-electron density at the C_2, C_4, and C_6 positions in pyridine is less than that in benzene so that even pyridine, in the pure state, may be characterized (11) by pyridine–pyridine interactions. The addition of aniline, *o*-toluidine (OT), formamide (FD) or *N*,*N*-dimethylformamide (NND) (B) to pyridine (A) may then bring changes in the topology (12) of A and or B components of these A + B mixtures. Consequently, graph–theoretical concepts that have been successfully utilized to explain a number of physical and chemical properties of non-electrolytes (13–17) could be helpful in understanding the nature of A and or B in binary mixtures of non-electrolytes. Following Kier and Hall (18), Singh *et al.* (11, 19) have recently employed the graph–theoretical approach to investigate the association and solvation of components of binary mixtures. It was felt that volumetric and enthalpic effects in A + B mixtures where A is pyridine and B is aniline, OT, FD, or NND may yield valuable information about the association and solvation of A and/or B in these A + B mixtures.

Experimental

Materials and methods

Aniline (E. Merck, Analytical grade 99.5%) was refluxed (20) with 10% acetone for 10 h, the mixture was acidified with hydrochloric acid to Congo red, and extracted with ethyl ether until it no longer showed any color. The hydrochloride was purified by crystallizations, the aniline freed, dried with potassium hydroxide pellets (AR grade), and distilled under nitrogen at reduced pressure. The middle fraction was stored in amber-coloured bottles in a nitrogen chamber.

o-Toluidine (Merck, Pro. Analysis 99.5%) was distilled (21) and then dissolved in four times its volume of ethyl ether. An etheral solution of an equivalent amount of oxalic acid (AR grade) was next added and the crystals of *o*-toluidine dioxalate were removed by filtration. These were then recrystallized from water containing some amount of oxalic acid (to prevent hydrolysis), treated with dilute sodium carbonate solution, dried with anhydrous calcium chloride, and distilled under nitrogen under reduced pressure. The middle fraction was collected and stored in amber-coloured bottles in a nitrogen chamber.

Formamide (BDH, Analytical reagent 98%) was purified by passing (22*a*) ammonia gas into it until a slight alkaline reaction was obtained. The reaction mixture was then treated with acetone to precipitate the ammonium formate. The filtered solution was dried over magnesium sulphate, fractionally distilled under nitrogen at reduced pressure, and the middle fraction was collected and stored in small bottles over anhydrous calcium chloride in a desiccator.

N,*N*-Dimethylformamide (LOBA, analytical reagent 99%) was shaken (22*b*) with powdered barium oxide, filtered, and the filtrate distilled under nitrogen at reduced pressure. The middle fraction was collected and stored in small bottles over anhydrous calcium chloride in a desiccator.

TABLE 1. Comparison of the measured densities at 298.15 ± 0.01 K of the various compounds with their corresponding literature values

Compound	Density (g cm^{-3}) This work	Literature value
Aniline	1.01745	1.01750 (23)
o-Toluidine	0.99435	0.99430 (22)
Formamide	1.12922	1.12918 (25)
N,*N*-Dimethylformamide	0.9440	0.94397 (25)
Pyridine	0.97756	0.9776 (26)

Pyridine (Merck, 99.5%, analytical reagents) was refluxed (22*c*) over KOH (AR) pellets and then distilled. The middle fraction was collected and stored over solid KOH pellets. All the compounds were used within 10 days of their purification.

The purities of the purified samples were checked by measuring their densities at 298.15 + 0.01 K and these agreed to within 5 × 10^{-5} g cm^{-3} with their corresponding available literature values (23–26) as is evident from Table 1.

Molar excess volumes, V^E, at 308.15 K for the various A + B mixtures were determined in a V-shaped dilatometer (27). A column of pure and distilled mercury was placed in the dilatometer and the dilatometer was weighed. One of the degassed component was then placed in one bulb of the dilatometer and the bulb was then closed with a vacuum tested B-7 standard cone in such a way that no air bubbles were entrapped in it. It was weighed again. The second component was similarly introduced in the other bulb and its stopper replaced in such a way that the liquid stood to a certain height in the dilatometer capillary. The entire assembly was then placed in a water bath controlled to ±0.01 K by a mercury-in-toluene regulator. The position of the liquid in the dilatometer capillary, relative to the reference mark, R, on it was then noted, at equilibrium by a cathetometer (M/S OSAW, India) within an accuracy of ±0.001 cm. The contents of the dilatometer were mixed, after equilibrium, by tilting it gently sideways several times. In order that the liquid in the capillary had the same composition as that of the bulk solution, the dilatometer was placed in a cold bath so that a minimum liquid was present in the capillary. The dilatometer was again placed in the thermostat maintained at the desired temperature and this process was repeated three or four times. The position of the liquid in the dilatometer capillary relative to the reference mark R on it was again noted. The dilatometer was taken out, dried completely, and weighed to determine the weight of the second liquid. Molar excess volume, V^E, for the A + B mixture at that composition was then calculated (27) from the expression,

$$V^E(T,x_A) = \pi r^2 \Delta h/(n_A + n_B)$$

where r is the radius of the dilatometer capillary, Δh is the change in the liquid level in the capillary after mixing, and $(n_A + n_B)$ are the total number of moles of A and B in the A + B mixture.

The radius of the dilatometer capillary was measured from the weight, w, of an average length, l, of mercury column in it (the length of the mercury column of density ρ at the room temperature at various positions in the capillary was measured by a travelling microscope that could read to ±0.001 cm) utilizing the relation $r^2 = w/\pi\rho l$.

Our measured V^E values are subjected to uncertainties in w, ρ, l, Δh, and $n_A + n_B$. The uncertainty in the measured V^E values is ca. 0.5%. The performance of the dilatometer was checked by determining V^E values at 298.15 K for benzene + cyclohexane mixtures and these agreed well within the experimental uncertainties with the values reported elsewhere (28).

Molar excess enthalpies, H^E, for the various mixtures were measured at 308.15 K in a flow microcalorimeter (LKB, Broma, Sweden) in the manner described by Monk and Wadso (29). According to the specification of the instrument, the temperature can be set with a precision of 0.1 K and its stability is 0.02 K/24 h. Two identical Braun Perfusor Pumps (B. Braun, Melsungen AG. W. Germany) and gas-tight Hamilton syringes were employed to pump liquids through the calorimeter. By using 10 and 20 cm^3 syringes and 10 speed gear boxes of the perfusor pumps different mixing ratios were achieved. The flow rates were determined by pumping distilled water through the calorimeter and weighing the amount collected in a specific time interval. For each typical H^E measurement, different calibration constants were determined according to the flow rates, amplification needed, and the composition of the mixture. Molar excess enthalpies were then evaluated from the relation.

$$H^E(T,x_A) = C^2R\left(\frac{\Delta h_1}{\Delta h_2}\right)\Big/(n_A + n_B)$$

where C is the current in amperes, R is the resistance (in ohms) of the calorimeter heater, $\Delta h_1/\Delta h_2$ is the factor used to determine the amount of heat during compensation, Δh_1, and Δh_2 have the same significance as described by Adcock and McGlashan (30). The performance of the calorimeter was checked by measuring the H^E values (31) for benzene + carbon tetrachloride mixtures at 298.15 K and these agreed to within the experimental limits with the corresponding literature values (32). The uncertainty in the measured H^E values is ca. 1%.

Results

The measured V^E and H^E data at 308.15 K (recorded in Tables 2 and 3) for the various binary mixtures were fitted to eq. [1]

$$[1]\quad X^E(X = V \text{ or } H) = x_A x_B \sum_n X^{(n)}(2x_A - 1)^n$$

where $X^{(n)}$ (n = 0–2 or 3) are adjustable parameters and x_A is the mole fraction of A in the A + B mixture. These parameters were evaluated by fitting X^E/x_Ax_B to eq. [1] by the least-squares method and are recorded together with the standard deviation of X^E, $\sigma(X^E)$, in Table 4. The choice of n to have 0–2 values was dictated by the consideration that the maximum deviation $\sigma_m(X^E)$ of X^E (as calculated from [1] from the corresponding experimental X^E values) satisfied the relation $\sigma_m(X^E) \leq 2\sigma(X^E)$.

Discussion

We are unaware of any V^E or H^E data at 308.15 K of the present A + B mixtures with which to compare our results.

V^E for pyridine (A) + FD or NND (B) mixtures are negative and while the V^E data for A + FD mixtures exhibit a maxima ($V^E_{max} = -0.2$ cm^3 mol^{-1}) at $x_A = 0.55$, V^E data for A + NND mixtures are highly unsymmetrical about x_A, and exhibit a maxima (V^E_{max} = 0.04 cm^3 mol^{-1} at x_A = 0.7). Further although V^E values for both pyridine + aniline or OT (B) mixtures are negative, yet while the V^E data for pyridine (A) + aniline (B) exhibit a maximum ($V^E_{max} = -0.42$ cm^3 mol^{-1}) at $x_A = 0.6$, the V^E values for pyridine (A) + OT (B) mixtures are unsymmetrical about x_A and exhibit a maxima (V^E_{max} = -0.440 cm^3 mol^{-1}) at $x_A = 0.58$. On the other hand, the H^E data for pyridine (A) + aniline, OT, FD, or NND (B) mixtures are negative and for equimolar mixtures, vary as FD > NND > aniline > OT.

As the addition of A influences the topology of B in the present A + B mixtures, their V^E data should be expressible (32) by [2]

$$[2]\quad V^E = \alpha_{AB}\left[\frac{1}{\sum_{i=A,B} x_i({}^3\xi_i)_m} - \sum \frac{x_i}{{}^3\xi_i}\right]$$

where $({}^3\xi_i)_m$ and ${}^3\xi_i$ denote respectively the connectivity parameters of the third degree of i (defined (18) by [3])

$$[3]\quad {}^3\xi_i = \sum_{m<n<o<p} (\delta_m^v \delta_n^v \delta_o^v \delta_p^v)^{-0.5}$$

in the mixture and in the pure state, x_A is the mole fraction of A, α_{AB} is a characteristic constant, and all other terms have their usual significance (33, 34). For this purpose we regarded $({}^3\xi_i)_m$ and $({}^3\xi_i)$ (i = A, B) as adjustable parameters (due to the complex nature of A and B in the present A + B mixtures), evaluated them by fitting the V^E data and V_I^E data (read at round mole fractions from V^E vs. x_A plot) to [2] by trial and error method and retained only those ${}^3\xi$ values for which the variance of fit, ρ (defined (11) by $|\Sigma(V^E(\text{calcd}) - V_I^E)^2/(Q - P)|$ was minimum. Such ${}^3\xi$ values (along with the range in their values to reproduce the V_I^E data points to $\pm 0.001\ cm^3\ mol^{-1}$) recorded in Table 4, when used to investigate the molecular state of B and A through [3] as explained elsewhere (11, 19), suggest that while FD exists mainly as cyclic dimer (${}^3\xi$ = 0.855) and open chain trimer (${}^3\xi'$ = 0.856), NND exists as open chain dimer (${}^3\xi'$ = 0.974) or dipolar dimer (${}^3\xi'$ = 0.794) or as an equilibrium mixture of open chain or dipolar dimer with the monomer (${}^3\xi$ = 0.210). Similarly while aniline (B_n) exists as an equilibrium mixture of B(${}^3\xi'$ = 1.37) and B_2(${}^3\xi'$ = 0.75), OT(B_n) exists as B(${}^3\xi'$ = 0.974), and pyridine A exists as A_2 (through weak N....π interaction) (10, 11) (${}^3\xi'$ = 0.706). This is consistent with the available information (1, 6–11) about them. Further, if changes in the topology of B and A is due probably to the formation of AB_n etc. species, then the $({}^3\xi)_m$ values (Table 4) for B in the present A + B mixtures answers specifically to the presence of the following species in these mixtures.

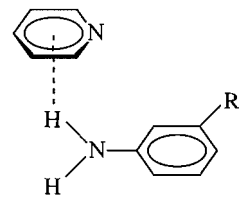
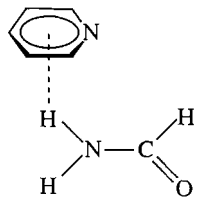
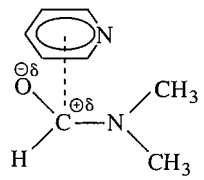
V^n ($n = 0$–2) are in cm^3 mol^{-1}
H^n ($n = 0$–2) are in J mol^{-1}



R = H, $({}^3\xi_B)_m = 1.035$ (**I**)
R = CH_3, $({}^3\xi'_B)_m = 1.355$ (**II**)



$({}^3\xi'_B)_m = 0.853$ (**III**)



$({}^3\xi'_B)_m = 0.726$ (**IV**)

In evaluating these $({}^3\xi'_B)_m$ values we have considered contributions from the π-cloud of A and valencies of all (*i*) the vertices of aniline for **I** and **II**, (*ii*) but the one hydrogen atom of the NH_2 group of FD for **III**, and (*iii*) but the aldehyde proton of NND for **IV**. This would then require that in the appropriate A + B mixture, in addition to the ring vibrations in A, the C—N, —NH_2 vibrations of aniline, =C=O, —C—N, and N—H bending vibrations of FD, and =C=O, C—N, and N—(CH_3), vibrations of NND should have been influenced. The infrared spectral data of pure A, B, and the 1:1 (V/V) appropriate A + B mixture do in fact support this.

Again if the A + B mixture formation involves (*a*) the establishment of A.....B contacts (with molar interaction energy X_{AB}) that cause (*b*) (*i*) rupture of self-association in B (molar interaction energy X_{BB}) to yield monomer and (*ii*) changes of intramolecular interactions in A (molar interaction energy X_{AA}) to yield free A entities, and (*c*) interaction of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

monomers of B with free "A" to yield AB species (molar interaction energy X_{12}), then the enthalpy changes due to (*a*), *b*(*i*), *b*(*ii*), and *c* would be given (10, 11) by

$$\Delta H_1 = x_A X_{AB} V_B / P$$

$$\Delta H_2 = K(x_A)^2 x_B X_{BB} V_B / P$$

$$\Delta H_3 = K(x_A)^2 x_B X_{AA} V_B / P$$

and

$$\Delta H_4 = K' x_A (x_B)^2 X_{12} V_B / P$$

where $P = \sum_{i=A,B} (x_i V_i)$ and V_i is the molar volume of i. The net enthalpy change, H^E, would then be given (10, 11) by [4]

$$[4] \quad H^E = \sum_{j=1}^{4} \Delta H_j = \frac{x_A x_B Y}{x_A + x_B Y}(X_{AB} + K x_A X_{BB} + K x_A X_{AA} + K' x_B X_{12})$$

where $Y = ({}^3\xi_A / {}^3\xi_B)$. For pyridine (A) + aniline/OT (B) mixtures it would be reasonable to assume that $X_{AA} \ll X_{AB}$, X_{BB}, or X_{12}, and if $X_{AB} = KX_{AA} = K'X_{12} = X$ and $KX_{BB} = X'$, then [4] reduces to [5]

$$[5] \quad H^E(T, x_A) = \frac{x_A x_B Y}{x_A + x_B Y}|2X + x_A X'|$$

However, for pyridine (A) + FD/NND (B), it would be more reasonable to assume that $X_{AB} = KX_{AA} = X^*$ and $X_{BB} = K'X_{12} = X^{(a)}$ so that in this case [4] yields [6]

$$[6] \quad H^E(T, x_A) = \frac{x_A x_B Y}{x_A + x_B Y}[(1 + x_A)X^* + X^{(a)}]$$

The parameters X and X' etc. of [5] and [6] were evaluated from the H^E (T, $x_A = 0.4$ and 0.5) data (read from H^E vs. x_A plot) of the appropriate A + B mixture and were re-employed to calculate the H^E data for the same mixture at other rounded-off mole fractions. Such the H^E data (recorded in Table 4) evidently compare well with the corresponding values read from H^E vs. x_A plot). Again for pyridine + aniline/OT mixtures, the X values in Table 4 suggest that compared to aniline, OT should not only boil at higher temperature (which is true), it should also interact strongly (as expected) with pyridine. However, no such conclusions could be deduced for FD and NND in their mixtures with pyridine. This is understandable as $H^E = H^E(\text{chem}) + H^E(\text{phys})$ and $H^E(\text{chem}) > H^E(\text{phys})$ only if H^E is large and negative. This is more true of pyridine aniline/OT mixtures than of pyridine + FD/NND mixtures.

The present study, therefore, reveals that volumetric and enthalpic effects in binary mixtures of non-electrolytes can be rationalized by graph–theoretical arguments to yield meaningful insight into the states of the components and the energetics of the formation of binary solution from the pure components.

JOAQUIN F. PEREZ-BENITO, ENRIQUE BRILLAS, and CONCHITA ARIAS. Can. J. Chem. **68**, 79 (1990).

An iodimetric technique has been developed to quantitatively analyze the oxidants present in organic solutions. Addition of excess tetrabutylammonium iodide and excess glacial acetic acid results in the formation of tetrabutylammonium triiodide, whose concentration can be measured spectrophotometrically at 295 or 365 nm. Application of this technique to the determination of the final oxidation state of manganese in permanganate reactions in methylene chloride solutions is described. The equilibrium constant for formation of tetrabutylammonium triiodide in methylene chloride has been measured: $K = (3.48 \pm 0.12) \times 10^4$ at 25.0°C.

Key words: iodimetric determinations, manganese oxidation states, methylene chloride, quaternary ammonium permanganate, quaternary ammonium triiodide.

JOAQUIN F. PEREZ-BENITO, ENRIQUE BRILLAS et CONCHITA ARIAS. Can. J. Chem. **68**, 79 (1990).

On a mis au point une technique iodométrique permettant d'analyser d'une façon quantitative les produits oxydants qui sont présents dans des solutions organiques. L'addition d'un excès d'iodure de tétrabutylammonium et d'un excès d'acide acétique glacial provoque la formation de triiodure de tétrabutylammonium dont la concentration peut être déterminée d'une façon spectrophotométrique à 295 ou à 365 nm. On décrit l'application de cette technique à la détermination de l'état final d'oxydation du manganèse dans des réactions du permanganate dans des solutions de chlorure de méthylène. A 25°C, on a déterminé que la constante d'équilibre pour la formation du triiodure de tétrabutylammonium dans le chlorure de méthylène est $K = (3,48 \pm 0,12) \times 10^4$.

Mots clés : déterminations iodométriques; états d'oxydation du manganèse; chlorure de méthylène; permanganate d'un sel d'ammonium quaternaire; triiodure d'un sel d'ammonium quaternaire.

Introduction

Potassium permanganate is one of the most useful oxidants in the laboratory. However, its insolubility in most organic solvents prevents this substance from being more widely used in organic synthesis. Different ways of solubilizing $KMnO_4$ in low-polarity organic solvents have been reported. Among them, the use of phase-transfer agents (1) is notable: in particular, crown ethers (2) and quaternary ammonium or phosphonium salts (3) have been used. Quaternary ammonium additives are appealing because of the possibility of preparing economical, relatively stable quaternary ammonium permanganates. Many studies of permanganate reactions in non-aqueous media concerning the identification of products (4–16) and a few concerning the kinetic and mechanistic aspects of those reactions (17–19) have been undertaken. Although the application of standard techniques allowed the identification of organic reaction products, a method to determine the oxidation state of product manganese has so far been lacking.

In this paper, we report a new iodimetric technique which allows the final oxidation state of manganese in methylene chloride solutions to be measured. The general applicability of this technique is demonstrated with several organic functional groups as reductants of permanganate.

Experimental

Reagents and instrumentation

Anhydrous methylene chloride was purified by double distillation over 4 Å molecule sieves in an all-glass apparatus. Methyltributylammonium permanganate ($QMnO_4$) was obtained by precipitation from a concentrated aqueous mixture of potassium permanganate and methyltributylammonium bromide. The precipitate was separated by filtration, washed with distilled water, and dried overnight under vacuum. Purple $QMnO_4$ degenerates into brown manganese dioxide at room temperature. However, when stored in the dark and at low temperature, its decomposition can be avoided for several months.

The compounds used to reduce permanganate in methylene chloride solutions were tributylamine, methyl cinnamate, 1-decyne, 1-tridecanol, perfluorocyclohexene, formic acid, and cinnamic acid. These commercial organic substances were purified when necessary by recrystallization from a methylene chloride solution (for solids) or by simple distillation (for liquids). The reagent grade substances for the iodimetric determinations, tetrabutylammonium iodide (Q'I) and glacial acetic acid, were used without further purification.

Absorbance measurements were made with a Hewlett-Packard 8450A and a Varian Cary 219 UV-vis spectrophotometers, both provided with a thermostated cuvette holder.

Procedure

Freshly made $QMnO_4$ was dissolved in 50 mL of a methylene chloride solution containing a reducing organic compound. The permanganate concentration was 3×10^{-4} mol dm^{-3} and the reductant was in five- to ten-fold excess of the oxidant. A 3 mL aliquot was extracted and transferred to a quartz cuvette (pathlength = 1 cm), and the disappearance of permanganate was monitored at its 526 nm peak ($\epsilon = 2.63 \times 10^3$ dm^3 mol^{-1} cm^{-1}). The remaining solution was kept in a thermostated bath whose temperature was the same as that of the thermostated cuvette holder in the spectrophotometer (25.0°C). When the spectrum indicated that all the permanganate had been reduced, a 5 mL aliquot was extracted from the solution kept in the thermostated bath and transferred to a 50 mL volumetric flask. Excess tetrabutylammonium iodide (0.02 g) and glacial acetic acid (5 mL) were added, followed by dilution with methylene chloride up to 50 mL. The solution was stirred and its absorbance was measured.

Some precautions have to be taken when using this iodimetric technique: (*1*) The solvent must be perfectly anhydrous to avoid precipitation of manganese dioxide during the reduction of permanganate; (*2*) a large excess of acetic acid (which acts as a catalyst) must be used to accelerate the iodimetric reaction; (*3*) the iodimetric absorbance measurement must be made as soon as the corresponding solution is

Printed in Canada / Imprimé au Canada

prepared because quaternary ammonium iodide in methylene chloride solutions tends to spontaneously liberate iodine in the presence of light.

Results and discussion

Iodimetric determinations

A red solution was expected to be obtained from the oxidation of Q'I, its spectrum being that of iodine in methylene chloride solutions (broad peak at 504 nm). However, a yellow solution was obtained instead, its spectrum showing two definite peaks at 295 and 365 nm. The same spectrum was recorded when excess quaternary ammonium iodide was added to a solution of iodine in methylene chloride, the colour changing from red to yellow. Moreover, the spectrum of the yellow species in methylene chloride very much resembled that of triiodide ion in water (peaks at 287 and 351 nm). Therefore, the product obtained from the iodimetric technique can be identified as $Q'I_3$, formed by addition of a molecule of Q'I to the iodine liberated by the oxidant contained in the methylene chloride solution.

Excess Q'I was added to several solutions of iodine in methylene chloride to prepare $Q'I_3$ solutions of different concentrations. Their respective absorbances at 295 and 365 nm were measured in the spectrophotometer. Fulfillment of the Beer's law at those wavelengths was excellent, the results being:

$$[1] \quad A(295) = (0.003 \pm 0.004) + (4.511 \pm 0.015) \times 10^4 [Q'I_3]$$

$$[2] \quad A(365) = (-0.005 \pm 0.003) + (2.577 \pm 0.013) \times 10^4 [Q'I_3]$$

The linear correlation coefficients in eqs. [1] and [2] are 0.99998 and 0.99995, respectively (six points per equation). Hence the concentration of $Q'I_3$ in a methylene chloride solution can be determined with accuracy by means of its absorbance at either of those two wavelengths.

The final oxidation state of manganese in the iodimetric experiments was obtained by reducing several methylene chloride solutions of $QMnO_4$ with excess Q'I in the presence of acetic acid. The results from different determinations indicated that the triiodide liberated and the permanganate consumed were in the following ratio:

$$[3] \quad [Q'I_3]/[QMnO_4] = 5/2\ (\pm 2\%)$$

which corresponds to the following stoichiometry:

$$[4] \quad 2QMnO_4 + 15Q'I + 16HAc \rightarrow 2MnAc_2 + 5Q'I_3 + 10Q'Ac + 2QAc + 8H_2O$$

Thus, the final oxidation state of the manganese atom in the iodimetries is II.

Therefore, if a solution containing manganese with an oxidation state equal to s (its value being between VII and II) is subjected to the iodimetric technique described above, the stoichiometric ratio expected for the reaction is:

$$[5] \quad [Q'I_3]/[Mn^s] = (s - 2)/2$$

It is clear that the value of s can be obtained by means of eq. [5]. However, more accurate values of the oxidation state can be determined if two identical aliquots of two solutions with the same concentration of oxidizing agent ($QMnO_4$ one of them, and Mn^s the other) are subjected to iodimetric titration. Then, s, can be obtained as:

$$[6] \quad s = 2 + 5\,[Q'I_3]_P/[Q'I_3]_R$$

where $[Q'I_3]_P$ and $[Q'I_3]_R$ are the concentrations of $Q'I_3$ liberated by the product (Mn^s) and the reactant ($QMnO_4$) solution, respectively. The higher reliability of eq. [6] (cf. eq. [5]) is based upon the fact that when eq. [6] is used the systematic errors made in the determination of $[Q'I_3]_P$ and $[Q'I_3]_R$ are partially compensated.

TABLE 1. Final oxidation states of manganese for the reduction of methyltributylammonium permanganate by several organic compounds in methylene chloride solutions[a]

Organic compound	Oxidation state
Tributylamine	4.04
Methyl cinnamate	4.01
1-Decyne	3.97
1-Tridecanol	3.97
Perfluorocyclohexene	3.25
Formic acid	3.25
Cinnamic acid	2.99

[a]The average standard deviation for each oxidation state was ±0.05.

The results obtained when this iodimetric technique was applied to the product solutions from the reduction of $QMnO_4$ by several organic compounds in methylene chloride are summarized in Table 1. These results were confirmed from the spectra of the corresponding solutions, since a broad band with the absorbance uniformly decreasing as the wavelength increases was recorded when the iodimetric technique showed that the oxidation state was ca. IV (tributylamine, methyl cinnamate, 1-decyne, and 1-tridecanol as reductants), that band being typical of colloidal MnO_2 (20–26), which may be stabilized in methylene chloride by adsorption of the substance used to reduce permanganate on the surface of its colloidal particles. However, when the iodimetric technique led to a value of ca. III (cinnamic acid as reductant) the spectra exhibited a peak at 470 nm typical of Mn (III) (27–29), the nature of the Mn(III) species being still unknown. On the other hand, the non-integral value s = 3.25 obtained when the reductants were perfluorocyclohexene and formic acid indicates the existence of either Mn(IV)–Mn(III) or Mn(IV)–Mn(II) mixtures.

Although the iodimetric technique described in this paper has been developed for the determination of manganese oxidation states in methylene chloride solutions, we believe that it might also be used to determine the presence of different kinds of oxidants in other low-polarity organic solvents.

Equilibrium constant

The equilibrium constant for the formation of $Q'I_3$ in methylene chloride has been determined. The method was tested first for the equilibrium corresponding to the formation of triiodide ion in water solutions. This reaction can be written as:

$$[7] \quad I_2 + I^- \rightleftharpoons I_3^-$$

Since I_2 is a non-charged species, its activity coefficient is near unity; since both I^- and I_3^- are monovalent ions, the ratio between their respective activity coefficients is (according to the Debye-Hückel theory) also near unity. Therefore, the equilibrium constant associated with eq. [7] can be approximately written as:

$$[8] \quad K = c_3/c_2c_1$$

where c_1, c_2, and c_3 are the molar concentrations of I^-, I_2, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

I_3^-, respectively (the subscript indicates the number of iodine atoms in the corresponding species). If I_3^- is formed from a mixture of I_2 and a great excess of I^-, then:

[9] $$K = c_3/(c_2^0 - c_3)\,c_1^0$$

where the concentration of iodine in the equilibrium mixture is given by the difference between the initial concentration of iodine (c_2^0) and the concentration of triiodide ion (c_3). The decrease in the concentration of iodide ion has been taken as negligible against its initial concentration (c_1^0): the condition $c_1^0 \gg c_2^0$ implies also that $c_1^0 \gg c_3$. From eq. [9] it can be inferred that

[10] $$c_1^0\,c_2^0/c_3 = 1/K + c_1^0$$

The following equation was obtained at 25.0°C for several solutions of iodine (ranging from 0.8 to 4.0×10^{-5} mol dm^{-3}) and potassium iodide (from 1.2 to 5.9×10^{-3} mol dm^{-3}) in water:

[11] $$c_1^0\,c_2^0/c_3 = (1.50 \pm 0.06) \times 10^{-3} + (0.985 \pm 0.014)\,c_1^0$$

The corresponding plot is linear (correlation coefficient = 0.9997, number of points = 5); furthermore, we can see that the slope is in good agreement with the value expected (unity, see eq. [10]). From the intercept, the equilibrium constant $K = (6.67 \pm 0.25) \times 10^2$ is obtained for the formation of triiodide ion in aqueous solutions at 25.0°C. This result agrees with the value reported in the literature (30).

The same procedure was repeated with several solutions of iodine (ranging from 0.2 to 1.1×10^{-5} mol dm^{-3}) and Q'I (from 0.5 to 2.6×10^{-4} mol dm^{-3}) in methylene chloride. The resulting equation is

[12] $$c_1^0\,c_2^0/c_3 = (2.87 \pm 0.10) \times 10^{-5} + (0.976 \pm 0.006)\,c_1^0$$

The corresponding plot was also linear (correlation coefficient = 0.99994, number of points = 5), and the slope was also near unity (see eq. [10]). From the intercept, the equilibrium constant for the formation of tetrabutylammonium triiodide in methylene chloride solutions is $K = (3.48 \pm 0.12) \times 10^4$ at 25.0°C. The availability of the latter equilibrium constant is important to the iodimetric technique described in this paper, since the spectrophotometric measurements require that the excess of Q'I with respect to I_2 be large enough to ensure that almost all the iodine liberated is present as $Q'I_3$. Since the ratio of equilibrium constants is $K(CH_2Cl_2)/K(H_2O) = 52$, the required excess of Q'I in methylene chloride solutions is lower than that of potassium iodide in aqueous media.

Received April 12, 1989

RONALD W. THRING, ESTEBAN CHORNET, JEAN BOUCHARD, PIERRE F. VIDAL, and RALPH P. OVEREND. Can. J. Chem. **68**, 82 (1990).

Lignin residues from the alkaline hydrolysis of solvolytic lignin have been characterized by elemental analysis, size exclusion chromatography, Fourier transform infrared spectroscopy, ^{13}C NMR, and for methoxyl content. All lignin residues were found to have higher carbon and lower oxygen contents than the original glycol lignin. Methoxyl contents decreased with increasing severity of treatment. All treated lignins have lower molecular weights than the original, which is indicative of the extensive depolymerization of glycol lignin by alkaline hydrolysis. The appearance of new bands in the 3050–2800 cm^{-1} and 900–800 cm^{-1} regions in the infrared spectra along with increasing absorption intensity under more severe conditions demonstrates that, despite the tendency to depolymerization, new carbon–carbon bonds are formed due to repolymerization reactions. ^{13}C NMR revealed that extensive cleavage of the side chains and β-O-4 interunit linkages had occurred during alkaline hydrolysis and that the new bonds formed due to condensation reactions at higher severities are of the methine, methylene, methyl and carboxyl types.

Key words: residual lignins, alkaline hydrolysis, characterization.

RONALD W. THRING, ESTEBAN CHORNET, JEAN BOUCHARD, PIERRE F. VIDAL et RALPH P. OVEREND. Can. J. Chem. **68**, 82 (1990).

Des lignines solvolytiques obtenus par un traitement solvolytique avec l'éthylène glycol ont été dépolymérisées hydrolytiquement en milieu aqueux alcalin à haute temperature. Une partie de la lignine est solubilisée en forme des monomères et d'oligomères. La fraction non-solubilisée constitue la lignine résiduelle que nous avons caractérisée par analyse élémentaire, teneur en groupements méthoxy, chromatographie d'exclusion par la taille, spectroscopie infrarouge à transformée de Fourier, et spectroscopie de RMN ^{13}C. Les lignines résiduelles issues de la dépolymérisation à différents niveaux de sévérité ont une teneur en carbone plus élevée que la lignine solvolytique initiale. La teneur en groupements méthoxy diminue avec la sévérité du traitement. Toutes les lignines résiduelles ont des poids moléculaires infrérieurs à ceux de la lignine initiale : effet de la dépolymérisation hydrolytique. La présence de pics, dans le spectre infrarouge dans les régions 3050–2800 cm^{-1} et l'augmentation de leur intensité avec la sévérité du traitement, suggère que de nouveaux liens C—C dus à des recondensations sont formés. Des analyses RMN au ^{13}C ont montré que le clivage des chaines alkyles et des liens β-O-4 a eu lieu pendant l'hydrolyse en milieu alcalin. Aussi de nouveaux liens ont été crées par des réactions de condensation induites à haute sévérité. Ces nouveaux liens sont du type méthine, méthylène et méthyle ainsi que carboxyle.

Mots clés : lignines résiduelles, hydrolyse alcaline, caractérisation.

Introduction

A large number of publications have dealt with the depolymerization of lignin to obtain monomeric compounds, and have been comprehensively reviewed by Goheen (1), Goldstein (2), and more recently by Chum *et al.* (3).

One method commonly employed to separate the reaction products derived from lignin depolymerization into liquid and solid phases uses acid to precipitate the unreacted (unconverted) lignin as well as to convert the phenate salts in solution to phenols. These phenolic compounds are then isolated from the liquid phase by extraction with a selective solvent (4–6). Such "residual lignins" recovered from the established degradation techniques have not been extensively studied or characterized. Connors *et al.* (7), for example, hydrocracked kraft lignin in a hydrogen-donor solvent (tetralin). The unconverted lignin, isolated as an "acetone soluble" solid, was examined by GPC, IR, and NMR, and it was concluded that extensive side-chain cleavage had occurred, as well as a reduction in molecular weight.

Much of the interest in lignin degradation has been focussed upon the production of low molecular weight chemicals, especially monomeric compounds. The work conducted in this area by many workers has confirmed the production of numerous compounds whose individual yields have so far been too low to warrant commercialization.

The aim of the present work was to characterize the lignin remaining after depolymerizing glycol lignin in alkaline media at conditions of different severities. Such a study would possibly elucidate new uses of isolated glycol lignin, which has been found to be a potential source of phenolic compounds by Thring *et al.* (8). This paper then deals with a comparative characterization of these lignin residues under conditions of increasing reaction severity.

Experimental

Preparation of residual lignins

Glycol lignin was isolated from the hardwood *Populus deltoides* by the method described previously (8).

The alkaline hydrolysis was carried out in a 500-mL stainless steel autoclave equipped with a magnetic stirrer. The procedure adopted was to load the reactor with 5 g of dried (50°C in a forced-air oven for 14 h) lignin and 100 mL of a 2% (w/w) aqueous sodium hydroxide solution. The glycol lignin dissolved completely upon agitation in this medium. After pressure testing for leaks, the batch autoclave was flushed twice with nitogen. The stirrer was then set to 500 rpm and switched on.

To start a run, the reactor was immersed in a preheated salt bath whose initial temperature was at a value such that the reaction temperature of the mixture reached the desired value (±2°C) within 10 min. The reaction temperature – time history was continuously

TABLE 1. Reaction conditions used for obtaining residual lignins

Expt. no.	Temp. (°C)	Time (h)	$\log_{10}R_0$
1 (RL-1)	180	1	3.6
2 (RL-2)	235	1	5.8
3 (RL-3)	300	1	7.7
4 (RL-4)	340	1	8.5

Heat-up rate, 30°C/min; cool down rate, 44°C/min. Rate of agitation, 500 rpm; substrate/solvent ratio, 5 g dry lignin/100 mL (2% wt. NaOH).

recorded for subsequent calculation of a reaction ordinate, to be defined later. These reaction conditions were as follows: temperatures of 180, 235, 300 and 340°C, for 1 hour (Table 1). Maximum reaction pressures did not exceed 3.8 MPa even for the most severe conditions (340°C, 1 h) employed.

To end the reaction, the reactor was quenched in a cold water bath. The stirrer and data acquisition system were stopped when the reactor temperature reached ambient. The reactor was depressurized, removed from its frame, opened, and its contents recovered.

The product slurry was filtered and the remaining residue rinsed with water. The residual lignin (RL) was precipitated from the filtrate by acidification to a pH of 1–2 with addition of a 10%(v/v) solution of aqueous HCl, filtered, and then dried in a vacuum desiccator for 2 days. The analysis carried out on the liquid phase and the results have been discussed (8).

Elemental analysis

The samples were analysed for C, H, and N using a Perkin–Elmer model 240 C elemental analyzer in our laboratories. Oxygen was determined by difference.

Methoxyl content

Determinations of methoxyl content were made according to the method initially proposed by Zeisel (9) and later modified by Haluk and Metche (10).

High performance size exclusion chromatography (HPSEC)

Analysis by HSPEC was performed with a Varian 5000 liquid chromatograph connected to an on-line computer (NEC APCIV) via a Waters Maxima 820 data system. Two stainless steel columns connected in series were used (length 30 cm; i.d. 7.5 mm) packed with PLgel spherical particles (Polymer Laboratories) of particle size 5–10 μm, and pore sizes 50 Å (column 1) and 500 Å (column 2). Detection was made with a UV monitor at 254 nm. A constant flow rate through the system was maintained by a single-piston reciprocating pump. The following operating conditions were utilized: eluent, tetrahydrofuran (continuously bubbled with N_2 to prevent the formation of peroxides); flow rate, 1 mL/min; pressure, 7.0 MPa; temperature, 20–25°C; injection volume, 10 μL; sample concentration, 1 mg/mL.

The calibration curve was obtained using monodisperse polystyrene compounds of known molecular weight as reference substances. A third-order polynomial of the form $y = ax^3 + bx^2 + cx + d$ best describes the relation between the log of the actual molecular weights of polystyrene standards (y) and their retention volumes (x). The following coefficients were calculated: $a = -0.00714$, $b = 0.3253$, $c = -5.149$, and $d = 30.69$. These gave a fit with a multiple regression coefficient of $r^2 = 0.998$.

Infrared spectra

Lignin samples were prepared in a KBr matrix at a concentration of 1–2% (w/w) by grinding in a stainless steel ball mill for 30 s at room temperature. Spectra were obtained from a 5DXB Nicolet FTIR spectrometer in diffuse reflectance mode using the collector cell (Spectra-Tech). Conditions of analysis were as follows: resolution 4 cm^{-1}; coadding 400 scans; frequency range of 400–4600 cm^{-1} (DTGS detector); Happ–Genzel apodization.

^{13}C NMR

^{13}C NMR spectra of the acetylated lignin samples were obtained with a Bruker 250 WM Fourier transform spectrometer. Deuterated dimethyl sulfoxide (DMSO-d_6) was used as solvent. Sample concentrations of ca. 800 mg in 2 mL of DMSO-d_6 were placed in 10 mm i.d. glass tubes and run at a temperature of 50°C. The instrument was set in proton inverse gated decoupled mode and the delay between scans was 2 s.

Acetylation of lignins

The criteria used for a successful acetylation method were the complete solubility in tetrahydrofuran and the absence of the OH absorption band in the IR spectrum of the acetylated product. An effective method for our samples consisted of adding 5 mL of pyridine to about 0.5 g of sample (dried at 60°C overnight *in vacuo*) with stirring. Acetic anhydride (5 mL) was then added, the mixture flask flushed with nitrogen and sealed, and stirring continued for 2 days at room temperature. The product was recovered by precipitation in an ice–water mixture, filtered, and dried at room temperature under vacuum overnight.

Results and discussion

The yields of lignin residue are shown in Fig. 1 as a function of severity of treatment R_0 whose significance and utility have been discussed elsewhere (11). The reaction ordinate, R_0, is defined as $R_0 = t \times \exp((T-100)/14.75)$; t = time (min), and T = temperature (°C). As seen, R_0 varies exponentially with temperature and linearly with time. In our case, R_0 was varied by increasing T, keeping t constant. A reduction in the yields with increasing severity may then be attributed primarily to the increasing importance of pyrolytic reactions. These reactions give rise to extensive C—C and C—O—C bond cleavage in the lignin and its primary decomposition fractions to produce volatile products and char.

Elemental composition of residual lignins

The results shown in Table 2 are average values from duplicate analyses of the samples. Using the original lignin as reference, a number of trends are observed.

The C content of all the residual lignins is higher than that of the original lignin and increases linearly with treatment severity when the latter is expressed as $\log_{10}R_0$, as shown in Fig. 2. The O content is observed to decrease with increasing severity. Chua and Wayman (12) observed a similar trend for autohydrolysis lignins of aspen (*Populus tremuloides*) at 195°C with increasing reaction time, and attributed these changes to (a) condensation reactions which involve the elimination of water, and (or) (b) incorporation into the lignin of entities derived from carbohydrates having higher C to H/O ratios formed during autohydrolysis, and (or) (c) the initial preferential removal of syringyl rather than guaiacyl units at the shorter hydrolysis times.

The higher heating values of the lignins, shown in Table 2, were determined using Dulong's formula (13). This formula is claimed to usually give heating values within 5% error. It is evident that the alkaline hydrolysis of glycol lignin with increasing severity of treatment produces residual lignins of higher heating values than the original lignin. It is noteworthy to point out that residual lignin RL-3 (C.V. = 28.5 MJ/kg) was obtained under the same reaction conditions that gave the highest amount (11%) of identifiable monomeric compounds, based on the original lignin, of which 9%, also based on the original lignin, were catechols (8). Thus, at these optimum reaction conditions, we not only obtain monomeric degradation products that can be used as chemical feedstocks, but also produce a residual lignin that can be utilized as a fuel source of higher heating value than the original glycol lignin.

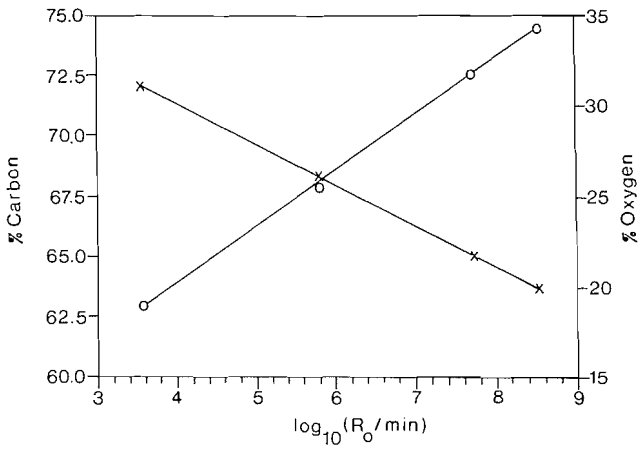

FIG. 2. Carbon (O) and oxygen (X) content of residual lignins versus severity of treatment.

Another trend is the steady decrease in the methoxyl content with increasing severity of reaction. This may be attributed to the increase in pyrolytic/hydrolytic reactions, giving rise to demethylation and demethoxylation of the lignin to produce gaseous and liquid products. Evidence of demethylation is found in the occurrence of catechol and its derivatives in the ether-soluble fraction containing low molecular weight products (8). These products occurred only under conditions of medium to high severity. The presence of methanol in the hydrolysate liquids, especially at higher R_0, provided direct evidence of demethoxylation of the lignin during alkaline

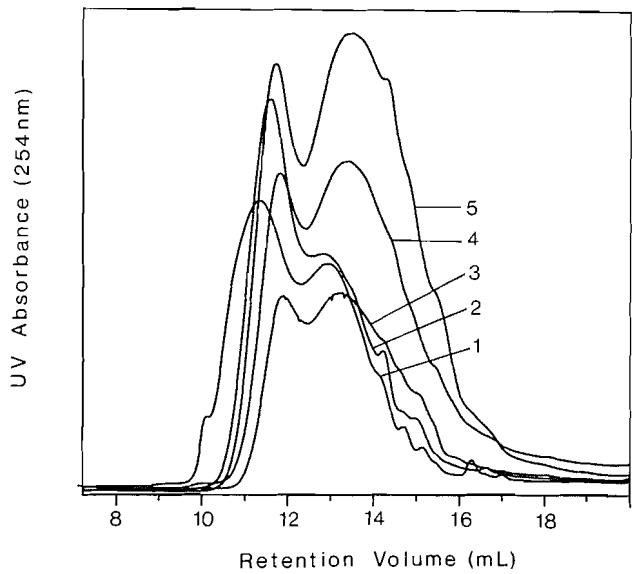

FIG. 3. Molecular weight distribution (polystyrene equivalents) of (1) glycol lignin, (2) RL-1, (3) RL-2, (4) RL-3, and (5) RL-4.

hydrolysis. Pepper and Siddiquellah (14), in their lignin acidolysis work, also encountered similar changes in the content of C, H, and O and a lowering in the methoxyl content with increasing time of acidolysis. Furthermore, it was previously seen (8) that the mass yields of syringol and guaiacol increased and then, under more severe reaction conditions, decreased. Since these contain most of the methoxyl groups in the lignin macromolecule, a variation in the proportion of these units would also account for the observed trend in methoxyl content in the residue.

High performance size exclusion chromatography (HPSEC)

In the last decade HPSEC, using polystyrene beads and organic solvents such as THF, has become a widely used method to study the molecular weight distribution (MWD) of isolated, modified lignin samples.

Although it is generally agreed that this technique allows the fractionation of a polydisperse polymer into fractions of difference molecular size, the quantification of each fraction into terms of molecules N_i (or weight fraction W_i) as well as the correlation between the elution volume and corresponding molecular weight M_i is still a matter of argument. The use of UV detection for lignins is very common. Since this detection method is governed at low substrate concentrations by the Beer–Lambert law, a usual assumption is that the molar extinction coefficients are proportional to the molecular weights, that is, the weight absorption coefficients are constant throughout the MWD. According to Lange *et al.* (15), non-homogeneity in such coefficients for organosolv lignins leads to an error of not more than 5% in the molecular weight determination by HPSEC. Moreover, when considering the method of calibration employed, the molecular weight values presented herein should be taken as polystyrene-standard equivalent molecular weights.

As shown in Fig. 3, a common and prominent feature of all the molecular weight distribution patterns is the occurrence of two absorption maxima. Table 3 presents the molecular weight values MW_{p1} and MW_{p2} at the two absorption maxima associated with the low and high MW fractions, their corresponding degree of depolymerization DP_1 and DP_2 calculated on the

basis of a monomer having a molecular weight of 205 daltons, as well as the H_2/H_1 ratio, which represents the height of the high-MW maximum over the height of the low-MW maximum derived from Fig. 3. The most important effects of the severity of the alkaline treatment on the glycol lignin are (a) a slow decrease of MW_{p1}, (b) a rapid decrease of MW_{p2} for reaction conditions having $\log_{10}R_0$ values in the range 3.6–5.8, followed by an increase under more severe conditions, and (c) a variation of the ratio H_2/H_1 from an initial value of 1.4 to a value of 1.6 at $\log_{10}R_0 = 3.6$ and to a plateau value close to unity for conditions having $\log_{10}R_0$ values in the range of 5.8–8.5.

When interpreting the results derived from Fig. 3, it may be concluded that the variation of the H_2/H_1 ratio reflects the depolymerization of high molecular weight material (MW_{p2}), which transforms significantly into low molecular weight material (MW_{p1}) under the three most severe conditions, while

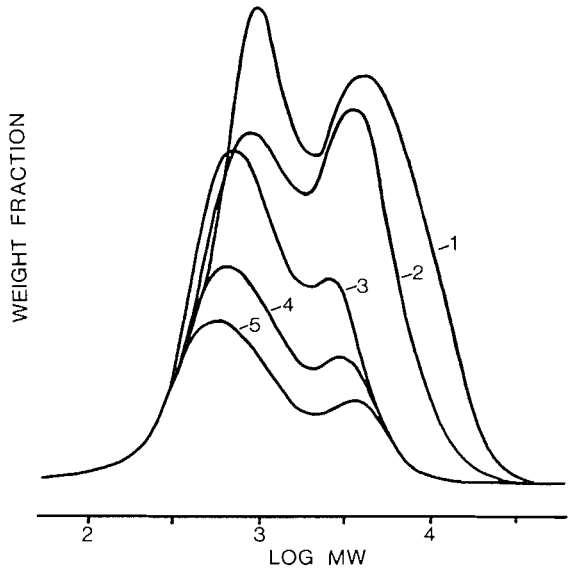

FIG. 4. Molecular weight distribution (polystyrene equivalents) by weight of (1) glycol lignin, (2) RL-1, (3) RL-2, (4) RL-3, and (5) RL-4.

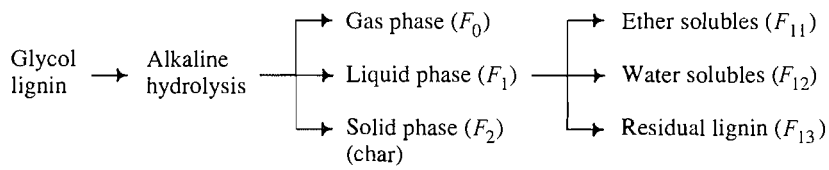
at $\log_{10}R_0 = 3.6$, the depolymerization of the low molecular weight material is predominant over the depolymerization of MW_{p2} into MW_{p1}.

This interpretation does not take into account the fact that the analysed residual lignin samples represent only a fraction of the starting glycol lignin, which depolymerizes and solubilizes in basic media according to the following process scheme:



SCHEME 1

In Fig. 4 we have plotted the molecular weight distributions of each sample so that the area under the curve is proportional to the reaction yield of the given residual lignin (shown in Table 4). The trend with increasing severity is now clear: while the yield of the residual lignin (F_{13}) decreases along with its molecular weight (Fig. 4), there is also an increase of the yield of the char fraction (F_2) as shown in Table 4. This char must be a result of extensive cross-linking of the residual lignin. It is clear that at the severity corresponding to the RL-3 experiment recondensation reactions begin to be significant and at the highest severity (RL-4) they predominate over the depolymerization reactions.

The picture that emerges is then rather straightforward. In the alkaline hydrolysis of glycol lignin, depolymerization is the predominant mechanism at low severities with recondensation dominating with increasing severities. The optimum reaction conditions, defined as those at which the maximum yield of monomer fraction is obtained concomitant with a decrease in the MW of the lignin without char formation, should lie at $\log_{10}R_0$ values in the range of 5.8–7.7. At optimum, the yield of ether solubles (F_{11}) attains a value of about 25% of the mass of initial glycol lignin used and the residual lignin (RL) still has molecular properties similar to those of the initial material.

From the MWD patterns in Figs. 3 and 4 it is clear that a bimodal MW distribution is present in glycol lignin, which is composed principally of a low molecular weight subunit (DP = 5–6) and a high molecular weight macrostructure (DP = 26). Wayman and Obiaga (16) proposed the concept of a "modular structure" of lignin and they provided experimental evidence by means of which a molecular weight of 5400 (DP = 26) was derived. This value coincides with our high molecular weight macrostructure. The presence of a low molecular weight subunit is consistent with the cleavage of specific bonds in the high molecular weight macrostructure. This cleavage is accomplished by the action of the OH^-ion in our experiments. Since the initial glycol lignin also shows a low molecular weight fraction, one must conclude that our ethylene glycol treatment either isolates a lignin fraction that has already been cleaved at specific linkages via an unknown mechanism in which the glycol must play a "solvolytic effect" or helps to disaggregate specific complexes that already have a low molecular weight material. The alkali treatment leads to the depolymerization of both the high and low molecular weight fractions. The preferred route is probably the cleavage of ether bonds (see below). At higher severities the loss of the alkyl groups (see also sections on FTIR and ^{13}C NMR) could explain why the DP of the low molecular

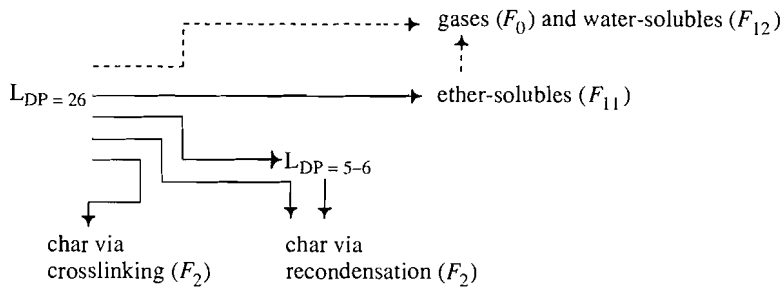
*Calculated by difference; F = product fractions (% of starting lignin).

weight unit is reduced to a value of 4. In fact, if the loss of alkyl groups is accounted for in the evaluation of the molecular weight of a monomer, then the DP would stay at 5–6 regardless of the treatment severity.

A mechanistic view of the alkaline depolymerization of glycol lignin consistent with our results can thus be presented as follows:



SCHEME 2

At low severities, the depolymerization of the higher molecular weight macrostructure (DP = 26), either through the intermediate (DP = 5–6) or directly through specific cleavages, liberates low molecular weight compounds that in the final separation appear predominantly as ether-solubles and some water-solubles. At high severities, extensive cross-linking of the macrostructure and recondensation of the DP = 5–6 subunit leads to char and gas formation with a decrease in the yield of liquid products.

FTIR spectra

In the present investigation, comparisons are made between the spectra of the residual lignins obtained from the alkaline hydrolysis of glycol lignin at different conditions of severity. Assignments for the absorption bands are based on the information given by Sarkanen *et al.* (17), Herget (18), and Winston (19).

The following comments may be made by comparing the spectra shown in Fig 5:

1. The spectra of RL-1 and RL-2 are essentially similar to that of the original lignin except for a general decrease in the relative band intensity in the 1600–1100 cm^{-1} region and a small broadening of the bands.

2. Increasing the severity of treatment to obtain the RL-3 and RL-4 fractions significantly modifies the residual lignin. Major absorption bands have disappeared and these spectra are now almost unrelated to that of the original lignin. However, the increase in the reaction severity between the RL-3 and RL-4 experiments does not significantly modify the residual lignins isolated, since the spectra are identical.

As the severity of the treatment increases, the hydroxyl absorption band spreads out and its maximum of absorbance shifts from 3460 cm^{-1} for glycol lignin to 3320 cm^{-1} for the RL-4 sample. This may be interpreted as a decrease in the aliphatic/phenolic hydroxyl group ratio with an increase in the carboxylic acid groups (also suggested by the increase in the relative intensity of the 1710 cm^{-1} band) with increasing severity.

Bands in the 1330–1035 cm^{-1} region, due to aromatic ether ring breathing and aromatic C–H deformation of the syringyl and guaiacyl units, decrease in relative intensity with increasing severity and have almost completely disappeared in the RL-3 and RL-4 samples. This indicates cleavage of the ether linkages and the liberation of methylene and methoxyl groups.

The spectra of RL-3 and RL-4 indicate that the glycol lignin has been extensively degraded and modified by the hydrolytic treatment, as seen by their characteristically less defined absorption bands. The similarity in band intensity of these residual lignins, even though the severities are substantially different, provides further evidence that glycol lignin degrades to products and a remaining core structure, which is relatively stable even at high severities of treatment. The position of the peaks indicates that these residual lignins are still aromatic in character, even though restructuring by degradation and recondensation has occurred as shown by the appearance of new bands in the 3050–2800 cm^{-1} and 900–800 cm^{-1} regions.

^{13}C NMR spectra

The ^{13}C NMR spectra of the acetylated samples of glycol lignin and residual lignins are given in Figs. 6(a) and (b). Table 5 presents assignments of the important signals as proposed by Lapierre *et al.* (20), Mörck and Kringstad (21, 22), Kanazawa *et al.* (23), and Robert (24). Comparison between the spectra reveals a number of important features.

Signals 1 and 2 (assigned to aliphatic carboxyl groups) are absent in glycol lignin but increase considerably in intensity for the series RL-1, RL-2 to RL-3, RL-4.

The intensities of signals 3 and 4 (primary and secondary aliphatic hydroxyl groups respectively) are highest in the glycol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

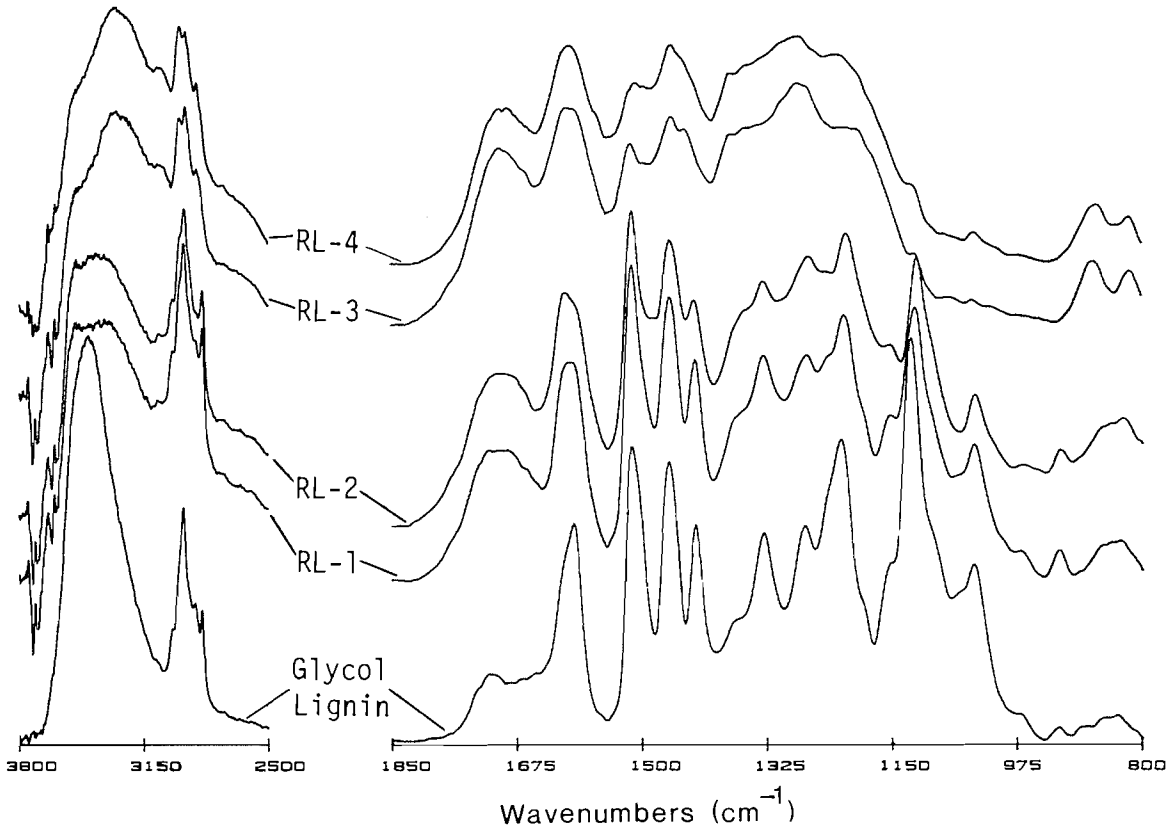


FIG. 5. Infrared spectra of glycol lignin and residual lignins.

lignin but are much lower in RL-1 and RL-2, and absent in RL-3 and RL-4. This indicates extensive cleavage of the alcohol-containing side chains of glycol lignin during alkaline hydrolysis. The intensity of signal 5 (phenolic hydroxyl), on the other hand, increases significantly in intensity from the initial lignin to RL-4. This is to be expected since it is known that hydrolysis of lignin with sodium hydroxide increases the phenolic hydroxyl groups in lignin (22).

The decrease in intensity of signals 6 and 8 (syringyl) and the corresponding increase in the intensity of signal 7 (guaiacyl) indicate that one of the important reactions occurring during the alkali treatment of glycol lignin with increasing severity of reaction conditions is demethoxylation/demethylation of syringyl-type groups to more stable guaiacyl-type structures within the lignin macromolecule.

The 110–148 ppm region (aromatic carbons) is difficult to interpret in detail. The broad signal at 137–148 ppm, particularly in RL-3 and RL-4, may originate from phenolic carbons in catchol units (23). The presence of well-defined signals in RL-4 in this region suggests that new C–C bonds are formed in the residual lignin due to condensation reactions.

The low intensity of signal 10 (carbohydrates) in glycol lignin and its absence in all the residual lignins indicate that this signal is probably from a lignin–carbohydrate complex (LCC). Analysis for sugars (monosaccharides) by acid hydrolysis in glycol lignin revealed that these were present in low quantities (<1%) (8). Since the lignin was thoroughly washed with distilled water during its preparation, these sugars are most likely from a LCC whose carbohydrate component is easily cleaved upon alkaline hydrolysis.

The presence and intensities of signals in the 64–85 ppm region (aliphatic carbons) in the spectrum of glycol lignin suggest that cleavage of interunit linkages (-C—C- and -C—O—C-) as well as those of side chains is insignificant during the lignin recovery step. This reaffirms the previous conclusion (8) on the high amount of oxygenated interlinkages of the β-O-4 type from observation of the spectrum of unacetylated glycol lignin. The noticeable reduction in intensity of the signals in this region

TABLE 5. Assignments of important signals in the ^{13}C NMR spectra of acetylated glycol lignin and residual lignins

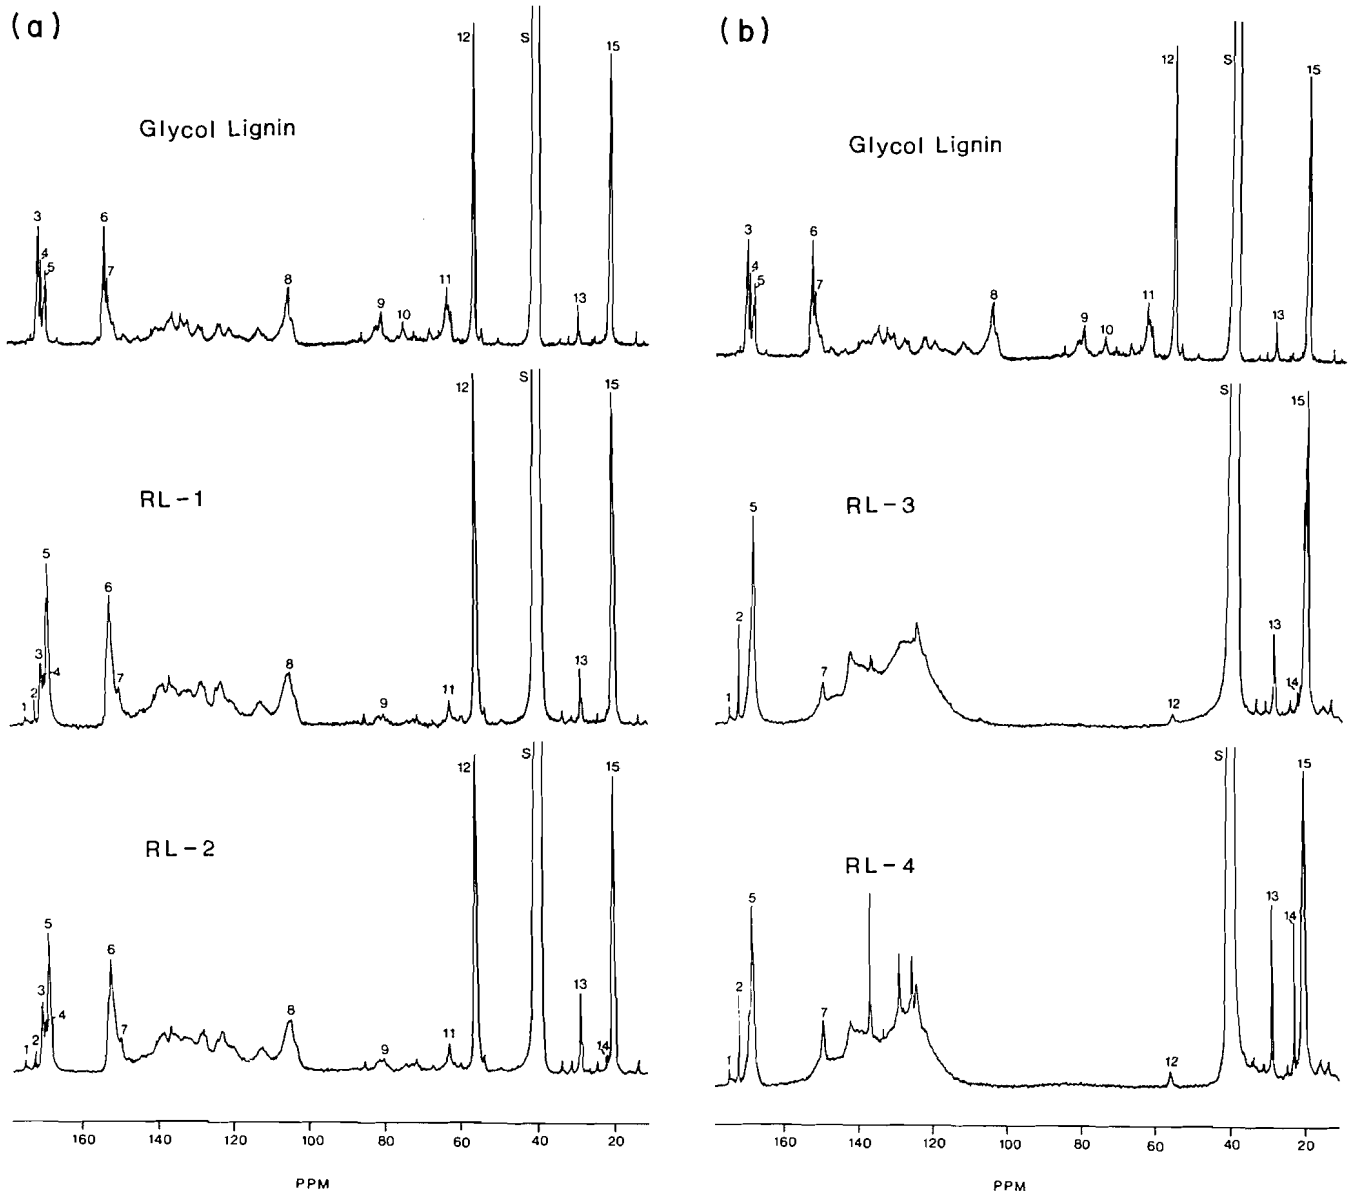

FIG. 6. ^{13}C NMR spectra of glycol lignin and residual lignins.

(RL-1 and RL-2) and their subsequent disappearance (RL-3 and RL-4) with increasing severity of reaction conditions, particularly signals 9 and 11 (β-O-4 carbons), demonstrate the facile rupture of these bonds in glycol lignin during alkaline hydrolysis.

The dramatic decrease in intensity of signal 12 (methoxyl carbons) from RL-2 to RL-3 is further evidence of the extensive demethoxylation of glycol lignin at higher reaction severities. This result confirms the analytically determined values of the methoxyl group content of the residual lignins shown in Table 2.

The appearance of new signals in the 10–34 ppm region (methine, methylene, and methyl carbons) and the increase in intensity of signals 13 and 14 at higher reaction severities suggest the formation of new bonds due to condensation reactions. As suggested by Gierer *et al.* (25), these reactions involve intermediary coniferyl alcohol structures generated after initial cleavage of phenolic β-aryl ether bonds, and may introduce conjugated double bonds as well as saturated hydrocarbon structures to the side chains in lignin. However, signals in the 25–34 ppm region, particularly signal 13, may include contributions from other types of condensation reactions (21).

Conclusions

The results of this study demonstrate how severity of treatment influences the structure and chemical composition of glycol lignin during depolymerization by alkaline hydrolysis. Complementary information on these chemical changes was obtained from elemental analysis, methoxyl determination, GPC, FTIR, and ^{13}C NMR methods.

It is apparent that as the severity is increased, the residual lignin becomes more highly condensed and even carbonized. The molecular weight distribution patterns show that the residual lignins largely consist of a high molecular weight fraction and a lower molecular weight one, with the latter increasing relative to the former with severity of treatment. Infrared spectroscopy and ^{13}C NMR have, in particular, demonstrated that during the alkaline hydrolysis of glycol lignin, depolymeriza-

tion/repolymerization reactions are competing, with the repolymerization reactions becoming more evident at higher severity conditions, as shown by the appearance of new bands and signals of increasing relative intensity in the spectra of the residual lignins. The lignin is extensively demethylated and demethoxylated at higher severity conditions during alkaline hydrolysis.

The evidence presented shows that the residual lignins obtained from the alkaline hydrolysis of glycol lignin, although drastically modified from the original lignin, still remain aromatic in character. Also, since the calorific value of these residual lignins is increased with treatment severity, they could be utilized as a fuel source of higher heating value than the original lignin, in a depolymerization process of glycol lignin by alkaline hydrolysis targeting monomeric compounds (i.e., catechol) and residual fuel to run the process.

Scaled *ab initio* force field and vibrational spectra of 2-methylthietane

R. A. SHAW, N. IBRAHIM, AND H. WIESER[1]

Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received July 18, 1989

R. A. SHAW, N. IBRAHIM, and H. WIESER. Can. J. Chem. **68**, 90 (1990).

The vibrational spectra have been measured for 2-methylthietane over the range 100–1600 cm^{-1} (Raman) and 400–3200 cm^{-1} (solution and vapour phase infrared). *Ab initio* calculations at the 3-21G and 6-31G* levels indicate that both the axial and equatorial conformers represent minima on the ring inversion potential surface, the latter suggesting the equatorial species to be more stable by 191 cm^{-1}. Vibrational force fields were evaluated for each of the two conformers and scaled using factors previously optimized for thietane and 2-methyloxetane. All of the major experimental features were readily assigned to the equatorial species, and most transitions expected for the axial species were also located. Calculated absorption intensities, although not accurate in an absolute sense, proved useful in predicting the relative intensities for corresponding axial and equatorial transitions.

Key words: 2-methylthietane, vibrational spectra, *ab initio* force fields, vibrational assignment, conformations.

R. A. SHAW, N. IBRAHIM et H. WIESER. Can. J. Chem. **68**, 90 (1990).

On a mesuré les spectres de vibration du 2-méthylthiétane de 100 à 1600 cm^{-1} (Raman) et de 400 à 3200 cm^{-1} (infrarouge en solution et en phase gazeuse). Des calculs *ab initio* aux niveau 3-21G et 6-31G* indiquent que les conformères tant axial qu'équatorial représentent des minima sur la surface de potentiel d'inversion du cycle; la dernière base suggère que l'espèce équatoriale est plus stable par 191 cm^{-1}. On a calculé les champs de force vibrationnels de chacun des deux conformères et on en a fixé l'échelle en utilisant des fracteurs qui ont été optimisés antérieurement pour le thiétane et le 2-méthyloxéthane. On a attribué pratiquement l'ensemble des caractéristiques expérimentales importantes aux espèces équatoriales; de plus, la plupart des transitions attendues pour les espèces axiales ont aussi été localisées. Même si les intensités d'absorption calculées ne sont pas nécessairement exactes en termes absolus, elles se sont avérées utiles pour prédire les intensités relatives des transitions axiale et équatoriales correspondantes.

Mots clés : 2-méthylthiétane, spectres de vibration, champs de force *ab initio*, assignation vibrationelle, conformations.

Introduction

Small chiral ring molecules play an important role in both experimental and theoretical studies of vibrational circular dichroism (VCD) (for reviews, see ref. 1). An accurate force field is an essential prerequisite to such an investigation, both as a means of assigning the vibrational spectrum and in providing the eigenvectors required for model calculations of the VCD (and infrared) intensities.

In this paper we report the vibrational spectra and *ab initio* MO structural calculations for 2-methylthietane (2MT, see Fig. 1). The vapour phase infrared absorption spectrum has been reported previously over the range 50–500 cm^{-1}, with the observed sequence of low frequency ring puckering transitions interpreted to suggest an inversion barrier of 341 cm^{-1} and an energy difference of 118 cm^{-1} separating the two conformers (2). The more stable conformer could not be inferred from the far-infrared study. We have evaluated the force constants and vibrational frequencies for each conformer using the 3-21G and 6-31G* basis sets, and adopted the scaling procedure of Pulay *et al.* (3) to correct for systematic deficiencies in the calculated force constants. The success of this approach in the accurate *prediction* of vibrational spectra rests upon the availability of scaling factors suitable for correcting the calculated force constants. Although different types of force constant may require quite different correction factors, it has been shown that for a particular coordinate type the scaling factor is transferable over a range of molecules (3–6).

We have previously reported scaled 3-21G force fields for 2-methyloxetane (4) and thietane (5), each of which incorporates structural features (and hence also vibrational coordinates) common to those of 2MT. In each case the spectra of several deuteriated isotopomers were recorded and assigned, providing sufficient experimental data that a relatively large number of scaling factors could be defined and optimized independently. The decision to permit such flexibility in the scaling procedure was motivated partially as a means of resolving certain ambiguities in the assignments. More importantly in the present context, we have suggested previously that such an approach should also optimize the predictive power of the scaling factors (4–6).

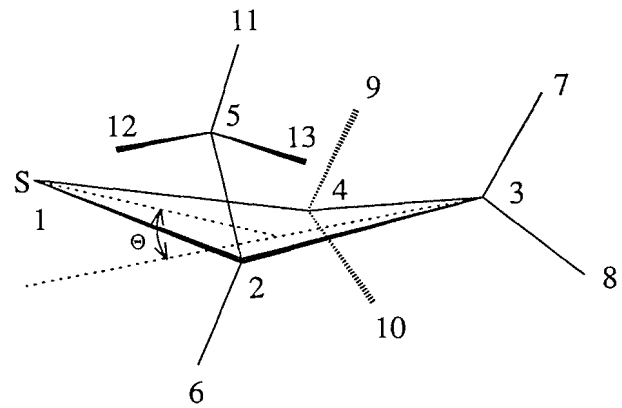

FIG. 1. Atom numbering for 2-methylthietane, used for defining structural parameters and local symmetry coordinates of Tables 2 and 3.

The spectra of 2MT offer an opportunity to test the reliability of this approach. Both the axial and equatorial 3-21G force fields are scaled using factors determined for thietane and 2-methyloxetane, and the spectra assigned on the basis of the predicted frequencies. Recognizing that this basis set has certain deficiencies, particularly in the C—S bond length, we have also reevaluated both the thietane and 2-methyloxetane force fields using the 6-31G* basis set and calculated both axial and

equatorial structures and force fields using the same basis set. The 3-21G and 6-31G* force fields are thus developed in exactly analogous fashion, which then permits assessment of the relative accuracy of the two basis sets in this application.

The calculated absorption intensities are examined both as a means of verifying the proposed assignments and in assessing the relative populations of the two conformers. The evidence derived through this study is then discussed in the context of both the experimental and calculated inversion potential surfaces. Finally, the normal coordinates and force constants are compared for the different conformers and force fields.

Experimental and computational details

2-Methylthietane was synthesized following the method outlined by Etienne and Soulas (7), with a purity of at least 98% as determined by gas chromatography.

Infrared spectra were run using a Nicolet 8000 FT-IR spectrometer at a pathlength of about 1.5 m (Wilkes cell) for the vapour, 0.1 mm for the solutions, and 0.015 mm for the neat liquid. The spectra are displayed in Figs. 2–5, and the measured positions listed in Table 1. Absorption intensities for the solution spectra were measured using the band fitting program CAPR supplied by Nicolet. The Fourier self-deconvolution (8) software, used for resolution enhancement of the solution spectra, was also supplied by Nicolet.

The Raman spectrum was recorded with a Jarell–Ash 25-100 double grating spectrometer, using the 5145 Å argon ion line of a Coherent Radiation laser, with the slitwidth set for 7 cm^{-1} resolution at 1000 cm^{-1}. The spectrometer is interfaced to an IBM PC and Tektronix digitizer. The plotted spectrum (Fig. 6) represents the average of 2 scans, with data points collected every 2 cm^{-1} and a dwell time of 1 s at each point.

Optimized structures were determined for 2-methylthietane (6-31G*), thietane (6-31G*), and both stable conformers of 2-methylthietane (3-21G and 6-31G*) using the Gaussian 82 program (9) modified by Rauk and Dutler (10) to run on the Cyber 205 supercomputer at the University of Calgary. The optimized structural parameters are listed in Table 2 (see refs. 4 and 5 for optimized 3-21G structures of 2-methyloxetane and thietane, respectively). The harmonic force constants were evaluated at the respective optimized structures using the same basis set(s), and transformed to local symmetry coordinates. The coordinates for thietane are given in ref. 5. For 2-methylthietane the coordinates used (Table 3) are identical to those for 2-methyloxetane. The atomic polar tensors (APT) were evaluated using a separate program that makes use of the analytical derivatives of the density

matrix provided by Gaussian 82. A list of the APTs is available from the authors upon request.

All force fields were scaled according to $F_{ij} = (C_iC_j)^{1/2}K_{ij}$, where C_i and C_j denote the scaling factors for modes "i" and "j", and K_{ij} and F_{ij} the unscaled and scaled *ab initio* force constants, respectively (3). For 2-methyloxetane and thietane the 6-31G* scaling factors were refined to fit the observed transitions reported in refs. 4 and 5. These optimized scaling factors were thus derived following a procedure exactly analogous to that used for the 3-21G basis set.

The absorption spectra for both conformers of 2-methylthietane were predicted by transferring the appropriate optimized scaling factors from thietane and 2-methyloxetane (see Table 4). Table 5 summarizes the calculated positions and infrared absorption intensities for each conformer. For the 3-21G and axial 6-31G* calculations the frequencies are listed such that the associated normal coordinates are matched with the corresponding modes of the equatorial conformer (6-31G* calculation), according to criteria outlined below.

Results and discussion

The *ab initio* calculations agree qualitatively with the experimental inversion potential, with both axial and equatorial structures predicted to be stable and similar in energy. The two basis sets differ somewhat with respect to the dihedral angles, 3-21G predicting the two conformers to be folded by equal and opposite amounts and 6-31G* indicating the axial to be slightly less puckered than the equatorial.

With respect to the structure calculations, the major advantage of 6-31G* lies in the improved C—S bond lengths and in the predicted relative energies for the two conformers. For thietane the C—S distance of 1.834 Å is within 0.013 Å of experimental (11), and the corresponding 2MT parameters are presumably equally accurate. The difference of 191 cm^{-1} calculated with 6-31G* is in good agreement with the experimental value of 124 cm^{-1}, while the 3-21G basis predicts the two conformers to be essentially equal (within 5 cm^{-1}) in energy. The 6-31G* basis set further suggests that the equatorial species is the more stable of the two.

Vibrational assignments

The mid-infrared assignments were initially approached following the guidance of the 3-21G calculated positions for the equatorial conformer (Table 5). All of the dominant features in the mid-infrared solution spectra were readily assigned on this basis, with the only ambiguity occurring in the 1220 cm^{-1} region. Two fundamental transitions are predicted here where only a single absorption is evident in the condensed phase spectra. Subsequent Fourier self-deconvolution (FSD) over this region revealed two closely spaced absorptions of nearly equal intensity, which are clearly resolved in the vapour phase absorption spectrum. The assignments for the equatorial species were thus completed with no apparent ambiguities. They are listed in Tables 1 and 6.

The vibrational spectrum was then predicted for the axial species, placing several transitions well separated from the corresponding equatorial modes (see Table 5). The search for these features in the experimental spectra was initially confined to the lower frequency modes, in particular ν_{26}–ν_{31}, each of which is suggested to shift by at least 14 cm^{-1}. Among these the

[d]From ref. 2.

ring deformation, ν_{29}, provided the clearest experimental evidence that the axial species is both stable and present in appreciable concentration at room temperature. The condensed phase spectra (Figs. 3 and 6) show a clear high frequency shoulder (peak no. 6) on the absorption at 516 cm^{-1} (peak no. 5). In CCl_4 solution the two transitions are clearly resolved upon Fourier self-deconvolution at 516.1 and 536.9 cm^{-1}. The corresponding vapour phase transitions at 514.4 and 545.2 cm^{-1} match very well the positions calculated for the equatorial and axial species, respectively. The excellent agreement between the calculated (33.7 cm^{-1}) and observed (30.8 cm^{-1}) frequency shifts further supports these assignments, and also suggests that the shifts calculated for other modes may be taken as a reliable guide in searching for other transitions of the axial conformer.

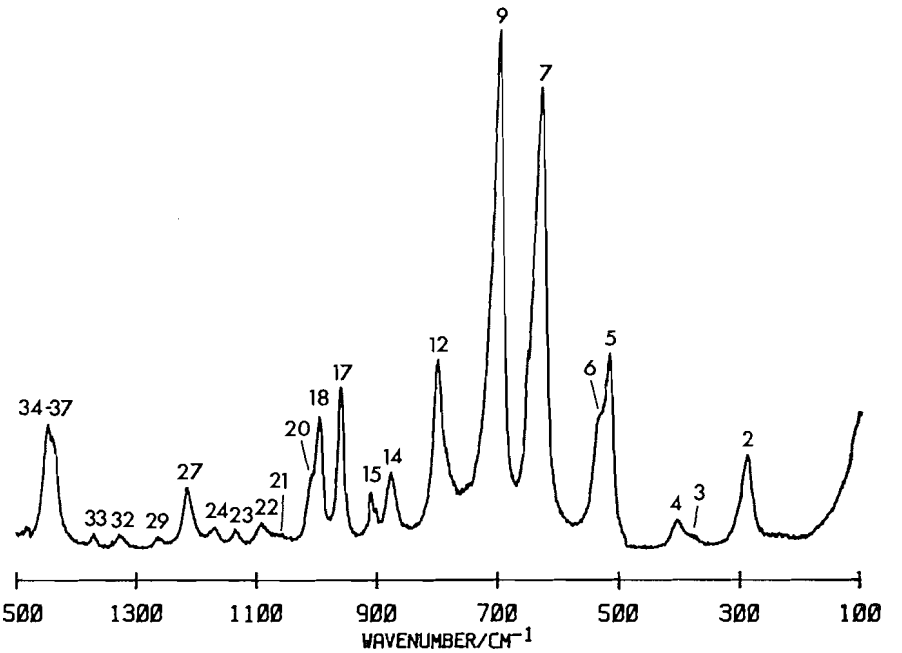

FIG. 6. Raman spectrum of 2-methylthietane (neat liquid). Peaks numbered as in Tables 1 and 6.

The two methyl bending modes ν_{30} and ν_{31} both occur below 450 cm^{-1} and appear in the absorption spectra reported in ref. 2 for the region 100–500 cm^{-1}. The predicted frequencies suggest that the two absorptions reported at 403.3 and 370 cm^{-1} correspond to equatorial and axial transitions in the CH_3 out-of-plane bending mode, ν_{30}, calculated at 411.3 and 380.7 cm^{-1}, respectively. These two bands are also clearly present in the Raman spectrum (Fig. 6). The two in-plane bends, ν_{31}, calculated at 280.3 cm^{-1} (equatorial) and 295.8 cm^{-1} (axial) are observed at 280.8 and 301.1 cm^{-1} in the vapour phase spectrum. In each case the lower intensity transition of the pair arises from the axial species.

The two C–S stretches for the equatorial conformer occur at 700.4 cm^{-1} (ν_{27}, H_2C–S stretch) and 633.7 cm^{-1} (ν_{28}, CH_3C–S stretch). The corresponding axial transitions are predicted about 15 cm^{-1} higher in frequency. Close examination of the solution spectrum reveals shoulders to high frequency (peaks no. 10 and 8, Fig. 3). Although FSD does resolve these axial transitions, albeit with a noise level nearly as intense as the resolved bands, they are clear enough to confirm the corresponding vapour phase transitions as fundamentals of the axial conformer.

The mode predicted with the largest shift is ν_{20}, the 3-21G calculation placing the fundamentals at 1125 cm^{-1} (equatorial) and 1085 cm^{-1} (axial). The 6-31G* calculation is more accurate, both in reproducing the position observed for the equatorial mode (obsd. 1101 cm^{-1}, calcd. 1093 cm^{-1}) and in confirming the weak band observed at 1061.5 cm^{-1} (peak no. 21, Figs. 2 and 6) as the corresponding axial fundamental (calcd. 1061 cm^{-1}). This example illustrates that where the two basis sets differ, the 6-31G* positions are probably the better guide in searching for the more elusive transitions of the axial conformer. This preference is important only for one other mode, ν_{25}, which is the only case in the 100–1600 cm^{-1} region where a shift predicted to exceed 5 cm^{-1} by 6-31G* is opposite in sign to that of 3-21G. Again, the former suggests a plausible assignment for the axial transition whereas the latter does not. For ν_{20} the equatorial fundamental is split into three separate features in the vapour phase spectrum (peak no. 22 of Fig. 2), which we suspect to represent the same fundamental occurring in the three different puckering levels within the equatorial well. Analogous transitions are evident also for ν_{28} and ν_{29} (peaks no. 7 and 5), corresponding to distinct Q-branches evident at slightly higher frequency in each case. The band splitting then confirms the sensitivity of these modes to subtle structural changes.

With these examples confirming that the axial species is present and that the calculated positions faithfully reproduce the observed frequency shifts, several of the remaining mid-infrared axial transitions were identified readily in the vapour phase spectrum. With the exception of the CH stretching and the CH_2 scissoring/CH_3 asymmetric deformation regions, both of which are too congested to permit positive identification of the axial transitions, all but four of the axial fundamentals in the region 250–1500 cm^{-1} have been located and are listed in Table 5.

The CH stretching region was assigned for the most part by considering the deconvolved (FSD) solution spectrum, which clearly displays a number of transitions that are not resolved in either the vapour phase or solution spectra. The transitions at 2858.6, 2865.7, and 2895.1 cm^{-1} (peaks no. 38, 39, and 40 in Fig. 5) are ascribed to Fermi resonances involving combinations and (or) overtones of the scissoring modes (at least one such resonance enhanced overtone has also been identified for the parent thietane molecule (5)) and the CH_3 asymmetric deformations. With the CH stretching region complicated by these resonances the calculated shifts become less dependable in attempting to assign the weaker transitions, which may or may not correspond to transitions of the axial conformer. The shifts are generally small in any case, and the calculated absorption profile (6-31G*, see Fig. 5) matches the observed very well for each of the conformers. The only qualitative difference occurs over the region 2935–2945 cm^{-1}, where only the equatorial conformer is predicted to display any absorption. Our assignment (peak no. 42) matches the equatorial prediction well, with the axial transition then assigned either as coincident with ν_4 (peak no. 45) or to the shoulder apparent to slightly lower frequency in the deconvolved spectrum (see Figs. 4 and 5). For all

other modes the equatorial and axial transitions are assumed to coincide. With three strong bands ascribed to combinations and (or) overtones it is likely that several of the lower frequency CH stretching fundamentals are perturbed and shifted to higher frequency as a result of the Fermi resonance interactions. This then accounts for the appearance of the experimental spectrum as being compressed along the frequency axis relative to the calculated spectrum, while qualitatively the two compare quite well in overall appearance.

The assignments are reproduced with an average error of 5.1 (equatorial) and 5.9 cm^{-1} (axial) for the 6-31G*, and 7.6 and 7.9 cm^{-1}, respectively, for the 3-21G force field. The calculated intensities for the two conformers must be weighted to reflect their relative populations in order to compare quantitatively the theoretical and experimental spectra. This is discussed in the following section.

Inversion potential and relative abundance of conformers

The relative populations of the two conformers may be estimated either through the relative intensities for corresponding axial and equatorial transitions or through consideration of the energy difference implied by the inversion potential func-

tion. In practice the first approach is limited to only one pair of transitions, namely peaks no. 5 and 6, corresponding to the ring deformation mode ν_{29}. Although both ν_{27} and ν_{28} also exhibit shoulders corresponding to the axial conformer, the bands are not sufficiently resolved for this purpose. For ν_{29} the measured absorption intensity for the equatorial transition is greater by a factor of 1.55, with the axial band being appreciably broader (23 vs. 13 cm^{-1} FWHH). The calculated molar absorptivities are in the opposite order, both basis sets predicting an intensity ratio of 1 to 1.77 equatorial to axial, thus suggesting an excess of the former by about 2.7 (1.55 × 1.77) or 73%.

One way of estimating the relative abundance of the two conformers from the inversion potential is to assume only two possible ring orientations, each of which corresponds to a local (axial or equatorial) energy minimum. The 6-31G* (191 cm^{-1}) and experimental (118 cm^{-1}) (2) energy differences separating these minima then indicate that, respectively, 73 or 64% of the molecules adopt the equatorial conformation. Probably the soundest method for evaluating the relative abundance in the vapour phase is to determine the population, at room temperature, of each energy level of the ring inversion mode. Among the levels below the barrier, three correspond to the equatorial conformer and two to the axial, with the Boltzmann distribution indicating overall populations of 52 and 24% respectively. The remaining 24%, which occupy the levels above the barrier, may either be designated as "equatorial" or "axial" in the same ratio, or divided equally between the two. These two alternatives indicate a range of 64–68% equatorial conformation.

Adopting the mean of 66% as a fair reflection of the experimental inversion potential, and with the solution infrared absorption intensities for ν_{29} suggesting that 73% of molecules occupy the equatorial conformation, we have taken the average of these two as our best estimate of the true value. The theoretical spectra plotted in Figs. 3 and 5 thus represent a sum of the spectra calculated for the equatorial and axial species, weighted by 70 and 30%, respectively.

Infrared intensities, force constants, and normal mode descriptions

The two weighted calculated spectra (3-21G and 6-31G*) are both in reasonably good qualitative agreement with the observed (see Figs. 3 and 5). Perhaps most surprising is that the mid-infrared 6-31G* spectrum is not clearly more accurate than the 3-21G. Most striking is the discrepancy for the β-CH_2 wag (ν_{15}, peak no. 29), for which the 6-31G* band is substantially weaker than either the experimental or 3-21G transition. A number of other apparent discrepancies between the 6-31G* and experimental spectra may be attributed to differences between the experimental bandwidths and the assumed value of 10 cm^{-1} used for the calculated spectrum.

The calculated infrared absorption intensities are useful in confirming many of the assignments for the axial conformer, particularly for cases where the calculated molar absorptivity differs for the two conformers. For example the relative prominence of ν_{29}^{ax} at 545.2 cm^{-1} (peak no. 6, Figs. 2 and 3) is rationalized by noting that the calculated intensity of 3.9 km mol^{-1} is nearly twice that predicted for the equatorial mode. Other cases where the axial transition is conspicuous include ν_{14} (peaks no. 32 and 31 equatorial and axial, respectively), ν_{25} (no. 29 and 30), ν_{18} (no. 24 and 25), and ν_{22} (no. 18 and 19). In each of these cases the molar absorptivity is calculated to be higher for the axial conformer than for the equatorial (see 6-31G* calculation, Table 5 and Fig. 2).

The normal modes of the equatorial conformer are described in terms of the potential energy distribution in local symmetry

coordinates. To demonstrate the correspondence between the normal modes of the two conformers we use a method analogous to "normal mode scrambling", which relates the normal coordinates of a deuterated species to those of the parent compound. We begin using the standard relationships,

$$[1] \quad Q_{eq} = L_{eq}^{-1} R_{eq}$$

$$[2] \quad Q_{ax} = L_{ax}^{-1} R_{ax}$$

where R denotes the local symmetry coordinates of Table 3, and Q and L the normal coordinates and eigenvectors in terms of displacements of R. We now define a new set of displacement coordinates for the axial conformer,

$$[3] \quad S_{ax} = L_{eq}^{-1} R_{ax}$$

whereby each coordinate S_{ax}^{i} corresponds to the normal coordinate Q_{eq}^{i} of the equatorial conformer. Combining [2] and [3] gives

$$[4] \quad S_{ax} = L_{eq}^{-1} L_{ax} Q_{ax}$$

where the eigenvectors of the matrix $L_{eq}^{-1}L_{ax}$ then express the normal coordinates Q_{ax} in terms of displacements of S_{ax}. Table 6 describes the normal coordinates of the axial conformer in terms of the potential energy distribution among diagonal elements of the matrix $L_{eq}' F_{ax}^{R} L_{eq}$ (F_{ax}^{R} being the scaled local symmetry force constants) whose elements are the force constants in the S_{ax} coordinate system,

$$[5] \quad PED_{ax}^{i} = \sum_{j} (L^{-1}{}_{eq} L_{ax})_{ji} (L_{eq}' F_{ax} L_{eq})_{jj} / \lambda_i$$

For clarity the S_{ax}^{i} have been identified with Q_{eq}^{i} in Table 6.

The correct correspondence among the CH_2 scissor/CH_3 asymmetric deformation modes is shown clearly by this analysis, with those calculated at 1448.9, 1447.7, and 1442.9 cm^{-1} for the axial conformer corresponding to ν_{12}, ν_{10}, and ν_{11} of the equatorial structure. The frequency ordering for ν_5 and ν_6 is similarly reversed when the ring is inverted, although in this case the two normal coordinates for the equatorial conformer essentially mix to form in-phase and out-of-phase combinations. The calculated intensities support interchanging the order for the axial conformer, with ν_5^{eq} (calcd. 2950.2 cm^{-1}, 44.8 km mol^{-1}) then matched with the axial transition calculated at 2950.9 cm^{-1} (52.0 km mol^{-1}), and ν_6^{eq} (2937.7 cm^{-1}, 17.8 km mol^{-1}) with the axial mode at 2955.0 cm^{-1} (10.8 km mol^{-1}). For the two bending modes ν_{21} and ν_{22} the normal coordinates of the axial conformer consist of in-phase and out-of-phase combinations of Q_{21}^{eq} and Q_{22}^{eq}. Here we have labelled the two modes ν_{21}^{ax} and ν_{22}^{ax} in order of descending frequency in Table 5, although in such a case the alternative designation is equally valid.

The apparent interchange in the ordering of ν_{26} and ν_{27} is very surprising. The transitions calculated at 796.8 and 704.9 cm^{-1} for the equatorial conformer are suggested to correspond to those predicted at 727.6 and 773.1 cm^{-1} for the axial, implying

[a]Force fields scaled using factors listed in Table 4. Absorption intensities (A_i) in parentheses are calculated for the scaled force field.
[b]Peak nos. correspond to bands labeled in Figs. 2–6, and listed in Table 1. All frequencies except those for certain C–H stretches (see Table 1) and ν_{26}^{ax} are from the vapour phase spectrum.

shifts of −69.2 and 68.2 cm^{-1} respectively. We have labelled these two modes for the axial conformer in Table 5 as ν_{26} and ν_{27} in order of descending frequency. The large changes in the nature of these normal coordinates does provide a rationalization of certain features in the vapour phase infrared spectrum. One would anticipate on this basis that the band contour for ν_{27}^{ax} would resemble closely that observed for ν_{26}^{eq}, and vice versa. Indeed, the transition assigned as ν_{27}^{ax} (peak no. 10, Fig. 2) shows a distinct Q-branch in the vapour phase spectrum, and in this respect is more similar in shape to ν_{26}^{eq} (peak no. 12) than to ν_{27}^{eq} (peak no. 9). The absence of any distinct vapour phase transition for ν_{26}^{ax} is then explained by the possibility that it adopts the same band contour as observed for ν_{27}^{eq} (peak no. 9), and is hence indistinguishable from the P-branch of ν_{26}^{eq} (peak no. 12).

We have compared the scaled 3-21G and 6-31G* force fields for the equatorial conformer in the same fashion, expressing the 3-21G normal coordinates as combinations of those predicted for the 6-31G* calculation (details not shown). The two force fields are very similar, with the leading term in the potential energy distribution exceeding 0.9 in all but 7 cases. Three of these are the very closely spaced modes ν_{10}–ν_{12}, where the normal coordinates are very sensitive to small changes in the relevant diagonal force constants. For similar reasons, $Q_{16}^{6\text{-}31G*}$ and $Q_{17}^{6\text{-}31G*}$ are mixed to some extent for 3-21G, with the two frequencies calculated at 1220.3 and 1224.3 cm^{-1} corresponding most closely to ν_{16}^{eq} and ν_{17}^{eq}, respectively. The frequency ordering is also interchanged for the two CH stretches ν_5 and ν_6, calculated for the 3-21G force field at 2949.2 and 2950.7 cm^{-1}, respectively, although in this case the normal modes match the 6-31G* coordinates very closely. Finally, the coordinates $Q_{13}^{6\text{-}31G*}$ and $Q_{14}^{6\text{-}31G*}$ are mixed for the 3-21G force field, with the normal coordinates $Q_{13}^{3\text{-}21G} = 0.9\ Q_{13}^{6\text{-}31G*} - 0.4\ Q_{14}^{6\text{-}31G*}$ and $Q_{14}^{3\text{-}21G} = 0.9\ Q_{14}^{6\text{-}31G*} + 0.4\ Q_{13}^{6\text{-}31G*}$. This reflects a relatively strong coupling of the CH_3 symmetric deformation and C*–H bending (out-of-plane) coordinates for the 6-31G* force field, which is almost entirely absent for 3-21G.

The 6-31G* force fields optimized for 2-methyloxetane and

[a]As inferred from potential energy distribution (PED) for the scaled 6-31G* force field. Coordinates with coefficients less than 0.1 are omitted. Abbreviations: sc, ro, wa, tw = scissor, rock, wag, twist; str = stretch; i/p, o/p = in-plane, out-of-plane. Designations α and β distinguish the CH_2 groups at the 4- and 3-positions, respectively. The CH_2 and CH_3 stretching coordinates are combined as in-phase/out-of-phase (CH_2) or C_{3v} symmetry coordinates for determining the potential energy distribution. Italics (e.g., CH_3*C*–*C*) indicate the bond involved for skeletal stretch.

[b]Potential energy distribution in group coordinates S_{ax} which are defined by the eigenvectors for the normal coordinates Q_i^{eq} of the equatorial compound. See text.

thietane have also been compared to the scaled 3-21G force fields reported previously (4, 5) with equally good correspondence among the normal modes. In addition, the infrared absorption intensities calculated for thietane in conjunction with the 6-31G* force field are invariably compatible with the published assignments (5). These comparisons thus support the accuracy of the scaled force constants in each case, which in turn reinforces the accuracy of the 2-methylthietane force fields scaled using the same factors.

For 2-methylthietane the scaled 3-21G force constants agree well with the corresponding 6-31G* values (see Table 7), with the changes that result upon inversion of the ring also reproduced. Such differences as do arise between corresponding 3-21G and 6-31G* values may be ascribed in general to differences in the optimized structures (G-matrices). This is confirmed by scaling the 3-21G force constants using factors that give diagonal force constants equal to the 6-31G* values. The frequencies calculated for this force field do not agree well either with the 6-31G* calculations or with the experimental positions. For the methyl C–C stretch (coordinate no. 5) the discrepancy between the 6-31G* and 3-21G force constants is very large. In this case we believe the 3-21G value to be high, which then explains the anomalously large discrepancy between the 3-21G and 6-31G* calculated positions for ν_{20}. The 3-21G scaling factor optimized for the methyl C–C stretch of 2-methyloxetane is evidently not suitable for transfer to 2-methylthietane, which is not surprising given the influence of the C—O bond upon the scaling factors for CH_2 and CH_3 deformations involving the -CH_2—O and CH_3—O units (5, 6).

Some of the larger frequency shifts that occur upon immersion of the ring may be explained by changes in the diagonal force constants. Such is the case for the two methyl bends ν_{30} and ν_{31}, which are, respectively, lowered and raised in frequency for the axial conformer in accordance with changes in the diagonal force constants for coordinates no. 28 and 27 of Tables 3 and 7. The C*–H stretching force constant increases

[c]Refers to orientation of the methyl group, as throughout this paper, and *not* to the orientation of the coordinates listed under "Type".

for the axial conformer (the C*–H bond assuming the *equatorial* orientation), with analogous changes occurring also for the α-CH stretching force constants. In the latter case the α-CH_2 symmetric and asymmetric stretching frequencies ν_1 and ν_5 are unaffected, as the roles simply interchange for the CH displacements comprising Q_1 and Q_5. For the C*–H stretch the increased diagonal force constant shifts the calculated position for ν_6 by over 17 cm^{-1}, in exact agreement with the shift expected for a CH bond undergoing the shift (0.057 mdyn/Å) calculated for the 6-31G* force field.

Conclusion

The vibrational spectra have been measured for 2-methylthietane from 400–3200 cm^{-1} (infrared) and 100–1600 cm^{-1} (Raman), and assigned through systematic scaling of harmonic force fields calculated at the 3-21G and 6-31G* levels. Each basis set gives two stable conformers (axial and equatorial) as energy minima. The spectra were assigned through prediction of the vibrational spectrum, by scaling the *ab initio* force fields using factors derived solely through optimization to other molecules. The accuracy of the frequencies calculated in each case results from the availability of a large pool of experimental data for the related molecules thietane and 2-methyloxetane, permitting in each case statistically meaningful refinement of a sufficiently flexible set of scaling factors. Both the axial and equatorial structures have been shown to contribute to the observed spectra of 2-methylthietane, with the latter confirmed as the more stable both by the 6-31G* *ab initio* results and by the intensity of the infrared spectrum as compared to that of the axial. All transitions of the equatorial and nearly all those of the axial conformer have been assigned, and the two are suggested to coexist in the ratio 70% equatorial to 30% axial as inferred from measurement of the solution infrared intensity measurements and consideration of the published inversion potential.

A method is outlined for comparing the normal coordinates as calculated for different basis sets or conformers. This procedure establishes the correspondence between the normal modes of the equatorial and axial conformers, and demonstrates clearly those instances where appreciable changes do occur. By the same criterion the scaled 3-21G and 6-31G* force fields are shown to provide very similar descriptions of the normal modes in general, with the only discrepancies occurring for very closely spaced transitions. Frequency shifts that occur upon ring inversion may in some cases be traced to alterations in the relevant diagonal force constants, with 3-21G invariably reproducing 6-31G* in this regard. We have thus found the 6-31G*

calculation to have only marginal advantages over 3-21G in the prediction of frequencies and, perhaps more surprising, the absorption intensities. Both basis sets clearly provide structures and force constants of sufficient accuracy to confirm the axial species as stable, with success of the vibrational analysis resting primarily upon the accuracy of scaling factors transferred to scale the force constants and, less critically, upon the choice of basis set. The evaluation of vibrational circular dichroism (VCD) intensities is certainly more sensitive to details of the force fields. This will be discussed in a forthcoming publication concerning the VCD spectrum of 2-methylthietane.[2]

Solutions of bis(fluorosulfuryl)peroxides, $S_2O_6F_2$, in fluorosulfuric acid, HSO_3F, are synthetically very useful. The nature of the solvent (HSO_3F)–solute ($S_2O_6F_2$ or $SO_3F^{\bullet}$) interaction is probed by Raman, ^1H and ^{19}F NMR, and ESR spectroscopy, the latter focussing on the radical $SO_3F^{\bullet}$ formed by the dissociation of $S_2O_6F_2$. Both $S_2O_6F_2$ and $SO_3F^{\bullet}$ behave as very weak bases in HSO_3F. Proton transfer between solvent and solute and SO_3F exchanges are suggested on the basis of NMR and ESR measurements. The symmetry and electronic structure of the $SO_3F^{\bullet}$ radical are altered in HSO_3F solution. A g_{iso} value of 1.97267 is obtained. The radical appears to be formed on dissolution of $S_2O_6F_2$ at room temperature and persists down to 183 K. The solvent–solute interaction depends on the acid strength of the protonic solvent and addition of the base KSO_3F to HSO_3F leads to a loss of solubility and the separation of $S_2O_6F_2$ as a second phase.

Key words: solution study in HSO_3F of weak bases, Raman spectrum, ESR study in HSO_3F.

Des solutions de peroxyde de bis(fluorosulfuryle), $S_2O_6F_2$, dans de l'acide fluorosulfurique, HSO_3F, sont très utiles en synthèse. On a étudié la nature de l'interaction solvant (HSO_3F)–soluté ($S_2O_6F_2$ ou $SO_3F^{\bullet}$) en faisant appel aux spectroscopies Raman, rmn du ^1H et ^{19}F ainsi que rpe; cette dernière méthode est orientée vers le radical $SO_3F^{\bullet}$ qui se forme par la dissociation du $S_2O_6F_2$. Le $S_2O_6F_2$ ainsi que le $SO_3F^{\bullet}$ se comportent comme des bases faibles dans le HSO_3F. Sur la base des mesures effectuées à l'aide de la rmn et de la rpe, on suggère qu'il existe un transfert de proton entre le solvant et le soluté ainsi qu'un échange avec le SO_3F. En solution dans le HSO_3F, la symétrie et la structure électronique du radical $SO_3F^{\bullet}$ sont modifiées. On a obtenu une valeur de g_{iso} de 1,97267. Le radical semble se former lors de la dissolution du $S_2O_6F_2$ à la température ambiante et sa présence persiste jusqu'à 183 K. L'interaction solvant–soluté dépend de la force de l'acide du solvant protonique; l'addition de la base KSO_3F à l'acide HSO_3F provoque une diminution de la solubilité et la séparation du $S_2O_6F_2$ dans une deuxième phase.

Mots clés : étude du solution des bases faibles dans HSO_3F, spectre Raman, étude RPE dans HSO_3F.

[Traduit par la revue]

Introduction

In the past, we have employed solutions of bis(fluorosulfuryl)peroxide, $S_2O_6F_2$ (1), in fluorosulfuric acid, HSO_3F (2), for the synthesis of a wide range of binary and ternary fluorosulfates by either one of the two general routes:

$$[1]\quad E + (n/2)S_2O_6F_2 \xrightarrow[HSO_3F]{25\text{–}135^\circ C} E(SO_3F)_n$$

or

$$[2]\quad mM^ISO_3F + E + (n/2)S_2O_6F_2 \xrightarrow[HSO_3F]{25\text{–}135^\circ C} M^I_m[E(SO_3F)_{n+m}]$$

where E = main group or transition metal, n = 2, 3, 4, or 5; M^ISO_3F = alkali metal fluorosulfate, prepared in situ from M^ICl and HSO_3F, and m = 1, 2, or 3. Recent representative examples with E = Au (3), Ta (3), Nb (3), Rh (4), Mn (5), Ru (6), Pt (7), Sn (8), Ge (8), Br or I (9), illustrate the wide range of this method. While $S_2O_6F_2$ is the principal oxidizing agent in this reagent combination, the role of HSO_3F is three-fold: (*a*) to allow an expansion of the temperature range well beyond the boiling point of $S_2O_6F_2$, 67.1°C (10), (*b*) to maintain in solution and hence at the reactive site a high concentration of $SO_3F^{\bullet}$ radicals formed by the reversible dissociation of $S_2O_6F_2$ (11), and (*c*) to dissolve reaction product from the metal surface during reaction. All three factors contribute to fast, complete oxidation reactions, where $S_2O_6F_2$ alone often gives only incompletely reacted products or requires excessively long reaction times.

Both $S_2O_6F_2$ and HSO_3F are miscible at 25°C in any proportion to give stable, clear, colorless solutions. On the other hand, $S_2O_6F_2$ is virtually insoluble at 25°C in the related protonic acid H_2SO_4. This observation is found useful when crude $S_2O_6F_2$, formed in the catalytic fluorination of SO_3 (12), is purified by extracting SO_3 with concentrated H_2SO_4. We became interested in investigating the HSO_3F–$S_2O_6F_2$ system to find an answer to this rather puzzling behaviour.

Previous studies of this system by cryoscopy and conductometry (13) allow preliminary conclusions. In HSO_3F solution, $S_2O_6F_2$ is said to be a non-electrolyte at 25°C (13). It is reportedly present in its molecular form and has been used to determine the cryoscopic constant of HSO_3F (13). However, the second observation based on cryoscopy is strictly valid only for temperatures at or around the melting point of HSO_3F at −88.98°C.

These observations by Gillespie *et al.* (13) appear to argue against two possible interaction modes between HSO_3F and $S_2O_6F_2$: (*i*) extensive ionizing solvation of $S_2O_6F_2$ in HSO_3F, with protonation the most probable initial process:

$$[3]\quad HSO_3F + S_2O_6F_2 \overset{HSO_3F}{\rightleftharpoons} HS_2O_6F_2^{+}{}_{(solv)} + SO_3F^{-}{}_{(solv)}$$

and (*ii*) electron transfer between the $SO_3F^{\bullet}$ radical and the self-ionization ion SO_3F^-, according to

$$[4]\quad SO_3F^{\bullet}{}_{(solv)} \overset{+e^-}{\underset{-e^-}{\rightleftharpoons}} SO_3F^{-}{}_{(solv)}$$

However, caution is indicated for two reasons: (*i*) the absence

of appreciable dissociation of $S_2O_6F_2$ into radicals at room temperature in HSO_3F–$S_2O_6F_2$ solutions needs to be demonstrated. An ESR study (14) on pure $S_2O_6F_2$ has concluded that $SO_3F^\bullet$ radicals are present at ambient temperature and may persist to 4°C. (*ii*) The conductivities measured on solutions of $S_2O_6F_2$ in HSO_3F are small but increase linearly with increasing $S_2O_6F_2$ concentrations (13). In a strongly acidic, protonic solvent like HSO_3F, a true non-electrolyte is expected to reduce proton mobility, and hence electrical conductance in these media, due to a structure breaking effect on the hydrogen bonded system. Based on the reported electrical conductivity alone, it appears more appropriate to view $S_2O_6F_2$ as a weak electrolyte in HSO_3F.

To address these points, three methods are employed in this study: (*i*) Raman spectroscopy on solutions of $S_2O_6F_2$ in HSO_3F. The vibrational spectra of the individual compounds are well known (15–17); (*ii*) NMR spectroscopy of both ^1H and ^{19}F nuclei; (*iii*) ESR spectroscopy of the system, to detect the onset of the formation of $SO_3F^\bullet$ radicals and their persistence in HSO_3F. Again, the ESR spectrum of the SO_3F radical has been reported (14).

Two variations are promising: (*a*) temperature variation of both the NMR and ESR spectra, the former between −75 and +45°C, the latter between −90 and +50°C; and (*b*) a variation of the acidity of HSO_3F. The autoprotolysis equilibrium:

$$[5] \quad 2HSO_3F \rightleftharpoons H_2SO_3F^+ + SO_3F^-$$

may be shifted to the basic side by addition of SO_3F^- in form of the standard base KSO_3F (18), while removal of the base ion results in an increase in overall acidity.

Experimental

Chemicals

Fluorosulfuric acid (Allied Chemical) was purified by double distillation at atmospheric pressure (18). Bis(fluorosulfuryl)peroxide, $S_2O_6F_2$ (12) and KSO_3F (18), were prepared by published methods. Anhydrous hydrogen fluoride was obtained from Matheson of Canada. The solutions studied were prepared by distilling weighed amounts of volatile compounds ($S_2O_6F_2$, HSO_3F) into reactor flasks equipped with Teflon coated stir bars, used for effective mixing. KSO_3F was added initially before distilling $S_2O_6F_2$ and HSO_3F onto the solid. Additions were carefully weighed. All solutions were vigorously stirred before use. Samples for Raman, ESR, or NMR studies were prepared inside an inert atmosphere box (3) from stock solutions previously prepared as described above. Solutions in anhydrous HF were obtained in Kel-F [poly(chlorotrifluoroethylene)] reaction vials fitted with Monel metal tops. A metal vacuum line was used for the HF transfer. All solutions in HSO_3F were made up in 25 or 50 mL Pyrex vessels fitted with Kontes Teflon stem valves.

Instrumentation

All NMR spectra were obtained on a Varian XL-300 FT spectrometer, operating at 282.231 MHz for the ^{19}F experiments. The Raman spectrometer has been described previously (8). Electron spin resonance measurements were made using an X-band (9.0 GHz) homodyne spectrometer employing a Varian 12 in. magnet equipped with a MK II Fieldial control. Phase-sensitive detection at 100 kHz was achieved with an Ithaco Dynatrac 391 A lock-in amplifier. The temperature was controlled to within ±0.1°C using a Varian E-257 temperature controller. The ESR samples were loaded via a Teflon-tipped syringe into 100 μL glass tubes under inert atmosphere and sealed with Teflon plugs. No signals were observed for background runs at room temperature with HSO_3F or N_2 gas.

^{19}F NMR chemical shifts are all relative to $CFCl_3$, while ^1H NMR chemical shifts are relative to TMS, with both utilizing $CDCl_3$ as the external locking agent.

Results and discussion

(a) Raman spectroscopy

The Raman spectrum recorded on a 1:2 (by volume) solution of $S_2O_6F_2$ in HSO_3F is shown in Fig. 1. A comparison with the previously reported Raman spectra for HSO_3F (15) and $S_2O_6F_2$ (16) as well as with a re-recorded spectrum on freshly distilled $S_2O_6F_2$ allows the following conclusions: (*i*) The solution spectrum is in first approximation a composite spectrum of the two major components. (*ii*) The relatively strong, polarized vibrational bands of $S_2O_6F_2$ are unperturbed and are clearly recognizable, while some of the weaker bands are not observed. It is clear that the bulk of bis(fluorosulfuryl)peroxide is present as such in solution of HSO_3F. (*iii*) The O—O stretching band at 801 cm^{-1} is unchanged in both position and relative intensity. It appears that the O—O bond strength is not altered in HSO_3F solution. This may be viewed as evidence that at room temperature no change in reactivity of $S_2O_6F_2$ in solution has occurred. (*iv*) The OH stretching mode is observed as a broad band centered at 3096 ± 10 cm^{-1}, a position comparable to the reported IR band at 3125 cm^{-1} in liquid HSO_3F (17). This implies that intermolecular interaction between HSO_3F and $S_2O_6F_2$ effects νOH in a very similar way as intermolecular association does in liquid HSO_3F. (*v*) Besides bands due to $S_2O_5F_2$ (19), the only other new, weak bands found at 1281, ~1100 and 774 cm^{-1} are attributed to the presence of SO_3F^- in solution, based on a precedent (15) and the fact that addition of KSO_3F results in an increase in intensity for all three bands. Weakly basic behavior of $S_2O_6F_2$, suggested previously from electrical conductivity data (13), is seen as the reason for the formation of SO_3F^- according to eq. [3].

If hydrogen bonding or even proton transfer plays a role in the solution process, it is valid to ask why HSO_3F is capable of interacting with $S_2O_6F_2$ in this manner while H_2SO_4 is seemingly not. There are two plausible, interrelated explanations: (*i*) HSO_3F is a better proton donor than H_2SO_4, as reflected in their respective $-H_0$ values of 15.07 and 11.93 (21, 22) or 10.09 for 96.5% H_2SO_4 (22*a*), and (*ii*) tight intermolecular hydrogen bonding in H_2SO_4, causing its high viscosity (22*b*), is not effectively broken up by the insufficiently basic $S_2O_6F_2$ molecule.

It should hence be possible to (*a*) dissolve $S_2O_6F_2$ in acids stronger than H_2SO_4 using the $-H_0$ values as a guide and (*b*) diminish the solubility of $S_2O_6F_2$ in HSO_3F by reducing its acidity through addition of KSO_3F.

(b) Solubility studies of $S_2O_6F_2$ in strong protonic acids

There are, in addition to HSO_3F, two simple protonic acids which are of higher acidity than H_2SO_4, are available in anhydrous form and will not dissociate or decompose at room temperature as, for example, HSO_3Cl or $HClO_4$: anhydrous HF, $-H_0$ = 15.1 (23) and HSO_3CF_3, $-H_0$ = 14.1 (24). The latter, trifluoromethylsulfuric acid is similar in acidity to a number of additional sulfonic acids with various other fluorocarbon substituents on sulfur (24).

As we reported some time ago (25), $S_2O_6F_2$ is extremely soluble in HSO_3CF_3. However, these solutions are unstable and slowly give rise to the evolution of heat and volatile products, among them CF_3OSO_2F. There is sufficient evidence from the reported interaction of the two acids HSO_3F and HSO_3CF_3 (26, 27) and from the thermal instability of the peroxide $(CF_3)_2S_2O_6$ (28) to conclude that oxidative cleavage of the S—C bond occurs (29). It appears then that HSO_3CF_3 is not a good solvent for $S_2O_6F_2$ in spite of high solubility of the latter, and synthetic

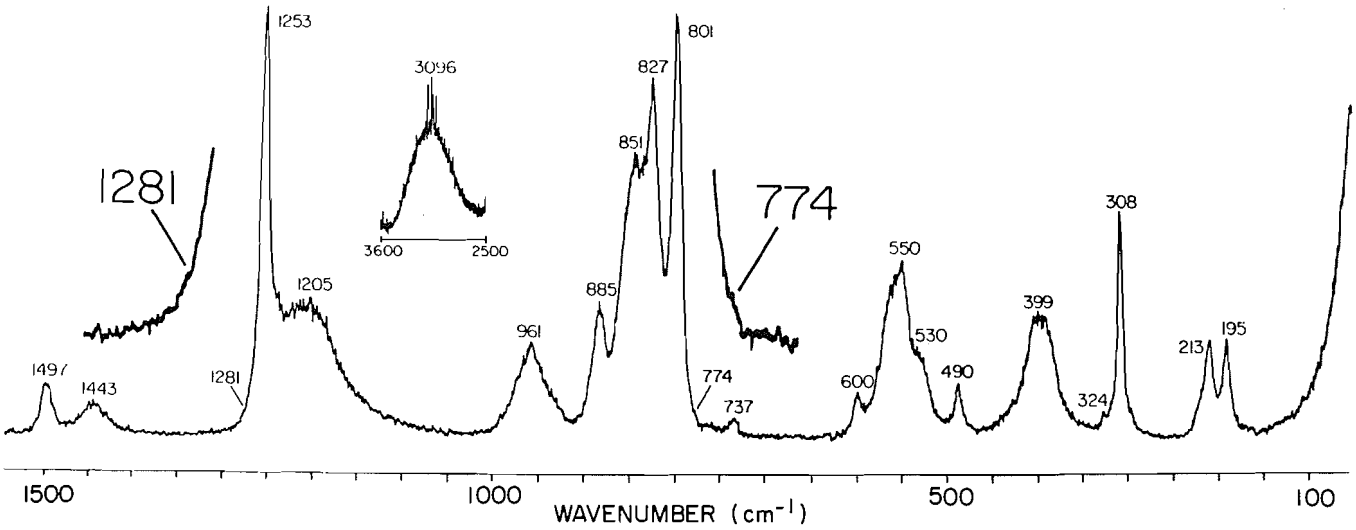

FIG. 1. Raman spectrum of $S_2O_6F_2$ in HSO_3F (1:2 solution by volume) at 20°C.

use of the mixture is only indicated where oxidation reactions proceed rapidly (25).

In anhydrous HF, the solubility of $S_2O_6F_2$ is lower than in either HSO_3F or HSO_3CF_3 but is still appreciable. The $-H_0$ value of 15.1 would suggest a higher solubility than is actually observed. This value, however, has been obtained by extrapolation during a study of the HF–SbF_5 system (23). On account of small amounts of H_2O acting as a base in "anhydrous" HF, measured $-H_0$ values have ranged as low as ~11 (24). Difficulties encountered in removing the last traces of water from HF (30), the low boiling point, and the possibility of F^- vs. SO_3F^- exchange during synthesis argue against extensive synthetic use of HF–$S_2O_6F_2$ solutions.

Addition of the base KSO_3F (13, 18) to a solution of $S_2O_6F_2$ in HSO_3F (molar ratio acid to peroxide = 1.72) at room temperature results in a separation into two phases once the concentration of KSO_3F exceeds 1.8 *M*. Assuming that KSO_3F is the only base in the system, its concentration would correspond to a $-H_0$ value of 11.8 (20).

As expected from the reported densities at 25°C of 1.726 g cm^{-3} (26) for HSO_3F and 1.645 g cm^{-3} for $S_2O_6F_2$ (31), the latter is the principle constituent of the upper layer. The volume of this upper layer increases steadily with increasing KSO_3F concentration or decreasing temperature and contains at 25°C the bulk of the $S_2O_6F_2$ for a 3.1 *M* KSO_3F solutions. The physical separation of both phases by pipetting inside the inert atmosphere box is now possible.

The observed solubility loss of $S_2O_6F_2$ can be explained by the lowered acidity as argued above. Alternatively, one may view the strongly basic SO_3F^- as competing effectively with $S_2O_6F_2$ for HSO_3F to form solvates. The strength of the SO_3F^-–HSO_3F interaction is evident from the isolation and structural characterization of solid monosolvates of the type $M^1[H(SO_3F)_2]$ with M^1 = Na or Cs (32, 33). It does seem that the acid strength of a protonic acid or superacid is instrumental in forming stable solutions of $S_2O_6F_2$. When the acid strength of HSO_3F is increased by addition of $Ta(SO_3F)_{5(solv)}$ (3*b*), complete miscibility with $S_2O_6F_2$ is noted over the whole temperature range (318–198 K).

The solubility loss found has some implications regarding the synthetic use of $S_2O_6F_2$ solutions in HSO_3F. Metal oxidation in the presence of alkali metal fluorosulfates, aimed at forming ternary fluorosulfato complexes according to eq. [2], may show (at least initially) the same phase separation. It becomes important to choose reaction conditions and reactant concentrations where sufficient $S_2O_6F_2$ remains in the acid phase to effect oxidation.

The qualitative solubility study described here has pointed to conditions where $S_2O_6F_2$ ceases to be soluble in HSO_3F and to the role acidity or protonating ability plays in the system. The subsequent section will probe into the nature of the interaction using NMR. There are now two sides to the problem: (*a*) the acid phase where $S_2O_6F_2$ is the solute and HSO_3F the solvent, and (*b*) the upper phase formed under basic conditions, where the roles may be reversed.

(c) ^{19}F and ^1H NMR spectroscopy studies

Both $S_2O_6F_2$ and HSO_3F give rise to sharp, single line resonances in the ^{19}F NMR spectrum, which at 298 K occur at 39.03 and 40.74 ppm relative to $CFCl_3$, respectively. Both resonances show only a small temperature dependence over the temperature range studied. The $S_2O_6F_2$ line gradually shifts from 39.04 ppm at 318 K to 38.83 ppm at 198 K, while the ^{19}F resonance line of HSO_3F shifts from 40.77 to 40.61 ppm in the same temperature range. The expected peak separation between both lines remains reasonably constant at 1.72 ± 0.04 ppm over the whole range.

The ^1H resonance of HSO_3F also shifts very gradually from 10.47 ppm relative to TMS at 298 K to 10.67 ppm at 198 K. Weak ^{19}F resonances due to coupling of ^{33}S or ^{34}S isotopes have previously been observed for both HSO_3F and $S_2O_6F_2$ (34, 35). The low natural abundance (0.76% for ^{33}S and 4.22% for ^{34}S) and ^{33}S–^{19}F coupling result in very weak signals.

It hence appears that in the anticipated absence of spin–spin interactions (^{19}F–^1H), only single lines are expected and any evidence for solvent–solute interaction will have to come from two sources: (*a*) ^{19}F and ^1H chemical shifts relative to their positions in pure HSO_3F and $S_2O_6F_2$ and (*b*) the integration of peak areas of the ^{19}F resonances obtained on mixtures of known composition. Of these two, chemical shift information obtained on a 300 MHz instrument should be more accurate and reliable than peak area integration, due to the ~10% systematic error

associated with the latter. However, peak integration is useful in the detection of SO_3F^- group exchange between solvent and solute.

From previous studies on the KSO_3F–HSO_3F system (36), it is expected that increased SO_3F^- concentration will cause a small, concentration dependent upfield shift of the ^{19}F solvent resonance line. Such a shift is indeed noticed at 298 and 318 K for mixtures of HSO_3F and $S_2O_6F_2$ of various molar ratios, as seen in Table 1. The solute resonance, on the other hand, shifts gradually downfield, but the magnitude of this shift decreases with decreasing temperature. Below 298 K, the ^{19}F resonance due to HSO_3F begins to move downfield as well, and at 198 K the initial peak separation is nearly restored. A downfield shift of the ^{19}F resonances, indicative of reduced shielding of the F-nucleus, is expected for protonated bis(fluorosulfuryl)peroxide, $HS_2O_6F_2^+$, as well as for its hydrogen bridged solvate, formulated tentatively as $S_2O_6F_2 \cdot HSO_3F$.

The observations made for various mole ratios and temperatures, summarized in Table 1, may be expressed in terms of two simple processes, *solvate formation* and *ionic dissociation of the solvate* according to the overall reaction scheme:

$$[6] \quad S_2O_6F_2 + HSO_3F \rightleftarrows S_2O_6F \cdot HSO_3F \rightleftarrows S_2O_6F_2H^+_{(solv)} + SO_3F^-_{(solv)}$$

It appears that ionic dissociation is slowed down at lower temperatures while solvate formation is now favoured. Consistent with this view is a noticeable upfield shift of the ^{1}H resonance by about 0.5 to 0.6 ppm which is best observed at 218 and 198 K for solutions with HSO_3F in excess.

The overall process [6] involving proton bridging and proton transfer from HSO_3F to $S_2O_6F_2$ is, however, not the only exchange process in the system. As peak area integrations (also summarized in Table 1) indicate, the "acid" ^{19}F resonance is increased at the expense of the signal attributed to $S_2O_6F_2$ over the whole temperature range (318 to 198 K), with no pronounced temperature dependency recognizable. It must be concluded that fluorosulfate exchange involving the acid, its self-ionization ions $H_2SO_3F^+$ and more so SO_3F^-, the solute ion $S_2O_6F_2H^+$ and the solvate, formulated as $S_2O_6F_2 \cdot HSO_3F$, occurs in addition to proton exchange. As seen from the tabulated integration ratios, SO_3F exchange is consistently observed, apparently independent of temperature and molar ratio of solute and solvent. This exchange involves about 10 to 20% of the $S_2O_6F_2$ present in the mixture, increasing slightly with temperature and acid/peroxide molar ratio.

Addition of KSO_3F to the HSO_3F–$S_2O_6F_2$ mixture initially has no significant effect on either proton or SO_3F-exchange, as long as the concentration of KSO_3F in HSO_3F remains below 1.8 M. This is apparent from the trends in the observed chemical shifts and measured integrated peak areas seen in Figs. 2 and 3, respectively. When the concentration of KSO_3F is raised above 1.8 M, a two-phase system results, and the ^{19}F NMR spectrum becomes more complicated.

Figure 4 shows the ^{19}F NMR spectrum of a typical two-phase system, with a KSO_3F concentration of 3.14 M, and a molar $HSO_3F/S_2O_6F_2$ ratio of 1.72. As the temperature is lowered from 298 to 198 K, peak A gets less intense and eventually completely vanishes, while peak B increases in intensity. The intense, unlabelled peak at ~40 ppm is due to HSO_3F while the two resonances labelled A′ and B′ are assigned to $S_2O_5F_2$ present as an impurity in both phases. Resonances A and A′ are attributed to $S_2O_6F_2$ and $S_2O_5F_2$, respectively, dissolved in HSO_3F, while B and B′ resonances are due to the same respective species found in the upper phase. As the temperature is lowered, the solubility of both $S_2O_6F_2$ and $S_2O_5F_2$ in HSO_3F decreases while the upper layer consequently increases in volume.

Peak B and the downfield B′ resonance are both distorted triplets, indicative of a comparable perturbation effecting both the $S_2O_6F_2$ and $S_2O_5F_2$ resonances. Similar triplets are observed in all solutions studied with the KSO_3F concentrations greater than 3 M. Unequal spacings, relative intensities and difference

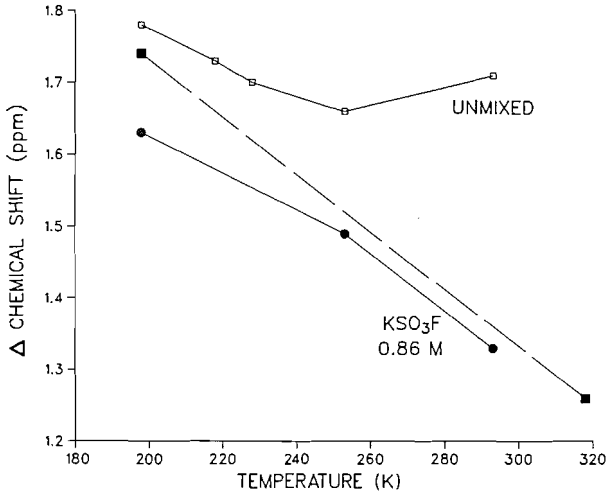

FIG. 2. Temperature dependence of the separation between HSO_3F and $S_2O_6F_2$ ^{19}F NMR signals (■: "neutral", H/OX molar ratio = 1.86; ●: "basic", H/OX molar ratio = 1.68; □: H and OX measured separately (unmixed)).

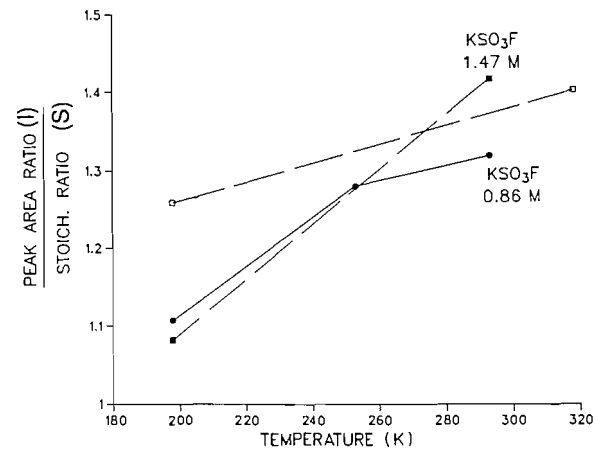

FIG. 3. Temperature dependence of $HSO_3F/S_2O_6F_2$ ^{19}F NMR integration peak area ratio relative to the stoichiometric fluorine content ratio (□: "neutral", H/OX molar ratio = 1.86; ■: "basic", H/OX molar ratio = 2.22; ●: "basic", H/OX molar ratio = 1.68).

in temperature dependency of the resonances within the triplet pattern argue against any spin-spin coupling as the cause. The most likely explanation of the triplet patterns is hence hydrogen bridging from the HSO_3F dissolved in the upper phase to both $S_2O_6F_2$ and $S_2O_5F_2$. A possible bridging conformation is shown in the Fig. 4-inset for $HSO_3F \cdot S_2O_6F_2$, where the acid proton is involved in a hydrogen bridge to one of the S—O bonds of $S_2O_6F_2$, creating different environments for each of the three fluorine atoms present. The intense middle peak of the triplet is assigned to F_2 in Fig. 4-inset, since its chemical shift is within ±0.05 ppm of the free $S_2O_6F_2$ resonance. Accordingly, the presence of free, unsolvated $S_2O_6F_2$ in the upper phase would contribute to this peak as well, accounting for its greater relative intensity, seen especially at 198 K. A similar interpretation applies to the $S_2O_5F_2$ resonance B′.

The structure observed for both $S_2O_6F_2$ and $S_2O_5F_2$ resonances in the upper phase also suggests the absence of exchange or ionization processes and the presence of well defined solvates at low temperatures with both sulfur(VI) oxyfluorides acting as proton acceptors. In the acid phase, with solvent and solute roles

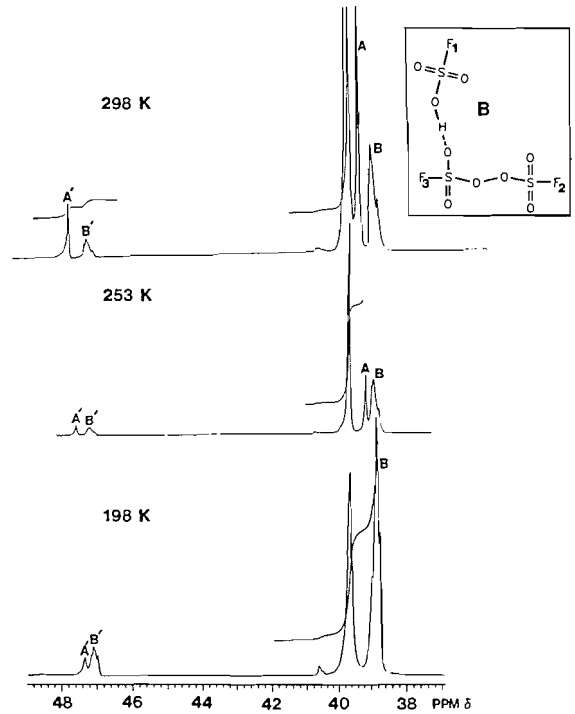

FIG. 4. ^{19}F NMR spectra of two-phase KSO_3F–$S_2O_6F_2$–HSO_3F solution ([KSO_3F] = 3.14 *M*, H/OX molar ratio = 1.72).

reversed, only single, reasonably sharp signals A and A′ (see Fig. 4) are present. Hence, no inferences can be made regarding the structure of the solvates in the strongly ionizing medium. The mechanism of SO_3F exchange between HSO_3F and $S_2O_6F_2$, reflected in the peak area integration for both, remains unclear. The question arises whether cleavage of the O—O bond resulting in the formation of radicals like $SO_3F^{\bullet}_{(solv)}$ and their subsequent recombination may occur differently in HSO_3F solution. The NMR spectra provide no indication for the presence of radicals in concentrations large enough to effect peak positions, in respect to previous reports (37), or to cause line broadening, which has been observed in liquid $S_2O_6F_2$ at elevated temperature (38). The possibility of finding radicals in HSO_3F solution at lower concentrations is therefore better probed by ESR.

(d) Electron spin resonance study of the solvated fluorosulfate radical

The reversible dissociation of bis(fluorosulfuryl)peroxide into radicals according to:

[7] $S_2O_6F_2 \rightleftarrows 2SO_3F^{\bullet}$

has been studied previously by ESR with the radical $SO_3F^{\bullet}$ observed in the liquid (14), gaseous (39), and solid phase (38, 40). In addition, the radical has been generated by photolysis of fluorine fluorosulfate, $FOSO_2F$ and studied in a solid $CFCl_3$ matrix at 77 K (40). All reports agree on a *g*-value of close to 2.011, with hyperfine splitting observed in the solid state (39). In the liquid phase a single, structureless component with a temperature dependent linewidth of ~25 G at 290 K is observed (14). A similar band shape is reported for the gas phase spectrum of the radical (39).

Our own observations for liquid $S_2O_6F_2$ at 293 K differ slightly and probably not significantly from the previous reports, considering differences in computational analysis and magnetic field calibration of the spectra (41). A slightly higher

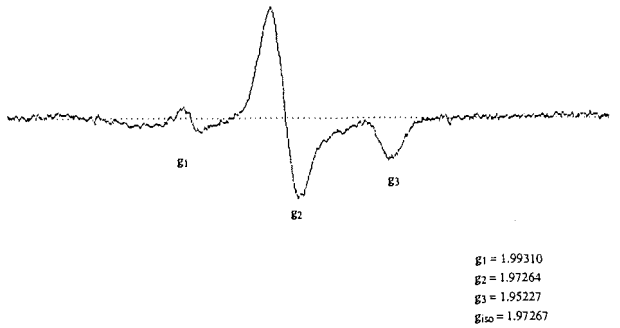

FIG. 5. Electron spin resonance spectrum of $S_2O_6F_2$ in HSO_3F (1:2.12 solution by volume) at 183 K.

g value of 2.0207 ± 0.0005 is obtained, but the linewidth of $\Delta H_{pp} \sim 26$ G is similar to previous reports (14).

When $S_2O_6F_2$ is dissolved in HSO_3F, a single, inhomogeneously broadened line is observed, which shows very little change in linewidth and g value between 283 and 323 K, with a g_0 value at 322 K of 1.9693. This signal persists when the temperature is gradually lowered and the spectrum obtained at 183 K is shown in Fig. 5. As can be seen, g is clearly anisotropic with g_{iso} found to be 1.97267. Hyperfine splitting is not observed.

The radical observed in solution is clearly not identical with $SO_3F^\bullet$ as reported previously (14, 38–40) or observed by us in liquid $S_2O_6F_2$. Consistent with the observation of three g-values (see Fig. 5), it can be concluded that the symmetry of the radical in HSO_3F solution is reduced below C_{2v}. On the other hand, $SO_3F^\bullet$ according to the vibrational analysis of the electronic spectrum (42) or to its vibrational spectrum studied in an inert gas matrix (43) has C_{3v} symmetry for both the electronic ground state ($^2A_2$) and the nearest excited state (^2E). Conversion of $SO_3F^\bullet$ to other radicals, such as $FSO_2^\bullet$ in solution (via a reduction), is rather unlikely because this species is short-lived and highly reactive, while the radical encountered here is persistent. Furthermore, $FSO_2^\bullet$ reportedly has a g value of 2.005 (40). It is more likely that the fluorosulfate radical, just like SO_3F^- (33) and to a lesser extent its dimer $S_2O_6F_2$, will form a solvate with HSO_3F which may subsequently (depending on the temperature) undergo ionic dissociation in an analogous manner as suggested for $S_2O_6F_2$ above:

[8] $$SO_3F^\bullet + HSO_3F \rightleftharpoons [FSO_3 \cdot HSO_3F]^\bullet \rightleftharpoons [HSO_3F^+]^\bullet + SO_3F^-$$

For both the mono-solvated or protonated radical, the overall symmetry would be at best C_s, assuming that protonation and hydrogen bridging involve oxygen, the more basic site, rather than fluorine on the $SO_3F^\bullet$ radical. Hence, three g values are expected and observed. In addition to the previously postulated radical displacement reaction in liquid $S_2O_6F_2$ (14) according to:

[9] $$SO_3F^\bullet + S_2O_6F_2 \rightleftarrows S_2O_6F_2 + SO_3F^\bullet$$

a similar displacement with HSO_3F:

[10] $$SO_3F^\bullet + HSO_3F \rightleftharpoons [FSO_3 \cdot HSO_3F]^\bullet \rightleftharpoons HSO_3F + SO_3F^\bullet$$

could compete effectively with the recombination reaction [7] and hence account for its persistence down to 183 K, close to the melting point of HSO_3F. Furthermore, a radical mediated SO_3F group exchange involving $S_2O_6F_2$ and HSO_3F could well explain observations made in the NMR section concerning peak area integrations. In view of the anticipated low radical concentration, alternate exchange pathways may, however, also be involved.

Finally, SO_3F radical migration via reactions [9] and [10] together with SO_3F^- migration involving a proton jump mechanism are seen to account for the fast and efficient metal oxidations performed in $HSO_3F/S_2O_6F_2$ (3–9). Hence, postulated hydrogen bridging to, and protonation of the $SO_3F^\bullet$ radical by HSO_3F not only explains the observed ESR spectrum, but also the radical's persistence in HSO_3F and its reactivity in this medium.

The proposed interaction of the $SO_3F^\bullet$ radical with HSO_3F is reversible, which accounts for the fact that both the solvent, HSO_3F, and the solute, $S_2O_6F_2$, can be separated quantitatively by distillation on account of differences in vapor pressures and boiling points (31). Hence, irreversible degradation of the $SO_3F^\bullet$ radical to, for example, $FSO_2^\bullet$ or other radical fragments is rather unlikely.

Summary and conclusions

The principle solute $S_2O_6F_2$ and its monomeric radical $SO_3F^\bullet$ behave as very weak bases in HSO_3F. All manifestations of the acid–base interaction are rather subtle with the possible exception of the ESR spectrum of solvated $SO_3F^\bullet$, where a change in symmetry and electronic structure seems to be apparent. Ironically, two principle conclusions reached in an earlier study of the HSO_3F–$S_2O_6F_2$ system (13), that $S_2O_6F_2$ is a non-electrolyte and present in undissociated form in HSO_3F are found to be not entirely valid. However, the solvated radical which is detectable at the freezing point of HSO_3F appears to be present in an extremely low concentration, and will not restrict the value of $S_2O_6F_2$ for cryoscopy in HSO_3F (13).

The techniques used in this study, Raman, ^1H, and ^{19}F NMR, and finally ESR spectroscopy show increasing usefulness (in the listed order) in studying the very weak bases. The solubility loss found for $S_2O_6F_2$ in HSO_3F–KSO_3F is very helpful in two respects: (*i*) it allows us to demonstrate that acidity or proton donor strength plays a key role in the weak acid–base interaction, and (*ii*) it permits the study of $S_2O_6F_2$ and HSO_3F in reversed roles, with $S_2O_6F_2$ now the solvent, using ^{19}F and ^1H NMR spectroscopy.

The formulation of monosolvated $S_2O_6F_2$ and $SO_3F^\bullet$ is chosen because for the related SO_3F^- ion such hydrogen bridged solvates are known (32), and in the case of $Cs[SO_3F \cdot HSO_3F]$ structurally characterized (33). Solvation of the $SO_3F^\bullet$ radical is seen to increase the lifetime and mobility of this species in HSO_3F. Both persistence and mobility of the radical contribute to the synthetic usefulness of the HSO_3F–$S_2O_6F_2$ system, demonstrated by us previously (3–9). While, consistent with the Raman spectra, there is no evidence for a weakening of the O—O bond in $S_2O_6F_2$ and hence a more facile formation of radicals in HSO_3F, there is evidence for a longer lifetime of the radical at low temperatures due to solvate formation.

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **68**, 109 (1990).

The tricarbonyl anions of Cr, Mo, and W incorporating unsymmetrical tridentate chelating pyrazolyl gallate ligands, $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2X)]M(CO)_3^-$, have been isolated as their crystalline Et_4N^+ salts. ^1H nmr and solution infrared studies indicate that the octahedral anions display a facial arrangement of the gallate ligand and the three carbonyl groups. This stereochemistry has been proven definitively for the tungsten complex with X = NMe_2 by an X-ray structure determination (see below). Fluxional behavior for the anions in d_6-acetone solution has been demonstrated by variable temperature ^1H nmr studies and is compared to similar behavior displayed by the neutral molybdenum "allyl" complex, $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe_2)]Mo(CO)_2(\eta^3\text{-}C_4H_7)$. Crystals of tetraethylammonium [dimethyl(3,5-dimethylpyrazol-1-yl)(2-*N*,*N*-dimethylaminoethoxy)gallato-N^2,N^3,*O*]tricarbonyltungstate are orthorhombic, a = 11.312(9), b = 33.111(9), c = 7.445(6) Å, Z = 4, space group $P2_12_12_1$. The structure was solved by conventional heavy atom methods and was refined by full-matrix least-squares procedures to R = 0.033 and R_w = 0.034 for 2508 reflections with $I \geq 3\sigma(I)$. The $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]W(CO)_3^-$ anion has *fac*-octahedral coordination geometry with W—O = 2.228(7), W—N(pyrazolyl) = 2.299(8), W—N(amine) = 2.37(1), and W—CO = 1.91(1)–1.92(1) Å.

Key words: pyrazolyl-gallate complexes, fluxional behavior of Ga–W complexes, crystal structure of Ga–W complex, gallate–tungsten complexes.

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **68**, 109 (1990).

On a isolé les anions tricarbonyl du Cr, du Mo et du W incorporant les ligands chélatants tridentates non-symétriques gallate de pyrazolyle, $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2X)]M(CO)_3^-$, sous la forme de sels cristallins de tétraéthylammonium. Les études rmn du ^1H et infrarouge en solution indiquent que les anions octaédriques présentent un arrangement facial du ligand gallate et des trois groupements carbonyles. On a démontré cette stéréochimie sans ambiguïté en déterminant la structure de la complexe de tungstène, avec X = NMe_2, par diffraction des rayons-X (voir plus bas). Faisant appel à la rmn du ^1H à température variable, on a démontré le comportement fluxionnel des anions en solution dans la d_6-acétone et on l'a comparé au comportement semblable que présente la complexe neutre de l'«allyl» molybdène, $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe_2)]Mo(CO)_2(\eta^3\text{-}C_4H_7)$. Les cristaux du [diméthyl(3,5-diméthylpyrazol-1-yl) (2-*N*,*N*-diméthylaminoéthoxy) (gallato-N^2,N^3,*O*] tricarbonyltungstate de tétraéthylammonium sont orthorhombiques, avec a = 11,312(9), b = 33,111(9) et c = 7,445(6) Å, Z = 4 et groupe d'espace $P2_12_12_1$. On a résolu la structure par les méthodes conventionnelles aux atomes lourds et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de R = 0,033 et R_w = 0,034 pour 2508 réflexions avec $I \geq 3\sigma(I)$. L'anion $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]W(CO)_3^-$ possède une géométrie de coordination *fac*-octaédrique avec W—O = 2,228(7), W—N(pyrazolyl) = 2,299(8), W—N(amine) = 2,37(1) et W—(CO) = 1,91(1)–1,92(2) Å.

Mots clés : complexes gallate de pyrazole, comportement fluxionnel des complexes Ga–W, structure cristalline d'une complexe Ga–W, complexes Ga–W.

Introduction

The preparation of THF solutions of the salts $Na^+[Me_2Ga(N_2C_3HR_2)(OCH_2CH_2X)]M(CO)_3^-$, (where R = H or Me, X = NH_2, NMe_2, or SEt, M = Cr, Mo, or W), has been reported previously (1, 2). At that time the salts were not isolated but, rather, their THF solutions were used directly in decarbonylation reactions to produce various neutral complexes of the type $[Me_2Ga(N_2C_3HR_2)(OCH_2CH_2X)]M(CO)_2L$, (where L = NO, N_2Ph, η^3-allyl, η^3-C_7H_7, or η^2-CH_2SMe) (1–5). The present account details the synthesis and characterization of representative tetraethylammonium salts of the above carbonyl anions where R = Me, X = NMe_2 or SEt, and M = Cr, Mo, or W, and describes the X-ray crystal structure determination of the $Et_4N^+[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]W(CO)_3^-$ complex. The fluxional behavior of the anions in d_6-acetone solution has been studied using variable temperature ^1H nmr techniques and a rationale for the observed behavior is proposed.

Experimental

Air-sensitive materials were handled in a glove box under an atmosphere of oxygen-free dry nitrogen, or in a nitrogen-blanketed apparatus. Tetrahydrofuran (THF) was dried by refluxing over sodium/benzophenone and used immediately following distillation. The sodium salts $Na^+[Me_2Ga(N_2C_3HR_2)(OCH_2CH_2X)]M(CO)_3^-$ were prepared in THF solution as described previously (1, 2).

Preparation of $Et_4N^+[Me_2Ga(N_2C_3HR_2)(OCH_2CH_2X)]M(CO)_3^-$

To the sodium salt, $Na^+[Me_2Ga(N_2C_3HR_2)(OCH_2CH_2X)]M(CO)_3^-$, in THF solution was added an equimolar amount of Et_4NCl dissolved in a minimum amount of MeOH. Formation of a precipitate (NaCl) was immediate. After 5–10 min, the mixture was filtered and the solvent removed from the filtrate *in vacuo* to leave a yellowish solid. This was recrystallized from THF to give yellow crystals of the product in approximately 50–60% yield. Physical data for the six salts prepared are presented in Table 1.

X-Ray crystallographic analysis of $Et_4N^+[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]W(CO)_3^-$

A crystal *ca.* 0.25 × 0.25 × 0.40 mm in size was mounted in a general orientation. Unit-cell parameters were refined by least-squares on setting angles for 25 reflections (2θ = 20–30°) measured on a diffractometer with Mo-$K\alpha$ radiation (λ = 0.71069 Å). Crystal data at 21°C are

$C_{23}H_{43}GaN_4O_4W$ f.w. = 598.04

Orthorhombic, a = 11.312(9), b = 33.111(9), c = 7.445(6) Å, V =

‡Measured as Nujol mulls.
§Measured as CH_2Cl_2 solutions.
‖J_{N-CH_3} = 1 Hz, J_{CH-CH} = 7 Hz.

2788(3) Å^3, Z = 4, ρ_c = 1.42 Mg m^{-3}, F(000) = 1176, μ(Mo-Kα) = 51.9 cm^{-1}. Absent reflections: *h*00, *h* odd, 0*k*0, *k* odd, and 00*l*, *l* odd, uniquely indicate the space group $P2_12_12_1$ (No. 19).

Intensities were measured with graphite-monochromated Mo-Kα radiation on a Rigaku AFC6S diffractometer. An ω scan at 16° min^{-1} over a range of (0.88 + 0.35 tan θ) degrees in ω (with up to nine rescans, background/scan time ratio = 0.5) was employed. Data were measured to 2θ = 60°. The intensities of three check reflections, measured every 150 reflections throughout the data collection, showed only small random fluctuations (<3%). After data reduction,[1] an empirical absorption correction, based on azimuthal scans for three reflections, was applied which resulted in transmission factors ranging from 0.843 to 1.000. Of the 4593 independent reflections measured, 2508 (54.6%) of these had intensities greater than or equal to $3\sigma(F^2)$ above background where $\sigma^2(F^2) = (S^2(C + 4B) + (0.35(F_o^2))^2)/Lp^2$ with *S* = scan rate, *C* = scan count, *B* = total background count, and Lp = Lorentz-polarization factor.

The structure was solved by conventional heavy atom methods, the W and Ga coordinates being determined from the Patterson function and those of the remaining non-hydrogen atoms from subsequent difference Fourier syntheses. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms were fixed in idealized positions (methyl orientations from difference Fourier, C—H = 0.98 Å, $U_H \propto U_{bonded\ atom}$). Scattering factors for all atoms and anomalous dispersion corrections for non-hydrogen atoms were taken from ref. 6. The weighting scheme $w = 4F_o^2/\sigma^2(F_o^2)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix refinement of 289 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at $R = 0.033$ and $R_w = 0.034$ for 2508 reflections with $I \geq 3\sigma(I)$. Parallel refinement of the opposite enantiomer (for the particular crystal used for data collection) resulted in substantially higher residuals (R_w and *R* factor ratios of 1.16 and 1.15, respectively). The anisotropic thermal parameters of C(13) indicate a probable minor conformational disordering of the chelate ring that would also involve the *N*-methyl carbon atoms C(14) and C(15). The inconsistency of the thermal parameters of C(15) with those of C(13) and C(14) suggest that little is to be gained by the refinement of a disordered model. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the maximum parameter shift corresponded to 0.07σ. The mean error in an observation of unit weight was 1.13. The final difference map showed maximum fluctuations of −0.73 to 0.90 e Å^{-3}, both near W. The final positional and equivalent isotropic thermal parameters for the non-hydrogen atoms appear in Table 2. Bond lengths and angles for the anion are listed in Tables 3–4. Hydrogen parameters, anisotropic thermal parameters, bond lengths and angles for the cation, torsion angles, intermolecular contacts, least-squares planes, and structure factors have been deposited.[2]

Spectra

Infrared spectra were recorded on a Perkin-Elmer 457 spectrophotometer and ^{1}H nmr on a Varian XL 100 spectrometer using FT techniques.

Results and discussion

The sodium salts, $Na^+[Me_2Ga(N_2C_3HR_2)(OCH_2CH_2X)]M(CO)_3^-$, are extremely sensitive to both oxygen and water (especially in solution), darkening visibly on exposure to air after several minutes. Qualitatively it was found that air-stability was in the order W > Mo > Cr and salts where R = Me were observed to be more stable than those with R = H. Representative anions for each metal (M = Cr, Mo, or W) and the ligands where R = Me; X = NMe_2 or SEt have been isolated as their crystalline tetraethylammonium salts. These salts, although considerably less air sensitive than the corresponding sodium salts, decomposed slowly over a period of days when exposed to the laboratory atmosphere. They are stable indefinitely under a nitrogen atmosphere.

The ir spectra of the anions, in both CH_2Cl_2 and as Nujol

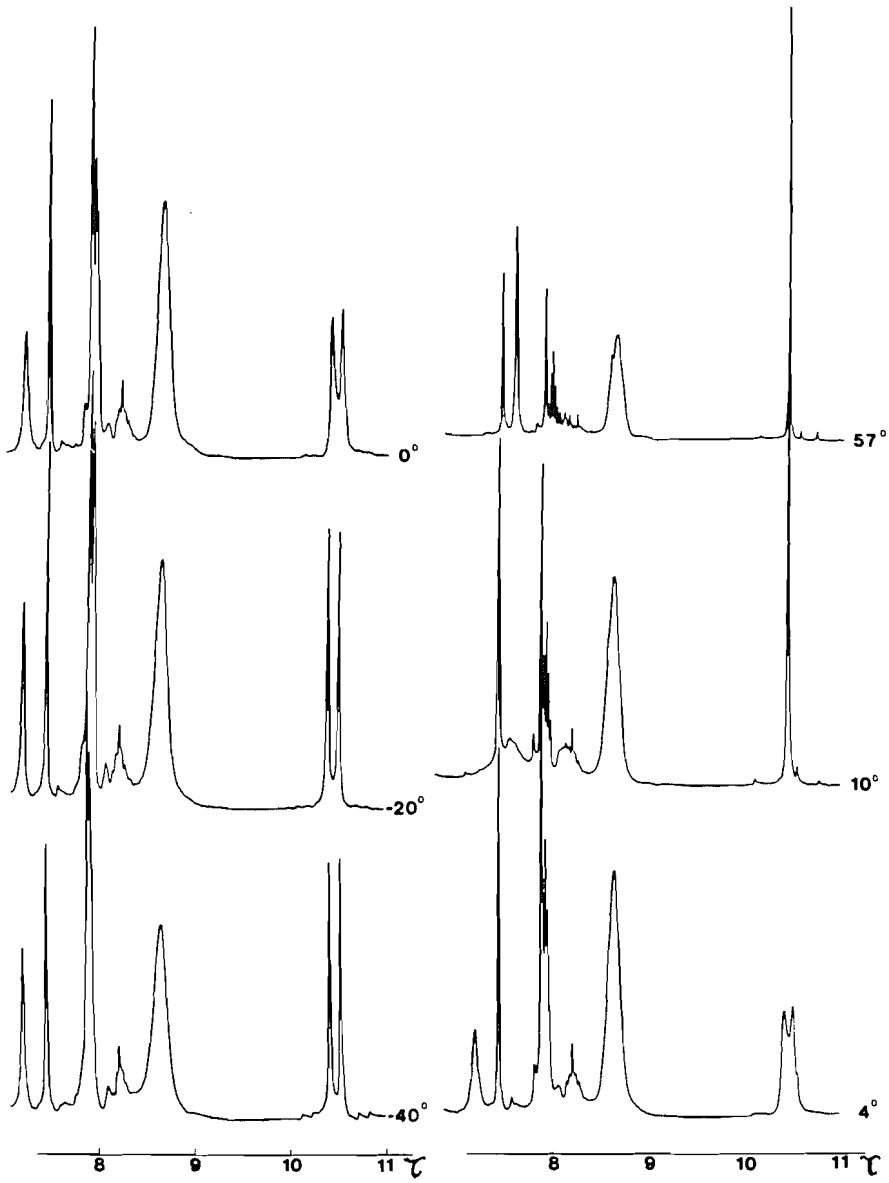

FIG. 1. Temperature-dependent 100 MHz ^{1}H nmr spectrum of $Et_4N^+[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Cr(CO)_3^-$ in d_6-acetone solution.

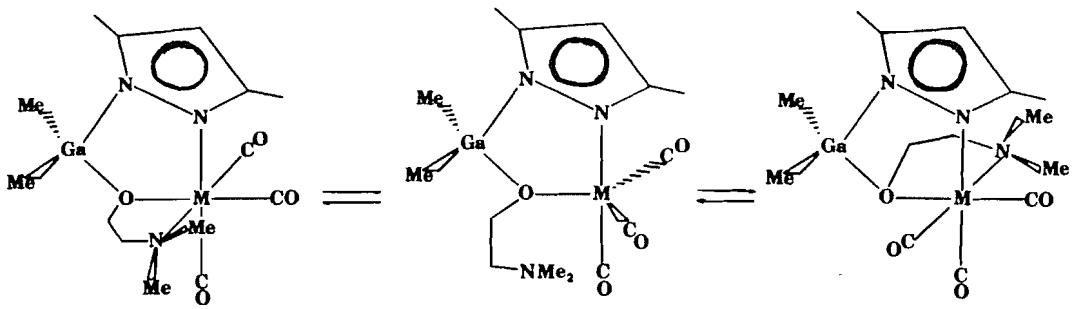

FIG. 2. Suggested fluxional behavior for the $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]M(CO)_3^-$ anions in d_6-acetone solution.

mulls (see Table 1) show two bands in the ν_{CO} region, bands of approximately equal intensity with the lower frequency band (*e* mode) being quite broad. This pattern is indicative of a facial arrangement for the three CO groups in the anions (7) although the lack of resolution of the broad band into two components, a splitting observed for the neutral, valence isoelectronic, manganese tricarbonyl compounds (1), is puzzling. The low temperature limiting ^{1}H nmr spectra obtained for the complexes (see Table 1) are in agreement with this assignment since the tridentate gallate ligands give ^{1}H nmr patterns consistent with a *facial* coordination geometry. Thus two signals are observed for the —$GaMe_2$ moiety, and, in the cases where X = NMe_2, two

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12

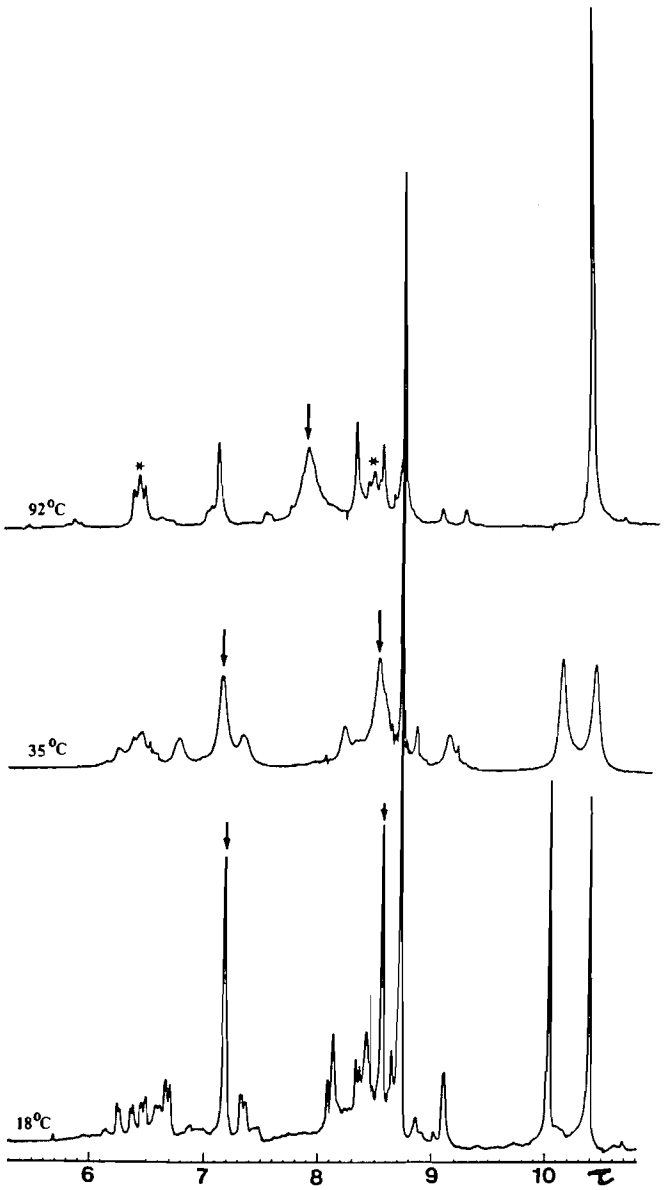

FIG. 3. Temperature dependent 100 MHz ^{1}H nmr spectrum of $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe_2)]Mo(CO)_2(\eta^3\text{-}C_4H_7)$ in C_6D_6 solution. (*): $—CH_2CH_2—$ protons (↓): $—NMe_2$ protons.

signals are observed for the $—NMe_2$ moiety. A *meridional* arrangement of the gallate ligands would lead to one signal for each of these groupings if the inversion from the λ to δ conformation of the $(OCH_2CH_2NMe_2)M$ five-membered ring were facile. Such facile inversions have been well documented in our earlier studies (8–12) and of necessity involve pyramidal inversion at the three-coordinate oxygen atom in the *mer* structures. However, the ^{1}H nmr spectra of five of the six complexes studied show, even at room temperature, only one signal for the $—GaMe_2$ group, and one signal for the $—NMe_2$ group, where applicable. A fluxional process, rather than a *meridional* coordination for the tridentate ligand, was immediately suspected to give rise to these observations and this was confirmed by variable temperature ^{1}H nmr studies. The temperature-dependent ^{1}H nmr spectrum of a representative sample, $Et_4N^+[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Cr(CO)_3^-$, in d_6-acetone solution is shown in Fig. 1. At −40°C, two signals are observed for each of the $—GaMe_2$ and $—NMe_2$ moieties. On warming the solution these signals broaden, collapse, and then at higher temperatures appear as one strong singlet for each of these groupings. Similar temperature-dependent spectra were observed for the remaining five compounds listed in Table 1. The coalescence temperatures (see Table 1) depend on both the transition metal, being lowest for Cr and highest for W, and also on the nature of the X group, being lower for a particular transition metal when X = SEt rather than NMe_2. The lower the coalescence temperature the more facile the fluxional process, and steric factors may play an important role with the variation of X and also with the change in transition metal M, but with the latter electronic factors may be of greater importance.

A suggested mechanism for the fluxional process is illustrated in Fig. 2. It is assumed that at low temperatures in solution the *facial* arrangement, as observed in the solid state, exists. The proposed mechanism requires the breaking of the $M—NMe_2$ bond, rearrangement to a five-coordinate intermediate having a plane of symmetry, and reforming of the $M—NMe_2$ bond (pyramidal inversion at oxygen in the *facial* arrangement without concomitant M—N bond breaking cannot be invoked to explain the observed spectra). A fast equilibrium, via inversion at the oxygen atom between the two limiting structures would result in the observation of one signal for each of the $—NMe_2$ and $—GaMe_2$ groups as seen in the higher temperature spectra. Bond length data would support the breaking of the weaker $W—NMe_2$ bond (2.37 Å) rather than the shorter, stronger, W—N(pz) bond (2.299 Å).

Interestingly the related neutral complex, $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe_2)]Mo(CO)_2(\eta^3\text{-}C_4H_7)$, which was suspected earlier (1) to exhibit fluxional behavior in solution because of the broad signals observed in the ^{1}H nmr spectrum at room temperature for the $—NMe_2$ and $—GaMe_2$ protons, has now been shown to display a temperature dependent ^{1}H nmr spectrum. Representative spectra are given in Fig. 3. The $—NMe_2$ and $—GaMe_2$ signals, broad at room temperature, are observed to sharpen at lower temperatures and collapse at higher temperatures. A fluxional process similar to that proposed above for the tricarbonyl anions but with the $\eta^3\text{-}C_4H_7$ group occupying the position opposite the pyrazolyl nitrogen in the five-coordinate intermediate could again rationalize the observed spectra. The much higher coalescence temperature observed for the allyl complex is expected considering the steric requirements of the methallyl vis-a-vis the carbonyl ligand. Supportive of this proposal is the positioning of the $\eta^3\text{-}C_4H_7$ group in the related complex $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NH_2)]Mo(CO)_2(\eta^3\text{-}C_4H_7)$. An X-ray crystallographic analysis has revealed the allyl ligand to be positioned *trans* to pyrazolyl nitrogen in this pseudo octahedral complex (13).

The structure of the $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]W(CO)_3^-$ anion (Fig. 4) shows the expected facial coordination by the unsymmetrical tridentate ligand. This is the first structure of a tricarbonyl anion incorporating a pyrazolyl gallate ligand. Crystal structures have been reported for neutral Mn and Re tricarbonyl species $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2X)]M(CO)_3$: X = SPh and M = Mn (14); X = SPh and NMe_2, M = Re (15); as well as the related molecules $[Me_2Ga(N_2C_5H_7)(OCH_2(C_5H_4N))]Re(CO)_3$ (9) and $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Mo(CO)_2(\eta^2\text{-}CH_2SMe)$ (4). The W—O, W—N(2), and W—N(3) bond lengths in the $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]W(CO)_3^-$ anion (2.228(7), 2.299(8), and 2.37(1) Å) are longer by an average of 0.085 Å than the corresponding distances in the isoelectronic neutral Re tricar-

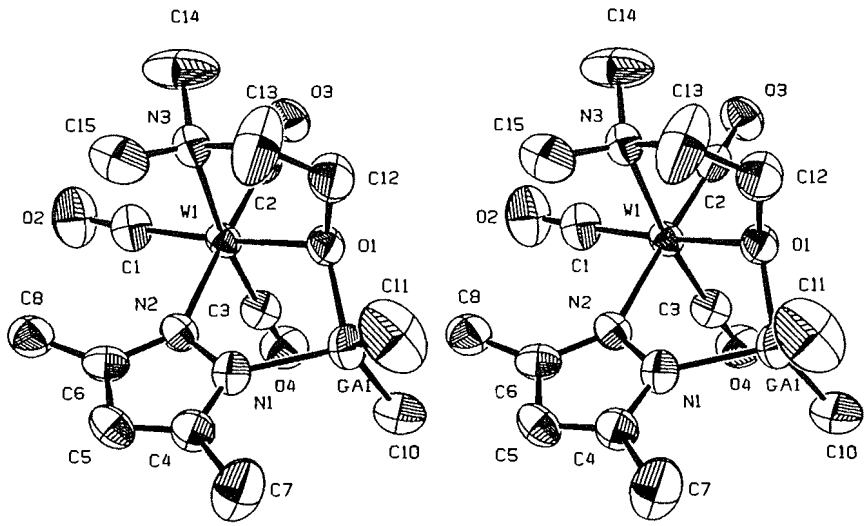

FIG. 4. Stereoscopic view of the $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]W(CO)_3^-$ anion; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

bonyl complex (15) (2.153(6), 2.189(7), and 2.300(7) Å) while the metal–carbonyl distances in these two species are equal within experimental error with W—CO = Re—CO = 1.91 Å. The W—O and W—N(3) distances are very similar to the Mo—O and Mo—N distances of 2.245(2) and 2.396(3) Å in $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Mo(CO)_2(\eta^2\text{-}CH_2SMe)$ (4), while the Mo—N(pyrazolyl) bond (trans to the η^2-CH_2SMe ligand) is shorter at 2.199(2) Å. The relatively long W—N(3) distance is consistent with the mechanism suggested above for the fluxional process in solution.

Other bond lengths and angles (Tables 3 and 4) are normal. The crystal structure of $Et_4N^+[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]W(CO)_3^-$ consists of discrete cations and anions, the most significant interspecies contacts being a pair of cation–anion C—H···O interactions. These interactions [C(16)—H(24)···O(3)(1 + x, y, z) and C(18)—H(30)···O(1)(1 + x, y, z), C···O = 3.41(1) and 3.43(1) Å, H···O = 2.53 and 2.53 Å, C—H···O = 152 and 149°] both involve hydrogen atoms associated with α-carbon atoms of the Et_4N^+ cation. Stereoviews of the cation and the packing arrangement have been deposited.[2]

Chem. **68**, 115 (1990).

This paper reports a retrosynthetic analysis that led to the conception of a synthetic strategy for the construction of ryanodol (**2**). The preparation of a key diene, i.e., spirolactone dienone **47** (**19** → **31** → **33** → **48** → **49** → **52** → **47**), and its Diels–Alder reaction with methyl vinyl ketone are reported.

Key words: strategy, synthesis, ryanodol, diterpene.

Chem. **68**, 115 (1990).

On rapporte l'analyse rétrosynthétique qui a conduit à la conception d'une stratégie menant à la synthèse du ryanodol (**2**). On décrit la synthèse du diène-clé, la spirolactone diénone **47** (**19** → **31** → **33** → **48** → **49** → **52** → **47**), et sa réaction de Diels–Alder avec la méthylvinylcétone.

Mots clés : stratégie, synthèse, ryanodol, diterpène.

Ryanodine (**1**), a natural product isolated from *Ryania speciosa Vahl*, is the ester of pyrrole α-carboxylic acid and the complex diterpene (+)-ryanodol (**2**) (1) (Scheme 1). The structure of ryanodine including its absolute configuration was elucidated by Wiesner *et al.* at the University of New Brunswick (2). This work constitutes one of the most brilliant accomplishments in structure elucidation using chemical degradation, and remains a classic piece. The X-ray analysis of the *p*-bromobenzyl ether **3** of ryanodol was carried out by Srivastava and Przybylska (3). The original assignment of Wiesner was confirmed except for a minor point; the X-ray analysis revealed that the configuration of the isopropyl and tertiary hydroxyl groups at C_2 had to be reversed and is as indicated in structures **1**–**3**.[2]

We completed a total synthesis of (+)-ryanodol in 1979. This work was published in a preliminary form (4) and we now wish to report our investigation in detail. In Part I (this paper), we explain our general synthetic strategy (5, 6) and describe the preliminary experiments leading to the discovery of a very convenient unsymmetrical diene, which was needed for the construction of a key tricyclic intermediate via a Diels–Alder cycloaddition. Parts II–IV describe the remaining work (see accompanying papers).

General strategy

Ryanodol, a $C_{20}H_{32}O_8$ compound, is a pentacyclic diterpene, which has a ring skeleton consisting of 14 carbons and one oxygen atom. Thus, four rings (A, B, C, and E) are carbocyclic whereas the fifth one (ring D) contains an oxygen atom. There is an isopropyl group as well as a tertiary methyl group in ring A, a tertiary methyl group in ring B, and an equatorially oriented secondary methyl group in ring C. In addition, there are five tertiary hydroxyl groups, one of which is part of a hemi-ketal function at one of the junctions of ring D and ring E (cf. C_{15}), and two secondary hydroxyl groups, one in ring A (α-oriented) and one in ring C (α-oriented and equatorial).

Ryanodol also has 11 contiguous asymmetric carbons (C_{1-6}, C_{9-12}, and C_{15}). Due to the bridged nature of the skeleton, five chiral centers (C_1, C_5, C_{11-12}, and C_{15}) are geometrically related and can only take the relative configuration shown. However, the other six chiral centers could, in principle, have a configuration opposite to that shown. It can be concluded from this analysis that ryanodol is indeed a very complex diterpene in which only three carbons of the skeleton (C_{7-8} and C_{14}) are left unfunctionalized as methylene groups.

With a complex target such as ryanodol, there are a rather large variety of synthetic strategies that can be devised theoretically. Our synthetic plan did not, however, originate directly from an analysis of the skeleton of ryanodol; it was based rather

SCHEME 1

on the structure of a degradation product, namely anhydroryanodol (**4**), and on the conviction that there must be a way to reconstruct ryanodol from this degradation product.[3]

In the course of the structure elucidation, it was observed that, under acidic conditions, ryanodol loses one molecule of water to produce anhydroryanodol (**4**). It turned out also that anhydroryanodol (**4**) became the principal degradation product; its structure was determined first (7) and that of ryanodol and ryanodine were deduced later on that basis.

Anhydroryanodol (**4**) contains three carbocyclic rings and a six-membered lactone. Rings A and B are five-membered while ring C is six-membered. Each carbocyclic ring possesses a methyl group, and ring A has in addition an isopropyl group. Four tertiary hydroxyl groups are attached to ring B, and one of them is part of the lactone ring. In addition, there is a tetrasubstituted double bond and an allylic secondary alcohol, which is also α-oriented in ring A, as well as a secondary equatorial alcohol in ring C. Thus, by comparison, the double bond and the lactone function of anhydroryanodol are replaced in ryanodol by one additional carbocyclic ring, two tertiary alcohols (one being part of a hemi-ketal), and three chiral centers (C_{1-2} and C_{15}). Thus anhydroryanodol (**4**) with its eight contiguous chiral centers is much less complex than ryanodol. Further comparison of the structure of anhydroryanodol with that of ryanodol indicates that the reconversion of the former into the latter involves essentially a reconnection of C_1 and C_{15} and the introduction of a β-oriented hydroxyl group at C_2.

The basic plan for the synthesis of anhydroryanodol is outlined in Scheme 2. We were very much interested in the rather simple tricyclic system **5**, which is a bicyclo[2.2.2.]octane derivative containing an extra five-membered ring, a tertiary methyl group at C_5, and a tetrasubstituted double bond. This interest was created by the fact that the oxidation of the double bond in **5** should yield the macrobicyclic diketone **6**, which is ideally built to undergo a transannular aldol condensation[4] yielding the tricyclic hydroxy-ketone **7**.

Some common features between **7** and anhydroryanodol can be foreseen already. Indeed, in compound **7** we can recognize the carbon atoms of the B, C, D rings of anhydroryanodol as well as the tertiary methyl group at C_5 and the tertiary alcohol at C_6. Furthermore, the carbonyl group at C_{10} can be used to introduce and control the stereochemistry of the methyl group at C_9. Also, reduction of this carbonyl group could yield the desired equatorial alcohol at C_{10}, and this would complete ring C.

In principle, what is required to complete the synthesis of anhydroryanodol from **7** is a functional group at C_{15} to induce the formation of the lactone ring, and functional groups at C_5 and C_{12}, which are necessary to incorporate ring A and to introduce the two hydroxyl groups at these positions. Thus, what is really needed initially is a compound such as **8** that incorporates all the prerequisite functional groups to build anhydroryanodol. Indeed, with its three additional functional groups, X, Y and Z, compound **8** can in principle yield compound **10** via intermediate **9**. The formation of **11** from **10**, which completes rings C and D, has already been discussed and would thus be straightforward. The next task would be the stereocontrolled introduction of ring A and the two hydroxyl groups at C_4 and C_{12} using the functional groups X and Y at C_4 and C_{12} of intermediate **11**. For this, it was necessary to envisage that an appropriate synthon such as **12**, which is a three-carbon fragment containing two functional groups (V and W) and an isopropyl group, could be discovered and would be capable of reacting with **11** to produce the tetracyclic intermediate **13**. The final conversion of intermediate **13** into anhydroryanodol would then involve a series of appropriate functional group modifications in ring A.

The above general scheme deserves further comment. For instance, in contrast to diketone **6**, the diketone **9** is no longer symmetrical, and the consequence of this is that **9** can now yield two different aldol products, compounds **10** or **14**. Also, we did not know what synthon **12** would be, or its regio- and stereoselectivity on reaction with an intermediate such as **11** or an equivalent thereof. It was therefore clear that it was impossible to circumvent all the difficulties beforehand, that we had to take several risks. However, we felt confident in finding adequate solutions to these problems by undertaking a meticulous study of the reactivity of the key intermediates that would become available in the course of this investigation.

We also believed that this synthetic plan had a great potential for an easy control of the stereochemistry of all the chiral centers of anhydroryanodol. This was based on our conviction that there are only three chiral centers in anhydroryanodol that need to be carefully controlled. These crucial centers are C_6, C_{11}, and C_{12}.

[3]This synthetic plan was in fact conceived in 1965, prior to the discovery of the real structure of ryanodol, which was found in 1967 (7).

[4]In **6**, alternative internal aldol condensations are disfavored because they would produce strained four-membered ring aldol products.

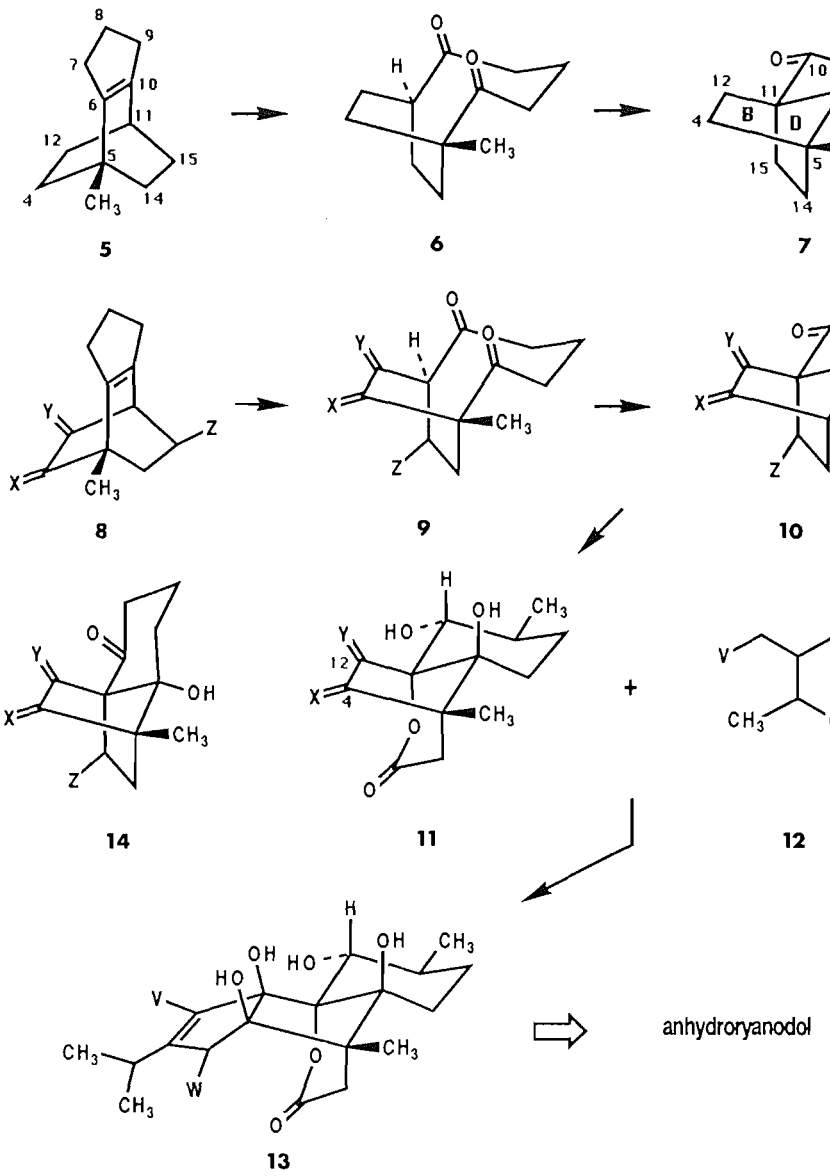

SCHEME 2

Indeed, chiral center C_5 is geometrically related to C_{11} and the relative stereochemistry of these two centers is automatically solved by the strategy used. Since rings A and B are both five-membered, it can be anticipated that production of a *cis* junction between these two rings could be a preferred pathway in our bond-forming process to produce ring A. Thus, C_4 is in principle also geometrically related to C_{12}. Similarly, the relative stereochemistry of rings C and B depends on the relative configuration at C_6 and C_{11}. Thus it follows that the relative stereochemistry of rings A, B, C, and D of anhydroryanodol depends on the relative configuration at C_6, C_{11}, and C_{12}. A solution for the control of these chiral centers will be presented later in this article. We have already discussed how to control the stereochemistry at C_9 and C_{10} and we did not anticipate any difficulty with the last chiral center of anhydroryanodol. Indeed, it is safe to expect that the hydride reduction of a carbonyl group at C_3 would occur from the least hindered face, producing the desired α secondary alcohol at that position.

When the structure of ryanodol was finally determined unambiguously (2, 3), it appeared clear to us that the reconversion of anhydroryanodol into ryanodol might be feasible in a relatively simple manner. An additional advantage of our strategy was that anhydroryanodol was readily available from the natural product and could be used to learn how to carry out the desired transformations concurrently with the synthetic work towards anhydroryanodol. Eventually, it turned out that a very simple reconversion of anhydroryanodol into ryanodol was discovered and is reported in detail in Part IV.

To begin our investigation, it was necessary to find an acceptable method for the preparation of tricyclic compounds of type **8**. The remaining part of this paper describes our work, which led to a very convenient synthesis of this type of compound.

Synthesis of compounds of type 8

Our approach to the synthesis of compounds of type **8** was influenced by the fact these compounds can be considered as bicyclo[2.2.2.]octene systems, which are in principle readily available by employing the Diels–Alder reaction.[5] It is conceivable on that basis that the simple dienophile **16** could react with

[5]We have also considered another approach, which is described in ref. 8.

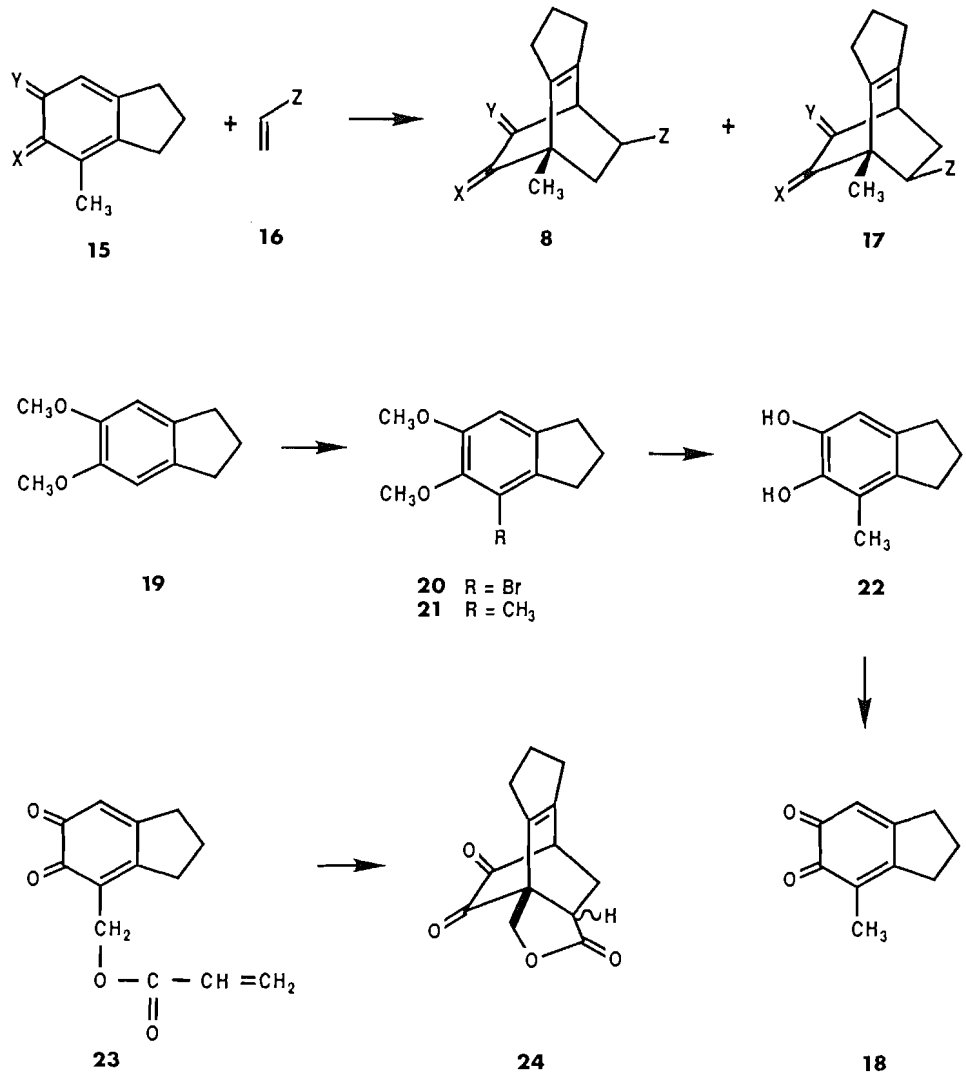

SCHEME 3

the diene **15** to yield the desired product **8** (Scheme 3). There was, however, a difficulty in this approach because the diene and the dienophile are both unsymmetrical and could give either the desired adduct **8** or its regioisomer **17**. First, we decided to find out if this type of Diels–Alder reaction would work, and then to try to solve the problem of regioselectivity later if the reaction occurred.

In this approach, the functional group Z, which is needed in **8**, can also serve to activate the dienophile **16**, and we concluded that the choice of Z can only be made experimentally. Ideally X and Y of the diene **15** should be oxygen atoms because these atoms will be needed to introduce ring A and to eventually form the hydroxyl groups at C_4 and C_{12} of anhydroryanodol (cf. **11** + **12** → **13**). On that basis, diene **15** should be the *o*-quinone **18**. We had some hope that *o*-quinone **18** could be used as a diene because *o*-quinones are reactive compounds that dimerize via the Diels–Alder reaction (9). Consequently they are good dienes and dienophiles. The next step was to find a dienophile of type **16** that would react with the diene of *o*-quinone **18**. We were encouraged by the fact that substituted *o*-benzoquinones were reported to react as dienes with styrene (10) or cyclopentadiene (11), yielding the corresponding Diels–Alder products.

5,6-Dimethoxyindane (**19**) was chosen as starting material. This compound can be easily obtained in large quantity from veratraldehyde (12). It can also be prepared in one step from 5,6-dimethoxy-1-indanone, which is commercially available. 5,6-Dimethoxyindane (**19**) was first treated with bromine to give the bromide **20**. Reaction of **20** with magnesium gave the corresponding Grignard reagent, which was reacted with dimethyl sulfate to yield methylindane **21**. Cleavage of the two methoxy groups in **21** was carried out with hydrobromic acid in acetic acid and the resulting phenol **22** was obtained pure by crystallization. The phenol **22** was then oxidized with silver oxide in ether (13) to yield the desired *o*-quinone **18**.

The *o*-quinone **18** was found to be quite unstable due to either dimerization or polymerization (14) and all attempts to trap **18** with dienophiles such as acrolein, methyl acrylate, or vinyl acetate failed. Before discontinuing this approach, we were interested in verifying whether a better result would be obtained by attaching the diene and the dienophile together. Therefore, the next goal was to prepare the *o*-quinone acrylate **23** in the hope that it would be converted into the intramolecular Diels–Alder adduct **24** (14).

The Grignard reagent **25** derived from 4-bromo-5,6-dimethoxyindane (**20**) was reacted with triethylorthoformate, heated a short time at 75°C, then hydrolyzed to give methoxyphenol aldehyde **26** (Scheme 4). When the final heating of the residue, before acid hydrolysis (see Experimental), was omit-

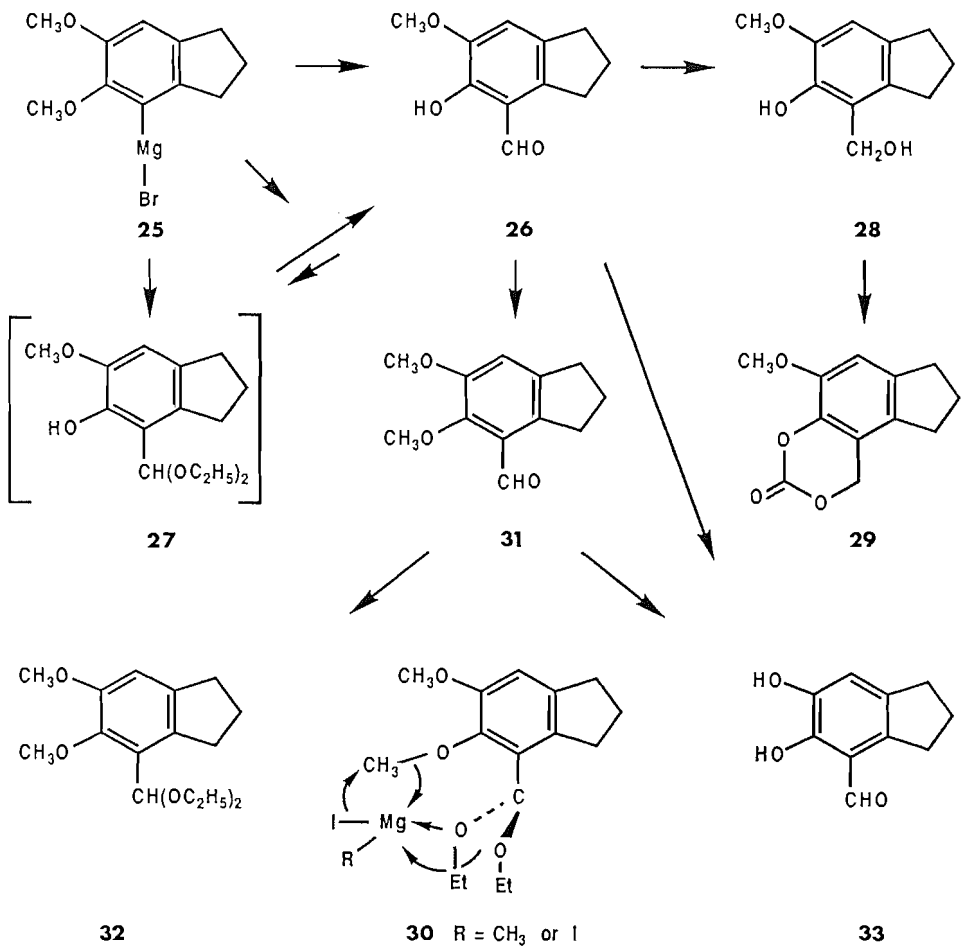
For personal use only.



SCHEME 4

ted, dimethoxyaldehyde **31** was isolated. The position of the methoxy group in **26** was established by transforming compound **26** into compound **28** ($LiAlH_4$, ether), which was then converted into the carbonate **29** by reaction with phosgene.

The unexpected cleavage of one methoxy group can be explained in the following manner: methylmagnesium iodide (15*a*) and (or) magnesium iodide (15*b*), which are present in the Grignard reaction, can act as a demethylating agent. The specificity of the process can be explained by invoking the chelation of the reagents by the two oxygen atoms of the acetal function (cf. **30**).[6]

Alkylation of methoxyphenol aldehyde **26** with dimethylsulfate gave dimethoxyaldehyde **31**, which was then converted into dimethoxyacetal **32** by acetalization.

Treatment of methoxyphenol aldehyde **26** with boron tribromide in dichloromethane (16) afforded the desired 4-formyl-5,6-dihydroxyindane (**33**). Compound **33** became an important key product in our synthesis and a more convenient method for its preparation was developed later on. Dimethoxyindane **19** was first directly converted into dimethoxyaldehyde **31** with α,α-dichloromethyl methyl ether in the presence of titanium tetrachloride in dichloromethane (17), which was then transformed (BBr_3, CH_2Cl_2) into *o*-diphenol aldehyde **33** (80% yield for the two steps).

The *o*-diphenol aldehyde **33** was converted into the carbonate aldehyde **34** by reaction with phosgene (Scheme 5). Compound **34** was then reduced (H_2, PtO_2, THF) to the corresponding carbonate alcohol **35**, which was esterified (acryloyl chloride, pyridine, benzene) to carbonate acrylate **36**. The next operation was the removal of the carbonate protecting group to obtain **37**, which would then be oxidized to the desired *o*-quinone acrylate **23**. However, the conversion of **36** into **37** was not successful. All attempts to selectively remove the carbonate group by mild hydrolysis (18) or mild reduction failed. We then tried a more direct approach that avoids the removal of the carbonate protecting group. *o*-Diphenol aldehyde **33** was reduced ($LiAlH_4$, ether) to *o*-diphenol benzyl alcohol **38**. Compound **38** was then oxidized to the unstable *o*-quinone alcohol **39**, which was characterized spectroscopically. All attempts to esterify compound **39** to give *o*-quinone acrylate **23** failed. This result indicated again that *o*-quinones are quite unstable and that it is difficult to work with them. An important modification in our synthetic approach was therefore necessary.

[6]This interesting hypothesis was confirmed by the treatment of dimethoxyacetal **32** with methylmagnesium iodide in ether, which gave after a short heating period at 75°C and acid hydrolysis the anticipated major product **26** along with other minor products: (a) 5,6-dimethoxy-4-(ethoxy-1)ethylindane; (b) 4-(ethoxy-1)ethyl 5-hydroxy-6-methoxyindane, and (c) 5-hydroxy-4-isopropyl 6-methoxyindane. Treatment of dimethoxyacetal **32** with freshly prepared magnesium iodide in ether gave compound **26** almost quantitatively after a 10-min heating period at 75°C followed by acid hydrolysis. Without the heating period, dimethoxyaldehyde **31** was obtained. We have further verified that dimethoxyaldehyde **31** does not yield methoxyphenol aldehyde **26** under the acidic conditions employed and that phenolacetal **27** is very easily hydrolyzed under those conditions.

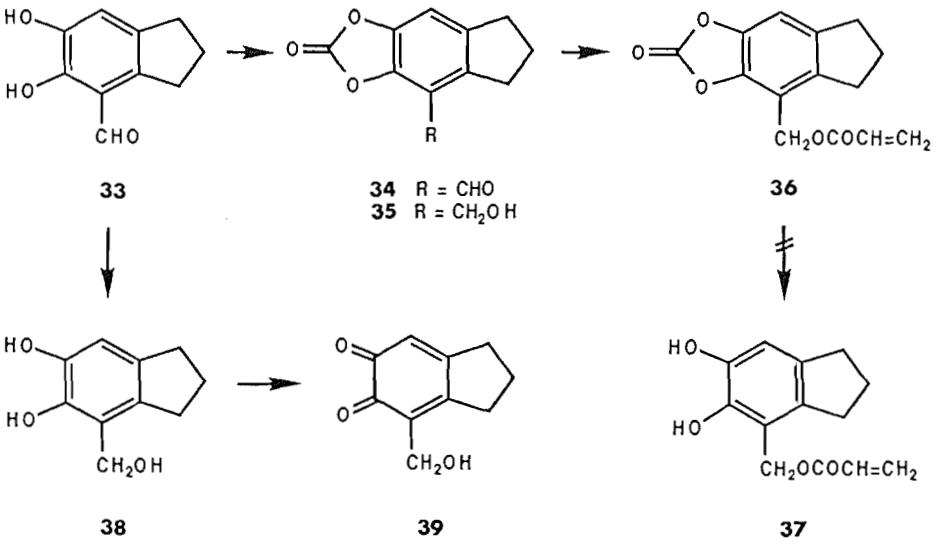
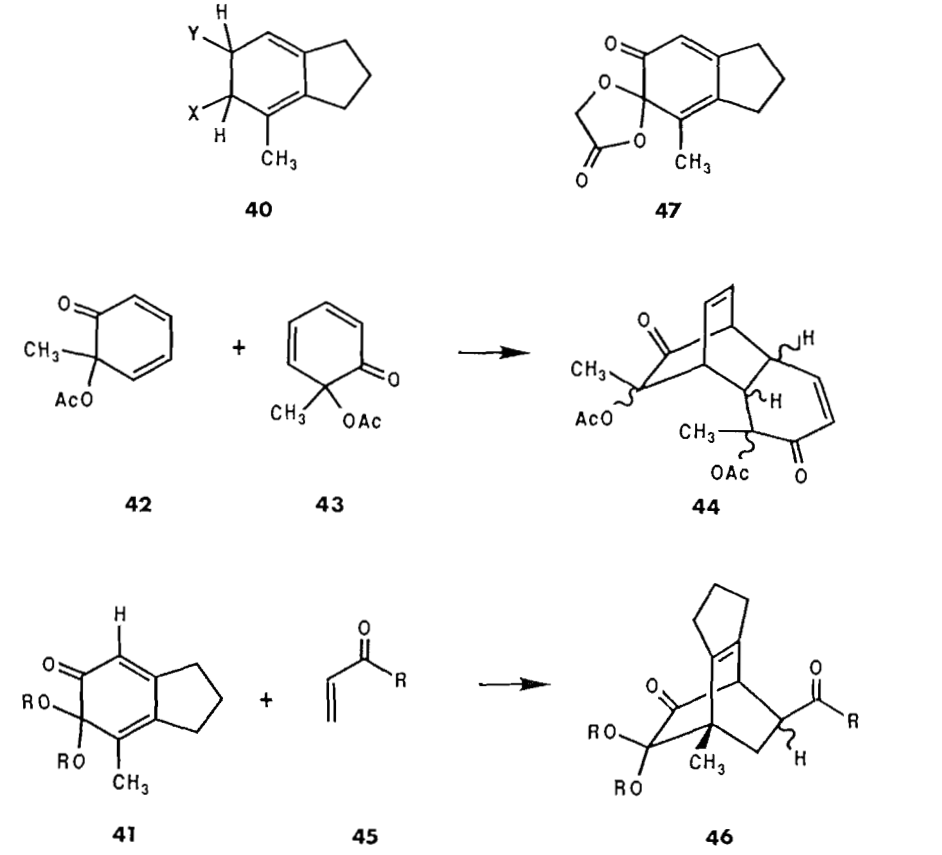


SCHEME 5



SCHEME 6

The difficulty in obtaining a convenient diene for our synthetic plan resides in the fact that the diene must also contain two extra functional groups X and Y. We could conceive dienes that would have a different level of oxidation than that of an *o*-quinone. For instance, we could envisage dienes of type **40** (Scheme 6), but we felt that such an approach was not very promising and it was not considered further because such dienes might not have the stability required to withstand the thermal conditions of an anticipated Diels–Alder reaction. Theoretically, the *o*-quinone was the ideal diene. It had just the right oxidation level to lead to a Diels–Alder adduct having the correct oxidation level, a 1,2-diketone, permitting the attachment of ring A directly. In practice, this approach did not work because *o*-quinones are unstable. Consequently, the only possibility that remained was to modify the *o*-quinone in such a way that the resulting derivative would be more stable, that it would not dimerize (or at least dimerize more slowly), and yet it would still be capable of reacting as a diene. The only modification that appeared attractive seemed to be at the carbonyl groups of the *o*-quinone, and on that basis we considered dienes of type **41**.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12

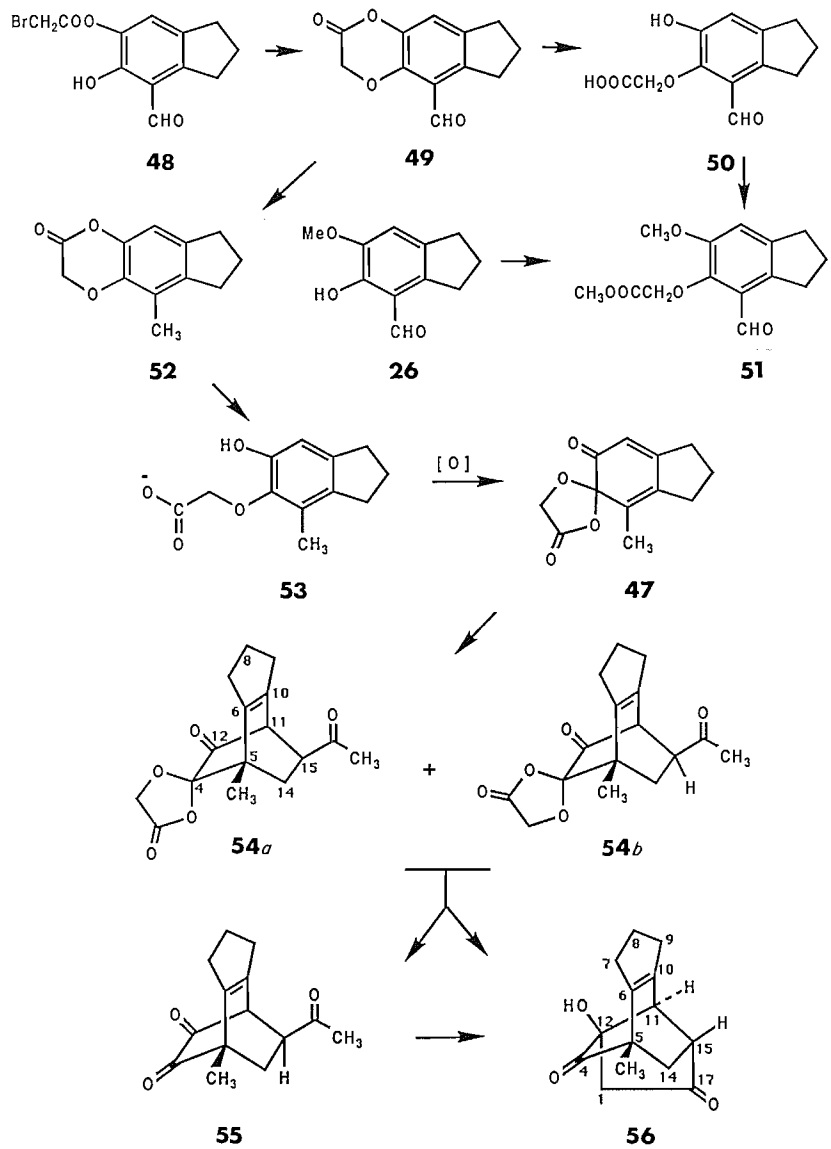

SCHEME 7

We had great hope with diene **41** because we thought that the ketal protecting group would not only make **41** a good diene, but it would render its reaction with an unsymmetrical dienophile completely regiospecific in the desired sense. This belief was based on the chemistry of quinol acetate.

It is known that quinol acetate (19) (or 6,6-disubstituted cyclohexadienone (20)) can act as a diene and as a dienophile (cf. **42** and **43**) to very readily give dimer **44** regiospecifically. Since diene **41** is more substituted than quinol acetate, we expected that **41** would dimerize slowly and it would prefer to react with a small active dienophile. There was one literature example of a substituted quinol acetate that underwent a Diels–Alder condensation with maleic anhydride as a dienophile (21). Furthermore, by analogy with the dimerization of quinol acetate, we could also expect that the reaction of diene **41** with an unsymmetrical dienophile such as vinyl ketone **45** should be completely stereo- and regiospecific. Indeed quinol acetate can be considered as a vinyl homolog (cf. **43**) of vinyl ketone **45**; thus both compounds should exhibit similar dienophilic behavior. Consequently, it was possible to predict that if vinyl ketone **45** reacted with diene **41**, it should give specifically the desired adduct **46**. We also decided that the most convenient diene of type **41** was the *o*-spirolactone dienone **47**. This decision was made on the basis that this type of compound should be easily prepared by oxidation of the corresponding *o*-hydroxyindanoxyacetic acid (*vide infra*). Indeed, there was literature precedent for such a transformation (22). We will now describe its preparation.

o-Diphenol aldehyde **33** was selectively esterified with α-bromoacetyl bromide in benzene containing pyridine to yield the monobromoacetate derivative **48** (Scheme 7). This crude product **48** was then heated to reflux in tetrahydrofuran in the presence of anhydrous sodium carbonate to furnish the crystalline lactone aldehyde **49** in 80% yield from **33**. A rigorous chemical proof for the position of the lactone ring in aldehyde **49** was obtained in the following way: alkylation of the known methoxyphenol aldehyde **26** with ethyl bromoacetate (K_2CO_3, THF) followed by basic hydrolysis and diazomethane esterification gave the methoxy aldehyde methyl ester **51**. Basic hydrolysis of **49** gave the corresponding phenol carboxylic acid **50**, which was successively esterified with diazomethane and alkylated with dimethyl sulfate (K_2CO_3, THF) to yield a product identical with compound **51**.

Wolff–Kishner reduction of lactone aldehyde **49** gave the

crystalline lactone **52** in 80% yield. The lactone **52** was then hydrolyzed with sodium hydroxide and the crude salt **53** was oxidized with *N*-bromosuccinimide in aqueous acetonitrile (22*b*, *c*) to give the desired crystalline *o*-spirolactone dienone **47** (≈90% yield). Interestingly, the *o*-spirolactone dienone **47** was found to be a stable crystalline compound. It did not dimerize even in refluxing benzene. The next task was to verify its reactivity as a diene with an active dienophile.

We discovered that *o*-spirolactone dienone **47** was an exceptionally good diene. With excess methyl vinyl ketone, it reacted in less than 1 h at room temperature to provide an almost 1:1 mixture of two isomers (**54***a* and **54***b*), which were separated. Brief treatment of either isomer (**54***a* or **54***b*) with aqueous base followed by acidification gave the same tricyclic ketone (**55**). This result showed that the two isomers differ by the configuration of the spirolactone ring only. This is not unexpected, as the attack of the dienophile can be just as facile from above or below the plane of structure **47**. Consequently, the Diels–Alder condensation between diene **47** and methyl vinyl ketone was essentially completely regio- and stereoselective.

The position of the methyl ketone side chain in compounds **54***a*, **54***b*, and **55** was easily established by ^{1}H nuclear magnetic resonance spectroscopy (H_{11} and H_{15} appear respectively as a doublet (J = 2 Hz) and an octuplet (J = 2, 6, and 9 Hz)). The configuration of the methyl ketone side chain was assigned *syn* to the double bond on the basis of the Alder *endo* rule (23), which predicts that the activating group of the dienophile must become *syn* to the double bond in the resulting adduct.

In the process of trying to obtain chemical evidence for the orientation of the methyl ketone side chain, we obtained a most interesting result. Treatment of tricyclic ketone **55** with aqueous tetrahydrofuran containing sodium hydroxide gave the tetracyclic hydroxydiketone **56**. We then found out that compound **56** was best prepared by directly treating the crude mixture **54***a* and **54***b* under the same basic conditions (75% yield). The direct conversion of **54***a* and **54***b* into **56** combines several steps in a single operation: (a) opening of the spirolactone to give a hemiketal, (b) breakdown of the hemi-ketal to give a carbonyl group, (c) epimerization of the methyl ketone side chain, and (d) aldol condensation of the methyl ketone group with one of the carbonyls of the α-diketone system.

The structure of **56** follows from the spectral data; for example, the ir shows a five-membered ring ketone. The formation of **56** was further confirmed by carrying out a series of deuterium experiments, and these results gave added support to the structures of **54***a* and **54***b*. When compound **56** was added to a deuterated basic medium (NaOD, D_2O–THF), it incorporated two deuterium atoms to give **56** deuterated at C_1. Since H_{15} was not exchanged, this result showed that the aldol condensation is an irreversible process. When **54***a* and **54***b* were placed in a deuterated basic medium, a trideuterated hydroxydiketone **56** (two D at C_1 and one D at C_{15}) was isolated in which H_{15} was totally exchanged for deuterium. These results were further confirmed by the treatment of trideuterated **56** with unlabelled aqueous sodium hydroxide, which gave monodeuterated hydroxydiketone **56** (D at C_{15}) exclusively.[7]

The above results show that the two primary objectives of our synthetic strategy were successfully reached. A good synthesis of spirolactone dienone **47** was achieved in six steps (**19** → **31** → **33** → **48** → **49** → **52** → **47**) from 5,6-dimethoxyindane (**19**) in an overall yield of ≈50%. It was also shown that spirolactone dienone **47** undergoes a selective Diels–Alder reaction with methyl vinyl ketone yielding the desired tricyclic structure **8**, i.e., compounds **54***a* and **54***b*. Furthermore, with the formation of the tetracyclic hydroxydiketone **56** in a single operation from **54**, we realized that we had made a greater advance than anticipated. Indeed, in compound **56**, one of the carbon–carbon bonds (C_1—C_{12}) of ring A of anhydroryanodol is generated and it is formed with the correct stereochemistry relative to ring A and ring B. Thus, two (C_{11}(or C_5) and C_{12}) of the three crucial asymmetric centers (C_6, C_{11}, and C_{12}) of ryanodol can be controlled.

The next objective was to show that the main basic idea of our strategy, i.e., the conversion **5** → **6** → **7**, can be realized. This work is reported in the following article.

Experimental

Apparatus, materials, and methods

Melting points were determined on a Büchi M-50 apparatus and are uncorrected. Ether, tetrahydrofuran, and 1,2-dimethoxyethane were dried by distilling over sodium benzophenone ketyl. Benzene, dichloromethane, dimethyl sulfoxide, and amines were distilled over calcium hydride. All reactions were performed under nitrogen or argon atmosphere. Analytical and preparative thin-layer chromotography (tlc) were carried out on glass plates precoated (0.25, 0.5, 1.0, 2.0 mm) with silica gel 60 F-250 (Merck). Materials were detected by visualization under an ultraviolet lamp (254 or 350 nm) and (or) by spraying with sulfuric acid (50%) or a solution of phosphomolybdic acid or vanillin followed by heating on a hot plate. Column chromatography was performed with silica gel (Baker (60–200 mesh) or Merck 60 (200–400 mesh)).

The infrared spectra (ir) were taken on a Perkin–Elmer 257 or 681 spectrophotometer. Proton nuclear magnetic resonance (^{1}H nmr) spectra were recorded (with chloroform or tetramethylsilane as internal standard) on a Varian A-60, a Bruker WP-60, a Bruker HX-90, or a Bruker WM-250 instrument. Carbon nuclear magnetic resonance (^{13}C nmr) spectra were measured on a Bruker HX-90 or WM-250 instrument. The following abbreviations have been used: s, singlet; d, doublet; dd, doublet of doublets; t, triplet; q, quartet; qn, quintet; m, multiplet; br, broad. For most of the hydroxylated compounds, the multiplicity of the hydrogens attached to a carbinol was analyzed after D_2O exchange. The mass spectra were recorded on a Hitachi–Perkin–Elmer RMU-6 mass spectrometer and peak matching (hrms) on a VG Micromass ZAB-2F spectrometer. The ultraviolet spectra (uv) were recorded on a Varian Techtron 635 spectrophotometer. Microanalyses were carried out by Mr J. Tamas, Laboratoire de microanalyses, Université de Sherbrooke; Schwarzkopf Microanalytical Laboratories, New York; and by Dr C. Daesslé, Organic Microanalyses, Montreal.

4-Bromo-5,6-dimethoxyindane (20)

A solution of bromine (46.0 g, 0.287 mol) in carbon tetrachloride (200 mL) was added dropwise, at room temperature, to a solution of 5,6-dimethoxyindane (**19**) (50.0 g, 0.284 mol) in carbon tetrachloride (200 mL). A strong flow of nitrogen was bubbled into the reaction mixture throughout the addition to remove hydrogen bromide formed during the reaction. After the addition, nitrogen bubbling was continued for an additional 30 min. The mixture was then washed with aqueous sodium thiosulfate (0.1 N) to remove traces of bromine. The organic phase was dried over anhydrous sodium sulfate, filtered, and evaporated to dryness. The yellow oil obtained (68 g, 93%) was kept in the cold (where it crystallized) and in the dark to avoid its rapid darkening by light; ^{1}H nmr ($CDCl_3$, δ ppm): 6.65 (s, 1H, Ar-H), 3.68 (s, 3H, O-CH_3), 3.55 (s, 3H, O-CH_3), 2.85 (m, 4H, 2 Ar-CH_2-), 2.08 (m, 2H, ArCH_2CH_2); ms *m/e*: 256 (M^+).

[7]The fact that there is a complete deuterium incorporation at C_{15} in the transformation **54**a + **54**b → **56** is a strong indication that the orientation of the methyl ketone side chain must be *syn* to the double bond as shown in structures **54**a and **54**b.

5,6-Dimethoxy-4-indanyl magnesium bromide (25)

A solution of 4-bromo-5,6-dimethoxyindane (**20**) (26.1 g, 0.101 mol) in anhydrous ether (250 mL) was added to magnesium turnings (12 g, 0.49 mol) in a three-neck, 1-L flask equipped with a mechanical stirrer and an efficient condenser. At the bottom of this mixture, methyl iodide (8 g, 0.057 mol) was slowly added with a pipet, care being taken not to disturb the phases of different density. After a few minutes, the reaction started and then methyl iodide (40 g, 0.28 mol) was slowly dropped into the mixture to maintain a strong reflux. The separation of an oily phase was reduced by strong mechanical stirring. When all the methyl iodide was added, the heating was stopped and this preparation was immediately used for the next step.

The formation of the Grignard reagent can be checked by hydrolysis of an aliquot (formation of 5,6-dimethoxyindane (**19**), R_f 0.47) and comparison on tlc (solvent: benzene – petroleum ether, 1:1) with the starting bromide **20** (R_f 0.67).

5,6-Dimethoxy-4-methyl indane (21)

To the Grignard reagent **25** prepared from bromide **20** (26 g, 0.10 mol) was added dropwise, with vigorous stirring, freshly distilled dimethyl sulfate (64 g, 0.51 mol). After the addition, the mixture was gently refluxed for 36 h (oil bath), then cooled, hydrolyzed (HCl, 1 M), and extracted with ether. The combined organic layers were evaporated to dryness and the residue was heated under reflux with aqueous sodium hydroxide (1 M, 10 mL) to remove the excess of dimethyl sulfate. Then the mixture was dissolved in ether, washed thoroughly with water, dried over anhydrous sodium sulfate, filtered, and the solvent removed under reduced pressure. Chromatography of the crude product (alumina, petroleum ether) gave 5,6-dimethoxy-4-methyl indane (**21**) (32%, 5.2 g of purity 85%) contaminated by 15% of a side product, 5,6-dimethoxyindane (**19**); ir ($CHCl_3$, ν cm^{-1}): 1660, 1330, 1105; ^1H nmr ($CDCl_3$, δ ppm): 6.68 (s, 1H, Ar-H), 3.83 (s, 3H), and 3.76 (s, 3H, OCH_3), 2.88 (t, 7.4 Hz, 2H), and 2.78 (t, 7.4 Hz, 2H) (2 ArCH_2), 2.18 (s, 3H, $ArCH_3$) 2.06 (quintet, 7.3 Hz, $ArCH_2CH_2$); ms *m/e*: 192 (M^+).

5,6-Dihydroxy-4-methyl indane (22)

A solution of 5,6-dimethoxy-4-methyl indane (**20**) (1.5 g, 9.1 mmol) in a mixture of glacial acetic acid (15 mL) and hydrobromic acid 47% (15 mL) was refluxed under nitrogen for 3 h. To that mixture was then added water (20 mL) and the reflux was pursued for an additional 10 min. The mixture was then cooled and extracted with ether. The combined extracts were washed with saturated aqueous sodium bicarbonate, dried over anhydrous sodium sulfate, filtered, and the solvent evaporated under reduced pressure. The residue was triturated with petroleum ether to dissolve the diphenol and the solution was filtered and the solvent evaporated. The colourless solid residue was recrystallized from petroleum ether to give 5,6-dihydroxy-4-methyl indane (**22**) (650 mg, 49%, mp 124°C); ir ($CHCl_3$, ν cm^{-1}): 3600, 3550, 1615, 1280; ^1H nmr ($CDCl_3$, δ ppm): 6.61 (s, 1H, Ar-H), 4.93 (s, 1H) and 4.88 (s, 1H) (2 OH), 2.82 (t, 7.4 Hz, 2H) and 2.77 (t, 7.4 Hz, 2H) (2 ArCH_2), 2.17 (s, 3H, $ArCH_3$), 2.04 (quintet, 7.3 Hz, $ArCH_2CH_2$); ms *m/e*: 164.

Oxidation of diphenol 22

To a solution of 5,6-dihydroxy-4-methyl indane (**22**) (1.00 g, 6.08 mmol) in anhydrous ether (100 mL) was added sodium sulfate (2 g) and freshly prepared silver oxide (3 g). The mixture was stirred at room temperature for 10 min, then filtered and the clear red solution evaporated to dryness to give a dark red residue; 0.95 g, 96%; ir (CH_2Cl_2): 1660 cm^{-1}.

4-Formyl-5-hydroxy 6-methoxyindane (26)

To the Grignard reagent **25** prepared from bromide **20** (26 g, 0.10 mol), under vigorous stirring, was slowly added ethyl orthoformate (83 g, 0.56 mol). The mixture was refluxed for 15 h (oil bath, 50°C), then ether was distilled out and the residue kept at 75°C (water bath) for 10 min under vacuum. The residue was then cooled (ice bath), cautiously hydrolyzed by slow addition of hydrochloric acid (300 mL, 3 M), and extracted with ether (3 × 300 mL). The combined extracts were dried over sodium sulfate, filtered, and concentrated to a volume of ~200 mL under reduced pressure. Then petroleum ether (600 mL) was added to precipitate the impurities. After filtration, the solution was cooled and 4-formyl-5-hydroxy-6-methoxyindane crystallized (13.5 g, 68%, mp 118–119°C); ir (CH_2Cl_2, ν cm^{-1}): 3525 (OH), 2780 (CHO), 1665 (C=O), 1610 (arom); uv (EtOH, λ_{max}): 273 mμ (ε 1620); ^1H nmr ($CDCl_3$, δ ppm): 11.37 (s, 1H, OH), 10.10 (s, 1H, CHO), 7.01 (s, 1H, ArH), 3.88 (s, 3H, OCH_3), 3.14 (t, 7.5 Hz, 2H) and 2.86 (t, 7.5 Hz, 2H) (2 ArCH_2), 2.16 (quintet), $ArCH_2CH_2$); ms *m/e*: 192 (M^+). *Anal.* calcd. for $C_{11}H_{12}O_3$: C68.74. H 6.29; found: C 68.67, H 6.05.

4-Diethoxymethyl-5-hydroxy 6-methoxyindane (27)

Triethylorthoformate (1 mL, large excess) was added at 25°C to a yellow solution of 4-formyl-5-hydroxy-6-methoxyindane (55 mg, 0.29 mmol) in dry ethanol (5 mL). To that mixture was added a crystal (≈1 mg) of *p*-toluenesulfonic acid. After 3 min the color was completely discharged. Potassium carbonate (≈3 mg) was then added and the volatile materials were removed under vacuum. The partly solid residue was triturated with dry ether and the ethereal fraction was filtered and evaporated. The almost colorless oil residue (75 mg, quant.) was kept in the cold and under argon. When exposed to moist air, it rapidly became yellow and crystallized (formation of compound **26**); ^1H nmr ($CDCl_3$, δ ppm): 8.42 (s, 1H, OH), 6.75 (s, 1H, Ar-H), 5.74 (s, 1H, *H*-$C(OEt)_2$), 3.84 (s, 3H, OCH_3), 3.65 (m, 4H, 2 CH_3CH_2O), 2.84 (t, 2H, 7.3 Hz) and 2.82 (t, 2H, 7.3 Hz) (2 ArCH_2), 2.04 (quintet, 2H, 7.3 Hz, $Ar(CH_2CH_2)$, 1.23 (t, 6H, 7.1 Hz) (2 CH_3CH_2O).

Carbonate 29

To a solution of 4-formyl-5-hydroxy-6-methoxyindane (**26**) (1.0 g, 5.2 mmol) in anhydrous ether (100 mL) was added portionwise lithium aluminium hydride (0.5 g). The mixture was stirred until decoloration occurred, then it was poured in small portions onto cold hydrochloric acid (100 mL, 0.2 M) and extracted with ether. The combined organic layers were washed with water, dried over magnesium sulfate, filtered, and evaporated under reduced pressure to give crystalline diol **28** (0.97 g, 96%, mp 99–100°C; ir 3650 cm^{-1}). To a solution of 4-hydroxymethyl-5-hydroxy-6-methoxyindane (**28**) (500 mg, 2.57 mmol) in benzene (50 mL) containing pyridine (960 mg) was slowly added a saturated benzenic phosgene solution (10 mL). The mixture was stirred for 15 min, then filtered. The filtrate was kept to dryness and the crude residue was recrystallized from petroleum ether to give pure white needles (420 mg, 74%, mp 146°C); ir (CH_2Cl_2, ν cm^{-1}): 1770; uv (EtOH, λ_{max}): 287 mμ (ε 350); ^1H nmr ($CDCl_3$, δ ppm): 6.83 (s, 1H, Ar-H), 4.50 (s, 2H, Ar-CH_2-O), 3.79 (s, 3H, -OCH_3), 2.90 (m, 4H, 2 Ar-CH_2-CH_2), 2.12 (quintet, 7 Hz, 2H, Ar-CH_2-CH_2); ms *m/e*: 220 (M^+). *Anal.* calcd. for $C_{12}H_{12}O_4$: C 65.45, H 5.49; found: C 65.65, H 5.48.

5,6-Dimethoxy-4-formylindane (31)

(*a*) *From 4-formyl-5-hydroxy-6-methoxyindane (26)*

To a solution of 4-formyl-5-hydroxy-6-methoxyindane (**26**) (500 mg, 2.60 mmol) in tetrahydrofuran (50 mL) was added finely powdered potassium carbonate (1.4 g) and dimethyl sulfate (480 mg, 3.8 mmol). The mixture was refluxed for 15 h with good stirring, then cooled and filtered. The filtrate was evaporated to dryness and the solid residue recrystallized from petroleum ether at −20°C to give cristalline aldehyde **31** (420 mg, 78%, mp 52°C); ir (CH_2Cl_2, ν cm^{-1}): 1685; uv (EtOH, λ_{max}): 263 mμ (ε 1050); ^1H nmr ($CDCl_3$, δ ppm): 10.42 (s, 1H, *CH*O), 7.05 (s, 1H, Ar-H), 3.89 (s, 3H, OCH_3), 3.85 (s, 3H, OCH_3), 2.98 (m, 4H, Ar-CH_2-), 2.08 (q, 7 Hz, $ArCH_2CH_2$); ms *me*: 206 (M^+). *Anal.* calcd. for $C_{12}H_{14}O_3$: C 69.89, H 6.84; found: C 69.91, H 7.06.

(*b*) *From 5,6-dimethoxyindane (19)*

In a 2-L three-necked flask equipped with a condenser, a mechanical stirrer, and a dropping funnel was dissolved 5,6-dimethoxyindane (**19**) (74.0 g, 0.416 mol) in dry dichloromethane (900 mL). To the cooled solution (0°C) was then added, at a good rate, titanium tetrachloride (96 mL). The solution became deep red-violet. Then dichloromethyl methyl ether (100 g, 0.97 mol) was added dropwise at the same temperature. The reaction mixture was stirred at 0°C for 15 min, at room temperature for 2 h, and refluxed for 2 h. The mixture was cooled, poured onto ice cold water (1 L), and stirred for 48 h. The two layers were separated and the aqueous phase extracted with dichloromethane

For personal use only.

(3 × 200 mL). The combined organic layers were washed with water (2 × 100 mL), dried ($MgSO_4$), filtered, and the solvent evaporated. The viscous residue was crystallized from petroleum ether to give crystalline aldehyde **31** (pale yellow crystals, 68 g, 80%, mp 52°C).

4-Diethoxymethyl-5,6-dimethoxyindane (*32*)

To a solution of aldehyde **31** (200 mg, 0.97 mmol) in anhydrous ethanol (10 mL) was added triethyl orthoformate (177 mg, 1.19 mmol) and *p*-toluenesulfonic acid (4 mg). The mixture was stirred at room temperature for 17 h, then reacted with saturated aqueous sodium carbonate, and extracted with ether. The organic layer was washed with water, dried over magnesium sulfate, and evaporated to dryness. The oily residue was purified by column chromatography on silica gel to give pure acetal **32** (170 mg, 62%); ir (CH_2Cl_2, ν cm^{-1}): 1605, 1480, 1330, 1100; ^1H nmr ($CDCl_3$, δ ppm): 6.78 (s, 1H, Ar-H), 5.79 (s, 1H, *H*-C(OEt)$_2$), 3.83 (s, 3H, OCH_3), 3.80 (s, 3H, OCH_3), 3.70 (m, 2H, OCH_2CH_3), 3.50 (m, 2H, OCH_2CH_3), 3.08 (t, 7.4 Hz, 2H) and 2.81 (t, 7.4 Hz, 2H) (2 $ArCH_2$-), 2.03 (quintet, 7.4 Hz, 2H, $ArCH_2CH_2$-), 1.22 (t, 7.4 Hz, 6H, OCH_2CH_3).

5,6-Dihydroxy-4-formylindane (*33*)

(*a*) *From 4-formyl-5-hydroxy-6-methoxyindane* (*26*)

To a solution of 4-formyl-5-hydroxy-6-methoxyindane (**26**) (18.0 g, 93.7 mmol) in dry methylene chloride (200 mL) was slowly added a solution of boron tribromide (25.0 g, 100 mmol) in dry methylene chloride (100 mL) (formation of a red complex). The reaction mixture was stirred at room temperature for 45 min, then reacted with aqueous methanol (20 mL, 90%). The volume was then reduced to ~50 mL under reduced pressure, water (50 mL) was added, and the resulting mixture extracted (3 × 300 mL) with the mixed solvent ether – petroleum ether (2:3). The combined extracts were dried ($MgSO_4$) and treated with silica gel (10 g) to adsorb acid impurities. After filtration, the solvent was evaporated under reduced pressure and the crude material crystallized from ether–pentane to give compound **33** (14 g of bright yellow crystals that darken in moist air, 84%, mp 130–131°C); ir CH_2Cl_2, ν cm^{-1}): 3550, 1650; uv (EtOH, λ_{max}): 278 mμ (ε 710); ^1H nmr ($CDCl_3$, δ ppm): 10.05 (s, 1H, CHO), 7.21 (s, 1H, Ar-H), 3.02 (m, 4H, 2 Ar-CH_2), 2.21 (quintet, 7 Hz, 2H, $ArCH_2CH_2$); ms *me*: 178 (M^+). *Anal.* calcd. for $C_{10}H_{10}O_3$: C 67.41, H 5.66; found: C 67.47, H 5.48.

(*b*) *From 5,6-dimethoxy-4-formylindane* (*31*)

Boron tribromide (81 mL, 0.854 mol) was slowly added to a cooled solution (−70°C) of 5,6-dimethoxy-4-formylindane (**31**) (80.0 g, 0.388 mol) in dichloromethane (1.5 L) under good mechanical stirring. When the addition was complete, the cold bath was removed and the mixture was allowed to warm to room temperature. The reaction was monitored by thin-layer chromatography. When the reaction was complete the mixture was cooled to −70°C and reacted successively with methanol (400 mL), aqueous methanol (1:1, 200 mL), and water (500 mL). The hydrolysis was then pursued for 15 h at room temperature. The two layers were separated and the aqueous phase was extracted with dichloromethane (4 × 250 mL). The combined organic layers were washed with water (2 × 250 mL), dried ($MgSO_4$), filtered, and the solvent evaporated under reduced pressure. The crude product was recrystallized (ether–pentane 1:1) to give an almost quantitative yield of the known (*vide supra*) 5,6-dihydroxy-4-formylindane (**33**) (68 g, 98%, mp 129–131°C).

5,6-Carbonyldioxy-4-formylindane (*34*)

To a yellow solution of 5,6-dihydroxy-4-formylindane (**33**) (5.50 g, 30.9 mmol) in dry benzene were added pyridine (8 g) and a benzenic saturated solution of phosgene until complete decoloration. The mixture was filtered, washed with dilute hydrochloric acid (0.1 M) and water, dried over magnesium sulfate, and the solvent evaporated. The crude product was recrystallized from ether–pentane to give carbonate **34** (5.9 g, 93%, mp 104°C); ir (CH_2Cl_2, ν cm^{-1}): 1835, 1780; ^1H nmr ($CDCl_3$, δ ppm): 10.35 (s, 1H, *CH*O), 7.41 (s, 1H, Ar-H), 3.13 (m, 4H, 2 Ar-CH_2), 2.20 (quintet, 7 Hz, $ArCH_2$-CH_2); ms *me*: 204 (M^+).

5,6-Carbonyldioxy-4-hydroxymethylindane (*35*)

A solution of 5,6-carboxyldioxy-4-formylindane (**34**) (2.0 g, 9.8 mmol) in tetrahydrofuran (100 mL), containing previously reduced platinum oxide (150 mg), was shaken in a hydrogen atmosphere for 24 h (atmospheric pressure, room temperature). The solution was then filtered and the solvent was evaporated under reduced pressure. The crude crystalline product was recrystallized from petroleum ether to give alcohol **35** (1.7 g, 84%, mp 107–109°C); ir (CH_2Cl_2, ν cm^{-1}): 3620, 1830; ^1H nmr ($CDCl_3$, δ ppm): 7.04 (s, 1H, Ar-H), 4.80 (s, 2H, -CH_2OH), 3.00 (m, 4H, 2 Ar-CH_2-CH_2), 2.16 (quintet, 7 Hz, 2H, Ar-CH_2-CH_2-); ms *me*: 206 (M^+). *Anal.* calcd. for $C_{11}H_{10}O_4$: C 64.08, H 4.89; found: C 64.16, H 4.73.

Ester 36

To a benzenic solution (250 mL) of 5,6-carbonyldioxy-4-hydroxymethylindane (**35**) (1.2 g, 5.8 mmol) containing pyridine (1.8 g) was added dropwise a solution of acryloyl chloride (0.9 g, 10 mmol) in benzene (50 mL). After 30 min at room temperature, the mixture was filtered, washed with dilute hydrochloric acid (0.1 M), water, then dried over magnesium sulfate, filtered, and the solvent evaporated. The solid residue was recrystallized from petroleum ether to give ester **35** (1.32 g, 87%, mp 60–61°C); ir (CH_2Cl_2, ν cm^{-1}): 1835, 1720; uv (EtOH, λ_{max}): 283 mμ (ε 320); ^1H nmr ($CDCl_3$, δ ppm): 7.15 (s, 1H, Ar-H), 6.13 (m, 3H, olefinic), 5.30 (s, 2H, $ArCH_2$-O-), 2.95 (m, 4H, 2 $ArCH_2$-CH_2), 2.16 (quintet, 7 Hz, 2H, $ArCH_2CH_2$-); ms *me*: 260 (M^+). *Anal.* calcd. for $C_{14}H_{12}O_5$: C 64.61, H 4.65; found: C 64.39, H 4.51.

o-*Quinone alcohol 39*

To a solution of 5,6-dihydroxy-4-formylindane (**33**) (1.00 g, 5.6 mmol) in anhydrous ether (100 mL) was added portionwise lithium aluminum hydride (0.5 g). The mixture was stirred until decoloration occurred, then it was poured in small portions over cold hydrochloric acid (100 mL, 0.2 M) and extracted with ether. The combined organic layers were washed with water, dried over magnesium sulfate, filtered, and evaporated under reduced pressure to give crystalline triol **38** (0.95 g, 94%, mp 118°C; ir (CH_2Cl_2, ν cm^{-1}): 3550). The oxidation was done following the procedure given for compound **22** (*vide supra*) using the following quantities: triol **38** (500 mg, 2.7 mmol) in ether (50 mL), sodium sulfate (1 g), and silver oxide (1.5 g). Quinone alcohol **39** was obtained (450 mg, 92%); ir (CH_2Cl_2, ν cm^{-1}): 3610, 1660; ^1H nmr ($CDCl_3$, δ ppm): 6.35 (s, 1H, Ar-H), 4.45 (s, 2H, -CH_2OH), 2.82 (m, 4H, 2 allylic CH_2), 2.06 (quintet, 7 Hz, 2H, CH_2-CH_2-CH_2).

6-Bromoacetoxy-4-formyl-5-hydroxyindane (*48*)

A solution of bromoacetylbromide (6.20 g, 30.6 mmol) in anhydrous benzene (50 mL) was added slowly (25 min) to a well-stirred solution of 5,6-dihydroxy-4-formylindane (**33**) (5.14 g, 28.7 mmol) in dry benzene and pyridine (8 mL). The mixture was washed with 3 M hydrochloric acid (2 × 100 mL) and water (2 × 100 mL). The organic layer was dried over magnesium sulfate, filtered, then evaporated. The solid residue was recrystallized from ether–pentane to give bromoacetate **48** (6.3 g, 73%); mp 109–110°C; ir: (CH_2Cl_2, ν cm^{-1}): 3300, 1750, 1660; ^1H nmr ($CDCl_3$, δ ppm): 9.94 (s, 1H, *CH*O), 7.15 (s, 1H, Ar-H), 4.05 (s, 2H, Br-CH_2-), 3.15 (t, J = 7 Hz, 2H), and 2.82 (t, J = 7 Hz, 2H) (benzylic hydrogens), 2.15 (quintet, 7 Hz, 2H, $ArCH_2$-CH_2); ms *me*: 298, 300 (M^+). *Anal.* calcd. for $C_{12}H_{11}O_4Br$: C 48.20, H 3.70; found: C 48.28; H 3.76.

4-Formyl-6-hydroxy-5-indanoxyacetic acid (*50*)

Anhydrous potassium carbonate (115 g, 0.835 mmol) was added to a solution of bromoacetate **48** (50 g, 0.167 mol) in freshly distilled tetrahydrofuran (800 mL). The mixture was stirred mechanically, refluxed for 48–50 h, then cooled, filtered, and the solid dissolved in water (1 L). This aqueous phase was acidified (pH 1, HCl 2 M) and extracted continuously with ether. The extract was dried ($MgSO_4$), filtered, and the solvent evaporated to give light yellow crystals: 4-formyl-6-hydroxy-5-indanoxyacetic acid (37.7 g, 96%). This product was shown to be a mixture of lactone **49** and acid **50** and was characterized in the form of lactone **49**.

Lactone aldehyde 49

A suspension of crude acid **50** (36.32 g, 0.154 mol) in benzene (750 mL) was refluxed in the presence of *p*-toluenesulfonic acid (100 mg) in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

a flask (1 L) equipped with a water trap (Dean–Stark) and a condenser. After 3 h, the solution was cooled and a small quantity of silica gel (~1 g) was added to the mixture. After filtration, evaporation of the benzene under reduced pressure afforded a residue that was crystallized from ether–pentane to give lactone aldehyde **49** (30.2 g, 92%); mp 131–132°C; ir (CH_2Cl_2, ν cm^{-1}): 1780, 1680, 1580; ^1H nmr ($CDCl_3$, δ ppm): 9.90 (s, 1H, CHO), 7.15 (s, 1H, Ar-H), 4.75 (s, 2H, O-CH_2-CO_2), 3.20 (t, J = 7 Hz, 2H) and 2.85 (t, J = 7 Hz, 2H) (benzylic hydrogens), 2.15 (quintet, 7 Hz, 2H, $ArCH_2CH_2$-). *Anal.* calcd. for $C_{12}H_{10}O_4$: C 66.22, H 4.78; found: C 66.05, H 4.62.

Methyl 4-formyl-6-methoxy-5-indanoxyacetate (***51***)

(*a*) *From 4-formyl-5-hydroxy-6-methoxyindane* (***26***)

To a solution of 4-formyl-5-hydroxy-6-methoxyindane (**26**) (1.5 g, 7.8 mmol) in anhydrous tetrahydrofuran (150 mL) was added finely powdered anhydrous potassium carbonate (6.0 g, 43 mmol) and ethyl bromoacetate (1.67 g, 10.0 mmol). The mixture was refluxed for 24 h, then cooled, filtered, and the volatiles removed under reduced pressure. The residue was crystallized from hexane in the cold to give ethyl 4-formyl-6-methoxy-5-indanoxyacetate (1.8 g, 83%, mp 83–84°C); ir (CH_2Cl_2, ν cm^{-1}): 1750, 1690, 1460, 1325, 1220; ^1H nmr ($CDCl_3$, δ ppm): 9.73 (s, 1H, -CHO), 7.10 (s, 1H, Ar-H), 4.78 (s, 2H, -OCH_2CO_2-), 4.28 (q, J = 7 Hz, 2H, -OCH_2CH_3), 3.92 (s, 3H, OCH_3), 3.25 (t, J = 7 Hz, 2H), and 2.90 (t, J = 7 Hz, 2H) (benzylic hydrogens), 2.10 (m, 2H, Ar-CH_2-CH_2), 1.30 (t, J = 7 Hz, 3H, -OCH_2CH_3). *Anal.* calcd. for $C_{15}H_{18}O_5$: C 64.73, H 6.52; found: C 64.43, H 6.63. That ethyl ester (1.0 g, 3.6 mmol) was dissolved in 5% methanolic potassium hydroxide (100 mL) and the mixture was refluxed for 1 h, cooled, acidified (HCl, 1 M), and extracted with ether (3 × 100 mL). The combined organic layers were dried ($MgSO_4$), filtered, and the solvent removed under reduced pressure. The residue (0.9 g) was dissolved in ether (50 mL) and reacted (0°C) with an ethereal solution of diazomethane. After removal of the volatiles *in vacuo*, the residue was crystallized from ether – petroleum ether to give crystalline methyl ester **51** (0.68 g, 72% from the ethyl ester; mp 99–100°C); ir (CH_2Cl_2, ν cm^{-1}): 1740, 1670, 1460, 1320, 1205; ^1H nmr $CDCl_3$, δ ppm): 10.48 (s, 1H, *CHO*), 7.00 (s, 1H, Ar-H), 4.75 (s, 2H, -OCH_2CO_2-), 3.85 (s, 3H, -CO_2CH_3), 3.75 (s, 3H, -Ar-OCH_3), 3.13 (t, J = 7 Hz, 2H), and 2.80 (t, J = 7 Hz, 2H) (2 Ar-CH_2-), 2.05 (quintet, 7 Hz, 2H, $ArCH_2CH_2$). *Anal.* calcd. for $C_{14}H_{16}O_5$: C 63.62, H 6.10; found: C 63.89, H 6.29.

(*b*) *From phenol carboxylic acid* ***50***

To a solution of phenol carboxylic acid **50** (2.0 g, 8.4 mmol) in ether (250 mL), at 0°C, was added dropwise an ethereal diazomethane solution until a yellow coloration persisted. The solution was evaporated and the residue was crystallized from ether to give methyl 4-formyl-6-hydroxy-5-indanoxyacetate (2.0 g, 97%, mp 110–111°C); ir (CH_2Cl_2, ν cm^{-1}): 3300, 2720, 1740, 1680, 1452; ^1H nmr ($CDCl_3$, δ ppm): 10.32 (s, 1H, -*CHO*), 6.92 (s, 1H, Ar-H), 4.52 (s, 2H, -OCH_2CO_2-), 3.76 (s, 3H, -CO_2CH_3), 3.06 (t, J = 7 Hz, 2H), and 2.76 (t, J = 7 Hz, 2H) (2 Ar-CH_2-), 2.08 (quintet, 7 Hz, $ArCH_2CH_2$). *Anal.* calcd. for $C_{13}H_{14}O_5$: C 62.39, H 5.64; found: C 62.22, H 5.77.

This phenol methyl ester (0.20 g, 0.80 mmol) in anhydrous tetrahydrofuran (30 mL) were reacted with anhydrous potassium carbonate (0.55 g, 3.9 mmol) and dimethyl sulfate (0.5 g, 2.4 mmol). The mixture was refluxed under good stirring for 36 h, then cooled, filtered, and the resulting solution evaporated *in vacuo* and using a water bath. The solid residue was recrystallized from ether–pentane and was shown to be identical with the compound **51** obtained in part (*a*).

Lactone ***52***

To a solution of the crude acid **50** (2.0 g, ~8.4 mmol) (*vide supra*) in ethylene glycol (50 mL) containing potassium hydroxide (2 g) was added hydrazine hydrate (3 mL, 85%) and the mixture was gradually heated to reflux temperature (195°C, oil bath). After 3 h, the brown mixture was cooled, poured onto iced water (300 mL), and acidified (pH 1, HCl 2 M). The aqueous phase was saturated with sodium chloride and extracted with ether (5 × 100 mL). The combined extracts were dried ($MgSO_4$), filtered, and the solvent evaporated under reduced pressure. The yellow-red partly crystalline residue (1.8 g) was dissolved in hot benzene (100 mL) and the solution was refluxed (Dean–Stark trap) for 2 h in the presence of *p*-toluenesulfonic acid (50 mg). It was then cooled, stirred some minutes with silica gel (~1 g), filtered, and the solvent evaporated to give crude lactone **52**, which was recrystallized from ether – petroleum ether (1.4 g, 81%, mp 75–76°C); ir (CH_2Cl_2, ν cm^{-1}): 1775, 1620, 1335, 1305; ^1H nmr ($CDCl_3$, δ ppm): 6.75 (s, 1H, Ar-H), 4.55 (s, 2H, O-CH_2-CO_2-), 2.80 (m, 4H, 2 $ArCH_2$-), 2.13 (s, 3H, Ar-CH_3), 2.08 (m, 2H, $ArCH_2CH_2$); ms *m/e*: 204 (M^+). *Anal.* calcd. for $C_{12}H_{12}O_3$: C 70.57, H 5.92; found: C 70.99, H 5.81.

o-*Spirolactone dienone* ***47***

To a solution of lactone **52** (2.41 g, 11.8 mmol) in acetonitrile (30 mL) containing aqueous sodium hydroxide (120 mL, 0.1 M) was added rapidly a solution of *N*-bromosuccinimide (2.10 g, 11.8 mmol) in water (100 mL) and acetonitrile (100 mL). After 3 min, water (200 mL) was added and the mixture was extracted with dichloromethane (3 × 100 mL). The combined extracts were dried over magnesium sulfate, filtered, and the solvent evaporated. The solid residue was crystallized from ether – petroleum ether to give *o*-spirolactone dienone **47** (2.3 g, 89%, mp 98–98°C); ir (CH_2Cl_2, ν cm^{-1}): 1790, 1665, 1640, 1600; uv (EtOH, λ_{max}): 355 mμ (ε 3100); ^1H nmr ($CDCl_3$, δ ppm): 6.03 (br s, 1H, olefinic proton), 4.75 (d, J = 15 Hz, 1H), and 4.40 (d, J = 15 Hz, 1H) (AB pattern) (O-CH_2-CO_2), 2.74 (m, 4H, two allylic CH_2), 2.05 (m, 2H, homoallylic CH_2), 1.90 (s, 3H, -CH_3); ms *m/e*: 220 (M^+). *Anal.* calcd. for $C_{12}H_{12}O_4$: C 65.44, H 5.49; found: C 65.48, H 5.54.

Isomers ***54***a *and* ***54***b (Diels–Alder reaction)

Dienone **47** (4.00 g, 18.2 mmol) was dissolved in methyl vinyl ketone (6 mL) and the mixture was refluxed for 20 min; then the volatiles were removed under reduced pressure (water bath) to give a 1:1 mixture of isomers **54***a* and **54***b*. These isomers were separated on a small scale by preparative thin-layer chromatography (benzene – petroleum ether 1:1).

Isomer ***54***a (mp 113–115°C, R_f 0.68); ir (CH_2Cl_2, ν cm^{-1}): 1810, 1740, 1720; ^1H nmr ($CDCl_3$, δ ppm): 4.64 (d, J = 14 Hz, 1H), and 4.32 (d, J = 14 Hz, 1H) (AB pattern, -OCH_2CO_2), 3.64 (d, J = 2 Hz, 1H, bridgehead), 3.17 (ddd, J = 2, 6, and 9.8 Hz, *CH*$COCH_3$), 2.46 (m, 4H, two allylic CH_2), 2.17 (s, 3H, CH_3CO), 2.16 (dd, 1H J_{AM} = 13 Hz, J_{AX} = 9.8 Hz, H_{endo}C14), 1.97 (m, 2H, H_2C8), 1.67 (dd, 1H, J_{AM} = 13 Hz, J_{MX} = 6 Hz, H_{exo}C14), 1.26 (s, 3H, CH_3-); ^{13}C nmr ($CDCl_3$, δ ppm): 204.8, 199.4, 170.5, 145.6, 133.7, 103.4, 65.2, 48.8, 46.9, 42.8, 33.4, 31.1, 28.0, 22.5, 13.5; ms *m/e*: 290 (M^+).

Isomer ***54***b (83–84°C, R_f 0.74); ir (CH_2Cl_2, ν cm^{-1}): 1810, 1740, 1720; ^1H nmr ($CDCl_3$, δ ppm): 4.66 (d, J = 14 Hz, 1H), and 4.26 (d, J = 14 Hz, 1H) (AB pattern, -O-CH_2-CO_2), 3.56 (d, J = 2 Hz, 1H, bridgehead), 3.07 (ddd, J = 2, 6, and 9 Hz, *CH*$COCH_3$), 2.48 (m, 4H, two allylic CH_2), 2.13 (s, 3H, CH_3CO), 2.12 (dd, 1H, J_{AM} = 13 Hz, J_{AX} = 9.8 Hz, H_{endo} C14), 1.97 (m, 2H, H_2C8), 1.73 (dd, 1H, J_{AM} = 13 Hz, J_{MX} = 6 Hz, H_{exo}C14), 1.25 (s, 3H, CH_3-); ^{13}C nmr ($CDCl_3$, δ ppm): 204.9, 197.3, 170.5, 146.7, 133.9, 102.9, 64.3, 46.6, 42.2, 33.9, 30.8, 30.7, 28.0, 22.4, 13.5. ms *m/e*: 290 (M^+). *Anal.* calcd. for $C_{16}H_{18}O_5$: C 66.18, H 6.24; found: C 66.13, H 6.10.

Tricyclic ketone ***55***

A mixture (~1:1) of isomers **54***a* and *b* (0.54 g, 1.86 mmol) in ether (50 mL) was vigorously shaken in a separatory funnel with aqueous sodium hydroxide (1 M, 50 mL) for 5 min. The mixture was then shaken with aqueous hydrochloric acid (1 M, 70 mL) during 3 min and the layers were separated. The aqueous phase was extracted with ether (3 × 50 mL) and the combined extracts washed with water (2 × 50 mL), brine, dried over magnesium sulfate, filtered, and the solvent evaporated under reduced pressure to give a single product, tricyclic ketone **55** (0.41 g, 95%); ir (CH_2Cl_2, ν cm^{-1}): 1725 br; ^1H nmr ($CDCl_3$, δ ppm): 3.76 (d, J = 2 Hz, 1H, bridgehead), 3.25 (ddd, J = 2, 6, and 9 Hz, 1H, *H*$CCOCH_3$), 2.21 (s, 3H, CH_3-CO), 1.36 (s, 3H, CH_3-); ms *m/e*: 232 (M^+).

Tetracyclic ketone ***56***

The crude mixture **54***a* + *b* (Diels–Alder adduct) (5.4 g) was dissolved in THF (250 mL) and treated with aqueous sodium hydroxide

(1 M, 50 mL) during 2 h. The main part of the tetrahydrofuran was evaporated under reduced pressure and the aqueous phase was saturated with sodium chloride and extracted with ether (3 × 100 mL). The combined extracts were dried over magnesium sulfate, filtered, and solvent evaporated. The residue was crystallized from ether – petroleum ether to give tetracyclic hydroxydiketone **56** (3.31 g, 76.6%, mp 69–70°C); ir (CH_2Cl_2, ν cm^{-1}): 3520, 1745, 1720; ^1H nmr ($CDCl_3$, δ ppm): 3.55 (br s, 1H, hydroxyl), 3.30 (d, $J = 4$ Hz, 1H, HC11), 2.42 (s, 2H, H_2Cl), 1.22 (s, 3H, $-CH_3$); ms *m/e*: 232 (M^+). *Anal.* calcd. for $C_{14}H_{16}O_3$: C 72.39, H 6.94; found: C 72.40, H 7.14.

Dideuterated tetracyclic ketone ***56***-d_2

To a stirred solution of tetracyclic ketone **56** (30 mg, 0.13 mmol) in tetrahydrofuran (5 mL) was added a solution of sodium hydroxide (1 M, 5 mL) in deuterium oxide (D_2O). After 2 h at room temperature the organic solvent was evaporated and the mixture was extracted with ether (3 × 10 mL). The combined extracts were washed with water (2 × 10 mL, exchange of hydroxyl), dried over magnesium sulfate, filtered, and the solvent evaporated to give **56**-d_2 (23 mg); nmr: same as **56** except that the singlet (2H) at δ 2.42 has disappeared; ms *m/e*: 234 (M^+).

Trideuterated tetracyclic ketone ***56***-d_3

To the crude mixture of isomers **54***a* and *b* (52 mg, 0.18 mmol) dissolved in tetrahydrofuran (5 mL) was added under good stirring a solution (5 mL) of sodium hydroxide (1 M) in deuterium oxide. After 2 h at room temperature the compound **56**-d_3 (41 mg) was obtained by an extraction similar to that described in the preceding experiment (*vide supra*); nmr: same as **54** except that the doublet (4 Hz) at δ 3.30 has become a singlet and the singlet (2H) at δ 2.42 has disappeared; ms *m/e*: 235 (M^+).

Monodeuterated tricyclic ketone ***56***-d_1

To a stirred solution of **56**-d_3 (21 mg, 0.09 mmol) in tetrahydrofuran (5 mL) was added aqueous sodium hydroxide (1 M, 5 mL). After 2 h at room temperature, the product **56**-d_1 (17 mg) was extracted following the preceding procedure (*vide supra*); nmr: same as **56**-d_3 except that the singlet (2H) at δ 2.42 has appeared, the singlet at δ 3.30 is still present; ms *m/e*: 233 ($^M+$).

Acknowledgements

A generous gift of 5,6-dimethoxyindane from Ayerst Laboratories (Montreal) is deeply appreciated. We also wish to thank Mr. Denis Viens for the large-scale preparation of spirolactone dienone **47**. Chem. **68**, 127 (1990).

This paper reports several model studies that were necessary for the rational conception of a simple four-step synthesis (**6** + (*S*)-**74** → **81***a*–*b* → **83** ↠ **87** → **89**) (Scheme 11) of the carbonate derivative **89** of the optically active pentacyclic dihydroxy ketoaldehyde **87**, an important key intermediate for the synthesis of (+)-ryanodol (**5**). The optically active vinyl ketone (*S*)-**74** that was used as starting material was prepared in four steps from *d*-carvone ((*S*)-**94**) (Scheme 13). The preparation of the other starting material, the *o*-spirolactone dienone **6**, was reported in Part I.

Key words: strategy, synthesis, ryanodol, key intermediate, diterpene.

LETURC, CHUN-CHEN LIAO, FREDERICK N. MACLACHLAN, JEAN-PIERRE MAFFRAND, FABRIZIO MARAZZA, ROBERT MARTINO, CLAUDE MOREAU, LUC RUEST, LOUISELLE SAINT-LAURENT, ROGER SAINTONGE et PIERRE SOUCY. Can. J. Chem. **68**, 127 (1990).

On rapporte plusieurs études modèles qui ont été nécessaires à la conception rationnelle d'une synthèse simple en quatre étapes (**6** + (*S*)-**74** → **81***a*–*b* → **83** ↠ **87** → **89**) (Schéma 11) d'un intermédiaire-clé important dans la synthèse du (+)-ryanodol (**5**) : le dérivé carbonate **89** du dihydroxy cétoaldéhyde pentacyclique **87** optiquement actif. La vinylcétone (*S*)-**74** optiquement active fut synthétisée à partir de la *d*-carvone ((*S*)-**94**) (Schéma 13). La synthèse de l'autre produit de départ, l'*o*-spirolactone diénone **6**, est rapportée dans la Partie I.

Mots clés : stratégie, synthèse, ryanodol, intermédiaire-clé, diterpène.

Our general strategy (1–3) for the construction of ryanodol (**5**) via anhydroryanodol (**4**) is summarized in Scheme 1. In this approach, the macrobicyclic diketone **2**, which can be obtained by oxidation of an appropriate precursor such as **1**, would undergo a transannular aldol condensation to produce the tricyclic hydroxyketone **3**. This compound would then be converted into ryanodol **5** via anhydroryanodol **4**.

This general strategy for the synthesis of ryanodol, which is based on an analysis of the skeleton of anhydroryanodol, is explained in detail in Part I (4). Our method for the preparation of a tricyclic compound such as **1**, which contains a bicyclo[2.2.2]octene unit, was also reported in that paper. More specifically, we have shown that the Diels–Alder reaction of methyl vinyl ketone with *o*-spirolactone dienone **6** gives a ≃1:1 mixture of adducts **7***a* and **7***b*, which are then converted under basic conditions into a single product, the tetracyclic hydroxydiketone **8**.

In this paper, we wish to report our studies demonstrating that the key transformation **1** → **2** → **3** can be realized in the laboratory. This work was carried out (1, 5) using the tricyclic hydroxydiketone **8** as a starting point. We also wish to report our detailed analysis and experimental studies (6–8), which led to the development of a very convenient strategy for the synthesis of a pentacyclic key intermediate that contains ring A of anhydroryanodol.

[1]Author to whom correspondence may be addressed.

In the key transformation **1** → **2** → **3**, the oxidative cleavage of the tetrasubstituted double bond should produce two carbonyl groups that are expected to undergo a transannular aldol condensation; it was therefore desirable to avoid the presence of other carbonyl groups in the same molecule (*vide infra*). Consequently, the two carbonyl groups in the tetracyclic hydroxydiketone **8** were first modified before attempting the desired key transformation. Compound **8** was converted (Ac_2O, pyridine) into the diketoacetate **9** (Scheme 2), which was then selectively ketalized under standard conditions to give monoketal acetate **10**. It was then found that the reduction of **10** with lithium borohydride gave mainly the *trans* diol **11** together with a very small quantity of the *cis* diol **12**. When the reduction was carried out with lithium in liquid ammonia, the *cis* diol **12** was obtained as the major isomer. The configuration of the *cis* ketal diol **12** was rigorously established by its transformation into the five-membered carbonate **13** upon reaction with phosgene.

The *trans* ketal diol **11**, which was easily purified by crystallization, was selected for the cleavage study and it was first converted into ketal monoacetate **14** by acetylation (Ac_2O, pyridine). The diketone resulting from ozonolysis of ketal monoacetate **14** can exist in two different conformations, **15** and **16** (Scheme 3), which can each undergo a transannular aldol condensation yielding, respectively, the aldol diastereoisomers **17** and **18**. The ozonolysis of **14** was carried out in methanol; it was followed by a catalytic reduction with palladium-on-charcoal and by a short reflux in pyridine. This series of

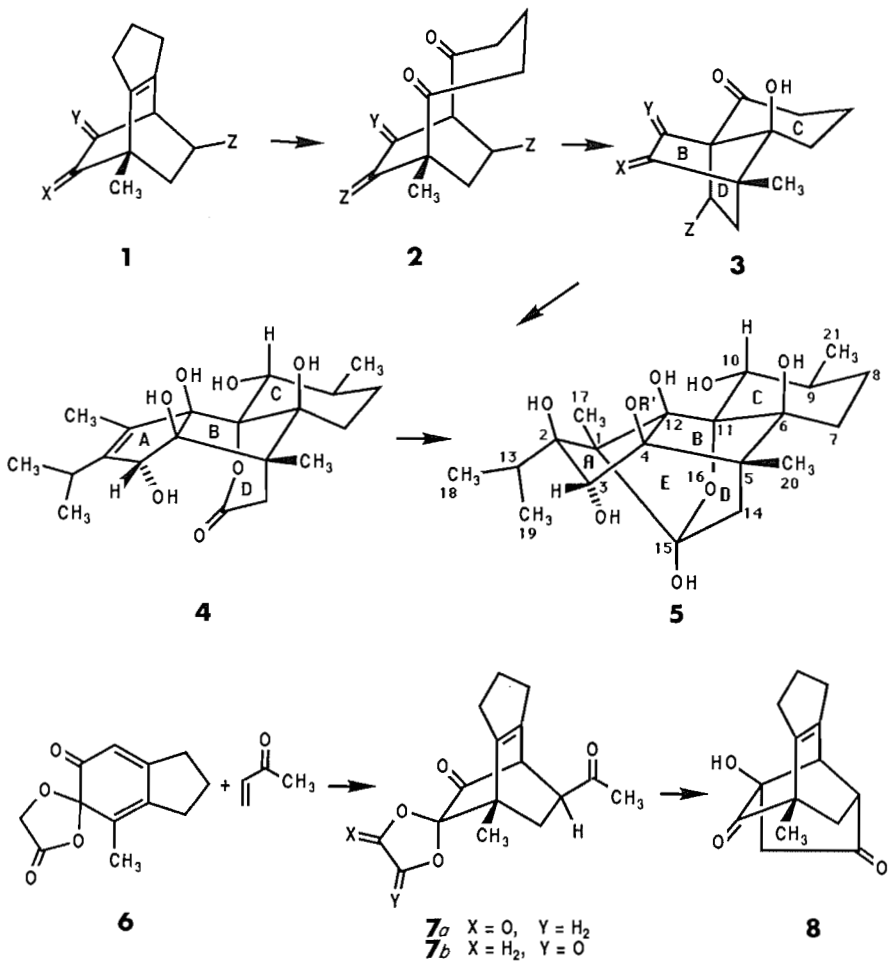
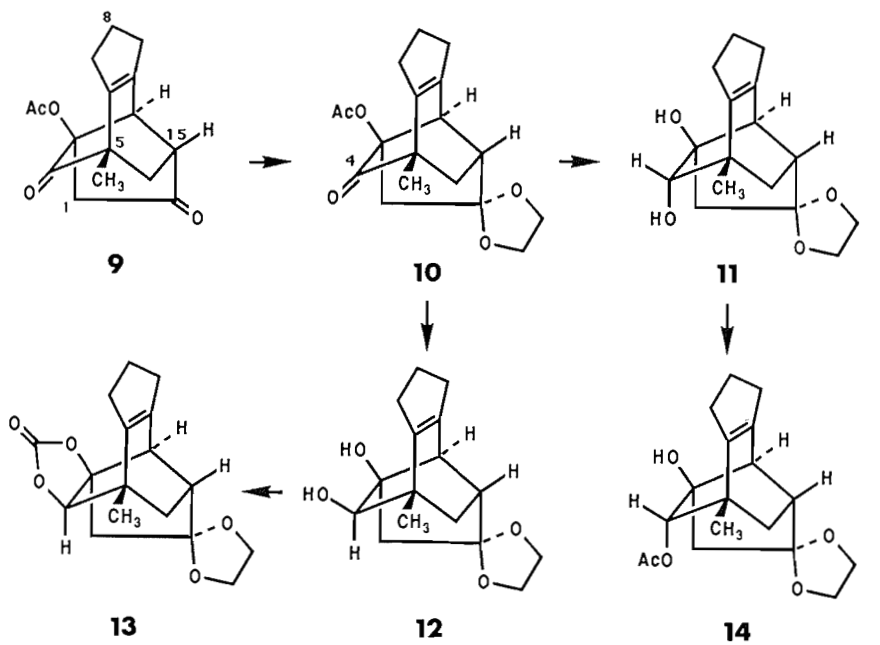
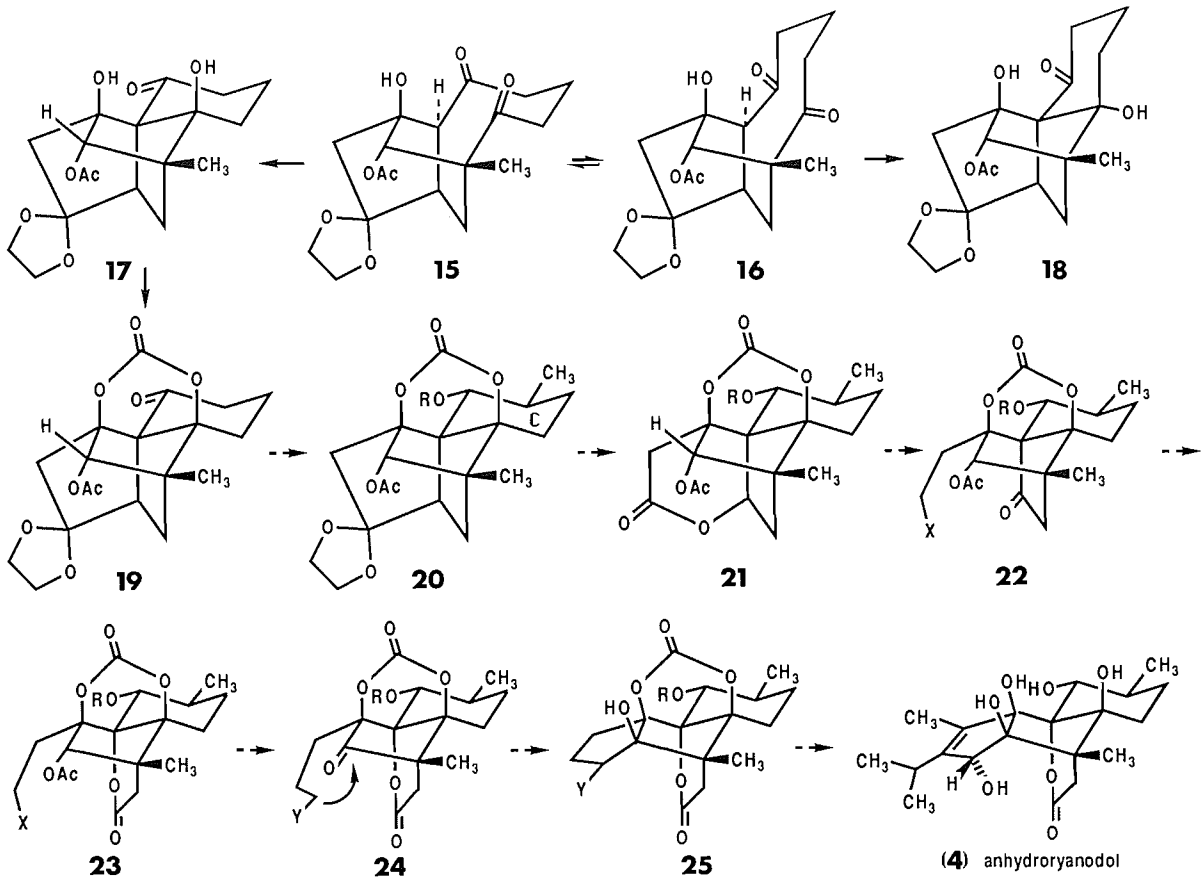


SCHEME 1



SCHEME 2



SCHEME 3

operations gave the dihydroxy ketoacetate **17** as the major product along with the isomer **18** (ratio 7:3), which were separated. The structure of **17** was firmly established by its reaction with phosgene, which afforded the crystalline six-membered carbonate derivative **19**.

The successful transformation of **14** into **17** proved that our basic synthetic strategy to build rings B and C of anhydroryanodol from the oxidative cleavage and the subsequent transannular aldol condensation of a tricyclic precursor containing a bicyclo[2.2.2]octene precursor was valid (1).

At this stage, we had to make a choice between two completely opposite directions for our future work. Either we accept compound **17** as a valuable key intermediate, or we consider the transformation **15** → **17** as a model experiment.

For instance, in the first case, one can imagine that after completing ring C, i.e., **19** → **20**, the removal of the ketal protecting group followed by Baeyer–Villiger oxidation would produce lactone **21**. This product could then be converted into ketone **22** (X to be determined), which in principle can also be oxidized via Baeyer–Villiger reaction to lactone **23**. Appropriate homologation of the side chain CH_2CH_2X and conversion of the secondary acetate at C_4[2] into a carbonyl group would then give an intermediate **24**, which would allow the formation of ring A, i.e., **25**. Anhydroryanodol would then be obtained from the tetracyclic intermediate **25**.

The proposed conversion **19** → **25** → anhydroryanodol, although certainly not easy to accomplish, is essentially a series of functional group transformations, which is quite attractive for producing a relatively simple synthesis of racemic anhydroryanodol. However, we deliberately refused to consider this route further because we felt that we would be missing a great opportunity to make a contribution to the development of knowledge in synthetic strategy.

One of the first priorities in doing organic synthesis is to discover simple schemes that avoid unnecessary steps. The preceding route already involves four extra steps, reduction of the carbonyl group at C_4, protection of the resulting secondary alcohol as an acetate (**10** → **11** → **14**), and, later on, removal of the acetate protecting group followed by reoxidation to a carbonyl group (**23** → **24**). These operations can in principle be eliminated by following one of the two alternative routes: (a) to simply carry out the ozonolysis and the transannular aldol condensation on a compound bearing a carbonyl group at C_4, i.e., **9** or **10**; (b) to transform the carbonyl group at C_4 into a hydroxyl group while forming the desired C_3—C_4 bond prior to the oxidative cleavage of the tetrasubstituted olefin. The second alternative meant that ring A would be constructed first. Both approaches were attractive because advantage was taken of the fact that our synthetic scheme generates intermediates that have the right level of oxidation at C_4 to produce ring A directly.

The first alternative route was tested with monoketal ketoacetate **10**. The ozonolysis of **10** was carried out and the expected

[2]The chemical abstract name for ryanodol: [3*S*-(3α,4β,4a*S*,6α,6aα,7α,8β,8aα,8bβ,9β,9aα] - hexahydro - 3,6a,9 - trimethyl - 7 - (1 - methyl-ethyl)-6,9-methanobenzo[1,2]pentaleno[1,6-*be*]furan-4,6,-7,8a,8b,9a(6a*H*,9*H*)-heptol) (Chem. Abstr. **101**, 6830CS (1984)). To facilitate the discussion on the synthetic strategy, the numbering system of ryanodol is used throughout, regardless of the skeleton considered.

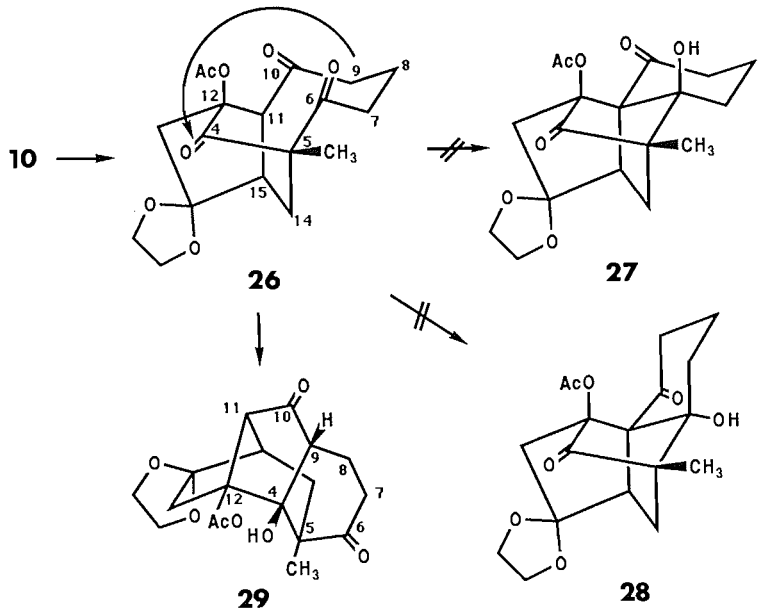

SCHEME 4

triketone **26** (Scheme 4) was isolated in good yield as crystals. Heating triketone **26** in pyridine produced a tetracyclic transannular aldol product that, on the basis of its nmr spectra, was found to have the undesired structure **29**. A close examination of a molecular model of triketone **26** revealed that in addition to the two aldol condensations that we have previously discussed, and which lead to **27** and **28**, a third aldol condensation is possible between C_4 and C_9, yielding the isomeric aldol product **29**. Compound **29** is presumably produced preferentially because enolization at C_9 might be favored over that at C_{11}. Since **29** appears less strained than the bridged isomers **27** and **28**, which each contain a bicyclo[2.2.1]heptane unit, the former might also be preferentially formed because of a thermodynamically controlled aldol process. This result meant that the oxidative cleavage of the olefin cannot be performed in the presence of a carbonyl group at C_4, and the first alternative pathway was thus eliminated from further considerations.

The second alternative route, which invokes the possibility of synthesizing ring A prior to the oxidative cleavage of the olefin, was then analysed in detail.

There are in principle two different approaches to building ring A from hydroxydiketone **8**. The first one is described by the route **8** → **32** → **33** → **4** (Scheme 5) and the second one by the route **8** → **31** → **34** → **4**. The first approach is interesting because there was a good possibility of generating the desired chirality at C_1 in **32** in a relatively simple manner. Indeed, with a dissymmetrical molecule like **8**, it is logical to expect a high degree of stereochemical control in the alkylation at C_1 and, depending on the course of this process, intermediate **32** would be produced from **8** from either of the monoalkylated products **30** or **31**. Once intermediate **32** is obtained, its conversion to pentacyclic intermediate **33** should be straightforward. The attractiveness of this route is the apparently facile construction of **33**. However, there might be a serious difficulty in this route because this compound has an extra carbon atom. By comparing the numbering system of anhydroryanodol (**4**) with that of **33**, it becomes clear that the carbonyl group (C*=O) in **33** is extra and will have to be removed eventually to produce anhydroryanodol. This means that some degradation chemistry will have to take place at a later stage. This appeared neither easy nor elegant; this route was not considered further on this basis, and also because the second approach appeared more promising.

The second approach, **8** → **31** → **34** → **4**, is interesting because the tetracyclic intermediate **34** does not have an extra carbon atom; the carbonyl group that corresponds to C_{17} can be eventually transformed into the methyl group of ring A of anhydroryanodol. The success of this route depends on the ease of controlling the configuration of the side chain at C_1 in **31**, which must be inside to produce ring A (cf. **31** → **34**). This approach was also quite interesting because there was a possibility of eliminating the alkylation step **8** → **31**. For instance, there was the possibility of producing intermediate **31** in two operations from the *o*-spirolactone dienone **6** and a methyl vinyl ketone derivative where the methyl group was replaced by a CH_2—CH_2—CH_2—Y group.

The next step was therefore to verify if substituted vinyl ketone could be used successfully in the Diels–Alder reaction and if the stereochemistry of the side chain at C_1 could be controlled.

The first study was carried out using ethyl vinyl ketone. The reaction of *o*-spirolactone dienone **6** with ethyl vinyl ketone proceeded as expected, producing a ≃1:1 mixture of adducts **35***a* and **35***b* isomeric at the spirolactone ring (Scheme 6). Treatment of crude **35***a* and **35***b* with sodium hydroxide in aqueous tetrahydrofuran gave a good yield (>60%) of two isomeric products in a 2:1 ratio; these were separated and identified as the *endo* and the *exo* epimers **36** and **37**. The assignment of configuration was carried out by ^1H nmr spectroscopy on their corresponding acetate derivatives **38** and **39**. In the major epimer **38**, H_1 appears as an octuplet (J = 2.3 and 7.2 Hz), whereas in the minor isomer **39**, H_1 appears as a quadruplet (J = 7.6 Hz). The additional coupling found in the major isomer **38** is the result of a W coupling between H_1 and H_{15}; such a coupling is not possible for the *exo* isomer **39**. This assignment was made unambiguous by observing the loss of W coupling in **38** on replacing the hydrogen at C_{15} by a deuterium atom. Monodeuterated **38** at C_{15} was obtained by repeating the epimerization – aldol condensation sequence **35***a*–*b* → **36** + **37**

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12

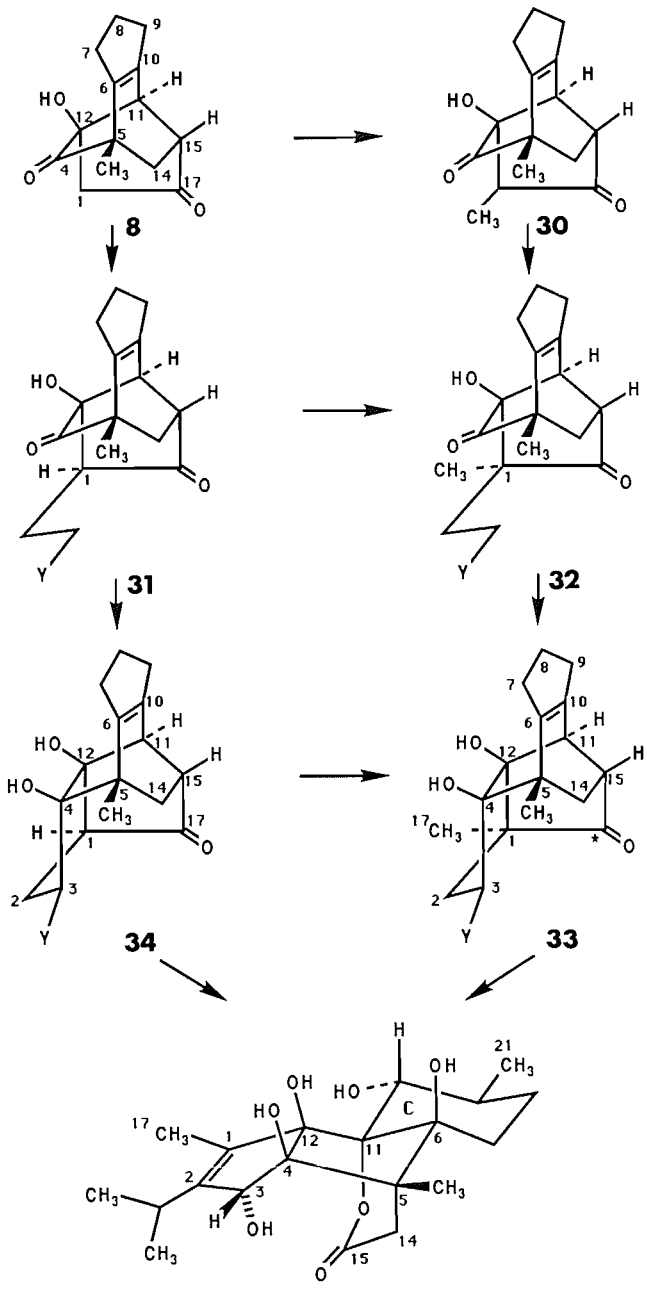

SCHEME 5

using deuterated water as solvent. This produced **36** and **37** having two deuterium atoms (at C_1 and C_{15}). Treatment of dideuterated **36** and **37** under basic conditions with H_2O gave **36** and **37** monodeuterated at C_{15} only, which upon acetylation and chromatography yielded the corresponding C_{15} monodeuterated acetates **38** and **39**.

This study demonstrated that substituted vinyl ketones could be used with success. More importantly, it also showed that the most stable epimer at C_1 had the *endo* configuration. This last result was not expected and came as a surprise.[3] It had, however, a very favorable consequence. It meant that there was no need to imagine a special device or strategy for the control of the *endo* stereochemistry at C_1, and a synthesis of a pentacyclic intermediate such as **34** via an intermediate like **31** could be readily envisaged.

The ketal vinyl ketone **44** (Scheme 7) was studied next (7). It was prepared from ethyl acetoacetate by a standard route via the intermediates **40–43**. The reaction of dienophile **44** with *o*-spirolactone dienone **6** proceeded well to give a ≃1:1 mixture of **45***a* and **45***b* that, after treatment with aqueous base followed by acidification, gave the tetracyclic triketone **46** in an impressive yield of over 95%. Acetylation of **46** with acetic anhydride and pyridine gave a diacetate, which on treatment with aqueous sodium carbonate produced the acetate derivative **47**.

We were hoping that the methyl ketone side chain in **46** could be used to induce the formation of ring A through an internal aldol condensation. However, all our attempts in this direction were unsuccessful. This is presumably due to the fact that compound **47** is too reactive and easily undergoes other reactions. For instance, treatment of **47** with anhydrous methanol containing *p*-toluenesulfonic acid provided mainly the *cis* enedione methyl ester **49**. This transformation can be explained by the addition of methanol to the five-membered ketone group, producing intermediate **48**, which undergoes on acid-catalyzed Grob type fragmentation (9). The *endo* methyl ketone side chain in **46** is responsible for the formation of the *cis* geometry of the enedione **49**. On heating at 150°C, *cis* enedione **49** was quantitatively converted into the more stable *trans* enedione **50**. When triketone alcohol **46** was treated with water under acidic conditions, the five-membered lactone **51** was isolated. Treatment of **51** with potassium *tert*-butoxide in *tert*-butanol furnished the *trans* enedione carboxylic acid **52**, which was transformed into the corresponding *trans* enedione methyl ester **50** by reaction with diazomethane. The formation of **51** must first take place via the addition of water at C_{17} followed by a fragmentation similar to that described by **47** → **48** → **49**, producing *in situ* the *cis* enedione carboxylic acid **53**, which underwent an intramolecular Michael addition to yield the five-membered lactone **51**. In the following step, it is anticipated that the basic elimination would produce directly the more stable *trans* enedione carboxylic acid **52**.

In conclusion, this study did not prove to be successful in providing a synthetic route for the construction of ring A, but it provided a rigorous chemical proof that compounds of type **31** are definitely more stable in the *endo* configuration.

We also learned from this study that the functional group of the side chain should be at a more remote position than C_2 in order to induce the formation of ring A while preventing fragmentation as previously observed. This left two possibilities, a functional group either at C_3 or linked to C_3.

An example of the second possibility is the vinyl ketone **58** (Scheme 8), which possesses a masked aldehyde linked to C_3. Compound **58** was prepared in three steps (6). Reaction of dihydropyran with 2,2-dimethylpropanediol gave the acetal alcohol **54**, which upon oxidation with Jones reagent gave the crystalline carboxylic acid acetal **55**. Treatment of the lithium salt of **55** with vinyllithium gave the vinyl ketone acetal **58**. In large-scale preparation, it was found more convenient to prepare vinyl ketone **58** via the intermediates **56** and **57**.

Diels–Alder reaction of **58** with *o*-spirolactone dienone **6** gave a quantitative yield of adducts **59***a* and **59***b* in a ≃1:1 ratio. This mixture was then treated under the now "usual" basic conditions to furnish the crystalline tetracyclic *endo* epimer **60** in 70% yield. The next step for the construction of ring A

[3]After the facts, it is, however, relatively easy to rationalize this result by an examination of molecular models of **38** and **39**: the methyl group appears to be more severely crowded in **39** (cf. steric interaction between CH_3 and H_{11}) than in **38**.

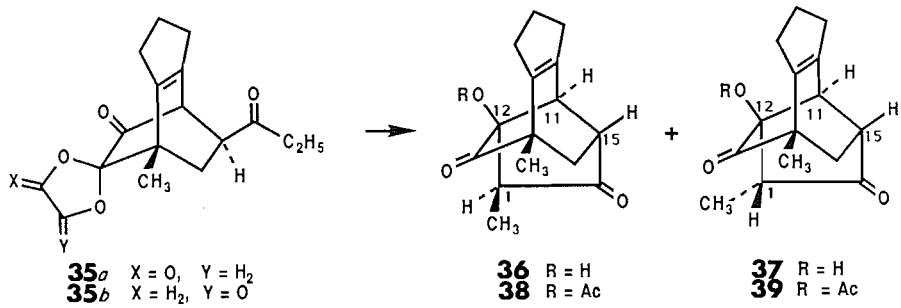
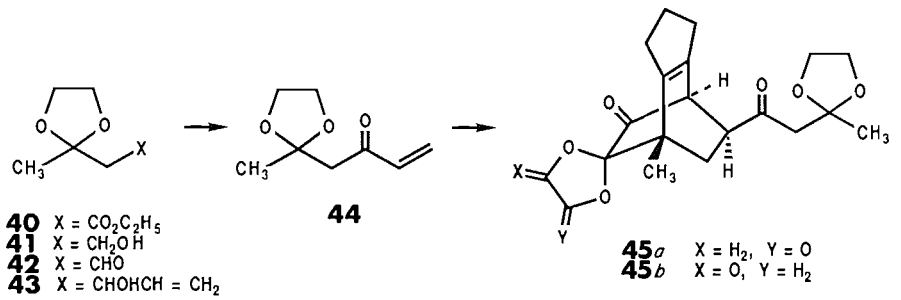
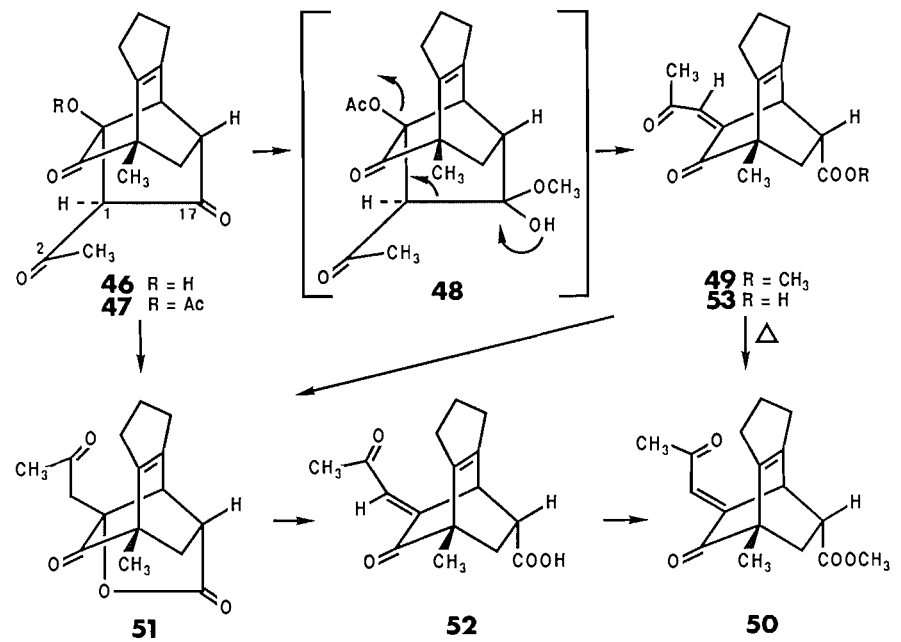


SCHEME 6





SCHEME 7

consisted of the deprotection of the aldehyde function to verify if the anticipated intramolecular aldol condensation would take place. When compound **60** was heated to reflux in a mixture of acetone and 3 M hydrochloric acid, hydrolysis and aldol condensation took place in a single operation, yielding directly the crystalline pentacyclic dihydroxyketone aldehyde **61**. However, the yield was only 25% and this was attributed mainly to the vigorous acidic conditions needed for the acetal hydrolysis.[4] Nevertheless, we had in hand an exceptionally short and simple synthesis of a pentacyclic intermediate containing ring A of anhydroryanodol. Indeed, the three steps, **58** + **6** → **59***a*–*b* → **60** → **61**, required very simple experimental conditions.

It was decided to regard this work as a model study essentially for two reasons. First, the acetal function of the dienophile had to be modified in order to be hydrolyzed under milder conditions. Second, there was also the possibility of taking further advantage of the dienophile. If a compound like **61** were accepted as an intermediate, the subsequent introduction of the isopropyl group had to be considered at a later stage. However, our strategy provided us with the opportunity of simplifying this task by pre-introducing this isopropyl group in the dienophile. We also retained the possibility of having a functional group

[4]A model study indicated that 2-alkyl-5,5-dimethyl-1,3-dioxanes require strong acidic conditions (>3 M HCl) for hydrolysis, and under such conditions compound **61** is not very stable.

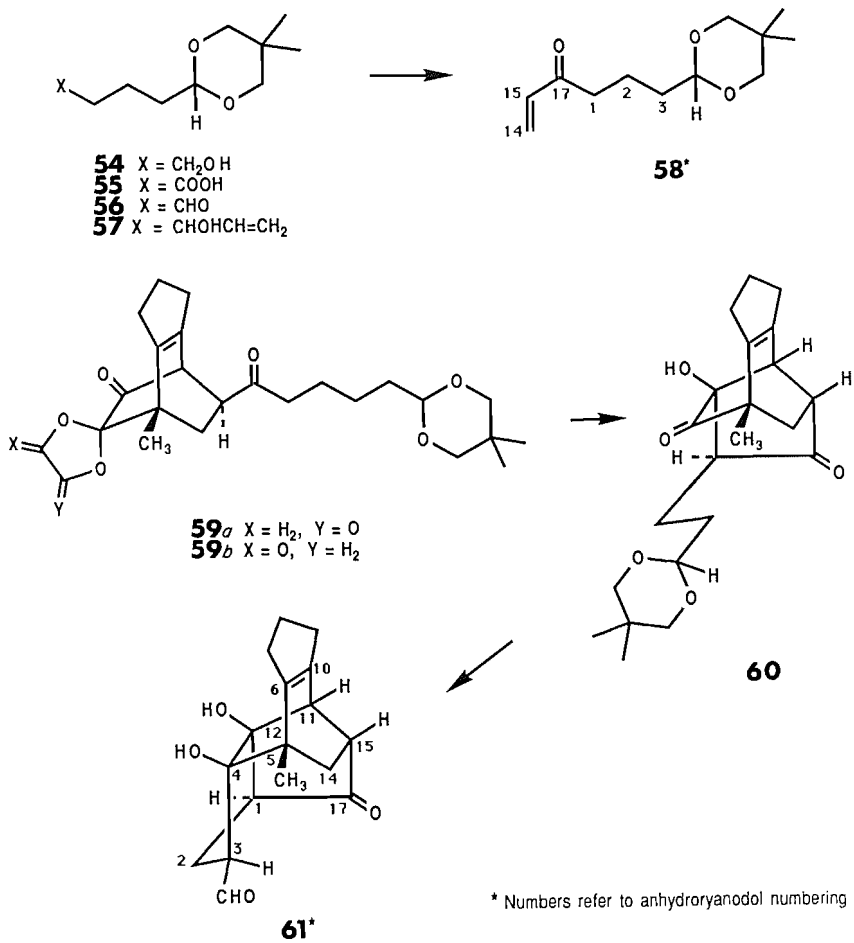


SCHEME 8

directly at C_3 or attached to C_3, and on that basis it was decided to study the dienophiles **67** and **74** (Scheme 9).

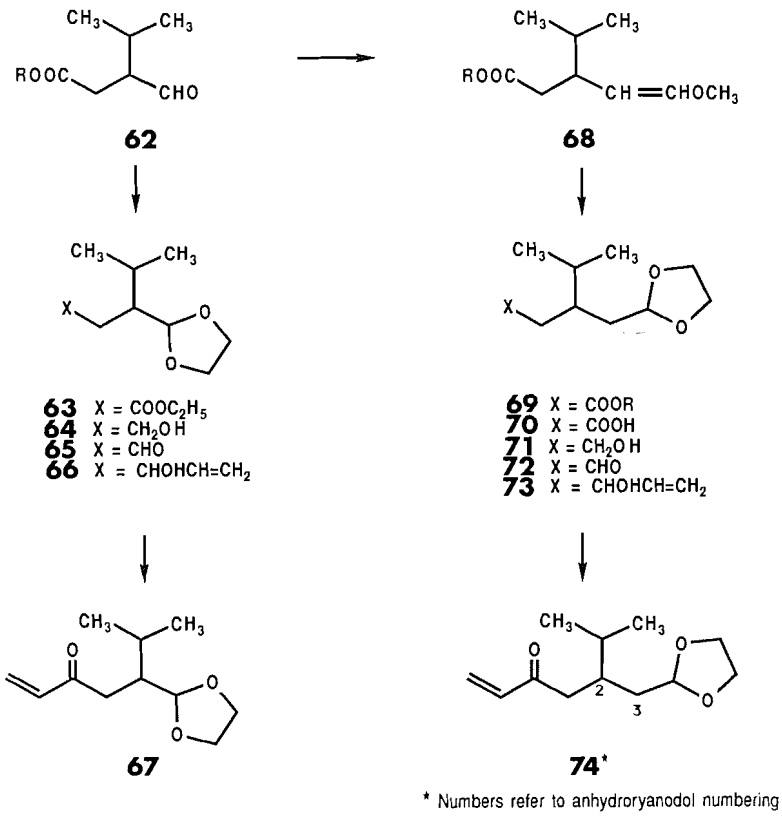
The racemic dienophiles **67** and **74** were (6) prepared from the same intermediate, the aldehyde ester **62**. Compound **62** was obtained from the condensation of the eneamine derived from diisobutylamine and isovaleraldehyde (10) with ethyl bromoacetate. Acetalization of **62** with ethylene glycol gave the acetal ester **63**, which was converted into the dienophile **67** via the intermediates **64–66** using standard conditions. Using methoxymethyl triphenylphosphorane as a reagent, the aldehyde **62** underwent a Wittig reaction to give a mixture of the *trans* and the *cis* (ratio 70:30) enol ether **68**, which can be separated by chromatography. Treatment of the isomeric mixture of enol ether **68** with ethylene glycol (PTSA, benzene) gave the homologated acetal ester **69** (R = CH_2CH_3). Basic hydrolysis of ester **69** gave the corresponding carboxylic acid **70**, which on reaction with 2 moles of vinyllithium furnished the vinyl ketone dienophile **74** having an isopropyl group at C_2 and an acetal group attached to C_3. Dienophile **74** was more conveniently prepared in large scale via the alternative route **69** → **71** → **72** → **73** → **74**.

The Diels–Alder reactions of **67** and **74** were next investigated. In both dienophiles, there is a chiral center and this will lead to the formation of diastereoisomers isomeric at C_2 and at the spirolactone moiety. For instance, the condensation of racemic dienophile **67** with *o*-spirolactone dienone **6** is expected to produce a mixture of four racemic diastereoisomers, i.e., 50% of **75***a* and **75***b* in a ≃1:1 ratio and 50% of **76***a* and **76***b* also in a ≃1:1 ratio (Scheme 10). These relative proportions are due to the fact that the chiral center at C_2, which carries the isopropyl group, is far from the vinyl ketone and it should not influence the ratio of isomers **75** and **76**. Also, our previous Diels–Alder studies have shown that the *o*-spirolactone moiety of the dienophile **6** has essentially no influence on the relative formation of the *a* and *b* spirolactone isomers in the Diels–Alder adducts. This mixture of four adducts should be convertible into a mixture of four racemic aldol condensation products **77–80**, which are diastereoisomeric at C_1 and C_2. Indeed, isomers **75***a* and **75***b* can each give a mixture of **77** and **78** whereas isomers **76***a* and **76***b* can each give a mixture of **79** and **80**. However, since the *endo* epimers are expected to predominate over the *exo* epimers, it is expected that the *endo* epimers **77** and **79** should be formed predominantly and with approximately equal ease.

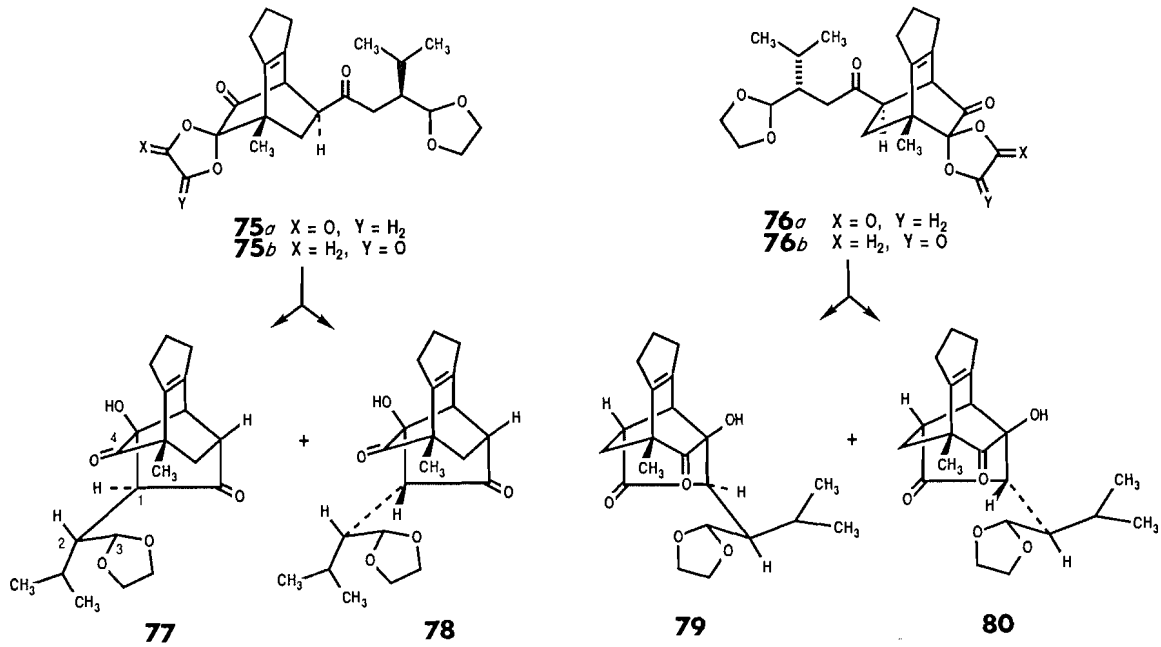
The Diels–Alder reaction of vinyl ketone **67** with *o*-spirolactone dienone **6** was carried out and gave the expected mixture of **75***a–b* and **76***a–b* as indicated by ^{1}H nmr spectroscopy. Treatment of this mixture under basic conditions gave the expected mixture of aldol products **77–80** from which one isomer was obtained pure, by a simple crystallization, in 35% yield. This crystalline product has either the *endo* structure **77** or **79**. The next step in this investigation was the determination of the orientation of the isopropyl group in the crystalline product. This would then be followed by the hydrolysis of the acetal functions at C_3 and attempts to induce the formation of the desired C_3—C_4 bond via a reductive cyclization process involving the C_3-aldehyde function and the C_4-carbonyl group.

There was no doubt a greater chance of success in pursuing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.



SCHEME 9

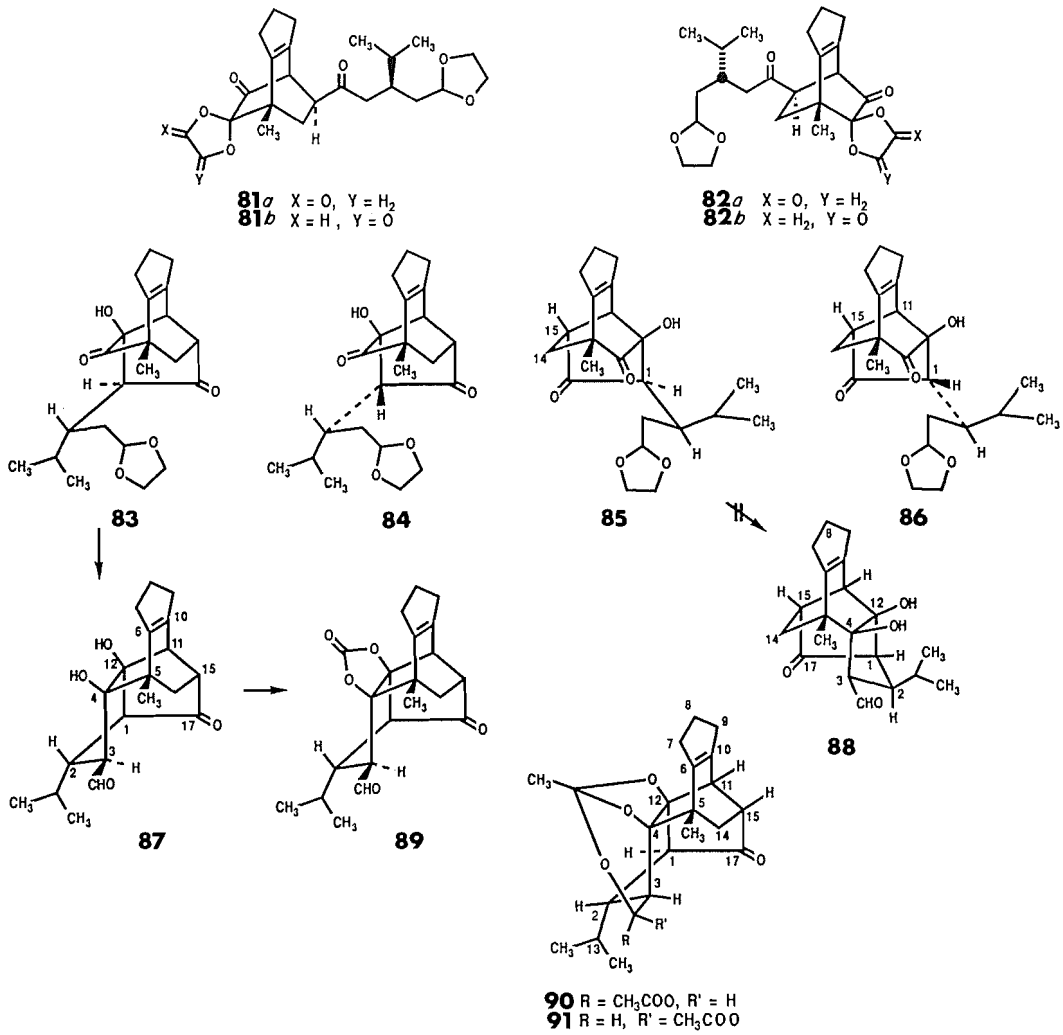


SCHEME 10

this route, but it was not investigated further because a concurrent study with the homologated dienophile **74** provided a very simple access to a pentacyclic system containing ring A. The strategy followed was essentially the same as that previously described in Scheme 8, except for the fact that the new dienophile i.e., **74**, had an isopropyl group, and a dioxolane rather than a dioxane acetal.

o-Spirolactone dienone **6** was reacted with racemic dienophile **74** to produce a quantitative yield of racemic adducts **81***a–b* and **82***a–b* (Scheme 11). Treatment of this crude mixture with sodium hydroxide in aqueous tetrahydrofuran gave a mixture of the four racemic diastereoisomers **83–86**. This mixture was heated in aqueous acetic acid and then treated with sodium hydroxide in aqueous tetrahydrofuran. This gave the racemic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.



SCHEME 11

pentacyclic dihydroxyketone aldehyde **87**, which was isolated by crystallization in 23% yield from *o*-spirolactone dienone **6**. On reaction with phosgene, compound **87** gave the corresponding five-membered carbonate derivative **89**. On reaction with acetic anhydride and *p*-toluenesulfonic acid, compound **87** gave the two epimeric orthoester derivatives **90** and **91**, which could be separated by chromatography.

The relative orientation of the isopropyl group was determined by examining the ^{1}H nmr spectra of orthoester derivatives **90** and **91**, which have an almost completely rigid conformation (7). This assignment is due to the fact that in both compounds, H_1 appears as a doublet of doublets (J = 6 and 2 Hz). Molecular models show that the dihedral angle between H_1 and H_2 is near 30° in derivatives **90** and **91** and this explains the J value of 6 Hz. If these derivatives had a configuration for the isopropyl group opposite to that shown in structures **90** and **91** (cf. **88**), the dihedral angle between H_1 and H_2 would be near 90°, and the J value would have been much smaller than 6 Hz. The additional coupling of 2 Hz is due to the occurrence of W coupling H_1 and H_{15}. This overall assignment was confirmed by the synthesis of derivatives **90** and **91** having a deuterium atom at C_{15}. In those monodeuterated compounds, H_{11} and H_1 appear as a singlet and a doublet (J = 6 Hz) respectively.

The preparation of **90** and **91** monodeuterated at C_{15} was carried out by the technique previously described for deuterium incorporation in compounds **8** (4), **36**, and **37**. Starting with the mixture **81–82**, the aldol condensation was repeated using deuterated water; this produced a mixture of **83–86** bis-deuterated at C_1 and C_{15}. This mixture was then treated under basic conditions using unlabelled water to produce a mixture of **83–86** monodeuterated at C_{15}. This mixture was resubmitted under the acidic and basic conditions previously described to produce monodeuterated **87**, which was then converted into **90** and **91** having each one deuterium at C_{15}.

An extremely simple, four-step synthesis (**74** + **6** → **81–82** → **83–86** ↠ **87**) of a pentacyclic intermediate containing the isopropyl side chain of ring A was in hand. This intermediate, **87**, also had the required hydroxyl groups at C_4 and C_{12}, the tertiary methyl group at C_5, and the tetrasubstituted olefin between C_6 and C_{10}. It had two additional functional groups, the aldehyde at C_3 and the carbonyl at C_{17}, both of which are essential for the completion of rings A and D of anhydroryanodol.

Thus we had arrived at a very interesting point in our investigation. We decided that the pentacyclic compound **87** should be considered seriously as a real intermediate for our synthesis. Yet, further analysis revealed that we could take additional advantage of our dienophile **74**! This analysis started by examining in more detail the chemistry that is taking place in the course of the formation of the pentacyclic intermediate **87**. We

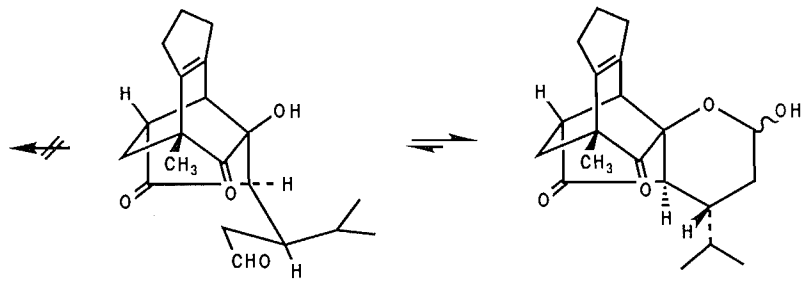

SCHEME 12

were interested in understanding why the other isomer **88** was not isolated. For instance, was it due to the fact that **87** crystallizes more readily than **88** or because only the former is being formed in the second aldol condensation process?

The tetracyclic diastereoisomeric mixture **83**–**86** was purified by chromatography (7). Isomers **83** and **85** were isolated pure and isomers **84** and **86** were obtained as a mixture from which isomer **86** could be isolated pure by crystallization. The relative configuration of the four isomers could be established by ^{1}H nmr spectroscopy and by the following reactions and chemical correlations. Equilibration[5] under basic conditions indicated that **83** and **84** are epimeric at C_1 and, since the former is the most stable epimer, **83** and **84** must have, respectively, the *endo* and the *exo* configuration. Similarly, equilibration showed that **85** and **86** are epimeric at C_1 and, since the former isomer is more stable, it has the *endo* orientation. Interestingly, when isomer **83** was submitted to the acidic and basic conditions necessary for the formation of the pentacyclic system, compound **87** was isolated in essentially quantitative yield. On the other hand, when compound **85** (or **86**) was submitted to the same reaction conditions, a complex mixture of products was formed, from which we did not succeed in isolating the anticipated pentacyclic isomer **88**. These experiments determined the relative configuration of the isopropyl group in isomers **83** and **85** since the configuration of this group has been established in compound **87** (*vide supra*). They also demonstrated that the specific formation of **87** is due to the fact that the aldehyde intermediate derived from **83** undergoes a quantitative internal aldol condensation, whereas that from **85**, under the same conditions, does not.

It is sometimes difficult to speculate on why a reaction takes place and more difficult on why a reaction does not take place. However, examination of molecular models suggests the following two alternative explanations. The isopropyl group is much more sterically hindered in isomer **88** than in **87**. On that basis, it is possible that in the case of **88** the equilibrium of the reaction is towards the retroaldol rather than the aldol product. It is also possible that the aldehyde **92** (Scheme 12) derived from **88** would prefer to exist in the form of the cyclic hemiacetal **93**, which has an isopropyl group in the equatorial orientation.[6] This would slow the rate of enolate formation from the aldehyde **92**, which is necessary for the aldol condensation, and, as a result, other competing reactions would take place and predominate. In the case of the aldehyde derived from **87**, formation of a cyclic hemiacetal would not occur because the isopropyl group would have to take an axial orientation. Thus enolization of the aldehyde would take place readily, followed by the internal aldol condensation.

The fact that the pentacyclic compound **88** is not formed and that the process leads to the specific formation of the pentacyclic isomers **87** has the disadvantage that the yield of the reaction cannot be higher than 50%. On the other hand, this approach has the advantage that if an optically active dienophile is used, the optically active enantiomer of pentacyclic **87** should be produced. To illustrate this point, let us assume that the dienophile would be optically active and would have the absolute configuration described by formula **74** (Scheme 13), i.e., having the *S* configuration. Optically active dienophile (*S*)-**74** has no preference for a particular face of the racemic diene **6**; the reaction will therefore take place with equal ease from the α and the β faces the racemic diene **6**, producing a 50:50 mixture of optically active **81***a*–*b* and **82***a*–*b* having the absolute configuration shown and where the *a*/*b* ratio due to the spirolactone isomerism will also be near 1:1. On treatment with base, optically active **81***a*–*b* will produce optically active *endo* and *exo* epimers having the absolute configuration described by structures **83** and **84**. Similarly, **82***a*–*b* will produce a mixture of optically active *endo* and *exo* epimers **85** and **86**. In the next step, **83** will be transformed into optically active **87** having the absolute configuration shown, whereas **85** cannot be converted into **88**. As a result, starting with dienophile **74** with the *S* absolute configuration leads to the optically active pentacyclic **87** having the absolute configuration shown. This also means that if one starts with dienophile **74** having the opposite *R* absolute configuration, the mirror image enantiomer of **87** would be produced. However, the absolute configuration of ryanodol is known and corresponds to formula **5**; consequently, we need the pentacyclic compound having the absolute configuration described by **87**. Thus we must synthesize an optically active dienophile **74** having the *S* absolute configuration.

The next step in our work was to find a method of obtaining an optically active dienophile of known absolute configuration in order to produce an optically active pentacyclic product. The monoterpene carvone was selected as starting material because

[5]More specifically, on treatment of **83** under basic equilibrating conditions for 18 h, **84** is not isolated but **83** was reisolated in only 85% yield. This indicates that **84** is much less stable than **83** and that **83** decomposed slightly under these conditions. Basic equilibration of **86** gave a mixture of **85** and **86** in 43% yield, where **85** predominates. Similar treatment of a mixture of **84** and **86** gave a mixture of **85** and **86**. This result confirms that isomer **84**, which can be characterized by nmr, is, however, unstable under basic conditions. It may also explain the unstability of isomer **83** because it is slowly converted into **84**, which is not stable under these conditions.

[6]These explanations were confirmed much later with the evidence of hemiketal formation (see **93**): nmr observation of anomeric proton signals at 5.38 (dd, J = 6 and 3 Hz) and 6.18 (dd, J = 12 and 3 Hz).

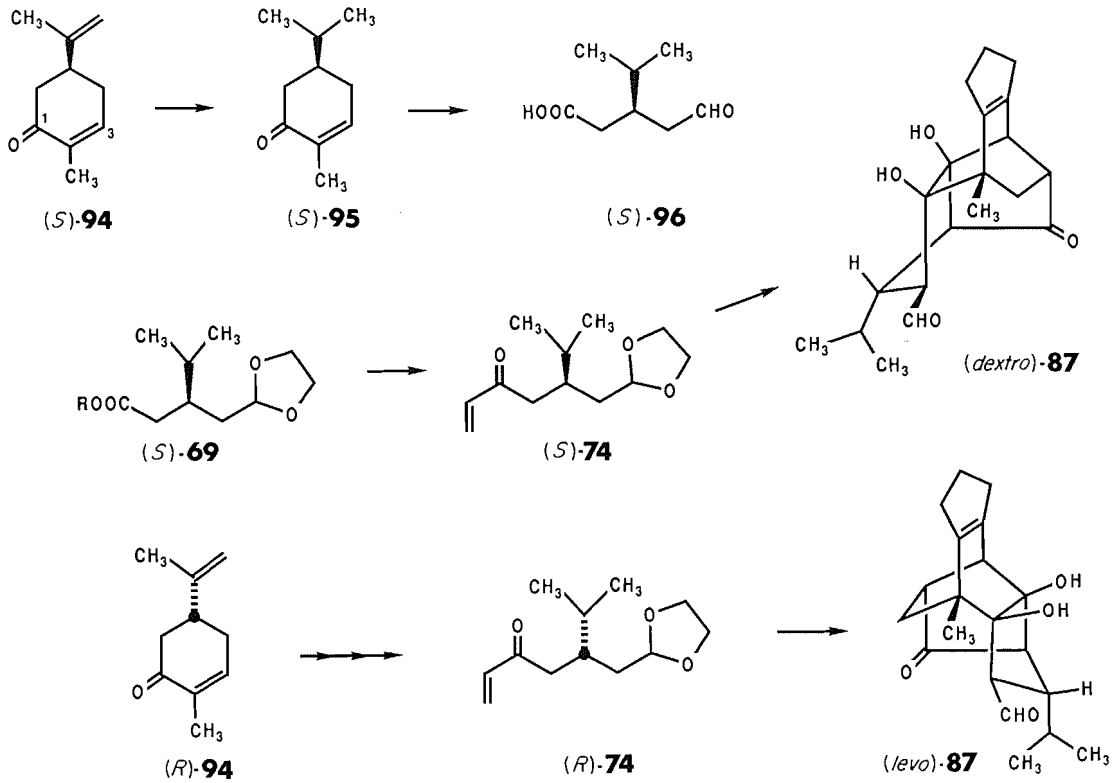

SCHEME 13

it presented several advantages. Both optically active forms *d* and *ℓ* are commercially available and their absolute configuration is well established as being *S* and *R* respectively (11). Also we were able to conceive and realize a very simple synthesis of the dienophile starting from carvone.

Scheme 13 describes the preparation of the optically active dienophile (*S*)-**74**. *d*-Carvone ((*S*)-**94**) was reduced catalytically (12) over platinum with hydrogen to give the dihydro derivative (*S*)-**95**. Ozonolysis of (*S*)-**95** (O_3 in CH_3COOEt; H_2–Pd/C) gave the aldehyde carboxylic acid (*S*)-**96**, which was transformed into the optically active acetal methyl ester (*S*)-**69** (R = CH_3) by successive acetalization (ethylene glycol, cat. PTSA in benzene; NaOH in CH_3OH) and esterification (CH_2N_2 or CH_3I, K_2CO_3 in acetone (13)). Using the methods previously described for the preparation of racemic material, acetal ester (*S*)-**69** was converted into optically active dienophile (*S*)-**74**, which was found to be dextrorotatory ($[\alpha]_{578}$ +0.6°). *o*-Spirolactone diene **6** was then heated with a slight excess of (*S*)-**74** in benzene. The crude Diels–Alder adduct was treated with an aqueous solution of sodium hydroxide in tetrahydrofuran to effect the first aldol condensation. It was then treated with aqueous acetic acid at 70°C followed by a treatment of the resulting crude material with aqueous sodium hydroxide in tetrahydrofuran. This produced, after chromatography, the crystalline pentacyclic dihydroxyketone aldehyde, which is dextrorotatory, i.e., (*dextro*)-**87** ($[\alpha]_{578}$ +142.2°). Starting with *ℓ*-carvone, i.e., (*R*)-**94**, a small quantity of the levorotatory dienophile (*R*)-**74** was also prepared and, following a sequence similar to that described above, (*R*)-**74** was converted into the crystalline levorotatory pentacyclic dihydroxyketone aldehyde, which is the mirror image of (*dextro*)-**87**, i.e., (*levo*)-**87** ($[\alpha]_{578}$ −137.5°). The pentacyclic key intermediate was thus available in both optically active forms. However, as previously mentioned, we needed (*dextro*)-**87** since its absolute configuration corresponds to that of ryanodol. In practice, it was easier to isolate the pentacyclic intermediate as the five-membered carbonate derivative **89** ($[\alpha]_D$ +121.3°) (Scheme 11). However, the overall yield of this product (**89**) from diene **6** was 27%. This 27% yields represents 54% of the theoretical yield. Our synthetic scheme being convergent, it meant that using ≈50 g of diene **6** with 50 g of dienophile (*S*)-**74** leads to approximately 25 g of (*dextro*)-**89**. It was thus relatively easy to obtain a large quantity of (*dextro*)-**89**, and we prepared approximately 100 g of it.[7]

Before preparing a large quantity of the optically active pentacyclic intermediate (*dextro*)-**89**, we carried out one additional study. So far, our investigation has led to improvement of the dienophile, but further analysis of our synthetic route revealed that there was also the possibility of improving the diene. This could be done by introducing, in the diene, the secondary methyl group that is found in ring C of ryanodol. This meant that the Diels–Alder reaction would take place with an *o*-spirolactone diene having a secondary methyl group at C_9. Since this diene would have a chiral center,[8] it could be optically active, having either the absolute configuration (*S*)-**97** or the opposite (*R*)-**97** (Scheme 14). This is theoretically interesting because each, the diene and the dienophile, have one chiral center.

This new situation can be analyzed by considering the combination of optically active dienophile (*S*)-**74** with the two

[7]When this material was prepared, Fourier transform nmr was not yet available. So, a large quantity of material was required for further investigation.

[8]*o*-Spirolactone diene **6** has one chiral center due to the spirolactone ring. However, as previously discussed, this chiral center is not important because it does not influence the Diels–Alder reaction and it is destroyed in the following step.

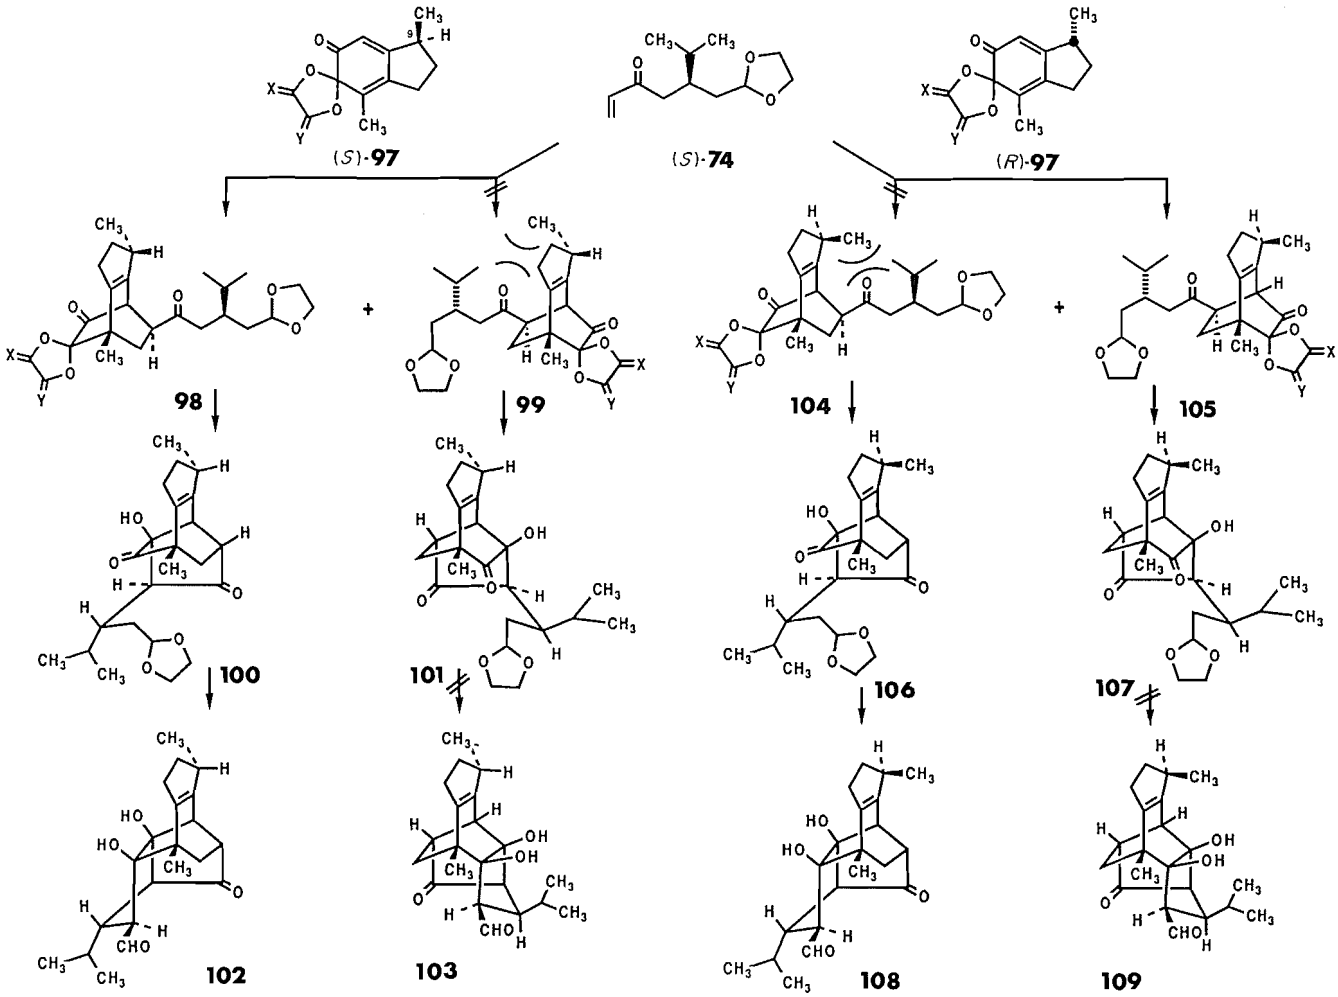

SCHEME 14

enantiomeric dienes (*S*)-**97** and (*R*)-**97**. The combination of (*S*)-**74** with (*S*)-**97** can theoretically produce **98** and **99**, which can lead to the formation of the tetracyclic intermediates **100** and **101** respectively. Then, due to the chirality of the isopropyl group, **101** would not be converted into **103** whereas **100** would lead to the formation of the pentacyclic intermediate **102**. Furthermore, it is also possible that **98** would be produced but not **99**, and this would be due to the fact that, in the transition state leading to **99**, the secondary methyl group of the diene comes close to the carbonyl group of the dienophile (cf. **99**). This is not the case during the formation of **98**, and it is possible that this steric interaction might be large enough to completely prohibit the formation of **99**. If this is true, it means that not only **103** but also **99** would not be formed and the net result would be that the theoretical yield for the production of **102** would be 100% rather than 50%.

Further advantage could also be drawn from this situation by examining the combination of optically active dienophile (*S*)-**74** with the other enantiomeric diene, i.e., (*R*)-**97**. This combination can theoretically lead to **104** and **105**, which can then yield **108** and **109** via **106** and **107** respectively. However, because of the additional steric hindrance caused by the secondary methyl group in the Diels–Alder reaction, **104** would not be produced, and only **105** would be observed. Then, **105** would be converted into **107**. However, due to the relative chirality of the isopropyl group, **107** would not yield **109**. The net result would be that the combination of (*S*)-**74** with (*R*)-**97** would not be productive. The interesting conclusion of this analysis is that it would not be necessary to resolve the diene, this resolution would be achieved by the dienophile (*S*)-**74**! Indeed, (*S*)-**74** would react with a racemic mixture of (*S*)-**97** and (*R*)-**97** producing a mixture of optically active Diels–Alder adducts **98** and **105** only, of which only the former (i.e., **98**) can lead to a pentacyclic optically active intermediate (i.e., **102**).

This interesting conclusion is valid only if the steric hindrance caused by the secondary methyl group is large enough to completely inhibit the formation of **99** and **104**. If not, it is expected that a mixture of the four Diels–Alder adducts would be produced where **98** and **105** should predominate. Since **99** and **105** cannot produce a pentacyclic product, a mixture of **102** (from **98**) and **108** (from **104**) would be produced, both optically active and where the former would predominate.

The preparation (8) of racemic *o*-spirolactone diene **97** is shown in Scheme 15. The reaction of 5,6-dimethoxyindanone (**110**) with methyllithium gave a crude mixture of **111** and **112**. Dehydration of **111** took place in the work-up and, upon purification by chromatography, crystalline methylindene **112** was isolated. Catalytic hydrogenation of **112** (PtO_2/H_2, CH_3COOH) gave methylindane **113**, which was converted into the racemic *o*-spirolactone dienone **97** by a route essentially identical to that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12

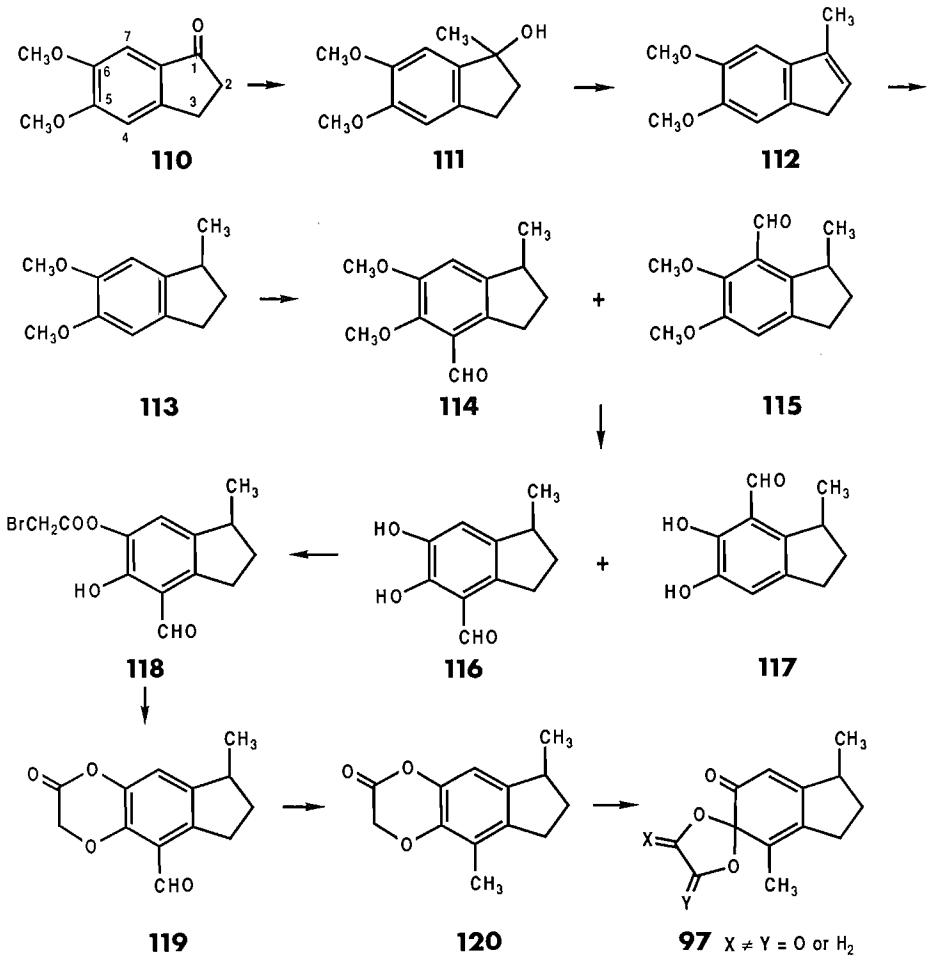

SCHEME 15

previously developed for the preparation of *o*-spirolactone dienone **6** (4). In this series, however, the chemistry was somewhat more complicated because the methylindane **113** is dissymmetric.

Reaction of methylindane **113** with dichloromethyl methyl ether and titanium tetrachloride in benzene (14) gave a 2:1 mixture of isomeric dimethoxyindane aldehydes **114** and **115**. Treatment of this mixture with boron tribromide (15) gave a 2:1 mixture of dihydroxyindane aldehydes **116** and **117**. Using the technique of fractional crystallization, **116** and **117** were obtained pure in low yield of 12 and 1% respectively. Nevertheless, this provided **116** in sufficient quantity to test our hypothesis. Reaction of **116** with bromoacetyl bromide in pyridine gave the bromoacetate **118**, which was then converted using potassium carbonate into the lactone aldehyde **119**. Catalytic reduction and hydrogenolysis of **119** with hydrogen in the presence of palladium-on-charcoal in acetic acid yielded the lactone indane **120**. Finally, treatment of lactone **120** with sodium hydroxyde followed by oxidation with *N*-bromosuccinimide (16) provided the racemic *o*-spirolactone dienone **97** ($X \neq Y = O$ or H_2).

The selectivity of diene **97** was first examined by studying its reactivity with methyl vinyl ketone (Scheme 16). This cycloaddition provided a mixture of the four isomers **121***a–b* and **122***a–b*, which were separated by chromatography. The relative stereochemistries of these compounds were not firmly established. This mixture was also treated with sodium hydroxide in water and tetrahydrofuran to produce a 55:45 mixture of isomers **123** and **124**, which were obtained pure by chromatography. The ratio obtained clearly demonstrated that the secondary methyl group in **97** does not create sufficient steric interaction to prevent the formation of **122***a–b* over that of **121***a–b*. It was therefore clear that the reaction of optically active dienophile (*S*)-**74** with racemic diene **97** would not lead to the exclusive formation of **102** as anticipated. Nevertheless, since we had both components in our hand, the Diels–Alder reaction of racemic diene **97** and optically active dienophile (*S*)-**74** was carried out, and the resulting product was treated successively with base (NaOH, THF–H_2O), acid (CH_3COOH–H_2O), and base (NaOH, THF–H_2O) to produce a crude material that was reacted with phosgene in the presence of pyridine in benzene. Preparative thin-layer chromatography provided a ≃55:45 mixture of isomers **125** and **126** in a low yield of 10%. Each isomer was then obtained pure by fractional crystallization.

This approach was abandoned because it was difficult to produce a large quantity of racemic diene **97**, and a low yield of an isomeric mixture of pentacyclic material was isolated. This approach is, however, theoretically interesting because it corresponds to a new strategy in synthesis, where the novel aspect comes from the fact that the resolving agent remains part of the target molecule afterward. It is likely that such a procedure will eventually be used with complete success in another synthesis.

Before ending Part II, we wish to add that we also considered to some extent another type of dienophile. The strategy previously described using vinyl ketone dienophiles requires a

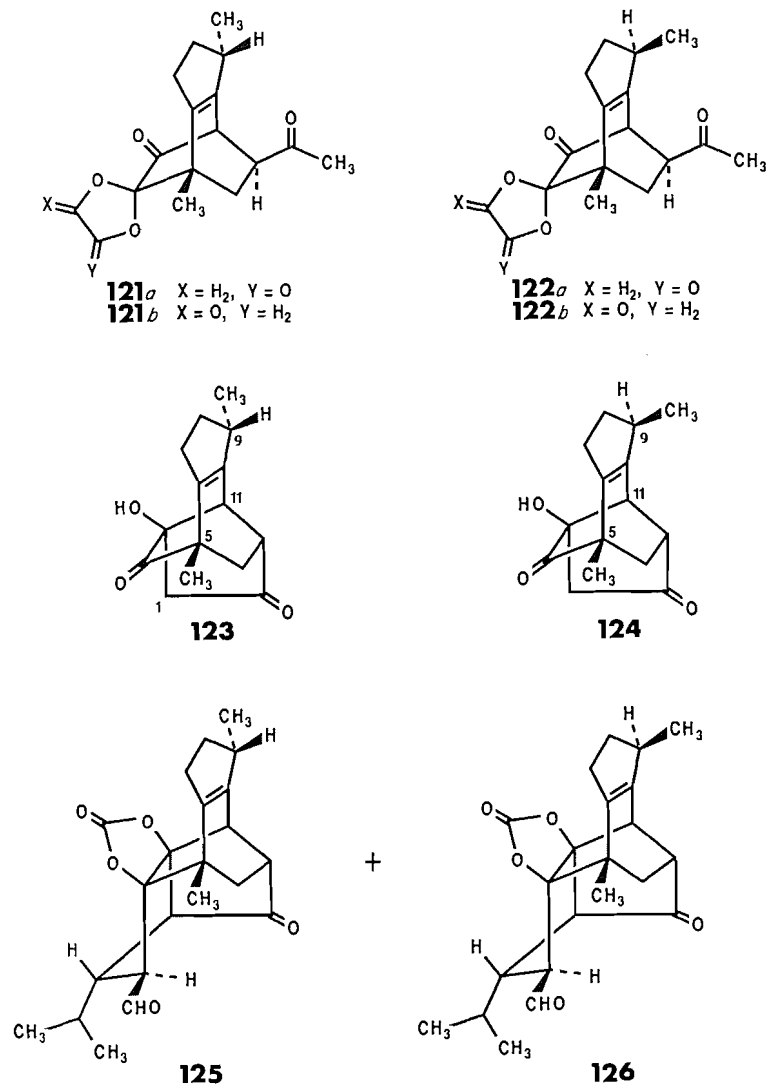
For personal use only.



SCHEME 16

cleavage of a carbon–carbon bond between C_{15} and C_{17} (cf. Scheme 5) at a later stage, and we have considered ways either to prevent or at least to ease this task. For this reason, we considered, as dienophile, acrylonitrile having an ester group at carbon-2 (8*a*).

The first dienophile investigated was the known (17) 2-acetoxy-acrylonitrile (**127**) (Scheme 17). The Diels–Alder reaction of **127** with *o*-spirolactone dienone went smoothly, but without following the *endo* rule, yielding a mixture of four stereoisomers **128***a–b* and **129***a–b* that could, however, be separated by chromatography. The most polar of these Diels–Alder adducts (mp 191–192°C) was shown to have structure **128***b* by single crystal X-ray diffraction analysis (8*b*). It was then hoped that the two isomers that correspond to **128***a–b* would undergo an intramolecular aldol condensation to produce the cyanohydrin lactone **130**. However, in our hands, all attempts to produce **130** under either basic or acidic conditions failed. In acidic conditions, isomers **129***a–b* showed their interrelation, giving the same cyanohydrin diketone, which therefore had structure **132** and not **131**. The cyanohydrin diketone **132** was further characterized by acetylation (Ac_2O, pyridine) to an acetate derivative, which should have structure **134** and not **133**. The failure of these aldol condensation experiments might be due to the fact that the acetate group requires strong conditions to enolize. To facilitate the aldol condensation, the more complex acrylonitrile **139** was synthesized (8) (Scheme 18). Thus using a strategy similar to that described for the β-diketone **46** (Scheme 7), it was hoped that **139** would react with *o*-spirodienone lactone **6** to produce **140***a–b*, which would undergo, after acetal hydrolysis, an internal aldol condensation. This would produce **142**, which might thus undergo a second aldol condensation yielding ring A (i.e., **143**).

The synthesis of **139** was started with the dioxolane acetal **40** of ethyl acetoacetate. Basic hydrolysis of **40** gave the corresponding carboxylic acid **135**, which was then converted ($(COCl)_2$, pyridine, benzene) into the acid chloride **136**. Reaction of **136** with the cyanohydrin of chloroacetaldehyde (**137**) gave the corresponding ester **138**. Treatment of ester **138** with triethylamine gave the desired substituted acrylonitrile **139**. The Diels–Alder reaction of **139** with *o*-spirolactone dienone **6** gave a mixture of isomers **140***a–b and* **141***a–b* from which two isomers were isolated pure by fractional crystallization. The most polar (mp 189–190°C) of these adducts was shown to have structure **140***b* (X = O, Y = H_2) by single crystal X-ray diffraction analysis (8*b*). Again, it was hoped that the isomers that correspond to **140***a–b* would have produced the aldol product **142**. However, all attempts were unsuccessful and this approach was abandoned.

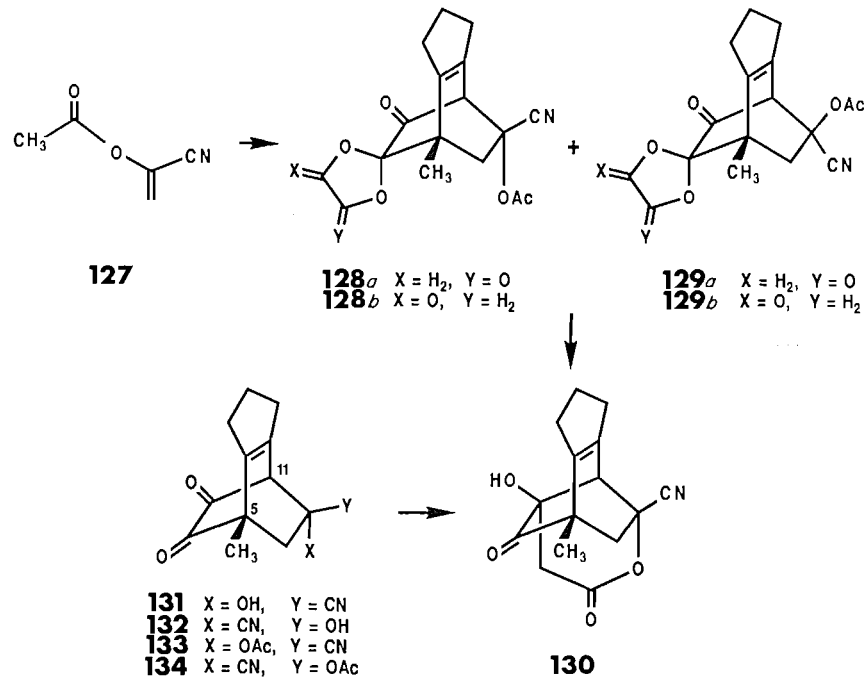
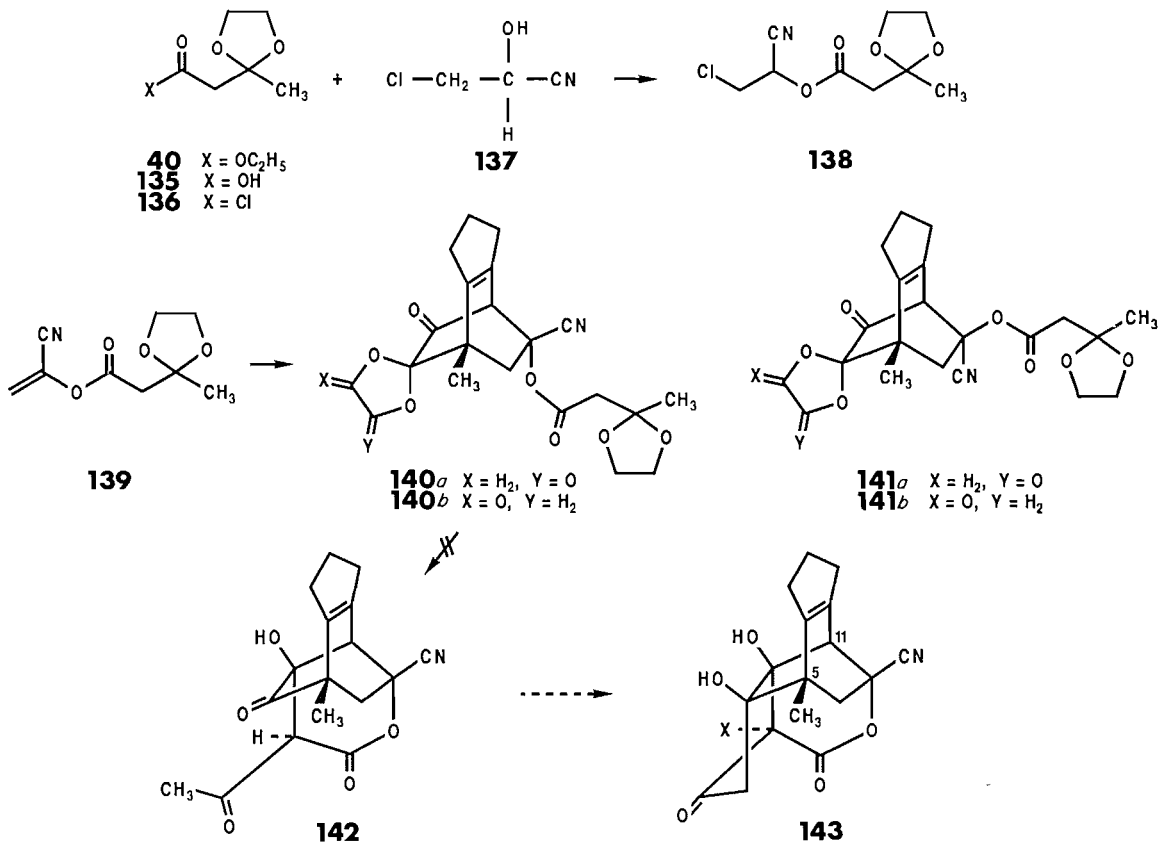


SCHEME 17



SCHEME 18

In conclusion, the chemistry described in Part II that is relevant to our total synthesis can be summarized in the following way. We have developed a simple synthesis of optically active dienophile (*S*)-**74** starting from carvone (*S*)-**94** (Scheme 13). Using this dienophile and racemic *o*-spirolactone dienone **6**, we have obtained, in four steps, the five-membered carbonate derivative **89** (Scheme 11) of the optically active pentacyclic dihydroxy ketoaldehyde **87**, having the desired absolute configuration, in 54% of a 50% theoretical yield, i.e., 27% overall yield.

Experimental

Apparatus, materials, and methods

Melting points were determined on a Büchi M-50 apparatus and are uncorrected. Ether, tetrahydrofuran, and 1,2-dimethoxyethane were dried by distilling over sodium benzophenone ketyl. Benzene, dichoromethane, dimethyl sulfoxide, and amines were distilled over calcium hydride. All reactions were performed under nitrogen or argon atmosphere. Analytical and preparative thin-layer chromatography (tlc) were carried out on glass plates precoated (0.25, 0.5, 1.0, and 2.0 mm) with silica gel 60 F-250 (Merck). Materials were detected by visualization under an ultraviolet lamp (254 or 350 nm) and (or) by spraying with sulfuric acid (50%) or a solution of phosphomolybdic acid or vanillin followed by heating on a hot plate. Column chromatography was performed with silica gel (Baker 60–200 Mesh) or Merck 60 (200–400 mesh)).

The infrared spectra (ir) were taken on a Perkin–Elmer 257 or 681 spectrophotometer. Proton nuclear magnetic resonance (^{1}H nmr) spectra were recorded (with chloroform or tetramethylsilane as internal standard) on a Varian A-60, a Bruker WP-60, a Bruker HX-90, or a Bruker WM-250 instrument. Carbon nuclear magnetic resonance (^{13}C nmr) spectra were measured on a Bruker HX-90 or WM-250 instrument. The following abbreviations have been used: s, singlet; d, doublet; dd, doublet of doublets; t, triplet; q, quartet; qn, quintet; m, multiplet; br, broad. For most of the hydroxylated compounds, the multiplicity of the hydrogens attached to a carbinol was analyzed after D_2O exchange. The mass spectra were recorded on a Hitachi–Perkin–Elmer RMU-6 mass spectrometer and peak matching (hrms) on a VG Micromass ZAB-2F spectrometer. The ultraviolet spectra (uv) were recorded on a Varian Techtron 635 spectrophotometer. Microanalyses were carried out by Mr. J. Tamas, Laboratoire de Microanalyses, Université de Sherbrooke; Schwarzkopf Microanalytical Laboratories, New York; and by Dr. C. Daesslé, Organic Microanalyses, Montreal.

Diketoacetate ***9***

A solution of diketoalcohol **8** (2.5 g, 10.4 mmol) in a mixture of pyridine (3 mL) and acetic anhydride (4 mL) was heated for 0.5 h at 100°C. The volatile materials were removed under vacuum and the residue was crystallized from ether–pentane to give pure acetate **9** (2.6 g, 91%); mp 128–130°C; ir (CH_2Cl_2, ν cm^{-1}): 1745, 1720, and 1230; ^{1}H nmr ($CDCl_3$, δ ppm): 3.75 (d, 1H, J = 5 Hz, HC11), 3.07 (dd, 1H, J_{AB} = 19.4 Hz, J_W = 2.3 Hz, H_{exo}-C1), 2.66 (d, 1H, J_{AB} = 19.4 Hz, H_{endo}-C1), 2.68 (m, 1H, H-C15), 2.45 (m, 4H, allylic protons), 2.05 (s, 3H, CH_3CO_2), 2.00 (m, 2H), 1.82 (dd, 1H, J_{AB} = 13.8 Hz, J_{AX} = 11.6 Hz, H_{exo}-C14), 1.52 (dd, 1H, J_{AB} = 13.8 Hz, J_{BX} = 1.6 Hz, H_{endo}-C14), 1.27 (3H, s, CH_3-C5); ms *m/e*: 274 (M^+). *Anal.* calcd. for $C_{16}H_{18}O_4$: C 70.05, H 6.61; found: C 69.97, H 6.52.

Monoketal acetate ***10***

A mixture of diketoacetate **9** (2.4 g, 8.8 mmol), ethylene glycol (2 mL), and *p*-toluenesulfonic acid (20 mg) in benzene (50 mL) was refluxed for 4 h (Dean–Stark water separator). The cooled reaction mixture was then washed with aqueous sodium carbonate solution (1 M) and brine. Evaporation of the solvent gave a solid residue, which was crystallized from ether (2.55 g, 91%); mp 149–152°C; ir (CH_2Cl_2, ν cm^{-1}): 1745, 1730, 1230; ^{1}H nmr ($CDCl_3$, δ ppm): 3.88 (m, 4H), 3.52 (d, 1H, 4 Hz, H-C11), 2.8–1.4 (m, 11H), 1.98 (s, 3H, CH_3CO_2), 1.25 (s, 3H, CH_3-C5); ms *m/e*: 318 (M^+). *Anal.* calcd. for $C_{18}H_{22}O_5$: C 67.91, H 6.97; found: C 68.22, H 6.96.

Reduction of ketoacetate ***10***

(a) With lithium borohydride

To a cooled (0°C) solution of monoketal acetate **10** (2.4 g, 7.6 mmol) in tetrahydrofuran (120 mL) was added lithium borohydride (0.42 g, 20 mmol). The mixture was stirred for 2 h at 0°C, 1 h at 25°C, and 1 h at reflux temperature. Then was added lithium aluminum hydride (0.80 g, 20 mmol) and the reflux was pursued for 1 h. The cooled mixture was then cautiously reacted with moist ether, then water. The mixture was extracted with ether. The organic phase was dried ($MgSO_4$) and evaporated to give a mixture (≈95:5) of *trans* diol **11** and *cis* diol **12** respectively. The crude mixture was crystallized from ether to give pure *trans* ketal diol **11** (1.6 g, 76%); mp 145–147°C; ir (CH_2Cl_2, ν cm^{-1}): 3580, 3400, 1030; ^{1}H nmr ($CDCl_3$, δ ppm): 4.00 (m, 4H), 3.16 (d, 1H, J_W = 2 Hz, H-C4), 3.03 (d, 1H, J = 4 Hz, HC11), 2.8–1.6 (m, 11H), 1.13 (s, 3H, CH_3-C5); ms *m/e*: 278 (M^+). *Anal.* calcd. for $C_{16}H_{22}O_4$: C 69.04, H 7.97; found: C 68.90, H 8.15.

(b) With lithium in ammonia

To a solution of monoketal acetate **10** (2.0 g, 6.3 mmol) in tetrahydrofuran (15 mL) and dry ethanol (5 mL), at −78°C, was added liquid ammonia (freshly distilled, ~50 mL). Small pieces of lithium (total 1.0 g) were added to that mixture over a period of 1 h. The cold bath was then removed, the ammonia was evaporated, and the residue was reacted with ethanol (2 mL), then diluted with water and extracted with ether (3 × 50 mL). The combined organic layer were dried over magnesium sulfate, filtered, and the solvents evaporated to give a mixture (31:58) of *trans* ketal diol **11** and *cis* ketal diol **12** respectively. The two isomers were separated by crystallization or by chromatography (silica, Et_2O). *trans* Ketal diol **11** (0.53 g, 31%) (*vide supra*); *cis* ketal diol **12** (1.0 g, 58%); mp 115–117°C; ir (CH_2Cl_2, ν cm^{-1}): 3400, 1180, 1060, 1030; ^{1}H nmr ($CDCl_3$, δ ppm): 3.90 (m, 4H), 3.35 (s, 1H, H-C4), 2.95 (d, 1H, J = 4 Hz, HC11), 2.6–1.3 (m, 1H), 1.24 (s, 3H, CH_3-C5); ms *m/e*: 278 (M^+). *Anal.* calcd. for $C_{16}H_{22}O_4$: C 69.04, H 7.97; found: C 68.83, H 7.78.

Carbonate ***13***

To a solution of *cis* ketal diol **12** (0.5 g, 1.8 mmol) in a mixture of benzene (30 mL) and pyridine (0.5 mL) was added, at 25°C, a saturated benzene solution of phosgene (20 mL). After 15 min the mixture was filtered and evaporated. The oily residue was crystallized from ether–hexane to give carbonate **13** (0.45 g, 82%); mp 102–103°C; ir (CH_2Cl_2, ν cm^{-1}): 1795, 1210, 1190, 1065; ^{1}H nmr ($CDCl_3$, δ ppm): 4.15 (s, 1H, H-C4), 3.95 (m, 4H), 3.20 (d, 1H, J = 4 Hz, H-C11), 2.7–1.4 (m, 11H), 1.30 (s, 3H, CH_3-C5); ms *m/e*: 304 (M+). *Anal.* calcd. for $C_{17}H_{20}O_5$: C 67.10, H 6.75; found: C 66.68, H 6.48.

Ketal monoacetate ***14***

A solution of *trans* ketal diol **11** (4.3 g, 14.2 mmol) in pyridine (10 mL) was reacted overnight with acetic anhydride (12 mL) at room temperature. Evaporation of volatile materials under vacuum afforded monoacetate **14** as an oil (5.0 g, quant.); ir (CH_2Cl_2, ν cm^{-1}): 3420, 1720, 1030; ^{1}H nmr ($CDCl_3$, δ ppm): 3.92 (d, 1H, J_W = 2 Hz, H-C4), 3.90 (m, 4H), 3.07 (d, 1H, J = 4 Hz, H-C11), 2.6–1.7 (m, 11H), 2.17 (s, 3H, CH_3CO_2), 1.09 (s, 3H, CH_3-C5); ms *m/e*: 320 (M^+).

Dihydroxy ketoacetates ***17*** *and* ***18***

A solution of ketal monoacetate **14** (4.90 g, 15.3 mmol) in methanol (100 mL) was reacted, at −78°C, with a stream of ozone for 25 min. The mixture was then shaken for 3 h in an atmosphere of hydrogen in the presence of 10% palladium-on-carbon catalyst (50 mg). After filtration, the solvent was evaporated and the residue dissolved in pyridine (5 mL), refluxed for 20 min, and kept to dryness. The residue was purified by column chromatography on silica gel (ether) to give dihydroxy ketoacetates **17** and **18**.

Dihydroxyacetate ***17*** (3.10 g, 57%); mp 176–177°C; ir (CH_2Cl_2, ν cm^{-1}): 3450, 1735, 1690; ^{1}H nmr ($CDCl_3$, δ ppm): 5.24 (d, 1H J_W = 2 Hz, H-C4), 4.3 (br s, 1H, -OH), 3.90 (m, 4H), 3.35 (br signal, 1H, -OH), 2.8–1.2 (m, 11H), 2.21 (s, 3H, CH_3CO_2), 1.02 (s, 3H, CH_3-C5). *Anal.* calcd. for $C_{18}H_{24}O_7$: C 61.35, H 6.86; found: C 61.03, H 6.72.

Dihydroxyacetate ***18*** (1.10 g, 20%); mp 99–101°C; ir (CH_2Cl_2, ν cm^{-1}): 3450, 1715; ^{1}H nmr ($CDCl_3$, δ ppm): 4.70 (d, 1H, J_W = 2 Hz, H-C4), 3.85 (m, 4H), 3.50 (br signal, 1H, -OH), 2.4–1.1 (m, 11H), 2.12 (s, 3H, CH_3CO_2), 0.80 (s, 3H, CH_3-C5).

Carbonate derivative ***19***

To a solution of dihydroxyacetate **17** (0.50 g, 1.42 mmol) in a mixture of benzene (30 mL) and pyridine (0.5 mL) was added, at 25°C, a saturated benzene solution of phosgene (30 mL). After 4 h, the mixture was filtered and evaporated. Crystallization of the crude product (CH_2Cl_2–Et_2O) yielded carbonate **19** (0.46 g, 86%); mp 204–205°C; ir (CH_2Cl_2, ν cm^{-1}): 1760, 1740, 1715, 1230, 1060; ^{1}H nmr ($CDCl_3$, δ ppm): 4.90 (d, 1H, J_W = 2 Hz, H-C4), 3.88 (m, 4H), 3.50 (br signal, 1H, -OH), 2.45–1.1 (m, 11H), 2.12 (s, 3H, CH_3CO_2), 0.80 (s, 3H,

CH_3-C5); ms *m/e*: 378 (M^+). *Anal.* calcd. for $C_{19}H_{22}O_8$: C 60.31, H 5.86; found: C 60.12, H 6.07.

Triketone **26**

A solution of monoketal ketoacetate **10** (0.80 g, 2.5 mmol) in ethyl acetate (50 mL) was reacted with a stream of ozone during 15 min. Then the mixture was shaken for 2 h in an atmosphere of hydrogen in the presence of 10% palladium-on-carbon catalyst (20 mg). After filtration, the solvent was evaporated and the solid residue was crystallized from ether to give triketone **26** (0.72 g, 82%); mp 212–218°C (dec.); ir (CH_2Cl_2, ν cm^{-1}): 1750, 1720, 1710, 1235; ^1H nmr ($CDCl_3$, δ ppm): 4.00 (m, 4H), 3.50 (m, 1H), 3.4–1.8 (m, 11H), 2.22 (s, 3H, CH_3CO_2), 1.32 (s, 3H, CH_3-C5). *Anal.* calcd. for $C_{18}H_{22}O_7$: C 61.70, H 6.33; found C 61.42, H 6.41.

Tetracyclic aldol product **29**

Triketone **26** (0.50 g, 1.43 mmol) was refluxed in pyridine (2 mL) for 1 h. Evaporation of pyridine yielded a solid residue, which was crystallized from dichloromethane–ether mixture to give compound **29** (0.43 g, 86%); mp 240–243°C; ir (CH_2Cl_2, ν cm^{-1}): 3450, 1760, 1720; ^1H nmr ($CDCl_3$, δ ppm): 3.80 (m, 4H), 3.6–1.6 (m, 12H), 2.01 (s, 3H, CH_3CO_2), 1.18 (s, 3H, CH_3-C5). *Anal.* calcd. for $C_{18}H_{22}O_7$: C 61.70, H 6.33; found: C 61.45, H 6.26.

Diels–Alder adducts **35***a and* **35***b*

A solution of spirolactone dienone **6** (500 mg, 2.27 mmol) and ethyl vinyl ketone (267 mg, 3.18 mmol) in benzene (3 mL) was refluxed for 4 h under nitrogen. Removal of the volatile substances under vacuum and a rapid filtration on silica gel (hexane–EtOAc, 20%) furnished a 1:1 mixture (680 mg, quant.) of isomers **35***a* and **35***b*; ^1H nmr ($CDCl_3$, δ ppm): ~4.5 (two embodied AB patterns, 2H, J_{AB} = 14 Hz, -OCH_2CO_2), 3.63 (two d, 1H, J = 2 Hz, H-C11), 3.4–1.5 (m, 9H), 2.5 (q, J = 6 Hz, CH_3CH_2CO), 1.28 (s, 3H, CH_3-C5), 1.08 (t, 3H, CH_3CH_2CO). This mixture was used without any further purification for the next step.

Tetracyclic ketones **36** *and* **37**

To a solution of the Diels–Alder adducts **35***a* and *b* (652 mg, 2.14 mmol) in tetrahydrofuran (25 mL) was added aqueous sodium hydroxide (1 M, 6 mL) and the mixture was stirred at room temperature for 20 h. The main part of the tetrahydrofuran was removed under reduced pressure and the residue was extracted with ether. Chromatography of the crude extract (540 mg, silica gel, benzene–ether 10%) furnished minor isomer *exo* **37** (110 mg, 20%) and major isomer *endo* **36** (more polar, 230 mg, 45%).

Major isomer endo **36**: mp: 135–136°C; ir (CH_2Cl_2, ν cm^{-1}): 3510, 1742, 1715; ^1H nmr ($CDCl_3$, δ ppm): 3.30 (d, 1H, J = 5.0 Hz, H-C11), 3.21 (br s, 1H, -OH), 2.73 (dddd, 1H, J = 11.6, 5.0, 2.4, 1.7 Hz, H-C15), 2.53 (qd, 1H, J = 7.5, 2.4 Hz, H_{exo}-C1), 2.55 (m, 2H), and 2.42 (m, 2H) (allylic protons), 2.04 (m, 2H, H_2-C8), 1.86 (dd, 1H, J_{AB} = 14.0 Hz, J_{AX} = 11.6 Hz, H_A-C14), 1.57 (dd, 1H, J_{AB} = 14.0 Hz, J_{BX} = 1.7 Hz, H_B-C14), 1.24 (s, 3H, CH_3-C5), 1.00 (d, 3H, J = 7.5 Hz, CH_3-C1); ms *m/e*: 246 (M^+).

Minor isomer exo **37**: mp: 110–111°C; ir (CH_2Cl_2, ν cm^{-1}): 3510, 1742, 1718; ^1H nmr ($CDCl_3$, δ ppm): 3.30 (d, 1H, J = 5.0 Hz, H-C11), 2.83 (br s, 1H, OH), 2.65 (ddd, 1H, J = 11.5, 5.0, 1.7 Hz, H-C15), 2.55 (m, 2H) and 2.44 (m, 2H) (allylic protons), 2.02 (m, 2H, H_2-C8), 1.85 (dd, 1H, J_{AB} = 14 Hz, J_{AX} = 11.5, H_A-C14), 1.57 (dd, 1H, J_{AB} = 14 Hz, J_{BX} = 1.7 Hz, H_B-C14), 1.28 (s, 3H, CH_3-C5), 1.18 (d, 3H, J = 7.7 Hz, CH_3-C1); ms *m/e*: 246 (M^+).

Diketoacetate endo **38**

A solution of diketoalcohol *endo* **36** (100 mg, 0.41 mmol) and *p*-toluenesulfonic acid (7 mg) in acetic anhydride was heated at 70°C for 2 h. After evaporation of acetic anhydride, the residue was extracted with ether, washed with dilute sodium bicarbonate, and the extract was dried ($MgSO_4$) and filtered. Evaporation of ether left a solid residue, which was recrystallized from ether–hexane (112 mg, 95%); mp 102–103°C; ir (CH_2Cl_2, ν cm^{-1}): 1745, 1725, 1235; ^1H nmr ($CDCl_3$, δ ppm): 3.79 (d, 1H, J = 5.1 Hz, H-C11), 3.23 (qd, 1H, J = 7.3, 2.3 Hz, H_{exo}-C1), 2.75 (dddd, 1H, J = 11.7, 5.1, 2.3, 1.7 Hz, H-C15), 2.45 (m, 4H, allylic protons), 2.06 (s, 3H, CH_3CO_2), 1.98 (m, 2H, H_2-C8), 1.84 (dd, 1H, J_{AB} = 13.9 Hz, J_{AX} = 11.7 Hz, H_A-C14), 1.49 (dd, 1H, J_{AB} = 13.9 Hz, J_{BX} = 1.7 Hz, H_B-C14), 1.23 (s, 3H, CH_3-C5), 1.06 (d, 3H, J = 7.3 Hz, CH_3-C1); ms *m/e*: 288 (M^+). *Anal.* calcd. for $C_{17}H_{20}O_4$: C 70.81, H 6.99; found: C 70.66, H 6.94.

Diketoacetate exo **39**

Acetylation of diketoalcohol *exo* **37** (40 mg, 0.16 mmol) was done as for compound **36** (*vide supra*). Filtration on silica gel (hexane–EtOAc, 20%) gave pure acetate **39** (44 mg, 94%); ir (CH_2Cl_2, ν cm^{-1}): 1745, 1725, 1230; ^1H nmr ($CDCl_3$, δ ppm): 3.42 (d, 1H, J = 5.0 Hz, H-C11), 2.66 (ddd, 1H, J = 11.8, 5.0, 1.5 Hz, H-C11), 2.61 (q, 1H, J = 7.6 Hz, H_{endo}-C1), 2.44 (m, 4H, allylic protons), 2.04 (s, 3H, CH_3CO_2), 1.93 (m, 2H, H_2-C8), 1.84 (dd, 1H, J_{AB} = 13.8 Hz, J_{AX} = 11.8 Hz, H_A-C14), 1.46 (dd, 1H, J_{AB} = 13.8 Hz, J_{BX} = 1.5 Hz, H_B-C14), 1.28 (s, 3H, CH_3-C5), 1.25 (d, 3H, J = 7.6 Hz, CH_3-C1); ms *m/e*: 288 (M^+).

Monodeuterated diketoacetates 15-d-endo **38** *and* exo **39**

To a stirred solution of compounds **35***a* and *b* (crude Diels–Alder adducts) (860 mg, 2.98 mmol) in tetrahydrofuran (50 mL) was added a solution of sodium hydroxide (1 M in D_2O, 14 mL). After 2 h at room temperature, the organic solvent was evaporated and the mixture was extracted with ether (3 × 20 mL). The combined organic layers were washed with water (2 × 10 mL), brine, and dried over magnesium sulfate. After evaporation of ether the crude dideuterated isomers **36** and **37** (485 mg, *m/e*: 248 (M^+)) were dissolved in THF (15 mL) and stirred with a solution of potassium hydroxide (1 M in H_2O, 5 mL) for 2 h at room temperature. After the usual ether extraction, the mixture was purified by chromatography (*vide supra*) to give monodeuterated (15-*d*) *endo* **36** (242 mg, 34% from **35**) and monodeuterated (15-*d*) *exo* **37** (17 mg, 11% from **35**). These compounds were acetylated separately (*vide supra*) to produce monodeuterated acetates **38** and **39**.

Monodeuterated diketoacetate 15-d endo **38**: ^1H nmr: identical with the unlabelled **38** (*vide supra*) except for the following: 3.79 (s, 1H, H-C11), 3.23 (q, 1H, J = 7.2 Hz, H-C1); ms *m/e*: 289 (M^+).

Monodeuterated diketoacetate 15-d exo **39**: ^1H nmr: identical with the unlabelled **39** (*vide supra*) except for the following: 3.42 (s, 1H, H-C11); ms *m/e*: 289 (M^+).

*Ethyl 3,3-ethylenedioxy-butanoate (***40***)*

A mixture of ethyl acetoacetate (200 g, 1.54 mol), ethylene glycol (150 mL, 2.68 mol), and *p*-toluenesulfonic acid (250 mg) in benzene (2.5 L) was refluxed for 24 h (Dean–Stark water separator), then cooled and washed with aqueous sodium bicarbonate (5%) and water. The organic layer was dried ($MgSO_4$), filtered, and solvent removed under reduced pressure. The crude product (255 g, 93%) did not need purification; ir ($CHCl_3$, ν cm^{-1}): 1724, 1180, 1042; ^1H nmr ($CDCl_3$, δ ppm): 4.10 (q, 2H, J = 7.2 Hz, -OCH_2CH_3), 3.89 (s, 4H, 2 × -OCH_2-), 2.50 (s, 2H, -CH_2CO_2-), 1.40 (s, 3H, CH_3-), 1.23 (t, 3H, J = 7.2 Hz, -OCH_2CH_3); ms *m/e*: 159 ($M^+ - CH_3$).

*3,3-Ethylenedioxy-1-butanol (***41***)*

A solution of ethyl acetoacetate ketal (**40**) (50.0 g, 0.287 mol) in dry ether (200 mL) was slowly added to a suspension of lithium aluminum hydride (12 g, 0.31 mol) in ether (1 L) (smooth reflux). The mixture was refluxed for 1 h, then cooled (0°C) and reacted with a slow addition of moist ether (350 mL), then water, (350 mL) until the formation of a white precipitate. The organic layer was decanted, dried ($MgSO_4$), filtered, and the solvent evaporated. The oily residue was distilled under reduced pressure (28 g, 75%); ir ($CHCl_3$, ν cm^{-1}): 3420, 1380, 1050; ^1H nmr ($CDCl_3$, δ ppm): 3.96 (s, 4H, OCH_2CH_2O), 3.72 (t, 2H, J = 6.0 Hz, CH_2OH), 3.35 (s, 1H, -OH), 1.92 (t, 2H, J = 6.0 Hz, -CH_2CH_2OH), 1.32 (s, 3H, CH_3-); ms *m/e*: 117 ($M^+ - 15$).

*3,3-Ethylenedioxy-butanal (***42***)*

A solution of 3,3-(ethylenedioxy)butanol (**41**) (13.2 g, 0.10 mol) in dimethyl sulfoxide (60 mL) was reacted with *N,N'*-dicyclohexylcarbodiimide (41.2 g, 0.20 mol) in the presence of pyridinium trifluoroacetate (10.0 g, 0.05 mol). After a few minutes of efficient mechanical stirring, an exothermic reaction took place together with orange coloration. After 1 h, benzene was added to precipitate di-

For personal use only.

cyclohexyl urea, which was separated by filtration. The solvents were evaporated under reduced pressure and the liquid residue was distilled under vacuum to give 3,3-ethylenedioxy-butanal (**42**), (10.3 g, 78%), bp 42°C/0.5 Torr; 1 Torr = 133.3 Pa); ir ($CHCl_3$, ν cm^{-1}): 2720, 1720, 1055; ^1H nmr ($CDCl_3$, δ ppm): 9.73 (t, 1H, J = 3 Hz, CHO), 4.01 (s, 4H, OCH_2CH_2O), 2.70 (d, 2H, J = 3 Hz, CH_2CHO), 1.42 (s, 3H, CH_3-); ms *m/e*: 115 ($M^+ - 15$).

*5,5-Ethylenedioxy-1-hexen-3-ol (**43**)*

Magnesium turnings (8.0 g, 0.32 mol) and one crystal of iodine were covered with dry tetrahydrofuran (40 mL). Vinyl bromide (50.0 g, 0.46 mol) was then added dropwise until an exothermic reaction took place (~3 mL). The addition was continued in order to maintain a good reflux. After the addition was completed, the mixture was refluxed for 45 min. A solution of ketal aldehyde **42** (37.2 g, 0.28 mol) in THF (70 mL) was then added dropwise to the mixture and the reflux was continued for 45 min. The reaction mixture was poured onto ice and brine (1.5 L), neutralized to pH 7 (2 M HCl), and extracted with dichloromethane (4 × 200 mL). Evaporation of the solvents yielded pure alcohol **43** (42 g, 92%) as an oil; ir ($CHCl_3$, ν cm^{-1}): 3500, 1650, 1380, 1060; ^1H nmr ($CDCl_3$, δ ppm): 6.2–4.9 (m, 3H, olefinic), 4.42 (m, 1H, *H*-C-OH), 4.00 (s, 4H, OCH_2CH_2O), 3.50 (br s, -OH), 2.00 (br s, 1H) and 1.80 (br s, 1H) (CH_2CHOH), 1.39 (s, 3H, CH_3-); ms *m/e*: 143 ($M^+ - 15$).

*5,5-Ethylenedioxy-1-hexen-3-one (**44**)*

A solution of allylic alcohol **43** (10.0 g, 63.4 mmol) in acetone (150 mL) was reacted at −30°C under good stirring with Jones reagent (dropwise, 23.7 mL, 63.5 mmol). After the addition, the mixture was warmed to room temperature and decanted. After evaporation of the acetone, the residue was dissolved in ether (300 mL), then washed with aqueous sodium bicarbonate solution and brine. The organic layer was dried ($MgSO_4$), filtered, and the ether evaporated. The oily residue was chromatographed on silica gel (benzene–ether, 98:2) to give vinyl ketone **44** (4.4 g, 44%) as an oil; ir ($CHCl_3$, ν cm^{-1}): 1680, 1610, 1050; ^1H nmr ($CDCl_3$, δ ppm): 6.52–5.70 (m, 3H, olefinic), 3.98 (s, 4H, $-OCH_2CH_2O-$), 2.95 (s, 2H, CH_2-CO), 1.44 (s, 3H, CH_3-); ms *m/e*: 141 ($M^+ - 15$).

*Isomers **45**a and **45**b*

Spirolactone dienone **6** (2.59 g, 11.8 mmol) was dissolved in benzene (4 mL) and reacted with ketal vinyl ketone **44** (2.20 g, 14.1 mmol) at reflux temperature for 45 min. Evaporation of benzene and removal of the excess of dienophile **44** under vacuum left an oily residue (4.4 g, ~quant.) containing two products (~1:1), isomers **45***a* and *b*, which were not separated; ir ($CHCl_3$, ν cm^{-1}): 1820, 1740, 1715; ^1H nmr ($CDCl_3$, δ ppm): 4.70 (d, 0.5H) and 4.35 (d, 0.5H), 4.65 (d, 0.5H) and 4.34 (d, 0.5H) (two embodied AB patterns), (J_{AB} = 14.5 Hz) (spirolactonic methylene), 3.94 (s, 4H, OCH_2CH_2O), 3.5–1.6 (m, 10H), 2.82 (s, 2H, CH_2-CO-), 1.38 (s, 3H, CH_3-COO-), 1.26 (s, 3H, CH_3-C5); ms *m/e*: 376 (M^+).

*Tetracyclic triketone **46***

A crude mixture of isomers **45***a* and *b* (4.44 g, 11.8 mmol) in tetrahydrofuran (16 mL) was stirred at 25°C with aqueous sodium hydroxide (1 M, 240 mL) for 24 h. The basic aqueous mixture was successively extracted with ether (2 × 75 mL), acidified with aqueous hydrochloric acid (2 M, 130 mL), then extracted with ether (4 × 100 mL). This acidic extract was dried ($MgSO_4$) and filtered, and solvents were evaporated under reduced pressure to give pure tetracyclic hydroxytriketone **46** (3.147 g, 97%); ir ($CHCl_3$, ν cm^{-1}): 3520, 1710, 1655, 1610; ^1H nmr ($CDCl_3$, δ ppm): 3.93 (br s, 1H, OH), 3.32 (d, 1H, J = 4 Hz, H-C11), 2.9–1.6 (m, 10H), 2.15 (s, 3H, CH_3-CO), 1.26 (s, 3H, CH_3-C5); ms *m/e*: 246 ($M^+ - CO$). *Exact Mass* (hrms) calcd. for $C_{16}H_{18}O_4 - CO$: 246.121; found: 246.125.

*Monoacetate derivative **47***

A solution of tetracyclic ketone **46** (3.25 g, 11.8 mmol) in pyridine (40 mL) and acetic anhydride (45 mL) was stirred in the absence of light for 24 h. The volatile substances were then evaporated under vacuum and the solid residue purified by crystallization and chromatography (3.1 g, 73%); mp 185–189°C (chloroform–hexane); ir ($CHCl_3$, ν cm^{-1}): 1760, 1725, 1645; ^1H nmr ($CDCl_3$, δ ppm): 3.93 (d, 1H, J = 5 Hz, H-C11), 2.9–1.7 (m, 10H), 2.41 (s, 3H, CH_3CO_2), 2.22 (s, 3H, CH_3CO), 2.10 (s, 3H, CH_3—C=), 1.27 (s, 3H, CH_3-C5).

A solution of that crystalline diacetate (0.619 g, 1.72 mmol) in tetrahydrofuran (13 mL) was reacted with aqueous sodium carbonate (5%, 30 mL) at room temperature for 6 h. The aqueous mixture was first washed with ether (3 × 15 mL), acidified with hydrochloric acid (2 M, 18 mL), and extracted again with ether to give monoacetate **47** (0.491 g, 90%) as a mixture of epimers in position 1; ir ($CHCl_3$, ν cm^{-1}): 1760, 1730, 1660, 1615; ^1H nmr ($CDCl_3$, δ ppm): 3.79 (d, 1H, H-C11), 2.9–1.6 (m, 10H), 2.12 (s, 3H, CH_3CO-), 2.08 (s, 3H, CH_3CO_2), 1.26 (s, 3H, CH_3-C5); ms *m/e*: 288 ($M^+ - 28$). *Exact Mass* (hrms) calcd. for $C_{18}H_{20}O_5 - CO$: 288.136; found: 288.131.

cis- *and* trans-*Enedione methyl esters **49** and **50***

A solution of crude monoacetate **47** (0.258 g, 0.817 mmol) and *p*-toluenesulfonic acid (5 mg) in dry methanol (6 mL) was stirred at 55–60°C for 6 h. The mixture was then poured into aqueous sodium bicarbonate (5%, 25 mL) and extracted with ether. The organic layer was dried and evaporated. By nmr, the crude residue (181 mg) showed a proportion of 86:14 for the *cis*/*trans* isomers **49** and **50**. Chromatography (benzene–ether 2:1) of this mixture on silica gave pure isomers **49** (more polar) and **50** (less polar).

*cis Enedione **49*** (102 mg, 43%); ir ($CHCl_3$, ν cm^{-1}): 1730, 1700, 1635; ^1H nmr ($CDCl_3$, δ ppm): 5.72 (s, 1H, olefinic), 3.67 (s, 3H, CO_2CH_3), 3.55 (d, 1H, J = 3 Hz, H-C11), 2.9–1.5 (m, 9H), 2.18 (s, 3H, CH_3CO), 1.24 (s, 3H, CH_3-C5); ms *m/e*: 288 (M^+).

*trans Enedione **50*** (43 mg, 20%); uv (λ max, ethanol): 251 nm (ε 8200); ir ($CHCl_3$, ν cm^{-1}): 1730, 1680, 1620; ^1H nmr ($CDCl_3$, δ ppm): 6.80 (s, 1H, olefinic), 4.91 (d, 1H, J = 3 Hz, H-C11), 3.67 (s, 3H, CO_2CH_3), 3.0–1.6 (m, 9H), 2.28 (s, 3H, CH_3CO), 1.32 (s, 3H, CH_3-C5); ms *m/e*: 288 (M^+). *Anal.* calcd. for $C_{17}H_{20}O_4$: C 70.80, H 6.99; found: C 70.65, H 7.05.

trans *Enedione methyl ester **50** by isomerization of* cis *isomer **49***

Pure *cis*-enedione methyl ester **49** (150 mg, 0.52 mmol, neat) was heated at 150°C in a sealed tube for 1.5 h. Chromatography (benzene–ether 2:1) of the crude product on silica gel furnished *trans* enedione methyl ester **50** (105 mg, 70%) and unreacted starting material (30 mg, 20%).

*Tetracyclic lactone **51***

A solution of tetracyclic triketone **46** (196 mg, 0.72 mmol) in methanol (5 mL) was poured into an aqueous solution of sulfuric acid (8 M, 40 mL) in a separatory funnel. The mixture was shaken for 2 min, then rapidly extracted with ether (4 × 50 mL). The combined organic layers were dried ($MgSO_4$), filtered, and the solvent evaporated. The solid residue was crystallized (ether–hexane) to give tetracyclic lactone **51** (100 mg, 49%); mp 95–96°C; ir ($CHCl_3$, ν cm^{-1}): 1785, 1730, 1710 (sh); ^1H nmr ($CDCl_3$, δ ppm): 3.95 (d, 1H, J = 4 Hz, H-C11), 3.25 (d, 1H, J_{AB} = 15 Hz) and 2.38 (d, 1H, J_{AB} = 15 Hz), 2.9–1.6 (m, 9H), 2.19 (s, 3H, CH_3CO), 1.29 (s, 3H, CH_3-C5); ms *m/e*: 274 (M^+). *Anal.* calcd. for $C_{16}H_{18}O_4$: C 70.05, H 6.62; found: C 69.74, H 6.49.

trans *Enedione carboxylic acid **52***

Lactone **51** (51 mg, 0.186 mmol) was dissolved in a solution of potassium (16 mg) in *tert*-butanol (10 mL) and stirred under nitrogen for 23 h at room temperature. The mixture was then poured onto water (20 mL) and extracted with ether (2 × 10 mL) to remove a neutral fraction (16 mg). The aqueous basic layer was acidified (HCl, 1 M, pH 4) and extracted with ether (3 × 25 mL). Evaporation of the solvent furnished crude acid **52** (36 mg, 70%); ir ($CHCl_3$, ν cm^{-1}): 3500–2500 (br), 1710, 1680, 1620; ^1H nmr ($CDCl_3$, δ ppm): 11.6 (br s, $-CO_2H$), 6.82 (s, 1H, olefinic), 5.00 (d, 1H, J = 3 Hz, H-C11), 2.9–1.5 (m, 9H), 2.28 (s, 3H, CH_3CO), 1.31 (s, 3H, CH_3-C5).

trans *Enedione methyl ester **50** by esterification of acid **52***

A solution of acid **52** (60 mg, 0.22 mmol) in ether at 0°C was reacted with a slight excess of diazomethane in ether (~2 mL). After 2 min of stirring, the volatile substances were evaporated and the crude product

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

was purified by thin-layer chromatography on silica gel (benzene–ether 2:1) to yield the known *trans* methyl ester **50** (30 mg, 48%) (*vide supra*).

*Alcohol **54** and acid **55***

Dihydropyran (88 g, 1.0 mol) and 2,2-dimethylpropanediol (125 g, 1.20 mol) were refluxed in toluene (500 mL) in the presence of *p*-toluenesulfonic acid (20 mg). After 24 h, the mixture was cooled and washed with water (3 × 50 mL). Evaporation of toluene left an oil (188 g) containing acetal alcohol **54** and the mono THP derivative of 2,2-dimethylpropanediol in a proportion of 4:1. Separation of these isomers is delicate and was performed at a later stage (*vide infra*). The analytical data for the major desired alcohol **54** come from reduction of acid **55** (*vide infra*). The crude product (1.88 g, 10.0 mmol) in dry acetone (60 mL) was cooled at −20°C and reacted with Jones reagent (3.75 mL, 10.0 mmol) over a period of 30–40 min. Isopropanol (1 mL) was added to the mixture and the organic layer was decanted, diluted with water (20 mL), and extracted with ether. The combined organic layers were washed with water, dried ($MgSO_4$), and solvents evaporated to leave an oil that was crystallized to give ketal acid **55** (1.60 g, 80%); mp 92–93°C; ir ($CHCl_3$, ν cm^{-1}): 3500–2500 (br), 1720; ^1H nmr ($CDCl_3$, δ ppm): 11.2 (s, 1H, CO_2H), 4.45 (br t, 1H, J = 5 Hz, HCO_2-), 3.5 (m, 4H, $(CH_2O)_2$), 2.42 (m, 2H, CH_2CO_2H), 1.7 (m, 4H), 1.16 (s, 3H, -CH_3), 0.70 (s, 3H, -CH_3). *Anal.* calcd. for $C_{10}H_{18}O_4$: C 59.39, H 8.97; found: C 59.35, H 9.16.

*Alcohol **54** from acid **55***

A solution of ketal acid **55** (2.02 g, 10.0 mmol) in dry ether (50 mL) was added to a mixture of lithium aluminum hydride (700 mg) in ether (25 mL) and refluxed for 12 h. The excess hydride was destroyed by slow addition, at 0°C, of moist ether and water and the mixture was extracted with ether to give pure alcohol **54** as an oil (1.69 g, 90%); ir ($CHCl_3$, ν cm^{-1}): 3590, 3450, 1140, 1030; ^1H nmr ($CDCl_3$, δ ppm): 4.45 (br t, 1H, J = 5 Hz, H-CO_2), 3.5 (m, 6H, 3 × CH_2O-), 1.6 (m, 6H), 1.18 (s, 3H, CH_3), 0.73 (s, 3H, CH_3). *Anal.* calcd. for $C_{10}H_{20}O_3$: C 63.79, H 10.71; found: C 63.70, H 10.69.

*Vinylketone **58** (via acid **55**)*

To a solution of acid **55** (2.02 g, 10.0 mmol) in dry ether (150 mL) was added, under nitrogen, a solution of vinyllithium (~2 M in THF, 10 mL, 20 mmol). After 40 min at 25°C, the mixture was hydrolyzed (pH ≃ 6, 2 M H_2SO_4) and extracted with ether. The purity of the crude oily product was largely related to the quality of the lithium reagent. Flash chromatography of the crude product (silica gel, benzene) furnished fragile enone **58** (1.1 g, 52%); ir ($CHCl_3$, ν cm^{-1}): 1700, 1620; ^1H nmr ($CDCl_3$, δ ppm): 6.5–5.7 (m, 3H, olefinic), 4.45 (br t, 1H, J = 5 Hz, HCO_2), 3.50 (m, 4H, $(CH_2O)_2$), 2.65 (m, 2H, CH_2CO), 1.75 (m, 4H), 1.20 (s, 3H, CH_3), 0.70 (s, 3H, CH_3).

*Aldehyde **56***

A solution of acetal alcohol **54** (1.88 g, 10.0 mmol) in dichloromethane (4 mL) was added at 15°C to a mixture of Collins reagent prepared from chromic oxide (8 g, 80 mmol) and pyridine (13 mL) in dichloromethane (350 mL). After 20 min, the mixture was poured onto ice-water and extracted with dichloromethane. The organic layer was washed several times with water, dried, and the solvents were evaporated. The residual colored oil was purified by chromatography on Florisil (benzene) to give pure aldehyde **56** (1.1 g, 60%); ir ($CHCl_3$, ν cm^{-1}): 2820, 2720, 1730; ^1H nmr ($CDCl_3$, δ ppm): 9.84 (t, 1H, J = 2 Hz, -CHO), 4.48 (br t, 1H, J = 5 Hz, HCO_2), 3.52 (m, 4H, $(CH_2O)_2$), 2.50 (m, 2H, CH_2CHO), 1.70 (m, 4H), 1.18 (s, 3H, CH_3), 0.71 (s, 3H, CH_3).

*Allylic alcohol **57***

To magnesium turnings (2.45 g, 0.10 mol) in dry tetrahydrofuran (30 mL) were added successively a crystal of iodine and a solution of vinyl bromide (10.5 g, 0.10 mol) in tetrahydrofuran. When the magnesium had almost disappeared, ketal aldehyde **56** (14.9 g, 80.0 mmol) in tetrahydrofuran (20 mL) was added dropwise. After 12 h at room temperature the mixture was poured onto ice-water, neutralized (pH 7) with hydrochloric acid (1 M), and extracted with dichloromethane. Chromatography of the crude extract (Florisil, benzene) furnished allylic alcohol **57** (15.9 g, 93%) as a colorless oil; ir ($CHCl_3$, ν cm^{-1}): 3600, 3450, 1650; ^1H nmr ($CDCl_3$, δ ppm): 6.1–4.9 (m, 3H, olefinic), 4.45 (br t, 1H, HCO_2), 4.1 (br m, 1H, OH), 3.80 (m, *H*-COH), 3.50 (m, 4H, $(CH_2O)_2$), 2.0–1.3 (m, 6H), 1.18 (s, 3H, CH_3), 0.70 (s, 3H, CH_3).

*Enone **58***

To a cooled (−20°C) and well-stirred solution of allylic alcohol **57** (2.14 g, 10.0 mmol) in dry acetone (60 mL) was added, dropwise, Jones reagent (3.75 mL, 10 mmol). After 2 h and addition of isopropanol (1 mL) the mixture was warmed to room temperature, diluted with water, and extracted with ether. The combined organic layers were washed with aqueous sodium bicarbonate, dried ($MgSO_4$), and evaporated under reduced pressure. The colorless oily residue (1.95 g, 91%) was stored in the cold. The ir and nmr data have been given (*vide supra*).

*Diels–Alder adducts **59a** and **59b***

Spirolactone dienone **6** (1.00 g, 4.54 mmol) was dissolved in benzene (5 mL) and reacted with vinyl ketone acetal **58** (975 mg, 4.60 mmol) at reflux temperature for 15 h. Evaporation of benzene left an oily residue (1.9 g, ~98%) containing two products (~1:1), isomers **59***a* and *b*, which were not separated ir (CH_2Cl_2, ν cm^{-1}): 1820, 1740, 1710; ^1H nmr ($CDCl_3$, δ ppm): 4.70 (d, 0.5H) and 4.32 (d, 0.5H), 4.65 (d, 0.5H) and 4.30 (d, 0.5H) (two embodied AB patterns, J_{AB} = 14.5 Hz) (spirolactonic methylene), 4.45 (br t, 1H, J = 5 Hz, HCO_2), 3.7–3.2 (m, 5H, $(CH_2O)_2$ and H-C11), 3.2–1.4 (m, 15H), 1.23 (s, 3H, CH_3-C5), 1.18 (s, 3H), and 0.70 (s, 3H) (two methyl groups of acetal moiety).

Tetracyclic endo *epimer **60***

To a crude mixture of Diels–Alder adducts **59***a* and *b* (982 mg, 2.27 mmol) in tetrahydrofuran (150 mL) was added aqueous sodium hydroxide (1 M, 9.1 mL). After 4 h of vigorous stirring at room temperature, the solvent was evaporated and the aqueous residue was extracted with ether. Evaporation of the ether furnished a solid residue, which was recrystallized from ether–hexane to give pure *endo* isomer **60** (606 mg, 71%); mp 142–143°C; ir (CH_2Cl_2, ν cm^{-1}): 3500, 1745, 1720; ^1H nmr ($CDCl_3$, δ ppm): 4.50 (br t, 1H, J = 5 Hz, HCO_2), 3.55 (m, 4H, $(CH_2O)_2$), 3.26 (d, 1H, J = 5 Hz, H-C11), 3.0–1.4 (m, 14H), 1.26 (s, 3H, CH_3-C5), 1.20 (s, 3H) and 0.70 (s, 3H) (two methyl groups of acetal moiety); ms *m/e*: 374 (M^+). *Anal.* calcd. for $C_{22}H_{30}O_5$: C 70.52, H 8.07; found: C 70.19, H 8.22.

*Pentacyclic aldehyde **61***

To a solution of tetracyclic diketoacetal **60** (174 mg, 0.46 mmol) in acetone (25 mL) was added hydrochloric acid (3 M, 12 mL) and the mixture was refluxed for 3 h. Acetone was then partly evaporated and the residue was extracted with ether. Chromatography (benzene–ether 1:1) of the crude product on silica gel furnished crystalline pentacyclic aldehyde **61** (33 mg, 25%); mp 147–149°C; ir (CH_2Cl_2, ν cm^{-1}): 3500, 2720, 1740, 1720; ^1H nmr ($CDCl_3$, δ ppm): 9.64 (d, 1H J = 1 Hz, CHO), 3.22 (d, 1H, J = 5 Hz, H-C11), 3.0–1.4 (m, 15H), 1.29 (s, 3H, CH_3); ms *m/e*: 288 (M^+). *Anal.* calcd. for $C_{17}H_{20}O_4$: C 70.81, H 6.99; found: C 70.96, H 6.91.

*Ethyl 3-formyl-4-methylpentanoate (**62**, R = C_2H_5)*

A mixture of diisobutylamine (103 g, 0.79 mol) and isovaleraldehyde (43 g, 0.5 mol) in benzene (250 mL) was refluxed for 12 h (Dean–Stark water separator). Benzene was evaporated and the residue distilled under reduced pressure to give the corresponding enamine (91.6 g, 93%); bp 82°C/1 Torr; ir ($CHCl_3$, ν cm^{-1}): 1650, 1465, 1120, 945; ^1H nmr ($CDCl_3$, δ ppm): 5.80 (br d, 1H, J = 15 Hz, N—C*H*=), 3.95 (dd, 1H, J = 15 and 8 Hz, N—CH=C*H*—), 2.70 (br s, 2H, CH_2), 2.58 (br s, 2H, CH_2), 2.40–1.40 (m, 3H, 3 × -CH-), 0.82 (apparent t, 18H, J = 7.5 Hz, 6 × CH_3-CH). The purified enamine (91.6 g) in acetonitrile (300 mL) was refluxed with ethyl bromoacetate (98 g, 0.55 mol) for 15 h. Water (50 mL) was then added to the mixture and the reflux was continued for 5 h. The cooled reaction mixture was then poured onto cold brine (800 mL) and extracted with ether.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

Evaporation of the dried extract left an oil that was distilled under reduced pressure to give ethyl 3-formyl-4-methylpentanoate (**62**, R = C_2H_5) (68 g, 79%); bp 92°C/3 Torr; ir (CH_2Cl_2, ν cm^{-1}): 2720, 1730, 1200; ^1H nmr ($CDCl_3$, δ ppm): 9.96 (br s, 1H, CHO), 4.15 (q, 2H, J = 7 Hz, OCH_2CH_3), 3.0–2.0 (m, 4H), 1.22 (t, 3H, J = 7 Hz, OCH_2CH_3), 1.05 (d, 3H, J = 6 Hz, CH_3CH), 0.95 (d, 3H, J = 6 Hz, CH_3CH); derivative: 2,4-dinitrophenylhydrazone: mp 96.5°C. *Anal.* calcd. for $C_{15}H_{20}O_6N_4$: C 51.13, H 5.59, N 15.90; found: C 51.39, H 5.47, N 15.70.

*Ethyl 3-(1,3-dioxolan-2-yl)-4-methylpentanoate (**63**)*

A mixture of aldehyde ester **62** (R = C_2H_5) (51.5 g, 0.33 mol), ethylene glycol (74 g, 1.2 mol), and *p*-toluenesulfonic acid (20 mg) was refluxed (Dean–Stark water separator) for 24 h. The cooled mixture was then washed with sodium bicarbonate and water and the solvent was evaporated. Distillation of the residue furnished pure acetal **63** (56 g, 91%); bp 96°C/1.5 Torr; ir (CH_2Cl_2, ν cm^{-1}): 1730, 1180, 1170; ^1H nmr ($CDCl_3$, δ ppm): 4.85 (br d, 1H, J = 3 Hz, H-CO_2), 4.09 (q, 2H, J = 7 Hz, -OCH_2CH_3), 3.83 (m, $(CH_2O)_2$), 2.25 (br s, 2H, CH_2CO_2), 2.5–1.6 (m, 2H), 1.21 (t, 3H, J = 7 Hz, OCH_2CH_3), 0.90 (br d, 6H, J = 6 Hz, 2 × CH_3CH). *Anal.* calcd. for $C_{11}H_{20}O_4$: C 61.08, H 9.32; found: C 60.99, H 9.39.

*3-(1,3-Dioxolan-2-yl)-4-methylpentanol (**64**)*

To a mixture of lithium aluminum hydride (9.5 g, 0.25 mol) in dry ether (600 mL) was added dropwise a solution of acetal ester **63** (54 g, 0.25 mol) in dry ether (500 mL). After a stirring period of 14 h at 25°C, the mixture was refluxed for 1 h, then cooled (0°C), and moist ether was added slowly to the mixture. After addition of water, the mixture was extracted with ether. Evaporation of the solvent left pure alcohol **64** (38.2 g, 88%); ir (CH_2Cl_2, ν cm^{-1}): 3600, 3450, 1050; ^1H nmr ($CDCl_3$, δ ppm): 4.82 (br d, 1H, J = 4 Hz, H-CO_2), 3.92 (m, 4H, $(CH_2O)_2$), 3.68 (br t, 2H, J = 7 Hz, CH_2OH), 2.98 (s, 1H, OH), 2.2–1.5 (m, 2H), 1.63 (t, 2H, J = 7 Hz, CH_2CH_2OH), 0.92 and 0.86 (two d, J = 6.5 Hz, $(CH_3)_2CH$). *Anal.* calcd. for $C_9H_{18}O_3$: C 62.04, H 10.41; found: C 61.75, H 10.48.

*3-(1,3-Dioxolan-2-yl)-4-methyl pentanal (**65**)*

Following exactly the same procedure as previously described for oxidation of alcohol **54** (*vide supra*, aldehyde **56**), alcohol **64** (1.74 g, 10.0 mmol) was oxidized to aldehyde **65**. The crude product was chromatographed (silica gel, benzene) to give pure aldehyde **65** (1.07 g, 62%) together with starting material (3.40 mg, 19%) (eluted with benzene–ether 2:1); ir (CH_2Cl_2, ν cm^{-1}): 2720, 1720, 1120, 1050; ^1H nmr ($CDCl_3$, δ ppm): 9.65 (t, 1H, J = 2.5 Hz, CHO), 4.96 (d, 1H, J = 4 Hz, H-CO_2), 3.86 (m, 4H, $(CH_2O)_2$), 2.33 (br s, CH_2CHO), 2.5–1.5 (m, 2H), 1.02 and 0.95 (two d, J = 6.5 Hz, $(CH_3)_2CH$).

*Allylic alcohol **66***

Following exactly the same procedure previously described for allylic alcohol **57** (*vide supra*), allylic alcohol **66** was obtained from aldehyde **65** (13.6 g, 80.0 mmol) in a pure form after chromatography on Florisil (hexane–ether 9:1) (14.9 g, 94%); ir (CH_2Cl_2, ν cm^{-1}): 3600, 3450, 1125; ^1H nmr ($CDCl_3$, δ ppm): 6.1–5.5 (m, 1H) and 5.4–4.8 (m, 2H) (olefinic), 4.78 (d, 1H, J = 4 Hz, HCO_2), 4.3–3.5 (m, 2H, CH-OH), 3.80 (m, 4H, $(CH_2O)_2$), 2.1–1.3 (m, 4H), 0.88 (d, 6H, J = 6.5 Hz, $(CH_3)_2CH$). *Anal.* calcd. for $C_{11}H_{20}O_3$: C 65.97, H 10.07; found: C 65.70, H 10.28.

*Enone **67***

Following exactly the same procedure previously described for enone **58** (*vide supra*), enone **67** was obtained from allylic alcohol **66** (2.0 g, 10 mmol) as a sensitive colorless oil. An analytical sample was prepared by thin-layer chromatography (benzene) (1.81 g, 90%); ir (CH_2Cl_2, ν cm^{-1}): 1720, 1620; ^1H nmr ($CDCl_3$, δ ppm): 6.4–5.5 (m, 3H, olefinic), 4.82 (d, 1H, J = 3 Hz, HCO_2), 3.80 (m, 4H, $(CH_2O)_2$), 2.8–2.1 (m, 2H, (CH_2CO), 2.0–1.4 (m, 2H), 0.88 (d, 3H, J = 6 Hz) and 0.82 (d, 3H, J = 6 Hz) ($(CH_3)_2CH$). *Anal.* calcd. for $C_{11}H_{20}O_3$: C 66.70, H 9.15; found: C 66.70, H 9.08.

*Ethyl 3-isopropyl-5-methoxy-4-pentenoate (**68**, R = C_2H_5)*

Sodium hydride (~50% oil, 3.12 g, 65 mmol) was washed with dry hexane (3 × 50 mL), then dissolved in dry dimethyl sulfoxide (33 mL). After stirring for 45 min at 60°C the mixture was cooled at ~15°C and reacted with a solution of (methoxymethyl)triphenylphosphonium chloride (22.3 g, 65 mmol) in dry dimethyl sulfoxide (70 mL). After 15 min at 25°C, the deep red mixture was treated with a solution of ester aldehyde **62** (R = C_2H_5) (8.6 g, 50 mmol) in dimethyl sulfoxide (25 mL), and stirring was continued for 17 h. The mixture was then poured onto ice-water (200 mL) and extracted several times with pentane. Solvent was evaporated from the dried extract and a rapid filtration (silica gel, hexane) of the crude product removed the residual triphenylphosphine oxide. A mixture of isomers, *cis* and *trans* (*30:70*) enol ethers **68** (R = C_2H_5), (6.79 g, 68%) was obtained pure after distillation under reduced pressure; bp 85°C/2 Torr; ir (CH_2Cl_2, ν cm^{-1}): 1730, 1675, 1660, 950; ^1H nmr ($CDCl_3$, δ ppm): 6.25 (d, 0.7H, J = 12 Hz, *trans*-CH_3O-CH=CH), 5.92 (d, 0.3H, J = 6 Hz, *cis*-CH_3OCH=CH), 4.7–4.2 (m, 1H, CH_3OCH=CH-), 4.10 (q, 2H, J = 7 Hz, OCH_2CH_3), 3.53 (s, 0.9H, *cis*-OCH_3), 3.48 (s, 2.1H, *trans*-OCH_3), 2.30 (m, 3H, -CH_2CO_2- and -$CHCH_2CO_2$), 1.66 (m, 1H, $CH(CH_3)_2$), 1.20 (t, 3H, J = 7.5 Hz, OCH_2CH_3, 0.85 (d, 3H, J = 6 Hz) and 0.81 (d, 3H, J = 6 Hz) ($(CH_3)_2CH$). *Anal.* calcd. for $C_{11}H_{20}O_3$: C 65.97, H 10.07; found: C 65.75, H 10.07.

*Ketal ester **69** (R = CH_2CH_3)*

A mixture of isomers **68** (R = CH_2CH_3) (10.0 g, 50 mmol), ethylene glycol (6.2 g, 100 mmol), and *p*-toluenesulfonic acid (10 mg) was refluxed in benzene (100 mL) for 24 h (Dean–Stark). The cooled mixture was then washed with aqueous sodium bicarbonate and water. Evaporation of the solvent from the dried extract furnished crude ketal ester **69** (R = CH_2CH_3), which was purified by distillation under reduced pressure (10.8 g, 94%); bp 96°C/1.5 Torr; ir (CH_2Cl_2, ν cm^{-1}): 1730, 1180, 1040; ^1H nmr ($CDCl_3$, δ ppm): 4.88 (t, 1H, J = 5 Hz, HCO_2), 4.10 (q, 2H, J = 7 Hz, -OCH_2CH_3), 3.85 (m, 4H, $(CH_2O)_2$), 2.4–1.5 (m, 6H), 1.25 (t, 3H, -OCH_2CH_3), 0.85 (d, 6H, J = 6 Hz, $(CH_3)_2CH$). *Anal.* calcd. for $C_{12}H_{22}O_4$: C 62.24, H 9.56; found: C 62.83, H 9.34.

*Ketal acid **70***

To a solution of acetal ester **69** (4.6 g, 20 mmol) in ethanol (100 mL) was added, at 25°C, aqueous sodium hydroxide (50 mL, 1 M). After 2 h of stirring, the main part of the ethanol was evaporated and the aqueous basic layer was first washed with ether (2 × 50 mL), then acidified (pH ~5) with hydrochloric acid (55 mL, 1 M) and extracted with ether (4 × 50 mL). Evaporation of the solvent furnished pure acid **70** (3.98 g, 98%); ir (CH_2Cl_2, ν cm^{-1}): 3500–2400 (br), 1710, 1150; ^1H nmr ($CDCl_3$, δ ppm): 11.18 (s, 1H, CO_2H), 4.90 (t, 1H, H-CO_2), 3.90 (m, 4H, $(CH_2O)_2$), 2.5–1.5 (m, 6H), 0.88 (d, 6H, J = 6 Hz, $(CH_3)_2CH$). *Anal.* calcd. for $C_{10}H_{18}O_4$: C 59.42, H 8.95; found: C 59.55, H 9.13.

*Alcohol **71***

This reduction was done as for ester **63** (*vide supra*, compound **64**). Thus, ester **69** (7.45 g, 32.4 mmol) furnished ketal alcohol **71** (6.0 g, 98%); ir ($CHCl_3$, ν cm^{-1}): 3600, 3450, 1050; ^1H nmr ($CDCl_3$, δ ppm): 4.91 (br t, 1H, J = 5 Hz, HCO_2), 4.05–3.5 (m, 6H, $(CH_2O)_2$ and CH_2OH), 2.77 (br s, 1H, OH), 1.8–1.3 (m, 6H), 0.80 (d, 6H, J = 6 Hz, $(CH_3)_2CH$).

*Aldehyde **72***

To a solution of chromic oxide – pyridine complex (25.0 g, 95 mmol) in dry dichloromethane (250 mL) was added rapidly a solution of alcohol **71** (3.05 g, 16 mmol) in dichloromethane (50 mL). After 30 min of vigorous stirring at 25°C, the mixture was poured onto ice-water and extracted with dichloromethane. The organic layer was dried over magnesium sulfate and the solvent was evaporated. The crude colored residue was filtered through a short pad of silica gel to give pure aldehyde **72** as a colorless oil (2.77 g, 95%); ir (CH_2Cl_2, ν cm^{-1}): 2720, 1720, 1122; ^1H nmr ($CDCl_3$, δ ppm): 9.79 (t, 1H, J = 3 Hz, CHO), 4.90 (t, 1H, J = 5 Hz, HCO_2), 3.90 (m, 4H, $(CH_2O)_2$), 2.6–1.2 (m, 6H), 0.90 (d, 6H, J = 6.5 Hz, $(CH_3)_2CH$).

*Allylic alcohol **73***

Following exactly the same procedure previously described for the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

formation of allylic alcohol **57** (*vide supra*), allylic alcohol **73** was obtained from aldehyde **72** (4.13 g, 23 mmol) as a colorless oil (4.9 g, 98%); ir (CH_2Cl_2, ν cm^{-1}): 3600, 3450, 1650; ^1H nmr ($CDCl_3$, δ ppm): 6.1–4.8 (m, 3H, olefinic), 4.91 (br t, 1H, J = 5 Hz, H-CO_2), 3.90 (m, 4H, $(CH_2O)_2$), 3.81 (m, 1H, *H*COH), 2.1–1.1 (m, 6H), 0.86 (d, 6H, J = 6 Hz, $(CH_3)_2CH$).

Dienophile 74

(a) From ketal acid 70

To a stirred suspension of lithium hydride (680 mg, 0.085 mol) in tetrahydrofuran (200 mL) was added dropwise a solution of ketal acid **70** (15.15 g, 0.075 mol) in tetrahydrofuran (40 mL). After 2 h at 75–80°C, the mixture was cooled at 0°C, treated with vinyllithium (2.9 M in THF, 36 mL, 0.10 mol), then warmed (50–55°C) for 1 h. It was then poured onto an ice – hydrochloric acid mixture (200 mL, 1 M), and extracted with ether. The organic layers were combined, washed with aqueous sodium carbonate solution (5%) and brine, dried, and the solvents evaporated to give a crude neutral extract. Acidification (pH 6) of basic aqueous washings and extraction (ether) gave unreacted starting ketal acid **70** (6.1 g, 40%). Chromatographic purification (silica gel, hexane, benzene–ether mixtures) of the crude neutral extract furnished enone **74** as a sensitive colorless oil (7.37 g, 78% based on reacted acid **70**); ir (CH_2Cl_2, ν cm^{-1}): 1690, 1615, 1410, 1140; ^1H nmr ($CDCl_3$, δ ppm): 6.4–5.6 (m, 3H, olefinic), 4.85 (t, 1H, J = 5 Hz, HCO_2), 3.85 (m, 4H, $(CH_2O)_2$), 2.7–2.4 (m, 2H, CH_2CO), 2.3–1.4 (m, 4H), 0.86 (br d, 6H, J = 6 Hz, $(CH_3)_2CH$).

(b) From alcohol 73

Following exactly the same procedure previously described for the formation of enone **58** (*vide supra*), oxidation of alcohol **73** (4.91 g, 22 mmol) by Jones reagent (8.6 mL, 23 mmol) gave enone **74** (3.77 g, 81%) as a pure colorless oil; ir and nmr data have been given (*vide supra*).

Diels–Alder adducts 75a + b and 76a + b

A solution of spirolactone dienone **6** (4.30 g, 19.5 mmol) and enone **67** (4.64 g, 23.4 mmol) in benzene (60 mL) was refluxed for 9 h. Evaporation of benzene left an oily residue containing compounds **75***a* and *b*, **76***a* and *b*, which were not separated; ^1H nmr ($CDCl_3$, δ ppm): 4.85 (br d, 1H, J = 3.5 Hz, H-CO_2), 4.70 (d, 0.5H) and 4.32 (d, 0.5H), 4.65 (d, 0.5H) and 4.30 (d, 0.5H) (two embodied AB patterns, J_{AB} = 14 Hz) (spirolactonic methylene), 3.82 (br s, 4H, $CH_2O)_2$), 3.60 (m, 1H, H-C11 for 4 isomers), 3.2 (m, 1H, H-CCO), 3.0–1.3 (m, 12H), 1.25 (br s, 3H, CH_3-C5), 0.93 (d, 3H, J = 7 Hz) and 0.88 (d, 3H, J = 7 Hz) $(CH_3)_2CH$).

Tetracyclic ketal diketones 77–80

To a crude mixture of Diels–Alder adducts **75***a* + *b* and **76***a* + *b* (3.00 g, 7.2 mmol) in tetrahydrofuran (200 mL) was added an aqueous solution of potassium hydroxide (1 M, 28.7 mL). After 20 h of stirring at 25°C, tetrahydrofuran was evaporated and the aqueous residue was extracted with ether. The crude extract (1.83 g) showed three acetalic protons as doublets at δ 5.25 (J = 9 Hz) (major one), 5.08 (J = 6 Hz), and 4.75 (J = 7 Hz). Crystallization of the crude mixture (ether) furnished ketal diketone **77** (or **79**) (750 mg, 29%) plus a mixture of **77** and *exo* epimer **78** (or **80**). This mixture was submitted to the same basic treatment and gave an additional crop of crystalline *endo* **77** (or **79**) (153 mg, 6%) (total 35% yield in isomer *endo* **77** (or **79**); mp 204–206°C; ir ($CHCl_3$, ν cm^{-1}): 3500, 1735, 1710, 1210 cm^{-1}; ^1H nmr ($CDCl_3$, δ ppm): 5.25 (d, 1H, J = 9 Hz, HCO_2), 4.0–3.6 (m, 4H, $(CH_2O)_2$), 3.26 (d, 1H, J = 5 Hz, H-C11), 3.01–1.6 (m), 1.25 (s, 3H, CH_3-C5), 0.90 (d, 6H, J = 6.5 Hz, $(CH_3)_2CH$); ms *m/e*: 360 (M^+). *Anal.* calcd. for $C_{21}H_{28}O_5$: C 69.98, H 7.83; found: C 69.88, H 7.76.

Diels–Alder racemic adducts 81a + b and 82a + b

A solution of spirolactone dienone **6** (0.935 g, 4.22 mmol) and racemic dienophile **74** (1.117 g, 5.26 mmol) in benzene (6 mL) was refluxed for 16 h under nitrogen. Benzene was then evaporated to leave a mixture containing essentially 4 components (hardly separated on tlc after multiple elutions). Rapid filtration on silica gel (hexane–Et_2O 30%) removed the unreacted dienophile to give a pure mixture of adducts **81** and **82** (1.84 g, 99%); ir ($CHCl_3$, ν cm^{-1}): 1815, 1735, 1710 cm^{-1}; ^1H nmr ($CDCl_3$, δ ppm): 4.80 (m, 1H, HCO_2), ~4.5 (two embodied AB patterns, J = 14 Hz, OCH_2CO_2), 3.85 (m, 4H, $(CH_2O)_2$), 3.60 (m, 1H, H-C11), 3.4–1.4 (m, 15H), 1.27 (s, 3H, CH_3C5), 0.85 (br d, 6H, J = 7 Hz, $(CH_3)_2CH$). This mixture was used for the next step without any further purification.

Racemic tetracyclic ketones 83–86

To a stirred solution of Diels–Alder racemic adducts **81***a* + *b* and **82***a* + *b* (1.840 g, 4.22 mmol) in tetrahydrofuran (75 mL) was added aqueous sodium hydroxide solution (1 M, 14 mL). After 15 h at room temperature, the main part of THF was evaporated and the residue was extracted with ether (4 × 75 mL). Evaporation of the solvent gave an oily residue containing four compounds: **83**:**84**:**85**:**86** in the relative proportions (37:19:16:28) as given by the integration of the bridgehead proton (H-C11) of each component of the mixture. These compounds showed the following relative R_f values (benzene–ether 15%, solutions): **85** < **83** < **84** < **86**. By preparative thin-layer chromatography (benzene–ether 10%, 4 elutions) and crystallization, it was possible to obtain pure compounds **83**, **85**, and **86**.

Isomer 83: mp 57°C, ir ($CHCl_3$, ν cm^{-1}): 3530, 1745, 1715 cm^{-1}; ^1H nmr ($CDCl_3$, δ ppm): 4.84 (t, 1H, J = 4.5 Hz, HCO_2), 3.87 (m, 4H, $(CH_2O)_2$), 3.28 (d, 1H, J = 5.0 Hz, H-C11), 2.68 (m, 1H, H-C14), 2.6–1.6 (m, 13H), 1.27 (s, 3H, CH_3-C5), 0.88 (d, 6H, J = 7.3 Hz, $(CH_3)_2CH$); ms *m/e*: 374 (M^+). *Anal.* calcd. for $C_{22}H_{30}O_5$: C 70.55, H 8.07; found: C 69.50, H 8.36.

Isomer 84: obtained as a mixture (~1:1) with **86**: ^1H nmr ($CDCl_3$, δ ppm): 4.90 (t, 1H, J = 4.6 Hz, HCO_2), 3.90 (m, 4H, $(CH_2O)_2$), 3.48 (d, 1H, J = 5.2 Hz, H-C11), 2.7–1.6 (m, 14H), 1.25 (s, 3H, CH_3-C5); 0.93 (d, 3H, J = 6.7 Hz, CH_3CH), 0.84 (d, 3H, J = 6.7 Hz, CH_3CH).

Isomer 85: mp 78–80°C; ir ($CHCl_3$, ν cm^{-1}): 3500, 1740, 1715 cm^{-1}; ^1H nmr ($CDCl_3$, δ ppm): 4.88 (t, 1H, J = 4.4 Hz, HCO_2), 3.90 (m, 4H, $(CH_2O)_2$), 3.54 (s, 1H, OH), 3.17 (d, 1H, J = 4.9 Hz, HC15), 3.01 (dd, 1H, J_{vic} = J_W = 2.3 Hz, H_{exo}-C1), 2.70 (dddd, 1H, HC15), 2.50 (m, 2H) and 2.40 (m, 2H) (allylic protons), 2.00 (m, 2H, H_2C8), 1.80 (m, 6H), 1.27 (s, 3H, CH_3-C5), 0.88 (d, 3H, J = 7 Hz) and 0.85 (d, 3H, J = 7 Hz) $(CH_3)_2CH$); ms *m/e*: 374. *Anal.* calcd. for $C_{22}H_{30}O_5$: C 70.55, H 8.07; found C 69.53, H 8.38.

Isomer 86: mp 120–122°C; ir ($CHCl_3$, ν cm^{-1}): 3530, 3400, 1740, 1715; ^1H nmr ($CDCl_3$, δ ppm): 4.86 (t, 1H, J = 4.8 Hz, HCO_2), 3.90 (m, 4H, $(CH_2O)_2$), 3.43 (d, 1H, J = 5.3 Hz, HC11), 3.14 (s, 1H, -OH), 2.57 (ddd, 1H, HC15), 2.52 (m, 2H), and 2.41 (m, 2H) (allylic protons), 2.29 (m, 1H, $CH(CH_3)_2$), 2.14 (d, 1H, J = 3.9 Hz, H_{endo}-C1), 2.02 (m, 2H, H_2C8), 1.95–1.50 (m, 5H), 1.25 (s, 3H, CH_3-C5), 0.93 (d, 3H, J = 6.7 Hz) and 0.87 (d, 3H, J = 6.7 Hz) $(CH(CH_3)_2)$; ms *m/e*: 374 (M^+).

Racemic pentacyclic diol aldehyde 87

A solution of the preceding crude mixture of compounds **83–86** (1.975 g, 5.28 mmol) in aqueous acetic acid (70%, 50 mL) was heated at 70°C for 1 h. The solvents and volatile substances were removed by evaporation under reduced pressure, then the oily residue was dissolved in tetrahydrofuran (150 mL) and stirred (25°C, 15 h) in the presence of aqueous sodium hydroxide (1 M, 40 mL). After removal of the organic solvent, the aqueous residue was extracted with ether (5 × 100 mL). The organic layers were combined, dried, filtered, and evaporated. The residue was crystallized from chloroform – petroleum ether to give racemic pentacyclic diol aldehyde **87** (400 mg, 23% from dienone **6**); mp 198–199°C; ir ($CHCl_3$, ν cm^{-1}): 3500, 2710, 1725; ^1H nmr ($CDCl_3$, δ ppm): 9.57 (d, 1H, J = 3.1 Hz, -CHO), 3.14 (d, 1H, J = 5.1 Hz, H-C11), 2.75 (dd, 1H, J = 5.1, 3.0 Hz, H-C1), 2.65 (dd, 1H, J = 11.0, 3.1 Hz, H-C3), 2.70–2.38 (m, 5H, H-C2, allylic protons, $HC(CH_3)_2$), 1.44 (m, 2H, H_2C14), 1.28 (s, 3H, CH_3C5), 1.11 (d, 3H, J = 6.4 Hz) and 0.77 (d, 3H, J = 6.7 Hz) $(CH(CH_3)_2)$; ms *m/e*: 330 (M^+). *Anal.* calcd. for $C_{20}H_{26}O_4$: C 72.70, H 7.93; found: C 72.63, H 8.06.

Pentacyclic carbonate aldehyde 89

To a solution of diol aldehyde **87** (120 mg, 0.36 mmol) in benzene (10 mL) was added pyridine (4 mL) and a saturated benzenic solution of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

phosgene (10 mL). After 15 min at room temperature the mixture was poured onto ice-water and extracted with ether. The crude product was crystallized from chloroform – petroleum ether to give carbonate aldehyde **89** (88 mg, 68%); mp 186–188°C; ir ($CHCl_3$, ν cm^{-1}): 1805, 1740, 1725; ^1H nmr ($CDCl_3$, δ ppm): 9.57 (d, 1H, J = 3.0 Hz, -CHO), 3.40 (d, 1H, J = 5.3 Hz, H-C11), 3.03 (dd, 1H, J = 6.7 Hz, 2.2 Hz, H-C1), 2.87 (m, 1H, H-C2), 2.74 (dd, 1H, J = 11.4, 3.0 Hz, H-C3), 2.50 (m, 5H, H-C15 and allylic protons), 2.1–1.8 (m, 3H, H_2C8 and $CH(CH_3)_2$), 1.56 (m, 2H, H_2C14), 1.36 (s, 3H, CH_3C5), 1.14 (d, 3H, J = 6.5 Hz) and 0.81 (d, 3H, J = 6.8 Hz) ($(CH_3)_2CH$); ms m/e: 356 (M^+).

*Orthoacetates **90** and **91***

A solution of diol aldehyde **87** (525 mg, 1.59 mmol) and *p*-toluenesulfonic acid (6 mg) in acetic anhydride (60 mL) was heated at 70°C for 3 h. Acetic anhydride was then evaporated and the oily residue was purified by preparative thin-layer chromatography (benzene–ether 9:1, three elutions) to give orthoacetates **90** (120 mg, 18%), and **91** (108 mg, 16%).

*Orthoacetate **90***: mp 157–158°C; ir ($CHCl_3$, ν cm^{-1}): 1735, 1370, 1230, 1040; ^1H nmr ($CDCl_3$, δ ppm): 6.06 (d, 1H, J = 2 Hz, *H*COAc), 4.09 (d, 1H, J = 5 Hz, H-C11), 3.68 (dd, 1H, J = 6.5, 2.0 Hz, H-C1), 2.7–1.5 (m, 13H), 2.15 (s, 3H) and 2.12 (s, 3H) (acetate and orthoacetate), 1.39 (s, 3H, CH_3-C5), 1.20 (d, 3H, J = 5.5 Hz) and 0.87 (d, 3H, J = 5.5 Hz) ($(CH_3)_2CH$); ms m/e: 414 (M^+). *Anal.* calcd. for $C_{26}H_{32}O_7$: C 68.40, H 7.06; found: C 68.50, H 7.20.

*Orthoacetate **91***: ir ($CHCl_3$, ν cm^{-1}): 1735, 1370, 1230, 1070, 1040; ^1H nmr ($CDCl_3$, δ ppm): 6.41 (d, 1H, J = 5.5 Hz, *H*COAc), 4.15 (d, 1H, J = 5 Hz, HC11), 3.65 (dd, 1H, J = 6.5, 2.0 Hz, H-C1), 2.8–1.2 (m, 13H), 2.15 (s, 3H) and 2.12 (s, 3H) (acetate and orthoacetate), 1.39 (s, 3H, CH_3C5), 1.26 (d, 3H, J = 6 Hz) and 0.78 (d, 3H, J = 6 Hz) ($(CH_3)_2CH$); ms m/e: 414 (M^+).

*Monodeuterated diol aldehyde **87**-d_1*

A crude mixture of tricyclic Diels–Alder adducts **81***a* + *b* and **82***a* + *b* (3.93 g, 9.1 mmol) in tetrahydrofuran (100 mL) was reacted with a solution of sodium hydroxide (1.22 g) in deuterium oxide (30.5 mL) at room temperature for 16 h. The main part of the tetrahydrofuran was evaporated and the aqueous residue extracted with ether. The crude extract (3.3 g, 96%) was dissolved in tetrahydrofuran (100 mL) and reacted with aqueous sodium hydroxide (1 M, 30 mL) for 6 h at room temperature. Evaporation of tetrahydrofuran and ether extraction of the aqueous residue gave crude monodeuterated (position 15) mixture **77–80** (2.5 g, 76%), which was dissolved in aqueous acetic acid (70%, 80 mL) and heated at 70°C for 45 min. Evaporation of the volatile substances left a residue that was dissolved in tetrahydrofuran (100 mL) and reacted with aqueous sodium hydroxide (1 M, 60 mL). After 16 h at room temperature the aqueous residue was extracted with ether to give an oily mixture, which was purified by chromatography and crystallization as previously described (*vide supra*, compound **87**) to give diol aldehyde **87**-d_1 (320 mg, 15%); ^1H nmr ($CDCl_3$) identical to nmr spectrum of **87** except for the following: 3.14 (s, 1H, H-C11), 2.75 (d, J = 5.1 Hz, HC1) and 2.33 (no multiplet).

*Monodeuterated orthoacetates **90**-d_1 and **91**-d_1*

A solution of monodeuterated diol aldehyde **87**-d_1 (280 mg, 0.85 mmol) was reacted with acetic anhydride and *p*-toluenesulfonic acid as previously described (see the preceding preparation) to give monodeuterated **90**-d_1 (82 mg, 21%, mp 156–157°C) and **91**-d_1 (90 mg, 23%).

*Orthoacetate **90**-d_1*: ^1H nmr ($CDCl_3$, δ ppm) same as for **90** except for the following: 4.09 (s, 1H, H-C11), 3.68 (d, 1H, J = 6.5 Hz, H-C1).

*Orthoacetate **91**-d_1*: ^1H nmr ($CDCl_3$, δ ppm) same as for **91** except for the following: 4.15 (s, 1H, H-C11), 3.65 (d, 1H, J = 6.5 Hz, H-C1).

*Basic treatment performed on isomers **83–86***

*On isomer **83***: To a stirred solution of isomer **83** (30 mg, 0.080 mmol) in tetrahydrofuran (3 mL) was added aqueous sodium hydroxide (0.75 mL, 1 M). After 18 h at 25°C, extraction of the reaction mixture with ether furnished unchanged starting material (26 mg, 86%) as shown by nmr and tlc analysis.

*On isomer **84***: same as for **83** with the following quantities: 14 mg of a mixture ~2:1 of **84** and **86**; NaOH, 1 M, 0.4 mL. Crude product (4 mg, 28%) showed the presence of **83**, **85**, and **86** by nmr.

*On isomer **85***: same as for **83** with the following quantities: isomer **85** (33 mg, 0.088 mmol), sodium hydroxide (0.8 mL, 1 M), tetrahydrofuran (3 mL). Crude product (10 mg, 30%) showed the presence of **85** and **86** (respectively ~2:1, by nmr).

*On isomer **86***: same as for **83**: isomer **86** (28 mg, 0.075 mmol), sodium hydroxide (0.8 mL, 1 M), tetrahydrofuran (3 mL). Crude product (12 mg, 43%) showed the presence of isomers **85** and **86** (respectively ~2:1, by nmr).

*Cyclization of isomer **83***

A solution of pure isomer **83** (30 mg, 0.080 mmol) in aqueous acetic acid (70%, 5 mL) was heated at 70°C for 45 min. Evaporation of the volatile substances left a residue that was dissolved in tetrahydrofuran (3 mL) and reacted with aqueous sodium hydroxide (1 mL, 1 M). After 16 h at room temperature, the mixture was extracted with ether to give pure diol aldehyde **87** (26 mg, 98%).

*(+)-Dihydrocarvone ((S)-**95**)*

A mixture of (+)-carvone ((*S*)-**94**) (50.0 g, 0.33 mol) and platinum oxide (0.10 g) was stirred under hydrogen at 25°C for 7 h. The catalyst was then removed by filtration through a short column of silica gel (ether). Evaporation of the solvent left colorless pure (+)-dihydrocarvone ((*S*)-**94**) (50 g, 99%); ir (neat, ν cm^{-1}): 1680, 1200; ^1H nmr ($CDCl_3$, δ ppm): 6.78 (m, 1H, H-C3), 2.7–1.3 (m, 6H), 1.77 (m, 3H, CH_3-C2), 0.88 (d, 6H, J = 5.5 Hz, $(CH_3)_2CH$). *(−)-Dihydrocarvone* ((*R*)-**95**): hydrogenation of (−)-carvone ((*R*)-**94**) (33.0 g, 0.217 mol) was done in the same way to furnish (−)-dihydrocarvone ((*R*)-**95**) (33 g, 99%).

*(3S)-3-Isopropyl-5-oxopentanoic acid ((S)-**96**)*

A solution of (+)-dihydrocarvone ((*S*)-**95**, 20.06 g, 131.5 mmol) in ethyl acetate (150 mL) was treated by a stream of ozone at −78°C until a blue color persisted (50 min approximately). The mixture was warmed at room temperature while a stream of nitrogen was bubbled through the yellowish solution. The reaction mixture was then cooled (ice water) and stirred in a hydrogen atmosphere in the presence of 10% palladium-on-charcoal (200 mg) catalyst. After 5 h, removal of the catalyst by filtration on Celite left the crude aldehyde acid (*S*)-**96** (20.5 g); ir (CCl_4, ν cm^{-1}): 3500–2800 br, 1770–1715 br; ^1H nmr ($CDCl_3$, δ ppm): 9.6 (m, 1H, CHO), 9.1 (br m, 1H, CO_2H), 2.8–1.2 (m, 6H), 0.90 (d, 6H, J = 6 Hz, $CH(CH_3)_2$).

*(3S)-5,5-Ethylenedioxy-3-isopropylpentanoic acid ((S)-**70**)*

To a solution of the crude aldehyde acid (*S*)-**96** (20.5 g, 130 mmol) in benzene (250 mL) were added ethylene glycol (25.2 g, 0.41 mol) and *p*-toluenesulfonic acid (0.50 g). The mixture was refluxed (Dean–Stark) for 16 h, then cooled, diluted with ether (200 mL), and washed with water (2 × 50 mL) and brine. Evaporation of the solvents left a crude mixture that was dissolved in methanol (150 mL) and reacted with aqueous sodium hydroxide (1 M, 150 mL) at 65°C for 4 h. Methanol was then evaporated under reduced pressure and the aqueous layer was washed with ether to remove neutral impurities. Acidification (pH 5, 0°C, 1 M HCl) of the basic aqueous layer and extraction with ether (4 × 100 mL) furnished ketal acid (*S*)-**70** (22.2 g, 99%): *vide supra* for spectroscopic data.

*(3R)-5,5-Ethylenedioxy-3-isopropylpentanoic acid ((R)-**70**)*

Same procedure as for (*S*)-**70** from aldehyde acid (*R*)-**96**.

*Methyl (3S) and (3R)-5,5-ethylenedioxy-3-isopropyl pentanoate ((S)-**69**, R = CH_3)*

(a) By esterification with diazomethane

A solution of ketal acid (*S*)-**70** (5.6 g, 27 mmol) or (*R*)-**70** (5.15 g, 25 mmol) in dry ether (100 mL) was reacted at −78°C with a slight excess of diazomethane in ether (~20 mg/mL, 100 mL). Evaporation of the solvent left ester (*S*)-**69** (R = CH_3, 5.3 g, 95%) or ester (*R*)-**69** (R

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

= CH_3, 5.18 g, 96%): ir (neat, ν cm^{-1}): 1740; ^1H nmr ($CDCl_3$, δ ppm): 4.93 (t, 1H, J = 5 Hz, HCO_2), 3.92 (m, 4H, $(CH_2O)_2$), 3.69 (s, 3H, OCH_3), 2.5–1.4 (m, 6H), 0.88 (d, 6H, $(CH_3)_2CH$); ms *m/e*: 216 (M^+). *Anal.* calcd. for $C_{11}H_{20}O_4$: (*S*)-**69** (R = CH_3): C 61.08, H 9.32; found: C 60.95, H 9.44; for (*R*)-**69** (R = CH_3): found: C 60.84, H 9.20; $[\alpha]_{578}^{25}$ for (*S*)-**69** (R = CH_3): +0.6°, neat, and for (*R*)-**69** (R = CH_3): −0.6°, neat.

(b) By esterification with methyl iodide

A mixture of the crude acetal acid (*S*)-**70** (142 g, 0.7 mol), anhydrous potassium carbonate (146 g), and methyl iodide (300 mL, 4.8 mol) in acetone (2 L) was refluxed for 25 h under nitrogen. The cooled mixture was then filtered and the solvent evaporated. The oily residue was dissolved in ether (1.4 L), washed twice with aqueous potassium carbonate (10%), twice with brine, and dried ($MgSO_4$). Evaporation of the solvent left an oil, which was distilled under reduced pressure (bp 84–86°C, 0.2 Torr, ~136 g, 90%) to give pure ketal ester (*S*)-**69** (R = CH_3).

Dienophile (S)-74

From ketal acid (*S*)-**70**. This reaction was done as for racemic dienophile **74** (*vide supra*). Dienophile **74** ($[\alpha]_{578}^{25}$ +0.7°, neat) was obtained in 75% yield based on reacted acid.

From ketal ester (*S*)-**69** (R = CH_3). This sequence was done exactly as for racemic material (*vide supra*, **69** → **74**) in an overall yield of ~80%.

Dienophile (R)-74

This material was obtained from ketal ester (*R*)-**69** (R = CH_3) as just described for dienophile (*S*)-**74** in the same overall yield of ~80% ($[\alpha]_{578}^{25}$ −0.6°, neat).

Pentacyclic diol aldehyde (dextro)-87

Starting from *o*-spirolactone dienone **6** (6.75 g, 30.6 mmol) and dienophile (*S*)-**74** (7.4 g, 34.8 mmol), the synthesis of (*dextro*)-**87** was done in the same way as described for racemic aldehyde **87** (*vide supra*); mp 165–165.5°C; $[\alpha]_{578}^{25}$ +142.2°.

Pentacyclic diol aldehyde (levo)-87

Starting from *o*-spirolactone dienone **6** (2.00 g, 9.13 mmol) and dienophile (*R*)-**74** (2.13 g, 10.04 mmol), aldehyde (*levo*)-**87** was obtained (0.52 g, 17%); mp 161–162°C; $[\alpha]_{578}^{25}$ −137.5°. *Anal.* calcd. for $C_{20}H_{26}O_4$: C 72.70, H 7.93; found: C 72.63, H 8.06.

Pentacyclic carbonate aldehyde (dextro)-89

This compound was synthesized from diol aldehyde (*dextro*)-**87** as for racemic **89** (*vide supra*); mp 186–188°C, $[\alpha]_D^{25}$ +121.3°.

5,6-Dimethoxy-1-methylindene (112)

To a solution of 5,6-dimethoxy-1-indanone (**110**) (100 g, 0.52 mol) in tetrahydrofuran (3.2 L) was added, at −55°C and under nitrogen, a solution of methyllithium in ether (1 mol, 500 mL). The mixture was then warmed to room temperature and stirred for 16 h. Water (100 mL) and hydrochloric acid (1 mol) were added to the cooled mixture and the organic layer was separated. The aqueous layer was then extracted (4 × 250 mL) with ether. The usual evaporation of the dried ($MgSO_4$) organic extract afforded a crude material, which was chromatographed on Florisil (benzene) to give pure compound **112** (96.4 g, 97%); mp 91–92°C (ether–hexane); ir ($CHCl_3$, ν cm^{-1}): 1610, 1580, 1490, 1340, 1270, 1220, 1130, 1060; ^1H nmr (CCl_4, δ ppm): 6.88 (br s, 1H, H-C7), 6.75 (s, 1H, H-C4), 5.99 (m, 1H, H-C2), 3.79 (s, 3H, OCH_3), 3.76 (s, 3H, OCH_3), 3.14 (m, 2H, H_2C3), 2.08 (m, 3H, CH_3-C1); ms *m/e*: 190 (M^+). *Anal.* calcd. for $C_{12}H_{14}O_2$: C 75.76, H 7.42; found: C 75.84, H 7.24.

5,6-Dimethoxy-1-methylindane (113)

A mixture of methylindene **112** (40 g, 0.21 mol) and platinum oxide (320 mg) in acetic acid (800 mL) was shaken in an hydrogen atmosphere for 48 h. The catalyst was removed by filtration and the acetic acid was evaporated under reduced pressure to leave an oil, which was filtered on Florisil (benzene as eluent) to give oily methylindane **113** (33.27 g, 83%): ir ($CHCl_3$, ν cm^{-1}): 1610; ^1H nmr (CCl_4, δ ppm): 6.17 (br s, 2H, aromatic), 3.72 (s, 3H, OCH_3), 3.69 (s, 3H, OCH_3), 3.2–1.5 (m, 5H), 1.22 (d, 3H, J = 7 Hz, CH_3-C1); ms *m/e*: 192 (M^+). *Anal.* calcd. for $C_{12}H_{16}O_2$: C 74.97, H 8.39; found: C 74.94, H 8.24.

Isomeric dimethoxyindane aldehydes 114 and 115

To a solution of methylindane **113** (7.50 g, 39 mmol) in dry dichloromethane (125 mL) was added, at 0°C, titanium tetrachloride (10.5 mL, 18.16 g, 95.7 mmol). To the red-violet mixture was then added a solution of dichloromethyl methyl ether (9.0 mL, 11.4 g, 100 mmol) in dichloromethane (25 mL). After stirring at 0°C for 15 min, at room temperature for 1 h, and at reflux for 4 h, the mixture was cooled and poured onto an ice–water mixture and stirred for 3 h. Separation of the organic layer and extraction of the aqueous phase with dichloromethane furnished an organic extract, which was dried (Na_2SO_4), filtered, and evaporated. The crude extract contained isomers **114** and **115** (respectively 2:1) together with unreacted starting material (~20%) as shown by nmr. As these aldehydes do not support chromatography, removal of the starting material was done by transforming these aldehydes to their corresponding Girard's T derivatives: a solution of the crude reaction mixture (4.58 g, ~20 mmol) in ethanol (35 mL) and acetic acid (3.5 mL) was reacted with Girard's T reagent (3.5 g, 20.8 mmol). After 1 h at reflux, the reaction mixture was cooled and diluted with brine (200 mL), and washed with ether (3 × 100 mL) to remove methylindane **113** and other impurities. Addition of hydrochloric acid (2 M, 20 mL) to the aqueous layer followed by ether extraction (5 × 100 mL) and a rapid filtration of the colored extract through a short path of silica gel (CH_2Cl_2) gave a pure mixture of aldehydes **114** and **115** (3.1 g, 68%).

Dihydroxyaldehydes 116 and 117

To a cooled (−70°C) solution of the purified mixture of compounds **114** and **115** (6.00 g, 27.3 mmol) in dry dichloromethane (250 mL) was added dropwise boron tribromide (6.0 mL, 62 mmol) over a period of 15 min. The mixture was then stirred at room temperature for 2 h, cooled again at −70°C, treated with methanol (10 mL), aqueous methanol (50%), and water (100 mL). After 4 h at room temperature, the organic layer was separated and the aqueous layer extracted with dichloromethane (4 × 100 mL). The combined extracts were washed with water, dried, and the solvent was evaporated. The crude extract (3.8 g) was filtered through a short path of Florisil (CH_2Cl_2). Fractional crystallization of the semicrystalline extract (3.0 g) (CH_2Cl_2 – Et_2O – hexane) furnished pure aldehydes **116** (630 mg, 12%) and **117** (49 mg, 1%).

Aldehyde 116: mp 91.5–92.5°C; ir ($CHCl_3$, ν cm^{-1}): 3500, 3460, 2760, 1660, 1605; ^1H nmr (CCl_4, δ ppm): 11.28 (s, 1H, HO-C5), 10.0 (s, 1H, CHO), 6.94 (1H, s, H-C7), 5.73 (s, 1H, HO-C6), 3.2–1.5 (m, 5H), 1.22 (d, 3H, J = 7 Hz, CH_3Cl); ms *m/e*: 192 (M^+). *Anal.* calcd. for $C_{11}H_{12}O_3$: C 68.74, H 6.29; found: C 68.75, H 6.15. Irradiation of methyl signal (δ 1.22) resulted in an increase (15%) of aromatic signal at δ 7.01.

Aldehyde 117: mp 81–82.5°C; ir ($CHCl_3$, ν cm^{-1}): 3560, 2760, 1660, 1605; ^1H nmr (δ ppm): 11.41 (s, 1H, HO-C6), 10.10 (s, 1H, CHO), 7.01 (s, 1H, H-C4), 6.04 (s, 1H, HO-C5), 3.8–1.6 (m, 5H), 1.24 (d, 3H, J = 7 Hz, CH_3-C1); ms *m/e*: 192 (M^+). Irradiation of the methyl signal (δ 1.24) had no apparent effect on the intensity of the aromatic proton signal.

Bromoacetate 118

To a solution of 4-formyl-5,6-dihydroxy-1-methylindane (**116**) (1.42 g, 7.4 mmol) in dry benzene (30 mL) and pyridine (0.6 mL, 7.4 mmol) was added dropwise at 25°C a solution of bromoacetyl bromide (1.63 g, 8.1 mmol) in benzene (10 mL). After 3 h, the mixture was washed with water and the solvent was evaporated to leave a yellow oil sufficiently pure for the next step (2.35 g, crude 98%); ir ($CHCl_3$, ν cm^{-1}): 3600–3000 (br), 1760, 1660; ^1H nmr ($CDCl_3$, δ ppm): 11.39 (s, 1H, OH), 10.04 (s, 1H, CHO), 7.19 (s, 1H, H-C7), 4.10 (s, 2H, $BrCH_2$-), 3.3–1.4 (m, 5H), 1.22 (d, 3H, J = 7 Hz, CH_3-); ms *m/e*: 312 and 314 (M^+).

Lactone aldehyde 119

To a solution of bromoacetate **118** (2.51 g, 8.0 mmol) in tetrahydrofuran (60 mL) was added powdered potassium carbonate (10.0 g,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

2.5 mmol). The mixture was refluxed for 48 h. After cooling, the mixture was centrifuged and decanted. The solid material was dissolved in water (100 mL), and the aqueous solution was acidified to pH 1 (2 M HCl) and extracted with ether (3 × 70 mL). The crude acid (2.0 g) was dissolved in benzene (50 mL) and refluxed (Dean–Stark, 4 h) in the presence of *p*-toluenesulfonic acid (25 mg). The cooled mixture was filtered through a short pad of silica gel. Evaporation of benzene left pure lactone **119** (1.69 g, 91%), which was crystallized from ether–hexane; mp 111.5–112°C; ir ($CHCl_3$, ν cm^{-1}): 2770, 1800, 1698, 1605, 1325, 1300, 1270, 1200; ^1H nmr ($CDCl_3$, δ ppm): 10.35 (s, 1H, CHO), 7.07 (br s, 1H, H-C7), 4.75 (s, 2H, $-OCH_2CO_2-$), 3.4–1.4 (m, 5H), 1.22 (d, 3H, J = 7 Hz, CH_3-); ms *m/e*: 232 (M^+). *Anal.* calcd. for $C_{13}H_{12}O_4$: C 67.23, H 5.21; found: C 67.13, H 5.15.

Lactone ***120***

A mixture of lactone aldehyde **119** (1.66 g, 7.1 mmol) and palladium-on-charcoal catalyst (10%, 440 mg) in acetic acid was shaken under hydrogen at 25°C for 24 h. Filtration of the catalyst and evaporation of the solvent left pure crystalline lactone indane **120** (1.55 g, 99%), which was recrystallized from hexane; mp 68–70°C; ir ($CHCl_3$, ν cm^{-1}): 1785, 1610; ^1H nmr (CCl_4, δ ppm): 6.70 (br s, 1H, H-C7), 4.49 (s, 2H, OCH_2CO_2), 3.3–1.4 (m, 5H), 2.11 (s, 3H, CH_3-C4), 1.22 (d, 3H, J = 7 Hz, CH_3Cl); ms *m/e*: 218 (M^+). *Anal.* calcd. for $C_{13}H_{14}O_3$: C 71.54, H 6.47; found: C 71.65, H 6.45.

Spirolactones ***97***

To a solution of lactone indane **120** (502 mg, 2.30 mmol) in acetonitrile (10 mL) was added aqueous sodium hydroxide (1 M, 2.7 mL). After 45 min of stirring at room temperature, a solution of *N*-bromosuccinimide (430 mg, 2.41 mmol) in aqueous acetonitrile (16 mL, 1:1) was rapidly added to the mixture. After 2.5 min, addition of brine and extraction with ether furnished a colored crude product, which was rapidly filtered on silica gel (benzene) to give a sensitive mixture of racemic lactones **97** (515 mg, ~95%); ir ($CHCl_3$, ν cm^{-1}): 1820, 1685, 1665, 1602; ^1H nmr ($CDCl_3$, δ ppm): 5.87 (br s, 1H, H-C7), 4.66 (br d, 1H, J = 14 Hz) and 4.39 (d, 1H, J = 14 Hz) (two embodied AB patterns, O-CH_2CO_2), 3.1–1.4 (m, 5H), 1.92 (br s, 3H, CH_3-C4), 1.22 (d, 3H, J = 7 Hz, CH_3Cl); ms *m/e*: 234 (M^+).

Adducts ***121****(a–b) and* ***122****(a–b)*

A solution of mixed dienones **97** (160 mg, 0.68 mmol) in excess methylvinylketone (0.3 mL) was refluxed for 20 min under nitrogen. Removal of the volatile substances under vacuum and careful chromatography of the oily residue (215 mg) on a thick layer of silica gel (carbon tetrachloride, ethyl acetate, benzene, hexane 1:1:5:3, two elutions) furnished four adducts (total yield ~65%). These compounds showed the following R_f values, 0.75, 0.70, 0.61, 0.56, and relative proportions 2:2:1:2.

Least polar isomer: mp 124–126°C; ir ($CHCl_3$, ν cm^{-1}): 1820, 1740, 1715; ^1H nmr (C_6H_6, δ ppm): 4.38 (d, 1H, J_{AB} = 14 Hz) and 3.77 (d, 1H, J_{AB} = 14 Hz) (AB pattern, OCH_2CO_2), 3.35 (d, 1H, J = 2 Hz, H-C11), 2.6–1.2 (m, 8H), 1.57 (s, 3H, CH_3CO), 1.00 (s, 3H, CH_3-C5), 0.77 (d, 3H, J = 7 Hz, CH_3-C9); ms *m/e*: 304 (M^+).

Second least polar isomer: mp 149–151°C; ir ($CHCl_3$, ν cm^{-1}): 1820, 1740, 1715; ^1H nmr (C_6H_6, δ ppm): 4.39 (d, 1H, J_{AB} = 14 Hz) and 3.77 (d, 1H, J_{AB} = 14 Hz) (AB pattern, OCH_2CO_2), 3.45 (d, 1H, J = 2 Hz, H-C11), 2.6–1.1 (m), 1.55 (s, 3H, CH_3CO), 1.15 (s, 3H, CH_3C5), 0.90 (d, 3H, J = 7 Hz, CH_3C9); ms *m/e*: 304 (M^+).

Third least polar isomer: mp 160–161°C; ir ($CHCl_3$, ν cm^{-1}): 1820, 1735, 1715; ^1H nmr (C_6H_6, δ ppm): 4.32 (d, 1H, J_{AB} = 14 Hz) and 3.76 (d, 1H, J_{AB} = 14 Hz) (AB pattern, OCH_2CO_2), 3.37 (d, 1H, J = 2 Hz, H-C11), 2.8–1.1 (m, 8H), 1.55 (s, 3H, CH_3CO), 1.01 (s, 3H, CH_3-C5), 0.77 (d, 3H, J = 7 Hz, CH_3C9); ms *m/e*: 304 (M^+).

Most polar isomer: ir ($CHCl_3$, ν cm^{-1}): 1820, 1745, 1715; ^1H nmr (C_6H_6, δ ppm): 4.34 (d, 1H, J_{AB} = 14 Hz) and 3.78 (d, 1H, J_{AB} = 14 Hz) (AB pattern, OCH_2CO_2), 3.48 (d, 1H, J = 2 Hz, H-C11), 2.8–1.1 (m, 8H), 1.55 (s, 3H, CH_3CO), 1.00 (s, 3H, CH_3-C5), 0.83 (d, 3H, J = 7 Hz, CH_3-C9); ms *m/e*: 304 (M^+).

Isomers ***123*** *and* ***124***

To a solution of the preceding Diels–Alder adduct mixtures (**121***a–b* and **122***a–b*) (200 mg, 0.66 mmol) in tetrahydrofuran (3 mL) was added aqueous sodium hydroxide (2.0 mL, 1 M). After 16 h of stirring at room temperature, the mixture was extracted with ether (5 × 20 mL). After evaporation of the solvents, the crude oily residue was chromatographed (preparative thick layer of silica gel, carbon tetrachloride, ether, benzene, 2:1:2) to give two products (55:45 of R_f values 0.30:0.25 respectively).

Less polar compound (**123** or **124**): R_f 0.30; mp 132–132.5°C; ir ($CHCl_3$, ν cm^{-1}): 3520, 1752, 1722; ^1H nmr ($CDCl_3$, δ ppm): 3.32 (d, 1H, J = 4.5 Hz, H-C11), 3.18 (br s, 1H, OH), 2.6–1.3 (m, 8H), 2.50 (br s, 2H, H_2Cl), 1.28 (s, 3H, CH_3-C5), 1.06 (d, 3H, J = 7 Hz, CH_3C9); ms *m/e*: 246 (M^+). *Anal.* calcd. for $C_{15}H_{18}O_3$: C 73.14, H 7.36; found: C 72.82, H 7.49.

More polar compound (**124** or **123**): R_f 0.25; mp 160–161°C; ir ($CHCl_3$, ν cm^{-1}): 3515, 1752, 1722; ^1H nmr ($CDCl_3$, δ ppm): 3.29 (d, 1H, J = 4.5 Hz, H-C11), 3.21 (br s, 1H, OH), 1.28 (s, 3H, CH_3-C5), 1.09 (d, 3H, J = 7 Hz, CH_3C9); ms *m/e*: 246 (M^+).

Diels–Alder adducts ***125*** *and* ***126***

A mixture of diene **97** (505 mg, 2.16 mmol) and optically active dienophile (*S*)-**74** (515 mg, 2.42 mmol) in benzene (4 mL) was refluxed for 12 h; then benzene was removed by evaporation to give an oily residue (1.0 g), which was dissolved in tetrahydrofuran (14 mL) and reacted with aqueous sodium hydroxide (5 mL, 1 M) for 24 h at 25°C. The mixture was then extracted with ether, washed with water, and ether was removed under reduced pressure to give a crude mixture (580 mg) that was dissolved in aqueous acetic acid (70%, 25 mL) and heated at 70°C for 1.5 h. Removal of acetic acid and ether extraction of the residue furnished a mixture of compounds (490 mg), which was dissolved in tetrahydrofuran (10 mL) and reacted with aqueous sodium hydroxide (1 M, 1.45 mL) for 16 h at 25°C. Extraction of the reaction medium with ether gave a crude mixture (400 mg) containing several compounds. This last mixture was dissolved in benzene (15 mL) and pyridine (0.25 mL) and reacted with an excess of phosgene in benzene during 1 h at room temperature. The mixture was then washed with water and extracted with ether. Chromatography of the crude extract on preparative thin layer (benzene–ether, 4:1) furnished a mixture (46 mg, 10%) of two compounds, isomers **125** and **126**, which were separated by fractional crystallization.

Isomer (***125*** or ***126***): mp 162–163°C; ir ($CHCl_3$, ν cm^{-1}): 2720, 1812, 1750, 1732; ^1H nmr ($CDCl_3$, δ ppm): 9.65 (d, 1H, J = 3 Hz, CHO), 3.40 (d, 1H, J = 5.5 Hz, H-C11), 3.2–1.5 (m), 1.35 (s, 3H, CH_3-C5), 1.14 (d, 3H, J = 7 Hz) and 0.80 (d, 3H, J = 7 Hz) ($CH(CH_3)_2$), 1.08 (d, 3H, J = 7 Hz, CH_3-C9). *Mol. Wt.* (ms) calcd. for $C_{21}H_{26}O_5$: 370.178; found 370.173.

Isomer (***126*** or ***125***): ir ($CHCl_3$, ν cm^{-1}): 2720, 1812, 1750, 1732; ^1H nmr ($CDCl_3$, δ ppm): 9.48 (d, 1H, J = 3 Hz, CHO), 3.38 (d, 1H, J = 5.5 Hz, H-C11), 3.2–1.5 (m), 1.35 (s, 3H, CH_3-C5), 1.14 (d, 3H, J = 7 Hz) and 0.80 (d, 3H, J = 7 Hz) ($CH(CH_3)_2$), 1.02 (d, 3H, J = 7 Hz, CH_3-C9); ms *m/e*: 370 (M^+).

Diels–Alder adducts ***128****a–b and* ***129****a–b*

A mixture of diene **6** (834 mg, 3.8 mmol) and acetoxy-2-acrylonitrile (1.0 g, 9.0 mmol) was heated at 127°C for 5 h. Removal of the dienophile under vacuum afforded a mixture of four compounds in the following proportion: 39:17:20:24, as determined by gas chromatography and increasing polarity. These were separated on a small scale by preparative thin-layer chromatography (carbon tetrachloride, ethyl acetate, benzene, 2:3:15).

Least polar compound (39%, R_f 0.70): mp 131–132°C; ir ($CHCl_3$, ν cm^{-1}): 1822, 1752; ^1H nmr ($CDCl_3$, δ ppm): 4.65 (d, 1H, J_{AB} = 15 Hz) and 4.38 (d, 1H, J_{AB} = 15 Hz) (AB pattern, OCH_2CO_2), 3.97 (s, 1H, H-C11), 2.7–2.0 (m, 8H), 2.12 (s, 3H, CH_3CO_2), 1.25 (s, 3H, CH_3C5); ms *m/e*: 331 (M^+). *Anal.* calcd. for $C_{17}H_{17}NO_6$: C 61.62, H 5.17, N 4.23; found: C 60.49, H 5.17, N 4.37.

Second least polar compound (17%, R_f 0.62): mp 182–182.5°C; ir ($CHCl_3$, ν cm^{-1}): 1822, 1752; ^1H nmr ($CDCl_3$, δ ppm): 4.70 (d, 1H, J_{AB} = 15 Hz) and 4.38 (d, 1H, J_{AB} = 15 Hz) (AB pattern, OCH_2CO_2), 3.99 (s, 1H, H-C11), 2.8–2.0 (m, 8H), 2.12 (s, 3H, CH_3CO_2), 1.25 (s, 3H, CH_3C5); ms *m/e*: 331 (M^+). *Anal.* calcd. for $C_{17}H_{17}NO_6$: C 61.62, H 5.17; found: C 62.17, H 5.16.

Third least polar compound (20%, R_f 0.55): ir ($CHCl_3$, ν cm^{-1}):

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

1822, 1752; ^{1}H nmr ($CDCl_3$, δ ppm): 4.65 (d, 1H, J_{AB} = 15 Hz) and 4.41 (d, 1H, J_{AB} = 15 Hz) (AB pattern, OCH_2CO_2), 4.14 (s, 1H, H-C11), 3.2–1.6 (m, 8H), 2.08 (s, 3H, CH_3CO_2), 1.25 (s, 3H, CH_3C5); ms *m/e*: 331 (M^+).

Most polar compound (24%, R_f 0.46): mp 191–192°C; ir ($CHCl_3$, ν cm^{-1}): 1822, 1752; ^{1}H nmr ($CDCl_3$, δ ppm): 4.70 (d, 1H, J_{AB} = 15 Hz) and 4.37 (d, 1H, J_{AB} = 15 Hz) (AB pattern, OCH_2CO_2), 4.16 (s, 1H, H-C11), 3.2–1.6 (m, 8H), 2.10 (s, 3H, CH_3CO_2), 1.25 (s, 3H, CH_3C5); ms *m/e*: 331 (M^+). *Anal.* calcd. for $C_{17}H_{17}NO_6$: C 61.62, H 5.17; found: C 60.99, H 5.25. Monocrystal X-ray diffraction analysis of this compound revealed that it had the structure shown by the formula **128***b* (Scheme 17). Complete X-ray data will be published elsewhere (8*b*).

Cyanohydrin diketone ***132***

(*a*) To Diels–Alder adduct **129***a* (or *b*) (least polar isomer, R_f 0.70, 18 mg, 0.054 mmol) in dimethoxyethane (1.5 mL) was added aqueous hydrochloric acid (0.2 mL, 1 M). After 12 h at 80°C, the mixture was extracted with ether to give a crude colored residue, cyanohydrin diketone **132** (17 mg); ir ($CHCl_3$, ν cm^{-1}): 3400, 1740; ^{1}H nmr ($CDCl_3$, δ ppm): 4.82 (br s, 1H, OH), 4.66 (s, 1H, HC11), 2.9–1.9 (m, 8H), 1.35 (s, 3H, CH_3-C5).

(*b*) With Diels–Alder adduct **129***b* (or *a*) (third least polar, R_f 0.55, 13 mg, 0.039 mmol), the same treatment gave the same cyanohydrin diketone **132** (9 mg).

Cyanohydrin diketone acetate ***134***

The preceding crude cyanohydrin diketone **132** (17 mg) was dissolved in pyridine (0.4 mL) and acetic anhydride (0.4 mL). After 20 h at room temperature, evaporation of the volatile materials left a residue that was dissolved in benzene, washed with water, and discolored with Norit. Removal of the solvent left a semicrystalline residue (18 mg). Crystallization from dichloromethane–ether gave an analytical sample of cyanohydrin acetate **134**; mp 210–210.5°C; ir ($CHCl_3$, ν cm^{-1}): 1752, 1740; ^{1}H nmr ($CDCl_3$, δ ppm): 4.24 (s, 1H, H-C11), 2.9–1.9 (m, 8H), 2.10 (s, 3H, CH_3CO_2), 1.37 (s, 3H, CH_3-C5); ms *m/e*: 273 (M^+). *Anal.* calcd. for $C_{15}H_{15}NO_4$: C 65.93, H 5.53; found: C 65.15, H 5.43.

*3,3-Ethylenedioxy-butanoic acid (****135****)*

A mixture of ketal ester **40** (*vide supra*) (15.0 g, 86 mmol) and aqueous potassium hydroxide (100 mL, 1.1 M) was refluxed for 5 h. The cooled mixture was then extracted with ether and the aqueous layer was acidified (pH 5) at 0°C with hydrochloric acid (1 M) and extracted with ether (3 × 50 mL). Evaporation of the solvent furnished pure acid **135** (7.02 g, 56%) as a white solid; mp 48–50°C; ir ($CHCl_3$, ν cm^{-1}): 3600–2900 (br), 1710; ^{1}H nmr (CCl_4, δ ppm): 11.45 (s, 1H, CO_2H), 3.92 (s, 4H, OCH_2CH_2O), 2.60 (s, 2H, CH_2CO_2), 1.47 (s, 3H, CH_3); ms *m/e*: 131 ($M^+ - CH_3$). *Anal.* calcd. for $C_6H_{10}O_4$: C 49.31, H 6.90; found: C 48.89, H 7.00.

*3,3-Ethylenedioxy-butanoyl chloride (****136****)*

To a cooled solution (6°C) of ketal acid **135** (17.5 g, 0.12 mol) in dry benzene (200 mL) and pyridine (10.7 mL, 0.132 mol) was added oxalyl chloride (16.8 g, 0.132 mol) in benzene (200 mL). After 3 h at room temperature the mixture was filtered and the solvent removed by evaporation. The residue was distilled under reduced pressure to furnish pure acid chloride **136** (18 g, 92%); bp 120°C (0.1 Torr); ir (CCl_4, ν cm^{-1}): 1811, 1100; ^{1}H nmr ($CDCl_3$, δ ppm): 3.96 (s, 4H, OCH_2CH_2O), 3.21 (s, 2H, CH_2CO_2), 1.43 (s, 3H, CH_3); ms *m/e*: 149 and 151 ($M^+ - 15$).

Ester ***138***

To a cooled (5°C) solution of acid chloride **136** (20.00 g, 120 mmol) in dry benzene (200 mL) and dry pyridine (9.50 g, 120 mmol) was added dropwise (10 min) a solution of 3-chloro-2-hydroxy propanenitrile (**137**) (12.65 g, 120 mmol) in benzene (200 mL). The mixture was warmed to room temperature, stirred for 12 h, and then decanted from the solid residue. The benzenic solution was washed with water and brine and the solvent evaporated. The oily residue was crystallized in the cold from ether–hexane to give pure ester **138** (22 g, 80%); mp 54–56°C; ir ($CHCl_3$, ν cm^{-1}): 1757, 1160, 1040; ^{1}H nmr ($CDCl_3$, δ ppm): 5.60 (t, 1H, *J* = 6 Hz, H-CCN), 4.00 (s, 4H, OCH_2CH_2O), 3.82 (d, 2H, H_2CCl), 2.74 (s, 2H, CH_2CO_2), 1.45 (s, 3H, $-CH_3$); ms *m/e*: 218 and 220 ($M^+ - 15$). *Anal.* calcd. for $C_9H_{12}NO_4Cl$: C 46.27, H 5.18, Cl 15.17; found: C 46.36, H 5.33, Cl 15.09.

*2-(3,3-Ethylenedioxy-butanoyloxy)acrylonitrile (****139****)*

To a solution of chloronitrile **138** (20.70 g, 89 mmol) in dry ether (200 mL) was added a solution of triethylamine (10.50 g, 98 mmol) in ether (200 mL). After 72 h of stirring at room temperature the mixture was decanted from the solid residue, which was washed with ether and the combined etheral fractions were evaporated. The residual liquid was distilled under vacuum to give pure nitrile **139** (13.34 g, 76%); bp 100°C, 0.03 Torr; mp 31°C; ir ($CHCl_3$, ν cm^{-1}): 2225, 1770, 1635; ^{1}H nmr ($CDCl_3$, δ ppm): 5.80 (d, 1H, J_{AB} = 3 Hz) and 5.74 (d, 1H, J_{AB} = 3 Hz) (AB pattern, H_2C=), 4.00 (s, 4H, OCH_2CH_2O), 2.84 (s, 2H, CH_2CO_2), 1.50 (s, 3H, CH_3); ms *m/e*: 182 ($M^+ - 15$). *Anal.* calcd. for $C_9H_{11}NO_4$: C 54.82, H 5.62; found: C 54.47, H 5.48.

Diels–Alder adducts ***140***a–b *and* ***141***a–b

A mixture of diene **6** (834 mg, 3.78 mmol) and dienophile **139** (1.020 g, 5.18 mmol) was heated at 120°C under nitrogen for 40 h. Crystallization of the crude mixture containing four main compounds of very similar polarity gave a low yield (30%) of a crystalline mixture of two compounds (470 mg), which were separated by thin-layer chromatography (silica gel, carbon tetrachloride – ethyl acetate – benzene, 2:3:15) to give two pure adducts.

Least polar compound (R_f 0.64): mp 151–152°C; ir ($CHCl_3$, ν cm^{-1}): 1820, 1750; ^{1}H nmr ($CDCl_3$, δ ppm): 4.60 (d, 1H, J_{AB} = 14 Hz) and 4.33 (d, 1H, J_{AB} = 14 Hz) (AB pattern, OCH_2CO_2), 3.96 (s, 4H, OCH_2CH_2O), 3.92 (s, 1H, H-C11), 2.70 (s, 2H, CH_2CO_2), 2.7–1.8 (m, 10H), 1.49 (s, 3H, CH_3-), 1.24 (s, 3H, CH_3-C5); ms *m/e*: 417 (M^+). *Anal.* calcd. for $C_{21}H_{23}NO_8$: C 60.42, H 5.55; found: C 60.46, H 5.67.

More polar compound **140***b* (R_f 0.56): mp 189–190°C; ir ($CHCl_3$, ν cm^{-1}): 1820, 1750; ^{1}H nmr ($CDCl_3$, δ ppm): 4.58 (d, 1H, J_{AB} = 15 Hz) and 4.34 (d, 1H, J_{AB} = 15 Hz) (AB pattern, OCH_2CO_2), 3.96 (s, 5H, OCH_2CH_2O and H-C11), 2.73 (s, 2H, CH_2CO_2), 2.42 (s, 2H, H_2C14), 2.8–1.8 (m, 6H), 1.47 (s, 3H, CH_3-), 1.24 (s, 3H, CH_3C5); ms *m/e*: 417 (M^+). *Anal.* calcd. for $C_{21}H_{23}NO_8$: C 60.42, H 5.55; found: C 60.10, H 5.32. Monocrystal X-ray diffraction analysis of this compound revealed that it had the structure shown by **140***b* (X = O, Y = H_2). Complete X-ray data will be published elsewhere (8*b*).

Chem. **68**, 153 (1990).

This paper reports several studies that were carried out to learn how to transform the dextrorotatory pentacyclic key intermediate **5** into (+)-anhydroryanodol (**6**). This transformation requires 24 steps, and takes place via the following intermediates: **5** → **11** → **19** → **34** → **36** → **39** → **144** → **150** → **6**. The preparation of the key pentacyclic intermediate **5** is reported in Parts I and II of this series.

Key words: anhydroryanodol, ryanodol, diterpene, organic synthesis, strategy.

Chem. **68**, 153 (1990).

On rapporte plusieurs études qui ont conduit à la transformation de l'intermédiaire-clé pentacyclique optiquement actif **5** en (+)-anhydroryanodol (**6**). Cette transformation de 24 étapes fait intervenir les intermédiaires suivants : **5** → **11** → **19** → **34** → **36** → **39** → **144** → **150** → **6**. La préparation de l'intermédiaire-clé pentacyclique **5** est rapportée dans les Parties I et II de la présente série.

Mots clés : anhydroryanodol, ryanodol, diterpène, synthèse organique, stratégie.

Introduction

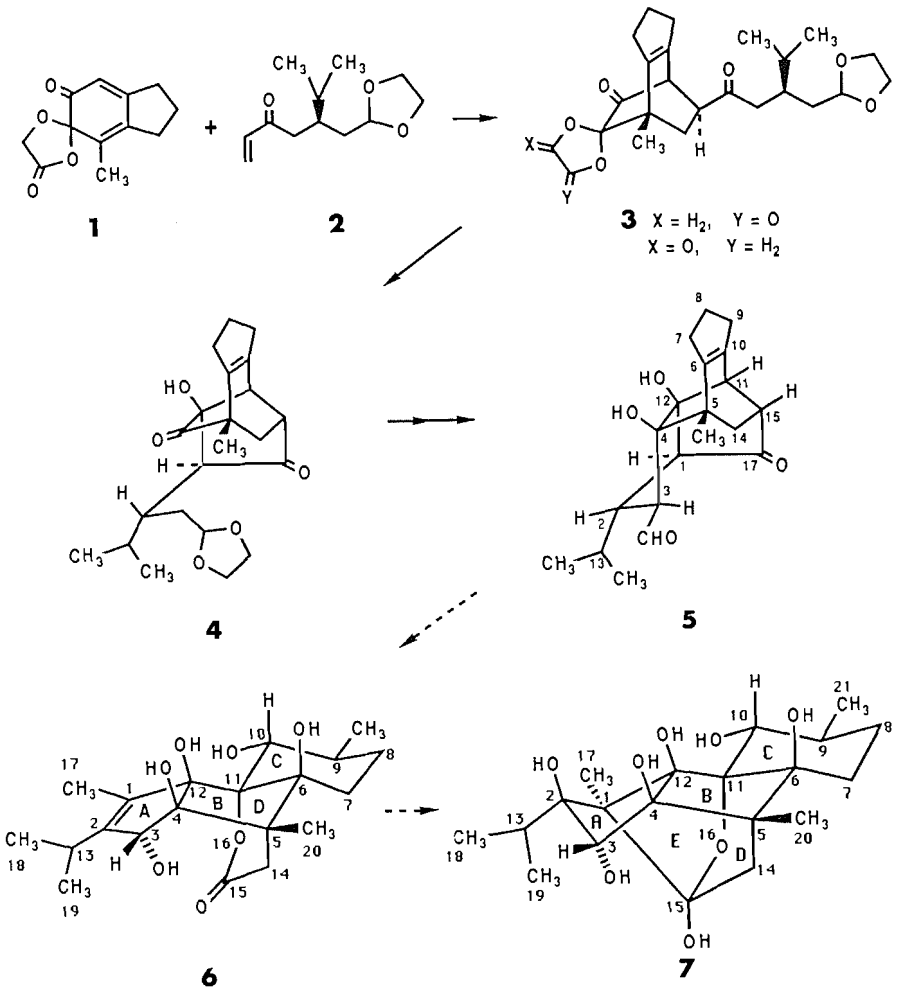
Part I (1) of this series of papers describes the general strategy that we have developed for the synthesis of (+)-ryanodol (**7**) (Scheme 1) via (+)-anhydroryanodol (**6**), and the finding that *o*-spirolactone dienone **1** is an excellent dissymmetrical diene, which undergoes a completely regiocontrolled Diels–Alder reaction with methyl vinyl ketone as a dienophile. Part II (2) describes our detailed investigations, which led to the discovery of a four-step synthesis (**1** + **2** → **3** → **4** →→ **5**) of the optically active dextrorotatory pentacyclic intermediate **5** starting from *o*-spirolactone dienone **1** and optically active vinyl ketone **2** (prepared from *d*-carvone). In this paper, we wish to report our studies leading to the transformation of the key pentacyclic intermediate **5** into (+)-anhydroryanodol (**6**).

The transformation of pentacyclic intermediate **5** into (+)-anhydroryanodol (**6**) requires several operations, which need to be examined in detail. First, comparison of the carbon structure of pentacyclic intermediate **5** with that of anhydroryanodol (**6**) revealed that the former contains all but one carbon atom to construct the latter, since it will be necessary to introduce one methyl group at C_9. There is, however, one extra carbon atom in intermediate **5**, i.e., that of the aldehyde functional group linked at C_3, which must be degraded into a C_3 *endo* alcohol. In addition to the methylation step at C_9 and the aldehyde degradation step at C_3, it is necessary to carry out a series of functional group transformations to produce anhydroryanodol (**6**) from intermediate **5**. These transformations are discussed next.

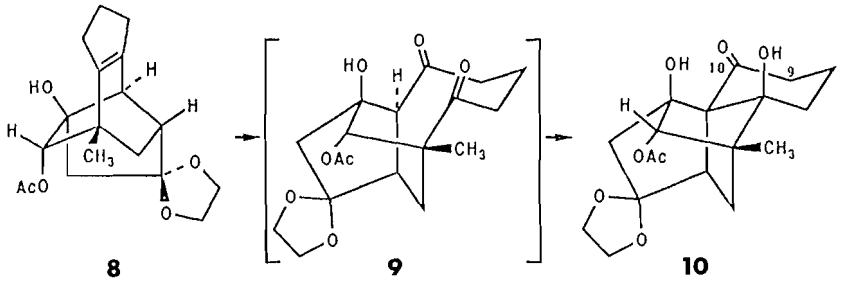
Using the carbonyl group at C_{17}, it will be necessary to discover a fragmentation process for the C_{15}—C_{17} bond that will leave functional groups at C_{15} and C_{17} respectively. The functional group left at C_{17} can then either be simply reduced to give a methyl group or can be used to produce the tetrasubstituted olefin at C_1—C_2 while generating the C_{17} methyl group by using a functional group transfer methodology. This second proposal is of course more profitable than the first one and it will be shown that we could very efficiently reduce this strategy to practice. Indeed, by utilizing a functional group at C_{17} it was possible to produce an *exo* olefin, between C_1 and C_{17}, which was then isomerized to simultaneously generate the endocyclic olefin between C_1 and C_2 and the C_{17} methyl group. Thus, alternative approaches to use a functional group at C_3 to introduce a degree of unsaturation between C_1 and C_2 were not seriously considered. It will, however, be shown that the functional group at C_3 was used to facilitate the formation of the exocyclic C_1—C_{17} olefin and its concomitant isomerization to the endocyclic position.

The functional group left at C_{15} from the C_{15}—C_{17} fragmentation process must be used to induce the formation of the lactone ring of anhydroryanodol (**6**). Originally, it was anticipated that the desired oxygen insertion between C_{11} and C_{15} would be carried out by a Baeyer–Villiger oxidation of a ketone function at C_{15}. It will, however, be shown that the oxidation of

[1]Author to whom correspondence may be addressed.



SCHEME 1



SCHEME 2

the C_{15} ketone function was attempted on several occasions, but was found to be completely unsuccessful. Consequently, a more lengthy procedure had to be conceived, which involves, first, a cleavage of the C_{11}—C_{15} bond, followed by lactone formation as a second step at a later stage.

To complete the synthesis, it was also necessary to oxidatively cleave the C_6—C_{10} tetrasubstituted olefin to generate *in situ* a macrocyclic diketone that would undergo a transannular aldol condensation producing simultaneously rings B and C as well as the hydroxyl group at C_6 and a carbonyl group at C_{10}. The feasibility of this important key transformation, which gives an entry into the anhydroryanodol skeleton from the oxidative cleavage of a tricyclic precursor containing a bicyclo[2.2.2]octene unit, had previously been verified using the model compound **8** (Scheme 2). Indeed, this compound was successively transformed into **10** via the intermediate formation of macrocyclic diketone **9** as described in Part II. The completion of the synthesis of anhydroryanodol would then be carried out by using the carbonyl group at C_{10} to introduce the methyl group at C_9 and to generate the secondary equatorial alcohol at C_{10} by reduction.

It can therefore be seen from the above analysis that several operations had to be performed to transform the key pentacyclic intermediate **5** into anhydroryanodol (**6**). In summary, these operations were (a) cleavage of the C_{15}—C_{17} bond, (b) introduction of a tetrasubstituted olefin between C_1 and C_2, (c) modification at C_{17} to yield a methyl group, (d) insertion of an oxygen atom between C_{11} and C_{15} to produce the lactone ring,

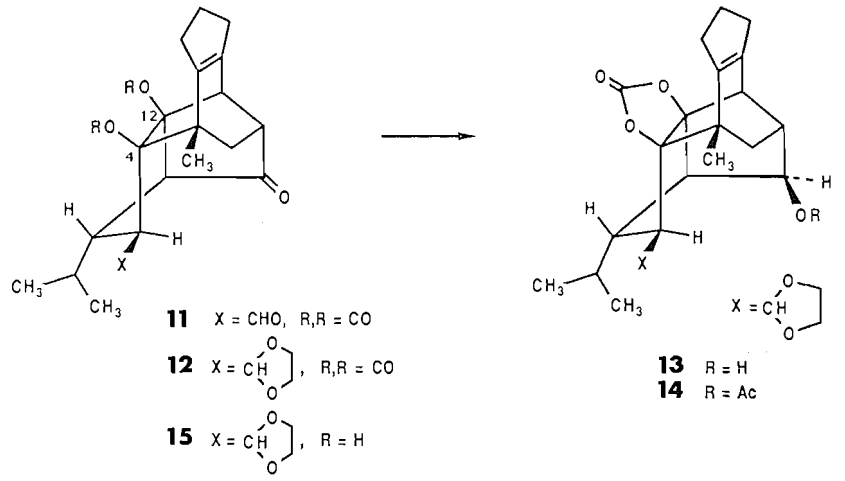
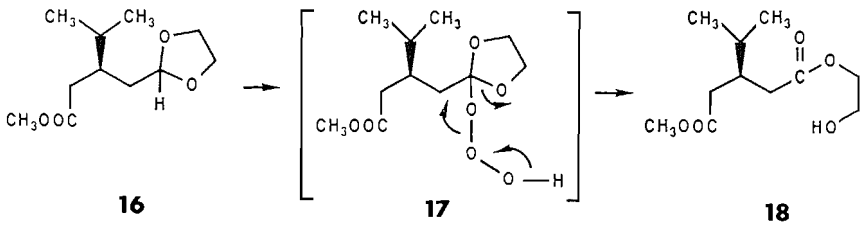


SCHEME 3



SCHEME 4

(e) oxidative cleavage of the double bond between C_6 and C_{10} and transannular aldol condensation, (f) introduction of a methyl group at C_9, (g) reduction of the newly generated ketone function at C_{10} into an equatorial alcohol, and (h) conversion of the aldehyde group at C_3 into an *endo* hydroxyl group.

Appropriate reagents and reaction conditions had to be found to carry out these various operations. Also, *it was important to discover the most convenient order* in which these transformations should be carried out from intermediate **5**, starting either from the aldehyde at C_3, the C_6—C_{10} olefin, or the ketone function at C_{17}. Among the above operations, some were considered more important than others, either because we were not completely sure how to realize them or because we had almost one unique way of achieving them. Operations (a) (cleavage of the C_{15}—C_{17} bond) and (d) (lactone formation) were classified in the former category whereas operation (e) (oxidative cleavage of olefin and transannular aldol condensation) was in the latter. We were convinced that there were several alternative solutions for solving the remaining chemical operations. Studies were therefore initiated to find acceptable pathways to solve operations (a), (d), and (e) first.

Oxidative cleavage and transannular aldol condensation (step (e))

Operation (e) was a great success in our model studies using compound **8** and we were confident that it would work equally well in the real series. However, we were most interested in verifying this and studies with the pentacyclic intermediate **5** were first started in this direction. The intermediate **5** was converted into the five-membered carbonate derivative **11** (cf. Part II) to prevent oxidative cleavage of the C_4—C_{12} *gem*-diol function. It was also decided that the aliphatic aldehyde function needs to be protected before attempting the oxidative cleavage of the tetrasubstituted olefin. The aldehyde **11** was therefore transformed into the dioxolane acetal **12** (Scheme 3) with ethylene glycol under standard acidic conditions (benzene, PTSOH).

The ozonolysis of **12** using a reductive work-up was carried out under conditions similar to those previously used in the model experiments. The starting material **12** was consumed rapidly but it gave a complex mixture of various products, as judged by thin-layer chromatography, from which no specific compound could be isolated. Furthermore, and to our complete dismay, various attempts at modification of the experimental conditions did not lead to further improvement. Being ignorant of the cause of this unpleasant and unexpected result, and being convinced that the dioxolane acetal was completely inert toward ozone, other derivatives of **12** were prepared by modification either of the C_{17} carbonyl group or of the 5-membered carbonate ring. Reduction ($NaBH_4$) of **12** gave the corresponding *endo* alcohol **13**, which was also converted to the acetate **14** (Ac_2O, Et_3N, DMAP). Also, basic hydrolysis of **12** gave the corresponding diol acetal **15**.

The oxidative cleavage of compounds **13**–**15** with ozone was also unsuccessful, yielding again an ill-defined mixture of products. Examination of the various reaction mixtures by ^1H nmr spectroscopy revealed that the characteristic doublet for the methine hydrogen of the dioxolane acetal had disappeared, and this suggested that, contrary to our expectation, this protecting group might not have survived the ozonolysis reaction. We therefore had to verify this assertion and submitted to ozonolysis the readily available acetal **16** (Scheme 4), an intermediate used in the preparation of optically active dienophile **2**. To our great surprise, compound **16** reacted with one equivalent of ozone, even at −78°C, producing the diester **18** quantitatively!

Thus, completely unexpectedly, we had discovered (3) a new reaction, which we decided to investigate in detail. Evidence was provided (4, 5) that this reaction proceeds via the insertion of ozone in the C—H bond of the acetal function, producing a hydrotrioxide tetrahedral intermediate (cf. **17**), which decom-

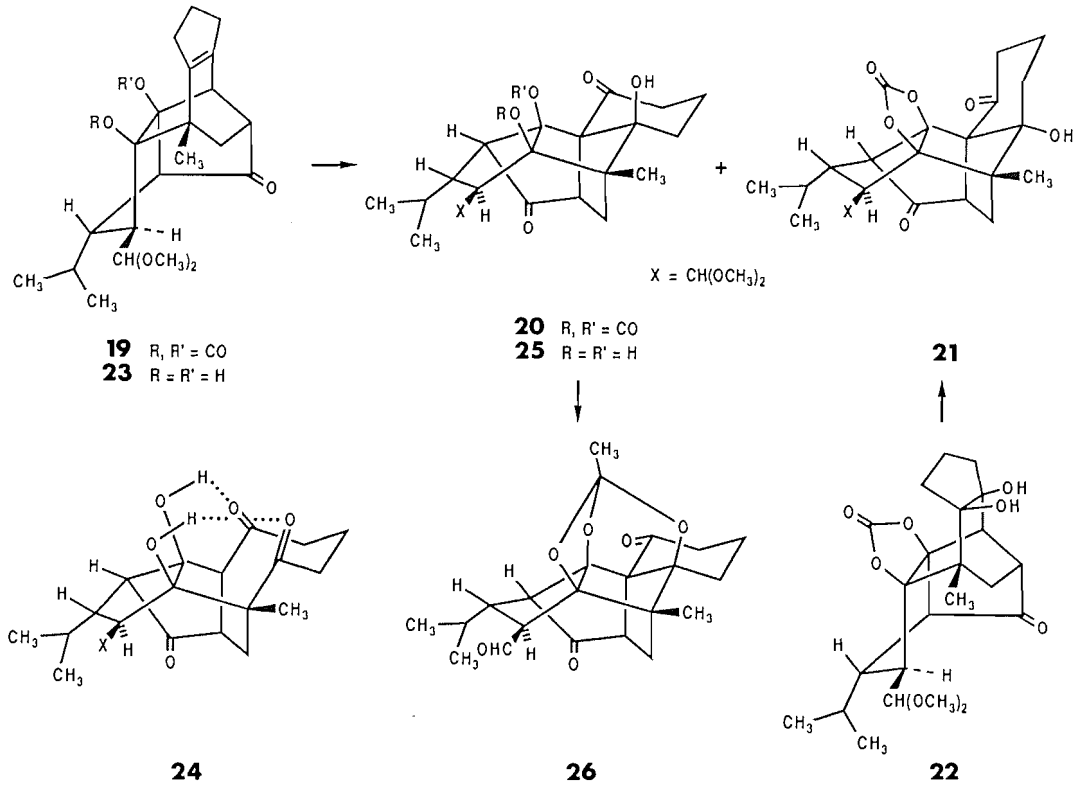

SCHEME 5

poses to yield the corresponding hydroxyester and molecular oxygen. We are now convinced that the ill-defined mixtures of products were obtained from compounds **13–15** because ozone reacted first with the dioxolane acetal, generating singlet oxygen (6) that must have been trapped by the tetrasubstituted olefin, producing unstable peroxide-containing compounds that underwent various decompositions.

Further studies (7, 8) of the ozonolysis reaction led us to discover that the ozone insertion is conformation dependent and is governed by stereoelectronic effects that come from the orientation of the nonbonded electron pairs of the oxygen atoms of the acetal function. It was also observed that the fragmentation of the resulting tetrahedral hydrotrioxide intermediates is also conformation dependent and the results could also be rationalized on the basis of stereoelectronic effects. Further studies (9, 10) on the stereocontrolled fragmentation of various tetrahedral intermediates were carried out in our laboratory and this work led us to propose a new general theory for the understanding of hydrolytic processes, which is primarily based on stereoelectronic principles (11–13). Consequently, this completely unexpected annoying result led to the discovery of a rather fruitful event!

In the course of the study on the ozonolysis of acetals, we had also found that by comparison with cyclic dioxolane acetals, dialkoxy acetals were oxidized at a much slower rate, and on that basis, a dimethoxy acetal could likely be used as a protecting group for the aldehyde function. The dimethoxyacetal **19** (Scheme 5) was therefore prepared from the pentacyclic aldehyde **11** under standard conditions (CH_3OH, $HC(OCH_3)_3$, PTSOH), and submitted to the ozonolysis reaction (O_3, CH_3OH, $(CH_3)_2S$). Contrary to the previous ozonolysis experiments, a very clean reaction took place, producing 95% yield of a mixture of the isomeric aldol products **20** and **21** in a 1:2 ratio. It was also observed that if the same ozonolysis reaction was carried out in the presence of an equivalent of *p*-toluenesulfonic acid, the proportion of the desired isomer **20** was raised (7:3 ratio). Since isomers **20** and **21** did not equilibrate under these conditions, the presence of acid must favor kinetically the formation of the desired isomer **20**. Interestingly, hydroxylation of olefin **19** with osmium tetroxide gave a *cis* diol assigned structure **22**, which upon cleavage with periodic acid gave exclusively the undesired aldol isomer **21**.

The ozonolysis of the diol olefin **23**, which was obtained from the basic hydrolysis of **19**, was also investigated. It was hoped that the presence of the diol function would create internal hydrogen bonding with the carbonyl groups in the diketone intermediate, favoring conformation **24**, which should lead to the desired aldol product **25**. The reaction was carried out and produced only the desired product **25** as anticipated, but the yield was only 28%. This low yield was explained by the presence of the vicinal diol, a grouping known to be sensitive to oxidative reagents. The structure of **25** was rigorously established by its conversion into the orthoacetate aldehyde **26** upon treatment with acetic anhydride containing perchloric acid followed by mild basic hydrolysis (Na_2CO_3, H_2O).[2]

In another series of experiments, mild acetylation (Ac_2O, AcONa) of pentacyclic diol aldehyde **5** gave a monoacetate assigned structure **27** (Scheme 6), which was also investigated. This compound was interesting because the aldehyde was left unprotected; also, one of the tertiary hydroxyl groups was available to direct the transannular aldol condensation (via intramolecular hydrogen bonding), and the presence of the acetate

[2]In acidic medium, **25** is first converted into the enol acetate (of the aldehyde at C_3) of compound **26**, which is then transformed under basic conditions into the orthoacetate aldehyde product **26**.

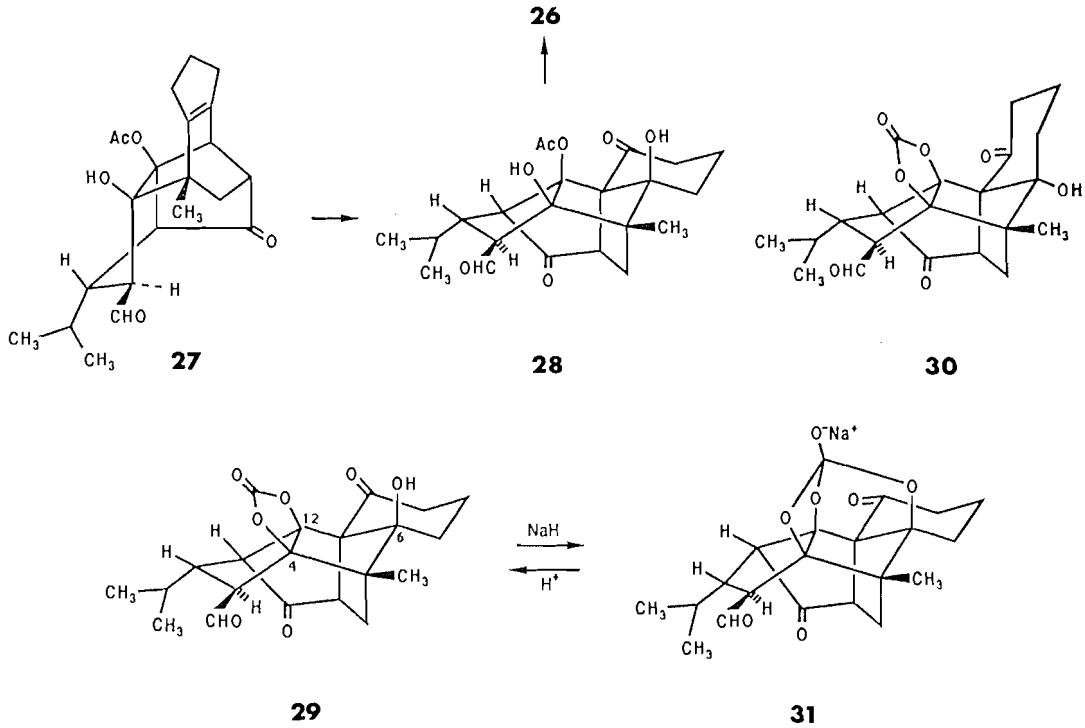

SCHEME 6

group was protecting the diol function from further oxidation. Ozonolysis of **27** gave a moderate 50% yield of monoacetate **28**, which on simple heating in benzene afforded the previously described orthoacetate **26** in 80% yield.

Formation of orthoacetate derivatives had previously been used in the chemical elucidation of anhydroryanodol (14) to establish the relative configuration for the tertiary alcohols at C_4, C_6, and C_{12}. In our work, the formation of orthoacetate derivative **26** rigorously established the stereochemistry of the desired aldol condensation products (i.e., **25** and **28**). There was also the possibility of using the orthoester as a protecting group. We found, however, that this group was extremely resistant to hydrolysis. For instance, on attempted acid hydrolysis with 50% sulfuric acid, compound **26** was completely recovered. So we learned that if the triol needs protection, an orthoacetate cannot be used.

We also learned from the oxidation of compound **27** that the aliphatic aldehyde does not need protection during the course of the oxidative cleavage of the tetrasubstituted olefin. This was further verified by treating the pentacyclic olefin **11** with ozone. Under neutral conditions, a 70% yield of **29** and **30** was obtained in a 1:2 ratio; under acidic conditions, the yield was the same but the ratio changed to 5:2. We thus realized that it is not absolutely necessary to protect the aldehyde function. On the other hand, had we not carried out the above investigation, we would not have discovered the ozonolysis reaction of acetals that led to the stereoelectronic theory!

Another interesting observation was made while trying to prove the relative stereochemistry of the isomeric aldol products **29** and **30**. Using isomer **29**, it was found that upon addition of sodium hydride in anhydrous tetrahydrofuran, the infrared bands at 3540 and 1825 cm^{-1} responsible for the tertiary alcohol and the five-membered ring carbonate disappeared. On addition of acid, these absorptions reappeared on the spectrum. This was explained by the formation of the hemi-orthocarbonate sodium salt **31**. This experiment thus provided a rigorous proof of stereochemistry for the aldol product **29** and gave us an indication on how to develop reversible protecting groups for the triol grouping at C_4, C_6, and C_{12} (*vide infra*).

We were also satisfied with the above results that demonstrated that the oxidative cleavage and transannular aldol condensation could easily take place on the pentacyclic system, and our attention was turned to the cleavage of the C_{15}—C_{17} bond followed by the insertion of an oxygen atom between C_{11} and C_{15} to produce the lactone of anhydroryanodol, i.e., operations (a) and (d) as previously classified.

Cleavage of the C_{15}—C_{17} bond (step (a)) and synthesis of intermediates 37, 38, and 39

The cleavage of the C_{15}—C_{17} bond was studied using two different reactions, the Beckmann rearrangement and the Baeyer–Villiger oxidation. In the first study, the ketone **19** was converted into the oxime derivative **32** (Scheme 7), which was mesylated and subjected to rearrangement by refluxing in dioxane–water. This provided one major product isolated in 70% yield, the structure of which corresponds to pentacyclic lactam **33**. By nmr spectroscopy, after deuterium exchange, the methine-bearing nitrogen atom appears at δ 3.93 as a doublet (J = 3.5 Hz). This multiplicity is possible for structure **33**. Thus, the undesired C_1—C_{17} cleavage had taken place and this approach was not continued further.

The second study, using the Baeyer–Villiger rearrangement, proved to be more successful. Oxidation of compound **19** with 40% peracetic acid gave a good yield of isomeric epoxylactones **34** and **35** in a 85:15 ratio. These compounds were easily distinguished by the multiplicity of their lactonic proton in nmr. Lactone **34** shows a doublet of doublets of doublets (J = 4.5, 2.5, and 9.8 Hz) at δ 4.60 for H-C_{15} and lactone **35** shows a doublet (J = 3.3 Hz) at δ 4.89 for H-C_1. Use of other peracids like *m*-chloroperbenzoic or trifluoroperacetic led to lower yields and a ratio less in favor of the desired epoxylactone **34**. The mixture of **34** and **35** was submitted to retroepoxidation condi-

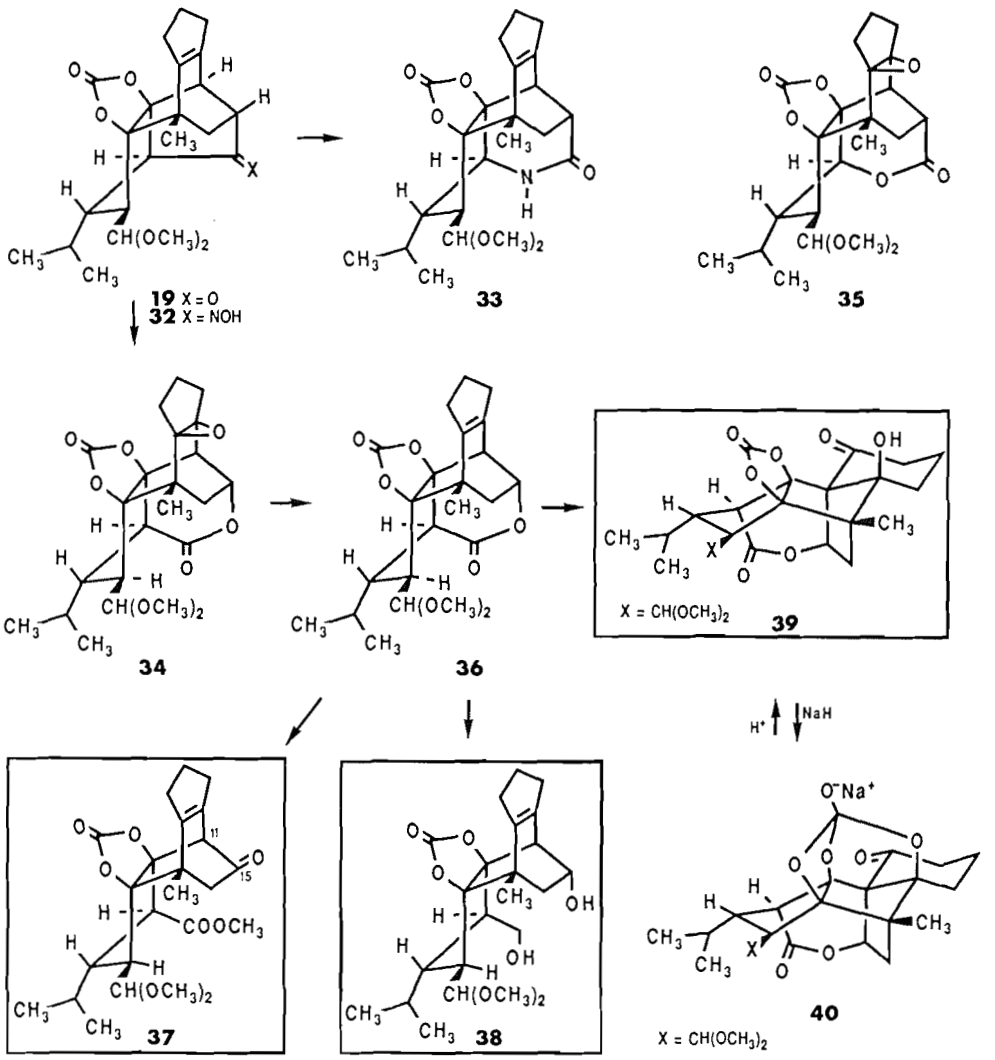


SCHEME 7

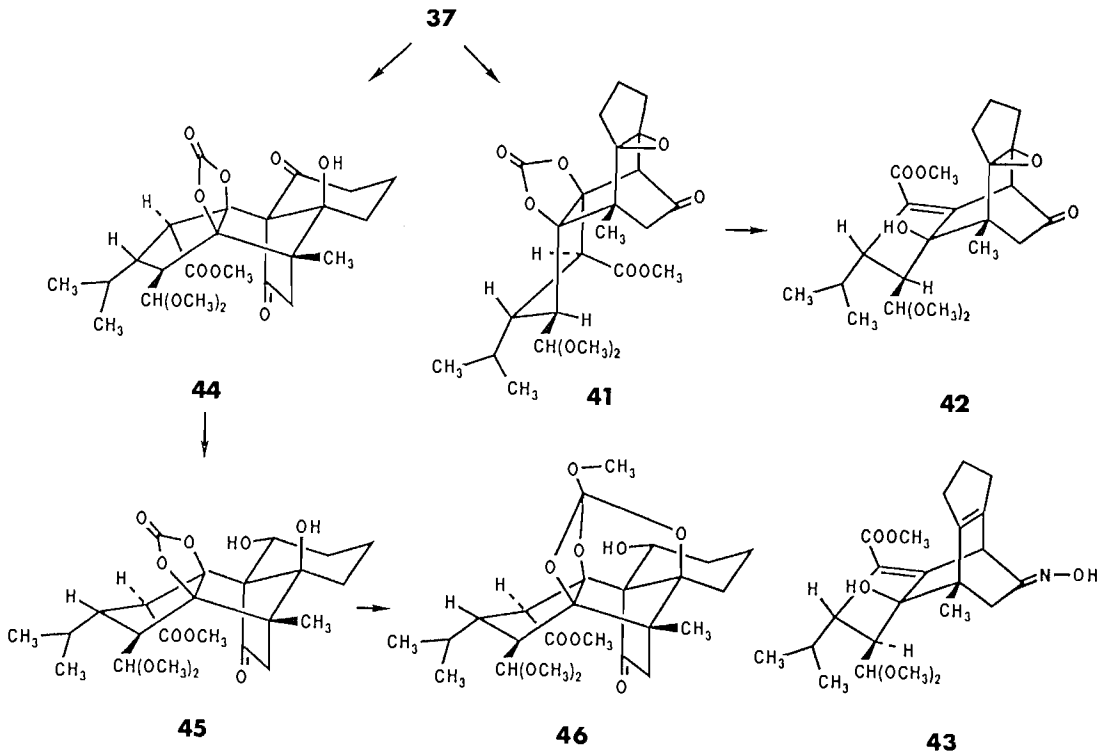
tions (WCl_6, 3BuLi in THF) (15), and the desired pentacyclic olefinic lactone **36** was obtained pure (chromatography followed by crystallization) with an overall yield of 75% from **19**.

The desired C_{15}—C_{17} cleavage had taken place with the formation of lactone **36**. The remaining chemical investigations were all carried out starting from this key intermediate from which three different type of products were obtained, the ketoester **37**, the diol **38**, and the transannular aldol product **39**. The chemical reactivity of each of these products was then studied in some detail to find the most appropriate method of elaborating the correct functionalities of ring A, and to learn when it would be most convenient to carry out step (e) (oxidative cleavage and transannular aldol condensation). These studies were also essential to discover a method for step (d) (oxygen insertion between C_{11} and C_{15}) to produce the lactone ring of anhydroryanodol.

The ketoester **37** was obtained in 74% yield from pentacyclic lactone **36** using the following three-step procedure: (a) selective hydrolysis of the lactone ring of **36** using lithium hydroxide in a mixture of dimethoxyethane and water, (b) esterification of the resulting hydroxycarboxylic acid salt with trimethyloxonium tetrafluoroborate (16) in the same aqueous medium (17, 18), and (c) oxidation of the secondary alcohol at C_{15} with Collins reagent (19). On the other hand, the diol **38** was conveniently obtained in a single operation by selective reduction of lactone **36** with lithium borohydride in tetrahydrofuran. Finally and most interestingly, the ozonolysis (O_3, PTSOH, CH_3OH; $(CH_3)_2S$) of pentacyclic olefin lactone **36** gave the desired transannular aldol isomer **39** in an impressive yield (>95%). The stereochemistry of aldol product **39** was again established by observing the formation of the hemi-orthocarbonate sodium salt **40** with sodium hydride in anhydrous tetrahydrofuran. It was also observed that, upon acidification, salt **40** gave back compound **39** as expected.

Studies with ketoester 37

The successful formation of ketoester **37** gave us our first opportunity to try the oxygen insertion between C_{11} and C_{15}. However, all attempts to carry out the Baeyer–Villiger reaction (step (d)) on ketoester **37** failed. The epoxyketoester **41** (Scheme 8) could be easily prepared from **37** under the Baeyer–Villiger reaction conditions, but it could not not be further transformed into the desired lactone. The poor reactivity of compound **41** towards the Baeyer–Villiger reaction is presumably due, at least in part, to the steric hindrance caused on one side of the carbonyl group by the oxirane ring, and by the carbomethoxy group on the other. Attempts were then made to epimerize the *endo* carbomethoxy group at C_1 in order to reduce



SCHEME 8

the steric hindrance of the C_{15} carbonyl group. However, no isomerization was observed with potassium *tert*-butoxide in *tert*-butanol and treatment of ketoester **37** with 1,5-diazabicyclo[4.3.0]non-5-ene (DBN) in dimethoxyethane led to the undesired elimination product, epoxyester **42**. Even the formation of the oxime derivative of **37** was not successful under mild conditions: the oxime isolated was that of the conjugated ester, i.e., compound **43**, indicating that the elimination of the carbonate was a rather facile process under those conditions.

Ketoester **37** was then submitted to the ozonolysis reaction (O_3, CH_2Cl_2–CH_3OH, PTSOH (cat); $(Me)_2S$) and it produced the desired aldol product **44** in 80% yield. Selective reduction of **44** with sodium borohydride gave dihydroxyketone **45** having an equatorial alcohol in ring C. Upon basic treatment (NaH, THF) compound **45** formed the corresponding hemi-orthocarbonic acid sodium salt, which gave back **45** by the addition of acid. Moreover, it was discovered that compound **45** reacts smoothly with diazomethane in chloroform–ether to provide the stable methyl orthocarbonate **46** in good yield. The formation of **46** suggested that alkyl orthocarbonate could be used to protect the triol grouping if that becomes necessary later on. Again, the Baeyer–Villiger oxidation was attempted with compounds **45** and **46**, but no reaction was observed. The poor reactivity of **45** and **46** towards the Baeyer–Villiger reaction is not surprising since molecular models clearly showed that the C_{15} carbonyl group is even more hindered in these two compounds than in epoxyketoester **41**. This is confirmed by the fact that under the conditions used to form the oxime derivative **43** from ketoester **37**, no reaction was observed with **45** and **46**, starting material being recovered in both cases. No further experiment was then carried out starting from ketoester **37**.

Studies with pentacyclic carbonate diol 38

One of the first experiments carried out with diol **38** was the Jones oxidation, which led to the isolation of hemi-ketal **47** in 80% yield (Scheme 9). This result is readily explained because (a) a secondary alcohol is usually oxidized faster than a primary one (28) and (b) as soon as the ketone is produced at C_{15}, the remaining primary alcohol forms the hemi-ketal and is thus protected from oxidation.

Further oxidation of hemi-ketal **47** was next investigated, and it was found that oxidation of **47** with ceric ammonium nitrate (20, 21) yielded the interesting bridged eight-membered lactone **48**. This compound was very interesting because the desired C_{11}—C_{15} bond cleavage, half of step (d), was being achieved by using this new oxidative cleavage reaction. The next step was to find a method to form the lactone ring that corresponds to that found in anhydroryanodol (cf. → **52**). Basic hydrolysis (LiOH in DME–H_2O) of **48** gave the corresponding hydroxycarboxylic acid **49**. This compound was further characterized by forming the acetate carboxylic acid **50** with acetic anhydride and pyridine, and the hydroxy methyl ester **51** with diazomethane. It was hoped that a treatment of the acetate carboxylic acid **50** with a strong proton source, such as *p*-toluenesulfonic acid in benzene, would result in the formation of the desired lactone **52**. However, the product formed under these conditions was the methoxylactone **53**. This result showed that, under these conditions, the lactonization of the carboxylic acid chain with the enol ether at C_3 (presumably formed *in situ* by the elimination of methanol from the dimethoxyacetal grouping) was more facile. It is in principle possible to avoid this undesired lactonization process either by changing the reaction conditions or by modification of the dimethoxyacetal into a more appropriate protecting group. This type of investigation was not continued further. However, it will be seen that an analogous C_{11}—C_{15} fragmentation involving the formation of a bridged eight-membered lactone was eventually used in the final sequence.

Two additional experiments within this particular series are worth reporting, both involving the oxidative cleavage – transannular aldol condensation process. Ozonolysis (O_3, CH_2Cl_2–

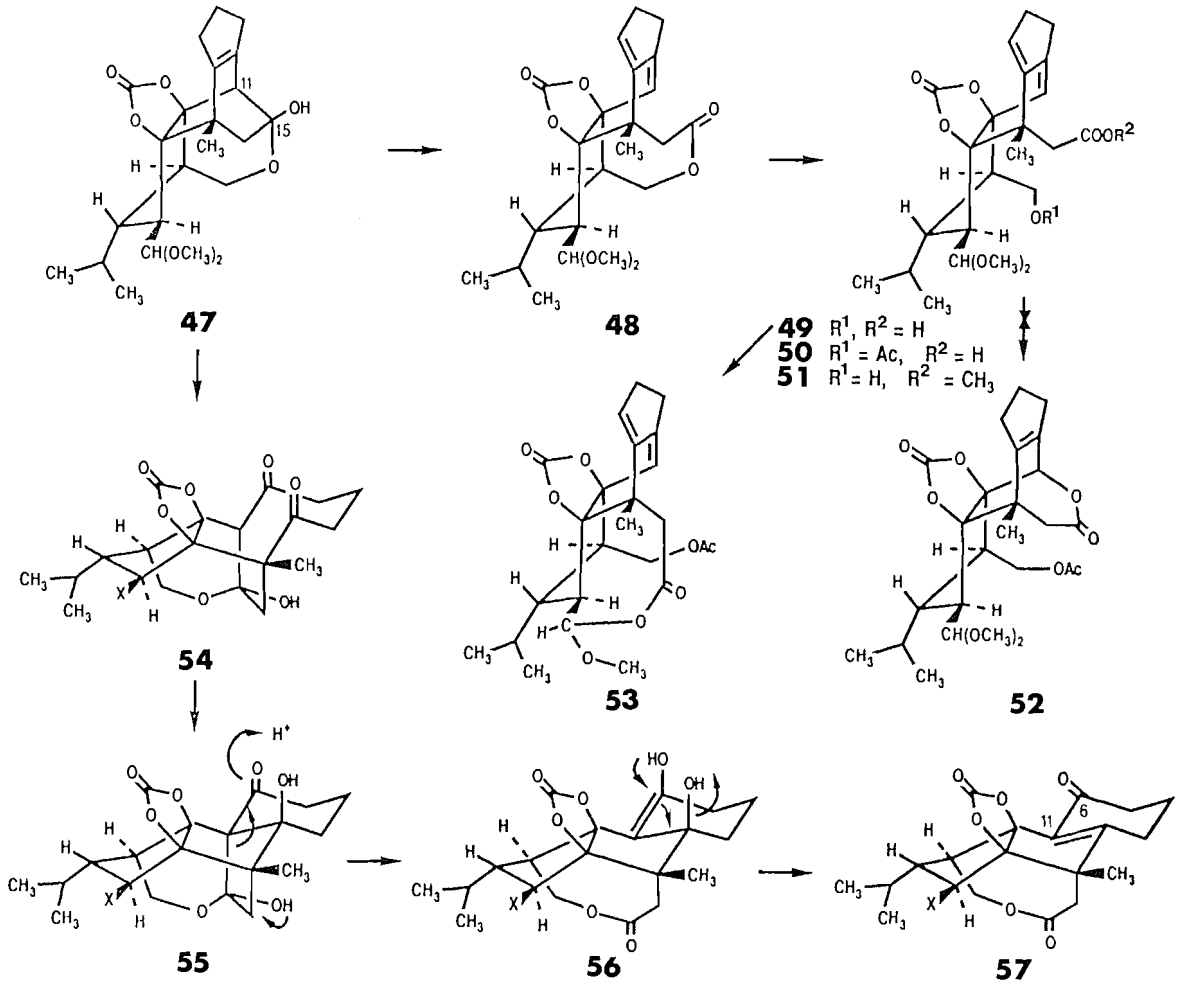

SCHEME 9

CH_3OH, PTSOH; $(CH_3)_2S$) of hemi-ketal **47** provided directly the lactone product **57** (75% yield) having a general skeleton corresponding to that of anhydroryanodol (**6**). This remarkable transformation can be explained via the intermediate formation of aldol product **55** via diketone **54**, which must have gone through a retro-Claisen fragmentation followed by the elimination of the OH group at C_6 (cf. **47** → **54** →→→ **57**) to produce conjugated enone **57**. In principle, *trans* hydroxylation at C_6 and C_{11} on **57** should yield a useful synthetic intermediate for the synthesis of anhydroryanodol; however, all attempts to realize such conversion were unsuccessful.

Olefin diol **38** was also treated with ozone under the above conditions and the tricyclic enone aldehyde **60** (Scheme 10) was isolated in moderate yield. The expected product should have had structure **58**; however, the formation of aldehyde **60** can be readily explained by a retro-aldol condensation of **58** followed by carbonate elimination as shown. Thus, contrary to the previous fragmentation process **47** → **57**, the carbonate group at C_{12} rather than the hydroxyl group at C_6 was eliminated. This result is easily understood because a carbonate oxygen is a much better leaving group than a hydroxyl group and step **59** → **60** is then not surprising. In the previous fragmentation **47** → **57**, the hydroxyl group at C_6 was preferably eliminated (**56** → **57**) because the ejection of the carbonate oxygen would have generated a highly strained C_{11}—C_{12} olefin (cf. **61**). Indeed, molecular models clearly indicate that this olefin is quite strained when the bridged eight-membered lactone ring is present as in **61**.

In another investigation (Scheme 11), diol **38** was selectively converted into a mono-*p*-nitrobenzoate, which was oxidized with Collins reagent (19) to yield keto-*p*-nitrobenzoate **62** (>95% yield) from which several important studies were undertaken. The *p*-nitrobenzoate ester was chosen in preference to an acetate, a benzoate, a methyl carbonate, or a mesylate (all of these have been prepared) protecting group for the following reasons: The selective esterification of the primary alcohol with *p*-nitrobenzoyl chloride in pyridine took place in high yield. Also, the various *p*-nitrobenzoate intermediates were stable compounds, and yet this group became a relatively good leaving group when it became necessary to generate the *exo* olefin (*vide infra*).

One of the main studies with *p*-nitrobenzoate **62** was the development of an appropriate sequence for the elaboration of the correct functionalization of ring A of anhydroryanodol (**6**). This is discussed next.

Functionalization of ring A (steps (b), (c), and (h))

Keto-*p*-nitrobenzoate **62** was converted into the epoxide **63** by treatment with *m*-chloroperbenzoic acid. As in the previous cases, epoxide **63** did not undergo the Baeyer–Villiger rearrangement, but it turned out to be a useful compound to elaborate ring A because the oxirane ring served to prevent the oxidative cleavage of the tetrasubstituted olefin in the course of the degradation of the dimethylacetal at C_3.

When compound **63** was heated to reflux in benzene contain-

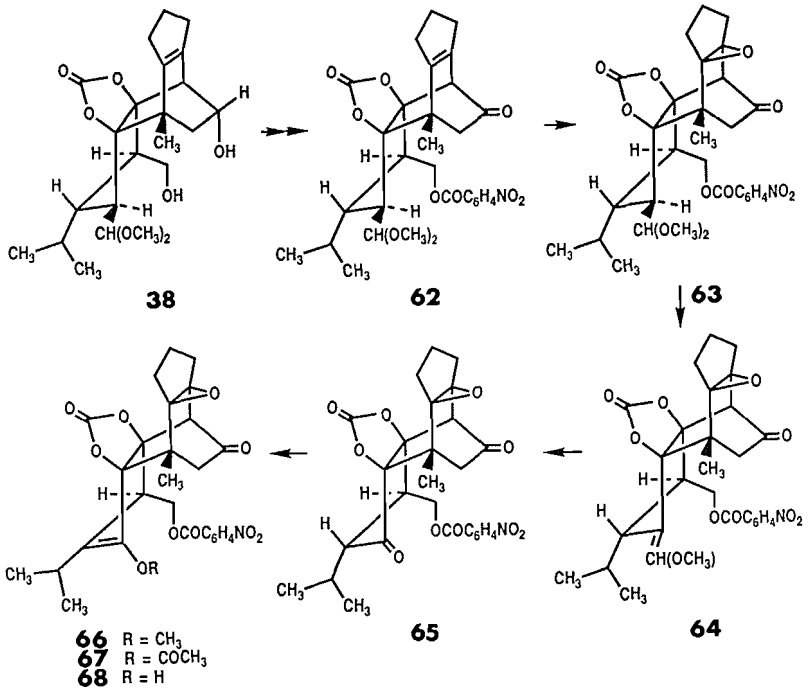

SCHEME 11

ing a catalytic amount of *p*-toluenesulfonic acid, there was obtained a mixture of isomeric enol ethers **64**, which were converted into norketone **65** (90% yield from **63**) by reaction with ozone. It was then discovered that norketone **65** reacted smoothly with diazomethane in ether at room temperature within a few hours, producing the endocyclic enol ether **66**. This smooth and unexpected reaction indicates that the unactivated five-membered ketone **65** must undergo enolization very readily. The easy formation of enol acetate derivative **67** from ketone **65** under mild conditions (CH_3COONa, $(CH_3CO)_2O$, 90°C, 1 h) further illustrates this facile enolization, and we suggest that steric strain might be responsible for this unusual reactivity. Indeed, molecular models show that the isopropyl group in **65** is quite severely hindered (raising the energy level of **65**) and that this steric repulsion is completely released in the corresponding enol **68**.

Reaction of enol ether **66** with 1,5-diazabicyclo[4.3.0]non-5-ene (DBN) in refluxing benzene afforded dienol ether **69** (76% yield from **65** (Scheme 12)). Under similar conditions, enol acetate **67** gave directly the enone **71** (65% yield from **65**). The absence of the expected dienol acetate **70** from **67** was explained by proposing that DBN should be basic enough to generate the enolate anion of the acetate grouping, which could then cleave to form ketene and the enolate anion of enone **71**. The facile elimination of the *p*-nitrobenzoate ester, which is a relatively poor leaving group, is likely due to the fact that the hydrogen at C_1 is allylic in compounds **66** and **67**.

The retroepoxidation step (WCl_6, 3BuLi in THF) (15) was carried out on epoxide **69** to give the corresponding olefin **72**, which was then converted into the desired enone **73** with boron trifluoride etherate, completing the appropriate functionalization of ring A of anhydroryanodol (**6**). Once the pentacyclic

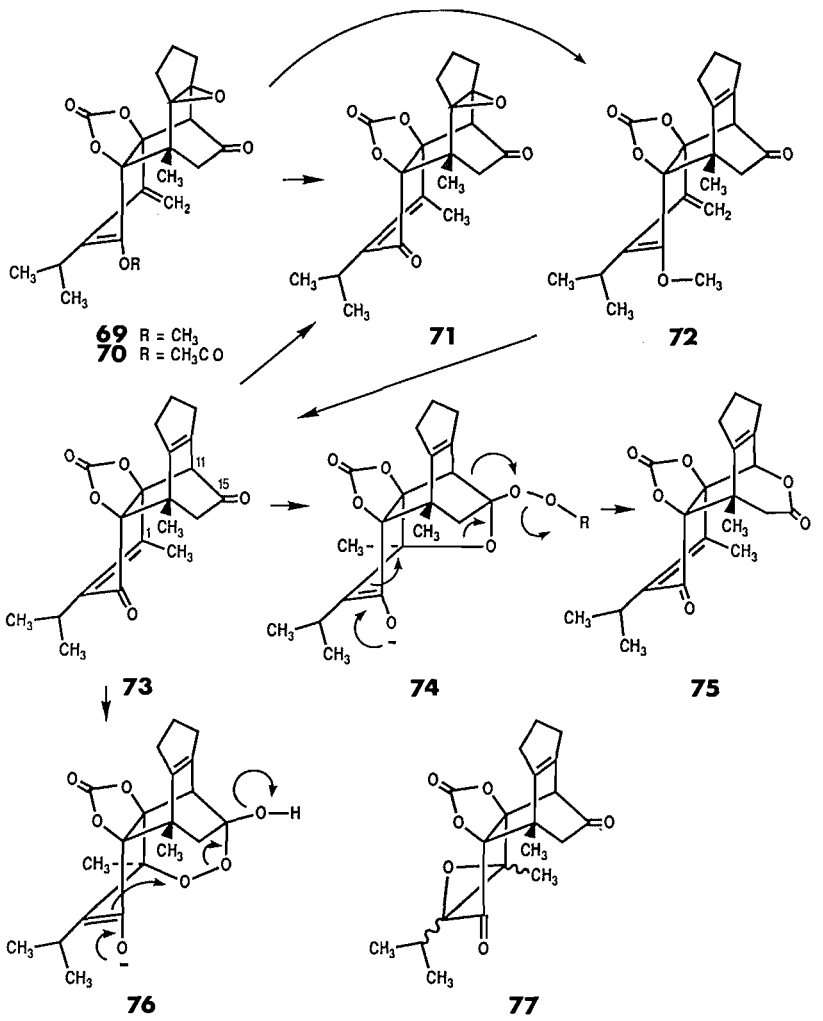

SCHEME 12

enone olefin **73** was secured, we had great hope that we could successfully accomplish step (d), i.e., the insertion of an oxygen atom between C_{11} and C_{15}. This was based on the fact that the carbonyl group at C_{15} is now much less hindered than in previous examples because C_1 is sp^2 hybridized. It could also be anticipated that the presence of an enone in ring A might activate the carbonyl group at C_{15} towards nucleophilic reagents. Indeed, it was plausible that the required intermediate for the Baeyer–Villiger oxidation **73** → **75** would form easily because it would exist in the trapped form **74**.

Treatment of enone **73** with trifluoroperacetic acid gave epoxyenone **71**, previously obtained from enol acetate **70**. Epoxyenone **71** proved to be completely inert toward various peracids and the desired Baeyer–Villiger oxidation could not be realized. Also, attempts to effect the Baeyer–Villiger rearrangement under basic conditions failed. For instance, enone **73** reacted under basic conditions with hydrogen peroxide to give α,β-epoxyketone **77** of undetermined configuration. It is possible that the epoxide has the α-configuration, which would be the result of the preferred formation of peroxide intermediate **76**. There are precedents in the literature for similar epoxidation being directed by a neighboring carbonyl group (22). However, the exact stereochemistry of the epoxide **77** was not established.

The oxidative cleavage of the olefin at C_6 and C_{10} followed by the transannular aldol condensation (step (e)) was also investigated with enone **73**. It led to the formation of interesting compounds that were, however, completely useless for the synthesis of anhydroryanodol. For instance, when the ozonolysis was carried out in dichloromethane–methanol, the bicyclic product **81** (Scheme 13) was isolated in excellent yield. This rather interesting transformation is easily understood: tetraketone **78** must first be formed and must react with methanol to undergo a Claisen rearrangement (**78** → **79** → **80**), producing *in situ* enol **80**, which then undergoes the elimination of the carbonate group. When methanol was omitted, the ozonolysis reaction took a completely different course, producing an unstable transannular aldol product that was identified spectroscopically. The undesired transannular aldol structure **82** was assigned to this product on the basis that it was found to be unreactive with diazomethane. Indeed, if this compound had the isomeric aldol structure at C_6, the corresponding methoxyorthocarbonate should have been observed.

No further work was carried out from enone **73**. We had learned how to functionalize ring A, and it was also concluded that the oxidative cleavage – transannular aldol condensation process had to be carried out first. With this in mind, we returned to keto-*p*-nitrobenzoate **62**.

Studies with p-*nitrobenzoate* ***62***

Ozonolysis (O_3, EtOAc, PTSOH; $(CH_3)_2S$) of keto-*p*-nitrobenzoate **62** gave the desired transannular aldol product **83** (Scheme 14), which was converted with diazomethane into the

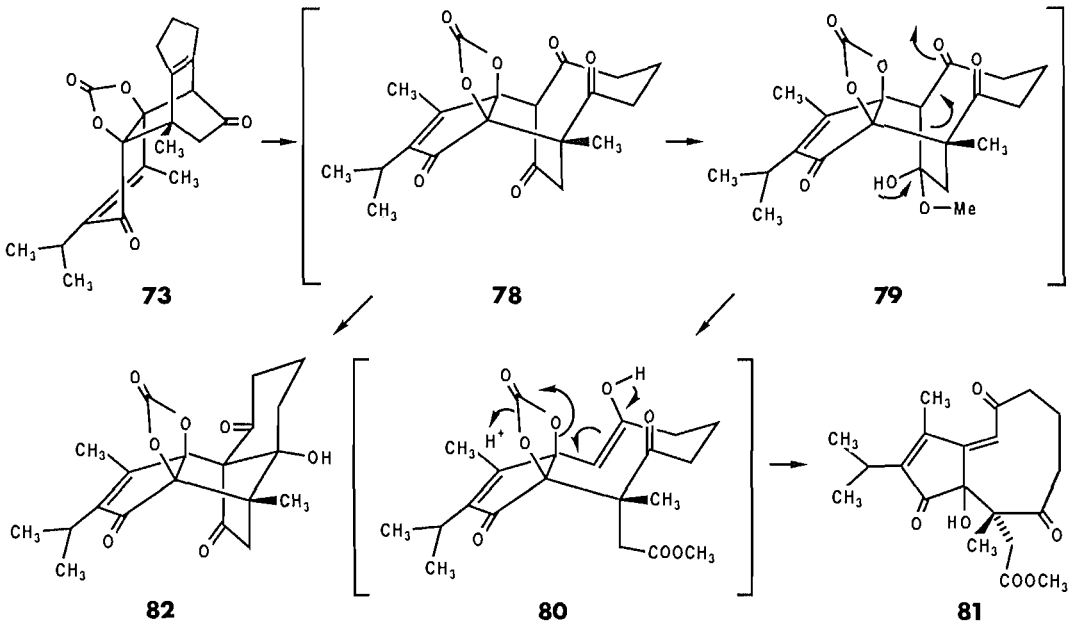
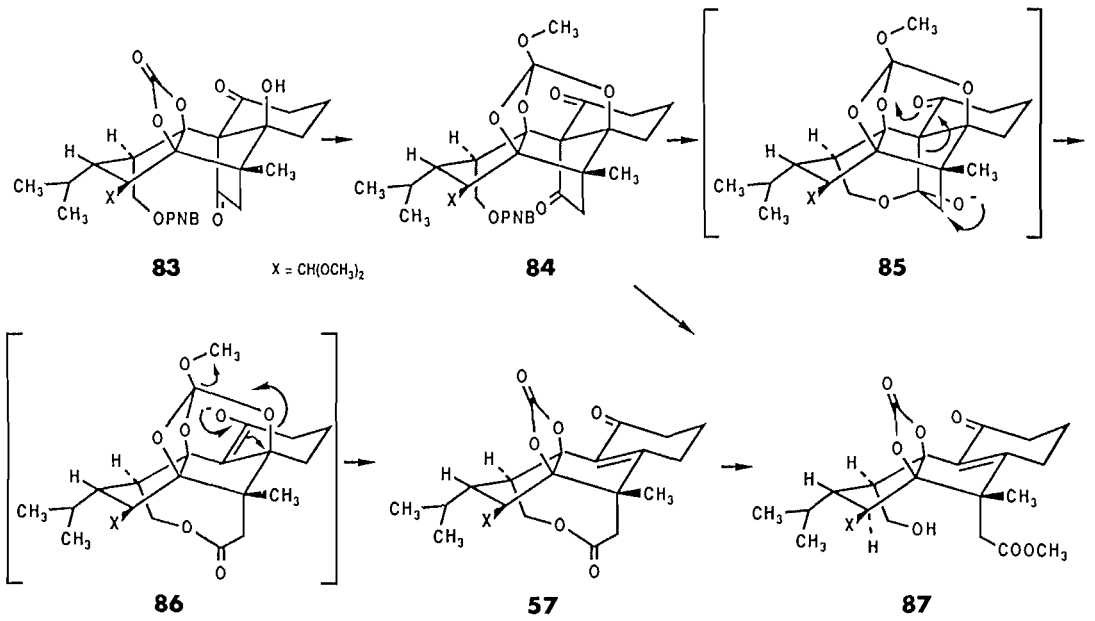


SCHEME 13



SCHEME 14

corresponding methoxyorthocarbonate diketone **84** (75% yield from **62**).

In an attempt to selectively reduce one of the carbonyl groups, compound **84** was treated with lithium tri-*sec*-butylborohydride (L-Selectride) at low temperature, and quite surprisingly the compound isolated was found to correspond to the known bridged eight-membered lactone **57**, which was previously described. This result could, however, be readily explained if the *p*-nitrobenzoate primary ester of compound **84** is preferably reduced, because this allows the formation of hemi-ketal oxyanion **85**, which can undergo a retro-Claisen reaction followed by the loss of methoxide ion from the fragmentation of the methoxyorthocarbonate moiety as indicated (**86** → **57**). It was also found that the bridged eight-membered lactone **57** was easily transesterified by reaction of lithium methoxide at 0°C, yielding the corresponding methyl ester **87**. If the above mechanistic interpretation is correct, it suggests that methoxyorthocarbonate **84** could be directly transformed into the methyl ester **87** by reaction with methoxide ion. Indeed, upon reaction of **84** with methoxide ion, transesterification of the primary *p*-nitrobenzoate ester should take place yielding *in situ* intermediate **85**, which should then give **87** via **57** and **86**. This proved to be the case experimentally; treatment of **84** with lithium methoxide (MeOH–THF) provided methyl ester **87** in 60% yield.

Having a good method for the preparation of methoxyorthocarbonate diketone **84**, the next step was its transformation into an intermediate having ring A correctly functionalized, i.e., diketone enone **91** (Scheme 15). This conversion was accomplished with an excellent overall yield of 70% following essentially our previous procedure: compound **84** was first transformed into the isomeric enol ethers **88**, which upon ozonolysis gave norketone **89**. Reaction of **89** with acetic anhydride and

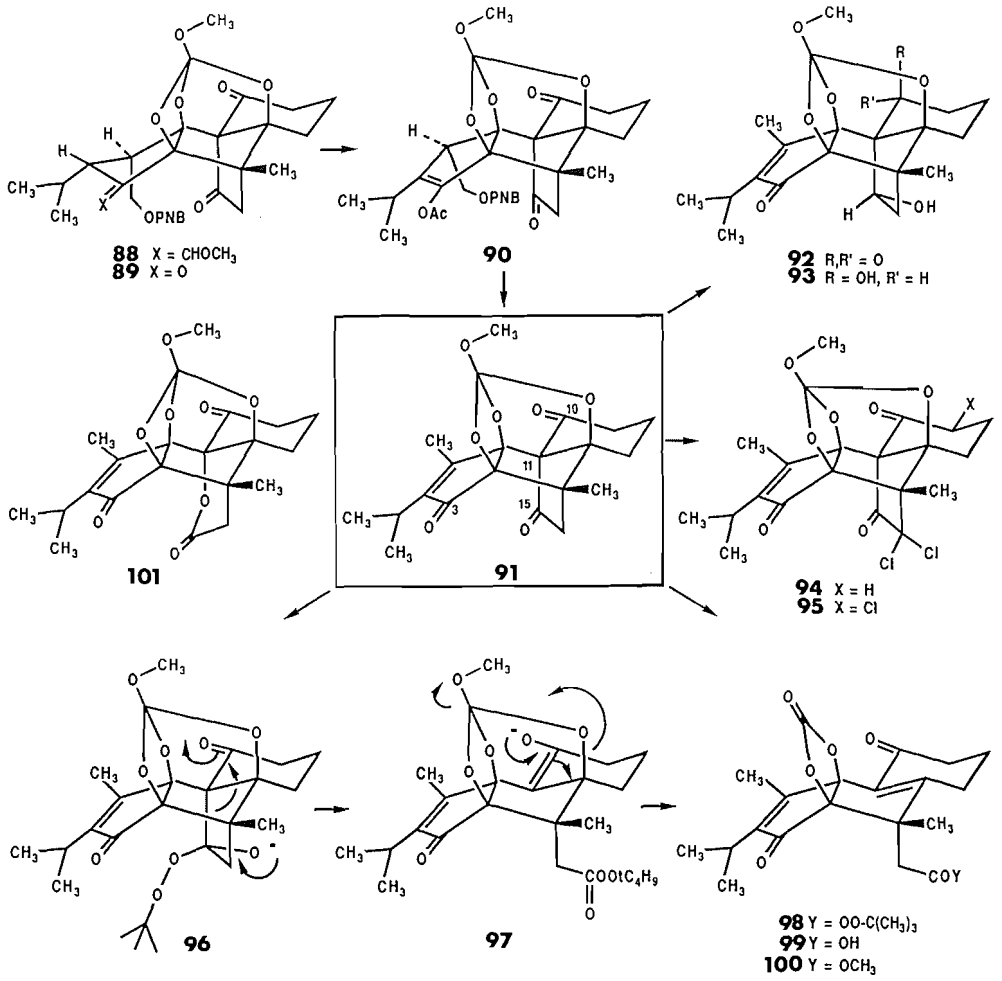

SCHEME 15

sodium acetate provided enol acetate **90**, which upon treatment with DBN in benzene gave the desired diketone enone **91**.

We had great hope with compound **91**, since we were very close to the anhydroryanodol structure **6**. Indeed, oxygen insertion between C_{15} and C_{11} would give the desired lactone ring. This, followed by methylation at C_9 and reduction of the carbonyl groups at C_3 and C_{10}, would complete the synthesis of anhydroryanodol (**6**). The reactivity of diketone enone **91** was therefore carefully examined.

Examination of a molecular model indicates that the C_{15} carbonyl group of diketone enone **91** is the most hindered of the three carbonyl groups; yet it was found to be the most reactive, and this gave us hope that we could accomplish the Baeyer–Villiger oxidation.

Reduction of diketone enone **91** with sodium borohydride at −78°C (THF–MeOH) gave a mixture of ketoalcohol **92** and diol **93**. On further reduction, **92** was converted into diol **93**. These results indicate that the C_{15} carbonyl group is the more easily reduced. However, diketone enone **91** was found to be inert in the presence of various peracids (*m*-chloroperbenzoic, peracetic, trifluoroacetic acid, H_2O_2) and we did not succeed with the desired Baeyer–Villiger oxidation. The next step was to try oxidation under basic conditions. Several experiments were carried out, none again were successful; however, some interesting results were observed. Upon treatment with an aqueous solution of sodium hypochlorite, diketone enone **91** gave two new products having infrared frequencies near 1780–1790 cm^{-1}. They were shown, however, not to have the desired lactone structure. Rather, their spectra (nmr and ms) showed that they had structures **94** and **95** respectively, which are the results of α-chlorination of the two saturated ketone functions.

Treatment of diketone enone **91** with lithium *tert*-butyl hydroperoxide (*t*-BuO_2Li) in tetrahydrofuran at −78°C gave a new compound identified as the *tert*-butyl perester **98**. Reduction of this perester with zinc gave the corresponding carboxylic acid **99**, which was then converted into the methyl ester **100**. This methyl ester **100** was also obtained directly from the reaction of diketone enone **91** with lithium methoxide.

In the above experiment with lithium *tert*-butyl hydroperoxide, we had gone as far as generating the required intermediate for the Baeyer–Villiger reaction: i.e., peroxide hemi-ketal **96**. However, this intermediate underwent a Claisen fragmentation to produce perester **98** via enolate **97** rather than the desired rearrangement, which would have produced lactone **101**.

Clearly, one way to prevent the undesired Claisen rearrangement is to transform the carbonyl group at C_{10} into an alcohol. However, we were also afraid that the removal of the C_{10} carbonyl group might considerably reduce the electrophilicity of the C_{15} carbonyl group and the desired Baeyer–Villiger oxidation would not take place. In diketone enone **91**, the π orbital of the C_{10} carbonyl group is parallel to the axially oriented C_{11}—C_{15} σ bond. As a result, the C_{15} carbonyl group must be less electron rich and more reactive towards nucleophilic reagents. This stereoelectronic effect, by which one carbonyl

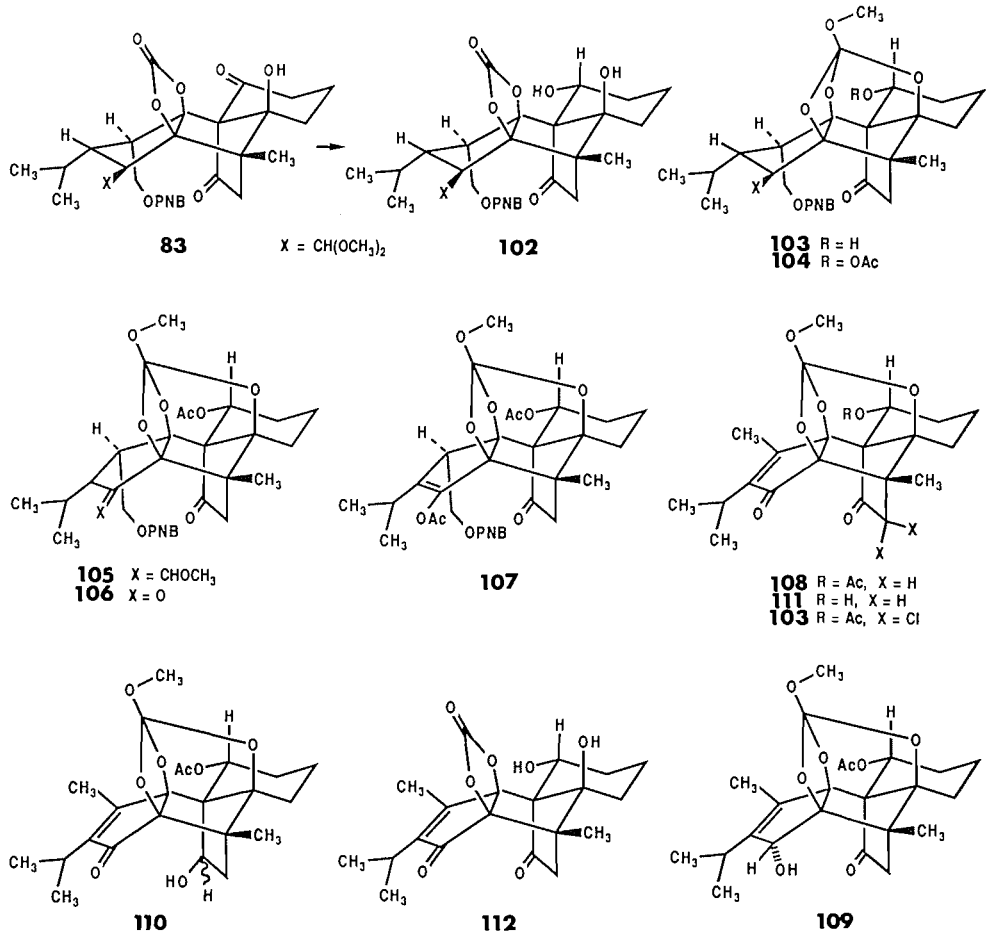
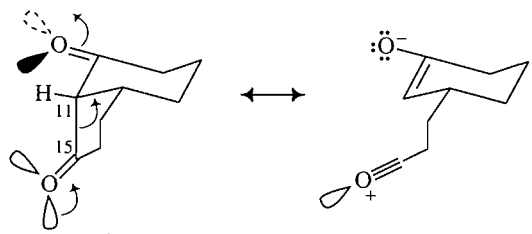


SCHEME 16

group of a β-diketone activates the other, can be best represented by the two resonance structures **i** and **ii**. We think that it does explain the observed reactivity of diketone enone **91**.



i ii

Returning to the synthetic discussion, our next task was clear; we had to prepare an intermediate without a carbonyl group at C_{10}, and then test the carbonyl reactivity at C_{15}. We have already described that the reduction of diketone enone **91** yields diol **93** having an axial alcohol at C_{10}. This result is probably due to an approach of the reducing agent from the less hindered face of the carbonyl group, because two oxygens (at C_6 and C_{12}) of the methoxyorthocarbonate severely hinder the axial approach of the reducing agent. The stereochemical course of this reduction can, however, be reversed by replacing the methoxyorthocarbonate by the hydroxycarbonate grouping. For instance, selective reduction of *p*-nitrobenzoate hydroxycarbonate diketone **83** with sodium borohydride gave a high yield of the equatorial alcohol **102** (Scheme 16). We presume that the free hydroxyl group at C_6 directs the axial approach of the hydride reagent. Reaction of compound **102** with diazomethane gave methoxyorthocarbonate **103** with an equatorial alcohol, which was further converted into the acetate derivative **104** upon reaction with acetic anhydride and pyridine.

Appropriate functionalization of ring A was then undertaken using our previously described method and the desired acetate derivative **108** was thus obtained from **104** via the formation of intermediates **105–107**. Reduction of **108** with sodium borohydride gave a mixture of the *endo*-allylic alcohol **109** and the alcohols **110**, indicating that by comparison with compound **91**, the electrophilicity of the C_{15} carbonyl group is reduced when the C_{10} carbonyl group is removed. Basic hydrolysis of **108** provided the corresponding alcohol **111**, which on mild acid hydrolysis was converted into dihydroxycarbonate **112**. The reactivity of the C_{10} carbonyl group with various oxidizing reagents was then tested experimentally.

First, compound **108** was found to be unreactive with a variety of reagents normally used for the Baeyer–Villiger reaction in acid and basic media. It reacted only with sodium hypochlorite to produce the α-dichlorinated product **113**. The monoketone **109** was used to verify whether a photochemical cleavage of the C_{11}—C_{15} bond could be realized (23). This was, however, not successful. Further, a rather interesting transformation was observed when dihydroxydiketone **112** was treated with lithium *tert*-butyl peroxide. Rather than producing the desired Baeyer–Villiger product, it gave the tricyclic ketodiol **116** (Scheme 17), which was further characterized as its diacetate **117**, in 75% yield. This interesting degradation is presumably the result of hemi-orthocarbonate salt formation, followed

by retro-aldol reaction and loss of carbon dioxide as shown by **114** → **115** → **116**.

The possibility that the lactone ring of anhydroryanodol could be obtained via the intermediate formation of a lactam was also investigated (24). We were confident that this approach could work because we successfully carried out this transformation using camphor lactam **119** as a model (Scheme 18). First, camphor lactam **119** was produced, albeit in a low yield, from the Beckmann rearrangement[3] of the unisolated oxime mesylate **118** of camphor. Then reaction of nitrosyl hexafluorophosphate (24, 26) with **119** gave the desired lactone **120**. Oximation of **108** gave the desired oxime **121**, which was successfully transformed into the lactam **123** via the oxime mesylate **122**. In the course of the Beckmann rearrangement, the methoxyorthocarbonate and the secondary acetate were both hydrolyzed under the reaction conditions (water–dioxane, 135°C, 17 h).

The lactam alcohol **123** was also converted into the acetate **124** by acetylation and into the ketolactam **125** by oxidation. The lactam–lactone transformation with compounds **124** and **125** was then attempted under the usual conditions, but it was not successful. This failure might be due to the fact that although camphor lactam **119** is a relatively close model to lactams **124** and **125**, the nitrogen in the latter compounds is more hindered than in the former. As a result, electrophilic species such as the nitrosonium ion could react on the oxygen rather than the nitrogen of the amide function, and that could of course inhibit the desired rearrangement!

A solution for the lactone ring of anhydroryanodol

Analysis of the above results led us to the conclusion that a major change in our strategy was necessary in order to effect the formation of the desired lactone ring. We started to think in terms of a two-stage process where the C_{11}—C_{15} bond would be cleaved first, and the lactone ring would then be formed later on. One conceivable approach was the cleavage of the C_{11}—C_{15} bond with concomitant formation of an unsaturation between C_{10} and C_{11}. Such an operation was in principle possible via a 1,4 "Grob" fragmentation process (27), which can be triggered by the functional groups at C_{10} and C_{15}. With that in mind, we started investigating with methoxyorthocarbonate alcohol **103**.

The equatorial alcohol **103** was converted into the corresponding mesylate **126** (Scheme 19), which on treatment with lithium methoxide yielded the corresponding cyclic hemi-ketal **127**. When compound **127** was submitted to dimsyllithium ($LiCH_2SOCH_3$) in dimethylsulfoxide, a smooth fragmentation took place, yielding the medium ring lactone **128**. This compound was found to be unstable under acidic conditions.

[3]Thus contrary to literature (25), Beckmann rearrangement of camphor oxime gives some of the expected lactam product **119**.

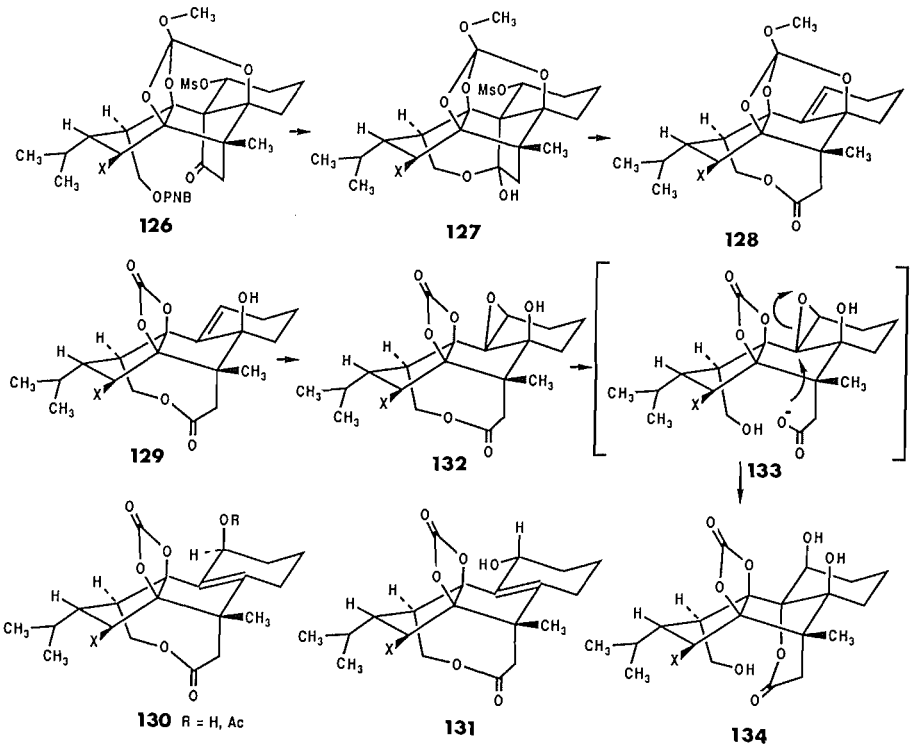


SCHEME 19 (X = $CH(OCH_3)_2$)

Mild acid hydrolysis of **128** gave a mixture of the desired hydroxycarbonate **129** and isomeric allylic axial alcohol **130** (R = H). The best conditions were found using fluoroboric acid (HBF_4) in water, giving a 3:1 ratio in favor of **129**. The structure of the minor product, i.e., axial allylic alcohol **130** (R = H), was further established by acetylation to acetate **130** (R = Ac) and by oxidation into the previously described lactone enone **57**. Furthermore, on reduction with sodium borohydride, enone **57** gave the corresponding equatorial allylic alcohol **131**, which was different from the axial isomer **130** (R = H).

Molecular models indicate that structure **128** is quite strained, and this tension is removed when the methoxyorthocarbonate is replaced by the hydroxycarbonate moiety (cf. **129**). The release of strain might be the main driving force for the relatively facile hydrolysis of **128**. Now, returning to the Grob fragmentation **127** → **128**, it is interesting to point out that this process can only work if ring C adopts a twist-boat conformation so that the leaving mesylate group becomes antiperiplanar to the C_{11}—C_{15} bond. Indeed, according to Grob (27), this stereoelectronic condition must be fulfilled in order to observe a given cleavage. Interestingly, the Grob fragmentation **127** → **128** is essentially the same reaction that transforms ryanodol into anhydroryanodol (see ref. 11, p. 264).

Compound **129** was treated with trifluoroperacetic acid to yield an epoxide that was assigned the β configuration on the basis that the medium lactone ring completely blocks the approach of a reagent on the α face of the C_{10}—C_{11} unsaturation. When epoxide **132** was treated with sodium hydroxide, it was smoothly converted into the desired lactone **134**. Thus, the anticipated intramolecular opening at the most substituted end of the oxirane ring by the carboxylic ion (cf. **133**) occurred with ease.

At last we had found a solution for the introduction of the lactone ring of anhydroryanodol. We had hope for a one-step conversion, but this stepwise method was of course quite an acceptable strategy. It led us to the axial rather than the desired equatorial alcohol at C_{10}, so an appropriate correction had to be made later on.

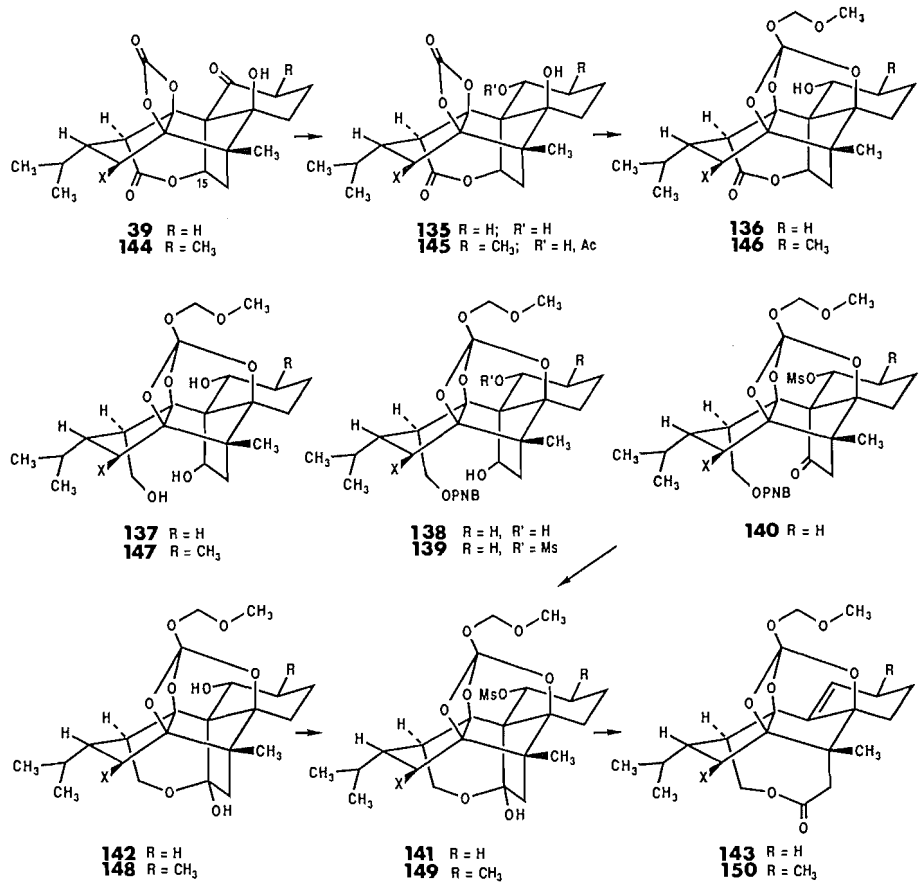
Synthesis of anhydroryanodol from lactone 39

Consideration of when the secondary methyl group at C_9 should be introduced led us to modify and, at the same time, simplify our method for the construction of the desired hemiketal mesylate that is necessary for carrying out the Grob fragmentation. For that matter, we decided to go back to a very early key intermediate, i.e., pentacyclic lactone carbonate **39**. Indeed this compound, which is easily prepared in four steps from the pentacyclic carbonate aldehyde **11** (**11** → **19** → **34** → **36** → **39**; cf. Scheme 7), possesses the correct functionality for the introduction of the methyl group at C_9 (*vide infra*). However, the new route was first explored using **39** without carrying out the methylation step at C_9.

Borohydride reduction of compound **39** gave the expected equatorial alcohol **135** (R′ = H) (Scheme 20). At this stage, we decided to modify the methoxyorthocarbonate protecting group[4] to avoid the formation of the secondary alcohol product **130** (R = H) (Scheme 19) during the acid hydrolysis. Treatment of **135** with sodium hydride in tetrahydrofuran and methoxymethyl chloride gave the corresponding methoxymethyl orthocarbonate **136**. We could easily envisage this reaction since we had already demonstrated the formation of the orthocarbonate sodium salt **40** from **39** (Scheme 7) under basic conditions. Now

[4]An additional reason to effect this modification was the fact that the formation of the corresponding methoxyorthocarbonate did not take place under our previously successful reaction conditions, i.e., there was no reaction between diazomethane and dihydroxycarbonate **135**. We also observed that the methoxyorthocarbonate derivative could be isolated by reacting **39** with diazomethane, but the reaction was slow and gave several products.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.



SCHEME 20 (X = $CH(OCH_3)_2$)

that the acid hydrolysis of the methoxymethyl orthocarbonate can be triggered by the hydrolysis of the methoxymethyl first, we could anticipate that the formation of the secondary product **130** (R = H) could be avoided (*vide infra*).

Reduction of **136** with lithium aluminium hydride provided the triol **137**, which was selectively esterified with *p*-nitrobenzoyl chloride to yield the corresponding primary *p*-nitrobenzoate **138**. Selective mesylation of **138** gave the secondary mesylate **139**, still having the most hindered secondary hydroxyl group free. Oxidation of **139** gave the corresponding ketone **140**, which on treatment with lithium methoxide gave the hemi-ketal mesylate **141** having a methoxymethyl orthocarbonate protecting group. This compound could also be prepared from a more simple two-step procedure starting from triol **137**. It was shown later that carefully controlled oxidation ($CrO_3 \cdot 2C_5H_5N$) of **147** provided the hemi-ketal alcohol **148**, which was then mesylated to give **149** (*vide infra*). The successful conversion **147** → **148** (or **137** → **142**) is due to the fact that hindered secondary alcohols are usually oxidized at a faster rate (28).

The previously described Grob fragmentation **127** → **128** was attempted under the same conditions with compound **141** and it gave the expected olefin lactone **143**, which was also found to be unstable. However, acid hydrolysis (HBF_4, H_2O) of crude product **143** provided the desired hydroxycarbonate **129** without any trace of the isomeric allylic alcohol **130**. Thus, the use of the methoxymethyl orthocarbonate was successful, as anticipated.

Having lactone **129** in hand, it remained, as previously mentioned, to introduce a secondary methyl group at C_9, to invert the alcohol configuration at C_{10}, and to complete ring A formation using the method previously described.

The last two operations were first carried out as a model series that provided 9-normethyl anhydroryanodol. This series of experiments will, however, not be reported, as it is essentially identical to the final route with the exception that the C_9 methyl group was missing.

Selective monomethylation was realized by the procedure of Rathke and co-workers (29), which uses triethylborane to form trialkylborane enolate intermediate, which then undergoes a single methylation. Thus reaction of ketone **39** with lithium diisopropyl amide in tetrahydrofuran followed by the successive addition of triethylborane ($(C_2H_5)_3B$) and iodomethane provided, after a brief treatment under basic conditions, the equatorial monomethylated derivative **144** in 70% yield (Scheme 20).[5]

The ketone function in **144** was selectively reduced with sodium borohydride to give the equatorial alcohol **145** (R′ = H) (95% yield), which was further characterized as its acetate derivative **145** (R′ = Ac). Compound **145** (R′ = H) was then transformed into the methoxymethyl orthocarbonate **146** (94% yield) using the previously described conditions. Reduction of **146** with lithium aluminium hydride produced the triol **147** (95% yield). Selective oxidation of **147** ($CrO_3 \cdot 2C_5H_5N$) gave hemi-ketal **148** (76% yield), which was converted into the mesylate **149** (89% yield). Then, the Grob fragmentation **149** →

[5]Careful examination of the crude product prior to the work-up under basic conditions indicated that the first product formed was the axial monomethylated isomer.

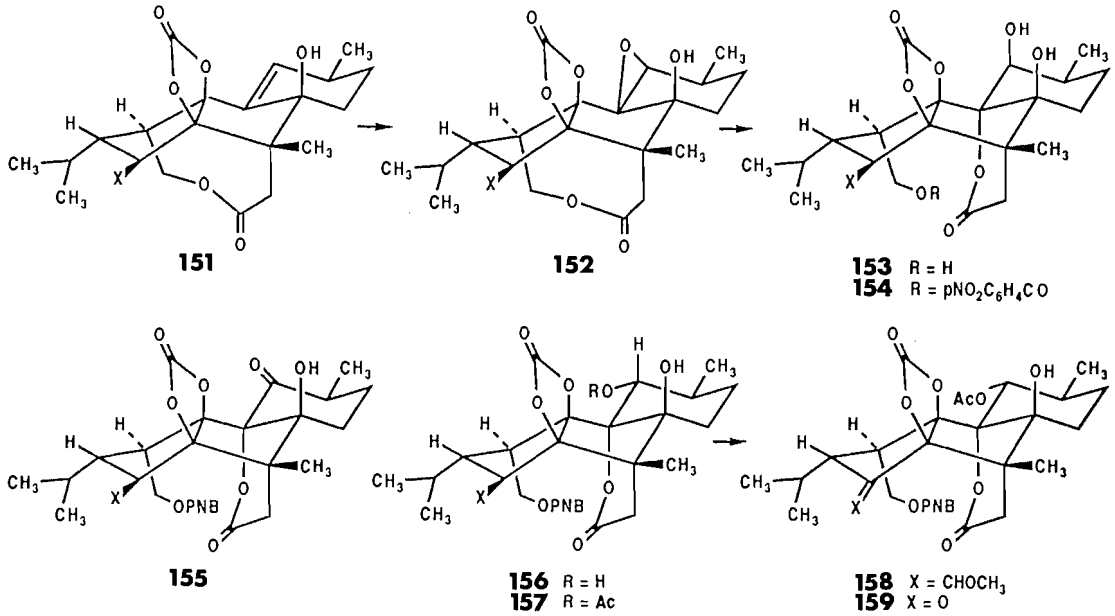
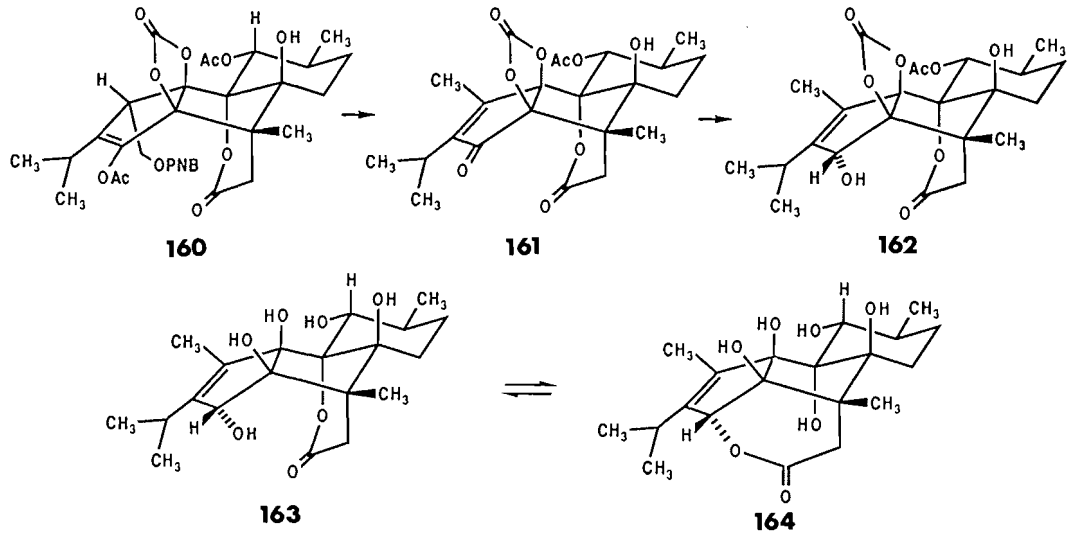


SCHEME 21 (X = $CH(OCH_3)_2$)



SCHEME 22

150 followed by mild acid hydrolysis (0.3 M HBF_4, THF, 0°C, 3 h) provided the desired hydroxycarbonate **151** in 97% yield (Scheme 21). Epoxidation of **151** afforded the β-epoxide **152** (98% yield), which upon aqueous basic treatment gave triol lactone **153** (77% yield).

Compound **153** was converted into the *p*-nitrobenzoate **154** (95% yield), which was oxidized (CrO_3·$2C_5H_5N$) to yield ketone **155** (78% yield). Reduction of ketone **155** with lithium borohydride in tetrahydrofuran (−30 to −20°C) gave the desired equatorial alcohol **156** in 73% yield after chromatographic separation from a small quantity of the axial isomer **154**. Acetylation (Ac_2O, C_5H_5N) of **156** gave the acetate **157** in good yield.

Modification of ring A in acetate **157** to produce enone **161** was then carried out by following the method previously described. Compound **157** was converted (PTSA, benzene, reflux) to a mixture of enol ethers **158**, which was oxidized (O_3, CH_2Cl_2; $(CH_3)_2S$) to cyclopentanone **159**. Compound **159** was transformed (Ac_2O, AcONa, 100°C) into the corresponding enol acetate **160** (Scheme 22), which under basic conditions (DBN, benzene, 75°C) gave the carbonate-acetate derivative **161** of 3-oxo-anhydroryanodol, the overall yield of **161** from acetate **157** being 50%.

Compound **161** was then reduced in good yield with sodium borohydride to give the *endo* allylic alcohol **162**, completing the synthesis of ring A. Finally, removal of the carbonate and the acetate groups in **162** under basic aqueous conditions gave a 3:1 mixture of anhydroryanodol **163** and epianhydroryanodol **164**, which were separated by chromatography. We had previously observed that under basic aqueous conditions anhydroryanodol **163** exists as a 3:1 equilibrium mixture with epianhydroryanodol **164**. Crystalline samples of synthetic anhydro- and epianhydroryanodol were found to be completely identical with authentic samples derived from natural ryanodine. The above comparison showed also that the synthetic and the naturally

derived material had essentially identical optical rotations, confirming that we had obtained optically active material with the correct absolute configuration.

Conclusion

In conclusion, the total synthesis of optically active (+)-anhydroryanodol **163** having the correct absolute configuration was completed via the following series of intermediates: **11** → **19** → **34** → **36** → **39** → **144** → **145** → **146** → **147** → **148** → **149** → **150** → **151** → **152** → **153** → **154** – **155** → **156** → **157** → **158** → **159** → **160** → **161** → **162** → **163**. This amounts to 24 different steps starting from optically active dextrorotatory pentacyclic carbonate aldehyde **11**. We consider this as a very acceptable solution within our synthetic strategy, although it could of course be improved on further work.

The next operation is the reconversion of (+)-anhydroryanodol into (+)-ryanodol and this is reported in the next article.

Experimental

Apparatus, materials, and methods

Melting points were determined on a Büchi M-50 apparatus and are uncorrected. Ether, tetrahydrofuran, and 1,2-dimethoxyethane were dried by distilling over sodium benzophenone ketyl. Benzene, dichloromethane, dimethyl sulfoxide, and amines were distilled over calcium hydride. All reactions were performed under nitrogen or argon atmosphere. Analytical and preparative thin-layer chromatography (tlc) were carried out on glass plates precoated (0.25, 0.5, 1.0, and 2.0 mm) with silica gel 60 F-250 (Merck). Materials were detected by visualization under an ultraviolet lamp (254 or 350 nm) and (or) by spraying with sulfuric acid (50%) or a solution of phosphomolybdic acid or vanillin followed by heating on a hot plate. Column chromatography was performed with silica gel (Baker (60–200 mesh) or Merck 60 (200–400 mesh)).

The infrared spectra (ir) were taken on a Perkin–Elmer 257 or 681 spectrophotometer. Proton nuclear magnetic resonance (^{1}H nmr) spectra were recorded (with chloroform or tetramethylsilane as internal standard) on a Varian A-60, a Bruker WP-60, a Bruker HX-90, or a Bruker WM-250 instrument. Carbon nuclear magnetic resonance (^{13}C nmr) spectra were measured on a Bruker HX-90 or WM-250 instrument. The following abbreviations have been used: s, singlet; d, doublet, dd, doublet of doublets; t, triplet, q, quartet; qn, quintet; m, multiplet; br, broad. For most of the hydroxylated compounds, the multiplicity of the hydrogens attached to a carbinol was analyzed after D_2O exchange. The mass spectra were recorded on a Hitachi–Perkin–Elmer RMU-6 mass spectrometer and peak matching (hrms) on a VG Micromass ZAB-2F spectrometer. The ultraviolet spectra (uv) were recorded on a Varian Techtron 635 spectrophotometer. Specific rotations were determined on a Perkin–Elmer polarimeter at 25°C. Microanalyses were carried out by Mr. J. Tamas, Laboratoire de Microanalyses, Université de Sherbrooke; Schwarzkopf Microanalytical Laboratories, New York; and by Dr. C. Daesslé, Organic Microanalyses, Montreal.

*Dioxolane acetal **12***

A mixture of aldehyde **11** (900 mg, 2.27 mmol), ethylene glycol (1.00 g, 16.1 mmol), and *p*-toluenesulfonic acid (10 mg) in benzene (80 mL) was refluxed (Dean–Stark) for 88 h. Ether was then added to the cooled mixture and the organic layer was washed with aqueous sodium bicarbonate and water. Evaporation of the dried (Na_2SO_4) extract furnished crystalline acetal **12** (877 mg, 87%); mp 143–144°C (chloroform–hexane); ir ($CHCl_3$, ν cm^{-1}): 1810, 1745; ^{1}H nmr ($CDCl_3$, δ ppm): 5.10 (d, 1H, J = 2 Hz, HCO_2), 3.95 (m, 4H, OCH_2CH_2O), 3.33 (d, 1H, J = 5 Hz, HC11), 3.1–1.4 (m, 13H), 1.31 (s, 3H, CH_3C5), 1.15 (d, 3H, J = 6.5 Hz), and 1.05 (d, 3H, J = 6.5 Hz) ($(CH_3)_2CH$); ms m/e: 400 (M^+). *Anal.* calcd. for $C_{23}H_{28}O_6$: C 68.98, H 7.04; found: C 69.18, H 7.34.

endo *Alcohol **13***

To a solution of ketone **12** (308 mg, 0.77 mmol) in dry methanol (40 mL) was added, at 0°C, sodium borohydride (35 mg, 0.92 mmol). After 45 min, ether (50 mL) was added and the mixture was washed with a mixture of brine (30 mL) and hydrochloric acid (2 M, 5 mL), then with brine. Evaporation of the dried extract furnished crystalline alcohol **13** (300 mg, 97%); mp 168–169°C (chloroform–hexane); ir ($CHCl_3$, ν cm^{-1}): 3620, 3500, 1800; ^{1}H nmr ($CDCl_3$, δ ppm): 5.12 (br s, 1H, HCO_2), 4.67 (m, 1H, HC17), 3.95 (m, 4H, OCH_2CH_2O), 2.98 (d, 1H, J = 5 Hz, HC11), 2.8–1.5 (m, 14H), 1.27 (s, 3H, CH_3C5), 1.00 (br t, 6H, $HC(CH_3)_2$); ms m/e: 402 (M^+). *Anal.* calcd. for $C_{23}H_{30}O_6$: C 68.64, H 7.51; found: H 68.70, H 7.62.

endo *Acetate **14***

To a solution of *endo* alcohol **13** (56 mg, 0.14 mmol) in triethylamine (2 mL) was added acetic anhydride (0.5 mL) and 4-dimethylaminopyridine (DMAP, 2 mg). After 4 h at 25°C, the volatile substances were evaporated and the residue was filtered on silica gel to give *endo* acetate **14** (61 mg, 98%); ir ($CHCl_3$, ν cm^{-1}): 1800, 1740; ^{1}H nmr ($CDCl_3$, δ ppm): 5.47 (dd, 1H, J = 11.0 and 6.8 Hz, HC17), 5.03 (s, 1H, HCO_2), 3.95 (m, 4H, OCH_2CH_2O), 2.99 (d, 1H, J = 5 Hz, HC11), 2.79 (dd, 1H, J = 11.0 and 5.1 Hz, HCl), 2.57 (m, 2H, HC2 and HC3), 2.43 (m, 5H, HC15, H_2C7, H_2C9), 2.10 (s, 3H, CH_3CO_2), 2.01 (m, 3H, H_2C8, HC13), 1.64 (d, 1H, J_{AB} = 14.2 Hz, *endo* HC14), 1.27 (s, 3H, CH_3C5), 1.02 (dd, 1H, J_{AB} = 14.2 Hz, J_{AX} = 10.2 Hz, *exo* HC14), 0.97 (d, 3H, J = 6.5 Hz) and 0.91 (d, J = 6.8 Hz) ($(CH_3)_2CH$); ms m/e: 444 (M^+).

*Diol acetal **15***

To a solution of carbonate **12** (21 mg, 0.052 mmol) in tetrahydrofuran (2 mL) was added aqueous sodium hydroxide (1 M, 0.5 mL, 0.5 mmol). The mixture was stirred under argon at room temperature for 15 h, then extracted with dichloromethane to give pure diol **15** (19 mg, 96%); ir ($CHCl_3$, ν cm^{-1}): 3500, 1735; ^{1}H nmr ($CDCl_3$, δ ppm): 4.92 (d, 1H, J = 3.3 Hz, HCO_2), 3.95 (m, 4H, -OCH_2CH_2O-), 3.88 (s, 1H, OH), 3.46 (s, 1H, OH), 2.99 (d, 1H, J = 4.8 Hz, HC11), 2.5 (m, 7H), 2.27 (m, 1H, HC15), 2.01 (m, 3H, H_2C8 and HC13), 1.44 (dd, 1H, J_{AB} = 14.5 Hz, J_{AX} = 1.6 Hz, *endo* HC14), 1.28 (dd, 1H, J_{AB} = 14.5 Hz, J_{BX} = 11 Hz, *exo* HC14), 1.20 (s, 3H, CH_3C5), 1.10 (d, 3H, J = 6.8 Hz) and 0.96 (d, 3H, J = 6.9 Hz) ($CH(CH_3)_2$); ms m/e: 374 (M^+).

*Ozonolysis of acetal **16***

A cooled (−78°C) solution of ketal **16** (310 mg, 1.43 mmol) in ethyl acetate (25 mL) was reacted with a stream of ozone for 10 min. To the blue reaction mixture was then added dimethyl sulfide (1 mL) and the mixture was allowed to warm to room temperature (25 min). After evaporation of the volatile substances the crude product was chromatographed on silica gel (hexane – ethyl acetate, 1:2) to give pure hydroxy diester **18** (316 mg, 95%); ir ($CHCl_3$, ν cm^{-1}): 3620, 3500, 1730; ^{1}H nmr ($CDCl_3$, δ ppm): 4.20 (t, 2H, J = 6 Hz, CO_2CH_2), 3.80 (m, 2H, CH_2OH), 3.66 (s, 3H, OCH_3), 2.4 (m, 1H, OH), 2.34 (s, 4H, CH_2CO_2), 1.75 (m, 2H), 0.90 (d, 6H, J = 7 Hz, $(CH_3)_2$); ms m/e: 232 (M^+).

*Dimethyl acetal **19***

To a solution of aldehyde **11** (500 mg, 1.41 mmol) in methanol (10 mL) was added *p*-toluenesulfonic acid (7 mg) and methyl orthoformate (165 mg, 1.55 mmol). The mixture was refluxed for 17 h under argon, then cooled, diluted with ether (100 mL), washed with aqueous sodium bicarbonate, and dried over magnesium sulfate. Evaporation of the solvents left pure dimethyl acetal **19** (550 mg, 98%); mp 114–115°C; $[\alpha]_D$ +106.4° (*c* 1.00, $CHCl_3$); ir ($CHCl_3$, ν cm^{-1}): 1805, 1745; ^{1}H nmr ($CDCl_3$, δ ppm): 4.31 (d, 1H, J = 1.5 Hz, *H*$C(OCH_3)_2$), 3.51 and 3.44 (2s, 6H, 2 × OCH_3), 3.27 (d, 1H, J = 5.1 Hz, HC11), 2.90 (m, 2H, HCl, HC2), 2.45 (m, 7H), 2.05 (m, 3H, H_2C8, HC13), 1.60 (dd, 1H, J_{AB} = 14.5 Hz, J_{AX} = 1.5 Hz, *endo* HC14), 1.46 (dd, 1H, J_{AB} = 14.5 Hz, J_{AX} = 11 Hz, *exo* HC14), 1.31 (s, 3H, CH_3C5), 1.10 (d, 3H, J = 6.9 Hz) and 0.97 (d, 3H, J = 6.9 Hz) ($CH(CH_3)_2$); ms m/e: 402 (M^+). *Anal.* calcd. for $C_{23}H_{30}O_6$: C 68.64, H 7.51; found: C 68.94, H 7.51.

*Ozonolysis of ketal olefin **19***

(*a*) A stream of ozone was bubbled through a solution of dimethoxyacetal **19** (200 mg, 0.497 mmol) in methanol (20 mL) at −78°C until a blue color persisted (~2 min); then dimethyl sulfide (1 mL) was added and the mixture was allowed to warm to room temperature (1.5 h). Evaporation of the volatile substances left a residue containing two components **20** and **21** in the relative proportion of 1:2 (nmr integration of acetal protons at ~4.29 ppm), which were separated by column chromatography on silica gel (dichloromethane–acetone 85:15).

*Compound **21*** (less polar, 130 mg, 60%): mp 196–197°C; ir ($CHCl_3$, ν cm^{-1}): 3600, 3400, 1815, 1750, 1705; ^1H nmr ($CDCl_3$, δ ppm): 4.31 (d, 1H, J = 3.9 Hz, $HC(OCH_3)_2$), 3.50 and 3.49 (2s, 6H, 2 × OCH_3), 3.01 (m, $H_{eq}C9$), 2.93 (dd, 1H, J = 10.4 and 2.8 Hz, HCl), 2.8–1.7 (m), 2.57 (dd, J = 3.9 Hz and 9 Hz, HC3), 2.45 (dd, 1H, J_{AB} = 14.1, J_{AX} = 11.5 Hz, $H_{exo}C14$), 1.45 (dd, 1H, J_{AB} = 14.1, J_{BX} = 2.0 Hz, $H_{endo}C14$), 1.18 (s, 3H, CH_3C5), 1.08 and 0.97 (2d, 6H, J = 6.9 Hz, $CH(CH_3)_2$); ms *m/e*: 434 (M^+). *Anal.* calcd. for $C_{23}H_{30}O_8$: C 63.57, H 6.96; found: C 63.31, H 6.73.

*Compound **20*** (more polar, 75 mg, 35%); mp 194–195°C; ir ($CHCl_3$, ν cm^{-1}): 3600, 3400, 1820, 1752, 1705; ^1H nmr ($CDCl_3$, δ ppm): 4.28 (d, 1H, J = 5.2 Hz, $HC(OCH_3)_2$), 3.51 and 3.48 (2s, 6H, 2 × OCH_3), 3.18 (dd, 1H, J = 6.8 and 2.5 Hz, HCl), 2.80 (m, 2H, HC2 and $H_{eq}C9$), 2.5–1.7 (m), 2.20 (dd, 1H, J_{AB} = 14.9, J_{AX} = 11.3 Hz, $H_{exo}C14$), 1.75 (dd, 1H, J_{AB} = 14.9, J_{BX} = 2 Hz, $H_{endo}C14$), 1.21 (s, 3H, CH_3C5), 1.10 and 0.91 (2d, 6H, J = 7.0 Hz, $CH(CH_3)_2$); ms *m/e*: 402 (M^+). *Anal.* calcd. for $C_{23}H_{30}O_8$: C 63.31, H 6.73; found: C 63.19, H 6.98.

(*b*) The same reaction was performed in the presence of *p*-toluenesulfonic acid (95 mg, 0.5 mmol). The crude product, after removal of the acid, left a residue containing compounds **20** and **21** in the relative proportion of 7:3 as shown by nmr.

cis-*Diol **22***

To a solution of pentacyclic olefin **19** (106 mg, 0.264 mmol) in ether (10 mL) was added osmium tetroxide (81 mg, 0.32 mmol) and the mixture was stirred at room temperature for 16 h. Evaporation left a brown residue, which was dissolved in ethanol (95%, 20 mL) and reacted with sodium sulfite (266 mg, 2.11 mmol) in water (2 mL) at reflux temperature for 1 h. The reaction mixture was filtered, ethanol was evaporated, and the reside was extracted with ether, washed with brine, and dried over sodium sulfate. Evaporation of ether left a solid residue, which was crystallized from chloroform – hexane (72 mg, 63%); mp 211–212°C; ir ($CHCl_3$, ν cm^{-1}): 3600–3420, 1810, 1750, 1075; ^1H nmr ($CDCl_3$, δ ppm): 4.36 (s, 1H, $HC(OCH_3)_2$, 3.53 and 3.45 (7H, 2s, 2 × OCH_3 and HC11), 3.0–1.0 (m, 13H), 1.21 (s, 3H, CH_3C5), 1.10 (d, 3H, J = 6.5 Hz), 0.96 (d, 3H, J = 6.5 Hz) ($CH(CH_3)_2$); ms *m/e*: 434 (M^+). *Anal.* calcd. for $C_{23}H_{32}O_8$: C 63.28, H 7.39; found: C 63.12, H 7.22.

Periodic cleavage of cis-*diol **22***

To a stirred solution of glycol **22** (50 mg, 0.12 mmol) in ether (20 mL) was added a solution of periodic acid in ether (3.5 mL, 16 mg/mL). After 5 h at room temperature the mixture was washed with aqueous sodium bicarbonate and brine. Evaporation of the dried extract gave pure compound **21** (40 mg, 80%).

*Diol **23***

To a solution of carbonate acetal **19** (300 mg, 0.746 mmol) in tetrahydrofuran (10 mL) was added aqueous sodium hydroxide (1 M, 11 mL) and the mixture was stirred at 65°C for 1.5 h, then poured onto brine and extracted with ether. Evaporation of the dried (Na_2SO_4) extract gave pure diol **23** (275 mg, 98%); ir ($CHCl_3$, ν cm^{-1}): 3450, 1745, 1080; ^1H nmr ($CDCl_3$, δ ppm): 4.44 (d, 1H, J = 2 Hz, $HC(OCH_3)_2$), 4.31 (s, 1H, OH), 3.47 (s, 6H, 2 × OCH_3), 2.97 (d, 1H, J = 5 Hz, HC11), 2.7–1.5 (m, 14H), 1.21 (s, 3H, CH_3C5), 1.10 (d, 3H, J = 6.5 Hz), 1.00 (d, 3H, J = 6.5 Hz) ($HC(CH_3)_2$); ms *m/e*: 376 (M^+).

*Ozonolysis of diol olefin **23***

A cooled (−78°C) solution of olefin **23** (194 mg, 0.517 mmol) in methanol (50 mL) was reacted with a stream of ozone for 10 min. The blue reaction mixture was reacted with dimethyl sulfide (10 mL) and allowed to warm to room temperature during 1.5 h. Evaporation of the volatile substances gave a residue that was dissolved in ether, then washed with water and brine. The dried extract was evaporated and the residue was chromatographed on thin layer (ether–methanol, 99:1) to give pure triol **25** (60 mg, 28%); mp 157–158°C; ir ($CHCl_3$, ν cm^{-1}): 3440, 1735, 1695, ^1H nmr ($CDCl_3$, δ ppm): 5.72 (s, 1H, OH), 4.67 (s, 1H, OH), 4.49 (s, 1H, OH), 4.44 (d, 1H, J = 2.5 Hz, $HC(OCH_3)_2$), 3.51 (s, 6H, 2 × OCH_3), 2.8–1.2 (m, 13H), 1.11 (s, 3H, CH_3C5), 1.10 (d, 3H, J = 6.5 Hz), 1.05 (d, 3H, J = 6.5 Hz) ($HC(CH_3)_2$); ms *m/e*: 376 (M^+–32). *Anal.* calcd. for $C_{22}H_{32}O_7$: C 64.69, H 7.89; found: C 64.56, H 7.63.

*Orthoacetate **26***

A cooled (−10°C) solution of triol **25** (148 mg, 0.363 mmol) in acetic anhydride (21 mL) was reacted with perchloric acid (70%, 3 drops). After 10 min, methanol (15 mL) was slowly added and the volatile substances were then removed under reduced pressure. The oily residue was extracted with ether, washed once with brine, and reacted with aqueous sodium hydroxide for 0.5 h at room temperature under good stirring. The aqueous layer was separated and extracted with ether. The combined organic layer extracts were dried and evaporated to yield a residue that was purified by crystallization in chloroform–hexane (59 mg, 42%); mp 263–267°C; ir ($CHCl_3$, ν cm^{-1}): 1745, 1725, 1710; ^1H nmr ($CDCl_3$, δ ppm): 9.48 (d, 1H, J = 3 Hz, CHO), 3.2–1.5 (m), 1.63 (s, 3H, CH_3CO_3), 1.16 (s, 3H, CH_3C5), 1.12 (d, 3H, J = 6.5 Hz), 0.80 (d, 3H, J = 6.5 Hz) $CH(CH_3)_2$); ms *m/e*: 386 (M^+). *Anal.* calcd. for $C_{22}H_{26}O_6$: C 68.38, H 6.78; found: C 68.52, H 7.03.

*Monoacetate **27***

A mixture of aldehyde **5** (59 mg, 0.18 mmol), acetic anhydride (5 mL), and anhydrous sodium acetate (50 mg, 0.61 mmol) was heated under nitrogen (70°C) for 37 h. The cooled reaction mixture was then filtered and the volatile substances were evaporated. The crude product was chromatographed (thin layer) (silica gel, benzene–ether, 7:3) to give monoacetate **27** (39 mg, 59%); mp 142–144°C; ir ($CHCl_3$, ν cm^{-1}): 3570, 2730, 1735, 1730, 1220; ^1H nmr ($CDCl_3$, δ ppm): 9.53 (d, 1H, J = 2.4 Hz, CHO), 3.96 (d, 1H, J = 5.5 Hz, HC11), 3.58 (dd, 1H, $J_{1,2}$ = 6.5 Hz, J_W = 2.5 Hz, HCl), 2.9–1.1 (m), 2.13 (s, 3H, CH_3CO_2), 1.32 (s, 3H, CH_3C5), 1.10 and 0.93 (2d, 6H, J = 6.5 Hz, $CH(CH_3)_2$); ms *m/e*: 372 (M^+).

*Ozonolysis of olefin **27***

A cold (−78°C) solution of olefin **27** (30 mg, 0.08 mmol) in methanol (20 mL) was reacted with a stream of ozone for 4 min, then methyl sulfide (5 mL) was added and the mixture was warmed to room temperature for 1 h. Evaporation of volatile substances left a residue that was dissolved in chloroform and washed with water. The dried extract was evaporated. The solid residue was recrystallized from chloroform–ether mixture to give monoacetate **28** (16 mg, 49%); mp 182–182.5°C; ir ($CHCl_3$, ν cm^{-1}): 3400, 2740, 1740, 1725, 1700; ^1H nmr ($CDCl_3$, δ ppm): 9.60 (d, 1H, J = 3.6 Hz, -CHO), 6.20 (s, 1H, OH), 4.38 (m, 1H, OH), 3.80 (dd, 1H, $J_{1,2}$ = 5 Hz, J_W = 1.5 Hz, HCl), 2.30 (s, 3H, CH_3CO_2), 3.4–1.5 (m), 1.28 (s, 3H, CH_3C5), 1.06 and 0.96 (2d, 6H, J = 6.5 Hz, $CH(CH_3)_2$); ms *m/e*: 404 (M^+). *Anal.* calcd. for $C_{22}H_{28}O_7$: C 65.33, H 6.97; found: C 65.36, H 6.99.

*Orthoacetate **26** from monoacetate **28***

A solution of monoacetate **28** (18 mg, 0.041 mmol) and *p*-toluenesulfonic acid (10 mg) in benzene (5 mL) was heated at 75°C for 2 h, then cooled, diluted with ether (30 mL), and washed with aqueous sodium carbonate and brine. The dried extract was evaporated and the residue was crystallized from chloroform–hexane to give orthoacetate **26** (14 mg, 82%, mp 265–266°C) (*vide supra*).

*Ozonolysis of aldehyde olefin **11***

(*a*) Ozonolysis was performed as for ketal olefin **19** on the following quantities: **11** (50 mg, 0.14 mmol) in methanol (50 mL) during 8 min. After the usual work-up the crude product was purified by thin-layer chromatography to give aldol isomers **29** and **30** (chloroform–acetone, 9:1).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12

Aldol isomer ***29*** (more polar) (12 mg, 21%): mp 261–264°C; ir ($CHCl_3$, ν cm^{-1}): 3400, 2720, 1798, 1745, 1725, 1700; ^1H nmr (acetone-d_6, δ ppm): 9.66 (br s, 1H, CHO), 3.3–1.6 (m), 1.26 (s, 3H, CH_3C5), 1.13 and 0.79 (2d, 6H, J = 6.5 Hz, $CH(CH_3)_2$); ms *m/e*: 388 (M^+). *Anal.* calcd. for $C_{21}H_{24}O_7$: C 64.94, H 6.23; found: C 64.97, H 6.25.

Aldol isomer ***30*** (less polar) (27 mg, 50%); mp 227–228°C; ir ($CHCl_3$, ν cm^{-1}): 3590, 3400, 2720, 1820, 1750, 1735, 1710, ^1H nmr (acetone-d_6, δ ppm): 9.71 (d, 1H, J = 2 Hz, CHO), 3.5–1.5 (m), 1.30 (s, 3H, CH_3C5), 1.12 and 0.77 (2d, 6H, J = 6.5 Hz, $CH(CH_3)_2$); ms *m/e*: 388 (M^+). *Anal.* calcd. for $C_{21}H_{24}O_7$: C 64.94, H 6.23; found: C 64.76, H 6.47.

(*b*) The same reaction was performed in the presence of *p*-toluenesulfonic acid (20 mg). The crude product was shown to be a 5:2 mixture of compounds **29**:**30** respectively (nmr integration of aldehydic proton).

Hemi-orthocarbonate sodium salt ***31***

To a solution of aldol product **29** (34 mg, 0.088 mmol) in dry tetrahydrofuran (680 μL) was added excess sodium hydride (10 mg, 57% oil dispersion) and the mixture was stirred under nitrogen for 1.5 h; stirring was then stopped and a part of the clear supernatant solution was injected into an ir cell (IRTRAN II): ir (THF, ν cm^{-1}): 1740, 1715. Acidification of the reaction mixture (1 M HCl, 2 mL) was followed by ether extraction and evaporation of the solvents, which gave back pure aldol product **29** (33 mg). A similar procedure performed on compound **30** did not result in the disappearance of the carbonate absorption at ~1820 cm^{-1}.

Oxime ***32***

To a solution of ketone **19** (105 mg, 0.273 mmol) in anhydrous methanol (10 mL) was added hydroxylamine hydrochloride (385 mg, 5.53 mmol) and anhydrous sodium acetate (450 mg, 5.48 mmol). After 19 h at reflux temperature, the mixture was cooled, extracted with chloroform, and washed with water and brine. Evaporation of the dried extract left a residue that was chromatographed on silica gel (benzene – ethyl acetate, 3:1) to give oxime **32** (99 mg, 91%); mp 186–187°C ($CHCl_3$–hexane); ir ($CHCl_3$, ν cm^{-1}): 3580, 3320, 1810; ^1H nmr ($CDCl_3$, δ ppm): 8.80 (br s, 1H, NOH), 4.33 (br s, 1H, $HC(OCH_3)_2$), 3.52 and 3.44 (2s, 6H, 2 × OCH_3), 3.5–1.4 (m), 1.29 (s, 3H, CH_3C5), 1.06 and 1.02 (2d, 6H, J = 6.5 Hz, $CH(CH_3)_2$); ms *m/e*: 417 (M^+). *Anal.* calcd. for $C_{23}H_{31}NO_6$: C 66.17, H 7.49; found: C 65.89, H 7.42.

Lactam ***33***

To a cooled solution (0°C) of oxime **32** (33 mg, 0.079 mmol) in dichloromethane (6 mL) was added an excess of triethylamine (200 μL) and methanesulfonyl chloride (100 μL). After 40 min, the mixture was extracted with methylene chloride, then washed with sodium bicarbonate solution and brine. Evaporation of the solvent left a residue, which was chromatographed on silica gel (benzene – ethyl acetate, 85:15) to give intermediate mesylate (38 mg, 97%): ir ($CHCl_3$, ν cm^{-1}): 1805, 1705, 1360, 1165; ^1H nmr ($CDCl_3$, δ ppm): 4.34 (s, 1H, $CH(OCH_3)_2$), 3.52 and 3.45 (2s, 6H, 2 × OCH_3), 3.15 (s, 3H, SO_2CH_3), 3.5–1.4 (m), 1.31 (s, 3H, CH_3C5), 1.10 and 1.06 (2d, 6H, J = 6.6 Hz, $CH(CH_3)_2$); ms *m/e*: 495 (M^+). This mesylate (38 mg, 0.077 mmol) was refluxed in a mixture of dioxane (4 mL), water (1 mL), and pyridine (25 μL) for 1.2 h. Evaporation of the solvents and chromatography of the residue (silica plate, chloroform:acetone, 9:1) furnished lactam **33** (22 mg, 69%); ir ($CHCl_3$, ν cm^{-1}): 3400, 1810, 1670; ^1H nmr ($CDCl_3$, δ ppm): 5.48 (br s, 1H, NH), 4.41 (s, 1H, $CH(OCH_3)_2$), 3.93 (d (after D_2O exchange), 1H, J = 3.5 Hz, HCl), 3.54 and 3.40 (2s, 6H, 2 × OCH_3), 3.15 (d, 1H, J = 3.7 Hz, HC11), 2.6–1.5 (m), 1.31 (s, 3H, CH_3C5), 1.07 and 1.02 (2d, 6H, J = 6.8 Hz, $CH(CH_3)_2$); ms *m/e*: 417 (M^+).

Isomeric epoxylactones ***34*** *and* ***35***

A mixture of ketone **19** (1.088 g, 2.71 mmol) and anhydrous sodium acetate (2.00 g, 24.4 mmol) in 40% peracetic acid in acetic acid (20 mL) was stirred at room temperature for 20 h, then at 85°C for 1 h. The mixture was cooled at 0°C, reacted slowly with aqueous sodium bisulfite (4 M, 50 mL), and extracted with chloroform. Evaporation of the solvents and remaining acetic acid left a residue (1.136 g, 95%) that contained two main compounds **34** and **35** (85:15 respectively, integration of lactonic proton at C15 for **34** and Cl for **35**); ir ($CHCl_3$, ν cm^{-1}): 1820, 1749; ^1H nmr ($CDCl_3$, δ ppm): 4.89 (d, ~0.15 H, J = 3.3 Hz, HCl in **35**), 4.60 (ddd, 1H, J = 4.5, 2.5, and 9.8 Hz, HC15 in **34**), 4.41 (s, 1H, $CH(OCH_3)_2$), 3.58 and 3.44 (2s, 6H, $CH(OCH_3)_2$), 3.03 (d, 1H, J = 4.5 Hz, HC11), 3.3–1.2 (m), 1.35 (s, 3H, CH_3C5), 1.10 and 0.96 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$). Several recrystallizations of this mixture from methylene chloride – methanol furnished a pure sample of **34** for analysis: mp 268–269°C; ms *m/e*: 434 (M^+). *Anal.* calcd. for $C_{23}H_{30}O_8$: C 63.58, H 6.96; found: C 63.56, H 6.82.

Olefinic lactones ***36*** *and* ***36a***

To cold (−78°C) tetrahydrofuran (180 mL) under argon was added all at once tungsten hexachloride (metallic black, 6.9 g, 17.4 mmol). Five minutes later, under good stirring, butyllithium (2.4 M in hexane, 21.7 mL, 52.2 mmol) was added dropwise over 20 min. After 10 min at −78°C, the mixture was warmed slowly (~1 h) to room temperature. After several gradual changes in the color of the reaction mixture (successively greenish brown, light yellow, dark brown), lithium iodide (60 mg, 0.45 mmol) was added and 5 min later a dry solid mixture of epoxy lactones (85:15) **34** and **35** (2.80 g, 6.45 mmol). After 6 h at room temperature, the reaction mixture was poured into a cold solution of basic sodium tartrate (200 mL, 1.5 M in sodium tartrate and 2 M in sodium hydroxide) and extracted several times with ether. The combined organic layers were washed with brine, dried, and evaporated. The crude product (2.8 g) was chromatographed on silica gel to furnish olefinic lactones **36** (less polar) and **36***a* (from **35**) (chloroform–acetone, 98:2).

Olefinic lactone ***36*** (2.15 g, 80%, colorless tetrahedrons from ether); mp 179–181°C; $[\alpha]_D$ −10.5° (*c* 1.0, $CHCl_3$); ir ($CHCl_3$, ν cm^{-1}): 1812, 1745; ^1H nmr ($CDCl_3$, δ ppm): 4.56 (ddd, 1H, J = 4.5, 4.5, and 8.5 Hz, HC15), 4.42 (s, 1H, $CH(OCH_3)_2$), 3.56 and 3.43 (2s, 6H, 2 × OCH_3), 3.16 (d, 1H, J = 4.5 Hz, HC11), 3.2–1.5 (m), 1.33 (s, 3H, CH_3C5), 1.29 and 0.98 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$); ms *m/e*: (M^+). *Anal.* calcd. for $C_{23}H_{30}O_7$: C 66.01, H 7.23; found: C 65.95, H 7.29.

Olefinic lactone ***36a*** (400 mg, 14%, needles); mp 168–169°C; ir ($CHCl_3$, ν cm^{-1}): 1810, 1740; ^1H nmr ($CHCl_3$, δ ppm): 4.90 (d, 1H, J = 4.5 Hz, HCl), 4.46 (s, 1H, $HC(OCH_3)_2$), 3.57 and 3.47 (2s, 6H, 2 × OCH_3), 3.28 (d, 1H, J = 4.5 Hz, HC11), 2.9–1.4 (m), 1.33 (s, 3H, CH_3C5), 1.15 and 1.05 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$); ms *m/e*: 418 (M^+).

Ketoester ***37***

To a solution of lactone **36** (150 mg, 0.359 mmol) in 1,2-dimethoxyethane (6 mL) was added a solution of lithium hydroxide (50 mg, 2.1 mmol) in water (2 mL). After 18 h at room temperature, the mixture was partly evaporated, neutralized with a stream of carbon dioxide (phenolphthalein), and reacted during 15 min alternatively, by small portions, with an excess of sodium bicarbonate (560 mg) and trimethyloxonium tetrafluoroborate (1.0 g). Dilution with water (~10 mL) and extraction with dichloromethane afforded a crude product (155 mg) that was dissolved in dry dichloromethane (2 mL) and added to chromium trioxide – pyridine complex (215 mg CrO_3, 356 μL pyridine) in dichloromethane (8 mL) at 0°C. After 10 min, isopropanol (1 mL) was added and the mixture was diluted with ether. The organic layer was washed with water, dried, and evaporated. Chromatography of the crude product on silica gel (hexane – ethyl acetate, 4:1) gave ketoester **37** (119 mg, 74%); mp 143–144°C; ir ($CHCl_3$, ν cm^{-1}): 1798, 1735, ^1H nmr ($CDCl_3$, δ ppm): 4.54 (s, 1H, $CH(OCH_3)_2$), 3.61 (s, 3H, CO_2CH_3), 3.56 (s, 1H, HC11), 3.55 and 3.30 (2s, 6H, $CH(OCH_3)_2$), 3.22 (d, 1H, J = 7 Hz, HCl), 3.10 (d, 1H, J_{AB} = 12 Hz) and 2.55 (d, 1H, J_{AB} = 12 Hz) (H_2C14); 2.8–1.4 (m), 1.41 (s, 3H, CH_3C5), 1.02 and 0.82 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$); ms *m/e*: 448 (M^+).

Carbonate diol ***38***

A mixture of olefinic lactone **36** (52.0 mg, 0.124 mmol) and lithium borohydride (50 mg, 2.5 mmol) in dry tetrahydrofuran (8 mL) was refluxed for 30 h, then cooled at −78°C and reacted with ammonium chloride aqueous solution. The mixture was warmed to room tempera-

For personal use only.

ture, extracted with dichloromethane, washed with brine, and the solvent was evaporated. Chromatography (chloroform–acetone, 4:1) of the crude product gave a small quantity of starting material and its hemi-ketal (2 mg, 4%) and carbonate diol **38** (48 mg, 95%); mp 213–214°C; ir ($CHCl_3$, ν cm^{-1}): 3600, 3350, 1790; ^1H nmr ($CDCl_3$, δ ppm): 4.37 (s, 1H, $CH(OCH_3)_2$), 3.9 (m, 3H, CH_2OH and HC15), 3.89 and 3.49 (2s, 6H, 2 × OCH_3), 3.48 (d, 1H, J = 4.5 Hz, HC11), 3.0–1.4 (m), 1.26 (s, 3H, CH_3C5), 0.98 and 0.96 (2d, 6H, $CH(CH_3)_2$); ms *m/e*: 422 (M^+). *Exact Mass* calcd. for $C_{23}H_{34}O_7-CH_3OH$: 390.2042; found: 390.2052.

Ozonolysis of olefin lactone 36

A stream of ozone was bubbled through a cold (−78°C) solution of olefin lactone (740 mg, 1.77 mmol) in dry methanol–dichloromethane (1:1, 25 mL) in the presence of *p*-toluenesulfonic acid (155 mg, 0.81 mmol) during 10 min. To the blue solution was then added dimethyl sulfide and the mixture was warmed to room temperature, extracted with chloroform, and washed with aqueous potassium carbonate and brine. Removal of the solvent left a residue that was purified by crystallization (acetone–hexane) and chromatography on silica gel ($CHCl_3$–acetone, 9:1) to give compound **39** (757 mg, 95%); mp 238–238.5°C; ir ($CHCl_3$, ν cm^{-1}): 3380, 1780, 1755, 1710; ^1H nmr (acetone-d_6, δ ppm): 5.38 (dd, 1H, J = 10.5 and 3.0 Hz, HC15), 4.42 (d, 1H, J = 3.6 Hz, $HC(OCH_3)_2$), 3.48 and 3.46 (2s, 6H, 2 × OCH_3), 3.22 (d, 1H, J = 4 Hz, HCl), 3.1–1.6 (m), 1.21 (s, 3H, CH_3C5), 1.16 and 0.93 (2d, 6H, J = 7.1 Hz, $CH(CH_3)_2$); ms *m/e*: 450 (M^+). *Anal.* calcd. for $C_{23}H_{30}O_9$: C 61.32, H 6.71; found: C 61.63, H 6.51.

Hemi-orthocarbonate sodium salt 40

Formation of orthocarbonate anion **40** from **39** was carried out as for compound **31** (*vide supra*). Analysis of its ir spectrum showed the disappearance of the carbonate absorption at 1780 cm^{-1} and the presence of the other two carbonyl absorptions at 1755 and 1710 cm^{-1}.

Epoxyketoester 41

A mixture of ketoester **37** (15 mg, 0.034 mmol) and anhydrous sodium acetate (25 mg, 0.30 mmol) in 40% peracetic acid in acetic acid (1 mL) was stirred at 25°C for 20 h, then at 85°C for 1 h. The mixture was cooled to 0°C, reacted with cold aqueous sodium bisulfite (4 M, 1.5 mL), and extracted with chloroform. The organic layer was washed with aqueous sodium bicarbonate, then brine, and evaporated. Chromatography of the crude product (silica gel, benzene – ethyl acetate, 4:1) gave pure epoxyketoester **41** (13 mg, 85%); mp 183–184°C; ir ($CHCl_3$, ν cm^{-1}): 1804, 1750, 1740; ^1H nmr ($CDCl_3$, δ ppm): 4.63 (s, 1H, $CH(OCH_3)_2$), 3.65 (br s, 7H, CO_2CH_3, CH-OCH_3 and HC11), 3.49 (s, 3H, CH-OCH_3), 3.27 (d, 1H, J = 7 Hz, HCl), 3.12 (d, 1H, J = 12 Hz, HC3), 2.9–1.2 (m), 1.48 (s, 3H, CH_3C5), 1.03 and 0.81 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$); ms *m/e*: 464 (M^+).

Basic treatment of ester 37

To a solution of ester **37** (50 mg, 0.11 mmol) in 1,2-dimethoxyethane (3 mL) was added 1,5-diazabicyclo[4.3.0]non-5-ene (DBN) (40 μL, 0.32 mmol) and the mixture was stirred for 4 h at 25°C. Evaporation of the volatile materials left a residue, which was filtered through silica gel (benzene – ethyl acetate, 9:1) to give unsaturated ketoester **42** (45 mg, 98%); λ_{max} (ethanol): 227 nm (ε 45 000); ir ($CHCl_3$, ν cm^{-1}): 3430, 1730, 1680, 1650; ^1H nmr ($CDCl_3$, δ ppm): 4.65 (d, 1H, J = 2.5 Hz, $CH(OCH_3)_2$), 4.58 (s, 1H, HC11), 3.83 (s, 3H, CO_2CH_3), 3.53 and 3.51 (2s, 6H, 2 × OCH_3), 2.8–1.5 (m), 1.32 (s, 3H, CH_3C5), 0.85 and 0.81 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$); ms *m/e*: 404 (M^+).

Oxime *43*

(a) From ketoester 37

A mixture of unsaturated ketoester **37** (21 mg, 0.047 mmol), hydroxylamine hydrochloride (65 mg, 0.70 mmol), and anhydrous sodium acetate (81 mg, 0.82 mmol) in dry methanol was refluxed for 20 h, then cooled and diluted with ether. The organic layer was washed with water, brine, then evaporated to give a residue, which was chromatographed on thin layer (silica gel, hexane–ether, 1:1) to give starting material **37** (11 mg, 52%) and oxime **43** (2 mg, 5%) (*vide infra*).

(b) From unsaturated ketoester 42

A mixture of unsaturated ketoester **42** (12 mg, 0.049 mmol), hydroxylamine hydrochloride (33 mg, 0.30 mmol), and anhydrous sodium acetate (41 mg, 0.41 mmol) in anhydrous methanol (1 mL) was refluxed for 1 h, then cooled and diluted with ether. After the usual extraction, the crude product was chromatographed to give oxime **43** (10 mg, 83%); mp 182–182.5°C; ir ($CHCl_3$, ν cm^{-1}): 3630, 3300, 1705, 1650; ^1H nmr ($CDCl_3$, δ ppm): 4.68 (s, 1H, HC11), 4.65 (d, 1H, J = 3 Hz, $CH(OCH_3)_2$), 3.82 (s, 3H, CO_2CH_3), 3.54 and 3.49 (2s, 6H, $CH(OCH_3)_2$), 2.90 (br s, 1H, OH), 2.8–1.1 (m), 1.37 (s, 3H, CH_3C5), 0.85 and 0.80 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$); ms *m/e*: 419 (M^+).

Ozonolysis of ketoester 37

Ozone was bubbled through a cold (−78°C) solution of ketoester **37** (25 mg, 0.056 mmol) and *p*-toluenesulfonic acid (5 mg) in a mixture of methanol–dichloromethane (2:1, 3 mL) during 2 min (blue color). Dimethyl sulfide (1 mL) was added, the mixture was warmed to room temperature, and the volatile substances were evaporated. The crude residue was dissolved in dichloromethane, washed with sodium bicarbonate solution and brine, and the solvent was evaporated to leave a residue that was chromatographed on silica gel (benzene – ethyl acetate, 3:2) to give aldol product **44** (20 mg, 80%), an amorphous solid: ir ($CHCl_3$, ν cm^{-1}): 3565, 3400, 1795, 1755, 1730, 1715; ^1H nmr ($CDCl_3$, δ ppm): 4.45 (d, 1H, J = 6 Hz, $CH(OCH_3)_2$), 3.57 (s, 3H, CO_2CH_3), 3.54 and 3.47 (2s, 6H, $CH(OCH_3)_2$), 3.40 (d, 1H, J = 4 Hz, HCl), 3.1–1.6 (m), 1.42 (s, 3H, CH_3C5), 1.00 and 0.76 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$); ms *m/e*: 480 (M^+).

Dihydroxyketone 45

To a cooled (0°C) solution of diketone ester **44** (20 mg, 0.042 mmol) in tetrahydrofuran (2 mL) and methanol (2 mL) was added sodium borohydride (40 mg, large excess). After 15 min, saturated aqueous ammonium chloride was added and the mixture was extracted with chloroform, washed with water and brine, and the solvent was evaporated. Chromatography of the residue (dichloromethane – acetone, 4:1) (thin layer) furnished diol **45** (18 mg, 90%): amorphous solid; ir ($CHCl_3$, ν cm^{-1}): 3530, 3420, 1795, 1740, 1730; ^1H nmr ($CDCl_3$, δ ppm): 4.39 (d, 1H, J = 5.8 Hz, $CH(OCH_3)_2$), 4.05 (after D_2O exchange, dd, 1H, J = 11 and 5 Hz, $H_{ax}C10$), 3.60 (s, 3H, CO_2CH_3), 3.50 (s, 3H) and 3.44 (s, 3H) (2 × OCH_3), 3.35 (dd, 1H, J = 14.4 and 5.9 Hz, HC3), 3.27 (d, 1H, J = 6.2 Hz, HCl), 2.78 (d, 1H, J_{AB} = 19.9 Hz) and 2.22 (d, 1H, J_{AB} = 19.9 Hz) (H_2C14), 2.51 (ddd, 1H, J = 14, 6.2, and 6.1 Hz, HC2), 2.03 (m, 1H, HC13), 1.75–1.2 (m), 1.31 (s, 3H, CH_3C5), 1.00 and 0.76 (2d, 6H, J = 6.8 Hz, $CH(CH_3)_2$); ms *m/e*: 482 (M^+).

Methyl orthocarbonate 46

To a cold (0°C) solution of carbonate **45** (25 mg, 0.051 mmol) in chloroform was added ethereal diazomethane (excess) and the mixture was warmed to room temperature for 1.5 h. Evaporation of volatile materials and chromatography (silica plate, ether – ethyl acetate, 4:1) gave orthocarbonate **46** (20 mg, 80%); ir ($CHCl_3$, ν cm^{-1}): 3515, 1735, 1730, 1430, 1320; ^1H nmr ($CDCl_3$, δ ppm): 4.43 (d, 1H, J = 6 Hz, $CH(OCH_3)_2$), 4.4–3.8 (br m, 1H, $H_{ax}C10$), 3.72 (s, 3H, O_3COCH_3), 3.60 (s, 3H, CO_2CH_3), 3.51 and 3.46 (2s, 6H, $CH(OCH_3)_2$), 3.3–2.7 (m, 2H, HCl and HC3), 2.88 and 2.12 (2d, 2H, J_{AB} = 20 Hz, H_2C14), 1.9–1.2 (m), 1.30 (s, 3H, CH_3C5), 1.05 and 0.75 (2d, 6H, J = 7.0 Hz, $CH(CH_3)_2$); ms *m/e*: 496, weak (M^+).

Hemi-ketal 47

To a cooled (0°C) solution of diol **38** (110 mg, 0.259 mmol) in acetone was added dropwise Jones reagent (0.29 mL, 0.29 mmol). After 2 min, the mixture was poured onto iced water and extracted with ether. The extract was washed with water and brine, and the solvent was evaporated. The crude product was chromatographed on silica plate (benzene – ethyl acetate, 4;1) to give pure hemi-ketal **47** (89 mg, 80%); mp 158–160°C; ir ($CHCl_3$, ν cm^{-1}): 3600, 3460, 1795; ^1H nmr ($CDCl_3$, δ ppm): 4.56 (s, 1H, $CH(OCH_3)_2$), 4.28–4.04 (m, 2H, CH_2O), 3.64 and 3.53 (2s, 6H, $CH(OCH_3)_2$), 3.20 (s, 1H, HC11), 1.33 (s, 3H, CH_3C5), 1.09 and 0.98 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$); ms *m/e*: 420 (M^+).

*Lactone **48***

To a solution of hemi-ketal **47** (30 mg, 0.071 mmol) in acetonitrile was added a solution of ceric ammonium nitrate (330 mg, 0.54 mmol) in water (3 mL). After 0.5 h at 0°C, the mixture was extracted with dichloromethane. Evaporation of the solvents left a residue, which was purified by chromatography on silica plate (benzene – ethyl acetate, 4:1) to give compound **48** (16.8 mg, 56%); mp 168–170°C; ir $CHCl_3$, ν cm^{-1}): 1800, 1765, 1660; ^1H nmr ($CDCl_3$, δ ppm): 6.35 and 5.48 (2m, 2H, olefinic protons), 4.75 (dd, 1H, J_{AB} = 12 Hz, J_{AX} = 2 Hz) and 4.30 (dd, 1H, J_{AB} = 12 Hz, J_{BX} = 3 Hz) (CH_2O), 4.60 (s, 1H, $CH(CH_3)_2$), 3.60 (s, 6H, $CH(OCH_3)_2$), 3.00 and 2.15 (2d, 2H, J_{AB} = 12 Hz, H_2C14), 3.3–2.5 (m), 1.60 (s, 3H, CH_3C5), 1.15 and 1.05 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$); ms *m/e*: 418 (M^+).

*Hydroxyacid **49***

To a solution of lactone **48** (2.0 mg, 0.0047 mmol) in 1,2-dimethoxyethane (DME) (1 mL) was added aqueous lithium hydroxide (0.72 mg, 0.0052 mmol). After 20 min at 25°C the mixture was poured onto water, acidified (pH 6.5, 0.1 M HCl), and extracted with dichloromethane to give crude acid **49** (2.0 mg, 95%); ir ($CHCl_3$, ν cm^{-1}): 3600–2700 (br), 1795, 1740, 1660; ^1H nmr ($CDCl_3$, δ ppm): 6.48 and 5.67 (2m, 2H, olefinic protons), 5.10 (very br, 1H, CO_2H), 4.61 (br s, 1H, $CH(OCH_3)_2$), 3.64 and 3.54 (2s, 6H, 2 × OCH_3), 3.2–1.3 (m), 1.50 (s, 3H, CH_3C5), 0.88 and 0.77 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$); ms *m/e*: 436 (M^+).

*Acetate acid **50***

To a solution of hydroxyacid **49** (7.4 mg, 0.015 mmol) in pyridine (0.7 mL) was added acetic anhydride (0.7 mL). After 3 h at room temperature, water (0.8 mL) was added and the mixture was stirred at 0°C for 30 min. Evaporation of the volatile materials left a residue, which was dissolved in dichloromethane, and washed with water and brine. Evaporation of the extract furnished pure acid **50** (7 mg, 86%); ir ($CHCl_3$, ν cm^{-1}): 3600–2400 (br), 1800, 1740, 1660; ^1H nmr ($CDCl_3$, δ ppm): 8.00 (br m, CO_2H), 6.48 and 5.62 (2m, 2H, olefinic protons), 4.50 (m, 2H, -CH_2O-), 4.30 (br s, 1H, $CH(OCH_3)_2$), 3.61 and 3.52 (2s, 6H, 2 × OCH_3), 3.0–1.1 (m), 2.11 (s, 3H, O_2CCH_3), 1.28 (s, 3H, CH_3C5), 0.85 and 0.75 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$); ms *m/e*: 478 (M^+).

*Hydroxyester **51***

To a solution of hydroxyacid **49** (2 mg, crude) in dichloromethane at 0°C was added ethereal diazomethane (0.5 mL). After 10 min, evaporation of the volatile substances left a residue, which was chromatographed on silica plate (benzene – ethyl acetate, 4:1) to give hydroxyester **51** (1.5 mg, 75%); ir ($CHCl_3$, ν cm^{-1}): 3500 (weak), 1800, 1740, 1650, 1600; ms *m/e*: 450 (M^+).

*Methoxylactone **53***

To a solution of acid **50** (6 mg, 0.013 mmol) in dry benzene was added *p*-toluenesulfonic acid (0.7 mg). The mixture was refluxed for 25 h, then cooled, poured onto water, extracted with dichloromethane, washed with water, and the solvent evaporated. The crude product was chromatographed on silica plate (benzene – ethyl acetate, 4:1) to give methoxylactone **53** (3.2 mg, 57%); ir ($CHCl_3$, ν cm^{-1}): 1810, 1745, 1665, 1600; ^1H nmr ($CDCl_3$, δ ppm): 6.10 and 5.52 (2m, 2H, olefinic protons), 5.03 (d, 1H, J = 6 Hz, $CH_3OCHOCO_2$), 4.01 (m, 2H, $CH_2OCO_2CH_3$), 3.50 (s, 3H, OCH_3), 3.2–1.8 (m), 2.00 (s, 3H, CH_3CO_2), 1.54 (s, 3H, CH_3C5), 1.30 and 0.97 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$); ms *m/e*: 446 (M^+).

*Lactone **57***

A solution of hemi-ketal **47** (110 mg, 0.26 mmol) and *p*-toluenesulfonic acid (60 mg) in dry dichloromethane (25 mL) was cooled to −78°C and reacted with a stream of ozone (~4 min). Then dimethyl sulfide (2 mL) was added to the mixture and after 5 min the excess of the sulfide was evaporated, and the reaction mixture was washed with aqueous sodium bicarbonate and brine. Evaporation of the solvent left a crude product, which was chromatographed to give crystalline enone lactone **57** (85 mg, 75%); mp 215–216°C (dec.); uv (λ_{max}, EtOH): 238 nm (ε 15 000); ir ($CHCl_3$, ν cm^{-1}): 1810, 1760, 1680, 1630; ^1H nmr ($CDCl_3$, δ ppm): 4.36 (d, 1H, J = 5.6 Hz, $CH(OCH_3)_2$), 4.23 (d, 2H, J = 1.5 Hz, H_2C17), 3.56 and 3.52 (2s, 3H each, 2 × OCH_3), 3.30 (dd, 1H, J = 11.1 and 5.6 Hz, HC3), 3.08 (d, 1H) and 2.42 (d, 1H) (J_{AB} = 12.6 Hz, H_2C14), 2.88 (m, 2H, HC2 and HC1), 2.4 and 2.13 (2m), 1.39 (s, 3H, CH_3C5), 1.07 and 1.03 (2d, 3H each, $CH(CH_3)_2$); ms *m/e*: 434 (M^+, weak).

*Tricyclic enone aldehyde **60***

A cold saturated solution of ozone in dichloromethane was added dropwise to a cold (−78°C) solution of olefin diol **38** (17 mg, 0.04 mmol) and *p*-toluenesulfonic acid (10 mg) in anhydrous methanol (7 mL) until the disappearance of the starting material. Dimethyl sulfide (1 mL) was added and the mixture was warmed to room temperature, then washed with aqueous sodium bicarbonate and brine. Evaporation of the solvent left a residue, which was chromatographed on silica gel to give enone aldehyde **60** (9.2 mg, 56%); ir ($CHCl_3$, ν cm^{-1}): 3450, 1720, 1658, 1570; ^1H nmr ($CDCl_3$, δ ppm): 9.71 (t, 1H, J = 3 Hz, OHC15), 4.60 (d, 1H, J = 5 Hz, $CH(OCH_3)_2$), 4.5 (m, 3H, OH and CH_2OH), 3.56 and 3.51 (2s, 6H, 2 × OCH_3), 2.5–1.5 (m), 1.43 (s, 3H, CH_3C5), 0.95 (d, 6H, J = 7 Hz, $CH(CH_3)_2$); ms *m/e*: 392 (M^+-H_2O).

*Keto p-nitrobenzoate **62***

To a cold (0°C) solution of diol **38** (200 mg, 0.474 mmol) in pyridine (4 mL) was added freshly recrystallized (petroleum ether) p-nitrobenzoyl chloride (105 mg, 0.566 mmol). After 1 h at 0°C the mixture was diluted with chloroform (100 mL), then washed with cold aqueous sodium carbonate and brine. Evaporation of the solvent left a solid residue (260 mg, 96%) that was used directly for the next step; mp 181–182°C (benzene); ir ($CHCl_3$, ν cm^{-1}): 3610, 3490, 1790, 1728, 1605, 1537, 1270; ^1H nmr ($CDCl_3$, δ ppm): 8.27 (s, 4H, aromatic), 5.10 (dd, 1H, J_{AB} = 11 Hz, J_{AX} = 10 Hz, H_AC17), 4.80 (dd, 1H, J_{AB} = 11 Hz, J_{BX} = 6 Hz, H_BC17), 4.28 (d, 1H, J = 1.9 Hz, $CH(OCH_3)_2$), 3.88 (m, 1H, HC15), 3.48 and 3.45 (2s, 6H, 2 × OCH_3), 3.21 (d, 1H, J = 2.5 Hz, HC11), 2.8–1.4 (m), 1.27 (s, 3H, CH_3C5), 0.95 (br d, 6H, J = 6.5 Hz, $CH(CH_3)_2$); ms *m/e*: 539 (M^+-CH_3OH). Collins reagent was prepared by the addition of anhydrous pyridine (1.47 mL) to a suspension of chromium trioxide (920 mg, 0.92 mmol) in dry dichloromethane (30 mL). After 15 min at 25°C, this reagent was cooled at 0°C and a solution of the preceding hydroxyester (260 mg, 0.455 mmol) in dichloromethane (2 mL) was added. Five minutes later, isopropanol (2 mL) was added and the mixture was poured onto cold aqueous sodium carbonate and extracted with dichloromethane. The extract was dried and the solvent was evaporated. The crude residue was purified by chromatography on silica gel (benzene – ethyl acetate, 9:1) to give pure ketone **62** (255 mg, 98%); ir ($CHCl_3$, ν cm^{-1}): 1794, 1737, 1600, 1524, 1265; ^1H nmr ($CDCl_3$, δ ppm): 8.29 (s, 4H, aromatic), 4.82 (dd, 1H, J_{AB} = 12 Hz, J_{AX} = 4 Hz, H_AC17), 3.90 (dd, J_{AB} = 12 Hz, J_{BX} = 11 Hz, H_BC17), 4.50 (br s, 1H, $CH(OCH_3)_2$), 3.85 (s, 1H, HC11), 3.58 and 3.46 (2s, 6H, 2 × OCH_3), 2.4–1.5 (m), 1.45 (s, 3H, CH_3C5), 1.09 and 1.03 (2d, 6H, J = 6.7 Hz, $CH(CH_3)_2$); ms *m/e*: 569 (M^+). *Exact Mass* calcd. for $C_{30}H_{35}O_{10}N$ (M^+): 569.2261; found: 569.2256.

*Epoxide **63***

To a solution of keto *p*-nitrobenzoate **62** (560 mg, 0.984 mmol) in dichloromethane (50 mL) was added solid *m*-chloroperbenzoic acid (1.7 g, 98% 9.8 mmol). The mixture was stirred in the dark (aluminium foil) for 18 h at room temperature, then cooled (0°C) and slowly added to cold aqueous sodium bisulfite (~4%, 100 mL). The organic layer was separated and washed with aqueous sodium bicarbonate. The aqueous layer was extracted with dichloromethane and the combined organic layers were dried and the solvent evaporated. The crude product was filtered through silica gel (benzene – ethyl acetate, 95:5) to give epoxide **63** (570 mg, 99%); ir ($CHCl_3$, ν cm^{-1}): 1815, 1755, 1737, 1605, 1526, 1260; ^1H nmr ($CDCl_3$, δ ppm): 8.30 (s, 4H, aromatic), 4.76 (dd, 1H, J_{AB} = 12 Hz, J_{AX} = 4 Hz, H_AC17), 3.81 (dd, 1H, J_{AB} = 12 Hz, J_{BX} = 11.5 Hz, H_BC17), 4.47 (br s, 1H, $CH(OCH_3)_2$), 3.68 (s, 1H, HC11), 3.2–1.2 (m), 1.48 (s, 3H, CH_3C5), 1.03 and 0.97 (2d, 6H, J = 6.5 Hz, $CH(CH_3)_2$). *Exact Mass* calcd. for $C_{30}H_{35}O_{11}N-CH_3O$ (M^+-CH_3O): 554.2026; found: 554.2038.

Enol ethers ***64***

From a solution of epoxide **63** (910 mg, 1.55 mmol) in benzene (350 mL), in a 3-neck 500-mL flask, was distilled a small quantity of benzene (~25 mL, Dean–Stark head filled with molecular sieve 4Å); then *p*-toluenesulfonic acid (~3 mg) was added on the inner side of the flask. The reflux was continued for 15 h and the reaction mixture was concentrated by distillation of benzene to a small volume (~10 mL), cooled to room temperature, and rapidly filtered through a small column of silica gel (benzene – ethyl acetate, 2:1). The crude product (850 mg, 99%) was used directly for the next step. The isomeric enol ethers **64** (~1:1) were separated by thin-layer chromatography (benzene – ethyl acetate, 20:1, two elutions).

Enol ether ***64***a (less polar): mp 258–259°C; ir ($CHCl_3$, ν cm^{-1}): 1808, 1750, 1740, 1668, 1608, 1527, 1256; ^1H nmr ($CDCl_3$, δ ppm): 8.30 (m, 4H, aromatic), 6.44 (br s 1H, =C*H*OCH_3), 4.95 (m, 1H) and 5.25 (m, 1H) (H_2C17), 3.75 (s, 4H, OCH_3 and HC11), 3.03 (m, 2H, HC1 and HC2), 2.5–1.5 (m), 1.43 (s, 3H, CH_3C5), 0.96 (m, 6H, $CH(CH_3)_2$); ms *m/e*: 553 (M^+).

Enol ether ***64***b (more polar): mp 127–128°C; ir ($CHCl_3$, ν cm^{-1}): 1808, 1748, 1740, 1667, 1610, 1528, 1255; ^1H nmr ($CDCl_3$, δ ppm): 8.28 (m, 4H, aromatic), 6.15 (d, 1H, J = 1.2 Hz, =C*H*OCH_3), 4.86 (dd, 1H, J_{AB} = 12 Hz, J_{AX} = 5 Hz, H_AC17), 4.20 (dd, 1H, J_{AB} = 12 Hz, J_{BX} = 11 Hz, H_BC17), 3.73 (s, 4H, OCH_3 and HC11), 3.3–1.3 (m), 1.51 (s, 3H, CH_3C5), 0.95 (d, 6H, J = 7 Hz, $CH(CH_3)_2$); ms *m/e*: 553 (M^+). *Anal.* calcd. for $C_{29}H_{31}O_{10}N$: C 62.92, H 5.64; found: C 62.88, H 5.78.

Norketone ***65***

To a cold (−78°C) solution of enol ethers **64** (35 mg, 0.063 mmol) in dichloromethane (10 mL) was added a cold (−78°C) saturated ozone solution in dichloromethane until the starting enol ethers disappeared (tlc monitoring). Then dimethyl sulfide (1.5 mL) was added and the mixture was warmed to room temperature. Evaporation of the volatile substances left a residue that was rapidly filtered on silica gel (benzene – ethyl acetate, 10%) to give pure slightly unstable norketone **65** (31 mg, 94%); mp 188–189°C; ir ($CHCl_3$, ν cm^{-1}): 1830, 1755, 1740, 1610, 1530; ^1H nmr ($CDCl_3$, δ ppm): 8.29 (m, 4H, aromatic), 4.84 (dd, 1H, J_{AB} = 12 Hz, J_{AX} = 4.4 Hz, H_AC17), 4.33 (dd, 1H, J_{AB} = 12 Hz, J_{BX} = 10.5 Hz, H_BC17), 3.93 (s, 1H, HC11), 2.88 (m, 1H, HC1), 2.45 (d, 1H, J_{AB} = 19 Hz, H_AC14), 1.60 (d, 1H, J_{AB} = 19 Hz, H_BC14), 2.5–1.2 (m), 1.51 (s, 3H, CH_3C5), 1.06 and 1.03 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$); ms *m/e*: 525 (M^+). *Anal.* calcd. for $C_{27}H_{27}O_{10}N$: C 61.71, H 5.17; found: C 61.53, H 4.91.

Endocyclic enol ether ***66***

To a cold (0°C) solution of norketone **65** (183 mg, 0.34 mmol) in tetrahydrofuran (4 mL) and ethanol (1 mL) was added a freshly prepared solution of diazomethane (~10 mL in ether, excess). After 18 h at 0°C, the volatile substances were evaporated to leave pure enol ether **66** (188 mg, 99%); ir ($CHCl_3$, ν cm^{-1}): 1815, 1750, 1735, 1665, 1605, 1525, 1255; ^1H nmr ($CDCl_3$, δ ppm): 8.28 (m, 4H, aromatic), 4.83 (dd, 1H, J_{AB} = 12 Hz, J_{AX} = 4 Hz, H_AC17), 4.03 (dd, 1H, J_{AB} = 12 Hz, J_{BX} = 11 Hz, H_BC17), 3.81 (s, 1H, HC11), 3.70 (s, 3H, OCH_3), 3.45 (dd, 1H, J = 4 and 11 Hz, HC1), 2.73 (m, 1H, *H*$C(CH_3)_2$), 2.35 (d, 1H, J_{AB} = 18.5 Hz) and 1.80 (d, 1H, J_{AB} = 18.5 Hz) (H_2C14), 2.1–1.3 (m), 1.61 (s, 3H, OCH_3), 1.16 and 1.08 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$).

Enol acetate ***67***

To a solution of norketone **65** (64 mg, 0.12 mmol) in acetic anhydride (3 mL) was added anhydrous sodium acetate (120 mg) and the mixture was heated to 95°C for 1 h. The cooled mixture was then filtered through cotton and the solvent was evaporated. Rapid filtration of the crude product through silica gel (benzene – ethyl acetate, 85:15) furnished pure enol acetate **67** (64 mg, 93%); ir ($CHCl_3$, ν cm^{-1}): 1822, 1780, 1755, 1740, 1670, 1610, 1530; ^1H nmr ($CDCl_3$, δ ppm): 8.28 (m, 4H, aromatic), 4.92 (dd, 1H, J_{AB} = 12 Hz, J_{AX} = 4 Hz, H_AC17), 4.25 (dd, 1H, J_{AB} = 12 Hz, J_{BX} = 10 Hz, H_BC17), 3.90 (s, 1H, HC11), 3.68 (dd, 1H, J = 10 and 4 Hz, HC1), 2.60 (qn, 1H, J = 7 Hz, *H*$C(CH_3)_2$), 2.45 (d, 1H J_{AB} = 20 Hz) and 2.05 (d, 1H, J_{AB} = 20 Hz, H_2C14), 2.33 (s, 3H, CH_3CO_2), 1.50 (s, 3H, CH_3C5), 1.08 and 0.93 (2d, 6H, $CH(CH_3)_2$).

Dienol ether ***69***

From a solution of enol ether **66** (390 mg, 0.723 mmol) in benzene (150 mL) was distilled some benzene (~20 mL). A quantity of 1,5-diazabicyclo[4.3.0]non-5-ene (DBN) (1.2 mL, freshly distilled, excess) was then added and the mixture was refluxed for 10 h. The cooled mixture was then poured onto ice-cold hydrochloric solution (0.5 M, 50 mL) and extracted with dichloromethane. The combined organic layers were washed with aqueous sodium bicarbonate and brine. Evaporation of the solvent left a colored residue, which was chromatographed (silica gel, benzene – ethyl acetate, 96:4) to give pure colorless dienol ether **69** (207 mg, 77%); mp 203–204°C; ir ($CHCl_3$, ν cm^{-1}): 1810, 1755, 1635, 1620; ^1H nmr ($CDCl_3$, δ ppm): 5.34 and 5.26 (2d, 2H, J = 1.4 Hz, H_2C17), 3.78 (s, 3H, OCH_3), 3.59 (s, 1H, HC11), 2.68 (qn, 1H, J = 7 Hz, *H*$C(CH_3)_2$), 2.20 (d, 1H, J_{AB} = 18 Hz) and 1.78 (d, 1H, J_{AB} = 18 Hz) (H_2C14), 1.58 (s, 3H, CH_3C5), 1.17 and 1.14 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$); ms *m/e*: 372 (M^+). *Anal.* calcd. for $C_{21}H_{24}O_6$: C 67.73, H 6.50; found: C 67.90, H 6.62. *Exact Mass* calcd. for $C_{21}H_{24}O_6$: 373.1573; found: 372.1569.

Enone ***71***

A solution of enol acetate **67** (40 mg, 0.073 mmol) in dry benzene (8 mL) was refluxed in the presence of freshly distilled DBN (2.2 equiv., 34 μL). After 20 h, the cooled mixture was diluted with dichloromethane, washed with water, and the extract was dried. Evaporation of the solvent left a residue that was purified by silica gel chromatography (benzene – ethyl acetate, 9:1) to give crystalline enone **71** (18 mg, 69%); mp 129–130°C; ir ($CHCl_3$, ν cm^{-1}): 1820, 1750, 1725, 1630; ^1H nmr ($CDCl_3$, δ ppm): 3.58 (s, 1H, HC11), 2.72 (qn, 1H, J = 7 Hz, *H*$C(CH_3)_2$), 2.13 (d, 1H, J_{AB} = 18 Hz) and 1.47 (d, 1H, J_{AB} = 18 Hz) (H_2C14), 2.08 (s, 3H, H_3C17), 1.50 (s, 3H, CH_3C5), 1.14 and 1.08 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$); ms *m/e*: 358 (M^+).

Olefin ***72*** (*vide supra*, preparation of compound ***36***)

To cold THF (8 mL, −78°C) under argon was added tungsten hexachloride (black, 80 mg, 0.20 mmol) and, 5 min later, *n*-butyllithium in hexane (dropwise, 266 μL, 2.2 M, 0.586 mmol, time of the addition ~20 min). The mixture was allowed to warm to room temperature and was stirred for 1 h. About half (~4 mL, ~3 equiv.) of the dark brown solution obtained was transferred, under argon, to crystalline epoxide **69** (25 mg, 0.067 mmol). The mixture was stirred for 3 h, then filtered through silica gel (~20 g) and eluted with ether. Evaporation of the solvents left a mixture of olefin **72** and starting material **69**, which were separated by chromatography (chloroform) to give starting material **69** (12 mg) and olefin **72** (10 mg, 80% based on recovered starting material). In our hands, modification of these conditions resulted in lower yield of the desired product; mp 181–181.5°C; ir ($CHCl_3$, ν cm^{-1}): 1810, 1745, 1640, 1620; uv (EtOH, λ_{max}): 240 nm (ε 17 320); ^1H nmr ($CDCl_3$, δ ppm): 5.34 and 5.27 (2d, 2H, J = 1.2 Hz, H_2C17), 3.76 (s, 3H, OCH_3), 3.74 (s, 1H, HC11), 2.70 (qn, 1H, J = 7.1 Hz, *H*$C(CH_3)_2$), 1.56 (s, 3H, CH_3C5), 1.20 and 1.15 (2d, 6H, J = 7.1 Hz, $CH(CH_3)_2$); ms *m/e*: 356 (M^+). *Exact Mass* calcd. for $C_{21}H_{24}O_5$: 356.1624; found: 356.1634.

Enone ***73***

To a solution of dienol ether **72** (90 mg, 0.253 mmol) in benzene (20 mL) was added boron trifluoride etherate (0.8 mL) and the mixture was stirred at room temperature for 18 h. The mixture was then washed with aqueous sodium bicarbonate, the aqueous phase was extracted with dichloromethane, and the combined organic layers were dried and evaporated. The residue was filtered through silica gel (hexane –ether, 4:1) to give pure enone **73** (80 mg, 93%); mp 135–136°C; ir ($CHCl_3$, ν cm^{-1}): 1825, 1740, 1725, 1630; uv (EtOH, λ_{max}): 233 nm (ε 7749); ^1H nmr ($CDCl_3$, δ ppm): 3.84 (s, 1H, HC11), 2.78 (qn, 1H, J = 7 Hz, *H*$C(CH_3)_2$), 2.15 (d) and 1.75 (d) (J_{AB} = 19 Hz, H_2C14), 2.15 (s, 3H, H_3C17), 1.56 (s, 3H, CH_3C5), 1.19 and 1.15 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$); ms *m/e*: 342 (M^+). *Exact Mass* calcd. for $C_{20}H_{22}O_5$: 342.1465; found: 342.1465.

Reaction of compound 73 with trifluoroperacetic acid

The reagent was prepared by mixing, at 0°C, 90% hydrogen peroxide (0.41 mL, 15 mmol) in dry dichloromethane (10 mL) and adding, with good stirring, trifluoroacetic anhydride (2.54 mL, 12 mmol). After 10 min of stirring at 0°C the reagent (which can be stored for weeks at −20°C) was ready for use. To a solution of enone **73** (3.0 mg, 0.0087 mmol) in dichloromethane (2 mL) was added powdered dibasic sodium phosphate (20 mg) and trifluoroperacetic acid solution prepared as above (1.0 mL, ~1.0 mmol). After 20 h in the dark, the solution was washed with aqueous sodium bicarbonate and dried over sodium sulfate. The crude product was shown to be pure enone epoxide **71** (3 mg, ~quant).

Epoxyketone 77

To a solution of enone **73** (6.0 mg, 0.017 mmol) in ether (5 mL) was added aqueous basic hydrogen peroxide (0.05 M in H_2O_2, 0.05 M in NaOH) (1 mL) and the mixture was vigorously stirred at 25°C for 40 h. The mixture was then poured into aqueous diluted sodium bisulfite and extracted with ether at pH 6. The organic layer was washed with brine and the solvent was evaporated. Chromatography (benzene – ethyl acetate, 9:1) on silica gel furnished epoxide **77** (3.2 mg, 50%); ir ($CHCl_3$, ν cm^{-1}): 1830, 1765, 1742; ^1H nmr ($CDCl_3$, δ ppm): 3.79 (s, 1H, HC11), 2.7–1.7 (m), 1.67 (s, 3H, H_3C17), 1.48 (s, 3H, CH_3C5), 1.25 and 1.11 (2d, 6H, J = 6.6 Hz, $CH(CH_3)_2$); ms *m/e*: 358 (M^+).

Bicyclic triketone 81

A solution of enone **73** (70 mg, 0.20 mmol) in dichloromethane (8 mL) containing methanol (3 mL) and *p*-toluenesulfonic acid (3 mg) was reacted at −78°C with a cold saturated solution of ozone in dichloromethane until the starting material disappeared (tlc monitoring). After the addition of dimethyl sulfide (1 mL) the mixture was warmed to 0°C, poured onto cold aqueous sodium bicarbonate, and extracted with dichloromethane. The crude product was purified by chromatography on silica gel (ether) to give light yellow crystalline bicyclic triketone **81** (60 mg, 81%); mp 99–100°C; uv (EtOH, λ_{max} nm): 296 (ε 21 000), 224 (ε 7000); ir ($CHCl_3$, ν cm^{-1}): 3350, 1724, 1680 (sh), 1662, 1631, 1588; ^1H nmr ($CDCl_3$, δ ppm): 5.96 (s, OH), 5.95 (s, 1H, HC11), 3.68 (s, 3H, OCH_3), 3.12 and 2.33 (2d, 2H, J_{AB} = 17.1 Hz, H_2C14), 2.94 (qn, 1H, J = 6.5 Hz, $CH(CH_3)_2$), 2.88 (dt, 1H, J_{AB} = 18.9 Hz, J = 6.7 Hz) and 2.66 (dt, 1H, J_{AB} = 18.9 Hz, J = 6.7 Hz) (H_2C9), 2.43 (br t, 2H, J = 7.3 Hz, H_2C7), 2.17 (s, 3H, H_3C17), 1.98 (qn, 2H, J = 6.9 Hz, H_2C8), 1.25 and 1.22 (2d, 6H, J = 6.5 Hz, $CH(CH_3)_2$), 1.15 (s, 3H, CH_3C5); ^{13}C nmr ($CDCl_3$, δ ppm): 216.1, 201.8, 196.6, 174.4, 158.8, 157.8, 152.7, 116.7, 78.5, 51.6, 48.9, 44.2, 38.9, 32.7, 26.2, 20.1, 19.8, 18.5, 17.7, 11.9; ms *m/e*: 362 (M^+). *Exact Mass* calcd. for $C_{20}H_{26}O_6-OCH_3$: 331.1545; found: 331.1538.

Ozonolysis of enone 73

To a cold (78°C) solution of enone **73** (4.0 mg, 0.011 mmol) in dry dichloromethane (2 mL) containing *p*-toluenesulfonic acid (1 mg) was added dropwise a cold solution of ozone in dichloromethane until the starting material disappeared (tlc monitoring). After addition of dimethyl sulfide (0.5 mL) the mixture was warmed to ~0°C, poured into cold aqueous bicarbonate solution, and extracted with dichloromethane. The extract was washed with water and brine, dried, and the solvent was evaporated to give a single, but unstable, compound, which could not withstand chromatography and to which was assigned structure **82** (crude, 4 mg, 95%); ir ($CHCl_3$, ν cm^{-1}): 3450, 1828, 1770, 1725, 1620; ^1H nmr ($CDCl_3$, δ ppm): 3.18 (br s, 1H, OH), 2.75 (qn, 1H, J = 7 Hz, $HC(CH_3)_2$), 2.60 and 2.00 (2d, 2H, J_{AB} = 18 Hz, H_2C14), 2.19 (s, 3H, H_3C17), 1.53 (s, 3H, CH_3C5), 1.18 and 1.12 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$; ms *m/e*: 374 (M^+).

Ozonolysis of keto p*-nitrobenzoate 62*

Ozone was added to a cold (−78°C) solution of keto *p*-nitrobenzoate **62** (774 mg, 1.36 mmol) and *p*-toluenesulfonic acid (228 mg) in ethyl acetate until the blue color persisted. After the addition of dimethyl sulfide (4 mL), the mixture was warmed to room temperature, poured onto an iced solution of sodium bicarbonate (~2%), and extracted with dichloromethane. Evaporation of the solvents left a residue that was shown to be the sensitive hydroxydiketone **83**; ir ($CHCl_3$, ν cm^{-1}): 3540, 3400, 1808, 1763, 1730, 1610, 1527, 1371, 1340, 1311, and 1265. The crude product was then dissolved in ethyl acetate (20 mL) and reacted with an excess of ethereal diazomethane for 2 h at 25°C. Evaporation of the volatile substances left a residue that was purified by chromatography on silica gel (hexane – ether, 2:3) to give diketone **84** (630 mg, 75%); ir $CHCl_3$, ν cm^{-1}): 1751, 1729, 1610, 1528, 1455, 1341, 1264; ^1H nmr ($CDCl_3$, δ ppm): 8.22 (m, 4H, aromatic), 4.6–3.5 (m, 2H, H_2C17), 4.32 (d, 1H, J = 5.1 Hz, $HC(OCH_3)_2$), 3.64 (s, 3H, CH_3OCO_3), 3.53 and 3.49 (2s, 6H, 2 × OCH_3), 2.9–1.3 (m), 1.35 (s, 3H, CH_3C5), 1.10 and 0.98 (2d, 6H, J = 7.4 Hz, $CH(CH_3)_2$); ms *m/e*: 585 (M^+-30).

Lactone 57

To a cold (−70°C) solution of diketone **84** (10.8 mg, 0.0175 mmol) in tetrahydrofuran (5 mL) was added a solution of lithium tri-*sec*-butylborohydride (1 M in THF, 70 μL, 0.070 mmol). After 1 h, additional reducing agent (30 μL) was added and, again, 1 h later (20 μL) for a total of ~7 equivalent. Acetone (3 mL) was added to the mixture 30 min after the last addition, followed by saturated aqueous ammonium chloride. Extraction with dichloromethane led to a residue that was chromatographed to give the known crystalline lactone **57** (*vide supra*, 5.0 mg, 64%).

Methyl ester 87

From lactone 57

A solution of lactone **57** (5.0 mg, 0.011 mmol) in dry methanol (5 mL) containing lithium methoxide solution in methanol (0.3 mL of a 0.2 M solution) was stirred at room temprature for 20 h. The mixture was then poured into aqueous ammonium chloride and extracted with dichloromethane to leave a residue that was chromatographed (ether) to give enone ester **87** (4 mg, 75%); ir ($CHCl_3$, ν cm^{-1}): 3500, 1800, 1740, 1680, 1633, 1390, 1220; ^1H nmr ($CDCl_3$, δ ppm): 4.30 (d, 1H, J = 6.5 Hz, $CH(OCH_3)_2$), 3.65 (s, 3H, OCH_3), 3.56 and 3.45 (2s, 6H, 2 × OCH_3), 3.7–3.3 (masked m, 2H, CH_2OH), 3.3–1.5 (m), 1.42 (s, 3H, CH_3C5), 1.05 and 1.00 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$; ms *m/e*: 464 (M^+).

From diketone 84

To a cold (0°C) solution of diketone **84** (25 mg, 0.040 mmol) in tetrahydrofuran (8 mL) was added a solution of lithium methoxide in methanol (0.2 M, 200 μL). After 5 h, the mixture was poured into aqueous ammonium chloride and extracted with dichloromethane. The residue was purified by chromatography on silica gel (ether) to give hydroxyester **87** (11.5 mg, 61%).

Enol ether 88

This elimination was carried out as for enol ether **64** (*vide supra*). From compound **84** (230 mg, 0.374 mmol) was thus obtained, after a rapid filtration through silica gel, a purified mixture of enol ether **88** (216 mg, 99%), which was used directly for the next reaction. Spectroscopic data for the more abundant, less polar isomer: ir ($CHCl_3$, ν cm^{-1}): 1751, 1730, 1698, 1611, 1528, 1455, 1341, 1316, 1266; ^1H nmr ($CDCl_3$, δ ppm): 8.26 (s, 4H, aromatic), 5.98 (d, 1H, J = 1.9 Hz, $=CHOCH_3$), 4.42 (dd, 1H, J_{AB} = 12 Hz, J_{AX} = 2 Hz, H_AC17), 3.72 (s, 3H, OCH_3), 3.67 (s, 3H, OCH_3), 3.55 (dd, 1H, J_{AB} = J_{BX} = 12 Hz, H_BC17), 3.1–1.4 (m), 1.52 (s, 3H, CH_3C5), 1.20 and 1.10 (2d, 6H, J = 6 Hz, $CH(CH_3)_2$); ms *m/e*: 553 (M^+-30).

Norketone 89

To a cold (−78°C) solution of enol ether mixture **88** (100 mg, 0.171 mmol) in dry dichloromethane (20 mL) was added a cold dark-blue solution of ozone in dichloromethane until both isomers of **88** had disappeared (tlc monitoring). Then dimethyl sulfide (1 mL) was added, the mixture was warmed to room temperature, and the volatile substances were evaporated. This crude product (yellowish foam) was used directly for the next reaction. A small quantity was chromatographed on silica plate (benzene – ethyl acetate, 3:1) to give sensitive norketone **89**; ir ($CHCl_3$, ν cm^{-1}): 1760, 1733, 1610, 1529, 1456, 1348, 1320, 1258; ^1H nmr ($CDCl_3$, δ ppm): 8.2 (m, 4H, aromatic), 4.40 (m, 2H, H_2C17), 3.73 (s, 3H, OCH_3), 3.4–1.5 (m), 1.26 (s, 3H, CH_3C5), 1.10 and 1.00 (2d, 6H, J = 6 Hz, $CH(CH_3)_2$).

Enol acetylation

This reaction was carried out as for enol acetate **67** (*vide supra*). Thus norketone **89** (crude, 102 mg) furnished crude enol acetate **90** (102 mg, crude). A small quantity was purified on silica plate (benzene – ethyl acetate, 2:1) for spectroscopic data: ir ($CHCl_3$, ν cm^{-1}): 1770, 1760, 1735, 1610, 1529, 1458, 1350, 1310, 1264; ^1H nmr ($CDCl_3$, δ ppm): 8.28 (s, 4H, aromatic), 4.75 (dd, 1H, J_{AB} = 13 Hz, J_{AX} = 2.5 Hz, H_AC17), 4.50 (dd, 1H, J_{AB} = 13 Hz, J_{BX} = 5 Hz, H_BC17), 3.65 (s, 3H, OCH_3), 3.50 (d, 1H, J = 15 Hz) and 2.90 (d, 1H, J = 15 Hz) (H_AH_BC14), 3.37 (dd, 1H, J = 5 and 2.5 Hz, H_XC1), 2.44 (qn, 1H, J = 7 Hz, $CH(CH_3)_2$), 2.32 (s, 3H, CH_3CO_2), 2.4–1.5 (m), 1.29 (s, 3H, CH_3C5), 1.13 and 1.06 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$.

*Diketone enone **91***

Following the procedure described for enone epoxide **71** (*vide supra*), crude enol acetate **90** (102 mg), after 3 h of reflux, led to enone **91** (52 mg, 78% from dimethyl acetal **84**); ir ($CHCl_3$, ν cm^{-1}): 1765, 1720, 1614, 1460, 1382, 1355, 1318; ^1H nmr ($CDCl_3$, δ ppm): 3.66 (s, 3H, OCH_3), 2.68 (qn, 1H, J = 6.9 Hz, $CH(CH_3)_2$), 2.50 and 1.99 (2d, 1H each, J_{AB} = 20 Hz, H_2C14), 2.25 (s, 3H, CH_3C1), 2.5–1.5 (m), 1.52 (s, 3H, CH_3C5), 1.16 and 1.13 (2d, 6H, J = 6.9 Hz, $CH(CH_3)_2$); ms m/e: 388 (M^+).

*Reduction of diketone enone **91***

To a cold (−78°C) solution of diketone enone **91** (27 mg, 0.069 mmol) in mixture of tetrahydrofuran (5 mL) and methanol (5 mL) was added a large excess of solid sodium borohydride (~10 mg) in small portions, until the starting material had just disappeared (tlc monitoring, benzene – ethyl acetate, 3:1). The mixture was then poured into saturated aqueous ammonium chloride and extracted with dichloromethane. The crude product was chromatographed on silica plate (benzene – ethyl acetate, 3:1) to give ketoalcohol **92** (6 mg, 22%) and diol **93** (15.6 mg, 57%).

*Ketoalcohol **92***: ir ($CHCl_3$, ν cm^{-1}): 3610, 3500, 1730, 1711, 1615, 1457, 1321, 1309; ^1H nmr ($CDCl_3$, δ ppm): 4.64 (dd, 1H, J = 10.7 and 4.6 Hz, HC15), 3.60 (s, 3H, OCH_3), 2.80 (qn, 1H, J = 7 Hz, $CH(CH_3)_2$), 2.6–1.15 (m), 2.33 (s, 3H, CH_3C1), 1.33 (s, 3H, CH_3C5), 1.19 and 1.16 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$; ms m/e: 390 (M^+).

*Diol **93***: mp 225–226°C; ir ($CHCl_3$, ν cm^{-1}): 3620, 3500, 1711, 1620, 1459, 1308; ^1H nmr ($CDCl_3$, δ ppm): 4.57 (m, 1H, $W_{\frac{1}{2}}$ = 6 Hz, $H_{eq}C10$), 4.30 (dd, 1H, J = 10.8 and 4.2 Hz, HC15), 3.65 (s, 3H, OCH_3), 2.79 (qn, 1H, J = 7 Hz, $CH(CH_3)_2$), 2.20 (s, 3H, CH_3C1), 1.25 (s, 3H, CH_3C5), 1.20 and 1.17 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$); ms m/e: 392 (M^+).

*Reduction of ketoalcohol **92***

Ketoalcohol **92** (5.0 mg, 0.013 mmol) was submitted to the same reaction conditions as above and furnished, after purification, diol **93** (3.8 mg, 76%).

*Dichloro and trichloroketones **94** and **95***

To a cold (−20°C) solution of enone **91** (6.3 mg, 0.016 mmol) in a mixture of tetrahydrofuran (1 mL) and dioxan (1 mL) was added an aqueous solution of sodium hypochlorite (0.92 M, 50 μL, 0.046 mmol) and the mixture was stirred at 0°C for 15 h. More reagent (25 μL, 0.023 mmol) was then added and after 9 h the mixture was poured into an aqueous solution of ammonium chloride and extracted with dichloromethane. The crude extract (7.4 mg) was chromatographed (hexane–ether, 1:2) on silica plate to give dichlorodiketone **94** (3.0 mg, 40%) and trichlorodiketone **94** (1.5 mg, 19%).

*Dichlorodiketone **94***: ir ($CHCl_3$, ν cm^{-1}): 1780, 1730, 1615, 1458, 1346, 1327, 1312, 810; ^1H nmr ($CDCl_3$, δ ppm): 3.64 (s, 3H, OCH_3), 2.70 (qn, 1H, J = 7 Hz, $CH(CH_3)_2$), 2.20 (s, 3H, CH_3C1), 2.5–1.7 (m), 1.83 (s, 3H, CH_3C5), 1.15 and 1.13 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$); ms m/e: 458 and 456 (M^+, weak).

*Trichlorodiketone **95***: ir ($CHCl_3$, ν cm^{-1}) 1790, 1751, 1730, 1610, 1458, 1348, 1325, 1312, 810; ^1H nmr ($CDCl_3$, δ ppm): 3.63 (s, 3H OCH_3), 2.95 (dd, 1H, J = 12 and 6 Hz, $H_{ax}C9$), 2.75 (qn, 1H, J = 7 Hz, $CH(CH_3)_2$), 2.29 (s, 3H, CH_3C1), 2.3–1.6 (m), 1.82 (s, 3H, CH_3C5), 1.15 and 1.14 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$); ms m/e: 493, 491, 489 (M^+).

tert-*Butyl perester **98***

To a solution of *tert*-butylhydroperoxide (80.5 mg, 0.89 mmol) in tetrahydrofuran (3 mL) was added at −70°C a solution of *n*-butyllithium (1.6 M in hexane, 0.53 mL, 0.85 mmol). After 15 min of stirring at this temperature, the reagent was used for the following reaction. To a cold (−78°C) solution of diketone enone **91** (50 mg, 0.13 mmol) in tetrahydrofuran (5 mL) were added quantities of the above solution of reagent (initially: 600 μL; 1 h later: 600 μL; 2 h later: 600 μL). After a total of 5 h of stirring, aqueous saturated ammonium chloride (2 mL) was added, and the mixture was warmed to room temperature and extracted with dichloromethane. The crude product was purified on silica plate to give unreacted starting material (10.5 mg, 21%) and perester **98** (35 mg, 61%): ir ($CHCl_3$, ν cm^{-1}): 1820, 1772, 1720, 1685, 1618; ^1H nmr ($CDCl_3$, δ ppm): 3.41 (d, 1H) and 2.53 (d, 1H) (J_{AB} = 18.5 Hz) (H_2C14), 2.75 (qn, 1H, J = 7 Hz, $CH(CH_3)_2$), 2.25 (s, 3H, CH_3C1), 1.26 (s, 3H, CH_3C5), 1.19 (s, 9H, $C(CH_3)_3$), 1.05 (d, 6H, J = 7 Hz, $CH(CH_3)_2$); ms m/e: 373 ($M^+ - t\text{-}C_4H_9O$).

*Acid **99***

To a solution of perester **98** (30 mg, 0.074 mmol) in glacial acetic acid (5 mL) stirred at 14–15°C was added zinc powder (200 mg). The mixture was warmed to room temperature and after 50 min was poured onto iced aqueous solution of potassium bicarbonate (1 M, 150 mL) and extracted with dichloromethane. The aqueous layer was acidified (1 M HCl, pH 5) and extracted with dichloromethane. The two extracts, identical by tlc (ethyl acetate – acetic acid, 98:2), were combined to give a crude product (33 mg) that after crystallization (dichloromethane – hexane) furnished pure acid **99** (17.5 mg, 63%); mp 144–145°C; ir ($CHCl_3$, ν cm^{-1}): 3600–2700 (br), 1825, 1730, 1687, 1620; ^1H nmr ($CDCl_3$, δ ppm): 3.44 (d, 1H) and 2.58 (d, 1H) (J_{AB} = 18 Hz) (H_2C14), 2.72 (qn, 1H, J = 7 Hz, $CH(CH_3)_2$), 2.29 (s, 3H, CH_3Cl), 2.5–1.6 (m), 1.26 (s, 3H, CH_3C5), 1.09 and 1.03 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$); ms m/e: 329 ($M^+ - 45$).

*Methyl ester **100***

*(a) From acid **99***

To a solution of acid **82** (30 mg, 0.080 mmol) in freshly distilled chloroform (10 mL) was added at 0°C an excess of ethereal diazomethane solution. After 10 min, the solvents were removed under vacuum and the solid residue was crystallized (dichloromethane – hexane) to give methyl ester **100** (22 mg, 76%); mp 188–188.5°C; ir ($CHCl_3$, ν cm^{-1}): 1826, 1745, 1730, 1687, 1621; ^1H nmr ($CDCl_3$, δ ppm): 3.50 (s, 3H, OCH_3), 3.39 (d, 1H) and 2.55 (d, 1H) (J_{AB} = 18.5 Hz) (H_2C14), 2.70 (qn, 1H, J = 7 Hz, $CH(CH_3)_2$), 2.30 (s, 3H, CH_3C1), 2.5–1.6 (m), 1.20 (s, 3H, CH_3C5), 1.09 and 1.06 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$); ms m/e: 388 (M^+). *Anal.* calcd. for $C_{21}H_{24}O_7$: C 64.94, H 6.23; found: C 65.19, H 6.42.

*(b) From diketone enone **91***

A solution of lithium methoxide (0.079 M, 88 μL, 0.0069 mmol) in dry methanol–tetrahydrofuran mixture (1:3) was added to a cold (0°C) solution of diketone enone **91** (2.7 mg, 0.0069 mmol) in tetrahydrofuran (1 mL). After 2.5 h, the mixture was poured into aqueous sodium bicarbonate and extracted with dichloromethane. The crude product was chromatographed on silica plate to give a small quantity of unreacted starting material and methyl ester **100** (0.7 mg, 26%), together with other products.

*Reduction of diketone **83***

To a cold (−22°C) solution of diketone **83** (168 mg, 0.28 mmol) in a mixture of tetrahydrofuran (15 mL) and methanol (5 mL) was added sodium borohydride (80 mg). After 1 h of stirring at the same temperature, saturated aqueous ammonium chloride and ice cold water were added. The mixture was extracted (pH ~6.0, 1 M HC1) with dichloromethane and the crude extract was used directly for the next step (crude 165 mg, compound **102**).

*Orthocarbonate **103***

To a cold (0°C) solution of diol **102** (195 mg, 0.323 mmol) in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

chloroform (30 mL) and methanol (1 mL) was added an ethereal solution of diazomethane (excess). After 1 h, the volatile substances were evaporated and the crude product was chromatographed on silica gel (benzene – ethyl acetate, 4:1) to give pure orthocarbonate alcohol **103** (170 mg, 85%); ir ($CHCl_3$, ν cm^{-1}): 3550, 1740, 1610, 1530, 1450, 1340, 1315, 1260; ^1H nmr ($CDCl_3$, δ ppm): 8.20 (m, 4H, aromatic), 4.83 (dd, 1H, J_{AB} = 15 Hz, J_{AX} = 2.5 Hz, H_AC17), 4.26 (dd, 1H, J_{AB} = 15 Hz, J_{BX} = 3.6 Hz, H_BC17), 4.30 (d, 1H, J = 4 Hz, $HC(OCH_3)_2$), 4.05 (m, 1H, HC10), 3.67 (s, 3H, OCH_3), 3.53 (s, 3H, OCH_3), 3.50 (s, 3H, OCH_3), 2.6–1.4 (m), 2.25 (d, 1H) and 1.80 (d, 1H) (J_{AB} = 20 Hz) (H_2C14), 1.24 (s, 3H, CH_3C5), 1.06 and 0.96 (2d, 6H, J = 7 Hz, $CH(CH_3)_2$); ms *m/e*: 617 (M^+, weak).

*Acetate **104***

A solution of alcohol **103** (95 mg, 0.154 mmol) in pyridine (5 mL) and acetic anhydride (3 mL) was heated at 80°C for 4 h. Evaporation of the volatile substances left a residue that was filtered through silica gel (benzene – ethyl acetate, 3:1) to give pure acetate **104** (94 mg, 93%); ir ($CHCl_3$, ν cm^{-1}): 1760, 1740, 1610, 1530, 1455, 1350, 1320; ^1H nmr ($CDCl_3$, δ ppm): 8.20 (m, 4H, aromatic), 5.40 (dd, 1H, J = 11 and 4 Hz, $H_{ax}C10$), 4.68 (dd, 1H, J_{AB} = 14 Hz, J_{AX} = 3 Hz, H_AC17), 4.31 (dd, 1H, J_{AB} = 14 Hz, J_{BX} = 4 Hz, H_BC17), 4.28 (d, 1H, J = 5.5 Hz, $HC(OCH_3)$, 3.65 (s, 3H, OCH_3), 3.50 and 3.46 (2s, 6H, 2 × OCH_3), 2.8–1.3 (m), 2.30 (d, 1H) and 1.80 (d, 1H) (J_{AB} = 20 Hz) (H_2C14), 2.08 (s, 3H, CH_3CO_2), 1.20 (s, 3H, CH_3C5), 1.00 (apparent t, 6H, J = 6.5 Hz, $CH(CH_3)_2$; ms *m/e*: 659 (M^+, weak).

*Enol ether **105***

Elimination of methanol was effected as for compound **64** (*vide supra*). Thus, after only 2 h, compound **104** (48.0 mg, 0.073 mmol) furnished a mixture of enol ethers **105** (47 mg, ~quant); ir ($CHCl_3$, ν cm^{-1}): 1755, 1735, 1695, 1605, 1530, 1450, 1330, 1315, 1260; ^1H nmr ($CDCl_3$, δ ppm, major isomer, less polar): 8.22 (m, 4H, aromatic), 6.27 (d, 1H, =$CHOCH_3$), 5.40 (br dd, 1H, J = ~12 and 5 Hz, HC10), 4.65 (dd, 1H, J_{AB} = 13 Hz, J_{AX} = 3 Hz, H_AC17), 4.25 (dd, 1H, J_{AB} = 3 Hz, J_{BX} = 6 Hz, H_BC17), 3.70 and 3.68 (2s, 3H each, 2 × OCH_3), 2.70 (m, 1H, $HC(CH_3)_2$), 2.5–1.4 (m), 2.10 (s, 3H, CH_3CO_2), 1.40 (s, 3H, CH_3C5), 1.05 (apparent t, 3H, J = 6 Hz, $CH(CH_3)_2$).

*Norketone **106***

Ozonolysis of enol ether **105** was carried out as for enol ether **88** (*vide supra*). Thus crude enol ether **105** (47 mg) furnished crude sensitive norketone **106** (43 mg, 94%); ir ($CHCl_3$, ν cm^{-1}): 1760, 1740, 1610, 1530, 1455, 1350, 1320, 1260. This compound was used directly in the next step.

*Enol acetate **107***

Enol acetylation of norketone **106** was effected as for ketone **65** (*vide supra*). Thus norketone **106** (43 mg, crude) furnished enol acetate **107** (44 mg, 95%); ir ($CHCl_3$, ν cm^{-1}): 1760, 1740, 1610, 1530, 1452, 1260; ^1H nmr ($CDCl_3$, δ ppm): 8.45 (s, 4H, aromatic), 5.40 (dd, 1H, J = 14 and ~5Hz, $H_{ax}C10$), 5.15 (dd, 1H, J_{AB} = 13 Hz, J_{AX} = 2 Hz, H_AC17), 4.40 (dd, 1H, J_{AB} = 13 Hz, J_{BX} = 5 Hz, H_BC17), 3.65 (s, 3H, OCH_3), 3.10 (dd, 1H, J = 5 and 2 Hz, HCl), 2.55 (qn, 1H, J = 7 Hz, $CH(CH_3)_2$), 2.29 (s, 3H, CH_3CO_2), 2.21 (s, 3H, CH_3CO_2), 1.25 (s, 3H, CH_3C5), 1.15 and 1.05 (2d, 3H each, J = 7 Hz, $CH(CH_3)_2$).

*Enone **108***

Elimination reaction on compound **107** was carried out as for enol acetate **67**. Thus from enol acetate **107** (40 mg, 0.062 mmol) was obtained enone **108** (17 mg, 63%) after a 4 h reflux period and purification by chromatography on silica gel (hexane–ether, 1:1); mp 155–156°C; ir ($CHCl_3$, ν cm^{-1}): 1755, 1740, 1720, 1620, 1455, 1230; ^1H nmr ($CDCl_3$, δ ppm): 5.31 (dd, 1H, J = 11 and 4.5 Hz, HC10), 3.69 (s, 3H, OCH_3), 2.72 (qn, 1H, J = 7 Hz, $HC(CH_3)_2$), 2.28 (d, 1H) and 1.88 (d, 1H) (J_{AB} = 20 Hz) (H_2C14), 2.15 (s, 3H, CH_3CO_2), 2.03 (s, 3H, CH_3C1), 1.43 (s, 3H, CH_3C5), 1.18 and 1.17 (2d, 3H each, J = 7 Hz) ($CH(CH_3)_2$); ms *m/e*: 432 (M^+).

*Reduction of enone **108***

To a cold (0°C) solution of ketoenone **108** (25 mg, 0.058 mmol) in a mixture of tetrahydrofuran (1 mL) and methanol (1 mL) was added sodium borohydride (~8 mg, excess). After the disappearance of the starting material (~1.5 h), aqueous saturated ammonium chloride was added and the mixture was extracted with dichloromethane. The crude product, containing three main products, each more polar than the starting material, was chromatographed on silica plate (benzene – ethyl acetate, 3:1) to give *endo* allylic alcohol **109** (6 mg, 24%, invisible under uv, R_f 0.4) and the alcohols **110** as a mixture that was rechromatographed (hexane – ether, 1:1, two elutions) to give alcohol **110**a (less polar, 8 mg, 32%) and alcohol **110**b (more polar, 10 mg, 40%).

*Allylic alcohol **109***: mp 228–230°C; ir ($CHCl_3$, ν cm^{-1}): 3600, 3450, 1755, 1740, 1640, 1450, 1300, 1230; ^1H nmr ($CDCl_3$, δ ppm): 5.26 (dd, 1H, J = 12 and 5 Hz, HC10), 4.88 (m, 1H, J = ~2 Hz, HC3), 3.66 (s, 3H, OCH_3), 3.14 (d, 1H) and 2.12 (d, 1H), (J_{AB} = 20 Hz) (H_2C14), 2.66 (qn, 1H, J = 7 Hz, $CH(CH_3)_2$), 2.13 (s, 3H, CH_3CO_2), 1.68 (d, 3H, J = 2 Hz, CH_3C1), 1.37 (s, 3H, CH_3C5), 1.13 and 1.08 (2d, 3H each, J = 7 Hz, $CH(CH_3)_2$); ms *m/e*: 434 (M^+).

*Alcohol **110***a (less polar): ir ($CHCl_3$, ν cm^{-1}): 3600, 3500, 1745, 1620, 1455, 1310, 1220; ^1H nmr ($CDCl_3$, δ ppm): 5.75 (dd, 1H, J = 12 and 6 Hz, HC10), 3.75 (dd, 1H, J = 10 and 5 Hz, HC15), 3.64 (s, 3H, OCH_3), 2.78 (qn, 1H, J = 7 Hz, $CH(CH_3)_2$), 2.14 (s, 3H, CH_3CO_2), 1.99 (s, 3H, CH_3C1), 1.31 (s, 3H, CH_3C5), 1.20 (d, 6H, J = 7 Hz, $CH(CH_3)_2$); ms *m/e*: 434 (M^+).

*Alcohol **110***b (more polar): ir ($CHCl_3$, ν cm^{-1}): 3600, 3450, 1750, 1715, 1620, 1455, 1320, 1220; ^1H nmr ($CDCl_3$, δ ppm): 5.70 (dd, 1H, J = 12 and 5 Hz, HC10), 4.72 (dd, 1H, J = 11 and 4.5 Hz, HC15), 3.63 (s, 3H, OCH_3), 2.75 (qn, 1H, J = 7 Hz, $CH(CH_3)_2$, 2.11 (s, 3H, CH_3CO_2), 1.99 (s, 3H, CH_3C1), 1.26 (s, 3H, CH_3C5), 1.19 and 1.18 (2d, 3H each, J = 7 Hz, $CH(CH_3)_2$); ms *m/e*: 434 (M^+).

*Alcohol **111***

To a solution of acetate **108** (10.5 mg, 0.024 mmol) in methanol (2 mL) was added aqueous sodium hydroxide (0.5 mL). After 3 h at room temperature, the mixture was poured into ammonium chloride solution and extracted with dichloromethane to give pure alcohol **111** (9.4 mg, quant): ir ($CHCl_3$, ν cm^{-1}): 3540, 1745, 1720, 1610, 1455; ^1H nmr ($CDCl_3$, δ ppm): 4.20 (dd, 1H, J = 12 and 5 Hz, HC10), 3.69 (s, 3H, OCH_3), 2.76 (qn, 1H, J = 7 Hz, $CH(CH_3)_2$), 2.27 (d, 1H) and 1.96 (d, 1H) (J_{AB} = 20 Hz) (H_2C14), 2.24 (s, 3H, CH_3C1), 2.2–1.1 (m), 1.43 (s, 3H, CH_3C5), 1.17 and 1.14 (2d, 3H each, J = 7 Hz) ($CH(CH_3)_2$); ms *m/e*: (M^+).

*Dihydroxycarbonate **112***

To a solution of orthocarbonate **111** (6.0 mg, 0.0154 mmol) in acetone (1 mL) was added hydrochloric acid (1 M, 0.5 mL) and the mixture was stirred at room temperature for 24 h. The mixture was then poured into cold water, extracted with dichloromethane, washed with brine, and the solvent was evaporated. The crude product was chromatographed on silica plate (ether) to give pure dihydroxycarbonate **112** (5.7 mg, 95%); ir ($CHCl_3$, ν cm^{-1}): 1815, 1752, 1725, 1618; ^1H nmr ($CDCl_3$, δ ppm): 4.50 (dd, 1H, J = 11 and 5 Hz, HC10), 3.01 (qn, 1H, J = 7 Hz, $CH(CH_3)_2$), 2.90 (d, 1H) and 1.95 (d, 1H) (J_{AB} = 19 Hz) (H_2C14), 2.4–1.3 (m), 2.03 (s, 3H, CH_3C1), 1.37 (s, 3H, CH_3C5), 1.25 and 1.22 (2d, 3H each, J = 7 Hz) ($CH(CH_3)_2$); ms *m/e*: 376 (M^+).

*Dichloroketone **113***

A solution of ketoenone acetate **108** (5.0 mg, 0.0115 mmol) in a mixture of tetrahydrofuran (0.3 mL), dioxan (0.3 mL), and water (0.1 mL) was reacted with aqueous hypochlorite (0.92 M, 24 μL) at 0°C for 2 h. The reaction mixture was then poured into water and extracted with dichloromethane. The crude product was chromatographed on silica plate to give less polar dichloroketone **113** (4.4 mg, 76%) together with some starting material (0.5 mg, 10%); mp 160–161°C; ir $CHCl_3$, ν cm^{-1}): 1780, 1740 (sh), 1730, 1620, 1460, 1350, 1310, 1220, 905, 820; ^1H nmr ($CDCl_3$, δ ppm): 5.46 (dd, 1H, J = 12 and 4.5 Hz, HC10), 3.66 (s, 3H, OCH_3), 2.72 (qn, 1H, J = 7 Hz, $CH(CH_3)_2$), 2.17 (s, 3H, CH_3C1), 1.99 (s, 3H, CH_3CO_2), 1.76 (s, 3H, CH_3C5), 1.14 and 1.11 (2d, 3H each, J = 7 Hz, $CH(CH_3)_2$); ms *m/e*: 500 (M^+, absent), 465 M^+-35).

*Tricyclic ketodiol **116***

To a solution of diol **112** (2.5 mg, 0.0064 mmol) in dry tetrahydrofuran (0.3 mL) at −78°C was added a solution of lithium *tert*-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

butylperoxide in tetrahydrofuran (0.099 M, 135 μL, ~2 equiv.). After 1 h, the same quantity of reagent was added and the temperature was raised to −22°C for 1 h. The mixture was then poured into water and extracted with dichloromethane. The crude product was chromatographed on silica plate (ether) to give tricyclic ketodiol **116** (1.7 mg, 75%); ir ($CHCl_3$, ν cm^{-1}): 3550, 1705, 1630; ^1H nmr ($CDCl_3$, δ ppm): 4.50 (dd, 1H, J = 11 and 5 Hz, HC10),[6] 3.04 (qn, 1H, J = 7 Hz, C*H*$(CH_3)_2$), 2.90 (d, 1H) and 1.95 (d, 1H) (J_{AB} = 19 Hz, H_2C14), 2.07 (s, 3H, CH_3C1), 1.37 (s, 3H, CH_3C5), 1.26 and 1.25 (2d, 3H each, J = 7 Hz, $CH(CH_3)_2$); ms *m/e*: 332 (M^+).

*Diacetate **117***

A solution of tricyclic ketodiol **116** (2 mg, 0.006 mmol) in pyridine (0.2 mL) and acetic anhydride (0.2 mL) was stirred 20 h at room temperature. Evaporation of volatile substances left a residue, which was chromatographed on silica plate (hexane – ether) to give diacetate **117** (2.3 mg, 90%); ir ($CHCl_3$, ν cm^{-1}): 1745, 1710, 1640, 1620, 1220; ^1H nmr ($CDCl_3$, δ ppm): 5.60 (dd, 1H, J = 9 and 4 Hz, HC10),[6] 3.00 (qn, 1H, J = 7 Hz, $CH(CH_3)_2$, 2.92 (d, 1H) and 1.92 (d, 1H) (J_{AB} = 18.5 Hz) (H_2C14), 2.07 (s, 3H, CH_3-C1), 2.04 and 2.02 (2s, 3H each, 2 × CH_3CO_2), 1.26 and 1.24 (2d, 3H each, J = 7 Hz, $CH(CH_3)_2$).

Camphor oxime

A solution of camphor (5.00 g, 0.0329 mol) and hydroxylamine hydrochloride (7.00 g, 0.10 mol) in pyridine (30 mL) was heated at 75°C for 2 h. The mixture was poured into cold water and extracted with dichloromethane to give a crude product that was recrystallized from ether – hexane to give pure camphor oxime (5.39 g, 98%, mp 116–117°C (lit. (26*c*, *d*) mp 116°C)).

*Lactam **119** and α-camphidone*

To a cold (−22°C) solution of camphor oxime (5.38 g, 0.0322 mol) in pyridine (25 mL) was added methanesulfonyl chloride (5.0 mL, 0.065 mmol) and the mixture was stirred 3 h. Then the temperature was raised. At ~10°C a strong exothermic reaction took place and the mixture became dark yellow. After 2 h of additional stirring at 25°C, the mixture was poured onto iced water and extracted with dichloromethane. The organic layer was washed with sodium bicarbonate and brine. The crude product was first filtered on silica gel to remove the major products of low polarity (mixture of nitriles, 4.03 g, ~84%, chloroform – acetone, 4:1). The polar compounds (450 mg) were eluted with acetone and chromatographed on silica gel (chloroform – acetone, 3:1) to give pure lactam α-camphidone (35 mg, 0.7%, mp 234–235°C (lit. (25*a*, *e*) mp 234–236°C), less polar) and "normal" camphor lactam **119** (390 mg, 7.2%); mp 196–197°C; ir ($CHCl_3$, ν cm^{-1}): 3400, 3200, 1680, 1420, 1400, 1385; ^1H nmr ($CDCl_3$, δ ppm): 5.91 (br, 1H, NH), 2.58 (ddd, 1H, J_{AB} = 18 Hz, J_{AX} = 4.7 Hz, J_W = 2.5 Hz, $H_{exo}CCO$), 2.16 (dd, 1H, J_{AB} = 18 Hz, J_{BX} = 1.6 Hz, $H_{endo}CCO$), 2.1–1.4 (m), 1.10 (s, 3H, CH_3), 1.00 (s, 3H, CH_3), 0.96 (s, 3H, CH_3); ^{13}C nmr ($CDCl_3$, δ ppm): 172.6, 63.4, 43.2, 42.8, 40.0, 39.3, 27.7, 23.3, 18.1, 17.8; ms *m/e*: 167 (M^+).

*Lactone **120***

To a solution of camphor lactam **119** (25 mg, 0.15 mmol) in dry pyridine (1.5 mL) was added, at room temperature, nitrosyl hexafluorophosphate (52 mg, 0.29 mmol). The coloured mixture was refluxed for 3 h, then cooled, poured onto cold water, and extracted with dichloromethane to give a neutral extract (21 mg, 83%) containing a mixture (~3:1) of lactone **120** and another unidentified lactonic compound together with a trace of starting lactam. The aqueous layer was acidified (1 M HCl, pH 5) and extracted with dichloromethane to give a mixture of two unsaturated carboxylic acids (2 mg, 8%) that was not examined further. The neutral extract was chromatographed on silica gel (benzene – ethyl acetate, 4:1) (14 mg, 66%) to yield pure lactone **120**, identical in all respects with authentic material obtained from the Baeyer–Villiger oxidation of camphor; ir ($CHCl_3$, ν cm^{-1}): 1730, 1340, 1260, 1140; ^1H nmr ($CDCl_3$, δ ppm): 2.85 (ddd, 1H, J_{AB} = 19, 4.0 and 2 Hz, $H_{exo}CCO_2$), 2.35 (dd, 1H, J_{AB} = 19 and 1.8 Hz, $H_{endo}CCO_2$), 2.2–1.4 (m), 1.29 (s, 3H, $OCCH_3$), 1.06 (s, 3H, CH_3), 1.00 (s, 3H, CH_3); ms *m/e*: 168 (M^+).[7]

*Oxime **121***

A solution of ketone **108** (54.0 mg, 0.125 mmol) and hydroxylamine hydrochloride (400 mg, large excess) in pyridine (8 mL) was refluxed for 15 h, then cooled, poured onto cold water, and extracted with dichloromethane. The crude product was chromatographed on silica gel (benzene – ethyl acetate, 4:1) to give pure oxime **121** (42 mg, 75%); ir ($CHCl_3$, ν cm^{-1}): 3575, 3360, 1740, 1715, 1620, 1455, 1350, 1255; ^1H nmr ($CDCl_3$, δ ppm): 10.22 (s, 1H, OH), 5.55 (dd, 1H, J = 12 and 5 Hz, HC10), 3.67 (s, 3H, OCH_3), 2.70 (qn, 1H, J = 7 Hz, C*H*$(CH_3)_2$, 2.41 (d, 1H) and 2.06 (d, 1H) (J_{AB} = 19 Hz) (H_2C14), 2.04 (s, 3H, CH_3Cl), 1.97 (s, 3H, CH_3CO_2), 1.37 (s, 3H, CH_3C5), 1.19 and 1.14 (2d, 3H each, J = 7 Hz, $CH(CH_3)_2$); ms *m/e*: 447 (M^+).

*Oxime mesylate **122***

To a solution of oxime **121** (40 mg, 0.089 mmol) in pyridine (1.5 mL) was added methanesulfonyl chloride (150 μL) and the mixture was stirred at 25°C for 3.5 h after which it was poured into cold dilute aqueous sodium bicarbonate and extracted with dichloromethane. Chromatography of the crude extract on silica plate (benzene – ethyl acetate, 5:1) gave pure oxime mesylate **122** (40 mg, 85%); ir ($CHCl_3$, ν cm^{-1}): 1740, 1720, 1615, 1455, 1360, 1315, 1230, 1170, 945; ^1H nmr ($CDCl_3$, δ ppm): 5.55 (d, 1H, J = 12 and 4 Hz, HC10), 3.67 (s, 3H, OCH_3), 3.13 (s, 3H, CH_3SO_2), 2.72 (qn, 1H, J = 7 Hz, C*H*$(CH_3)_2$), 2.60 (d, 1H) and 2.20 (d, 1H) (J_{AB} = 20 Hz) (H_2C14), 2.10 (s, 3H, CH_3C1), 2.06 (s, 3H, CH_3CO_2), 1.34 (s, 3H, CH_3C5), 1.17 and 1.15 (2d, 3H each, J = 7 Hz, $CH(CH_3)_2$).

*Lactam alcohol **123** and acetate **124***

A solution of oxime mesylate (13 mg, 0.025 mmol) in dioxane (1 mL) and water (0.5 mL) was heated in a sealed (vacuum) tube at 135°C for 17 h. The crude product was then poured into cold dilute aqueous sodium bicarbonate solution and extracted with dichloromethane to give a crude product, which was chromatographed on silica plate (ethyl acetate) to give pure lactam alcohol **123** (more polar, 5.5 mg, 57%) and lactam acetate **124** (less polar, 3.5 mg, 33%). *Lactam alcohol **123***: mp 240°C (dec.); ir ($CHCl_3$, ν cm^{-1}): 3600, 3480, 3360, 1825, 1720, 1670, 1620, 1230, 1050; ^1H nmr ($CDCl_3$, δ ppm): 6.27 (br s, 1H, NH), 4.60 (m, 1H, HC10), 2.75 (qn, 1H, J = 7 Hz, C*H*$(CH_3)_2$), 2.82 (s, 2H, H_2C14), 2.22 (s, 3H, CH_3C1), 2.2–1.4 (m), 1.23 (s, 3H, CH_3C5), 1.16 (d, 6H, J = 7 Hz, $CH(CH_3)2$); ms *m/e*: 391 (M^+). *Lactam acetate **124***: ir ($CHCl_3$, ν cm^{-1}): 3600, 3380, 1825, 1745 (sh), 1720, 1680, 1620, 1220, 1050; ^1H nmr ($CDCl_3$, δ ppm): 5.97 (br s, 1 H, NH), 5.65 (dd, 1H, J = 12 and 5 Hz, HC10), 2.78 (qn, 1H, J = 7 Hz, C*H*$(CH_3)_2$), 2.37 (s, 2H, H_2C14), 2.18 (s, 1H, OH), 2.14 and 2.13 (2s, 3H each, CH_3Cl and CH_3CO_2), 2.3–1.3 (m), 1.31 (s, 3H, CH_3C5), 1.18 (d, 6H, J = 7 Hz, $CH(CH_3)_2$); ms *m/e*: 433 (M^+).

*Acetylation of lactam alcohol **123***

A solution of alcohol **123** (15 mg, 0.038 mmol) in pyridine (0.5 mL) and acetic anhydride (0.5 mL) was stirred at 25°C overnight. Evaporation of volatile materials and rapid filtration on silica gel (ethyl acetate) furnished a quantitative yield of acetate **124** (16.5 mg).

*Oxidation of alcohol **123***

To a solution of alcohol **123** (12 mg, 0.031 mmol) in acetone (1.5 mL) was added freshly prepared Jones reagent (3 drops) at 25°C and the

[6]Ryanodol numbering.

[7]The other lactone (less polar, 6 mg, 27%) probably has the structure shown below according to its spectroscopic data: ir ($CHCl_3$, ν cm^{-1}): 1765, 1370, 1310, 1230; ^1H nmr ($CDCl_3$, δ ppm): 2.86 (dd, 1H, J_{AB} = 15 and 11.5 Hz, $HCCO_2$), 2.60 (dd, 1H, J_{AB} = 15 and 0.5 Hz, $HCCO_2$), 1.30 (s, 3H, CH_3CO), 1.09 (s, 3H, CH_3), 0.90 (s, 3H, CH_3); ms *m/e*: 168 (M^+).

For personal use only.

mixture was stirred for 45 min, poured into cold water, and extracted with dichloromethane. The crude product was chromatographed on silica plate (ethyl acetate) to give ketolactam **125** (12 mg, quant); mp 205–207°C; ir ($CHCl_3$, ν cm^{-1}): 3600, 3300, 1810, 1725, 1680, 1620, 1230, 1050; ^1H nmr ($CDCl_3$, δ ppm): 6.26 (br s, 1H, NH), 3.40 (br s, OH), 2.70 (qn, 1H, J = 7 Hz, C*H*$(CH_3)_2$), 2.35 (s, 2H, H_2C14), 2.18 (s, 3H, CH_3C1), 2.6–1.5 (m), 1.32 (s, 3H, CH_3C5), 1.16 and 1.14 (2d, 3H each, J = 7 Hz, CH(C*H*$_3)_2$); ms m/e: 389 (M^+).

Mesylate ***126***

Methanesulfonyl chloride (0.50 mL, 6.4 mmol) was added to a cold (0°C) solution of alcohol **103** (95 mg, 0.154 mmol) in pyridine (5 mL). The mixture was stirred for 30 min, then poured into cold aqueous sodium bicarbonate and extracted with dichloromethane. The crude product was chromatographed (hexane – ethyl acetate, 1:1) on silica plate to give pure mesylate **126** (102 mg, 95%); ir ($CHCl_3$, ν cm^{-1}): 1755, 1735, 1610, 1530, 1450, 1340, 1315, 1260, 1160; ^1H nmr ($CDCl_3$, δ ppm): 8.25 (m, 4H, aromatic), 5.50 (dd, 1H, J = 11 and 5 Hz, HC10), 4.40 (m, 3H, H_2C17 and C*H*$(OCH_3)_2$), 3.72 (s, 3H, OCH_3), 3.56 and 3.52 (2s, 3H each, 2 × OCH_3), 3.08 (s, 3H, CH_3SO_2), 2.70 (m, 3H), 2.35 (d, 1H) and 1.82 (d, 1H) (J = 20 Hz) (H_2C14), 2.3–1.4 (m), 1.27 (s, 3H, CH_3C5), 1.03 (apparent t, J = 7 Hz, CH(C*H*$_3)_2$).

Hemi-ketal ***127***

A solution of lithium methoxide (0.21 M in methanol, 0.58 mL, 1.1 equiv.) was added to a cold (0°C) solution of compound **126** (82 mg, 0.12 mmol) in tetrahydrofuran (10 mL). After 3 h the mixture was poured into aqueous ammonium chloride and extracted with dichloromethane. Chromatography (benzene – ethyl acetate, 1:1) of the crude extract on silica plate furnished pure hemi-ketal **127** (56 mg, 87%); ir ($CHCl_3$, ν cm^{-1}): 3580, 1450, 1350, 1315, 1160; ^1H nmr ($CDCl_3$, δ ppm): 5.35 (dd, 1H, J = 11 and 6 Hz, HC10), 4.37 (dd, 1H, J_{AB} = 13 Hz, J_{AX} = 4.5 Hz, H_AC17), 4.24 (d, 1H, J = 5.6 Hz, C*H*$(OCH_3)_2$), 4.01 (dd, 1H, J_{AB} = 13 Hz, J_{BX} = 12 Hz, H_BC17), 3.67 (s, 3H, CH_3O), 3.46 and 3.44 (2s, 3H each, 2 × OCH_3), 3.07 (s, 3H, CH_3SO_2), 2.62 (m, 3H), 2.4–1.3 (m), 1.13 (s, 3H, CH_3C5), 1.05 and 0.98 (2d, 3H each, J = 7 Hz, CH(C*H*$_3)_2$); ms m/e: 546 (M^+).

Lactone ***128***

A solution of *n*-butyllithium (1.6 M in hexane, 427 μL, 0.683 mmol) was added to dry, freshly distilled dimethyl sulfoxide (20 mL) at room temperature. After 1 h this reagent was transferred to hemi-ketal **127** (187 mg, 0.342 mmol) and the reaction mixture was stirred at room temperature for 3.5 h, then poured into cold water and extracted with dichloromethane. The organic layers were washed with water, dried, and evaporated. The sensitive lactone **128** (155 mg, crude quantitative) was used directly for the next step; ir ($CHCl_3$, ν cm^{-1}): 1750, 1600, 1450, 1310; ^1H nmr ($CDCl_3$, δ ppm): 6.02 (dd, 1H, J = 5 and 3 Hz, HC10), 4.81 (ddd, 1H, J_{AB} = 12 Hz, J_{AX} = 2 Hz, J_W = 1 Hz, $H_{exo}C17$), 4.40 (dd, 1H, J_{AB} = 12 Hz, J_{BX} = 2 Hz, $H_{endo}C17$), 4.22 (d, 1H, J = 6.7 Hz, C*H*$(OCH_3)_2$), 3.63, 3.55, and 3.47 (3s, 3H each, 3 × OCH_3), 3.32 (dd, 1H, J = 11 and 6.7 Hz, HC3), 2.67 (d, 1H) and 2.22 (d, 1H) (J_{AB} = 13.8 Hz) (H_2C14), 2.8–1.6 (m), 1.27 (s, 3H, CH_3C5), 1.10 and 1.06 (2d, 3H, each, J = 7 Hz, CH(C*H*$_3)_2$).

Hydrolysis of ***128***

The crude product **128** from the preceding reaction (155 mg) was dissolved in tetrahydrofuran (20 mL) containing water (6 mL) and reacted at 0°C with an aqueous solution of tetrafluoroboric acid (0.3 M, 80 μL). After 3 h, the mixture was poured into dilute aqueous sodium bicarbonate and extracted with dichloromethane. Evaporation of the solvents left a residue that was chromatographed on silica gel (hexane – ethyl acetate, 25%) to give hydroxycarbonate **129** (less polar, 107 mg, 72% for 2 steps) and allylic alcohol **130** (R = H) (more polar, 28 mg, 19%). *Compound* ***129***: mp 169–170°C; ir ($CHCl_3$, ν cm^{-1}): 3600, 1805, 1750, 1255; ^1H nmr ($CDCl_3$, δ ppm): 6.14 (dd, 1H, J = 5 and 3 Hz, HC10), 4.60 (ddd, 1H, J_{AB} = 12 Hz, J_{AX} = 2 Hz, J_W = 0.5 Hz, $H_{exo}C17$), 4.25 (d, 1H, J = 5 Hz, C*H*$(OCH_3)_2$), 4.24 (dd, 1H, J_{AB} = 12 Hz, J_{BX} = 2 Hz, $H_{endo}C17$), 3.53 and 3.50 (2s, 3H each, 2 × OCH_3), 3.46 (dd, 1H, J = 12 and 5 Hz, HC3), 2.85 (qn, 1H, J = 7 Hz, C*H*$(CH_3)_2$), 2.75 (d, 1H) and 2.28 (d, 1H) (J_{AB} = 13 Hz) (H_2C14), 2.6–1.4 (m), 1.30 (s, 3H, CH_3C5), 1.05 (d, 6H, J = 7 Hz, CH(C*H*$_3)_2$); ms m/e: 436 (M^+). *Compound* ***130*** (R = H): ir ($CHCl_3$, ν cm^{-1}): 3600, 1810, 1760, 1265; ^1H nmr ($CDCl_3$, δ ppm): 4.33 (d, 1H, J = 5.4 Hz, C*H*$(OCH_3)_2$), 4.32 (ddd, 1H, J_{AB} = 12.2 Hz, J_{AX} = 1.5 Hz, J_W = 0.5 Hz, $H_{exo}C17$), 4.26 (m, 1H, $W_{\frac{1}{2}} \simeq 5$ Hz, $H_{eq}C10$), 4.20 (dd, 1H, J_{AB} = 12.2 Hz, J_{BX} = 2.2 Hz, $H_{endo}C17$), 3.53 and 3.50 (2s, 3H each, 2 × OCH_3), 3.33 (dd, 1H, J = 11.6 and 5.4 Hz, HC3), 2.95 (d, 1H) and 2.35 (d, 1H) (J_{AB} = 12.7 Hz) (H_2C14), 2.89 (ddd, 1H, $J \simeq 12$, 6 and 4 Hz, HC2), 2.63 (br d, 1H, J = 6.2 Hz, HC1), 2.11 (qn, 1H, J = 7 Hz, C*H*$(CH_3)_2$), 2.1–1.6 (m), 1.27 (s, 3H, CH_3C5), 1.06 and 1.01 (2d, 3H each, J = 7 Hz, CH(C*H*$_3)_2$); ms m/e: 436 (M^+).

Acetylation of alcohol ***130*** (R = H)

Acetic anhydride (100 μL, excess) was added to a stirred (25°C) solution of alcohol **130** (22 mg, 0.050 mmol), triethylamine (100 μL), and *p*-dimethylaminopyridine (DMAP, ~1 mg) in dichloromethane (2 mL). After 1 h the mixture was poured into dilute aqueous sodium bicarbonate and extracted with dichloromethane to give a residue that was filtered through silica gel (hexane – ethyl acetate, 4:1) to give pure axial acetate **130** (R = Ac) (24 mg, quantitative); mp 137–138°C; ir ($CHCl_3$, ν cm^{-1}): 1800, 1750, 1730, 1650, 1370, 1270, 1250, 1045; ^1H nmr ($CDCl_3$, δ ppm): 5.51 (narrow m, 1H, $W_{\frac{1}{2}}$ = 5 Hz, $H_{eq}C10$), 4.37 (dd, 1H, J_{AB} = 12.3 Hz, J_{AX} = 0.5 Hz, H_AC17), 4.34 (d, 1H, J = 5.2 Hz, C*H*$(OCH_3)_2$, 4.23 (dd, 1H, J_{AB} = 12.3 Hz, J_{BX} = 2.3 Hz, H_BC17), 3.54 and 3.52 (2s, 3H each, 2 × OCH_3), 3.28 (dd, 1H, J = 11.6 and 5.2 Hz, HC3), 2.96 (d, 1H) and 2.24 (d, 1H) (J_{AB} = 12.5 Hz) (H_2C14), 2.86 (ddd, 1H, J = 11.6, 6.6, and 5.0 Hz, HC2), 2.50 (br d, 1H, J = 6.6 Hz, HC1), 2.13 (qn, 1H, J = 7 Hz, C*H*$(CH_3)_2$, 2.06 (s, 3H, CH_3CO_2), 2.1–1.7 (m), 1.30 (s, 3H, CH_3C5), 1.06 and 1.01 (2d, 3H each, J = 7 Hz, CH(C*H*$_3)_2$).

Oxidation of alcohol ***130*** (R = H)

To a stirred suspension of chromic anhydride (100 mg) in dry dichloromethane (5 mL) was added anhydrous pyridine (170 μL). After 15 min at 25°C, the mixture was cooled to 0°C and treated with a solution of alcohol **130** (R = H) (5.0 mg, 0.011 mmol) in dichloromethane (0.5 mL). After 5 min, isopropanol (1 mL) was added to the mixture, which was poured into aqueous sodium bicarbonate and extracted with dichloromethane. Chromatography of the crude product (benzene – ethyl acetate, 4:1) furnished the known enone **57** (4.5 mg, 92%, mp 214–216°C (dec.)).

Equatorial allylic alcohol ***131***

Sodium borohydride (5 mg, excess) was added to a cold (0°C) solution of enone **57** (20 mg, 0.046 mmol) in dry tetrahydrofuran. After 30 min, saturated aqueous ammonium chloride was added and the mixture was extracted with dichloromethane to give alcohol **131** (17 mg, 85%); ir ($CHCl_3$, ν cm^{-1}): 3500, 1800, 1750, 1650, 1050, 1030; ^1H nmr ($CDCl_3$, δ ppm): 4.85 (dd, 1H, J_{AB} = 12 Hz, J_{AX} = 1 Hz, H_AC17), 4.36 (d, 1H, J = 5 Hz, C*H*$(OCH_3)_2$), 4.4–4.2 (m, 1H, $W_{\frac{1}{2}}$ = 12 Hz, $H_{ax}C10$), 4.19 (dd, 1H, J_{AB} = 12 Hz, J_{BX} = 2.5 Hz, H_BC17), 3.55 and 3.53 (2s, 3H each, 2 × OCH_3), 3.30 (dd, 1H, J = 12 and 5 Hz, HC3), 2.98 (d, 1H) and 2.35 (d, 1H) (J_{AB} = 13 Hz) (H_2C14), 2.9–1.3 (m), 1.26 (s, 3H, CH_3C5), 1.08 and 1.04 (2d, 3H each, J = 7 Hz, CH(C*H*$_3)_2$); ms m/e: 436 (M^+).

Epoxide ***132***

To a mixture of olefin lactone **129** (28.6 mg, 0.0656 mmol) and sodium bicarbonate (350 mg, large excess) in 1,2-dichloroethane (5 mL) was added, at room temperature, freshly prepared trifluoroperacetic acid (130 μL, 1.1 M in dichloromethane). After 2 h at room temperature the volatile substances were carefully evaporated and the residue was washed with dichloromethane, filtered, and evaporated. The residue (26 mg) was submitted to the same reaction conditions for 3 h, then the volatile materials were evaporated, the residue was triturated with dichloromethane, and the extract was filtered. Evaporation of the solvent gave a crude product (54 mg), which was purified by crystallization (ether) and chromatography on silica plates (hexane – ethyl acetate, 1:1, two elutions) to give pure epoxide **132** (27 mg, 92%), slightly less polar than olefin **129**: mp 200–205°C (dec.); ir

*Triol lactone **134***

To a solution of epoxylactone **132** (40 mg, 0.088 mmol) in a mixture of 1,2-dimethoxyethane (10 mL, freshly distilled) and water (1 mL) was added at 25°C aqueous sodium hydroxide (0.1 M, 350 μL, 0.4 equiv.). After 2 h and 4 h of reaction, the same quantity of reagent was added for a total of 1.2 equivalents. After a total of 6 h of reaction time, the mixture was poured into water, acidified to pH 6.5 (0.5 M, HC1), and extracted with dichloromethane to give a crude product that was chromatographed on silica plate (ether – ethyl acetate, 4:1) to give pure lactone **134** (34 mg, 82%); mp 194–195°C; ir ($CHCl_3$, ν cm^{-1}): 3600, 3450, 1810, 1750, 1250, 1015; ^1H nmr ($CDCl_3$, δ ppm): 4.86 (narrow m, 1H, $W_{\frac{1}{2}} \simeq 6$ Hz, $H_{eq}C10$), 4.31 (d, 1H, J = 5.3 Hz, $CH(OCH_3)_2$), 3.86 (dd, 1H, J_{AB} = 12 Hz, J_{AX} = 5 Hz, H_AC17), 3.58 (dd, 1H, J_{AB} = J_{BX} = 12 Hz, H_BC17), 3.47 and 3.45 (2s, 3H each, 2 × OCH_3), 2.95 (d, 1H) and 2.63 (d, 1H) (J_{AB} = 20 Hz) (H_2C14), 2.79 (m, 1H, HC1), 2.48 (m, 1H, HC2), 2.33 (dd, 1H, J = 12 and 5.3 Hz, HC3), 2.15–1.5 (m), 1.21 (s, 3H, CH_3C5), 1.04 and 0.91 (2d, 3H each, J = 7 Hz, ($CH(CH_3)_2$); ms m/e: 470 (M^+). *Exact Mass* calcd. for $C_{23}H_{34}O_{10}$–CH_3OH: 438.1889; found: 438.1890.

*Equatorial alcohol **135***

Sodium borohydride (43 mg, 1.1 mmol) was added to a cold (0°C) solution of ketone **39** (400 mg, 0.888 mmol) in a mixture of methanol (10 mL) and tetrahydrofuran (10 mL). After 30 min, the mixture was poured into dilute aqueous ammonium chloride, brought to pH 6 (1 M, HC1), and extracted with dichloromethane. Evaporation of the solvent gave a solid residue that was purified by crystallization (acetone–hexane) and chromatography on silica gel (benzene – ethyl acetate, 1:1) to yield diol **135** (381 mg, 95%); mp 281–282°C; ir ($CHCl_3$, ν cm^{-1}): 3580, 3420, 1802, 1745, 1070; ^1H nmr (acetone-d_6, δ ppm): 5.20 (dd, 1H, J = 10.5 and 3 Hz, HC15), 4.45 (d, 1H, J = 3 Hz, $CH(OCH_3)_2$), 4.28 (br m, $W_{\frac{1}{2}} \cong 12$ Hz, $H_{ax}C10$), 3.50 and 3.47 (2s, 3H each, 2 × OCH_3), 3.2–1.6 (m), 1.23 (s, 3H, CH_3C5), 1.35 and 0.96 (2d, 3H each, J = 7 Hz, $CH(CH_3)_2$); ms m/e: 452 (M^+). *Anal.* calcd. for $C_{23}H_{32}O_9$: C 61.05, H 7.13; found: C 61.11, H 6.99.

*Methoxymethyl orthocarbonate **136***

Sodium hydride (dry, washed with THF from commercial 60%in oil, 40 mg large excess), was added to a solution of diol **135** (75.0 mg, 0.166 mmol) in tetrahydrofuran (10 mL). After 30 min at 25°C, chloromethyl methyl ether (100 μL, freshly distilled from calcium hydride) was added and the mixture was stirred for 18 h at 28°C, then cooled to −78°C, and treated with aqueous ammonium chloride. The mixture was warmed to room temperature and extracted with dichloromethane to give a residue that was chromatographed on silica gel (chloroform – acetone, 4:1) to give a small quantity of starting material (4 mg, 5%) and compound **136** (70 mg, 85%); mp 147–151°C; ir ($CHCl_3$, ν cm^{-1}): 3600, 3450, 1735, 1200; ^1H nmr ($CDCl_3$, δ ppm): 5.15 (s, 2H, OCH_2O), 5.08 (dd, 1H, J = 8.7 and 3.5 Hz, HC15), 4.50 (br m, 1H, HC10), 4.36 (d, 1H, J = 5.5 Hz, $CH(OCH_3)_2$), 3.55, 3.51, and 3.48 (3s, 3H each, 3 × OCH_3), 3.00 (dd, 1H, J = 5.5 and 3 Hz, HC3), 3.2–1.5 (m), 1.15 (s, 3H, CH_3C5), 1.21 and 0.96 (2d, 3H each, J = 7 Hz, $CH(CH_3)_2$); ms m/e: 496 (M^+). *Anal.* calcd. for $C_{25}H_{36}O_{10}$: C 60.47, H 7.31; found: C 60.76, H 7.30.

*Reduction of lactone **136***

To a solution of lactone **136** (49 mg, 0.10 mmol) in tetrahydrofuran (6 mL) was added lithium aluminium hydride (30 mg, large excess) and the mixture was stirred for 4 h at room temperature. The mixture was cooled (−78°C) and reacted with ammonium chloride solution, warmed to 25°C, and extracted with dichloromethane. Chromatography of the crude extract on silica column (chloroform – acetone, 5:1, containing ~0.01% of pyridine) furnished triol **137** (45 mg, 91%); ir ($CHCl_3$, ν cm^{-1}): 3600–3200, 1445, 1285, 1050; ^1H nmr ($CDCl_3$, δ ppm): 5.04 (s, 2H, OCH_2O), 4.70 (dd, 1H, J_{AB} = 11 Hz, J_{AX} = 4 Hz, H_AC17), 4.60 (d, 1H, J_{AB} = 11 Hz, J_{BX} = 1.5 Hz, H_BC17), 4.24 (d, 1H, J = 4.5 Hz, $CH(OCH_3)_2$), 4.00 (br m, 2H, HC10 and HC15), 3.49, 3.47, and 3.43 (3s, 3H each, 3 × OCH_3), 2.6–1.2 (m), 1.07 (s, 3H, CH_3C5), 0.94 and 0.85 (2d, 3H each, J = 7 Hz, $CH(CH_3)_2$; ms m/e: 500 (M^+).

Primary p*-nitrobenzoate **138***

Freshly recrystallized (hot hexane) *p*-nitrobenzoyl chloride (8 mg, 0.04 mmol) was added to a solution of triol **137** (18 mg, 0.036 mmol) in pyridine (1.5 mL). After 1 h at room temperature the mixture was poured into dilute aqueous sodium bicarbonate and extracted with dichloromethane. Chromatography (chloroform – acetone, 3:1) of the crude product on silica gel furnished pure compound **138** (21.6 mg, 92%); ir ($CHCl_3$, ν cm^{-1}): 3600–3400, 1725, 1605, 1528; ^1H nmr ($CDCl_3$, δ ppm): 8.25 (s, 4H, aromatic), 5.05 (s, 2H, OCH_2O), 5.0–4.3 (m, 4H, H_2C17, HC15, and HC10), 4.30 (d, 1H, J = 4 Hz, $CH(OCH_3)_2$), 3.48, 3.46, and 3.45 (3s, 3H each, 3 × OCH_3), 2.9–1.2 (m), 1.06 (s, 3H, CH_3C5), 0.95 (d, 6H, J = 7 Hz, $CH(CH_3)_2$).

*Mesylate **139***

Methanesulfonyl chloride (100 μL, excess) was added to a cold (0°C) solution of diol **138** (6.8 mg, 0.010 mmol) in pyridine (1.0 mL). After 45 min, the mixture was poured into aqueous sodium bicarbonate (1 M) and extracted with dichloromethane. Chromatography of the crude product (chloroform – acetone, 4:1) on silica plate gave pure monomesylate **139** (6 mg, 79%); ir ($CHCl_3$, ν cm^{-1}): 3550, 1728, 1605, 1528, 1350–1310, 1160; ^1H nmr ($CDCl_3$, δ ppm): 8.25 (s, 4H, aromatic), 5.60 (br m, 1H, HC10), 5.06 (s, 2H, OCH_2O), 4.76 (br d, 3H, J = 6 Hz, H_2C17 and HC15), 4.32 (d, 1H, J = 4 Hz, $CH(OCH_3)_2$, 3.50, 3.49, and 3.47 (3s, 3H each, 3 × OCH_3), 3.14 (s, 3H, CH_3SO_2), 2.9–1.4 (m), 1.12 (s, 3H, CH_3C5), 1.04 and 0.93 (2d, 3H each, J = 7 Hz, $CH(CH_3)_2$).

*Ketone **140***

To a stirred suspension of chromic anhydride (100 mg) in dry dichloromethane (5 mL) was added anhydrous pyridine (170 μL). After 15 min at 25°C, the mixture was cooled (0°C) and treated with a solution of alcohol **139** (5 mg, 0.007 mmol) in dichloromethane (0.5 mL). After 5 min, isopropanol (0.5 mL) was added and the mixture was poured into aqueous sodium bicarbonate and extracted with dichloromethane. The crude extract was chromatographed on silica plate (hexane – ethyl acetate, 1:1) to give ketone **140** (4.3 mg, 88%); ir ($CHCl_3$, ν cm^{-1}): 1758, 1737, 1605, 1527, 1342, 1262, 1163; ^1H nmr ($CDCl_3$, δ ppm): 8.23 (m, 4H, aromatic), 5.33 (br m, 1H, HC10), 5.17 (d, 1H) and 5.05 (d, 1H) (J_{AB} = 6 Hz, OCH_2O), 4.40 (m, 3H, H_2C17 and $CH(OCH_3)_2$), 3.56, 3.54, and 3.51 (3s, 3H each, 3 × OCH_3), 3.11 (s, 3H, CH_3SO_2), 2.8–1.3 (m), 2.40 (d, 1H), and 1.90 (d, 1H) (J = 20 Hz) (H_2C14), 1.28 (s, 3H, CH_3C5), 1.11 and 0.98 (2d, 3H each, J = 7 Hz) ($CH(CH_3)_2$).

*Hemi-ketal **141***

This reaction was carried out as for hemi-ketal **127** (*vide supra*). In the same conditions compound **140** (3.1 mg, 4.3 μmol) furnished pure hemi-ketal **141** (2.2 mg, 90%); ir ($CHCl_3$, ν cm^{-1}): 3600, 1440, 1350, 1320, 1160; ^1H nmr ($CDCl_3$, δ ppm): 5.42 (dd, 1H, J = 11 and 6 Hz, HC10), 5.07 (br s, 2H, OCH_2O), 4.38 (dd, 1H, J_{AB} = 13 Hz, J_{AX} = 4 Hz, H_AC17), 4.23 (d, 1H, J = 5.5 Hz, $CH(OCH_3)_2$), 4.05 (dd, 1H, J_{AB} = 13 Hz, J_{BX} = 12 Hz, H_BC17), 3.52, 3.46, and 3.43 (3s, 3H each, 3 × OCH_3), 3.06 (s, 3H, CH_3SO_2), 2.65 (m, 3H), 2.5–1.3 (m), 1.14 (s, 3H, CH_3C5), 1.06 and 0.96 (2d, 3H each, J = 7 Hz, $CH(CH_3)_2$); ms m/e: 576 (M^+).

*Fragmentation and hydrolysis of hemi-ketal **141***

Following exactly the same experimental conditons used for fragmentation of compound **127** (*vide supra*), hemi-ketal **141** (2.0 mg, 0.0035 mmol) furnished very sensitive lactone **143** (1.8 mg), which was submitted to acid hydrolysis in the same conditions as for lactone **128** (THF, HBF_4, 0.3 M) (*vide supra*) to furnish a single compound, crystalline lactone **129** (1.4 mg, >90%) already described (*vide supra*).

Monomethylation of ketone ***39***

To a cold (−78°C) solution of ketone **39** (1.002 g, 2.23 mmol) in dry tetrahydrofuran (100 mL) was added dropwise, over 16 min, a cold (0°C) solution of lithium diisopropylamide (0.487 M in THF, 10.0 mL, 4.87 mmol, 2.19 molar equivalents) in tetrahydrofuran. The mixture was kept at −78°C for 1 h, warmed to −25°C for 3 h, then treated with a cold (0°C) solution of triethylborane in tetrahydrofuran (1.278 M, 3.6 mL, 4.6 mmol, 2.06 molar equivalents). After 0.5 h at −25°C a clear solution resulted and dry iodomethane (2.28 g, 7.2 molar equivalent) was added. The temperature was maintained at −22°C for 16 h before the addition of saturated ammonium chloride (100 mL) and water (50 mL) to the red solution. Extraction with dichloromethane furnished a crude product that was chromatographed on silica gel (chloroform – acetone, 20:1) to separate the less polar dimethylated derivative (105 mg, ~10%) and the more polar starting material (196 mg, 19%) from a mixture (719 mg, 69.8%) of monomethylated compounds (~3:1, nmr integration of the C15 protons). This mixture in methanol (20 mL) was submitted to aqueous sodium carbonate (0.1 N, 5 mL) for 2 h, then extracted with dichloromethane to give pure crystalline equatorial monomethylated compound **144** (disappearance of the dd at δ 5.17 and the d at δ 1.15); mp 245.5–254°C (dec.); $[\alpha_D$ −56.6° (*c* 1.00, THF); ir ($CHCl_3$, ν cm^{-1}): 3500, 1820, 1760, 1720; ^1H nmr (acetone-d_6, δ ppm): 5.40 (dd, 1H, *J* = 10.3 and 2.9 Hz, HC15), 4.38 (d, 1H, *J* = 4.5 Hz, C*H*(OCH_3)$_2$), 3.48 and 3.46 (2s, 3H each, 2 × OCH_3), 3.2–1.7 (m), 1.23 (s, 3H, CH_3C5), 1.08 (d, 3H, *J* = 7 Hz, CH_3C9), 1.05 and 0.95 (2d, 3H each, *J* = 7 Hz, CH(C*H*$_3$)$_2$), ms *m/e*: 464 (M^+). *Anal.* calcd. for $C_{24}H_{32}O_9$: C 62.06, H 6.95; found: C 62.33, H 7.08.

Equatorial alcohol ***145*** (R′ = H)

This reduction was carried out under the same conditions as for the formation of alcohol **135** (*vide supra*). Thus ketone **144** (1.024 g, 2.207 mmol) furnished crude diol **145** (995 mg, 97%); mp 257–267°C (dec.); ir ($CHCl_3$, ν cm^{-1}): 3600–3450, 1810, 1740, 1060; ^1H nmr ($CDCl_3$, δ ppm): 5.08 (dd, 1H, *J* = 9 and 3.5 Hz, HC15), 4.29 (d, 1H, *J* = 4 Hz, C*H*(OCH_3)$_2$), 3.88 (br d, 1H, *J* ≃ 11 Hz, HC10), 3.50 and 3.49 (2s, 3H each, 2 × OCH_3), 3.2–1.5 (m), 1.15 (s, 3H, CH_3C5), 1.18 and 1.06 (2d, 3H each, CH(C*H*$_3$)$_2$); ms *m/e*: 466 (M^+). This product was analyzed as its acetate **145** (R′ = Ac).

Acetate ***145*** (R′ = Ac)

A solution of diol **145** (R′ = H) (59 mg, 0.13 mmol) in pyridine (2 mL) and acetic anhydride (1 mL) was stirred at 25°C for 18 h. The volatile substances were evaporated and the crude product was chromatographed (silica plates, chloroform – acetone, 4:1) to give pure crystalline (dichloromethane – hexane) acetate **145** (R′ = Ac) (55 mg, 78%) and unchanged starting material (4.7 mg, 8%); mp 244–246°C; $[\alpha]_D$ −34.7° (*c* 1.00, $CHCl_3$); ir ($CHCl_3$, ν cm^{-1}): 3600, 3460, 1815, 1750, 1370, 1230, 1065; ^1H nmr ($CDCl_3$, δ ppm): 5.47 (d, 1H, *J* = 10 Hz, HC10), 5.10 (dd, 1H, *J* = 10 and 3.5 Hz, HC15), 4.30 (d, 1H, *J* = 4 Hz, C*H*(OCH_3)$_2$), 3.49 and 3.48 (2s, 3H each, 2 × OCH_3), 2.95 (m, 2H, HC2 and C*H*(CH_3)$_2$), 2.88 (d, 1H, *J* = 8 Hz, HC1), 2.74 (dd, 1H, *J* = 10 and 4 Hz, HC3), 2.26 (m, 1H, HC9), 2.18 (dd, 1H, J_{AB} = 14 Hz, J_{AX} = 10 Hz, H_{exo}C14), 2.03 (s, 3H, CH_3CO_2), 1.93 (dd, J_{AB} = 14 Hz, J_{BX} = 3 Hz, H_{endo}C14), 1.8–1.3 (m, 3H), 1.16 (s, 3H, CH_3C5), 1.15 (d, 3H, *J* = 7 Hz, CH_3C9), 0.98 and 0.93 (2d, 3H each, *J* = 7 Hz, CH(C*H*$_3$)$_2$); ms *m/e*: 508 (M^+). *Anal.* calcd. for $C_{26}H_{36}O_{10}$: C 61.40, H 7.13; found: C 61.60, H 7.37.

Methoxymethyl orthocarbonate ***146***

To a suspension of freshly washed (THF) sodium hydride (400 mg, of 50% in oil, ~8.3 mmol) in tetrahydrofuran (40 mL) was added a solution of hydroxycarbonate **145** (R′ = H) (341 mg, 0.732 mmol) in tetrahydrofuran. After 30 min at 25°C, methoxymethyl chloride (freshly distilled from CaH_2, 440 μL, 5.78 mmol) was added to the mixture and the temperature of the oil bath was raised to ~33°C. After 6 h, the mixture was concentrated to one third of the initial volume, then cooled (−75°C) and treated with pyridine (~0.8 mL) and a saturated solution of sodium carbonate in methanol (6 mL, foam!). The mixture was then warmed to room temperature (~20 min), poured into cold water, and extracted with dichloromethane to give a crude product that was chromatographed on silica gel (chloroform – acetone, 5:1, trace of pyridine) to give methoxymethyl orthocarbonate **146** (350 mg, 94%); mp 169–170°C; $[\alpha]_D$ −12.1° (*c* 1.00, $CHCl_3$); ir ($CHCl_3$, ν cm^{-1}): 3610, 3450, 1745, 1450, 1050; ^1H nmr ($CDCl_3$, δ ppm): 5.06 (s, 2H, OCH_2O), 5.00 (dd, 1H, *J* = 9 and 3.5 Hz, HC15), 4.28 (d, 1H, *J* = 5 Hz, C*H*(OCH_3)$_2$), 3.90 (m, 1H, HC10), 3.52, 3.47, and 3.43 (3s, 3H each, 3 × OCH_3), 3.02 (d, 1H, *J* = 5 Hz, HC1), 3.1–1.4 (m), 1.20 (d, 3H, *J* = 7 Hz, CH_3C9), 1.13 (s, 3H, CH_3C5), 1.06 and 0.95 (2d, 3H each, *J* = 7 Hz, CH(C*H*$_3$)$_2$); ms *m/e*: 510 (M^+). *Anal.* calcd. for $C_{26}H_{38}O_{10}$: C 61.16, H 7.50: C 61.33, H 7.49.

Triol ***147***

To a solution of lactone **146** (137 mg, 0.269 mmol) in tetrahydrofuran (15 mL) was added lithium aluminium hydride (70 mg); the mixture was stirred at 25°C overnight, then cooled (−78°C). An aqueous saturated solution of sodium sulfate (1 mL) was added and the mixture was allowed to warm to room temperature, poured into cold water, and extracted with dichloromethane. Filtration of the crude product through silica gel (chloroform – acetone, 5:1) gave pure triol **147** as a foam (131 mg, 95%); $[\alpha]_D$ −40.1° (*c* 1.00, $CHCl_3$); ir ($CHCl_3$, ν cm^{-1}): 3350 (br), 1450, 1290, 1050; ^1H nmr ($CDCl_3$, δ ppm): 5.03 (s, 2H, OCH_2O), 4.80 (dd, 1H, *J* = 11 and 5.5 Hz, HC15), 4.25 (d, 1H, *J* = 4 Hz, C*H*(OCH_3)$_2$), 4.14 (dd, 1H, J_{AB} = J_{AX} = 11.1 Hz, H_AC17), 4.06 (d, 1H, *J* = 10 Hz, HC10), 4.01 (dd, 1H, J_{AB} = 11.1 Hz, J_{BX} = 6.2 Hz, H_BC17), 3.48, 3.45, and 3.41 (3s, 3H each, 3 × OCH_3), 3.43 (dd, 1H, *J* = 12 and 4 Hz, HC3), 2.8–2.4 (m), 2.0–1.4 (m), 1.10 (d, 3H, *J* = 6.2 Hz, CH_3C9), 1.05 (s, 3H, CH_3C5), 0.95 and 0.88 (2d, 3H each, *J* = 6.8 Hz, CH(C*H*$_3$)$_2$); ms *m/e*: 514 (M^+). *Anal.* calcd. for $C_{26}H_{42}O_{10}$: C 60.68, H 8.23; found: C 60.44, H 7.98.

Hemi-ketal ***148*** *by selective oxidation of triol* **147**

Chromium trioxide (770 mg) was added to a cold (0°C) solution of pyridine (1.4 mL) in dichloromethane (70 mL). After 15 min, this stock solution of reagent was used in small portions (~4–5 mL portions) for the selective oxidation of triol **147** (500 mg, 0.972 mmol) in dichloromethane (125 mL) maintained below −22°C. The reaction was monitored by thin-layer chromotography and was complete after a total addition of about 40 mL of the stock solution. Then isopropanol (~2 mL) was added and the mixture was warmed to 0°C, poured into aqueous sodium bicarbonate, and extracted with dichloromethane. The crude product was chromatographed on silica gel (chloroform – acetone, 93:7) containing traces of pyridine ~0.1%) to give pure hemiketal **148** (380 mg, 76%); mp 123–123.5°C; $[\alpha]_D$ −39.2° (*c* 1.00, $CHCl_3$); ir ($CHCl_3$, ν cm^{-1}): 3550 (br), 1740,[8] 1455, 1318, 1290, 1050; ^1H nmr ($CDCl_3$, δ ppm):[8] 5.06 (s, 2H, OCH_2O), 4.78 (dd, 1H, J_{AB} = 12 Hz, J_{AX} = 4 Hz, H_AC17), 4.23 (d, 1H, *J* = 5.5 Hz, C*H*(OCH_3)$_2$), 4.05 (d, 1H, *J* = 12 Hz, HC10), 3.77 (dd, 1H, J_{AB} = 12 Hz, J_{BX} < 0.5 Hz, H_BC17), 3.51, 3.45, and 3.43 (3s, 3H each, 3 × OCH_3), 2.8–1.3 (m), 1.11 (s, 3H, CH_3C5), 1.07, 1.05, and 0.93 (3d, 3H each, *J* = 7 Hz, CH_3C9 and CH(C*H*$_3$)$_2$); ms *m/e*: 512 (M^+). *Anal.* calcd. for $C_{26}O_{40}O_{10}$: C 60.92, H 7.88; found: C 60.96, H 8.11.

Hemi-ketal mesylate ***149***

To a cold (0°C) solution of hemi-ketal **148** (380 mg, 0.742 mmol) in pyridine (16 mL) was added methanesulfonyl chloride (378 μL, 4.89 mmol). After 1 h the mixture was concentrated under vacuum (<30°C), then poured into aqueous sodium bicarbonate and extracted with dichloromethane. The crude mesylate was chromatographed on silica gel (hexane – ethyl acetate, 1:1, traces of pyridine) to give mesylate **149** (391 mg, 89%); ^1H nmr ($CDCl_3$, δ ppm); 5.27 (d, 1H, *J* = 11 Hz, HC10), 5.15 (d, 1H) and 5.01 (d, 1H) (J_{AB} = 6 Hz, OCH_2O), 4.33 (dd, 1H, J_{AB} = 12 Hz, J_{AX} = 4 Hz, H_AC17), 4.23 (d, 1H, *J* = 5 Hz, C*H*(OCH_3)$_2$), 3.88 (dd, 1H, J_{AB} = 12 Hz, J_{BX} = 2 Hz, H_BC17), 3.52, 3.47, and 3.43 (3s, 3H each, 3 × OCH_3), 3.11 (s, 3H, CH_3SO_2),

[8]The open form hydroxyketone of **148** is present in solution ($CHCl_3$, ~15%).

For personal use only.

2.7–1.4 (m), 1.10 (d, 3H, J = 7 Hz, CH_3C9), 1.01 and 0.98 (2d, 3H each, J = 7 Hz, $CH(CH_3)_2$); ms m/e: 448 ($M^+ - CH_3SO_3H - CH_3OCH_2$).

*Hydroxycarbonate lactone **151***

This reaction was carried out exactly as for compounds **141** and **127** (*vide supra*). Thus mesylate **149** (255 mg, 0.43 mmol) furnished very sensitive lactone **150**, which was hydrolyzed as for lactone **128** (*vide supra*) to yield hydroxycarbonate lactone **151**. This sequence was repeated on two quantities of hemi-ketal **149** (300 and 323 mg) for a total yield of compound **151** (650 mg, 97% from **149**); mp 229.5–231°C; $[\alpha]_D$ −126° (*c* 0.98, $CHCl_3$); ir ($CHCl_3$, ν cm^{-1}): 3600, 1800, 1754, 1680, 1450, 1353, 1045, 1025; ^1H nmr ($CDCl_3$, δ ppm): 5.93 (br d, 1H, $J \simeq 2$ Hz, HC10), 4.62 (ddd, 1H, J_{AB} = 12.5 Hz, J_{AX} = 2 Hz, $J_W \cong 0.5$ Hz, $H_{exo}C17$), 4.28 (d, 1H, J = 5 Hz, $CH(OCH_3)_2$), 4.25 (dd, 1H, J_{AB} = 12.5 Hz, J_{BX} = 2 Hz, $H_{endo}C17$), 3.56 and 3.53 (2s, 3H each, 2 × OCH_3), 3.45 (dd, 1H, J = 12 and 5 Hz, HC3), 2.76 (d, 1H) and 2.23 (d, 1H) (J_{AB} = 13 Hz, H_2C14), 3.1–1.4 (m), 1.30 (s, 3H, CH_3C5), 1.07 (d, 9H, J = 7 Hz, CH_3C9 and $CH(CH_3)_2$); ms m/e: 450 (M^+). *Anal.* calcd. for $C_{24}H_{34}O_8$: C 63.98, H 7.61; found: C 64.40, H 7.24.

*Epoxide **152***

A solution of freshly prepared trifluoroperacetic acid (1.125 M; 720 μL, 0.81 mmol) in 1,2-dichloroethane was added dropwise (over 2 min) to a cold (0°C) mixture of anhydrous disodium hydrogen phosphate (3.46 g, 24.4 mmol) and olefin **151** (163 mg, 0.362 mmol) in dry 1,2-dichloroethane (35 mL). After 2 h the same quantity of peracid was added; after an additional 3.5 h, the mixture was cooled to −24°C for 15.5 h, then poured into aqueous sodium bicarbonate and extracted with dichloromethane. Evaporation of the solvents gave a pure crystalline (dichloromethane – ether – hexane) compound, epoxy lactone **152** (165 mg, 98%); mp 173–175°C; ir ($CHCl_3$, ν cm^{-1}): 3550, 1810, 1755, 1250, 1050; ^1H nmr ($CDCl_3$, δ ppm): 4.51 (br d, 2H, J = 2.5 Hz, H_2C17), 4.11 (d, 1H, J = 4 Hz, $CH(OCH_3)_2$), 3.67 (br s, 1H, HC10), 3.54 and 3.53 (2s, 3H each, 2 × OCH_3), 3.2–1.7 (m), 1.36 (s, 3H, CH_3C5), 1.15 (d, 3H, J = 7 Hz, CH_3C9), 1.08 and 1.04 (2d, 3H each, $CH(CH_3)_2$); ms m/e: 466 (M^+).

*Triol lactone **153***

This translactonisation was accomplished exactly as for lactone **132** (*vide supra*). Thus lactone epoxide **152** (341 mg, 0.732 mmol) furnished triol lactone **153** (273 mg, 77%) after crystallization and chromatography on silica gel (ether – ethyl acetate, 4:1); mp 246–248°C; $[\alpha]_D$ −32.9° (*c* 1.00, $CHCl_3$); ir ($CHCl_3$, ν cm^{-1}): 3600, 3450, 1810, 1760, 1440, 1020; ^1H nmr ($CDCl_3$, δ ppm): 4.58 (dd, 1H, J = 3.0 and ~0.5 Hz, $H_{eq}C10$), 4.30 (d, 1H, J = 5.4 Hz, $CH(OCH_3)_2$), 3.86 (dd, 1H, J_{AB} = 12 Hz, J_{AX} = 5 Hz, H_AC17), 3.58 (dd, 1H, $J_{AB} = J_{BX}$ = 12 Hz, H_BC17), 3.47 and 3.45 (2s, 3H each, 2 × OCH_3), 2.95 (d, 1H) and 2.60 (d, 1H) (J_{AB} = 20 Hz, H_2C14), 2.78 (m, 1H, HCl), 2.47 (m, 1H, HC2), 2.32 (dd, 1H, J = 12 and 5.4 Hz, HC3), 2.04 (m, 2H, HC9 and $CH(CH_3)_2$), 1.8–1.4 (m), 1.21 (s, 3H, CH_3C5), 1.05, 1.02, and 0.92 (3d, 3H each, J = 7 Hz, CH_3C9 and $CH(CH_3)_2$); ms m/e: 484 (M^+). *Anal.* calcd. for $C_{24}H_{36}O_{10}$: C 59.49, H 7.48; found: C 59.67, H 7.55.

p-*Nitrobenzoate **154***

Freshly recrystallized (hot hexane) *p*-nitrobenzoyl chloride (444 mg, 2.39 mmol) was added to a cold (4°C) solution of triol lactone **153** (480 mg, 0.991 mmol) in dry pyridine (15 mL). After 25 min, the mixture was poured into saturated aqueous sodium bicarbonate (20 mL) and extracted with dichloromethane. The crude product was filtered through silica gel (hexane – ethyl acetate, 1:1 containing a trace of pyridine) to give pure ester lactone **154** (552 mg, 95%); mp 130–131°C (benzene); $[\alpha]_D$ −33.0° (*c* 1.0, $CHCl_3$); ir ($CHCl_3$, ν cm^{-1}): 3600, 3480, 1820, 1765, 1730, 1610, 1530, 1260, 1080, 1030; ^1H nmr ($CDCl_3$, δ ppm): 8.26 (m, 4H, aromatic), 4.63 (dd, 1H, J_{AB} = 12 Hz, J_{AX} = 6 Hz, H_AC17), 4.48 (dd, 1H, J_{AB} = 12 Hz, J_{BX} = 10 Hz, H_BC17), 4.37 (d, 1H, J = 2 Hz, $H_{eq}C10$), 4.35 (d, 1H, J = 5.4 Hz, $CH(OCH_3)_2$), 3.50 and 3.48 (2s, 3H each, 2 × OCH_3), 3.02 (m, 1H, HC1), 2.96 (d, 1H) and 2.64 (d, 1H) (J_{AB} = 20 Hz, H_2C14), 2.63 (m, 1H, HC2), 2.39 (dd, 1H, J = 12 and 5.4 Hz, HC3), 2.16 (m, 1H, HC9), 1.97 (m, 1H, $CH(CH_3)_2$), 1.8–1.4 (m), 1.23 (s, 3H, CH_3C5), 1.14 (d, 3H, J = 7 Hz, CH_3C9), 1.04 and 0.82 (2d, 3H each, J = 7 Hz, $CH(CH_3)_2$); ms m/e: 633 (M^+). *Anal.* calcd. for $C_{31}H_{39}O_{13}N$: C 58.78, H 6.21; found: C 59.05, H 6.36.

*Ketone **155***

Chromium trioxide (400 mg, 4.0 mmol) was added to a cold (0°C) solution of pyridine (680 μL, 8.4 mmol) in dichloromethane (30 mL). After 15 min, a solution of diol **154** (100 mg, 0.158 mmol) in dichloromethane (~1 mL) was added to the mixture and the temperature was raised to 25°C. After 45 min, isopropanol (1 mL) was added and the mixture was poured onto aqueous sodium bicarbonate and extracted with dichloromethane. The same reaction was performed on another quantity of diol **154** (200 mg, 0.316 mmol) and the combined crude extracts were chromatographed on silica gel (chloroform, acetone, 4:1) to give pure *more* polar ketone **155** (233 mg, 78%); $[\alpha]_D$ −30.3° (*c* 1.00, $CHCl_3$); ir ($CHCl_3$, ν cm^{-1}): 3600, 3450, 1820, 1775, 1740, 1610, 1530, 1260; ^1H nmr ($CHCl_3$, δ ppm): 8.20 (m, 4H, aromatic), 4.68 (dd, 1H, J_{AB} = 12 Hz, J_{AX} = 6 Hz, H_AC17), 4.38 (d, 1H, J = 5 Hz, $CH(OCH_3)_2$), 4.21 (dd, 1H, $J_{AB} = J_{BX}$ = 12 Hz, H_BC17), 3.50 and 3.48 (2s, 3H each, 2 × OCH_3), 3.22 (d, 1H) and 2.78 (d, 1H) (J_{AB} = 18 Hz, H_2C14), 3.0–1.6 (m), 1.25 (s, 3H, CH_3C5), 1.25 (d, 3H, J = 7.5 Hz, CH_3C9), 1.10 and 0.90 (2d, 3H each, J = 7 Hz, $CH(CH_3)_2$); ms m/e: 631 (M^+). *Exact Mass* calcd. for $C_{31}H_{37}O_{13}N$: 631.2274; found: 631.2263. *Anal.* calcd. for $C_{31}H_{37}O_{13}N$: C 58.97, H 5.89; found: C 59.37, H 6.34.

*Equatorial alcohol **156***

To a cold (−30°C) solution of ketone **155** (200 mg, 0.317 mmol) in tetrahydrofuran (45 mL) was added lithium borohydride (15 mg, 0.69 mmol). Four hours later another quantity (5 mg, 0.23 mmol) of reagent was added, and after 1 h the mixture was cooled (−70°C), quenched with saturated ammonium chloride, and warmed to room temperature. The mixture was poured into dilute aqueous ammonium chloride and extracted with dichloromethane. Chromatography of the crude product (hexane – ethyl acetate, 1:1) furnished the already known axial alcohol **154** (30 mg, 15%) and equatorial alcohol **156** (150 mg, 75%), less polar than starting ketone **155**; $[\alpha]_D$ −15.3° (*c* 1.00, $CHCl_3$); ir ($CHCl_3$, ν cm^{-1}): 3600, 3470, 1810, 1765, 1735, 1610, 1530, 1270; ^1H nmr ($CDCl_3$, δ ppm): 8.20 (m, 4H, aromatic), 4.78 (m, 2H, H_2C17), 4.38 (d, 1H, J = 5 Hz, $CH(OCH_3)_2$), 4.12 (d, 1H, J = 10 Hz, $H_{ax}C10$), 3.53 and 3.51 (2s, 3H each, 2 × OCH_3), 3.00 (d, 1H) and 2.50 (d, 1H) (J_{AB} = 20 Hz, H_2C14), 2.9–1.5 (m), 1.23 (s, 3H, CH_3C5), 1.20, 1.12, and 1.05 (3d, 3H each, CH_3C9 and $CH(CH_3)_2$); ms m/e: 633 (M^+). *Anal.* calcd. for $C_{31}H_{39}O_{13}N$: C 58.78, H 6.21; found: C 58.71, H 6.41.

*Acetate **157***

Acetic anhydride (5 mL) was added to a solution of alcohol **156** (252 mg, 0.398 mmol) in pyridine (5 mL) at 25°C. After 20 h, the volatile substances were evaporated and the crude product was filtered through a small silica column (benzene – ethyl acetate, 4:1) to give pure acetate **157** (258 mg, 96%); mp 318–319°C (dec.); $[\alpha]_D$ +20.6° (*c* 1.00, $CHCl_3$); ir ($CHCl_3$, ν cm^{-1}): 3600, 3445, 1820, 1770, 1740, 1610, 1530, 1260; ^1H nmr ($CDCl_3$, δ ppm): 8.24 (m, 4H, aromatic), 5.57 (d, 1H, J = 11 Hz, HC10), 4.80 (dd, 1H, J_{AB} = 12 Hz, J_{AX} = 4 Hz, H_AC17), 4.72 (dd, 1H, J_{AB} = 12 Hz, J_{BX} = 6 Hz, H_BC17), 4.36 (d, 1H, J = 5.6 Hz, $CH(OCH_3)_2$), 3.54 and 3.50 (2s, 3H each, 2 × OCH_3), 2.94 (d, 1H) and 2.54 (d, 1H) (J_{AB} = 20 Hz, H_2C14), 2.78 (dd, 1H, J = 13.0 and 5.6 Hz, HC3), 2.69 (m, 1H, HC1), 2.53 (m, 1H, HC2), 2.14 (m, 2H, HC9 and $CH(CH_3)_2$), 2.07 (s, 3H, CH_3CO_2), 1.78–1.54 (m), 1.23 (s, 3H, CH_3C5), 1.10 (d, 3H) and 0.93 (d, 6H) (J = 7 Hz, CH_3C9 and $CH(CH_3)_2$); ms m/e: 675 (M^+). *Anal.* calcd. for $C_{33}H_{41}O_{14}N$: C 58.68, H 6.12; found: C 58.61, H 6.16.

*Enol ethers **158***

Elimination of methanol from dimethylacetal **157** (385 mg, 0.570 mmol) was accomplished in the same way as already described for compound **64** (*vide supra*). Thus after 5 h in refluxing benzene, acid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

treatment furnished a mixture (~5:1) of isomeric enol ethers **158**, which were not separated (368 mg, crude 100%); mp 298–300°C (dec.)); ir ($CHCl_3$, ν cm^{-1}): 3600, 3450, 1815, 1765, 1740, 1690, 1610, 1530, 1260.

*Norketone **159** and enol acetate **160***

Crude enol ethers **158** (368 mg, 0.570 mmol) were ozonized in the same way as previosuly described for enol ethers **88** (*vide supra*). Thus was obtained crude norketone **159**, which was immediately acetylated in acetic anhydride (15 mL), at 95°C for 12 h, in the presence of dry sodium acetate (1.6 g). After evaporation of the volatile substances, filtration, and chromatography of the crude product (benzene – ethyl acetate, 1:1) on silica gel, enol acetate **160** (224 mg, 65% from **157**) was isolated; mp 316–318°C (dec.); ir ($CHCl_3$, ν cm^{-1}): 3450, 1825, 1770, 1735, 1680, 1610, 1530, 1265, 1170, 1035; ^1H nmr ($CDCl_3$, δ ppm): 8.25 (m, 4H, aromatic), 5.69 (d, 1H, J = 11 Hz, HC10), 5.66 (dd, 1H, J_{AM} = 12.5 Hz, J_{AX} = 2.0 Hz, H_AC17), 4.48 (dd, 1H, J_{AM} = 12.5 Hz, J_{MX} = 8.4 Hz, H_MC17), 3.62 (dd, 1H, J = 8.4 and 2.0 Hz, HCl), 2.89 (d, 1H) and 2.62 (d, 1H) (J_{AB} = 19.4 Hz, H_2C14), 2.56 (qn, 1H, J = 7 Hz, $CH(CH_3)_2$), 2.23 (s, 3H, CH_3CO_2-C3), 2.20 (m, 1H, HC9), 2.10 (s, 3H, CH_3CO_2), 1.85–1.60 (m), 1.12 (s, 3H, CH_3C5), 1.13 and 1.01 (2d, 3H each J = 7.0 Hz, $CH(CH_3)_2$), 0.95 (d, 3H, J = 6.5 Hz, CH_3C9); ms m/e: 657 (M^+).

*Enone **161***

Benzene (~30 mL) was distilled from a solution of enol acetate **160** (124 mg, 0.188 mmol) in benzene (100 mL), then freshly distilled (CaH_2) 1,5-diazabicyclo[4.3.0]non-5-ene (DBN) (0.8 mL) was added and the mixture was refluxed for 2.5 h. The reaction was followed by extraction and analysis (tlc) of aliquots. The mixture was then cooled, poured into cold hydrochloric acid (150 mL, 0.2 M), and extracted with dichloromethane to give a crude product that was chromatographed on silica gel (benzene – ethyl acetate, 3:1) to give enone **161** (70 mg, 83%); mp 301–302°C; $[\alpha]_D$ +150.6° (*c* 1.00, $CHCl_3$); uv λ_{max} (MeOH): 238 nm (ε 8775); ir ($CHCl_3$, ν cm^{-1}): 3600, 3470, 1835, 1770, 1730, 1620, 1025; ^1H nmr ($CDCl_3$, δ ppm): 5.72 (d, 1H, J = 10 Hz, HC10), 2.70 (qn, 1H, J = 7 Hz, $CH(CH_3)_2$), 2.71 (s, 1H, OH), 2.57 (s, 2H, H_2C14), 2.21 (s, 3H, H_3C17), 2.19 (s, 3H, CH_3CO_2), 1.9–1.5 (m), 1.34 (s, 3H, CH_3C5), 1.19 and 1.17 (2d, 3H each, J = 7 Hz, $CH(CH_3)_2$), 0.97 (d, 3H, J = 6.8 Hz, CH_3C9); ms m/e: 448 (M^+). *Exact Mass* calcd. for $C_{23}H_{28}O_9$: 448.1733; found: 448.1743.

*Allylic alcohol **162***

To a cold (0°C) solution of enone **161** (6.1 mg, 0.014 mmol) in tetrahydrofuran (2 mL) containing methanol (1 mL) was added sodium borohydride (~2 mg). After 2 h, the mixture was poured into cold aqueous ammonium chloride and extracted with dichloromethane. Chromatography of the crude product (benzene – ethyl acetate, 1:1) on silica plate furnished pure anhydroryanodol carbonate-acetate derivative **162** (5.8 mg, 95%); mp 300–301°C (dec.); $[\alpha]_D$ +89.6° (*c* 1.00, CH_3OH); ir ($CHCl_3$, ν cm^{-1}): 3600, 3470, 1810, 1770–1745, 1230, 1030; ^1H nmr ($CDCl_3$, δ ppm): 5.56 (d, 1H, J = 10 Hz, HC10), 5.09 (m, 1H, HC3), 3.95 (d, 1H) and 2.35 (d, 1H) (J_{AB} = 20 Hz, H_2C14), 2.70 (m, 1H, $CH(CH_3)_2$), 2.20 (m, 1H, HC9), 2.14 (s, 3H, CH_3CO_2), 1.83 (d, 3H, J = 2 Hz, H_3C17), 2.0–1.5 (m), 1.29 (s, 3H, CH_3C5), 1.15 and 1.12 (2d, 3H each, J = 7 Hz, $CH(CH_3)_2$), 0.92 (d, 3H, J = 6 Hz, CH_3C9); ms m/e: 450 (M^+).

*Anhydroryanodol **163*** and epianhydroryanodol ***164***

To a solution of carbonate acetate **162** (38 mg, 0.084 mmol) in tetrahydrofuran (6 mL) was added aqueous sodium hydroxide (0.1 M, 2.5 mL, 0.25 mmol). After 20 h at 0°C, the mixture was poured into saturated aqueous ammonium chloride and thoroughly extracted with dichloromethane (8 times). The crude product was chromatographed on silica gel (chloroform – methanol, 9:1) to give less polar epianhydroryanodol (**164**, 6 mg, 20%) and anhydroryanodol **163** (19 mg, 62%): *Epianhydroryanodol* (***164***): mp 227–228°C, $[\alpha]_D$ −97.8° (*c* 0.41, CH_3OH); ir ($CHCl_3$, ν cm^{-1}): 3500, 1750; ^1H nmr (CD_3OD, δ ppm): 5.05 (q, 1H, J = 2.0 Hz, HC3), 4.05 (d, 1H, J = 9.7 Hz, HC10), 3.57 (dd, 1H, J_{AB} = 15.8 Hz, J_W = 1.0 Hz, H_AC14), 2.81 (qn, 1H, J = 7 Hz, $CH(CH_3)_2$), 2.02 (d, 1H, J_{AB} = 15.8 Hz, H_BC14), 1.84 (d, 3H, J = 2.0 Hz, H_3C17), 1.83–1.20 (m), 1.65 (m, 1H, HC9), 1.25 (d, 3H, J = 7 Hz, $CH(CH_3)$), 1.03 (d, 3H, J = 1.0 Hz, CH_3C5), 1.02 (d, 3H, J = 6.3 Hz, CH_3C9), 0.97 (d, 3H, J = 7 Hz, $CH(CH_3)$); ms m/e: 382 (M^+). *Anhydroryanodol* (***163***): mp 148–150°C (from dichloromethane); $[\alpha]_D$ +54.3° (*c* 1.00, CH_3OH); ir (KBr, ν cm^{-1}): 3480 (br), 1750, 1240, 1010; ^1H nmr (CD_3OD, δ ppm): 4.70 (q, 1H, J = 2.4 Hz, HC3), 3.98 (d, 1H, J = 10.2 Hz, HC10), 3.61 (d, 1H) and 2.28 (d, 1H) (J_{AB} = 20 Hz, H_2C14), 2.74 (qn, 1H, J = 7 Hz, $CH(CH_3)_2$), 1.79 (m, 1H, HC9), 1.76 (d, 3H, J = 2.4 Hz, H_3C17), 1.62–1.40 (m), 1.16 (s, 3H, CH_3C5), 1.14 (d, 3H, J = 7 Hz) and 1.10 (d, 3H, J = 7 Hz) ($CH(CH_3)_2$), 1.07 (d, 3H, J = 6.3 Hz, CH_3C9); ms m/e: 382 (M^+).

Chem. **68**, 186 (1990).

This paper reports the transformation of (+)-anhydroryanodol (**6**) to (+)-ryanodol (**7**) by reductive cyclization of lactone epoxide derivatives **9** and **20** (Scheme 4).

Key words: anhydroryanodol, ryanodol, diterpene, synthesis, reductive cyclization.

On rapporte la transformation du (+)-anhydroryanodol (**6**) en (+)-ryanodol (**7**) par cyclisation réductrice des lactones époxydes intermédiaires **9** et **20** (Schéma 4).

Mots clés : anhydroryanodol, ryanodol, diterpène, synthèse, cyclisation réductrice.

Introduction

Part I (1) of this series of papers discloses the general plan that we have elaborated for the construction of (+)-ryanodol (**7**) via the key intermediate (+)-anhydroryanodol (**6**) (Scheme 1). It also describes the preparation of *o*-spirolactone dienone **1** and its reactivity as a diene in the Diels–Alder reaction. Part II (2) reports the four-step synthesis of the optically active key pentacyclic intermediate **5** starting from *o*-spirolactone dienone **1** and optically active vinyl ketone **2** prepared from *d*-carvone. Part III (3) describes the transformation in 24 steps of pentacyclic intermediate **5** into (+)-anhydroryanodol (**6**). There remains only a description of the conversion of (+)-anhydroryanodol (**6**) into (+)-ryanodol (**7**) to have a total synthesis of this compound. This conversion is the object of this paper.[2]

Discussion

The conversion of (+)-anhydroryanodol (**6**) into (+)-ryanodol (**7**) consists essentially of the formation of a bond between C_1 and C_{15} and the introduction of a hydroxyl group in the β configuration at C_2. It is thus necessary to discover a reductive cyclization process that will generate a C—C bond between the lactone carbonyl group and the tetrasubstituted olefin at C_1, and an oxidation process that will introduce the required β-hydroxyl group at C_2.

Before starting our investigation, we considered two different routes to achieve the above transformations. In the first one, it was hoped that the epoxidation of the olefin of (+)-anhydroryanodol (**6**) would take place from its less hindered face to yield the β-epoxide **9**, which would then be directly converted into (+)-ryanodol (**7**) under reductive conditions (Scheme 2). For instance, it was conceivable that under treatment with lithium in liquid ammonia, the lactone carbonyl group of **9** would be reduced to the dianion **10** (or a radical anion), making C_{15} nucleophilic enough to undergo a transannular displacement of the epoxide function at C_1, and generating at the same time the C_2 tertiary hydroxyl group of (+)-ryanodol (**7**). Examination of molecular models further suggested that competitive opening of the oxirane ring at C_2 would be less probable due to severe steric hindrance from the *endo* alcohol at C_3.

In the second route, we considered that the cyclopentenone **11** (Scheme 2), which can be obtained by oxidation of (+)-anhydroryanodol (**6**), could undergo a cyclization to produce the enolate-hemiacetal **13** under reductive conditions such as lithium in liquid ammonia. In this step, the enone **11** would first be reduced into the anticipated dianion (or radical-anion) **12** (5), which would then undergo a transannular nucleophilic addition to the lactone carbonyl group.[3] This step would then be followed by an oxidation of the resulting enolate **13** from its less hindered face, using a peroxide to yield the β-hydroxyketone hemiacetal **14**. This compound would then be converted into (+)-ryanodol (**7**) using a hydride reducing agent.

Both routes were mechanistically highly attractive and most probably feasible. The first approach was investigated because

[2]For a preliminary report on the total synthesis of (+)-ryanodol, see ref. 4.

[3]The enolate-hemiacetal **13** can also be obtained by reducing first the lactone carbonyl of **11**, producing a dianion (similar to that described in **10**) that can undergo a transannular 1,4-addition on the cyclopentenone moiety.

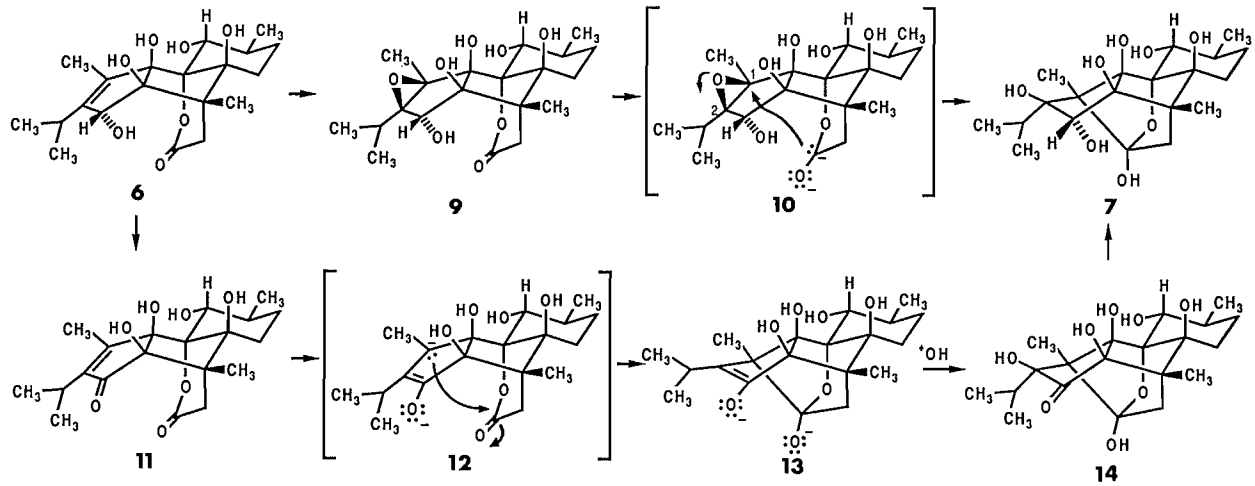

SCHEME 2

it appeared simpler and more readily realizable. Indeed, we did not anticipate difficulties in the epoxidation step and there were relatively close precedents in the literature (6) for the remaining reductive transannular cyclization step. It turned out that this approach was successful and the second one was therefore not investigated.

Results

As (+)-anhydroryanodol (**6**) can be easily obtained from (+)-ryanodine (**8**) (7), the desired transformation of (+)-anhydroryanodol (**6**) to (+)-ryanodol (**7**) was first carried out with material derived from the natural source. This transformation was then repeated with synthetic (+)-anhydroryanodol (**6**) obtained as described in the preceding paper (Part III).

Ryanodine (**8**) was isolated (7, 8)[4] and converted by basic hydrolysis to (+)-ryanodol (**7**), which was transformed under acidic conditions into (+)-anhydroryanodol (**6**) following the procedure described by Wiesner and his collaborators (7).

Direct epoxidation of (+)-anhydroryanodol (**6**) with *m*-

[4]A generous gift of powdered Ryania wood from Professor K. Wiesner was greatly appreciated.

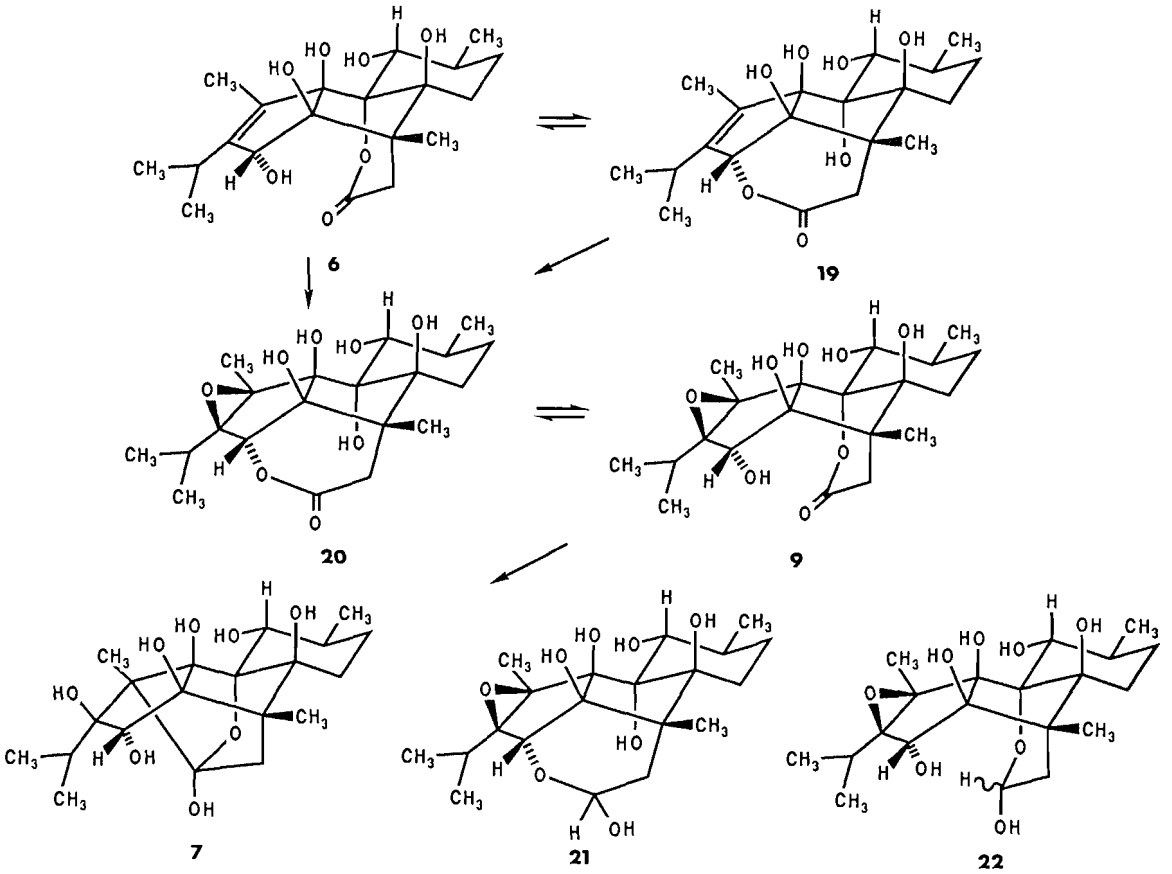

SCHEME 4

chloroperbenzoic acid was shown to be very slow and gave, instead of the desired epoxide **9** (Scheme 2), a small amount of cyclopentenone **11** along with a complex mixture of unidentified products. Cyclopentenone **11** could also be obtained by oxidation of **6** with manganese dioxide in chloroform. This result indicated that the allylic alcohol must be protected before carrying out the epoxidation reaction, and several experiments were undertaken on (+)-anhydroryanodol (**6**) with that in mind.

It soon became apparent that the selective protection of the C_3 hydroxyl group would not be a simple task. For example, simple acetylation (Ac_2O, pyridine or Ac_2O, NaOAc) led to a complex mixture that contained di- and triacetates with one of the hydroxyl groups, at either C_4, C_6, or C_{12}, being acetylated. These compounds were relatively fragile as they were readily transformed into their corresponding orthoacetate derivatives, even on silica gel during their purification. From this mixture, the diacetate **15** and triacetate **16**, having one of the tertiary OH groups at C_4, C_6, or C_{12} acetylated (Scheme 3), were isolated. On heating in benzene in the presence of *p*-toluenesulfonic acid (PTSA), compounds **15** and **16** were converted into the corresponding orthoacetates **17** and **18** respectively. These compounds had previously been isolated by Babin and are reported in his thesis (9). He also showed that orthoacetate **18** could be obtained directly from anhydroryanodol (**6**) using another method ($HClO_4$, Ac_2O).

The orthoacetate moiety appeared at first to be a very effective protecting group, which could in principle be used in the course of the synthesis of (+)-ryanodol. It was, however, shown (cf. Part III of this series) that the orthoacetate moiety was very stable (10) even under very strong acidic conditions (50% H_2SO_4). Since it was clear that (+)-ryanodol (**7**) would not survive under such strong acidic conditions, this idea was

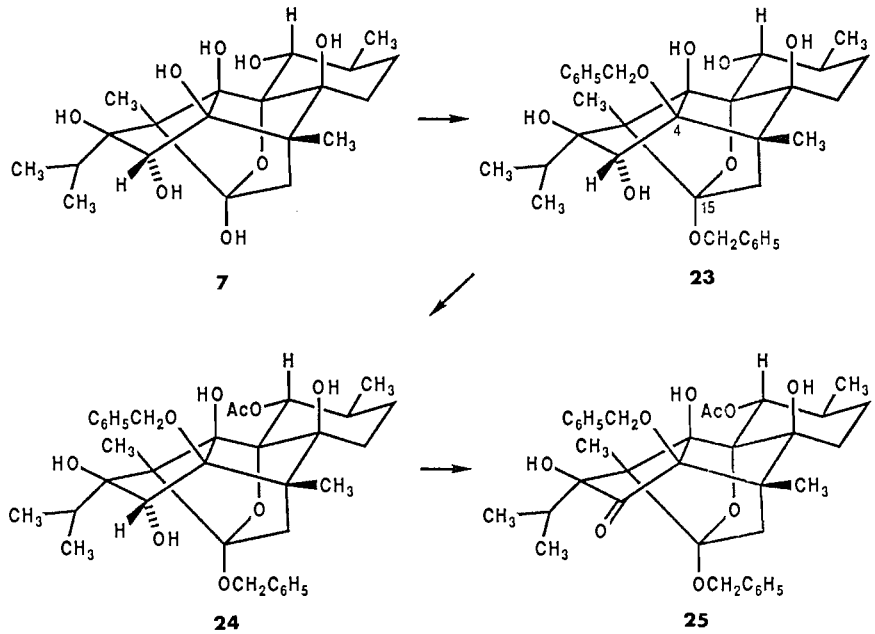

SCHEME 5

rapidly abandoned. Meanwhile, it was observed that under basic (1 M NaOH, THF) or acidic (dioxan, PTSA) conditions, (+)-anhydroryanodol (**6**) forms (Scheme 4) an equilibrium mixture (~3:1) with (−)-epianhydroryanodol (**19**) that can be separated by chromatography. The formation of (−)-epianhydroryanodol (**19**) is the result of a translactonization process with the allylic alcohol function at C_3. Once this compound was characterized,[5] it appeared clear that the problems encountered in the course of the epoxidation of (+)-anhydroryanodol (**6**) could be avoided since the allylic alcohol is now protected.

(−)-Epianhydroryanodol (**19**) was submitted to *m*-chloroperbenzoic acid (11) ($CHCl_3$, K_2CO_3) to give the β-epoxide **20** of epianhydroryanodol in 55% yield. This yield was increased to 85% using trifluoroperacetic acid in 1,2-dichloroethane in the presence of disodium hydrogen phosphate (12). It was also found that when (+)-anhydroryanodol (**6**) is submitted to these later conditions, it also yields directly, in 85% yield, the epoxide **20** of epianhydroryanodol. Thus, under those buffered acidic conditions, (+)-anhydroryanodol (**6**) must first isomerize into **19** before undergoing the epoxidation reaction. Finally, basic treatment (1 M NaOH, THF) of epianhydroryanodol epoxide **20**, followed by neutralization with acetic acid, afforded a mixture of epoxides **20** and **9**, which were separated for the characterization of epoxy-anhydroryanodol **9**. Having prepared the desired epoxide **9**, the reductive cyclization step was next attempted. It was found that treatment of epoxide **9** with lithium in liquid ammonia and tetrahydrofuran afforded, as anticipated, a satisfactory 60% yield of (+)-ryanodol (**7**) along with the minor formation of two dihydro compounds, the more polar of which was isolated in 20%, and the other in 10%, yield. These compounds were separated by chromatography and (+)-ryanodol (**7**), isolated, was found to be identical in all respects with an authentic sample.[6]

On oxidation (Br_2, CH_3OH–H_2O, $NaHCO_3$, 6 h, 25°C), the more polar dihydro derivative was transformed into epianhydroryanodol epoxide **20**. As anhydroryanodol epoxide **9** does not isomerize to **20** under the same conditions, this compound must have structure **21**. The stereochemistry at C_{15} was not defined since both epimers at that position (in two different twist conformations) can account for the observed coupling constants (10 and 1.7 Hz) for the hydrogens at C_{14} and C_{15}.

Although the ^1H nmr spectrum of the less polar dihydro compound is consistent with structure **22**, we found that this compound was not oxidized under the above conditions. Also, it did not isomerize to **21** in basic (CH_3OH, K_2CO_3) or acidic (PTSA, THF or CH_3OH) medium at room temperature. On that basis, the structure of the minor dihydro compound cannot be **22**, but no attempts were made to characterize its structure further.

The minor formation of hemiacetal epoxide **21**, which must come from the reduction of the lactone carbonyl group of epianhydroryanodol epoxide **20** followed by protonation of the resulting dianion, is an indication that the proposed mechanistic pathway (cf. Scheme 2) for the production of (+)-ryanodol (**7**) from anhydroryanodol epoxide **9** is probably correct.

The formation of (+)-ryanodol (**7**) was also observed starting directly either from the epi-epoxide **20** or from a mixture of **9** and **20**, indicating that prior to the reductive cyclization process, epi-epoxide **20** must first be isomerized into epoxide **9** in the reaction mixture. This sequence was then applied to synthetic (+)-anhydroryanodol (**6**) (see Part III) and furnished totally synthetic (+)-ryanodol (**7**) as expected.

The reconversion of (+)-ryanodol (**7**) into (+)-ryanodine (**8**) was also considered but only briefly investigated. Analysis of molecular models shows that the hydroxyl group at C_3 is

[5]To our knowledge the presence of the lactone isomer **19** of anhydroryanodol (**6**) was already observed by Babin (ref. 9, p. 109 ("isoanhydroryanodol"), pp. 143–144 and 155) but at that time its structure was not completely clarified. We called that compound **19** "epianhydroryanodol" to avoid confusion with the "iso-series," so called by Wiesner (7) to describe a different isomeric series.

[6]Synthetic (+)-ryanodol (**7**) was further identified by its reconversion into (+)-anhydroryanodol (**6**) and (−)-epianhydroryanodol (**19**) under acidic conditions.

severely hindered, and presumably impossible to esterify in a selective manner. To protect the most reactive hydroxyl groups, (+)-ryanodol (**7**) was benzylated (Scheme 5) under standard conditions ($C_6H_5CH_2Br$, NaH, THF) to provide a mixture from which dibenzyl ether derivative **23** was isolated as the major product of the reaction. Acetylation of compound **23** gave monoacetate **24**, which can be oxidized to cyclopentanone **25**.[7] However, several attempts to esterify the C_3-hydroxyl group of compound **24** with α-pyrrole carboxylic acid or its derivatives were not successful. The conversion of (+)-ryanodol (**7**) into (+)-ryanodine (**8**) was not investigated further.

Conclusion

The successful conversion of (+)-anhydroryanodol (**6**) into (+)-ryanodol (**7**) has been accomplished in two steps (**6** → **9** → **7**). The total synthesis of optically active (+)-ryanodol (**7**) is thus completed. There remains the task of converting (+)-ryanodol (**7**) into (+)-ryanodine (**8**).

Experimental

Apparatus, materials, and methods

Melting points were determined on a Büchi M-50 apparatus and are uncorrected. Ether, tetrahydrofuran, and 1,2-dimethoxyethane were dried by distilling over sodium benzophenone ketyl. Benzene, dichloromethane, dimethyl sulfoxide, and amines were distilled over calcium hydride. All reactions were performed under nitrogen or argon atmosphere. Analytical and preparative thin-layer chromatography (tlc) were carried out on glass plates precoated (0.25, 0.5, 1.0, and 2.0 mm) with silica gel 60 F-250 (Merck). Materials were detected by visualization under an ultraviolet lamp (254 or 350 nm) and (or) by spraying with sulfuric acid (50%) or a solution of phosphomolybdic acid or vanillin followed by heating on a hot plate. Column chromatography was performed with silica gel (Baker (60–200 mesh) or Merck 60 (200–400 mesh)).

The infrared spectra (ir) were taken on a Perkin–Elmer 257 or 681 spectrophotometer. Proton nuclear magnetic resonance (^{1}H nmr) spectra were recorded (with chloroform or tetramethylsilane as internal standard) on a Varian A-60, a Bruker WP-60, a Bruker HX-90, or a Bruker WM-250 instrument. Carbon nuclear magnetic resonance (^{13}C nmr) spectra were measured on a Bruker HX-90 or WM-250 instrument. The following abbreviations have been used: s, singlet; d, doublet, dd, doublet or doublets; t, triplet, q, quartet, qn, quintet; m, multiplet; br, broad. For most of the hydroxylated compounds, the multiplicity of the hydrogens attached to a carbinol was analyzed after D_2O exchange. The mass spectra were recorded on a Hitachi–Perkin–Elmer RMU-6 mass spectrometer and peak matching (hrms) on a VG Micromass ZAB-2F spectrometer. The ultraviolet spectra (uv) were recorded on a Varian Techtron 635 spectrophotometer. Specific rotation data were determined on a Perkin–Elmer polarimeter at 25°C. Microanalyses were carried out by Mr. J. Tamas, Laboratoire de Microanalyses, Université de Sherbrooke; Schwarzkopf Microanalytical Laboratories, New York; and by Dr. C. Daesslé, Organic Microanalyses, Montreal.

(+)-Ryanodol (7) from ryanodine (8)

Ryanodol was obtained as described in the literature (7) by basic hydrolysis of ryanodine **8** with potassium hydroxide in ethanol; mp 266–267°C; $[\alpha]_D$ +40.0° (CH_3OH); ^{1}H nmr (CD_3OD, δ ppm): 4.11 (s, 1H, HC3), 3.76 (d, 1H, J = 10.1 Hz, HC10), 2.49 (d, 1H, J = 13.4 Hz, H_AC14), 2.16 (qn, 1H, J = 6.8 Hz, HC13), 2.05 (m, 1H), 1.82 (m, 1H, HC9), 1.73 (d, 1H, J = 13.4 Hz, H_BC14), 1.55–1.19 (m), 1.32 (s, 3H, CH_3C5), 1.10 (s, 3H, CH_3C1), 1.07 (d, 3H, J = 6.4 Hz), 0.99 (d, 3H, J = 6.4 Hz), 0.98 (d, 3H, J = 6.4 Hz); ms m/e: 400 (M^+). *Exact Mass* calcd. for $C_{20}H_{32}O_8$: 400.2097; found: 400.2099.

Dehydration of ryanodol (7): anhydroryanodol (6) and epianhydroryanodol (19)

With aqueous sulfuric acid 20%

Following literature procedure (7), ryanodol (**7**) was dehydrated to give a mixture (~1:2) of epianhydroryanodol (**19**, less polar) and anhydroryanodol (**6**, more polar) in a total yield of ~90%. The mixture was separated by chromatography on silica gel (chloroform–methanol: 9:1). Epianhydroryanodol (**19**): mp 225–226°C; $[\alpha]_D$ −103.2° (CH_3OH); ir ($CHCl_3$, ν cm^{-1}): 3500, 1750; ^{1}H nmr (CD_3OD, δ ppm): 5.05 (q, 1H, J = 2.0 Hz, HC3), 4.05 (d, 1H, J = 9.7 Hz, HC10), 3.57 (dd, 1H, J_{AB} = 15.8 Hz, J_W = 1.0 Hz, H_AC14), 2.81 (qn, 1H, J = 7 Hz, $CH(CH_3)_2$), 2.02 (d, 1H, J_{AB} = 15.8 Hz, H_BC14), 1.84 (d, 3H, J = 2.0 Hz, H_3C17), 1.83–1.20 (m), 1.65 (m, 1H, HC9), 1.25 (d, 3H, J = 7 Hz, $CH(CH_3)$), 1.03 (d, 3H, J = 1.0 Hz, CH_3C5), 1.02 (d, 3H, J = 6.3 Hz, CH_3C9), 0.97 (d, 3H, J = 7 Hz, $CH(CH_3)$); ms m/e: 382 (M^+).

Anhydroryanodol (**6**): mp 150–151°C (CH_2Cl_2); $[\alpha]_D$ +53.3° (*c* 1.00, CH_3OH); ir (KBr, ν cm^{-1}): 3480 (br), 1750, 1240, 1010; ^{1}H nmr (CD_3OD, δ ppm): 4.70 (q, 1H, J = 2.4 Hz, HC3), 3.98 (d, 1H, J = 10.2 Hz, HC10), 3.61 (d, 1H) and 2.28 (d, 1H) (J_{AB} = 20 Hz, H_2C14), 2.74 (qn, 1H, J = 7 Hz, $CH(CH_3)_2$), 1.79 (m, 1H, HC9), 1.76 (d, 3H, J = 2.4 Hz, H_3C17), 1.62–1.40 (m), 1.16 (s, 3H, CH_3C5), 1.14 (d, 3H, J = 7 Hz) and 1.10 (d, 3H, J = 7 Hz) ($CH(CH_3)_2$), 1.07 (d, 3H, J = 6.3 Hz, CH_3C9); ms m/e: 382 (M^+).

With p-toluenesulfonic acid in dioxane

To a solution of ryanodol (**7**) (17 mg, 0.042 mmol) in pure dioxane (3 mL) was added *p*-toluenesulfonic acid (15 mg, 0.079 mmol). After 18 h at 25°C, the mixture was poured onto saturated aqueous sodium bicarbonate and extracted 10 times with chloroform to give a mixture (~1:2) of compounds **19** and **6**.

Enone 11 from anhydroryanodol 6

By treatment with m-chloroperbenzoic acid

To a solution of anhydroryanodol **6** (20 mg, 0.052 mmol) in chloroform (10 mL) was added *m*-chloroperbenzoic acid (12 mg, 82%, 0.059 mmol) dissolved in chloroform (2 mL). After 24 h, the same quantity of reagent was added and 10 h later the mixture was poured onto a diluted aqueous solution of sodium carbonate and extracted with chloroform. Chromatography of the crude product furnished starting material (8 mg, 40%) together with enone **11** (5 mg, 20%) and a complex mixture of less polar unidentified products. Enone **11**: ir (KBr, ν cm^{-1}): 3450 (br), 1750, 1720, 1625; uv (λ_{max}, EtOH): 234 nm (ε 8500); ^{1}H nmr ($CDCl_3$, δ ppm): 4.04 (d, 1H, J = 10.3 Hz, HC10), 2.74 (qn, 1H, J = 7.0 Hz, $CH(CH_3)_2$), 2.59 (d, 1H, J_{AB} = 19.8 Hz, H_AC14), 2.24 (d, 1H, J_{AB} = 19.8 Hz, H_BC14), 2.21 (s, 3H, H_3C17), 2.21 (m, 1H), 1.75 (m, 1H, HC9), 1.64–1.45 (m), 1.17, 1.14, and 1.11 (3d, 3H each, J = 7 Hz, 3 × $CH(CH_3)$); 1.10 (s, 3H, CH_3C5); ms m/e: 380 (M^+). *Exact Mass* calcd. for $C_{20}H_{28}O_7$: 380.1835; found: 380.1845.

By oxydation with manganese dioxide

A solution of anhydroryanodol (**6**) (50 mg, 0.13 mmol) in chloroform (35 mL) was refluxed with manganese dioxide (500 mg) during 42 h. The mixture was then filtered (Celite) and the solvent evaporated. The residue was chromatographed on silica plate ($CHCl_3$–CH_3OH, 9:1) to give enone **11** (22 mg, 44%).

Acetylation of anhydroryanodol (6)

Following literature procedure (9), anhydroryanodol (**6**) (75 mg, 0.20 mmol) in a mixture of pyridine (2 mL) and acetic anhydride (2 mL) was stirred at 25°C for 4 days. Evaporation of volatile

[7]The assignment of the position of the *O*-benzyl ether groups in compound **23** has not been rigorously established. This assignment is based on the following facts: (a) successful conversion of **23** into **24** and **25**; (b) the major mono-*p*-bromobenzyl ether derivative of (+)-ryanodol is known by X-ray diffraction, and the *p*-bromobenzyl ether group is located at C_4 (ref. 13); (c) compound **23** was shown to be stable under acidic conditions that transform (+)-ryanodol into (+)-anhydroryanodol, suggesting that the hemiketal OH group at C_{15} has been protected, and (d) compound **23** does not react under the *cis*-glycol cleavage conditions ($NaIO_4$, CH_3OH), which readily cleave the C_4—C_{12} bond in ryanoids (7).

substances left a residue that was chromatographed (chloroform–methanol 2%) to give two major products: diacetate **15** (more polar, 26 mg, 28%) and triacetate **16** (less polar, 35 mg, 35%), together with several other minor products. Diacetate **15**: mp 230–231°C (dec.); ir (KBr, ν cm^{-1}): 3450 (br), 1740 (br), 1230; ^1H nmr ($CDCl_3$, δ ppm): 5.66 (d, 1H, J = 10.7 Hz, HC10), 5.04 (q, 1H, J = 2.3 Hz, HC3), 3.55 (d, 1H, J = 20 Hz, H_AC14), 2.79 (qn, 1H, J = 7.2 Hz, $CH(CH_3)_2$), 2.55–1.3 (m), 2.35 (d, 1H, J = 20 Hz, H_BC14), 2.11 (s, 3H, CH_3CO_2), 2.05 (s, 3H, CH_3CO_2), 1.67 (d, 3H, J = 2.3 Hz, H_3C17), 1.19 (s, 3H, CH_3C5), 1.14 (d, 6H, J = 7.0 Hz, $CH(CH_3)_2$), 0.92 (d, 3H, J = 6.5 Hz, $CHCH_3$); ms m/e: 466 (M^+, weak). *Exact mass* calcd. for $C_{24}H_{34}O_9$: 466.2203; found: 466.2195. Triacetate **16**: mp 204–206°C (dec.); ir (KBr, ν cm^{-1}): 3450, 3250 (br, 1750 (br), 1230; ^1H nmr ($CDCl_3$, δ ppm): 5.90 (q, 1H, J = 2.3 Hz, HC3), 5.69 (d, 1H, J = 10.7 Hz, HC10), 3.05 (d, 1H, J = 19.7 Hz, H_AC14), 2.80 (qn, 1H, 7.0 Hz, $CH(CH_3)_2$), 2.39 (d, 1H, J = 19.7 Hz, H_BC14), 2.21, 2.10, and 2.04 (3s, 3H each, 3 × CH_3CO_2), 2.08 (m, 1H), 1.72 (d, 3H, J = 2.3 Hz, H_3C17), 1.8–1.4 (m), 1.12 and 1.03 (2d, 3H each, J = 7.0 Hz, 2 × $CH(CH_3)$), 0.96 (s, 3H, CH_3C5), 0.92 (d, 3H, J = 6.6 Hz, $CH(CH_3)$); ms m/e: 508 (M^+, weak), 491 (M^+ − OH). *Exact Mass* calcd. for $C_{26}H_{36}O_{10}$ − OH: 491.2281; found: 491.2268.

*Acid treatment of diacetate **15***

To a solution of diacetate **15** (10 mg, 0.021 mmol) in benzene (3 mL) was added *p*-toluenesulfonic acid (6 mg) and the mixture was stirred for 3 h at 25°C, then poured onto aqueous sodium bicarbonate and extracted with dichloromethane. The crude product was purified on silica plate to give orthoacetate monoacetate **17** (9.5 mg, 98%), also described by Wiesner (7) and Babin (9); mp 271–272°C; ir (KBr, ν cm^{-1}): 3550 (br), 1750 (br), 1650, 1230; ^1H nmr ($CDCl_3$, δ ppm): 5.78 (d, 1H, J = 10 Hz, HC10), 4.90 (q, 1H, J = 2 Hz, HC3), 3.95 (d, 1H, J = 20 Hz, H_AC14), 2.60 (qn, 1H, J = 7 Hz, $CH(CH_3)_2$), 2.26 (d, 1H, J = 20 Hz, H_BC14), 2.12 (s, 3H, CH_3CO_2), 1.73 (d, 3H, J = 2 Hz, H_3C17), 1.62 (s, 3H, CH_3CO_3), 1.20 (s, 3H, CH_3C5), 1.10, 1.00, and 0.90 (3d, 3H each, $J \approx$ 7 Hz, 3 × $CH(CH_3)$); ms m/e: 449 (MH^+). *Exact Mass* calcd. for $C_{24}H_{32}O_8$: 449.2175 (MH^+); found: 449.2149.

*Acid treatment of triacetate **16***

A mixture of triacetate **16** (17 mg, 0.033 mmol) and *p*-toluenesulfonic acid (10 mg) in benzene (2 mL) was stirred at 25°C for 24 h, then poured onto aqueous sodium bicarbonate and extracted with dichloromethane. The crude product was purified on silica plate to give orthoacetate diacetate **18** (13 mg, 80%) (also described by Babin (9)), and starting triacetate **16** (3 mg, 18%): mp 224–225°C; ir ($CHCl_3$, ν cm^{-1}): 1750, 1730, 1650, 1220; ^1H nmr ($CDCl_3$, δ ppm): 6.01 (q, 1H, J = 2 Hz, HC3), 5.80 (d, 1H, J = 10 Hz, HC10), 3.40 (d, 1H, J = 20 Hz, H_AC14), 2.75 (qn, 1H, J = 7 Hz, $CH(CH_3)_2$), 2.50 (d, 1H, J = 20 Hz, H_BC14), 2.18 and 2.13 (2s, 3H each, 2 × CH_3CO_2), 2.2–0.9 (m), 1.78 (d, 3H, J = 2 Hz, H_3C17), 1.68 (s, 3H, CH_3CO_3), 1.08 (s, 3H, CH_3C5), 1.04, 0.96, and 0.90 (3d, 3H each, $J \approx$ 7 Hz, 3 × $CHCH_3$); ms m/e: 491 (MH^+). *Exact Mass* calcd. for $C_{26}H_{34}O_9H^+$: 491.2281; found: 491.2272.

*Basic equilibration of anhydroryanodol (**6**): epianhydroryanodol (**19**)*

To a solution of epianhydroryanodol (**19**) (1.93 g, 5.05 mmol) in tetrahydrofuran (30 mL) was added aqueous sodium hydroxide (8 mL, 1 M) and the mixture was stirred vigorously for 30 min at room temperature. The mixture was then poured onto water, neutralized with 1 M acetic acid, and the aqueous phase was saturated with sodium chloride and extracted with dichloromethane to give a mixture (~3:1) of anhydroryanodol (**6**) and epianhydroryanodol (**19**) (1.88 g).

*Epianhydroryanodol epoxide (**20**)*

*From anhydroryanodol (**6**)*

To a solution of anhydroryanodol (**6**) (19.6 mg, 0.051 mmol) in 1.2-dichloroethane (8 mL) was added, at 25°C, disodium hydrogen phosphate (40 mg) followed by a freshly prepared trifluoroperacetic acid (96 μL, 1.08 M) solution in 1,2-dichloroethane (12). After 2 h, the mixture was filtered, the volatile substances were evaporated, and the residue was chromatographed on silica plate (chloroform–methanol 10%) to give epianhydroryanodol epoxide (**20**) (17.5 mg, 85%); $[\alpha]_D$ (from natural source) −43.2° (*c* 1.00, $CHCl_3$); (from synthetic anhydroryanodol): −41.7° (*c* 1.00, $CHCl_3$); ir ($CHCl_3$, ν cm^{-1}): 3550, 1750; ^1H nmr (CD_3OD, δ ppm): 4.57 (s, 1H, HC3), 4.06 (d, 1H, J = 9.9 Hz, HC10), 3.64 (d, br, 1H, J = 16 Hz, H_AC14), 2.16 (d, 1H, J = 16 Hz, H_BC14), 1.8 (m, 3H), 1.65 (m, 1H), 1.62 (s, 3H, H_3C17), 1.55–1.12 (m), 1.22, 1.07, and 1.06 (3d, 3H each, 3 × $CH(CH_3)$), 1.00 (s, 3H, CH_3C5); ms m/e: 398 (M^+, weak), 380 ($M^+ - H_2O$). *Exact Mass* calcd. for $C_{20}H_{30}O_8$: 398:1943; found: 398.1931.

*From epianhydroryanodol (**19**)*

To a solution of epianhydroryanodol (**19**) (5.6 mg, 0.014 mmol) in 1,2-dichloroethane (4 mL) was added at 25°C dihydrogen phosphate (12 mg) and freshly prepared trifluoroperacetic acid solution in 1,2-dichloroethane (27 μL, 1.08 M). After 2 h, the mixture was filtered, and evaporation of the volatile substances left a residue that was chromatographed on silica plate to give epoxide **20** (5 mg, 86%).

*Anhydroryanodol epoxide (**9**)*

To a solution of epianhydroryanodol epoxide (**20**) (32 mg, 0.080 mmol) in tetrahydrofuran (2 mL) was added aqueous sodium hydroxide (0.6 mL, 1 M). The mixture was stirred at 25°C for 30 min, then poured onto brine containing acetic acid (0.6 mL, 1 M), and extracted with chloroform. Evaporation of the solvent left a residue that was chromatographed on silica plate to give starting epoxide **20** (19 mg, 59%) and anhydroryanodol epoxide **9** (12 mg, 37%); mp 232–234°C (dec.); $[\alpha]_D$ +29.9° (*c* 1.00, CH_3OH); ir (KBr, ν cm^{-1}): 3450 (br), 1750; ^1H nmr (CD_3OD, δ ppm): 4.18 (d, 1H, J = 20.6 Hz, H_AC14), 4.13 (s, 1H, HC3), 4.03 (d, 1H, J = 10.4 Hz, HC10), 2.43 (d, 1H, J = 20.6 Hz, H_BC14), 1.80 (m, 2H), 1.68 (qn, 1H, J = 7.1 Hz, $CH(CH_3)_2$), 1.57 (s, 3H, H_3C17), 1.65–1.4 (m), 1.19 and 1.15 (2d, 3H each, J = 7.1 Hz, 2 × $CH(CH_3)$), 1.12 (s, 3H, CH_3C5), 1.06 (d, 3H, J = 6.2 Hz, $CH(CH_3)$); ms m/e: 398 (M^+). *Exact Mass* calcd. for $C_{20}H_{30}O_8$: 398.1943; found: 398.1939.

*Totally synthetic ryanodol (**7**)*

*From totally synthetic epianhydroryanodol epoxide (**20**)*

A solution of synthetic epianhydroryanodol epoxide (**20**) (20 mg, 0.050 mmol) in tetrahydrofuran (5 mL) was added to liquid ammonia (20 mL) maintained at −78°C. Then small pieces of freshly cut lithium wire (~20 mg) were added until a blue color persisted. After 1 h, solid ammonium chloride (~500 mg) was added and the mixture was warmed to room temperature (evaporation of ammonia), dissolved in a minimum volume of water, and extracted four times with dichloromethane. This first extract (7 mg) furnished a mixture of two products, less polar than ryanodol, which were chromatographed on silica plate (chloroform–methanol, 9:1).

Less polar dihydro compound (2 mg, 10%); mp 170–171°C; ir (KBr, ν cm^{-1}): 3600–3350 (br), 1470, 1110; ^1H nmr (CD_3OD, δ ppm): 5.55 (d, 1H, J = 3.4 Hz, HC15), 4.54 (s, 1H, HC3), 3.90 (d, 1H, J = 10.2 Hz, HC10), 2.53 (d, 1H, J = 15.2 Hz, H_AC14), 2.43 (qn, 1H, J = 7.0 Hz, $CH(CH_3)_2$), 1.95 (m, 1H, $H_{ax}C7$), 1.75 (m, 1H, HC9), 1.56 (s, 3H, H_3C17), 1.53 (dd, 1H, J = 15.3 and 3.4 Hz, H_BC14), 1.55–1.15 (m, 3H, H_2C8 and $H_{eq}C7$), 1.06 (s, 3H, CH_3C5), 1.02 and 0.94 (2d, 3H each, J = 7.0 Hz, $CH(CH_3)_2$), 1.00 (d, 3H, J = 6.4 Hz, H_3C21); ms m/e: 400 (M^+). *Exact Mass* calcd. for $C_{20}H_{32}O_8$: 400.2097; found: 400.2093.

More polar dihydro compound (**21**) (4 mg, ~20%); mp 143–145°C; ir ($CHCl_3$, ν cm^{-1}): 3600, 3470 (br), 1460, 1100; ^1H nmr (CD_3OD, δ ppm): 4.73 (dd, 1H, J = 10.0 Hz, HC15), 4.00 (s, 1H, HC3), 3.88 (d, 1H, J = 10.1 Hz, HC10), 2.41 (dd, 1H, J_{AB} = 12 Hz, J_{AX} = 10 Hz, H_AC14), 2.0–1.7 (m), 1.74 (dd, 1H, J_{AB} = 12 Hz, J_{BX} = 1.6 Hz, H_BC14), 1.55 (s, 3H, H_3C17), 1.54–1.08 (m), 1.20 (d, 3H, J = 6.9 Hz), 1.18 (d, 3H, J = 7.3 Hz), and 1.04 (d, 3H, J = 6.4 Hz) (3 × $CH(CH_3)$), 0.99 (s, 3H, CH_3C5); ms m/e: 400 (M^+). *Exact Mass* calcd. for $C_{20}H_{30}O_8$: 400.2097; found: 400.2100.

The aqueous layer was then saturated with carbon dioxide (9) and sodium chloride and extracted continuously with chloroform (40 h) to give almost pure totally synthetic ryanodol (**7**) (12 mg, 60%), which was recrystallized from dichloromethane and a trace of methanol; mp 267–268°C; $[\alpha]_D$ +38.5° (CH_3OH). *Exact Mass* calcd. for $C_{20}H_{32}O_8$:

For personal use only.

400.2097; found: 400.2090. This material was found to be totally identical (^{1}H nmr, tlc, mass spectrum, mixture mp, rotation) with authentic ryanodol (*vide supra*) obtained from ryanodine (**8**). It was also dehydrated in acidic medium (dioxan; PTSA, *vide supra*) to give compounds **6** and **19**.

*From equilibrium mixture of epoxylactones **9** and **20***

The same reductive cyclization was performed on a mixture (~3:2) of epoxides **9** and **20** (natural source, 125 mg, 0.314 mmol) to give ryanodol (**7**) as well as the two dihydro compounds (**21** and unknown) in approximately the same yields and proportions.

*Ryanodol dibenzylether **23***

To a solution of ryanodol (**7**) (470 mg, 1.18 mmol) in a mixture of tetrahydrofuran (10 mL) and benzene (10 mL) was added sodium hydride (~99%, 85 mg, 3.5 mmol). After 25 min of stirring at room temperature, benzyl bromide (343 μL, 493 mg, 2.88 mmol) was added and the mixture was stirred for 54 h at the same temperature, then poured onto cold brine, and extracted ten times with chlorofom. The crude product was chromatographed on silica gel (chloroform–methanol, 97:3) to give ryanodol dibenzyl ether **23**[7] (472 mg, 69%); mp 183–184°C; ir (KBr, ν cm^{-1}): 3400 (br), 1600, 1130, 890; ^{1}H nmr (CD_3OD, δ ppm): 7.36 (m, 10 H, Ar-H), 5.13 and 4.91 (2d, 1H each, J_{AB} = 10.8 Hz, $ArCH_2O$), 4.82 (s, 1H, HC3), 4.75 and 4.68 (2d, 1H each, J_{AB} = 10 Hz, $ArCH_2O$), 3.84 (d, 1H, J = 10.1 Hz, HC10), 2.46 and 2.17 (2d, 1H each, J_{AB} = 13.5 Hz, H_2C14), 2.21 (qn, 1H, J = 7 Hz, $CH(CH_3)_2$), 2.05–1.80 (2m), 1.50 (m), 1.38 and 1.27 (2s, 3H each, CH_3C5 and CH_3C1), 1.06, 1.02, and 0.99 (3d, 3H each, J = 6.9 Hz, 3 × $CHCH_3$); ms m/e: 580 (M^+). *Exact Mass* calcd. for $C_{34}H_{44}O_8$: 580.3036; found: 580.3089.

*Ryanodol dibenzylether acetate **24***

To a solution of ryanodol dibenzyl ether **23** (150 mg, 0.241 mmol) in pyridine (2 mL) was added acetic anhydride (1.5 mL) and the mixture was stirred at 25°C for 30 h. Evaporation of the volatile substances left a residue that was filtered on silica gel (chloroform–methanol, 98:2) to give pure acetate **24** (155 mg, 97%); ir (KBr, ν cm^{-1}): 3500, 3400, 1720, 1600, 1250; ^{1}H nmr ($CDCl_3$, δ ppm): 7.36 (m, 10H, Ar-H), 5.27 (d, 1H, J = 10.5 Hz, HC10), 5.06 (d, 1H) and 5.00 (d, 1H) (J_{AB} = 11.2 Hz, $ArCH_2O$), 4.82 (s, 1H, HC3), 4.83 (d, 1H) and 4.71 (d, 1H) (J_{AB} = 11.7 Hz, $ArCH_2O$), 2.41 (d, 1H) and 2.18 (d, 1H) (J_{AB} = 13.7 Hz, H_2C14), 2.17 (qn, 1H, $CH(CH_3)_2$), 2.09 (s, 3H, CH_3CO_2), 2.00 (m), 1.65 (m), 1.42 (s, 3H) and 1.41 (s, 3H) (CH_3C5 and CH_3C1), 1.13, 1.02, and 0.87 (3d, 3H each, 3 × $CH(CH_3)$); ms m/e: 622 (M^+, weak), 605 (M^+ − OH). *Exact Mass* calcd. for $C_{36}H_{46}O_9$ − OH: 605.3114; found: 605.3100.

*Ryanodol dibenzyl ether ketone **25***

Chromic trioxide (32 mg, 0.32 mmol) was added to a solution of pyridine (55 μL, 0.64 mmol) in dichloromethane (3 mL) and the mixture was stirred 15 min at room temperature. To this preparation was added ryanodol dibenzyl ether acetate **24** (20 mg, 0.032 mmol); the mixture was stirred for 10 min at 25°C, then poured onto aqueous sodium bicarbonate and extracted with dichloromethane. The crude product was chromatographed on silica plate (chloroform–methanol, 98:2) to give starting material (3 mg, 15%) and ketone **25** (12 mg, 60%); ir ($CHCl_3$, ν cm^{-1}): 3500, 3420, 1750, 1720, 1450, 1230; ^{1}H nmr ($CDCl_3$, δ ppm): 7.35 (m, 10H, Ar-H), 5.34 (d, 1H, J = 10.4 Hz, HC10), 4.96 and 4.69 (2d, 1H each, J_{AB} = 10.9 Hz, $ArCH_2O$), 4.83 and 4.65 (2d, 1H each, J_{AB} = 11.6 Hz, $ArCH_2O$), 2.31 and 1.48 (2d, 1H each, J_{AB} = 14.3 Hz, H_2C14), 2.25–1.90 (m), 2.17 (s, 3H, CH_3CO_2), 1.75–1.2 (m), 1.42 (s, 3H, CH_3C5), 1.25, 1.13, and 0.93 (3d, 3H each, J = 6.7 Hz, 3 × $CH(CH_3)$), 1.05 (s, 3H, CH_3C1); ms m/e: 620 (M^+, weak). *Exact Mass* calcd. for $C_{36}H_{44}O_9$: 620.2985; found: 620.2971.

Crystals of 7-azaindole ($P\bar{1}$, a = 11.312(4), b = 14.960(6), c = 15.509(5) Å, α = 102.86(3), β = 108.78(3), γ = 90.71(3)°, Z = 16, R = 0.052) contain tetrameric units of approximate S_4 symmetry, in which the molecules are associated by means of four complementary N—H...N hydrogen bonds. [CH_3Hg(7-azaindole)]NO_3 ($P\bar{1}$, a = 7.818(3), b = 7.884(3), c = 9.135(4) Å, α = 97.89(3), β = 109.13(3), γ = 103.28(3)°, Z = 2, R = 0.039) contains well-separated nitrate ions and complex cations in which the methylmercury group is linearly bonded to the pyridine nitrogen atom, whereas the five-membered ring remains protonated. In the neutral [CH_3Hg(azaindolate)] complex ($P\bar{1}$, a = 10.926(10), b = 11.333(8), c = 11.647(10) Å, α = 92.13(8), β = 104.83(9), γ = 111.86(7)°, Z = 6, R = 0.048), methylmercury groups have substituted the N—H proton in the five-membered ring for the three symmetry-independent molecules. Intermolecular secondary Hg...N bonds are found with pyridine nitrogens.

Key words: azaindole, methylmercury, crystal structure.

PASCAL DUFOUR, YVES DARTIGUENAVE, MICHÈLE DARTIGUENAVE, NATHALIE DUFOUR, ANNE-MARIE LEBUIS, FRANCINE BÉLANGER-GARIÉPY et ANDRÉ L. BEAUCHAMP. Can. J. Chem. **68**, 193 (1990).

Les cristaux de l'aza-7 indole ($P\bar{1}$, a = 11,312(4), b = 14,960(6), c = 15,509(5) Å, α = 102,86(3), β = 108,78(3), γ = 90,71(3)°, Z = 16, R = 0,052) contiennent des motifs tétramères de symétrie voisine de S_4, dans lesquels l'association se fait au moyen de quatre liaisons hydrogène N—H...N complémentaires. [CH_3Hg(7-azaindole)]NO_3 ($P\bar{1}$, a = 7,818(3), b = 7,884(3), c = 9,135(4) Å, α = 97,89(3), β = 109,13(3), γ = 103,28(3)°, Z = 2, R = 0,039) contient des ions nitrate et des cations complexes où le groupe méthylmercure est lié linéairement à l'atome d'azote pyridinique, tandis que le cycle à cinq chaînons demeure protoné. Dans le complexe neutre [CH_3Hg(azaindolate)] ($P\bar{1}$, a = 10,926(10), b = 11,333(8), c = 11,647(10) Å, α = 92,13(8), β = 104,83(9), γ = 111,86(7)°, Z = 6, R = 0,048), un groupe méthylmercure a substitué le proton du cycle à cinq chaînons dans les trois molécules symétriquement indépendantes. Il existe des liaisons secondaires Hg...N intermoléculaires avec l'azote pyridinique.

Mots clés : azaindole, méthylmercure, structure du cristal.

Introduction

Purines and related rigid N-donor ligands have attracted our attention as potential binucleating agents for stabilizing pairs of bonded metal atoms via extended aromatic systems. 7-Azaindole[2] (Scheme 1) can be regarded as a simplified purine, retaining only a pair of nitrogen atoms properly arranged for bridging. We are currently examining its reactions with various dimetal units like Mo_2^{4+}, Rh_2^{4+}, Ru_2^{5+}, Re_2^{6+}, etc. In a previous paper (1), we reported the structure of a dinuclear molybdenum system in which half of the carboxylates in Mo_2(acetate)$_4$ had been replaced by bridging azaindole anions. We were able to interpret the X-ray data in terms of azaindole units disordered over two orientations, the positions of the five- and six-membered rings being interchanged. Disorder probably resulted from the very similar van der Waals envelopes in these two orientations. The same situation has been noted for complexes of Co, Ni, and Cu (2, 3), so that disorder in complexes of the azaindole anion is likely to be the rule rather than the exception.

The present study was undertaken to help solve some of the problems encountered with our dinuclear systems. The structure determination of azaindole was intended to provide an accurate reference geometry that could be imposed when describing overlapping ligands in disordered crystalline complexes. However, when preliminary work revealed that the triclinic cell contained 16 independent molecules, it became obvious that the structure would be unusual and interesting in its own right. On the other hand, probably because of the disorder, dinuclear metal complexes generally fail to grow into crystals large enough for X-ray diffraction to be used. Hence, elucidation of the structures has to depend solely on spectroscopic data. However, no reliable diagnostic tools are available at the moment. We felt that the CH_3Hg^+ ion could yield compounds corresponding to the different possible coordination patterns. The present paper also includes structure determinations on two types of 1:1 methylmercury complexes with 7-azaindole. The

preparation and spectroscopic work in the methylmercury complexes will be discussed elsewhere.[3]

Experimental

Single crystals of 7-azaindole were obtained by slow evaporation of a benzene solution of the commercial compound (Aldrich). The methylmercury complexes were prepared as described elsewhere.[3] Crystals were obtained directly from the reaction mixtures.

The crystallographic work was done with an Enraf–Nonius CAD-4 diffractometer, following similar procedures for the three compounds. The reduced cell was determined from a set of 25 randomly distributed reflections generated by the automatic search routine of the CAD-4 software and centered in the counter aperture of the diffractometer. The cell was checked by means of long-exposure oscillation photographs taken along each of the cell axes. In the case of free azaindole and $[CH_3Hg(aza)]$, where the asymmetric unit contains more than one formula, cell dimensions and space group were checked by repeating the above procedure on a different crystal mounted differently. In all cases, the Niggli coefficients unambiguously ruled out all lattices of higher symmetry. Thus, the possible space groups were $P1$ or $P\bar{1}$. The structures solved and refined normally in the centric $P\bar{1}$ space group.

The intensity data were measured as described earlier (5). For the methylmercury compounds, they were collected on crystals glued to the tip of a glass fiber. The crystal of azaindole had to be sealed in a Lindermann capillary, because it sublimed. The crystal data are given in Table 1. Standard reflections were monitored for crystal decay every hour and for misorientation every 200 reflections. The four octants defining the half-sphere data set were collected for each compound. These data were corrected for the effects of Lorentz and polarization. An absorption correction based on crystal geometry was applied for the Hg compounds (Gaussian integration, grid 10 × 10 × 10).

The structures were refined on $| F |$. Individual weights based on counting statistics were applied. The coordinates and isotropic temperature factors of all non-hydrogen atoms were first refined by full-matrix least-squares procedures. The block-diagonal approximation was used in the final steps of the anisotropic refinement. The scattering curves were from standard sources (6). The anomalous dispersion components for Hg (7) were included in structure factor calculations. The computer programs used are listed elsewhere (8).

$[CH_3Hg(Haza)]NO_3$

The asymmetric unit corresponds to one formula. The Hg atom was located from a Patterson map. The remaining non-hydrogen atoms were then positioned from a difference Fourier (ΔF) map. Hydrogens on the ring were fixed at idealized positions (B = 6 Å^2). The methyl hydrogens were visible in the ΔF map; an idealized methyl group was defined to give optimum fit with these positions. The coordinates of the hydrogens were recalculated after each cycle. All non-hydrogen atoms were refined anisotropically.

$[CH_3Hg(aza)]$

There are three molecules per asymmetric unit. The three Hg atoms

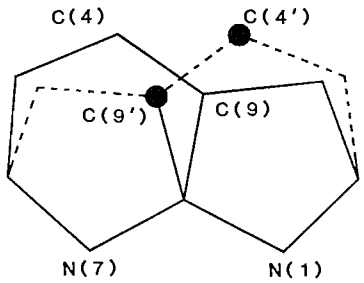

FIG. 1. Disorder found in the crystal of 7-azaindole (molecules A–D). Full bonds represent one of the components, the dashed ones correspond to the same molecule after inversion. Residual electron densities corresponding to ca. 1/8 C atom are found in the ΔF map at positions marked by black circles.

were located by the direct methods of the SHELX package (9). The remaining non-hydrogen atoms were then found from a ΔF map. The ring hydrogens were treated as above. The methyl hydrogens were neglected. All non-hydrogen atoms were refined anisotropically.

7-Azaindole

Solving this structure was not straightforward, because the asymmetric unit contained 8 independent molecules. After a series of attempts using different starting reflections in the phasing procedure of MULTAN (10), four consistent azaindole molecules could be recognized. Subsequent ΔF maps revealed the remaining four molecules in the unit cell. Isotropic refinement of the non-hydrogen atoms by full-matrix least squares converged to $R = 0.117$ and $R_w = 0.124$. Refinement was continued with the block-diagonal approximation, anisotropically for the non-hydrogen atoms, isotropically for the hydrogens.

After the known model had been refined to convergence, it was noticed that molecules A–D had some of their distances and angles systematically different from those of E–H (see next section and Table A-2, supplementary material[4]). The eight strongest peaks in the ΔF map occurred in pairs, which were located as shown in Fig. 1 with respect to azaindole molecules A–D. A similar situation had been encountered with $Mo_2(acetate)_2(azaindolate)_2.2DMF$ (1), where the disorder depicted in the figure is also present. Starting with occupancy factors of 0.1 deduced from peak height (0.35 e/Å^3), four C(4′) atoms were introduced in the structure and independently refined. The second peak in each pair corresponded to an alternate position C(9′) for the inverted individual. However, these fractional carbons were too close to the main C(9) components to be refined independently. The other atomic positions were not resolved.

The fractional carbons C(4′A–D) were first assigned an isotropic temperature factor B of 5.4 Å^2, the mean refined value for the C(4) atoms in the E–H tetramer. Their coordinates and occupancy factors were refined, together with the positions and anisotropic temperature factors of the remaining non-hydrogen atoms. Occupancies converged to 0.12 ± 0.01 ($\sigma = 0.01$). For the rest of the refinement, fixed values of 0.12 were used for C(4′A–D) and 0.88 for C(4A–D). Interpretation was completed by refining the non-hydrogen atoms anisotropically, the hydrogens and the C(4′A–D) atoms isotropically.

The refined coordinates for the three compounds are listed in Tables 2–4.[4]

Results and discussion

7-Azaindole

The unit cell contains eight independent 7-azaindole molecules associated into two tetramers via hydrogen bonding (Fig. 2). Individual distances and angles are available in the supplementary material (Table A-2). Mean values for each tetramer are listed in Table 5. Since the geometry can be artificially distorted by disorder for the tetramer that contains molecules A–D (see below), the results obtained for the E–H unit will be used in the discussion.

The molecules are planar as expected (Table A-4, supplementary material). The mean and maximum deviations from the least-squares planes through the nine non-hydrogen atoms are 0.006(4) and 0.014(4) Å, respectively. This is within the range reasonably ascribed to normal packing forces. The distances in the six-membered ring are similar to those of pyridine (C—C = 1.380(4), C—N = 1.336(4) Å) (11), except for the C(8)—C(9) bond shared by the two rings, which is longer (1.398(5) Å). The common C—C bonds are also long for 1-azacarbazole (12) and indole derivatives (13, 14). Deviations from 120° in the ring follow a pattern well documented for purines (15): the nitrogen lone pair decreases the angle at N(7) by 6.1(3)°, whereas the adjacent angles at C(6) and C(8) react in the opposite direction by 4.8(3)° and 6.3(3)°, respectively. The remaining angles undergo small changes, keeping the ring planar. The geometry of the five-membered ring follows the pattern noted for indole compounds (13, 14, 16) and it is consistent with greater bond localization. Bond order is clearly lower for C(9)—C(3) (1.419(5) Å) than for C(3)—C(2) (1.342(5) Å). Also, the C—N bonds (mean 1.366(5) Å) are loser to single bonds that in the six-membered ring (mean 1.339(5) Å).

Four molecules form tetrameric units (Fig. 2) of approximately 4 (S_4) symmetry in the crystal. The nitrogens occupy the central region, where they all participate in complementary hydrogen bonding. This pocket is shielded from the surrounding molecules by the rings directed outward and providing a hydrophobic surface. The hydrogen bonds are all very strong: the N(1)—N(7) separations (Table 6) are at the lower limit of the range (2.88—3.88 Å) proposed by Stout and Jensen (17), and departure from linearity is within 15°.

7-Azaindole can be compared with 1-azacarbazole, which contains an extra benzene ring (Fig. 3). This molecule crystallizes as flat cyclic dimers associated via a pair of complementary N—H...N bonds (N...N = 2.946(2) Å, N—H...N = 172°) (12). A similar arrangement has been proposed for a 7-azaindole dimer detected in nonpolar solution (18, 19). A tetrameric arrangement had also been considered as possible on the basis of model building, but no evidence for its formation had been obtained.

Assuming that the hydrogen-bonding framework in a cyclic azaindole dimer would have the geometry observed in 1-azacarbazole, several factors can be put forward to explain that a tetrameric structure is preferred for 7-azaindole in the solid state:

(*i*) The N...N separation (mean 2.917 Å) is shorter than in the dimer.

(*ii*) Hydrogen lies closer to the expected lone-pair direction: the difference between the C(6)—N(7)...H and C(8) — N(7)...H angles, which should ideally be 0°, is only 6° on average here, but it is 12° in the dimer.

(*iii*) The van der Waals interactions between the π systems of the roughly parallel rings are retained within the tetramer, although they could be somewhat less efficient than between strictly parallel molecules.

(*iv*) The van der Waals envelope of the tetramer corresponds roughly to a box, favoring efficient packing and some intertetramer "stacking" interactions between the ring π systems

[4]The supplementary material includes tables of refined temperature factors, fixed hydrogen coordinates (Hg compounds), distances and angles involving the light atoms and the hydrogens, least-squares plane calculations, and structure factor amplitudes. Complete set of data may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

(Fig. 4). For a compound with bulky substituents pointing outward and producing a less regular volume, packing of such a tetramer could be less efficient, and a flat cyclic dimer might be preferred.

Disorder is often observed in crystals of compounds containing fused five- and six-membered rings, unless large substituents destroy the near equivalence of the van der Waals envelopes of the two halves of the molecule. Indole (20) and its trinitrobenzene adduct (21) are disordered, as are all the known metal complexes with the azaindole anion playing a bridging role (1–3, 22). Until a very late stage in structure resolution, 7-azaindole seemed not to follow this rule. However, careful inspection of the refined results for an ordered model showed unexplained differences in the C(3)—C(9)—C(4) region between the two tetramers. Mean values for each tetramer are given in Table 5. Details are available in the supplementary material. Corresponding distances or angles within a given tetramer were usually equal within experimental errors, but some large discrepancies between the tetramers were identified. For instance, tetramers A–D and E–H showed differences of +0.059 and −0.042 Å for the C(3)—C(9) and C(4)—C(9) bond lengths, respectively. Angles were also affected, e.g., C(2)—C(3)—C(9), +3.0°. A Fourier map showed residual

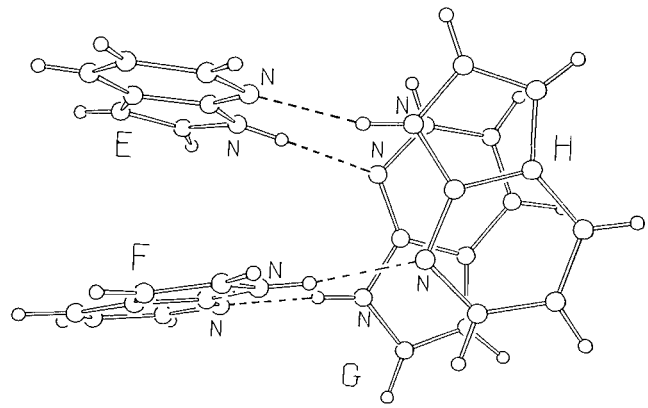

FIG. 2. 7-Azaindole molecules E–H defining a hydrogen-bonded tetramer in the crystal. The atoms are represented by spheres of arbitrary size and can be identified by reference to Scheme 1. Dashed lines correspond to hydrogen bonds. The same tetramer is formed by molecules A–D.

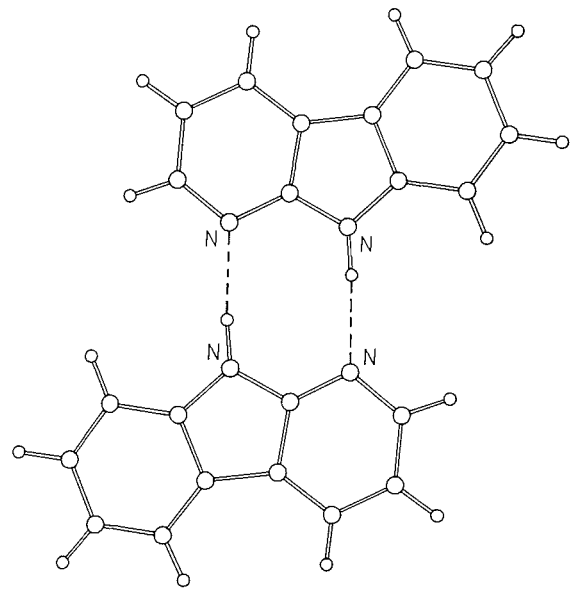

FIG. 3. Planar hydrogen-bonded cyclic dimer observed in the crystal structure of 1-azacarbazole (ref. 12).

electron density near molecules A–D. The eight highest peaks in the map, corresponding to ca. 1/8 C atom, were located in pairs at corresponding positions about each of the four azaindole molecules. The two positions (black atoms, Fig. 1) could correspond to alternate positions for C(4) and C(9) of an inverted molecule. The remaining atoms were too close to those of the other unit to be detected as resolved contributions in the electron density map. Refinement of occupancy factors (see experimental section) led to a 88%–12% distribution of the two orientations in tetramer A–D. There was no evidence of disorder for tetramer E–H.

Although the X-ray results cannot determine how the inverted molecules are locally distributed, it can safely be argued that inversion must take place simultaneously for the four molecules in a given tetrameric unit. Partial inversion would destroy the pattern of complementary hydrogen bonds. The resulting repulsions between N—H bonds should force severe molecular reorientations, which are not observed here.

Methylmercury complexes

The methylmercury cation has been found to be a convenient probe to study the relative affinity of the various sites in multidentate ligands like purines (4). This same cation was used to prepare complexes that could exemplify the different possible coordination patterns for 7-azaindole. Once unambiguously characterized by X-ray diffraction, these complexes could be used to calibrate routine spectroscopic methods and identify diagnostic features to be applied to our dinuclear compounds.

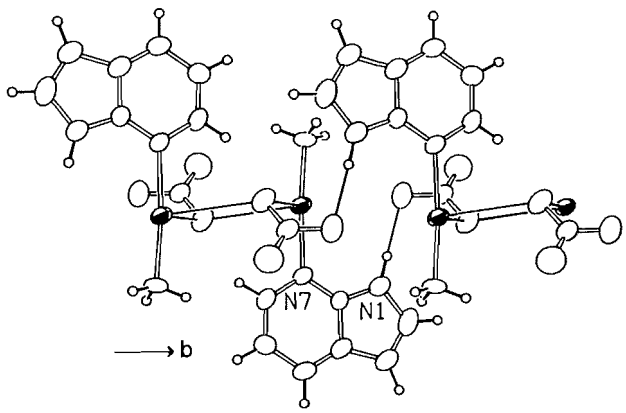

FIG. 5. Ribbons of molecules along the *b* axis showing the interactions between the nitrate ions and the complex cations in $[CH_3Hg(Haza)]NO_3$. Ellipsoids correspond to 50% probability, hydrogens are shown as small spheres of arbitrary size. Thin lines represent Hg...O contacts and dashed lines, hydrogen bonds.

In the compound obtained by reacting CH_3HgNO_3 with azaindole, the CH_3Hg^+ and H^+ ions are in competition for the two nonequivalent nitrogens. In the free ligand, the proton is bound to N(1), as confirmed by the above X-ray work. The structure of $[(CH_3Hg)(Haza)]NO_3$ (Fig. 5) is found to contain N(7)-coordinated $[CH_3Hg(Haza)]^+$ cations, without displacement of the proton from N(1).

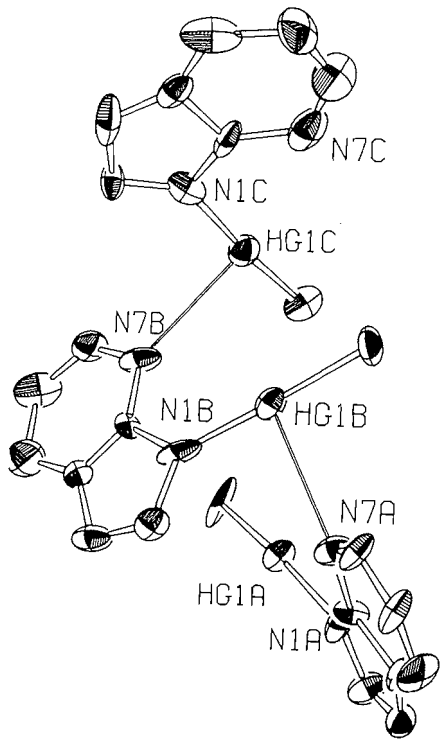

FIG. 6. Asymmetric unit containing three [CH_3Hg(aza)] molecules. Ellipsoids correspond to 50% probability. Thin lines correspond to secondary Hg...N bonds. Hydrogens are omitted for simplicity.

Selected distances and angles are listed in Table 7. The metal shows a roughly liner coordination (N—Hg—C = 174.8(5)°), and it lies along the expected direction of the N(7) lone pair, making equal C—N(7)—Hg angles. A portion of the ribbon resulting from anion–cation interactions is shown in Fig. 5. Nitrate oxygen O(10) forms a hydrogen bond of 2.86(2) Å with N(1)—H, whereas O(11) is bridging two consecutive Hg atoms by means of secondary Hg—O bonds (2.95(1), 2.98(1) Å) near the plane perpendicular to the N(7)—Hg—CH_3 direction.

When 7-azaindole is reacted with CH_3HgOH, the 1:1 compound obtained is neutral and contains azaindole in the deprotonated form. The asymmetric unit consists of three unequivalent [CH_3Hg(aza)] molecules, in which the CH_3Hg^+ ion is bound to the N(1) site formerly occupied by the proton (Fig. 6). The coordination of mercury is roughly linear (Table 7).

The presence of three independent molecules is apparently needed to produce secondary Hg—N(7) bonding interactions. Generally speaking, azaindole is not a good chelating ligand, as the resulting ring would be four-membered and the lone pairs are divergent (1). As for the CH_3Hg^+ compound, the definite preference of Hg for linear two-coordination makes the N(1)-bound Hg atom unsuitable for coordination to N(7) via intramolecular chelating interactions. The structure is a compromise between packing efficiency and intermolecular Hg...N(7) secondary bonding. As shown in Fig. 6, the N(7) atoms of molecules A and B form secondary intermolecular Hg...N bonds of 2.88(2) and 2.82(2) Å, respectively. Mercury makes no contact shorter than 3.3 Å with N(7C), which is less accessible than N(7A) and N(7B) because the N(1)-bonded methylmercury group is displaced in its direction (Hg(1C)—N(1C)—C(2C) = 133.3(17), Hg(1C)—N(1C)—C(8C) = 117.6(16)°).

Distances and angles in the ligand for both complexes are compared with those of uncoordinated azaindole in Table 5. Large esd's on light-atom distances and angles cannot be avoided in these structures, because mercury has a high atomic number. Any coordination-induced structural changes in the ligand remain within the limits of error of the present study.

Conclusion

The structure of 7-azaindole has revealed that the molecule does not form the hydrogen-bonded flat dimer often encountered for similar systems and proposed to exist in 7-azaindole solution. Instead, the crystal contains unusual tetrameric units, with a central region containing four complementary N—H...N interactions and a hydrophobic surface. These tetramers interact by van der Waals forces.

The coordination sites for the methylmercury cation have been determined for two types of 1:1 complexes. In the neutral [CH_3Hg(aza)] compound, the N(1)-H proton has been displaced by mercury, and the N(7) lone pair participates only in secondary Hg...N intermolecular contacts. In [CH_3Hg(Haza)]NO_3, however, the metal is bound to N(7) and the N(1)-H proton is retained. [$(CH_3Hg)_2$(aza)]X complexes have also been prepared[3], but they have not been studied by X-ray diffraction. They obviously contain CH_3Hg^+ groups coordinated to both nitrogens of azaindole according to a pattern observed with purines (4). These structural results will be used to interpret the vibrational spectra and NMR data on these complexes and those obtained with the dinuclear systems.

Acknowledgments

We wish to thank M. Simard for assistance in solving the structure of azaindole and collecting the X-ray data. The financial support of the Natural Sciences and Engineering Research Council of Canada, and the Programme d'Échanges Interuniversitaires Franco-Québecois is gratefully acknowledged.

Heterojunctions of the type CdS/chloroaluminum phthalocyanine have been obtained by using the following methods to prepare the CdS layer: electrochemical deposition in dimethylsulfoxide (I); electrochemical aqueous deposition at constant reduction potential (II), or cyclic potential (III), or constant oxidation current (IV); and chemical aqueous deposition (V). The CdS films were characterized by SEM, EDAX, optical microscopy with Nomarski interference, X-ray diffraction, and photoelectrochemistry in polysulfide solution. The best cells show a conversion efficiency of about 0.2% under white light illumination of 90 mW cm^{-2}. They were obtained with a 1.0 μm thick layer of the organic semiconductor and a 0.4 μm thick CdS film prepared by method I. This method yields a polycrystalline electrode characterized by large plates (1–3 μm) of tightly packed single oriented (111) cubic CdS crystallites showing low sub-bandgap absorption. The better performances of the CdS/ClAlPc heterojunctions obtained by method I can be understood in terms of absorbance of the CdS layer of optimum thickness, hole diffusion length in the CdS and electron–hole recombination efficiency at the CdS/ClAlPc interface.

Key words: CdS, phthalocyanine, heterojunction, organic semiconductor, photovoltaic cell.

L. GASTONGUAY, J. P. DODELET, R. CÔTÉ, M. F. LAWRENCE et D. GRAVEL. Can. J. Chem. **68**, 202 (1990).

Des hétérojonctions du type CdS/phtalocyanine de chloroaluminium ont été obtenues en utilisant les méthodes de préparation suivantes pour la couche de CdS : dépôt électrochimique dans le diméthylesulfoxyde (I); dépôt électrochimique en phase aqueuse à potentiel de réduction constant (II), ou potentiel cyclique (III), ou courant d'oxydation constant (IV); et dépôt par bain chimique (V). Les films de CdS ont été caractérisés par MEB, EDAX, microscopie optique avec interférence Nomarski, diffraction des rayons X et photoélectrochimie en solution de polysulfure. Les meilleures cellules ont une efficacité de conversion de 0,2% environ, sous lumière blanche à 90 mW cm^{-2}. Elles ont été obtenues avec une couche de semiconducteur organique de 1,0 μm d'épaisseur et un film de CdS de 0,4 μm préparé par la méthode (I). Cette méthode produit une électrode polycristalline caractérisée par une mosaïque de larges plaques (1–3 μm) contenant un ensemble très serré de petits cristaux de CdS cubique ayant une orientation cristallographique unique (111) et une faible absorption pour des photons dont l'énergie est inférieure à la bande interdite. Les meilleures performances des hétérojonctions du type CdS/ClAlPc obtenues par la méthode I peuvent s'expliquer en termes d'absorbance de la couche de CdS ayant l'épaisseur optimum, de longueur de diffusion des trous dans le CdS et de l'efficacité de recombinaison des charges à l'interface CdS/ClAlPc.

Mots clés : CdS, phtalocyanine, hétérojonctions, semiconducteurs organiques, cellules photovoltaïques.

Introduction

In recent years, phthalocyanines (Pcs) have generated interest as inexpensive organic semiconductors for use in solar energy conversion. Since most of the Pcs investigated are characterized by a p-type behavior, the photovoltaic effects were first observed with Schottky barriers obtained by contacting the dyes with metals like Al or In (1–4). Besides showing stability problems, these metallic electrodes also absorb a large fraction of the light in the Q band absorption region of the organic semiconductor.

Later on, following the example of inorganic cells like n-CdS/p-Cu_2S, photovoltaic devices of the type n-CdS/p-Pc were developed (5–9). Under an AM2 illumination of 75 mW cm^{-2}, conversion efficiencies of 0.22% were measured for the most performing Pcs: ClAlPc and ClAlClPc (7). Unlike the case of n-CdS/p-Cu_2S, where the space charge region is situated in the CdS layer, it has been demonstrated that for an heterojunction with a phthalocyanine (5, 8), the space charge region is located exclusively in the organic semiconductor film. Using CdS instead of a metal allows an increase in the amount of light reaching the active region of the cell because CdS absorbs mainly in the visible below 500 nm, while Pcs absorb above that wavelength. Using CdS also increases the open circuit photopotential of the cell due to its smaller electroaffinity compared to the affinity of metals used previously to produce the Schottky barriers.

In previous studies, the CdS electrode used with the Pcs was always prepared by cathodic electrodeposition of Cd^{2+} in the presence of sulfur in non-aqueous solution (5–9). The purpose of this work is to investigate other electrochemical techniques to prepare CdS. These electrodes, after characterization by SEM, EDAX, optical microscopy using Nomarski interference, X-ray diffraction, and photoelectrochemistry in polysulfide solution have been tested in heterojunction with chloroaluminum phthalocyanine. Chemical bath deposition of CdS is also included in this investigation to compare between electrochemical and a non-electrochemical CdS preparation technique.

Experimental

CdS and CdS/ClAlPc preparation

CdS was electrochemically and chemically deposited on various substrates: indium – tin oxide (PPG Industries) and SnO_2 coatings

(Pyrex infrared reflecting glass, Swift glass Co), 99.999% Cd foil (Alfa Products), Puratronic Pt foil (Johnson Matthey), and graphite electrodes (Fisher).

CdS was electrochemically deposited in non-aqueous solution according to the method described by Baranski and Fawcett (10). The cadmium chloride, elemental sulfur, and dimethylsulfoxide were reagent grade. In aqueous solution, CdS films were prepared by three different methods: (*i*) at constant reduction potential (−1 V vs. SCE) according to Power *et al.* (11). For this deposition, $Na_2S_2O_3$, $CdSO_4$, and HCl were all reagent grade; (*ii*) at cyclic potential (−1.3 to 0 V vs. SCE and 5 mV s^{-1} sweep rate) according to Fatas *et al.* (12). For this deposition, two solutions A and B were mixed together: solution A contained $CdSO_4$, $(NH_4)_2SO_4$, and glycerol; solution B contained $Na_2S_2O_3$ and NaCl. HCl was used to induce the sulfur generation by decomposition of $Na_2S_2O_3$. All chemicals were reagent grade; (*iii*) at constant oxidation current (50 mA cm^{-2}) following the method of Miller and Heller (13). A 1 *M* reagent grade sulfide solution was used for this anodization.

CdS was chemically deposited in aqueous solution according to Mondal and Chaudhuri (14). The chemicals used for this deposition were reagent grade cadmium acetate, triethanolamine, ammonium hydroxide, and thiourea.

Chloroaluminum phthalocyanine was synthetized by a modified Owen procedure (15). The solvents for the reaction were nitrobenzene and quinoline (dried over CaH_2). The crude ClAlPc was purified by two subsequent sublimations. The elemental analysis of the pigment shows good agreement between the expected C (66.84%), H (2.81%), N (19.49%), and Cl (6.17%) contents and the measured ones: C (66.79%), H (2.72%), N (19.50%), and Cl (6.06%). The Al content was measured by neutron activation analysis: expected value (4.7%), measured value (4.8%). To form the heterojunctions, films of ClAlPc were sublimed onto the CdS film previously deposited on ITO or SnO_2 substrates by the methods mentioned above. The sublimation of the organic material was done at a temperature between 350 and 375°C and under a pressure of about 1×10^{-5} Torr. The deposition rate was about 0.2 μm min^{-1}.

The heterojunction cell was completed by evaporating, under vacuum ($\leq 5 \times 10^{-6}$ Torr), a gold collecting (0.5 cm^2) and guard electrodes (99.9% pure from Alfa).

Characterization

CdS

CdS electrodes (between 1 and 2 cm^2) were characterized by (*i*) scanning electrode microscopy (Hitachi, SEM Model S570); (*ii*) electron dispersive analysis; (*iii*) X-ray diffraction (Philips PW 1849) using CuKα; (*iv*) visible absorption spectroscopy (Hitachi Model 100-60), and (*v*) photoelectrochemistry in a three-electrode single compartment cell. A saturated calomel electrode (SCE) served as the reference and Pt foil (15 cm^2) served as a counterelectrode. The redox solution was S^{2-}/S_x^{2-} 1 *M*/1 *M* in 1 *M* NaOH. The working electrode was placed as close as possible to the cell window to minimize the amount of light absorbed by the solution. The white light illumination source was a 300 W Xe lamp equipped with a 10 cm water filter and a 385 nm cut-off UV filter (Oriel corp.). The light intensity was measured with a United Detector Technology 21A power meter equipped with a radiometric filter. Neutral density filters (Oriel corp.) were used to vary the light intensity.

All electrochemical measurements were performed in a Faraday cage. When working in the photogalvanic mode, the measurements were taken with a Keithley 614 electrometer. *J–V* curves were obtained with a Model 173 potentiostat and a Model 175 programmer from Princeton Applied Research. Mott–Schottky plots for the CdS electrodes were done in polysulfide solution using a Model 273 potentiostat and a Model 5206 two phase Lock-in analyser from Princeton Applied Research driven by an Apple IIe computer.

Heterojunctions

The cells were installed in a Faraday cage where they could be irradiated through the ITO or SnO_2 electrode with monochromatic light from a 650 W tungsten–halogen lamp (Schoeffel) passing through a Kratos monochromator (Schoeffel) and/or with white light from a Kodak Ektagraphic slide projector (300 W tungsten–halogen lamp). The reported intensities correspond to light incident on the cell. *J–V* curves measured for the cells were obtained with a Model 175 programmer and a Keithley 616 electrometer.

Results

CdS characterization

To obtain meaningful results, it is important to characterize CdS films of about the same thickness as those used in making heterojunctions with the phthalocyanine. In the latter case, photogenerated holes in the CdS diffuse to the interface where they react with electrons photogenerated in the organic semiconductor. As light penetrates the cell on the CdS side, the optimum CdS thickness corresponds to the hole diffusion length in the CdS film. This was found to be about 0.4 μm in CdS prepared electrochemically in DMSO (8). Larger CdS thicknesses cause a filtering effect resulting in decrease of number of holes reaching the interface and therefore smaller short circuit photocurrents. The following characterizations, unless mentioned otherwise, were performed on CdS films of about 0.4 μm thick.

SEM and EDAX

Figures 1 and 2 depict the scanning electron microscope (SEM) photographs of all the CdS electrodes used in this study. In Fig. 1: electrochemical non-aqueous (DMSO) deposition on ITO at three magnifications: ×10K, ×25K, ×50K; in Fig. 2: electrochemical aqueous deposition at constant reduction potential on SnO_2 (A), cyclic potential on SnO_2 (B), constant oxidation current on Cd foil (C), and chemical aqueous deposition on ITO (D), respectively. All films are shown at the same magnification (×10K). For CdS electrochemically deposited in aqueous solution (Fig. 2A, B, and C), individual crystallites are visible. In Fig. 2A and B, all crystallites have about the same size (0.3 μm) while for Fig. 2C, the size of the crystallites varies between 0.3 to 2 μm.

Individual crystallites are not easily distinguished in Fig. 1 and in Fig. 2D. Both films seem to be made of a homogeneous CdS layer with an intricate pattern of crevices attributed to solvent loss. The crevices, however, are more numerous in Fig. 2D compared to Fig. 1. The surface of CdS obtained by electroreduction of Cd^{2+} in the presence of sulfur in DMSO looks very flat when it is observed by SEM. Under optical microscopy with Nomarski interference (Fig. 3), the same electrode shows a surface morphology completely different from the other CdS films studied. It is composed of a mosaic of tightly packed elements of various shapes having sizes estimated between 1 and 3 μm. Nomarski interference yields an image with high contrast and enables the observation of fine scale surface roughness. Looking at Fig. 3, one might think that each element of the mosaic is a CdS crystallite but this does not agree with Fig. 1. In fact, irregularities in the film flatness revealed by Nomarski interference seem to follow a pattern corresponding mainly to the largest crevices, assuming that these were extended and joined to define the complete perimeter of each element in the mosaic. At a magnification greater than ×10K, the film surface begins to show some structure which resembles a very dense aggregation of small crystallites. The crystallinity of CdS obtained by the non-aqueous method is confirmed by the X-ray diffraction study. Chemically deposited CdS films seem rather amorphous even at magnifications up to 50K. This is also confirmed by X-ray diffraction. The white

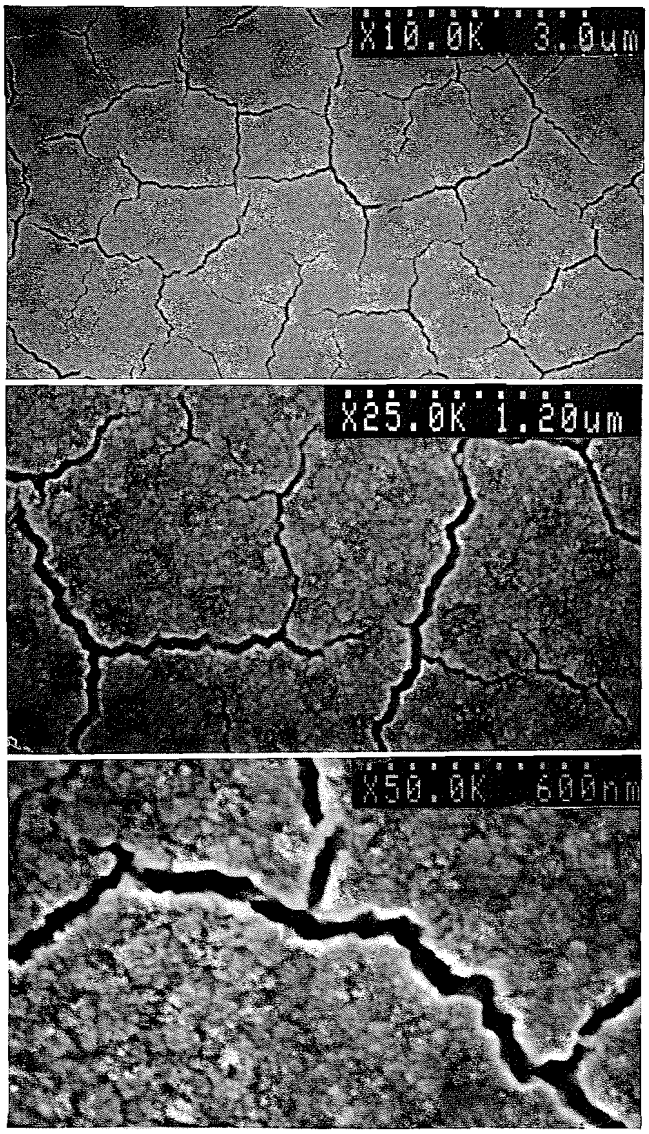

FIG. 1. SEM pictures of a 0.4 μm thick CdS film prepared electrochemically in non aqueous solution (DMSO).

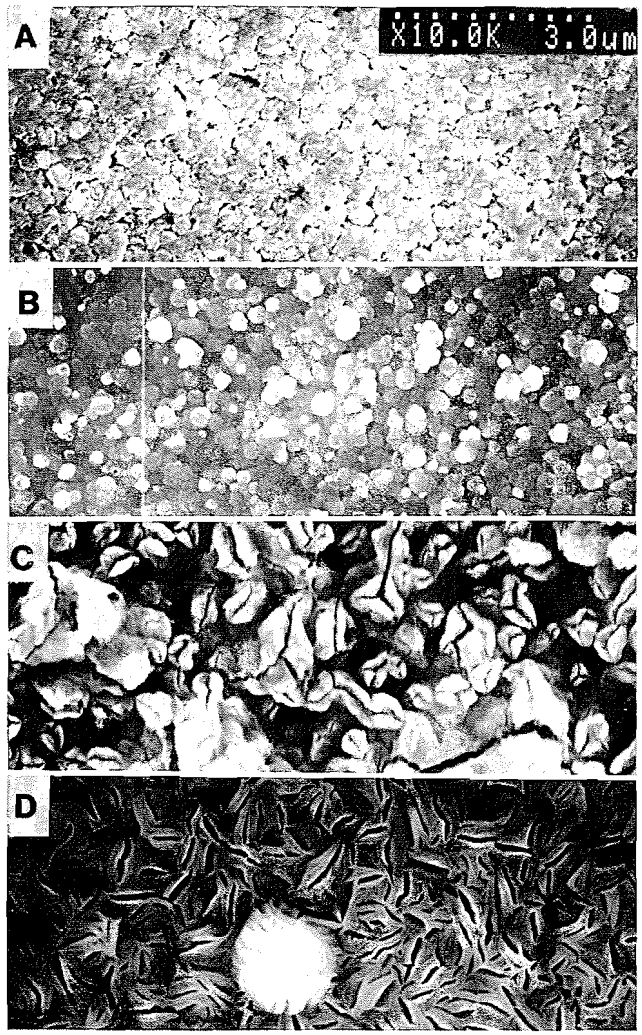

FIG. 2. SEM pictures of a 0.4 μm thick CdS film prepared electrochemically in aqueous solution at constant reduction potential (A), at cyclic potential (B), at constant oxidation current (C) and prepared by chemical bath (D).

spot seen in the picture is probably due to the presence of elemental sulfur.

Table 1 presents the Cd and S weight percentage obtained by EDAX for each CdS deposition method. For the EDAX measurements, the CdS films were prepared on graphite electrodes except for the anodization. Stoichiometric CdS is characterized by 77.8% of Cd and 22.2% of S. Therefore, from the results presented in Table 1, it can be concluded that all the preparation methods show about the same excess of S incorporated either by the solvent (DMSO), or as elemental S for the aqueous depositions. These results agree with the EDAX results already published for deposition method III (12, 16).

X-ray

X-ray diffraction spectra have been obtained for the CdS films prepared by all the deposition methods used in this work. CdS obtained electrochemically in DMSO and obtained chemically in aqueous solution, could be prepared on ITO. This substrate shows no specific diffraction peaks. Therefore, the only peak seen for method I at $2\theta = 26.8°$, which corresponds to an interplanal distance of 3.33 Å, can be attributed to the (111)

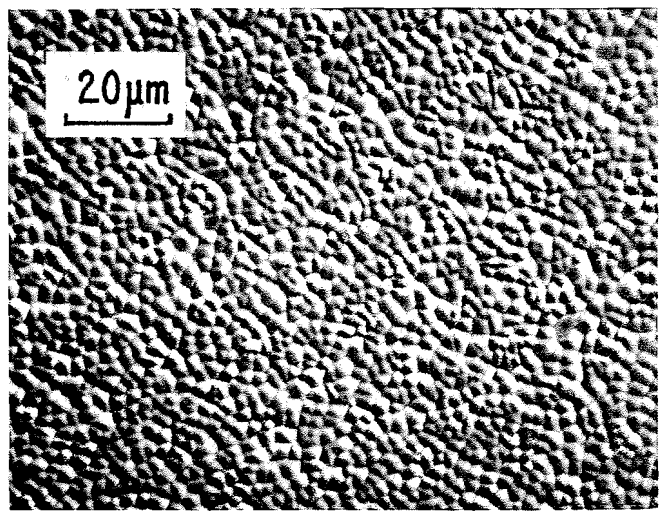

FIG. 3. Optical microscope picture using Nomarski interference of a 0.4 μm thick CdS film prepared electrochemically in non-aqueous solution (DMSO) on ITO.

planes of cubic CdS. This result agrees with the previous report (17). For method V, the X-ray diffraction pattern shows no specific peak that could be attributed to the CdS layer. For the other deposition methods where acidic solutions had to be used for the preparation of the CdS layer, ITO substrates had to be substituted by SnO_2 electrodes or Cd foils. The contribution to the diffraction pattern by the CdS layer is so small that no difference is observed for the diffraction pattern of the SnO_2 and Cd foil substrates before and after CdS deposition. It seems, therefore, that the crystallinity of the ~0.4 μm thick films obtained by all the CdS deposition methods, except for the non-aqueous one (I), is quite poor.

Photoelectrochemistry

The photoelectrochemicals properties of the CdS layers deposited on metallic substrates by the five methods used in this work, have been measured. Our results (short-circuit photocurrents, J_{sc}, and open-circuit photovoltages, V_{oc}) are reported in Table 2 along with literature values. CdS layers of thickness ranging from 1 to 2 μm had to be used to yield results comparable with those previously reported under comparable light intensities. This is easily deduced from the data of Table 2, since it was found that J_{sc} varies quite linearly with the light intensity for all the CdS preparation methods. Changing the substrate on which the deposition was done, from Cd foil to SnO_2, only affects the reverse dark J–V characteristics. Indeed, leakage currents are already observed for CdS deposited on SnO_2 at −0.5 V as compared to 0 V for equivalent currents in the case of CdS depositions on Cd foil. The equilibrium potential of the electrolyte is −0.74 V. Leakage currents are also observed at −0.5 V in the reverse dark J–V characteristics of the bare SnO_2. For this reason, C–V Mott–Schottky plots were measured for CdS deposited on Cd. Table 3 reports the flatband potential, V_{fb}, and the charge carrier density, N_D, for the CdS electrodes used in this work. The $1/C^2$ vs. V curves are almost the same when the applied modulated voltage is varied from 1 to 15 kHz. They always display two regions with different slopes. The V_{fb} is obtained by extrapolation of the straight line occurring in the voltage region spanning from −0.7 to −1.1 V. It is to be noticed that the V_{fb} obtained by Mott–Schottky curves are always lower than the photocurrent onset potential (−1.1 to −1.2 V). This discrepancy is probably due to the fact that the V_{fb} values are obtained by extrapolation of $1/C^2$ vs. V data over only a small range of voltage. A value of $V_{fb} = -1.05$ V has already been published (21) for polycrystalline CdS in polysulfide redox using Mott–Schottky curves.

Charge carrier densities reported in Table 3 are high and cover practically three orders of magnitude. However, the measurements are sensitive to the actual area of the electrode which could be quite different from the geometrical one as it can be seen from the SEM pictures (Figs. 1 and 2). Therefore, the reported values in Table 3 correspond to the upper limit of N_D. Hall measurements have been performed on CdS electrodeposited from aqueous diethylene glycol solutions. In that case, values of N_D ranging from 8.3×10^{16} to $\geq 2 \times 10^{18}$ cm^{-3} have been reported (22). They are of the same order of magnitude as the N_D values obtained in this work.

CdS/ClAlPc heterojunctions

Heterojunctions have been produced using sublimation of ClAlPc onto previously characterized CdS. All CdS preparation methods have been used except for anodization (IV). In the case of anodization, small currents yielded uniform CdS films, but showed bad adhesion to SnO_2. The CdS layers obtained by applying large anodization currents were found to have pinholes.

Table 4 presents the J_{sc}, V_{oc}, fill factor (ff), and conversion efficiency (η) measured in this work for the various hetero-

FIG. 4. SEM picture of a 1 μm thick ClAlPc film sublimed onto CdS.

junctions under white light illumination at 90 mW cm^{-2}. The CdS and ClAlPc thicknesses used in Table 4 are 0.4 and 1 μm, respectively. The ClAlPc film with an optimum thickness of about 1 μm is not compact as illustrated by the SEM picture (×50K) in Fig. 4. The organic semiconductor is made of crystallites having a length of 1 μm and a cross section of about 50 to 100 nm. From Table 4 it can be seen that the best heterojunction is obtained with CdS prepared by electrodeposition in DMSO. Lowering the light intensity to 30 mW cm^{-2} increases the conversion efficiency to a maximum of 0.25%. These values of η correspond to the ones already published for a similar cell (7).

The CdS thickness used in Table 4 is, however, optimum for the CdS preparation method in DMSO. The optimum thickness of CdS prepared by chemical bath is about 0.15 μm. A CdS/ClAlPc heterojunction obtained with this thickness yields J_{sc} = 220 $\mu A\ cm^{-2}$, V_{oc} = 0.63 V, ff = 0.26, and η = 0.039%. The other CdS preparation methods have not been optimized. The optimum thicknesses obtained for both methods allow the ClAlPc film, which absorbs above 500 nm, to receive the same amount of light as shown in Fig. 5. The stability of the heterojunction formed with the CdS obtained by electrodeposition in DMSO has been checked. It was found that over a period of 5 h, the photocurrent decreases by about 10%. Only 60% of the initial J_{sc} value remains after 30 h.

Discussion

Table 4 shows that the best performing heterojunctions are obtained with CdS electrodeposited in DMSO. Furthermore, there is a factor of about five between the optimum efficiency of that cell and the next best one which uses CdS obtained by chemical bath. As the fill factors and open circuit voltages for all cells are quite similar, the difference in power conversion of these cells is essentially related to large variations in their short circuit photocurrents.

It is not possible to explain differences for J_{sc} given in Table 4 on the basis of either differences in the CdS film composition (Table 1) or in their photoelectrochemical properties (Table 2 shows that $\eta = 1.6 \pm 0.3 \times 10^{-2}$%), or in the charge carrier densities of the CdS (Table 3 indicates that $N_D \geq 10^{18}\ cm^{-3}$). The only major difference observed between all the CdS films used in this work is the peculiar crystallinity of CdS grown by method I. Indeed, it is the only method that not only gives a distinct diffraction pattern for layers as thin as 0.4 μm, but the X-ray diffractogram also shows that these films are characterized by only one crystallographic orientation (111).

The mechanism for photocurrent collection in CdS/Pc junctions is illustrated in Fig. 5. It has previously been observed (8) that when such junctions are illuminated with red light only (600 nm) in the absorption region of the Pc, the cell photocurrent decreases rapidly and continues to do so unless a certain amount of blue light (430 nm) is added. Under white light illumination, electron–hole pairs are formed simultaneously in both semiconductors. The major mechanism at work for current production involves the recombination, at the junction, of electrons from the Pc conduction band (minority carriers) with holes from the CdS valence band (minority carriers), leaving extra electrons in CdS and extra holes in Pc to be recuperated. Another mechanism of current production, however secondary, involves a direct injection of holes from the CdS valence band

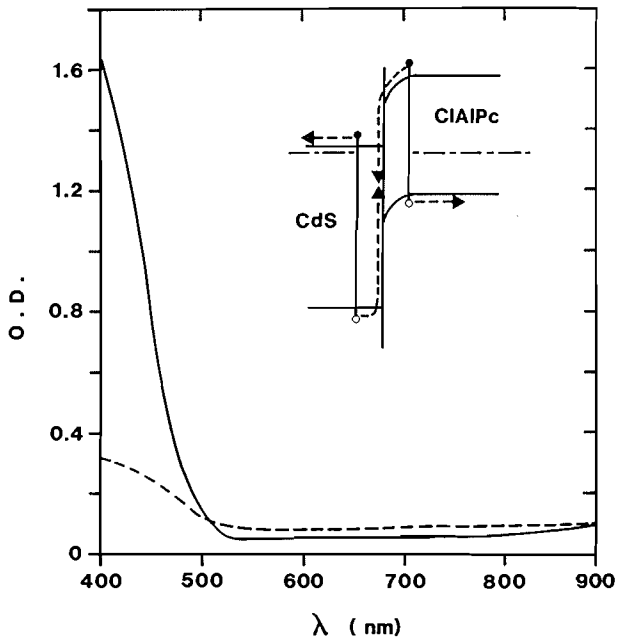

FIG. 5. Optical densities for the optimum CdS film thicknesses prepared electrochemically in DMSO (—) and by chemical bath (- - -). The insert describes the major mechanism for current production.

into the Pc valence band (8). The short circuit photocurrent measured in CdS/Pc junctions is then essentially a function of three factors: (*i*) the collection efficiency of the holes photogenerated in the ClAlPc layer, (*ii*) the collection efficiency of the electrons photogenerated in the CdS layer, and (*iii*) the photogenerated electron–hole recombination efficiency at the CdS/ClAlPc interface. Let us see how it is possible to rationalize a ratio of about five between J_{sc} (method I) and J_{sc} (method V).

Figure 5 shows the optical density of the CdS layers obtained in DMSO and by chemical bath, after optimization of their thicknesses to yield the maximum power efficiency in heterojunction with ClAlPc. This optimum thickness is 0.4 and 0.15 μm for CdS prepared by methods I and V, respectively. In the wavelength region between 500 and 900 nm, it is clear from Fig. 5 that about the same light intensity reaches the ClAlPc layer after passing through the CdS prepared by method I or V. This wavelength range covers the Q band absorption region of Pc. Excitation of the Soret band of the pigment can be disregarded because only a small intensity of light with $\lambda <$ 400 nm is emitted by tungsten–halogen lamp and these photons are mainly absorbed by CdS. It seems therefore that the amount of electrons and holes generated in the 1 μm thick ClAlPc layer and the hole collection from that layer will be independent of the CdS preparation method.

On the other hand, Fig. 5 shows that the absorbance of the CdS layer below 500 nm is drastically different for both optimum thicknesses. The amount of electrons collected from the CdS layer is a function of the photo-generated charge density. It also depends on the hole diffusion length in CdS. Between 400 and 500 nm, there is about 1.7 times more photons absorbed in the optimum CdS layer obtained by method I compared to the optimum film produced by method V. The same ratio is expected between the densities of photogenerated charges in these films. As far as the hole diffusion length is concerned, a value of 0.4 μm was determined (8) for CdS obtained in DMSO on the basis of a drastic decrease of the photocurrent for cells with CdS layers thicker than 0.4 μm. On the same basis, the hole diffusion length for CdS obtained by chemical bath would only be 0.15 μm. However, it is possible that the value of 0.15 μm, deduced for the hole diffusion length of CdS obtained by method V, is only a lower limit estimate. Indeed, part of the photocurrent decrease observed for CdS layers thicker than 0.15 μm could be attributable to the decrease of the Pc illumination since, for those films, the absorbance of CdS above 500 nm is not negligible anymore compared to their absorbance below the same wavelength. If the optimum thickness of CdS prepared by method V is smaller than the hole diffusion length in that material, a lowering of the short circuit photocurrent is then expected. By comparison, for CdS prepared by method I, there is a 1.3 times reduction in the cell photocurrent when the CdS layer is reduced from 0.4 to 0.15 μm (8).

The third factor to take into account is the electron–hole recombination efficiency at the CdS/Pc interface. As it was already mentioned, the CdS/ClAlPc needs to be illuminated at the same time by blue and red light to reach a steady-state photocurrent. Blue light is essential because the holes it generates in CdS are needed to balance the electrons generated by red light in ClAlPc. When the photocurrent produced with red light only (600 nm) is balanced with just the right amount of added blue light (430 nm), it is found that $N(e)/N(ph) = 0.7 \pm 0.1$ for CdS obtained in DMSO, but only 0.5 ± 0.02 for CdS prepared by chemical bath, where $N(e)$ is the total number of electrons collected per second and $N(ph)$ is the total number of blue photons absorbed in the CdS within a distance from the phthalocyanine not exceeding the diffusion length of holes in CdS.

By combining the CdS absorbance effect, the electron–hole recombination efficiency at the CdS/Pc interface, and the possibility of using a CdS layer with an optimum thickness smaller than the hole diffusion length for CdS obtained by chemical bath, it is therefore possible to rationalize J_{sc} (method I:method V) ratios ranging from 2.6 to 3.8. The experimental value obtained from Table 4 is 4.9.

Conclusion

In the framework of our investigation, the best performing CdS/ClAlPc heterojunctions are obtained when the organic semiconductor is sublimed on a 0.4 μm thick CdS film prepared by cathodic electrodeposition in DMSO. This method yields a polycrystalline electrode characterized by large plates (1–3 μm) of tightly packed single oriented (111) cubic CdS crystallites showing low sub-bandgap absorption. The better performances of the CdS/ClAlPc heterojunctions obtained by that method can be understood in terms of absorbance of the CdS layer, of optimum thickness vs. hole diffusion length in the CdS, and electron–hole recombination efficiency at the CdS/ClAlPc interface.

This work demonstrates that the current density in these organic–inorganic heterojunctions could be limited by the inorganic layer which has to play an active role in the photogeneration and transport of the charges. It seems that future developments in this particular area of solar collectors will favor the use of an all organic heterojunction since power efficiencies of about 1% have already been obtained for these junctions under 75 mW cm^{-2} AM2 irradiation (23).

The voltammetric determination of cobalt(II) in seawater — adsorptive preconcentration of the dimethylglyoxime complex

W. W. WESTENBRINK, J. A. PAGE, AND G. W. VANLOON[1]

Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received June 9, 1989

W. W. WESTENBRINK, J. A. PAGE, and G. W. VANLOON. Can. J. Chem. **68**, 209 (1990).

Conditions for the determination of trace Co in seawater are described. The method involves formation of the dimethylglyoxime complex and adsorptive accumulation onto a hanging mercury drop electrode at an applied potential of −0.70 or −0.96 V vs. SCE. The adsorbed complex is then reduced by scanning the electrode potential to −1.20 V; the reduction peak potential (E_p) is −1.12 V. Nickel behaves in a similar manner with E_p of −0.99 V but the Co complex appears to be preferentially adsorbed, making analysis for Co possible even in the presence of a large excess of Ni. Adsorption of organic matter also occurs; this does not affect analytical sensitivity but limits the maximum deposition time allowed in the analysis.

Determination of Co in six seawater samples yielded results ranging from 4 to 114 ng L^{-1}. Good agreement was obtained with the one reference sample (NASS-1) for which there was a certificate value.

Key words: cobalt, dimethylglyoxime, stripping voltammetry, adsorption, seawater.

W. W. WESTENBRINK, J. A. PAGE et G. W. VANLOON. Can. J. Chem. **68**, 209 (1990).

On décrit des conditions permettant de déterminer des traces de Co dans l'eaud e mer. La méthode implique la formation du complexe avec la diméthylglyoxime et une accumulation par adsorption sur une électrode à goutte de mercure pendante, à un potentiel appliqué de −0,70 ou−0,96 V vs. SCE. Le complexe adsorbé est alors réduit en balayant le potentiel de l'électrode jusqu'à −1,20 V; le potentiel maximal de la réduction (E_p) se situe à −1,12 V. Le nickel se comporte d'une manière semblable avec un E_p de −0,99 V; toutefois, le complexe de Co semble être adsorbé d'une façon préférentielle et cette propriété permet d'analyser le Co même en présence d'un large excès de Ni. Il se produit aussi une adsorption des composés organiques; cette propriété n'affecte pas la sensibilité analytique mais elle limite le temps maximal de déposition permis par l'analyse.

La détermination du Co dans six échantillons d'eau de mer a fourni des résultats allant de 4 à 114 ng L^{-1}. On a obtenu une bonne corrélation avec le seul échantillon de référence (NASS-1) pour lequel il existe une valeur certifiée.

Mots clés : cobalt, diméthylglyoxime, voltamétrie, adsorption, eau de mer.

Introduction

Anodic stripping voltammetry (ASV) is an appropriate technique for the determination of metal ions in aqueous solutions and seawater at sub-ppb levels. The method is highly sensitive and, in the case of seawater the dissolved salts do not constitute an interference but rather serve as the supporting electrolyte for the voltammetry. Applications of the technique are limited by the requirement that the metal be readily deposited at the electrode and then stripped within a potential window appropriate to the aqueous solution. Methods, usually employing a Hg drop or thin film electrode, exist for about 10 elements in seawater (1). In some cases, the technique can distingush amongst the oxidation states and forms of a metal on the basis of differences in electroactivity of the analyte species (2).

Recently, a technique derived from ASV but involving the collection of the metal species at an electrode surface by adsorptive accumulation (AdAc) has widened the scope of voltammetric analysis (3). There are variants, but the method usually involves complexation of the metal ion followed by adsorption of the complex on the electrode surface. The amount or surface concentration of the adsorbed species is then determined by scanning the electrode potential through a range of values. If the species is electroactive and the charge transfer process relatively rapid, a current–potential response in the form of a peak at a characteristic potential is obtained. The peak height (current) or peak area (quantity of electricity) is the analytical signal. Variables include the choice of complexing agent, electrolyte composition and pH, electrode material and adsorption potential, adsorption time and mass transfer parameters; appropriate choices enable a selective determination of a number of elements. Calibration of the method is usually by standard addition of the analyte ion.

One widely used AdAc method is the determination of Ni(II) after complexation with excess dimethylglyoxime (DMG, butane-2,3-dione dioxime). The method is attributable to Nurnberg (4) and involves adsorption of the metal complex ($Ni(DMG)_2$) onto a Hg drop electrode from a slightly basic, buffered medium. The electrode potential is then scanned to reduce the adsorbed complex. Using the method, good results have been obtained in intercalibration studies on reference seawater samples. Since Co(II) forms a $Co(DMG)_2$ complex similar to that of Ni(II), a related method is to be expected. The possibility has been recognized and it has been indicated that trace Co(II) in seawater can be determined although details, procedure or results were not given (3). Methods for trace Co(II) in biological materials (6–9), sediments (8), reactor water coolant (10), rain water (11), and estuarine and fresh water samples containing elevated Co levels (12) have been described. Each of the methods involves the accumulation of the $Ni(DMG)_2$ and $Co(DMG)_2$ complexes at a Hg electrode followed by a voltammetric determination of the adsorbed species.

Recently, a determination of Co in seawater samples based on AdAc of the related Nioxime (cyclohexane-1,2-dione dioxime) complex at a Hg drop electrode has been reported (13). The sensitivity of the method was highly dependent upon the pH of the electrolyte and the buffer used, but with a HEPES (*N*-(2-hydroxyethyl)piperazine-*N*′-2-ethanesulfonic acid) buffer at pH 7.6, a detection limit of 0.35 ng L^{-1} Co was achieved

using a 15 min adsorption and differential pulse voltammetry. The method was successfully applied to seawater samples after uv irradiation to destroy organic surfactants.

In the present work, the adsorption of $Co(DMG)_2$ at a Hg drop electrode is used for the determination of Co(II) in seawater. Since Ni(II) is usually present in seawater at much higher concentrations than Co(II), a particular concern was the effect of this element in the determination. Surface active materials are also known to interfere in adsorption processes (12) and a study of the effect of organic material in the analyte on the determination was also undertaken.

Experimental

The voltammograms were recorded using an EG & G Princeton Applied Research Model 384 Polarographic Analyzer and a Model 303 Static Hg Drop Electrode with a Model 305 Stirrer. The cell and electrodes were identical to those in a previous study (5). A Ag/AgCl/seawater reference electrode and a Pt counter electrode were used with the counter electrode isolated from the analyte by a bridge tube. Stirring in the adsorption stage was by a magnetically driven stirring bar. Sample handling and cell manipulation were done in a laminar flow clean hood. The seawater (SW) analyzed in the study included a NASS-1 reference water (14) and samples taken from Sandy Cove (SC) and Bedford Basin (BB), Nova Scotia, and Passamaquoddy Bay (PB), New Brunswick. Samples of ICES-5 seawater used in a previous study (15) were also analyzed. The Co(II) and Ni(II) standard stock solutions were prepared determinately from pure metal dissolved in excess reagent grade HNO_3. Dilute standard solutions were prepared from the stock solution as needed.

For analysis, the cell was rinsed and filled with a 8.0 mL sample and 200 μL of a 4.0 *M* NH_3/NH_4Cl aqueous buffer and 20 μL of a 0.010 *M* ethanolic dimethylglyoxime reagent added. This gave a pH of 9.2 and a reagent concentration $C_{DMG} = 2.5 \times 10^{-4}$ *M*. The final seawater analyte had ionic strength $I = 0.70$ *M* and chloride concentration $C_{Cl^-} = 0.55$ *M*. The electrolyte was dearated and blanketed with purified N_2 gas for analysis. The buffer and reagent concentrations are identical to those which may be used for the determination of Ni(II) in seawater.

The adsorptive accumulation of the $Co(DMG)_2$ was carried out at −0.70 V or −0.96 V under controlled mass transfer conditions with accumulation times of 100 to 360 s. Stirring during this stage was at "slow" (500 Hz). A fresh Hg drop (Size "M") was used for each run. Since adsorption of the complex begins on formation of the drop, the drop was dispensed immediately at the start of the accumulation stage. At the end of the first stage there was a further 20 s rest stage without stirring; then the electrode potential was scanned to −1.30 V at 0.020 V s^{-1} and the voltammogram recorded. The peak for the reduction of the adsorbed complex was well defined, even with trace amounts of $Co(DMG)_2$, as shown in Fig. 1. For analysis, peak heights were measured with respect to a tangent fit baseline and calibration was by the method of standard additions. An analysis normally involved repeated additions of Co(II). Up to 12 measurements were thus made on each sample with an accompanying accumulation of Hg in the cell. A fresh sample was taken for each replicate analysis. The standard addition plots were highly linear indicating that the Hg drops were reproducibly dispensed during the analysis and calibration.

Results and discussion

In developing the method, the type and strength of the buffer, the pH and DMG concentration were set at values used for the determination of Ni(II) so that a simultaneous determination of the two elements could be considered. The effect of variation of the other operational parameters was systematically studied.

Using an adsorption potential of −0.70 V, the voltammetry gave a Co reduction peak at −1.12 V with the Ni peak at −0.99 V. Since Co(II) concentrations in seawater are generally much less than those of Ni(II) (e.g. 1:64 in NASS-1 seawater) simultaneous analysis is difficult as the Co peak tends to be

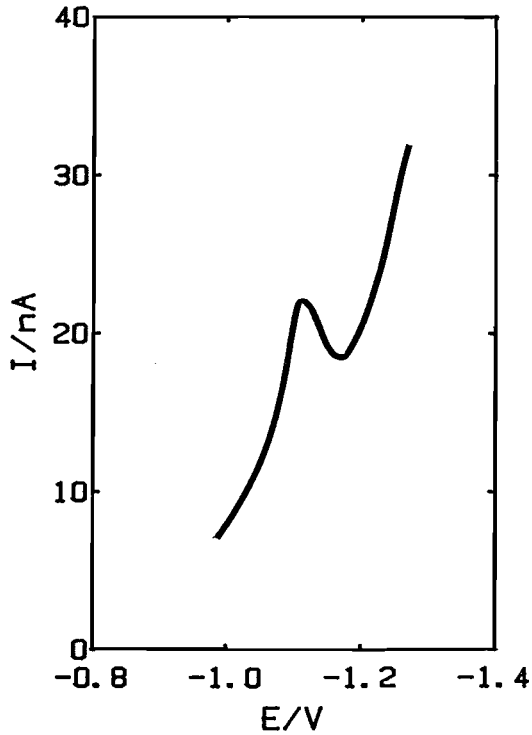

Fig. 1. Typical voltammogram for adsorbed $Co(DMG)_2$. NASS-1 seawater spiked with 0.11 μg L^{-1} Co. $E_{ads} = -0.96$ V, $t_{ads} = 120$ s, scan rate = 0.020 V s^{-1}.

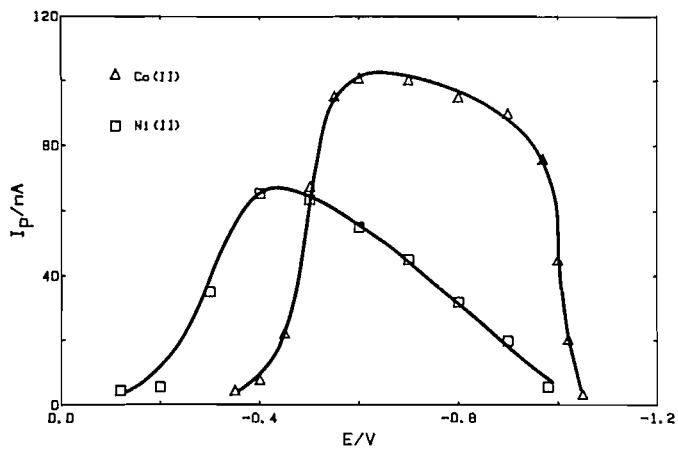

FIG. 2. The effect of E_{ads} on Co and Ni response. Sandy Cove seawater, spiked with 0.91 μg L^{-1} Co. $t_{ads} = 120$ s, scan rate = 0.020 V s^{-1}.

obscured by the preceding Ni peak. An attempt was made to identify an electrode potential which would permit the determination of Co with a minimal Ni interference and Fig. 2 shows the peak currents obtained for reduction of the complexes after adsorption for a fixed time at differing potentials from a seawater containing added Co(II) and Ni(II). For $Co(DMG)_2$, potentials more negative than −0.60 V were required for significant adsorption, but $Ni(DMG)_2$ was adsorbed at less negative potentials. At potentials that resulted in adsorption of both species, there was evidently preferential adsorption of the $Co(DMG)_2$ as shown by the decrease in the Ni peak signal at increasingly negative adsorption potentials. In the absence of added Co(II), the Ni peak signal obtained was constant over a wide range of adsorption potentials. At adsorption potentials

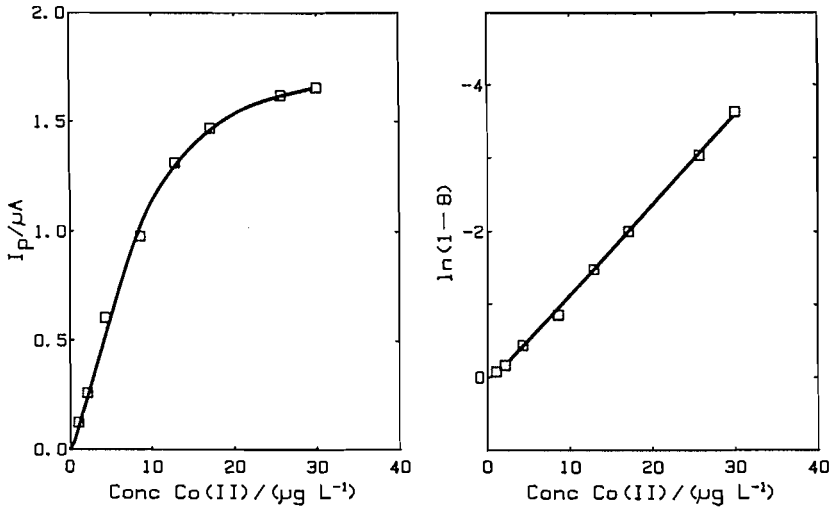

FIG. 3. (*a*) Calibration curve for Co analysis by adsorption stripping voltammetry. NASS-1 seawater with added Co(II). t_{ads} = 300 s, scan rate = 0.050 V s^{-1}. (*b*) Plot of data from (*a*) exhibiting Langmuir adsorption behaviour.

approaching −0.96 V the Ni peak disappeared, probably because of simultaneous adsorption and reduction of the $Ni(DMG)_2$. For the analysis of seawater where Co(II) is at a lower concentration than the Ni(II) an adsorption potential of −0.96 V appears appropriate. For cases where the simultaneous determination of Co(II) and Ni(II) is feasible, an adsorption potential of −0.70 V is recommended.

Using adsorption potentials of −0.70 V and −0.96 V, calibration curves for Co(II) exhibited the behaviour in Fig. 3. With Co(II) concentrations higher than 1 μg L^{-1}, there was an asymptotic approach to a limiting value of peak current and peak area. The behaviour is similar to that previously observed with $Ni(DMG)_2$ and the limit probably corresponds to saturation of the electrode surface with adsorbed $Co(DMG)_2$. For Fig. 3, the limiting values were I_p = 1.7 μA and Q_p = 2.3 μC. If the reduction process involves 2 Faradays per mol, the 2.3 μC corresponds to 1.4 × 10^{-11} mol of adsorbed $Co(DMG)_2$. Assuming monolayer coverage of the electrode surface (A = 0.014 cm^2) each adsorbed $Co(DMG)_2$ molecule then occupies 0.18 nm^2. The crystal structure of $Co(DMG)_2$ has evidently not been determined; however the 0.87 nm^2 for $Ni(DMG)_2$ in the 001 plane should be a reasonable approximation to the area of a planar $Co(DMG)_2$ molecule (16). An explanation for the large discrepancy could be that saturation of the electrode surface does not correspond to a simple monolayer but rather to a multilayer or compact layer (where the $Co(DMG)_2$ is not planar to the electrode surface). An alternative argument is that the adsorbed complex forms a simple monolayer but reduction of the $Co(DMG)_2$ is not a simple 2 electron process. Recent work (unpublished) with the $Ni(DMG)_2$ system lends support to the latter hypothesis. Catalytic mechanisms have been postulated to explain the enhanced currents observed in the polarographic reduction of both $Ni(DMG)_2$ and $Co(DMG)_2$ (17).

There is also a simple time-dependent relation between the concentration of $Co(DMG)_2$ in the analyte and the coverage of the electrode by adsorbed complex. The data of Fig. 3 were obtained using a fixed adsorption time, but the ratio of peak current to the limiting value representing surface saturation is a measure of the fractional coverage of the electrode with adsorbed complex ($\theta = i_p/1.7\ \mu A$). Figure 3 also shows a plot of ln (1 − θ) vs. $Co(DMG)_2$ concentration. If it is presumed that adsorption results in no significant decrease in the concentration of $Co(DMG)_2$ in the electrolyte, the linear plot is characteristic of a Langmuir isotherm and indicates that the rate of adsorption is proportional to both the concentration of $Co(DMG)_2$ and to (1 − θ), the fraction of the electrode surface not covered by adsorbed complex. Linear analytical calibration curves should result when coverage of the electrode with adsorbed complex is restricted to small fractional values of the electrode area. In the absence of other effects, adsorption times of 300 s are appropriate for concentrations of Co(II) up to a few μg L^{-1}, but for larger concentrations the adsorption time should be proportionately less.

Interferences

Seawater spiked with Cd(II), Cr(III), Cu(II), Fe(II), Mn(II), Pb(II), and Zn(II) at concentrations up to 10 mg L^{-1} produced no new peak, nor did the additions have any effect on the Co response. As noted before, Ni(II) gives a preceding reduction peak at −0.99 V. The effect of added Ni on the Co peak was investigated by adding increasing amounts of Ni(II), to solutions containing between 1 and 18 μg L^{-1} added Co(II). The analyses were carried out using a 300 s adsorption at both −0.70 V and −0.96 V. The Ni(II), up to at least 30 μg L^{-1}, affected neither the sensitivity of the Co determination nor the blank signal value. However, Co(II) did interfere in the Ni(II) response as shown in Fig. 4. The significant decrease in the Ni peak can be explained by a preferential adsorption of $Co(DMG)_2$ and displacement of adsorbed $Ni(DMG)_2$. Similar conclusions have been stated elsewhere (10), although a small enhancement of the Co signal by Ni was reported in that work.

In the analysis for Ni(II), a decrease in sensitivity in the presence of surface-active organic materials has been observed (3, 12) and similar effects are to be expected in the Co(II) determination. Figure 5 shows the effect of added humic material (HM) on the Co peak. In the presence of added HM, the Co peak current shows an initial increase with adsorption time but at increasingly longer adsorption times reaches a maximum value and then decreases. The adsorption time required to reach the maximum is dependent upon the concentration of added HM. The slope of the initial linear region is however independent of the concentration and indicates that organic material does not affect the sensitivity of the analysis at short adsorption times. The behaviour suggests that there is a preferential slow

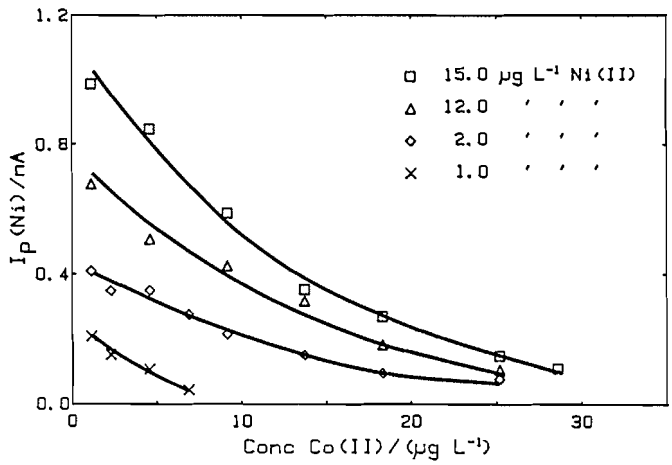

FIG. 4. Ni response in the presence of added Co. NASS-1 seawater with added Co and Ni t_{ads} = 300 s, scan rate = 0.050 V s^{-1}.

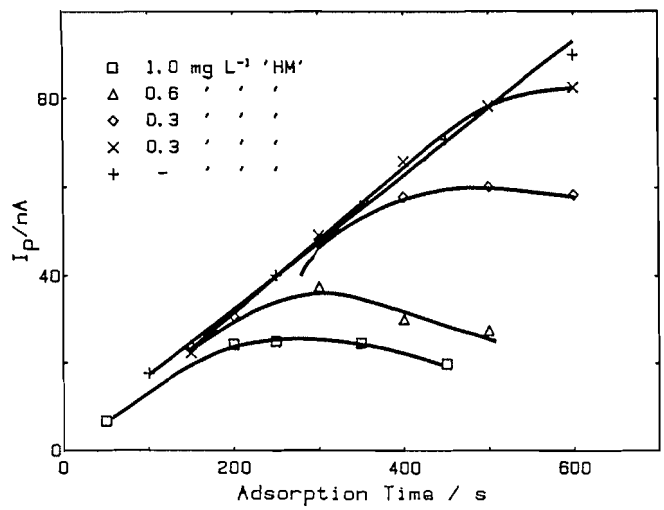

FIG. 5. The effect of added humic acid on Co response. NASS-1 seawater spiked with 0.30 μg L^{-1} Co. E_{ads} = −0.96 V, scan rate = 0.020 V s^{-1}.

adsorption of HM on the Hg drop and this can interfere with the adsorption and reduction of $Co(DMG)_2$.

The effect is a limitation in the analysis of real samples. For very low concentrations of Co(II) the sensitivity of the method can, in theory, be increased by increasing the adsorption time. However, the presence of HM or other surface-active materials in the analyte will restrict the analysis to short adsorption times and limit the sensitivity obtainable. Fulvic acid and Triton X-100 were also found to produce effects similar to that of the added humic material. The interference from Triton X-100 was substantially greater than from HM on a mass concentration basis. Added albumin and linoleic acid produced no significant change in the Co response.

A claim has been made that the DMG complexes compete effectively with the dissolved organic material in the adsorption processes and there is no interference in analyses for Co(II) and Ni(II) (12). The adsorption times reported were short and if mass transfer conditions are comparable the claim is within the limits where an interference was not apparent in Fig. 5.

Figure 6 shows response curves obtained with three seawater samples containing added Co(II). The slopes at short adsorption times are proportional to the concentration of Co(II) in the samples. Each curve shows a broad maximum, with that for the NASS-1 seawater at the longest time. This can be explained if the NASS-1 water is regarded as 'clean' while the Passamaqu-

oddy Bay and Bedford Basin waters contain significantly greater concentrations of dissolved organic material.

Analytical results

Analyses were performed on a variety of seawater samples and the results are reported in Table 1. The uncertainty in each of the individual values reported was derived from the intercepts of the confidence band associated with the standard addition calibration curve. Considering the trace levels of Co(II) reported, the replicate analyses exhibited good reproducibility, indicating that sample handling did not contribute significantly to the overall error.

The adsorption times used in the analyses were chosen as the longest time possible without significant interference from surface active materials in the analyte. The Bedford Basin seawater appeared to contain a level of surface-active material higher than that of the other samples and with this sample an adsorption time of much over 120 s produced a dramatic decrease in the (normalized) sensitivity of the analytical system. Variations in the sensitivities between samples can be attributed at least partly to the use of a number of different electrode capillaries and other electrodes as well as cells with different mass transfer parameters over the period of time involved in this work. The results for the NASS-1, ICES-5, Sandy Cove, and Passamaquoddy Bay Basin, surrounded by a major urban centre, are significantly higher. The ratio of Co to Ni in the latter sample is near 1:8 compared to a ratio of 1:64 in the NASS-1 seawater. The analyses of the NASS-1 water were carried out blind as a part of the interlaboratory analysis program of the Marine Analytical Chemistry Standards Program of the National Research Council of Canada (14). The voltammetric results coincide with the certificate value of 0.004 $\mu g\ L^{-1}$ derived from values obtained by a number of techniques. The main attribute of the present procedure is that the determination of Co(II) is direct and requires only a minimal sample pretreatment.

Due to the lack of a sample with a negligible Co(II) concentration, estimation of a detection limit based on repeated measurements of a blank signal was not possible. Instead, a detection limit was estimated from the peak current values obtained in the repeated measurements on 'clean' seawater samples. In each standard addition analysis, the measurements of the unspiked sample were made in triplicate and for the NASS-1 seawater, the sample standard deviation was ± 0.154 nA (3×5 values) corresponding to ± 0.58 ng L^{-1} and for the ICES-5 sample it was ± 0.90 nA (3×8 values) or ± 0.51 ng L^{-1}. The pooled sample standard deviation was ± 0.54 ng L^{-1}. Therefore, the detection limit for the analytical system ($3 \times$ SD) would be 1.6 ng L^{-1}. The Co(II) concentrations of the NASS-1, ICES-5, and Sandy Cove seawater samples were thus about twice the system detection limit value.

A multinuclear (^{13}C, ^{31}P, ^{77}Se, ^{125}Te, ^{199}Hg) magnetic resonance study of the adamantane-like clusters $[(\mu\text{-}ER)_6(HgE'PR'_3)_4]^{2+}$ (E = S, Se, Te; E′ = S, Se; R′ = Ph, c-C_6H_{11}) and the precursors $[Hg(E'PR'_3)_n]^{2+}$ [1-3]

PHILIP A. W. DEAN[4] AND VEERAGATHY MANIVANNAN
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received June 30, 1989

PHILIP A. W. DEAN and VEERAGATHY MANIVANNAN. Can. J. Chem. **68**, 214 (1990).

The cations $[Hg(E'PR'_3)_n]^{2+}$ (E′ = S or Se; R′ = c-C_6H_{11}, n = 2–4; R′ = Ph, n = 3 or 4) are obtained in solution from the new salts $[Hg(E'PR'_3)_n](ClO_4)_2$ (E′ = S or Se; n = 2, R′ = c-C_6H_{11}; n = 3, R′ = Ph) and their stoichiometric mixtures with $E'PR'_3$. They have been characterized at reduced temperature using multinuclear (^{13}C, ^{31}P, ^{77}Se (where appropriate), and ^{199}Hg) NMR. Cations of the type $[(\mu\text{-}ER)_6(HgE'PR'_3)_4]^{2+}$ (ER = S alkyl, SePh, or TePh, but not SPh), prepared cleanly in solution from $Hg(ER)_2$, $[Hg(E'PR'_3)_n](ClO_4)_2$, and $E'PR'_3$ in the correct stoichiometric ratio, have been characterized in the same manner, and shown to possess an adamantanoid structure. The product with ER = TePh, $E'PR'_3$ = $SPPh_3$ has been isolated analytically pure. These tetranuclear cations are the first discrete species containing the adamantanoid skeleton $(\mu\text{-}ER)_6(HgE')_4$ (E, E′ = chalcogen). At reduced temperature, inversion at E is slow on the NMR time scale for ER = TePh. Under these conditions, the TePh-bridged cations occur predominantly as an isomer of C_1 symmetry for $E'PR'_3$ = $SPPh_3$, $SPCy_3$, $SePPh_3$. However, the $SePCy_3$ analogue appears to exist as an equilibrium mixture of an isomer of C_1 symmetry and an isomer of C_3 symmetry. Ligand redistribution occurs in the binary system $[(\mu\text{-}SePh)_6(HgE'P(C_6H_{11})_3)_4]^{2+}$ (E′ = S or Se):$[(\mu\text{-}SePh)_6(HgPPh_3)_4]^{2+}$, giving equilibrium mixtures of $[(\mu\text{-}SePh)_6(HgPPh_3)_{4-n}(HgE'P(C_6H_{11})_3)_n]^{2+}$ for which the individual components have been fully characterized using NMR.

Key words: adamantanoid clusters, benzene chalcogenate, mercury(II), NMR, phosphine chalcogenide.

PHILIP A. W. DEAN et VEERAGATHY MANIVANNAN. Can. J. Chem. **68**, 214 (1990).

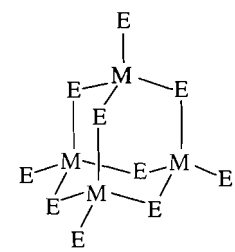
On a obtenu les cations $[Hg(E'PR'_3)_n]^{2+}$ (E′ = S ou Se; R′ = c-C_6H_{11}, n = 2–4; R′ = Ph, n = 3 ou 4) en solution en faisant réagir les nouveaux sels $[Hg(E'PR'_3)_n](ClO_4)_2$ (E′ = S ou Se; n = 2, R′ = c-C_6H_{11}; n = 3, R′ = Ph) ainsi que leurs mélanges stoechiométriques avec du $E'PR'_3$. On les a caractérisés à basse température en faisant appel à la RMN multinucléaire (^{13}C, ^{31}P, ^{77}Se (lorsqu'approprié) et ^{199}Hg). On peut préparer très proprement des solutions des cations du type $[(\mu\text{-}ER)_6[Hg(E'PR'_3)_4]^{2+}$ (ER = S-alkyle, SePh ou TePh, mais pas SPh) en faisant réagir des quantités stoechiométriques de $Hg(ER)_2$, de $[(Hg(E'PR'_3)_n](ClO_4)_2$ et de $E'PR'_3$, on les a caractérisés de la même manière et on a démontré qu'ils possèdent une structure adamantanoïde. On a isolé à l'état pur le composé dans lequel ER = TePh et $E'PR'_3$ = $SPPh_3$. Ces cations tétranucléaires constituent les premières espèces définies contenant le squelette adamantanoïde $(\mu\text{-}ER)_6(HgE')_4$(E, E′ = chalcogène). À basse température, lorsque ER = TePh, l'inversion au niveau de E est lente par rapport à l'échelle de temps de la RMN. Dans ces conditions, les cations dans lesquels $E'PR'_3$ = $SPPh_3$, SPCy, et SePPh, et qui comportent un pont TePh se présentent principalement sous la forme d'un isomère de symétrie C_1. Toutefois, l'analogue $SePCy_3$ semble exister sous la forme d'un équilibre entre deux isomères de symétrie respectives C_1 et C_3. Il se produit une redistribution de ligand dans les systèmes binaires $[(\mu\text{-}SePh)_6(HgE'P(C_6H_{11})_3)_4]^{2+}$ (E′ = S ou Se) : $[(\mu\text{-}SePh)_6(HgPPh_3)_4]^{2+}$, et elle conduit à des mélanges en équilibre des ions $[(\mu\text{-}SePh)_6(HgPPh_3)_{4-n}(HgE'P(C_6H_{11})_3)_n]^{2+}$ dont les composants individuels ont été complètement caractérisés par la RMN.

Mots clés : groupes adamantanoïde, benzene chalcogénate, mercure(II), RMN, phosphine chalcogénide.

[Traduit par la revue]

Introduction

In the zinc family, adamantanoid anions of the type $[(\mu\text{-}ER)_6(MER)_4]^{2-}$ are firmly established for M = Zn or Cd, E = S or Se (refs. 1–3, and unpublished work by P. A. W. Dean, J. J. Vittal, and N. C. Payne).[5] They have the skeleton **I**. Previous studies from this laboratory have dealt with the terminal substitution of these Zn_4 and Cd_4 species by halogens (3*b*, *c*, 4)[6] and pseudohalogens (3*c*) to give $[(\mu\text{-}ER)_6(MX)_4]^{2-}$. Attempts to synthesize analogous Hg(II) anions containing the $(\mu\text{-}ER)_6Hg_4$ core have so far been unfruitful (8). However, this



I

core has been shown to exist in the adamantanoid *cations* $[(\mu\text{-}ER)_6(HgL)_4]^{2+}$ (E = S or Se; L = tertiary phosphine or $AsPh_3$) (9), and very recently we have extended the series to include $[(\mu\text{-}TeR)_6(HgL)_4]^{2+}$ and $[(\mu\text{-}TePh)_6(Hg)(HgL)_3]^{2+}$ (L = PR'_3) (10). It seemed to us that, in the absence of $[(\mu\text{-}ER)_6(HgER)_4]^{2-}$, cationic species might provide an alternative way of investigating the properties of the $(\mu\text{-}ER)_6(HgE')_4$ skeleton (E, E′ = chalcogen). Accordingly we report here the results of a study of cations of the general type $[(\mu\text{-}ER)_6(HgE'PR'_3)_4]^{2+}$ (E′ = S or Se). These cations may possess a variety of spin-1/2

probe nuclei, making them favorable candidates for study by NMR: ^{13}C, ^{31}P, and ^{199}Hg are always present, and also the bridging E atoms may be ^{77}Se or ^{125}Te, while E′ may be ^{77}Se.[7]

Though many complexes of Hg(II) with phosphine chalcogenides are known (12), the compounds $[Hg(E'PR'_3)_n](ClO_4)_2$, containing monodentate $E'PR'_3$,[8] do not seem to have been described earlier. These salts are required in the synthesis of the title adamantanoid cations. Their synthesis and characterization in solution by the NMR method are included here.

In principle, four configurational isomers of $(\mu\text{-}ER)_6M_4$ are possible as a result of inversion at the pyramidal E atoms of the six μ-ER groups, two of C_3 symmetry and two of C_1 symmetry (4, 5). Examples of each of the possible isomers are known in the solid state (4, 5), but the cations containing the $(\mu\text{-}TeR)_4Hg_4$ cage (10) are the first species of this type for which it has been possible to detect preferential isomer formation in solution using NMR. The TeR-bridged cations included in the present work provide several further examples of this phenomenon.

Experimental

Materials

The ligands Ph_3PE and Cy_3PE (E = S or Se) were prepared as in earlier studies (14), as were $Hg(SR)_2$ (R = Et, *n*-Pr or Ph) and $Hg(SePh)_2$ (9) and $Hg(TePh)_2$ (10). Dimethyl diselenide (Strem) showed no significant impurities by NMR and was used as received, as were $Hg(ClO_4)_2\cdot 3H_2O$ and $AgClO_4$ (both from Strem). Following ref. 15, an attempt was made to synthesize $Hg(SeMe)_2$ by stirring Me_2Se_2 and Hg in benzene at room temperature. It was anticipated that pure $Hg(SeMe)_2$ would be yellow, like $Hg(SePh)_2$. However, the product was always dull green and apparently contaminated with finely dispersed Hg, and no satisfactory method of separation was found. Accordingly, the $Hg(SeMe)_2$ was used in its crude form.

For synthesis or preparation of NMR samples of the chalcogenate-bridged clusters, all solvents were dried over 3Å molecular sieves and thoroughly deoxygenated with Ar before use.

Carbon and hydrogen microanalyses were performed by Analytische Laboratorien, Gummersbach, West Germany and Guelph Chemical Laboratories, Guelph, Ontario.

Synthesis

CAUTION! While no problems have been experienced in the synthesis or handling of the perchlorate salts used in this work, such salts are known to represent an explosion hazard.

$[Hg(SPCy_3)_2](ClO_4)_2$

Initially $HgCl_2(SPCy_3)_2$ was prepared following the procedure described for $HgCl_2(PR_3)_2$ (16*a*). To a solution of $HgCl_2$ (0.669 g, 2.46 mmol) in 20 mL of Me_2CO was added a solution of $SPCy_3$ (1.55 g, 4.95 mmol) in 80 mL of Me_2CO. The mixture was reduced in volume and on cooling gave a white solid, which was separated by filtration and dried *in vacuo*, to give a yield of 1.6 g (72%). The chloride complex was converted to the ClO_4^- salt using $AgClO_4$ in exactly the same way used for various $Hg(PR_3)_2(ClO_4)_2$ (16*b*). After recrystallization from CH_2Cl_2/hexane, the yield of the white crystalline ClO_4^- complex (after recrystallization from CH_2Cl_2/hexane) was 1.1 g (66%). *Anal.* calcd. for $C_{36}H_{66}Cl_2HgO_8P_2S_2$ (*Mol.Wt.* 1024.49): C 42.21, H 6.49; found: C 42.40, H 6.43.

$[Hg(SePCy_3)_2](ClO_4)_2$

This compound was prepared in the same manner as the Cy_3PS analogue. $HgCl_2(SePCy_3)_2$ was isolated in 63% yield, then converted to the ClO_4^- salt in 86% yield. *Anal.* calcd. for $C_{36}H_{66}Cl_2HgO_8P_2Se_2$ (*Mol.Wt.* 1118.27): C 38.67, H 5.95; found: C 37.99, H 5.78.

$[Hg(SPPh_3)_3](ClO_4)_2$

Following the method used for $[Hg(dppmSe_2)_2](ClO_4)_2$ (13), this complex was synthesized by direct reaction of $Hg(ClO_4)_2$ and Ph_3PS. A mixture of $Hg(ClO_4)_2\cdot 3H_2O$ (0.54 g, 1.2 mmol) and Ph_3PS (1.1 g, 3.6 mmol)[9] in CH_2Cl_2 (60 mL) was stirred at room temperature, then warmed carefully on a steam bath until dissolution of the ClO_4^- salt was complete. The solution was filtered, then concentrated, at which point addition of hexane gave the crude material. The yield of the white crystalline product (after recrystallization from CH_2Cl_2/hexane) was 1.2 g (78%). *Anal.* calcd. for $C_{54}H_{45}Cl_2HgO_8P_3S_3$ (*Mol.Wt.* 1282.55): C 50.57, H 3.54; found: C 50.07, H 3.45.

$[Hg(SePPh_3)_3](ClO_4)_2$

The procedure was the same as that used for the sulfur analogue. The yield of the pale yellow crystalline product was 88%. *Anal.* calcd. for $C_{54}H_{45}Cl_2HgO_8P_3Se_3$ (*Mol.Wt.* 1423.25): C 45.57, H 3.19; found: C 44.61, H 3.43.

$[\mu\text{-}TePh)_6(HgSPPh_3)_4](ClO_4)_2$

Into a solution of $Hg(SPPh_3)_3(ClO_4)_2$ (0.19 g, 0.15 mmol) in 3 mL of CH_2Cl_2 at room temperature was stirred first solid $SPPh_3$ (0.045 g, 0.15 mmol), then solid $Hg(TePh)_2$ (0.27 g, 0.45 mmol). The mixture was stirred for 5 min, then filtered to remove traces of mercury. Onto the yellow filtrate was layered Et_2O (4 mL). Crystallization occurred on cooling to 5°C in the refrigerator. The yellow crystalline product was separated by decantation of the mother liquor, washed with Et_2O, and dried *in vacuo* to yield 0.30 g (58%). *Anal.* calcd. for $C_{108}H_{90}Cl_2Hg_4O_8P_4S_4Te_6$ (*Mol.Wt.* 3406.58): C 38.08, H 2.66; found: C 37.70, H 2.77.

Attempts to synthesize $[(\mu\text{-}SePh)_6(HgSPCy_3)_4](ClO_4)_2$ and $[(\mu\text{-}TePh)_6(HgSePCy_3)_4](ClO_4)_2$ in an essentially identical manner gave yellow and orange crystals, respectively. These products gave elemental analyses consistent with the formulation $[Hg_4(EPh)_6(E'PR'_3)_3](ClO_4)_2$. *Anal.* calcd. for $C_{90}H_{129}Cl_2Hg_4O_8P_3S_3Se_6$ (*Mol.Wt.* 2875.04): C 37.59, H 4.52; found: C 37.20, H 4.33. *Anal.* calcd. for $C_{90}H_{129}Cl_2Hg_4O_8P_3Se_3Te_6$ (*Mol.Wt.* 3307.58): C 32.68, H 3.93; found: C 32.72, H 3.70. In the absence of additional supporting evidence (see below) we regard these formulations as tentative.

Nuclear magnetic resonance spectra

All samples were prepared on the basis of (mass of solute/volume of solvent).

NMR spectra were measured and referenced as reported in earlier papers from this laboratory (3*c*, 10). For ^{13}C, ^{31}P, ^{77}Se, ^{125}Te, and ^{199}Hg NMR spectra, chemical shifts are quoted relative to internal TMS, external 85% H_3PO_4, external pure Me_2Se, external pure Me_2Te, and external pure Me_2Hg, respectively.

Results and discussion

The complexes $[Hg(E'PR'_3)_n]^{2+}$

Treatment of $HgCl_2(E'PCy_3)_2$ (E = S or Se) with $AgClO_4$ gave $[Hg(E'PCy_3)_2]^{2+}$ as the ClO_4^- salt. We were unable to synthesize the $E'PPh_3$ analogues by this route, but $[Hg(E'PPh_3)_3](ClO_4)_2$ results from the direct stoichiometric reaction of $E'PPh_3$ and $Hg(ClO_4)_2\cdot 3H_2O$.

The new cations were characterized in solution by ^{13}C, ^{31}P, ^{199}Hg, and (where appropriate) ^{77}Se NMR (Table 1). Stepwise addition of further $E'PR'_3$ causes formation of more highly ligated complexes up to $[Hg(E'PR'_3)_4]^{2+}$, and NMR data for these species are included in Table 1 also. For each of the complexes at reduced temperature, the ^{31}P NMR spectrum shows a singlet centreband with ^{199}Hg satellites due to $^2J(PHg)$. Under these conditions, the ^{31}P NMR spectra of the phosphine selenide complexes show the expected ^{77}Se satellites in addition

[7]The natural abundances of ^{13}C, ^{31}P, ^{77}Se, ^{125}Te, and ^{199}Hg are 1.108, 100, 7.58, 6.99, and 16.84% respectively; their relative receptivities, D^C, are 1, 3.77×10^2, 3.01, 12.7, and 5.57, respectively (11).

[8]The synthesis and ^{31}P, ^{77}Se, and ^{199}Hg NMR spectra of $[Hg(dppmSe_2)_2](ClO_4)_2$ have been given recently (13); the $dppmSe_2$ behaves in a bidentate manner.

[9]Use of $SPPh_3/Hg(ClO_4)_2 < 3$ also yields $[Hg(SPPh_3)_3](ClO_4)_2$ as the soluble product.

	4		63.7 (4.6)	−319.8[n] (149.3)	−1111	185	560 (−104)	36.60 (−0.04)	32 (−8)

[a]Concentration is 0.05 moles per litre of CH_2Cl_2 at room temperature.
[b]^{31}P, ^{77}Se, and ^{199}Hg NMR chemical shifts are quoted relative to 85% H_3PO_4, pure Me_2Se, and pure Me_2Hg at 295 K as external references (see experimental section), with estimated errors of ±0.1, ±0.5, and ±1 ppm or less. ^{13}C NMR chemical shifts are relative to internal TMS with estimated errors of ±0.02 ppm or less. Complexation changes, $\Delta X(X = \delta$ or $J)$, are relative to the free ligand property at the temperature of interest; $\Delta X = X_{complex} - X_{free\ ligand}$.
[c]Estimated error ±2 Hz, except as noted.
[d]Estimated error in ^1J is ±3 Hz.
[e]At 295 K.
[f]Estimated error in ^1J is ±1 Hz, except as noted.
[g]Estimated error ±3 Hz.
[h]^1J(HgSe) = 1270 ± 3 Hz.
[i]^1J(HgSe) = 1130 ± 3 Hz.
[j]Estimated error ±2 Hz.
[k]^1J(HgSe) = 1645 ± 5 Hz.
[l]Estimated error ±5 Hz.
[m]^1J(HgSe) = 1502 ± 4 Hz.
[n]^1J(HgSe) = 1308 ± 3 Hz.

to ^{199}Hg satellites, and the corresponding ^{77}Se NMR spectra are doublets (from ^1J(PSe)) with ^{199}Hg satellites (from ^1J(HgSe)). As a result of ^2J(PHg), the centrebands in the corresponding ^{199}Hg NMR spectra are triplets, quartets, and quintets for two, three, and four E'PR'$_3$ coordinated, respectively, with the SePR'$_3$ complexes showing ^{77}Se satellites from ^1J(HgSe). When the temperature is raised, the ^{199}Hg satellites collapse in the ^{31}P and ^{77}Se NMR spectra, as do the ^2J(HgP) coupling and ^{77}Se satellites in the ^{199}Hg NMR spectra, showing that intermolecular ligand exchange is occurring.

Full ^{13}C NMR data have been deposited.[10] Here we point out only those changes in the free ligand ^{13}C NMR spectra that indicate coordination, as these may be of general utility. As can be seen from the data in Table 1, complexation of $SPPh_3$ or $SePPh_3$ is associated with a marked deshielding of C_1 but negligible change in ^1J(PC), while complexation of $SPCy_3$ or $SePCy_3$ causes a negligible change in $\delta(C_1)$ but a marked reduction in ^1J(PC). For the phosphine selenides, coordination is at least as easily detected by the larger changes observed in ^1J(PSe) and δ_{Se} (see below). However, for the phosphine sulfides only a small change in δ_P may otherwise be available to show coordination. In this case the ^{13}C NMR spectral changes could provide the major evidence for ligation, though in the complexes of interest here the ^{199}Hg NMR spectra provide clear evidence for coordination.

Complexation of Ph_3PSe or Cy_3PSe causes a reduction in the magnitude of ^1J(PSe). At the same time, extensive deshielding of the ^{77}Se resonance occurs. Both of these effects have been observed in earlier NMR studies of phosphine selenide complexes (e.g., refs. 13, 14, 17–19 and references therein). In the series $[Hg(SePCy_3)_n]^{2+}$ (n = 2–4) it is worth noting that both $\Delta\delta_{Se}$ and Δ^1J(PSe) change close to linearly with n. A further point of interest is the remarkable similarity between the values of ^1J(PSe) in the various Hg(II) complexes and those in the analogous complexes of divalent Zn (19) and Cd (14*b*, *c*).

For analogous complexes, $[M(E'PR'_3)_n]^{2+}$, the range of the ^{199}Hg NMR chemical shifts is close to four times that of the ^{113}Cd NMR chemical shifts found (20) for the Cd(II) analogues. More normally this ratio is smaller (21). Particularly unusual is the reversal of chemical shifts found for the complexes $[M(SePCy_3)_n]^{2+}$ (n = 3 or 4). Whereas the ^{113}Cd chemical shifts are $\delta_{4:1} > \delta_{3:1}$, the ^{199}Hg NMR shifts are in the reverse order.[11]

The values of ^2J(PHg) given in Table 1 are ca. 3.5 times larger than the values of ^2J(PCd) found (14*b*, *c*) for the Cd(II) analogues. Grim *et al.* (17) observed a similar ratio for $(n\text{-}Bu_3PSe)_2MBr_2$ (M = Cd or Hg). The ratio seems to indicate a substantial Fermi Contact component for ^2J: we note that for the ground state atoms $|\Psi_{ns}(0)Hg|^2/|\Psi_{ns}(0)Cd|^2$ is ca. 3.3 after relativistic correction (22).

The complexes $[(\mu)\text{-}ER)_3(HgE'PR'_3)_4]^{2+}$

These complexes can be prepared in solution in CH_2Cl_2 according to eq. [1]. This reaction is the exact analogue of that used earlier to prepare $[(\mu\text{-}ER)_6(HgL)_4]^{2+}$ (E = S or Se, L = PR'$_3$ or $AsPh_3$; E = Te, L = PR'$_3$) (9, 10). In the case of ER = SeMe, SePh, and TePh, reaction was indicated by dissolution of the poorly soluble $Hg(ER)_2$. With the four ligands used here (E' = S or Se, R' = Ph or Cy) no dissolution was observed for ER =

[a]Concentration 0.05 moles of Hg_4 per litre of CH_2Cl_2 at room temperature.
[b]^{31}P, ^{77}Se, and ^{199}Hg NMR chemical shifts are quoted relative to 85% H_3PO_4, pure Me_2Se, and pure Me_2Hg at 295 K as external references (see experimental section), with estimated errors of ±0.1, ±0.5, and ±1.5 ppm or less. Complexation changes, ΔX ($X = \delta$ or J), are relative to the free ligand properties at the temperature of interest; $\Delta X = X_{complex} - X_{free\ ligand}$.
[c]Measured in the ^{31}P NMR spectrum.
[d]Estimated error ±2 Hz or less, unless noted otherwise.
[e]Estimated error ±3 Hz or less.
[f]Measured in the ^{77}Se NMR spectrum.
[g]Not observed.
[h]For *Se*PR'$_3$.
[i]At 178 K; not observed at 213 K; estimated error ±3 Hz.
[j]For bridging *Se*R.

SPh. The solubility of $Hg(SPh)_2$ is not significantly increased in the 3:1:(4 − n) mixture required for eq. [1], and we could obtain no evidence for $[(\mu\text{-SPh})_6(HgE'PR'_3)_4]^{2+}$. The thiolates $Hg(SR)_2$(R = Et or *n*-Pr) are quite soluble in CH_2Cl_2 at room temperature, but not at reduced temperature. In these two cases, reaction is shown by enhanced solubility of $Hg(SR)_2$ at reduced temperatures. At the concentration used for NMR (0.05 mol/L of CH_2Cl_2) the colours of the solutions are colourless (with SPR'$_3$) to pale yellow (with SePR'$_3$) for the μ-SEt and μ-SPr^n complexes. For both SPR'$_3$ and SePR'$_3$ as terminal ligands, the solutions are yellow for the μ-SeMe and μ-SePh complexes, and yellowish orange for the μ-TePh complexes.

[1] $3Hg(ER)_2 + [Hg(E'PR'_3)_n](ClO_4)_2 + (4 - n)\ E'PR'_3 \rightarrow [(\mu\text{-ER})_6(HgE'PR'_3)_4](ClO_4)_2$

Using multinuclear NMR, a total of 15 new adamantanoid complexes were characterized in solution (ER = SPr^n, SePh, or TePh, E' = S or Se, R' = Ph or Cy; ER = SEt, E' = S or Se, R' = Cy; ER = SeMe, E' = S, R' = Cy). All of these complexes except $[(\mu\text{-SeMe})_6(HgSPCy_3)_4]^{2+}$ were formed cleanly (≥95%) in solution. The ^{31}P spectrum of the μ-SeMe complex contained broad unidentified resonances, but the ^{77}Se and ^{199}Hg NMR spectra showed no extra resonances. We attribute this problem to the absence of pure $Hg(SeMe)_2$ (see Experimental). Selected NMR data for RS- and RSe-bridged clusters are given in Table 2. Table 3 contains data for PhTe-bridged species. The various NMR data are discussed below.

The μ-SePh complexes with SePR'$_3$ showed significant decomposition on standing at or around room temperature, with the formation of red selenium. Most of the SPR'$_3$ complexes seem to be fragile also, but we were able to isolate the salt $[(\mu\text{-TePh})_6(HgSPPh_3)_4](ClO_4)_2$ analytically pure. To our surprise, attempts to isolate $[(\mu\text{-ER})_6(HgE'PR'_3)_4](ClO_4)_2$ with ER = SePh, E'PR'$_3$ = $SPCy_3$ and ER = TePh, E'PR'$_3$ = $SePCy_3$ gave compounds analyzing for $[(\mu\text{-ER})_6(HgE'PR'_3)_3Hg](ClO_4)_2$, for which there is precedent in $[(\mu\text{-TePh})_6(HgPAr_3)_3Hg](ClO_4)_2$ (10). NMR studies of these compounds in solution gave no evidence for $[(\mu\text{-ER})_6(HgE'PR'_3)_3(Hg)]^{2+}$, however; the major component of these solutions was $[(\mu\text{-ER})_6(HgE'PR'_3)_4]^{2+}$. Accordingly we regard their formulations as tentative.

(i) E = Se

The existence of $[(\mu\text{-SePh})_6(HgSePCy_3)_4]^{2+}$ in solution at reduced temperature is evident from a combination of ^{31}P, ^{77}Se, and ^{199}Hg NMR (see Fig. 1 and Table 2). In the ^{31}P NMR spectrum (Fig. 1a) the magnitude of ^1J(PSe) is reduced from the free ligand value, as normally found for coordinated SePR'$_3$ (see above), and in addition a two-bond coupling to ^{199}Hg is observed. The ^{77}Se NMR spectrum contains signals in two regions (Fig. 1b). The singlet from *Se*Ph is in the same general region as for SePh in $[(SePh)_6(HgPR'_3)_4]^{2+}$ (9, 10), and has ^{199}Hg satellites with ^1J(HgSe) comparable to the PR'$_3$ clusters (9, 10). The signal from *Se*PCy$_3$ is a doublet, from ^1J(PSe), less shielded than that of free $SePCy_3$, as expected (see above). A one-bound coupling to ^{199}Hg is observed, which is larger than the coupling to SePh but smaller than the values found for $[Hg(SePCy_3)_4]^{2+}$ (Table 1). The ^{199}Hg NMR spectrum is a doublet, from ^2J(PHg), showing the presence of one $SePCy_3$ per mercury (Fig. 1c). The ^{199}Hg NMR signal is more shielded than those of $[(\mu\text{-SePh})_6(HgPAr_3)_4]^{2+}$ (9, 10) but less shielded than $Hg(SePh)_2$ itself (9). An increase in σ_{Hg} relative to $[(\mu\text{-SePh})_6(HgPAr_3)_4]^{2+}$ is expected from the ^{199}Hg NMR chemical shifts of, say, $[Hg(SePCy_3)_4]^{2+}$ vs. $[Hg(PAr_3)_4]^{2+}$ ($\delta_{Hg}([Hg(SePCy_3)_4]^{2+}) < \delta_{Hg}([Hg(PAr_3)_4]^{2+})$ (Table 1 and ref. 16*b*)), if substituent effects on the $(\mu\text{-SePh})_3HgL$ kernel of the clusters are approximately additive. Selenium-77 satellites

[a]Concentration 0.05 moles of Hg_4 per litre of CH_2Cl_2 at room temperature; ^{31}P, ^{77}Se, ^{199}Hg, and ^{125}Te NMR chemical shifts are quoted relative to 85% H_3PO_4, pure Me_2Se, pure Me_2Hg, and pure Me_2Te at 295 K as external references (see experimental section) with estimated errors of ±0.1, ±0.5, ±1.5, and ±2 ppm or less, except as noted.

[b]Where multiple resonances are observed, the correlation between ^{31}P, ^{77}Se, ^{125}Te, and ^{199}Hg resonances is not known.

[c]See text.

[d]Measured in the ^{31}P NMR spectrum, except as noted; estimated errors ±3 Hz or less, except as noted.

[e]As measured in the ^{125}Te NMR spectrum; estimated errors ±50 Hz or less, except as noted.

[f]Probably a C_1 isomer (see text).

[g]At 193 K six approximately equally intense ^{125}Te NMR signals are observed: $\delta_{Te}(^1J(HgTe))$ = −252(3560 ± 75), −166(3180 ± 75), −161(3050 ± 75), −147(3160 ± 75), −145(3200 ± 75), −141(3150 ± 100). At this temperature two ^{31}P NMR signals (δ_P = 42.4, 45.4) and three ^{199}Hg signals (δ_{Hg} = −1248, −1240, −1120, approximate relative intensities 1,1, and 2) are seen.

[h]Relative intensity ≈1.

[i]Not observed.

[j]Relative intensity ≈3.

[k]Too broad to be observed.

[l]In order of decreasing ^{77}Se shielding, ^1J(PSe) and approximate relative intensity = 644 ± 15 and 2, 624 ± 10 and 1, 644 ± 10 Hz and 2.

[m]Estimated error ±100 Hz.

[n]Estimated error ±6 Hz.

[o]Relative intensity ≈2.

[p]Broad resonance: probable signal overlap.

[q]This sample decomposes at 295 K.

[r]At 173 K.

[s]Possibly a mixture of a C_1 isomer and a C_3 isomer (see text).

[t]Tentatively assigned to a C_3 isomer.

[u]Estimated error ±2 ppm.

[v]^1J(PSe) ≈600 Hz.

[w]Tentatively assigned to a C_1 isomer.

[x]^1J(PSe) ≈640 Hz.

[y]Could not be measured with certainty.

are expected in the ^{199}Hg NMR spectrum, with coupling to both *Se*PCy$_3$ and *Se*Ph, but these are weak and somewhat broad and consequently it is easier to measure the values of ^1J(HgSe) in the ^{77}Se NMR spectrum.

The NMR data for $[(\mu\text{-SePh})_6(HgSePCy_3)_4]^{2+}$ at reduced temperature show that the cation has the adamantane-like structure. The NMR spectra are simpler than expected for the static C_1 or C_3 symmetries that are possible for $(\mu\text{-ER})_6M_4$ (see Introduction) showing that inversion at the bridging selenium atom is rapid on the NMR time scale. Further confirmation of the proposed formulation was obtained by observing the number of species in $[(\mu\text{-SePh})_6(HgSePCy_3)_4]^{2+}$:$[(\mu\text{-SePh})_6(HgPPh_3)_4]^{2+}$ mixtures. The PPh_3 complex has been characterized unambiguously by NMR in earlier work (9). In the mixtures a total of five species occur. This is just as expected for redistribution of terminal ligands between the two tetranuclear clusters, thereby confirming the formulation of the $SePCy_3$ species. The ^{31}P, ^{77}Se, and ^{199}Hg NMR spectra of

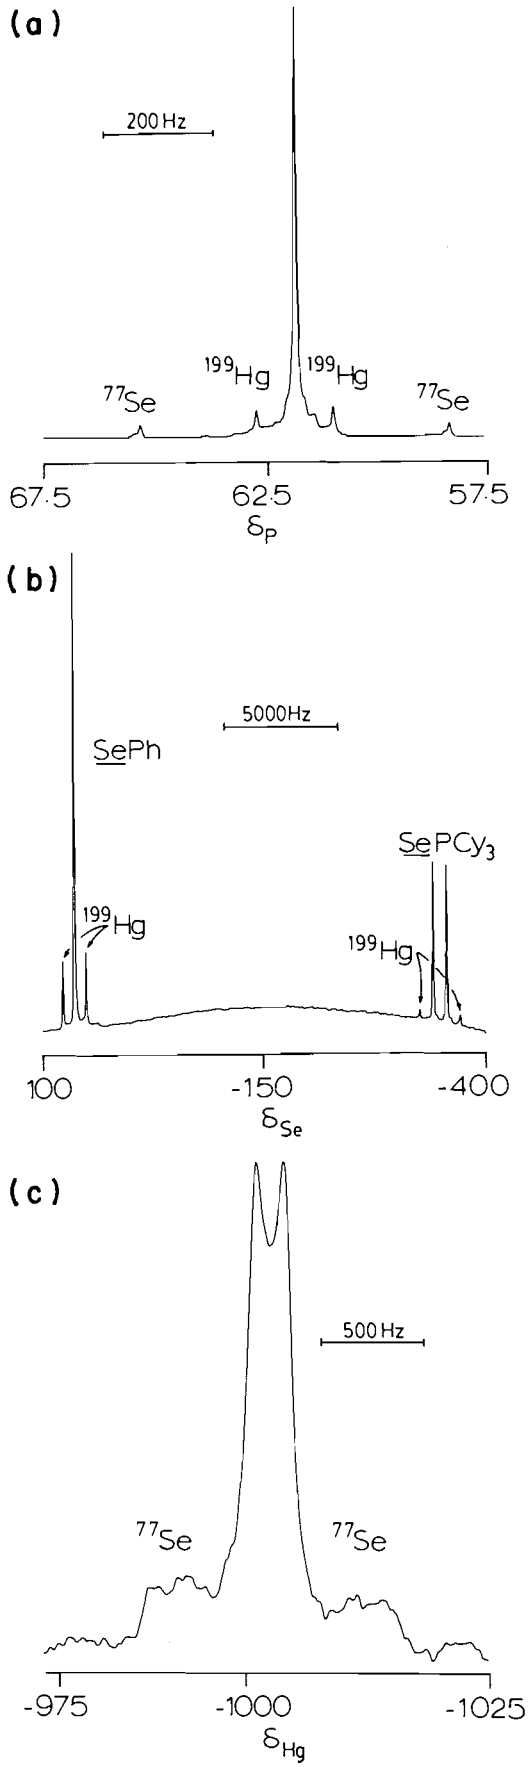

FIG. 1. NMR spectra of $[(\mu\text{-SePh})_6(HgSePCy_3)_4]^{2+}$ in CH_2Cl_2 at 213 K: (a) 80.98 MHz ^{31}P; (b) 38.15 MHz ^{77}Se; (c) 35.75 MHz ^{199}Hg.

$[(SePh)_6(HgPPh_3)_{4-n}(SePCy_3)_n]^{2+}$ can be analyzed straightforwardly and the results are included in Table 4. The ^{31}P and ^{77}Se NMR spectra of a mixture with n = 2(ave) have been deposited.[10]

When the temperature of $[(\mu\text{-SePh})_6(HgSePCy_3)_4]^{2+}$ is raised from 213 K, the two-bond P–Hg coupling collapses by ca. 238 K and both one-bond Hg–Se couplings collapse by ca. 243 K. Cleavage of both types of Hg–Se bonds must be rapid on the ^2J and ^1J time scales by 243 K. We note that both ^{77}Se resonances become less shielded as the temperature is raised. Decomposition to red Se starts to occur at ca. 273 K.

The various NMR spectra of $[(\mu\text{-SePh})_6(HgSePPh_3)_4]^{2+}$ at 178 K resemble closely those of the $SePCy_3$ cluster at 213 K. They can be analyzed similarly in terms of an adamantanoid skeleton with rapid inversion at μ-Se, and the results are given in Table 2. In the $SePPh_3$ complex ^2J(PHg) is collapsed by ca. 213 K, showing that the intermolecular ligand exchange is faster than for the $SePCy_3$ analogue. By 233 K, the *Se*PPh_3 doublet in the ^{77}Se NMR spectrum is broad. The *Se*Ph signal still shows ^{199}Hg satellites, but these too are collapsed by ca. 253 K.

The reduced temperature ^{31}P, ^{77}Se, and ^{199}Hg NMR spectra of $[(SePh)_6(HgSPR'_3)_4]^{2+}$ (R′ = Ph or Cy) show sufficient features in common with their $SePR'_3$ analogues that they can also be assigned the same (time-averaged) structure. Details of the spectra are included in Table 2. In the SPR'_3 complexes σ_{Hg} is less than in the corresponding $SePR'_3$ complexes, as it is in mononuclear $[Hg(E'PR'_3)_n]^{2+}$ also (Table 1). The coupling ^2J(PHg) could not be observed for $[(\mu\text{-SePh})_6(HgSPPh_3)_4]^{2+}$ at any temperature. In the $SPCy_3$ analogue this coupling is observed but it has collapsed by ca. 253. In both cases ^1J(HgSe) is observed up to ca. 273 K. For $[(\mu\text{-SePh})_6(HgSPCy_3)_4]^{2+}$, tetranuclearity is confirmed by the occurrence of a total of five species in $[(\mu\text{-SePh})_6(HgSPCy_3)_4]^{2+}$:$[(\mu\text{-SePh})_6(HgPPh_3)_4]^{2+}$ mixtures. The NMR spectra of $[(\mu\text{-SePh})_6(HgPPh_3)_{4-n}(HgSPCy_3)_n]^{2+}$ are summarized in Table 4.

The ^{31}P NMR spectrum of $[(\mu\text{-SeMe})_6(HgSPCy_3)_4]^{2+}$ at 213 K is a singlet with ^{199}Hg satellites from ^2J(PHg). The ^{199}Hg NMR spectrum shows the doublet splitting expected for one terminal ligand. In the ^{77}Se NMR spectrum, the signal from μ-SeMe is less shielded than found for the μ-SePh clusters described above, occurring close to the region ascribed to μ-SeMe in $[(\mu\text{-SePh})_{6-x}(\mu\text{-SeMe})_x(ZnI)_4]^{2-}$ (3*b*). The μ-SeMe signal shows ^{199}Hg satellites, with ^1J(HgSe) comparable to that of the μ-SePh complexes. Clearly the μ-SeMe species has the adamantane-like structure, and again the comparative simplicity of the NMR spectra are explicable in terms of rapid inversion at μ-SeMe.

(ii) E = S

A complete series of complexes $[(\mu\text{-SR})_6(HgE'PR'_3)_4]^{2+}$ was characterized with the stereotypical alkanethiolate PrS^-, and in addition the complexes $[(\mu\text{-SEt})_6(HgE'PCy_3)_4]^{2+}$ (E′ = S or Se) were examined. Details of the various NMR spectra are given in Table 2.

Except for the absence of a signal from the bridging group in their ^{77}Se NMR spectra, the various low temperature NMR spectra of $[(\mu\text{-SPr})_6(HgSePR'_3)_4]^{2+}$ (R′ = Ph or Cy) show the same features as do the RSe-bridged analogues (Table 2 and discussion above). Evidently the cations have the same (time-averaged) structure. This conclusion can be drawn for $[(\mu\text{-SEt})_6(HgSePCy_3)_4]^{2+}$ also. Mercury-199 is less shielded in the μ-SPr complexes than in the corresponding μ-SePh species, as expected from earlier results for $[(\mu\text{-ER})_6(PR'_3)_4]^{2+}$ (9).

TABLE 4. NMR spectra of the complexes $[(\mu\text{-SePh})_6(HgPPh_3)_{4-n}(HgL)_n]^{2+}$ (L = $SPCy_3$ or $SePCy_3$) in CH_2Cl_2 at 213 K[a]

[s]In all the complexes $\delta_P(SePCy_3) = 61.9$, $^2J(PSeHg) = 148 \pm 2$ Hz, $^1J(PSe) = 562 \pm 2$ Hz.
[t]$2(^2J(PSe)) + {}^4J(PSe) \approx 2(^2J(PSe)) \approx 56$ Hz.
[u]Values given in parentheses are for $SePCy_3$.
[v]$^2J(PSe) = 33 \pm 3$ Hz.
[w]$^2J(PSe) = 23 \pm 3$ Hz.

The $^2J(PHg)$ coupling found in the NMR spectra of $[(\mu\text{-SPr})_6(HgSePR'_3)_4]^{2+}$ at 178 K has collapsed by ca. 213 K showing the occurrence of intermolecular exchange of $SePR'_3$. The ^{77}Se resonances broaden and become less shielded as the temperature is raised. This change is particularly large for the $SePCy_3$ complex for which δ_{Se} changes from −381 to −329 as the temperature is changed from 178 K to 298 K. A chemical shift of −329 ppm is close to that of $Hg(SePCy_3)_4]^{2+}$ (−320 ppm (Table 1)). This might be taken to indicate dissociation of $[(\mu\text{-SPr})_6(HgSePCy_3)_4]^{2+}$ to $Hg(SPr)_2$ and $[Hg(SePCy_3)_4]^{2+}$ at 298 K. However, on the basis of ^{13}C NMR spectra in the aliphatic region (Table 5) the extent of dissociation to give free $Hg(SPr)_2$ appears to be slight for any of the μ-SPr species. The ^{13}C NMR spectra of the complexes do not change a great deal from low to ambient probe temperature and are at all times quite distinct from the spectrum of $Hg(SPr)_2$. For comparison, Table 5 includes data for $[(\mu\text{-SPr})_6(HgPPh_3)_4](ClO_4)_2$ and $[(\mu\text{-SPr})_6(HgPPh_3)_4](O_2CCF_3)_2$. Both these salts contain undissociated $[(\mu\text{-SPr})_6(HgPPh_3)_4]^{2+}$ at 213 K. At ambient probe temperature this cation persists as the ClO_4^- salt, but as the $CF_3CO_2^-$ salt is extensively dissociated to $Hg(SPr)_2$ and $[Hg(PPh_3)_4]^{2+}$ (9).

Less NMR information is available for $[(\mu\text{-SPr})_6(HgSPR'_3)_4]^{2+}$ than for other complexes included in this study. Nevertheless, the similarity between the ^{13}C NMR spectra of $[(\mu\text{-SPr})_6(HgSPR'_3)_4]^{2+}$ and $[(\mu\text{-SPr})_6(HgSePR'_3)_4]^{2+}$ (Table 5), and a comparison of the pattern of ^{199}Hg chemical shifts for the series $[(\mu\text{-SPr})_6(HgE'PR'_3)_4]^{2+}$ and $[(\mu\text{-SePh})_6(HgE'PR'_3)_4]^{2+}$ (Table 2), leave little doubt that $[(\mu\text{-SPr})_6(HgSPR'_3)_4]^{2+}$ is the correct formulation.

(iii) E = Te

The complexes $[(\mu\text{-TePh})_6(HgE'PR'_3)_4]^{2+}$ show much more complicated NMR spectral behaviour at reduced temperature than do their S- and Se-bridged analogues. This additional complexity can be accounted for in terms of slow inversion at the bridging tellurium, a phenomenon we have demonstrated recently for $[(\mu\text{-TeR})_6(HgPR'_3)_4]^{2+}$ and $[(\mu\text{-TePh})_6(HgPAr_3)_3(Hg)]^{2+}$ (10). When inversion at Te is slow on the NMR time scale, separate NMR spectra can be observed for

the isomer(s) (see Introduction) occurring in the equilibrium mixture. In the slow exchange limit, each of the two isomers of C_1 symmetry should give rise to four ^{31}P NMR signals, four ^{199}Hg NMR signals, and six ^{125}Te NMR signals, while the corresponding numbers for each of the isomers of C_3 symmetry are two (relative intensities 3 and 1), two (relative intensities 3 and 1), and two (relative intensities 3 and 3) (10). It is possible for the spectra of any of these isomers to be simplified by intra- and (or) inter-molecular exchange, e.g., ref. 10.

Figures 2a and b show that ^{31}P and ^{199}Hg NMR spectra of $[(\mu\text{-}TePh)_6(HgSPCy_3)_4]^{2+}$ at 173 and 178 K (the temperatures of best resolution), respectively. The ^{31}P spectrum shows four major centreband signals, with ^{199}Hg satellites.[12] Four major signals are seen in the ^{199}Hg NMR spectrum also, three of them with clear $^2J(PHg)$ coupling. Evidently the cation exists predominantly as one C_1 isomer under these conditions. In the ^{125}Te NMR spectrum at 178 K (Fig. 2c) there are five signals covering the range δ_{Te} −76 to −269, with ^{199}Hg satellites. Six ^{125}Te NMR signals are expected for a C_1 isomer, but one of the observed resonances (δ_{Te} −148) is comparatively broad, indicating probable partial overlap of two signals. The ^{125}Te NMR spectrum collapses as the temperature is raised until, at temperatures above 253 K, only a single ^{125}Te resonance with one pair of ^{199}Hg satellites is found. Above 253 K, inversion at Te must be rapid on the time scale of δ_{Te}. The ^{199}Hg NMR spectrum broadens also as the temperature is raised. In this case site exchange must still be occurring at an intermediate rate at 295 K, since the ^{199}Hg resonance is unobservably broad at this

[12]The small signal at δ_P = 62.8 may indicate the presence of a minor isomer.

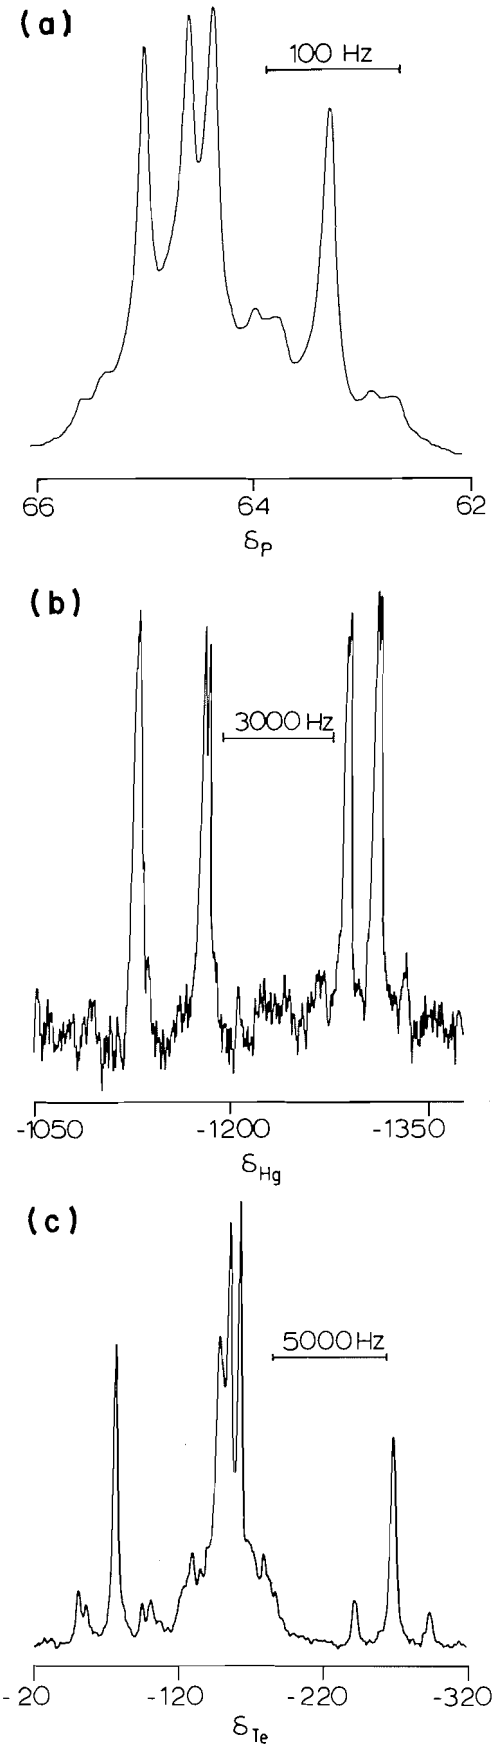

FIG. 2. NMR spectra of $[(\mu\text{-}TePh)_6(HgSPCy_3)_4]^{2+}$ in CH_2Cl_2: (a) 80.98 MHz ^{31}P at 173 K; (b) 35.75 MHz ^{199}Hg at 178 K; (c) 63.14 MHz ^{125}Te at 178 K.

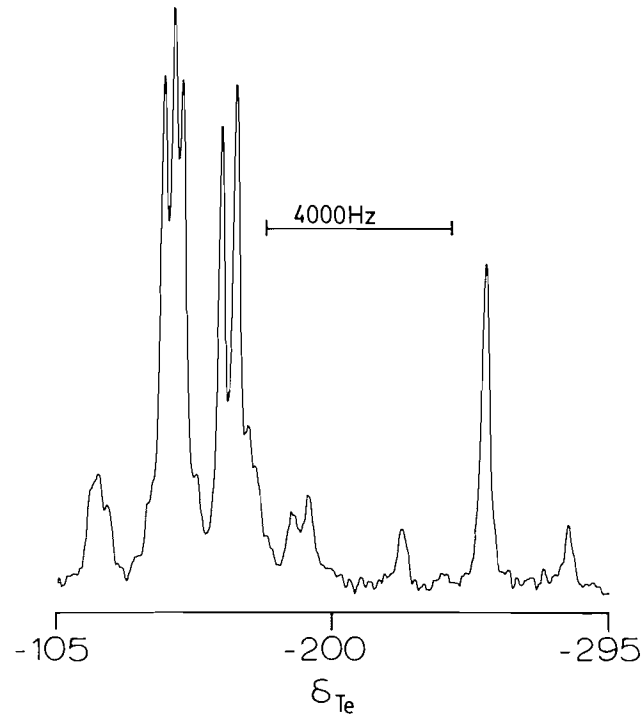

FIG. 3. 63.14 MHz ^{125}Te NMR spectrum of $[(\mu\text{-TePh})_6(HgSPPh_3)_4]^{2+}$ in CH_2Cl_2 at 193 K.

temperature. The ^{31}P NMR spectrum collapses to a singlet with no ^{199}Hg satellites around 213 K, indicating the occurrence of rapid intermolecular exchange of $SPCy_3$. The NMR spectra of $[(\mu\text{-TePh})_6(HgSPCy_3)_4]^{2+}$ are summarized in Table 3.

The NMR spectroscopic behaviour of $[(\mu\text{-TePh})_6(HgSPPh_3)_4]^{2+}$ is generally very similar to that of the $SPCy_3$ analogue, and the analysis is identical. An important difference is the observation of six clear resonances in the ^{125}Te NMR spectrum at 193 K, as shown in Fig. 3. This spectrum provides strong evidence for an adamantanoid cation of C_1 symmetry. At 178 K, the three highest frequency ^{125}Te NMR signals overlap. However, the ^{31}P and ^{199}Hg NMR spectra at 178 K are consistent with C_1 symmetry: both show four major resonances. As the temperature is raised, the spectra of the $SPPh_3$ cluster collapse in essentially the same manner described for the SPCy complex. Representative NMR data for the $SPPh_3$ cation are included in Table 3.

The ^{31}P NMR spectrum of $[(\mu\text{-TePh})_6(HgSePPh_3)_4]^{2+}$ at 178 K shows four resonances, as expected for a species of C_1 symmetry. The corresponding ^{125}Te and ^{199}Hg NMR spectra of $[(\mu\text{-TePh})_6(HgSePPh_3)_4]^{2+}$ are also consistent with this symmetry, though three of the expected six ^{125}Te resonances overlap (cf. for the $SPPh_3$ complex at 178 K), as do two of the expected four ^{199}Hg signals. For C_1 symmetry, four different doublets (from ^1J(PSe)) are expected in the ^{77}Se NMR spectrum also. In fact, three are found, one approximately twice as intense as the other two. Clearly two of the expected resonances are isochronous. Table 3 shows NMR data for this complex. As can be seen from the data given, the multiple ^{31}P and ^{125}Te signals collapse to singlets, with and without ^{199}Hg satellites, respectively, as the temperature is raised. Similarly, the three doublets of the low temperature ^{77}Se NMR spectrum are reduced to a single doublet. The ^{199}Hg NMR spectrum is unobservably broad at 233 K (above which decomposition becomes apparent). Once more, fast Te inversion and intermolecular exchange of the terminal ligands must be occurring.

The NMR spectra of $[(\mu\text{-TePh})_6(HgSePCy_3)_4]^{2+}$ are more complicated than those of the μ-TePh complexes already discussed. Typical NMR results are given in Table 3. At 178 K, the ^{77}Se NMR spectrum contains only two doublets (from ^1J(PSe)). These are broad, almost certainly as a result of signal overlap. The corresponding ^{31}P, ^{125}Te, and ^{199}Hg NMR spectra contain six, eight, and five resonances, respectively. Such results are inconsistent with the presence of any single isomer (see above) or with a mixture of the two C_3 isomers. The spectra are consistent with a mixture of a C_1 isomer and a C_3 isomer, and we have made tentative assignments on this basis, primarily from approximate relative intensities. Independent of the exact assignments, the ^{125}Te NMR spectrum shows that the population ratio C_1/C_3 is ca. 3. By 273 K, complete time-averaging occurs for all of the various nuclei. Above ca. 273 K, the complex is thermally unstable.

Characterization and spectroelectrochemical properties of a binuclear *trans,trans*-bis(ferrocenylidene)acetone $[(C_5H_5)Fe(C_5H_4CHCH)]_2CO$

PIERRE D. HARVEY[1] AND JEFF G. SHARMAN

Département de chimie, Université de Sherbrooke, Sherbrooke (Québec), Canada J1K 2R1

Received March 28, 1989

PIERRE D. HARVEY and JEFF G. SHARMAN. Can. J. Chem. **68**, 223 (1990).

The binuclear compound *trans,trans*-bis(ferrocenylidene)acetone $[(C_5H_5)Fe(C_5H_4CHCH)]_2CO$ (dFca) has been synthesized in quantitative yield and characterized by FT-IR, ^1H and ^{13}C NMR, and mass spectroscopy. Cyclic voltammetry and coulometry measurements suggest that a reversible two-electron oxidative process takes place at 0.68 V vs. SSCE. FT-IR and UV–VIS spectroelectrochemical analyses show that this oxidative process occurs at the ferrocenyl centers. The compound is also found to be emissive in the solid state (λ_{max} = 780 nm), and charge transfer assignments for the lowest singlet and triplet excited states are made.

Key words: ferrocenyl, spectroelectrochemistry, electronic charge transfer, emission spectroscopy.

PIERRE D. HARVEY et JEFF G. SHARMAN. Can. J. Chem. **68**, 223 (1990).

Le complexe binucléaire *trans,trans*-bis(ferrocenylidène)acétone $[(C_5H_5)Fe(C_5H_4CHCH)]_2CO$ (dFca) a été synthétisé avec un rendement quantitatif et a été caractérisé par FT-IR, ^1H et ^{13}C RMN et spectroscopie de masse. Les mesures de voltamétrie cyclique et de coulométrie suggèrent qu'un processus oxydatif réversible de deux électrons survient à 0,68 V vs. SSCE. Les analyses spectroélectrochimiques FT-IR et UV–VIS montrent que ces processus surviennent aux centres ferrocènyliques. Une émission (λ_{max} = 780 nm) pour le composé à l'état solide est montrée, et des attributions de type de transfert de charge sont données pour les états singulet et triplet de plus basse énergie.

Mots clés : ferrocenyl, spectroélectrochimie, transfert de charge électronique, spectroscopie d'émission.

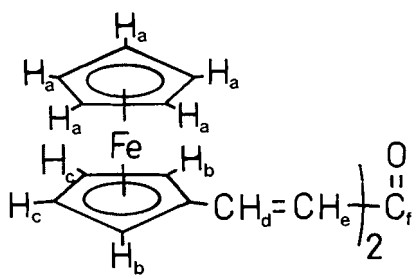
Introduction

The cross-conjugated diarylideneacetone ligands (Ar—CH=CH—(CO)—CH=CH—Ar) are capable of forming a few stable organometallic compounds both in the solid state and in solutions (1–9). In the non-complexed state, they generally exhibit rich photochemical (9–12), electrochemical (12–14), and photoluminescent properties (12).[2] Recent resonance Raman, UV–VIS, and emission spectroscopic investigations of the binuclear Pd(O)– and Pt(O)–dibenzylideneacetone complexes reveal the metal-to-ligand charge transfer (MLCT) character of the lowest singlet and triplet excited states (15). Further studies have shown that these binuclear compounds appear photochemically inert (12). We have undertaken the synthesis and study of a series of new diarylideneacetone ligands where the aryl groups are either photo- or electroactive in order to tune photoreactivity in organo-transition binuclear Pd(O) and Pt(O) complexes (12).

We wish to report our recent results on the newly synthesized electroactive *trans,trans*-bis(ferrocenylidene)acetone $[(C_5H_5)Fe(C_5H_4CHCH)]_2CO$ (dFca) (see structure in Scheme 1). We chose the ferrocene-based substituent (Fc), because ferrocene-centered oxidations should be reversible (16). There are many examples of spectroscopic property and reactivity changes induced in a metal center by reduction of a pendant redox-active substituent (17–19). In this paper, it is shown that inductive perturbation is indeed felt along the dienylketone moiety upon change of state of charge of the ferrocenes. The dFca compound also exhibits low-energy emission in the solid state, and appears to be reasonably photochemically stable.



SCHEME 1. Structure of dFca.

Experimental

Chemicals

Ferrocenealdehyde ($[(C_5H_5)Fe(C_5H_4CHO)]$) (Aldrich Chem. Co.) was used as received. Acetone, ethanol, methylene chloride, carbon tetrachloride (Anachemia), tetrahydrofuran (THF), and 2-methyltetrahydrofuran (2MeTHF; Aldrich Chem. Co.) were purified according to standard procedures (20, 21). The spectrograde solvents benzene, ethyl acetate, acetone, ethyl ether, and chloroform (Fisher) were used as received; purity was checked by UV–VIS spectroscopy. Chloroform-*d* and benzene-d_6 (Aldrich Chem. Co.) were also used as received. Tetra-*n*-butylammonium hexafluorophosphate (TBA(PF_6); Aldrich Chem. Co.) was recrystallized three times from ethanol, and tetraethylammonium perchlorate (TEAP) was prepared according to literature procedures (22).

Instruments

The ^1H and ^{13}C NMR spectra were obtained on a Bruker WM 250 spectrometer at room temperature; they were recorded with reference to the deuterium signal of $CDCl_3$ and they are reported with reference to TMS (see Table 1). The mass spectra were collected on a VG ZAB-1F spectrometer in EI mode at 70 eV. The FT-IR spectra were measured on a BOMEM DA 3.002 spectrometer. The UV–VIS data were acquired on a Perkin–Elmer Lambda 3B spectrophotometer. The emission spectra measurements were made on an Instruments SA Raman spectrometer equipped with a U-1000 Jobin–Yvon 1.0 m double monochromator using the 647.088 nm red line of a Spectra Physics krypton ion laser for excitation. A 200 W Rayonet photochemical reactor was used for the photolysis.

Electrochemistry

Electrochemical measurements were made with a PAR model 173 potentiostat, a model 175 voltage programmer, and a current follower model 176 and were recorded on a EG & G Princeton Research model RE 0089 X–Y recorder. Cyclic voltammograms were measured

in CH_2Cl_2/0.1 M TBA(PF_6) and in CH_3CN/0.1 M TEAP. Typically cyclic voltammograms were obtained at concentrations less than 1.5 mM. The Pt disk electrodes (0.5 mm diameter) were polished with alumina (0.3 μm size) for 15 min in distilled water before use. The experiments were done under an atmosphere of N_2(g) or Ar(g) and carried out using a Pt disk as working electrode, a tungsten wire as the reference electrode, and a mercury pool as the counter electrode. The three-electrode cell was equipped with a luggin capillary (in which the reference electrode was inserted) and IR compensation was applied. Coulometry measurements were performed in an H-cell with Pt gauze (1 cm × 1 cm) working and auxiliary electrodes under an atmosphere of Ar(g). The SSCE reference electrode in the bulk electrolysis experiments was filled with a 3% agar-agar solution (~0.5 m thickness) at the fritted junction to minimize solvent and water diffusion, and was inserted in the auxiliary electrode compartment. The coulometry setup was checked by measuring the number of electrons transferred during oxidation of ferrocene (1.0 e). The spectroelectrochemical IR cell was built from a conventional IR cell in which the Pt gauze working and auxiliary electrodes were in the same compartment, and an Ag wire was used as quasi-reference electrode in these experiments. The solution concentrations were typically 5 mM in the IR and UV–VIS experiments. In a typical experiment, the cell was purged with Ar(g), filled with solution, and the initial IR and UV–VIS spectra were measured. A cyclic voltammogram was recorded (100 mV/s) and the potential was held fixed at the potential at which the current was about one-half the peak current in the cyclic voltammogram. At the end of the electrolysis (~10 min) no further spectroscopic changes in the IR and UV–VIS spectra were observed. The IR and UV–VIS spectra were obtained and stored electronically. The difference spectra were obtained by subtracting the final spectrum from the initial one, and produce positive and negative components. The positive components correspond to the neutral species that disappear upon oxidation and the negative ones to the oxidized species appearing. Then the potential was moved ~0.6 V negative to regenerate the original species and the final IR and UV–VIS spectra were obtained. The difference spectrum is obtained by taking the last spectrum from the oxidation experiment as initial spectrum and the last spectrum from the subsequent reduction experiment, and by again making the mathematical subtraction. This time the positive components are the regenerated species (neutral) and the negative ones are oxidized species disappearing upon reduction.

Synthesis of [(C_5H_5)Fe(C_5H_4CHCH)]$_2$CO

To a cooled solution of 50 mL 1:1 ethanol/10% aqueous NaOH, a saturated ethanol solution containing 5 g (23.4 mmol) of [(C_5H_5)Fe(C_5H_4CHO)] and 0.87 mL of acetone (11.7 mmol) was added dropwise. After stirring the solution for 1 h, a red oil appeared, and was decanted. The oily residue was dissolved in a minimal amount of acetone and precipitated by adding water dropwise (precipitation occurred at a 1:1 addition ratio). The deep red solid was filtered and dried *in vacuo* (10^{-6} Torr; 1 Torr = 133.3 Pa). No trace of the sublimable [(C_5H_5)Fe(C_5H_4CHO)] was observed. The dried product provided 4.9 g (93% yield); mp >250°C. *Anal.* calcd. for $C_{25}H_{22}Fe_2O$: C 66.71, H 4.93, Fe 24.81%; found: C 66.35, H 4.85, Fe 25.27%. On some occasions, residual impurities were identified as the monocondensed ferrocenylideneacetone compound (Fc—CH=CH—$COCH_3$) (23) by comparison with ^{1}H NMR, IR, and UV–VIS data.

Results and discussion

Spectroscopic characterization

The synthesis proceeds via a double aldehyde–acetone condensation in the presence of a strong base such as the hydroxy anion. In stoichiometric amount, the reaction is conveniently quantitative, as shown in reaction [1]:

[1] $2FcCHO + CH_3COCH_3 \xrightarrow[H_2O/EtOH]{OH^-} \underset{(dFca)}{Fc—CH=CH—(CO)—CH=CH—Fc} + 2H_2O$

where Fc = (C_5H_5)Fe(C_5H_4). The deep red product is appreciably stable up to 250°C in the solid state. This new molecule contains three active parts: two electroactive groups (Fc), one spectroscopic IR probe (C=O), and two conjugated groups (CH=CH) providing the possibility of electronic density transfer via resonance structures between the Fc and CO groups.

[a]In $CDCl_3$ at 293 K, the chemical shifts are reported with reference to TMS (see Scheme 1 for nuclei labelling).

[b]In CCl_4 at 293 K, s = strong, m = medium, w = weak, v = very. The vibrational assignments are based upon reports in the literature (see, for example, ref. 25).

[c]The reported peaks are the eight dominating peaks of the spectra; Cp = C_5H_5.

The dFca complex was characterized by a combination of IR, UV–VIS, ^{1}H and ^{13}C NMR, and mass spectroscopies. Some relevant spectroscopic data are reported in Table 1. From the NMR data, the $^3J_{HH}$ values averaging 15.6 Hz clearly establish the *trans* geometry of the olefinic groups. Furthermore, the large ^{1}H and ^{13}C NMR chemical shifts associated with these vinylic groups and the unusually low ν(CO) suggest that large e$^-$-delocalization occurs along the Fc—CH=CH—C=O moieties. The FT-IR spectrum of dFca in CCl_4 is shown in Fig. 1. The 800–1500 cm^{-1} region is characteristic of an Fc group absorption (25), while the IR bands located in the 1500–1700 cm^{-1} region arise from the presence of the CH=C—(CO)—CH=CH moiety. The particularly intense IR band associated with the vinylic ν(C=C)'s implies that there is a significant dipole moment located at the vinylic centers, and is consistent with the large differences in chemical shifts

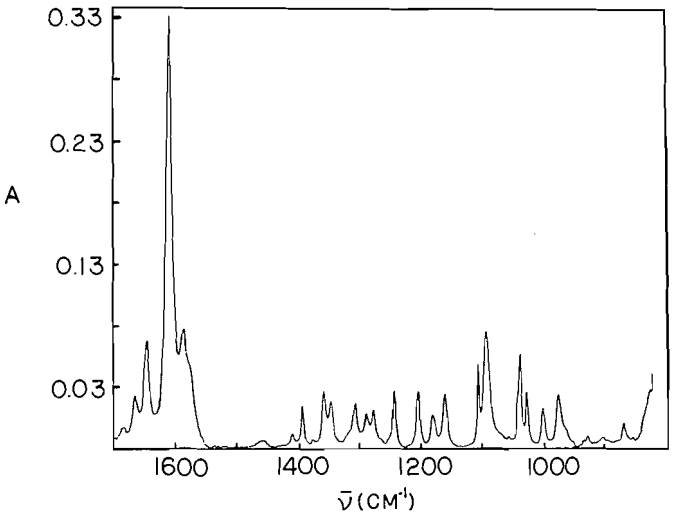

FIG. 1. FT-IR spectrum in the 800–1700 range of dFca in saturated CCl_4 solution at 293 K. Experimental conditions: 32 scans; 2 cm^{-1} resolution.

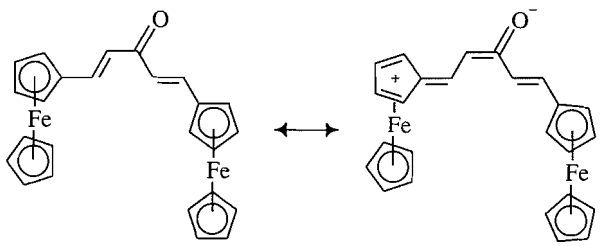
between the two C's (see details in Table 1). These spectroscopic observations show that the resonance structures play an important role in the postulated planarity of the biferrocenyl complex (see Scheme 2). There is no indication whether the Fc groups adopt the *cis* or *trans* geometry relative to each other.



SCHEME 2. Two possible resonance structures of dFca.

The mass spectra of dFca have been obtained and the data are reported in Table 1. Eight peaks dominate the spectra, from which five are assigned. Attempts to obtain Raman data failed uniformly.

Spectroelectrochemistry

The cyclic voltammogram (cv) of 1.3 mmol dFca in CH_3CN containing 0.1 M TEAP is shown in Fig. 2. There is a quasi-reversible electrochemical oxidation process at 0.53 V vs. tungsten wire (ip, c/ip, a = 1.0). In a CH_2Cl_2 solution containing 0.1 M TBA(PF_6) this oxidation process occurs at 0.68 V vs. SSCE. No other redox process takes place between 0.68 and 2.00 V vs. SSCE. The key feature of the CV results is that with sweep rate of 100 mV/s, the ΔEp is 96 mV. At 20 and 50 mV/s, ΔEp is still 96 mV. This ΔEp independence with the scan rate is unusual and two hypotheses are given: first, dFca adsorption at the surface of the electrode can produce such behavior; second, the possibility that two one-electron processes (see the coulometry results below) occurring at very close potentials is also considered. No further experiment was attempted to elucidate the exact nature of this phenomenon. Nevertheless, from a plot of the peak current vs. the square of the scan rate, the linearity of the slope suggests that the redox processes are diffusion controlled. Coulometric measurements suggest that a 1.9-e^- oxidation process takes place at 0.68 V vs. SSCE. Typically, when ferrocene is oxidized to ferrocenium, a

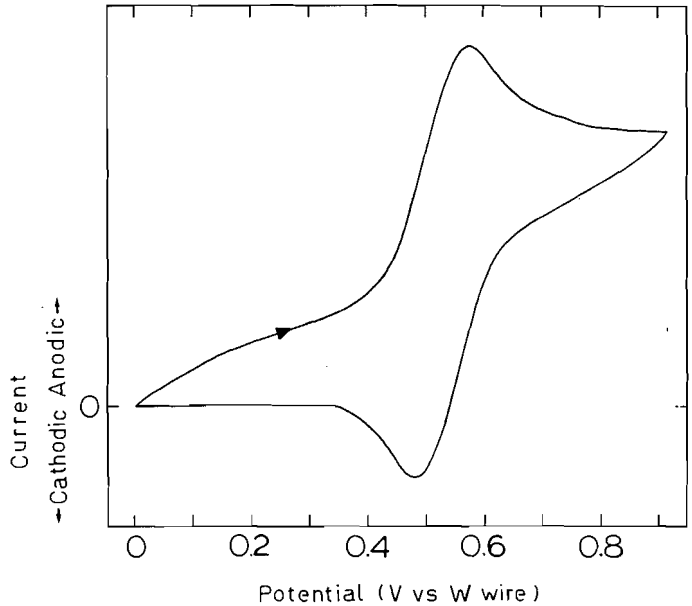


FIG. 2. Cyclic voltammograms for dFca measured at 100 mV/s in CH_3CN/0.1 M TEAP at a Pt electrode at 293 K.

new UV band located at 617 nm, with ε being 450 M^{-1} cm^{-1}, appears (24). Complete electrooxidation of a dFca solution in CH_2Cl_2 produces a color change from red to violet (λ_{max} = 750 nm, ε ~ 1000 M^{-1} cm^{-1}), which is indeed characteristic of the presence of ferrocenium centers and the larger value for ε is consistent with the coulometry results. This double oxidation process seems to occur almost simultaneously within the time frame of the experiment (see reaction [2]).

[2] Fc—CH=CH—(CO)—CH=CH—Fc

$$\xrightarrow{-2e^-} Fc^+—CH=CH—(CO)—CH=CH—Fc^+$$

There is no reduction process in the −2.0–0.0 V vs. SSCE region, contrary to the dba analogues (12–14).

The FT-IR spectra of the dFca compound in CH_2Cl_2 solutions containing 0.1 M of TBA(PF_6) have been monitored as a function of potential. Figure 3 shows the *difference* FT-IR spectra of dFca upon oxidation and reduction of the oxidized species. The IR bands associated with the Fc groups (which appear in the 800–1500 cm^{-1} region) are minimally affected as expected, while the strong vinylic ν(C=C) and ν(C=O) bands vanish (they appear as the strong negative components in the difference IR spectra) and a new weaker feature at 1675 cm^{-1} (attributable to ν(C=O)) appears upon oxidation (positive component). This result shows that the oxidation of the Fc groups is felt along the cross-conjugated system where the increase in ν(CO) is believed to be related to a less extended set of resonance structures in the oxidized species as shown in Scheme 3. Features attributable to new vinylic ν(C=C) are not observed in the spectra, presumably due to weak intensity. This redox experiment is perfectly reproducible upon multiple cycling.

Electronic spectra

The lowest electronic excited states for dFca are expected to be centered at the Fc groups. The electronic absorption spectrum of ferrocene is well known and consists of ligand field (LF), ligand-to-metal charge transfer (LMCT), and MLCT bands. The two low-energy singlets (at 22 700 cm^{-1}, ε =

[a]±1 nm.

91 $M^{-1}\,cm^{-1}$, and at 30 800 cm^{-1}; ε = 49 $M^{-1}\,cm^{-1}$) are LF bands (24, 26). Substitution of ferrocene by conjugated groups such as olefins, ketones, and aromatics produces an increase in absorptivity ($400 < \varepsilon < 1000\,M^{-1}\,cm^{-1}$) and a small red shift of the low-energy LF band (<1000 cm^{-1}; see Table 2 and ref. 27). The 77 K absorption spectrum of dFca in 2MeTHF is shown in Fig. 3 and the 293 K spectroscopic data are reported in Table 2. The low-energy band is now located at 19 100 cm^{-1} (ε = 5450 $M^{-1}\,cm^{-1}$ at 293 K) in dFca and the presence of two Fc groups together with the substituent effect does not account for the large intensity and transition energy changes with respect to ferrocene. Table 3 shows the solvent dependence on the electronic band position of dFca. There is a variation in λ_{max} for the lowest energy band, while the second appears to remain unaffected. Similar solvent dependencies have been reported for dba (28), for which a CT electronic transition has been attributed to the low-energy band. The spectroscopic data on dFca and literature observation strongly suggest that the lowest energy excited state in dFca possess a significant CT character.

Solid dFca is also found to be luminescent (see Fig. 4). The emission band (ν_{max} = 12 800 cm^{-1}) lies at ~6300 cm^{-1} from the lowest energy absorption band and this energy gap (Δ) is longer than the one for ferrocene (ν(singlet) − ν(triplet) ~ 4000 cm^{-1} where ν(triplet) = 18 600 cm^{-1}; see refs. 24, 29–32). The Δ value (5000 cm^{-1}) for $Ru(bpy)_3^{2+}$ (which possesses a low-energy MLCT absorption system) compares better with the Δ value observed for dFca (33). These spectroscopic data suggest that both low-energy singlet and triplet excited states possess significant CT character.

Long-term (48 h) broad band irradiation (λ_{max} = 350 nm) of both degassed and oxygenated dFca-containing solutions (C_6D_6 and $CDCl_3$) have produced only small photodegradation (less than 3% from the NMR measurements). The photoproducts have not been isolated.

Conclusion

The synthesis of this diarylideneacetone compound has provided an example of an easy preparation of a compound containing electroactive centers, a spectroscopic probe, and a conjugated system linking these groups. The presence of the olefins makes this type of compound attractive as they provide at least two binding sites for one or two extra metallic centers to enter the conjugated system. Such a concept introduces the idea of tuning thermo- and photochemical reactivity of the *added* metallic centers to the dFca-type compounds by changing the state of charge of the electroactive groups. This work has demonstrated that such a compound exhibits the required chemical and physical properties necessary to achieve the targeted goals. The electrochemistry findings show the essential chemical reversibility, where the CO group acts as a sensitive spectroscopic IR probe, and the compound is definitely thermally stable and reasonably photochemically stable.

The binding of transition metals (particularly of Pd and Pt) with dFca and other related ligands as well as their characterization and reactivity studies will be published in due course.

Acid–base behaviour of the ferricyanide ion in perchloric acid media. Spectrophotometric and kinetic study

PEDRO L. DOMINGO, BEGOÑA GARCÍA, AND JOSÉ M. LEAL[1]

Universidad de Valladolid, Departamento de Química Física, Colegio Universitario Integrado, 09001 Burgos, Spain

Received May 19, 1989

PEDRO L. DOMINGO, BEGOÑA GARCÍA, and JOSÉ M. LEAL. Can. J. Chem. **68**, 228 (1990).

A wide study was carried out of the acid–base behaviour of ferricyanide ions in aqueous perchloric acid media in the range 0.1–11.5 M. This study shows that protonation and decomposition of the ferricyanide ions occur simultaneously. The three successive protonation equilibria were found in the acidity ranges 0.1–4.0, 3.5–8.5, and 7.0–11.5 M $HClO_4$, respectively. A kinetic study was also made of the decomposition reaction at 60°C. The kinetic data are explained by considering a reaction mechanism involving homolytic and heterolytic dissociation steps. The homolytic and heterolytic rate constants corresponding to each of the four protonated species were determined, along with the acid–base protonation constants, $pK_1 = -6.25 \pm 0.10$; $pK_2 = -3.23 \pm 0.03$; and $pK_3 = -0.60 \pm 0.02$.

Key words: acid–base behaviour, protonated species, decomposition, homolytic dissociation, heterolytic dissociation.

PEDRO L. DOMINGO, BEGOÑA GARCÍA et JOSÉ M. LEAL. Can. J. Chem. **68**, 228 (1990).

On a réalisé une étude importante du comportement acide–base des ions ferricyanures en solution dans de l'acide perchlorique aqueux, à des concentrations allant de 0,1 à 11,5 M. Cette étude a permis de démontrer que la protonation et la décomposition des ions ferricyanures se produisent simultanément. On a observé trois équilibres de protonations à des plages d'acidités respectives de 0,1 à 4,0, 3,5 à 8,5 et 7,0 à 11,5 M de $HClO_4$. On a aussi réalisé une étude cinétique de la décomposition, à 60°C. On explique les données cinétiques à l'aide d'un mécanisme réactionnel impliquant des étapes de dissociation homolytique ainsi qu'hétérolytique. On a déterminé les constantes de vitesse des étapes homolytique et hétérolytique de chacune des quatre espèces protonées ainsi que les constantes de protonation acide–base, $pK_1 = -6{,}25 \pm 0{,}10$; $pK_2 = -3{,}23 \pm 0{,}03$ et $pK_3 = -0{,}60 \pm 0{,}02$.

Mots clés : comportement acide–base, espèces protonées, décomposition, dissociation homolytique, dissociation hétérolytique.

[Traduit par la revue]

Introduction

In a previous paper, the acid–base behaviour of the ferrocyanide ion in perchloric acid media was studied by potentiometry and spectrophotometry (1). In this paper, the corresponding acid–base investigation of the ferricyanide ion is undertaken; this study, however, involves also kinetic measurements, since ferricyanide ions decompose at high acid concentrations.

The potentiometric titration of a sample of 0.01 N $K_3Fe(CN)_6$ with aqueous HCl shows no evidence of protonation; the curve coincides with that obtained in the titration of a blank solution containing pure water, this fact indicating that the three ionization constants of ferricyanic acid, $H_3Fe(CN)_6$, are higher than 0.1 (2, 3). On the other hand, the titration curves of a sample of 0.01 M $H_3Fe(CN)_6$ with NaOH, obtained by potentiometric and conductimetric techniques, are identical to those achieved titrating 0.03 M HCl. Thus the three constants must be quite high (4). None of the three pK values was found in the literature; however, to be able to explain the effect of acidity on the rate constant, several contributions on the oxidation of organic substrates by ferricyanide in acid media (5–11) suggest that the first protonation occurs in the range 0.1–3.8 M $HClO_4$.

Results and discussion

The effect of acidity on the absorption UV–VIS spectra of ferricyanide shows no noticeable change in the range 0–3.5 M $HClO_4$; however, the appearance of isosbestic points in the range 3.5–8.0 M indicates the existence of an acid–base equilibrium. Above 7.0 M, the UV–VIS spectral curves of ferricyanide change with time and a characteristic smell of HCN is observed, which evidences the decomposition of ferricyanide. This phenomenon constitutes a major difficulty in studying the influence of acidity on the spectra (Fig. 1).

The appearance of a brown suspension is observed in freshly prepared solutions of ferricyanide above 5×10^{-4} M, using aqueous $HClO_4$ 7 M and above; the higher the acid concentration, the more abundant the suspension becomes. This suspension was isolated and identified as $H_3Fe(CN)_6$; identification was made by comparison with a sample of this acid prepared according to Brauer's method (12). Figure 2 shows the most characteristic IR peaks, which are coincident for both samples.

The successive protonation equilibria may be expressed in the following simplified notation:

$$[1] \quad H_3Fe(CN)_6 \overset{K_1}{\rightleftharpoons} [H_2Fe(CN)_6]^- + H^+$$

$$[2] \quad [H_2Fe(CN)_6]^- \overset{K_2}{\rightleftharpoons} [HFe(CN)_6]^{2-} + H^+$$

$$[3] \quad [HFe(CN)_6]^{2-} \overset{K_3}{\rightleftharpoons} [Fe(CN)_6]^{3-} + H^+$$

K_1, K_2, and K_3 being the thermodynamic ionization constants of the tri-, bi-, and mono-protonated species, which will be designated BH_3, BH_2^-, and BH^{2-}; B^{3-} refers to the non-protonated species.

Equilibrium [3] should occur in the range 0.1–3.8 M $HClO_4$, since the species BH^{2-} exist mainly within this range (5–11); no appreciable change was observed in the spectral curves, but this fact should not be sufficient to discard equilibrium [3], given that the UV–VIS spectra of ferrocyanide change by addition of different cations due to ion-pair formation, but no change is observed in the case of ferricyanide (13–15) in spite of the conductimetric evidence supporting such association. As an example, $pK_{ass} = 1.3$ for the association $Fe(CN)_6^{3-} - K^+$ (16). The formation of ferricyanic acid as a brown suspension indicates that equilibrium [1] occurs above 7.0 M $HClO_4$; the spectral changes observed in the range 3.5–8.0 M $HClO_4$ should be attributed to equilibrium [2].

To explore the acid–base behaviour of the ferricyanide ion, it was necessary to make a kinetic study of the decomposition process by studying the influence of acidity on the rate constant.

Decomposition of the ferricyanide ion in high acidity media

Several authors (17–19) have studied the formation of pentacyanoferrate(III), $[Fe(CN)_5H_2O]^{2-}$, from ferricyanide solutions in the pH range 0–14. In this work, the decomposition of ferricyanide is investigated at acidity levels of 0.1 M $HClO_4$ and above, where protonation equilibria are evidenced to start, and the analysis of reaction products confirms that decomposition does not stop in pentacyanoferrate. Some authors describe the reaction only qualitatively; the effect of mineral acids above 2 M on the ferricyanide ion is not noticeable in cold media, but at high temperature HCN is produced, along with a Prussian Blue precipitate. Ferricyanic acid is still more unstable than ferrocyanic acid, so the physical properties are not well known; it generates Prussian Blue when exposed to light and produces HCN under air atmosphere (20).

A very small decomposition is observed after 2 h in a sample of 10^{-4} M ferricyanide in the acidity range 0.1–7.0 M $HClO_4$ at 25°C; the UV–VIS spectra remain unchanged. This is not the case above 7.0 M: the absorption maxima at 420 and 300 nm decrease, and the first of these disappears with the result of a final spectral curve identical to that of ferrocyanide. The decomposition was investigated at 60°C over the whole acidity range above 0.1 M $HClO_4$.

A quantitative analysis of the reaction products reveals that about 80% ferricyanide decomposes, producing HCN and ferric ion, and 20% reduces, generating ferrocyanide. An independent test showed that 8×10^{-5} M $K_4Fe(CN)_6$ in 8.7 M $HClO_4$ did not exhibit any change in the UV–VIS absorption spectra after 3 h; Fig. 3 shows the spectral changes recorded during the decomposition of ferricyanide, with the isosbestic point at 280 nm characteristic of the ferricyanide–ferrocyanide system. The kinetics was monitored following the changes in absorbance with time; the A/t data fitted fairly well the first-order rate equation:

$$[4] \quad \ln (A - A_\infty) = \ln (A_0 - A_\infty) - kt$$

The data processing was carried out using the program RLP (weighting linear regression) with weighting $W_i \sim A^2$; Fig. 4 shows a typical straight line obtained. The variation in the initial concentration of ferricyanide did not affect the observed rate constant. Figure 5 shows the influence of acidity on the pseudo-first-order rate constant; three different regions can be distinguished: 0.1–3.5, 3.5–7.5, and 7.5–11.5 M $HClO_4$, corresponding to the first, second, and third protonation, respectively. On the other hand, the use of H_2SO_4 instead of $HClO_4$ leads to the same results for the rate constant: $k_{obs} = 3.21 \times 10^{-3}$ min^{-1} in 2 M H_2SO_4 ($[H^+] = 2.6$ M), and $k_{obs} = 4.03 \times 10^{-3}$ min^{-1} in 4.4 M H_2SO_4 ($[H^+] = 5$ M) (Table 1).

The variation of the ionic strength did not affect the reaction rate (see Table 2). Above 1.2 M $NaClO_4$ a Prussian Blue suspension appeared, $Fe^{III}NaFe^{II}(CN)_6$, which shortened the

limit in the ionic strength to be used. This observation leads to the conclusion that noncharged species participate in the rate-determining step.

The addition of cyanide ions did not affect the rate constant, which indicates that the decomposition is not reversible and also that HCN does not react in the rate-determining step (Table 3), and may be excluded as reductant of the ferricyanide ions.

The addition of potassium ferrocyanide also has no effect on the reaction rate (Table 4), which indicates that the decomposition is not reversible; neither does the addition of Fe^{3+} ions change the rate constant, which denotes a nonreversible decomposition and excludes the Fe^{3+} ions as reactant in the rate-determining step (Table 5).

The variation of the dielectric constant of the medium displays no noticeable influence on the decomposition rate (Table 6). However, in a kinetic run using aqueous 1–4 dioxane

35% v/v, a Prussian Blue suspension appeared after the first 30% of the reaction, due to the low dielectric constant of the medium.

Table 7 exhibits the variation of the observed pseudo-first-order rate constant with temperature at five acidity levels, and Table 8 collects the activation parameters. The activation energy decreases as the acidity increases, indicating an easier decomposition.

According to these features, the following possibilities may be discussed with respect to the reductant of the ferricyanide ions:

1. HCN is to be excluded, since the external addition of cyanide does not change the decomposition rate. Two contributions were found in the literature on the reduction of ferricyanide by cyanide (21, 22). In basic medium, cyanide reduces ferricyanide to ferrocyanide in 48 h; this reduction is pH dependent. Below pH 9 the reaction rate decreases greatly and becomes negligible after three weeks at pH 1–2; at this acidity level cyanide is present mainly as HCN, which confirms our observations.

2. Water may also be excluded; in view of the standard redox potentials, a direct water/ferricyanide reaction should be excluded. Although a self-reduction process of Fe^{3+} has already been described in the literature (23):

$$[5] \quad Fe^{3+} + [Fe(CN)_6]^{3-} + 2H_2O \rightarrow Fe^{2+} + [Fe(CN)_5]^{3-} + NH_4^+ + CO_2$$

this reaction was not confirmed in our observations, since ammonium ion was not detected as a reaction product.

3. Traces of Cu^{2+} present as impurities could be responsible for the reduction of ferricyanide; in basic medium Cu^{2+} catalyzes the reduction of ferricyanide by cyanide (24). In the process, Cu^+ ions produced by reduction of Cu^{2+} by cyanide are oxidized again to Cu^{2+} by ferricyanide, which in turn is reduced to ferrocyanide; in this cyclic redox process, Cu^{2+} ions act simply as catalyst. However, the observed rate law (24) does

TABLE 8. Thermal and thermodynamic activation parameters of the decomposition reaction of ferricyanide

$[HClO_4]$ (M)	E_a (kJ mol^{-1})	$\Delta H_{\neq}$ (kJ mol^{-1})	$\Delta S_{\neq}$ (eu)
0.10	37.8 ± 3.7	37.3 ± 3.7	32.7 ± 11.6
4.00	29.8 ± 1.6	29.2 ± 1.6	10.0 ± 4.9
7.50	16.8 ± 2.0	16.3 ± 2.0	−27.5 ± 6.2
8.73	12.0 ± 0.3	11.4 ± 0.3	−38.9 ± 1.0
10.60	10.1 ± 0.6	9.5 ± 0.6	−42.9 ± 1.9

not agree with our results:

[6] $-d[Fey]/dt = k[Fey]^2[Cu]/[Feoy]$

where Fey stands for ferricyanide and Feoy for ferrocyanide; moreover, the initial addition of (2–4) × 10^{-5} M Cu^{2+} in the decomposition reaction of 10^{-4} M ferricyanide in 8.7 M $HClO_4$ did not affect the process, but the addition of 10^{-4} M Cu^{2+} into a 10^{-4} M ferricyanide solution in 1.0 M $HClO_4$ generated a yellow solid, cupric cyanide, which overlaps and obstructs the study. Thus this route appears to be unacceptable.

4. A fourth path may be considered, in which the aquo-cyanide complex of Fe^{3+}, generated during the course of the decomposition, undergoes reduction with HCN, generating the aquo-cyanide complex of Fe^{2+}; this, finally, looses the central atom Fe^{2+}, which undergoes a fast oxidation to Fe^{3+} by ferricyanide, forming ferrocyanide.

Reaction [7] takes place in basic medium (25)

[7] $2[Fe(CN)_5H_2O]^{2-} + CN^- + 2OH^- \rightarrow 2[Fe(CN)_5H_2O]^{3-} + CNO^- + H_2O$

but in acid medium this reaction is not possible, as happened in the reduction of ferricyanide by cyanide. In any event, in this type of reaction, the external addition of cyanide should accelerate the formation of an aquo-cyanide complex of Fe^{2+} and more ferricyanide would be consumed to oxidize it to Fe^{3+}; consequently, the rate of decomposition would increase, which is not in agreement with our observations. Thus, this path seems to be very improbable.

5. A last way lies in the possibility of causing the homolytic breakdown of HCN into H· and CN· radicals by the action of UV light. It is well known that hydrogen atoms reduce ferricyanide rapidly (26, 27); this route is not probable since the only light used in this investigation was selected at 416 nm, out of the UV region.

A more reasonable possibility would consist of both homolytic and heterolytic steps, where CN· and HCN· radicals and complex species of Fe^{2+} would be generated. Although this kind of rupture is unusual, a few references were found in the literature involving complexes of cobalt, chromium, and others (28–34); it was also found in the decomposition of hexacyanomanganate(III) and hexacyanomanganato(IV) ions in aqueous acid media (35, 36). However, the best proof was recently supplied (37): potassium ferricyanide is slowly reduced under dry air atmosphere, forming cyanogen and ferricyanide in small amounts, according to reactions [8]–[10]:

[8] $[Fe(CN)_6]^{3-} \rightarrow [Fe(CN)_5]^{3-} + CN\cdot$

[9] $CN\cdot + [Fe(CN)_6]^{3-} \rightarrow [Fe(CN)_5]^{3-} + C_2N_2$

[10] $2CN\cdot \rightarrow C_2N_2$

If water vapour is contained in the atmosphere, HCN and CNOH are produced according to

[11] $2CN\cdot + H_2O \rightarrow HCN + CNOH$

The predictions including homolytic and heterolytic steps are in agreement with our observations; thus, this route is suggested to explain the decomposition of ferricyanide.

Rhodes' test (38) for the detection of cyanogen was negative, which means that CN· and HCN· radicals disappear by the hydrolysis process. This hydrolysis may occur (22) either by reaction [12] or [13]:

[12] $(CN)_2 + 2OH^- \rightarrow CN^- + CNO^- + H_2O$

[13] $(CN)_2^- + xH_2O \rightarrow P + CN^-$

Reaction [12] may be discarded, since ammonium ion was not detected among the reaction products. On the other hand, the species P was identified containing C, N, O, and H, and underwent a further reaction, generating a polymeric material hardly recognizable. This matches our findings, since in very concentrated solutions of $K_3Fe(CN)_6$ the whole system forms a spongy dark blue polymer.

The following mechanism is proposed for the decomposition of ferricyanide in acid media:

[14] $[Fe(CN)_6]^{3-} + H_3O^+ \rightarrow [HFe(CN)_6]^{2-} + H_2O$

[15] $[HFe(CN)_6]^{2-} + H_3O^+ \rightarrow [H_2Fe(CN)_6]^- + H_2O$

[16] $[H_2Fe(CN)_6]^- + H_3O^+ \rightleftharpoons [H_3Fe(CN)_6] + H_2O$

[17] $[H_nFe(CN)_6]^{n-3} \xrightarrow[\text{slow}]{k_{het}(n)} [H_{n-1}Fe(CN)_5]^{n-3} + HCN$

[18] $[H_{n-1}Fe(CN)_5]^{n-3} + H_2O \xrightarrow[\text{fast}]{} [H_{n-1}Fe(CN)_5H_2O]^{n-3}$

[19] $[H_{n-1}Fe(CN)_5H_2O]^{n-3} + 5H_2O \xrightarrow[\text{fast}]{} [Fe(H_2O)_6]^{3+} + (n-1)HCN + (6-n)CN^-$

[20] $[H_nFe(CN)_6]^{n-3} \xrightarrow[\text{slow}]{k_{hom}(n)} [H_{n-1}Fe(CN)_5]^{n-4} + CN\cdot + H^+$

[21] (recombination and probable hydrolysis of CN·)

[22] $[H_{n-1}Fe(CN)_5]^{n-4} + H_2O \xrightarrow[\text{fast}]{} [H_{n-1}Fe(CN)_5H_2O]^{n-4}$

[23] $[H_{n-1}Fe(CN)_5H_2O]^{n-4} + 5H_2O \xrightarrow[\text{fast}]{} [Fe(H_2O)_6]^{2+} + (n-1)HCN + (6-n)CN^-$

[24] $[H_nFe(CN)_6]^{n-3} + [Fe(H_2O)_6]^{2+} \xrightarrow[\text{fast}]{} [H_nFe(CN)_6]^{n-4} + [Fe(H_2O)_6]^{3+}$

[25] $[H_nFe(CN)_6]^{n-4} + [Fe(H_2O)_6]^{3+} + K^+ \xrightarrow[\text{fast}]{} Fe^{III}K^+[Fe^{II}(CN)_6] + 6H_2O$

In steps [17] and [20] the linkage Fe^{3+}–CNH is considered to be weaker than Fe^{3+}–CN^-, so that the first of these is broken much more easily. Reactions [19] and [23] take place in several irreversible fast steps (39). Step [24] is fast and, in accordance with step [25], a Prussian Blue precipitate is formed at a given concentration. The rate-determining steps [17] and [20] are S_N1 dissociative processes, since the existence of six ligands around the central atom does not allow enough room for a seventh ligand. Dissociative processes are the most frequent in substitution reactions of octahedral complexes (40); moreover, the proton enables the cyanide ligand to be released (41).

Activation entropies decrease with increasing acidity, as

TABLE 9. Homolytic and heterolytic rate constants calculated

n	$[HClO_4]$ (M)	$k_{het}(n)(min^{-1})$	$k_{hom}(n)(min^{-1})$
0	0.1	0.00125	0.00031
1	4.0	0.00308	0.00077
2	7.0	0.00436	0.00109
3	11.5	0.09126	0.02281

observed in the decomposition of hexacyanomanganate(IV) (35), which was explained by considering an intramolecular hydrogen linkage in the activation step. From the above reaction mechanism, the following rate law is obtained:

$$[26] \quad -\frac{d[\text{hexacyanoferrate (III)}]_{total}}{dt} = \frac{d\sum_{n=0}^{3}[(H_nFe(CN)_6)^{n-3}]}{dt} = \sum_{n=0}^{3}[k_{het}(n) + k_{hom}(n)][(H_nFe(CN)_6)^{n-3}]$$

A quantitative analysis of the reaction products reveals that $k_{het} \sim 4k_{hom}$; if the acidity of the medium is selected so that only one species $[H_nFe(CN)_6]^{n-3}$ is predominant, it will be possible to determine the different k_{het} values. Table 9 collects the results obtained; k_{hom} and k_{het} increase similarly as n increases either from $n = 0$ to $n = 1$, or from $n = 1$ to $n = 2$. However, this is not the case when passing from $n = 2$ to $n = 3$. This surprising effect suggests a certain change in the reaction mechanism when $n = 3$. A possible reason, not yet sufficiently investigated, lies in the solvent effect on the rate-determining steps at acidity levels above 8 M, according to the observation that the use of ethanol–water mixtures accelerates the disappearance of the ferricyanide ions in 9 M $HClO_4$. This fact was explained by considering the oxidation of ethanol, since the oxidizing power of ferricyanide increases with increase in acidity; however, further investigation remains to be done.

Determination of the dissociation constants

The curves $A/[HClO_4]$ and $k_{obs}/[HClO_4]$ exhibited in Fig. 5 may be interpreted considering the [1]–[3] acid–base equilibria. In media containing a high concentration of mineral acid, the activity coefficients involved in the definition of pK cannot be calculated by means of the Debye–Hückel equation, so we need to resort to one of the general alternative methods; in this work the determination of pK was carried out by means of the Cox–Yates equation (42):

$$[27] \quad \log I - \log C_{H^+} = m^*X + pK$$

where X, the excess acidity function, which is the same for all the bases in a single system, is calculated by an iterative method based on the ionization of a large number of different bases; for aqueous perchloric acid, used in this investigation, the function X is determined by starting from the percentage of mineral acid (42). The ionization ratio I = [basic form]/[acid form], can be estimated by means of Gold–Hawes' equation (43):

$$[28] \quad I = (P_B - P)/(P - P_A)$$

where P, the property of the system, stands for the observed rate constant in the cases of equilibria [1] and [3], and for the absorbance at 416 nm in the case of equilibrium [2]; P_B is the property of the basic species and P_A that of the conjugate acid, each corresponding to the limits of acidity in which the equilibrium takes place; P is the property corresponding to intermediate acidities. The pK is obtained as the ordinate of the linear regression $(\log I - \log C_{H^+})/X$, while from the slope we obtain the parameter m^*, which is particular to each base and can be interpreted in terms of hydration.

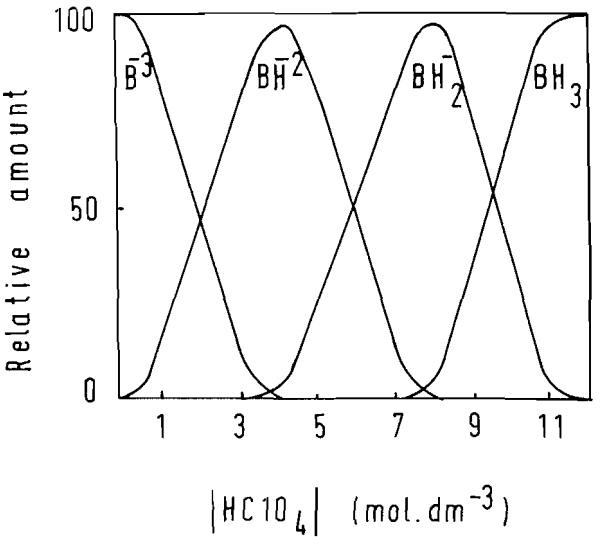

FIG. 6. Distribution of the various protonated forms of ferricyanide ions as a function of aqueous perchloric acid concentration.

In a previous paper (44), the separation method for overlapping equilibria was proposed and applied to investigate the successive protonations of the ferrocyanide ions (1). Although equilibria [1], [2], and [3] partially overlap, the procedure utilized in this work also includes measurements coming from the decomposition process, and avoids the need for using the separation method. Equilibrium [3] occurs in the range 0.1–4.0 M $HClO_4$ and the following values were obtained from the k_{obs} data: $pK_3 = -0.60 \pm 0.02$; $m_3^* = 1.01 \pm 0.04$; $r_{xy} = 0.9955$. Equilibrium [2] occurs in the range 3.5–8.5 M $HClO_4$, and the following values were obtained from the absorbance data: $pK_2 = -3.23 \pm 0.03$; $m_2^* = 0.99 \pm 0.01$; $r_{xy} = 0.9903$. Finally, equilibrium [1] occurs in the range 7.0–11.5 M $HClO_4$ and the following values were obtained from the k_{obs} data: $pK_1 = -6.25 \pm 0.10$; $m_1^* = 1.24 \pm 0.02$; $r_{xy} = 0.9983$. Figure 6 displays the distribution of the various protonated forms of ferricyanide ions as a function of aqueous perchloric acid concentration.

Conclusions

Due to the existence of two simultaneous processes, protonation and decomposition, the study of the acid–base protonation equilibria of the ferricyanide ions gives results more complicated than those of the ferrocyanide ions. Although the interpretation given in this paper is consistent with our own results, some additional experiments will complete a better knowledge of the acid–base behaviour of ferricyanide; thus, the influence of the solvent on the decomposition rate constant, using organic solvent – water mixtures, will provide useful information. On the other hand, the formal reduction potential of the ferricyanide/ferrocyanide pair was obtained at different acidity levels, being 0.410 V in pure water; 0.688 V in 1 M $HClO_4$; 0.798 V in 4 M $HClO_4$; 0.899 V in 7 M $HClO_4$; and 0.986 V in 10 M $HClO_4$. Thus, the oxidizing power of ferricyanide

increases with the acidity; this fact is important and should be taken into account, since certain organic solvents could be oxidized by ferricyanide in acid media. Finally, a deconvolution process by adaptation of characteristic vector analysis will be applied to the UV–VIS spectra of ferricyanide with the aim of separating them into independent bands and assigning the maxima wavelengths to the corresponding electronic transitions; the purpose is to evaluate the alterations in the spatial symmetry of ferricyanide as a consequence of the protonation reactions.

Experimental

Reactants

All reactants used were of analytical grade. When necessary, the ionic strength was controlled with sodium perchlorate in the kinetic experiments; in the spectrophotometric experiments, however, it was not necessary to control the ionic strength, since this factor is included in the excess acidity function method. All solutions were prepared with twice distilled and deionized water as solvent, over which nitrogen gas was made to flow before being used. In every case, the solutions used had been freshly prepared and kept out of the light. Values of C_{H^+} were calculated directly from molar concentrations of perchloric acid, since this species is fully ionized at least up to 60% w/w (42).

Equipment

The UV–VIS spectral curves were recorded with a Bodenseewerk Perkin Elmer 554 spectrophotometer with double beam, slit 1 nm, optic path 1 cm, and thermostatable cells; this permits multiple expansion in both absorbances and wavelengths and an accuracy of ± 0.001 in the absorbance readings. The reference cell contained the same solvent as the sample under measurement. The temperature of all solutions was kept constant with a P-Selecta thermostat. The kinetic experiments were followed with a Philips Pye Unicam 8600 spectrophotometer, furnished with a Pye Unicam cell temperature controller. The data processing was carried out with an Olivetti 240 computer.

General

In the decomposition of ferricyanide ions the reaction products were determined by analyzing solutions containing 0.05 g $K_3Fe(CN)_6$ in 20 mL of 1 M and 4 M $HClO_4$, respectively. After 48 h at 60°C a blue precipitate and a characteristic smell of HCN gas were observed.

1. This gas was bubbled with a nitrogen stream into a solution of $AgNO_3$ 10% w/w, acidified with HNO_3, and a white solid precipitated; this gas was also bubbled into a solution of NaOH containing Mohr salt, a few drops of $FeCl_3$, and, after 15 min, dilute H_2SO_4 for dissolving the ferrous and ferric hydroxides; a blue coloration and blue precipitate appeared. These facts indicate the formation of HCN.

2. Addition of ferricyanide to a sample of the liquid portion produced a red coloration, confirming the presence of ferric ions. This also confirms the absence of ferrous ions; otherwise, a blue coloration and blue precipitate would have appeared. On the other hand, addition of ferric ions generates a blue coloration, due to the presence of ferrocyanide; this evidence is also supported by the UV–VIS spectrum of a sample of the decomposition products in very dilute solutions of ferricyanide, where no precipitate was observed.

HCN undergoes a hydrolysis reaction when boiled, forming ammonium ions and formic acid. This reaction, however, was not confirmed, since a typical test for NH_4^+ led to negative results.

3. The blue precipitate, once recovered, isolated, and dried, gave an IR spectrum coincident with that of a sample of Prussian Blue obtained by mixing ferrocyanide and ferric ions, and also with that of a sample of Turnbull Blue obtained by mixing ferricyanide and ferrous ions; it is well known that both species are the same, ferric ferrocyanide, since ferricyanide oxidizes Fe^{2+} to Fe^{3+}, being itself reduced to ferrocyanide (45–48). There exist, in fact, two different types of Prussian Blue: (a) soluble Prussian Blue, $Fe^{III}M^+Fe^{II}(CN)_6$, which is formed when the alkaline ion M^+ is in excess, and (b) insoluble Prussian Blue, $Fe_4[Fe(CN)_6]_3$, when the alkaline and ferric ions are present in similar amounts (49, 50); the IR spectra of both species are identical.

During the process of decomposition, the concentration of K^+ ions is at any moment much higher than that of Fe^{3+} ions, which are released slowly, and the first of these becomes predominant; the Fe^{3+} ions released could, in the presence of ferricyanide, react to generate the red complex $FeFe(CN)_6$ (21, 51, 52); however, such coloration was not observed during the decomposition, and the UV–VIS spectrum of the reacting mixture showed no absorption above 500 nm, the spectral region of the red complex.

Several papers exist, reporting on the thermal decomposition of ferricyanide within the pH 0–14 region to generate $[Fe(CN)_5H_2O]^{2-}$ (17–19); the rate constant is 6×10^{-7} s^{-1} at 25°C and pH 4.6. The maximum band of this species is located at 565 nm (53); however, our reacting mixtures showed no noticeable absorption above 500 nm at any moment during the course of the decomposition.

The quantitative analysis of the reaction products in aqueous 1 M and 4 M $HClO_4$ was carried out by isolating the blue precipitate and collecting the HCN released over an NaOH solution, where the cyanide ions were titrated vs. $AgNO_3$, following the Liebig–Déniges' method (54). Independently of the acidity of the medium, the amount of HCN collected was about 75–80% of the total cyanide in the sample and the Prussian Blue collected was about 20–25% of the solid sample of $K_3Fe(CN)_6$ used. In media of 7 and 10 M $HClO_4$, $H_3Fe(CN)_6$ acid precipitates, this fact making advisable concentrations lower than 5×10^{-4} M; under these conditions, only small amounts of blue precipitate are collected, and the quantitative analysis of HCN is carried out as already described, the HCN being about 70–80% of the total cyanide in the sample. These results lead to the conclusion that about four fifths of the ferricyanide decomposes, producing HCN and ferric ions, and one fifth reduces, producing ferrocyanide.

Most chemicals contain traces of metal ions as impurities; the levels of Cu^{2+} detected by atomic absorption (324 nm) were 0.200 ppm in 0.303 M ferricyanide and 0.261 ppm in 0.267 M ferrocyanide. For this reason, the possibility of Cu^{2+} ions being responsible for the decomposition of ferricyanide was investigated.

Thermodynamic behaviour of molten metal oxychlorides. 1. The $PbO–PbCl_2$ system

A. HACETOGLU[1] AND S. N. FLENGAS

Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ont., Canada M5S 1A4

Received February 28, 1989[2]

A. HACETOGLU and S. N. FLENGAS. Can. J. Chem. **68**, 236 (1990).

Partial molar and integral molar properties of mixing for $PbO–PbCl_2$ melts have been investigated by using solid electrolyte galvanic cells of the type: Ni–NiO | $CaO–ZrO_2$ | $PbO–PbCl_2$ | Pb. Thermodynamic properties, such as activities and partial molar enthalpies of mixing, calculated from the measured cell potentials show pronounced negative deviations from ideality. To explain this behaviour and to predict the concentration dependence of the thermodynamic properties of these solutions, a theoretical model based on a number of possible reaction mechanisms has been developed. It is shown that in a non-ideal solution, the activity of any component A^+X^- is given as

$$a_{A_xB_y} = (N_{A^+}^x \cdot N_{B^-}^y)_{\text{equilibrium}}$$

where N_{A^+} and N_{B^-} are respectively the cation and anion fractions in a solution that has reached the ionic composition representing a specific reaction mechanism at equilibrium. From the activity data, the limiting experimental conditions for removing the oxygen impurity from $PbCl_2$ melts and for recovery of Pb and O_2 by fused salt electrolysis have been established.

Key words: oxychlorides, activities, solution properties, $PbO–PbCl_2$, EMF.

A. HACETOGLU et S. N. FLENGAS. Can. J. Chem. **68**, 236 (1990).

Utilisant des cellules galvaniques d'électrolytes solides du type : Ni–NiO | $CaO–ZrO_2$ | $PbO–PbCl_2$ | Pb, on a étudié les propriétés de mélanges molaires partiels et molaires intégrales de mélanges de $PbO–PbCl_2$ fondus. Les propriétés thermodynamiques, telles que les activités et les enthalpies molaires partielles qui ont été calculées à partir des potentiels mesurés, présentent des déviations négatives importantes par rapport à l'idéalité. Pour expliquer ce comportement et pour arriver à prédire la relation entre la concentration et les propriétés thermodynamiques de ces solutions, on a développé un modèle théorique qui est basé sur un certain nombre de mécanismes réactionnels possibles. On a démontré que dans une solution qui n'est pas idéale, l'activité de tout composant A^+X^- peut être représentée par l'équation suivante :

$$a_{A_xB_y} = (N_{A^+}^x \cdot N_{B^-}^y)_{\text{équilibre}}$$

dans laquelle N_{A^+} et N_{B^-} correspondent respectivement aux fractions cationiques et anioniques que l'on retrouve en solution lorsqu'on atteint la composition ionique représentant un mécanisme réactionnel spécifique à l'équilibre. À partir des données relatives à l'activité, on a déterminé les conditions expérimentales qui limitent l'enlèvement de l'oxygène présent sous forme d'impureté dans du $PbCl_2$ fondu ainsi que la récupération du Pb et du O_2 par électrolyse du sel fondu.

Mots clés : oxychlorures, activités, propriétés de solution, $PbO–PbCl_2$, FEM.

[Traduit par la revue]

Introduction

Molten solutions of $PbO–PbCl_2$ represent the only metal oxide – metal chloride system in which oxide solubility occurs over a wide concentration and temperature range at relatively low temperatures.

Recently the phase diagram of the system was revised by Renaud *et al.* (1) and significant differences from the earlier work by Ruer (2) and Varoni (3) were found. At a temperature of 973 K the range of liquid solutions extends from pure $PbCl_2$ to about 80 mol% PbO.

Activities of PbO in this system have been measured electrochemically by Sugawara *et al.* (4) at temperatures between 506 and 1063°C.

In the present investigation the reversible EMF of the cell,

$$(+)Pb_{(liq)}, PbO_x–PbCl_{2_{(1-x)}} \mid ZrO_2–CaO \mid NiO_s, Ni_s(-)$$

was measured for PbO compositions varying from pure PbO to 1 mol% PbO, and in the temperature range 723–1223 K. From the results, the thermodynamic properties of PbO and of $PbCl_2$ in the $PbO–PbCl_2$ melts have been calculated. In addition to its theoretical significance, the thermodynamic information has been used to predict the limiting equilibrium conditions for the chlorination of PbO at high temperatures, for the preparation of pure $PbCl_2$ through the electrochemical removal of an oxygen impurity, and for the recovery of metallic lead by fused salt electrolysis of the $PbO–PbCl_2$ solutions in the temperature range 773–873 K.

Experimental

The design of the cell for the EMF measurements is given in Fig. 1. The reference electrode consisted of a CaO stabilized zirconia tube containing 13 mol% CaO, closed at one end, having a total length of about 30 cm. To make this electrode, nickel wire 1 mm in diameter having a spiral end was inserted into the zirconia tube and was covered with 2–3 cm of a compacted mixture of Ni and predried NiO powders. The open end of this tube was closed with a glass bell cemented into place and the entire system could be evacuated and sealed under vacuum. During its operation the thermal decomposition of NiO at the temperature of the experiment established the oxygen gas pressure and the EMF measurements did not contain errors due to mixed potentials that are created by nonequilibrium oxygen pressure conditions (5).

The indicator electrode was molten lead in contact with the $PbO–PbCl_2$ melt contained in a zirconia crucible. Electrical contact to the lead was through iridium wire, about 1 mm in diameter and 10 cm long, connected to a platinum wire lead.

The entire electrode assembly, including the crucible with the salt mixture, was placed in a silica tube closed at one end. The top of this tube was covered with a nickel plate machined to contain entry ports for the various cell components, as shown in Fig. 1. A vacuum-tight seal was provided by De Khotinsky cement covering the entire surface of the top plate and all openings. To prevent the escape of the volatile $PbCl_2$ from the zirconia crucible containing the $PbO–PbCl_2$ melt, the

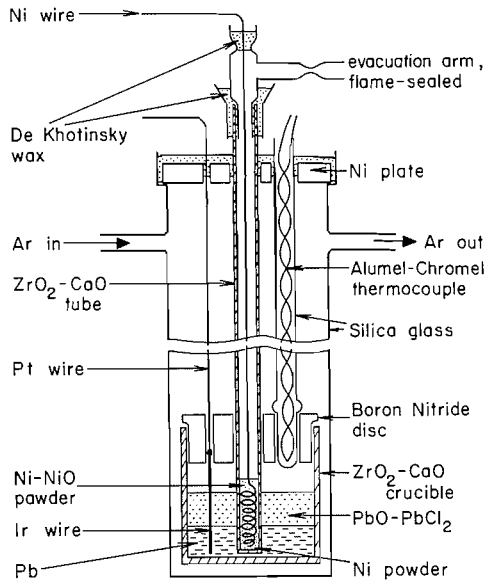

FIG. 1. Schematic drawing of the experimental EMF cell.

top of the crucible was also closed with a boron nitride lid machined to fit tightly. This lid had openings for the insertion of the reference electrode and the other cell components shown in Fig. 1. A further precaution against possible volatilization of $PbCl_2$ was provided by operating the indicator electrode compartment under a static blanket of purified argon. A gas valve, connected in parallel with the argon supply to the cell, maintained a slightly positive gas pressure while it prevented the flow of gas and created semistatic conditions.

Materials losses due to possible volatilization were determined by weighing the contents of the crucible before and after a run, during runs that duplicated the experimental conditions in terms of melt composition, temperature, and duration. No significant loss of materials was observed. For example, for a total melt weight of 50 g containing 70 mol% $PbCl_2$, at a temperature of 1023 K over a period of 10 h the weight loss was only 0.2 g. Accordingly, melt compositions did not have to be corrected for losses due to volatilization.

The PbO and $PbCl_2$ used for these experiments were anhydrous high purity reagents and argon was dehydrated and oxygen purified by using Ti pellets at 1273 K.

Potential measurements taken during a heating and cooling cycle at each composition were in agreement to within ±2 mV. Maximum duration of a run was about 10 h.

Results and data treatment

Reversible potentials were measured as a function of temperature and composition. The data have been treated by least squares to correspond to linear equations of the form:

$$[1] \qquad E\ (\text{in mV}) = A - BT$$

where A and B are constants for a given composition and T is given in degrees Kelvin. The constants, and the calculated standard and maximum deviations, are given in Table 1.

The activities of PbO were calculated from the Nernst equation given as

$$[2] \qquad E = (E^0_{NiO} - E^0_{PbO}) - RT/2F \ln a_{PbO}$$

where a_{PbO} is the activity of PbO calculated with respect to pure molten PbO as the standard state. R and F have the values of 8.3136 J mol^{-1} and 96 484 J $volt^{-1}$, respectively. E is given in volts and E^0_{NiO} and E^0_{PbO} are, respectively, the formation potentials of pure solid NiO and pure molten PbO at the same temperature as T. T is given in degrees Kelvin.

1.0	1160–1371	222.98	0.05052	±0.57

NOTE: Negative EMF values imply a reversal in the electrode reaction.

The formation potentials for pure solid NiO at various temperatures have been established in previous investigations (5–11). With regard to pure molten PbO, the standard Gibbs free energies reported by several investigators (12–14) and by Charette and Flengas (5) are in substantial agreement to within 2–4 mV. Accordingly, the standard formation potentials for NiO and for PbO used for the calculation of the activities from eq. [2] are those reported in our previous work (5). The latter were obtained by EMF measurements in closed cells similar to those used in the present investigation. The data for the standard potentials of NiO and PbO are given in Table 2.

The activities of PbO at the selected temperatures of 1023 and 1123 K are given in Table 3. The activities of $PbCl_2$, which are also included in Table 3, have been calculated using the well-known Gibbs–Duhem relationship (15).

The partial molar enthalpies of mixing for PbO, given in Table 3, have been calculated from the A constants that are presented in Table 1, using the readily derived expression:

$$[3] \qquad \overline{\Delta H}_{PbO} = 19.2968(A - 223.3)$$

These values are given in kJ mol^{-1}.

Activities of PbO in this system reported by Sugawara *et al.* (4) are in disagreement with the present results, particularly at high PbO contents. For solutions containing more than 80 mol% of PbO, the reported activities are greater than unity, which is thermodynamically impossible for the chosen reference states, which were the same as in the present calculations. For compositions lower than 30 mol% PbO, there is better agreement with the present results, although the temperature dependences of the EMFs differ.

Activity isotherms for the PbO and the $PbCl_2$ components are shown in Fig. 2. Activities calculated by Sugawara *et al.* (4) are also included for comparison.

Discussion

The pronounced negative deviations from ideality shown by the activity data in Table 3 and by the strongly exothermic partial molar heats of mixing for PbO are indicative of strong interactions between the solute ions in the PbO–$PbCl_2$ melts.

The result of such interactions could be the formation of complex oxychloride configurations of the general type $(Pb_pO_qCl_r)^{(2p-2q-2r)+}$ where p, q, and r are integers having

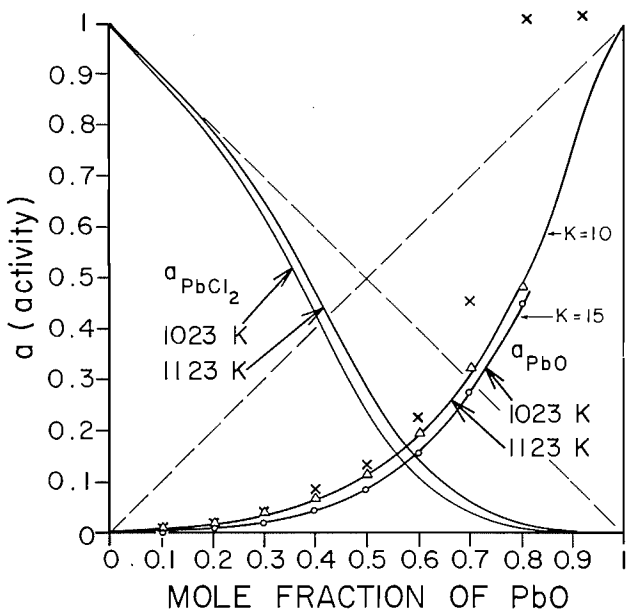

FIG. 2. Activity isotherms for PbO and $PbCl_2$ at 1023 K and 1123 K, respectively. Points (circles and triangles) are from experimental work. Solid lines are calculated from eqs. [10] and [11]. x's are experimental activity data for PbO reported by Sugawara *et al.* (4).

values greater than zero, as in the incongruently melting compounds $3PbCl_2.2PbO$, $PbCl_2.PbO$, $PbCl_2.2PbO$, and $PbCl_2.4PbO$, which have been identified as existing in a solid state within the phase diagram of the system (1–3).

Considering a solution that initially contains n_1 and n_2 moles of PbO and $PbCl_2$, respectively, it will be assumed that a complex forming reaction is taking place until equilibrium is reached.

If a is the fraction of the initial oxygen that has reacted and has been incorporated in the complex oxychloride, then the enthalpy change for the formation of the solution is given as

$$[4] \qquad \Delta H_m = n_1 a \Delta H_r^0$$

where ΔH_r^0 is the enthalpy change for the formation of one mole of oxychloride specie containing one gram-atom of oxygen, such as in a molten $(Pb_{p/q}\cdot O\cdot Cl_{r/q})^{(2p-2q-2r/q)+}$ type compound.

The "reaction" part of the enthalpy of mixing is considered to be a major contribution to the total energy released during mixing, and any other secondary interactions between the solute atoms in the reacted system will not be taken into account.

The total entropy of mixing is considered to consist of two major contributions: (*i*) the entropy for the formation of the amount of oxychloride complex present at equilibrium and (*ii*) the configurational contribution for the random mixing of the various specie i present at equilibrium.

The total entropy of mixing may be written as

$$[5] \qquad \Delta S_m = n_1 a \Delta S_r^0 - R\sum_i n_1 \ln N_i$$

where n_i and N_i are, respectively, the number of moles and the ionic fractions of species i present in the mixture at equilibrium.

Combination of eqs. [4] and [5] into the Gibbs–Helmholtz relationship yields the Gibbs free energy of mixing as

$$[6] \qquad \Delta G_m = n_1 a(\Delta H_r^0 - T\Delta S_r^0) + RT\sum_i n_i \ln N_i$$

where

$$[7] \qquad \Delta H_r^0 - T\Delta S_r^0 = -RT \ln K$$

K is the equilibrium constant for a given oxychloride formation reaction, which is dependent only on temperature.

The expression for the activities of PbO is obtained by partial differentiation of eq. [7] with respect to n_1 at constant n_2 and under the restriction that

$$[8] \qquad \sum_i N_i = 1, \qquad \text{at equilibrium,}$$

or

$$\sum_i \left| \frac{n_i}{N_i} \cdot \frac{dN_i}{dn_1} \right|_{n_2} = 0$$

The final equation takes the form:

$$[9] \qquad \ln a_{PbO} = \sum_i \left| \ln N_i \left(\frac{dn_i}{dn_1} \right)_{n_2} \right| - \left| n_i \left(\frac{da}{dn_1} \right)_{n_2} + a \right| \ln K$$

It is readily seen that the expression for the activity of PbO contains the equilibrium constant K as the only adjustable parameter.

The solution of eq. [9] is readily found by considering the mass balances representing various reaction mechanisms. Irrespective of the scheme chosen, the expression for the activity is always found to have the following form:

[10] $$a_{PbO} = (N_{Pb^{2+}} \cdot N_{O^{2-}})_{equilibrium}$$

In eq. [10], $N_{Pb^{2+}}$ and $N_{O^{2-}}$ are, respectively, the ionic fractions for Pb^{2+} and O^{2-} in a molten mixture of PbO and $PbCl_2$ that has reacted internally in accordance with a specific reaction mechanism and has reached a state of equilibrium.

From similar considerations it may be shown that the activity of $PbCl_2$ is given by the expression:

[11] $$a_{PbCl_2} = (N_{Pb^{2+}} \cdot N_{Cl^-}^2)_{equilibrium}$$

For the PbO–$PbCl_2$ solutions, several reaction mechanisms have been considered, such as the formation of the complex oxychlorides, Pb_2OCl^+, Pb_2O^{2+}, $PbCl_2O^{2-}$, as well as the compositions representing the various incongruently melting compounds mentioned earlier.

From all these possible schemes the experimental data appear to be best represented by the reaction:

[12] $$2Pb^{2+} + O^{2-} + Cl^- = Pb_2OCl^+$$

The mass balance representing eq. [12] is given in Table 4. The equilibrium constant is written as

[13] $$K = \frac{N_{Pb_2OCl^+}}{N_{Pb^{2+}}^2 \cdot N_{O^{2-}} \cdot N_{Cl^-}}$$

for which the expressions for the ionic fractions are given in Table 4.

Degrees of reaction α have been estimated for various selected K values from eq. [13], and are given in Table 5.

From the equilibrium ion fractions given in Table 4, the activities for PbO and $PbCl_2$ are readily calculated as

[14] $$a_{PbO} = \frac{1 - 2aX_1}{1 - aX_1} \cdot \frac{X_1(1 - a)}{1 + X_2 - 2aX_1}$$

and

[15] $$a_{PbCl_2} = \frac{1 - 2aX_1}{1 - aX_1} \cdot \left| \frac{2X_2 - aX_1}{1 + X_2 - 2aX_1} \right|^2$$

where X_1 and X_2 in these expressions are respectively the primary mole fractions of PbO and $PbCl_2$ in the "unreacted" mixture. Details for the mathematical treatment are given in Appendix A.

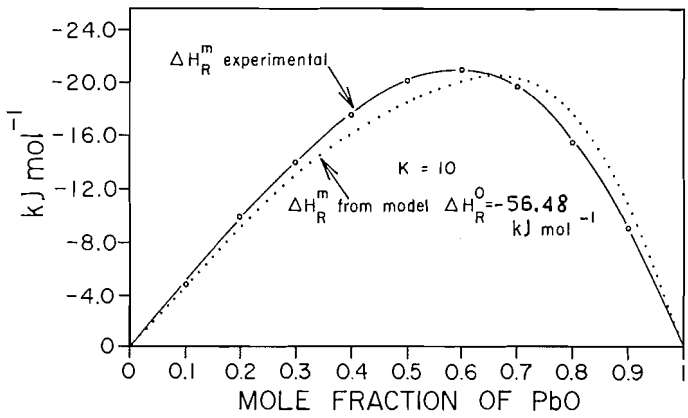

FIG. 3. Plot of the integral heat of mixing as a function of the PbO mole fraction in the PbO–$PbCl_2$ melts. Dotted line has been calculated from eq. [17] for $K = 10$.

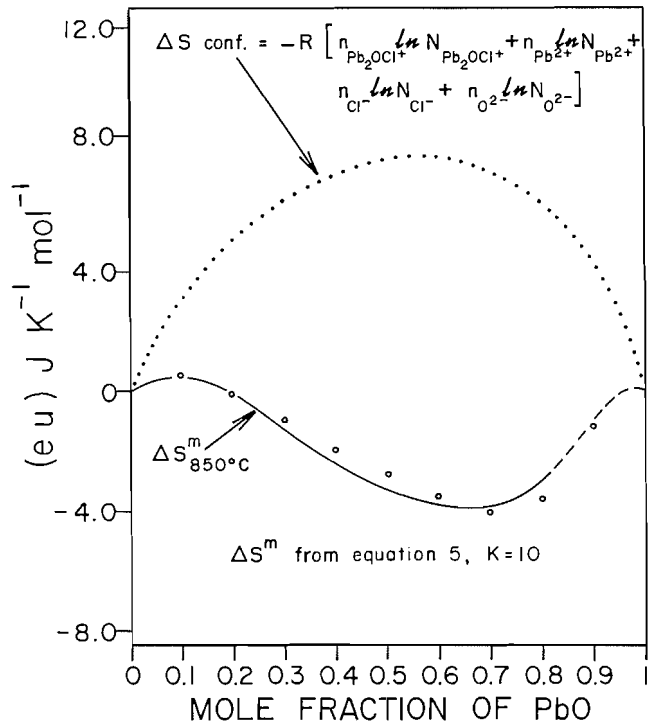

FIG. 4. Integral molar entropies of mixing plotted as a function of the PbO content in the PbO–$PbCl_2$ melts. Solid line represents the total entropy calculated from eq. [5] for $K = 10$. Points are from the experimental results. Dotted line represents the configurational component of the total entropy.

The activity isotherms shown in Fig. 2 were calculated from eqs. [14] and [15] (solid lines), while the points are experimental. The 1023 K isotherm was calculated from a values corresponding to $K = 15$. The isotherm at 1123 K was calculated from a values based on $K = 10$.

It should be noticed that at constant composition the activity of a_{PbO} increases as K decreases.

The integral enthalpy of mixing for the system was calculated from the expression:

$$[16] \quad \Delta H_m = X_1\overline{\Delta H}_{PbO} + X_2\overline{\Delta H}_{PbCl_2}$$

For the calculation, the partial molar enthalpies of mixing for $PbCl_2$ were obtained from the partial molar enthalpies of mixing of PbO using the Gibbs–Duhem relationship.

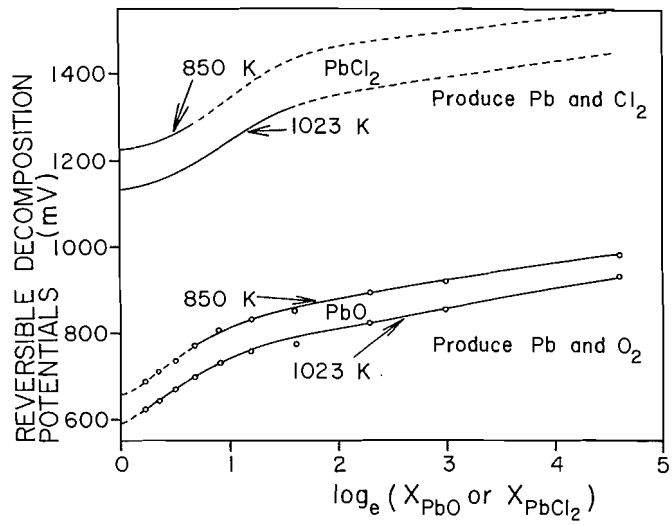

FIG. 5. Reversible decomposition potentials for PbO and $PbCl_2$ in the PbO–$PbCl_2$ melts at 850 K and 1023 K, respectively.

The results of these calculations are given in Fig. 3. On this graph the points are experimental, while the dotted line has been derived from eq. [4] written in the form:

$$[17] \quad \Delta H_m = aX_1\Delta H_r^0$$

which represents the enthalpy of mixing *per mole* of solution.

For the calculation, the degrees of reaction, based on reaction [12] for $K = 10$, have been used. The value for the ΔH_r^0 term, which must be common for all compositions, is -56.48 kJ mol^{-1}.

Entropies of mixing, calculated from the enthalpies of mixing and the corresponding Gibbs free energies, are plotted in Fig. 4 as a function of composition. Here the solid line represents the experimental values for the total integral entropy of mixing, while the points are calculated from eq. [5], as applied to reaction [12], for $K = 10$. For this calculation the a values that correspond to $K = 10$ and a common value of $\Delta S_r^0 = -32.34$ eu were found to satisfy the entire composition range. The dotted line in Fig. 4 represents only the configurational component of the total integral entropy of mixing.

Considering the uncertainty that is always present when calculating entropies, the agreement between the experimental and the theoretical entropies of mixing and, particularly, the correct prediction of their concentration dependence indicates the validity of the present thermodynamic model.

Electrolytic behaviour of the PbO–$PbCl_2$ melts

From eq. [2] and its equivalent for $PbCl_2$, it is possible to calculate the reversible potentials for the electrochemical separation of Pb and O_2, or of Pb and Cl_2, from a molten solution of PbO and $PbCl_2$.

For the reactions

$$[18] \quad Pb_{liq} + Cl_{2(g,\ 1\ atm)} = (PbCl_2)_{in\ solution}$$

and

$$[19] \quad Pb_{liq} + \tfrac{1}{2}O_{2(g,\ 1\ atm)} = (PbO)_{in\ solution}$$

the reversible electrode potentials at 850 and 1023 K, respectively, were calculated using the previously derived activity values and the standard potentials given in Table 2.

The results of these calculations are plotted in Fig. 5. Because of the wide potential separation, the electrolysis of the PbO–$PbCl_2$ is almost independent of melt composition and, consequently, lead chloride melts may be deoxygenated by pre-electrolysis.

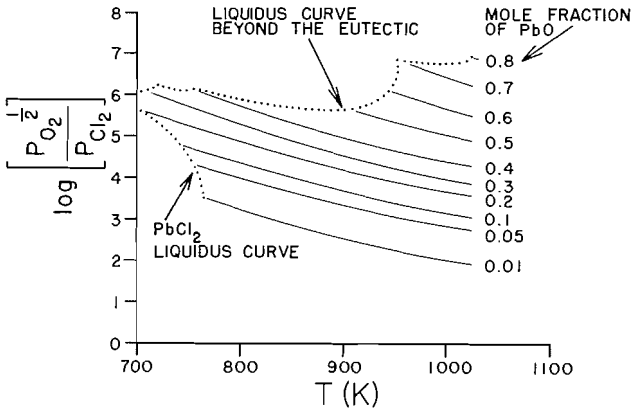

FIG. 6. Chlorination conditions for PbO in PbO–$PbCl_2$ molten solutions, at various temperatures and $P_{O_2}^{1/2}/P_{Cl_2}$ gas ratios.

Fused salt electrolysis of PbO dissolved in a $PbCl_2$ solvent is expected to produce lead and oxygen, respectively, as cathodic and anodic products.

Chlorination of PbO

The reaction of PbO in solution with gaseous chlorine at high temperatures may be written as

[20] $$(PbO) + Cl_{2(g)} \rightleftharpoons (PbCl_2) + \tfrac{1}{2}O_{2(g)}$$

where PbO and $PbCl_2$ are present as a molten solution.

Considering chlorination at constant temperature, in a closed system, equilibrium will be established between the molten solution and a gaseous mixture containing Cl_2 and O_2.

For reaction [20] the equilibrium constant is

[21] $$K = \frac{P_{O_2}^{1/2}}{P_{Cl_2}} \cdot \frac{a_{PbCl_2}}{a_{PbO}}$$

where K calculated from the standard potentials listed in Table 2 has the following values:

T (K)	K
725	3.5×10^{7}
850	5.3×10^{6}
960	5.9×10^{5}
1023	2.1×10^{5}

From the present results the activities of PbO and of $PbCl_2$ are readily calculated over the entire composition range at the same temperatures.

Accordingly, the equilibrium ratio P_{O_2}/P_{Cl_2} has been calculated from eq. [21] for various compositions and the results are given in Fig. 6, as an equilibrium predominant area type diagram in which the temperature–composition boundaries of the molten solutions correspond to those given in the phase diagram of the PbO–$PbCl_2$ system (1).

In any open system, the chlorination of PbO would require that the P_{O_2}/P_{Cl_2} ratios over the melts satisfy at all times the thermodynamic conditions given in Fig. 6. It is evident that chlorination of mixtures containing about 1 mol% at a low temperature of about 773 K is possible with a gaseous mixture containing chlorine at a partial pressure of only 10^{-4} atm (1 atm = 101.3 kPa).

Conclusions

The thermodynamic properties of the PbO–$PbCl_2$ molten solutions show pronounced negative deviations from ideality that are indicative of strong interactions between the ionic species in solution. To explain this behaviour and to predict the concentration dependence of the activities of PbO and of $PbCl_2$, of the enthalpies and of the entropies of mixing, a thermodynamic model based on the presence of strong complex oxychloride species has been developed. In this model the concentration dependence of the activities at each temperature requires the equilibrium constant K as the only adjustable parameter. The concentration dependence of the enthalpy of mixing is predicted from eq. [17] in which the only other adjustable parameter is the term ΔH_r^0, which, however, is constant over the entire composition range. The calculation of the entropies of mixing does not require any other adjustable parameters. K and ΔS_r^0 are related by eq. [7] and ΔS_r^0 cannot be adjusted independently.

It is shown that in non-ideal solutions the activity of any component A_xB_y is expressed by the simple relationship:

$$a_{A_xB_y} = (N_{A^{x+}}^{x} \cdot N_{B^{y-}}^{y})_{\text{equilibrium}}$$

In this expression $N_{A^{x+}}$ and $N_{B^{y-}}$ are the respective cation and anion fractions in a solution that has the ionic composition corresponding to a specific reaction mechanism *at equilibrium*.

Thus Temkin's rule (16) is of general validity for *ideal* and *non-ideal* solutions, providing that the correct reaction mechanism and dissociation schemes are formulated.

In this treatment non-ideality is attributed to changes in the composition of a solution as the result of complex forming reactions. The theory does not account for secondary interactions between the reaction products. Equilibrium ion fractions of the assumed ionic forms are used throughout, the basic assumption being that the reactivity of the simple ionic species like Pb^{2+}, O^{2-}, or Cl^- has been satisfied through the formation of the complex and that all other interactions are not too significant.

Under such circumstances, the equilibrium constant K is expected to be composition independent and to depend only on temperature over the composition range within which the above assumptions are valid.

Appendix A

Considering the reaction model

$$2Pb^{2+} + O^{2-} + Cl^- \rightleftharpoons Pb_2OCl^+$$

the activity of PbO is given by eq. [9], which may be written in an expanded form as

$$[A\text{-}1] \quad \ln a_{PbO} = -\left[x\left(\frac{\partial \alpha}{\partial n_1}\right)_{n_2} + \alpha \right] \ln K + \ln N_{Pb^{2+}}\left(\frac{\partial n_{Pb^{2+}}}{\partial n_1}\right) + \ln N_{Cl^-}\left(\frac{\partial n_{Cl^-}}{\partial n_1}\right)_{n_2} + \ln N_{O^{2-}}\left(\frac{\partial n_{O^{2-}}}{\partial n_1}\right)_{n_2} + \ln N_{Pb_2OCl^+}\left(\frac{\partial n_{Pb_2OCl^+}}{\partial n_1}\right)_{n_2}$$

where

$$[A\text{-}2] \quad K = \frac{N_{Pb_2OCl^+}}{N^2_{Pb^{2+}} \cdot N_{O^{2-}} \cdot N_{Cl^-}}$$

where the n's are mole numbers and α is the degree of reaction per mole of O^{2-}; n_1 and n_2 are, respectively, the moles of PbO and $PbCl_2$ initially present in the melt.

The expressions for the partial differentials given in eq. [A-1] are readily obtained as

$$[A\text{-}3] \quad \left(\frac{\partial n_{Pb^{2+}}}{\partial n_1}\right)_{n_2} = 1 - 2\alpha - 2n_1\left(\frac{\partial \alpha}{\partial n_1}\right)_{n_2}$$

$$[A\text{-}4] \quad \left(\frac{\partial n_{Cl^-}}{\partial n_1}\right)_{n_2} = -\alpha - n_1\left(\frac{\partial \alpha}{\partial n_1}\right)_{n_2}$$

$$[A\text{-}5] \quad \left(\frac{\partial n_{O^{2-}}}{\partial n_1}\right)_{n_2} = 1 - \alpha - n_1\left(\frac{\partial \alpha}{\partial x}\right)_{n_2}$$

and

$$[A\text{-}6] \quad \left(\frac{\partial n_{Pb_2OCl^+}}{\partial n_1}\right)_{n_2} = \alpha + n_1\left(\frac{\partial \alpha}{\partial n_1}\right)_{n_2}$$

Introduction of the expressions [A-2], [A-3], [A-4], [A-5], and [A-6] into expression [A-1] yields

$$a_{PbO} = (N_{Pb^{2+}} \cdot N_{O^{2-}})_{equilibrium}$$

It should be noted that an analytical expression for $\left(\frac{\partial \alpha}{\partial n_1}\right)_{n_2}$ may be obtained from the condition that, at constant temperature, $\left(\frac{\partial K}{\partial n_1}\right)_{n_2,T} = 0$.

All terms in eq. [A-1] that contain $\left(\frac{\partial \alpha}{\partial n_1}\right)_{n_2}$ cancel out.

Single-ion Setschenow coefficients for several hydrophobic non-electrolytes in aqueous electrolyte solutions

P. PEREZ-TEJEDA, A. MAESTRE,[1] AND P. DELGADO-COBOS
Departamento de Química Física, Universidad de Sevilla, Sevilla 41072, Spain
AND
J. BURGESS[1]
Department of Chemistry, University of Leicester, Leicester LE1 7RH, U.K.

Received July 1, 1988[2]

P. PEREZ-TEJEDA, A. MAESTRE, P. DELGADO-COBOS, and J. BURGESS. Can. J. Chem. **68**, 243 (1990).

Setschenow coefficients have been derived from solubility measurements on cyclohexane, benzene, naphthalene, 1-naphthol, 1,5-dihydroxynaphthalene, and anthracene in alkali halide, tetraalkylammonium bromide, and tetraphenylarsonium chloride aqueous solutions at 298.2 K. Single ion Setschenow coefficients have thence been obtained by an assumption involving extrapolation of the tetraalkylammonium bromide results to zero cation volume. Setschenow coefficients for the tetraalkylammonium cations correlate well with a hydrophobicity parameter based on their transfer chemical potentials from water into 1,2-dichloroethane.

Key words: solubilities, aqueous salt solutions, Setschenow coefficients.

P. PEREZ-TEJEDA, A. MAESTRE, P. DELGADO-COBOS et J. BURGESS. Can. J. Chem. **68**, 243 (1990).

On a évalué les coefficients de Setschenow, en se basant sur des mesures de solubilité du cyclohexane, de l'hexane, du benzène, du naphtalène, du 1-naphtol, du 1,5-dihydroxynaphtalène et de l'anthracène dans des solutions aqueuses d'halogénures alcalins, de bromure de tétraalkylammonium et de chlorure de tétraphénylarsonium effectuées à 298,2 K. On a ensuite déterminé les coefficients de Setschenow pour des ions uniques en utilisant une hypothèse impliquant une extrapolation, à un volume cationique de zéro, des résultats obtenus avec le bromure de tétraalkylammonium. Il existe une bonne corrélation entre les coefficients de Setschenow obtenus pour les cations tétraalkylammonium et un paramètre d'hydrophobicité basé sur les potentiels de transfert chimique de l'eau au 1,2-dichloroéthane.

Mots clés : solubilités, solutions aqueuses de sels, coefficients de Setschenow.

Introduction

Salt effects on solubilities of non-electrolytes have been the focus of numerous studies for several decades. Several theories have been used to characterise the essential features of the salting phenomenon (1–3). The influence of a salt on the solubility of a non-electrolyte is usually characterised and quantified by the Setschenow coefficient, or salting constant, k_s. This is estimated by solubility, distribution, or vapour pressure experiments:

$$\log(S_0/S) = \log(D/D_0) = m_s k_s$$

Here m_s is the concentration of the dissolved electrolyte, S_0 and S are, respectively, the solubilities of the non-electrolyte in water and in the salt solution, or D_0 and D are the respective distribution ratios between water or salt solution and organic layer. On multiplication of k_s by $2.3RT$ one obtains the change in the standard Gibbs function or, in other words, the transfer chemical potential between water and salt solution. Setschenow coefficients are available for the effects of a number of electrolytes on solubilities of a range of non-electrolytes, but there have been relatively few attempts to determine single ion Setschenow coefficients. However, Fromon and Treiner have detailed two procedures for establishing single ion Setschenow coefficients from k_s values for electrolytes in their extensive study, by vapour pressure measurements, of solubilities of tetrahydrofuran in aqueous salt solutions (4).

In a previous paper (5) we reported Setschenow coefficients for naphthols, noting that k_s decreased with increasing hydrophilic character of the non-electrolyte for a given salt, and that the nature and location of substituents affected k_s in different ways. In the present paper we report extensions of this earlier investigation to the determination of k_s values for cyclohexane, benzene, naphthalene, 1-naphthol, 1,5-dihydroxynaphthalene, and anthracene in aqueous solutions of alkali halides, tetraalkylammonium bromides, and tetraphenylarsonium chloride. We derive Setschenow coefficients for each electrolyte, and discuss the division of these values into single ion components.

Experimental

Materials

1-Naphthol, naphthalene, and anthracene (Fluka puriss.) were used as received. 1,5-Dihydroxynaphthalene (Sigma) was purified by repeated recrystallisation from aqueous methanol. Cyclohexane was HPLC grade (Scharlau); benzene (Riedel De Haën, min. 99.9% GC) was kept over 4A molecular sieve.

Sodium chloride and sodium bromide (Merck p.a.) were dried at 150°C; Ph_4AsCl (Merck) was used as received. Me_4NBr, Et_4NBr, Pr_4NBr, and Bu_4NBr (Fluka) were purified by the method described by Conway *et al.* (6). All salts were kept in a vacuum desiccator prior to use.

Distribution measurements

Distribution ratios of a known amount of 1-naphthol (2.0×10^{-4} mol dm^{-3}) between water or salt solution and cyclohexane were determined after vigorous agitation of thermostatted small aliquots for 15 min. These were allowed to stand in the thermostat bath for a further 2 h before aliquots of the respective layers were taken and analysed spectrophotometrically (Perkin Elmer Lambda 5; $\varepsilon_{293.0} = 4.79 \times 10^3$ and $\varepsilon_{290.3} = 5.27 \times 10^3$ dm^3 mol^{-1} cm^{-1} for 1-naphthol in water and in cyclohexane respectively). These measurements were used to get preliminary estimates of k_s; the main series of experiments used solubility measurements (next paragraph) to obtain k_s values more directly.

Solubility measurements

The solubilities of cyclohexane, benzene, naphthalene, 1-naphthol, 1,5-dihydroxynaphthalene, and anthracene in water and in salt solutions were determined in the following manner. An excess of the non-electrolyte was added to 40 cm^3 of water or salt solution in a Pyrex flask with a Teflon stopper, and allowed to equilibrate (at 298.2 K) for 30 min. The solutions were stirred at ca. 25 000 rpm for 8 min with a Virtis model 23 homogenizer. After equilibrium was reached, aliquots from these solutions were removed and the concentrations of the non-electrolytes were obtained by an appropriate technique.

Spectrophotometric measurement was used for naphthalene ($\varepsilon_{275} = 4.68 \times 10^3$) and for 1,5-dihydroxynaphthalene ($\varepsilon_{328.7} = 5.13 \times 10^3$) with all salts studied. The very low solubility of anthracene in water precluded the determination of an accurate extinction coefficient. To obtain k_s values for this non-electrolyte we plotted log(absorbance) vs. salt concentration and measured the slopes of these plots. This method was used for R_4NBr solutions (at $\lambda = 251.3$ nm). Solubilities of anthracene in water and in NaCl and NaBr solutions were obtained by fluorescence measurements (Perkin Elmer 650-40 spectrofluorimeter); the excitation and fluorescence wavelengths were chosen at 355 and 401 nm respectively. Aliquots were removed and diluted (50% by volume aqueous ethanol) prior to their quantification.

Chromatographic methods were used for determining solubilities of cyclohexane with all salts studied, of benzene in water and in Ph_4AsCl solution, and of naphthalene in water. A Hewlett-Packard model 5890 instrument equipped with a flame ionisation detector was used. A small amount of glass wool was introduced into the glass liner to trap the salts. A packed stainless steel column (2 m × 1/8 in.) filled with 10% FFAP/Chromosorb W-AW-DMCS (80/100 mesh) was used. Concentrations were determined by measuring areas under chromatographic peaks with a Hewlett–Packard 3390A integrating recorder, using the internal standard method.

Results and discussion

Solubilities of 6.63×10^{-4}, 2.28×10^{-2}, 2.64×10^{-4} (spectrophotometry) and 2.58×10^{-4} (chromatography), 9.39×10^{-3}, 1.46×10^{-3}, and 3.40×10^{-7} mol dm^{-3} were obtained for cyclohexane, benzene, naphthalene, 1-naphthol, 1,5-dihydroxynaphthalene, and anthracene respectively. These values agree within experimental uncertainty with those obtained by previous workers (7–10).

Values of k_s, for each salt on each non-electrolyte, on the molar scale, are given in Table 1. We have also included in this table data for benzene in NaCl and R_4NBr solutions (11). Uncertainties are given as $\pm t\sigma/\sqrt{N}$ (95% confidence limits). Our results are compatible with k_s values obtained by earlier workers for aromatic non-electrolytes in alkali and tetraalkylammonium halide solutions (1–5, 12). The data in this table provide a reasonably self-consistent assembly according to the "additivity rule", and it is thus not unreasonable to attempt to dissect the k_s values for the electrolytes into single ion values. Fromon and Treiner discussed two methods for such a dissection, and showed that in their system they gave very similar results. The first method involved the use of the ubiquitous TATB assumption (13), in this case simply that $k_s(Ph_4As^+) = k_s(BPh_4^-)$. The TATB assumption has been used in many aspects of electrochemistry and is favoured by many workers (14). Unfortunately we cannot use this assumption here, for several reasons. Most seriously, we are unable to obtain precise and reproducible values for k_s for solutions of non-electrolytes in $NaBPh_4$ solutions. This is mainly attributable to the low solubility of $NaBPh_4$ in water and the consequent short range of concentrations available for Setschenow plots. However, there are other problems with this salt, such as its small but significant solubility in several organic solvents, which precludes the use of distribution methods. The TATB assumption is also difficult to apply to anthracene, since both Ph_4As^+ and BPh_4^- cause quenching problems with the spectrofluorimetric determination of the anthracene, and to 1,5-dihydroxynaphthalene, where solubility measurements proved unsatisfactory in Ph_4AsCl (Table 1).

We therefore employed Fromon and Treiner's second method, based on extrapolation to zero molecular weight for results for Me_4N^+, Et_4N^+, Pr_4N^+, and Bu_4N^+ bromides (but not Ph_4As^+, see below). Plots of k_s for R_4NBr against the molecular weights of the cations (Fig. 1) when extrapolated to zero molecular weight give values of k_s (Br^-) for the respective non-electrolytes. Once these values have been established, they can be used with the whole salt values in Table 1 to obtain a complete set of single ion k_s values (Table 2). There is a general increase in magnitude of k_s with increasing size of the non-electrolyte, for the hydrocarbon solutes; the incorporation of a hydroxyl group also leads to a marked increase in k_s, both for cations and for anions. These qualitative trends are in accord with trends earlier observed in relation to k_s values for whole salts (12, 15). Table 2 also includes Fromon and Treiner's results for tetrahydrofuran (4), where k_s values are of a similar order of magnitude to those for cyclohexane for the halides. However, for cations, k_s values for tetrahydrofuran are smaller than those for all the compounds we have studied.

The salting-out effects of Cl^- and of Br^- may be considered in terms of the combined action of two factors (16). First, water molecules are usually more polarised by ionic fields than non-electrolyte molecules. Therefore water will be more attracted by these ions, resulting in an increase in the non-electrolyte activity coefficient (salting-out). This attraction follows the order of increasing ionic field, $Cl^- > Br^-$. Secondly, the overlap bet-

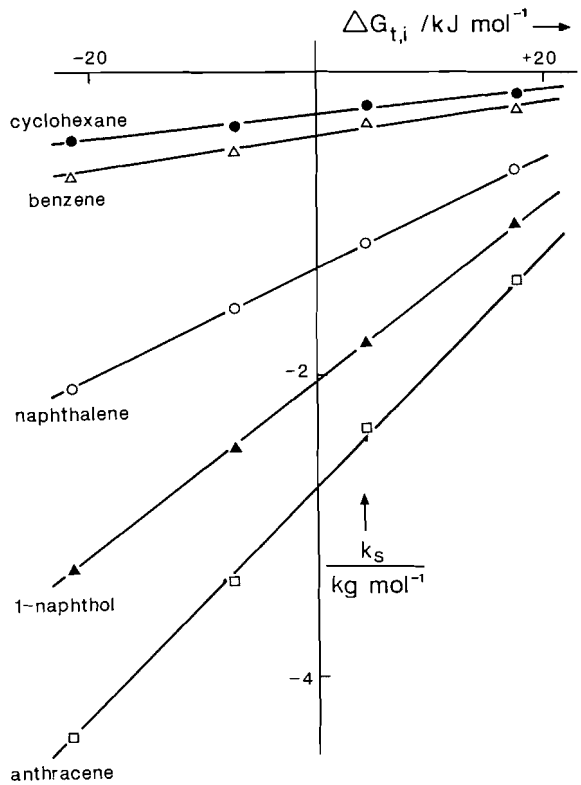

FIG. 2. Plots of single-ion Setschenow coefficients, k_S, against Gibbs free energies of transfer of R_4N^+ cations from water into 1,2-dichloroethane.

ween the cospheres around ions and non-electrolytes may produce a repulsive interaction, also resulting in salting-out (17, 18). However, these cosphere interactions are complicated, and it would be wise to wait until considerably more experimental data are available before attempting to produce a general rationalisation.

The decrease in single ion k_s values with increasing size of R_4N^+ ions is principally caused by the combined action of two factors, van der Waals dispersive forces and hydrophobic interactions. The former seems the more important, at least in the cases of cyclohexane and benzene. However, cyclohexane, being bigger and more hydrophobic than benzene, should show a stronger salting-in effect than benzene. A possible explanation for the observed (Table 2) salting-in difference between cyclohexane and benzene is that van der Waals interactions are higher in the case of benzene because of its aromatic character (19). In this connection we note that k_s for Ph_4As^+ in relation to cyclohexane is out of line with the overall pattern of values in Table 2. It is interesting to relate single ion k_s values for the R_4N^+ cations with other hydrophobicity parameters (20), such as their Gibbs free energies of transfer from water into an organic solvent such as 1,2-dichloroethane (21). Figure 2 indicates a linear correlation in this case; the hydrophobic nature of these R_4N^+ cations is manifested in a similar manner in these two parameters. The Ph_4As^+ cation cannot be included in these correlations; points for this cation lie a long way off the R_4N^+ correlation lines of Figs. 1 and 2. This is also true when Fromon and Treiner's data (4) for tetrahydrofuran are plotted in similar fashion. Again, a plot of k_s values for trisacetylacetonatocobalt(III) against partial molar volumes shows a marked discontinuity between the points for aliphatic R_4N^+ and aromatic Ph_4P^+ and BPh_4^- (22). Clearly, size is not the only factor for these large hydrophobic ions; various types of specific interactions must be invoked. In this context it is interesting to compare the k_s values of $Fe(CN)_2(bipy)_2$, $Fe(CN)_2(sbl)_2$, and $Fe(CN)_2(sb2)_2$ in 0.2 mol dm^{-3}

sb1 R = Me, R' = H
sb2 R = R' = Ph

Ph_4AsCl solution.[3] Salting-in is very much more marked for the complex containing the very hydrophobic Schiff base ligand (sb2) than for that containing 2,2′-bipyridyl, which in turn is salted-in slightly more efficiently than the smaller and less hydrophobic species $Fe(CN)_2(sbl)_2$; $k_s = 56$, 3.5, and 2.3 respectively. Ligand nature is very important here, as indeed was indicated in the earlier study of k_s values for compounds of this $Fe(CN)_2(LL)_2$ and related types (12). It seems likely that a wider range of non-electrolytes will need to be studied before it is possible to disentangle the various contributions to single-ion k_s coefficients. In particular, it will probably prove advantageous to expand the number and range of uncharged inorganic complexes, as well as of the organic solutes that have dominated this field for so long.

Thermodynamic properties of the ternary Na–Cu–Te alloy by electromotive force measurements with an alumina solid electrolyte[1]

PETER J. TUMIDAJSKI[2] AND JOHN KUEHLER[3]

Argonne National Laboratory, Chemical Technology Division/Materials Science Program, 9700 South Cass Avenue, Argonne, IL 60439-4837, U.S.A.

Received July 13, 1989

PETER J. TUMIDAJSKI and JOHN KUEHLER. Can. J. Chem. **68**, 247 (1990).

Activity coefficients for sodium metal in the equimolar CuTe alloy were measured up to 54 at.% sodium at 913 K. The experimental technique consisted of an alloy concentration cell with a solid alumina electrolyte. The results indicated that the solutions were Henrian up to 1 at.% sodium. In addition, for dilute sodium concentrations, there is an exosolution effect. However, for the more concentrated solutions, there is some ionicity.

Key words: tellurides, thermodynamics, alkali metals.

PETER J. TUMIDAJSKI et JOHN KUEHLER. Can. J. Chem. **68**, 247 (1990).

Opérant à 913 K et jusqu'à 54 at.% de sodium, on a mesuré les coefficients d'activité du sodium moléculaire dans un alliage équimolaire de CuTe. La technique expérimentale implique une cellule à concentration d'alliage et un électrolyte d'alumine solide. Les résultats indiquent que les solutions obéissent à la loi de Henry jusqu'à 1 atome pourcent de sodium. De plus, pour des concentrations diluées de sodium, on observe un effet d'exosolution. Toutefois, pour les solutions plus concentrées, on observe un certain caractère ionique.

Mots clés : tellurures; thermodynamique; métaux alcalins.

Introduction

Pure liquid tellurium occupies an unique position in the periodic table. Albeit commonly considered to be a metal, its electrical properties, like conductivity, cannot be adequately explained by the nearly free electron model for metals. Structurally, tellurium is different from other metals because it has mixed covalent and metallic bonding (1). A structure consisting of tellurium covalently bonded in a network of hexagonal rings or in chain-like assemblies has been proposed to account for many of the unusual properties (2).

The alloys of tellurium have recently attracted much attention because the tellurides exhibit metal-to-nonmetal transitions at specific compositions. A particularly interesting class of tellurium based alloys are the copper tellurides. The electronic properties of the liquid copper tellurides are unusual. The conductivities display a sharp minimum at the stoichiometric composition Cu_2Te_3 and a weak maximum near 15 at.% Cu. In fact, the conductivity of liquid Cu_xTe_{1-x} for alloys with $x < 0.2$ are greater than for pure liquid tellurium (3, 4). Warren, using an NMR technique (5), showed that charge transfer occurs between copper and tellurium, suggesting some ionicity for liquid copper tellurides. Enderby *et al.* (6–8) presented neutron scattering patterns for liquid copper tellurides. Subsequently, the results were interpreted (9, 10) as indicating the existence of Te^{2-} anions in a close packed assembly similar to the molten salt concept of a complex (11). However, there is direct copper-to-copper interaction, and, as a result of bond overlap, there is a significant effect on the bonding characteristics of copper tellurides. The thermodynamic measurements for copper tellurides (12–15) indicate that the chemical interactions are of a mixed metallic and covalent type in consonance with the NMR and neutron diffraction experiments.

The addition of alkali metal to bismuth tellurides has been found to dramatically influence the nature of chemical interactions (16). In this paper, we report on the thermodynamic behavior of sodium in equimolar copper tellurium alloy up to 54 at.% sodium at 913 K. The results provide further insight on how structure and the nature of interactions can be modified in chalcogenide alloys. To our knowledge, this is the first report on the thermodynamic behavior of sodium in copper tellurium alloys.

Experimental

The experimental apparatus and procedure has been described in previous publications (16, 17). The electromotive force cell was a simple alloy concentration cell described schematically as,

$$\underset{\text{(RE)}}{\text{Bi–Na}\|\beta\text{-}Al_2O_3\|}\underset{\text{(CE)}}{\text{Bi–Na}\|\beta\text{-}Al_2O_3\|}\underset{\text{(WE)}}{\text{(CuTe)–Na}}$$

The reference electrode (RE) contained 5 at.% alkali metal. Reference electrodes were calibrated against pure sodium metal using a similar concentration cell. All emfs are reported with pure liquid sodium metal as the reference. The composition of the working electrode (WE) was changed by coulometric titration. In this context, the counter electrode (CE) provided electrical contact, as well as a source or sink of alkali metal during coulometric titration.

Cells were loaded and operated under the protective atmosphere of a He glovebox. Approximately 1.8 g of CuTe were added to the cell in small pieces of vacuum-filtered copper and tellurium. Sodium was added to the WE by coulometric titration technique involving application of a potential across β-Al_2O_3 between the WE and CE. Overvoltages were always maintained to less than 250 mV. Sodium cations are transported through the β-Al_2O_3 solid electrolyte and are subsequently reduced to sodium metal at the WE. There is negligible electronic transport through the solid electrolyte and exactly one mole of the alkali metal will be transported for each Faraday of charge. The introduction of oxides and impurity ions into the WE is prevented, and compositional changes can be closely controlled.

TABLE 1 (*concluded*)

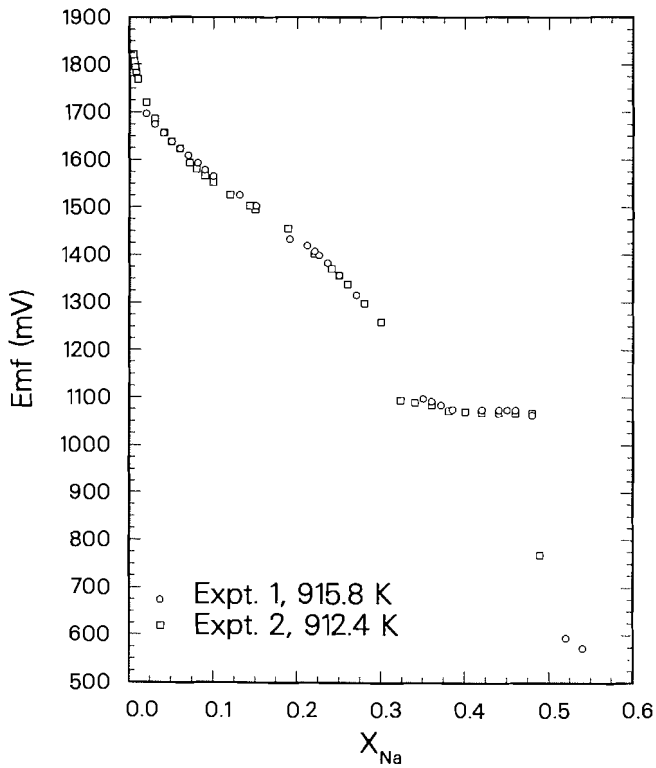

FIG. 1. Variation of cell voltage with composition for the Na–Cu–Te system.

Temperatures were measured with a calibrated (Pt–Pt 10 at.% Rh) thermocouple directly immersed into the CE.

Results and discussion

The cell reaction for the sodium metal concentration cell is,

[1] $Na_{(pure,\ l)} \rightleftarrows \underline{Na}$

where, the line beneath sodium denotes sodium in solution with an equimolar copper telluride. The corresponding Nernst expression is,

$$[2] \quad E = -\frac{RT}{F} \ln \gamma_{Na} - \frac{RT}{F} \ln X_{Na}$$

where F is the Faraday constant, R is the universal gas constant, T is the absolute temperature, and γ_{Na} and X_{Na} represent, respectively, the alkali metal activity coefficient and mole fraction. Figure 1 and Table 1 show the variation of cell voltage as a function of composition for both data sets. There are several interesting features in the Na–CuTe alloy system. There is a region ($0.3 < X_{Na} < 0.5$) where the cell voltage is almost

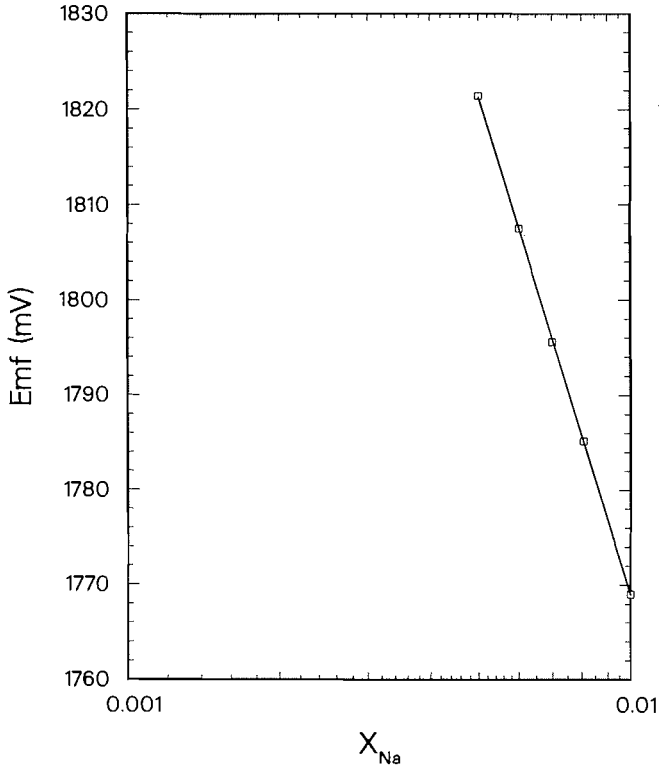

FIG. 2. Nernst plot for the Na–Cu–Te system at 912.4 K. The points represent experimental values; the line is the linear least squares line through the experimental data.

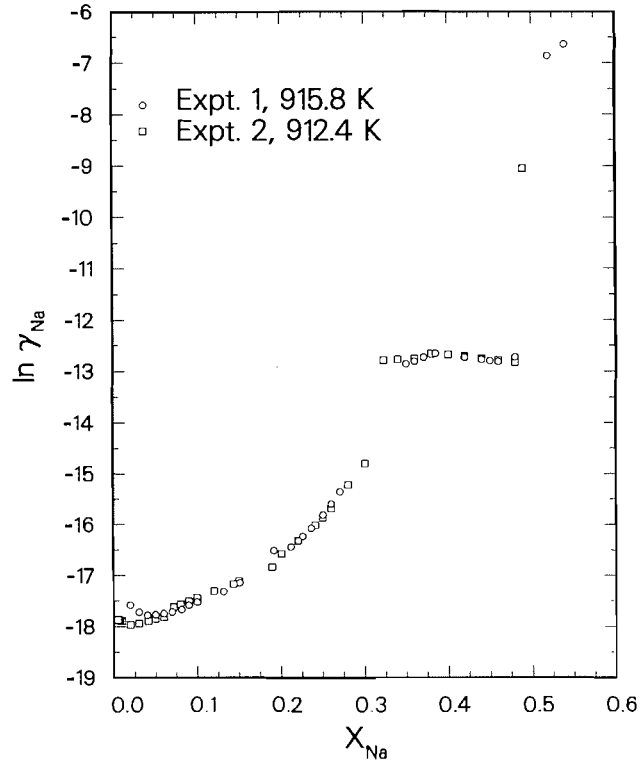

FIG. 3. Variation of ln γ_{Na} with X_{Na} in the Na–Cu–Te system.

composition independent. At $X_{Na} = 0.5$, the cell voltage changes very rapidly with composition, and it appears that for compositions greater than $X_{Na} = 0.5$, the cell voltage again tends to be a constant value. For compositions less than $X_{Na} = 0.30$, the cell voltage varies continuously with composition. The results will be discussed in detail later.

For dilute solutions, less than about $X_{Na} = 0.01$, Henry's law applies. In this case, eq. [2] simplifies to

$$[3] \quad E = E^0_{\underline{Na}} - \frac{RT}{F} \ln X_{Na}$$

where $E^0_{\underline{Na}}$ represents the limiting standard potential of sodium in the molten CuTe alloy. The limiting standard potential defines a hypothetical standard state where the mole fraction of sodium in the CuTe approaches unity, but the sodium metal behaves thermodynamically as if it were infinitely diluted. The Nernst plot at 912.4 K as expressed by eq. [3] is given in Fig. 2 where the emf is plotted against $\log_{10} X_{Na}$. It should be noted that the emf results were obtained for both directions of current in coulometric titration (i.e., $i > 0$, and $i < 0$). Least-squares fitting of the experimental data led to a value of 1.04 for the number of Faraday's transferred, compared to the expected result of one. The limiting standard potential at 912.4 K was calculated to be 1406 ± 2 mV. The corresponding value in the Na–Te binary alloy at 753 K was previously given as 1620 mV (18) and 1596 mV at 800 K (19). It is difficult to ascertain the influence on the sodium limiting standard potential when the solvent composition changes from pure tellurium to CuTe. Lack of data for the Na–Cu binary is compounded by the variances in temperatures in different investigations. However, the resistivity data (3, 4) show that the conductivity for the tellurium-rich side in liquid CuTe has a very weak dependence on composition. It appears that a similar situation exists for limiting standard potentials.

A thermodynamic property, related to limiting standard potential, is the limiting excess chemical potential defined by the expression,

$$[4] \quad \mu^E_0[\underline{Na}] = -FE^0_{\underline{Na}}$$

Accordingly, the value in the present Na–Cu–Te system is $-135.7\,\text{kJ mol}^{-1}$.

As can be seen from Fig. 2, Henrian behavior for sodium in liquid CuTe occurs below approximately $X_{Na} = 10^{-2}$. When the sodium metal content in the CuTe alloys increases, the deviations from Henry's law are significant. The activity coefficient, γ_{Na}, can be calculated at each alloy concentration from eq. [2] which is rearranged to

$$[5] \quad \ln \gamma_{Na} = \left(\frac{FE}{RT}\right) - \ln (X_{Na})$$

Figure 3 shows the isothermal compositional dependence of ln γ_{Na}. The Henrian activity coefficient has been calculated to be $\ln \gamma^h_{Na} = -17.8829$ at 912.4 K. There is a pronounced dip in the ln γ_{Na} values immediately following the Henrian regime. The Na–Te binary system exhibits the same trend (18). Furthermore, in agreement with the cell voltage values reported in Fig. 1, there is an almost negligible concentration dependence for ln γ_{Na} from $X_{Na} = 0.30$ to $X_{Na} = 0.50$, indicating a two-phase regime. It would appear that sodium complexes strongly with tellurium (18); at $X_{Na} = 0.30$, there is sufficient sodium to form sodium telluride. Any remaining sodium reacts less strongly with copper. As a result, the thermodynamic behavior of sodium is primarily determined by the value of sodium activity coefficient in the formed sodium telluride

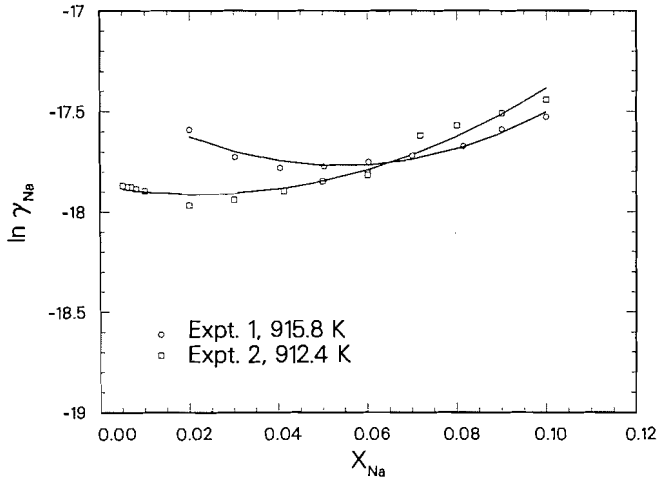

FIG. 4. Plot of ln γ_{Na} versus composition in the dilute solution range ($X_{Na} < 0.11$).

complex. At approximately $X_{Na} = 0.50$, there is a steep change in the sodium activity coefficient. At this composition, there is now sufficient sodium available, and a Na–Cu complex forms. Consequently, the activity coefficient of sodium is determined by its behavior in Na–Te and Na–Cu complexes.

According to the Kirkwood–Buff formalism (20), and subsequently reinterpreted by Saboungi and Corbin (21), the limiting slope, defined as,

$$[6] \quad \epsilon = \left(\frac{\partial \ln \gamma_{Na}}{\partial X_{Na}}\right)_{X_{Na}\to 0}$$

is related to the kind and degree of ordering within solutions. A positive value for ϵ is indicative of attraction between the sodium atoms and either copper or tellurium and a high probability of preferred coordination (i.e., complex formation) in the liquid state. A zero value for ϵ means that there is a random distribution for neighboring atoms. A negative ϵ value represents the situation where there are attractive forces between the sodium atoms, e.g., formation of Na_2 and repulsive forces between unlike atoms. Figure 4 is a plot of ln γ_{Na} versus composition in the dilute solution range ($X_{Na} < 0.11$). The experimental data points have been fitted to quadratic polynomial equations given as

$$[7] \quad \ln \gamma_{Na} = -17.402 - 13.662X_{Na} + 126.44X_{Na}^2$$

and

$$[8] \quad \ln \gamma_{Na} = -17.868 - 4.029X_{Na} + 88.517X_{Na}^2$$

for 915.8 K and 912.4 K, respectively. The limiting slopes, evaluated with eq. [6], are −13.662 and −4.029 for the 915.8 K and 912.4 K experiments, respectively. The values imply a segregation of sodium atoms in copper telluride. There is a demixing process very much like the onset of a miscibility gap, and the results would indicate pairing between sodium atoms occurs in dilute solutions. Consequently, for the dilute solutions, sodium in copper telluride is mainly covalently bonded. As the sodium content increases within the dilute solution range, the slopes of ln γ_{Na} versus composition become positive, suggesting that there is a development of a more ionic-like character.

Acknowledgment

SHRIKANT S. JOSHI, TEJRAJ M. AMINABHAVI, and SHYAM S. SHUKLA. Can. J. Chem. **68**, 251 (1990).

Densities and viscosities have been determined for six binary mixtures of bromoform, aniline, *n*-hexane, benzonitrile, butyronitrile, and benzylnitrile at different mole fractions and temperatures. The excess volumes V^E, apparent excess values of viscosity $\delta\eta$, excess Gibbs energy of activation of flow ΔG^{*E}, and partial molar volumes V_i, have been calculated from the experimental data. Furthermore, attempts were made to calculate theoretically the excess isobaric thermal expansion coefficient $\delta\alpha$, of the mixtures using the refractive index mixture rules. These results are in good agreement with the experimental data obtained from densities. Various excess functions and thermodynamic parameters have been used in the discussion of results to understand the nature and type of interactions in binary mixtures.

Key words: excess volume, refractive index mixture rules, interactions, bromoform, density, viscosity.

SHRIKANT S. JOSHI, TEJRAJ M. AMINABHAVI et SHYAM S. SHUKLA. Can. J. Chem. **68**, 251 (1990).

On a déterminé les densités et les viscosités de six mélanges binaires du bromoforme, de l'aniline, du *n*-hexane, du benzo-nitrile, du butyronitrile et du phénylacétonitrile, à diverses fractions molaires et à diverses températures. En se basant sur ces données expérimentales, on a calculé les volumes en excès, V^E, les valeurs des excès apparents de la viscosité, $\delta\eta$, l'énergie d'activation d'écoulement de Gibbs en excès, ΔG^{*E}, ainsi que les volumes molaires partiels, V_i. De plus, utilisant les règles de mélange des indices de réfraction, on a essayé de calculer d'une façon théorique le coefficient d'expansion thermique isobare, $\delta\alpha$, des mélanges. Ces résultats sont en bon accord avec les données expérimentales obtenues à l'aide des densités. On a utilisé diverses fonctions en excès et divers paramètres thermodynamiques pour discuter les résultats, dans le but de comprendre la nature et le type d'interactions présentes dans les mélanges binaires.

Mots clés : volume en excès, règles de mélange des indices de réfraction, interactions, bromoforme, densité, viscosite.

Introduction

Solution properties of binary mixtures of bromoform with a number of organic solvents have been the subject of intensive research in view of their importance as media to study preferential adsorption of polymers in mixed solvents (1). Thermodynamic properties of a number of bromoform containing mixtures have been studied earlier in our laboratories (2–5). To the best of our knowledge, extensive thermodynamic data on mixtures of bromoform with aniline, benzonitrile, benzylnitrile, butyronitrile, and *n*-hexane have not been made. Such mixtures are of considerable interest from the viewpoint of the existence of intermolecular interactions between the mixing components.

In this paper, we report the density and viscosity data for five binary mixtures containing bromoform at different mole fractions and at 298.15, 303.15, 308.15, and 313.15 K. From the experimental results the excess volumes V^E, apparent excess values of the viscosity $\delta\eta$, excess Gibbs energy of activation of flow ΔG^{*E}, and partial molar volumes V_i, have been computed using the appropriate relations. From a temperature dependence of viscosity, enthalpy ΔH^{+} and entropy ΔS^{+}, of activation of flow have also been estimated using the theory of Eyring and co-workers (6). Furthermore, attempts have been made to compute the isobaric thermal expansion coefficient α_m, of the mixture using the available refractive index mixture rules. These data compare satisfactorily with the experimental data of α_m and are further used to predict the apparent excess values of the expansion coefficient $\delta\alpha$.

Experimental

Bromoform (Thomas Baker, Bombay) was obtained in its highest purity and was used as supplied. The remaining solvents were all purified by the standard procedures as described by Weissberger *et al.* (7). Density of pure liquids and their mixtures was determined by a pycnometer with an accuracy of ± 0.0001 g cm^{-3}. Viscosities were measured by using a Cannon–Fenske viscometer, size 100, and the accuracy was found to be ± 0.002 cP. Details of the procedures for these measurements have been given earlier (8). A thermostatically-controlled bath, constant to ± 0.02 K was used in all these measurements. The experimental densities and viscosities at 298.15, 303.15, 308.15, and 313.15 K have been measured for pure components and their mixtures over the entire range of mole fractions.[3] The observed data for pure liquids are in agreement with those available in the literature (7, 9).

Results

The values of V^E, $\delta\eta$, and ΔG^{*E} were calculated from the experimental data with the following equations (10).

$$[1] \quad V^E = V_m - \sum_{i=1}^{2} V_i x_i$$

[2] $$\delta\eta = \eta_m - \sum_{i=1}^{2} \eta_i^0 x_i$$

[3] $$\Delta G^{*E} = RT[\ln \eta_m V_m - \sum_{i=1}^{2} (x_i \ln \eta_i^0 V_i^0)]$$

where x_i, V_i^0 and η_i^0 represent the mole fraction, molar volume, and viscosity of the ith pure component of the mixture; the subscript, m refers to the property of the mixture, and RT has the conventional meaning.

The molar volume V_m of the mixture was calculated from

[4] $$V_m = \sum_{i=1}^{2} x_i M_i / \rho_m$$

Where ρ_m is mixture density and M_i represent the molecular weight of component i in the mixture.

The partial molar volumes, V_1 and V_2, of components 1 and 2 were calculated from (11)

[5] $$V_1 = V_1^0 + V^E/x_1 + x_1x_2[\partial(V^E/x_1)/\partial x_1]$$

[6] $$V_2 = V_2^0 + V^E/x_2 + x_1x_2[\partial(V^E/x_2)/\partial x_2]$$

The various quantities $Y(V^E, \delta\eta, \Delta G^{*E}, V_1$, and $V_2)$ over the entire range of composition have been fitted to empirical equation (12):

$$[7] \quad Y = x_1x_2 \sum_{i=0}^{3} A_i(x_1 - x_2)^i$$

A nonlinear least-squares method (Marquardt algorithm) was used to estimate the coefficients, A_i. In each case, the optimum number of coefficients was ascertained from an examination of the variation of the standard error (σ) of the estimate with:

$$[8] \quad \sigma = [\Sigma(X^E_{obs} - X^E_{cal})^2/(n - P)]^{1/2}$$

where n is the total number of data points and P is the number of coefficients considered ($P = 4$ in the present calculation).

The last term of eqs. [5] and [6] was obtained by differentiating eq. [7] for V^E. Although this procedure is not adequate for small x_i, the results obtained can be considered valid since the contribution of the last term of eqs. [5] and [6] to the partial molar volume is less than 0.5% over the entire mole fraction scale. All these results are summarized in Table 1.

The isobaric thermal expansion coefficients, α_m of the mixture at a particular composition can be obtained either from the temperature variation of densities or by adding the contributions of the expansivities of each component in the mixture. Application of the latter method gives the relation for α_m of the mixture as:

$$[9] \quad \alpha_m = (1/\bar{V}_m)[\Sigma_i \frac{(M_ix_i)}{\bar{\rho}_i^0}\bar{\alpha}_i^0 + (\partial V^E/\partial T)_{P,x}]$$

where $\bar{V}_m$ is the average value of the molar volume of the mixture at each composition; $\bar{\rho}_i^0$ and $\bar{\alpha}_i^0$ are the average values of density and expansivity of pure components. Such average values are considered to be constant within the range of temperature used in this work. The values of $\bar{\alpha}_i^0$ were computed from the application of refractive index mixture rules (13, 14) using the known values of $(dn/dT)_i$ for ith liquid using the following relations:

For Gladstone–Dale (G–D) relation (15)

$$[10] \quad \bar{\alpha}_i^0(\text{G–D}) = -(1/n_i - 1)(dn/dT)_i$$

For Lorenz-Lorentz (L–L) relation (16)

$$[11] \quad \bar{\alpha}_i^0(\text{L–L}) = -[6n_i/(n_i^2 - 1)(n_i^2 + 2)](dn/dT)_i$$

For Eykman (Eyk) relation (17)

$$[12] \quad \bar{\alpha}_i^0(\text{Eyk}) = -[(n_i^2 + 0.8n_i + 1)/(n_i^2 - 1)(n_i + 0.4)](dn/dT)_i$$

For Oster (Ost) relation (18)

$$[13] \quad \bar{\alpha}_i^0(\text{Ost}) = -[2n_i(2n_i^4 + 1)/(n_i^2 - 1)(2n_i^4 + n_i^2)](dn/dT)_i$$

The values of $(dn/dT)_i$ for pure components needed in the above relations viz., eqs. [10]–[13], were either computed by extrapolation of the refractive index data over an interval of temperature or in some cases, these were directly obtained from the literature (9). On the other hand, experimentally, α_m can be obtained by using.

$$[14] \quad \alpha_m = -(\partial \ln \rho_m/\partial T)$$

The excess isobaric thermal expansion coefficient α^E of the mixture is a parameter which can be calculated from the following considerations:

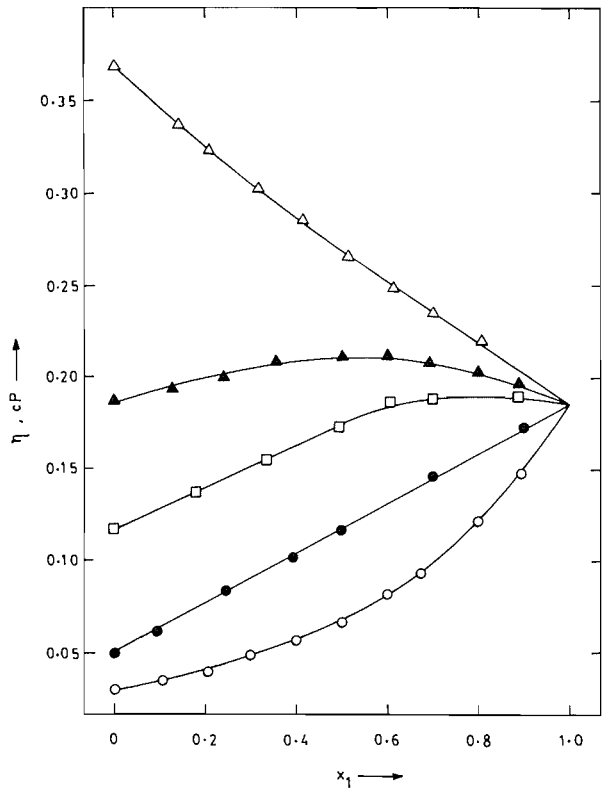

FIG. 1. Viscosity, η_m versus mole fraction, x_1 for binary mixtures at 298.15 K for mixtures of bromoform with (○) n-hexane; (△) aniline; (□) benzonitrile; (●) butyronitrile; (▲) benzylnitrile.

$$[15] \quad \alpha_m = \sum_{i=1}^{2} \bar{\alpha}_i^0 x_i + \Delta\alpha$$

As a first approximation, $\Delta\alpha$ may be described by means of a constant α^E according to:

$$[16] \quad \Delta\alpha = \alpha^E x_1x_2$$

Alternatively, α^E can be expressed more generally, as a function of x_1 and x_2 fitted to the experimental data by a polynomial. Thus,

$$[17] \quad \alpha_m = \sum_{i=1}^{2} \bar{\alpha}_i^0 x_i + x_1x_2 \sum_{i=1}^{3} A_i(x_1 - x_2)^i$$

Here, the values of $\bar{\alpha}_i^0$ have been calculated from the mixture rules. The fitted values of α^E are used to trace the plots of Figs. 7 and 8.

In view of the importance of enthalpy, $\Delta H^{\ddagger}$, and entropy, $\Delta S^{\ddagger}$, of activation of flow, we have calculated these quantities from the theory of Eyring *et al.* (6):

$$[18] \quad \eta_m = (N_Ah/V_m) \exp(\Delta H^{\ddagger}/RT - \Delta S^{\ddagger}/R)$$

Where N_A is Avogadro constant and h is Planck's constant. A plot of $\ln(\eta_mV_m/N_Ah)$ versus $1/T$ should be a straight line; the values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ were obtained from the slope and intercept, respectively.

To the best of our knowledge, there are no literature data on densities and viscosities of the studied mixtures with which the present results can be compared. Figures 1 and 2 show the dependence of viscosity and density of mixtures at 298.15 K.

However, the dependence of V^E, $\delta\eta$, and ΔG^{*E} on x_1 at

298.15 K for all the mixtures is shown in Figs. 3, 4, and 5. In Fig. 6, the dependence of V_1 and V_2 for a few typical mixtures is presented. The computed α^E values from the mixture rules, i.e., eqs. [10] to [13] and those of experimental α^E are presented in Figs. 7 and 8 for only a few typical mixtures.

Discussion

From a linear dependence of η_m on x_1, as shown in Fig. 1, it is found that the mixture, bromoform (1) + butyronitrile (2) exhibits an ideal behavior; this is due to their identical molar volumes (i.e., ~88 cm^3 mol^{-1} at 298.15 K). This is further confirmed by the linear variation of ρ_m with x_1 (Fig. 2). However, a large negative deviation as observed for bromoform (1) + *n*-hexane (2) in both viscosity and density profiles is attributed to their large differences in molar volumes (e.g., for bromoform, V_1^0 = 87.8 cm^3 mol^{-1}; for *n*-hexane V_2^0 = 131.2 cm^3 mol^{-1} at 298.15 K). Similarly, mixtures of bromoform with benzylnitrile and benzonitrile show significant deviations from linearity. On the other hand, for bromoform (1) + aniline (2), a slight deviation from linearity is prevalent for both ρ_m and η_m. This is because the molar volume of aniline (V_2^0 = 91.44 cm^3 mol^{-1} at 298.15 K) is somewhat close to that of bromoform. The same dependencies are observed at higher temperatures. However, to avoid overcrowding, these curves are not drawn.

Figure 3 shows the variation of excess molar volumes of the binaries at 298.15 K. For all mixtures, it is noticed that V^E tend to increase with an increase in temperature; this increase is somewhat insignificant for the chosen systems in the temperature interval of 298.15 to 313.15 K and thus, only the room temperature data are plotted. A close inspection of the V^E plots reveals positive V^E values for mixtures of bromoform with benzylnitrile and aniline; no sharp maxima are observed in both cases. The molecular interactions in these mixtures are thus characterized by dispersion type forces. Replacement of NH_2 group as in aniline by a more bulkier group like —CH_2CN as in benzylnitrile increases their steric repulsions with bromine atoms of bromoform. This would mean that benzylnitrile (due to its increased electron-donating capacity) will be attracted to the bromine atoms of bromoform leading to increased repulsion. Since V^E reflects the packing of the components of a binary mixture, it should be more positive for bulkier groups. This explains the observed higher V^E values of bromoform (1) + benzylnitrile (2) mixture as compared to bromoform (1) + aniline (2). Such observations can also be found in the literature (19).

A small but negative V^E as observed for bromoform (1) + benzonitrile (2) mixture may be due to the fact that benzonitrile (dipole moment, μ = 4.05 D at 303.15 K) is more polar than bromoform (μ = 0.99 D at 303.15 K). Thus, there is an induced dipole–dipole interaction leading to negative V^E (20). Similarly, mixtures of bromoform with *n*-hexane and butyronitrile suggest the existence of specific interactions as evidenced by large but negative values of V^E; sharp minima are observed around middle of the composition scale for both the mixtures. However, the highest negative V^E shown by bromoform (1) + *n*-hexane (2) mixture is attributed to a large difference in their molar volumes. In general, the trend in the variation V^E followed the sequence:

benzylnitrile > aniline > benzonitrile > butyronitrile > *n*-hexane

Figure 4 shows the dependence of $\delta\eta$ on x_1; mixtures of bromoform with aniline or with *n*-hexane exhibit negative $\delta\eta$. On the other hand, mixtures of bromoform with benzylnitrile or benzonitrile exhibit positive $\delta\eta$ with maxima or minima occurring around the middle of the composition scale. Surprisingly, the system bromoform (1) + butyronitrile (2) exhibits an entirely different behavior i.e., both positive and negative $\delta\eta$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12

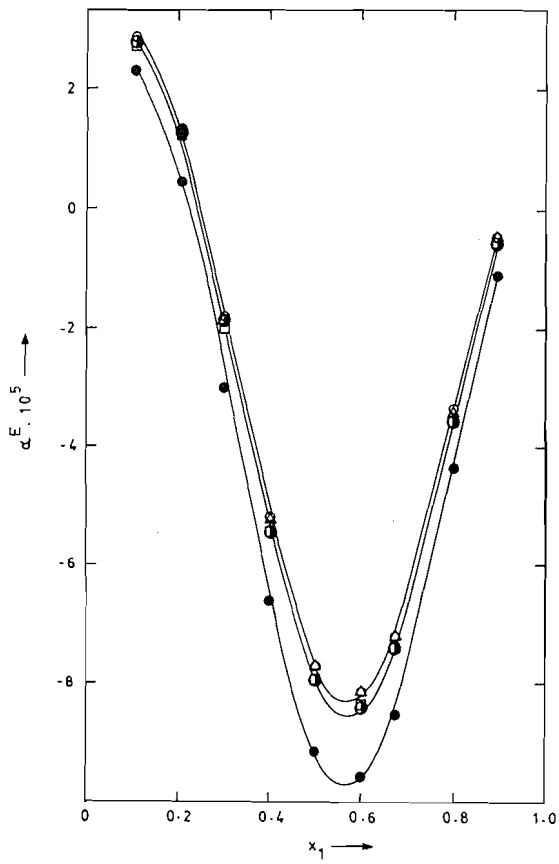

FIG. 8. Same as in Fig. 7 for bromoform + *n*-hexane mixture at 298.15 K. Symbols have the same meaning as in Fig. 7.

values are observed. Values of $\delta\eta$ increase with increase in temperature. This indicates that in these binary mixtures, the forces between pairs of unlike molecules are somewhat less than the forces between pairs of like molecules and that is why the mixture is less viscous (10).

Bromoform is less polar as compared to the three nitriles used here. Thus, in mixtures, it is expected that highly polar nitriles induce a dipole moment on somewhat less polar molecule like bromoform leading to the rupture of the molecular order as evidenced by the positive excess free energy of flow (Fig. 5). However, small but positive ΔG^{*E} for bromoform (1) + aniline (2) system is due to the less polar nature of the aniline ($\mu = 1.51$ and $\epsilon = 6.9$). The negative ΔG^{*E} for bromoform (1) + *n*-hexane (2) mixture indicates the absence of dipole–dipole type interactions because the dipole moment of *n*-hexane is smaller than bromoform. For all mixtures, except bromoform (1) + aniline (2), the ΔG^{*E} profiles are highly symmetric over the entire x_1 scale and the maxima or minima occurred for values of x_1 between 0.4 to 0.6.

The trend in the variation of $\delta\eta$ and that of ΔG^{*E}, vary respectively, in the following sequence: $\delta\eta$: benzylnitrile > benzonitrile > butyronitrile > aniline > *n*-hexane; ΔG^{*E}: butyronitrile > benzonitrile > benzylnitrile > aniline > *n*-hexane.

Thus, on the whole, it appears that there are strong specific interactions between bromoform and *n*-hexane in solution.

Figure 6 shows the variation of V_1 and V_2 with x_1 for some representative mixtures viz., nitriles with bromoform. It is seen that the convex shapes are observed for V_2 in case of mixtures of bromoform with benzonitrile and benzylnitrile whereas a reverse tendency is seen for the dependence of V_1. Similar observations are seen with other mixtures of bromoform except bromoform (1) + butyronitrile (2) wherein V_1 showed convex behavior and V_2 the concave shape.

Following the approach developed by Eyring and co-workers (6), the values of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ are estimated for the mixtures considered here. It is found that in all cases, $\Delta S^{\neq}$ values are negative and small. Nitriles when mixed with bromoform produced almost identical $\Delta S^{\neq}$ values and vary generally in the range ~42 to 59 J mol^{-1} K^{-1}. However, no systematic variation of $\Delta S^{\neq}$ is seen with x_1 for many mixtures, except bromoform (1) + aniline (2), wherein $-\Delta S^{\neq}$ values increased systematically from ~27 to 52 J mol^{-1} K^{-1} with an increase in bromoform content of the mixture. In general, the negative $\Delta S^{\neq}$ values confirm the formation of activated weak molecular complexes leading to increased order as result of flow. For all the mixtures, the positive $\Delta H^{\neq}$ which range from ~5 to 2 kJ mol^{-1} K^{-1} suggest the endothermic nature of the mixing process.

The variation of α^E on x_1 for the system, bromoform (1) + aniline (2) at 298.15 K is shown in Fig. 7. It is found that Eykman relation agrees somewhat closer to the experimental α^E than the other mixture rules. Similar observations are also seen for the bromoform (1) + *n*-hexane (2) mixture (see Fig. 8) and other mixtures of bromoform with nitriles.

Infrared and vibrational circular dichroism intensities of model systems CH_3OH, CH_3NH_2, NH_2NH_2, NH_2OH, and HOOH and the deuterated species, ND_2ND_2, DOOH, and DOOD: A theoretical study using the vibronic coupling formalism

ARVI RAUK,[1] REMO DUTLER, AND DANYA YANG

We have implemented at the *ab initio* level the vibronic coupling formalism for infrared and vibrational circular dichroism (VCD) intensities of Nafie and Freedman. We report here the results of a series of calculations on model systems. Hydrazine and hydrogen peroxide exist in chiral conformations. Although low barriers to racemization preclude the possibility of optical resolution of the parent compounds, the local *gauche* configuration at the heteroatom bond is preserved in substituted hydrazines and peroxides and these chiral fragments may contribute significantly to the vibrational chiroptical properties of the molecules in which they appear. The calculated VCD rotational strengths for the chiral *gauche* forms of both molecules suggest that the torsional mode is very intense in the VCD spectrum. In *gauche* hydrazine of P chirality, the in- and out-of-phase umbrella motions of the nitrogen atoms, $\nu 6$ and $\nu 12$, respectively, give rise to an intense CD couplet with negative rotational strength to the long wave length side. In hydrazine, all combinations of NH stretches are relatively weak in the IR but the highest frequency mode of b symmetry, $\nu 8$, has moderate positive strength. The in- and out-of-phase OOH bends of HOOH behave as a coupled oscillator system, exhibiting a strong bisignate CD pattern. The signals calculated for the OH stretches are not consistent with a coupled oscillator model. The nearly degenerate stretches result in a single band arising from the more intense negative rotational strength of the antisymmetric mode $\nu 5$, in HOOH of *P* chirality. An alternative model, based on induced charge flow along the chirally disposed skeleton (i.e., Nafie and Freedman's 3-bond electronic current model), explains the calculated sign of the antisymmetric mode, $\nu 5$. Significant changes in the VCD patterns due to deuterium substitution in both chiral molecules are discussed.

Key words: vibrational circular dichroism (VCD), *ab initio*, infrared intensities, molecular orbital, vibronic coupling theory, methanol, methanamine, hydrazine, hydroxylamine, hydrogen peroxide.

ARVI RAUK, REMO DUTLER et DANYA YANG. Can. J. Chem. **68**, 258 (1990).

On a implanté au niveau *ab initio* le formalisme de couplage vibronique développé par Nafie et Freedman pour les intensités infrarouges et du dichroïsme circulaire vibrationnel (DCV). On rapporte maintenant une série de calculs sur des systèmes modèles. L'hydrazine et le peroxyde d'hydrogène existent dans des conformations chirales. Même si les barrières à la racémisation sont tellement basses qu'il est impossible d'effectuer la résolution optique des composés parents, la configuration *gauche* locale de la liaison de l'hétéroatome est préservée dans des hydrazines et des peroxydes substitués et ces fragments chiraux peuvent contribuer d'une façon importante aux propriétés chiroptiques des molécules dans lesquelles ils apparaissent. Les forces rotationnelles calculées pour le DCV des formes *gauches* chirales de ces deux molécules suggèrent que le mode de torsion est très intense dans le spectre de DCV. Dans l'hydrazine *gauche* de chiralité *P*, les mouvements du parapluie des atomes d'azote qui sont ou qui ne sont pas en phase, respectivement $\nu 6$ et $\nu 12$, donnent lieu à un couplage de DC qui est intense et dont la force rotationnelle est négative jusqu'à la portion des grandes longueurs d'onde. Dans l'hydrazine, toutes les combinaisons des élongations NH sont relativement faibles dans l'IR; toutefois, le mode de symétrie b à la plus haute fréquence, $\nu 8$, possède une force positive d'intensité modérée. Les torsions dans le plan et hors du plan du OOH du HOOH se comportent comme un système oscillateur couplé présentant un DC fort à double signe. Les signaux calculés pour les élongations OH ne sont pas en accord avec un modèle d'oscillateur couplé. Dans le HOOH de chiralité *P*, les élongations pratiquement dégénérées sont le résultat d'une seule bande provenant de la force rotationnelle négative la plus intense du mode antisymétrique $\nu 5$. Un modèle alternatif, basé sur le flux de la charge induite le long du squelette disposée d'une façon chirale (soit le modèle actuel à trois liaisons électroniques de Nafie et Freedman), permet d'expliquer le signe calculé du mode antisymétrique, $\nu 5$. On discute des changements importants observés dans les DCV lorsqu'on introduit des atomes de deutérium dans ces deux molécules chirales.

Mots clés : dichroïsme circulaire vibrationnel (DCV), *ab initio*, intensités infrarouges, orbitales moléculaires, théorie du couplage vibronique, méthanol, méthanamine, hydrazine, hydroxylamine, peroxyde d'hydrogène.

[Traduit par la revue]

Introduction

Chiroptical measurements in the vibrational region of the electromagnetic spectrum promise to yield more structural information than other spectroscopic techniques but have suffered from the intractibility of the theory underlying the phenomenon and severe experimental difficulties. With the recent advent of Fourier transform methods (1) and other improvements in instrumentation, most of the vibrational region is amenable to measurements of both vibrational circular dichroism (VCD) and Raman optical activity (ROA), and numerous experimental results have emerged. Recent advances in the underlying theory (2–5) have kept pace with the advances in instrumentation. Semiempirical implementations of VCD theories have served to correlate some structural features and suggest new insights but have suffered from a general lack of predictability. Significant advances have had to await *ab initio* implementations. This was first accomplished by Stephens and co-workers (6) who reported the calculation of the CH and CD stretching IR and VCD intensities of *trans*-dideuteriocyclopropane and subsequently demonstrated encouraging agreement with experimentally measured values for *trans*-1,2-dideuteriocyclobutane and propylene oxide (7). Successive applications to a number of small model and real systems ensued (8).

The vibronic coupling formalism for infrared (IR) and vibrational circular dichroism (VCD) intensities of Nafie and Freedman (4) has recently been implemented at the *ab initio* level (9) and the complete IR and VCD spectra of (*S*,*S*)-2,3-dideuterooxirane as well as the other deuterated isotopomers have appeared (10). This provides an alternative to the VCD formalism of Stephens (5). We report here the results of a series of calculations on model systems, methanol **1**, methanamine **2**, hydrazine **3**, hydroxylamine **4**, and hydrogen peroxide **5**. Some are intrinsically chiral, while others may be rendered so by virtue of isotopic substitution. All compounds contain polar bonds and are expected to exhibit strong IR and/or VCD activity. Hydrazine **3** and hydrogen peroxide **5** exist in chiral conformations. Low barriers to racemization preclude the possibility of optical resolution except in the solid state. However, the local *gauche* configuration at the heteroatom bond is preserved in substituted hydrazines and peroxides and these chiral units may contribute significantly to the vibrational chiroptical properties of the molecules in which they appear. We present here the results of an *ab initio* investigation using the vibronic coupling theory of Nafie and Freedman (4) of the IR intensities of **1**–**5**, as well as the VCD properties of the chiral systems, **3** and **5**, perdeuterio-**3** and -**5**, and monodeuterio-**5**.

Theory

The following is an abbreviated derivation of the vibronic theory of Nafie and Freedman (4). The dipole strength, $D_{g,e}$, and rotational strength, $R_{g,e}$, are given by:

$$[1] \qquad D_{g,e} = (\mu)_{g,e}(\mu)_{e,g} = (\langle\Phi_g|\mu_{el}|\Phi_e\rangle\langle\Phi_e|\mu_{el}|\Phi_g\rangle)$$

$$[2] \qquad R_{g,e} = (\mu)_{g,e}(m)_{e,g} = Im(\langle\Phi_g|\mu_{el}|\Phi_e\rangle\langle\Phi_e|\mu_{mag}|\Phi_g\rangle)$$

where Φ_g and Φ_e are the total molecular wavefunction of the ground state g and a vibrationally excited state e. The operators μ_{el} and μ_{mag}, the electric and magnetic dipole operators are given by:

$$[3] \qquad \mu_{el} = \mu^n_{el} + \mu^e_{el} = \Sigma_{n=1}^{n=n_{atoms}}\chi_n r_n + \Sigma_{i=1}^{i=n_{electrons}}\chi_i r_i$$

$$[4] \qquad \mu_{mag} = \mu^n_{mag} + \mu^e_{mag} = \Sigma_{n=1}^{n=n_{atoms}}\frac{\chi_n}{2m_n c}(r_n \times p_n) + \Sigma_{i=1}^{i=n_{electrons}}\frac{\chi_i}{2m_i c}(r_i \times p_i)$$

where μ^n_{el}, μ^e_{el}, μ^n_{mag}, and μ^e_{mag} denote the nuclear and electronic contributions of the electric and magnetic dipole transition moment operators, respectively. χ_k is the charge of particle k with mass m_k which is located at a point r_k relative to the origin of coordinates and moving with linear momentum p_k. The wavefunctions Φ_e and Φ_g may be represented as $\Phi_{0\nu'}$ and are expanded in terms of adiabatic Born–Oppenheimer functions $\{\Psi^a_e(r,Q)\phi_{e\nu}(Q)\}$:

$$[5] \qquad \Phi_{0\nu'} = \Psi^a_0\phi_{0\nu'} - \Sigma_{e\nu}\frac{\langle\Psi^a_e\phi_{e\nu}|T_N|\Psi^a_0\phi_{0\nu'}\rangle}{E_{e\nu} - E_{0\nu'}}\Psi^a_e\phi_{e\nu}$$

The variable ν' is either 0 or 1, denoting the vibrational ground or first excited state. The perturbation operator T_N is taken as that part of the nuclear kinetic energy operator which involves only first derivatives with respect to nuclear coordinates (normal modes) Q, acting separately on the electronic and nuclear parts of wavefunction, namely

$$[6] \qquad T_N = -\left(\frac{h}{2\pi}\right)^2\left(\frac{\partial}{\partial Q}\right)_{elec}\left(\frac{\partial}{\partial Q}\right)_{nuc}$$

The normal mode dependence of Ψ^a_0 is expressed as a Taylor expansion about the equilibrium geometry, keeping only the first order terms, and using the identity $1 = \Sigma_e|\Psi^a_e\rangle\langle\Psi^a_e|$,

$$[7] \qquad \Psi^a_0 = (\Psi^a_0)_0 + \left(\frac{\partial\Psi^a_0}{\partial Q}\right)_0 Q = (\Psi^a_0)_0 + \Sigma_e\langle\Psi^a_e\left|\frac{\partial}{\partial Q}\right|\Psi^a_0\rangle_0 Q\Psi^a_e$$

Use of eqs. [3]–[7], the approximation that the separation between vibrational levels of different electronic states is approximately equal to the difference between Born–Oppenheimer surfaces at the ground state equilibrium geometry, namely

$$[8] \qquad \frac{1}{E_{e\nu} - E_{01}} = \frac{1}{E^0_e - E^0_0}$$

and the expansion of the normal modes in terms of internal coordinates R_n,

$$[9] \qquad Q^j = \Sigma_{n=1}^{n_{atoms}} R_n s^j_n$$

allows one to obtain, after some algebra, expressions for the electric and magnetic dipole transition moments used in eqs. [1] and [2]. Specifically, for the jth normal mode, one obtains [4]

$$[10.1] \qquad \mu^{VC}_{(00,01)j} = \left(\frac{\hbar}{2\omega_j}\right)^{1/2}\left[\Sigma_{n=1}^{n_{atoms}}\chi_n s^j_n - 2\Sigma_{n=1}^{n_{atoms}}\Sigma_{i=1}^{n_{electrons}}\Sigma_{e=1}^{n_{ex}}\langle\Psi^a_0|r_i|\Psi^a_e\rangle\langle\Psi^a_e\left|\frac{\partial}{\partial R_n}\right|\Psi^a_0\rangle s^j_n\right]$$

$$[10.2] \qquad = \left(\frac{\hbar}{2\omega_j}\right)^{1/2}\left[\Sigma_{n=1}^{n_{atoms}}\chi_n s^j_n - 2\Sigma_{n=1}^{n_{atoms}}\Sigma_{i=1}^{n_{electrons}}\langle\Psi^a_0\left|r_i\frac{\partial}{\partial R_n}\right|\Psi^a_0\rangle s^j_n\right]$$

and

$$[11] \qquad m^{VC}_{(00,01)j} = \frac{1}{2c}\left(\frac{\hbar}{2\omega_j}\right)^{1/2}\left[i\Sigma_{n=1}^{n_{atoms}}\chi_n(R_n \times s^j_n) - 2\Sigma_{n=1}^{n_{atoms}}\Sigma_{i=1}^{n_{electrons}}\Sigma_{e=1}^{n_{ex}}\langle\Psi^a_0|r_i \times p_i|\Psi^a_e\rangle \times \langle\Psi^a_e\left|\frac{\partial}{\partial R_n}\right|\Psi^a_0\rangle s^j_n\frac{1}{E^0_e - E^0_0}\right]$$

The superscript VC denotes that these expressions describe a vibronic coupling mechanism for IR and VCD intensities. The subscript (00,01) signifies that the transition is between the $\nu = 0$ and $\nu = 1$ vibrational levels of the ground electronic state of the molecule. Electric dipole strengths derived from eq. [10] are formally equivalent to the Atomic Polar Tensor (APT) theory. Stephens circumvents the summation over excited states in eq. [11] by invoking the magnetic field dependence of the wavefunction, a procedure which requires solution of the perturbed Hartree–Fock equations in the presence of a magnetic field (5). In the present case, the sum over excited states which appears in eq. [10.2] and in the second term of eq. [11] is explicitly evaluated, in the first instance as a check for the "completeness" of the set of excited states (i.e. eqs. [10.1] and [10.2] should yield identical results), and in the second case out of necessity, since the presence of the energy dependence within the summation in eq. [11] precludes closure as is possible for eq. [10]. "Completeness" by the criterion that eqs. [10.1] and [10.2] give nearly identical results is only satisfied if the basis set is expanded by addition to it

of derivatives of the normal basis functions with respect to nuclear displacements (11).

Method

The geometries of **1**–**5** were determined by complete optimization at the restricted Hartree–Fock level of theory using the analytical procedures of the GAUSSIAN 82 system of programs (12) and the internal 6-31G** basis set (13). Normal coordinate analysis at the 6-31G** equilibrium geometry was carried out by analytical second differentiation of the Born–Oppenheimer RHF energy (14) using a basis set we designate as 6-31G~ (see below). Harmonic frequencies for isotopically substituted species, as well as IR and VCD (where appropriate) intensities were accomplished by the program system Freq85 (9), which implements the vibronic coupling theory of Nafie and Freedman (4) at the *ab initio* level. For improved agreement with experiment, frequencies were uniformly scaled by 0.9 (15). The intensity evaluations were accomplished using the 6-31G~ basis set, which is constructed by addition to the 6-31G basis set all non-redundant derivatives of the 6-31G basis functions with respect to nuclear displacements (11). Previous experience (9, 10) has shown that 6-31G~ geometries are very similar to 6-31G** geometries. Consequently, geometry optimization was not repeated with the 6-31G~ basis which is comparable in size to the larger standard 6-311G** basis set. The origin of coordinates in all intensity calculations was the molecular center of mass. Simulated IR and VCD spectra were obtained assuming a Lorentzian lineshape of half width 12 cm^{-1} and using uniformly scaled frequencies ($\times 0.9$).

Results and discussion

The RHF/6-31G** geometries are shown in Fig. 1. The structures of all systems agree reasonably well with corresponding experimental values (16, 17) and are virtually the same as the results of other *ab initio* calculations using large basis sets (18–20). At the present level of theory, bond angles generally agree to within 1.4° and bond lengths are underestimated by about 0.028 Å (18). Of the parent molecules, only hydrazine, **3**, and hydrogen peroxide, **5**, have chiral skeletons. The absolute configurations shown in Fig. 1 correspond to *P*, or right-handed, chirality. The other systems belong to molecular point group C_s. Simulated IR and VCD spectra of the parent systems are shown in Figs. 2, 4–6, and listed in Tables 1–5. The results are discussed separately below.

Methanol 1. The RHF/6-31G** geometry of **1** is shown in Fig. 1. The calculated geometry agrees well with experiment (C—O = 1.421 Å, O—H = 0.963 Å, ⟨C—H⟩ = 1.094 Å, C—O—H = 108.0° (16)) in all respects. The molecular point group is C_s. The C—H bond in the C—O—H plane is significantly shorter (1.082 Å) than the out-of-plane C—H bonds (1.088 Å). Raw and scaled harmonic frequencies and VC intensities calculated from the 6-31G~ force field are presented in Table 1. The simulated IR spectrum is shown in Fig. 2. The IR intensities agree quite well with qualitative experimental results (21) and the simulated spectrum resembles the experimental high pressure gas phase spectrum of Person (22) quite closely. The VC/6-31G~ results differ in some important respects from the CNDO/2 FORCE results of Kuczera (23) which are also given in Table 1. Specifically, with the present method, the intensities of the very strong band, $\nu 8$, and the very weak band, $\nu 5$, are qualitatively correct. Infrared intensities for **1** have been calculated by *ab initio* methods and using atomic polar tensors transferred from smaller molecules by Person (22). The main features of the experimental spectrum are very well reproduced in the simulated spectrum of Fig. 2.

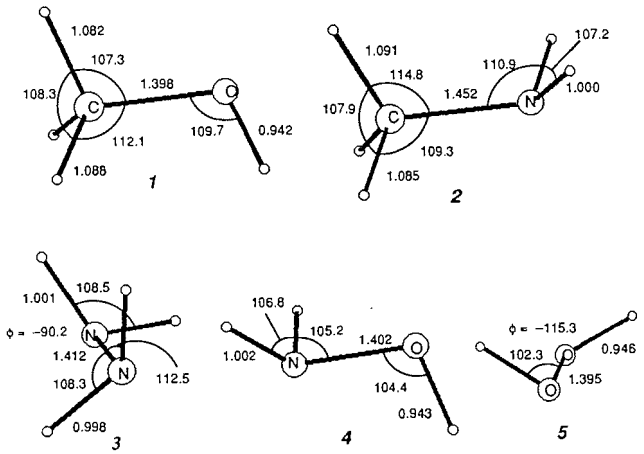

FIG. 1. The 6-31G** equilibrium structures (point groups) of methanol **1** (C_s), methanamine **2** (C_s), hydrazine **3** (C_2) hydroxylamine **4** (C_s), and hydrogen peroxide **5** (C_2). The absolute configurations of hydrazine and hydrogen peroxide shown have *P* chirality. Bond lengths are in Angstroms, bond and dihedral angles are in degrees.

Methanamine 2. The RHF/6-31G** geometry of **2** is shown in Fig. 1. The calculated geometry agrees well with experiment (C—N = 1.471 Å, N—H = 1.010 Å, ⟨C—H⟩ = 1.099 Å, C—N—H = 110.3° (16)) in all respects. The molecular point group is C_s. As in the case of **1**, the C—H bond opposite the lone pair is significantly longer (1.091 Å) than the other C—H bonds (1.085 Å). Raw and scaled harmonic frequencies calculated from the 6-31G~ force field are presented in Table 2. The simulated IR spectrum is shown in Fig. 2. The in- and out-of-phase N—H stretching modes, $\nu 1$ and $\nu 10$, at ~3400 cm^{-1} (scaled value) are very weak. The three methyl stretching distortions are separated by virtue of the interaction of one of the C—H bonds with the N non-bonded pair of electrons. The stretching mode at lowest frequency, $\nu 3$, formally the Me symmetric stretch, is more intense than the other two modes, and has a much larger component from the C—H bond which is *anti* to the N lone pair of electrons (Fig. 3*a*). The most intense band in the IR spectrum of **2** is calculated to arise from the pyramidal inversion motion at the nitrogen centre, $\nu 9$ (Fig. 3*b*), at 855 cm^{-1} (scaled). The torsion mode, $\nu 12$ (Fig. 3*c*), is relatively weak compared to the corresponding mode of **1**.

Hydrazine 3. The RHF/6-31G** geometry of **3** is shown in Fig. 1. The calculated geometry agrees well with experiment (N—N = 1.447 Å, ⟨N—H⟩ = 1.008 Å, N—N—H = 109.2°, H—N—H = 113.3°, ϕ = 88.9° (16)). The molecular point group is C_2. Raw and scaled harmonic frequencies calculated from the 6-31G~ force field are presented in Table 3. Hydrazine has been the subject of numerous IR and Raman investigations (24), as well as a thorough theoretical study by Morokuma and co-workers (25) who carried out a complete assignment of the vibrational spectrum based on *ab initio* force fields. The frequencies calculated using a CI–6-31G* force field and the association with observed bands shown in Table 3 are according to Morokuma and co-workers who revised a number of previous assignments (25). Our calculated frequencies (after uniform scaling) and our assignments agree entirely with theirs except in the NH stretching modes, $\nu 1$ and $\nu 8$, which we and they

calculate to be nearly degenerate and which are not resolved experimentally. Our IR and VCD intensities are tabulated in Table 3 and simulated spectra are displayed in Fig. 4. The most intense band in the IR spectrum, ν12 at 1001 cm^{-1} (scaled) corresponds to the out-of-phase umbrella motion of the two nitrogen atoms. The in-phase umbrella motion, ν6, at 873 cm^{-1} is also intense. These motions give rise to an intense conservative CD couplet in the VCD spectrum (Fig. 4*b*) of NH_2NH_2, as well as its tetradeuterio analogue, ND_2ND_2 (Fig. 4*a*). A symmetrical CD couplet is also predicted for the NH_2 rocking

modes, ν4 and ν11, near 1300 cm^{-1}. The effect of deuteration on IR and VCD spectra, besides the obvious frequency shift due to the increased mass, is to reduce the intensities of those modes where the motion of H/D dominates. Thus the VCD spectrum of ND_2ND_2 shown in Fig. 4 is only about one quarter as intense as the VCD spectrum of NH_2NH_2. The rocking modes of the ND_2 groups do not give rise to a CD couplet as was observed in the case of NH_2NH_2 since these modes are shifted closer to the N—N stretch, ν5, and the increased coupling of ν4 and ν5 redistributes their negative rotatory intensity to both sides of the positive CD band due to ν11. The VCD spectra of all of the deuterated isotopomers of **3** will be described in greater detail elsewhere (26).

Hydroxylamine ***4***. The RHF/6-31G** geometry of **4** is shown in Fig. 1. The calculated geometry agrees well with experiment (N—O = 1.453 Å, N—H = 1.016 Å, O—H = 0.962 Å, O—N—H = 103.2°, N—O—H = 101.4°, H—N—H = 107.1° (16)) except that the N—O bond length is shorter by 0.051 Å. The molecular point group is C_s. Raw and scaled harmonic frequencies calculated from the 6-31G~ force field are presented in Table 4 and the simulated IR spectrum is shown in Fig. 2. The strongest calculated absorption, ν9, corresponds to the torsional mode. This has been reported as *very weak* by Giguere and Liu (27). The second most intense absorption, ν5,

[e]Our calculated frequencies multiplied by 0.9 (ref. 15).
[f]$\times 10^{40}$.

is calculated to be the out-of-phase combination of umbrella motion at N and the N—O—H bend, dominated by the former. The umbrella mode, ν5, of **4** is markedly shifted to higher frequency compared to ν9 of **2** or ν6 and ν12 of **3**, due to the repulsive 4-electron interaction between the non-bonding lone pair on N and the lower non-bonding electron pair on O. The NH_2 rocking mode, ν8, is extremely weak and is expected to occur near 1330 cm^{-1}. The N—O—H bend is the major component of the motion responsible for the band, ν4, at 1405 cm^{-1} (scaled), observed at 1357 cm^{-1} (27). The NH_2 scissor, ν3, occurs at 1657 cm^{-1} (scaled), 1605 cm^{-1} (observed (27)). The calculated position is very similar to the values obtained for the same mode in **2** (ν4, at 1643 cm^{-1}) and **3** (ν3, at 1670 cm^{-1}, and ν10, at 1659 cm^{-1}). As was the case for **2** and **3**, the NH stretches, ν2 and ν7, are calculated to be very weak.

Hydrogen peroxide **5**. The RHF/6-31G** geometry of **5** is shown in Fig. 1. The calculated geometry agrees reasonably well with experiment (O—O = 1.464 Å, O—H = 0.965 Å, O—O—H = 99.4°, ϕ = 121.6° (17)). Systematic deviations at the RHF level could be corrected by inclusion of electron

correlation in the calculations (18, 20) but this is beyond the scope of the present model studies. The molecular point group is C_2. Raw and scaled (by 0.9) harmonic frequencies calculated from the 6-31G~ force field are presented in Table 5 together with calculated IR and VCD intensities. It is noteworthy that even with the usual scaling factor, all of the calculated frequencies are higher than observed. Simulated IR and VCD spectra are shown in Fig. 5. Rogers and Hillman (29) have previously calculated absolute intensities for **5** by APT theory, using a combination of theoretical and empirical APTs for H_2O, CH_3OH, and HOCl. Their values, shown in Table 5, are in qualitative agreement with our 6-31G~ values. The most intense band in the IR is calculated to be the torsional mode, $\nu 4$. Its intensity may be exaggerated somewhat since the optimized torsional angle is too small by 6°.

The predicted VCD spectrum of *P*-H_2O_2 is shown in Fig. 5, and again in Fig. 6 for comparison to the predicted VCD spectra of the mono- and dideuterio isotopomers. The torsional mode, $\nu 4$, is calculated to give rise to the most intense VCD band (Fig. 4). The most striking feature of the VCD spectrum is the CD couplet between 1300 cm^{-1} and 1500 cm^{-1}. Polavarapu (30) has analysed the expected intensity distribution among symmetric and antisymmetric bending vibrational modes in A_2B_2 systems and has predicted that for H_2O_2 of *P* chirality, the higher frequency symmetric O—O—H bend, should be considerably weaker in the IR than the antisymmetric O—O—H bend, and have negative rotatory strength of about the same magnitude as the antisymmetric mode if the fixed-partial-charge (FPC) mechanism dominates. Our calculated VCD spectrum displays just these features, but with a two-fold asymmetry favouring the antisymmetric bending CD band, $\nu 6$. From Table 5, it is apparent that the symmetric and antisymmetric O—H stretching modes, $\nu 1$ and $\nu 5$, respectively, are not consistent with features expected from a simple coupled oscillator mechanism from which one would predict a negative rotatory strength for the symmetric O—H mode, $\nu 1$. The signs are reversed and there is a five-fold asymmetry favouring the antisymmetric band. The near degeneracy calculated and observed (28) of the frequencies of the two stretching modes has the effect of completely cancelling the weaker positive CD band. An explanation for the origin of the "anomalous" rotatory strength is offered in connection with the VCD spectrum of DOOH discussed below. Apparently, **5** does crystallize in a single enantiomeric form (31) so in principle the VCD spectrum can be measured.

The simulated VCD spectrum of dideuterio-**5** is shown in Fig. 5. The VCD intensities are greatly attenuated by deuterium substitution but the same features as were found in **5** are reproduced in the O—D stretching and torsional regions. The mid-IR region is predicted to be markedly different, however. The isotopic shift places the O—O—D bending frequencies into the vicinity of the O—O stretch and the strong mixture of the modes results in the disappearance of the CD couplet found for **5** itself.

The simulated VCD spectrum of DOOH is also shown in Fig. 5. In this system, the O—H and O—D stretches and

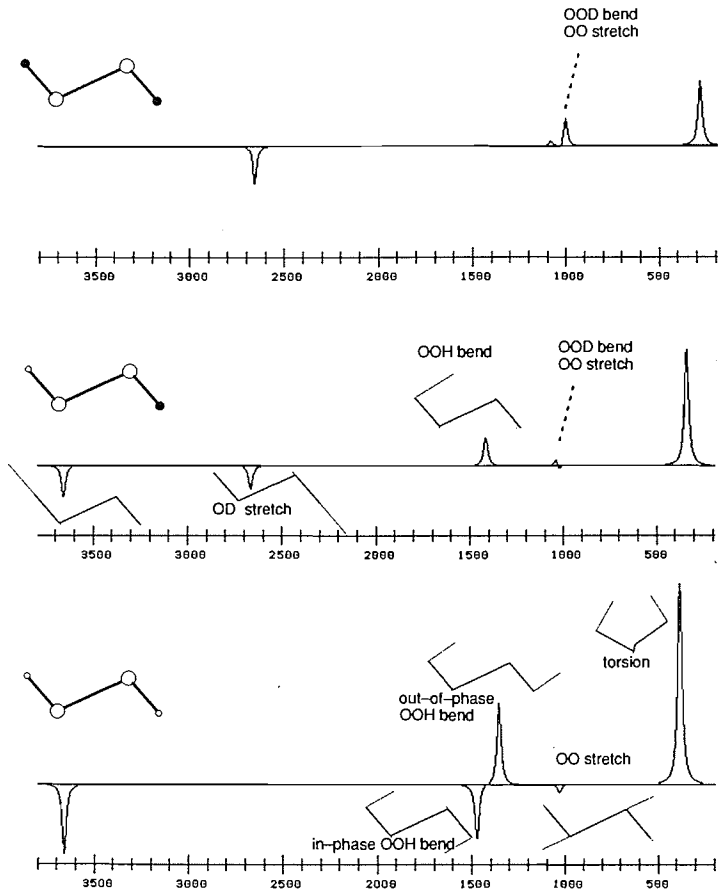

FIG. 6. Simulated VCD spectra of HOOH, HOOD, and DOOD, plotted on the same scale.

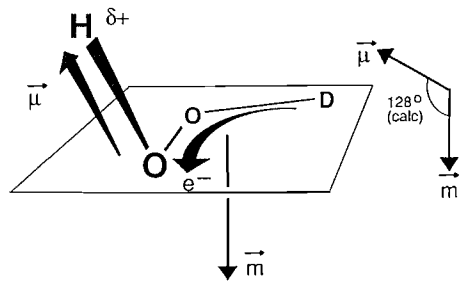

FIG. 7. Model for rotatory strength of O—H stretching vibration of HOOD of *P* chirality. Motion of the positive H away from the O—O—D group induces a flow of electrons toward it. The associated electric (μ) and magnetic (m) dipole transition moments are directed as shown. The calculated angle between the moments is −128°.

the O—O—H and O—O—D bends are well separated and essentially decoupled. Each of the isotopes, H or D, resides in a chiral environment of the same handedness. The O—O—H bend results in a positively signed band of similar intensity to the two stretches. The O—O—D bend and O—O stretch are almost degenerate and, as was the case for DOOD, the mixture of the two modes results in almost a complete cancellation of VCD intensity.

In DOOH, both stretching modes, O—H and O—D, yield a negative VCD signal, the origin of which may be explained by Nafie and Freedman's "3-bond electronic current model" (36) which is applied to DOOH in Fig. 7. The O—H bond is strongly polarized in the direction expected from electronegativity considerations. The bond dipole is positive and a stretch of the bond results in a positive change in the bond dipole (and the permanent molecular dipole moment) in the direction of the O—H(D) bond. The remainder of the molecule, the O—O—D(H) fragment, forms an arc along which negative charge is drawn toward the O—H(D) bond being stretched. The induced flow of charge around the arc is associated with an induced magnetic dipole moment perpendicular to the O—O—D(H) plane on the side opposite to the O—H(D) dipole. Thus the scalar product of the change in the electric dipole moment and the induced magnetic dipole moment is negative. The calculated angle between the electric and magnetic dipole transition moments is |128|°. In HOOH and DOOD where the stretching modes are coupled, the induced flow of charge along the bonds is cooperative in the case of the antisymmetric stretch, resulting in greater intensity for this mode.

Summary of VCD results

The calculated VCD rotational strengths for the *gauche* forms of *P* chirality shown in Fig. 1 for both chiral molecules, **3** and **4**, suggest that the torsional mode is very intense in the VCD spectrum. In hydrazine, the in- and out-of-phase umbrella motions of the nitrogen atoms, $\nu 6$ and $\nu 12$, respectively, give rise to an intense CD couplet with negative rotational strength to the long wave length side. The umbrella modes and the rocking modes of the NH_2 groups each form a coupled oscillator system which gives rise to very symmetrical CD couplets. This pattern is largely destroyed in ND_2ND_2 for the rocking modes because these are shifted into the region of, and mix with the NN stretch. In hydrazine, all combinations of NH stretches are relatively weak in the IR but the highest frequency mode of *b* symmetry, $\nu 8$, has moderate positive rotatory strength. The in- and

For personal use only.

out-of-phase OH stretches of HOOH, $\nu 1$ and $\nu 5$, respectively, nominally also a coupled oscillator system, reveal a significant asymmetry and anomalous signs in the expected bisignate CD pattern. The higher frequency mode, $\nu 5$, has a negative rotational strength four times as intense as the lower frequency mode, $\nu 1$, and completely cancels it in the calculated VCD spectrum. The results of the calculations are explained in terms of a simple model (36) involving an induced flow of electrons around the O—O—H arc in the direction of the O—H bond being stretched.

THOMAS EGGIMANN, TRACY L. SMITHSON, HAL WIESER, PRIMOŽ LORENČAK, PAMELA BERGQUIST, HASSAN BADAWI, SCOTT P. SIBLEY, and ROBERT L. KUCZKOWSKI. Can. J. Chem. **68**, 267 (1990).

The structure of 8-oxabicyclo[3.2.1]octane was calculated by *ab initio* means at the STO-3G level, and the structural data used to assign the microwave spectrum of the title compound in the range of 26.5 to 40 GHz fitting 144 lines up to $J = 48$ by adjusting the rotational and three centrifugal distortion constants in the Watson *A* reduction. Structural parameters were deduced from the rotational constants by allowing all bond lengths and angles to vary in a least-squares manner. These parameters were in good agreement with those calculated at the STO-3G and 3-21G levels. Of many satellite lines observed, only the most intense could be utilized for locating the two lowest fundamental vibrations, estimated to occur at 190 and 240 cm^{-1}. The far-infrared spectrum is reported in the region of 80 to 300 cm^{-1}, exhibiting only one distinct sequence of Q branches at 264 cm^{-1}. On the basis of unscaled *ab initio* force fields at both levels of the theory the corresponding fundamentals are assigned, respectively, to a twisting (A'') and a bending (A') of the cycloheptane ring.

Key words: 8-oxabicyclo[3.2.1]octane, microwave and far-infrared spectra, *ab initio* STO-3G and 3-21G geometries.

THOMAS EGGIMANN, TRACY L. SMITHSON, HAL WIESER, PRIMOŽ LORENČAK, PAMELA BERGQUIST, HASSAN BADAWI, SCOTT P. SIBLEY et ROBERT L. KUCZKOWSKI. Can. J. Chem. **68**, 267 (1990).

Utilisant des méthodes *ab initio* au niveau STO-3G, on a calculé la structure du 8-oxabicyclo[3.2.1]octane et on a utilisé les données de structure ainsi obtenues pour attribuer 144 bandes, jusqu'à $J = 48$ dans la zone allant de 26,5 à 40 GHz, du spectre de micro-ondes du composé mentionné dans le titre en procédant à un ajustement de la constante de rotation et de trois constantes de centrifugation de la réduction A de Watson. On a pu déduire les paramètres de structure à partir des constantes de rotation et en permettant à toutes les longueurs de liaison et à tous les angles de varier selon le mode des moindres carrés. Ces paramètres sont en bon accord avec ceux calculés aux niveaux STO-3G et 3-21G. Parmi toutes les bandes satellites observées, seules les plus intenses ont pu être utilisées pour établir la location des deux vibrations fondamentales les plus basses qui se situeraient à 190 et 240 cm^{-1}. On a déterminé le spectre infrarouge lointain dans la région de 80 à 300 cm^{-1} et l'on n'a observé qu'une seule séquence de branches Q à 264 cm^{-1}. En se basant sur les champs de force *ab initio* des deux niveaux de la théorie, on a pu attribuer les bandes fondamentales correspondantes respectivement à une torsion (A'') et à une déformation (A') du noyau cycloheptane.

Mots clés : 8-oxabicyclo[3.2.1]octane, spectres de micro-ondes et infrarouge lointain, structures *ab initio* aux STO-3G et 3-21G.

[Traduit par la revue]

Introduction

Bicyclic compounds continue to be of considerable interest to mechanistic organic as well as to structural chemists probing, both experimentally and theoretically, the relationship between electronic structure and spectroscopic properties (1–5). As a continuation of related studies in our separate laboratories, we have investigated the microwave and far-infrared spectra of 8-oxabicyclo[3.2.1]octane, and compared the experimental geometry to that calculated by *ab initio* means at the STO-3G and 3-21G levels.

The analysis of the microwave spectrum was of interest especially for two reasons. First, the far-infrared spectra of several related bicyclo[3.2.1]octane molecules exhibit well resolved hot band sequences (6) normally characteristic of large amplitude anharmonic skeletal deformations which should lead to corresponding rotational lines in a number of excited vibrational states. Second, the interpretation of vibrational circular dichroism spectra of certain chiral analogs of the title compound, currently in progress, depends on a reliable force field best obtained by *ab initio* methods (7), for which in turn the geometry must be ascertained with commensurate accuracy. Only two experimental structures have been reported in the literature for related bicyclo[3.2.1]octane systems (8, 9) which could be compared with the *ab initio* geometries of the analog molecules of interest. As the experimental bond lengths contained in those reports differed widely from those we calculated by *ab initio* means, additional structural information from microwave spectra seemed appropriate.

Experimental and computational methods

Microwave spectra were obtained with a Hewlett-Packard 8460A spectrometer in the region 26.5 to 40 GHz. Frequency measurements were accurate to ±0.05 MHz. Radiofrequency–microwave double resonance (RFMWDR) spectra were obtained by replacing the Stark modulator with a tunable amplitude modulated radio frequency source covering 1–60 MHz at 50–5000 mW output.

The far-infrared spectrum was recorded with a Nicolet 8000 Fourier transform interferometer at 45 m path length in an optically matched long path cell, also manufactured by Nicolet (10). A globar was used as the light source in conjunction with a 3 μm Mylar beamsplitter and a liquid helium cooled bolometer, made by Infrared Laboratories, operating at 4.2 K and filtered to 400 cm^{-1}. With a resolution of 0.12 cm^{-1}, a moderate vapor pressure, and appropriate mirror velocity, 300 scans were deemed sufficient to give an adequate signal-to-noise ratio. Calibrated against standard water absorptions the reported peak positions are believed to be accurate to 0.03 cm^{-1}.

The Raman spectra including the polarization measurements were recorded with a Jarrell Ash model 25–100 double grating monochro-

mator using slit widths of 5 cm^{-1}. The incident beam was the 514.5 nm line of an argon ion laser (Coherent Radiation) with 300 mW power at the sample. The data were collected with a microcomputer interfaced to the instrument, allowing for co-adding of eight scans in the present case. Observed Raman lines were calibrated against liquid CCl_4. The solid sample was sealed into a capillary and melted in a special cell heated with a stream of hot air at 50°C.

8-Oxabicyclo[3.2.1]octane was prepared from cyclopentanone by a nine-step procedure involving in sequence, among other intermediates, 2-*N*-pyrrolidylbicyclo[3.2.1]octan-8-one, 5-cycloheptenol, and 8-oxabicyclo[3.2.1]octane-2-mercurial iodide. Details of this synthesis will be given elsewhere in due course (6). The final product was a waxy solid which was purified by sublimation at 85°C and atmospheric pressure to better than 99% as determined by analytical gc.

The GAUSSIAN 82 program package (11), running on a Cyber 205 supercomputer (12), was used for the computation with the STO-3G basis set. Due to computer disk limitations the later version, GAUSSIAN 86, as implemented on a Convex C120 was used for the calculations at the 3-21G level of theory. The equilibrium geometry of the molecule was evaluated by analytical gradient techniques based on *ab initio* Hartree–Fock molecular orbital calculations. No constraints were imposed in the calculations on the molecular structure other than C_s symmetry and starting the refinement process from a structure with the C_2—C_3—C_4 plane in the chair conformation. The optimization procedures in GAUSSIAN 82 and 86 in our experience are very reliable so that we can be certain that the rigid structure of this bicyclic molecule would not allow any minima other than the true one even with the low levels of theory. A second conceivable minimum could exist with the six-membered ring in the boat conformation. We have tested this hypothesis with 6,8-dioxabicyclo[3.2.1]octane obtaining an energy difference of about 1500 cm^{-1} between the two conformations, and no minima in-between (13). While we have not determined the magnitude of the barrier to inversion, it is reasonable to assume that it will be very much higher. Presumably the title compound will not be very different qualitatively. Vibrational frequencies were then obtained with unscaled harmonic force constants determined in the GAUSSIAN programs by analytical second differentiation of the energy at the stationary point.

Results and discussion

Microwave spectrum

Initially STO-3G *ab initio* structural parameters were used to predict a trial spectrum. The calculated geometry was later repeated at the 3-21G level. A selection of the most useful parameters is given in Table 1, while their complete listing is available as supplementary material (Table 1S).[1] Cartesian coordinates computed with the higher level of theory also have been deposited as supplementary material (Table 2S). The atom numbering used in these tables is explained in Fig. 1. Guided by the STO-3G predictions, five sets of doublets were observed between 36.7 and 39.0 GHz using RFMWDR techniques. One of these pairs, split by 102.5 MHz, was readily assigned to the μ_c K doublet 7(2,5) → 6(1,5) and 7(3,5) → 6(2,5), when pumped at this frequency. The remaining four doublets were split by 1.2 to 16.5 MHz. By trial and error the correct pair arising from the 7(1,6) → 6(0,6) and 7(2,6) → 6(1,6) transi-

tions was located. The identification of these four transitions led to the straightforward assignment of the crowded Stark modulated spectrum. Other prominent features in the Stark spectrum were strong Q branch μ_c transitions. A selection of transitions is given in Table 2, with the complete set of 144 assigned transitions available as supplementary material (Table 3S). The rotational and centrifugal distortion constants, listed in Table 3, were determined with the program ZFAP (14).

Second order Stark splittings were measured for several low J transitions. Since the spectrum was very crowded, resulting in interference with neighbouring lines, not all Stark shifts could be readily traced for different electric field settings. The fit of

the observed Stark shifts as a function of electric field to all three dipole moment components resulted in an imaginary μ_b consistent with the expected C_s symmetry. Holding $\mu_b = 0$ during the fitting process resulted in the dipole moment components given in Table 4.

The observed moments of inertia were used to test the structure determined from theoretical calculations. Lacking isotopically substituted data, 30 additional constraints involving structural parameters were employed during the fitting process with our modified version of Schwendeman's program STRFIT (15). In essence, this program will adjust those input structural assumptions which are allowed to vary, equivalent to a "predicate observables" or diagnostic least squares fitting procedure (16); see Appendix for a more detailed description of the fitting method and its reliability. Three fitting strategies were employed. If many bond distances were held fixed to the values from theoretical calculations (weight 20), the observed moments of inertia (weight 1) and assumed bond angles (weight 0.1) produced a reasonable fit (ΔI_{rms} = 0.247 amu Å^2, see Table 1) and bond angles close to those from theoretical calculations. When bond angles were held fixed and bond distances were allowed to vary, a nearly exact fit of the observed moments was obtained. However, this calculation produced

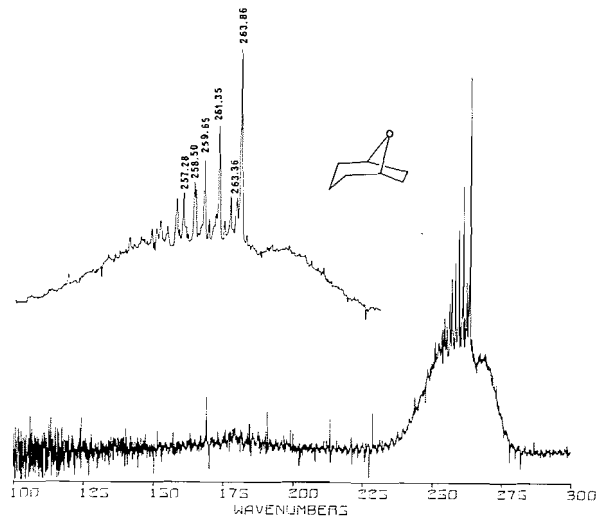

FIG. 2. Far-infrared spectrum of 8-oxabicyclo[3.2.1]octane, 0.12 cm^{-1} resolution, 3 μm Mylar beamsplitter, 300 scans, 45 m path length, and moderate vapour pressure.

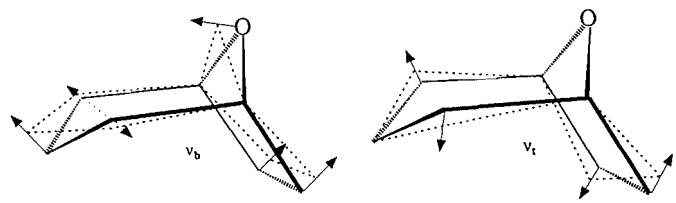

FIG. 3. Skeletal bending (ν_b) and twisting (ν_t) vibration of 8-oxabicyclo[3.2.1]octane.

some unreasonably short C—H distances (C_6—H_{19} = 1.022 Å) and poorly determined values for all dihedral angles involving hydrogen atoms. A similar fit to the observed moments was obtained when bond lengths and angles were allowed to vary. This fit gave reasonable values for most of the parameters. The structural parameters from all three calculations are given in Tables 1 and 1S.

It is interesting to note that the C_1—C_2 and C_2—C_3 bond distances from the last fit are 1.527 and 1.543 Å, respectively, compared to 1.528 and 1.540 Å in cyclopentene ozonide (5). Moreover, this fit predicts all *endo* C—H bond distances to be shorter than *exo* ones, similar to what has been observed for cyclobutene ozonide (16). The same order for the two C—C bonds is confirmed by the *ab initio* predictions using the 3-21G basis set, while STO-3G predicts the reverse order (Table 1). The corresponding bond lengths are 1.507 and 1.524 Å, respectively, for the 5,7-dimethyl-7-phenyl derivative of 6,8-dioxabicyclo[3.2.1]octane according to an X-ray study (9), while electron diffraction measurements for bicyclo[3.2.1]octane yielded 1.553 and 1.532 Å for C_1—C_2 and C_2—C_3, respectively (8), the order apparently agreeing with an MM2 geometry (18) which gave 1.540 and 1.537 Å, respectively.

Several low-lying vibrational states were observed in the microwave spectrum as weaker satellites to the ground state transitions. Sixteen low *J* transitions of the most intense satellite series were assigned (σ = 0.02 MHz). The rotational constants are reported in Table 3. Estimates of vibrational spacings were not as accurate as they could be in more ideal circumstances, since the spectrum for the low *J* lines was weak, crowded, and base line determinations were difficult. Nonetheless, relative intensities at room temperature of five of the most intense lines gave 190 ± 30 cm^{-1} as the lowest vibrational separation. The

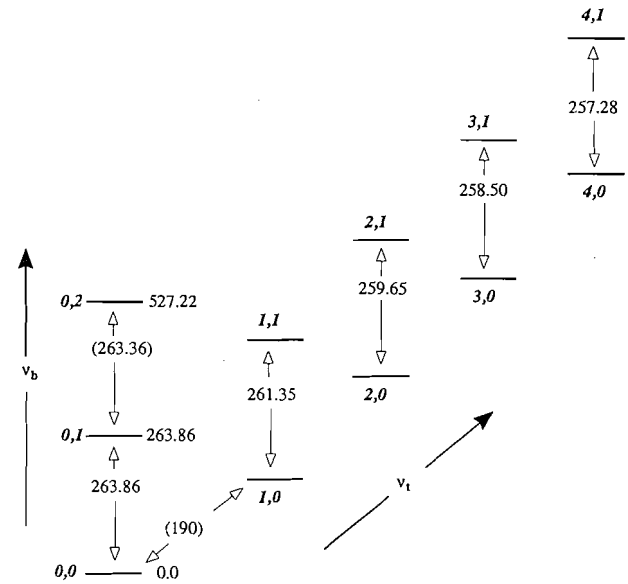

FIG. 4. Energy level diagram for skeletal bend and twist vibrations (ν_b and ν_t) of 8-oxabicyclo[3.2.1]octane. Energies in cm^{-1}.

next lowest state according to satellite intensities was estimated as 240 ± 40 cm^{-1} from the ground state.

Far-infrared spectrum

The far-infrared spectrum from 80 to 300 cm^{-1} is characterized by one series of pronounced Q bands starting at 263.86 cm^{-1} and extending to lower wavenumbers (Fig. 2). No other bands in this region are observed. The same fundamental is found in the Raman spectrum of the melted solid as a polarized line at 263 cm^{-1}, clearly corresponding to the 240 cm^{-1} absorption suggested by relative microwave intensities. *Ab initio* calculations of harmonic force constants at the STO-3G and 3-21G levels (unscaled) place this vibration at 270.7 and 287.5 cm^{-1}, respectively, and predict it to be an *A'* bending of the cyclopentane ring about the C—O—C bridge (Fig. 3) with its major contribution to the dipole moment change along the *C* rotational axis. The lowest transition, estimated near 190 cm^{-1} from microwave satellites, apparently has little intensity in the vapour phase infrared spectrum where it would have a *B* contour, but is seen in the Raman of the melted solid at 184 cm^{-1}. According to the *ab initio* predictions, it should occur at 191.2 and 183.0 cm^{-1} for the two levels of theory respectively, and arises from a twisting with *A"* symmetry of the cycloheptane ring (Fig. 3). The infrared intensities calculated with GAUSSIAN 86 from 3-21G atomic polar tensors are 94.8 × 10^3 and 10.0 × 10^3 cm/mol for the *A'* and *A"* modes, respectively, in qualitative agreement with the intensities observed in the vapour phase spectrum.

An assignment of the far-infrared sequence is suggested in Fig. 4. Only the most prominent members of the sequence can be assigned as bend (ν_b) transitions in consecutive excited states of the twist (ν_t). There are indications of additional sequences in this band (see Fig. 2), but their assignment is not corroborated by other information. The transitions are therefore not included in the energy level diagram. Additional series of microwave satellites which can be clearly seen but not assigned must originate from various other bend–twist excited states. Modeling of the potential energy surface to reproduce the far-infrared transitions would require at least these two coordinates. Of these, the ring bending mode may be thought of as leading to an inversion from the chair to the boat form of the six-membered

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

ring via a planar conformation of the C_1—C_2—C_3—C_4—C_5 skeletal fragment. Unfortunately, not enough of the transitions from either the far-infrared or microwave spectra are known to determine a best-fitting potential function and hence estimate the inversion barrier with an appropriate two-dimensional Hamiltonian.

Conclusions

As far as we are aware, this is the first documented evidence of vibrational anharmonicity in low energy skeletal deformations for a bicyclo-octane ring system. Evidence for this anharmonicity is observed in the rotational spectrum in the region of 26.5 to 40 GHz in terms of many satellite lines in vibrationally excited states, and in the vibrational spectrum in the region of 80 to 300 cm^{-1} in terms of a distinctive sequence of Q branches arising from the ring bending vibration (264 cm^{-1}) in excited states of a skeletal twist mode (190 cm^{-1}). The former in the extreme would lead to the inversion of the six-membered ring from the chair to the boat form. Assignment of the rotational lines in the vibrationally excited states is complicated by the inherent low intensities and by the density of the lines. The vibrational assignments are uniquely determined by an *ab initio* calculation of the force field using either the STO-3G or 3-21G levels of the theory.

The geometry deduced from the microwave rotational constants is reproduced well by the *ab initio* calculations with the two levels of theory differing only slightly in few respects. The ordering of the C—C bond lengths calculated with the 3-21G basis set is the same as that derived experimentally, with the exception of C_6—C_7 which 3-21G overestimates by 0.020 Å compared to the latter. The C_1—O_8 bond length and $\angle C_1O_8C_5$ bond angle are larger by 0.010 Å and 1.6°, respectively, for 3-21G than for STO-3G and the experimental values. Notwithstanding these minor differences, the agreement between the microwave and *ab initio* structures suggests that the latter constitute presently the best structural parameters available for the title molecule. With this assurance, it will be possible to approach the interpretation of the infrared absorption and VCD spectra with the commensurate confidence.

Acknowledgements

The microwave work was performed at the University of Michigan with the support of Grant CHE-8614340 from the National Science Foundation, Washington, D.C. We are grateful to Dr. Kurt W. Hillig II for assistance with the spectroscopic analysis.

The far-infrared spectroscopic work and the *ab initio* calculations were done at the University of Calgary supported by an Operating Grant from the Natural Sciences and Engineering Research Council of Canada. We gratefully acknowledge the substantial assistance from Drs. A. Rauk and R. Dutler with the calculations using the GAUSSIAN 82 and 86 systems of programs, and the Academic Computing Services and Supercomputer Committee of the University of Calgary for financially assisted access to the Convex C120 and the Cyber 205 supercomputer. We thank Mr. Ken Schmidt for the loan of a specially built variable temperature Raman cell, and Ms. Nan Ibrahim for preparing the compound under investigation.

Appendix

The determination of a unique set of structural parameters from the three rotational constants (observables) is, of course, impossible. The method of predicate observables provides the additional fitting equations necessary to determine a plausible structure consistent with the observables. The procedure distinguishes between real observables (moments of inertia) and predicate observables, i.e. structural parameters which are either held fixed to assumed values or permitted to vary from the assumption over a narrow but plausible range in order to arrive at ("determine") a structure which fits the rotational constants. The range of variance assigned to a predicate observable can be incorporated inversely as a weight assigned to the equation for that variable in the least squares fitting analysis, or the weight can be assigned ad hoc. An unlimited number of combinations of fixing some of the structural parameters and treating others as variables is feasible. The results in Table 1, column 4, were obtained by fixing all the bond lengths and allowing all the angles to vary, while in column 5 the angles were fixed and the bond lengths were varied. The results when all structural parameters were allowed to vary are in column 6. These procedures arrived at a generally sensible structure, consistent with the observables, but not necessarily the true structure. The structure is deemed sensible by comparison with other information such as the structure of cyclopentene ozonide (column 7) and the *ab initio* results (columns 2 and 3). The scatter in the distances and angles among the determinations in Table 1 (except for the CH distances) are a useful indicator of the range of structural parameters consistent with the observables, and of the uncertainty in the structure.

Received May 1, 1989

TORBJÖRN DRAKENBERG, PETER BRODELIUS, DEANE D. MCINTYRE, and HANS J. VOGEL. Can. J. Chem. **68**, 272 (1990).

The ^1H and ^{13}C NMR spectra of the cardenolides digitoxigenin, digoxigenin, digitoxin, and mono- and bis-digitoxigenin digitoxosides have been completely assigned by two-dimensional NMR spectroscopy. The techniques used include phase-sensitive COSY, multiple relay COSY, and carbon–proton correlation (HETCOR and HMQC) spectra. Various aspects of the solution conformation of the steroid moiety of digitoxin and digoxigenin could be determined from coupling constants and NOE difference experiments and they are indicative of an all-chair conformation. The carbohydrate rings in digitoxin and the mono- and bis-digitoxigenin digitoxosides are also in the chair conformation.

Key words: cardenolides, digitoxigenin, digitoxin, 2-dimensional NMR, conformational analysis.

TORBJÖRN DRAKENBERG, PETER BRODELIUS, DEANE D. MCINTYRE et HANS J. VOGEL. Can. J. Chem. **68**, 272 (1990).

Faisant appel à la RMN bidimensionnelle, on a pu attribuer l'ensemble des bandes des spectres RMN du ^1H et du ^{13}C des cardénolides digitoxigénine, digoxigénine, digitoxine et des digitoxosides des mono- et bis-digitoxigénines. Les techniques utilisées comprennent : COSY, COSY à relais multiples ainsi que les spectres (HETCOR et HMQC) de corrélation carbone–proton. En se basant sur les constantes de couplage et sur des expériences d'EON différentiel, on a pu déterminer divers aspects de la conformation en solution de la portion stéroïdale de la digitoxine et de la digoxigénine et ils suggèrent qu'il s'agit d'une conformation complètement chaise. Les cycles carbohydrates de la digitoxine et des digitoxosides des mono- et bis-digitoxigénines existent aussi dans la conformation chaise.

Mots clés : cardénolides, digitoxigénine, digitoxine, RMN bidimensionnelle, analyse conformationnelle.

Introduction

The cardenolide digitoxin **4**, and related cardenolides such as digoxin, are steroidal compounds with a carbohydrate moiety in the 3β position that are isolated from the plant genus *Digitalis*. They have also been found in a number of unrelated species of plants (1). Cardenolides are of considerable importance in the treatment of heart disease (2) and have been used since ancient times as arrow poisons (3). Due to the toxicity of digitoxin and related cardenolides, considerable effort has been expended on the study of the biotransformation of these compounds by plant cell suspension cultures (4). Also, large numbers of plant species have been screened (5) in an attempt to separate the cardiotonic activity from the toxic side effects, but to date these have met with little success.

Nuclear magnetic resonance (NMR) spectroscopy has for the past quarter century been the method of choice in the elucidation of the chemical structure of new natural products of all types. However, for the cardenolides, as is the case with steroids generally, the complexity of the ^1H NMR spectrum has made a complete assignment of such spectra difficult due to excessive signal overlap in the 1.0–2.5 ppm chemical shift range (6). Carbon-13 NMR spectra of steroids generally do not suffer from this problem, because the signals are spread out over a much larger chemical shift range (7). However, the ^{13}C chemical shifts and couplings are somewhat less informative than the proton chemical shifts and the proton–proton coupling constants in studies leading to the determination of molecular conformations. As the latter determine the biological activity, it would be desirable to apply techniques by which the proton NMR spectra of steroids and other biomolecules can be analyzed. Once these have been assigned, the information about the solution conformation of the molecule can be obtained from qualitative internuclear distances and from dihedral angles between vicinal protons, which are determined from NOE data and proton–proton coupling constants respectively (6).

In this work we report two-dimensional NMR studies that have lead to the complete assignment of the proton NMR spectra of digitoxin **4**, its aglycon, digitoxigenin **1**, the related mono- and bis-digitoxigenin digitoxosides **2** and **3**, and the aglucon of diogoxin, digoxigenin **5**. These assignments have allowed us to determine various aspects of the conformation of digitoxin in solution. Attempts to correlate the biological activity with the conformation of the E ring relative to that of the D ring have been reported previously (8), as has a study of the binding of digitoxin to human serum albumin by NMR (9). Partial proton assignments of digitoxigenin and some related compounds have also recently been reported (10–12).

Experimental

NMR spectra were obtained on a Nicolet NT-360 WB (^1H, 360 MHz; ^{13}C, 90.4 MHz) or a Bruker AM-400 WB (^1H, 400.1 MHz; ^{13}C, 100.6 MHz) operating in the Fourier transform mode, at 25°C in $CDCl_3$ solutions using tetramethylsilane (TMS) as an internal reference for both nuclei. All compounds were commercially obtained: **1**, **4**, and **5** from the Sigma Chemical Company, St. Louis, MO, and **2**, and **3** from Carl Roth GmbH, Karlsruhe, FRG. Due to the limited solubility of **5** in chloroform, spectra of this compound were obtained in a 1:4 $(CD_3)_2SO/CDCl_3$ mixture. In the case of ^{13}C spectra, a relaxation delay of 2.0 s was used between the 70° pulses. The ^{13}C relaxation

times were determined by the inversion–recovery method, using eight different delay times and delay list cycling, and were processed using standard Bruker software. A mixing time of 500 ms was used in the NOE difference experiments.

The two-dimensional COSY, relayed COSY, and HETCOR spectra were recorded using standard pulse sequences and Bruker Aspect 3000 software. The mixing time in all relayed COSY experiments was 60 ms. All two-dimensional spectra were weighted with a standard sine bell function and zero-filled along both axes prior to transformation. The phase-sensitive COSY spectrum was obtained using the Time-Proportional Phase Increment (TPPI) approach, with 1024 increments in $t1$, 16 scans each. The HMQC spectra were obtained in the phase-sensitive mode (TPPI), with a bilinear (BIRD) pulse (13). A delay of 0.4 s was inserted between the BIRD pulse and the first preparation pulse of the HMQC sequence. The number of increments in $t1$ was 128, and 128 scans (256 data points each) were collected per experiment. The resulting data were weighted with a sine bell squared function shifted $\pi/4$ radians in $t2$ (proton) and a Lorentz–Gauss function in $t1$ (carbon) and zero-filled twice in each dimension prior to transformation.

Results and discussion

Carbon-13 NMR

Our initial objective was to confirm whether we could reproduce the previously reported ^{13}C NMR spectral data (14–17) as these spectra would be an important tool in the assignment of the ^{1}H spectra via ^{13}C–^{1}H correlation experiments. The results (Table 1) for digitoxigenin **1**, digitoxin **4**, and digoxigenin **5** were in general in good agreement with those previously reported; small differences in chemical shift likely arise from the temperature dependence of the chemical shift. We also determined the ^{13}C spectra of the related mono- and di-glycosides **2** and **3** (see Table 1). In the case of digitoxin, an attached proton test (APT) (18) was performed to determine the number of protons attached to each carbon; these results were again in agreement with previously reported data. The ^{13}C relaxation

times (T_1) were also determined for digitoxin, and are included in Table 1. They do not reveal large differences in mobility throughout the molecule.

*^{1}H NMR. Digitoxigenin **1**, **2**, and **3***

The proton NMR spectra of these compounds were assigned as described in detail for digitoxin **4** below. The assignments are given in Tables 2 and 3.

*^{1}H NMR. Digitoxin **4***

Due to the complexity of the ^{1}H NMR spectrum of digitoxin (Fig. 1) only the resonances downfield of 2.5 ppm, and the two methyl groups, are resolved from other signals, and can be readily assigned by inspection and comparison with model compounds. The methyl groups can be assigned as C-18 (0.87 ppm) and C-19 (0.92 ppm). The assignment of the downfield signals

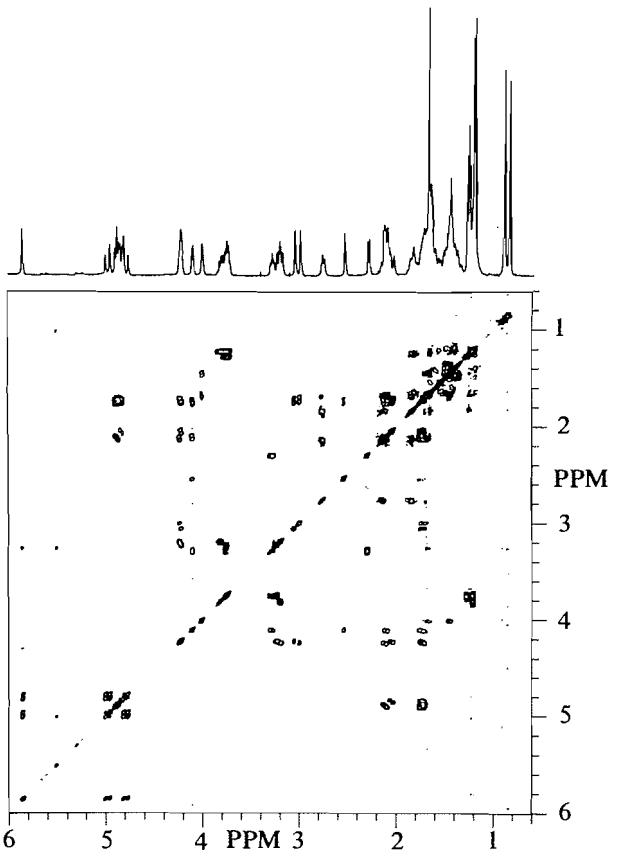

FIG. 1. One-dimensional and COSY proton NMR spectra of **4** in $CDCl_3$ solution at 25°C.

is as follows: H-22 (5.87 ppm), H-21 (4.82 and 4.98 ppm), H-3 (4.02 ppm), and H-17 (2.78 ppm). These assignments were confirmed by appropriate decoupling experiments. To assign, as far as possible, the signals in the 2.5–1.0 ppm region of the spectrum a proton 2-D correlation spectrum (COSY) (Fig. 1) was obtained. In this type of spectrum protons that are coupled to each other produce "cross peaks" at coordinates corresponding to the chemical shifts of the two protons involved. Starting from the previously assigned H-17 (2.78 ppm), we can assign resonances at 2.16 and 1.88 ppm as being due to protons 16β and 16α. As these signals also show correlation with signals at 2.12 and 1.70 ppm, the latter chemical shifts represent the 15α and 15β resonances. As axial protons usually absorb upfield of the equatorial proton attached to the same carbon atom, it is possible to assign the α and β protons of methylene groups by inspection of a molecular model of the compound (*vide infra*). These assignments were also confirmed by decoupling experiments.

With the assignment of the protons of the D and E rings complete, the next step was the considerably more difficult task of the assignment of the A, B, and C ring protons. These protons form one extended spin system, so in principle, once one is assigned (H-3 in this case), it should be possible to trace out the connectivity of the entire spin system by simple inspection of the COSY spectrum. In the case of steroids, however, this is not straightforward because of overlapping cross peaks and some cross peaks that may not be observed due to low intensity resulting from weak coupling. Starting from H-3 (4.02 ppm) in the magnitude mode COSY spectrum, signals at 1.70 and 1.57 ppm can be assigned to H-2 and (or) H-4 protons; however, due

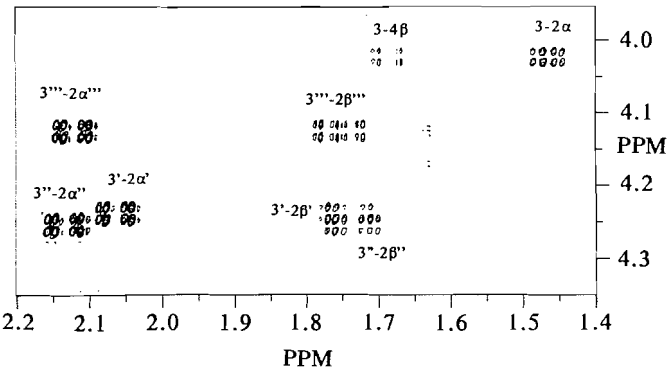

FIG. 2. Region of a phase-sensitive COSY spectrum of **4** in $CDCl_3$ at 25°C, illustrating the fine structure of selected crosspeaks, which were used to obtain the coupling constants.

to the complexity of the COSY spectrum, further assignments based solely on the magnitude mode COSY data would be doubtful. To resolve this difficulty, recourse was made to ^{13}C–^{1}H correlation (HETCOR) spectroscopy (19). In this type of spectrum, cross peaks are observed for each carbon at the coordinates of the ^{13}C chemical shift and the ^{1}H chemical shift of the attached proton(s); thus, quaternary carbons are not observed in this type of spectrum. Using the assignment of the ^{13}C spectrum reported by Habermehl *et al.* (17), and confirmed by us, as a starting point we can confirm that our previous proton assignments are correct. In addition, all remaining proton signals can be assigned, at least approximately (within 0.05 ppm), from the HETCOR spectrum. Once the approximate chemical shifts were known, careful inspection of the COSY and one-dimensional spectra, combined when necessary with decoupling experiments, gave reasonably accurate chemical shifts (within 0.02 ppm) for the remaining protons.

It was possible to obtain even more accurate chemical shifts, as well as coupling constants, from phase-sensitive COSY spectra (Fig. 2). This spectrum was recorded at fairly high resolution (ca. 1.0 Hz in the F-2 domain) so that the appropriate coupling constants necessary to define the conformation of the molecule could be obtained (*vide infra*). The chemical shifts and selected coupling constants are tabulated in Table 2. Due to the increased resolution, virtually the entire steroid could be assigned by inspection of the phase-sensitive COSY spectrum, independently of the more time-consuming HETCOR experiments.

The assignment of the carbohydrate portion of the spectrum of digitoxin from the phase-sensitive COSY (Fig. 2) was straightforward. Beginning with the anomeric protons, the connectivity for each digitoxose ring was readily traced out, including the -OH protons, which are in slow exchange in chloroform solution. The terminal ring was readily identified as such as it is the only one bearing an -OH at the 4 position. The ring bound to the steroid was identified on the basis of upfield chemical shifts for the 1′ and 2′α protons, and a downfield chemical shift for the methyl group, compared to the other two rings.

To further confirm the assignment of the carbohydrate resonances of digitoxin, a series of relayed coherence transfer (Relay) COSY spectra (20) were also obtained (Fig. 3). In these spectra, magnetization is transferred sequentially from proton to proton, thus giving rise to cross peaks between protons not directly coupled to each other. In all cases a total mixing time of 60 ms for each coherence transfer was employed for obtaining a relay, double-relay, and triple-relay COSY spectrum. This mixting time is optimal for the 8–10 Hz couplings that are observed

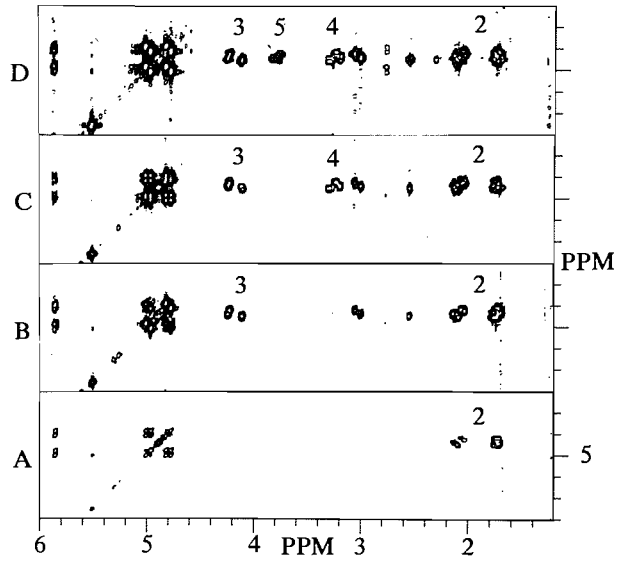

FIG. 3. Magnitude mode COSY and relay-COSY spectra of **4** in $CDCl_3$ solution at 25°C, showing the carbohydrate protons (a) COSY, (b) relay COSY, (c) double-relay COSY, (d) triple-relay COSY. New crosspeaks from the anomeric protons, which appear with each successive relay, are labeled. Note the overlap resulting from near chemical shift equivalence from corresponding protons in each of the three carbohydrate rings. Crosspeaks between 2.4 and 3.1 ppm arise from -OH protons.

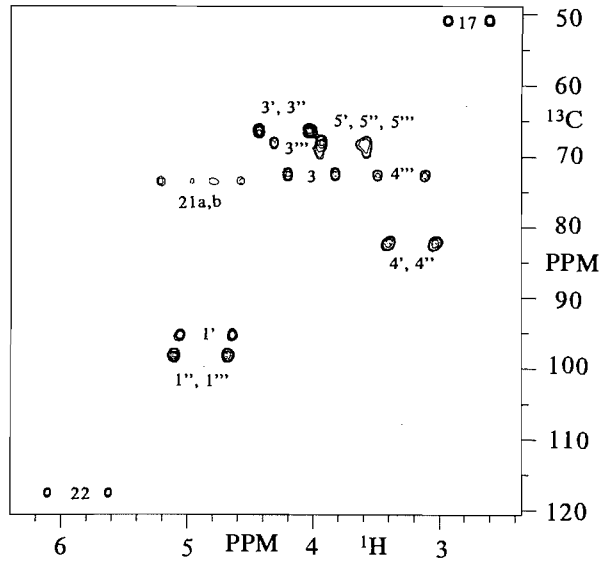

FIG. 4. Carbon-13–proton correlation (HMQC) spectrum of **4** in $CDCl_3$ solution at 25°C. Only the downfield region is shown. The spectrum was obtained without decoupling; thus all signals appear as doublets. The horizontal axis represents the proton chemical shifts; the vertical axis, the carbon chemical shifts.

between axial protons in carbohydrates. Despite the fact that H-3 is equatorial in the digitoxose ring system (and thus its coupling constant with the vicinal protons H-2 and H-4 is considerably less than 8 Hz), good multiple relayed COSY spectra were obtained. In the case of the triple-relay COSY spectrum, coherence transfer was observed between H-1 and H-5 for all three sugar rings. However, a quadruple-relay COSY spectrum did not show correlation between H-1 and H-6, probably due to loss of signal intensity through T_2 relaxation during the mixing periods and loss of magnetization resulting from multiple coherence transfer pathways (data not shown). These results demonstrate the utility of multiple relay COSY experiments for the assignment of carbohydrate spectra. Similar data can be obtained by using total correlation spectra such as HOHAHA (21) and TOCSY (22). Due to the diverse range of coupling constants between the steroid protons, the multiple relay COSY experiments were somewhat less useful in the assignment of the steroid protion of the spectra, although some assignments could be confirmed in this manner. In addition to the above, an HMQC (13) spectrum was obtained for digitoxin (Fig. 4). In principle, this proton-detected heteronuclear correlation experiment provides information that is similar to that obtained in the carbon-detected HETCOR experiment, but with much improved sensitivity. In this case, the spectrum was obtained without decoupling, and hence approximate coupling constants, useful in making assignments, can be obtained from the typical doublet appearance of the peaks. With digitoxin, considerble overlap was observed among some of the carbohydrate resonances.

As far as the complete assignment of the proton NMR spectrum of digitoxin is concerned, our results are in complete agreement with a previously reported partial assignment (23).

^1H and ^{13}C NMR. Digoxigenin 5

Digoxigenin **5**, the aglycon of digoxin, is 12β-OH-**1**. Using digitoxigenin as a model, the complete proton and carbon-13 assignments were obtained using HETCOR and COSY spectra. The results (Tables 1 and 2) indicate that substitution at the 12 position results in a large (0.56 ppm) downfield shift of H-17, and a large upfield shift of approximately 5 ppm for the C-17 (see also ref. 17). Steric compression (γ *gauche* effect) results in a large (approximately 6 ppm) upfield shift for C-18. Appreciable downfield shifts for both protons attached to C-15 were also observed.

Conformation

The X-ray structures of digitoxin and digitoxigenin have not been reported to our knowledge. However, the structure of two closely related compounds, 3-α digitoxigenin (24) (which differs from digitoxigenin only in the configuration at C-3) and dihydro digitoxigenin (25) (digitoxigenin with the C20—C22 double bond saturated), have been determined. In both compounds all the steroid six-membered rings adopt a chair conformation in the crystal lattice.

The coupling constant of 12 Hz measured between H-8 and H-9 indicated that they are *trans* to each other, as is common for a *trans*-ring junction. The $J_{9,11\beta}$ (4 Hz), $J_{7\beta,8}$ (4 Hz), and $J_{6\beta,7\beta}$ (8 Hz) couplings all support the view that the six-membered steroid rings B and C are in the chair conformation. By inspection of molecular models it is readily apparent that for reasons of steric hindrance, the A ring is most likely also in the chair conformation. This was confirmed by the use of NOE-difference experiments. Upon irradiation of the C-19 methyl protons at 0.87 ppm, an enhancement was observed in the intensity of the signals arising from the 1β and 6β protons; upon irradiation of the H-3 signal at 4.02 ppm, an enhancement was obtained for the 2α and 4α protons. These results confirm that the A ring indeed has a chair conformation. Unfortunately, due to excessive signal overlap, it was not possible to obtain accurate coupling constants for the A-ring protons from the phase-sensitive COSY spectrum. Thus it appears that the all-chair configuration of the steroid moiety found in the crystal lattice in this case is preserved in solution.

From the observed coupling constants (Table 2) for each digitoxose ring, the anomeric proton is *antiperiplanar* to one of the protons on C-2 and *gauche* to the other. All digitoxose H-3 protons are *gauche* to the vicinal protons 2α, 2β, and 4, and the latter proton is *antiperiplanar* to H-5 in all rings. Therefore, it can be concluded that the three digitoxose rings in digitoxin are all in the chair conformation, as are the digitoxose rings in the mono- and bis-digitoxigenin digitoxosides **2** and **3**. This is the same conformation as observed for free digitoxose (26).

The kinetics of formation of electron donor–acceptor complexes. A temperature-jump study

M. A. ZON, H. FERNANDEZ, L. SERENO, AND J. J. SILBER[1]

Departamento de Química y Física, Universidad Nacional de Río Cuarto, Estafeta No. 9, Río Cuarto, 5800, Córdoba, Argentina

Received June 12, 1989

M. A. ZON, H. FERNANDEZ, L. SERENO, and J. J. SILBER. Can. J. Chem. **68**, 278 (1990).

The kinetics of the Electron Donor–Acceptor (EDA) complex between *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine and *m*-dinitrobenzene in acetonitrile has been studied by the temperature-jump technique. The magnitude of the rate constants of association and dissociation, although relatively large, is well below the diffusion control values. The calculated rates closely coincide with those obtained by chronoamperometry. An entropy control is suggested for this reaction. The results obtained in this work are useful to demonstrate that the concept about EDA complexes being formed by diffusion-controlled reactions should not be generalized.

Key words: electron donor–acceptor complexes, *m*-dinitrobenzene, *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine, T-jump, kinetics.

M. A. ZON, H. FERNANDEZ, L. SERENO et J. J. SILBER. Can. J. Chem. **68**, 278 (1990).

Utilisant la technique des sauts de température, on a étudié la cinétique du complexe accepteur–donneur électronique (ADE) formé par la *N,N,N′,N′*-tetraméthyl-*p*-phénylènediamine et le *m*-dinitrobenzène dans l'acétonitrile. L'amplitude de la constante de vitesse, même si elle est relativement importante, est beaucoup plus faible que les valeurs attendues sur la base d'un contrôle par diffusion. Les vitesses calculées coïncident bien avec celles obtenues par chronoampérométrie. On suggère que cette réaction est contrôlée par l'entropie. Les résultats obtenus dans ce travail sont utiles pour démontrer que l'on ne devrait pas généraliser le concept selon lequel les complexes ADE se forment au cours de réactions contrôlées par la diffusion.

Mots clés: complexes accepteur–donneur électronique, *m*-dinitrobenzène, *N,N,N′,N′*-tétraméthyl-*p*-phénylènediamine, saut de température, cinétique.

Introduction

Electron donor–acceptor (EDA) complexes play a considerable role in general chemistry reactivity as well as in biological and therapeutical reactions of living organisms (1, 2). Thus knowledge of the kinetic parameters of their formation becomes important for mechanistic studies.

It is generally considered that the forward and back reactions of the complex components are diffusion controlled (1, 3) or nearly so (4–6). However, actual measurements of these rates have been few. Moreover, several examples have been found in the literature (7–10) in which the rate constants are reported to be small enough to be measured by conventional techniques. Hence this matter appears to be somewhat controversial, particularly when considering that these kinetics seem to depend strongly on the donor and the acceptor structure and on the solvent medium (6, 11).

In a previous work we reported the application of an electrochemical technique, chronoamperometry, to measure the kinetic parameters of the EDA complex between *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine (TMPD) and *m*-dinitrobenzene (MDB) in acetonitrile (ACN) (12). The magnitude of the rate constants obtained, although relatively large, is well below the diffusion control values. This was the first example of the use of chronoamperometry to evaluate kinetic parameters of EDA complexes and showed that this type of study could be very valuable provided that the lifetimes of complexation are within the time constant of the technique.

Nevertheless, our results were actually obtained in the detection limit of the chronoamperometry. Hence, considering that it is necessary to clarify some of the controversial ideas about the rates of EDA complexation, we decided to reinvestigate the system by a different technique. Thus in this work we report temperature-jump (T-jump) studies of the TMPD–MDB complex in ACN.

Results and discussion

The equilibrium that involves the formation of the complex studied can be represented by eq. [1]:

$$[1]\quad \mathrm{TMPD} + \mathrm{MDB} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{TMPD\text{–}MDB}$$

where TMPD–MDB represents the EDA complex and k_1 and k_{-1} are the association and dissociation rate constants, respectively. Previous studies of the thermodynamic parameters of this complex (13) demonstrated the formation of a 1:1 complex and the stability constant (K_s) was determined at different temperatures. The value of $\Delta H = -30$ kJ mol^{-1} obtained is acceptable for performing the kinetic analysis by T-jump experiments (14, 15). Thus solutions of the complex at varying concentrations of MDB and TMPD were subjected to temperature jumps and the ensuing relaxation effect was spectrophotometrically monitored.

One single relaxation time (τ) was observed, as expected, under all experimental conditions, Typical results of the semilog plots of the signal intensity (I_s) vs. time are shown in Fig. 1. As can be observed, good linear relationships are obtained. The relaxation time for this system is given by eq. [2]:

$$[2]\quad \tau^{-1} = k_1 ([\mathrm{TMPD}]_e + [\mathrm{MDB}]_e) + k_{-1}$$

where $[\mathrm{TMPD}]_e$ and $[\mathrm{MDB}]_e$ are the concentrations at the new equilibrium situation. Since the study was performed under pseudo first-order conditions, i.e., $[\mathrm{MDB}]_0 > [\mathrm{TMPD}]_0$, eq. [2] can be expressed as

$$[3]\quad \tau^{-1} = k_1 [\mathrm{MDB}]_0 + k_{-1}$$

where $[\mathrm{MDB}]_0$ is the initial concentration of the acceptor.

0.10	52	50	53	51	50	19 ± 1
0.28	33	36	36	33	37	28 ± 2
0.40	31	29	31	26	32	34 ± 4
0.44	26	27	32	29	27	35 ± 4

[a] $\bar{\tau}$ is the average relaxation time. Errors are calculated from $e = (\sigma_{n-1}^2 + \varepsilon^2)^{1/2}$, where σ_{n-1} is the standard deviation and ε is the time scale precision.

Typical values of τ at different $[MDB]_0$ are gathered in Table 1. A plot of τ^{-1} vs. $[MDB]_0$ should be linear with slope k_1 and intercept k_{-1}. The ratio k_1/k_{-1} should agree with the values of K_s previously determined (13). Some of these plots, obtained at different temperatures, are shown in Fig. 2.

The values of the rate constants calculated through eq. [3] by a least-squares procedure are given in Table 2 along with the values previously obtained by an electrochemical technique (12). It should be pointed out that similar results are obtained if we use the previously measured values of K_s (13) in finding $k_1 = 1/(\tau\{[MDB]_0 + K_s^{-1}\})$ for each relaxation time.

As can be observed, the magnitudes of k_1 and k_{-1} for the complex, although relatively large, are well below the diffusion control values.

On the other hand, these values are in close agreement with those obtained by chronoamperometry. Moreover, the calculated K_s values agree with the ones previously calculated. Thus we believe that these are quite reliable results and give an indication that, at least for these complexes, the rates of formation (and dissociation) are relatively low compared with those expected for complexes of other nitro compounds with, for example, aliphatic amines (3, 4).

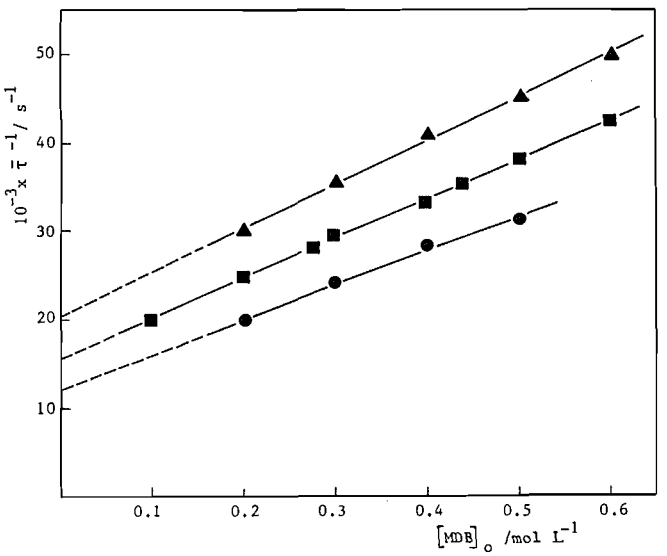

FIG. 2. $\bar{\tau}^{-1}$ as a function of $[MDB]_0$ and temperature: (●) 10°C; (■) 20°C; and (▲) 30°C.

Although the temperature range allowed by our experimental conditions is rather small for making precise calculations of the activation parameters, it is still possible to establish that they are in the order of the values obtained electrochemically (12). They have the characteristic of a low activation enthalpy, $\Delta H^{\neq}$, and of a large and highly negative value for the activation entropy, $\Delta S^{\neq}$, for the association process. This suggests that there is no activation-energy barrier but there is an entropy control for this reaction. An ubiquitous explanation for these results is not easy to ascertain. Either steric and (or) solvent reorganization effects may be adduced for such entropy control.

TMPD–MDB is a weak EDA complex, as inferred from the

[a]$\Delta H^{\ddagger} = 7 \pm 1$ kJ/mol and $\Delta S^{\ddagger} = -123 \pm 5$ J/K mol at 25°C.
[b]$\Delta H^{\ddagger} = 15 \pm 1$ kJ/mol and $\Delta S^{\ddagger} = -103 \pm 2$ J/K mol at 25°C.

hypsochromic shift of the λ_{max} of its charge transfer band and the decrease in the K_s value in polar solvents with respect to nonpolar ones (13, 16). Then, a small contribution of the dative (ionic) structure in the ground state of this complex is expected (17). In these cases is more probable that solvation is controlled by local polar centers on donor and acceptor than by the, usually small, ground state complex dipole. On these grounds solvent reorganization in the transition state should be more significant in the dissociation process.

On the other hand, although solvent reorganization around local dipoles generated by complex formation cannot be disregarded, a preferential orientation of the donor and the acceptor structures may be the dominant factor in the association process.

The need of preferred sites of approach of two moieties has been proposed (1) and is actually observed for several EDA complexes (18). Also, our previous studies of the complexes between dinitro and dicyanobenzenes with aliphatic amines show that preferred orientations determine the relative stabilities of the complexes (19).

For the TMPD–MDB complex, the steric and electronic effects exerted by the *N*-methyl groups of TMPD are assumed to be the cause of the entropy control in the complex formation. Such effects have also been adduced to explain the differences in the electronic interactions and thermodynamic stabilities observed by *N*-methyl substitutions in the EDA dimerizations of *p*-phenylenediamine cation radicals (20).

In summary, the kinetics of the TMPD–MDB complex in ACN, although fast, is not diffusion controlled, as proved by two completely different techniques. Thus we want to emphasize that no generalization can be made about the rates of EDA complexation.

Considering that EDA complexes are being proposed as the actual intermediates in the new mechanistic approach to several organic reactions believed to occur via electron transfer (21), the need for knowledge of the factors that influence their kinetic parameters becomes immediately apparent.

Experimental

ACN (Carlo Erba, R.P.) and $NaClO_4$ (Koch-Light A.R.) were purified as previously described (22). TMPD, obtained from its dihydrochloride (Fluka A.G.), and MDB (Carlo Erba R.P.) were purified as reported before (13).

The relaxation times were measured on a temperature-jump transient apparatus from Messanlagen Studiengesellschaft Gottingen, Germany. The solutions were subjected to temperature jumps of 4°C; the temperatures of the preequilibrated solutions were chosen to be 10, 20, and 30 ± 0.5°C respectively after the jump.

The concentration of MDB was varied in the range 0.1–0.6 M and that of TMPD from 1 to 3×10^{-3} M in ACN as solvent. The ionic strength was kept constant at 1 M by adding $NaClO_4$.

Relaxation curves were recorded at $\lambda = 480$ nm, which is the previously determined absorption maximum wavelength for the complex in this medium (13). The absorbance vs. time transients were stored in a Leader LBO-5825 digital storage oscilloscope and later recorded in a Houston 2000 *X–Y* instrument. The relaxation times were calculated as the average values from at least five relaxation curves, generated from the same solution, or often from separately prepared solutions, on different days. The estimated accuracy associated with each relaxation time was not greater than 10%.

Received August 21, 1989

HERBERT L. HOLLAND, FRANCES M. BROWN, P. CHINNA CHENCHAIAH, and J. APPA RAO. Can. J. Chem. **68**, 282 (1990).

A series of racemic substituted cyclopentanones, with alkyl groups corresponding to the upper prostanoid side chain and (or) the lower prostanoid side chain without the C-15 alcohol, has been synthesized. Using a steroid template for the prostanoid molecule as a basis for selection, fungi capable of hydroxylating steroids have been used to biotransform the prostanoid substrates. The predominant products were hydroxylated at the prostanoid C-18 and C-19 positions. The hydroxylations were enantioselective, with excesses in the range 10–60%, and in most cases the predominant configuration corresponded to that of the natural prostanoids. The stereochemistry of the C-19 hydroxyl group was found to be *R* by degradation of products to methyl 6-acetoxyheptanoate and comparison of that material with a resolved sample, obtained via crystallization of the brucine salt of ethyl 6-phthaloxyheptanoate. Hydroxylation at C-18 gave the *S* configuration of alcohol. Hydroxylation at prostanoid C-15 was observed, but in all cases this was accompanied by other reactions. Hydroxylation of *Rhizopus arrhizus* has been used in a preparation of (−)-15-deoxy-19-(*R*)-hydroxy-PGE_1 and (−)-15-deoxy-18-(*S*)-hydroxy-PGE_1.

Key words: biotransformation, hydroxylation, prostaglandins, prostanoids.

HERBERT L. HOLLAND, FRANCES M. BROWN, P. CHINNA CHENCHAIAH et J. APPA RAO. Can. J. Chem. **68**, 282 (1990).

On a synthétisé une série de cyclopentanones substituées racémiques portant des groupements alkyles correspondant à la chaîne latérale prostanoïde supérieure et (ou) à la chaîne latérale prostanoïde inférieure ne portant pas la fonction alcool en C-15. Utilisant comme base de sélection un gabarit stéroïdal pour représenter la molécule prostanoïde, on a fait appel à un champignon capable d'hydroxyler les stéroïdes pour effectuer la biotransformation des substrats prostanoïdes. Les produits principaux sont les prostanoïdes hydroxylés en positions C-18 et C-19. Les hydroxylations sont énantiosélectives, avec des excès de l'ordre de 10–60%, et, dans la plupart des cas, la configuration prédominante correspond à celle des prostanoïdes naturels. En se basant sur une dégradation des produits en 6-acétoxyheptanoate de méthyle et sur une comparaison de ce produit avec un échantillon résolu, obtenu par cristallisation du sel de brucine du 6-phtaloxyheptanoate d'éthyle, on a démontré que la stéréochimie du groupement hydroxyle en C-19 est *R*. L'hydroxylation en C-18 fournit un alcool de configuration *S*. On a observé une hydroxylation en C-15 du prostanoïde; toutefois, cette réaction est toujours accompagnée par d'autres réactions. On a fait appel à une hydroxylation par le *Rhizopus arrhizus* pour la préparation des (−)-15-désoxy-19-(*R*)-hydroxy-PGW_1 et (−)-15-désoxy-18-(*S*)-hydroxy-PGW_1.

Mots clés : biotransformation, hydroxylation, prostaglandins, prostanoïdes.

Introduction

The prostaglandins constitute a small but extremely valuable group of human hormones. Prostaglandins of the PG_1 and PG_2 series (Fig. 1) have in common a *trans* relationship of substituents on a cyclopentane ring, and a C-15-(*S*) allylic alcohol. The necessity of achieving the correct absolute stereochemistry at both ring and chain substituents has resulted in many ingenious syntheses of prostaglandins (e.g., refs. 1 and 2), but final product costs are still high and, as a result, can limit the commercial development of prostanoids.

In view of the value of microbial, and particularly fungal, biotransformation as a means of introducing the hydroxyl group in a regio- and stereospecific manner into a wide range of organic molecules (3), especially steroids (4), we have undertaken a study of the fungal biotransformation of a series of simple racemic prostaglandin precursors and model compounds (**2**, **4**, **5**, **14**, **20**, and **29**). Although biotransformation of the natural prostanoids has been studied (5), and enzymic reactions such as ester hydrolysis (6), carbonyl/alcohol reduction/oxidation (7), and toluene dioxygenation (8) have been used to produce chiral prostaglandin synthons, the use of fungal biotransformation to enantioselectively hydroxylate simple racemic prostanoid precursors has not been reported by others.

The rationale behind our approach has been outlined elsewhere (9). The spatial and structural similarities between steroids and prostanoids of the PG_1 series outlined in Fig. 2 have been used to select fungi as candidates for testing for their ability

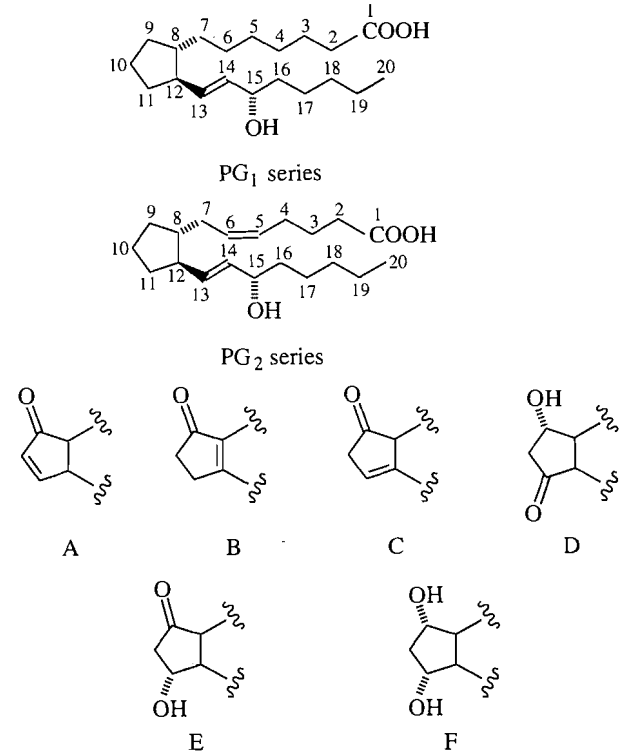

FIG. 1

(a) (b)

FIG. 2 Structural similarities between steroids (a) and prostanoids (b).

to hydroxylate 15-deoxyprostanoids, based on the reported ability of such fungi to hydroxylate steroids at an analogous position.

It is remarkable that one of the commonest positions of hydroxylation of steroids by both fungal and mammalian enzymes, C-6β (10), corresponds to the C-15α hydroxyl of the natural prostaglandins using the relationship of Fig. 2. Fungi that are known to hydroxylate androstanes at C-6β, for example, might therefore be able to introduce a hydroxyl group at C-15α into a suitable prostanoid precursor. Furthermore, the correct prostanoid absolute stereochemistry of ring substituents, shown in Fig. 2(b), is a better fit into an enzyme active site designed for a steroid than the opposite stereochemistry would be, leading to the prediction that hydroxylation of racemic prostanoids carried out by a steroid hydroxylase should be enantioselective for the correct absolute stereochemistry of prostanoid product. The above relationships, and the fact that the solution conformation of natural prostaglandins is similar to that represented in Fig. 2(b) (11), were instrumental in the development of our approach to prostanoid hydroxylation.

The choice of hydroxylating fungi was also based on the relationship of Fig. 2. The steroid C-6β hydroxylating fungi *Rhizopus arrhizus* and *Rhizopus stolonifer* (10) were examined for hydroxylation at C-15 of the prostanoid precursors; *Aspergillus ochraceus* and *Curvularia lunata*, both hydroxylators of steroids at C-11 (12, 13) in addition to C-6, were selected for examination in the hope of also achieving hydroxylation at C-6 of the PG upper side chain (the site of oxygenation in prostacyclin); *Calonectria decora* was selected on the basis of its ability to hydroxylate a wide variety of steroidal substrates (12); and *Cunninghamella echinulata* var. *elegans* was examined because of its ability to perform allylic hydroxylation of 5(6)-unsaturated steroids (14).

Results

To avoid problems of solubility and pH maintenance, we opted to use substrates in their ester rather than acid forms, where appropriate. This is justified by the fact that PG esters are as efficient as the acids in many biological systems (15), and by the observation that rapid ester hydrolysis by the fungus would precede or accompany the hydroxylation reactions (16). To examine any stereoselection that might be attributable to esterase activity, we first examined the biotransformation of the model substrates **2** and **4**. The results of these and subsequent biotransformations are summarized in Table 1.

Both **2** and **4** were hydrolyzed by the fungi listed in Table 1 to give the acids **1** and **3**, respectively, re-isolated as the methyl esters following treatment with diazomethane. In all cases, low (5–10%) enantioselectivity was observed (based on optical rotation comparisons (17)), giving the 2-(*S*) enantiomer of **2** and the 2-(*R*) enantiomer of **4** (both configurations identical and opposite to that of the corresponding natural prostaglandin side chain). Such low stereoselection by esterases is unlikely to be a major factor in determining the stereoselectivity of any biotransformation process that may also involve hydroxylase enzymes.

Before proceeding with a study of the prostanoid substrates **20** and **29**, model substrates possessing only the lower prostanoid side chain, namely **5** and **14**, were examined. Hydroxylation

5

of racemic **5** by either *R. arrhizus* or *R. stolonifer* gave four products, **6**, **9**, **10**, and **11**, all of which carried a hydroxyl group at C-7′, corresponding to C-19 of the prostanoid skeleton. The structures of these products were determined by spectral analysis (see experimental section), with nmr data being particularly valuable. The position of the newly introduced hydroxyl group at C-7′ is apparent from the appearance of a doublet in the ^1H nmr attributable to the terminal methyl group, while the ^{13}C nmr data, presented in Table 2, confirm the proposed structures. Thus the presence of the C-7′ hydroxyl is reflected in the appearance of characteristic α, β, and γ shifts in the side chain, while the *cis* relative stereochemistry of ring substitution in product **9** is proposed on the basis of comparison of the chemical shifts of C-1 and C-3 with those of *cis* and *trans* substituted 3-alkyl cyclopentanols (18). The structure of **10** is based on analysis of its ^{13}C nmr spectrum (Table 2), the high field methylene signal at δ 21.7, assigned to C-5′ influenced by two upfield γ shifts due to the combined influence of the hydroxyl groups at C-3′ and C-7′, being particularly diagnostic.

The *trans* relative stereochemistry of the vicinal hydroxyl groups in product **11** is derived from ^{13}C nmr analysis. The absolute stereochemistry is tentatively assigned as 1(*S*),2(*S*) on the basis of comparison of the sign of rotation of **11** with those of similar cyclic *trans*-1,2-diols of known configuration (19, 20). The assignment of absolute stereochemistry at C-3 of the products **6**, **9**, and **10** was achieved by analysis of optical rotatory data. Thus a positive $n \rightarrow \pi^*$ Cotton effect in the cd spectrum of both **6** and its oxidation product **8** confirms the 3(*R*) absolute configuration for these two compounds (21), while the presence of a negative $n \rightarrow \pi^*$ Cotton effect in the spectrum of the diketone obtained by Jones' oxidation of **9** indicates that the latter compound has the (*S*) absolute stereochemistry at C-3 (21).

The enantiomeric excesses (ee) of compounds **6** and **9** at C-3 were determined following oxidation to the diketone **8**, and conversion of the latter to the bis(ketal) using 2(*R*),3(*R*)-butane-2,3-diol (22). The ^{13}C nmr spectrum of the bis(ketals) obtained from **6** and **9** showed pairs of signals attributable to the presence of diastereomeric components for C-2–C-5 and C-1′, and the enantiomeric excesses (shown in Table 1) were obtained directly from the signal intensities.

Product **10** is tentatively assigned the 3(*S*) configuration on the basis of a comparison of its optical rotation (−ve) with those of **6** (+ve) and the oxidation product of **9** (−ve), it having been shown that the configuration of substituent allylic hydroxyl groups on the alkyl chain of molecules such as **10** does not influence the overall sign of rotation of the molecule at longer wavelengths (7, 23, 24). The observation that the predominant configuration of **9** is different from that of **6**, from which it is presumably derived, is not exceptional: the enantiomeric excess of **6** is not high, and an enzyme converting **6** to **9** need not operate with the same enantioselectivity at C-3 as one that produces **6**, the enzymic functions of carbonyl reduction (by alcohol dehydrogenases) and hydroxylation (by mono-oxygenases) being unrelated.

The absolute stereochemistry of the newly introduced hydroxyl group at C-7′ in **6** has been determined to be (*R*) by conversion of **6** to the acetate **7** and oxidation of the latter to give, following methylation of the corresponding acid, (*R*)-(−)-methyl 6-acetoxyheptanoate (**39**). An authentic sample of this compound was prepared, as its (*S*)-(+) enantiomer, following resolution of ethyl 6-phthaloxyheptanoate (**37**) as the brucine salt. The (−) enantiomer of **39** is assigned the (*R*) absolute configuration by comparison with other methylcarbinol esters of different chain lengths but known configurations. In all cases, the (−) enantiomer has the (*R*) configuration at the carbinol centre (25). Within the experimental limits, the hydroxylation at C-7′ of **6** was found to be stereospecific. The absolute stereochemistry at other hydroxylation sites in this series of products has not been determined.

Of the other fungi used to biotransform **5**, *C. lunata* gave a complex mixture of products, while *C. elegans* gave no detectable products. *Aspergillus ochraceus* gave, in addition to other products, the 7′-alcohol **6** and a new product, **12**, identified as the 6′-alcohol on the basis of ^{13}C nmr (Table 2) and other spectral data (see Experimental). This latter product was also obtained as the sole metabolite of **6** by *C. decora*. In this case, the predominant absolute stereochemistry of **12** was identified as 3(*S*) by the observation of a negative $n \rightarrow \pi^*$ Cotton effect at 296 nm in the cd spectrum (21), and the enantiomeric excess determined following Jones' oxidation to the diketone **13** and conversion to the bis(ketal) with 2(*R*),3(*R*)-butane-2,3-diol as described above. The result is presented in Table 1.

The absolute configuration at the newly introduced C-6′ position of **12** was again determined by conversion to the acetate and oxidation to give, following diazomethane treatment of the resulting acid, (*S*)-(+)-methyl 5-acetoxyheptanoate (**40**). The absolute configuration of **40** is assigned by comparison of its sign of rotation with that of other ethylcarbinol esters with differing chain lengths: in all cases where the absolute configuration is known, the (*S*) enantiomer has a positive rotation (25).

The next model system to be studied was the PGE analogue **14**. The *Rhizopus* species again gave the same product profile: products **15**, **17**, and **18** all carried a newly introduced hydroxyl group at C-7′, and were identified largely by their ^{13}C nmr spectra (Table 2). It is probable that both **17** and **18** arise from **15**, by dehydration and reduction, respectively. The relative stereochemistry of ring substitution in **18** follows from ^{13}C nmr data. The *trans* relationship between the C-4 hydroxyl and C-3 alkyl groups is dictated by the substrate stereochemistry, while the *cis* relationship between the C-1 and C-3 substituents is determined by comparison of the ^{13}C nmr chemical shifts of C-1 and C-3 with those of equivalent carbons in *cis* and *trans*-1,3-alkyl cyclopentanols (18).

The ring absolute stereochemistry of **18** is tentatively assigned as 1(*S*),3(*S*),4(*R*) based on a comparison of its rotation (negative) with those of other alkyl substituted cyclic 1,3-diols of known configuration (26) and comparison with the absolute stereochemistry proposed for compound **9**. The absolute stereochemistry at C-3 and -4 of **15** is also based on

optical data, the observation of a negative rotation confirming the predominant 3(*S*),4(*R*) configuration shown (21). In this case, the enantiomeric excess was determined to be 20% by chiral shift reagent analysis of the ^{1}H nmr spectrum of **15**. The absolute stereochemistry of **17** has not been determined, but the 4(*R*) configuration may be suggested by comparison of its sign of rotation with those of PGA compounds, which carry similar ring functionality (27).

The absolute stereochemistry of the C-7′ hydroxyl group in **15** was determined as outlined above for compound **6**, and was again found to be (*R*). Thus compounds **6** and **14** are both hydroxylated at the C-7′ position by *R. arrhizus* to give the 7′-(*R*) alcohol, although the enantioselectivity of conversion of the two substrates is different, presumably due to the presence of the C-4 alcohol functionality in **14**.

Products **15** and **18** were also obtained (along with other unidentified products) from *C. decora* and *C. elegans*. *Curvularia lunata* gave a complex product profile, but *A. ochraceus* gave only two products, **15** and **19**, the latter identified by its spectral data (see experimental section and Table 2). The appearance of a new signal at δ 4.15 in the ^{1}H nmr spectrum, assigned to an allylic hydrogen geminal to hydroxyl, the absence of the usual C-4 hydrogen signal, and ^{13}C nmr chemical shifts assigned to a conjugated cyclopentenone (see Table 2) suggested structure **19**. Dehydration of PGE structures such as **14** in aqueous medium at pH ≤4 or ≥8, giving rise to PGA and PGB systems (the latter via the PGC structure, see Fig. 1) is well documented (28), and *Aspergillus* growth medium is acidic, in this case pH 3.5. The absolute stereochemistry at C-3′ of **19** has not been determined, but (−)-alkenyl alkyl carbinols are known to have the (*S*) configuration at the carbinol carbon (25). The enantiomeric excess at C-3′ determined by chiral ^{1}H nmr shift reagent analysis was 35%.

As with the other substrates used in this study, the 11-deoxy-PGE analogue **20** gave the same product profile from both

R. arrhizus and *R. stolonifer*. In addition to the C-6″ and C-7″ alcohols **21** and **24**, isolated and fully characterized by nmr and other spectral data (see experimental section and Table 3), and their corresponding reduction products, tentatively assigned structures **26** and **27** on the basis of ^{13}C nmr data, the dihydroxylated product **28** was obtained in low yield. The structure of **28** was deduced by comparison of its ^{13}C nmr spectral data (Table 3) with those of substrate **20** and product **10** (*vide supra* and Table 2).

The absolute configurations at C-2 and -3 of products **21** and **24** were determined by cd data. In both cases, the observation of a negative Cotton effect attributable to the $n \rightarrow \pi^*$ transitions at 296 and 297 nm for **21** and **24** respectively confirmed the 2(*R*),3(*R*) configuration shown (21). The enantiomeric excesses were determined as described above following oxidation to the ketones **23** and **25** and their conversion to the bis(ketals) with 2(*R*),3(*R*)-butane-2,3-diol. The ^{13}C nmr analysis of the ketals so obtained was used to determine the ee values given in Table 1. Product **28** was also assigned the 2(*R*),3(*R*) absolute configuration and an approximate ee of 20% based on the published negative rotation value of the corresponding C-7″-deoxy compound (7).

Products **21** and **24** were also obtained from incubation of **20** with *A. ochraceus*, *C. elegans*, and *C. decora*, but only characterized fully in the case of the latter fungus. The configuration and ee values listed in Table 1 were then derived from a comparison with the values determined for the corresponding products from *R. arrhizus*.

For both **21** and **24** derived from *R. arrhizus*, the configurations at the newly introduced carbinol centres were determined by acetylation, oxidation, and methylation as previously described to give the degradation products **39** and **40**, respectively. In both cases the results obtained were identical with those of earlier degradations, confirming that hydroxylation had occurred to give the C-7″(*R*) configuration in **21** and the C-6″(*S*) configuration in **24**.

The final compound used in this study was the PGE_1 precursor **29**. As a result of the experiments outlined above, which suggested that the *Rhizopus* species were the most efficient hydroxylating fungi of those studied for this series of compounds, biotransformation of **29** was limited to *R. arrhizus* and *R. stolonifer*. Two products were isolated and characterized as the C-19 alcohol **30** and the C-18 alcohol **32** (PG numbering). The structures followed from their ^{13}C nmr (Table 3) and other spectral data (see experimental section), the positions of hydroxylation being characterized by the shift parameters discussed above for products **6** and **12**. Unfortunately, no product of dihydroxylation at C-15 and C-18 or -19, corresponding to **28**, could be isolated, although ^{13}C nmr analysis of the minor products (see Experimental) indicated the possible presence of the reduction products **33** and **34**.

The absolute stereochemistry at C-2, -3, and -4 of **30** and **32** was determined, as before, by cd analysis (21), and the enantiomeric excesses were estimated by a comparison of the magnitudes of the $n \rightarrow \pi^*$ Cotton effects at 296 nm with that reported for natural PGE_1 (29): the C-15 allylic alcohol of the latter does not contribute appreciably to the $n \rightarrow \pi^*$ transition in the cd spectrum (23), and the effect of a hydroxyl group at C-18 or -19 unrelated to the carbonyl chromophore can be neglected. The configurations at the sites of hydroxylation were determined as before by conversion of the biotransformation products to the acetates, followed by oxidation and conversion of the resulting acids to the esters **39** (from **30**) and **40** (from **32**). As for previous hydroxylation products, the configurations were found to be 19(*R*) and 18(*S*) in **30** and **32**, respectively.

In view of the predominance of hydroxylation of the above substrates at the prostanoid C-18 and -19 positions, and the comparative rarity of hydroxylation at C-15, an attempt was made to suppress the former in favour of the latter by the use of the enzyme inhibitor 11-dodecynoic acid in the incubations of compound **5** with *R. arrhizus*. Such acetylenic fatty acids are known to be effective inhibitors of enzymes that hydroxylate at

the terminal and penultimate positions of fatty acids and related compounds (30, 31), but in the present study no change in the product profile obtained from **5** and *R. arrhizus* was observed when the acetylenic fatty acid was added to the fungus prior to the addition of **5**.

In a series of experiments designed to suppress the activity of oxidoreductases (manifested by the frequent observation of carbonyl reduction accompanying hydroxylation) the solvent for the addition of **5** to *R. arrhizus* was changed from 95% ethanol to varying concentrations of DMF and DMSO. The absence of ethanol denies the fungus access to relatively large amounts of reducing equivalents, but neither these experiments, nor trials in which the substrate was added without any solvent, caused an appreciable change in the product profile.

Discussion

While no direct data on the nature of the enzymes responsible for the hydroxylation products obtained in this study exist, their identity may be speculatively assigned as fatty acid or steroid cytochrome P-450 dependent monooxygenases (12, 30, 32). Fatty acid hydroxylases typically produce terminal, penultimate, or peripenultimate alcohols (33–35), and are known to hydroxylate non-fatty acid substrates (35). On the other hand, a steroid C-6β hydroxylase operating as outlined in Fig. 3 could produce the major hydroxylation products discussed above, reaction from the "α" side giving the prostanoid C-19(*R*) or

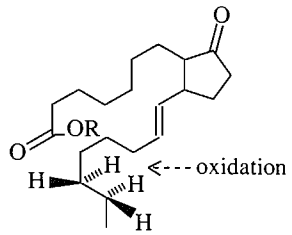

FIG. 3 Model for prostanoid C-18 or C-19 hydroxylation by a steroid hydroxylase.

C-18(*S*) alcohols. The steroid C-6β hydroxylase of *R. arrhizus* can hydroxylate from the α face in the absence of the steroid 3-keto-4-ene π system (10). This fact, together with the observation that highest yields of C-18 and -19 hydroxylated products were obtained from steroid C-6β hydroxylating fungi, the absence of terminal oxidation products, and the report that other natural products with long alkyl chains, e.g., cannabinoids, are also metabolized by steroid hydroxylating fungi to products with hydroxyl groups at the penultimate and peripenultimate (but not terminal) carbons of the alkyl chain (36), supports the model of Fig. 3.

Irrespective of the nature of the fungal hydroxylating enzymes, it is remarkable that their sites of attack, C-18 and -19, are identical with the sites of hydroxylation of natural prostaglandins by mammalian enzymes (37–43). Furthermore, the absolute stereochemistry at C-19 in the human metabolite 19-hydroxy-PGB_1 has been identified as (*R*) (44), identical to that observed in the present study. The 19-hydroxy-PG's, particularly in the PGE series (45), have greater physiological effects on smooth muscle than do the parent PG's (46), and are used in treatment of male infertility attributable to lack of seminal fluid PGE_1 metabolites (47).

In contrast to the 19-hydroxy-PGE's, whose formation and activities are understood, the 18-hydroxy-PGE's produced by mammalian PGE metabolism remain an enigma (43). They have no defined physiological role, and are of unknown configuration at C-18. In view of the correspondence of stereochemistries at C-19 between the mammalian metabolites and the products obtained in this study, it is tempting to speculate that the mammalian 18-hydroxy-PG's may have the 18(*S*) configuration.

The enantioselectivity observed in the fungal biotransformation of the PG precursors **20** and **29** was not high, but in view of the ease of their preparation, and the stereospecificity of their hydroxylation at C-18 or -19, fungal biotransformation must be considered a serious candidate for any synthetic route aimed at producing 18- or 19-hydroxy PG analogues.

Experimental

Apparatus, material, and methods

Melting points were determined on a Kofler heating stage and are uncorrected. Infrared spectra were recorded with an Analect 6260FX spectrometer. Proton nmr spectra were recorded at 200 MHz and carbon nmr spectra at 50.3 MHz (J MOD mode) with a Bruker AC200 spectrometer, using $CDCl_3$ as solvent and internal standard. Chiral shift reagent work used tris[3-(heptafluoropropylhydroxymethylene)-(+)-camphorato], europium(III) derivative in CCl_4 solution at relative concentrations of 0.1–0.3 M with respect to the compound under investigation. Mass spectra were obtained with an AEI MS30/Kratos DS55 system. Optical rotations were measured at 20°C in 95% ethanol solution using a Rudolph Autopol 3 polarimeter with a sample pathlength of 1 dm. The cd spectra were acquired by Dr. A. F. Drake

of the S.E.R.C. national CD service, Birkbeck College, University of London, U.K., or at the Department of Biochemistry, McMaster University, Hamilton, Ontario. The hplc analysis was performed on a Perkin–Elmer Series 3 chromatograph. Thin-layer chromatography was performed on Merck silica gel 60F-254, and flash column chromatography used silica gel (230–400 mesh, Merck 9385 or equivalent). Microanalysis was carried out by Guelph Analytical Laboratories.

Maintenance of microorganisms

Rhizopus arrhizus ATCC 11145 and *Rhizopus stolonifer* ATCC 6227b were maintained on malt agar slopes. *Aspergillus ochraceus* ATCC 18500 was maintained on Czapek's agar, *Curvularia lunata* ATCC 12017 on rabbit food agar, and *Calonectria decora* ATCC 14767 and *Cunninghamella echinulata* var. *elegans* ATCC 9245 on potato dextrose agar.

Synthesis of substrates

The following compounds were prepared by standard procedures and gave analytical and spectral data in agreement with those reported. The ^{13}C nmr data are reported in the tables. (±)-Methyl 2-oxocyclopentaneheptanoate (**2**) (48); (±)-methyl *Z*-7-(2′-oxocyclopentyl)-5-heptenoate (**4**) (48, 49); (±)-*trans*-2-(6′-carbomethoxyhexyl)-3-(*E*-1″-octenyl)-cyclopentanone ((±)-11,15-dideoxyprostaglandin E_1) (**20**) by diazomethane treatment of the acid (48); (±)-*trans,trans*-2-(6′-carbomethoxyhexyl)-3-(*E*-1″-octenyl)-4-hydroxycyclopentanone ((±)-15-deoxyprostaglandin E_1) (**29**) by diazomethane treatment of the acid (48).

*(±)-3-(*E*-1′-Octenyl)-cyclopentanone (**5**)*

A solution of *E*-1-iodo-1-octene (7) (6.69 g) in dry ether (100 mL) was cooled to −85°C and then treated with a solution of *tert*-butyllithium (30 mL, 1.9 M in pentane) over a period of 5 min. The resulting mixture was stirred at −78°C for 2 h, and then transferred under positive argon pressure into a flask containing a solution of copper(I) iodide (5.4 g) and tri-*n*-butyl phosphine (18.5 mL) in dry THF (360 mL) maintained at −78°C. The mixture was then stirred at −78°C for 15 min, and next treated over a period of 50 min with a cooled (−78°C) solution of 2-cyclopentenone (1.86 g) in dry THF (180 mL) under a positive pressure of argon. The reaction mixture was stirred at −78°C for a further period of 1 h, and then treated with aqueous ammonium chloride (270 mL) and the resulting mixture shaken vigorously for 10 min. The organic layer was then separated and the aqueous layer extracted with ether (3 × 150 mL). The combined organic material was dried and evaporated to yield a residue (16 g) that afforded a pure product **5** (2.5 g, oil) on chromatography (eluent hexane/ethyl acetate 7:1); ir ν_{max}: 1745 cm^{-1}; ^1H nmr included signals at δ 0.89 (3H, t, C-8′ CH_3) and 5.5 (2H, m, C-1′,2′ H's) ppm; ^{13}C nmr: see Table 2. *Anal.* calcd. for $C_{13}H_{22}O$: C 80.35, H 11.33%; found: C 80.14, H 11.45%.

*(±)-*trans*-3-(*E*-1′-Octenyl)-4-hydroxycyclopentanone (**14**)*

This was prepared by the route outlined below.

(±)-4-Hydroxy-2-cyclopentenone

This was most conveniently prepared by rearrangement of furfuryl alcohol (50). A solution of furfuryl alcohol (50 g) in 0.066 M phosphate buffer was adjusted to pH 4.1 by addition of phosphoric acid, and the mixture then maintained at reflux temperature under an atmosphere of argon for 15 h. The solution was then cooled and extracted twice with toluene (100 mL) and the aqueous layer then evaporated to dryness. The residue was then extracted with methylene chloride and the extract dried and evaporated to give an oil (22 g), which was purified by chromatography (eluent hexane/ethyl acetate 3:2) and afforded 18 g of (±)-4-hydroxy-2-cyclopentenone with spectral data identical to those reported (6).

(±)-4-Tetrahydropyranyloxy-2-cyclopentenone

This was prepared from the above alcohol (6 g) and dihydropyran (16 g) by the addition of concentrated HCl (3 drops); the mixture so produced was allowed to stand at room temperature for 3 h, and then worked up by the addition of ether and water to give the pyranyl ether in 95% yield. The ^1H nmr included signals at δ 1.5 (6H, m, tetrahydropyranyl hydrogens), 2.0–2.8 (2H, m, C-5 CH_2), 3.5–4.0 (2H, m, CH_2—O—), 4.8–5.0 (2H, m, C-4 H and O—CH—O), 6.1 (1H, d, C-2 H), and 7.5 (1H, m, C-3 H) ppm.

*(±)-*trans*-3-(*E*-1′-Octenyl)-4-hydroxycyclopentanone (**14**)*

This was prepared from the above THP ether (4.16 g) using the procedure outlined for the preparation of **5**. To the reaction product (2.9 g) was added a solution of acetic acid in water (65% vol/vol, 60 mL), and the cloudy suspension then made homogeneous by the addition of THF (6 mL). The resulting solution was stirred at 30°C for 12 h, and then neutralized (solid sodium bicarbonate) and extracted with ether. The extract was dried and evaporated to give an oil that, on chromatography (eluent hexane/ethyl acetate 1:1), afforded the title compound (1.9 g); ir ν_{max}: 1745, 3400 cm^{-1}; ^1H nmr included signals at δ 0.8 (3H, t, C-8′ CH_3), 4.1 (1H, dd, C-4 H), and 5.2–5.8 (2H, m, C-1′,2′ H's) ppm; ^{13}C nmr: see Table 2. *Anal.* calcd. for $C_{13}H_{22}O_2$: C 74.24, H 10.54%; found: C 74.02, H 10.28%.

Biotransformations

The results are summarized in Table 1. Incubations with the following fungi were performed as described, unless otherwise stated: *R. arrhizus* (51), *R. stolonifer* (51), *A. ochraceus* (52), *C. lunata* (13), *C. decora* (53), and *C. elegans* (54). Incubations were performed on a 1 g scale for a period of 3 days unless otherwise stated. Following the incubation period, the medium was extracted with dichloromethane (continuous extraction for 4 days). The extract was then dried and evaporated and, in the case of substrates **2**, **4**, **20**, and **29**, the residue treated with an excess of diazomethane in ether solution, and the resulting solution then evaporated. The final residue was subjected to chromatography to yield the products described below. Listed below under substrate headings and microorganism subheadings are conditions of incubation (if different from standard procedures); products; isolated yield (%); spectral and physical data. All products listed were homogeneous by chromatographic analysis (tlc, hplc), unless otherwise stated: no diastereomeric separations due to less than 100% ee of ring substituents were observed.

*(±)-Methyl 2-oxocyclopentaneheptanoate (**2**)*

Rhizopus arrhizus, R. stolonifer, Aspergillus ochraceus, Curvularia lunata

Methyl 2-oxocyclopentaneheptanoate; 10–20; identical with authentic material except $[\alpha]_D$ +6 to +10°.

*(±)-Methyl Z-7-(2′-oxocyclopentyl)-5-heptenoate (**4**)*

Rhizopus arrhizus, R. stolonifer, Aspergillus ochraceus, Curvularia lunata

Methyl *Z*-7-(2′-oxocyclopentyl)-5-heptenoate; 5–20; identical with authentic material except $[\alpha]_D$ +6 to +10°.

*(±)-3-(*E*-1′-Octenyl)-cyclopentanone (**5**)*

Rhizopus arrhizus, R. stolonifer

3-(*E*-1′-Octen-7′-olyl)-cyclopentanone (**6**); 10; ir ν_{max}: 1740, 3500 cm^{-1}; $[\alpha]_D$ +8.1° (*R. arrhizus*), +6.3° (*R. stolonifer*); ^{13}C nmr, see Table 2; ^1H nmr included signals at δ 1.17 (3H, d, C-8′ CH_3, collapsed to s on irradiation at δ 3.6–3.8 ppm), 3.6–3.8 (1H, m, C-7′ H), 5.3–5.7 (2H, m, C-1′,2′ H's) ppm; cd λ_{max}: 296 nm, Δε +0.028 (*R. arrhizus*); ms *m/e* (%): 192 ($M^+ - H_2O$, 3), 163 (7), 136 (60), 94 (68), 83 (85) relative to 80 (100). *cis*-3-(*E*-1′-Octen-7′-olyl)-cyclopentanol (**9**); 1; ir ν_{max}: 3345 cm^{-1}; $[\alpha]_D$ +7.0°; ^{13}C nmr, see Table 2; ^1H nmr included signals at δ 1.17 (3H, d, C-8′ CH_3), 3.5–3.9 (2H, m, C-1,7′ H's), 5.3–5.7 (2H, m, C-1′,2′ H's) ppm. Jones' oxidation of **9** (11 mg) gave 3-(7′-oxo-1′-octenyl)-cyclopentanone (**8**) (8 mg); ir ν_{max}: 1716, 1741 cm^{-1}; $[\alpha]_D$ −6.3°; ^{13}C nmr, see Table 2; ^1H nmr included signals at δ 2.15 (3H, s, C-8′ CH_3) and 5.5 (2H, br s, C-1′,2′ H's) ppm; ms *m/e* (%): 208 (20), 165 (5), 123 (50) relative to 95 (100). 3-(*E*-1′-Octen-3′,7′-diolyl)-cyclopentanone (**10**); 2; ir ν_{max}: 1738, 3400 cm^{-1}; $[\alpha]_D$ −8.3°; ^{13}C nmr, see Table 2; ^1H nmr included signals at δ 1.17 (3H, d, C-8′ CH_3), 3.0 (2H, br s, exchanges with D_2O, OH), 3.7–3.8 (1H, m, C-7′ H), 3.95 (1H, br s, C-3′ H), and 5.3–5.4 (2H, m, C-1′,-2′ H's) ppm; 4-(*E*-1′-Octen-7′-olyl)-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

cyclopentane-*trans*-1,2-diol (**11**); 14; ir ν_{max}: 3460 cm^{-1}; $[\alpha]_D$ +24.0°; ^{13}C nmr, see Table 2; ^1H nmr included signals at δ 1.17 (3H, d, C-8′ CH_3), 3.3–3.9 (3H, m, C-1,-2,-7′ H's), 5.3–5.5 (2H, m, C-1′,-2′ H's) ppm.

Rhizopus arrhizus, R. stolonifer, *time and solvent studies*

Variation of the time of incubation of substrate with *R. arrhizus* and *R. stolonifer* using periods of 24, 36, 48, and 72 h produced only minor variations in yield of products. Change of the solvent for substrate addition from 95% ethanol to DMF or DMSO (0.020–1 mL per 75 mg of substrate), or the addition of substrate in the absence of a solvent, produced no change in the range of products produced.

Rhizopus arrhizus, *inhibitor studies*

11-Dodecynoic acid (31) (0.25 and 0.5 mg/mL in separate experiments) was added to the fungal culture following the normal growth period but prior to addition of substrate **5** at the normal concentration (6). Subsequent biotransformation of **5** proceeded to give the range of products described above.

Curvularia lunata

Incubation of **5** (1 g) with *C. lunata* gave an extract (0.8 g). Thin-layer chromatographic analysis indicated a complex, multicomponent mixture, which was not investigated further.

Aspergillus ochraceus

3-(*E*-1′-Octen-7′-olyl)-cyclopentanone (**6**); 5; spectral data as described above. 3-(*E*-1′-Octen-6′-olyl)-cyclopentanone (**12**); 5; ir ν_{max}: 1743, 3490 cm^{-1}; ^{13}C nmr, see Table 2; ^1H nmr included signals at δ 0.90 (3H, t, C-8′ CH_3), 4.02 (1H, m, C-7′ H), and 5.3–5.5 (2H, m, C-1′,-2′ H's) ppm. Additional, more polar, minor products were detected by tlc analysis, but not investigated further.

Calonectria decora

3-(*E*-1′-Octen-6′-olyl)-cyclopentanone (**12**); 9; spectral data as described above in addition to $[\alpha]_D$ +10.4°; cd λ_{max}: 296 nm, Δε −0.18; ms *m/e* (%): 193 (28), 192 (M − H_2O, 33), 177 (5), 163 (72), 136 (60) relative to 80 (100).

Cunninghamella elegans

Incubation of **5** (1 g) with *C. elegans* gave an extract (0.11 g) from the growth medium that, on analysis (tlc, nmr), was found to contain only endogenous fungal products. Extraction of the fungal biomass yielded the unchanged starting material.

*(±)-*trans*-3-(*E*-1′-Octenyl)-4-hydroxycyclopentanone (**14**)*

Rhizopus arrhizus, R. stolonifer

3-(*E*-1′-Octen-7′-olyl)-4-hydroxycyclopentanone (**15**); 18; ir ν_{max}: 1740, 3480 cm^{-1}; $[\alpha]_D$ −14.4°; ^{13}C nmr, see Table 2; ^1H nmr included signals at δ 1.15 (3H, d, C-8′ CH_3), 3.1 (2H, br s, exchanges with D_2O, OH), 3.6–3.8 (1H, m, C-7′ H), 4.0–4.2 (1H, d of t, C-4 H) and 5.2–5.6 (2H, m, C-1′,-2′ H's) ppm, chiral shift reagent analysis using the C-4 hydrogen signal indicated an ee of 20%; ms *m/e* (%): 208 (M − H_2O, 3), 189 (10), 181 (30) relative to 55 (100). 4-(*E*-1′-Octen-7′-olyl)-cyclopent-2-en-1-one (**17**); 10; ir ν_{max}: 1709 cm^{-1}; $[\alpha]_D$ −11.7°; ^{13}C nmr, see Table 2; ^1H nmr included signals at δ 1.17 (3H, s, C-8′ CH_3), 3.5–3.8 (1H, m, C-7′ H), 5.2–5.6 (2H, m, C-1′,-2′ H's), 6.20 (1H, d, C-5 H), and 7.57 (1H, d of d, C-4 H) ppm; ms *m/e* (%): 208 (3), 190 (4), 166 (3), 149 (6), 95 (90), 82 (40), 67 (55), relative to 55 (100). 3-(*E*-1′-Octen-7′-olyl)-cyclopentane-*trans*-1,4-diol (**18**); 20; ir ν_{max}: 3400 cm^{-1}; $[\alpha]_D$ −11.4°; ^{13}C nmr, see Table 2; ^1H nmr included signals at δ 1.15 (3H, d, C-8′ CH_3), 3.4–4.1 (3H, m, C-1,-4,-8′ H's), and 5.3–5.6 (2H, m, C-1′,-2′ H's) ppm.

Curvularia lunata

Incubation of **14** (0.95 g) with *C. lunata* gave an extract from the aqueous medium (0.45 g) that, upon tlc examination, was found to consist of multiple components, and was not examined further.

Aspergillus ochraceus

3-(*E*-1′-Octen-7′-olyl)-4-hydroxycyclopentanone (**15**); 5; spectral data identical with those listed above. 3-(*E*-1′-Octen-3′-olyl)-cyclopent-2-ene-1-one (**19**); 3; ir ν_{max}: 1710, 3450 cm^{-1}; $[\alpha]_D$ −2.7°; ^{13}C nmr, see Table 2; ^1H nmr included signals at δ 0.96 (3H, t, C-8′ CH_3), 4.15 (1H, m, C-3′ H), 5.80 (1H, d, C-2 H), 6.25 (1H, d, C-1′ H), and 7.75 (1H, d, C-2′ H) ppm, chiral shift reagent analysis indicated an ee at C-3′ of 35%; ms *m/e* (%): 208 (1), 190 (10), 166 (3) relative to 55 (100).

Calonectria decora, C. elegans

Incubation of **14** (1 g) with each of these fungi gave extracts from the aqueous media (0.35 and 0.65 g, respectively); tlc examination indicated the presence of **15** and **18** in both extracts, together with other unidentified products. These extracts were not examined further.

*(±)-*trans*-2-(6′-Carbomethoxyhexyl)-3-(*E*-1″-octenyl)-cyclopentanone (**20**)*

Rhizopus arrhizus, R. stolonifer

2-(6′-Carbomethoxyhexyl)-3-(*E*-1″-octen-7″-olyl)-cyclopentanone (**21**); 12; ir ν_{max}: 1738, 3450 cm^{-1}; $[\alpha]_D$ −4.7° (*R. arrhizus*), −6.0° (*R. stolonifer*); ^{13}C nmr, see Table 3; ^1H nmr included signals at δ 1.15 (3H, d, C-8″ CH_3), 3.6–3.8 (1H, m, C-7″ H), 3.63 (3H, s, OCH_3), and 5.25–5.7 (2H, m, C-1″,-2″ H's) ppm; cd λ_{max}: 296 nm, Δε −0.23 (*R. arrhizus*); ms *m/e* (%): 334 (M − H_2O, 2), 303 (3), 225 (2), 223 (2), 191 (3) relative to 55 (100). 2-(6′-Carbomethoxyhexyl)-3-(*E*-1″-octen-6″-olyl)-cyclopentanone (**24**); 10; ir ν_{max}: 1740, 3480 cm^{-1}; $[\alpha]_D$ −20.0 (*R. arrhizus*), −21.07 (*R. stolonifer*); ^{13}C nmr, see Table 3; ^1H nmr included signals at δ 0.90 (3H, t, C-8″ CH_3), 3.4–3.7 (1H, m, C-6″ H), 3.61 (3H, s, OCH_3), and 5.25–5.6 (2H, m, C-1″,-2″ H's) ppm; cd λ_{max}: 297 nm, Δε −0.52 (*R. arrhizus*); ms as reported above for compound **21**. 2-(6′-Carbomethoxyhexyl)-3-(*E*-1″-octen-3″,7″-diolyl)-cyclopentanone (**28**); 4; ir ν_{max}: 1735, 3450 cm^{-1}; $[\alpha]_D$ −8.5° (*R. arrhizus*), −6.8° (*R. stolonifer*); ^{13}C nmr, see Table 3; ^1H nmr included signals at δ 1.15 (3H, d, C-8″ CH_3), 3.6–4.0 (2H, m, C-3″,-7″ H's), 3.61 (3H, s, OCH_3), and 5.2–5.4 (2H, m, C-1″,-2″ H's) ppm. 2-(6′-Carbomethoxyhexyl)-3-(*E*-1″-octen-6″-olyl)-cyclopentanol (**27**) and 2-(6′-carbomethoxyhexyl)-3-(*E*-1″-octen-7″-olyl)-cyclopentanol (**26**), mixture, approximately 1:3; 12; ^{13}C nmr included peaks at δ 10.0 (C-8″ of **27**), 23.4 (C-8″ of **26**), 68.0 (C-7″ of **26**), 73.3 (C-6″ of **27**), 77.7 and 78.8 (C-1) ppm; ^1H nmr included signals at δ 0.90 (t, C-8″ CH_3 of **27**), 1.15 (d, C-8″ CH_3 of **26**) in the ratio 1:3, in addition to signals at 3.4–3.8 (m, -CHOH-), 3.58 (OCH_3), and 5.2–5.4 (olefinic H) ppm.

Aspergillus ochraceus, C. elegans

Incubation of **20** (1 g) with these fungi gave extracts (0.5 and 0.8 g, respectively). Initial chromatography to remove endogenous fungal products gave, in each case, oils that by tlc analysis appeared to consist of a mixture of **21** and **24** (15 and 10%, respectively). These mixtures were not separated further, but their identity was confirmed by ^{13}C and ^1H nmr analysis by comparison with the spectra of isolated materials (see above).

Curvularia lunata

Incubation of **20** (1 g) with *C. lunata* gave an extract (0.65 g) that was found by tlc analysis to consist of a complex mixture of components. This extract was not analysed further.

Calonectria decora

2-(6′-Carbomethoxyhexyl)-3-(*E*-1″-octen-7″-olyl)-cyclopentanone (**21**); 1.5; spectral data identical with those reported above except $[\alpha]_D$ −3.4°. 2-(6′-Carbomethoxyhexyl)-3-(*E*-1″-octen-6″-olyl)-cyclopentanone (**24**); 2; spectral data identical with those reported above except $[\alpha]_D$ −9.4°.

*(±)-*trans*-2-(6′-Carboxymethylhexyl)-3-(*E*-1″-octenyl)-4-hydroxycyclopentanone (**29**)*

Rhizopus arrhizus

2-(6′-Carboxymethylhexyl)-3-(*E*-1″-octen-7″-olyl)-4-hydroxycyclopentanone (15-deoxy-19-hydroxy-PGE_1, **30**); 12; ir ν_{max}: 1735, 1740, 3450 cm^{-1}; $[\alpha]_D$ −18°; ^{13}C nmr, see Table 3; ^1H nmr included signals at δ 1.15 (d, C-8″ CH_3), 3.60 (3H, s, OCH_3), 3.5–3.8 (1H, m, C-7″ H), 4.0 (1H, d of t, C-4 H), 5.3 and 5.6 (each 1H, m, C-1″ and -2″ H's) ppm; cd λ_{max}: 296, Δε −1.80; ms *m/e* (%): 332 (20, M − $2H_2O$), 301 (35), 300 (30) relative to 55 (100). 2-(6′-Carbomethoxyhexyl)-3-(*E*-1″-octen-6″-olyl)-4-hydroxycyclopentanone (15-deoxy-18-hydroxy-PGE_1, **32**); 5; $[\alpha]_D$ −25.4°; ^{13}C nmr, see Table 3, ^1H nmr included signals at δ 0.92 (3H, t, C-8″ CH_3), 3.55 (3H, s, OCH_3), 3.6–3.8 (1H, m, C-6″ H), 3.96 (1H, m, C-4 H), and 5.25–5.7 (2H, m, C-1″,-2″ H's) ppm; ms, see that reported for **30**, above. Other, more

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

polar products (total 2%), were obtained. The ^{13}C nmr spectra of the mixture contained, in addition to methylene and methine resonances, peaks at δ 10.0 and 23.6 (CH_3), and 68.1, 72.5, 78.6, and 79.0 (CHOH) ppm, but no ketone C=O, suggesting possible structures **33** and **34**, but these products were not investigated further.

Determination of enantiomeric excesses and absolute configuration

1. At ring carbons

The direct values reported in Table 1 were obtained by Jones' oxidation of the biotransformation products, followed by ^{13}C nmr analysis of the diastereomeric ketals obtained by reaction of the products of Jones' oxidation with 2*R*,3*R*-butane-2,3-diol.

*3-(*E*-1′-Octen-7′-olyl)-cyclopentanone (6) (from* R. arrhizus*).* The above alcohol (20 mg) was reacted with Jones' reagent in the usual way, and the reaction mixture worked up to give the corresponding ketone (**8**) (18 mg), spectral data identical with those reported above except $[\alpha]_D$ +6.0°, cd λ_{max}: 279 nm, Δε +0.022. The above dione (18 mg) was dissolved in dry benzene, and to this solution was added 2*R*,3*R*-butane-2,3-diol (30 mg) and *p*-toluene sulphonic acid (1 mg). The resulting mixture was refluxed for 7 h and then cooled, diluted with ether (50 mL), and washed with 10% sodium bicarbonate solution. The organic layer was then dried and evaporated, and the residue dissolved directly in $CDCl_3$ for nmr analysis; ^{13}C nmr: 16.6, 16.9, 17.0, 17.2 (ketal CH_3's), 23.5 (C-5′), 25.7 (C-8′), 29.8 (C-4′), 30.9 and 31.2 (ratio 40:60, C-4), 32.4 (C-3′), 37.8 and 38.1 (ratio 38:62, C-3), 40.4 (C-6′), 40.7 and 41.2 (ratio 41:59, C-5), 44.9 and 45.1 (ratio 35:65, C-2), 78.0, 78.3, 78.5, and 78.8 (ketal -O*C*H(CH_3)-), 109.3 (C-7′), 118.0 (C-1), 129.2 and 129.8 (ratio 60:40, C-1′), and 133.8 and 134.0 (ratio 58:42, C-2′) ppm, indicating an average diastereomeric ratio of 40:60, or an enantiomeric excess for **6** of 20%.

*3-(*E*-1′-Octen-7′-olyl)-cyclopentanol (9) (from* R. arrhizus*).* Jones' oxidation of **9** gave the dione **8**, $[\alpha]_D$ −6.0°, ketalization of which as described above gave a sample whose ^{13}C nmr spectrum was identical with that described above except for the peaks assigned to C-2, -3, -4, -5, -1′, and -2′. Analysis of the spectrum indicated an enantiomeric excess for **9** of 20%.

*3-(*E*-1′-Octen-6′-olyl)-cyclopentanone (12) (from* C. decora*).* Jones' oxidation of **12** (37 mg) gave the dione **13** (32 mg); $[\alpha]_D$ −6.0°; ^{13}C nmr, see Table 2; ^1H nmr included signals at δ 1.0 (3H, t, C-8′ CH_3), 2.38 (2H, q, C-7′ CH_2), and 5.3–5.6 (2H, m, C-1′,-2′ H's) ppm; cd λ_{max}: 295 nm, Δε −0.36, converted to the ketal with 2*R*,3*R*-butane-2,3-diol as described above; ^{13}C nmr, δ: 8.12 (C-8′), 16.6, 16.9, 17.0, and 17.2 (ketal CH_3's), 23.7 (C-4′), 29.7 (C-7′), 30.9 and 31.2 (ratio 53:47, C-4), 31.4 (C-3′), 32.7 (C-3′), 37.7 (C-5′), 38.1 and 37.7 (C-3, overlapping with C-5′), 40.7 and 41.3 (ratio 54:46, C-5), 44.9 and 45.1 (ratio 53:47, C-2), 78.3, 78.5, 78.6, and 78.7 (-*C*H(CH_3)O-), 111.2 (C-6′), 117.0 (C-1), 129.0 (C-2′), and 134.0 and 134.3 (ratio 54:46, C-1′) ppm, indicating an enantiomeric excess for **12** on ca. 10%.

*2-(6′-Carbomethoxyhexyl)-3-(*E*-1″-octen-7″-olyl)-cyclopentanone (21) (from* R. arrhizus*).* Oxidation of **21** (50 mg) with Jones' reagent gave the diketone **23** in quantitative yield; ^{13}C nmr, see Table 3; ^1H nmr included a signal at δ 2.0 (3H, s, C-8″ CH_3), 3.58 (3H, s, OCH_3), and 5.3–5.6 (2H, m, C-1″,-2″ H's) ppm, converted to the ketal with 2*R*,3*R*-butane-2,3-diol as described above; ^{13}C nmr included doubled signals at 46.1 and 46.3 (ratio 36:64, C-12), 49.9 and 50.1 (ratio 39:61, C-8), and 129.5 and 130.0 (ratio 65:35, C-1″) ppm, indicating an average ee for **21** of 26%.

*2-(6′-Carbomethoxyhexyl)-3-(*E*-1″-octen-6″-olyl)-cyclopentanone (24) (from* R. arrhizus*).* The diketone **25** obtained by Jones' oxidation of **24** was converted to the bis ketal as described above. The ^{13}C nmr included doubled signals at δ 46.9 and 47.2 (ratio 22:78, C-12), 51.0 and 51.2 (ratio 24:76), and 129.7 and 129.8 (ratio 72:28, C-1″) ppm, indicating an average ee for **24** of 50%.

2. At hydroxylation sites

(a) By chiral nmr shift reagent

This method as used on compounds **6** from *R. arrhizus* and *R. stolonifer*, **12** from *C. decora*, **21** from *R. arrhizus* and *R. stolonifer*, and **24** from *R. arrhizus* and *R. stolonifer*. No evidence for diastereomeric complex formation was observed at concentrations of shift reagent capable of moving the -CH(OH)- signal under observation to chemicals shift of δ 15–20 ppm. The same phenomenon was observed by monitoring the CH_3 signal of the methyl carbinols **6** and **21** (with decoupling irradiation of the -CH(OH)- resonance) over the range 3–7 ppm.

(b) By degradation

(i) Methyl carbinols 6, 15, 21, and 30 from R. arrhizus. These were converted to the corresponding acetates **7**, **16**, **22**, and **31**, and then to (−)-methyl 6-acetoxyheptanoate (**39**) by the procedure outlined below in the case of **21**. The alcohol **21** (47 mg) was dissolved in dry pyridine (1 mL), and treated with acetic anhydride (1 mL). The resulting solution was allowed to stand at room temperature overnight, and then worked up in the usual way to afford the acetate **22** (37 mg); ^{13}C nmr δ (PG numbering): 19.9 (C-20), 21.3 (acetate CH_3), 23.1 (C-17), 24.8 (C-3), 26.7 (C-7), 28.2 (2C, C-6,-11), 29.1 (C-5), 31.3 (C-4), 32.2 (C-15), 33.8 (C-2), 35.7 (C-18), 37.4 (C-10), 46.2 (C-12), 51.4 (OCH_3), 53.6 (C-8), 70.0 (C-19), 131.7, 132.4 (C-13,-14), 170.6 and 174.0 (ester C=O), and 219.0 (C-9) ppm; ^1H nmr included signals at δ 1.20 (3H, s, C-20 CH_3), 3.66 (3H, s, OCH_3), 4.8–5.1 (1H, m, C-19H), and 5.2–5.6 (2H, m, C-13,-14 H's) ppm. The above acetate was dissolved in acetone (20 mL), and to this solution was added solid potassium permanganate (0.8 g). The resulting mixture was stirred and heated under reflux for 18 h, then evaporated, and water (10 mL) was added to the residue. This mixture was treated with solid sodium bisulphite until the purple color was discharged, and then acidified (10% HCl) to give a clear solution, which was extracted with ether (3 × 10 mL). The combined extract was washed with water, and then extracted with saturated aqueous sodium bicarbonate (3 × 10 mL). The aqueous extract was washed with ether, then acidified (10% HCl), and extracted with ether (3 × 10 mL). The ethereal extract was then dried and evaporated to give a residue (22.9 mg), which was treated with excess ethereal diazomethane in the usual manner to give a further residue. This was chromatographed by elution with 5% ethyl acetate/hexane to afford (−)-methyl 6-acetoxyheptanoate (**39**) (9 mg), identical in spectral properties with an authentic sample of racemic material (see below) except $[\alpha]_D$ −8.1°. Samples of **39** obtained in an identical manner from **6**, **15**, and **30** had $[\alpha]_D$ −8.5, −8.0, and −8.8° respectively.

(ii) Ethyl carbinols 12 from C. decora *and 24 and 32 from* R. arrhizus. These were converted to the corresponding acetates as described above, and the latter then treated with potassium permanganate and the resulting acids esterified as also described above. Chromatography (elution with 5% ethyl acetate/hexane) gave *S*-(+)-methyl 5-acetoxyheptanoate (**40**); ^{13}C nmr δ: 9.3 (C-7), 20.8 (C-3), 21.3 (acetate CH_3), 26.1 (C-6), 32.4 (C-4), 33.1 (C-2), 51.4 (OCH_3), 76.4 (C-5), 170.6 and 173.4 (ester C=O) ppm; ^1H nmr, δ: 0.90 (3H, t, C-7 CH_3), 1.2–1.9 (6H, m, C-3,-4, and -6 CH_2's), 2.02 (3H, s, OAc), 2.30 (2H, t, C-2 H's), 3.68 (3H, s, CH_3-O), and 4.9–5.3 (1H, m, C-5 H) ppm. Samples of **40** obtained from **12**, **24**, and **32** had $[\alpha]_D$ +11.6, +13.8, and +12.3° respectively. Analysis by chiral nmr shift reagent failed to provide evidence for the existence of more than one enantiomer of **40**.

Resolution of ethyl 6-phthaloxyheptanoate and the preparation of (+)-methyl 6-acetoxyheptanoate

(±)-Ethyl 6-hydroxyheptanoate (36)

6-Oxoheptanoic acid (commercial sample) was converted to the methyl ester **35** by treatment with diazomethane in the usual manner. Sodium borohydride (0.5 g) was then dissolved in a solution **35** (5 g) in absolute ethanol (200 mL), and the resulting mixture allowed to stand at room temperature for 24 h and then poured onto water and extracted with ether. The extract was washed with 5% HCl and water, and then dried and evaporated to give **36** (4.8 g, oil); ^{13}C nmr, δ: 14.0 (ethyl CH_3), 23.3 (C-7), 24.7, 25.1 (C-3,-4), 34.1 (C-2), 38.7 (C-5), 60.0 (ethyl CH_2), 67.4 (C-6), and 173.6 (C-1) ppm; ^1H nmr, δ: 1.12 (3H, d, C-7 CH_3), 1.22 (3H, t, ethyl CH_3), 1.25–1.9 (6H, m, C-3,-4,-5 H's), 2.30 (2H, t, C-2 H's), 3.75 (1H, m, C-6 H), and 4.12 (2H, q, ethyl CH_2) ppm. Chiral nmr shift reagent analysis showed clear separation of the C-6 hydrogen signals of the diastereomeric complexes at chemical

For personal use only.

shifts >13.0 ppm. *Anal.* calcd. for $C_9H_{18}O_3$: C 62.04, H 10.41%; found: C 61.95, H 10.50%.

(±)-Ethyl 6-phthaloxyheptanoate (37)

A solution of the alcohol **36** (5.22 g) and phthalic anhydride (4.44 g, freshly sublimed) in dry pyridine (40 mL) was allowed to stand at room temperature for 72 h, then poured onto 10% aqueous HCl and the mixture extracted with chloroform (3 × 200 mL). The chloroform solution was then washed (10% HCl), dried, and evaporated to give a residue that was dissolved in a mixture of ether and saturated aqueous sodium bicarbonate (200 mL of each). The ether layer was discarded, the aqueous layer washed further with ether (2 × 100 mL), and then acidified (10% HCl) and extracted with chloroform (3 × 100 mL). The final extract was dried and evaporated to give the half-ester **37** (7.5 g, oil); ^{13}C nmr, δ: 14.0 (ethyl CH_3), 19.4 (C-7), 24.6, 24.7 (C-3,-4), 34.0 (C-2), 35.2 (C-5), 60.3 (ethyl CH_2), 72.5 (C-6), 128.5, 129.4, 130.3, 130.5, 131.7, and 133.6 (aromatic C's), 167.6 (acid C=O), and 171.3 and 174.0 (ester C=O's) ppm; ^{1}H nmr, δ: 1.25 (3H, s, ethyl CH_3), 1.37 (3H, d, C-7 CH_3), 1.3–2.0 (6H, m, C-3,-4,-5 CH_2's), 2.35 (2H, t, C-2 H's), 4.10 (2H, q, ethyl CH_2), 5.0–5.3 (1H, m, C-6 H), and 7.4–7.9 (4H, aromatic H's) ppm. *Anal.* calcd. for $C_{17}H_{22}O_6$: C 63.34, H 6.88%; found: C 63.56, H 6.74%.

S-(+)-Ethyl 6-phthaloxyheptanoate

A mixture of the phthalate half-ester **37** (21 g), brucine dihydrate (30.42 g), and acetone (50 mL) was heated to boiling, and maintained under reflux conditions until a clear solution was obtained (ca. 10 min). The solution was then placed in a 4°C refrigerator for 48 h, and the resulting solid material (21 g) then collected by filtration. This was subsequently redissolved in acetone (50 mL) by heating, and the solution left undisturbed at 4°C for 24 h to produce 17.1 g of crystalline salt. Two further crystallizations from acetone (each 50 mL) resulted in 14.1 g of salt, mp 128–130°C, which was then shaken with a mixture of chloroform (100 mL) and 10% aqueous HCl (100 mL). The chloroform layer was removed and the aqueous layer extracted with further chloroform (3 × 100 mL); the combined organic extracts were dried and evaporated to yield *S*-(+)-**37** (4.9 g), with spectral data identical to those reported above except $[\alpha]_D$ +25.3°.

S-(+)-Methyl 6-hydroxyheptanoate (38)

Sodium borohydride (0.3 g) was added to a solution of the phthalate ester **37** (1 g) in absolute methanol (100 mL), and the resulting solution heated under reflux for 48 h. The solution was then evaporated, and the residue partitioned between 5% aqueous HCl and ether (50 mL of each). The ethereal layer was removed and the aqueous layer extracted further with ether (2 × 50 mL). The combined organic extract was then washed with saturated aqueous sodium bicarbonate, dried, and evaporated to give **38** (0.14 g, oil, ref. 55); $[\alpha]_D$ +21.9°; ^{13}C nmr, δ: 21.1 (ester CH_3), 23.2 (C-7), 24.7 and 25.0 (C-3,-4), 33.7 (C-2), 38.7 (C-5), 67.6 (C-6), and 173.0 (C-1) ppm; ^{1}H nmr, δ: 1.10 (3H, d, C-7 CH_3), 1.25–1.8 (6H, m, C-3,-4,-5 CH_2's), 2.27 (2H, t, C-2 H's), 3.4–3.8 (1H, m, C-6 H), and 3.60 (3H, s, OCH_3). Analysis by chiral nmr shift reagent showed no evidence for the existence of more than one enantiomer under conditions that shifted the C-6 hydrogen signal to 16.5 ppm. Conversion to the Mosher ester by reaction with 3,3,3-trifluoro-2-methoxy-2-phenylpropanoyl chloride and hplc analysis of the product were performed as described (56) and indicated an enantiomeric excess for **38** of ≥95%.

S-(+)-Methyl 6-acetoxyheptanoate

Treatment of the above alcohol with acetic anhydride in pyridine and work-up in the usual manner gave the acetate; $[\alpha]_{589}$ +8.5°, $[\alpha]_{546}$ +11.0°, $[\alpha]_{435}$ +18.7°, $[\alpha]_{405}$ +21.9° (*c* 0.31); ^{13}C nmr, δ: 19.7 (C-7), 24.6, 24.7 (C-3,-4), 33.8 (C-2), 35.4 (C-5), 51.4 (OCH_3), 70.5 (C-6), and 173.4 (C-1) ppm; ^{1}H nmr, δ: 1.20 (C-7 CH_3), 1.1–2.0 (6H, m, C-3,-4,-5 CH_2's), 2.32 (2H, t, C-2 H's), 3.65 (3H, s, OCH_3), and 4.8–5.6 (1H, m, C-6 H) ppm.

Thermodynamics of electrolyte solutions: activity coefficients of NaCl in the NaCl–$NiCl_2$–H_2O system at 25, 35, and 45°C

CH. VENKATESWARLU AND J. ANANTHASWAMY[1]

Department of Chemistry, Osmania University, Hyderabad – 500 007, India

Received June 9, 1989

CH. VENKATESWARLU and J. ANANTHASWAMY. Can. J. Chem. **68**, 294 (1990).

The activity coefficients of NaCl in the NaCl–$NiCl_2$–H_2O system were estimated at 25, 35, and 45°C and total ionic strengths of 0.5, 1.0, 2.0, and 3.0 *m* by an EMF method using a Na-ion selective electrode and a silver–silver chloride reference electrode. The Harned coefficients were calculated at all the temperatures studied. At 25°C the data were analysed using the Pitzer formalism. The osmotic coefficients and the excess free energies of mixing were also calculated at 25°C.

Key words: activity coefficients, sodium chloride, nickel chloride, Pitzer equations, thermodynamics.

CH. VENKATESWARLU et J. ANANTHASWAMY. Can. J. Chem. **68**, 294 (1990).

Opérant à des températures de 25, 35 et 45°C et à des forces ioniques totales de 0,5, 1,0, 2,0 et 3,0 *m* et faisant appel à une méthode de FEM utilisant une électrode sélective à l'ion Na et une électrode de référence d'argent/chlorure d'argent, on a évalué les coefficients d'activité du NaCl dans le système NaCl–$NiCl_2$–H_2O. On a calculé les coefficients de Harned à toutes les températures étudiées. À 25°C, on a analysé les données à l'aide d'un formalisme de Pitzer. On a aussi calculé les coefficients osmotiques et les énergies libres en excès, à 25°C.

Mots clés : coefficients d'activité, chlorure de sodium, chlorure de nickel, équations de Pitzer, thermodynamique.

Introduction

Activity and osmotic coefficient data are essential for predicting the thermodynamic behaviour of mixed electrolyte solutions, and extensive data is available for mixtures of alkali and alkaline earth metal halides (1–5). However, very few studies have been reported on aqueous mixtures of alkali metal halides with transition metal halides. Recently, Rard (6) determined the osmotic and activity coefficients of pure aqueous $NiCl_2$ at 25°C using the isopiestic method. The heat capacities and volumes of aqueous nickel chloride were measured by Perron *et al.* (7). The osmotic coefficients of the NaCl–$NiCl_2$–H_2O system at 25°C were estimated by Filippov *et al.* using an isopiestic method (8). However, the activity coefficients of NaCl in aqueous mixtures of NaCl–$NiCl_2$ have not yet been estimated as a function of temperature. In continuation of our earlier studies (9) on ternary mixtures of the aqueous alkali metal halides with transition metal halides, we are now reporting the mean ion activity coefficients of NaCl in the system NaCl–$NiCl_2$–H_2O by an EMF method at 25, 35, and 45°C and total ionic strengths of 0.5, 1.0, 2.0, and 3.0 *m*.

Results and discussion

The experimental mean activity coefficients of NaCl in the NaCl–$NiCl_2$–H_2O system at all the ionic strengths ($I = m_{NaCl} + 3m_{NiCl_2}$) and at 25, 35, and 45°C are summarized in Table 1 at different values of y_B, where $y_B = 3m_{NiCl_2}/(m_{NaCl} + 3m_{NiCl_2})$. The $\log \gamma_\pm$ vs. y_B plots at 25°C are shown in Fig. 1.

The activity coefficient data at each ionic strength were fitted to the Harned equation (10)

$$[1] \quad \log \gamma_A = \log \gamma_A^0 - \alpha_{AB} y_B$$

where γ_A^0 is the activity coefficient of pure NaCl at the same ionic strength as the mixture. The Harned coefficient values, i.e., α_{AB}, along with the root-mean-square deviations (RMSD) are listed in Table 2.

At 25°C the activity coefficient data were also analysed using the Pitzer formalism (11–13). The values of the Pitzer coefficients for NaCl and $NiCl_2$ are given below.

$$\beta^0_{NaCl} = 0.07537;\ \beta^1_{NaCl} = 0.2770;\ C^\phi_{NaCl} = 0.001407$$

$$\beta^0_{NiCl_2} = 0.34991;\ \beta^1_{NiCl_2} = 1.5300;\ C^\phi_{NiCl_2} = -0.00471$$

The experimental activity coefficient data at 25°C were fitted to the Pitzer equations and the binary ($^s\theta_{NaNi}$) and ternary (ψ_{NaNiCl}) interaction coefficients were evaluated at each of the ionic strengths studied. These values are given in Table 3. Also, the common $^s\theta$, ψ values and corresponding RMSD values are listed in Table 3.

It may be possible to compare the ternary mixtures HCl–$CoCl_2$–H_2O with NaCl–$CoCl_2$–H_2O, and HCl–$NiCl_2$–H_2O with the present system. The binary interaction parameter of the second system (14), i.e., $^s\theta_{NaCo} = 0.0382$, is lower than that of the first system (14), i.e., $^s\theta_{HCo} = 0.0829$. A similar trend is exhibited by $^s\theta_{NaNi} = 0.06795$ obtained in the present work, as it is lower than the $^s\theta_{HNi} = 0.0895$ value (14). This may be due to the increase in ionic size as we go from H^+ to Na^+. The same decreasing trend is observed as well in the case of the ternary interaction parameters (ψ).

The common $^s\theta$ and ψ values ($^s\theta = 0.06795$; $\psi = -0.03026$) were used to calculate the osmotic coefficients of the mixture at various compositions using the Pitzer equations (15). Osmotic coefficients of the mixture at 25°C are listed in Table 4. These osmotic coefficients, up to $I = 3.0$, are in good agreement with the values reported by Filippov *et al.* (8), with an RMSD of 1.36×10^{-2}.

Then, the excess free energies of the mixture were calculated using the equation

$$\Delta_m G^E = -2.3026 y_A y_B RTI^2(\alpha_{AB} + \alpha_{BA})$$

where all the symbols have their usual significance (16). These excess free energies of mixing are listed in Table 5 at the ionic strengths studied.

Experimental

Analytical grade NaCl (GR:S Merck) and $NiCl_2$ (GR:S Merck) were used without further purification. All solutions were prepared by

weight using double distilled conductance water. The NaCl and $NiCl_2$ solutions were standardized by volumetric titration against $AgNO_3$ using a potentiometer. All the stock solutions were prepared and standardized with utmost care to maintain an accuracy of five significant figures (±0.01%) in the molalities. Also, all titrations and dilutions were made using weight burettes.

The cell (17) consisted of a Na-ion selective electrode (Elico: India) of the glass membrane type and a silver – silver chloride electrode (18). These electrodes were immersed in a double walled glass vessel whose temperature was maintained constant by circulation of thermostated water. The temperature was maintained constant within ±0.01°C. The cell arrangement was

Na-ion selective electrode (glass membrane)	NaCl (m_A) + $NiCl_2$ (m_B)	Ag/AgCl electrode

TABLE 5. Excess free energies of mixing for the $NaCl–NiCl_2–H_2O$ system at 25°C

	$\Delta_m G^E$ (J kg^{-1} of water)			
y_{NaCl}	$I = 0.5$	$I = 1.0$	$I = 2.0$	$I = 3.0$
0.1	0.9327	11.07	82.96	146.1
0.2	1.658	19.68	147.5	259.7
0.3	2.176	25.83	193.6	340.9
0.4	2.487	29.52	221.2	389.6
0.5	2.591	30.75	230.5	405.8

The potentials were measured with a Keithly $5\frac{1}{2}$ digit electrometer/multimeter after processing the signals with a unit gain amplifier of input impedance $\simeq 10^{12}$ Ω. The accuracy of the EMF measurements was ±0.01 mV.

The EMF values of the Na-ion selective electrode vs. the Ag/AgCl electrode in $NaCl–NiCl_2$ mixtures are given by the relation

$$[2] \quad E = E_0 + k \log (a_{Na} a_{Cl} + K a_{Ni}^{1/2} a_{Cl})$$

where k is the Nernst slope and K is the selectivity coefficient of Na electrode for Ni^{2+} ions.

In pure NaCl solution, i.e., where $a_{Ni} = 0$,

$$[3] \quad E_{NaCl} = E_0 + k \log a_{Na} a_{Cl}$$

In pure $NiCl_2$ solutions, $a_{Na} = 0$ and, therefore,

$$[4] \quad E_{NiCl_2} = E_0 + k \log K a_{Ni}^{1/2} a_{Cl}$$

or

$$[5] \quad K^2 = (1/a_{NiCl_2}^3) \exp [4.606(E_{NiCl_2} - E_0)/k]$$

At each ionic strength in the first set, the EMFs of the aqueous NaCl solutions (E_{NaCl}) were measured and these EMFs were fitted to eq. [3] using the least-squares procedure to evaluate the E_0 and k values. The activity coefficients of pure NaCl are taken from NBS data (19). In the second set, the EMFs of the pure $NiCl_2$ solutions (E_{NiCl_2}) were measured and substituted in eq. [5] to estimate selectivity coefficient (K) values. The activity coefficients of pure $NiCl_2$ solution were taken from the work of Rard (6). These selectivity coefficient (K) values at all the ionic strengths studied were less than 1×10^{-4}. Therefore the second term within the parentheses on the right hand side of eq. [2] was neglected. The third set consisted of the EMF measurements ($E_{NaCl-NiCl_2}$) of the aqueous mixtures of NaCl and $NiCl_2$ solutions. Then, substituting these $E_{NaCl-NiCl_2}$ values in the following equations,

$$[6] \quad E_{NaCl-NiCl_2} = E_0 + k \log \{m_A (m_A + 2m_B) \gamma_\pm^2\}$$

or

$$[7] \quad \gamma_\pm^2 = (1/m_{Na} m_{Cl}) \exp \{2.303(E_{NaCl-NiCl_2} - E_0)/k\}$$

the activity coefficients of NaCl in aqueous $NaCl–NiCl_2$ mixtures were calculated. In eq. [6], the m_A and m_B represent the molalities of NaCl and $NiCl_2$ respectively in the mixture $NaCl–NiCl_2–H_2O$. Further experimental details were given earlier (17).

2-Methoxy-3,5-dinitropyridine, $C_6N_3O_5H_5$, crystallizes in the monoclinic system, space group $P2_1/n$, with cell parameters a = 7.496(5), b = 18.38(1), c = 6.068(2) Å, β = 77.18(4)°, V = 815(1) Å^3, and four molecules per unit cell. Its structure was solved by direct methods and refined by least-squares procedures to a final R = 4.99%, R_w = 5.42%, for 753 observed independent reflections. The molecule is not planar, a rotation of the methoxy and 3-nitro groups out of the pyridine ring (7° and 16°, respectively) is observed. The methoxy group is located *syn* to the ring nitrogen atom to avoid repulsion with the 3-NO_2 group and adopts a geometry different from the mean reported in the literature for methoxyaromatic groups. Geometrical parameters suggested by Domenicano and Murray-Rust and Norrestam and Schepper are used to analyze substituent effects on the pyridine shape and the possible causes of non-additivity of substituent effects are discussed. The relation of molecular conformation with reactivity of the title compound with amines is examined.

Key words: methoxy pyridine, substituted nitropyridines, crystal structure.

G. PUNTE, B. E. RIVERO, S. CERDEIRA et N. S. NUDELMAN. Can. J. Chem. **68**, 298 (1990).

Les cristaux de la 2-méthoxy-3,5-dinitropyridine, $C_6N_3O_5H_5$, sont monocliniques et ils appartiennent au groupe d'espace $P2_1/n$, avec a = 7,496(5), b = 18,38(1) et c = 6,068(2) Å, β = 77,18(4)°, V = 815(1) Å^8 et Z = 4. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés jusqu'à une valeur finale de R = 0,0499 et R_w = 0,0542 pour 753 réflexions observées d'une façon indépendante. La molécule n'est pas plane; on a observé que les groupements méthoxy et 3-nitro sont déplacés hors du plan du noyau pyridine par 7 et 16° respectivement. Afin d'eviter une répulsion de la part du groupement 3-nitro, le groupement méthoxy est *syn* par rapport à l'atome d'azote du cycle et sa géométrie est différente de celle généralement rapportée dans la littérature pour les groupements méthoxyaromatiques. On a utilisé les paramètres géométriques suggérés par Domenicano et Murray-Rust et par Norrestam et Schepper pour analyser l'effet des substituants sur la forme de la pyridine et on discute des causes qui pourraient expliquer la non-additivité des effets de substituant. On a aussi examiné la relation entre la conformation moleculaire et la réactivité des amines avec le composé mentionné dans le titre.

Mots clés : méthoxypyridine, nitropyridine, conformation moleculaire.

[Traduit par la revue]

Introduction

Several X-ray single crystal (1, 2–5), quantum-chemical (1, 6, 7), kinetic (7), and spectroscopic (8–10) studies have been performed on methoxyaromatic compounds to establish the relationship between either reactivity or pharmacological activity and the orientation of methoxy group with respect to the aromatic ring in solid state, gas phase, and solution. Some of these studies (1, 4, 5, 10) have shown that *ortho* disubstitution has a strong effect on methoxy orientation.

In fact, in methoxyphenyl systems with no *ortho* substitution, the favoured conformation for the methoxy group is coplanar with the ring (1, 6, 11) and *ortho* monosubstituted anisoles (1, 5) and veratroles (4) in solid state present the methoxy group only slightly twisted out of the benzene ring; by contrary, in 2,6-disubstituted anisoles the methoxy group tends to be almost perpendicular to the aromatic ring (4, 5, 7, 10). Nuclear magnetic resonance studies of 2,6-disubstituted methoxybenzenes (8) have indicated that for these compounds in solution, the perpendicular conformation tends to be preferred. X-ray single crystal study of 2,6-dinitroanisol (5) has shown, as expected, that the influence of two nitro groups adjacent to the methoxy group forces it out of the benzene ring. Contrary to anisoles, structural studies on methoxypyridines are scarce. Therefore we report here an X-ray single crystal examination of 2-methoxy-3,5-dinitropyridine to add to the understanding of the effect of di-*ortho* substitution on methoxyaromatic geometry in the pyridine series.

Experimental

The title compound was synethesized from 2-chloro-3,5-dinitropyridine by treatment with 0.39 *M* sodium methoxide in anhydrous methanol. After 2 h refluxing, the solvent was distilled at reduced pressure, the orange residue was treated with a small amount of distilled water, and white crystals appeared. They were crystallized from anhydrous methanol until constant mp 89–91°, Talik and Plazck reported mp 88–89° (12). The product was recrystallized by slow evaporation from methanol. It must be mentioned that it was rather difficult to get crystals of acceptable quality for intensity collection. Preliminary photographic studies using CuK_α radiation showed the crystals presented either short order arrangements or thermal disorder since intensities decayed quite quickly with increased θ. Besides, the crystals proved to react with several types of adhesives, the reaction being apparently enhanced by X-ray exposure. Therefore, after several tries a needle-shaped crystal of approximate dimensions 0.15 × 0.20 × 0.5 mm, fixed with water soluble plastic glue, was used for data collection. The measurements were done at T = 296 K in an automatic four-circle Huber diffractometer with graphite-monochromated MoK_α radiation (λ = 0.71073 Å), $\mu(MoK_\alpha)$ = 1.38 cm^{-1}. Calculated density D_X = 1.622 g cm^{-3}. Lattice parameters were obtained from the setting angles of twenty reflections in the range $10° < 2\theta < 28°$. Systematic absences, $h0l$, $h + l$ odd and $0k0$, k odd, indicated the space group $P2_1/n$, unique axis b.

*Defined according to Hamilton (16).

X-ray data were collected in the ω step scan mode, with scan width 1°, min–max scan speed 0.77–4.62° min^{-1}, to $2\theta_{max} = 50°$, index range: h −8, 8; k 0, 21; l 0,7. Three standard reflections (111, $\bar{2}82$, $27\bar{2}$) measured each 90 min showed only random intensity variations, max: 4%. Lorentz and polarization corrections were applied. Isotropic secondary extinction correction of the form $F' = F(1 - CF^2 \sin\theta)$ was applied on F_c, refined C value: 8.5×10^{-3}. No absorption correction was done. $F(000)$ value: 408. Of the 1952 measured intensities (1431 unique, $R_{int} = 0.034$) 753 were considered observed using the criterion: $I > 2\sigma(I)$, where $\sigma(I)$ is the standard deviation based on counting statistics.

The structure was solved using direct methods, Multan-80 (13). From the partial model obtained all non-hydrogen atoms were located and refined from alternated difference Fourier syntheses and isotropic least-squares refinement cycles. After refinement by full-matrix least-squares, based on F's and employing anisotropic thermal parameters, the hydrogens were stereochemically positioned (with C—H = 1.08 Å, ideal tetrahedral H—C—C and H—C—H angles for Me group and ideal trigonal H—C—C and H—C—H for CH groups) and refined, isotropically, with their positions riding on the bonded atoms; an overall temperature factor for hydrogens of the methoxy group was refined.

The final refinement, with 131 parameters, converged to $R = 0.0499$, $R_w = 0.0542$, weighting scheme: $w = 1/[\sigma^2(F_0) + 0.00035F_0^2]$, maximum shift/esd = 2×10^{-3}. Minimum and maximum values of the residual electron density were −0.23 and 0.19 e Å^{-3}, respectively. Scattering factors for H and scattering factors and anomalous dispersion corrections for O, C, and N were taken from SHELX76 (14). Calculations were carried out on a MicroVAXII system using the programs MULTAN80 (13), SHELX76 (14), and ORTEP (15).

Fractional atomic parameters with equivalent isotropic thermal parameters for the non-hydrogen atoms are given in Table 1.[3] The numbering scheme is shown in a stereoscopic view of the molecule, Fig. 1. Table 2 shows intramolecular bond lengths and angles.

Discussion

As can be observed from Fig. 1 the main feature of the molecular conformation is the location of the OMe group *syn* to the ring nitrogen, N(1), to avoid repulsion with the 3-nitro group. A methoxy group in a position *anti* to the 2-nitro group has been reported for 2,4-dinitroanisole from X-ray single crystal data (5). ^{1}H and ^{13}C nmr spectra of the title compound in $CDCl_3$ solution (9) suggest that the methoxy group may adopt the same conformation in solution. Nuclear magnetic resonance spectra of 2-methoxy-3-nitropyridine in solution would also indicate the same conformation (9, 10).

The pyridine ring is planar within 3σ[3] and the sum of the internal angles is 720°. The methoxy–oxygen and the nitrogens N(2) and N(3) from the 3-nitro and 5-nitro groups are bent out of the mean ring plane ($\Delta = -0.045(3)$, 0.025(4), and 0.018(4) Å, respectively).

The dihedral angles of the methoxy and nitro groups with the aromatic ring were determined from their least-squares planes.[3] The 5-nitro group makes a small angle with the ring, 3.9°, whereas the methoxy and 3-nitro groups are twisted out of the mean ring plane making angles of 7.4 and 15.6°, respectively.

The effect of the different substituents on the pyridine system can be analyzed from the comparison of the geometry adopted by the ring in the title compound (**I**) with that observed in pyridine from microwave spectroscopy (**II***a*) (17) and from single crystal X-ray study (**II***b*) (18) and with single-crystal X-ray data reported by Destro, Pilati, and Simonetta (19) for 3,5-dinitropyridine (**III**), see Table 3.

It is well known that substitution causes redistribution of the electrons of aromatic rings and thus affects both intramolecular angles and bonds. A systematic study of the effects of different substituents on the benzene ring have been performed by Domenicano and Murray-Rust (DMR) (20) and by Norrestand and Schepper (NS) (21). These last authors have studied heterocyc-

lic six-member rings as well. Therefore we have used the angular parameters of NS for the hetero N and NO_2 groups and those proposed by DMR for OMe in order to examine the data presented in Table 3. The predicted values are shown in Table 4.

The additivity of the substituent effects on valence angles in the ring was studied analyzing $\Sigma|\theta_c - \theta_o|_i$ for the three compounds. In the cases of compounds **II***a*, **II***b*, and **III** the value of the summations (1.59, 1.07, and 1.69°, respectively) indicate that additivity is held within experimental errors. Inclusion of the OMe substituent, however, seems to modify the ring geometry in a way that it is not accounted for by the predictions of the NS and DMR models. In fact, both models predict stronger angular deformations than the actually observed ones. The methoxy geometry found in **I** is different from the mean one reported by various authors based on surveys of methoxyaromatic groups (1, 11). Besides, conflicting interactions between the methoxy and 3-nitro groups are observed. Therefore, it can be assumed that the OMe parameters proposed by DMS may be unsuitable for describing the OMe group effect on ring geometry in the title compound. This would explain the observed non additivity of the effects of the substituents ($\Sigma|\theta_c - \theta_o|_i = 7.1°$).

The examination of the methoxy geometry in the title compound shows that the C(1)—O(1) distance, 1.312(5) Å, is

‡3,5-Dinitropyridine.

shorter than the mean, 1.37(2) Å (1), that the N(1)—C(1)—O(1) angle, 119.6(4)°, is smaller than the mean, 124(1)° (1), and that the C(2)—C(1)—O(1) angle, 119.6(4)°, is larger than the mean, 115(1)° (1). The shortening of the C(1)—O(1) bond suggests a certain degree of double bond and a strong resonance with the 5-nitro group. This assumption is reinforced by the fact that the dihedral angle between the 5-nitro group and the aromatic ring is smaller than the angle between the 3-nitro group and the aromatic ring as has been described above.

On the other hand, the C(1)—C(2) bond length, 1.414(5) Å, is larger than the mean value for the other four C—C bonds: 1.38(1) Å. Besides, an increase in the exocyclic N(2)—C(2)—C(1) bond angle, 122.3(4)° and a corresponding shrinking of the N(2)—C(2)—C(3) angle, 117.3(4)°, from their expected sp^2 value are observed. These deviations from ideal aromatic ring geometry clearly tend to relieve steric compression.

In spite of these ring deformations and the rotation of 3-nitro group out of the pyridine ring a rather short intramolecular distance involving O(1) and O(21) atoms (d = 2.594(4) Å) is

§Methoxy 2,4,6-trinitrophenetole (23).

observed. We have retrieved data from some mono- and di-nitro *ortho* substituted methoxyaromatic compounds and we have found that though the orientation of methoxy and *o*-nitro groups are quite different in **I**, in 2,4-dinitroanisole (**V**) (5), in 2,6-dinitroanisole (**VI**) (5), in α-chloro-α-chlorosulfenyl-4-nitro-2,5-dimethoxyphenylacetyl chloride (**VII**) (22) and in methoxy-2,4,6-trinitrophenetole (**VIII**) (23), short distances, less than the sum of oxygen van der Waals radii, 1.4 Å (24), between the O of the OMe group and at least one oxygen of the *o*-nitro group are observed, see Table 5.

The manifest interaction between the 2-OMe and the 3-nitro groups mentioned above could be the reason of the observed enhanced reactivity of the 2-methoxy-3-nitropyridine with amines when compared with the 2-methoxy-5-nitropyridine (25) in spite of the greater steric hindrance. In fact, when forming the zwitterionic intermediate the sp^3 configuration that C(1) holds relieves strain in the 3-nitro substituted compound.

A stereoscopic view of crystal packing is shown in Fig. 2. Assuming as van der Waals radii for carbon, nitrogen, oxygen, hydrogen, and methyl group the values 1.6, 1.5, 1.4, 1.2, and 2.0 Å, respectively, according to Pauling (24), only N(1)...H(5) [x, y, 2 − z] and O(31)...H(61) [1 + x, y, 1 + z] distances (2.625(5) and 2.561(7) Å, respectively) would indicate some intermolecular interactions. Packing forces involving O(31) might cause the deviations of N(3) from mean aromatic ring plane in spite of the conjugation effects mentioned above.

Inert films on electrodes. Electrochemical properties of carbon fibre electrodes modified by α- and β-naphthol electropolymerization

PANTELIS KARABINAS

Laboratory of Physical Chemistry, Aristotelian University of Thessaloniki, 540 06, Thessaloniki, Greece

Received July 13, 1989

PANTELIS KARABINAS. Can. J. Chem. **68**, 302 (1990).

Modification of carbon fibre electrodes has been achieved by electropolymerization of α- and β-naphthols. The formation of the film was followed spectrophotometrically by probing the decrease of the concentration of the corresponding monomer in dilute solutions. The electrochemical behaviour of several depolarizers on the modified electrodes showed that the charge transfer takes place at the electrode–film interface. The film structure can be satisfactorily described by the "pin-hole" model.

Key words: carbon fibres, inert film, electromodification, α-naphthol, β-naphthol.

PANTELIS KARABINAS. Can. J. Chem. **68**, 302 (1990).

On a modifié des électrodes en fibre de charbon en effectuant une électropolymérisation des α- et β-naphthols. On a suivi la formation du film par spectrophotométrie en déterminant l'abaissement de la concentration du monomère correspondant dans des solutions diluées. Le comportement électrochimique de plusieurs dépolarisants sur les électrodes modifiées montre que le transfert de charge se produit à l'interface film-électrode. On peut décrire la structure du film d'une façon satisfaisante à l'aide du modèle du «trou d'aiguille».

Mots clés : fibres de carbon, film inert, électromodification, α-naphthol, β-naphthol.

Introduction

There is much current interest focused on the electrochemical applications of modified electrodes especially in electrocatalysis or passivation of electrodes to corrosion. Films formed by polmerization of radicals obtained during the oxidation of phenol or naphthol derivatives show catalytic or inhibitory behaviour depending on the presence or absence of active redox groups. Moreover, carbon fibres (c.f.) have nowadays been used successfully in numerous fields of technology, mostly as reinforced composites. The permeability and the roughness of a film on c.f. are the major factors that define the quality of the modified fibres as matrix for the attachment of epoxy resins.

Dubois *et al.* proposed the protective coating of metallic surfaces with a polyphenylene oxide film obtained by the electrooxidation of disubstituted phenols from concentrated alkaline aqueous-methanolic solutions (1). The polymerization mechanism suggested the propagation of the film by head-to-tail coupling of the phenate radicals. In recent studies 5-hydroxy-1,4-naphthoquinone and its derivatives have been found to follow the same electropolymerization mechanism on carbon, Pt, and Au electrodes (2–4). The film obtained showed catalytic effect on oxygen reduction due to the presence of the redox quinone group.

Furthermore, the electrosorption of nitro- and nitroso- derivatives of α- and β-naphthol has been studied lately (5, 6). It was found that the irreversible oxidation of the —OH group of 2-nitroso-1-naphthol results in the formation of a film, while in the case of reversible oxidation of 1-nitroso-2-naphthol no modification is observed.

The stability of the polymeric film depends on the substituent, pH and solvent composition. Thus, the polynaphthoquinone film is not stable in alkaline solutions and films bearing nitro- or nitroso- groups are stable only up to the reduction potential of the corresponding groups.

In all of the above cases the surface coverage exceeds a monolayer. Submonolayer coverage has been found for the electrosorption of β-naphthol, performed at a negative potential range where no oxidation of the —OH group occurs. In this case the adsorption increases at less negative potentials and follows the Langmuir adsorption isotherm (7).

Recently, Zinger *et al.* (8) suggested the electropolymerization of hydroxyalkyl-methacrylates and aniline for the improvement of the interlaminar shears strength of the c.f.

In the present paper the electrooxidation and electropolymerization of α- and β-naphthol is studied, since phenol — the parent compound of the monocyclic series — follows mainly dimerization reactions during its electrooxidation (9, 10). Our objective is to verify the electrochemical formation, the stability and the properties of films which have no functional groups attached to highly oriented c.f. electrodes. The amount of naphthol electrosorbed was calculated from its bulk concentration decrease. The permeability of the film in relation to the film thickness is investigated on the basis of the electrochemical behaviour of several reactants with various molecular sizes. The structure of the film is interpreted according to the existing theories.

Experimental

The PAN-based carbon fibres (Celion GY-70) used in this study were product of Celanese Corporation U.S.A.

The fibres were pretreated with ethanol or acetone in a Soxhlet-type apparatus for 2 h, washed with water, and vacuum dried to remove the adhesive resins which were deposited during the production process.

Absorbance values of the electrosorption experiments were measured with a PMQ-3 Zeiss spectrophotometer at 292 nm and 224 nm for α- and β-naphthol, respectively.

Micrographs were taken in the Physics Department using the JEOL-CX electron microscope in the SEM mode.

Cyclic voltammetric measurements were carried out using a conventional set up consisting of a voltage scan generator Wenking VSG 72 (G. Bank), a standard potentiostat Wenking ST 72 (G. Bank) and an X-Y recorder Servogor 733 B.B.C. (Goertz).

Current densities are expressed per mg fibres. All potential values are referred to the aqueous calomel electrode (SCE). A Pt sheet was used as counter electrode. Both the counter and the reference electrodes were separated from the working electrode compartment by glassy diaphragms.

α- and β-Naphthols puriss. p.a. (Fluka) were used after recrystal-

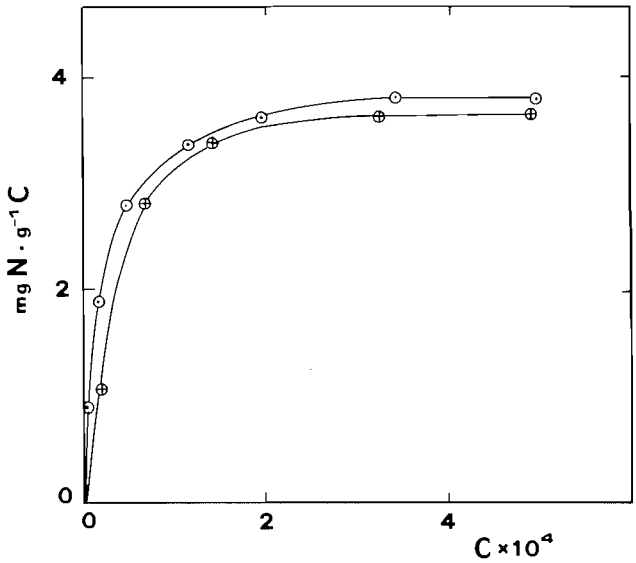

FIG. 2. Concentration dependence of the electrosorbed quantity of (α-) ○ and (β-) ⊕ naphthol (pH = 4).

lization from 80% ethanol. The study was carried out at 25 ± 0.1°C in aqueous 5% methanolic Britton–Robinson buffered solutions (pH = 1–12) prepared with triply distilled water.

Results and discussion

The electrosorption experiments were carried out on large bundles of highly oriented carbon fibres and the applied electrosorption potential covered a wide range of positive values. The concentration decrease, after the adsorption equilibrium, was followed spectrophotometrically. The largest amount of naphthol electrosorbed was observed at the potential where the oxidation of the naphthol at the corresponding pH takes place.

Figure 1 curve a represents the cyclic voltammogram of β-naphthol on carbon fibre electrodes at pH = 4. The i_p value varies linearly with the square root of the potential scan rate, as is expected for diffusion-controlled processes. The E_p is shifted 0.059 V per pH unit towards more negative values up to pH = 9 i.e. for pH < pK (p$K_{\beta\text{-N}}$ = 9.57). This behaviour suggests that a one-electron oxidation takes place, resulting in the formation of the naphthoxy radical. α-Naphthol exhibits exactly the same electrochemical behaviour.

The naphthoxy radical formed on the electrode surface undergoes further reactions, depending on the naphthol concentration. At high concentrations the polymerization through head-to-tail coupling is the predominant process (1–4), while at lower concentrations tail-to-tail dimerization (9, 10) as well as addition of water molecule (10, 11) can also take place.

Controlled potential electrolysis at 180–200 mV more positive than the E_p of the wave of Fig. 1 and simultaneous determination of the bulk concentration decrease showed that the amount of naphthol electropolymerized levels off to a limiting value with increasing electrolysis time. Each limiting value, which is attained at greater electrolysis time as the concentration of naphthol in the solution is decreased, suggests termination of the polymerization. These limiting values, expressed in mg naphthol per g of c.f., obtained from various naphthol concentrations (5×10^{-4}–10^{-6} M) reach a maximum as in Fig. 2. It may also be concluded from Fig. 2 that the

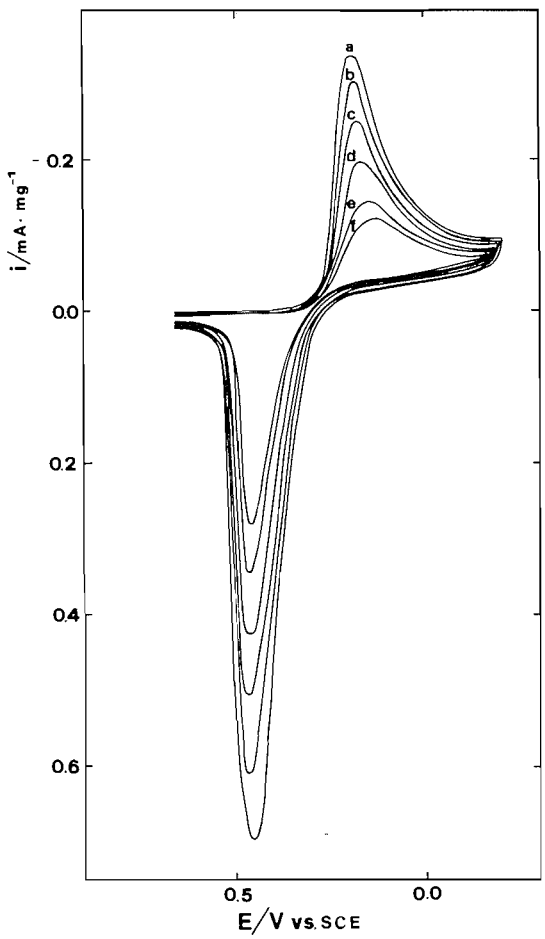

FIG. 3. Cyclic voltammogram of $AgNO_3$ (u = 100 mV s^{-1}, C = 1 mM, pH = 4) on electrodes modified with β-naphthol charged from the following concentrations: (a) without naphthol, (b) 10^{-5} M, (c) 5×10^{-5} M, (d) 10^{-4} M, (e) 2×10^{-4} M, and (f) 5×10^{-4} M.

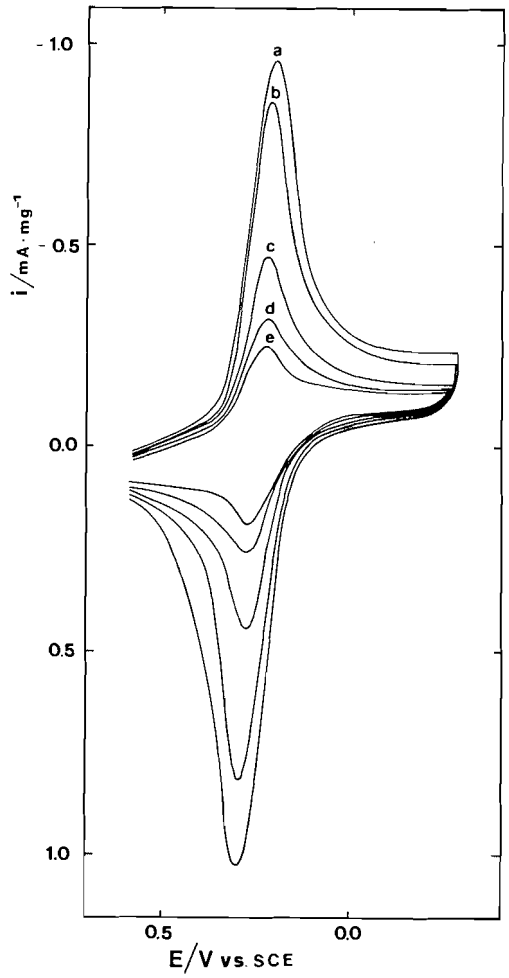

FIG. 4. Cyclic voltammogram of $K_4Fe(CN)_6$ (u = 100 mV s^{-1}, C = 2 mM, pH = 4) on electrodes modified with β-naphthol charged from the following concentrations: (*a*) bare electrode, (*b*) 5×10^{-6} M, (*c*) 2×10^{-5} M, (*d*) 5×10^{-4} M, (*e*) 10^{-4} M.

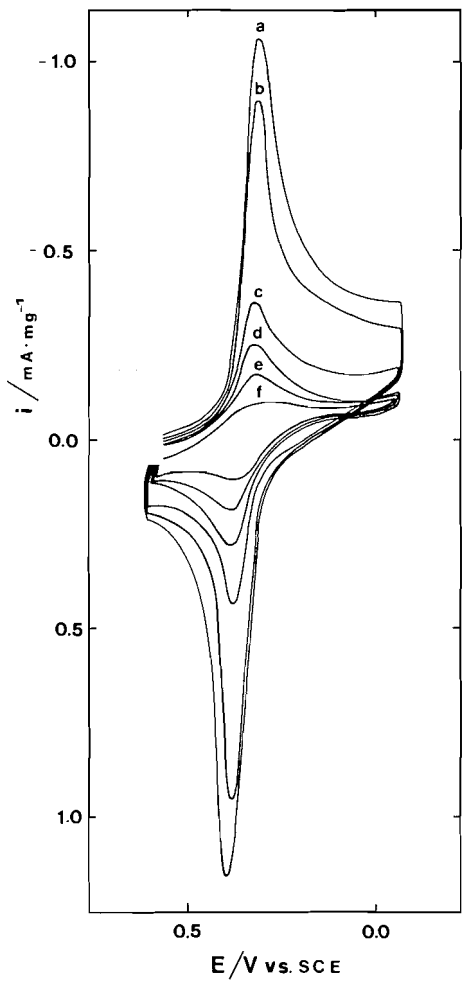

FIG. 5. Cyclic voltammogram of *p*-benzoquinone (u = 100 mV s^{-1}, C = 1 mM, pH = 4) on electrodes modified with β-naphthol charged from the following concentrations: (*a*) bare electrode, (*b*) 10^{-6} M, (*c*) 5×10^{-5} M, (*d*) 10^{-4} M, (*e*) 2×10^{-4} M, and (*f*) 5×10^{-4} M.

maximum amount of naphthol electropolymerized is achieved for concentrations greater than 3×10^{-4} M. This behaviour suggests that the film formed from relatively low concentrations can not exceed a critical thickness.

Projected molecular areas for both naphthols of 6.6×10^{-15} cm^2 and 2.6×10^{-15} cm^2 in the planar and perpendicular orientations (12, 13) yield values for surface coverage of 70 and 25 equivalent monolayers, respectively. These values were obtained taking into account that 1 mg of carbon fibres correspond to 1.5 cm^2 of effective area (14).

On an electrode bearing the limiting amount of the film the oxidation of naphthol itself is totally hindered, as curve *b* in Fig. 1 shows.

The film remains strongly attached to the carbon fibre over a wide potential range of about 2.5 V and is removed only after prolonged remaining at potentials where extreme hydrogen evolution occurs. After the film detachment the oxidation and electrosorption of naphthol can be carried out again on the regenerated fibre. The film is very stable in aqueous solutions (pH = 1–12) and in benzene. However, it is removed after remaining for 24 h in 1 M NaOH solution and by immersion of the fibre in ethanol, acetone, and acetonitrile.

Cyclic voltammetry has been employed to verify the film structure. It was found that at the whole potential range where

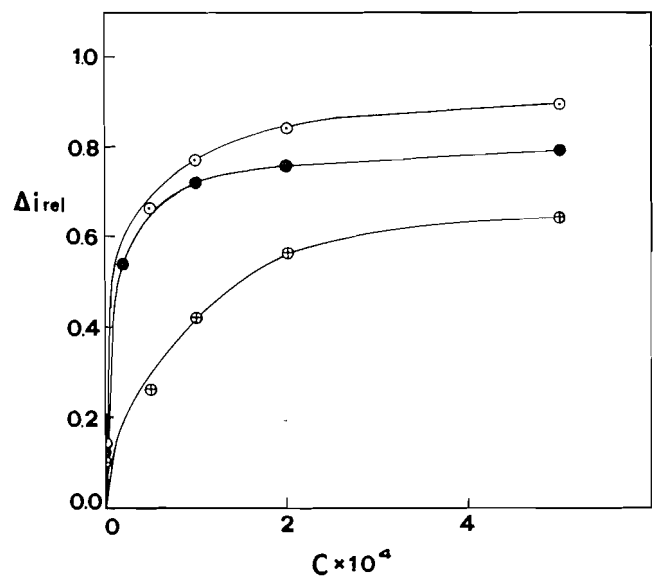

FIG. 6. Dependence of Δi_{Prel} for ○ $AgNO_3$, ● $K_4Fe(CN)_6$, and ⊕ *p*-Benzoquinone on the bulk equilibrium concentration of β-naphthol employed for modification.

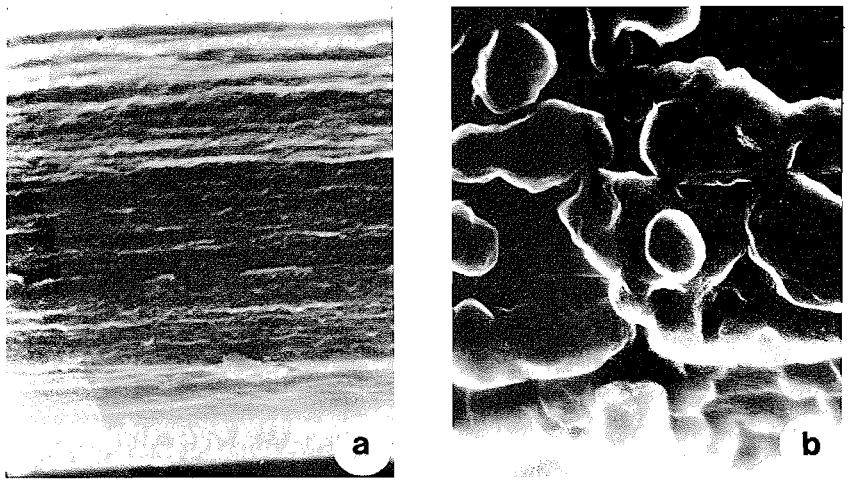

FIG. 7. Scanning electron micrograph of (*a*) bare carbon fibre (×30 000) and (*b*) partially modified fibre with β-naphthol (×40 000).

the film exists, several electrochemical reactions are considerably hindered, with the magnitude of inhibition depending on the extent of modification.

Figures 3, 4, and 5 show the gradual i_p decrease with increasing film thickness for three different depolarizers Ag^+, $Fe(CN)_6^{4-}$, and benzoquinone. It can be seen that in all cases the redox potential remains constant and the shape of the wave is the same, independent of the film thickness. On the other hand, on electrodes with the same modification a different inhibition is observed depending on the molecular size of the reactant. Thus, for an electrode coated with 1.7×10^{-8} mole β-naphthol cm^{-2} the Ag^+ reduction is almost 65% inhibited, whereas the Fe^{2+}/Fe^{3+} and quinone/hydroquinone reactions are inhibited about 80% and 90%, respectively.

The plot of $(\Delta i)_{rel} = i_p - i_m/i_p$, where i_p and i_m represent the peak current on pristine and modified fibres respectively, vs. the concentration of β-naphthol employed for modification, results in the curves presented in Fig. 6. It is observed that, for low β-naphthol concentrations, the limiting value of $(\Delta i)_{rel}$ is different for each depolarizer depending on its diffusion through the film.

Three possibilities can be considered for the reduction of the above depolarizers: (*a*) electron exchange taking place at the film–solution interface considering electron propagation through the film (15–18), (*b*) diffusion of the species through pores or channels (pin-hole model) (19–21) or through the film itself (membrane model) (22) with electron exchange at the electrode–film interface (23), and (*c*) diffusion of the species and propagation of the electrons with electron exchange in the film (24, 25). It must be noted that the film under consideration is inactive due to the absence of functional groups.

If the reduction of the depolarizer occurred at the film–solution interface (case *a*), the electrons had to diffuse through the film and the electrochemical reaction should occur at a potential different than that for a bare electrode (17). It follows that the magnitude of inhibition should be the same for each depolarizer depending only on the film thickness.

If electron propagation and species diffusion simultaneously occurred in the film (case *c*) a shift of the redox potential and a change of the shape of the wave should be observed. These effects should be more pronounced as the film thickness is increased (16, 24).

In case *b*, where the species is diffused through the film, the redox potential remains unaffected by the extent of modification

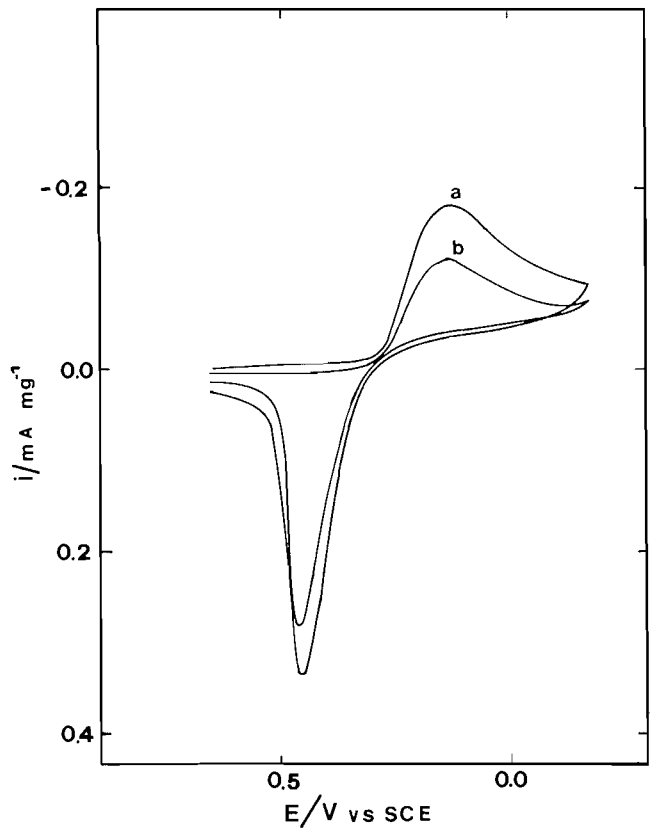

FIG. 8. Cyclic voltammogram of $AgNO_3$ (u = 100 mV s^{-1}, C = 1 mM, pH = 4) on modified electrodes (15 min electrolysis in a 1 mM β-naphthol solution at 0.75 V for different supporting electrolyte concentrations (*a*) CH_3COOH 1.6 M, CH_3COONa 0.4 M, and (*b*) CH_3COOH 0.16 M, CH_3COONa 0.04 M.

and the process is kinetically controlled by the diffusion of the species through the film (case "S" in the Andrieux and Savéant notation) (16).

As it has already been pointed out, in the case of films derived from naphthol electropolymerization, the redox potential of the depolarizers remains unaffected by the film thickness and is the same as that on a bare electrode. This indicates that the charge transfer takes place at the electrode–film interface and the height of the wave reflects merely the magnitude of the species

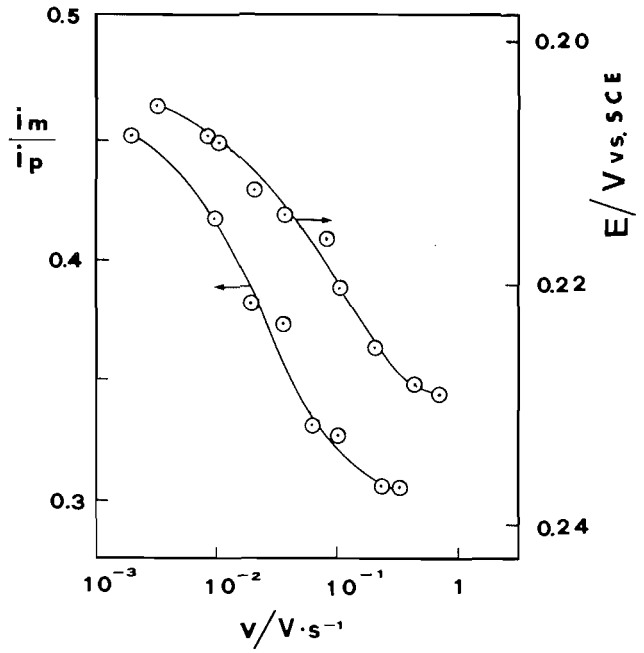

FIG. 9. Variation of the ratio i_m/i_p and of E_{pa} vs. u for $K_4Fe(CN)_6$ electrooxidation on a modified electrode bearing 1.5×10^{-8} mole β-naphthol cm^{-2}.

penetration through the film. Thus, it may be considered that on a modified electrode there are still active regions on the surface which are exposed to the solution.

The film formation may be described as an island growth of inactive regions on the electrode, so that the surface becomes inhomogeneous and the active species from the solution penetrates the film only through pores or channels. As the film thickness increases the size of the holes and the distribution of active sites decrease significantly and a smaller wave is observed. This also explains why for the same film thickness the inhibition is proportional to the molecular size of the corresponding reactant and even though the surface coverage exceeds several monolayers the electrochemical reaction is still observed. The structure suggested is very similar to that presented in the scanning electron micrographs of Fig. 7. Figure 7*a* shows a top view of pristine c.f. and Fig. 7*b* shows an image of the polymer particles deposited on the electrode where pores are clearly observed. The deposit appears distally brightened due to its insulating properties.

Further evidence is provided by the effect of the concentration of the supporting electrolyte on the film compactness. At high concentrations the film is swelled with solvent and electrolyte ions. This results in an increase of holes and/or channels in the film and consequently the peak current of the depolarizer is increased (Fig. 8).

In Fig. 9 the variation of the ratio i_m/i_p vs. u for the ferrocyanide on an electrode modified with 1.5×10^{-8} mole β-naphthol/cm^2 is given. This variation is rather in agreement with the theory predicted by Gueshi *et al.* (21) and further supports that the film structure fits the pin-hole model.

When the modification is performed from a concentrated solution of naphthol (10^{-2} *M* in 10% MeOH) the film becomes compact, the naphthol molecule is unable to reach the electrode surface and termination of the electropolymerization occurs. In this case channels and/or pores are blocked and the film exhibits properties of an impermeable inert insulator. These properties are different from those predicted by the membrane model since in the latter the current is governed by the extraction and diffusion coefficients of the species in the two phases (26).

Étude cinétique de la N-chloration de l'acide cyanurique en phase aqueuse

DENISE MATTE,[1] BERNARD SOLASTIOUK, ANDRÉ MERLIN ET XAVIER DEGLISE[2]
Université de Nancy I, Laboratoire de photochimie appliquée (Unité associée n° 238 du Centre national de la recherche scientifique), Boite postale 239, 54506 Vandœuvre-les-Nancy CEDEX, France

Reçu le 10 février 1988

DENISE MATTE, BERNARD SOLASTIOUK, ANDRÉ MERLIN et XAVIER DEGLISE. Can. J. Chem. **68**, 307 (1990).

Nous présentons une étude des mécanismes et déterminons les constantes de vitesse des N-chlorations d'acide cyanurique en milieu aqueux basique. Les énergies d'activation des processus mis en cause ont été déterminées. Ces cinétiques rapides ont été étudiées sur spectrophotomètre à écoulement bloqué. Dans le domaine de pH étudié nos résultats expérimentaux sont en accord avec un modèle cinétique comprenant la contribution de deux couples de processus indiscernables.

$$H_3Cy + ClO^- \xrightarrow{k_2} \text{produits}$$

ou

$$H_2Cy^- + ClOH \xrightarrow{k_3} \text{produits}$$

et

$$H_2Cy^- + ClO^- \xrightarrow{k_4} \text{produits}$$

ou

$$HCy^{2-} + ClOH \xrightarrow{k_5} \text{produits}$$

Les valeurs limites des constantes de vitesse dans le cas où, pour chaque couple, un seul des processus participe à la cinétique de chloration sont les suivantes :

$$k_2 = (5{,}4 \times 10^{11}) \exp(-35500/RT)\ M^{-1}\ s^{-1}$$

$$k_3 = (2{,}0 \times 10^{11}) \exp(-36700/RT)\ M^{-1}\ s^{-1}$$

$$k_4 = (1{,}4 \times 10^{13}) \exp(-55200/RT)\ M^{-1}\ s^{-1}$$

$$k_5 = 2{,}2 \times 10^7\ M^{-1}\ s^{-1} \text{ (à 298 K)}$$

À partir de ces valeurs, nous avons pu calculer les constantes de vitesse d'hydrolyse des dérivés monochlorés de l'acide cyanurique.

Mots clés : cinétique, N-chloration, 1,3,5-triazine 2,4,6-trione, phase aqueuse, spectrophotométrie à écoulement bloqué.

DENISE MATTE, BERNARD SOLASTIOUK, ANDRÉ MERLIN, and XAVIER DEGLISE. Can. J. Chem. **68**, 307 (1990).

A complete kinetic study of the N-chlorination, in basic aqueous medium, of cyanuric acid by the stopflow spectrophotometric method is presented. Our experimental results can be interpreted by two pairs of kinetically indistinguishable mechanisms.

$$H_3Cy + ClO^- \xrightarrow{k_2} \text{products}$$

or

$$H_2Cy^- + ClOH \xrightarrow{k_3} \text{products}$$

and

$$H_2Cy^- + ClO^- \xrightarrow{k_4} \text{products}$$

or

$$HCy^{2-} + ClOH \xrightarrow{k_5} \text{products}$$

The rate constants and their corresponding activation energies were determined in the limiting case where one of the elementary steps in each pair is involved alone in the kinetics of reaction.

$$k_2 = (5.4 \times 10^{11}) \exp(-35500/RT)\ M^{-1}\ s^{-1}$$

$$k_3 = (2.0 \times 10^{11}) \exp(-36700/RT)\ M^{-1}\ s^{-1}$$

$$k_4 = (1.4 \times 10^{13}) \exp(-55200/RT)\ M^{-1}\ s^{-1}$$

$$k_5 = 2.2 \times 10^7\ M^{-1}\ s^{-1} \text{ (at 298 K)}$$

The rate constants for hydrolysis of the monochlorinated cyanuric acid derivatives were derived from our experimental values.

Key words: kinetics, N-chlorination, 1,3,5-triazine-2,4,6-trione, aqueous medium, stopped flow.

Introduction

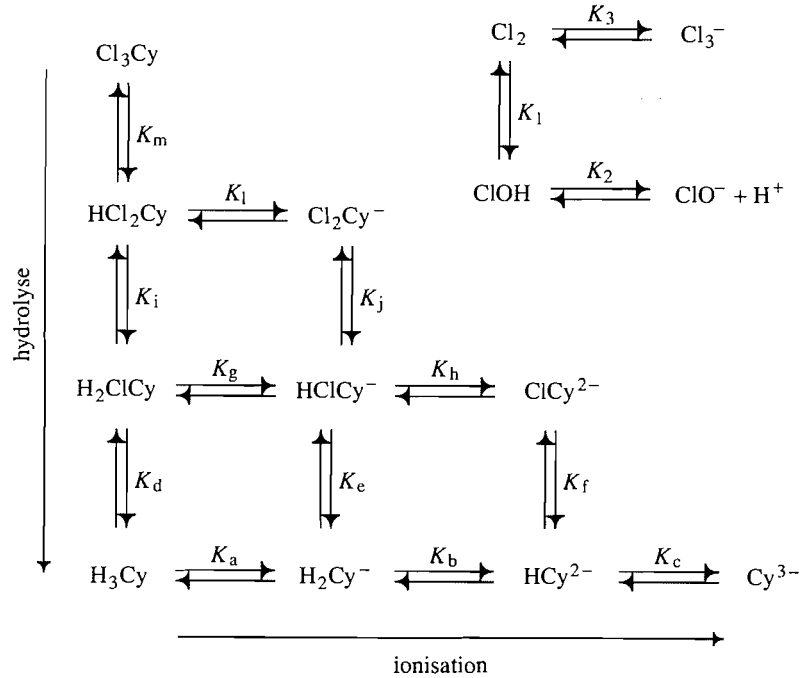
Les dérivés N-chlorés de la triazine-1,3,5 trione-2,4,6 ou acide cyanurique (H_3Cy) sont des sources sèches de chlore couramment utilisées dans les détergents et les eaux de piscines.

Mises en solution, ces molécules constituent un réservoir de chlore actif pouvant être libéré par leurs hydrolyses successives :

$$Cl_{(3-x)}CyH_x + H_2O \rightleftarrows HOCl + Cl_{(2-x)}CyH_{(x+1)}$$

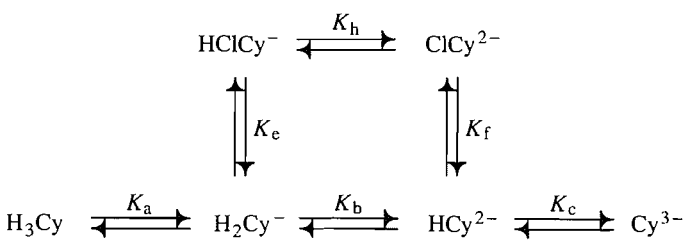
où x est compris entre 0 et 2.

Suivant les conditions de pH, la concentration en ions chlorures et le rapport [chlore]/[Cy] et compte tenu des propriétés acido-basiques de ces dérivés, on peut recenser en solution dix composés comprenant un noyau cyanurique en présence de différentes espèces du chlore libre (Cl_2, ClOH, ClO^-).



Les constantes d'équilibre entre ces composés ont été déterminées par O'Brien *et al.* (1, 2). À partir de ces valeurs, nous avons mis au point un mode de calcul appliqué à la micro-informatique permettant de déterminer la composition complète de ce système dans des conditions variées (3).

Ce calcul permet de vérifier qu'en milieu basique, le système précédent se simplifie notablement, en particulier un excès d'acide cyanurique permet de ne tenir compte que de la réaction de première chloration de celui-ci :



Pour le chlore libre, dans ces mêmes conditions, on ne tient compte que de l'équilibre entre l'acide hypochloreux et les ions hypochlorites :

$$ClOH \xrightleftharpoons{K_2} ClO^- + H^+$$

À ces pH, la composition de ce milieu ne dépend donc pas des ions chlorures en dehors d'un effet de force ionique.

Il n'existait pas de données cinétiques ou mécanistiques sur ces réactions rapides et équilibrées. Nous nous sommes donc intéressés à l'étude cinétique de la première chloration de l'acide cyanurique en milieu basique.

Techniques expérimentales (réf. 4)

Nous avons suivi la chloration de l'acide cyanurique par des solutions diluées d'ions hypochlorites. Le maximum d'absorption de ClO^- se situant à 290 nm et les dérivés monochlorés de H_3Cy absorbant à des longueurs d'onde plus faibles, nous avons pu, par *spectrophotométrie à écoulement bloqué*, déterminer les paramètres cinétique de cette réaction en observant la disparition de ClO^- à cette longueur d'onde.

En opérant en large excès d'acide cyanurique par rapport au chlore, nous avons pu mesurer une constante de vitesse expérimentale du pseudo-premier ordre (k_{obs}), pente de la droite $\ln(A - A_\infty)$ en fonction du temps (A est la densité optique de la solution à un instant donné). Dans ces conditions, le chlore est totalement consommé et la réaction s'arrête à la formation du composé monochloré.

Résultats expérimentaux

Nous avons tout d'abord vérifié que les résultats obtenus dans les conditions précédemment décrites étaient parfaitement représentés par le modèle d'une cinétique du pseudo-premier ordre. La relation liant $\ln(A - A_\infty)$ avec le temps étant linéaire, la réaction est du premier ordre par rapport à la concentration en chlore total $[Cl]_t$. La vitesse globale de réaction s'exprime donc, en présence d'un excès d'acide cyanurique ($[Cy]_t \gg [Cl]_t$), par :

$$[1] \quad v = -\frac{d[Cl]_t}{dt} = k_{obs}[Cl]_t$$

À pH constant, nous avons observé que k_{obs} est proportionnelle à la concentration totale d'acide cyanurique (fig. 1).

La réaction est donc globalement du second ordre et d'ordre

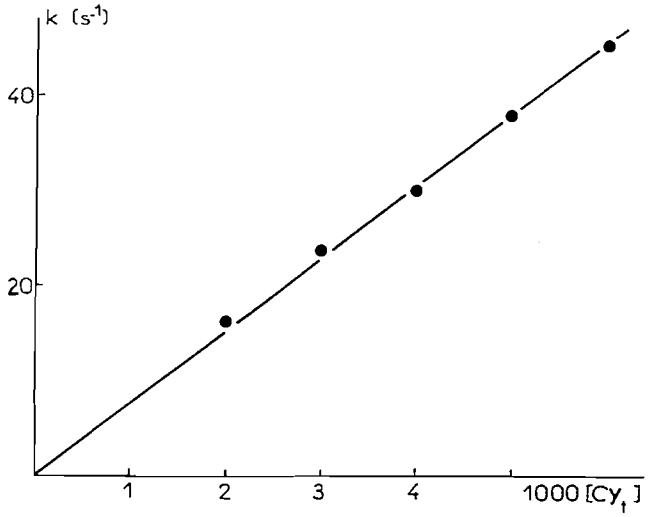


FIG. 1. Influence de la concentration en acide cyanurique : T = 298 K; pH = 8,60; $Cl_t = 3{,}5 \times 10^{-4}$ M pour $[Cy_t] < 4 \times 10^{-3}$ M; $Cl_t = 7{,}0 \times 10^{-4}$ M pour $[Cy_t] \geq 4 \times 10^{-3}$ M. k pente de la droite $\ln(A - A_\infty)$ en fonction du temps.

1 par rapport à chacun des deux réactifs

[2] $\quad v = k_{exp}[Cy]_t[Cl]_t$

où k_{exp} la constante de vitesse globale du second ordre s'exprime simplement pour nos conditions expérimentales à partir de [1] et [2] :

[3] $\quad k_{exp} = \dfrac{k_{obs}}{[Cy]_t}$

Les variations de k_{exp} en fonction du pH à 25°C sont représentées sur la figure 2.

Nous avons aussi suivi l'influence de la température sur ce paramètre à différents pH (fig. 3). Les relations exprimant $\ln(k_{exp})$ en fonction de la température pour les pH étudiés sont regroupées dans le tableau 1.

Interprétation

L'acide cyanurique est un triacide faible que l'on peut trouver en solution sous les quatre formes H_3Cy, H_2Cy^-, HCy^{2-} et Cy^{3-} en équilibre dans des proportions qui dépendent du pH (fig. 4). Corrélativement la concentration totale en acide cyanurique sera la somme des concentrations de ces espèces :

[4] $\quad [Cy]_t = [H_3Cy] + [H_2Cy^-] + [HCy^{2-}] + [Cy^{3-}]$

Compte tenu du domaine de pH des solutions utilisées (pH > 8) et de la vitesse de la réaction qui exclut qu'une espèce trop minoritaire intervienne dans le mécanisme, nous considérons le chlore libre sous forme d'acide hypochloreux ou d'ions hypochlorites qui sont les espèces majoritaires de ce milieu (fig. 5) :

[5] $\quad [Cl]_t = [ClOH] + [ClO^-]$

Les concentrations de ces différentes espèces peuvent être exprimées en fonction des constantes d'équilibre K_2, K_a, K_b et K_c, de leurs coefficients d'activité (γ_i), du pH et de $[Cy]_t$ et $[Cl]_t$. Le détail de ce calcul qui conduit aux expressions [6]–[9] est présenté en annexe.

[6] $\quad [H_3Cy] = \dfrac{1}{\mathscr{A}}[Cy]_t$

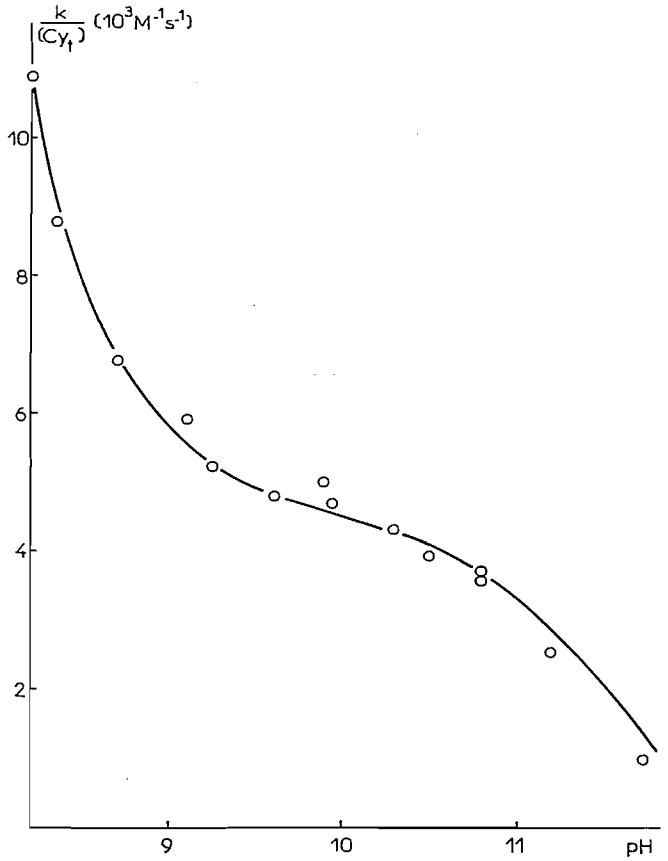

FIG. 2. Constante de vitesse expérimentale de chloration de l'acide cyanurique en fonction du pH; T = 298 K; $[Cy_t] = 5 \times 10^{-3}$ M; $[Cl_t] = 7 \times 10^{-4}$ M.

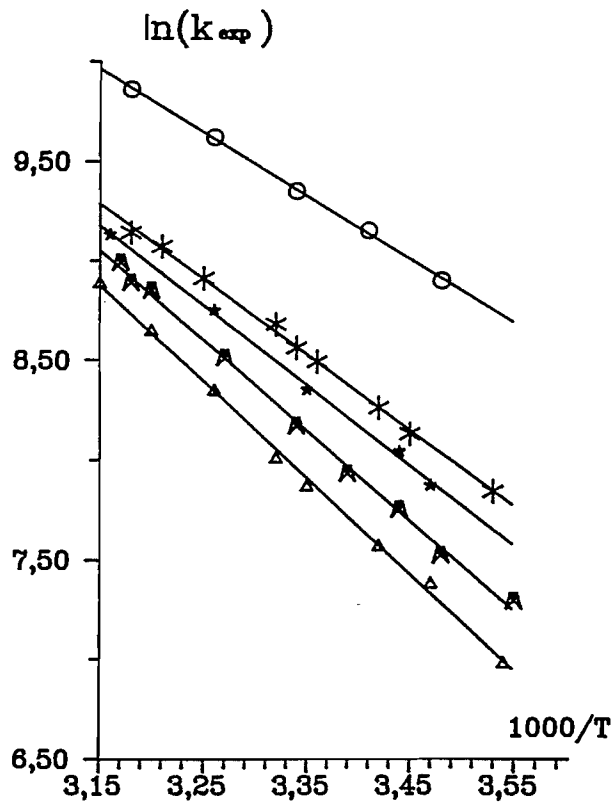

FIG. 3. Énergies d'activation globales à différents pH. ○ : pH = 8,15; ✳ : pH = 9,30; * : pH = 10,05; A : pH = 10,80; Δ : pH = 11,15.

TABLEAU 1. Énergies d'activation globales de la chloration de l'acide cyanurique à différents pH

pH	$\ln(k_{exp}/M^{-1}s^{-1})$	Énergie d'activation globale (kJ mol^{-1})
8,15	$-(3190/T) + 20,0$	26,5
9,30	$-(3800/T) + 21,3$	31,6
10,05	$-(4070/T) + 22,0$	33,8
10,80	$-(4540/T) + 23,4$	37,7
11,15	$-(4850/T) + 24,2$	40,3

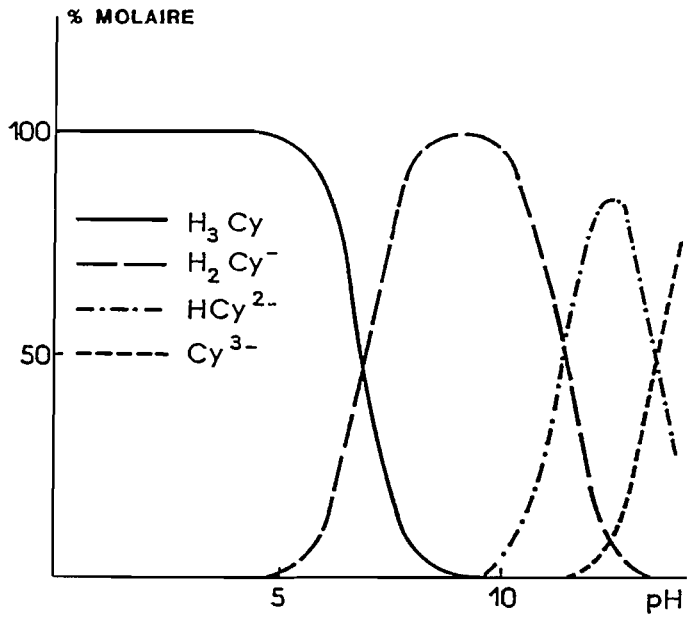

FIG. 4. Fractions molaires de chaque espèce dans une solution aqueuse d'acide cyanurique en fonction du pH (courbes calculées).

$$[7]\quad [H_2Cy^-] = \frac{K_a\gamma_{H_3Cy}}{\mathcal{A}(H^+)\gamma_{H_2Cy^-}}[Cy]_t$$

$$[8]\quad [HCy^{2-}] = \frac{K_aK_b\gamma_{H_3Cy}}{\mathcal{A}(H^+)^2\gamma_{HCy^{2-}}}[Cy]_t$$

$$[9]\quad [Cy^{3-}] = \frac{K_aK_bK_c\gamma_{H_3Cy}}{\mathcal{A}(H^+)^3\gamma_{Cy^{3-}}}[Cy]_t$$

Pour le chlore en posant : $d = K_a\gamma_{ClOH} + (H^+)\gamma_{ClO^-}$

$$[10]\quad [ClOH] = \frac{(H^+)\gamma_{ClO^-}}{d}[Cl]_t$$

et

$$[11]\quad [ClO^-] = \frac{K_a\gamma_{ClOH}}{d}[Cl]_t$$

Les équilibres de protonation et d'ionisation caractérisés par les constantes K_2, K_a, K_b et K_c sont rapides devant la cinétique de chloration et les relations [4]–[11] restent vérifiées au cours de la réaction.

Compte tenu de la mise en évidence expérimentale d'un ordre un par rapport à chacun des réactifs, nous pouvons envisager huit processus différents susceptibles de limiter la vitesse globale de réaction :

$P_1 : H_3Cy + ClOH \longrightarrow$ produits
$P_2 : H_3Cy + ClO^- \longrightarrow$ produits
$P_3 : H_2Cy^- + ClOH \longrightarrow$ produits
$P_4 : H_2Cy^- + ClO^- \longrightarrow$ produits
$P_5 : HCy^{2-} + ClOH \longrightarrow$ produits
$P_6 : HCy^{2-} + ClO^- \longrightarrow$ produits
$P_7 : Cy^{3-} + ClOH \longrightarrow$ produits
$P_8 : Cy^{3-} + ClO^- \longrightarrow$ produits

Le comportement de la constante de vitesse expérimentale en fonction du pH (fig. 2) semblant indiquer la participation de plusieurs processus à la cinétique globale de la réaction, nous envisagerons tout d'abord une participation ($v_{(P_i)}$) de chacun des processus P_1–P_8.

$$v = \frac{d[CyCl]_t}{dt} = v_{(P_1)} + v_{(P_2)} + v_{(P_3)} + v_{(P_4)} + v_{(P_5)} + v_{(P_6)} + v_{(P_7)} + v_{(P_8)}$$

Pour un processus bimoléculaire en solution réelle ($A + B \leftrightarrows C^{\neq} \rightarrow$) où $C^{\neq}$ est le complexe activé du processus :

$$[12]\quad v_{(P_1)} = k_1^0\frac{\gamma_A\gamma_B}{\gamma_{C^{\neq}}}[A][B]$$

d'où :

$$v = k_1^0\frac{\gamma_{H_3Cy}\gamma_{ClOH}}{\gamma_{Cl^{\neq}}}[H_3Cy][ClOH] + k_2^0\frac{\gamma_{H_3Cy}\gamma_{ClO^-}}{\gamma_{C2^{\neq}}}[H_3Cy][ClO^-] + \ldots$$

À partir des relations [6]–[11] donnant les concentrations des différentes espèces et en posant

$$X = \frac{\gamma_{H_3Cy}\gamma_{ClOH}\gamma_{ClO^-}}{\mathcal{A}d}$$

nous obtenons l'expression de la vitesse globale de réaction en fonction de $[Cy]_t$ et $[Cl]_t$:

$$v = \left[\frac{k_1^0}{\gamma_1^{\neq}}(H^+) + \left(\frac{k_2^0}{\gamma_2^{\neq}}K_2 + \frac{k_3^0}{\gamma_3^{\neq}}K_a\right) + \left(\frac{k_4^0}{\gamma_4^{\neq}}K_2K_a + \frac{k_5^0}{\gamma_5^{\neq}}K_aK_b\right)\frac{1}{(H^+)} + \left(\frac{k_6^0}{\gamma_6^{\neq}}K_2K_aK_b + \frac{k_7^0}{\gamma_7^{\neq}}K_aK_bK_c\right)\frac{1}{(H^+)^2} + \frac{k_8^0}{\gamma_8^{\neq}}K_2K_aK_bK_c\frac{1}{(H^+)^3}\right]X[Cy]_t[Cl]_t$$

Cette expression permet de regrouper les processus en fonction de la dépendance de leur contribution vis à vis de l'activité du proton hydraté : P_1; (P_2, P_3); (P_4, P_5); (P_6, P_7) et P_8.

Pour chacun des couples, (P_2, P_3), (P_4, P_5) et (P_6, P_7), nous pouvons vérifier que les deux complexes activés à l'intérieur de chaque couple ont même charge et même composition. Ainsi leurs coefficients d'activité peuvent être considérés comme égaux ou en tout cas comme variant de façon identique avec la force ionique du milieu. Comme le pH influe de la même manière sur leurs contributions à la vitesse globale de réaction, les pro-

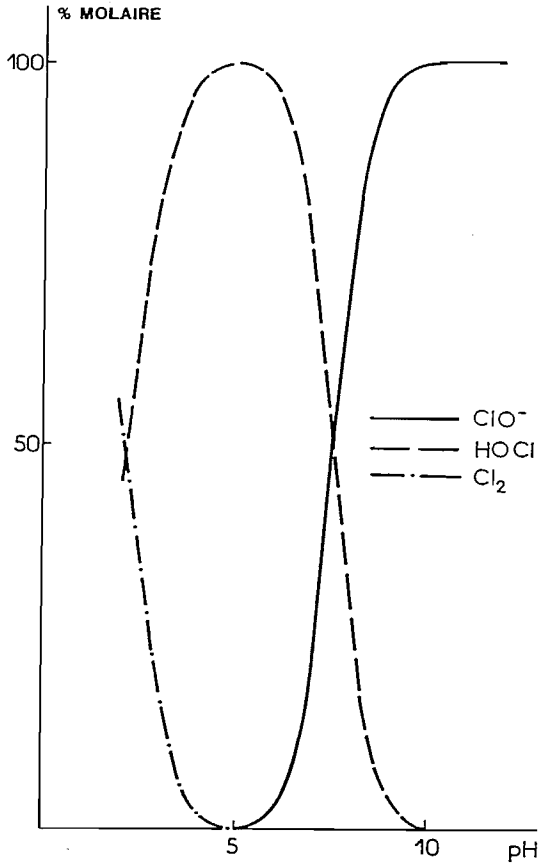

FIG. 5. Fractions molaires de chaque espèce du chlore en solution aqueuse en fonction du pH (courbes calculées).

cessus sont indiscernables à l'intérieur de chaque couple et notre étude se ramène à cinq cas : P_1; P_2 ou P_3; P_4 ou P_5; P_6 ou P_7 et P_8.

Nous avons déjà observé et décrit ce phénomène d'indiscernabilité de processus pour la N-chloration d'amines secondaires (4, 8).

En notant F les facteurs caractérisant ces contributions (les facteurs F ne dépendent pas du pH et restent constants à force ionique constante) nous obtenons :

$$v = \left(F_1(H^+) + F_{2\text{-}3} + \frac{F_{4\text{-}5}}{(H^+)} + \frac{F_{6\text{-}7}}{(H^+)^2} + \frac{F_8}{(H^+)^3}\right) X[Cy]_t[Cl]_t$$

et en identifiant à la relation [2] une expression théorique de la constante de vitesse expérimentale :

$$k_{exp} = \left(F_1(H^+) + F_{2\text{-}3} + \frac{F_{4\text{-}5}}{(H^+)} + \frac{F_{6\text{-}7}}{(H^+)^2} + \frac{F_8}{(H^+)^3}\right) X$$

Soit Y, obtenu à partir de nos points expérimentaux et des valeurs de X calculées pour les conditions correspondantes, défini par :

$$Y = \frac{k_{exp}}{X} = \left(F_1(H^+) + F_{2\text{-}3} + \frac{F_{4\text{-}5}}{(H^+)} + \frac{F_{6\text{-}7}}{(H^+)^2} + \frac{F_8}{(H^+)^3}\right)$$

En portant $\log_{10}(Y)$ en fonction du pH (fig. 6), nous pouvons déterminer les facteurs qui influencent la cinétique de réaction.

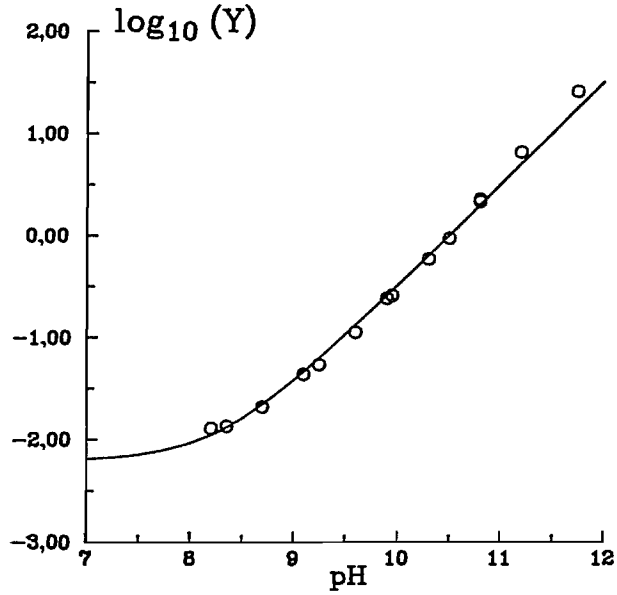

FIG. 6. $\text{Log}_{10}(Y)$ en fonction du pH

$$Y = k_{exp}\frac{\mathcal{A}d}{\gamma_{H_3Cy}\gamma_{ClOH}\gamma_{ClO^-}}$$

À pH > 10, les points obtenus sont portés par une droite de pente 1, ce qui indique une participation exclusive dans ce domaine des processus 4 ou 5. Pour des pH plus faibles, l'amortissement de la courbe indique que la participation des processus 2 ou 3 est prépondérante (pH < 8,5). Il apparaît donc que, dans le domaine de pH étudié, les résultats expérimentaux sont correctement décrits en considérant une expression de la forme :

$$[13]\quad Y = k_{exp}\frac{\mathcal{A}d}{\gamma_{H_3Cy}\gamma_{ClOH}\gamma_{ClO^-}} = \left(F_{2\text{-}3} + \frac{F_{4\text{-}5}}{(H^+)}\right)$$

Une optimisation permet de trouver les valeurs de ces paramètres à 298 K :

$$F_{2\text{-}3} = \frac{k_2^0}{\gamma_2^{\neq}}K_2 + \frac{k_3^0}{\gamma_3^{\neq}}K_a = 11{,}5 \times 10^{-3}\,s^{-1}$$

$$F_{4\text{-}5} = \frac{k_4^0}{\gamma_4^{\neq}}K_2K_a + \frac{k_5^0}{\gamma_5^{\neq}}K_aK_b = 2{,}35 \times 10^{-11}\,M\,s^{-1}$$

Dans le cas limite où l'un des processus de chaque couple devient prépondérant, nous pouvons calculer la valeur théorique maximale des constantes de vitesse à 25°C :

si $\frac{k_2^0}{\gamma_2^{\neq}}K_2 \gg \frac{k_3^0}{\gamma_3^{\neq}}K_a$ $\quad k_2^0 = 3{,}25 \times 10^5\,M^{-1}\,s^{-1}$

si $\frac{k_2^0}{\gamma_2^{\neq}}K_2 \ll \frac{k_3^0}{\gamma_3^{\neq}}K_a$ $\quad k_3^0 = 7{,}27 \times 10^4\,M^{-1}\,s^{-1}$

si $\frac{k_4^0}{\gamma_4^{\neq}}K_2K_a \gg \frac{k_5^0}{\gamma_5^{\neq}}K_aK_b$ $\quad k_4^0 = 2{,}92 \times 10^3\,M^{-1}\,s^{-1}$

si $\frac{k_4^0}{\gamma_4^{\neq}}K_2K_a \ll \frac{k_5^0}{\gamma_5^{\neq}}K_aK_b$ $\quad k_5^0 = 2{,}16 \times 10^7\,M^{-1}\,s^{-1}$

La détermination des constantes de vitesse expérimentales obtenues pour une série de pH constants à des températures variant de 10 à 45°C (tableau 1) a permis l'étude de l'influence de ce facteur sur les paramètres $F_{2\text{-}3}$ et $F_{4\text{-}5}$. Le calcul des

TABLEAU 2. Les valeurs de $F_{2\text{-}3}$ et $F_{4\text{-}5}$ sont obtenues par optimisation à partir des expressions du tableau 1 et de la relation [13]. Pour chaque température, une valeur de ces paramètres correspond à deux valeurs limites de la constante de vitesse selon le processus envisagé. Pour calculer les coefficients d'activité des espèces chargées nous utilisons la loi limite de Debye et Hückel en tenant compte de l'effet de la force ionique et de la température.

$P_5: HCy^{2-} + ClOH \rightarrow$	$2{,}16\times10^{7}$	—	—	—

coefficients $\mathcal{A}$ et d dans cette gamme de températures a été fait en utilisant pour expression des constantes d'ionisation les relations :

$$pK_2 = (3000/T) - 10{,}0686 + 0{,}0253T \text{ (réf. 5)}$$

$$pK_a = 31{,}08 - 0{,}154T + (2{,}441\times10^{-4})T^2 \text{ (réf. 6)}$$

$$pK_b = 35{,}86 - 0{,}1215T + (1{,}39\times10^{-4})T^2 \text{ (réf. 6)}$$

$$pK_c = pK_{c(298)}(298/T) \text{ (réf. 6)}$$

Les valeurs des constantes de vitesse déduites de ce calcul sont reportées dans le tableau 2.

Pour les processus P_2, P_3 et P_4 le logarithme des constantes de vitesse versus $1/T$ est porté par des droites dont les pentes donnent les énergies d'activation des processus.

$$\ln(\dot{k}_2) = -\frac{4272}{T} + 27 \qquad E_2^{\neq} = 35{,}5\text{ kJ/mol}$$

$$\ln(\dot{k}_3) = -\frac{4419}{T} + 26 \qquad E_3^{\neq} = 36{,}7\text{ kJ/mol}$$

$$\ln(\dot{k}_4) = -\frac{6640}{T} + 30{,}3 \qquad E_4^{\neq} = 55{,}2\text{ kJ/mol}$$

$\dot{k}_5$ apparait constant avec la température dans la limite des erreurs expérimentales.

Le tableau 3 résume les résultats obtenus : constantes de vitesse des processus à 298 K, énergies d'activation des différents processus ($d\ln k/dT = E^{\neq}/RT^2$) et valeurs $\Delta H^{\neq}$ et $\Delta S^{\neq}$ calculées en identifiant les expressions tirées de l'expérience aux valeurs de la dérivée de la constante de vitesse exprimée par la relation $k = (k_bT/h)K^{\neq}$.

Calcul des constantes de vitesse d'hydrolyse

Nos résultats nous permettent à partir des valeurs des constantes d'équilibre ($pK_d = 4{,}07$, $pK_e = 5{,}62$, $pK_f = 6{,}90$ (1, 2)) de calculer les constantes de vitesse d'hydrolyse des différentes formes de dérivés monochlorés de l'acide cyanurique :

$$H_2CyCl + HO^- \underset{k_2}{\overset{k_{-2}}{\rightleftharpoons}} ClO^- + H_3Cy$$

$$\left(K_{II} = \frac{k_{-2}}{k_2} = K_d\frac{K_2}{K_w}\right)$$

$$HCyCl^- + H_2O \underset{k_3}{\overset{k_{-3}}{\rightleftharpoons}} ClOH + H_2Cy^-$$

$$\left(K_e = \frac{k_{-3}}{k_3}\right)$$

$$HCyCl^- + HO^- \underset{k_4}{\overset{k_{-4}}{\rightleftharpoons}} ClO^- + H_2Cy^-$$

$$\left(K_{II} = \frac{k_{-4}}{k_4} = K_e\frac{K_2}{K_w}\right)$$

$$CyCl^{2-} + H_2O \underset{k_5}{\overset{k_{-5}}{\rightleftharpoons}} ClOH + HCy^{2-}$$

$$\left(K_f = \frac{k_{-5}}{k_5}\right)$$

où K_w est la constante de dissociation de l'eau, et K_2 la constante d'ionisation de ClOH. Nous obtenons à 25°C les valeurs suivantes :

$$k_{-2} = 8\times10^{7}\,M^{-1}\,s^{-1}$$

$$k_{-3} = 0{,}17\,s^{-1}$$

$$k_{-4} = 2\times10^{4}\,M^{-1}\,s^{-1}$$

$$k_{-5} = 2{,}72\,s^{-1}$$

Conclusions

Les résultats obtenus pour la première chloration de l'acide cyanurique peuvent être comparés aux valeurs correspondantes des amines aliphatiques. Nous avons aussi étudié précédemment (8) la N-chloration de la diéthylamine :

$$Et_2NCl + H_2O \underset{k_{ClOH}}{\overset{k_h}{\rightleftharpoons}} Et_2NH + ClOH$$

$$\left(K = \frac{k_h}{k_{ClOH}} = 5{,}89 \times 10^{-16}\,M \text{ (réf. 7)}\right)$$

et $k_{ClOH} = 5{,}3 \times 10^7\,M^{-1}\,s^{-1}$ à 25°C (8).

Ce qui correspond à une constante d'hydrolyse $k_h = 4{,}3 \times 10^{-8}\,s^{-1}$, soit un temps de demi réaction de 4500 h.

Comparativement les temps de demi-réaction des hydrolyses des chlorocyanuriques n'excédent pas quelques secondes.

Du point de vue cinétique et thermodynamique, le chlore fixé par un noyau cyanurique apparaît beaucoup plus labile qu'un chlore lié à une amine.

Sachant de plus que dans l'utilisation habituelle de ces produits, en présence d'un excès d'acide cyanurique (25–60 ppm d'acide cyanurique pour 1 ppm de chlore dans une eau de piscine), la majeure partie du chlore est sous forme d'acide monochlorocyanurique et est ainsi protégée de la photolyse due au rayonnement solaire (3). Nos résultats confirment que dérivés chlorocyanuriques sont une excellente source de chlore *actif* pour la désinfection et *stabilisé* vis à vis des pertes par photolyse.

Annexe

Les expressions des concentrations des différentes espèces plus ou moins ionisées de l'acide cyanurique sont établies d'une part à partir du bilan en acide cyanurique total :

$$[Cy]_t = [H_3Cy] + [H_2Cy^-] + [HCy^{2-}] + [Cy^{3-}]$$

et d'autre part à partir des trois lois d'action de masse correspondant aux équilibres acido-basiques :

$$K_a = \frac{[H_2Cy^-](H^+)}{[H_3Cy]}\,\frac{\gamma_{H_2Cy^-}}{\gamma_{H_3Cy}}$$

$$K_b = \frac{[HCy^{2-}](H^+)}{[H_2Cy^-]}\,\frac{\gamma_{HCy^{2-}}}{\gamma_{H_2Cy^-}}$$

$$K_c = \frac{[Cy^{3-}](H^+)}{[HCy^{2-}]}\,\frac{\gamma_{Cy^{3-}}}{\gamma_{HCy^{2-}}}$$

Par substitutions successives dans ces relations d'équilibre, nous obtenons l'expression des concentrations des espèces ionisées en fonction de celle de H_3Cy.

$$[H_2Cy^-] = [H_3Cy]\,\frac{K_a\gamma_{H_3Cy}}{(H^+)\gamma_{H_2Cy^-}}$$

$$[HCy^{2-}] = [H_2Cy^-]\,\frac{K_b\gamma_{H_2Cy^-}}{(H^+)\gamma_{HCy^{2-}}} = [H_3Cy]\,\frac{K_aK_b\gamma_{H_3Cy}}{(H^+)^2\gamma_{HCy^{2-}}}$$

$$[Cy^{3-}] = [HCy^{2-}]\,\frac{K_c\gamma_{HCy^{2-}}}{(H^+)\gamma_{Cy^{3-}}} = [H_3Cy]\,\frac{K_aK_bK_c\gamma_{H_3Cy}}{(H^+)^3\gamma_{Cy^{3-}}}$$

D'où la relation liant $[Cy]_t$ à $[H_3Cy]$:

$$[Cy]_t = [H_3Cy]\left(1 + \frac{K_a\gamma_{H_3Cy}}{(H^+)\gamma_{H_2Cy^-}} + \frac{K_aK_b\gamma_{H_3Cy}}{(H^+)^2\gamma_{HCy^{2-}}} + \frac{K_aK_bK_c\gamma_{H_3Cy}}{(H^+)^3\gamma_{Cy^{3-}}}\right)$$

En posant

$$\mathcal{A} = 1 + \frac{K_a\gamma_{H_3Cy}}{(H^+)\gamma_{H_2Cy^-}} + \frac{K_aK_b\gamma_{H_3Cy}}{(H^+)^2\gamma_{HCy^{2-}}} + \frac{K_aK_bK_c\gamma_{H_3Cy}}{(H^+)^3\gamma_{Cy^{3-}}}$$

nous retrouvons la relation [6] : $[H_3Cy] = [Cy]_t/\mathcal{A}$, puis par déductions successives les relations [7]–[9] du texte.

Enantioselectivity of carbonic anhydrase catalyzed hydrolysis of mandelic methyl esters

ROBERT CHÊNEVERT[1] AND MARTIN LÉTOURNEAU

Département de chimie, Faculté des sciences et de génie, Université Laval, Québec (Québec), Canada G1K 7P4

Received March 20, 1989

ROBERT CHÊNEVERT and MARTIN LÉTOURNEAU. Can. J. Chem. **68**, 314 (1990).

We report the first enantioselective hydrolysis of esters catalyzed by carbonic anhydrase. We found that mandelic methyl esters are good substrates for carbonic anhydrase. The *R* enantiomers are better substrates and enantiomeric excess values are moderate (40–51%).

Key words: carbonic anhydrase, mandelic esters, enantioselectivity, hydrolysis.

ROBERT CHÊNEVERT et MARTIN LÉTOURNEAU. Can. J. Chem. **68**, 314 (1990).

Nous avons découvert que les esters mandéliques sont des substrats de l'anhydrase carbonique. L'enzyme est stéréosélectif pour les énantiomères *R* et les valeurs de l'excès énantiomère sont modérées (40–51%). Il s'agit de la première étude sur l'énantiosélectivité de l'anhydrase carbonique.

Mots clés : anhydrase carbonique, esters mandeliques, énantiosélectivité, hydrolyse.

Carbonic anhydrase (EC 4.2.1.1) is a zinc-containing metalloenzyme. The sole natural function of this ubiquitous enzyme is to catalyze the reversible hydration of carbon dioxide (eq. [1])

[1] $CO_2 + H_2O \rightleftharpoons HCO_3^- + H^+$

(1–3). In addition to its known physiological role, carbonic anhydrase catalyses in vitro the reversible hydration of carbonyl compounds (4, 5) and the hydrolysis of some esters (5–12), among other reactions (12–16). The unnatural substrates used in the previous studies were achiral and as far as we know the enantioselectivity of carbonic anhydrase has never been investigated. We report here the first enantioselective hydrolysis of esters catalyzed by bovine carbonic anhydrase (BCA). We found that mandelic methyl esters are good substrates for BCA and offer a good opportunity to investigate the enantioselectivity of this enzyme.

The racemic ester substrates **1**–**7** were prepared by esterification of the commercially available corresponding acids with methanol in the presence of 2,2-dimethoxypropane and *p*-toluenesulfonic acid. Preparative-scale enzyme catalyzed hydrolyses were performed on 2 mmol of the substrates with 40 mg of BCA in a phosphate buffer at pH 7.5. The reaction was indicated by the decrease of pH, which was maintained at its initial value by the addition of a dilute NaOH solution. The reactions were monitored from the consumption of the base and terminated when 50% of the substrate was hydrolyzed. The unreacted esters were recovered from the reaction mixtures by extraction with diethyl ether at the initial pH. The product acids that are present in the aqueous phase as sodium salts were extracted with ether after acidification to pH 2.0.

The results are summarized in eq. [2] and Table 1. Recovery yields ranged from 70 to 91%. Optical purities and absolute configurations were determined by comparison with the optical rotations reported in the literature (17–22). Optical purities (enantiomeric excess values) were further confirmed by ^{1}H nmr analysis using tris[3-(heptafluoropropylhydroxymethylene)-*d*-camphorato]ytterbium as a chiral shift reagent (23). Samples of the acids were converted to their methyl esters by the method mentioned above before nmr analysis. Substituted mandelic methyl esters **2**–**6** are hydrolyzed more rapidly than the parent compound **1**. In every case, the absolute configuration of the preferentially hydrolyzed enantiomer is *R*, and ee values cover a range from 37 to 55%. The enantioselectivity of the enzyme is slightly better than indicated by the ee value. In control experiments, we found that esters **1**–**7** are slowly hydrolyzed in the buffer at pH 7.5 in the absence of the enzyme (5–10% of the esters was hydrolyzed in 24 h). Enzymatic hydrolyses at pH 7.0 did not give a better enantioselectivity and the reaction times were 2.5 times longer.

Since the values of enantiomeric excess increase with the extent of conversion (24), it is possible to improve the optical purity of the unreacted ester by extending reaction times, but at the expense of decreased yield. For example, BCA-catalyzed hydrolysis of methyl *p*-chloromandelate **3** gave a 55% ee value at 50% conversion and a 73% ee value at 60% conversion. Acids can be prepared with higher values of ee by carrying hydrolysis to low conversions. Methyl phenyllactate **7**, which is a homolog of the mandelic esters, is also a good substrate, but the enantioselectivity of its hydrolysis drops significantly

(13–15%). Other related compounds such as methyl lactate **8**, tropic acid methyl ester **9**, and methyl 2-phenoxypropionate **10** are not substrates for BCA. Finally, to check that the enzymatic activity was not caused by the presence of hydrolases as impurities, the hydrolyses were repeated and found strongly inhibited in the presence of acetazolamide. It is well documented that acetazolamide is a strong inhibitor of carbonic anhydrase activity with respect to both hydration and hydrolysis (1, 3, 6).

BCA is a stable enzyme commercially available in a pure lyophilized form. The substrate specificity and the enantioselectivity of BCA is not yet well known but this enzyme could be useful as a catalyst in organic syntheses. A search of highly enantioselective hydrolyses is in progress.

Experimental

Carbonic anhydrase (from bovine erythrocytes, dialyzed and lyophilized, 2500 W-A units/mg) was purchased from Sigma. Methyl mandelate **1**, substituted mandelic acid, and phenyllactic acid were obtained from Aldrich or from Lancaster Synthesis. NMR studies were performed on a Varian XL-200 spectrometer on $CDCl_3$ solutions with TMS as internal standard. Samples for ee measurements were prepared by dissolving 30 mg of the ester in 1 mL of dry $CDCl_3$, to which solid Yb(hfc)$_3$ (150 mg) was then added incrementally. The ester methyl ($COOCH_3$) was shifted downfield and the enantiomeric shift difference was in the range 11–18 Hz. Optical rotations were measured with a Jasco DIP-360 digital polarimeter. Mass spectra were recorded on a Hewlett–Packard 5992 spectrometer.

Esterification of mandelic acids, general procedure

The acid (0.125 mol), 2,2-dimethoxypropane (0.185 mol), and a catalytic amount of *p*-toluenesulfonic acid (15 mg) were dissolved in dry methanol (0.185 mol). The solution was stirred magnetically overnight at 55°C under a dry atmosphere. Acetone and methanol were evaporated and the crude ester was dissolved in dichloromethane (250 mL). The organic phase was washed successively with 5% $NaHCO_3$ (50 mL) and saturated brine (50 mL). Dichloromethane was dried over magnesium sulfate and evaporated. The crude ester was purified by recrystallization or distillation.

BCA-catalyzed hydrolyses of esters 1–7, general procedure

The ester (2 mmol) was suspended in a buffered aqueous solution (50 mL, phosphate pH 7.5) at room temperature (25°C). The enzyme (40 mg, 100 000 units) was added and the pH was maintained at its initial value by addition of 0.1 M aqueous NaOH from a burette. The reaction was stopped at the 50%-of-hydrolysis point. The mixture was first extracted at initial pH with ether (3 × 50 mL) to remove the unchanged ester. The aqueous mixture was then acidified to pH 2.0 with 2 M hydrochloric acid and was again extracted with ether (3 × 50 mL) to remove the product acid. The ether extracts were dried on magnesium sulfate and evaporated. The physical and spectral properties of the recovered esters were identical with those reported above, and properties of the acid products were identical with those of commercially available samples, except for the magnitudes of their rotations. The $[\alpha]_D^{25}$ values observed for recovered esters and acid products were as follows.

Substrate **1**: recovered ester, [α] +89.2° (*c* 2.6, $CHCl_3$); commercially available sample, [α] 174.2° (*c* 2.5, $CHCl_3$). Acid, [α] −61.1° (*c* 2.1, acetone); commercially available sample, [α] −154.3° (*c* 2.1, acetone).

Substrate **2**: recovered ester, [α] +47.5° (*c* 2.6, acetone); lit. (18): [α] +113.8° (*c* 1, acetone). Acid, [α] −67.4° (*c* 2.6, acetone); lit. (17) [α] −140° (*c* 1, acetone).

Substrate **3**: recovered ester, [α] +54.3° (*c* 1.4, acetone); lit. (18) [α] +99.6° (*c* 0.9, acetone). Acid, [α] −69.4° (*c* 2.1, acetone); lit. (17) [α] −136° (*c* 0.7, acetone).

Substrate **4**: recovered ester, [α] +32.9° (*c* 2.1, acetone); lit. (18) [α] +88.2° (*c* 1, acetone). Acid, [α] −46.5° (*c* 2.3, acetone); lit. (17) [α] −115° (*c* 0.6, acetone).

Substrate **5**: recovered ester, [α] +69.8° (*c* 2.3, ethanol); lit. not available. Acid, [α] −57.0° (*c* 0.4, water), lit. (19) [α] −141° (*c* 0.3, water).

Substrate **6**: recovered ester, [α] +44.5° (*c* 2.2, ethanol); lit. not available. Acid, [α] −48.8° (*c* 2.6, ethanol); lit. (19) [α] −117° (*c* 0.3, ethanol).

Substrate **7**: recovered ester, [α] −1.9° (*c* 2.5, benzene); lit. (20) [α] −12.6° (*c* 2.4, benzene). Acid, [α] +3.5° (*c* 2.0, acetone); commercially available sample, [α] +27.7° (*c* 2, acetone).

The synthesis of protected 5-azido-5-deoxy-D-gluconononitriles as precursors of glycosidase inhibitors

P. BIRD, D. H. DOLPHIN, AND S. G. WITHERS[1]

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received May 30, 1989

P. BIRD, D. H. DOLPHIN, and S. G. WITHERS. Can. J. Chem. **68**, 317 (1990).

The successful syntheses of 5-azido-2,3,4,6-tetra-*O*-benzyl-5-deoxy-D-gluconononitrile and 2,3,4,6-tetra-*O*-benzyl-5-deoxy-5-trifluoroacetamido-D-gluconononitrile starting from D-glucose are described. Unsuccessful attempts were made to convert these two compounds into a protected 5-amino-5-deoxy-D-gluconononitrile and to subsequently cyclize them to an amidine analogue of glucose as a possible glycosidase inhibitor.

Key words: synthesis, amino-sugars, glycosidase inhibitors.

P. BIRD, D. H. DOLPHIN et S. G. WITHERS. Can. J. Chem. **68**, 317 (1990).

On décrit des synthèses réalisables des 5-azido-2,3,4,6-tétra-*O*-benzyl-5-désoxy- et 2,3,4,6-tétra-*O*-benzyl-5-désoxy-5-trifluoroacétamido-D-gluconononitriles à partir du D-glucose. On a essayé sans succès de transformer ces deux composés en un 5-amino-5-désoxy-D-gluconononitrile et éventuellement de les cycliser en une amidine analogue du glucose qui aurait pu être évaluée comme inhibiteur de la glycosidase.

Mots clés : synthèse, amino-sucres, inhibiteurs de la glycosidase.

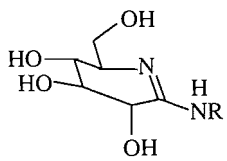
Introduction

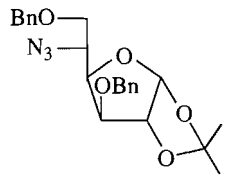
Considerable effort has been expended in recent years in the design and synthesis of glycosidase inhibitors. These synthetic endeavours have been motivated by the discovery of a number of naturally occurring glycosidase inhibitors such as nojirimycin (1) and acarbose (2) and by their possible use in the treatment of diabetes and obesity (3, 4). These inhibitors are often nitrogen-containing analogues of glucose and glucooligosaccharides and their effectiveness as glycosidase inhibitors can be understood in terms of the generally accepted mechanism (5) of such enzymes where protonation of the glycosidic oxygen and departure of the protonated aglycone generate a glycosyl enzyme intermediate via an oxocarbonium ion transition state stabilized by interaction with an enzyme carboxylate group. Hydrolysis of this intermediate completes the reaction. Tight binding of aminoglycoside inhibitors presumably results from protonation of the nitrogen atom, generating an ammonium/carboxylate ion pair in the active site. In addition, a number of these inhibitors contain a partially planar ring, which may mimic the conformation of the transition state in the enzymic reaction. Glycosylamines, containing an exocyclic nitrogen atom at the anomeric centre, have also been shown (6) to be good inhibitors of a number of glycosidases. This suggested that a compound that combined the endo- and exo-cyclic nitrogen atoms in an unsaturated ring system might be an excellent glycosidase inhibitor. An example of such a compound is **1**, the amidine analogue of glucose.

A retrosynthetic analysis (7) gives two reasonable routes. The one that we attempted involves intramolecular attack of an amine on a nitrile (8), itself synthesized using an appropriately protected precursor such as an azido nitrile or an amino nitrile. An alternative route (not followed) could start with a protected 5-amino-5-deoxy-D-gluconolactam (9, 10), which could be converted to the desired amidine by first converting it to an *N*-alkylimino ester (11) or imidate (12), and then reacting this with an amine.

This paper describes the synthesis of the intermediates necessary for the first route, namely the azido nitrile and the amido nitrile. It also describes attempts at selective reductions of the azide moiety to give the desired amino nitrile.



1



2

Results and discussion

Several slightly different routes to the desired protected 5-azido-5-deoxy-D-gluconononitrile were followed, all of which originated from the same starting material, the azido acetonide derivative (**2**). This was prepared from glucose according to literature procedures (13–15).

The first route attempted involved the formation of an oxime derivative at C-1, which could then be converted to the desired azido nitrile by an elimination reaction. Thus, the acetonide **2** was hydrolysed using aqueous trifluoroacetic acid to yield the hemiacetal **3**, which, on treatment with hydroxylamine (16), gave a mixture of the *E*- and *Z*-oximes **7**. Since these oximes could not be separated readily, the mixture was subjected to acetylation under basic conditions (17), effecting the facile elimination of the *Z*-oxime to give the desired nitrile (**8**) as the major product. The *E*-oxime, however, was inert to elimination and was isolated as the acetoxime **9**. Since the next step was to be the selective reduction of the azide to an amine, to which the acetate protecting groups would migrate, it was necessary to change protecting groups. Numerous attempts (e.g., 10% H_2SO_4/EtOH (18), KCN/MeOH (19)) were made to remove the acetates under neutral to acid conditions to avoid cyanohydrin decomposition, but none were successful. The direct dehydration of the unprotected oximes **7** was also attempted under a variety of conditions, but without success: e.g., treatment with selenium dioxide (20) regenerated the hemiacetal **3** while copper(II) acetate (21) gave degradation products.

Although ultimately unsuccessful, this approach demonstrated that a protected azido nitrile could be formed using this chemistry, so further attempts were made in which the desired

hydroxyl protecting groups were inserted prior to nitrile formation. Selective protection of the C-2 hydroxyl was achieved by conversion of the hemiacetal **3** to the methyl furanosides **4**, then benzylation of the free C-2 hydroxyl using sodium hydride and benzyl bromide to give the tribenzyl ether **5**. Hydrolysis of the acetal (trifluoroacetic acid/water) yielded the hemiacetal **6**, which was converted into the oximes (**10**) by treatment with hydroxylamine. Unfortunately, it proved impossible to convert this oxime to the nitrile either by the previous protocol, or by using more reactive reagents such as trifluoroacetic anhydride (22), 2,4,6-trichloro-*s*-triazine (23), or carbonyldiimidazole (24), all of which gave complex mixtures. Presumably the bulky benzyl group at C-2 hinders the elimination process, rendering the less reactive reagents inactive. Failure of the more reactive reagents (which led to decomposition) was probably a result of reaction at, and elimination of, the C-4 hydroxyl or intramolecular attack of the free C-4 hydroxyl on the C-1 nitrile or the activated oxime (16).

Protection of the C-4 hydroxyl would alleviate these problems, making the use of the more vigorous dehydrating agents more feasible. The hemiacetal **3** was therefore reacted with methoxylamine hydrochloride yielding the methoximes **12** in which both the C-2 and the C-4 hydroxyls are exposed. Benzylation of **12** yielded the tetrabenzyl ether **13**, which we planned to either convert directly to the desired nitrile by elimination of methanol from the methoxime, or at least to convert it back to the aldehyde whence the nitrile could be formed. However, hydrolysis of **13** under acidic conditions (25) led to extensive decomposition, while attempted exchange with semicarbazide hydrochloride (26) failed completely. Direct formation of the nitrile from **13** by treatment with base (27) under a variety of conditions also failed, since either no reaction occurred, or there was extensive decomposition.

Failure of this approach necessitated a new strategy wherein the aldehyde is protected temporarily as the dithioacetal while the free hydroxyl groups are benzylated, the aldehyde then being regenerated and converted back into the nitrile. Treatment of the hemiacetal **3** with ethanethiol in concentrated hydrochloric acid (28) resulted in formation of the β-thiofuranoside **14** as the major product, with the α-thiofuranoside **15** and the desired dithioacetal **17** being produced as minor components. Considerable effort was expended in an attempt to produce a dithioacetal as the major product. This included changes (29) in temperature, reaction time, acid catalysts (e.g., zinc chloride, *p*-toluenesulfonic acid, boron trifluoride etherate), solvents, and thiol reagents (1,2-ethanedithiol, 1,3-propanedithiol), but all failed to significantly improve the yield of dithioacetal. Resubjecting the isolated major product (**14**) to the reaction conditions resulted in a slow conversion to **15** and **17** along with decomposition products. Since these could not be separated easily by column chromatography, the crude mixture was benzylated directly to give the benzyl ethers **16** and **18**, which were readily separable by chromatography. Hydrolysis of the dithioacetal **18** was accomplished in good yield using mercury(II) chloride (30), and the resulting aldehyde was converted directly to the oximes (**20**) by treatment with hydroxylamine. Reaction of these oximes with methanesulfonyl chloride in pyridine yielded the desired azido nitrile **21**.

While this route was ultimately successful, the yield of the dithioacetal was poor. An alternative approach was therefore explored, involving reduction of the aldehyde group in **3**, selective protection of the primary hydroxyl thus generated, and benzylation of the free hydroxyls at C-2 and C-4. Subsequent selective removal of the C-1 protecting group and oxidation should yield the desired aldehyde **19**. Therefore, hemiacetal **3** was reduced with sodium borohydride (31) to furnish the triol **22**, which was selectively protected at C-1 by treatment with pivaloyl chloride (32), giving the pivaloate ester **23** in good yield. Benzylation of the free hydroxyl groups yielded the tribenzyl ether **24**, which was then treated with sodium methoxide in methanol to remove the pivaloate ester at C-1 and expose the primary alcohol (**25**). Oxidation of this primary alcohol with pyridinium chlorochromate (33) proceeded reasonably smoothly to give the aldehyde **19**. This latter route proved to be the more efficient in terms of both yield and time.

The next step in the synthesis required the selective reduction of the azide in the presence of the nitrile to yield an amino nitrile, the required precursor to the amidine. Reductions were attempted under a number of conditions, as follows. No reaction whatsoever was observed with tin(II) chloride (34), or upon transfer hydrogenation with ammonium formate over palladium (35). Both hydrogen sulfide (36) and sodium ethoxide reacted preferentially with the nitrile moiety. Complex reaction mixtures were obtained with 1,3-propanedithiol (37), triphenylphosphine (38), and upon transfer hydrogenation with cyclohexene over palladium (39). Treatment with more vigorous

reducing reagents such as lithium aluminum hydride (40) or sodium borohydride (41) resulted in the reduction of both the azide and the nitrile moieties.

Since selective reduction had proved more difficult than anticipated, an alternative route involving reduction of the azide and acylation of the resultant amine prior to formation of the nitrile was attempted. Treatment of the azido pivaloate **24** with lithium aluminum hydride resulted in the reduction of the azide and removal of the pivaloate ester, yielding the amino alcohol **26** in one step. Selective protection of the amine by reaction with trifluoroacetic anhydride, then with methanol, yielded the desired trifluoroacetamide **27** with a free primary alcohol. This was oxidized using pyridium chlorochromate to yield the protected aldehyde **28**, which was directly converted to the mixture of oximes (**29**) by treatment with hydroxylamine. Dehydration of the oximes was again achieved using methanesulfonyl chloride in pyridine, producing the desired trifluoroacetamido nitrile **30**.

Attempted removal of the trifluoroacetamide protecting group was unsuccessful. Treatment of **30** with potassium carbonate in aqueous methanol (42) or with sodium borohydride in boiling ethanol (43) yielded a mixture of at least four products, while no reaction was observed on treatment with triethylamine.

These attempts were therefore unsuccessful in generating the desired amino nitrile for cyclization to the amidine. However, they did generate viable routes to the precursor azido nitrile and amido nitrile, compounds that may have other applications in amino sugar chemistry.

Experimental

Thin-layer chromatography (tlc) was performed on Merck silica gel $60F_{254}$ aluminum backed plates. Chromatograms were visualized by charring with 10% sulphuric acid in methanol. Flash chromatography was carried out on Merck silica gel (230–400 mesh). The ^1H nmr spectra were recorded either on a Bruker WH-400 spectrometer, a Varian 300 MHz spectrometer, or a modified Bruker/Nicolet 270 MHz spectrometer, using $CDCl_3$ solutions and tetramethylsilane as an internal standard, unless otherwise stated. Chemical shifts are expressed as d and coupling constants (J) are given in hertz (s = singlet, d = doublet, t = triplet, m = multiplet).

2,4-Di-O-acetyl-5-azido-3,6-di-O-benzyl-5-deoxy-D-gluconononitrile (8)

The acetonide (15) **2** (1 g, 2.35 mmol) was suspended in trifluoroacetic acid (12 mL)/water (8 mL) and stirred for 3.5 h. Water (10 mL) was added, the mixture concentrated by evaporation, and the residue further dried by dissolving in toluene (25 mL), then concentrating by evaporation of solvent, three times over. The dark syrup obtained slowly solidified on standing at 4°C, and was usually used directly in subsequent reactions. Chromatography on silica gel (1:1 ethyl acetate–hexane) gave a light yellow syrup of 5-azido-3,6-di-*O*-benzyl-5-deoxy-α/β-D-glucofuranose **3**, which solidified (723 mg, 80%); $[\alpha]_D$ −2.9° (*c* 0.018, $CHCl_3$); ν_{max}(KBr): 3412 cm^{-1} (OH), 2100 cm^{-1} (N_3); ^1H nmr (300 MHz, $CDCl_3/D_2O$) δ: 7.44–7.24 (m, 10 H, C_6H_5), 5.47 (d, $J_{1,2}$ 3.7 Hz, H-1β), 5.09 (s, H-1α), 4.70–4.54 (m, $C_6H_5CH_2$), 4.24 (s, H-2α), 4.18 (dd, $J_{1,2}$ 3.7 Hz, H-2β), 4.15, 4.04–3.85, 3.75–3.62 (m, 5H, H-3,4,5,6,6′).

The hemiacetal **3** (904 mg, 2.35 mmol) in dry pyridine (20 mL) containing hydroxylamine hydrochloride (350 mg, 5.0 mmol) was kept at room temperature for 24 h. The solvent was evaporated and the residue concentrated from toluene (20 mL) three times over, dissolved in $CHCl_3$ (100 mL), washed with $NaHCO_3$ (40 mL), saturated brine (40 mL), and dried (Na_2SO_4). The syrup was chromatographed on silica (1:1 ethyl acetate – hexane) to give a mixture of *E*- and *Z*-5-azido-3,6-di-*O*-benzyl-5-deoxy-D-glucose oxime **7** (800 mg, 85%); $[\alpha]_D$ −7.7° (*c* 0.008, $CHCl_3$); ν_{max}(KBr): 3400 cm^{-1} (OH), 2100 cm^{-1} (N_3); ^1H nmr (270 MHz, $CDCl_3/D_2O$) δ: 7.52–7.14 (m, 10 H, C_6H_5), 7.49 (d, $J_{1,2}$ 5 Hz, H-1 *E* isomer), 6.90 (d, $J_{1,2}$ 7 Hz, H-1 *Z* isomer), 4.79–4.42 (m, 4H, $C_6H_5CH_2$), 3.98 (dd, 1H, H-2), 3.91–3.80 (m, 2H, H-3,4), 3.75–3.61 (m, 2H, H-5,6), 3.54 (m, 1H, H-6′).

To the oximes **7** (110 mg, 0.275 mmol) in dry pyridine (5 mL) was added acetic anhydride (1 mL) and triethylamine (1 mL). After standing at room temperature for 1 h, the solution was heated at 30°C for 20 h, then cooled and stirred with aqueous sodium bicarbonate (16 mL) for 2 h. The solution was extracted with $CHCl_3$ (40 mL), washed with $NaHCO_3$ (20 mL) and water (20 mL), and dried (Na_2SO_4). Evaporation of the solvent left a thick syrup, which was chromatographed on silica (1:3 ethyl acetate – hexane). The early fractions contained (*E*)-2,4-di-*O*-acetyl-5-azido-3,6-di-*O*-benzyl-5-deoxy-D-glucose acetoxime **9** (20 mg, 14%) as a colourless syrup; $[\alpha]_D$ +4.4° (*c* 0.001, $CHCl_3$); ν_{max}(KBr): 2100 cm^{-1} (N_3), 1760 cm^{-1} (OAc); ^1H nmr (300 MHz, $CDCl_3$) δ: 7.58–7.14 (m, 11H, C_6H_5, H-1 *E* isomer, H-1 *Z* isomer), 6.35 (br s, 3H, NOAc), 5.34 (br s, 1H, H-2), 4.79 (m, 1H, H-4), 4.70–4.53 (m, 4H, $C_6H_5CH_2$), 4.26 (m, 1H, H-3), 4.10–3.78 (m, 2H, H-5,6), 3.63 (m, 1H, H-6′), 2.15, 2.10–2.00 (2s + br s, OAc).

The later fractions contained the nitrile **8** (73 mg, 57%) as a colourless syrup; $[\alpha]_D$ +11.9° (*c* 0.0057, $CHCl_3$); ν_{max}(KBr): 2100 cm^{-1} (N_3), 1760 cm^{-1} (OAc); ^1H nmr (300 MHz, $CDCl_3$) δ: 7.44–7.35 (m, 10 H, C_6H_5), 5.48 (d, 1H, $J_{2,3}$ 6.5 Hz, H-2), 5.19 (dd, 1H, $J_{3,4}$ 2.0, $J_{4,5}$ 9.3 Hz, H-4), 4.78, 4.57 (2s, 4H, $C_6H_5CH_2$), 4.11 (dd, 1H, $J_{2,3}$ 6.5, $J_{3,4}$ 2.0 Hz, H-3), 3.96 (m, 1H, H-5), 3.66 (dd, 1H, $J_{5,6}$ 3.3, $J_{6,6'}$ 10.0 Hz, H-6), 3.60 (dd, 1H, $J_{5,6'}$ 7.3, $J_{6,6'}$ 10.0 Hz, H-6′), 2.15, 2.14 (2s, 6H, OAc); ^{13}C nmr (100.6 MHz, $CDCl_3$) δ: 169.7, 168.3 (CO), 137.3, 136.3 (Ar, C-1), 128.7, 128.6, 128.4, 128.3, 127.9, 127.8 (Ar), 114.8 (C≡N), 74.7, 74.6, 73.6, 69.6, 68.9 (*C*H, *C*-N_3), 59.7, 59.4 (CH_2), 20.7, 20.1 (*Me*).

(E,Z)-5-Azido-2,3,4,6-tetra-O-benzyl-5-deoxy-D-glucose methoxime (12)

The hemiacetal **3** (1.5 g, 3.89 mmol) in dry methanol (50 mL) containing Amberlite IR-120(H^+) resin (1.4 g) and 4 Å molecular sieves (1 g) was heated at reflux for 10 h. The cool solution was filtered, the solvent evaporated, and the resultant syrup dissolved in $CHCl_3$

(100 mL), washed with $NaHCO_3$ (40 mL), then with brine (40 mL), and dried (Na_2SO_4). Evaporation gave a syrup, which was chromatographed on silica (1:2 ethyl acetate – hexane) to give the product as an anomeric mixture (1.19 g, 77%).

The early fractions contained the β-anomer: $[\alpha]_D$ +10.2° (*c* 0.01, $CHCl_3$); ^1H nmr (300 MHz, $CDCl_3$) δ: 7.49–7.10 (m, 10 H, C_6H_5), 5.02 (d, 1H, $J_{1,2}$ 4.4 Hz, H-1), 4.74–4.58 (m, 4H, $C_6H_5CH_2$), 4.23 (ddd, 1H, $J_{1,2}$ 4.4, $J_{2,3}$ 0.4, $J_{2,OH}$ 3.1 Hz, H-2), 4.11 (dd, 1H, $J_{3,4}$ 4.3, $J_{4,5}$ 9.2 Hz, H-4), 3.97 (m, 2H, H-3,5), 3.87 (dd, 1H, $J_{5,6}$ 2.5, $J_{6,6'}$ 10 Hz, H-6), 3.64 (dd, 1H, $J_{5,6'}$ 7.4, $J_{6,6'}$ 10 Hz, H-6'), 3.46 (s, 3H, OMe), 2.84 (d, 1H, $J_{OH,2}$ 3.1 Hz, OH).

The later fractions contained the α-anomer: $[\alpha]_D$ −13.8° (*c* 0.023, $CHCl_3$); ^1H nmr (300 MHz, $CDCl_3$) δ: 7.48–7.21 (m, 10 H, C_6H_5), 4.77 (s, 1H, H-1), 4.70–4.61 (m, 4H, $C_6H_5CH_2$), 4.20 (s, 1H, H-2), 4.17 (dd, 1H, $J_{3,4}$ 5.1, $J_{4,5}$ 9.7 Hz, H-4), 4.03 (m, 1H, H-5), 3.91 (m, 2H, H-3,6), 3.67 (dd, 1H, $J_{5,6'}$ 7.2, $J_{6,6'}$ 10.1 Hz, H-6'), 3.33 (s, 3H, OMe), 1.8 (br s, 1H, OH).

The alcohol **4** (1.19 g, 2.98 mmol) in dry DMF (20 mL) was stirred at 0°C under an argon atmosphere, sodium hydride (115 mg, 4.79 mmol) was rapidly added, and the mixture stirred for 1 h. Benzyl bromide (0.4 mL, 3.34 mmol) was added and the mixture slowly warmed to room temperature. After 4 h, dry methanol (4 mL) was added dropwise and stirred for 1 h. The solution was concentrated, the residue partitioned between chloroform (100 mL) and aqueous sodium bicarbonate (50 mL), and the organic phase washed with saturated brine (50 mL), dried (Na_2SO_4), and the solvent evaporated. Chromatography on silica (1:6 ethyl acetate – hexane) gave the methyl 5-azido-2,3,6-tri-*O*-benzyl-5-deoxy-α/β-D-glucofuranosides **5** as a colourless syrup (1.23 g, 84%); $[\alpha]_D$ +40.0° (*c* 0.006, $CHCl_3$); ν_{max}(KBr): 2100 cm^{-1} (N_3); ^1H nmr (300 MHz, CCl_3) δ: 7.38–7.25 (m, 15H, C_6H_5), 4.88 (s, H-1α), 4.87 (d, $J_{1,2}$ 4 Hz, H-1β), 4.67–4.52 (m, 6H, $C_6H_5CH_2$), 4.20–3.83 (m, 5H, H-2,3,4,5,6), 3.70–3.59 (m, 1H, H-6'), 3.38, 3.34 (2s, OMe).

The methyl glycosides **5** (1.13 g, 2.31 mmol) in trifluoroacetic acid (14 mL)/water (6 mL) were stirred for 6 h at room temperature. The solution was diluted with water (15 mL) and the solvent evaporated to give a dark residue, which was dried by evaporation from toluene (3 × 20 mL). The thick syrup was dissolved in chloroform (60 mL), washed with $NaHCO_3$ (100 mL), saturated brine (40 mL), dried (Na_2SO_4), concentrated, and chromatographed on silica (1:4 ethyl acetate – hexane) to give 5-azido-2,3,6-tri-*O*-benzyl-5-deoxy-α/β-D-glucofuranose **6** as a light yellow syrup (910 mg, 83%); $[\alpha]_D$ −3.8° (*c* 0.015, $CHCl_3$); ν_{max}(KBr): 3400 cm^{-1} (OH), 2100 cm^{-1} (N_3); ^1H nmr (270 MHz, $CDCl_3$) δ: 7.56–7.13 (m, 15H, C_6H_5), 5.45 (dd, $J_{1,2}$ 4, $J_{1,OH}$ 11 Hz, H-1β), 5.21 (d, $J_{1,OH}$ 12 Hz, H-1α), 4.70–4.41 (m, 6H, $PhCH_2$), 4.11–3.79 (m, 5H, H-2,3,4,5,6), 3.71–3.58 (m, 2H, H-6', OH), 3.37 (d, 1H, $J_{1,OH}$ 12 Hz, OH).

Hemiacetal **6** (461 mg, 0.97 mmol) was treated in the same manner as for the preparation of compound **7**. Chromatography on silica (1:2 ethyl acetate – hexane) gave (*E*,*Z*)-5-azido-2,3,6-tri-*O*-benzyl-5-deoxy-D-glucose oxime **10** as a colourless syrup (394 mg, 83%); $[\alpha]_D$ −31.2° (*c* 0.008, $CHCl_3$); ν_{max}(KBr): 3400 cm^{-1} (OH, NOH), 2100 cm^{-1} (N_3); ^1H nmr data (300 MHz, $CDCl_3/D_2O$) δ: 7.49–7.14 (m, C_6H_5, H-1 *Z* isomer), 6.89 (d, H-1 *E* isomer), 4.95–4.18 (m, 7H, $C_6H_5CH_2$, H-2), 4.01–3.80 (m, 2H, H-3,4), 3.73–3.43 (m, 3H, H-5,6,6').

To hemiacetal **3** (164 mg, 0.42 mmol) in dry pyridine (6 mL) was added methoxylamine hydrochloride (100 mg, 1.19 mmol). After 22 h at room temperature the solution was concentrated, the residue dissolved in $CHCl_3$ (50 mL), washed with $NaHCO_3$ (40 mL), brine (30 mL), dried (Na_2SO_4), and concentrated to a dark syrup. Chromatography on silica (1:2 ethyl acetate – hexane) gave (*E*,*Z*)-5-azido-3,6-di-*O*-benzyl-5-deoxy-D-glucose methoxime **12** as a colourless syrup (163 mg, 93%); $[\alpha]_D$ +18° (*c* −0.006, $CHCl_3$); ^1H nmr (300 MHz, $CDCl_3/D_2O$) δ: 7.49 (dd, H-1 *Z* isomer), 7.51–7.40 (m, 10 H, C_6H_5), 6.88 (dd, H-1 *E* isomer), 4.91, 4.82–4.48 (m, 7H, H-2,3,4; $C_6H_5CH_2$), 3.98–3.51 (m, 3H, H-5,6,6'), 3.89 (s, OMe, *Z* isomer), 3.85 (s, OMe, *E* isomer).

Diol **12** (120 mg, 0.289 mmol) was benzylated using the same procedure as for compound **5**. Chromatography on silica (1:8 ethyl acetate – hexane) gave the product (*E*,*Z*)-5-azido-2,3,4,6-tetra-*O*-benzyl-5-deoxy-D-glucose methoxime **13** as a light yellow syrup (132 mg, 77%); $[\alpha]_D$ +5.0° (*c* 0.01, $CHCl_3$); ν_{max}(KBr): 2100 cm^{-1} (N_3), 1640 cm^{-1} (C=N); ^1H nmr (270 MHz, $CDCl_3$) δ: 7.69–7.07 (m, C_6H_5, H-1 *Z* isomer), 6.88 (d, H-1 *E* isomer), 4.79–4.40 (m, 9H, $C_6H_5CH_2$, H-2), 4.35–4.28 (m, 2H, H-3,4), 3.88–3.47 (m, 3H, H-5,6,6'), 3.85 (s, 3H, OMe). Exact mass calcd. for $C_{35}H_{38}N_4O_5$: 594.2842; found: 594.2849.

*5-Azido-2,3,4,6-tetra-*O*-benzyl-5-deoxy-D-glucononitrile (**21**)*

Hemiacetal **3** (1 g, 2.59 mmol) in ethanethiol (20 mL) was cooled to 0°C, concentrated hydrochloric acid (1 mL) was added, and the mixture stirred at 0°C for 4 h. The mixture was poured into aqueous sodium bicarbonate (100 mL) and the solution extracted with $CHCl_3$ (50 mL). The organic phase was washed with $NaHCO_3$ (40 mL), water (40 mL), dried (Na_2SO_4), the solvent evaporated, and the dark syrup chromatographed on silica (2:7 ethyl acetate – hexane) to give a colourless syrup (948 mg) containing ethyl 5-azido-3,6-di-*O*-benzyl-5-deoxy-1-thio-β-D-glucofuranoside (**14**), the -α-D-anomer (**15**), and 5-azido-3,6-di-*O*-benzyl-5-deoxy-D-glucose diethyldithioacetal (**17**).

Early fractions were enriched with the β-anomer (**14**): ^1H nmr (400 MHz, $CDCl_3$) δ: 7.41–7.26 (m, 10 H, C_6H_5), 5.39 (d, 1H, $J_{1,2}$ 4 Hz, H-1), 4.65, 4.58 (2s, 4H, $C_6H_5CH_2$), 4.28 (ddd, 1H, $J_{1,2}$ 4, $J_{2,3}$ 1, $J_{2,OH}$ 5 Hz, H-2), 4.15–3.96 (m, 3H, H-3,4,5), 3.89 (dd, 1H, $J_{5,6}$ 2.5, $J_{6,6'}$ 10 Hz, H-6), 3.63 (dd, 1H, $J_{5,6}$ 7.5, $J_{6,6'}$ 10 Hz, H-6'), 2.64 (q, 2H, *J* 7 Hz, SCH_2), 2.43 (d, 1H, $J_{2,OH}$ 5 Hz, OH), 1.28 (t, 3H, *J* 7 Hz, SCH_2CH_3).

The middle fractions were enriched with **17**: ^1H nmr (270 MHz, $CDCl_3$) δ: 7.39–7.27 (m, 10 H, C_6H_5), 4.91–4.77 (m, 2H, $C_6H_5CH_2$), 4.58 (s, 2H, $C_6H_5CH_2$), 4.22 (dd, 1H, H-2), 4.14–3.70 (m, 5H, H-1,3,4,5,6), 3.59 (m, 1H, H-6'), 3.25, 3.14 (2 br s, 2H, OH), 2.65 (q, 4H, *J* 8 Hz, SCH_2), 1.26 (t, 6H, *J* 8 Hz, SCH_2CH_3).

A mixture of **14**, **15**, and **17** (410 mg) was benzylated in the same manner as for compound **5**. Chromatography on silica (1:12 ethyl acetate – hexane) gave 5-azido-2,3,4,6-tetra-*O*-benzyl-5-deoxy-D-glucose diethyldithioacetal **18** (135 mg) as a colourless syrup; $[\alpha]_D$ −6.8° (*c* 0.003, $CHCl_3$); ν_{max}(KBr): 2100 cm^{-1} (N_3); ^1H nmr (300 MHz, $CDCl_3$) δ: 7.40–7.14 (m, 20 H, C_6H_5), 4.88–4.50 (m, 8H, $C_6H_5CH_2$), 4.13 (dd, 1H, $J_{2,3}$ 6.7, $J_{3,4}$ 4.3 Hz, H-3), 4.01 (dd, 1H, $J_{2,3}$ 6.7, $J_{1,2}$ 3.8 Hz, H-2), 3.92–3.83 (m, 3H, H-1,4,5), 3.72 (m, 2H, H-6,6'), 2.70, 2.54 (2 dq, 4H, SCH_2), 1.22, 1.16 (2t, 6H, SCH_2CH_3). The later fractions contained ethyl-5-azido-2,3,6-tri-*O*-benzyl-5-deoxy-1-thio-α/β-D-glucofuranose **16** as a colourless syrup (360 mg); $[\alpha]_D$ −10.3 (*c* 0.0015, $CHCl_3$); ν_{max}(KBr): 2100 cm^{-1} (N_3); ^1H nmr (300 MHz, $CDCl_3$) δ: 7.47–7.23 (m, 15H, C_6H_5), 5.48 (d, $J_{1,2}$ 4.5 Hz, H-1β), 5.06 (d, $J_{1,2}$ 2.3 Hz, H-1α), 4.64–4.42 (m, 6H, $C_6H_5CH_2$), 4.15–3.85 (m, 5H, H-2,3,4,5,6), 3.63 (m, 1H, H-6'), 2.66, 2.63 (2q, *J* 7.4 Hz, SCH_2), 1.28, 1.26 (2t, *J* 7.4 Hz, SCH_2CH_3).

To the dithioacetal **18** (127 mg, 0.189 mmol) in acetonitrile (6 mL)/water (1 mL) was added calcium carbonate (111 mg, 1.11 mmol) and mercury(II) chloride (260 mg, 0.957 mmol). After stirring at room temperature for 4 h, the solids were removed by filtration through a Celite plug and washed with $CHCl_3$ (2 × 50 mL). The combined filtrate was washed with sodium iodide (1 mol dm^{-3}, 2 × 30 mL), dried (Na_2SO_3), and concentrated to a colourless syrup of 5-azido-2,3,4,6-tetra-*O*-benzyl-5-deoxy-D-glucose **19** (95 mg, 89%), which was used immediately in subsequent reactions.

Crude aldehyde **19** (106 mg, 0.189 mmol) was reacted with hydroxylamine hydrochloride in the same manner as for the preparation of compound **7**. Chromatography on silica (1:4 ethyl acetate – hexane) gave (*E*,*Z*)-5-azido-2,3,4,6-tetra-*O*-benzyl-5-deoxy-D-glucose oxime **20** as a colourless syrup (74 mg, 68%); $[\alpha]_D$ +17.5° (*c* 0.0033, $CHCl_3$); ν_{max}(KBr): 3390 cm^{-1} (NOH), 2100 cm^{-1} (N_3); ^1H nmr data (270 MHz, $CDCl_3$) δ: 7.57–7.10 (m, C_6H_5, H-1 *Z* isomer), 6.95 (d, H-1 *E* isomer), 4.77–4.33 (m, 9H, $C_6H_5CH_2$, H-2), 4.27 (dd, 1H, $J_{2,3}$ 6, $J_{3,4}$ 7.7 Hz, H-3), 3.94–3.48 (m, 4H, H-4,5,6,6').

The oximes **20** (123 mg, 0.212 mmol) in dry pyridine (2.5 mL) were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

cooled to 0°C under an argon atmosphere, methanesulphonyl chloride (0.1 mL, 1.29 mmol) was added dropwise, and the solution kept on ice for 0.25 h, then at room temperature for 1 h. Saturated $NaHCO_3$ (3 mL) was added dropwise and, after concentration, the residue was partitioned between $CHCl_3$ (50 mL) and $NaHCO_3$ (40 mL). The aqueous phase was extracted with $CHCl_3$ (2 × 20 mL), and the combined organic phase washed with water (20 mL), dried, and evaporated. Chromatography on silica (1:5 ethyl acetate – hexane) gave 5-azido-2,3,4,6-tetra-*O*-benzyl-5-deoxy-D-glucononitrile **21** as a colourless syrup (112 mg, 94%); $[\alpha]_D$ +37.0° (*c* 0.004, $CHCl_3$); ν_{max}(KBr): 2100 cm^{-1} (N_3, C≡N); ^1H nmr (300 MHz, $CDCl_3$) δ: 7.40–7.18 (m, 20 H, C_6H_5), 4.89–4.47 (m, 8H, $C_6H_5CH_2$), 4.34 (d, 1H, $J_{2,3}$ 6.8 Hz, H-2), 3.94 (m, 2H, H-4,5), 3.81 (dd, 1H, $J_{2,3}$ 6.8, $J_{3,4}$ 2 Hz, H-3), 3.74–3.63 (m, 2H, H-6,6′); ^{13}C nmr (75 MHz, $CDCl_3$) δ: 137.37, 137.24, 137.09, 135.29 (4s, Ar), 128.71–127.76 (14s, Ar), 116.63 (1s, C≡N), 78.07, 76.99, 68.52, 60.49 (4s, C-2,3,4,5), 75.29, 74.98, 73.32, 72.81, 68.90 (5s, C-6, $PhCH_2O$). Exact mass calcd. for $C_{34}H_{34}N_4O_4$: 562.2580; found: 562.2579.

*2,3,4,6-Tetra-*O*-benzyl-5-deoxy-5-trifluoroacetamido-D-glucitol (27)*

To hemiacetal **3** (1.75 g, 4.55 mmol) in absolute ethanol (50 mL) was added sodium borohydride (166 mg, 4.36 mmol) and water (4 mL) and the solution heated at reflux for 3 h. The cooled solution was acidified with glacial acetic acid and concentrated. The residue was partitioned between dilute HCl (50 mL) and $CHCl_3$ (50 mL), the aqueous phase extracted with $CHCl_3$ (2 × 25 mL), then the combined organic phase was washed with $NaHCO_3$ (50 mL) and dried (Na_2SO_4). Evaporation of solvent gave a dark syrup, which was chromatographed on silica (1:1 ethyl acetate – hexane) to give 5-azido-3,6-di-*O*-benzyl-5-deoxy-D-glucitol **22** as a thick colorless syrup (1.25 g, 71%); $[\alpha]_D$ −53.3° (*c* 0.0075, $CHCl_3$); ν_{max}(KBr): 3420 cm^{-1} (OH), 2100 cm^{-1} (N_3); ^1H nmr data (270 MHz, $CDCl_3/D_2O$) δ: 7.56–7.22 (m, 10 H, C_6H_5), 4.69–4.58 (m, 4H, $C_6H_5CH_2$), 3.94–3.50 (m, 8H, H-1,1′,2,3,4,5,6,6′).

The triol **22** was acetylated (Ac_2O, pyridine, room temp.) to give 1,2,4-tri-*O*-acetyl-5-azido-3,6-di-*O*-benzyl-5-deoxy-D-glucitol; $[\alpha]_D$ 7.4° (*c* 0.004, $CHCl_3$); ν_{max}(KBr): 2100 cm^{-1} (N_3), 1750 cm^{-1} (OAc); ^1H nmr (300 MHz, $CDCl_3$) δ: 7.39–7.20 (m, 10 H, C_6H_5), 5.26 (m, 1H, $J_{1,2}$ 2.8 Hz, H-2), 5.08 (dd, 1H, $J_{3,4}$ 2.8, $J_{4,5}$ 8.3 Hz, H-4), 4.72 (m, 2H, $C_6H_5CH_2$), 4.53 (d, 2H, *J* 5.2 Hz, $C_6H_5CH_2$), 4.40 (dd, 1H, $J_{1,1'}$ 12.3, $J_{1,2}$ 2.8 Hz, H-1), 4.02 (m, 2H, H-1′,3), 3.87 (m, 1H, H-5), 3.61 (dd, 1H, $J_{5,6}$ 3.7, $J_{6,6'}$ 10 Hz, H-6), 3.54 (dd, 1H, $J_{5,6'}$ 7.1, $J_{6,6'}$ 10 Hz, H-6′), 2.04, 1.99, 1.96 (3s, 9 H, OAc).

The triol **22** (1.12 g, 2.89 mmol) in dry pyridine (20 mL) was cooled to −40°C under an argon atmosphere. Pivaloyl chloride (0.356 mL, 2.89 mmol) was added dropwise and the solution kept at −40°C for 1 h, then slowly warmed to room temperature over 1.5 h. Methanol (0.1 mL) was added, solvent evaporated, and the residue was then dissolved in $CHCl_3$ (100 mL), washed with $NaHCO_3$ (40 mL), brine (40 mL), dried (Na_2SO_4), and concentrated. The crude syrup of 5-azido-3,6-di-*O*-benzyl-5-deoxy-1-*O*-pivaloyl-D-glucitol **23** (1.36 g, 100%) was further dried by concentration from toluene (3 × 15 mL) and used directly in the formation of compound **24**; $[\alpha]_D$ −38.2° (*c* 0.008, $CHCl_3$); ν_{max}(KBr): 3460 cm^{-1} (OH), 2100 cm^{-1} (N_3), 1730 cm^{-1} (CO).

Diol **23** (1.35 g, 2.86 mmol) was benzylated using the same procedure as for compound **5**. Chromatography on silica (1:6 ethyl acetate – hexane) gave a colourless syrup of 5-azido-2,3,4,6-tetra-*O*-benzyl-5-deoxy-1-*O*-pivaloyl-D-glucitol **24** (1.69 g, 90%); $[\alpha]_D$ +0.4° (*c* 0.0176, $CHCl_3$); ν_{max}(KBr): 2100 cm^{-1} (N_3), 1735 cm^{-1} (CO); ^1H nmr (270 MHz, $CDCl_3$) δ: 7.36–7.14 (m, 20 H, C_6H_5), 4.76–4.41 (m, 8H, $C_6H_5CH_2$), 4.36–4.17 (2dd, 2H, $J_{1,1'}$ 12 Hz, H-1,1′), 3.83–3.63 (m, 6H, H-2,3,4,5,6,6′), 1.20 (s, 9H, Me_3C).

A solution of sodium (50 mg, 2.17 mmol) dissolved in dry methanol (3 mL) was rapidly added to compound **24** (310 mg, 0.47 mmol) in dry methanol (10 mL). After heating at 45°C for 4 days, the cooled solution was neutralized with glacial acetic acid, concentrated, dissolved in $CHCl_3$ (50 mL), washed with $NaHCO_3$ (30 mL) and brine (20 mL), dried (Na_2SO_4), and the solvent evaporated. Chromatography on silica (1:3 ethyl acetate – hexane) gave recovered **24** (75 mg) and the syrupy product, 5-azido-2,3,4,6-tetra-*O*-benzyl-5-deoxy-D-glucitol **25** (170 mg, 63%); $[\alpha]_D$ −2.7° (*c* 0.002, $CHCl_3$); ν_{max}(KBr): 3460 cm^{-1} (OH), 2100 cm^{-1} (N_3); ^1H nmr (270 MHz, $CDCl_3$) δ: 7.56–7.10 (m, 20 H, C_6H_5), 4.81–4.31 (m, 8H, $C_6H_5CH_2$), 3.91 (m, 2H, H-2,4), 3.85 (m, 1H, H-3), 3.77, 3.73 (2 br s, 2H, H-1,1′), 3.55 (dd and m, 2H, $J_{5,6}$ 5, $J_{6,6'}$ 9.5 Hz, H-5,6), 3.41 (dd, 1H, $J_{5,6'}$ 7, $J_{6,6'}$ 9.5 Hz, H-6′).

The alcohol **25** (43 mg, 0.075 mmol) in dry dichloromethane (2 mL) was stirred at room temperature, pyridinium chlorochromate (36 mg, 0.167 mmol) was added, and stirring was continued for 3 h. The mixture was diluted with 1:4 ethyl acetate – hexane (10 mL) and applied to a short silica column. Elution with 1:4 ethyl acetate – hexane gave 5-azido-2,3,4,6-tetra-*O*-benzyl-5-deoxy-D-glucose **19** (30 mg, 71%), which was used immediately in subsequent reactions: ν_{max}(KBr): 2100 cm^{-1} (N_3), 1685 cm^{-1} (CHO).

To the azido ester **24** (86 mg, 0.132 mmol) in dry oxolane (10 mL) was added lithium aluminium hydride (15 mg, 0.39 mmol) and the mixture stirred at room temperature for 1.5 h. Sodium sulphate decahydrate (50 mg) was added; the solids were removed by filtration and then washed with $CHCl_3$ (4 × 10 mL). The combined filtrates were concentrated and the syrup dissolved in dry acetonitrile (6 mL). After cooling to 0°C, trifluoroacetic anhydride (0.1 mL, 0.70 mmol) was added dropwise, and the solution kept on ice for 5 min, then at room temperature for 5 min. The solvent was evaporated and the syrup dissolved in $CHCl_3$ (20 mL), washed with $NaHCO_3$ (20 mL), saturated brine (10 mL), dried (Na_2SO_4), and concentrated to a syrup of the bistrifluoroacetyl derivative; ν_{max}(KBr): 3390 cm^{-1} (NH), 1790 cm^{-1} ($OCOCF_3$), 1730 cm^{-1} ($NCOCF_3$). This syrup was dissolved in dry methanol (10 mL) and heated at 45°C for 8 h. Evaporation of solvent gave a crude syrup, which was chromatographed on silica (1:3 ethyl acetate – hexane) to give 2,3,4,6-tetra-*O*-benzyl-5-deoxy-5-trifluoroacetamido-D-glucitol **27** as a colourless syrup (49 mg, 58%); $[\alpha]_D$ +2.8° (*c* 0.0083, $CHCl_3$); ν_{max}(KBr): 2390 cm^{-1} (OH), 1730 cm^{-1} (CO); ^1H nmr (270 MHz, $CDCl_3$) δ: 7.54–7.17 (m, 20 H, C_6H_5), 4.72–4.34 (m, 8H, $C_6H_5CH_2$), 4.60 (m, 1H, H-5), 3.93 (m, 2H, H-3,4), 3.85 (m, 1H, H-2), 3.76 (dd, 1H, $J_{1,1'}$ 12, $J_{1,2}$ 3.5 Hz, H-1), 3.55 (2dd, 2H, $J_{1,1'}$ 12, $J_{1,2}$ 4 Hz, H-1′, $J_{5,6}$ 5, $J_{6,6'}$ 9.5 Hz, H-6), 3.42 (dd, 1H, $J_{5,6'}$ 6.5, $J_{6,6'}$ 9.5 Hz, H-6′). Exact mass calcd. for $C_{36}H_{38}NF_3O_6$: 637.2651; found: 637.2627.

*2,3,4,6-Tetra-*O*-benzyl-5-deoxy-5-trifluoroacetamido-D-glucononitrile (30)*

Alcohol **27** (42 mg, 0.065 mmol) was oxidized in the same manner as for the preparation of aldehyde **19**. The crude reaction mixture was filtered through a short silica column, eluting with 1:3 ethyl acetate – hexane to give 2,3,4,6-tetra-*O*-benzyl-5-deoxy-5-trifluoroacetamido-D-glucose **28** as a colourless syrup (31 mg, 76%), which was immediately used in subsequent transformations; ν_{max}(KBr): 1730 cm^{-1} ($NHCOCF_3$), 1690 cm^{-1} (CHO); ^1H nmr (270 MHz, $CDCl_3$) δ: 9.67 (s, 1H, CHO), 7.62–7.07 (m, 20 H, C_6H_5), 4.88–4.09 (m, 9H, H-5, $C_6H_5CH_2$), 4.09, 3.96 (2dd, 2H, *J* 2.5, *J* 5.5 Hz, H-3,4), 3.99 (d, 1H, $J_{2,3}$ 5.5 Hz, H-2), 3.54 (dd, 1H, $J_{5,6}$ 4.5, $J_{6,6'}$ 9.5 Hz, H-6), 3.33 (dd, 1H, $J_{5,6'}$ 7, $J_{6,6'}$ 9.5 Hz, H-6′).

The aldehyde **28** (41 mg, 0.065 mmol) was treated in the same manner as for the preparation of compound **3**. Chromatography on silica (1:3 ethyl acetate – hexane) gave (*E*,*Z*)-2,3,4,6-tetra-*O*-benzyl-5-deoxy-5-trifluoroacetamido-D-glucose oxime **29** as a colourless syrup (30 mg, 71%); $[\alpha]_D$ +10.0° (*c* 0.01, $CHCl_3$); ν_{max}(KBr): 3390 cm^{-1} (NOH), 1728 cm^{-1} (CO); ^1H nmr (270 MHz, $CDCl_3$) δ: 7.60–7.12 (m, 21H, C_6H_5, H-1 *E* isomer, H-1 *Z* isomer), 4.80–4.24 (m, 9H, $C_6H_5CH_2$, H-2), 4.57 (m, 1H, H-5), 3.99–3.89 (m, 2H, H-3,4), 3.52 (dd, 1H, $J_{5,6}$ 4.5, $J_{6,6'}$ 9.5 Hz, H-6), 3.30 (dd, 1H, $J_{5,6'}$ 7.5, $J_{6,6'}$ 9.5 Hz, H-6). Exact mass calcd. for $C_{36}H_{37}N_2F_3O_6$: 650.2604; found: 650.2604.

The oximes **29** (42 mg, 0.064 mmol) were treated in the same manner as for the preparation of compound **21**. Chromatography on silica (1:3 ethyl acetate – hexane) gave 2,3,4,6-tetra-*O*-benzyl-5-deoxy-5-trifluoroacetamido-D-glucononitrile **30** as a colourless syrup

(31 mg, 76%); $[\alpha]_D$ +23° (*c* 0.025, $CHCl_3$); ν_{max}(KBr): 3390 cm^{-1} (NH), 2100 cm^{-1} (CN), 1729 cm^{-1} (NHCO); ^1H nmr (270 MHz, $CDCl_3$) δ: 7.50–7.06 (m, 20 H, C_6H_5), 4.89–4.24 (m, 8H, $C_6H_5CH_2$), 4.67 (m, 1H, H-5), 4.57 (d, 1H, $J_{2,3}$ 7 Hz, H-2), 4.11 (dd, 1H, $J_{3,4}$ 3, $J_{4,5}$ 5 Hz, H-4), 4.05 (dd, 1H, $J_{2,3}$ 7, $J_{3,4}$ 3 Hz, H-3), 3.53 (dd, 1H, $J_{5,6}$ 5.5, $J_{6,6'}$ 9.5 Hz, H-6), 3.34 (dd, 1H, $J_{5,6'}$ 8, $J_{6,6'}$ 9.5 Hz, H-6′). Exact mass calcd. for $C_{36}H_{35}N_2F_3O_5$: 632.2478; found: 632.2488.

Received August 12, 1989

SALAH M. ABDEL-KADER, MOHAMADY A. ISSA, and MOHAMED A. EL-SHAFEI. Can. J. Chem. **68**, 323 (1990).

An extracellular acidic polysaccharide, elaborated by *Bacillus polymyxa*, was composed of D-glucose, D-mannose, D-galactose, and D-glucuronic acid (approximate molar ratio of 4:3:1:1). Methylation and fragmentation analysis by partial acid hydrolysis indicated that the polysaccharide had a complicated, highly branched structure, consisting mainly of β(1 → 3) and (1 → 4) D-glycosidic linkages. The backbone chain containing D-glucose, D-mannose, and D-glucuronic acid residues is attached at the C-4, C-3, and C-4 positions, respectively, one out of every three glucose residues being substituted at the C-2 position to form two kinds of branches at the C-2 and C-4 positions, with side chains of single or a few carbohydrate units that are terminated by D-glucose and (or) D-mannose residues.

Key words: acidic polysaccharide, *Bacillus polymyxa*.

SALAH M. ABDEL-KADER, MOHAMADY A. ISSA et MOHAMED A. EL-SHAFEI. Can. J. Chem. **68**, 323 (1990).

Un polysaccharide acide extra-cellulaire obtenu à partir du *Bacillus polymyxa* est composé de D-glucose, de D-mannose, de D-galactose et d'acide D-glucuronique (rapport molaire approximatif de 4 : 3 : 1 : 1). Une analyse de la méthylation et de la fragmentation effectuée en faisant appel à une hydrolyse acide partielle indique que la structure du polysaccharide comporte de nombreuses ramifications complexes formées principalement de liaisons D-glycosidiques β(1 → 3) et (1 → 4). Le squelette de la chaine contient des résidus de D-glucose, de D-mannose et d'acide D-glucuronique qui sont attachés respectivement aux positions C-4, C-3 et C-4; un résidu glucose sur trois est substitué en position C-2 et il en résulte deux sortes de ramifications, en positions C-2 et C-4, comportant des chaines latérales avec une ou quelques unités de carbohydrates qui se terminent par des résidus de D-glucose et (ou) de D-mannose.

Mots clés : polysaccharide acide, *Bacillus polymyxa*.

Introduction

Some microorganisms belonging to *Bacillus* species have been known to produce extracellular polysaccharides, such as cellulose (1), dextran (2), levan (3), and an acidic polysaccharide (4). A previous study (5) showed that an extracellular acidic polysaccharide produced by a newly isolated microorganism, designated *Bacillus polymyxa*, reduced the cholesterol levels in serum and liver of hypercholesterolemic rats (6). Recently, some plant polysaccharides, such as pectin, guar gum, and sodium alginate have attracted attention for their hypocholesterolemic effects on experimental rats. In the course of study, it has been found that some strains of *Bacillus* sp. were capable of producing new types of acidic heteropolysaccharides composed of D-glucose, D-mannose, D-galactose, D-glucuronic acid, and D-mannuronic acid in a complicated highly branched structure, consisting mainly of (1 → 3) and (1 → 4) D-glycosidic linkages.

This work was conducted to study the possible structural features of the acidic polysaccharide produced by *Bacillus polymyxa*, as revealed by methylation and also fragmentation analysis as a result of partial acid hydrolysis.

Materials and methods

General methods

The procedure of concentration by evaporation was carried out under reduced pressure at 35–40°C. Paper chromatography was carried out on Whatman No. 1 filter paper by the descending technique with the following systems (v/v): (a) 1-butanol – acetic acid – water (4:1:5); (b) ethyl acetate – acetic acid – water (7:1:1); (c) ethyl acetate – acetic acid – formic acid – water (18:3:1:4); and (d) benzene–ethanol–water (190:50:5), for methylated sugars, which were detected on the chromatogram by spraying with alkaline silver nitrate (7) and *p*-anisidine hydrochloride reagent (8).

Gas–liquid chromatography (glc) was performed with a Shimadzu model GC-GAM gas chromatography apparatus fitted with a flame ionization detector, with a glass column (0.4 × 200 cm) packed with 5% OV-101, at 180°C. Analysis was done at 175°C at a nitrogen flow rate of 15 mL/min. Polysaccharides (2–5 mg) were hydrolyzed in sealed tubes with 1 M sulfuric acid for 8 h using a boiling water bath. Total carbohydrate was determined by the phenol – sulfuric acid method (9). Colorimetric determination of uronic acid was done by the carbazole method (10).

Production and purification of polysaccharide

Bacillus polymyxa was grown in a medium (7 L, pH 6.8) by the method of Holding and Collee (11) for 5 days at 28°C in a 10-L jar fermenter with vigorous aeration. The culture broth (500 mL) was diluted with 0.01 M sodium hydroxide (500 mL), sterilized for 5 min at 75°C, clarified by filtration, deionized with Amberlite IR-120, and then lyophilized to give a crude polysaccharide (10–13 g).

For purification of the polysaccharide, the crude polysaccharide (10 g) was dissolved in 0.03 M sodium sulfate (1000 mL), and selectively precipitated by gradual addition of cetylpyridinium chloride (CPC, 12 g) until no more precipitate was formed. The precipitated CPC complex was collected by centrifugation, washed several times with ethanol, and dissolved in 10% sodium chloride (500 mL). The solution was filtered, dialyzed, and concentrated to 300 mL (Fraction A). The purified polysaccharide precipitated upon the addition of ethanol (900 mL) was redissolved in warm water and precipitated again with ethanol, yielding a white powder (6.5 g) of an acidic polysaccharide.

The supernatant solution of the precipitate was dialyzed, concentrated (Fraction B), and then poured into ethanol, yielding a neutral polysaccharide (2.1 g), which was kept for further study.

Fehling's solution (50 mL) was added to fraction A (200 mL) and the mixture was allowed to stand for 7 days. The resulting copper complex (2.6 g) was separated by centrifugation, washed several times with alcohol, and dried in a desiccator. *Anal.* calcd. for $[C_{1.6}H_{2.4}O_{1.4}-0.1Cu(NH_3)_2]n$: Cu 11.94%; found : Cu 14.08%.

The polysaccharide was recovered from the copper complex by treatment with 1 M hydrochloric acid (50 mL) with stirring and pouring into ethanol (150 mL). The white precipitate was filtered off, washed successively with ethanol and ether, then dried under reduced pressure; $[\alpha]_D$ +78° (*c*, 0.1% in H_2O).

Identification of sugar components

The polysaccharide (300 mg) was hydrolyzed with 1 M sulfuric acid (15 mL) for 8 h in a boiling water bath. After neutralization with $BaCO_3$, filtration, deionization on Rexyn-101(H^+) resin, and concentration, the mixture of acidic and neutral sugars was fractionated on a column of IR-48 resin. The column was eluted, first with 250 mL of water to remove the neutral sugars, followed by gradient elution with ethanolic ammonia (100 mL) to obtain the uronic acids.

(a) Neutral sugars (9)

The column eluates were concentrated, and on examination on paper chromatograms they were found to contain three components. These gave the same colour reactions, moved to the same extent, and were indistinguishable from authentic samples of D-galactose (R_f 0.11), D-glucose (R_f 0.13), and D-mannose (R_f 0.15) respectively (solvent a). The ratio of sugars was determined after eluting the corresponding zones from the paper chromatogram, with solvent a, by the phenol – sulfuric acid method.

(b) Uronic acid fraction (10)

This was indistinguishable from an authentic sample of D-glucuronic acid (R_f 0.07). The proportion of glucuronic acid was estimated after eluting the corresponding zone, by colorimetric determination with carbazole reagent (uronic acid 12.77%).

Methylation analysis of polysaccharide

The polysaccharide (500 mg) was methylated by the method of Hakomori (12) with methylsulfinyl carbanion and methyl iodide. The reaction mixture was dialyzed exhaustively against water and evaporated to dryness. Successive methylation processes were required until complete methylation was achieved, as judged from the ir spectrum (elimination of free hydroxyl groups). *Anal.* calcd. for 93.4% methylation, $[C_{3.2}H_{3.77}O_{1.3}–(OCH_3)_{1.43}]n$: OMe 41.37%; found: OMe 41.54%.

Methylated polysaccharide (300 mg) was hydrolyzed with 90% formic acid (2 mL) for 16 h at 100°C, followed by heating with 2 M trifluoroacetic acid (1 mL) for 5 h. Acids were removed by evaporation, and the product was examined by paper chromatography using solvent d, and found to contain at least nine components with R_f values of 0.016, 0.12, 0.23, 0.45, 0.59, 0.69, 0.71, 0.84, and 0.88. The methylated sugars in the hydrolyzate were converted into their corresponding alditol acetates by the usual manner (13) and then analyzed by glc.

The glucuronic acid was confirmed by reduction of polysaccharide, using the method of Taylor and Conrad (14).

An aqueous solution of the native polysaccharide (50 mg in 100 mL of water) was adjusted to pH 4.7 with 0.1 M hydrochloric acid, followed by the addition of 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (500 mg), and the stirred reaction mixture was maintained at pH 4.7 for 3 h by the addition of 0.02 M hydrochloric acid. After addition of sodium borohydride (500 mg) and one drop of *n*-octanol, the mixture was kept overnight with stirring, dialyzed exhaustively, deionized with Amberlite IR-120(H^+ form), and evaporated to dryness. The methylation of reduced polysaccharide was carried out by the method of Hakomori (12).

The partially methylated sugars in the hydrolyzate were converted into the corresponding alditol acetates as described previously (13) and then analyzed by glc.

Partial acid hydrolysis of polysaccharide

The polysaccharide (3.5 g) was heated with 0.5 M trifluoroacetic acid (300 mL) for 3 h at 100°C. After evaporation of the acid, the hydrolyzate was dissolved in water (100 mL), ethanol (300 mL) was added to the solution, and the resultant precipitate was collected by centrifugation to give a degraded polysaccharide. The supernatant was evaporated to a small volume, passed through a column of Dowex-1 × 4) resin (5 × 20 cm, formate form), and washed with water to give a mixture of neutral oligosaccharides (1500 mL). Acidic oligosaccharides absorbed on the column were eluted with 1 M formic acid (1000 mL).

The neutral oligosaccharides were fractionated by a column (2 × 30 cm) of activated charcoal. After washing the column with water, the oligosaccharides were eluted stepwise with 4%, 7%, 12%, and 25% aqueous ethanol, and finally with warm 50% ethanol. Each fraction was evaporated to dryness and further purified by preparative paper chromatography using Whatman No. 1 filter paper (solvents a and c).

Structural analysis of oligosaccharides

The neutral oligosaccharides (1.5–3 mg each) were hydrolyzed with 2 M TFA for 6 h at 100°C. After the acid was evaporated, monosaccharides in the hydrolyzate were examined by paper chromatography. Methylation of the oligosaccharides was done by the method of Hakomori (12) as described previously. After evaporating the methyl iodide, the methylated oligosaccharide was extracted with chloroform and purified on a Sephadex LH-20 column (1 × 20 cm) by elution with chloroform to give the purified methylated product. The methylated oligosaccharide was hydrolyzed successively with 90% formic acid and 2 M TFA as described previously, and then analyzed by glc after converting into its alditol acetate.

Each of the acidic oligosaccharides (2–4 mg) was methylated in the same manner. It was dissolved in diethyl ether and treated with diazomethane. The resulting methyl esters of the uronic acid residues were reduced with lithium aluminium hydride (10 mg) in diethyl ether by heating with refluxing for 4 h, after which water was added dropwise to decompose the excess reagent. After filtration, the residue was washed repeatedly with acetone and dried *in vacuo*. The methylated carboxyl-reduced oligosaccharide was remethylated by the method of Hakomori (12), hydrolyzed, and then analyzed by glc as described previously.

Periodate oxidation and Smith degradation

The polysaccharide (150 mg) was oxidized with 0.3 M sodium metaperiodate (225 mL) at room temperature in the dark (15). Aliquots (5 mL) were removed after 18 h and the consumption of periodate and production of formic acid were determined (16, 17). The results, based on 163.75 g of polysaccharide in the glucose–mannose–galactose – glucuronic acid (ratios of 2.7:2.3:0.4:0.8), were as follows: periodate consumed, 0.78 mole; formic acid produced, 0.26 mole.

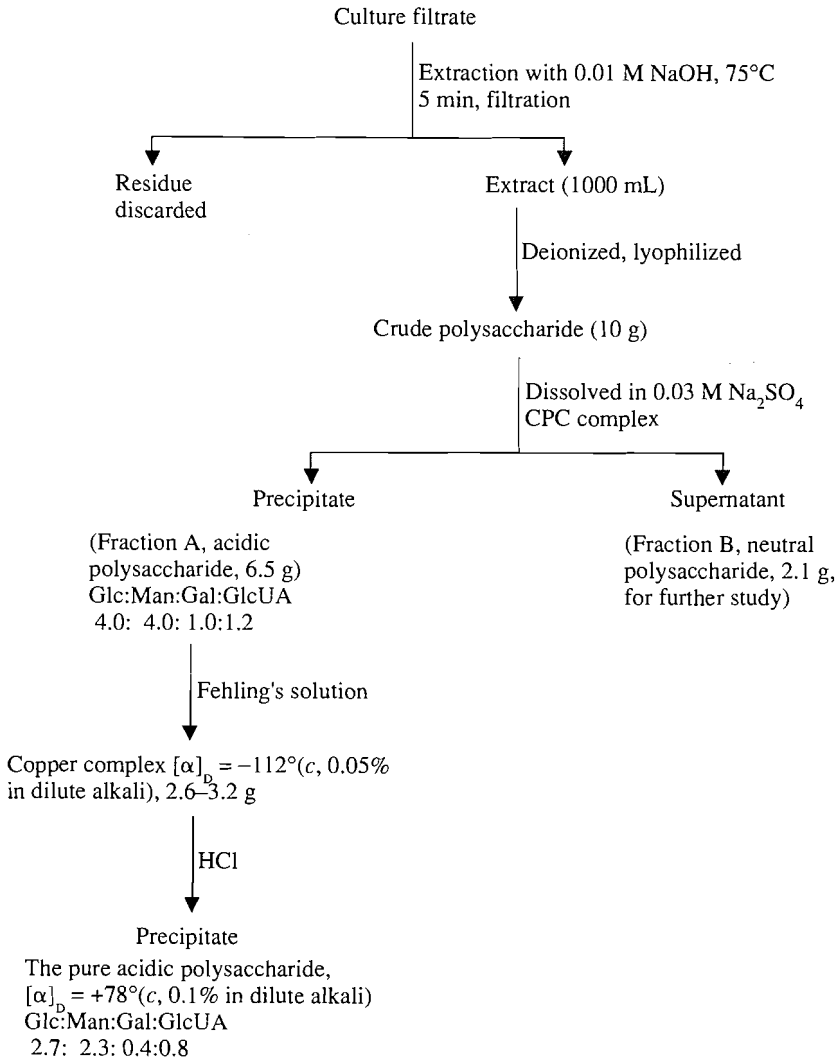
After complete oxidation (5 days), the oxidation was stopped by the addition of ethylene glycol and the solution dialyzed. The polyaldehyde was reduced with excess of $NaBH_4$ at room temperature overnight. The reaction was terminated by addition of ice-cold 4 N acetic acid and the solution was again dialyzed and lyophilized (120 mg polysaccharide-polyalcohol). A portion of the resulting polysaccharide-polyalcohol was hydrolyzed with 1 M sulfuric acid for 6 h at 100°C. The hydrolyzate was neutralized ($BaCO_3$), centrifuged, concentrated to a syrup, examined by paper chromatography using solvent a, and finally analyzed by glc after conversion into the corresponding alditol acetate.

The remainder of the polysaccharide-polyalcohol (90 mg) (18) was hydrolyzed with 0.05 M sulfuric acid for 18 h at 40°C. The mild hydrolysis product (oligosaccharide components) was isolated by paper chromatography (solvent a), and its structure was examined by methylation analysis as described previously.

Results and discussion

When *Bacillus polymyxa* was grown for 5 days at 28°C in a medium containing 2% sucrose, appropriate amounts of nitrogen compounds, and inorganic nutrients, the culture medium became viscous due to the production of an extracellular polysaccharide. The procedure for fractionation is shown in Scheme 1. The crude polysaccharide was extracted successively with 0.01 M sodium hydroxide at 75°C for 5 min. The crude polysaccharide dissolved in sodium sulfate was further fractionated by treatment with CPC, to give an acidic polysaccharide (Fraction A) and a neutral polysaccharide (Fraction B; for further study).

The acidic polysaccharide was purified by repeated fractional precipitations with ethanol, and then via its copper complex. In addition, the polysaccharide contained one kind of aldouronic acid, as shown by paper chromatography.



SCHEME 1. Fractionation of polysaacharide from *Bacillus Polymyxa*.

In another experiment, the polysaccharide was treated with carbodiimide and sodium borohydride by the method of Taylor and Conrad (14), and the resulting carboxyl-reduced polysaccharide was hydrolyzed with acid and quantitatively analyzed by paper chromatography (9) as described previously. The comparison of sugar compositions of the native and carboxyl-reduced polysaccharides indicated that the original polysaccharide was composed of D-glucose, D-mannose, D-galactose, and D-glucuronic acid (Glc UA) in a molar ratio of 2.7:2.3:0.4:0.8.

This polysaccharide is unique, containing a small but significant amount of D-glucuronic acid, which usually occurs in plant gum polysaccharides such as arabic gum and khaya gums (19) but is rare in microbial polysaccharides, such as Pneumococci (for a survey up to about 1959, see ref. 20).

Methylation study

To obtain information on the mode of glycosidic linkages of these sugar residues, the native and carboxyl-reduced polysaccharides were methylated by the method of Hakomori (12). The polysaccharides exhibited considerable resistance towards complete methylation and successive methylation processes were required to yield methylated products containing 0.934 OCH_3 and 0.971 OCH_3 per hydroxyl group in the native and carboxyl-reduced polysaccharides respectively (as judged from the ir spectrum, by the absence of the OH band at 3400–3600 cm^{-1}). The comparison of methylated sugars of the native and carboxyl-reduced polysaccharides was made by glc after hydrolysis with acid and conversion into the corresponding alditol acetates.

As shown in Table 1, D-glucose, D-mannose, and D-glucuronic acid residues in the inner chains of the polysaccharide are linked mainly with (1 → 3) and (1 → 4) D-glycosidic linkages, as indicated by the presence of 2,4,6-tri-*O*-methyl-D-mannose and 2,3,6-tri-*O*-methyl-D-glucose and -D-galactose. The identification of 2,3,4,6-tetra-*O*-methyl derivatives of D-mannose and D-glucose indicates that the polysaccharide has a highly branched structure and the side chains are terminated with D-mannose and also with D-glucose residues. In addition, the presence of 3,6-di-*O*-methyl-D-glucose suggests that some of the (1 → 4)-linked D-glucose residues might form branch points.

As regards the glycosidic linkages of D-glucuronic acid residues, the methylated carboxyl-reduced polysaccharide, but *not* the native polysaccharide, gave, on acid hydrolysis, 2,6-di-*O*-methyl-D-glucose, indicating that D-glucuronic acid residues are located in the main chain at the branch point by double substitutions at the O-3 and O-4 atoms.

However, in view of the failure to detect any tetra-*O*-methyl-

			2,6-Di-*O*-methyl-D-glucose	0.71

*The polysaccharide (3.5 g) was partially hydrolyzed with 0.5 M TFA for 3 h at 100°C.
†R_{Glc}: paper-chromatographic mobility relative to that of D-glucose (solvent a).

D-galactose in the hydrolyzate of the methylated product of the native and carboxyl-reduced polysaccharides, it has been suggested that the reason for the presence of most of the tri-*O*-methyl-D-galactose may be complete methylation of the polysaccharide, and demethylation during hydrolysis. Another reason could be the presence of a "start point" for establishing a repeating unit. The isolation of mono-*O*-methyl-D-glucose as a trace quantity of D-glucose derivative is suggestive of branching at positions 2 and (or) 6 of the glucose units. Nevertheless, the presence of mono-*O*-methyl-D-glucose may be due to incomplete methylation or to demethylation. Other authors (21, 22) have reported similar observations.

Fragmentation of polysaccharide by partial acid hydrolysis

To investigate the sequential arrangement of the sugar residues, the polysaccharide was subjected to partial acid hydrolysis. After the acid was distilled off, the high molecular weight fraction (degraded polysaccharide) was separated by precipitation with ethanol (3 volumes). The oligosaccharides in the supernatant solution were fractionated by a column of Dowex-1 × 4) and charcoal, and were respectively isolated by preparative paper chromatography. These procedures afforded four kinds of neutral oligosaccharides (**1**–**4**) and an acidic oligosaccharide (**5**). They were characterized mainly by methylation analysis.

As shown in Table 2, the two neutral disaccharides were characterized as 3-*O*-D-mannopyranosyl-D-mannose (**1**) and 4-*O*-D-glucopyranosyl-D-glucose (**2**).

Oligosaccharide **2** gave 2,3,4,6-tetra-*O*- and 2,3,6-tri-*O*-methyl-D-glucose in a molar ratio 1.0:1.2 on methylation followed by acid hydrolysis (1 M H_2SO_4 for 6 h). This oligosaccharide had $[\alpha]_D^T$ +35°, while the authentic cellobiose had $[\alpha]_D^T$ +34.6° (*c*, 0.1% in water); as well, it has the same R_f as an authentic sample (R_f 0.35, solvent a).

The trisaccharide (**3**) was shown to contain one nonreducing terminal D-mannose residue and the substituted D-mannose residue at the O-3 position. Since its specific rotation, $[\alpha]_D^T$ +23°, was lower than that of the disaccharide (**1**), both terminal D-mannose residues must have the β-configuration. In addition, the tetrasaccharide (**4**) was shown to contain two nonreducing termini of D-glucose and D-mannose residues, and the double substituted D-glucose residue at the O-2 and O-4 positions, as revealed by methylation analysis (Table 2). Since its specific rotation, $[\alpha]_D^T$ +10°, was lower than that of the trisaccharide (**3**), both terminal D-glucose and D-mannose residues must have the β-configuration. On consideration of the structure of the related di- and trisaccharides (**1**, **2** and **3**), the tetrasaccharide is tentatively characterized as shown in **4**.

The acidic oligosaccharide fraction was a mixture of three major components, as detected by paper chromatography with solvent c. Their mobilities on a paper chromatogram were R_{GlcA}

FIG. 1. Structural formulas of oligosaccharides.

0.31, 0.35, and 0.43 respectively. Among them, oligosaccharide **5** (R_{GlcA} 0.31 and $[\alpha]_D^T$ +46), adsorbed on a Dowex-1 × 4 (formate form) column and eluted with 1 N formic acid, was purified by paper chromatography. The acidic oligosaccharide **5** was methylated, carboxyl-reduced, and hydrolyzed, and 2,3,4,6 tetra-*O* and 2,3-di-*O*-methyl-D-glucose and 2,4,6-tri-*O*-methyl-D-mannose (ratio 1:1:1.1) were identified, while the corresponding carboxyl-reduced oligosaccharide gave, on remethylation and acid hydrolysis, 2,3,4,6-tetra-*O*- and 2,3,6-tri-*O*-methyl-D-glucose and 2,4,6-tri-*O*-methyl-D-mannose in a ratio 1:1.05:1. From these results, the acidic oligosacharide **5** was characterized as 4-*O*-β- D-glucopyranosyl-3*O*-α-D-glucopyranosyl uronic acid-D-mannose. The highly positive $[\alpha]_D^T$ values (+78° and +16.8° respectively) for the unmethylated and methylated polysaccharides, and the presence of an absorption band at 890 cm^{-1} in the infrared spectrum, are characteristic of β-configuration (23).

The sequential arrangements of the sugar residues in the (galacto-glucurono-manno-glucan) polysaccharide were also examined by Smith degradation. On complete Smith degradation it gave D-glucose, D-mannose, and D-glucuronic acid in addition to erythritol and glycerol, as shown in Table 3.

Smith degradation and methylation products of the original polysaccharide together may indicate that D-glucose, D-mannose, and D-glucuronic acid should have arisen from a branching unit, and joined to other units at (1 → 2)-linked D-glucose, and (1 → 3)-linked D-mannose and D-glucuronic acid residues. Comparison of the molar ratio of D-glucose and D-mannose to D-glucuronic acid in the hydrolyzate of the complete Smith degradation product and in the original polysaccharide (0.65: 1.13: 0.79 and 2.7:2.3:0.80 respectively) may indicate that all glucuronic acid units are resistant to oxidation by periodate.

The glycerol and erythritol should have arisen from the nonreducing terminal sugar units; in addition the polysaccharide contains (1 → 4)- and (1 → 2)-linked D-glucose, and (1 → 3)-linked D-mannose residues.

Furthermore, comparison of the unit ratio of mannose and glucose to glucuronic acid in the hydrolyzate of the periodate-oxidized polysaccharide with branching units in the original polysaccharide (0.8:1.4:1.0 and 1.0:2.0:1.0 respectively) may indicate that some mannose and glucose units were lost (20%) during overoxidation.

TABLE 3. Complete Smith degradation products from the native polysaccharide

Degradation product	Molar ratio
D-Mannose	1.13
D-Glucose	0.65
D-Glucuronic acid	0.79
Erythritol	1.48
Glycerol	1.56

The polysaccharide-polyalcohol derived from the native polysaccharide was hydrolyzed under mild conditions with 0.05 M sulfuric acid for 18 h at 40°C. After neutralization with $BaCO_3$ as described previously, the high molecular weight fraction was separated by precipitation with ethanol (3 volumes). The water soluble fraction gave, on the paper chromatogram with solvent a, at least one spot, having R_{GlcA} 0.97.

On acid hydrolysis, it yielded D-glucose, D-glucuronic acid, and erythritol (ratio 1.0:1.1:0.9). By methylation and then acid hydrolysis, it gave 2,3,4,6-tetra-*O*-methyl-D-glucose and 2,4-di-*O*-methyl-D-glucose. Therefore, this oligosaccharide should have the structure shown as **6**. On consideration of the results of methylation analysis of the polysaccharide and the structures of oligosaccharides **4**, **6** might have arisen from the following sequence of sugar residue in the side chain of the polysaccharide.

The water-insoluble fraction comprised mainly D-mannose, D-glucuronic acid, and erythritol (ratio 2:1:1). This fraction might be a mixture of oligosaccharides or a degraded polysaccharide containing D-glucuronic acid and D-mannose; this oligo-

β-D-Glcp

saccharide should have the structure shown as **7**. However, the details of the structure have not been studied. Since the D-glucuronic acid residues must be located in the main chain to form branch points, a part of the sequential arrangement of sugar residues in the backbone chain may be elucidated as follows:

→3)-β-D-Manp(1→4)-D-Glcp(1→
3
↑
1
→3)-β-D-Manp(1→4)-D-Glcp

The aforementioned results indicate that the polysaccharide has a complicated branched structure, where major portions of both D-glucose and D-mannose residues are linked by β(1 → 4) and β(1 → 3) bonds, respectively. The minor portions of D-glucuronic acid residues are joined by α-D linkages with both D-glucose and D-mannose residues. The minor portions of D-glucuronic acid are located in the main chain by α(1 → 3) and (1 → 4) linkages with both D-mannose and D-glucose residues. There are two kinds of side chains, one consisting of β(1 → 3)-linked D-glucose and glucuronic acid residues and the other consisting of the β-D-glycopyranosyl-(1 → 2)-D-glucose unit, attached at the C-3 positions of the D-glucuronic acid residues. However, similarly, a small proportion of D-glucose residues must be located in the side chain to form branch points.

On reacting the polysaccharide with Fehling's solution, a copper complex that contained one-third atomic equivalent of copper per mole of sugar unit was formed. Comparison of the specific rotation of the galacto-glucurono-manno-glucan in dilute alkali (+78°) with that in cuprammonium (−112°), showed that a levorotatory complex was formed in cuprammonium. This has been shown (24) to occur in reactions involving the 2- and 3-hydroxyl groups in both D-glucopyranoside and -galactopyranoside as well as the 2- and 3- or the 3- and 4-OH groups of D-mannopyranoside. Such shifts in the case of starch and glycogen, where reaction involves all the sugar units, are from +375° to −715° and from +366° to −597°, respectively (24).

In the acidic polysaccharide of *Bacillus polymyxa*, the copper complex isolated involves only 36.25% of the sugar units and the levorotatory shift is about one third (36.25%) of the starch or glycogen.

Acknowledgments

The authors wish to express their thanks to Dr. Safwat, M.S.A. and Dr. EL-dahtory, Th., Microbiology Department, EL-Minia University, for their help, particularly in providing the purified culture of *Bacillus polymyxa*.

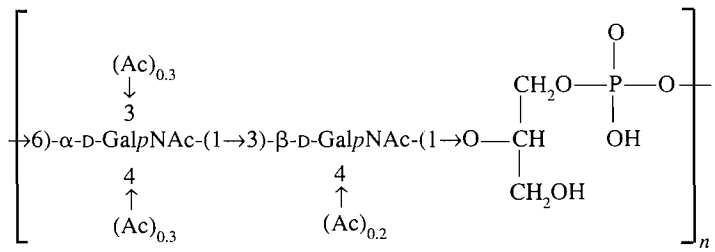
Structural characterization of the capsular polysaccharide and *O*-chain of the lipopolysaccharide of *Actinobacillus pleuropneumoniae* serotype 8 (strain 405)[1]

ELEONORA ALTMAN, JEAN-ROBERT BRISSON, AND MALCOLM B. PERRY[2]
Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received August 22, 1989

ELEONORA ALTMAN, JEAN-ROBERT BRISSON, and MALCOLM B. PERRY. Can. J. Chem. **68**, 329 (1990).

The capsular polysaccharide of *Actinobacillus pleuropneumoniae* serotype 8 (strain 405) was found to be a teichoic acid type polysaccharide composed of 2-acetamido-2-deoxy-D-galactose (two parts), glycerol (one part), and phosphate (one part). From hydrolysis, dephosphorylation, methylation, and ^{1}H and ^{13}C nuclear magnetic resonance studies, the polysaccharide was found to be a high molecular weight linear polymer having the structure:

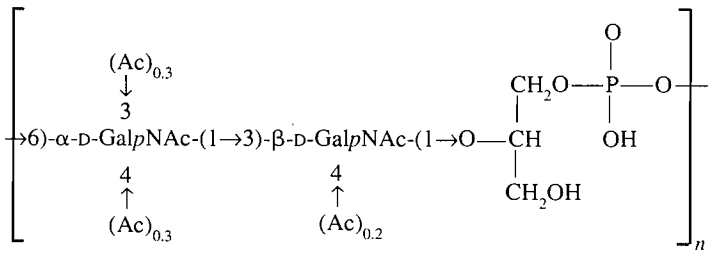


The lipopolysaccharide *O*-antigen of *A. pleuropneumoniae* serotype 8 was shown to be a high molecular weight unbranched linear polymer of a repeating pentasaccharide unit having the structure identical to that produced by *A. pleuropneumoniae* serotype 3, as follows:

Key words: *Actinobacillus pleuropneumoniae* polysaccharide, lipopolysaccharide, NMR.

ELEONORA ALTMAN, JEAN-ROBERT BRISSON et MALCOLM B. PERRY. Can. J. Chem. **68**, 329 (1990).

On a trouvé que la polysaccharide capsulaire de l'*Actinobacillus pleuropneumoniae* du sérotype 8 (souche 405) est un polysaccharide du type de l'acide teichoïque qui est composé de 2-acétamido-2-désoxy-D-galactose (deux parties), de glycérol (une partie) et de phosphate (une partie). En se basant sur des études d'hydrolyse, de déphosphorylation, de méthylation et de résonance magnétique nucléaire du ^{1}H et du ^{13}C, on a trouvé que le polysaccharide est une polymère de poids moléculaire élevé de structure :



On a montré que le liposaccharide du *O*-antigène du *A. pleuropneumoniae* du sérotype 8 est un polymère linéaire sans ramification de poids moléculaire élevé contenant une unité pentasaccharide qui se répète, qui possède une structure identique à celle produite par l'*A. pleuropneumoniae* du sérotype 3 et qui correspond à la suivante :

Mots clés : polysaccharide de l'*Actinobacillus pleuropneumoniae*, lipopolysaccharide, RMN.

[Traduit par la revue]

Introduction

Actinobacillus pleuropneumoniae (APP) infections cause severe respiratory disease in pigs. The organism is encapsulated and 12 serotypes based on the structurally distinct polysaccharide capsular antigens (CPS) have been identified (1–4). In addition, similar to other Gram-negative bacterial pathogens, *A. pleuropneumoniae* have cell wall lipopolysaccharides (LPS) that play a significant role in the interaction between the bacteria and the host, on the serological identification of the organisms, and in the pathogenesis of disease.

Because the immunobiological properties of the LPS and CPS are only explainable at a molecular level in terms of their three-dimensional structures, a complete analysis of these major antigens produced by 12 known serotypes of *A. pleuropneumoniae* has been undertaken. This paper reports the structural analysis of the CPS and *O*-polysaccharide component of the LPS produced by *A. pleuropneumoniae* serotype 8 (strain 405).

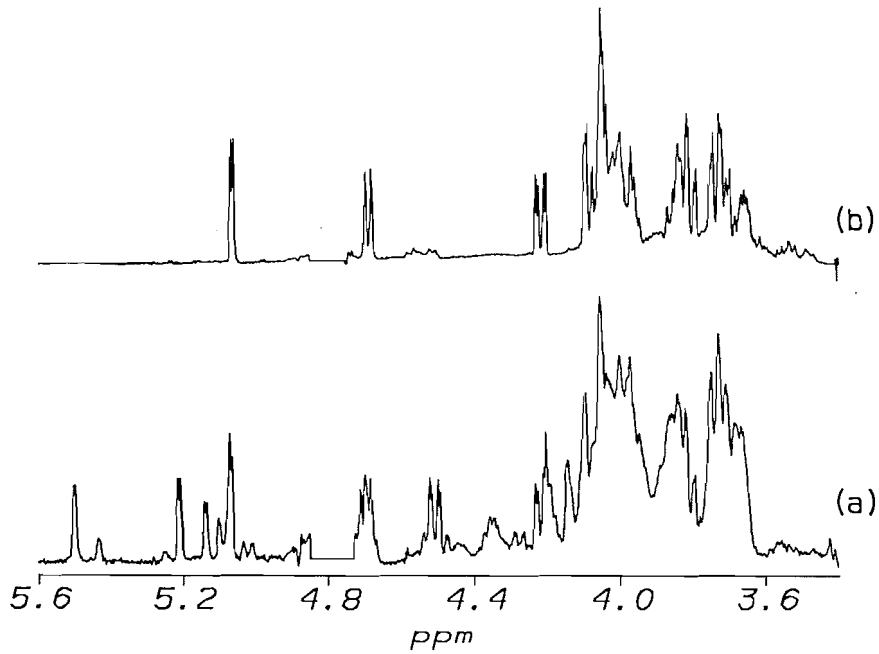

FIG. 1. The ^{1}H nmr spectra (24°C, 500 MHz) of the capsular polysaccharide of *A. pleuropneumoniae* serotype 8. (a) Native polysaccharide, (b) *O*-deacetylated polysaccharide.

Experimental

Production of the capsular polysaccharide and of the O*-polysaccharide*

Actinobacillus pleuropneumoniae serotype 8 (strain 405) cells were grown in Difco brain heart infusion (BHI) (37 g/L) supplemented with β-NAD (Sigma) (50 μg/L) and D-glucose (1% final concentration) (yield ~ 3 g wet weight/L).

The LPS was isolated from the aqueous phase of the phenol extract by ultracentrifugation. A solution of LPS (0.2 g) in aqueous 2% acetic acid (100 mL) was kept at 100°C for 2 h, the precipitated liquid A was removed by low speed centrifugation, and the *O*-polysaccharide was recovered by Sephadex G-50 filtration as previously described (5).

The CPS was isolated from the above ultracentrifugate via its insoluble cetyltrimethylammonium complex as previously described (6) and it was obtained pure by Sephadex G-50 gel filtration followed by ion-exchange chromatography on a DEAE–Sephacel column, from which it was eluted as a single peak with approximately 0.13 M NaCl (6).

Analytical methods

Quantitative methods for glycose analysis and glc and glc–ms methods used were the same as previously described (6).

Samples (0.5 mg) of oligo- and polysaccharides were hydrolyzed with 2 M hydrochloric acid (1 mL) or with 1 M sulfuric acid for 17 h at 100°C. Glycoses were determined by glc of their alditol acetate derivatives (7) using *myo*-inositol as an internal standard. The configuration of glycoses was established by capillary glc of their acetylated (−)-2-butyl glycosides (8). Lipids were identified by glc–ms of their methyl esters as previously described (6). Gel filtration was performed on columns of Sephadex G-50 (2 × 100 cm) or Bio-Gel P-2 (1.6 × 100 cm) (200–400 mesh) (Bio-Rad Labs). SDS-PAGE and methylation analyses were made under previously reported conditions (6).

Polysaccharide dephosphorylation with aqueous hydrofluoric acid

Polysaccharide (16.1 mg) was dissolved in cold 40% hydrofluoric acid (1 mL) and kept at 4°C for 24 h. The solution was concentrated to dryness in high vacuum over NaOH and the residue was neutralized with 5% ammonium hydroxide and lyophilized. The products were fractionated by gel filtration on the Bio-Gel P-2 column.

Nuclear magnetic resonance

Decoupled ^{13}C nmr 125-MHz spectra were recorded at 27°C for a 25-kHz spectral width, using a $\pi/2$ pulse and a 32K data set with a Bruker AM-500 spectrometer. DEPT experiments (9) were performed for a 12.5-kHz spectral width using a $3\pi/2$ pulse to distinguish between CH and CH_2 resonances. The delay between pulses $(2J)^{-1}$ was set at 3.4 ms. Chemical shifts were expressed relative to internal acetone (1%, 31.07 ppm). Proton spectra at 500 MHz were recorded at 24°C and 34°C using a spectral width of 2.5 kHz, a $\pi/2$ pulse, and a 16K data set for digital resolution of 0.3 Hz/point. Chemical shifts were expressed relative to internal acetone (0.1%, 2.225 ppm). Coupling constants are reported in hertz.

Proton homonuclear-correlated 2D-nmr experiments, phase-sensitive COSY (10, 11) and relay COSY (12), were performed at 24°C, using the standard software provided by Bruker (DISNMR), and all experiments were done in the magnitude mode. The heteronuclear ^{13}C–^{1}H shift correlated spectrum (13, 14) was recorded at 24°C on a polysaccharide sample of 40 mg/mL in a 5-mm tube with proton decoupling in the F_1 domain.

Results and discussion

Actinobacillus pleuropneumoniae serotype 8 CPS was obtained via its precipitated cetyltrimethylammonium salt complex from the 1% saline washings of the aqueous phase crude LPS isolated by the phenol extraction procedure (yield: 10 mg of purified CPS/100 g cells (wet weight)). The crude CPS was applied to the Sephadex G-50 gel filtration column from which it eluted as a single peak (K_{av} 0.03), indicating that it had a high molecular weight, and was homogeneous across the collected fractions with respect to neutral glycose, aminodeoxyglucose, and phosphate. Pure CPS was obtained by ion-exchange chromatography using a DEAE–Sephacel column from which it was eluted by approximately 0.13 M sodium chloride. It was readily soluble in water and had $[\alpha]_D$ +52° (*c* 0.8, water) (Anal. found C 38.31, H 5.30, N 5.00, ash 5.7%). Analysis of component sugars by glc of their derived alditol acetates showed that the CPS

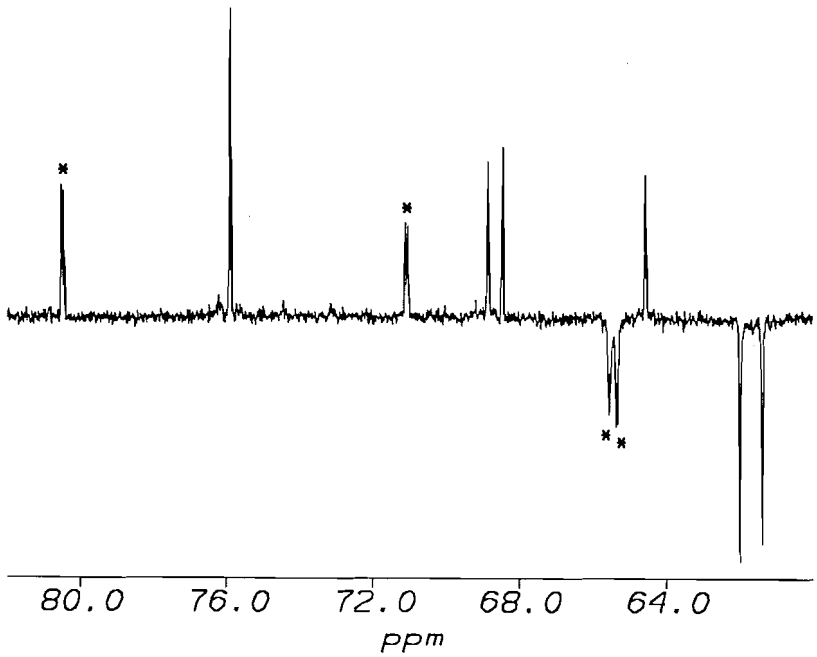

FIG. 2. Partial ^{13}C DEPT spectrum of the *O*-deacetylated capsular polysaccharide from *A. pleuropneumoniae* serotype 8, recorded at 27°C. Carbon–phosphorus couplings are marked with asterisks.

was composed of 2-amino-2-deoxy-D-galactose and glycerol (2.0:0.4). The D configuration of 2-amino-2-deoxygalactose was established by glc of its acetylated (−)-2-butyl glycosides by comparison with authentic reference derivatives according to the method of Leontein *et al.* (8).

The ^1H nmr spectrum of the native CPS (Fig. 1a) (24°C, 500 MHz) exhibited multiple signal patterns of differing intensities due to partial *O*-acetylation. This was further substantiated by analysis of the ^{13}C nmr spectrum of the native CPS (27°C, 125 MHz), which displayed signals for three *O*-acetyl groups at δ 20.86, 20.98, 21.16, 172.62, 173.82, and 174.18 ppm. The ^{13}C nmr spectrum of the native CPS was less complex and showed the presence of two anomeric carbons of equal intensity at δ 94.33 and 102.25 ppm, indicating that two sugar residues were involved in the repeating unit of the CPS.

The *O*-deacetylation of the native CPS significantly simplified its ^1H nmr spectrum (24°C, 500 MHz), which now showed two signals in the anomeric region at δ 5.07 (d, 1H, $J_{1,2}$ 4.0 Hz) and 4.69 (d, 1H, $J_{1,2}$ 8.5 Hz) ppm, and two signals at 2.04 (s, 3H) and 2.08 (s, 3H) ppm corresponding to the CH_3 of the *N*-acetyl group, confirming that both sugar residues were aminodeoxyglycoses (Fig. 1b). The ^{13}C nmr spectrum (27°C, 125 MHz) of the *O*-deacetylated CPS contained 18 carbon signals, indicating that in addition to two 2-acetamido-2-deoxy-D-galactopyranose residues, a three-carbon fragment was also present. The presence of four phosphorus coupled carbons (Fig. 2) suggested that the CPS was of a teichoic acid type involving glycerophosphate linkages.

An attempted dephosphorylation of the CPS with 48% hydrofluoric acid (4°C, 48 h) resulted in cleavage of the glycerol moiety, yielding, almost exclusively, a reducing disaccharide. The unusual lability of the *O*-glycosidic bond between the 2-acetamido-2-deoxy-β-D-glucopyranosyl or galactopyranosyl residue and an acyclic polyol was reported earlier (15). Dephosphorylation of the CPS was achieved using 40% hydrofluoric acid (4°C, 24 h), followed by purification of the

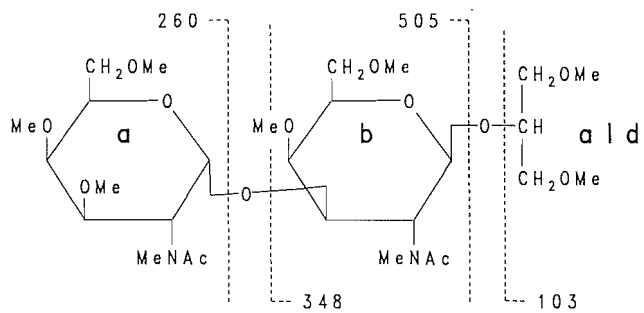

FIG. 3. The glc–ms of methylated oligosaccharide obtained during dephosphorylation of the capsular polysaccharide from *A. pleuropneumoniae* serotype 8 with some primary fragments.

resulting product by Bio-Gel P-2 gel filtration, which yielded a non-reducing disaccharide glycoside (K_{av} 0.40, 1.8 mg) that had $[\alpha]_D$ +38.7° (*c* 0.16, water) and afforded 2-acetamido-deoxy-D-galactose and glycerol on hydrolysis (2.0:0.4). Partial ^1H nmr (27°C, 500 MHz) showed signals at δ 5.07 (d, 1H, $J_{1,2}$ 3.8 Hz), 4.66 (d, 1H, $J_{1,2}$ 8.5 Hz), 2.06 (s, 3H, $NHCOCH_3$), and 2.04 (s, 3H, $NHCOCH_3$) ppm. Partial ^{13}C nmr (27°C, 125 MHz) showed signals at δ 175.41 ($NHCOCH_3$), 101.79 (anomeric C), 94.24 (anomeric C), 22.96 ($NHCOCH_3$), and 22.74 ($NHCOCH_3$) ppm.

Consistent with the nmr and compositional data, glc–ms of the permethylated oligosaccharide (16) (Fig. 3) confirmed presence of two 2-acetamido-2-deoxyhexosyl residues and a glycerol moiety: a base peak at *m/z* 260 (aA_1), peaks at *m/z* 228 (aA_2), 505 (abA_1); those of the glycerol moiety were *m/z* 103 (ald A_1), 163 (bald J_1), and 348 (bald). Hydrolysis of the permethylated oligosaccharide yielded products that after reduction ($NaBD_4$) and acetylation on glc analysis (program B) were identified as 1,5-di-*O*-acetyl-2-deoxy-2-(*N*-methylacetamido)-3,4,6-tri-*O*-methyl-D-galactitol-1-*d*, and 1,3,5-tri-*O*-acetyl-2-deoxy-2-(*N*-methylacetamido)-4,6-di-*O*-methyl-D-galactitol-

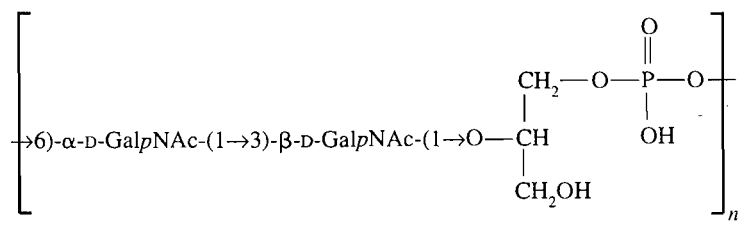
1-*d* (1.0:0.3). Consideration of the composition, glc–ms data, and nmr evidence allows an oligosaccharide to be identified as D-Gal*p*NAc-(1→3)-D-Gal*p*NAc-(1→2)-glycerol. The anomeric configurations of the component monosaccharides were confirmed by 2D-nmr studies.

The position of the monophosphate diester linkage was established by 2D-nmr studies of the *O*-deacetylated CPS. A complete assignment of the proton resonances in the ^{1}H nmr spectrum was made from phase-sensitive COSY (10, 11) and relay COSY (12) experiments, and, following convention, the anomeric signals were labelled **a**–**c** in order of their decreasing chemical shifts. Most of the proton resonances could be assigned through their cross-peaks (Table 1). The assignments of the proton resonances corresponding to the hydroxymethyl groups were confirmed by correlation with the corresponding ^{13}C resonances via a ^{13}C–^{1}H shift correlated experiment (13, 14), which also enabled a complete assignment of the resonances in the ^{13}C nmr spectrum of polymer (Table 2) to be made. Based on the polymer composition, proton chemical shift data, and $J_{1,2}$ values (4.0 Hz), unit **a** was assigned to the 2-acetamido-2-deoxy-α-D-galactopyranosyl residue and **b** to the 2-acetamido-2-deoxy-β-D-galactopyranosyl residue ($J_{1,2}$ 8.5 Hz). The ^{13}C–^{31}P couplings for C-6**a** ($^2J_{^{31}P,^{13}C}$ 3.6 Hz) and C-1**c** ($^2J_{^{31}P,^{13}C}$ 3.7 Hz) and the large three-bond coupling for C-5**a** (9.3 Hz) and C-2**c** (8.2 Hz) located the monophosphate diester group at the *O*-6 position of the 2-acetamido-2-deoxy-α-D-galactopyranosyl residue and at *O*-1 of the glycerol moiety. The above evidence leads to the conclusion that the *O*-deacetylated CPS of *A. pleuropneumoniae* serotype 8 is a linear polymer having the structure

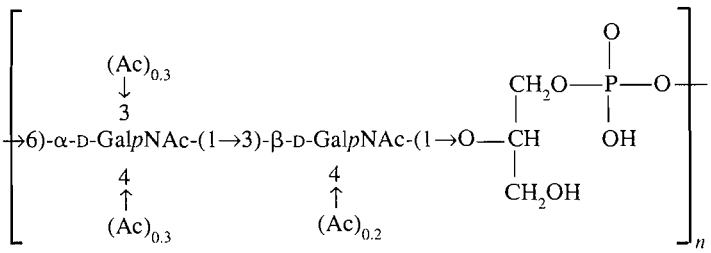


The *O*-acetyl substitution pattern of the native CPS, derived by comparison of its ^{13}C nmr and ^{13}C DEPT experimental spectral data with those of the *O*-deacetylated material, specified that both sugar residues were partially *O*-acetylated. The substitution pattern of residue **a** was complex since it carried two *O*-acetyl groups on the positions *O*-3 and *O*-4 (~30%, based on the ^{13}C nmr resonance intensities). The C-4**a** resonance exhibited a downfield shift of 2.35 ppm and the C-5**a** resonance

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

was upfield shifted by 1.97 ppm. The C-3**a** resonance experienced a downfield shift of 1.35 ppm, which reflected a cumulative effect of a positive increment due to the *O*-acetylation of C-3**a** and negative increment due to the presence of an *O*-acetyl group on the adjacent carbon (C-4**a**). Similarly, C-2**a** exhibited an upfield shift of 2.13 ppm due to the *O*-acetylation of the adjacent C-3**a** carbon. The *O*-acetylation pattern of the residue **b** was less obvious. Partial *O*-acetylation of the C-4**b** (~20%, based on the carbon-13 resonance intensities) was derived from its downfield shift by 2.45 ppm together with the upfield shift of the C-5**b** (4.19 ppm). The carbon resonance corresponding to the expected upfield shift of C-3**b** could not be located, although the cumulative effect of several *O*-acetyl groups could be difficult to predict (17).

In conclusion, the primary structure of the native capsular polysaccharide of *Actinobacillus pleuropneumoniae* serotype 8 (strain 405) was established as



Structural studies were also made on the *O*-chain liberated by mild acid hydrolysis of the aqueous phase LPS, which was extracted by the lysozyme phenol–water method from saline-washed cells of *A. pleuropneumoniae* serotype 8. The purified *O*-chain had $[\alpha]_D$ +3° (*c* 1.2, water) (Anal. found: C 37.64, H 5.56, N 0.08, ash 0%). On the basis of glc of the derived alditol acetates and the acetylated derivatives of their (−)-2-butyl glycosides, the *O*-polysaccharide was found to be composed of D-glucose and D-galactose in the molar ratio ~ 2:3. The results of methylation studies and the analysis of ^1H and ^{13}C nmr spectra of the *O*-chain showed it to be identical with the *O*-chain of the *A. pleuropneumoniae* serotype 3 (ATCC 33590) (6) previously determined to have the structure:

→[3)-α-D-Glc*p*-(1→2)-β-D-Gal*f*-(1→6)-α-D-Gal*p*-(1→6)-β-D-Glc*p*-(1→3)-β-D-Gal*f*-(1→]

Serological cross-reactions between *A. pleuropneumoniae* serotypes 3, 6, and 8 have been reported (18). Our structural studies show that the apparent serotype cross-reactions could be due to the common epitopic features shared by the *O*-polysaccharide chains of these serotypes (6, 19). The study of the cross-reactions at the ultrastructural level using immunostabilization technique (20) also suggested that the observed cross-reactivity may be due to the somatic antigens. Only the capsules of serotypes 6 and 8 were completely cross-immunostabilized by the corresponding heterologous antisera when examined by transmission electron microscopy (20). The results of the present study show that although the CPS of serotypes 6 (21) and 8 have similar structural features, which probably contribute to the observed cross-reactivity, they are sufficiently distinct to allow the production of serotype specific antisera.

The recently synthesized iminium salt 8-acetamido-2,4,4,8-tetramethyl-3-azanium-bicyclo[3.3.1]non-2-ene perchlorate (ATABNEP) shows unusual reluctance to undergo hydrolysis. It was established that ATABNEP is not attacked by water in acid or neutral media but readily reacts in alkaline solutions yielding the corresponding imine by direct abstraction of the iminium proton. The imine crystallizes as a monohydrate. Crystals belong to the monoclinic space group $P2_1$ with a = 6.915(2) Å, b = 8.459(4) Å, c = 13.287(6) Å, β = 92.53(3)°. Crystal structure of this compound was determined by X-ray diffraction using direct methods and refined to an R factor of 5.6%. As expected, the organic molecule structure is practically the same as that of ATABNEP. The imine molecules are arranged in sheets parallel to the *ab* plane linked, within a sheet, through a net of hydrogen bonds via the water protons and the hydrogen atom of the acetamido group.

Key words: iminium salt, hydrolysis, X-ray diffraction, molecular structure.

J. A. CARAM, B. E. RIVERO, O. E. PIRO, E. G. GROS et C. M. MARSCHOFF. Can. J. Chem. **68**, 334 (1990).

Le perchlorate de 8-acétamido-2,4,4,8-tetramethyl-3-azanium-bicyclo[3.3.1]non-2-ène (ATABNEP) présente une remarquable résistance à s'hydrolyser. On a établi que l'ATABNEP ne réagit pas dans les milieux acides ou neutres, mais réagit par abstraction du proton du groupe iminium en solution alcaline, en donnant l'imine correspondante. Ce produit crystallise comme un monohydrat. La structure crystalline de ce composé a été étudié par diffraction des rayons X. Il appartient au groupe spatial monoclinique $P2_1$ avec a = 6,915(2) Å, b = 8,459(4) Å, c = 13,287(6) Å, β = 92,53(3)°. La structure a été déterminée par méthodes directes et affinée jusqu'à une valeur du facteur d'accord R de 5,6%. Comme attendu, la structure du produit d'hydrolyse est pratiquement la même que celle du sel d'origine. Les molécules d'imine sont arrangées en couches parallèles au plan *ab*, liées par des ponts hydrogène faisant intervenir les protons de la molécule d'eau et l'hydrogène du groupe acétamide.

Mots clés : sel iminium, hydrolyse, diffraction des rayons X, structure moléculaire.

Introduction

Iminium salts have received increasing attention during the last 15 years because of the important role they play in many reactions that occur both in the laboratory and in nature (1–3). However, potential applications of these compounds have been limited because, as is well known (4), the iminium group is quite sensitive to hydrolysis, yielding a secondary ammonium salt and a carbonyl compound. This reaction is quite fast and therefore iminium salts cannot be stored under ambient conditions.

We recently reported the synthesis of a new iminium salt, namely, 8-acetamido-2,4,4,8-tetramethyl-3-azanium-bicyclo-[3.3.1]non-2-ene perchlorate (ATABNEP) (5), which shows an unusual stability when exposed to the laboratory atmosphere. Moreover, the solid salt not only showed no changes after several days of being exposed to air but was also recrystallized from neutral aqueous solutions.

Because of this behaviour, ATABNEP is thus the first iminium compound, to our knowledge, that might be considered for practical uses and, in fact, it has been proposed that the dielectric properties of this and related compounds should be studied (6). It was, therefore, considered of interest to have a better understanding of the hydrolysis behaviour of this salt, particularly with regard to its pH dependence.

Experimental

In a first series of experiments, some crystals of ATABNEP were dissolved in 10% H_2SO_4 and refluxed for 1 h. Surprisingly enough, the organic salt was quantitatively recovered when the experiment was over. In another group of experiments ATABNEP was first dissolved in 10% H_2SO_4 and then 20% NaOH was added dropwise: when pH values higher than 7 were reached, a colourless precipitate was obtained. Following these preliminary observations, this product was synthesized under controlled conditions and its molecular formula was solved by means of the usual analytical techniques. X-ray diffraction analysis was employed in solving the crystal structure of the new compound.

Thus (1*S*,5*R*,8*R*) 8-acetamido-2,4,4,8-tetramethyl-3-aza-bicyclo-[3.3.1]non-2-ene perchlorate, obtained as described elsewhere (5) (0.722 g), was dissolved in 10% H_2SO_4 (20 mL) and 20% NaOH was

added dropwise until complete precipitation of a white product. The precipitate (0.378 g) was recrystallized from hexane.

Melting points are uncorrected. The IR spectrum was registered in KBr pellets using a Beckman IR-33 spectrophotometer. FT-NMR spectra (^{1}H and ^{13}C) were recorded at 100 MHz and 25.2 MHz with a Varian XL-100-15 spectrometer. Mass spectra were obtained at 70 eV (direct inlet) with a Varian-Mat CH7-A spectrometer interfaced to a Varian-Mat Data System 166 computer. X-ray data were obtained with a Huber four-circle diffractometer used with graphite monochromated MoKα radiation (λ = 0.7093 Å).

Results and discussion

The compound obtained had mp 155–156°C, $[\alpha]_D^{20}$ −144.1° (*c* 1.3, chloroform), and spectral data were as follows. IR: 3330 (OH), 3050 (NH), 1670 (C=N), 1650, 1560 (—N—C=O), 1300 (C—CO—NH···OH$_2$); ^{1}H NMR ($CDCl_3$–TMS), δ: 1.16 (3H, s, Me-4), 1.28 (3H, s, Me-4), 1.47 (3H, s, Me-8), 1.50–1.80 (8H, m, CH_2CH), 2.00 (3H, s, Me-C=O), 2.10 (3H, s, Me-C=N); ^{13}C NMR ($CDCl_3$–TMS), δ: 23.8 (*Me*-CO), 23.9 (Me-4), 24.3 (Me-4), 26.0 (C-6), 27.0 (Me-8), 29.3 (*Me*-C=N), 31.4 (C-7), 32.6 (C-9), 33.7 (C-5), 40.2 (C-1), 55.4 (C-4), 57.5 (C-8), 166.4 (C=N), 169.6 (C=O); MS (*m/z*, %): 236 (M^+, 37), 221 (*M* − 15, 12), 177 (*M* − 59, 35), 162 (177 − 15, 26), 150 (177 − 27, 29), 136 (177 − 41, 38), 122 ($C_8H_{12}N$, 82), 43 (C_2H_5N, 56), 42 (C_2H_4N, 100).

According to these results the solid was identified as a previously unreported imine, namely, 8-acetamido-2,4,4,8-tetramethyl-3-aza-bicyclo[3.3.1]non-2-ene (ATABNE), and the molecular formula $C_{14}H_{24}N_2O.H_2O$ and structure **2** were proposed in view of the following considerations.

The mass spectrum is almost identical to that of ATABNEP (5) and this strongly suggests that the structure of the new compound, after losing a fragment of 18 amu, is the same as that of compound **1** after losing the $HClO_4$ molecule. This conclusion is supported by the resonances at δ 1.16, 1.28, and 1.47 in the ^{1}H NMR spectrum, which indicate that the bicyclic structure of the original cation is maintained. The IR band at 1670 cm^{-1} points to the existence of an imine group, without signals of olefinic protons in the ^{1}H NMR spectrum, confirmed by the resonance at 166.4 ppm in the ^{13}C NMR spectrum. On the other hand, the IR band at 3330 cm^{-1} suggests the existence of O—H bonds, while those at 3050, 1650, and 1560 cm^{-1} correspond to the acetamide group and the one at 1300 cm^{-1} might be ascribed to the existence of a hydrogen bond with the amidic nitrogen, which approaches then the behaviour of a secondary amide.

Elemental analysis carried out on the crystals obtained agrees with this proposal as shown by the resulting data, which are given as follows. *Anal.* calcd. for $C_{14}H_{24}N_2O.H_2O$: C 66.10, H 10.30, N 11.01; found: C 66.07, H 10.34, N 10.91.

Structure **2**, as a monohydrate, was confirmed by X-ray diffraction analysis performed under the following conditions. A complete data set was obtained from a prismatic crystal of approximate dimensions 0.3 × 0.2 × 0.4 mm. The unit cell dimensions and orientation matrix for data collection were produced from 16 centred reflections by least-squares refinement. The reflections in the $\pm h$, $+k$, $-l$ reciprocal space quadrant having θ in the range 0–25° were measured by the ω-scan technique, working in the constant precision mode. Intensities of two standard reflections, which were monitored every 180 min, were essentially constant within 1% throughout the experiment.

The crystal structure was established from 935 independent reflections such that $I > 2\sigma(I)$. $\sigma(I)$ are based on counting statistics. Data were corrected for Lorentz, polarization, and extinction effects but not for absorption. The structure was solved employing direct methods to locate a fragment of the molecule. The remaining non-hydrogen atoms were positioned by isotropic least-squares refinement and difference Fourier syntheses. The two hydrogen atoms of the water molecule and some of the hydrogen atoms in the organic molecule were located in a difference Fourier synthesis phased on the positions of the non-hydrogen atoms. The remaining hydrogen atoms were located on stereochemical grounds. All hydrogen atoms were refined riding on the bonding atoms, with the following B_{iso} values (in Å^2): 6.2 (8) (CH and NH), 6.6 (9) (CH_2), 9.9 (7) (CH_3), and 6.2 (1) (H_2O). The quantity minimized was $M = \Sigma w[|F_o| - |F_c|]^2$ with $w = 0.85[\sigma^2(F_o) - 0.0028(F_o)^2]^{-1}$. The number of independent reflections per parameter was 4.8 and the final difference Fourier synthesis is essentially flat (maximum and minimum peaks were 0.24 and −0.28 e/Å^3, respectively). Final agreement factors were R = 5.6% and R_w = 6.1%.[6] The atomic dispersion scattering factors of Cromer and Waber (10) and the anomalous dispersion coefficients of Cromer and Ibers (11) were employed in the calculations. Most of these calculations were performed on a PDP 11/34 computer with the SHELX program (12). The projection was drawn with the program ORTEP (13).

Crystal data are as follows:

$C_{14}H_{24}N_2O.H_2O$ FW = 254.4

Monoclinic, space group $P2_1$, a = 6.915(2) Å, b = 8.459(4) Å, c = 13.287(6) Å, β = 92.53(3)°, V = 776.4(8) Å^3, z = 2, ρ_c = 1.088 g cm^{-3}, ρ_m = 1.05(1) g cm^{-3}, μ(MoKα) = 0.41 mm^{-1}, and F(000) = 280 electrons. Final positional parameters and equivalent isotropic temperature factors computed following Hamilton (7) are given in Table 1 for all non-hydrogen atoms. Bond lengths and bond and torsional angles for these atoms are listed in Table 2 and interatomic distances and angles involving the hydrogen bonds are shown in Table 3. In Fig. 1, a schematic

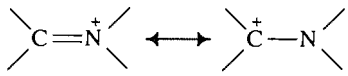
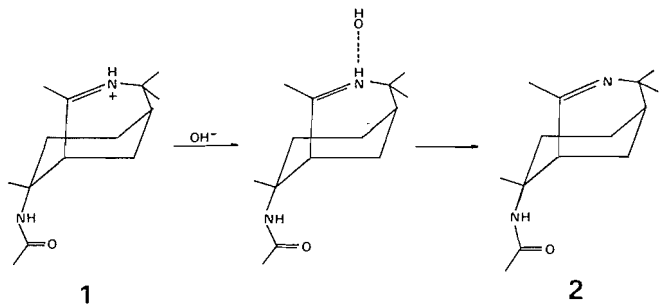
drawing of the molecule with the numbering of the heavy atoms is given, while in Fig. 2 a stereoscopic view showing the structure and crystal packing of the new imine, including H-bonding atoms, is displayed.

The six-carbon ring of the imine has a well-defined chair configuration with a mean C—C distance of 1.53(3) Å and a mean C—C—C angle of 111(3)°. The other ring, which contains the imine group, has five of its atoms, i.e., C(1), C(2), N(3), C(4), and C(5), as well as the substituting carbon C(10) almost in the same plane (within 0.06 Å). As expected, these structural data are in very close agreement with those obtained for the organic cation in the unhydrolyzed salt (9). Crystal analysis also shows that the imine molecules are arranged in sheets parallel to the *ab* plane, with molecules linked to each other within the sheet through a network of hydrogen bonds involving the water protons and the hydrogen in the acetamido group (see Fig. 2 and Table 3). Neighbouring sheets are held together by van der Waals interaction.

Regarding the mechanism through which compound **2** is formed, it must be recalled that the electronic structure of the iminium group is best described by admitting contributions from two resonance forms, which correspond, respectively, to a pure iminium cation and a carbonium ion (8):



Thus, formation of the imine could proceed via direct abstraction of the iminium proton or, alternatively, by addition of an OH group on the carbon, followed by the loss of a water molecule. The much larger contribution of the iminium form in ATABNEP (9) suggests that the first path should be preferred. This conclusion is confirmed by theoretical calculations,[7] which indicate that the activation energy for OH addition is much larger than that for H abstraction. Consequently, Scheme 1 is proposed as a description for the reaction mechanism.



SCHEME 1

The present study shows that ATABNEP is unusually stable when compared to other iminium compounds, a fact that must be related to the bicyclic nature of the organic cation, which leads to low contribution of the carbonium ion resonance form (9). This, in turn, suggests that related iminium salts, obtained from the same monoterpenes but employing different nitriles, should also be stable to hydrolysis and, thus, able to be stored and handled without special care. This conclusion has been experimentally confirmed in several cases, as will be reported in future papers.

Computations and measurements of the structures and conformations of 2- and 3-fluorobenzaldehyde in the gas and in solution

TED SCHAEFER AND CRAIG S. TAKEUCHI
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received September 7, 1989

TED SCHAEFER and CRAIG S. TAKEUCHI. Can. J. Chem. **68**, 339 (1990).

Precise ^1H and ^{19}F nuclear magnetic resonance chemical shifts and spin–spin coupling constants are reported for 4 mol% solutions of 2-fluorobenzaldehyde (2FB) and 3-fluorobenzaldehyde (3FB) in $CS_2/C_6D_{12}/TMS/C_6F_6$ and acetone-d_6/TMS/C_6F_6 solvent mixtures at 300 K. A small amount of the *O-cis* conformer of 2FB is present even in the nonpolar solvent mixture, corresponding to a free energy difference of 7.6(3) kJ/mol between the planar *O-cis* and *O-trans* conformers. In the polar solvent, this number decreases to 4.5(2) kJ/mol. The *O-cis* and *O-trans* conformers of 3FB have very similar abundances in the two solvent mixtures, the former being favored by a free energy difference of 0.38(4) kJ/mol in the nonpolar medium and, unexpectedly, considering its highly polar nature, by only 0.27(4) kJ/mol in the polar environment. STO-3G MO computations, with geometry optimization, of the internal rotational potentials of 2FB and 3FB confirm the planarity of the *O-cis* conformer of 2FB, that is, that the planar form is more stable than a somewhat twisted conformer. 6-31G MO calculations for the four planar conformers yield structures of potential use in the fitting of rotational spectra in the vapor. Extrapolation of the ^1H nmr data for 2FB implies a free energy difference of 11.5 ± 0.6 kJ/mol at 300 K in the vapour favoring the *O-trans* form, midway between the two theoretical estimates. The present experiments and computations are compared with the latest rotational, vibrational, and electronic spectra and with other assessments of the relative conformer stabilities in the vapor and in solution.

Key words: NMR for 2- and 3-fluorobenzaldehyde; conformations in solution and vapor, for 2- and 3-fluorobenzaldehyde; MO calculations, 2- and 3-fluorobenzaldehyde.

TED SCHAEFER et CRAIG S. TAKEUCHI. Can. J. Chem. **68**, 339 (1990).

Opérant à 300 K, dans des mélanges de solvant $CS_2/C_6D_{12}/TMS/C_6F_6$ et acétone-d_6/TMS/C_6F_6, on a déterminé d'une façon précise les déplacements chimiques et les constantes de couplage spin–spin observées des spectres de résonance magnétique nucléaire du ^1H et du ^{19}F de solutions à 4 mol% de 2-fluorobenzaldéhyde (2FB) et de 3-fluorobenzaldéhyde (3FB). Même dans le mélange de solvants non-polaires, on peut observer la présence de faibles quantités du conformère *O-cis* du produit 2FB; on peut donc établir que la différence d'énergie entre les conformères *O-cis* et *O-trans* est de 7,6(3) kJ/mol. Dans le solvant polaire, cette valeur diminue à 4,5(2) kJ/mol. Les abondances relatives des conformères *O-cis* et *O-trans* du produit 3FB sont assez constantes dans les deux mélanges de solvants; le premier est favorisé par une différence d'énergie libre de 0,38(4) kJ/mol dans le milieu non-polaire et par seulement 0,27(4) kJ/mol dans le milieu polaire ce qui est très surprenant compte tenu de la nature très polaire de ce mélange de solvants. Des calculs d'OM STO-3G, avec optimisation de la géométrie, ont été effectués sur les potentiels à la barrière de rotation interne des composés 2FB et 3FB; les résultats de ces calculs confirment le fait que le conformère *O-cis* du produit 2FB est plan, c'est à dire que la forme plane est plus stable qu'un conformère légèrement déformé. Des calculs d'OM au niveau 6-31G effectués sur les quatre conformères plans fournissent des structures de potentiel qui ont été utilisées pour ajuster le spectre de rotation en phase vapeur. Une extrapolation des données de la rmn du ^1H pour le composé 2FB implique que, à 300 K, en phase gazeuse la différence d'énergie libre favorise la forme *O-trans* par 11,5 ± 0,6 kJ/mol, valeur à mi-chemin entre les deux évaluations théoriques. On compare les expériences et les calculs réalisés ici avec les derniers spectres de rotation, de vibration et électroniques disponibles ainsi qu'avec d'autres évaluations des stabilités relatives des conformères tant en phase vapeur qu'un solution.

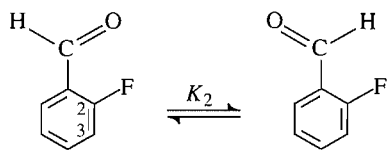
Mots clés : RMN de 2- et 3-fluorobenzaldehyde; conformations, en solution et en phase vapeur, de 2- et 3-fluorobenzaldéhyde; calculs d'OM sur 2- et 3-fluorobenzaldéhyde.

[Traduit par la revue]

Introduction

The conformational behaviour of 2-fluoro- and 3-fluorobenzaldehyde is again a topic of discussion (1) in connection with the microwave spectra of these compounds in the gas phase. Only the spectrum of the *O-trans* conformer is detected (1) for 2-fluorobenzaldehyde (2FB). From relative intensity measurements of certain rotational transitions in the spectrum of 3-fluorobenzaldehyde (3FB), the free energy difference between the conformers is assessed at 1.25 ± 0.84 kJ/mol at 260 K, the *O-cis* form being present in greater abundance (1). The microwave spectra also establish the planarity of the three detected conformers (1). These conclusions follow a long history of disagreement about the conformational equilibria of these compounds.[1]

[1]In the following discussion, only the latest reference to a given technique is cited; the disagreements have been repeatedly rehearsed and can be found in the present citations.



The latest (2) of numerous dipole moment measurements are interpreted to mean that, in CCl_4 at 298 K, 3FB exists as a roughly equimolar mixture of the two conformers, the *O-cis* form being present to the extent of 53 ± 5%. The *O-trans* conformer of 2FB is considered to be strongly and probably exclusively favoured (2).

Perhaps the most marked disagreements about conformational stabilities of 2FB and 3FB arose from vibrational spectra. The most recent data (3) for the liquids and for solutions imply the existence of both conformers for each of 2FB and 3FB, but afford no evidence concerning their relative proportions.

In acetone-d_6 solutions at 303 K containing 30 mol% of the

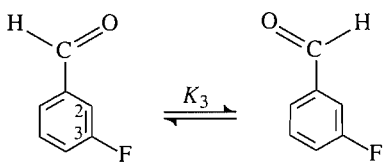
[f]The solvent dependence of $^nJ(^1H, ^{19}F)$ in aromatic systems is documented (28).

benzaldehyde derivatives, stereospecific long-range spin–spin coupling constants (4) yield an 86% abundance of the *O-trans* form of 2FB, that is, K_2 above is 6.1; K_3 is found as unity for 3FB (4). However, at 123 K, the ^{13}C nmr spectra of 0.5 M solutions of 2FB and 3FB in a mixture of CCl_2F_2 and $CHCl_2F$ provide no evidence for the *O-cis* conformer of 2FB. The fraction of the *O-trans* form of 3FB is 0.26 (K_3 = 0.35), the interconversion of the two conformers being slow on the nmr chemical shift time scale at 123 K (5).



The emissive and absorptive $n\pi^*$ electronic spectra of 2FB and 3FB in the vapour phase (5), studied as to their vibrational fine structure, are analyzed to mean that the *O-trans* conformer is dominant for both compounds in the ground electronic state. A disagreement with the microwave spectrum of 3FB is apparent.

The most recent semiempirical and, apparently, geometry unoptimized STO-6G computations for 3FB predict (7) equal energies for the two planar conformers. The STO-6G calculations have the *O-cis* conformer of 2FB as 5.1 kJ/mol more stable than the *O-trans* (7), whereas the INDO method has the latter as more stable by 3.9 kJ/mol (4).

Three comments are appropriate. First, the four conformers in question have significantly different dipole moments so that perturbations of the conformational equilibria by the solvent are probable; these are likely to be most easily probed by the highly precise nmr measurements possible with modern instruments. Second, *ab initio* molecular orbital calculations with a minimal basis set (8) happen to be reliable for the internal motion in benzaldehyde and may well be useful for the prediction of the relative energies of the planar conformers of 2FB and 3FB *if* geometry optimization is included. Third, the microwave spectra have been fit to assumed structures (1); here 6-31G computations may well provide a fairly reliable basis for the refinement of such structures (9).

Accordingly, this paper reports precise ^{1}H nmr and ^{19}F nmr spectral parameters for dilute solutions of 2FB and 3FB in the nonpolar solvent mixture, CS_2/C_6D_{12}, and in the polar solvent, acetone-d_6. In addition, geometry optimized STO-3G and 6-31G MO structures and energies are given for the two compounds. Comparisons with solution and gas phase data are thereby facilitated.

Experimental

Dilute solutions (see Table 1) of 2FB and 3FB (Aldrich) in CS_2/C_6D_{12}/TMS/C_6F_6 and acetone-d_6/TMS/C_6F_6 solvent mixtures were filtered into 5 mm o.d. nmr sample tubes. The solutions were then degassed by numerous freeze–pump–thaw cycles and the sample tubes were sealed under vacuum. The ^{1}H nmr and ^{19}F nmr spectra were

For personal use only.

acquired on a Bruker AM300 spectrometer, in a manner previously described (10), at a probe temperature of 300 K.

STO-3G (11) and 6-31G MO (12) computations employed the program Gaussian 86 (13) on an Amdahl 5870 system. The geometry optimization procedures allowed all bond angles and lengths to vary, with the constraint, however, that the nuclei of the benzene moiety remain in a plane. The STO-3G energies were computed in steps of 15°, between 0° and 180°, in the angle of the rotation about the exocyclic C_{sp^2}—C_{sp^2} bond. The minimal basis set happens to reproduce the internal barrier to rotation in benzaldehyde much more reliably than do the split-valence bases, even those with polarization functions (8). The 6-31G computations were done for the planar conformers only.

Results and discussion

The nmr spectra were analyzed with the program Numarit (4). The ensuing chemical shifts and spin–spin coupling constants appear in Table 1. The signs of the coupling constants are known from the earlier experiments (4) at lower magnetic field intensities. Figure 1 demonstrates the resolution obtainable in the spectra.

The conformational equilibria in solution

(i) 2-Fluorobenzaldehyde

The crucial coupling constant is ^5J(H, CHO) over five bonds and involving the aldehydic and ring protons. A recent analysis of the ^{1}H nmr spectra of benzaldehyde in the same solvent mixtures (apart from a tiny amount of C_6F_6) as in Table 1 gave ^5J(H, CHO) as 0.431(2) and 0.430(1) Hz in CS_2/C_6D_{12} and acetone-d_6, respectively (15). The methyl group-replacement procedure (16) showed (15) that ^5J(H, CHO) is a pure σ electron coupling (for these essentially planar benzaldehyde derivatives) and hence ^5J(H-5, CHO) is expected to vanish in the *O-cis* forms above, as it does in 2-hydroxybenzaldehyde (17) and, from recent unpublished work in this laboratory, in 3-fluoro-2-hydroxybenzaldehyde. In each of the latter two compounds, the strong intramolecular hydrogen bond ensures the exclusive existence at 300 K of the conformation analogous to *O-cis* above. In benzaldehyde, therefore, it is safe to write ^5J(H, CHO) as 0.861(5) Hz for an all-*trans* arrangement of the intervening bonds, applicable to either solvent.

For 2FB in CS_2/C_6D_{12}, the sum of the two ^5J(H, CHO) values is 0.869(2) Hz. The salient fact is the finite value of ^5J(H-3, CHO); at 0.039(1) Hz it demonstrates the presence of a small proportion of the *O-cis* form. If ^5J(H, CHO) for this form is taken as 0.869(2) Hz, then 4.5% of the 2FB molecules exists as the *O-cis* conformer, corresponding to a K_2 of 21.3(1.3) at 300 K and a free energy difference of 7.6(2) kJ/mol between the *O-cis* and *O-trans* forms. This conclusion assumes that the fluorine substituent does not perturb the extrema in ^5J(H, CHO). As pointed out above, all available evidence indicates the absence of ^5J(H, CHO) in the non-zigzag bond arrangement for planar conformers. However, suppose that the fluorine substituent, appended to the coupling pathway for ^5J(H-3, CHO) in 2FB, increases the extremum in ^5J(H-3, CHO) to 0.877 Hz, leaving the extremum in ^5J(H-5, CHO) unchanged from its value in benzaldehyde. Then the fractional population of the *O-trans* conformer becomes 0.830(1)/0.861(5) = 0.964(7) and that of the *O-cis* conformer is 0.039(1)/0.877 = 0.044(1), compatible within experimental error. It appears that a free energy difference of 7.6 ± 0.3 kJ/mol will encompass uncertainties in the extrema of ^5J(H, CHO).

In acetone-d_6 solution, the sum of the ^5J(H, CHO) numbers is 0.850(2) Hz, 0.01 Hz smaller than for benzaldehyde. Furthermore, ^5J(H-3, CHO) has increased to 0.117(1) Hz, indicating a significant enhancement of the population of the *O-cis* conformer. Qualitatively, it is expected that the more polar *O-cis* form, whose dipole moment is estimated from group moments as 4.35 D (2), as compared to the estimate of 3.15 D for the *O-trans* form, will be stabilized by the polar acetone-d_6 (18); a reaction field model in first order (18), treating the medium as a dielectric continuum, implies that the *O-cis* conformer is stabilized by 2.7 kJ/mol when 2FB transferred from CS_2 to acetone-d_6. The ^5J(H, CHO) values are in rough agreement with this implication, to be seen as follows.

If the extrema in ^5J(H, CHO) are both 0.850(2) Hz, the sum of the two values in acetone-d_6 solution, then the fractional population of the *O-trans* conformer is 0.733(1)/0.850(2) or 0.862(4) and that of the *O-cis* conformer is 0.117(1)/8.50(2) or 0.138(2). Hence, at 300 K, the free energy difference is 4.6 kJ/mol. However, if the extremum in ^5J(H-5, CHO) is unchanged from its value in benzaldehyde, then the population of the *O-trans* form becomes 0.733(1)/0.861(5) or 0.851(5) and hence that of the *O-cis* form is 0.149(5). This result entails a value of 0.785 Hz for ^5J(H-3, CHO) in the *O-cis* conformer, just the opposite trend assumed above for the CS_2 solution. The free energy difference is now 4.3 kJ/mol. Suppose the extremum in ^5J(H-3, CHO) is 0.877 Hz. Then the population of the *O-cis* conformer becomes 0.133 and implies a value of 0.846 Hz for the extremum in ^5J(H-5, CHO). The free energy difference is now 4.7 kJ/mol. It seems that a free energy difference of 4.5 ± 0.2 kJ/mol is a reliable value. The stabilization by 3.1 ± 0.5 kJ/mol of the *O-cis* conformer in the polar solvent, *relative* to the nonpolar solvent, agrees reasonably well with the reaction field model in first order (dipole terms only). This result may well be coincidental because quadrupolar terms (18) in the reaction field model are not small. However, as demonstrated in calculations for 2-pyridine aldehyde (19), uncertainties in the dipole moments of the individual conformers and in the origin for the estimation of quadrupole moments, themselves calculated from dipole vector components, not to speak of other corrections (18), introduce errors as large as 2.5 kJ/mol into the

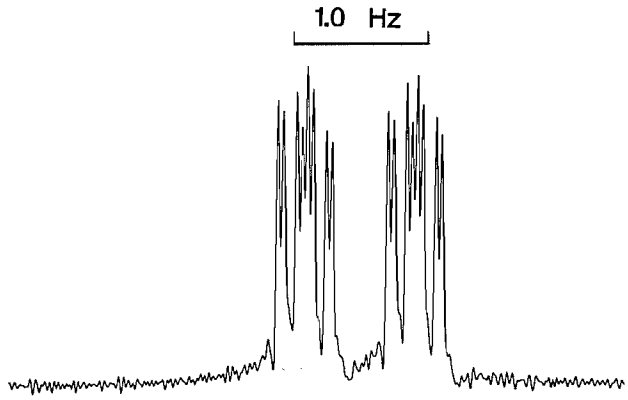

FIG. 1. The aldehyde proton magnetic resonance spectrum, at 300.135 MHz and 300 K, is shown for a 4.0 mol% solution of 2-fluorobenzaldehyde in a $CS_2/C_6D_{12}/TMS/C_6F_6$ solvent mixture. The 16 peaks arise from spin–spin coupling to H-3, H-5, H-6, and F-2 (see Table 1 for the magnitudes of the coupling constants). The small splitting of 0.039(1) Hz, as given by the spectral analysis, arises from an interaction over five bonds with H-3. This splitting is also cleanly resolved in the ^{1}H nmr spectrum of the latter, which is relatively isolated from the spectra of the other ring protons (Table 1) and does not display artifacts near the base line due to bad field shimming; such artifacts are evident in the figure above.

computed differences in the solvation energies for the two solvents. Hence the calculations were not pursued further. It may be noted that the dipolar and the quadrupolar interactions both act to increase the stability of the *O-cis* form of 2FB in polar solvents so that, qualitatively, the model agrees with the present experimental data.

The dielectric constant of the $CF_2Cl_2/CHFCl_2$ mixture at 123 K will lie between that of the CS_2 and acetone-d_2 solutions. Therefore an energy difference of, say, 5 kJ/mol between the conformers in the former mixture corresponds to a population of less than 1% for the *O-cis* form at 123 K. Its absence (5) in the ^{13}C nmr spectrum is therefore anticipated.

The discussion in this section has been somewhat elaborate; it is meant to illustrate the reliability of precise ^5J(H-5, CHO) numbers in applications to conformational analysis.

3-Fluorobenzaldehyde

In 3FB the substituent is further removed from the coupling pathway for ^5J(H, CHO) and should therefore minimally perturb its extreme value. In CS_2 solution, ^5J(H-5, CHO) is 0.398(1) Hz (Table 1). If ^5J(H-5, CHO) is 0.851(5) Hz for the *O-trans* conformer, as in benzaldehyde, then its population is 0.462(4) and K_3 is 0.859(14). The free energy difference at 300 K follows as 0.38(4) kJ/mol, the *O-cis* conformer being favoured. For the acetone-d_6 solution, this difference becomes 0.27(4) kJ/mol.

(iii) Comparison with other conformational data

In CCl_4 solution the population of the *O-trans* conformer of 3FB was determined as 0.47(5) from dipole moment measurements (2). The intensities of the rotational transitions in the gas phase gave the free energy difference as 1.25 ± 0.84 kJ/mol at 260 K (1). Within experimental error this number agrees with that for the CS_2 solution at 300 K. One might have expected that the *O-cis* conformer, with an estimated (2) dipole moment of 3.47 D, would be less stable in the gas phase than the *O-trans* form, with an approximate dipole moment of 1.73 D; the arrangement of the bond dipoles in the former should lead to an electrostatic repulsion. Worse, the polar acetone-d_6 solution causes an insignificant change in the conformer distribution. In the reaction field model, the quadrupolar now opposes the dipolar term and acts to stabilize the *O-trans* form (19). It seems rather unlikely that the two terms cancel to the same extent in the two solvents. Within experimental error, the microwave, dipole moment, and coupling constant data imply a state-independent conformational equilibrium for 3FB. The striking exception to this implication is the ^{13}C nmr result at 123 K (5). The population of the *O-trans* conformer, being 0.26, has the free energy difference between the conformers as 2.6 kJ/mol, *O-cis* favored.

An attempt at the resolution of the disparate results for 3FB goes as follows. If all these data are treated on an equal footing it follows that the enthalpy of the *O-trans* form of 3FB is 4.10 ± 0.52 kJ/mol larger than that of the *O-cis* form and, furthermore, that its entropy is 11.8 ± 2.2 J deg^{-1} mol^{-1} larger. This result is unlikely (see the molecular orbital calculations below and, for example, the various contributions to the entropy of benzaldehyde at 298.15 K (20)). One possibility is that, for the 0.5 M solution of 3FB in $CF_2Cl_2/CHFCl_2$ at 123 K, the much more polar *O-cis* conformer undergoes a significant degree of self-association, hence its *apparent* lower enthalpy and entropy in the egalitarian approach above. Another possibility is that the more polar *O-cis* form is more stabilized by specific dipole–dipole interactions with solvent molecules than is the *O-trans* form (18), also compatible with the *apparent* lower entropy of the former. It is also noted that on solidification (in a mull) no significant change occurs in the vibrational spectrum of 3FB, implying no change in the conformational equilibrium found in the liquid (3). A third possibility concerns the well-known π complexes formed between benzene and the polar C—H bond in chloroform molecules. It is therefore conceivable that, at 123 K, the $CHFCl_2$ molecules in the solvent mixture preferentially interact with the π electron cloud of the *O-cis* conformer of 3FB, thereby increasing its population.

TABLE 2. STO-3G MO energies for various conformations of 2-fluoro- and 3-fluorobenzaldehyde

θ/degrees[a]	2FB	3FB	θ/degrees	2FB	3FB
0	0.000[b,c]	0.000[b,c]	105	18.386	21.697
15	1.203	1.483	120	13.907	17.408
30	4.614	5.616	135	7.858	11.537
45	9.618	11.477	150	1.881	5.692
60	14.935	17.464	165	−2.441	1.551
75	18.892	21.814	180	−3.999	0.019
90	20.185	23.332			

[a]θ = 0° corresponds to the *O-cis* conformer for both compounds.
[b]Relative energies in kJ/mol, the *O-cis* conformer having a total energy of −436.578 586 au for 2FB and −436.580 023 au for 3FB.
[c]The relative energies are fit by Fourier series, as given by eqs. [1] and [2] of the text.

As to 2FB, the ^5J(H-5, CHO) data leave no doubt of the existence of the *O-cis* conformer in both polar and nonpolar solutions at 300 K, as do the vibrational spectra of the liquid (3). The dipole moment in CCl_4 (2) at 298 K is compatible with the result for the CS_2 solution in the present work. In the vapor phase the fraction of the *O-cis* conformer at 260 K, judging by ^5J(H, CHO) in the CS_2 solution, will be less than 4% and perhaps not detectable by microwave spectroscopy (1). This matter is further discussed below.

Molecular orbital calculations

(i) STO-3G MO internal barriers

Table 2 presents the energies of 2FB and 3FB as a function of the internal angle of rotation about the exocyclic C_{sp^2}—C_{sp^2} bond. According to this minimal basis, the planar conformers do indeed represent minima in the internal potential, even for the *O-cis* conformer of 2FB, calculated as 4.00 kJ/mol higher in energy than the *O-trans* form. The two planar conformers of 3FB are computed to be essentially isoenergic.

The energies in Table 2 can be fit to composite sinusoidal potentials, as in eq. [1] for 2FB and in eq. [2] for 3FB.

$$[1]\quad V/\text{kJ mol}^{-1} = -3.28\sin^2(\theta/2) + 22.23\sin^2\theta - 0.67\sin^2(3\theta/2) - 0.36\sin^2 2\theta - 0.06\sin^2 3\theta$$

$$[2]\quad V/\text{kJ mol}^{-1} = 0.02\sin^2(\theta/2) + 23.38\sin^2\theta + 0.03\sin^2(3\theta/2) - 0.17\sin^2 2\theta - 0.08\sin^2 3\theta$$

In these equations, θ is zero for the *O-cis* conformer and the standard error in the fit is 0.04 kJ/mol in each term of eq. [1] and 0.03 kJ/mol in each term of eq. [2]. These numbers may be compared with the STO-3G computations for benzaldehyde (8), which yield the twofold term, in $\sin^2\theta$, as 24.28(3) kJ/mol and the fourfold term, in $\sin^2 2\theta$, as −0.30(3) kJ/mol. According to Table 2, the internal barriers in 2FB and 3FB are both somewhat lower than in benzaldehyde (8). The computed decrease of 1.0 kJ/mol for 3FB roughly agrees with some free energies of

[a]Not informative about the actual population.

[b]On the assumption that differences in zero point energies and corrections for enthalpies at finite temperatures are negligible. See ref. 29, for example, for indications of how such corrections could be made, given enough information. In our opinion, these corrections would not alter the populations by more than about 5%.

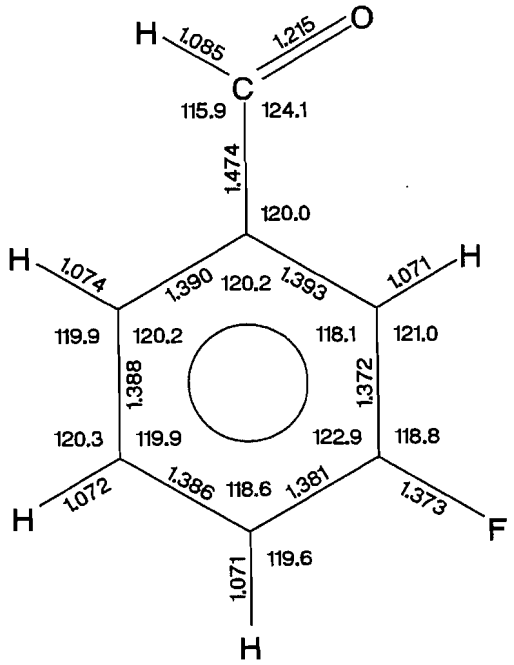

FIG. 2. The 6-31G MO geometry of the *O-cis* conformer of 3-fluorobenzaldehyde is shown. Its total energy is computed as −442.120 139 au. The geometry within the aldehyde group is not very different from that computed for benzaldehyde (8). The geometry of the *O-trans* conformer, not shown, is very similar to that of the *O-cis* form, apart from the orientation of the CHO group.

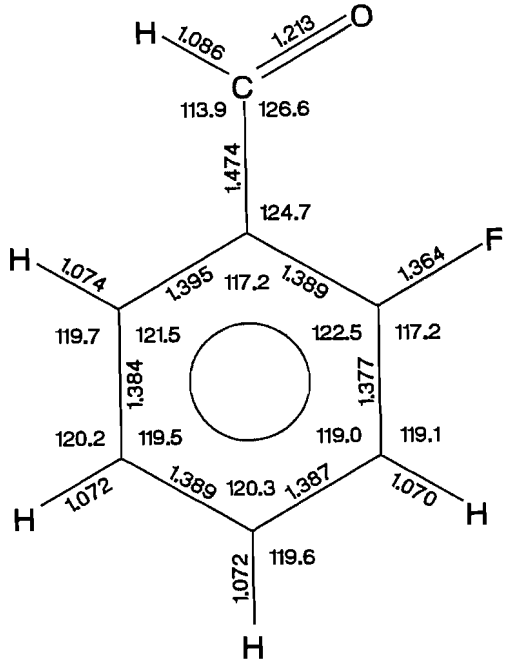

FIG. 3. The 6-31G structure of the *O-cis* conformer of 2-fluorobenzaldehyde displays a geometry in the vicinity of the aldehyde group indicative of strong repulsion between the C=O and C—F bonds, as expected. Its total energy, at −442.112 822 au, is 20.22 kJ/mol higher than that calculated for the *O-trans* conformer.

activation measured in solution (5, 21). No experimental value for the internal barrier is known for 2FB.

(ii) STO-3G and 6-31G MO energies of the planar conformers and extrapolation from solution

The STO-3G energy difference between the two conformers of 2FB, at 4.0 kJ/mol, is too small to explain the apparent absence of the *O-cis* conformer in the vapor phase. The 6-31G MO energies have the *O-trans* conformer of 2FB as 20.2 kJ/mol more stable than the *O-cis*. A simple extrapolation of a plot of the log of the equilibrium constants in the CS_2 and acetone-d_6 solutions versus $(\varepsilon - 1)/(2\varepsilon + 1)$, where ε is the dielectric constant, implies a K_2 of 100 at 300 K in the vapor phase, that is, for $\varepsilon = 1$. The reaction field model actually yields free energy differences (22, 23), so that this estimate is reasonable in principle. Allowance for uncertainties in the dielectric constants of the dilute solutions in Table 1, and for small correction terms to the dielectric function used above (examine in detail eq. 13.18 in ref. 18 and the many examples), suggests that K_2 in the vapor is 100 ± 20. Hence the free energy difference at 300 K in the vapor for 2FB is 11.5 ± 0.6 kJ/mol, *O-trans* more stable. If the entropy difference between the conformers is small, then K_2 is 200 ± 50 at 260 K, accounting for the absence of the microwave spectrum of the *O-cis* conformer at this temperature. The experimental estimate above lies midway between the two theoretical energy differences.

The essentially equal stabilities of the two planar forms of 3FB at the STO-3G level of MO theory, while the 6-31G basis

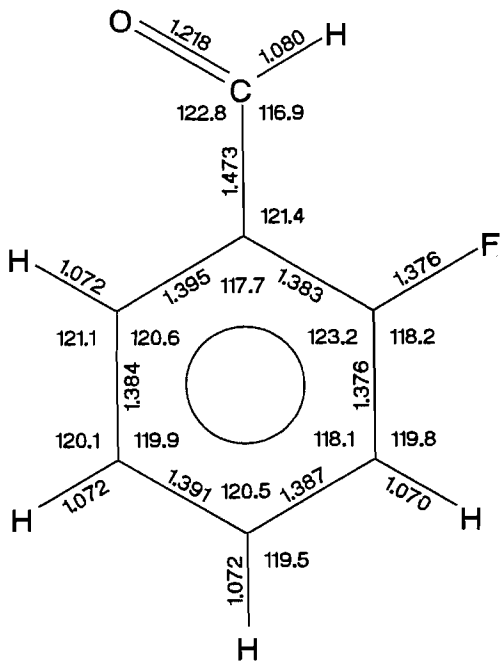

FIG. 4. The 6-31G structure of the *O-trans* conformer of 2-fluorobenzaldehyde is the one relevant to spectroscopic studies in the vapor phase, it probably being about 11.5 kJ/mol more stable than the *O-cis* form (see text).

implies the *O-trans* form as more stable by 0.12 kJ/mol, are not congruent with the microwave data (Table 3) unless the latter assumed somewhat incorrect dipole moment components. The $n\pi^*$ electronic spectra (6), in contrast to the microwave spectra, imply a greater abundance of the *O-trans* form (temperature not given). The coupling constants in Table 1 indicate very nearly equal populations of the two conformers in the CS_2 and acetone-d_6 environments (Table 3) and therefore that the conformer ratio will be the same in the vapor. This result is compatible with the theoretical stabilities.

(iii) The 6-31G MO geometries

These are given in Figs. 2–4 and should be useful to molecular spectroscopists, if it is remembered that the C—F bond length is computed as too long by about 0.02 A (24) with the 6-31G basis. The bond angles in the ring are probably reliable (8, 24–27).

(iv) Dipole moments

Table 4 collects some theoretical dipole moments for the planar conformers of 2FB and 3FB and also gives those estimated from group moments. To assess the reliability of these numbers, it will be assumed that the populations of the *O-cis* and *O-trans* conformers in CCl_4 solution are the same as those in the CS_2 solutions (Table 3). This assumption is probably correct to within one or two percent. Immediately clear is the underestimate of the dipole moments by the STO-3G and a corresponding overestimate by the 6-31G basis. As it turns out, the mean of the dipole moments of a conformer given by the two basis sets is very nearly correct. Thus, the dipole moment for 2FB in CCl_4 solution is then predicted as 3.12 D, as measured, while that for 3FB is predicted as 2.61 D, the measured value being 2.80 D. The moments obtained from INDO MO calculations (4) yield predicted dipole moments in solution that are rather close to experiment.

Discussions (30, 31) about the relative merits of the various basis sets for the computation of charge distributions in aromatic systems are available. Of course, the computed dipole moments depend on the way in which the overlap populations are divided among the atomic sites; the standard Mulliken procedure is used here.

Synthesis and characterization of a new crystalline tin(IV) arsenophosphate ion exchanger

K. V. SURENDRA NATH AND S. N. TANDON[1]

Department of Chemistry, University of Roorkee, Roorkee-247 667, India

Received May 6, 1989

K. V. SURENDRA NATH and S. N. TANDON. Can. J. Chem. **68**, 346 (1990).

A new crystalline layered inorganic ion exchanger tin(IV) arsenophosphate with the formula $Sn(HAsO_4)(HPO_4).H_2O$ has been prepared by refluxing the amorphous precursor. This exchanger has been characterized by X-ray powder pattern, chemical analysis, IR spectra, and thermal dehydration. Its ion exchange behaviour towards sodium ions is reported. The exchanger has an exchange capacity of 5.36 mequiv./g for Na^+. The performance of tin(IV) arsenophosphate is compared with crystalline tin(IV) phosphate and arsenate.

Key words: cation exchanger, crystalline tin(IV) arsenophosphate, ion exchange, thermal behaviour, X-ray studies.

K. V. SURENDRA NATH et S. N. TANDON. Can. J. Chem. **68**, 346 (1990).

En portant au reflux son précurseur amorphe, on a préparé un nouvel arsénophosphate d'étain(IV) cristallin qui peut agir comme échangeur d'ions inorganique et dont la formule est $Sn(HAsO_4)(HPO_4).H_2O$. On a caractérisé cet échangeur par le patron de diffraction des rayons-X par sa poudre, par une analyse chimique, par son spectre infrarouge et par une déshydratation thermique. On a déterminé son comportement comme échangeur d'ions et il possède une capacité d'échange de 5,36 méquiv./g de Na^+. On a comparé la performance de l'arsénophosphate d'étain(IV) à celles des phosphate et arsénate d'étain(IV).

Mots clés : échangeur de cations, arsénophosphate d'étain(IV) cristallin, échange d'ions, comportement thermique, études par rayons-X.

[Traduit par la revue]

Introduction

Over the years efforts have been directed towards synthesizing crystalline inorganic ion exchangers of the type $M(IV)(HXO_4)_2.H_2O$ (M = tetravalent metal and X = P, As), primarily for a better understanding of their ion exchange reactions (1, 2). These materials also have great potential for use as membranes for proton conduction, as superion conductors and as catalysts (1, 3). Crystalline materials are preferred over amorphous exchangers because of their high ion exchange capacity and resistance towards hydrolysis.

Every layered material is expected to have its own characteristic behaviour towards diffusion of the counter ions and thermal properties. However, among several known insoluble acid salts of tetravalent metals, α-layered zirconium phosphate (α-ZrP) and its other salt forms have received the maximum attention. In this series of compounds two new mixed layered materials, namely, zirconium–titanium phosphate (4, 5) and zirconium arsenophosphate (6) have been synthesized and studied for their ion exchange properties. These mixed salts are reported to be isomorphous with the parent single salts, nevertheless, they do show some variations in ion exchange and thermal properties. α-Zirconium arsenophosphate is obtained in almost complete miscible phases though it contains two anions of different sizes.

Ion exchange studies on α-tin(IV) phosphate (α-SnP) and α-tin(IV) arsenate (α-SnAs) (7) reveal that they behave more or less in a similar fashion but in some respects differently from α-ZrP and other similar compounds. Thus, it is of sufficient interest to synthesize crystalline tin(IV) arsenophosphate to determine how the presence of two anions of different dimensions affects the crystalline structure, vis-a-vis the ion exchange and thermal properties of the material. Crystalline tin(IV) arsenophosphate has been synthesized and the reproducibility and chemical stability of the exchanger checked. Its ion exchange behaviour towards sodium ions is reported together with phase changes which occur at different degrees of exchange and temperatures. The results thus obtained have been compared with those of α-SnP and α-SnAs.

[1]To whom correspondence should be addressed.

Experimental

Chemicals

All the chemicals used were analytical grade.

Preparation of the exchangers

(i) Tin(IV) hydrogen arsenate hydrogen phosphate

A 250 mL of 0.30 *M* $SnCl_4$ solution was added under stirring at room temperature to a 250 mL solution containing 15 mL of 14.5 *M* H_3PO_4 and 34.5 g of As_2O_5. A white gel was immediately formed. To it 250 mL of 15.5 *M* HNO_3 were added and the slurry was refluxed for 100 h. The solid thus obtained was filtered off, washed with distilled water till pH 4.5, and dried over $CaCl_2$ under vacuum to constant weight.

(ii) Tin(IV) hydrogen arsenate and tin(IV) hydrogen phosphate

These were prepared as described (6) by refluxing the slurries obtained by taking As/Sn = 2 and P/Sn = 30 molar ratios in over all 4 *M* HNO_3 for 100 h.

Analytical procedures

The composition of the tin(IV) arsenophosphate (SnAsP) samples was determined as follows: About 300 mg of the exchanger was boiled in 25 mL of 1.0 *M* NaOH; 10 mL of concentrated HCl was added to ensure complete solubility. This solution was then diluted to 100 mL with distilled water. Sn, As, and P contents were determined using Inductively Coupled Plasma-Atomic Emission Spectrometer (ICP-AES) Model LABTAM (Australia).

Na^+ ions and the As and P released to the external solutions during titration of the samples were also estimated by ICP-AES.

The solids (at various degrees of exchange) obtained from the titration were washed and conditioned over $CaCl_2$ under vacuum. X-Ray powder diffraction patterns were taken on a Phillips PW 1130 diffractometer using nickel-filtered Cu-Kα radiation. Thermogravimetric (TG) and differential thermal analysis (DTA) measurements were carried out on a Stanton Redcroft STA 780 at a heating rate of 10°C min^{-1}. Infrared spectra were taken on KBr pellets on a Beckmann IR-20 spectrophotometer.

[a]Dried over $CaCl_2$.
[b]Heated at 300°C.
[c]Heated at 500°C.
[d]Heated at 800°C.

Ion exchange capacity

The ion exchange capacity was determined by the batch method. Several samples of exchanger (~0.5 g) in H^+ form were equilibrated with 100 mL of 0.10 *M* (NaCl + NaOH) solutions in various mixing ratios. The titrant was added in small increments to minimize hydrolysis. The solutions were shaken intermittently for 5 days at room temperature. The solutions were centrifuged and the supernatant liquid was analysed for alkali metal, arsenate, and phosphate contents; its pH was also measured.

Results and discussion

The composition of samples of three representative preparations shows reproducible results. The mean weight percentages of Sn, As, P, and H_2O in the samples dried at 50 ± 1°C for 24 h are 31.58, 20.13, 8.32, and 10.0 with standard deviation 0.18, 0.19, 0.61, and 0.33, respectively as against theoretical values 31.86, 20.11, 8.31, and 9.66 calculated for the formula $Sn(HAsO_4)(HPO_4).H_2O$.

The X-ray powder diffraction pattern for the H^+ form of the sample shown in the Fig. 2(*a*) (corresponding *d* values are listed in Table 1) shows a great similarity with those of α-$Sn(HPO_4).H_2O$ and α-$Sn(HAsO_4).H_2O$. The first *d* value at 7.97 Å is assumed as the distance between two adjacent planes of tin atoms (d_{002}).

Infrared spectra

The IR spectra for SnAsP samples show five characteristic absorption bands corresponding to interstitial water and hydroxyl groups (3700–2600 cm^{-1}), interstitial water (1800–1500 cm^{-1}), phosphate groups (1300–1000 cm^{-1}), arsenate groups (1000–750 cm^{-1}), and Sn—O bond (650–300 cm^{-1}).

Ion exchange behaviour of crystalline $Sn(HAsO_4)(HPO_4).H_2O$ towards sodium ions

The sodium uptake curve (Fig. 1) gives an ion exchange capacity of 4.49 mequiv./g at pH 7.3. Since 0.87 mmol of arsenate and phosphate are released at this pH to the external solution, the total ion exchange capacity of the sample can be taken as 5.36 mequiv./g. This value is in good agreement with the theoretical exchange capacity (5.37 mequiv./g) calculated by considering two exchangeable hydrogens per formula weight of $Sn(HAsO_4)(HPO_4).H_2O$. The observed exchange capacity for SnAsP falls in between α-SnP (6.08 mequiv./g) and α-SnAs (4.8 mequiv./g). The sodium exchange takes place appreciably in the pH range 5–6 and at pH 7 and beyond severe hydrolysis of the product takes place with consequent loss of Na^+ to the

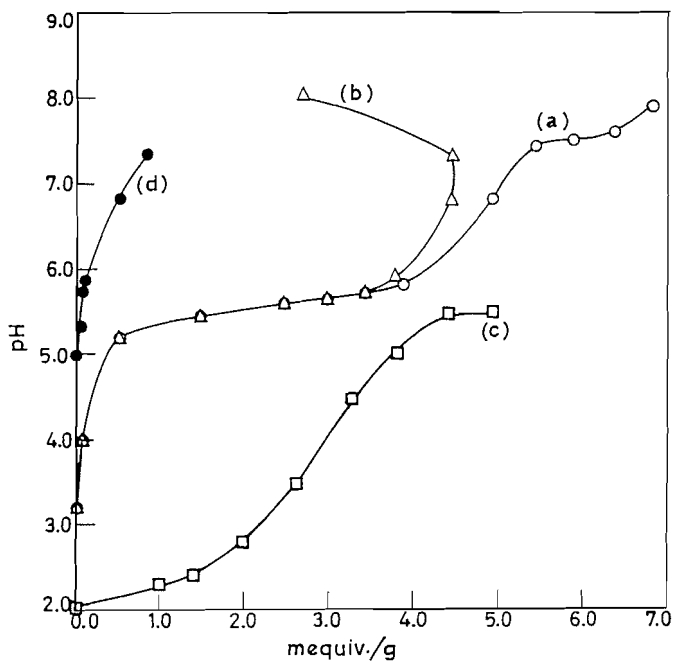

FIG. 1. Titration-uptake curves for $Sn(HAsO_4)(HPO_4).H_2O$. (*a*) Forward titration: titrant 0.1 *M* NaCl + 0.1 *M* NaOH; (*b*) Na^+ ion uptake; (*c*) reverse titration: titrant 0.1 *M* NaCl + 0.1 *M* HCl; and (*d*) mmol/g of arsenate and phosphate released to solution.

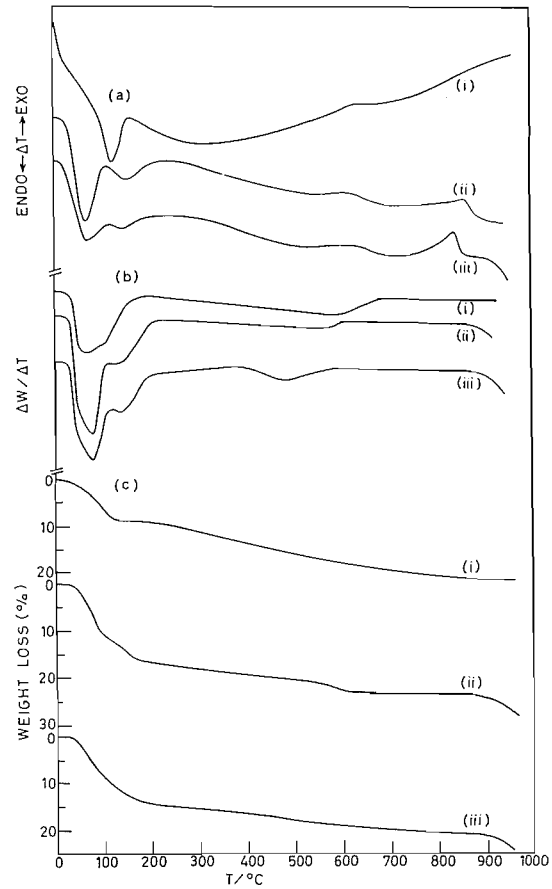

FIG. 3. (*a*) DTA, (*b*) DTG, and (*c*) TG curves of (*i*) $SnH_2(PO_4)_2.4H_2O$, (*ii*) $SnH_2(AsO_4)(PO_4).4H_2O$, and (*iii*) $SnH_2(AsO_4)_2.4H_2O$.

solution (Fig. 1(*b*)). The initial rise of pH from 3.2 to 5.0 in the titration curve signifies that the Na^+ is going into solid solution up to about 0.5 mequiv./g. X-Ray diffraction patterns of the sample at various degrees of Na^+ uptake shown in Fig. 2 are in good agreement with the shape of the titration curve. Beyond 0.5 mequiv./g of Na^+ uptake a second phase with an interlayer distance of 10.17 Å starts appearing and coexists with the first phase at 7.97 Å along the plateau of the titration curve. At the end of $Na^+ \rightarrow H^+$ process the first phase completely vanishes and only the second phase remains unchanged. This process of change from hydrogen to disodium form in one stage is also apparent from the single plateau obtained in the sodium exchange titration curve. A similar behaviour of one-stage transformation is observed in the case of α-SnP and α-SnAs (7). In contrast, α-ZrP and like compounds exhibit two plateaus, indicating the formation of mono- and disodium phases. The exchange of hydrogen ions in these materials in two stages is not due to the presence of protons at two different acidic sites but attributed to the two-phase changes involved in $Na^+ \rightarrow H^+$ process (8). All the hydrogen ions present in the SnP, SnAsP, and SnAs are supposed to be available for exchange to take place in a single step. The sodium exchange titration curve exhibits a shorter plateau and wider slope. It is known that the lower the degree of crystallinity of the material, the shorter is the plateau and therefore, the wider is the step involving the solid solution formation (slope) (9). The broadness of the peaks obtained in the X-ray patterns (Fig. 2(*a*)) is due to a lower degree of crystallinity in the sample. The fully exchanged sodium phase used for the back titration has more or less the same Sn:As:P ratio as the sample in H^+ form and the reverse titration of this material shows a marked hysteresis (Fig. 1(*c*)). The replacement of Na^+ ions by protons occurs at a lower pH than that required for forward reaction and yields a highly hydrated phase.

Thermal behaviour

The TG, DTG, and DTA curves of the samples in H^+ form and fully exchanged sodium forms are shown in Figs. 3 and 4, respectively. The samples dried over $CaCl_2$ show a total weight loss of about 20–22% up to 600°C. The weight loss at 35–200°C is ascribed to the loss of water of crystallization (~4 mol), and the loss at 350–600°C to condensation of phosphate and arsenate groups (~1 mol of H_2O). The DTG curve reveals that the dehydration of water of crystallization occurs in two stages and the corresponding two endothermic peaks in DTA curves are obtained in the range 35–100°C and 100–200°C. The third endothermic peak in DTA and weight loss in DTG curves corresponds to the condensation of arsenate and phosphate groups and the process takes place in the range 350–600°C. The analogous processes for SnP and SnAs occur in the ranges 350–650°C and 375–570°C, respectively. However, for these compounds the dehydration steps in TG curves are not distinct as the weight loss is continuous throughout the range up to 600°C. Constantino and Gasperoni (7) observed analogous behaviour on α-SnP and α-SnAs and demonstrated that the condensation of phosphate and arsenate groups begins before the water of crystallization is completely lost. Nevertheless, the

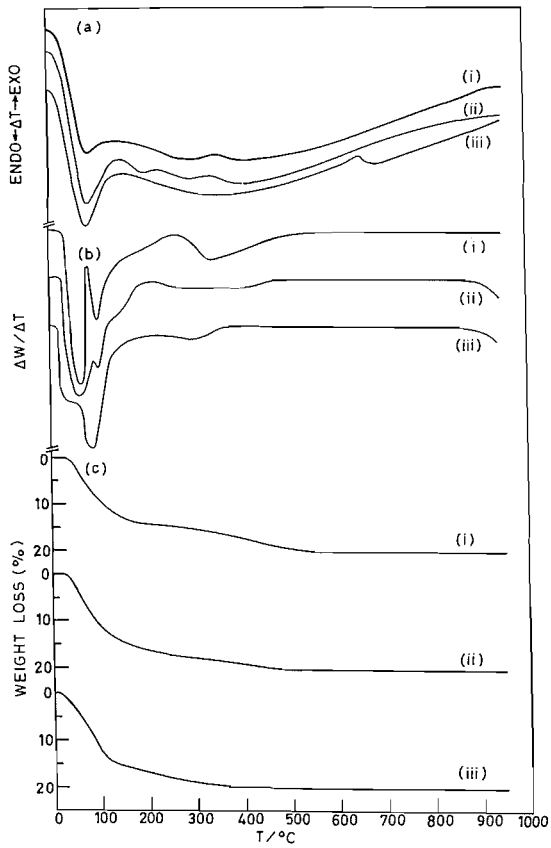

FIG. 4. (*a*) DTA, (*b*) DTG, and (*c*) TG curves of (*i*) $SnNa_2(PO_4)_2.4H_2O$, (*ii*) $SnNa_2(AsO_4)(PO_4).4H_2O$, and (*iii*) $SnNa_2(AsO_4)_2.4H_2O$.

samples heated up to 300°C still maintained the same layered structure in X-ray diffraction (Table 1(*b*)) indicating that the water held up to 300°C in the exchanger can be assumed only to be the constitution water. After the condensation process a layered tin pyroarsenophosphate is formed; above 800°C, this transforms into a cubic pyrocompound (Table 1, columns 3 and 4). The exothermic peak around 800°C in DTA curves (Figs. 3 and 4) signifies the phase transformation of the layered pyro-compounds to cubic pyro-compounds. The weight loss after 900°C in SnAsP and SnAs samples is related to the loss of arsenic pentoxide.

In the dehydration process of the sodium exchanged materials water molecules are lost at lower temperatures than the exchangers in H^+ form. The decrease in the temperatures of dehydration process can be attributed to the weaker bonds of water and to some degradation in the crystallinity of the fully exchanged sodium forms (Fig. 2(*e*)). The interlayer spacings in the samples vary with the degree of water of crystallization. The sample with 4 mol of water of crystallization has larger interlayer spacing (7.97 Å) than the dehydrated product (7.76 Å) (Table 1, columns 1, 2).

Although the structure of the new mixed compound is not known precisely, its X-ray powder diffraction pattern shows a great similarity to those of α-SnP and α-SnAs. From its chemical analysis, ion exchange, and thermal behaviour, this material can be classified as an α-type layered structure.

The investigations indicate that it is possible to prepare a tin(IV) based mixed ion exchanger with a single crystalline phase containing phosphate and arsenate anions in 1:1 ratio. The material, $Sn(HAsO_4)(HPO_4).H_2O$, shows a wide miscibility and is isostructural with α-$Sn(HPO_4).H_2O$ and α-$Sn(HAsO_4).H_2O$. It possesses an interlayer spacing of 7.97 Å intermediate between the parent single acid salts.

D. Y. Gin, M. S. R. Cader, J. R. Sams, and F. Aubke. Can. J. Chem. **68**, 350 (1990).

Addition of 1,3,5-trimethylbenzene (mesitylene or mes) to the tin(II) salts, $Sn(SO_3F)_2$ and $Sn(SbF_6)_2$, results in the formation of adducts of the composition $Sn(SO_3F)_2 \cdot$mes and $Sn(SbF_6)_2 \cdot 2$mes in very high yield. The adducts are characterized by chemical analysis and infrared spectra. The adduct formation is followed by ^{119}Sn Mössbauer spectroscopy. It appears that only tin(II) compounds with large, weakly nucleophilic anions are capable of forming mesitylene adducts, while $SnCl_2$, SnF_2, and stannocene do not give any indication of adduct formation under similar conditions.

Key words: tin(II)–mesitylene complexes, synthesis, vibrational study, ^{119}Mössbauer spectra.

L'addition de 1,3,5-triméthylbenzène (mésitylène ou mes) aux sels d'étain(II), $Sn(SO_3F)_2$ et $Sn(SbF_6)_2$, fournit des adduits de composition $Sn(SO_3F)_2 \cdot$mes et $Sn(SbF_6)_2 \cdot 2$mes, avec des rendements très élevés. On a caractérisé les adduits par des analyses chimiques et par leurs spectres infrarouges. On a suivi la formation des adduits à l'aide de la spectroscopie Mössbauer du ^{119}Sn. Il semble que seuls les composés de l'étain(II) portant des anions faiblement nucléophiles et volumineux peuvent former des adduits avec le mésitylène; dans des conditions semblables, il ne semble pas y avoir de formation d'adduits avec le $SnCl_2$, le SnF_2 et le stannocène.

Mots clés : complexes de l'étain(II)–mésitylène, synthèse, spectres de vibration, spectres Mössbauer du ^{119}Sn.

Introduction

Arene π-complexes, where low valent post-transition metal centers act as acceptors, and benzene or various alkyl benzenes, function as π-donors, form a small but interesting group of weakly bound complexes. Structural and bonding aspects of these compounds have become more widely known through the work of Amma and co-workers (1), and Schmidbaur (2). A review on the more general topic of π-complexes of main group elements has also appeared recently (3).

Within this group of π-complexes, interest has focussed mainly on arene complexes with univalent metal centers such as Ag(I), Cu(I), Hg(I), Ga(I), In(I), and Tl(I) and comparatively little is known about similar compounds with the group 14 centers such as Sn(II) (4–7) and Pb(II) (1, 8). There are commonly two reasons given for the paucity of arene π-complexes in group 14. As exemplified by the structural chemistry of divalent tin (9), the $5s^2$ pair is stereochemically far more active than in compounds of isoelectronic In(I), with the Sn(II) derivatives apparently less inclined to form π-complexes with arenes (2). In addition, lattice energies for Sn(II) and Pb(II) -salts tend to be considerably higher than those of Ga(I), In(I), or Tl(I) salts. The non-polar, π-donating arenes are normally incapable of breaking up such lattices effectively. To reduce the lattice energy and to facilitate complex formation, salts with large, univalent anions are chosen and the vast majority of arene π-complexes reported so far feature tetrahalometallate(III) anions of the type MX_4^- with M = B, Al, Ga, In, or Tl, and X = Cl or Br (1–8) as counter anions, however, weakly basic anions like $OTeF_5^-$ appear to be suitable as well (10).

The tin(II)–π-arene complexes reported so far are limited largely to mono-arene complexes with either Sn^{2+} (4) or the chloride-bridged moieties $(Sn_2Cl_2)^{2+}$ (5) or $(Sn_4Cl_4)^{4+}$ (7) as acceptors, but very recently a bis(arene) complex has been reported: $[(\eta^6\text{-}C_6H_6)_2SnCl(AlCl_4)]_2$ (6). Benzene functions primarily as donor, bonded to tin in the η^6-mode, and $AlCl_4^-$ is the counter anion, with Cl atoms bridging to tin. Frequently, however, arenes are also present in the lattice, without being coordinated to tin (4, 6, 7). Detailed crystal structures are reported for all compounds (4–7) and have been used in the development of bonding concepts based on MO theory (1, 4, 5).

We have been interested in the chemistry of tin for some time now, with two specific related objectives: (*a*) the use of ^{119}Sn Mössbauer spectroscopy as a structural tool and (*b*) stemming from our interest in superacids, the stabilisation of "bare", non- or very weakly coordinated cations like Sn^{2+} (11) or R_2Sn^{2+} (12). Two recent objects of our investigation (13), tin(II) bis(fluorosulfate), $Sn(SO_3F)_2$, and tin(II) bis(hexafluoroantimonate), $Sn(SbF_6)_2$, both originally reported by Gillespie and co-workers (14), seemed to us to be potentially capable to function as acceptors in arene π-complexes. Both give rise to broad line ^{119}Sn Mössbauer spectra with large positive isomer shifts relative to SnO_2, and, in case of $Sn(SO_3F)_2$, a small quadrupole splitting (11, 14) suggesting non-directional, nearly spherical distribution of the $5s^2$ electron pair. The anions, SO_3F^- and SbF_6^-, function frequently as weakly coordinated, tridentate ligands towards divalent metal ions giving rise to layer structures, based on the $CdCl_2$-prototype. This structural type is commonly found for most sulfonates of divalent metals, and the reported structure of $Ca(SO_3CH_3)_2$ (15) provides an example. The recently reported structure of $Ag(SbF_6)_2$ (16) may serve as an example for the layer structure formed by $M(SbF_6)_2$. Both SO_3F^- and SbF_6^- are very weakly basic, and covalent contributions to the lattice energies of their tin(II) salts should be small. Alternatively, both anions may stabilize arene complexes of tin with the help of oxygen or fluorine bridges. As donor, 1,3,5-trimethylbenzene (mesitylene) is chosen, because it is expected and found (2) to be a better donor than benzene. ^{119}Sn Mössbauer spectroscopy is found to be a useful tool during this investigation. Its application to the study of tin(II) compounds has recently been reviewed (17).

Experimental

(a) Chemicals

1,3,5-Trimethylbenzene (mesitylene) obtained from Aldrich was dried over CaH_2 and distilled *in vacuo* before use. Fluorosulfuric acid technical grade was obtained from Orange County Chemicals and doubly distilled at atmospheric pressure as described previously (18). Antimony(V) fluoride (Ozark Mahoning-Pennwalt) was purified by repeated distillation, first at atmospheric pressure in a stream of dry N_2 and subsequently *in vacuo*. $Sn(SO_3F)_2$ was obtained from $SnCl_2$ (B.D.H.) and HSO_3F as described (19), and $Sn(SbF_6)_2$ resulted from the solvolysis of $Sn(SO_3F)_2$ in an excess of SbF_5 as reported recently (13). Stannocene, $(\eta^5\text{-}C_5H_5)_2Sn$, was synthesized from $SnCl_2$ and NaC_5H_5 (Aldrich). The crude product was purified by sublimation and the purity checked by microanalysis. SnF_2 and $SnCl_2$ were obtained from Matheson Coleman & Bell in 98 and 98.5% purity, respectively.

(b) Instrumentation

Infrared spectra were obtained on either a Perkin-Elmer 1710 FT-IR spectrometer or a Perkin Elmer 598 spectrometer. Samples were contained as thin, solid films between AgBr plates. For the recording of Raman spectra a Spex Ramalog 5 instrument equipped with an Ar^+ Laser was available. Ultraviolet–visible spectra of Nujol mulls were obtained on a Hewlett Packard 8452-A diode array spectrophotometer with the mull contained in an air-tight cell fitted with quartz windows. ^1H nmr spectra were recorded on a Varian XL-300 spectrometer.

Mössbauer spectra were collected on a constant acceleration spectrometer, using $Ba^{119}SnO_3$ as the γ-ray source. Data counts were acquired on a Tracer-Northern multichannel analyzer linked to the mainframe computer via an IBM-PC. The relative velocity scale was calibrated with an iron foil absorber and a ^{57}Co source.

Standard vacuum line techniques were used for the transport of volatile materials. Filtration apparatus, similar in design to equipment described by Shriver (20), was used for product isolation.

All moisture-sensitive solids were handled in a Vacuum Atmospheres Corp. "Dri-Lab" Model No. He-493, filled with purified dry nitrogen and equipped with a Dri-Train circulating unit. The reactions were performed in Pyrex reaction vessels of about 50-mL capacity made from round bottom flasks fitted with Kontes Teflon stem valves and equipped with Teflon-coated spin bars. The reactions were monitored by weight. Chemical analysis was carried out by the Analytische Laboratorien, Gummersbach, West Germany, and by Mr. P. Borda of this Department.

(c) Synthetic reactions

(i) Synthesis of $Sn(SO_3F)_2 \cdot 1,3,5\text{-}(CH_3)_3C_6H_3$

To a one-part reactor a sample of $Sn(SO_3F)_2$ (1.06 g, 3.35 mmol) was added and after evacuation of the reactor, dry mesitylene (ca. 7 mL, ~50 mmol) was transferred into the reaction vessel via a distillation bridge. The white suspension was stirred *in vacuo* at room temperature for 3 days. Excess mesitylene was removed *in vacuo* at −20 to −15°C (ice/NaCl bath) over a period of 3 days yielding 1.39 g of a white powder, of the composition $Sn(SO_3F)_2 \cdot$mes with a decomposition point of 97.2–98°C.

Anal. calcd. for $C_9H_{12}F_2O_6S_2Sn$: C 24.74, H 2.77, F 8.70, S 14.67, Sn 27.16; found: C 25.77, H 2.87, F 8.53, S 14.84, and Sn 27.10.

An alternate preparation with mesitylene removed *in vacuo* at −5°C gave the following analysis:

Anal. Calcd: C 24.74, H 2.77, S 14.67; found: C 24.97, H 2.80, S 14.55.

Infrared bands and estimated intensities: (cm^{-1}) 2910w,b, 2860vw, 1760vw, 1604m, 1575w,sh, 1446w, 1337w, 1191vs, 1127w,sh, 1054vs, 888s, 786w, 667w, 589ms, 544m, 507vw, and 405m.

(ii) Synthesis of $Sn(SbF_6)_2 \cdot 2[1,3,5\text{-}(CH_3)_3C_6H_3]$

To the bottom portion of a two-part reactor, freshly prepared $Sn(SbF_6)_2$ (3.11 g, 5.27 mmol) was added. The flask was then fitted to the bottom end of the filtration apparatus. On the top end of the filtration apparatus a second 100-mL flask was fitted and the entire apparatus was then evacuated. Through a Teflon valve in the bottom chamber of the apparatus mesitylene (15 mL, 108 mmol) was transferred via a distillation bridge. Upon exposure to the mesitylene vapor, the white powder immediately turned yellow and then during the filtration, pale, off-white. When the mesitylene distillation was complete, the suspension was stirred *in vacuo* for 1.5 h. The apparatus was inverted, and the mixture filtered. The filtrate flask was cooled to −10°C (salt/ice bath) and the mixture was left to filter for 17 h. When gravity filtration was complete, the filtrate chamber of the apparatus was evacuated to dry the solid further. The apparatus was refilled with dry nitrogen, and the filtrate chamber was evacuated again. This drying procedure was repeated three more times, giving a pale, off-white solid (4.18 g, or 5.04 mmol, 95.5% yield) and yellow–green filtrate, which was discarded. The product was transferred to a two-part reactor and was further dried *in vacuo* for 24 h at room temperature. No further weight change was observed. The solid decomposed between 69.5 and 71.5°C to a greenish yellow liquid.

Anal. calcd. for $C_{18}H_{24}F_{12}Sb_2Sn$: C 26.03, H 2.91, F 27.45, Sb 29.32, Sn 14.29; found: C 26.87, H 3.00, F 27.31, Sb 29.05, Sn 14.20; total 100.43.

Infrared bands and estimated intensities (cm^{-1}): 2920mw, 2860w, 1601m, 1580m, 469w, 1384m, 1168vw, 1080vw, 1040vw, 1007w, 960vw,b, 860w, 687s, 671vs, 635s,sh, 580m,b, 544m, 512w, 440w, and 395w.

Results and discussion

(a) Synthesis

The previously reported synthesis of Sn(II) containing benzene π-complexes (4–7) involves either the reaction of $SnCl_2$ and $AlCl_3$ at different mole ratios and temperatures (4, 5), or of molten $Sn(AlCl_4)_2$ (6, 7) with the arene to give either Sn^{2+}, $(Sn_2Cl_2)^{2+}$, or $(Sn_4Cl_4)^{4+}$ containing complexes as white colorless crystals. Crystals suitable for single crystal X-ray diffraction studies are obtained (4–7) in all instances. The course of the reaction appears to be influenced in part by the mole ratios of the reactants used and in part by the reaction temperature. The different products, with Sn^{2+} or $(Sn_nCl_n)^{n+}$, $n = 2$ or 4, are not totally surprising since in the binary system $SnCl_2$–$AlCl_3$, phase studies (9) have revealed the existence of two distinct phases: $SnCl_2 \cdot AlCl_3$ and $SnCl_2 \cdot 2AlCl_3$. It appears that the same two phases crystallise now in the form of π-arene complexes with $AlCl_4^-$ as coordinated counter ion and in several instances with lattice arene present (4, 6, 7).

The synthetic reactions reported here differ in a number of ways. Binary rather than tertiary reaction mixtures are used, the reaction temperature is room temperature and the tin(II) substrates are synthesized and characterized prior to their reaction with mesitylene.

Addition of mesitylene occurs smoothly according to:

$$[1]\quad Sn(SO_3F)_2 + \text{mes} \xrightarrow[\text{mesitylene}]{25^\circ C} Sn(SO_3F)_2 \cdot \text{mes}$$

or

$$[2]\quad Sn(SbF_6)_2 + 2\ \text{mes} \xrightarrow[\text{mesitylene}]{25^\circ C} Sn(SbF_6)_2 \cdot 2\ \text{mes}$$

mes = mesitylene or 1,3,5-trimethylbenzene, and the two complexes are formed in nearly quantitative yield. Solid material remains present throughout the reaction and in case of $Sn(SO_3F)_2$ as acceptor, there is no visible sign of a reaction, except for an increase in the bulk of the solid residue. Complete removal of excess mesitylene *in vacuo* is difficult to judge and the conditions quoted in the Experimental section are arrived at by trial and error. It does appear that samples submitted

for microanalysis (C, H, and S contents) immediately after isolation had small amounts of residual mesitylene trapped while samples sent to Germany for further analysis (S, Sn, Sb, and F contents) seemed to have lost the excess reactant.

The reaction of mesitylene with $Sn(SbF_6)_2$ differs even further. A 2:1 complex forms and a color change to bright yellow is noted as soon as the tin salt is exposed to mesitylene vapor. However, the color of the solid quickly fades during product isolation and an off-white solid is obtained in very high yield together with a yellow–green filtrate. The origin of the initially observed color is unclear. A uv–visible spectrum taken as Nujol mull on a solid sample at this stage shows an intense uv-absorption at ~240 nm tailing off in the visible region with weak shoulders 486, 580, and 656 nm, respectively. Observations made during product isolation suggest that the intense color is due to a by-product, which is very soluble in excess mesitylene. A complex formed by mesitylene and small, residual amounts of SbF_5 becomes a distinct possibility and addition of mesitylene to pure SbF_5 results in an intensely colored dark brown solid, which is not investigated further. There is little doubt that the final product like other arene complexes of group 13 and 14 metals (1–8) is white.

The use of gravity filtration as a means of product isolation is important in case of the $Sn(SbF_6)_2 \cdot 2mes$ synthesis. Attempts to isolate this compound by slow, careful removal of excess mesitylene *in vacuo* or in a stream of dry N_2 at room temperature and at −5°C result in partial decomposition and materials that analyse as $Sn(SbF_6)_2 \cdot 1.5mes$. In addition the product has a slight yellow tint.

The thermal stability of both mesitylene complexes described here is limited. $Sn(SO_3F)_2 \cdot mes$ melts with decomposition at 97–98°C while $Sn(SbF_6)_2 \cdot 2mes$ has a decomposition range of 69.5–71.5°C, where a greenish yellow liquid forms.

Attempts to extend the mesitylene addition reaction to three other tin(II) compounds are unsuccessful. Both $SnCl_2$ and SnF_2 are recovered unchanged. Both salts have Sn^{2+} in distorted octahedral environments (7) and the structures of $SnCl_2$ (21) and orthorhombic SnF_2 (14, 22), one of the two polymorphic forms, may be regarded as layer structures. It must be concluded that the lattice energies of both compounds are too high and adduct formation does not occur.

Stannocene, $(\eta^5\text{-}C_5H_5)_2Sn$, has a molecular structure with a tilted arrangement of the C_5H_5-rings (23) and presumably a stereochemically active electron pair. Its ^{119}Sn Mössbauer spectrum shows a detectable quadrupole splitting of 0.86 mm s^{-1} (24). It dissolves well in mesitylene, but stannocene is again recovered unchanged after removal of the arene *in vacuo*. The ^1H nmr spectrum of stannocene in mesitylene is studied down to −40°C, but only rather subtle changes are noted. The principle resonance due to stannocene (25) shifts from 5.96 ppm in $CDCl_3$ to 5.91 ppm relative to TMS in the presence of mesitylene while $J(^1H\text{–}^{119/117}Sn)$ changes from 15.76 to 15.16 Hz. Beginning at −20°C and more pronounced at −40°C, a second, smaller, and rather broad resonance at 5.88 ppm emerges with a similar separation of the satellite peaks. Mesitylene resonances appear virtually in the same positions as in pure mesitylene as single lines at 2.28 (CH_3) and 6.78 (C—H) ppm and do not shift with decreasing temperature. While there may be a weak interaction between stannocene and mesitylene at reduced temperature, all attempts to isolate a reaction product by low temperature filtration have failed.

Hence it appears that tin(II) is sufficiently acidic only when bulky and very weakly nucleophilic anions like $AlCl_4^-$, SO_3F^-, and SbF_6^- are present, and when lattice energies are reduced in the resulting layer structures. From a correlation of ^{119}Sn Mössbauer data of dimethyltin(IV) salts (12) it appears that SbF_6^- is the weaker nucleophile of the two fluoroanions, and formation of a 2:1 complex with mesitylene is not unexpected, while $Sn(SO_3F)_2$ forms a 1:1 complex only. Complex formation by addition of mesitylene to a solid tin(II) salt as described here does not allow the formation of single crystals suitable for structural studies. Hence evidence for the presence of π-arene complexes has to come from ^{119}Sn Mössbauer and vibrational spectra. They will be discussed subsequently.

(b) ^{119}Sn Mössbauer spectra

Isomer shifts, relative to SnO_2 for tin(II) compounds, fall within the range of ~2.1 mm s^{-1}, viewed as the borderline between Sn(II) and Sn(IV), and calculated values of about 5.1–7.7 mm s^{-1} for a "bare" Sn^{2+} with a spherically distributed $5s^2$ electron pair (9, 26). Experimental values have not reached the ionic limit. The highest values reported so far are 4.69 mm s^{-1} for the tin(II) moiety in $Sn(II)[Sn(IV)(SO_3CF_3)_6]$ (27) and 4.66 mm s^{-1} for $Sn(SbF_6)_2 \cdot 2AsF_3$ (28) where an X-ray diffraction study reveals a distorted nine-coordinated environment for Sn^{2+}.

In these close approaches to a Sn^{2+} ion no quadrupole splitting is observed (27, 28), however, with decreasing isomer shift first line broadening, already evident for $Sn(SbF_6)_2$, is noted and eventually small but well resolved quadrupole splittings are found (29). Hence ^{119}Sn Mössbauer spectroscopy provides two criteria for the ionic character of Sn(II) compounds: the isomer shift which should be high, close to, or in excess of 4.69 mm s^{-1} relative to SnO_2 and the quadrupole splitting which should be zero.

Some ^{119}Sn Mössbauer data for Sn(II) compounds of interest in this study are listed in Table 1. Of the five tin(II) compounds studied here $Sn(SO_3F)_2$ (4.18 mm s^{-1}) and $Sn(SbF_6)_2$ (4.44 mm s^{-1}) have the highest isomer shifts of those listed and only the former has a small, resolvable quadrupole splitting. Not unexpectedly the more acidic $Sn(SbF_6)_2$ is the better acceptor, seemingly capable of coordinating two mesitylene donors, while $Sn(SO_3F)_2$ forms a 1:1 complex only.

Upon arene uptake the isomer shift is reduced, for $Sn(SO_3F)_2$ by 0.17 mm s^{-1} and for $Sn(SbF_6)_2$ by 0.40 mm s^{-1}. This reduction suggests that mesitylene is interacting with Sn(II) and, judging by the magnitude of the shift, that in case of $Sn(SbF_6)_2 \cdot 2mes$ both mesitylene molecules are probably coordinated to tin. A similar isomer shift of 3.93 mm s^{-1} is reported for $(\pi\text{-}C_6H_6)Sn(AlCl_4)_2 \cdot C_6H_6$ (4*c*) but no Mössbauer data appear to have been reported for the two $SnCl_2$–$AlCl_3$ phases (9), to allow an estimate of the decrease on arene addition. The reduction in isomer shift upon binding to mesitylene is accompanied by an increase in quadrupole splitting to 1.04 mm s^{-1} for $Sn(SO_3F)_2 \cdot mes$ while in case of $Sn(SbF_6)_2 \cdot 2mes$ a slightly asymmetrical doublet results (see Fig. 1) and a ΔE_Q value of 1.13 mm s^{-1} is obtained. These findings are consistent with trends in δ and ΔE_Q summarized above. The occurrence of quadrupole splitting suggests increasing asymmetry in the coordination environment of tin(II) when coordination to only oxygen or fluorine changes to include coordination to the arene as well. For both mesitylene adducts the ^{119}Sn Mössbauer parameters obtained remain well within the range reported for typical tin(II) compounds (17). The addition of mesitylene to Sn^{2+}, as suggested by the ^{119}Sn Mössbauer data, is expected to cause a change in the manner in which the anions coordinate

[f]Present study.

to tin. This change in anion denticity is probed by infrared spectroscopy and discussed in the subsequent section.

(c) Infrared spectra

Attempts to obtain Raman spectra of both mesitylene adducts are unsuccessful and quick darkening of areas exposed to laser light indicates thermal degradation is occurring even at very low laser power. Hence evidence rests on infrared spectra obtained on solid films between silver halide windows.

Both infrared and Raman spectra for $Sn(SO_3F)_2$ (14, 19) and $Sn(SbF_6)_2$ (14) have been reported previously, and for tridentate SbF_6-groups present in $M(SbF_6)_2$ compounds a useful vibrational assignment has been presented (13, 30). To account for the observed spectral complexity in the SbF-stretching region, a subdivision into metal coordinated, through fluorine bridges Sb—F^b, and non-coordinated or terminal Sb—F^t stretches is suggested with the former usually between 550 and 650 cm^{-1} and the latter above 650 cm^{-1} (30). Vibrational bands reported for $Sn(SbF_6)_2$ (14) allow such a division as well, even though a distorted environment around tin introduces additional complexity. Assignments for $Sn(SO_3F)_2$ have suggested the presence of ionic SO_3F^- with the symmetry of the anion reduced from C_{3v} for the free ion to C_s due to coordination to tin (14, 19), but there are still unresolved problems, best reflected in the occurrence of two equally intense bands at ~770 and 830 cm^{-1} possibly due to $\nu SF(A_1)$ and a splitting found for $\delta SO_3(A_1)$. It seems more appropriate to us to view the spectrum as being due to two non-equivalent SO_3F groups with approximately C_{3v} symmetry with some band overlap in the area of deformation modes. This implies either ionic groups or more likely O-tridentate groups.

Addition of mesitylene to both Sn(II) compounds has two general effects: (*a*) the infrared spectrum is dominated in both instances by bands due to the SO_3F and SbF_6 groups, respectively, with all mesitylene bands of very low intensity, and (*b*) the vibrational spectra of the anions appear to change, and at least the SbF_6 bands reflect a change in anion coordination. Low intensity of vibrational bands due to organic groups is commonly found for organotin(IV) salts (31), and this feature appears to extend to the mesitylene adducts of tin(II) salts as well.

The observed infrared frequencies for the two mesitylene adducts are listed in the Experimental section together with

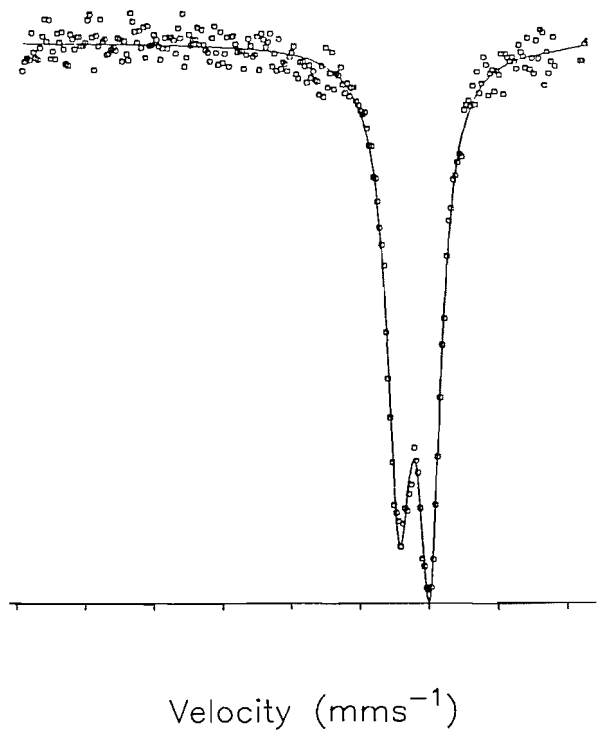

FIG. 1. ^{119}Sn Mössbauer spectrum of $Sn(SbF_6)_2\cdot 2$ mes at 77 K.

estimated relative intensities. The discussion in this section will center around two aspects, (*i*) the mesitylene bands in neat mesitylene and in the complexes, and (*ii*) the "anion" bands before and after mesitylene addition to $Sn(SO_3F)_2$ and $Sn(SbF_6)_2$, respectively. Vibrational bands attributed to mesitylene are listed in Table 2 for both adducts and compared to bands observed for liquid mesitylene. The listing of bands for the adducts is incomplete because of the very low intensity mentioned above which causes medium and weak bands to be unobservable and in case of $Sn(SO_3F)_2\cdot$mes partial overlap of mesitylene bands with more intense anion bands, in particular in the region of 800–1300 cm^{-1}.

In regions where no anion bands are expected, small band shifts are observed, mostly to lower frequencies. The aromatic C=C stretch at 1608 cm^{-1} in free mesitylene is a good

example. This peak is shifted to 1604 and 1601 cm^{-1} for $Sn(SO_3F)_2 \cdot mes$ and $Sn(SbF_6)_2 \cdot 2mes$, respectively. The lower frequency indicates a very slight withdrawal of π electron density of the aromatic ring towards tin.

Interestingly, some bands assigned to bonded mesitylene appear to be split compared with those of free mesitylene. This is noticeable in the 1570–1610 cm^{-1} region of both spectra, and especially in the 1000–1200 cm^{-1} region for $Sn(SbF_6)_2 \cdot 2mes$. The splitting can be attributed to a reduction in symmetry of the bonded mesitylene, and/or the presence of two non-equivalent mesitylenes in particular in $Sn(SO_3F)_2 \cdot mes$, but some solid state splitting is possible as well.

All features affecting bands due to mesitylene are subtle, and the observed features are in general consistent with a very weak interaction between the arene and the two Sn(II) salts.

The infrared bands attributed to the anion are summarized in Table 3 and are compared to the reported values for the parent compounds $Sn(SO_3F)_2$ (14, 19) and $Sn(SbF_6)_2$ (14). For $Sn(SO_3F)_2 \cdot mes$ the ir spectrum is dominated by an intense broad band centered at 1054 cm^{-1} and two bands at 1191 and 1127 cm^{-1}. These are assigned collectively as SO_3 stretching modes, probably masking some of the less intense motions of the mesitylene component in the adduct.

The most noticeable change appears to have occurred in the S—F stretching region. The two intense bands at 772 cm^{-1} and 833 cm^{-1} in $Sn(SO_3F)_2$ (Table 3) are now replaced by a single strong band at 888 cm^{-1}, with a weak band at 786 cm^{-1} (possibly due to mesitylene).

From this overall band distribution and the increased wavenumber of the νS—F band, it appears that a change in denticity of the anion has taken place during mesitylene adduct formation. The findings are consistent with a bidentate, possibly bridging configuration tentatively formulated as $[(\eta^6\text{-mes})Sn(SO_3F)_2]_n$ rather than an ionic (perturbed) or tridentate grouping (32).

Compared to the rather complicated pattern observed for $Sn(SbF_6)_2$ in the region of 520–750 cm^{-1} (Table 3), the band pattern displayed by the anion in the adduct $Sn(SbF_6)_2 \cdot 2mes$ is very simple: a very strong band at 671 cm^{-1}, a sharp, medium band at 635 cm^{-1}, and a weak band at 580 cm^{-1} are found. For

a free SbF_6^- anion, a peak at ~660 cm^{-1} is attributed to the asymmetric stretch with Raman-active bands observed at ~660 again and at 575 cm^{-1}. The pattern observed for $Sn(SbF_6)_2 \cdot 2mes$ suggests the presence of a weakly coordinated SbF_6^- anion. Peak splitting in the SbF_6^- stretching region produces bands at 671 and 635 cm^{-1}, with the loss of a symmetry center allowing detection of a Raman-active fundamental at 580 cm^{-1} (33).

It appears then that addition of mesitylene has a different effect on the anion bands in $Sn(SO_3F)_2 \cdot mes$ and $Sn(SbF_6)_2 \cdot 2mes$, respectively. In the former adduct the SO_3F group appears to be still coordinated to tin, but more likely in a bidentate, possibly bridging manner. In $Sn(SbF_6)_2 \cdot 2mes$ only weak coordination of the SbF_6 group is evident and any departure from an ionic SbF_6^- with O_h symmetry is rather slight. It is unfortunate that, particularly for this compound, support from Raman spectroscopy is lacking.

The findings for $Sn(SbF_6)_2 \cdot 2mes$ are consistent with the view that both mesitylene groups are coordinated to tin, which in turn is supported also by the ^{119}Sn Mössbauer spectra.

Conclusions

Direct addition of an arene, in this case mesitylene, to suitable Sn(II) salts like $Sn(SO_3F)_2$ and $Sn(SbF_6)_2$ at room temperature, and product isolation well below room temperature, allow the high yield synthesis of very weakly bound mesitylene complexes. However, only microcrystalline materials result which precludes structural studies by single crystal X-ray diffraction. Alternatively, ^{119}Sn Mössbauer spectroscopy allows not only product characterisation, but also, using the isomer shift and the absence of quadrupole splitting as criteria, the identification of other suitable substrates for complex formation.

Poly(vinyl acetate) as a template for polymerization of methacrylic acid

NEETA TEWARI AND A. K. SRIVASTAVA[1]
Department of Chemistry, H.B. Technological Institute, Kanpur 208002, India
Received June 5, 1989

NEETA TEWARI and A. K. SRIVASTAVA. Can. J. Chem. **68**, 356 (1990).

The template polymerization (TP) of methacrylic acid (MAA) using polyvinyl acetate (PVAc) of $\bar{M}_v$ 66 400 at 60°C for 120 minutes in dimethyl formamide (DMF) has been studied dilatometrically to study the effect of template, and of the monomer and initiator (α-α′ azobisisobutyronitrile) concentrations upon the kinetics. Viscometric measurements showed that complexation between PVAc and PMAA was maximum when the template/polymer ratio was 1:1, and the time required for complete complexation was 7 minutes. The overall energy of activation was the same, i.e., 115 kJ/mol, in the presence and absence of template. The overall system follows mechanism II.

Key words: template polymerization, polyvinyl acetate, methacrylic acid, α,α′-azobisisobutyronitrile, relative rate of polymerization.

NEETA TEWARI et A. K. SRIVASTAVA. Can. J. Chem. **68**, 356 (1990).

Dans le but d'évaluer l'effet du gabarit, des concentrations du monomère et de l'initiateur (α,α′-azobisisobutyronitrile) sur la cinétique de la réaction, faisant appel à la dilatométrie et opérant à 60°C, dans le diméthylformamide (DMF), on a étudié pendant 120 minutes la polymérisation sur gabarit (TP) de l'acide méthacrylique (AMA) sur de l'acétate de polyvinyle (AcPV). Des mesures de viscosité ont montré que la complexation entre l'AcPV et l'APMA est maximale lorsque le rapport de gabarit/polymère est égal à 1 : 1 et que le temps requis pour la complexation totale n'est que de 7 minutes. La valeur globale de l'énergie d'activation est la même, soit 115 kJ/mol, que le gabarit soit présent ou non. Le système global suit le mécanisme II.

Mots clés : gabarit de polymérisation, acétate de polyvinyle, acide méthacrylique, α,α′-azabisisobutyronitrile, vitesse relative de polymérisation.

Introduction

A search of the literature reveals that template polymerization (TP) of MAA using isotactic poly(methyl methacrylate) (1), poly(*N*-vinyl pyrrolidone) (2), poly(ethylene oxide) (3), poly(4-vinyl pyridine) (4), poly(2-vinyl pyridine) (5), poly(1-lysine) (6), ionene (7), and polyethylene glycol (8) as templates has been extensively reported. However, data regarding applications of PVAc as template for polymerization of vinyl monomers is still scarce. In this paper we report the first results of the TP of MAA in the presence of PVAc templates, obtained using a dilatometric technique, at 60°C.

Experimental

Reagent grade vinyl acetate (Loba), methacrylic acid (Ranbaxy), and solvents were distilled under reduced pressure before use. α-α′ Azobisisobutyronitrile (AIBN) (Loba) was recrystallized twice before use. PVAc was prepared by polymerizing [VAc] = 5.4 M in inert solvent benzene under nitrogen in a three-necked flask at 60°C using [AIBN] = 0.01 M. The polymerized content was precipitated in *n*-hexane and dried. It was purified by reprecipitation from its acetone solution into *n*-hexane and finally dried. The viscosity-average molecular weights ($\bar{M}_v$) of PVAc were calculated by means of the relationship (9) $[\eta] = 22 \times 10^{-5} \bar{M}_v^{0.65}$ (dL/g), the intrinsic viscosity being determined viscometrically in benzene at 30°C.

Kinetic measurements

Rates of polymerization were measured isothermally at 60°C by employing a modified dilatometric apparatus for 120 min under an inert atmosphere of N_2. Dilatometric measurements were carried out by injecting the reaction mixture of PVAc and MAA and AIBN in DMF into the dilatometer and noting the progress of the reaction, monitored as volume contraction (meniscus movement in cm per unit volume per unit time), with the help of a cathetometer. The polymerized content was precipitated in diethyl ether and dried to a constant weight. The weight of the daughter polymer was obtained by subtracting the weight of template from that of precipitated polymers. The template and daughter polymers were separated by refluxing the polymers with water; percentage separation was about 30%. The rate of polymerization (R_p) was calculated from the slope of conversion–time plots (Fig. 3). The $\bar{M}_v$ of the daughter polymers were calculated by means of the relationship (10) $[\eta] = 24.2 \times 10^{-4} \bar{M}_v^{0.51}$, the intrinsic viscosity (in dL/g) being determined viscometrically in methanol at 26°C. An Ubbelhode type viscometer was used.

Results and discussion

Viscometric measurements

To investigate complexation between PVAc and PMAA, the polymers were dissolved separately in DMF and mixed just before the measurements. The total polymer concentration was 0.1 g dL^{-1}. The change in reduced viscosity, $\eta_{red}(= \eta_{sp}/c)$, of the mixture of PVAc and PMAA in DMF as a function of composition is shown in Fig. 1. The minimum in both the cases lies at a percentage by weight of PVAc corresponding to a 1:1 base molar ratio. Complexation was very fast, as illustrated in Fig. 2. The rapid drop of η_{red} within less than 7 min down to a level that remained constant for 2 h signifies that complexation was virtually completed within 7 min. Early reports regarding complex formation in template polymerization (11–13) also show that the time required for complete complex formation is generally 10–20 min.

Effect of template concentration

The influence of [template](PVAc) upon the polymerization of MAA was investigated by comparing the initial rate of polymerization in the absence and presence of various concentrations of PVAc from 9.07×10^{-2} to 90.75×10^{-2} base M. The results are compiled in Table 1 and shown in Fig. 4.

The influence of the template is expressed as a relative rate of polymerization, V_R, defined as

$$V_R = \frac{\text{rate of a TP system}}{\text{rate of the blank system}}$$

It is clear from Table 1 that the rate of polymerization is enhanced in the presence of the template due to the growing contribution of template propagation. A study of Fig. 4 further reveals a sudden rise in R_p between [T] 63.52×10^{-2} and 72.60

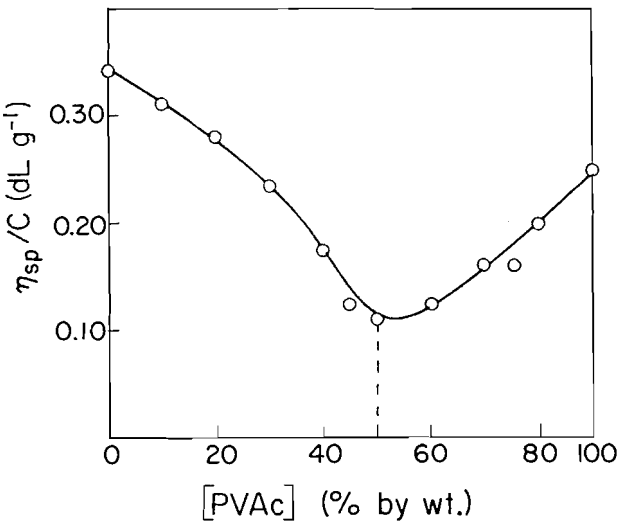

FIG. 1. Reduced viscosity (η_{sp}/c) as a function of weight percentage of PVAc for PVAc/PMAA mixtures in DMF, with PVAc ($\bar{M}_v$ = 66 400) and PMAA ($\bar{M}_v$ = 20 600). The temperature used was 60°C and the total polymer concentration 0.1 g dL^{-1}.

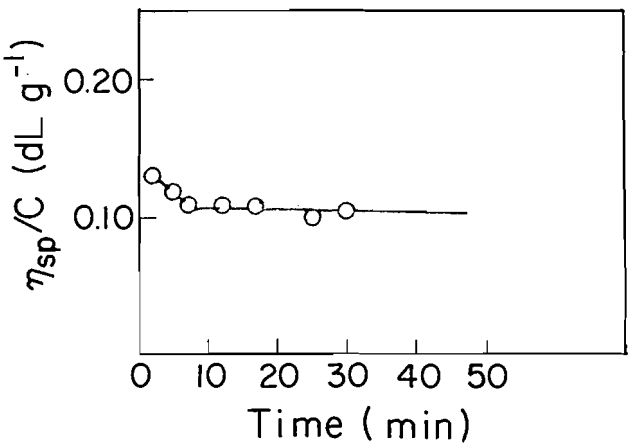

FIG. 2. Reduced viscosity, η_{sp}/c versus time t as a function of molar mass of PMAA for PVAc/PMAA mixtures (1:1 base mole ratio) in DMF, with PVAc ($\bar{M}_v$ = 66 400). The temperature used was 60°C and the total polymer concentration 0.1 g dL^{-1}.

$\times 10^{-2}$ base M. It may be caused by jumping of propagating chain radicals from one template coil to another as has already been reported by Gons *et al.* (14) for other template systems. The increase stops only at a stage when the whole reaction volume is homogeneously occupied by template coils, i.e., at [T] = 72.60 $\times 10^{-2}$ base M. Above this value only template propagation takes place, hence the rate remains constant. The course of the relative rate of polymerization as a function of template concentration at constant [MAA] (Fig. 4) gave insight into the mechanism of the present system, which follows mechanism II (15) and is characterized by a constant maximum value of V_R above the critical concentration of beginning coil overlap, whereby every growing chain can find a template with which to complex.

The enhancement of V_R is a result of the decrease of termination rate due to strongly hindered segmental mobility of polymer radical chains adsorbed on the template. The rate of complexation of polymer radicals is assumed to be first order in both free radical and template concentration. The diffusion of the chain towards the template limits the buildup of template-

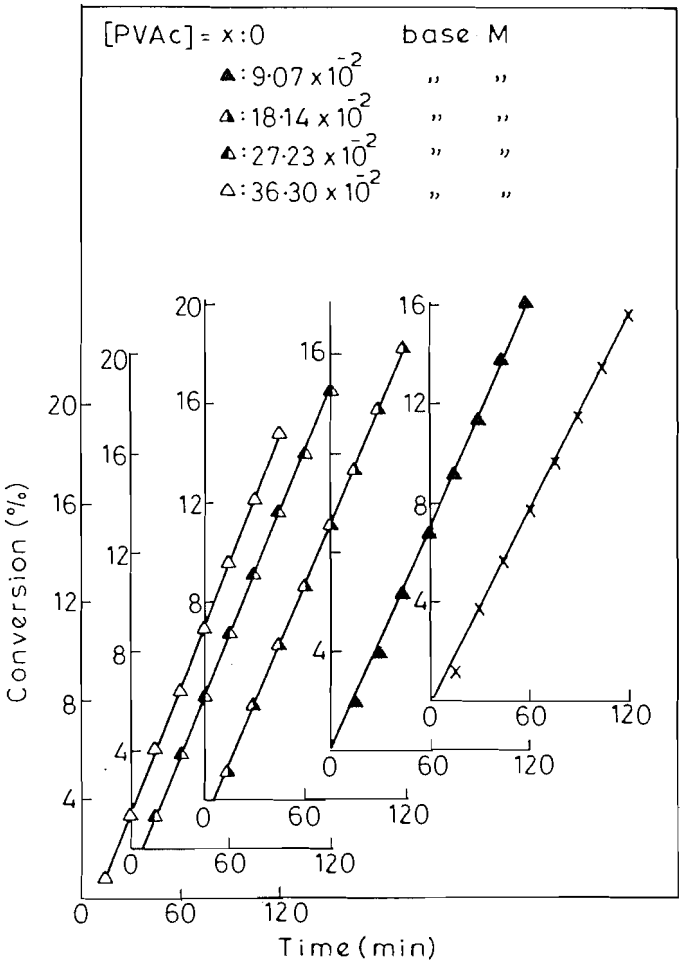

FIG. 3. Time-conversion plots showing effect of [PVAc] for MAA polymerization initiated by AIBN in the presence of template (PVAc) at 60°C in DMF using 23.82 $\times 10^{-3}$ mol L^{-1} of [AIBN] and 0.78 mol L^{-1} of [MAA].

associated radicals. To be certain that the influence is due to the polymeric character of the template, the rate was also determined in the presence of a low molecular weight analogue of PVAc, i.e., ethyl acetate, which had no effect on R_p. The viscosity average molecular weight $\bar{M}_v$ of the daughter polymers increases as the concentration of template increases. Table 2 shows the effect of $\bar{M}_v$ of the templates on V_R and $\bar{M}_v$ of the daughter polymers. As expected for the template effect, the V_R increases as the $\bar{M}_v$ of template increases.

Effect of monomer concentration

The influence of monomer concentration on the template polymerization rate was investigated by varying the concentration of MAA from 0.39 to 1.18 mol L^{-1} at fixed [template] = 72.60 $\times 10^{-2}$ base M and [AIBN] = 23.82 $\times 10^{-3}$ mol L^{-1}. The results are summarized in Table 3 and Fig. 5. V_R is a direct function of [MAA]. From Fig. 5 it is clear that there is no preferential adsorption of monomer on the template site, since in that case the shape of the curve would have been concave. It has already been reported in the literature (16) that if there is preferential adsorption of monomer by template sites (mechanism I), then a plot between [monomer] and V_R must show a concave curve due to lowering of monomer concentration in the bulk solution, thereby decreasing the blank rate as well as the template "pick-up" propagation rate. Thus oligomers created

Microwave acid dissolution of soil samples for elemental analysis

BYRON KRATOCHVIL[1] AND SIPHO MAMBA[2]
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received June 9, 1989

BYRON KRATOCHVIL and SIPHO MAMBA. Can. J. Chem. **68**, 360 (1990).

Closed vessel microwave acid dissolution is compared with conventional open vessel methods for the determination of trace zinc and copper in a series of soil samples collected from sugarcane fields in Swaziland. Analytical measurements by flame atomic absorption spectroscopy show that all the zinc and copper in the samples is released within 7 min in a commercial microwave oven at 400 W. Up to seven 500-mg portions can be handled at a time. Attention must be paid to the amount of organic matter present in a soil so that excess pressure build up does not occur during dissolution.

Key words: microwave dissolution, soil analysis, trace metal determination, atomic absorption spectroscopy.

BYRON KRATOCHVIL et SIPHO MAMBA. Can. J. Chem. **68**, 360 (1990).

Pour la détermination de traces de zinc et de cuivre dans une série d'échantillons de sols provenant de champs de canne à sucre du Swaziland, on a comparé la méthode conventionnelle utilisant des contenants ouverts avec celle inpliquant une dissolution acide effectuée dans des contenants fermés et faisant appel à des micro-ondes. Des mesures analytiques faisant appel à la spectroscopie d'absorption atomique à flamme démontrent que tout le zinc ainsi que tout la cuivre des échantillons est dissous en moins de 7 min lorsqu'on utilise un four à micro-onde commercial de 400 W. On peut traiter jusqu'à sept échantillons de 500 mg à la fois. On doit s'assurer que la quantité de substances organique présente dans les sols ne créera pas un excés de pression au cours de la dissolution.

Mots clés : dissolution à l'aide de microondes; analyse des sols, détermination de traces de métaux, spectroscopie d'absorption atomique.

Introduction

In trace element analysis of soil by flame atomic absorption spectroscopy (FAAS), sample dissolution is often the most time-consuming step. While HNO_3 alone may be sufficient to liberate metals which are bound to organic matrices, Jackson and Newman (1) warn against its use for metals in inorganic material. Unless HF and hot, concentrated $HClO_4$ are used, metals contained in crystal lattices of unweathered primary minerals resist conventional open vessel digestions (2, 3). The best alternative, dissolution using $HClO_4$, requires careful supervision and special fume hoods equipped with wash-down facilities. The introduction of microwave ovens for analytical sample dissolution (4) has allowed many of the problems associated with conventional methods to be overcome (5–9). Several types of closed vessels for microwave digestions have been used. These provide the elevated pressures and temperatures necessary for rapid decomposition of samples. In this work, the completely closed type (CCT) vessels described by Berman and co-workers (10) were used for the treatment of a weathered tropical soil prior to analysis for zinc and copper. These vessels of Teflon PFA are suitable for samples containing small quantities of organic matter.

Experimental section

Apparatus

The microwave oven was a 700 W Sears Kenmore (Model 87751) operating at a frequency of 24.5 MHz. It has a timing cycle ranging from 1 s to 100 min in 1 s increments and a heating cycle based on power settings ranging from 0% (0 W) to 100% (700 W) in 1% increments. Up to eight 60-mL digestion vessels were handled at a time. These screw-cap, wide-mouth vessels were made of Teflon PFA with a fully fluorinated alkoxy-side chain (Savillex Corp. Minnetonka, MN, USA). A microwave-transparent rotating platform (Litton Corp.) was used to avoid hot spots due to inhomogeneities in microwave energy inside the cavity.

Atomic absorption measurements were performed on a microprocessor-controlled atomic absorption spectrophotometer with deuterium background correction (SpectrAA-10, Varian Techtron). Acetylene (flow rate of 1.5 L/min) was used as fuel and air (12 L/min) as oxidant. The 324.8 and 213.9 nm lines for Cu and Zn respectively were used.

Reagents and samples

All blanks and standard solutions were prepared using distilled demineralized water. All volumetric ware was soaked in 3:1 v/v H_2O/HNO_3 (analytical reagent, BDH Chemicals) before use. 70% $HClO_4$ (analytical reagent, Mallinckrodt Chemical Works), 49% HF (reagent grade, Fisher), and 65% HNO_3 (Seastar Chemicals, Sidney, BC, Canada, produced by double sub-boiling distillation in quartz) were used for all ashing procedures. Solutions were stored prior to measurement in 60-mL polyethylene bottles (Nalgene).

The soil samples were collected in a systematic grid pattern from a sugarcane field of the Royal Swaziland Sugar Corporation (Field 201, Simunye Plantation, Kingdom of Swaziland). The 500-mg increments were dried and sterilized by heating for a week at 110°C, then transferred to polyethylene bottles for shipment to Canada. The dry samples were gound in a motorized mortar and pestle to allow 95% passage through a 150-mesh seive. Canadian (CCRMP) certified reference soil standards SO-2, SO-3, and SO-4 were used to evaluate the validity of the procedures.

Analytical procedures

Open vessel dissolution of soil using HNO_3, HF, and $HClO_4$

To a finely divided 500-mg test portion of soil in a Teflon digestion vessel were added 6 mL HNO_3, 3 mL HF, and 2 mL $HClO_4$. The vessel was tightly capped and placed in a boiling water bath for 2.5 h. After cooling the contents were transferred to a Teflon beaker and fumed to near dryness at 200°C inside a stainless steel perchloric acid fume hood. (CAUTION: Use only a system specifically designed for $HClO_4$ fumes.) The resulting residue was dissolved in 2 mL HNO_3 and 2 mL $HClO_4$ and fumed again to near dryness. The colorless residue was re-dissolved in 2 mL HNO_3 to give a clear solution which was diluted to

100 mL. A blank, prepared by running the acid mixtures without the sample through all the procedures, was included with each set of samples run.

Closed vessel microwave acid digestion using HNO_3 and HF

A maximum of 500 mg of soil was weighed into Savillex Teflon vessels. To each vessel was added 4 mL HNO_3 and 7 mL HF and the lids tightened with a plastic wrench. Eight vessels, including one blank, were positioned in a ring in a 4-L polyethylene container with a tight fitting lid to contain fumes from possible leakage. This container was then placed in the microwave oven. A beaker containing 400 mL of water was also placed in the oven and the power and time settings adjusted. (CAUTION: Excessive gas generation within closed container may cause vessel rupture and explosion. The use of vessels with safety rupture disks, which have recently become commercially available, is strongly recommended.)

After digestion and cooling, the contents of each vessel were transferred to 100-mL polyethylene volumetric flasks and diluted to volume with deionized water.

Standard additions and AAS measurements

For each sample, four 20-mL aliquots of solution were pipetted into four 50-mL polyethylene volumetric flasks. A Socorex micropipet was used to transfer 5 to 75 μL volumes of 1000 ppm Zn^{2+} and Cu^{2+} stock solutions into the flasks. Standard additions plots, together with calculated values for the concentration axis intercepts using linear regression, were obtained from an on-line Epson (Spectrum LX-80) printer.

Results and discussion

Validity of conventional open vessel technique

Several 500-mg portions from selected samples of Swaziland soil were digested with $HClO_4$ and analyzed by standard additions. Reference soil sample SO-4 was included to evaluate the accuracy of the dissolution scheme. The results obtained are presented in Table 1.

All samples were completely dissolved after 10–12 h. The SO-4 results are in good agreement with certified values at the 95% confidence level. This method is therefore reliable, and can be used as a control method for testing the accuracy of the microwave procedure.

Microwave acid dissolution vs. control method

A preliminary study using HNO_3 and HF digestion gave the results presented in Table 2. The scheme used in this initial study involved an initial 15-min exposure to microwave energy at 15% power, followed by cooling and venting of the Teflon vessels. The venting step was necessary to release pressure build up by acid fumes and gaseous oxidation products. After retightening, the vessels were heated for a further 60 min at 30% microwave power.

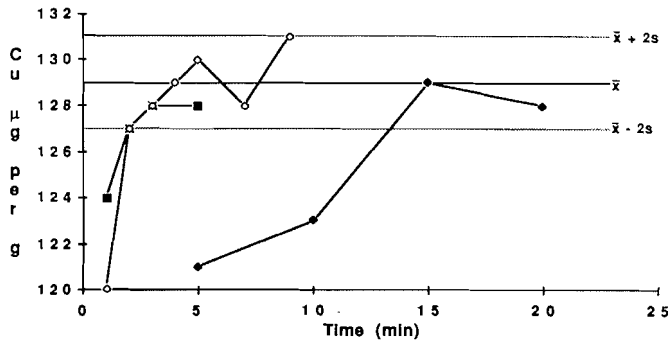

FIG. 1. Copper results vs. time for microwave digestion of sample 201-24 at 35 (◆), 50 (◇), and 100% (■) power. Dotted lines are 95% confidence limits for average obtained by control method.

The data in Table 2 show that results obtained by both methods fall within one standard deviation of each other. The microwave scheme is therefore as efficient as the control method at extracting Zn and Cu from the soil matrix. The effect of longer dissolution times is shown in Table 3. The reported times do not include an initial 15% power–15 min venting stage. For these runs, venting was necessary every 30 min during the first 2 h of digestion and every 60 min thereafter. The results indicate that no advantage is gained by using digestion periods longer than 1 h at 30% microwave power; in fact, time constraints and deterioration of the digestion vessels mitigate against extended times. Even with pressure release each 30 min, pressure build up during the digestion caused the vessels to bulge permanently around the seals. Some residue remained even after 6 h digestion; the extraction of Zn and Cu was complete, however.

Effect of microwave power

Higher power settings were investigated with the aim of finding optimum conditions for complete extraction of Zn and Cu from the soil matrix in the shortest possible time and with minimum pressure build up. Plots of the results obtained for Cu and Zn analyses at power settings of 35% (300 W), 50% (400 W), and 100% (700 W) are shown in Figs. 1 and 2. In both figures the solid horizontal line represents mean estimates obtained by the control method and microwave digestions of test portions, while the broken lines are the 95% confidence limits based on the standard deviation estimates. The plots show a decrease in the time required to achieve complete extraction of Zn and Cu as microwave power increases. At the same time, however, risks of sample loss, container deformation and explosion increase. Full power (700 W) is not recommended for sample digestions by this method. On the basis of convenience, safety, and fast dissolution, 50% power (400 W) was found to be a satisfactory compromise. Even though complete recovery

SO-4[3]	95	95 (1)	25	24

*Numbers in parentheses are number of test portions analyzed.

†Certified values: [1]Zn = 124 ± 5, Cu = 7 ± 1; [2]Zn = 52 ± 3, Cu = 17 ± 1; [3]Zn = 94 ± 3, Cu = 22 ± 1.

of Zn and Cu is observed after 4 to 5 min digestion at a 50% power setting, 7 min was chosen for subsequent sample preparation to provide a safety margin.

Reliability of microwave acid dissolution

Standard reference materials SO-2, SO-3, SO-4, and several randomly selected samples from the field were analyzed using the HF-HNO_3 scheme at 400 W for 7 min. In Table 4, the results are compared with those obtained by total dissolution with $HClO_4$, and also with certified values. There is no significant difference between the means obtained by the two methods for Zn and Cu, and the results by microwave dissolution are in good agreement with certified values for the standard reference soils.

Conclusions

The microwave acid dissolution procedure described gives the same results as conventional total dissolution, but is faster and has less likelihood of contamination than open vessel methods which employ HF, HNO_3, and $HClO_4$. However, since 100% dissolution of test portions may not be achieved by this method, tests should be performed to ensure that the insoluble residue does not contain significant quantities of the element(s) being investigated. Other soil types besides the ones investigated in this study may require different dissolution conditions, and hence the optimum conditions described here should be used only as a guide. Pressure build up inside the digestion vessels may cause leakage of contents and possibly explosions if the samples being digested contain large quantities of organic matter. Therefore caution and close supervision are recommended for all digestions under closed conditions. After this work was completed commercial vessels provided with rupture disks became available. Use of such vessels is highly recommended.

Excess volumes, isentropic compressibilities, and viscosities of binary mixtures containing cyclohexene

P. RAJA SEKAR, R. VENKATESWARLU, AND KALLURU S. REDDY
Department of Chemistry, Sri Venkateswara University, Tirupati 517 502, India

Received July 13, 1989

P. RAJA SEKAR, R. VENKATESWARLU, and KALLURU S. REDDY. Can. J. Chem. **68**, 363 (1990).

Excess volumes, excess isentropic compressibilities, and excess viscosities have been reported for the binary liquid mixtures of cyclohexene with *n*-hexane, cyclohexane, benzene, trichloromethane, tetrachloromethane, and 1,4-dioxane at 303.15 K. V^E results are negative for mixtures of cyclohexene with *n*-hexane and tetrachloromethane and are positive for the remaining systems. k_S^E values are negative for mixtures of cyclohexene with *n*-hexane and positive for all other systems. The data of $\Delta \ln \eta$ are positive for cyclohexene with cyclohexane and tetrachloromethane, and negative for the remaining systems. Prigogine–Patterson–Flory equation of state theory has been applied to predict excess volumes and excess enthalpies, and the viscosity relations proposed by Bloomfield are used to calculate free energy and free volume contributions to excess viscosity.

Key words: excess volumes, excess isentropic compressibilities, excess viscosities.

P. RAJA SEKAR, R. VENKATESWARLU et KALLURU S. REDDY. Can. J. Chem. **68**, 363 (1990).

Opérant à 303,15 K, on a mesuré les volumes en excès, les compressibilités isentropiques en excès et les viscosités en excès de mélanges liquides binaires de cyclohexène avec le *n*-hexane, le cyclohexane, le benzène, le trichlorométhane, le tétrachlorométhane et le 1,4-dioxane. Les valeurs de V^E sont négatives pour les mélanges de cyclohexène avec le *n*-hexane et le tétrachlorométhane alors qu'elles sont positives avec les autres systèmes. Les valeurs de k_S^E sont négatives pour les mélanges de cyclohexène avec le *n*-hexane et elles sont positives pour tous les autres systèmes. Les données de $\Delta \ln \eta$ sont positives pour le cyclohexène avec le cyclohexane et avec le tétrachlorométhane et elles sont négatives pour tous les autres systèmes. On a utilisé l'équation de Prigogine–Patterson–Flory relative à la théorie de l'état pour prédire les volumes et les enthalpies en excès alors qu'on a utilisé les relations de viscosité proposées par Bloomfield pour calculer les contributions d'énergie libre et de volume libre à la viscosité en excès.

Mots clés : les volumes en excès, les compressibilités isentropique en excès, les viscosités en excès.

[Traduit par la revue]

Introduction

As a part of our study on thermodynamic and physical properties of liquid mixtures, here we report excess volumes, excess isentropic compressibilities, and excess viscosities for mixtures containing an unsaturated hydrocarbon. The properties have been measured at 303.15 K for the following binary mixtures: cyclohexene with *n*-hexane, cyclohexane, benzene, trichloromethane, tetrachloromethane, and 1,4-dioxane. These systems have been selected with a view to study the nature of interaction of π electrons of cyclohexene in different mixtures in which the second components vary systematically from nonpolar to polar. Excess enthalpies for these systems have been reported in the literature (1–5) but there is no such measurements on the properties selected here except excess volumes for some systems at 298.15 K (6).

The experimental excess volumes are analysed in light of the Prigogine–Patterson–Flory theory (7–10). The various contributions to excess volume are evaluated and the importance of cohesive energy factor in the prediction of excess volumes is discussed. The viscosity relation proposed by Bloomfield and Dewan (11, 12) is also used to calculate the free volume and the free energy contributions to excess viscosity.

Experimental

Analar samples of benzene (SD's), tetrachloromethane (SD's), *n*-hexane (SD's), cyclohexane (BDH), and 1,4-dioxane (BDH) were purified by the methods described earlier (13–15). Trichloromethane was dried over calcium chloride for 2 days and fractionally distilled. Cyclohexene was purified by refluxing over sodium for 7 h and fractionally distilled. The purity of the samples was ascertained by comparing boiling points and densities with the literature data (16, 17) and are shown in Table 1.

Excess volumes were measured using batch dilatometer technique described earlier (18) and were accurate to ± 0.003 cm^3 mol^{-1}.[1] Densities were calculated from excess volumes using the relation

$$[1] \qquad \rho = \frac{x_1 M_1 + x_2 M_2}{x_1 V_1 + x_2 V_2 + V^E}$$

for mixtures, and with the aid of a bicapillary pycnometer for pure components. Densities of mixtures and of pure components were accurate to $\pm 5 \times 10^{-5}$ g cm^{-3}.

Isentropic compressibilities were calculated using the relation

$$[2] \qquad k_S = 1/u^2\rho$$

The sound velocities, u, were measured with an accuracy of $\pm 0.1\%$ using an ultrasonic interferometer at a fixed frequency of 1 MHz. Viscosities were measured using an Ostwald viscometer and the values were accurate to $\pm 0.5\%$.

[1]Nomenclature used in this article is as follows: C_P, molar heat capacity at constant pressure; ΔG^R, residual free energy; H^E, excess enthalpy; ΔH^M, enthalpy of mixing; k_S, isentropic compressibility; k_T, isothermal compressibility; P_i^*, characteristic pressure of component $i = \alpha T \tilde{v}^2 k_T^{-1}$; ΔS^R, residual entropy; $\tilde{T}_i$, reduced temperature of component $i = (\tilde{v}_i^{1/3} - 1)\tilde{v}_i^{-4/3}$; T_i^*, characteristic temperature of component $i = T\tilde{T}_i^{-1}$; U_i^*, characteristic energy of component $i = P_i V_i^*$; V_i, molar volume of component i; V_i^*, characteristic volume of component $i = V_i \tilde{v}_i^{-1}$; $\tilde{v}_i$, reduced volume of component

$$i = \left[\frac{(3 + 4\alpha_i T)}{3(1 - \alpha_i T)}\right]^3$$

V^E, excess volume; x_i, mole fraction of component i; X_{12}, Flory interaction parameter; α, thermal expansion coefficient; η, viscosity; ϕ_i, segment fraction of component $i = x_i V_i^* / \Sigma x_i V_i^*$; ψ_i, energy fraction of component $i = x_i U_i^* / \Sigma x_i U_i^*$; θ_2, surface fraction of component $2 = x_2 V_2^{*2/3} / (x_1 V_1^{*2/3} + x_2 V_2^{*2/3})$; σ, standard deviation.

1,4-Dioxane	1.02056	1.02230	373.65	374.47

Theory

Excess volumes were predicted using the following relation (7) developed on the basis of Van der Waals model used by Flory (19, 20) for the dependence of energy on volume.

$$[3]\quad \frac{V^E}{x_1V_1^* + x_2V_2^*} = \tilde{T}\frac{\partial\tilde{\nu}}{\partial\tilde{T}}\psi_1\theta_2X_{12}/P_1^* + (\tilde{\nu}_1 - \tilde{\nu}_2)(\psi_1 - \phi_1) - \frac{1}{2}\left[\frac{\tilde{\nu}_1 - \tilde{\nu}_2}{\partial\tilde{\nu}/\partial\tilde{T}}\right]^2\frac{\partial\tilde{\nu}}{\partial\tilde{T}^2}\left\{\psi_1\psi_2 + (\psi_1 - \phi_1)^2\right\}$$

where $\tilde{\nu} = \phi_1\tilde{V}_1 + \phi_2\tilde{V}_2$ and $\tilde{T}$ corresponds to $\tilde{\nu}$. The first term in the equation is represented as $V^E(X_{12})$ which is the excess volume contribution arising from interactional, steric hindrance, and disorder effects. The second term represents $V^E(P^*)$, it is the excess volume contribution due to cohesive energy difference between unlike components. The third term, V^E(f.v.) depends on the difference between free volumes of unlike components.

An appropriate form of the Prigogine–Patterson–Flory theory has been used to evaluate the interactional and free volume (f.v.) contributions of excess enthalpy. The free volume contribution is defined as

[4] $$H^E(\text{f.v.})/(x_1U_1^* + x_2U_2^*) = \tilde{C}_P(\tilde{T}_U)[\psi_1\tilde{T}_1 + \psi_2\tilde{T}_2 - \tilde{T}_U]$$

where $\tilde{T}_U$ is the average reduced temperature for the solution appropriate to the energy $\tilde{U}$ and is given by

[5] $$\tilde{U}(\tilde{T}_U) = \psi_1\tilde{U}(\tilde{T}_1) + \psi_2\tilde{U}(\tilde{T}_2)$$

Applying the Van der Waals model used by Flory, $\tilde{T}_U$ is obtained with the relation

[6] $$\tilde{T}_U = \tilde{V}_U^{-1}(1 - V_U^{-1/3})$$

where $\tilde{V}_U^{-1} = (\psi_1/\tilde{V}_1 + \psi_2/\tilde{V}_2)$ and $\tilde{C}_P(\tilde{T}_U)$ in eq. [4] is defined as $(\frac{4}{3}\tilde{V}_U^{-1/3} - 1)^{-1}$.

The interactional contribution to H^E is defined in terms of the Flory parameter X_{12} which also includes the contributions due to disorder and steric hindrance effects. The X_{12} parameter was correlated using the following relation

[7] $$\frac{H^E(\text{exp}) - H^E(\text{f.v.})}{x_1U_1^* + x_2U_2^*} = \frac{X_{12}}{P_1}\psi_1\theta_2 f(\tilde{V}_U)$$

where $f(\tilde{V}_U)$ is defined by $(4\tilde{V}_U - 3\tilde{V}_U^{4/3})^{-1}$.

The theory is applied to predict excess volumes for all the mixtures at equimolar composition using eq. [3]. The interaction parameter X_{12} required in this equation is obtained from experimental excess enthalpies (1–5). Similarly, H^E values were predicted using eqs. [4] and [7] with X_{12} values taken from experimental excess volumes.

According to Bloomfield and Dewan (11), theoretical excess viscosity is represented as

[8] $$\ln\eta - (x_1\ln\eta_1 + x_2\ln\eta_2) = -\frac{\Delta G^R}{RT} + \left[\frac{1}{\tilde{\nu} - 1} - \frac{x_1}{\tilde{\nu}_1 - 1} - \frac{x_2}{\tilde{\nu}_2 - 1}\right]$$

[9] $$\Delta\ln\eta_{\text{the}} = \ln\eta_G + \ln\eta_v$$

where $\ln\eta_G$ and $\ln\eta_v$ are the viscosity contributions to theoretical excess viscosity according to absolute rate and free volume theories, respectively. Equation [9] can be written as

[10] $$\Delta\ln\eta_{\text{the}} = \ln\eta_H + \ln\eta_S + \ln\eta_v$$

where

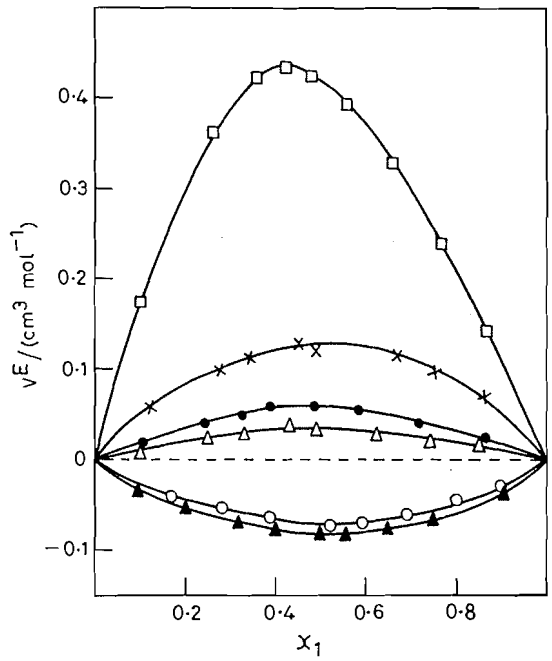

FIG. 1. Excess volumes versus mole fraction of cyclohexene for the systems cyclohexene + *n*-hexane (○), + cyclohexane (●), + benzene (×), + trichloromethane (△), + tetrachloromethane (▲) and + 1,4-dioxane (□) at 303.15 K.

$$\ln \eta_H = -\frac{H^E}{RT},$$

$$\ln \eta_S = \frac{\Delta S^R}{R}$$

and

$$\ln \eta_V = \frac{1}{\tilde{v} - 1} - \frac{x_1}{\tilde{v}_1 - 1} - \frac{x_2}{\tilde{v}_2 - 1}$$

The enthalpy contributions, $\ln \eta_H$, to theoretical excess viscosity are calculated from the experimental excess enthalpies (1–5). The residual entropy of mixing, ΔS^R, required in the calculation of entropy contribution to theoretical excess viscosity, is obtained from the Flory (18) equation,

[11] $$\Delta S^R = -3\left[\frac{x_1 P_1^* V_1^*}{T_1^*} \ln \frac{\tilde{v}_1^{1/3} - 1}{\tilde{v}^{1/3} - 1} + \frac{x_2 P_2^* V_2^*}{T_2^*} \ln \frac{\tilde{v}_2^{1/3} - 1}{\tilde{v}^{1/3} - 1}\right]$$

Reduced volumes for the mixture and for the pure components are calculated with experimental densities using the equations

[12] $$\tilde{v} = \frac{V}{(x_1 V_1^* + x_2 V_2^*)}, \quad \tilde{v}_i = \frac{V_i}{V_i^*} \qquad (i = 1, 2)$$

The parameters of the pure components used in the above equations have the same significance as described by Flory (18, 19) and are defined in the list of symbols (see footnote 1).

Results and discussion

Excess volumes are given in Table 2. Excess isentropic compressibilities are calculated using the relation

[13] $$k_S^E = k_{S,\text{mix}} - (\phi_1 k_{S_1} + \phi_2 k_{S_2})$$

where ϕ_1 and ϕ_2 are volume fractions. Excess isentropic

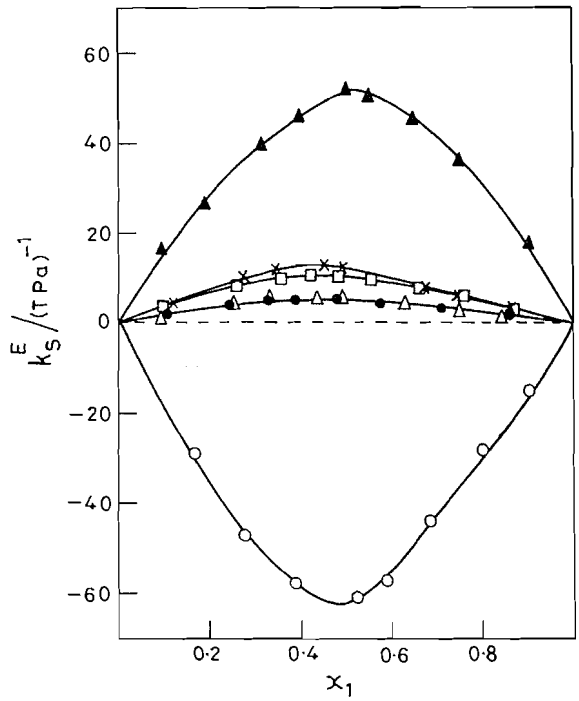

FIG. 2. Excess isentropic compressibilities versus mole fraction of cyclohexene for the systems cyclohexene + *n*-hexane (○), + cyclohexane (●), + benzene (×), + trichloromethane (△), + tetrachloromethane (▲), and + 1,4-dioxane (□) at 303.15 K.

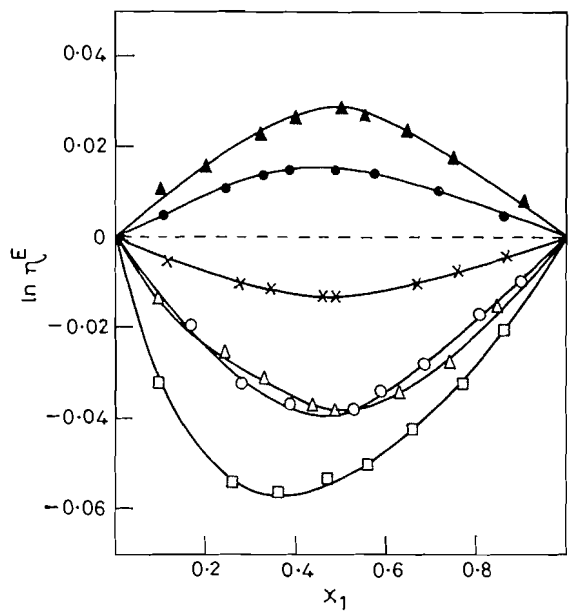

FIG. 3. Excess viscosities versus mole fraction of cyclohexene for the systems cyclohexene + *n*-hexane (○), + cyclohexane (●), + benzene (×), + trichloromethane (△), + tetrachloromethane (▲), and + 1,4-dioxane (□) at 303.15 K.

compressibilities, densities, and sound velocities are given in Table 3. Excess viscosities are calculated using the relation

[14] $$\Delta \ln \eta = \ln \eta_{\text{mix}} - (x_1 \ln \eta_1 + x_2 \ln \eta_2)$$

and are included in Table 3. Excess properties as a function of mole fraction are shown in Figs. 1 to 3 and are also fitted into an empirical equation

[15] $$x^E = x_1(1 - x_1)[a_1 + a_2(1 - 2x_1) + a_3(1 - 2x_1)^2]$$

The parameters a_1, a_2, and a_3 are calculated by the method of

k_S^E (TPa^{-1})	42.89	−11.06	−13.09	0.4
$\Delta \ln \eta$	−0.2129	0.1014	−0.0698	0.001

least squares and are given in Table 4 along with the standard deviation $\sigma(x^E)$. x^E represents V^E, k_S^E, and $\Delta \ln \eta$.

The values of the parameters of pure components required in the prediction of V^E, H^E, and $\Delta \ln \eta$ are given in Table 5. The values of the interaction parameter X_{12} and various contributions to excess volume are included in Table 6 along with the experimental V^E for equimolar mixtures. The comparison of theoretical and experimental excess enthalpies at $x_1 = 0.5$ are shown in Table 7, along with the interaction parameter X_{12}. Excess viscosity results for all the mixtures at $x_1 = 0.5$ are compared in Table 8.

Excess volumes are negative for the systems cyclohexene with *n*-hexane and tetrachloromethane and positive for the remaining systems over the entire range of mole fraction. k_S^E values are negative for mixtures containing *n*-hexane and positive in all other systems. $\Delta \ln \eta$ are positive for the systems cyclohexene with cyclohexane and tetrachloromethane and negative in the remaining systems. The results show no simple pattern and cannot be interpreted only in terms of π–π, π–H, and π–n interactions.

The results presented in Table 6 reveal that the experimental and theoretical excess volumes at $x_1 = 0.5$ agree in sign in all the systems except in the mixtures containing tetrachloromethane. Quantitative agreements is also satisfactory in the systems of cyclohexene with cyclohexane and 1,4-dioxane. In the system, cyclohexene + *n*-hexane, the interactional contribution to excess volumes is positive but it is dominated by the negative contributions due to $V^E(P^*)$ and V^E(f.v.). This suggests that the contributions to V^E(calc) due to packing effects are dominant over the interactional contributions. Further, the large negative $V^E(P^*)$ indicate that *n*-hexane with low P^* (less cohesive) contracts more in the solutions and hence

TABLE 8. Entropy ln η_S, enthalpy ln η_H, free volume ln η_v, and free energy ln η_G contributions to viscosity. Theoretical Δ ln η_{the} and experimental Δ ln η_{exp} excess viscosities, and reduced volume $\tilde{v}$, for equimolar mixtures at 303.15 K

Cyclohexene +	$\tilde{v}$	ln η_S	ln η_H	ln η_G	ln η_v	Δ ln η_{the}	Δ ln η_{exp}
n-Hexane	1.3107	0.018	−0.065	−0.047	−0.028	−0.075	−0.038
Cyclohexane	1.2940	0.009	−0.036	−0.027	−0.010	−0.037	0.015
Benzene	1.2961	0.013	−0.127	−0.114	−0.015	−0.129	−0.013
Trichloromethane	1.2960	0.002	0.042	0.044	0.002	0.046	−0.038
Tetrachloromethane	1.2930	0.012	0.092	0.104	0.013	0.117	0.029
1,4-Dioxane	1.2873	0.074	−0.357	−0.283	−0.083	−0.366	−0.052

molecules have more compact arrangement. In all other systems $V^E(P^*)$ contributions are small so that the sign and magnitude of V^E(calc) depend mainly on interactional contributions. The results in Table 7 reveal that the theoretical and experimental excess enthalpies are in semiquantitative agreement in cyclohexene with cyclohexane and 1,4-dioxane, and in sign agreement in the systems cyclohexene with benzene and tetrachloromethane. However, the H^E results are not even in qualitative agreement in the other two systems.

The data presented in Table 8 indicate that the free volume contribution to excess viscosity are nearer to the experimental excess viscosity in all the systems than the free energy contribution to excess viscosity or theoretical excess viscosity. Even here ln η_v and ln η_{exp} are not in sign agreement for the systems cyclohexene with cyclohexane and tetrachloromethane; however, in other systems the results are semiquantitative.

Received August 29, 1989

LI YA, GEORGE M. STRUNZ, and LARRY A. CALHOUN. Can. J. Chem. **68**, 371 (1990).

1-Desacetylwilfordine, **8**, 1-desacetylwilfortrine, **9**, and 2-debenzoyl-2-nicotinoylwilforine, **10**, have been isolated from root extracts of the Chinese medicinal and insecticidal plant *Tripterygium wilfordii*. Analysis of the ^1H and ^{13}C NMR spectra of **8** and **10**, with the aid of COSY, HCCOSY, and COLOC experiments, has allowed unambiguous chemical shift assignments of all protons and carbons of these alkaloids.

Key words: alkaloids, sesquiterpene, Celastraceae, *Tripterygium*, NMR.

LI YA, GEORGE M. STRUNZ et LARRY A. CALHOUN. Can. J. Chem. **68**, 371 (1990).

On a isolé le wilfordine-désacétyl-1, **8**, le wilfortrine-désacétyl-1, **9**, et le wilforine-débenzoyl-2-nicotinoyl-2, **10**, des extraits de racines de la plante médicinale et insecticide chinoise, *Tripterygium wilfordii*. L'analyse des spectres RMN du ^1H et ^{13}C, des composés **8** et **10**, à l'aide des expériences COSY, HCCOSY et COLOC a permis d'attribuer de façon définitive tous les déplacements de tous les protons et de tous les atomes de carbone de ces alcaloïdes.

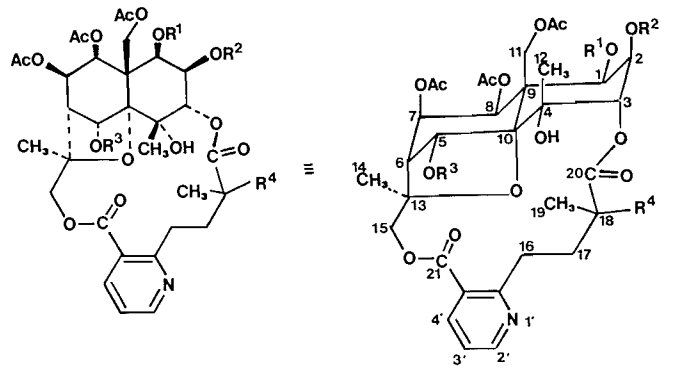
Mots clés : alcaloïdes, sesquiterpène, Celastraceae, *Tripterygium*, RMN.

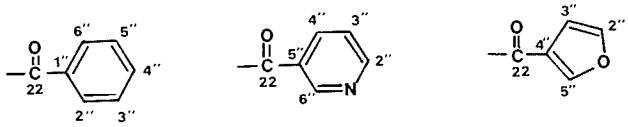
Introduction

The presence of alkaloids in plants of the Celastraceae family has been recognized for more than 50 years (1). It was not, however, until 1970 that the first complete structures were announced for members of this large group of sesquiterpene alkaloids (2). The Thunder God Vine, *Tripterygium wilfordii* Hook, belonging to the Celastraceae family, is widely distributed in southern China and has been utilized in traditional Chinese medicine for treatment of cancer, rheumatism, and lupus (3). The insecticidal properties of *T. wilfordii* are also noteworthy, and this species, as well as *T. forrestii*, were commonly used as contact insecticides in rural China (1). A number of alkaloids, including wilfordine, wilforine, wilforzine, wilforgine, and wilfortrine, were isolated from *T. wilfordii* by Beroza (refs. cited in ref. 1). The structure of wilfordine, **1**, $C_{43}H_{49}NO_{19}$, was elucidated by Yamada *et al.* (4), and structures of wilforine, **2**, and wilfortrine, **3**, postulated by Smith (1) on the basis of Beroza's earlier research (refs. cited in ref. 1), were established by Wu *et al.* (5, 6).

In recent studies, a group at the Shanghai Institute of Materia Medica, including one of us (Li Ya), has reisolated these alkaloids from *T. wilfordii*, and proved the structure of wilforgine, **4**, postulated earlier by Smith (1), and that of wilforzine, **5** (7). An alkaloid, designated wilformine, was found (7) to be identical with euonine, **6**, previously isolated from *Euonymus sieboldiana* (8). The Shanghai researchers have, in addition, established the structure of the new alkaloid wilforidine, **7** (9).

In this communication, we report the isolation and structure determination of three additional related alkaloids from *T. wilfordii*. The chemical shifts of *all* protons and carbons in the NMR spectra of two of these alkaloids are unambiguously assigned.





Wilfordine (**1**) R^1 = Ac, R^2 = benzoyl, R^3 = Ac, R^4 = OH

Chromatography of the crude crystalline alkaloid mixture obtained from extracts of *T. wilfordii* afforded the previously reported alkaloids followed, in later fractions, by additional compounds, three of which could readily be separated by preparative thin-layer chromatography on silica gel. On the basis of its mass spectrum (*m/z* 841; $C_{41}H_{47}NO_{18}$), it was surmised that the most mobile of these (solvent system ethyl acetate – chloroform, 4:1) was a desacetylwilfordine. The relationship with wilfordine was confirmed when acetylation of the new compound yielded the parent alkaloid.

The proton NMR data and chemical shift assignments for wilfordine (cf. ref. 6, 9) and desacetylwilfordine are listed in Table 1. The assignments are based on ^{1}H–^{1}H shift correlation (COSY) experiments (10). The placement of the distinguishing unacetylated hydroxyl group of desacetylwilfordine at C-1, as in **8**, follows, *inter alia*, from the 1.16-ppm upfield shift of H-1 relative to its position in wilfordine.

The carbon-13 NMR data and chemical shift assignments are listed in Table 2. As expected, the carbon-13 spectra of wilfordine, **1**, and 1-desacetylwilfordine, **8**, are very similar; however, carbons 2 and 11 of wilfordine are significantly shielded in comparison with those of 1-desacetylwilfordine, whereas carbon 1 does not display the anticipated 2-ppm shift associated with acetylation (11). These observations suggest that a conformational change may occur in the B ring of wilfordine upon deacetylation at position 1, resulting in a partial release of steric compression.

The assignments of the hydrogen-bearing carbons were established by ^{1}H–^{13}C shift correlation (HCCOSY) experiments (12). Quaternary carbons were assigned by the COLOC (13) experiment, which allows proton–carbon correlations over two and three bonds. Thus the placement of the benzoate group at C-2 was confirmed by the detection of chemical shift correlations between the protons at δ_H 5.36 (H-2) and δ_H 8.03 (H-2″, H-6″) ppm and the carbonyl (C-22) at δ_C 165.88 ppm. The resonance at δ_C 172.19 ppm could be assigned to C-20 by a correlation to δ_H 5.14 ppm (H-3). This, in turn, allowed the assignment of δ_H 1.46 ppm to the 19-methyl group by an observed correlation to C-20. The positions and assignments of the acetate groups were also discernible by an analysis of the COLOC experiment. For example, the methyl carbon at δ_C 20.95 ppm was correlated with the methyl protons at δ_H 1.97 ppm by the HCCOSY experiment. The COLOC *F*1 trace at δ_C 169.47 ppm showed correlations with δ_H 1.97, 4.60 (H-11a), and 5.59 (H-11b) ppm, placing this acetate group at the C-11 position. Similarly, the other acetate groups could be assigned to positions C-5, C-7, and C-8, confirming the placement of the distinguishing hydroxyl group at C-1.

Thus, an analysis of the proton, carbon-13, COSY, HCCOSY, and COLOC spectra of wilfordine and 1-

[a]Multiplicities were determined by DEPT (14) experiments.
[b]Broadened lines.
[c,d]May be interchanged due to the proton chemical shift degeneracy of H-7 and H-8 (δ_H 5.60 ppm).

desacetylwilfordine resulted in a complete, unambiguous chemical shift assignment of all protons and carbons of these alkaloids, as well as providing confirmation of their structures.

The FAB mass spectrum of the second new alkaloid (m/z 832, $C_{39}H_{45}NO_{19}/H$; 95, C_5H_3O) was indicative of a desacetylwilfortrine, and the relationship between the new alkaloid and its known acetylated relative (6, 15) was confirmed by an acetylation experiment. Proton NMR data and chemical shift assignments for desacetylwilfortrine, based on comparison with the previously reported spectrum of wilfortrine (15) and confirmed by COSY experiments, are compiled in Table 1. Carbon-13 data are in Table 2.

The salient feature of the ^1H spectrum of desacetylwilfortrine is the 1.16-ppm upfield shift of the H-1 signal relative to its position in the spectrum of wilfortrine. Thus the unacetylated hydroxyl group is again at C-1, establishing the new compound as 1-desacetylwilfortrine, **9**.

The mass spectrum of the least mobile of the new alkaloids (m/z 868, $C_{42}H_{48}N_2O_{18}$) suggested that it might be 2-debenzoyl-2-nicotinoyl wilforine, **10**,[2] and this hypothesis was confirmed by ^1H and ^{13}C NMR analysis (cf. Tables 1 and 2). Proton NMR assignments were established by a COSY (10) experiment, while the carbon assignments were made by comparison with those of wilfordine. With the obvious exception of the nicotinoyl moiety, carbons 17, 18, and 19 of the macrocyclic ring, and the site of attachment at C-3, the NMR data for compound **10** are in excellent agreement with those of wilfordine. The analysis of the carbon-13 spectrum of **10** was complicated initially by the "fluctional" behavior of the macrocyclic ring in this molecule, which resulted in broadened lines for carbons 16, 2′, and 4′. Re-recording of the spectrum at temperatures of 35 and 40°C resulted in a progressive sharpening

[2]While this manuscript was in preparation, a paper came to our attention reporting the isolation of compound **10**, designated wilfornine, from *T. wilfordii* (16).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

of these lines as the fast exchange limit was reached. The fluctionable behavior was not observed in wilfordine, 1-desacetylwilfordine, and 1-desacetylwilfortrine. Whereas this may reflect conformational changes that are too rapid to be observed on the NMR time scale, a more likely explanation may be that in **1**, **8**, and **9**, where R^4 = OH, hydrogen bonding involving this C-18 hydroxyl group locks the macrocyclic ring into a more rigid conformation.

Experimental

Melting points were determined on a hot-stage apparatus and are uncorrected. Infrared spectra were recorded on a Philips Pye Unicam PU9516 infrared spectrophotometer. FAB mass spectra were provided by Dr. A. Hogg, University of Alberta. Accurate mass measurements were made on a Kratos MS-50 instrument. All NMR spectra were recorded in $CDCl_3$ on a Varian XL-200 spectrometer operating at frequencies of 200.068 MHz for ^1H and 50.308 MHz for ^{13}C. Tetramethylsilane was used as an internal standard. The COSY and HCCOSY spectra were obtained using standard Varian software. COLOC spectra were recorded twice for compounds **1** and **8**, with constant evolution time period, T_1, values of 60 and 100 ms. The refocussing delay time, $\Delta 2$, was 30 ms. For each spectrum, 256 transients were recorded for each of 128 t_1 increments with a recycle delay time of 1 s/transient for a total experiment time of 14 h. The digital resolution was 0.06 and 0.09 ppm in F_1 and F_2, respectively.

Isolation of alkaloids

Air-dried roots of *T. wilfordii* were milled to a coarse powder. Powdered root material (5 kg) was moistened with 10% NH_4OH solution and then extracted with refluxing ether. The mixture, when cold, was filtered at the pump, and the residue was reextracted with ether four times. The combined extracts were reduced to a small volume *in vacuo*, and then washed four times with equal volumes of 2.5% HCl solution. The aqueous phase was adjusted to pH 9 by addition of concentrated NH_4OH solution, and the resulting precipitate was collected by filtration at the pump. The yield of crude amorphous alkaloidal material thus obtained was 13.0 g (0.26%). The white powdery alkaloid mixture was dissolved in hot methanol and the resulting solution, on standing for several days at ambient temperature, deposited crystals (10% of crude mixture).

The crystalline alkaloid mixture was chromatographed on a column of silica gel (100–120 mesh), using chloroform–acetone (4:1) as eluent.

Fractions displaying similar mobilities on TLC were pooled, and four groups of compounds were thus separated. Fractions 1–3, rechromatographed on a column of silica gel H (30–40 μm) under a pressure of 1.5 kg cm^{-2} with EtOAc–$CHCl_3$ (4:1) as eluent, afforded wilformine[3] (7). The second group, fractions 4–6, chromatographed on silica gel H (or G) (10–40 μm) under 1.5 kg cm^{-2} pressure with cyclohexane–acetone (3:2) as eluting solvent, yielded wilforine (5) and wilforgine (7). Rechromatography of the third group in the same manner produced wilforzine (7), wilfordine (4), and wilfortrine (6). The fourth group, fractions 28–29, was subjected to flash chromatography using EtOAc–$CHCl_3$ (3:2) as eluent, and yielded wilforidine[3] (9), plus a mixture of three new alkaloids, which were separated by preparative thin-layer chromatogrphy.

1-Desacetylwilfordine, obtained in a yield of 185 mg, melted at 182–184°C; IR ($CHCl_3$): *inter alia*, 3680, 3550, 3480, 3040, 3000, 2960, 1750, 1730, 1600, 1590, and 1570 cm^{-1}; ^1H and ^{13}C NMR, see text; mass spectrum (FAB, Cleland matrix): *inter alia*, *m/z* 842 $(MH)^+$, $(C_{41}H_{47}NO_{18}/H)^+$; 105 $(C_7H_5O)^+$, $(PhCO)^+$.

[3]All of the known alkaloids were identified by comparison of their physical and spectroscopic characteristics with those of authentic material, or with literature data.

1-Desacetylwilfortrine, obtained in a yield of 44 mg, melted at 179–182°C; IR ($CHCl_3$): *inter alia*, 3690, 3550, 3480, 3040, 2960, 1745, 1735 (sh), 1602, and 1572 cm^{-1}; ^1H and ^{13}C NMR, see text; mass spectrum (FAB, Cleland matrix): *inter alia*, *m/z* 832 (MH^+), $(C_{39}H_{45}NO_{19}/H^+)$; 95 $(C_5H_3O)^+$, $(Furan\text{-}3\text{-}CO)^+$.

2-Debenzoyl-2-nicotinoylwilforine, obtained in a yield of 20 mg, melted at 177–178°C; IR ($CHCl_3$): *inter alia*, 3680, 3530, 3450, 3040, 2980, 2960, 2880, 1745, 1735 (sh), 1590, and 1570 cm^{-1}; ^1H and ^{13}C NMR, see text; mass spectrum, (FAB, Cleland matrix): *inter alia*, 869 $(MH)^+$, $(C_{42}H_{48}N_2O_{18}/H)^+$;106 $(C_6H_4NO)^+$, $(Pyr\text{-}3\text{-}CO)^+$. Exact mass calcd. for $C_{42}H_{48}N_2O_{18}$: 868.2888; found: 868.2871.

Conversion of 1-desacetylwilfordine to wilfordine

A solution of 1-desacetylwilfordine (34 mg) in pyridine (1.5 mL) and acetic anhydride (0.15 mL) was stirred under anhydrous conditions at ambient temperature for 7 h. Additional acetic anhydride (1.5 mL) was then added and the mixture was set aside with stirring for a further 16 h. Work-up, followed by chromatography of the crude product on preparative layer silica gel plates with cyclohexane–acetone (3:2) as eluting solvent, afforded amorphous wilfordine (33 mg, 92%), Crystallization from methanol gave crystals, mp 174–177°C, identical in all respects with an authentic specimen of wilfordine. No depression of the melting point was observed on admixture with authentic wilfordine.

Conversion of 1-desacetylwilfortrine to wilfortrine

A solution of 1-desacetylwilfortrine (28 mg) in pyridine (1.5 mL) and acetic anhydride (0.5 mL) was stirred under anhydrous conditions at ambient temperature for 16 h.

Work-up and preparative layer chromatography on silica gel plates with EtOAc–$CHCl_3$ (4:1) as eluent afforded 25 mg (85%) of a product, mp 233–235°C, identical with an authentic specimen of wilfortrine. No depression of melting point was observed on admixture with authentic wilfortrine.

Laser flash photolysis in aqueous basic solutions of the ortho acid derivatives 1-(phenyldimethoxymethyl)benzimidazole **2** and 4-bromo-1-(phenyldimethoxymethyl)imidazole **3** results in production of the phenyldimethoxymethyl cation, which has λ_{max} at 260 nm. The cation decays in reactions with water ($k = 9.9 \times 10^4\ s^{-1}$) and hydroxide ion ($2.5 \times 10^8\ M^{-1}\ s^{-1}$) to finally yield methyl benzoate, whose formation was monitored at 234 nm. In solutions with pH 10–12, rate constants measured at this wavelength are the same as those obtained at 260 nm, but with pH >13 and pH <9, rate constants at 234 nm are smaller. With pH 9–10 and pH 12–13, single exponential kinetics are not observed at 234 nm. This behavior is interpreted in terms of a scheme where at each pH there are two consecutive first-order reactions, cation → phenyldimethoxyhydroxymethane (**5**) → ester, and the pH dependencies of the rate constants are such that they cross twice over the pH range of this study. The intermediate **5** is the tetrahedral intermediate formed in the methanolysis of methyl benzoate, and the 234-nm buildup at pH >13 and pH <9 directly measures its breakdown. At pH >13 the rate constant is independent of pH with $k = 9 \times 10^6\ s^{-1}$. This represents the rapid expulsion of methoxide from the conjugate base of **5**. At pH <9 the rate constants are proportional to hydroxide ion concentration, with $k_{OH^-} = 7.5 \times 10^9\ M^{-1}\ s^{-1}$. In these solutions the neutral intermediate predominates and the dependence on [OH^-] of its rate of conversion to ester is interpreted in terms of breakdown of the anion and protonation of this species by water occurring at comparable rates. Thus, k_{OH^-} represents a situation where there is partial rate-limiting deprotonation of the neutral intermediate by hydroxide. The intermediate of this study bears a close resemblance to the tetrahedral intermediate of the hydrolysis of methyl benzoate. The observation that the anionic forms of such intermediates undergo breakdown at rates similar to those associated with the establishment of proton transfer equilibrium explains why the ester undergoes carbonyl oxygen exchange in base at a rate slower than hydrolysis.

Key words: tetrahedral intermediate, flash photolysis, ester hydrolysis.

ROBERT A. MCCLELLAND, V. M. KANAGASABAPATHY et STEEN STEENKEN. Can. J. Chem. **68**, 375 (1990).

La photolyse éclair au laser de solutions basiques aqueuses de dérivés d'ortho acides (1-(phényldiméthoxyméthyl)-benzimidazole **2** et 4-bromo-1-(phényldiméthoxyméthyl)imidazole **3**), conduit à la formation du cation phényldiméthoxy-méthyle qui présente un λ_{max} à 260 nm. Le cation se décompose par réaction avec l'eau ($k = 9{,}9 \times 10^4\ s^{-1}$) et l'ion hydroxyde ($2{,}5 \times 10^8\ M^{-1}\ s^{-1}$) pour donner finalement du benzoate de méthyle dont on détermine la formation en suivant la progression de la bande à 234 nm. Dans des solutions dont le pH varie de 10 à 12, les constantes de vitesse telles que mesurées à cette longueur d'onde sont identiques à celles que l'on obtient à 260 nm; toutefois, à des pH >13 ou <9, les constantes de vitesse évaluées à 234 nm sont plus faibles. À 234 nm et à des pH de 9 à 10 ou de 12 à 13, on n'observe pas de cinétiques exponentielles uniques. On interprète ce comportement en fonction d'un schéma selon lequel il existe, pour chaque pH, deux réactions consécutives du premier ordre : cation → phényldiméthoxyhydroxyméthane (**5**) → ester, et les variations des constantes de vitesse en fonction du pH sont telles qu'elles se coupent deux fois sur la plage de pH examinée au cours de cette étude. Le composé **5** correspond à l'intermédiaire tétraédrique qui se forme lors de la méthanolyse du benzoate de méthyle et l'accumulation observée à 234 nm, pour des pH >13 ou <9, mesure directement sa décomposition. À un pH >13, la constante de vitesse est indépendante du pH et $k = 9 \times 10^6\ s^{-1}$. Cette valeur représente une expulsion rapide du méthylate à partir de la base conjuguée du composé **5**. À des pH <9, les constantes de vitesse sont proportionnelles à la concentration en ion hydroxyde et $k_{OH^-} = 7{,}5 \times 10^9\ M^{-1}\ s^{-1}$. Dans ces solutions, l'intermédiaire neutre prédomine et on interprète la relation qui existe entre la concentration en ions OH^- et sa vitesse de conversion en ester en fonction de deux réactions compétitives, soit une décomposition de l'anion et une protonation de cette espèce par l'eau, qui se produiraient à des vitesses comparables. Ainsi, le k_{OH^-} représenterait une situation dans laquelle il existerait une déprotonation partielle de l'intermédiaire neutre par l'ion hydroxyde qui limiterait la vitesse de la réaction. L'intermédiaire observé au cours de cette étude ressemblerait beaucoup à l'intermédiaire tétraédrique impliqué au cours de l'hydrolyse de benzoate de méthyle. L'observation que les formes anioniques de tels intermédiaires subissent des décompositions à des vitesses semblables à celles associées avec l'établissement d'un équilibre de transfert protonique explique pourquoi, en milieu basique, l'ester subit un échange de l'oxygène du carbonyle à une vitesse inférieure à celle de l'hydrolyse.

Mots clés : intermédiaires tétraédriques, photolyse éclair, hydrolyse des esters.

[Traduit par la revue]

Hemiorthoesters **1** are the tetrahedral intermediates of ester interchange reactions (R′ = alkyl), and obviously bear a close relationship to tetrahedral intermediates of ester hydrolysis (R′ = H).

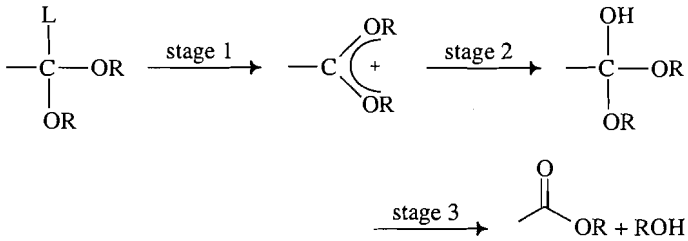
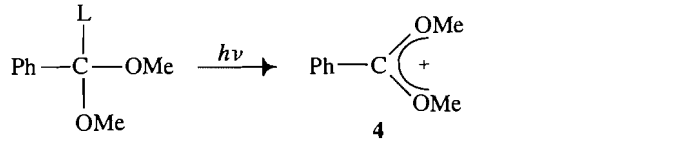
The same intermediates **1** are also encountered in the three-stage hydrolysis of ortho esters and appropriate derivatives, arising from the hydration of an initially formed dialkoxycarbocation.



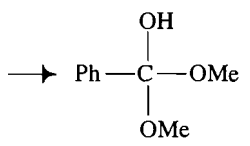
These latter systems have the interesting feature that with some derivatives, under some conditions, stage 3 has been found to be the slowest step in the overall reaction (1–3). When this occurs, the hemiorthoester **1** actually accumulates and can be observed, and rate constants for its breakdown to the final products can then be directly measured. Such kinetic information is normally unobtainable from an investigation of the appropriate ester interchange reaction, where only immeasurably small stationary state concentrations of the tetrahedral intermediate are formed.

For **1** to accumulate it is necessary that both stage 1 and stage 2 in the reaction sequence be faster than stage 3. Stage 2, the hydration of the dialkoxycarbocation, is normally fast (4–6). There is, however, an efficient base catalysis of stage 3, while stage 1 usually occurs only with acid catalysis. The consequence is that, regardless of the relative rates of stage 1 and stage 3 in acidic solutions, stage 1 is invariably the slowest step in neutral and basic solutions and, in such solutions, kinetic information for the hemiorthoester decomposition can no longer be obtained.

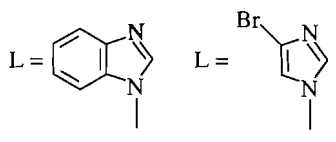
One way of overcoming the problem of the slow first stage would be to have this reaction occur photochemically, thus providing a rapid entry into stages 2 and 3, whose kinetic behavior could then be monitored using the technique of laser flash photolysis. We have recently described experiments involving short-lived carbenium ions being generated by photoheterolysis and photoprotonation (7–10), and dialkoxycarbocations being generated by radical cation fragmentation (6). With the latter system we recognized that the immediate product of the reaction of the cation with water was a hemiorthoester, and wondered whether it might be possible to find conditions to study its decomposition. In this paper we report such an investigation, from the photolysis of the ortho ester derivatives **2** and **3**. These compounds undergo a photoheterolysis, generating as an observable intermediate the phenyldimethoxymethyl cation **4**. Hydration of this produces the hemiorthoester **5**,



4



5



2 3

whose decomposition can be followed even under strongly basic conditions where it exists in its conjugate base anionic form.

Experimental

Substrates

The ortho ester derivatives **2** and **3** were prepared by the reaction of a two- to threefold excess of trimethyl orthobenzoate with benzimidazole and 4(5)-bromoimidazole. The mixture was stirred at 120°C for 6 h, with the methanol that was released in the reaction being allowed to distil off. After cooling to 40–50°C the mixture was evacuated to 0.1 Torr (1 Torr = 133.3 Pa) to remove excess trimethyl orthobenzoate. Compound **2** was purified by column chromatography on neutral alumina, eluting progressively with diethyl ether in hexanes; **2** had mp 90–92°C; ^{1}H NMR ($CDCl_3$) δ: 3.25 (s, 6H), 7.1–7.8 (m, 9H), 8.55 (s, 1H); mass spectrum, *m/e*: 268 (M^+, 2%), 237 ($M^+ - OCH_3$, 5%), 151 ($PhC(OCH_3)_2^+$, 100%), 105 ($PhCO^+$, 23%). Anal. calcd. for $C_{16}H_{16}N_2O_2$: C 71.62, H 6.01; found: C 72.03, H 6.16. Compound **3** was purified by column chromatography on alumina, eluting progressively with ethyl acetate in hexanes; **3** had mp 81–83°C; ^{1}H NMR ($CDCl_3$) δ: 3.19 (s, 6H), 6.87 (d, J = 1.3 Hz, 1H), 7.35–7.5 (m, 5H), 7.72 (d, J = 1.3 Hz, 1H); ^{13}C NMR δ: 49.2, 106.3, 115.6, 116.3, 126.4, 128.6, 129.7, 135.5, 137.5; mass spectrum, *m/e*: 265/267 ($M^+ - OCH_3$, 1.4%), 151 ($PhC(OCH_3)_2^+$, 100%), 136 ($PhCOOMe^+$, 12.5%), 105 ($PhCO^+$, 34%). Anal. calcd. for $C_{12}H_{13}BrN_2O_2$: C 48.50, H 4.41, N 9.43; found: C 48.65, H 4.47, N 9.43. The reaction conditions and spectral and analytical data are consistent with the structure **3** as written above or with the isomer with the bromine attached to the 5-position in the imidazole ring. The two possibilities cannot be distinguished with the data available; we favor the 4-bromo isomer on steric grounds.

Flash photolysis experiments

Aqueous solutions were prepared with water from a Millipore-Q system, with the pH adjusted by the addition of sodium hydroxide (pH >9.5) or 1 mM borate buffer (pH <9.5). Stock solutions with concentration ~ 1 M of the substrates in acetonitrile were prepared. The appropriate volume to give a final concentration of 0.1 mM substrate was added to the aqueous solution shortly before irradiation and the pH recorded. Photolyses were carried out with ~20 ns pulses of 248 nm light (KrF) from a Lambda Physik EMG 103 MSC excimer laser. Descriptions of the detection and analyzing systems have been given elsewhere (7).

Results

Figure 1 shows absorption spectra recorded in 0.001 M NaOH after laser photolysis of the substrate **3**. Immediately after the flash there appeared two bands, one centered at 300 nm and a second at 260 nm. Although these decayed at approximately the same rate in the solution employed in generating Fig. 1, they must be due to different transient species, since the decay at 300 nm was markedly accelerated by oxygen while there was no effect at 260 nm. We have not identified the 300 nm transient, since this is not the one of interest, and its decay did not interfere with our desired kinetic studies. The quenching by oxygen implies that it is a radical, or possibly a triplet. One possibility is that it is a radical derived from homolysis of the carbon–bromine bond. A piece of evidence that is at least consistent with this explanation is that this transient was not observed with the benzimidazole derivative **2**, where there is no bromine.

The 260 nm transient, on the other hand, can be identified as the phenyldimethoxymethyl cation **4**. An authentic spectrum of this ion obtained by the addition of trimethyl orthobenzoate to concentrated sulfuric acid is shown in Fig. 2. In this solution **4** is formed from the ortho ester and is stable to further reaction (4, 11); it can be unambiguously identified by ^{1}H and ^{13}C NMR spectroscopy (4, 12). Decay of the transient cation followed good exponential kinetics, with the rate constant unchanged in

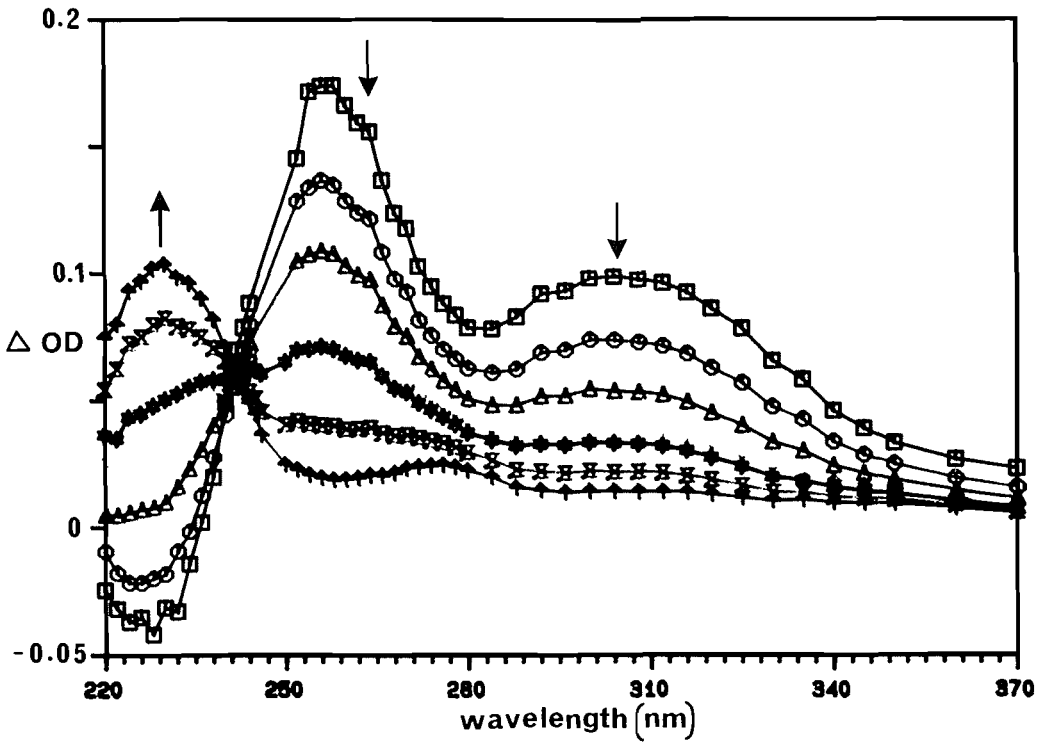


FIG. 1. Transient absorption spectra following 248-nm excitation of the bromoimidazole amide acetal **3** in argon-saturated 0.002 M sodium hydroxide. Spectra were recorded in the windows 200–300 ns, 1.2–1.6 μs, 2.4–2.8 μs, 5.6–6.0 μs, 9.6–10 μs, and 36–40 μs after the flash. The arrows indicate the direction of the change in optical density with time.

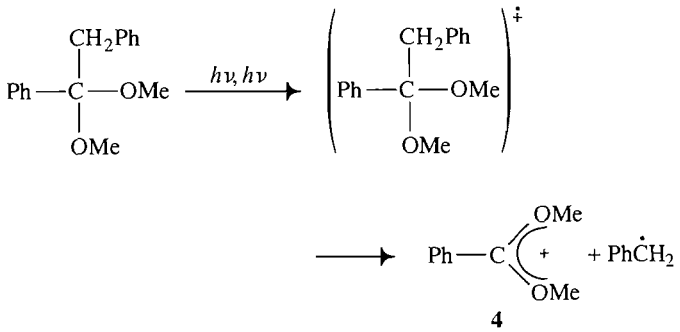
oxygen-saturated solutions, but dependent on the concentration of hydroxide ion.

Also apparent from Fig. 1 is that immediately after the laser pulse there was a negative signal in the region around 230 nm, arising from bleaching of the precursor that absorbs in this region. However, as the cation decayed, an absorbance built in, and after disappearance of the cation there was a net positive signal. This absorbance was permanent and can be assigned to methyl benzoate, the final product of the reaction of the cation. For comparison, the spectrum of this ester in water is shown in Fig. 2. The ester also has absorbance at ~280 nm and this could also be seen at long times in the photolysis experiments. One further comment about Fig. 1 is that in this particular solution the exponential increase at 230 nm had the same rate constant as that for the decrease at 260 nm, and there was a good isosbestic point at 242 nm. As will be discussed, such behavior was not always observed.

An identical pattern, a transient at 260 nm whose decay was matched by an increase in absorbance at 230 nm, was also observed with **2**. This precursor obviously must give the same cation as **3**, and the kinetic behavior with the two compounds was identical. As noted above, the benzimidazole derivative gave none of the second transient at longer wavelength. However, for the purpose of the detailed kinetic studies described below, **3** was preferred since it was more soluble in 100% aqueous solution. It should also be noted that there was ground state hydrolysis with both compounds. As discussed previously in kinetic studies of the hydrolysis of imidazole amide acetals of this type (13, 14), this occurs by reversible protonation of the imidazole or benzimidazole ring, and at high pH (> ~7) the rate constant is proportional to H^+ concentration. The consequence of this hydrolysis is that flash photolysis experiments could only be carried out at high pH where the substrates were reasonably stable, the limits being pH >9 with **2** and pH >7.5 with **3**.

Our other method for generating dialkoxycarbocations involved C—C fragmentation of photochemically generated radical cations (6). The cation **4** has been studied by this method, using the acetal precursor shown below, and decay rate constants agree well with those obtained from the two heterocyclic precursors.



4

The mechanism for the formation of **4** from the heterocyclic systems appears to involve a straightforward photoheterolysis (15, 16). This means that the final products are methyl benzoate (and methanol) and the N-1 unsubstituted heterocycle. This point was established for the benzimidazole derivative **2** by photolysis at 254 nm in a Rayonet reactor in a solution in 0.001 M sodium hydroxide. After photolysis appeared complete, as judged by the observation of no further change in the UV spectrum of the solution, the pH was adjusted to 7, and the solution was extracted with methylene chloride. After separation and removal of the organic solvent, a 200 MHz ^{1}H NMR spectrum was recorded, showing only the signals of methyl benzoate and benzimidazole.

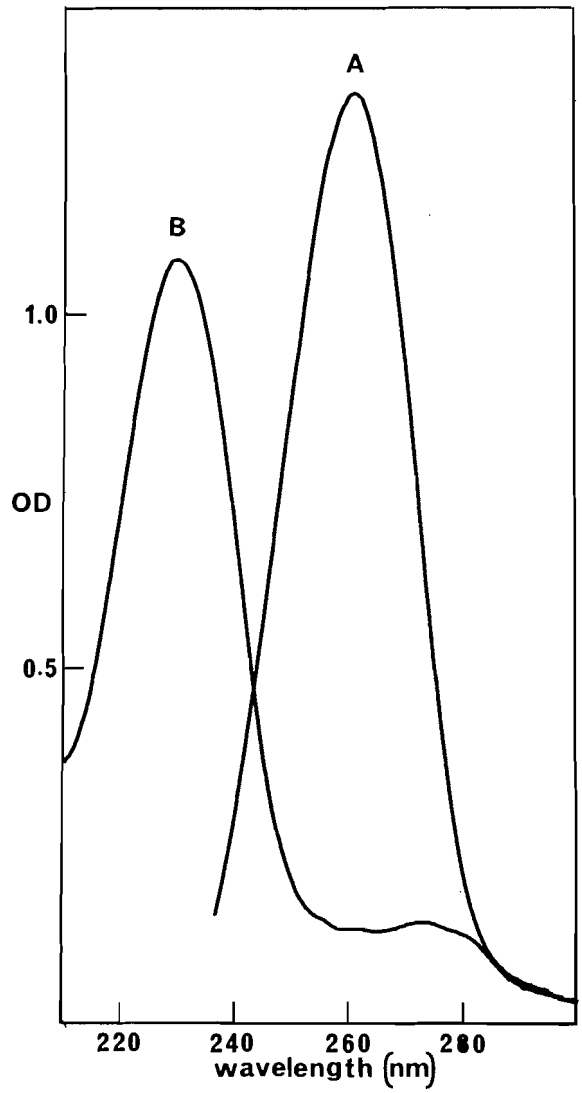


FIG. 2. Absorption spectra of 0.1 mM solutions of (A) trimethyl orthobenzoate (phenyldimethoxymethyl cation **4**) in 96% H_2SO_4 and (B) methyl benzoate in water.

A flash photolysis experiment with time-resolved AC conductivity detection corroborates the mechanistic conclusion. In this experiment **2** was photolyzed in 0.0001 M aqueous sodium hydroxide. A rapid conductivity increase, occurring within the resolution of the conductance method, was observed, followed by a slower exponential decrease to the original conductivity level, the latter occurring with the same rate constant as measured at 260 nm in this solution using optical detection. The initial increase represents the formation of the two ions, with the benzimidazole anion (pK_a of benzimidazole is ~12 (17)) then being rapidly protonated by water to give hydroxide. Reaction of the cation then consumes the hydroxide and the conductivity returns to its original level.

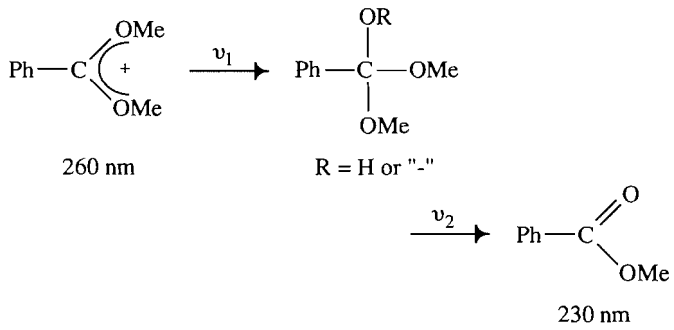
A mechanism that is not excluded by either the product or conductivity results involves nitrogen protonation in the excited state, followed by C—N bond breaking to give the cation and the neutral heterocycle. There is substantial evidence that heterocyclic compounds in the singlet excited state are considerably more basic than in their ground state (18).

Figure 3 summarizes rate constants, obtained mainly with **3**, measured following the decay in absorbance at 260 nm, and the increase at 234 nm. At the higher wavelength, good exponential kinetics were seen in all solutions, with the rate constants independent of pH below pH 10, and increasing at higher pH until at pH >13 the decay was complete within the laser flash and could not be observed. In these very basic solutions, however, the increase at 234 nm was still seen. (This rules out the possibility that the photoheterolysis does not occur at high pH as an explanation for the failure to observe the 260 nm decay.) The 234 nm increase at high pH was very rapid, with rate constants, within experimental error, constant. On decreasing pH the 234 nm traces went through a region centered around pH 12.5 where good exponential behavior was not observed. This was followed by an extended region (pH 10–12) where reasonable exponential behavior was again seen, with rate constants within experimental error identical to those measured at 260 nm. A second non-exponential region, this time centered around pH 9.5, then followed. Finally at low pH (<8.8) good exponential behavior was again observed, with the rate constants measured at 234 nm smaller than those measured at 260 nm. Representative kinetic traces are shown in Fig. 4.

Discussion

Kinetic analysis

The kinetic behavior can be described by a system where at each pH there are two consecutive first-order reactions, with the neutral and conjugate base forms of the hemiorthoester as intermediate species.



The equations relating concentration and time for this general kinetic system are well established (19). Under all conditions the disappearance of the starting material is expected to follow exponential kinetics, as is observed here at 260 nm, with a first-order rate constant equal to the rate constant of the first step. With this system this is the parameter υ_1 of the above equation. This constant does vary with pH since both solvent and hydroxide ion can act as nucleophiles. Rate constants for these two reactions are $9.9 \times 10^4\ s^{-1}$ and $2.5 \times 10^8\ M^{-1}\ s^{-1}$ respectively. (The water rate constant was calculated as the average value of the observed rate constants in solutions with pH <9.5. The hydroxide ion rate constant was obtained from linear regression of k_{obs} versus $[OH^-]$ in solutions with pH <12.3. The k_{obs} values for cation decay in solutions with higher pH show small negative deviations from this line, but this can be ascribed to an ionic strength effect.)

The equation for the appearance of product is more complex, taking the form of a double exponential (19). Single exponential behavior is, however, found when there are significant differences in the magnitudes of υ_1 and υ_2, in which case product forms in a first-order fashion with a rate constant equal to that of the slower process. Using idealized concentration–time data calculated with the appropriate equation (19), we found that a factor of 5 difference in υ_1 and υ_2 was sufficient to produce a

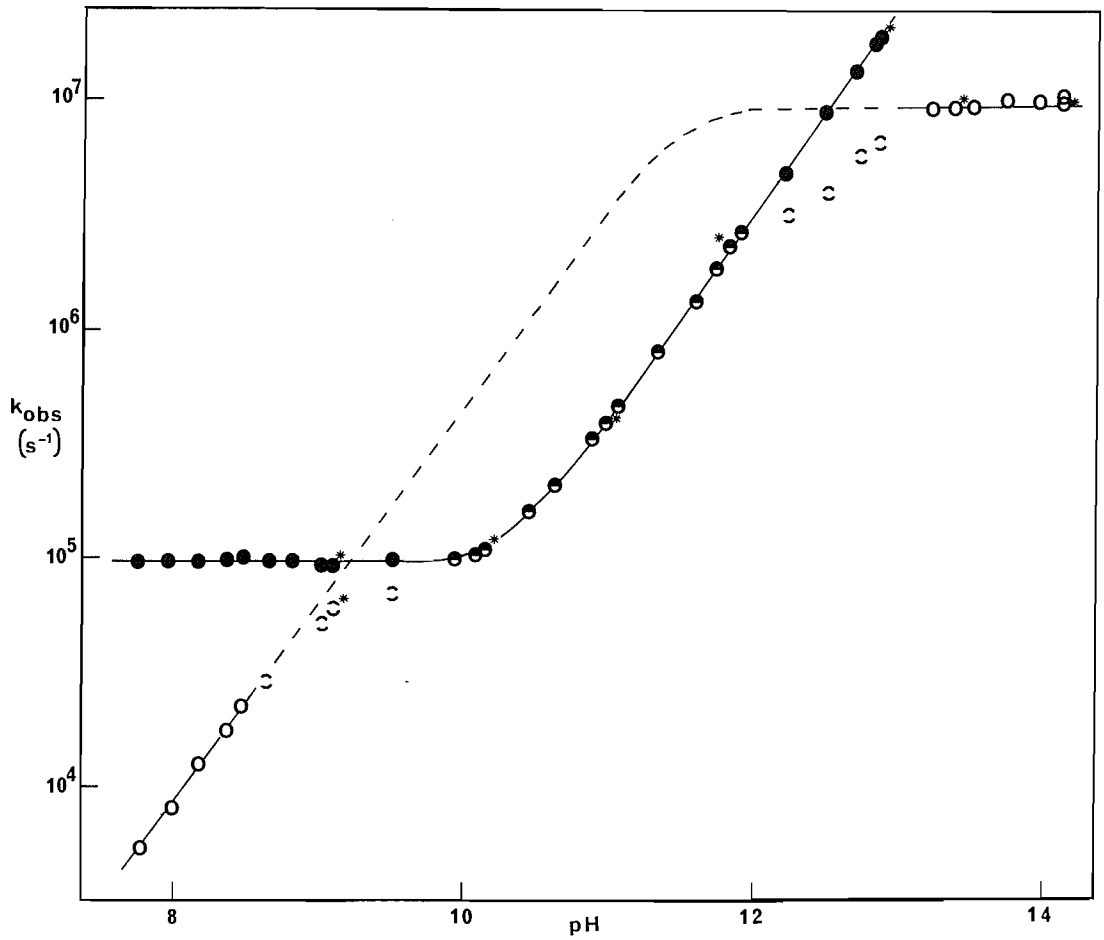

FIG. 3. First-order rate constants measured at 260 nm and 234 nm following laser photolysis of the bromoimidazole amide acetal **3**. Explanation of symbols: (●) monitoring exponential decay at 260 nm; (◓) monitoring exponential decay at 260 nm and exponential rise at 234 nm. In these solutions rate constants measured at 234 nm are within 5% of rate constants measured at 260 nm. (○) monitoring exponential rise at 234 nm. In these solutions reasonable exponential behavior is observed at this wavelength, but the rate constants are smaller than those measured at 260 nm. (◌) monitoring the rise at 234 nm, but poor adherence to single exponential behavior (see Fig. 4). Rate constant given in figure as (◌) was obtained from single exponential fit to data. Points indicated with an asterisk were obtained with the benzimidazole amide acetal **2**. The curve through the 260-nm points represented by both the symbols (●) and (◓) has the formula $(9.9 \times 10^4) + (2.5 \times 10^8)[OH^-]$. The curve through the 234-nm points represented by the symbol (○) has the formula $(9.0 \times 10^6)[OH^-]/(1.2 \times 10^{-3} + [OH^-])$.

reasonable fit to a single exponential, with the first-order rate constant within 10% of the smaller of υ_1 and υ_2.

Thus when $\upsilon_1 < \upsilon_2$, the situation which exists here between pH 10 and 12, rate constants measured for product appearance are υ_1, the same number as are obtained following reactant disappearance. In these solutions the hemiorthoester is reacting faster than it is formed, and it does not accumulate, at least to any significant extent. When $\upsilon_1 > \upsilon_2$, however, product appearance and reactant disappearance are uncoupled, the intermediate must accumulate during the reaction, and the rate constant measured following product appearance is υ_2. The indicator of such behavior is that the ester forms more slowly than the cation disappears. This is obviously then the situation at both very high pH and at neutral pH. As shown by the curves drawn in Fig. 3, the pH dependencies of υ_1 and υ_2 are such that the two cross twice in the region pH 7 – pH 14. In the crossover regions, where the two constants are similar in magnitude, single exponential behavior in product appearance is not observed, as is demonstrated in Fig. 4D. In such solutions the rate constants measured by forcing a single exponential on the data have no significance, being smaller than both υ_1 and υ_2. In principle, the absorbance–time data in the crossover regions could have been fit using multiple regression analysis to the double exponential expression. In practice we found that this procedure was not very satisfactory, the values of the two constants not agreeing particularly well with those estimated by extrapolation from the regions where single exponential kinetics were observed. The problem of a multiparameter fit to a curve where there is a single monotonic change has been noted in a review of computer methods of kinetic analysis (20). It can also be noted that the intermediate is not observed, since it is not expected to have a significant absorbance above 220 nm. For example trimethyl orthobenzoate, an appropriate model, has only a weak absorbance with λ_{max} ~260 nm and extinction coefficient ~400. The cation and ester have extinction coefficients on the order of 10^4, and their spectral changes therefore dominate.

Hemiorthoester breakdown

The two regions with the condition $\upsilon_1 > \upsilon_2$ provide a direct measure of the rate of decay of the hemiorthoester to product. These show different types of behavior: at pH >13, the reaction being independent of pH, with a rate constant of 9×10^6 s^{-1}; and at pH <9, the reaction being first order in hydroxide

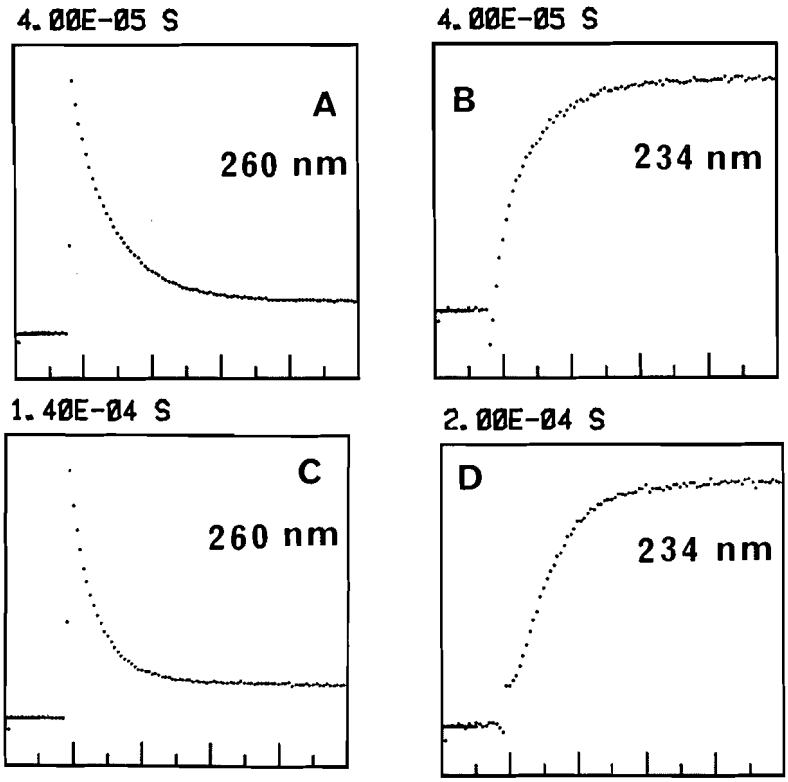

FIG. 4. Changes in optical density with time at 260 nm (A, C) and 234 nm (B, D) following 248-nm photolysis of **3** in aqueous solutions with pH = 10.7 (A, B) and 9.1 ((C, D). Traces A and B are exponential, with rate constants $2.09 \times 10^5\ s^{-1}$ and $2.15 \times 10^5\ s^{-1}$ respectively. Trace C is also exponential with a rate constant of $9.6 \times 10^4\ s^{-1}$. Trace D cannot be fit with a single exponential. The number indicated at the top of each trace is the time for the full range.

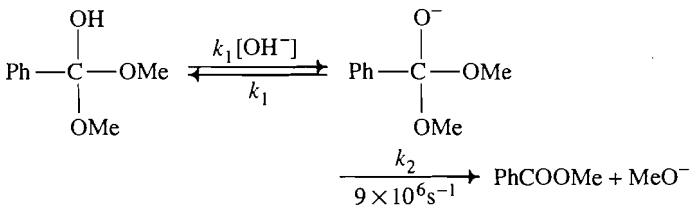
ion concentration, rate = k_{OH^-}[hemiorthoester][OH^-], with a second-order rate constant k_{OH^-} of $7.5 \times 10^9\ M^{-1}\ s^{-1}$.

The mechanism normally accepted for the hydroxide ion mediated decomposition of hemiorthoesters involves deprotonation to its conjugate base, followed by expulsion of alkoxide (1–3).



The pH independent reaction that is observed at high pH must therefore represent a situation where the anion predominates in the initial equilibrium reaction, and what is being measured is the breakdown of this species. With the high concentrations of hydroxide ion that are present in these solutions, it is not unreasonable that an initially formed neutral hemiorthoester will deprotonate very rapidly (see later). Hydroxide ion addition to the cation to form this neutral adduct is also rapid, as seen in the failure to observe the cation when [OH^-] > 0.1 M. What is present therefore after the 20-ns laser pulse is the anionic hemiorthoester, and what is observed kinetically is the breakdown of this species by expulsion of methoxide ion. Thus the pH-independent rate constant observed at high pH is equal to k_2 of the above reaction.

The interpretation normally made of the OH^--dependent reaction at lower pH is that the neutral hemiorthoester predominates in the deprotonation equilibrium, and there is rate-limiting breakdown of the anionic species present in small quantities in the equilibrium. According to such a mechanism, the observed k_{OH^-} is equal to k_2K_a/K_w, where K_a is the acidity constant for the neutral intermediate and K_w is the autoprotolysis constant of water. Unlike the situation in most investigations, k_2 is known from the high pH data, so that with this interpretation the acidity constant can actually be calculated, as 11.08 (as the pK_a value).

This number for the acidity constant of a tetrahedral intermediate is reasonable. For example, Guthrie and Cullimore (21), using a linear free energy equation originally suggested by Hine and Koser (22) based upon data for carbonyl hydrates, have estimated the pK_a of $PhC(OH)_2OMe$ to be 11.01. For $PhC(OMe)_2OH$ itself, an alternative relationship of Fox and Jencks (23), with a simple alcohol as a starting point, provides a pK_a value of 10.90. Moreover there is a measured value of 10.4 for the more stable derivative 2-hydroxy-2-(4-nitrophenyl)-4,4,5,5-tetramethyl-1,3-dioxolane (24).

However, a closer examination reveals that the assumption of a rapid equilibrium of the neutral and ionic forms of the hemiorthoester cannot be correct. This equilibrium at basic pH will have deprotonation with hydroxide ion, while the microscopic reverse protonation will occur with solvent water molecules as the acid. The equation relating the acidity constant to the individual rate constants is therefore $K_a = k_1K_w/k_{-1}$. With p$K_a \sim 11$, the deprotonation with hydroxide ion is the reaction in the thermodynamically favored direction, and k_1 must be of the order of $10^{10}\ M^{-1}\ s^{-1}$, and $k_{-1} \sim 10^7\ s^{-1}$. This, however, means that k_2 and k_{-1} are of the same order of magnitude, and the condition is not obeyed that is required for a

TABLE 1. Values of constants for the equilibrium of the hemiorthoester $PhC(OMe)_2OH$ with its conjugate base, which satisfy the experimental parameters k_2 (at high pH) = 6×10^9 s^{-1} and $k_{OH} = 7.5 \times 10^9$ M^{-1} s^{-1} and the assumption of a stationary state in the hemiorthoester anion at low pH

pK_a	k_1, M^{-1} s^{-1}	k_{-1}, s^{-1}
10.20	8.6×10^9	1.4×10^6
10.40	9.5×10^9	2.4×10^6
10.60	1.1×10^{10}	4.5×10^6
10.80	1.6×10^{10}	1.0×10^7
10.90	2.2×10^{10}	1.8×10^7
11.00	4.5×10^{10}	4.5×10^7
11.05	1.2×10^{11}	1.3×10^8
11.07	3.4×10^{11}	4.2×10^8
11.08	-4×10^{12}	

rapid pre-equilibrium, namely that k_2 be significantly smaller than k_{-1}. A further indication of the inconsistency of the pre-equilibrium assumption is that the observed k_{OH^-} is of the same order of magnitude as the value expected for k_1, the rate constant for deprotonation with hydroxide ion.

In consequence, this system at lower pH must be treated by making a stationary state assumption in the hemiorthoester anion, leading to the equation

$$\text{Rate} = \left(\frac{k_1 k_2}{k_{-1} + k_2}\right)[\text{hemiorthoester}][OH^-]$$

where the experimentally observed k_{OH^-}, 7.5×10^9, is given by the term in parentheses. Although the individual k_1, k_{-1}, and K_a values cannot be obtained, only one of these is independent, since k_2 is known from the high pH data. Possible combinations of these three constants that satisfy the experimental parameters are given in Table 1. It can be noted that there is an upper limit on pK_a of 11.07 which satisfies the data; higher values require negative values for k_1 and k_{-1}. A pK_a value of 10.5–11.0 seems to most reasonably fit the data, and at the same time to satisfy the previous estimates and determinations of the acidity of tetrahedral intermediates. Eigen lists a rate constant of 1.4×10^{10} M^{-1} s^{-1} for the reaction of hydroxide ion with phenol (25), an OH acid whose acidity is not dissimilar to the one of this study. Such a value for k_1 requires a pK_a value of 10.75.

Despite the uncertainty in the magnitudes of these constants, it can be concluded that decomposition of the hemiorthoester anion competes with protonation by water, and, starting from neutral hemiorthoester, deprotonation by hydroxide ion is partially rate limiting in the breakdown to products. Such a conclusion has been reached previously with other tetrahedral adducts (14, 26–28), based upon examinations of the effects of catalyzing buffers, or observations of k_{OH^-} values approaching 10^{10} M^{-1} s^{-1}. The novel feature of this study is the direct determination of the rate constant for the breakdown of the anion, with this demonstration that this process is very fast.

Comparison with hydrolysis of methyl benzoate

The hemiorthoester of this study bears a close resemblance to the tetrahedral intermediate formed in the hydrolysis of methyl benzoate. The mechanistic tool introduced by Bender to identify the intermediacy of tetrahedral adducts in the hydrolysis of acyl derivatives involved the demonstration of carbonyl oxygen exchange in unreacted starting material isolated after partial hydrolysis (29, 30). Alkyl benzoates do undergo such exchange, during both their acid and base hydrolysis (29, 31, 32). However, a careful reexamination of the latter has shown that hydrolysis dominates, the k_{hyd}/k_{ex} ratio for methyl benzoate in 100% water being 28, with the ratio increasing as dioxane is added (32). As seen in the mechanism,

there are two explanations for the high ratio, either that methoxide is a better leaving group than hydroxide, so that the intermediate prefers to go on to products, or that the intermediate is sufficiently short lived that the protonic equilibrium required for exchange does not occur. The importance of these two factors is seen in the equation

$$\frac{k_{hyd}}{k_{ex}} = \left(\frac{k_d(OMe)}{k_d(OH)}\right)\left(\frac{k_d(OH) + k_d(OMe) + 2k_p}{k_p}\right)$$

derived from a stationary state treatment in the intermediates with neglect of $^{18}O/^{16}O$ isotope effects. The first term in parentheses represents the competition between hydroxide and methoxide leaving groups, and the second term reflects the competition between breakdown and protonation. If $k_p > (k_d(OMe) + k_d(OH))$, the intermediates are at equilibrium, and the hydrolysis–exchange ratio is determined solely by the partitioning factor, $k_{hyd}/k_{ex} = 2k_d(OMe)/k_d(OH)$, with the factor of 2 appearing since, half the time, return to ester results in the same carbonyl oxygen as was there initially. If, however, protonation is not fast compared to breakdown, k_{hyd}/k_{ex} is larger than the partitioning ratio. The intermediate can return to starting ester, but the ^{18}O exchange does not reflect this, since proton transfer is necessary to expel the original carbonyl oxygen. The results of this study clearly suggest that this latter situation is likely to hold. Unfortunately it is not possible to put exact numbers on the various rate constants, since the tetrahedral intermediates are not exactly the same. Our results suggest that protonation by water and breakdown occur at comparable rates, and if this were to be true for the ester intermediate, the effect would be to increase k_{hyd}/k_{ex}, but not by a large factor. We conclude therefore that the failure to achieve proton transfer equilibrium does contribute to the large k_{hyd}/k_{ex}, but the effect is probably not sufficient to account for the entire ratio; therefore $k_d(OMe)$ must be larger than $k_d(OH)$. (A reviewer has suggested that this may occur since the expulsion of the methoxide group can be assisted by simultaneous protonation by the intramolecular OH group (perhaps through a chain of solvent molecules), while no such assistance is available for the OH group when it departs.)

Bacteriorhodopsin analogue from anthryl chromophores

ANIL K. SINGH[1] AND MITA ROY

Department of Chemistry, Indian Institute of Technology, Powai, Bombay 400 076, India

Received May 18, 1989

ANIL K. SINGH and MITA ROY. Can. J. Chem. **68**, 383 (1990).

Preparation and properties of the bacteriorhodopsin (bR) analogue having the 3,7-dimethyl-9-(9-anthryl)-2*E*,4*E*,6*E*,8*E*-nonatetraenal (**12**) chromophore is described. Synthesis of the chromophore has been achieved by successive introduction of C_5 units to 9-anthraldehyde (**3**) via the Horner reaction. The all-*trans* chromophore has been characterized by its ultraviolet–visible and ^1H nuclear magnetic resonance spectra. Incubation of **12** with bacterioopsin suspension (prepared by photobleaching of bR isolated from *Halobacterium halobium*) at ambient temperature in the dark gave the new bR analogue **15**, which showed an absorption band at 545 nm, and an opsin shift of 5575 cm^{-1}. The new pigment is stable to hydroxyl amine in the dark. It showed light–dark adaptation with the light-adapted form absorbing at a slightly red-shifted value of 550 nm. All-*trans*-retinal did not replace the anthryl chromophore in competitive bindings. Photolysis of the bR analogue **15**, followed by difference spectrophotometric analysis, indicated formation of a photoproduct with an absorption band near 400 nm. The results are discussed in terms of the stereoelectronic requirements of the bR reaction centre.

Key words: bacteriorhodopsin (bR), retinal analogue, reconstitution, opsin shift (OS), external point charge model (EPC).

ANIL K. SINGH et MITA ROY. Can. J. Chem. **68**, 383 (1990).

On décrit la préparation et les propriétés d'un analogue de la bactériorhodopsine (bR) possédant le chromophore 3,7-diméthyl-9-(9-anthryl)-2*E*,4*E*,6*E*,8*E*-nonatétraènal (**12**). On a réalisé la synthèse du chromophore en faisant appel à la réaction de Horner pour introduire des unités successives en C_5 sur le 9-anthraldéhyde (**3**). On a établi le caractère complètement *trans* du chromophore à l'aide de données d'UV–VIS et de RMN du ^{13}C. L'incubation, à la température ambiante et en l'absence de lumière, du composé **12** avec une suspension de bactérioopsine (préparée par photoblanchiment d'une bR isolée à partir de *Halobacterium halobium*) fournit le nouvel analogue **15** de la bR qui présente une bande d'absorption à 545 nm et un déplacement opsine de 5575 cm^{-1}. Le nouveau pigment ne réagit pas avec l'hydroxylamine, en l'absence de lumière. Il présente une adaptation de la lumière à la noirceur; la forme adaptée à la lumière absorbe à une valeur de 550 nm, qui est légèrement déplacée vers le rouge. Le rétinal complètement *trans* ne remplace pas le chromophore anthryle dans les sites où ils sont en compétition. La photolyse de la bR analogue **15**, suivie par une analyse spectrophotométrique différentielle, indique qu'il y a formation d'un photo-produit possédant une bande d'absorption près de 400 nm. On discute des résultats en fonction des facteurs stéréoélectroniques inhérents au centre réactionnel de la bR.

Mots clés : bactériorhodopsine (bR), analogue rétinal, reconstitution, déplacement opsine, modèle de point-charge externe.

[Traduit par la revue]

Introduction

Bacteriorhodopsin (bR), the sole protein component of the purple membrane (pm) of *Halobacterium halobium* (1, 2), is produced by the bacterial cell in response to oxygen starvation. The protein displays some characteristic features in terms of its colour and physiological functions. These aspects of bR have been the subject of intense investigations in recent years. The primary and secondary structures of bR are known (3, 4). The three-dimensional structure of bR has been elucidated to a resolution of 7–14 Å (5). The chromophore of bR is a retinal molecule attached to the ε-amino group of lysine-216 (4) of the apoprotein, bacterioopsin (bOP), via a protonated Schiff base (PSB) (6) linkage (Fig. 1). There are two forms of bR, the light-adapted bR (bR^{LA}, λ_{max} 570 nm) and the dark-adapted bR (bR^{DA}, λ_{max} 560 nm), the chromophores of which are respectively all-*trans*-retinal and a 1:1 mixture of all-*trans*- and 13-*cis*-retinal. Absorption of photons by bR leads to a photochemical cycle (7), which begins with the photochemical all-*trans* to 13-*cis* isomerization of the retinyl prosthetic group in the pigment. The pigment then decays through the K_{610} and L_{550} intermediates, and the Schiff base nitrogen deprotonates, producing the blue-shifted M_{412} species. The photocycle of bR drives the extrusion of protons from the cell to generate a proton gradient, which is then utilized by the Halobacteria to fuel active transport and ATP synthesis.

Specific active-site interactions (8, 9) between chromophore and apoprotein are believed to be responsible for the characteristic features of bR. An approach to the study of the nature of chromophore–apoprotein interactions has been to strip the natural pigment of its chromophore and then to incubate the apoprotein with suitably tailored retinal analogue to generate bioorganic models of bR (8). Such studies have greatly enhanced our understanding of the absorption behaviour of rhodopsins. However, several aspects of the structure, and mechanism of function, of bR are not yet fully understood.

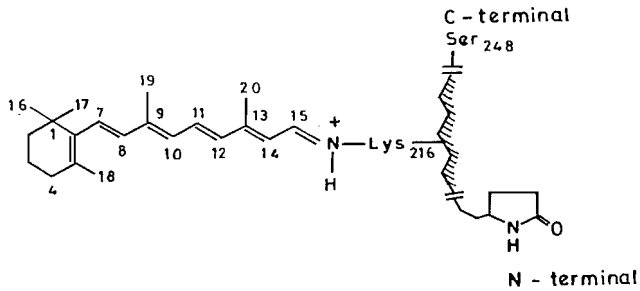

FIG. 1. All-*trans* retinal bound to bR apoprotein via a protonated Schiff base linkage.

The chromophore of bR has three distinct regions, the ring, the side chain, and the Schiff base region. To investigate the nature of the binding site in these regions, a bR analogue with a chromophore having modifications in a particular region can be prepared. The stereoelectronic properties of the ring binding site can thus be studied if bR analogues can be prepared from chromophores that have been suitably modified in the ring portion of the natural chromophore. In our earlier work (10) it

was observed that the iodophenyl retinal analogue binds rapidly to bOP and shows a dramatically altered opsin shift (OS). An anthryl dienal chromophore (**6**) was also found to bind bOP readily, and showed an OS unexpected for a bR analogue having a chromophore with only two double bonds in its side chain. The results were explained in terms of the External Point Charge (EPC) model (8, 9) wherein opsin-bound charges are evoked to electrostatically interact with the chromophore's excited state positive charge near the β-ionyl ring. Thus, EPC attributes the OS to an interaction through space with a negative charge introduced by the protein, in addition to the Schiff base counterion. In bR (OS, 4870 cm^{-1}), it has been suggested that the negative charge is located in the vicinity of the β-ionyl moiety.

The present communication deals with the preparation and properties of the bR analogue from the anthryl chromophore (**12**) in which all four double bonds of the side chain are present, as in the natural chromophore, but the trimethyl cyclohexenyl ring has been replaced by an anthryl moiety.

Experimental

C_5-Phosphonate, methyl-4-(diethyl phosphono)-3-methyl-2-butenoate, was synthesized by following the procedures indicated in standard text (11). AR grade organic solvents were from Spectrochem, Bombay, and were purified before use. Other chemicals were either from Aldrich (USA) or Sigma (USA), and were used as received. Activated manganese dioxide (MnO_2) was prepared by following the published procedure (12). Sodium hydride (NaH) was used as a 50% oil dispersion, which was washed with two portions of anhydrous petroleum ether (40–60°C) prior to use. Horner reactions were carried out under an inert atmosphere of dry nitrogen gas, with anhydrous conditions. All the operations pertaining to retinal and related light-sensitive compounds were performed in a dark room having a dim red light. Column chromatography was done by using 100–200 mesh silica gel (SISCO Laboratories, Bombay). Flash column chromatography was performed on 230–400 mesh silica gel (Merck) according to the reported procedure (13).

Ultraviolet–visible spectra were recorded either on Beckman DU 6 or on Shimadzu UV 260 spectrophotometers. The ir spectra were recorded with a Perkin Elmer 681 IR spectrophotometer. Proton nmr spectra were taken either on Bruker 80 and 500 MHz or on Varian 100 MHz nmr spectrometers. Mass spectra were measured on a Shimadzu QP 1000 mass spectrometer. High pressure liquid chromatographic (hplc) analyses were carried out on a Beckman 110 A instrument using a Microporacil (10 μm, 4.5 × 250 mm, Si-60) column, and spectrophotometric detection. Ultracentrifugations were done on a Beckman L-8-55 M ultracentrifuge. Sonications were performed on a Branson B-12 sonifier. pH measurements were made on a Radiometer PHM-84 pH meter with GK 2401C electrodes.

Isolation of bR, from the cells of *Halobacterium halobium* grown under low oxygen tension and illumination conditions, was done according to the reported procedure (14). The apoprotein was prepared by photobleaching of bR in the presence of hydroxylamine at 4°C.

*9-Anthraldehyde (**3**)*

Anthracene (8.9 g, 0.05 mol), *N*,*N*-dimethyl formamide (DMF, 3.5 mL), phosphorous oxychloride (8.75 mL), and *ortho*-dichlorobenzene (20 mL) were placed in a round-bottomed flask fitted with a reflux condenser and mechanical stirrer. The mixture was heated at 90–95°C for 40 min with simultaneous stirring. Anthracene dissolved during this period to give a deep red solution. The reaction mixture was further refluxed for 3 h and then allowed to cool. The cold mixture was poured into an aqueous solution of sodium acetate (140 g/250 mL), and kept in a refrigerator overnight. Solid material deposited in the flask was recovered by filtration. The crude solid was further purified by column chromatography (5% ethyl acetate in petroleum ether, 40–60°C). Recrystallization of the column-purified material from glacial acetic acid, and further washing of the crystalline material with methanol, gave yellow needle-shaped crystals of 9-anthraldehyde; 6 g, 50%; mp 101–102°C; ir (KBr), ν: 2860, 1670, 1555, 1448, 900, 872, 851 cm^{-1}; uv (MeOH), λ_{max}, nm (ε): 390 (5748), 261 (68 210); ^1H nmr ($CDCl_3$, 100 MHz) δ: 7.60 (4H, m), 8.10 (2H, m), 8.80 (1H, s), 9.10 (2H, m), 11.70 (1H, s); ms, EI (*m*/*e*, % rel. int.): 206 (M^+, 86), 177 (M^+ − CHO, 100); hplc (5% ethyl acetate in hexane, 1.5 mL/min, 360 nm) R_t, 4.6 min.

Methyl 3-methyl-5-(9-anthryl)-2 E,*4* E*-pentadienoate (**4**)*

A solution of C_5-phosphonate (2.33 g, 8.9 mmol) in dry tetrahydrofuran (THF, 10 mL) was added dropwise to a suspension of NaH (0.43 g, 17.8 mmol) in 15 mL dry THF maintained at 0°C. The mixture was stirred (Teflon) for 1 h under N_2. The colour of the mixture turned gradually from colourless to pale yellow and then to dark yellow. A solution of 9-anthraldehyde (**3**, 1.83 g, 8.9 mmol) in 10 mL THF was added dropwise to the yellow reaction mixture at 0°C. The reaction mixture was further stirred for 1 h. The reaction was quenched with brine at 0°C, and the contents taken up in ether. The ethereal layer was separated, washed with brine, and dried over anhydrous sodium sulphate. Removal of ether under diminished pressure on a Rota-vapour gave a solid, which was purified by column chromatography (5% ethyl acetate in petroleum ether, 40°C–60°C). Crystallization of the column-purified material from a mixture of petroleum ether and ethyl acetate (5:1) yielded yellow crystals of ester **4**; 1.10 g, 50%; mp 90–92°C; ir (KBr), ν: 1721, 1170 (ester), 1621, 1525, 1451, 851 (aromatic) cm^{-1}; uv (MeOH), λ_{max}, nm (ε): 387 (18 287), 254 (216 286); ^1H nmr ($CDCl_3$, 80 MHz) δ: 2.76 (3H, s, 3-CH_3), 3.70 (3H, s, -$COOCH_3$), 6.04 (1H, s, H-2), 6.78 (1H, d, J = 16 Hz, H-4), 7.52 (4H, m, arom.), 7.94 (1H, d, J = 16 Hz, H-5), 8.20 (4H, m, arom.), 8.56 (1H, s, 10-H, arom.); ms, EI (*m*/*e*, % rel. int.): 302 (M^+, 71), 256 (100); hplc (5% ethyl acetate in petroleum ether, 1.5 mL/min) R_t, 4.2 min.

3-Methyl 5-(9-anthryl)-2 E,*4* E*-pentadienal (**6**)*

An ethereal solution (15 mL) of pentadiene ester **4** (1 g, 3 mmol) was added dropwise to a suspension of lithium aluminum hydride (LAH) (0.22 g, 5.7 mmol) in 20 mL dry ether. The mixture was stirred (Teflon) for 1 h at −10°C. Reaction was quenched by dropwise addition of water at the same temperature. Ether was added to the reaction mixture, and the aqueous layer was separated. The ethereal layer was washed with brine, and dried over anhydrous sodium sulphate. Ether was then removed under reduced pressure. The resultant alcohol, 3-methyl 5-(9-anthryl)-2*E*,4*E*-pentadien-1-ol (**5**) was stirred with MnO_2 (2.03 g, 24 mmol) in 20 mL THF under N_2 at ambient temperature for 2.5 h. The dark brown mixture was filtered through a G-3 filter. THF was then removed by careful distillation on a Rota-vapour under reduced pressure. The resultant aldehyde **6** was purified by flash column chromatography (7% ethyl acetate in petroleum ether, 40°C–60°C). Further purification of the compound by crystallization from a mixture of ethyl acetate/petroleum ether (1:5) yielded dark-yellow-coloured crystals of **6**; 0.30 g, 40%; mp 70–72°C; ir (KBr) ν: 2860, 1668 (aldehyde), 1625, 1515, 1440, 850 (aromatic) cm^{-1}; uv (MeOH), λ_{max}, nm (ε): 387 (11 252), 252.6 (205 286); ^1H nmr ($CDCl_3$, 80 MHz) δ: 2.68 (3H, s, 3-CH_3), 6.18 (1H, d, J = 11.8 Hz, H-2), 6.80 (1H, d, J = 16.5 Hz, H-4), 7.35 (1H, d, J = 16.5 Hz, H-5), 7.53 (4H, m, arom.), 8.23 (4H, m, arom.), 8.44 (1H, s, 10-H, arom.), 10.32 (1H, d, J = 11.8 Hz, H-1); ms, EI, (*m*/*e*, % rel. int.): 272 (M^+, 84.7), 257 ($M^+ - CH_3$, 77), 243 (M^+ − CHO, 50.5), 228 ($M^+ - C_2H_4O$, 100); hplc (5% ethyl acetate in petroleum ether 40°C–60°C, 1.5 mL/min) R_t, 4.4 min.

Methyl 3,7-dimethyl-9-(9-anthryl)-2 E,*4* E,*6* E,*8* E*-nonatetraenoate (**10**)*

A solution of C_5-phosphonate (0.562 g, 2.23 mmol) in 10 mL dry THF was added to a suspension of NaH (0.107 g, 4.46 mmol) in 20 mL dry THF. The mixture was stirred (Teflon) at 0°C in the dark under N_2 for 1 h. A solution of compound **6** (0.5 g, 1.84 mmol) in 15 mL dry THF was syringed in slowly over a period of 30 min while stirring was continued. After complete addition of the aldehyde, the reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

mixture was further stirred at 0°C for 1 h, and then allowed to warm up to ambient temperature over a period of 3 h. At the end of the 3 h period, the reaction mixture was again brought to the low temperature (−10°C), and worked up by addition of brine and ether. The ethereal layer was washed throughly with brine and water, and further dried over anhydrous sodium sulphate in the dark. Removal of ether gave a viscous material, which was subjected to multiple flash column chromatography (7% ethyl acetate in petroleum ether, 40°C–60°C). Repetitive flash column separations gave ester **10** (0.029 g) as a yellowish gummy material; ir (KBr) ν: 1721, 1170 (ester), 1621, 1525, 1451, 851 (aromatic) cm^{-1}; ^1H nmr ($CDCl_3$, 500 MHz) δ: 2.19 (3H, s, 3-CH_3), 2.30 (3H, s, 7-CH_3), 3.75 (3H, s, -OCH_3), 5.80 (1H, s, H-2), 5.82 (1H, d, J = 15 Hz, H-4), 6.29 (1H, d, J = 11 Hz, H-6), 6.74 (1H, d, J = 16 Hz, H-8), 6.79 (1H, d, J = 16 Hz, H-9), 7.10 (1H, dd, J = 11 Hz, 15 Hz, H-5), 7.14–8.42 (9H, m, arom.); ms, EI, (m/e, % rel. int.): 367 (M^+, 67); hplc (7% ethyl acetate in petroleum ether, 40°C–60°C, 1.5 mL/min) R_t, 4.3 min.

*3,7-Dimethyl-9-(9-anthryl)-2*E*,4*E*,6*E*,8*E*-nonatetraenal (12)*

An ethereal solution (15 mL) of nonatetraenoate **10** (0.22 g, 0.76 mmol) was added to a suspension of LAH (0.057 g, 1.5 mmol) in 10 mL dry ether at −10°C. The reaction mixture was stirred (Teflon) at that temperature in the dark for 30 min. Reaction was terminated by careful addition of about 2 mL of brine to the reaction mixture maintained at −10°C. Ether was added, and the aqueous layer was removed. The ethereal layer was washed with brine and water, and dried over anhydrous sodium sulphate. About two thirds of the ether was removed from the yellow solution on a Rota-vapour under reduced pressure, and the remaining ether was evaporated by gentle N_2 jet. The dark yellowish viscous alcohol **11** obtained was immediately treated with a 20 mL THF suspension of MnO_2 (0.61 g, 6.75 mmol) in the dark under N_2. After 3 h of stirring (Teflon) at ambient temperature, the mixture was filtered through a G-3 filter, and finally through a Celite column (2 cm, in a 5-mm pipette). Most of the THF was removed on a Rota-vapour, and the residue was subjected to flash column chromatography (5% ethyl acetate in petroleum ether, 40°C–60°C), when an orange viscous material (0.1 g) was recovered from the effluent. High pressure liquid chromatographic analysis (7% ethyl acetate in petroleum ether, 40°C–60°C, 1.5 mL/min) showed it to contain approximately 60% of the desired aldehyde **12**; ir (KBr), ν: 2770, 1668 (CHO), 1621, 1528, 1451, 851 (aromatic) cm^{-1}; uv (MeOH), λ_{max}: 410 nm; ^1H nmr ($CDCl_3$, 500 MHz) δ: 2.34 (3H, s, 3-CH_3), 2.37 (3H, s, 7-CH_3), 6.00 (1H, d, J = 8.00 Hz, H-2), 6.35 (1H, d, J = 11 Hz, H-6), 6.43 (1H, d, J = 15.20 Hz, H-4), 6.75 (1H, d, J = 16.30 Hz, H-9), 6.76 (1H, d, J = 16.30 Hz, H-8), 7.26 (1H, d, J = 15.20 and 11.00 Hz, H-5), 7.40–8.42 (9H, m, arom.), 10.13 (1H, d, J = 8.00 Hz, H-1); hplc, R_t, 4.5 min.

Protonated Schiff bases (PSB, 8 and 14)

The PSBs were prepared by addition of dry, freshly distilled *n*-butyl amine to methanolic solutions of the respective aldehydes. The reaction was carried out over 4 Å molecular sieves at 0°C under N_2 in the dark. After 12 h, the methanol and excess *n*-butyl amine were removed under vacuum, and the semisolid residue was redissolved in anhydrous methanol. Protonation of the Schiff bases thus prepared was accomplished by addition of methanol saturated with dry hydrogen chloride gas. Protonation of the Schiff bases was indicated by a red shift in their absorption spectra.

The bR analogue (15)

An ethanolic solution of anthryl retinal analogue **12** was incubated with freshly prepared bOP at ambient temperature in the dark over a period of 24 h. The final ethanol concentration was ≤1% v/v. The growth of the pigment was followed by periodic recording of the absorption spectrum of the mixture. A new peak at 545 nm appeared as a result of binding of anthryl analogue **12** with bOP. The competitive displacement experiments were done by adding an aliquot of ethanolic solution of all-*trans*-retinal to the synthetic pigment. The synthetic pigment was purified by washing of excess chromophore by ultracentrifugation (*n*-hexane, 50 000 g, 10 min).

Preparation of light- and dark-adapted pigments

The dark-adapted bR analogue (bR^{DA}_{545}-**15**) suspensions were irradiated with a 500 W tungsten lamp at a distance of 5 cm using 1% $CuSO_4$–H_2O solution as filter at 4°C. The sample was continuously stirred with a small Teflon bar. The photolysed sample showed an absorption band at 550 nm corresponding to the light-adapted form of **15** (bR^{LA}_{550}-**15**). Incubation of bR^{LA}-**15** in the dark over a period of 24 h regenerated bR^{DA}-**15**.

Photolysis of bR analogue 15 at low temperature

bR-Analogue **15** was suspended in a solution containing 3 mL of 25% NaCl and 75% glycerol. The pH of the sample was adjusted to 9.0 by adding 0.5 M NaOH solution. The sample was cooled to 0°C, and light adapted as described in the previous section. The light-adapted sample was further cooled to −60°C, and irradiation was continued. The difference uv–vis spectrum was obtained by recording the absorption spectra of photostationary and initial-stage samples. A new species with absorption near 400 nm was detected from the difference spectrum. A control experiment was performed by observing changes in the cooled non-irradiated sample.

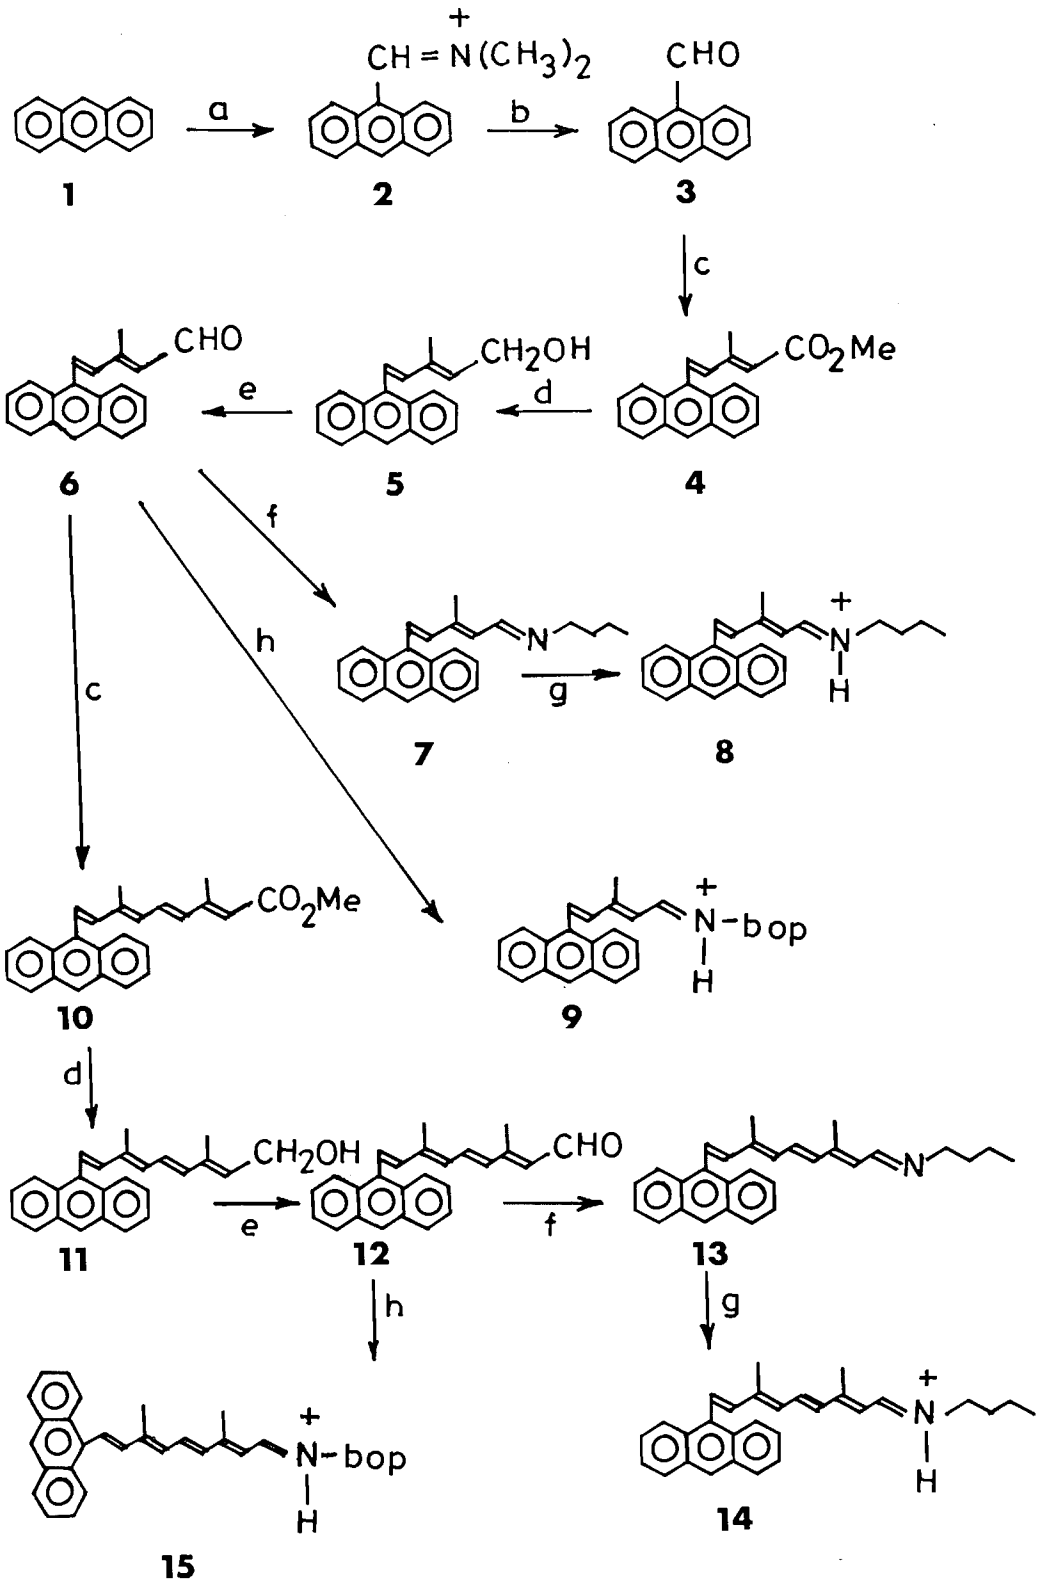
Results and discussion

Synthesis of retinal analogue 12

The procedure adapted for the synthesis of analogue **12** is outlined in Scheme 1. 9-Anthraldehyde (**3**) was prepared (15) by formylation of anthracene in 50% yield. The adduct **2**, formed as a dark red liquid, was hydrolysed with aqueous sodium acetate solution, and the mixture was allowed to stand overnight at 4°C. This resulted in the solidification of aldehyde **3** as a yellow solid. *ortho*-Dichlorobenzene did not hinder solidification; rather, it helped in partially purifying the desired compound by dissolution of the products in the last step. Thus the purity of the aldehyde was improved by allowing it to solidify in the presence of dichlorobenzene, such that it retained the unreacted anthracene. Long needle-shaped crystals of **3** gave satisfactory physicochemical analysis.

The desired C_5-phosphonate was synthesized starting from 3,3-dimethyl acrylic acid (11). Esterification of the acid involved the usual preparation of its acyl chloride followed by its *in situ* reaction with dry methanol. Allylic bromination of the acrylate with *N*-bromosuccinimide in carbon tetrachloride under reflux conditions, followed by fractional distillation of the reaction residue, afforded the extremely lachrymatic bromoester, methyl 4-bromo-3-methyl-2-butenoate. Reaction of the bromoester with triethyl phosphite at 180°C for 1 h gave the desired phosphonate, which was isolated from the reaction mixture by fractional distillation. The ^1H nmr analysis of the phosphonate showed it to be a 2:3 mixture of 2-*cis*- and 2-*trans* butenoate. The identity of the isomers was established by the appearance of two singlets, in the nmr spectrum, at δ 2.30 and 2.05, corresponding to 3-CH_3 protons of 2-*cis* and 2-*trans* isomers, respectively. The allylic methylene protons at C-4 adjacent to the phosphonate group appeared at δ 3.25 and δ 2.90 for the two isomers. All other intermediate compounds also showed satisfactory data conforming to their structure.

Condensation of 9-anthraldehyde (**3**) with C_5-phosphonate in the presence of NaH gave the diene ester **4**. It could be purified by flash column chromatography, and gave the expected physicochemical analyses. It showed an intense, sharp uv band at 254 nm due to ^1B transition, and weak but structured bands centered at 387 nm due to transversely polarized ^1L_a transitions. The ir spectrum of **4** exhibited an intense band at 1721 cm^{-1} featuring an ester carbonyl. Mass spectroscopic analysis of **4** revealed the molecular ion peak at m/e 302, and the base peak at m/e 256 corresponding to $M^+ - C_2H_6O$. Another prominent



SCHEME 1. (a) DMF–$POCl_3$, *o*-dichlorobenzene; (b) NaOAc; (c) $(EtO)_2POCH_2.(CH_3)CH{=}CH.COOMe$, THF, NaH; (d) $LiAlH_4$–Et_2O; (e) MnO_2–THF; (f) *n*-butyl amine, MeOH; (g) MeOH–HCl, dry; (h) bOP, HEPES, dark.

mass peak was observed at *m/e* 271 due to the $M^+ - OMe$ fragment. The proton nmr spectrum of **4** showed the expected singlets at δ 3.70 (-COOMe), δ 2.76 (-3-CH_3), and δ 6.04 (H-2). The coupling constant of 16 Hz between protons at C-4 and C-5 was indicative of a *trans* configuration between the C_4—C_5 double bond. The anthryl ring showed three signals. The two multiplets at δ 7.52 and 8.20 corresponded to four protons each. The C-10 proton of the anthryl ring was observed as a singlet at δ 8.56.

Reduction of the ester function in **4** by LAH required low temperature and early termination of the reaction. Reactions at ambient temperature resulted in the formation of several side

products that did not analyse for the desired dienol group. Prolonged reaction even at low temperatures gave similar undesired results. The alcohol **5** obtained from the careful reduction of **4** was oxidised by MnO_2 to aldehyde **6**. Dienal **6** was purified by a combination of flash column chromatography and crystallization. Both the reduction of ester **4** and oxidation of the resulting alcohol proceeded with no detectable stereochemical change as evidenced by homogeneous hplc patterns and by spectral analyses. The ir spectrum of **6** showed characteristic bands for an aldehyde group at 1668 and 2860 cm^{-1}. Significant features in the ^1H nmr spectrum of **6** were the appearance of a doublet at δ 6.18 with a coupling constant of 11.80 Hz for the C-2 proton (which was a singlet at 6.04 in the ester **4**) that arose due to coupling of the adjacent proton at C-1. As expected, the configuration at the C_4—C_5 double bond was *trans*, with a coupling constant of 16 Hz between protons at C-5 and C-4. Mass spectrometric analysis showed a fragmentation pattern characteristic of a dienal.

Further elongation of the chain of **6** was done by adding one more C_5 unit to it. The resulting ester **10** could be purified by flash column chromatography. While its intense ir band at 1721 cm^{-1} was very characteristic of an ester carbonyl group, the 500 MHz ^1H nmr spectrum provided confirmation of its configurational structure. The tetraenyl chain showed the expected signals for its *trans*-coupled protons. LAH reduction of **10**, followed by MnO_2 oxidation of the resulting alcohol **11**, gave tetraenal **12**, which could be satisfactorily characterized by its uv–vis and ^1H nmr analyses. As expected, the tetraenyl compound was obtained as a mixture of several configurational isomers. The all-*trans* analogue showed characteristic nmr signals for olefinic and aldehydic protons. The aldehyde proton for the all-*trans* compound resonated at δ 10.13 as a doublet with a coupling constant of 8 Hz. The corresponding H-2 proton is seen at δ 6.00, also as a doublet with a *J* value of 8.00 Hz. The *trans* coupling between the H-4 and H-5 protons and *s-trans* coupling between H-5 and H-6 were observed to be 15.2 and 11.0 Hz, respectively. Compound **12** showed the characteristic aldehyde peak at 1668 cm^{-1}. Expected uv–vis absorption bands at 410 and 261 nm due to ^1L_a and ^1B transitions, respectively, confirmed the conjugated nature of the elongated side chain. The absorption properties of the anthryl chromophores are discussed in the following section.

Ultraviolet–visible absorption properties of anthryl chromophores

The uv–vis absorption data for the anthryl compounds are given in Table 1. The spectrum of parent anthracene, a *cata*-condensed nucleus, shows an intense peak at 254 nm (ε, 180 000) due to ^1B transitions. The other major band in the spectrum of anthracene is due to ^1L_a transitions, and consists of a series of five vibrational sub-bands, the longest of which occurs at about 380 nm with ε of 9000. Introduction of an olefinic chain at C-9 in anthracene did not result in any major change in the shape of the spectrum. With the introduction of a chain at the C-9 position, an increase in the resonance stabilization of the vertically polarized excited states could be anticipated and the absorption band associated with this transition (^1L_a) should be shifted to longer wavelength. However, only a small shift of 7 nm was observed. The failure to observe a significant red shift may be due to less resonance coupling between the chain and the nucleus. This could be a result of increased size of the substituent, and accordingly enhanced potentialities for steric interference with resonance. As the steric strain in aldehyde **6** gets relieved due to twisting of the essentially single bond between the anthracene ring and the diene chain, departure from coplanarity is experienced, and thus the absence of a significant red shift in the absorption spectrum of **6**. On further extension of the chain, as in compound **12**, a bathochromic shift of the ^1L_a band to 410 nm was observed, probably due to an increased conjugation in the chain.

The Schiff base (SB) of aldehyde **6** and *n*-butyl amine in MeOH showed a ^1L_a band only at 386 nm. On the other hand, the SB of aldehyde **12** and *n*-butyl amine showed a 17-nm blue-shifted absorption band as compared to the parent aldehyde. On protonation, however, a red shift of 68 nm for the transversely polarized band was observed for the protonated Schiff base (PSB) **8** of dienal **6**. However, the PSB **14** of tetraenal **12** showed a red shift of only 25 nm for the transversely polarized band. The additional resonance energy acquired by the conjugation with the powerful chromophore ($=\overset{+}{N}HR$) acts to rotate the substituent in the PSB of dienal **6** into the plane of the anthracene ring, and thus accounts for the marked bathochromic shift. In the PSB of tetraenal, however, the resonance effect acting to bring the chain to coplanarity is opposed by the steric overlap of the methyl group with the hydrogens in the anthryl ring.

The bR analogue

Synthesis of the new pigment is carried out by combining a concentrated ethanolic solution of the retinal analogue with freshly bleached protein. Apoprotein, when incubated with retinal analogue **12**, resulted in the formation of a new bR analogue, which showed an absorption band at 545 nm in its dark-adapted form. Most of the binding occurred in the first 30 min of the incubation (Fig. 2). Further characterization of the pigment was done by determining the opsin shift (OS) value.

OS is expressed by the λ_{max} of PSB in cm^{-1} minus the λ_{max} of the pigment in cm^{-1} (8). The PSB is usually prepared by reacting the retinal or its analogues with *n*-butyl amine, followed by its production with HCl. The bR regenerated from all-*trans* retinal shows an OS of 4870 cm^{-1}. Following a similar procedure, the OS of bR analogue **15** has been determined to be 5575 cm^{-1}. The bR analogue prepared from dienal **6** exhibited an OS of 3911 cm^{-1} (Table 2). It is interesting to note that bR analogues can be prepared by a chromophore having only two double bonds in the side chain. The bR active site is thus found to be quite flexible and nonspecific, at least in the ring binding site. The bR analogue prepared from 11,12-dihydro retinal, essentially a dienal, has no measurable OS in the uv–vis region (8). The 9,10-dihydro retinal, a trienal, has an OS of only 300 cm^{-1} (8). In view of these results, the OS shown by anthryl dienal-based bR is quite interesting. The anthryl analogue may be considered as having some of the required double bonds in the anthryl ring. This imparts a more planar conformation to the

chromophore. Besides, as has been observed, the protonated anthryl dienyl chromophore shows more of planar characteristics. In addition, the dienyl chromophore may be undergoing interactions with opsin-bound charges present in the vicinity of the flattened anthryl moiety at the active site. The anthryl ring could be disposed in the region of the active site, which is occupied by C-8 to C-10 of the natural chromophore, retinal. According to the EPC model, electronic and steric perturbations at the active site are expected to strongly influence the absorption spectra of the protein. The PSB of dienal **6** and tetraenal **12** showed absorption bands at 454 and 418 nm respectively. However, when these aldehydes were attached to lysine-216 of the protein in the form of a protonated Schiff base, they exhibited absorption bands at 550 (10) and 545 nm respectively. The longer chromophore **12** shows absorption that is now only 5 nm blue-shifted as compared to the shorter chromophore. The source of the 96-nm shift in dienyl anthryl-based bR (as compared to the absorption of *n*-butyl amine PSB of dienal) and the 127-nm shift in tetraenal anthryl-based bR (as compared to the absorption of *n*-butyl amine PSB of tetraenal) has to be partly due to additional interactions between the anthryl chromophore and opsin-bound charges. In this context, it is important to note the recent suggestion (16) that the bR active site has opsin-bound charges in the form of ion pairs. A comparison of the absorption data of native bR and the bR analogues prepared from anthryl retinal analogues **6** and **12** indicates that there is less conjugation in the polyene chain and

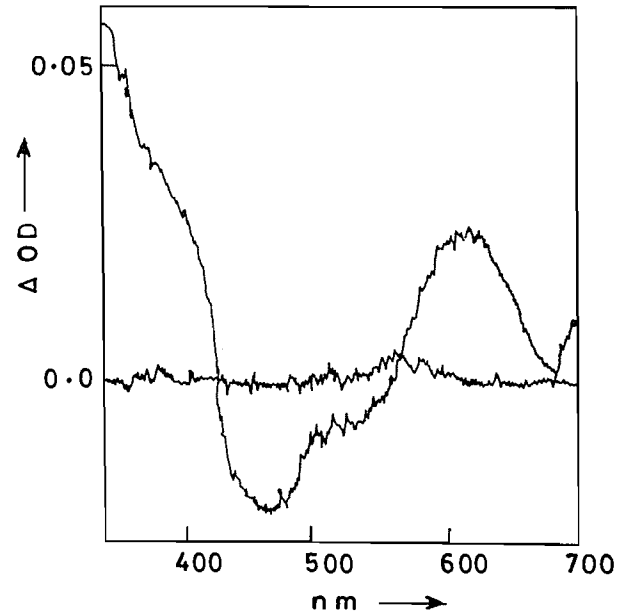

FIG. 3. Difference uv–vis absorption spectrum of the photolysed bR analogue **15** at −60°C.

the anthryl ring in the case of the chromophore in bR analogue **15**. Similar observations were made in the absorption behaviour of chromophore **14** in solution. However, decreased interactions between the twisted chromophore and the now more distant opsin-bound charges can also be partly responsible for such behaviour of the chromophore in the protein.

It has been found that the ring binding site readily accepts acyclic polyenes (17). The ring binding site appears to be quite unrestrictive, as large groups such as aromatic derivatives and 4-substituted analogues (18) can be easily accommodated by bR. Bioorganic models of bR from retinal analogues with a locked 6-*s*-*trans* conformation (9), the phenyl (10, 19) and naphthyl (18, 20, 21) compounds, have suggested a view of the binding site in which the bR protein appears to bind the chromophore in its planar conformation.

Stability of the bR analogue

Stability of the pigment can be inferred from competitive binding with all-*trans* retinal, and with the behaviour of the bR analogue towards hydroxylamine. It was found that addition of all-*trans* retinal did not displace the anthryl chromophore, as the appearance of the bR band at 560 nm was not more than 5%. Similarly, addition of hydroxylamine to bR analogue and incubation in the dark did not significantly alter the 545 nm absorption of the pigment. However, it was found that the bR analogue with the anthryl tetraenyl chromophore was relatively more stable (>24 h) than the bR analogue with anthryl dienal chromophore (~8 h). It can thus be inferred that a complete longitudinal fitting of the chromophore at the active site is necessary for the stability of bR. This also suggests that the longitudinal chain binding site is more important than the ring binding site.

The anthryl bR analogue **15** also showed expected light and dark adaptation. Thus, on illumination, dark-adapted **15** showed a red-shifted absorption band at 550 nm.

The M intermediate generation

During the photocycle of bR a blue-shifted M intermediate with absorption band at 412 nm is formed. Concomitantly a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.144.44.67 on 09/07/12
For personal use only.

proton is released in the medium. This proton is later taken up in the photocycle with the decay of the M intermediate. To see whether such an intermediate is generated for the anthryl bR analogue, photolysis of analogue **15** was carried out at low temperature. For measuring the absorption spectra of the blue-shifted intermediate a temperature of −60°C, high salt concentration, and a pH of 9.0 was maintained. Difference uv–vis analysis (Fig. 3) of the photomixture showed the appearance of a band near 400 nm, which could be due to the unprotonated Schiff base chromophore of the M anthryl bR formed during the photolysis of bR-**15**. Thus it is apparent that the presence of the trimethyl cyclohexenyl moiety may not be essential for bR to undergo the photocycle.

Conclusions

Thus, synthetic retinal analogue **12** binds to bacterioopsin to give a new bR analogue. It is found that the ring binding site is unrestrictive and nonspecific. The binding site of bR prefers to bind the chromophore in a planar conformation. The longitudinal chain binding site appears to play a more important role than the ring binding site. Both resonance and steric compatibility of the chromophore seem to play important roles in the regulation of the absorption behaviour of bR. The presence of the trimethyl cyclohexenyl ring does not seem to have much effect on the functional properties of the protein. However, a proper fit of the chromophore at the active site seems to be important for both the structural and functional features of bR.

The effects of metal salts on the photosensitized (electron transfer) carbon–carbon bond cleavage of the 2,2-diphenylethyl ether system[1]

LAURIE J. LAMONT AND DONALD R. ARNOLD[2]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received September 11, 1989

LAURIE J. LAMONT and DONALD R. ARNOLD. Can. J. Chem. **68**, 390 (1990).

Irradiation of an acetonitrile solution of *para*-dicyanobenzene (**1**), 3,3-diphenyltetrahydrofuran (**2**), and magnesium perchlorate leads to the formation of 4,4-diphenyl-1,3-dioxane (**7**). Similarly, irradiation of an acetonitrile solution of **1**, methyl 2,2-diphenylcyclopentyl ether (**5**), and magnesium perchlorate leads to the formation of 6,6-diphenyl-2-methoxytetrahydropyran (**8**). The mechanism proposed for these reactions involves formation of the radical cations $\mathbf{2}^{+\cdot}$ and $\mathbf{5}^{+\cdot}$ with the first excited singlet state of **1** acting as the photosensitizer (electron transfer). The radical cations $\mathbf{2}^{+\cdot}$ and $\mathbf{5}^{+\cdot}$ then cleave to give 1,5 radical cations. Reaction of the cationic site with water, followed by futher oxidation of the radical site by the perchlorate anion, gives the diphenylalkyl carbocation that can cyclize via a six-membered intermediate to the observed products **7** and **8**. While the addition of other perchlorate salts (lithium and tetra-*n*-butylammonium) also lead to the formation of **7** and **8**, lithium trifluoroacetate is ineffective. The proposal that water is involved as the nucleophile is supported by incorporation of ^{17}O in the products **7** and **8** when ^{17}O-enriched water was added to the reaction mixture.

Key words: photosensitization, electron transfer, radical cations, bond cleavage, 2,2-diphenylethyl ether.
